Titanium-Containing Raney Nickel Catalyst for Hydrogen Electrodes in Alkaline Fuel Cell Systems

K. Mund, G. Richter, and F. von Sturm

Forschungslaboratorien der Siemens AG, 8520 Erlangen, Federal Republic of Germany

ABSTRACT

In alkaline hydrogen-oxygen fuel cells Raney nickel is employed as catalyst for hydrogen electrodes. The rate of anodic hydrogen conversion has been increased significantly by using a titanium-containing Raney nickel. The properties of the catalyst powder, the influence of particle diameter, and the behavior of electrodes under load are described. Impedance measurements have been used to characterize the electrodes. In fuel cell systems the supported electrodes are normally operated at current densities up to 0.4 $A \cdot cm^{-2}$; the overload current density of 1 $A \cdot cm^{-2}$ can be maintained for several hours.

The economic factors of the H_2-O_2 fuel cell are determined essentially by the costs of the catalysts employed in the electrodes. Hence it is rational for commercial applications to avoid the expensive and rare materials such as noble metals. In alkaline electrolyte, the metals nickel and silver are suitable as catalysts for the anode and the cathode, respectively (1, 2). Catalyst powder with large interior surface is used to have a large reactive surface area available. Raney nickel has thus proved useful for the H_2 electrode (2) and it is considered in detail. The active material can be depyrophorized by a slow surface oxidation and the catalytic activity could be increased by annealing at 300°C in hydrogen atmosphere (3). The attainable current density of the electrodes depends strongly on the pretreatment of Raney nickel (2, 4).

A further increment in catalytic activity could be achieved by changing from a binary Raney alloy to a ternary system in which an additional metal such as iron, molybdenum, or titanium has been alloyed to nickel and aluminum (5-7). The objective of the alloy additives is to produce ternary phases in which Ni, Al, and the additive metal are distributed homogeneously. Only such phases yield homogeneous alloy catalysts with highest activity. The additive metals lead to a lower filling of d bands and to lattice defects.

The properties of titanium-containing Raney nickel catalyst are reported here.

Experimental

Preparation of the catalyst.—The Raney alloy has a mass fraction of 50% Al; the rest consists of Ni and Ti in which the titanium content can be varied from 0 to 5%. When the liquid alloy is quenched in a water bath titanium remains dissolved in the two compounds $NiAl_3$ and Ni_2Al_3. A granulate is formed which can be powdered easily in a mill. Powder with a particle diameter of less than 50 μm is employed.

Aluminum is extracted to an extent of 95% in 6M potassium hydroxide at 80°C, titanium remains completely in the catalyst. After washing, the powder is dried in vacuum and subjected to surface oxidation by slow addition of oxygen. This causes the material to lose its pyrophorosity and can be processed readily to electrodes.

Preparation of electrodes.—The alkaline H_2-O_2 cells are constructed according to the principle of supported electrode (Fig. 1) (8, 9). The catalyst layer is supported by a finely porous, asbestos covering layer on the electrolyte side and by a metal screen on the gas

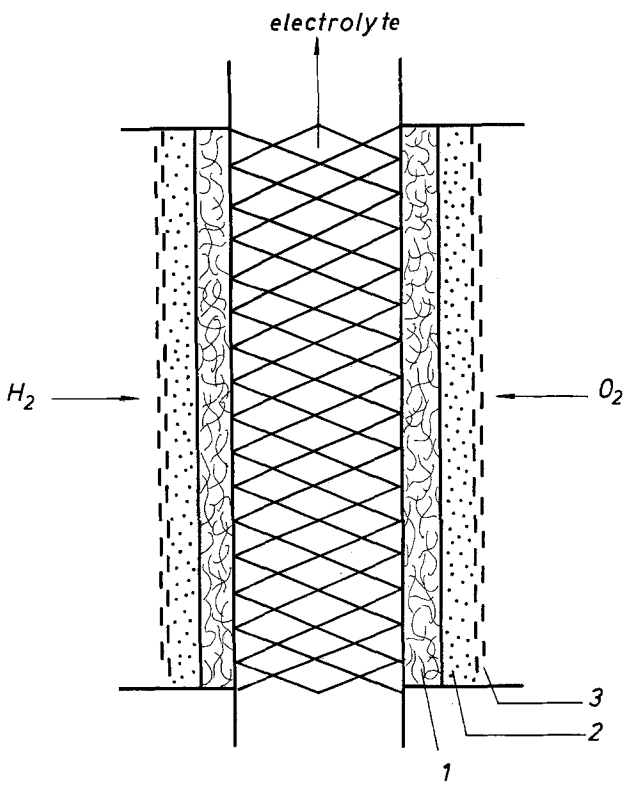

Fig. 1. Principle of a H_2-O_2 fuel cell with supported electrodes: 1, covering layer; 2, catalyst layer; and 3, contacting screen.

Key words: electrocatalyst, fuel cell, hydrogen electrode, Raney nickel, pore model, impedance measurement.

side. The electrolyte flows between both electrodes: the H_2 anode and the O_2 cathode.

Setup for electrode measurements.—If the task involves investigating Raney nickel electrodes only it is practical to use two nickel electrodes and to subject the one to anodic and the other to cathodic current. Only one reaction gas is needed in such a case. This arrangement is also employed for impedance measurements at equilibrium potential and has the advantage that no reference electrode is required (10, 11). The impedance is measured in the frequency range between 10^3 and 10^{-3} c/sec.

Description of the Catalyst Particle and the Reaction Mechanism in Supported Electrodes

The catalyst powder obtained from Raney alloy has a BET surface area of about 70 $m^2 \cdot g^{-1}$ (12). A mean pore radius r_p of $1.6 \cdot 10^{-7}$ cm is found in catalyst particles having a volume porosity p of 34%. Hence it can be estimated that there are about 10^7 pore mouths at the outer surface of a catalyst grain having a radius of $r_k = 10^{-3}$ cm. The catalyst particle is dispersed with long and narrow pores like a sponge.

Various concepts for the reaction in porous electrodes have been developed, each is valid for a special case (13-15). Our conceptions regarding the reaction mechanism in supported Raney nickel electrode can be illustrated by means of Fig. 2. The catalyst particles of the working layer are schematically represented; their micropores are filled with electrolyte. The gas can stream into the active layer via the macropores. Electrolyte bridges are formed between the particles and the particles remain in metallic contact with each other. At the gas/electrolyte interface hydrogen dissolves in the liquid. This reaction is fast and it can be assumed that the saturation concentration is always attained here. Since the outer surface of the catalyst particles is small compared with the internal surface and since the charge-transfer reaction is retarded, the dissolved gas diffuses into the pores and is chemisorbed at the pore wall. After the charge-transfer reaction, the electrons flow across the metallic phase. The electrolyte current seeks its way through the electrolyte to the counterelectrode; during this, a voltage drop at the diaphragm resistance results in the working layer.

The supply of reaction gas to the pores of the catalyst particles is essential for the polarization resistance of supported electrodes; Raney nickel is best utilized if the diffusion paths and correspondingly the pores are not long (16).

Experimental Results and Discussion

Influence of Ti content on the polarization resistance.—The steady-state current-voltage characteristics of supported Raney nickel hydrogen electrodes are linear up to a polarization of 0.1V in 6M KOH as electrolyte; the polarization resistance can therefore be used as a characteristic datum. Figure 3 shows the influence of titanium content in Raney alloy on the polarization

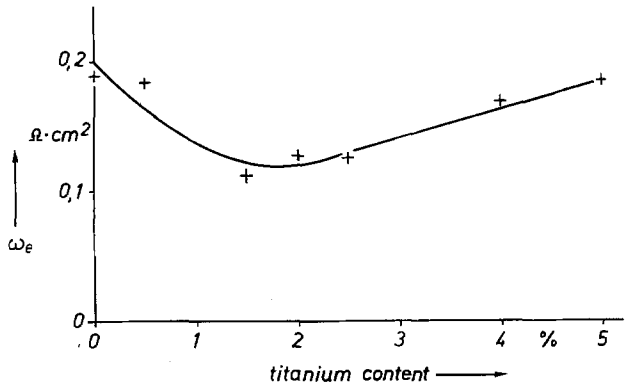

Fig. 3. Effect of Ti content of the Raney alloy on the polarization resistance of supported H_2 electrodes; catalyst loading 100 mg · cm^{-2}, 6M KOH, 80°C, $\Delta p_{H_2} = 1$ bar, *IR* drop eliminated.

resistance when operated on hydrogen. At an electrolyte temperature of 80°C and a catalyst loading of 100 mg · cm^{-2}, a minimum polarization resistance is found at a titanium content of 1.5-2% in the starting alloy. In comparison to the binary Raney alloy 50:50, the polarization resistance is halved at the minimum. The polarization resistance increases at a Ti content of more than 2%; it is assumed in this case that too much oxide covers the catalyst surface.

In all further experiments, a catalyst with a Ti content of 2% in the Raney alloy was used.

Influence of temperature.—The influence of electrolyte temperature on the current-voltage curve of a hydrogen electrode with a catalyst loading of 100 mg · cm^{-2} can be seen in Fig. 4. At 90°C and at a polarization of 60 mV, a current density of 600 mA · cm^{-2} is attained. The electrode can be loaded in steady state with a current density of 1 A · cm^{-2} for several hours. Current densities up to 100 mA · cm^{-2} are possible at room temperature.

Dependence of the polarization resistance on the particle size of catalyst powder.—The large reactive area in the interior of a catalyst particle can be utilized only when the diffusion paths of hydrogen are short. The degree of utilization of the electrocatalyst will reach the ideal value 1 if the diameter of the powder particles is not too large.

The characteristics of supported electrodes consisting of different particle fractions were investigated. Figure 5 shows at the first instance, how the extreme fractions are influenced by the working pressure. The coarse grained material can be loaded even below a pressure of 0.4 bar and the polarization resistance remains constant in spite of further rise in pressure. The polarization resistance is least at a pressure of 1 bar if powder with a diameter < 10 μm is employed.

Current-voltage curves recorded at a working pressure of 1 bar are represented in Fig. 6. They are traced at an electrolyte temperature of 80°C and by choosing

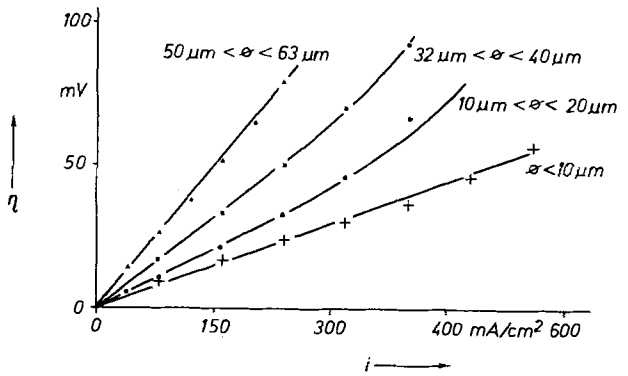

Fig. 6. Characteristic curves of supported Raney-Ni-Ti 2 electrodes with the particle diameter as parameter: catalyst loading 100 mg · cm^{-2}, 6M KOH, $\Delta p_{H_2} = 1$ bar, *IR* drop eliminated, 80°C.

a catalyst loading of 100 mg · cm^{-2}. It can be perceived that the current density of the electrode increases if a catalyst powder with smaller diameter is used.

The reciprocal polarization resistance ω_e^{-1} is plotted against the catalyst loading b at 22° and 80°C in Fig. 7 and 8, respectively. The curves were calculated after matching two parameters with the points of measurement. Considering that the polarization resistance k of the catalyst powder is independent of the potential and that a voltage drop results in the electrolyte inside the working layer of the electrode, the polarization resistance ω_e depending on the thickness d of the electrode can be expressed as (10)

$$\omega_e = \sqrt{\rho \cdot k} \cdot \coth \sqrt{\frac{\rho \cdot d^2}{k}} \qquad [1]$$

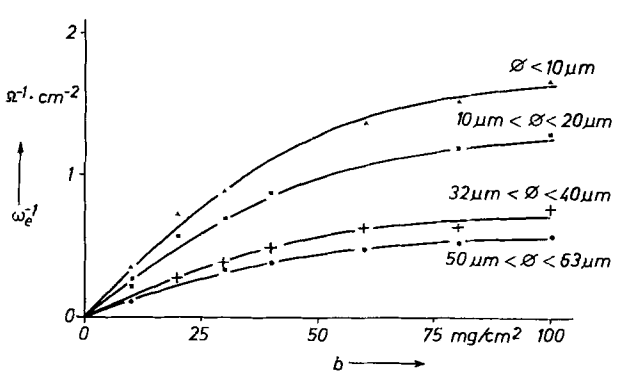

Fig. 7. Reciprocal polarization resistance ω_e^{-1} as a function of the catalyst loading for different particle fractions: 6M KOH, 22°C, $\Delta p_{H_2} = 1$ bar.

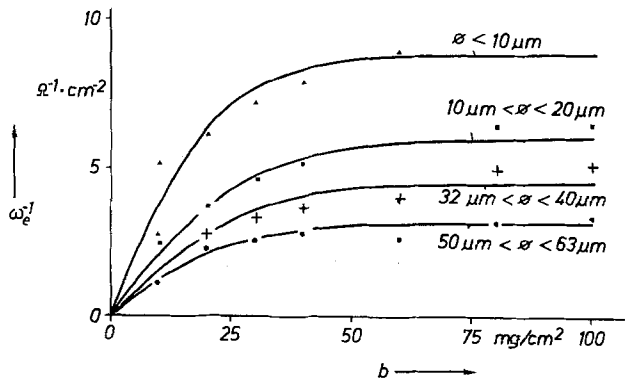

Fig. 8. Reciprocal polarization resistance ω_e^{-1} as a function of the catalyst loading for different particle fractions: 6M KOH, 80°C, $\Delta p_{H_2} = 1$ bar.

where ρ is the electrolyte resistivity inside the working layer; we denote it as diaphragm resistivity. Equation [1] states that at thinner electrodes ($\rho d^2 << k$) the polarization resistance ω_e is determined only by k and d and that for thicker electrodes ($\rho d^2 >> k$) the polarization resistance tends toward a limiting value $\sqrt{\rho k}$.

By matching of the curves with the readings the quantities ρ and k can be determined. In Fig. 9, the diaphragm resistivity ρ is plotted as a function of the mean particle radius r_k of particle fractions; the diaphragm resistance decreases if powder with smaller particle diameter is used.

Polarization resistance k is the second parameter which is recorded as a function of the mean particle radius r_k at temperatures of 22°C in Fig. 10. It is found that with larger radii k increases linearly along with the radius r_k. The traced curves were calculated with the help of a model. The model indicates that there is a limiting value k_o for small radii.

Model for steady-state operation of the hydrogen electrode.—A consideration of the stationary behavior of the electrodes has led to the assumption that with the diffusion in the electrolyte inside the pore, also a surface diffusion of chemisorbed hydrogen along the pore wall is possible (10). An estimation showed that the voltage drop in the electrolyte inside the pore is small compared with the charge-transfer polarization (11). If a single narrow pore of the catalyst particle is regarded and if in addition to the diffusion of hydrogen in pore electrolyte and along the pore wall the charge-transfer mechanism is considered, an expression is obtained for the polarization as a function of the pore current. In the polarization range up to 100 mV, an almost linear relationship between polarization and pore current results. By summing up all pores and by taking into account that the number of pores decreases

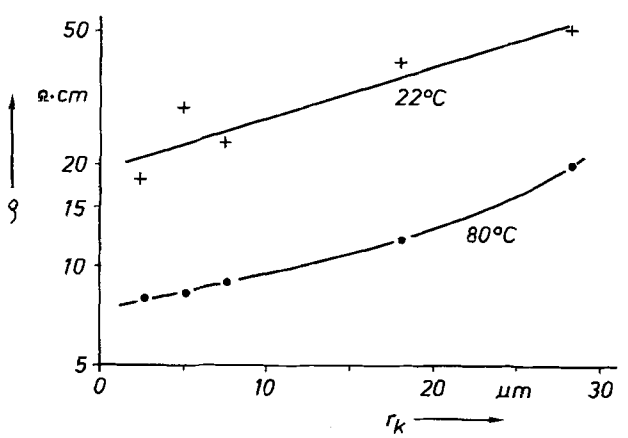

Fig. 9. Diaphragm resistivity ρ as a function of the mean particle radius r_k of the catalyst powder.

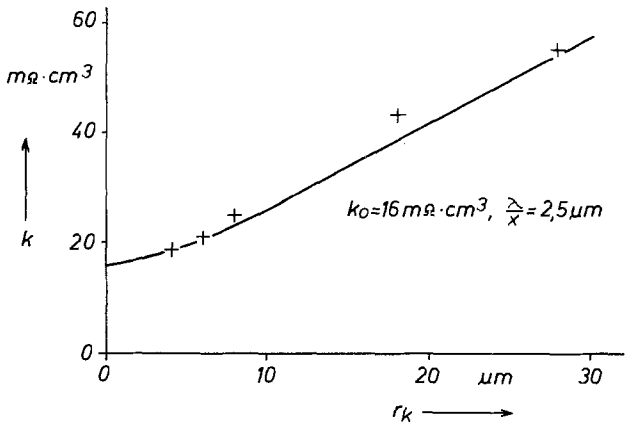

Fig. 10. Polarization resistance k of the catalyst powder as a function of the mean particle radius r_k of the catalyst powder: 6M KOH, 22°C.

from surface to interior of the sphere, an equation is obtained for the polarization resistance k of the catalyst powder (9)

$$k^{-1} = k_o^{-1} \cdot \frac{12\lambda}{r_k^4 \cdot x} \int_0^{r_k} r^2 \cdot \tanh \frac{x(r_k - r)}{r} \cdot dr \quad [2]$$

with

$$k_o = \frac{RT}{0.7\mathbf{F} \cdot \gamma \cdot f \cdot i_o} \quad [3]$$

and

$$\lambda = \sqrt{\frac{n\mathbf{F}}{2i_o} \cdot (r_p \cdot c_{vo} \cdot D_v + 2c_{so} \cdot D_s)} \quad [4]$$

where λ is a depth of penetration and it is dependent on the current density i_o, pore radius r_p, diffusion coefficients D_v and D_s for volume and surface diffusions, and saturation concentration c_{vo} and c_{so} of hydrogen in the electrolyte and at the pore wall. The integral in Eq. [2] contains the radius r inside the sphere, its radius r_k as well as the labyrinth factor x of the pores. The polarization resistance k_o can be evaluated in the case of vanishing radii r_k, it is independent of the parameters of diffusion and is determined by the BET surface area f of the catalyst, the exchange current density i_o, and the density γ of the material in the working layer.

The quotient λ/x and the exchange current density i_o remain as parameters for the calculation of the curve in Fig. 10; all other quantities are known. The value obtained for i_o at 22°C is 2 $\mu A \cdot cm^{-2}$ and at 80°C it is 27 $\mu A \cdot cm^{-2}$. If a labyrinth factor $x = 2$ is assumed, the values found for the depth λ of penetration are 5 and 4 μm, respectively.

Along with Eq. [4], these values of depth of penetration serve to compare the surface and volume diffusion. Values for the saturation concentration c_{vo} and the diffusion coefficient D_v of hydrogen in electrolyte are known ($c_{vo} \cdot D_v = 2 \cdot 10^{-12} \cdot cm^{-1} \cdot sec^{-1} \cdot mol$ at 22°C). It reveals that in the expression for λ (Eq. [4]), the term $2c_{so} \cdot D_s$ should be greater than the term $r_p \cdot c_{vo} \cdot D_v$; this denotes that more hydrogen is transported along the pore wall than in the pore electrolyte. The product $c_{so} \cdot D_s$ amounts to $2.4 \cdot 10^{-18}$ mol $\cdot sec^{-1}$. In order to utilize the catalyst well, a powder with a particle diameter of less than 20 μm should be used.

Impedance measurements for analyzing supported Raney nickel electrodes.—In addition to evaluating the steady-state current-voltage curves it is also possible to analyze the supported Raney nickel electrodes by means of impedance measurements. In order to be able to interpret the locus curves a corresponding model has to be developed.

As in the treatment of steady-state behavior the diffusion of hydrogen and the charge-transfer reaction in a single pore was considered. The pore current has

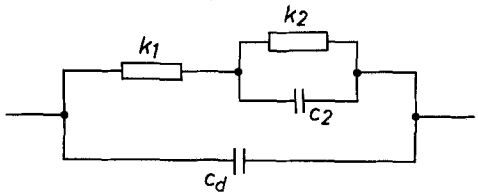

Fig. 11. Equivalent circuit diagram of the catalyst powder determined on the basis of the model.

been calculated for the case of an alternating polarization with smaller amplitudes. Only the double layer capacity remains to be included in the calculation so that the impedance at equilibrium potential can be determined. The equations for the real and imaginary parts of impedance are vague at the first instance. But if the frequency response is considered, the equivalent circuit diagram for the impedance of catalyst powder can be arrived at as represented in Fig. 11. The equivalent circuit diagram consists of two resistances k_1 and k_2 as well as two capacities c_2 and c_d. The following equations are obtained for the resistances (11)

$$k_1 = \frac{RT}{\mathbf{F}} \frac{1}{i_o \cdot f \cdot \gamma} \quad [5]$$

$$k_2 = k_1 \left(-1 + \frac{l}{\lambda} \coth \frac{l}{\lambda} \right) \quad [6]$$

Equation [5] denotes that k_1 is a charge-transfer resistance since it is dependent on the exchange current density i_o and does not contain the diffusion parameters. The pore length l and the depth λ of penetration are concealed in resistance k_2 which is in turn dependent on the exchange current density i_o and the dimensions of diffusion. If the penetration depth is large, k_2 and k_1 tend toward each other. It follows for the capacity c_2

$$c_2 = \frac{n\mathbf{F}(r_p \cdot c_{vo} + 2c_{so})}{2i_o \cdot k_1} \left(1 + \frac{\frac{l}{\lambda} - 3 \sinh \frac{l}{\lambda} \cosh \frac{l}{\lambda}}{2 \frac{l}{\lambda} \cosh^2 \frac{l}{\lambda}} \right) \quad [7]$$

In case of a low penetration depth, Eq. [7] is simplified to

$$c_2 = \frac{n\mathbf{F}}{2} \left(\frac{\mathbf{F}}{RT} \right) (r_p \cdot c_{vo} + 2c_{so}) \gamma \cdot f \quad [8]$$

The capacity c_2 is determined in this limiting case by the concentrations c_{vo} and c_{so} of hydrogen in the pore electrolyte and at the pore wall.

The course of an impedance measurement can be demonstrated by Fig. 12 and 13. At the beginning the electrodes are supplied with hydrogen at low pressure; the electrode is flooded but maintains the reversible potential. Beside the locus curve Im(Re), the imaginary part of the impedance is represented as a function of the angular frequency ω (curves 1 and 2 in Fig. 12). The locus curve traces a quadrant before running almost parallel to the ordinate. In addition to the charge-transfer resistance k_1, the double layer capacity c_d is thus obtained. If the electrode is not supplied with H_2 but with Ar instead and the working pressure Δp is maintained at 1 bar, an impedance diagram is obtained as represented in Fig. 12, curves 3 and 4. In the locus curve the slope of 45° is conspicuous and this could be understood if the complete equivalent circuit diagram of a supported electrode in Fig. 14 is examined. The diaphragm resistivity is denoted as ρ. The impedance Z contains in addition to the impedance k of the cata-

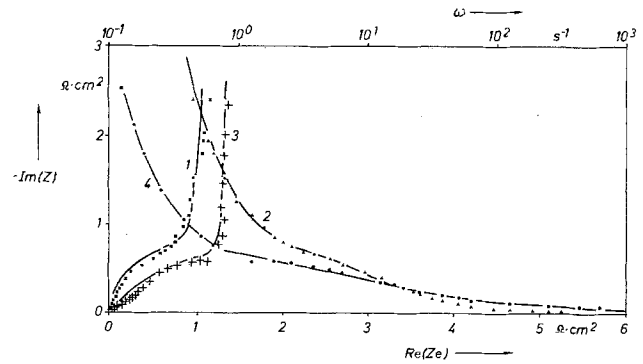

Fig. 12. Impedance measurement of an electrode with H_2 supply at low working pressure (curves 1 and 2) and with Ar supply at $\Delta p_{Ar} = 1$ bar; fraction 50-63 μm, 20 mg · cm^{-2}, 6M KOH, 22°C, $\Delta p_{H_2} = 0.2$ bar, evaluated by matching; $k_1 = 0.6\ \Omega \cdot cm^2$, $\rho d = 1.6\ \Omega \cdot cm^2$.

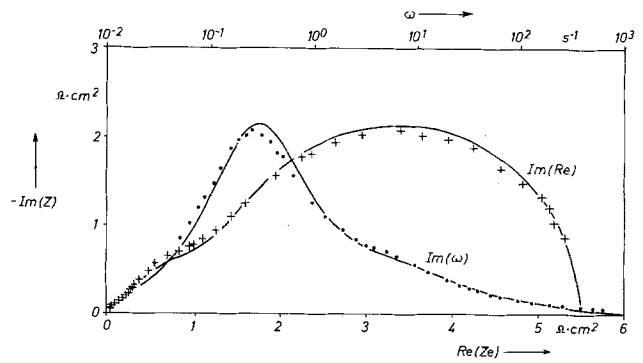

Fig. 13. In comparison to Fig. 12, the electrode is supplied with H_2 at the working pressure $\Delta p_{H_2} = 1$ bar, evaluated by matching: $k_1 = 0.6\ \Omega \cdot cm^2$, $k_2 = 1.6\ \Omega \cdot cm^2$, $c_d = 0.9$ F · cm^{-2}, $c_2 = 1.2$ F · cm^{-2}, $\rho d = 1.6\ \Omega \cdot cm^2$.

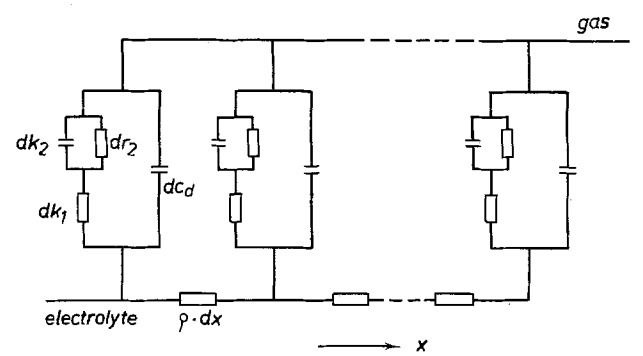

Fig. 14. Equivalent circuit diagram of a supported Raney nickel electrode. In addition to the impedance of catalyst powder, the diaphragm resistance is also considered.

lyst, the diaphragm resistivity ρ and the thickness d of the working layer

$$Z = \sqrt{\rho \cdot k}\coth\sqrt{\frac{\rho \cdot d^2}{k}} \qquad [9]$$

At high frequencies, the impedance k of the catalyst is essentially given by the double layer capacity c_d; Eq. [9] is thus simplified to

$$Z = \sqrt{j \cdot \rho \cdot \omega \cdot c_d} \qquad [10]$$

and it is now realized that the locus curve should have a slope of 45° at high frequencies. If the electrode is supplied with Ar (Fig. 12) it effects the impedance measurement at low frequencies because the capacities c_2 and c_d become dominant in the impedance k of the catalyst; the resistance k_2 is very high. The term coth in Eq. [9] becomes less significant in comparison to Eq. [1] and Eq. [9] is simplified to

$$Z = \frac{k}{d} + \rho\frac{d}{3} \qquad [11]$$

This diaphragm resistivity ρ comes into the real part of the impedance as an additive quantity and can be thus easily evaluated by comparison of locus curves in Fig. 12.

The results of impedance measurement while supplying hydrogen to the electrode under working pressure are represented in Fig. 13. The figure shows that the calculated curves could be matched satisfactorily with the five parameters of the model: k_1, k_2, ρ, c_d, and c_2. In the locus curve, the charge-transfer resistance k_1 acts at high frequencies whereas the resistance k_2 is effective at low frequencies.

From the charge-transfer resistance of 0.6 $\Omega \cdot cm^2$ and from Eq. [5], an exchange current density $i_o = 3$ $\mu A \cdot cm^{-2}$ is obtained. This value can be compared with that of 2 $\mu A \cdot cm^{-2}$ evaluated by steady-state measurements. With pure Raney nickel we found an exchange current density $i_o = 0.4$ $\mu A \cdot cm^{-2}$. From the values of capacity c_2 a surface concentration of hydrogen at the pore wall is obtained as $c_{so} = 2 \cdot 10^{-11}$ mol · cm^{-2}. The calculation of the diffusion coefficient D_s of surface diffusion is quite uncertain because it is strongly influenced by the pore length l which cannot be measured directly and which can only be estimated by the particle radius and a labyrinth factor. The value derived for the diffusion coefficient D_s ranges between $3 \cdot 10^{-8}$ and 10^{-7} cm^2 · sec^{-1}.

The considerations of steady-state and impedance measurements show that the charge-transfer phenomenon and the diffusion of hydrogen are essential for the reaction mechanism in the catalyst; the electrode, as such, is additionally governed by the diaphragm resistance.

Long-term performance and results of a cell.—The long-term performance of the catalyst is essential for the technical exploitation. At an electrolyte temperature of 80°C and at a current density of 300 mA · cm^{-2}, no rise in polarization could be observed over a period of 1000 hr. As the current density was raised to 400 mA · cm^{-2} the polarization increased by 13 $\mu V \cdot hr^{-1}$ (Fig. 15). At 500 mA · cm^{-2} the increase was 24 $\mu V \cdot hr^{-1}$. A fuel cell with an oxygen cathode containing silver as the catalyst yielded a voltage of 0.85V at a current density of 300 mA · cm^{-2} and at an electrolyte temperature of 80°C. This value dropped to 0.7V at a current density of 600 mA · cm^{-2}.

Activity Coefficients of Dilute Solutions of Lithium in Liquid Aluminum-Tin Alloys: Electromotive Force Measurements and Interpretation

Marie-Louise Saboungi* and Milton Blander

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The activity coefficients of Li solutions dilute in the binary alloy Al-Sn were determined from emf measurements. At $T = 949°K$, dilute solutions of Li in pure liquid Al and in pure liquid Sn follow the Nernst law. The data provide an independent and accurate evaluation of the limiting excess chemical potentials of Li in Al and in Sn, $\mu^{xs}_{Li(Al)} = -2.54$ kcal mol^{-1} (or -10.63 kJ mol^{-1}), and $\mu^{xs}_{Li(Sn)} = -12.22$ kcal mol^{-1} (or -51.14 kJ mol^{-1}), respectively. Variations of the Li activity coefficients with the solvent composition are discussed and various models for the interpretation of dilute solution activity data are reviewed. A refinement of the quasi-lattice theory is suggested where ΔA_i, the specific "bond" free energy corresponding to the changes in interactions in the equilibria (Eq. [16]) for forming the $LiAl_{(Z-i)}Sn_i$ species becomes a function of composition and of i. This new approximation for ΔA_i (Eq. [19]) is shown to give a better representation of the data than previous approximations (*e.g.*, Eq. [18]).

In recent years, there have been an increasing number of experimental investigations of alkali metals and their alloys as a consequence of their potential use in modern technology, *i.e.*, thermonuclear reactors, off-peak energy storage, etc. More specifically, in high temperature batteries, lithium and its alloys appear to be the most attractive candidates for the active

* Electrochemical Society Active Member.

Key words: electromotive forces, lithium alloys, solution theory, activity coefficient, ternary metallic systems.

material in the negative electrode (1, 2). Measurements on such alloys are important not only to broaden the data base but should also prove to be significant from a theoretical point of view. Several theories and models have been developed to provide fundamental insights into the thermodynamic (3-10) and structural (11-16) properties of liquid metals and alloys.

Using the quasi-chemical theory, Alcock and Richardson calculated the activity coefficient of a solute in a binary alloy solvent, assuming equal sizes for the atoms and considering several possibilities for the distribution of the atoms and their preferential surroundings (3, 4). Furthermore, on the basis of the formation of hypothetical molecules in the bulk alloy, Jacob and Alcock (5) carried out more detailed calculations. Wagner has recently worked out significant modifications of the quasi-chemical theory (6). Wagner reaches conclusions equivalent to those derived by Mathieu and co-workers (7, 8) and Lupis and co-workers (9, 10) who used the "surrounded" or "central" atom theory.

A different theoretical approach to this problem deals primarily with the energetics rather than with the form of the thermodynamic functions. The metallic interactions are studied using an effective pair potential, *i.e.*, hard sphere potential (11) coupled with simple or optimized pseudopotentials (12-14). There have been some improvements in these calculations such as the development of optimized electron potentials (15) and of screened potentials (16). However, it seems that more refinements are needed in order to completely describe a system, and to understand both the thermodynamic and the structural data.

In this paper, we report on electromotive force measurements of dilute solutions of Li in molten Al-Sn alloys using the cell

Bi(l) saturated with Li_3Bi(s)/

LiCl-LiF (eutectic mixture)/Li-Al-Sn [1]

Dilute solutions of Li in Al or in Sn are found to behave according to the Nernst law. Furthermore, the limiting excess chemical potentials of Li in pure liquid Al and in pure liquid Sn are close to those obtained by extrapolating earlier data reported in more concentrated solutions by Yatsenko and Saltykova (17) and by Foster, Crouthamel, and Wood (18), respectively. Dilute solutions of Li in the binary solvent, Al-Sn, exhibit negative deviations from ideality for all compositions of the solvent. The variations of the activity coefficients of lithium as a function of the tin atom fraction are discussed on the basis of a generalized quasi-lattice theory developed first for molten salt mixtures by Blander and co-workers (19-21). The equations derived by Blander (19), when rewritten for alloys, are the same as those later derived by Wagner (6). Here, we use a new linear approximation for the energetics of the metallic interactions where the deviations from ideality of the binary solvent are included. In addition, the relative free energies of "bond" formation between Li and Sn are defined and the types of species which might be present in the ternary alloys are discussed.

Experimental

Materials.—The electrolyte was prepared by weighing the appropriate amounts of the salts [70 mol percent (m/o) LiCl, 30 m/o LiF]. Anhydrous purified LiCl was supplied in 200g ampuls by the Anderson Physics Laboratory, Champaign, Illinois. Pure single crystals of LiF (optical grade) from the Harshaw Chemical Company, Cleveland, Ohio, were used without further purification.

Lithium metal (99.97% purity) was purchased from the Foote Mineral Company, Philadelphia, Pennsylvania, in the form of 1 lb ingots sealed in cans under an argon atmosphere. Prior to use, the metal was purified by a method described elsewhere (22, 23). A typical analysis indicated 200 ppm N_2 and 600 ppm O_2.

Aluminum metal (99.9999% purity) was obtained in the form of rods from Materials Research Corporation, Orangeburg, New York. Bismuth metal (99.999% purity) was purchased from United Mineral and Chemical Corporation, New York. Tin metal (99.9% purity) from J. T. Baker Chemical Company, Phillipsburg, New Jersey, was used. Any oxide coating present on the surface of these metals was removed by manual filing; the filing was done slowly to avoid any possible oxidation due to frictional heating of the surface.

Experimental procedure.—The experimental arrangement of the cells and the procedure followed in this investigation are similar to those previously described in Ref. (22). An outer tantalum crucible contained the molten alloy (the positive electrode). A porous high purity beryllia cup suspended in the alloy contained the molten electrolyte, the LiF-LiCl eutectic mixture, in which was immersed the reference electrode. The BeO cup served as a barrier between the two electrode compartments. Presoaking of the cup with the molten electrolyte minimized any possible chemical attack due to penetration into the pores by corrosive elements such as lithium (24). The reference electrode consisted of a premelted (at 1123°K) two-phase binary system with an overall composition of 60.5 atom percent (a/o) Li and 39.5 a/o Bi held in a small tantalum cup which was submerged in the electrolyte. At the temperature of our measurements, $T = 949$°K, this composition provides a Li-Bi solution saturated with the compound Li_3Bi(s). The electromotive force of this two-phase electrode relative to pure Li is well known (25, 26) and has proved to be very stable with respect to small composition changes. In addition, the solubility of metallic Li in the electrolyte is negligible, probably less than 10^{-2} m/o (27, 28), because of its low activity in the reference electrode.

Tantalum leads connected both electrodes to a digital voltmeter (Dana Model 5000, input resistance greater than $10^{10}\Omega$). The temperature was held constant within a couple of degrees and measured with a tantalum-sheathed calibrated (Pt-Pt 10% Rh) thermocouple.

The cells were operated starting with different solvents which were either pure aluminum, pure tin, or an appropriate mixture of Al-Sn. The composition in the bulk alloy was changed by adding successive weighed quantities of Li, Sn, or Al. For each point, the equilibration of the cell with respect to temperature and voltage was rapidly attained [usually less than 2 hr (or 7200 sec) for large additions and 10 min (or 600 sec) for small additions which led to an increment of less than 1 m/o]. The emf's measured were steady and stable within several tenths of a millivolt for periods of observation up to a day. After temperature cycling, the emf's generally returned to the original value, thus demonstrating the reversibility of the cell.

Finally, it should be pointed out that all these operations were completely carried out inside a glove box filled with helium purified according to a method described elsewhere (29). In this inert atmosphere, there were less than 5 ppm water and oxygen was undetected (limit of detection 1 ppm).

Results.—In all that follows, unless specified differently, pure liquid Li is defined as the standard state.

Dilute solutions of Li in Al and in Sn.—Checks of the Nernst law for dilute solutions of Li-M (M ≡ Al or M ≡ Sn) were first carried out at a constant tem-

perature, $T = 949°K$. The emf's, E, of the alloys vary with composition according to the relation

$$E = E°_{Li(M)} - \frac{RT}{F} \ln a_{Li} \quad [2]$$

where R is the gas constant; F, the Faraday constant; a_{Li}, the activity of lithium in the alloys; and $E°_{Li(M)}$, the limiting potential of Li in pure liquid M *vs.* the two-phase reference electrode.

Figure 1 shows the results obtained at 949°K in two separate runs of the cell

Bi(l) saturated with Li_3Bi(s)/
LiCl-LiF(eutectic)/Li-Al [3]

The emf's are plotted as a function of atom fraction of Li in the binary alloy, together with the calculated Nernst slope: $2.3026\ RT/F = 188.30$ mV. A least squares fit of the data leads to a slope of 188.07 ± 0.59 mV which is in excellent agreement with the theoretical value, and to a value of $E°_{Li(Al)} = -536.39 \pm 1.54$ mV. At 949°K, our present value of $E°_{Li(Al)}$ combined with the potential of the reference electrode *vs.* pure lithium, 646.41 mV, as reported previously (25, 26) provides a limiting excess chemical potential of Li in pure liquid Al

$$\mu^{xs}_{Li(Al)} = -2.54 \text{ kcal mol}^{-1} \text{ (or } -10.63 \text{ kJ mol}^{-1})$$

If one extrapolates the data of Yatsenko and Saltykova (17) measured at higher concentrations (≥ 5 m/o Li) and at 1023°K, one obtains an approximate value: $\mu^{xs}_{Li(Al)} \simeq -2.6$ kcal mol^{-1} (or −10.9 kJ mol^{-1}) which is in good agreement with our measurements. The difference of 0.06 kcal mol^{-1} corresponds to an emf discrepancy of 2.5 mV which is remarkably good considering the extrapolation and the difference in temperatures.

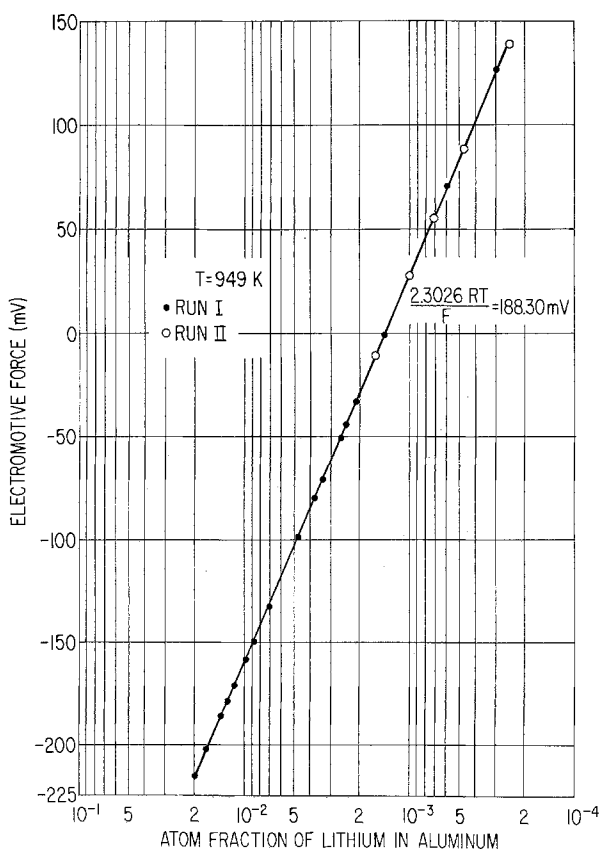

Fig. 1. Electromotive force of the cell
Bi saturated with Li_3Bi(s)/LiF-LiCl(eutectic)/Li-Al at $T = 949°K$ The full and empty circles represent data collected in two different runs. The slope of the line is equal to the calculated Nernst slope, 188.30 mV.

For the dilute solutions of Li in Sn, the data obtained *vs.* the two-phase reference electrode fit well along the Nernst slope of 188.30 mV with a value of $E°_{Li(Sn)} = -116 \pm 1$ mV. The limiting excess chemical potential of Li in pure liquid tin is consequently

$$\mu^{xs}_{Li(Sn)} = -12.22 \text{ kcal mol}^{-1} \text{ (or } -51.14 \text{ kJ mol}^{-1})$$

This value is consistent with the value of −12.36 kcal mol^{-1} (or −51.71 kJ mol^{-1}) obtained by extrapolating the data of Foster *et al.* (18) from higher concentrations of Li (≧10 m/o). Foster *et al.* reported experimental difficulties with their cells, and the standard deviations in the least squares fit of the emf values varied between 1 and 3 mV (18). The difference between these two values of $E°_{Li(Sn)}$ corresponds to about 6 mV.

The fit of the Nernst law equation in the Li atom fraction demonstrates that both dilute solutions of Li-Al and Li-Sn follow Henry's law and therefore the activity coefficient of Li is constant in this concentration range.

Dilute solutions of Li in the Al-Sn alloy.—The potentials of the cell [1] were measured at 949°K for different compositions of the alloy Al-Sn. In all these runs, the atom fraction of Li did not exceed 2.01×10^{-2}, which is within the range of concentration where the Nernst law is obeyed.

Two separate series of measurements were carried out by adding small weighed amounts of Sn to a Li-Al alloy of a given composition ($X_{Li} = 1.63 \times 10^{-3}$ or $X_{Li} = 2.01 \times 10^{-2}$, respectively, with X_i referring to the atom fraction of the ith component in the solution). The experimental values obtained for the electromotive forces, E, at different compositions of the alloy are listed in Table I. By choosing as a standard state the solution of Li at infinite dilution in Al, the activity coefficients of Li, $\gamma_{Li}^{(Al)}$, can be calculated from the following equation

$$\ln \gamma_{Li}^{(Al)} = \ln \frac{\gamma_{Li}}{\gamma_{Li(Al)}} = \frac{-F(E - E°_{Li(Al)})}{RT} - \ln X_{Li} \quad [4]$$

where γ_{Li} represents the activity coefficient of Li referred to pure liquid lithium and $\gamma_{Li(Al)}$, the activity coefficient of lithium at infinite dilution in Al.[1] The values of $\ln \gamma_{Li}^{(Al)}$ are plotted *vs.* X_{Sn} in the inset of Fig. 2.

At higher concentrations of Sn, two separate runs were performed. In the first series of measurements, successive additions of Al were made to a solution

[1] In order to convert these activity coefficients to activity coefficients with pure liquid lithium as standard state, one should add to the right-hand side of Eq. [4] the natural logarithm of $\gamma_{Li(Al)}$ · ($\ln \gamma_{Li(Al)} = -2540$ cal/$RT = -1.347$).

I refers to the set of measurements performed starting with the binary alloy Li-Al at a given composition ($X_{Li} = 0.0201$).
II refers to the set of measurements performed starting with the binary alloy Li-Al at a given composition ($X_{Li} = 0.00163$).
In both cases, weighed amounts of Sn were added to the initial alloy.
X_{Al} and X_{Sn} represent the atom fractions of Al and Sn, respectively, in the Li-Al-Sn alloy.
E represents the emf values obtained in cell [1].

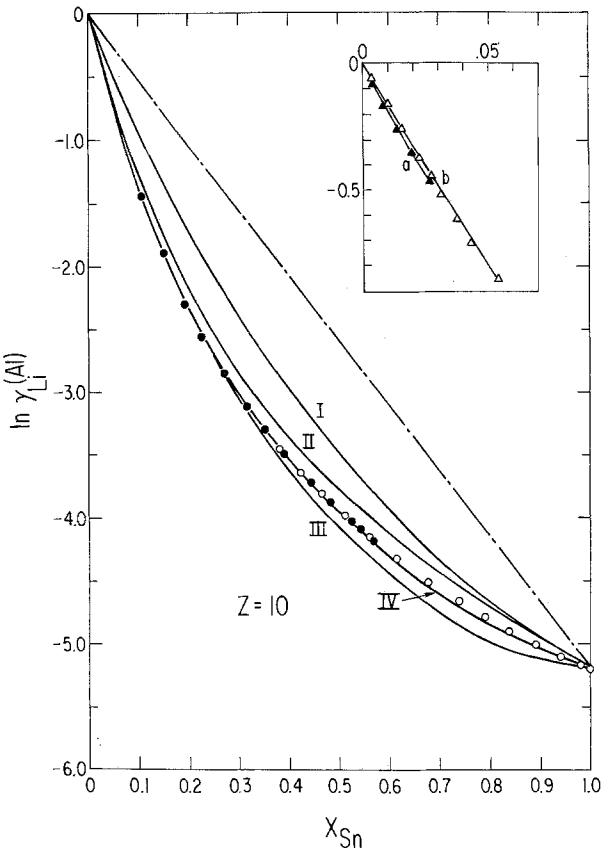

Fig. 2. Variations of $\ln \gamma_{Li}^{(Al)}$ with the composition of the solvent Al-Sn at 949°K, for dilute solutions of Li. ○ refers to the run performed starting with Li-Sn ($X_{Sn} = 0.9850$), ● refers to the run performed starting with Li-Al-Sn ($X_{Li} = 0.0145$ and $X_{Al} = 0.3968$), △ refers to the run performed starting with Li-Al ($X_{Li} = 1.63 \times 10^{-3}$), and ▲ refers to the run performed starting with Li-Al ($X_{Li} = 2.01 \times 10^{-2}$). Curve I is calculated using Eq. [27], curve II is calculated using Eq. [28], curve III is calculated using Eq. [18] for ΔA_i and Eq. [17] for $\gamma_{Li}^{(Al)}$, and curve IV is calculated using Eq. [19] for ΔA_i and Eq. [17] for $\gamma_{Li}^{(Al)}$. Curves a and b give the calculated values of $\ln \gamma_{Li}^{(Al)}$ for the two different runs (initial values of $X_{Li} = 2.01 \times 10^{-2}$ and 1.63×10^{-3}, respectively).

of Li-Sn ($X_{Li} = 0.0150$); in the second series, successive additions of Al were made to a solution of Li-Al-Sn ($X_{Li} = 0.0145$ and $X_{Al} = 0.3968$). By this method, we were able to cover the entire range of Al-Sn concentrations and to double-check the reproducibility of our data. Values of E, X_{Li}, and X_{Sn} are reported in Table II; it should be pointed out that where the compositions overlapped, the emf values in the two runs were remarkably self-consistent (within less than 1 mV). In Fig. 2 values of $\ln \gamma_{Li}^{(Al)}$ calculated from Eq. [4] are plotted *vs.* the mole fraction of tin. The slope of the curve becomes less negative as the atom fraction of Sn increases.

The interpretation of the variations of $\ln \gamma_{Li}^{(Al)}$ are discussed later in terms of the theory presented in the following section.

Theory and Calculations

For the sake of generality, the calculations presented in this section deal with the substitutional ternary system designated as A-B-C. (As the molar volumes of liquid Li, Al, and Sn do not differ greatly, the system under consideration can probably be best considered as a substitutional alloy.)

First, formation of complexes or groupings between A and B are postulated to describe the thermodynamics of dilute solutions of A and B in C. Second, an extension and a modification of the quasi-latttice theory (19-21) are suggested for dilute solutions of

A refers to the set of measurements performed starting with a binary Li-Sn alloy to which successive weighed amounts of Al were added.
B refers to the set of measurements performed starting with an initial alloy of Li-Al-Sn ($X_{Al} = 0.3968$ and $X_{Li} = 0.0145$) to which successive weighed amounts of Al were added.
X_{Al} and X_{Li} represent the atom fractions of Al and Li, respectively, in the Li-Al-Sn alloy.
E represents the emf values obtained in cell [1].

A in the binary solvent B-C. At all compositions of the solvent, it is assumed that the addition of A leads to changes in the "bonds" between atoms B and C. Finally, the equations obtained for the activity coefficients of A are compared with those derived from other theories.

In all that follows, γ_A (and $\gamma_A^{(C)}$) designate the activity coefficients of A with pure liquid A (and a solution of A at infinite dilution in C) as standard state.

Dilute solutions of A and B in C.—For the two interacting species A and B, the definition of associated species is most precise and meaningful in dilute solutions of A and B in the solvent C.

In this range of concentrations, groupings such as

$$A + B \rightleftharpoons AB \quad K_1 \qquad [5]$$

$$AB + B \rightleftharpoons AB_2 \quad K_2 \qquad [6]$$

$$AB + A \rightleftharpoons A_2B \quad K_{12}, \text{etc.} \qquad [7]$$

may occur in solution. The K_i's are defined as equilibrium constants

$$K_1 = \frac{X'_{AB}}{X'_A X'_B} \qquad [8]$$

$$K_2 = \frac{X'_{AB_2}}{X'_{AB} X'_B} \qquad [9]$$

$$K_{12} = \frac{X'_{A_2B}}{X'_{AB} X'_A}, \text{etc.} \qquad [10]$$

where X'_i refers to the atom fractions of the ith "free species." The atom fractions X_i and X'_i are related by the mass balance relations. The K_i's are true constants in solutions dilute enough so that Henry's law is obeyed. Consequently, deviations from ideality caused only by the formation of these groupings can be calculated using the following definition for the activity coefficients of A: $\gamma_A^{(C)} = X'_A/X_A$. After a series of expansions similar to those used for molten salts (30), one obtains

$$-\ln \gamma_A^{(C)} = K_1 X_B + (K_1 K_2 - \frac{1}{2} K_1^2) X_B^2 + (2K_1 K_{12} - K_1^2) X_A X_B + \ldots \qquad [11]$$

The coefficients in Eq. [11] are similar to the interaction coefficients introduced earlier by Wagner (31). They have thermodynamic significance when calculated as limiting values at infinite dilution of A and B in C.

There are two ways to evaluate the K_i's. One way is graphical; for example, K_1 is the limiting slope of the curve representing the variations of $\ln \gamma_A^{(C)}$ with X_B. The second way consists of a least squares method; values of $\ln \gamma_A^{(C)}$, at fixed values of the number of moles of A, are fitted to the equation

$$-\ln \gamma_A^{(C)} = MX_B + NX_B^2 \quad [12]$$

Details on the advantage of using either procedure and an analysis of the errors related to the coefficients derived are given in a paper by Braunstein, Lindgren, and Blander (30).

In a quasi-lattice formulation (30), a specific bond free energy change, ΔA_i, corresponding to the equilibria [5]-[7] can be defined; ΔA_i is associated with the replacement of an atom C by an atom B in the first coordination shell of an atom A. Statistically, the distribution of the atoms B between the bulk of the solvent B-C and the first coordination shell of A is calculated assuming the nonadditivity of pair bond interactions. (Nonadditivity means that the values of ΔA_i differ for consecutive values of i.) The equations thus derived can be written in our notation

$$K_1 = Z(\beta_1^\circ - 1) \quad [13]$$

$$K_1K_2 = \frac{Z(Z-1)}{2}(\beta_1^\circ\beta_2^\circ - 2\beta_1^\circ + 1) \quad [14]$$

$$K_1K_{12} = \frac{Z(Z-1)}{2}(\beta_1^\circ\beta_{12}^\circ - 2\beta_1^\circ + 1) \quad [15]$$

where $\beta_i^\circ = \exp(-\Delta A_i^\circ/RT)$ and ΔA_i° is the limiting value of ΔA_i at infinite dilution of B in C. These equations combined with Eq. [11] define ΔA_i° for any given value of Z. A negative sign for ΔA_i° indicates a preferential distribution of B atoms around A.

Dilute solutions of A in the solvent B-C.—The thermodynamic properties of A dilute in the binary alloy B-C can readily be described for all compositions of the solvent, in terms of the quasi-lattice theory by properly adapting the expressions obtained for similar situations in molten salt mixtures (19). In this range of concentrations, equilibria [5]-[7] can be written more generally as

$$A[B_{i-1}C_{Z-i+1}] + B[B\,C] \rightleftharpoons A[B_iC_{Z-i}] + C[B\,C] \quad [16]$$

The brackets $[B_{i-1}C_{Z-i+1}]$ and $[B_iC_{Z-i}]$ define the distribution of B and C in the Z positions of the coordination shell of A while [B C] means that the atom preceding the brackets (B or C) is an atom in the bulk alloy and occupies positions which are not near an A atom.

The two regions for the distribution of B and C, that next to an A atom and that in the bulk alloy, are considered in the statistical mechanical calculations. For the activity coefficient of A, one derives the following expression

$$\gamma_A^{(C)} = \left[\sum_{i=0}^{Z} \frac{Z!}{i!(Z-i)!} X_B{}^i(1-X_B)^{Z-i}\beta_o \ldots \beta_i\right]^{-1} \quad [17]$$

where $\beta_o = \exp(\mu^{xs}{}_C(X_B))/RT$ and $\mu^{xs}{}_C(X_B)$ is the excess chemical potential of C in the solvent B-C. The quantity β_o arises from a consideration of the dissolution of A in B-C to form a configuration $A[C_Z]$. β_o represents a correction for the difference between making the configuration $A[C_Z]$ in the binary B-C and in pure C. The quantity β_i ($i = 1, \ldots, Z$) is expressed by $\beta_i = \exp(-\Delta A_i/RT)$.

In principle, one can utilize Eq. [17] to extract values of specific bond free energies for all species by fitting the experimental data for a given value of Z (*e.g.*, $Z = 10$ or $Z = 12$). In practice, there are ambiguities inherent in attempting to fit such a high order polynomial to a curve; in addition, the evaluation of the high order coefficients (*e.g.*, $i > 2$) would be very uncertain. However, as shown in the preceding section, the evaluation of the lower order coefficients, especially that for $i = 1$, K_1 or β_1, is less ambiguous and less uncertain.

A more practical way would be to find an expression allowing one to calculate approximately the relative values of ΔA_i.

Mathieu (7, 8), Lupis (9, 10), and recently Wagner (6), using as a framework for their calculations different models of alloys, suggested a heuristic approximation for ΔA_i which, in our notation, reads

$$\Delta A_i = \Delta A_1^\circ + (i-1)h \quad [18]$$

The quantity h is a constant defined as the free energy difference for consecutive values of i. This particularly convenient approximation is generated from the assumption that the solvation energy of A atoms in the solvent has a parabolic dependence on i.

If one examines Eq. [18], one finds that ΔA_i is assumed to be concentration independent since ΔA_i° is derived at infinite dilution of B in C. Appropriate modifications of Eq. [18] appear to be needed.

The replacement of a C atom by a B atom in the coordination shell of A breaks one bond A-C and creates another bond A-B (reaction [16]). This process also breaks $(1/Z)$ of the contacts between a B atom and the bulk alloy and makes $(1/Z)$ new contacts between a C atom and the bulk alloy. Therefore, a correction to Eq. [18] taking into account deviations from ideality of the solvent is necessary. This correction can be approximated by, $(\mu^{xs}{}_C(X_B) - \mu^{xs}{}_B(X_B))/Z$, where $\mu^{xs}{}_B(X_B)$ is the excess chemical potential of B in the binary solvent B-C. Consequently, a new form for ΔA_i is deduced

$$\Delta A_i = \Delta A_1^\circ + (i-1)h + Z^{-1}[(\mu^{xs}{}_C(X_B) - \mu^{xs}{}_C(X_B = 0)) - (\mu^{xs}{}_B(X_B) - \mu^{xs}{}_B(X_B = 0))] \quad [19]$$

The quantity $(i-1)h$ takes into account the interactions of B and C in the coordination shell around an A atom. The factor Z^{-1} implies that the interactions with the solvent are additive. If such bond additivity is a reasonable approximation for the bulk alloy, then the dependence of ΔA_i on i is expressed independently of its dependence on concentration.

If the quantity $h = 0$, the specific bond free energies are all equal: $\Delta A_1 = \Delta A_i$ ($i = 1, \ldots, Z$). Substituting Eq. [19] in Eq. [17] leads then to the equation derived by Alcock and Richardson (4).

If the solvent B-C behaves as an ideal solution, ΔA_i becomes concentration independent and $\beta_o = 1$. Equations [17] and [19] then become identical to those derived by Mathieu *et al.* (7, 8) and Wagner (6) for interstitial alloys.

If the binary solvent B-C behaves as a regular solution, ΔA_i varies linearly with the composition. The excess Gibbs free energy of mixing of the solvent is then given by

$$\Delta G^{xs}(B\text{-}C) = X_B\mu^{xs}{}_B + (1-X_B)\mu^{xs}{}_C = \frac{1}{2}X_B(1-X_B)\lambda \quad [20]$$

where λ is defined as an interaction coefficient in the alloy B-C. In this case, ΔA_i is expressed by the simple relation

$$\Delta A_i = \Delta A_1^\circ + (i-1)h + \lambda Z^{-1}X_B \quad [21]$$

One may consider some other modifications to Eq. [19]. If the assumption of bond additivity of the

$(Z - 1)$ contacts with the bulk alloy of the atoms surrounding A does not seem appropriate, then one might consider the parameter h to be concentration dependent and/or a function of i. In such cases, at least one more parameter would be necessary to describe the solution properties.

Finally, interstitial alloys can be studied following the same treatment as for reciprocal[2] molten salt mixtures (19). Equations similar to Eq. [17] and [19] should apply. The deviations from ideality of the solvent B-C should be included in the approximate relation for ΔA_i. The factor Z^{-1} preceding the term in brackets in Eq. [19] is replaced by a larger number dependent on the geometry of the sites around A. In addition, the only other changes are due to the differences in the numbers of sites available to an atom; such formal, but not fundamental, differences can always be included by a modification of the concentration scale of the X's in the equilibrium constants, K_i, so that the concentrations are expressed as a fraction of the total sites available to an atom and not necessarily as an atom fraction.

Reconciliation of Theory and Experiment

In this section, our results will be examined in light of the equations we have discussed. A comparison will be made between the experimental results and the calculations for dilute solutions of Li in the binary solvent Al-Sn. We consider that A ≡ Li, B ≡ Sn, and C ≡ Al.

Evaluation of the equilibrium constants.—Values of K_1, K_2, and K_{12} are derived from a least squares fit of the data obtained in dilute solutions of Li and Sn in Al (Table I)

$$K_1 = 17.4 \pm 0.15,\ K_2 = 7.1 \pm 0.3,\ \text{and}\ K_{12} = 10.0 \pm 0.15$$

The uncertainties in these constants are probably about four times larger than the stated precision. The presence of a significant concentration of polynuclear species with more than two Li atoms would increase the uncertainty in K_{12}. In addition, the presence of such species other than Li_2Sn cannot be ascertained with measurements at only two concentrations of Li. For $Z = 10$, for example, we deduce values of the specific bond free energies of $\Delta A_1^\circ = -1.90$ kcal mol^{-1} (or -7.95 kJ mol^{-1}), $\Delta A_2^\circ = -1.83$ kcal mol^{-1} (or -7.66 kJ mol^{-1}) and $\Delta A_{12}^\circ = -2.10$ kcal mol^{-1} (or -8.79 kJ mol^{-1}). The fact that the ΔA_i° are negative indicates that there is a preferential distribution of Sn about Li and of Li about Sn.

At the tin-rich end, one may evaluate the equilibrium constant, K_1', and the specific bond free energy, $\Delta A_1'$, corresponding to

$$Li[Sn_Z] + Al[Sn_Z] \rightleftharpoons Li[Sn_{Z-1}Al] + Sn[Sn_Z] \qquad [22]$$

The quantity, $\Delta A_1'$ is positive since Li is preferentially coordinated by Sn. At $X_{Sn} = 1$, one may write

$$\Delta A_1' = -\Delta A_Z(X_{Sn} = 1) \qquad [23]$$

and

$$\beta_1' = 1/\beta_Z(X_{Sn} = 1) \qquad [24]$$

Consequently, the formal equilibrium constant, K_1', is negative. The reason for this peculiarity has been discussed elsewhere (19). Only if there is an energetic preference for an aluminum in the coordination shell of Li in the Sn-rich solution can K_1' be positive and the limiting slope, $(d \ln \gamma_{Li}^{(Al)}/dX_{Al})_{X_{Li}=X_{Al}=0} = -K_1'$, negative. However, as long as $\Delta A_1'$ is positive, K_1' is negative and the limiting slope is positive.

[2] A reciprocal ionic system contains two different kinds of cations; A^+ and B^+, and two different kinds of anions, X^- and Y^-; it can be schematized by $(A^+,B^+/X^-,Y^-)$. Formally, reciprocal systems are equivalent to interstitial alloys.

A least squares fit of our data leads to $K_1' = -1.72 \pm 0.01$ and $\Delta A_1' = 0.35$ kcal mol^{-1} (or 1.46 kJ mol^{-1}), for $Z = 10$.

The specific bond free energies, ΔA_1° (negative) and $\Delta A_1'$ (positive), usually cannot be determined with the same precision; even if one uses the same method to calculate both of them, the relative uncertainty of $\Delta A_1'$ is generally larger and is especially so when K_1' is close to $-Z$.

Variations of the activity coefficients of Li with the composition of the binary solvent Al-Sn in dilute Li solutions.—Figure 2 gives the variations of $\ln \gamma_{Li}^{(Al)}$ with the tin atom fraction in the ternary alloy Li-Al-Sn dilute in Li. In order to understand these results and to estimate the influence of certain parameters discussed previously, we will calculate $\ln \gamma_{Li}^{(Al)}$ using equations derived from different models.

Using the quasi-chemical theory, Alcock and Richardson (3) derived a simple relation for $\ln \gamma_{Li}$ which in our notation reads

$$\ln \gamma_{Li}^{(Al)} = X_{Sn} \ln \frac{\gamma_{Li(Sn)}}{\gamma_{Li(Al)}} - \frac{\Delta G^{xs}(Al\text{-}Sn)}{RT} \qquad [25]$$

$\Delta G^{xs}(Al\text{-}Sn)$ designates the excess Gibbs free energy of mixing of the binary Al-Sn. It should be pointed out that Darken (32) obtained Eq. [25] without reference to any particular physical model. Later, Alcock and Richardson (4), modifying their assumptions, proposed another equation

$$\gamma_{Li}^{(Al)} = \left[X_{Al}(\gamma_{Al})^{1/Z} + X_{Sn}\left(\frac{\gamma_{Sn}\gamma_{Li(Al)}}{\gamma_{Li(Sn)}}\right)^{1/Z}\right]^{-Z} \qquad [26]$$

where γ_{Al} and γ_{Sn} refer to the activity coefficients of Al and Sn, respectively, in the binary solvent Al-Sn. Substituting the values for $\Delta G^{xs}(Al\text{-}Sn)$, γ_{Al} and γ_{Sn} given in the literature (33, 34) and our experimental values of $\gamma_{Li(Al)}$ and $\gamma_{Li(Sn)}$, Eq. [25] or [26] leads to a poor description of the experimental data. (Note that Eq. [26] can be obtained from Eq. [17] and [19] as a limiting case when $h = 0$.)

One may improve Alcock and Richardson's equations by an empirical modification. To do this, the atom fractions, X, are replaced by volume fractions, $\overline{V}$, defined as follows

$$\overline{V}_{Al} = \frac{X_{Al}V_{Al}}{X_{Al}V_{Al} + X_{Sn}V_{Sn}} \quad \text{and} \quad \overline{V}_{Sn} = 1 - \overline{V}_{Al}$$

where V_{Al} and V_{Sn} represent the molar volumes of Al and Sn, respectively. Equations [25] and [26] can be rewritten as

$$\ln \gamma_{Li}^{(Al)} = \overline{V}_{Sn} \ln\left(\frac{\gamma_{Li(Sn)}}{\gamma_{Li(Al)}}\right) - \frac{\Delta G^{xs}(Al\text{-}Sn)}{RT} \qquad [27]$$

and

$$\gamma_{Li}^{(Al)} = \left[\overline{V}_{Al}(\gamma_{Al})^{1/Z} + \overline{V}_{Sn}\left(\frac{\gamma_{Sn}\gamma_{Li(Al)}}{\gamma_{Li(Sn)}}\right)^{1/Z}\right]^{-Z} \qquad [28]$$

For $Z = 10$, the values obtained for $\ln \gamma_{Li}^{(Al)}$ using Eq. [27] and [28] are plotted in Fig. 2 (curves I and II, respectively). The differences between experiments and curve I are much larger than the combined uncertainties. Curve II gives a much better fit than Eq. [25]-[27]; nevertheless, it does not describe the behavior of these alloys accurately. On the other hand, Eq. [28] is attractive in that there are no adjustable parameters. However, if Z, the coordination number of Li, is used as a parameter, the calculations fit the experiments fairly well for $Z = 7$.

The experimental data may be compared with Eq. [17], using one of the approximations for ΔA_i. The simplest approximation would be Eq. [18] which assumes that ΔA_i is concentration independent. The value of h is obtained from the relation

$$RT \ln \gamma_{Li}^{(Al)}(X_{Sn} = 1) - RT \ln \gamma_{Li}^{(Al)}(X_{Sn} = 0) = \sum_{i=1}^{Z} \Delta A_i(X_{Sn} = 1) = Z\Delta A_1^\circ + \frac{Z(Z-1)}{2} h \quad [29]$$

For $Z = 10$ and $\Delta A_1^\circ = -1.90$ kcal mol^{-1} (or -7.95 kJ mol^{-1}), we derive $h = 0.20$ kcal mol^{-1} (or 0.86 kJ mol^{-1}). The calculated values for $\ln \gamma_{Li}^{(Al)}$ plotted *vs.* X_{Sn} define curve III in Fig. 2. The differences between experimental data and curve III are more important at the tin-rich end than at the aluminum-rich end. This is obviously due to the fact that the calculation uses the limiting slope determined for low values of X_{Sn} which constrains the curve to follow the experimental points initially. The calculations do match the data somewhat better for smaller values of Z ($Z = 8$).

Since the solvent, Al-Sn, exhibits deviations from ideality, the new approximation for ΔA_i (Eq. [19]) should be considered. The quantity h is then evaluated from the following equation similar to Eq. [29]

$$RT \ln \gamma_{Li}^{(Al)}(X_{Sn} = 1) - RT \ln \gamma_{Li}^{(Al)}(X_{Sn} = 0) = Z\Delta A_1^\circ + \frac{Z(Z-1)h}{2} + \mu^{xs}{}_{Sn}(X_{Sn} = 0) \quad [30]$$

For $Z = 10$, we obtain $h = 0.12$ kcal mol^{-1} (or 0.52 kJ mol^{-1}). The curve calculated for $\ln \gamma_{Li}^{(Al)}$ as a function of X_{Sn} is plotted in Fig. 2 and labeled curve IV. The correspondence between the measurements and the calculations is surprisingly good; curve IV exhibits the same asymmetry as the experimental data. This excellent agreement leads us to conclude that, for this case, Eq. [19] gives an accurate approximation for ΔA_i. Finally, calculations were also performed using different values for Z ($Z = 8$ and $Z = 12$); they led to reasonably good agreement with the data.

Within the context of the quasi-lattice theory, the good fit of the measurements with the calculations implies that the distribution of the species can be tentatively estimated. The relative fraction of lithium atoms present in the ith species, $N_i^*(Li)$, can be written as

$$N_i^*(Li) = \frac{Z!}{(Z-i)!i!} X_{Sn}{}^i (1 - X_{Sn})^{Z-i} \gamma_{Li}^{(Al)} \beta_0 \ldots \beta_i \quad [31]$$

where i is an integer varying between 0 and the coordination number, Z. Calculated values of $N_i^*(Li)$ are, of course, model dependent. For $Z = 10$, the relative fractions of Li having 0, 1, 5, 9, and 10 Sn atom(s) as nearest neighbors, are calculated as a function of the atom fraction of Sn. The results are plotted *vs.* X_{Sn} in Fig. 3. As expected, both species 0 and 10 vary monotonically between 0 and 1. However, there is an obvious asymmetry in these curves: the curve for species 0 falls more steeply at $X_{Sn} = 0$ than the curve for species 10 rises at $X_{Sn} = 1$. The curves representing the species 1, 5, and 9 exhibit a maximum and go to zero at both ends $X_{Sn} = 0$ and $X_{Sn} = 1$. It should be noted that the maximum of the curve of the species $i = 1$ is greater than that for the species $i = 9$. In addition, the positions of all the maxima are at values of X_{Sn} less than (i/Z); this arises largely because the values of ΔA_i are always negative and increase monotonically with an increase of i and X_{Sn}. Despite the fact that the plots of Fig. 3 are model dependent, they probably provide a reasonable picture of the distributions of species in the real solution. Similar curves could be obtained for values of Z other than 10.

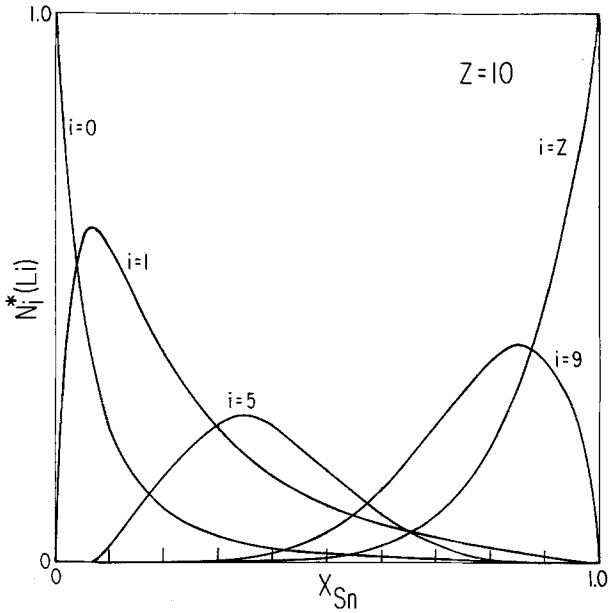

Fig. 3. Variations of the calculated relative fraction of lithium atoms present in the *i*th ($i = 1, \ldots, Z$) species ($LiSn_i$) with the atom fraction X_{Sn} for $Z = 10$.

Concluding Remarks

Accurate measurements of the activity coefficients of dilute solutions of Li in the binary Al-Sn are presented and discussed in the light of several models

The equations derived by Alcock and Richardson (4) from the quasi-chemical theory lead to a fair fit with the data only if an empirical modification is introduced, in which volume fractions are substituted for atom fractions. If, in addition, the coordination number, Z, is considered as an adjustable parameter, the modified equation fits our data fairly well for $Z = 7$.

The equations proposed in this paper are based on the quasi-lattice theory of Blander *et al.* (19-21). The relation obtained for the activity coefficients of lithium is the same as the one derived later using other models (6-10). These equations, with an approximation for the energetics suggested by Wagner (6), Mathieu *et al.* (7, 8), and Lupis *et al.* (9, 10), lead to a satisfactory representation of the data when Z is adjusted to be 8.

Our new approximation for the specific bond free energy, ΔA_i, takes into account the deviations from ideality of the binary solvent. It differs from prior work where ΔA_i is assumed to be concentration independent. Excellent agreement between experiments and calculations is obtained. A more decisive test of this approximation could be made on ternary systems where the solvent exhibits larger deviations from ideality than the present system Al-Sn. In addition, one can use these calculations to estimate the relative proportions of Li in species coordinated with different numbers of Al and Sn atoms.

A theory based on more general principles allowing an exact evaluation of the dependence of ΔA_i on i is obviously needed. Such advances might be realized through analyses of the energetics involved in binary and ternary alloy systems.

Acknowledgments

We gratefully acknowledge fruitful discussions with Professor Carl Wagner. We are indebted to Dr. H. M. Feder for bringing to our attention Eq. [27] and [28] and we thank Mr. R. M. Yonco for purifying the lithium used in these experiments. We appreciate the efforts of Mrs. J. Steinquist for typing this manuscript.

Electrocatalytic Activity of Metals and Alloys Electrodeposited on Foreign Substrates

II. Oxygen Adsorption on Electrodeposited Palladium on Pyrolytic Graphite

Ikram Morcos*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

ABSTRACT

Oxygen coverage was determined as a function of the oxidizing potential in acid and alkaline media on both massive and electrodeposited palladium on pyrolytic graphite electrodes. Oxygen adsorption and oxide formation start at significantly more cathodic potentials in the case of the electrodeposited palladium on graphite as compared to the massive metal. The cathodic shift in the potential and the amount of adsorbed oxygen increase with the increase in the current density applied in depositing the palladium on the graphite substrate. Variation in surface roughness obtained on the basis of differential capacity measurement is too small to account for the increase in electrocatalytic activity. It is concluded that the observed difference in the electrocatalytic activity of both palladium surfaces is most probably due to difference in specific surface energy.

The study of oxygen reduction on electrodes of metal films electrodeposited on pyrolytic graphite (1-3) suggests that the electrocatalytic activity of the deposited metal may be higher than the corresponding activity of the same metal in the massive form. The oxygen reduction is, however, a complex reaction that involves mass transfer, adsorption of reactants and intermediates, as well as charge-transfer reactions of more than one species; and depending on the strength of the metal-oxygen bond, oxygen adsorption may decrease or increase the rate of oxygen reduction at

Key words: palladium, electrodeposited palladium on pyrolytic graphite, oxygen adsorption, scanning electron microscopy, electrocatalytic activity.

the metal surface. Consequently, direct, conclusive, and quantitative information on the intrinsic electrocatalytic properties of the mentioned metal films could not be unambiguously derived from the study of oxygen reduction. But the reverse is true, *i.e.*, the proper understanding of the electrocatalytic properties may be extremely helpful in interpreting the kinetics of such reactions as oxygen reduction.

It is therefore desirable to examine independently the electrocatalytic activity of electrodeposited metal films on pyrolytic graphite toward some single and relatively simple surface processes such as oxygen or hydrogen adsorption. A study of oxygen adsorption on a palladium surface electrodeposited on pyrolytic graphite has been the purpose of the present work.

Experimental

The method of study is one that is well established (4-6) and involves the formation at a fixed potential of an adsorbed layer of oxygen (or oxygen-carrying species), which is then reduced by the application of a cathodic sweep. The amount of charge equivalent to the quantity of oxygen adsorbed is determined by integrating[1] the oxygen reduction peak of the voltammetric curve.

The potential program applied is similar to that used by Rand and Woods (6, 7) and involves the use of a Wenking potentiostat, a Tacussel sweep generator, a Tacussel-type GSTP step function generator, and a Hewlett Packard Type 7004B X-Y recorder. Various oxidizing potentials were used with each electrode and the oxidizing time was always 10 sec. The potential was cathodically swept at a rate of 20 mV/sec.

The study was carried out in both acidic and alkaline media using 1.0*N* H_2SO_4 and 0.1*N* KOH. The first solution was prepared from ultrapure material while the second from AR quality KOH material using in both cases triply distilled water, twice from a permanganate solution.

Palladium on graphite electrodes were prepared by electrodepositing palladium from palladium chloride solution. The substrate was in the form of pyrolytic graphite rods which were mounted on Kel-F exposing only a flat circular area of 0.338 cm^2. The electrodeposition was carried out galvanostatically and different surfaces were prepared by using different current densities and times of deposition. The highest and lowest current densities applied correspond approximately to the maximum and minimum current densities at which a complete adequately adherent palladium layer can be obtained on the graphite. Since pyrolytic graphite is a nonporous material there is no ambiguity in estimating the apparent area of the deposited metal. The electrode was thoroughly washed with triply distilled water after removal from the plating bath. X-ray fluorescence showed that the deposit contained no other metallic impurity. The oxygen adsorption studies were all compared with those obtained on a massive palladium electrode which had an area of 0.478 cm^2 and was in the form of a disk embedded in a Teflon sleeve. The later electrode was, prior to any voltammetric experiment, mechanically polished with alumina, cleaned in conc sulfuric acid and then thoroughly washed in triply distilled water.

A Teflon cell was used which consisted of a large compartment for the working and counterelectrodes and a small one for the reference electrode. The reference electrode was Hg/HgO; 1.0*N* KOH for alkaline medium and Hg/Hg SO_4, saturated K_2SO_4 for acid medium. The solutions were thoroughly saturated with helium before and during each experiment and the electrode was rotated throughout the measurement at 1600 rpm.

The electrodeposited palladium surface was examined by the scanning electron microscope under a magnification of 10,000×. Attempts were also made to estimate the ratio of real surface area of the electrodeposited palladium to that of the massive electrode. For that, the potential dependence of the differential capacitance was measured by an a-c bridge and a d-c polarizing circuit.

[1] The cathodic current following the peak was taken as a base line for the integration to correct for double layer charge.

Results and Discussion

Figure 1 shows the different cathodic sweeps for the reduction of oxygen layer formed on massive palladium at the different oxidizing potentials in He-saturated 1.0*N* H_2SO_4. Figures 2-6 show the corresponding cathodic sweeps obtained under the same experimental conditions as those of Fig. 1, but on different palladium layers which were deposited on pyrolytic graphite at the current densities of 148, 118, 60, 30, 5.1 mA/cm^2 and time of deposition 12 sec, 15 sec, 30 sec, 60 sec and 35 min, respectively. The values of oxidizing potentials are indicated on each figure. The corresponding results obtained in 0.1*N* KOH on massive as well as electrodeposited palladium on graphite electrodes are shown in Fig. 7-12. Tables I and II summarize the dependence of the reduction's peak potential on the oxidizing potential and the type of palladium surface used in each experiment in both acidic and alkaline media, respectively. The dependence of the quantity of adsorbed oxygen obtained by integration from Fig. 1-12 on the oxidizing potential is shown for both media in Fig. 13 and 14, respectively.

The experimental results show significant qualitative and quantitative differences between the characteris-

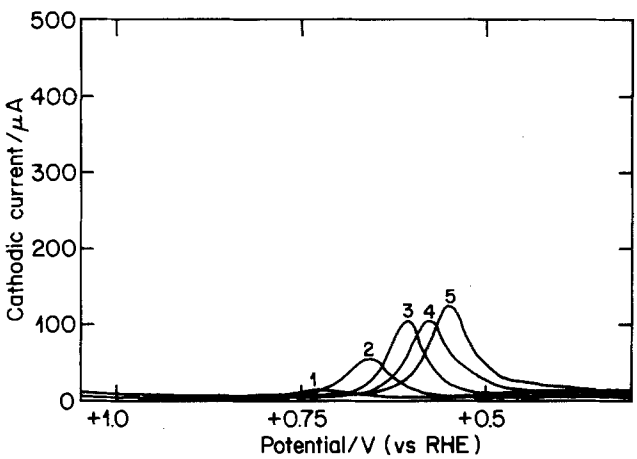

Fig. 1. Oxygen reduction's peak as a function of oxidizing potential on a massive palladium electrode in 1*N* H_2SO_4. Oxidizing potential: curve 1, 1.08V; curve 2, 1.28V; curve 3, 1.48V; curve 4, 1.68V; curve 5, 1.88V.

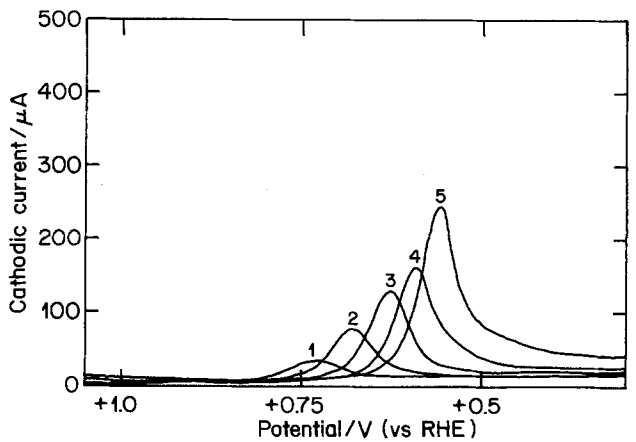

Fig. 2. Oxygen reduction's peak as a function of oxidizing potential in 1*N* H_2SO_4 on a palladium surface electrodeposited on pyrolytic graphite at a current density of 5.1 mA/cm^2. Oxidizing potential: curve 1, 1.08V; curve 2, 1.28V; curve 3, 1.48V; curve 4, 1.68V; curve 5, 1.88V.

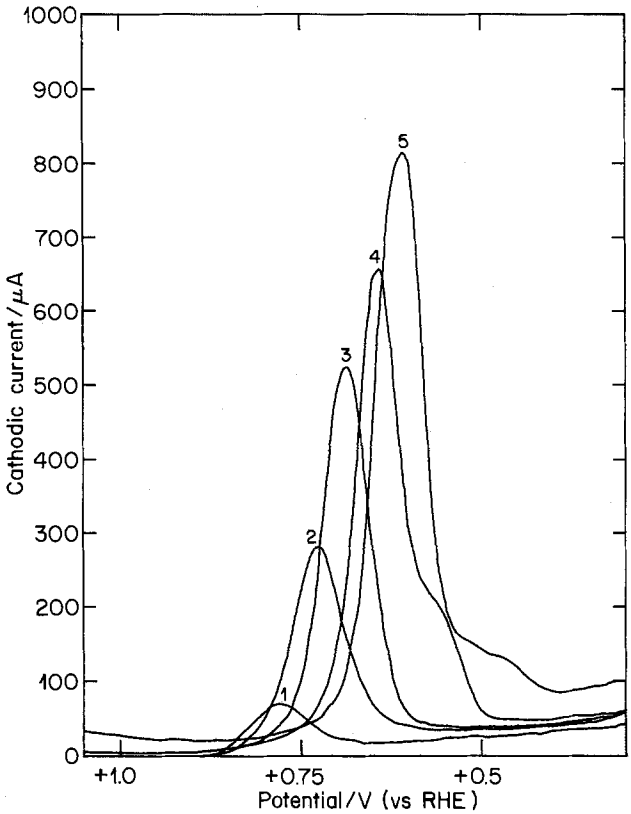

Fig. 3. Oxygen reduction's peak as a function of oxidizing potential in 1N H_2SO_4 on a palladium surface electrodeposited on pyrolytic graphite at a current density of 30 mA/cm^2. Oxidizing potential: curve 1, 1.08V; curve 2, 1.28V; curve 3, 1.48V; curve 4, 1.68V; curve 5, 1.88V.

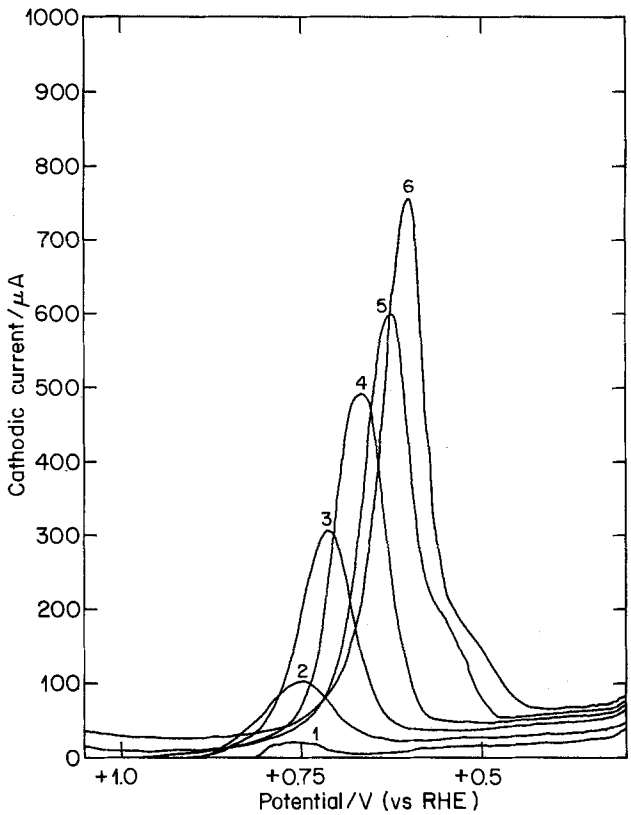

Fig. 4. Oxygen reduction's peak as a function of oxidizing potential in 1N H_2SO_4 on a palladium surface electrodeposited on pyrolytic graphite at a current density of 60 mA/cm^2. Oxidizing potential: curve 1, 0.88V; curve 2, 1.08V; curve 3, 1.28V; curve 4, 1.48V; curve 5, 1.68V; curve 6, 1.88V.

tics of oxygen adsorption on massive and electrodeposited-on graphite palladium. Table I for example shows that the reduction's peak in acid medium is shifted toward more positive potentials in the case of Pd-on graphite as compared to the massive Pd. The magnitude of the shift generally increases with the increase in the current density of the deposition of Pd. A 65-80 mV shift (the exact quantity depends on the oxidizing potential) is observed between the reduction's peak of massive Pd and that of electrodeposited Pd at 148 mA/cm^2. In alkaline medium Table II shows that the corresponding shift in the reduction's peak occurs in the opposite direction and has a smaller magnitude of 20-55 mV. The voltammetry curves for the Pd-on graphite surface are also characterized in alkaline medium by the presence of a small peak at potentials more anodic than those corresponding to the main peak. Figures 13 and 14 show that oxygen adsorption starts at more cathodic potentials in the case of Pd-on graphite as compared with massive Pd, and here again the magnitude of the potential shift increases with the increase in the current density of deposition of Pd. At a surface electrodeposited at 148 mA/cm^2 oxygen adsorption starts in acidic and alkaline media at potentials 300 and 500 mV, respectively, more cathodic than in the case of massive Pd.

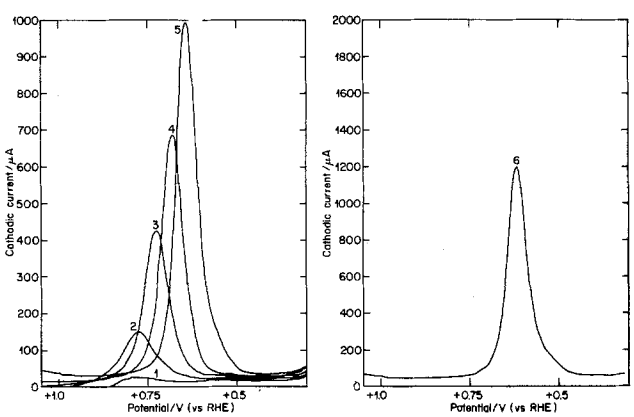

Fig. 5. Oxygen reduction's peak as a function of oxidizing potential in 1N H_2SO_4 on a palladium surface electrodeposited on pyrolytic graphite at a current density of 118 mA/cm^2. Oxidizing potential: curve 1, 0.88V; curve 2, 1.08V; curve 3, 1.28V; curve 4, 1.48V; curve 5, 1.68V; curve 6, 1.88V.

The amount of adsorbed oxygen on a massive electrode reaches a limiting value of 485 and 513 μC/geometric cm^2 in acidic and alkaline media, respectively. If

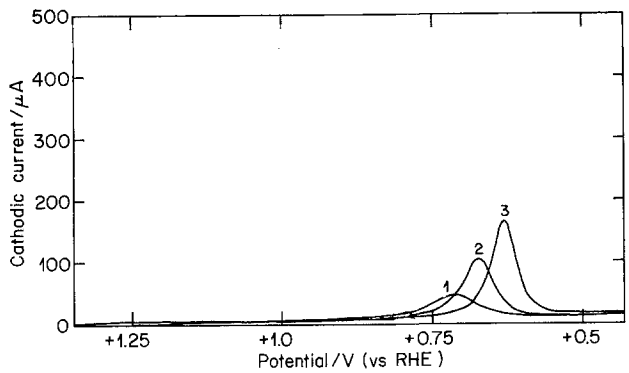

Fig. 8. Oxygen reduction's peak as a function of oxidizing potential in 0.1*N* KOH on a palladium surface electrodeposited on pyrolytic graphite at a current density of 5.1 mA/cm². Oxidizing potential: curve 1, 1.325V; curve 2, 1.525V; curve 3, 1.725V.

the stoichiometry of adsorption is 1 oxygen atom/surface palladium atom and the adsorption of each atom requires the transfer of two electrons, then the charge required for the adsorption of one monolayer of oxygen atoms on a (100) plane would require 424 μC/real cm² (7). The experimentally obtained values in both acid and alkaline media indicate a monolayer adsorption with a surface roughness factor of 1.15-1.2. Rand and Woods (7) reported a similar observation except that the experimental coverage was 690 μC/geometric cm² and consequently they had to assume a surface roughness factor of 1.6.

Pd-on graphite electrodes adsorb significantly larger quantities of oxygen/geometric cm². The plots of Fig. 13 and 14 do not exhibit with such electrodes any limiting adsorption step except in the case of a palladium layer electrodeposited at 5.1 mA/cm² and in alkaline medium. The higher the current density of deposition, the higher is the quantity of adsorbed oxygen. These

results mean either a very large surface roughness or a palladium surface which is intrinsically more active (*i.e.*, higher specific surface energy) than a massive palladium electrode, and if the latter assumption is correct one is forced to assume that a phase-oxide layer

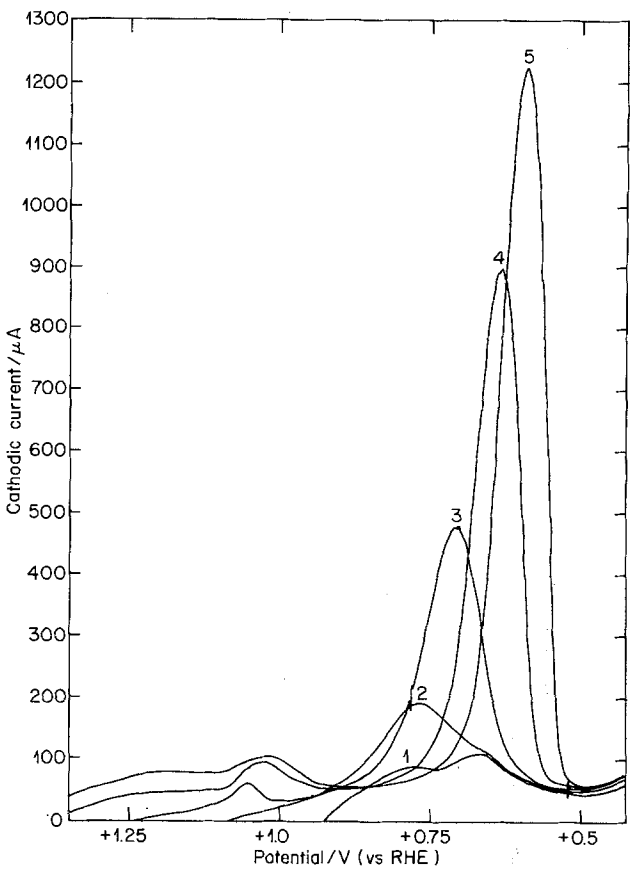

Fig. 12. Oxygen reduction's peak as a function of oxidizing potential in 0.1*N* KOH on a palladium surface electrodeposited on pyrolytic graphite at a current density of 148.0 mA/cm^2. Oxidizing potential: curve 1, 0.925V; curve 2, 1.125V; curve 3, 1.325V; curve 4, 1.525V; curve 5, 1.725V.

is formed at potential more cathodic than in the case of massive palladium. With regard to the latter surface Rand and Woods (7) observed that a palladium-phase oxide does not form at anodizing potentials lower than $\simeq$ 1.8V (RHE) for an oxidizing time of 10 sec.

A qualitative opinion concerning the morphology and surface roughness of the palladium deposits can be obtained from the scanning electron micrographs at 10,000$\times$ magnification, which are shown in Fig. 15. The deposit obtained at 148 mA/cm^2 appears to have more surface roughness than the deposit obtained at 5.1 mA/cm^2, but it is very unlikely that the variation in surface roughness is anything near a ratio of $\simeq$20 which is necessary to account for the observed increase in the amount of adsorbed oxygen.

A conclusive interpretation of the data requires a quantitative evaluation of electrode surface roughness. For the purpose of the present discussion, a knowledge of the relative values of surface roughness is sufficient. This is still a complex problem because hydrogen diffusion into Pd excludes the use of the hydrogen adsorption method (6), which has been successfully used to determine the real surface area of Pt electrodes, and the electrochemical activity toward both hydrogen and oxygen adsorption complicates the use of the capacitance method. At certain potentials however, the latter method can be used to give useful information on the relative surface roughness of the Pd surfaces used in the present work.

Figure 16 shows the cathodically swept capacitance *vs.* potential relationships in 1.0*N* H_2SO_4 for massive Pd and Pd surfaces electrodeposited at 5.1 and 30 mA/geometric cm^2. At a potential of $\simeq$0.4V the capacitances are 32, 32, and 67 μF/cm^2 for the three mentioned surfaces. At this particular potential there should not be any adsorbed hydrogen or oxygen at the surface as indicated on the voltammetry curves of Fig.

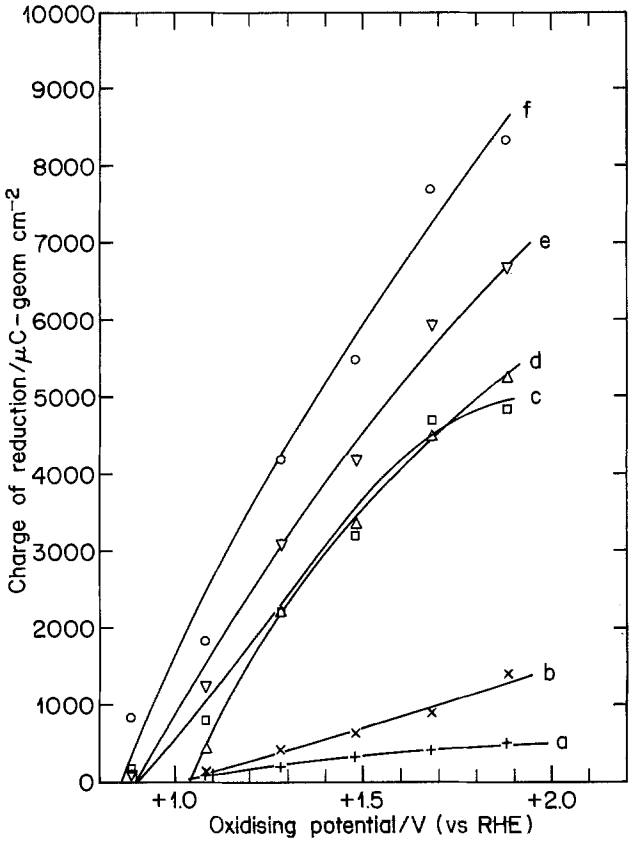

Fig. 13. Quantity of adsorbed oxygen as a function of oxidizing potential in 1.0*N* H_2SO_4 as calculated from Fig. 1-6. a, massive palladium; b, c, d, e, and f, palladium surface electrodeposited on pyrolytic graphite at a current density of 5.1, 30, 60, 118, and 148 mA/cm^2, respectively.

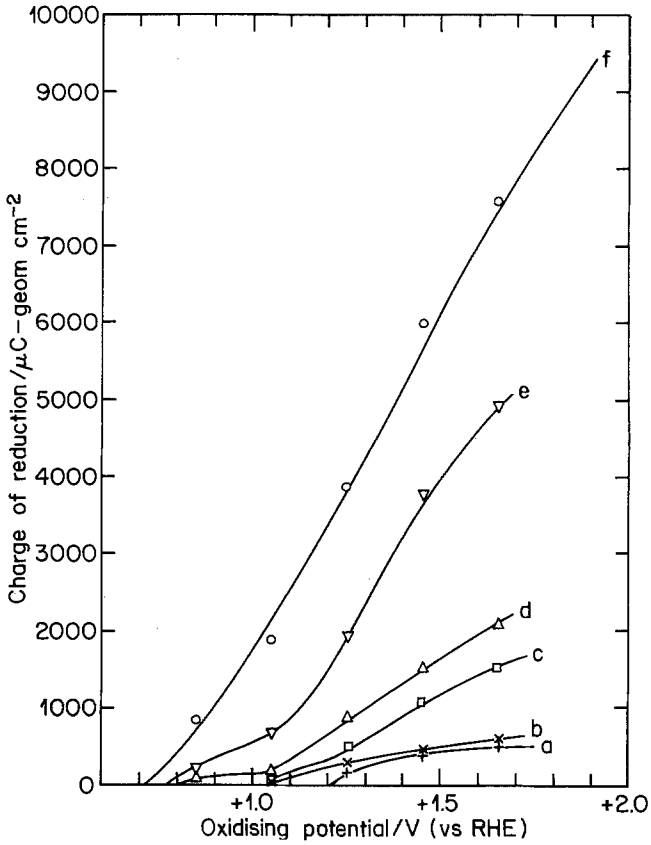

Fig. 14. Quantity of adsorbed oxygen as a function of oxidizing potential in 0.1*N* KOH as calculated from Fig. 7-12. a, massive palladium; b, c, d, e, and f, palladium surface electrodeposited on pyrolytic graphite at 5.1, 30, 60, 118, and 148 mA/cm^2, respectively.

1-3. Consequently these capacitance values should be proportional to the real surface area of the electrodes. These values give relative surface roughness (*i.e.*, surface roughness of electrodeposited Pd/surface roughness of massive Pd) of 1 and 2 for the two Pd electrodeposits, respectively. At potentials more anodic or cathodic the capacitance values of Fig. 16 give approximately the same roughness factors. The capacitance curves obtained in 0.1*N* KOH solution are shown in

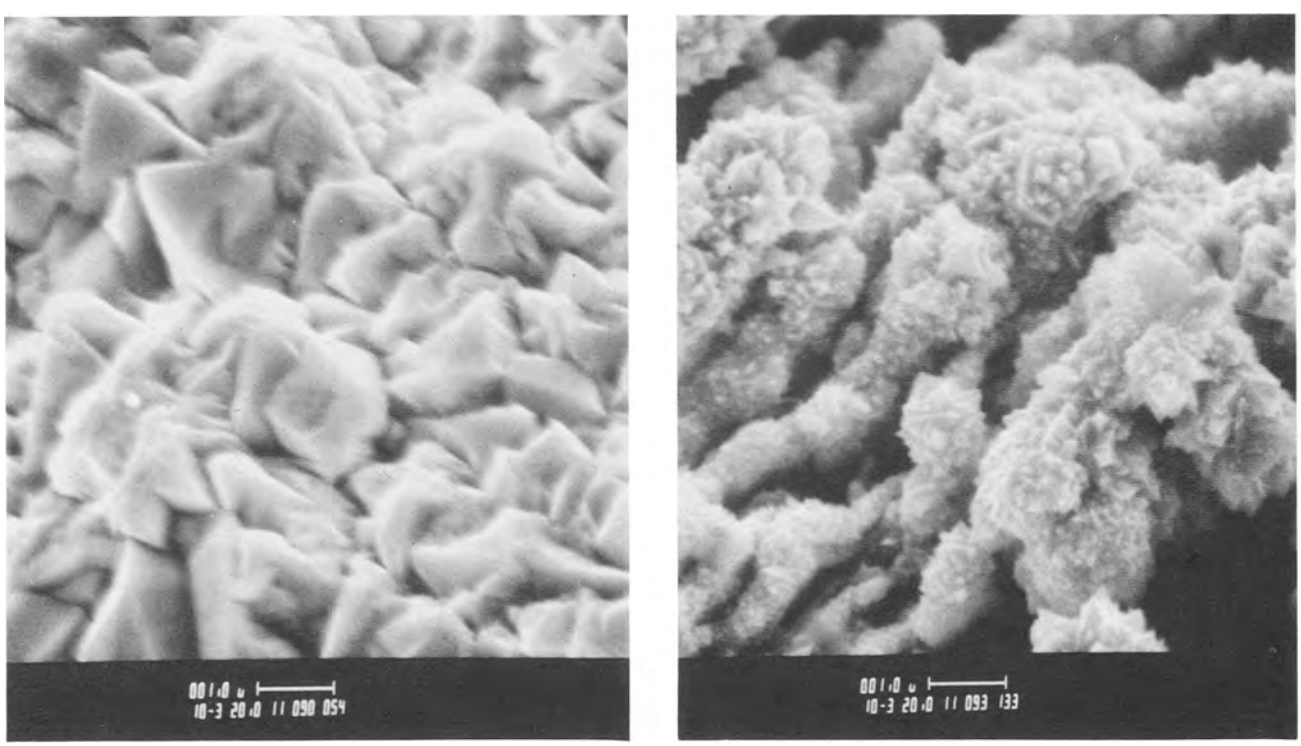

Fig. 15. Scanning electron micrographs for palladium surface electrodeposited on pyrolytic graphite at a 10,000× magnification. Current density of deposition is a (above left), 5.1 mA/cm^2; b, 148 mA/cm^2.

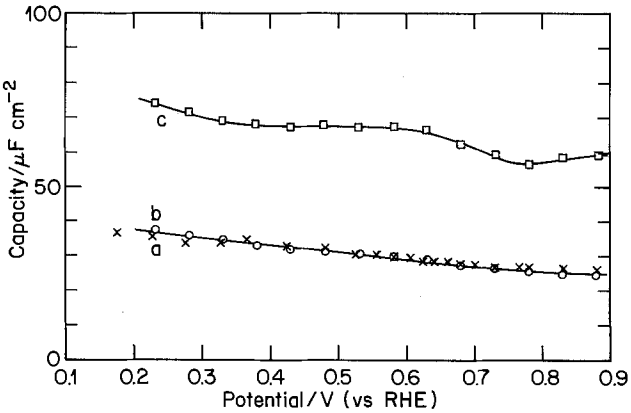

Fig. 16. Differential capacitance vs. potential curves in 1N H_2SO_4 for a, massive palladium; b, c, palladium electrodeposited on pyrolytic graphite at 5.1 and 30 mA/cm², respectively.

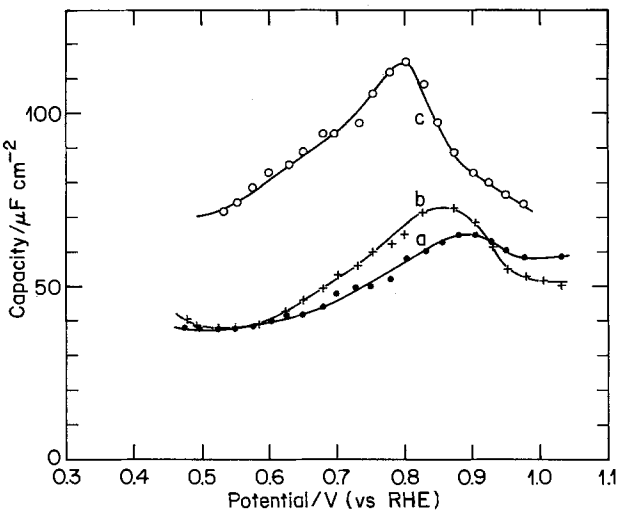

Fig. 17. Differential capacitance vs. potential curves in 0.1N KOH for a, massive palladium; b, c, palladium electrodeposited on pyrolytic graphite at 5.1 and 30 mA/cm², respectively.

Fig. 17. Applying the same argument, it is found that the relative roughness at 0.5V is 1.0 and 2.0 for palladium deposits obtained at 5.1 and 30 mA/cm², respectively. Palladium deposits obtained at the mentioned current densities give sufficiently reproducible capacitance curves. The capacitance can be measured for deposits obtained at higher current densities but the increase in surface roughness is accompanied by an increase in frequency dispersion, and as shown in the present work by an increase in the electrocatalytic activity. Consequently capacitance data obtained with the later deposits may give misleading values of relative surface roughness and will not be used here.

The relative surface roughness values obtained from the capacitance measurement can only account for a very small portion of the observed increase in the electrocatalytic activity of the palladium surface when the latter is electrodeposited on pyrolytic graphite. One must then conclude that the electrodeposited palladium must have a much higher intrinsic activity than the massive surface. The large magnitude of adsorbed oxygen observed in Fig. 13 and 14 must then correspond to the formation of a phase oxide at potentials significantly more cathodic than those at which an oxide forms at massive palladium. This can only occur if the specific surface energy of the electrodeposited palladium is considerably larger than that of the massive surface. A higher specific surface energy will reduce the activation energy necessary to start the formation of the phase oxide. The phenomenon observed here is definitely distinguished from the characteristics of dispersed palladium surfaces studied by Burshtein *et al.* (8). The latter authors reported that the quantity of chemisorbed oxygen on a palladium powder does not exceed a monolayer.

The interpretation of the extraordinary high electrocatalytic activity of Pd-on graphite must have to do with the nature of graphite surface and the effect of such nature on the structural features of the deposited metal. The structure of the resulting deposit must depend on the mechanism of deposition, and in the case of a foreign substrate must also depend on the magnitude of nucleation overpotential at the onset of polarization. The magnitude of nucleation overpotential for the galvanostatic electrodeposition of palladium from palladium chloride solution on both pyrolytic graphite and massive palladium can be determined from the potential-time plots shown in Fig. 18. At a current density of 3 mA/cm² the nucleation overpotential is 100 mV on pyrolytic graphite and is virtually absent on massive palladium. Graphite does not form mixed crystals with electrodeposited metals and that explains the large nucleation overpotential which is indicative of three-dimensional nucleation. It is also noticed that at steady state palladium is electrodeposited with a ≃30 mV higher overpotential as compared to the same on massive palladium. This indicates a variation in the mechanism of palladium deposition in the two cases even after the formation of the first layer of nuclei.

The lack of strong interaction between the electrodeposited metal and the graphite substrate will result in the formation of frozen nonequilibrium structures. The higher the current density of deposition, the higher will be the shift from equilibrium and associated surface energy. That may explain the strong dependence of structure on current density observed in Fig. 15 for the deposition of palladium on pyrolytic graphite. Such dependence is not observed as shown in Fig. 19 when palladium is electrodeposited on massive palladium.[2] In the latter case the variation in current density of deposition causes only a variation in the grain size. In other words, regardless of the rate of the deposition process, a palladium substrate exhibits a strong orienting effect on the deposited palladium. With a graphite substrate this orienting effect is absent and the structure of the deposit becomes almost completely under the influence of the externally controlled conditions of the current density, temperature, bath composition, and

[2] An electrodeposited palladium surface on a massive palladium electrode does not exhibit higher electrocatalytic activity than that of the massive substrate.

solution transport, with the current density playing a major role.

Previous attempts (9-13) to study the effect of structure on the electrocatalytic properties of metal surfaces were all carried out on platinum electrodes. Consequently, it would not be fruitful to discuss previously published work in the light of the present results. Such a discussion will be more meaningful after the approach used in the present paper has been extended to study the electrocatalytic properties of electrodeposited platinum on pyrolytic graphite. The study of the latter properties is presently in progress.

Acknowledgments

The author is indebted to A. Joly for doing the scanning electron microscopy and to A. Gendron for his assistance in obtaining the electrochemical data. For many helpful remarks the author would like to thank Dr. G. Bélanger.

Physical Principles Governing Nonideal Behavior of the Zirconia Oxygen Sensor

William J. Fleming*

General Motors Corporation, Research Laboratories, Electronics Department, Warren, Michigan 48090

ABSTRACT

Zirconia galvanic cells of the form

exhaust gas, Pt || stabilized ZrO_2 || Pt, air

are installed in the exhaust pipe of automobile engines to provide a voltage signal indicative of engine air-fuel ratio. To account for deviation of experimental sensor behavior from predicted ideal performance, a physical model of nonideal sensors is derived. Nonideal behavior is accounted for by simultaneous presence of two electrochemical reactions occurring at the anode (exhaust gas) electrode; one reaction involves oxygen and the other involves carbon monoxide. Correlation of calculated sensor characteristics with experimental results shows that nonideal sensor electrodes possess surface adsorption properties and catalytic activities which are many orders of magnitude less than ideal equilibrium values. The present theory indicates that undesired temperature-dependent shifting of sensor voltage curves with respect to engine air-fuel ratio is caused by competition between O_2 and CO gases for triple-point adsorption sites on the anode electrode.

One approach to the problem of reducing exhaust emissions from an automobile engine is to place a catalytic converter into the exhaust gas stream. One such catalyst, called a three-way or equilibrium catalyst, has been reported (1) to convert a high percentage of each of the exhaust gases, HC, CO, and NO, into the gases H_2O, CO_2, and N_2. However, to achieve the three-way conversion, precise metering of the air-fuel (A/F) mixture entering the engine must be maintained throughout the normal operating modes of the engine (1, 2). Closed-loop process control methods are used to regulate the air-fuel ratio of the engine (2-4). The utility of the closed-loop control system depends critically on the availability of a reliable sensor to detect A/F. An electrochemical sensor made of stabilized zirconium dioxide has been demonstrated to serve this purpose (2, 5).

The exhaust gas sensor usually consists of a zirconia tube with porous platinum electrodes formed on both its inner and outer surfaces. One end of the tube is closed so that it can be inserted into the exhaust stream which heats the tube; a schematic illustration of the sensor is shown in Fig. 1. For exhaust temperature in excess of approximately 400°C, the sensor becomes activated due to onset of oxygen ion conduction in the zirconia electrolyte.

To a first approximation the sensor voltage, V, can be calculated from the thermodynamic relationship for reversible transfer of oxygen from cathode to anode. One obtains the equation (6, 7)

$$V = (RT/4\mathbf{F}) \ln [p_{O_2}(\text{air})/p_{O_2}(\text{exh})] \qquad [1]$$

where R is the universal gas constant, T is absolute temperature of the active region of the electrolyte, $\mathbf{F}$ is Faraday's constant, $p_{O_2}(\text{air})$ is the oxygen partial pressure of atmospheric air, and $p_{O_2}(\text{exh})$ is the oxygen partial pressure of the exhaust for the engine A/F ratio and exhaust temperature of interest. It is further assumed that the anode electrode has sufficient catalytic activity to fully equilibrate exhaust gas reactions. Sensor voltage curves calculated by the above procedure are shown in Fig. 2.

Actual sensor behavior deviates from the ideal behavior shown in Fig. 2. The objective of the present work is to derive a physical model of a nonperfect zirconia sensor which will account for nonideal behavior. Particular attention is given to identification of those physical parameters defining the observed performance of experimental sensors.

Experimental

A representative curve of sensor voltage *vs.* engine air-fuel ratio obtained using a computer controlled test facility (8) is shown in Fig. 3. Rate of change of A/F did not exceed 1 A/F ratio unit/min; at this rate transient effects were eliminated and sensor characteristics were measured under essentially steady-state conditions. Further details of the measurement techniques are given elsewhere (5).

Voltage curves like the one in Fig. 3 are usually obtained for at least three exhaust temperatures. Different sensors often exhibit distinguishable characteristics which suggest that sensors can be separated into general groupings. For example, sensors with sharply stepped voltage curves (group A) having better agreement with ideal behavior can be contrasted to sensors with washed-out curves (group B) having poor agreement with ideal behavior. Voltage characteristics for

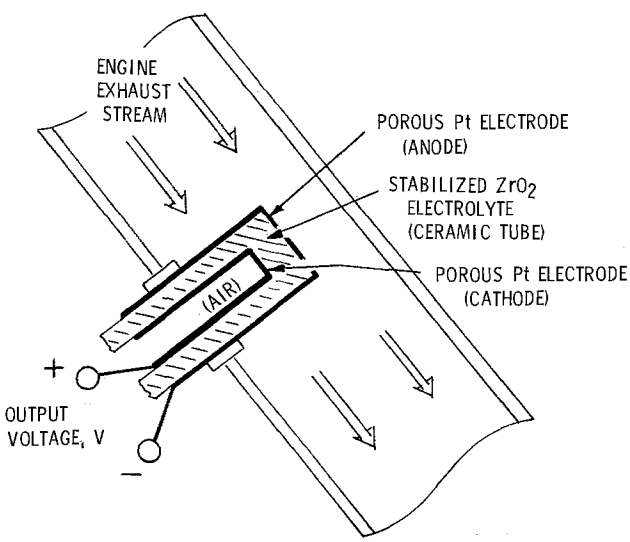

Fig. 1. Schematic illustration of zirconia exhaust sensor (cross-sectional view).

* Electrochemical Society Active Member.
Key words: zirconia, galvanic cells, exhaust gas sensor, solid electrolyte, high temperature.

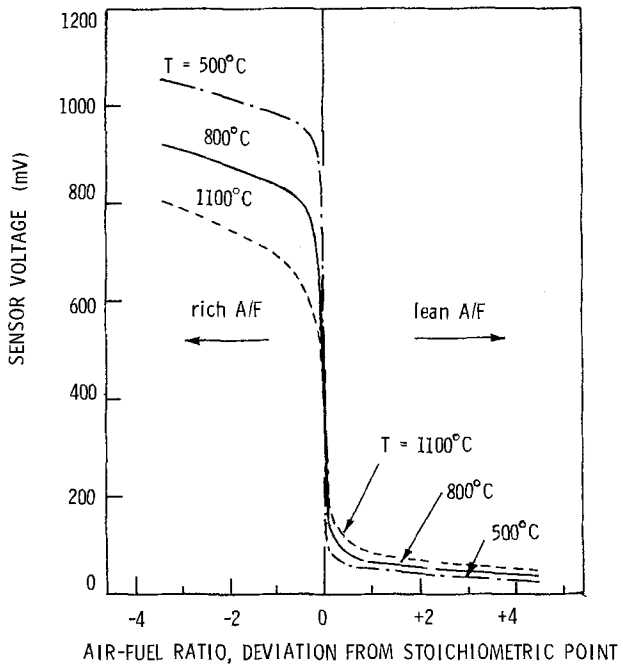

Fig. 2. Ideal sensor voltage curves

a sensor typical of group A are shown in Fig. 4, whereas characteristics typical of group B are shown in Fig. 5.

Departures of sensor behavior shown in Fig. 4 and 5 from the ideal behavior shown in Fig. 2 are summarized as follows: (*i*) transition steplike slopes of the voltage curves of the group B sensor are reduced compared to those of the group A sensor; (*ii*) pronounced drop of voltage level over the entire A/F range with increased exhaust temperature for the group B sensor; (*iii*) shifting of the steplike transitions of the voltage curves of both sensors toward richer A/F for increased exhaust temperature.

Departures of sensor behavior from ideal behavior are detrimental to performance of closed-loop engine control systems. These systems rely on invariance of the steplike voltage transition of the zirconia sensor

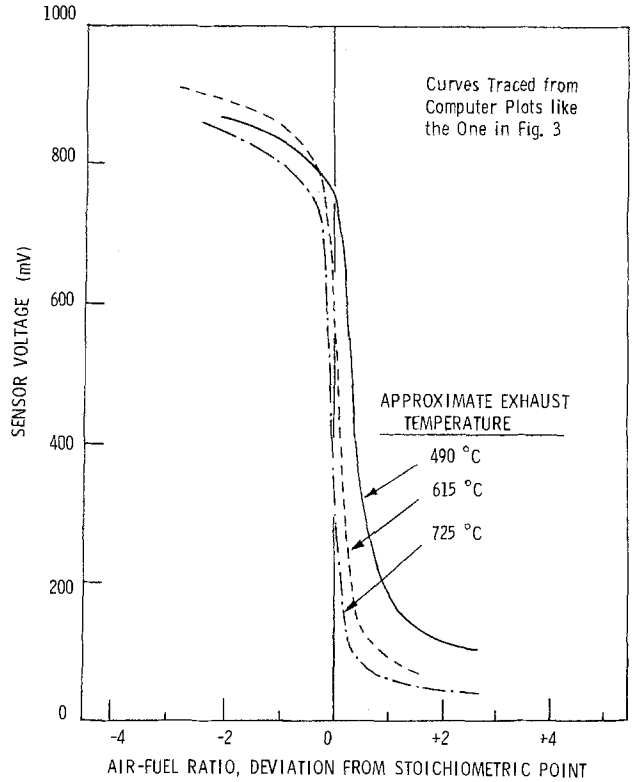

Fig. 4. Experimental voltage curves typical of group A sensors (sharp transition step in good agreement with ideal sensor behavior).

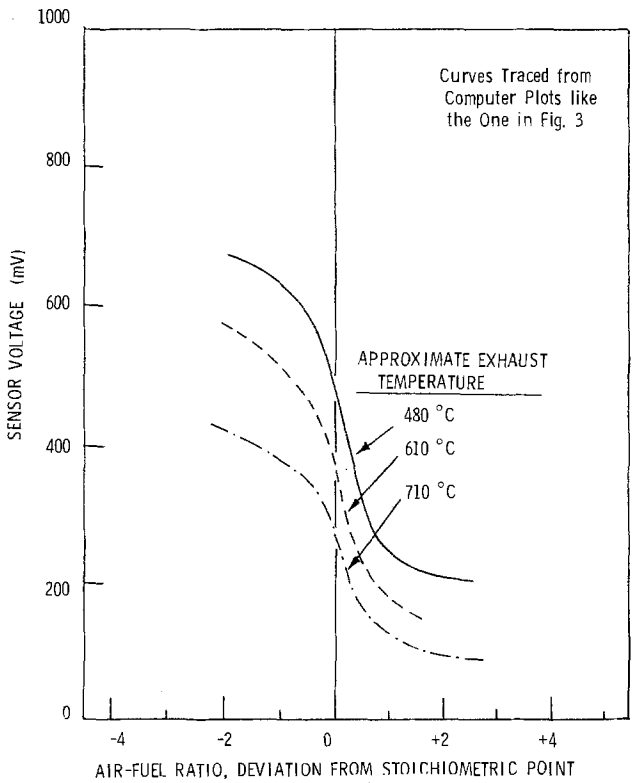

Fig. 5. Experimental voltage curves typical of group B sensors (washed-out transition step in poor agreement with ideal sensor behavior).

for desired accuracy (2-4). In the discussion below, a physical model of nonperfect sensor behavior in automobile exhaust is developed which is intended to provide better understanding of the origins of nonideal sensor characteristics.

Discussion

Derivation of a physical model of the zirconia exhaust gas sensor is difficult because of the complexity of its operating environment. Effort is made here to develop a model which is sufficiently complete to account for the above-described nonideal sensor behavior. One point of emphasis is that in the present application the zirconia galvanic cell simply provides an open-circuit voltage; thus, thermodynamic rather than kinetic considerations are important.

Derivation of physical model.—Simplification is made by assuming homogeneity of the active area of the zirconia cell; active cell area consists of the surface area of the zirconia tube which is exposed to exhaust gas (*cf.* Fig. 1). Effects due to temperature gradients, both lengthwise and transverse to the zirconia tube wall, are ignored. The ionic transport number for oxygen ions in zirconia is assumed equal to unity.

Sensors are represented by an electrochemical cell of the type

$$\text{exhaust gas, Pt} \,||\, \text{stabilized } ZrO_2 \,||\, \text{Pt, air reference} \qquad [2]$$

Since platinum is known to serve as a good cathode material for the air reference electrode (9), electrochemical reactions occurring there are assumed to be well defined. The over-all cathode reaction is

$$O_2 + 4e^- \rightleftarrows 2\,O^= \qquad [3]$$

where $O^=$ denotes an oxygen ion found in the zirconia anion sublattice.

Electrochemical reactions occurring at the anode electrode are not nearly so well defined. It has been suggested that one major cause of the departure of experimental sensor characteristics from ideal behavior is the lack of catalytic activity of the anode electrode (7). Evidence also indicates that the presence of oxidizable gas residuals such as CO, H_2, and hydrocarbons causes pronounced increases in cell voltage even when excess oxygen exists (10, 11). Since automobile exhaust contains a plethora of oxidizable gas residuals including CO, H_2, and up to 200 species of hydrocarbons, the above effects must be considered.

Although CO and H_2 comprise less than a few percent of the total of exhaust gas concentrations, they are nonetheless the major species of oxidizable gases, being at least ten times more abundant than the total of the hydrocarbons. Due to their relatively low concentration, hydrocarbons are assumed to have negligible effect on cell voltage. Effects of H_2 on cell voltage are also neglected for the following reasons. First, studies of gas adsorption show that CO preferentially adsorbs onto Pt when a dilute mixture of CO and H_2 gases is exposed to a Pt surface (12). Second, analytical measurement of gas species evolving during sharp rises in the voltage of a zirconia vacuum gauge indicates that CO is an active gas residual involved in the process of anomalous voltage increase (11). Thus, only the effects of the oxidizable gas, CO, are considered in the present work.

Electrochemical anode reactions.—The presence of CO can affect sensor voltage in either of two ways. First, CO may deplete the local concentration of O_2 at the anode surface by means of the reaction

$$CO' + \tfrac{1}{2}\,O_2' \overset{K_0}{\rightleftarrows} CO_2' \qquad [4]$$

where the anode electrochemical reaction is

$$O_2' + 4e^- \rightleftarrows 2\,O^= \qquad [5]$$

in which case the electrochemical cell is simply an oxygen cell, as shown below

$$p_{O_2'}\text{(anode), Pt} \,||\, \text{stabilized } ZrO_2 \,||\, \text{Pt, } p_{O_2}\text{(air)} \qquad [6]$$

In the above equations O_2', CO', and CO_2' denote gases in the vicinity of the anode electrolyte surface; $p_{O_2'}$ (anode) is the partial pressure of O_2' which exists after completion of reaction [4]; and K_0 is an equilibrium constant for this reaction.

Open-circuit voltage generated by cell [6], subject to electrochemical reactions [3] and [5], is given by

$$V_{O_2} = V_{O_2}^\circ + (RT/4\mathbf{F}) \ln [p_{O_2}\text{(air)}/p_{O_2'}\text{(anode)}] \qquad [7]$$

The standard cell potential, $V_{O_2}^\circ$, in Eq. [7] is determined by the difference of electron electrochemical potentials, $\mu_{e^-}^\circ$, between electrodes (13)

$$V_{O_2}^\circ = [\mu_{e^-}^\circ\text{(anode)} - \mu_{e^-}^\circ\text{(cathode)}]/\mathbf{F} \qquad [8]$$

When all constituent phases (gas, metal electrode, and solid electrolyte) are in thermodynamic equilibrium, electrochemical potentials, $\mu_{e^-}^\circ$, will be the same at both electrodes for cell [6] and $V_{O_2}^\circ$ will equal zero. Exhaust sensors, however, can possess nonequilibrium conditions whereupon the term $V_{O_2}^\circ$ takes on a nonzero value. Nonequilibrium conditions include irreversible reactions, reaction with chemical impurities, and insufficient catalytic activity of the electrodes.

A second way that CO can affect sensor voltage is by direct participation in an electrochemical process by means of the anode reaction

$$CO' + O^= \rightleftarrows CO_2' + 2e^- \qquad [9]$$

in which case the electrochemical cell is the following

$$p_{CO'}\text{(anode), Pt} \,||\, \text{stabilized } ZrO_2 \,||\, \text{Pt, } p_{O_2}\text{(air)} \qquad [10]$$

Open-circuit voltage generated by cell [10], with electrochemical reactions [3] and [9], is given by

$$V_{CO} = V_{CO}^\circ + (RT/2\mathbf{F}) \ln [p_{O_2}{}^{1/2}\text{(air)}\; p_{CO'}\text{(anode)}/p_{CO_2'}\text{(anode)}] \qquad [11]$$

When thermodynamic equilibrium conditions exist, the standard cell potential, V_{CO}°, computed from Eq. [3], [8], and [9] is found equal to

$$V_{CO}^\circ = [\mu_{CO}^\circ\text{(anode)} - \mu_{CO_2}^\circ\text{(anode)} + \tfrac{1}{2}\,\mu_{O_2}^\circ\text{(cathode)}]/2\mathbf{F} \qquad [12]$$

where the electrochemical potentials, μ°, are equal to the Gibbs chemical free energies of the gases CO, CO_2, and O_2 determined at the temperature of interest. For typical exhaust temperatures which range between 450° and 750°C, the equilibrium value of V_{CO}° computed from Eq. [12] decreases from 1140 to 1000 mV as temperature increases. Due to the nonequilibrium conditions cited above, exhaust sensors can possess V_{CO}° values as much as 300 mV lower than the equilibrium values.

Exhaust gas reactions.—For purposes of the present discussion the anode electrode is depicted by the schematic illustration shown in Fig. 6. Exhaust gases of

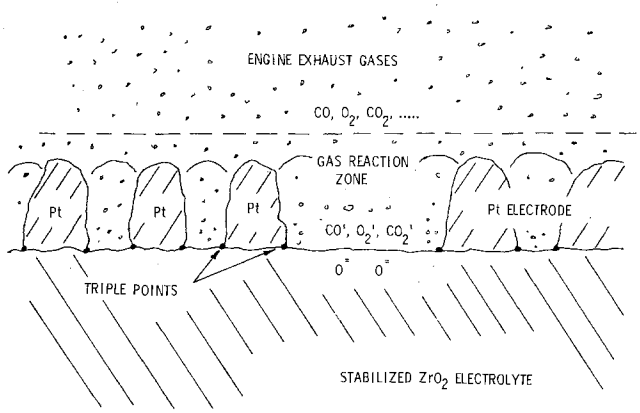

Fig. 6. Schematic representation of physical structure of anode electrode/electrolyte region.

greatest interest here are CO, O_2, and CO_2. Within the electrode pore spaces these gases undergo reaction, thereby giving rise to reacted gases CO′, O_2′, and CO_2′ in the vicinity of the electrode/electrolyte surface.

The method of computing equilibrium partial pressures of engine exhaust gases is well known (14, 15). For simplicity, gas species in the exhaust are herein restricted to the major products of combustion: CO_2, CO, H_2O, H_2, O_2, and N_2. Mole concentrations of these gases are related to engine A/F by chemical balance equations (15). Calculations are made using the assumption that the water gas reaction

$$CO_2' + H_2' \overset{K_w}{\rightleftarrows} CO' + H_2O' \qquad [13]$$

governs the relationship between H_2′ and CO′. Detailed analysis by Barnes *et al.* (14) shows that for exhaust temperatures greater than 480°C, mole concentrations of CO′ and CO_2′, and O_2′ as a function of engine A/F are, to good approximation, determined by standard chemical balance equations combined with the following equilibrium solutions for Eq. [4] and [13]

$$K_o = [CO_2']/[CO'][O_2']^{1/2} \qquad [14]$$

and

$$K_w = [CO'][H_2O']/[H_2'][CO_2'] \qquad [15]$$

Total mixture pressure, p_{mix}, of the exhaust gas is set equal to 1 atm; this value is representative of automobile engines run at low power levels. Solutions for $p_{CO'}$ and $p_{O_2'}$, computed from the expressions $[CO'] \cdot p_{mix}$ and $[O_2'] \cdot p_{mix}$, are shown in Fig. 7 where four cases are computed. [Values of $p_{CO_2'}$ *vs.* A/F have relatively little variation and are not shown here, but can be found elsewhere (14).] Cases 2 through 4 represent various degrees of reaction completion, whereas case 1 is included to show typical levels of CO and O_2 as found in unreacted engine exhaust. Degrees of reaction for cases 2 through 4 are defined by assuming that the constants K_o and K_w of Eq. [14] and [15] could be assigned values which did not correspond to the actual

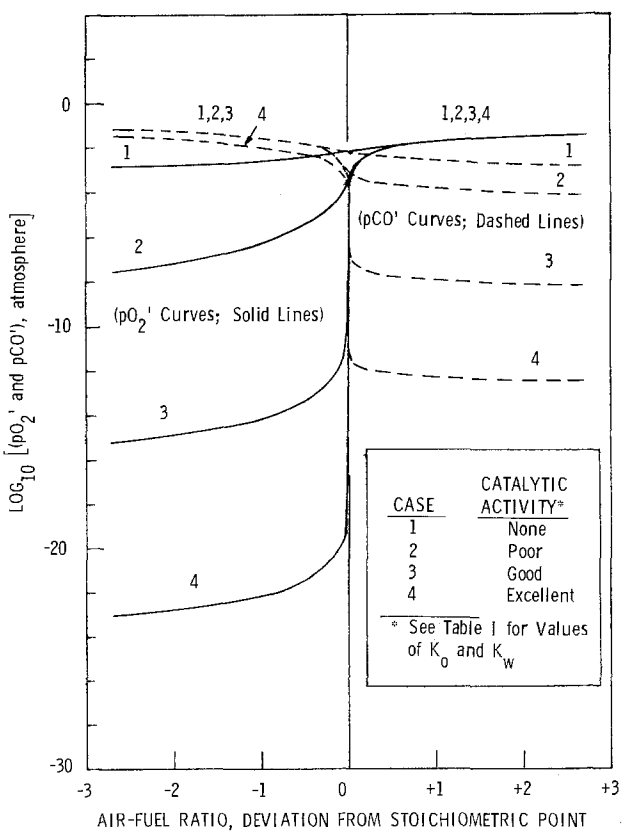

Fig. 7. Partial pressures of reacted gases O_2′ and CO′ in vicinity of anode electrode/electrolyte surface. (Total mixture pressure equals 1 atm.) Table I gives values of constants.

temperature of the exhaust. That is, combustion gas reactions in the engine cylinder were assumed to have stopped at the freezing temperatures given in Table I.

One might think that exhaust flow rate would also affect the degree of completion of gas reactions at the anode electrode. This possibility was investigated by means of a special experiment. Sensor voltage was observed during independent adjustment of engine exhaust flow and temperature (5). Effects of flow on sensor voltage were found to be small compared to those of temperature; for this reason effects of flow are ignored in the present analysis.

Gas adsorption at triple points.—Attention is now given to the electrode/electrolyte interface region of the anode electrode. As depicted in Fig. 6, the anode electrode has a labyrinthine structure with interspersed pores permitting gas/electrolyte contact. Locations where the triple contact electrode/electrolyte/gas exist are shown in Fig. 6. Electrochemical reactions of Eq. [5] and [9] can only occur at or near triple points because these reactions require the simultaneous presence of gases, electrons, and oxygen ions.

Regardless of how fully reacted the exhaust gases, there always exists a joint presence of CO and O_2 in the vicinity of the triple points on the anode electrode; this behavior is shown by the curves of Fig. 7. The problem at hand is as follows. Given the simultaneous presence of CO and O_2, what fraction of the triple points will support electrochemical cell reaction [5] involving O_2, and what fraction will support reaction [9] involving CO? The solution used here is to postulate that CO and O_2 gases compete for adsorption at the triple point sites on the anode electrode. Fuel cell reactions [9] are assumed to occur at sites where CO is adsorbed, whereupon the adsorbed CO state is taken as an intermediate step in the physical mechanism of reaction [9]. In a like manner, triple point sites where CO is not adsorbed are assumed to support the O_2 concentration cell reaction [5]. Existence of adsorbed O_2 and/or absence of adsorbed gas are taken as intermediate steps in the physical mechanism of reaction [5].

The fraction of triple point sites occupied by adsorbed CO is calculated using the Langmuir adsorption isotherm (16). When CO and O_2 molecules occupy single sites in adsorption, the Langmuir expression for the fraction, θ_{CO}, of triple point sites occupied by CO can be written as

$$\theta_{CO} = K_{CO}p_{CO'}/(1 + K_{CO}p_{CO'} + K_{O_2}p_{O_2'}) \qquad [16]$$

where K_{CO} and K_{O_2} are adsorption constants for CO and O_2. For both gas species, CO and O_2, the adsorption constant K is estimated from kinetic gas theory using the following equations (16)

$$K = K^\circ \exp(Q/RT) \qquad [17]$$

and

$$K^\circ = \sigma\Psi^\circ/\nu n_s \quad [18]$$

where Q is the heat of adsorption, σ is the condensation coefficient of sticking probability, Ψ° is the flux of gas molecules at pressure equal to 1 atm colliding with unit area of surface per unit time, ν is the frequency of gas molecule vibration, and n_s is the number of triple point sites at which CO and O_2 compete for adsorption.

As discussed above, the fraction of triple point sites, f_{CO}, supporting CO cell reaction [9] is equated to θ_{CO}

$$f_{CO} = \theta_{CO} \quad [19]$$

where θ_{CO} is given by Eq. [16]. Similarly, the fraction of sites, f_{O_2}, supporting the O_2 cell reaction [5] is given by the fraction of sites where CO is not adsorbed; namely

$$f_{O_2} = 1 - \theta_{CO} \quad [20]$$

Sensor output voltage.—Output voltage of the exhaust sensor due to simultaneous existence of O_2 and CO cell reactions [5] and [9] is determined using the equivalent electrical network model shown in Fig. 8. An independent electrochemical cell is assumed to exist for each triple point site where either reaction [5] or [9] occurs. Of the total number of cells, the fraction f_{O_2} gives rise to voltages V_{O_2} given by Eq. [7], whereas the fraction f_{CO} gives rise to voltages V_{CO} given by Eq. [11]. Furthermore, each cell has internal resistance R_i, assumed identical for all cells. Sensor output voltage, V, is found by application of Norton's theorem to the network shown in Fig. 8; the resulting solution is

$$V = f_{O_2} V_{O_2} + f_{CO} V_{CO} \quad [21]$$

Combination of Eq. [7], [11], and [21] gives the desired final result

$$V = f_{O_2}\{V_{O_2}^\circ + (RT/4\mathbf{F}) \ln [p_{O_2}(\text{air})/p_{O_2}(\text{anode})]\} + f_{CO}\{V_{CO}^\circ + (RT/2\mathbf{F}) \ln [p_{O_2}^{1/2}(\text{air}) \cdot p_{CO}(\text{anode})/p_{CO_2}(\text{anode})]\} \quad [22]$$

where f_{O_2} and f_{CO} are given by Eq. [19] and [20].

Theoretical Results

Effects of the parameters in Eq. [22] on theoretical voltage *vs.* air-fuel ratio (A/F) curves are demonstrated by calculated results. A nominal set of parameter values which describe nonideal sensor behavior is first determined; the parameters then serve as a reference set of values about which a systematic variation of parameter values is made to analyze Eq. [22].

Selection of parameter reference values.—Sensor electrolyte temperature, T, is assumed equal to exhaust temperature which, in turn, is arbitrarily set equal to 600°C. The anode electrode is assumed to possess limited catalytic activity and exhaust gas reactions of Eq. [4] and [13] are assumed to have frozen at 1480°C; the corresponding p_{O_2} and p_{CO} values are shown by case 2 in Fig. 7. Values of p_{CO_2} *vs.* A/F have little variation, ranging between 0.09 and 0.14 atm; appropriate values are used (14). The air reference value, p_{O_2}, is set equal to 0.21 atm. Standard cell potential, $V_{O_2}^\circ$, is assumed negligible and is set equal to zero. Cell potential V_{CO}°

Table II. Values of parameters used to evaluate adsorption constants

PARAMETERS	SYMBOL	RANGE OF VALUES
Condensation Coefficient*	σ	10^{-4} to 10^{0}, dependent on mobility, transition states, and intermediate complexes involved in gas adsorption process.
Gas flux at pressure of one atmosphere*	Ψ°	3.5×10^{27} to 5.0×10^{27} molecules/m^2-s, dependent on gas molecular weight and gas temperature.
Gas Molecular Vibration Frequency*	ν	1.4×10^{13} to 2.1×10^{13} s^{-1} dependent on gas temperature.
Number of Triple Point Adsorption Sites*	n_s	10^{18} to 10^{16} sites/m^2, dependent on area of electrode/electrolyte interface.**
Universal Gas Constant	R	1.987 cal/g-mole-°K
Exhaust Gas Temperature (Sensor Operating Temperature)	T	720 to 1030°K, dependent on engine operating state.
Heat of Adsorption for CO on Pt	Q_{CO}	10 to 48 kcal/g-mole, dependent on degree and type of coverage, and presence of impurities.***
Heat of Adsorption for O_2 on Pt	Q_{O_2}	10 to 70 kcal/g-mole, dependent on degree and type of coverage, and presence of impurities.***

* Parameter values so denoted apply for both CO and O_2 gases.

** Maximum number of triple point sites is estimated by assuming there exists at most one triple point, i.e., one conducting path for $O^=$ ions per four unit cells of the ZrO_2 lattice; one ZrO_2 unit cell area equals 25 $Å^2$ or 25×10^{-20} m^2. The lower limit of 10^{16} sites/m^2 is arbitrarily chosen equal to 1% of the maximum number.

*** Maximum values of Q_{CO} and Q_{O_2} equal to 48 and 70 kcal/g-mole, respectively, were reported by Heyne and Tompkins (17) for the limited case of near zero coverage on clean Pt films. The lower limit values of 10 kcal/g-mole are arbitrarily chosen to represent cases of high coverage in the presence of impurities.

is assumed to involve nonequilibrium thermodynamic processes and is set equal to 800 mV, which is 270 mV below its equilibrium value at 600°C of 1070 mV.

Adsorption constants K_{O_2} and K_{CO} are more difficult to estimate. Limiting values for the constituent parameters which determine K_{O_2} and K_{CO} are given in Table II; when these values are substituted into Eq. [18], the factors $K_{O_2}^\circ$ and K_{CO}° take on values ranging between 1.7×10^{-8} and 3.6×10^{-2}. Suitable values within the range of values in Table II are chosen on the basis of the following assumptions: (*i*) condensation coefficient equal to 0.5; (*ii*) triple point sites equal to maximum number, 1×10^{18} sites/m^2; (*iii*) heats of adsorption reduced in value due to high coverage and presence of impurities on Pt sites. Resulting values are $K_{O_2}^\circ = K_{CO}^\circ = 1 \times 10^{-4}$ and $Q_{O_2} = Q_{CO} = 25$ kcal/g-mole; these values are used in Eq. [17] to calculate the constants $K_{O_2} = K_{CO} = 1.8 \times 10^2$ for $T = 600$°C.

Calculation of sensor voltage curve.—Systematic variation of parameter values about the above set of reference values is made to study effects on the sensor voltage *vs.* A/F curves calculated from Eq. [22]. Effects due to variation of catalytic activity of the anode electrode are shown in Fig. 9, where curve 2 is calculated for the reference set of parameter values, and curves 1 and 3 correspond to the p_{O_2} and p_{CO} values of cases 1 and 3 shown in Fig. 7. As reaction freezing temperature approaches exhaust temperature, improved catalytic activity of the anode electrode allows exhaust gas reactions to approach equilibrium conditions. The sensor voltage curves of Fig. 9 take on a sharper, more step-like transition at the stoichiometric A/F ratio due to the improved catalytic activity of the electrode.

Effects due to variation of adsorption constants are shown in Fig. 10; here again curve 2 is calculated for

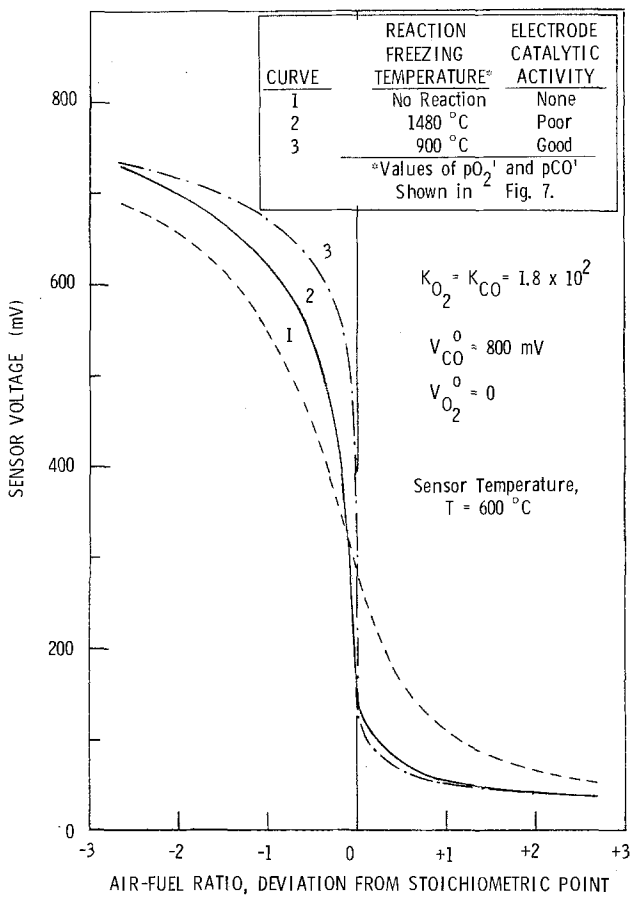

Fig. 9. Effects due to variation of catalytic activity of anode electrode, computed using theoretical model of nonideal sensor.

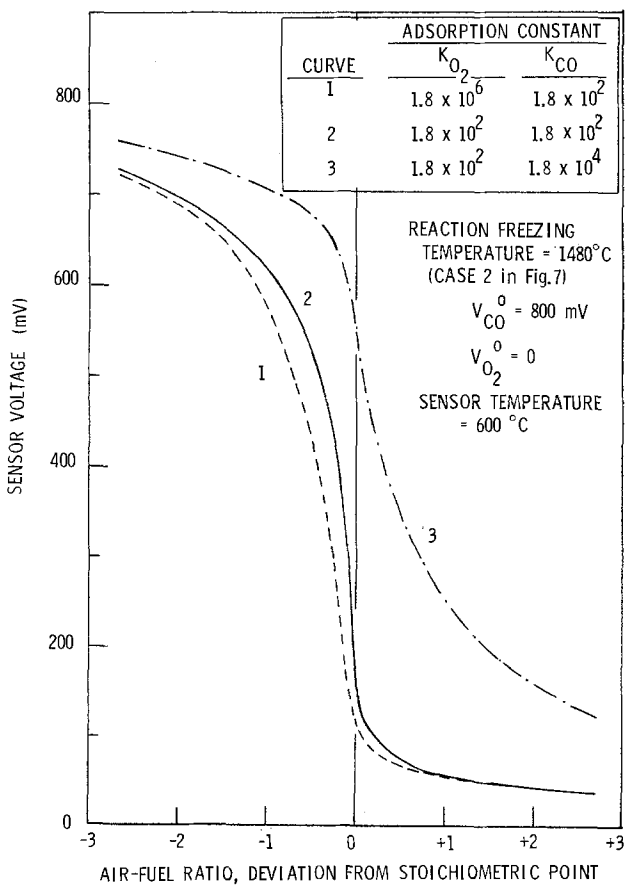

Fig. 10. Effects due to variation of adsorption properties of anode electrode, computed using theoretical model of nonideal sensor.

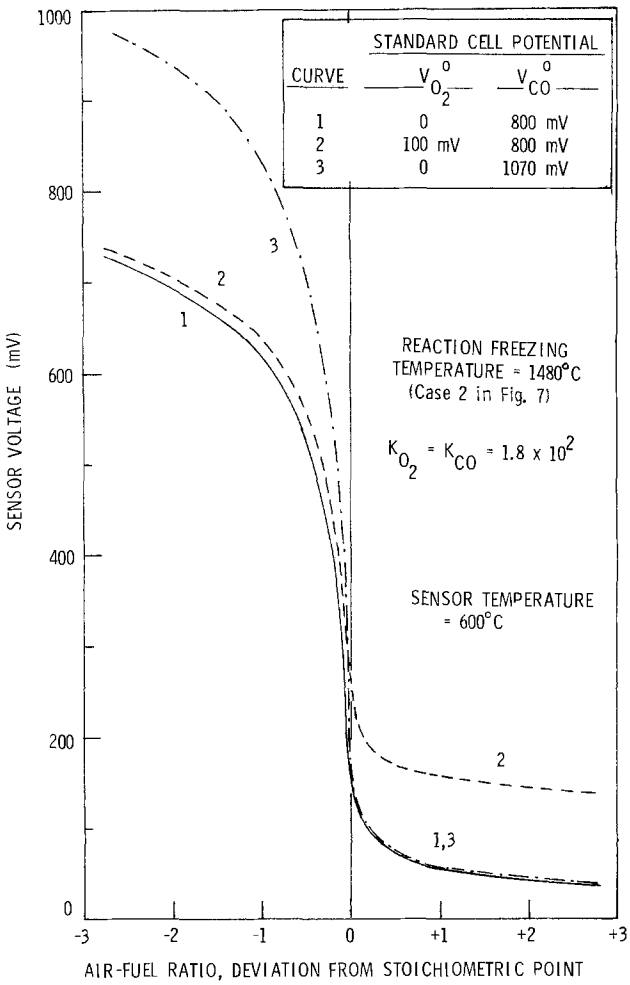

Fig. 11. Effects due to variation of standard cell potentials, computed using theoretical model of nonideal sensor.

the reference set of parameter values. Curves 1 and 3 correspond to varying values of K_{O_2} and K_{CO}. As the magnitude of K_{CO} relative to K_{O_2} decreases, the sensor voltage curves shift toward richer A/F ratios.

Effects due to variation of standard cell potentials are shown in Fig. 11; curve 1 is calculated for the reference set of parameter values, whereas curves 2 and 3 correspond to varying values of $V_{O_2}^\circ$ and V_{CO}°. Voltage levels of the rich and lean A/F tails of the curves are established by the values of the standard cell potentials.

Comparison to experiment.—The characteristics of the sensor curves shown in Fig. 4 and 5 can be related to the theory of Eq. [22] on the basis of the following observations. First, both groups of experimental curves exhibit a shifting of the steplike voltage transitions toward richer A/F for increased exhaust temperature. Second, group A sensor curves of Fig. 4 possess generally sharper voltage transition steps at A/F stoichiometry than do group B sensors of Fig. 5.

Parameter values of Eq. [22] are chosen to reflect the above-described behavior of experimental sensors. All temperature dependence is ascribed to the adsorption constants in order to account for the temperature dependent shifting of the voltage curves toward richer A/F. To obtain this curve shifting trend, the K_{CO} value must exceed the K_{O_2} value at lower temperature, and be smaller than the K_{O_2} value at higher temperature. Parameter values are chosen to give this behavior while being consistent with the range of values given in Table II. The values $K_{O_2}^\circ = 1 \times 10^{-2}$, $K_{CO}^\circ = 1 \times 10^{-7}$, $Q_{O_2} = 20$ kcal/g-mole, and $Q_{CO} = 40$ kcal/g-mole are chosen; K_{O_2} and K_{CO} are each given by Eq. [17] and are evaluated as follows

$$K_{O_2} = 1 \times 10^{-2} \exp(20/RT) \qquad [23]$$

and

$$K_{CO} = 1 \times 10^{-7} \exp(40/RT) \quad [24]$$

Sharper steplike transitions of group A sensors compared to group B sensors are attributed to better catalytic activity of the anode electrode. This behavior is obtained by assigning zero catalytic activity to group B sensor electrodes, whereby the p_{O_2}, and p_{CO}, values of case 1 shown in Fig. 7 are used. A reaction freezing temperature of 1480°C is assigned to group A sensor electrodes, whereby the p_{O_2}, and p_{CO}, values of case 2 shown in Fig. 7 are used. In both cases values for p_{CO_2}, *vs.* A/F have little variation, ranging between 0.09 and 0.14 atm, and appropriate values are used (14). Values of standard cell potentials are chosen to approximate the levels of the rich and lean A/F tails of the experimental sensor curves; the values $V_{CO}^{\circ} = 800$ mV and $V_{O_2}^{\circ} = 0$ are used for the group A sensor and $V_{CO}^{\circ} = 700$ mV and $V_{O_2}^{\circ} = 0$ are used for the group B sensor.

The above parameter values are substituted into Eq. [22] and the computed results are shown in Fig. 12 and 13. Good agreement between the computed curves and the experimental curves shown in Fig. 4 and 5 corroborates the validity of the physical sensor model developed in the preceding section of this paper. Agreement between relative shapes of curves and temperature trends of curves is noteworthy.

One can compare the physical properties of the theoretical models of group A and group B sensors to those of an ideal sensor. Tabulated values of relevant parameters are given in Table III. Note that major differences between ideal sensor parameter values and values for nonideal sensors in Table III are found in catalytic activity and adsorption properties. In particular, group A sensors which have catalytic activity only reduce p_{O_2}, some four orders of magnitude from that of unreacted exhaust, whereas the ideal sensor exhibits twenty orders of magnitude reduction of p_{O_2}, for the same A/F conditions. Moreover, the adsorption constants of both group A and group B sensors are from seven to thirteen orders of magnitude lower than the ideal values. It is beyond the scope of this paper to attempt to identify microscopic properties of electrode materials which give rise to the nonideal values of these parameters. However, future work in this area is suggested as a next step in further understanding of zirconia exhaust gas sensors.

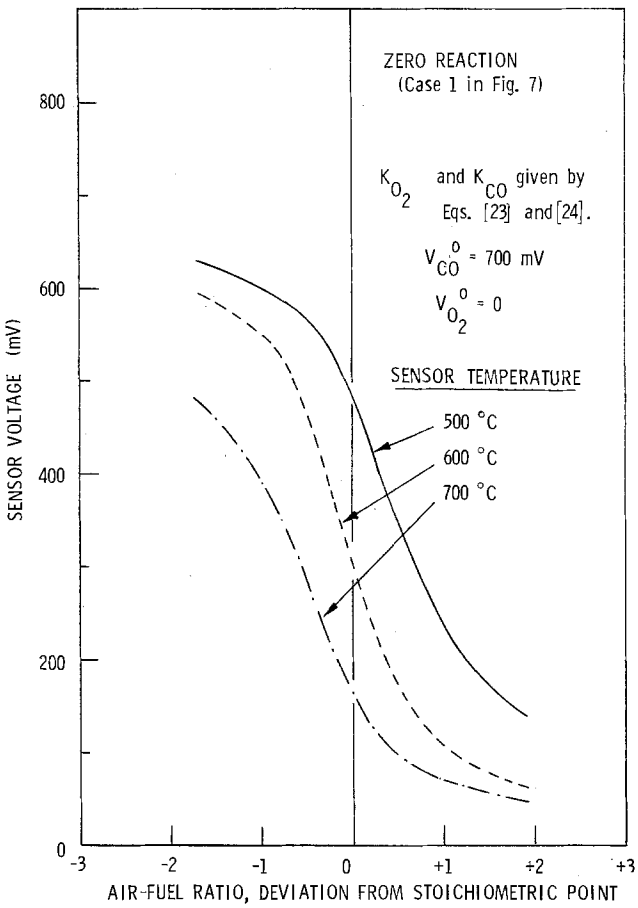

Fig. 13. Theoretical curves exhibiting behavior of group B sensors (*cf.* Fig. 5).

Conclusions

To summarize, there are three physical processes involved in the operation of the zirconia oxygen sensor and each process controls different characteristics of the sensor voltage *vs.* A/F curves. First, the degree of exhaust gas reaction, determined by catalytic activity of the anode electrode, controls the sharpness of the voltage transition step which occurs at the stoichiometric A/F point. Second, relative magnitudes of O_2 and CO gas adsorption properties of the anode electrode determine the A/F ratio at which the steplike voltage transition takes place. Third, standard cell potentials of the O_2 and CO cell reactions establish the voltage

Table III. Comparison of parameter values for theoretical sensor models at exhaust temperature of 600°C

SENSOR TYPE	CATALYTIC ACTIVITY: REACTION FREEZING TEMPERATURE	CATALYTIC ACTIVITY: pO_2 VALUE AT TRIPLE POINTS*	ADSORPTION CONSTANTS: K_{O_2}	ADSORPTION CONSTANTS: K_{CO}	STANDARD CELL POTENTIALS: $V_{O_2}^{\circ}$	STANDARD CELL POTENTIALS: V_{CO}°
Ideal (Fig. 2)	600°C	5.5×10^{-23} atm.	(1×10^{16})†‡	(3×10^{10})†	0	1070 mV
Nonideal Group A (Fig. 12)	1480°C	3.9×10^{-7} atm.	1×10^{3}	1×10^{3}	0	800 mV

* Values of pO_2 are taken from Fig. 7 at a point one air-fuel ratio rich of the stoichiometric point; the ideal value comes from Case 4, the Group A value comes from Case 2, and the Group B value comes from Case 1.

† Maximum values of K_{O_2} and K_{CO} are computed for the ideal sensor using Eqs. [17] and [18] together with the limiting values of Table II.

levels of the rich and lean A/F tails of the sensor curves.

To obtain agreement between experimental sensor characteristics and calculated results, it is found that sensor electrodes must possess surface adsorption properties and catalytic activities which are many orders of magnitude less than ideal equilibrium values. Future efforts to identify microscopic properties of electrode materials which give rise to the nonideal values of these parameters is suggested as a next step in further understanding of zirconia exhaust gas sensors.

Acknowledgments

Experimental results presented here were made possible by assistance provided by W. D. Creps, D. S. Howarth, A. J. Kotwicki, and L. S. Vora of the Automotive Systems Group of the Electronics Department, General Motors Research Laboratories. Special thanks go to fellow members of General Motors Research for helpful discussions on theoretical aspects of this work. These individuals include: J. S. Dunning, J. P. Hoare, and R. A. Sharma of the Electrochemistry Department, G. G. Tibbits of the Physics Department, G. J. Barnes, J. L. Gland, and K. C. Taylor of the Physical Chemistry Department, and D. S. Eddy, D. S. Howarth, and A. J. Kotwicki of the Electronics Department. The author very much appreciates the excellent typing done by J. Fiebelkorn.

The Ionic Conductivity of Beta Lead Fluoride

R. W. Bonne and J. Schoonman*

Solid State Department, State University of Utrecht, Sorbonnelaan 4, Utrecht-De Uithof, The Netherlands

ABSTRACT

The electrical conductivity of nominally pure and doped β-PbF_2 was investigated in the temperature range 300°-700°K. From our measurements, together with literature data, the temperature dependences of the concentration and mobility of the mobile species were calculated. The expression for the anion vacancy mobility is

$$\mu_{V_F} \cdot T = (54 \pm 18) \exp [-(0.23 \pm 0.02)\ \mathrm{eV}/kT]\ \mathrm{cm^2\ V^{-1}\ sec^{-1}\ ^\circ K}$$

and for the mobility of the interstitial anions

$$\mu_{F_i'} T = (5.4 \pm 1.9)\ 10^4 \exp [-(0.60 \pm 0.06)\ \mathrm{eV}/kT]\ \mathrm{cm^2\ V^{-1}\ sec^{-1}\ ^\circ K}$$

The intrinsic concentration of either anion-Frenkel defect was calculated to be

$$[V_F \cdot]_0 = [F_i']_0 = (1.6 \pm 0.5)\ 10^{23} \exp [-(0.44 \pm 0.02)\mathrm{eV}/kT]\ \mathrm{cm^{-3}}$$

The solid electrolyte properties of nominally pure and doped β-PbF_2 have been the subject of recent investigations (1-10). Derrington and O'Keeffe (2) and Benz (8) reported on the unusually high conductivity above about 700°K up to the melting point. The observed behavior cannot be understood from classical ionic motion theories (11, 12). Conductivities below 700°K, however, seem to be governed by the migration of point defects via normal lattice sites and interstitial sites. It is presently well established that these defects are thermally generated in the anion sublattice (3, 7, 13).

Investigations with the Wagner polarization cell have demonstrated that lead fluoride exhibits predominantly ionic conduction (4, 6, 8, 9). Incorporation of monovalent cations on lead ion sites increases the ionic conductivity by increasing the concentration of fluoride ion vacancies (7, 9). The influence of the substitutional incorporation of trivalent cations on the ionic conduc-

Key words: β-lead fluoride, extrinsic conductivity, intrinsic conductivity, ionic conductivity, solid electrolyte.

tivity is still ambiguous. Arkhangel'skaya (14) and Liang and Joshi (7) reported an increased conductivity of lead fluoride upon doping with trivalent impurities. To the contrary, Kennedy and Miles (9) showed the conductivity of β-PbF_2:BiF_3 pellets to decrease as compared to the conductivity of nominally pure material.

In regard to this ambiguity, the nature of applied electrode material has been discussed recently (15, 16). The conductivity of β-PbF_2:BiF_3 pellets exceeds the conductivity of nominally pure samples, when graphite electrodes were used. On the other hand, when Pb electrodes were used the conductivity was lower than that of the nominally pure material. Liang and Joshi (16) proposed the reaction

$$2BiF_3 + 3Pb \rightarrow 2Bi + 3PbF_2 \quad [1]$$

to explain the low conductivity of β-PbF_2:BiF_3 in between Pb electrodes. This reaction, however, will be strictly limited to the electrode surface area, since Bi^{3+} on a lead ion site is expected to be quite immobile, especially in a structure which favors mobile anion Frenkel defects. A recent paper (17) on the novel solid electrolyte $Pb_{1-x}Bi_xF_{2+x}$ ($0 \leqq x \leqq 0.50$) shows that the conductivity increases when x increases to values up to 0.25, whereas for $0.25 < x < 0.50$ the conductivity starts to decrease upon increasing x. The decrease has been accounted for by annihilation of anion vacancies by the excess fluoride ions from BiF_3. Gold electrodes were used in this study (17).

Studies of the frequency dispersion of lead fluoride in between ionically blocking electrodes in order to separate the influence of interfacial polarization phenomena from the bulk electrolyte parameters have attracted much attention as well (3, 5, 10, 17). Several authors observed a strong frequency dependence for frequencies above 1 kHz (3, 5, 9, 17), while others did not observe any dependence in that frequency range (1, 7). It has become evident from the literature data that the type of electrode material is of much importance. The present authors (10) arrive at the conclusion that the frequency-independent values of the conductance are representative for the electrolyte conductivity. The present investigation aims to provide additional data on this electrolyte conductivity of nominally pure and doped β-PbF_2. It is shown that these data, together with the literature data, fit a defect model for β-PbF_2 which adequately describes the reported temperature and concentration dependence of the conductivity of nominally pure and doped β-PbF_2.

Experimental

Materials preparation.—Lead fluoride (Merck, Ultrapure) in the orthorhombic modification (α-PbF_2) was used as starting material. To prepare doped material, LaF_3 (Koch-Light) and AgF (Merck) were used. Before the drying procedure weighted amounts of dopant are added. The materials were dried in graphite crucibles, using the procedure described by Jones (18), and subsequently melted for a few minutes. The melt was then cooled down to room temperature in 5 hr. This procedure yielded transparent crystalline pieces in the case of nominally pure β-PbF_2.

Thin specimens (thickness 0.1-0.2 cm, surface area 0.1-0.5 cm^2) were cut from the crystalline pieces. Surfaces were polished before conductivities were measured.

Liang and Joshi (16) observed that the solubility of YF_3 in β-PbF_2 is less than 0.1 mole percent (m/o). In the present preparations opaque β-PbF_2:LaF_3 was obtained, when 0.5 m/o dopant was added. As is substantiated below, conductivity data reveal that the solubility of LaF_3 in β-PbF_2 amounts to $\sim$ 0.1 m/o. Doping experiments with AgF yielded almost transparent pieces of β-PbF_2:AgF. AgF was added to the β-PbF_2 in a glove box. A small amount of a second phase, presumably AgF, could, however, be observed by an optical microscope in these materials. The interpretation of the conduction data on the doped samples is, therefore, restricted to the observed temperature dependence.

In one experiment a β-PbF_2:AgF crystal was used, which had been kindly made available by Dr. L. Shields of the University of Bradford (U.K.). This material was doped with CaF_2 as well. However, CaF_2 will not be of influence with respect to concentrations of point defects in β-PbF_2.

Conductivity measurements.—The samples were spring loaded between two platinum electrodes in a stainless steel conductivity cell. Electrical contacts between the crystal and the platinum electrodes were established by means of colloidal graphite (Aquadag) or platinum paint (Leitplatin 308A). In the case of doped samples an ambient of purified nitrogen was maintained in the cell, while the nominally pure samples were measured in air, vacuum, and nitrogen (10).

The conductivity of β-PbF_2 in between ionically blocking electrodes is strongly dependent on frequency. Frequency independent conductances represent true bulk properties (10). The admittance parameters of the nominally pure and doped samples were measured in the frequency range 100 Hz-50 kHz with a General Radio Impedance bridge (1608A) with external oscillator (1210C) and an amplifier-null-detector (1232A). For frequencies below 50 Hz admittances were measured in terms of a parallel R-C combination with an a-c bridge in combination with a Wavetek sweep generator (Model 144) and a Tektronix storage scope (Model 504B). To increase the sensitivity a power amplifier (PAR Type 214) was used. The amplitude of the a-c signal was kept below 20 mV peak-to-peak (10).

Results

The temperature dependence of the bulk electrical conductivity as obtained from complex admittance data for β-PbF_2, β-PbF_2:AgF, and β-PbF_2:LaF_3 is shown in Fig. 1. The nominally pure material exhibits two slopes. The conductivity can be represented in these two regions by

$$\sigma T = (1.175 \pm 0.018)\ 10^6 \exp\left[-(0.674 \pm 0.007)\,eV/kT\right]\ \Omega^{-1}\,cm^{-1}\,°K \quad [2]$$

for the low temperature region, and

$$\sigma T = (1.35 \pm 0.06)\ 10^9 \exp\left[-(1.04 \pm 0.06)\ eV/kT\right]\ \Omega^{-1}\,cm^{-1}\,°K \quad [3]$$

for the high temperature region. Conductivities in the high temperature region were corrected for conductivities expressed by Eq. [2], before the calculation was made, which lead to Eq. [3].

The incorporation of the trivalent impurity LaF_3 increases the conductivity. For the extrinsic region the conductivity of β-PbF_2:LaF_3 is represented by (Fig. 1, curve b)

$$\sigma T = (7.59 \pm 0.12)\ 10^4 \exp\left[-(0.496 \pm 0.006)\ eV/kT\right]\Omega^{-1}\,cm^{-1}\,°K \quad [4]$$

At the higher temperatures the conductivity coincides with those represented by Eq. [3]. This points to an intrinsic behavior at the higher temperatures.

The incorporation of the monovalent dopant AgF increases the conductivity as well. The conductivity in the extrinsic region is given by (Fig. 1, curve d)

$$\sigma T = (8.5 \pm 0.5)\ \exp\left[-(0.196 \pm 0.004)\ eV/kT\right]\ \Omega^{-1}\,cm^{-1}\,°K \quad [5]$$

After the first knee the conductivity of these specimens almost coincides with that of the nominally pure material after correction for the low temperature conductivity.

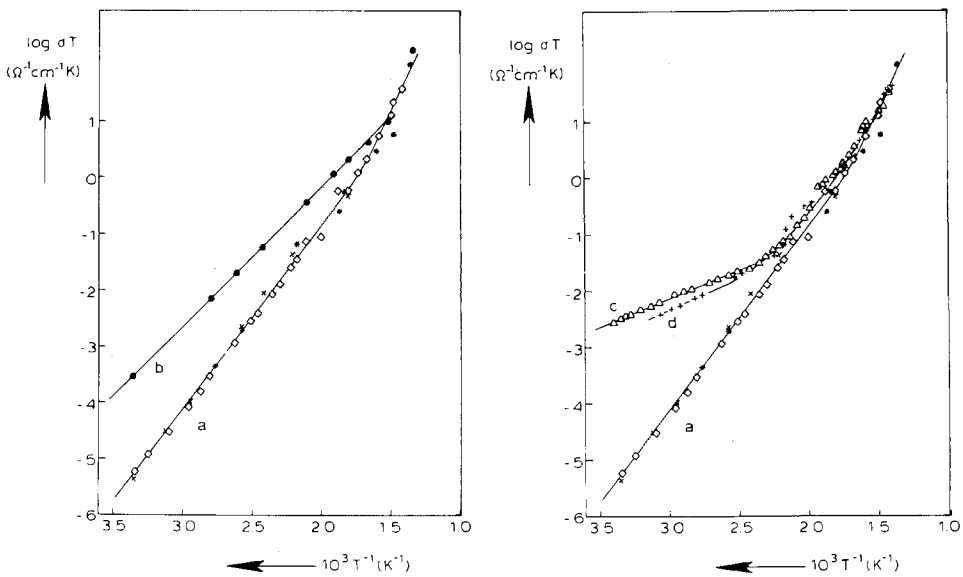

Fig. 1. Temperature dependence of the ionic conductivity of β-PbF_2. Curve a, Nominally pure (10); ×, vacuum; □, N_2; ✻, air. Curve b, LaF_3-dope, N_2. Curve c, AgF-dope, N_2. Curve d, AgF-dope (measurement on a crystal obtained from Dr. L. Shields), N_2.

It should be mentioned that complex admittance plots of the undoped and doped materials pass through the origin over the temperature region involved, indicating negligible electronic conduction in all materials. The present data strongly indicate that the undoped, nominally pure material used in this study exhibits only intrinsic conduction. It is, therefore, possible to determine the migration and formation parameters for fluoride ion vacancies and interstitial fluoride ions. A comparison with the reported data on β-PbF_2 specimens not only supports the model evaluated from the present study, but also provides conclusive evidence as to the nature of the conductivity in these specimens.

Theoretical Aspects of the Ionic Conductivity

In this section we summarize the relevant expressions necessary to give a quantitative description of the electrical conductivity of β-PbF_2. It is generally agreed that β-PbF_2 conducts via point defects in the anion sublattice. The thermal generation of intrinsic point defects is, according to a Frenkel mechanism, given by

$$F_F^{\times} + V_i^{\times} \rightleftarrows V_F^{\cdot} + F_i' \qquad [6]$$

The general relation governing the concentrations of these point defects is

$$K_F = [V_F^{\cdot}][F_i'] = NN' \exp\left(\frac{\Delta S_f}{k}\right) \exp\left(-\frac{\Delta H_f}{kT}\right) \qquad [7]$$

where K_F is the anion Frenkel equilibrium constant, ΔS_f and ΔH_f the formation entropy and formation enthalpy, respectively, N the number of fluoride lattice sites, and N' the number of interstitial sites. The substitutional incorporation of monovalent cations is given by

$$MF \rightarrow M_{Pb}' + V_F^{\cdot} + F_F^{\times} \qquad [8]$$

The incorporation of trivalent cations is represented by

$$MF_3 \rightarrow M_{Pb}^{\cdot} + F_i' + 2F_F^{\times} \qquad [9]$$

Our conductivity data do not indicate the presence of associated defects. In the present evaluation interaction between point defects are therefore not taken into account.

The electrical mobility (μ_i) of point defect i may be expressed by

$$\mu_i = \frac{r_i^2 e}{kT} \nu_i = \frac{r_i^2 e}{kT} \nu_{0,i} \exp\left(\frac{\Delta S_i}{k}\right) \exp\left(-\frac{\Delta H_i}{kT}\right) \qquad [10]$$

where r_i denotes the jump distance, ν_i the jump frequency, ΔS_i and ΔH_i the entropy and enthalpy of motion, respectively, and $\nu_{0,i}$ an attempt frequency of the same order of magnitude as the Debye frequency of particle i. For materials with the fluorite structure r_i will be $(a/2)\sqrt{2}$ for the interstitials, where a is the lattice constant, while for vacancies this jump distance will be $a/2$ (19). If both the anion vacancies and the anion interstitials are mobile, the total intrinsic conductivity can be expressed by (19)

$$\sigma = (K_F)^{1/2} e\mu_{V_F^{\cdot}} + (K_F)^{1/2} e\mu_{F_i'}$$
$$= \frac{a^2e^2}{2kT} (NN')^{1/2} \exp\left(\frac{\Delta S_f}{2k}\right) \exp\left(-\frac{\Delta H_f}{2kT}\right)$$
$$\left\{\frac{\nu_{0,V_F^{\cdot}}}{2} \exp\left(\frac{\Delta S_{V_F^{\cdot}}}{k}\right) \exp\left(-\frac{\Delta H_{V_F^{\cdot}}}{kT}\right)\right.$$
$$\left. + \nu_{0,F_i'} \exp\left(\frac{\Delta S_{F_i'}}{k}\right) \exp\left(-\frac{\Delta H_{F_i'}}{kT}\right)\right\} \qquad [11]$$

For the conductivity in the extrinsic region, one obtains, in the case of a monovalent dopant ($[V_F^{\cdot}]\mu_{V_F^{\cdot}} >> [F_i']\mu_{F_i'}$)

$$\sigma = [V_F^{\cdot}]e\mu_{V_F^{\cdot}} = \frac{a^2e^2}{4kT} [V_F^{\cdot}]\nu_{0,V_F^{\cdot}} \exp$$
$$\left(\frac{\Delta S_{V_F^{\cdot}}}{k}\right) \exp\left(-\frac{\Delta H_{V_F^{\cdot}}}{kT}\right) \qquad [12]$$

and in the case of a trivalent dopant ($[F_i']\mu_{F_i'} >> [V_F^{\cdot}]\mu_{V_F^{\cdot}}$)

$$\sigma = [F_i']e\mu_{F_i'} = \frac{a^2e^2}{2kT} [F_i']\nu_{0,F_i'} \exp$$
$$\left(\frac{\Delta S_{F_i'}}{k}\right) \exp\left(-\frac{\Delta H_{F_i'}}{kT}\right) \qquad [13]$$

These expressions are used in the evaluation of the conductivity data.

The Mobility of the Anion Vacancies

The observed activation enthalpy of ~0.20 eV in the extrinsic conductivity region of the AgF-doped material is well in line with the values reported in the literature (7, 9). Liang and Joshi (7), and also Kennedy and Miles (9), observed an increase in conductivity upon increasing the monovalent dopant concentration, the increased conductivity being concordant with vacancy conduction. Contrary to assumptions of Kennedy (15), the literature provides sufficiently accurate conductivity data for β-PbF_2 doped with KF to obtain a quantitative expression for the temperature dependence of the mobility of the fluoride ion vacancies.

From Eq. [12] it follows that a plot of log $(\sigma T/[V_F^{\cdot}]e)$ $(= \log(\mu_{V_F^{\cdot}} T))$ *vs.* T^{-1} will give a straight

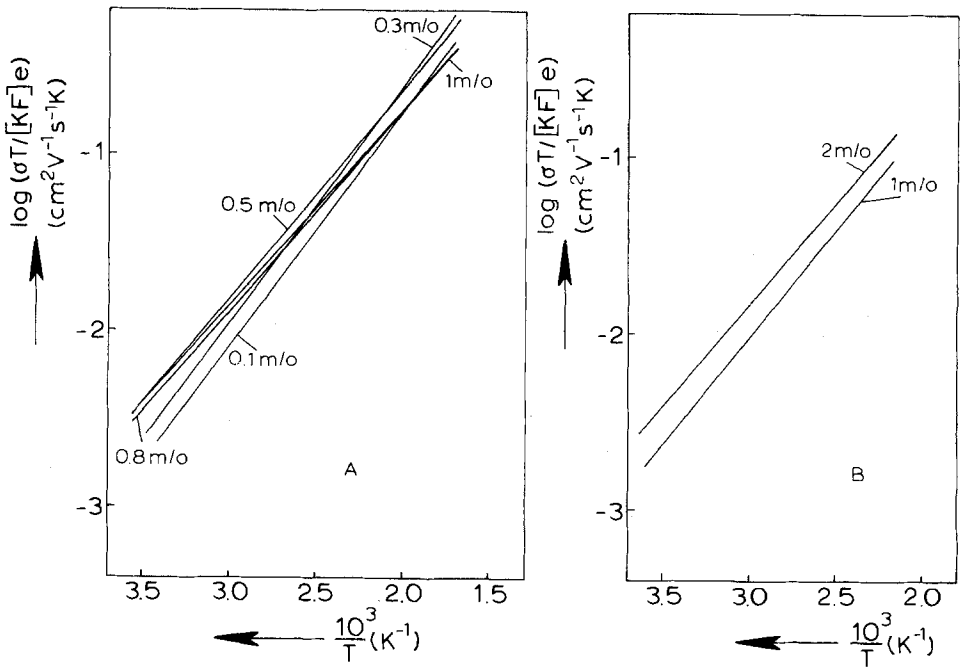

Fig. 2. The logarithm of $\mu_{V_F}\cdot T$, presented as log $(\sigma T/[KF]e)$ vs. T^{-1} for doped crystals. A, Data obtained from Ref. (7). B, Data obtained from Ref. (9).

line, the slope being the enthalpy for vacancy migration. In Fig. 2 the data of Ref. (7) and (9) are plotted as $\log(\sigma T/[KF]e)$ *vs.* T^{-1}, under the assumption $[KF] = [V_F\cdot]$ in accord with reaction [8]. The data for β-PbF_2 doped with 0.1 and 0.5 m/o KF as obtained from Kennedy and Miles (9) were not included in the analysis. It is at present not understood why doping through solid-state diffusion as was done by Kennedy and Miles leads to anomalies for low impurity contents. At higher impurity levels doping by a melt procedure (7) or by solid-state diffusion (9) yields, however, comparable data. From the data of Fig. 2, which exhibit little scatter, we derived for the vacancy mobility,

$$\mu_{V_F}\cdot T = (54 \pm 18)\exp[-(0.23 \pm 0.02)\ eV/kT]\text{cm}^2\,\text{V}^{-1}\,\text{sec}^{-1}\,^\circ\text{K} \quad [14]$$

This expression is to be compared with Eq. [10]. Together with the value 5.927Å (23) for the lattice constant one obtains from the preexponential factor of Eq. [14] for the jump frequency of the fluoride ion vacancies

$$\nu_{V_F}\cdot = (5.3 \pm 1.8)\,10^{12}\exp[-(0.23 \pm 0.02)\,\text{eV}/kT]\text{sec}^{-1} \quad [15]$$

With the approximation (20)

$$\nu_{0,V_F}\cdot = \frac{1}{r_{V_F}\cdot}\left(\frac{\Delta H_{V_F}\cdot}{2m}\right)^{1/2} \quad [16]$$

where m is the mass of the fluoride ion, an estimate for $\nu_{0,V_F}\cdot$ is calculated to be 2.6×10^{12} sec^{-1}. This agrees reasonably with the frequency observed in infrared studies, *viz.*, about 3×10^{12} sec^{-1} (21, 22). With this value, and relation [10], one obtains for the entropy of motion

$$\Delta S_{V_F}\cdot = 0.7k$$

The Frenkel Equilibrium Constant

The scatter in activation enthalpies for conduction of nominally pure β-PbF_2 is considerable at low temperatures (Table I). Speculations as to the nature of the mobile species responsible for activation enthalpies in

** A recalculation has shown that the value of 0.94 is correct instead of the reported value of 1.05 eV.
† Kennedy and Miles (9) mention these possibilities. Assuming the vacancy assignment Kennedy and Miles (9) arrive at a value of 0.90 for ΔH_i. According to these authors this low value cast doubt on the extrinsic-intrinsic region hypothesis (see discussion section).

this temperature region vary from extrinsic conduction via vacancies to extrinsic conduction via interstitials. At first glance it is not evident from the present measurements in which intrinsic region vacancy conduction or interstitial conduction predominates. In Table II the two possibilities are gathered. Possibility (a) assumes that in the low temperature intrinsic region (Eq. [2]) vacancies are the conducting species. Equation [3] then presents the conduction via interstitials. The reversed situation is given by possibility (b). From the values of the experimental conduction activation enthalpies, it is only possible to find a consistent value for the activation enthalpy of the Frenkel equilibrium constant in the case of model (a). In this model intrinsic conduction changes upon increasing temperature from conduction by vacancies to interstitials. From Eq. [11], where in the low temperature (intrinsic) region, $\mu_{V_F^\cdot} > \mu_{F_i'}$, and Eq. [2] and [14] we get for K_F

$$K_F = (2.4 \pm 0.8)10^{46} \exp[-(0.89 \pm 0.04)\,\mathrm{eV}/kT]\,\mathrm{cm}^{-6} \quad [17]$$

In order to arrive at a firm value for ΔH_f we have preferred the use of Eq. [14], since this equation is based on an extended series of doped materials. The value of 0.89 ± 0.04 eV is well in line with the model evaluation presented in Table II.

Equation [17] is to be compared with Eq. [7]. With N, the number of fluoride ion sites, and N', the number of interstitial sites which is equal to $\frac{1}{2}N$, the value of the entropy of formation is calculated to be

$$\Delta S_f = 3.5k$$

The Mobility of the Anion Interstitials

In the previous section we have shown that the high temperature intrinsic region can only be ascribed to conduction via interstitials. It is, therefore, possible to calculate from this region the mobility of the anion interstitials. With Eq. [11], where now $\mu_{F_i'} > \mu_{V_F^\cdot}$, and Eq. [3], and the value of K_F, the mobility of the interstitials is calculated to be

$$\mu_{F_i'}T = (5.4 \pm 1.9)10^4 \exp[-(0.60 \pm 0.06)\,\mathrm{eV}/kT]\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{sec}^{-1}\,^\circ\mathrm{K} \quad [18]$$

The jump frequency of the interstitials can be calculated according to Eq. [15]. This gives

$$\nu_{F_i'} = (2.7 \pm 0.9)10^{15} \exp[-(0.60 \pm 0.06)\,\mathrm{eV}/kT]\,\mathrm{sec}^{-1} \quad [19]$$

The entropy of motion of the interstitials can be calculated in analogy with the calculation of the entropy of motion of the vacancies. With the estimated value of $\nu_{0,F_i'} = 3.0 \times 10^{12}$ sec^{-1}, the entropy is

$$\Delta S_{F_i'} = 6.8k$$

One should bear in mind that the β-PbF_2:LaF_3 crystal exhibited a value of (0.496 ± 0.006) eV for $\Delta H_{F_i'}$. The present calculation also yields the preexponential factor in the equation describing the temperature dependence of the mobility. This preexponential factor cannot be obtained from the low temperature data of the β-PbF_2:LaF_3 sample since LaF_3 was present as a second phase. Figure 3 presents the temperature dependence of the mobilities of the mobile point defects in β-PbF_2.

From the calculated mobility and the observed conductivity in the extrinsic region of β-PbF_2:LaF_3 (Eq. [4]) the concentration of trivalent dopant responsible for the increase in conductivity turns out to be $\sim 2 \times 10^{19}$ cm^{-3}. With the concentration of lead ions, 1.9×10^{22} cm^{-3}, we arrive at a dissolved impurity content of about 0.1 m/o.

Discussion

Kennedy and Miles (9) observe two slopes in the log σT *vs.* T^{-1} curve for nominally pure β-PbF_2 and for β-PbF_2:KF (0.1 m/o). They discuss two possible mechanisms to explain this knee in the conductivity curve. First a transition from extrinsic to intrinsic conduction by $V_F^\cdot$ is considered; this leads to a formation enthalpy of 0.90 eV for anion Frenkel disorder. Their second possibility is a transition from extrinsic conduction $V_F^\cdot$ to extrinsic conduction by F_i'. Kennedy and Miles (9) doubt the first mechanism because of the rather low value of ΔH_f. In addition, they do not rule out the simultaneous presence of Schottky and Frenkel disorder. It should be pointed out that these authors did not observe the third (high temperature) slope as we did for the nominally pure, the β-PbF_2:AgF and the β-PbF_2:LaF_3 samples. In fact, it is this observation which supports the present evaluation and, therefore, the first mechanism of Kennedy and Miles. Their value of 0.90 eV is well in line with the present data.

The present authors (10) have reported the value 0.78 eV for ΔH_f. The conduction activation enthalpy of 0.66 eV (calculated from a log σT *vs.* T^{-1} plot), originally ascribed to the migration enthalpy for interstitials (7), is now interpreted as $(\Delta H_f/2 + \Delta H_m)$ for vacancies. Evaluations of ΔH_f values are very sensitive to extrinsic conduction activation enthalpies. Nevertheless, a rather low value for ΔH_f seems now well established.

Table I summarizes conduction activation enthalpies from reported literature data and the present study on β-PbF_2. If necessary literature data were converted to log σT *vs.* T^{-1} in order to obtain the correct conduction activation enthalpies. The measurements of Derrington and O'Keeffe (2) and Benz (8) are not gathered in this table, since their conductivity plots (log σT *vs.* T^{-1}) show a curvature from low temperature up to temperatures where the conductivity starts

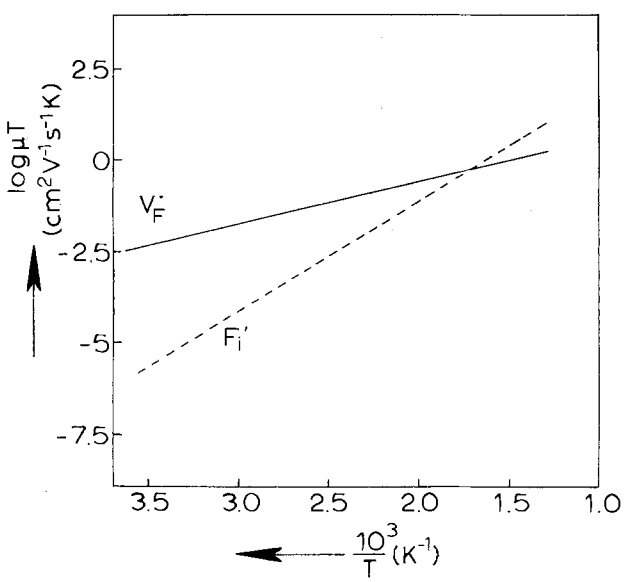

Fig. 3. Mobility of anion vacancies and interstitials as a function of temperature.

to level off. However, both plots clearly show the two regions which we ascribe to intrinsic conduction by V_F' and intrinsic conduction by F_i', while the magnitude of the conductivity in both regions is concordant with the present data. The present model allows in many cases an identification of the mobile species and the nature of the conductivity.

Uncertainties in the calculated values of $\mu_{Fi'}$ and K_F originate mainly from the uncertainty in the mobility of the anion vacancies and Eq. [3]. This mobility was extracted from measurements on samples with different concentrations of KF, and from different literature sources (7, 9). Moreover, different preparation techniques were used in these studies, *e.g.*, melting (7) or solid-state diffusion (9). In neither case, however, is it known to what degree added impurities are actually incorporated into the lattice. Information as to the nature and concentration of remaining impurities in the nominally pure materials is not presented by Liang and Joshi (7), nor by Kennedy and Miles (9). Insight into this parameter could also improve the accuracy of the calculated mobilities. In regard of these considerations the scatter in the log $(\sigma T/[KF]e)$ *vs.* T^{-1} plot is surprisingly low.

From the derived parameters it is possible to calculate the total conductivity as well as the contributions due to the fluoride ion vacancies and to the interstitial fluoride ions in the extrinsic and intrinsic region as a function of temperature. In Fig. 4 the total conductivity is plotted for different monovalent dopant concentrations. In Fig. 5 the total conductivity is plotted for different trivalent-dopant concentrations. Interestingly this plot clearly shows the conductivity to decrease for low dopant concentrations. At high enough dopant levels the conductivity starts to increase. This phenomenon is caused by a change from vacancy conduction to interstitial conduction and originates from the condition $\mu_{Fi'} << \mu_{V_F'}$ at lower temperatures.

In comparison with the commercially available β-PbF_2 crystals (1), which all show intrinsic conductivity, only a few of the undoped crystals prepared for this study exhibited intrinsic conductivity for temperatures above 300°K. The temperature dependence of the conductivity of most of the undoped materials resembled that of the silver-doped β-PbF_2, indicating an effective monovalent impurity content. Our efforts to reproduce experimentally the predicted temperature dependence of crystals with a low trivalent-impurity level as given in Fig. 5, curve b, were, therefore, not successful.

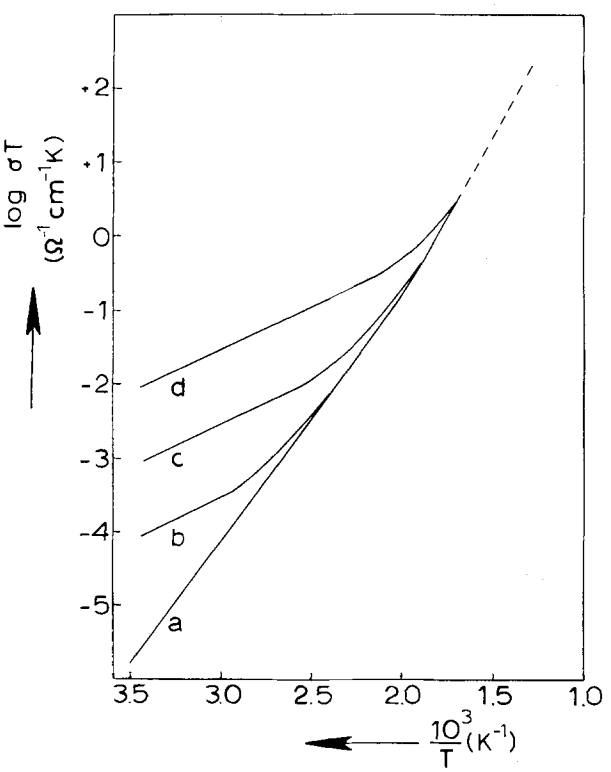

Fig. 4. Calculated intrinsic and extrinsic conductivity of β-PbF_2, doped with monovalent impurities. Curve a, Intrinsic conduction. Curve b, $[10^{17}]$ cm^{-3}. Curve c, $[10^{18}]$ cm^{-3}. Curve d, $[10^{19}]$ cm^{-3}. The dashed line represents conductivity by interstitials, and the solid lines represent conductivity by vacancies.

Curve d, $[10^{19}]$ cm^{-3}. Curve e, $[10^{20}]$ cm^{-3}. The dashed lines represent conductivity by interstitials, and the solid lines represent conductivity by vacancies.

In Table III the defect parameters for other materials with fluorite structure are gathered. Lead fluoride exhibits, in comparison with these materials, remarkably low enthalpies of formation and migration. In Fig. 6 we have plotted the temperature dependence of the intrinsic point defects in β-PbF_2 and the alkaline earth fluorides. The different behavior of β-PbF_2 probably originates from the large polarizability of the lead ion.

The literature provides several empirical relations between formation enthalpies and melting temperatures. Maycock and Pai Verneker (30) introduced the relation

$$\Delta H_f(\text{eV}) = 3.47 \times 10^{-3}\, T_m(°\text{K}) - 1.08 \qquad [20]$$

Data for a series of alkali halides, silver halides, and polyatomic anion potassium salts, which exhibit either Schottky or Frenkel disorder, were used to derive this relation. The relation (1)

$$\Delta H_f(\text{eV}) = 1.2 \times 10^{-3}\, T_m(°\text{K}) + 0.34 \qquad [21]$$

was derived from data reviewed by Barr and Lidiard (31) for silver halides and anion conductors with Frenkel disorder, among which are the alkaline earth fluorides (1). It should be pointed out that the majority of the compounds used to derive relation [20] exhibit Schottky disorder. Relation [21] seems, therefore, more appropriate for an estimation of the value of ΔH_f for β-PbF_2. These relations lead to ΔH_f values for β-PbF_2 ($T_m = 1095°K$) of 2.72 and 1.66 eV, respectively. Kennedy and Miles (9) used the value 2.72 eV to illustrate that the low ΔH_f value (0.90 eV) for β-PbF_2 casts doubt on the extrinsic-intrinsic region hypothesis. Relation [21] leads, however, to a much lower value. Moreover, it has been well demonstrated (2) that above *ca.* 700°K β-PbF_2 exhibits an almost temperature-independent liquidlike conduction due to a liquidlike disorder in the anion sublattice of β-PbF_2. If this "melting" temperature were to be used, ΔH_f has the value of only 1.2 eV.

CaF_2 and SrF_2 (11) exhibit also a leveling off of the conductivity. However, the differences between the actual melting temperature and the temperature at which liquidlike conduction starts in these fluorides are smaller than for β-PbF_2. A refinement by using the latter temperatures of CaF_2 and SrF_2 will hardly improve relation [21].

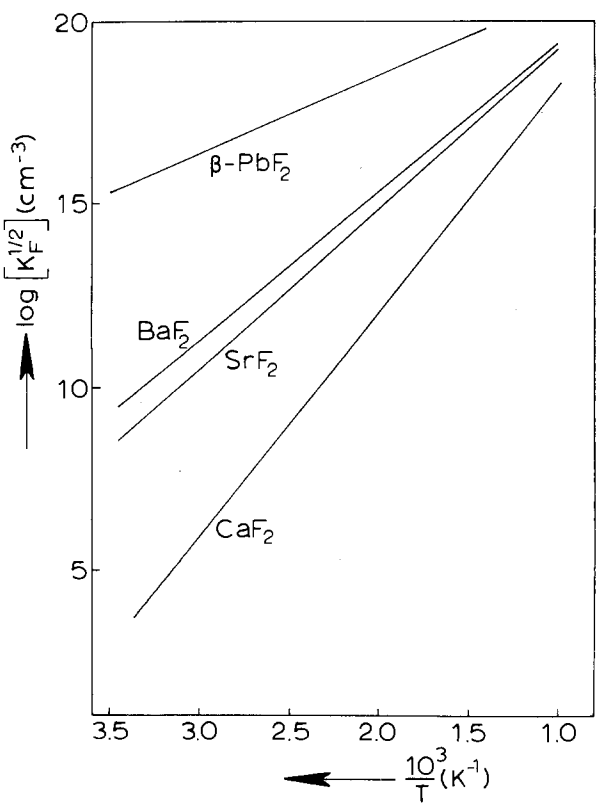

Fig. 6. Concentrations of the anion-Frenkel defects as a function of temperature in CaF_2 (28), SrF_2 (19), BaF_2 (27), and β-PbF_2 (this work).

Ionic Conductivity of Solid and Liquid $LiAlCl_4$

W. Weppner and R. A. Huggins*

Center for Materials Research, Stanford University, Stanford, California 94305

ABSTRACT

The electrical conductivity of lithium chloroaluminate has been investigated in the temperature range between room temperature and 180°C. It is molten above 145°C. The conduction is practically purely ionic and is attributed to the transport of lithium ions. The experiments show high values for ionic conductivity in the solid state, only exceeded by Li-β-alumina and some LiI-based materials. At 25°C the conductivity was found to be $1 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$, with an activation enthalpy for σT of 0.47 eV. A-C conductivity measurements were influenced by sample preparation and cell arrangement. The ionic conductivities of this and several other newly found lithium ionic conductors, as well as those previously known, are compared in the temperature range between 20° and 250°C.

In the present efforts to develop new types of high energy and power density storage devices it is of considerable importance to search for better solid lithium ionic conductors. The obvious main advantages of systems based on lithium are its low atomic weight, its relatively rich abundance, the high negative Gibbs free energy of formation of many lithium compounds, and the possibility of using liquid electrodes with fast kinetic properties.

Conduction experiments upon the low melting LiCl-$AlCl_3$ eutectic melt indicated a considerable ionic conductivity even after solidification had occurred. Therefore a detailed investigation of the compound $LiAlCl_4$, one component of the expected eutectoid structure, has been carried out.

The compound lithium chloroaluminate $LiAlCl_4$ was first reported in 1923 by Kendall *et al.* (1). However, there is not yet much information about the properties of this phase. According to the proposed phase diagrams (1-3) (which differ considerably in detail), $LiAlCl_4$ is the only ternary phase that exists in the system LiCl-$AlCl_3$. Especially remarkable is the very low eutectic temperature of about 104°C (1, 2) at the composition of 41 mole percent (m/o) LiCl and 59 m/o $AlCl_3$, and the low melting point of 146°C (1, 2, 4) [132°C (3)] for the compound $LiAlCl_4$.

The crystal structure has not yet been accurately determined. X-ray experiments (3, 4) have indicated that the structure is not isomorphous with the other alkali metal chloroaluminates (4). However, the chlorine ions form tetrahedra about the aluminum ions, and the structure can thus be considered as a quasi-binary compound made up of these isolated tetrahedral $AlCl_4^-$ ions, between which the positively charged alkali metal ions exist. Some evidence has indicated that the tetrahedra may also be distorted (4).

The electrical conductivity of molten LiCl-$AlCl_3$ has been reported in the literature, with values up to 0.35 $\Omega^{-1}cm^{-1}$ at 174°C measured (6). In a few cases this melt has been used as an electrolyte in conventional isothermal (7-9) and thermal batteries (10). More often because of the solubility and dissociation of $LiAlCl_4$ into Li^+ and $AlCl_4^-$ ions in several inorganic and organic nonaqueous solvents, it has been used as a soluble electrolyte in many types of batteries operating in the region of room temperature (11-24).

Experimental Considerations

Lithium chloroaluminate has been prepared by blending and reacting LiCl with $AlCl_3$. LiCl (> 99.3%) from Baker Chemical Company and $AlCl_3$ (puriss. ≥ 99%, iron and water free) from Fluka AG were used. Both materials were pulverized in a mortar and mixed in the appropriate equal molar ratio. The powder was then melted by heating it to 150°-180°C in a Pyrex glass tube in a helium-filled dry box. The initial color of the melt was yellowish brown and a small amount of precipitated LiCl was observed. Water was removed by holding the liquid sample at 180°C overnight. In order to clean the melt from other impurities, small pieces of pure metallic lithium were added gradually. First, the lithium changed both its color and shape rapidly, indicating the reduction of impurities with lower thermodynamic stability than the corresponding lithium compounds. Any aluminum metal that may be formed in this way is not a serious problem, because it can be assumed to be practically insoluble in the molten chloroaluminate (25). The amount of solid LiCl at the bottom of the melt increased slightly during the cleaning procedure. Through this treatment the melt finally became waterlike; colorless, transparent, and with a low viscosity.

Two different experimental arrangements were used to determine the electrical conductivity of solid $LiAlCl_4$ prepared from the melt. In one set of experiments the melt was poured into a test tube containing two parallel molybdenum sheets of about 1 × 5 cm in dimension and with a 0.4 cm spacing, which were kept in position by Teflon holders. The sample was crystallized by cooling the melt *in situ* at a very slow rate. Molybdenum is chemically inert in the presence of lithium (26).

In the second set of experiments the melt was decanted into a Teflon crucible. After quenching, a fine-grained pellet of several millimeters thickness and about 1 cm in diameter resulted. The surfaces were polished with corundum paper in the dry box. Molybdenum sheet electrodes were applied, the system was compressed by springs, and the sample-electrode assembly annealed at 100°C overnight. The cell was then

* Electrochemical Society Active Member.
Key words: solid electrolyte, solid-state ionics, lithium ion conductivity, a-c conductivity, d-c polarization measurements.

placed in an electrically heated glass tube furnace, and flushed with a small flow of carefully dried helium gas. The colors of the samples ranged from translucent to white. At temperatures above 100°C, they became quite soft and ductile.

The electrical conductivity was determined by using a-c bridge techniques in the frequency range between 50 Hz and 100 kHz. The resistances were derived by interpretation (27) of complex impedance plane diagrams of the data, and conductivities were calculated from the measured resistances and the physical dimensions of either the solidified melts or the pellets.

X-ray investigations produced the same diffraction pattern as previously given in the literature (4) for $LiAlCl_4$.

Results and Discussion

Figure 1 is a semilogarithmic plot of the specific conductivity σ, times the absolute temperature T, *vs.* the inverse temperature in the region between 20° and 180°C. As can be seen from Fig. 1, the values for the *in situ* crystallized sample are systematically higher by about 25% than those for the pellets. This is probably due to the less well-defined geometry of the volume of material that contributes to the electrical conductivity in the case of the *in situ* solidified system. Because of the larger dimensions of the sample, the temperature is probably also less uniform,

The activation enthalpy for σT of the solid $LiAlCl_4$ was found to be 0.47 eV (45 kJ/mole). At 25°C the specific conductivity was observed to be about $1 \times 10^{-6}\Omega^{-1}cm^{-1}$. It increases to $1.4 \times 10^{-4}\Omega^{-1}cm^{-1}$ at 140°C, shortly before the compound melts. At the phase transformation the conductivity rapidly increases by a factor of 800. Above the melting point it shows the typically low activation energy and high conductivity of many molten salt electrolytes.

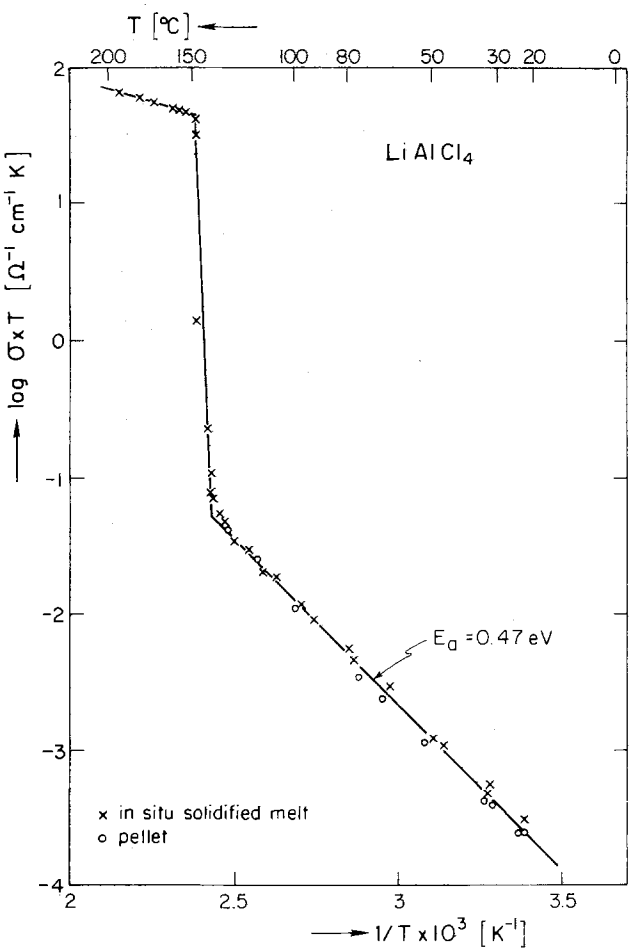

Fig. 1. Semilogarithmic plot of the bulk conductivity of $LiAlCl_4$ times the absolute temperature as a function of the inverse absolute temperature. Results for different experimental situations are indicated as follows: x, *in situ* solidified melt; o, cast pellet.

Significant differences were observed in the complex impedance and admittance plots between the different experimental situations that were investigated. Figure 2 shows the reactance X *vs.* the series resistance R of $LiAlCl_4$, measured under three different circumstances. In one case measurements were made on a cast pellet that was only polished and assembled without further treatment. In the second, the sample as well as the electrodes were annealed at 100°C for 14 hr. A third case involved results obtained on the *in situ* solidified melt. It can be seen from the figure that the heat-treatment of the pellet-electrode system drastically increased the interfacial capacitance by promoting better contact between the electrodes and the electrolyte. This resulted in a better separation of the bulk and interface capacitances, and thus aided the interpretation of the data. The situation is even simpler for the case in which the melt was solidified directly between the electrodes. In this latter case, only a comparatively short straight line with an inclination of about 45° was found over the frequency range between 0.1 and 100 kHz. The difference between the intercepts of the straight lines with the R axis in this figure for the measurements made on the pressed pellet are only due to the somewhat different temperatures at which the two sets of experiments were carried out. As has been shown elsewhere (27, 40), the differences in the observed frequency dependence of the two types of samples cannot be due to internal voids in the electrolyte, but differences in the intergrain contact may make a secondary contribution to the observations. Figure 2 clearly shows that it is very important to examine the frequency dependence of the measured conductivities or resistances in order to properly determine the bulk conductivity. Otherwise, considerable errors may be present in monofrequency measurements in unfavorable experimental setups.

In order to verify the information obtained from the shape of the X-R and B-G plots that the measured conductivities were not determined by transport of electronic species, d-c polarization measurements were made at voltages between 20 and 400 mV.

If the sample is a practically pure electronic semiconductor, the sum of the conductivities of the electrons, σ_e, and the holes, σ_h, calculated from the current

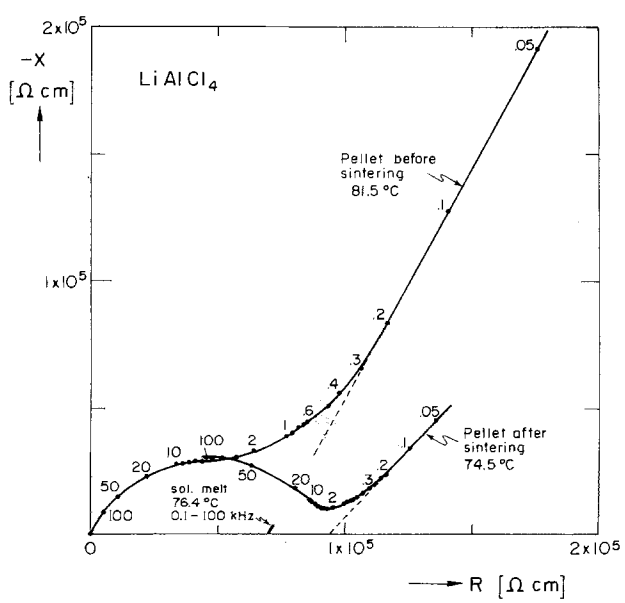

Fig. 2. Complex impedance plane plot for various samples of $LiAlCl_4$. The upper curve resulted from using a cast pellet without further treatment. The intermediate curve shows results from the same pellet, but after annealing the sample and electrodes together at 100°C overnight. The lower line represents the results of the *in situ* solidified melt. The numbers along the curves are the frequencies in kilohertz.

density i and the voltage drop E across a cell of length L

$$\sigma_e + \sigma_h = -\frac{iL}{E} \quad [1]$$

has to have the same magnitude as the conductivity determined by a-c measurements. If the sample is mainly ionic, but also a partially electronic conductor, the situation is similar to that in Hebb-Wagner d-c polarization experiments (28, 29), in which the ionic current is blocked by an inert electrode that is not able to deliver ions. However, in this case the electron and hole conductivities are not fixed at one side. Wagner's d-c polarization current i-voltage E relation (29) may be transformed into

$$i = -\frac{RT}{\mathbf{F}L}\left[1 - \exp\left(-\frac{\mathbf{E}\mathbf{F}}{RT}\right)\right][\sigma_e(O) + \sigma_h(L)] \quad [2]$$

and which becomes under the (often fulfilled) condition $\mathbf{E}\mathbf{F} >> RT$

$$i = -\frac{RT}{\mathbf{F}L}[\sigma_e(O) + \sigma_h(L)] \quad [3]$$

$\sigma_e(O)$ and $\sigma_h(L)$ are the electron conductivity at the left-hand phase boundary and the hole conductivity at the right-hand side of the sample, respectively. The Wagner equation was derived under the limiting assumptions of the validity of the laws of ideal dilute solutions for the concentrations of the electronic species, concentration independent mobilities of electrons and holes, and locally independent chemical potentials of the mobile ions. Therefore, it is identical to Fick's first law and may also be directly derived from it. An inner electric field is not present because of the high ionic conductivity, and the electronic current is only due to diffusion under a concentration gradient.

While the electronic conductivities are essentially locally independent in the case of predominantly electronic conduction, they vary with the position in the sample if we assume a mainly ionic conductor. For the present purpose it is worth noticing that $\sigma_e(O)$ and $\sigma_h(L)$ in Eq. [2] and [3] are both the maximum values of the conductivities of the electrons and holes, respectively, over the entire sample. The measured current density is, therefore, the upper limit of the total electronic and hole conductivities of the sample.

Application of the above analysis of the steady-state d-c polarization results according to Eq. [1], [2], and [3] showed electronic conductivities well below 1% of the total a-c conductivity for the compound $LiAlCl_4$. This indicates essentially pure ionic conductivity in this material. Because of the big, and therefore probably relatively immobile $AlCl_4^-$ ions, the conduction can be regarded as being due to motion of the Li^+ ions exclusively.

In Fig. 3 the conductivity of $LiAlCl_4$ is compared with other well-known and several other newly discovered solid lithium electrolytes. As can be seen from this compilation, $LiAlCl_4$ exceeds all the other materials except Li-β-Al_2O_3 (which is not stable and therefore probably not of importance in many applications) and several lithium iodide-based materials. Also, the activation energy is lower than for most of the other lithium electrolytes, probably because of a structure more favorable to movement of the ions. However, since the detailed structure of $LiAlCl_4$ is not yet known, it is very speculative to discuss the structural reasons for the high ionic conductivity of this material.

In the investigations described here no effort was given to the modification of the $LiAlCl_4$ structure by adding dopants. As observed for closely related materials (30, 31) it seems that it may be possible to improve the ionic conductivity by several orders of magnitude in this manner, and experiments are being undertaken to investigate this possibility.

Anodic Polarization and Localized Corrosion Behavior of Amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ in Near-Neutral and Acidic Chloride Solutions

T. M. Devine*

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

The anodic polarization and localized corrosion behavior of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ were obtained in 0.02, 0.2, 0.6, and 2.0M chloride ion solutions of pH 6.6, 4.0, and 1.0. Regardless of the hydrogen ion and chloride ion concentrations of the solution, the alloy remained immune to pitting corrosion. The passive corrosion current density was insensitive to changes in chloride ion concentration. The passive corrosion current density was independent of solution pH between pH 6.6 and 4.0. Decreasing the pH from 4.0 to 1.0 resulted in a threefold increase in passive corrosion current density. The alloy was susceptible to crevice corrosion. Plastic deformation affected neither the passive corrosion current density nor the pitting corrosion resistance. Severe cold-rolling resulted in cracking and crevice corrosion occurred at cracks. The results suggest that the great resistance of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ to pitting corrosion is due to its resistance to pit nucleation which can be attributed to its high degree of chemical homogeneity and lack of inclusions. The as-received amorphous ribbon is highly chemically inhomogeneous. Auger electron spectroscopy indicates the top surface of the ribbon is greatly enriched with chromium and both surfaces are depleted of phosphorus. Anodic polarization measurements suggest the top surface is covered with a Cr_2O_3 film.

While the electrical, magnetic, and mechanical properties of amorphous alloys have received a great deal of attention, it is only recently that the remarkable corrosion characteristics of some amorphous alloys have been explored (1-4). In particular, we have illustrated the immunity of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ to pit corrosion in 0.17M NaCl solution (1, 2). By comparison, when the alloy was crystallized by heat-treating in vacuum at 400°C for 2 hr, it became susceptible to pit corrosion in 0.17M NaCl at potentials above +440 mV *vs.* standard hydrogen electrode (SHE). The present work was undertaken to further define the nature and extent of the localized corrosion resistance of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ and to determine, if possible, whether its corrosion resistance was inherent to its amorphous structure or was related to its chemical composition. The current study presents the anodic polarization, pitting corrosion, and crevice corrosion behavior of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ in solutions of varying pH and chloride ion activity.

* Electrochemical Society Active Member.
Key words: amorphous alloys, pitting corrosion, anodic polarization.

Experimental Procedure

Amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ was obtained from the Allied Chemical Corporation in the form of ribbon 0.36 cm wide and ~0.007 cm thick. Specimens for potentiodynamic anodic polarization were mechanically polished with silicon carbide paper, finished with 3 μm diamond polishing compound, soldered at one end to an electrical test lead, ultrasonically cleaned in acetone, and rinsed with distilled water. The soldered joint was then masked off from the remainder of the sample with Glyptal® paint. This provided an effective sample size of 4 cm in length by 0.36 cm in width by 0.005 cm in thickness.

The anodic polarization behavior and localized corrosion tendency of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ were determined at room temperature (22°-25°C) in deoxygenated sodium chloride and hydrochloric acid solutions made from distilled water and chemicals of certified ACS purity. The 1 liter volume test solutions were deoxygenated by bubbling ultrahigh purity nitrogen gas at a flow rate of 0.15 std ft^3/hr for a minimum of 4 hr before testing.

The polarization cell contained the deoxygenated test solution, the test electrode, and two platinum-mesh counterelectrodes. A Luggin-Haber probe and salt bridge filled with the test solution provided a low resistance path between the test specimen and a saturated calomel reference electrode ($E^\circ = 0.244$V) located in a separate beaker filled with the test solution. All measured potentials are reported relative to the standard hydrogen electrode. Polarization tests were conducted by first cathodically polarizing the sample to −1200 mV for ≃30 sec and then, starting at the corrosion potential, cathodically polarizing the sample to a current density of ≃30 μA/cm² before reversing the direction of potential variation and anodically polarizing the specimen. This particular cathodic pretreatment provided highly reproducible corrosion potentials. During polarization the potential difference between the reference electrode and specimen was either continuously varied at a rate of 1 mV/sec with the aid of a Princeton Applied Research Model 173 potentiostat and Model 175 universal programmer, or was incremented in 20 mV steps every 20 sec with the aid of a Wenking potentiostat. Identical polarization results were obtained on similar samples polarized by the two different techniques. Samples were anodically polarized to a maximum potential of 1744 mV. The occurrence of pitting corrosion during polarization was indicated by the presence of hysteresis in the polarization curve on backscanning the potential. Following testing, the surfaces of all samples were examined with an optical microscope at 100× and 500× magnifications.

Results

In an earlier note (2) we indicated the surfaces of as-received $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ to be very different chemically from each other and from the bulk composition. In the Appendix the nature and extent of the difference in chemical composition between the two surfaces of the ribbon is further defined and shown to result in different anodic polarization behavior for the two surfaces. Briefly stated, the as-received amorphous ribbon is covered on the top (shiny) surface with a chromium-rich layer. The bottom (dull) surface is relatively rich in iron. Both surfaces are low in nickel and practically devoid of phosphorus. The effect of metallographic polishing is to remove the chemically inhomogeneous surface layers of the amorphous alloy. In order to avoid compositional differences between the two surfaces, all testing was performed on samples metallographically polished to 3 μm diamond.

The effect of chloride ion concentration on the anodic polarization of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ in solutions of pH 6.6, 4.0, and 1.0 is illustrated in Fig. 1-3. The amorphous alloy was initially active in all solutions and the corrosion potential (as defined by the potential of zero applied current during anodic polarization from the cathodic to the anodic region) decreased with increasing chloride ion content and, for a given chloride ion content, decreased with increasing pH at a rate of ≃55 mV/pH unit. Because of the relatively low critical anodic current densities for passivity and low primary passivation potentials, only a small region of Tafel behavior was observed within the region of active dissolution. As such it is difficult to measure a Tafel slope, β, very accurately. However, β did

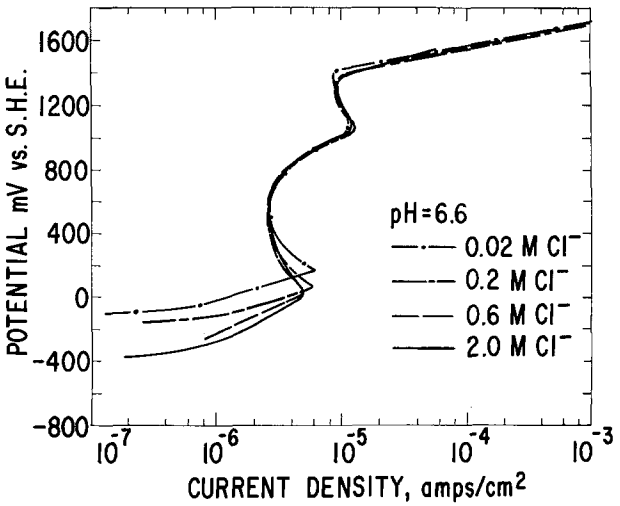

Fig. 1. Anodic polarization of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ in solutions of pH 6.6 with various chloride ion concentrations.

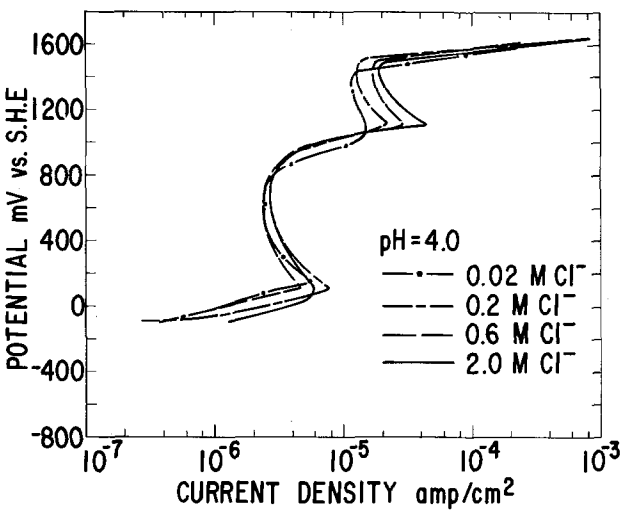

Fig. 2. Anodic polarization of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ in solutions of pH 4.0 with various chloride ion concentrations.

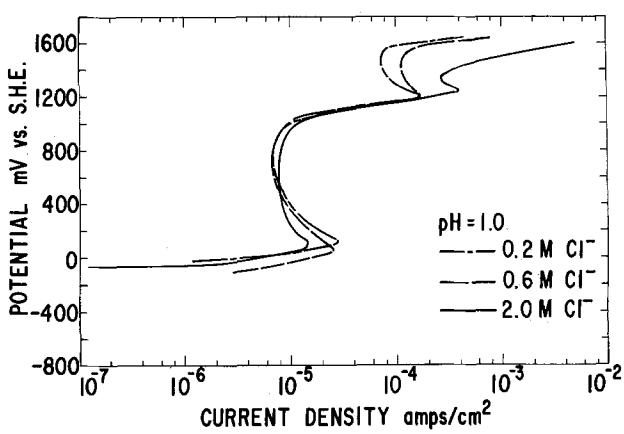

Fig. 3. Anodic polarization of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ in solutions of pH 1.0 with various chloride ion concentrations.

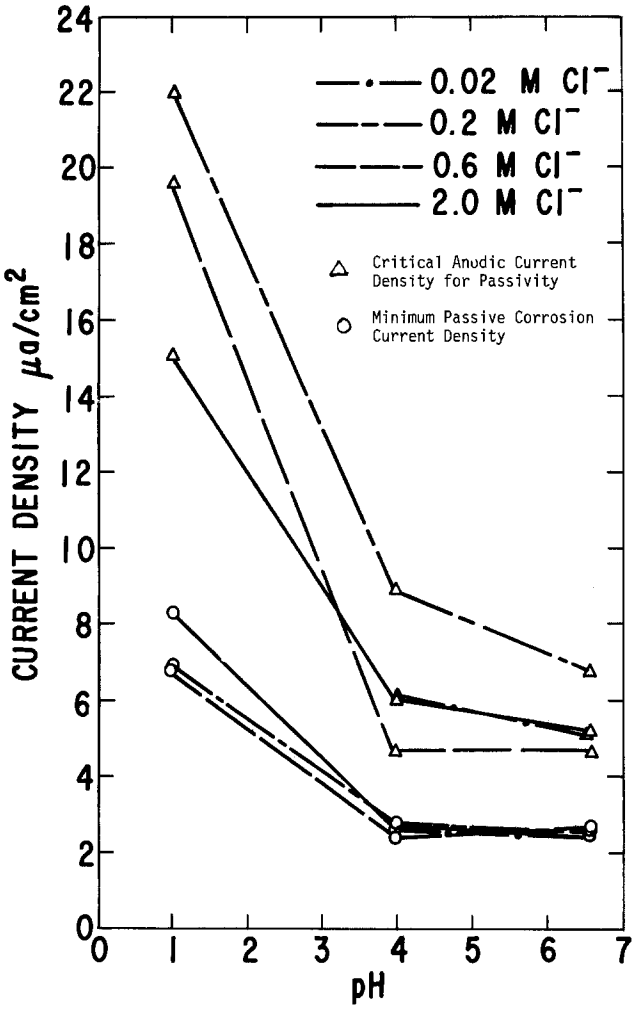

Fig. 4. Critical anodic current density for passivity and minimum passive corrosion current density of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ as a function of pH and chloride ion concentration.

not vary with chloride ion content in any consistent fashion but an average value of β obtained from solutions of different chloride ion activity progressively decreased with decreasing pH from 0.313 to 0.208 to 0.140V in solutions of pH 6.6, 4.0, and 1.0, respectively. The primary passivation potential decreased as the pH and chloride ion concentration increased. The rate of change of primary passivation potential with pH was $\simeq$24 mV/pH unit. Figure 4 plots the critical anodic current density for passivity in solutions of varying chloride ion content as a function of pH. Each point represents the average value of a minimum of three tests. The maximum deviation from the average value was by a factor of two for the solution of pH 1.0 and a factor of one-half for the solutions of pH 4.0 and 6.6. As indicated, the ease of passivation, when determined by the critical anodic current density, increased with increasing pH. The critical anodic current density for passivity was nearly three times as great in solutions of pH 1.0 as in solutions of pH 4.0 and 6.6. Chloride ion concentration did not have a clear effect except in solutions of pH 1.0 where the critical anodic current density increased with decreasing chloride ion concentration. Figure 4 also plots the minimum passive corrosion current density in solutions of varying chloride ion concentration as a function of pH. Again, each point represents the average value of a minimum of three tests. The maximum deviation from the average value was by a factor of 1.3 for the solutions of pH 1.0 and a factor of 1.08 for the solutions of pH 4.0 and 6.6. The chloride ion concentration clearly had no effect on the minimum passive corrosion current density. The minimum passive corrosion current density was approximately three times as great in solutions of pH 1.0 as in solutions of pH 4.0 and 6.6.

Regardless of chloride ion content, the anodic current density begins to increase at potentials of 540, 640, and 840 mV in solutions of pH 6.6, 4.0, and 1.0, respectively. These potentials were more accurately determined by employing a slower potential sweep rate (6 mV/min) and are plotted in Fig. 5 as a function of solution pH. Also plotted is the potential at which the oxidation reaction rate increases during anodic polarization of the top (shiny) surface of the as-received, unpolished ribbon in 0.17M NaCl (see Fig. 11 and 12 in the Appendix). As indicated, the measured potentials are well below the measured potentials for the evolution of oxygen on platinum. As discussed below, the transpassive potentials probably correspond to the oxidation of Cr_2O_3 in the passive film to $CrO_4^=$.

Regardless of the chloride ion and hydrogen ion concentrations, no pitting corrosion attack occurred in any of the solutions as indicated by microscopic examination of the surface as well as by the lack of hysteresis in the polarization curve on backscanning the potential. Additional anodic polarization tests were conducted in 2.0M HCl and the amorphous alloy was again found immune to pitting corrosion.

In order to further assess the resistance of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ to localized corrosion in chloride ion media, specimens were potentiostatically polarized in 0.17M NaCl at 844 mV and then scratched with 320 grit silicon carbide paper. In less than 1 sec after the abra-

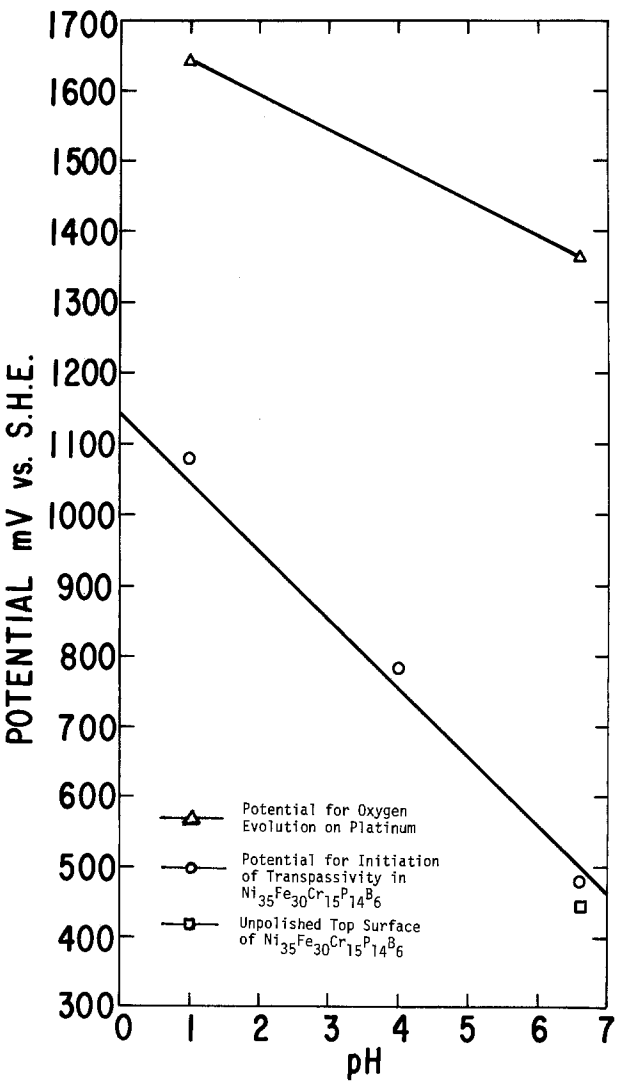

Fig. 5. Potential of initiation of transpassivity of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ as a function of pH and variation with pH of the potential of oxygen evolution on platinum.

sion stopped, the corrosion rate fell to the same low value as existed prior to the scratching and no localized corrosion was detected.

In spite of the immunity of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ to pitting corrosion in solutions of low and high hydrogen ion concentration and high chloride ion activity, the material was nevertheless susceptible to crevice corrosion in even dilute NaCl solutions. Figure 6 depicts the anodic polarization behavior in 0.17M NaCl of an amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ specimen in which the Glyptal® paint used to mask the sample test surface was not permitted sufficient time to dry. This produced a crevice at the Glyptal®-metal-solution interface. The appearance of the sample after testing and after the Glyptal® was removed by soaking in acetone is illustrated in Fig. 7. The highly localized nature of the corrosion attack which occurred underneath the Glyptal® at the Glyptal®-specimen-solution interface is evident. The increased corrosion rate at potentials above 800 mV in Fig. 6 is due to the crevice corrosion attack.

Enhanced dissolution is known to accompany the cold-working of crystalline ferrous alloys (5). The anodic polarization behavior of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ following plastic deformation is illustrated in Fig. 8. The appearance of the sample deformed in pure bending to an outer fiber strain of 3.6% after anodic polarization in 0.17M NaCl to +1645 mV is depicted in Fig. 9. The discrete deformation bands common to amorphous alloys are apparent (6). No enhanced corrosion occurred along these slip steps as has been reported to occur during chemical etching of $Pd_{77.5}Cu_6Si_{16.5}$ (7) and $Ni_{55}Pd_{35}P_{10}$ (8). Plastic deformation to a total strain of 3.6% had no effect on the passive corrosion rate nor on the pitting corrosion resistance of the material. However, as indicated in Fig. 8, cold-rolling the material to 32% reduction in thickness markedly increased the corrosion rate of the alloy. Extensive cracking accompanied the severe cold-work. The appearance of the cold-rolled sample following anodic polarization is depicted in Fig. 10. The sample is severely pitted.

Discussion

The difference in chemical composition between the two surfaces of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ ribbon can be attributed to oxidation during processing. As the liquid alloy is ejected from the melt and shot against the substrate, the surface is oxidized. Phosphorus oxide forms rapidly and being volatile leaves the surface entirely. Chromium is also rapidly oxidized to form Cr_2O_3. Iron, nickel, and boron are also oxidized but not nearly as rapidly as chromium. The bottom surface of the ribbon is low in chromium possibly because the chromium oxide film was cracked and removed from the surface when impacted against the cold substrate. The quenched surface was not at tem-

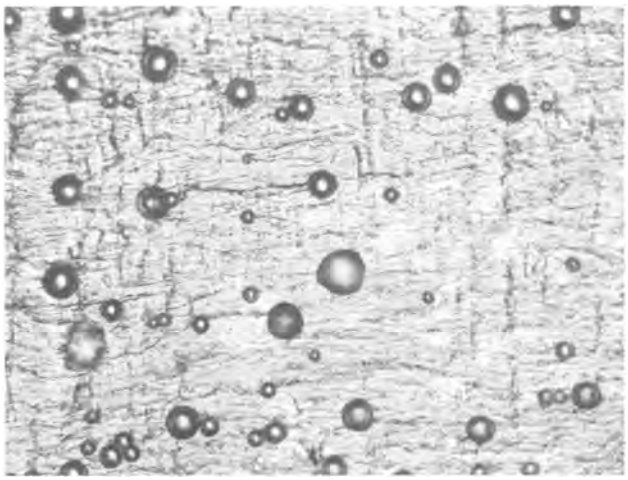

Fig. 10. Photomicrograph of Metglas 2826A cold-rolled to 32% reduction in thickness and anodically polarized in 0.17M NaCl.

perature for sufficient time to permit replenishment with chromium by diffusion from the bulk. The entire top surface was exposed to the atmosphere while still in the liquid state and became covered with a Cr_2O_3 film. This is indirectly supported by the anodic polarization behavior of the top surface in 0.17M NaCl if, as discussed below, we assume the increase in oxidation rate at 445 mV to represent the oxidation of Cr_2O_3 to $CrO_4^=$.

As illustrated in Fig. 5, transpassivity initiated at potentials below the measured potential of oxygen evolution on platinum. The onset of transpassivity probably corresponds to the oxidation of Cr_2O_3 to either $CrO_4^=$ or $Cr_2O_7^=$ according to

$$Cr_2O_3 + 5H_2O \rightarrow 2CrO_4^= + 10\,H^+ + 6e^-$$

$$Cr_2O_3 + 4H_2O \rightarrow Cr_2O_7^= + 8H^+ + 6e^-$$

Although $Cr_2O_7^=$ has a lower standard free energy of formation than $CrO_4^=$, the pH dependence of the transpassive potential is better accounted for by the oxidation of Cr_2O_3 to $CrO_4^=$. Assuming a $CrO_4^=$ activity of $10^{-6.5}$M, the pH dependency of the equilibrium potential for the formation of $CrO_4^=$ from Cr_2O_3 at 25°C is represented in Fig. 5 by the straight line drawn through the data. As can be seen, the measured potentials at which transpassivity initiates agree quite well with the calculated values of the equilibrium potential for the oxidation of Cr_2O_3 to $CrO_4^=$.

Regardless of the chloride ion activity and hydrogen ion concentration of the test solution, pitting did not occur during anodic polarization. Additionally, the passive film formed on amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ repairs itself very well as demonstrated by the ability of the alloy to repassivate after being abraided *in situ* with 320 grit silicon carbide paper while polarized anodically at 844 mV in 0.17M NaCl. In view of the well-known corrosion inhibition properties of phosphate ions, there has been some speculation that phosphorus strongly contributes to the passivity and resistance to pitting of amorphous Fe-Ni-Cr-P alloys (9). This should not be the case based on the early work of Pryor (10) who demonstrated that phosphate ions inhibit the corrosion of iron by increasing the adsorption of oxygen and that inhibition is possible only in solutions of high pH ($pH > 7$) and high dissolved oxygen content. In solutions of low dissolved oxygen content or with $pH < 7$, additions of phosphate ions failed to inhibit corrosion. The inability of chromium-free amorphous alloys $Fe_{80}P_{13}C_7$ (4), $Ni_{40}Fe_{40}P_{14}B_6$, and $Fe_{80}P_{14}B_6$ (11) to passivate during anodic polarization in 1M NaCl demonstrates the inability of phosphorus to passivate the alloys and the necessity of chromium to establish passivity.

Although the amorphous alloy was immune to pitting corrosion in solutions of high hydrogen ion concentration and high chloride ion activity, it was nevertheless susceptible to crevice corrosion in even dilute NaCl solutions. This can be related to the increased corrosion rate of the amorphous alloy in solutions of high hydrogen ion concentrations such as can exist in a crevice. The absence of pitting on the sample strained in tension to 3.6% indicates the film formed on the slip steps to be as resistant to breakdown as the undeformed material. The cracking which resulted from cold-rolling to 32% reduction in thickness has also been observed at the intersection of deformation bands in Ni-Pd-P amorphous alloys following heavy rolling deformation (8). The localized corrosion which occurred during anodic polarization of the cold-rolled sample can be attributed to crevice corrosion at the numerous cracks present.

In view of the susceptibility of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ to crevice corrosion, the great resistance of the amorphous alloy to pitting corrosion can be attributed to its resistance to pit nucleation. Bond and Lizlovs (12) have demonstrated the immunity of high purity crystalline Fe-Ni-Cr alloys to pitting corrosion in low pH, high chloride ion activity solutions. Such alloys were nevertheless susceptible to crevice corrosion. The immunity of the high purity crystalline alloys to pitting corrosion is lost when impurities such as sulfur are present. Since amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ is quite susceptible to crevice corrosion, one can speculate that if highly soluble inclusions such as sulfides were present in the amorphous alloy, then pits could nucleate at sites of sulfide particle dissolution and pit growth would occur quite readily as in crystalline Fe-Ni-Cr alloys (13). In summary, the ease of passivation and resistance to pitting of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ can be attributed to its great chemical homogeneity and lack of inclusions. Similarly, the high reproducibility of anodic polarization curves of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ as compared with the lack of reproducibility (in terms of critical anodic current density for passivity and passive corrosion current density) in crystalline Fe-Ni-Cr alloys can also be attributed to the great chemical homogeneity and lack of inclusions in the amorphous alloy (14).

APPENDIX

Surface Composition Inhomogeneity of Amorphous Alloy Ribbon of Metglas 2826A ($Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$)

In an earlier note, we indicated the surfaces of amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$ to be highly chemically inhomogeneous (1, 2). The present results further define the nature and extent of this inhomogeneity. Figure 11 compares the anodic polarization characteristics in 0.17M NaCl of as-received Metglas 2826A ($Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$) with specimens of the same material which have been metallographically polished to 3 μm diamond. The as-received amorphous ribbon is initially active, exhibits a maximum active dissolution current of 4.4×10^{-6} A/cm^2 at a potential of 125 mV, and is passive at a potential of 245 mV. It is difficult to estimate the passive corrosion current density of the as-received material because it appears that a second oxi-

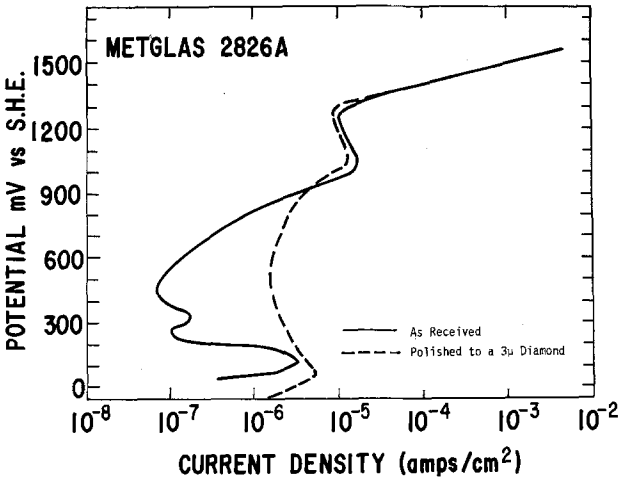

Fig. 11. Anodic polarization of as-received and metallographically polished Metglas 2826A (amorphous $Ni_{35}Fe_{30}Cr_{15}P_{14}B_6$) in 0.17M NaCl.

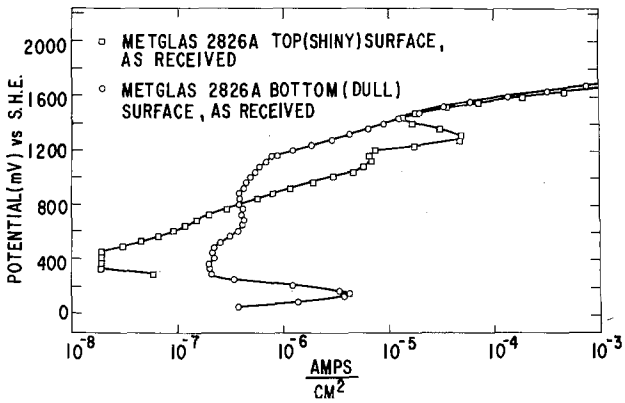

Fig. 12. Anodic polarization of top and bottom surfaces of as-received Metglas 2826A in 0.17M NaCl.

dation reaction occurs at potentials above ~445 mV. The as-received material exhibited secondary passivity between 1125 and 1365 mV. The material was free of pitting as indicated by the absence of hysteresis in the polarization curves on backscanning of the potential. This conclusion was supported by microscopic examination of the specimens after testing with a light microscope at 100× and 500× magnifications. Figure 12 depicts the different anodic polarization characteristics of the two surfaces of the amorphous ribbon sample in 0.17M NaCl. These results were obtained by masking off either the "top" or "bottom" surface of the ribbon with Glyptal® paint and potentiodynamically polarizing the other surface. The bottom surface is dull in appearance; this surface made direct contact with the substrate when the alloy was rapidly cooled from the liquid state by impingement with the cold substrate. This surface is initially active, undergoes an active-to-passive transition during anodic polarization, and does not exhibit secondary passivity. Only a relatively minor increase in oxidation rate was observed at potentials greater than 445 mV during potentiodynamic anodic polarization of the bottom surface. The top surface of the ribbon is shiny in appearance and was the last to solidify. This surface is initially passive and exhibits a very low passive corrosion current density. A marked increase in the oxidation reaction rate occurred at 445 mV. The absence of pitting on both surfaces of the as-received material during anodic polarization was indicated by the absence of hysteresis in the polarization curves on backscanning the potential. This conclusion was confirmed by viewing the sample with a light microscope at 100× and 500× magnifications after anodic polarization.

Chemical analysis of the two surfaces by Auger spectroscopy was performed to determine if compositional differences exist between the two surfaces which would explain their different electrochemical behavior. Figure 13 compares the Auger spectra of the top and bottom surfaces of the ribbon. The top surface is greatly enriched with chromium with only a minor trace of iron present. Both surfaces have little nickel present and no detectable phosphorus. The boron peak-to-peak height is small on both surfaces. The bottom surface has only a small amount of chromium and is chiefly composed of iron. The presence of oxygen and carbon is strongly indicated on both surfaces. The former is probably due to an air-formed film while the presence of the latter is due to contamination. Figure 14 illustrates the change in composition of the top surface following ion milling for 5 min with argon (equivalent to removal of ~700Å). The chromium peak-to-peak height has been reduced by approximately 25% and the iron and nickel peak-to-peak heights have increased by nearly an order of magnitude. The boron peak is approximately unchanged and the phosphorus peak is strongly evident. Similarly, Fig. 15 depicts the changes in composition of the bottom surface following ion milling with argon for 5 min. The chromium peaks are stronger, the iron peak-to-peak heights are reduced by approximately 30% and the nickel peak-to-peak height is increased by a factor of ~8. The phosphorus peak is now strongly apparent. The Auger spectra of the top and bottom surfaces after ion milling for 5 min are practically identical. In order to avoid compositional differences between the two surfaces, all subsequent testing was performed on samples mechanically polished and cleaned as described above.

Anodic Oxidation of Zirconium: Evidence of Typical Valve Metal Behavior

M. A. Hopper,*[1] J. A. Wright,[2] and D. J. DeSmet*

Department of Physics, University of Alabama, University, Alabama 35486

ABSTRACT

The anodic oxidation of zirconium in dilute sodium carbonate solution was studied by steady-state and transient electrical techniques. An *in situ* ellipsometric method was employed to determine the oxide thickness. The electrical characteristics of the anodization process were found to be similar in most respects to those observed with other valve metals. For growth at constant current, the field in the anodic oxide was found to be independent of oxide thickness, and on suddenly changing the applied current typical voltage transients were observed. The relation between the ionic migration processes involved in the growth of the anodic oxide film and the electrical behavior of the system is discussed.

On anodic oxidation zirconium behaves much like a valve metal but certain features of the anodization process on this metal appear unique. The most marked difference between zirconium and the other valve metals is that growth of the anodic oxide apparently involves the migration of anionic species only, the cationic transport number being essentially zero (1-3). All other valve metals show some detectable cationic transport (1). It might be expected that this unusual ionic migration process would be reflected, in some way, in the electrical behavior of this metal on anodization.

The electrical behavior of zirconium has been examined by a number of workers. Charlesby (4) performed experiments using several electrolytes and estimated the refractive index of the film to be 2.2. He also noted that films formed in sulfuric acid were different in thickness from films formed in other electrolytes under similar conditions. Adams *et al.* (5) studied the electrical behavior of zirconium at potentials below the oxygen evolution potential using aqueous solutions of ammonium borate and sodium carbonate. These authors noted that when the current applied to the zirconium electrode was abruptly raised the potential would overshoot its final value before returning to steady growth conditions. Vermilyea (6), on the other hand, observed only very small electrical transients when the oxidation conditions were abruptly altered above the oxygen evolution potential. This is in contrast to the rather large transients observed with other valve metals when subjected to similar changes. Young (7) noted the absence of voltage transients on zirconium when the formation current density was changed and later reported (8)

that rapid transient effects could be resolved on switching from constant current to constant potential control. These results suggest that the transient electrical behavior of zirconium on anodization may be related to the nature of the ionic transport process in zirconium oxide.

In his study of the kinetics of anodization of zirconium with electrolytes containing sulfate ions, Young (7) concluded that the electric field in the oxide increased with increasing oxide thickness for a constant applied current. Rogers *et al.* (9) present results that confirm the thickness dependence of the field when anodization is carried out in solutions containing sulfate. They also observed that the field was thickness independent in other electrolytes showing that incorporation of electrolyte species into the zirconium oxide is correlated with the observation of thickness-dependent fields. It should be noted that many other valve metal oxides show measurable electrolyte incorporation but only with zirconium does this appear to result in thickness-dependent fields for constant current growth. For this reason we chose to avoid electrolytes containing sulfate and employed an aqueous solution of sodium carbonate as an electrolyte. It should be noted that the experiments on ionic transport were also performed in electrolytes free of sulfate (1-3).

The present investigation of the anodic oxidation of zirconium was undertaken to determine the extent of the differences in the electrical behavior of the anodization process on this metal from that exhibited by other valve metals. Both steady-state and transient measurements were employed, and an *in situ* ellipsometric technique was used to continuously monitor the thickness of the anodic film. The results obtained are compared with similar measurements on other valve metals and with previous investigations on zirconium. In general the data obtained indicate that the electrical characteristics associated with the anodization of zirconium are similar, in almost all respects, to that of many other valve metals.

Experimental

The samples were prepared from high purity 99.99% zirconium rod (0.6 cm diameter, obtained from Materials Research Corporation) and formed into cylinders approximately 0.6 cm long with a flat ground on the cylindrical surface for use in the optical experiments. The samples were mounted between Teflon washers in a glass sample holder similar to that described previously (10). Removal of the anodic oxide from a zirconium surface is a difficult task and care had to be taken to produce a surface that is "film free" and optically flat. After considerable experimentation the method finally adopted involved careful removal of all visible signs of oxide with fine emery paper, followed by chemical polishing following the procedure described by Cain (11). A bright surface suitable for optical examination is produced using this procedure. The sample area was taken to be the geometrical area of the metal exposed to the solution when the sample was mounted in the holder.

The anodization cell consists of a hollow equilateral glass prism fitted with ground glass joints for mounting the sample holder, reference electrode, and platinum cathode. With this arrangement optical measurements were made at an angle of incidence of 60° with the light passing normally through the cell windows. The solution used for all experiments reported here was 0.1M Na_2CO_3 and reasons for the choice of this particular electrolyte are given below. All measurements were made at room temperature.

The electronic circuitry used was identical to that described previously (10). Potentials and open-circuit transients were recorded on a fast strip chart recorder.

The self-nulling automated ellipsometer used in the investigation was constructed in these laboratories following the general design concepts described by Ord (12). The performance of this instrument has been described elsewhere (13) and is only summarized here. With our zirconium surface the instrument has a nulling time of about 4 sec and provides an angular resolution of 0.01° in both the polarizer and analyzer settings. A quarter-wave plate with its fast axis fixed at −45° is situated between the polarizing prism and the sample. The readings of the polarizer and analyzer angles along with the electrode potential were recorded on a digital printer at the end of every nulling sequence. A He/Ne laser is used as the light source in the instrument and all optical constants reported in this communication are determined at 6328Å.

Results

Optical measurements.—The ellipsometric data obtained during steady-state anodization at 0.5 mA/cm² is shown in Fig. 1. During this experiment the ellipsometer recorded more than 2000 data points only a few of which are plotted in Fig. 1. Starting from point S, corresponding to the nominally bare metal surface, the data trace out the curve in a clockwise direction. The outward spiraling loops shown in this figure are indicative of the growth of a slightly absorbing film on the zirconium substrate. The data can be fit with reasonable precision assuming the oxide has a refractive index of 2.17-0.033i which is independent of oxide thickness. The refractive index of the substrate used in this fit is 2.21-3.04i. The deviation of the data from the theoretical curve for thickness greater than 400 nm may be the result of slight nonuniformities in optical properties of the film or the substrate.

From the optical fit the dependence of the thickness of the film on the potential drop across the oxide was estimated. A linear thickness-potential relationship was observed for the formation of oxide from a solution of 0.1M Na_2CO_3 at constant applied current, the slope giving the field in the oxide as 4.75×10^6 V/cm at a current density of 0.5 mA/cm². The measured field is independent of oxide thickness at this current. The dependence of the electric field in the oxide on the applied current density was estimated from measurement of the voltage-current dependence at 1500 and 3300Å of oxide coverage. The field at

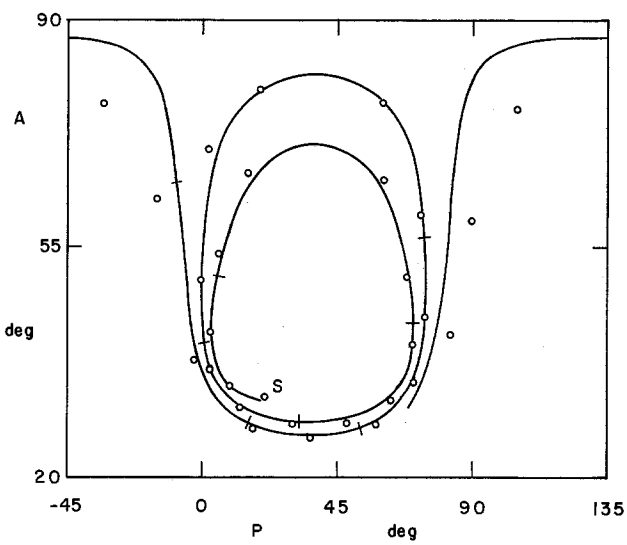

Fig. 1. Ellipsometric data observed on growth of an anodic film on zirconium in 0.1M Na_2CO_3 at 0.5 mA/cm². Data start at point S and trace out loops clockwise. The solid curve represents the best theoretical fit to the data, obtained with a film of refractive index 2.17-0.033i on a substrate of index 2.21-3.04i. Hatch marks indicate thickness increments of 50 nm.

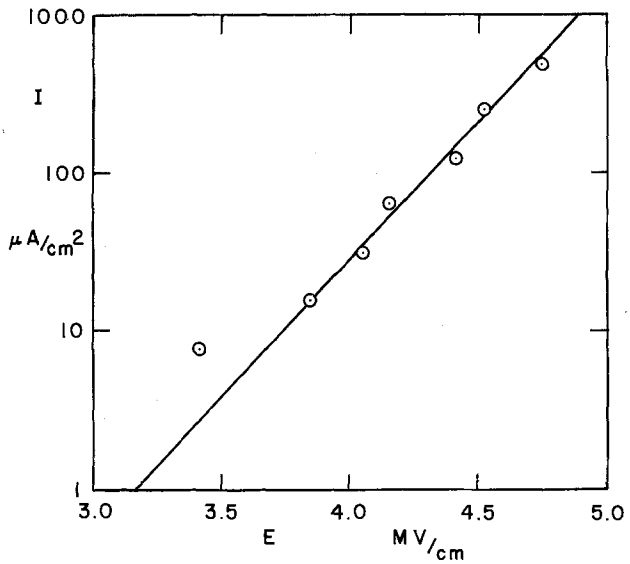

Fig. 2. Current-field dependence for formation of an anodic film on zirconium in 0.1M Na_2CO_3.

any current being equated to the ratio $\Delta V/\Delta D$, where ΔV is the voltage difference between the 1500 and 3300Å data points for the particular applied current, and ΔD is 1800Å. The dependence of the electric field, E, on the applied current density, i, as determined in the above experiment is shown in Fig. 2. This figure exhibits the typical log i *vs.* E dependence found for the formation of valve metal oxides. Writing the dependence of i on E as $i = A \exp(BE)$, the constants A and B have the values 6.9×10^{-12} A/cm² and 3.81×10^{-6} cm/V, respectively, for the data shown in Fig. 2.

An additional observation in the present ellipsometric experiments on zirconium is that changes in the applied current density appear not to affect the optical properties of the anodic film in any detectable way. We observe no optical changes that would indicate the presence of electric field induced birefringence in the layer nor any changes in the refractive index or thickness with changes in the electric field.

Transient electrical measurements.—Studies of the voltage decay following an interruption of the applied current have been used to investigate the oxidation kinetics of tantalum (14), bismuth (10), and vanadium (15). This technique provides an alternative method for obtaining the relation between the applied current density and the electric field strength for a process involving high field ionic conduction. The method has been fully described in the papers quoted above and is only outlined here.

In the present study with zirconium the decay of the electrode potential following an interruption of the current was found to fit a relation of the form

$$V = V_i - V_o \ln(1 + t/\tau) \quad [1]$$

for at least 60% of the total potential change. The fit is performed by varying the single parameter τ to provide a best fit, in the least squares sense, to the measured time dependence of the potential. From this analysis the parameter V_o can be estimated for each separate determination of the open-circuit voltage decay.

Assuming the process occurring after an interruption of the applied current can be modeled by the discharge of the layer capacitance, C, through the anodic film (which only allows passage of an ionic current, i_I), the following differential equation may be applied

$$C dV/dt = -i_I \quad [2]$$

Substitution of V from Eq. [1] gives

$$i_I = CV_o/(\tau + t) \quad [3]$$

This may also be written in the form

$$i_I = i_o \exp(V/V_o) \quad [4]$$

where

$$i_o = \frac{CV_o}{\tau} \exp(-V_i/V_o)$$

The layer capacitance may be estimated using Eq. [3], for $t = 0$ this becomes

$$i = CV_o/\tau \quad \text{or} \quad C = i\tau/V_o \quad [5]$$

In a preliminary investigation of the anodic oxidation of zirconium many different electrolytes were examined. We found that 0.1M Na_2CO_3 gave the most reliable electrical behavior for use with Eq. [1] and the data reported here are confined to experiments with this electrolyte. It is of interest to note that the results of Rogers *et al.* (9) show that, for the low current densities employed in our study, less carbonate is incorporated into anodic zirconium films than are borate or sulfate derived species.

The dependence of V_o on the potential, V_f, appearing across the film prior to interrupting the current was determined for applied current densities of 10, 35, and 100 μA/cm². The results obtained are shown in Fig. 3. V_o increases linearly with V_f at each current density, the slope V/V_o being 10.7, 9.8, and 9.0 at 100, 35, and 10 μA/cm², respectively. The transient analysis also allows the dependence of the reciprocal of the layer capacity, $1/C$, on the formation voltage to be estimated. Experimental $1/C$ *vs.* V_f data are shown in Fig. 4. The $1/C$ data increase linearly with V_f above 30V, below that potential the data appear to lie below that expected on extrapolation of the high voltage linear $1/C$ *vs.* V_f region.

From the experiments described above i_o may be estimated at 10, 35, and 100 μA/cm². The values obtained at these current densities are 1.23, 1.94, and 2.25 nA/cm², respectively. i_o increases with applied current density, and assuming the relation between i_o and i is $i_o = ki^\alpha$ [see Ref. (14)], α may be evaluated. For the limited set of data presented here α is approximately 0.25.

When the anodic applied current density was suddenly switched from one value to another potential transients were consistently observed. Results obtained near a formation potential of 23V on switching from 200 to 40 and then back to 200 μA/cm² are pre-

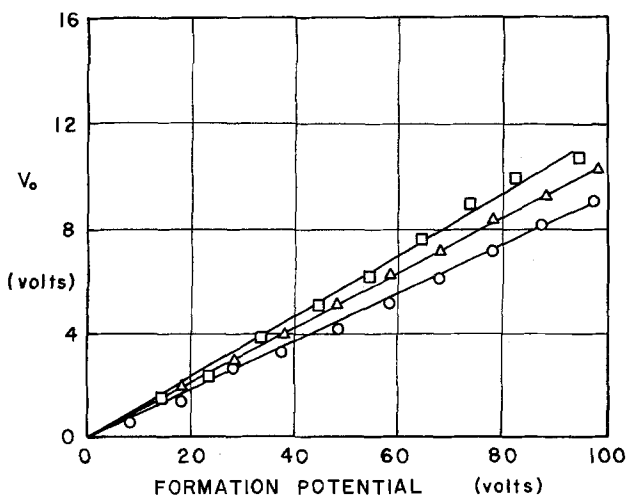

Fig. 3. Measured dependence of V_o on the formation potential, V_f, for applied current densities of 10 μA/cm² (□), 35 μA/cm² (△), and 100 μA/cm² (○).

sented in Fig. 5. The changes in potential are shown plotted against the charge passed. The results given in this figure are similar to those found with tantalum (14) and many other metals that form thick insulating anodic oxides (8).

Discussion

The ellipsometric data presented in this communication show that the electric field in the oxide formed on zirconium from a 0.1M sodium carbonate solution is thickness independent at constant applied current. Our measurements were made only up to a current density of 0.5 mA/cm^2 and it is possible that for higher currents other effects occur. These results are in general agreement with the data obtained using a spectrophotometric method of thickness measurement reported by Rogers *et al.* (9). They found that the field in the anodic film on zirconium was independent of thickness for formation at 1 mA/cm^2 but at 10 mA/cm^2 the field increased with increasing thickness. Rogers *et al.* also determined the extent of carbon incorporation into the film and found a correlation between impurity concentration and the thickness-dependent electric field. Other valve metals show considerable electrolyte incorporation on anodization, the system receiving the most attention being tantalum anodized in phosphoric acid electrolytes. With that system, however, no thickness-dependent fields have ever been reported and zirconium thus appears anomalous in this respect. It would appear that the unique ionic migration mechanism is not directly responsible for the thickness-dependent field observed with zirconium, the effect is mainly the result of electrolyte incorporation.

Our optical results indicate that the anodic oxide film formed on zirconium is slightly absorbing at 6328Å. To our knowledge this is the only anodic oxide formed on a valve metal using a wet anodization procedure that exhibits this optical absorption. Masing, Orme, and Young (16) noted a similar absorption effect in reflectivity measurements on zirconium oxide film formed in sulfuric acid solution. They did not determine the optical constants of the film but since their measurements were made at 4358Å no comparison with the present results is possible. Ruiz-Urbeita *et al.* (17) found that sputtered ZrO_2 films show absorption at 6328Å and it would appear reasonable to assume that the optical absorption is an intrinsic property of ZrO_2 and not an artifact associated with electrolyte incorporation.

It is uncertain how film absorption, which almost certainly will vary with wavelength, influences measurement of oxide thickness with a spectrophotometric technique. Estimates of the electric fields based on that method should thus be viewed with caution. Rogers *et al.* (9) fit their spectrophotometric data using a refractive index that is smaller, by about 5% at 6328Å, than our ellipsometric determined index. If this percentage difference applies over the whole optical range, it would lead to an overestimation in the thicknesses measured by Rogers *et al.* by at least 5%. In addition, no correction for film absorption was made and thus the value of the field (4.4×10^6 V/cm) at an applied current of 1 mA/cm^2 given by Rogers *et al.* is not in contradiction with our estimate of 4.9×10^6 V/cm obtained by extrapolation of the data shown in Fig. 2.

The observation that the anodic zirconium oxide film is unaltered by changes in the electric field should be contrasted with the results reported for the anodic oxides on tantalum, niobium, and tungsten (18) and vanadium (19). In addition there is no indication of field induced binefringence in the layer similar to that reported for tantalum (20) or niobium (21) even though the field strength in the zirconium oxide is of similar magnitude. The reason for the absence of field-induced changes in the optical properties of the anodic zirconium oxide film is not known but cannot be ascribed to a lack of experimental sensitivity as we have observed changes in the refractive index with tantalum and niobium oxide films using our ellipsometer.

The dependence of the electric field in the oxide on the applied current density shown in Fig. 2 indicates that the simple relationship $i = A \exp(BE)$ may be applied, as a first-order approximation, to anodization of zirconium in sodium carbonate solution. For the limited range of current used no evidence of a nonlinear ln i *vs.* E dependence was detected. At the lowest current used (approximately 8 μA/cm^2) the experimental field value appears low compared with higher current points. This is probably an indication of some nonionic current becoming important in this region. Generally this behavior is ascribed to "leakage" or some other electronic current. Our experimental values for the parameters A and B in the above equation (viz., 6.9×10^{-12} A/cm^2 and 3.81×10^{-6} cm/V, respectively) are in good agreement with the results of Charlesby (4), who determined $A = 1.6 \times 10^{-11}$ A/cm^2 and $B = 3.4 \times 10^{-6}$ cm/V for anodization of zirconium using a saturated ammonium borate solution, and Adams *et al.* (5) who found $A = 2.9 \times 10^{-11}$ A/cm^2, $B = 4.6 \times 10^{-6}$ cm/V for anodization in ammonium borate and $A = 2 \times 10^{-12}$ A/cm^2, $B = 6 \times 10^{-6}$ cm/V on anodizing in sodium carbonate solution. Even with the sodium carbonate

solution results obtained at currents greater than those used here might lead to complications from electrolyte incorporation. Rogers *et al.* (9) have shown that the impurity content of the anodic film depends strongly on current density above 1 mA/cm^2 and this has a drastic influence on the electrical behavior.

We find that potential transients are readily observable during anodization of zirconium when the applied current is charged abruptly. The transients show all the features of similar effects reported with other valve metal systems. The effects we observe (see Fig. 5) are fairly large: The magnitude of the observed potential overshoot on zirconium is 70% of similar transients observed on tantalum but the relaxation of the potential back to the steady state is more rapid with zirconium. Since marker experiments (1-3) show that growth of the anodic zirconium oxide involves migration of anionic species only the existence of potential translations on changing the anodic current suggests that bipolar ionic transport is not a requirement for potential overshoot.

The form of time dependence of the potential following an interruption of the applied current is similar to that previously reported for similar experiments with Ta (14), V (15), and Bi (10). Analysis of open-circuit potential decay shows that the parameter V_o increases linearly with oxide thickness for constant current growth. The ratio V/V_o is independent of oxide thickness and increases with increasing current. V/V_o is proportional to the electric field in the oxide. The quantity i_o, defined in Eq. [4], was found to increase with applied current in agreement with the results reported for tantalum (14), vanadium (15), and bismuth (10).

Measurements of the potential changes accompanying changes in the applied current density allows a comparison of the steady-state and open-circuit electrical techniques. Using the steady-state relation $i = A \exp(BE)$ an estimate of the change in the steady-state potential, $|\Delta V|_s$, accompanying a change in applied current may be obtained. For the same current change the total change in potential, $|\Delta V|_t$, (measured experimentally at the maximum of the potential overshoot) may be calculated using $i = i_o \exp(V/V_o)$ assuming i_o is constant. For the assumptions outlined above a current change from i_1 to i_2 gives

$$|\Delta V|_t \cdot V/V_o = |\Delta V|_s \cdot BE \qquad [6]$$

Note that if the variation of i_o with i is $i_o = ki^\alpha$ [see Ref. (13)] then the relation between BE and V/V_o is

$$(1 - \alpha)BE = V/V_o \qquad [7]$$

Combination of Eq. [6] and [7] yields

$$(1 - \alpha)|\Delta V|_t = |\Delta V|_s \qquad [8]$$

The present experiments on zirconium oxide gives the field in the oxide at an applied current density of 100 μA/cm^2 as 4.33×10^6 V/cm, and using the experimentally determined value of B, viz., 3.81×10^{-6} cm/V, the value of BE at this current is 16.5. The open-circuit measurements yield a value of 10.7 for V/V_o at 100 μA/cm^2, and using Eq. [7] a value of $\alpha = 0.35$ was determined on substituting the results given above. For transient experiments similar to those shown in Fig. 5 measurements of $|\Delta V|_s$, made by extrapolating the potentials obtained in regions of steady-state growth to the switching point, and $|\Delta V|_t$ gives an estimate of $|\Delta V|_t$: $|\Delta V|_s$ which on substituting in Eq. [8] gives a value for α of 0.3. Our measurement of the current dependence of i_o gives α as 0.25, assuming $i_o = ki^\alpha$. Thus all three separate estimates of this quantity yield a reasonably consistent value, considering the experimental errors involved in each measurement.

Comparison of these transient results with those reported for tantalum (13) shows the similarity in electrical behavior of zirconium and tantalum on anodization. The only significant difference between the metals is that for tantalum $\alpha = 0.63$ which is almost twice the magnitude of the present value, $\simeq$0.3, found with zirconium. It should be noted that only if $\alpha = 0$ would there be no potential overshoot on changing the oxidation current.

In summary the present experiments indicate that the electrical behavior during the formation of an anodic film on zirconium shows most of the characteristics of other valve metals even though oxide growth on this metal occurs via a unique ion transport process. Further, these results should be useful in indicating the wide degree of similarity in electric behavior of metals on anodization under controlled conditions with the eventual goal of obtaining a comprehensive model of the anodization process.

Catalytic Decomposition of Nitric Oxide in the Presence of Alkaline Earth Oxides

Paul Meubus*

Centre du Moyen Nord, Université du Québec à Chicoutimi, Chicoutimi, Quebec, Canada G7H 2B1

ABSTRACT

The alkaline earth oxides of barium, strontium, and calcium have been studied as catalysts for the decomposition of nitric oxide. The low work function characterizing these oxides is liable to favor an electron donor catalytic process which decomposes the nitric oxide molecule. The latter was used diluted in helium and the concentration was varied between 0.5 and 2.5%. Experiments were carried out at, respectively, 650°, 750°, and 850°C. After passage over the catalyst, nitric and nitrous oxides were found in the gaseous phase, as well as nitrogen and oxygen. Within the limits of concentrations used, it was found that the decomposition reaction rates of nitric and nitrous oxides are mutually independent. Reaction rate constants were calculated, showing that constants related to nitric oxide were at least one order of magnitude higher than those related to nitrous oxide this explaining, within the limits of concentrations used, the independent behavior mentioned. The total conversion for nitric oxide was highest for barium oxide, attaining 80% at 850°C, followed by strontium and calcium oxides. Increasing efficiencies coincide with a decrease in work function. Within the limits of nitric oxide used, up to 3% oxygen do not show any inhibitive effect on nitric oxide decomposition. This may be attributed to a large equilibrium constant for oxygen desorption.

Nitric oxide is well known as an air pollutant, the main sources being urban domestic heating during winter and automobile exhaust gases. The role of this oxide in the photochemical processes occurring during urban atmospheric smog conditions has been well described (1) and a large number of studies have been made on the subject of nitric oxide pollution abatement. Some years ago, the decomposition of nitrous oxide (2, 3) was investigated on various metallic oxides, while more recently extensive research was carried out in relationship with the decomposition of nitric oxide in the presence of metallic oxides (4-6), the associated problem of oxygen inhibition also receiving much attention (7, 8). However, most of these oxides, whether considered for the decomposition of nitrous or nitric oxides, do not seem to fulfill the requirements of a suitable catalyst, the main drawback being the slow nitrogen oxides decomposition reaction rate. In this respect, oxygen seems to have a pronounced inhibitive effect in the process of nitrogen oxides catalytic decomposition on metallic oxides. Recently, an interesting method was reported (9), where catalytic decomposition of nitric oxide was performed on zirconia, while the oxygen produced (an inhibitor in this case) was electrolytically removed from the catalyst's surface.

The catalytic decomposition of nitric or nitrous oxides over metallic oxides involves, in most cases, the partial or total rupture of the gas molecule by means of an electron donor type catalytic process. In this respect, metallic oxides with a low work function should deserve some further attention, the alkaline earth oxides being typical examples for this category of oxides (10). Referring to an extensive work related to the subject under consideration, Winter (7) studied the behavior of calcium and strontium oxides among 40 metallic oxides. However, only one initial nitric oxide pressure is used, which is about ten times the maximum nitric oxide pressure experimented in this study. He also predicts an inverse dependence of nitric oxide decomposition rate upon oxygen pressure, but no experimental results are given. Fraser and Daniels (4) include calcium oxide in their study of metallic oxides as possible catalysts for nitric oxide decomposition. Here again, nitric oxide pressure is at least four times higher than in the present study. Also, oxygen effect is not considered. It should be added that the catalysts are prepared by the different authors in a number of ways which preclude any comparison. In the present study, the alkaline earth oxides are obtained by complete decomposition of the corresponding carbonates at 1500°C. In this respect, it is interesting to note that Amirnazmi (8) observes an increased catalytic activity after heating a number of oxides at high temperatures.

In conclusion, only few and scattered results are available in the literature on the subject of nitric oxide decomposition in the presence of alkaline earth oxides. In this respect, the present work describes some further investigation of this type of oxides, using nitric oxide concentrations in helium between 0 and 2.5%. Also, the inhibitive effect of oxygen was experimented with 3% oxygen and 0.5% nitric oxide in helium, the catalyst used being barium oxide. The latter was found the most efficient catalyst among the alkaline earth oxides used, while the nitric oxide and oxygen concentration used were those liable to occur in the case of actual nitric oxide generation in combustion media.

Apparatus and Mode of Operation

The experimental layout is shown on Fig. 1. The reactor was made of a quartz tube 12 cm long and 0.6 cm diameter, surrounded by a graphite mantle which was used as an electrical resistor. The latter took the form of a cylindrical annulus, 8 cm long with outside and inside diameters, respectively, equal to 1.3 and 1.0 cm. Both ends were provided with cooled electrodes and the electrical current was derived from the secondary of a transformer whose primary was controlled with a rheostat. The voltage drop through the graphite heater was of the order of 2V and the current was around 300A. The graphite heater and quartz tube were enclosed in a vessel filled with an inert gas and temperatures inside the quartz tube were recorded with a Chromel-Alumel thermocouple, as a function of the graphite color temperature using a Leeds and Northrup pyrometer (750°-6000°C range). Calibrations were made with various gas flow rates inside the quartz

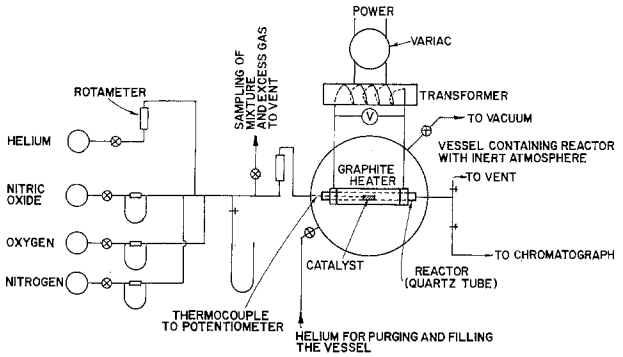

Fig. 1. Experimental layout

tube. Also, a piece of tungsten metal with polished surfaces was positioned in the quartz tube in place of the catalyst sample used for the experiments. Since the geometrical configuration of the quartz tube and metal sample was such that the latter could be considered as a blackbody, surface temperature evaluations were equivalent to those of the catalyst used. Finally, it was found that the gas and solid surface temperatures differed by about 20°C. The temperature (average between bulk gas and catalyst surface) could then be obtained from a measurement of the graphite temperature as mentioned previously. As far as the nitric oxide concentration in the gas bulk and at the catalyst surface was concerned, the diffusion effects were mostly eliminated by using a gas velocity high enough so that the decomposition reaction rates became independent of gas velocity. In this way, pure reaction rates were measured. The helium and nitric oxide used were, respectively, 99.99% (Linde Company) and 99.0% (Canadian Liquid Air). The carbonates used were reagent quality (Baker Company).

The gas mixture was analyzed for nitric and nitrous oxides as well as oxygen and nitrogen, before and after reaction. Also, blank tests were carried out, including all the variables except for the catalyst. A Fisher Hamilton gas partitioner was used, which was provided with a Thermistor detector, 4 ft Porapak Q, and 12 ft Molecular Sieve 5A. The nitric oxide chromatographic detection presents some problems which are summarized in Ref. (8). Referring to these authors, the method adopted in this study was the one described for 3% initial oxygen concentration and less in the mixture nitric oxide-helium used for the experiments. The maximum oxygen concentration generated by the nitric oxide itself was below 1.25% (half the largest nitric oxide concentration used for the tests, say 2.5%), while oxygen inhibition experiments were carried out with 3% oxygen and 0.5% nitric oxide, which could not result in a maximum oxygen concentration higher than 3.25%. This justifies the choice of the method adopted which was not integrally applied, in this respect that the molecular sieve pretreatment with nitric dioxide was omitted. The purpose of this treatment is to avoid nitric oxide disproportionation or oxidation reactions with oxygen. Indeed, it was observed in the present study that the molar $[N_2O/2 + N_2]\%$ was always nearly equal to the molar percent (m/o) oxygen, as recorded at the end of the process, this indicating that no oxygen addition reaction with nitric oxide did occur in the course of reactions.

A helium (carrier gas) velocity of 50 cm³/min was used for the chromatographic analysis of the gas mixtures and the column temperature was kept at 70°C. In this way, adverse effects (nitric oxide oxidation in the gaseous phase) could be obviated in the analysis of the products of reaction. The catalyst was prepared by heating alkaline earth carbonates at 1500°C, in the presence of air, until complete decomposition into oxides and carbon dioxide. In order to determine the conditions required for complete decarbonation, preliminary tests were made and samples were withdrawn at different times from the furnace. Carbon dioxide evolution tests in the presence of acids were performed on these samples. They were also tested in the experimental setup and exposed to a helium-nitric oxide-oxygen mixture with the presence of small amounts of water vapor so as to generate nitric oxide. Resulting gas samples were then checked for the presence of carbon dioxide on the chromatogram. Small alumina vessels were used as containers for the carbonates and resulting oxides. They were 1 cm long and of hemicylindrical shape whose outside diameter fitted with the inside of the quartz tube, thus leaving a free reactor volume of 0.28 cm³ corresponding to the catalytic surface exposed. The latter acquired a glassy and apparently impervious surface after thermal treatment, so that the kinetic calculations could be related to the magnitude of this surface, say 0.60 cm² in all cases, and reaction rates were accordingly expressed in terms of catalyst surface.

Results

Initial nitric oxide concentrations in helium between 0.5 and 2.5% were used for the experiments which were made at atmospheric pressure and catalytic decomposition was carried out at 650°, 750°, and 850°C in the presence of barium, strontium, and calcium oxides, each of these oxides being tested separately. The blank tests did not show any significant variation of the initial nitric oxide concentration. As already mentioned, reaction rate results could have been altered by diffusion processes. Therefore, preliminary tests were made, which showed that velocities of 17 cm³/min were sufficient to make reaction rates independent from diffusion effects. Resulting residence times were of the order of 1 sec and less. Nitric and nitrous oxides, as well as oxygen and nitrogen were found as products of reaction. The rates for nitric and nitrous oxides were calculated from the expressions

$$r = \frac{V}{S}(C_{in} - C_{out}) \qquad [1]$$

or

$$r = \frac{V}{SRT}(p_{in} - p_{out}) \qquad [2]$$

Average pressures were calculated from p_{in} and p_{out} in the case of nitric oxide. In most cases p_{out} did not differ from p_{in} by more than 20%, yielding an average value that could be considered as a constant for the reaction process. Considering the case of nitrous oxide pressure, a balance in nitrogen may be written

$$[NO] + 2[N_2O] + 2[N_2] = [NO]_o \qquad [3]$$

Since [NO] may be considered as an average constant value during the reaction process, one obtains

$$[NO] = \frac{[NO]_o + [NO]_E}{2}$$

and from [3]

$$[N_2O] + [N_2] = \frac{[NO]_o - [NO]_E}{4} \qquad [4]$$

$$[N_2O] + [N_2] = \text{constant} \qquad [5]$$

The rate of formation of nitrous oxide can be written

$$\frac{d[N_2O]}{dt} = \frac{1}{2}\frac{d[NO]}{dt} - \frac{d[N_2]}{dt} \qquad [6]$$

[NO] is a constant and a first-order decomposition reaction rate with respect to nitrous oxide is reported in the literature. As a result, Eq. [6] can be written

$$\frac{d[N_2O]}{dt} = A - B[N_2O] \qquad [7]$$

As discussed later in this study, the reaction rate constant related to A is at least one order of magnitude higher than B. In view of this fact and the form of Eq.

[7], fast accumulation of nitrous oxide should occur at the early stages of the nitric oxide decomposition reaction, so that the initial nitrous oxide pressure can be approximately derived from Eq. [4] where $[N_2] = 0$. This procedure has been adopted in order to determine an average pressure for nitrous oxide

$$p'_{AV} = \frac{4[N_2O]_E + [NO]_o - [NO]_E}{8} \qquad [8]$$

all the terms in the equation being determined either by initial conditions or chromatographic analysis results.

Figures 2, 3, and 4 show the nitric oxide decomposition rate variation when the alkaline earth oxides of, respectively, barium, strontium, and calcium are used. It is observed that, all conditions being equivalent, the decomposition rate is highest for barium oxide, being about two times higher than the corresponding reaction rates for strontium and calcium oxides. Decomposition reaction rates of the nitrous oxide resulting from the decomposition of nitric oxide in the preceding stage are shown in Fig. 5, 6, and 7 for the catalysts already mentioned and in the same order (barium, strontium, calcium oxides). The decomposition rates for nitrous oxide were calculated from Eq. [1] and used for p' and c', while the average pressure for this constituent was determined from Eq. [8]. From these results, it was found that the reciprocal of the decomposition rate for nitric or nitrous oxides was a linear function of the reciprocal of the respective partial pressures. This was true for all the catalysts used, at the various operating temperatures. Results are shown for nitric oxide in Fig. 8, 9, and 10, while those related to nitrous oxide appear in Fig. 11, 12, and 13. It has already been mentioned that gas mixtures made of 0.5% nitric oxide and 3% oxygen in helium were experimented with in order to observe possible oxygen inhibition effects upon the catalyst used. Since 0.5% nitric oxide generates a maximum of 0.25% oxygen, the addition of 3% oxygen should have resulted in a variation of decomposition reaction rate if any inhibition effect had taken place. Barium oxide was experimented with and no inhibition effect was found. It is quite possible that nitric oxide or oxygen concentrations other than those used in this study could lead to different conclusions. However, the

contemplated objective was an evaluation of alkaline earth oxides as nitric oxide decomposition catalysts in the case of combustion media. Therefore, the most efficient catalyst among the three alkaline earth oxides and nitric oxide as well as oxygen concentrations close to combustion exhaust gases were chosen for this kind of investigation. In relationship with the absence of oxygen effect, it should be mentioned that the rate

equations, [22] and [29], found in this work for describing the decomposition reactions of nitric and nitrous oxides imply that the number of adsorption sites of oxygen should be small since the desorption equi-

librium constants K_3 and K_3' should be high. This could possibly result from the high temperature carbonate treatment and consecutive increase in positive holes associated with the alkaline earth metal formation, which are more liable to accept the electron from O^- in the process of oxygen desorption. However, this is a mere assumption and has not been verified in this study.

Discussion

The nitric oxide molecule may be considered as resonating between the electronic structures (11)

$$: \dot{N} = \ddot{O} : \qquad [9]$$

$$\overset{-}{:} \ddot{N} = \dot{O} \overset{+}{:} \qquad [10]$$

The structure [10] lends itself to an electron donor catalyst mechanism, while equilibrium rupture between [9] and [10] supplies further [10] species at the expense of [9].

Then

$$NO + \overset{\text{from catalyst}}{e} \rightarrow \tfrac{1}{2}N_2O + (\tfrac{1}{2}O)^-_{ADS} \qquad [11]$$

$$(\tfrac{1}{2}O)^-_{ADS} \rightarrow \tfrac{1}{4}O_2 + \overset{\text{to catalyst}}{e} \qquad [12]$$

also, nitrous oxide resonates between the species (12)

$$\overset{-}{:} \ddot{N} = N^+ = \underset{\cdot\cdot}{O} : \qquad [13]$$

$$\overset{-}{:} \underset{\cdot\cdot}{N} = N^+ = \ddot{O} : \qquad [14]$$

$$\overset{-}{:} N \equiv N^+ - \underset{\cdot\cdot}{\ddot{O}} : \qquad [15]$$

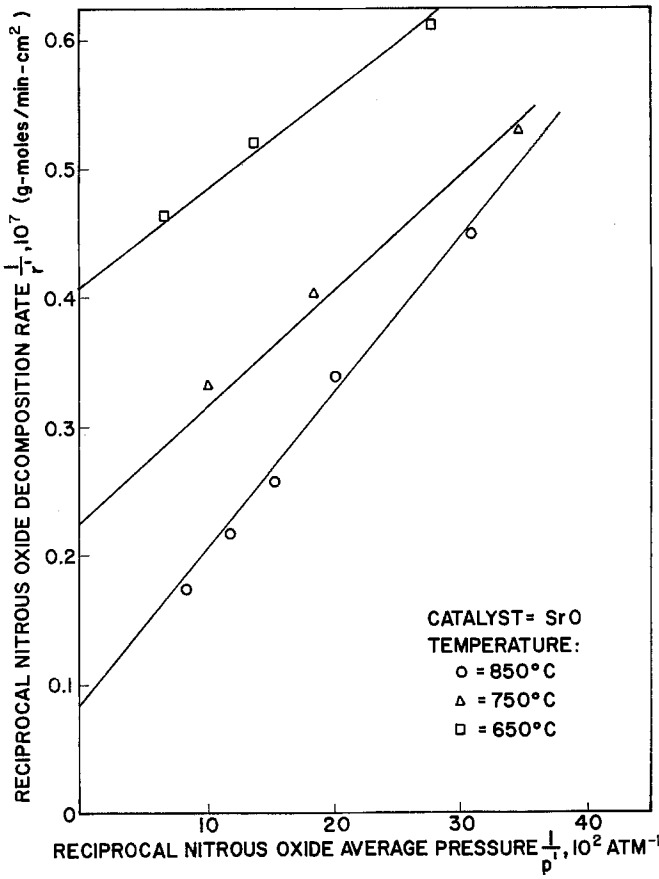

Fig. 12. Linear relationship between nitrous oxide reciprocal decomposition rate and reciprocal nitrous oxide average pressure, measured at various temperatures and nitrous oxide average pressures as well as total atmospheric pressure. Catalyst: strontium oxide.

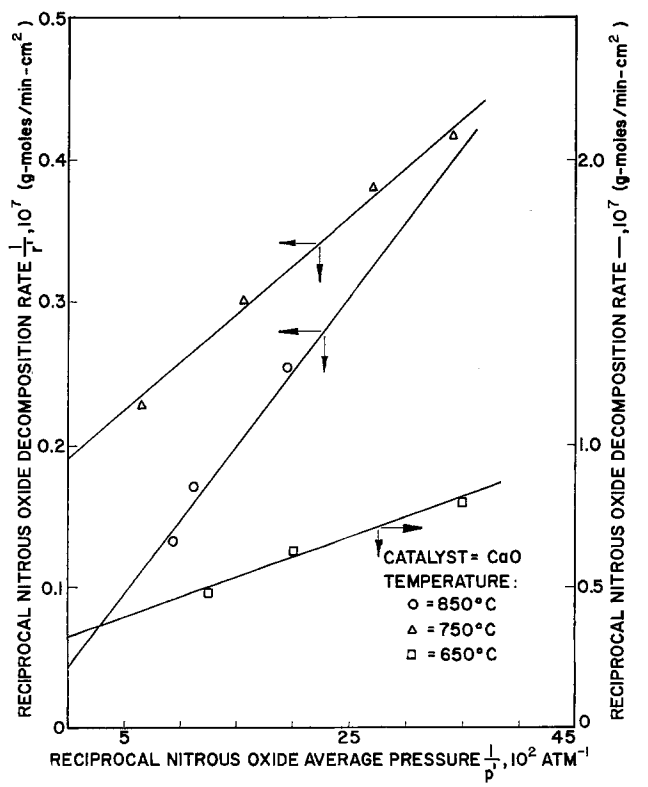

Fig. 13. Linear relationship between nitrous oxide reciprocal decomposition rate and reciprocal average pressure, measured at various temperatures and nitrous oxide average pressures as well as total atmospheric pressure. Catalyst: calcium oxide.

[13] and [14] differing by the nature of some orbitals involved. In the presence of an electron from the catalyst, one nitrogen atom is neutralized, while an excess electron is added to the oxygen atom in [13] and [14], contributing to oxygen attachment to the catalyst. Then

$$N_2O + \overset{\text{from catalyst}}{e} \rightarrow N_2 + (O^-)_{ADS} \quad [16]$$

$$(O^-)_{ADS} \rightarrow \tfrac{1}{2}O_2 \quad [17]$$

These equations suggest that catalysts with low work functions could favor the electronic processes involved. It is well known (10) that alkaline earth oxides behave as n-type semiconductors. The role of impurity levels in the forbidden band seems to be played by metals resulting from dissociated oxides, a reaction which could possibly occur in this case during the carbonate decomposition process carried out at around at least 1500°C. Work functions are as low as 1.2, 1.4, and 1.9 eV for barium, strontium, and calcium oxides, respectively. It is for such reasons that these oxides were tried as catalysts in the present study. The information supplied by Fig. 2-4 on one hand and Fig. 5-7 on the other, shows that the decomposition rates of nitric and nitrous oxides behave independently, implying a fast accumulation of nitrous oxide at the start of the decomposition reaction process, followed by a nitrous oxide pressure variation described by an equation similar to [7]. This aspect has already been discussed in relationship with the nitrous oxide average pressure. Also, the presence of nitrous oxide in the gaseous phase suggests a process of consecutive reactions. The nitric oxide decomposition should proceed through the intermediate desorption of nitrous oxide from sites with adsorption energy Q and subsequent readsorption on sites with adsorption energy Q' and final decomposition into nitrogen and oxygen. The mutual independence of the nitric and nitrous oxides decomposition mechanisms leads to two possible distinct sets of decomposition reaction equations related to these oxides. From Fig. 8-10, $1/r$ and $1/p$ are linearly related and the same holds for $1/r'$ and $1/p'$, this being derived from Fig. 11-13. These features, together with a previous knowledge of general results on the kinetics for solid-gas reaction (13), lead to the conclusions that the sequence of reactions, characterizing the decomposition reaction of nitric and nitrous oxides, should be one site, first-order forward reaction and the surface reaction should be the controlling step. One can now write down the reactions involved and derive some further calculations.

Nitric oxide.—The sequence of steps for a one-site, first-order forward surface reaction with respect to nitric oxide can be written

adsorption

$$NO + X \rightarrow (NOX) \quad [18]$$

surface reaction

$$(NOX) \rightarrow \tfrac{1}{2}N_2O + \tfrac{1}{2}(X - O - X) \quad [19]$$

desorption

$$\tfrac{1}{2}(X - O - X) \rightarrow \tfrac{1}{4}O_2 + X \quad [20]$$

Writing the rate expressions for reactions [18] to [20] with the condition that reaction [19] is the controlling step, one obtains

$$r = \frac{\bar{c}_m k_2 \left(K_1 p - \frac{1}{K_2 K_3} p'^{1/2} p_{O_2}^{1/4} \right)}{1 + k_1 p + \frac{1}{K_3} p_{O_2}^{1/4}} \quad [21]$$

Taking the maximum coverage $\bar{c}_m$ as unity, Eq. [21] meets the requirements of linear relationship between $1/r$ and $1/p$ when

$$r = \frac{k_2 K_1 p}{1 + K_1 p} \quad [22]$$

Table I. Nitric and nitrous oxides decomposition reaction rate and adsorption equilibrium constant for various alkaline earth oxide catalysts

Oxide	Catalyst	k or k', liter/min 650°C	750°C	850°C	K or K', atm^{-1} 650°C	750°C	850°C
NO	BaO	5.0×10^{-6}	8.0×10^{-6}	2.0×10^{-5}	13.0	25.0	40.0
	SrO	2.0×10^{-6}	4.0×10^{-6}	7.0×10^{-6}	25.0	30.0	40.0
	CaO	1.6×10^{-6}	8.0×10^{-6}	1.6×10^{-5}	25.0	13.0	10.0
N_2O	BaO	5.0×10^{-7}	10^{-6}	2.0×10^{-6}	2×10^2	10^3	3×10^3
	SrO	2.0×10^{-7}	5.0×10^{-7}	9.0×10^{-7}	5×10^2	2×10^3	5×10^3
	CaO	2.5×10^{-7}	6.0×10^{-7}	1.6×10^{-6}	3×10^3	5×10^2	2.5×10^2

$$\frac{1}{r} = \frac{1}{k_2}\frac{1}{p} + \frac{1}{k_2 K_1} \qquad [23]$$

Since p is of the order of 10^{-2} atm and p_{O_2} is $p/2$ at most, it may be seen that K_3 in [21] must be large if the equivalence of [21] and [22] is to be obtained. Following Eq. [20], this does mean that the number of sites for oxygen adsorption should be small, also explaining why oxygen does not seem to play an inhibitive role, at least within the limits of concentration used for nitric oxide. This is a possible result of the catalyst preparation at high temperature, as already discussed. Also, a low concentration in oxygen adsorption centers should be associated with a corresponding high nitrous oxide pressure following Eq. [19]. This fact, together with the finding calculated later in this work that the rate constant for nitric oxide decomposition is larger than the corresponding constant for the decomposition of nitrous oxide, confirms the validity of fast initial accumulation for nitrous oxide.

The values for K_1 and k_2 in Eq. [22] were derived from Fig. 8, 9, and 10 which are graphical representations of Eq. [22] for the various oxides studied. As a result, K_1 and k_2 were obtained for barium, calcium, and strontium oxides at temperatures equal to 650°, 750°, and 850°C. Table I summarizes the calculated results. The activation energy could then be obtained from

$$k_2 = k_{O_2}\, e^{-E_2/RT}$$

or

$$\log_{10}K_2 = \log_{10}k_{O_2} - 0.434\frac{E_2}{R}\frac{1}{T} \qquad [24]$$

Figures 14, 15, and 16 show the linear relationship between $\log_{10}k_2$ and $1/T$, from which E_2 was obtained for the various catalysts. Results are contained in Table II. Figures 14, 15, and 16 also show the linear relationship between $\log_{10}K_1$ and $1/T$, following a relationship analog to Eq. [24].

Nitrous oxide.—In view of the linear relationship between $1/r'$ and $1/p'$, the decomposition reaction of nitrous oxide should also be a one-site first-order forward reaction with respect to nitrous oxide. Hence, the following steps may be written, nitrous oxide reacting with new sites X'

adsorption

$$N_2O + X' \rightarrow (N_2OX') \qquad [25]$$

surface reaction

$$(N_2OX') \rightarrow N_2 + (OX') \qquad [26]$$

desorption

$$(OX') \rightarrow \tfrac{1}{2}O_2 + X' \qquad [27]$$

Here again, the surface reaction should be the controlling step and, in a manner similar to that used for nitric oxide, the reaction rate can be written

$$r' = \frac{k_2'\left(K_1' p' - \dfrac{1}{K_2'K_3'} p'_{N_2} p'^{1/2}_{O_2}\right)}{1 + K_1' p' + \dfrac{1}{K_3'} p^{1/2}_{O_2}} \qquad [28]$$

which becomes, for reasons of compatibility with the linear relationship between $1/r'$ and $1/p'$

$$r' = \frac{k_2'K_1' p'}{1 + K_1' p'} \qquad [29]$$

It should be noted here that a model equation, [7], has been used for describing the nitrous oxide pressure variation. The first-order decomposition reaction rate for nitrous oxide used in Eq. [7] is in accordance with the rate equation, [29], experimentally found in this study when p' is small, this being an acceptable approximation in this case. Equation [29] can be written

$$\frac{1}{r'} = \frac{1}{k_2'}\frac{1}{p'} + \frac{1}{k_2'K_1'} \qquad [30]$$

The constants K_1' and k_2' were derived from Fig. 11, 12, and 13, using the relationship expressed by Eq. [23] and their values are found in Table I. The activation energies E_2' were found from Eq. [24] when applied to nitrous oxide, this equation being used in conjunction with Fig. 14, 15, and 16. The calculated values appear in Table II.

Table II. Energy of activation for the decomposition reaction of nitric and nitrous oxides for various alkaline earth oxide catalysts

Catalyst	Energy of activation, kcal/g-mole NO decomposition (E_2)	N_2O decomposition (E_2')

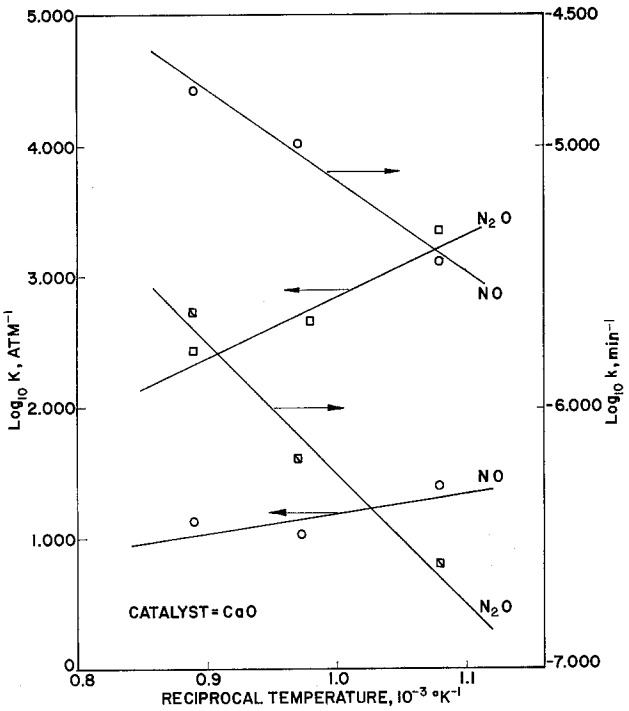

Fig. 16. Linear relationship between $\log_{10}k$ (decomposition rate constant), $\log_{10}K$ (adsorption equilibrium constant), and temperature reciprocal for nitric and nitrous oxides, using calcium oxide as catalyst.

Comparative results between nitric and nitrous oxides decomposition process parameters.—Figure 17 shows the global decomposition of nitric oxide, expressed as percent nitric oxide decomposed, for a 0.5% initial concentration in helium and a residence time of about 1 sec. It is seen that the most efficient catalyst among the alkaline earth oxides used is barium oxide which decomposes up to 60% nitric oxide at 850°C, with extrapolated values at 1000°C showing a decomposition of around 90%. Decomposition efficiencies of

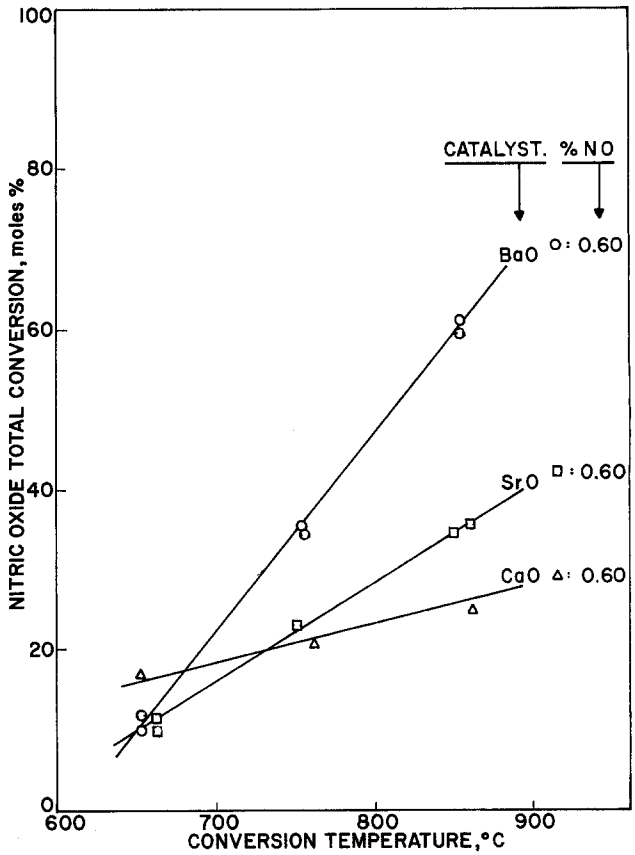

Fig. 17. Nitric oxide total conversion for a 0.6% nitric oxide concentration in helium at atmospheric pressure and a residence time of 1 sec. Catalysts: barium, strontium, and calcium oxides.

around 35 and 45% (extrapolated) are found at 850° and 1000°C, respectively, for strontium oxide, while for the same temperatures, calcium oxide shows efficiencies of 25 and 30%, respectively. At lower temperatures, calcium oxide exhibits higher nitric oxide conversion values than strontium oxide, becoming equivalent to the performance of barium oxide.

Examination of Table I shows calculated rate and equilibrium constants which are in conformity with the observations made on Fig. 17. Indeed, the barium oxide rate constant is more than two times higher than the corresponding constant for strontium oxide for most of the temperatures investigated. However, the nitric oxide adsorption equilibrium constant being higher for strontium oxide at lower temperatures, a combination of reaction rate and equilibrium constants, following Eq. [22] yields results which are in accordance with the trends indicated for barium and strontium oxides on Fig. 17. The same reasoning applies to barium and calcium oxides, for which both effects of rate constant k and equilibrium constant K lead to an explanation of the trends implied by Fig. 17. In this case, it is seen that higher K compensates for lower k at lower temperatures, thus explaining the similar efficiencies of barium and calcium oxides at lower temperatures. On the other hand, at higher temperatures both k and K are higher for barium oxide than for calcium oxide and a considerable difference in efficiency is apparent at 850°C. A comparison of strontium and calcium oxides performance follows in a straightforward way. From these considerations, it is concluded that higher temperatures increase the decomposition efficiency of the alkaline earth oxides; the efficiency being highest for barium oxide followed by strontium and calcium oxides in the order given. Although rate constants increase with temperature in all cases, it should be noted that the adsorption equilibrium constants only increase in the case of barium and strontium oxides, decreasing as far as calcium oxide is concerned. The trends ob-

served for the decomposition of nitrous oxide are quite similar to those reported for nitric oxide, thus corroborating further the results obtained in Fig. 17. Considering the results in Table I, one should note that the decomposition rate constants are generally one order of magnitude higher for nitric oxide when compared to nitrous oxide. This is in accordance with the assumption made for explaining the mutual independency of nitric and nitrous oxides conversion rates, the effect of higher adsorption constant value found for nitrous oxide being compensated by the lower average partial pressure of nitrous oxide prevailing in the gas phase (see Fig. 5-7). Energy of activation values are found in Table II, but do not add much for the interpretation of the results obtained, except for the high relative value of the activation energy related to calcium oxide.

The results obtained seem to confirm the possible relationship between catalyst efficiency and work function, as noted at the start of this study. Indeed, it has been found that the nitric oxide conversion efficiency (global) at 1000°C amounts to 90% for barium oxide, 45% for strontium oxide, and 30% for calcium oxide. Keeping in mind that the respective work functions are 1.1, 1.4, and 1.9 eV, a similar trend is followed by the latter values although other considerations besides the aspect of work function should probably be brought into the picture.

Results of this work vs. literature data.—Since the nitrous oxide decomposition reaction appears to be the controlling step in the present study, the data obtained for this step are compared with the over-all reaction rate data available in the literature for nitric oxide decomposition. The results of this compilation appear on Table III. It can be seen that the activation energy found in this work (14.7 kcal/g-mole) for strontium compares very well with the corresponding value found in Ref. (7). An energy of activation of 23 kcal/g-mole is found in this work for calcium oxide, while exactly the same value is found in Ref. (4) and a somewhat higher one (28 kcal/g-mole) is found in Ref. (7), although this latter value is well within the dispersion that can be found in the literature, discrepancies of 50% being attained for some oxides.

As far as reaction rate constants are concerned, only one value was found in the literature which was related to the present work. Reference (4) gives the nitric oxide over-all decomposition reaction rate constant for calcium oxide at 1033°K or 760°C. These authors obtain a zero order reaction rate constant equal to 5.2×10^{-4} mole liter^{-1} sec^{-1} g^{-1}, the initial nitric oxide concentration in helium being 10%. It can be seen from Eq. [29] that, for such a nitric oxide concentration, the rate constant for calcium oxide found in this work also reduces to a zero order rate constant, since p' should be high enough so that $K'p' >> 1$ (assuming a nitrous oxide concentration of at least 2%). In this case, k_2' can be found from either Fig. 7 for $p' \to \infty$ or Table I, where $k_2' = 6.0 \times 10^{-7}$ g · mole/min · cm^2 for a flow rate of 17 cm^3/min, as indicated above. Since Ref. (4) also supplies the information that 1g CaO presents a surface of 7.9 m^2, one can write

$$k\,[\text{Ref. (4)}] = \frac{5.2 \times 10^{-4}}{7.9 \times 10^4 \times 10^3}\ \text{g mole/cm}^3\ \text{cm}^2\ \text{sec}$$

$$k\,[\text{Ref. (4)}] = 6.6 \times 10^{-12}\ \text{g mole/cm}^3\ \text{cm}^2\ \text{sec}$$

Table III. Compared values for energy of activation and rate constants for nitric oxide decomposition on alkaline earth oxides. The controlling step is the nitrous oxide decomposition rate.

Oxide	Temperature, °C: This work	Ref. (7)	Ref. (4)	Energy of activation, kcal/g-mole: This work	Ref. (7)	Ref. (4)
				Controlling step	Over-all reaction	
SrO	650-850	620-750	—	14.7	15	—
CaO	650-850	580-720	760-1,040	23	28	23

Also

$$k_2'\,[\text{this work}] = \frac{6.0 \times 10^{-7}}{17 \times 60}\ \text{g mole/cm}^3\ \text{cm}^2\ \text{sec}$$

$$k_2'\,[\text{this work}] = 5.4 \times 10^{-10}\ \text{g mole/cm}^3\ \text{cm}^2\ \text{sec}$$

As a result, $k_2'/(k\,[\text{Ref. (4)}] = 80$. Although rather high, this discrepancy still remains within the limits of the variations that can be met in the literature (7) where factors as high as 300 may be found. Finally, if one compares results obtained in this work with the few data found in the literature, it is observed that energy of activation values are very close while reaction rate constants show some discrepancy which is, however, still within the limits of variation found for this kind of thermodynamic parameter.

Conclusions

In the course of this study, it has been found that, among the three alkaline earth oxides experimented with as catalysts for the decomposition of nitric oxide, barium oxide is the most efficient. Using this oxide in conjunction with nitric oxide concentrations between 0 and 2.5% in helium, global decomposition efficiencies of around 60% are attained at 850°C, yielding nitrous oxide, oxygen, and nitrogen. Since nitrous oxide is harmless, this process could be accepted as a possible means for nitric oxide abatement, the noted efficiency being attained for a residence time of around 1 sec. Strontium and calcium oxides have a similar behavior, but to a lesser extent as far as nitric and nitrous oxides decomposition is concerned. For strontium oxide, this global decomposition attains 35% at 850°C and amounts to 25% for calcium oxide at the same temperature.

It was observed that within the limits of nitric oxide concentrations used, the nitric and nitrous oxides decomposition rates are mutually independent, this being true for the three catalysts used. This feature is related to much higher values for decomposition rate constants related to nitric oxide. A combination of the calculated decomposition rate constants and adsorption equilibrium constants for nitric and nitrous oxide values explains the relative conversion efficiencies observed for the catalysts used. The presence of 3% oxygen associated with 0.5% nitric oxide did not seem to have any effect on the performance of barium oxide. Such a behavior is possibly related to a rather low concentration of oxygen adsorption sites. Finally, this catalyst was experimented with for several hours at 850°C without showing any efficiency alteration.

Without definitely qualifying the alkaline earth oxides as catalysts for decomposing nitric oxide at concentrations usually found in pollution problems, the observations made in the present study show interesting features which are worthwhile being investigated further.

Anodic Phenomena in Cryolite-Alumina Melts

II. Chronopotentiometry at Gold and Platinum Anodes

E. W. Dewing*

ABSTRACT

Chronopotentiometric measurements with wire anodes have shown that the transition time is diffusion controlled up to 0.7% Al_2O_3 on gold and up to 1.6% Al_2O_3 on platinum. The diffusion coefficient is $(2.51 \pm 0.12) \times 10^{-5}$ cm² sec^{-1} (std error), at 1020°C. At higher concentrations, formation of oxide films becomes the limiting factor; effectively, the electrodes are being anodized. On an anodized gold electrode fluorine can be discharged. If the current density is high enough (~250 A cm^{-2}), the discharge is diffusion controlled and seems to correspond to "free" (*i.e.*, uncomplexed) fluoride. In pure cryolite, this is estimated to be about 5% of the total fluorine present (corresponding to ~16% dissociation of AlF_6^{3-} to AlF_4^-). It is reduced by addition of Al_2O_3 and also by addition of AlF_3; it is increased by adding NaF.

An instrumental method of determining the alumina content of molten cryolite *in situ* in the electrolytic cells would obviously be of immense interest to the aluminum industry, and this has led to work on chronopotentiometry. Both Richards and Russell (1) and Thonstad (2, 3) have employed graphite anodes, and they seem to have gotten good results. Nonetheless, graphite as an anode material has its problems. The surface is liable to be rough and/or porous, it is subject to air oxidation during introduction into and removal from the cell, and above all, it is difficult to get a small, reproducible surface area. Since alumina concentrations to be measured are high by most electroanalytical standards [2-8 weight percent (w/o)] with a corresponding need for high current densities, this is important.

An obvious way out of the problem is to try metal wire electrodes, which means, in effect, the noble metals since oxygen is going to be liberated. The temperature involved is above the melting point of silver. The work reported here was carried out with platinum and gold.

Initial work in the range 2-8 w/o Al_2O_3 gave most confusing results. At high current densities transitions leading to anode effects were readily observed (*i.e.*,

* Electrochemical Society Active Member.
Key words: cryolite, alumina, chronopotentiometry, gold, platinum, diffusion coefficient, complex ions, dissociation.

the voltage rose to ~50V when the transition occurred, leading to destruction of the wire unless the current was promptly interrupted), but for Pt the transition time was independent of alumina content and with Au it decreased as the Al_2O_3 content went up. Reproducibility with Au was not good enough for the phenomenon to form the basis of an analytical method. In order to sort out the problem the work was extended to alumina concentrations below the range of industrial interest.

Experimental

Several circuits were used in this work, but their principle was the same. Capacitors were charged with a d-c power supply and then discharged through a resistor by triggering a General Electric C30D SCR electronic switch. If the capacitor has capacity C and the total resistance in the circuit is R, then the time constant for the discharge is RC. Provided that $RC >> \tau$, the transition time, then the circuit is effectively constant current for the period of time required. The current itself is given by V/R, where V is the voltage on the capacitor.

Depending on the capacity and voltage rating of the capacitors available and the voltage of the power supply, different circuits can be constructed to suit the current density and transition time ranges desired. Two in particular were used; 6000 μF charged to 40V and 2400 μF charged to 160V. Current densities as high as 360A cm^{-2} were obtained.

It is desirable (and indeed essential when dealing with anode effects where the voltage rises to 50V or more) to have some means of cutting the flow of current when the transition is over. For the high voltage circuit, this was done with a second SCR across the cell. The gate was connected through a Zener diode; as soon as the voltage rose to the level where the diode conducted the second SCR was triggered and the cell was shorted out. For the low voltage circuit, the current was interrupted by an electromechanical relay which opened some 4-10 msec after the current was started. In some of the very high current density work, the electrode was depolarized between pulses with a 4 mA cm^{-2} cathodic current. This did not seem to make any significant difference.

Transition times were read directly from an oscilloscope by eye. Although somewhat subjective, this was not a factor limiting the accuracy of the results. The current was measured by determining the voltage drop across a standardized resistor (either 1 or 0.1 ohm), again with the oscilloscope, the voltage scale of which was calibrated.

Melts were made up by weight from Greenland cryolite and Bayer alumina, and were held in graphite crucibles which served as cathode. The anode wires were immersed 1 cm; their diameters (nominally 0.5 mm), were measured with a traveling microscope.

Results

To give an overview of the problem, Fig. 1 shows values of $i\tau^{1/2}$ (where i is current density and τ is transition time), interpolated for $\tau = 1$ msec, as a function of current density. A diffusion-controlled region does exist at low alumina contents, terminating at about 0.8% Al_2O_3 for gold and 1.7% Al_2O_3 for platinum. Beyond that, it is apparent that some other process has intervened.

The diffusion-controlled region.—Tables I and II show the results obtained in the diffusion-controlled region with gold and platinum wires, respectively, and Fig. 2 shows the transition on platinum. $i\tau^{1/2}$ is effectively independent of current density. If, for the line in Fig. 2, potential is plotted against ln $(\tau^{1/2} - t^{1/2})$, the slope ($= RT/n\mathbf{F}$), corresponds to $n = 2.2$. This treatment is based on the premise that the oxidation product is left on the electrode at constant activity, so that only the concentration of oxide enters the Nernst equation. If on the other hand, one assumes that soluble O^- is

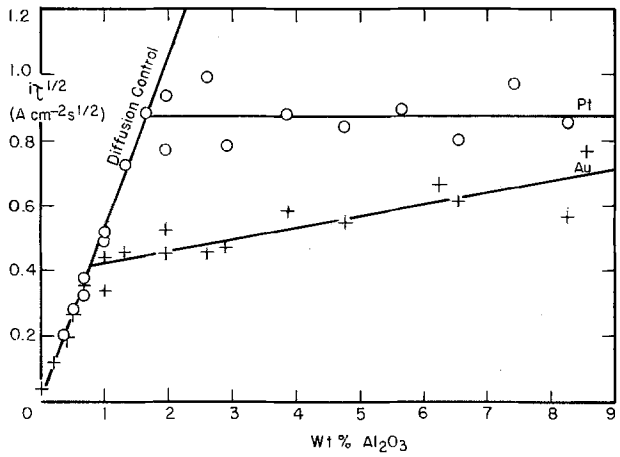

Fig. 1. Plot of $i\tau^{1/2}$ (interpolated for $\tau = 1$ msec), against w/o Al_2O_3. Temperature 1018°-1026°C.

being formed, then the proper function to plot is ln $(\tau^{1/2}/t^{1/2} - 1)$. n, however, is then found to be 3.4, which is completely inconsistent with the hypothesis. It is therefore apparent that a 2-electron oxidation of O^{2-} is occurring.

Figure 3 shows a more detailed plot of the diffusion-controlled region. The line is straight but does not quite pass through the origin, implying that the Greenland cryolite used has a small alumina content itself. The intercept of the line shows this to be 0.027% for this particular batch of cryolite. This may be compared with wet chemical analysis which gave 0.15% Al_2O_3. After displacing the origin to allow for the blank, the line may be represented by

$$\text{w/o } Al_2O_3 = (1.914 \pm 0.046)\ (i\tau^{1/2}) \qquad [1]$$

with a standard deviation of ±0.04% Al_2O_3. The uncertainty of the slope is a standard error.

There is no significant effect of temperature over the 8° range encountered, and there is no significant difference between the results with gold and platinum wires. It is therefore permissible to apply the Sand equation

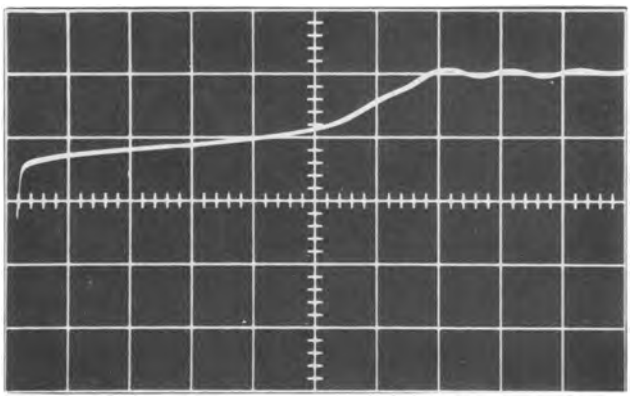

Fig. 2. Diffusion-controlled transition on platinum. 1 w/o Al_2O_3, 22.5 A cm^{-2}, 220 mV/cm vertical, 100 μsec/cm horizontal, τ = 570 μsec. Ripples beyond 700 μsec are believed to be due to platinum being oxidized.

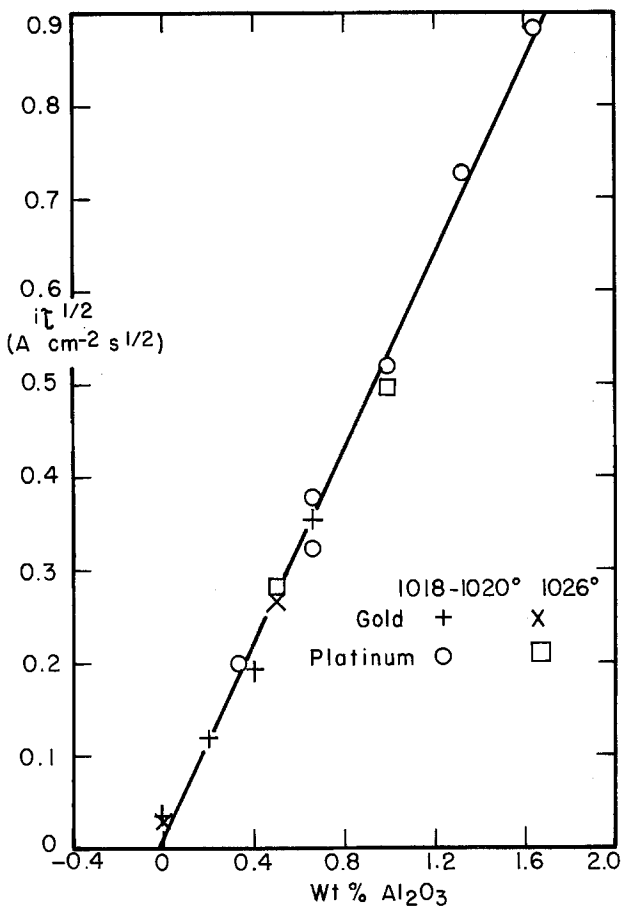

Fig. 3. Diffusion-controlled transition times (τ) as a function of alumina content.

to determine the diffusion coefficient of oxide in the melt

$$\frac{i\tau^{1/2}}{nFC} = \frac{(\pi D)^{1/2}}{2} \qquad [2]$$

where i is the current density (A cm^{-2}), τ is the transition time (sec), n is the number of electrons involved (= 6 for Al_2O_3), **F** is the Faraday (96,487 C/g-equiv.), **C** is the concentration (g mole/ml), and D is the diffusion coefficient (cm^2 sec^{-1}). It should be noted that the product nC is totally independent of any assumptions which may be made about the form in which alumina exists in the melt (*e.g.*, as Al_2O_3, $AlOF_2^-$, etc.). For a solution containing 1 w/o Al_2O_3 at 1020°C, $C = 2.03 \times 10^{-4}$ mole/ml. Hence, with the constant in Eq. [1], $D = (2.51 \pm 0.13) \times 10^{-5}$ cm^2 sec^{-1}. The uncertainty is a standard error. This value may be compared with 2.2×10^{-5} cm^2 sec^{-1} given by Desclaux and Rolin (4) from rotating disk experiments on the rate of solution of alumina, and 1.5×10^{-5} cm^2 sec^{-1} found by Thonstad (2) from chronopotentiometric experiments with graphite anodes. His low value shows that his transition times were short in comparison with the present ones, and suggests that on a graphite electrode not all the surface is working (a maximum of 75%). This is readily understandable if graphite crystallites can only be attacked on the edges and not on the basal plane.

Initial oxide film formation on platinum.—With platinum wires at low alumina contents two separate transitions were observed, as recorded in Table II. One is the diffusion-controlled transition discussed above; the other, coming in general at much shorter times, is illustrated in Fig. 4. Figure 5 shows these other transitions plotted on the basis of log τ *vs.* log i, together with some similar points for higher alumina contents from Table III. The line drawn has a slope of −1, implying that $i\tau$ is constant, rather than $i\tau^{1/2}$ being constant as in the case of diffusion control. $i\tau$ is a quantity of charge, and is

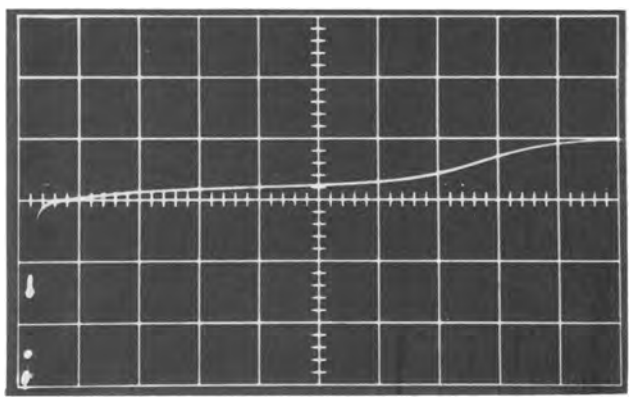

Fig. 4. Initial oxide film formation on platinum. 1 w/o Al_2O_3, i = 10.1 A cm^{-2}, 220 mV/cm vertical, 10 μsec/cm horizontal, τ = 75 μsec. Note the much shorter time scale compared to Fig. 2.

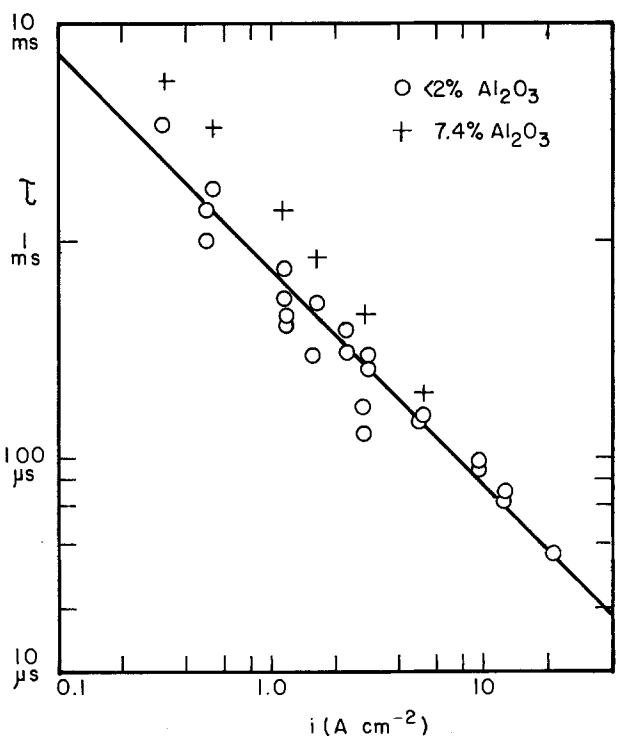

Fig. 5. Initial oxide film formation on platinum. The transition time τ is proportional to $1/i$.

$$i\tau = 735\ \mu C/cm^2 \pm 182\ \text{(std deviation)}$$
$$\pm\ 35\ \text{(std error)}$$

This represents formation of a surface film (presumably of platinum oxide), of constant thickness. Similar phenomena have been observed by Mayell and Langer (5) in aqueous solution. They detect several different types of film, but say that 760 μC cm^{-2} corresponds to a monolayer of PtO_2. Although their reasoning regarding the composition is open to question, there seems little doubt that the transitions observed correspond to the completion of the first layer of oxide; the number of oxygen atoms discharged per square centimeter is, however, more than would be expected if the surface is covered with a single close-packed layer of oxygen ions. The radius of an oxygen ion is 0.132 nm, so that in a hexagonal array each ion covers 0.0603 nm^2, and one expects 1.68×10^{15} atoms/cm^2. 735 μC cm^{-2} corresponds to 2.30×10^{15} atoms/cm^2. Either the oxygen ions are forming more than a monolayer, or the surface is rough with a roughness factor of 1.4.

At 7.5% Al_2O_3 the number of coulombs required to form the first layer of oxide seems to have gone up, and at the same time $i\tau$ is not quite constant, ranging from 1040 μC cm^{-2} at 5 A cm^{-2} to 1760 μC cm^{-2} at 0.3 A cm^{-2}. The reason for this effect is not known.

Thicker oxide film formation on platinum.—Table III and Fig. 6 show the results obtained with platinum at high alumina contents. Statistically, temperature and alumina content are not significant, and the slope of the log-log plot is −1.38 with a standard error of ±0.07. A value of −1.5 is thus within the 95% confidence interval (2 std errors), and since this is a value which can be interpreted, it has been adopted. The line drawn in Fig. 6 has a slope of −1.5.

The situation thus is that three separate transitions have been identified. The first, on a log-log plot, has a slope of −1 (*i.e.*, $i\tau$ = constant) and corresponds to the completion of the first layer of oxide. The second has a slope of −2 (*i.e.*, $i\tau^{1/2}$ = constant) and corresponds to diffusion control. The third has a slope of −1.5 (*i.e.*, $i\tau^{2/3}$ = constant); to what is it to be attributed? The situation is shown in Fig. 7, from which all points have been omitted for clarity.

The hypothesis is going to be advanced that the third transition is due to the discharge process being limited by the rate of growth of a relatively thick oxide film (*i.e.*, many atomic layers thick). For such films (which are normally regarded as thin) the growth law when they are forming in the presence of an unrestricted supply of oxidant is often cubic, *i.e.*

$$kt = x^3 \qquad [3]$$

or

$$x \propto t^{1/3} \qquad [4]$$

where x is the thickness of the film and t is time, and k is a constant. At large thickness (above ~100 nm), the exponent changes from 1/3 to 1/2, leading to the normal parabolic law. (For discussion of the implications of these laws see Hauffe (6)). From Eq. [3], which it must be realized represents the maximum rate of film growth

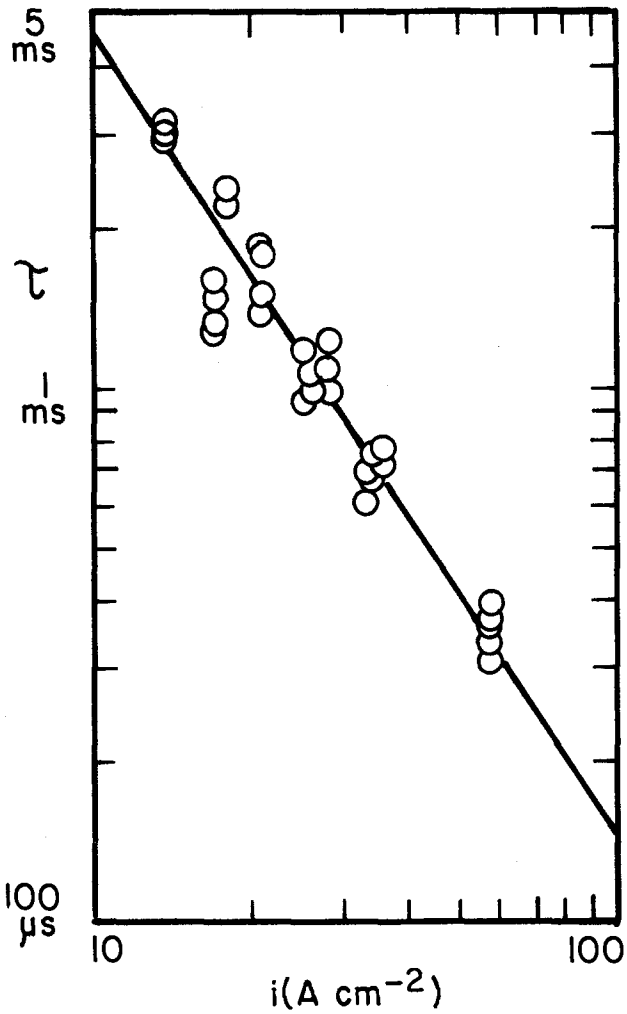

Fig. 6. Transition time as a function of current density for alumina contents above 1.96% (Pt wires). Line drawn has a slope of −1.5.

1025	2.91	8-32	3	148 ± 7
1026	4.76	8-32	3	173 ± 8
1026	6.54	9-32	5	194 ± 7
1026	8.25	9-32	4	179 ± 10
975	8.25	9-26	4	184 ± 3

$$dt/dx \propto x^2 \quad [5]$$

and

$$dx/dt \propto x^{-2} \quad [6]$$

This gives an infinite rate at $x = 0$, and the rate decreases as the thickness increases.

In the case of electrolytic oxidation with a constant current density, i, the thickness of the film is proportional to the number of coulombs passed, so that

$$dx/dt \propto i \quad [7]$$

It is assumed that the transition at time τ occurs because the rate of electrolytic oxidation has become equal to the maximum rate, so that

$$dx/dt \propto i \propto x^{-2} \propto (i\tau)^{-2} \quad [8]$$

Hence

$$i^3\tau^2 = \text{constant} \quad [9]$$

or

$$i\tau^{2/3} = \text{constant} \quad [10]$$

which is what is observed.

If this explanation is correct, it implies that the oxygen discharged at the anode is not liberated as gas but goes to form an oxide film. Diffusion control of the transition ceases when the alumina concentration becomes high enough that more oxygen is generated than the oxide film is capable of holding; after that the transition time (for a given current density), becomes independent of the oxide content of the melt.

Initial oxide film formation on gold.—With gold electrodes no reproducible transitions occur analogous to those for the initial oxidation of platinum. Transitions (usually two separate ones) are sometimes but not always seen in the appropriate region.

Thicker oxide film formation on gold.—Figure 8 is a typical example, Table IV shows the results, and some

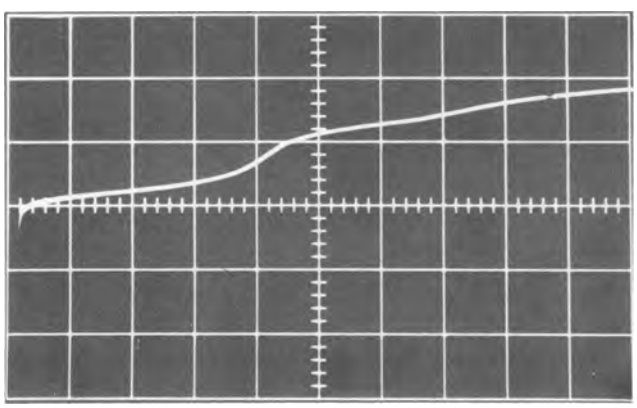

Fig. 8. Oxide film limitation on gold. 1 w/o Al_2O_3, i = 21.9 A cm^{-2}, 220 mV/cm vertical, 100 μsec/cm horizontal, τ = 440 μsec. Note that in contrast to Fig. 2, electrolysis continues smoothly thereafter.

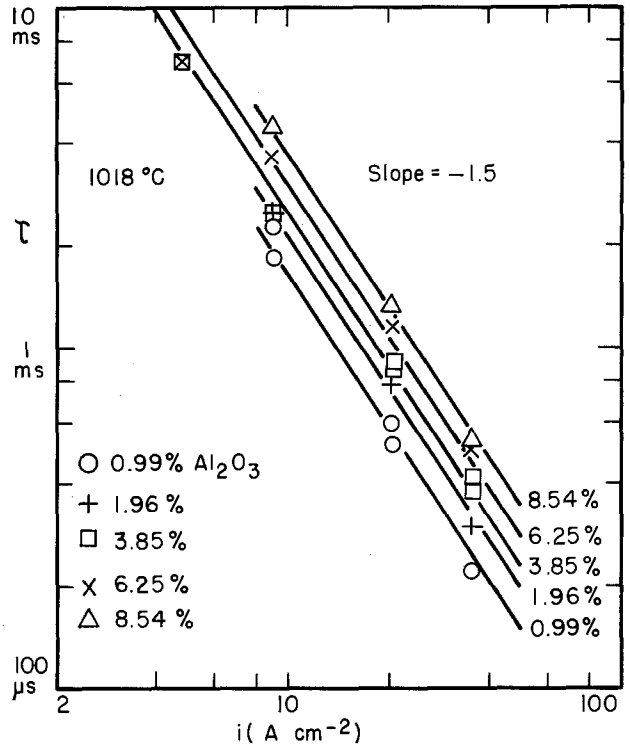

Fig. 9. Transition times as functions of current density for alumina contents above 0.99% (Au wires).

of them are plotted in Fig. 9. Again, a slope of −1.5 is obtained, but this time the values vary somewhat with alumina content. This variation is shown in Fig. 1, where the values interpolated to 1 msec are plotted. The implication is that the inherent rate of oxide film growth is faster in high alumina melts, and this can only be accounted for if the composition of the film is changing. The only change which can be envisaged is that some fluoride ions are being incorporated in the film, the proportion of them varying with alumina content.

Figure 10 shows the results for 8-9% Al_2O_3, including some for very high current densities. The line drawn

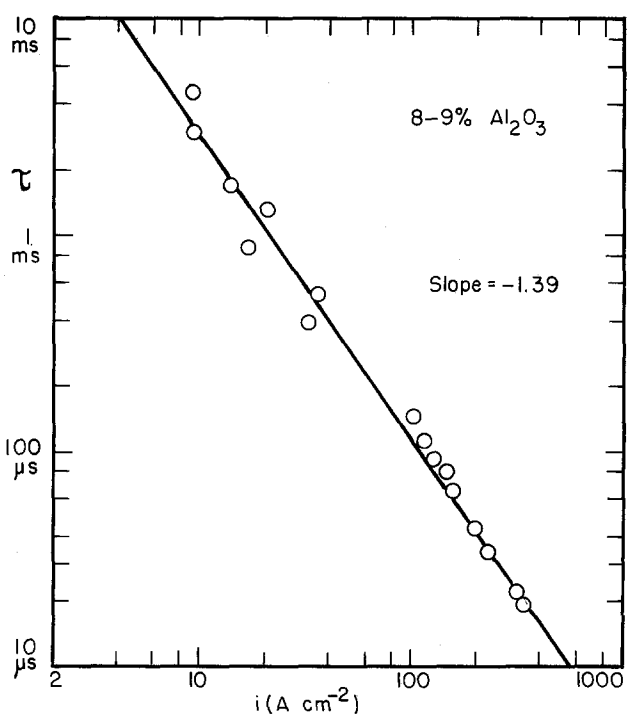

Fig. 10. Transition times as a function of current density for melts containing 8-9% Al_2O_3 (Au wires).

has a slope of -1.39 with a standard error of ± 0.04. This indicates that the film formation mechanism is operative over a very wide range of current densities at this alumina content. At the high current densities the transitions were anode effects.

Discussion of Oxide Film Formation

To postulate that oxide films are forming on platinum and gold at over 1000°C is unorthodox since they are thermodynamically unstable, but it must be borne in mind that the times are less than 5 msec and the current densities are correspondingly high. In 5 msec with $i = 7$ A cm^{-2} (see Fig. 7), a total of 35 mC cm^{-2} are passed, and they will give an oxide film about 14 nm thick. With 200 A cm^{-2} for 44 μsec, a total of 8.8 mC are passed and the calculated thickness is 3.6 nm. These thicknesses are well within the limit of 100 nm, below which the cubic growth law can be expected to hold. The logic for accepting the oxide film hypothesis is as follows:

1. There are only three anodic processes possible; discharge of O^{2-}, discharge of F^-, and dissolution of Au (or Pt).
2. In the diffusion-controlled region, there is no doubt that O^{2-} is being discharged.
3. If it were being discharged as gaseous oxygen, substantial amounts of gas would be formed. For example, with platinum and 1.64% Al_2O_3 a transition time of 1720 μsec was recorded at 21.1 A cm^{-2}. This corresponds to 36 mC cm^{-2} and would generate a gas layer 10^{-2} cm thick. At the same time, the thickness of the diffusion layer ($= \sqrt{2Dt}$) is 3×10^{-4} cm. Generation of this volume of gas would thus inevitably disrupt the diffusion layer and lead to a breakdown of the Sand equation, and yet no such deviation from the Sand equation is observed.
4. If the oxygen is not appearing as gas, it must be present either as an oxide film or in solution in the melt. The latter is inherently unlikely; oxygen is not appreciably soluble in cryolite, and such a mechanism would not account for the difference in results between gold and platinum or for the behavior of the transition outside the diffusion region.
5. There can be no question that when sufficient alumina is present to be beyond the diffusion region the discharge prior to the transition is of oxygen.
6. The law $i\tau^{2/3} =$ constant is, as already shown, consistent with oxide film formation.
7. In melts with no added alumina, chronopotentiometry at high current densities does not lead to anode effects, and the wire dissolves. Similar experiments in melts with 2% or more alumina give anode effects and the wire dissolves very little. This implies that the surface of the electrode is physically changed when operating in the presence of alumina. Some barrier has been formed which prevents gold dissolving.
8. Since gold oxide (Au_2O_3?) and platinum oxide (PtO_2?) are different substances, the difference in behavior of gold and platinum is readily accounted for. Tyurikov *et al.* (7) have also found differences in the discharge of oxygen from molten carbonate on Au and Pt, although they talk in terms of adsorbed oxygen rather than relatively thick layers of oxide.

Fluorine Discharge

Under some circumstances electrolysis on gold continues after the transition due to film growth limitation. It is not possible that oxygen is still the only ion being discharged; if it were the diffusion-controlled transition would be observed subsequently. Presumably oxygen is still discharged as fast as the growing film can absorb it, but the rest of the current must either dissolve gold or discharge fluorine, and little gold dissolution is observed. (If the film formation hypothesis is correct, gold solution would be impossible, as Au ions are presumably already diffusing through the film at the maximum possible rate in order to permit the film to grow.) One therefore concludes that F^- discharge is occurring.

At current densities less than about 100 A cm^{-2} no further transitions were observed, but at very high current densities anode effects occur, as illustrated in Fig. 11. This implies that no subsequent electrochemical process was available to carry the current.

For a melt containing 2% Al_2O_3 the situation is shown in Fig. 12, which gives the observed line for film formation control, where the oxide diffusion control line would be if it were observed, and the experimental results. At very high current densities ($i > 150$ A cm^{-2} or $\tau < 200$ μsec), the line has a slope of -2, showing diffusion control. At lower currents the product $i\tau^{1/2}$ increases rapidly, and below about 100 A cm^{-2} the anode effects are no longer observed at all. Figure 13 shows how the product $i\tau^{1/2}$ varies with alumina content and NaF/AlF_3 ratio; values have been averaged over the range 200-300 A cm^{-2}. It is apparent that transition times become shorter as Al_2O_3 is added and longer as NaF is added.

The most plausible explanation of the results is that fluorine is indeed being discharged, but that not all the fluorine in the melt is available for discharge in times

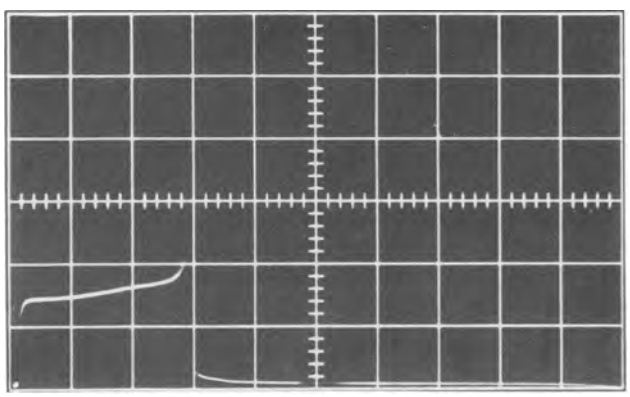

Fig. 11. Anode effect on gold. 6 w/o Al_2O_3, $i = 122$ A cm^{-2}, 11 V/cm vertical, 50 μsec/cm horizontal, $\tau = 145$ μsec. Note that the electronic cutout was set at 53V (4.8 cm on photo); although it has not registered on the film the trace rose to that level in ~5 μsec and then reappeared at the bottom.

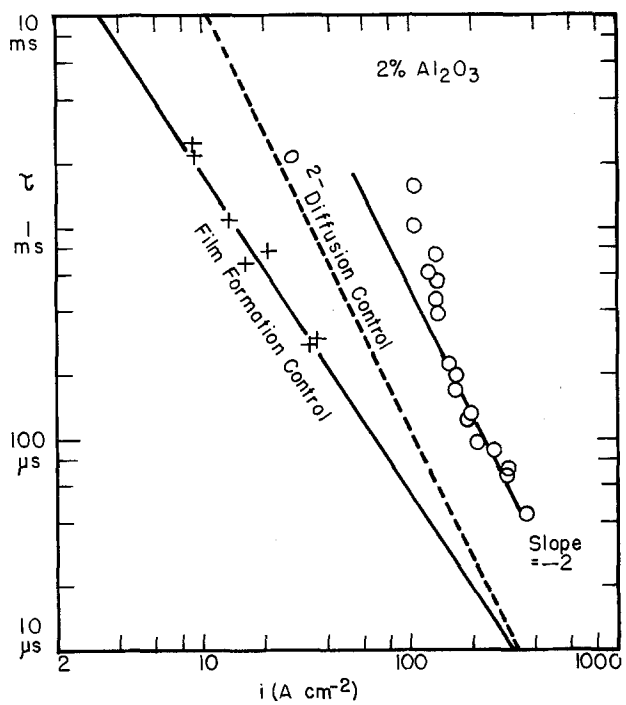

Fig. 12. Transition times as a function of current density for melts containing 2% Al_2O_3 (Au wires).

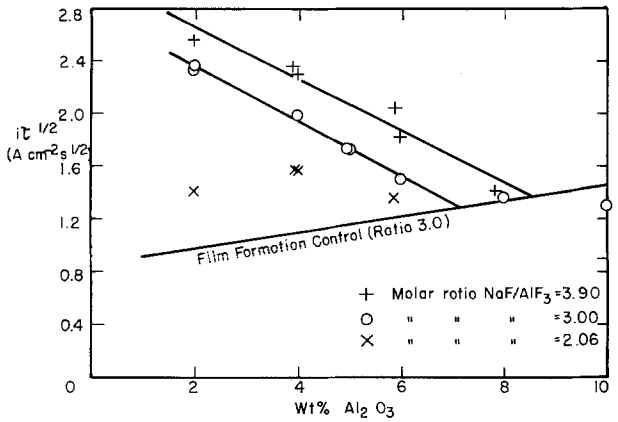

Fig. 13. Transitions at Au anodes at current densities 200-300 A cm^{-2}.

of the order of 100 μsec. For many years models of cryolite melts in terms of partially dissociated AlF_6^{3-} ions (and other complex species), have been invoked to explain the shapes of liquidus curves; the most common equilibrium proposed is

$$AlF_6^{3-} \rightleftharpoons AlF_4^- + 2F^- \qquad [11]$$

Without wishing to tie ourselves to this stoichiometry, we propose that the observed transitions are due to discharge of the "free" fluoride only. On this basis, we can account for the following features:

1. At high current densities the transition is diffusion controlled; at lower currents and longer times the "free" fluoride is replenished by dissociation of complexes (or possibly the diffusion is disrupted by gas bubble formation). According to Paunovic (8), "a decrease in the product $i\tau^{1/2}$ with current density is a diagnostic criterion for the occurrence of a prior chemical reaction, *e.g.*, dissociation of a complex."

2. Addition of NaF increases the supply of free fluoride, addition of Al_2O_3 reduces it, presumably by forming complexes of the type $AlOF_n^{(n-1)-}$. It looks as if the "free" fluoride is being titrated with Al_2O_3, with an end point around 7% Al_2O_3 for an NaF/AlF_3 molar ratio of 3.0, and around 8.5% Al_2O_3 for a ratio of 3.9.

3. Numerical interpretation is reasonable. For a ratio of 3.0, extrapolation to zero alumina (where the transition cannot be observed because of the absence of the protective oxide film) gives $i\tau^{1/2} = 2.8$ A cm^{-2} $sec^{1/2}$. From this must be subtracted a correction for the formation of the oxide film, which is taking all the current initially and some of it subsequently. If the first process of two successive reactions is diffusion controlled the proper procedure (9) is to subtract $i\tau^{1/2}$ for the first transition; in this case this will not be accurate, but the error will not be serious for the present purpose. We therefore subtract 0.9 A cm^{-2} $sec^{1/2}$ to give $i\tau^{1/2} = 1.9$ A cm^{-2} $sec^{1/2}$. Using the Sand equation, [2], and with an estimated value of $D = 5 \times 10^{-5}$ cm^{-2} $sec,^{-1}$ C is found to be 0.0031 moles F^-/ml. The density of cryolite at 1020°C is 2.077 g/ml, so that 1 mole (210g) occupies 101 ml, and the same volume contains 0.32 moles "free" F^-. In terms of equilibrium [11] this represents 16% dissociation of AlF_6^{3-}. A decrease of a factor of 2 in the estimate of D would increase the calculated dissociation to 23%, but it is unlikely that D for "free" F^- is as low as 2.5×10^{-5} cm^2 sec^{-1} since that is the value found for Al_2O_3 which is present as bulky $AlOF_n^{(n-1)-}$ complexes.

Gilbert, Mamantov, and Begun (10) have just published work on the Raman spectrum of molten cryolite from which they deduce that the AlF_6^{3-} ions are about 25% dissociated. In view of the totally different type of experiment and the different assumptions made in working out the results, the agreement is good enough to lend strong support to the view that we are observing transitions due to the discharge of "free" F^-, and that the latter does have a real physical existence.

Although we have not been able to give any quantitative treatment, to explain the departure from the diffusion-controlled line in Fig. 12 requires a lifetime for AlF_6^{3-} ions of the order of a millisecond. The lines in Fig. 13 could form the basis of an analytical method for determining alumina in molten cryolite, but the sensitivity of the calibration to the NaF/AlF_3 ratio (and probably also to CaF_2 content), limits its attraction.

The Effect of Surfactants on the Electro-oxidation of Benzhydrol in Emulsion and Micelle Systems

Thomas C. Franklin* and Lewis Sidarous

Department of Chemistry, Baylor University, Waco, Texas 76703

ABSTRACT

A study was made of the effect of surfactants on the yields of product obtained in the anodic oxidation of aromatic alcohols in water-organic solvent emulsion and micelle systems. It was found that cationic surfactants caused marked increases in the yield while anionic or neutral surfactants caused only small increases in the yield. It was concluded that at least part of the effect was caused by the formation of a film on the surface of the anode which inhibited the competing process, the evolution of oxygen.

As part of the comparison of some electro-oxidations with chemical oxidations a study was initiated into the electro-oxidation of some aromatic alcohols to compare with results obtained in a study using metal oxides as chemical oxidizing agents. This basically is the same problem being investigated in studies of the electrochemical oxidation of organic compounds using nickel peroxide electrodes (1-3). Because of solubility problems it was decided to use emulsion and micelle systems to solubilize the organic compounds while still maintaining the conductivity of an aqueous solution of an electrolyte. Emulsion systems, which have been used for some time in the electrolysis of insoluble liquids suspended in an electrolyte (4, 5), have recently been shown to be especially useful when phase transfer catalysts are used (6, 7). Recently there has been a series of polarographic studies in which the organic compounds were solubilized in the form of micelles (8-12).

Experimental

The model compound chosen for oxidation was benzhydrol and the aqueous phase was 2*N* sodium hydroxide and the organic phase in the emulsion studies was varied but in most experiments it was benzene. The synthesis cell consisted of a 400 ml beaker containing a porous porcelain cup separating the anode and cathode compartments. A saturated calomel reference electrode was connected to the anodic compartment with a Luggin capillary and all voltages listed are referred to the SCE. The counterelectrode was a platinum gauze electrode with a geometrical area of 63.7 cm^2. Similar results were obtained when an H-type cell was used as the reaction vessel with the two compartments separated with a coarse fritted glass disk.

The anode potential was controlled with a Wenking Model 66TA1 potentiostat. In cases where current-voltage curves were recorded, the potential of the potentiostat was varied using a motor-driven potentiometer. The same cell and electrodes were used. The working electrode was a large platinum foil (40.9 cm^2 in area).

All synthesis experiments were performed for 1 hr at room temperature unless otherwise indicated. A variety of stirring conditions was tried including ultrasonic mixing. In the results included in this report the system was mixed and stirred vigorously during the process by using a cone drive stirrer. This was sufficient in these experiments to maintain the emulsion.

After electrolysis, the anolyte mixture was placed in a separatory funnel. In the micelle experiments, the anolyte was extracted with 50 ml of benzene. The organic and aqueous phases were then separated and the analysis was performed using the organic phase. When water miscible solvents were used, the anolyte solution was evaporated to dryness in a flash evaporator; the solid residue was then extracted with benzene, mixed in a separatory funnel with 30 ml of distilled water, and the aqueous layer was discarded.

After washing with water the product, benzophenone, was determined quantitatively either gravimetrically as the 2, 4 dinitrophenylhydrazone derivative or by liquid chromatography. The benzophenone was originally identified by infrared spectrophotometry and by the melting point of 2,4 dinitrophenylhydrazone derivative. It was further confirmed by high pressure liquid chromatography. The benzopinacol was identified and determined using high pressure liquid chromatography.

High pressure liquid chromatography was the primary analytical tool used to identify products and determine yields of the various aldehydes and ketones. The chromatograph used was a Waters ALC202 instrument with a differential refractometer detector. A 2 ft silica gel (Corasil I) column was used with a 50:50 mixture (by volume) of benzene and cyclohexane being used as the solvent. The recorded peaks were integrated with a planimeter. The products were identified by comparing retention times with the retention times of knowns.

The gases evolved at the anode in the benzhydrol reaction were tested using a Model 6500 Basic Carle Gas Chromatograph with parallel silica gel and molecular sieve columns and thermal conductivity detectors.

The following commercial surfactants were used: (*i*) neutral surfactants: Triton X-405 (Rohm and Haas), 70% aqueous solution of octyl phenoxy polyethoxy ethanol, Siponic L-4, L-12, and L-25 (Alcolac, Incorporated), laural alcohol ethoxylate; (*ii*) anionic surfactants: Triton 770 conc (Rohm and Haas), 30% aqueous solution of sodium alkyl aryl polyether sulfate, Triton W-30 conc (Rohm and Haas), sodium alkyl ester sulfonate solution in isopropyl alcohol and water, Spencer Poly-EMII Anionic (Spencer Chemical Company); (*iii*) cationic surfactants: Hyamine 2389 (Rohm and Haas), 50% aqueous solution of 80% methyldodecylbenzyl trimethyl ammonium chloride and 20% methyldodecylxylene bis (trimethyl ammonium chloride), Arquad 2C-50 (Armour Industrial Chemical Company), dicocodimethyl ammonium chloride.

Benzhydrol and benzophenone were recrystallized twice from distilled petroleum ether (60°-110°C). Other solid organic compounds were recrystallized from appropriate distilled solvents. All organic solvents used in this investigation were distilled before

* Electrochemical Society Active Member.
Key words: phase transfer, solubilization.

use. The organic materials were checked for purity by either liquid or gas chromatography.

The other chemicals were the best grade that were conveniently available commercially. The experiments were run on the desk top at room temperature.

The yields reported in the tables are calculated on the basis of the amount of reactant added. Yields calculated on the basis of the amount of reactant consumed would be higher. As expected, as the benzhydrol was consumed the current in a run decayed slowly with time. The decay was, within experimental error, linear. For example, in one run the current varied from 480 to 440 mA and the current at the halfway point was 460 mA; in another run where the current varied from 185 to 160 mA the halfway current was 170 mA. Since this decay was essentially linear, the average current density for a typical run recorded in the tables was obtained by taking the mean of the current density at the beginning and end of the experiment. The current efficiencies were determined by using this mean current and multiplying it by the time to calculate the quantity of electricity passed. The current efficiencies and yields are the averages of several runs.

Results and Discussion

Micelle studies.—Table I shows the yields obtained in a suspension containing 0.005 moles of benzhydrol in 2*N* sodium hydroxide containing 2% (by volume) of commercial preparations of cationic, anionic, and neutral surfactants as solubilizing agents when the potential of the anode was 1.90V. Because of the insolubility of the benzhydrol no yield was obtained in the absence of surfactants. It can be seen that the introduction of a cationic surfactant into the system markedly increased the yield while anionic and neutral surfactants had only small effects. However, the neutral surfactant did increase the yield slightly more than did the anionic surfactants. These results are in agreement with the work of Eberson (6, 7) on the use of phase transfer catalysts to increase the yield of products obtained in anodic cyanations since the cationic detergents are phase transfer catalysts.

In order to obtain a clearer picture of the cause of the effects of the surfactants, current-voltage curves were obtained in the different solutions and suspensions using a voltage scan rate of 3 mV/sec. Figure 1 shows curves obtained in 2*N* sodium hydroxide. It can be seen that the cationic surfactant caused a marked shift in the anodic current voltage curve while the neutral and cationic surfactants caused only slight shifts. It can also be seen that the curve obtained in the presence of the cationic surfactant has a maximum in it. Repeated running of linear voltage sweeps, one after the other, caused this maximum to decrease in height with the number of runs. This type of behavior indicates that something is being oxidized to form a difficultly soluble film on the surface of the platinum. That some substance was being oxidized was further indicated by electrolysis of a solution of the cationic surfactant in sodium hydroxide. Upon extraction of this solution with benzene, a red benzene layer was obtained. Although the color was intense, no peak was obtained with high pressure liquid chromatography so that the product was not identified.

Since quaternary ammonium salts are used as supporting electrolytes in electrolytic oxidations, some question exists as to whether the quaternary salt is the substance being oxidized to form the film. Since the 2*N* sodium hydroxide is expected to slowly degrade the salt to form a tertiary amine, a study was made of the effect of some amines on the yields (Table II). As can be seen, these amines did not cause the increase in yield caused by the quaternary ammonium salts. Also, they did not shift the current-potential curves to an appreciable extent. Although this is indicative that the amines do not cause the observed facts, it does not eliminate the possibility that the tertiary amine formed by the degradation of these long chain surfactants is the cause of the film formation.

Figure 2 shows typical current voltage curves obtained in 2*N* sodium hydroxide containing the cationic surfactant and the same solution containing benzhydrol. These curves were obtained after repeated running of current-voltage curves until the maximum observed in Fig. 1 had disappeared. From these results it was concluded that the hydrophobic film formed on the surface of the platinum excludes water from the electrode surface which increases the potential

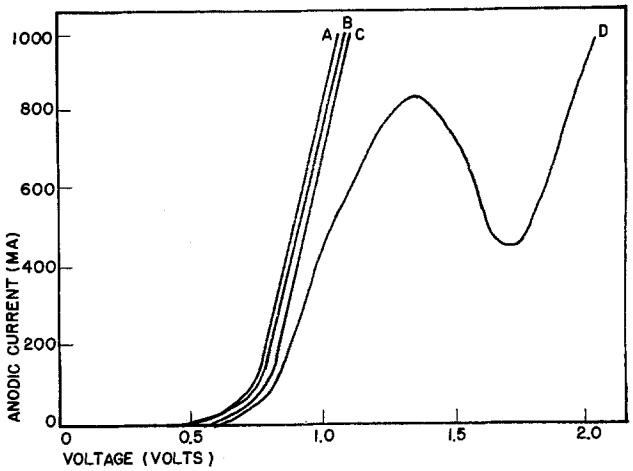

Fig. 1. Effect of different surfactants on the anodic current-potential curves obtained in 2*N* sodium hydroxide: A = no surfactant, B = anionic surfactant, C = neutral surfactant, D = cationic surfactant.

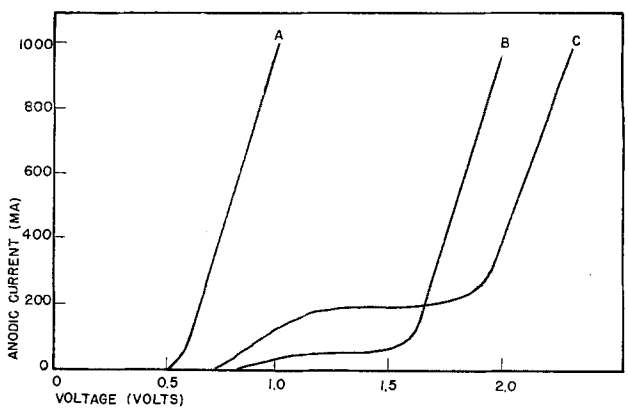

Fig. 2. Current-voltage curves obtained in 2*N* sodium hydroxide containing benzhydrol: A = 2*N* sodium hydroxide, B = 4% solution of Hyamine 2389 in 2*N* sodium hydroxide, C = 0.005M benzhydrol in 4% solution of Hyamine 2389 in 2*N* sodium hydroxide.

Table I. The effect of different types of surfactants on the electro-oxidation of benzhydrol solubilized in micelles

Types of surfactants	% Yield Benzophenone	% Yield Benzopinacol	Typical average current density (mA/cm²)	Average current efficiency
Cationic	29.4	2.9	3.6	64.7%
Anionic	3.5	0.1	2.1	8.3%
Neutral	4.8	0.2	2.1	12.0%

Table II. Effect of amines on the electro-oxidation of benzhydrol in benzene emulsions using platinum electrodes

Amine	Yield of benzophenone
Octylamine	0.0%
sec-butylamine	1.5%
Triethylamine	0.3%

needed to oxidize the water. However, this film is apparently conductive and the organic compound is oxidized on the surface of the film.

The increased yield in the presence of the cationic surfactant then can be attributed, at least in part, to the inhibition of the competing oxidation process, the evolution of oxygen.

Figure 3 shows the effect of different concentrations of surfactants on the yield of benzophenone. It increases with increasing concentration of surfactant until one reaches about 4% then the yield drops off. Correspondingly there is a sharp drop in the current.

Figure 4 shows the variation of percent yield with current efficiency. This data was obtained by increasing the concentration of cationic surfactant. As one increases the concentration of Hyamine 2389, the yield and total current efficiency increase. In fact, the total current efficiency rises above 100%. This led to the conclusion that at least some of the products were produced from a chain mechanism.

$$Ph_2CHOH + OH^- \xrightarrow{-e^-} Ph_2\dot{C}OH + H_2O \quad \text{initiation}$$

$$Ph_2\dot{C}OH \longrightarrow Ph_2C{=}O + H\cdot$$
$$Ph_2\dot{C}HOH + H\cdot \xrightarrow{-e^-} Ph_2\dot{C}OH + H_2 \quad \text{propagation}$$

$$Ph_2\dot{C}OH + H\cdot \longrightarrow Ph_2C{=}O + H_2 \quad \text{termination}$$

Gas chromatographic analysis showed the presence of hydrogen in the gaseous products produced at the anode in agreement with the above mechanism.

Another possible cause of the high current efficiencies would be oxidation of intermediates in the electrolysis in air. This possibility was checked in the benzene emulsion studies by running identical experiments in air, under nitrogen and under oxygen atmospheres. The yield of benzophenone in air was 23.4%, under nitrogen it was 23.6%, and under oxygen it was 23.2%. This lack of change in yield led to the conclusion that autoxidation was not involved. Although this might be different in other solvents it was felt that it was not a likely explanation of the results.

As one increases the temperature one increases both the current and the yield. Table III shows this result using a 4.0% concentration of the cationic surfactant.

Electro-oxidation in Aqueous-Organic Two-Phase Emulsion Systems

Similar studies were made in aqueous-organic emulsions. Benzhydrol could not be oxidized to produce appreciable yields in reasonable times in the benzene emulsions without a surfactant present. Table IV shows that in benzene-2*N* sodium hydroxide emulsions containing 0.4% surfactant, similar to the micelle results, the presence of quaternary ammonium cationic surfactants sharply increased the yield and the current efficiency while anionic and neutral surfactants increased the yield only slightly. Current-voltage curves obtained in these emulsion systems were similar to those obtained in the micelle systems.

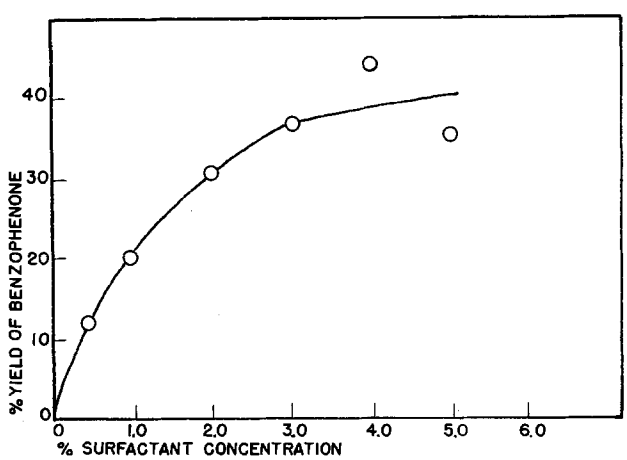

Fig. 3. Effect of cationic surfactant concentrations on the yield of benzophenone obtained from benzhydrol solubilized as micelles in Hyamine 2389.

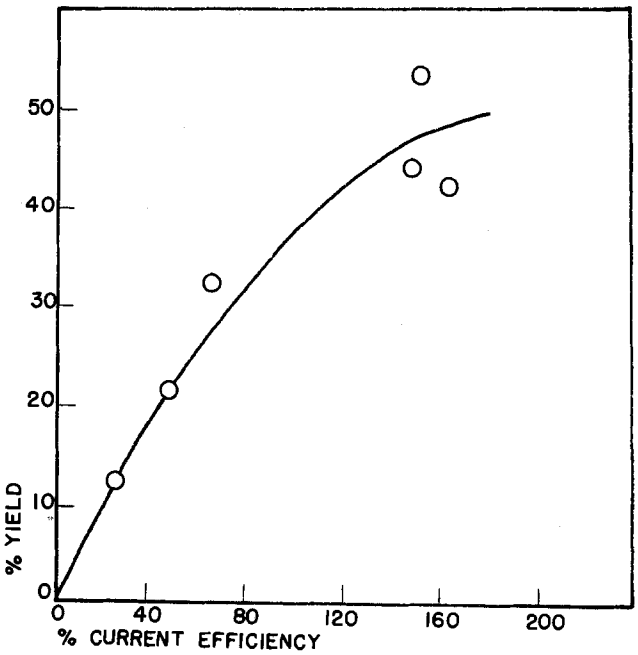

Fig. 4. Relation between the current efficiency and the yield of benzophenone and benzopinacol obtained from the electrolytic oxidation of benzohydrol solubilized in micelles.

Studies were made with different cationic, neutral, and anionic surfactants. In all cases the cationic surfactants increased the yield sharply but the anionic and neutral surfactants changed the yield only by relatively small amounts. Figure 5 shows a comparison of the effect of two different cationic surfactants. It can be seen that with similar surfactants the results are similar.

Although these studies show, in agreement with Eberson, that phase transfer catalysts increase the yield of product it was observed that these long chain cationic surfactants had much more effect than did the more conventional smaller phase transfer catalysts. For example, under conditions similar to Table IV tetraethylammonium bromide produced a yield of only 4.2% and tetraethylammonium chloride produced a yield of 4.1%.

Table III. The effect of temperature on the electro-oxidation of benzhydrol solubilized in micelles

Temperature	% Yield Benzophenone	% Yield Benzopinacol	Typical average current density (mA/cm²)	Average current efficiency
Room temperature	43.4	4.8	2.2	154.6%
60°	86.3	0.2	4.5	128.9%
80°	97.7	0.2	11.7	53.9%

Table IV. Effect of different types of surfactants on the electro-oxidation of benzhydrol in benzene emulsions

Type of surfactant	% Yield Benzophenone	% Yield Benzopinacol	Typical average current density (mA/cm²)	Average current efficiency
None	0.4	0.0	0.3	17%
Anionic (Triton GR-5)	2.8	0.0	3.5	14%
Neutral (Triton X-405)	4.0	0.2	2.7	20%
Cationic (Hyamine 2389)	23.4	1.8	1.9	87%

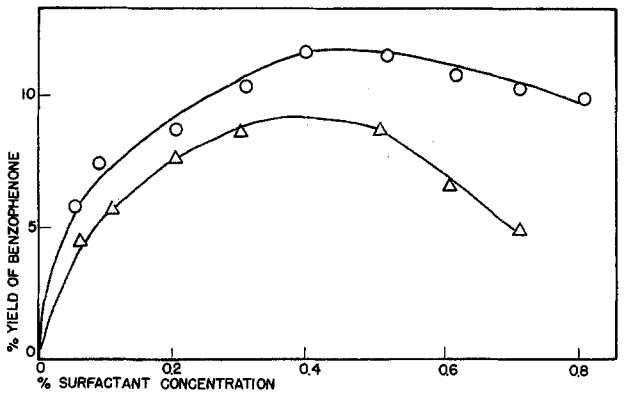

Fig. 5. Effect of different concentrations of cationic surfactant on the yield of benzophenone obtained in benzene emulsions: ○ Hyamine 2389, △ Arquad 2C-50.

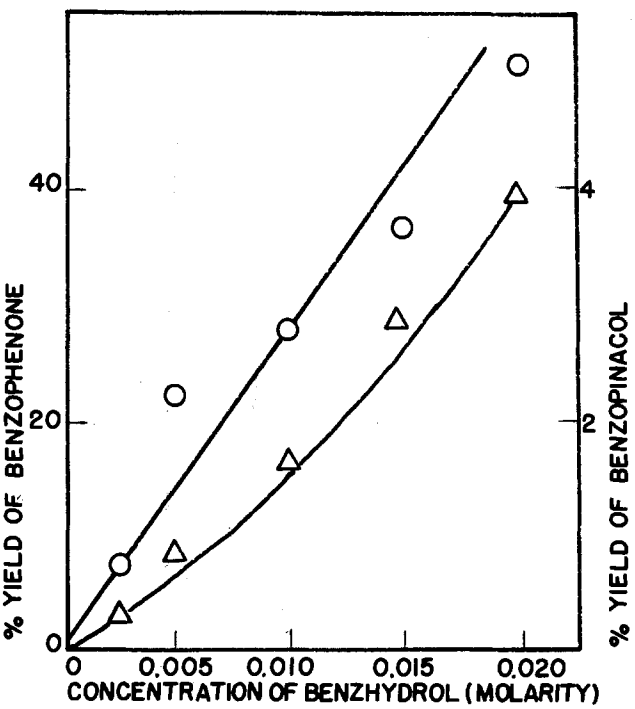

Fig. 6. Relation between the concentration of benzhydrol and the yields of benzophenone and benzopinacol: ○ benzophenone, △ benzopinacol.

As one would expect in a competitive process as the concentration of benzhydrol is increased, the percent yield increases, as can be seen in Fig. 6. There is a small amount of benzopinacol formed in the process and this also can be seen, in Fig. 6, to increase as one increases the concentration of benzhydrol.

Figure 7 shows the effect of potential on the yield of benzophenone and benzopinacol. The curves are similar in shape to the current-voltage curve for oxidation of benzhydrol in the emulsion. The yield increases as the potential rises to about 1.0V. The slight increase in yield between 1.0 and 1.6V follows the slight increase of the current in this region. Above 1.6 the yield rises appreciably. Since this potential region involves the evolution of oxygen, the stirring of the solution probably increases the rate of transport of material to the electrode, thus increasing the yield.

Table V shows the effect of different electrode materials on the yields obtained after electrolysis for 1 hr in benzene emulsions containing 0.4% of Hyamine 2389. It can be seen that best results with the potential held at 1.90V were obtained with platinized and bright platinum.

Table VI shows the effect of different organic solvents on the yield obtained upon addition of 0.4% of

the surfactant (Hyamine 2389) after electrolysis for 1 hr using a bright platinum anode. The decomposition potential of water was essentially shifted to the same potential with all solvents except diethyl ether, dioxane, acrylonitrile, pyridine, acetone, tetrahydrofuran, and methanol. In these solvents there was only a slight shift in the potential and, correspondingly, a low yield. Possibly this means that the electrode film is

Acetonitrile	90.0	2.0	286

Table VII. Yield of product obtained in electro-oxidation reactions on platinized platinum anodes in benzene emulsions with a cationic surfactant present (in all cases there was essentially no yield without the surfactant present)

Reactant	Product	% Yield	% Current efficiency
Benzyl alcohol	Benzaldehyde	17.8	56.0
α Methylbenzyl alcohol	Acetophenone	21.3	156.0
p Methylbenzyl alcohol	p Tolualdehyde	29.9	87.0
p Nitrobenzyl alcohol	p Nitrobenzaldehyde	23.3	46.0

soluble in these solvents. Of the other solvents, acetonitrile caused the largest shift and produced the most yield. It is felt that this is caused by the solubility of the acetonitrile in water which increases the solubility of the organic compound in the water (13).

The oxidation of several other aromatic alcohols was studied. In all cases the cationic surfactant caused a major increase in the yield while anionic and neutral surfactants caused only small increases. Table VII shows the results obtained with different alcohols after electrolysis for 1 hr in a solution containing 0.4% Hyamine 2389.

Summary

It has been observed that the introduction of a cationic surfactant markedly increases the yield of product obtained in the electro-oxidation of several aromatic alcohols solubilized in emulsions and micelles, while anionic or neutral surfactants change the yield only slightly. It was concluded from studies using current-voltage curves that this was caused by the formation of a conducting hydrophobic layer on the surface of the electrode. The best results were obtained with the oxidation of benzhydrol to benzophenone.

A General Oscillator Model for Charge Transfer in Polar Media

S. G. Christov

Institute of Physical Chemistry, Bulgarian Academy of Sciences, Sofia 13, Bulgaria

ABSTRACT

The two-frequency oscillator model is used to describe both electron and proton transfer processes in polar solvents. A low frequency is related to the librations of the solvent medium and a high frequency to either the vibrations in the inner coordination shell of an ion or to that of a proton. The general quantum mechanical formulation of reaction rate theory is employed to overcome the restrictions of previous semiclassical treatments of the same model based on perturbation theory. Thus, a complete treatment of the two-frequency oscillator model is proposed which comprise the whole range between adiabatic and nonadiabatic processes and involves nuclear tunneling at arbitrary temperatures as well. The results of earlier theories are derived as particular cases of this more general consideration of the model. A critical discussion of the oscillator model and a comparison with some experimental facts are made.

In a previous paper (1) a quantum theory of electron transfer in solution was proposed, which rests on a recent general formulation of chemical kinetics (2). The role of the polar solvent was taken into account by using the harmonic oscillator model with a single vibration frequency (3, 4). In this way it is possible to treat separately the extreme cases in which either the outer or the inner solvation sheath of the ion changes during the electron transfer. The general method used permits one to avoid the restrictions of the classical theory (3) and the quantum-mechanical perturbation theory previously used (4) in treating electron transfer processes. In this way the whole region between the adiabatic and the nonadiabatic processes was included in a unified treatment, which takes into account nuclear tunneling at any temperature. The main results of earlier theories (3, 4) were obtained as particular cases in the framework of this treatment.

In the present paper we consider a more general oscillator model with two frequencies ν_x and ν_y ($\nu_y > \nu_x$) which can be related to the solvent medium and the inner coordination shell when treating electron transfer between two ions. The same model is also ap-

Key words: potential barrier, adiabatic and nonadiabatic reactions, nuclear tunneling.

plicable to proton transfer processes if the high frequency (ν_y) is attributed to the proton vibration and the low one (ν_x) to the librations of solvent molecules (5). The purpose of this investigation is to apply the general approach used in Ref. (1) to this more general model and to compare the results with those obtained by other authors (5, 6) with the same model but in a different way. A discussion of the approximations introduced in previous treatments and the limitations involved in the oscillator model, in general, are given in the last section of this paper.

The exact expression for the rate constant of any reaction can be written as (1, 2)

$$k_{12} = \kappa \frac{kT}{h} \frac{Z^H}{Z} e^{-E_a/kT}, \quad \kappa = \kappa_t \chi \qquad [1]$$

where E_a is the classical activation energy (at 0°K), Z is the full partition function of reactants (including solvent molecules) and Z^H is a partition function in which the motion along the reaction path is excluded,[1] $\kappa \gtrless 1$ is a quantum correction factor, $\chi \leq 1$ is the "transmission coefficient," and $\kappa_t \geq 1$ is the nuclear "tunneling correction." Both Z^H and Z refer to the initial state[1] for which an equilibrium energy distribution is postulated. The derivation of Eq. [1] implies that a classical "reaction coordinate" x_r can be defined, which is dynamically separable from the other coordinates in the initial state of the system. A hypersurface S_r in the reactants region, normal to x_r, has to be crossed in a direction to the products region for the reaction to occur with a given probability. Equation [1] involves an integration over S_r and summations over all initial and final states of the systems crossing S_r and passing from the reactants to the products region.

From Eq. [1] we obtain the parameters of the Arrhenius equation

$$k_{12} = K_{12}' e^{-E_a'/kT}$$

defined by

$$E_a' \equiv -k \frac{\partial \ln k_{12}}{\partial (1/T)}, \quad K_{12}' \equiv k_{12} e^{E_a'/kT} \qquad [2]$$

as well as the transfer coefficients (1, 2, 7)

$$\beta \equiv -kT \frac{\partial \ln k_{12}}{\partial Q} = \beta_c - kT \frac{\partial \ln \kappa}{\partial Q} \qquad [3a]$$

and

$$\beta' \equiv \frac{\partial E_a'}{\partial Q} = \beta_c + kT^2 \frac{\partial^2 \ln \kappa}{\partial T \, \partial Q} \qquad [3b]$$

where $\beta_c \equiv \partial E_a / \partial Q$ is the classical transfer coefficient and Q is the reaction heat. The corresponding equations for the Arrhenius parameters $E_a' - Q$ and K_{21}' as well as for the transfer coefficients $\alpha = 1 - \beta$ and $\alpha' = 1 - \beta'$, related to the inverse direction of the reaction, can be easily obtained from the above expressions (1, 2, 7).

The Potential Barrier

We consider the two reactants at a fixed distance R and represent the potential energies in the initial and final state in a harmonic approximation by

$$V_1(x,y) = ax^2 + by^2 + Q_1$$
$$V_2(x,y) = a(x - x_o)^2 + b(y - y_o)^2 + Q_2 \qquad [4]$$

where x and y are Cartesian coordinates describing two vibrations with frequencies

$$\nu_x = \frac{1}{2\pi} \sqrt{\frac{2a}{\mu_x}}, \quad \nu_y = \frac{1}{2\pi} \sqrt{\frac{2b}{\mu_y}} \qquad [4a]$$

μ_x and μ_y being the corresponding effective masses.

The equilibrium position of the initial state is chosen to be at the origin ($x = 0$, $y = 0$) of the coordinate system and that of the final state is at the point

[1] The notion of a "transition state" in the sense of Eyring's theory is not introduced in the above formulation (2a,b).

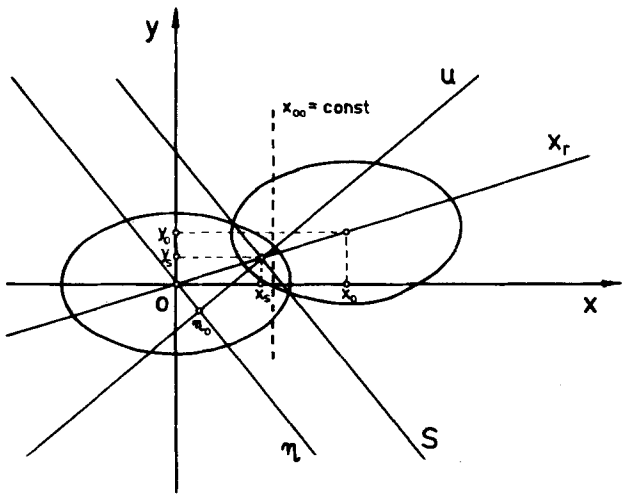

Fig. 1. Projection of the potential surfaces [4] on the plane x,y. The two ellipses correspond to a section $V_1(x,y) = V_2(x,y) =$ const.; $0(x = 0, y = 0)$ initial, x_o,y_o final configuration; S intersection plane of the two paraboloids; x_s,y_s saddle-point; x_r reaction coordinate; u line normal to S, η line parallel to S, η_o crossing point of u and η, x_{oo} = const. line parallel to y ($x_{oo} > x_s$).

($x = x_o$, $y = y_o$). Equation [1] describes two elliptic paraboloids. Their projections on the plane x, y are represented on Fig. 1 by elliptic curves each corresponding to a constant energy value ($V_1 = V_2 =$ const.).

The two paraboloids, Eq. [1], interesect in a plane S and the intersection line has a minimum at a point representing a "saddle-point" with coordinates

$$x_s = \frac{x_o}{2}\left(1 + \frac{Q}{E_r}\right), \quad y_s = \frac{y_o}{2}\left(1 + \frac{Q}{E_r}\right) \qquad [5]$$

where $Q = Q_2 - Q_1$ is the "reaction heat" and

$$E_r = E_r^x + E_r^y = ax_o^2 + by_o^2 \qquad [6]$$

is the sum of the "reorganization energies" of the two oscillators. The height of the "saddle-point," measured from the Q_1 level, is given by

$$E_c' = \frac{(E_r + Q)^2}{4E_r} \qquad [7]$$

Because of the electronic interaction between reactants there is a resonance splitting in the intersection region of the potential surfaces, Eq. [4] so that the height of the saddle-point is lowered by an amount equal to the resonance energy V_{12} at that point. Thus, instead of Eq. [7], we have

$$E_c = E_c' - V_{12} \qquad [8]$$

The line connecting the equilibrium positions (0,0) and (x_o,y_o) is a straight line which goes through the saddle-point (x_s,y_s). It represents the classical "reaction coordinate" x_r, defined by

$$x_r = x\left(1 + \frac{y_o^2}{x_o^2}\right)^{1/2} \qquad [9]$$

The energy profile in a cross cut along x_r (Fig. 2) is obtained by the intersection of two parabolic curves

$$V_1(x_r) = a_r x_r^2 + Q_1$$
$$V_2(x_r) = a_r(x_r - x_r^o)^2 + Q_2 \qquad [10]$$

corresponding to an effective vibration frequency

$$\nu_r = \frac{1}{2\pi} \sqrt{\frac{2a_r}{\mu_r}} = \frac{E_r}{E_r^x/\nu_x + E_r^y/\nu_y} \qquad [11]$$

being the same for the initial and final state. The two curves, Eq. [10], intersect just at the saddle-point

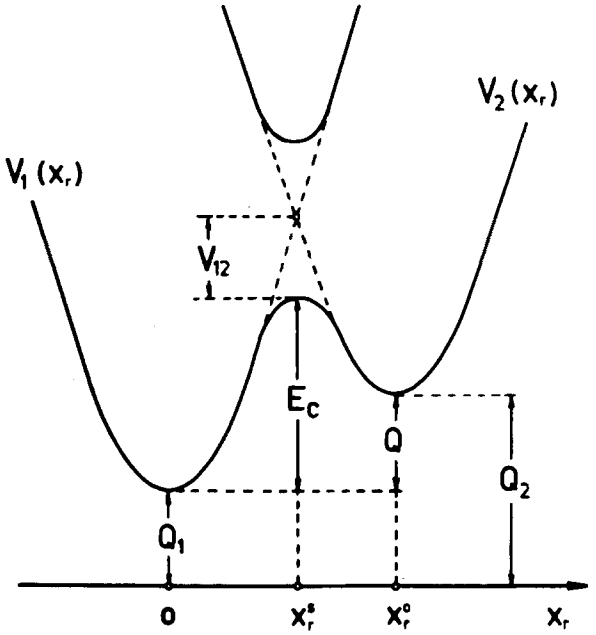

Fig. 2. Energy profile along the reaction coordinate x_r. $V_1(x_r)$ and $V_2(x_r)$ are the potential curves [10] corresponding to the initial and final state; $V_{1,2}$ electronic resonance energy at the crossing point ($x_r = x_r^s$); E_c is the classical activation energy [8] for the endothermic transfer direction ($x_r = 0$ initial, $x_r = x_r^0$ final configuration); $Q = Q_2 - Q_1$ reaction of heat.

(x_s,y_s). Therefore, Eq. [8] represents the classical activation energy for a transition from the initial state (0,0) to the final state (x_o,y_o) along the reaction coordinate x_r.

If the electronic interaction is very weak so that $V_{12} << E_c'$, we have $E_c \simeq E_c'$, hence Eq. [7] is a good approximation for the activation energy. If the interaction is strong (V_{12} large) we can use the expression (1-8)

$$E_c = E_c^\circ + \frac{Q}{2}\left(1 + \frac{\gamma^2 Q}{8E_c^\circ}\right) \qquad [12]$$

where

$$E_c^\circ = \frac{E_c}{4} - V_{12}, \quad \gamma = \frac{2d_o}{x_o} < 1 \qquad [13]$$

and $2d_o$ is the width of a parabolic barrier which approximates the top of the barrier $V(x_r)$ at $Q = 0$. For $V_{12} = 0$, Eq. [12] reduces to Eq. [7] if we set formally $\gamma = 1$.

The classical reaction coordinate, Eq. [9], is a somewhat unusual one since it does not correspond to a minimum of potential energy for motions normal to it except at the points $x_r = 0$, $x_r = x_r^s$, and $x_r = x_r^o$, which determine the initial, the transition, and the final state, respectively. In the initial and final states the reaction coordinate x_r is separable which justifies the use of the rate equation, Eq. [1]. However, in the transition state x_r does not coincide with the coordinate u crossing the saddle-point normal to the intersection plane S of the potential surfaces Eq. [4]. The energy profiles along u are given by the equations

$$V_1(u) = a_u u^2 + \frac{2ax'}{\sqrt{1 + (by_o/ax_o)^2}}u + ax'^2 + Q_1$$

$$V_2(u) = a_u(u - u_o)^2 + \frac{2ax'}{\sqrt{1 + (by_o/ax_o)^2}}(u - u_o) + a(x'' - x_o)^{2+}Q_2 \qquad [14]$$

corresponding to the initial and final state, where

$$\nu_u = \frac{1}{2\pi}\sqrt{\frac{2a_u}{\mu_u}} = \frac{\nu_x^2 E_r^x + \nu_y^2 E_r^y}{\nu_x E_r^x + \nu_y E_r^y} \qquad [15]$$

is the frequency of vibration along u. A comparison with Eq. [11] shows that $\nu_u > \nu_r$. If the resonance splitting is sufficiently large, we can approximate the barrier along u by a parabola with a curvature $|f_u^H| \geq 2a_u$. Therefore, we can define a "characteristic temperature" by (1, 2)

$$T_k = \frac{h\nu_u^H}{\pi k} \geqq \frac{h\nu_u}{\pi k}, \quad \nu_u^H = \frac{1}{2\pi}\sqrt{\frac{f_u^H}{\mu_u^H}} \qquad [16a]$$

where k is the Boltzmann constant, provided $h\nu_u < kT$. If the resonance energy V_{12} is small ($2V_{12} < h\nu_u$) and $h\nu_u > kT$, the characteristic temperature can be estimated by (1)

$$T_k \simeq \frac{h\nu_u}{kK(E_m)}, \quad K(E_m) = \frac{4\pi\sqrt{2\mu_u}}{h}\int_{u_1}^{u_2}\sqrt{V(u) - E_m}du \qquad [16b]$$

where μ_u is the effective mass for motion along u, u_1, and u_2 are the roots of $V(u) - E_m$, and E_m is the highest energy level just below the saddle-point ($E_m < E_c < E_{m+1}$). The derivation of [16a, b] implies an equilibrium energy distribution for motion along u.

We may introduce in a similar way a characteristic temperature T_k^r for the reaction coordinate x_r, hence

$$T_k^r = \frac{h\nu_r^H}{\pi k} \geqq \frac{h\nu_r}{\pi k}, \quad \nu_r^H = \frac{1}{2\pi}\sqrt{\frac{f_r^H}{\mu^H}} \qquad [17a]$$

if the resonance splitting is large and $h\nu_r < kT$, or

$$T_k^r \simeq \frac{h\nu_r}{kK(E_m)}, \quad K(E_m) = \frac{4\pi\sqrt{2\mu_r}}{h}\int_{x_{r,1}}^{x_{r,2}}\sqrt{V(x_r) - E_m}\,dx_r \qquad [17b]$$

if $2V_{12} < h\nu_r$ and $h\nu_r > kT$. Since $\nu_r < \nu_u$, we see that $T_k^r < T_k$, and, therefore, Eq. [16a, b] are to be used as more relevant expressions for the characteristic temperature than Eq. [17a, b].

As shown previously (1, 2) if $T >> T_k$ ($T > 2T_k$) the nuclear tunneling is negligible and if $T << T_k$ ($T < T_k/2$) it plays a dominant role. In the intermediate range ($T_k/2 < T < 2T_k$) the tunneling and the classical transfer mechanism are comparable. In these three temperature ranges we can use different approximations to calculate the rate constant on the basis of expression [1].

The Semiclassical Temperature Range ($T > 2T_k$)

In the high temperature range the most probable path of reaction is the classical reaction coordinate Eq. [9]. Then, the tunneling correction in Eq. [1] is $\kappa_t = 1$ and the transmission coefficient is given by (1, 2)

$$\chi = \int_o^\infty k(\epsilon_r)e^{-\epsilon_r/kT}d\epsilon_r/kT \qquad [18]$$

where $\epsilon_r = E_{x_r} - E_c$, $E_{x_r} = E_o$ being the initial energy for motion along x_r from the initial state ($x_r = 0$) to the final state ($x_r = x_r^o$). The transition probability $k(\epsilon_r)$ can be calculated using the Landau-Zener theory (9) which implies a classical or quasi-classical motion along a separable rectilinear coordinate x_r, *i.e.*, conservation of the energy ϵ_r during the motion along it.[2] Applying the method described in (1) we obtain

$$\chi = \frac{2}{\sqrt{\pi}}\left(\frac{c^2}{kT}\right)^{1/2} << 1 \qquad [19a]$$

$$\chi = 1 - \frac{1}{2}\sqrt{\frac{\pi}{3}}\left(\frac{c^2}{kT}\right)^{1/6}\left\{1 + \mathrm{erf}\left[\sqrt{3}\left(\frac{2c^2}{kT}\right)^{1/6}\right]\right\}e^{-3(c^2/kT)^{1/3}} \qquad [19b]$$

[2] The conditions of validity of the Landau-Zener method have been discussed by Bates (10a) and particularly by Coulson and Zalewski (10b). See also Marcus (3c).

where

$$c = \frac{(2\pi V_{12})^2}{2hF_r}\sqrt{\frac{\mu_r}{2}} = \frac{\pi V_{12}^2}{2h\nu_r\sqrt{E_r}} \quad [20]$$

V_{12} is the resonance integral, μ_r is the effective mass for motion along x_r, $F_r = |\partial(V_1 - V_2)/\partial x_r|_{x=x_r^s}$, x_r^s is the crossing point of the curves, Eq. [10], ν_r is the vibration frequency Eq. [11], and E_r is the total reorganization energy, Eq. [6]. Equation [19a] is valid under the condition $c^2/kT << 1$, *i.e.*, $\chi = 1$ (nonadiabatic reactions) while [19b] applies for the whole range of variation of χ except for $c^2/kT << 1$. If $c^2/kT > 1$, one obtains $\chi \simeq 1$ (adiabatic reactions).

The partition function ratio in Eq. [1] is easily found to be (1)

$$\frac{Z^H}{Z} = \frac{1}{Z_r} = 2\sinh\frac{h\nu_r}{2kT}, \quad \left(\frac{h\nu_r}{kT} < \frac{3}{2}\right) \quad [21]$$

with ν_r given by Eq. [11]. The condition $h\nu_r/kT < 3/2$ follows from Eq. [16a] and [17a].

The classical activation energy is

$$E_a = E_c + Q_1 \quad [22]$$

where for nonadiabatic reactions $E_c \simeq E_c'$ is given by Eq. [7] and for adiabatic reactions $E_c = E_c' - V_{12}$ is to be calculated by Eq. [12].

In this way using Eq. [1] a complete evaluation of the rate constant is possible in the classical temperature range ($T > 2T_k$) for any arbitrary value of c^2/kT and any value of $h\nu_r/kT < 3/2$. In particular, if $h\nu_r/kT << 1$ ($h\nu_r/kT < 0.5$) one gets

$$k_{12} = \frac{V_{12}^2}{h}\left(\frac{\pi}{E_r kT}\right)^{1/2} e^{-Q_1/kT}\, e^{-(E_r+Q)^2/4E_r kT} \quad [23]$$

for nonadiabatic reactions ($\chi << 1$) and

$$k_{12} = \nu_r\, e^{-(Q_1+E_c^0)/kT}\, e^{-\frac{Q}{2kT}\left(1+\frac{\gamma_0^2 Q}{8E_c^0}\right)} \quad [24]$$

for adiabatic reactions ($\chi = 1$), where ν_r is given by Eq. [11], E_r by Eq. [6], and E_c^0 and γ_0 are defined by Eq. [13].

An equation identical with Eq. [23] has been derived by Dogonadze and Kuznetsov (6) in the framework of first-order perturbation theory under the conditions $h\nu_x/kT << 1$ and $h\nu_y/kT << 1$ which are replaced here by the unique conditions $h\nu_r/kT < 0.5$. No equations related to Eq. [24] have been obtained earlier using the oscillator model for charge transfer but similar expressions were derived for arbitrary potentials along the classical reaction path (7, 8). The present treatment covers, however, the whole range between the limiting cases of nonadiabatic and adiabatic reactions for which the formulas [19] for χ apply.

The Intermediate Temperature Range ($2T_k > T > T_k/2$)

Considering the one-dimensional reaction coordinate x_r as a completely separable one, we can calculate the rate constant by Eq. [1] for any temperature ($T \gtrless T_k$) and any vibration frequency ν_r ($h\nu_r/kT \gtrless 1$) using the expressions derived in Ref. (1). Actually, x_r is not separable in the transition region ($x_r \approx x_r^s$) because it does not represent a normal coordinate there. In this intermediate temperature range the nuclear tunneling plays a moderate role and the most probable reaction path is that along the normal coordinate u which crosses the intersection plane S through the saddle-point (Fig. 1). We, therefore, consider a surface S_r which goes through the initial state ($x = y = 0$) along the line η parallel to S. Then, Eq. [1] can be written as

$$k_{12} = \kappa_u \frac{kT}{h}\frac{Z_\eta^H}{Z} e^{-E_a/kT} \quad [25]$$

where

$$\kappa_u = \int_{-E_c}^{\infty} k(\epsilon_u)\, e^{-\epsilon_u/kT}\, d\epsilon_u/kT, \quad Z_\eta^H = \sum_n e^{-E_n^\eta/kT} \quad [26]$$

$\epsilon_u = E_u - E_c$, $E_u = E_u(\eta_0)$ is the initial energy for motion along u, η_0 being the cross-point of η and u, $k(\epsilon_u)$ is the transition probability along u, Z_η^H is the partition function for motion along η.

The transition probability $k(\epsilon_u)$ in Eq. [26], which involves both the electron and nuclear rearrangement, cannot be evaluated exactly in the intermediate temperature range. However, an approximate estimation is possible by independent calculations of the electron transfer probability using the Landau-Zener theory (9) and the nuclear transfer probability by applying stationary state methods (1). This combined treatment is allowed since the Landau-Zener method is valid also for a quasi-classical motion of nuclei (10) involved in a moderate tunneling correction.

The exact transmission coefficient for motion along u is obtained from Eq. [26] if we neglect the nuclear tunneling which gives the expression

$$\chi_u = \int_0^{\infty} k(\epsilon_u)\, e^{-\epsilon_u/kT} d\epsilon_u/kT \quad [27]$$

which is similar to [18] and can be calculated in the same way. Thus, we get again expressions [19a, b] with c replaced by

$$c_u = \frac{(2\pi V_{12})^2}{2hF_u}\sqrt{\frac{\mu_u}{2}} = \frac{\pi V_{12}^2}{2h\nu_u\sqrt{E_r^u}} \quad [28]$$

where ν_u is given by Eq. [15] and the corresponding reorganization energy

$$E_r^u = a_u u_0^2 = \frac{\nu_u}{\nu_y^2}(\nu_x E_r^x + \nu_y E_r^y) \quad [29]$$

is determined by the intersection point u_0 of u with the line $y = y_0$.

If the reaction is adiabatic ($\chi_u = 1$) Eq. [26] gives the nuclear tunneling correction which is found to be (1, 2, 7)

$$\kappa_t = \frac{(\pi/2)(T_k/T)}{\sin[(\pi/2)(T_k/T)]}, \quad (T > T_k/2) \quad [30]$$

where T_k is given by Eq. [16a] if $h\nu_u < kT$. The same expression may be used for approximate estimates of κ_t also for $\chi < 1$, although it may be inaccurate when the exchange integral V_{12} is very small. If the resonance splitting is so small that $2V_{12} < h\nu_u$ and $h\nu_u > kT$, the tunneling correction can be estimated by[3]

$$\kappa_t = 1 + \frac{e^{h\nu_u/kT}}{1 + e^{h\nu_u/kT_k}} \quad [31]$$

where T_k is now defined by [16b]. Thus, the formulas [30] and [31] for κ_t and the expressions [19a, b] for χ with [28] and [29] permit an approximate evaluation of the quantum-correction $\kappa_u \simeq \kappa_t\chi_u$ in [25] in the temperature range $2T_k > T > T_k/2$ (1).

The ratio Z_η^H/Z in [25] is given by

$$\frac{Z_\eta^H}{Z} = \frac{1}{Z_u}\, 2\sinh\frac{h\nu_u}{2kT} \quad [32]$$

which is similar to [21].

[3] Under the above conditions κ_t is given approximately by the formula (1)

$$\kappa_t = 1 + \frac{\sum_n^{0,m} W(E_n^u)\, e^{-E_n^u/kT}}{\sum_n^{m+1,\infty} e^{-E_n^u/kT}}, \quad W(E_n^u) = \frac{1}{1 + e^{K(E_n^u)}}$$

where m is the highest energy level below the barrier peak ($E_m < E_c < E_{m+1}$). In the temperature range $2T_k > T > T_k/2$ the main contributions to the above sums are that from the m level (in the nominator) and the $m + 1$ level (in the denominator) so that using [16b] one gets [31].

Using the above expressions, we can calculate the rate constant in the intermediate temperature range. Especially, we obtain for nonadiabatic reactions the approximate expressions

$$k_{12} = \frac{V_{12}^2}{h}\left(\frac{\pi}{E_r^u kT}\right)^{1/2} \frac{(\pi/2)(T_k/T)}{\sin[(\pi/2)(T_k/T)]} e^{-Q_1/kT} e^{-(E_r^u+Q)^2/4E_r^u kT} \quad [33a]$$

if $h\nu_u/kT < 0.5$ and

$$k_{12} = \frac{V_{12}^2}{h}\left(\frac{\pi}{E_r^u kT}\right)^{1/2}\left(1+\frac{e^{h\nu_u/kT}}{1+e^{h\nu_u/kT_k}}\right) e^{-\left(Q_1-\frac{h\nu_u}{2}\right)\Big/ kT} e^{-(E_r^u+Q)^2/4E_r^u kT} \quad [33b]$$

if $h\nu_u/kT > 2$. For adiabatic reactions one gets

$$k_{12} = \nu_u \frac{(\pi/2)(T_k/T)}{\sin[(\pi/2)(T_k/T)]} e^{-(Q_1+E_c^o)/kT} e^{-\frac{Q}{2kT}\left(1+\frac{\gamma_u^2 Q}{8E_{c,u}^o}\right)} \quad [34a]$$

if $h\nu_u/kT < 0.5$ and

$$k_{12} = \frac{kT}{h}\frac{(\pi/2)(T_k/T)}{\sin[(\pi/2)(T_k/T)]} e^{-\left(Q_1+E_c^o-\frac{h\nu_u}{2}\right)\Big/ kT} e^{-\frac{Q}{2kT}\left(1+\frac{\gamma_u^2 Q}{8E_c^o}\right)} \quad [34b]$$

if $h\nu_u/kT > 2$. The conditions of validity of [33] and [34] are certainly compatible with the limits of the intermediate temperature range $2T_k > T > T_k/2$ ($h\nu_u^H > kT > h\nu_u^H/2\pi$) if $\nu_u^H >> \nu_u$.

The presence of a quantum correction of the form $\kappa = \kappa_t\chi$ in [33a, b] takes into account, although approximately, the compensating effect (1) arising from the electron and the nuclear tunneling, related to χ and κ_t, respectively.

The application of the expression [30] or [31] for κ_t implies that the reaction heat varies in the range (1, 7, 11)

$$-4E_{c,u}^o < Q < 4E_{c,u}^o, \quad E_{c,u}^o = \frac{E_r^u}{4} - V_{12} \quad [35]$$

If, however, $Q \sim \pm 4E_{c,u}^o$, then κ_t depends on Q and can be estimated by (7, 11)

$$\kappa_t = \frac{(\pi/2)(T_k/T)}{\sin[(\pi/2)(T_k/T)]} - \frac{T_k/T}{1-(T_k/T)} e^{(T_k/T-2)\delta_o(E_c^u-Q)}, \quad (T > T_k/2) \quad [36a]$$

$$\kappa_t = 2\delta_o(E_c^u - Q)\left[1+\frac{1}{2}\left(\frac{T_k}{T}-2\right)\delta_o(E_c^u-Q) - \dots\right], \quad (T \simeq T\kappa/2) \quad [36b]$$

if $h\nu_u/kT < 1$. Here $\delta_o = \pi^2 d_u\sqrt{2\mu_u E_{c,u}^o}/hE_{c,u}^o$, $d_u = \gamma_u l_u$ is the half-width of a parabolic barrier which approximates the top region of the real barrier $V(u)$ at $Q = 0$, l_u is the half-width of the barrier, E_c^u is the barrier height which is given by [12] with E_c^o replaced by $E_{c,u}^o$ and γ by $\gamma_u = d_u/l_u < 1$. Therefore

$$E_c^u - Q = E_{c,u}^o - \frac{Q}{2}\left(1-\frac{\gamma_u^2 Q}{8E_{c,u}^o}\right) \quad [37]$$

From the above equations one easily gets the corresponding expressions for the Arrhenius parameters [2] and the transfer coefficients [3a, b]. According to [19] and [30] both χ and κ_t are independent of Q, therefore, from [3a, b], [33], and [34]

$$\beta' = \beta = \beta_c = \frac{1}{2}\left(1+\frac{\gamma_u^2 Q}{4E_{c,u}^o}\right) \quad [38]$$

However, near the boundaries of the range [35], using [36] instead of [30], we get different expressions for β' and β, which give us evidence for nuclear tunneling (1, 2a, 7). We thus find that $\beta' > \beta_c$ and $\beta > \beta_c$. For instance, from [3b] and [36b] ($T \gtrsim T_k/2$)

$$\beta = \beta_c + \frac{kT}{E_c^u - Q} \quad [39a]$$

$$\beta' = \beta_c + \frac{\delta_o kT_k}{4}\left(1-\frac{\gamma_u^2 Q}{4E_{c,u}^o}\right) \quad [39b]$$

where β_c is given by [38], $E_c^u - Q > kT$, $|Q| < 4E_{c,u}^o$ and $\gamma_u < 1$. In particular, from [3b] and [39b] it follows that

$$E_a' = Q, \quad \beta_c = 1 - \frac{\delta_o kT_k}{4}\left(1-\frac{\gamma_u^2 Q}{4E_{c,u}^o}\right) \quad \text{for } \beta' = 1 \quad [40a]$$

$$E_a' = 0, \quad \beta_c = -\frac{\delta_o kT_k}{4}\left(1-\frac{\gamma_u^2 Q}{4E_{c,u}^o}\right) \quad \text{for } \beta' = 0 \quad [40b]$$

Equations [40a, b] refer to the so-called barrierless and activationless processes, respectively. Since $|Q| \lesssim 4E_{c,u}^o$ and $\gamma_u < 1$, we see that in [40a] $\beta_c < 1$ and in [40b] $\beta_c < 0$.

A treatment of the intermediate temperature range using the oscillator model has not been given in previous theories of charge transfer in solution. However, the adiabatic case ($\chi = 1$) was actually considered earlier (7, 8) for more general potentials along the reaction coordinate and the main results of these investigations are related to Eq. [34a, b]. The present paper includes also the whole range between adiabatic and nonadiabatic reactions, the latter being represented by [33a, b]. The barrierless and activationless processes are treated here using [36a, b] which permits inclusion of nuclear tunneling, usually neglected in previous considerations (5, 6). In this respect, it should be emphasized (1, 2a, 7) that the difference between the transfer coefficients β and β', defined by [3a, b] is not taken into account by other authors.

The Low Temperature Range ($T < T_k/2$)

If $\nu_x \sim \nu_y$ and $E_r^x \sim E_r^y$, the most probable reaction path will remain that along the normal coordinate u in the low temperature range ($T < T_k/2$) too. Then, Eq. [25] applies again and $\kappa_u = \chi_u\kappa_t^u$ can be estimated using the procedure developed earlier (1).

We consider now the low temperature range by assuming that in [4] $\nu_y >> \nu_x$ and $y_o << x_o$, so that in [6] $E_r^y < E_r^x$. Then, the nuclear tunneling occurs mainly along lines parallel to the y-axis. The most probable reaction path is that which goes initially from the origin of the coordinate system ($x = y = 0$) along x till some point x_{oo} near to x_s, then crosses the saddle parallel to y till the point $x = x_{oo}$, $y = y_o$ and goes further parallel to x until the final state $x = x_o$, $y = y_o$. We, therefore, consider a surface S_r, representing the initial state, which goes through the origin (0,0) along the y-axis. This surface has to be crossed in direction x. The motion along x is assumed to be a quasi-classical one. Equation [1] can be then written as

$$k_{12} = \kappa_x \frac{kT}{h}\frac{Z_y^H}{Z} e^{-E_a/kT} \quad [41]$$

where (2)

$$\kappa_x = \int_{-E_c}^{\infty} k(\epsilon_x) e^{-\epsilon_x/kT} d\epsilon_x/kT,$$

$$k(\epsilon_x) = \sum_n f(\epsilon_n, T) \sum_{n'} k_{nn'}(\epsilon_x) \quad [42]$$

$$f(\epsilon_n,T) = \frac{e^{-\epsilon_n/kT}}{Z_y^H}, \quad Z_y^H = \sum_n e^{-\epsilon_n/kT} \qquad [43]$$

Here $\epsilon_x = E_x - E_c$, $E_x = E_o$ is the initial energy for motion along x; ϵ_n is the vibration energy along y, Z_y^H is the corresponding partition function; $k_{nn'}$ is the transition probability from the initial state n to the final state n'; $k(\epsilon_x)$ is an average value of the total transition probability $k_n = \sum_{n'} k_{nn'}$ over the initial states n.

The summations over n and n' in [42] must be consistent with the conservation of total energy E, for which using [4] we write the equations

$$E_1 = E_x + \epsilon_n = ax^2 + Q_1 + \epsilon_x + \epsilon_n$$

$$E_2 = E_x' + \epsilon_{n'} = a(x - x_o)^2 + Q_2 + \epsilon_x' + \epsilon_{n'} \qquad [44]$$

corresponding to the initial and final states. Setting $E_1 = E_2$, since $\epsilon_x = \epsilon_x'$, we obtain

$$x_{nn'} = \frac{x_o}{2}\left(1 + \frac{Q - (\epsilon_n - \epsilon_{n'})}{ax_o^2}\right), \quad Q = Q_2 - Q_1 \qquad [45]$$

which determines a set of lines $x = x_{nn'} = \text{const.}$, parallel to y, along which tunneling transitions are possible. The set of points $x_{nn'}$ can be defined as a "transition state" configuration.

Since $\nu_y >> \nu_x$, the motion along x is very slow compared with that along y, so that during the passage of a small interval Δx the system is making many vibrations along y both in the reactants and products potential valley. Traveling slowly from the initial state ($x = 0$, $y = 0$) to the transition state ($x_{nn'}$) in the reactant's valley the system remains in the same quantum state (n). Therefore, there also exists an equilibrium energy distribution in the transition state given by [43]. Passing along any of the lines $x_{nn'} = \text{const.}$ in the product's valley, the system could change its vibrational state ($n = n'$) but afterwards moving slowly parallel to x to the final state ($x = x_o$, $y = y_o$) it remains again in the same quantum state (n'). However, because of the slow motion along x, the probability of a nonadiabatic transition ($n \to n'$) is very small. Therefore, we have reasons to assume that no changes of the quantum number n occur in the transition state too, so that $n = n'$. Then, the transition configuration [45] is reduced to a single point

$$x_{nn} = x_{oo} = \frac{x_o}{2}\left(1 + \frac{Q}{E_r^x}\right), \quad E_r^x = ax_o^2 \qquad [46]$$

Hence, there is a unique line $x_{oo} = \text{const.}$, parallel to y, along which all the transitions from the reactant's to product's valley occur (Fig. 1). It results, at these conditions, that throughout the course of reaction the system remains all the time in the same quantum state n, *i.e.*, the reaction is vibrationally adiabatic. This justifies the use of the notion of an "activated complex" as a stationary state configuration, defined by [46]. It should be noted, however that the line $x_{oo} = \text{const.}$, does not pass through the saddle-point Fig. 1, as seen from a comparison between [5] and [46] ($x_{oo} > x_s$). Only when $E_r^y << E_r^x$ ($E_r \simeq E_r^x$), then, according to [6], $x_{oo} \simeq x_s$ and the system crosses the saddle very near to the saddle-point.

The energy profile along the line $x_{oo} = \text{const.}$ (Fig. 3) represents a symmetric barrier, described by the equations

$$V(x_{oo},y) = \begin{cases} V_1(x_{oo},y) = ax_{oo}^2 + by^2 + Q_1 + u_{12}(y), \\ \qquad\qquad (y < y_o/2) \\ V_2(x_{oo},y) = a(x_{oo} - x_o)^2 + b(y - y_o)^2 \\ \qquad + Q_2 + u_{12}(y), \quad (y > y_o/2) \end{cases} \qquad [47]$$

$u_{12}(y)$ being the electron exchange energy. The barrier height is given by

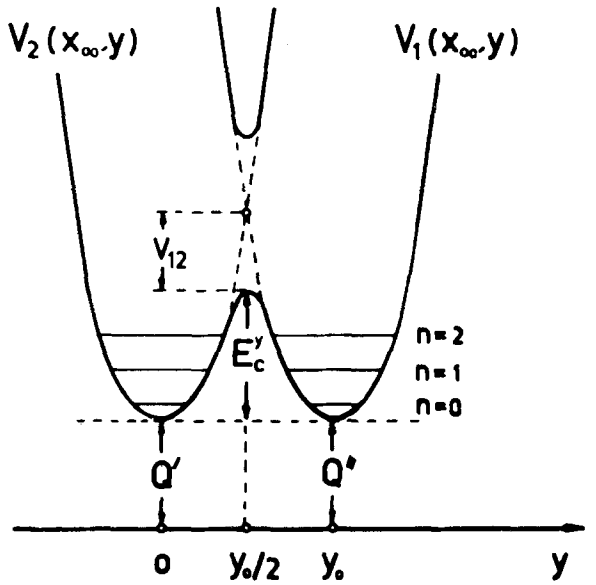

Fig. 3. Energy profile along the line $x_{oo} = \text{const.}$ corresponding to Eq. [47]; $y = 0$ initial and $y = y_o$ final configuration for tunneling parallel to y. $Q' = ax_{oo}^2 + Q_1$ and $Q'' = a(x_{oo} - x_o)^2 + Q_2$ are equal ($Q' = Q''$); V_{12} electronic exchange energy at the intersection point ($y = y_o/2$) of the unperturbed ($u_{12} = 0$) potential curves [47]; E_c^y is the barrier height given by [48].

$$E_c^y = \frac{E_r^y}{4} - V_{12}, \quad E_r^y = by_o^2 \qquad [48]$$

where $V_{12} = u_{12}(y_o/2)$, so that $2V_{12}$ is the resonance splitting at the crossing point ($y = y_o/2$) of the unperturbed parabolic curves [47] ($u_{12} = 0$).

The vibrational adiabatic, involved in the above definition of the activated complex, allows one to assume an identical equilibrium energy distribution in the two symmetrical potential wells on both sides of the barrier [48]. The distribution function is given by [43], hence the partition function Z_y^H, which refers to the initial state, can be related to the transition state as well.

The adiabatic condition $n = n'$ requires that in [42]

$$k_{nn'}(\epsilon_x) = 0 \text{ for } n \neq n';$$

$$k_{nn'}(\epsilon_x) = k_{nn}(\epsilon_x) \neq 0 \text{ for } n = n' \qquad [49]$$

Then [41] can be considered as a generalized expression of activated complex theory which includes a relevant quantum correction κ_x (2b). The adiabatic justification of the usual classical equation ($\kappa_x = 1$) of this theory (12, 13) allows one to describe the slow motion along the reaction coordinate x by a potential function

$$V_n(x) = \begin{cases} V_1(x) + \epsilon_n + u_{nn}(x) = ax^2 + Q_1 \\ \quad + \left(n + \frac{1}{2}\right)h\nu_y + u_{nn}(x), \quad (x < x_{oo}) \\ V_2(x) + \epsilon_n + u_{nn}(x) = a(x - x_o)^2 + Q_2 \\ \quad + \left(n + \frac{1}{2}\right)h\nu_y + u_{nn}(x), \quad (x > x_{oo}) \end{cases} \qquad [50]$$

which involves the electronic energy $V_{12}(x)$ and the energy ϵ_n of the fast vibration along y, including some resonance energy $u_{nn}(x)$, assumed to be large, which is necessary for the adiabatic transition to occur (Fig. 4).

Equation [50] represents a set of potential curves corresponding to the different vibrational states n. These potentials may be used also when considering the quantum effects, *i.e*, the nuclear tunneling along x and the nonadiabatic transitions which can take place only at the "intersection" point x_{oo} of each pair of

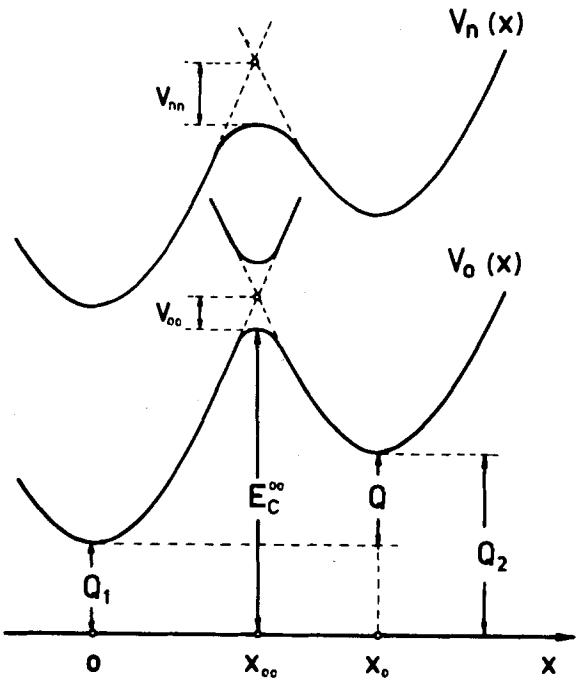

Fig. 4. Adiabatic potential curves corresponding to Eq. [50] ($n = 0$ and $n = n$); $x = 0$ initial and $x = x_0$ final configuration. V_{nn} is the resonance energy [57] at the crossing point ($x = x_{oo}$) of the unperturbed ($u_{nn} = 0$) potential curves [50]. (Note that $V_{nn} > V_{oo}$); E_c^{oo} is the height [53] of the ground state ($n = 0$) potential barrier for the endothermic transfer direction ($0 \rightarrow x_0$); $Q = Q_2 - Q_1$ heat of reaction.

curves [50], corresponding to a given n, if the resonance splitting is not very large.

Using [49] from [41]-[43] we obtain

$$k_{12} = \frac{kT}{hZ} \sum_n \kappa_n e^{-E_c^{nn}/kT} \qquad [51]$$

with

$$\kappa_n = \int_{-E_c^{nn}}^{\infty} k_{nn}(\epsilon_x^n) e^{-\epsilon_x^n/kT} d\epsilon_x^n/kT \qquad [52]$$

$$E_c^{nn} = ax_{oo}^2 + \epsilon_n - V_{nn} + Q_1 \qquad [53]$$

where $\epsilon_x^n = E_x - E_c^{nn}$, E_c^{nn} is the height of any of the potential barriers [50], $2V_{nn} = 2u_{nn}(x_{oo})$ being the resonance splitting at the corresponding crossing point. Setting $\kappa_n = 1$, one gets from [51] a classical rate equation which is related to the Eyring's expression of transition state theory (12b).

To calculate the quantum factors κ_n in [51] we first assume a classical motion along x, *i.e.*

$$k_{nn} = 0 \text{ for } \epsilon_x^n = 0 \quad (E_x < E_c^{nn});$$

$$k_{nn} \neq 0 \text{ for } \epsilon_x^n > 0 \quad (E_x > E_c^{nn}) \qquad [54]$$

so that [52] turns into

$$\chi_n = \int_0^{\infty} k_{nn}(\epsilon_x^n) e^{-\epsilon_x^n/kT} d\epsilon_x^n/kT \qquad [55]$$

which is similar to [18] and [27]. The transition probability k_{nn} involves now the nuclear tunneling only along the line $x_{oo} = \text{const.}$, parallel to y, with a simultaneous rearrangement of the electronic state. This suggests (1, 5) to use again the Landau-Zener theory (9), which leads to the expressions [19] with c replaced by

$$c_{nn} = \frac{(2\pi V_{nn})^2}{2hF_{nn}} \sqrt{\frac{\mu_x}{2}} = \frac{\pi V_{nn}^2}{2h\nu_x \sqrt{E_r^x}} \qquad [56]$$

where

$$V_{nn} = \int \psi_n^{(1)}(y) V_{12} \psi_n^{(2)}(y) dy \qquad [57]$$

is the exchange integral expressed in terms of the wave functions of the y-vibrations in the two potential wells of the "transition state" ($x_{oo} = \text{const.}$) and the electronic resonance energy $V_{12} = u_{12}(y_o/2)$ at the intersection point of the curves [47].

The exchange integral V_{nn} can be used as a matrix element to calculate the transition probability W_{nn} along $x_{oo} = \text{const.}$ in the framework of first-order perturbation theory, which gives (1)

$$W_{nn} = \left(\frac{2\pi V_{nn}}{h\nu_y}\right)^2 << 1 \qquad [58]$$

Alternatively, W_{nn} can be represented as

$$W_{nn} = W_e(\epsilon_n) W(\epsilon_n) \qquad [59]$$

where $W_e(\epsilon_n)$ and $W(\epsilon_n)$ are the probabilities of electron and nuclear rearrangement, respectively. We see from [58] that $W_{nn} << 1$ when either V_{nn} is small or $h\nu_y$ is large and from [59] that $W_{nn} << 1$ when either $W_e(\epsilon_n) << 1$ or $W(\epsilon_n) << 1$. From [58] and [59]

$$V_{nn}^2 = \left(\frac{h\nu_y}{2\pi}\right)^2 W_e(\epsilon_n) W(\epsilon_n) \qquad [60]$$

If $W(\epsilon_n) << 1$ and $0 \lesssim W_e(\epsilon_n) \lesssim 1$, we can use the expressions[4] (14)

$$W_e(\epsilon_n) = \frac{2\pi}{\gamma_n \Gamma^2(\gamma_n)} e^{-2\gamma_n(1 - \ln \gamma_n)},$$

$$\gamma_n = \frac{V_{12}^2}{2\pi h\nu_y} \left[\frac{\pi^2}{E_r^y(E_r^y/4 - \epsilon_n)}\right]^{1/2} \qquad [61]$$

and (1)

$$W(\epsilon_n) = e^{-K(\epsilon_n)},$$

$$K(\epsilon_n) = \frac{4\pi\sqrt{2\mu_y}}{h} \int_{y_1}^{y_2} \sqrt{V(x_{oo}, y) - \epsilon_n}\, dy \qquad [62a]$$

$$W(\epsilon_n) = \frac{h}{4\mu_y \nu_y} \left(\psi_n^{(2)} \frac{d\psi_n^{(1)}}{dy} - \psi_n^{(1)} \frac{d\psi_n^{(2)}}{dy}\right)_{y = y_0/2} \qquad [62b]$$

The quasi-classical formula [62a] has been treated in (1) where $K(\epsilon_n)$ is calculated exactly with the potential [47] at condition that $V_{12} << E_r^y/4$. The more accurate current density expression [62b] is also evaluated exactly, at the same condition, using the harmonic oscillator wave functions (1). The agreement between both formulas is quite good in a large range of variation of the ratio $E_r/h\nu$ (between 10 and 100). The condition $W(\epsilon_n) << 1$ is practically fulfilled if $K(\epsilon_n) > 2$ (14b) which corresponds to $\epsilon_n << E_r^y/4$. This allows one to use [61] with the approximation $\gamma_n \simeq \gamma_o$, *i.e.*

$$W_e(\epsilon_n) \simeq W_e(\epsilon_o), \quad \gamma_n \simeq \gamma_c \simeq \frac{V_{12}^2}{h\nu_y E_r^y} \qquad [61']$$

If $W_e(\epsilon_n) << 1$ and $0 \lesssim W(\epsilon_n) \lesssim 1$ one may use the approximations

$$W_e(\epsilon_n) = 2\pi\gamma_n \qquad [63]$$

$$W(\epsilon_n) = \frac{1}{1 + e^{K(\epsilon_n)}} \qquad [64]$$

[4] Using linear approximation for the potential curves $V_1(y)$ and $V_2(y)$ in their intersection region, the transfer probability is found [14] to be a product $W = W_e W_n$ of two factors, corresponding to electron and nuclear rearrangement, given by [61] and [62a], respectively. The use of these expressions in the low energy range is justified also for the parabolic potentials [47]. One obtains, indeed, for $\gamma_n << 1$, using expressions [63] and [61']

$$W_e(\epsilon_n) \simeq 2\pi\gamma_o = 2\pi V_{12}^2/h\nu_y E_r^y$$

which just coincides with the factor in Eq. [51] in Ref. (4b) related to the harmonic oscillator model. For $\gamma_n >> 1$, $W_e(\epsilon_n) = 1$ and $W(\epsilon_n)$ is again correctly given by [62a]. This suggests that [61] and [62a] may be used for any intermediate value of γ_n ($\gamma_n \gtrless 1$) too.

the first one being obtained from [61] for $\gamma_n << 1$ and the second one is a generalization of [62a] (15, 16).

In this way using [60] to [64] we are able to estimate the exchange integrals [57] for all n consistent with the condition $W_{nn} << 1$. Thus, by means of [56] the transmission coefficients [55] can be evaluated for all values of c_{nn}^2/kT, *i.e.*, for the whole range $0 \leq \chi_n \leq 1$ for which the formulas [19a, b] are applicable.

If $\chi_n = 1$ [*i.e.*, $(c_{nn}^2/kT)^{1/3} > 1$], then κ_n in [51] will represent the nuclear tunneling correction to be calculated by [52] using the potential functions [50]. This has been actually done (1) for arbitrary temperatures both for $h\nu < kT$ and $h\nu > kT$. In particular, if $h\nu_x < kT$, in the region of moderate tunneling along x ($T > T_k/2$) we may use an expression like [30], in which T_k is replaced by

$$T_k^n = \frac{h\nu_{x,n}^H}{\pi k} \qquad [65]$$

$\nu_{x,n}^H$ being determined for any potential $V_n(x)$ by the curvature of the barrier top ($x = x_{oo}$). Expressions for the large tunneling region ($T < T_k^n/2$) are available too (1). The full quantum corrections κ_n in [51] can be estimated approximately by the product[5] $\kappa_n \simeq \kappa_t^n \chi_n$ for any values of χ_n ($0 < \chi_n \leq 1$).

Retaining only the first term ($n = 0$) in [51], by assuming that $h\nu_x/kT < 0.5$ and $h\nu_y/kT > 2$, one gets

$$K_{12} = \nu_x \kappa_o e^{-(E_c^{oo})/kT} \qquad [66]$$

If $T > T_k^o/2$, this expression with [19], [30], [56], [60], [61], [62b], and [65] yields

$$K_{12} = \frac{V_{12}^2}{h}\left(\frac{\pi}{E_r^x kT}\right)^{1/2} e^{-E_r^y/h\nu_y} \frac{(\pi/2)(T_k^o/T)}{\sin[(\pi/2)(T_k/T)]} e^{-Q_1/kT} e^{-(E_r^x+Q)^2/4E_r^x kT} \qquad [67]$$

for nonadiabatic reactions ($\chi_o << 1$) and

$$K_{12} = \nu_x \frac{(\pi/2)(T_k/T)}{\sin(\pi/2)(T_k/T)} e^{-(Q_1+E_{c,x}^o)/kT} e^{-\frac{Q}{2kT}\left(1+\frac{\gamma_x^2 Q}{4E_{c,x}^o}\right)} \qquad [68]$$

for adiabatic reactions ($\chi_o = 1$), where $E_{c,x}^o = E_r^x/4 - V_{oo}$, $\gamma_x = 2d_x/x_o$, $2d_x$ is the width of a parabolic barrier approximating the barrier [50], $V_0(x)$, near its top. Expressions for the intermediate range of χ_o ($0 < \chi_o < 1$) can be easily derived from [66] using [19] and [56].

The parameters [2] of the Arrhenius equation can be calculated from the above rate equations. In the normal range of variation of Q

$$-4E_{c,x}^o < Q < 4E_{c,x}^o, \quad E_{c,x}^o = E_r^x/4 - V_{oo} \qquad [69]$$

we find again that the transfer coefficients [3a, b] are equal ($\beta' = \beta = \beta_c$) and can be expressed by [38] by replacing $E_{c,u}^o$ by $E_{c,x}^o$ and γ_u by γ_x. Near the limits of the range [69], using [36] with T_k^o instead of T_k, one gets equations similar to [39] and [40], which refer to the barrierless and activationless processes in the low temperature range ($T < T_k/2$).

If $T > 2T_k^o$, according to [30] $\kappa_t^o \simeq 1$. Then, the formula [67] turns into an expression which has been first derived by Dogonadze and Kuznetsov (6). The presence of the factor κ_t^o in [67] takes into account for the compensation effect between electron tunneling and nuclear tunneling in nonadiabatic reactions (1). Equations related to [68], which refer to adiabatic reactions have been obtained earlier (7, 8) using arbitrary potentials along the reaction coordinate. In the work of Dogonadze and Kuznetsov (6) the oscillator model is used to derive a classical equation ($\kappa_o = 1$) for adiabatic processes, however, not any explicit relation $E_a(Q)$ between activation energy and heat of reaction is found in that derivation.

[5] See Ref. (1). Note added in proof.

Discussion

The harmonic oscillator model has been first used by Marcus (3a), Levich and Dogonadze (4), to describe the role of the polar solvent in outer sphere electron transfer processes using dielectric continuum theory. Subsequently, the changes of the inner coordination shell have been taken into account by Marcus (3b, c) by making use of the potential energy surfaces. His treatment is essentially based on the classical activated complex theory and is mainly concerned with adiabatic reactions.

The proton transfer processes have been investigated by the present author from point of view of quantum mechanics in a series of papers (7, 8, 10, 15). Initially, use has been made of a rectilinear reaction coordinate, *i.e.*, a one-dimensional potential barrier which involves the interactions of the proton with all surrounding particles (including solvent molecules).[6] Later, a curvilinear reaction coordinate has been considered in the frame of a many dimensional treatment (7a, b, c) which includes all degrees of freedom of the system. On the basis of a recent formulation of reaction rate theory 2) a reconsideration of the previous results of the author's work has been made (7c).

Dogonadze *et al.* (5, 6) have used an oscillator model to treat the proton transfer and, in a similar way, the influence of the inner coordination shell on the electron transfer (6). In that model, an effective low frequency vibration, describing the solvent polarization in terms of continuum theory, is treated classically, while another high frequency (proton) vibration is treated quantum-mechanically. Use is made of first-order perturbation theory and the Franck-Condon approximation, by assuming that the proton transfer takes place at a fixed point of the solvent coordinate. A related modified approach is recently employed by Schmickler (18) in considering redox reactions at electrodes.

The present paper provides a complete treatment, not made in earlier work, of the two-frequency oscillator model for charge transfer. It differs essentially from previous quantum theories (3-6, 18) by using a general method based on a recent formulation of chemical kinetics (2), which overcome the limitations of these theories. In this way, it has been possible to consider the whole range between the limits of adiabatic and nonadiabatic reactions without any restriction concerning nuclear tunneling. Three temperature ranges, corresponding to negligible, moderate, and large tunneling, have been investigated using suitable approximations. The results of the previous treatments of the oscillator model are obtained as special cases as discussed earlier in this paper.

The harmonic approximation for the high frequency vibration does not lead to any limitation of the rate equations obtained. Indeed, the second term in Eq. [4] can be replaced by the expression of a Morse-like potential without changing the following derivations.

The work of Dogonadze *et al.* (5, 6) refers either to the high temperature range ($T > 2T_k$) of nonadiabatic reactions ($\chi << 1$) or to the low temperature range ($T < T_k/2$) of both adiabatic and nonadiabatic reactions ($\chi = 1$ and $\chi << 1$) with the limitation of a classical motion along the solvent coordinate. In that treatment use is made of a harmonic approximation for the proton vibration or, instead, at low temperatures, a "double adiabatic approximation" is used, which consists in including the ground-state energy of the proton into the electronic energy in order to obtain an effective potential governing the motions of the solvent oscillators. Evidently, this is essentially the approach used before by Hirschfelder *et al.* (11) to give a justification of Eyring's transition state theory. However, in addition, account is taken by Dogonadze *et al.* of the nonadiabatic transitions, which are neglected in that justification.

[6] The statement of Dogonadze *et al.* (17) that in the author's work the role of the solvent is entirely ignored is completely misleading. A comment of this point is given elsewhere (18).

Our treatment of the low temperature range, giving expression [51], represents a generalization of the procedure of Hirschfelder *et al.* (12) which permits the inclusion of quantum effects (nuclear tunneling and electronically nonadiabatic transitions) in a vibrationally adiabatic derivation of the equation of activated complex theory. The result of Dogonadze *et al.* (5, 6) is a particular case of formula [51] in which only the first term ($n = 0$) is taken into account and $\kappa_0 \gtrsim 1$ is replaced by $\chi_0 << 1$ to obtain [67] with $\kappa_t^0 = 1$ ($T > T_k^0/2$).

The restriction to the nonadiabatic proton transfer ($\chi_0 << 1$) is, however, not in accordance with the Tafel equation of electrode kinetics which is known to be valid for hydrogen evolution in a very wide range $\Delta\psi$ of electrode potentials ($\Delta\psi \gtrsim 1$V). Equation [67] does not give, indeed, a linear relationship ln k_{12} *vs.* $Q = e_c(\psi - \psi_0)$ (4). In this respect [68], which refers to adiabatic reactions ($\chi_0 = 1$), is certainly to be preferred because of the presence of the factor $\gamma_x < 1$ in the exponent which is shown to be responsible for the practical validity of the Tafel relation (7b, 8).

The restriction to the ground-state proton vibration in [51] is apparently justified as far as $h\nu_y/kT >> 1$.[7] It means that no change of the A-H$^+$ bond length occurs, and consequently, the activation energy in [67] and [68] involves only the reorganization of the solvent. This result disagrees, however, with the well-known experimental fact that the isotope substitutions affect the observed activation energy (20). We, therefore, conclude that either the oscillator model, in general, or at least the above limitation to the ground-state vibration of the proton is not adequate to the real situation in most cases.[7]

The oscillator model is certainly very useful, because of its inherent simplicity, for a quantitative description of the role of the solvent in charge transfer reactions. It appears, however, that it greatly overestimates the part played by the solvent in the activation process. The main imperfection of the model seems to be that it neglects the translation and rotation motions of reactants and solvent molecules (1, 3c). A more complete treatment should take into account, at least for the relative translation of reactants, which would lead to a curvelinear (nonseparable) reaction coordinate, crossing the saddle of the potential surface. Using two dimensional models for gas phase reactions of the type AH + B → A + HB it has been shown (21) that there is a considerable stretching of the A-H bond in the transition region where tunneling mainly occurs. It is plausible that this situation takes place in proton transfer in solution, too. A dynamical description of the process then requires a three-dimensional potential surface but a full quantitative treatment of such a more complicated model seems to be very difficult.

However, it has been shown (7) that in the region of moderate tunneling, rate expressions of the form [33] and [34] can be derived on the basis of [1] for any arbitrary many dimensional system. It should be emphasized that different definitions of the quantum corrections κ_t and χ are valid if instead of [1] a formally similar generalized expression of activated complex theory is used (2b). Only when the reaction coordinate is completely separable both formulations become identical.

These considerations may contribute to a clarification of a much discussed question concerning the role of nonequilibrium solvent polarization in proton transfer processes (4-7, 22, 23). Our treatment of the oscillator model shows that a fluctuation of the solvent would be necessary to make possible the proton transfer only in the low temperature range provided that the transfer distance is relatively small ($y_0 << x_0$), the proton vibration frequency being very high ($\nu_y >> \nu_x$). However, in the intermediate and high temperature ranges the orientation of the solvent molecules keep pace with the proton transfer. Consequently, the irreversible polarization may be important if $T < T_k/2$, while reversible polarization takes place if $T > T_k/2$. These conclusions are likely to be valid for more general barrier models for charge transfer too.

An analysis of the experimental facts concerning isotope effects shows (7) that the tunneling correction to Eyring's rate equation can usually be estimated by the formula [30], which is valid for $T > T_k/2$, T_k being defined by [16a] in terms of the curvature of the barrier along the reaction coordinate just at the saddle-point of the many dimensional potential surface (2, 7). Therefore, the intermediate temperature range is the most important one for proton transfer reactions and probably for redox processes involving high frequency vibrations in the inner coordination shell for which, as discussed above, an equilibrium polarizaton of the solvent medium in the transition state is likely to take place. There are, however, a number of reactions with anomalously large isotope effects (20a) which certainly occur in the low temperature range ($T < T_k/2$). Just for such reactions a more complicated, many dimensional model is needed, which may involve in a large extent nonreversible polarization of the solvent.

The oscillator model considered in this paper is probably adequate to the situation in some solid-state electron and proton transfer processes, where translations and rotations in the medium are strongly restricted. It would be interesting, for instance, to treat on the basis of this model the proton conductance of ice as well as some proton transfer reactions for which extremely large kinetic isotope effects have been observed (20a).

Finally, it should be noted that there is no great difficulty in treating a more general oscillator model, which involves a set of low frequencies and another set of high frequencies, in the same way as the two-frequency model considered in the present paper.

Manuscript received Feb. 25, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

[7] According to [51]-[53] the contribution of each vibrational state n is determined by the product of two factors: the one $\kappa_n \exp V_{nn}/kT$ increases and the other $e^{-\epsilon_n/kT}$ decreases with n. The first factor involves the proton transfer probability [62], which depends very sensitively on the transfer distance y_0. Assuming $y_0 \simeq 0.5$-1A one finds that the term $n = 0$ is the most important in the sum [51]. Replacing the parabolic potentials by Morse-like potentials leads to a more rapid increase of the transfer probability with increasing n, *i.e.*, to a larger contribution of the excited states of the proton.

ABSTRACT

Chronopotentiometry with electromigrational depletion (ED) is applied to the evaluation of interdiffusion coefficients in the binary molten salt mixtures 53-47, 65-35, and 70-30 BeF_2-LiF. The effect of composition dependence on the measured values of the diffusion coefficients is discussed for these mixtures and for $AlCl_3$-NaCl mixtures. The method of analysis of the chronopotentiograms is applicable also to the evaluation of mass transfer polarization in high temperature battery electrolytes.

A number of proposed high temperature battery systems employ electrolytes which are complex (1, 2) or polymeric (3, 4), or in which complex or polymeric species are formed. In such systems appreciable changes of mass transport properties occur during charge or discharge. With increasing temperature, electrode kinetics become more rapid, activation polarization decreases, and mass transfer polarization may become a significant factor in the rate of charge and discharge of high temperature batteries. Consequently, reliable values of transport parameters are needed for design and modeling studies. Among needed transport coefficients are the interdiffusion coefficients, which may undergo considerable changes of magnitude with electrolyte composition change, and which are difficult to determine in electrolytes at high temperatures, particularly in viscous melts. The classical methods for determination of diffusion coefficients in liquids, such as the capillary, diaphragm, and NMR spin-echo measurements, are difficult to apply at elevated temperatures and in viscous systems.[1] While pulsed spin-echo measurements may extend the applicability of the NMR method, this method requires nuclei of appropriate spin and, in any case, leads to self-diffusion coefficients rather than interdiffusion coefficients. Electrochemical scanning methods such as polarography, chronopotentiometry, and linear sweep voltammetry have been employed frequently to obtain diffusion coefficients in electrolytes, both at room temperature and at elevated temperatures. With few exceptions, however, these methods are employed with low concentrations of solute ions under conditions such that electrical migration of the electroactive species is suppressed, thus providing only the limiting interdiffusion coefficient at vanishing solute concentration, which is the solute self-diffusion coefficient.

We have shown (5, 6) that electrochemical scanning methods for the measurement of diffusion coefficients need not be restricted to dilute solute ions, and we have employed anodic chronopotentiometry with beryllium electrodes in molten beryllium fluoride-lithium fluoride mixtures containing between 5 and 22 mole percent (m/o) lithium fluoride. Equations have been developed, with the thermodynamics of irreversible processes, to identify the interdiffusion coefficient in this binary system under conditions of simultaneous diffusion and electrical migration. Computations have been developed to obtain mean values of interdiffusion coefficients and to resolve the composition dependent interdiffusion coefficients. The method, with suitable modification for specific systems, should be useful for studying contributions to mass transfer polarization on charge and discharge at electrodes in high temperature battery systems.

We have used the term electromigrational depletion (ED) chronopotentiometry to describe the application of chronopotentiometry to binary melts such as LiF-BeF_2 since the anodic chronopotentiometric transition with an electrode such as beryllium could be attributed to depletion of Li^+ from the anode region via migration, rather than to depletion of an electroactive constituent via the faradaic process, which is responsible for the transition in ordinary chronopotentiometry. We have shown the transference number of Be^{2+} relative to fluoride ions to be zero (and consequently that of Li^+ to be unity) over the composition range between 20 and 80 m/o BeF_2 (7). Our previous measurements have been mainly at higher BeF_2 concentrations, where

Key words: molten fluorides, molten chloroaluminates, mass transfer polarization, interdiffusion, high temperature battery.

[1] Recently reported capillary-tracer measurements of fluoride self-diffusion in molten $LiBeF_3$ lead to unusually high diffusivity and Arrhenius energy (16).

it was presumed that the transference number remained constant and equal to unity. However, it could not be ascertained that the apparent composition dependence of the diffusion coefficients did not include also some concentration dependence of transference numbers. In this paper we present the results of chronopotentiometric measurements in LiF-BeF_2 melts of composition 53, 65, and 70 m/o BeF_2, for which the transference number of Li^+ is known to be constant and equal to unity; these measurements therefore constitute a valid application of ED chronopotentiometry. We show that, although the chronopotentiograms reflect the variation of the interdiffusion coefficient with concentration from the bulk composition to pure BeF_2, analysis of the early portions of the chronopotentiograms, corresponding to melts of compositions close to the bulk composition, yields the interdiffusion coefficient in the bulk melt. In addition to this application of chronopotentiometry to the polymeric melt, BeF_2-LiF, we discuss its application to the complex melt NaCl-$AlCl_3$ and to melts with normal composition-dependent transference numbers, such as $NaNO_3$-$AgNO_3$.

Experimental

The cells, electrodes, purification of materials, and the experimental procedure have been described previously (5). Chronopotentiograms in the 70 m/o BeF_2, 65 m/o BeF_2, and 53 m/o BeF_2 LiF-BeF_2 melts were recorded with a Hewlett-Packard 141A storage oscilloscope and photographed with a Polaroid camera, rather than recorded on a chart recorder. In these mixtures all of the chronopotentiograms were shorter than 10 sec and some were shorter than 1 sec. In order to avoid convection, faster chronopotentiograms were required than in our previous measurements in the more viscous BeF_2-rich melts.

Figure 1 shows a typical chronopotentiogram, obtained in 53 m/o BeF_2 at 380°C. The initial increase of potential is very fast and has been shown (5, 6) to correspond to the *IR* drop for melt of the bulk composition. Because the electrode configuration was not designed to provide a suitable conductance cell, the measurements provide only a relative electrical conductance. However, as shown previously (6), the temperature dependence of the relative conductance, $I/(IR)$, leads to activation energies for conductance consistent with those obtained from directly measured electrical conductance in these melts (8).

The final portion of the chronopotentiogram appears to rise sharply. As will be seen from the discussion to follow, however, the apparent sharpness of the transition may be deceptive. In any case, since the transition corresponds to the composition of nearly pure BeF_2 at the working electrode, and since the diffusion coefficient may be strongly composition dependent, this transition time is not related simply to the diffusion coefficient in the melt of the bulk composition. Rather, the transition time corresponds to a weighted mean diffusion coefficient over the range of compositions varying between the bulk composition and pure beryllium fluoride (6).

At the lowest temperature (380°C), noisy chronopotentiograms such as the one in Fig. 2 were sometimes obtained when low current densities were used. At higher temperatures, even with chronopotentiograms of similar duration (10 sec) to those in the more viscous melts at 380°C, the chronopotentiograms are reproducible and not noisy. Therefore convection probably is not the cause of the noise. The appearance of the noise rather seems related to the slow scanning of composition at low temperature. As the concentration of BeF_2 near the anode increases, the liquidus temperature of the mixture becomes much higher than the temperature of the melt, and solid BeF_2 may precipitate in the vicinity of the working electrode. Similar behavior has been reported by Gilbert *et al.* (9) for anodic chronopotentiometry at an Al electrode in $AlCl_3$-NaCl mixtures. This behavior has not been further investigated, but could prove useful in studies of nucleation and precipitation kinetics.

Analysis of Chronopotentiograms

The analysis of the experimental results must differ from that of ordinary chronopotentiometry. Ordinary chronopotentiometry is applied to very dilute solutions of an electroactive constituent and consequently leads to the self-diffusion coefficient of the dilute constituent. As we have shown previously in ED chronopotentiometry of LiF-BeF_2 mixtures (5, 6) and NaF-BeF_2 mixtures (10), a large range of concentration is spanned and the measurements lead to the mutual diffusion coefficient of Li and Be and of Na and Be. At long times there is a greater difference between the properties of the melt at the indicator electrode and the properties of melt of bulk composition in ED than in ordinary chronopotentiometry. Thus in ED chronopotentiometry of a 50 m/o BeF_2 melt, the composition changes to nearly pure BeF_2 at the indicator electrode. The viscosities (11) change from 0.27 P to 7.63×10^5 P at 600°C and there are comparable differences in electrical conductance. Since the equations have been derived previously, we here give only the essential results.

The potential difference between the reference and working or indicator electrodes may be broken into two parts: a resistive term (*IR*) and the emf of a concentration cell with transference. In a melt MA-$M'A_n$ (such as LiF-BeF_2 or NaCl-$AlCl_3$) where M'^{n+} is the cation produced by the faradaic process at the indicator

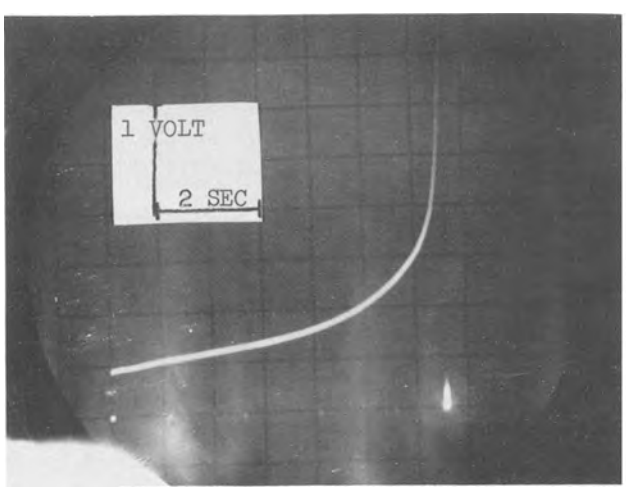

Fig. 1. Typical chronopotentiogram, in 53 m/o BeF_2 melt at 380°C with current density of 1.26 A/cm². EMF at working electrode *vs.* time.

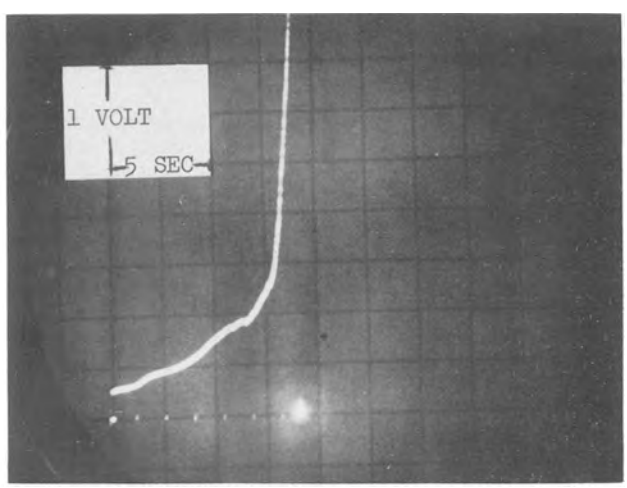

Fig. 2. Noisy chronopotentiogram at slow scan rate in 53 m/o BeF_2 melt at 380°C with current density of 0.72 A/cm².

electrode, the emf of the cell

$$M|MA,M'A_n \;\vdots\; MA,M'A_n|M$$

may be written (5, 6)

$$E = (IR) + \frac{1}{n\mathbf{F}}\int_{y_o}^{y} t_{M^A}\frac{1+(n-1)y}{1-y}\,d\mu_{M'A_n} \quad [1]$$

where y is the mole fraction of $M'A_n$ at the anode surface, $\mu_{M'A_n}$ the chemical potential of $M'A_n$, and t_{M^A} the transference number of M relative to A. The chronopotentiometric transition occurring when MA is depleted at the electrode is a consequence of the thermodynamics of the system as in classical chronopotentiometry, rather than of the buildup of a resistive layer, and should be observed even with measurement of the emf under current interruption conditions.

The flow of cations, M, relative to the common anions taken as frame of reference is (5)

$$J_{M^A} = -D_{M-M'}\frac{\partial C_M}{\partial \xi} + t_{M^A}\,I/\mathbf{F} \quad [2]$$

where $D_{M-M'}$ is the mutual diffusion coefficient of cations, M and M', t_{M^A} is the transference number of cation M relative to anions A, C_M is the concentration of M in equivalents per volume unit[2], and ξ is a distance variable such that equal increments of ξ contain equal numbers of anions A. This transformation accounts for the effects of volume changes with composition on the reference frame for diffusion.

The equation of diffusion may be derived by differentiation of Eq. [2] with respect to the distance variable, leading to

$$\frac{\partial C_M}{\partial t} = \frac{\partial}{\partial \xi}\left(D_{M-M'}\frac{\partial C_M}{\partial \xi}\right) - \frac{\partial}{\partial \xi}\left(t_{M^A}\frac{I}{\mathbf{F}}\right)$$

$$= D_{M-M'}\frac{\partial^2 C_M}{\partial \xi^2} + \frac{dD_{M-M'}}{dC_M}\left(\frac{\partial C_M}{\partial \xi}\right)^2 - I/\mathbf{F}\frac{dt_{M^A}}{dC_M}\left(\frac{\partial C_M}{\partial \xi}\right) \quad [3]$$

Since at the electrode surface the flux of cations M is zero because no M ions cross it, Eq. [2] provides one of the boundary conditions

$$\frac{I}{\mathbf{F}} = \frac{D_{M-M'}}{t_{M^A}}\frac{\partial C_M}{\partial \xi} \qquad \xi = 0, \quad t \geqq 0 \quad [4a]$$

The other boundary condition and the initial condition are the usual ones of chronopotentiometry for semi-infinite diffusion to a plane electrode

$$C_M(t) = C_o \qquad t \geqq 0, \quad \xi \to \infty \quad [4b]$$

$$C_M(\xi) = C_o \qquad t = 0, \quad \xi \geqq 0 \quad [4c]$$

The general second-order nonlinear differential equation (Eq. [3]) is not amenable to analytical solution. With constant diffusion coefficient and unity transference number the diffusion equation and boundary conditions are identical to those of ordinary chronopotentiometry, and the solution is of the same form as the Sand equation, although D is an interdiffusion coefficient rather than a self-diffusion coefficient. However, a useful result can be derived also for the slightly less restrictive assumption of a constant although nonunity transference number. With a constant diffusion coefficient, which could apply over only a small range of composition, Eq [3] and [4a] may be written

[2] In a two-component molten salt mixture (three ion constituents) the faradaic, migrational, and diffusive flows uniquely determine the change of a single composition variable in the system (conveniently taken as the equivalent concentration) irrespective of the number, complexity, and charge of the "species" which may be present.

$$\frac{\partial C_M}{\partial t} = D'_{M-M'}\frac{\partial^2 C_M}{\partial \xi'^2} = (D_{M-M'}/(t_{M^A})^2)\frac{\partial^2 C_M}{\partial (\xi/t_{M^A})^2} \quad [5]$$

$$I/\mathbf{F} = D'_{M-M}\frac{\partial C_M}{\partial \xi'} = (D_{M-M'}/(t_{M^A})^2)\frac{\partial C_M}{\partial (\xi/t_{M^A})} \quad [6]$$

Under these assumptions, the transformations

$$D' = D_{M-M'}/(t_{M^A})^2$$

$$\xi' = \xi/t_{M^A}$$

thus lead to equations of the same form as for ordinary chronopotentiometry for the concentrations at the electrode surface as a function of time

$$C_M(\xi = 0) = C^o - \frac{2I}{\mathbf{F}\sqrt{\pi D_{M-M'}/(t_{M^A})^2}}\sqrt{t} \quad [7]$$

Because the assumption of a constant interdiffusion coefficient is unrealistic, Eq. [7] does not apply rigorously over a wide range of concentration.

In the present work, the three bulk compositions are melts where independent measurements (7) have demonstrated unicationic conduction by lithium ions. As before, by using Eq. [1], including the activity coefficient term, the time dependence of concentration at the electrode surface is calculated from the time dependence of the potential along the experimental chronopotentiograms. Equation [7] is reminiscent of the Cottrell equation for the time dependence of current in chronoamperometry. Setting the concentration of M at the electrode surface equal to zero gives the analog of the Sand equation, but as pointed out earlier, a diffusion coefficient calculated from a transition time may be difficult to interpret. Equation [7] may be put in a useful form for graphical analysis

$$(1 - C_M/C_o)/I = \frac{2}{C_o\mathbf{F}\sqrt{\pi D_{M-M'}/(t_{M^A})^2}}\sqrt{t} \quad [8]$$

In the hypothetical case of diffusion coefficient and transference number independent of composition over the entire composition range, plots of the left-hand side of Eq. [8] *vs.* the square root of time would be linear, with slope inversely proportional to $\sqrt{D_{M-M'}/(t_{M^A})^2}$, up to the transition time, at which $C_M = 0$. The limiting value of the ordinate is then equal to the reciprocal of the current density. Applying such plots to LiF-BeF_2 mixtures in the composition range in which t_{Li^F} is known to be unity (20-80 m/o BeF_2), deviations from linearity result from composition dependence of the diffusion coefficient, providing a useful diagnosis. However, the interdiffusion coefficient in melt of the bulk composition can be obtained from the initial linear portion of plots of the left-hand side of Eq. [8] *vs.* the square root of time, *i.e.*, at short times. The limiting ordinate at long times still should be $1/I$, and the plots at different current densities should be superimposed along the initial linear portions of the curves. This provides a test for consistency of the diffusion coefficients from measurements at different current densities, and is the analog of the constancy of $I\tau^{1/2}$ in classical chronopotentiometry.

Results

ED chronopotentiometric measurements were made in the three bulk compositions of 53, 65, and 70 m/o BeF_2 at several temperatures. At each temperature and composition chronopotentiograms with different current densities were obtained. Figure 3 shows typical plots of Eq. [8] at 570°C in the melt of bulk composition 53 m/o BeF_2. The different symbols refer to different current densities at the working electrode, and the mole fractions of BeF_2 at the indicator electrode are indicated. The three plots are obviously sigmoid in shape, indicating the variation of the interdiffusion coefficients. However a common straight line through the origin of the square root of time plot can be drawn

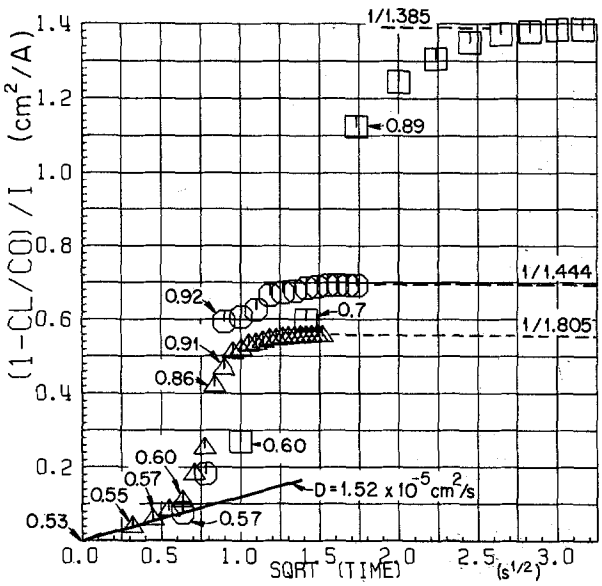

Fig. 3. Dependence of composition at the Be anode on square root of time (Eq. [8]) for the 53 m/o BeF_2 melt at 570°C and with different currents (mA). 500, △; 400, ①; 200, ⊡. Area of the working electrode: 0.277 cm^2. The compositions in mole fraction of BeF_2 are indicated, as is the diffusion coefficient calculated from the initial slope. Horizontal dashed lines are the plateaus calculated as the reciprocal current densities.

through the ordinates calculated from the early parts of chronopotentiograms obtained at differing current densities, as long as the composition change at the electrode surface is sufficiently small. Over the concentration range between 53 and 57 m/o BeF_2, the composition dependence of the interdiffusion coefficient may be neglected in Eq. [7] and [8]. The initial slope of Fig. 3, using Eq. [8] gives the value 1.52×10^{-5} cm^2/sec for the mutual diffusion coefficient of lithium and beryllium in the 53 m/o BeF_2 melt at 570 °C. (The precision is estimated to be about 5%.) As the concentration of BeF_2 increases beyond 60 m/o BeF_2, a sharp departure from proportionality to $\sqrt{t}$ occurs, and as the curves approach their limiting values the plots are no longer exactly superimposable. Since independent measurements (7) show that the transference number is constant up to 80 m/o BeF_2 the curvature in that region arises from the composition dependence of the mutual diffusion coefficient. If mean values of the diffusion coefficient are calculated from Eq. [8], the apparent anomaly of increasing mean values of interdiffusion coefficient with increasing BeF_2 content is found, because of the weighting function. When the concentration of BeF_2 exceeds 80 m/o BeF_2, the transference number of lithium relative to fluoride may decrease; at all three current densities a rapid decrease of slope occurs at about 90 m/o BeF_2. The final parts of plots are plateaus as $(1 - C_L/C_0)/I$ attains slowly its expected value of $1/I$. The corresponding compositions are very close to pure BeF_2 and very likely in this concentration range both interdiffusion coefficient and transference number decrease. In the absence of an analytical solution of the diffusion equation with a concentration-dependent diffusion coefficient, the most reliable results are those from the very early parts of chronopotentiograms where average values of the diffusion coefficient are taken over a small concentration range. However the current densities must be chosen low enough to provide compositions not too far removed from the bulk composition in the early part of the chronopotentiograms. In our previous measurements (5, 6) at higher BeF_2 contents, the initial composition change was too rapid to provide data as close to the bulk composition as in the present work, and the plots probably correspond to the second, or rising portion of the sigmoid curve. However it was possible to resolve the weighted mean diffusion coefficients into composition-dependent values which were mutually consistent when the values calculated for a given composition at the electrode surface in melts of differing initial compositions were compared. In the present work, the composition undergoes too large a change for convenient resolution of the weighted mean. Table I gives values of the mutual diffusion coefficient in melts of three compositions, together with the concentration interval over which the value is averaged. Temperature dependence of the mutual diffusion coefficient in the eutectic melt between 380° and 600°C leads to an activation energy for diffusivity of 9 kcal/mol compared to a value of about 15 kcal/mol for the activation energy for viscous flow (11).

Table I. Mutual diffusion coefficient (cm^2/sec) of lithium and beryllium in LiF-BeF_2 melts

Melt composition, m/o BeF_2	Temperature, °C			
	380	570	600	700
70				1.5×10^{-4} (70-85)
65			4.6×10^{-4} (65-74)	
53	3.4×10^{-6} (53-55)	1.52×10^{-5} (53-55)	1.6×10^{-5} (53-60)	

Discussion

The magnitudes of the interdiffusion coefficients in 53-70 m/o BeF_2 mixtures, shown in Table I, and the activation energy for diffusion, indicate the approach to values expected in ionic liquids with increasing alkali ion concentration and the breakdown of the network structure of BeF_2. Our previous measurements in mixtures containing 78-95 m/o BeF_2 led to estimated interdiffusion coefficients in the range 10^{-6}-10^{-8} cm^2/sec. Solute self-diffusion coefficients of the order of 10^{-6} cm^2/sec have been reported (12) in 30 m/o BeF_2 melts.

In plots such as Fig. 3, the slope of the chord between the origin and a point on the curve corresponds to a mean interdiffusion coefficient for compositions between the bulk or initial composition and the composition at the electrode surface at the corresponding time along the chronopotentiogram. It is clear from the sigmoid shape that these weighted mean values will first decrease with time (increasing chord slope) and then increase with time (decreasing chord slope) as the plateau is approached. In our previous work (6) at higher BeF_2 concentrations, assumption of a weighting function proportional to the alkali ion concentration led to consistency between diffusion coefficients calculated at differing times and concentrations along an individual chronopotentiogram, and diffusion coefficients calculated at the same concentration but different time from chronopotentiograms in melts of differing initial composition. Such a weighting function reflects the fact that in a system in which the diffusion coefficient is decreasing with time, the compositions with higher alkali concentration (and hence higher diffusion coefficient) contribute longer times toward the attainment of a given composition change than do the compositions with low diffusion coefficient.

The sigmoid shape of the approach to the limiting plateau also indicates that the evaluation of a transition time may be rather difficult, and that apparent sharpness of chronopotentiograms may be deceptive. If one applies the Sand equation to a 6 sec, apparently sharp, transition in Fig. 1, the calculated apparent diffusion coefficient is 2×10^{-6} cm^2/sec. The diffusion coefficient calculated from the initial slope in Fig. 3 would require the unrealistic estimate of 9 sec for the transition time if the diffusion coefficient were constant.

ED chronopotentiometric measurements have been reported (9) in NaCl-$AlCl_3$ melts where unicationic

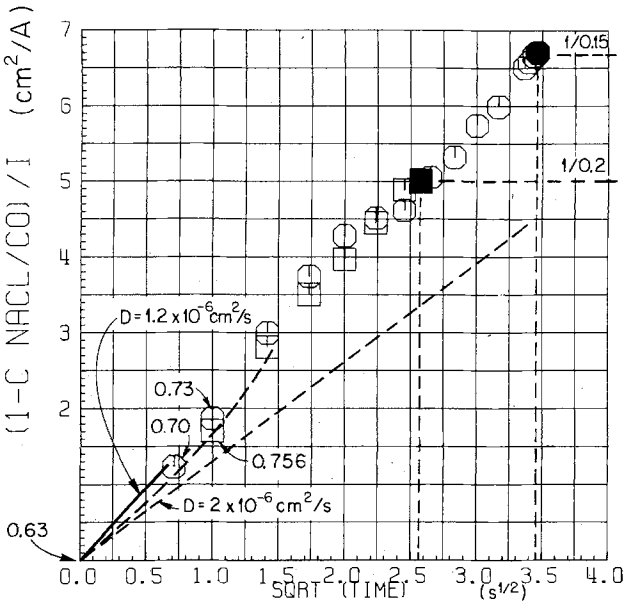

Fig. 4. Dependence of composition at Al anode surface on square root of time in 63 m/o $AlCl_3$-37 m/o NaCl melt from experimental data of Ref. (9) with different currents (mA) at 140°C. 40, ⊡; 30, ⊙. Area of the working electrode: 0.2 cm^2. The filled symbols correspond to the reported graphical transition times (9): 6.6 sec; 12.1 sec. The compositions in mole fraction of $AlCl_3$ at the aluminum anode surface are indicated. The slope of the solid line corresponds to the reported (9) diffusion coefficient, that of the dashed line to the limiting slope of the curve. The plateaus are calculated from the reciprocal current densities.

conductance by sodium ions (relative to chloride) is expected (10) to result from the complexity ($NaAlCl_4$-Al_2Cl_6) of the melts rather than from a network structure as in BeF_2-LiF melts. However, the interdiffusion coefficient of sodium and aluminum probably varies less sharply with composition than that for LiF and BeF_2, since the viscosity does not change as much. Since the diffusion coefficients of Al and Na were calculated from apparently sharp transition times, it seemed of interest to investigate a possible composition dependence by calculations such as those we have presented above.

Figure 4 shows a plot $(1 - C_M/C_0)/I$ derived from the published chronopotentiograms (9) with 0.2 and 0.15 A/cm^2 in the melt 63 m/o $AlCl_3$-37 m/o NaCl at 140°C. The superposition of the two sets of points indicates excellent consistency of the data at the two different current densities. The two filled symbols in Fig. 4 are obtained by taking $C_{Na} = 0$ at transition times of 6.6 and 12.1 sec as graphically determined by the authors in Ref. (9). Although the plateaus are of lesser extent in this chloroaluminate melt than in LiF-BeF_2 mixtures, the assumption of both constant interdiffusion coefficient and transference number probably does not hold over the full composition range spanned during the chronopotentiograms. Because of difficulty in reading the emf at very short times, the initial points probably correspond to compositions already far enough from the bulk composition to belong to the nonlinear intermediate section of the plotted function, and extrapolation through the origin must assume some curvature. This would lead to a lower initial slope and thus a slightly higher value of the diffusion coefficient (perhaps 1.5-1.8 $\times$ 10^{-6} cm^2/sec) than the value 1.2 $\times$ 10^{-6} calculated from the transition time. Since there is little variation of the interdiffusion coefficient in this system, the use of the transition time here does not lead to significant error, as it would in the case of the LiF-BeF_2 system, but it would appear advisable to use all of the potential time data along the chronopotentiogram rather than a single point, the transition time, in the calculation. Similarly, Piron (13) has pointed out the need to test for composition dependence of self-diffusion coefficients obtained from transition times and the Sand equation in anodic dissolution chronopotentiometry of a metal into a supporting electrolyte. In a comparative study of cathodic chronopotentiometry for Ni(II) and of anodic dissolution chronopotentiometry of an Ni electrode in molten LiCl-KCl eutectic, he finds differences of 10-30% between the diffusion coefficients calculated from cathodic and anodic dissolution chronopotentiometry. Moreover, the calculations discussed in this paper should be applicable to mixtures with composition-dependent transference numbers such as LiCl-KCl and other mixtures. We have observed anodic chronopotentiometric transitions at silver electrodes in sodium nitrate-silver nitrate mixtures, for which independent measurements of diffusion coefficients and transference numbers have been made. Preliminary analysis of our measurements is consistent with the reported values of the interdiffusion coefficients (14).

Conclusions

Interdiffusion coefficients may be evaluated from chronopotentiometric measurements over much broader ranges of concentration than in the classical application of this method. Development of the method has passed through three stages. Initially (5) it was applied to a relatively narrow composition range, 95-100 m/o BeF_2, providing mean interdiffusion coefficients approaching the self-diffusion coefficient of Li^+. Next (6) it was applied to melts in which the composition was swept through the range 78-100 m/o BeF_2, and a method was developed for resolving the weighted mean diffusion coefficients into composition-dependent values. Extending the method to mixtures containing 53 m/o BeF_2, in which the composition change is too large to use the weighted mean resolution, we have in this paper presented calculations of interdiffusion coefficients for compositions close to the initial or bulk composition in a region where the transference number is known from independent measurements (7). These estimates of the composition dependence of the interdiffusion coefficients are needed as preliminary values in the development of numerical solution of the flux equations. Although the method has been applied to chronopotentiometry, it should be applicable to other kinds of electrochemical scanning programs, *e.g.*, linear sweep voltammetry and chronoamperometry. In fact, other types of scanning function may prove more useful than chronopotentiometry for resolving diffusion coefficients at compositions near the bulk composition, *i.e.*, at short times. ED chronopotentiometry has been applied to binary polymeric melts and binary complex melts, and should be applicable to the evaluation of transport parameters in electrolytes of wider variety, including proposed battery systems. With suitable modifications it should prove useful in systems where composition-dependent diffusion coefficients may be expected, as in silicates (15) and in the anodic dissolution of metals (13).

LIST OF SYMBOLS

A	common anion
C_M	concentration of MA (moles/cm^3); (L for LiF, Na for NaCl)
C_o	concentration of alkali halide in the bulk (moles/cm^3)
$D_{M-M'}$	mutual diffusion coefficient of M and M' (cm^2/sec)
D'	transformed mutual diffusion coefficient, $D/(t_M^A)^2$
E	emf between reference and indicator electrodes (V)
F	the faraday (96.487C)
I	current density (A/cm^2)
J_M^A	flow of M relative to A (common anion), equiv./(cm^2/sec)
(IR)	IR drop (V)
M	alkali cation
M'	cation Be or Al
n	charge number of cation
t	time (sec)
t_M^A	transference number of cation M relative to anion A
$\overline{V}_i$	partial equivalent volume of i (i = A or M)
x	distance from electrode surface
y	mole fraction of MA
y_o	mole fraction of MA in the bulk
$\mu_{M'A_n}$	molar chemical potential of $M'A_n$
ξ	distance variable
ξ'	transformed distance variable, ξ/t_M^A

ABSTRACT

This paper considers the effect of mass transfer and ohmic limitations on the current-polarization relations for porous flow-through electrodes with fine pores, for reversible one-electron transfer reactions. The model includes mass transfer by both axial forced convection and axial diffusion. A new analytical solution is presented which reduces to a previous solution when axial diffusion is negligible. The effects of axial diffusion and ohmic potential drop in the pore electrolyte on the current and concentration distributions inside the electrode are investigated. Experimental confirmation is presented for some of the predictions and a quantitative comparison between theory and experiment is presented. It is concluded that axial diffusion effects are negligible under many experimental conditions, *e.g.*, normal diffusion coefficient, flow rate, electrode length, etc. The results demonstrate the validity of the one-dimensional model presented here under these conditions.

A porous, flow-through electrode is here defined as a porous inert electrode through which is forced electrolyte containing dissolved reactant, *e.g.*, a redox couple. This type of electrode is of interest because the limiting current density is not controlled by diffusion or natural convection to the interior of the electrode, and very high limiting currents can be obtained even at relatively low electrolyte flow velocities through the electrode. In addition, complete conversion of certain reactants to products can be easily achieved by working at the limiting current. Figure 1 illustrates the system and defines rear supply of reactant to the electrode. Theoretical steady-state treatments of this system have been given by Perskaya and Zaidenman (1), Austin *et al.* (2), Gurevich and Bagotsky (3), and more recently Wroblowa *et al.* (4, 5). A primary assumption in these treatments is that the rate of forced mass flow of reactant through the porous system dominates over axial diffusion so that axial diffusion is not included in the treatments. For this system, there are several theoretical treatments but little experimental work, especially experimental results properly designed to

test the validity of a certain model. There are references (5, 6) in the literature in which gross discrepancies between theoretical predictions and experimental findings are left unexplained.

This paper presents some new solutions where axial diffusion is included and gives careful experimental confirmation of some of the solutions. This part gives an analytical solution for one-electron transfer reactions with reversible kinetics, and the corresponding experimental results.

Theoretical Steady-State Treatment

The physical system analyzed consists of a fine pore, isotropic matrix electrode, where the mean pore radius is small (say 1 μm) compared to the electrode thickness, with highly interlinked pores. Under these conditions, the system is treated as one dimensional since radial diffusion will be sufficiently rapid to keep concentration uniform across the pore radius. It is assumed that current density and liquid flow are uniform in the plane of the electrode. Ohmic voltage loss due to electronic conduction in the material of the electrode is assumed negligible, and strongly supported electrolyte is used so that the specific conductance of the electrolyte and the effective diffusion coefficients can be assumed constant, and streaming potential is negligible. It is also implicit in the treatments that flow is fully developed at a short distance into the electrode.

The rear supply case is treated as follows: The Nernst equation for reversible one-electron transfer reaction $R \rightarrow P + e$ can be expressed in the form

$$\eta(x) = \frac{RT}{\mathbf{F}} \ln\left(\frac{P(x)/P_b}{R(x)/R_b}\right) \qquad [1]$$

where R_b is the concentration of reactant in the feed electrolyte, P_b the concentration of product, etc. In the absence of significant diffusion, a mass balance gives $R(x) + P(x) = R_b + P_b$, where $R(x)$ is the reactant concentration at position x in the electrode and $P(x)$ the product concentration. This relation also holds when significant diffusion is present providing the diffusion coefficients of reactant and products are equal. Thus

$$\eta(x) = b \ln\left[\frac{1 + \gamma - \gamma R(x)/R_b}{R(x)/R_b}\right] \qquad [2]$$

where $\gamma = R_b/P_b$ and $b = RT/\mathbf{F}$. Rearranging the above equation and putting it in dimensionless form gives

$$\bar{R}(x) = (1 + \gamma)/[\gamma + \exp\bar{\eta}(x)] \qquad [3]$$

where $\bar{R}(x) = R(x)/R_b$ and $\bar{\eta}(x) = \eta(x)/b$.

Performing a steady-state mass balance on an element of thickness dx at x gives

$$di(x)/dx = n\mathbf{F}[D_{eff}d^2R(x)/dx^2 - udR(x)/dx]$$

Again using dimensionless quantities $\bar{x} = x/L$, $\bar{i}(x) = i(x)/i_L$, and substituting in the above equation gives

$$d\bar{i}(x)/dx = \theta d^2\bar{R}(x)/d\bar{x}^2 - d\bar{R}(x)/d\bar{x} \qquad [4]$$

where θ is the dimensionless group D_{eff}/Lu, and i_L is the maximum current which can be obtained when the reactant is entirely consumed, *i.e.*, $i_L = n\mathbf{F}uR_b$ where u is superficial velocity. For convenience in presentation the bars will be dropped, and it is to be understood that the subsequent equations are in dimensionless form. The rate of mass transfer of reactant in the x direction through a plane at x is the sum of convective and diffusive fluxes $uR(x) - D_{eff}dR(x)dx$, and this must equal the total reactant flux entering the system minus the amount reacted up to x. In dimensionless form this is

$$1 - i(x) = R(x) - \theta dR(x)/dx \qquad [5]$$

which, of course, can also be obtained by integration of Eq. [4].

Ohm's law in dimensionless form is

$$i(x) = (1/\Delta)d\eta(x)/dx \qquad [6]$$

where $\Delta = i_L L\rho_{eff}/b$ is the maximum ohmic potential drop in multiples of b and is obtainable only when the limiting current is supported by reaction over an infinitesimally small element at $x = 0$. Differentiating Eq. [3] and substituting in Eq. [5] using Eq. [6] gives

$$i(x) = \frac{[\exp(\eta(x)) - 1]/[\exp(\eta(x)) + \gamma]}{1 + (1 + \gamma)\Delta\theta \exp\eta(x)/[\exp(\eta(x)) + \gamma]^2} \qquad [7]$$

At $x = 1$, Eq. [7] becomes

$$i = \frac{[\exp(\eta_L) - 1]/[\exp(\eta_L) + \gamma]}{1 + (1 + \gamma)\Delta\theta \exp(\eta_L)/[\exp(\eta_L) + \gamma]^2} \qquad [8]$$

Thus by combining the Nernst equation, the mass-reaction balance and Ohm's law, we have obtained the relation between the exit face polarization and the total current i. Since $\eta_L > 0$, the second term in the denominator of Eq. [8] can be negligible for appropriate values of the product $(1 + \gamma)\Delta\theta$. Equation [8] then becomes

$$\eta_L = 2.3 \log[1 + \gamma i)/(1 - i)] \qquad [9]$$

as previously obtained for the same conditions assuming negligible axial diffusion (2).

The relation between η and x is obtained as follows. Combining Eq. [7] with Eq. [6], separating and integrating from $\eta = \eta_0$ at $x = 0$ to $\eta(x)$ at x gives

$$x\Delta = (1 + \gamma) \ln\left[\frac{\exp(\eta(x)) - 1}{\exp(\eta_0) - 1}\right] + \Delta\theta \ln\frac{[\exp(\eta(x)) - 1][\exp(\eta_0) + \gamma]}{[\exp(\eta_0) - 1][\exp(\eta(x)) + \gamma]} - \gamma[\eta(x) - \eta_0] \qquad [10]$$

Note that η_0 is not zero at $x = 0$ unless η_L and, hence, i are also zero. From Eq. [7], then $i(0)$ is not necessarily zero. This means that to apply the Nernst reversible equation strictly, a finite amount of reac-

tion will occur in an infinitesimal region at $x = 0$ to generate an $i(0)$ which is compatible with Eq. [7] and [8]. The true boundary condition is $i(-0) = 0$ and $i(+0)$ finite. In practice, of course, a finite $i(+0)$ will be supplied by two dimensional reaction in a thin region (as illustrated in Fig. 1b at $x = 0$) including the outside face of the electrode and the pore mouth; the transfer processes become one dimensional at larger values of x. These boundary conditions apply even in the absence of a significant diffusion term in the mass balance.

At $x = 1$, $\eta = \eta_L$; substituting in the above equation and rearranging gives

$$\Delta = \frac{(1+\gamma)\ln\dfrac{\exp(\eta_L)-1}{\exp(\eta_0)-1} - (\eta_L - \eta_0)}{1 - \theta\ln\dfrac{[\exp(\eta_L)-1][\exp(\eta_0)+\gamma]}{[\exp(\eta_L)+\gamma][\exp(\eta_0)-1]}} \quad [11]$$

For a certain η_L (given γ, Δ, and θ as constants) the corresponding value of i is calculated from Eq. [8]. However, for each value of η_L (and, hence, i) there is only one value of η_0 given by Eq. [11], but the form of this equation makes it difficult to separate variables η_0 and η_L. The single correct value of η_0 which corresponds to the specified value of η_L was calculated from Eq. [11] using a simple dichotomous search technique. The value of η_0 thus obtained was used in Eq. [10] to obtain the polarization distribution $\eta(x)$, where $\eta(x)$ was extracted using the same search technique. The value of $\eta(x)$ was then substituted either in Eq. [3] to obtain concentration distribution or in Eq. [7] to obtain current distribution. The use of Eq. [11] with experimental values of η_0, η_L, and i will be given in the results section; if the effect of axial diffusion is negligible, the equation reduces to a simpler form since then the denominator of the right-hand side approaches unity.

Results of Computations

Equations [7] and [10] show that the distribution of reaction through the electrode depends on the parameters Δ and θ. As Δ increases, the location of the reaction is forced toward the exit face. This is illustrated in Fig. 2, which shows the reactant concentration and polarization profiles through the electrode at close to limiting current where nonuniformity of reaction is most pronounced, for a value of γ of 1. For $\Delta = 0$, the current is produced by reaction over an infinitesimally small element at $x = 0$ or, practically, at the external entry surface of the electrode. The total current then crosses the electrode with zero potential drop. This is clearly a hypothetical case. At the other limit of a very large Δ, the current would be supported by reaction in a narrow element at $x = 1$, and $\eta(x) = 0$ for $x < 1$. Generally, η_0 is forced closer to zero as Δ increases, Fig. 2. Considering Eq. [7], [8], and [11], it is seen that the effect of axial diffusion occurs in the terms containing the product $\Delta\theta$. But $\Delta\theta = i_{L\rho_{eff}}D_{eff}/bu = i_L\rho D/bu = n\mathbf{F}\rho DR_b/b = \phi$, where ϕ is similar to the parameter used previously by Austin *et al.* (7-9) to describe the balance between diffusional and ohmic effects in porous flooded-diffusion electrodes

$$\phi = n\mathbf{F}\rho DR_b/b = \Delta\theta \quad [12]$$

Since a large Δ causes less uniform reactant distribution, it also increases the concentration gradient $dR(x)/dx$. Therefore it is the product $\theta\Delta$ and not just θ which is the index of axial diffusion effects. For simple dilute binary electrolyte, the Einstein relation is $D/\mu = RT/\mathbf{F} = b$ and $1/\rho = \mathbf{F}\mu R_b$, where μ is the electrical mobility. Thus $\phi = \mathbf{F}\rho DR_b = 1$, which is the maximum usual value of ϕ for this type of electrolyte, since a supported electrolyte will have a lower value of ρ. In the experiments reported later, reactant concentrations were of the order of 10^{-3}M but the electrolyte was supported by 4*N* HCl, thus giving values of ϕ of 10^{-3} or lower.

For large values of ϕ, the denominator of Eq. [7] becomes significantly greater than one. Figure 3 shows a comparison of the exit face polarization η_L *vs.* current for $\phi = 1$ and 10 and ϕ negligible ($\leq 10^{-2}$). The curve of $\phi = 10$ is obtainable for any combination of Δ and θ values which gives $\phi = \Delta\theta = 10$, *i.e.*, $\theta = 1$, $\Delta = 10$ or $\theta = 10$ and $\Delta = 1$. Significant axial diffusion increases η_L and hence η_0 according to Eq. [11].

Alternatively, for negligible axial diffusion, *i.e.*, $\Delta\theta < 0.01$, the only controlling parameter is Δ, in-

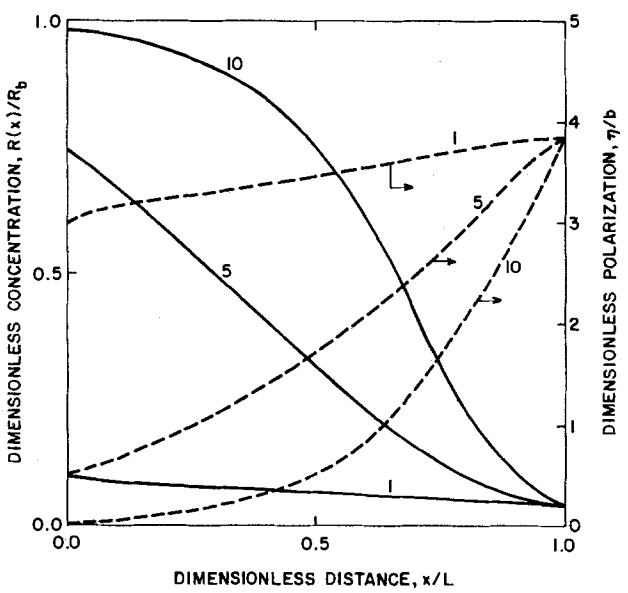

Fig. 2. Effect of ohmic parameter Δ (numbers on the curves) on polarization and concentration profiles in electrode with reversible kinetics; i/i_L — 0.96, negligible diffusion.

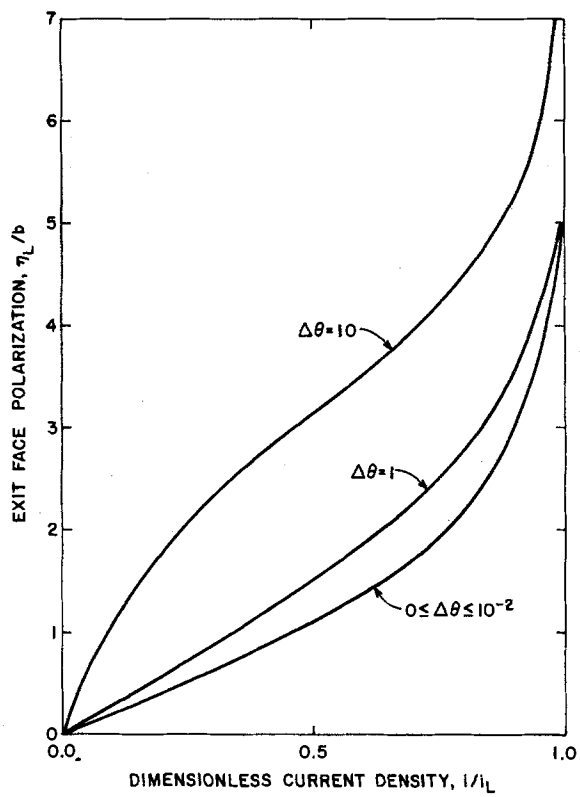

Fig. 3. Effect of axial diffusion on the current *vs.* η_L curves. Values on the curves are for $\phi(= \Delta\theta)$.

crease of which at a constant η_L (Eq. [8]) decreases η_0 according to Eq. [11] (cf. Fig. 7). Under this condition, the current-polarization relation follows the Nernst equation (Eq. [8], and bottom curve in Fig. 3). Note that $\Delta = i_L \rho L/b$ is the product of a convective mass transfer parameter i_L and an ohmic parameter η_L. Hence when Δ is the only controlling parameter, the over-all process is controlled by the rates of both convective mass transfer and ohmic effects. A large Δ value, *i.e.*, high concentration and/or resistivity indicates predominance of ohmic effects, whereas a small Δ value (low concentration and high conductivity) indicates that the process is controlled by convective mass transfer.

Experimental Techniques

To test the equations it was necessary to use redox couples with simple reversible kinetics. The couples chosen were potassium ferro-ferricyanides in 0.5M K_2SO_4 and ferrous-ferric perchlorates in 4*N* HCl. Determination of the diffusion coefficients and kinetics parameters of these couples on basal and edge planes of nonporous pyrolitic graphite are reported elsewhere (10). Porous electrodes were prepared from SP1 graphite (National Carbon Company, New York) which consists of natural graphite flakes of about 20-30 μm diameter and 0.3-0.4 μm thickness, containing a total of less than 6 ppm of impurities.

Nitrogen was purified in a train consisting of a column of anhydrous calcium sulfate, and SP1 graphite trap cooled in a Dry Ice-acetone mixture, a 1 ft long column of copper turnings heated to ~500°C, and finally two different portions of the test electrolyte, through which the gas was bubbled before entering the test solution.

The water used throughout this work was prepared following the procedure recommended by Powers (11). The specific conductivity of the water was about 8×10^{-7} Ω^{-1}-cm^{-1} at 25°C. Hydrochloric acid was prepared by distilling the constant boiling mixture (~6*N*, 108°C) obtained by diluting the concentrated reagent grade material.

Solutions containing the redox couples were prepared by dissolving the calculated weights of Baker reagent grade materials in redistilled water made up to the appropriate concentrations of the respective supporting electrolytes. Some SP1 graphite was added to the solution, and nitrogen bubbled through overnight to deaerate the solution and to stir it with graphite, which removed adsorbable material from the electrolyte. The graphite was then filtered off, and the filtrate kept under nitrogen to retard air oxidation. Dilute solutions were prepared by accurate volumetric dilution of the standard concentrated solutions. Solutions of potassium permanganate, potassium thiosulfate, and iodine were prepared and standardized according to standard analytical procedures (12). The amount of ferric iron present in a ferrous-ferric chloride solution was determined by a simple iodometric technique. The amount of ferrous iron was obtained by titrating against a standard solution of potassium permanganate in the presence of Zimmermann's reagent (13).

Potassium ferrocyanide is known to be a good primary standard substance (13), and potassium ferricyanide was determined by replacing the iron with zinc and then determining the liberated iron iodometrically (14).

The electrode holder for the flow-through tests is illustrated in Fig. 4, and was made from Teflon. The electrode holder was fitted in its place in the cell and a high porosity fritted disk put in the bottom of the holder. A certain weight of SP1 graphite was then introducted evenly in small additions. After every addition the resulting bed was pressed with a pure graphite rod (1/4 in. diameter). When the desired weight of graphite had been added the upper current collector was put on the top of the packed bed and covered with a high porosity filter paper disk. The upper and lower parts of the cell were held together tightly by four bolts, which compressed the bed. The porosity of the resulting packed bed electrode was calculated from a knowledge of its volume and the density of graphite single crystals, 2.266 g/cm^3.

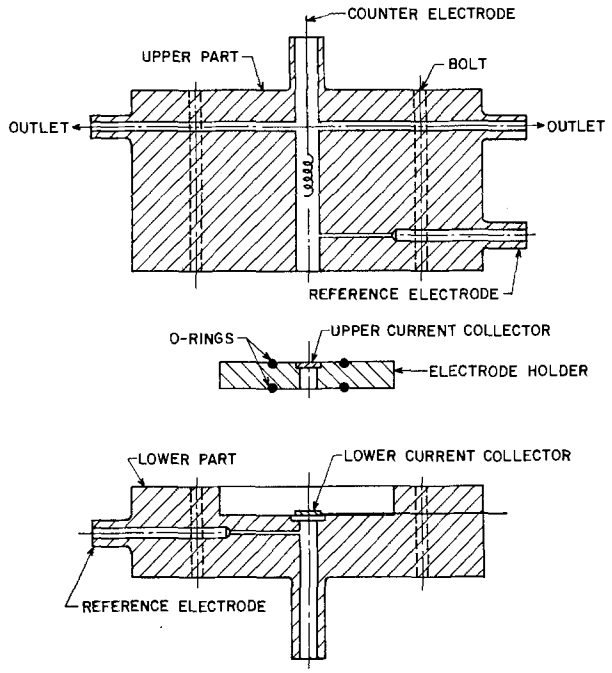

Fig. 4. Schematic of flow-through cell

A longitudinal section of the Lucite flow-through cell used for measuring current-voltage curves on flow-through electrodes, as well as for permeability measurements, is also shown in Fig. 4. It has two current collectors, one on either side of the test electrode in order to enable the electronic conductivity of the test electrode to be measured. A typical specific resistivity value was less than 0.06 Ω-cm. The counter-electrode and current collectors were made of platinum wire and platinum gauze.

A device was constructed (10) to deliver the flowing reactant electrolyte upward through the electrode at constant head. A few minutes were allowed to elapse before measurements were taken. Potentials were measured using a Keithley guarded ground d-c differential digital voltmeter (Type 660). The reference electrode used was a saturated calomel electrode. A steady voltage reading was obtained in less than 1 min and no drift was observed on standing for a few more minutes. The dead space of the cell was about 1.0 cm^3, so at typical flow rates of 0.1 cm/sec, the residence time in the cell was of the order of 30 sec. When the current is increased, the electrolyte leaving the cell is lower in reactant concentration and the possibility exists for back diffusion from previously exited electrolyte. However, because of the low residence time the new steady-state concentrations were soon established.

The *IR* polarization was measured using a fast-switching mercury relay circuit, an oscilloscope, and a C-12 Polaroid camera. While the oscilloscope measured the open-circuit potential, the diaphragm of the camera was opened and a large current was immediately applied to the electrode. The *IR* polarization was given by the blanked-out portion on the voltage-time trace. This was repeated using several faster sweep rates (one to two orders of magnitude faster) to ensure a correct result.

The residual current was measured while the supporting electrolyte flowed through the electrode at

the specified flow rate. The maximum value obtained in the useful potential range was about 0.1 mA/cm² and was thus negligible under all test conditions.

Results and Discussion

Hydrodynamic considerations.—Levich (15) gives the lengths of the entrance regions for laminar flow in a cylindrical tube as $h \sim 0.1\ R\ \mathrm{Re}$ and for the establishment of fully developed diffusion flow, $H \sim uR^2/D$, where R is tube radius and Re the Reynolds number. Typical values for the experimental system we used are $u = 0.1$ cm/sec, $R \approx 1\ \mu$m, kinematic viscosity $\nu \approx 0.01$ cm²/sec, and $D = 5 \times 10^{-6}$ cm²/sec, giving $\mathrm{Re} = 2uR/\nu = 2 \times 10^{-3}$, $h \sim 2 \times 10^{-8}$, and $H \sim 2 \times 10^{-4}$ cm. Thus the regions of developing flow and diffusional regime are negligible compared to any reasonable electrode thickness. Turbulent flow in porous media starts to occur at Reynolds numbers of 1 to 10 (16), so flow in the system considered is well within the laminar region.

Reversibility of the Redox System

By measuring the double layer capacity of both planar (17) and porous (10) graphite electrodes, it was concluded that the surface area of SP1 graphite is approximately 2×10^4 cm²/g. This agrees with the BET area measurement of 2×10^4 cm²/g. The exchange current density of $2 \times 10^{-3}N$ ferro-ferricyanide in 0.5M K_2SO_4 was estimated to be about 10 mA/cm² (10). For an electrode of 0.5 cm thickness and porosity of 0.5 the effective exchange current density i_oSL would be larger than 100 A/cm² of geometric surface area of porous electrode, where S is the specific surface area of the porous electrode in cm²/cm³. This value is much greater than the limiting current for all the flow rates used in the tests. Theoretically, then for negligible axial diffusion the flow-through results with this couple should fit Eq. [9]. Figure 5 shows the results; the slope of 58 mV/decade is the required theoretical result. Kinetic tests (17) showed the exchange current density of the ferrous-ferric couple in $4N$ HCl to be about 0.1 mA/cm² but the high value of effective i_oSL for the porous electrode again predicted a fit to Eq. [9], see Fig. 5.

The limiting currents were calculated from the known velocity and concentration, but it was also easy to determine unambiguously a measured limiting current. Figure 6 shows the excellent correspondence of determined-to-calculated i_L values, where i_L is given by $n\mathbf{F}uR_b$. The data of the Sn^{2+}/Sn^{4+} system were obtained from Ref. (10). It should be noted that it is by no means axiomatic that the measured limiting current should agree with the theoretical value. Both Austin *et al.* (2) and Sioda (18) give experimental results where this is not true. The figure suggests the possible use of flow-through electrodes in coulometric analysis for similar systems.

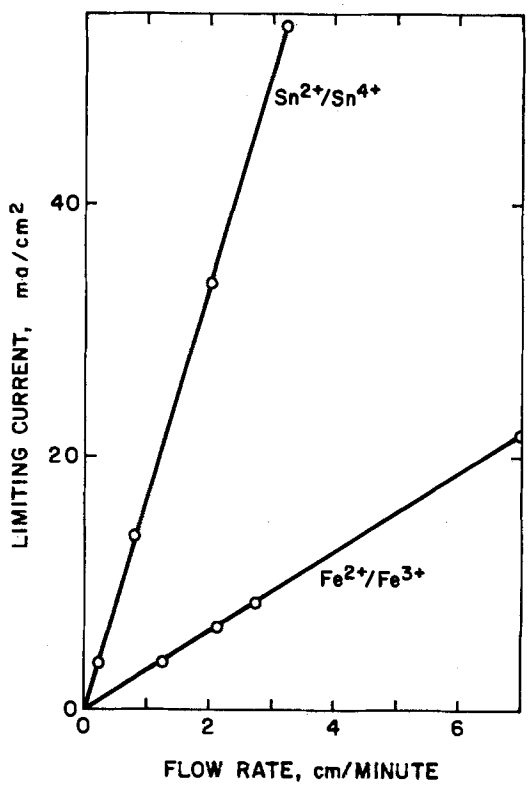

Fig. 6. Comparison of experimental and calculated limiting currents.

Referring again to the theory, it is expected that both of the above sets of experimental results should fit Eq. [11], which is the relation between η_O, η_L, γ, Δ, and θ for reversible conditions. Substituting the measured values of η_O and η_L in Eq. [11] gives values

						Mean 1.16

of Δ shown in Table I for the value of θ of 5.7×10^{-5} calculated from $u = 0.035$ cm/sec, $L = 0.5$ cm, $D_{eff} = 5 \times 10^{-6}$ cm^2/sec (13), porosity = 0.5, and tortuosity = 2.5.

In this connection it may be argued that under conditions of flow of electrolyte through a porous medium there is hydrodynamic dispersion superimposed on molecular diffusion. The over-all longitudinal mass transfer coefficient equals $D_{eff} + E$ where E is the longitudinal dispersion coefficient. Thus axial diffusion effects may be more significant than what we expected on the basis of molecular diffusion alone. Obviously the longitudinal dispersion coefficient depends on the electrolyte flow speed and the properties of the porous medium. This particular area of mass transfer in porous media is not well understood in terms of quantitative relationships (19). For packed sand beds (20), E is given by

$$E = 1.75ud_p, \; 2 < ud_p/D < 50 \qquad [13]$$

where d_p is average particle diameter. Based on an area of 2 m^2/g, the spherical equivalent diameter of the carbon particles of the porous electrode is about 1.5 μm and $E \sim 10^{-5}$. Thus the sum $D + E$ is not of different order than that of D alone, and derived values of θ are still much too small to give significant axial diffusion effects in the current-polarization relations.

It is seen that for both sets of data the axial diffusion term is negligible compared to one. This proves the prediction that under normal conditions (normal diffusion coefficient, flow rate, electrode length, etc.) axial diffusion can be neglected. The values of Δ in Table I enable the tortuosity factor of the electrode to be calculated from the electrode porosity of 0.5. Defining the tortuosity factor q by $\rho_{eff} = q\rho_{true}$/porosity, q is 2.5 from the ferrous-ferric results and 2.1 from the ferro-ferricyanide results. In order to test the effect of Δ on entry and exit face polarizations η_O and η_L, the experimental and theoretical results are compared in Fig. 7. The experimentally measured values of η_L agree very well with the calculated values and are independent of the value of Δ, as predicted by theory. As Δ increases, η_O decreases in quantitative agreement with the theory.

Conclusions

A model is presented for a porous flow-through electrode for one-electron transfer reactions with reversible kinetics. The equations for the system considered include two controlling parameters expressed in dimensionless form. These are (*i*) the ohmic parameter Δ, which is a measure of the ohmic potential drop in the pore electrolyte, which increases with limiting current, pore electrolyte resistivity, and electrode length and (*ii*) the index of diffusion θ, which measures the relative influence of axial diffusion compared to axial convective flow. The effect of axial diffusion is to minimize the concentration gradients caused by the nonuniform distribution of the reaction. Whether the axial diffusion effect is significant or not depends on the product of Δ and θ, which is related to the ϕ criteria by $\Delta\theta = \phi$. For $\phi \leq 10^{-2}$, which is commonly the case under normal experimental conditions, the axial diffusion effect is negligible and the exit face polarization is given by a simple (Nernst) equation and is independent of the value of Δ. As Δ increases, however, the entry face polarization tends to zero. The agreement between theory and experiment is excellent under conditions of negligible axial diffusion which indicates the validity of the proposed model, and the theoretical predictions.

From Fig. 3, it is clear that any meaningful axial diffusion effects should be obtained only for $\Delta\theta \geq 1$. Taking $\Delta = 10$, then $\theta = D/Lu < 0.1$ must be satisfied in order for axial diffusion to be significant. Taking $D = 5 \times 10^{-6}$ cm^2 sec^{-1} and $L = 0.5$ cm, then $u \leq 10^{-4}$ cm sec^{-1} is a necessary condition for detecting axial diffusion effects. Such mass transfer rates are comparable to those obtainable by molecular diffusion and would give residence times of several hours. By operating a porous flow-through electrode at such low flow rates, the main virtue of the system would be eliminated. At low flow rates diffusion of the unconsumed reactant of the exiting electrolyte back into the electrode caused experimental inaccuracy in measurements of the limiting current and could not be readily corrected.

The question of radial diffusion usually arises in treating flow-through electrodes. It has been recently shown (21-23) that the efficiency of reactant conversion is not affected by radial diffusion if $\psi = R^2/2DL \leq 1$. For the present work $\psi \simeq 10^{-4}$, hence radial mass transfer limitations are negligible. The validity of this conclusion was borne out by the good agreement between theoretical and experimental results. For values of $\psi > 1$, a slow radial mass transport process may influence the maximum degree of conversion of a simple redox reaction. This may be accepted for electrodes of large pore diameter, *e.g.*, the 80 mesh folded platinum screen electrode used by Sioda (18, 24), but such electrodes are of limited practical utility because of low reactive area and poor reactant utilization.

Technical Notes

Surface Preparation of Epoxy Laminate to Promote Bonding of Electroless Copper

G. V. Elmore*

IBM Corporation, System Products Division, Endicott, New York 13760

The traditional method of obtaining a suitable surface for bonding electroless copper to an epoxy surface is to treat the surface with a solvent swelling agent followed by a chromic-sulfuric acid etch (1). An alternate method of forming a suitable surface is by lamination of the epoxy with a metal foil which has been treated for satisfactory bonding. The metal is then etched away, leaving a replicated surface on the epoxy. Copper foil (2) has been used for this purpose and anodized aluminum (3) also has been used.

* Electrochemical Society Active Member.

Key words: adhesion, aluminum, microroughening.

Experimental

In this investigation a modified zincate treatment for aluminum foil has been developed which creates a micronodular surface coating on the aluminum. This surface, when replicated on epoxy, is suitable for bonding to electroless copper. In this treatment a highly alkaline zincate solution is saturated with CuO (approximately 0.2 g/liter), and the aluminum foil after cleaning is treated in this solution. The simultaneous deposition of copper and zinc creates the micronodular surface on the aluminum. The treatment uses

Table I. Process steps for treatment of aluminum foil

1. 5 min in solution of 20 g/liter of NaOH
2. Spray rinse
3. 1 min in 35% HNO_3
4. Spray rinse
5. 10 min in a solution of 270 g/ilter NaOH, 100 g/liter ZnO, and 0.2 g/liter CuO (saturated)
6. Spray rinse
7. Dry

0.001 in. thick 1145 aluminum of temper H-19. The process steps are given in Table I.

In the laboratory tests, 2 × 3 ft sheets of foil were stretched on plastic frames and were processed 15 sheets at a time in a stainless steel basket. For production, processing a continuous roll would be preferable.

The treated aluminum sheets were laminated with FR-4 epoxy-glass prepreg and the aluminum foil and zinc coating were then removed with HCl. The remaining copper was removed with $CuCl_2$-HCl etchant. The epoxy-glass substrate was then catalytically seeded for electroless copper deposition by treating with a one step solution of $PdCl_2$, $SnCl_2$, and HCl, followed by rinsing. A photoresist was applied, exposed with the desired circuitry, and developed. Copper was deposited by an additive process and the photoresist then stripped away. After stripping, the copper epoxy glass panel was baked for 15 min at 170°C to improve bonding of the copper to epoxy. The bond of the copper to epoxy on four representative panels is shown in Table II.

The peel strength values shown in Table II, 4-6 lb/in., can be compared with other techniques. Anodized aluminum commercially obtained was laminated to FR-4 epoxy, etched, and additively plated with copper. A peel strength of 2.75 lb/in. resulted. Typical solvent swell and etch with chromic-sulfuric acid yielded average values of 4 lb/in. Treated copper foil laminated to FR-4 epoxy glass, etched and additively plated with copper, gave values from 3.5 to 4.25 lb/in.

To test insulation resistance, panels were made with circuitry of parallel lines with 10 mil spacing. Measurements were made after 24 hr and 168 hr while maintaining in a chamber at 32°C and 80% relative humidity. The results are shown in Table III. They show a variation of resistance between 2×10^4 to 2×10^6 megohms, which is quite satisfactory.

Scanning electron microscopy (SEM) was used to obtain the topography of the treated aluminum, the epoxy surface, and the copper surface. These surfaces are shown in Fig. 1, 2, 3, and 4. The micronodular pattern which is capable of forming a mechanical interlocking-type surface is evident. From Fig. 4, it is also evident that the bond fracture was in the epoxy layer since particles of epoxy which pulled off with the copper can be seen.

In later tests with larger volumes of panels, it was found that the bond achieved was sensitive to the number of laminates in a book between press platens. The reason for this is that quality of duplication of the aluminum surface on the epoxy is affected by the flow characteristics of the epoxy during lamination and cure of the epoxy. Thus, in books of 10 laminates, the peel strength varied from 2 to 5.25 lb/in. with an average of 4 lb/in. It was found necessary to restrict the number of laminates between heating platens to two panels for this reason.

Conclusions

These data show that bonding of electroless copper to epoxy can be achieved with a surface on the epoxy that provides mechanical interlocking of the copper and epoxy. This surface can be obtained by replication of treated aluminum foil on the epoxy to obtain bonds of from 4 to 6 lb/in. between the epoxy and copper.

A Mechanistic Model for the Calculation of Material Balance for a Diaphragm-Type Chlorine Caustic Cell

Z. Nagy[*,1]

Diamond Shamrock Corporation, Divisional Technical Center, Painesville, Ohio 44077

Computer modeling of complex chemical systems, such as an electrochemical cell, can be carried out in two basically different ways. The statistical approach is based on regression equations of the operating variables and on judicious use of adjustable parameters which tailor-fit the model to the experimental data. The mechanistic approach is based on the understanding of the physical-chemical processes taking place in the cell. Often hybrid models are used: the statistical approach is usually based on some prior understanding of the process, and the mechanistic approach is usually forced into the use of adjustable parameters by the lack of reliable physical-chemical constants. The advantage of the mechanistic model is its applicability under a wide range of operating conditions; it is possible to run experiments with the model to predict performance in new situations. The statistical model is applicable only within the range of the original data base of the regression equations. If the model is based on plant data, this range is usually narrow and any extrapolation is questionable.

* Electrochemical Society Active Member.
[1] Present address: Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439.
Key words: chlorine, caustic, electrolysis, diaphragm, computer.

The only published model for the diaphragm-type chlorine caustic cell is a statistical type by MacMullin (1, 2). A recent accumulation of published physical-chemical constants makes it possible to attempt to mechanistically model this cell. The model can be divided into three parts for convenience of preparation: material balance, energy balance, and diaphragm behavior. These parts are, of course, interrelated and will have to be merged at a later stage. In this communication only the material balance will be discussed. This part of the model uses literature values for most constants and has only one equation with adjustable parameters.

The Mechanistic Base of the Model

The processes occurring in the cell are considered in a somewhat simplified way, not to avoid computational difficulties, but to stay away from areas for which the required physical-chemical constants are not available. These processes, and the simplifying assumptions, will be described briefly before giving the computational details. The over-all assumption is that of steady-state cell operation, and the perfect mixing of the solution by gas evolution both in the anolyte and the catholyte.

That is, all bulk processes are independent of time and space coordinates.

Anode side.—The main electrode reaction, on the titanium-based RuO_2 anode, is the oxidation of chloride ions while the oxidation of water is an efficiency loss

$$2Cl^- \rightarrow Cl_2 + 2e \quad [1]$$

$$2H_2O \rightarrow O_2 + 4H^+ + 4e \quad [2]$$

The portion of the total current lost by water oxidation is expressed as a function of current density, temperature, and the NaCl concentration and *p*H of the anolyte. This is the parametric equation fitted to experimental data.

Some of the chlorine gas produced at the anode will take part in chemical side reactions resulting in unwanted impurities. The chlorine will dissolve in the anolyte and will react to form trichloride ion and hydrolysis products

$$Cl_2(g) \rightleftharpoons Cl_2(aq) \quad [3]$$

$$Cl_2(aq) + Cl^- \rightleftharpoons Cl_3^- \quad [4]$$

$$Cl_2(aq) + H_2O \rightleftharpoons HOCl + H^+ + Cl^- \quad [5]$$

$$HOCl \rightleftharpoons H^+ + OCl^- \quad [6]$$

These reactions are considered to be in equilibrium in the anolyte; all equilibrium constants are known. A reaction too slow to reach equilibrium is the chemical chlorate formation

$$2HOCl + OCl^- \rightarrow ClO_3^- + 2H^+ + 2Cl^- \quad [7]$$

the rate equation of which is also known. These are essentially the same reactions as those considered by de Valera (3) and Kircher *et al.* (4, 5).

Diaphragm.—In the material balance part of the model, the diaphragm is assumed to be a simple, chemically inert and physically stable porous barrier which is preventing the free mixing of the anolyte and catholyte. The solution transfer through the pores is taken to be plug flow. It is assumed that no chemical reactions take place in the diaphragm, neither amongst the dissolved species nor with the diaphragm material. The processes to be considered then are only those of mass transfer from the anode side to the cathode side of the cell. (The hydroxide transfer in the reverse direction is to be calculated by the more complex diaphragm part of the model.) The diffusion in the forward direction can be neglected, as one can estimate that it will be only a few percent of the total mass transport. A flux equation can then be written for each species as

$$J_i = t_i I/z_i F + C_i v \quad [8]$$

The concentration, and through it the transference number, of the species will vary with the distance coordinate in the diaphragm. This complication can be avoided if one divides the diaphragm, in principle, into thin layers so that the concentration variation within a layer will be negligible. Under the conditions of the model (namely the assumptions of steady state and no reaction in the diaphragm), the flux of any species will be the same through all the layers; therefore it is sufficient to carry out the calculations for one arbitrarily selected layer. It is convenient to select the first layer toward the anolyte, in which case one can take the composition of the solution to be the same as that of the anolyte.

Cathode side.—The main cathodic reaction is the reduction of water

$$2H_2O + 2e \rightarrow H_2 + 2\,OH^- \quad [9]$$

Two electrochemical and a chemical side reactions also occur

$$OCl^- + H_2O + 2e \rightarrow Cl^- + 2\,OH^- \quad [10]$$

$$ClO_3^- + 3H_2O + 6e \rightarrow Cl^- + 6\,OH^- \quad [11]$$

$$OCl^- + H_2 \rightarrow Cl^- + H_2O \quad [12]$$

The reduction of hypochlorite in the chlorine cell catholyte has been well documented (4-8), and it is an experimental fact that the catholyte overflow of a normally operating cell does not contain any hypochlorite. There is no basis for dividing the reduction between the electrochemical and the chemical routes, but, as long as the reduction is complete, it is immaterial for the present purposes. The reduction of chlorate has been somewhat controversial (4, 8-10). Our laboratory measurements have confirmed the results of Veselovskaya *et al.* (9), indicating a slow electrochemical reduction of chlorate on the steel cathode.

Computational Details

A flow chart of the program is shown in Fig. 1. The input requirements are summarized in Table I; the parameters in parenthesis are needed as an input for the material balance, but in the full model they will be calculated by the diaphragm and the energy balance sections. The first step is the calculation of the chlorine and caustic production efficiencies from the hydroxide backmigration rate and acid/base content of the feed.

The calculation of the anolyte composition is started with the calculation of the NaCl concentration using Eq. [8] written for sodium ions. An iterative procedure is used since the required parameters depend on the NaCl concentration to be determined. The total flux is known from the feed rate. The transference number has been measured by Mussini and Pagella (11) and their results can be expressed as

$$t_{Na} = 0.3754377 + 4.864677 \times 10^{-4} \times t + (-0.03151785 + 1.455249 \times 10^{-4} \times t) \times m_1 + (0.011552 - 3.588446 \times 10^{-5} \times t) \times m_1^2 + (-1.297191 \times 10^{-3} + 3.044053 \times 10^{-6} \times t) \times m_1^3 \quad [13]$$

The convective flow rate through the anolyte can be obtained by correcting the total feed rate for the materials removed in the anode gas and the material transported by electromigration through the diaphragm. The water vapor pressure over the anolyte is calculated using the equations given by MacMullin (12) neglecting all dissolved components but the NaCl. A correction for water condensation at anode gas temperature is made if needed. The oxygen generation rate is assumed, subject to later iteration. The CO_2 generation rate is calculated from the carbonate content of the feed assuming acidic anolyte and 100% conversion. The gas mixture is treated as ideal gas; the deviation from ideality of the major components is less than 1% at 1 atm pressure and 90°C (13-15). The concentration of the minor anion components of the anolyte is neglected here and the NaCl concentration is set equal to the Na^+ concentration.

The next step is the calculation of the concentration of the minor components based on reactions [3]-[7].

Table I. Summary of input and output

Input	Output
Feed rate	Anolyte composition and flow rate
Feed composition	NaCl, available chlorine (Cl_2(aq), Cl_3^-, HOCl, OCl^-), $NaClO_3$, *p*H
Current	Catholyte composition and flow rate
Geometrical dimensions of cell	NaOH, NaCl, $NaClO_3$
Anolyte level	Anode gas composition and flow rate
(Hydroxide backmigration rate)	Cl_2, O_2, CO_2, H_2O
(Temperature of anolyte, catholyte)	Cathode gas composition and flow rate
(Temperature of anode gas, cathode gas)	H_2, H_2O
	Current efficiencies of Cl_2, NaOH, and H_2 production
	Cl_2 and NaOH loss to O_2, $NaClO_3$, and available chlorine
	Cl_2 or NaOH loss to basic or acid feed
	H_2 loss to ClO_3^- and OCl^- reduction
	Input/output balance for Na, Cl, O, H, and C

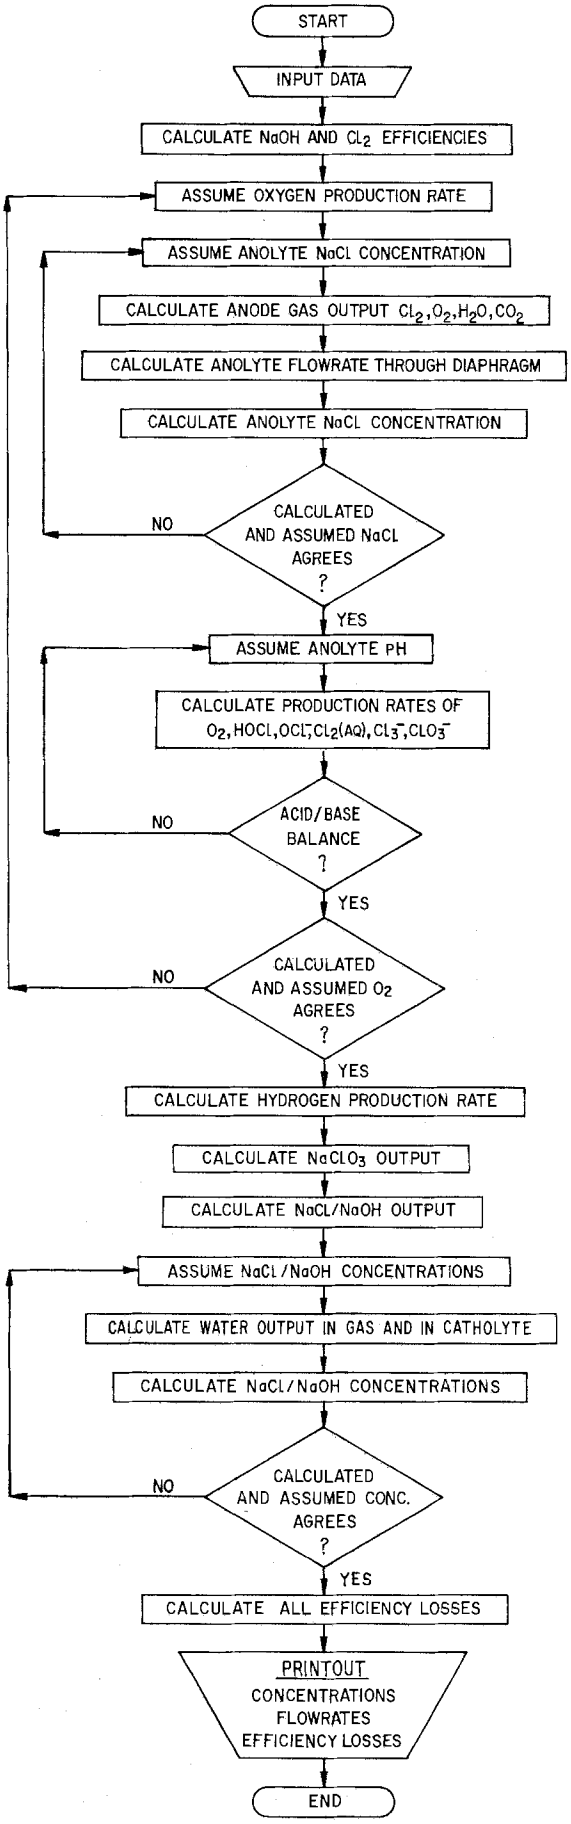

Fig. 1. Flow chart of the program

This is another iterative procedure involving the anolyte *p*H. The chlorine solubility as the sum of $Cl_2(aq) + Cl_3^-$ has been measured by Yokota (16)

$$C_3 = (2.20997 \times 10^{-5} - 2.32597 \times 10^{-6} \times C_1) \times P \times \exp(2302.59/T) \quad [14]$$

The equilibrium constant of reaction [4] is expressed as

$$K = 6.4498 \times 10^{-3} \exp(1030.87/T) \quad [15]$$

based on the data of Cerquetti *et al.* (17, 18). The hypochlorous acid concentration resulting from the chlorine hydrolysis was also measured by Yokota (16) and can be given as

$$C_4 = \exp(-13.8385 - 2.30259 \times 10^{-3} \times t + 5.92106 \times 10^{-2} \times C_1 + 2.30259 \times pH) \quad [16]$$

The dissociation constant of the hypochlorous acid was expressed as

$$K = 3.7508 \times 10^{-6} \exp(-1450.6/T) \quad [17]$$

based on the data of Ref. (19) and other sources identified therein. The activity coefficient of the hydrogen ion was determined from the data of Schwabe (20) giving the *p*H shift resulting from the effect of sodium chloride as

$$\Delta pH = -0.192 \times m_1 \quad [18]$$

The activity coefficients of hypochlorous acid and hypochlorite ions were taken as 2.0 and 0.1, respectively, after Imagawa and Jaksic (21, 22). The production rate of these components is calculated as a product of their concentration and the convective flow rate of the anolyte. That is, for these components the electromigration term is neglected in Eq. [8] as only a negligible portion of them is ionic.

The chlorate production rate is calculated by the kinetic equation of Knibbs and Palfreeman (23) which is in agreement with numerous other determinations (24)

$$\frac{dC_6}{d\tau} = 5.555 \times 10^{-3} \exp(0.6 + 0.056 \times t) \times C_4^2 \times C_5 \quad [19]$$

To obtain the total chlorate production, this is multiplied by the anolyte volume which can be calculated from the anolyte level and cell geometry input data using a 10% correction for bubble filling. The chlorate concentration is calculated with Eq. [8] assuming that the mobility of the chlorate ions is the same as that of the chloride.

The oxygen production rate is calculated with either of the following parametric equations. This is the only equation in the present model which has adjustable parameters; their values were selected to achieve agreement between the calculated and measured oxygen content of the anode gas. (See discussion below.)

$$I_1 = (6.3115 \times 10^{-4} + 1.48291 \times 10^{-6} \times t - 1.61334 \times 10^{-4} \times C_1) \times I^{0.63} \times \exp(1.15129 \times pH) \quad [20]$$

$$I_1 = (1.35066 \times 10^{-3} + 3.17343 \times 10^{-6} \times t - 3.45255 \times 10^{-4} \times C_1) \times I^{0.63} \times \exp(1.15129 \times pH) \quad [21]$$

An acid/base balance is then set up: the acid produced by reactions [2] and [5]-[7] is compared to the hydroxide backmigration corrected for the acid/base in the feed. An equality is required by the steady-state assumption, which allows the iterative determination of the *p*H. Finally, the iteration of oxygen production rate is carried out.

The hydrogen losses are calculated assuming complete reduction of hypochlorite and partial reduction of chlorate (9)

$$I_2 = 3 \times 10^{-3} \times I \times C_6 \quad [22]$$

The final calculation of the catholyte composition is another iterative loop; the vapor pressure equations of MacMullin (12) are used and correction is made for

water condensation in the gas if needed. The cathode gas is treated as an ideal gas mixture. All specific efficiency losses are calculated and the results printed as summarized in Table I.

The algorithms for solution densities were based on International Critical Table (25) values for the NaCl solution and on Ref. (26-29) for the mixed NaCl-NaOH solution.

$$d_1 = 1.0004075 - 7.1687895 \times 10^{-6} \times t - 5.1792075 \times 10^{-6} \times t^2 + 1.054032 \times 10^{-8} \times t^3 + (7.4569085 \times 10^{-3} - 2.960572 \times 10^{-5} \times t + 3.0564225 \times 10^{-7} \times t^2 - 9.3493315 \times 10^{-10} \times t^3) \times w_1 + (1.8372605 \times 10^{-5} + 4.2360185 \times 10^{-7} \times t - 5.1483125 \times 10^{-9} \times t^2 + 1.794537 \times 10^{-11} \times t^3) \times w_1^2 \quad [23]$$

$$d_2 = 1.00686 + 1.147527 \times 10^{-2} \times w_2 - 1.722033 \times 10^{-5} \times w_2^2 - 3.585138 \times 10^{-4} \times t - 2.143812 \times 10^{-6} \times t^2 + 7.550802 \times 10^{-3} \times w_1 \quad [24]$$

Results and Discussion

The model was tested with a series of data sets obtained from two sources. Data were collected from five commercial production cells in the Painesville, Ohio, plant of Diamond Shamrock Corporation; three DS-45 and two DS-85 cells were used. The second set was obtained from four small experimental cells which were built according to the same design principles as the above-mentioned production cells. The results are shown in Table II. The main components were predicted within a few grams per liter and the minor components within a few tenths of a gram per liter. This good fit indicates that the major effects were correctly identified and the neglections and simplifications did not introduce a serious error.

There was, however, an unaccounted effect of the cell hardware design which resulted in the use of two different oxygen equations for the experimental and the production cells (Eq. [20] and [21]). The data of each cell were first individually evaluated for the determination of the oxygen parametric equations. The constants in every equation were somewhat different, but within each group they were close enough for the establishment of the over-all equations. The diaphragm did not introduce any effects as the individual cell equations remained valid after repeated diaphragm changes. While one could indulge in speculations, there is not enough information in the present set of data to allow the identification of the variable responsible for this effect. This, however, introduces only a small variation in the model, the physical-chemical basis of which seems to be well substantiated by the good agreement of the experimental and calculated values.

Acknowledgments

The author is indebted to Mr. E. I. Fogelman for many useful discussions and for supplying the experimental cell data. Thanks are also due to the R&D Management of the Electrochemical Division of Diamond Shamrock Corporation for their encouragement during the course of this work and for their permission to publish it.

On the Complex Formed by Addition of $TiCl_4$ to Anhydrous Dimethylsulfoxide

C. M. Marschoff,* C. Urribarrí, and P. J. Aragón*,[1]

Departamento de Química, Laboratorio de Electroquímica y Corrosión, Universidad de los Andes, Mérida, Venezuela

In the course of studies on the electrochemical behavior of titanium salts in nonaqueous solvents, it was found that when $TiCl_4$ is added to anhydrous dimethylsulfoxide a very exothermic reaction takes place, and a solid, whose color and texture varies according to the reaction temperature, is formed.

This reaction is only briefly mentioned in the literature (1, 2) and the molecular formula $TiCl_4(DMSO)_2$ is proposed (1). Since no further information on this reaction and the resulting complex was available, and because of the technological importance of titanium, some tests were performed in order to confirm this proposed formula and to study some characteristics of the complex and its solutions that might be of interest for practical purposes.

Experimental

As the reaction showed to be very exothermic and the product reacted both with oxygen and water, the synthesis and analysis of the obtained solid were carried out in an inert atmosphere. DMSO was distilled four times under reduced pressure until it showed no reaction with calcium hydride. Then, it was introduced into the dry box. $TiCl_4$ previously purified by reaction with copper in an inert atmosphere (3) was then added dropwise with continuous stirring.

When the reaction temperature was kept below 40°C, the product was a crystalline, light yellow solid. When the reaction was allowed to proceed at higher temperatures the product was an oily, yellowish orange solid which did not show a definite melting point, suggesting that a mixture of complexes or a polymer had been obtained. The crystalline solid was dried for 3 days at 10^{-4} Torr and then used for the different tests.

Results

Melting point.—The melting point was determined to be 144°-145°C.

Chemical analysis.—Chlorine and sulfur contents were determined gravimetrically. Titanium was also determined by classical gravimetric methods by making the solid react with water and weighing the obtained TiO_2. Carbon was analyzed as CO_2. See Table I.

IR spectrum.—An *IR* spectrum of the solid was scanned using the KBr pellet. The obtained frequencies, together with the results of the elementary analysis, Table II, confirm the molecular formula proposed by previous work (1).

Properties of the solutions.—The solid showed to be insoluble in a wide variety of solvents, including carbon tetrachloride, chloroform, benzene, toluene, ethyl ether, ethyl acetate, carbon disulfide, and acetone. It reacted with water and the lower alcohols giving a white precipitate which, under x-ray analysis, showed to be TiO_2. The complex was found to be soluble only in excess of DMSO, Fig. 1, and was recrystallized from DMSO-benzene mixtures.

Solubility and conductivity measurements were carried out as a function of temperature. The equivalent conductance at infinite dilution, Fig. 2, does not follow a straight line when plotted against temperature and its value between 25° and 45°C is within the range 31-40 Siemens cm^2 $equiv.^{-1}$.

The fact that the Λ° increases with temperature does not correspond, as it should, to a linear relationship (4) and the change in shape of the solubility curve about 40°C suggests that the nature of the solute is modified near this temperature. This is in accordance with the observed change in the reaction product when the reaction temperature reaches 40°C. If the yellow solid is kept at temperatures higher than 40°C a change in color is also observed. According to existing data on the $Cl_4Ti(DMSO)_2$ complex (2, 5) it is concluded that sulfoxide groups are changed into sulfide.

The observed equivalent conductance is sufficiently high that it may be concluded that the complex dissociates into ions. The addition of a few drops of $AgNO_3$ immediately produces precipitation of AgCl. This

Brief Communications

An Interferometric Study of Low Temperature Charging of the Lead-Acid Cell

R. N. O'Brien*

Department of Chemistry, University of Victoria, Victoria, British Columbia, Canada V8W 2Y2

A number of models to explain the relatively low charge acceptance of lead-acid secondary cells at temperatures below −20°C have been proposed. The most recent is that of Valeriote and Gallop (1). Using in part the heterogeneous compositions of the anodic layer postulated by Pavlov and co-workers in a long series of papers which in 1968 (2) gave a correlation of the composition of potentiostatically formed films by x-ray diffraction (and electron microscope) studies with measurements of current, charge, applied potential, and electrode capacitance, they have evolved a relatively satisfactory model. According to Pavlov and Valeriote the method of forming β-PbO_2, the active material, varies with the previous history of

* Electrochemical Society Active Member.
Key words: interferometry, convection, cold-charging, lead acid.

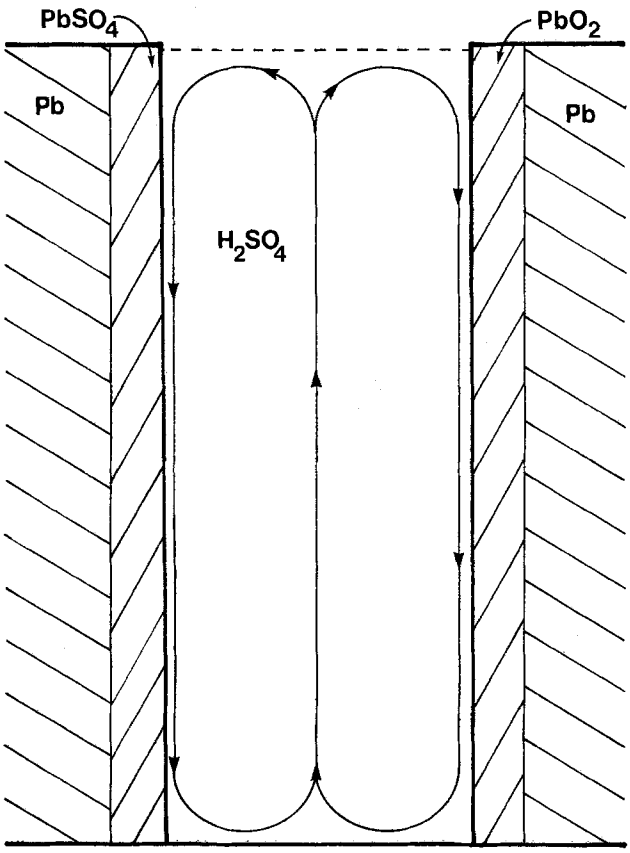

Fig. 1. The natural convection regime expected during the charging cycle.

discharge of the cell and the method of charging. The low temperature resistance to charge acceptance can be explained by one sequence of discharge-charge conditions using Pavlov's mechanism to explain the existence of electrode phases which are chemically unstable in bulk acid solution.

A critical aspect of charge acceptance is the existence of pores in the multicomponent layer between the lead and bulk electrolyte. Valeriote and Gallop suggest several inhibiting mechanisms to charging including pore blockage by precipitation of $PbSO_4$ or PbO_2 or ice formation in the relatively dilute electrolyte in the pores. The present work was begun to investigate solution conditions accompanying low temperature resistance to charge acceptance.

An interferometer containing a micro lead-acid cell of a design previously described (3) was used. The cell was 0.318 cm thick with an electrode area of 0.80 cm^2. Electrodes were made by cycling 99.99% Pb sheet in 4M H_2SO_4 or cut from a standard automotive battery. Interferograms were recorded on videotape and selected ones analyzed. Tapes were viewed and reviewed to assess solution changes at leisure.

If a soluble reducible material were produced at the anode which could diffuse to the cathode and be reduced at temperatures below −20°C, then inability to charge a battery would be explainable but not as simple nonacceptance of charge. A refractive index gradient, caused by higher refractive index for the more oxidized product plus greater concentration of it at the anode, would be expected. No such gradient appeared at any temperature. When the electrolyte in a cell charged at 25° and −30°C was drained, diluted approximately four times, and analyzed by atomic absorption spectrometry, the lead content was the same within the accuracy of the instrument for each sample, but above the predicted solubility. It is considered that suspended lead particles dissolved on sample dilution. In view of these analyses and the absence of a visible concentration gradient, an ionic discharge mechanism of the correct magnitude seems unlikely.

If charging were a simple conversion of $PbSO_4$ to PbO_2 at the anode and $PbSO_4$ to Pb at the cathode with H_2SO_4 evolved at both electrodes, a natural convection pattern as shown in Fig. 1 would result. Because H_2SO_4 is heavier than water, downward convective currents would be generated at both electrodes. Such a pattern was looked for by suspending activated charcoal particles in the electrolyte and recording their movements and also looking for convection-limited diffusion layers. The pattern (Fig. 1) was observed but only on a few of the many runs done.

All possible situations were observed, that is, where there were no concentration gradients and no gas evolution and hence no convection to the most complicated situation where part of each electrode was gassing and other parts showing concentration gradients resulting in erratic convection patterns. Pavlov's model as modified by Valeriote and Gallop predicts such changes in behavior as a function of time when the electrodes are subjected to varying potential regimes in charging and discharging cycles. Figure 2 shows three interferograms taken at 15 sec intervals of charging at 1 mA cm^{-2}, a concentration gradient at the anode (right-hand side PbO_2 formation) with downward convection at that electrode (charcoal particles in suspension were observed) with gas evolution at three points, the bubbles showing as black spheres. The concentration gradient is a maximum at 30 sec and shows convection limitation at 60 sec.

Electrodes cut from an old automotive battery showed the same behavior in general, but the sizes

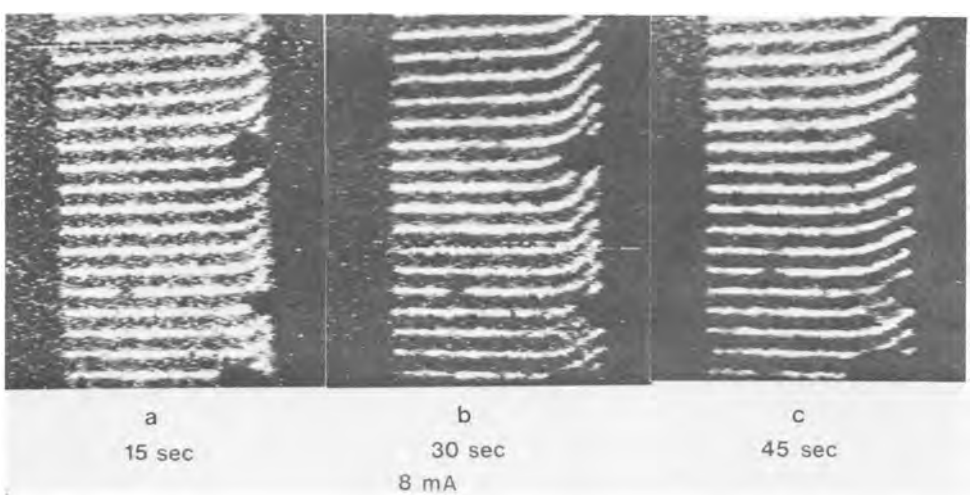

Fig. 2. A series of interferograms taken at 15 sec intervals during a charging cycle at −30°C and 1 mA cm^{-2}.

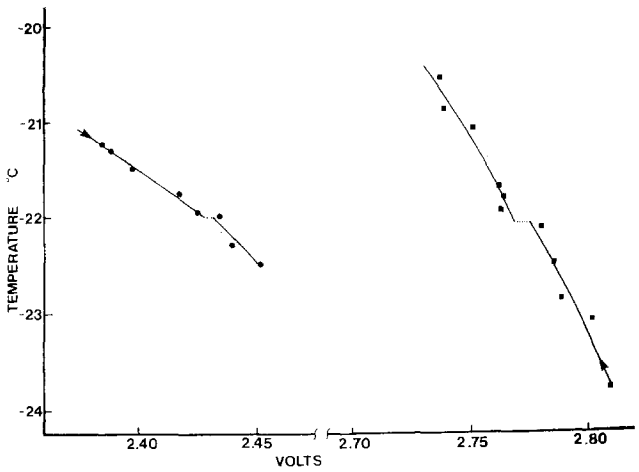

Fig. 3. A plot of the potential required to charge the cell at 10.00 mA cm^{-2} at temperatures between −20° and −24°C.

of electrode surface that tended to behave differently (with and without gas evolution and with and without concentration gradients) were smaller tending to have linear dimensions less than 1 mm.

The electrodes from the automotive battery showed a distinct change in impressed voltage required to charge at a constant current density of 10.00 mA cm^{-2} at −22°C as the temperature was raised or lowered. Figure 3 shows that the slope of the cooling run ($\partial V/\partial T$) is greater than the warming run, but each shows an abrupt change of about 10 mV at −22°C. Valeriote (4) has suggested this is freezing of the liquid in the pores of the heterogeneous $PbSO_4$-PbO_2 layer at the anode.

The Stability of Photoelectrodes

J. O'M. Bockris* and K. Uosaki

School of Physical Sciences, The Flinders University of South Australia, Adelaide, Australia

The stability of a semiconductor electrode under illumination is one of the key points in the prospect for the photoelectrochemical production of hydrogen.

Recently, Harris *et al.* (1) reported that TiO_2 single crystals were not stable and the photocurrents decreased with time in all cases they examined. Similar results were reported by Wrighton *et al.*, although they found no sign of decomposition of TiO_2 (2). Also, Yoneyama *et al.* (3) found that p-GaP was not stable under illumination, although they mentioned that there could be a possibility of obtaining a stable condition by choosing a suitable electrolyte, etc.

The stability of a TiO_2 single crystal cut perpendicularly to the c axis [(001) face] obtained from Nakazumi Crystal Corporation and of a p-type GaP wafer [Zn doped, (111) face] donated by Dr. K. Akita of the Fujitsu Laboratory Limited was examined in 1*N* NaOH solution.

The TiO_2 single crystal was reduced in a hydrogen atmosphere at 800°C for 5 hr (4). An ohmic contact to TiO_2 was obtained by means of indium (5) and a copper wire was soldered onto the indium. The specific resistance of the crystal was 2.0 Ω · cm.

A p-type GaP was etched in HNO_3-HCl (2:1) mixture (6) and an ohmic contact was made by means of Zn-In alloy (3). The specific resistance was 1.3 Ω · cm.

The semiconductor electrodes were mounted in a Teflon electrode holder with an epoxy resin so that only the faces to be examined were exposed to the solution. The electrode area was 0.125 cm^2. A 900W Xe lamp (Canrad-Hanovia 538 C1) was used as a light source and an infrared absorbing filter (Oriel G-776-7100) was placed between the light source and the electrochemical cell. A PAR 173 potentiostat was employed to maintain the electrodes at given potential.

* Electrochemical Society Active Member.

Key words: photoelectrode, titanium dioxide, gallium phosphide, semiconductor electrode.

The results are shown in Fig. 1 for TiO_2 and in Fig. 2 for p-GaP.

Although Harris *et al.* (1) mentioned that the photocurrent of TiO_2 decreased in all cases studied by them and Wrighton *et al.* (2) reported the fall of the photocurrents with time but without details, the photocurrents in our work did not change detectably over 1000 min (Fig. 1).

Also, the photocurrent of p-GaP decreased only slightly with time (Fig. 2). This behavior is different from that reported by Yoneyama *et al.* (3).

These results suggest that the stability of the photocurrent at semiconductors depends upon the preparation, dopant, and pretreatment of the semiconductor

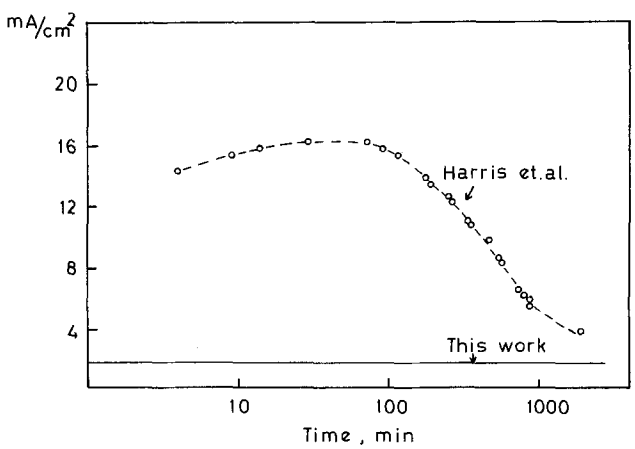

Fig. 1. The photocurrents as a function of time on TiO_2 for the work of Harris *et al.* compared with that of the present work. Potential used by Harris *et al.* at pH = 0 was 2.24V (NHE). Potential used by us at pH = 14 was 1.2V (NHE).

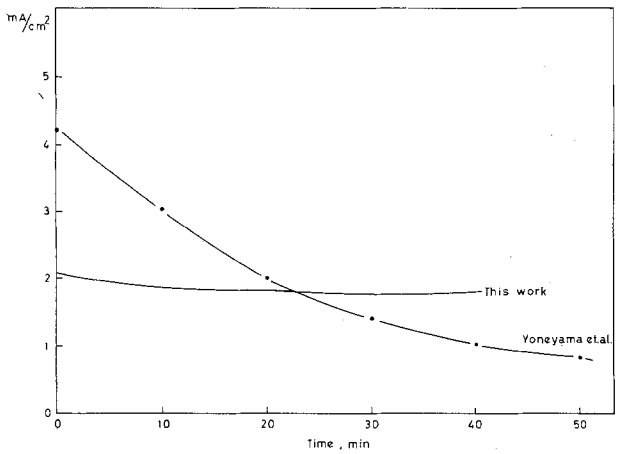

Fig. 2. The photocurrent as a function of time on Zn-doped GaP from the work of Yoneyama *et al.* and that of the present work. Potential used by Yoneyama *et al.* in 1*N* H_2SO_4 was +0.19V (NHE) and the potential used by us in 1*N* NaOH was −0.76V (NHE).

and also solution and illumination conditions. Thus, for the TiO_2 electrode, we carried out a hydrogen atmosphere reduction for 5 hr at 800°C, whereas Harris *et al.* (1) used 15 min at 600°C and Wrighton *et al.* (2) reduced TiO_2 at 700°C for 4 hr.

The main difference both for the TiO_2 and the GaP crystals seems to be the illumination condition. The intensity of light was 0.08 W/cm² in this work, 1.4 W/cm² in the experiment of Harris *et al.* (1), and 8 × 10^{-6} einstein/min (1 mm diam spot) (351, 361 nm doublet emission) which is equivalent to about 5 W/cm² in the work of Wrighton *et al.* (2). Accordingly, the current density of this work was 1.7 mA/cm² and that of Harris *et al.* and Wrighton *et al.* were 16 mA/cm² at maximum and 100 mA/cm², respectively.

The intensity of light was not reported by Yoneyama *et al.* (3) but one may hypothesize that it is stronger than that of this work, because the light of a 500W Hg lamp was focused on to the electrode, while collimated light of a 900W Xe lamp was used in this work.

ERRATUM

The following section of the paper, "The Effects of Counterion Size on the Equilibrium Properties of Charged Interfaces," by W. R. Fawcett and T. A. McCarrick, which appeared on pp. 1325-1331 in the September 1976 issue of this JOURNAL was printed incorrectly due to an editorial error.

Counterion effects at other charged interfaces.—Examination of the literature reveals that counterion effects have been observed in studies of the electrical properties of other charged interfaces (27). From a biological point of view, the physical properties of charged monolayers and bilayer lipid membranes (BLM) are often studied in the hope that the experimental results will help elucidate the behavior of membranes in living systems. However, it must be emphasized that counterion effects at artificial membranes do not necessarily correspond to those in living systems. In the following discussion only those effects due to cations as counterions will be considered. In this regard one may distinguish two cation effects at negatively charged monolayers and BLM. The first is the selectivity for cation transport which is often observed in these systems and which depends both on the chemical nature of the film and also on the presence of lipid soluble carriers (28-30). The second effect and that with which this paper is concerned is the nature of the average and local potential profiles at the interfaces of the system and its influence on adsorption of other ions and dipolar molecules and on transport through the film.

Goddard and co-workers (31-34) have studied the effects of counterion nature on the surface pressure and potential at both positively and negatively charged monolayers. For negatively charged head groups, these properties depend both on the nature of the head group and on the nature of the cation in solution. Examination of the literature on cation effects at negatively charged colloids reveals that cation interaction depends very much on the nature of the anionic group and that more than one interaction sequence for alkali metal cations is observed experimentally (35). Cation interaction with BLM does not appear to have been studied in any detail (29, 30) but electrical properties such as BLM capacitance have been found to depend on the nature and concentration of the electrolyte in the surrounding solution (29).

Erlander (35) has shown that cation interaction sequences at negatively charged colloids can be rationalized on the basis of the Frank and Wen model (36) of water structure surrounding the interacting ions with consideration of their effective dielectric constants. Accordingly, ions with high charge to radius ratios are surrounded by A-type water which is strongly bound to the ion by ion-dipole interactions. Most ions are also surrounded by B-type water in which the normal structure is broken and neither ion-dipole nor dipole-dipole interactions predominate. The normal water structure which is determined by dipole-dipole interactions and hydrogen bonding is designated C-type. Thus, Li^+, Mg^{++}, Ca^{++}, Sr^{++}, and Ba^{++} ions are surrounded immediately by A water with a layer of B water beyond the tightly bound dipoles. Cs^+, Rb^+, K^+, Cl^-, Br^-, and I^- do not have any ordering effect and thus are surrounded by a B region only. Na^+ and F^- are considered to have an A region but no B region. Erlander has estimated the effective dielectric constant of the B region surrounding the ions and has argued that ion-ion interaction increases when the effective dielectric constants are similar in magnitude (37). In order to apply these ideas to biological membranes one must know something about the effect of the charged groups at the surface on the structure of the surrounding water molecules. Erlander has argued that the phosphate group in phospholipids which is in close proximity to a base is surrounded by B water with a low effective dielectric constant. Thus, it interacts most strongly with K^+ which has similar characteristics. The interaction sequence ($K^+ > Na^+ > Rb^+ > Li^+ > Cs^+$) then depends on whether the cation has an A region and on the effective dielectric constant of the B region. Similar concepts can be applied to cation interaction with other common negative sites such as carboxylate (35).

In order to develop an electrostatic model for the potential distribution at the membrane/solution interface one must know the relative positions of the charged head group and counterions. At mercury the counterions are normally assumed to be ~5Å from a homogeneous, geometrically smooth metal/solution interface; more precisely, the distance of closest approach of the counterion and thus the potential distribution at the interface depend on the nature of the interaction of both the charged metal surface and the counterion with surrounding water molecules. The surface of the natural membrane is much more heterogeneous in character containing more than one type of phospholipid molecule with interdispensed globules of protein (38); moreover, the phospholipid distribution is often different on the inside and outside walls of the cell membrane (39). Thus, the local potential profile near the interface undoubtedly varies considerably over the surface of the membrane. From the above discussion the interaction of charged head groups at a given site with counterions will be chiefly a function of local water structure. Although one may obtain some impression of this structure by studying artificial membranes with the same charged head groups, it would be preferable to study interfacial structure at the real membrane. Reeves and co-workers (40, 41) have developed an NMR technique for studying the orientation of double layer ions at model membranes based on lyotropic liquid crystals. Application of this technique or another spectroscopic method to real membrane systems could be of considerable help in elucidating the spatial distributions of charged groups and ions at the membrane's surfaces. Levine *et al.* (42) have reviewed the electrostatic models developed to account for the surface potential and surface pressure observed at charged interfaces. They have emphasized the importance of considering the discrete nature of the charge as well as the distribution of counterions with respect of the charged head groups. Undoubtedly, the models developed for charged monolayers could be modified to deal with the potential distribution at each of the charged interfaces of the membrane. An understanding of the electrostatic situation could then be used to elucidate electrostatic factors which play a role in ion transport.

Semiconductor/Electrolyte Photoelectric Energy Conversion: The Use of a Molydenum Oxide Coating to Avoid Corrosion

S. Gourgaud and D. Elliott

Department of Chemistry, University of Queensland, St. Lucia, Queensland 4067, Australia

ABSTRACT

The electrolytic corrosion of n-type GaAs under illumination is avoided by a coating of hydrated molybdenum oxide (probably MoO_2). This has the properties of a solid redox system and acts as a hole acceptor to the substrate. It is in turn rereduced by some redox species in solution and thus effectively couples hole generation to the oxidation of the electrolyte. The molybdenum oxide can be coated electrolytically to a calculated thickness of at least several hundred angstroms and is capable of storing charge reversibly of many tens of millicoulombs per square centimeter.

Photoelectric energy conversion employing electrolytes rather than solid-state junctions has received some attention in recent years (1-4). A number of experiments have centered on the generation of hydrogen gas in an electrolytic cell containing a suitable semiconductor and counterelectrode [*e.g.*, (5, 6)]. Others have considered the direct conversion to electric power with a similar arrangement.

The general design of a direct conversion device would be according to Fig. 1 for an n-type semiconductor. Light entering the surface of the semiconductor causes electron-hole pair generation if of sufficient energy to cross the bandgap. Electrons promoted to the conduction band drift toward the interior while holes, the minority carriers, drift to the surface. Here they encounter the reduced form, M(red), of the redox couple in solution. This component is oxidized by the holes, transported to the counterelectrode and, there, rereduced. This reduction is driven by the external connection from the semiconductor. The result is a passage of electrons externally in a circuit doing work with no net change in the electrolyte. Analogous arguments may be used for a p-type semiconductor where electrons (the minority carriers) drift to the surface and cause a reduction of some oxidized species in solution.

A photoelectric device based on this design has potential advantages over a conventional solid-state diode in ease of manufacture and scale-up to large sizes. This arises from the following factors: (*i*) use of polycrystalline substrates since no junctions need be grown; (*ii*) optimum light penetration and segregation of optical and electroconductive phenomena; (*iii*) the choice of a wide range of compound semiconductors (*e.g.*, oxides, sulfides, etc.) of which only one carrier type can be made.

In a number of investigations of these types of devices, the principal disadvantages have been the electrolytic corrosion of the semiconductor and the inherent slowness of electrode reactions at such materials. Corrosion occurs for example with holes at an n-type semiconductor because of the preferential oxidation of the substrate compared with that of some ion in solution. Though there are some materials resistant to corrosion, *e.g.*, TiO_2 and SnO_2, their bandgaps are too high for conversion of sunlight. The inherent slowness of electrode reactions involving oxidation or reduction of ions in solution is more fundamental and is related to the relatively small carrier density at the surface of a semiconductor. This slowness is responsible for the preferential oxidation of the electrode and when corrosion can be avoided it then causes unacceptably low currents. Some attempts have been reported where these disadvantages have been obviated by means of a surface coating, *e.g.*, a metal film (7).

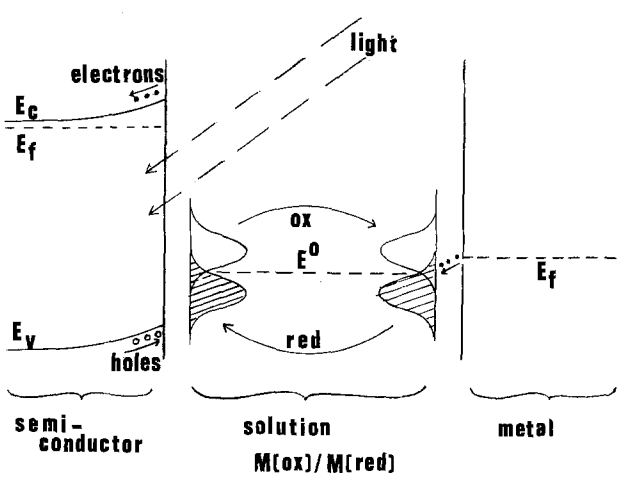

Fig. 1. Diagrammatic representation of photoelectric conversion device: E_c = conduction band; E_v = valence band; E_F = Fermi level; $E°$ = standard potential of M(ox)/M(red).

Key words: photocell, gallium arsenide, semiconductor electrochemistry.

The present investigation had its genesis in the laboratory of Professor P. Handler (University of Illinois). A patent application (Momin and Handler, 1969) described the operation of a $GaAs/H_2SO_4/Pt$ light-sensitive cell with the corrosion problem described above. This paper describes the use of an electrolytically generated surface film consisting of some form of molybdenum oxide ("Mo Ox") which has the properties of a solid redox system. This is able to compete successfully for holes at the surface on an n-type semiconductor, *e.g.*, GaAs, and in turn be rapidly reduced by a soluble redox species, *e.g.*, V^{2+}.

The Electrochemical Generation and Properties of "Mo Ox"

The generation and the oxidation/reduction properties of this material on a solid electrode were observed accidentally as the result of a molybdenum impurity in a sample of KCl (8). It is probably identical with a material described earlier by other authors (9). This was obtained as a dark brown film during the reduction of acidified molybdate on a mercury surface and was identified as a hydrated molybdenum dioxide. For the purpose of investigating its electrochemical properties it has been examined at a hanging mercury drop electrode (HMDE).

Experimental.—The electrode was prepared by catching mercury drops from a polarographic capillary onto a fine platinum wire (0.004 in.). The surface area of the drop was estimated from the mass flow rate through the capillary and the drop time. Potential control was accomplished using a Heath polarograph and measurements were recorded on a Riken-Denshi D72B X-Y recorder. All potential measurements were with respect to the SCE.

Results.—The generation and growth of surface layers were observed under cyclic linear sweep voltammetry (Fig. 2). Starting at −0.1V and scanning negatively in a deaerated but unstirred solution, a peak is observed at about −0.44V due to the reduction of molybdate ion. On scanning positively, a two-step oxidation occurs, with one peak at about −0.37V and another further drawn out at about −0.15V. After resting the electrode (at zero current) and stirring the electrolyte to restore equilibrium, the scan cycle is repeated. The reduction and oxidation peaks are enhanced compared with the initial scan indicating the buildup of some solid material on the electrode surface. Further cycles continue this process. Each negative excursion causes the reduction of molybdate from solution plus the rereduction of the accumulated surface layer which had previously been left in the oxidized form. Each positive excursion causes the oxidation of the accumulated surface layer. The rate of growth slows down as the layer builds up and it eventually reaches a limit (several hours in unstirred solutions). It can conveniently be characterized by the value of stored charge. On a mercury surface this varies with the method of generation and the concentration of Mo in solution. Values of the order of tens of millicoulombs per square centimeter have been observed. 10 mC/cm^2 would correspond to about a 300Å thick layer if the standard density of MoO_2 is assumed (150Å for a two-electron change).

The layer as first produced is initially transparent and shows interference colors. However, it shows a deepening yellow color as it gets thicker and eventually becomes a heavy brown coating. Since the layer is many molecules thick it must be somewhat conductive. The growth is probably limited ultimately by the resistance which causes the potential at the surface to lag behind that of the metal electrode. This also explains the gradual shift of the reduction peaks negatively as the layer grows.

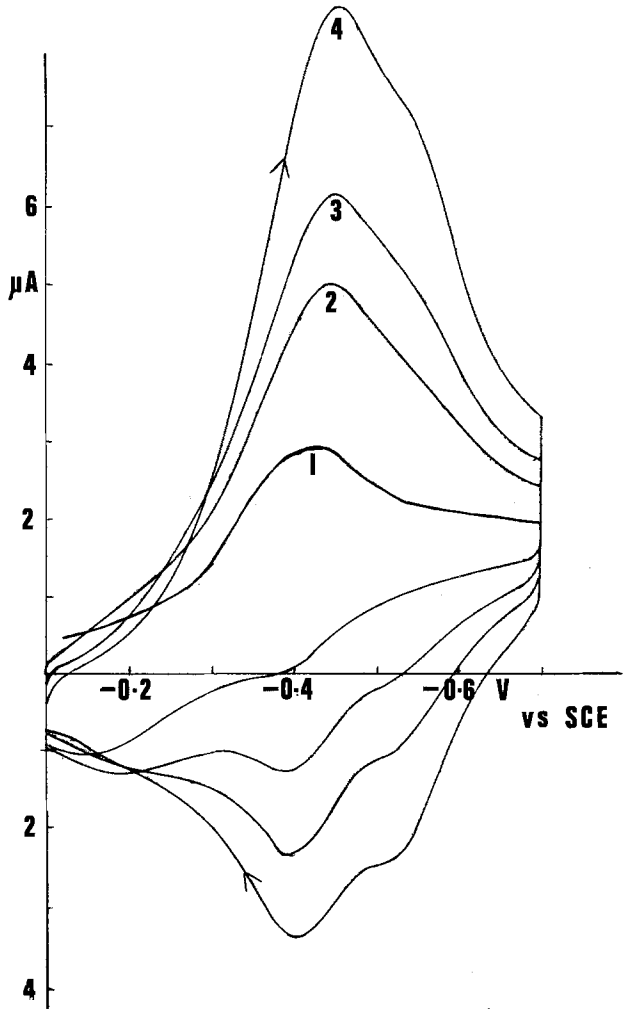

Fig. 2. Current-voltage curve for the reduction of molybdate at the HMDE: sweep rate = 0.5 V/min; area = 0.029 cm^2; solution = 1M NaCl, 0.01M HCl (*p*H 1.8), 7×10^{-4}M Mo (as ammonium molybdate). The numbers on the curves represent successive sweeps.

The reduction/oxidation linear sweep voltamogram is asymmetrical about the current axis; there is much more cathodic current passing than anodic. It is presumed that the hydrogen overvoltage is lowered compared with a mercury surface, so that appreciable hydrogen ion reduction takes place on the layer.

The growth of the layer is sensitive to *p*H, occurring roughly between *p*H 1 and *p*H 4. Figure 3 shows a series of first cyclic scans as a function of *p*H. The first anodic peak is only detectable as a slight inflection in the first scan but the way it subsequently grows can be seen in Fig. 2. Taking the average of the cathodic and first anodic peaks for the second scans as indicating the equilibrium potential of the system, the variation with *p*H is about 0.110 V/*p*H unit, indicating that $2H^+$ ions are involved per electron. A second anodic peak (−0.18V at *p*H 1.8) is prominent at the beginning but ultimately disappears as the layer grows. It also shifts with *p*H (Fig. 3), but at about half the rate compared with the main system. It may represent the reoxidation of some of the layer back to the VIth state (presumably soluble) and is a further explanation for the asymmetry about the current axis; much more Mo(VI) is reduced and reoxidized than subsequently accumulates on the electrode as a stable insoluble layer.

Polarographic measurements have also been made. A two-stage reduction is observed, the first of which is very poorly defined and is approximately half that of the second part. This has been interpreted previously (10-14) as a VI → V step followed by a

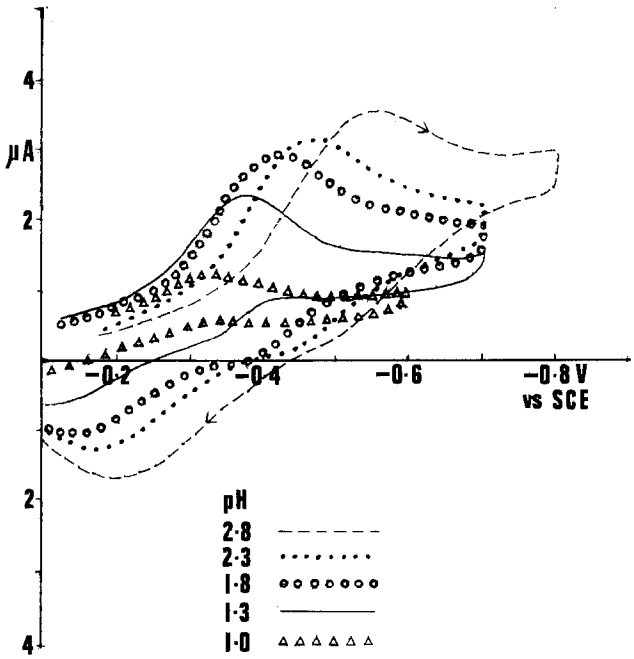

Fig. 3. Reduction of molybdate at the HMDE as a function of pH. First current-voltage cycle. Data as for Fig. 2 except pH varied as shown by addition of HCl.

V → III step. It is therefore suggested that the V and III compounds are solid in this pH range and are responsible for the cyclic linear sweep pattern. The reduction/oxidation can be provisionally represented by the scheme

$$Mo(V)Ox + 4H^+ + 2e \rightleftarrows Mo(III)Ox + 2H_2O$$

Some confirmation of the two-electron transfer may be gained from the shape of the later curves (Fig. 2). As the layer grows a secondary anodic peak emerges, more negative than the main one by about 0.1V. A slight inflection on the cathodic curve in an analogous position seems to represent the same process taking place during reduction. As further growth proceeds, this feature eventually grows to dominate the whole linear sweep pattern. This causes a negative shift to the apparent equilibrium potential (judged from the mean point of the cathodic and anodic peaks). Compared with the graph in Fig. 3, the values for a fully grown layer may be 0.1V or more negative. This factor varies greatly with various parameters, *e.g.*, sweep rate, Mo concentration, etc., which probably influence the physical form of the deposit if not its actual composition.

Physical Properties and Structure of Mo Ox

The material has been examined by a number of techniques. It was prepared in relative bulk for this purpose by electrolytic reduction on a mercury pool ($\approx$ 20 cm^2). A cyclic potential sweep was used, between −0.1 and −0.7V *vs.* SCE at the rate of 2 V/min. 10^{-3}M molybdenum was used (as ammonium molybdate) in a 1M NaCl solution adjusted to pH 1.5 with dilute HCl. The layer was generated for about 3 hr with constant stirring with nitrogen. The Mo Ox film was detached from the mercury by shaking, forming a suspension of small flakes that could be withdrawn from the vessel. The material was collected by centrifuging and was repeatedly washed with 100% alcohol to remove water. It was finally dried under vacuum.

The material appears to be amorphous down to the limit of resolution of the electron microscope. No electron diffraction pattern was detected and no x-ray powder pattern (24 hr Cu-Kα).

Spectroscopic examinations were made in both the infrared and the u.v./visible region. For the former, the material was incorporated into KBr disks and examined on a PE 225 spectrophotometer. The spectra, compared with those for some other molybdenum compounds, showed a large increase in the number of absorption bands (six bands were observed between 1400 and 1000 cm^{-1}, whereas hydrated Mo O_3 has only one and ammonium molybdate has none). This is attributed to a much lower site symmetry in the relatively amorphous compound. Bands appearing at 3595, 3450, 3150, and 1622 cm^{-1} suggest the material is hydrated. However, the direct connection of hydroxyl groups to the metal atom is not indicated from the spectrum. According to Adams (15), evidence for this should occur in the range 500-576 cm^{-1}.

By comparing the spectrum of the film with data given by Mitchell and Trifiro (16), the following assignments have been made:

970 cm^{-1}	stretching	M-O (terminal)
920 cm^{-1}	stretching	M-O (bridging)
735 cm^{-1}	stretching	M-O (bridging)

u.v./visible spectra were determined on a Cary 17 spectrophotometer. The material was ground and in the form of a suspension in absolute alcohol was evaporated onto a quartz plate. No peak was observed in the visible, but a band in the u.v. was observed at 41,500 cm^{-1} (241 nm) which does not correspond to a band in any reported compound.

The tentative conclusion is that the material is a condensed molybdenum oxide molecule of average oxidation state IV involving bridging oxygen linkages and arranged amorphously in the film. This description is similar to that for a colloid and the material has a similar appearance to a gelatinous film when viewed in the visible microscope. It should be noted that in the pH range at which the material is generated condensed polyanions are the stable form for Mo(VI) in solution (*e.g.*, $Mo_6O_{21}^{-6}$).

The Generation and Properties of Mo Ox on n-GaAs

A specimen of n-type GaAs ($\sim 10^{17}$ carriers/cm^3) was cemented with epoxy resin into the end of a glass tube and mounted vertically in a rotating-electrode assembly. The surface of the electrode could be illuminated from underneath using a 100W quartz-iodine projector lamp.

Figure 4 shows the current-voltage behavior for the rotating electrode under cyclic sweep conditions. The reduction peak for molybdenum (IV) is superimposed on the hydrogen evolution reaction and is displaced negatively with respect to the values previously reported for a mercury electrode. This large overvoltage illustrates the slowness of the reduction at the semiconductor surface. On scanning positively, no oxidation of the layer takes place in the absence of light. On illumination, however, the two-stage oxidation occurs, the first peak at about −1.0V, which is close to the flatband potential. The holes responsible for the oxidation are released at the valence band edge about 1.4V more positive than this. The layer grows satisfactorily only when the electrode is scanned in the presence of light between −0.7 and −1.1V. Initial chemical etching is also necessary.[1] If the potential is allowed to go more positive than about −0.6V, the electrode enters a region of anodic dissolution that disrupts the surface Mo Ox layer. Satisfactory growth of the layer does not occur at a surface so eroded and it must be reetched chemically.

[1] 1 part 30% H_2O_2, 1 part H_2O, 3 parts concentrated H_2SO_4.

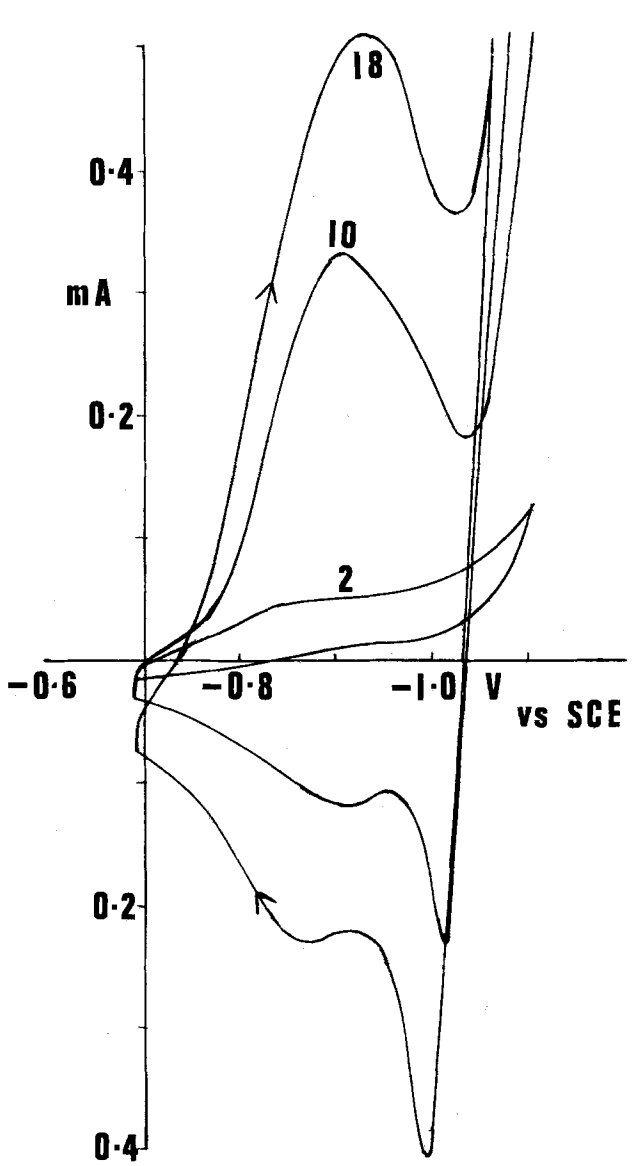

Fig. 4. Current-voltage curves for the reduction of molybdate at a GaAs electrode (under illumination): sweep rate = 2 V/min; area = 0.27 cm^2; rotation = 2000 rpm; solution = 1M NaCl, pH 1.85, 5.6 × 10^{-4} Mo. The numbers on the curves represent particular stages in the sequence of 18 continuous cycles.

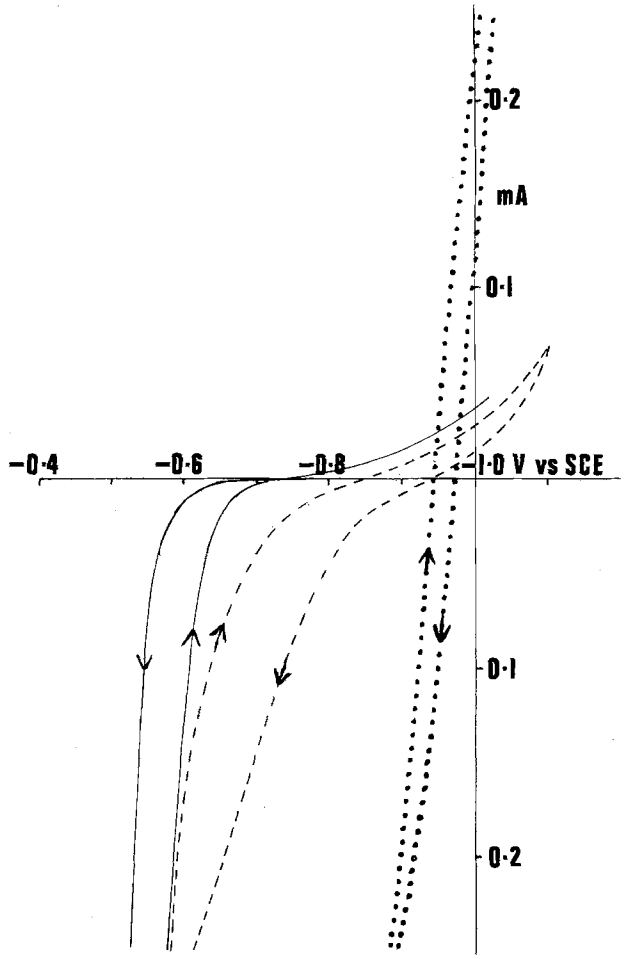

Fig. 5. Oxidation of V^{2+} at a GaAs electrode (under illumination): sweep rate = 0.1 V/min; area = 0.27 cm^2; rotation = 2000 rpm; solution = 1M NaCl, pH 1.35. ——— Oxidation of GaAs alone; – – – – oxidation of V^{2+} at bare GaAs electrode (10^{-1}M V^{2+}); .... oxidation of V^{2+} at Mo Ox-covered GaAs electrode (2×10^{-1}M V^{2+}).

The Oxidation of V^{2+} at a Mo Ox Covered GaAs Surface

The direct oxidation of V^{2+} at an illuminated, bare GaAs surface is sluggish and merges quickly into the anodic dissolution region (Fig. 5). This is a typical result for semiconductors and illustrates the poor coupling between holes accumulating at the surface and any reducing agent in solution. This is in spite of the fact that the holes appear at the valence band edge approximately 0.9V more positive than the V^{2+}/V^{3+} potential. With a surface covering of Mo Ox, however, a large oxidation current for V^{2+} occurs. The V^{2+}/V^{3+} potential is more negative than that for Mo Ox, and presumably the latter is kept in the reduced form. Holes generated in the semiconductor cause the oxidation of the Mo Ox which is then rapidly reduced by the V^{2+} in solution. It is not known at this stage what is the rate-determining step. The net result is the oxidation of V^{2+} in solution at a velocity very much greater than without the Mo Ox layer.

The currents are not very reproducible and are critically dependent on many factors, *e.g.*, the precise composition and performance of the layer, its thickness, the *p*H and composition of the solution, etc. For the particular layer whose growth is shown in Fig. 4 (9.4 mC/cm^2), the currents at constant voltage, after an initial transient, declined very slowly and the following values given in Table I were observed after a few minutes.

The current appears saturated at a potential more positive than about −0.7V suggesting that it is limited by the hole generation process and not by electrode kinetics. The saturation current observed is less than that for a silicon cell with the same light source (11 mA/cm^2). However, since the lamp used was uncorrected and has its peak well in the infrared, the silicon cell (bandgap 1.12 eV, 1.1 μm) would be expected to be more sensitive. Another factor causing lower currents is the absorption of light in the liquid layer between the electrode surface and the glass window. This was not closely controlled for the rotating electrode,

Table I. Solution: 1M NaCl, 0.2M V^{2+}, *p*H 1.5

V (*vs.* SCE)	mA/cm^2
−0.9	0.41
−0.8	1.48
−0.7	2.0
−0.65	2.1

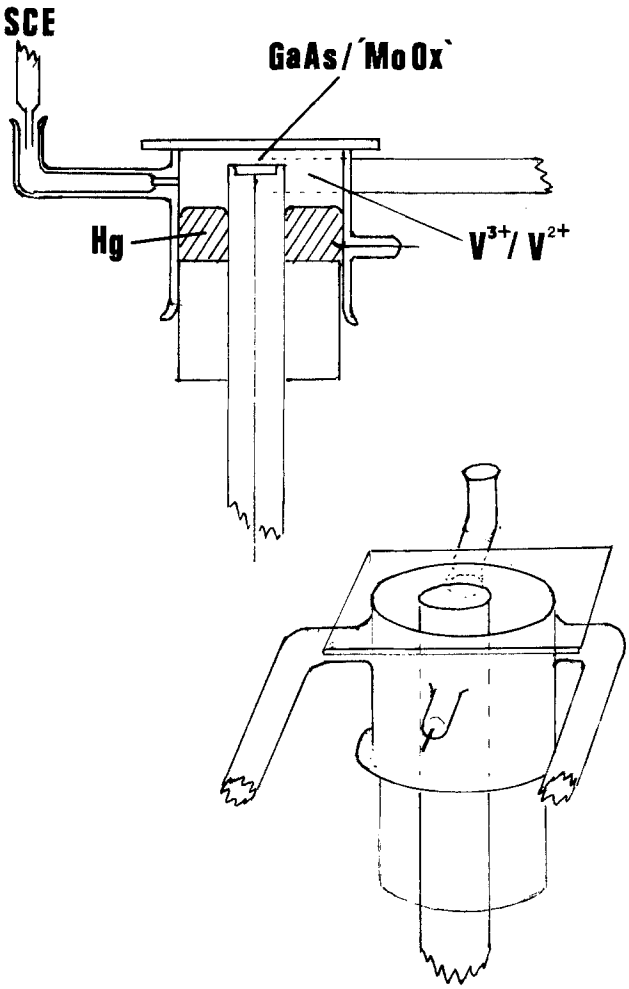

Fig. 6. Diagram of experimental photoelectric conversion cell

but in a working cell could be made very small by making the layer thin enough.

An Experimental Photoelectric Conversion Cell

An experimental cell was constructed as shown in Fig. 6. The GaAs electrode was first plated with the Mo Ox layer before mounting. The counterelectrode was an annular pool of mercury chosen for its high H^+/H_2 overvoltage. The solution containing approximately equal quantities of V^{2+} and V^{3+} was prepared externally by electrolytic reduction and pumped into the cell. Beside the two working electrodes, contact was made to the solution via a SCE. This enabled the potential of the GaAs electrode to be monitored to make sure it did not enter the anodic dissolution region. The open-circuit potential of the cell is the difference between that of the semiconductor (monitored at between -0.95 and -1.0V depending on the precise characteristics of the Mo Ox layer) and the counterelectrode which is determined by the V^{2+}/V^{3+} potential (about -0.52V). A working value of about 0.45V has been obtained. The maximum current is governed by the overvoltage characteristic of each electrode. The properties of the semiconductor/Mo Ox/V^{2+} half of the system have been described above, and the observed currents are not much reduced because of the electrode being stationary, indicating that mass transfer is not a serious limiting effect for these currents.

At the counterelectrode, the intrinsic rate constant of the V^{3+}/V^{2+} system is sufficiently great at a clean Hg surface ($\approx 10^{-3}$ cm/sec) that negligible activation overvoltage should result at *ca.* 20 mA/cm^2. In the actual cell constructed, a significant overvoltage was observed which considerably lowered the operating voltage of the cell. This may be due to surface contamination or concentration polarization, but could be largely eliminated by proper design.

Conclusion

A photoelectric conversion cell based on the preceding concepts seems a practical proposition. However, several factors have to be considered in justifying such a construction over conventional solar cells.

Efficiency.—The intrinsic efficiency of solid-state cells depends on the bandgap of the semiconductor and in sunlight reaches a theoretical maximum for materials with a gap of about 1.4 eV. However, in the present construction the operating voltage depends on electrochemical potentials unrelated to the bandgap, namely the difference between the flatband potential and the redox potential of the electrolyte. The optimum bandgap should be just a little larger than this for maximum conversion. The redox potential should be sufficiently negative to maintain a significant part of the Mo Ox layer in the reduced form, *ca.* < -0.4V. Consequently the only practicable variable is the flatband potential.

This potential at a given carrier concentration and electrolyte composition depends on the chemical nature of the material. With compound semiconductors it becomes more negative with lower molecular weight, *e.g.*, CdS is more negative than CdSe and GaP is more negative than GaAs. This is also the direction of increasing ionic bonding between the elements. Since the bandgap also increases in the same sense (causing lower light absorption and therefore loss of efficiency), there is no advantage in looking for too negative values. There is not enough experimental information available on flatband potentials generally, particularly as a function of electrolyte composition to predict the material of highest efficiency. However, any material with a potential of -1.0V or more negative is worth pursuing experimentally. This includes GaAs, GaP, and probably CdS. An interesting possibility is that the potential may be shifted by surface-active materials in a manner similar to the shift in the ecm (or zero charge potential) of mercury and other metals.

Cost.—The semiconductor/electrolyte construction seems to offer advantages in reducing the cost per watt factor, particularly for large installations. There are, for example, a large range of materials (often one-carrier types, usually n-type) that would lend themselves to large-scale thin film polycrystalline construction. Also, the separation of the optical and electrical regions offers new design possibilities. A major limitation in the unit size of existing solid-state cells arises from the current-carrying capacity of the thin surface layer. If thin enough to allow adequate light penetration, its resistance limits the area to about 10-20 cm^2 for silicon cells (*i.e.*, 0.1-0.2 W/unit for 10% efficiency).

Electrolytes should have a more favorable combination of optical/electrical properties and the layer can be made very thin providing that a cathode of sufficient surface area can be placed nearby. The necessary cathode area is also a flexible design parameter and it could take the form of a transparent conductive film or a metal grid. A grid provided with multiple feed-through contacts passing through holes in the semiconductor would enable the unit to be scaled up to meter sizes.

Stability.—The major problem of semiconductor corrosion is eliminated by operating in a potential range where it does not occur. The Mo Ox layer may also

exert a moderate protective action. The long-term stability of this layer has not been measured in this particular configuration. However, previous results (8) suggest it is very stable. In any case it is renewable by a simple electrolytic process.

The particular electrolyte used, V^{2+}/V^{3+}, is of course prone to oxidation by air and by H^+ (the latter oxidation is dependent on *p*H and the presence of catalytic metal surfaces). Persistence of V^{2+} for several days can be obtained with minimal precautions and it is to be expected that oxidation can be made almost negligible with good design. This electrolyte can also be regenerated electrolytically and since a moderate volume of solution could be used with a large area it could be periodically renewed at negligible energy cost. Even this would be eliminated by the use of more stable redox systems, *e.g.*, Ti^{3+}/TiO^{2+}, in various media. The latter is currently under investigation.

Electro-oxidation of Gallium Arsenide

I. Initial Phase of Film Formation in Tartaric Acid-Water-Propylene Glycol Electrolyte

S. Szpak*

Naval Electronics Laboratory Center, Electronic Material Sciences Division, San Diego, California 92152

ABSTRACT

A standard galvanostatic procedure was used to study the initial phase of anodic oxidation of n-GaAs in a 3 weight percent (w/o) aqueous solution of tartaric acid mixed with propylene glycol. The initial phase is controlled by a two-dimensional growth of oxide from nuclei generated at a rate of about 10^7 cm^{-2} sec^{-1}. The effect of *p*H and illumination was examined in terms of the kinetics of nucleation in a heterogeneous system involving the semiconductor as the solid phase.

Although anodic oxidation of the III-V compound semiconductors in general, and gallium arsenide in particular, has been of considerable interest (1-4), only recent disclosures by Hasegawa, Forward, and Hartnagel (5, 6) and by Hasegawa and Hartnagel (7) have made it attractive for use in the fabrication of electronic devices based on planar configuration. Their approach is of special interest to the semiconductor technologist because of electrolyte stability, reliability of procedure, and excellent reproducibility under normal process control. Glasslike films, approximately 7000Å in thickness, can be obtained in a few minutes.

The electrochemical behavior of this system however, has not been completely investigated. In particular, the initial stages of the film growth need to be explored. It is this aspect of the anodic oxidation that is addressed in this communication.

Experimental

The galvanostatic technique was selected to follow the initial phase of the anodic oxidation because it may

* Electrochemical Society Active Member.
Key words: anodic oxidation, nucleation, growth kinetics, gallium arsenide.

provide clues as to the type of film conductivity and mode of its formation (8). This technique, if combined with an additional observation, *e.g.*, scanning electron microscopy, may yield sufficient information for the determination of the probable mechanism operating during the early stages of anodic oxidation.

Materials and procedure.—All chemicals were of reagent quality and were used without further purification. Triply distilled water was used exclusively throughout this investigation.

A thin slice of the Sn-doped, (111) oriented n-type GaAs (carrier density: 3.8×10^{17} cm^{-3}, mobility: 2200 cm^2 V^{-1} sec^{-1}, and resistivity: 8.5×10^{-3} Ω cm) was mounted on a glass slide using high quality beeswax with the (111)B side contacting the electrolyte. A Ge-Au eutectic alloy ohmic contact was provided on the (111)A side. To assure good reproducibility, the GaAs (111)B surface was anodically oxidized, the oxide stripped in diluted HCl (1:4 by volume), followed by a water rinse and immersion in diluted NH_4OH (1:4 by volume). This procedure was repeated several times.

A current regulator, Model R2 (Leichner Manufacturing Company, Champaign, Illinois), in conjunction with a regulated power supply, Model 3-150B (Dressen-Barnes Corporation, Pasadena, California), served as the constant current source. Electrode potentials were measured against a saturated calomel electrode and were recorded on a Speedomax-G recorder (Leeds and Northrop, North Wales, Pennsylvania). All experiments were carried out in 3 w/o aqueous solution of tartaric acid mixed with propylene glycol in the volume ratio 1:3. Special attention was given to a thorough equilibration of the n-GaAs/electrolyte interphase prior to experimental runs. This was achieved by immersion in an electrolyte until the continuously recorded rest potential attained a steady-state value to within ± 10 mV between samples. The relatively good reproducibility of the rest potential and the reported solubility of the oxide film in the electrolyte employed (7) may well assure the existence of a bare surface prior to the initiation of an anodic process.

Results.—It was concluded, on the basis of published data (7), that two types of observations ought to be helpful in determining the mechanism of film formation, namely (*i*) the effect of electrolyte composition, specifically the OH^- ion concentration and, (*ii*) for the n-type GaAs, the effect of illumination.

A set of potential-time curves for the galvanostatic oxidation of GaAs is shown in Fig. 1. Each curve exhibits characteristics typical of the formation of an ion-conducting layer as indicated by the steep portion of the potential-time curve (8). The increase in the slope with increase of the anodic current is further indication of the ionic conductivity of the anodic film.

Additional information can be extracted from the time needed to achieve full surface coverage, t_{cr} (see discussion below). Qualitatively, as the anodic current is increased, the critical time becomes shorter. It is also of interest to note that no film was formed when the applied anodic current was less than 10.4×10^{-5} A cm^{-2} in an electrolyte with the pH adjusted to 5.1.

The effect of electrolyte pH on the potential-time curves is summarized in Fig. 2. Evidently, their shape is independent of the OH^- ion concentration, within the investigated pH range, but both, the critical time, t_{cr}, and the anodic current density needed for the initiation of film formation, j_{cr}, are strongly affected. The higher the pH, the shorter the critical time, t_{cr}, and the lower the critical anodic current density. This observation refers to the pH of the bulk electrolyte. The pH value in the neighborhood of the surface is affected by the dissolution process to the extent governed by the electrolyte buffer capacity. Here, this change is expected to be rather small in view of relatively flat tartaric acid-NH_4OH neutralization curve for pH < 6.5.

The effect of illumination on the potential-time relationship is shown in Fig. 3. This effect is similar to the one observed on increasing the electrolyte acidity. If the GaAs/electrolyte interphase is illuminated, then both the critical time is longer and the critical anodic current density is larger.

The flat portion of the potential-time curves is associated with the growth of surface coverage with an insulating or badly conducting layer. The relatively small increase in potential with time is, in effect, an increase in the overpotential of the electrochemical process taking place over the continuously decreasing available surface area. A set of scanning electron microscope photographs, shown in Fig. 4, illustrates the time evolution of the surface coverage. In particular, Fig. 4a and 4b show a surface sparingly covered with circular patches. The light patches, indicating an oxide-covered surface, photographed 30 and 60 sec after initiation of the anodic process (points A and B in Fig. 2), are of different sizes indicating different nucleation times and/or different growth rates. With the passage of time, there is an increase in the surface coverage accompanied by a merging of individual

patches. As the critical time was approached (point C, Fig. 2), the surface was about 80% covered and when the anodization time exceeded the critical time (point D, Fig. 2), the surface was nearly totally covered with a thin layer. An increase in the surface coverage by a growth of individual patches is not an unusual occurrence. This mode of growth may be due to an interaction between various competing processes or it may arise because of preferential dissolution sites induced by an advancing film (9).

Discussion

A cursory examination of Fig. 4 indicates a two-dimensional growth from randomly placed nucleation sites. This observation together with the examination of the effect of illumination on the critical time and critical anodic current density forms a basis for the present analysis.

Kinetics of surface coverage.—An idealized growth of surface coverage is illustrated in Fig. 5. Points P_1, P_2, . . ., are the nucleation sites which grow along the peripheries. Assume for simplicity circular patches having growth rates independent of their radii provided that they grow as separate entities and that the characteristic length of the preceding process, *e.g.*, the diffusion length, is smaller than the patch radius. Assume further that, as the individual patches begin to merge, their growth is by addition of newly formed small patches P_1', P_2', P_3', . . ., rather than by the addition of molecules. The latter assumption is made to emphasize the importance of merging or overlapping of individual patches on the over-all growth of the surface coverage. Under these conditions, a nucleus formed at time, τ, attains at time, t, a radius $r = v(t - \tau)$, where v, cm sec^{-1}, denotes the velocity of radial growth. If the rate of nucleation is Z, cm^{-2} sec^{-1}, then within the time interval, $d\tau$, $Zd\tau$ new nuclei will be generated and the gain in the surface covered, dA, will be given by

$$dA = Z\ (A_o - A)\ v^2\pi(t - \tau)^2 d\tau \qquad [1]$$

or in an equivalent form

$$d\theta = Z\ (1 - \theta)\ v^2\pi(t - \tau)^2 d\tau \qquad [1a]$$

where $\theta = A/A_o$ is the surface coverage. The term $(A_o - A)$ in Eq. [1], or $(1 - \theta)$ in Eq. [1a], was added to indicate that nucleation is excluded from occurring on the surface already covered.

The functional dependence of v on the anodic current density, j, is considered to account for all elementary processes participating in the film formation. The form of this dependence must be consistent with the experimental facts, *e.g.*, with the existence of a critical anodic current density. This requirement suggests a form

$$v = [kj - k_1(x_1, x_2, \ldots, \epsilon)](A_o - A) \qquad [2]$$

Equation [2] consists of two terms multiplied by the available surface area. The first term, kj, denotes the ionization of surface atoms while the second term, $k_1(x_1, x_2, \ldots, \epsilon)$, reflects the effect of electrolyte composition $(x_1, x_2, \ldots)$ as well as the effect of illumination, ϵ, on the formation and growth of the anodic film, that is, it contains also applicable transport information. Adopting Eq. [2] one gets for the critical current

$$j_{cr} = k_1(x_1, x_2, \ldots, \epsilon)/k \qquad [3]$$

Evidently, Eq. [2] is valid for $j > j_{cr}$ and within the time interval $0 < \tau < t_{cr}$.

Substituting Eq. [2] into Eq. [1] and integrating the resulting expression, one obtains

$$\frac{1}{2[kj - k_1]^2}\left[\theta_{cr}^{-2} - 1\right] = \frac{Z\pi}{3} t_{cr}^3 \qquad [4]$$

The integration limits, $\theta = 0$, $\theta = \theta_{cr}$ and $\tau = 0$, $\tau = t_{cr}$ are consistent with the interpretation of the SEM photographs (Fig. 4c and 4d) and the shape of the potential-time curves (*e.g.*, Fig. 2), respectively. They are also consistent with the concepts illustrated in Fig. 5, where the total current, i, in an external circuit, is the sum of currents crossing the GaAs/electrolyte interface, $i_1 = (1 - \theta)A_o j$, and the current crossing the GaAs/oxide interface, $i_2 = \theta A_o j_2$

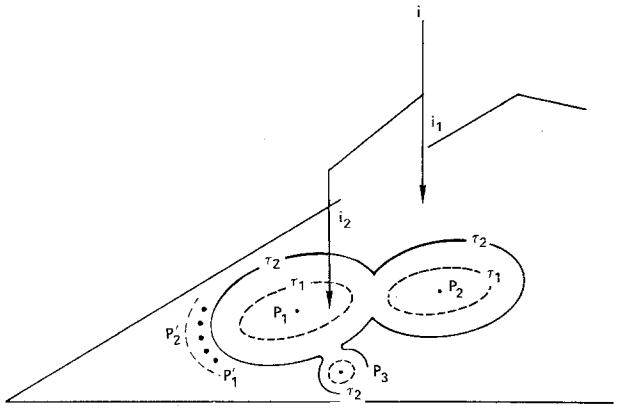

Fig. 5. Representation of model kinetics for surface coverage growth.

$$i/A_o = (1 - \theta)j + \theta j_2 \qquad [5]$$

The magnitude of these currents depends on the resistivity in their paths. Evidently, at $\theta > \theta_{cr}$ or at $\tau > t_{cr}$ the anodic current flows entirely through the GaAs/oxide interface, *i.e.*, $i/A_o = \theta j_2$, and Eq. [1] no longer describes the dominant set of events.

A plot of j *vs.* $t_{cr}^{-3/2}$, shown in Fig. 6, obeys Eq. [4], except at low current densities. A pronounced effect of both OH^- ion concentration and illumination is quite evident.

Kinetics of nucleation.—The rate of formation of critical embryos which can develop into a new phase, *e.g.*, droplet or crystallite, is given by an expression

$$Z = K \exp(-\Delta F/kT) \qquad [6]$$

where K is a constant and ΔF is the free energy of embryo formation (10-12). Since neither the pre-exponential factor nor the free energy of embryo formation are known for this system, the rate of nucleation cannot be assessed. However, with the aid of Eq. [2], [3], and [4] and the examination of Fig. 1 and 4, the nucleation rate can be estimated as follows: The critical surface coverage can be estimated from Fig. 4c and 4d at $\theta_{cr} = 0.9$. The radial velocity, $v = 10^{-6}$ cm sec^{-1}, was found by averaging the patch size measured from the SEM photographs, Fig. 4a and 4b. Over 200 measurements were used for this purpose. The critical current density, $j_{cr} = 10.4 \times 10^{-5}$ A cm^{-2}, was determined by direct observation, *cf.* Fig. 1. Using these values, one gets the rate of nucleation in the electrolyte adjusted to *p*H 5.1 to be approximately 10^7 cm^{-2} sec^{-1}.

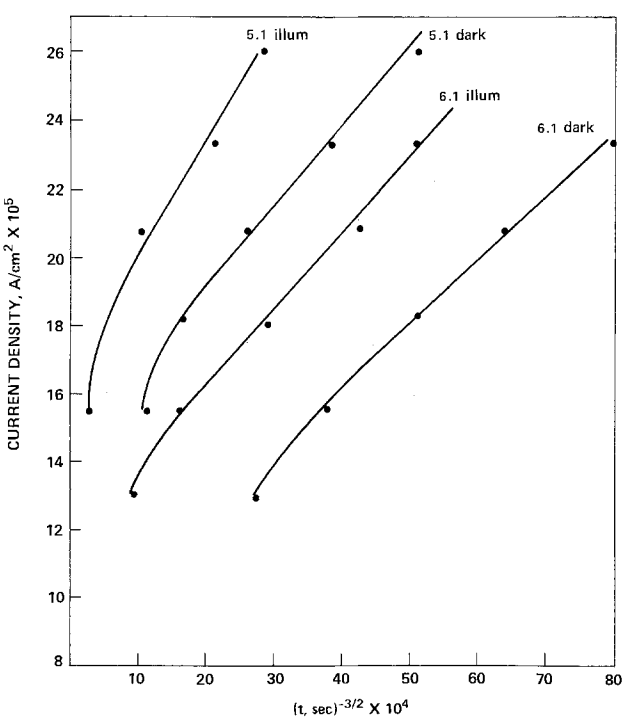

Fig. 6. Plot of j *vs.* $t_{cr}^{-3/2}$

The effect of illumination on the growth of surface coverage can be analyzed in terms of elementary processes. These processes can be divided into two groups: the first group comprises the events that involve the GaAs/electrolyte interface, *e.g.*, adsorption heterogeneous nucleation, etc., while the second group entails the processes which occur in the liquid phase, *e.g.*, homogeneous nucleation, transport phenomena, and the like. It is expected that only the events of the first group will be affected by illumination, especially if the space charge of the extrinsic n-GaAs is in depletion or inversion (13). Conversely, the processes listed in the second group are not likely to be affected by illumination.

In order to follow the effect of illumination on the rate of nucleation, consider Eq. [4] and its graphical representation in Fig. 6. The slope, $s = (C/Z)^{1/2}$, where $C = 3(\theta_{cr}^{-2} - 1)/2k^2\pi$, which was already used in the estimate of the nucleation rate ($Z = 10^7$ cm^{-2} sec^{-1}), can also be used to determine the effect of illumination, with much greater accuracy, however. Better estimates are likely because all quantities entering an expression for C are insensitive to illumination. Thus, when Eq. [4] is combined with Eq. [6], and the ratio taken, then the relationship, Eq. [7]

$$2kT \ln (s_\epsilon/s) = -\Delta F + \Delta F_\epsilon \qquad [7]$$

can be obtained. The subscript ϵ refers to the condition of illumination.

Evidently the condition of illumination is that of a gain in the free energy of the critical embryo formation ($s_\epsilon/s > 1$, *cf.* Fig. 6). In particular, this gain was found to be approximately 0.6 kT per critical embryo for the n-GaAs/electrolyte interphase, when the bulk electrolyte was adjusted to *p*H 5.1.

Additional information concerning the n-GaAs/electrolyte interphase may be obtained by the use of an expression relating ΔF to the surface tension. This relationship for the nucleation on solid surfaces is given by Eq. [8] (10, 14)

$$\Delta F = \frac{1}{3}[\sigma_{12}S_{12} + \sigma_{23}S_{23} - \sigma_{13}S_{13}] \qquad [8]$$

where σ is the surface tension, S the interphase area and subscripts 1, 2, and 3 refer to the solid phase, GaAs, the electrolyte, and the newly formed phase, $Ga_2O_3 \cdot As_2O_3$, respectively. As written, Eq. [8] does not contain an explicit dependence on overpotential. This dependence however, is implied in an expression for σ_{12} and it is likely to be more complex for the semiconductor than for the metal/electrolyte interface.

Substituting Eq. [8] into Eq. [7], and noting that $\sigma_{23}S_{23}$ does not change with illumination, one gets

$$[\sigma_{12}S_{12} - \sigma_{13}S_{13}]_\epsilon - [\sigma_{12}S_{12} - \sigma_{13}S_{13}] = 6\ kT \ln(s_\epsilon/s) \qquad [9]$$

Taking $k = 1.372 \times 10^{-16}$ erg/°K, $s_\epsilon/s = 1.38$ and assuming the radius of the critical embryo, $r_{cr} = 10^{-6}$ cm, one calculates from Eq. [9] an increase in the surface tension due to illumination of approximately 3×10^{-2} erg cm^{-2}. The numerical value of $r_{cr} = 10^{-6}$ cm was selected as a compromise between large critical embryos consisting of 50-250 molecules associated with

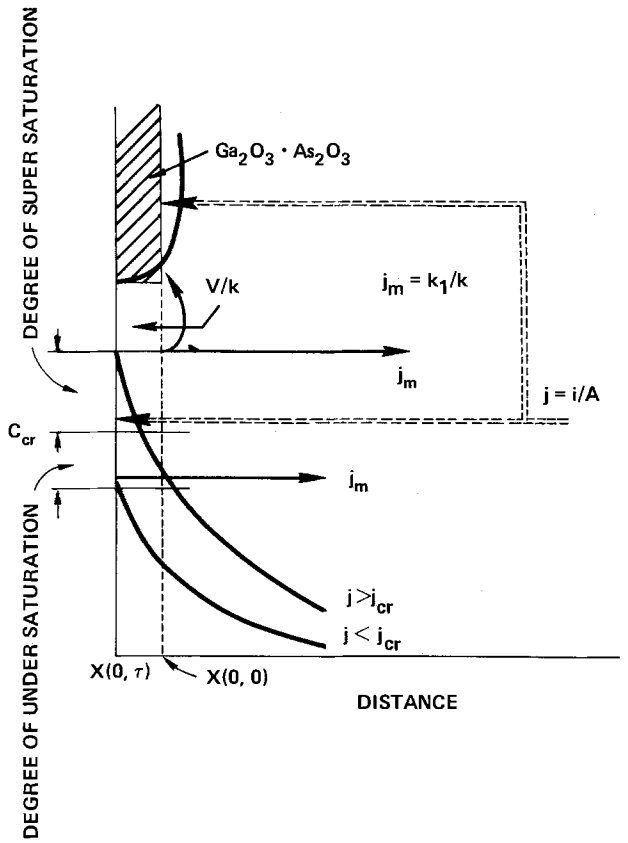

Fig. 7. Representation of elementary processes participating in film growth.

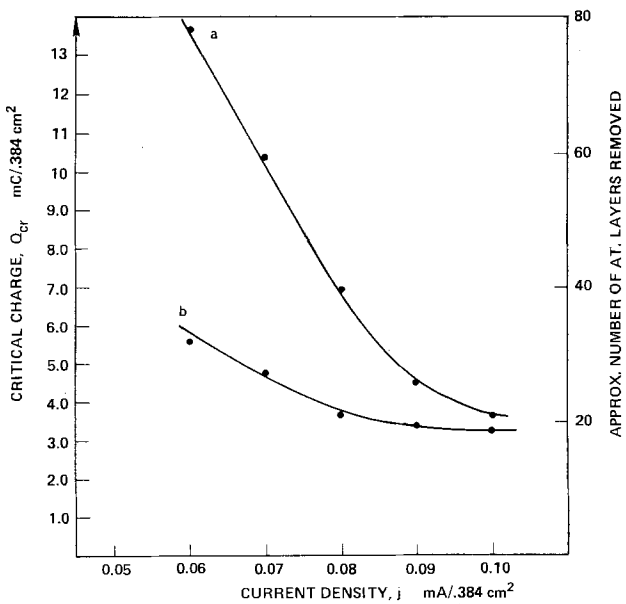

Fig. 8. Critical surface coverage, Q_{cr}, as a function of applied anodic current.

homogeneous nucleation (10) and considerably smaller embryos typical of heterogeneous nucleation, particularly in electrochemical systems (15).

Mechanism of growth.—The set of events leading to the initiation and growth of the surface coverage is summarized in Fig. 7. The anodic current, i, just as in Fig. 5, is split into i_1 and i_2, with the latter being insignificant throughout the considered time interval.

The passage of current across the GaAs/electrolyte interface causes the destruction of the semiconductor surface resulting in ionization of its components and a shift of the interface from $x(0, 0)$ to $x(0, \tau)$. The detailed mechanism of the anodic reaction in this system is not known. For this reason, it will be assumed that the ionized species Ga^{+3} and As^{+3} exist in the same composition as the molecules forming critical embryos immediately after leaving the crystal lattice.

The presence of these species at the interface creates the concentration gradient and initiates mass transport away from the interface, j_m. It is convenient for the present discussion to rewrite Eq. [2] as

$$j = v/k + k_1/k \qquad [10]$$

Here, the first term indicates the part of the equivalent current used up in the formation and the growth of the film and the second term accounts for losses by transport or other causes. The relative magnitude of these terms for the film formation in an electrolyte with the pH adjusted to 5.1 is demonstrated in Fig. 8, where the number of coulombs needed for nearly complete coverage, Q_{cr}, is plotted against the anodic current density. At low current densities, as many as 80 atomic layers were dissolved prior to attainment of full surface coverage, while at higher current densities approximately 9.2 mC cm^{-2}, corresponding to *ca.* 20 atomic layers, were consumed. In the absence of illumination, Fig. 8 curve b, the situation is quite similar except that lower values of Q_{cr} were recorded; the difference due to the applied current density and illumination being attributed to the second term in Eq. [10]. Moreover, the relative magnitudes of these terms vary with time, namely as $\tau \rightarrow t_{cr}$, the first term increases while the second term decreases. In the neighborhood of t_{cr} only the first term needs to be considered.

The spatial distribution of the ionized components of GaAs is shown in Fig. 7. The highest concentration of the relevant species is expected at the GaAs/electrolyte interface extending by diffusion into the bulk. The concentration at the interface should increase monotonically with time at a rate being governed by the diffusional transport and the applied current density. Since the necessary condition for the appearance of a new phase is the existence of supersaturation, it follows that the nucleation should occur preferentially at the GaAs/electrolyte interface. Moreover, because the free energy for the critical embryo formation is less at a solid/liquid interface than in the bulk, the preference for the nucleation at the solid surface is strengthened, thus leading to a two-dimensional film growth.

The effect of illumination is that of an increase in the surface energy of the GaAs/electrolyte interphase. As the free energy for the embryo formation becomes larger, more molecules are required to form the critical embryo. Consequently, the frequency of the appearance of a new phase is less. This results in an enhancement of mass transport for the same anodic current density.

Conclusions

1. The initial stage of film formation is controlled by a two-dimensional growth from nucleation sites generated at a rate of about 10^7 events per cm^2 per second. The initial velocity of radial growth was found to be *ca.* 10^{-6} cm sec^{-1} being substantially higher as the critical time was approached.

2. An expression of the form $j = (C/Z)^{1/2} t_{cr}^{-3/2}$ was derived for this model and experimentally verified for $4.5 < pH < 6.5$ and $0.104 < j < 0.25$ mA cm^{-2}.

3. A reaction path comprising a set of elementary processes for the formation of the anodic film was postulated.

4. The effect of illumination was examined in terms of the kinetics of heterogeneous nucleation on an n-type semiconductor surface and was related to the transport of relevant species.

Surface Morphology and Shape Stability in Silicon Ribbons Grown by the Edge-Defined, Film-Fed Growth Process

Mobil Tyco Solar Energy Corporation, Waltham, Massachusetts 02154

ABSTRACT

The morphology and shape stability of silicon ribbons grown by the edge-defined, film-fed growth (EFG) technique are described. A theoretical analysis of shape stability is presented for controlled-shape growth (where the ribbon shape is determined by the shape of the meniscus); experimental evidence is introduced to show the inherent stability of the ribbon side and the relative instability of the ribbon edges, in agreement with the theory. The characteristic meniscus angle ϕ_o for constant-dimension growth is shown to depend on the crystallographic orientation of the ribbon surface; the ϕ_o anisotropy is associated with the anisotropy in the crystal-vapor surface free energy in silicon. Growth features which result from faceted growth on peripheral octahedral planes are described, and the competition between faceted growth and controlled-shape growth is analyzed. Various morphological features associated with variations and fluctuations in the EFG process variables are described.

There is considerable interest in applying the edge-defined, film-fed growth (EFG) process to the production of ribbon-shaped crystals of silicon for solar cell applications (1-4). In the EFG method, a capillary die conducts the melt from the crucible to the crystal growth interface just above the top of the die (Fig. 1). The resultant shape of the crystal is determined by the shape of the liquid film (or growth meniscus) which, in turn, is controlled by the perimeter of the die top. In essence, then, crystals of any desired cross-sectional shape can be grown by this technique using an appropriately designed die top. Deviations from controlled-shape crystal growth can occur, however, as a result of the crystallization properties of the material (5).

The fundamental physical problem in controlled-shape crystal growth is the geometric relationship between the meniscus and crystal surface directions at the crystallization front. Recent experiments (6) have shown that the requirement for the constant cross-sectional growth of silicon crystals is that the angle ϕ between the tangent to the meniscus and the growth axis be a constant designated as ϕ_o (for {111} orientation Si crystal surface, $\phi_o = 11°$). Complete analysis of the meniscus shape then shows that the ribbon thickness is related to the die and meniscus geometries by an expression of the form (3, 7)

$$t = f(t_d, s, h_{eff}, \phi_o) \qquad [1]$$

* Electrochemical Society Active Member.

Key words: silicon, shaped crystal growth, crystallization and crystal structure, growth stability, crystal-liquid-vapor interfacial energies.

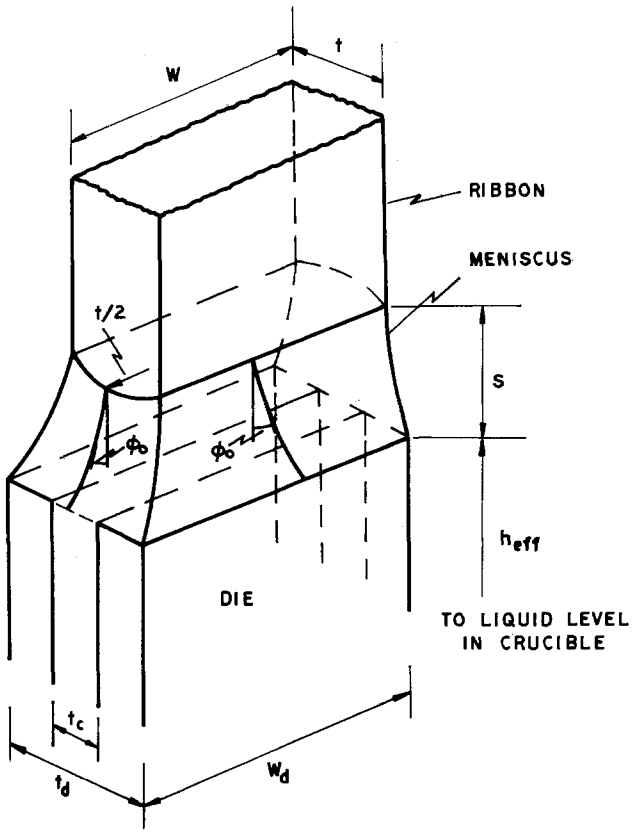

Fig. 1. Schematic illustration of ribbon growth by the EFG process showing the geometrical variables which determine the ribbon shape.

where t_d is the die thickness, s is the height of the meniscus or growth film, and h_{eff} is the effective height of the growth interface above the liquid level in the crucible (see Fig. 1). From the known functional form of f and the experimentally measured values of the other parameters, the ribbon thickness can be readily calculated; good quantitative agreement has been found (7) between the experimental and theoretical values of the ribbon thickness.

The stability of the ribbon dimensions (such as the thickness) in controlled-shape growth will be a function of the process parameters t_d, s, and h_{eff}, and of the material parameter ϕ_o. Variations in the die thickness can, of course, occur during growth as a result of mechanical changes in the edge-defining die dimensions (for example, caused by chemical reaction of the die with liquid silicon). The variable s, in practice, is determined by the details of the heat balance at the crystallization front; for steady-state growth, the rate of heat removal by conduction-radiation through the ribbon must be equal to the sum of the rate of latent heat generation at the interface and the rate at which heat arrives to the interface by conduction through the meniscus film. Perturbations in the parameter h_{eff} can occur as a result of fluctuations in the melt level in the crucible or in the rate of crystal growth (if viscous flow effects in the die capillary are appreciable); in addition, h_{eff} continuously changes during growth as the melt in the crucible is depleted. The angle ϕ_o has been shown previously (6) to depend on the orientation of the crystal surface; the anisotropy of ϕ_o undoubtedly results from the anisotropies of the crystal-vapor and crystal-liquid interfacial free energies of silicon.

In this paper, we examine the theory of ribbon shape stability in EFG as a function of perturbations in the geometrical variables, and present experimental evidence of ϕ_o anisotropy effects on ribbon shape. We then consider the effects of the anisotropic crystallization properties (*i.e.*, faceting) of silicon on controlled-shape growth based on observations in EFG ribbons. Finally, we examine various morphological features frequently observed in EFG silicon ribbons which are primarily associated with variations or fluctuations in the process variables during growth.

Theory of EFG Ribbon Shape Stability

The criterion for the stability of the external shape of a crystal in a meniscus-controlled process such as EFG derives from the finding (6) that the crystal dimension changes when $\phi \neq \phi_o$; the relevant crystal dimension increases when $\phi > \phi_o$ and decreases when $\phi < \phi_o$. Shape stabilization takes place when the resultant change in crystal dimension is such that ϕ approaches ϕ_o again. A condition of shape instability, on the other hand, occurs when ϕ deviates even further from ϕ_o as a result of the shape change. This criterion was recently applied (8) to the various techniques of crystal growth from the melt (Czochralski, floating zone, and EFG of various crystal shapes); here we consider the shape stability of EFG ribbons when the growth is subjected to perturbations in the geometrical variables discussed above. The analysis is divided into separate discussions of the thickness and width dimensions of the ribbon.

Stability of the ribbon thickness.—Figure 2a shows the variation of ribbon thickness with meniscus height for typical values of the experimental variables (*i.e.*, solution of Eq. [1] for $h_{eff} = 2$ cm and $t_d = 0.04$ cm). The curve for $\phi = \phi_o = 11°$ represents all possible pairs of s-t values for growth with a uniform thickness. If a steady-state system (s_A, t_A) in Fig. 2a is perturbed by raising the meniscus height to B, the ribbon thickness should decrease (since $\phi < \phi_o$ at B) to a new steady-state thickness $t_{B'}$. Similarly, a lowering of the meniscus height to C in the figure will lead to a new steady-state thickness $t_{C'}$.

A perturbation in the die thickness t_d is considered in Fig. 2b. When the die thickness increases from t_{d1} to t_{d2}, the initially steady-state system (s_A, t_A) in the figure will fall on the dashed curve $\phi > \phi_o$ for the larger die thickness. It is readily seen that the ribbon thickness should therefore increase to a new steady-state value t_B. Of course, changes in meniscus height may also occur (as a result of changes in the thermal profile accompanying the t_d change), but these can be accommodated in a stable manner (*cf.* Fig. 2a). Localized fluctuations in the die thickness occur frequently in silicon ribbon EFG when graphite dies are used (*e.g.*, as a result of the growth of SiC particles at the die top). A change in the effective die thickness from t_d to the capillary spacing t_c (see Fig. 1) can occur when a critical value of the meniscus height is exceeded; at this height, the angle between the meniscus and the horizontal at the die edge is equal to 30° [the wetting angle of liquid Si on graphite (9)]. For the case examined in Fig. 2a, the critical height is 0.10 cm, thus it is not reached before the ribbon thickness becomes zero. Growth (with a new steady-state thickness) would continue from the inner edges of the die in Fig. 1 if this critical meniscus height were exceeded.

A fluctuation in h_{eff} is examined in Fig. 2c. Here we consider a hypothetically large change in h_{eff} from 4 to 2 cm; the initially steady-state system (s_A, t_A) is again seen to respond to this change by attaining a new steady-state thickness t_B. A similar stabilizing behavior is seen in Fig. 2d when the characteristic value of ϕ_o changes from ϕ_o^1 to $\phi_o^2 < \phi_o^1$ (for example, as a result of a change in the orientation of the ribbon surface caused by twinning).

Stability of the ribbon width.—The treatment of the stability of the width dimension of the ribbon is perforce less satisfying than that of the thickness dimension. The principal difficulty arises in attempting to

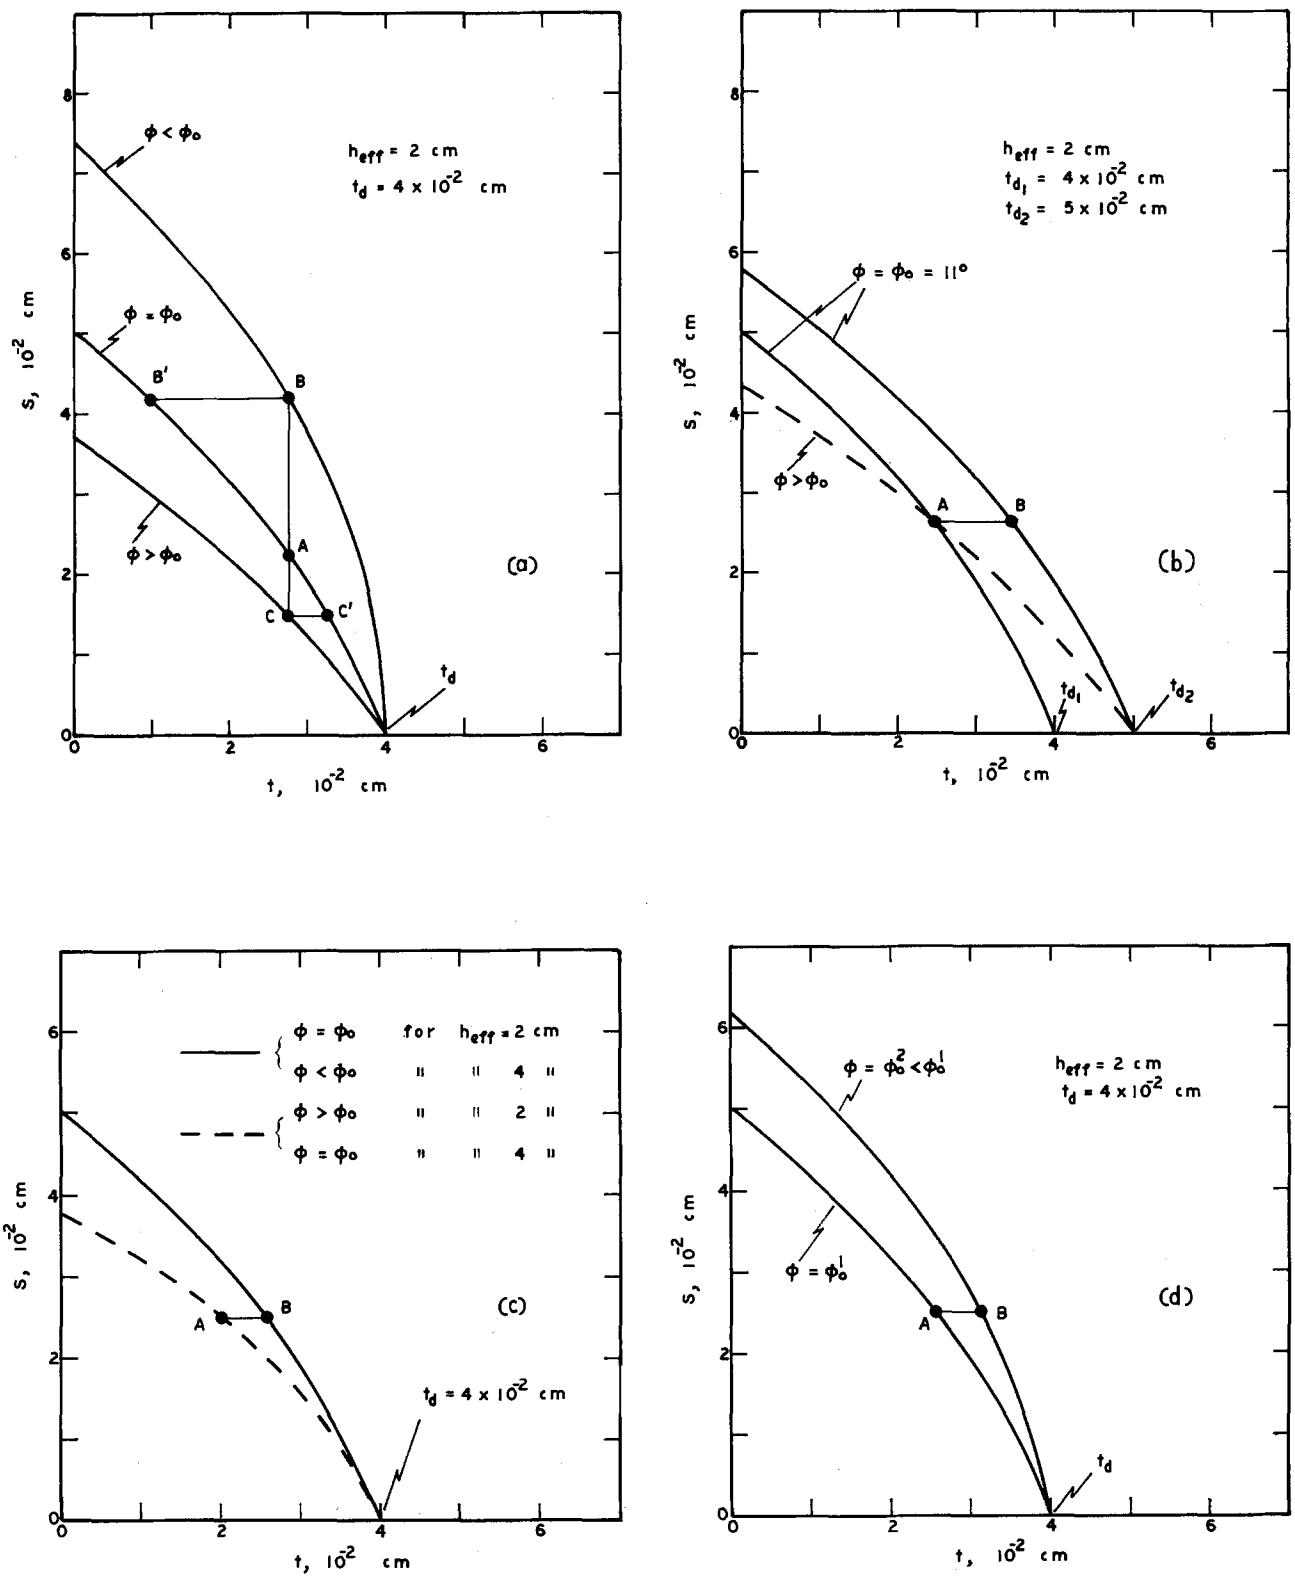

Fig. 2. Meniscus height-ribbon thickness curves in silicon ribbon EFG for various values of die thickness, meniscus angle, and h_{eff}, and analysis of perturbations in the geometrical variables. (a) Perturbation in meniscus height; the steady-state ($\phi = \phi_o$) and non-steady-state ($\phi <$ and $> \phi_o$) curves were calculated for $\phi = 11°$, 0°, and 20°, respectively. (b) Perturbation in die thickness; $\phi = 20°$ for the non-steady-state curve for t_{d_2}. (c) Perturbation in h_{eff}; $\phi_o = 11°$. (d) Perturbation in meniscus angle; $\phi_o^1 = 11°$ and $\phi_o^2 = 5°$.

calculate the meniscus shape near the end of the ribbon where the radius of curvature of the ribbon surface changes continuously from infinity along the side of the ribbon to approximately $t/2$ at the very end of the ribbon (see Fig. 1). An approximation to the ribbon end problem was obtained (8) by considering the shape stability of a rod-shaped crystal of radius $t/2$ growing from a die shaper with a wetted top surface of radius $t_d/2$. Figure 3a shows the variation of $t/2$ with meniscus height for $h_{eff} = 2$ cm and $t_d = 0.04$ cm. The solid line in the figure (where $\phi = \phi_o = 11°$) again represents all possible pairs of s-$t/2$ values for steady-state growth. It can be readily argued in the figure that a steady-state point such as A is stable whereas a point such as D is unstable when the meniscus height is perturbed from the respective steady-state values. In the latter case, for example, an increase in meniscus height to E will result in a de-

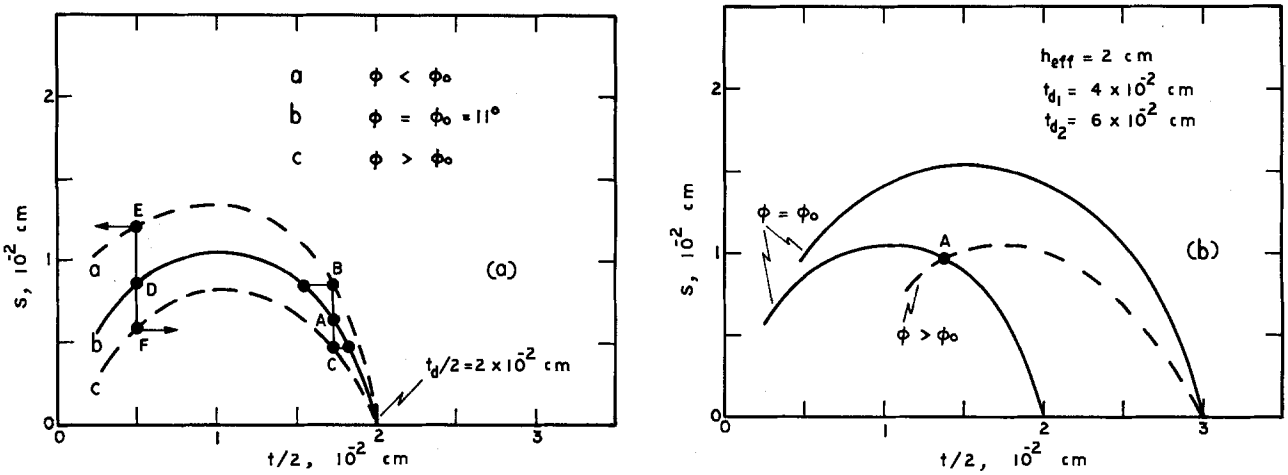

Fig. 3. (a) Variation of t/2 at ribbon end with meniscus height for various values of the meniscus angle and $h_{eff} = 2$ cm. The non-steady-state curves ($\phi \neq \phi_0$) are shown schematically. The steady-state point A is stable, while point D is unstable when the meniscus height is perturbed. (b) Perturbation in the edge-defining die radius ($t_d/2$). The $\phi > \phi_0$ curve for t_{d_2} is shown schematically.

crease in the crystal radius t/2 (since $\phi < \phi_0$); this will lead to a still greater deviation of ϕ from ϕ_0, and thus to an even faster decrease in radius, and so on. It is readily seen in Fig. 3a that the entire portion of the $\phi = \phi_0$ curve where $ds/d\ (t/2) > 0$ is unstable, whereas shape stabilization occurs in the region where $ds/d\ (t/2) < 0$. The detailed analysis (8) of the ribbon end problem shows that the requirement for shape stability is that the edge-defining die radius ($t_d/2$) should not exceed approximately twice the radius of curvature of the ribbon ($t/2$) at the ribbon edge.

The conclusion we reach from the above analysis of the ribbon shape stability is that the side of the ribbon (*i.e.*, the thickness dimension) is inherently stable, whereas the ribbon edge (and, therefore, the width dimension) is only conditionally stable. Perturbations in the geometrical variables at the ribbon edge can readily upset the condition of shape stability, as demonstrated in Fig. 3b. Here we see that an increase in the edge-defining die radius from t_{d_1} to t_{d_2} has resulted in an initially stable system (s_A, $t_A/2$) to fall on a curve with $\phi > \phi_0$ for the new die radius; the system will be unstable with the radius increasing at an ever-increasing rate. In the following sections, we present the results of experimental investigations of the ribbon shape stability, and show frequent examples of the inherent stability of the ribbon side and the comparative instability of the ribbon edge.

Effects of Meniscus Angle Anisotropy on Shape Stability

Previous experience (6) has indicated that the characteristic value of the meniscus angle for the steady-state cross-sectional growth of silicon crystals (*i.e.*, ϕ_0) is a function of the orientation of the crystal surface. This dependence is probably the result of the influence of the surface free energies of the three interfaces on the relative directions of the interfaces at the crystal-liquid-vapor triple junction (10). In this section, we report some morphological observations in EFG ribbons which confirm the existence of a ϕ_0 anisotropy in silicon crystal growth; the observations are extended to obtain a measure of the anisotropy in the crystal-vapor surface free energy in silicon. It should be pointed out here that the $\phi = \phi_0$ requirement is satisfied when the crystal shape is controlled by the shape of the meniscus; when faceted growth occurs on peripheral regions of the solid-liquid interface, this condition is no longer satisfied, as described in the next section.

Crystal defects which have been observed frequently in EFG silicon ribbons are twin boundaries (3, 4). Examples of twin boundary traces on the surface of the ribbon are shown in Fig. 4 for typical low-index seed orientations used in silicon ribbon EFG; the twins extend through the entire thickness of the ribbon. The occurrence of such twinning generally leads to a change in the crystallographic orientation of the ribbon surface and to a change in the growth direction. Since the meniscus height was kept constant in the experiments, the only plausible explanation for the readily visible change in ribbon thickness (see Fig. 4) is that the characteristic value of ϕ_0 has changed upon twinning. In effect, the twinning has resulted in a perturbation in ϕ_0 (*cf.* Fig. 2d); the deviation of the instantaneous meniscus angle from the "new" ϕ_0 during a brief transient period following the twinning then accounts for the change in the ribbon thickness.

Measurements of the thickness change in EFG ribbons were made using a Sloan Dektak surface profile recorder; the results are summarized in Table I. The table lists the average surface elevation change (and root mean square deviation) across the twin boundaries for a number of surface profile traces; the traces were made in both directions across the twin (*e.g.*, {111} to {115} as well as {115} to {111}). The elevation change is typically several microns (the change in ribbon thickness is approximately twice the elevation change), and the transient occurs over a ribbon length of a few tenths of a millimeter (the growth rate was 1-2 cm/min in the experiments and the ribbon thicknesses were in the range of 0.02-0.04 cm).

From the signs of the elevation changes in Table I, we can immediately deduce the relative values of ϕ_0 for the various crystal surface orientations: *viz.*, $\phi_0\{111\} > \phi_0\{115\}$, $\phi_0\{110\} > \phi_0\{114\}$, and $\phi_0\{100\} < \phi_0\{122\}$. From a model (10) which balances the surface tensions at the crystal-liquid-vapor triple junction, one expects that a decrease in ϕ_0 would be associated with an increase in crystal-vapor surface free energy. Indeed, the above variations in ϕ_0 are consistent with the probable order of the surface free energies for these low index faces. A simple calcula-

Table I. Changes in ribbon surface elevation caused by the anisotropy in ϕ_0

(111)[1$\bar{1}$0] to (511)[$\bar{1}$14] or to (151)[$\bar{1}$14]	22	7.7 ± 3.0	0.2-0.6
(111)[$\bar{2}$11] to (151)[$\bar{2}$17]	7	9.0 ± 2.2	0.3-0.8
(110)[1$\bar{1}$1] to ($\bar{1}$14)[5$\bar{1}$1]	2	1.5 ± 0.7	0.2-0.4
(100)[001] to (122)[2$\bar{2}$1]	3	−1.5 ± 0.4	0.1-0.5
(110)[1$\bar{1}$0] to (110)[$\bar{1}$14]	3	1.8 ± 0.9	0.2-0.5
(110)[1$\bar{1}$1] to (110)[1$\bar{1}$5]	6	3.3 ± 1.2	0.3-0.8

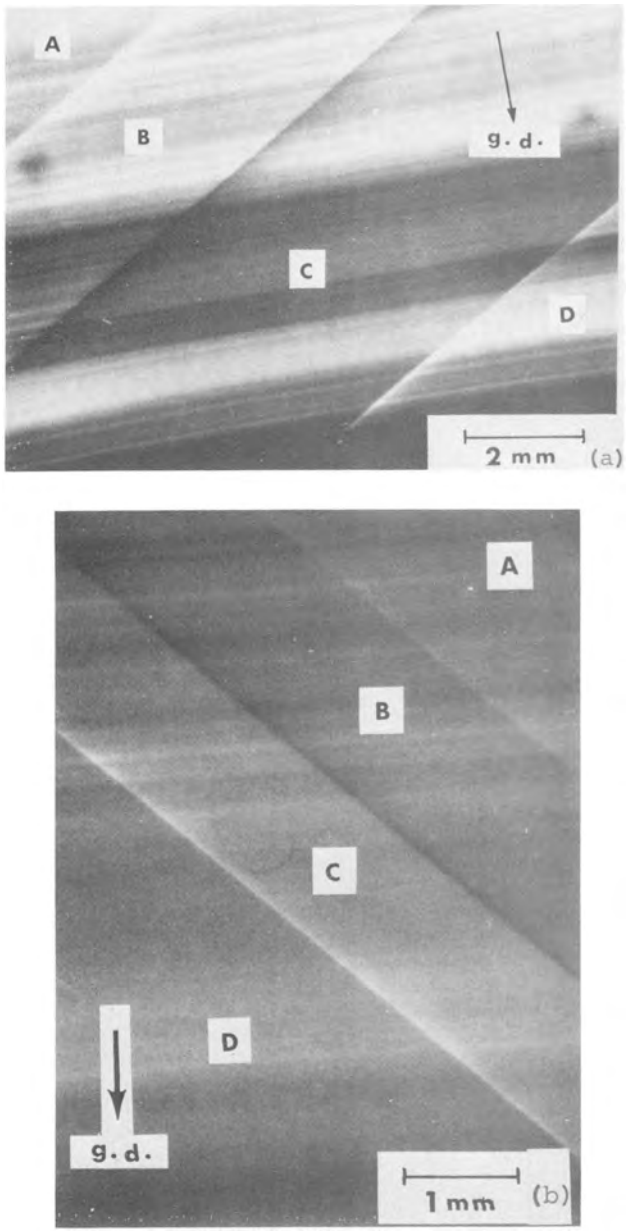

Fig. 4. Examples of twins in EFG silicon ribbon which lead to changes in steady-state ribbon thickness as a result of the ϕ_0 anisotropy. (a) Surface orientation changes from {111} to {115} to {111} to {115} for regions A to D, respectively. (b) Surface orientation changes from {100} to {122} to {100} to {122} for regions A to D, respectively. The arrow denotes the crystal growth direction (g.d.)

tion based on the assumption that the surface energy for each plane varies in proportion to its area resolved in nearest {111} planes gives the ratio of the surface free energies $\gamma\{111\}/\gamma\{122\}/\gamma\{110\}/\gamma\{114\}/\gamma\{115\}/\gamma\{100\}$ as 1.0/1.15/1.22/1.41/1.46/1.73. With the exception of the {122} to {100} transition (where only a small elevation change is observed), the magnitudes of the elevation changes are seen to reflect the change in the surface free energy. The value of ϕ_0 is also expected to depend on the direction and free energy of the solid-liquid interface at the triple junction (10). It is seen in Table I that the crystal growth direction also changes upon twinning; in fact, the last two entries in the table show that a change in the growth direction alone can lead to a change in surface elevation (*i.e.*, a change in ϕ_0). Unfortunately, without the knowledge of the detailed shape of the solid-liquid interface at the triple junction, it is not possible to speculate about the anisotropy in the solid-liquid surface free energy from these results.

Similar transient variations are observed in the width dimension of the ribbon when a twin or other high angle grain boundary emerges at the ribbon edge. Examples of twins initiating from and terminating at the edge of the ribbon are shown in Fig. 5a and 5b, respectively; Fig. 5c shows the change in ribbon width occurring when a high angle grain boundary intersects the surface at the ribbon edge. The changes in ribbon width are seen to be several orders of magnitude greater than the thickness changes in Table I. Of course, it is not practical to describe these variations in ribbon width in terms of a change in crystal surface orientation (which, clearly, is a variable around the ribbon edge). The perturbation now is in the "distribution" of ϕ_0 around the edge of the ribbon which, together with the detailed kinetics of the crystal growth (such as the faceting effects described in the next section), leads to a change in ribbon width. The perturbations at the ribbon edges, as seen in the photographs in Fig. 5, are far more severe than at the ribbon sides, and can frequently lead to large-scale variations in the ribbon width and, on occasion, to an arrest in stable ribbon growth. This would be expected from the shape stability considerations described in the preceding section, where it was shown that the ribbon end stability was a sensitive function of the relative dimensions of the ribbon edge and the die edge.

Figure 6 shows an extreme case of edge instability where many high angle grain boundaries have nucleated in the vicinity of the ribbon edge; the width dimension is seen to be extremely unstable under these conditions. It is not clear at this time, however, whether the polycrystalline structure has resulted from the width being unstable and the growth conditions fluctuating, or the width instability is caused by the polycrystalline growth.

Finally, it should be pointed out that the present examples (Fig. 4 and 5) used to demonstrate the effects of ϕ_0 anisotropy were obtained in the proximity of the seed (*i.e.*, within about 10 cm of ribbon growth) where large single crystal areas are frequently observed. At larger distances from the seed, the seeded orientation is lost as a result of interactions of primary twins, higher order twins, and various other grain boundaries. Recent evidence (11) indicates that, irrespective of the seed orientation, an equilibrium defect structure eventually develops in the ribbon; the orientation is approximately (110) $[\bar{1}12]$ and the ribbon contains a high density of linear boundaries parallel to the growth direction (an example of this structure is shown in a later section). The effects of the ϕ_0 anisotropy are nevertheless observed in all EFG ribbons; the slight changes in surface elevation which result from the ϕ_0 anisotropy, in fact, cause the various boundaries to be readily discernible in the as-grown ribbon.

Effects of Faceting on Ribbon Shape Stability

An important consideration in attempting to achieve controlled-shape growth involves the crystallization properties of the material. Because of the anisotropy in growth rate, silicon often exhibits singular (*i.e.*, faceted) growth on regions of the crystallization front near the {111} orientations. When such faceted growth occurs on peripheral regions of the solid-liquid interface, various ridgelike features result on the crystal surface; such features have been previously observed and analyzed in silicon crystals grown by the Czochralski (12) and floating zone (13) methods and in germanium crystals grown by the Stepanov technique (5). The basic effect of faceted growth on the external shape of the crystal is that the latter is no longer uniquely determined by the shape of the meniscus

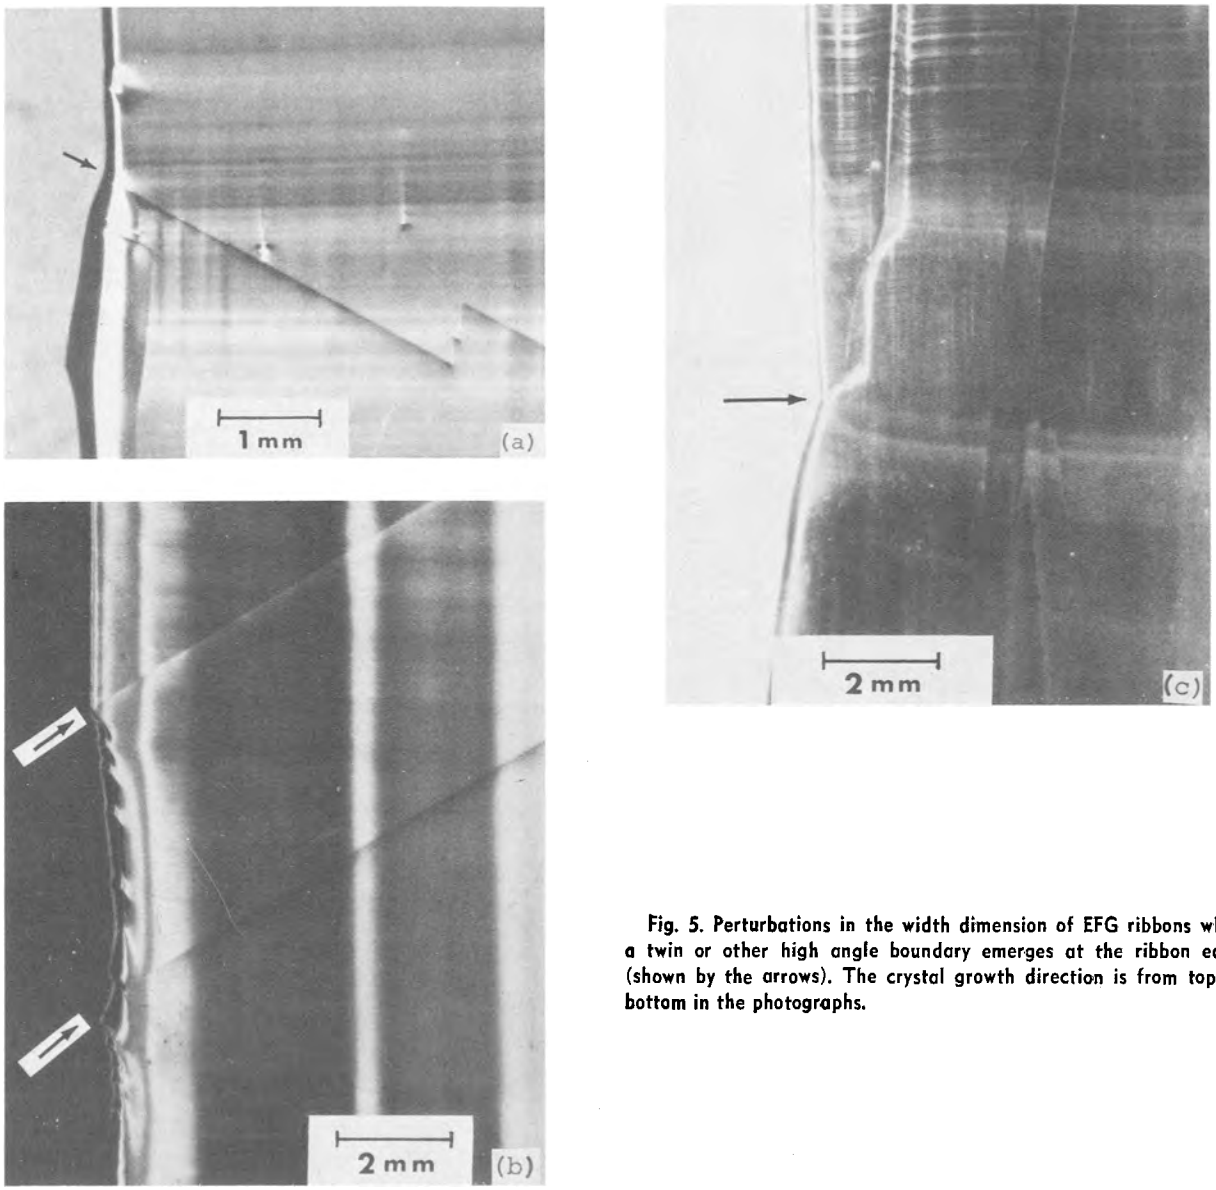

Fig. 5. Perturbations in the width dimension of EFG ribbons when a twin or other high angle boundary emerges at the ribbon edge (shown by the arrows). The crystal growth direction is from top to bottom in the photographs.

at the crystal-liquid-vapor triple junction (*i.e.*, by the $\phi = \phi_0$ requirement), but it is also affected by the detailed kinetics of the layer nucleation and growth on the facets.

All descriptions of faceted growth in silicon consider supercooling as the basis of its origin; for a {111} facet to appear at the solid-liquid interface and for growth to be maintained, a greater supercooling of the melt is required at the faceted region of the crystallization front in order to nucleate the new layer sources. Clearly, then, the shape of the freezing isotherm and its relationship to the close-packed {111} planes affects the faceting tendency and the location of the facets. In general, peripheral faceting is enhanced by a concave (toward the melt) freezing isotherm near the periphery; the tendency to facet is also expected (5, 12, 13) to increase with increasing crystal growth rate, decreasing melt temperature or gradient in the melt at the growth interface, increasing impurity concentration in the melt, and decreasing concentration of crystal dislocations (which can serve as easy nucleation sites for new {111} growth layers). In turn, faceting affects the distribution of dislocations and impurities in the grown crystal. The location of the ridgelike surface features is determined by the anisotropy of growth rate of ledges in various directions on the close-packed (111) surface; the "easy" growth directions (where the ridges appear) correspond to the $[\bar{1}\bar{1}2]$ directions, whereas lateral growth is much slower in the $[11\bar{2}]$ directions (13).

Faceted growth has also been observed frequently, albeit unpredictably, in EFG silicon ribbon growth. The occurrence of faceting is observed during growth by a localized rise (or, on occasion, a fluctuating rise and fall) in the crystallization front; following growth, faceting is evidenced by the various characteristic growth features on the external surface of the ribbon. Below, we describe some typical features observed at the side and edge surfaces of EFG ribbons.

Faceting at the ribbon sides.—The most frequently observed feature of growth faceting is illustrated in Fig. 7. During growth, a sharp, angular rise in the meniscus height is observed about a high angle grain boundary (twin boundary in Fig. 7); the tilt of the growth interface on either side of the boundary depends on the orientation of the {111} planes relative to the growth direction. In the grown ribbon, faceting is evidenced by the breaks in the horizontal surface striae which delineate the instantaneous shape of the solid-liquid interface. (A detailed description of the surface striae is given in a later section.) In the example shown in Fig. 7, the ribbon surface orientation is near (110) and the growth direction is within a few degrees of the $[1\bar{1}2]$ orientation (*i.e.*, approximately $[33\bar{5}]$) on either side of the twin boundary.

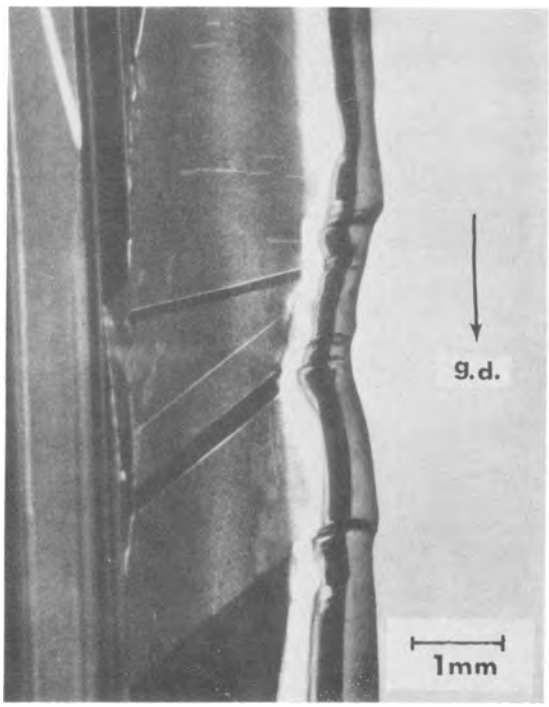

Fig. 6. Fluctuations in ribbon width accompanying the nucleation of many high angle grain boundaries. The arrow denotes the crystal growth direction.

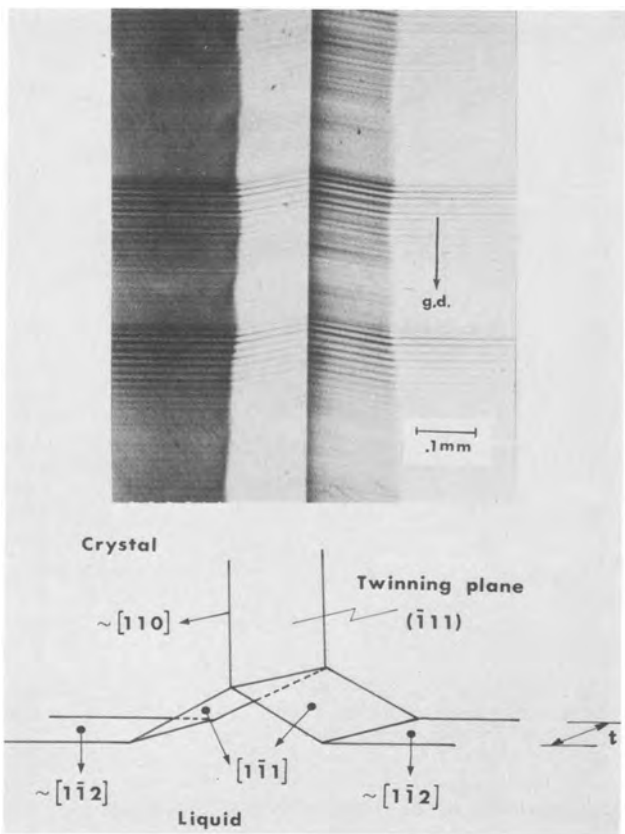

Fig. 7. Growth faceting at a twin boundary in silicon ribbon EFG. The surface striae delineate the shape of the solid-liquid interface (shown in the sketch) during growth.

Faceted growth thus occurs on the $(1\bar{1}1)$ planes, as shown in the sketch in Fig. 7; the angle of ~13° measured from the striae in the figure is close to the value of 14.4° for the angle between the $(1\bar{1}1)$ and $(3\bar{3}5)$ planes.

Growth faceting of the type depicted in Fig. 7 is not restricted to faceting only on peripheral regions of the solid-liquid interface; rather, the entire interface across the thickness of the ribbon can be faceted, as shown in the sketch. Indeed, corresponding breaks in the surface striae can be seen on the reverse side of the ribbon in Fig. 7. Nucleation of new growth layers is likely to occur in these cases along the line of intersection of the two facets where the supercooling is the greatest. For a typical vertical gradient in the liquid of 150°C/cm in EFG ribbon growth, we estimate a maximum supercooling of ~0.4°C from Fig. 7. This undercooling is considerably less than the value of 6°C estimated from studies of faceting in float-zoned silicon crystals (13); the difference is probably the result of the easy nucleation site at the intersection of the facets in this case.

Examples of another type of peripheral faceting are shown in Fig. 8. When the ribbon surface is very close to a {111} orientation, we frequently obtain surface segments which are extremely smooth or mirrorlike. The presence of such "surface facets" is evidenced by a lack of continuity of the horizontal surface striae across these regions, as indicated by the arrows in the figures. Basically, the crystal here exhibits a tendency to extend the low energy {111} external surface, irrespective of the shape which is commanded by the instantaneous meniscus shape (and the $\phi = \phi_0$ requirement). When the ribbon surface plane is slightly misoriented from {111} (which is invariably the case), the tendency to continue the surface facet is counteracted by the meniscus angle effect and the changing thermal conditions as the facet extends into or out of the ribbon plane; faceting thus gets relieved by an appropriate transient in the ribbon thickness. In the example shown in Fig. 8a, the surface facet extends into the ribbon (the angle between the ribbon plane and the facet is ~4° as determined by the Sloan Dektak recorder) and is relieved by an increase in ribbon thickness (where the striae reappear). In Fig. 8b, the surface faceting on the (111) plane (near a (111) $[\bar{2}11]$ ribbon seed) is constricted by growth faceting near the periphery on the oblique $(\bar{1}11)$ plane.

On occasion, complex faceted features are observed on the ribbon surface, as exemplified in Fig. 9. Region A in the figure is primary-twin related to the original ribbon seed orientation, (100) [011]; regions B and C are both first-order twins of region A, hence the boundary between regions B and C is a second-order twin boundary. It is interesting to observe that the faceted features are different on the front (Fig. 9a) and back (Fig. 9b) sides of the ribbon. Of course, this is the result of the octahedral planes on which faceted growth occurs having different inclinations relative to the freezing isotherm near the periphery. The example shows that crystallization (and the formation of the external crystal surface) in one region of the crystal occurs independently of any other region. With the orientation in region A being $(\bar{1}22)$ $[\bar{4}\bar{1}\bar{1}]$, it appears that faceting is more prevalent on the $(\bar{1}11)$ planes at the front of the ribbon than it is on the $(\bar{1}\bar{1}\bar{1})$ planes (which are less inclined to the growth interface) at the back side. A detailed study of the various ridgelike features seen in the figure requires an analysis of the supercooling on the various octahedral planes and of the anisotropic ledge kinetics on these facets. The periodic pattern which is apparent along the second-order twin boundary in Fig. 9a (and extends some 15 cm of growth length) is probably the result of a competition between outward growth on the interface facets in the easy <112> directions and the meniscus angle effect which would tend to contract the ribbon thickness. The changing meniscus angle and shape at the crystal-liquid-vapor

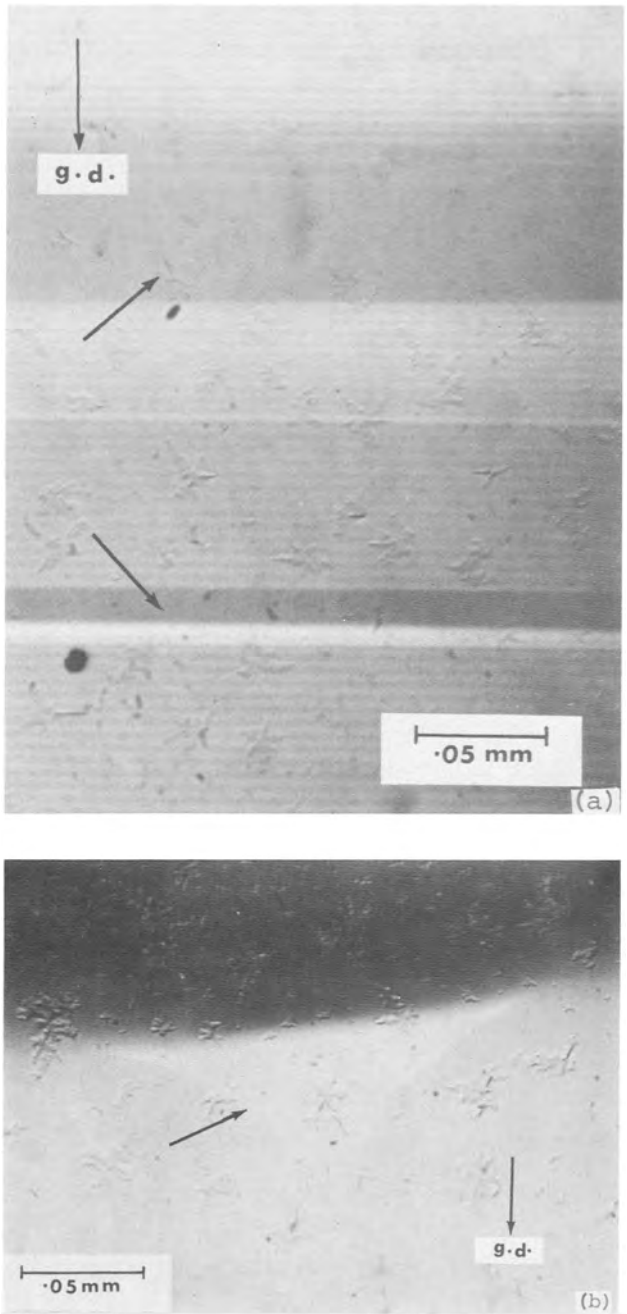

Fig. 8. Surface facets (specular {111} faces) on the side faces of EFG ribbons grown with a nearly {111} surface orientation.

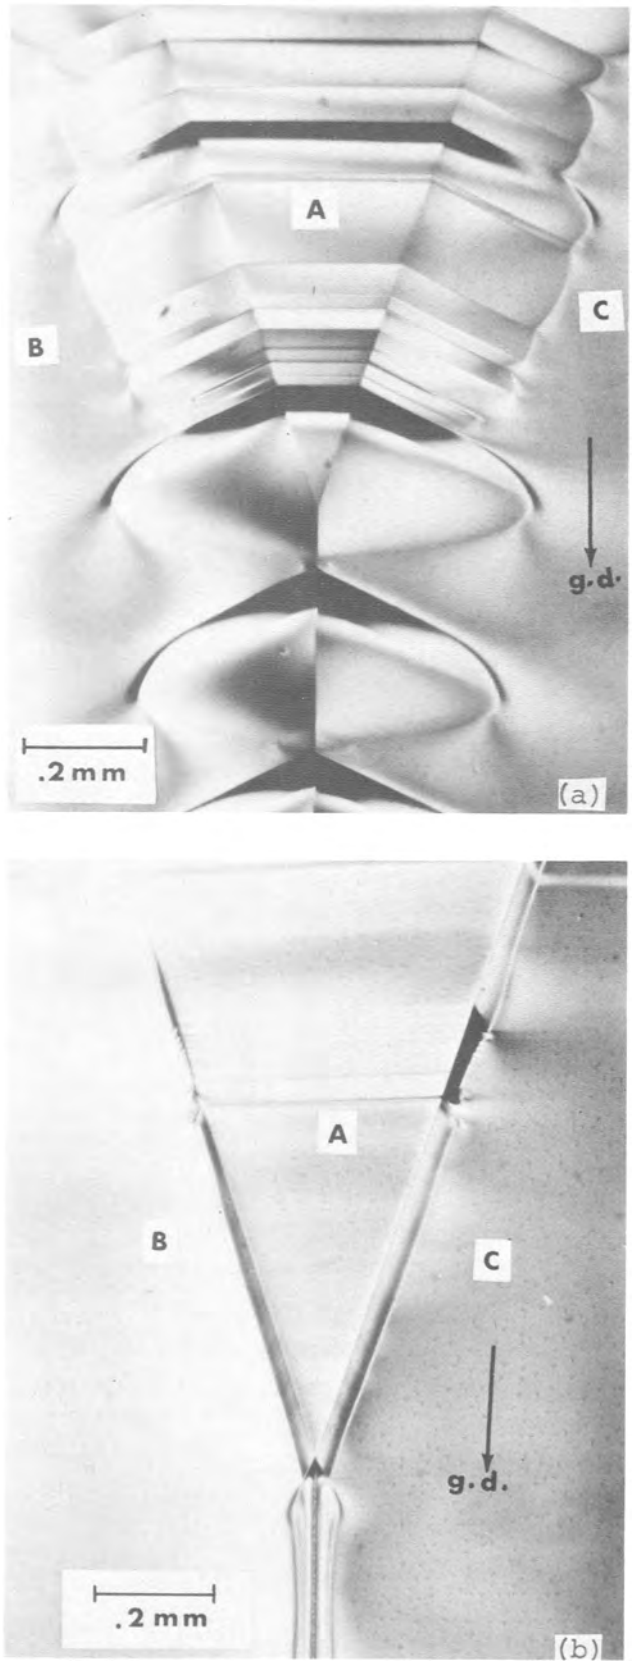

Fig. 9. Complex growth facets observed on the (a) front and (b) back sides of an EFG ribbon seeded in the (100) [011] orientation. The figure demonstrates that crystallization (and the formation of external surface features) occurs in various regions of the ribbon independent of any other region.

triple junction also affect the thermal conditions (*i.e.*, supercooling) at the facet planes.

In general, faceted growth at the ribbon sides has been observed to be very stable; the facets can extend several inches (or, as in the case of the facets in Fig. 7, several feet) along the ribbon length.

Faceting at the ribbon edges.—Examples of faceting at the ribbon edges and its effects on the ribbon width are shown in Fig. 10. Figure 10a is the most frequently observed feature; during growth, it is accompanied by a somewhat periodic fluctuation in the meniscus height at the ribbon edge. These fluctuations can usually persist in a stable manner for a short growth length ($\lesssim$ few centimeters) by which time the growth conditions and crystal orientation (hence the supercooling conditions on the facet planes) may change. As would be expected from the shape stability considerations described above, fluctuations in the shape variables at the ribbon edges are undesirable in that the marginal stability of the ribbon edge (*cf.* Fig. 3) can be readily upset by these fluctuations. Figure 10b shows a case of edge instability associated

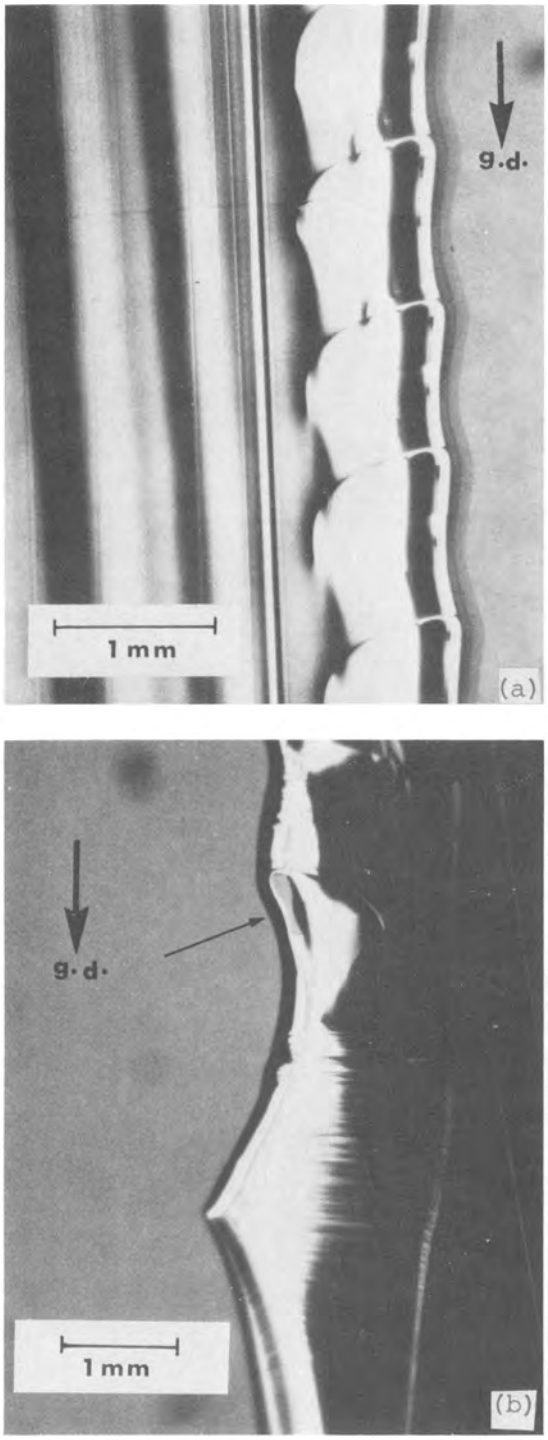

Fig. 10. Growth faceting at the edges of EFG ribbons: (a) faceting accompanied by nearly periodic fluctuations in meniscus height at the ribbon edge (the ribbon orientation is approximately (231) [$\bar{3}$13] near the edge); (b) edge instability caused by rapid lateral growth on peripheral facets. The arrow shows a small, specular surface facet at the ribbon edge.

with faceted growth; extremely rapid lateral growth here has caused the ribbon edge to almost spread past the edge of the die. Faceting at the ribbon edges, and the fluctuating growth conditions which are generally associated with it, often lead to twin nucleation at the ribbon edges (*e.g.*, Fig. 6 and 10b).

Under unusual growth conditions, faceted growth can lead to extremely stable ribbon edges; an example of this is shown in Fig. 11. Here the ribbon surface orientation is (111) and the growth direction is [1$\bar{1}$0]; the ribbon edge has a "lipped" shape (see Fig. 11b)

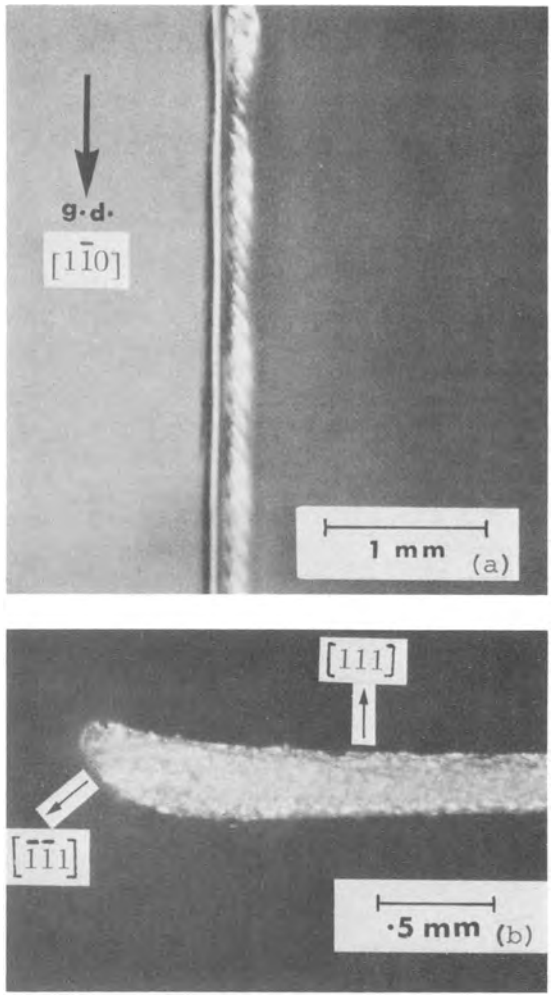

Fig. 11. (a) Side and (b) cross-sectional views of "lipped" ribbon; faceting at the ribbon edges has resulted in extremely stable growth in this case.

with a ($\bar{1}\bar{1}$1) surface facet along the outer edge, as shown in the figure. The lip is curved in the opposite direction at the other edge of the ribbon. The ribbon edge was stable for a few centimeters of growth on one side and nearly 20 cm on the other side; the "stable" growth conditions which were obtained in this growth run could not be consistently reproduced in subsequent trials, however.

In summary, faceted growth is frequently observed in EFG ribbon growth. By far the most important consequence of faceting appears to be that it can override (or, at least, it can compete with) the meniscus angle requirement (*i.e.* $\phi = \phi_0$) for constant cross-sectional growth. The periodic fluctuations of the faceted features are probably the result of such a competition between the two effects. Similar interactions between faceted and controlled-shape growth have been observed in the growth of rod-shaped crystals and ribbons of germanium by the Stepanov process (5). As described above, the tendency for faceted growth is a complex function of the crystal growth conditions such as the growth rate, thermal profiles, impurities, dislocation density, and crystal orientation. Correlations of faceting with the growth conditions in silicon ribbon EFG have not been successful thus far, probably as the result of inhomogeneities in the distribution of dislocations and in the crystallinity of the ribbons. Nevertheless, growth conditions have been achieved where faceting at the ribbon edges (which is, clearly, the primary problem area from the point of view of growth stability) is avoided.

Other Morphological Observations in EFG Ribbons

In this section, we examine some morphological features frequently observed in EFG silicon ribbons which are associated with variations or fluctuations in the process variables during growth.

Variations in the edge-defining die dimensions.—As described above [also in Ref. (4)], mechanical changes in the edge-defining die dimensions occur frequently when graphite dies are used in silicon ribbon EFG (*e.g.*, as a result of SiC particles, die spreading open, mechanical damage, or spill-over at die edges, etc.). Figure 12a shows the typical vertical striae seen on the ribbon surface which result from the meniscus wetting around the SiC particles growing at the die top. Figure 12b illustrates the effect of a spill-over near the edge of the die; the breaks in the striation (denoted by the arrows) were caused by the lateral displacement of the ribbon during growth. In addition to demonstrating the over-all stability of the thickness dimension of the ribbon when subjected to perturbations in the die thickness (*cf.* Fig. 2b), these figures illustrate the effectiveness of the "edge definition" in EFG. In essence, the ribbon surface is a true reproduction of the actual edge-defining die shape. As the meniscus height increases, the resolution of the die features decreases, as would be expected, and the ribbon surface is smoother.

Variations in meniscus height.—The dependence of ribbon thickness on meniscus height for given values of die thickness and h_{eff} (*cf.* $\phi = \phi_0$ line in Fig. 2a) has been quantitatively verified in silicon ribbon growth experiments (7). When the meniscus height was purposely changed in the experiments (by changing the crystal pull rate or the temperature gradient in the meniscus film), the ribbon thickness attained a new steady-state value (as depicted in Fig. 2a) following a brief transient period. The same variations in meniscus height at the ribbon edges were generally observed (7) to lead to an instability (*i.e.*, continued spreading or tapering) of the width dimension of the ribbon.

Localized fluctuations or variations of the meniscus height near faceted regions of the growth interface were described in the preceding section; in these cases, the crystal shape was found to be governed by the detailed kinetics of layer nucleation and growth on the facet planes rather than by a geometrical relationship such as in Eq. [1]. Another type of localized variation in meniscus height frequently occurs at the intersection of high angle grain boundaries (*e.g.*, twin boundaries) with the growth interface at the solid-liquid-vapor triple junction. The effect is probably similar to the grain boundary grooves in solid-liquid interfaces (14); an example of the resulting surface features in EFG ribbon is shown in Fig. 13. The striae delineate the "groove" at the twin boundary; the surface is slightly depressed (*i.e.*, thickness is less) in this region.

Horizontal surface striae.—Many examples of the horizontal striae which are always observed on the surface of EFG ribbons have already been presented, *e.g.*, Fig. 7 and 13. The following observations have been made in relation to these striae: (*i*) the striae are periodic markers of the growth interface; (*ii*) the striae are parallel, except in regions of local acceleration of growth rate (*e.g.*, start of an interface facet); (*iii*) the striae spacing (approximately a few micrometers) is much greater than the amplitude of the striae; (*iv*) striae on either side of a thin ribbon are "in phase," *i.e.*, the ribbon thickness increases on both sides simultaneously; (*v*) the striae never cross (*i.e.*, meltback, if any, is much less than the striae spacing); (*vi*) the striae are not associated with localized variations in impurity or dopant concentration in the ribbon; (*vii*) the striae frequency is independent of the suspended length of the ribbon, of the puller mechanism, and of the frequency of the furnace power supply (60 Hz, 9.6 kHz, and 450 kHz); (*viii*) the striae frequency has been observed to vary from 0 (near the seed where the crystal growth rate is low) to ~150 Hz at the fastest ribbon growth rates achieved thus far (~5 cm/min). There is some evidence that the striae frequency is, in fact, roughly proportional to the growth rate. Further work is in progress to identify the mechanism of the striae formation; it appears to be associated with transient variations of

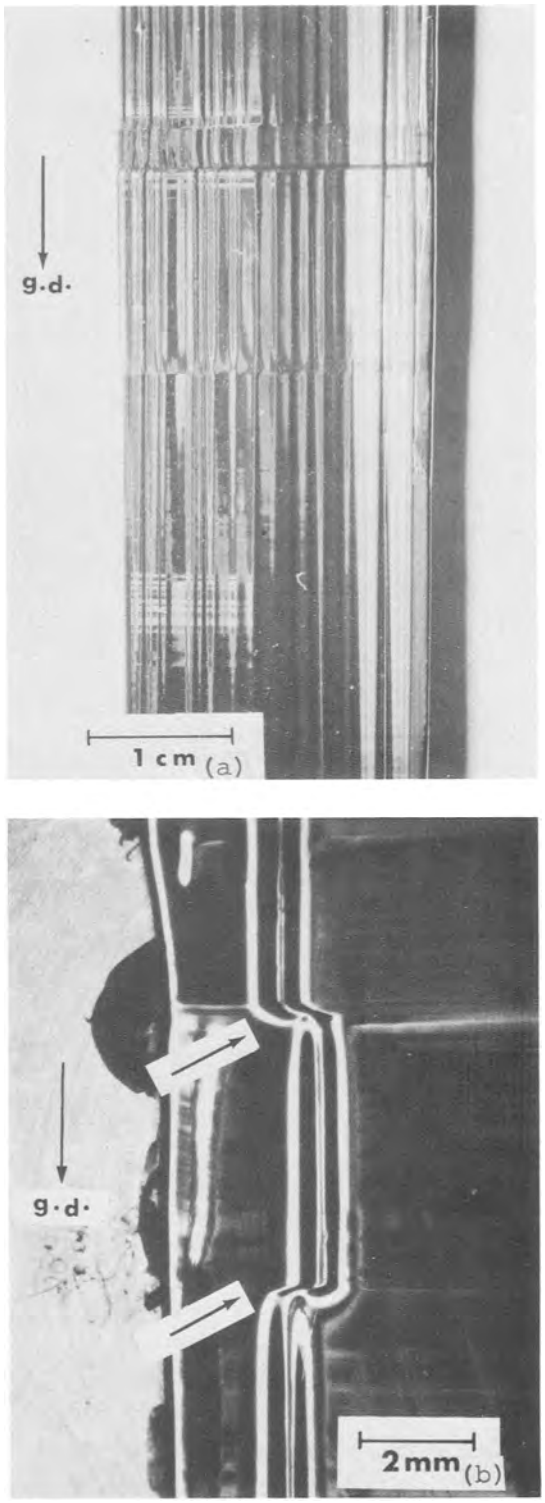

Fig. 12. (a) Vertical striae on EFG silicon ribbon caused by SiC particles which grow at die top. (b) Thick (~1 × 1 mm) striation on ribbon surface caused by spill-over near one edge of die. The ribbon was moved sideways where indicated by the arrows.

the process variables in Eq. [1]. A recent analysis (15) of the time dependence of perturbations in the geometrical variables in the floating zone process showed an oscillatory behavior for that system; the frequency of the oscillations was found to be proportional to the ratio of the growth rate to the length of the molten zone.

Interface breakdown.—In EFG ribbons produced under low gradient, high growth rate conditions (*e.g.*, near the maximum growth rate, which is a function of the thermal environment of the growth setup), we have observed various morphological features which indicate interfacial breakdown phenomena. These features usually take the form of corrugated, dendritic patterns, or wavy surface ridges such as illustrated in Fig. 14. These ridge patterns appear on both sides of the ribbon (nearly simultaneously) and tend to be somewhat symmetrical about the ribbon axis (this is not the case in the example shown in Fig. 14). Analyses have shown that the interfacial breakdown is caused by thermal and/or constitutional supercooling, as described in detail elsewhere (16).

Conclusions

1. Silicon ribbon growth by the EFG process has been shown to occur under one or both of the following conditions: (*i*) controlled-shape growth, where the ribbon shape is determined by the shape of the meniscus at the crystal-liquid-vapor triple junction (*i.e.*, $\phi = \phi_0$ for steady-state cross-sectional growth) and hence by the geometrical process variables (t_d, h_{eff}, and s in Eq. [1]): or (*ii*) faceted growth, where the external shape of the crystal is determined by the detailed kinetics of ledge nucleation and growth on peripheral {111} facets.

2. Theoretical analysis of the ribbon shape stability for controlled-shape growth has shown that the side of the ribbon (*i.e.*, the thickness dimension) is inherently stable, whereas the ribbon edge (*i.e.*, the width dimension) is only conditionally stable when a steady-state growth system is subjected to perturbations in the geometrical variables. The stability of the ribbon edge requires that the edge-defining die radius should not exceed approximately twice the radius of curvature of the ribbon at the ribbon edge. Experimental evidence has been presented to show the inherent stability of the ribbon side and the relative instability of the ribbon edges.

3. The characteristic meniscus angle ϕ_0 for the growth of a constant-dimension crystal in controlled-shape growth has been shown to depend on the crystallographic orientation of the ribbon surface.

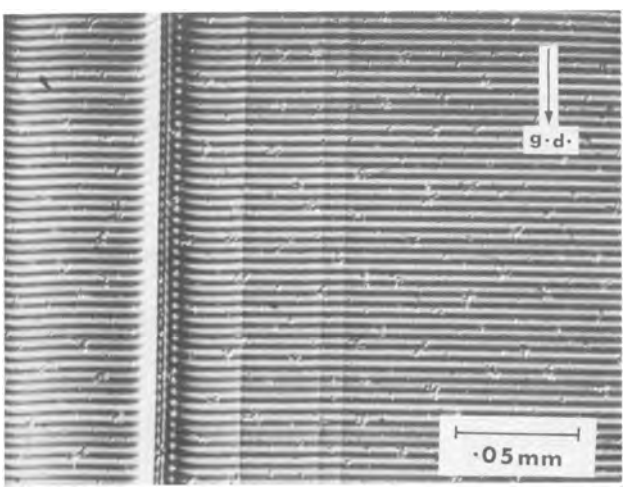

Fig. 13. Groove in growth interface at its intersection with a twin boundary in silicon ribbon EFG showing slight depression in the crystal surface at the groove.

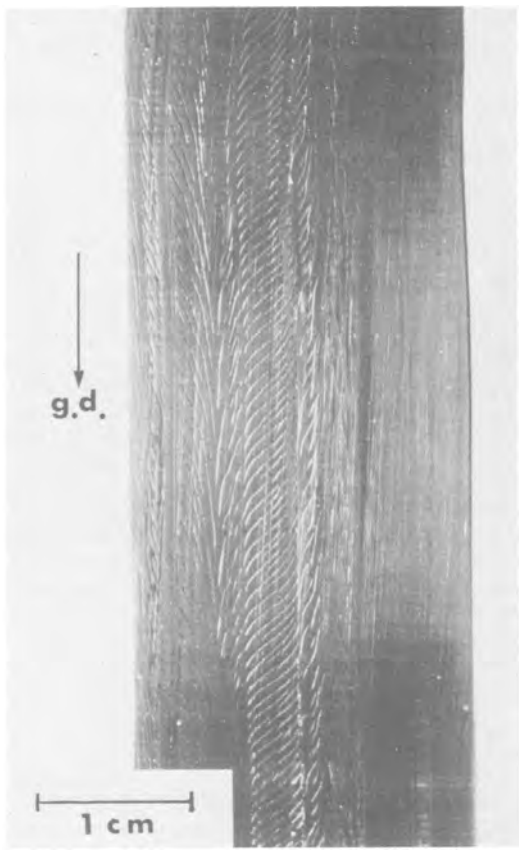

Fig. 14. Wavy surface ridges on EFG ribbon resulting from interfacial breakdown. The growth rate was 5 cm/min.

Observations of ribbon thickness changes which resulted from the ϕ_0 anisotropy were used to obtain a measure of the anisotropy in the crystal-vapor surface free energy in silicon.

4. Faceted growth has been shown to compete with, and, on occasion, completely override controlled-shape growth. If the surface shape in a given region of the ribbon is the result of faceted growth, then the $\phi = \phi_0$ condition does not apply in this region.

5. Faceted growth and ϕ_0 anisotropy did not affect the stability of the ribbon side (*i.e.*, thickness), but were generally observed to lead to instabilities at the ribbon edges (*i.e.*, spreading or tapering of the width dimension).

6. Experiments with various ribbon seed orientations were carried out to obtain the various ϕ_0 anisotropy and faceting features reported in this paper. Irrespective of the seed orientation, an equilibrium defect structure eventually developed in the ribbons; the orientation was approximately (110) [$\bar{1}$12] and the ribbons contained a high density of linear boundaries parallel to the growth direction. An example of this structure is shown in Fig. 15; the edge stability where the linear boundaries extend to very near the ribbon edge (indicated by the oblique arrow) should be noted. Further analysis of this equilibrium defect structure is given in a separate publication (11).

Impurity Effects in the Nucleation of Alpha (bcc)-Tantalum or Beta-Tantalum Films

N. Schwartz* and E. D. Feit

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Although most studies report β-Ta as the thin film phase deposited during cathodic sputtering, a few reports indicate that α(bcc)-Ta is the initial phase, and β-Ta occurs only because of reaction with oxygen or nitrogen. This study details qualitative evidence that an "X" impurity can exist which at low concentrations prevents the formation of β-Ta and induces the formation of α-Ta, but which may be deactivated by oxygen or nitrogen in a glow discharge. Monolayer films of carbon-containing compounds can act as an X impurity. Organic polymers in particular can be used to nucleate low resistivity α-Ta during deposition over large areas in vacuum stations which previously could only yield β-Ta. Low resistivity α-Ta has applications in thin film capacitors to achieve higher frequency performance.

When β-Ta films were first reported (1), it was stated that it was the form that was obtained by sputtering at the lowest background pressure, while the addition of nitrogen or other gases resulted in the deposition of α-Ta (*i.e.*, bcc) films. Figure 1 is a typical result, showing the phases, resistivity, and temperature coefficient of resistance for 5000Å tantalum films deposited by d-c diode sputtering at various partial pressures of nitrogen in 10-20 mTorr of argon. The persistence of β-Ta down to the lowest background pressures was established in an ultrahigh vacuum station study (2). Since α-Ta films were mechanically unstable (3), β-Ta films became the preferred form for tantalum thin film capacitors (4) in thin film integrated circuits (5). Since that time well over 500,000 ft^2 of thin film tantalum has been deposited in a variety of oil-diffusion-pumped and turbomolecular-pumped batch and in-line d-c diode sputtering systems with the structure being that of β-Ta.

In recent years (6) there have been several very contradictory studies, however, which have indicated that at the lowest background pressure, α-Ta is de-

posited, while the addition of oxygen or nitrogen to the argon sputtering gas is a necessary condition for the formation of the β-form. Figure 2 shows several studies of the resistivity and structure of tantalum films sputtered in oxygen-argon mixtures. These studies are significant in that they are the only ones where the oxygen concentrations were determined directly in the films. Figure 3 shows similar studies for the addition of nitrogen and carbon (7), although in all of these studies the analytical techniques are quite different, as are the detailed sputtering conditions. Figure 4 shows another study of the resistivity and structure as a function of nitrogen pressure in the argon gas, and this result has an initial α-phase

followed by the β-phase, which then reverts to the α-phase at higher nitrogen pressures and eventually results in the deposition of the tantalum nitride.

In Fig. 2, the results of Gerstenberg and Calbick (8), for films deposited at 500°C, indicated that the initial phase was α-Ta up to about 18 atom percent (a/o) oxygen, and further addition of oxygen results in a cermet of α-Ta plus insulating tantalum oxide,[1] and no β-Ta is formed at these high oxygen concentrations. Feinstein and Gerstenberg (10) repeated those experiments in a later study in a more usual sputtering machine (17) which routinely allowed the deposition of β-Ta; their results indicated the β-phase persisted up to about 10 a/o oxygen, with the subsequent phase being a mixture of α, β, and TaO_z; again after the appearance of the α-phase, the β-phase does not form on the addition of more oxygen. The contradictory studies were those of Waterhouse *et al.* (11) and Westwood (12), who initially observed α-Ta, for films not deliberately heated, while at 10 a/o oxygen the β-phase was formed and persisted up to at least 16 a/o; at 20 a/o the reported x-ray data

[1] This was the only sputtering machine in Bell Laboratories which consistently formed α-films on any clean glass substrate. The α-Ta film formation was not due to deposition on carbon as proposed by Mills (9).

are too indeterminate to decide whether the structure was the α- or β-form. Based on these findings those workers claimed that 10 a/o of oxygen is necessary to form β-Ta. The need for considerable interstitial impurity seems to be confirmed by the results of Schauer *et al.* (13) (Fig. 4), where considerable nitrogen is needed in the gas phase to form the β-phase.

The conclusion that appreciable amounts of oxygen or nitrogen are necessary to form β-Ta has been contradicted by many accurate analyses with a variety of techniques including flash discharge gas analysis (14), electron microprobe (10), Auger analysis (7), and a most sensitive technique, nuclear microanalysis (15). This latter method indicates that β-Ta films can be formed with nitrogen and oxygen concentrations as low as of 0.1-0.2 a/o. However, the evidence by Westwood and Schauer incontrovertibly indicates that under some conditions the addition of oxygen or nitrogen to the argon is necessary to form the β-phase.

A very significant study was performed by Feinstein and Hutteman (16) and confirmed by Axelrod and Marcus (25) (called FHA in this paper) who used a variety of different substrates simultaneously in a standard turbomolecular pumped system (17) and found, under the same vacuum and sputtering conditions, that α-Ta or β-Ta formed depending only upon the substrate type. This indicates that the α- or β-structure is determined at the nucleation stage. They were able to group the substrates (see Table I) into those that yielded α-Ta consistently (Table I, group II) those that formed β-Ta consistently (Table I, group I), or those that formed α-Ta initially but formed β-Ta when the substrate was slightly oxidized or hydrated (Table I, group III). However, even this important result does not have complete generality, since other studies do not always result in the same phase on the same substrate [see the double asterisked items in Table I under "This work" and "Schauer *et al.*"].

In the early phases of a previous study on the resistivity and temperature coefficient of resistance of β-Ta films (18), there were some unreported anomalous and irreproducible results which could be explained by an impurity hypothesis, which also might explain the inconsistencies in the results of the studies described above. The model requires that β-Ta actually is deposited at the very lowest background pressures possible, but that there is a low concentration impurity, to be called "X," either on substrates or in the gas phase, which has an extreme sensitivity for inducing the formation of the α-phase. This hypothesis requires that the addition of oxygen or nitrogen in the gas phase in a glow discharge can remove this low concentration impurity. Moreover, it requires that all studies that report α-Ta as the initial phase have had a variable amount of this X impurity, either in their vacuum station or on their substrates.

This paper reports the qualitative experiments which lead to the X impurity proposal, as well as results which indicate that some model compounds can act as the X impurity, although it is believed that many other species can perform similarly, and perhaps with greater sensitivity.

Experimental

Since the controversy summarized above is founded to some extent on the residual gases in the vacuum system, it is imperative that some specification of systems be made in order to eventually compare results. Although many of the other studies have not qualified their stations, it was done with some care in this study. In this paper several quantities will be used: the final pressure with the high vacuum valve completely open after a 4 hr pumpdown, p_F; the pressure before sputtering with the high vacuum valve in the throttling position, p_B; the leak-up rate of the system, L^I, determined by closing the high vacuum valve and measuring the rate of rise of pressure with an ionization gauge; the residual gas spectrum at p_B measured with an EIA 1110A quadrupole residual gas analyzer (QRGA), which has a partial pressure sensitivity of 10^{-14} Torr; and the individual species leak-up rate, L^I_S, measured with the QRGA.

The vacuum station and conditions used were stated previously (18), but briefly, it was a 6 in. CVC DC 704 silicone oil diffusion pumped system, with a liquid nitrogen trap, and a 250 liter glass bell jar. The system was always backfilled with nitrogen and always kept open for a minimum time. Some of those experiments were carried out over a long period of time and the vacuum capability shifted. There were three separate vacuum conditions under which the experiments were performed, and these are given in Table II. Condition A existed when the vacuum station was completely new and had no deposited tantalum on the electrode structure and on the glass bell jar, and no heating was used during the 4 hr pump down period. Condition B existed after many runs, and the deposited tantalum did not adsorb as much gas as glass when the bell jar was opened and also acted as an internal getter when under vacuum; compared to condition A, both p_B and L^I were down by a factor of 2. The last condition, C, was obtained when the station was in condition B but the substrate heater was employed at 550°C (as measured in the heater, 1 cm away from the substrates) for 2 hr during pump down which generally warmed up all parts of the electrode structure and bell jar, and then cooled for 2 hr; after this treatment, p_B was a factor of 10 lower and L^I was a factor of 6 lower than that existing at condition B.

The residual gas spectrum for condition B is given in Fig. 5. For each run, the QRGA was calibrated with nitrogen and the individual peaks are given in terms of equivalent nitrogen pressure. H_2O^+ is the main species, with N_2^+, CO^+, and CO_2^+ being at 2-3% of H_2O, while H_2^+ is about 0.7% of H_2O. There is an appreciable organic background spectrum above mass 44, and the species responsible for mass 78 is present at about 0.4% of that of H_2O^+. Great detail was paid to obtaining these individual unit masses from 1 to

110, since it was suspected that the X impurity might exist at low concentrations.

Figure 6 shows the residual gas spectrum for condition C; the species below mass 44 have decreased in pressure considerably, while the background organic spectrum above mass 44 is essentially similar to condition B. Water is still the main species but is present at 8% of that in condition B. N_2^+, CO^+, and CO_2^+ are now 10% of the H_2O^+ species, H_2^+ is 2.5%, and the species responsible for mass 78 is now 2.7%, primarily because the H_2O peak has decreased by over a factor of 10.

Sputtering systems have to be considered as flow systems, since the gases passing through the space around the electrode structure may consist of the gases desorbing from the walls or entering through small leaks, and leaving by the pumping mechanism of the system. Therefore the leak-up rate of the individual species before the sputtering run and after pumping for 4 hr was determined with the QRGA. When the high vacuum valve is closed there is a large burst of pressure (composed mainly of the species measured in the subsequent leak-up) due to the wiping of the Viton O-ring across the mating flange, and due to the compression of the O-ring. The value of L^I (reported in Table II) was determined during the first 60 sec after this burst of pressure subsides, and then the values of L^R_S were determined. Zero time in Fig. 7 shows the value of the individual species before the valve is closed and $18(H_2O^+)$ is the major peak while $28(N_2^+, CO^+, C_2H_4^+)$ is the second major peak. When the valve is closed, there is the described large burst of pressure, and individual readings start initially for $2(H_2^+)$ at 65 sec. At the end of the run at 700 sec, the major peaks are 28 (identified as N_2^+ because of the identical rate of rise of 14), $2(H_2^+)$, $40(A^+)$, while the initial major species $18(H_2O^+)$ has hardly increased at all. This means that nitrogen is the major incoming species, with a leak-up rate over a factor of 10 higher than that of H_2O, but since it gets pumped faster than H_2O, in a residual gas spectrum it appears lower. This nitrogen is not due to an air leak, since the system was extensively tested with He without finding leaks of this magnitude. Argon is adsorbed in this system because of its use as the sputtering gas, and its leak-up rate is similar to nitrogen. A similar leak-up spectrum is not available for condition B, but initial leak-up rates, determined for the first 100 sec, are compared in Table III. For condition B, the leak-up rate for $18(H_2O)$ is still smaller than that of $28(N_2)$, even though it is the major peak. This phenomenon of inversion of the ratio of mass 18/28 final pressures and leak-up rates has also been found in turbomolecular pump systems. This effect needs further investigation in other systems where the desorbing surfaces can be better defined after exposure to atmosphere.

The substrates used in this work were Corning 7059 glass (an aluminoborosilicate); Ta_2O_5-coated glass formed by complete oxidation of tantalum films sputtered on 7059; unoriented single crystal sapphire; high resistivity (100) silicon; bulk beryllium foil; bulk platinum foil; and evaporated Ti-Pt, Ti-Au, Mo, and W on sapphire. When standard chemical cleaning was used it was the same as used previously (18). Silicon was cleaned sequentially with detergent, etched

deeply with $HF-HNO_3$, cleaned in $H_2O_2-NH_4OH-H_2O$ at 80°C, followed by a deionized water overflow rinse which gave a hydrophylic surface; in some cases after the H_2O_2 treatment, the surfaces were re-etched slightly with HF, followed by a deionized water overflow rinse to give hydrophobic surfaces. Beryllium foil was degreased and then washed with isopropyl alcohol. The platinum foil was special flow oxygen content foil used for flash discharge analysis, and was cleaned by heating to redness in the oxidizing portion of a Bunsen flame. This technique has been demonstrated earlier to give the lowest oxygen content by flash discharge analysis (14). The metal films were prepared by electron beam evaporation in an ion-pumped system, removed from the system, and stored in a turbomolecular pumped vacuum system at pressure from 1×10^{-7} to 10×10^{-3} Torr. All insulator substrates were given the standard chemical clean, followed by a 550°C air bake.

Since β-Ta converts to the α-form at elevated temperatures, it is necessary to determine the substrate temperatures during deposition. To evaluate this, thin film thermocouples on sapphire were used (19) in the usual substrate position, and the temperature rise determined as a function of presputtering time and sputtering time (*i.e.*, after the shutter was removed). The substrate temperatures at the start and end of the film deposition are given in Table II. Since it will be important later, the shutter temperature was also measured with a bulk thermocouple, and after a 45 min presputtering period at 5 kV and 25 mA, the shutter temperature was 285°C.

The sheet resistance of the films was determined by a four-point probe, while the thickness was determined by weighing a monitor substrate before and after a run, and using the measured area and density of tantalum to calculate the thickness. This weight gain measurement was calibrated against a Talysurf measurement several times. All films deposited in this study were in the 450-500 nm range.

Table III. Individual gas leak-up rates

	B condition	C condition
	(Torr-liters)/sec

Results

"The new system effect."—The sputtering electrode and ground electrode holders, made of 300 series stainless steel and degreased in trichloroethylene, were installed in the new vacuum station, and sputtering performed under the A condition given in Table I. The resistivities of films deposited in the first consecutive fifty-five days are shown in Fig. 8. The results were highly variable, with the low resistivity films being α-Ta, while the high resistivity films were β-Ta. The dashed lines in Fig. 8 are meant to indicate that the α-Ta films tended to be formed when the system was not used for several days, which seemed to be related to an atmospheric gas effect. After the 44th day (shown by the arrow), the system routinely was opened only for very short periods of time to change substrates only, and from then on, β-Ta films were formed routinely.

Following these series of runs, runs were made which resulted in the data of Fig. 1 under the same vacuum condition A, but deliberate additions of nitrogen were made to the gas phase. In Fig. 1, the α-Ta films were only formed at a flow rate of nitrogen equivalent to a pressure of 2×10^{-5} Torr (the nitrogen flow rate at this pressure is approximately 2.5×10^{-3} Torr-liter/sec). Nitrogen is the gas which has been shown to be the most sensitive addend to the gas phase which causes the formation of α-Ta, yet the α-Ta films formed as shown in Fig. 8, were being deposited at leak-up rates and throttled pressures of 10-100 times less than that of nitrogen. It was at this point that it was realized that an X effect might be possible.

Since atmospheric gases appeared to be implicated a search for possible culprits was made. Baker (20) reported in rf sputtered tantalum films that there was a high variability in the deposit, also obtaining either α- or β-Ta films under nominally the same background pressure and sputtering conditions. In his work, oxygen was not found to form α-Ta preferentially at low partial pressure. Baker supposed that another factor, "such as the absence or presence of water vapor, as suggested by Nakamura *et al.* (21) probably decides which phase is formed." Nakamura states that presputtering for long times leads to the preferential formation of β-tantalum, and by mass

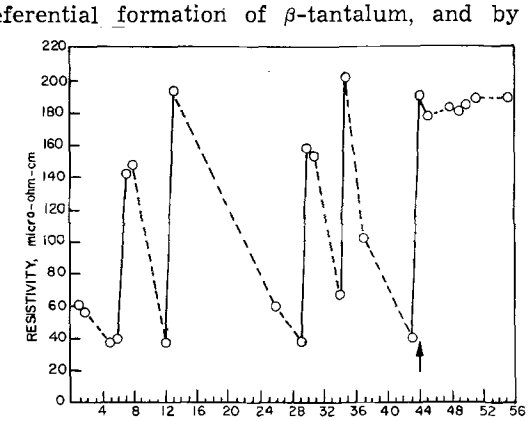

Fig. 8. Resistivity of tantalum films in the first 55 days of use of the new vacuum station.

spectroscopic investigation, this result was correlated with the reduction of water vapor to less than 1×10^{-7} Torr. Slight amounts of added nitrogen also lead to a decrease in water content due to the formation of NO. To confirm whether water vapor could be the X component, deliberate additions of water vapor were made in this system, using the C vacuum conditions, and the results are shown in Fig. 9. In fact, only slight amounts of α-Ta are formed, and only at 1×10^{-4} Torr partial pressure, a factor of 100 times the background pressure during the experiments on the new system effect (Fig. 8).

Silicone oil is the usual charge for diffusion pumps and frequently for turbomolecular pumps when used for oxygen service, and silicon might be considered a possible X candidate. In a later series of experiments in this same vacuum station, under condition C vacuum, tantalum-silicon alloy films were formed by the addition of silane to the argon (22). During the course of those experiments, it was demonstrated that α-Ta films were barely formed, and only at partial pressures of silane slightly above 1×10^{-4} Torr.

A few experiments were made at $1\text{-}5 \times 10^{-6}$ Torr of added CO_2 to the argon and these runs only yielded β-Ta films; this is consistent with the results shown in Fig. 3, which indicates that carbon in the gas phase is less efficient than nitrogen in causing the formation of α-Ta.

These series of experiments appeared to rule out N, H_2O, C, and Si, when introduced in the gas phase, as the X impurity.

The α-Ta dip.—The other evidence for the X impurity hypothesis was in this same system, operating in the B vacuum conditions. This effect is called for convenience, the α-Ta dip and in its most extreme cases is illustrated in Fig. 10. For the first two runs with shutter A, which had been used for a long time in the system, the deposition results consistently in β-Ta. In run 3, a new shutter was put into the system, and left there for the succeeding four runs. In the first run after the new shutter was installed, very low resistivity α-Ta was formed: moreover the effect lasted through the succeeding run, and only after three successive runs with the new shutter was the system again producing high resistivity β-Ta.

The following conditions and treatment of shutters led to the α-Ta dip:

1. Use of a 300 series stainless steel shutter, directly received from the machine shop and stored in air for 3 months, washed with isopropyl alcohol, and air dried before use. Separate experiments indicated that isopropyl alcohol was never responsible for the dip.

2. Taking out either a high purity Ta or stainless steel shutter and etching with $HF\text{-}HNO_3$ to remove

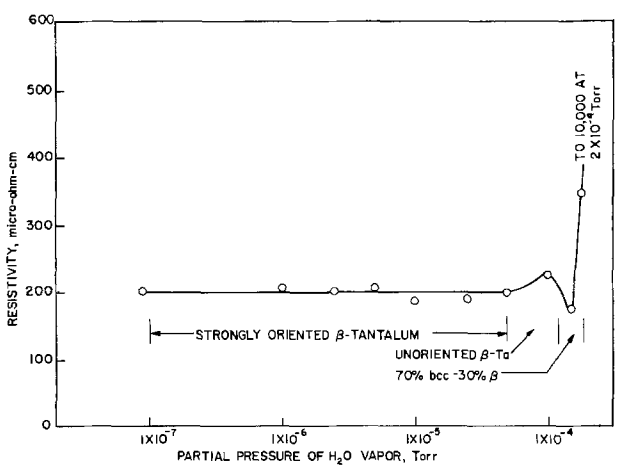

Fig. 9. Resistivity of tantalum films sputtered in argon with various partial pressures of water.

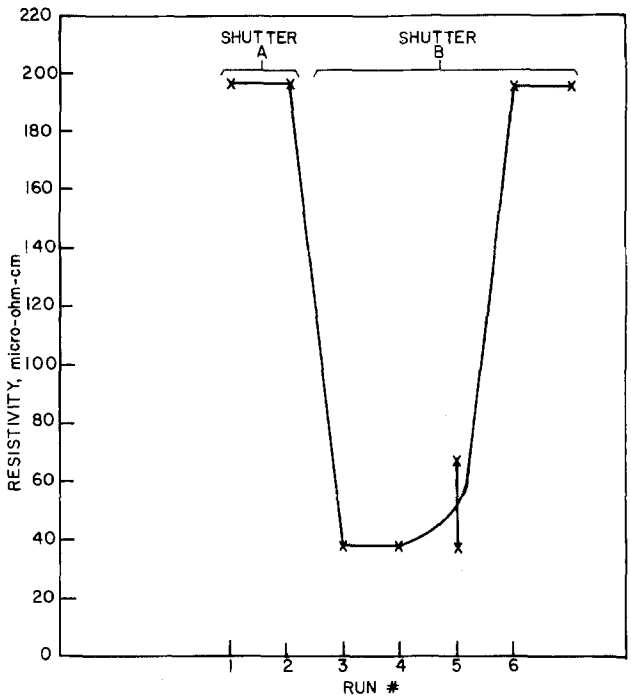

Fig. 10. The α-Ta dip

deposited Ta, washing with either cold or boiling water, isopropyl alcohol and air dried did cause the dip. Drying the shutter at 110°C for 2 days, still caused the dip. Baking a stainless steel shutter at 300°C in air overnight, which caused a brown scale on the surface, prevented the α-Ta dip.

3. Taking out a tantalum shutter and boiling for 2 hr in water, followed by isopropyl alcohol rinse, and air dried, did cause the dip.

4. Taking out a stainless steel shutter, and filing the top and bottom of the shutter to remove the deposited Ta, and putting the shutter directly back, did cause the dip.

Several months later some of these experiments were repeated with the same machine in a new clean laboratory with a copious supply of very high purity deionized water, and the details could not be reproduced exactly. What could be reproduced was that the α-Ta dip was related to an elusive and nonreproducible contaminant in tap water which was used to rinse the shutters in cases 2 and 3 above. Moreover, in the cases discussed above, the substrates were all Corning 7059 glass. In the subsequent experiment, all the normal β-Ta producing substrates were used like Ta_2O_5, 7059, Si, and Al_2O_3. The α-Ta dip was most easily observed with the unoriented single crystal sapphire; with the next most sensitive being 7059 and Ta_2O_5, equally; while the α-Ta dip was never observed with Si(100), even though all of these substrates were simultaneously in the vacuum station whenever a new shutter was installed.

The α-Ta dip could also be observed on the most sensitive substrate, sapphire, when a shutter was taken out of the vacuum station, and stored for about one month completely protected in a glass petri dish, in a Class 100 laminar flow hood in a Class 1000 clean room. Apparently there is an interaction between a tantalum-film coated-stainless steel shutter and air which is capable of acting as an X impurity in a subsequent film deposition on sapphire. If the shutter was stored in air under these conditions for 7 months, then all of the normal β-Ta producing substrates yielded α-Ta.

What these experiments demonstrate is that an impurity, frequently in tap H_2O, and also in air, can be present on the shutter; during the presputter pe-

riod, as the shutter surface warms up to 285°, the impurity is transferred to the substrate surface. However, it is either more strongly adsorbed or is more active on a sapphire surface when compared to a Si(100) surface. Preheat-treatment of the shutter at 110°C does not remove the impurity, but heating in air to 300°C does.

An attempt was made to identify this X impurity using a very sensitive technique, Auger analysis. Two runs were made on 7059 glass: (*i*) The shutter was prepared where it would normally allow the formation of β-Ta on the 7059, and the run proceeded through the presputtering period, but the substrate removed without any Ta deposition; and (*ii*) exactly the same procedure was followed, except the shutter was prepared in such a way that it normally caused the α-Ta dip.

Unfortunately, after the substrates were transferred to the Auger apparatus, no significant differences could be detected between these two 7059 surfaces. In both of these cases, residual gas spectra similar to Fig. 5 differed over the entire spectrum no more than the normal variation.

All of these experiments prove that it is possible to easily contaminate substrates by parts of a sputtering system not in contact with these items. The transfer takes place by very small amounts of an impurity at exceptionally low pressures, and this impurity can prevent the formation of β-Ta. Moreover, it frequently can persist over several runs.

The Feinstein-Hutteman-Axelrod substrate-nucleation effect (FHA).—As indicated, previously detailed studies (16, 25) have concretely shown (Table I) that different substrates in the same vacuum station, under the same deposition conditions, can give either the α- or β-Ta form. Moreover, substrates had been classified as to whether they were α- or β-Ta producing substrates. Verification of this effect in another system was important since it is conceivable that the X impurity was causing the difference in the initial study. This seemed conceivable, since it had already been determined in the present system that foil beryllium and foil platinum had given results in contradiction to FHA (see Table I, This work).

Substrates, used previously by Feinstein-Hutteman, were checked, and were prepared in essence in the same way. Particular substrates were picked either because of their pertinence to thin film technology, or because they had earlier in this work showed some contradiction in their results. Silicon (100) was used with either a hydrophylic surface or hydrophobic surface with identical results. The deposition was performed under the cleanest condition; *i.e.*, Table II-B. The results are summarized in Table I under "This work." All of the substrates used previously by FHA (*i.e.*, 7059, Ta_2O_5, sapphire, W, Mo, Au, Pt) gave the same results as FHA.

FHA classified the substrates into three types: (*i*) oxidized surfaces which always give β-Ta (*i.e.*, Ta_2O_5; 7059; sapphire; and Si, presumed to have an oxide film on surface; (*ii*) essentially oxide-free surfaces which always give α-Ta, and do not oxidize when heat-treated in O_2 or H_2O and continue to give α-Ta (*i.e.*, Pt, Au, W); and (*iii*) essentially oxide-free surfaces which yield α-Ta, but oxidize when heat-treated in O_2 or H_2O and subsequently yield β-Ta (*i.e.*, Ta_2N, Mo). Although the observation of three classifications is essentially correct, the present result on bulk platinum is not compatible with group II, since it should be no different than thin films. One conceivable explanation for FHA is that the X impurity exists in variable amounts in these classes of substrates, and can be removed by heat-treatment in water or oxygen. These possibilities will be considered in the discussion.

Table IV. Resistivity of 5000Å tantalum films deposited on Ta_2O_5 underlay after rubbing with the given material

Teflon rod†	36
Scotts laboratory paper wipes*	52
Ta_2O_5*	190

* No transfer of material observed visually.
† Some scattered markings of Teflon observed on surface.

The rubbing effect.—In the course of verifying the FHA, some totally uncleaned 7059 substrates were used simultaneously with all the other cleaned substrates, and this particular 7059 substrate gave α-Ta. The procurement of 7059 has been well specified for Bell System work, and it was surprising that the entire substrate should have the X impurity. The possible major source of impurity is the Dextilose[2] paper which is always interleaved between sheets of 7059 to prevent scratching. To test whether a possible source of X was this paper, cleaned Ta_2O_5 underlay coated substrates were rubbed gently and uniformly with this paper. As controls, various other sources of paper and clean cloth, available in the laboratory, were also used. In order to distinguish the possible mechanical disturbance of the surface from an actual transfer of a chemical constituent, two cleaned Ta_2O_5 underlay surfaces were rubbed against each other. Table IV gives the resistivity of 5000Å tantalum films obtained after rubbing the various specified organic or inorganic materials on the substrates. All the organic materials resulted in low resistivity α-Ta uniformly formed over the 10 cm^2 of the substrate rubbed while the other half of the same substrate resulted in β-Ta. The Ta_2O_5 rubbed substrate resulted in the usual high resistivity β-Ta.

In order to estimate the upper limit of the thickness of the organic layer transferred during rubbing, a 400Å anodic tantalum oxide was rubbed in a similar way with Dextilose paper. According to Vermilyea (23), this thickness of anodic oxide is most sensitive to a visual color match due to change of thicknesses, and has a visual sensitivity equivalent to a change of thickness of 2Å. Since the index of refraction of the film responsible for the thickness change is involved in the color change, and organic polymers have an index of refraction of about 1.4 compared to 2.2 for Ta_2O_5, this thickness sensitivity should be of the order of 3Å. The rubbing experiment caused no change in the color of the anodic oxide, and thickness of the layer of organic material is less than 3Å, or less than a monolayer.

Cast organic films.—In order to achieve α-Ta routinely for potential capacitor applications where its low resistivity would result in better frequency performances (24) hand rubbing did not seem convenient, so a casting technique was applied. Tantalum oxide underlay coated slides were dipped into a very dilute solution of polymer in a highly volatile solvent like acetone. As the substrate is withdrawn from the solution, the acetone evaporates and a uniform, exceptionally thin, layer of polymer can be deposited. The polymer used was Union Carbide VMCA, which is a terpolymer of vinyl chloride, vinyl acetate, and maleic acid. The results of the dipping slides (2.5 × 7.5 cm^2) partially into various decreasing concentrations of this polymer in acetone at room temperature is illustrated in Fig. 11, where the dark colored areas are α-Ta, while the light colored areas are β-Ta. The

[2] Dextilose paper is a purified, lint-free paper, similar to lens paper. R.H. Dexter Company.

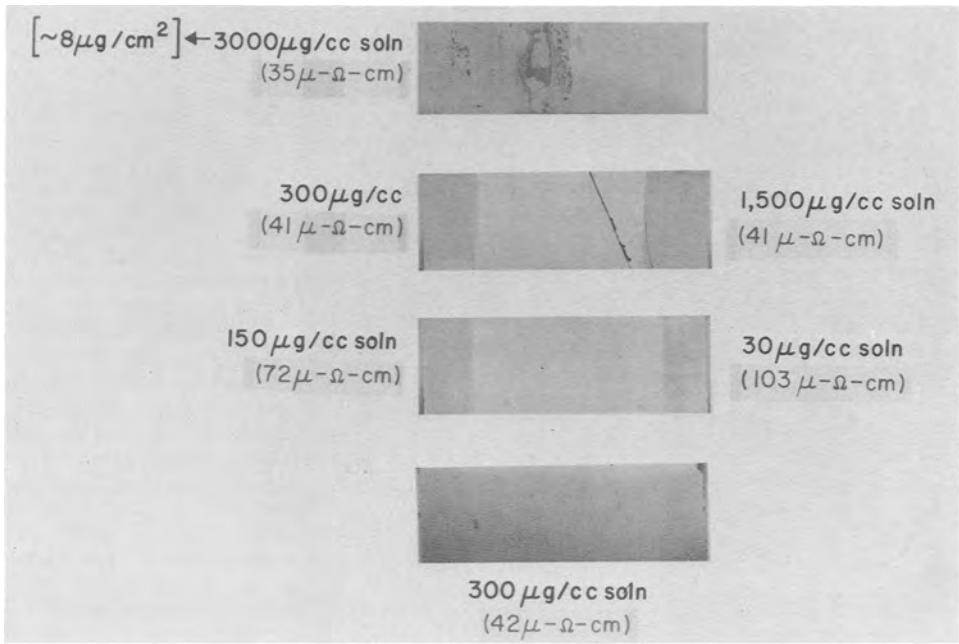

Fig. 11. Nucleation of bcc tantalum on monolayer organic films. α-Ta and β-Ta were formed on the same slide during the same deposition run. The α-Ta was caused by preliminary treatment of the Ta_2O_5 surface with polymer. α-Ta is the dark colored film, while β-Ta is the light colored film. The number in square brackets in the upper left is the weight of VMCA deposited on the surface when the slide was dipped in a solution of 3000 μg VMCA/cm^3 acetone.

demarcation between these areas are the exact position where the slide was dipped into the polymer solution.

In the upper slide (left), 35 $\mu\Omega$-cm α-Ta results when that end was dipped into a solution of 3000 μg VMCA/cm^3 acetone (the amount deposited in the slide was 8 μg/cm^2), while the untreated other end yielded the usual β-Ta in the same deposition. This concentration of polymer was excessive, since some crazing appeared near the interface of α- and β-Ta. The next two[3] slides show the effect of the polymer solution concentration where the concentration was decreased in steps from 1500 to 300 to 150 to 30 μg/cm^3. The resistivity increases slightly to 41 $\mu\Omega$-cm and then rises to 103 $\mu\Omega$-cm. All of these end α-Ta areas have high degree of adherence and are mechanically stable. The lowest slide in this figure was dipped entirely in the same solution as the second-left, to demonstrate that α-Ta can be formed uniformly over a large area. Polypropylene dissolved in toluene is just as effective as VMCA, and the criterion appears to be a carbon-containing compound in small quantities on the surface. The use of polymers, cast out of solution or sprayed on the surface, is an exceptionally convenient and inexpensive technique for preparing surfaces to obtain α-Ta.

Discussion

The verification of the proposal of the possible existence of an X impurity seems amply verified by the new system effect and the α-Ta dip effect. This work has also demonstrated that very low vapor pressure organic compounds are possible candidates for X, while the FHA work suggests other possible candidates like Pt, Au, W, Mo, etc. Finally there may be species which have yet to be investigated, such as that present in tap water or that responsible for the air-shutter interaction.

Of these known species, carbon would have a high probability of clean-up in a sputtering discharge upon the addition of oxygen or nitrogen. Carbon is ubiquitous, and might explain the α-Ta dip when it comes to interactions due to pollutants in tap water and the atmosphere, although other species are still possible. These results should surely indicate that the X impurity can exist, and that it must be taken into account when considering possible mechanisms for the formation of α-Ta. As a direct technological benefit, the cast organic film approach as illustrated in Fig. 11, allows for a simple nonvacuum method to choose whether α-Ta or β-Ta will be formed in the majority of vacuum stations which heretofore have been restricted to producing β-Ta films. Moreover, the α-Ta films so produced have very low resistivity, applicable to specific capacitor applications.

In a glow discharge, the interaction of energetic particles, including secondary electrons, with a monolayer of organic material could be the formation of Ta_2C or TaC. These phases are isomorphous with Ta_2N and TaN, which have already been demonstrated by FHA to yield α-Ta. One possible explanation of the group III type substrates in the FHA is that treatment with hot water or slight oxidation, although actually adding oxygen to the surface, is really destroying the crystallinity of the surface resulting in amorphouslike films which tend to yield β-Ta or is destroying an X impurity like carbon. In this mechanism, the presumed most stable form, α-Ta, needs nucleation by specific surface configurations like Ta_2C particles, while the amorphous surface or unnucleated form results in the presumed metastable phase, β-Ta. Further studies are required to explore the impurity nucleation dominated growth of α-Ta.

Summary

It has been demonstrated that impurities, available in common sources in the laboratory, can prevent the formation of β-Ta.

A polymer casting technique has been developed which allows for nonvacuum preparation of substrates which routinely results in low resistivity α-Ta. This material has benefits for fabricating thin film capacitors with high frequency performance.

This impurity catalyzed formation of α-Ta should be considered as a possible mechanism for those workers who cannot prepare β-Ta.

Spectroscopic Investigation of Photovoltaic Effects in Doped $LiNbO_3$

E. Krätzig and H. Kurz

Philips GmbH Forschungslaboratorium Hamburg, D 2 Hamburg 54, West Germany

ABSTRACT

Photo-induced currents and voltages determining the photorefractive effect in transition metal doped $LiNbO_3$ crystals have been measured in the spectral region between 1.5 and 4.0 eV. The current density j, the constant κ describing the anisotropic charge transfer, the conductivity σ during illumination, and the saturation field E_s have been investigated. The results yield information on the photorefractive centers and on the optical storage properties of mono- and double-doped $LiNbO_3$.

Light-induced refractive index changes in pyroelectric crystals like $LiNbO_3$ are of considerable interest for the reversible storage of thick phase holograms (1, 2). As shown by Glass *et al.* (3) the index changes result from photovoltaic effects in these crystals induced without externally applied fields; diffusion effects have only small influences under usual experimental conditions. The short-circuited steady-state current density along the crystallographic c axis induced by uniform illumination determines the photorefractive sensitivity, the photo-induced voltages and fields determine the refractive index change and hence the storage capacity. The current density j along the c axis is given by the relation: $j = \kappa \cdot \alpha \cdot J - \sigma \cdot E$, where J is the light intensity, α the absorption coefficient, κ a constant describing the anisotropic charge transport, E the photo-induced field, and $\sigma = \sigma_d + \sigma_l$ the conductivity during illumination containing contributions of dark- and photoconductivity. For $j = 0$ the saturation field E_s is obtained: $E_s = \kappa \cdot \alpha \cdot J/\sigma$.

In this paper we report on spectroscopic investigations of the quantities j, κ, σ, and E_s determining the storage properties of transition metal doped $LiNbO_3$ crystals. We use mono-doped crystals containing various concentrations of Fe, Cu, Mn, and Cr and double-doped crystals containing Fe/Cr, Cu/Cr, Fe/Mn, and Fe/Cu.

Key words: pyroelectrics, photovoltaic effects, photorefractive effects, optical storage.

Experimental

The poled single crystals used in these experiments were grown from congruent melt by A. Räuber, Institut für Angewandte Festkörperphysik, Freiburg, Germany. The crystals have been oxidized and partially reduced by common annealing treatments.

Short-circuited photocurrents in thermal equilibrium have been induced in the spectral range between 1.5 and 4.0 eV by incoherent light of a 1 kW xenon lamp in combination with a grating monochromator. The crystals were uniformly illuminated and edge electrodes of silver paste were used. Because of the influence of light absorption the measured currents are related to a mean light intensity $\bar{J} = J_0 (1 - e^{-\alpha d}) (\alpha \cdot d)^{-1}$, where J_0 is the incident intensity and d the crystal thickness. To reduce the influence of absorption as much as possible very thin crystals (d between 0.1 and 0.2 mm) have been used.

Photo-induced voltages and fields have been measured by applying external fields for compensation. The deviation of j under the influence of an external field has been found to be proportional to the field strength up to values of 10 kV/cm, the largest fields externally applied. For this reason the compensation field can be extrapolated for large values of E_s.

The optical absorption has been measured with a Cary 17 spectrometer *vs.* an undoped reference crystal or *vs.* air. In this case the contribution of reflection

calculated from the refractive index has been subtracted.

Results and Discussion

Mono-doped crystals.—For all dopants investigated the photocurrents in $LiNbO_3$ are directed along the c axis with the +c end negative (4). The photocurrent spectra, however, depend specifically on the dopants. The evaluation of κ from the short-circuited current density j according to the relation $j = \kappa \cdot \alpha \cdot J$ is impeded by different contributions to light absorption. We have always used the entire absorption including transitions, which do not contribute to the photocurrent.

The spectral dependence of κ is shown in Fig. 1 for various Fe-doped crystals partially reduced by common annealing treatments. Because of the small influence of light polarization the results are confined to unpolarized light. For each individual Fe concentration, κ increases with increasing photon energy, reaches a maximum around 3 eV, and decreases at larger photon energies. The κ-values increase with increasing Fe content up to 0.25 weight percent (w/o) Fe_2O_3, the largest Fe concentration used. The dependence of the maximum value κ_{max} on chemical treatments is shown in Fig. 2 for a crystal containing 0.02 w/o Fe_2O_3 and reduced by gradual steps. A measure for the chemical state is the optical absorption band at 2.6 eV, growing by reducing treatments. In the case of oxidized crystals very small κ-values are obtained for all Fe concentrations investigated. However, it should be kept in mind that small inefficient contributions to absorption have large effects on the evaluation of κ in the case of oxidized crystals with very small absorption coefficients. The maximum value of κ grows with increasing absorption, remains constant for a large absorption range, and decreases again in the case of very strongly reduced crystals.

For Cu- and Mn-doped crystals the κ-values are smaller than in the case of Fe dopants, the maximum values are about 1 (pA · cm/mW) for Cu-doped and 0.2 (pA · cm)/mW for Mn-doped crystals. The influence of various concentrations and chemical treatments on κ is smaller than for $LiNbO_3$:Fe.

Glass *et al.* (3) have proposed a model for the photocurrents in $LiNbO_3$:Fe generated without external fields. Electrons are excited directionally from Fe^{2+} to Nb^{5+} ions (intervalence transfer) and are trapped again by Fe^{3+} ions. The directional properties along the c axis result from an asymmetrical lattice site of the Fe^{2+} ions. Dischler and Räuber (5) have suggested that the efficient Fe^{2+} ions are associated with oxygen vacancies.

The maximum of the photocurrent at 3.2 eV differs from the absorption maximum at 2.6 eV corresponding to the intervalence transfer (4). This behavior indicates the increase of the unidirectional transport properties even in the spectral region where the transition probability decreases. Similar results are obtained for Cu-doped crystals, where the photocurrent maximum is observed at 3.7 eV and the maximum of the difference absorption between a reduced and an oxidized crystal at 3.3 eV.

The relatively small influence of chemical treatments on κ indicates that the total directional charge transport is mainly determined by the excitation and not by the recombination process.

A further quantity determining the storage properties is the conductivity $\sigma = \sigma_d + \sigma_l$ during illumination. The dark conductivity σ_d of $LiNbO_3$ crystals is increased by impurities and by reducing treatments. However, for impurity concentrations smaller than 0.1 w/o and moderate reductions the dark conductivity of our samples remains smaller than $2 \cdot 10^{-16}$ $(\Omega\text{-cm})^{-1}$. For very strong reductions σ_d can be increased by several orders of magnitude supporting the interpretation that in this case Nb^{4+} centers have been formed.

The spectral dependence of the photoconductivity σ_l is represented in Fig. 3 for an oxidized and for a partially reduced $LiNbO_3$:Fe crystal. With increasing photon energy σ_l increases for all dopants and chemical treatments investigated. Two different spectral regions for σ_l can be distinguished: In the visible region σ_l increases by reduction, in the near u.v. region σ_l increases by oxidation. This behavior leads to the requirement of two different kinds of centers contributing to photoconductivity.

In the visible region σ_l can be described by the relation $\sigma_l \propto \alpha \cdot J/N$, where the absorption constant α is proportional to the number of Fe^{2+} ions acting as donors and the number of traps N is proportional to the concentration of the Fe^{3+} ions. For this reason we

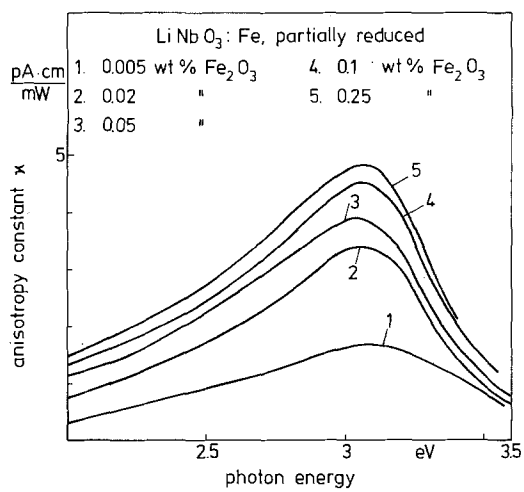

Fig. 1. Spectral dependence of the anisotropy constant κ for various $LiNbO_3$:Fe crystals.

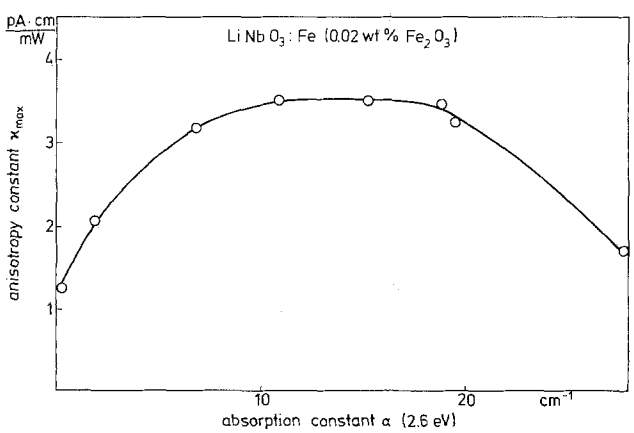

Fig. 2. Dependence of the anisotropy constant κ_{max} on chemical treatments for $LiNbO_3$:Fe.

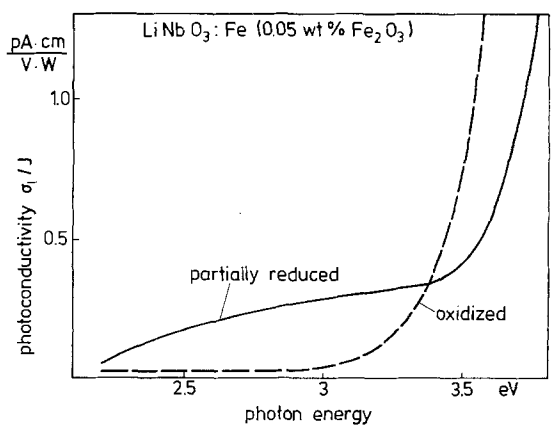

Fig. 3. Spectral dependence of photoconductivity for $LiNbO_3$:Fe

attribute the photoconductivity to field-sensitive electron transfers from Fe^{2+} to Fe^{3+} ions. The above relation is satisfied for Fe concentrations smaller than 0.1 w/o. For crystals with higher concentrations σ_l grows more rapidly than expected indicating additional contributions.

In the near u.v. region the optical absorption is decreased by reducing treatments and is mainly determined by charge transfer processes from oxygen π-orbitals to Fe^{3+} ions. Therefore we attribute the photoconductivity to these excitations and migration of the holes in the valence band. In reduced crystals σ_l decreases rapidly in the region because the holes are trapped by Fe^{2+} ions.

The photo-induced saturation field E_s is independent of light intensity since $E_s = (\kappa \cdot \alpha \cdot J)/\sigma$ and $\sigma \propto J$, if σ_d is small compared to σ_l. In the case of our crystals this is always true for impurity concentrations smaller than 0.1 w/o, for moderate reduction and light intensities of the order of 1 mW/cm². For higher impurity concentrations or stronger reductions the value of E_s for high intensities can be determined by substracting σ_d from σ.

The field E_s grows with increasing photon energy because κ increases, reaches a maximum around 3 eV for Fe, Cu, and Mn dopants and decreases at larger photon energies because σ increases. The spectral dependence of E_s for various Fe concentrations is shown in Fig. 4. The largest E_s values are obtained for concentrations of about 0.1 w/o Fe_2O_3. The dependence of the maximum value $E_{s\,max}$ on chemical treatments is presented in Fig. 5. The smallest E_s values are obtained for oxidized crystals. With an increasing Fe^{2+} concentration, E_s grows rapidly and decreases again due to the increase of σ_l.

A different behavior is observed for Cu-doped crystals: In this case the largest E_s values are observed for oxidized samples.

Double-doped crystals.—In double-doped $LiNbO_3$ crystals two kinds of effects are observed. For certain dopants the optical properties depend on illumination via photochromic effects as discovered by Staebler and Phillips (6). On the other hand the quantities κ and E_s determining the storage properties of Fe- or Cu-doped crystals may be modified by codopants.

For example in Cr-doped $LiNbO_3$ photocurrents and photovoltages are not increased at photon energies smaller than 3.5 eV compared to undoped $LiNbO_3$. In crystals containing Fe/Cr or Cu/Cr, however, the quantities j, κ, σ, and E_s differ from those of Fe- or Cu-doped crystals, respectively. Photochromic effects are of less importance in these double-doped crystals: Fe/Cr-doped samples show very small photochromic effects in the oxidized state vanishing by reducing treatments, Cu/Cr-doped samples show no photochromic effects at all.

For quantitative evaluation we compare a $LiNbO_3$ crystal doped with 0.05 w/o Fe_2O_3 and a crystal doped with 0.05 w/o Fe_2O_3 and 0.05 w/o Cr_2O_3 oxidized and partially reduced by common annealing treatments. In the oxidized state the κ-values of the Fe/Cr-doped sample are a factor of two larger than that of the Fe-doped crystal. In the partially reduced state nearly equal κ-values are obtained for both crystals. However, in the case of the Fe/Cr-doped crystals the absorption contains large contributions from transitions on Cr ions inefficient for the photovoltaic effect as determined from measurements of $LiNbO_3$ crystals doped with Cr only. The subtraction of this inefficient absorption yields also for partially reduced Fe/Cr-doped crystals κ-values which are about a factor of two larger than that of the Fe-doped crystals. Similar results are obtained from measurements of Cu/Cr-doped (0.05 w/o CuO and 0.05 w/o Cr_2O_3) and Cu-doped (0.05 w/o CuO) crystals.

The saturation fields E_s of these crystals indicating the interplay between κ and σ also exhibit considerable differences. In Fig. 6 the fields of Cu/Cr- and Cu-doped samples are compared. In the oxidized and the partially reduced state the fields of the double-doped crystal are considerably larger.

The reason for the increase of κ and E_s in the double-doped crystals is not yet clear. By the additional Cr dopants new centers may be formed or the crystal stoichiometry may be changed. The results on mono-doped samples concerning the impurity concentration and chemical treatments seem to favor the second possibility.

In double-doped $LiNbO_3$ crystals containing Fe/Mn and Fe/Cu photochromic effects are found. A model for the charge transfer during illumination with u.v. or visible light in Fe/Mn-doped samples has been proposed by Staebler and Phillips (6)

$$Mn^{2+} + Fe^{3+} \underset{\text{vis.}}{\overset{\text{u.v.}}{\rightleftharpoons}} Mn^{3+} + Fe^{2+}$$

The analogous process for Fe/Cu-doped samples reads

$$Cu^{+} + Fe^{3+} \underset{\text{vis.}}{\overset{\text{u.v.}}{\rightleftharpoons}} Cu^{2+} + Fe^{2+}$$

Photochromic effects are observed for impurity concentrations smaller than about 0.1 w/o and for oxidized or lightly reduced crystals. In the case of stronger reductions the photochromic effects decrease considerably.

Figure 7 shows the spectra of the photocurrent density and the absorption of a $LiNbO_3$ crystal doped with

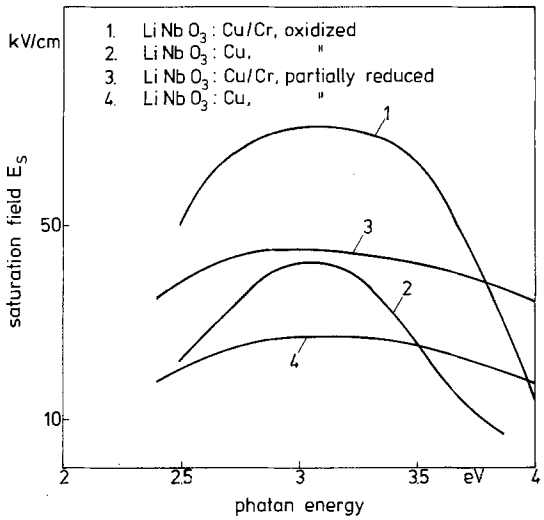

Fig. 6. Comparison of the saturation fields E_S of a Cu (0.05 w/o CuO)- and a Cu/Cr (0.05 w/o CuO, 0.05 w/o Cr_2O_3)-doped $LiNbO_3$ crystal.

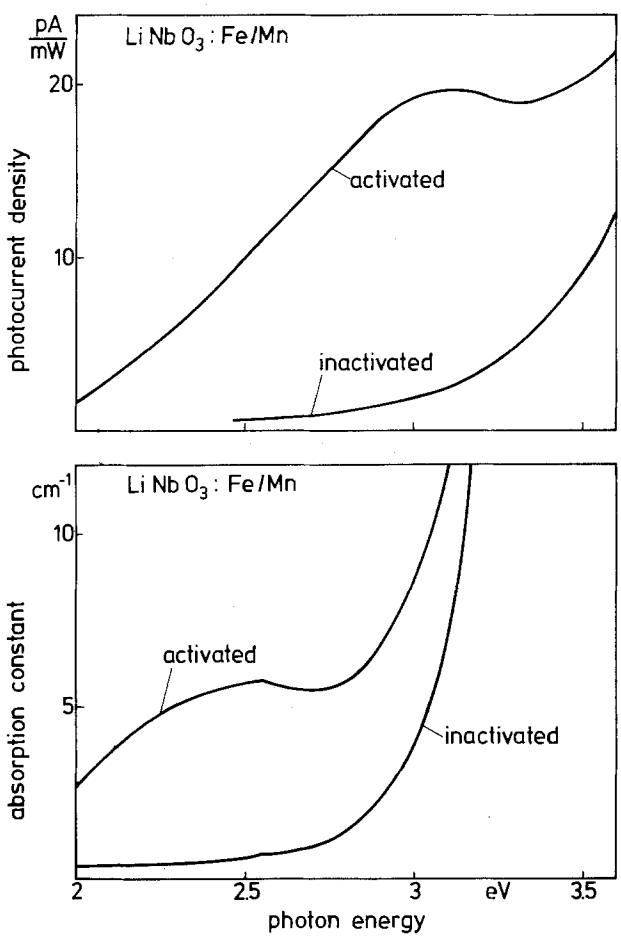

Fig. 7. Photocurrent and absorption spectra of a $LiNbO_3$:Fe/Mn crystal after illumination with u.v. light (activated) and visible light (inactivated).

0.03 w/o Fe_2O_3 and 0.01 w/o $MnCO_3$. The crystal has been activated and inactivated by illumination with u.v. (3.4 eV) and visible (2.5 eV) light, respectively. In the activated state the characteristic photocurrent spectrum of the Fe dopants is observed, in the inactivated state the spectrum of Mn dopants is obtained supporting the above model. Only 5-10% of the Fe dopants are involved in the photochromic switching.

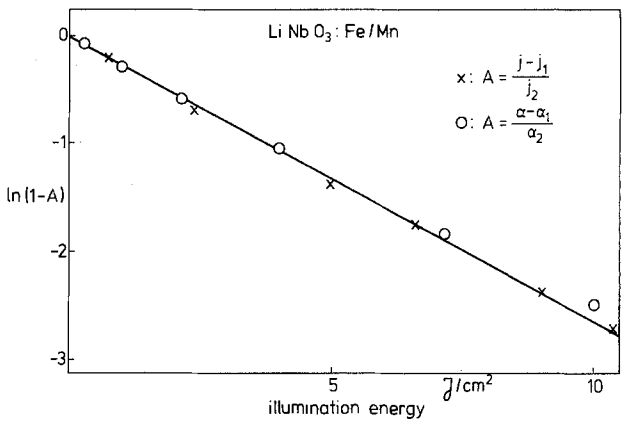

Fig. 8. Simultaneous increase of absorption at 2.6 eV and photocurrent during illumination with u.v. light (3.4 eV) of an inactivated $LiNbO_3$:Fe/Mn crystal.

Measurements of photochromic $LiNbO_3$:Fe/Mn crystals clearly demonstrate the correlation of the absorption band centered at about 2.6 eV and the photocurrent. A crystal has been inactivated by illumination with visible light (2.5 eV). As shown in Fig. 8 the simultaneous increase of the absorption and the photocurrent during u.v. illumination can be described by the relations

$$j(J \cdot t) = j_1 + j_2 (1 - \exp(-k \cdot J \cdot t))$$

and

$$\alpha(J \cdot t) = \alpha_1 + \alpha_2 (1 - \exp(-k \cdot J \cdot t))$$

where j_1, j_2, α_1, α_2, and k are constants. The values of κ and E_S in Fe/Mn- and Fe/Cu-doped samples also depend on optical treatments. In activated crystals κ-values characteristic for Fe dopants are obtained, in inactivated crystals the κ-values correspond to those of Mn or Cu dopants. In these crystals rather large saturation fields have been measured, the values in the activated state exceed 100 kV/cm.

Influence of the Growth Parameters in GaAs Vapor Phase Epitaxy

L. Hollan, J. M. Durand, and R. Cadoret[1]

Laboratoires d'Electronique et de Physique Appliquee, Limeil-Brévannes, France

ABSTRACT

The vapor growth of gallium arsenide by the arsenic trichloride transport method has been studied by measurement of the growth rate *vs.* several growth parameters varied in broad intervals. Thus the influence of the supersaturation of the source and deposition temperature and of the input arsenic trichloride partial pressure has been studied. Growth has mainly been carried out on (100) crystalline planes, with some experiments on (110). The experimental data allows an estimation of the growth possibilities in unusual conditions, namely at low temperature, low supersaturation, and in a broad range of arsenic trichloride partial pressure. In these latter conditions, pure material is obtained at very high growth rates. All the experimental results can be qualitatively explained by a kinetically controlled growth mechanism involving a surface adsorption layer.

In spite of the very numerous papers dealing with vapor phase epitaxy of GaAs [see for instance review paper of Shaw (1)], the influence of the different growth parameters is not sufficiently known. This is probably due to the fact that the principal motivation is material supply for devices, so that previous authors have not tried to deviate too far from growth conditions giving more rapidly good electrical and morphological results. These conditions then have been generalized in the different laboratories of the world. Furthermore, the few researchers (2) who attempted to vary the growth parameters in much larger intervals came up against experimental difficulties; uncontrolled parasitic nucleation, out-of-equilibrium conditions, etc., made it difficult to obtain significant and reproducible results. Finally, the lack of growth mechanism models did not incite the scientific workers to compile other experimental data than those necessary for the growth of layers orientated toward device production.

Our laboratory having now a long experience of this growth method as well as a suitable growth mechanism model (3), has undertaken a study with very large variations of the growth parameters.

In the "arsenic trichloride" method, the main experimental parameters are the following: (*a*) deposition temperature T_D, (*b*) source temperature T_S, (*c*) input $AsCl_3$ partial pressure p_o, and (*d*) crystallographic orientation of the substrate.

Some authors have already studied the influence of these parameters, but only little mention is made of T_D outside of the 700°-750°C interval (4), 750°C being currently used. Similarly T_S, which determines, for a fixed T_D, the supersaturation and to a lesser extent the Ga/As ratio (5), in most published data is given only indicative values, since, depending on the source geometries, equilibria are only partially reached. The influence of p_o has been studied by Di Lorenzo (6) and also by others (7, 8), because this parameter allows the control of the residual doping through the effect of secondary equilibria on the quartz walls. In our laboratory, a study showing the influence of very large variations of this parameter on the doping and on the growth rate at three deposition temperatures (720°, 750°, and 770°C) has been published (9). Now this study has been extended to a larger temperature range and to the influence of supersaturation. Finally the influence of the crystallographic plane has been studied by several authors (10-13) and a very pronounced anisotropy pointed out. In the present study, besides the common deposition on misoriented 3° off the (001) plane toward the [110], we have also performed some experiments on the less well-known (110) plane which leads to unusual results.

Key words; crystal growth from vapor, gallium arsenide, crystal structure.

Experimental Results

The experimental growth of GaAs by the $AsCl_3$ method was carried out in equipment similar to that already described elsewhere (14). As we have already mentioned, for an exact knowledge of the growth parameters, it is necessary to reach equilibrium at the source. So, in this study, we have mainly used a boat filled up with GaAs, in which the surface of contact between the polycrystalline material and the $AsCl_3$ and hydrogen mixture is large enough to reach this equilibrium. We have also experimentally checked that the weight loss at the source linearly increased with the arsenic trichloride partial pressure (p_o) even for the highest values of the latter. Another advantage of a GaAs source is to avoid the problems occurring during the saturation (15) so that the supersaturation value and the partial pressures cannot be evaluated. Nevertheless, several experiments have also been carried out with Ga sources, using boats with large Ga surface areas and relatively low gas flow rates in order to reach equilibrium.

The study of the different growth parameters requires a large number of experiments; since it was necessary to limit this number, we have proceeded as follows. In order to avoid any instabilities which could occur during the beginning of the growth, the growth is started with a n^+-doped buffer layer (time t_1). After stabilization, a growth with given conditions (T_S, T_D, p_o) and without doping is carried out during a time t_2 (this time is long enough to grow more than 10 μm); then the dopant is added again and the growth conditions changed (*e.g.*, decrease T_S and T_D by 20°C); after a new period t_3 which is chosen to be much longer than that required for the temperature stabilization, the dopant flow is switched off, and a growth with the new growth conditions is carried out during a time t_4. This procedure can be repeated several times (for practical reasons we have limited it to five) and at the end of the growth the successive layers are revealed on a cleavage plane, and the growth rates are easily evaluated. The doping level of each undoped layer can also be determined by successive etching and $C = f(V)$ measurements. Nevertheless, this procedure is not applicable with Ga sources for any change in the source temperature because of the saturation problems.

Results and Discussion

Influence of the growth temperature.—In any vapor phase growth process, the growth temperature is obviously one of the main parameters and the growth rate τ is usually represented, in previous papers, in the $\log \tau = f(1/T_D)$ diagram, *i.e.*, the logarithm of growth rate *vs.* the inverse of the deposition temperature (5, 16, 17) in order to point out a linear decrease which was roughly interpreted by a kinetic limitation.

Figure 1 shows these types of $\log \tau$ *vs.* $1/T_D$ curves. It must be noticed that contrary to previous studies, the supersaturation was maintained close to a constant value ($T = 80°C$, see definition below), this was necessary to point out the influence of the growth temperature variation only. The curves corresponding to the (100) plane show clearly that with these conditions (namely at constant supersaturation) the generally reported decrease of the growth rate at higher temperatures is not observed. On the other hand, it appears that the previously reported linear decrease, related to an activation energy (5, 16) is not a simple Arrhenius plot. The shape of the curve is in good agreement with the theoretical treatment of Cadoret (3) which explains the nonlinear decrease by an increase of the surface coverage with As-Ga-Cl molecules.

Figure 1 also shows the growth rate variation observed on a (110) plane which is discussed below.

Influence of the source temperature (and supersaturation).—With a given deposition temperature, the supersaturation is mainly determined by the source temperature.

The degree of excess related to the supersaturation by the equation $\beta = \gamma + 1$ can be defined (18) as

$$\beta = \frac{K_{TS} \times d^{1/4}}{K_{TD}} \qquad [1]$$

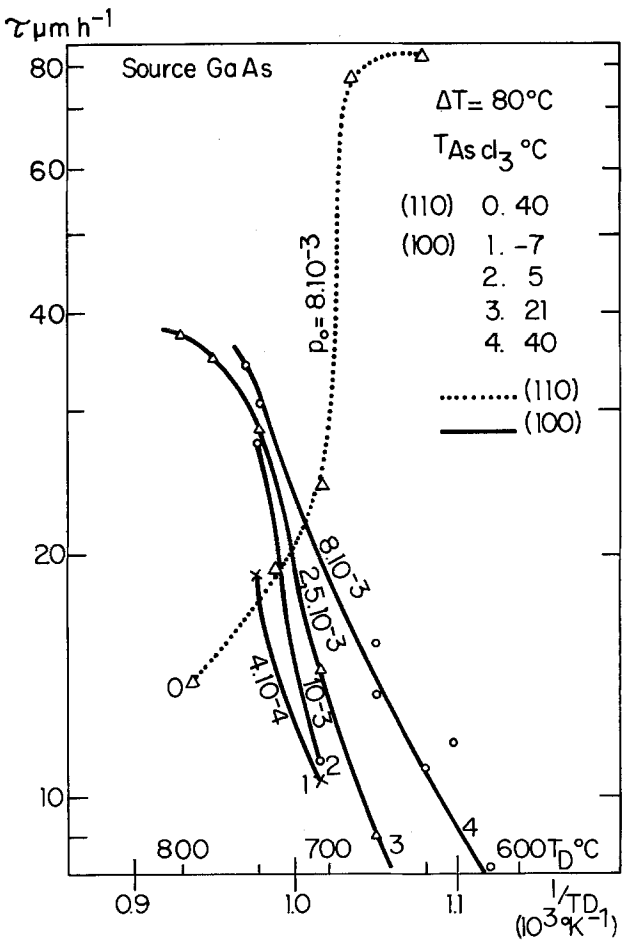

Fig. 1. Effect of substrate temperature on GaAs epitaxial deposition rates for various $AsCl_3$ molecular fraction and for two crystallographic orientations of the substrate.

where d is a dilution factor ($d = 1$ without dilution and $d < 1$ with a hydrogen bypass flow) and K_T are the equilibrium constants corresponding to

$$GaCl + \tfrac{1}{2}H_2 + \tfrac{1}{4}As_4 \rightleftarrows GaAs + HCl$$

at the source and deposition temperatures, respectively. It has been shown experimentally (5) that to a first approximation, and for $T_D > 700°C$, K_T can be represented by Fergusson's thermodynamical data (19)

$$K_T = e^{-\frac{G}{RT}}$$

$$G° \text{ (cal/mole)} = 32170 - 37.2T + 1.07 \ln T + 1.6 \times 10^{-3}T^2 \qquad [2]$$

Experimentally we have measured the growth rate for a given deposition temperature and with increasing source temperatures. These results are first represented in the growth rate *vs.* ΔT diagram (Fig. 2a) in which

$$\Delta T = T_S - T_D \qquad [3]$$

From a theoretical point of view, one of the most interesting parameters is the supersaturation, which can be easily evaluated for each T_D and ΔT using expressions [1], [2], and [3]. Figure 2b gives the representation of the growth rate *vs.* degree of excess.

According to the theoretical treatment of Cadoret (3) the growth rate is given by the relation

$$\tau_{\mu/k} = 1.005 \times 10^{10}\, T_D^{-1/2} \left(\exp -\frac{1.656 \times 10^4}{RT_D} \right) (1 - \theta_{As} - \theta_{AsGaCl}) \cdot p_{HCl} \cdot \gamma \qquad [4]$$

θ_{As} and θ_{AsGaCl} are, respectively, the surface coverages with arsenic atoms and arsenic gallium monochloride molecules, $(1 - \theta_{As} - \theta_{AsGaCl})$ is the surface coverage with the vacant half crystal sites for the arsenic

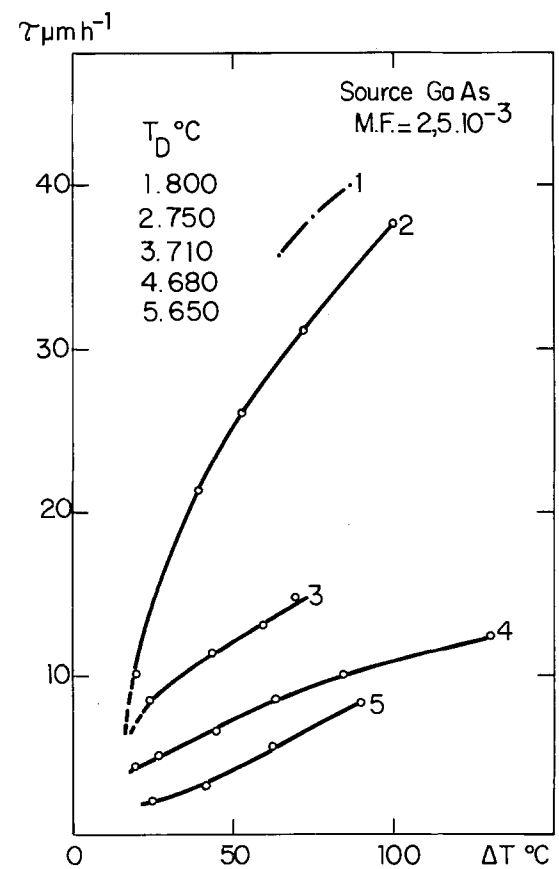

Fig. 2a. Gallium arsenide deposition rates as a function of ΔT ($\Delta T = T_S - T_D$, with T_S = source temperature and T_D = deposition temperature) at several T_D.

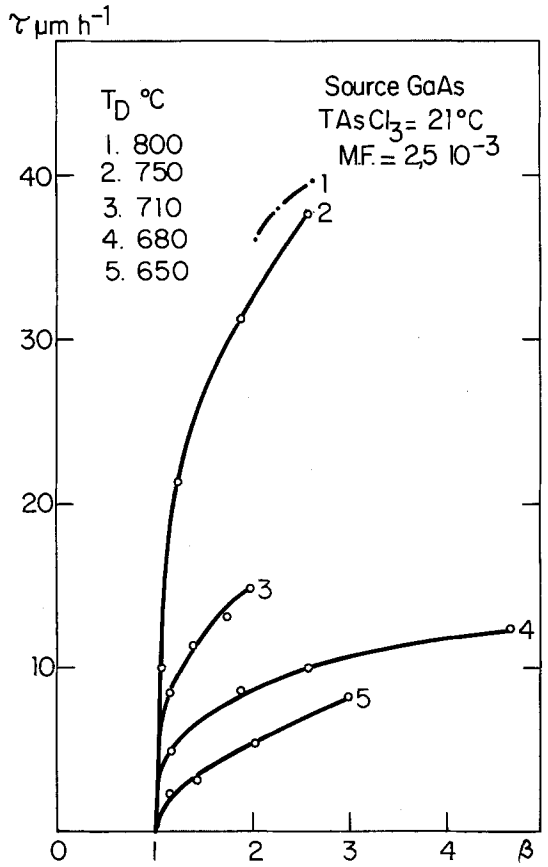

Fig. 2b. Gallium arsenide deposition rates as a function of the degree of excess β related to the supersaturation γ ($\beta = \gamma + 1$) at several T_D.

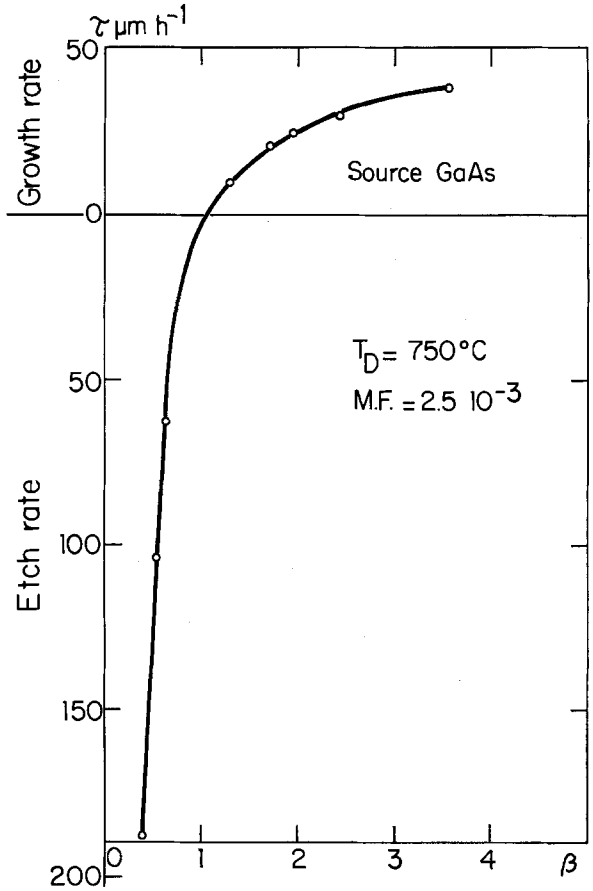

Fig. 3. Effect of the degree of excess β related to the supersaturation on GaAs epitaxial growth or etch rates at $T_D = 750°C$.

deposition, p_{HCl} is the hydrogen chloride partial pressure.

The expression of $(1 - \theta_{As} - \theta_{AsGaCl})$ may be calculated by applying the absolute rate theory to the equilibrium between surfaces and vapor molecules. It increases with the reciprocal partial pressure of gallium monochloride and the substrate temperature

$$(1 - \theta_{As} - \theta_{AsGaCl}) = f(T_D, 1/p_{GaCl}) \qquad [5]$$

Experimentally, an increase of ΔT involves: (*i*) an increase of p_{GaCl} and consequently, according to [5], a decrease of the surface coverage vacant half crystal sites $(1 - \theta_{As} - \theta_{AsGaCl})$, (*ii*) a decrease of p_{HCl}, and (*iii*) an increase of γ [1]. In expression [4] these three variations are in opposition. Since the experimental growth rate increases, the variation of γ appears in this case (increasing ΔT) to be predominant. At the same time, the partial derivative $\partial T/\partial\gamma$ must decrease, which is clearly apparent on Fig. 2a and b.

In order to test the continual increase of $\partial\tau/\partial\gamma$ with decreasing values of the relative supersaturation, we have realized some experiments with negative values of this parameter. The observed etch rates (Fig. 3) give evidence of this behavior which leads to a nonsymmetric but continuous behavior of the etching and growth processes.

Influence of the partial pressures.—In the As-Ga-Cl adsorption controlled growth mechanism, the partial pressures of the chemical species, in equilibrium with the vapor phase, take an important part. It can be shown easily that all these partial pressures are proportional to the input $AsCl_3$ partial pressure. Furthermore, it can also be shown (19) that by varying the $AsCl_3$ molar fraction MF, the supersaturation remains constant.

Consequently, MF appears as a basic parameter in the growth system. The numerical values of MF are deduced from the experimentally determined saturation temperature using the relation $\log p_{o(mm\,Hg)} = 8.7 - (2300/T)$ from Ref. (5) and taking into account a dilution factor d due to the addition of a separate hydrogen carrier flow [see experimental setup in Ref. (20)]. Then $MF = p_o \times d$. In our experiments, $d = 0.4$ with Ga and 0.3 with GaAs source.

Figure 4a and b represent the growth rate variation *vs.* MF at different deposition temperatures, and with two different ΔT values (50° and 80°C). Figure 5 shows the influence of ΔT for a given growth temperature ($T_D = 750°C$). Figures 4a and b clearly show that for deposition temperatures higher than 710°C the growth rate first increases with the $AsCl_3$ molecular fraction and remains constant or slightly decreases in a similar way to that in Ref. (3). This behavior can be explained by Eq. [4].

Nevertheless, the results observed for $T_D > 710°C$ are not always in good agreement with the theoretical anticipations. Such a behavior could be explained either by an adsorption of GaCl molecules in a second layer before filling up the first one, or by a desorption process of two neighboring chlorine atoms by a GaCl molecule according to

$$GaCl + 2(As\text{-}Ga\text{-}Cl) \rightleftarrows 2AsGa + GaCl_3 \qquad [6]$$

Experiments carried out with very high MF values reveal (Fig. 5) a new and unexpected phenomenon: over a critical MF value, the growth rate increases sharply reaching values as high as 50-100 µm/hr. This phenomenon appears more sharply with a Ga source than a GaAs one. In fact, the experimentation at such high MF values becomes difficult: low ΔT values (for instance $\Delta T = 50°C$) must be used to avoid excessive parasitic depositions on the reactor walls. If parasitic depositions occur, obviously the whole phenomenon of growth rate increase is masked. In the case of Fig. 6 a small amount of parasitic nucleation appeared for $MF > 2\text{-}3\ 10^{-2}$. It is therefore possible that in the

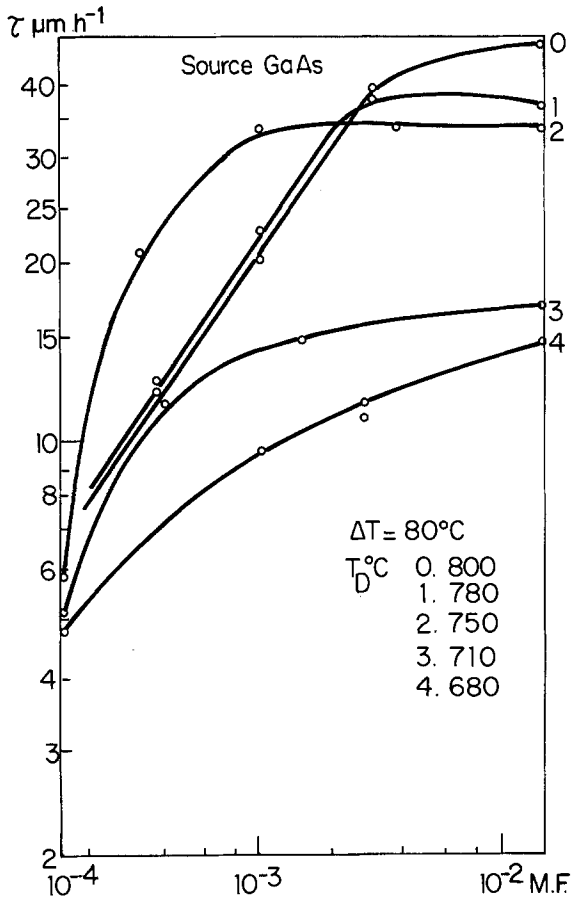

Fig. 4a. Gallium arsenide deposition rates as a function of the $AsCl_3$ molecular fraction at $\Delta T = 80°C$ and for several T_D.

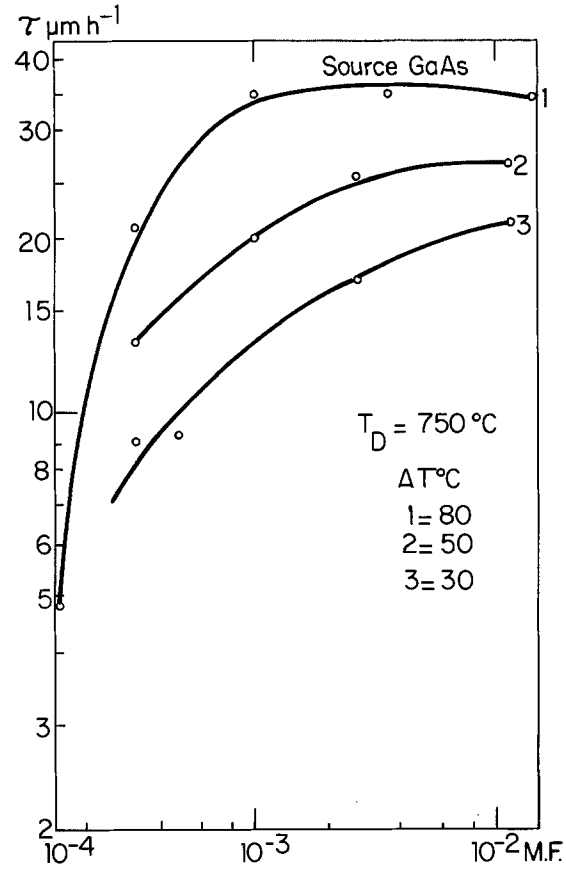

Fig. 5. Gallium arsenide deposition rates as a function of the $AsCl_3$ molecular fraction at $T_D = 750°C$ and for several ΔT.

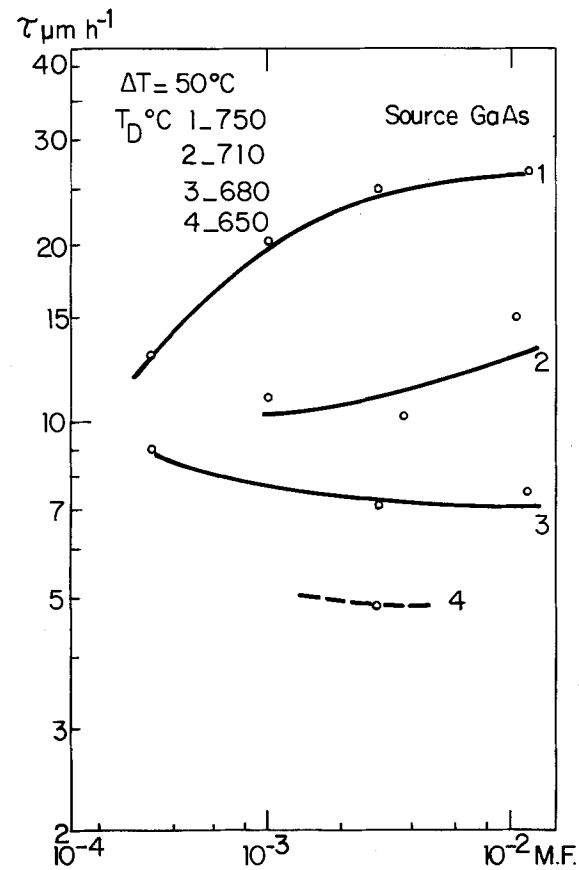

Fig. 4b. Gallium arsenide deposition rates as a function of the $AsCl_3$ molecular fraction at $\Delta T = 50°C$ and for several T_D.

absence of any parasitic deposition, the sharp increase in growth rate would continue (Fig. 6, MF = 10^{-2}).

The two layer model presented by Mutaftschiev (21) and Mutaftschiev and Bonnissen (22) suggests, assuming a two layer GaCl adsorption, that the sharp increase observed might be due to a change in GaCl surface structure, similar to the change in surface roughness of a singular face.

From a practical point of view, this phenomenon could be interesting because of the high growth rate which is accompanied by a low residual dope and high mobility (*e.g.*, with $p_o = 1.8\ 10^{-2}$ atm, $T = 50°C$, $\tau = 55\ \mu m/hr$, $n_{77°K} = 7.7\ 10^{13}$, $\mu_{77°K} = 178{,}000$).

It is pointed out that once more there is an argument in favor of Di Lorenzo's assumption of the p_{HCl} control of the residual doping (6) because in the present case, for a very different growth rate and presumably also quite different growth mechanism, the residual doping is still that given by the extrapolation of the $\log n = f(p_o)$ curve (9).

Growth on the (110) plane.—The (110) faces are characterized by a surface ending through a plane of Ga and As atoms. It is a stepped face and so it may be considered as a face with a great number of half crystal sites like (100). The interaction energy between the As-Ga-Cl molecules adsorbed on such a face having an important effect on the theoretical growth rate, it was particularly interesting to compare the measurements performed on (110) and (100).

In order to obtain reliable experiments in epitaxial growth on a single crystallographic plane, it is necessary to know the influence of the misorientation on the growth rate, the facet growth effects, and also to choose a misorientation (direction and angle) allowing a surface free of macroscopic defects. Analogically to Ref. (23), a study of the growth on (110) centered lens form substrates has been undertaken (24). Thus, for the present experiments, we have chosen a misorienta-

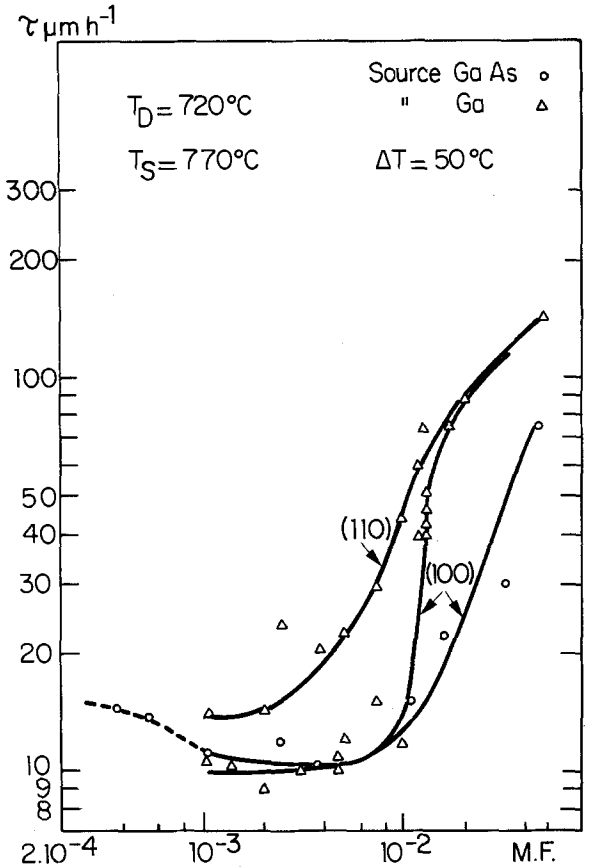

Fig. 6. Effect of the $AsCl_3$ molecular fraction on GaAs epitaxial deposition rates at T_D = 720°C and ΔT = 50°C for two crystallographic orientations of the substrate.

tion of 2° in the 110 direction, which gives perfectly shiny growth surfaces.

In comparison with the usual (100) plane, the (110) presents two anomalous behaviors: The first is the increase of the growth rate with decreasing growth temperature at nearly constant supersaturation values (Fig. 1). In this respect, the (110) plane behaves in a different way than most of the other low index planes: (100), (115), (113)A and B, (112)A and B, (111)A (12, 10) (as far as these experiments realized at increasing supersaturation can be compared). The second is the constant increase of the growth rate with MF in the interval $10^{-3} < MF < 10^{-2}$ (Fig. 6).

The practical consequences of these two effects is that at usual deposition temperature (750°C) and MF (10^{-3} atm), the (110) growth rate value is poor ($\tau \sim 10$ μm/hr), but at low deposition temperature (<720°C) and high MF values, it can be very high. A theoretical explanation may be found in a higher interaction energy between the As-Ga-Cl molecules adsorbed on the (110) surface compared with the (100) one.

Conclusions

As it has been shown throughout this study, the shapes of the growth rate *vs.* growth parameters curves are in good qualitative agreement with a previously described growth model (3) based on a surface adsorption layer of As-Ga-Cl. For instance, the decrease of the $\tau = f(1/T)$ curves appears much more complex than a simple Arrhenius plot. It also appears that at lower temperatures, or on another crystallographic plane, or at very high MF, other desorption processes than this considered in the original paper (3) (*e.g.*, those giving $GaCl_3$ at lower temperature) or other lateral interactions energies [*e.g.*, on (110)] or even double adsorption layers (very high MF) must be considered.

Also, from a practical point of view, some important observations must be emphasized:

With the help of the reported data, the influence of all the main parameters (T_D, ΔT, $AsCl_3$ MF) on the growth rate can be evaluated semiquantitatively by interpolation or extrapolation.

It is possible to grow good surface quality layers at temperatures as low as 600°-650°C (Fig. 1).

It is also possible to use very low partial pressures, for instance values 20 times lower than those usually employed and yet the growth rate remains nearly the same.

At very high MF it is possible to obtain pure material (in the $n = 10^{13}$ at. cm^{-3} range) and this with unusually high growth rates (50-100 μm/hr).

Chemical Vapor Deposition and Isotope Separation

P. J. Severin

Philips Research Laboratories, Eindhoven, The Netherlands

and H. Lydtin

Philips Forschungslaboratorium Aachen, Aachen, Germany

ABSTRACT

Because chemical vapor deposition (CVD) is based on diffusion, isotope separation should take place if the process is in the diffusion-limited range. The enrichment in a horizontal reactor as used for silicon epitaxy is calculated including thermal diffusion effects. It is found that whereas the deposition rate decreases exponentially along the reactor with characteristic length Λ, the isotope enrichment decreases linearly over the length from maximum to zero at $x = \Lambda$. The maximum value depends in a complex way on the masses and concentrations of the gas to be separated and the second gas, present as a reaction component or carrier gas. The requirements for efficient CVD isotope enrichment, which include fast mixing, a high deposition rate, and high enrichment ratio can be satisfied better by a liquid-source CVD system. An experimental arrangement is described and discussed in terms of heat transfer by film boiling. The absence of an unstable range in the plot of the heat flux against the temperature is ascribed to the effects of the decomposition process which dominates the evaporation. The importance of the increased rate of heat transfer due to the reversible accumulation of energy in chemical reaction products is stressed. The effect of an applied electric field is mentioned. Experiments with carbon deposition from $C_{12}H_{26}$ have shown a $^{12}C/^{13}C$ enrichment ratio up to 0.8%, whereas $\Delta M/2M = 0.3\%$. This effect is attributable to mass and thermal diffusion, selective evaporation, spray fractionation by drops acting as micro-ultracentrifuges, and geometry effects. The possibility of achieving uranium isotope separation with a CVD process has been considered theoretically. Thermodynamically possible reactions are specified by which liquid UF_6 is transformed into solid UF_3, UF_4, and UF_5. In this way uranium should be transported quickly from one condensed phase to another with an increasing lighter isotope concentration in the deposited reaction product. The reactor products can easily be retransformed into UF_6 so that the enrichment cycle can be repeated until the desired isotope ratio is achieved. In principle CVD can also be used as a collector mechanism with laser-induced isotope enrichment.

It is hard to find a field of research more rewarding in terms of direct concern to society than the search for more efficient methods for the generation of electrical energy. Because a fairly large amount of energy must be invested in the nuclear fuel produced by the usual uranium enrichment process, newly formulated proposals are eagerly pursued. The suggested rotating plasma method, the high power laser enrichment method, and the aerodynamic stationary-wall centrifuge technique may become of great importance if the promises of the early research work are realized. The feasibility of each of these methods should in practice be considered not only in terms of the return on the capital invested, but also on the basis of the energy account. A detailed review of proposals and prospects of a number of techniques for isotope separation, particularly of uranium, has been presented recently (1).

Conventional methods of isotope separation are based on gaseous, mass, or thermal diffusion, the method of gaseous diffusion being foremost in the uranium enrichment industry. Because chemical vapor deposition (CVD), as used for the epitaxial growth of silicon, is based on mass and thermal diffusion the deposited product should provide evidence of isotope separation as compared to the starting material. This separation process could even be quite effective, for by the very nature of the CVD process the thermal and partial pressure gradients are high and give rise to a high steady-state mass flow. Upon closer elaboration of this idea it became clear that a number of restricting conditions would have to be imposed to make the CVD process suitable for the purpose of isotope separation. It turned out that a new CVD method (2), though operating under different conditions, satisfied most requirements quite well.

Key words: carbon, chemical vapor deposition, enrichment, film boiling, heat transfer, isotope separation, liquid-source epitaxy, silicon, surface energy.

The purpose of this paper is to draw attention to CVD as a potentially useful method of isotope separation. Therefore, in the next section the principles and constraints of isotope separation by chemical vapor deposition are outlined and some formulas deduced from a simplified model. Thereafter a liquid-source CVD reactor and experimental results and conclusions are discussed. In the last section consideration is given to possible technical applications of this method, especially in the field of uranium isotope enrichment.

Isotope Separation with the CVD Method

Principles of CVD reactor operation.—A number of years ago the epitaxial growth of silicon from SiH_4 diluted in hydrogen in a horizontal water-cooled reactor became the object of a more detailed study. Eversteyn *et al.* (3) concluded from experiments with TiO_2 smoke that the gas flowing over a heated susceptor gave rise to a stagnant layer, whereas the gas in the remaining height of the tube above the susceptor was highly turbulent and thus destroyed all semblance of a temperature gradient. Hence the temperature should drop entirely across the stagnant layer. It was assumed then that the turbulent gas acted as a source of uniform concentration of SiH_4, which diffused across the stagnant layer to be reduced by pyrolysis on the substrate.

A quantitative model was developed which described the flux of SiH_4 by diffusion from the concentration of the flowing source gas to zero concentration at the substrate. The ideal gas law was assumed to be valid in

the stagnant layer with a linear temperature drop. The thickness of the stagnant layer as a function of the gas velocity was determined experimentally and approximated analytically in the theory. The growth rate as a function of the position along the susceptor, as predicted by the theory, was experimentally verified. The angle of tilt of the susceptor needed to minimize the effect of depletion of SiH_4 in the source gas along the reactor was calculated and experimentally confirmed.

It is important to stress that the discussion in this paper is restricted to the CVD process in the diffusion-limited range. With decreasing susceptor temperature the chemical reaction kinetics increasingly control the deposition process. Van den Brekel (4) recently discussed the Nusselt number for mass transfer as the characteristic parameter separating the two regimes in $SiHCl_3$. Mehalso and Diefendorf (5) described in a similar way a system in which the reduction of BCl_3 was limited by HCl desorption.

In the plane geometry shown in Fig. 1 the molecular flux J_y across the stagnant layer follows from the equation of diffusion for a mixture of two gases of widely different concentrations

$$J_y = -\frac{D}{kT}\left(\frac{\partial p}{\partial y} + \alpha\frac{p}{T}\frac{\partial T}{\partial y}\right) \qquad [1]$$

Here the temperature T drops linearly across the stagnant layer of thickness δ from the high value T_s at the susceptor, $y = b$, to the low value T_m at the boundary of the stagnant layer, $y = b - \delta$, according to

$$T(y) = T_s - (T_s - T_m)\frac{b - y}{\delta} \qquad [2]$$

Experimentally the diffusion coefficient has been found to depend on temperature as T^ϵ, where $1.5 \leq \epsilon \leq 2$ corresponds theoretically to various models ranging from elastic spheres to Maxwellian molecules. For mathematical convenience the diffusion coefficient D is here assumed to depend on the temperature as

$$D = D_0\frac{T^2}{T_0^2} \qquad [3]$$

where D_0 is the diffusion coefficient at $T_0 = 300°K$. For the highly diluted SiH_4 the equation of state

$$p = n\,k\,T \qquad [4]$$

would be valid. The thermal diffusion factor α is discussed later. Equation [1] is slightly at variance with the expression used by Eversteyn *et al.* (3), who neglected the thermal gradient. The expression was used correctly by Bloem (6) for a similar problem.

The partial pressure, p, of the diffusing species not only depends on y, as described in Eq. [1], but also varies with the position x along the reactor. Therefore the equation of continuity should be satisfied anywhere in the turbulent layer

$$\frac{\partial J_x}{\partial x} + \frac{\partial J_y(x,y)}{\partial y} = 0 \qquad [5]$$

The above equations can be combined to yield the deposition rate $J_y(x)$, which decreases with x because of depletion due to the deposition reaction

$$J_y(x) = \frac{pD_0T^*}{kT_0^2\delta}\exp -\frac{D_0T^*x}{V_0T_0b\delta} \qquad [6]$$

where p and V_0 are the pressure and velocity of the SiH_4 at the entrance of the reactor and T^* is given by

$$T^* = \frac{\alpha(T_s - T_m)T_m^\alpha}{T_s^\alpha - T_m^\alpha}$$

It can easily be verified that with $\alpha = 1$ the pre-exponential and the exponential factors are smaller by a factor 2 than those found by Eversteyn *et al.* (3), who admitted that the value of D_0 was chosen smaller than suggested elsewhere (7). Effectively, they thus compensated for the neglected thermal gradient.

In principle the velocity, the thermal and the mass boundary layers which all result from horizontal flow in a free convective system as used in CVD, should be effectively describable by dimensionless numbers. This has not yet been done and is beyond the scope of this paper; the above equations will be used only to illustrate the essential requirements to be satisfied in isotope separation and to stress the difference from CVD-reactor optimization for deposition only.

Isotope separation due to diffusion and thermal diffusion.—In the absence of thermal diffusion, the relation of the molecular flux, J, to the partial pressure, p, of the diffusing species can be obtained by integration of Eq. [1], subject to Eq. [2], [3], and [4]

$$J = \frac{pD_0}{kT_0^2\delta}(T_s - T_m)\left(\ln\frac{T_s}{T_m}\right)^{-1} \qquad [6a]$$

In a binary mixture the diffusion coefficient D_{10} depends on the molecular masses M_1 and M_0 of the two components and on the cross-section S as (8)

$$D_{10} \sim \frac{1}{S}\left(\frac{M_0 + M_1}{M_0M_1}\right)^{1/2} \qquad [7]$$

The dependence of D_{10} on M_1 suggested by Shepherd (7) cannot be as $1/\sqrt{M_1}$, but should be due to S which increases with M_1. In agreement with experiments, D_{10} depends on the concentration ratio only to a second approximation in which also the effects of the nature of the intermolecular forces are included. In a mixture of two isotopes of molecular masses M_1 and M_2, diluted in a gas of molecular weight M_0, the two fluxes can be considered independent and therefore the flux of the lighter isotope J_1 exceeds the flux of the heavier isotope J_2 by a factor

$$\frac{J_1}{J_2} = \frac{D_{10}}{D_{20}}\frac{p_1}{p_2} \qquad [8]$$

Writing $\Delta M = M_2 - M_1$ and assuming $\Delta M << M$, where M is M_1 or M_2, the deposited material is enriched over the starting ratio p_1/p_2 by the separation factor γ_D

$$\gamma_D = \frac{D_{10}}{D_{20}} = \left(1 + \frac{\Delta M}{2M}\right)\left(1 - \frac{\Delta M}{2(M + M_0)}\right) \qquad [9]$$

In the determination of the dependence of γ_D on M_0/M, with $\Delta M/M$ as a parameter, it turned out that $\gamma_D^2 - 1$ depended almost linearly on $\Delta M/M$ over the relevant range between 0.1 and 0.01. Thus $(\gamma_D^2 - 1)/(\Delta M/M)$ has been plotted against M_0/M in Fig. 2.

It is evident from Eq. [6a] that always the lighter component is enriched, the effect varying from $\Delta M/2M$ for $M_0 >> M$ down to a very small value for $M_0 << M$. For example, SiH_4 diluted in H_2 with $M_0 = 2$, $M_1 = 32$, $M_2 = 33$, $M_3 = 34$, yields $\gamma_{12} = 1.00089$ and $\gamma_{13} = 1.0017$, whereas SiH_4 diluted in Ar with $M_0 = 40$ yields similarly $\gamma_{12} = 1.0086$ and $\gamma_{13} = 1.0167$. Mass diffusion of a lighter gas in a heavier gas has been described by

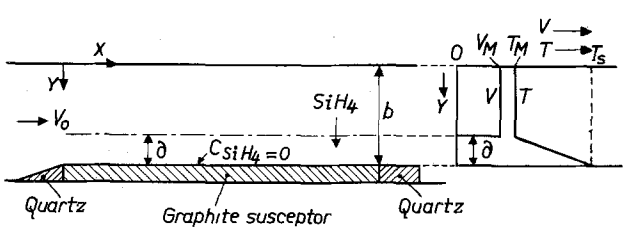

Fig. 1. Stagnant layer of thickness δ and convective layer of thickness b — δ above the horizontal susceptor. The velocity and temperature profiles are shown on the right-hand side.

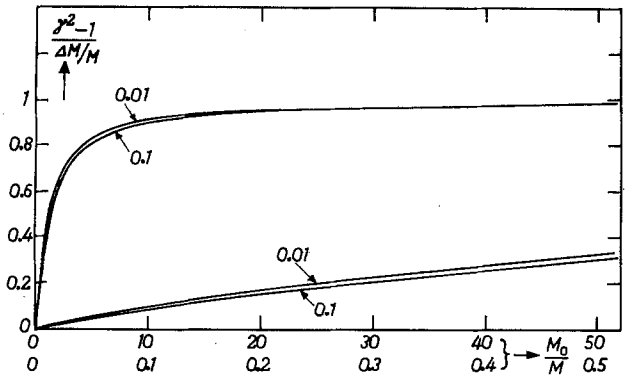

Fig. 2. The dependence of $(\gamma^2 - 1)$ normalized by $\Delta M/M$ as a function of M_0/M for two values of $\Delta M/M$, the lower expanded horizontal scale corresponding to the lower set of curves. Here, γ is γ_D defined in Eq. [2].

Benedict and Boas (9). Technically it is difficult to maintain a pressure difference across the diffusion screen, and though γ_D may be high under the more favorable circumstances of separation of isotopes of a lighter gas diluted in a heavy gas, the amount of separated material deposited decreases as the diffusion coefficient D_{10}, according to Eq. [7].

If thermal diffusion is not neglected, a similar reasoning can be followed with utilization of the result of integration of the full Eq. [1]

$$J = \frac{pD_0}{kT_0^2\delta} T^* \qquad [6b]$$

where T^* is defined in connection with Eq. [6].

The thermal diffusion factor α_{10} of a gas of molecular weight M_1 in a gas of molecular weight M_0 depends in a complex manner on the ratio of the concentrations, masses, and diameters of the molecules and the nature of their interaction (8). Assuming that the molecules are rigid elastic spheres it can be derived that for a diluted gas to a first order of approximation

$$\alpha_{10} = a\left(\frac{M_1}{M_0 + M_1}\right)^{1/2} \qquad [10]$$

where a is a factor of order unity.

Now the ratio of the two fluxes J_1 and J_2 is modified by the combined effects of mass and thermal diffusion to

$$\frac{J_1}{J_2} = \frac{p_1}{p_2} \frac{T^*(\alpha_{10})}{T^*(\alpha_{20})} \gamma_D \qquad [11]$$

Writing $\Delta\alpha = \alpha_{20} + \alpha_{10}$, and assuming $\Delta\alpha << \alpha$, where α is α_{10} or α_{20}, the solid deposited material is enriched over the starting ratio p_1/p_2 in the gas by the separation factor

$$\gamma = \gamma_D \cdot \gamma_T \qquad [12]$$

where γ_T, due to thermal diffusion, can be approximated by

$$\gamma_T = 1 - \Delta\alpha\left[\frac{1}{\alpha} + \frac{1}{1 - \left(\frac{T_m}{T_s}\right)^{\alpha}} \ln\frac{T_m}{T_s}\right] = 1 - c\Delta\alpha \qquad [12a]$$

The difference $\Delta\alpha$ of the thermal diffusion factors can be calculated from Eq. [9] and [10] to be positive and approximately equal to

$$\Delta\alpha = a\left(\frac{M_1}{M_0 + M_1}\right)^{1/2}\left(\frac{D_{10}}{D_{20}} - 1\right) \qquad [12b]$$

so that the deposited material is enriched by the separation factor

$$\gamma = \gamma_D\left[1 - ac\left(\frac{M_1}{M_0 + M_1}\right)^{1/2}(\gamma_D - 1)\right] \qquad [12c]$$

It turns out that, for the usual values of T_m/T_s between 0.3 and 0.5 and of α between 0.1 and 2, the value of c is negative and smaller than unity.

This result is as to be expected on physical grounds: both diffusion and thermal diffusion preferentially transport the lighter isotope to the heated susceptor. The effects of diffusion and thermal diffusion on the growth rate are of about equal importance, and the isotope separation factor turns out to be about equally due to both effects.

The final result Eq. [6] describes the combined effects of diffusion and of thermal diffusion in the reactor. This can be expressed formally, thus defining A and B by

$$J_y = \frac{pDT^*}{A} \exp - \frac{DT^*x}{B} \qquad [6c]$$

With the approximations used, the factor γ can be written as $1 + \Delta\gamma$ with $\Delta\gamma << 1$; hence the relative difference $\Delta J/J$ of the two normalized deposition rates J_1/p_1 and J_2/p_2 can be written as

$$\frac{\Delta J}{J} = \frac{J_1p_2}{J_2p_1} - 1 = \left[\gamma \exp - \frac{DT^*}{B} x\,\Delta\gamma\right] - 1 \qquad [13]$$

Because the exponent is much smaller than unity, this expression can be approximated as

$$\frac{\Delta J}{J} = \Delta\gamma\left(1 - \frac{DT^*}{B} x\right) \qquad [13a]$$

For small values of x the isotope concentration ratio in the deposited material, J_1/J_2, shows the maximum degree of enrichment attainable over the starting ratio p_1/p_2.

Whereas the total deposition rate, $J_1 + J_2$, drops exponentially with decay constant $\Lambda = B/T^*D$ due to depletion, the relative difference $\Delta J/J$ drops linearly, changing sign at a distance Λ. In the actual situation of many deposition processes, *e.g.*, in the case of silicon epitaxy, the characteristic length over which the source gas flux is depleted, is about 0.5m and cannot be varied strongly. Hence with a reactor length of about 1m the enrichment process not only decreases but actually changes sign as the depletion increases, slightly more for the lighter than for the heavier isotope. Only close to the entrance of the reactor is the enrichment process fully operative, over-all the separation process is fully nullified by compensation in the second stage.

The requirements for an ideal CVD reactor for isotope separation.—The strong dependence on position due to depletion substantiates the intuitive feeling that it is at least an order of magnitude easier to maintain a constant flux $J_1 + J_2$ than to maintain a constant isotope ratio J_1/J_2.

In the same way that the isotope separation process is more sensitive to depletion than the deposition process, so any deviation from complete mixing is more harmful to the isotope separation process. Incomplete mixing implies that for the material deposited at position x_0 an extra memory effect exists which originates in the material deposited at positions $x < x_0$. As shown in Eq. [6c] and [13a], this spoils the isotope separation process more than the deposition process. It can also be considered as an effectively smaller value of b, and hence of Λ, with a similar effect.

It is evident from the experimental results on silicon deposition (3) that the mixing due to turbulence is satisfactory to maintain the condition of uniform source gas concentration. If the condition of complete mixing did not hold, so that the lower strata did indeed show a higher depletion of SiH_4 than calculated, this would be manifested by a decrease of the deposition rate and a more pronounced effect of depletion toward the end of the tube. Diffusion of SiH_4 in such a weakly turbulent top layer toward the boundary of the stagnant layer would decrease this effect. The growth rate is

usually chosen to be about 0.6 μm/min, which means about 3 mm of gas is depleted per minute at the interface. The characteristic time for diffusion $\tau \approx b^2/D_0$ is so large that at the usual flow rates the gas has already been replaced several times over the reactor length in such a period. It has been calculated earlier that the mixing time is of the order of about 0.1 sec and probably less. Apparently this is fast enough to maintain the negligible temperature and concentration gradients actually observed. This does not imply that mixing is also intense enough to satisfy the isotope separation requirements.

Let us assume now that complete mixing takes place on a small enough time scale. The main conclusion from the preceding discussion is that the process in which the characteristic length for deposition is slightly shorter than the reactor length, is not ideal for isotope separation. The purpose of the normal CVD process is effective depletion of the source gas with a high growth rate, but the deposited product in isotope separation should comply as nearly as possible with the optimum combination of separation factor and growth rate. The silicon deposition rate can be made almost uniform along the reactor by tilting the susceptor (3). Physically the effect is due to an increase in the gas velocity and a decrease in the boundary layer thickness with increasing x, or a decrease of A and B in Eq. [6c] with increasing x. In the usual range for silicon epitaxy, A turns out to be dominant because $\Lambda \sim B$ is about 0.5m, *i.e.*, about the reactor length. In Eq. [13] the factor A drops out and, due only to B, the effect of tilting on isotope separation is negative. A positive effect could be reached by tilting the susceptor the other way, so that the free space above the susceptor would increase. Although then it would be easier to keep the isotope ratio constant, this effect is counteracted by a decreased over-all deposition rate and efficiency. The effects of tilting are shown schematically in Fig. 3.

In an ideal CVD reactor for isotope enrichment the following properties should be aimed at: (*i*) the mixing time should be short enough to enable the source gas to present a uniform concentration, (*ii*) the growth rate should be small with respect to the amount of source gas available per unit length and presented per unit time, and (*iii*) both the growth rate J and the separation factor γ should be maximized, so that separative power per unit surface area $J(\gamma - 1)^2$ will be maximum.

To sum up this section the proposed CVD system for isotope separation is contrasted to the conventional systems used for isotope separation based on gaseous, mass, or thermal diffusion. The method used for $^{235}UF_6/^{238}UF_6$ isotope separation is based on gaseous diffusion of UF_6 through a thin porous membrane under rarefied gas conditions, corresponding to $M_0 \to \infty$, with $D_{10} \sim 1/\sqrt{M_1}$. With the proposed CVD system the concentration drops over a very small length determined by the thermal boundary layer from a value corresponding to room temperature and about 1 atm to a negligible value, because gaseous material is converted to solid material. The enormous energy losses involved in the diffusion process, due to repeated compression and rarefaction of the gas, should be compared with the nonrecoverable part of the energy accumulated in the reaction products. Mass diffusion has not been widely applied because for the separation factor γ_D to be high, the molecular weight M_1 of the gas to be separated should be low, and the molecular weight of the separating agent M_0 should be high, whereas the concentration gradient and the flux are basically limited by the properties of the diffusing screen. Thermal diffusion has initially been widely used and is still in use for special purposes. Because it is based on the steady-state equilibrium between thermal and concentration gradients, in which only α_{12} is involved, it is an essentially slow process. In the proposed CVD method mass and thermal diffusion cooperate to transport a steady flux of material, slightly more of the lighter than of the heavier component, over very steep concentration and thermal gradients. This should compensate the effects of the modest separation factor which is small due to the properties of mass diffusion mentioned and because for the thermal effect only the difference of the thermal diffusion factors is involved. The separation factor can be enhanced by a higher concentration of the gas to be separated in a gas of higher molecular mass. This system should be analyzed using three dependent equations of diffusion coupling the three species instead of the two independent equations of the type of Eq. [1] used for the two isotopes. Also a more complex expression for α should be used, eventually dependent on y because the concentration ratio depends on y.

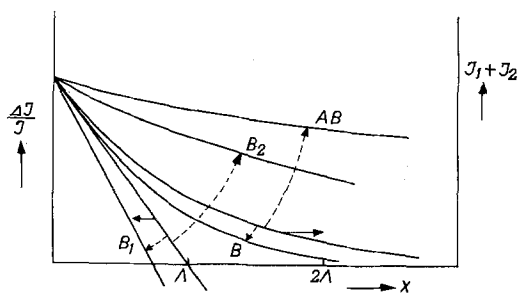

Fig. 3. The x dependence of the total rate of deposition $J_1 + J_2$, on the right-hand side, and of the relative difference $\Delta J/J$, on the left-hand side both schematically indicated. The effects of tilting upward due to the dependence $B(x)$ and due to the dependence of both $A(x)$ and $B(x)$, are shown in the curves labeled B and AB for the total current, and in the curve labeled B_1, for the relative difference, which is unaffected by $A(x)$. In the text it is made clear that downward tilting produces a more uniform relative difference $\Delta J/J$, shown in the curve labeled B_2.

It is shown in the next section that the requirements formulated above for a CVD reactor ideal for isotope separation can be fairly well satisfied if source material from a liquid source is used. Experimental results obtained with silicon in a conventional horizontal reactor have been found and will be reported elsewhere.

Description of the Liquid-Source CVD Process

An experimental reactor for CVD in which both the requirements of intense mixing and small depletion are combined has been described earlier (10), though the requirements for isotope separation were of no relevance then. A tantalum wire was mounted between two arms which also serve as electrical contacts to heat the wire. This assembly as a whole was made to rotate at high speeds (up to 6 m/sec) in an enclosure filled with gas which is pyrolyzed on the heated wire. In this way a carbon layer could be grown from CH_4. Due to the viscosity of the gas it finally rotated as a body with the wire. This undesired effect could be overcome by intense mixing of the gas or by using two arms one above another and rotating in opposite directions.

The experimental work with this arrangement gave rise to the idea (2) of using a liquid instead of a gas as a source material. A similarly heated horizontal wire, 3-5 cm long and 100 μm in diameter, is then surrounded automatically by a cylindrical gas-filled space. This thermal boundary layer plays the role of the stagnant layer in the preceding section. In the theory of heat transfer this phenomenon is known as film boiling (11-14); it is related to the Leidenfrost phenomenon giving rise to the spheroidal state (15).

In general, boiling is considered to be an effective means of heat transfer, the heat flux increasing linearly with the temperature at low temperature. At a critical temperature T_{c1}, however, the nucleate boiling mode changes to the film boiling mode characterized by a much smaller heat transfer coefficient because of the gas film separating the heated solid from the liquid. Between T_{c1} and a higher critical temperature, T_{c2}, the

heat flux density decreases with increasing temperature: the gas film fluctuates and is unstable. Beyond T_{c2} the heat flux increases again with the temperature because the gas film has become continuous and stable.

The dimensions of the layer are determined in a complex way by a number of parameters: a description of heat and mass transport is again beyond the scope of this paper. The pressure in the space is the sum of the partial pressures of evaporated liquid and gaseous reaction products which, of course, in the stationary state is equal to the applied hydrostatic pressure. The gas generated by evaporation at the gas-liquid interface diffuses, as described in the preceding section, to the wire where it is decomposed. The liquid is heated directly by radiation which is emitted by the heated wire and absorbed in a thin layer of liquid and secondly by heat conducted by the gas across the thermal boundary layer. The driving force of the evaporation is the difference between the actual partial pressure of the source gas at the interface and the pressure of the saturated gas at the temperature of the interface. The deposition rate is roughly proportional to the net evaporation rate. Clusters which may be formed in the gaseous layer under some experimental conditions are driven into the liquid by thermal diffusion. As shown in Fig. 4, the liquid is circulated and these particles are filtered out. Noncondensable reaction products leave the gas space as bubbles, of course also transporting part of the source gas. These are separated at the gas-liquid separator.

Film boiling has been the subject of much experimental and theoretical study, because of its crucial importance when the heat flux is the independent variable, as in nuclear reactors (14) and when cooling should be slow at high temperatures, as in actual quenching of metals. In the stationary state the heat flux density at the interface equals the mass of vapor generated per unit time and surface area times the latent heat of evaporation. However, in the film boiling mode as applied to CVD not only the latent heat of evaporation but also the energy of decomposition contribute to the heat transfer rate. Therefore it is much easier to achieve a stable boundary layer with CVD than with conventional film boiling only. In fact in the CVD reactor the unstable region between the two critical temperatures, mentioned above, appears to be absent. Therefore it is reasonable to assume that with increasing temperature the rate of decomposition increases so much that the decrease in heat flux due to the formation of an insulating film by coagulation of an increasing number of gas bubbles is fully compensated. The increased rate of heat transfer due to the accumulation of chemically recoverable energy is an important aspect of liquid-source CVD.

Up to now, carbon, silicon, and silicon carbide have been prepared by the liquid-phase deposition method.

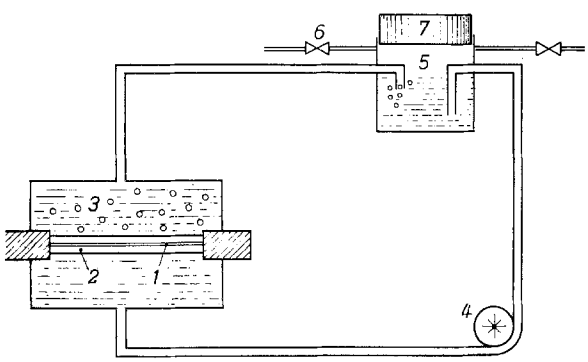

Fig. 4. The liquid-source CVD equipment schematically drawn. The heated wire, 1, is surrounded by a gas-filled cylinder, 2, in the liquid, 3. The liquid is circulated with a pump, 4, the gaseous reaction products and solid reaction products produced in the gas-filled space are separated in the separator, 5. The external pressure of the gas supplied at the inlet, 6, can be controlled with a pressure piston, 7, to influence the reaction rate.

For carbon and silicon carbide deposition, liquid hydrocarbons, such as toluene or dodecane and methylchlorosilanes ($(CH_3)_2SiCl_2$) were used as source materials. For silicon deposition from liquid $SiCl_4$ the reaction mechanism is more complicated, because $SiCl_4$ itself is thermodynamically stable at the temperature of the heated wire and therefore two reaction components, $SiCl_4$ and H_2, should be available at the wire. Gaseous hydrogen was kept under a pressure of as much as 100 atm above the liquid. From the results obtained it is evident that hydrogen transport through the liquid does not limit the growth rate. In all systems deposition rates up to, typically, several millimeters per minute could be obtained, roughly a factor of thousand greater than that of the gas source deposition systems. Increasing the hydrostatic pressure of the system leads in general to an increased deposition rate. With SiC a growth rate of 16 mm/min has been obtained with 100 atm hydrostatic pressure.

In the actual experimental arrangement the growth rate depended on the growth time, because the voltage across the wire was kept constant at about 30V. Hence the current increased due to increasing diameter, and so did the electrical power consumed and the temperature. On the other hand, the temperature tended to decrease because of the increasing area of the radiating surface from about 2900° to 2500°C. Reactions typically last up to 10 sec only. Hitherto no systematic study designed to correlate the various process parameters and physical and chemical properties has been undertaken. Therefore the experiments still show some irreproducibilities in the quantitative results.

In all experiments the energy expenditure turned out to be between 5 and 10 eV per deposited C atom. This energy is partly recoverable when the material is recycled, the total efficiency of the system being of course dependent on the temperatures of decomposition and recomposition. It is interesting to note that because only heating is required, the energy introduced into the system does not need to be electrical. Per carbon atom, the evaporation energy is negligible compared to the decomposition energy.

In sum, the experiments show that CVD from pressurized liquid-source material is a versatile and reliable method to transport rapidly without any loss of material, a certain element from one condensed phase to another. It is also a highly efficient method of transporting heat from a solid, the heat being available partly in the heated vapor, but for the greater part in the high temperature reaction products.

Next, some experimental results of isotope separation with liquid-source CVD and some theoretical considerations are presented.

Some Experimental Results and Their Consequences

Three experiments were set up with the liquid-source equipment described in the preceding section. On a tantalum wire, 100 μm across, carbon was deposited from $C_{12}H_{26}$, known as Shell-Sol T. The layers were grown very fast, at about 1 mm/min, but under not exactly reproducible conditions, as indicated in the preceding section. The three samples as well as the liquid were mass analyzed and the $^{12}C/^{13}C$ ratios were compared.

Because the ratio $^{12}C/^{13}C$ normally amounts to about 98.89/1.11, most of the $C_{12}H_{26}$ molecules will consist of only ^{12}C atoms, 13% will contain only one ^{13}C atom, and the number of those with more ^{13}C atoms can be considered negligible. Therefore, on the assumption that $C_{12}H_{26}$ is the species diffusing in hydrogen, the separation factor γ is a function of the molecular weights $M_0 = 2$, $M_1 = 170$, $M_2 = 171$ and the parameter $\Delta M/2M = 0.003$.

Two samples were deposited in two separate experiments and subsequently mass analyzed by Mook (16). The $^{12}C/^{13}C$ ratios of the starting liquid and of the two samples were determined several times with a reproducibility of $\pm$ 0.05% and the enrichment of ^{12}C in

the deposited material was found to be 0.65% in the first and 0.8% in the second experiment. A third sample deposited in a third experiment and its starting liquid were similarly mass analyzed elsewhere by de Bièvre (17). The enrichment of ^{12}C in the deposited material was found to be $0.33 \pm 0.1\%$.

It is evident that though the experimental conditions prevailing in the thermal boundary layer of the liquid-source equipment are quantitatively different from the experimental conditions in the stagnant layer of a horizontal epitaxial reactor, mainly because of the latent heat of evaporation and the cylindrical geometry, in the transport and deposition processes essentially the same mechanisms are operating.

As it has been remarked before, the description in terms of two independent equations of diffusion and a simple expression for α is not adequate for a system in which the gas cannot be considered as diluted everywhere. A more realistic description could yield a higher separation factor but is beyond the scope of this paper. The experimental results suggest that the proposed isotope separation mechanism may be operative, but also that other mass-dependent processes can be invoked to account for the high separation factor. A number of effects related specifically to this mode of heat transfer are discussed below.

Probably quite important are a number of effects related to evaporation. The evaporation rate below the boiling temperature depends on the mass as $1/\sqrt{M_1}$, and this effect would yield an enrichment of about 0.3%. As stated before, the liquid-to-gas interface across which the evaporation takes place can be far below the boiling temperature. Secondly, the hydrogen released upon pyrolysis leaves the gas-filled space with heavy perturbation of the interface. The processes taking place at a gas-to-liquid interface when gas bubbles are crossing the interface in either direction are spectacular. These phenomena are at present being studied more actively since they are related directly to the environmental effects of the sea (18). A gas bubble on crossing the interface generates a strong deviation from the original surface, which is restored by surface tension. Due to inertial forces the surface generates a jet in which accelerations of up to $10^4 g$ can be reached. Effectively, the bubbles and drops giving rise to accelerated jets may be considered as micro-ultracentrifuges with which fractionation effects can be explained both in seawater and at the heated gas-to-liquid interface. Similar effects are described in Zuber's theory of film boiling (13) where he states that "at high evaporation rates the vapor release appears like small jets." The instability at the gas-to-liquid interface is known as Taylor instability (19), which has been demonstrated experimentally by Lewis (20). The relation to surface tension and viscosity in the development of Taylor instability has been studied by Bellman and Pennington (21).

It is evident that electrical effects must play a role: any excess of lighter ions in conducting liquids should be electrically compensated to reduce the charge of the drop. Drops are known to bear a charge: the splitting off of many fine, negatively charged drops from a big drop of water, which is left positively charged, forms the basis of the theory of the formation of thunderstorms. As demonstrated recently by Kim and Turnbull (22) with drops of freon, also nonconducting liquids can be influenced electrically, surface charge contributing to the conventional surface energy. Not only the formation of drops but also the generation of jets at the gas-to-liquid interface, should be influenced by a d-c field, the basic mechanisms being related (13). A pronounced effect was found indeed in the liquid-source carbon deposition rate when a high d-c field was applied between the heated wire and an electrode outside the CVD reactor, independent of sign of the voltage, as the theory predicts. The authors believe that also the isotope separation factor is affected favorably. From these experiments can be concluded to which extent the isotope enrichment actually found is due to micro-ultracentrifuge effects. It is evident also that with an a-c voltage layers of varying isotope separation can be grown which could have interesting applications. If these effects are studied as a function of frequency the time scales and hence the nature of the processes involved can be analyzed.

Finally the effects of the cylindrical geometry, giving rise to flux crowding near the hot wire, could be of importance.

To sum up, we feel that the enrichment shown in carbon separation may be the result of a number of weighted effects, each of which can give rise to fractionation. The factors discussed are mass diffusion, thermal diffusion, evaporation, spray fractionation, and geometry effects. For a better understanding each of these factors would warrant a more detailed study so that the effect of fractionation in terms of growth rate and separation factor might be optimized.

Possible Applications in the Field of Uranium Isotope Enrichment

In the preceding sections a model for isotope separation with CVD has been elaborated and the equations and ensuing efficiency requirements have been derived. Also some feasible operating arrangements and some experimental results have been discussed. One might, of course, speculate on the possibility of practical application of CVD, perhaps even as an industrial process, to uranium isotope enrichment. Though the well-established technique of diffusion of a rarefied gas through a porous membrane is dominating the scene, with the ultracentrifuge and the gas nozzle techniques as second bests, mass diffusion, thermal diffusion, chemical exchange, distillation, and various other techniques based on physico-chemical transport mechanisms have in the past been studied and used.

The alternative diffusion method based on CVD described in this paper has the advantage of a high partial pressure difference across a short length with a limited source in the gaseous process and a virtually unlimited source in the liquid process, hence a high through-put. Though the process is thought to be based on mass and thermal diffusion, other processes such as evaporation, micro-ultracentrifuge effects, and geometry effects all make integrated contributions by the very nature of the process. The relative importance of these five effects is not known and difficult to assess without much more detailed study.

It is interesting to speculate on the reactions which in this system could be used for uranium enrichment. Uranium hexafluoride is used almost universally because it can be easily volatilized and because fluorine has only one isotope. Therefore it is very well suited to serve as a starting liquid in the CVD process as well.

Thermodynamic calculations, based on data compiled by Barin and Knacke (23), show that UF_6 reacts with hydrogen over a wide temperature range. The reaction products should be solid UF_3, solid or liquid UF_4 (mp 1309°K), solid or liquid UF_5 (mp 621°K), and gaseous HF with the following values of the reaction constant K

$$UF_6 + 3/2\ H_2 \rightarrow \langle UF_3 \rangle_{sol} + 3HF;$$

$$\log K\ (300°\text{-}1000°K) = \frac{8571}{T} + 4.43$$

$$UF_6 + H_2 \rightarrow \langle UF_4 \rangle_{sol} + 2HF;$$

$$\log K\ (300°\text{-}1000°K) = \frac{15644}{T} - 0.146$$

$$UF_6 + \tfrac{1}{2}\ H_2 \rightarrow \langle UF_5 \rangle_{sol} + HF;$$

$$\log K\ (300°\text{-mp°K}) = \frac{10072}{T} - 3.502$$

$$UF_6 + \tfrac{1}{2}\ H_2 \rightarrow \langle UF_5 \rangle_{liq} + HF;$$

$$\log K\ (\text{mp-}900°K) = \frac{7979}{T} - 0.15$$

It is reasonable to assume that these reduction processes are kinetically blocked at low temperatures, as they are in the system WF_6/H_2. The reduction to metallic uranium is thermodynamically impossible in the relevant temperature range

$$UF_6 + 3H_2 \rightarrow \langle U \rangle_{sol} + 6HF;$$

$$\log K\ (300°\text{-}1200°K) = -\frac{26479}{T} - 15.97$$

Deposition of one of the above-mentioned liquid or solid uranium fluorides is thermodynamically possible when a substrate mounted inside liquid UF_6 under a controlled H_2 pressure is heated. If the deposition parameters can be chosen such that the ^{235}U enriched deposited uranium fluoride is in the liquid state, the process can be made to work continuously until the liquid source has reached the critical isotope ratio where further depletion becomes uneconomical. In case the deposition parameters cannot be chosen so favorably as to form a liquid reaction product, the solid deposited reaction product should be removed from the reactor at that critical stage. This removal can be conceived of as a continuous process also. The transformation of UF_3, UF_4, and UF_5 with HF into UF_6 does not present any technical problem and the product is then available for iteration of the enrichment cycle, up to the desired isotope ratio. At this stage, part of the chemically accumulated energy is recovered and used for heating of the substrate. The efficiency of the process depends on the operation temperatures, which should be determined experimentally.

A quite different application of these reactions would be to use CVD as a collector mechanism for selectively laser-excited ^{235}U compounds. In the mechanism, as described vaguely (1), a gas containing molecules of both uranium isotopes is irradiated with laser light of a sufficiently small bandwidth that only ^{235}U containing molecules are excited. These excited molecules are subsequently ionized by incident light of a not so critical wavelength and collected. The ionization should have taken place before the molecule could have lost the excitation energy by collisions and the molecule should be removed sufficiently fast out of the exciting beam to avoid depletion of the gas. It is well known that the chemical reaction velocity can be increased by exciting one of the reaction components. By irradiating the substrate with narrow-band laser light which excites the ^{235}U compound only, the heterogeneous decomposition reaction velocity for this compound is increased above the deposition velocity of the ^{238}U compound. In this way CVD serves as a selective and almost instantaneous collector mechanism for the ^{235}U compound.

Manuscript submitted April 13, 1976; revised manuscript received Aug. 23, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by Philips Research Laboratories.

The Reduction of Photoresist Stripping Rates in an Oxygen Plasma by By-product Inhibition and Thermal Mass

James F. Battey

International Plasma Corporation, Hayward, California 94544

ABSTRACT

It has been observed that the photoresist stripping rate in an oxygen plasma is slower for a full load of silcon wafers than it is for the center wafer of a three-wafer array. For molecular oxygen flow rates of 500 cm^3/min corresponding to reactor residence times of approximately 5 sec and substrate temperatures from 120° to 200°C, it is shown that 200 cm^3/min of carbon monoxide or 15 cm^3/min of water vapor reduces the atomic oxygen flow from about 33 cm^3/min to about 15 cm^3/min and reduces the stripping rate also by about a factor of two. If water vapor is added to a mixture of molecular oxygen and 200 cm^3/min of carbon monoxide or if carbon monoxide is added to a mixture of molecular oxygen and 15 cm^3/min of water vapor, the atomic oxygen concentration is not appreciably changed. However, the photoresist stripping rates are reduced by a factor of 1.5-2.0. A model is proposed which explains some aspects of the results, and it is shown that the difference in strip times between the full boat and three-wafer array is in most current instances a thermal effect.

The surface chemistry in the planar processing of silicon semiconductor wafers is being done with increasing frequency by gas plasmas excited by rf energy, rather than by liquid reagents. The oldest of the semiconductor plasma applications is the stripping of photoresist from silicon wafers with an oxygen plasma, as reported by Irving (1) and Bersin (2).

It is observed that under otherwise identical conditions an array of 50 2-in. diameter silicon wafers on 3/16-in. spacing will take several times as long to strip as the interior wafer of a three-wafer array spaced 3/16 in. apart. It is known that the reaction rate increases with temperature, and part of the disparity is due to the greater thermal mass of the 50-wafer array.

Another cause for reduced reaction rates is the by-products of the reaction inhibiting the reaction. This work was undertaken to find the conditions under which the most probable by-products of the stripping reaction inhibit the reaction, and the conditions under which stripping is delayed by thermal mass.

Experimental Arrangement

The experimental work was done in an 8-in. diameter cylindrical quartz reactor 13 in. in length. A schematic of the apparatus is shown in Fig. 1. The back of the reactor is a spherical sectioned quartz dome, and the front is a flat quartz door. The gas is introduced into the reactor through a quartz manifold on the bottom of the reactor and parallel to its axis. The gas is exhausted by a forepump from the reactor through a quartz manifold on the top of the reactor and parallel to the reactor axis. The plasma is excited by a rf generator operating at 13.56 Hz and coupled into the plasma through a 50Ω cable, a π impedance-matching network, and two half-cylinder metal electrodes placed around the outside walls of the cylindrical reactor. The top electrode is at electrical ground, and the bottom electrode oscillates between positive and negative voltage with the generator.

Key words: atomic oxygen, catalytic reaction, CO and H_2O by-products.

The exhaust manifold is sufficiently large that the pressure drops in it are negligible, and the pressure in the reactor is measured with a Hastings VT4 vacuum gauge in a quartz tube leading out of the exhaust manifold. A metered flow of molecular oxygen is fed into the reactor from a cylinder of 99.6% minimum-purity oxygen at high pressure through a regulator which reduces the pressure to approximately

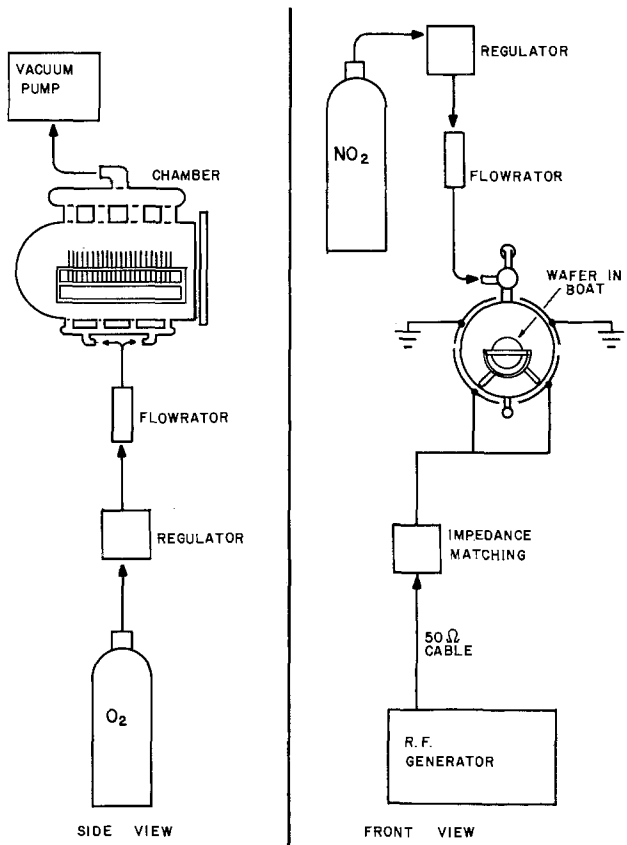

Figure 1.

1 atm, and through a flowmeter, which is connected to the inlet manifold. All gases used were obtained from Matheson. The rf power in the reactor converts some of the molecular oxygen to atomic oxygen (3), and the flow of atomic oxygen in the exhaust can be measured by titrating it (4) with a flow of NO_2 which is introduced into the quartz tube that extends out of the exhaust manifold. The NO_2 was the vapors from 99.5% minimum-purity liquid.

To get reproducible stripping times it was found necessary to put the single wafer on a large aluminum block which had a thermometer inserted in a hole in the block, and to place the block in the same position in the reactor. It was also found necessary to place two thermometers on the external walls of the reactor and require all three thermometers to assume the same temperatures as in a prior experiment.

An additional requirement for reproducibility of strip times is that the internal walls of the quartz reactor, the door, the inlet and exhaust manifolds, the aluminum block and its quartz support structure be "clean." The sole criteria for cleanliness was the ability to reproduce a given minimum stripping time within a few percent under a set of standard conditions. The method of cleaning used was fire polishing with a glassblower's torch and acid etching. Quartz and aluminum oxide presumably have a lower surface recombination rate for atomic oxygen when they are "clean."

The experiments were run with 2-in. diam silicon wafers, covered with 2.0 mg of Waycoat viscosity 40 photoresist spun on with a Headway spinner at 2900 rpm for 20 sec, and then baked for 30 min at 120°C in air.

A Proposed Reaction Rate Model

It has been shown by Abe (5) that photoresist is removed linearly with time from which he concludes that the removal reaction occurs at the surface of the photoresist. Thus, it seems reasonable to treat the photoresist stripping or plasma etching as a three-stage process comprised of the adsorption of an oxygen atom, the reaction of the oxygen with the photoresist to form a simple volatile compound, and the desorption of the compound. Using the notation of catalytic kinetics (6)

$$A_R + X_1 \underset{K_{-1}}{\overset{K_1}{\rightleftarrows}} X_2 \underset{K_{-2}}{\overset{K_2}{\rightleftarrows}} X_3 \underset{K_{-3}}{\overset{K_3}{\rightleftarrows}} A_p + X_1$$

The atomic oxygen, A_R, adsorbs on the site, X_1, to form the adsorbed complex X_2, which reacts to produce the adsorbed product, X_3, which desorbs to give the product, A_p, and regenerates the site to X_1 status. Since photoresist is primarily comprised of CH_2 groups, the principal products might be CO and H_2O. This requires the cooperative action of only a few atoms. If it is assumed that the total number of sites $X_0 = X_1 + X_2 + X_3$ is conserved, and the time rate of change of X_1, X_2, and X_3 is equated to zero in the steady state, an expression for the reaction rate, $R_s = K_2X_2 - K_{-2}X_3$, is obtained. If it is assumed that the reverse reaction rate $K_{-2}X_3$ is small compared to the forward reaction rate, K_2X_2, this reduces to $R_s = K_2X_2$. If it is further assumed that the reaction is the rate-limiting process, and the adsorption and desorption processes are essentially at equilibrium, then $K_1C_RX_1 = K_{-1}X_2$ and $K_3X_3 = K_{-3}C_pX_1$, where C_R is the concentration of reactant and C_p the concentration of the reaction product.

These equalities substituted in the statement of the conservation of site give

$$X_2 = \frac{X_0\left(\frac{K_1}{K_{-1}}\right)C_R}{1+\left(\frac{K_1}{K_{-1}}\right)C_R\left(\frac{K_{-3}}{K_3}\right)C_p} \equiv X_0\left[\frac{K_RC_R}{1+K_RC_R+K_pC_p}\right]$$

and

$$R_S = K_2X_0\left[\frac{K_RC_R}{1+K_RC_R+K_pC_p}\right]^1$$

where K_R and K_p are the equilibrium constants for adsorption of the reactant (atomic oxygen) and product (carbon monoxide and water), respectively. This is the Langmuir-Hinshelwood equation. The K_pC_p term in the denominator of the reaction rate indicates that the products of the reaction can cover the reaction sites and make them unavailable for further reactions. If observations are made in a region of reactant concentrations where the stripping rates are proportional to C_R in the absence of any C_p, then in this region of reactant concentration $K_RC_R << 1$ for any C_p, and the Langmuir-Hinshelwood equation reduces to

$$R_S = K_2X_0\left[\frac{K_RC_R}{1+K_pC_p}\right]$$

If C_p is below some critical values, R_s should be proportional to C_R. Above this value it should be proportional to C_R/C_p.

Strip Rates as a Function of Carbon Monoxide Concentration

Evidence that chemical equilibria exist in a plasma, and that chemical concentrations can be shifted to favor greater or lesser amounts of product formation has been discussed by Blaustein and Fu (7) and by Manes (8). The former authors studied H_2 + CO and H_2 + CO_2 systems with water as a varied additive. Product concentration shifts were found to be consistent with the predictions of Le Chatelier's principle. The latter author showed that statistical mechanics predicted a mass-action law for chemical reactions in a plasma if it is assumed that each degree of freedom of each specie involved in the reaction is in equilibrium. Thus, it was decided to see if the more probable by-products of the reaction would inhibit the reaction.

At constant power and oxygen flow, strip rates were measured on a single wafer as a function of the flow rates of 99.0% minimum-purity CO which was introduced along with the O_2. After the wafer was stripped, the atomic oxygen flow was measured. It is assumed that C_R is proportional to the atomic oxygen flow, and C_p is proportional to the CO flow.

Flow rates are all stated at 1 atm and room temperature. For a flow rate of 500 cm^3/min of molecular oxygen, the light from the titration could not be observed for flow rates of CO in excess of 200 cm^3/min. Hence, the measurements were not made at higher flow rates. Difficulty was experienced in finding a flow rate gauge which would give reproducible measurements of the flow rate of NO_2 over a number of hours' time. Apparently, the NO_2 attacks the gauges. Consequently, gauges were not used for this measurement. Instead, all the gas flows were shut off except the NO_2, which was temporarily suspended with a solenoid valve, while the system was pumped to a low pressure. The NO_2 was then turned back on and the pump was shut off. The time it took the NO_2 flow

[1] It no assumptions are made as to the relative reaction rates, R_s is of the form $X_0\left[\frac{Q_1C_R + Q_2C_p}{1 + Q_3C_R + Q_4C_p}\right]$, where the Q's are complicated algebraic functions of the K's.

rate to raise the pressure in the reactor from 0.2 to 0.7 Torr was then measured with a stopwatch. Since the volume of the reactor is known, the NO_2 flow rate can be calculated.[2] The time required to make the pressure change with a known flow rate was also measured.

After running for the order of an hour with O_2, CO, and NO_2 in a plasma, the time to strip a wafer at 165°C with 100W and 500 cm³/min of O_2 (and no other gases present) became appreciably longer, and traces of a brownish yellow deposit were visible on parts of the reactor and the aluminum block. Combustion analysis showed the presence of hydrogen, carbon, and smaller amounts of nitrogen in the deposit. Presumably oxygen was present also. It was then necessary to acid etch and fire polish the equipment before measurement at standard conditions could be reproduced and data taken.

Strip time and atomic oxygen concentration were measured as a function of carbon monoxide flow in a range from zero to 200 cm³/min in the presence of a background flow of 500 cm³/min of molecular oxygen at five temperatures. Increasing carbon monoxide concentration monotonically decreases strip rates and atomic oxygen concentration; however, plots of strip rate *vs.* atomic oxygen flow rate as shown in Fig. 2 are linear, suggesting that the way in which the carbon monoxide is inhibiting the reaction is by reducing the atomic oxygen concentration. The strip time with no carbon monoxide agrees with other data; however, the slope of strip time *vs.* fill time is about one when the atomic oxygen concentration is varied with molecular oxygen pressure and is about one-half when the atomic oxygen concentration is varied with carbon monoxide. It is as if the presence of the carbon monoxide makes the residual atomic oxygen more effective in stripping. A carbon monoxide plasma itself will strip, but at a rate which is about twenty times slower than an oxygen plasma. Thus, the disparity in slopes is not understood.

The amount of CO required to increase the strip time by a factor of two is larger than the amount of atomic oxygen available with no CO present. The proposed model required two atomic oxygen atoms to be consumed for the creation of each CO molecule when stripping without introducing any CO. Thus, it is improbable that the CO alone created when stripping a boatload of wafers is responsible for the fact that this operation takes several times as long as the stripping of the interior wafer of a three-wafer array. This is particularly clear when consideration is given to the fact that most of the atomic oxygen flows from where it is generated to the exhaust of the reactor without ever diffusing between the wafers and reacting with the photoresist. In the body of the reactor the CO concentration must be considerably smaller than the atomic oxygen concentration.

Stripping time of a single wafer in the presence of CO_2 instead of CO under the same conditions of temperature, power, pressure, and gas flow is not significantly different, within the reproducibility of the data. An explanation for this would be the reaction $CO_2 \rightarrow CO + O$ going essentially to completion, which would give the same concentration of carbon monoxide and atomic oxygen as with the CO plasma, once the atomic oxygen adjusted to steady state. There should be a little less atomic oxygen in the CO_2 plasma, because the amount of atomic oxygen decreases as the pressure of molecular oxygen increases above 1.0 Torr.

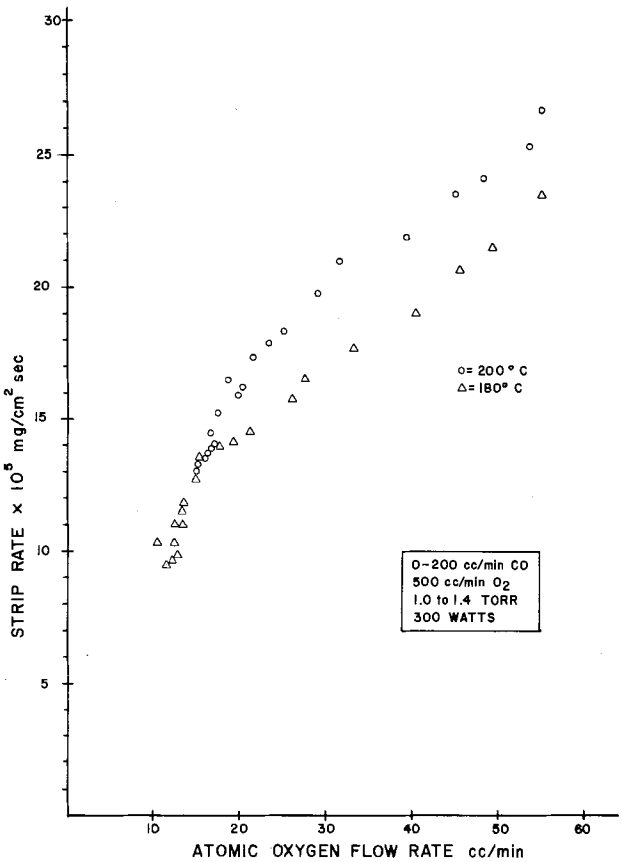

Fig. 2. Strip rate in an oxygen plasma in the presence of carbon monoxide. Increasing carbon monoxide flow rates decreases atomic oxygen flow rates and strip rates.

Strip Rate as a Function of Water Vapor Concentration

The reactor was then fed with two incoming oxygen lines, one of which was drawn through a water bubbler. A total flow rate of 500 cm³/min was maintained, and the water vapor flow rate was varied between zero and about 15 cm³/min by varying the flow of oxygen that went through the bubbler and the flow that did not. The strip times and titration fill times were then measured as a function of H_2O concentration at various temperatures.

Increasing concentrations of water vapor decreased the strip rates and atomic oxygen concentration. Measurements were made at five temperatures. Again, plots of strip rate *vs.* atomic oxygen flow, as shown in Fig. 3, show a linear relationship, suggesting that the way the water vapor inhibits the stripping reaction is by reducing the atomic oxygen concentration. The strip time with no water vapor present agrees with other data, and the slope of strip rate *vs.* atomic oxygen flow is about the same as it is when the atomic oxygen concentration is varied by varying the molecular oxygen pressure. In a number of instances it appears that the initial slope is steeper than the subsequent slope when small amounts of water vapor are being introduced. It is as if the initial amount of water vapor was more effective in slowing the reaction than subsequent amounts. The strip times are essentially doubled at 120°, 140°, and 160°C by the addition of

[2] In mixing the CO and O_2, it was necessary to have a known concentration and consequently pressure of each of the two gases in the reactor. However, if a mass flow rate is first established for one gas, the pressure measured, the first gas turned off, a similar procedure followed for the second gas alone, and then both gases turned on, the resulting total pressure in the reactor is not the sum of the pressures of the two gases taken alone. The mass flow of each gas through the pump must equal the mass flow through the flow rate gauges. Thus, the pressure of each gas at the pump must remain the same, whether they are on individually or together. However, the viscous mass flow through the hose requires that there be a certain difference in the square of the pressure at the ends of the hose. The procedure followed was to set with a flowrator the flow rate of the oxygen coming from the tank to be 500 cm³/min. The flow rate of the CO with no oxygen flowing was then set with a second flowrator to be some desired fraction of the oxygen flow. A large valve between the reactor and the hose was then adjusted so that the total pressure was the sum of the two individual pressures and the flows are in the reported ratios, although the exact values are not known. The effect was only appreciable at the higher CO flow rates.

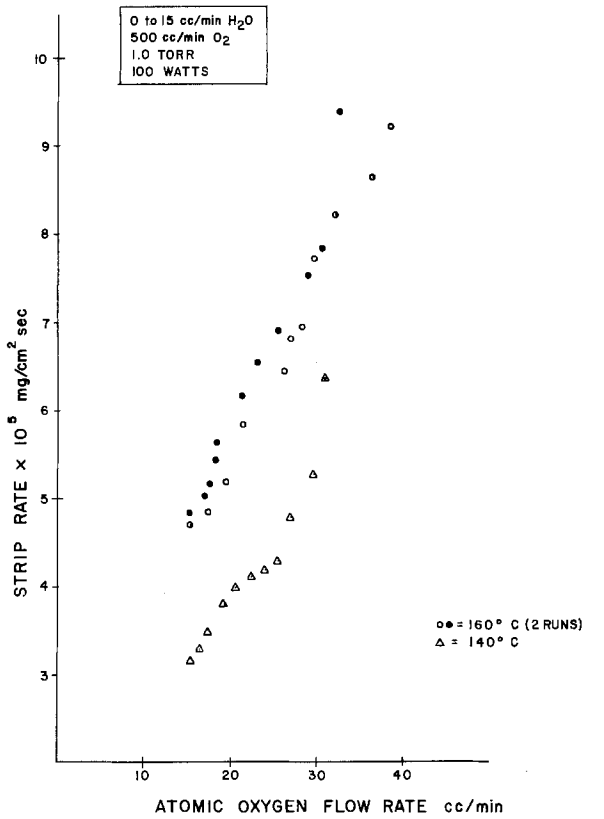

Fig. 3. Strip rate in an oxygen plasma in the presence of water vapor. Increasing water vapor flow rates decreases atomic oxygen flow rates and strip rates.

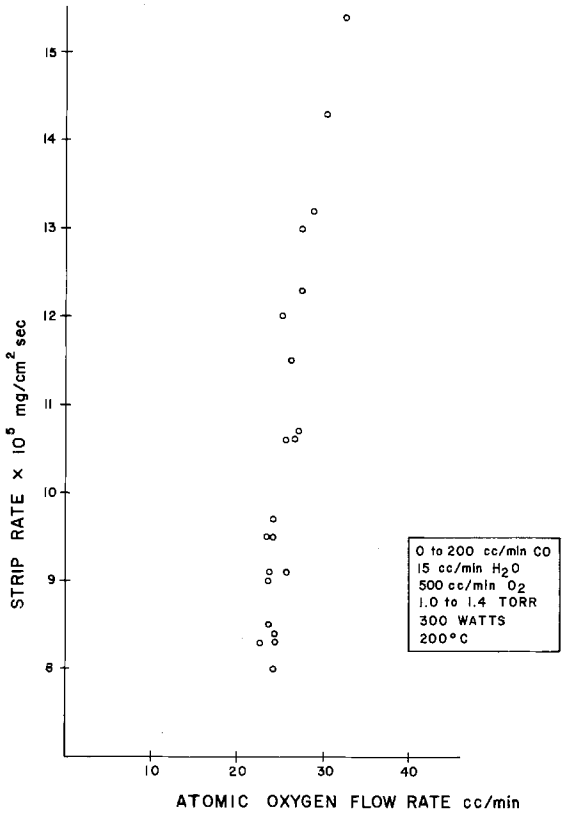

Fig. 4. Strip rate in an oxygen and water vapor plasma in the presence of carbon monoxide. Increasing carbon monoxide flow rates decreases strip rates but has little effect on atomic oxygen flow rates.

15 cm^3/min of water vapor flow. The change seems to be somewhat less at 180° and 200°C.

Extrapolation of the present data suggests that at 1.0 Torr and 300W, the flow of atomic oxygen out the exhaust would be about 75 cm^3/min with no load. It seems unlikely that 15 cm^3/min got converted to H_2O in the stripping reaction, even when it is considered that the atomic oxygen flow in the exhaust where the titration was performed may be smaller than the flow in the chamber due to wall and bulk recombination in the exhaust manifold.

If it is assumed that the principal products of the stripping reaction are CO and H_2O, then these should be generated in more or less equal quantities. Since the inhibiting effect of a given amount of water vapor is much greater than the same amount of carbon monoxide, the water vapor alone would inhibit the stripping first.

A flow of argon in the absence of any CO was added to the molecular oxygen flow in quantities equal to the flow of CO which had been used. The effects are small compared to comparable amounts of CO and can be explained by a reduction in the amount of atomic oxygen, due to the increased pressure.

Strip Rates as a Function of Carbon Monoxide Concentration in the Presence of Water Vapor

All 500 cm^3/min of incoming molecular oxygen was then run through the water bubbler, and CO was introduced in amounts up to 200 cm^3/min. Data were taken at five temperatures. The results were surprising. The CO did not markedly change the flow of NO_2 required to titrate the atomic oxygen. On the other hand, the stripping times were approximately doubled, as can be seen in Fig. 4. The strip time is approximately linear in the flow rate of CO, as shown in Fig. 5. However, the initial slope is steeper, and this effect is more pronounced at 120° and 140° than at 180° and 200°C. The abscissa is plotted as proportional

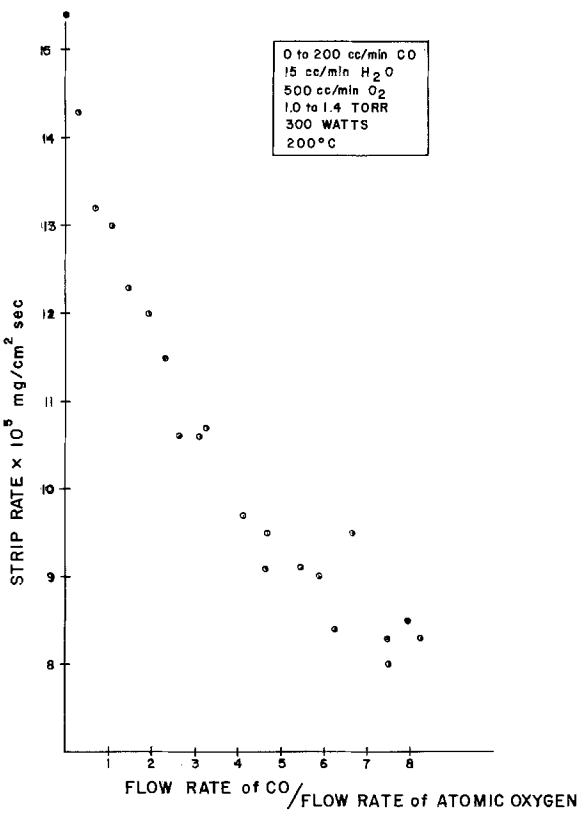

Fig. 5. Strip rate in an oxygen and water vapor plasma as a function of the flow rate of carbon monoxide divided by the flow rate of atomic oxygen.

to the flow rate of CO divided by the flow rate of atomic oxygen under the presumption that strip rate is proportional to the atomic oxygen concentration

divided by the CO concentration. However, since the oxygen concentration is approximately constant for a given temperature, an abscissa that is proportional to the flow rate of CO plots as well.

Increasing the flow of molecular oxygen by 200 cm³/min in the absence of any CO caused no measurable change in either the concentration of atomic oxygen or the strip rate. Titrations were also performed with no CO present and then with CO introduced in the exhaust a few centimeters before the point of titration, with no perceptible change in the amount of NO_2 needed for titration.

Strip Rates as a Function of Water Vapor Concentration in the Presence of Carbon Monoxide

200 cm³/min of CO were then added to the 500 cm³/min of molecular oxygen, and the pressure was allowed to rise from 1.0 to 1.4 Torr. Again, the incoming oxygen was split between a line that went through a water bubbler and one that did not. Measurements were made of strip times and titration fill time at 160°C. Again, within the accuracy of the data, atomic oxygen flow rate and consequently the atomic oxygen concentration was unaffected by the amount of oxygen which had gone through the bubbler, as can be seen in Fig. 6, whereas the strip time approximately doubled between when no oxygen went through the bubbler and when all 500 cm³/min went through the bubbler, as shown in Fig. 7.

Apparently, the role of CO in the presence of about 15 cm³/min of water vapor and of water vapor in the presence of 200 cm³/min of CO is to decrease the stripping rate by covering the reaction sites without substantially changing the concentration of atomic oxygen. Either one of them alone decreases the stripping rate by reducing the atomic oxygen without decreasing the number of reaction sites.

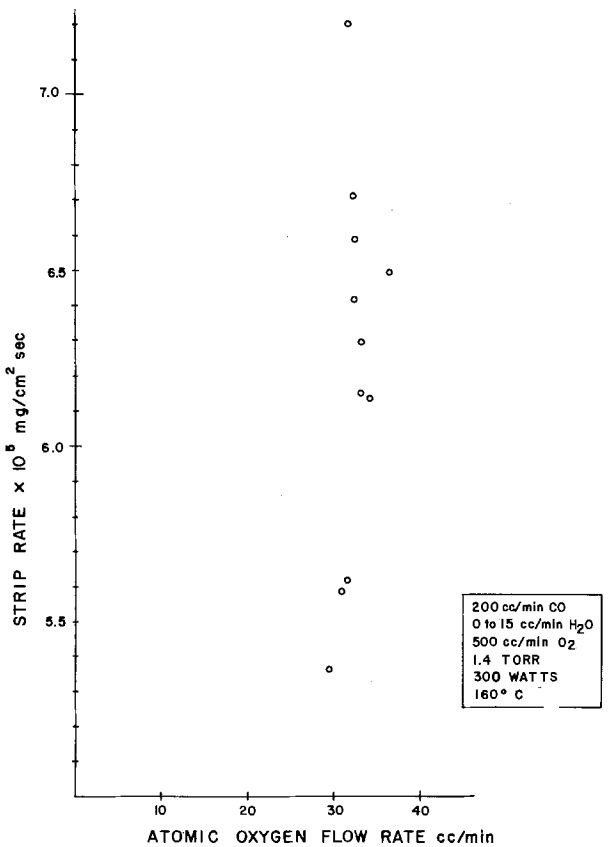

Fig. 6. Strip rate in an oxygen and carbon monoxide plasma in the presence of water vapor. Increasing water vapor flow rates decreases strip rates but has little effect on atomic oxygen flow rates.

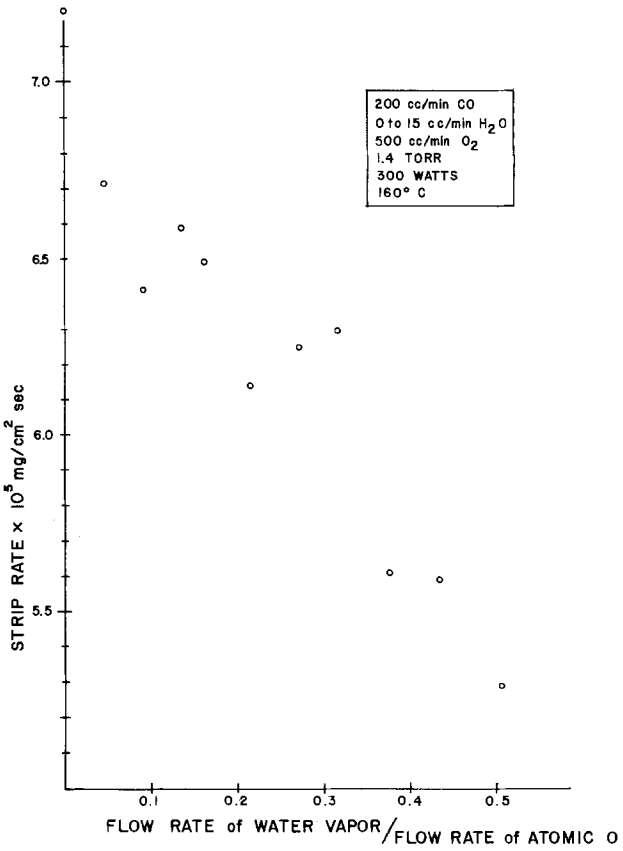

Fig. 7. Strip rate in an oxygen and carbon monoxide plasma as a function of the flow rate of water vapor divided by the flow rate of atomic oxygen.

Strip Time vs. Thermal Load

An experiment was then run in which boatloads of 50 2-in. silicon wafers were stripped with a flow rate of 500 cm³/min at a pressure of 1 Torr with 100W, starting with the reactor at room temperature. A thermometer was thermally coupled to the boat. In the first batch the front, a middle, and a rear wafer were covered with photoresist. The rest of the wafers were bare. The front wafer was stripped clean in 21 min, at which point the power was shut off. The center wafer was completely stripped. The rear wafer had a small spot of photoresist in its center.

A second run was made in which all 50 wafers were covered with photoresist. The front wafer cleared in 18 min and something less than 10 sec. The other wafers were all completely stripped, except for a couple at each end of the boat, which had small spots of photoresist near their centers.

For the same load of wafers variations are to be expected, depending on the thermal contact between the wafers and the boat, and the boat and the reactor. The temperature as a function of time is shown for the two runs, and it will be seen that the boat is heating more slowly in the second run. However, it would seem quite clear that under present operating conditions the principal reason why a load of 50 wafers strips more slowly than the interior wafer of a three-wafer array has to do with the larger thermal mass and slower heating of the 50-wafer system.

Conclusions

The addition of carbon monoxide or water vapor to an oxygen plasma in amounts comparable to the atomic oxygen present reduces the stripping rates of photoresist by approximately a factor of two. The reduction is effected by reducing the atomic oxygen by the same factor. If both carbon monoxide and water vapor are added to an oxygen plasma, the stripping rates are reduced by approximately another

Table I. Temperature as a function of time

Time (min)	Temperature run 1 (°C)	Temperature run 2 (°C)
0	26	26
2	100	72
3	112	84
4	116	89
8	108	108
14	116	120
18	128	127
20	—	130
21	—	130

factor of two without any further reduction in atomic oxygen concentration. Presumably the added gases are covering half of the reaction sites, making them unavailable for further reactions.

Stripping rates are very slow at photoresist temperatures less than 120°C. Thus, greater thermal mass as well as by-product inhibition explains why a full boatload of silicon wafers are slower to strip than a three-wafer array of the same wafer spacing.

Acknowledgments

The author would like to thank Dennis S. Enjaian for taking the experimental measurements and Joseph M. Welty for a major contribution to all aspects of the thinking.

Nitrogen Diffusion in Zirconium Nitride

J. G. Desmaison[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Nitrogen diffusion in polycrystalline $ZrN_{0.71-0.79}$ spheres, 60 and 90 μm diameter, was studied by the gas-solid exchange technique using ^{15}N as a tracer at a nitrogen pressure of 220 Torr and at temperatures in the range 1000°-1200°C. These specimens were characterized by chemical analyses, density, lattice parameter, and structural measurements. The tracer diffusion coefficient can be expressed as $D^*(cm^2/sec) = 3.0 \times 10^{-10} \exp(-23{,}000/RT)$. This result, when compared to a previous determination obtained in the same conditions with 254 μm thick plates, confirms that nitrogen transport in this polycrystalline solid at temperatures less than 1200°C is associated with a short-circuit diffusion mechanism.

Using the ^{15}N gas-solid exchange technique we investigated recently (1, 2) the diffusion of nitrogen in 254 μm thick $ZrN_{0.93}$ plates obtained by direct nitridation of 99.995 weight percent (w/o) zirconium sheets at 1150°C. The tracer diffusion coefficient measured at a nitrogen pressure of 220 Torr and at temperatures in the range 1000°-1200°C could be expressed as

$$D^*_N\,(cm^2/sec) = \left(4.1\,^{+88.2}_{-3.9} \times 10^{-6}\right) \exp(36{,}600 \pm 8{,}500)/RT \quad [1]$$

This result when compared to determinations of the chemical diffusion coefficient obtained from Zr nitriding kinetics demonstrated that nitrogen transport in the polycrystalline solid at temperatures less than 1200°C is associated with a short-circuit diffusion mechanism.

The purpose of this investigation was to study the influence of the nitrogen to zirconium ratio in order to gain complementary information on the transport process. Indeed if the role of short-circuiting paths is predominant in the process, the values of the diffusion coefficient should be more dependent on the microstructure of the polycrystalline materials than on the nonstoichiometry, *i.e.*, on the nitrogen vacancy concentration. Accordingly, the reverse situation would prevail for volume nitrogen diffusion in the hypothesis of a vacancy mechanism. In order to obtain substoichiometric nitride samples presenting sufficient homogeneity for diffusion experiments we prepared microspheres in the 45-105 μm range.

Experimental

Preparation and characterization of the spheres.— The spheres were prepared by dropping particles in the 45-75 μm size range through an electric arc, where they melted and spheroidized due to surface tension. The method of preparation and the arc assembly have been described in detail elsewhere (3, 4). The operating characteristics of the arc were 100V and 10-20A in a nitrogen argon atmosphere. Tungsten electrodes and UHP gases (>99.999%), were used. Separation of the spheres from irregularly shaped particles which missed the arc was accomplished by dropping the powder on an inverted watch glass. Only the spheres

would roll quickly to the bottom. The yield after one pass, ranging between 5-10 w/o was increased to approximatively 25 w/o by recycling the incompletely fused particles through the arc several times.

The starting material was >99% zirconium nitride; the analytical data are shown in Table I. Due to the rather low nitrogen content of this material, the spheres were renitrided for 10 days at 1050°C and subsequently characterized by the techniques (chemical analysis, density, lattice parameter, and structural measurements) presented in our previous work (1, 2).

Determination of the diffusion coefficient.—Nitrogen diffusion was determined by the gas-solid isotopic exchange technique using ^{15}N as a tracer. The details of the apparatus and the procedures have also been described (1, 2). In brief, the nitride sample is heated in a constant and limited volume of ^{15}N enriched nitrogen gas. From the depletion of ^{15}N in the gas, followed by mass spectrometric technique, the diffusion coefficient in the solid can be evaluated by applying the error function equation developed by Carman and Haul (5) with the assumption of an instantaneous phase boundary reaction

$$\frac{C_t - C_s}{C_g - C_s} = \frac{\gamma_1}{\gamma_1 + \gamma_2} e \operatorname{erfc} \frac{3\gamma_1}{\lambda}\sqrt{\tau} + \frac{\gamma_2}{\gamma_1 + \gamma_2} e \operatorname{erfc} \frac{-3\gamma_2}{\lambda}\sqrt{\tau} \quad [2]$$

where $\tau = D^* t/a^2$, $\gamma_1 = \frac{1}{2}\{(1 + 4\lambda/3)^{1/2} + 1\}$ and $\gamma_2 = \gamma_1 - 1$. Here C_t, C_s, and C_g represent the atom fraction of ^{15}N in the atmosphere at time t, in the solid at time zero (taken as the natural abundance 0.0037), and in the atmosphere at time zero, respectively. a is the radius of the spheres, and λ is the ratio of the total mass of nitrogen in the gas phase to that in the solid. The usual criterion for a surface exchange limitation is a curvature of a τ *vs.* t plot, or if the curvature is too small, any offset from the origin of an extrapolated line through the experimental points.

Results

Characteristics of the spheres.—A batch of ~ 6g of golden yellow spheres was obtained and graded using Tyler Sieves. The majority of the spheres were in the diameter ranges 45-75 μm (avg diam = 60 μm) and 75-105 μm (avg diam = 90 μm). Powder photographs and diffractometer traces contained only the characteristic lines of ZrN, proving the single phase structure of the material. X-ray diffraction photographs taken of a few spheres with a precession camera using Zr-filtered Mo radiation demonstrated the polycrystalline nature of the spheres. These spheres consisted of substoichiometric, ZrN_x, with $x = 0.74 \pm 0.01$ for the 60 μm diam and $x = 0.71 \pm 0.01$ for the 90 μm diam. Microscopic examination of the spheres showed that they were not cracked and had a smooth surface with a few irregularites (Fig. 1). Polished cross sections presented a rather rough surface finish resulting partly from a small degree of internal porosity but mainly from surface damage occurring during polishing due to the brittleness of the nitride. Etching revealed a dense network of grain boundaries delimiting grains with average diameter measured to be approximately 10 μm for the 60 μm spheres, and 15 μm for the 90 μm spheres (Fig. 2). The lattice parameter and the experimental density were measured on 60 μm spheres at 23°C. These results are shown in Table II along with the corresponding calculated vacancy concentrations. The sample homogeneity was confirmed by x-ray powder photographs which exhibited sharp splitting of the $K_{\alpha 1}$ and $K_{\alpha 2}$ lines for angles greater than 45°.

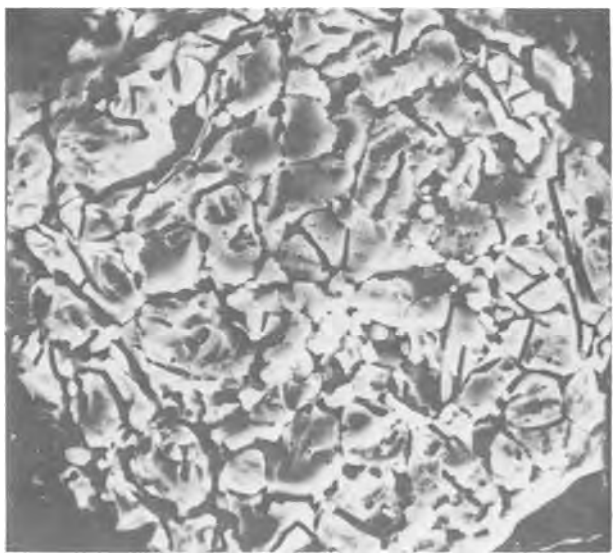

Fig. 2. Etched cross section of a sphere (×1400)

Table II. Vacancy concentration in 60 μm spheres at 23°C

d_p (g/cm³)	a (A)	d_X (g/cm³)	V_{Zr} (%)	V_N (%)
(pycnometer density) 6.80 ± 0.08	(lattice parameter) 4.578 ± 0.002	(x-ray density) 7.03	3.3	28.4

Diffusion.—Runs were performed at 1000°, 1053°, 1101°, 1148°, and 1203°C, and at 220 Torr nitrogen pressure. At the three intermediate temperatures 60 μm spheres were used and 90 μm spheres at the two extreme temperatures. In addition, before the runs at 1101°, 1148°, and 1203°C the samples were annealed for 2 days under the same experimental conditions of temperature and pressure of normal isotopic composition as used for the exchange run. This annealing increased the N/Zr ratio up to 0.79 in the case of 60 μm spheres and 0.78 for 90 μm spheres. For all the runs a sample mass of 500 mg was used, C_g was maintained in the 4.36-7.60% range and λ was kept approximately equal to 1($1.09 < \lambda < 1.21$). With the chosen value of λ the over-all change in C_t for a run ranged from 2.1 to 4.7%.

The dimensionless parameter $D^* t/a^2$ calculated from the experimental data through Eq. [2] *vs.* time is shown in Fig. 3; the corresponding plots can be represented by straight lines passing through the origin which indicate that the surface exchange is not the limiting process. The values of the tracer diffusion coefficient were determined from these plots and an Arrhenius plot of these evaluations is given in Fig. 4. The equation obtained by the least squares method is

$$D^*(\text{cm}^2/\text{sec}) = \left(3.0 \pm \frac{18.8}{2.6}\right) \times 10^{-10} \exp - (23{,}000 \pm 5{,}400)/RT \quad [3]$$

where the limits are at the 95% confidence level.

During the diffusion anneal the samples increased slightly in weight (0.28-0.75%). Also, after exposures higher than 10 hr a few spheres became of brown grayish color and attached to each other, this second effect increasing in intensity with temperature. Microscopic examination and x-ray analysis showed that the change in color and particle agglomeration were due to a slight oxidation of the spheres accompanied with a beginning of sintering of the zirconia formed.

Discussion and Conclusions

Because of the abundance of nitrogen vacancies in substoichiometric zirconium nitride (Table II) nitrogen diffusion in this material ought to be a particularly simple property to interpret. The tracer diffusion coefficient D^* for a vacancy mechanism is proportional to the vacancy concentration. This concentration in the spheres was approximatively 4 times larger than in the $ZrN_{0.93}$ plates consequently, it could be expected to lead to slightly higher values of D^* for spheres. In fact it is the reverse situation which is observed (Fig. 4), the diffusion coefficients for spheres being nearly 100 times smaller. This result is not surprising, as the low values of the preexponential factors and the activation energies, as well as the relatively low temperatures of the diffusion anneals (<0.45 Tm) all suggest that the two sets of measurements represent structure-sensitive diffusion rather than intrinsic volume diffusion.

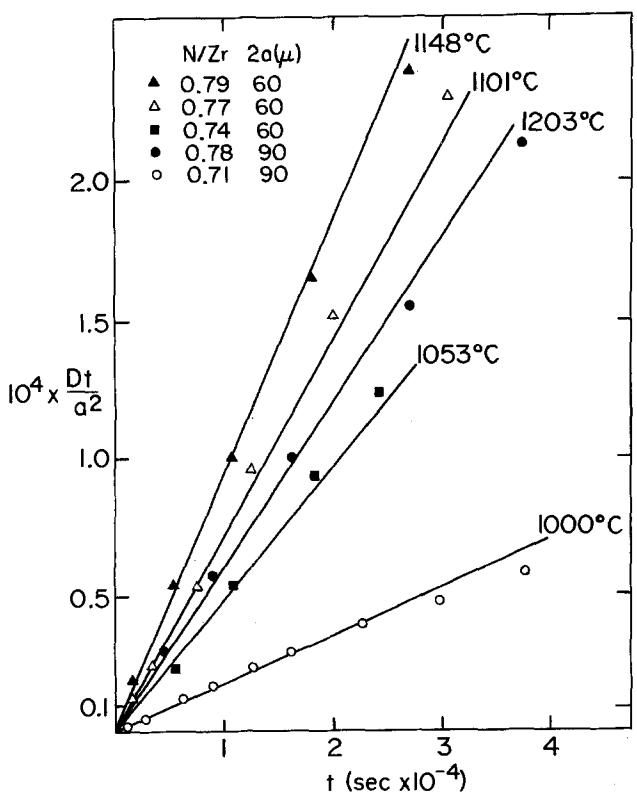

Fig. 3. Experimental results for ^{15}N diffusion in spheres

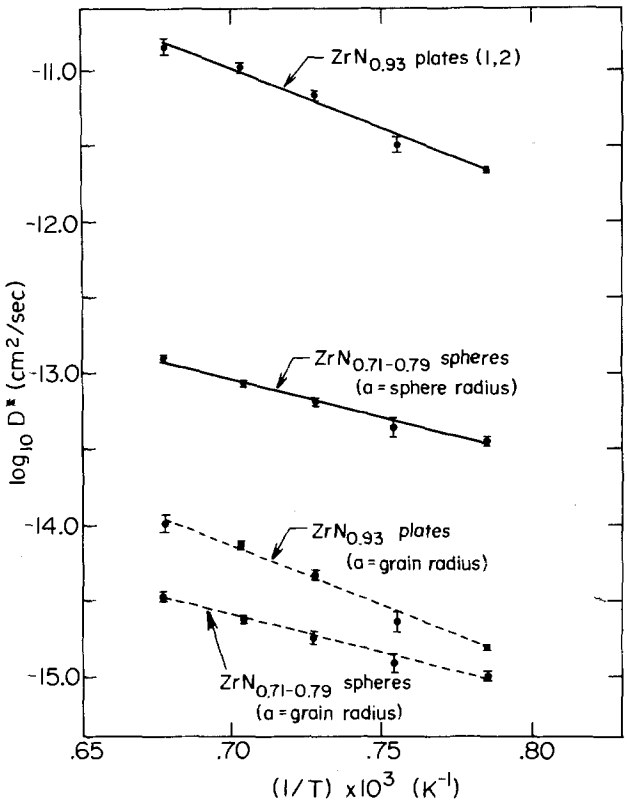

Fig. 4. Arrhenius plot of the nitrogen tracer diffusion coefficients for $ZrN_{0.71\text{-}0.79}$ spheres and $ZrN_{0.93}$ plates. (1,2) text references.

The influence of the microstructure is tested following the procedure by Oishi, Shirasaki *et al.* (6-8) in their investigations of preferential diffusion of oxygen along grain boundaries in polycrystalline MgO and $MgAl_2O_4$. These authors using the ^{18}O gas-solid isotopic exchange technique found that the self-diffusion coefficients in the polycrystalline samples were several orders of magnitude greater than that of single crystals. When they recalculated the diffusion coefficients by taking the grain radius instead of the particle radius, the new values were in good agreement with those for the single crystals. The higher diffusion coefficients for the polycrystalline solid were then interpreted as being due to enhanced oxygen diffusion along the grain boundaries. Thus by applying this computation procedure to the present results it should be possible to gain information on the role played by short-circuit diffusion through grain boundaries. The diffusion coefficients calculated through Eq. [2] by taking the average radii of the grains, *i.e.*, 5 μm for 60 μm spheres, 7.5 μm for 90 μm spheres, and 10 μm for plates can be expressed as

$$D^*(\text{spheres}) = \left(8.0 \begin{matrix} +50.7 \\ -\ 6.9 \end{matrix} \times 10^{-12}\right) \exp - (23{,}000 \pm 5{,}400)/RT \quad [4]$$

$$D^*(\text{plates}) = \left(2.9\ ^{+63.0}_{-\ 2.8} \times 10^{-9}\right) \exp - (36{,}700 \pm 8{,}500)/RT \quad [5]$$

The corresponding Arrhenius plots are shown by dashed lines in Fig. 4. The agreement between the two sets of experiments is greatly improved and can be even considered as good if the uncertainty of the grain size distribution is taken in account. Therefore this result is consistent with the interpretation that preferential diffusion of nitrogen along grain boundaries predominates in the temperature range of interest.

This analysis also demonstrates that other low resistance diffusion paths in the materials play a role, since the activation energies from Eq. [4] and [5] are in poor agreement and both values are much too small for lattice diffusion even though a correction has been made for grain size differences. Such paths can be of structural origin such as ingrown dislocations and microporosity and of excess extrinsic defectiveness in the solid lattice caused by the influence of impurities. The difference between the ZrN density determined by the pycnometer and x-ray techniques (~3 *vs.* 0.7%) and the impurity levels (0.28 *vs.* 0.01%) was higher in the spheres than in plates. The relative effect of these different parameters, however, cannot be distinguished using the presently obtained results. There is also an additional contributing factor to the determination of the lower activation energy for diffusion in the spheres: the spheres increased detectably in weight during a diffusion anneal, and this nitridation which increased with temperature could lower the isotopic exchange, and by extension, the temperature dependence of the diffusion constant.

Technical Note

Auger Characterization of Chemically Etched GaAs Surfaces

I. Shiota, K. Motoya, T. Ohmi, N. Miyamoto, and J. Nishizawa*

Research Institute of Electrical Communication, Tohoku University, Sendai, Japan

Low resistance ohmic contact and high quality Schottky contact on GaAs single crystals are required especially for high frequency devices including IMPATT diodes (1), TUNNET (tunnel injection transit time) diodes (2), and Schottky gate FET (3). However, the surface processing technique of GaAs has not yet been fully established in contrast to that of Si. This is partly ascribed to the deviation from stoichiometry which is characteristic of compound semiconductors such as GaAs (4) and GaP (5), and to the difference in reactivity against a chemical reagent between III and V components. These two factors are closely related to each other and make it very difficult to control precisely the surfaces of III-V compound semiconductors.

The present work was conducted to determine which processing is best suited to the preparation of GaAs surfaces with the minimum oxide film (6, 7). For the purpose of investigation, Auger electron spectroscopy was used in combination with Ar sputter etching which may be most reliable for the analysis of thin film. Auger spectra were taken in a vacuum of 10^{-9} mm Hg at an excitation voltage of 4 kV and a beam current of 1 μA. Simultaneous sputter etching was made at a sputtering voltage of 1 kV and an emission current of 30 mA under a 5×10^{-5} mm Hg Ar atmosphere. In the case of in-depth profiling, the $L_3M_{4,5}M_{4,5}$ Auger peaks for Ga and As and the $KL_{2,3}L_{2,3}$ peaks for oxygen were monitored automatically by a Physical Electronics multiplex control system. Oxide thickness was determined from the sputtering time at which the $OKL_{2,3}L_{2,3}$ Auger peak height attained a minimum value. The sputtering rate of the native Ga oxide produced by chemical etching was assumed to be the same as that of thermally grown Ga oxide on GaAs (8) which was 20 Å/min.

First, we adopted a $H_2SO_4 + H_2O_2 + H_2O$ mixture in the volume ratio of 4:1:1 as a fast etchant of an original GaAs (100) surface which was thoroughly degreased using trichlorethylene and methanol cycles in an ultrasonic bath, followed by a doubly distilled

* Electrochemical Society Active Member.
Key words: slow chemical etching, residual oxide film, low resistance ohmic contact, high quality Schottky contact.

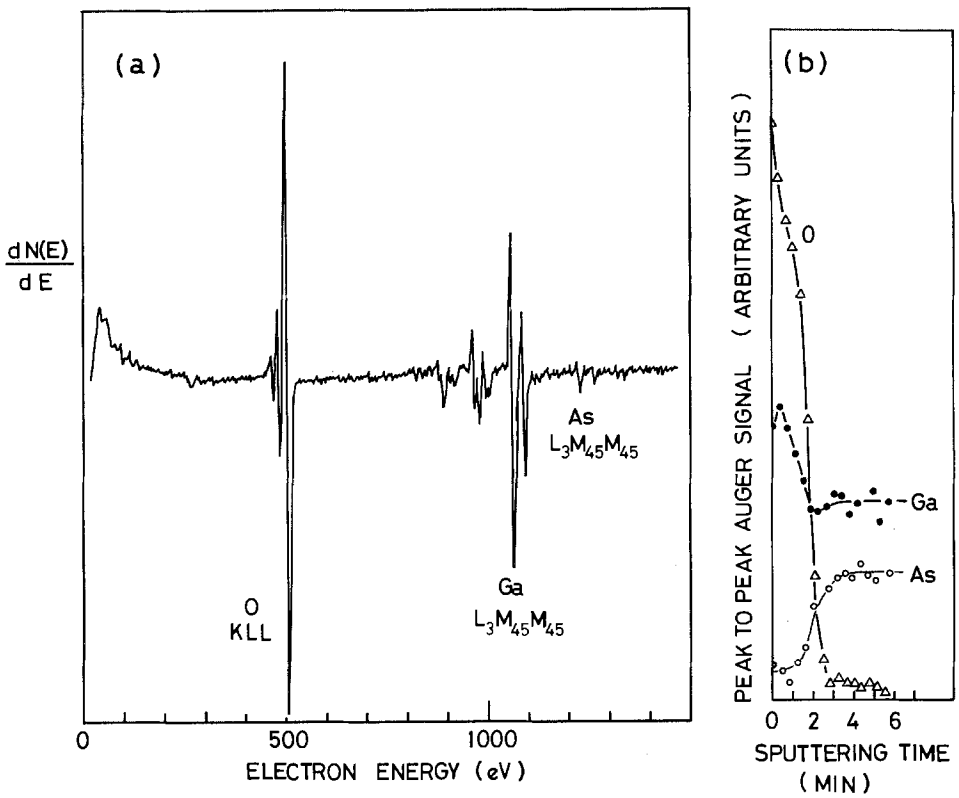

Fig. 1. (a) Auger spectrum of the top surface of a chemically etched GaAs (100) surface by $H_2SO_4 + H_2O_2 + H_2O = 4:1:1$ in volume ratio at 50°C for 3 min (fast etch). (b) Composition profile of the surface of (a).

methanol rinse prior to chemical etching. The Auger spectrum and the composition profile of the surface are shown in Fig. 1 (a) and (b), respectively, after chemical etching at 50°C for 3 min. It is shown that the etched surface is covered with a Ga oxide film, about 50Å thick, containing a small amount of As. Deficiency of As atoms in the oxide is the prominent nature of the thermally grown oxide film on GaAs surfaces at rather high temperatures (8). Such a surface is not appropriate for the formation of low resistance ohmic and Schottky contacts. We found that fast etching produces a thick residual oxide film, while slow etching results in formation of a thin residual oxide film. The thick oxide film remaining after removal of the damaged layer using the fast etch was very slowly dissolved by a slow etchant. Therefore, prior to the application of slow etching, the thick oxide film should first be removed.

Concentrated HF solution was used for removing a considerable thickness of the oxide film by dipping the sample in the solution for 5 min, resulting in a remaining oxide layer thickness of 25 ~ 30Å. Finally, the surface was lightly etched by NaOH (1 mole) + H_2O_2 (0.76 mole) in the volume ratio of 1:1 at 30°C for at least 1 min. The etching rate of this slow etchant was 0.2 μm/min. It is clearly shown in Fig. 2 (a) and (b) that the oxide thickness could be reduced to below 10Å after 1 min of final etching and that the Auger peak heights of Ga and As became smaller in the surface region than in bulk, although the Auger peak ratio of As/Ga was nearly the same as that in bulk. The method described above can also be applied following other etchants with high etching rates such as $CH_3OH + Br_2$ and $NaOH + H_2O_2$. Main results are summarized in Table I where GaAs (100) surfaces are evaluated in terms of residual oxide thick-

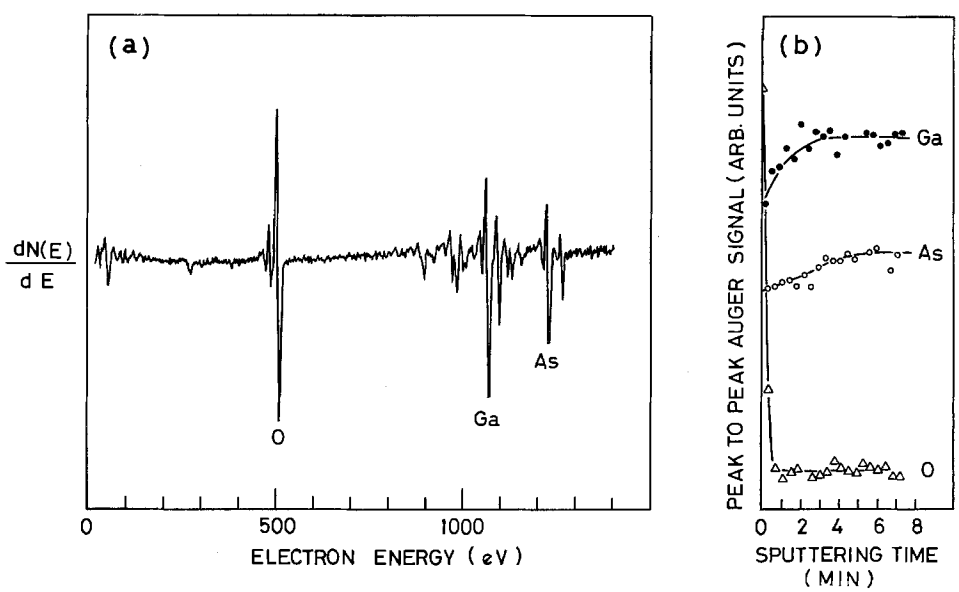

Fig. 2. (a) Auger spectrum from the GaAs (100) surface which was successively processed by conc HF and a slow etching (1 min) following fast etching. (b) Composition profile of the surface of (a).

Table I

	Etching procedure	Residual oxide thickness in Å
I	4:1:1* (50°C, 3 min)	50
	4:1:1 (50°C, 3 min) + conc HF** (5 min)	30
	4:1:1 (50°C, 3 min) + conc HF (5 min) + 1:1*** (30°C, 0.5 min)	10
	4:1:1 (50°C, 3 min) + conc HF (5 min) + 1:1 (30°C, 1 min)	≲10
II	1:1*** (55°C, 10 min)	60
	1:1 (55°C, 10 min) + conc HF	25
	1:1 (55°C, 10 min) + conc HF + 1:1 (30°C, 0.5 min)	15
	1:1 (55°C, 10 min) + conc HF + 1:1 (30°C, 1 min)	10

* 4:1:1 means the volume ratio of H_2SO_4 (98 w/o): H_2O_2 (30 w/o): H_2O. Etching rate is ~3 μm/min at 50°C.
** Conc HF is 49 w/o.
*** 1:1 means the volume ratio is NaOH (1 mole): H_2O_2 (0.76 mole). Etching rate is 0.2 μm/min at 30°C and 1 μm/min at 55°C, respectively.

ness. From the table, it is clear that slow etching for at least 1 min is required to reduce the surface oxide thickness to below 10Å. Not only the aforementioned NaOH + H_2O_2 mixture but also any other etchants with slow etching rates such as 10 H_2SO_4:1 H_2O_2:1 H_2O can serve as slow etchants, regardless of the rate-limiting process of etching kinetics. Table I suggests that the successive processing including HF and slow etching subsequent to fast etching may be a very promising technique for producing a GaAs (100) surface with the least amount of oxide.

By applying this method to the fabrication of ohmic and Schottky contacts, the good contacts were obtained resulting in excellent performance of microwave and millimeter wave GaAs devices. Evaporation and alloy process of Au-Ge is very popular and useful in ohmic contacts to GaAs, however, two main problems exist which give rise to high contact resistance, *i.e.*, the ball-up phenomena and the formation of Au-Ga alloy due to the heat cycle of the alloying process. Thin layer evaporation of Ni following Au-Ge evaporation is usually used in order to suppress the ball-up phenomena with conventionally etched GaAs surfaces, but the ball-up phenomena are not observed if the oxide-free GaAs surface is used. Formation of Au-Ga alloy in the alloying process is suppressed by using the rapid temperature rise alloy process (9) where the temperature of samples is raised within at most 10 sec up to 450°C in the alloying heat cycle (Au-Ga alloy formation occurs at around 300°C). Combination of the oxide-free GaAs surfaces with the rapid temperature rise alloy process leads to excellent ohmic contacts and contact resistance as low as 1×10^{-6} Ω-cm² or less. In addition, a good quality Schottky barrier could be made between Pt and n-GaAs with a very small scatter of 0.93 ± 0.01 eV in barrier height, and the wettability was improved between the GaAs substrate and Ga solvent for multilayer liquid phase epitaxial growth.

For $(\bar{1}\bar{1}\bar{1})$ surfaces, however, the situation is different from that for (100) surfaces; the growth of the native oxide film was limited to a level of 10 ~ 15Å even with fast etchants such as H_2SO_4:H_2O_2:H_2O (3:1:1) and CH_3OH:Br_2 (20:1). The change in composition was observed in the very thin surface layer as in the case of (100) surfaces. The trend that the oxide film is thinner at $(\bar{1}\bar{1}\bar{1})$ surfaces than at (100) surfaces is the same as the trend for oxide films produced by thermal oxidation of GaAs surfaces below 500°C. This result will be presented elsewhere (8).

The present surface processing technique has been found to be useful for the fabrication of various types of contacts and effective as a simple surface preparation method for other purposes.

Brief Communication

Poly(methyl α-chloracrylate) as a New Positive Electron-Beam Resist

J. N. Helbert, C. F. Cook, Jr., and E. H. Poindexter

U.S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

Production of high density integrated circuits by electron-beam lithography relies heavily upon polymer resists for pattern delineation. Although there are many negative resists (1) known, far fewer positive e-beam (1) resists have been found. In this communication, we report positive e-beam resist behavior for poly(methyl α-chloracrylate) homopolymer. Previous radiation experiments (2, 3) with this material indicate that this polymer undergoes radiation degradation at a fairly high rate per unit radiation dose.

Methyl α-chloracrylate monomer was purchased from Polysciences, Incorporated, and was vacuum distilled before use. Poly(methyl α-chloracrylate) (PMCA) polymer was synthesized by conventional azodi-isobutyronitrile free-radial induced polymerization (4). The polymer was fractionally reprecipitated twice from dimethyl formamide using methanol as nonsolvent. The resulting polymer had a number average molecular weight ($\overline{M}_N$) of 125,000 as determined by membrane osmometry, and a polydispersivity of 2.6 as determined by gel permeation chromatography.

Electron-beam exposures were made with an AMR-900 scanning electron microscope operating at 10 kV, which was modified for raster scan pattern control with a flying spot scanner. The beam diameter was 1000Å. The electron dose was measured with a Faraday cup. The electron exposure charge density measurement was checked against the known sensitivity of PMMA using the standard developer (5). The test patterns consisted of sequential groups of lines with varying exposure densities; line widths were typically 1-2 μm with 1-3 μm spacings.

Electron-etched lines in PMCA films dissolved much faster than the unexposed resist when subjected to developer solutions. This occurs because the molecular weight of the irradiated polymer is much smaller (3) than that of the polymer in the unexposed region. The dependence of dissolution rate $\dot{d}$ upon polymer molecular weight has been shown to be (6)

$$\dot{d} = KM^{-A}$$

where M is the molecular weight, and K and A are constants. Although polymer solubility may change with radiation exposure, it is the dissolution rate that is most important for line development in positive resists. Table I lists line exposure charge densities employed for representative line groups in this study. Figure 1 is an SEM photograph of representative developed lines.

The e-beam developer composition is a very important consideration, but its selection is not scientifically clear-cut .Of the many developer solution compositions tried, two were fairly good. The first, a 1:1 $CHCl_3/CCl_4$ mixture, developed the lines, but with line edge blotchiness. The second, 1:1 $CHCl_3$/isopropanol (IPA), was an improvement over the first developer, but some unexposed polymer surface roughness was apparent. Isopropanol is probably a better nonsolvent for PMCA, because its larger molecular size could restrict molecular permeation of nonsolvent.

Key words: electron-beam resists, polymer degradation, acrylate polymers.

Table I. Development charge densities and remaining resist thicknesses for PMCA positive e-beam resist samples

Resist	Exposure development charge density, C/cm²	Remaining resist thickness, Å	Developer	Development time, min
PMCA	5.3×10^{-6}	3400 ± 300*	1:1 $CHCl_3/CCl_4$**	27
PMCA	1.0×10^{-5}	3500 ± 300*	1:1 $CHCl_3/CCl_4$**	17
PMCA	8.4×10^{-6}	2700 ± 300†	1:1 $CHCl_3$/IPA	40
PMCA	6.5×10^{-6}	2600 ± 300†	1:1 $CHCl_3$/IPA	91
PMMA	5×10^{-5}	5400 ± 300‡	1:3 MEK/IPA	1.5

* Original resist thickness 3700 ± 400Å and measured by scanning electron microscope.
** Blotchy and poor line edge development which was improved by replacing CCl_4 nonsolvent with IPA.
† Original resist thickness 3900 ± 300Å and measured by scanning electron microscope.
‡ Original resist thickness 6000 ± 300Å.

Our e-beam development charge densities indicate that PMCA is a significantly more sensitive resist than PMMA (see Table I). These findings are consistent with the higher observed radiation degradation susceptibilities (2, 3) observed for PMCA with respect to PMMA in other types of experiment. Since the only difference between PMMA and PMCA is the substitution of Cl for CH_3 at the α-acrylate group,

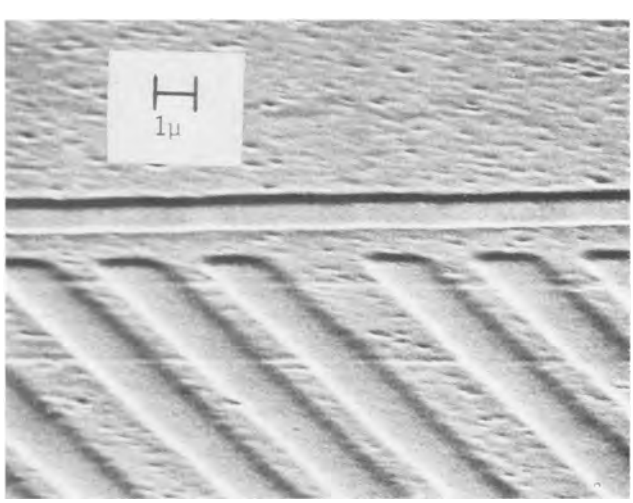

Fig. 1. Developed electron-beam etched lines in PMCA at 3800×. The substrate is a silicon wafer with a 4000Å thick oxide and the exposure dose is 8.4×10^{-6} C/cm². The other sample conditions are found in Table I and text.

the increased sensitivity in PMCA must be attributed to the chlorine substituent. The high electronegativity for chlorine is well known, and it is reasonable to expect a weakening of the main-chain C-C bond by electron polarization toward the halogen substituent (3).

Discharge Characteristic and Performance of Lithium-Silver Tungstate and Lithium-Silver Molybdate Organic Solvent Batteries

B. Di Pietro and B. Scrosati*

Istituto di Chimica Fisica, University of Rome, Rome, Italy

ABSTRACT

The discharge characteristic and performance of the Li/Ag_2WO_4 and Li/Ag_2MoO_4 couples in $LiAsF_6$-γ-butyrolactone are reported in terms of discharge mechanism, polarization, and cathode efficiency. In both cases the discharge process seems to be characterized by two distinct plateaus. Attention has been mainly focused on the first plateau of the two systems and by means of x-ray and coulometric analyses it has been possible to relate to these plateaus the electrochemical processes consisting of the formation of silver and lithium tungstate, and silver and lithium molybdate, respectively.

Lithium organic solvent batteries are of considerable technological interest since, due to their high specific energy density, they may find important applications as power sources in miniaturized electronic devices such as electric watches, hearing aids, and pacemakers. In recent years several materials have been investigated in order to select the best cathode to couple with lithium in batteries of practical use. Among these materials, silver oxyacid salts have received particular attention because of their insolubility and excellent electrochemical behavior in the most common organic electrolytes. The salts which so far have been most extensively studied are silver chromate (1) and silver phosphate (2). In this work the investigation of the cathodic behavior of the silver oxyacid salts was extended by examining the electrochemical properties of lithium-silver tungstate and lithium-silver molybdate couples in various organic electrolytes. The latter system has been partially examined by Dey and Holmes (3) who reported in a patent the utilization of silver molybdate as a cathode in lithium batteries. Nevertheless, it seemed worthwhile to reconsider the investigation of this system, especially in terms of discharge mechanism and, mainly, to compare the results with those related to the Li/Ag_2WO_4 couple which, to our knowledge, has never been investigated.

Experimental

Silver tungstate was prepared by precipitation adding a solution of silver nitrate to one of sodium tungstate. The precipitate was washed and dried at about 60°C under a purified nitrogen stream. A similar procedure was used to prepare silver molybdate. The purity of the silver salts was controlled by chemical and x-ray analyses. The results of the latter are shown in Fig. 3 and 8 for the tungstate and the molybdate, respectively. Lithium ribbon (Foote Mineral Company) was used as received. Lithium aluminum tetrachloride was prepared by melting equimolar amounts of anhydrous LiCl and $AlCl_3$ at 200°C under nitrogen (4). Lithium hexofluoroarsenate was an Alfa Ventron reagent grade product and was used without further purification.

High purity γ-butyrolactone (BL) was obtained by shaking the commercial product (Merck) in the presence of lithium to remove hydroxylate impurities. Methyl formate (MF) was purified by distillation over molecular sieves (4Å).

The electrolyte solutions, *i.e.*, 1M $LiAlCl_4$-BL, 1.5M $LiAsF_6$-BL, and 2M $LiAsF_6$-MF, prepared following the general procedure described by Campanella and Pistoia (5), were kept in a dry box where the electrochemical cells also were assembled and tested. The latter were of the "button type" and formed by placing into contact a lithium disk, three separator (glass wool) disks soaked with the electrolyte solution, and a pellet of the cathodic material. This pellet was obtained by pressing a thin layer of a mixture of the silver oxosalt and graphite [10 weight percent (w/o) of graphite] on a substrate of inert supporting metal (silver or, in the case of x-ray analyses, copper). The cells, of average total thickness of 0.3 cm and surface area of 1.25 cm^2, were then housed in a plastic container having gold-plated terminals.

The chemical, electrochemical, and x-ray analyses were carried out using standard procedures and equipment.

Results and Discussion

Lithium-silver tungstate system.—The applicability of Ag_2WO_4 as an electrode when coupled with lithium in organic electrolytes was tested by assembling the cell

$$Li/LiAlCl_4\text{-BL}/Ag_2WO_4 \qquad [1]$$

This cell has, at 22°C, an open-circuit voltage (OCV) of 3.0V and a typical polarization curve is reported in Fig. 1. This curve illustrates the ideal behavior of the system in sustaining high current densities before undergoing serious polarization. After examining the discharge capability of the Li/Ag_2WO_4 couple, the influence of the electrolyte on its performance was next considered by using $LiAsF_6$-BL and $LiAsF_6$-MF as

* Electrochemical Society Active Member.

Key words: organic solvent batteries, lithium-silver molybdate and lithium-silver tungstate systems.

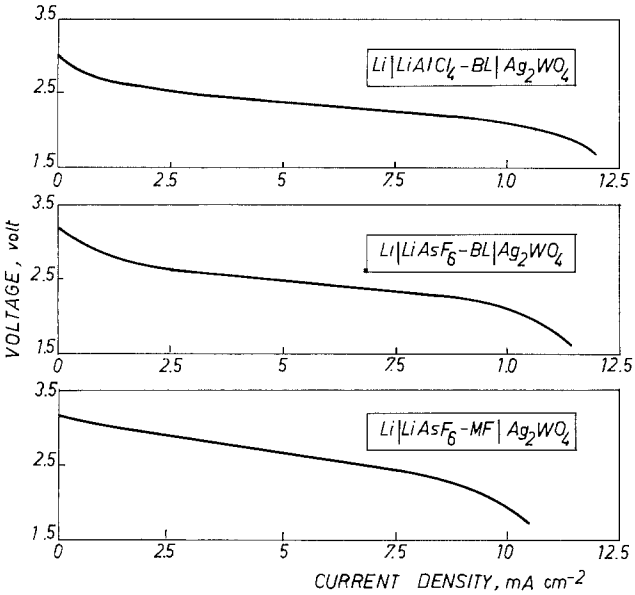

Fig. 1. Typical polarization curves of the Li/Ag_2WO_4 couple in $LiAlCl_4$-BL, $LiAsF_6$-BL, and $LiAsF_6$-MF electrolytes at room temperature.

alternative electrolyte solutions. Their typical polarization curves are also reported in Fig. 1.

The comparison indicates the cell

$$Li/LiAsF_6\text{-}BL/Ag_2WO_4 \qquad [2]$$

as the most effective both in terms of voltage and discharge characteristics. Cell [2] has in fact an OCV of 3.2V at 22°C, and a typical discharge curve (0.5 mA cm^{-2}) is reported in Fig. 2, where are also shown, again for comparison purposes, the typical discharge curves for the other two systems investigated.

It may be noted from Fig. 2 how the discharge process of cell [2] is characterized by two distinct plateaus. In order to determine the number of electrons involved in this process, a coulometric analysis was carried out. Cells containing a known amount of cathodic material (typically around 50 mg) were discharged at low rates (typically 0.25 mA cm^{-2}) and the voltage was followed as a function of time. When the voltage reached zero, the process was considered to be complete and from the coulombs delivered the number of electrons was obtained. This number, as an average of various determinations, was found to be two at the end of the first plateau and close to four at the end of the discharge.

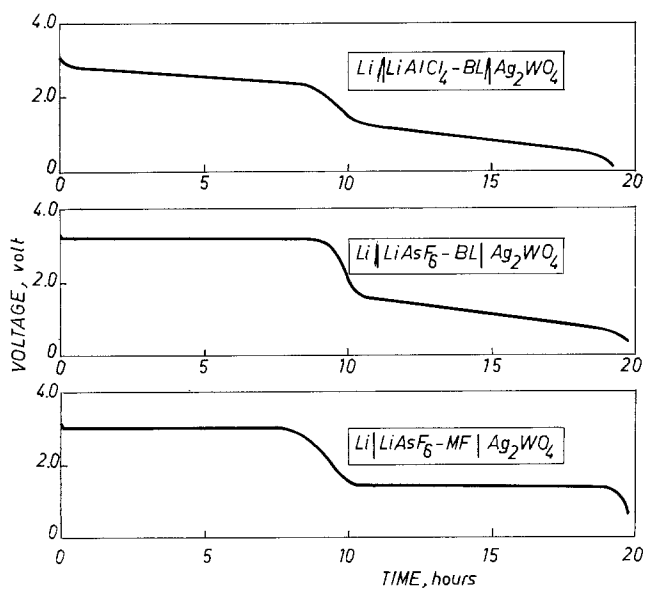

Fig. 2. Typical discharge curves of the Li/Ag_2WO_4 couple in $LiAlCl_4$-BL, $LiAsF_6$-BL, and $LiAsF_6$-MF electrolytes at 0.5 mA cm^{-2} and at room temperature. Average cathodic weight: 40 mg.

In an attempt to characterize further the electrochemical reaction, a low rate discharge of a cell similar to [2], with copper as supporting metal, was interrupted at the end of the first plateau. The cell was disconnected and its cathodic mass was submitted to x-ray analysis. The results of this analysis are schematically reported in Fig. 3 together with the diffraction patterns of the starting material (Ag_2WO_4), of silver and lithium tungstate in its most stable form in air.

It may be first noted from Fig. 3 that the lines of Ag_2WO_4 are absent in the discharge product for the initial reaction. This indicates that this reaction had proceeded to completion after the first plateau and gives further validity to the coulometric analysis. One of the basic assumptions of this analysis was in fact to consider the electrochemical reaction as complete at the end of a slow discharge.

Furthermore, Fig. 3 shows that in the x-ray diffraction pattern for the discharge product, all the lines of silver and the majority of those of lithium tungstate are present. On the basis of this result and of that of the coulometric analysis, one may assume the following

$$2Li + Ag_2WO_4 \rightarrow Li_2WO_4 + 2Ag \qquad [3]$$

as the most probable electrochemical reaction for the initial discharge of cell [2].

The investigation of the electrochemical reaction for the second plateau was carried out with a procedure analogous to that above described. After a complete low rate discharge, the cathodic mass was recovered and submitted to x-ray analysis. The results are compared in Fig. 4 with those for the discharge product

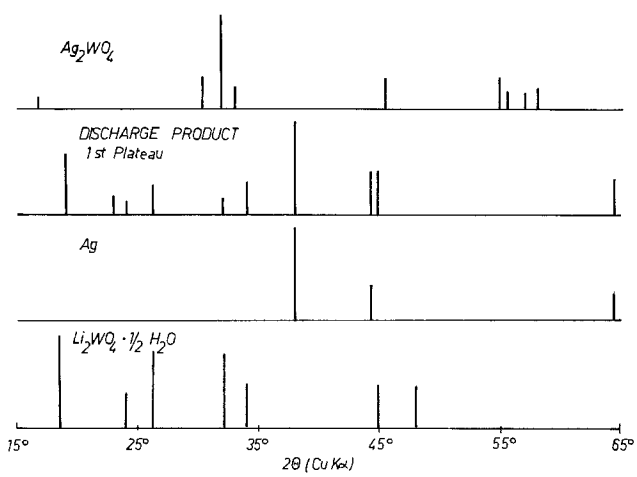

Fig. 3. X-ray diffraction patterns of the starting and discharged cathodic material of the $Li/LiAsF_6$-BL/Ag_2WO_4 cell (first plateau). Data for Ag and $Li_2WO_4 \cdot 1/2\ H_2O$ have been obtained from ASTM card indexes.

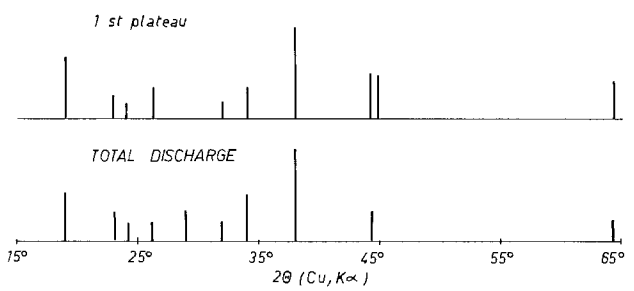

Fig. 4. X-ray diffraction patterns of the cathodic material for the $Li/LiAsF_6$-BL/Ag_2WO_4 cell after the first plateau and after complete discharge.

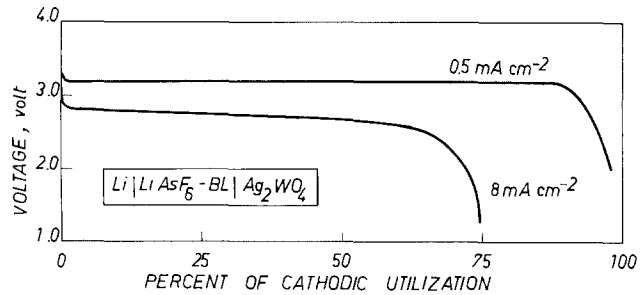

Fig. 5. Typical discharge curves for the Li/LiAsF$_6$-BL/Ag$_2$WO$_4$ cell at low (0.5 mA cm^{-2}) and high (8 mA cm^{-2}) rates and at room temperature (first plateau).

after the first plateau. There are no really substantial differences in the two patterns and therefore the reaction for the second plateau is difficult to interpret. One could tentatively imagine a lithium intercalation process and in an attempt to find evidence for this hypothesis as well as receiving additional information on the over-all cell reaction, open-circuit voltages were determined as a function of discharge depth. On the basis of four electrons change, the OCV was constant at a value of 3.20V for the discharge range from 10 to 40%, corresponding to an equilibrium voltage for reaction [3]. The OCV corresponding to the second plateau decreased monotonically from 2.70 to 1.70V over the discharge range of 60-90%. This seems to support the possibility of an intercalation compound forming as the discharge product in the second reaction. Further work is however necessary to identify this compound.

Further characterization of the Li/Ag$_2$WO$_4$ cell was therefore restricted to the first plateau which remains technologically the most interesting because of its high and constant voltage. Typical discharge curves for various rates are reported in Fig. 5. The excellent behavior of the cell is demonstrated by the fact that, even at discharge current densities of 8 mA cm^{-2}, the discharge voltage and the cathodic efficiency remain as high as 2.7V and 75%, respectively.

Finally, the performance and the energetic characteristic of silver tungstate as cathodic material in type [2] cells are summarized in Table I.

Lithium-silver molybdate system.—The electrochemical behavior of the Li/Ag$_2$MoO$_4$ couple was investigated considering the following cells

$$\text{Li/LiAlCl}_4\text{-BL/Ag}_2\text{MoO}_4 \qquad [4]$$

and

$$\text{Li/LiAsF}_6\text{-BL/Ag}_2\text{MoO}_4 \qquad [5]$$

Cells [4] and [5] showed values of 2.9 and 3.0V at 22°C and the typical polarization and discharge curves (0.5 mA cm^{-2}) are reported in Fig. 6 and 7, respectively.

From Fig. 7, the discharge process of the Li/Ag$_2$MoO$_4$ couple also appears to be characterized by two plateaus, even if not so sharply defined as in the Li/Ag$_2$WO$_4$ case. The electrochemical characterization of the process, based on coulometric analyses, indicated a value

Table I. Performance and energetic characteristic of Ag$_2$WO$_4$ and Ag$_2$MoO$_4$ coupled with lithium in LiAsF$_6$-BL electrolyte at room temperature (first plateau only)

	Ag$_2$WO$_4$		Ag$_2$MoO$_4$

Specific capacity (A-hr/g)	0.115	0.075	0.145	0.070
Mean discharge voltage (V)	3.2	2.7	2.8	2.1
Specific energy density (W-hr/g)	0.370	0.200	0.410	0.150
Efficiency (percent)	98	75	98	50

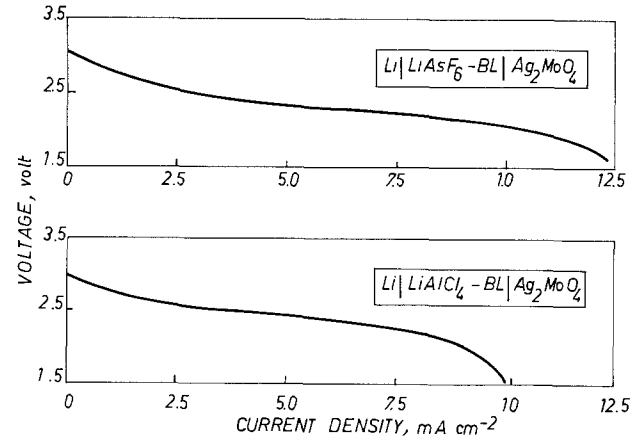

Fig. 6. Typical polarization curves for the Li/Ag$_2$MoO$_4$ couple in LiAsF$_6$-BL and LiAlCl$_4$-BL electrolytes at room temperature.

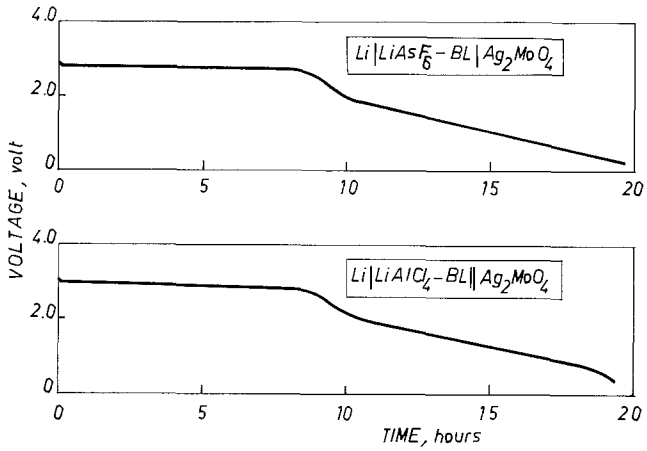

Fig. 7. Typical discharge curves for the Li/Ag$_2$MoO$_4$ couple in LiAsF$_6$-BL and LiAlCl$_4$-BL electrolytes at 0.5 mA cm^{-2} and at room temperature. Average cathodic weight: 40 mg.

of two electrons at the end of the first plateau and of about four at the end of the discharge. The x-ray diffraction patterns of the cathodic mass recovered after the first plateau are reported in Fig. 8, where the diffraction patterns of silver molybdate, silver, and lithium molybdate are also schematically shown. On the basis of the above-reported analyses, one may then assume the following

$$2\text{Li} + \text{Ag}_2\text{MoO}_4 \rightarrow \text{Li}_2\text{MoO}_4 + 2\text{Ag} \qquad [6]$$

as the most probable electrochemical reaction associated to the first plateau of the discharge of cell [5].

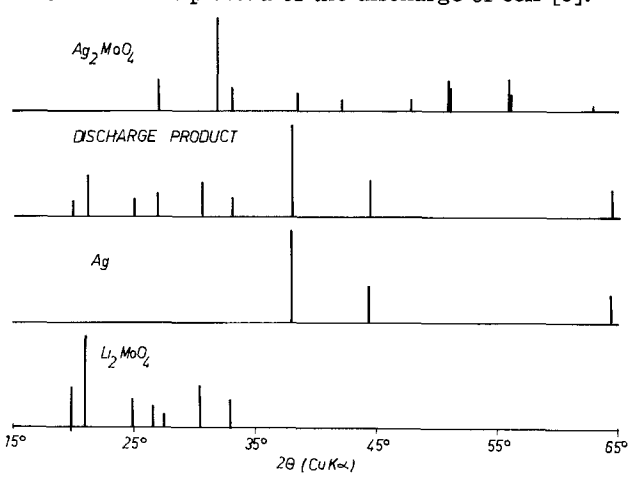

Fig. 8. X-ray diffraction patterns of the starting and discharged cathodic material (first plateau) for the Li/LiAsF$_6$-BL/Ag$_2$MoO$_4$ cell. Data for Ag and Li$_2$MoO$_4$ have been obtained from ASTM card indexes.

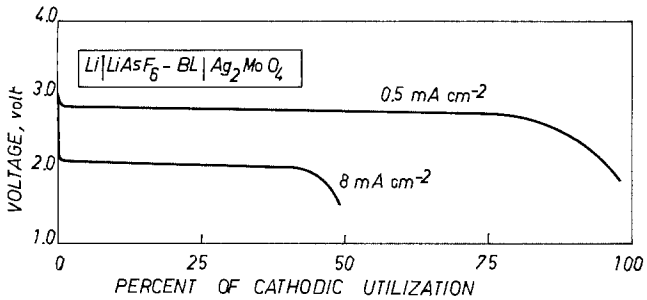

Fig. 9. Typical discharge curves for the $Li/LiAsF_6$-BL/Ag_2MoO_4 cell at low (0.5 mA cm^{-2}) and high (8 mA cm^{-2}) rates and at room temperature (first plateau).

In this case also attention was focused on this plateau due to its high constant voltage, as illustrated by the typical discharge curves of cell [5] at various rates reported in Fig. 9. It may be noted how the voltage of this cell remains always slightly inferior to that of the Li/Ag_2WO_4 cell discharged under comparable conditions (see Fig. 5). In this respect silver tungstate appears to be a more interesting cathode than silver molybdate. On the other hand, the latter shows better energetic characteristics, as indicated by the results in Table I where the performances of the two cathodic materials are compared.

The preference of one of the above-mentioned silver oxosalts would then depend on the type of application. In view of proper technological applications, additional studies may be required for thoroughly defining the stability and the shelf-life of the two systems. These studies are in progress in our laboratory.

Reaction of the Gallium Analog of β''-Alumina with Water

L. M. Foster* and G. V. Arbach

IBM Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The reaction of the gallium analog of β''-Al_2O_3 with moisture was investigated. This material in finely divided form reacts rapidly with moisture from humid atmospheres to pick up approximately 1 mole of water for each gram-atom of sodium. The water uptake is accompanied by an expansion in the c axis of 11-12%. Monocrystals of the β''-gallate do not show measurable water pickup, and particles of intermediate sizes show intermediate degrees of pickup. The size effect is explained as peripheral attack of water on the crystal, which ceases after a fixed penetration depth. An association of water molecules with the sodium ions to form a complex such as $(NaH_2O)^+$, which increases the coordination of the site, is suggested as the reaction mechanism.

The layered sodium aluminates, β- and β''-alumina, have analogs in the Na_2O-Ga_2O_3 system (1). These gallium-based materials exhibit similar fast ion conduction (2), easy exchange of the alkali ion (3), strongly anisotropic properties, and other characteristics of the alumina prototypes. In particular, they exhibit a sensitivity to moisture similar to some preparations of β- and β''-alumina, but to a greatly enhanced degree.

Moisture take-up by the β-aluminas is a serious technological problem, since it can result in loss of strength and conductivity and eventual deterioration of the formed and sintered bodies that are employed as the conducting separators between the anode and cathode compartments of sodium-sulfur batteries, such as are under development both in the United States and abroad.

There are statements throughout the industry that the β''-form of the sodium aluminate appears to exhibit a greater sensitivity to moisture than the β-form. One must be careful in making this assessment, however, since it is not possible to compare the two materials in identical form. β''-Al_2O_3 transforms to β-Al_2O_3 at about 1500°-1600°C. A sintered ceramic body produced in the β''-phase field will not have the same physical properties, such as grain size, porosity, surface area, etc., as one sintered at a considerably higher temperature in the β-phase field. Moreover, there is usually a change in the Na_2O/Al_2O_3 ratio during this transformation that could result in the formation of a second phase. These extraneous effects could greatly affect moisture sensitivity even though there were no intrinsic differences between the two pure materials. The latest report of the Ford Motor Company effort on the Na-S battery (4) suggests that the sensitivity of β''-Al_2O_3 to moisture is due largely to the presence of the very hygroscopic $NaAlO_2$ at the grain boundaries of the sintered body. This material occurs because of incomplete conversion of the sample to β''-Al_2O_3 at the firing temperature. They found that if the β''-phase is stabilized by the addition of Li_2O so that firing can be carried out at higher temperatures, the conversion to β'' is more complete and the sensitivity to moisture is greatly reduced. Other workers maintain, however, that there is still a

* Electrochemical Society Active Member.

Key words: ionic conductors, sodium gallates, solid electrolytes.

difference in sensitivity between β and β'', irrespective of these complicating factors (5).

The present work is concerned with behavior of the β''-phase of sodium gallate in the presence of moisture. This material was obtainable as pure, large monocrystals, well characterized as to composition, composition uniformity, and the absence of extraneous phases which could complicate interpretation of the results. Information obtained about moisture reaction with this gallium analog will be useful in understanding the moisture problem with the aluminum-based battery separators.

Experimental

Some of the sodium gallate samples that were prepared early in the present study showed a remarkable sensitivity to moisture without parallel in the Na_2O-Al_2O_3 materials. The samples were polycrystalline aggregates obtained by prereacting Na_2CO_3-Ga_2O_3 mixtures, followed by pressing and sintering to form a ceramic body. Some samples of this material would completely deteriorate to powder on standing for a few hours in room air of moderate relative humidity. X-ray powder diffraction examination of the product showed substantial loss of structure, as evidenced by line broadening and a general diffuseness of the pattern. Reaction of alkali oxides with water is in itself not surprising except that in the present cases the moisture was re-evolved and the original highly crystalline character was completely restored by brief heating at 200°-300°C.

The equivalent of the sodium aluminate, $NaAlO_2$, which was held responsible for moisture sensitivity of some β''-Al_2O_3 preparations by the Ford workers, exists in the Na_2O-Ga_2O_3 system as well. This material is also very reactive with water. In the latter system, however, there are two additional phases that are not present in the Na_2O-Al_2O_3 system. These are $3Na_2O \cdot 5Ga_2O_3$ and $Na_2O \cdot 3Ga_2O_3$. $NaGaO_2$ was never encountered in our sintered preparations of β'' sodium gallate that were used in the early studies. If reaction to β'' was incomplete only $3Na_2O \cdot 5Ga_2O_3$ and/or $Na_2O \cdot 3Ga_2O_3$ was found as the second phase. In separate experiments each of these compounds was found to be totally inert to moisture and, if admixed with sintered β''-samples, could not result in spurious behavior with water. Nevertheless, because of the difficulty in fully characterizing those early sintered samples, particularly with regard to the possible presence of small amounts of extraneous phases, emphasis was changed to investigation of single phase, monocrystalline samples. Monocrystalline β''-sodium gallate was prepared by Na_2O vaporization from soda-rich Na_2O-Ga_2O_3 melts. The details of this procedure will be published elsewhere.

Moisture sorption experiments.—Moisture take-up was determined by weight gain of approximately 0.25g samples, as measured with a Cahn recording microbalance. Relative humidity was maintained constant in the balance envelope at 50% with continuously stirred H_2O-H_2SO_4 solutions. Each material was dried at 300°C prior to exposure to moisture. It had been established that this treatment would restore the dry weight of any sample that had taken up moisture during grinding or storage. All sorption experiments were made at room temperature.

Figure 1 shows the weight gain of β''-sodium gallate samples expressed as moles of H_2O per gram-atom of sodium. The various curves are for samples of different particle size. The reason for investigating the behavior of various-size particles will be apparent in the discussion below. The materials were obtained by starting with a monocrystal, which actually showed too little weight gain to appear on the plot (bottom, dashed curve), and then grinding similar monocrystals and screening the material to the sieve fractions indicated on the other curves. The smallest fraction (top curve) was passed through a 325 mesh sieve, with no attempt being made to establish the lower size limit.

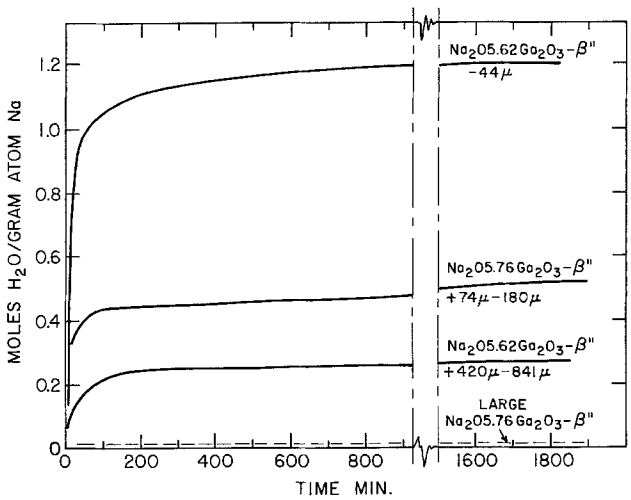

Fig. 1. Moisture take-up as a function of particle size in β''-sodium gallate.

The moisture take-up curves for the β''-gallate do not actually arrive at zero slope in any reasonable time. In one case a sample of the <44 μm material was left in 50% humidity air for 300 hr at which time it had taken up 1.82 moles of H_2O per gram-atom of Na and was still rising extremely slowly.

If a sample that had been carried through a sorption run was heated to 200°-300°C to restore its original weight and then exposed to the humid atmosphere again, the second sorption curve would essentially retrace the first. If there was a difference, it would be as an even sharper knee after the initial very rapid pick-up.

The composition of the crystals was obtained by spectrophotometric determination of sodium compared with that of suitable standards. These gallium materials are completely soluble in hot 50% HCl-H_2O mixtures, and the analysis is straightforward. The two different compositions shown in Fig. 1 are for two different lots of crystals. Their spread (*ca.* ± 1%) is considered to be well within the precision of the determination.

X-ray diffraction analysis.—Crystallographic changes that accompanied the sorption of moisture were observed by x-ray powder diffraction analysis, using nickel-filtered Cu-Kα radiation. The pattern of as-grown β''-$Na_2O \cdot 5.76Ga_2O_3$ is shown in Fig. 2 (top). The structure is rhombohedral with the $R\bar{3}m$ space group. The lattice parameters are $a = 5.84$Å, and $c = 34.53$Å. The pattern of a <44 μm sample that had taken

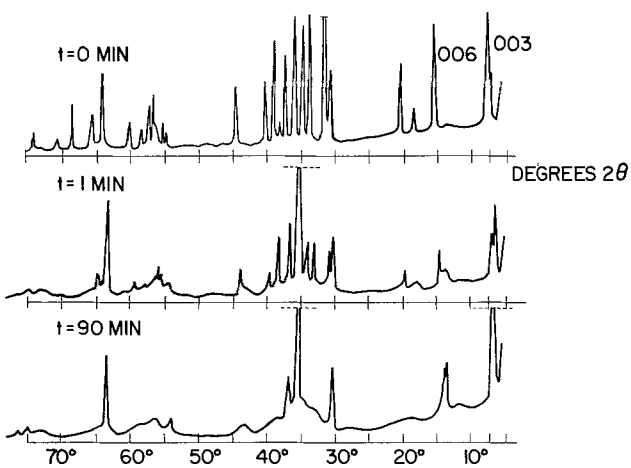

Fig. 2. X-ray diffraction patterns of β''-sodium gallate as a function of time of exposure to 50% humidity air.

up moisture more or less to saturation, and then been redried at 300°C, would be identical. The parameters for the corresponding β''-Al_2O_3 are $a = 5.61$Å, and $c = 35.85$Å (6).

Figure 2 (center) is for a <44 μm sample that had been exposed to humid room air for 1 min. The conspicuous change that has occurred is a general broadening and loss of intensity of the (hkl) reflections with the exception of the (001) which remain narrow but are being replaced by another set corresponding to a new c axis spacing 10-11% larger. Figure 2 (bottom) shows this change complete after 90 min exposure to moisture.

The powder diffraction pattern of the large monocrystal of Fig. 1 after exposure to moisture was identical to Fig. 2 (top), confirming the fact that there had indeed been no water pickup. The patterns for the other two samples of intermediate particle size showed mixtures of "wet" and "dry" phases.

Discussion

The attack of moisture on the β-aluminas that are under development as solid electrolytes for Na-S batteries was early recognized as an important technological problem that had to be overcome. There is still an opinion in the industry that this moisture sensitivity is an intrinsic property of the pure materials (5, 7), and not entirely attributable to extraneous phases, grain boundaries, etc., that reflect the method of preparation of the sample, as has been suggested by others (4). The exceptionally rapid attack of moisture on pure single phase β''-sodium gallate that was observed in the present study shows that this view is unquestionably true, at least in the case of the gallium analog.

The course of the curves of Fig. 1 indicates that water pickup is not determined by a simple diffusion mechanism, for that would allow particles of any size to reach the same level of saturation, given sufficient time. In the short-time regime of the curves, approximately up to the knee, the weight gain very roughly varies directly as the time. After the knee, the water take-up occurs much more slowly. This suggests a surface sorption, although the surface would have to be extremely rough or very deep to account for the amount of water pickup.

The fact that moisture pickup had essentially ceased in the three coarsest samples of Fig. 1, even though large proportions of the samples were still unattacked, as evidenced by the presence of the "dry" phase in their x-ray diffraction patterns, suggests that water diffuses into the surface to some fixed distance, then stops. Assume that the moisture diffuses only along the c planes, and that it penetrates to a depth that is just sufficient to saturate the smallest size fraction, *i.e.*, 44/2 = 22 μm. Then the expected weight gains are calculated as 56, 14, and ≃0% of that of the <44 μm fraction for the >74, <180 μm, >420, <841 μm, and large monocrystal, respectively, in reasonable agreement with the 45, 23, and ≃0% that were calculated from the sorption curves. For these calculations the particle size was taken to be the average for each size fraction.

A very surprising observation was made when a moisture sorption experiment was attempted with particles of a sieve size intermediate between the <44 and >74, <180 μm sizes shown in Fig. 1. Upon exposure to the humid atmosphere, the sample immediately began to lose weight and it was observed that particles were flying out of the sample basket. It was apparent that when particles with a surface-to-volume ratio of some critical value encounter moisture, the strain that sets up around the edges of the highly anisotropic bodies is sufficient to cleave them along the c planes, almost explosively. In smaller particles only small strains can be tolerated before the pieces fall apart and allow access of moisture to all parts; in larger particles the strain is insufficient to cleave them. It was a common observation, however, that even large monocrystals of the β''-gallate frequently cleaved when subjected to small stresses such as encountered during handling and, especially, during sawing. This effect is now understood to be the result of moisture that has penetrated along the c planes to a fixed depth. This places that portion of the crystal under a large compressional stress which, in turn, places the unpenetrated portion under high tensile stress. In this condition, the crystal is very susceptible to cleavage when subjected to additional external stresses.

The mechanism for the entry of water molecules into β''-crystals, and the reason for the penetration ceasing at a fixed depth, is not fully understood at this time and is the subject of continuing study. It is assumed that moisture attack is initially at high energy sites, possibly steps, on the surface. Once the water sites become filled at those locations, no further water can penetrate that volume of the crystal but must diffuse along the misfit dislocation bordering the damaged volume. As these islands of penetrated crystal grow both inwardly and laterally, they eventually coalesce to annihilate the threading dislocations between adjacent islands, thereby preventing further penetration at those points. The final result of such a process would be a crystal which is now impervious to more water, whose edges are under compressional stress due to their water content, and whose center is thereby under tension stress. Similar behavior has been observed in other materials such as MgO monocrystals when exposed to moisture (5).

We will now look at the sites into which water molecules might go. Figure 3 shows three oxygen layers, including the conduction plane, in the β'' precursor structure. If the B plane were filled with oxygens in close-packed arrangement, there would be three more atoms in the positions marked +, and the cubic close-packing sequence of ABC would be maintained through the conducting plane. The three + sites are empty, however, and become the midoxygen (MO) sites between the B plane oxygen (open circle) and similar oxygens in the two adjacent cells.

In the β-Al_2O_3 structure, the two sodium sites, which are in the same positions within a plane as in Fig. 3, are nonequivalent, with the lower energy site, the Beevers-Ross(BR) site, alone being occupied in the

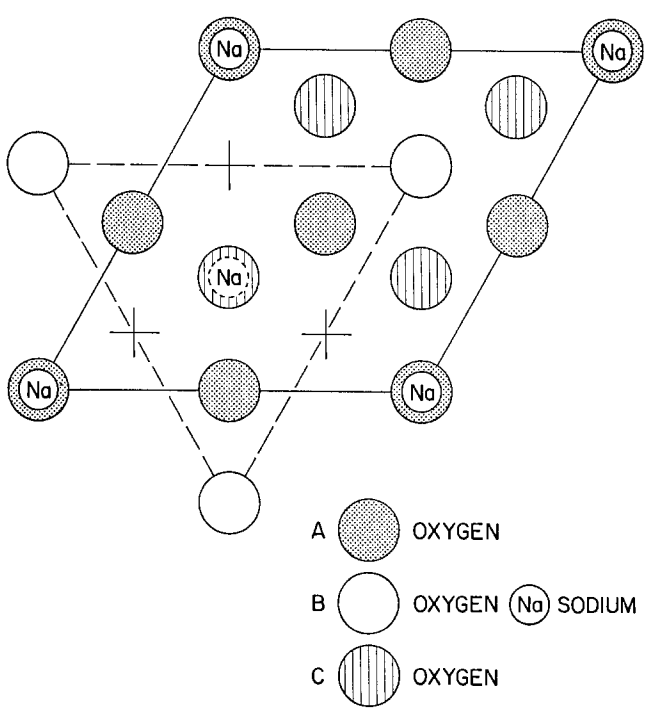

Fig. 3. Three oxygen layers, including the bridging oxygen, of the β''-structure (looking along c axis).

ideal $Na_2O \cdot 11Al_2O_3$ crystal (8). In the actual crystal, which appears to always have excess sodium, the excess goes mostly into the (MO) sites rather than into the second Na site, the anti-Beevers-Ross (ABR) site.

In the β''-structure, because of the different crystal symmetry, the two sodium sites are equivalent, and statistically equal occupancy is expected. The sodiums in both sites are in tetrahedral coordination, with the one shown within the cell in Fig. 3 being immediately below an oxygen of the C plane and above the center of the triangle of oxygens of the A plane, and the corner sodiums being in the reverse situation. The maximum sodium content of the β''-structure is thus twice that of the ideal β-structure, or $Na_2O \cdot 5.5Ga_2O_3$ for the gallium analog. The (MO) positions are also possible sites for sodium in the β''-structure and, in fact, are probably substantially occupied. However, because of repulsion by like charges, it seems highly unlikely that two "normal" Na sites and the (MO) site between them could be occupied simultaneously and, on the average, only two of the three can be occupied at a given time.

As the formula $Na_2O \cdot 5.5Ga_2O_3$ is written, the charge of the additional Na is compensated by oxygen. In the older β-Al_2O_3 literature this was not thought necessarily to be the case, and compensation by aluminum vacancies was proposed as an alternative (6). More recent work of Roth *et al.* (9) has shown, however, that in β-Al_2O_3, at least, compensation of sodium over and above the $Na_2O \cdot 11Al_2O_3$ composition is accomplished by additional oxygen atoms in the conducting plane.

If the mechanism of charge compensation is the same in the β''-structure, ½ oxygen on the average would have to be added per plane in one of the (MO) sites for the formula $Na_2O \cdot 5.5Ga_2O_3$. Roth *et al.* (9) proposed that this was accomplished by M^{+++} ions in the octahedral sites on each side of an (MO) position moving toward the conducting plane and bonding together across the plane through the new oxygen atom. Each new oxygen bridge would thus fill one more close-packed oxygen site in the B layer of Fig. 3. For the β''-formula with the maximum possible sodium, $Na_2O \cdot 5.5Ga_2O_3$, there would thus be $3 - ½ = 2½$ (MO) sites and $2 + ½(2) = 3$ empty octahedral holes (1 on each side of the original oxygen bridge, and ½ on each side of the ½ new oxygen bridge) as possible sites for water molecules.

The actual average analysis of a number of β''-sodium gallate crystals that were used in the present study was $Na_2O \cdot 5.7Ga_2O_3$. This is 1.93 Na atoms per plane, or 0.93 more than in the β-$Na_2O \cdot 11Ga_2O_3$ structure. Thus, there is slightly less sodium than the maximum of 2 atoms per plane that can be accommodated by the structure. This additional 0.93 Na requires 0.465 additional oxygen atoms per plane for charge compensation, which requires that $2 \times 0.465 = 0.93$ Ga atoms (0.465 from each side of the plane) move from their octahedral sites to form the new oxygen bridge. This fills 0.465 (MO) sites to compensate the $¼ \times 4 = 1$ Na atoms that go into the cell corners, and leaves $3 - 0.465 = 2.535$ (MO) sites open per plane.

If these (MO) sites filled with water indiscriminately, there would be a continuous weight gain to 2.535 moles of H_2O per 1.93 gram-atom of Na, or a ratio of 1.31 to 1. The $2 + 0.93 = 2.93$ octahedral holes could accommodate more water to give a total weight gain of $2.535 + 2.93 = 5.465$ moles of H_2O per 1.93 gram-atom of Na, or a ratio of 2.83 to 1.

The above calculations show that there is more than enough space in the conduction plane of the β''-lattice to accommodate a water molecule for each Na atom, and that a discontinuity in the water curve might be expected if such an association occurs. Another break might be expected at 1.31 to 1 when the remainder of the (MO) sites is filled, followed by termination of absorption at 2.83 to 1 when the octahedral sites are full. Only the first was observed in the experimental curve, and it is concluded that the principal interaction of the water is to form a 1 to 1 coordination complex of H_2O with the Na^+ ion. The alkali in the β''-structure is in fourfold coordination as compared to sixfold in the β-structure and eightfold in the (MO) sites. It is a general rule of thumb that a complex will form at a site if by doing so the coordination at the site is increased. Perhaps the action of water is to form a complex analogous to hydronium ion, H_3O^+, *i.e.*, $(NaH_2O)^+$, as had been suggested by Roth and Mitoff (10).

If a hydrate of well-defined composition results when a water molecule bonds to Na, one might expect a sharp x-ray diffraction pattern of this new phase. The fact that this was not observed, as shown in Fig. 2, bottom, indicates that structural changes are occurring in addition to extension of the c parameter. Rotation of spinel-like blocks with respect to each other in a somewhat ill-defined manner could account for the changes.

Filling of the remaining sites in the β''-structure is clearly very difficult and the process is so slow that nothing can be learned from that part of the sorption curve to shed light on the mechanisms involved. In the one experiment where moisture sorption had reached 1.86 moles of H_2O per gram-atom of Na in 300 hr, one could imagine that the curve might be asymptotically approaching 2.83, as required for complete site filling, but it would clearly require several months to demonstrate.

Because of the great similarity between the β''-gallate and β''-Al_2O_3, it is expected that moisture sensitivity of the latter material must also be a property of the pure substance, and that all of the observations of degradation of β''-Al_2O_3 bodies by water cannot be attributed to the presence of impurities and extraneous phases alone.

The Behavior of Lead Alloys as PbO_2 Electrodes

Thomas F. Sharpe*

General Motors Corporation, Research Laboratories, Warren, Michigan 48090

ABSTRACT

An understanding of the corrosion behavior of lead alloys is important because grid corrosion affects the cycle life of the positive plate of the lead-acid battery. Comparisons between pure lead, lead-antimony, and lead-arsenic alloys in various electrochemical studies are discussed in terms of effects of the alloying element on the development and subsequent discharge behavior of PbO_2 in H_2SO_4 electrolyte.

In a previous study (1), low-rate (~0.5 mV/sec) cathodic potential sweeps were carried out on a preanodized antimonial (Pb-4.5%Sb-0.6%Sn) and a nonantimonial (Pb-0.06%Ca-0.6%Sn) alloy to elucidate their behavior near the $PbO_2/PbSO_4$ potential. The cathodic sweep profiles were sensitive to the potential and time of anodic treatment and reflected the buildup of α- and β-PbO_2 in the corrosion film. More importantly, the cathodic sweeps were markedly different for the two alloys for a given anodic pretreatment, which could be ascribed, in part, to an effect of antimony in lowering the rate of forming β-PbO_2 during the anodic pretreatment. That effect was suggested to partially account for the substantial increase in positive plate cycle life when using antimonial grids.

To further elucidate the mechanism by which antimony prolongs positive plate life, these studies were extended to determine the effect of antimony concentration in the alloy, and to compare the effect of antimony and arsenic in the alloy on the behavior of lead as a PbO_2 electrode.

Experimental

Alloys were prepared in ~1 kg master ingots using 99.99+% lead and reagent grade metals. Portions of the ingots were used for the casting of test electrode tabs having a geometric area of 4 cm^2 exposed to the electrolyte.

The full anodic scans extended from the hydrogen evolution region (−1500 mV *vs.* Hg/Hg_2SO_4) to the oxygen evolution region (1600 mV *vs.* Hg/Hg_2SO_4) and were obtained immediately after maintaining the electrodes at −1500 mV *vs.* Hg/Hg_2SO_4 for 0.3 ksec (5 min).

Following the constant potential anodic treatments at values above the $PbO_2/PbSO_4$ reversible potential, the electrodes were discharged either by a cathodic voltage sweep (as previously described) (1) or by an arbitrary constant current of 1.5 mA. The constant current discharge was started within 10 sec after completion of the anodic treatment.

Results

A number of anodic sweeps are shown in Fig. 1. The intensity of the anodic current peak for the Pb → $PbSO_4$ reaction, occurring just above the $Pb/PbSO_4$ reversible potential, was not appreciably affected by either arsenic or antimony at the concentration levels considered in this study. The increase in current above *ca.* 1200 mV is due to PbO_2 formation and oxygen evolution. The anodic peak at −325 mV (Fig. 1-A) is ascribed to the oxidation of antimony in the alloy, with the peak intensity increasing with an increase in antimony concentration. The anodic current peak for oxidation of arsenic in the alloy occurs at −90 mV (Fig. 1-B). That current peak was just discernible at an arsenic concentration of 0.25%.

Cathodic sweeps following 3.6 ksec (1 hr) control at various potentials are shown in Fig. 2, and examples showing the effect of sweep rate following anodic control are given in Fig. 3 and 4. As discussed previously (1), the sweeps are influenced by an anodic reaction occurring at nearly the same potential as the PbO_2 discharge, so that they often exhibit a peculiar oscillatory behavior. In these sweeps, the anodic peaks a are believed to be part of a continuous anodic current profile (as represented schematically by the broken line in Fig. 5) that becomes masked by the buildup of the major cathodic peak b (β-PbO_2 → $PbSO_4$ discharge peak) and the sporadic minor peak c (α-PbO_2 → $PbSO_4$ discharge peak).

At the higher sweep rates and generally following control at high potentials, there is an additional minor cathodic peak (arrow, Fig. 3), at potentials above the β-PbO_2 discharge peak. This peak is believed to be associated with the desorption of excess oxygen reported (2) to exist in these corrosion films.

The effect of antimony additions to pure lead on the shape of current-time (i-t) curves during a constant potential treatment is shown in Fig 6-A. In the case of pure lead, the major process at that potential is oxidation of $PbSO_4$ to β-PbO_2, as indicated by the single current peak in the i-t curve (3). With increased antimony concentration, the current peak has shifted along the time axis and has almost disappeared at the 3.8% Sb concentration level. At 8.2% antimony, the marked

increase in current is presumably due to antimony oxidation.

Cathodic potential sweeps obtained after the anodic treatment of Fig. 6-A are shown in Fig. 6-B. These were somewhat sensitive to an antimony concentration at least as low as 2.2%, and displayed a marked reduction in "reactivity" at the 3.8 and 8.2% level. Sweeps following 3.6 ksec (1 hr) control at various potentials for the higher concentrations of antimony are given in Fig. 7, to be compared to those for pure lead in Fig. 2. An interesting result is shown in Fig. 8 for the Pb-3.8% Sb alloy, where the measured current in the sweep (solid line) switches from primarily anodic to primarily cathodic values as the sweep rate is increased. The sweeps in Fig. 8 and in Fig. 3 (for pure lead) were obtained following the minimum time required at the high potential (1600 mV) of anodic pretreatment before significant reactivity was observed (*e.g.*, 0.90 ksec for antimonial lead *vs.* 0.18 ksec for pure lead). For shorter anodic pretreatment, the current in the sweeps was linear and very slightly (<0.5 mA) anodic.

Current-time curves showing the effect of arsenic concentration are exemplified by Fig. 9. The curves are markedly distorted evidently because of background currents due to oxidation of arsenic in the alloy. Examples of cathodic sweeps following anodic treatment, Fig. 10, show that the net current shifts in the anodic direction with increasing arsenic concentration.

In a number of experiments, electrodes were discharged by a constant current following the anodic treatment. These were intended to supplement the cathodic sweeps especially in instances when it was not obvious from the sweeps whether dischargeable PbO_2 had been produced during the anodic pretreatment. The discharges were characterized by two potential plateaus about 30 mV apart (4, 5), occurring just below the $PbO_2/PbSO_4$ reversible potential. For pure lead, the growth of the upper plateau with time of anodic pretreatment was observed to be in proportion to growth of the major cathodic current peak (peak b, Fig. 2) in the cathodic potential sweeps. The lower discharge plateau was always less than 10% of the length of the upper plateau and may be related to the minor cathodic peak (peak c, Fig. 2) in the potential sweeps.

Discharge capacities of the anodically formed PbO_2, calculated from the length of the upper plateau, are given in Table I.

Discussion

An important aspect is the anodic current peaks that appear in the cathodic potential sweeps. A number of sweeps (*e.g.*, Fig. 2-4) suggest that each anodic peak might be treated as an entity, but this leads to difficulty when attempting to explain their buildup and

decay as a function of anodic pretreatment and sweep rate. It is felt that the results can be explained according to the schematic in Fig. 5, where the anodic peaks result from the subtraction of cathodic peaks for the PbO_2 discharge reaction from a continuous background anodic current profile extending throughout the PbO_2 discharge potential region. As greater quantities of dischargeable PbO_2 are formed (Fig. 2), a greater portion of the anodic current profile becomes masked. As the sweep rate is increased (Fig. 3 and 4), both the anodic current profile and the current for β-PbO_2 discharge are enhanced because of diffusion effects, and the β-PbO_2 discharge becomes shifted along the anodic current profile to more negative potentials because of irreversibility.

The anodic current profile would indicate that there is further substrate corrosion during the PbO_2 discharge, since anodic currents are not observed in cathodic potential sweeps for PbO_2 in contact with inert substrates (6). It has been pointed out by Rüetschi (8) that $PbSO_4$ films on lead can act as perm-selective membranes which become impermeable to $SO_4^=$ and HSO_4^- when they have reached a thickness of 1 to several microns. Under that condition, further corrosion of the lead substrate would occur by dissociation of water underneath the $PbSO_4$, precipitation of anodically generated Pb^{2+} in the form of PbO, and the migration of H^+ ions away from the electrode interface. In the present studies, it is postulated that in the cathodic potential sweeps, the $PbSO_4$ forming on the surface of the discharging PbO_2 may possess such perm-selectivity, so that OH^- ions become localized in the interior of the corrosion film and are the species involved in the diffusion process to give the anodic current profile reaction

$$Pb + 2\,OH^- = PbO + H_2O + 2e^-$$

Effect of alloying elements.—In the anodic voltage sweeps (Fig. 1), it is observed that the alloying element reacts at potentials significantly below the PbO_2/$PbSO_4$ reversible potential, so that the element may become depleted from reaction sites before overvoltages for PbO_2 formation are reached. This could account for the observation (7, 9) that when using such an anodic treatment, antimony has no measurable effect on the

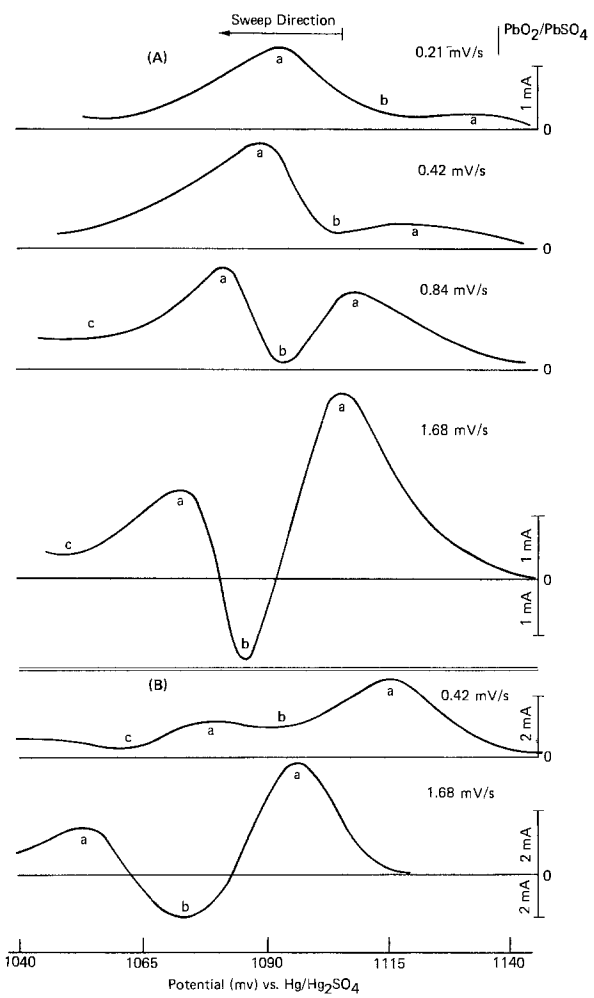

Fig. 4. Effect of cathodic sweep rate on pure lead following anodic control at (A) 1500 mV *vs.* Hg/Hg_2SO_4 for 10 min, (B) 1300 mV *vs.* Hg/Hg_2SO_4 for 1 hr. Electrolyte = 1.26 sp gr H_2SO_4; electrode area = 4 cm^2.

development or subsequent discharge behavior of PbO_2. In the present work, however, effects are evident when the alloy is immediately polarized and potentiostated above the $PbO_2/PbSO_4$ reversible potential. That situation would insure reaction of the alloying element in parallel with the development of PbO_2 and is therefore believed to simulate more closely the condition during electrochemical formation of the positive plate.

The effect of increasing antimony concentration on the shape of i-t curves during constant potential treatment above the $PbO_2/PbSO_4$ reversible potential is presumed to be caused by a shift from oxidation of $PbSO_4$ to β-PbO_2 as the major process to oxidation of antimony as the major process. At the potential indicated in Fig. 6-A, the current peak for $PbSO_4$ oxidation has almost disappeared at the 3.8% level, an observation similar to that in earlier work (1) for a 4.5% antimonial alloy.

A treatment of the effect of antimony on the cathodic potential sweeps is complicated by factors such as changes in electrode true surface area and the net currents involved, so that precise determinations of the onset of reactions, current peak areas, etc. is not feasible. In some instances, it appeared that the cathodic current peak for PbO_2 discharge was "buried" in the anodic current profile; an example of this is represented by the uppermost curve in Fig. 8 where one might conclude that there is no PbO_2 discharge (current is a smooth anodic wave). However, the cathodic

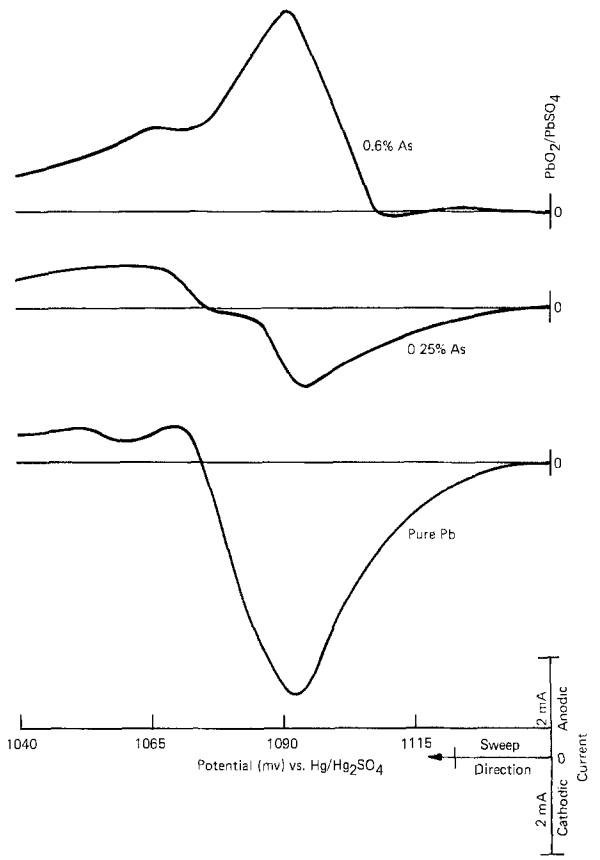

Fig. 10. Effect of arsenic on cathodic sweeps at 0.42 mV/sec following 1 hr anodic control at 1600 mV *vs.* Hg/Hg_2SO_4. Electrolyte = 1.26 sp gr H_2SO_4; electrode area = 4 cm^2.

peak may grow along a profile approximated by the broken lines. This hypothesis is made in context with the curves for the faster sweep rates (which would enhance the cathodic peak) and the observation that on other electrodes, capacity could be obtained in a constant current discharge following the same anodic pretreatment (see Table I).

In view of the complexities, it is yet possible to speculate on the behavior of antimony in accord with the schematic proposed in Fig. 5: At the 2.2% level, there is slightly greater irreversibility in the PbO_2 discharge from that observed on pure lead at a comparable sweep rate, so onset of the major cathodic peak is shifted very slightly along the anodic current profile. At the 3.8 and 8.2% level, the sweeps are consistent with a significant decrease in dischargeable β-PbO_2. The results of Fig. 7, when compared to Fig. 2 for pure lead, confirm an earlier (1) observation that significantly higher anodic pretreatment potentials are required before PbO_2 discharge is indicated in the cathodic sweeps.

At the higher concentrations of antimony, there is also an indication that the nature of the anodic current profile is altered from that for pure lead. This is especially emphasized by comparing the sweeps of Fig. 8 with those of Fig. 3 which were obtained following the incipient formation of PbO_2. For the antimonial alloy, the cathodic peak can be envisioned as a growing along an anodic current profile that is less intense and less dependent on sweep rate than that for pure lead, *i.e.*, the PbO_2 behaves as if it is being discharged from a more inert substrate. Such a condition would be favored if there is less tendency for the proposed Pb → PbO reactions to occur during the cathodic sweeps. Hampson *et al.* (9) obtained electrical impedance measurements on pure lead and lead-antimony binary alloys which could be interpreted in accord with a reduction in thickness and an increase in porosity of the corrosion films with increasing concentrations of antimony. Such a condition may lead to corrosion films having lower perm-selectivity (8) and therefore reduced alkalinity in the film interior.

It is suggested, then, that an alloying element may influence the shape of the cathodic sweeps in a rather complex way by altering both the amount of dischargeable PbO_2 for a given anodic pretreatment, and the anodic current profile intensity, *i.e.*, extent of substrate corrosion during the sweeps. The effect of arsenic on the cathodic sweeps is ascribed, in part, to a decrease in dischargeable PbO_2, since a reduction in capacity was measured in a constant current discharge (Table I) for the same anodic pretreatment indicated in Fig. 10. However, the shift of the net current in the anodic direction occurs in greater proportion than that expected from the decrease in capacity measured by the constant current discharge experiments. Therefore, it is assumed that the sweeps are also influenced because of greater substrate corrosion as the arsenic concentration is increased.

Conclusions

The effect of increasing the antimony concentration in pure lead on the shape of *i-t* curves during potentiostatic control above the $PbO_2/PbSO_4$ reversible potential is attributed to a shift from oxidation of $PbSO_4$ to β-PbO_2 as the major process to oxidation of antimony as the major process.

Cathodic potential sweeps in the region 1140-1040 mV, obtained following the potentiostatic control, can be interpreted in terms of two diffusion-controlled reactions occurring in parallel; PbO_2 discharge and corrosion of the substrate beneath the discharging PbO_2. For the more concentrated antimonial alloys, the sweeps reflect the higher potentials and/or longer times required in the anodic pretreatment to form significant quantities of dischargeable PbO_2, and were also consistent with the view that the PbO_2 behaves as if it is being discharged from a more inert substrate. For an increase in arsenic concentration, the cathodic sweeps were interpreted in terms of a decrease in dischargeable PbO_2 and an increase in substrate corrosion.

Cost and Size Estimates for a Redox Bulk Energy Storage Concept

Marvin Warshay and Lyle O. Wright

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

Preliminary capital cost and size estimates were made for an electrochemical bulk energy storage concept. The electrochemical system considered was an electrically rechargeable flow cell with a titanium trichloride|titanium tetrachloride[1]||ferric chloride|ferrous chloride ($TiCl_3|TiCl_4$[1]$||FeCl_3|FeCl_2$) redox couple. The preliminary calculations were made to help determine whether the redox-flow-cell system has an attractive potential as a bulk energy storage system for power load leveling. With the rise in demand for electric power, the problem facing the electric utility industry of meeting peak power demands has been growing more acute. Because present methods of meeting peak power demands are not entirely adequate the electric utility industry has been interested in new methods for meeting peak power demands. On the basis of preliminary capital cost estimates, size estimates, and several other important considerations, the redox-flow-cell system emerges as having great promise as a bulk energy storage system for power load leveling. The size of this system would be less than 2% of that of a comparable pumped hydroelectric plant. The capital cost of a 10 MW, 60 and 85 MW-hr redox system is estimated to be \$190-\$330 per kilowatt. This cost compares well with that of competing systems, especially when one considers that for many sites a saving in transmission costs (up to \$200 per kilowatt) could be realized with the redox system. This saving could be achieved because the redox systems could be built in various sizes and located near the load centers. The other important features of the redox system contributing to its load-leveling application are its low adverse environmental impact, its high efficiency, its apparent absence of electrochemically related cycle life limitations, and its fast response.

The problem of meeting peak power demands is a very important concern of the electric utility industry. The problem is growing more acute as the pressure of rapidly rising demand is being felt.

For future power needs, it would be uneconomical to simply "overdesign" new base-load plants to meet peak power needs. The capital costs of base-load plants are higher than those of most power peaking equipment in use today (2). But the methods of power generating for peak periods used today are not entirely adequate. Most modern peaking is done with internal combustion equipment, gas turbines, and diesel engines, which run on natural gas or petroleum derived fuel. Not only is the efficiency of this equipment lower than that of base-load plants, but also, and more importantly, the fuel cost can be expected to increase greatly and the fuel availability can be expected to continue to decline. Finally, this type of equipment presents potential air pollution problems.

Another method of power peaking which has been attracting increased interest is the pumped hydroelectric system (2). Aside from relatively low cost, it is appealing because of its bulk energy storage capacity. There is an increasing desire to keep base-load plants operating at capacity, even during off-peak hours, and to store the energy for periods of peak demand. In some cases it is because the base-load plants use cheaper fuel (*e.g.*, coal) than the power peaking plants (oil or gas). For a nuclear power plant, maximum economy requires running at full load. Thus, pumped storage offers a means of accomplishing this objective.

However, even the very efficient (on the order of 66%) pumped hydroelectric plants have their disadvantages. Siting and environmental limitations restrict this type of energy storage system. Thus, the growing demands will require development of new energy storage systems to meet the particular requirements of a power plant in the region it serves.

The present report looks into the use of an electrochemical system for bulk energy storage to meet peak power demands. In many ways, electrochemical systems make ideal energy storage and peaking systems. They could be free of siting and environmental problems, provide instant start-up in emergencies, operate at high efficiency, permit minimum distance peak load transmission, and require short construction lead times.

The electrochemical system proposed for consideration is an electrically rechargeable flow cell, which is a new concept for bulk energy storage. The heart of the flow cell is two redox couples (a pair of oxidation-reduction reactions in which the ions of the pair remain soluble in their electrolytes in either their oxidized or reduced states). The two redox couples considered were titanium trichloride|titanium tetrachloride||ferric chloride|ferrous chloride ($TiCl_3|TiCl_4||FeCl_3|FeCl_2$, or $Ti^{+3}|Ti^{+4}||Fe^{+3}|Fe^{+2}$). Preliminary measurements

[1] Current electrochemical evidence (1) suggests that for titanium in acid solution in its +4 valence state, the titanyl ion, TiO^{+2} rather than $TiCl_4$ or Ti^{+4}, is the predominant participant. However, for the purpose of this paper, the reactions will continue to be written and discussed in the simpler form indicating $TiCl_4 \rightarrow TiCl_3 (Ti^{+4} \rightarrow Ti^{+3})$.

Key words: energy storage, redox system, load leveling.

were made with laboratory cells at the NASA Lewis Research Center. [See Ref. (3). In that report, Thaller also discusses several criteria for selection of the redox couples.] In the present report, size and cost calculations are presented for this redox-flow-cell system. The size calculations include electrochemical characteristics and physical size of the power unit and characteristics of the principal auxiliaries. In the cost calculations an estimate is made of the possible cost of a 10 MW, 85 MW-hr plant for load leveling.

The cost estimates for the redox-flow-cell system are quite preliminary. They were made to help determine whether this system has an attractive potential for bulk energy storage in load-leveling applications.

Description of Redox-Flow Cell

The redox-flow cell consists of two compartments containing separate electrolytes and inert carbon electrodes separated by an anion permeable selective ion exchange membrane. On one side an aqueous electrolyte containing a $TiCl_3$-$TiCl_4$ solution (the anolyte) is circulated from its storage tank into the cell and then back to its tank. On the other side an aqueous electrolyte containing an $FeCl_3$-$FeCl_2$ solution (the catholyte) is similarly circulated into the cell and back to its tank (Fig. 1). On discharge, $FeCl_3$ is reduced to $FeCl_2$, while $TiCl_3$ is oxidized to $TiCl_4$. The ion exchange membrane allows the passage of chlorine ions (Cl^-) from one compartment to the other to preserve electroneutrality. Alternatively, a hydrogen ion (H^+) membrane may also be used. (See Fig. 2 for details of electrochemical reactions with either membrane.) The redox-flow cell is electrically rechargeable by simply reversing the direction of flow of current. The redox-flow cell operates at relatively low temperatures, from room temperature to perhaps 80°C.

Size of Redox-Flow-Cell Power Plant

The basis of the size calculation was a 10 MW peak-power-load-leveling plant operating a maximum of 8.5 hr, with an over-all efficiency of 70% and with both electrolytes at 4*M* concentration. The results of this analysis are shown in Table I. The table gives electrochemical characteristics and physical size of the power unit and the characteristics of the principal auxiliaries. Table II contains selected data from a pumped hydroelectric facility [Northfield, Massachusetts, Ref. (4)] which are useful for purposes of comparison. Also see Fig. 3 for a pictorial representation of the 10 MW, 85 MW-hr redox system.

Cost Estimates for Redox-Flow-Cell Power Plant

A cost estimate was made for a 10 MW, 85 MW-hr power plant. A current density of 108.0 mA/cm² (100 A/ft²), 70% over-all efficiency, [W-hr (a.c.) out/W-hr (d.c.) in], and 4*M* concentrations of electrolytes were assumed.

Pricing.—The capital cost estimates were made during the summer of 1973. The costs of electrochemical materials were obtained from suppliers or from trade publications. The unit costs used in the calculations are shown in Table III. The cost estimates for process equipment were made chiefly with the assistance of process equipment manufacturers.

A good deal of judgment was involved in making these cost estimates. For example, judgment had to be used in selecting the grade of chemical required and also in securing the estimate of electrochemical materials costs. It was obvious that the estimated costs of the electrochemical materials were not necessarily the lowest. The membrane manufacturers, for instance, predicted that future development and increased production savings could halve the present cost of the membrane. Furthermore, one research worker in membrane technology predicted that the membrane cost might even be reduced to less than one-tenth of its present cost. For reasons such as these, two types of electrochemical materials costs were calculated. One was higher or conservative, the other lower or optimistic.

The only pieces of process equipment for which conservative and optimistic costs were calculated were the reactant tanks. If lined, carbon-steel tanks would be suitable for this process, they would be approximately half as costly as stainless steel tanks.

As can be seen in Table III, the differences between the conservative and optimistic capital cost totals are considerable. For the base case power plant (operation at 10 MW for 8.5 hr with 70% efficiency), the difference was over a million dollars; the conservative total cost was $2,867,000, while the optimistic total cost was $1,846,000.

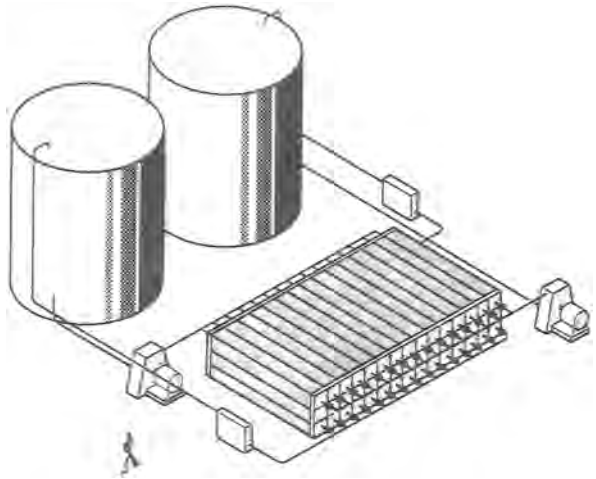

Fig. 3. Pictorial representation of 10 MW, 85 MW-hr redox system.

In addition to this basic cost estimate, conservative and optimistic costs were projected for three other cases. One reflected an assumption of a higher efficiency system, 85% instead of the 70% for the base case. The other two cost projections were for a shorter period of power-load-leveling operation, 6 hr instead of the 8.5 hr for the base case. One of these cost projections was made for 70% efficiency, the other for 85% efficiency.

Design basis.—Some pieces of process equipment, such as pumps, heat exchanger, and filters, were more or less within the standard series of types available. Other pieces of process equipment would have to be

custom fabricated, which could make their cost estimates more uncertain. However, storage tanks are normally custom fabricated. In the opinion of a leading tank manufacturer, the requirements of the redox-flow-cell system would present no special difficulties.

Estimating the cost of the redox-cell frames did present a unique problem, since redox-cell frames had never been built. However, the redox battery of cells containing graphite sheet electrodes, a diaphragm, and flowing liquids resembles the filter press to a reasonable extent. Consequently, cost estimates were obtained in cooperation with filter press manufacturers.

Discussion

The redox-flow-cell system has several attractive features. Electrochemically the system is a simple one. Unlike batteries, there are no apparent cycle life limitations due to morphology changes in the active materials of the electrodes. Furthermore, repeated deep discharges should be possible without reducing cycle life. The cell should operate at very high over-all efficiency. Finally, high efficiency does not require high cell temperatures.

The preliminary cost estimates made in this report show that the redox-flow-cell system is also attractive from a cost standpoint for use in bulk energy storage for power peaking. The estimate for the 10 MW plant ranged from \$150 to \$290 per kilowatt, depending upon whether the plant is designed for 6 or 8.5 hr use and whether optimistic or conservative costs are used. In keeping with the paper by Heredy and Parkins (5), a \$40/kW cost was added for a-c—d-c converters, transformers, and switch gear, so that the cost range was brought up to \$190/kW. In the same paper the capital cost of a pumped hydroelectric system in the 10 MW range (2.4-10 hr daily operation) is estimated to range from \$85 to \$200 per kilowatt, while a gas turbine system was estimated to cost \$100-\$200 per kilowatt.

On the basis of these cost estimates plus other reflecting cost of operation, the pumped hydroelectric storage system is potentially the cheapest. [In Ref. (5) the delivered energy cost estimate for the pumped hydroelectric system is the lowest.] However, as mentioned above, geographic or environmental considerations or both may preclude its use. No doubt the high end of the capital cost estimate represents the case where geographic conditions are considerably less than optimum. Also, because of environmental considerations, it may not be possible to create a lake holding 17.1m (56 ft) of water and covering 1.31×10^6 m^2 (323 acres) or to have a site which could provide a 252m (825 ft) head, as was done, for example, for the Northfield hydroelectric project (Table II). On the other hand, a redox bulk energy storage plant of the same output as the Northfield plant would occupy less than one-fiftieth of the volume (Tables I and II). Furthermore, the fact that the redox-flow-cell system can be built in different sizes can be put to good advantage. For example, significant savings in transmission costs can be achieved by dispersing suitably sized redox energy storage devices throughout the system near the load centers rather than using a very large pumped hydroelectric facility at a single site. One report estimates that this transmission cost saving would range between \$60 and \$200 per kilowatt (6). This estimate would hold for a typical utility system where the average transmission length would be about 100 miles and the dispersed energy storage facilities would be sited within urban areas.

Naturally, to advance the redox-flow-cell system toward commercialization will require a great deal of effort. In the research and development area there are numerous performance questions and problem areas which will have to be resolved. Some of these are discussed in this report. In the performance category are the as-yet-unattained 648 W/m^2 (60 W/ft^2) power density and the assumed electrochemical performance at the 4*M* concentrations. In this connection, calculations were made to determine the sensitivity of the capital cost to reduced electrochemical performance, a power density of 324 W/m^2 instead of 648 W/m^2. These are shown in Table IV. In this case the battery stack costs were affected. Also shown in Table IV are the results of calculations made to determine the sensitivity of the capital cost to operation at much lower reactant concentrations, 1*M* instead of 4. In this case the process equipment costs are affected. Comparing these capital costs with the original costs in Table III, it is obvious that the capital costs are quite sensitive to both electrochemical performance (power density) and reactant concentration. The assumed decrease in power density to one-half the original adds between \$63 and \$110 per kilowatt; the assumed decrease in reactant concentration to one-fourth the original adds between \$52 and \$104 per kilowatt. Apparently the capital cost is more sensitive to power density than to reactant concentration. The effects of concentration and power density upon power plant size are shown pictorially in Fig. 4.

Current laboratory work at NASA Lewis Research Center on redox systems is producing some encouraging results. A number of redox couples show promise. The Lewis work on the Ti/Fe system, which has been given the greatest emphasis thus far, indicates

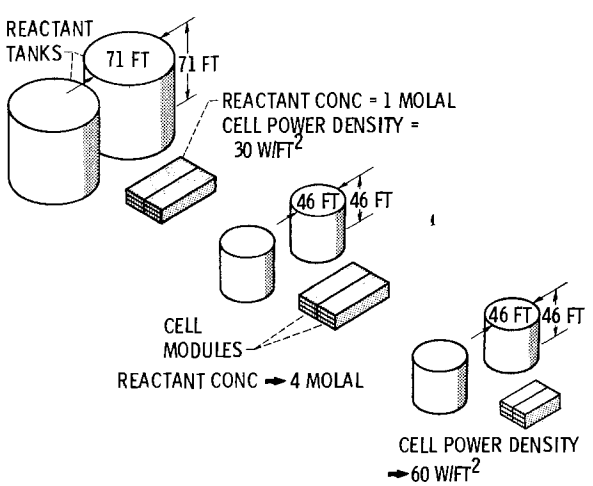

Fig. 4. Pictorial representation of effects of changes in reactant concentration and power density upon size of 10 MW, 85 MW-hr redox system.

that the performance goals cited in this paper are still reasonable. Recently, a power density of 324 W/m^2 has been attained. Part of the Lewis redox program involves work on the membrane, a major technical consideration in this redox concept. Presently, no membrane is available with very low ionic resistance coupled with very good selectivity. In addition, a suitable membrane must be compatible with the reactants, dimensionally stable for long periods, and inexpensive to produce in large sheets. A conclusion of the laboratory work is that membrane life does not appear to be a major problem thus far. While the membranes tested permitted some ion crossover, they exhibited no signs of degradation after several thousand hours of operation. This was evident from the fact that with replacement of the reactant solutions with fresh reactant solutions, the initial performance of the cells was restored.

Another phase of the NASA Lewis Research Center redox work involved the important question of circulating electrical currents between the cells and of the distribution of the reactant flow within the cells. The conclusion of this analytic treatment was that proper design of the cell flow passages is required in order to minimize ionic shunt currents without creating excessive parasitic pumping requirements.

Conclusion

On the basis of capital cost estimates, size estimates, and several other very important considerations, the redox-flow-cell system emerges as having great promise as a bulk energy storage system for power load leveling. The size of this system was estimated to be less than 2% of the size of a comparable pumped hydroelectric storage plant. The capital cost of a 10-MW, 60 and 85 MW/hr redox-flow system was estimated to range from $190 to $330 per kilowatt.

This capital cost range compares well with that for other peaking systems ($85 to $200 per kilowatt), especially when one considers that no transmission credit ($60 to $200 per kilowatt) was included in the redox system capital cost estimates. The transmission savings could be achieved because of the possibility of building redox systems of various sizes and dispersing them throughout the electrical network near the load centers. Coupling these attractive estimates of capital costs and size of the redox-flow system with its low environmental impact, its high efficiency at low temperatures, its apparent absence of electrochemically related cycle life limitations, and its fast response produces a power-load-leveling system of strong potential.

Electrochemical Characterization and Modification of Cadmium Sulfide Composition at 25°C

Jacques Vedel, Michel Soubeyrand, and Egil Castel

Laboratoire d'Electrochimie Analytique et Appliquée, Associé au C.N.R.S., E.N.S.C.P., 75231 Paris Cedex 05, France

ABSTRACT

The feasibility of electrochemical characterization and modification of the composition of a cadmium sulfide sample has been shown. The sample (thickness, 1 μm) was prepared by anodic oxidation of an electrolytic cadmium layer, plated on a platinum electrode, in an aqueous solution of sulfide ions. The sample composition was changed by coulometric oxidation, and the composition variation was observed by the means of the galvanic cell Cd: Cd^{2+} (aq.): Cd_xS. The electrode reaction is thermodynamically reversible in the considered composition range. Two potential-composition diagrams are given, as well as an attempt to interpret some of their parts.

The semiconducting properties of some binary compounds depend on their composition, particularly on their deviation from stoichiometry. The present work describes an electrochemical approach to the characterization of thin layers of cadmium sulfide (the thickness of which varies between 1 and 2 μm) following a technique similar to that proposed by Mathieu and Rickert (1) for the study of copper sulfides.

Key words: cadmium sulfide, stoichiometry, coulometry, potentiometry.

The emf of the galvanic cell

$$\text{Pt} \mid \text{Cd} \;\big|\; \begin{matrix}\text{aqueous solution}\\ \text{of } Cd^{2+} \text{ ions}\end{matrix} \;\big|\; Cd_xS \mid \text{Pt} \qquad [1]$$

is related to the chemical potential of the cadmium in cadmium sulfide, $\mu_{Cd}(Cd_xS)$ by the equation

$$\mu_{Cd}(Cd_xS) - \mu^\circ_{Cd} = -2\mathbf{F}E(x) \qquad [2]$$

where $\mathbf{F}$ is the Faraday constant and μ°_{Cd} the standard

chemical potential of pure cadmium. Thus, $E(x)$ is a measure of cadmium activity in Cd_xS, a thermodynamical quantity that may be related to the activity of a defect, for example, the noncharged interstitial cadmium represented by Cd_i^*. Then, one has

$$\mu_{Cd}(Cd_xS) = \mu^\circ_{Cd_i^*} + RT \ln a(Cd_i^*) \quad [3]$$

By choosing as reference state ($a(Cd_i^*) = 1$) the cadmium-saturated solution (cadmium sulfide in equilibrium with cadmium), for which $E(x) = 0$, one obtains

$$-2\mathbf{F}E(x) = RT \ln a(Cd_i^*) \quad [4]$$

On the other hand, the CdS composition may be modified by the means of an electrochemical reaction: if an emf $E'(x)$ greater than $E(x)$ is applied to cell [1] the flow of a current through the cell is observed. With the aqueous solution acting as a blocking electrode for electrons, the charge transfer reaction must take place at the sulfide-solution interface in order to allow the current flow. This reaction may be schematically represented in the following way

$$Cd_xS - 2(x - x')e \rightarrow Cd_{x'}S + (x - x')Cd^{2+}(aq.) \quad [5]$$

showing a decrease in the cadmium content of the sample.

The composition variation $(x - x')$ is related to the quantity of electricity Q that has flown through the cell by equation

$$x - x' = \frac{Q}{2n_S\mathbf{F}V} \quad [6]$$

where n_S is the number of sulfur atoms per cubic centimeter and V the volume of the sample.

In fact, a constant oxidizing current I was forced to flow through the cell during a time t. Thus, the quantity of electricity was $Q = It$. The cell emf increased during this operation until the value E_{max}. Then the new equilibrium potential value was allowed to establish itself. One must be careful lest the emf E_{max} should ever be less than the emf corresponding to the oxidation of cadmium sulfide into sulfur ($E_{max} \leq 0.7V$). A study of diffusion in thin layers of cuprous sulfide realized in a similar condition (2) has shown us that for polycrystalline layers the transformation was first realized in the joint grains, the equilibration of the small crystal being effected afterwards. In cadmium sulfide, the phenomenon is similar but owing to the low values of diffusion coefficient at room temperature equilibration times varying from 6 to 8 hr were observed for composition changes of 10^{-4} and layers of approximately 1 μm thickness.

Thus, from an analytical point of view, this is a question of coulometric titration with a potentiometry (zero current) as the indicator method.

Experimental

The electrochemical cell (Fig. 1) is the same as that used in a previous study to determine the chemical diffusion coefficient of copper in Cu_xS (2). It allows the two electrochemical operations: coulometric oxidation and potentiometry. To keep equilibration time as short as possible, the working electrode (4) and the auxiliary electrode (7) for the coulometry were disposed perpendicularly in a Pyrex tube ($\phi = 8$ mm) and occupying the entire cross section. Thus, the current lines distribution was uniform, giving a composition variation uniform on the entire sample surface. The reference electrode for potentiometry is a cadmium electrode and is placed in a side compartment (2), connected to the working electrode compartment by a fritted glass disk (3).

The cadmium-rich CdS layers [low values of $E(x)$] are easily oxidized by oxygen. The working electrode compartment and the auxiliary electrode compartment are continuously flushed by a high purity argon flow (1), purified by circulation over a BASF copper activated column. A liquid joint prevents the oxygen retrodiffusion.

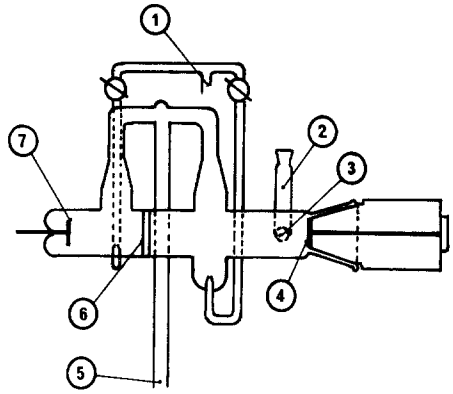

Fig. 1. Schema of the electrochemical cell: 1, argon inlet; 2, reference electrode compartment; 3, fritted glass disk (porosity = 4); 4, cadmium sulfide electrode on platinum support; 5, argon outlet; 6, fritted glass disk separating the two compartments of the electrochemical cell; 7, auxiliary electrode for the coulometry.

The electrochemical cell was maintained in darkness. Electrolyte composition was: Na_2SO_4;0.1 mol liter^{-1}; $CdSO_4$, 0.01 mol liter^{-1}; temperature, 23°C; sample surface area, 33 mm^2; thickness, 1.2 μm. Sample volume was determined by chemical analysis of the layer, following the method indicated by Nechiporenko *et al.* (3).

The CdS layers were prepared by anodic oxidation of an electrolytic cadmium layer, in a solution containing sulfide ions. A cadmium layer (10m) is deposited on a platinum electrode, from a nonstirred solution of 0.1 mole liter^{-1} $CdCl_2$. The platinum electrode was previously submitted to a series of successive electrochemical oxidations and reductions in concentrated nitric acid (current density 1300 Am^{-2}; last operation, oxidation). This allowed a well-adhering sulfide deposit. Afterwards, cadmium was anodically oxidized at controlled potential (— 0.9V *vs.* SCE) in a Na_2S solution (0.5 mole liter^{-1}, pH = 9). The emf $E(x)$ given by one of these layers was equal to zero: thus the formed cadmium sulfide is the so-called cadmium sulfide in equilibrium with cadmium.

Results and Discussion

Verification of the reversibility of the electrochemical reaction.—In order that expression [2] be valid, the electrochemical reaction at the solution-sulfide interface must be thermodynamically reversible. It was assumed that the Cd_xS electrode was reversible toward the activity variations (in the aqueous solution) of Cd^{2+} ions, it was also reversible toward variations of cadmium activity (in the solid). This has been verified using a galvanic cell of the type

Saturated calomel electrode	Aqueous solution of Cd^{2+} ions	Cd_xS or Cd	[7]

The emf of this cell is related to the activity of the aqueous Cd^{2+} ions, $a(Cd^{2+})$, and to the cadmium activity in the sulfide by

$$E = E^\circ + \frac{2.3RT}{2\mathbf{F}} \log \frac{a(Cd^{2+})}{a(Cd)} \quad [8]$$

For constant x values, $a(Cd)$ is also constant and Eq. [8] becomes

$$E = E^{\circ\prime} + \frac{2.3RT}{2\mathbf{F}} \log a(Cd^{2+}) \quad [9]$$

with

$$E^{\circ\prime} = E^\circ - \frac{2.3RT}{2\mathbf{F}} \log a(Cd)$$

Table I. Characteristic parameters of the straight lines $E = f(\log a(Cd^{2+}))$ (Eq. [9])

Electrode	$E^{\circ\prime}$/V potential vs. ENH	Slope/V ±0.001
Cd	-0.408 ± 0.002	0.029
CdS_{x_1}	-0.362 ± 0.002	0.030
CdS_{x_2}	$+0.066 \pm 0.004$	0.030
CdS_{x_3}	0.470 ± 0.003	0.032

The variation of emf E has been determined as a function of the cadmium ion concentration for some unknown values of x. The concentration varied between 10^{-4} and 10^{-1} mole liter^{-1} and the ionic strength remained fixed to the value 0.3, so that the activity coefficient of the Cd^{2+} ions was constant and equal to 0.19. The curves $E = f(\log c(Cd^{2+}))$ were straight lines; the characteristic parameters are reported in Table I. At 23°C, the standard potential of cadmium is equal to −0.403V (4) and the value of the coefficient 2.3 $RT/2F$ is equal to 0.0295V. The observed values of the slopes allow the conclusion of a reversible interface exchange reaction. Thus, the emf of cell [1] is effectively a measure of the cadmium activity in the cadmium sulfide sample. However, one must remark that the standard potential value for the $CdS/S/Cd^{2+}$ system is equal to +0.31V (4). The observed value for the sulfur-saturated sample (composition CdS_{x_3}) is greater (0.47V). This deviation may be attributed to the formation of sulfur in a state different from the standard state of the element. The difference between these two potentials corresponds to a free energy equal to −7500 cal that may be compared with the free energies of some other sulfur species (5): $S_2(g)$, 17,500 cal; $S_6(g)$, −8800 cal; and $S_8(g)$, −5700 cal.

Potential-composition diagrams.—The potential variations as a function of composition are shown on Fig. 2. They were obtained from two different runs, starting from two different electrolytic samples (t = 23°C). Composition variation was obtained by anodic oxidation at constant current. Conversion of experimental It values into x values was obtained using Eq. [6], after determination of the V values by chemical analysis. On one of the curves (solid line) characteristic points are plotted as A, B, C, etc., and on the other one (dashed line), the corresponding points are a, b, c, etc. On these curves the cadmium-rich medium corresponds to points on the left of the diagram, and the cadmium-poor one on the right. The position of the stoichiometric point $x = 1$ is unknown. In order to plot the two curves on the same diagram, it was first observed that both their left parts showed a sigmoidal shape recalling that of

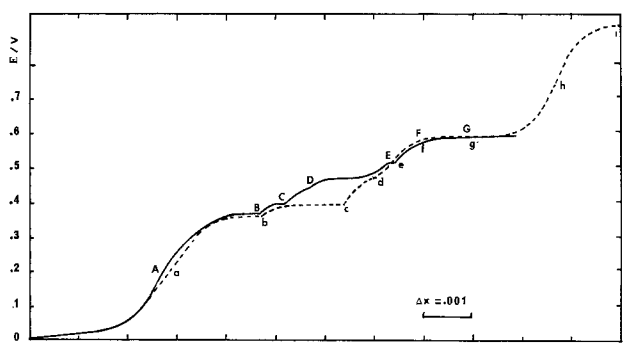

Fig. 2. Potential-composition diagram of cadmium sulfide (t = 23°C). The stoichiometric ratio x is modified by anodic oxidation at constant current, but the stoichiometric point $x = 1$ is unknown. The two curves correspond to two different runs and the correspondence between them was obtained by superposing the two equivalent points A and a.

titration curves. The correspondence has been realized by superimposing both inflection points A and a.

Thus, some similarity may be observed between the two titration curves, with the points A, B, C, ..., as equivalent points. The potentials of the plateaus preceding the points B, C, E, and G are equal to within a few millivolts while their lengths are different. The HI part (corresponding to hi) has not been determined. As for the interpretation of titration curves, the potential variations were studied against the quantity log $|x_J - x|$, where x_J is the value of x at the equivalent point J. For the best defined parts of the curves, that is to say the arcs hi, efg (and EFG), ab (and AB), a0 (and A0), linear variations were observed, the slopes of which are, respectively 0.090, 0.060, 0.120, and 0.180V. They are simply related to the value of the Nernst coefficient at 23°C (0.059V) and the first of them may be explained by making simple assumptions.

Let us first consider the arc hi, which corresponds to cadmium-poor medium. One can suppose that the species causing the deviation to stoichiometry was the doubly ionized cadmium vacancy V_{Cd}'' (6). When the x value is equal to x_H, the vacancy concentration $|V_{Cd}''|$ is very low ($|V_{Cd}''|_{x=x_H} \simeq 0$). When x is modified by anodic oxidation, for example according to the following reaction

$$Cd_{Cd} \rightarrow V_{Cd}'' + 2h^{\cdot} + Cd^{2+}(aq.) + 2e^{-} \qquad [10]$$

the vacancy concentration expressed in site fraction is increased by the quantity

$$|V_{Cd}''|_x - |V_{Cd}''|_{x=x_H} \simeq |V_{Cd}''|_x = x_H - x \qquad [11]$$

where $x_H - x$ is obtained by means of Eq. [6]. (The two electrons appearing in the right-hand side of reaction [10] are brought by the external source of energy to cause the modification of composition; the two electron holes arise from the ionization of the neutral cadmium vacancy: $V_{Cd}^{x} \rightarrow V_{Cd}'' + 2h^{\cdot}$.)

The cadmium vacancies are assumed to be in equilibrium with metallic cadmium, the activity of which is measured by the electrochemical cell. This cadmium activity plays, in fact, the same part as the gaseous cadmium (or sulfur) pressure often used as composition parameter in high temperature studies. The equilibrium is

$$Cd + V_{Cd}'' + 2h^{\cdot} \rightleftharpoons Cd_{Cd} \qquad [12]$$

together with the relation

$$K = a(Cd) \cdot |h^{\cdot}| \cdot f(V_{Cd}'') \cdot |V_{Cd}'')_x \qquad [13]$$

where $|h^{\cdot}|$ is the electron hole concentration, expressed in site fraction, and $f(V_{Cd}'')$ the activity coefficient of ionized vacancies. Considering the electroneutrality condition

$$2|V_{Cd}''|_x = 2|h^{\cdot}|$$

one obtains

$$a(Cd) = \frac{K}{4f(V_{Cd}'')} \cdot \frac{1}{|V_{Cd}''|_x^3} \qquad [14]$$

Combining expressions [4], [11], and [14] gives

$$E = \text{const.} + \frac{3}{2} \cdot \frac{2.3RT}{F} \log (x_H - x) \qquad [15]$$

At 23°C, the value of the coefficient $2.3RT/F$ is equal to 0.059V. Thus, the theoretical slope of the straight line $E = f(\log(x_H - x))$ is equal to 0.0885V, very close to the observed one (0.090V). This result suports the hypothesis of the existence of the defect V_{Cd}''. If the existence of nonionized vacancy is assumed, for example, equilibrium [12] would be replaced by equilibrium [16]

$$Cd + V_{Cd}^{x} = Cd_{Cd} \qquad [16]$$

with

$$K' = a(Cd) \cdot f(V_{Cd}^{x}) \cdot V_{Cd}^{x}$$

and the potential variation would be

$$E = \text{const.} + \frac{1}{2} \cdot \frac{2.3RT}{F} \log (x_H - x)$$

with a calculated slope equal to 0.0295V instead of 0.0885V. Similarly, the defect V_{Cd}' would give a slope equal to 0.059V.

The hypothesis can be made that the plateaus observed in the titration curves are due to impurities introduced in the sample, either during the cadmium electrodeposition or during the formation of the sulfide layer. Particularly, the samples could contain cadmium oxide and/or sodium sulfide. As sulfide and oxide species are similar the presence of dissolved cadmium oxide (*i.e.*, the replacement of a sulfur atom S_S by an oxygen atom O_S) could only slightly modify the cadmium sulfide properties. Sodium sulfide is an ionic compound which dissolves in CdS with more difficulty. It is also possible that the remaining sodium sulfide is transformed into cadmium sulfide during the oxidation of the cadmium in excess. However, as it stands now, it is not possible to state precisely what kind of impurities are involved. But the obtained results show that electrochemical analysis is a possible method of studying cadmium sulfide and, more generally, semiconductors having a possible deviation from stoichiometry.

Theoretical and Experimental Study of Flow-Through Porous Electrodes

M. Paulin, D. Hutin, and F. Coeuret*,[1]

Laboratoire des Sciences du Genie Chimique, C.N.R.S., E.N.S.I.C., 54042 Nancy, France

ABSTRACT

The paper deals with the study of flow-through porous electrodes consisting of fixed beds of highly conductive spherical grains. The theoretical treatment is similar to that used to solve chemical engineering problems. It leads to a general expression which allows the calculation of the active volume fraction in an electrode working in industrial operating conditions, and to the subsequent design of such an electrode. The experiments which concern the cathodic deposition of copper from sulfuric $CuSO_4$ solutions allow the determination of effectiveness factors of the electrodes and corresponding effectiveness criterions. For electrodes operated in industrial-like overpotential ranges, the comparison between theory and experiment is satisfactory.

Papers on flow-through porous electrodes are frequently encountered in the literature. This type of electrode is often justified by the fact that it presents a high specific area which makes it suitable for the treatment of dilute solutions that need low current densities. Among its industrial applications, the electrowinning of metals from dilute solutions (liquors from leaching of poor ores, industrial liquid wastes) is frequently considered. Thus the literature of recent years has referred to the fluidized bed electrode (1, 2) for continuous electrowinning and to the fixed bed electrode (3-5) for the concentration of dilute solutions.

The study of the behavior of flow-through electrodes falls within the scope of electrochemical engineering which can be considered as applying to electrochemical processes the principles of analysis and design of the chemical engineering discipline. The analogy between porous electrodes and gas-solid catalytic reactors is not new, at least in the concept of reaction layers which guided the early discussions of porous electrode behavior (6-8). Many other papers on porous electrodes have dealt with the concept of nonuniform reaction rates for different forms of the polarization equation expressing the electrochemical kinetics (9-14). They have been extensively reviewed in a recent paper (15).

In a recent experimental work on flow-through porous electrodes (16), the above-mentioned analogy was confirmed. An effectiveness criterion was defined and studied for the special case of very low overpotentials within the electrodes whereas a generalization was attempted for practical operating conditions. This notion of effectiveness of flow-through porous electrodes is connected with their three-dimensional behavior which would be their main advantage. Such a notion is primordial if it is considered that a very low electrochemically active thickness of the electrode does not bring any further advantage over a classical plate electrode.

The present paper deals with the theoretical and experimental study of flow-through porous electrodes when high local overpotentials exist in the electrodes. The theoretical part examines the behavior of such electrodes by using a mathematical approach similar to that proposed by the chemical engineering discipline for gas-solid catalytic reactors and also for gas-liquid absorption with chemical reaction. The experimental part tests the validity of the theoretical considerations for copper deposition from sulfuric $CuSO_4$ solutions in electrodes consisting of fixed beds of spherical conduct-

Key words: electrochemical engineering, fixed bed electrode, penetration depth, effectiveness criterion, overpotential distribution.

ing grains; it is aimed towards the determination of the effectiveness factors and of the overpotential distributions.

Theoretical

The flow-through porous electrodes selected in the study.—The selected electrode is represented in Fig. 1a. It is considered to be a fixed bed of highly conductive nonporous particles the specific area of which is a_g ($a_g = 6/d_p$ for spherical particles of diameter d_p). Its height is L and its porosity considered as uniform is ϵ. The bottom of the bed is in contact with a current feeder (grid) which acts also as a bed support and through which the electrolyte can flow. The superficial velocity u of the electrolyte entering the bed is assumed uniform in the cross-section area Ω of the containing tube. The electrical conductivity of the electrolyte is γ_0. The counterelectrode is located downstream of the bed with respect to the general flow direction.

The following hypotheses are made:

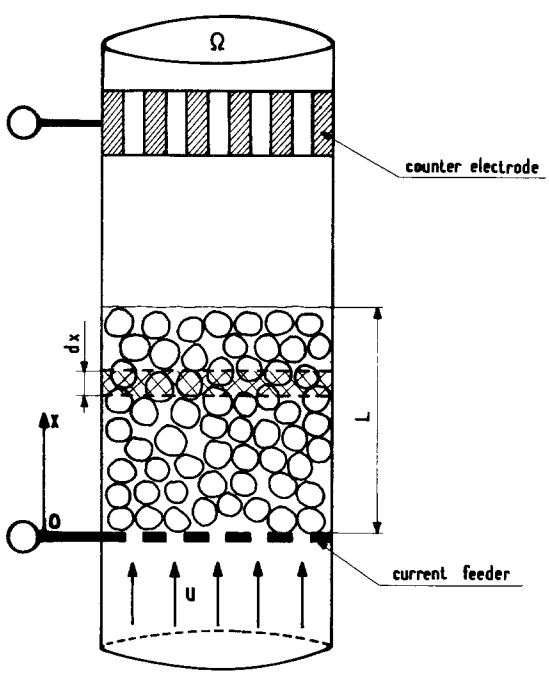
1. The hydrodynamical and electrochemical operating conditions are steady.
2. The electrical potential and the current density within the electrode depend only on the height x above the current feeder.
3. The continuous phase (electrolyte) in the electrode can be considered as a continuous medium whose electrical conductivity is γ depending on γ_0 and on the tortuosity of the current lines around the particles. For spherical particles γ would be a function of γ_0 and ϵ (17).
4. The velocity u of the electrolyte is sufficiently high to ensure that the concentration change of the electrolyte over the bed height is negligible. This assumes that the equilibrium electrode-solution potential E_{eq} is the same at every point in the electrode. The disposition of Fig. 1a can consequently be seen as simulating the behavior of a horizontal slab of the electrode of Fig. 1b the geometry of which would probably be adopted in industrial uses.
5. The electrical potential ϕ_M of the dispersed phase is considered as constant.
6. The conduction through the continuous phase, whose electrical potential is $\phi_S(x)$, obeys Ohm's law.
7. Double layer and migration effects are negligible.
8. Pore structure and porosity distribution are uniform.
9. The operation is isothermal.

The following theoretical developments consider the absolute values of the electrode potential $E(x) = \phi_M - \phi_S(x)$, of the overpotential $\eta(x) = E(x) - E_{eq}$ and of the current density $i_s(x)$ relative to Ω in the pores of the bed. Consequently they could be applied for cathodic or anodic operation of the flow-through porous electrode.

Differential equation giving the overpotential distribution.—For very low values of the electrode overpotential, η, it is well known that the current density is given by the linear expression

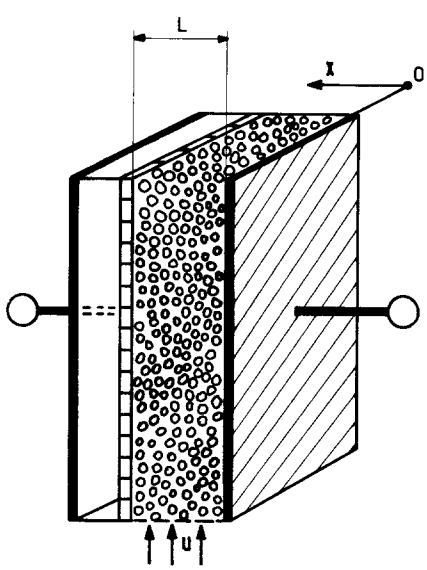
$$i = i_0 \frac{zF}{RT} \eta \qquad [1]$$

where i_0 is the exchange current density (Fig. 2a). The overpotential distribution has been previously obtained for flow-through porous electrodes working accordingly to Eq. [1], *i.e.*, near equilibrium (16). However, such a case is only academic because the practical operating conditions in electrolysis use high overpotentials. Unfortunately the kinetic expressions for the ranges of overpotentials far from equilibrium are too complicated to permit an analytical solution of the problem in a manner similar to Ref. (16).



The examination of the present case of practical interest is possible if we recognize that it is always possible to approximate an experimental curve $i = f(\eta)$ to a power function of η

$$i = i_0 \cdot \frac{z \cdot F}{R \cdot T} \cdot \alpha^{1-n} \cdot \eta^n \qquad [2]$$



in which n would be a positive exponent lower than one and α a dimensional coefficient (Fig. 2b).

As in previous papers (6, 12, 16), after applying Ohm's law to the electrical conduction through the electrolyte within the bed

$$i_S(x) = -\gamma \cdot \frac{d\phi_S(x)}{dx} = \gamma \cdot \frac{d\eta(x)}{dx} \qquad [3]$$

(a)

(b)

Fig. 1. Schematic view of the cell.

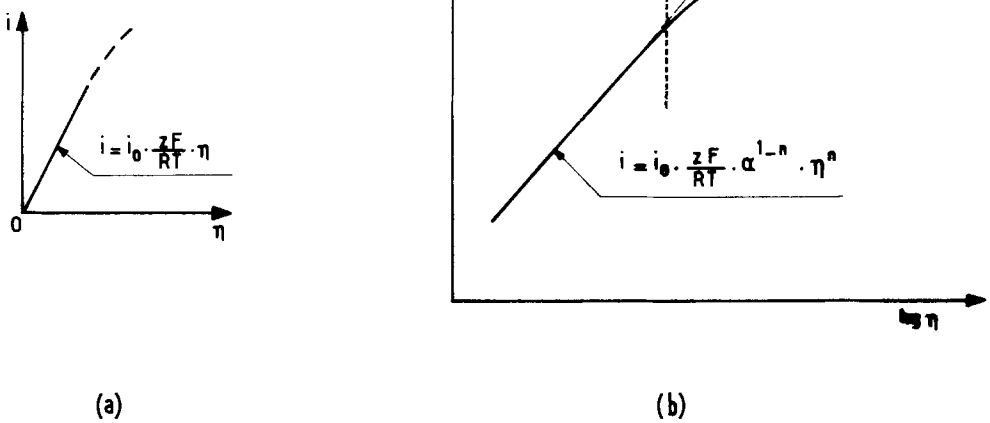


Fig. 2. Kinetic curves for low and high overpotentials.

a balance of the electrical charges in a differential element of thickness dx of the electrode leads to the following equation

$$\frac{d^2\eta(x)}{dx^2} - i_o \cdot \frac{zF}{RT} \cdot \alpha^{1-n} \cdot (1-\epsilon) \cdot a_g \cdot \frac{1}{\gamma} [\eta(x)]^n = 0 \quad [4]$$

the solution of which has to satisfy the boundary conditions

$$\eta(x) = \eta(0) \quad \text{at } x = 0$$

$$\eta(x) = \eta(L) \quad \text{at } x = L$$

It can be seen that for $n = 1$ expressions [2] and [1] are identical and therefore the overpotential distribution $\eta(x)$ obtained by integrating [4] is the distribution previously presented for very low overpotentials (16).

Effectiveness factor and effectiveness criterion.—The effectiveness factor $\mathcal{E}_n$ of the electrode which represents the fraction of the height electrochemically reactive in the electrode is defined by the ratio

$$\mathcal{E}_n = \frac{\text{observed electrolytic current}}{\text{current which would be obtained if } \eta(x) = \eta(L) \text{ at every height } x} = \frac{\gamma \cdot \Omega \cdot \left[\frac{d\eta(x)}{dx}\right]_{x=L}}{i_o \cdot \frac{zF}{RT} \cdot (1-\epsilon) \cdot a_g \cdot \Omega \cdot L \cdot \alpha^{1-n} \cdot [\eta(L)]^n} \quad [5]$$

When $n = 1$ the solution of [4] leads to the following expression of the effectiveness factor

$$\mathcal{E}_1 = \frac{\tanh K_1}{K_1} \quad [6]$$

where K_1 is a dimensionless number which appears as an effectiveness criterion because its value determines the effectiveness factor $\mathcal{E}_1$, *i.e.*, the extent of the three-dimensional character of the electrode (16). The expression for K_1 is

$$K_1 = \left\{ i_o \cdot \frac{zF}{RT} (1-\epsilon) \cdot a_g \cdot \frac{L^2}{\gamma} \right\}^{1/2} \quad [7]$$

Relation [6] has the same mathematical form as that known for the effectiveness of a catalytic reactor with first-order chemical reaction (18). At this point it must be noted that K_1 is not a new parameter. Indeed, expression [7] is the limiting case for a highly conductive dispersed phase of the most general equation [38] of Ref. (15) which expressed a dimensionless exchange current characterizing the penetration depth of the reaction within a porous electrode of uniform electrolyte composition.

This penetration depth, *i.e.*, the distance to which the reaction can penetrate the electrode, is given by

$$\mathcal{E}_1 \cdot L = \frac{\tanh K_1}{K_1} \cdot L \quad [8]$$

The asymptotic expression L/K_1 of [8] is valid only when K_1 is higher than 3 (*i.e.*, when the effectiveness is lower than 0.33) and not for any K_1 value as it can be found in the literature (15).

In the general case, Eq. [4] gives after a first integration

$$\frac{d\eta^+(x)}{dx} = \frac{M}{L} \sqrt{[\eta^+(x)]^{n+1} - [\eta^+(0)]^{n+1}} \quad [9]$$

where $\eta^+(x) = \eta(x)/\eta(L)$ is a reduced overpotential and

$$M = K_1 \cdot \left\{ \frac{2}{n+1} \cdot \left[\frac{\alpha}{\eta(L)} \right]^{1-n} \right\}^{1/2} \quad [10]$$

The value of $\eta^+(0)$ has to satisfy the following equality which is derived from [9]

$$\int_{\eta^+(0)}^{1} \frac{d\eta^+(x)}{\sqrt{[\eta^+(x)]^{n+1} - [\eta^+(0)]^{n+1}}} = \int_0^1 M \cdot d(x/L) = M \quad [11]$$

and the application of definition [5] of the effectiveness would lead to the general expression of $\mathcal{E}_n$

$$\mathcal{E}_n = \frac{1 - [\eta^+(0)]^{n+1}}{K_n} \quad [12]$$

where

$$K_n = \left\{ \frac{n+1}{2} \cdot i_o \cdot \frac{zF}{RT} (1-\epsilon) \cdot a_g \frac{L^2}{\gamma} \left[\frac{\alpha}{n(L)} \right]^{1-n} \right\}^{1/2} \quad [13]$$

The effectiveness, $\mathcal{E}_n$, has been plotted as a function of K_n on bilogarithmic paper for $n = 0$, 0.5, and 1 (Fig.

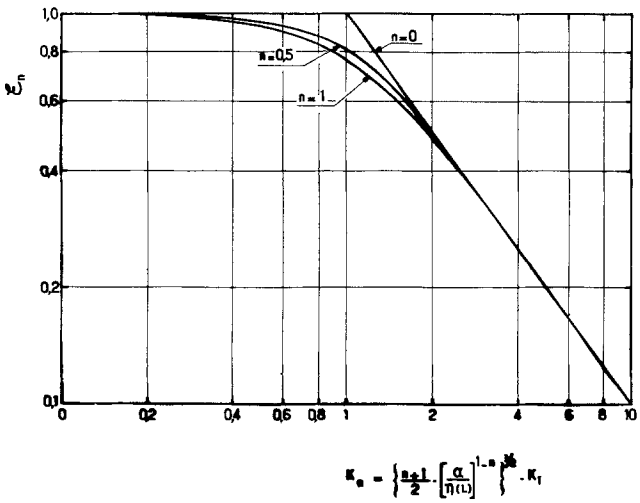

Fig. 3. Representation of expression [12] for $n = 0$, 0.5, and 1

3). Expression [12] for $n = 0.5$ and 0.8 has been calculated from previous numerical determinations of $\eta^+(0)$ using expression [11]; the relative deviation $(\mathcal{E}_n - \mathcal{E}_1)/\mathcal{E}_1$ is represented *vs.* K_n in Fig. 4 for $n = 0.5$ and 0.8. It can be seen that the maximum deviation for $n = 0.5$ is 6.5%, *i.e.*, low compared to the over-all uncertainty in the value of K_n calculated by the user of the diagram in Fig. 3. On the other hand, experience will show later that the practical values of n are higher than 0.5. Therefore it is quite justified to accept the following approximation of [12]

$$\mathcal{E}_n = \frac{\tanh(K_n)}{K_n} \qquad [14]$$

for all practical operating conditions. A similar approximation has been made by Hikita (19) for gas-liquid mass transfer with an irreversible chemical reaction of general order.

Expression [14] allows the calculation of the effectiveness of a flow-through porous electrode with a highly conductive dispersed phase if the effectiveness criterion is known

when $K_n \to 0$, $\mathcal{E}_n \to 1$	(entirely three-dimensional electrode)
when $K_n \to \infty$, $\mathcal{E}_n \to 0$	(two-dimensional electrode, the top of the bed in $x = L$ only being reactive)
when $0 < K_n < \infty$	the electrochemical reaction takes place in a slab whose thickness $\mathcal{E}_n \cdot L$ decreases with increasing values of K_n

Consequently a high effectiveness, *i.e.*, an electrode working throughout almost its whole depth, would be obtained for low K_n values.

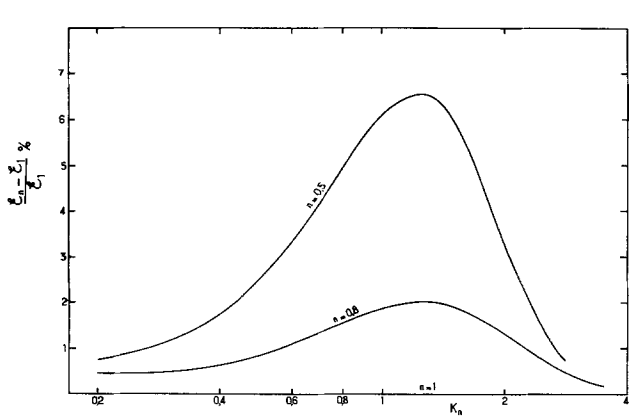

Fig. 4. Relative deviation of $\mathcal{E}_n$ from $\mathcal{E}_1$, for $n = 0.5$ and 0.8

Consequences.—The derivation of the general expression [14] allows the kinetic equation [2] to be approximated in the following manner

$$i = i_0 \cdot \frac{z \cdot F}{R \cdot T} \cdot \alpha^{1-n} \cdot \eta^n \sim \frac{n+1}{2} \cdot i_0 \cdot \frac{z \cdot F}{R \cdot T} \left[\frac{\alpha}{\eta(L)}\right]^{1-n} \cdot \eta \qquad [15]$$

and, as a consequence, the solutions for the overpotential distribution can be transposed from those obtained for the electrode working near equilibrium (16) simply by changing K_1 to K_n. They are

$$\eta(0) = \frac{I \cdot L}{\gamma \cdot \Omega \cdot K_n \cdot \sinh(K_n)} \qquad [16]$$

$$\frac{\eta(L)}{\eta(0)} = \cosh\left(K_n \cdot \frac{x}{L}\right) \qquad [17]$$

$$\frac{\eta(x) - \eta(0)}{\eta(L) - \eta(0)} = \frac{\cosh\left(K_n \cdot \frac{x}{L}\right) - 1}{\cosh(K_n) - 1} \qquad [18]$$

The dimensionless relationship [18] is represented in Fig. 5 for several values of K_n. We can see how the value of K_n influences the form of the distribution and, particularly, that the "penetration depth" of the overpotential profile in the bed decreases with increasing K_n.

Experimental

The cells and their uses.—Two cells have been employed:

Cell I (Fig. 6).—Figure 6a shows a circular column made of altuglass (ID 4 cm) and containing a fixed bed of spherical highly conductive particles (copper or copper-plated graphite). The cathodic current feeder to the bed is a copper grid which also acts as the bed support; the anode is a perforated copper disk. The electrolyte is flowing upward with a uniform superficial velocity u and is successively recirculated through a tank, a centrifugal pump, a valve, and a rotameter. The local electrochemical electrode potential $E(x)$ within the bed is measured by means of the composite probe indicated in Fig. 6a, the bottom of which is detailed in Fig. 6b. This probe was already used and described in Ref. (16). The velocity u is sufficiently high

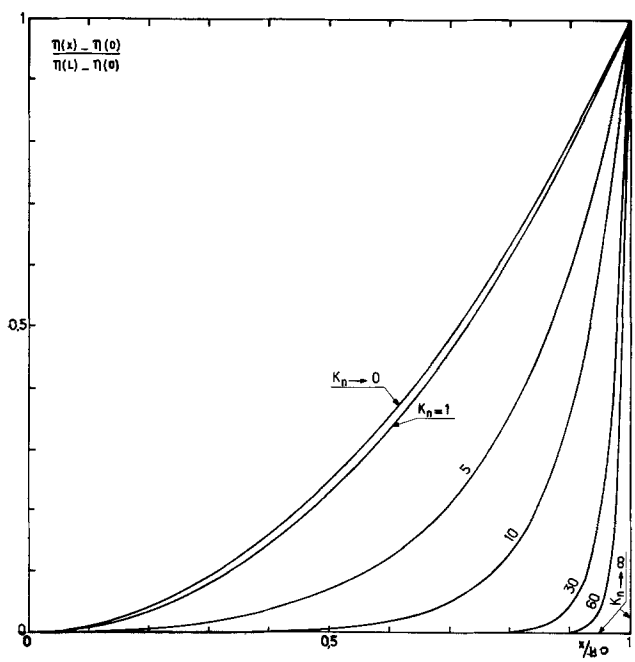

Fig. 5. Influence of K_n on the overpotential distribution

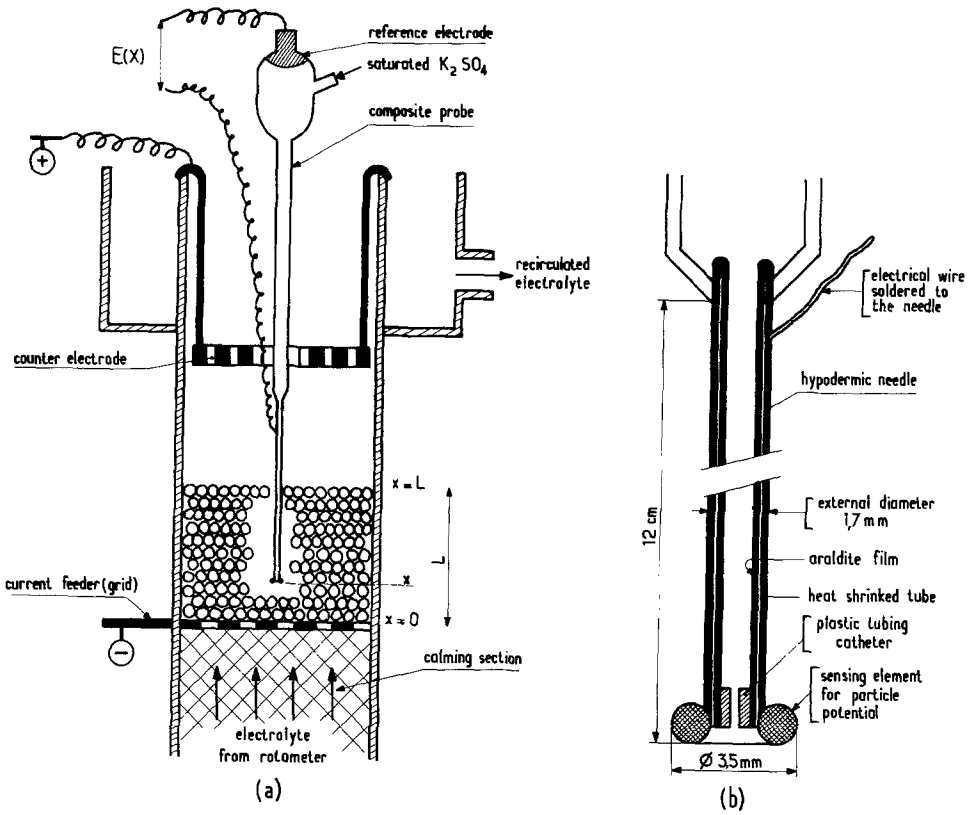

Fig. 6. Schematic view of cell I and of the probe.

so that the copper concentration change is negligible along the bed height L. Therefore the local equilibrium potential E_{eq} may be considered as constant in the bed and the local overpotential $\eta(x)$ can be calculated directly from the indication of the probe. The position x of the sensing element (copper) of the probe is precisely measured within 1/10 mm. The cell is operated at a constant intensity using a potentiostat Tacussel PRT 20-2; the electrode potentials $E(x)$ and the current flowing through the cell are measured with two digital instruments. In all the experimental beds the dispersed phase was equipotential as controlled by measuring the potential drop between the current feeder and the sensing element of the composite probe when this element is located just at the top of the bed. Also, the condition of hypothesis 5 was controlled for the higher beds by finding the metal potential distributions along the bed height. The potential distribution $E(x)$ was always determined a few minutes after applying the current to the cell so that the electrochemical conditions in the bed were steady (at any point, the indication of the probe was constant).

Cell II (Fig. 7).—The cell schematically represented in Fig. 7a obeys the principle of the cell Bennion and

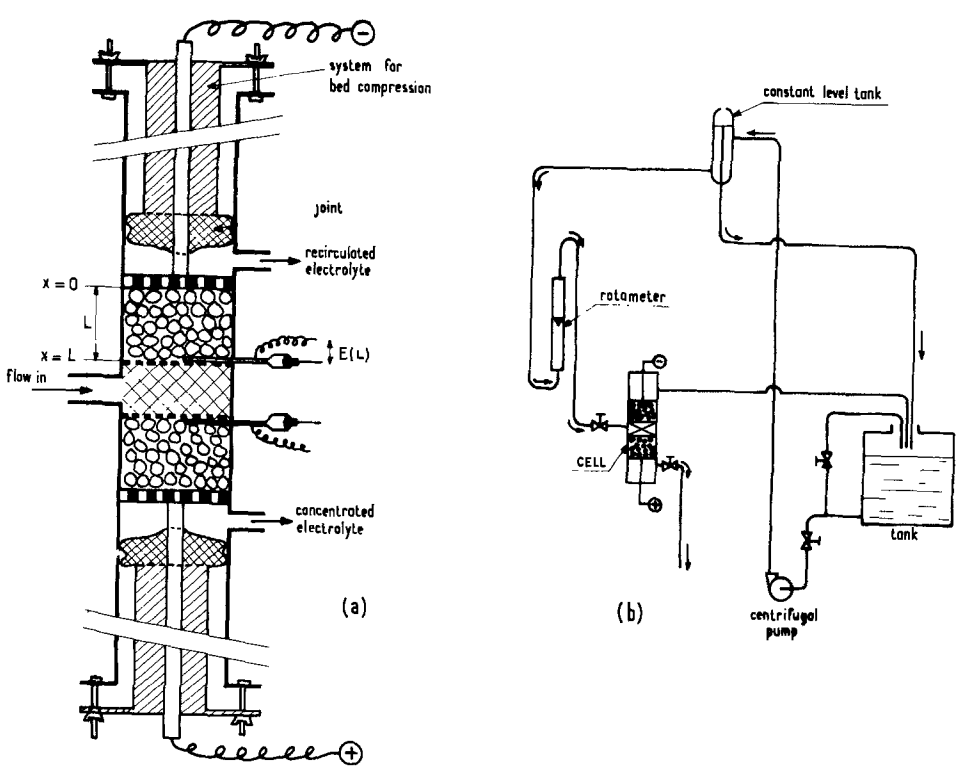

Fig. 7. Schematic view of cell II and of the hydraulic circuit.

Newman proposed (3) for the concentration of dilute solutions of heavy metals; it is incorporated in the hydraulic circuit of Fig. 7b. The cell itself is constructed with two 2.6 cm ID medical syringes made of transparent polyethylene. They have been truncated and assembled on both sides of a calming section of glass beads in which the electrolyte to be treated is distributed.

The upper compartment (cathodic) is supported by a perforated altuglass disk and the bed itself is maintained strongly compressed between that disk and a perforated copper disk which is the current feeder. A hypodermic needle is placed adjacent to the upper face of the altuglass disk. It acts as a composite probe which allows the electrode potential $E(L)$ at $x = L$ to be measured. This probe is realized as that of Fig. 1b except that its external surface is not insulated and is always in contact with the grains of the first layer. Its extremity has no sensing element since this role is played by the external surface of the needle itself. Its internal canal is connected to a saturated K_2SO_4 reference electrode. The lower compartment (anodic) of the cell is realized similarly to the other. The electrolyte flowing out of the cathodic bed is recirculated whereas the concentrated anolyte which is flowing down very slowly is eliminated.

Initially, the cathodic compartment is packed with spherical graphite or lead grains whereas the anodic compartment is packed with previously coppered spherical graphite grains. The compression strength of each bed is such that every dispersed phase is equipotential as can be controlled by measuring the potential drop between the current feeder and the external surface of the corresponding composite probe. From the color change of the grains packed in the cathodic compartment, the bed fraction coppered, *i.e.*, the effectiveness factor, can be determined directly through the wall of the cell after a time sufficiently long (90 min) but not too long to modify the bed texture.

The cell is fed by a Tacussel PRT 20-2 potentiostat, the potential $E(L)$ being imposed in the electrochemical operation. Owing to the negligible variation of the copper electrolyte concentration through the cathodic bed, the equilibrium potential is constant, thus the imposed value $E(L)$ determines the overpotential $\eta(L)$.

Physical and electrochemical data.—Grains and electrolytes.—The spherical grains indicated as A to H in Table I are of various natures and have different diameters d_p. The electrolytes designated as 1 to 6 in the same table are solutions of various $CuSO_4$ concentrations in 1*N* sulfuric acid; their stationary flow rates through the experimented cathodic beds are given in another column of Table I. The bed porosity ϵ in all the experiments was obtained by means of a weight balance on the dispersed phase (known bed weight and particle density, measured bed height) and was found to be between 0.418 and 0.421 for cell I and between 0.384 and 0.395 for the restrained beds of cell II. The uncertainties in such determinations allow for acceptance of ϵ being maintained equal to 0.42 for cell I and to 0.39 for cell II. The electrochemical experiments were carried out at room temperature (20°C).

Exchange current densities.—As in Ref. (16), the exchange current density i_0 for each electrolyte has been determined at 20°C in an adjoining apparatus using the linear expression [1]. The extent $0 \leq \eta \leq 10$ mV of this range has been respected during the determinations. The experimentally obtained values for i_0 are tabulated in Table I.

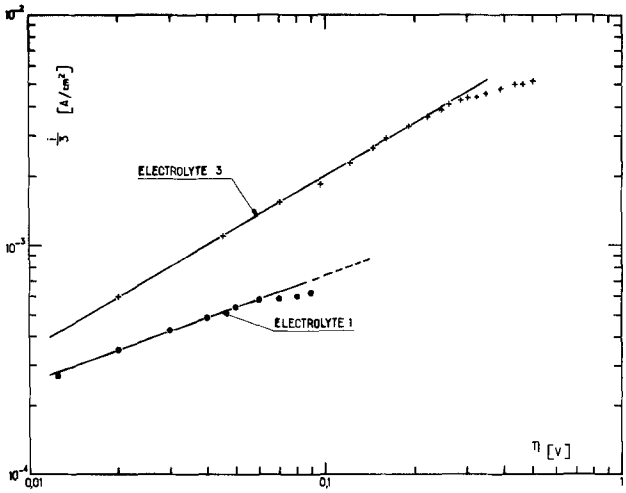

Fig. 8. Examples of experimental kinetic curves

Electrical conductivities.—The electrical conductivity γ_0 of each electrolyte has been measured in the column of Fig 6a itself by determining the solution potential gradients between the anode and the top of the cathodic bed. The method uses only the canal of the composite probe as a Luggin capillary. The γ_0 values are given in Table I.

The apparent electrical conductivity γ of the electrolyte in the pores of the bed was introduced in the model of the flow-through porous electrode. In our study, it can be calculated for each electrolyte by using the following expression

$$\frac{\gamma}{\gamma_0} = \frac{2 \cdot \epsilon}{3 - \epsilon}$$

which satisfactorily gives the relative conductivity of fixed beds of spherical particles and filled with a solution of conductivity γ_0 (20).

Kinetic equations.—For overpotentials far from the equilibrium overpotential, expression [2] is proposed to approximate the kinetic equation. Such an approximation was verified for all the electrolytes using cell I. In order to do it, the sensing element of the composite probe of Fig. 6b is replaced by a coppered graphite grain of diameter 0.3 cm. Such a modified probe is immersed within a fixed bed of glass beads of the same diameter as the sensing element. The flow rate of each electrolyte is set equal to the corresponding flow rate used in the experiments with flow-through electrodes.

The polarization curve $i = f(\eta)$ of the sensing element has been obtained experimentally and reported on double log paper as in Fig. 8 which shows two examples of results. The experimental points are aligned over an extended range of overpotentials allowing the variation of i as given in [2] to be accepted. The values of n and α corresponding to the straight lines and assuming the previously measured values of i_0 are tabu-

lated in Table I. It can be seen that in the present study n is always higher than 0.5.

Results and Discussion

Comparison between theory and experiments.—The steady overpotential distributions along the bed height, as measured in cell I, have been plotted according to the reduced form of [18] and give curves like those represented in Fig. 9 and 10 which show the influence of the grain diameter d_p and of the bed height L, respectively. It is seen that the "penetration depth" of the overpotential profile increases with increasing d_p or decreasing L, *i.e.*, with decreasing K_n.

When $\eta(0)$ is almost zero (current feeder at equilibrium) and the product $K_n\ x/L$ large enough, expression [18] takes the simplified form

$$\frac{\eta(x)}{\eta(L)} \approx \exp\left[K_n \cdot \left(\frac{x}{L} - 1\right)\right] \qquad [19]$$

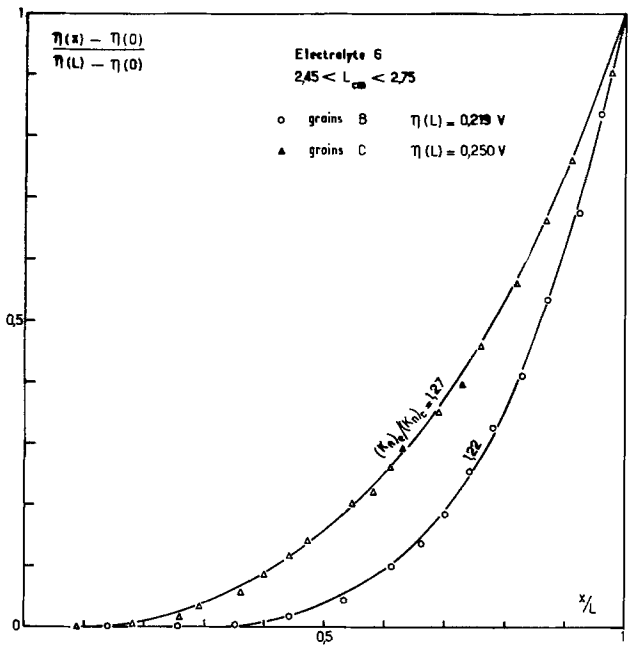

Fig. 9. Experimental dimensionless overpotential distributions showing the influence of d_p.

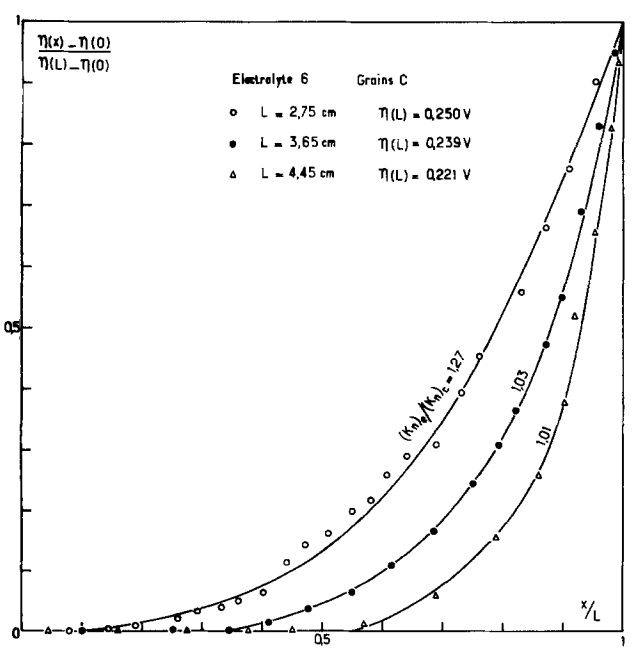

Fig. 10. Experimental dimensionless overpotential distributions showing the influence of L.

which can be used to deduce the experimental values of K_n, $(K_n)_e$, from the overpotential distributions by using semilog paper. Figure 11 gives three examples of such a use of the experimental data.

In order to compare the experimental criterion $(K_n)_e$ with the corresponding theoretical criterion $(K_n)_c$ obtained from [13], the value of the ratio $(K_n)_e/(K_n)_c$ is also indicated for each curve in Fig. 9 and 10. It can be seen that this value is close to unity.

The intercept with the horizontal axis of the lines of Fig. 11 yields the penetration depth of the overpotential profile within the electrode, therefore the value of the experimental effectiveness $(\mathcal{E}_n)_e$, which is equal to the ratio of that depth to the bed height. On the other hand, the calculated value $(\mathcal{E}_n)_c$ of $\mathcal{E}_n$ is given by [14] by introducing the corresponding criterion $(K_n)_c$. The superior part of Table II resumes the values of L, $(\mathcal{E}_n)_e$, $(\mathcal{E}_n)_c$, and of the ratio $(\mathcal{E}_n)_e/(\mathcal{E}_n)_c$ for all the experiments in cell I.

For cell II, and as previously stated, the effectiveness $(\mathcal{E}_n)_e$ of the electrode is obtained directly from the measurement of the height fraction covered with copper since the color transition between graphite and coppered graphite is very sharp. For each experiment, $(\mathcal{E}_n)_c$ is calculated in the same manner as for cell I. The value of L, $(\mathcal{E}_n)_e$, $(\mathcal{E}_n)_c$, and of $(\mathcal{E}_n)_e/(\mathcal{E}_n)_c$ are reported in the inferior part of Table II.

The values of $(\mathcal{E}_n)_e/(\mathcal{E}_n)_c$ in Table II are between 1.01 and 2.04 which indicates that the calculated effectiveness is always underestimated relative to the effectiveness really observed. This is still more evident in Fig. 12 where all the values of $(\mathcal{E}_n)_e$ are reported in function of the corresponding $(K_n)_c$. Comparison of the experimental dotted curve with the continuous theoretical curve obeying Eq. [13] shows that the deviation between these two curves increases with decreasing $(K_n)_c$ and is of the order of 50% for $(K_n)_c = 3$, 25% for $(K_n)_c = 4$, and 17.5% for $(K_n)_c = 15$.

Also, deviations have been previously reported with flow-through porous electrodes operating near equilibrium (16). They were attributed to the fact that the two phases of the electrode were considered as two continuous media from the electrical point of view. Such an explanation still seems reasonable here because the agreement between theory and experiment is better when K_n is high, *i.e.*, all the other parameters being unchanged, when d_p is small or L is high. The smaller d_p or the higher L is, the less local electrical conductivity of the electrolyte in the pores of the bed deviates from the over-all apparent electrical conductivity.

Validity of the model.—Approximation [15] assumes that $[\eta(x)]^n$ is identical to $(n+1)/2 \cdot \eta \cdot [\eta(L)]^{n-1}$ at every point in the electrode. In order to test such an approximation, the experimental overpotential distributions for different values of $\eta(L)$ in a given electrode have to be compared. Figure 13 gives five experimental dimensionless distributions obtained during the treatment of an electrolyte in a given bed. In this figure two curves have been drawn from [18] by using, respectively, the lowest $\eta(L)$ value (curve 1) and the highest $\eta(L)$ value (curve 2). It can be seen that these two curves deviate only slightly from each other and enclose satisfactorily the experimental points which justifies approximation [15] for all $\eta(L)$.

Equation [2] also supposes that n is constant over all the local electrode overpotential range, thus may be inaccurate when $\eta(x)$ reaches very low values (electrode working in some parts near equilibrium). The theory could be improved by replacing the single equation [2] by a sequence of several kinetic equations, each valid in a specified variation range of η and characterized by a given pair of n and α values. Such a complication would probably bring nothing more to the user of the model. Indeed, the contribution of the bed fraction with very low overpotentials is usually negligible in comparison with the contribution of the rest of the bed.

If the experimental difficulties and the complexity of the system studied are taken into account, the agreement between theory and experiment is satisfactory. Furthermore the fact that the theory gives an underestimated electrode effectiveness makes it very useful for practical calculations.

As was recently outlined (15), many experimental investigations have dealt with current distributions within porous electrodes but only a small number of experimental studies concern the electrochemically active surface area. The present paper gives new information in this last area for electrodes working well below the limiting current, *i.e.*, in conditions where diffusional effects are absent.

Obviously the hypothesis of uniform electrolyte concentration within the electrode restricts the applicability of the analytical approach to systems in which the electrolyte velocity is not low. Also, a restriction follows from the hypothesis of a highly conductive dispersed phase. It is thought that the approach presented here could be used for systems such as low expanded fluidized bed electrodes and more generally for moving beds in which the dispersed phase behaves as highly conductive. For such systems, it is essential that the different parameters which determine the value of K_n are conveniently chosen in order to insure a good effec-

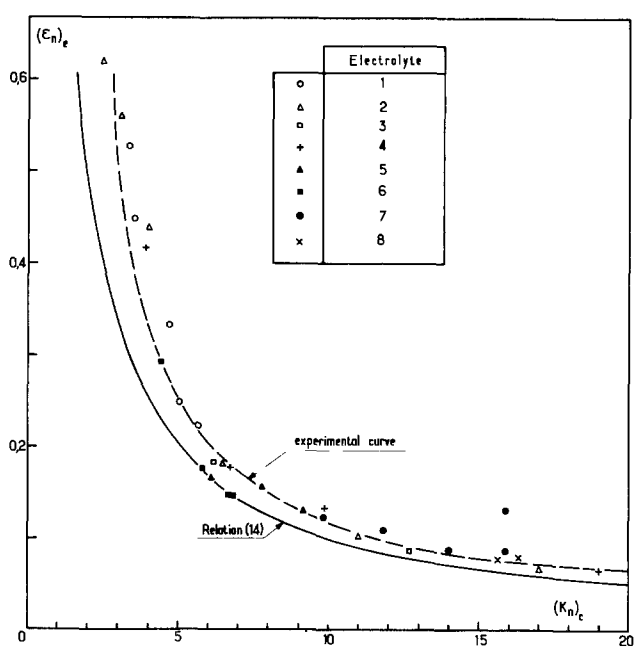

Fig. 12. Variations of $(\mathcal{E}_n)_e$ with $(K_n)_c$ and comparison with the theory.

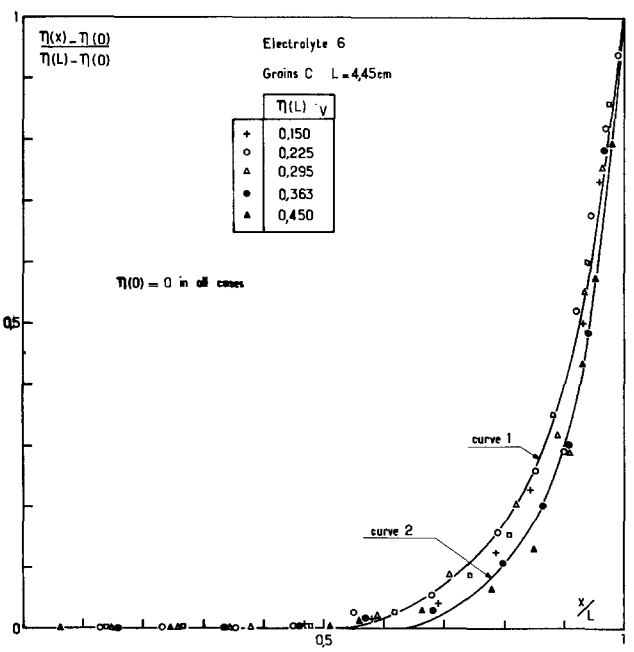

Fig. 13. Experimental dimensionless overpotential distributions in a given electrode for several imposed $\eta(L)$ values.

tiveness which would be an important factor of the investment cost for a given electrochemical reaction.

Expression [13] shows how the parameters can be chosen for guaranteeing a good effectiveness. K_n is small if: (*i*) the exchange current density has a low value (dilute solutions, bad electrocatalytic properties of the constituent material of the particles); (*ii*) the porosity ϵ of the bed is high (loose highly conductive packing); (*iii*) the specific area of the particles is small (not small particle diameters); (*iv*) the dimension L of the bed in the direction of the current lines is small; (*v*) the electrical conductivity γ is high (high values of γ_0 and particles such that the tortuosity of the current lines around them is reduced); (*vi*) the overpotential $\eta(L)$ at the electrode boundary opposite the counterelectrode has a high value.

Conclusion

Flow-through porous electrodes with highly conductive dispersed phases have been studied in a similar manner to solved chemical engineering problems in which mass transfer between two phases results from a competition between diffusion and chemical reaction (gas-solid catalysis, gas-liquid absorption). The analogy between the porous electrode seen as an heterogeneous electrochemical reactor and the gas-solid catalytic reactor is realistic; in the former the electrochemical overpotential plays the same role as the gaseous reactant concentration in the latter.

The general notions of effectiveness criterion K_n and effectiveness factor $\mathcal{E}_n$ which have been introduced are very important for the design of flow-through porous electrodes because the applications of these electrodes are mainly considered with regard to their high specific electrode area and their ability to act as three-dimensional electrodes. The criterion K_n is calculable *a priori* if the electrode, the electrolyte, and the operating conditions are fixed. Conversely, if an effectiveness $\mathcal{E}_n$ is chosen, it is possible to calculate K_n and to find the values of the different parameters of a flow-through porous electrode having the effectiveness $\mathcal{E}_n$. In addition, the approximated theory of these electrodes underestimates the performance which is advantageous from a practical point of view.

It has been shown that the behavior of the electrodes can be studied without using complex kinetic equations. In fact, it is sufficient for the designer to reason as in the chemical engineering discipline by finding a rational approximation. It is hoped that such an approach, which is very convenient for the electrochemical engineer, will be used more and more frequently.

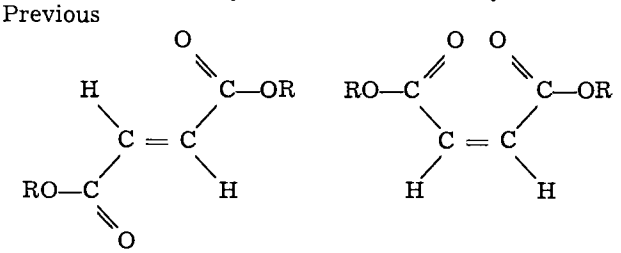
Rotating Ring-Disk Electrodes

V. Isomerization and Reductive Coupling of Dialkyl Maleates



Lun-Shu R. Yeh* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The rates of isomerization and coupling of the radical anions produced on electroreduction of several dialkyl maleates [methyl (DMM), ethyl (DEM), n-butyl (DBM)] in N,N-dimethylformamide solutions were investigated at the rotating ring-disk electrode (RRDE). Digital simulation methods were employed to obtain appropriate working curves and techniques were established to obtain both the first order isomerization constant (k_1) and the second order dimerization constant (k_2) from collection efficiency measurements. The measured k_1 values; DMM, 2.2; DEM, 6.0; and DBM, 6.7 (sec^{-1}) show an increasing isomerization rate with increasing size of alkyl substituent (R). The coupling rates decrease with increasing R; the k_2 values are: DMM, 1.9×10^5; DEM, 9.1×10^4; and DBM, 6.9×10^4 (M^{-1} sec^{-1}). Comparison of these results to previous measurements of the coupling rates of the corresponding trans-species (*i.e.*, fumarates) indicate that the *cis*-radical anions couple about two thousand times faster than do the *trans*.

The rotating ring-disk electrode has been useful in the investigation of the kinetics of electrode reactions, even for rather complicated mechanisms involving parallel reaction paths and higher order reactions [see (1-6) and references therein]. A particularly interesting electrochemical reaction scheme involves the difference in behavior upon reduction of the *cis*- and *trans*-isomeric dialkyl fumarates and dialkyl maleates. Previous

trans-isomer (or F) *cis*-isomer (or M)

R = CH_3 dimethyl fumarate (DMeF)	R = CH_3 dimethyl maleate (DMM)
R = C_2H_5 diethyl fumarate (DEF)	R = C_2H_5 diethyl maleate (DEM)
R = n-C_4H_9 di-n-butyl fumarate (DBF)	R = n-C_4H_9 di-n-butyl (DBM)

studies (7-10) have shown that in aprotic media the fumarates on reduction form the *trans*-radical anion ($F^{-\cdot}$) which undergoes a relatively slow coupling reaction to a dimeric dianion (D^{2-}) which ultimately produces hydrodimer, while the

$$F + e \rightarrow F^{-\cdot} \qquad [1]$$

$$2F^{-\cdot} \rightarrow D^{2-} \qquad [2]$$

maleates form the *cis*-radical anion ($M^{-\cdot}$) which isomerizes to $F^{-\cdot}$ and also couples much more rapidly to produce the dimeric dianion

$$M + e \rightarrow M^{-\cdot} \qquad [3]$$

$$2M^{-\cdot} \xrightarrow{k_2} D^{2-} \qquad [4]$$

$$M^{-\cdot} \xrightarrow{k_1} F^{-\cdot} \qquad [5]$$

While the qualitative nature of the reaction scheme for DEF and DEM was described, the rate constants for the various processes and the effect of alkyl substituent on the rates of isomerization and coupling were not given. The over-all reaction sequence for the reduction of a dialkyl maleate is quite complex and involves, in addition to reactions [2]-[5], the possibility of cross-coupling ([6]) and electron transfer ([7])

$$M^{-\cdot} + F^{-\cdot} \xrightarrow{k_2} D^{2-} \qquad [6]$$

$$M^{-\cdot} + F \xrightarrow{k_2''} F^{-\cdot} + M \qquad [7]$$

We describe here a digital simulation treatment (2-4, 6) of this reaction scheme at the RRDE and a strategy for determination of the rate constants from the experimental data. The values of these constants for the isomerization and coupling rates for several dialkyl fumarates and maleates are reported and discussed.

Experimental

Apparatus.—The general apparatus and procedures have been previously described (5, 8). A Tacussel Electronique Bipotentiostat, Model Bipad 2, was used for all RRDE experiments. A Wavetek function generator provided a linear d-c potential ramp to drive the Bipotentiostat. A simple operational amplifier adder circuit was used to adjust the starting potential of the scan. In all of the experiments, either the disk or ring was held at a constant potential while the other was scanned. The voltammograms were recorded using a Moseley Model 7100B dual pen strip chart recorder. A Moseley Model 2D-2 Autograf X-Y recorder and Model 7005A X-Y recorder were also used to record the disk and the ring currents simultaneously. A Digitec digital voltmeter Model 204 and a Hewlett-Packard digital voltmeter Model IM-102 were used to measure the potentials of the disk and the ring electrodes. These voltmeters were also used to record the steady-state disk and ring currents simultaneously as well as to calibrate the recorder responses. The RRDE, comprising platinum ring and disk electrodes separated by Teflon, was constructed by Pine Instrument Company, Grove City, Pennsylvania, and had the following dimensions: $r_1 = 0.187$ cm, $r_2 = 0.200$ cm, and $r_3 = 0.332$ cm. The theoretical collection efficiency, *i.e.*, the collection efficiency for a stable intermediate generated at the disk electrode, N, for this RRDE is 0.555. The reference electrode was a silver wire, and the counterelec-

** Electrochemical Society Active Member.
Key words: digital simulation, isomerization, dimerization, cyclic voltammetry, reductive coupling.

trode was platinum foil contained in different compartments separated from the main working electrode (RRDE) compartment by medium porosity sintered-glass frits.

Reagents.—N,N-dimethylformamide (DMF) obtained from Matheson, Coleman, and Bell Chemicals, was treated with molecular sieves and anhydrous cupric sulfate and then by vacuum distillation (11). The purified DMF was subjected to at least three freeze-pump-thaw cycles and was then stored in the dry box (Vacuum Atmospheres Corporation, Hawthorne, California). Tetra-n-butylammonium iodide (TBAI), polarographic grade, obtained from Southwestern Analytical Chemicals, Incorporated, was dried under vacuum and stored in the dry box. Diethyl fumarate (DEF), puriss, purchased from Aldrich Chemical Company was used without further purification. Diethyl maleate (DEM) (Matheson, Coleman, and Bell) containing about 5% diethyl fumarate impurity, was stored in a refrigerator. The DEF in the DEM was removed by preparative gas chromatography using a 6 meter chromatographic column filled with 30% SE 30 on 60/80 Chromosorb P and a column temperature of 175°C. Di-n-butyl fumarate (DBF) and di-n-butyl maleate (DBM) were purchased from Aldrich Chemical Company and used as received. Dimethyl maleate (DMM) was prepared by esterification of maleic anhydride with sulfuric acid and methanol purified by vacuum distillation yielding polarographically pure DMM. The maleic anhydride was purchased from Aldrich Chemical Company. The dimethyl fumarate (DMeF), also from Aldrich Chemical Company, was used after sublimation.

Digital simulation.—The RRDE voltammogram for a solution of DEM (2.55 mm) containing a small amount of DEF in 0.1*M* TBAI-DMF is shown in Fig. 1. The disk voltammogram (curve a) which shows the disk current i_d *vs.* disk potential, E_d, is characterized by the reduction of DEF to the radical anion, at −0.75V, (zone II) followed by the reduction of DEM to its radical anion in zone III. Thus for curve a the following reactions occur at the different potentials at the disk electrode surface and in the bulk solution near the electrode:

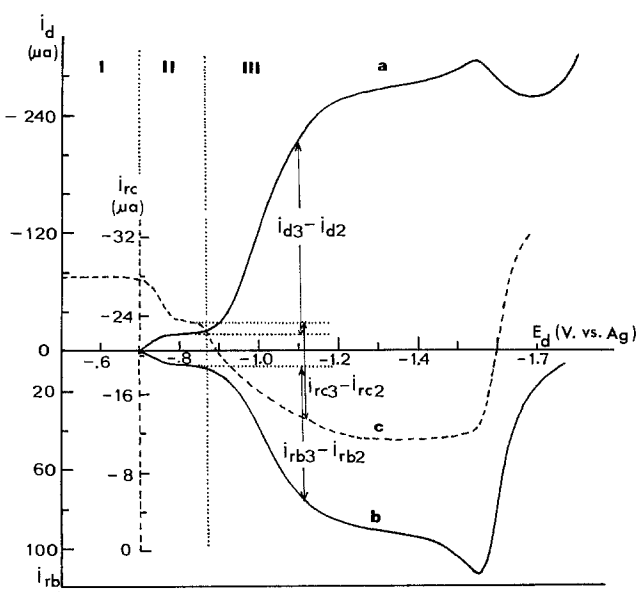

Fig. 1. RRDE voltammograms of diethyl maleate (2.55 mM) with diethyl fumarate impurity in TBAI (0.11M) DMF at a rotation speed of 201 radians/sec. a. Disk current b. Ring current at E_r = 0.0V. c. Ring current at E_r = −0.83V *vs.* Ag R.E.

A. Zone I: no reaction

Zone II: $F + e \rightarrow F^{\cdot -}$ $\quad i_{d2}$

$2F^{\cdot -} \rightarrow D^{2-}$

Zone III: The above reactions and

$M + e \rightarrow M^{\cdot -}$ $\quad (i_{d3} - i_{d2})$

$M^{\cdot -} \rightarrow F^{\cdot -}$ (rotational isomerization)

$2M^{\cdot -} \rightarrow D^{2-}$

$M^{\cdot -} + F^{\cdot -} \rightarrow D^{2-}$

$M^{\cdot -} + F \rightarrow F^{\cdot -} + M$ (charge transfer isomerization)

For the ring electrode held at a ring potential, E_r, of 0.0V any DEF or DEM radical anion formed at the disk which reaches the ring will be oxidized. Thus a scan of the ring current, i_r, *vs.* E_d (curve b) shows waves for the following reactions at the ring in the different zones:

B. Zone I: no reaction

Zone II: $F^{\cdot -} \rightarrow F + e$ $\quad (i_{rb2})$

Zone III: $F^{\cdot -} \rightarrow F + e$ (for $F^{\cdot -}$ generated from F at disk) (i_{rb2})

$F^{\cdot -} \rightarrow F + e$ (for $F^{\cdot -}$ resulting from isomerization) $\}$ $(i_{rb3} - i_{rb2})$

$M^{\cdot -} \rightarrow M + e$

For the ring electrode held at E_r = −0.83V (on the reduction plateau for DEF), a plot of i_r *vs.* E_d (curve c) shows waves for the following reactions:

C. Zone I: $F + e \rightarrow F^{\cdot -}$ (reduction of F transported to ring from disk, gap, and directly) (i_{rc1})

Zone II: $F + e \rightarrow F^{\cdot -}$ (shielded reduction of F transported to ring from gap and directly) (i_{rc2})

Zone III: The above reaction and

$M^{\cdot -} \rightarrow M + e$ $\quad (i_{rc3} - i_{rc2})$

The rate constants for the coupling of $F^{\cdot -}$ can be obtained, as previously described, by studies in the absence of maleate. The goal then is to find the rate constants for the isomerization (k_1) and coupling (k_2) of $M^{\cdot -}$ (Eq. [4] and [5]) from the available data. Let us assume first a negligible contribution from the reactions in [6] and [7]. The collection of $M^{\cdot -}$ left after all possible following reactions at the ring is represented by the current $i_{rc3} - i_{rc2}$. Thus the collection efficiency for $M^{\cdot -}$, N_k, is given by

$$N_k = |(i_{rc3} - i_{rc2})/(i_{d3} - i_{d2})| \qquad [8]$$

The ring current which represents the amount of $F^{\cdot -}$

produced by the isomerization of $M^{\cdot -}$ that reaches the ring, I_R, is

$$I_R = (i_{rb3} - i_{rb2}) - (i_{rc3} - i_{rc2}) \quad [9]$$

The total i_r which would be observed for $M^{\cdot -}$ in the absence of any chemical reactions would be $N(i_{d3} - i_{d2})$, where N is the collection efficiency of the electrode. Thus $N(i_{d3} - i_{d2}) - I_R$ is a measure of the extent of the isomerization reaction, and the isomerization collection efficiency parameter, n_k, defined in [10] can be

$$n_k = N - I_R/(i_{d3} - i_{d2}) \quad [10]$$

used to determine k_1. As in earlier work (5-8), a convenient variable is one related to the flux of reduced species from the disk, *i.e.*, $i_{d3} - i_{d2}$, divided by its limiting value (at *ca.* −1.3V), $(i_{d3,l} - i_{d2,l})$ called *CONI*

$$CONI = \frac{i_{d3} - i_{d2}}{i_{d3,l} - i_{d2,l}}$$

The digital simulations were carried out using the programs and methods previously described (2-6), modified for this reaction mechanism. A listing and description is available (12). The following dimensionless parameters were used to represent the rate constants; (notation follows previous practice and the diffusion coefficients of all species were assumed to be equal)

$$XKT = (0.51)^{-2/3}(\nu/D)^{1/3}\omega^{-1}k_1 \quad [11]$$

$$XKTC = (0.51)^{-2/3}(\nu/D)^{1/3}\omega^{-1}Ck_2 \quad [12]$$

Since the isomerization of $M^{\cdot -}$ to $F^{\cdot -}$ is a first order reaction and the half-life of $M^{\cdot -}$ is independent of the original concentration, a straight line parallel to the $1 - CONI$ axis results in the n_k *vs.* $1 - CONI$ plot for $k_1 >> k_2$. On the other hand when $k_2 >> k_1$ the N_k *vs.* $1 - CONI$ plot will show the upward curvature previously reported (6). Because the isomerization does not depend upon concentration or *CONI* when both isomerization and dimerization are significant, the N_k *vs.* $1 - CONI$ curve will generally show the second order dimerization trend, and the effect of isomerization moves the whole curve up or down, depending upon the relative magnitude of the isomerization effect. Simulation results are shown for keeping *XKT* constant and varying *XKTC* (Fig. 2), and keeping *XKTC* constant and varying *XKT* (Fig. 3). Note that when *XKT* predominates, the N_k *vs.* $1 - CONI$ curve straightens out, when *XKTC* does, it is curved. At high *XKT* and low *XKTC* values the line is almost independent of $1 - CONI$. A rough estimate of n_k can be obtained by extrapolating the N_k *vs.* $1 - CONI$ curve to $1 - CONI \rightarrow 1$, where $i_d \rightarrow 0$, and dimerization is negligible compared to isomerization.

The existence of species $F^{\cdot -}$ (either from the presence of more easily reduced F originally in solution or from isomerization of $M^{\cdot -}$) makes consideration of an additional reaction, the cross coupling to form D^{2-}, reaction [6], necessary. Simulations including this possibility were also carried out, with the dimensionless parameter *XKTD* representing the rate of this reaction, where *XKTD* is exactly the same as *XKTC*, except k_2 is replaced by k_2'. These simulations assume that the coupling of two $F^{\cdot -}$'s is slow compared to the $M^{\cdot -}$ reactions, and need not be considered. Typical results are shown in Fig. 4. The results here depend upon the relative amounts of F and M in the bulk solution (taken as 4:1 in the results of Fig. 4) and this provides a method for ascertaining the importance of cross coupling. Increasing the bulk concentration of F decreases the slope of the N_k *vs.* $1 - CONI$ curve.

Similar behavior results from inclusion of the electron transfer cross reaction [7], with *XKTCC* representing the appropriate dimensionless parameter, containing k_2''. The occurrence of this reaction alone, along with isomerization, causes a negative slope in the N_k *vs.* $1 - CONI$ curves (A and B in Fig. 5), as expected from the similar behavior found for the $R + R^{\cdot -}$ reaction in

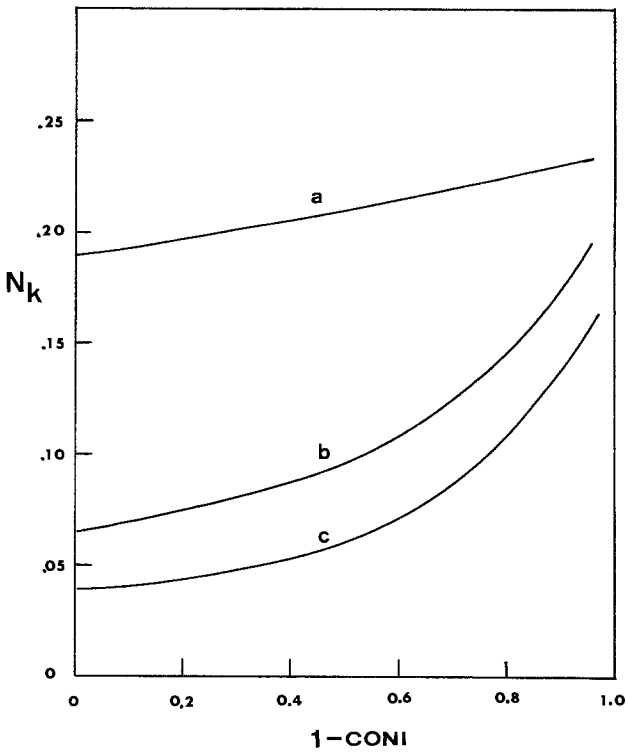

Fig. 2. Simulated collection efficiency for simultaneous reactions: first order parameter *XKT* = 0.77 and second order parameter *XKTC* of a, 0.5; b, 7.0; and c, 15.0.

hydrodimerizations (6). The inclusion of [7] along with [4] and [5] thus results in decreasing slopes of the working curves (Fig. 5).

Results

Diethyl maleate.—The experimental RRDE voltammogram for DEM containing a small amount of DEF is shown in Fig. 1 and typical experimental results at several values of ω and C are given in Table I. The experimental data were fitted by first obtaining an *XKT* value by simulating the calculated n_k from Eq. [10]. The *XKT* value can also be estimated from the extrapolated N_k value at *CONI* → 0. This value is then used with different trial values of *XKTC*, and the best fit parameters are obtained by a trial and error procedure. The resulting simulated curves based on these two parameters fit the experimental data quite well (Fig. 6). The calculated values of k_1 and k_2 are shown in Table II, based on results with solutions where the DEF concentration was less than 5% that of the DEM. To establish the importance of the cross-coupling reaction [6], experiments where DEF was added to the DEM solutions, were carried out. Typical results of such an experiment, where the concentration of DEF was 24% that of DEM are shown in Fig. 7.

These data could be fitted with a $k_1 = 5.7$ sec^{-1} and $k_2 = 9.6 \times 10^4$ M^{-1} sec^{-1}, which are very close to the values obtained in the absence of excess DEF. This suggests that the $F^{\cdot-}/M^{\cdot-}$ reaction is slow compared to $M^{\cdot-}/M^{\cdot-}$ dimerization. Previous results using double potential step techniques and electron spin resonance spectroscopy (13-15) have fixed the rate constant for the $F^{\cdot-}/F^{\cdot-}$ reaction, [2], under similar conditions at about 44M^{-1} sec^{-1}, so that the *cis*-radical anion dimerizes about 2000 times faster than the *trans*-form.

Dimethyl maleate.—The general behavior of DMM is similar to that of DEM. Freshly prepared DMM, however, does not show a reduction wave for the fumarate during RDE voltammetry, in contrast to the behavior of DEM, where even a sample freshly separated by preparative gas chromatography showed a small DEF wave. A cyclic voltammogram of DMM in the absence of DMeF (Fig. 8) shows an unusual "cross-over" behavior on reversal. On the first reduction scan only the single DMM reduction peak is observed. On the

Solid lines are simulation curves at a, *XKT* = 0.42, *XKTC* = 14.5 (corresponding to k_1 = 6.3 sec^{-1} and $k_2 = 8.25 \times 10^4$ liters/mole-sec); b, *XKT* = 0.53, *XKTC* = 24.0 (corresponding to $k_1 = 5.9$ sec^{-1} and $k_2 = 10.0 \times 10^4$ liters/mole-sec).

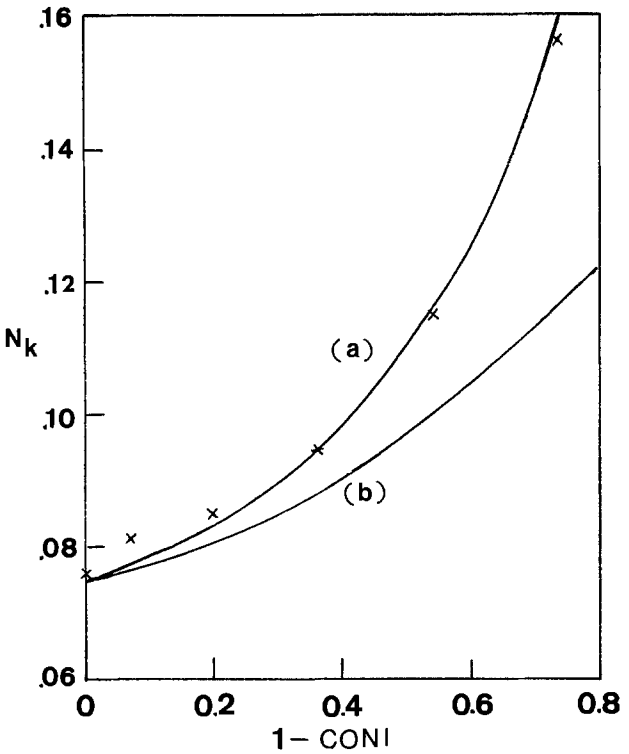

Fig. 7. Collection efficiency of the radical anion of diethyl maleate, 0.95 mM, in the presence of diethyl fumarate, 0.23 mM, in 0.1M TBAI-DMF solution. Experimental results (x) were obtained at rotation rate of 164 radians/sec. Solid lines are simulation curves at (a), $XKT = 0.51$, $XKTC = 7.0$ (corresponding to $k_1 = 5.7$ sec^{-1} and $k_2 = 9.6 \times 10^4$ liters/mole-sec); (b), $XKT = 0.51$, $XKTC = 4.5$, $XKTD = 4.5$.

reverse scan (oxidation of $M^{\cdot-}$ and $F^{\cdot-}$) the curve crosses over the reduction scan curve. This effect implies that a greater amount of reduction in this region (at *ca.* −0.9V) is occurring on the reverse scan than on the forward one. This can be attributed to the $M^{\cdot-}$ catalyzed isomerization of M to F (7) via the reaction sequence [3], [5], and [7], so that the amount of F at the electrode surface on reversal is larger than that present during the first forward scan. Note that this behavior does not occur with subsequent scans or for solutions originally containing DMeF. Similar cyclic voltammograms have been noted by Saveant (16). Notice also that the M reduction wave decreases strongly on repeated scans because of the loss of M via the dimerization, while the $F/F^{\cdot-}$ couple establishes a steady-state wave pair. RRDE studies of DMM exactly parallel those of DEM; typical data are in Table I and the resulting values of k_1 and k_2 are listed in Table II. Experiments in which DMeF was added in amounts up to 25% that of DMM were carried out and again the cross-coupling reaction did not appear to affect the results to a significant extent. Previous measurements of the dimerization rate of DMeF radical anion (5, 14) yield a rate constant of *ca.* $110M^{-1}$ sec^{-1} again about 2000 times smaller than that of the *cis*-radical anion.

Di-n-butyl maleate.—The behavior of DBM is very similar to that of DEM; both show the presence of the fumarate even in highly purified samples. The RRDE experiments parallel those of DEM; typical data and results are given in Tables I and II. The rate constant for DBF radical anion dimerization has been reported as $25M^{-1}$ sec^{-1} (14).

Discussion

The effect of substituent (methyl, ethyl, n-butyl) for the maleates is opposite for the isomerization (k_1) and dimerization (k_2) rate constants. For the dimerization, as the size of the substituent is increased, k_2 decreases; a similar trend is observed for the fumarates (14). Thus the bulky groups hinder the coupling of the radical anions, as expected. For the isomerization, increasing the substituent size causes k_1 to increase. The radical anions isomerize much more rapidly than the parent compounds probably because (*i*) the addition of an electron to the antibonding molecular orbital causes a decrease in the bond order of the central ethylenic bond and (*ii*), the negative charge on the molecule resides to a large extent on the oxygens, causing a coulombic repulsion of the carbonyl groups. Increasing the size of the substituents provides an added steric repulsion and thus increases k_1. Finally, for all compounds the *cis*-radical anions dimerize about 2000 times as rapidly as the *trans*. This can be explained by a larger electron density residing on the ethylenic carbons because of the coulombic repulsion of charge from the *cis*-carbonyls or because of partial twisting around the central bond. Not only is the coupling reaction larger, but these *cis*-radical anions react more rapidly with

added electrophiles such as acrylonitrile (7) or CO_2 (12, 17).

We conclude by referring to some related studies of isomerization of radical anions. Hayon and Simic (18) used a pulse radiolysis technique to study the formation and reactions of DMM and DMeF radical anions in aqueous solutions. They found no appreciable isomerization of DMM^- within the time window of their experiment ($\sim$ 0.1 μsec), which is consistent with the k_1 value reported here. Moreover strong hydrogen bonding in water may stabilize the *cis*-configuration. Ion pairing can also stabilize the radical anion and decrease the isomerization rate. Thus Szwarc and co-workers (19, 20) found that in THF solutions in the presence of alkali metal ions, stilbene radical anion isomerized slowly and the over-all isomerization reaction proceeded via the ion paired dianion. In HMPA, however, where the ion pairs were dissociated, isomerization of *cis*-stilbenide was reported. A study of the effect of ion pairing on the isomerizaton of maleate radical anions in DMF would be of interest but would probably be difficult, because the dimerization rates would be expected to become very rapid under these conditions (14).

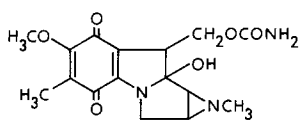
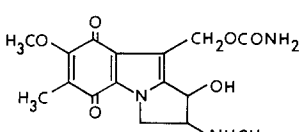
Electrochemical Studies of Antitumor Antibiotics

I. Cyclic Voltammetric Study of Mitomycin B



Gopalakrishna M. Rao,* J. William Lown, and James A. Plambeck*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada



ABSTRACT

Mitomycin B, a mitosane quinone-containing antibiotic, was investigated by HMDE cyclic voltammetry in aqueous media at 37.5°C. The observations are consistent with a mechanism in which mitomycin B is reversibly reduced, at −0.200V *vs.* SCE, to the hydroquinone, following which the aziridine ring opens rapidly. The significance of the mechanism is discussed in relation to the antineoplastic activity of certain antibiotics of the mitosane class.

Mitomycin B, **1**, is a member of the mitosane class of agents and is produced by *Streptomyces caespitosus* together with mitomycin C, an antitumor antibiotic of clinical significance (1, 2). This class of agents is part of the larger group of aminoquinone-containing antibiotics which act as inhibitors of DNA synthesis, such as streptonigrin (3), porfiromycin (1), the actinomycins (4), and aziridinoquinones (5), many of which exhibit significant antineoplastic activity. It is currently considered (6) that the mitosanes *in vivo* undergo an initial reduction by a cellular reductase, mediated by NADPH, to form the hydroquinones. The latter rapidly lose methanol or water to form an activated species which can induce covalent cross-links between complementary strands of DNA. These cross-links prevent strand separation during the semiconservative replication process (2)

1

2

MITOMYCIN B

Mitomycin C and related quinone-containing derivatives have been observed to cause extensive degradation of DNA in addition to cross-linking (7, 8). Hitherto this has been attributed to the stimulation of the production of intracellular deoxyribonucleases in the cell repair cycle (9, 10). Recently, however, we demonstrated (11) that when mitomycin C and streptonigrin are reduced in the presence of oxygen they generate superoxide and hydroxyl radicals which degrade DNA by single strand scission analogous to radiation damage.

For these reasons a detailed study of the redox behavior of the mitosanes is of interest; it is our purpose to investigate the initial reduction process *in vitro*, together with such related chemical processes as are accessible to electroanalytical investigation.

Experimental

The Princeton Applied Research (PAR) Model 9300-9301 polarographic cell was employed in a three-electrode configuration which included a conventional aqueous saturated calomel reference electrode, to which all potentials in this paper are relative unless otherwise specified, a platinum counterelectrode, and a PAR Model 9323 hanging mercury drop working electrode. The cell temperature was maintained at physiological temperature of 37.5° ± 0.02°C by circulation of thermostated water. Cyclic voltammetry was done using the PAR Model 173-175-176 configuration. The resulting curves were recorded on an X-Y recorder or photographed on an oscilloscope as required by the scan rate, ν, which was varied from 20 mV/sec to 500 V/sec. The pH of each solution was measured both before and after each run using an Accumet Model 520 pH meter and a combination glass-SCE electrode.

Samples of mitomycin B were kindly supplied by American Cyanamid Company Lederle Laboratories, Pearl River, New York, and by Kyowa Hakko Chemical Company, Japan, and were used as received. A derivative of this compound, **2**, in which the aziridine ring was opened was prepared by mild acid hydrolysis according to the procedure of Stevens *et al.* (12). The crude hydrolysate was then recrystallized from the mixture of ether and pentane as a yellow-orange solid. This derivative **2**, which we do not believe to have been prepared previously, is a yellow solid, mp 70°-72°C, soluble in water, chloroform, and ether; it can be precipitated from ether by addition of pentane. Its spectral characteristic absorbances (nanometers) and log of molar absorptivity are: 236, 4.16; 286, 4.06; 355, 3.26; 442, 2.89. Its infrared spectrum in $CHCl_3$ has the following absorbances (nanometers): 2960, 2920 (CH_3 sym. str.); 2860; 1715 (carbamate C=O); 1660, 1645 (quinone C=O); 1595; 1450; 1395; 1250 (=C—O—C antisym. str.); 1085; 1000 (=C—O—C sym. str.). All other chemicals were reagent grade and were used without further purification.

Fresh stock solutions of $1.3 \times 10^{-3}M$ mitomycin B were prepared daily and protected from light. Sample solutions were prepared in a cell itself as $3.3 \times 10^{-4}M$ mitomycin B, 0.1*M* phosphate buffer, and 0.1*M* KCl supporting electrolyte. The derivative **2** was treated in a similar manner. All solutions were deaerated with purified nitrogen for 10 min prior to a run and blanketed with it during a run.

Results

Typical results for the cyclic voltammetry of **1** at pH 6.58 are shown in Fig. 1, which shows a pair of well-defined peaks (cathodic IC and anodic IA) and a second pair of small peaks (cathodic IIC and anodic IIA). No other peaks were observed even when the potential scan was extended up to supporting electrolyte discharge at −1.6V.

* Electrochemical Society Active Member.
Key words: cyclic voltammetry, antibiotic mitosane, quinone, DNA, antineoplastic, antitumor.

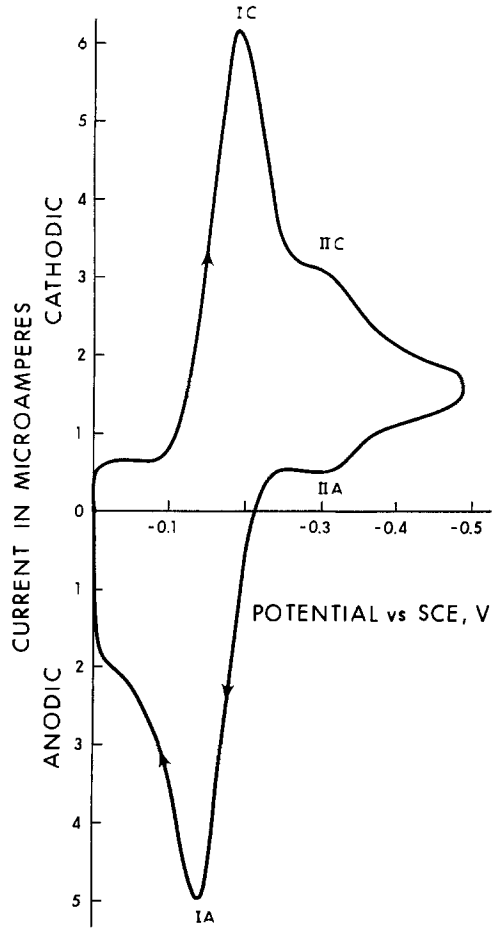


Fig. 1. Cyclic voltammogram of 1, pH 6.58 ± 0.02 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

The pH dependence, over the range of 6-8.5, of E_p of IC corresponds to the theoretical slope of 61.7 mV/pH unit as expected for a two-electron, two-proton process at 37.5°C. The ratio of $I_p(IA)/I_p(IC)$ was unity throughout this pH range. The peak potentials of IC and IA at pH 7 are

$$E_p(IC) = -0.215 \pm 0.005V$$

and

$$E_p(IA) = -0.180 \pm 0.005V$$

These peak potentials are independent of ν up to at least 50 V/sec. At higher ν, to 500 V/sec, $E_p(IC)$ shifts more cathodic by about 30-50 mV/tenfold increase in ν and $E_p(IA)$ shifts less cathodic by 15-50 mV/tenfold increase in ν. The ratio of $I_p(IC)/\nu^{1/2}$ remains virtually constant with scan rate up to 5 V/sec, and thereafter increases slightly with further increase in ν. All the above-mentioned facts and the separation of $E_p(IC)$ and $E_p(IA)$ by *ca.* 30 mV suggest that the electrode process is a reversible two-electron transfer at $\nu \leq 10$ V/sec. This is supported by the fact that the difference between the peak potential E_p and the half-peak potential $E_{p/2}$ for IC is 30 ± 2 mV. The value of the reversible formal potential (equivalent to a polarographic half-wave potential) calculated from these peak potentials is −0.200 ± 0.005V.

Multicycle runs at 500 mV/sec of **1** (Fig. 2) show IC and IA; IIC and IIA appear as barely visible shoulders to IC and IA during the first cycle. The peak potentials of both IC and IA do not change over the first ten cycles. Further cycling shifts IC more cathodic and IA less cathodic. Both peak heights decrease as expected with cycling and the peaks are no longer distinguishable beyond twenty cycles. The peak potentials of IIC and IIA shift little if at all with continued cycling. For the first three cycles, $I_p(IIC)$ decreases with cycling while $I_p(IIA)$ increases. Thereafter, both $I_p(IIC)$ and

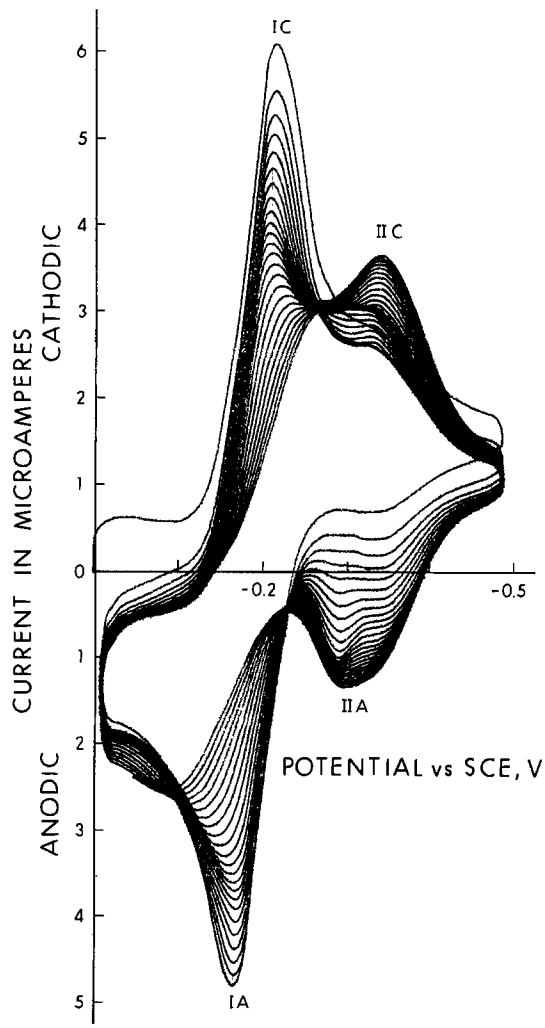

Fig. 2. Multicycle voltammogram of 1, pH 6.95 ± 0.02 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

$I_p(IIA)$ increase with cycling. With continued cycling, a shoulder and a peak appear on IIA and finally are seen to merge with it into one single peak (−0.305V). After the first three cycles, IIC starts to grow and finally gives a well-developed peak at −0.340V. Multicycle runs at 50 mV/sec (Fig. 3) are similar to those at 500 mV/sec except that only four to five cycles are needed to reach steady state while twenty cycles are needed at 500 mV/sec.

The multicycle runs of **1** described above indicate that both of the second peaks, II, grow at the expense of the first peaks, I. It was suspected that the species giving rise to peaks II was mitomycin B in which the aziridine ring had opened. This latter compound can be formed by acid hydrolysis of **1**. Therefore, a solution of **1** at pH 6.6 was treated with a few drops of hydrochloric acid to obtain a solution of pH 2; the acid hydrolysis was allowed to continue for 20 min. The cyclic voltammetry (ν = 500 mV/sec) of this new solution, **1′**, gave three cathodic peaks (IIC, IVC, and VC) and an anodic peak (IIA). [When the pH of solution **1** of pH 6.6 was made highly acidic, *i.e.*, 2, the positive shift of IC and IA was so great they could no longer be observed. The peaks of IIC and IIA were still within the observable potential range.] The peaks IIC and IIA were fully developed and their heights are comparable with IC and IA of **1**.

A few drops of concentrated KOH were added to solution **1′** to restore its pH to about 6. Let this solution be **1″**. A typical cyclic voltammogram of **1″** at ν = 500 mV/sec (Fig. 5) shows two cathodic peaks (IIC and IIIC), an anodic peak (IIA), and the absence

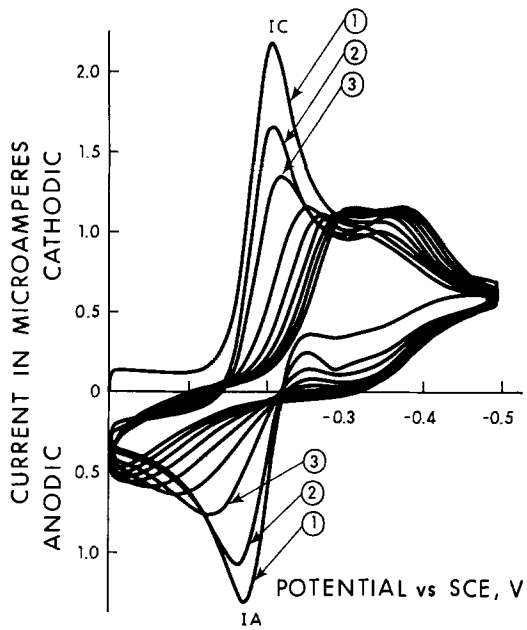

Fig. 3. Multicycle voltammogram of 1, pH 6.95 ± 0.02 in phosphate buffer, 37.5°C, ν = 50 mV/sec.

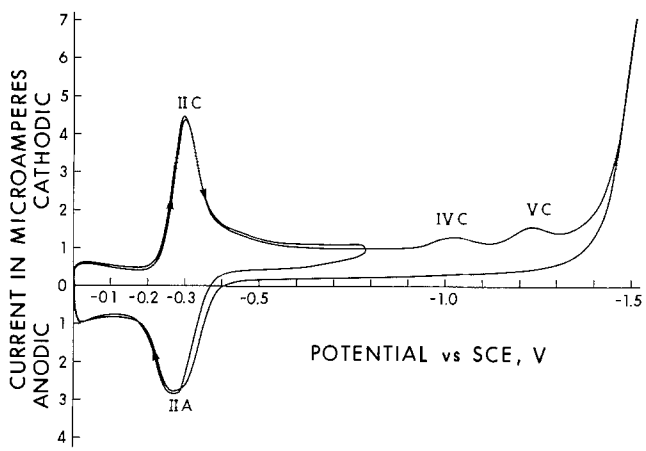

Fig. 4. Cyclic voltammogram of 2, pH 6.38 ± 0.02 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

of peaks IC and IA. Cyclic voltammetry of **1"** over the larger potential range of 0 to −1.6V showed, in addition to IIC, IIIC, and IIA, and the absence of IC and IA, two cathodic peaks IVC and VC and a barely visible anodic peak at IIIA. These are discussed below since the same peaks are observed with the solution of ring-opened derivative 2. The peak height of IIA is visibly less when the 0 to −1.6V cycle is used than when the 0 to −0.6V cycle is used.

The pH dependence of E_p(IIC) of **1"** over the pH range 6-8.5 corresponds to the theoretical slope of 61.7 mV/pH unit as expected for a two-electron, two-proton process at 37.5°C. The ratio of I_p(IIA)/I_p(IIC) was slightly less than unity in this pH range. The peak potential of IIC and IIA at pH 7 are

$$E_p(\text{IIC}) = -0.335 \pm 0.005\text{V}$$

and

$$E_p(\text{IIA}) = -0.305 \pm 0.005\text{V}$$

The peaks IIC and IIA of **1"** behave similarly to the peaks IC and IA of **1** with scan rate. However, I_p(IIC)/$\nu^{1/2}$ increases with ν at higher ν to a greater extent than does IC. The separation of E_p(IIC) and E_p(IIA) by *ca.* 30 mV suggests that the electrode process is a reversible two-electron transfer process at $\nu \leq 10$ V/sec. This

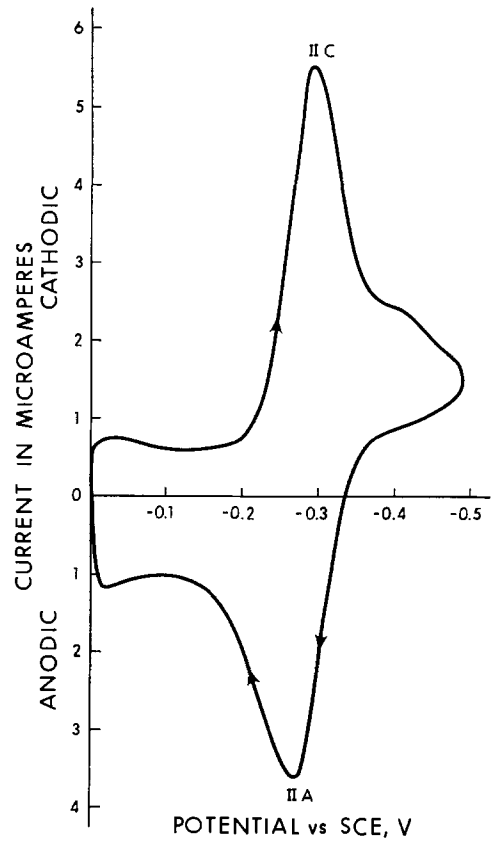

Fig. 5. Cyclic voltammogram of 1", pH 6.3 ± 0.02 in phosphate buffer, 37.5°C, ν = 500 mV/sec.

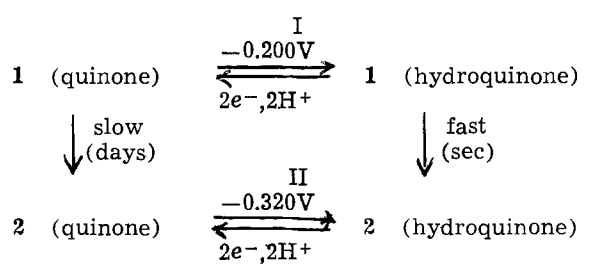
is supported by the fact that E_p(IIC) − $E_{p/2}$(IIC) is 30 ± 2 mV. The value of reversible formal potential (equivalent to a polarographic $E_{1/2}$) calculated from E_p of the second process is −0.320 ± 0.005V.

Both the IIIC and IIIA peaks are poorly defined, the definition of IIIC being slightly better than that of IIIA. These peaks are observed primarily in the biological pH region (pH 6-7.5). The pH dependence of E_p(IIIC) corresponds to 62 mV/decade and E_p at pH 7 is 0.450 ± 0.01V. The disappearance of IIIC and IIIA above pH 7.5 does not mean that the species responsible for this process are destroyed because these peaks reappear after restoration of pH to 6.0.

The appearance of IVC and VC and the absence of the corresponding anodic peaks show that these processes are not reversible. The peaks IVC and VC appear around −1.05 and −1.25V, respectively. Disappearance of IIIC results in slight increase in the peak height of IVC.

Cyclic voltammetric analysis of solutions of the ring-opened derivative, 2, gave peaks IIC, IIA, IVC, and VC (Fig. 4). The peaks IVC and VC are irreversible and appear at similar potentials as those for **1'** (and **1"**). The peaks IIC and IIA are identical in potential [E_p(IIC) = −0.325 ± 0.005V and E_p(IIA) = −0.300 ± 0.005V at pH 7] and behavior with scan rate and pH to the peaks of IIC and IIA of **1"**.

Multicycle runs of solutions of 2 at 500 and 50 mV/sec are identical. There is very little to no change in IIA with cycling. After the first cycle, E_p of IIC shifted by *ca.* 20 mV cathodic and its I_p decreased sharply by perhaps ¼ of its original value. On continued cycling, E_p of IIC shifted very slightly toward negative values and its I_p increased very slightly. The final peak potentials are: E_p(IIC) = −0.370 ± 0.005V and E_p(IIA) = −0.300 ± 0.005V.



Discussion

On the basis of the above results we may conclude that under these conditions the initial reduction of

mitomycin B is a reversible two-electron, two-proton reduction of the quinone structure to the hydroquinone. This process is responsible for the peaks designated I and has a reversible formal potential of -0.200 ± 0.005V. The aziridine ring of mitomycin B can be opened by acid hydrolysis and the resulting compound, **2**, can also undergo a reversible two-electron, two-proton reduction of the quinone structure. This process is responsible for the peaks designated II and has a reversible formal potential of -0.320 ± 0.005V. The remaining processes, which are the possibly reversible III and the irreversible cathodic IV and V, cannot be unambiguously defined other than as due to further reaction products of the reduced form of **2**. Loss of the carbamate moiety can occur, but soluble carbamates (urethane, n-butylcarbamate, and phenylcarbamate) were not found to be electrochemically active over the region 0 to -1.6V. Increases of ν to even 500 V/sec showed no evidence of additional peaks or of peak splitting such as would be expected if a semiquinone intermediate of lifetime greater than *ca.* 1 msec were present in the reduction of **1**. This observation does not exclude the formation of semiquinones of **1** or **2** as intermediates *in vivo* or in oxygenated solutions by subsequent air oxidation of the hydroquinones. Indeed, semiquinones are obligatory intermediates in the production of superoxide and hydroxyl radicals which degrade DNA (11). Semiquinone EPR signals were obtained (13) on reduction of mitomycin B in dimethylformamide, a solvent in which, however, the stability of the semiquinone would be much greater than in the present aqueous work.

The observations of increases in the IIC-IIA peaks, and decrease in the IC-IA system as this occurs, with multiple cycles demonstrates that the opening of the aziridine ring of mitomycin B is very slow, in that solutions are stable for several days in the absence of light at physiological pH, but that ring opening of the reduced form is very much more rapid, of the order of at most a few seconds. This quantitative demonstration is in agreement with previous postulates concerning the reductive activation of the mitosanes (2). Specifically, reduction to the hydroquinone releases the pyrrolizidine ring nitrogen lone pair for conjugative assistance in the opening of the aziridine ring.

The magnitude of the difference in potential between the reversible reductions of the quinones of **1** and of **2**, 120 mV, also indicates a close relationship between the redox power of the quinone system and the opening of the aziridine ring. The reduction of mitomycin B is so much easier than reduction of the ring-opened form **2** that, for both thermodynamic and kinetic reasons, the activation process *in vivo* probably begins with the reduction of mitomycin B itself to the hydroquinone

This explanation is consistent with the available *in vivo* evidence. Iyer and Szybalski (14) studied the cross-linking of native DNA by the mitomycins in the presence of cell lysates. Activation of the mitomycins was observed when a cell lysate of *bacillus subtilis, sarcina lutea, or cytophaga johnsonii* was added to a reaction mixture containing mitomycin and DNA, either that of the above-mentioned bacteria or of other species including human cells. Heating, aging, or aeration destroyed the ability of the cell lysate to activate the mitomycin; however, this ability of the dialyzed lysate could be restored by the addition of NADPH or of a system capable of generating NADPH, whereas [in contrast to streptonigrin (15)] NADPH is ineffective as a mitomycin-activating agent in the absence of the lysate.

Further, enzymatic reduction of mitomycin C and its metabolic inactivation by liver homogenates was reported by Schwartz, Sodergren, and Philips (16), who also postulated that reduction is associated with the metabolic activation of mitomycin. Their results indicate that the activation process of mitomycin action is related to NADPH-dependent enzymatic reduction of mitomycin to its hydroquinone derivative by a quinone reductase within the cell (17).

The redox behavior of mitomycin examined herein is therefore directly relevant to the *in vivo* situation. Also, the subsequent reoxidation of the hydroquinone form of the antibiotic is necessary to produce the superoxide radical anion shown to be involved in the degradation of cellular DNA (11). Since the oxidative machinery of the cell is integrated into or associated with its membrane, it seems likely that a similar ECE reaction may occur *in vivo* with the antibiotic at this site.

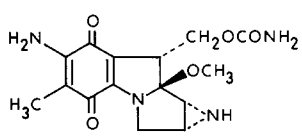
Electrochemical Studies of Antitumor Antibiotics

II. Polarographic and Cyclic Voltammetric Studies of Mitomycin C

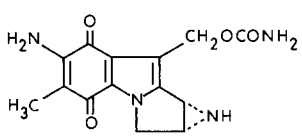
Gopalakrishna M. Rao,* Asher Begleiter, J. William Lown, and James A. Plambeck*



Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada

ABSTRACT

Mitomycin C, a quinone-containing antibiotic, was investigated by polarography and cyclic voltammetry in aqueous media at 37.5°C. The observations are consistent with a mechanism in which mitomycin C is reversibly reduced, at −0.368V vs. SCE, to the hydroquinone, following which the aziridine ring opens rapidly. The significance of the mechanism is discussed in relation to the antineoplastic activity of mitomycin C.



Mitomycin C, **1**, a member of the mitosane class of agents (1, 2), is an antitumor antibiotic used, for example, in the treatment of stomach cancer in Japan. Like mitomycin B, the subject of our previous paper (3), it is produced by *Streptomyces caespitosus* and acts as an inhibitor of DNA synthesis. It is currently considered (3, 4) that mitosanes *in vivo* undergo an initial reduction by a cellular reductase, mediated by NADPH, to form the hydroquinones. The hydroquinones rapidly lose water or methanol to form an activated species which can induce covalent cross-links between complementary strands of DNA. These cross-links prevent strand separation during the semiconservative replication process (1). Degradation of DNA by mitomycin C and related compounds has also been observed (5-7) which we (7) have shown can be attributed to the formation of superoxide and hydroxyl radicals by reaction of oxygen with the reduced forms of mitomycin C and other mitosanes.

It is therefore the purpose of the present paper to investigate the initial reduction process of mitomycin C *in vitro*, together with such related processes as are amenable to electroanalytical investigation. To this end we have employed polarography and cyclic voltammetry to study mitomycin C itself, **1**, mitomycin C which has undergone demethoxylation, **2**, and mitomycin C which has undergone both demethoxylation and opening of the aziridine ring, **3**

Experimental

Polarographic glass and Teflon cells of conventional design were employed in three-electrode assembly. The current-sampled d-c polarographic studies were made with a Model 174A polarographic analyzer (Princeton Applied Research) equipped with Model 174/70 drop timer. Polarograms were recorded on a Sargent model recorder. Cyclic voltammetric measurements and the other experimental conditions were as described previously (3).

* Electrochemical Society Active Member.

Key words: polarography, cyclic voltammetry, antibiotic, mitomycin C, quinone, DNA, antineoplastic, antitumor.

Mitomycin C was obtained from Calbiochem and Kyowa Hakko Kogyo Chemical Company, Japan, and was used as received. Demethoxylated mitomycin C, **2**, and ring-opened mitomycin C, **3**, were prepared as follows.

Demethoxylated mitomycin C, **2**: Mitomycin C (33 mg, 0.1 mmole) was hydrogenated over 5% palladium on charcoal in 10 ml of ethyl acetate. After one equivalent of hydrogen was absorbed, the solution was filtered and the filtrate exposed to air oxidation. Removal of the solvent *in vacuo* gave 8 mg of **2** as a purple solid which was purified by recrystallization from ethyl acetate: petroleum ether. The absorption spectrum in H_2O was: (λ_{max} in nanometers, log of molar absorptivity ϵ): 248, 3.90; 318, 3.60; 364, 3.79; 547, 2.52 in the ultraviolet/visible. The infrared peaks observed had ν_{max} (KBr disk) of: 3320 (Br), 1713 (CO of $OCONH_2$), 1650 (quinone C=O), 1600, 1548, 1325, 1210 cm^{-1}. This preparation follows the general procedure of Ref. (8).

Aziridine ring-opened mitomycin C, **3**: Hydrolysis of mitomycin C was carried out according to the procedure of Ref. (8) using hydrochloric acid. The crude hydrolysate was recrystallized from dimethylformamide:water and isolated in 17% yield. The absorption spectrum in CH_3OH was: (λ_{max} in nanometers, log of molar absorptivity ϵ): 248, 3.95; 309, 3.78; 343, 3.32; 562, 2.73 in the ultraviolet/visible. The infrared peaks observed had ν_{max} (KBr disk): 3390 (Br), 1695 (CO of $OCONH_2$); 1650 (quinone C=O), 1594 and 1376 cm^{-1}.

In addition to phosphate buffer ($5.9 < pH < 8.1$), acetate ($pH < 5.9$), and tris ($pH > 8.1$) buffers were also used in polarographic measurements. The polarographic drop time was controlled at 1.0 sec and the mercury flow rate was 0.93 mg/sec. The reversibility of the polarographic electrode reaction was determined from conventional log $((i_d - i)/i)$ plots.

Results

Polarographic analysis of aqueous **1** solutions yielded graphs containing the cathodic waves IC-IVC, of which IVC is observable only at $pH > 6.5$. The IC wave ($E_{1/2} = -0.368 \pm 0.003$V at pH 7) log plot gave a reversible two-electron slope. The pH dependence of $E_{1/2}$ corresponds to the theoretical slope of 61.7 mV/pH unit expected for a two-electron, two-proton process at 37.5°C at $pH > 5.4$ (Fig. 1) and the wave height remains approximately constant at 0.57 μA over the range $5.4 < pH < 8.5$. At $pH < 5.4$, the height of the wave decreased markedly and the $E_{1/2}$ *vs.* pH plot had a slope of over 90 mV/pH unit. The material responsible for this wave is irrecoverably destroyed immediately at $pH < 4$, so that the decrease cannot be due to a reversible protonation equilibrium. The second wave IIC ($E_{1/2} = -0.486 \pm 0.005$V at pH 7) is drawn out in shape (and shown by a log analysis not to be reversible); its height decreased from 0.53 μA from pH 4-6, then rose again to regain its original height at pH

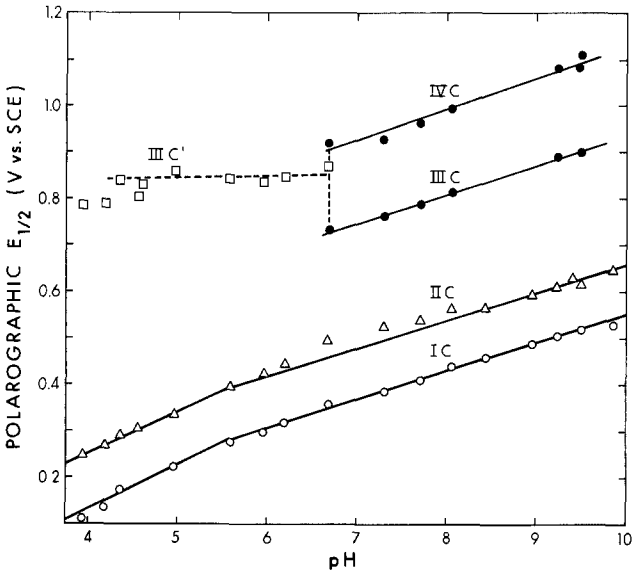

Fig. 1. pH dependence of half-wave potentials of aqueous 1. 3.4 × 10^{-4}M solutions in solutions of buffer, acetate (pH < 5.9), phosphate (5.9 < pH < 8.1), trizma (pH > 8.1); ○, first wave; △, second wave; □, third wave with no splitting; ●, third wave with splitting.

> 8.5. The value of $E_{1/2}$ varied with pH by 90 mV/pH unit at pH < 5.8 and 61 mV/pH unit at pH > 5.8 (Fig. 1). This wave is not affected by making the solution acidic (pH < 4) for a short period of time. A third wave IIIC', irreversible, appears to split into two smaller waves, IIIC and IVC (total height of IIIC + IVC observed in the basic range is less than or equal to the height of the single wave IIIC' observed in the acidic range), neither reversible, at pH > 6.5 (Fig. 1). The slope of $E_{1/2}$ *vs.* pH is approximately the theoretical slope of 61.7 mV/pH unit for both of the split waves; the value of $E_{1/2}$ for IIIC' in the acidic region changes less, if at all, with pH. At pH 7.0, we have $E_{1/2}$ values of −0.745 ± 0.005V for IIIC and −0.925 ± 0.005V for IVC. The variation in the height of IIIC' (or total height of IIIC + IVC) with pH follows the trend of IIC, that is, greater at both acidic and basic ends, and lesser in the intermediate pH range. This variation suggests that the species reduced at the potentials corresponding to IIIC and IVC may be the product or products of the reduction which occurs at the potential corresponding to IIC.

Figure 2 is a typical cyclic voltammogram of **1** at 200 mV/sec. It shows four cathodic peaks (IC-IVC) and one anodic peak (IIA; IA is absent). The appearance of IIIC and IVC, and the absence of the corresponding anodic peaks IIIA and IVA, show that these processes are not reversible, in agreement with our polarographic findings. These peak potentials E_p are more negative than E_p values calculated from corresponding $E_{1/2}$ values, as is expected for irreversibility. Most of the cyclic voltammetric studies were restricted to the potential range 0 to −0.85V to avoid complications arising from these processes. With the range thus restricted, only IC and IIC are observed at ν < 100 mV/sec. At ν = 100 mV/sec, IA and IIA become visible; at ν = 200 mV/sec. IIC splits into two peaks. With increasing ν, the increase in the height of IC and IA is much greater than the corresponding increase in height of IIC and IIA. At very fast scan rates, 2 V/sec ≤ ν ≤ 10 V/sec, IC and IA are very well defined and separated by 35 ± 5 mV (Fig. 3). The peak potential E_p of IC shifts toward more cathodic potential by *ca.* 10 mV for each tenfold increase in scan rate, which is consistent (9) with the mechanism proposed below. Correspondingly, E_p of IA shifts toward more negative potential by *ca.* 20 mV for each tenfold increase in scan rate. The $I_{p,cath}/\nu^{1/2}$ ratio increases slightly with the increase in scan rate. For IC, the difference between the peak potential E_p and the half-peak potential $E_{p/2}$ is 28 ± 2 mV and the measured polarographic $E_{1/2}$ of −0.368 coincides with the calculated $E_{1/2}$ of −0.369V obtained from E_p of −0.383V as expected (9) for a two-electron reversible process. For IIC, E_p remains constant at −0.506 ± 0.005V over the range 500 mV/sec ≤ ν ≤ 10 V/sec. However, IIC appears to split into two peaks at ν = 200 mV/sec with E_p of −0.470 and −0.510V, the latter value being the same as that for IIC at ν > 200 mV/sec. Nevertheless, at ν < 200 mV/sec there appears only one broad peak, whose peak potential shifts toward more cathodic potential from −0.470V by about 60 ± 5 mV for every tenfold decrease in scan rate. The corresponding broad anodic peak IIA, which does not split, is not present if the switching potential is −0.85V *vs.* SCE and ν < 100 mV/sec. On further increase in scan rate, IIA appears and E_p shifts toward more cathodic potential by about 60 ± 10 mV up to ν = 2 V/sec; it remains constant at −0.509 ± 0.003V at faster scan rates. The ratio I_p of IIA/I_p of IIC was found to be approximately constant at 0.75. The ratio $I_p/\nu^{1/2}$ for IIC is also nearly constant. The separation of peak potentials between IIC and IIA is 60 ± 10 mV, at 200 mV/sec ≤ ν ≤ 1 V/sec.

Polarographic analysis of a solution of the slightly soluble ring-opened derivative **3** gives curves in which IC is barely observable. Cyclic voltammetry of **3** shows very small peaks for IC and IA identical in potential and behavior with those of **1**, such as would arise from

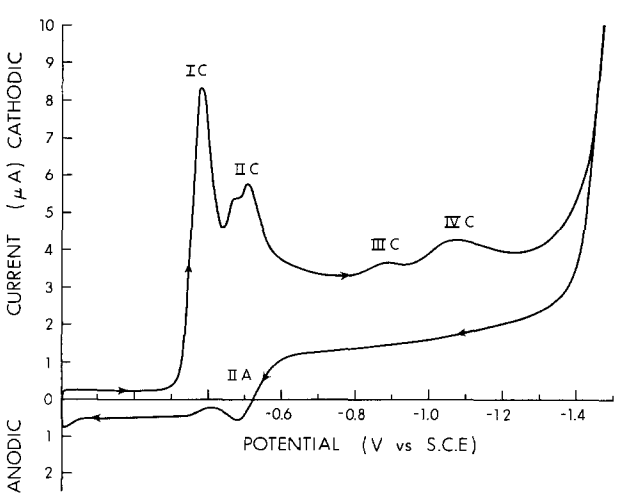

Fig. 2. Cyclic voltammogram of 1 (3.4 × 10^{-4}M), pH 6.98 ± 0.02 in phosphate buffer, 37.5°C, ν = 200 mV/sec.

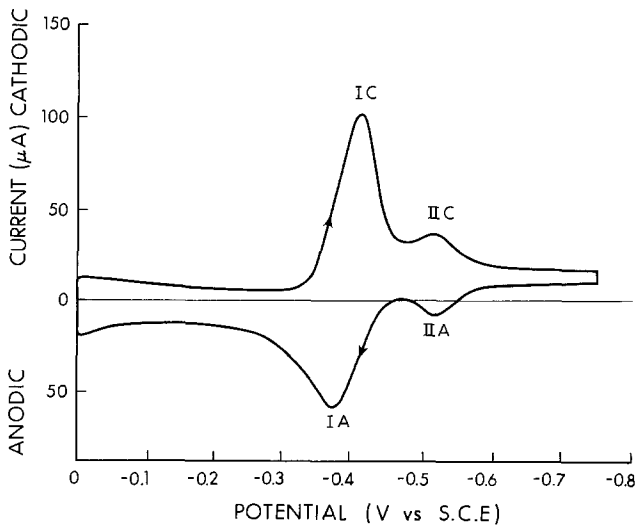

Fig. 3. Cyclic voltammogram of 1 (3.4 × 10^{-4}M), pH 6.98 ± 0.02 in phosphate buffer, 37.5°C, ν = 10 V/sec.

< 5% of unreacted **1** remaining in the preparation of **3** as could reasonably be the case since the preparation was carried out on only a few milligrams. The irreversible waves IIIC and IVC of solutions of **3** are identical to those of **1**.

The polarographic wave for IIC is present in distorted form. It cannot be resolved even using differential pulse mode, in which two barely distinguishable peaks appear at $pH > 9$ while the second is a small shoulder upon the first at $pH < 9$. The combination has a value of $E_{1/2}$ identical to that of IIC for **1** and $dE_{1/2}/dpH$ is 60 mV/pH unit. The irreversible waves IIIC and IVC observed with **3** behave identically to those observed with **1**. The cyclic voltammetric peak IIC behaves similarly to peak IIC of **1** for 200 mV/sec $< \nu <$ 50 V/sec. However, IIC splits into two peaks at scan rates 200 and 100 mV/sec. The height of the leading peak is slightly greater at 200 mV/sec. At $\nu < 100$ mV/sec, only one broad peak IIC can be distinguished. Its potential shifts slightly more negative from −0.475V by *ca.* 15 mV for every tenfold decrease in ν. The corresponding anodic peak IIA is visible at all scan rates and becomes sharper at faster scan rates; E_p remains constant at −0.470 ± 0.005V at all scan rates. The ratio $I_pC/\nu^{1/2}$ for IIC is almost constant up to scan rate 200 mV/sec and then increases with further increase in scan rate. The difference $(E_p - E_{p/2})$ is 40-50 mV for IIC, and E_p for IIA and IIC are separated by *ca.* 35 mV.

Polarographic analysis of a solution of the slightly soluble demethoxylated derivative **2** gave waves identical to those of **1**; the $E_{1/2}$ of IC for **2** differed by less than 5 mV from that of IC for **1**. The distortion of IIC, though of the same form as that observed for **3**, was barely noticeable. The cyclic voltammogram of **2** was similar to that of **1**. At 10 mV/sec $< \nu <$ 1000 mV/sec, the E_p of IC and IA and their dependence with scan rate are identical to those of **1**. At $\nu > 1000$ mV/sec, however, both IC and IA of **2** become severely distorted. The ratio $I_p/\nu^{1/2}$ for IC is nearly constant up to $\nu = 1000$ mV/sec and then increases with ν. The difference $(E_p - E_{p/2})$ for IC is 35 mV. The potentials E_p of IA and IC are separated by *ca.* 60 mV for 200 mV/sec $< \nu <$ 1000 mV/sec. The splitting and values of E_p for IIC and IIA of **2** at scan rates up to 2 V/sec are identical to those of **3**. At scan rates faster than 2 V/sec, E_p for IIC and IIA of **2** shift toward more anodic potentials. The ratio $I_p/\nu^{1/2}$ for IIC remains constant up to $\nu = 1000$ mV/sec, and then appears to increase with further increase in ν.

A typical example of a multicycle sweep is shown in Fig. 4 for **2**; similar waves are observed for **1** and **3**, except that for **3** the IC peak is extremely small. All compounds show a IC, a split IIC, and a IIA peak during the first cycle; **1** also shows a small IA peak. In the second cycle, we can see IC only as a shoulder, IIC (the split peak appearing at more negative potential than during the first cycle), and IIA. Only IIC and IIA appear after the second cycle. Although both **2** and **3** reach steady state in five cycles, **1** reached steady state only after sixteen cycles. The cathodic peak height decreases and E_p shifts toward more negative potential as the number of cycles increases, while the anodic peak height increases and E_p shifts toward more negative potential (for **2** and **3**, the shift in E_p with the number of cycles is negligible). At steady state, the cathodic and the anodic peak potentials are separated by *ca.* 65 ± 5 mV and the absolute ratio of I_p of IIA to I_p of IIC is 0.60 ± 0.05; the procedure of Nicholson (10) gives a value for this ratio of approximately unity as expected for a reversible process.

Multicycle runs at 20 mV/sec are similar to those at 200 mV/sec for **1** and **3** but not for **2**, which then takes considerably more cycles to reach the steady state.

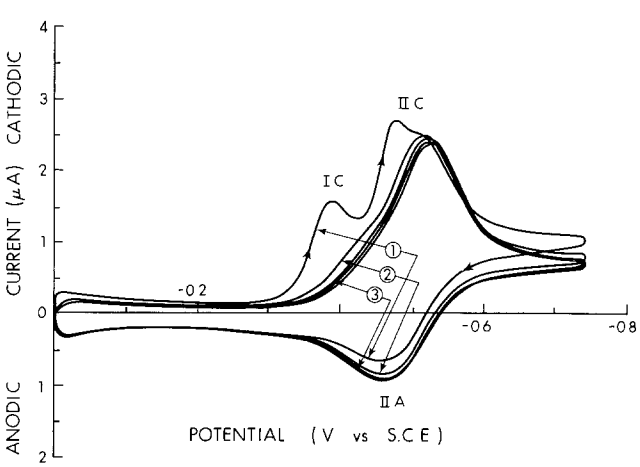

Fig. 4. Multicycle voltammogram of 2 (3.4×10^{-4}M), pH 6.98 ± 0.02 in phosphate buffer, 37.5°C, $\nu = 200$ mV/sec.

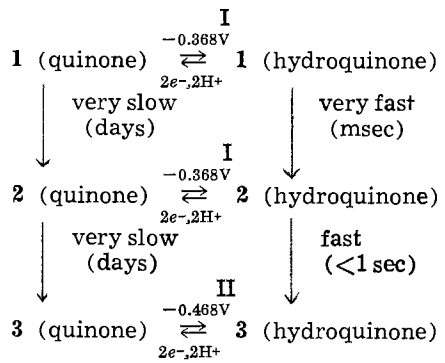
Discussion

On the basis of the above results, the mechanism of the reduction of mitomycin C at pH 7 is considered as belonging to the ECE (electrochemical-chemical-electrochemical) class, where C represents one or more steps. The electrochemical steps are considered to be R-R (reversible-reversible) (11) and the chemical steps are considered irreversible. The initial electrochemical step responsible for the waves and peaks designated I has a reversible formal potential of −0.368 ± 0.003V at pH 7 and is a reversible two-electron, two-proton reduction of the quinone structure to the hydroquinone. At $pH < 5.4$, the polarographic current is lower due to the irreversible opening of the aziridine ring. This view is reinforced by the cyclic voltammetry which shows peak IA at, and only at, very high scan speeds.

Polarography is not capable of providing information on the chemical step which follows reduction of **1** but this step can be characterized using the cyclic voltammetric data. This reaction must be both rapid and irreversible to explain the single-scan voltammetric curves, and the absence of IC and IA from the later scans of the multicycle voltammetry provides additional proof.

From our cyclic voltammetric measurements of mitomycin B, we have recently shown that the ring opening of the reduced form is very rapid, of the order of seconds (3), compared to the ring opening of the oxidized form. Thus the chemical reaction of mitomycin probably is demethoxylation and aziridine opening following the reduction to the hydroquinone. The differences in the behavior of wave I between **1** and **2**, though slight, are real at high scan rates indicating that the demethoxylation following reduction proceeds at an extremely high but finite rate. The observation that wave I is absent from the electrochemical reduction of the aziridine ring-opened **3** and the close similarity to the behavior of **2** shows that the kinetic chemical process following reduction is, at least in part, due to the aziridine ring-opening reaction. The process responsible for the waves and peaks designated II has a reversible formal potential −0.486 ± 0.005V at pH 7 and is clearly the two-electron, two-proton reduction of the ring-opened and demethoxylated **3** to corresponding hydroquinone. This process is almost certainly electrochemically reversible as shown by the cyclic voltammetry of **3** but does not appear so in voltammetry of **1** due to the irreversible chemical steps preceding it.

The rate of the chemical reaction K_f that follows the initial reduction of **1** can be estimated from the cyclic voltammetry. Use of the ratio I_p for IA to I_p for IC in the voltammetric curves in which IA is measurable (9, 10) does not give a satisfactory value of K_f, probably due to the interference of process II; however, estimated K_f values are close to 10 sec^{-1}. The half-life for the hydroquinone of **1** is estimated as 0.07 sec. This is consistent with a mechanism in which at the reduction



potential of **1** there is an initial reduction of **1** to its hydroquinone, which rapidly converts to the hydroquinone of **2** and, slightly less rapidly, to the hydroquinone of **3**. At this potential, the hydroquinone of **3** is immediately oxidized to the quinone **3**, which is then present and available for reduction in process II at a more negative potential later in the scan. As scan speeds increase, the time available for the chemical steps is decreased and hence the height of IIC decreases, relative to that of IC, with ν as can be seen by comparison of Fig. 2 and 3.

Mild acid hydrolysis of **1** affords regiospecifically a mixture of the stereoisomeric ring opened compounds *cis* and *trans* in a ratio of 86:14 (8, 12). Therefore, the two split peaks at $\nu = 100$ mV/sec separated by 40 mV may be due to the *cis* and *trans* isomers of ring opened mitomycin C. The remaining processes corresponding to the irreversible cathodic IIIC and IVC are probably due to the further reaction products of the reduced form of **3**; a similar explanation was given for IIIC, IVC, and VC of mitomycin B (3).

Our experimental findings do not demonstrate the presence of semiquinone intermediates of mitomycin C derivatives, which are obligatory intermediates in the production of superoxide and hydroxyl radicals which degrade DNA (7). Our observations, however, do not preclude the formation of semiquinones of mitomycin C derivatives as intermediates *in vivo*, under alkaline conditions, or in oxygenated solution by subsequent air oxidation of the hydroquinones. Moreover, *in vivo* the semiquinone may be produced within the DNA helix from the free hydroquinone by interaction with cytosine as postulated by Murakami (13) to explain the promoting effect of deoxycytidilic acid observed by Iyer and Szybalski (14). Recent sulfite oxidation evidence may indicate mitomycin C semiquinone formation in a liver microsomal system open to oxygen (17).

In general, semiquinone EPR signals are obtained under alkaline conditions (15) because the stability of semiquinones increases with increasing *p*H. The existence of the semiquinone of mitomycin C with a 10 sec lifetime under the highly alkaline conditions of sodium borohydride reduction as shown by Nagata *et al.* (16) therefore does not contradict our results, which were carried out in the physiological *p*H region.

Compounds **1** and **2** are closely similar if not identical in reduction potential whereas **3** is markedly more difficult to reduce. The magnitude of the difference in potential between the reversible reduction of the quinones of **1** and of **3**, 120 mV, is the same value observed for the difference in reversible formal potential of mitomycin B and its ring-opened derivative (3). This reinforces our earlier statement that there exists a close relationship between the redox power of the quinone system and the opening of the aziridine ring. The reduction of mitomycin C, like that of mitomycin B, is so much easier than reduction of the ring-opened form **3** that, for both thermodynamic and kinetic reasons, the activation process *in vivo* (3) probably begins with the reduction of mitomycin C itself to its hydroquinone

The Oxidation of Alcohols at a Nickel Anode in Alkaline t-Butanol/Water Mixtures

Mohammed Amjad, Derek Pletcher, and Carmen Smith

Department of Chemistry, The University, Southampton S09 5NH, England

ABSTRACT

The oxidation of a range of phenylethanols, benzyl alcohols, and allyl alcohols at a nickel electrode in a series of t-butanol/water mixtures has been investigated. The alcohols give well-formed but kinetically controlled oxidation waves at the potential of the Ni^{II}/Ni^{III} surface change, and the limiting current densities are low. The phenylethanols and allyl alcohols give only carboxylic acids in good yields; the benzyl alcohols give a mixture of aldehyde and carboxylic acid although in a good combined yield. The ratio of aldehyde/carboxylic acid can be changed substantially by variation of the hydroxide ion concentration and in some cases the product may be all acid or all aldehyde depending on the electrolysis conditions.

In an earlier paper (1) it was reported that at a nickel anode in aqueous potassium hydroxide, simple n-alcohols were oxidized to carboxylic acids in current and organic yields in excess of 90%. It was suggested that the rate-determining step in this oxidation was a chemical reaction, hydrogen abstraction from the α-carbon of the alcohol by a nickel oxide [closely related to the chemical reagent, nickel peroxide (2)] formed anodically on the surface of the nickel, *i.e.*

$$Ni \xrightarrow{\text{aqu.KOH}} Ni(OH)_2 \overset{-e}{\rightleftarrows} NiO(OH) + H^+ \qquad [1]$$

$$NiO(OH) + RCH_2OH \xrightarrow{\text{r.d.s.}} Ni(OH)_2 + \dot{R}CHOH \qquad [2]$$

$$\dot{R}CHOH \xrightarrow[\text{further steps}]{} \text{products} \qquad [3]$$

Although these oxidations are not synthetically significant, nickel peroxide has been reported to be a useful reagent for the oxidation of a range of benzyl and allyl alcohols (2, 3). Hence it was considered of interest to attempt the oxidation of larger alcohols at a nickel electrode in alkaline media.

In order to carry out such electrolyses simply it is necessary to find a solvent where such alcohols are soluble but the electrochemistry of the nickel electrode is essentially the same as in aqueous solution. Hence in this paper we discuss the electrochemistry of nickel and the oxidation of benzyl alcohols and phenylethanols in a series of tertiary butanol/water mixtures. It should also be noted that the solvent medium is important in determining the products from the chemical oxidations with nickel peroxide; in aqueous alkali the products were carboxylic acids but in an organic solvent the main products were aldehydes (3). Thus it is possible that the products from the anodic oxidations could be controlled by suitable choice of the solvent medium.

Experimental

Steady-state and cyclic voltammetric experiments were carried out in a two-compartment cell. The working electrode was constructed from Koch Light, Limited nickel rod (purity > 99.998%) and was in the form of a disk electrode with a PTFE sheath. Prior to the electrochemical measurements the nickel electrode was polished with fine alumina powder and washed with distilled water; its potential was then cycled in the electrolysis medium at 0.1v sec^{-1} between 0.0 and 0.7V until the charge associated with the Ni^{II}/Ni^{III} transition became constant [approximately 5-8 cycles]. The auxiliary electrode was a Pt loop in the same compartment as the nickel anode but the saturated calomel reference electrode (Radiometer Type K401) was in a different compartment separated by a tap and Luggin capillary mounted on a glass syringe, so that the position of the tip with respect to the nickel disk could readily be adjusted. Preparative electrolyses were carried out employing a constant current (0.3 mA cm^{-2} unless otherwise stated) and a one-compartment cell, volume 250 cm^3. The working electrode was a 300 cm^2 nickel gauze (purity > 95%) in the form of a cylinder, and the stainless steel rod cathode was placed at the axis of the cylinder; during electrolyses the solution was stirred by a slow stream of nitrogen. All electrochemical experiments were carried out using a Chemical Electronics valve or transistorized potentiostats; where necessary a Chemical Electronics pulse generator, Type R.B.1 and a Hewlett-Packard 7035 X-Y recorder were also employed. An electronic integrator was employed for coulometry.

Solutions were prepared from triply distilled water, GPR grade tertiary butanol (Hopkin and Williams, Limited), and AR grade potassium hydroxide (B.D.H., Limited), sodium hydroxide (B.D.H., Limited), and sodium perchlorate (Koch-Light, Limited). The organic substrates were obtained from B.D.H., Limited, May and Baker, Limited, Koch Light, Limited, Aldrich Chemical Company, Limited, or Chemical Procurement, Limited, and where necessary the purity of the compounds was checked using glc. (a Pye 104 chromatograph and an OV-17 silicon oil column at 140°C).

Preparative electrolyses were generally carried out using a constant current of 0.3 mA cm^{-2} and 0.04 moles of the alcohol dissolved in 200 cm^3 of the solvent/electrolyte. The electrolyses were terminated after the passage of 2**F**/mole of substrate. Alcohol and aldehyde products were extracted from the electrolysis medium with ether, and carboxylic acids were extracted similarly after the solution had been acidified. Following evaporation of the ether and any t-butanol the products were examined by IR, NMR and mass spectroscopy using a Unicam SP 200, a Perkin Elmer R12 at 60 MHz, and a AEI MS12 mass spectrometer, respectively. The yields of the carboxylic acids were based on the weight of isolated pure product, and the amount of alcohol and aldehyde in the alkaline extracts was estimated from the NMR spectra and by glc. Where aldehydes were major products, their yields were checked by preparing the 2,4-dinitrophenylhydrazone derivatives and weighing. In most cases retention times and spectra were compared with those for authentic samples.

Results

The electrochemistry of nickel in alkaline t-butanol/water mixtures.—Curve (a) of Fig. 1 shows a cyclic

Key words: nickel oxide, electrosynthesis, aldehydes, dehydrogenation.

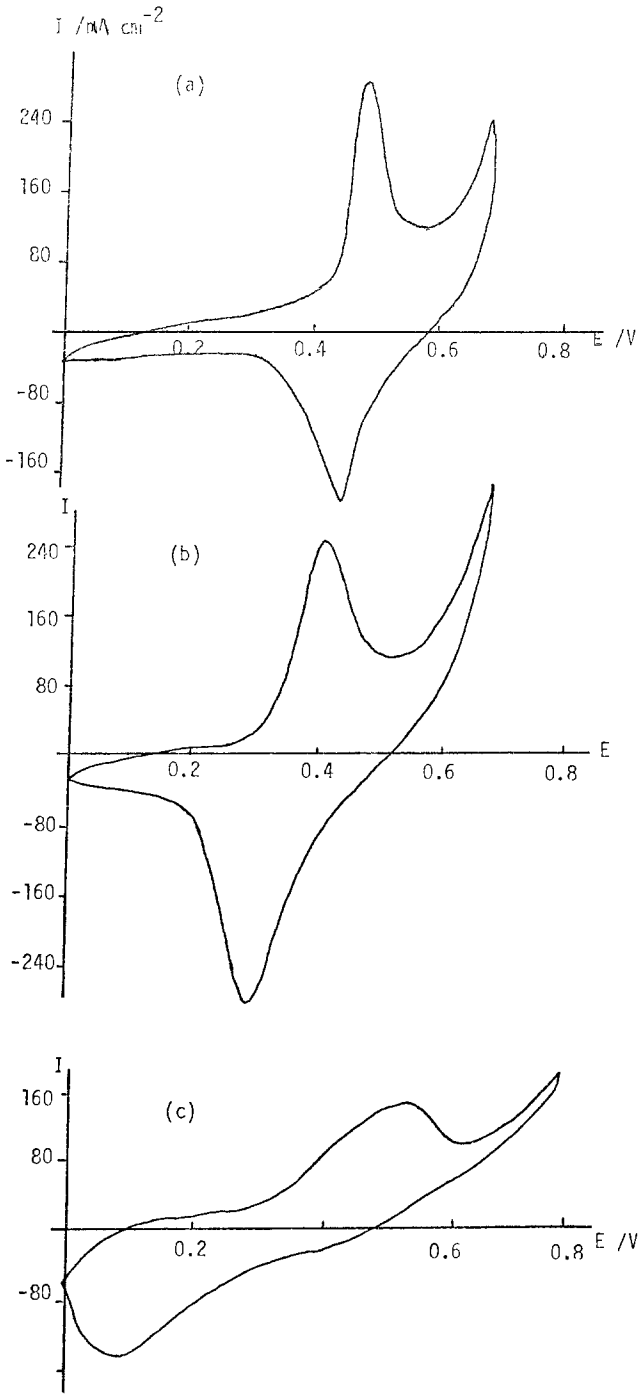

Fig. 1. Cyclic voltammograms for a nickel electrode in various t-butanol/water mixtures containing 0.1M KOH. Potential scan rate 0.03 V sec^{-1}. Potentials vs. SCE (a) 0% t-C_4H_9OH; (b) 67% t-C_4H_9OH; (c) 80% t-C_4H_9OH.

voltammogram run between 0.0 and 0.65V *vs.* SCE for a nickel electrode in purely aqueous 0.1M potassium hydroxide; the major features are an oxidation peak at + 0.46V and a reduction peak at + 0.41V on the reverse sweep. No steady-state current is observed in this potential range although oxygen evolution occurs at slightly more positive potentials, and hence the peaks on the cyclic voltammograms must be due to surface changes. This is confirmed by the shape of the peaks and the observation that the charges under the oxidation and reduction peaks are equal and approximately independent of potential scan rate. Several earlier papers (4-7) have discussed the nature of this surface oxidation/reduction process which is generally written

$$Ni(OH)_2 \rightleftarrows NiO(OH) + H^+ + e$$

The charge under the peaks ($\simeq$700 μC cm^{-2}) indicates that with a polished nickel electrode at most a few monolayers of the surface are oxidized. Moreover most of the features of the voltammograms indicate that the electron transfer is rapid although if this is the case the observation of a peak separation remains unexplained.

When the cyclic voltammetry is repeated in a series of t-butanol/water mixtures each containing 0.1M potassium hydroxide, it can be seen that with increasing t-butanol content the peaks become less sharp and the peak separation increases. Up to 70% t-butanol, however, the cyclic voltammograms continue to show well-formed surface oxidation and reduction peaks and the charges associated with each process remain the same; curve (b) of Fig. 1 shows the cyclic voltammogram for 67% t-butanol/33% water, and it can be seen that at 0.03 V sec^{-1} the oxidation process occurs at E_p = 0.40V and the peak separation is 125 mV (in contrast to the purely aqueous solutions these parameters depend slightly on scan rate). Above 70% t-butanol the quality of the peak shape deteriorates rapidly [see curve (c) in Fig. 1]. This change is not associated with uncompensated solution resistance and hence these experiments suggest that above 70% butanol the electrochemistry of nickel changes, the electron transfer rates decreasing markedly. Below 70% t-butanol, however, the electrochemistry of nickel is apparently essentially similar to that in completely aqueous alkaline media.

Variation of the temperature between 0° and 70°C did not produce marked changes in the cyclic voltammetry at any solvent composition.

Kinetic experiments with 2-phenylethanol.—The *I-E* curve from a slow linear potential sweep experiment for a solution of 2-phenylethanol (0.1M) in 67% t-butanol/33% water containing 0.1M potassium hydroxide at a nickel electrode is shown in Fig. 2. It can be seen that there is a well-formed oxidation wave $E_{1/2}$ = 0.37V but the current in the plateau region (0.15 mA cm^{-2}) is much less than that expected for a diffusion-controlled oxidation of 2-phenylethanol. The kinetic nature of the wave is confirmed by experiments with a rotating nickel electrode; the current in the plateau region is independent of rotation rate. The plateau current is also independent of hydroxide ion concentration.

Steady-state *I-E* data obtained by a point by point technique showed that the Tafel slope was (60 mV)$^{-1}$ and that over the whole oxidation wave the current is proportional to the concentration of 2-phenylethanol (0.01—0.25M). *I-E* curves were also measured at a series of temperatures for a solution 0.1M in 2-phenylethanol in the 67% t-butanol/33% water + 0.1M potassium hydroxide. As expected for a kinetically controlled wave, the limiting current increases substantially with increasing temperature (see Table I); with increasing temperature, the oxygen evolution current also commenced at less positive potentials and hence the plateau region became more restricted.

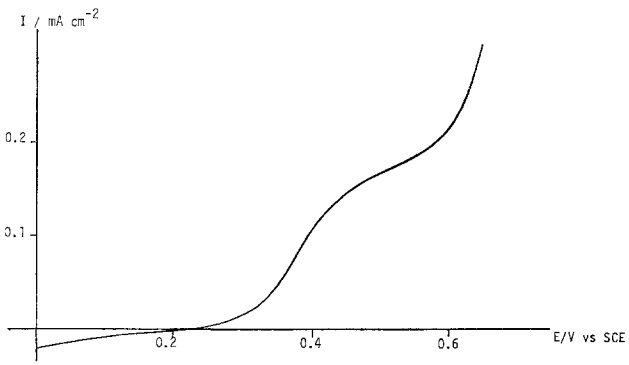

Fig. 2. *I-E* curve recorded by a slow linear potential sweep technique for a solution of 0.1M 2-phenylethanol in 67% t-butanol/33% water + 0.1M KOH at a nickel electrode.

Table I. Limiting currents for the oxidation of 0.1M 2-phenylethanol at a Ni electrode in 67% t-C_4H_9OH/33% H_2O + 0.1M KOH at a series of temperatures

T(°C)	I_L(mA cm^{-2})
15	0.11
25	0.16
35	0.21
45	0.30
55	0.44
80	0.90

Finally the *I-E* curves were investigated as a function of solvent composition and the limiting current varied substantially with the ratio of t-butanol/water; in water, the limiting current was 0.34 mA cm^{-2} but in 67% t-butanol the value was much lower, 0.15 mA cm^{-2}.

No variation in the product of the oxidation (2-phenylacetic acid, see later) was observed with changes in these reaction conditions.

Kinetic experiments with other alcohols.—*I-E* curves were recorded for 0.1M solutions of a range of primary alcohols in 67% t-butanol/33% water containing 0.1M potassium hydroxide. Each gave a well-formed oxidation wave at the potential for the oxidation of the nickel but although all the waves are clearly kinetically controlled, the magnitude of the limiting currents varied substantially; values of the limiting currents are reported in Table II. In all cases the Tafel slopes were (65 ± 5 mV)$^{-1}$ and the current was proportional to the substrate concentration (0.01-0.2M) over the whole oxidation wave.

I-E curves were similarly recorded for 0.1M solutions of a number of aldehydes; uniformly the limiting currents were much lower than for the corresponding alcohol.

Preparative electrolyses.—It is clear from the experiments above that a range of 2-phenylethanols, benzyl alcohols, and allyl alcohols may be oxidized at a nickel anode in alkaline t-butanol/water. The maximum current densities at which the oxidations may be performed are low, however, and the formation of several grams of product on a reasonable timescale requires the use of a large area anode. On the other hand it is possible to carry out the electrolysis at constant current and in an undivided cell.

In Table III the products and yields from a series of electrolyses carried out at room temperature in 67% t-butanol/33% water containing 0.1M potassium hydroxide are reported. The yields of major products are based on the weight of the isolated product (or derivative) and are characterized spectroscopically. Minor products were estimated by glc and NMR spectroscopy. No radical coupling products could be identified. The product of the cathode reaction was generally hydrogen and in some electrolyses slow oxygen evolution from the anode was also observed. In such cases the current yields could presumably be improved by use of a lower current density. The kinetic experiments would indicate that the rate of product

* Approximately one half of this product was reduced at the cathode to benzpinacol.

formation could be increased by use of a higher temperature and where solubility considerations permit, the use of a solvent with less t-butanol. A few experiments with 2-phenylethanol and benzyl alcohol would suggest that this is the case; yields were not much affected by such changes in the electrolysis conditions.

Table IV reports the yields of products from the oxidation of benzyl alcohol at different *p*H. It can be seen that the ratio of aldehyde to acid changes dramatically, the aldehyde being favored in the less alkaline solutions. The current yields do decrease, however, presumably as oxygen evolution becomes more important. In the "neutral" 0.1M sodium perchlorate medium a cyclic voltammogram does not show the characteristic oxidation peak prior to oxygen evolution which is observed in alkaline media. On extending the sweep into oxygen evolution, however, a poorly formed reduction peak is observed on the reverse sweep.

In no electrolyses was corrosion of the cathode observed. A small amount of nickel corrosion was occasionally seen; this was not reproducible, it contributed negligibly to the current, and seemed to occur at random patches on the gauze. It also appeared that corrosion of the anode was minimized by use of a high purity nickel.

Discussion

Alkaline t-butanol/water mixtures have been shown to be a convenient medium for the oxidation of alcohols at a nickel anode despite the low current densities at

Table IV. Products and yields from the anodic oxidation of benzyl alcohol in various electrolytes. Other conditions as Table III

Electrolyte	Current yield		Organic yield	
	Aldehyde	Acid	Aldehyde	Acid
1M Et_4NOH	24	64	28	57
0.1M NaOH	36	32	45	21
0.01M NaOH + 0.1M $NaClO_4$	42	5	79	3
0.1M $NaClO_4$	30	—	91	—

which the oxidations must be carried out. A range of primary alcohols have been studied and in all cases the total organic yield of aldehyde and carboxylic acid is high (see Table III). The 2-phenylethanols, 3-phenylpropanol, and the simple allylic alcohols give only the carboxylic acid, while the alcohols with a conjugated unsaturated system α to the site of primary oxidation, *i.e.*, the benzyl alcohols and cinnamyl alcohol, give a mixture of aldehyde and carboxylic acid. The fraction of aldehyde is increased by an electron donating group in the phenyl ring.

The aldehydes are synthetically the more interesting products and a number of experiments with the object of maximizing the fraction of this product were carried out. The most useful experimental parameter proved to be the pH of the electrolysis medium. The results of a series of oxidations of benzyl alcohols are reported in Table IV; in 1.0M hydroxide the major product is benzoic acid but in 0.01M hydroxide the amount of aldehyde exceeds that of the acid by a factor of twenty-six and in the "neutral" medium no benzoic acid was isolated.

In earlier papers (1, 4) it was shown that the mechanism of the oxidation of simple aliphatic alcohols (and amines) at a nickel anode in aqueous alkaline solutions is

$$Ni(OH)_2 \rightleftarrows NiOOH + H^+ + e$$

$$NiOOH + RCH_2OH \xrightarrow{\text{slow step}} Ni(OH)_2 + \dot{R}CHOH$$

$$\dot{R}CHOH \xrightarrow{\text{further steps}} \text{products}$$

In addition, an equation relating the rate constant for the slow chemical step to the limiting current density was formulated (4). Although this derivation requires certain assumptions which were later criticized (8), there is little doubt that the limiting currents for a series of related compounds is a useful guide to the relative rates of the reaction between the compounds and the higher nickel oxide. The electroanalytical experiments with the phenylethanols and benzyl alcohols in the t-butanol/water mixtures would suggest that the mechanisms of these oxidations are similar.

Curve (a) in Fig. 3 shows a plot of log I_L *vs.* σ, the Hammebb substituent constant for the series of p-substituted benzyl alcohols; these substitution constants reflect the electron withdrawing/donating ability of the p-substituent. In view of the variation in the products isolated and the dependence of the limiting current density on n, the over-all number of electrons transferred as well as the rate constant for the chemical step, however, it is more correct to plot log I_L/n_{avg} *vs.* σ where n_{avg} is the average number of electrons transferred calculated from the product distribution. Curve (b) of Fig. 3 is such a plot. It can be seen that I_L/n_{avg} and hence the rate constant is independent of the electron donating ability of the para-substituent; this is further evidence that the transition state for the chemical reaction is uncharged, and hence this data is compatible with the chemical step being hydrogen abstraction.

Some limited conclusions are also possible concerning the nature of the reactions following the rate-determining step. Clearly it is unlikely that the aldehydes are intermediates in the formation of the carboxylic acids since (*i*) it has been shown that in this system aldehydes oxidize much less rapidly than the corresponding alcohols and (*ii*) in the case of the benzyl alcohols, the ratio of acid/aldehyde products does not reflect the predicted relative ease of oxidation of the

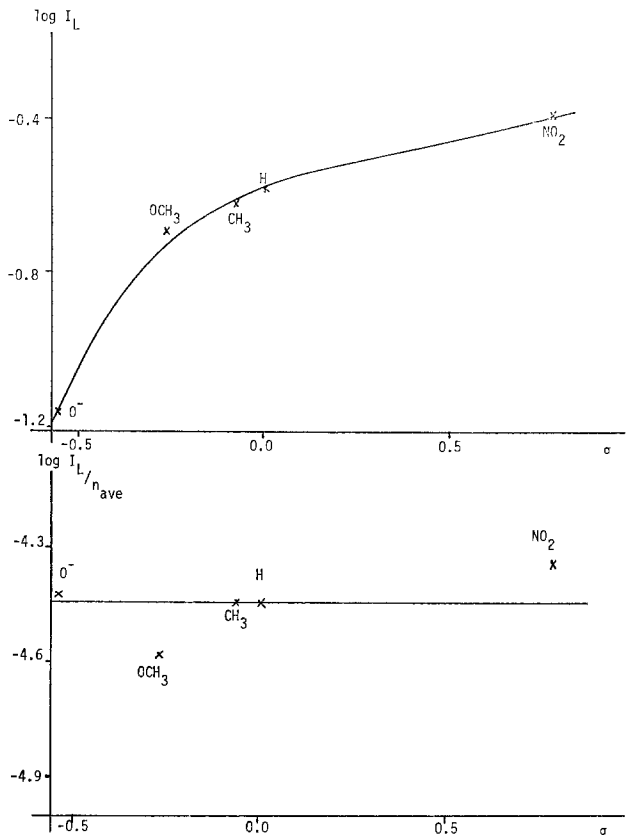

Fig. 3. Variation of the rate of oxidation with substituent for a series of p-substituted benzyl alcohols. (a) log I_L *vs.* σ; (b) log I_L/n_{avg} *vs.* σ.

aldehydes, *i.e.*, contrary to the experimental data it would be expected that an electron donating group would make oxidation easier and reduce any tendency to stabilize the aldehyde by hydration. Hence it must be concluded that the oxidation of these alcohols occurs on the surface of the nickel oxide electrode and that the formation of aldehyde or acid depends on the stability to desorption of a surface species with an intermediate degree of oxidation. The variation of the products with hydroxide ion concentration must then be attributed to a change in the nickel oxide surface with pH.

Single Electrode Heat Effects

I. Peltier Entropies of Gas Electrodes in Carbonate Paste Electrolytes

T. Jacobsen

Fysisk-Kemisk Institut, The Technical University of Denmark, DTH 2800 Lyngby, Denmark

and G. H. J. Broers

Inorganic Chemistry Department, State University at Utrecht, Utrecht, The Netherlands

ABSTRACT

Standard Peltier entropies for the reactions

$$\tfrac{1}{2}\,O_2 + CO_2 + 2e^- \rightarrow CO_3^{--}$$

$$2CO_2 + 2e^- \rightarrow CO + CO_3^{--}$$

in molten carbonate paste electrolytes at 1000°K have been determined from thermogalvanic measurements. The results are −217 and −118 J/mole°K, respectively. No dependence on electrolyte composition is observed. The reversible part of the Peltier entropy for the oxygen electrode reaction is estimated from thermodynamic data and reasonable agreement with the experimental results is found. It is concluded that the main contribution to the Peltier entropy arises from the transition from gaseous to liquid state, whereas the transfer entropies of the ionic species are of minor importance.

In power-producing electrochemical cells, heat is liberated from the electrode reactions and the irreversible losses. In most cells working on solid- or liquid-state reactants, the entropy of reaction will in practice be of minor importance compared to the contributions from ohmic resistance and electrode polarization. However, if the electrode reactions have a net consumption or production of gaseous components, the entropy change will be considerable, due to the transition of state, and has to be taken into account. On the basis of the over-all heat evolved in a single cell during load, the temperature distribution in fuel cell batteries has been treated (1-3), but so far little attention has been paid to the single electrode heat balance and temperature gradients inside single cells caused by nonsymmetrical heat evolution at cathode and anode.

The heat evolved at a reversible electrode is determined by the Peltier entropy of the electrode reaction, which may be found from thermogalvanic measurements. Previously, the Peltier entropies of high temperature gas electrodes in ionic conducting oxides like ZrO_2 (4) and ThO_2 (5) have been investigated, and we have reported some preliminary results for carbonate electrolytes (6), which still left some uncertainty about the dependence on temperature and carbonate composition.

In this paper, the Peltier entropies of the $O_2 + CO_2$ and the $CO + CO_2$ electrode are determined. In part II of this paper, the heat evolved at the electrode during the irreversible passage of current is related to the Peltier entropies and some effects of the temperature gradients created are discussed.

Theory

For the thermogalvanic cell involving a mixture of molten carbonates

$$Pt(T)\,|O_2 + CO_2|Me_2CO_3|O_2 + CO_2|Pt(T + \Delta T) \qquad [A]$$

with the electrode reaction

$$1/2\,O_2 + CO_2 + 2e^- \rightarrow CO_3^{--} \qquad [1]$$

the Peltier entropy $\Delta S_P(O_2, CO_2)$ may be determined from the thermogalvanic force ΔTGF by the equation (7)

$$2\mathbf{F}\frac{\Delta TGF}{\Delta T} = \Delta S_P(O_2, CO_2) = \Delta S_P^{\circ}(O_2, CO_2) + R \ln p(O_2)\,\tfrac{1}{2}p(CO_2) \qquad [2]$$

where the standard Peltier entropy is given by

$$\Delta S_P^{\circ}(O_2, CO_2) = [S^{\circ}(CO_3^{--}) - 1/2S^{\circ}(O_2) - S^{\circ}(CO_2) - 2S^{\circ}(e^-)] + \Delta\hat{S} \qquad [3]$$

The first term in Eq. [3] is the reversible entropy of reaction, whereas $\Delta\hat{S}$[1] is the entropy of transfer corresponding to the homogeneous part of the thermogalvanic force, *i.e.*, the thermal diffusion potential in the electrolyte and the electrode leads.[2] $\Delta\hat{S}$ is composed of the transfer entropies of the species carrying the current according to

$$\Delta\hat{S} = t(CO_3^{--})\hat{S}(CO_3^{--}) - 2t(Me^+)\hat{S}(Me^+) - 2\hat{S}(e^-) \qquad [4]$$

These excess entropies of transfer arise from the fact that transported particles are not average particles but a selected ensemble, thus carrying an excess entropy, the transfer entropy (8). Compared to the equilibrium term in Eq. [3], involving a transition from gaseous to liquid state, the transfer term [4] is expected to be of secondary importance.

For the cell

$$Pt(T)\,|CO + CO_2|Me_2CO_3|CO + CO_2|Pt(T + \Delta T) \qquad [B]$$

having the electrode reaction

$$2CO_2 + 2e^- \rightarrow CO + CO_3^{--} \qquad [5]$$

we obtain the expressions

[1] The entropy of transfer $\hat{S}$ is related to the transported entropy S^* used in Ref. (7) by the equation $\hat{S} = S^* - S$.

[2] It is noted that since the single electrode potential is not a measurable quantity, the numerical separation of the thermal emf into contributions from the homogeneous and heterogeneous transfer processes can only be performed on the basis of a convention.

Key words: thermocell, Peltier entropy, molten carbonate, gas electrodes.

$$2\mathbf{F}\frac{\Delta TGF}{\Delta T} = \Delta S_P(CO, CO_2) = \Delta S_P^\circ(CO, CO_2) + R\ln\frac{p^2(CO_2)}{p(CO)} \quad [6]$$

$$\Delta S_P^\circ(CO, CO_2) = [S^\circ(CO_3^{--}) + S^\circ(CO) - 2S^\circ(CO_2) - 2S^\circ(e^-)] + \Delta\hat{S} \quad [7]$$

where $\Delta\hat{S}$ is also determined by Eq. [4].

Subtracting [7] from [3] yields

$$\Delta S_P^\circ(O_2, CO_2) - \Delta S_P^\circ(CO, CO_2) = S^\circ(CO_2) - 1/2S^\circ(O_2) - S^\circ(CO) \quad [8]$$

which shows that Peltier entropies of different electrodes in the same media are related by well-known thermodynamic magnitudes, not involving single ion or transport properties.

When a cell similar to [B] contains an equilibrated mixture of "C-H-O gases" (such as reformed hydrocarbons), the only species of importance above the carbon deposition temperature are the gases H_2, CO, CH_4, H_2O, and CO_2 (9). Their equilibrium partial pressures are given by the reactions

$$H_2 + CO_2 \rightleftarrows H_2O + CO \quad [9]$$

$$K_s = \frac{p(H_2O)p(CO)}{p(H_2)p(CO_2)} \quad [10]$$

$$4H_2 + CO_2 \rightleftarrows CH_4 + 2H_2O \quad [11]$$

$$K_m = \frac{p(CH_4)p(H_2O)^2}{p(H_2)^4p(CO_2)} \quad [12]$$

The Peltier entropy of this cell can be found from simple thermodynamic equilibrium considerations for the isothermal cell

$$(a)\,Pt(T)|C\text{-}H\text{-}O|Me_2CO_3|O_2 + CO_2|Pt(T)\,(c) \quad [C]$$

The "C-H-O" electrode reaction is a superposition of CO, H_2, and CH_4 oxidation reactions. In the case of an equilibrated gas mixture, these reactions will be linear combinations of the CO equilibrium [5] and the gas phase equilibria [9] and [11]. The Peltier entropy for the mixed "C-H-O" electrode reaction can, therefore, be calculated from the temperature dependence of the emf on the basis of the CO electrode reaction [5] when the change in gas phase composition is taken into account.

$$\Delta S = 2\mathbf{F}\frac{dE}{dT} = \Delta S_P(O_2, CO_2) - \Delta S_P(C\text{-}H\text{-}O)$$

$$\Delta S = -\tfrac{1}{2}S^\circ(O_2) - S^\circ(CO) + S^\circ(CO_2) + R\ln[p(O_2)^{1/2}p(CO_2)]_c + R\frac{d}{dT}\left[T\ln\frac{p(CO)}{p(CO_2)^2}\right]_a \quad [13]$$

This yields in combination with [2] and [8]

$$\Delta S_P(C\text{-}H\text{-}O) = \Delta S_P^\circ(CO, CO_2) - R\ln\frac{p(CO)}{p(CO_2)^2} - RT\frac{d}{dT}\ln\frac{p(CO)}{p(CO_2)^2} \quad [14]$$

Equation [14] reduces to [6] for the pure CO, CO_2 cell [B]. The last two terms in [14] can be calculated from the equilibrium constants K_s and K_m and the corresponding standard reaction enthalpies ΔH_s° and ΔH_m° when C/H/O atomic ratios of the fuel gas are given. An example is given in part II of this paper.

Experimental

Figure 1 shows the experimental arrangements. The electrolyte, a rather stiff paste of 45 weight percent (w/o) Me_2CO_3 and 55 w/o MgO prepared by careful mixing of the dry powders, heating overnight at 750°C in an Al_2O_3 crucible, and subsequent grinding in an alumina ball mill, is pressed into an alumina tube at a temperature just above the melting point.

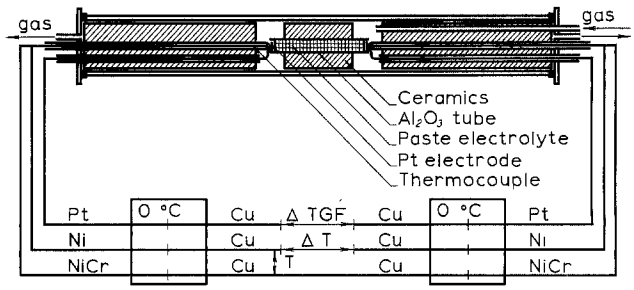

Fig. 1. Experimental setup for the determination of thermogalvanic forces in paste electrolyte.

The platinum electrodes are fixed at the end of the thermocouple protection tubes. During the initial heating of the oven, when the temperature had just passed the melting point of the electrolyte, the thermocouples were pressed against the electrolyte in order to ensure a proper electrode-electrolyte contact.

The gas mixtures were fed to the center of the oven and removed from both ends in order to avoid disturbance from CO disproportionation with associated carbon deposition in the colder parts when reducing atmosphere was applied. Furthermore, the gas volume and space time were reduced by ceramic plugs also serving as heat insulation between the two electrode compartments.

The oven is equipped with two separate bifilar heating coils supplied from voltage-stabilized transformers. The thermocouples are Ni/NiCr. The thermogalvanic force and the thermocouple voltage difference, ΔTEF, are recorded on a Servogor two-channel recorder connected to the outputs of the two Hewlett-Packard 3420 differential voltmeters. Utilizing the zero suppression feature of these instruments, full scale deflections of 100 μV for TGF and 10 μV for TEF are obtained on the recorder.

The experimental procedure is as follows: 45 min after a change of heating coil voltage, ΔTGF and ΔTEF are recorded for 15 min. Before and after the recording the temperature is read. The recordings are made in order to eliminate the effect of minor instabilities and drift due to voltage fluctuations in the mains. The voltage of the colder heating coil is then increased, thus creating a reverse temperature difference of approximately 15°C and a higher average temperature. After a 45 min equilibration period, the next set of readings is made. When the upper temperature limit of 900°C is reached, the measurements are repeated for decreasing temperature levels till the point of solidification, or in case of CO-CO_2 mixtures to the carbon deposition temperature of about 760°C (9).

Because of the thermocouple-electrode distance and the rather high thermal conductivity of the alumina tubes, the measured temperature differences are about 10% larger than the actual electrode temperature differences. To correct for this systematical error, the electrolyte is substituted by a Pt 10% Rh wire embedded in MgO and contacting the Pt electrodes. The thermoelectric force of this differential thermocouple is then determined using the procedure described above. A correction function is calculated from literature data.

Computation Procedure

The experimental procedure where only one set of ΔTGF, ΔTEF, and TEF readings is obtained at each temperature makes the calculation of the Seebeck

coefficient more complex than with the usual technique, where the Seebeck coefficient is calculated from the slope of a ΔTGF *vs.* ΔTEF plot at a fixed temperature. On the other hand, the method yields more information from the experimental effort, especially with respect to the temperature dependence.

The relation between the thermogalvanic force and the thermoelectric force of the thermocouples may be written as

$$\Delta TGF = \frac{\epsilon_E}{\epsilon_T'} [\Delta TEF + A(T)] \quad [15]$$

where ϵ_E and ϵ_T' are the Seebeck coefficients of the electrode and the apparent Seebeck coefficient of the thermocouples containing the systematical temperature error mentioned above. $A(T)$ is the temperature dependent offset error of the thermocouples.

If $\epsilon_E(T)$ and $A(T)$ are expanded in power series with respect to temperature

$$\epsilon_E = \sum_{i=0} e_i (T - T_0)^i \quad [16]$$

$$A = \sum_{j=0} a_j (T - T_0)^j \quad [17]$$

Eq. [15] may be rewritten as

$$\Delta TGF = \frac{1}{\epsilon_T'} \left[\Delta TEF \sum_{i=0} e_i (T - T_0)^i + \sum_{i=0} e_i \sum_{j=0} a_j (T - T_0)^{i+j} \right] \quad [18]$$

This equation shows how $\epsilon_E(T)$ may be determined from a multiple regression analysis with respect to $\Delta TEF\ (T - T_0)^i$, i = 0, 1, 2, . . . and $(T - T_0)^l$, l = 0, 1, 2, . . . when $\epsilon_T'(T)$ is known.

$\epsilon_T'(T)$ may be obtained from the calibration experiments, where the thermogalvanic cell is substituted by a differential Pt/Pt 10% Rh thermocouple. In this case the Seebeck coefficient of Pt/Pt 10% Rh relative to ϵ_T' may be determined from Eq. [18]. Comparing this power series with literature data (10), also expanded in a power series, yields an analytical expression for ϵ_T' and allows the calculation of the Seebeck coefficients for the electrodes on the basis of Eq. [18].

Results and Discussion

In all cases, the colder electrode constituted the positive pole of the cell. Tables I and II give the experimental Seebeck coefficients and the standard Peltier entropies for the $O_2 + CO_2$ and the $CO + CO_2$ electrode. No temperature dependence is observed in any case. It is noted that the deviations between values obtained for identical electrolytes are larger than expected from the standard deviations calculated in the regression analysis. This indicates that the main error source is the reproduction from one experiment to another of electrode and thermocouple position inside the oven. Thus no significant dependence of the Peltier entropy on carbonate composition is found. This very small dependence of the Peltier entropy on the melt composition is expected, since the main entropy contribution originates from the transition from gaseous to liquid state, whereas the change with composition is in the order of mixing entropies.

Table I. Peltier entropy for the reaction $1/2\ O_2 + CO_2 + 2e^- \rightarrow CO_3^{--}$ in the temperature range 800°-1150°K

Electrolyte equimolar	mV/°K	Std dev, mV/°K	p_{CO_2}, atm	p_{O_2}, atm	ΔS_P^o, J/mole °K
$(Li,Na)_2CO_3$	−1.18	0.02	0.62	0.38	−220
$(Li,Na)_2CO_3$	−1.17	0.07	0.65	0.35	−218
$(Li,K)_2CO_3$	−1.14	0.01	0.65	0.35	−213
$(Li,Na,K)_2CO_3$	−1.14	0.02	0.67	0.33	−212
$(Li,Na,K)_2CO_3$	−1.20	0.02	0.65	0.35	−223
Average					−217

Table II. Peltier entropy for the reaction $2CO_2 + 2e^- \rightarrow CO + CO_3^{--}$ in the temperature range 1050°-1150°K

Electrolyte equimolar	mV/°K	Std dev, mV/°K	p_{CO_2}, atm	p_{CO}, atm	ΔS_P^o, J/mole °K
$(Li,Na)_2CO_3$	−0.66	0.02	0.50	0.50	−122
$(Li,K)_2CO_3$	−0.64	0.02	0.55	0.45	−120
$(Li,Na,K)_2CO_3$	−0.63	0.01	0.50	0.50	−116
$(Li,Na,K)_2CO_3$	−0.63	0.03	0.50	0.50	−116
Average					−118

As a check on the experimental values, the difference between the Peltier entropies for the two electrodes may, according to Eq. [8], be calculated and compared to literature data. Using the mean values in Tables I and II we obtain

$$S^o(CO_2) - \tfrac{1}{2}S^o(O_2) - S^o(CO) = \Delta S_P^o(O_2, CO_2) - \Delta S_P^o(CO, CO_2) = -217 + 118 = -99\ \text{J/mole°K}$$

compared to the value of −87.4 J/mole°K at 1000°K given in (11). This discrepancy is somewhat larger than expected from the standard deviations. The $CO + CO_2$ electrode is, in contrast to the $O_2 + CO_2$ electrode, very sensitive to minor changes in gas phase composition, which may be caused by convective mixing at the electrodes with partly decomposed gas from colder parts of the oven. Thus, the Peltier entropy determined for the $CO + CO_2$ electrode is less reliable and may be responsible for the deviation.

The reversible part of the Peltier entropy can be estimated on the basis of thermodynamic data. However, in order to obtain the entropy of the carbonate ion, it is necessary to know the contributions from vibration and rotation of the polyatomic ion. This difficulty may be avoided if, for example, the oxygen electrode reaction [1] is separated into the reactions

$$\tfrac{1}{2}\ O_2 + 2e^- \rightarrow O^{--} \quad [19]$$

$$O^{--} + CO_2 \rightarrow CO_3^{--} \quad \text{(solvation of } O^{--}) \quad [20]$$

From literature data the entropies of alkali oxides in the liquid state have been estimated as a function of temperature (12). Distributing the entropy equally among the ions and neglecting the mixing entropy, we obtain for an equimolar mixture of Li_2O and Na_2O at 1000°K the value

$$S^o(O^{--}) = (152 + 204)/6 = 59\ \text{J/mole°K}$$

For the combination of O^{--} and CO_2, Andersen (12, 13) has determined the free energy and entropy change in different carbonate melts. Using the value for $(Li, Na)_2CO_3$ gives

$$\Delta S^o(2\,O) = -126\ \text{J/mole°K}$$

which yields the estimate on the entropy of the carbonate ion in the liquid state

$$S^o(CO_3^{--}) = \Delta S^o(2\,O) + S^o(CO_2) + S^o(O^{--}) = -126 + 269 + 59 = 202\ \text{J/mole°K}$$

The transported entropy, $S^*(e^-)$, of the electron is calculated from the absolute thermoelectric force of Pt at 1000°K (10)

$$S^*(e^-) = S^o(e^-) + \hat{S}(e^-) = 17.1\ 10^{-6}\ 96{,}500 = 1.65\ \text{J/mole°K}$$

The reversible part of the Peltier entropy is now calculated as

$$\Delta S_{P,rev}^{\circ}(O_2, CO_2) = S^{\circ}(CO_3^{--}) - \tfrac{1}{2} S^{\circ}(O_2) - S^{\circ}(CO_2) - 2S^{\circ}(e^-) \simeq 191 \text{ J/mole°K}$$

which is rather close to the experimental Peltier entropy of −217 J/mole°K. The uncertainties introduced by the assumptions made above may readily account for the discrepancy. Thus, as expected the entropies of transfer only constitute a minor part of the Peltier entropies of gas electrodes in molten carbonates.

ABSTRACT

The heat evolution at a single irreversibly working electrode is treated on the basis of the Brønsted heat principle. The resulting equation

$$\frac{dQ}{dt} = \left(T\frac{\Delta S_P}{n\mathbf{F}} + \eta \right) i$$

is analogous to the expression for the total heat evolution in a galvanic cell with the exception that $-\Delta S$ is substituted by the Peltier entropy, ΔS_P, of the electrode reaction. η is the overvoltage at the electrode. This equation is applied to a high temperature carbonate fuel cell. It is shown that the Peltier entropy term by far exceeds the heat production due to the irreversible losses, and that the main part of heat evolved at the cathode is reabsorbed at the anode. Finally, effects like thermal corrosion, caused by internal temperature gradients, are discussed.

Most treatments of heat effects in galvanic cells are based on the over-all heat evolution calculated from the reversible heat evolution, $-T\Delta S$, and the polarization losses. So far, little attention has been paid to the single electrode heat evolution. In galvanic cells working on solid- or liquid-state reactants and products, the main heat evolution is caused by the polarization losses, whereas in most fuel cells involving a net consumption of gaseous components, the single electrode reactions contribute considerably to the heat evolution at moderate loads. They may give rise to rather large temperature gradients inside the cell. In porous gas diffusion electrodes, temperature gradients may cause convection in the electrolyte film through gradients in

Key words: heat evolution, molten carbonate fuel cells, Peltier entropy, thermal corrosion.

surface tension (1), thus reducing the effective diffusion layer thickness. Furthermore, in high temperature cells where the equilibrium concentration of electrode metal in the electrolyte is not extremely low, temperature gradients along the electrode surface may cause thermal corrosion, ruining the electrode structure by removing active parts of the electrode. This phenomenon has been observed in practice (2) when a leakage of anode gas into the cathode compartment caused a local temperature rise, which removed the electrode area surrounding the leak. Finally, the so-called self-regulation mechanism of porous high temperature cathodes preventing sintering of the porous structure (3) may possibly be explained in terms of a dissolution redeposition reaction caused by temperature gradients in the electrode.

The aim of this paper is a thermodynamic treatment of the single electrode heat evolution in a galvanic cell under load. These heats are calculated for high temperature carbonate fuel cells on the basis of the Peltier entropies determined in part I of this paper (8). An experimental verification of the heat effect is also presented. Finally, some of the effects caused by temperature gradients are briefly discussed.

Single Electrode Heat Balance

Considering the molten carbonate fuel cell anode reaction

$$CO + CO_3^{--} \rightarrow 2CO_2 + 2e^- \qquad [1]$$

the mass fluxes will be as outlined in Fig. 1.

It is noted that a bulk flow of electrolyte is introduced in Fig. 1 in order to obtain the apparent transport numbers of zero for Me^+ and unity for CO_3^{--} with the electrode as reference frame. The transport numbers t_+ and t_- describe the movement of ions relative to the liquid structure and might be determined by the diaphragm method (4). In contrast to the transport numbers with reference to the electrode, these transport numbers do not depend on the nature of the electrode, *i.e.*, whether anion or cation electrodes are used. This distinction between transport numbers relative to the electrodes and to the liquid structure is, in principle, important, since the movement of ions through the liquid structure involves an excess entropy of transport (5). In practice, it is of minor importance for gas electrode reactions, where the main heat effect is caused by the transition from gaseous to condensed state.

In order to determine the heat flow into the electrode compartment during steady-state conditions, we apply the Brønsted heat principle (6)

$$T\delta S'' = -\Sigma\, \Delta P_i \delta K_i \qquad [2]$$

The heat principle states that in an infinitesimal process transferring the quantity δK_i from the potential P_i to $P_i + \Delta P_i$ the loss of work $-\Delta P_i \delta K_i$ is equivalent to the irreversible heat production $T\delta S''$. In the case of reversibility, the thermodynamic equilibrium conditions may be derived from [2] on the basis of the conditions $\delta S'' = 0$ (7).

Performing an entropy balance on the electrode compartment in the steady state yields

$$\delta S = \delta S' + \delta S'' = 0 \qquad [3]$$

where $\delta S'$ is the entropy flow from the surroundings,

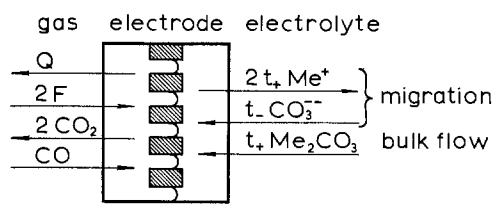

Fig. 1. Mass and heat fluxes into the anode compartment. Electrode reaction: $CO + CO_3^{--} \rightarrow 2CO_2 + 2e^-$.

in the form of heat and reactants. If the heat principle [2] is applied to the process in Fig. 1, we obtain for the transfer of an electric charge δq

$$T\delta S'' = -\left[(2\mu(CO_2) + 2\mu(e^-) - \mu(CO) - \bar{\mu}(CO_3^{--})\right]\frac{\delta q}{2F} \qquad [4]$$

which may be rewritten as

$$T\delta S'' = \left[\left(-\frac{\bar{\mu}(e^-)}{F} - \phi\right) - \{2\mu(CO_2) - \mu(CO) - \mu(CO_3^{--})\}\frac{1}{2F}\right]\delta q \qquad [5]$$

where the term $(-\bar{\mu}(e^-)/F - \phi)$ is the single electrode potential. In Eq. [5] the chemical potentials refer to the system boundary and since this is chosen to enclose all irreversible processes like diffusion and reaction at the electrode, except for the electric conduction in electrode leads and electrolyte, they do not depend on the degree of irreversibility. As $\delta S'' = 0$ holds for equilibrium conditions, we obtain the relation for the entropy production

$$T\delta S'' = \left[\left(-\frac{\bar{\mu}(e^-)}{F} - \phi\right] - \left(-\frac{\bar{\mu}(e^-)}{F} - \phi\right)\right]_{eq}\delta q = \eta\delta q \qquad [6]$$

where η is the overvoltage.

Taking into consideration that species transported by a migration mechanism carry an entropy, S^*, differing from the partial molar entropy (5), the entropy flux into the electrode compartment is, according to Fig. 1, written as

$$\delta S' = -\frac{\delta Q}{T} + [-2S^*(e^-) - 2S(CO_2) + S(CO) - 2t(Me^+)S^*(Me^+) + t(CO_3^{--})S^*(CO_3^{--}) + t(Me^+)S(Me_2CO_3)]\frac{\delta q}{2F} \qquad [7]$$

Introducing the excess entropy of transported species, $\hat{S} = S^* - S$, we obtain

$$\delta S' = -\frac{\delta Q}{T} + [-2S(e^-) - 2S(CO_2) + S(CO) + S(CO_3^{--}) + \Delta\hat{S}]\frac{\delta q}{2F}$$

where

$$\Delta\hat{S} = t(CO_3^{--})\hat{S}(CO_3^{--}) - 2t(Me^+)\hat{S}(Me^+) - 2\hat{S}(e^-) \qquad [8]$$

Comparing the entropy terms in Eq. [8] with Eq. [4]-[7] in part I of this paper (8), they are identified as the Peltier entropy ΔS_P of the CO electrode reaction. Thus, combining Eq. [3], [6], and [8], we obtain the final expression for the heat evolution due to the partly irreversible n electron single electrode reaction[1]

$$\frac{dQ}{dt} = \left(T\frac{\Delta S_P}{nF} + \eta\right)i \qquad [9]$$

where the sign convention of a positive anodic current is adopted. Since the term ηi, is always positive, whereas

[1] Although Eq. [9], to simplify the notation, has been derived on the basis of the CO,CO_2 electrode reaction, the result holds for the "general" reaction Red + $CO_3^{--} \rightarrow$ Ox + CO_2 + 2e$^-$ where (Ox,Red) is ($\frac{1}{2}O_2$,), (CO_2,CO), (H_2O,H_2), or ($2H_2O$ + CO_2,CH_4)/4. This is easily seen by substituting $2\mu_{CO}$, $2S_{CO}$, μ_{CO_2}, and S_{CO_2} with μ_{Red}, S_{Red}, $\mu_{Ox} + \mu_{CO_2}$, and $S_{Ox} + S_{CO_2}$ in the derivation.

the sign of $i\Delta S_P$ changes with the current direction, Eq. [9] holds for both anodic and cathodic reactions.

Peltier Entropy of a Mixed Electrode Reaction

As practical fuel cell applications will often involve mixed electrode reactions, like the oxidation of reformed hydrocarbons, we shall go into detail somewhat on the calculation of the Peltier entropy for the C-H-O fuel electrode.

For gaseous mixture of H_2 (h), CO (c), CH_4 (m), H_2O (w), and CO_2 (d) in thermal equilibrium, the Peltier entropy per mole CO_3^{--} has been derived previously (Ref. (8), Eq. [14]). Denoting the partial pressures of the different species by the above-mentioned symbols h, c, etc., we have

$$\Delta S_P(\text{fuel}) = \Delta S_P^\circ(CO,CO_2) - R \ln \frac{c}{d^2} - RT \frac{\partial}{\partial T}\left(\ln \frac{c}{d^2} \right) \quad [10]$$

It is noted that the Peltier entropy of the mixed electrode reaction does not depend on the kinetically controlled relative contributions from the different electrode reactions. This is due to the assumption of a gas in thermal equilibrium, which implies that the gas phase composition at a total pressure P and a given C/H/O ratio is fixed by the equilibrium conditions

$$H_2 + CO_2 \rightarrow H_2O + CO, \text{ with } K_s = cw/hd \quad [11]$$

$$\frac{1}{4}[4H_2 + CO_2 \rightarrow CH_4 + 2H_2O], \text{ with } K_m^{1/4} = \frac{m^{1/4}w^{1/2}}{hd^{1/4}} \quad [12]$$

$$h + c + m + w + d = P \quad [13]$$

A method to calculate the various partial pressures at given P and T from tabulated values of K_s and K_m has been given earlier (9).

The value of the last term in [10] can be calculated on the basis of a mass balance applied to Eq. [11] and [12], using the relations involving the reaction enthalpies: $\partial \ln K_s/\partial T = \Delta H_s^\circ/RT^2$ and $\partial \ln K_m^{1/4}/\partial T = \Delta H_m^\circ/4RT^2$. The result can be written as

$$-RT \frac{\partial}{\partial T}\left(\ln \frac{c}{d^2} \right) = -\left(\frac{1}{c} + \frac{2}{d} \right) \frac{P}{T} \frac{\alpha_{22}\Delta H_s^\circ - \alpha_{12}\Delta H_m^\circ/4}{\alpha_{11}\alpha_{22} - \alpha_{12}^2} + \left(\frac{1}{2d} - \frac{1}{2P} \right) \frac{P}{T} \frac{\alpha_{12}\Delta H_s^\circ - \alpha_{11}\Delta H_m^\circ/4}{\alpha_{11}\alpha_{22} - \alpha_{12}^2} \quad [14]$$

where

$$\alpha_{11} = P(1/h + 1/c + 1/w + 1/d) \quad [15]$$

$$\alpha_{12} = P(1/h + \tfrac{1}{2}w + \tfrac{1}{4}d) \quad [16]$$

$$\alpha_{22} = P(1/h + 1/16m + 1/4w + 1/16d - 1/4P) \quad [17]$$

For fuels containing negligible amounts of CH_4 (high temperatures, low hydrogen contents), $\alpha_{22} \rightarrow \infty$, and [14] reduces to

$$-RT \frac{\partial}{\partial T}\left(\ln \frac{c}{d^2} \right) = -\frac{\Delta H_s^\circ}{T}\left(\frac{1}{c} + \frac{2}{d} \right) \Big/ \left(\frac{1}{h} + \frac{1}{d} + \frac{1}{w} + \frac{1}{d} \right) \quad [14a]$$

From the basic data given in Tables I and II, typical heat evolutions at the electrodes of a working molten carbonate cell have been calculated in Table III. It is observed that the heat evolution due to the Peltier effect exceeds the irreversible losses by more than an order of magnitude and equals the amount of heat produced by an overvoltage in the order of 1V. Furthermore, it is noted that about two-thirds of the heat evolved at the cathode is reabsorbed at the anode. Thus, the internal heat fluxes in the working cell are by far larger than would be estimated from a heat balance on the entire cell and rather large temperature gradients will be present in the electrolyte.

Table I. Equilibrium composition of fuel gas at 1 atm and 1000°K. Nominal composition 0.5 atm H_2 + 0.5 atm CO_2.

	H_2 (h)	CO (c)	CH_4 (m)	H_2O (w)	CO_2 (d)
Partial pressure (atm)	0.269	0.229	7.5×10^{-4}	0.230	0.271

The calculation is based on the thermodynamic data (9): K_S = 0.723; ΔH_S° = 34.8 kJ/mole; Eq. [11] and K_m = 0.404 atm$^{-1/2}$; $\Delta H_m^\circ/4$ = −47.7 kJ/mole; Eq. [12].

Table II. Peltier entropies at 1 atm and 1000°K

$\Delta S_P(O_2,CO_2)$	= −236 J/mole °K	Calculated from Eq. [2] in Ref. (8)
$\Delta S_P^\circ(CO,CO_2)$	= −129.5 J/mole °K	Calculated from Eq. [8] in Ref. (8)
ΔS_P(fuel)	= −167 J/mole °K	Calculated from Eq. [10]-[14]

The calculated values are based on $\Delta S_P^\circ(O_2,CO_2)$ = −217 J/mole °K (8).
Cathode gas = 0.14 atm O_2 + 0.28 atm CO + 0.58 atm N_2.
Anode gas = composition given in Table I.

Table III. Heat evolution in a working molten carbonate fuel cell at 100 mA/cm²

		Anode	Cathode	Electrolyte
$iT\Delta S_P/2F$	mW/cm²	−86.5	122.3	
$i\eta$	mW/cm²	5.0	5.0	5.0
dQ/dt	mW/cm²	−81.5	127.3	5.0

The values calculated are based on the data given in Tables I and II and the assumption of a polarization at cathode, anode, and electrolyte corresponding to 0.5 Ω · cm² each.

Verification of the Heat Effect

The heat effect predicted by Eq. [9] has been experimentally determined in the high temperature cell shown in Fig. 2. Details in the construction of the cell

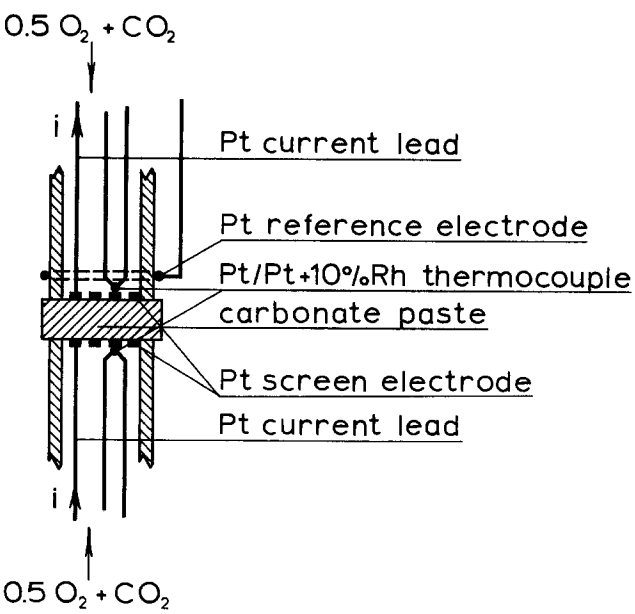

Fig. 2. Cell used for the investigation of heat effect

and the preparation of the carbonate paste electrolyte are given elsewhere (10). The Pt screen electrodes were contacted by Pt/Pt + 10% Rh thermocouples and the temperature rise, ΔT, at each electrode was determined as a function of the current. For practical reasons a mixture of 0.5 vol O_2 + 1 vol CO_2 was applied to both electrodes giving the electrode reactions

$$\tfrac{1}{2}\,O_2 + CO_2 + 2e^- \underset{\text{anode}}{\overset{\text{cathode}}{\rightleftharpoons}} CO_3^{--} \qquad [18]$$

For not-too-large current densities, the steady-state overvoltage may be expressed in terms of an electrode resistance, and the temperature rise, being proportional to the heat evolution, can, according to Eq. [9], be written as

$$\Delta T = k\frac{dQ}{dt} = k\left[\, T\frac{\Delta S_P}{n\mathbf{F}} + i(Z_o + R) \,\right] i \qquad [19]$$

where k (cm^2 °K/W) is a constant inversely proportional to the local heat conduction, Z_o is the d-c impedance due to the electrode reaction (diffusion, charge transfer etc.), and R is the electrolyte resistance. For symmetry reasons the joule heating will be distributed almost equally between the electrodes and R is thus expected to be approximately half the total anode-cathode electrolyte resistance.

Figures 3 and 4 show the experimental results plotted as $\Delta T/i$ *vs.* i and, as predicted by Eq. [19], a linear relationship is obtained. It is noted that whereas the cathode reaction causes a temperature rise, the entropy absorption in the anodic direction cools the electrode. From the standard Peltier entropy, ΔS_P^o, given in part I of this paper, we obtain

$$\Delta S_P(O_2,CO_2) = \Delta S_P^o(O_2,CO_2) + R \ln p_{O_2}^{1/2} p_{CO_2} = -225 \text{ J/mole°K}$$

The polarization resistances were determined from steady-state current-voltage curves measured against the reference electrode and corrected for IR drops. The total electrolyte resistance was measured by a.c. at 10 kHz. The results were

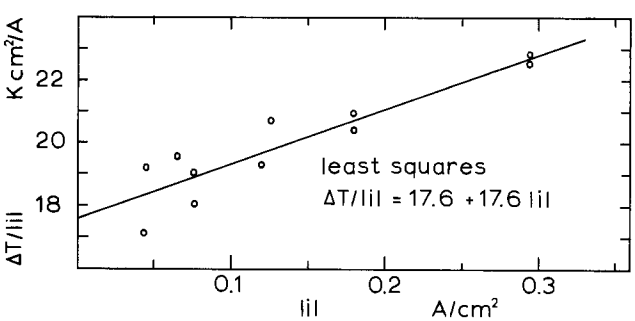

Fig. 3. $\Delta T/|i|$ *vs.* $|i|$ for the cathodic reaction 1/2 O_2 + CO_2 + $2e^- \rightarrow CO_3^{--}$.

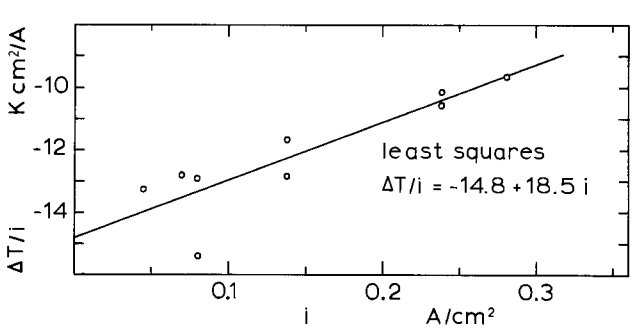

Fig. 4. $\Delta T/i$ *vs.* i for the anodic reaction $CO_3^{--} \rightarrow$ 1/2 O_2 + CO_2 + $2e^-$.

cathode	$Z_o = 0.50\ \Omega \cdot cm^2$
anode	$Z_o = 0.55\ \Omega \cdot cm^2$
electrolyte	$2R = 1.60\ \Omega \cdot cm^2$

Inserting these values and $T = 1006$°K in Eq. [19], we obtain the theoretical temperature rise

$$\text{cathode} \quad \Delta T = ik(-1.17 + 1.30i);\ i < 0$$

$$\text{anode} \quad \Delta T = ik(-1.17 + 1.35i);\ i > 0$$

Comparing these expressions with the experimental equations in Fig. 3 and 4, good agreement is obtained with the values $k = 15$°K cm^2/W and 13°K cm^2/W for cathode and anode, respectively. The somewhat differing k values obtained are probably due to the vertical position of the cell, involving some asymmetry in heat conduction.

It should be noted that the large temperature effect of 35°K cm^2/A observed here holds for a small cell with 0.8 cm^2 electrode area and 0.4 cm electrolyte thickness. As this cell has severe heat losses through the electrode leads and thermocouples, a larger effect should be expected for practical cells.

Thermal Corrosion

In gas diffusion electrodes, the electrode structure is obviously one of the most important properties. It is known that high temperature fuel cell electrodes, after a certain period of time, obtain a porosity which is essentially determined by the operating conditions and does not depend on the initial electrode structure (3, 10). This very feature of high temperature systems reflects the fact that in the time scale relevant for practical applications, months or even years, the solubility and thus the mobility of electrode material is not negligible. The structural regenerating process, counteracting electrode sintering, has been illustrated by an Ag wire immersion experiment in liquid carbonate (3). It was observed that Ag was removed from the wire below the electrolyte level and redeposited in a porous form at the meniscus. As is shown below, this process, can be explained in terms of thermal corrosion, rather than by gradients in oxygen partial pressure as originally suggested.

The equilibrium

$$2Ag + \tfrac{1}{2}\,O_2 + CO_2 \rightarrow Ag_2CO_3 \text{ (in } Me_2CO_3) \qquad [20]$$

has been studied as a function of temperature for a series of carbonate melts (3). In most cases, the solubility of Ag was found to decrease with increasing temperature. Thus, a thermal process where Ag is dissolved at low temperature and redeposited at higher temperature might be expected to proceed spontaneously. This will indeed be the case as long as there is no electronic contact between the metal at the two temperatures. However, in the immersed wire experiment the contact is established and the redistribution process may be the electrochemical reaction

$$Ag \rightarrow Ag^+ + e^- \qquad [21]$$

The temperature dependence of [21] can be determined from the Peltier entropy which may be estimated as

$$\Delta S_P(Ag^+) = S_{Ag} - S_{Ag^+}{}^* - S_{e^-}{}^* \simeq \tfrac{1}{2}(\Delta S_{Ag_2CO_3} - \Delta S_P(O_2,CO_2)) \qquad [22]$$

where $\Delta S_P(O_2,CO_2)$ is the Peltier entropy of the oxygen electrode given by Eq. [3] in part I of this paper (8). $\Delta S_{Ag_2CO_3}$ (*cf.* [20]) is estimated from the temperature dependence of the solubility equilibrium and we obtain a value in the order of 100 J/mole°K for the Peltier entropy of reaction [21] in equilibrium with $p_{O_2} = p_{CO_2} = 1$ atm. As this entropy difference is positive, in contrast to the entropy difference for the chemical dissolution of Ag [20], a transport of Ag from

high to low temperature through the electrochemical mechanism involves a simultaneous transfer of entropy from high to low temperature and the process is spontaneous. Thus, the effect of the electronic contact is a reversing of the thermal corrosion process. Aten *et al.* (11) observed and interpreted similar phenomena for silver and copper in 1925 and in aqueous solutions also this kind of process has been observed for Ag electrodes and explained in terms of a thermal emf (12), which is equivalent to the entropy argument

In the immersion wire experiment as well as in single laboratory fuel cells, the electrode leads will act as heat sinks and create a temperature gradient at the electrolyte surface. Thus, the thermal process will remove electrode material dipping into the electrolyte and deposit material at the gas side of the electrode. This continuous renewal of the electrode surface may be, at least partially, responsible for the stability of high temperature porous electrodes (3, 10). In a fuel cell battery the effect of the thermal redistribution is difficult to predict since the temperature gradients depend on the position inside the battery. However, the existence of this process means that temperature gradients should be taken into account in the construction of high temperature systems in order to ensure long-term stability. Temperature gradients along the electrodes should be reduced as far as possible. Since Peltier entropies are dependent on the various partial pressures, large fuel and oxygen conversions per single pass may entail these gradients and thus active parts of the electrodes may be removed completely and redeposited elsewhere. An extreme case has been observed by Trachtenberg (2). Furthermore, cathodes should be kept under constant load in order to reduce the equilibrium concentration of ions from the electrodes in the electrolyte.

Finally, it should be mentioned that temperature gradients may contribute to the formation of the electrolyte films in porous gas electrodes through the Marangoni effect, *i.e.*, flow due to gradients in surface tension. Lightfoot (1) has treated this effect quantitatively and concludes that temperature gradients as low as a few tenths of a degree per centimeter may produce a 1 μm film, which is the order of magnitude observed in practice (13, 14).

Acknowledgments

The authors are indebted to Mr. H. J. J. van Ballegoy who carried out the experimental verification of the heat effect. The many valuable discussions with B. K. Andersen and other colleagues are greatly appreciated. This work has been supported by Statens Teknisk Videnskabelige Fond.

Semiconductor Electrodes

X. Photoelectrochemical Behavior of Several Polycrystalline Metal Oxide Electrodes in Aqueous Solutions

Kenneth L. Hardee* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

An investigation was made of the photoelectrochemical properties of several polycrystalline metal oxide electrodes prepared by chemical vapor deposition, direct oxidation of the metal, or heating of suitable metal salt solutions. Further data are given on the behavior of the previously discussed TiO_2 and Fe_2O_3 electrodes including tunneling effects and the operation of the Fe_2O_3 in a solar cell. Other n-type materials studied were V_2O_5, WO_3, and PbO. WO_3 and PbO showed good anodic photocurrents but only WO_3 appeared stable. Bi_2O_3 showed both n- and p-type photocurrents, but had a poor stability. CuO produced a good cathodic photocurrent (indicating p-type behavior) with a photoresponse at wavelengths of 700 nm and below. Two other oxides, Cr_2O_3 and CoO, exhibited small p-type photoeffects.

Recent research on photosensitized reactions at semiconductor electrodes, aimed toward the photodecomposition of water and the construction of photogalvanic cells for use in solar energy conversion devices, has prompted investigations of new electrode materials. Suitable electrodes should be easily prepared and inexpensive, show stable behavior in use over long time periods of operation, and have a small bandgap (E_g) to allow efficient utilization of the solar energy spectrum. Most investigations to date have centered upon the more familiar semiconductor compounds, *e.g.*, Si, GaAs, GaP, ZnO, CdS, and TiO_2, usually in the form of single crystals. Stable electrodes, such as TiO_2, are large bandgap materials ($E_g \geq 3$ eV), while materials with smaller gaps, *e.g.*, Si and CdS, tend to be unstable. Moreover, the high cost and difficulty of obtaining single crystals of other compounds have limited investigations of other materials. Recently, polycrystalline semiconductors, prepared, for example, by chemical vapor deposition, have been shown to be suitable electrode materials and to behave similarly to single crystal electrodes (1, 2). The use of polycrystalline materials allows investigation of a wider range of compounds and is also of interest in any practical utilization of semiconductor electrodes. We describe here the photoelectrochemical behavior of a number of semiconducting oxides prepared in polycrystalline form. Further details are given on the nature and behavior of polycrystalline TiO_2 and Fe_2O_3, which we discussed previously (1, 2). Other oxides that show photoelectrochemical effects are Bi_2O_3, WO_3, PbO_2, V_2O_5, and CuO. Several other polycrystalline oxides, *i.e.*, CdO, MnO_2, and SrO exhibited little or no photoeffects.

Experimental

Several different methods of preparation of the polycrystalline electrodes were employed (Table I). The chemical vapor deposition (CVD) (TiO_2, Fe_2O_3, V_2O_5, WO_3, CdO, Cr_2O_3, MnO_2) followed the procedure outlined previously (1, 2). The corresponding acetylacetonate served as the vapor source, except for W and Ti where WCl_6 and $Ti(O_2C_3H_7)_4$ were used. Pt-foil substrates were employed for all electrodes. Oxides could also be prepared by direct oxidation of the metal. Thus Bi_2O_3 and lead oxide electrodes were prepared by melting the metal and allowing a surface film to form by air oxidation, at *ca.* 450°C. Finally, oxide films were formed by painting a suitable salt solution on Pt foil and then heating in a flame. Electrodes of WO_3, CuO, manganese oxide, CdO, Cr_2O_3, and SrO were produced in this manner. All Pt substrate electrodes had a copper wire attached to the back of the Pt foil with indium solder and were then sealed in a glass tube with Apiezon wax or silicone rubber (Dow Corning).

The single crystal V_2O_5 was generously donated by Professor A. B. Scott of Oregon State University. A 0.3 cm^2 piece was used with two Ag paint (Ernest Fullam, Incorporated, Schenectady, New York) contacts and was mounted in silicone rubber. The current-voltage response between the two contacts indicated ohmic behavior. The hematite was obtained from David New-Minerals (Stevensville, Montana). Contact was made to an approximately 0.5-1 cm thick sample with Ag paint.

X-ray diffraction was done on a General Electric XRD-6 diffractometer. A Joel, Incorporated (Tokyo, Japan) scanning electron microscope was used for examining the electrode surfaces. All electrochemical measurements were performed with buffered Na_2SO_4

Table I. Preparation and properties of materials used in this study

Substance	Preparation*	Type	E_g**	V_{fb}***	Photocurrent†
TiO_2	CVD	n	3.0	0 5 (*i*)	Good, stable

solutions. A simple H-cell with separate auxiliary and working compartments and with a Pyrex window was used. A saturated calomel (SCE) was the reference electrode. Electrochemical equipment consisted of a Princeton Applied Research (PAR) Model 173 potentiostat, a PAR Model 175 universal programmer, and a Houston Instruments (Austin, Texas) Model 2000 omnigraphic X-Y recorder. Illumination was done with either the full output of a 450-W xenon lamp (Oriel Corporation, Stamford, Connecticut) or the output of a Model 7240 grating monochromator (Oriel Corporation). Absolute light intensity measurements were made using an EG&G Model 550 Radiometer (EG&G, Incorporated, Salem, Massachusetts). The current *vs.* wavelength curves were corrected for intensity variations by normalizing the spectral output of the lamp-monochromator system to 470 nm and using the resulting values to correct the measured photocurrent curves, shown by dotted i-λ curves.

Results and Discussion

Titanium dioxide.—As reported earlier (1), the current (i) *vs.* potential (E) curves for a CVD TiO_2 electrode are quite similar to those of single crystal rutile. Typical i-E and i *vs.* wavelength (λ) curves for a CVD TiO_2 electrode are shown in Fig. 1. Examination of the CVD electrode surface with a scanning electron microscope (SEM) reveals a uniform, smooth surface of polycrystalline material (Fig. 2). There are no grain boundaries visible, but there are numerous cracks across the surface which range up to 1000Å wide. These cracks probably form during the high temperature treatment the electrode is subjected to during preparation. An edge view of the surface, accomplished by cutting the electrode and polishing the edge, reveals layers of oxide corresponding roughly to the different deposition (3-5 layers). The cracks are visible along the surface but none appear to penetrate directly to the substrate. From this edge view, the total thickness of the oxide layer was measured as about 40 μm.

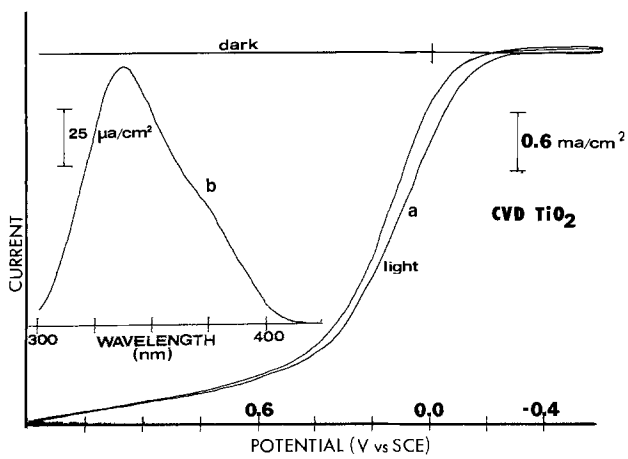

Fig. 1. (a) Current *vs.* potential curve for CVD TiO_2, 0.5M KCl, in dark and illuminated with Xe lamp. (b) Current *vs.* wavelength curve under same conditions, $E = +0.800$V *vs.* SCE.

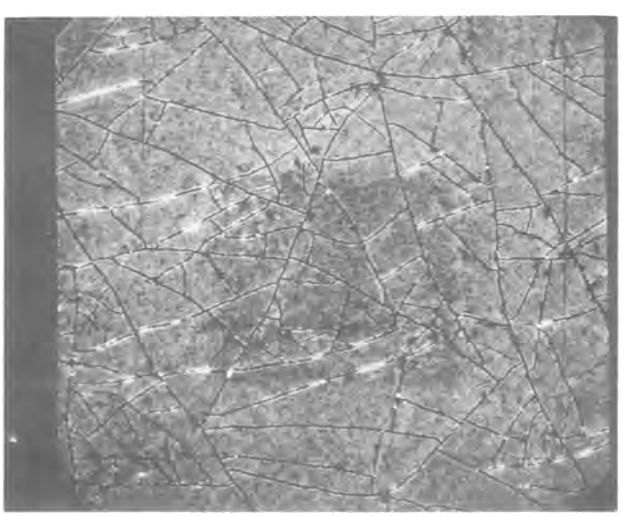

Fig. 2. Scanning electron micrograph of surface of CVD TiO_2. Magnification is 600×.

X-ray diffraction patterns of the CVD TiO_2 electrode were typical powder patterns indicating polycrystalline material primarily in the rutile form of TiO_2. A small percentage ($\leq$ 10%) of anatase was also present. X-ray diffraction of an electrode that only had one coat of oxide deposited at about 150°C, but which was not heated further, revealed a pattern that was totally anatase. This electrode showed only a very low photocurrent. Thus the high temperature treatment is necessary not only to prevent flaking between coats and allow thicker coats to be deposited, but also to convert the film into the photoresponsive rutile form of TiO_2.

The thickness of the film on the electrodes affects the shape and magnitude of the photocurrent *vs.* potential curve. In Fig. 3 are given curves for several CVD TiO_2 electrodes prepared with increasing relative thicknesses (by depositing successive coats). As the film becomes thicker, the shape of the curve becomes more typical of a single crystal n-type semiconductor, exhibiting a sharper current rise and a more well-defined plateau. The effect of thickness on curve shape might be explained by the increasing absorbance of light in the space charge region (3). Alternately, the extent of recombination of electrons and holes might decrease with thickness as a more homogeneous film forms. The current *vs.* wavelength curves were similar for all of the electrodes.

The quantum efficiency of the CVD TiO_2 electrode is quite high in the plateau region. Typically, the quantum efficiency is $\geq$ 60% at the wavelength of maximum response (*ca.* 335 nm). Variations in the quantum efficiency from one electrode to another can be ascribed to variations in the thickness, as described above, and in the percentage of rutile actually present in the electrode.

As reported previously (1), at potentials of about 2.0V *vs.* SCE in neutral solutions (and at more nega-

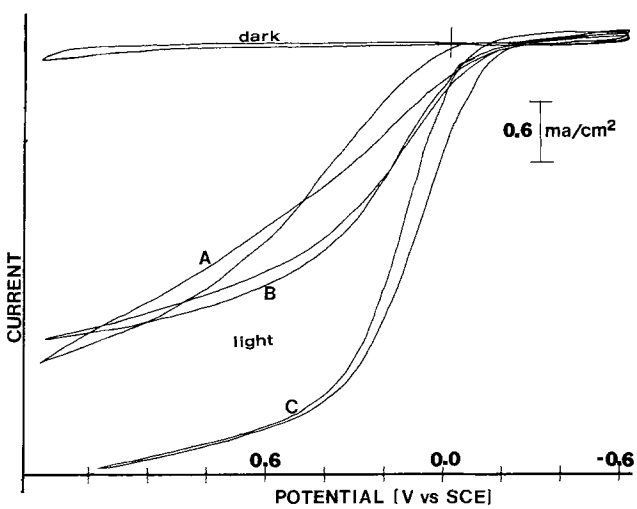

Fig. 3. Current *vs.* potential curves for CVD TiO_2 with varying relative thickness of film: (a) one 1 min coat, (b) two 2 min coats, (c) four 2 min coats.

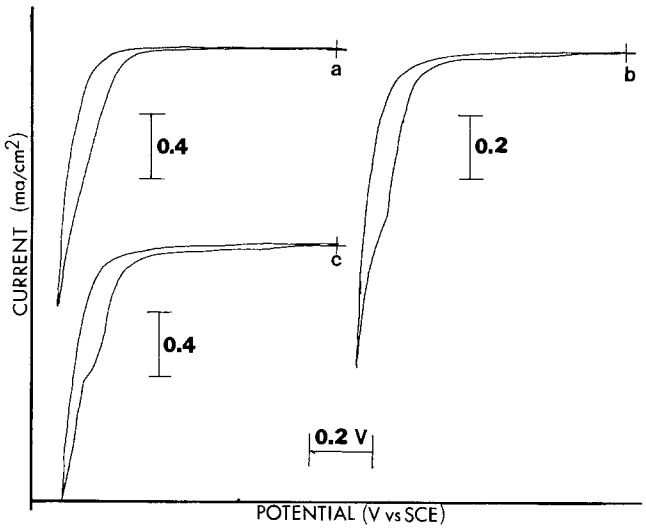

Fig. 4. Current *vs.* potential curves for CVD TiO_2 with addition of I^-: (a) 0.5M Na_2SO_4 (b) 0.5M Na_2SO_4 + 3.8 mM NaI, (c) 0.5M Na_2SO_4 + 7.5 mM NaI.

tive potentials at higher pH values), a large anodic current rise is observed in the dark for the CVD TiO_2 electrodes (Fig. 4a). Vigorous gas evolution is observed on the electrode surface. This current is attributed to tunneling of electrons from solution through the space charge region and into the conduction band. The narrow space charge region which is necessary for this tunneling is the result of the high doping level in the CVD TiO_2 electrode. For a single crystal electrode, appreciable anodic currents are usually not observed until potentials > 3V *vs.* SCE (16), depending, again, upon the doping level. The higher doping level in the CVD TiO_2 is the result of the more homogeneous reduction possible with thin films. The influence of a titanium substrate on the doping is apparently minimal, since similar effects are obtained with Pt substrates.

Addition of I^- to the solution produces a shoulder on the dark anodic current rise (Fig. 4b and c) with a height proportional to the concentration of I^-. The current is due to the oxidation of the I^-, and is similar to that observed on highly doped ZnO (6). The redox level of I^- lies nearer the flatband potential than the H_2O/O_2 level does. Thus the I^- is located where a narrower part of the space charge exists and electrons will tunnel at lower potentials, producing the observed curve. Addition of Br^- to the solution instead of I^- produced no noticeable addition to the tunneling current, since its level is near that of the H_2O/O_2 potential.

The behavior of CVD TiO_2 is fairly typical of an n-type semiconductor, with low anodic dark currents and well-defined anodic photocurrent plateaus. Because of the ease of doping of the thin films, they exhibit tunneling effects usually seen only at highly doped single crystal electrodes. With these properties, as well as its stability, CVD TiO_2 is useful as a comparison electrode in examining the behavior of the other oxide electrodes investigated in this study.

Iron oxide.—We have previously shown that iron oxide shows a good photoelectrochemical response at longer wavelengths in the visible region than that of TiO_2 (2). In that study we assumed, from the wavelength for the onset of the photocurrent, that the bandgap was about 2.2 eV, and from the procedure used in fabrication, that the oxide was Fe_2O_3. We have now examined the material with x-ray diffraction and a SEM. The results show that the film is primarily α-Fe_2O_3 (hematite), with a small amount of γ-Fe_2O_3

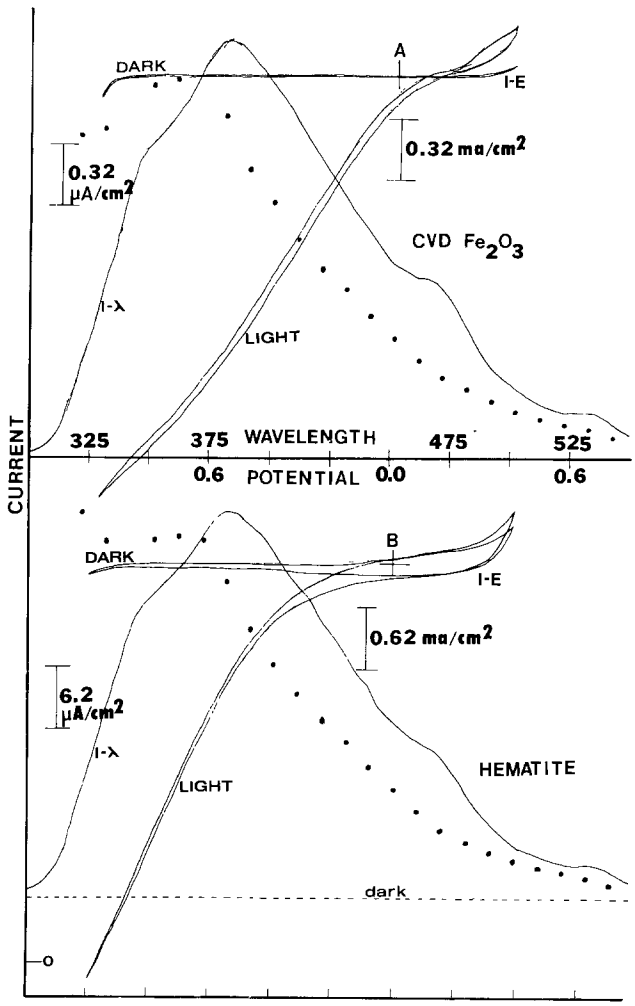

Fig. 5. Current *vs.* potential and current *vs.* wavelength curves for (a) CVD Fe_2O_3 in 0.25M Na_2SO_4, pH 9, (b) natural hematite in 0.5M Na_2SO_4. E = 0.600V *vs.* SCE for i-λ curves. Current scale for corrected i-λ curve is 2× uncorrected scale shown.

(*ca.* 20%) and γ-Fe_2O_3 (*ca.* 10%). The surface was very smooth with no visible cracks seen with the SEM for magnifications of 20,000×.

The i-E and i-λ curves for a CVD Fe_2O_3 electrode and a piece of natural hematite are shown in Fig. 5. The two i-λ curves are almost identical in shape, suggesting that the α-Fe_2O_3 form of the oxide is indeed the photoresponsive one.

Attempts made to deposit Fe_2O_3 on iron were unsuccessful, because the film flaked off during the high heat-treatment. Films on Pt which were not heated showed a very poor photoresponse, so the treatment is necessary to convert the film to α-Fe_2O_3 and make it n-type (7). Attempts at heating Fe_2O_3 on Fe in vacuum were also not successful, since the apparatus could not apparently achieve the required high temperatures (*ca.* 1200°-1400°C). Simply heating Fe plates until an oxide coating formed produced a slight photoresponse, but it was not nearly as large as that of CVD Fe_2O_3 on Pt, since, again, the formation of the required structure and doping levels could not be achieved without the oxide flaking off. CVD of the Fe_2O_3 was not necessary for good photoresponse, however. Electrodes made by heating a mineral oil slurry of the acetylacetonate or a solution of $FeCl_3$ in a flame on a Pt substrate showed good response. CVD does, however, allow better control of the reaction and thus more uniformity in the film, making it more useful for producing large area electrodes.

As with CVD TiO_2, the thickness of the film affects the shape and magnitude of the photocurrent *vs.* po-

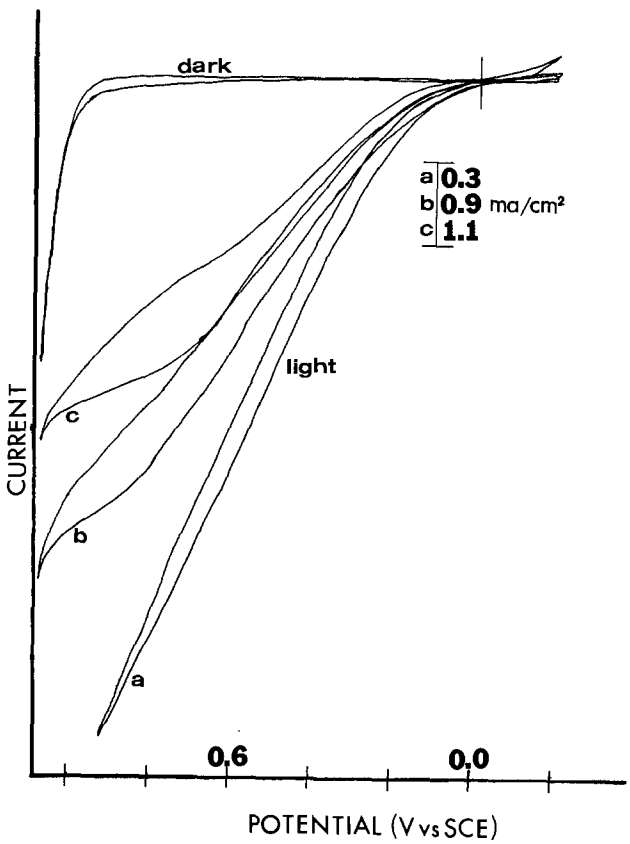

Fig. 6. Current vs. potential curves for CVD Fe_2O_3 of varying thicknesses in 0.25M Na_2SO_4 pH 9.2 solution: (a) 0.6 μm thick, (b) 1.7 μm thick, (c) 6.8 μm thick.

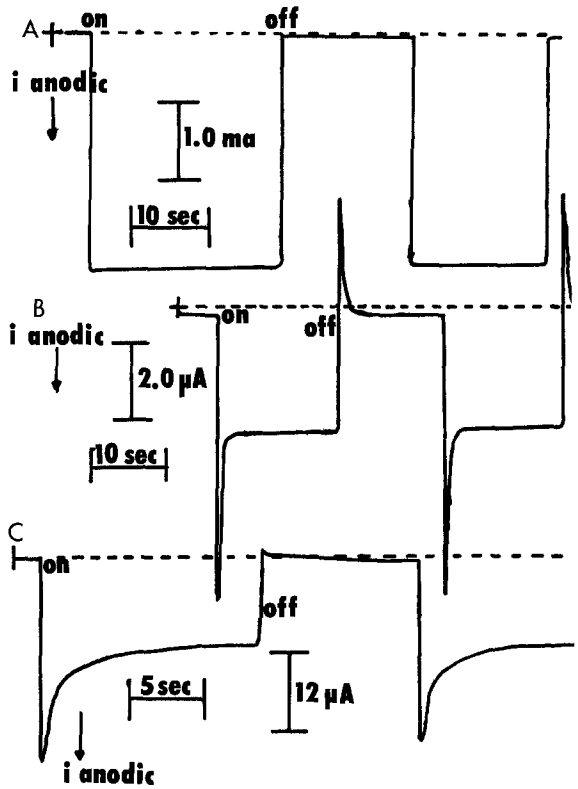

Fig. 7. Transient (*i-t*) curves in 0.25M Na_2SO_4 pH 9 for (a) CVD Fe_2O_3, white light, $E = 0.600$V; (b) CVD Fe_2O_3, monochromatic light, $\lambda = 375$ nm; (c) CVD TiO_2, $E = -0.300$V, $\lambda = 375$ nm.

tential curve (Fig. 6). The much lower anodic current observed on the return sweep is due to adherence of gas bubbles to the electrode surface. Tapping the electrode dislodges the bubbles and increases the current. Thicknesses were estimated by weighing the samples before and after deposition and assuming a density of 5.2 g/cm^3 for Fe_2O_3. For the thickest film twelve coats of Fe_2O_3 were chemically vapor deposited. (One coat equals approximately the amount required to cause no further changes in the interference color, *i.e.*, color becomes steady blue gray). As the film becomes thicker, a plateau region appears, but it never becomes as sharp as that for TiO_2. This indicates a greater recombination effect or lower absorptivity for the Fe_2O_3. Similar *i-E* curves were observed by depositing successive coats on the same electrode and making photocurrent measurements between coats.

The efficiency for the CVD Fe_2O_3 electrode depends, as does that for TiO_2, on the potential and wavelength. Photocurrent densities of the order of 6 mA/cm^2 have been obtained with Xe white light, which is comparable to that for TiO_2 with the same lamp. However, since Fe_2O_3 responds over a wider wavelength region, higher current densities would be expected. Thus the over-all quantum efficiency for Fe_2O_3 is somewhat lower than that of TiO_2. The transient photocurrent-time behavior found with Fe_2O_3 depends upon the light intensity and E and differs from that seen with CVD TiO_2 (Fig. 7). Under high illumination intensities (full Xe lamp output) no transient peaks are observed (curve a). When the intensity was decreased to about 1% of its level with a neutral density filter, a small anodic transient peak appears. At the very low light intensities of monochromatic light (curve b), sharp anodic transients were observed, with the steady photocurrent at these intensities being less than half of the peak value. When the light was turned off, a cathodic peak transient appeared. Similar behavior occurred at all wavelengths where Fe_2O_3 is responsive at similar light intensities (less than 1 mW/cm^2). Vigorous stirring of the solution had only a small effect on the steady current. Memming (8) observed a similar transient response at TiO_2. We have also observed this effect at CVD TiO_2; however, it occurs only on the rising portion of the *i-E* curve (Fig. 7c). On the plateau the transient for TiO_2 is like that for Fe_2O_3 in white light, with both intense white and weak monochromatic light. Notice that in the TiO_2 transient the cathodic peak occurring when the light is turned off is much smaller than the very small anodic one, while with Fe_2O_3 (Fig. 7b) the cathodic transient is of the order of one-half of the anodic one. As the potential is increased for TiO_2, the anodic transient remains well defined, disappearing on the plateau region.

This transient can be explained in terms of surface recombination or backreaction of the photogenerated species. Thus the oxygen (or hydroxyl radicals) which is produced by the photogenerated holes is thermodynamically reducible at potentials on the rising portion of the *i-E* curve. A backreaction between these and any electrons at the surface produces a backreaction [which is equivalent to a surface electron-hole recombination (3)] and a cathodic current component. This component decreases as the potential is made more positive, as expected. The effect of light intensity suggests that the extent of the backreaction is rather constant and independent of the intensity level, *e.g.*, reaching its maximum level when the surface is saturated with oxidized species. Thus, at high light intensities these transients are not observed. The results also suggest that this backreaction is more important for Fe_2O_3 than for TiO_2. The existence of this backreaction cathodic current can also be demonstrated by the following experiment. If the initial potential of a Fe_2O_3 electrode in the dark is set at $+0.80$V and scanned in a negative direction, a small cathodic current is observed at high sensitivity. Illuminating the electrode briefly and then scanning shows an increase

in this cathodic current due to the oxygen produced. Thus the quantum efficiency for photo-oxidation depends upon the light intensity, being smaller at lower intensities and giving anomalously low results for the monochromatic light. The effect of the backreaction is negligible, however, at the higher white (Xe) light intensities, since the transients are not observed under these conditions.

As with CVD TiO_2, Fe_2O_3 shows a large anodic current rise and gas evolution in the dark at potentials greater than about +1.2V. This probably represents tunneling of electrons into the conduction band. However, addition of I^- and $Fe(CN)_6^{4-}$ produced markedly different results at Fe_2O_3 than at TiO_2. The cyclic voltammetric curves for Fe_2O_3 and Pt electrodes of similar area with these species are shown in Fig. 8. For iodide oxidation E_{pa} at Fe_2O_3 is 0.417V, with a peak separation of 0.142V (compared to E_{pa} = 0.417V and ΔE_p of 0.118V at Pt). From simple area considerations, this anodic current for I^- oxidation at Fe_2O_3 cannot be due to exposed Pt under the Fe_2O_3. Neither does the SEM picture show cracks in the film. The curve for $Fe(CN)_6^{-4}$ is markedly different between Pt and Fe_2O_3. These results can be explained by a combination of conduction band and tunneling mechanisms. From the photocurrent *vs.* potential curves, the onset of photocurrent gives an estimate of the flatband potential. For Fe_2O_3 the flatband potential lies about 0.5V positive of that of TiO_2. This implies that the conduction band of Fe_2O_3 is 0.5 eV lower than that of TiO_2. Since the $E^{o'}$s for I^-/I_2 and $Fe(CN)_6^{-4}/Fe(CN)_6^{-3}$ are +0.54 and +0.35V *vs.* NHE, respectively, the redox levels of these couples must lie in the vicinity of the conduction band of Fe_2O_3. The near reversible behavior of the I^-/I_2 couple indicates that the overlap with the conduction band is quite good. The anodic current could be either tunneling or normal electron transfer at the conduction band edge. The $Fe(CN)_6^{-4}/Fe(CN)_6^{-3}$ curve appears irreversible with the anodic wave being almost a plateau. The cathodic wave is shifted in a negative direction but has a more diffusion-controlled shape. If the distribution functions of the $Fe(CN)_6^{-4}/Fe(CN)_6^{-3}$ couple are widely separated, such that $Fe(CN)_6^{-4}$ does not overlap well with the conduction band of Fe_2O_3, then the oxidation would proceed by tunneling and the reduction by a normal conduction band mechanism. The anodic wave is similar to that seen by Pettinger, Schoppel, and Gerischer (6) for Fe^{+2} at highly doped ZnO, which was interpreted as due to tunneling currents. Thus the Fe_2O_3 electrode must be highly doped, since it shows large anodic current rise in the dark, accompanied by gas evolution. The difference in behavior between Fe_2O_3 and TiO_2 can be ascribed to the higher lying conduction band in TiO_2, resulting in a poorer overlap with both the I^-/I_2 and $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ distribution functions.

Fe_2O_3 solar cell.—A large (*ca.* 10 cm^2 area) Fe_2O_3 electrode was fabricated and operated in a solar cell arrangement with a fuel cell-air cathode similar to that of Laser and Bard for TiO_2 (4). In such a cell, oxygen is photogenerated at the Fe_2O_3 and is reduced at the fuel cell cathode, so that the net effect is conversion of light to electrical energy. Figure 9a gives the response curves (current, voltage, and power) for a typical cell with 1*M* NaOH electrolyte and irradiation with the Xe lamp. The potentiostatic *i-E* curves for this cell in the dark and under illumination are shown in Fig. 10. Maximum response of the electrode was achieved by focusing the light onto about 4 cm^2 of the electrode. The corresponding curves for operation in direct, unfocused sunlight are given in Fig. 11. If the sunlight was focused onto 1 cm^2 with a 10.5 cm diameter lens, currents of at least 8 mA could be achieved through a 1Ω load resistor. Vigorous gas evolution was observed from the illuminated spot. This Fe_2O_3 solar cell operated for more than 6 hr in unfocused sunlight and over 2 hr with the Xe lamp with no deterioration in response. Because the flatband potential of the Fe_2O_3 is rather positive, the output voltage and power of this cell are rather low. The current capabilities in the sunlight are quite good and suggest that it would be useful for solar decomposition of water in conjunction with a suitable p-type cathode.

The Fe_2O_3 solar cell was also operated using the I^-/I_2 reaction at a *p*H of about 9 with Xe lamp illumination (Fig. 9b). Initially no I_2 was present in the solution. After operation for a short time through a 1Ω load, the solution became yellow, indicating the production of I_2. The Fe_2O_3 electrode was very near

the window, so the absorption of light by the I_2 was minimal. Prolonged bubbling of N_2 gas through the cell produced only a small decrease in the current. In contrast, during the operation of the cell without the I^-/I_2 couple, N_2 caused the current to decay ten times as fast, with the current finally approaching zero. The current was restored by bubbling O_2. Thus, the over-all solar cell reaction involves I^- oxidation at the Fe_2O_3 and I_2 reduction at the cathode. The rapid production of I_2 and the over-all effect on cell operation with I^- present indicate that the efficiency for photocatalytic generation of I_2 is relatively high, as it also is at TiO_2 (5). Thus Fe_2O_3 should work well and offer the advantage of longer wavelengths when used as an electrode for photoelectrosynthesis (5).

Bismuth oxide.—Photocurrents with anodic gas evolution were also observed at bismuth oxide electrodes prepared by heating bismuth metal; attempts at producing the oxide by CVD using $BiCl_3$ were unsuccessful. Typical *i-E* and *i-λ* curves in *p*H 8, Na_2SO_4 solution, with and without illumination, are shown in Fig. 12. There is a very low anodic and cathodic dark current (<0.1 $\mu A/cm^2$), although on the initial scan with a new electrode some anodic current was observed (dotted line), probably representing further oxidation of the surface. This current disappeared on subsequent scans. Scanning first in the dark to −0.4V *vs.* SCE did not result in any increase in the anodic dark current. With illumination both anodic and cathodic photocurrents are observed. The anodic photocurrent begins at approximately the same potentials as with Fe_2O_3 and exhibits a similar shape. Because of the method of preparation, the oxide film thickness could not be controlled easily, so that the effect of thickness on the *i-E* curve shape was not determined. Heating the sample longer (45 min *vs.* 2 min) produced lower photocurrents, but similar shapes. When the potential was held at +0.60V, gas evolution was observed during illumination. The photocurrent slowly decayed with time, unlike the behavior at TiO_2 or Fe_2O_3. After 1 hr of illumination, the photocurrent had decayed to about 0.4 its original value.

The maximum anodic photocurrent densities [*ca.* 1.6 mA/cm^2 with white (Xe) light] were obtained for Bi_2O_3 electrodes heated only a few minutes. Thus the over-all efficiency for photo-oxidation appears much less than that for TiO_2 or Fe_2O_3. After illumination, the electrode surface color had changed from an initial gray to yellow. The resistance of the electrode (measured with an ohmmeter between the surface and the contact) remained of the order of a few ohms. Dark currents before and after illumination also remained low.

Examination of the electrode surface by x-ray diffraction reveals the presence of two forms of Bi_2O_3, and α- and γ-forms. The relative amount of the two forms was dependent on the length of time the Bi sample was heated. After heating 3-5 min the $\alpha:\gamma$

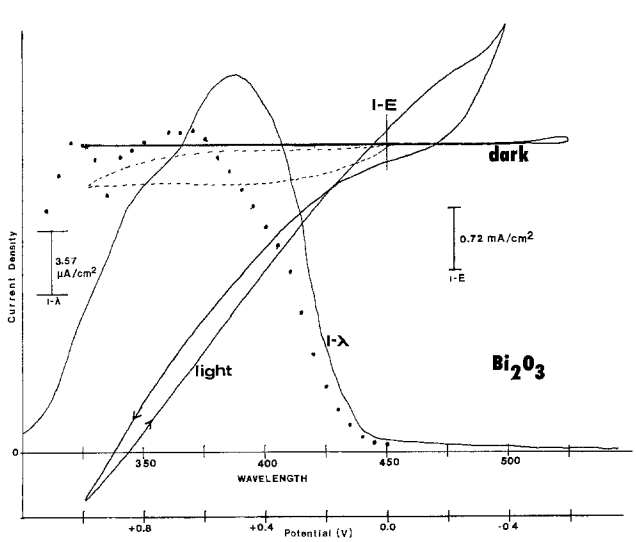

Fig. 12. Current *vs.* potential and current *vs.* wavelength curves for Bi_2O_3 in 0.25M Na_2SO_4 *p*H 8. $E = 0.80$V for *i-λ* curve. Current scale for corrected *i-λ* curve (···) is 2× value shown for uncorrected curve.

ratio was 60:40; after 45 min, the α:γ ratio was 90:10. Since these latter samples had less γ-Bi_2O_3 and showed lower photocurrents, the anodic photocurrent is probably attributable to the γ-Bi_2O_3.

X-ray examination of the electrode after the 1 hr illumination with subsequent decay in photocurrent and appearance of a yellow surface revealed no new forms of bismuth oxide. The x-ray data were not accurate enough to conclude whether or not the γ was converted to α-form, causing the photocurrent decay, or whether the yellow coating which could be a thin film of α-Bi_2O_3, was blocking the surface to further anodic photocurrents.

Unlike the other semiconductors, Bi_2O_3 exhibited both anodic and cathodic photocurrents. Bi_2O_3 has been reported to be an amphoteric semiconductor with n- and p-type behavior (12). It is not known how the presence of both the α- and γ-Bi_2O_3 affects the type of conductivity of the material. Figure 13 shows a cathodic i-E scan from 0.00V. The light was manually chopped during the course of the scan revealing the current to be a cathodic photocurrent, and not the result of the reduction of an anodically produced species (*e.g.*, O_2). The cathodic current is increased after an anodic scan with light, but the primary increase is a photosensitive one. The current becomes cathodic at about +0.2V and also responds to the chopping of the light. This cathodic photocurrent is probably due to the reduction of absorbed oxygen, while at more negative potentials reduction of the Bi_2O_3 also seems to occur. If the potential is held at −0.48V under illumination, a larger anodic dark current is seen similar to the dotted line in Fig. 12 upon a subsequent scan to positive potentials.

When the potential is scanned to −1.4V (Fig. 14), a large reduction peak at −1.05V *vs.* SCE is observed. Illumination shifts the peak to more positive potentials by about 0.1V and alters its shape slightly. The anodic dark current increased as a result of this scan and did not return to the low values initially present. The yellow color formed anodically under illumination disappeared after scanning over the reduction peak. It only reappeared with anodic scans and illumination, or in scans to large positive potentials, where oxygen evolution occurs, in the dark. The exact nature of this coating is, again, unknown as no x-ray peaks assignable to any other form of bismuth oxide were distinguishable.

The photocurrent *vs.* wavelength curves are given for both the anodic (Fig. 12b) and cathodic photocurrents (Fig. 13b). The onset of the photocurrent

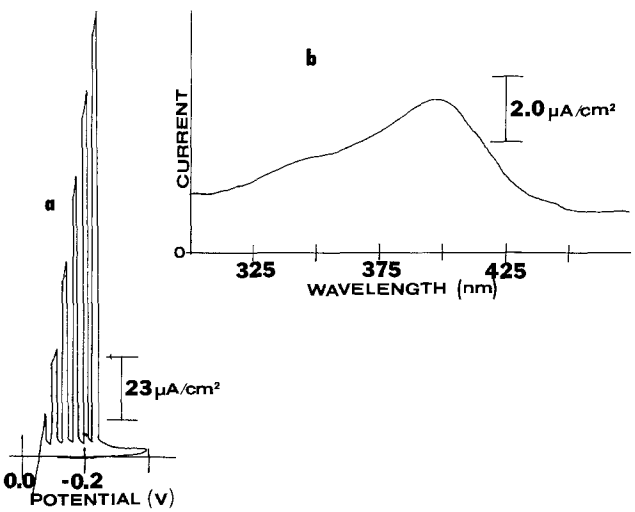

Fig. 13. (a) Current *vs.* potential curve for Bi_2O_3, chopped white light, in 0.25M Na_2SO_4, pH 9. (b) Current *vs.* wavelength for cathodic photocurrent; E = −0.475V *vs.* SCE.

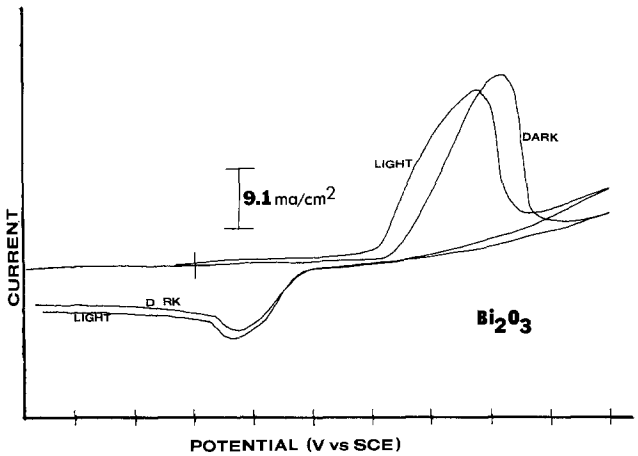

Fig. 14. Current *vs.* potential curve for Bi_2O_3 in 0.25M Na_2SO_4, pH 9.

occurs at about 450 nm (corresponding to an E_g of 2.8 eV) for both curves. The shape of the cathodic curve is not accurate because of the instability in the cathodic currents, and reduction of the oxide. The curve shape is similar to the anodic photocurrent curve, however. Note that the observed photoeffects cannot be ascribed to changes in photoconductivity of the Bi_2O_3 film, since the measured film resistance is low (a few ohms) and was not affected appreciably by illumination. The differences in semiconductor behavior between α- and γ-Bi_2O_3 are not known. The corrected anodic photocurrent *vs.* potential curve shows a steeper rise than those for Fe_2O_3 on TiO_2, possibly indicating a difference in transitions. Although Bi_2O_3 is not stable and has a bandgap only slightly smaller than that of TiO_2, it offers the interesting property of both n- and p-type behavior.

Tungsten oxide.—Hodes, Cahen, and Manassen (9) have observed photosensitized generation of oxygen at polycrystalline WO_3 electrodes prepared by oxidation of the metal or by decomposition of ammonium tungstate on glass. We have observed similar behavior at WO_3 electrodes made by heating W foil, thermally decomposing WCl_6 on Pt, and CVD of WO_3 on Pt. The i-E curves for all of these electrodes show quite similar behavior (Fig. 15). Unlike Hodes *et al.*, we found the anodic photocurrent at a W-foil electrode changed upon repetitive anodic scans with light. The photocurrent increased on each subsequent scan and two anodic peaks appeared at 0.2 and 0.4V *vs.* SCE. After these scans, the dark i-E scan showed a much higher anodic current (about one-half of the photocurrent) which showed the same peaks. This behavior could represent some further oxidation of the W foil or the oxide which, although nominally WO_3 by x-ray diffraction, is probably a nonstoichiometric form. This same behavior occurred for several different W-foil electrodes. The electrode surface was a deep blue before and after illumination. This behavior (appearance of peaks) was not observed for either of the WO_3-Pt electrodes. The photocurrent *vs.* time curves at E = 0.60V *vs.* SCE were quite stable for 10-20 min, with gas evolution observed. The photocurrent then gradually decayed. Examination of the surface revealed that parts of the electrode were bare Pt. Apparently the film had poor adhesion to the Pt. X-ray diffraction revealed the material on the Pt to be WO_3, but did not distinguish slight alterations in composition.

The differences in the oxide composition between the three types of electrodes are evident from the photocurrent *vs.* wavelengths curves (Fig. 15). All show an absorbency beginning at wavelengths corresponding to about 2.6 eV *vs.* the 2.8 eV reported as

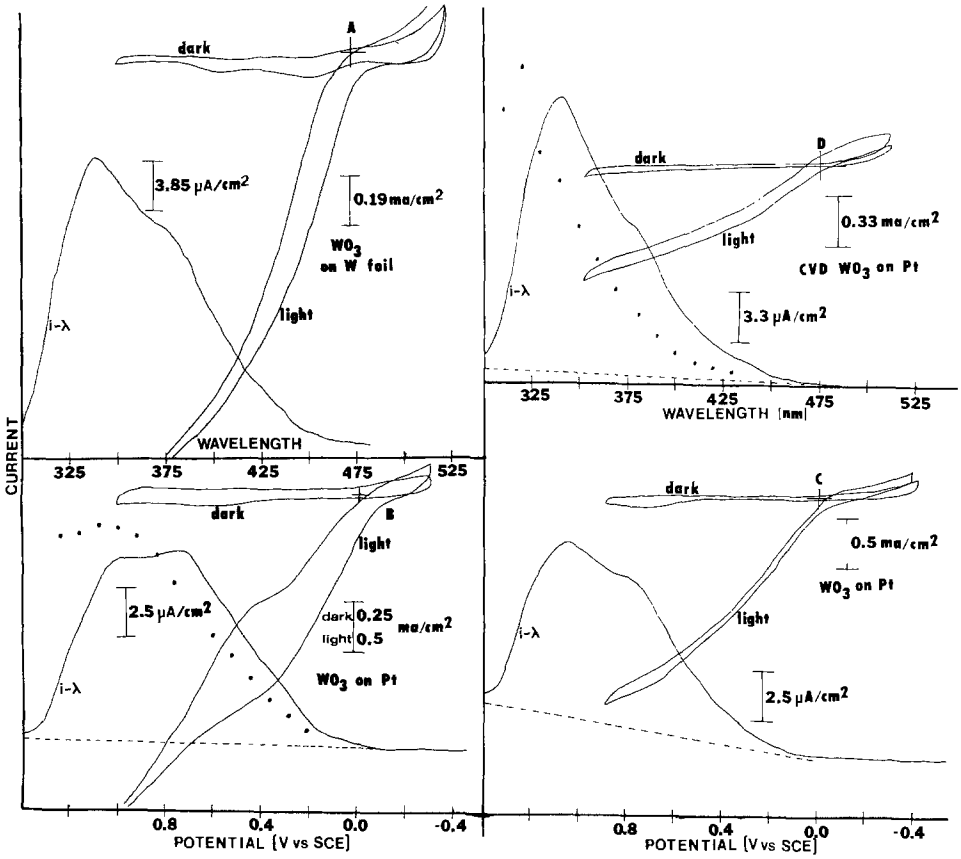

Fig. 15. Current vs. potential and current vs. wavelength curves for (a) WO_3 on W foil, 0.25M Na_2SO_4, pH 8; (b-c) WO_3 on Pt (formed from heating WCl_6 in EtOH solution), 0.25M Na_2SO_4, pH 9; (d) CVD WO_3 on Pt, 0.25M Na_2SO_4, pH 9. All i-λ curves at E = 0.600V vs. SCE. Corrected current scale is 2× uncorrected scale.

the bandgap of WO_3 (10). The shift in the peak location, similar to that observed by Hodes *et al.* (9), must represent structural or composition differences between the polycrystalline and single crystal materials.

Lead oxide.—Another metal oxide that has been found to exhibit photoelectrochemical effects is lead oxide; an i-E curve with a pH 9 0.25*M* Na_2SO_4 solution is shown in Fig. 16. The anodic dark current was usually low, although on some electrodes it was quite high initially but decreased to values shown in Fig. 16a or lower after illumination. With light a somewhat larger photocurrent was observed on the initial scan of a new electrode. The current then remained approximately constant on subsequent scans. The surface changed from an initial blue gray to a bronze brown color; this, coupled with the decrease in dark currents observed after illumination, indicates that at least part of the photocurrent contributes to further oxidation of the surface.

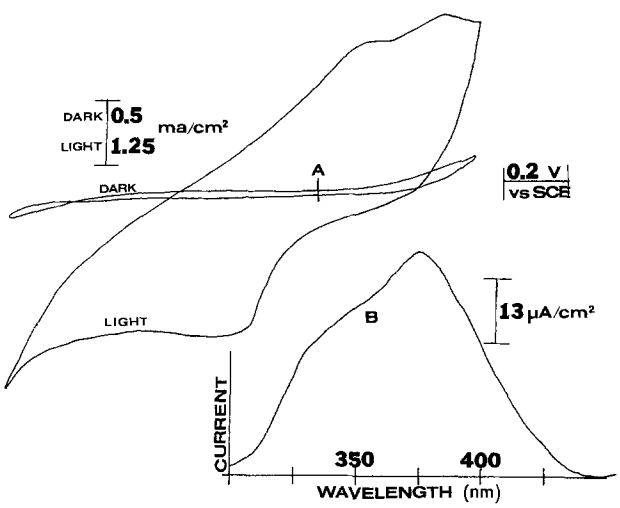

Fig. 16. Current vs. potential and current vs. wavelength curves for lead oxide in 0.25M Na_2SO_4, pH 9. E = 0.600V vs. SCE for i-λ curve.

After an anodic scan with light, the subsequent cathodic current was much higher, sometimes exceeding the anodic photocurrents. The cathodic current gradually decayed in the dark over several scans. It decayed rapidly when the potential was held at −0.2 to −0.4V. However, anodic scans under illumination again increased the subsequent cathodic current. A few gas bubbles were visible on the electrode surface under illumination, but the quantity was much less than that observed at TiO_2 or Fe_2O_3 at similar currents. Moreover, the magnitude of the cathodic current was too large to be accounted for by reduction of adsorbed oxygen. Both an anodic and cathodic transient response similar to those observed with Fe_2O_3 but present even under white light illumination were also found with lead oxide. This again is an indication of a reductive current causing an over-all loss in efficiency in the electrode.

Thus the anodic photocurrent is probably primarily that due to further oxidation of the electrode surface, while the cathodic current is the reduction of the newly formed oxide. X-ray diffraction examination performed on an electrode surface after prolonged illumination indicated the presence of Pb, PbO (litharge), PbO_2 (platernite), and Pb_3O_4 (minium). The bandgaps of these oxides are approximately 2.8, 2.0, and 2.1 eV, respectively (10). From the photocurrent *vs.* wavelength curve, Fig. 16b, a value of about 2.8 eV is obtained, suggesting that PbO is probably responsible for the photocurrent. PbO has been studied as a photoconductor in the solid state (13-15). According to Tennant (13), PbO is a photosensitizer with an absorption spectrum similar to what we observed at the PbO electrode (Fig. 16b). Thus the properties of the electrode are consistent with PbO and the other oxides are, then, the products of the photo-oxidation. The existence of other stable oxides offers a competing path for photo-oxidation of water at PbO

electrodes, compared to TiO_2 and Fe_2O_3 which have no such stable higher oxides. These preliminary experiments showing the reversible behavior of the lead oxide electrode, *i.e.*, photo-oxidation and dark reduction

$$PbO + 2\,OH^- \underset{\text{dark } (+2e)}{\overset{\text{light } (+2h^+)}{\rightleftharpoons}} PbO_2 + H_2O$$

suggest the interesting possibility of using a lead oxide electrode in a "photochargeable" battery. Moreover, PbO_2 has been used often as an electrode for the oxidation of organic compounds (17), so the PbO electrode might also be useful in photoelectrosynthesis. These possibilities are under investigation.

Copper oxide.—A typical *i-E* curve for a copper oxide electrode formed by the oxidation of $CuNO_3$ on Pt is shown in Fig. 17. For comparison, the *i-E* curve for a Pt foil of similar area in the same solution (0.25*M* Na_2SO_4, pH 6.7) is also given. X-ray diffraction of the oxide coating reveals it to be all CuO, which, as shown by the cathodic photoeffect, exhibits a p-type behavior. The onset of the photocurrent occurs at about 0.28V (*vs.* SCE), giving a potential shift of about 0.5V from the dark current rise at the same electrode. Both curves showed negative shifts in potential with increasing *p*H. The shapes of the dark and light curves are significantly different, suggesting that the photocurrent processes are not the same as those occurring during passage of the dark current. The dark current rise showed a hysteresis loop which usually indicates a change in the electrode surface. No loop is seen in the photocurrent curve, which is quite similar in shape to the *i-E* curve seen with the Pt electrode, where the cathodic current rise represents H^+ reduction and the resultant anodic peak on reversal is hydrogen oxidation.

No gas bubbles were seen at the CuO electrode under illumination. However, this could be the result of the relatively low currents and to the instability of the photocurrent. Over a 10 min period, the photocurrent decayed to approximately a quarter of its original value. The surface color changed from an initial black to a black interspersed with gold. Anodic dark scans after prolonged illumination revealed a larger anodic current similar to that in Fig. 17a. An x-ray diffraction pattern of the electrode after formation of the gold areas still revealed only CuO present, but some Pt was also found (~1%) where it had been absent before, indicating removal of some of the CuO.

The photocurrent *vs.* wavelength curve given in Fig. 18 shows a very wide spectral range for CuO, extending to about 700 nm corresponding to a bandgap of 1.7 eV. No literature value of the bandgap was found for comparison. The monochromatic photocurrent depended upon the stirring rate, indicating some diffusional nature to the photocurrent consistent with at least some H^+ reduction. The cathodic current in the dark probably represents reduction of the oxide, since it shows the hysteresis loop and occurs about 0.5V before the H^+ reduction on Pt. The cathodic photocurrent probably represents both H^+ and oxide reduction. The wide spectral range of CuO and its p-type behavior offer interesting possibilities in conjunction with an n-type electrode (*e.g.*, Fe_2O_3) for solar energy use, provided the apparent instability can be overcome.

Vanadium oxide.—Although V_2O_5 dissolves in aqueous solutions (acidic or alkaline), it was of interest to see if it also exhibited any photoeffect. Electrodes of single crystal and CVD material were used. The *i-E* and *i-λ* curves for both electrodes are given in Fig. 19. Onset of the photocurrent occurs at about 0.58V for CVD material and at about 0.8V for the single crystal. The crystal had a higher resistance (about 12 kohm) than the CVD electrode. Both *i-λ* curves are similar, although the CVD curve is broader in the shorter wavelength region. Both give an absorption edge of 450 nm corresponding to a bandgap of 2.75 eV, which is about the bandgap listed for V_2O_5 (10). The CVD electrode dissolved during use which probably affected the magnitude of the photocurrent, and thus the shape of the *i-λ* curve. The single crystal electrode, which was initially smooth, had striations in the surface after use. Because of its instability and the relatively low photocurrents observed, the processes giving rise to the photocurrent were not investigated further.

Other oxides.—Oxides of Cd, Co, Cr, Mn, and Sr were formed by CVD and by thermal decomposition of suitable solutions onto Pt substrates. No noticeable (at least a 10 μA difference between dark and light) photoeffects were observed for the oxides of Mn, Cd, or Sr. Oxide electrodes of Cr and Co exhibited low cathodic photocurrents superimposed on the dark currents. Both Cr_2O_3 and CoO have been reported to be p-type semiconductors (11). For Cr_2O_3 in *p*H 9, 0.25*M* Na_2SO_4, an approximately constant cathodic photocurrent of 45 μA/cm² (observed by manually chopping the light) was superimposed on a dark current of 0-150 μA/cm² (potential range, 0.0 to −0.80V).

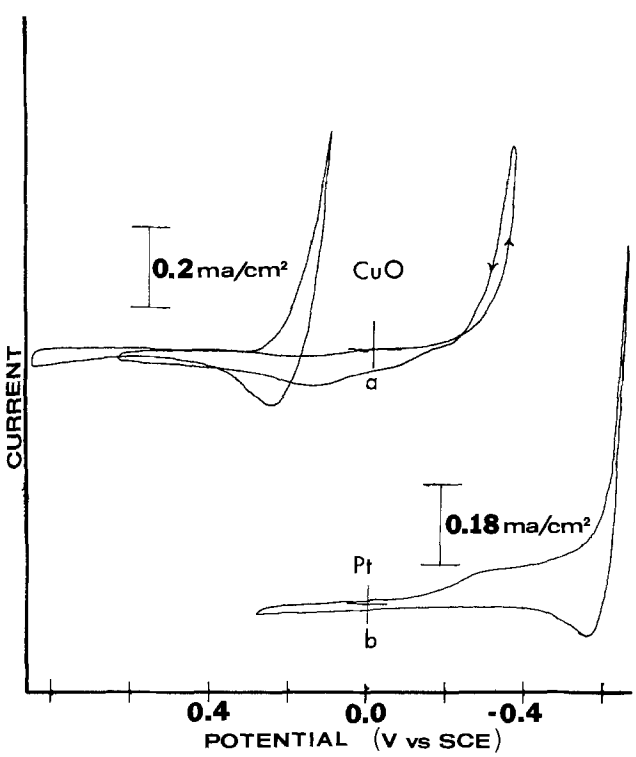

Fig. 17. Current *vs.* potential curve for (a) CuO and (b) Pt in 0.25M Na_2SO_4, *p*H 6.72.

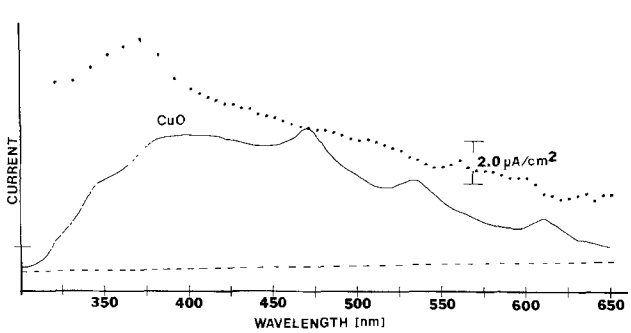

Fig. 18. Current *vs.* wavelength curve for CuO. $E = 0.00V$ *vs.* SCE, 0.25M Na_2SO_4, *p*H 6.72.

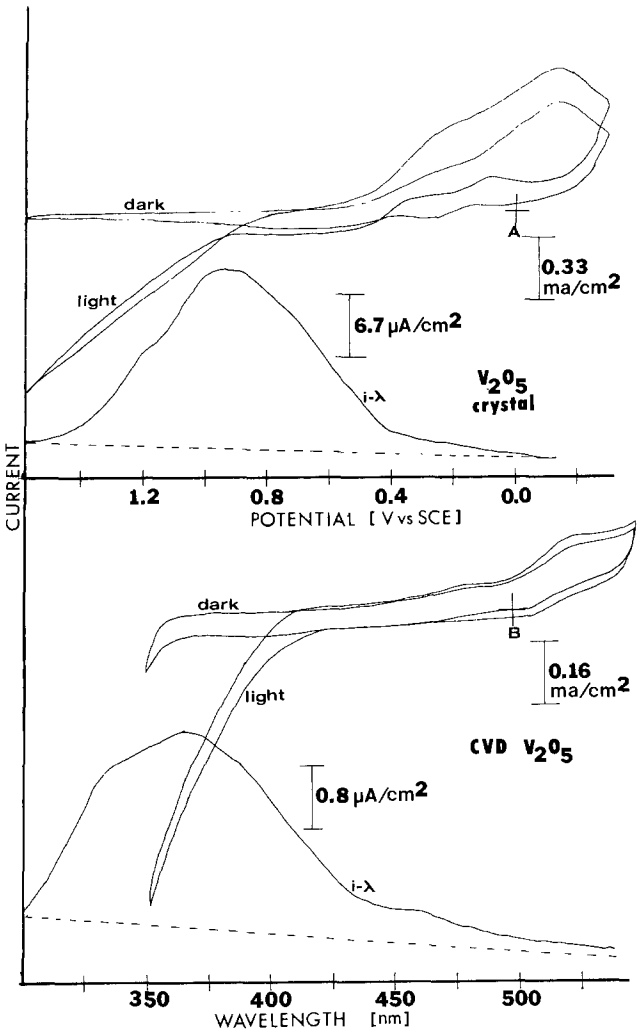

Fig. 19. Current vs. potential and current vs. wavelength curves in 0.5M Na_2SO_4 for (a) V_2O_5 single crystal, $E = 1.50V$ vs. SCE for i-λ curve; (b) CVD V_2O_5, $E = 1.00V$ vs. SCE for i-λ curve.

For CoO the photocurrent increased with potential. An instantaneous photocurrent of 0.2 mA/cm^2 at −0.90V was observed, superimposed on a dark current of 0.3 mA/cm^2. The current for these electrodes (in both dark and light) was not sufficiently stable with time to obtain good i-λ curves.

Conclusion

The results given here demonstrate that a number of metal oxides can be used as semiconductor electrodes which show photosensitized electrode reactions. Moreover, polycrystalline materials are useful for surveying promising semiconductor materials. Several methods (CVD, thermal decomposition of solutions, direct oxidation of metals, anodization, and sintering) can be employed with similar results. Thus, while single crystals are still valuable for detailed studies of the effect of structure on the photoeffect and fundamental studies of efficiency, information on the nature of the photocurrent and material stability can be easily gained from polycrystalline materials. For use in practical devices, good stability is required, including small tendency to dissolve directly or under illumination, stability against photo-oxidation (for n-type materials), and stability against photoreduction (for p-type materials). This stability depends upon the location of the valence band, but also upon the existence of higher or lower oxidation states.

Of the oxides examined only TiO_2, Fe_2O_3, and possibly WO_3 appeared to be stable enough for water oxidation. Only Fe_2O_3 offers stability and the relatively low bandgap needed for solar energy uses. None of the oxides examined seemed to have as negative a flatband potential as TiO_2. However, the shapes of most of the i-E curves did not exhibit the well-defined shape of that for TiO_2, making estimates of the actual flatband potential from the onset of the photocurrent difficult. Fe_2O_3, WO_3, Bi_2O_3, and PbO all showed an onset of photocurrent at approximately the same potential, indicating that the conduction band locations are about the same. One approach to finding useful materials may involve modification of the structure or composition of TiO_2, Fe_2O_3, and WO_3 by introduction of impurity bands or the formation of ternary compounds involving these.

Semiconductor Electrodes

XI. Behavior of n- and p-Type Single Crystal Semconductors Covered with Thin n-TiO_2 Films

Paul A. Kohl,* Steven N. Frank, and Allen J. Bard****

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Single crystal semiconductors (n-Si, p-Si, n-GaAs, p-GaAs, n-GaP, n-InP, and n-CdS) were coated with n-type TiO_2 by a chemical vapor deposition technique, and the electron and hole transfer properties across the heterojunction so produced were investigated. The quality of the deposited TiO_2 film depended upon several factors including temperature and substrate material. When high quality crack-free TiO_2 coats were obtained on n-type substrates, the substrate was stabilized with no dissolution during the photo-oxidation of water. However, the oxidation was due only to the photoexcitation of the TiO_2, and any holes produced in the substrate were not transferred through the TiO_2 to the solution. The use of p-type substrates coated with TiO_2 as photocathodes was limited by band-bending requirements at the p-n heterojunction and the TiO_2-solution interface.

The utilization of small bandgap (E_g) semiconductor electrodes, *i.e.*, $E_g < 2.5$ eV, such as CdS, Si, and GaAs, for the efficient conversion of solar energy to electrical or chemical energy in electrochemical cells is limited by the dissolution or decomposition of the semiconductor itself (1). Photoeffects and the electrochemical behavior of semiconductor electrodes have been described elsewhere [see, *e.g.*, (2-4) and references therein]. Various attempts have been made to stabilize the surface of small bandgap semiconductors without changing their electrochemical properties for hole or electron transfer through the electrode-solution interface. For example, thin metal films have been deposited on the surface of the semiconductor (5) or different redox couples (*e.g.*, Na_2S/S with CdS) have been added to the solution to allow a preferential electrode reaction rather than the dissolution of the semiconductor (6-9). N-type TiO_2, SnO_2, and $SrTiO_3$ show sufficient stability so as not to decompose during the photo-oxidation of water (10-12). However, these have bandgaps $\geq$ 3.0 eV so that they utilize only a very small percentage of the solar spectrum.

There has recently been some interest in using chemically vapor deposited coatings on semiconductor electrodes. For example, CVD TiO_2 coats on n-CdS have been reported (13) to increase its efficiency as a photoanode and decrease the dissolution of the CdS. Other work in this area (14) indicates that n-GaP with TiO_2 coatings stabilize the GaP against photodissolution at potentials positive of the flatband. The heterojunction produced at the interface of the two dissimilar semiconductors creates an energy barrier to the transfer of carriers across the junctions with a magnitude determined by the relative position of the conduction and valence bands, as shown in the discussion following. This barrier would be expected to hinder the flow of photogenerated carriers from the substrate through the protective coating. However, energy levels and surface states may exist in the bandgap region and be utilized for electron transfer reactions, *e.g.*, an intermediate level has been proposed for TiO_2 (6). If these levels extend into the semiconductor and can be considered "bandlike," the possibility exists for the transfer of electrons and holes through the coating via these intermediate levels.

In this work, various small bandgap semiconductors (n-Si, p-Si, n-CdS, n-GaAs, p-GaAs, n-GaP, and n-InP) were coated with polycrystalline TiO_2 by chemical vapor deposition (CVD) to examine the resulting electrical properties both with and without a solution interface. The position of the valence and conductions bands *vs.* vacuum for the various semiconductors is shown in Fig. 1 (15, 16). The procedure for obtaining a good TiO_2 film on small bandgap single crystal semiconductors, a modification of the one previously described (17), the electrode properties, and the conditions by which photoexcited electrons or holes are transferred from the substrate to the solution via the large bandgap TiO_2 film on the surface are reported.

Experimental

The low resistivity single crystal semiconductors used as substrates for chemical vapor deposition of polycrystalline TiO_2 were about 1 mm thick and were polished with 0.5 μm alumina. The CVD, with the apparatus described previously (17), was done at various substrate temperatures (100°-600°C) to find the optimum temperature for a good quality TiO_2 film. The annealing process was performed either on a hot plate

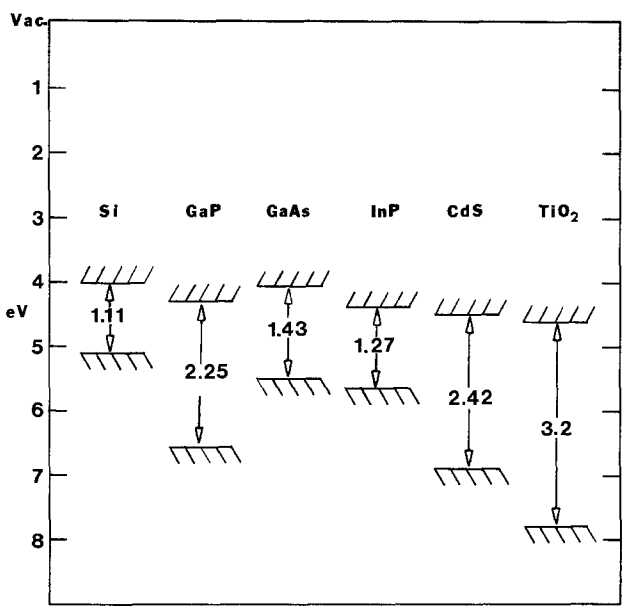

Fig. 1. Relative position of the valence and conduction bands vs. vacuum of the various semiconductors used.

at 600°C or under high vacuum at 700°C; the flame method used previously was not employed here because of the easy oxidation of most semiconductor materials at flame temperatures in the presence of oxygen. The n-type TiO_2 was reduced to increase its conductivity by passing hydrogen gas over the heated sample or by heating in a high vacuum.

The n-GaP, n-GaAs, and p-GaAs were obtained from Atomergic Chemicals (Long Island, New York). The n-Si and p-Si crystals were donated through the courtesy of Texas Instruments (Dallas, Texas), and the n-CdS and n-InP were originally obtained from National Lead and donated by Dr. D. I. Tchernev (Lincoln Laboratories, Massachusetts Institute of Technology). Ohmic contacts were made to the n-CdS, n-InP, and n-GaP by electroplating indium on the back side of the crystals using a 0.1*M* $InCl_3$ solution. The n-GaP contact was heated in a hydrogen atmosphere at about 400°C for several hours to make it ohmic. Ohmic contacts were obtained with p-GaAs and p-Si (3) by electroplating gold from a 0.1*M* $Au(CN)_2^-$ solution on the rear side. Contact to n-Si (3) was made by electroplating nickel from a 0.1*M* $Ni(NO_3)_2$ solution and to n-GaAs (18) by first plating indium, then gold, and alloying at 400°C in a hydrogen atmosphere. To confirm that the contacts were ohmic, a second contact was made to the rear side; in all cases of good contacts the resistance between the contacts was small and the current was directly proportional to the applied potential independent of polarity. A wire was connected to the ohmic contact with conducting silver epoxy (Allied Products Corporation, New Haven, Connecticut). The back and sides of the crystal were then sealed with nonconducting 5 min epoxy (Devcon Corporation, Danvers, Massachusetts). The crystals were then mounted on a small glass disk connected to a glass tube with silicone adhesive (Dow Corning, Midland, Michigan) which allowed a path for the wire. When an ohmic contact was made on the front side of the crystal on the TiO_2, it was accomplished with silver epoxy and the contacts insulated as described above. Duplicate semiconductor electrodes were prepared in an identical manner except without the TiO_2 film for comparison with the filmed electrodes.

All chemicals were reagent grade and all solutions were prepared with triply distilled water, with the first distillation from alkaline potassium permanganate.

A three-compartment cell, similar to previous designs (6), was used for all electrochemical measurements. The reference compartment made electrical contact with the main compartment via a porous Vycor glass junction. The counterelectrode was a platinum wire and the reference electrode was a silver wire in 0.1*M* $AgNO_3$. However, all values are reported *vs.* a saturated calomel electrode (SCE). The main compartment had an optically flat Pyrex window.

A PAR 173 potentiostat and PAR 175 universal programmer (Princeton Applied Research Corporation, Princeton, New Jersey) were used. Data were recorded on a Houston Instruments Model 2000 X-Y recorder. For photoexcitation experiments, a 450W xenon lamp and grating monochromator (Oriel Corporation, Stamford, Connecticut) were used. The electron micrographs were taken with a scanning electron microscope (SEM) JSM-2 (Japan Electron Optical Laboratory Company, Limited) with an x-ray fluorescence spectroscopy attachment (Canberra Industries) for elemental analysis of the surfaces.

The concentrations of Cd^{+2} and Ga^{+3} in solution from dissolution of the electrodes were determined polarographically at a dropping mercury electrode using a PAR 170 electrochemical system. Standard solutions were prepared from cadmium chloride and gallium metal dissolved in sulfuric acid. The solutions were degassed with prepurified nitrogen gas and the gallium was diluted and buffered with a 1*M* NH_3/1*M* NH_4Cl solution.

Results

The polycrystalline TiO_2 coats obtained were all hard and durable. The number of cracks and holes which formed in these coatings depended upon several factors, including the nature of the substrate material, the substrate temperature during deposition, the rate of heating and cooling of the substrate, the thickness of the TiO_2 coats, the number of TiO_2 coats applied, and the method of doping the TiO_2.

N-type substrate/n-TiO_2/solution.—Durable, crack- and hole-free coats of TiO_2 were obtained on n-Si and n-InP (Fig. 2a) by performing the CVD at a substrate temperature of 500°-600°C. At this temperature the coats annealed without additional heating and cooling (17). The substrate was held at this temperature for several hours to give at least a partial conversion from the anatase to ruile structure, and hydrogen gas was then passed over the surface to reduce it. The sample was then allowed to cool slowly over a 24 hr period.

The current *vs.* potential (i-E) curve for the n-InP/TiO_2 electrode with the TiO_2 exposed to solution (Fig. 3a) showed a cathodic dark current characteristic of an n-type semiconductor and an anodic photocurrent due to the oxidation of water, with bubbles being given off at the electrode surface and approximately a 60 mV/*p*H change in the onset of photocurrent. The current *vs.* wavelength (i-λ) plot (Fig. 3b) showed that the photocurrent absorption spectrum for the n-InP/TiO_2 electrode was identical to that of TiO_2. After several hours of illumination at +0.5V, there was no change in the amount of photocurrent or in the i-λ plot. There was also no visual decomposition of the TiO_2 film or apparent dissolution of the InP. In Fig. 3, the results of an uncoated n-InP electrode are shown for comparison. Similar results were observed with the n-Si/TiO_2 electrode. The TiO_2 was crack- and hole-free with anodic photoeffects observed and bubbles evolved at the surface only for $\lambda < 400$ nm (3.1 eV).

Crack-free TiO_2 coats were never obtained on n-CdS, even after repeated attempts using different conditions, as discussed above. The best coats were obtained by CVD at 600°C as before, but with reduction in high vacuum at 600°C. The electron micrographs are shown in Fig. 2b. With fast heating and cooling processes, there were at least ten times as many cracks. The i-λ curve, Fig. 4a, showed a large peak at about 480 nm due to the absorption of CdS with the current increasing with subsequent scans. The small current at about 350 nm, due to the excitation of TiO_2, decreased with time as the TiO_2 film deteriorated, as shown in Fig. 2c. The current *vs.* time curve, Fig. 4b, showed that the anodic photocurrent of pure CdS decreased, probably because of the formation of sulfur on the surface. With a TiO_2 film, the current increased with time, corresponding to the breakup of the TiO_2 film; the final current was limited by the sulfur buildup. Even for the portions of the TiO_2 that do not flake off, a sulfur layer can be seen to underlie the remaining and still durable TiO_2 film. Analysis of the solution, after passage of an anodic photocurrent for a given time, showed about 1% less Cd^{+2} from the dissolution of CdS with TiO_2 on the surface as compared to CdS without TiO_2. Bubbles were not seen on the surface because of the small amounts of current going to the oxidation of water.

Crack- and hole-free coats were also not obtained on n-GaAs and n-GaP. Similar i-λ plots to those of n-CdS/TiO_2 were obtained with an absorption peak at about 350 nm, and a photocurrent which decreased with time. However, the substrate absorption peak currents increased with time because of the soluble products of dissolution. Bubbles were evolved at the electrode surface until a visible deterioration of the TiO_2 film was evident and solution analysis confirmed the presence of gallium.

P-type substrate/n-TiO_2/solution.—To examine further the band structure and possibilities for electron

and hole transfer through the TiO_2, p-type materials were used as the substrates. This, in effect, gives holes in the substrate which are available for possible electron transfer to the solution without illumination.

Crack-free and stable coats of TiO_2 were obtained on p-Si and p-GaAs by the same procedure as described for n-Si and n-InP. The *i-E* curve of p-Si/TiO_2 (Fig. 5a) can be divided into three regions as indicated.

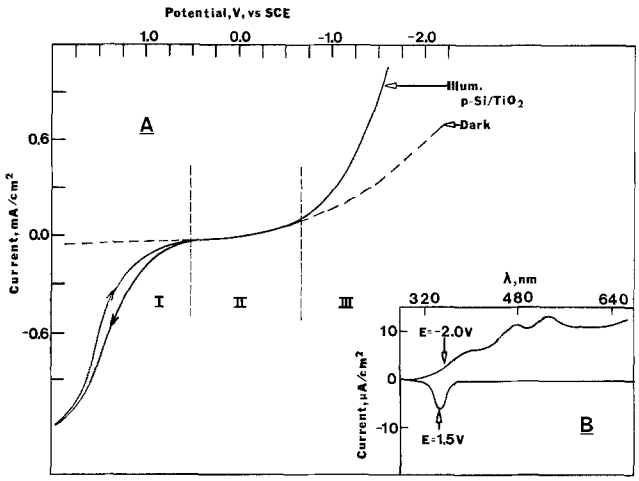

Fig. 5. (a) Current *vs.* potential for p-Si/TiO_2 in the dark and illuminated in 0.5*M* Na_2SO_4; (b) current *vs.* wavelength for p-Si/TiO_2 in 0.5*M* Na_2SO_4 at +1.5V and −2.0V *vs.* SCE (uncorrected for lamp intensity-monochromator spectral variations).

Significant photocurrents occurred in regions I and III. The anodic photocurrent in region I (Fig. 5b) is due to electron/hole pair formation in the TiO_2 resulting in the oxidation of water with bubbles evolved at the electrode surface. The potential for the onset of anodic photocurrent was *p*H dependent (*i.e.*, 60 mV/*p*H). In region III, the cathodic photocurrent can be attributed to the reduction of H^+ by photoexcitation of the p-silicon with again approximately a 60 mV/*p*H change in the onset of cathodic photocurrent. After several hours of illumination, there was no change in the cathodic or anodic photocurrents, nor was there a change in the i-λ curves. The same characteristic three regions were obtained on p-GaAs/TiO_2, but with the onset of significant anodic photocurrent at about +0.2V and significant cathodic photocurrent at about −0.7V in 0.5*M* Na_2SO_4.

i-V curves.—To investigate the TiO_2-substrate heterojunction, the current-voltage (i-V) curves on the solid-state junctions alone were taken by applying the indicated voltage to the front TiO_2 contact with respect to the rear substrate contact (Fig. 6a). Similar results were obtained for the various other substrate materials used. These results are discussed in the next section.

Discussion

The results for n-InP and n-Si with TiO_2 on the surface show the photo-oxidation of water can only be accomplished by the excitation of an electron-hole pair in the TiO_2. The creation of a hole in the n-type substrate has no mechanism for transfer through the TiO_2 to the solution. The observed 60 mV/*p*H shift in the onset of photocurrent at the TiO_2-covered substrates reflects the shift in the surface hydroxide equilibrium brought about by *p*H changes, as discussed by Honda and co-workers (19) for TiO_2 single crystals. The small bandgap substrates are stabilized with completely reproducible results from day to day and with no passivation or change in behavior.

Although the results are inconclusive, it appears that a similar lack of hole transfer through the film occurs in the other n-type semiconductors used in this study. The dissolution processes which occur at n-GaP, n-CdS, and n-GaAs appear to be taking place through the cracks in the TiO_2 (Fig. 2b and 2c). The increase in anodic photocurrent with time correlates with the removal of TiO_2 from the surface, just as the decrease in current at $\lambda = 350$ nm and the decrease in evolution of bubbles correlates with the removal of TiO_2.

The results for p-GaAs and p-Si with TiO_2 on the surface (Fig. 5) also show that the anodic photo-oxidation of water, region I, is due only to the excitation of an electron-hole pair in the TiO_2. The small dark current, even at +2.0V, shows that holes are not transferred through the TiO_2 to the solution. The cathodic photocurrent, region III of Fig. 5, is due to the reduction of hydrogen ion by photoexcited electrons in the conduction band of the substrate material that transfer through the TiO_2 to the solution. The potential at which this takes place is even more negative than that required for the reduction of hydrogen ion at a platinum electrode in the same solution. Region II of Fig. 5 lies between these two extreme regions with very small anodic photocurrents due to the excitation of TiO_2 and very small cathodic photocurrents from the excitation of the substrate. The substrates were again stable with no change in behavior with time.

The nature of the heterojunction produced between the small bandgap substrate and TiO_2 can be represented to a first approximation by simple band structures, shown in Fig. 7 (20). This neglects such things as the change in work function of TiO_2 with interaction with the water (21) or air pressure (16). This also does not consider the possibility of intermediate compounds being formed at the junction creating additional barriers, or the presence of surface states. The potential barrier at the n-n heterojunction arises from the mismatch of the conduction bands and Fermi levels. If the energies of the conduction bands and Fermi levels of the n-substrate and TiO_2 were equal with an ideal junction, there would be no barrier to the majority carriers (22). This model is qualitatively confirmed by the results in Fig. 6a, where the current varies with the exponential of the barrier potential, which changes in proportion to the applied potential. This is demonstrated in Fig. 6b by the linearity of the ln i *vs.* V plot. Therefore, because of the higher barrier for an electron to go from the TiO_2 to the n-type substrate, the conduction band of the substrate is higher than that of the TiO_2. The valence band of the TiO_2 must then lie far below that of the substrate. Therefore, a hole in the valence band of the substrate cannot travel downhill to the TiO_2 valence band without extreme band bending even if the nonidealities in the heterojunction, as mentioned above, are considered. It might be possible for hole transfer to occur through an intermediate level located in the bandgap region of the TiO_2 (6). However, no evidence for this type of transfer was found in these studies.

When the electrodes are used in solution, there are two junctions to be considered: the substrate/TiO_2 heterojunction and the TiO_2/solution interface. At equi-

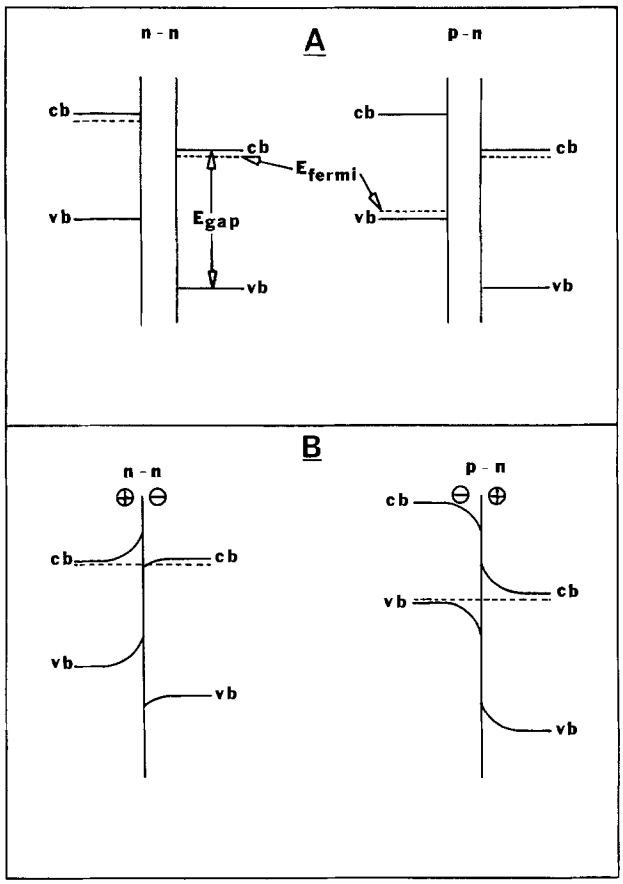

Fig. 7. Example of a n-n heterojunction and a p-n heterojunction (a) before contact, (b) after contact with the resulting band bending and charge separation.

librium, all Fermi levels must be equal. When a potential, ΔE, is applied to the electrode with respect to the solution and current flows, the position of the TiO_2 Fermi level is determined by the relative barriers at the two junctions (22). Assuming that the rate-determining step of the reaction at the TiO_2/solution interface is first order in concentration of holes or electrons at the surface, the current will depend not only upon the band bending of the TiO_2 at the solution interface but also upon the band bending of the substrate and TiO_2 at the heterojunction. A given current corresponds to a unique band-bending situation at both junctions. If a change in pH affects the potential drop between the electrode surface and solution, then the applied potential must be changed an equal amount to obtain the same band-bending situation and current. This explains the observed 60 mV/pH shift in onset of photocurrent.

Conclusion

Protective films of TiO_2 can be obtained by CVD on some semiconductor substrates without cracks. However, when cracks are present, dissolution of the substrate material can occur, with photocurrents caused by substrate dissolution at absorption wavelengths of the substrate. There does not appear to be any advantage in depositing TiO_2 on the n-type substrates used in this work, compared to the photo-oxidation of water over a CVD TiO_2 electrode itself, because of the inability to transfer holes from the substrate through the TiO_2. The use of p-type substrates coated with n-TiO_2 as photocathodes is limited by the band-bending requirements at the junctions and the barrier potential which must be overcome at the heterojunction, so that the required "negative overpotentials" for useful conversion of light energy do not occur.

The Transient Response of the Sulfur/Polysulfide Electrode Based on a Varying Concentration Model

Yuen-Koh Kao[1] and Peter C. Wayner, Jr.

Department of Chemical and Environmental Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

A computer simulation of the transient behavior of the sulfur electrode of a Na/S battery operating in the single phase region was obtained. The results show the relative, effect of concentration and conductivity on the cell performance. The predominant effect is due to the variation of the chemical potential of sulfur with concentration which causes the cell to operate uniformly. This advantage is partially offset by high current densities, large cell dimensions, and unmatched melt and felt conductivities. Capacity loss, which has been experimentally observed, is theoretically demonstrated.

The application of the sodium/sulfur system as a secondary battery has attracted considerable attention. It has the potential to fulfill the need for an efficient and inexpensive energy storage device. The transport processes associated with this battery are somewhat unique in that the "electrolyte" is a ceramic, β-alumina, which is permeable to only the sodium ion. The β-alumina separates one of the reactants, liquid sodium, from the other, polysulfide (sulfur when fully charged) which is usually contained within a graphite felt electronic conductor matrix (1). The operating characteristics are further complicated by the sulfur/Na_2S_x phase diagram which, depending on the composition, shows both immiscible and solid phases (2).

Most of the previous work concerning the battery concentrated on the material properties of the system and the experimental operation of the battery, *e.g.*, (3-5). Except for Ref. (5, 6), very little research addressed the problem of modeling the complicated sulfur electrode. Gibson (6) using the continuum modeling approach of Newman and Tobias (7) evaluated the effect of melt and felt conductivity on the reaction rate distribution. However, he neglected the more significant effect of concentration. The results of the study showed a large spatial variation in the reaction rate which would lead to incorrect conclusions concerning the operation of the battery. In a later work by the present authors (8), a sulfur electrode model was developed that included the effect of a hypothetical concentration distribution. The results of the study demonstrated that the dominant effect on cell operation was due to concentration gradients.

The present study concerns the transient behavior of the sulfur electrode using the more realistic uniform concentration of $Na_2S_{5.25}$ as the starting point. These results demonstrate how the selective effects of conductivity and the transient change in the concentration affect the operation of the sulfur electrode. The predominant effect is due to the variation of the chemical potential of sulfur with concentration which causes the cell to operate uniformly. The annoying phenomenon of capacity loss, which has been observed in many experimental studies, (3-5), is also present in the results of these studies.

Formulation

The annular shaped sulfur electrode studies herein is bounded on the inside by the outer wall of the ceramic tube ($r = R_o$) which contains the sodium and which is an ionic conductor of sodium ions. It is bounded on the outside ($r = R_1$) by an electronic conducting container. The annular space contains graphite felt impregnated with sodium polysulfide and/or molten sulfur. During discharge, the sodium ions, after giving up an electron to the external circuit, migrate through the solid β-alumina electrolyte to form various polysulfides in the sulfur electrode when sulfur atoms receive two electrons from the external circuit. The basic approach followed is the continuous model of Newman and Tobias (7). Some of the following equations [1]-[4] were developed in an earlier paper (8). The following assumptions were used in deriving the equations:

1. The sulfur electrode can be modeled by the superposition of two continua.

2. There is no capacitance effect in the melt/felt interface; the conservation of charge gives the following equation

$$(i_1 + i_2)\, r = I_{R_o} R_o$$

where i_1 and i_2 are the current densities in the melt and felt phases, and I_{R_o} is the current of the melt phase at the β-alumina and sodium polysulfide interface.

3. The electrode kinetics can be modeled using a diffusion model. The electrode reaction is assumed to be $S + 2e^- \rightleftarrows S^=$. The limiting species are assumed to be S and $S^=$ in the anodic and cathodic direction, respectively. Further simplification is achieved by assuming that the respective limiting current densities are the same in either direction (8)

$$i_s = -i_l \tanh(\alpha\eta)$$

where

$$\alpha = \mathbf{F}/RT,\ \eta = \phi_2 - \phi_1 - \Delta\phi_e;\ \Delta\phi_e = (\phi_2 - \phi_1)_{i_s=0}$$

4. The current equation for the melt which includes the effect of concentration gradients is (8)

$$i_1 = -k_1 \nabla\phi_1 + \frac{k_1}{2\mathbf{F}}(1 - 2W_s)\nabla\mu_1{}^2$$

where $k_1 = 1.5376 - 1.9264\, w_s$ [this interpolation equation, in which w_s is the weight fraction of atomic sulfur, is based on experimental results (9)], W_s is the "Washburn number" which is defined as the number of moles of sulfur that passes through a reference plane in the same direction as a Faraday of charges passes through that plane. The plane is chosen such that no sodium ion passes through it. Cheaver and Davies (10) indicated that sulfur atom moves only with the sulfur ion and hence $W_s = -c_1/2c_3$. The chemical potential of atomic sulfur which is also based on the same work is interpolated and gives the following equation

$$\frac{\mu_1}{2\mathbf{F}} = \frac{\mu_1{}^*}{2\mathbf{F}} + (-690.9970 + 384.9642x - 74.8151x^2 + 5.05331x^3),$$

[1] Present address: Department of Chemical and Nuclear Engineering, University of Cincinnati, Cincinnati, Ohio 45221.

Key words: single-phase, discharge, molten salt, capacity loss.

[2] This equation can also be obtained according to Eq. [34] of Newman and Tiedman's work (15).

in mV for $x \leq 5.25$ at 350°C. The formulation is completed by including following conservation of changes equations for each phase

$$\frac{\partial i_1}{\partial r} = \frac{1}{r} i_1 - a i_s$$

$$\frac{\partial i_2}{\partial r} = \frac{1}{r} i_2 + a i_s$$

Eliminating ϕ_1, ϕ_2, i_2 from the above equations and after defining appropriate dimensionless variable leads to the following dimensionless current equation (8)

$$\frac{\partial^2 j}{\partial y^2} = C_t \frac{\partial j}{\partial y} + C_t{}^2 j + \left[1 - \beta^2 \left(\frac{\partial j}{\partial y} + C_t j \right)^2 \right] \quad [1]$$

$$\left[\gamma \left\{ j - \frac{k_1}{k_1 + k_2} \left(\frac{R_o}{R_o - y\Delta R} \right) \right\} - \frac{x}{\beta} (b' + 2c'x + 3d'x^2) \frac{\partial x}{\partial y} \right]$$

where $j = i_1/I_{R_o}$, x is the "x" in Na_xS_x,

$$y = (r - R_o)/(R_1 - R_o)$$

$$C_t = \frac{\Delta R}{y\Delta R + R_o}$$

$$\beta = \frac{I_{R_o}}{a i_1 \Delta R}$$

$$\gamma = a i_1 \Delta R^2 \left(\frac{1}{k_1} + \frac{1}{k_2} \right)$$

The molar flux equations for atoms sulfur, sodium ions, and sulfide ions are obtained from the multicomponent diffusion equations. Introducing the chemical potential of sodium sulfide μ and the current density of the melt i_1, and by choosing v_2, the velocity of sodium ions, as the reference velocity, after the elimination of v_1 and v_3 resulted in the following flux equations

$$N_1 = \frac{K_{31} c_1}{(K_{21} + K_{31}) c_3 Z_3} \frac{i_1}{\mathbf{F}} + \frac{c_1}{K_{12} + K_{13}} c \nabla \mu + c_1 v_2$$

$$N_2 = c_2 v_2$$

$$N_3 = \frac{i_1}{Z_3 \mathbf{F}} + c_3 v_2$$

According to Cleaver and Davies (10), sulfur atoms move with sulfide ions, that is $K_{13} = \infty$, therefore the flux equation now becomes

$$N_1 = W_s \frac{i_1}{\mathbf{F}} + c_1 v_2 \quad [2]$$

$$N_2 = c_2 v_2 \quad [3]$$

$$N_3 = \frac{i_1}{2\mathbf{F}} + c_3 v_2 \quad [4]$$

Notice that N_1 and N_3 are redundant and only one of them is needed to describe the system. The equations of continuity for the species in cylindrical coordinates are

$$\frac{\partial c_i}{\partial t} = -\frac{1}{r} \frac{\partial}{\partial r} \left[r \frac{\partial N_i}{\partial r} \right] + R_i \quad [5]$$

where R_i is the rate of production of species i in molar units, with $R_2 = 0$ and

$$R_3 = -R_1 = -\frac{1}{2\mathbf{F}r} \frac{\partial}{\partial r} (r\, i_1) \quad [6]$$

The determination of the reference velocity, v_2, follows the approach proposed by Kirkwood *et al.* (11). The flux relative to the cell is related to the flux relative to v_2 by the following equation

$$(rN_i)_C = (rN_i)_R + c_i v_2 r \quad [7]$$

where c_i is the molar concentration of species i and subscript C and R denote quantities relative to the cell and relative frames.

After differentiating the above equation with respect to r, taking the sum over all i and multiplying both sides by their respective partial molar volumes, the following equation is obtained

$$\sum_{i=1}^{3} V_i \frac{\partial}{\partial r} (rN_i)_C = \sum_{i=1}^{3} V_i \frac{\partial}{\partial r} (rN_i)_R + \frac{\partial}{\partial r} (v_2 r) \sum_{i-1}^{3} c_i V_i + \sum_{i=1}^{3} \left(\frac{\partial c_i}{\partial r} V_i \right) v_2 r \quad [8]$$

Since $\sum c_i V_i = 1$ and $\sum V_i \frac{\partial c_i}{\partial r} = 0$ by the Gibbs-Duhem equation the above equation becomes

$$\sum_{i=1}^{3} V_i \frac{\partial}{\partial r} (rN_i)_C = \sum_{i=1}^{3} V_i \frac{\partial}{\partial r} (rN_i)_R + \frac{\partial}{\partial r} (v_2 r) \quad [9]$$

Then summing the equations of continuity of all species after multiplying both sides by their respective partial molar volumes and using the Gibbs-Duhem equation, the following equation is obtained

$$\sum_{i=1}^{3} V_i \frac{\partial c_i}{\partial t} = 0 = \sum_{i=1}^{3} \left[-\frac{1}{r} \frac{\partial}{\partial r} (rN_i)_C \right] V_i + \sum_{i=1}^{3} R_i V_i \quad [10]$$

Combining Eq. [9] and [10], the following equation for the reference velocity, v_2, is obtained

$$\frac{\partial}{\partial r} (rv_2) = V_1 \frac{\partial}{\partial r} \left[r(1 - 2W_s) \frac{i}{2\mathbf{F}} \right] \quad [11]$$

For simplicity the following equations are used to relate the concentration to the value of x in Na_2S_x

$$c_1 = (x - 1)/(19 + 18.4x)$$

$$c_2 = 2/(19 + 18.4x)$$

$$c_3 = (19 + 18.4x)^{-1}$$

The partial molar volumes are: $V_1 = 18.4$, $V_2 = V_3 = 37.4/3$ cm³/mole.

In arriving at these values, it was assumed that the partial molar volumes of Na^+ and $S^=$ ions, V_2 and V_3, were the same. As was stated in a paper by Newman and Chapman (12), this assumption is adopted for convenience only and should not be attached to any physical interpretation. Since only one equation is needed because of electroneutrality, we use the equation for atomic sulfur, which is

$$\frac{\partial c_1}{\partial t} = -\frac{1}{r} \frac{\partial}{\partial r} \left\{ r \left[(1 - 2W_s) \frac{i}{2\mathbf{F}} + c_1 v_2 \right] \right\} \quad [12]$$

After using $W_s = -c_1/2c_3$ and Eq. [11], the above equation becomes

$$\frac{\partial c_1}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[\left(\frac{1}{V_1} - c_1 \right) v_2 r \right] \quad [13]$$

In terms of x in Na_2S_x, Eq. [13] becomes

$$\frac{\partial x}{\partial t} = \frac{(18.4x + 19)^2}{18.4r} \frac{\partial}{\partial r} \left(\frac{v_2 r}{18.4x + 19} \right) \quad [14]$$

After introducing the dimensionless current density and space coordinate, j and y, into Eq. [11] and [14] we obtain

$$\frac{\partial}{\partial y}\left(\frac{v_2}{C_t}\right) = \frac{V_1 I_{R_0}}{2F}\frac{\partial}{\partial y}\left(\frac{jx}{C_t}\right) \quad [15]$$

$$\frac{\partial x}{\partial t} = \frac{(19+18.4x)^2 C_t}{18.4\,\Delta R}\frac{\partial}{\partial y}\left[\frac{v_2}{C_t(19+18.4x)}\right] \quad [16]$$

Equations [1], [15], and [16] form the set of equations that describe the transient response of the sulfur electrode, or more precisely, the polysulfide phase of the sulfur electrode. Since sulfur is nonconductive, no electrochemical reaction takes place in the sulfur zone of the electrode.

The boundary conditions for the current equation on discharge are defined so that all the current is in the melt at $y = 0$, the ceramic/melt interface, and in the felt at $y = 1$, the sulfur/polysulfide interface

$$j(0,t) = 1; \quad j(1,t) = 0 \quad [17]$$

The boundary condition for v_2 can only be defined consistently for the case when the cell operates in the single phase region. This difficulty arises from the use of the Washburn number, W_s, which implies that atomic sulfur moves only with the sulfide ion. Therefore, no mechanism is available in this model for transporting the reactant, sulfur, across the sulfur/polysulfide interface. Hence, the following numerical simulation is limited to the single phase region where the over-all sulfur content is less than the saturation value. For the cases studied below the maximum value of x

in Na_2S_x is 5.25, which corresponds to a cell temperature of 350C.

The slight volume change resulting from the change in sulfur concentration was included as a slight variation in the thickness of the electrode. In this case, v_2 at the backing plate is given by

$$v_2(R_1, t) = \frac{dR_1}{dt} = \frac{I_{R_0}R_0}{2\mathbf{F}}(2V_2 + V_3 - V_1) = 19\frac{I_{R_0}R_0}{2\mathbf{F}R_1} \quad [18]$$

For the following results based on the simulation of the sulfur electrode using Eq. [1], [15], and [16] the initial concentration profile was assumed to be uniform, $x(y, 0) = 5.25$.

Numerical Results and Discussion

The orthogonal collocation method (13) with ten interior collocation points was used to obtain the solution to the coupled nonlinear partial differential equations [1], [15], and [16] with boundary conditions [17]. The results show several interesting features. In general, the initial nonuniform reaction rate distribution tends to become more uniform as the discharge proceeds and the initial uniform concentration distribution becomes less uniform. For some cases, the computed potential loss is less than that obtained using a uniform concentration model. Due to the resulting nonuniform concentration profile, there is a capacity loss which depends on the current density. Therefore, a closely monitored operation is necessary to prevent the accumulation of capacity losses from cycle to cycle.

In Fig. 1 and 2, the transient values of concentration and reaction overpotential are presented for the following cell: $R_0 = 0.3$ cm, $\Delta R = 0.2587$ cm, $I_{R_0} = 0.12345$ A/cm^2 based on the outer surface area of the ceramic tube, uniform initial concentration of $Na_2S_{5.25}$, $i_l = 50$ mA/cm^2, $a = 100$ cm^{-1}, $k_2 = 3$ ohm^{-1} cm^{-1}. In Fig. 3 and 4, the results for the same cell with $I_{R_0} = 0.823$ A/cm^2 are presented. The simulation was continued until the value of x in Na_2S_x dropped below 3.0 at some point in the cell. At this point, the precipitation of solid, nonconductive sodium disulfide was presumed to occur. Comparison of Fig. 1 with Fig. 3 demonstrates that the nonuniformity of concentration increases with current

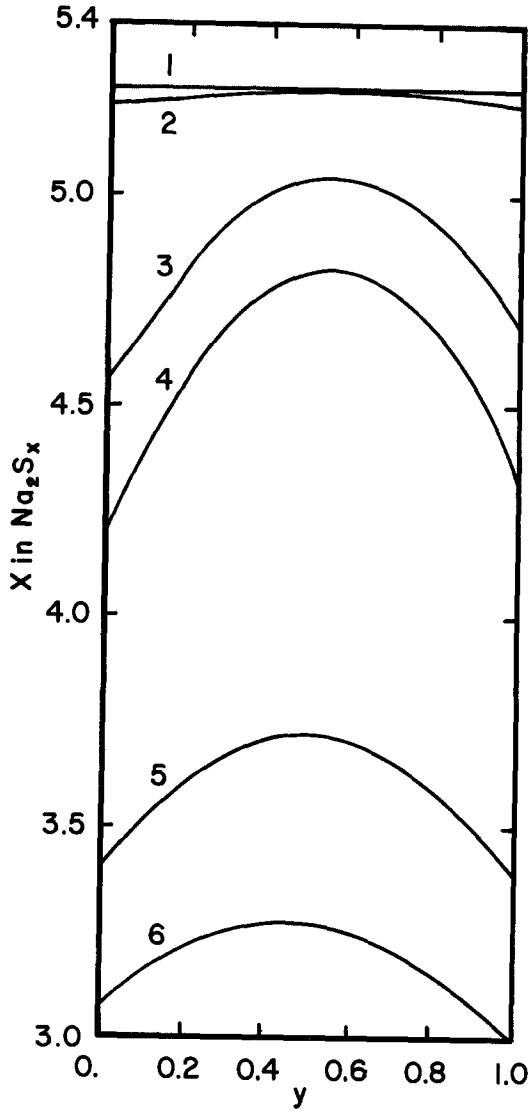

Fig. 5. Concentration profiles of polysulfide electrode after curve 1, 0 sec; curve 2, 2.25 sec; curve 3, 54 sec; curve 4, 99 sec; curve 5, 346.5 sec; curve 6, 492.8 sec; $k_2 = 0.3$ ohm^{-1}cm^{-1}; all other conditions are the same as those listed in the caption of Fig. 1.

load. Therefore, the unusable capacity (represented by the area under curve 4) increases with current load. The concentration and reaction rate profiles at earlier stages of discharge at the lower current load are different from those at the higher current load. This is an inherent feature of the diffusional kinetics used herein. This feature disappears with the use of a linear kinetics model.

The numerical results for a lower felt conductivity ($k_2 = 0.3$ ohm^{-1}cm^{-1}) and a higher current load ($I_{R_0} = 0.823$ A/cm^2) are presented in Fig. 5 and 6. All other parametric values are the same as those used above. In contrast to the higher felt conductivity case shown in Fig. 3, the sulfur rich zone is now located in the midsection of the electrode. The initial reaction rate distribution is very nonuniform but tends to become more uniform as the concentration distribution becomes nonuniform. The initial reaction rate distribution is similar to that calculated by Gibson (6) for the uniform concentration case with equal melt and felt conductivities. However, in contrast to the uniform concentration results, as this cell discharges the nonuniform concentration of sulfur causes the reaction distribution to become more uniform. The capacity loss for this cell is represented by the area under curve 6. It can also be concluded that the sulfur rich zone will form in the region where less reaction is predicted by the simpler uniform concentration model. However, the transient

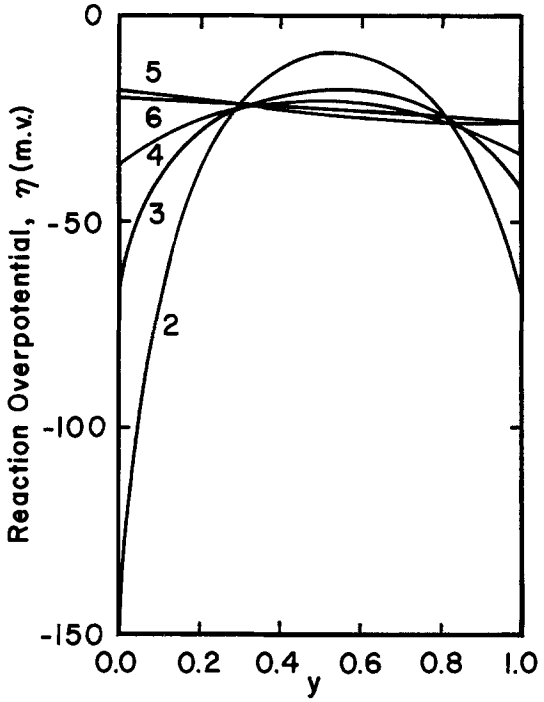

Fig. 6. Overpotential distributions for conditions listed in the caption of Fig. 5.

magnitude of the concentration distribution cannot be predicted by the simpler model.

Comparison of Fig. 7 and 8 with Fig. 1 and 2 shows the effect of electrode thickness. The initial thickness of the electrode for the case presented in Fig. 7 and 8 is 1 cm. In the other cases this thickness is 0.2587 cm. The results demonstrate that a larger variation in the concentration develops in the thicker electrodes. According to Eq. [1], a larger concentration distribution is needed to offset the increased ohmic effect resulting from the thicker electrode.

In Fig. 9 the computed cell voltage history for the following three operating conditions is presented: (*i*) $I_{R_0} = 0.12345$ A/cm^2; (*ii*) $I_{R_0} = 0.37035$ A/cm^2; and (*iii*) $I_{R_0} = 0.823$ A/cm^2. In these calculations the ceramic was assumed to have a thickness of 0.2 cm with a resistivity of 5 Ω-cm and the contact resistance between the graphite felt and backing plate was assumed to be 0.1 Ω-cm^2. It is interesting to note that there is an increase in the cell voltage at the earlier stages of discharge in the single phase region for the case of a discharge rate equal to 0.823 A/cm^2. This phenomenon has also been observed experimentally (14). The initial reduction in cell resistance results from the development of the concentration profile which reduces the effective resistance of melt. A higher OCV is also available in the nonuniform concentration case compared to the uniform concentration case because the concentration of sulfur in part of the cell is above the average value. The discharge curves in Fig. 9 are terminated at the instant when x in Na_2S_x is less than 3.0 in some region of the cell. At this point the precipitation of solid, nonconductive sodium disulfide is presumed to occur. The results demonstrate that, for a cell of the same expected capacity, the capacity loss increases with current load. The percent of theoretical capacity available for use is plotted as a function of load in Fig. 10. For a cell operating at 0.823 A/cm^2, the capacity loss is 20% based on a cell operating in the single phase region only or approximately 6% based on an initial charge of pure sulfur.

These results can be applied qualitatively to a cell with a two-dimensional concentration profile by assuming that the model applies to small regions of the electrode. In this case, the concentration effect enhances

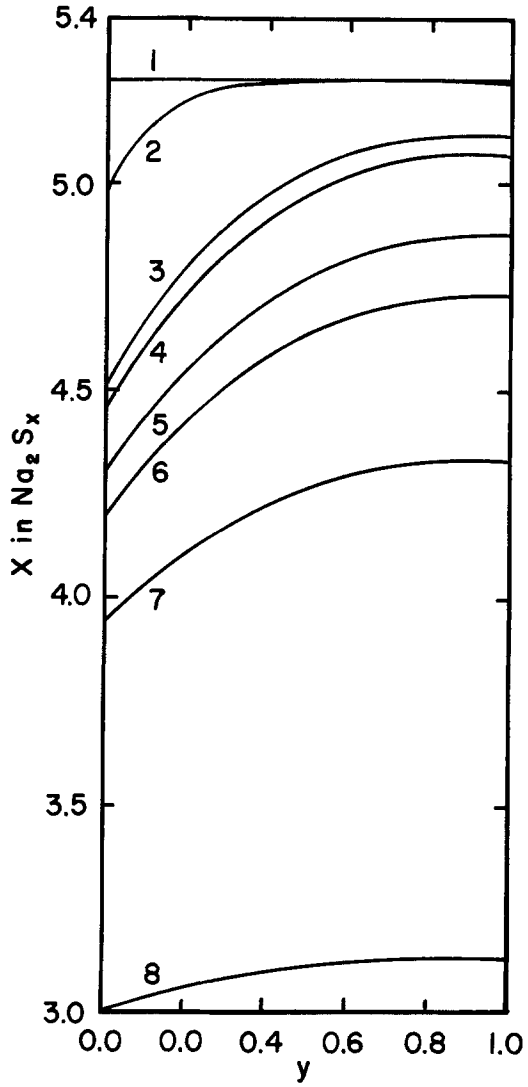

Fig. 7. Concentration profiles of a thicker polysulfide electrode, after curve 1, 0 sec; curve 2, 720 sec; curve 3, 1650 sec; curve 4, 2070 sec; curve 5, 3630 sec; curve 6, 4800 sec; curve 7, 8310 sec; curve 8, 24,660 sec; with initial thickness $\Delta R = 1.0$ cm, $I_{R_0} = 0.12345$ A/cm^2, all other conditions are the same as those listed in the caption of Fig. 1.

the local reaction distribution until nonconductive sodium disulfide precipitates. Then this region becomes inoperative, and the total cell slowly loses capacity. This effect can become accumulative unless these regions are recharged or the precipitation avoided on discharge. The design of a reliable high capacity battery depends on minimizing the capacity losses described by the above transient model.

Conclusions

The predominant effect on cell performance is due to the variation of the chemical potential of sulfur with concentration which causes the cell to operate uniformly. This advantage is partly offset by high current densities, large cell dimensions, and unmatched melt and felt conductivities. Further, a nonuniform concentration distribution results in the loss of cell capacity due to the premature precipitation of sodium disulfide, which can be cumulative. Therefore, a battery should be designed so that the nonuniform concentration effect is used to enhance the operation of the cell but is restricted to small regions so that the accompanying capacity loss is minimized.

Brief Communication

Investigation into the Immobilization of the Sodium Electrode in the Sodium-Sulfur Battery

Reinhard Knödler, Werner Baukal, and Wolfgang Kuhn

Battelle-Institut e.V., Frankfurt am Main, West Germany

The negative electrode in the sodium-sulfur battery consists of liquid sodium at a temperature of 300°-400°C. Investigations were carried out in order to find out whether liquid sodium can be immobilized without influencing the electrical performance of the electrode. In the case of the lithium-sulfur battery this has been successful (1).

Experimental

The electrochemical behavior of an immobilized sodium electrode was investigated in cells of the type

Na (immobilized)/β-Al_2O_3/Na (freely mobile)

Immobilization has been achieved using stainless steel felts (Brunswick Corporation, Skokie, Illinois, and Württembergische Metallwarenfabrik, Geislingen, West Germany). The felts investigated had porosities between 80 and 90% and pore sizes between about 40 and 120 μm. β-Al_2O_3 was used in the form of closed-end tubes[1,2] (9 mm ID, 50 mm length) or of disks[3] onto which an α-Al_2O_3 cylinder was sealed with a special glass, thus giving "cups" (18 mm ID). In either configuration the outside contained freely mobile sodium and the inside the sodium immobilized by the felt.

The experiments were carried out in an argon atmosphere at 350°C. Double-distilled sodium was filled into the outer compartment and was transferred to the inner one by electrolysis through the β-Al_2O_3. In the tube configuration the sodium in both compartments was at the same level. For operation of the cell, a current was applied and its bias was reversed after equal time intervals so that the sodium level at both sides remained almost unchanged. The current densities applied ranged from 10 up to 400 mA/cm^2. From the voltage measured and the dimension of the cup/tube, it was possible to calculate a specific resistance. Its value does, in general, not represent the resistivity of the ceramic, but is rather a convenient standardized figure. For example, if part of the ceramic surface is not covered with sodium because of wetting problems, the standardized cell resistance increases, though the ceramic itself remains unchanged.

Results

The β-Al_2O_3 cups showed essentially the same behavior as the tubes. It was possible to extract sodium electrically and again fill it into the felt. Figure 1 shows a plot of the standardized resistance for a typical experiment using a β-Al_2O_3 tube. The resistance during charge (*i.e.*, filling the felt from outside) remained almost unchanged, whereas during discharge (removing the sodium from the felt) the resistance started to rise toward the end of the process.

This resistance increase can be employed to set a limit to the amount of sodium which can usefully be discharged from the felt. Choosing arbitrarily an increase by a factor of 2 as the limit, 70-80% of the sod-

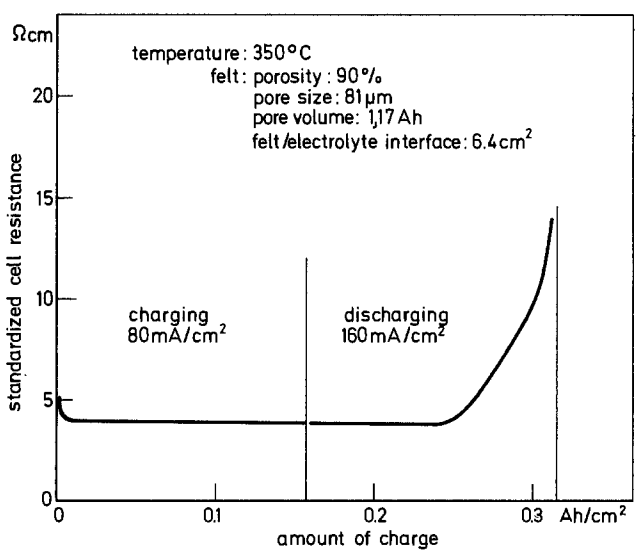

Fig. 1. Cycling behavior of a cell of the type Na (immobilized)/β-Al_2O_3/Na (freely mobile). The amount of sodium in the felt at the beginning of the cycle corresponded to 0.16 A-hr equivalent to 14% of the pore volume.

[1] Tubes: 9.3 weight percent (w/o) Na_2O, 3.0 w/o MgO, balance Al_2O_3.

[3] Disks: 8.7 w/o Na_2O, 0.7 w/o Li_2O, balance Al_2O_3.

Key words: sodium-sulfur battery, sodium immobilization, battery design, safety.

ium content in the felt may be utilized under optimized conditions. This optimization concerns the felt and the contact between felt and ceramic and will be discussed later. A total amount of at least 95% of the sodium can be discharged if higher resistances are taken into account.

In the region where the resistance increased, the cell showed nonohmic behavior, *i.e.*, the resistance depended on the current density. In addition, the resistance rise started at a higher discharge depth if a lower current density was applied. In the region of constant resistance, however, the current-voltage relationship was linear within several orders of magnitude of current density. In this ohmic region, the standardized resistance of the cell had the same value as the resistivity of the ceramic which had been determined by independent a-c measurements using graphite electrodes (2).

Contrary to the behavior described above, the removal of nonimmobilized sodium from the inner part of the tube resulted in a linear increase in resistance.

From a series of measurements using various felts the optimum pore size turned out to be about 80 μm at an optimum porosity of about 90%.

Further experiments with β-Al_2O_3 tubes showed that it is important to achieve a close contact between the electrolyte and the felt in order to utilize the highest possible amount of the immobilized sodium in discharging the cell. A good fit and, consequently, a good contact at the interface have been achieved by forming the felt by spark erosion. In some cases this good fit could also be obtained by using a smaller inner metal felt core without exact fit and a layer of steel wool wrapped around this core.

Immobilization of the sodium in the felt has been confirmed by an experiment in the cup configuration, in which the felt was kept at a distance of about 3 mm from the electrolyte surface. After the cup had been filled in the usual way, only the freely mobile sodium below the felt could be discharged. The sodium in the felt remained there even against the effect of gravity. Thus, the contact between the felt and the β-Al_2O_3 ceramic is essential for draining the sodium off the felt by a cathodic current.

Some experiments were discontinued in the course of a charge or a discharge half-cycle when, according to the charge balance over all previous cycles, the moiety of the pore volume of the felt was filled. After cross-sectioning and polishing under moisture-free conditions, microscopic inspection revealed that the sodium was distributed uniformly over the whole volume of the felt.

This has led to a new design concept for the battery: the sulfur electrode is kept inside the beta-alumina tubes, thus minimizing corrosion problems, and the sodium electrode, immobilized in metal felt, can be placed outside. Since the resistance of the metal felt is much lower than that of graphite felt, a multicell arrangement in parallel connection with a common sodium electrode can be conceived.

Experiments over several charge/discharge cycles showed that there was no change in the behavior of the metal felt with respect to its immobilizing properties and that the presence of the felt had no influence on the degradation of the ceramic.

Discussion

The outstanding feature of the interface between the sodium-filled metal felt and the β-Al_2O_3 ceramic is the resistance rise and the simultaneous transition from ohmic to nonohmic behavior when the felt is being depleted of sodium. The onset and magnitude of this phenomenon depends on the pore size of the felt, on the electric current applied, and on the quality of the contact between felt and ceramic.

In the ohmic part, the agreement between the standardized resistance of the cell and the resistivity of the ceramic shows that the whole interface felt/ceramic is covered with a continuous sodium film. A sodium film should also be present at the individual fibers of the felt. Delivery of sodium from the volume of the felt to the interface is then accomplished over those fibers which touch the ceramic surface.

On prolonged depletion of the felt, the nonohmic region is entered: the counteraction between the retaining capillary force exerted by the felt pores and the drain exerted by the cathodically polarized ceramic is shifted toward the retention side. Only part of the felt fibers touching the ceramic surface are still covered with a sodium film and are able to deliver sodium to the electrolyte. The sodium reaching the interface is drained off immediately and cannot spread over the whole ceramic surface. Thus, the standardized cell resistance increases.

Conclusion

The results of the investigation show that a sodium-sulfur battery with no freely mobile sodium is feasible. In particular, immobilization of the sodium can be achieved without major influence on the performance of the sodium electrode and, hence, the battery.

On the Mechanism of GaAs Anodization

D. J. Coleman, Jr., D. W. Shaw, and R. D. Dobrott

ABSTRACT

The oxygen distribution in anodic oxides on GaAs grown from electrolytes prepared with H_2O^{16} and H_2O^{18} has been analyzed with an ion microprobe mass analyzer. The data show that as the oxide grows, additional oxygen is incorporated into the film at the oxide-electrolyte interface. The implications to the mechanism of oxide growth are discussed.

Anodic oxide films grown on GaAs have been reported by many authors (1-4) using various electrolytes. Because of the potential technological significance of these oxides, the details of their growth mechanism is of primary importance. Basic to this understanding is the identification of the nature of the mobile species within the growing oxide film during anodization. Consider, for example, interstitial ion transport. If oxygen were the only mobile species, then the oxide would grow by formation of new layers at the oxide/semiconductor interface. On the other hand, if the ions from the semiconductor were the mobile species, then the oxide would thicken by addition of layers at the oxide/electrolyte interface. Presumably if both ions were mobile new oxide would be produced at both interfaces or even within the bulk of the existing oxide.

Pursuant to such arguments, several techniques have been utilized to identify the mobile species in metal and semiconductor anodization. A simple technique places an inert marker layer in the oxide and the subsequent location of its position (5) or its effect on the substrate (6) infers the mobile ionic species. α- and β-spectroscopy have been useful by implanting radioisotopes (7, 8) into the surface to be oxidized and tracking their depth at various stages of oxidation by observation of the emitted lineshape characteristic of the implanted isotope. Amsel and Samuel (9) grew sequential oxides from aqueous electrolytes prepared with H_2O^{18} and H_2O^{16} on aluminum and then determined the location of the O^{18} isotope by means of the O^{18} (p, α) N^{15} reaction.

In spite of its increasing significance to GaAs technology, the GaAs anodization process has not been investigated with respect to the nature of the mobile species. Accordingly, we have examined ionic mobility in GaAs anodization from an aqueous electrolyte. The GaAs anodic oxides were prepared in a manner similar to that of Ansel and Samuel in that sequential anodic oxides were grown from H_2O^{18} and H_2O^{16} electrolytes. However, for analysis of the isotopic distribution of the oxygen atoms in resulting oxides, an ARL ion microprobe mass analyzer (IMMA) was employed. This instrument sputters small areas of the oxides with a relatively high energy ion beam and mass analyzes the sputtered ions by double focusing techniques. IMMA is ideally suited for this type of study in that depth distributions are easily obtained by collecting the signal in a number of equal time increments each of which corresponds to a thin depth section of the sputtered oxide.

Key words: anodic films, anodic oxides, ion transport.

The anodizations were performed in small (about 1 cm^3) Pyrex containers that could be stoppered when not in use to prevent loss by evaporation. A 0.02M $NH_4H_2PO_4$ electrolyte was used with a Pt cathode. Two electrolyte baths were prepared, one from deionized water with natural abundance (99.8%) of O^{16} and the other from O^{18} enriched water received from Mound Laboratory certified as 96.6% O^{18}. Initial oxidations performed in the enriched water electrolyte exhibited runaway current-time behavior and surface pitting typical of electrolyte contamination (10). After a single distillation in a Pyrex apparatus, the enriched water electrolyte exhibited the usual current-time behavior.

The anodizations were carried out on {001} surfaces of n-type (2×10^{17} cm^{-3}) GaAs wafers. The wafers were 200 μm thick and chemical-mechanically polished on both sides. Residual damage after polishing was removed by a 10 min etch in an H_2SO_4:H_2O_2:H_2O, 8:1:1 etchant. Just prior to oxide growth each specimen was cleaned with an initial anodization with subsequent stripping of the resulting oxide in dilute HCl. Sample dimensions of approximately 5×15 mm were utilized with cleaved edges. Each sample was held in Au plated tweezers for anode contact and immersed approximately 10 mm into the electrolyte. A constant 30V anodic potential was applied to grow the first oxide. The initial current was about 30 mA for all samples in both electrolyte baths and fell rapidly decreasing to about 0.5 mA after 1 min. After growth of the first oxide layer each sample was removed from the electrolyte, rinsed, and blown dry. The initial oxides were uniformly gold colored and approximately 300Å thick. A second anodization was performed by immersing the lower 5 mm of each sample in the opposite electrolyte bath from that used to form the first oxide and applying a constant 60V potential. For this second oxidation, the initial currents were typically 15 mA and fell rapidly again to near 0.5 mA after 1 min. The oxide on the lower half of each sample was, thereby, increased in thickness to nearly 800Å and appeared royal blue in color.

A total of four samples including two controls were prepared according to Table I to form a complete complement of combinations of the natural and enriched water electrolyte baths for the two oxidations.

Table I. Electrolyte combinations used for sample preparation

Sample designation	Initial 30V oxidation	Sequential 60V oxidation
HL	H_2O^{18}	H_2O^{16}
LH	H_2O^{16}	H_2O^{18}
HH	H_2O^{18}	H_2O^{18}
LL	H_2O^{16}	H_2O^{16}

After oxidation each sample was depth profiled in the IMMA using a 10 kV N_2^+ primary sputter beam which was focused to a diameter of approximately 25 μm. The beam was rastered to cut a crater of 400 × 320 μm which gave an effective sputter rate of about 0.4 Å/sec. Both mass 16 and 18 positive ion data were obtained from the same sputter crater by electrostatic isotope switching the mass analyzed beam and synchronous gating of two identical 200 MHz scalers every 100 msec with a 10 msec scintillator decay period between each isotope period. To avoid the effects of the crater wall at the extrema of the raster, the scalers were gated on only when the primary beam was sputtering the central 1/9 of the crater bottom. The primary beam was rastered at 30 frames/sec and 50 lines/frame to assure that the crater wall rejection gating and the isotope gating were asynchronous. The depth collection time increment was 22 sec which corresponds to an apparent depth resolution of approximately 8Å ignoring ion plasma intermixing of the atoms in the solid.

Figures 1 through 4 show the distribution of O^{18} and O^{16} obtained from the IMMA analysis of the four samples. The data clearly show that the oxygen isotope

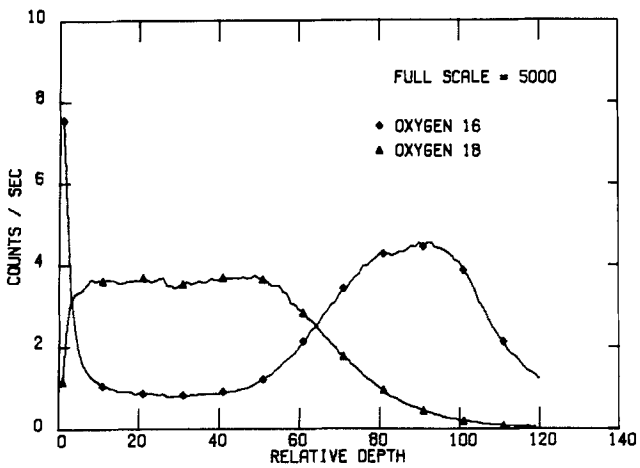

Fig. 1. Isotopic oxygen distribution for sample LH oxidized first in H_2O^{16} and then in H_2O^{18}.

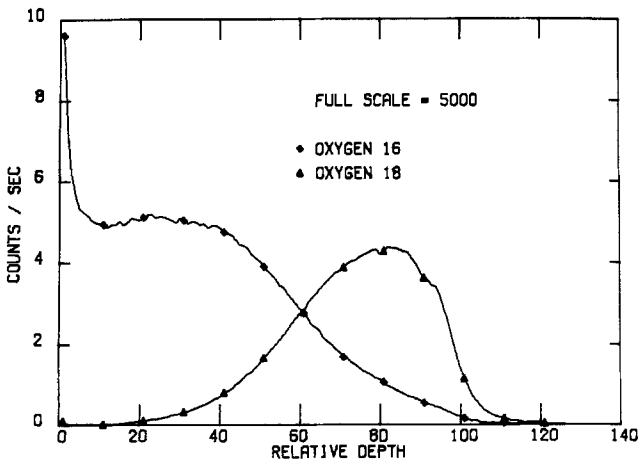

Fig. 2. Isotopic oxygen distribution for sample HL oxidized first in H_2O^{18} and then in H_2O^{16}.

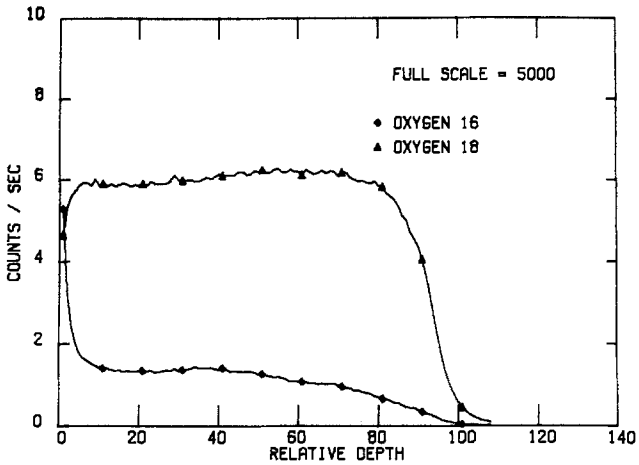

Fig. 3. Isotopic oxygen distribution in control sample HH oxidized in H_2O^{18}.

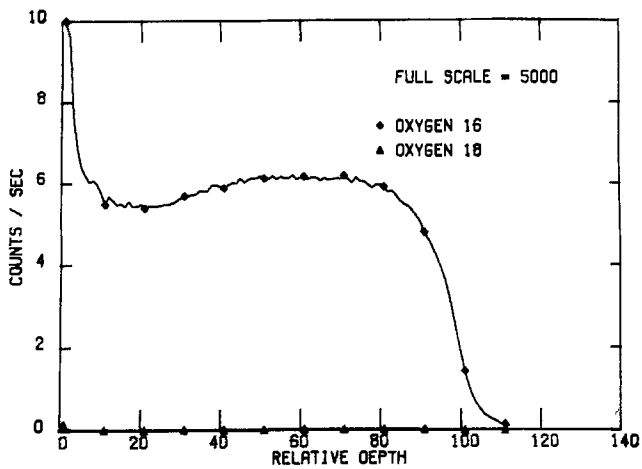

Fig. 4. Isotopic oxygen distribution in control sample LL oxidized in H_2O^{16}.

near the surface of each anodized specimen is incorporated from the last electrolyte from which the oxide was grown. The oxygen signal from the first 10 relative depth units should be ignored in the depth profiles since the oxygen ionization probability does not reach equilibrium until the sputtered depth reaches the initial implant depth of the primary ions (~100Å). The O^{16} content of the oxides grown in the enriched water electrolytes was higher than expected. However, this does not affect the interpretation, since control samples, HH and LL, were used to establish the reference isotopic abundances. The intersection of the O^{16}-O^{18} profiles are at about the half-maximum of each profile and appear symmetrical around this point. This suggests the actual interface is rather sharp and the width is entirely due to the analysis technique. This broadening is inherent in the sputtering process where the high energy sputter ions can penetrate the solid to a significant depth (100-200Å) and, by a collision process, these ions redistribute atoms in both backward and forward directions.

In summary, we have demonstrated that in GaAs anodization, oxygen is incorporated into the growing oxide at the oxide-electrolyte interface as opposed to the oxide-semiconductor interface. This fact and the simple hypothesis that mass transport occurs through the interstices of the growing oxide leads one to conclude that Ga and As are mobile in the oxide. An alternate hypothesis is substitutional migration. As shown by Amsel and Samuel substitutional propagation of either oxygen or metal ions can result in an oxygen distribution similar to that observed. However, the results of the experiments reported here eliminate interstitial

oxygen migration as the predominate transport process during GaAs anodization.

Photoluminescence Due to Al, Ga, and B Acceptors in 4H-, 6H-, and 3C-SiC Grown from a Si Melt

A. Suzuki,* H. Matsunami, and T. Tanaka

Department of Electronics, Kyoto University, Kyoto 606, Japan

ABSTRACT

Single crystals of 4H-, 6H-, and 3C-SiC have been grown from a silicon melt in a graphite crucible. Visible photoluminescences due to Al, Ga, and B acceptors in these crystals are studied in the temperature range from 2° to 450°K. The luminescence color varies from violet to near-infrared depending on the energy level of the acceptor and the energy gap of the polytype. All the luminescences at low temperatures are thought to be due to pair recombination between the N donor introduced unintentionally and the Al, Ga, or B acceptor. Each spectrum consists of a zero-phonon peak and its phonon replicas. At higher temperatures, another emission appears owing to the recombination of free electrons with bound holes at the acceptors. From the luminescence spectra and the thermal quenching of the emission intensity, the ionization energy of Ga is found to be a little larger than that of Al, while B has much larger ionization energy. The values obtained for 4H-SiC are 168 meV + E_x, 249 meV + E_x, and 628 meV + E_x for Al, Ga, and B, respectively, where E_x is the exciton binding energy of the order of 10 meV. Owing to the deep level of the B acceptor, the luminescence has a different spectrum from those due to Al and Ga, and is intense even at room temperature.

Silicon carbide (SiC) has a large number of different crystal structures referred to as "polytypes." Since each polytype has a different energy gap (2.3-3.3 eV), SiC will be a useful semiconductor for various visible light emitting devices by a combination of polytypes and luminescent centers. A number of SiC light emitting diodes have been fabricated up to date, but their luminescent efficiencies have been low (1). One of the main causes is a high temperature process (above 2000°C) usually used for the crystal growth and the impurity doping, which makes it difficult to obtain good crystals and control impurity doping.

Brander *et al.* (2) and the authors (3) have fabricated 6H-SiC blue light emitting diodes by liquid phase epitaxial growth from a silicon (Si) melt. The blue luminescence has shown relatively high quantum efficiency. Since this method has the advantage of low growth temperature (about 1600°C), it will be suitable for the fabrication of light emitting devices. But there have been very few reports on visible-luminescence centers in SiC crystals grown from a Si melt. In this paper, visible photoluminescences due to Al, Ga, and B acceptors in 4H-, 6H-, and 3C-SiC crystals grown from a Si melt are investigated. The ionization energies of the three acceptors are presented and the recombination processes are discussed.

Crystal Growth

The method of solution growth from a Si melt in a graphite crucible has been used for the preparation of 3C-SiC crystals by several researchers (4, 5). But the authors have found that single crystals of 4H- and 6H-SiC in addition to 3C-SiC were obtained without any seed crystal when the following two conditions were satisfied: (*i*) the temperature of the Si melt is higher (about 1800°C) than usually used for the growth of 3C-SiC; (*ii*) the temperature gradient of the melt is kept as small as possible (less than 5°C/cm). The arrangement for the crystal growth is shown in Fig. 1. In order to realize condition *ii*, the temperature of the bottom of the crucible was set slightly higher than that of the upper part, because the bottom was apt to be cooled by thermal conduction through the graphite support.

The crucible was made of dense and high purity graphite (apparent density 1.60 g/cm^3, ash content 0.02%). Its size was 40 mm in depth and 25 mm in

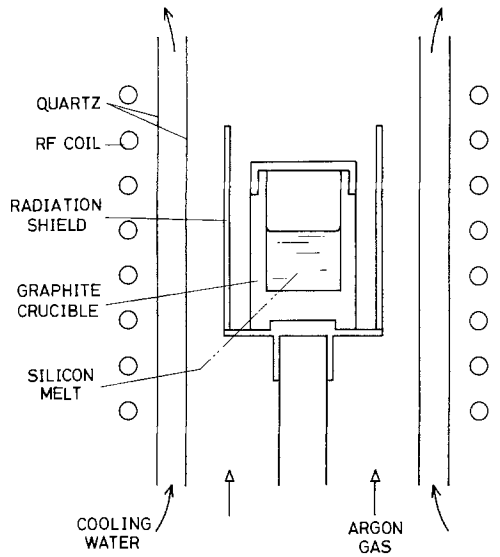

Fig. 1. Arrangement for solution growth of SiC single crystals

inner diameter. A graphite lid was used to avoid evaporation of silicon. The crucible was baked at about 1850°C for 2-3 hr under the flow of pure argon gas before the growth. After the crucible was filled with a 26g charge of pure polycrystalline silicon, it was kept at a growth temperature of 1800°C for 8 hr. The gas ambient during the growth was pure argon flowing at about 200 cm^3/min. After the growth, the silicon was removed with a 1:1 mixture of HF and HNO_3.

A large number of SiC single crystals grew on the inner wall of the crucible. The typical crystal size was 0.8 × 0.8 × 0.2 mm^3. The inner wall near the bottom was dissolved away slightly. The polytypes of the crystals in the crucible were identified as 4H, 6H, and 3C by x-ray oscillation photographs about their <0001> axes. Some examples of the photograph are shown in Fig. 2. The quality of 6H-SiC crystals seemed to be poorer than those of 4H- and 3C-SiC, because every spot in the photograph of 6H-SiC was somewhat diffused.

Nine kinds of samples were prepared for the photoluminescence measurements, that is, 4H-, 6H-, and 3C-SiC doped with Al, Ga, and B. Al-doped and Ga-doped crystals were grown from the Si melt with 0.01-0.1 atomic percent (a/o) Al metal and 1 a/o Ga metal in excess, respectively. B-doped crystals were obtained using B-doped (2×10^{-3} a/o) silicon as a source material. The impurities of Al, Ga, and B act as acceptors in SiC, but all the crystals were n-type containing unknown donors of the order of 10^{19} cm^{-3}. The donors were probably nitrogen introduced unintentionally from the residual air in the crucible material and in the ambient, because nitrogen is very apt to be introduced into SiC and acts as a donor (3).

Photoluminescence

Using a 250W high pressure mercury lamp as an excitation source, photoluminescence was measured at various temperatures between 2° and 450°K. The suitably filtered u.v. light of 365 nm from the lamp was focused on the sample. Luminescence from the sample was detected by a grating spectrometer and a photomultiplier.

At low temperatures, all the samples emitted intense photoluminescences of various visible colors from violet for 4H-SiC:Al to red for 3C-SiC:Ga. Only 3C-SiC:B emitted near-infrared luminescence. The color of each luminescence and the wavelength of its maximum emission peak at 77°K are shown in Table I. The luminescences of the Al-doped and the

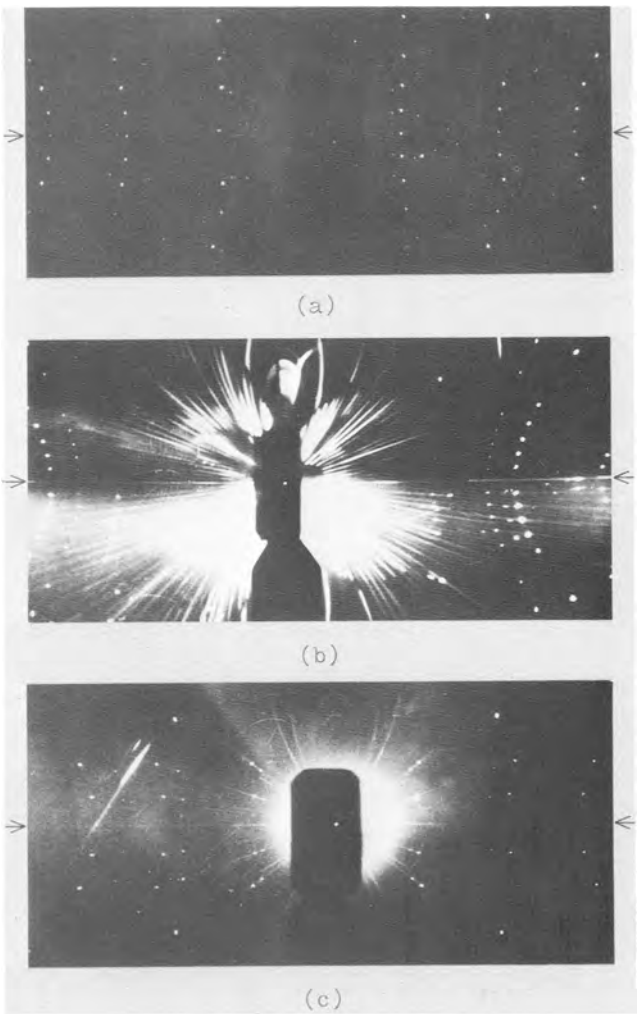

Fig. 2. X-ray oscillation photographs about the <0001> axes of SiC crystals, (a) 4H, (b) 6H, and (c) 3C polytypes. (The arrows indicate the center lines.)

Ga-doped samples were quenched below room temperature. But the B-doped samples showed intense luminescence even at room temperature, and the colors were much the same as at low temperatures.

Figure 3 shows luminescence spectra due to the different luminescent centers in 4H-SiC at 77°K. Spectra due to the same kind of centers in the different polytypes are shown in Fig. 4, 5, and 6. These spectra had the following five features. (*i*) The spectra due to Ga and B were on the lower energy side than the spectrum due to Al by 50-100 meV and 500-700 meV, respectively, for the three polytypes. (*ii*) The spectra of 6H-SiC and 3C-SiC due to the same kind of centers were on the lower energy side than 4H-SiC by 250-300 meV and 850-950 meV, respectively. (*iii*) All the spectra due to Al and Ga were similar in shape. Each spectrum had several peaks, among which the highest energy one (B_0) was rela-

tively sharp. (*iv*) The spectra due to B were "bell-shaped" ones with a very broad spectral width. (*v*) Each peak in the spectra of 6H-SiC was a little broader than that of 4H- and 3C-SiC.

Luminescence spectra at 2°K were much the same as at 77°K, but each peak was a little sharper. The energy of the highest energy peak or hump (B_0) of each spectrum, and the energy differences between B_0 and the other peaks on the lower energy side (B_1-B_6) are given in Table II from the data at 2°K. [For 3C-SiC:B, the data reported by Yamada *et al.* (6) were adopted. Their crystals were prepared by a similar method to ours.] The spectrum of 6H-SiC:B showed two humps on the higher energy side at 2°K like the spectrum of 4H-SiC:B at 77°K shown in Fig. 6.

Above 77°K, another peak (A_0) appeared on the higher energy side of the B_0 peak and became dominant with increasing temperature as shown in Fig. 7 for 3C-SiC:Al as an example. The energies of the A_0 peaks obtained for several samples are given in Table III.

The temperature dependence of the luminescence intensity of 4H-SiC is shown in Fig. 8 as a function of reciprocal temperature. The luminescences due to Al, Ga, and B decreased exponentially above 150°, 175°, and 350°K, with activation energies of 160 ± 20, 240 ± 20, and 520 ± 20 meV, respectively. The luminescences of 6H- and 3C-SiC also showed similar temperature dependences. The emission intensity due to B considerably increased with increasing tempera-

ture before the thermal quenching occurred, which will be discussed elsewhere (7).

Discussion

Comparisons of the spectra.—The authors have investigated the luminescences of the Al-doped and the Ga-doped 4H-SiC in detail (8). The luminescences were found to be due to donor-acceptor pair recombination at low temperatures and due to free-to-acceptor recombination at higher temperatures. The five features of the spectra described in the preceding section offer some properties of the three acceptors in the three polytypes. Considering feature *iii*, all the luminescences due to Al and Ga may be pair emissions between the N donor and the Al or Ga acceptor. Each relatively sharp peak (B_0) at the highest energy is a zero-phonon peak and the others (B_1-B_6) are its phonon replicas. Since the spectra due to B of the three polytypes resembled that of 3C-SiC:N,B reported by Yamada and Kuwabara (6,9), they also may be due to pair recombination between the N donor and the B acceptor. The first hump (B_0) at the highest energy can be regarded as a zero-phonon peak. All the A_0 peaks which were observed on the higher energy side of the B_0 peaks at higher temperatures are thought to be due to the recombination of free electrons with bound holes.

Table III. Photon energy of the A_0 peak

Sample	Photon energy (eV)	Temperature (°K)
4H-SiC:Al	3.101	129
4H-SiC:Ga	3.025	148
4H-SiC:B	2.644	126
6H-SiC:Al	2.801	132
3C-SiC:Al	2.150	120

The energy differences among the spectra of the three polytypes (feature *ii*, Fig. 4, 5, and 6) are ac-

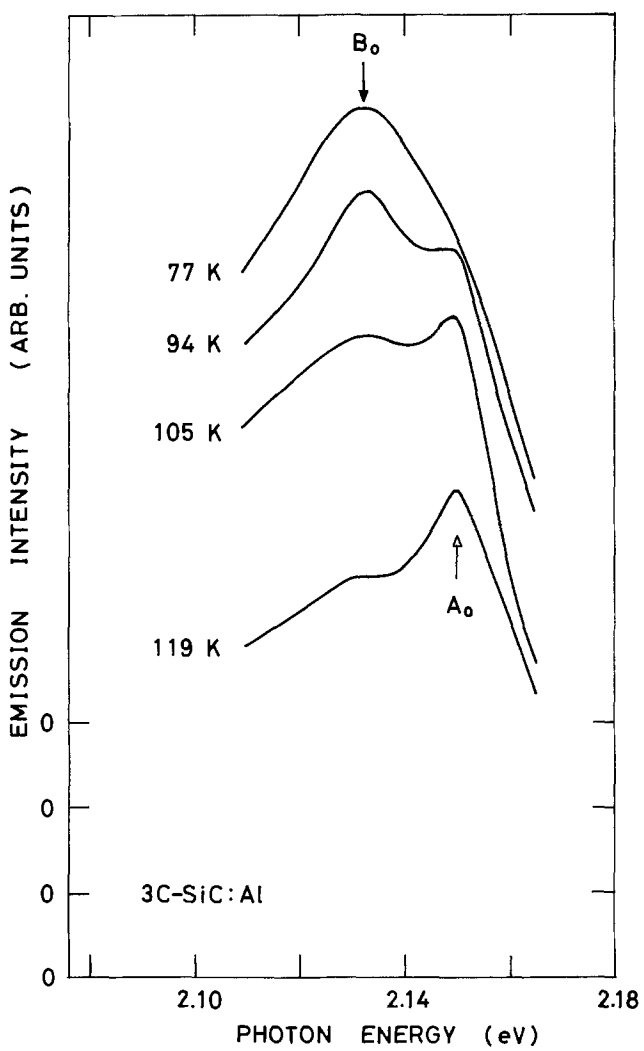

Fig. 7. Spectral change of the A_0 and the B_0 peaks of the Al-doped 3C-SiC crystal with increasing temperature.

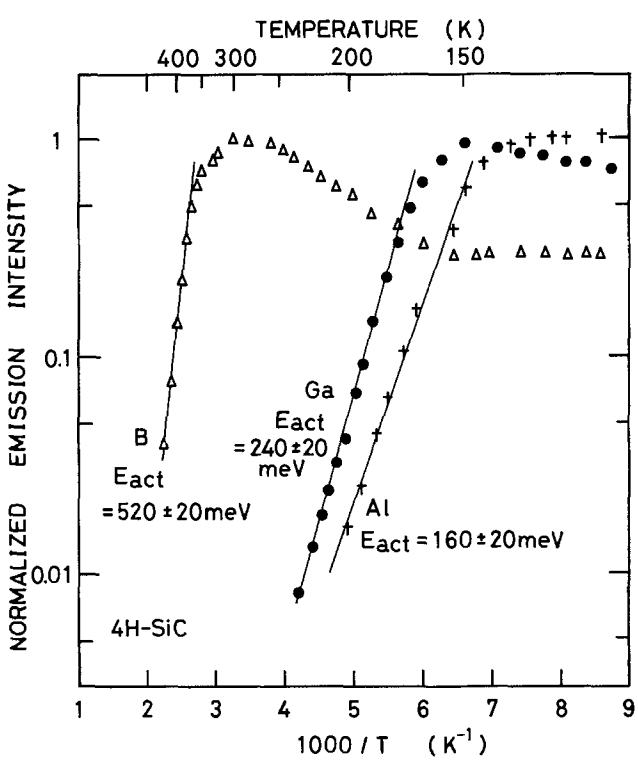

Fig. 8. Temperature dependence of the emission intensities of the Al-doped, Ga-doped, and B-doped 4H-SiC crystals.

counted for by the difference of the energy gap, because the energy gaps at 2°K are 2.390 eV + E_x, 3.023 eV + E_x, and 3.265 eV + E_x for 3C-, 6H- and 4H-SiC, respectively (10), where E_x is the exciton binding energy of the order of 10 meV (11).

The energy differences among the spectra due to the three acceptors (feature *i*, Fig. 3) may be attributed to the different energy levels of the acceptors. Therefore, the ionization energy of the Ga acceptor is a little larger than that of the Al acceptor, while that of the B acceptor is much larger.

Each peak of 6H-SiC was somewhat broader than that of 4H- and 3C-SiC (feature *v*). This might be related to the relatively poor quality of 6H-SiC crystals as shown in Fig. 2.

Spectra due to the B acceptors.—The bell-shaped spectra with a very broad spectral width of the B-doped samples (feature *iv*, Fig. 6) are presumably caused by the deep energy level of the B acceptor. Generally, the luminescence spectrum due to a deep center is composed of a weak zero-phonon peak and intense phonon replicas with simultaneous emissions of multiple phonons owing to the strong lattice-impurity interaction (12, 13). It is due to this strong interaction that the B_6 peaks were the maximum peaks for the B-doped samples, while the B_2 or B_3 peaks for the Al-doped and the Ga-doped samples as in Table II.

SiC has two kinds of lattice sites, namely, Si sites and C sites. Previous luminescence studies have shown that N and B substitute the same kind of sites, while Al the other one (6, 14). According to the relative atomic sizes, N and B probably occupy the C sites, while Al and Ga the Si sites. This may be related to the result that the B acceptor has much larger ionization energy than the Al and the Ga acceptors.

Phonon replicas.—Much the same dispersion curves have been reported for the same mode of phonons of every polytype (15, 16). In Table II, the same B_i peak of every sample is separated from each zero-phonon peak B_0 by an almost constant value independent of polytypes and acceptors. This may indicate that the same mode of phonon contributes to the same B_i peak of every sample. From the values in Table II and the phonon energies, the B_1 and the B_2 peaks are found to be LA and LO phonon replicas, respectively. The other replicas may be due to combinations of these two modes as given in Table II. The phonon energies of the B_1 replicas are a little smaller than the value of LA phonon at the zone boundary (75-80 meV), while those of the B_2 replicas are near the value of LO phonon at the zone center (119-121 meV) rather than at the zone boundary (102-105 meV) (15, 16).

Ionization energies.—From the photon energy $h\nu_A$ of the zero-phonon peak A_0 due to the recombination of free electrons with bound holes, the ionization energy E_a of the acceptor can be obtained by the following relation (17)

$$E_a = E_{gx} + E_x + kT - h\nu_A \qquad [1]$$

where E_{gx}, E_x, and kT are the exciton energy gap, the exciton binding energy, and the thermal energy of the free electron, respectively. The sum of E_{gx} and E_x is the energy gap.

The photon energy $h\nu_B$ of the zero-phonon peak B_0 of pair emission is expressed by

$$h\nu_B = E_{gx} + E_x - (E_d + E_a) + E_c \qquad [2]$$

where E_d is the ionization energy of the donor and E_c is the coulomb energy term (18). From Eq. [1] and [2], one gets

$$E_d = h\nu_A - h\nu_B - kT + E_c \qquad [3]$$

Using the values of $h\nu_B$ and $h\nu_A$ in Tables II and III, and E_{gx} given in Ref. (10), one obtains E_a and E_d by Eq. [1] and [3]. The results thus obtained are shown in Table IV. [The values of E_a and E_d for 4H-SiC:Al and 4H-SiC:Ga were obtained by more detailed investigations by the authors (8).]

Table IV. Ionization energies of Al, Ga, and B acceptors and N donor (unit = meV)

	4H Al	4H Ga	4H B	4H Al	6H Al	3C Al
E_a	168 + E_x	249 + E_x	628 + E_x	168 + E_x	231 + E_x	248 + E_x
E_d	59	51	23 + E_c	59	16 + E_c	7 + E_c

E_a, E_d = the ionization energies of the acceptor and the donor, respectively.
E_x = the exciton binding energy.
E_c = the coulomb energy term.

Since the value of E_x is 13.5 meV for 3C-SiC (11), the ionization energy of Al in 3C-SiC is obtained as 262 meV, which is in good agreement with 260 ± 15 meV by Long *et al.* (19). (Their crystals were prepared by vapor phase growth.) The value of 168 meV + E_x for Al in 4H-SiC may be compared with 150 meV + E_x by Hagen *et al.* (20) and 180 meV + E_x by Gorban' *et al.* (21). (Their crystals were also prepared by vapor phase growth.) When E_x is assumed to be of the same order in the three polytypes, the ionization energy of Al in 4H-SiC is 60-80 meV smaller than those in 6H- and 3C-SiC. The value of E_x possibly differs among the three polytypes. But since E_x does not probably exceed E_d [55 ± 7 meV (8)], the difference of 60-80 meV cannot be accounted for only by the difference in E_x. The Ga and the B acceptors in 4H-SiC also seemed to show somewhat smaller ionization energies than those in 6H- and 3C-SiC.

The ionization energy of the Ga acceptor in SiC was obtained by the authors for the first time. The ionization energy of the B acceptor has been found to be 390 meV for 6H-SiC by Hall-effect measurements (22). Kuwabara *et al.* have recently reported much larger ionization energy of 735 meV for B in 3C-SiC by luminescence studies (9). The present investigation has also given a large ionization energy of 628 meV + E_x for B in 4H-SiC.

The coulomb energy term E_c obtained for 4H-SiC:Al and 4H-SiC:Ga was 29 and 25 meV, respectively (8). If these values are used as E_c in Table IV, 48-52 meV is obtained as E_d for 4H-SiC:B. This value is in agreement with 59 and 51 meV for 4H-SiC:Al and 4H-SiC:Ga, respectively, obtained by another method in Ref. (8). Therefore, one kind of donor, namely nitrogen, participates in the pair recombination of the three kinds of 4H-SiC samples with the different acceptors. Similarly, 41-45 meV for 6H-SiC:Al and 32-36 meV for 3C-SiC:Al are obtained as E_d. These are a little smaller than the value for 4H-SiC. Since 6H- and 3C-SiC have larger absorption coefficients for the exciting light owing to their smaller energy gaps, the excitation is probably done in a smaller volume near the sample surface. This may produce the same effect that is brought about by the increase of excitation intensity. Then, the pair separation making the most contribution to the B_0 peak becomes small and the coulomb energy term E_c becomes large (18). Therefore, E_d for 6H- and 3C-SiC will be able to approach the value for 4H-SiC.

Thermal quenching.—The thermal quenching shown in Fig. 8 was probably brought about by thermal release of bound holes at the acceptors into the valence band, because the luminescences due to the three acceptors began to be quenched at different temperatures with different activation energies. The probability of thermal ionization of bound holes may be expressed as $s \cdot \exp(-E_a/kT)$, where s is a constant and E_a is the ionization energy of the acceptor. Then,

the quenching activation energy can be regarded as E_a, and the quenching begins at higher temperature for larger E_a (23). The activation energies of 160 ± 20, 240 ± 20, and 520 ± 20 meV obtained for the luminescences due to Al, Ga, and B in 4H-SiC (Fig. 8) almost agree with the ionization energies of the respective acceptors determined above (Table IV).

Summary

In 4H-, 6H-, and 3C-SiC grown from a Si melt, Al, Ga, and B acceptors were found to act as visible-luminescence centers at low temperatures. The luminescence color varied from violet to near-infrared depending on the energy level of the acceptor and the energy gap of the polytype. The luminescences at low temperatures were due to pair recombination between the N donor introduced unintentionally and the Al, Ga, or B acceptor. Each spectrum consisted of a zero-phonon peak and its phonon replicas. The contributing phonons were LA, LO phonons and their combinations. At higher temperatures, another emission appeared owing to the recombination of free electrons with bound holes.

From the luminescence spectra and the temperature dependence of the emission intensity, the ionization energy of Ga was found to be a little larger than that of Al in the three polytypes, while B had much larger ionization energy. The ionization energies of Al, Ga, and B in 4H-SiC were 168 meV + E_x, 249 meV + E_x, and 628 meV + E_x, respectively, where E_x is the exciton binding energy of the order of 10 meV. The ionization energy of the N donor was 55 ± 7 meV.

Owing to the deep level of the B acceptor, the spectra were different from those due to Al and Ga, and phonon replicas with simultaneous emissions of multiple phonons were dominant. The luminescence due to B was intense even at room temperature.

The ionization energies of the Al acceptor in 6H- and 3C-SiC were 231 meV + E_x and 248 meV + E_x, respectively. Even if the difference in E_x among the polytypes is taken into consideration, the value for 4H-SiC was smaller than those for 6H- and 3C-SiC.

Acknowledgment

The authors would like to thank Dr. K. Kuroiwa for his valuable advice about the crystal growth.

Fluorescence of Eu^{3+} in Lithium Zinc Tantalate, $Li_{14}ZnTa_4O_{18}$

A. Wachtel* and T. J. Isaacs

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania 15235

ABSTRACT

A new compound, $Li_{14}ZnTa_4O_{18}$, was found and its Eu-activated fluorescence as well as its crystal symmetry was studied. It is face-centered cubic, with $a_o = 4.212$Å. The emission spectrum shows considerable line broadening and the fluorescence as a function of Eu concentration suggests the presence of two emitting sites, both of which tend to dissociate into nonluminescent defects at high firing temperatures. Replacement of Zn by Mg or of Ta by Nb leads to isomorphic compounds with similar fluorescence; replacement of Zn by Ca produced a multiphase material containing a moderate amount of the same cubic phase.

There has been considerable interest in Eu^{3+} activated phosphors for over a decade because of their technical usefulness as red emitters. Thus far, only four compounds, Y_2O_3, Gd_2O_3, Y_2O_2S, and YVO_4, have met the spectral, quantum efficiency, physical, and cost requirements for successful phosphor hosts, although YVO_4 degrades somewhat under 254 nm excitation.

Calcium oxide (CaO) (1), when activated with Eu^{3+}, has excellent spectral energy distribution and quantum efficiency, but it is hygroscopic, and therefore presents certain difficulties in lamp applications. This compound has the rock salt structure, with the Eu^{3+} probably in a defect associated center. We decided to look into other materials with this type of lattice.

Four compounds initially were studied. These are Li_3TaO_4, Li_3NbO_4, Li_3SbO_4, and "$Li_2Zn_{0.5}Ta_{0.5}O_3$" (2).[1] Both Li_3TaO_4 and Li_3SbO_4 were reported to be tetragonal; Li_3NbO_4 and $Li_2Zn_{0.5}Ta_{0.5}O_3$ were thought to be cubic. All are supposed to have orderings of the halite structure. Of these four compounds, when activated with Eu^{3+}, only $Li_8Zn_2Ta_2O_{11}$ and Li_3SbO_4 displayed significant fluorescence in the 610 nm region; the latter, however, accompanied by a broad band in the blue region. The others emitted only weakly under 254 nm excitation. Further work in attempting to optimize $Li_8Zn_2Ta_2O_{11}$:Eu^{3+} led to the discovery of $Li_{14}ZnTa_4O_{18}$.

Experimental

Samples were prepared by solid-state reaction of the component oxides or carbonates (reagent or luminescent grade purity) in covered 99.9% alumina crucibles in air at temperatures of 800°-1400°C. Weight losses due to volatilization of Li_2CO_3 were compensated for by appropriate additions between firings in order to obtain stoichiometric compositions. Some of the products were subsequently fired in sealed platinum capsules at 1500°C.

The materials thus prepared were examined by x-ray powder diffraction using either the Debye-Scherrer method or diffractometer. Some samples also were studied under the polarizing microscope to detect extraneous phases.

Fluorescence intensity of Eu^{3+} under 254 nm excitation was measured with a spectra brightness spot meter using filters to favor the region of $^7F_2$ emission near 613 nm. Data are reported as percent of Y_2O_3:Eu^{3+}.

Emission spectra were taken with a resolution of 0.3 nm over the range of 500-720 nm, using 300 nm excitation. The scanning system was corrected for response *vs.* wavelength.

The excitation spectrum was run with a 500W xenon arc passed through two tandem quarter-meter Jarrell-Ash monochrometers. The resolution was again 0.3 nm. The correction for quantum output *vs.* wavelength was made relative to 2,2'-dihydroxy-1, 1'-naphtaldiazine (3).

Results

Our x-ray diffraction powder patterns of $Li_8Zn_2Ta_2O_{11}$ indicated the presence of more than one phase in significant amounts. We obtained the same results at firing temperatures up to the fusion point of the material, and concluded that there was not a true compound of this composition.

Because of the interesting fluorescence spectrum, however, we searched for the emitting compound by examining various compositions in the system Li_2O-ZnO-Ta_2O_5. Among these, only the compound having the ratio $7Li_2O \cdot ZnO \cdot 2Ta_2O_5$ produced the same spectrum and with much higher intensity, when activated with Eu^{3+}. In order to synthesize it, relatively high firing temperatures (≧1300°C) were required. Our analysis of the x-ray powder diffraction pattern (Table I) indicated that this compound has face-centered cubic symmetry (the possible space groups being F23, Fm3, F432, F$\bar{4}$3m, and Fm3m) with lattice parameter $a_o = 4.212$Å. This cell size is in good agreement with the value of 4.214Å given for $Li_2Zn_{0.5}Ta_{0.5}O_3$ (2), and comparison of the powder patterns of these two materials shows that $Li_{14}ZnTa_4O_{18}$ is a major constituent in our composition corresponding to $Li_8Zn_2Ta_2O_{11}$. We did not ascertain the other phases present in this composition.

Compositions of the type $(7 \pm 1)Li_2O \cdot (1 \pm 0.5\ ZnO) \cdot (2 \pm 0.5\ Ta_2O_5)$ contained additional phases and displayed weaker fluorescence if activated by Eu^{3+}. This was particularly pronounced on reducing Li_2O or ZnO or increasing Ta_2O_5.

Introduction of Eu in $Li_{14}ZnTa_4O_{18}$ gives rise to red fluorescence which is well excited by 254 nm, and

[1] According to the proportion $4Li_2O \cdot 2ZnO \cdot Ta_2O_5$ which was employed in the present study, the formula should read $Li_8Zn_2Ta_2O_{11}$.

Key words: lithium zinc tantalate, lithium magnesium tantalate, europium, fluorescence, cubic, x-ray diffraction.

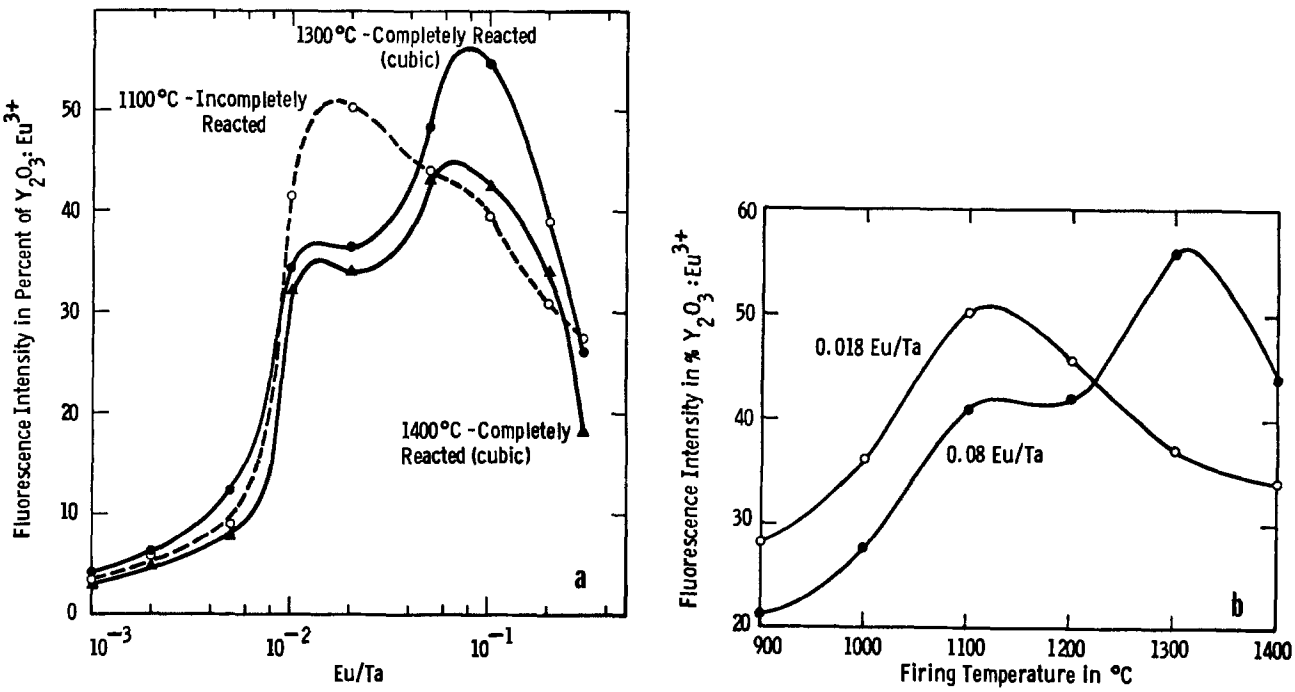

Fig. 1. (a) 254 nm-excited fluorescence intensity of $Li_{14}ZnTa_4O_{18}$ prepared at three firing temperatures as a function of Eu concentration. (b) 254 nm-excited fluorescence intensity of $Li_{14}ZnTa_4O_{18}$:0.036 Eu_2O_3 and of $Li_{14}ZnTa_4O_{18}$:0.16 Eu_2O_3 as a function of firing temperature.

whose intensity bears an interesting relationship to Eu concentration and firing temperature. This is illustrated in Fig. 1. In Fig. 1a, we note that there are two maxima with respect to Eu concentration, the relative intensities of which are a function of firing temperature. In Fig. 1b, the same data are replotted for the two presumably optimum Eu concentrations, and we again note the occurrence of two maxima which are now in terms of firing temperature and whose relative intensities are a function of Eu concentration. Some samples with 0.0035 and 0.05 Eu/Ta were fused at 1500°C in sealed Pt tubes and displayed still weaker fluorescence although the x-ray powder diffraction patterns remained the same. Introduction of 0.1 Eu/Ta resulted in complete solubility and near-maximum fluorescence; introduction of 0.2 Eu/Ta resulted in the appearance of faint lines of a second phase in the x-ray powder diffraction pattern. The doping by Eu_2O_3 also causes a slight lattice expansion (a_o = 4.222Å for 0.05 Eu/Ta). Attempts at charge compensation were generally unrewarding; compositions prepared according to $Li^+ + Zn^{2+} = Eu^{3+}$, $Zn^{2+} + Eu^{3+} = Ta^{5+}$, or $Zn^{2+} + Ta^{5+} = Eu^{3+} + Zr^{4+}$ remained cubic but displayed slightly reduced fluorescence, while compositions corresponding to $Li^+ + Eu^{3+} = 2Zn^{2+}$ also gave rise to extraneous phases at higher doping levels in addition to lowered fluorescence intensity.

Figure 2 shows the emission spectra of $Li_{14}ZnTa_4O_{18}$: 0.007 Eu_2O_3 fired at 1100°C (dashed curve) and fused at 1500°C (solid curve). It can be seen that in spite of the relatively low doping level (0.0035 Eu/Ta), there is considerable line broadening, particularly in the high temperature fired (single phase cubic) material. Because of the width of the $^7F_2$ manifold, its relative intensity, compared to total emission, is appreciably higher than $Y_2O_3:Eu^{3+}$. The emission spectrum of preparations fired at 1100°C shows better resolution of the satellite lines but is otherwise quite similar.

In contrast to the emission, the excitation spectrum for 612.5 nm emission is highly structured. This is seen in Fig. 3 for $Li_{14}ZnTa_4O_{18}$:0.2 Eu_2O_3 fired at 1300°C, *i.e.*, despite a relatively high doping level (0.1 Eu/Ta). The primary excitation occurs in a broad band centered near 245 nm; excitation into the Eu levels near 400 nm ($^7F_0$-$^5D_3$) and 470 nm ($^7F_0$-$^5D_2$) is weak due to low absorption strength.

Replacement of Zn by Mg resulted in the same cubic powder pattern (a_o = 4.202Å), as well as similar emission and excitation spectra. The primary $^5D_0$-$^7F_2$ emission line as well as most of the excitation lines of $Li_{14}MgTa_4O_{18}:Eu^{3+}$ are displaced 0.5-1 nm to shorter wavelength as compared to the Zn compound, and the 254 nm excited emission intensity is slightly lower than that of similarly prepared $Li_{14}ZnTa_4O_{18}:Eu^{3+}$. Somewhat weaker fluorescence is also observed in the analogous composition containing Ca instead of Zn. This, however, is a multiphase system containing unidentified lines in the powder pattern along with the group of lines belonging to the cubic structure seen in the Zn and Mg compounds. It was not investigated further. Replacement of Zn by other divalent ions led to different structures and weak fluorescence. $Li_{14}ZnNb_4O_{18}:Eu^{3+}$ displays the same structure (a_o = 4.220Å with 0.1 Eu_2O_3) as the tantalate after formation

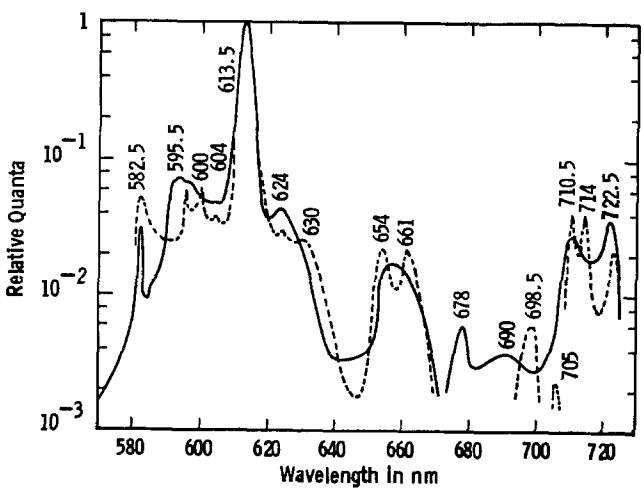

Fig. 2. Emission spectra of $Li_{14}ZnTa_4O_{18}$:0.007 Eu_2O_3 prepared at two firing temperatures: dashed curve = 1100°C; solid curve = 1500°C.

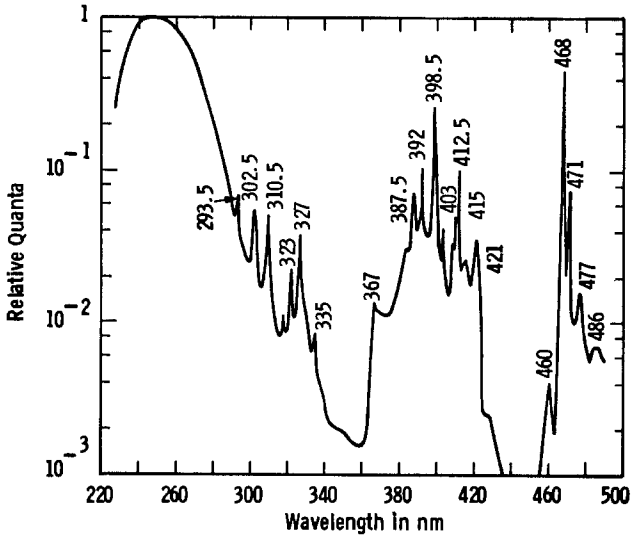

Fig. 3. Excitation spectrum for 612.5 nm emission of $Li_{14}ZnTa_4O_{18}$:0.2 Eu_2O_3.

at only 1100°C (sintering) but its fluorescence is only about one-third as intense. The analogous vanadate is noncubic and nonfluorescent.

Figure 4 shows that an appreciable difference between the Eu-activated Zn and Mg compounds is seen only in the diffuse reflectance spectra in the 290-390 nm region. Otherwise, both compounds clearly show a fundamental absorption edge near 230 nm which is not very different for the Zn or Mg species, and a broad absorption of $Li_{14}MgTa_4O_{18}$:0.2 Eu_2O_8 which is in good agreement with its excitation spectrum. The additional absorption of the doped Zn compound between 290 and 390 nm is apparently not related to excitation. On the other hand, weak absorption at the two conspicuous Eu-excitation lines could be detected.

A search for Eu^{3+} emission in known compounds in the Li_2O-ZnO-Ta_2O_5 system revealed very weak intensities throughout except for Li_7TaO_6:0.05 Eu (4), which emits a broad line centered at 610.5 nm with about 20% of the intensity of $Y_{1.9}Eu_{0.1}O_3$. Moreover, all

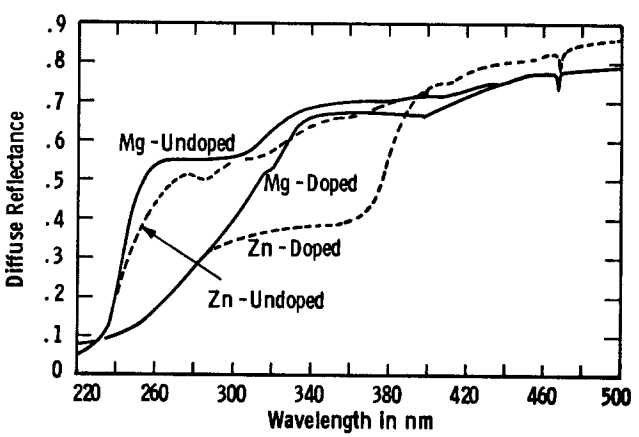

Fig. 4. Diffuse reflectance spectra of cubic $Li_{14}ZnTa_4O_{18}$ and $Li_{14}MgTa_4O_{18}$ with and without 0.2 Eu_2O_3 per mole.

compounds except for the multiphase composition $Li_8Zn_2Ta_2O_{11}$ displayed emission spectra which are different from that of $Li_{14}ZnTa_4O_{18}$:Eu^{3+}.

We found that the compound $Li_{14}ZnTa_4O_{18}$ hydrolyzes fairly readily in water.

Discussion

The presence of two maxima of fluorescence intensity as a function of Eu concentration (Fig. 1) suggests that the one which predominates in incompletely reacted mixtures (low Eu) is due to some other compound which forms in the course of the solid-state reaction which leads to $Li_{14}ZnTa_4O_{18}$ at higher firing temperatures. We have observed, however, that at least none of the known Li- or Zn-tantalates or the known ternary compound $LiZnTa_3O_9$ (5) can be responsible for this. Moreover the emission spectrum of the multiphase composition corresponding to $Li_8Zn_2Ta_2O_{11}$:Eu, obtained at high temperatures, is identical to that of $Li_{14}ZnTa_2O_{18}$:Eu (Fig. 2), although the fluorescence intensity is appreciably lower. We conclude, therefore, that intermediary phases formed during the solid-state reaction are essentially nonfluorescent and that two emitting Eu^{3+} sites in $Li_{14}ZnTa_2O_{18}$ are formed, one of which obtains early in the reaction ($\leq$1100°C) and is metastable. At temperatures sufficient to complete the reaction (~1300°C), another Eu^{3+} center predominates at higher Eu concentrations and could be due to association of two or more Eu sites. This concept is also supported by the widths of the Eu^{3+} emission lines in the compound (Fig. 2). At still higher firing temperatures (1400°, 1500°C) the emission of both centers decreases; thus, it seems that even the second center which forms at high temperature is unstable and tends to decompose into isolated impurities and defects. The mechanism for the phenomenon was not determined. It is unlikely, however, that it occurs via interaction with vacancies which seem to be the only source of charge compensation in this system.

Acknowledgments

We wish to express appreciation to Dr. F. M. Ryan for emission and excitation spectra, to W. Gaida for x-ray diffraction powder patterns, and to E. Metz for help in preparing the materials.

Generation and Propagation of Defects in Indium Antimonide

H. U. Walter[1]

Department of Physics, University of Alabama, Huntsville, Alabama 35807

ABSTRACT

Density of volume defects due to foreign particle inclusions in Czochralski-grown InSb crystals is 10^2-10^3/cm^3 as detected by x-ray topography. The larger ones of these inclusions are frequently sources of dislocations. Dislocations in Czochralski-grown crystals are randomly oriented and curvilinear. InSb crystals prepared in space by partial remelting of Czochralski-grown seeds and regrowth after a 1 hr thermal soak period are markedly different. The density of inclusions is greatly reduced since foreign particles are accumulated during soak at the remelt boundary and at the melt surface. Dislocations originating from particles at the seed boundary are the cause of a sudden increase of dislocation density in the first portion of regrown material. Rectilinear dislocations (pure edge and 60° type) are observed rather exclusively in the bulk of space-grown crystals. Since larger inclusions are absent, few defects are generated, and the density of dislocations decreases along the axis of the samples due to outgrowing of rectilinear dislocations that are inclined to the growth axis. Increasing radial thermal gradients causes an increase of dislocation density in the crystal section solidified last. Generation and multiplication of dislocations due to radial thermal gradients become appreciable at gradients of about 10°-15°C/cm.

The catalogue of possible defects in the zinc blende (sphalerite) structure, in which indium antimonide crystallizes, has been derived by Holt (1) on the basis of Hornstra's theoretical analysis of possible structures of dislocations in the diamond lattice (2). Experimentally, dislocations in indium antimonide were overwhelmingly studied by chemical etching techniques, *e.g.*, (3-10); x-ray topography was not employed extensively (11-17).

It is well known that mechanisms by which dislocations are generated are not intrinsic to the growth process, but rather due to insufficient control of growth conditions. The following mechanisms have been identified: propagation of dislocations into the growing crystal from the seed, poor epitaxy during seeding, incorporation of foreign particles, shear strains arising from thermal strains or external mechanical constraints, shear strains due to compositional variations accompanied by lattice parameter changes, misorientation due to dendritic growth, and the mechanism of collapsing vacancy disks, which is especially important in metal crystals.

Because of the variety of causes of dislocations and the complexity of solidification processes, cause and effect relationships are difficult to analyze. Lack of control of solidification is largely due to transient fluid flow that is inherent with some of the crystal growth techniques, and, more importantly, transient flow due to gravity-driven convection. These random convective disturbances affect the solidification rate and solid-liquid interface morphology, which results in degradation of structural perfection and in chemical inhomogeneities of crystals grown from the melt.

One approach to virtually eliminate gravity-driven convection is to experiment in orbiting laboratories. With quiescent melts that could presumably be obtained in a low gravity environment, programmable and stable temperature fields could be applied, and solid-liquid interface shape would reflect isotherm shape not only on a macroscale, but on a microscale as well. Solidification rates could be programmed and constitutional supercooling could be avoided by applying sufficiently steep thermal gradients without introducing turbulent gravity-driven convection. In addition, novel containerless processing techniques could be employed in low gravity environment, thus not only eliminating contamination from crucible material, but also eliminating mechanical stress and spurious nucleation at crucible walls. Space experimentation should, therefore, be of particular interest for studying highly doped semiconductors, high melters, and highly reactive materials, structural perfection of melt-grown crystals in general should be improved.

This paper describes the defect properties of InSb single crystals prepared by a containerless technique on board of Skylab. Defect properties of space-grown crystals are compared with Czochralski-grown crystals that were used as seeds. This comparison is of interest since it should aid in understanding the influence of disturbances due to convective fluid flow on crystal perfection.

Experimental

Crystal growth.—Crystals used as seeds were grown by the Czochralski method from ingot compounded from 6*N* elemental material under the following conditions: crucible, high purity (6*N*) carbon; growth atmosphere, 1 atm high purity (6*N*) hydrogen; pulling rate, 5-25 μm sec; crucible rotation, 30 rpm; seed rotation, 0 rpm; growth direction, [$\bar{1}\bar{1}\bar{1}$] for undoped material (5 samples) and approximately [110] seed crystal orientation for heavily selenium-doped ($n \approx 10^{19}$/cm^3) material (1 sample). Crystal growth in space was performed as follows: Czochralski-grown crystals (8 mm diameter) were partially backmelted (18 mm) in a gradient furnace so that large drops ($\approx$ 15 mm diameter) of uncontained melt were formed at the end of the seed crystals. These drops were directionally solidified during controlled cool-down (0.6°C/min) of the furnace after a 1 hr soak period. Thermal equilibration and melt homogenization was achieved during soak. Additional parameters were as follows: gradient in the melt, 15°-35°C/cm; growth rate, 3-7 μm/sec; gravity levels during growth, 10^{-4}-10^{-7}G; growth atmosphere, 6*N* hydrogen; size of samples obtained, $\approx$ 18 mm long, $\approx$ 10 mm diameter, bottle-shaped. Crystal growth procedure and crystal

morphology have been described in detail elsewhere (18).

Etching.—Density and distribution of defects in seed crystals and sections regrown in space were first determined by chemical etching. Crystals grown along [$\bar{1}\bar{1}\bar{1}$] were cut in 1.5 mm thick wafers perpendicular to the axis of growth. Cutting was done with a wire saw (wire thickness 0.25 mm) carrying a slurry of 10-20 μm SiC in glycerine and water. After mechanical polish with 0.03 μm alumina, the wafer surfaces were chemically polished and etched in a modified CP-4 etchant (2 conc HNO_3 + 1 conc HF + 1 glacial CH_3COOH). After counting of etch pits, the wafers were again etched in an etchant consisting of 1 part 30% H_2O_2, 1 part 48% HF, 8 parts H_2O, 0.4% n-butylthiobutane. Modified CP-4 reveals In dislocations (α-dislocations) on {111} faces, the etchant with butylthiobutane as inhibitor reveals Sb dislocations (β-dislocations) (8, 19) on both {111} and {$\bar{1}\bar{1}\bar{1}$} surfaces. Both types of etch pits are generally associated with 60° dislocations as has been shown by successive grinding and etching (3, 5, 19). Since pits due to Sb dislocations could not always be identified unambiguously, some wafers were also etched in 0.2*N* Fe^{+++} in 6*N* HCl at 95°C (5). Material grown along [110] was etched in the same fashion, {111} cuts parallel and inclined to the growth direction were studied.

X-ray topography.—Seed material and space-grown crystals were investigated by means of scanning reflection topography (20), transmission Lang topography (21), and anomalous transmission topography (22-24). CuKα and AgKα radiation were used; beam divergence was kept such that recorded images were due to Kα_1 radiation only. Geometrical (vertical) resolution was typically 2-4 μm; topographs were recorded on Ilford nuclear plates, emulsion L-4, 25 μm thick; plates were developed at 0°C.

Linear mass absorption coefficient μ for InSb is about 1500/cm for CuKα and 90/cm for AgKα radiation. Required sample thickness t for $\mu t \leqq 1$ (Lang topographs) is $t \leqq 0.1$ mm for AgKα, and for $\mu t \geqq 10$ (Borrmann topographs) thickness is $\geqq 1$ mm for AgKα and $\geqq 0.07$ mm for CuKα radiation. Samples were prepared by lapping with 0.03 μm alumina followed by chemical polishing one side at a time in $5HNO_3$:$3CH_3COOH$:2HF at 0°C. Preparation of sufficiently thin, large and undamaged crystal wafers with constant thickness is difficult; InSb is very brittle and cleaves well along {110}, chemical polishing results frequently in terracing of the surfaces. Larger, sufficiently thin wafers tend to bend elastically under their own weight; smaller sections were, therefore, investigated.

Results

Undoped crystals grown in [$\bar{1}\bar{1}\bar{1}$] direction.—Over-all morphology of a typical crystal grown along [$\bar{1}\bar{1}\bar{1}$] is shown in Fig. 1. The boundary between Czochralski-grown seed and space-grown section is clearly delineated. Scanning reflection topographs obtained from as-grown surfaces are shown in Fig. 2. Figures 2a and b are symmetrical reflections from {110} surface facet areas with <220> diffraction vector; Fig. 2c shows a reflection from a ($\bar{1}\bar{1}1$) surface facet, diffraction vector is [$\bar{1}\bar{1}1$]. Single Bragg reflexes indicate over-all single crystallinity; structure due to imperfections is only observed in the seed areas and the very first and last portions of space-grown crystals. The flat ($\bar{1}\bar{1}1$) surface facet region is clearly visible in Fig. 2c; otherwise, reflexes from the center of the space-grown crystals are remarkably homogeneous.

Figure 3 gives In-dislocation profiles obtained by etching of wafers cut perpendicular to the axis of growth (sample E1 and D2). A sudden increase in

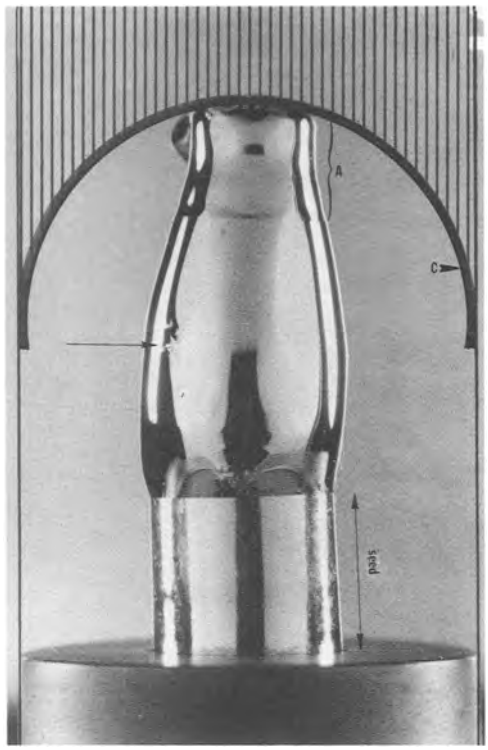

Fig. 1. InSb crystal grown by a containerless method during Skylab mission SL-3. Czochralski-grown, [$\bar{1}\bar{1}\bar{1}$] oriented, 8 mm diameter cylindrical seed is mounted in graphite support at bottom. Boundary between seed and space-grown crystal is clearly delineated. The morphology of the section indicated by A was affected by interference of the melt with the graphite heating cavity C. Arrow indicates an accumulation of oxide particles on surface of space-grown crystal.

etch pit density in the first few millimeters of space-grown material is followed by a steep, rather linear decrease over the major portion of the crystals. Minima are reached at $\approx$ 70/cm^2 (D2) and $\approx$ 40/cm^2 (E1). Dislocation density increases sharply to 10^4/cm^2 in both crystals within the last few millimeters.

Dislocation clusters shown in Fig. 4a and pseudo-hexagonal arrays of etch pits ("stars") shown in Fig. 4b could only be observed in Czochralski-grown seed material and at the meltback interface between seeds and space-grown crystals. Density of clusters and stars was 1-10/cm^2; this type of defects has to be attributed to foreign particle inclusions as is discussed later. β-dislocations were by a factor of 2 to 10 less frequent than α-dislocations; axial distribution of β-pits was similar as for α-pits.

Scanning reflection topographs of {110} and {211} longitudinal sections of crystals grown along [$\bar{1}\bar{1}\bar{1}$] were rather featureless. An example is shown in Fig. 5. The only structure resolved is due to surface roughness resulting from chemical polishing. Dislocations and inclusions in seed material as revealed by Borrmann anomalous transmission topography are shown in Fig. 6; no particular directionality of dislocation lines is observed. Lang topographs of the interface between seed and space-grown crystal (meltback interface) and of various sections of space-grown material are shown in Fig. 7-10. Dark dots decorate the meltback interface (Fig. 7); the diffraction contrast was independent of reflections employed, which indicates that these features are due to strain fields around inclusions of foreign material. Interface curvature radius for the initial meltback interface determined from these topographs is 20-25 mm. At the very end of solidification when the melt is in contact with the graphite heating cavity, the interface radius ultimately

(a, left) [$2\bar{2}0$] reflection from ($1\bar{1}0$) facet region, (b, center) [$2\bar{2}0$] reflection from ($1\bar{1}0$) facet region, (c, right) [$\bar{1}\bar{1}\bar{1}$] reflection from ($\bar{1}\bar{1}\bar{1}$) facet region. Structure next to the meltback interface is due to surface irregularities that were caused by accumulations of solid particles.

assumes the radius of the cavity, which is 8 mm. Dislocations in the bulk of space-grown crystals are exclusively rectilinear (Fig. 8, 9). Increasingly dense and irregular networks of dislocations as well as strain fields appear toward the heating cavity end of the crystals (Fig. 10). Axes of rectilinear dislocations in the bulk are [$1\bar{1}0$], [$\bar{1}0\bar{1}$], and [$0\bar{1}\bar{1}$], inclined (35°, 26°) to the [$\bar{1}\bar{1}\bar{1}$] growth direction. Departure from strict orientation along <110> directions amounts to a few degrees. Directions of Burger's vectors were determined in the usual manner by determining diffraction vectors for which maximum significant differences in diffraction contrast of dislocation images is obtained. Burger's vectors are along <110> and 60° inclined to the axes of rectilinear dislocations. Dislocations in the bulk of crystals grown in space along [$\bar{1}\bar{1}\bar{1}$] are, therefore, 60° dislocations with {111} slip planes oblique to the growth direction. [$1\bar{1}0$] dislocations (Fig. 8) appear as long streaks since they are (within accuracy of wafer orientation) parallel to the surface of the ($1\bar{1}0$) wafer investigated. [$\bar{1}0\bar{1}$] and [$0\bar{1}\bar{1}$] oriented dislocations are inclined to the wafer surface at an angle of 30°. They are, therefore, much shorter in the topographs (Fig. 9), approximately 0.2 mm according to a wafer thickness of about 100 μm. No discrimination could be made between α- and β-dislocations in the topographs since this would require determination of the sense of Burger's vectors. Dislocations at the heating cavity end of crystals (Fig. 10) are also of the 60° type, whereas, segments consisting of pure screw and pure edge dislocations with axes along <211> directions could be observed in seed material.

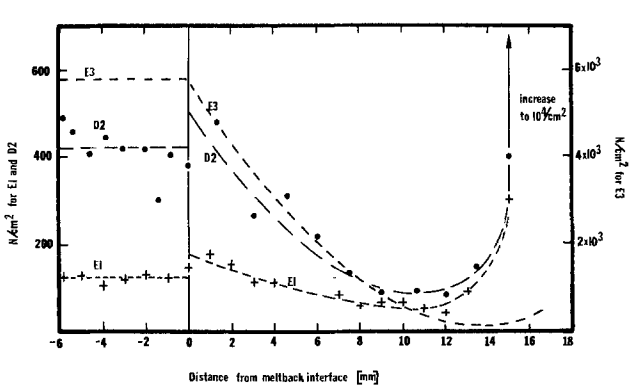

Fig. 3. Variation of density of In dislocations along axes of specimens. E1, D2 are undoped samples grown along [$\bar{1}\bar{1}\bar{1}$]; E3 is selenium doped, seed orientation approximately [110].

Selenium-doped crystal grown in [$\bar{1}32$] direction.— Aside from dopant striations in the initial and terminal transient of solidification, which could be explained by a basic mechanism not associated with fluid flow (25), defect characteristics of material grown perpendicular to [$\bar{1}\bar{1}\bar{1}$], the usual growth direction for InSb, were significantly different.

A scanning reflection topograph of a central, longitudinal (111) section of the crystal is shown in Fig. 11. The topograph was taken using AgKα radiation with 2θ setting at the slope of the Kα_1 peak, and not as usually with 2θ setting coinciding with the Kα_1 intensity maximum. Contrast due to lattice parameter variations is exaggerated by this technique. A schematic of this topograph is given in Fig. 12. Dopant striations perpendicular to the growth axis in the first third, visible only in the original emulsion, and wavelike striations in the section solidified last (region G in Fig. 12) could be attributed to changes of liquidus temperature and growth kinetics (25). In this context, they are of interest only insofar as they contribute to the defect properties of the sample. Delineation of the meltback interface (H in Fig. 12) is due to an abrupt change in selenium concentration ($k_{eff} \approx 0.2$). Curvature radius is $\approx$ 20 mm. Most distinct are traces of ($\bar{1}11$) slip planes (A in Fig. 12) that were originally present in the seed and two dark streaks (B in Fig. 12) that are due to shadows cast by distinct grooves in the surface resulting from chem-

ical etching of rectilinear dislocations lying directly at the wafer surface. Arrow-shaped features (C) are due to dislocations close to the surface within reach of the probing beam (4-6 μm).

A striking feature is the over-all intensity variation along the axis of the topograph, highest x-ray intensity is reflected from the seed region (D in Fig. 12). This effect is not caused by shifts of the Bragg angle due to selenium concentration variation but reflects crystalline perfection instead. Diffracted intensity is greater for imperfect regions since a larger wavelength spread and larger beam divergence contribute to the diffracted intensity. Of an incident beam, that has, for example, 4 min divergence, a typical value required for separation of $K\alpha_1$ and $K\alpha_2$, perfect crystals will diffract only within a divergence of a few seconds of arc. This spread increases with increasing crystal imperfection. Similar considerations apply for wavelength spread. The decrease of diffracted intensity along the axis as shown in a transmittance curve (intensity values reversed) in Fig. 13 is, therefore, indication of gradually improving crystal perfection. This interpretation is confirmed by density profiles of dislocation etch pits (Fig. 3 and 14), and also by the geometry and density of defects revealed in x-ray topographs (Fig. 15). Again, dislocations are rectilinear in the space-grown section, they lie rather ex-

clusively in the (111) plane parallel to the axis of growth. 60° dislocations with $[0\bar{1}1]$ dislocation axis (Fig. 15a) and pure edge dislocations with $[1\bar{2}1]$ axis (Fig. 15b) are inclined 10.9° and 19.1°, respectively, to the $[1\bar{3}2]$ growth axis. Consequently, these dislocations terminate on the crystal surface as seen in the topographs. The last section (G in Fig. 12) is virtually free of dislocations (Fig. 15); intensity variations are due to wavelike dopant striations that were also observed by differential etching in the terminal region of solidification.

Discussion

The simplest complete dislocations in the sphalerite structure with slip plane {111} are 60° dislocations (α and β) with axis $\vec{a}$ and Burger's vector $\vec{b}$ along <110> directions, edge dislocations (α and β) with $\vec{a}$ <112> and $\vec{b}$ <110>, 30° dislocations (α and β) with $\vec{a}$ <112> and $\vec{b}$ <110>, and screw dislocations along <110> (1). All of these types have been observed in as-grown and in plastically deformed InSb (9, 12, 15-17). Single crystals virtually free of dislocations have been reported; typical values given by Shesta-

kova *et al.* (26) are 2-11 $\times$ 10^2/cm^2 for Czochralski-grown and 10^4-10^6/cm^2 for zone-refined crystals.

Regarding the dislocation profiles for samples E1 and D2 (Fig. 3), it is evident that there are mechanisms leading to a sudden increase in density of dislocations in the regrown material directly adjacent to the seed, another mechanism by which the density gradually decreases along the axis, and finally a mechanism due to which the density increases sharply toward the heating cavity end.

The increase at the seed boundary is caused by inclusions of foreign material accumulated at the meltback interface. Imperfections caused by poor epitaxy as well as multiplication of dislocations by thermal shock when bringing an insufficiently preheated seed in contact with melt are ruled out due to the approach of backmelting of a larger seed to provide the molten material.

Oxide particles are always observed on InSb melt surfaces unless double crucible or bottom pouring techniques are used. As a result of crucible rotation and since crucible and crystal axis do not usually coincide during Czochralski growth, the particles are constantly swept to the solid-liquid interface and are consequently grown in.

Inclusions of foreign species have been observed in a variety of materials, *e.g.*, Si (27), GaAs (28, 29), and also InSb (12, 13, 14, 16). Size of inclusions in InSb is usually 10-20 μm (12, 13, 16); density may be as high as 10^3/cm^3 (13). Excess Al, Si, and O could be detected by electron microprobe analysis at these sites (13, 16). Depending on the difference of the thermal expansion coefficients between crystal matrix and inclusions, strain fields that develop around larger inclusions (>20-40 μm with InSb) can cause plastic deformation (Fig. 4).

As mentioned, molten material for space solidification was provided by partial remelting of a larger seed. During melting and 1 hr soak, particles in the melt could drift to the melt surface and to the seed interface. For reasons of free energy balance, these interfaces acted as sinks. Particle accumulations could be found on the surfaces of all crystals (arrow in Fig. 1); size of inclusions visible at the remelt boundary (Fig. 7) is 5-25 μm, concentration is of the order of 1000/cm² interface. Only one line defect seems to originate from one of the inclusions in Fig. 7. However, to produce an increase of dislocation density in the space-grown material adjacent to the seed of the order of 100/cm² as in E1 and D2 (Fig. 3), only one dislocation needs to originate from one out of 10 inclusions at the interface. Curve E3 in Fig. 3 shows no such maximum, the reason is that the seed had a 10 times higher dislocation count to start with; an increase of the order of 100/cm² is, therefore, not noticeable.

Heterogeneous nucleation experiments indicate that there are 10^6-10^8 foreign particles per cubic centimeter in most molten materials. Their removal from the bulk of the melt due to adsorption at the remelt interface and accumulation at the melt surface resulted in a melt that had exceptionally low concentration of foreign particles. This was especially so since the melt was not in contact with a container and there were no sources of renewed contamination. Aside from serving as nucleation sites for grains and twins (30) and acting as dislocation sources, inclusions may serve as pinning sites for dislocations, a prerequisite for Frank-Read sources. Strain fields surrounding the great number of submicroscopic inclusions may also be one of the reasons for the striking difference between the geometry of line defects in seed (irregular) and space-grown material (rectilinear). Without local strain centers dislocations are more likely to be arranged in minimum free energy configurations. The energy per unit length of a dislocation is proportional to the square of the Burger's vector, minimum free energy may, therefore, be achieved by configurations where the total length of dislocation lines per unit volume is minimum (rectilinear). It is generally observed that dislocations tend to become increasingly unidirectional with lower dislocation density and improved crystal perfection.

The fact that dislocations follow basic crystallographic directions as straight lines may also be understood as an indication of a solidification process that was undisturbed by random fluid flow. Convective flow results in transient growth rate and interface

morphology perturbations, resulting local radial thermal gradients may become sufficiently large so that new dislocations are generated due to thermal stress. However, the overwhelming number of smaller local strain fields may only affect the directionality of already present defects.

Rectilinear dislocations with axes inclined to the growth direction terminate on the crystal surface after a characteristic growth distance. With the dislocation systems observed ({111} slip planes), outgrowing of dislocations is most favored if the angle between growth axis and {111} slip planes is large; most preferable is <100> seed orientation, and increasingly less favorable are <111>, <211>, <321>, <110> orientations. Since there is no evidence of sources of dislocations in the main volume of space-grown crystals, the continuous decrease of dislocation density is simply a result of outgrowing of disloca-

tions that were originally projected from the seed and from the meltback interface. Outgrowing is also reflected in radial dislocation density profiles, they are rather flat near the meltback interface and become increasingly U-shaped toward the end with minimum in the center of crystals (*e.g.*, Fig. 11).

The steep increase in dislocation density to $\approx 10^4$/cm^2 in material solidified when in contact with the graphite heating cavity (Fig. 3) is readily explained in terms of increasing thermal stress. Interface curvature radius for samples D2 and E1 was 20-25 mm at the beginning of solidification (see Fig. 7) and assumed the radius of the furnace cavity of 8 mm when in contact with it at the end. For E3 the radius was approximately 25 mm at the beginning of solidification in space (see Fig. 11 and 14), 18 mm after 14 mm of growth and 14 mm at the end since this crystal did not extend to the bottom of the heating cavity. Axial thermal gradients in the solid determined experimentally and by computation were 65° ± 5°C/cm. Radial thermal gradients from center to periphery of samples are about 7°C/cm at 25 mm radius, 9°C/cm at 20 mm, 11°C/cm at 18 mm, 14°C/cm at 14 mm, and 25°C/cm at 8 mm interface curvature radius. Dislocation density increases at coordinates that correspond to radial gradients of about 20°C/cm (D2 and E1, Fig. 3) and 14°C/cm (E3). InSb becomes plastic above 200°C, which is equivalent to about 2/3 T_m [°K] (31). The density of dislocations N produced by radial gradients and plastic flow can be estimated from the equation (32)

$$N = \frac{\alpha}{b}\frac{dT}{dr}$$

α is the linear expansion coefficient ($\approx 5 \cdot 10^{-6}$/°C), b is the Burger's vector ($4.58 \cdot 10^{-8}$ cm for <1/2 1/2 0> in InSb), dT/dr is the radial thermal gradient. At radial gradients of 14°-20°C/cm N is calculated as $1.5 \cdot 10^3$/cm^2 to $2.2 \cdot 10^3$/cm^2. These values are in good agreement with the observed densities

Generation of dislocations due to compositional stress in selenium-doped material could not be observed, even though striae in the initial transient region of solidification mark abrupt changes in dopant concentration as determined by differential etching and spreading resistance measurements.

Molecular Beam Epitaxial Growth of InP

J. H. McFee* and B. I. Miller*

Bell Laboratories, Holmdel, New Jersey 07733

and K. J. Bachmann*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Epitaxial layers of InP have been grown on the $(\bar{1}\bar{1}\bar{1})$ face (P face) of InP substrates by molecular beam epitaxy. The layers were grown at substrate temperatures ranging from 220° to 510°C, using separate In and P sources. Unintentionally doped layers grown above ~350°C appear to be single crystal with $n = 2\text{-}5 \times 10^{16}$ cm^{-3} and $\mu = 2000\text{-}3500$ cm^2/Vsec. Layers grown at substrate temperatures below ~350°C appear to be composed of well-oriented crystallites, and have poor electrical and photoluminescent properties. Orientation-dependent faceting is a prominent feature of layers grown on $(\bar{1}\bar{1}\bar{1})$ substrates at temperatures >350°C. Epitaxial InP layers have also been grown on the (111) face (In face) and the (100) face of InP substrates. Orientation-dependent faceting is much less prominent for growth on the (100) face, and it is possible to obtain smooth, featureless (100) epitaxial layers.

Molecular beam epitaxy (MBE) is now an established technique for growing epitaxial semiconductor layers. MBE has been applied to GaAs (1-7), AlGaAs (1, 2), GaP (8), GaAsP (8), InP (9-11), and to the II-VI semiconducting compounds (12). The significant characteristics of MBE are: (*i*) kinetic (as opposed to equilibrium) growth conditions, (*ii*) relatively slow growth rates (a few monolayers per second), and (*iii*) simplicity of flux control (*e.g.*, by opening and closing shutters in front of the beam sources). Therefore, as compared to LPE or VPE growth techniques, a different set of conditions determines the composition and dopant incorporation in MBE. Also MBE permits abrupt changes, almost on an atomic scale, in the composition and doping profiles of the growing layer. Because of this precise flux control, MBE has been successfully used to grow "superlattice" structures (13-15) in GaAs, having periodicities as small as ~50Å. In addition, MBE has been successfully applied to the fabrication of GaAs and GaAs/AlGaAs semiconductor devices such as injection lasers, varactor and IMPATT diodes, FET's, etc., where precise tailoring of the composition and/or doping profile is a critical requirement. [See Ref. (1) for a comprehensive list of references dealing with MBE device fabrication.]

In this paper, we present our results on the MBE growth of InP from elemental In and P sources. This study was initiated primarily because of the recent interest in the InP/CdS heterojunction solar cell (16). The objective was to fabricate a thin film version of such a cell. In addition, InP shows promise for making low noise microwave devices such as transferred electron amplifiers (17) and oscillators. MBE grown InP layers would be especially advantageous in this application, because here again the doping profile is a crucial parameter.

Farrow (9-11) has recently reported growing InP on (100) and $(\bar{1}\bar{1}\bar{1})$ InP substrates by MBE using In and InP as sources. At growth temperatures in excess of 400°C, he reports smooth epitaxial growth on the (100) face. His unintentionally doped layers were typically n-type with $N_D\text{-}N_A \sim 10^{17}$ cm^{-3}, and with 300°K mobilities in the range 1000-2000 cm^2/Vsec. Growth from elemental sources (P and In) affords independent control of the P_4/In ratio as well as the possibility of lower unintentional doping due to the higher purities (99.9999+% pure) of the elements as compared to InP (generally less than 99.999% pure). In addition, because of the requirement to lattice match InP to CdS in the InP/CdS solar cell, our growth efforts have been concentrated on the InP $(\bar{1}\bar{1}\bar{1})$ growth face which lattice matches to CdS and which can be polished to a damage-free condition. We also report some preliminary results of growth on the (111) and (100) faces. A further objective of our study has been to establish the limits on the substrate temperature for epitaxy. For CdS and many other substrates a low growth temperature is desirable to prevent decomposition.

Experimental

MBE Growth System

The MBE growth system used here is similar to that used by Cho (1) and others to grow epitaxial semiconductor films. It consists of an 18 in. diameter bakeable ultrahigh vacuum system capable of pumping down to the 10^{-10} Torr range. The horizontal cross section of the system is shown in Fig. 1. Installed on the vacuum system are evaporating ovens, a 3 keV electron diffraction system (RED), a 10 keV Auger system with a 3 keV sputter gun, a quadrupole mass analyzer, a precision sample manipulator, and a scattered laser light detector.

Ovens.—The main ovens are cylindrical in shape (5 cm long × 1 cm diam) consisting essentially of a helical-wound Ta heating element which encloses a pyrolytic BN (99.999% pure) crucible. Several layers of 0.0005 in. Ta foil are wound on the outside of each oven as a heat shield. Heater and support construction is entirely of Ta or Mo. Each oven has its own shutter and all five main ovens are enclosed by a liquid nitrogen (LN_2) shroud. A gold-plated copper nose cone (see shaded parts in Fig. 1) is attached to the LN_2 shroud to limit beam spread from the main ovens. The main ovens are used for high temperature evaporants, *i.e.*, In or Ga, and dopants like Sn, Be, Mg, etc. The cylindrical BN crucibles are reentrant on the bottom and open at top. The reentrant tube allows the thermocouple to be inserted toward the center of the crucible providing a better thermal contact between it and the charge.

For the high vapor pressure phosphorus, we use a large capacity (20 cm^3) auxiliary oven similar to that suggested by Ilegems (18) for As in GaAs MBE. This oven has an Al body with embedded heaters and a separately heated ceramic "snout" aimed at the substrate.

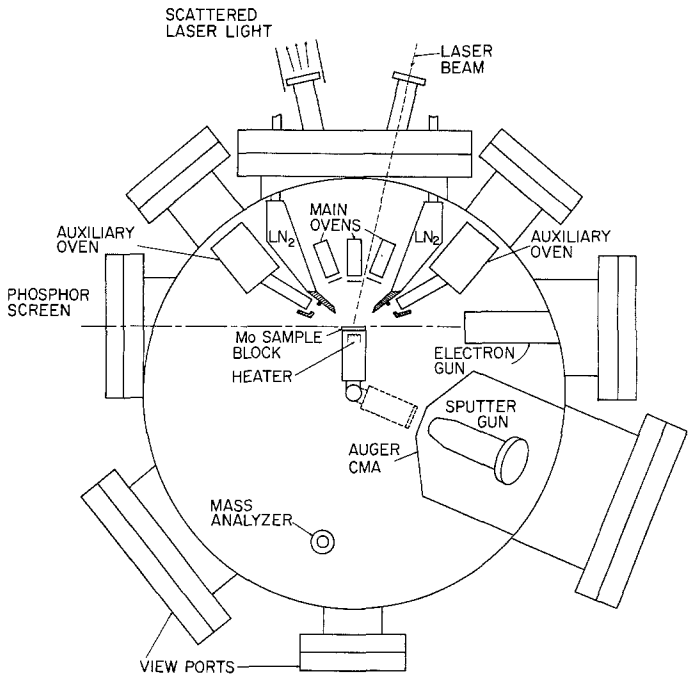

Fig. 1. Horizontal cross section of 18 in. diameter ultrahigh vacuum system. Section taken through growth plane of stainless steel bell jar.

Generally, the auxiliary ovens are run at temperatures less than 400°C and for that reason Al was found to be a convenient construction material. Subsequent use of these ovens in MBE growth has shown no attack on the Al by the phosphorus and no apparent contamination problems. In fact, layers grown using one of the main ovens (BN crucible) as the phosphorus source exhibited the same electrical and photoluminescent properties as those layers grown using the Al auxiliary oven as the phosphorus source. In order to limit the phosphorus beam spread from the snout, a gold-plated copper "ear" is attached to the nose cone of the LN_2 shroud. Generally, with the auxiliary ovens ten growth runs can be made before reloading.

Reflection electron diffraction (RED).—A RED system similar to one described by Cho (1) and others is used to monitor the surface crystal structure before and during growth. It consists of a 3 keV electron gun which produces a 1 mm diameter beam at glancing incidence to the sample. The RED pattern is observed on a 4 in. diameter phosphor screen (Fig. 1).

Auger cylindrical mirror analyzer (CMA).—In order to determine the surface stoichiometry as well as impurities on the surface a 10 keV CMA made by Varian Associates was used. With care, surface impurities as small as 0.1% could be detected. In addition, a 3 keV sputter gun is mounted 15° from the vertical so that the sample can be sputtered while an Auger spectrum is being taken. Generally sputtering is done at 3 keV with 2 $\mu A/cm^2$ Ar^+ current density. A useful feature of the Auger system is a scanning mode, similar to that found on a scanning electron microscope, which allows precise visual determination of the area being analyzed or sputtered.

Quadrupole mass analyzer.—A precision quadrupole mass analyzer (U.T.I. Model 100C, 1-300 amu) is used to monitor the partial pressures in the system before and during a growth run. In addition, the mass analyzer is located so that it has an unobstructed view of the main ovens allowing the beam fluxes to be monitored continuously during a run. Furthermore, the axis of the analyzer is perpendicular (approximately) to the incoming beams so that the quadrupole elements will not become coated during the course of several evaporations, causing the analyzer to change calibration. To enhance the sensitivity of the mass analyzer, a beam chopper is placed in the system ahead of the analyzer so that phase sensitive techniques can be used. Typically growth proceeds at In fluxes of 3×10^{14} cm^{-2} sec^{-1} corresponding to a growth rate of 0.5 μm/hr. Using the chopper, dopant fluxes in many instances as low as a few parts per million of In can be detected.

Precision sample manipulator.—The sample holder is a Varian precision sample manipulator modified to allow heating of the substrates to 800°C. All parts of the sample holder subject to heating were replaced by Mo and Ta. The substrates are mounted on a Mo sample block 2.5 cm × 2.5 cm × 3 mm thick. A thermocouple is inserted into a hole drilled in the sample block. As shown in Fig. 1, the sample can be rotated to face the main ovens (growth position) or to face the CMA for sputter cleaning and/or surface composition analysis.

Scattered laser light system.—In order to observe the smoothness of the epitaxial layer during growth, a laser beam is incident on the layer and the scattered (nonspecular) light is monitored as shown in Fig. 1 (19). The incident beam is provided by a 6328Å He-Ne laser and is chopped at 90 Hz. The scattered light is detected by a photomultiplier and lock-in amplifier. It is found that the scattered light signal is extremely sensitive to any change in surface smoothness. This technique has proved to be our most useful real-time monitor of layer quality.

Determination of Growth Parameters

From earlier MBE experiments on III-V semiconductors, it is clear that the substrate temperature and the ratio of excess P_4 to In fluxes will be critical parameters for the growth of high quality epitaxial layers of InP. As in the case of GaAs, the congruent temperature (*i.e.*, the temperature above which the substrate no longer evaporates stoichiometrically) is a safe upper limit on substrate temperature during epitaxial growth. Farrow finds that for the (100) face of InP, the congruent temperature is 365° ± 10°C (9) and for the $(\bar{1}\bar{1}\bar{1})$ he finds it to be 325° ± 10°C (11). We have roughly determined the upper limit of the congruent temperature for the $(\bar{1}\bar{1}\bar{1})$ face of InP and get a value of about 415°C. Farrow (9), for example, grew at 300°C and obtained stoichiometric growth of InP on a (100) InP substrate, however a large percentage of his samples were polycrystalline. The question therefore arises: Is it possible to grow above the congruent temperature? From these studies Farrow concluded that the maximum congruent evaporation rate from the (100) InP surface is only 10^{-5} monolayers/sec. It appears, therefore, that even above the congruent temperature it may be possible to grow epitaxial layers if enough P_4 (or P_2) is present in the beam to compensate for the loss of phosphorus from the surface. In fact, Farrow (10) was able to stabilize an InP (100) surface with a P_4 beam at temperatures in excess of 450°C. More recently (11) he has reported the growth of epitaxial films of InP at temperatures greater than the congruent temperature. Using this approach, we have grown epitaxial layers at substrate temperatures up to 510°C with a suitably high P_4 flux. For example, to grow at a rate of 0.5 μm/hr at 450°C, the P_4 and In fluxes at the sample are 3×10^{15} and 3×10^{14} cm^{-2} sec^{-1}, respectively. We find, at 450°C, that when the P_4:In ratio falls below about 10:1 nonstoichiometric growth occurs as evidenced by the buildup of In droplets on the surface.

Sample and Sample Preparation

The InP substrates used in these studies were grown by the liquid encapsulated Czochralski (LEC) method, details of which have been described earlier (20, 21). The InP crystals were pulled along the (100) axis and had a dislocation density which ranged from 10^3 to 10^5 cm^{-2}. For morphology studies, Sn-doped substrate material ($n = 5 \times 10^{17}$) was used and for electrical tests

Cr-doped substrate material ($\rho = 5000$ Ω-cm) was used at first; subsequently, semi-insulating Fe-doped (22) substrate material ($\rho > 10^8$) was used.

The InP substrates were mounted on Mo blocks using In solder. In the case of the (100) and ($\bar{1}\bar{1}\bar{1}$) (phosphorus) faces, the samples were lapped to a mirror finish on dextalose paper saturated with a 5% Br:95% CH_3OH solution. In order to gauge the perfection of the lapped surface, the sample was subjected to illumination by He-Ne laser light while being viewed under a microscope (19). Again, as in the scattered laser light probe on the MBE system, any surface imperfections will scatter the laser light into the objective of the microscope where they appear as points of light. Typically, the samples are polished so that there are less than 2-4 points appearing per square millimeter.

In the case of the (111) (In) face of InP, we were unable to find a purely chemical technique, so Syton HT-30 chemo-mechanical polish was used. Now, under incident laser light several hundred points of light per square millimeter were visible in addition to many scratches and other imperfections.

Run Procedure

The InP was grown from elemental sources of In and red P, both of which were 99.9999+% pure. In the case of In, the major impurity was Sn at 0.7 ppm, while for the P the major impurity was Mg at 0.3 ppm.

After the sample is prepared as described above, it is immediately loaded into the vacuum system which is flushed with dry N_2 during the loading operation. When a vacuum of 10^{-6} Torr is obtained, the sample is heated to 365°C and the In oven to 440°C overnight. In addition, during the same period the vacuum chamber walls are baked at about 150°C. Under these bakeout conditions, the partial pressure of phosphorus coming from the auxiliary oven remains negligible. The following morning, after the walls have cooled, the LN_2 traps are filled and the Ti sublimitation pump turned on. A short time later the total pressure in the system is 10^{-9} Torr or less. A typical partial pressure spectrum of the residual gas under these conditions is shown in Fig. 2. It can be seen from Fig. 2 that the above procedure has resulted in a minimal H_2O vapor content. Omission of the bakeout may result in a H_2O vapor content an order of magnitude larger. The largest components of residual gas prior to growth appear to be H_2, Ar, Ne, and P. Smaller amounts of CO_2, He, and N_2 (or CO) are also present. Under growth conditions, when the In and P_4 sources are at operating temperatures, the predominant background gas is P_4 at 2×10^{-6} Torr. The only significant changes observed in the background spectrum under growth conditions are an increase of an order of magnitude in the $M = 28$ amu peak (N_2 or CO) and a decrease in H_2O vapor by a factor of two.

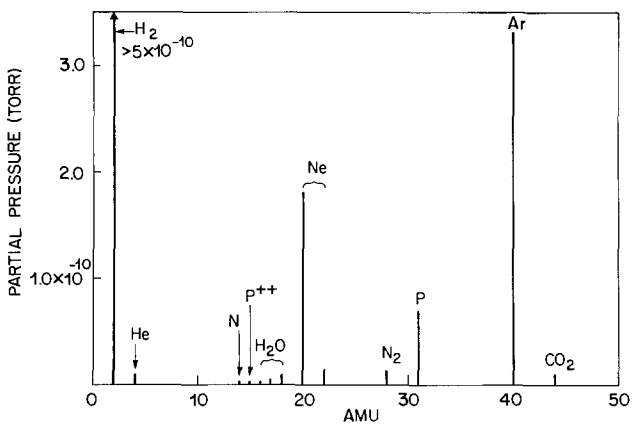

Fig. 2. Partial pressure spectrum of residual gases in bell jar after pump down and bakeout. Total pressure approximately 10^{-9} Torr. Substrate at 365°C, In oven at 440°C, and P oven at room temperature.

Once the base pressure of $\leq 10^{-9}$ Torr has been reached, the source ovens are heated to their operating temperatures. For ~0.5 μ/hr growth rate the In source temperature is at 690°C while the P_4 source temperature is at 345°C. These numbers are appropriate for an In source to sample distance of 6.5 cm.

Before commencing growth, it is essential that the substrate surface be free of contamination. In order to insure this condition, the surface is routinely sputtered in a 5×10^{-5} Torr Ar atmosphere at 3 kV with a current of 1.5 μA/cm² for 10 min. The beam from the sputter gun is scanned over the substrate to obtain uniform removal of contaminants. Following sputtering an Auger spectrum is taken to determine the cleanliness of the surface. An illustration of the effectiveness of this procedure is shown in Fig. 3. Figure 3a shows

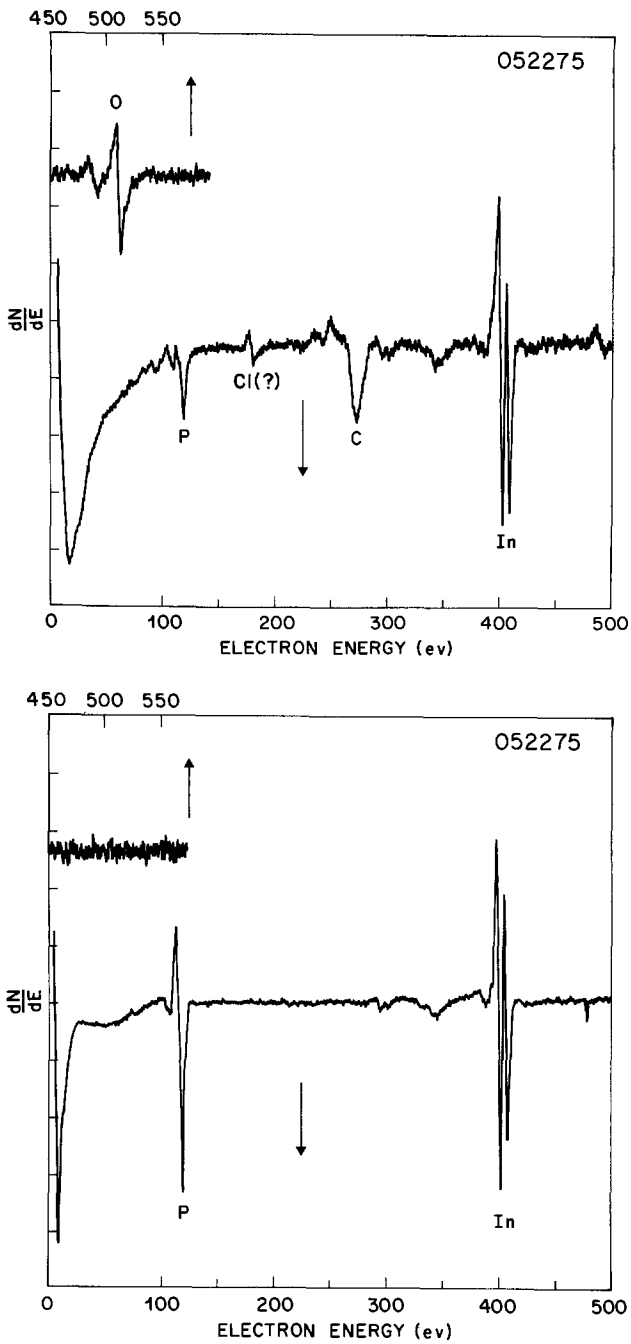

Fig. 3. (a, top) Auger spectrum of an unsputtered InP substrate which has not been outgassed overnight at 365°C in the usual manner. (b, bottom) Auger spectrum after sputtering of same InP substrate referred to in (a). Sputtering conditions: 3 keV Ar^+, 1.5 μA/cm², 10 min duration.

the Auger spectrum of an unsputtered InP substrate which had not been baked out overnight. It can be seen that the surface is rather heavily contaminated with O and C and has a trace of Cl. Also, there is considerable disparity between the amplitudes of the P and In peaks. Figure 3b shows the spectrum obtained after sputtering. All traces of C, O, and Cl have disappeared and the In and P peaks are more nearly equal in size. It should be noted that the P peak shape and height is very sensitive to the presence of surface contaminants and thus is a very useful gauge of surface contamination.

It is possible to obtain a relatively clean sample exhibiting a spectrum similar to that shown in Fig. 3b without sputtering, by heating the sample overnight as described above. However, this result is strongly dependent on the sample preparation technique and in order to insure reproducibility from run to run, sputtering is routinely done. The substrate is normally annealed at 365°C for 1 hr after sputtering.

After the substrate surface has been sputtered clean and annealed, it is rotated into growth position (see Fig. 1) where the RED pattern can be observed on the phosphor screen before, during, and after a growth run. For example, by following the sample preparation and sputter cleaning procedure described earlier, a RED pattern like that shown in Fig. 4 is obtained in the case of a $(\bar{1}\bar{1}\bar{1})$ substrate face. This pattern exhibits streaks whose spacing corresponds to the InP (111)-2 surface structure. In other words, the streaked nature of Fig. 4 is indicative of an undamaged, reconstructed two-dimensional crystal surface. Further evidence of the essentially undamaged nature of the substrate surface are the diagonal bright bands (Kikuchi lines) seen in Fig. 4 which would not be observed if an appreciable amount of point defects or elastic strain was present (23). Depending on the temperature and orientation of the substrate, various changes may occur in the RED pattern when growth is started. These details are discussed below.

Another technique which is very useful for monitoring the smoothness of the substrate and epitaxial layer is the use of scattered (nonspecular) laser light. As in the case of RED, the scattered light can be observed before and during a growth run. A properly lapped substrate will scatter very little light, as described earlier. Upon initiation of growth, a change occurs in the scattered light level. Growth of a very smooth epitaxial layer such as on the (100) surface causes a gradual decrease in the scattered light level during the course of a run. In contrast, when growing on the $(\bar{1}\bar{1}\bar{1})$ surface, the scattered light will increase gradually as the layer grows due to faceting. An abrupt increase in the scattered light level upon initiation of growth indicates either a polycrystalline or a nonstoichiometric (*i.e.*, In droplets on the surface) layer.

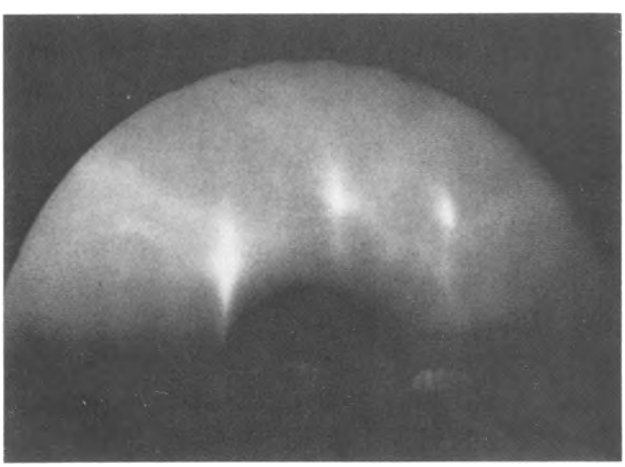

Fig. 4. 3 keV RED pattern obtained from $(\bar{1}\bar{1}\bar{1})$ InP substrate after overnight outgassing at 365°C and sputter cleaning (110 azimuth). Half-order streaks indicate a $(\bar{1}\bar{1}\bar{1})$-2 surface structure.

Results

$(\bar{1}\bar{1}\bar{1})$ Orientation

InP layers have been grown at substrate temperatures ranging from 220° to 510°C. These layers were undoped and typically were 2 μm thick. At a growth rate of 0.5 μm/hr, we find that single crystal epitaxial growth occurs at substrate temperatures above 325°-350°C. Above these temperatures the surface morphology of the epitaxial layer exhibits a faceted structure with threefold symmetry characteristic of the $(\bar{1}\bar{1}\bar{1})$ growth axis. Also, these epitaxial layers are n-type ($n \sim 3 \times 10^{16}$) and have Hall mobilities which are comparable to that of bulk InP of this same carrier concentration. The photoluminescent efficiency of these epitaxial layers is also comparable to that of bulk InP; layers grown at 450°C have a maximum photoluminescent efficiency.

Below 325°-350°C, the epitaxial layers exhibit a gradual loss of crystalline properties as a function of decreasing growth temperatures. The deterioration of crystalline properties is evidenced by the gradual disappearance of the threefold faceted morphology of the epitaxial surface and changes in the RED and x-ray diffraction patterns. Scanning electron microscope (SEM) photographs of these epitaxial surfaces indicate that the layers are polycrystalline. Furthermore, the layers grown below 325°-350°C have very low mobilities and high carrier concentrations ($n \sim 10^{18}$) and exhibit very poor photoluminescent efficiencies.

In order to study the nature of the threefold morphology of the epitaxial layers grown at high temperature, we selected a growth temperature of 450°C. This temperature is well above the lower limit of substrate temperatures necessary for single crystal epitaxial growth.

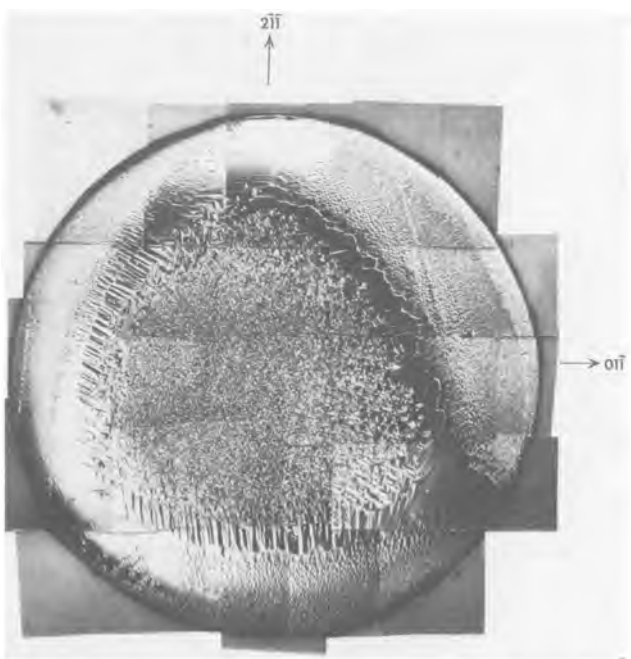

Fig. 5. Nomarski interference-contrast photograph of an InP epitaxial layer grown at 450°C on a disk-shaped $(\bar{1}\bar{1}\bar{1})$ substrate. Chemical polishing of the substrate produces a lens-shaped convex surface whose central area is aligned parallel to $(\bar{1}\bar{1}\bar{1})$ within $\pm$10 min and whose perimeter is tilted off $(\bar{1}\bar{1}\bar{1})$ by $\sim$1°. Arrows indicate azimuthal directions in the plane of the substrate.

Growth at 450°C.—Initially it was observed that epitaxial layers grown on the $(\bar{1}\bar{1}\bar{1})$ face showed prominent nonuniform morphological features such as pyramids, smooth bands, and "shingles." At first, these features were suspected to be caused by surface defects related to sample preparation or by nonuniform growth condition, *i.e.*, spatial variation of the In or P_4 beams. As more layers were grown, it became obvious that there was a strong correlation between these morphological features and substrate orientation. This dependence of the morphology of epitaxial layers on orientation and not on defects has been observed by Shimbo *et al.* (24) in VPE silicon. In the VPE growth of GaAs, DiLorenzo (25) has reported a dramatic decrease of pyramidal growth for small misorientations of the substrate from (100). Rode (26) has developed a theory of surface energy as a function of misorientation from a singular surface such as the (100) and (111) surfaces of diamond-type and zinc blende crystal structures. He finds that morphological features such as low angle terraces, hillocks, and pyramids are probable for surface orientations within a few degrees of (100) and (111). An essential result of Rode's theory when applied to epitaxial growth is the critical dependence of surface morphology on the precise orientation of the substrate.

In order to elucidate the morphological features of the InP epitaxial layers grown on the $(\bar{1}\bar{1}\bar{1})$ face at 450°C, a series of growth runs were made on disk-shaped substrates. The disk-shaped substrates were x-ray oriented to within 10 min of the $(\bar{1}\bar{1}\bar{1})$. During lapping and polishing, the surface of the disk-shaped sample becomes lens shaped (convex) with the local normal at the perimeter tilted off the $(\bar{1}\bar{1}\bar{1})$ by ~1°. Figure 5 shows an epitaxial layer grown at 450°C on such a disk-shaped substrate (5 mm diameter), taken by Nomarski interference contrast to enhance the surface features. As can be seen, the morphology clearly exhibits the threefold nature of the [111] growth axis. This threefold pattern always appears for layers grown on accurately oriented $(\bar{1}\bar{1}\bar{1})$ disk-samples grown under identical conditions. On this basis we conclude that the morphological features seen on this face are solely dependent on the local substrate normal. Three distinct areas can be seen in Fig. 5:

1. The central region, which is within ±10 min of the $(\bar{1}\bar{1}\bar{1})$, shows a pyramidal growth the details of which are shown in Fig. 6a. It should be emphasized that the features in Fig. 5 and 6 are greatly exaggerated by the Nomarski interference contrast. For example, the pyramids of Fig. 6a are extremely shallow, having heights of only 2000-5000Å and faces inclined to the $(\bar{1}\bar{1}\bar{1})$ by ~0.9°.

2. The three equivalent smooth bands occurring at the 12, 4, and 8 o'clock positions in Fig. 5 appear mirror

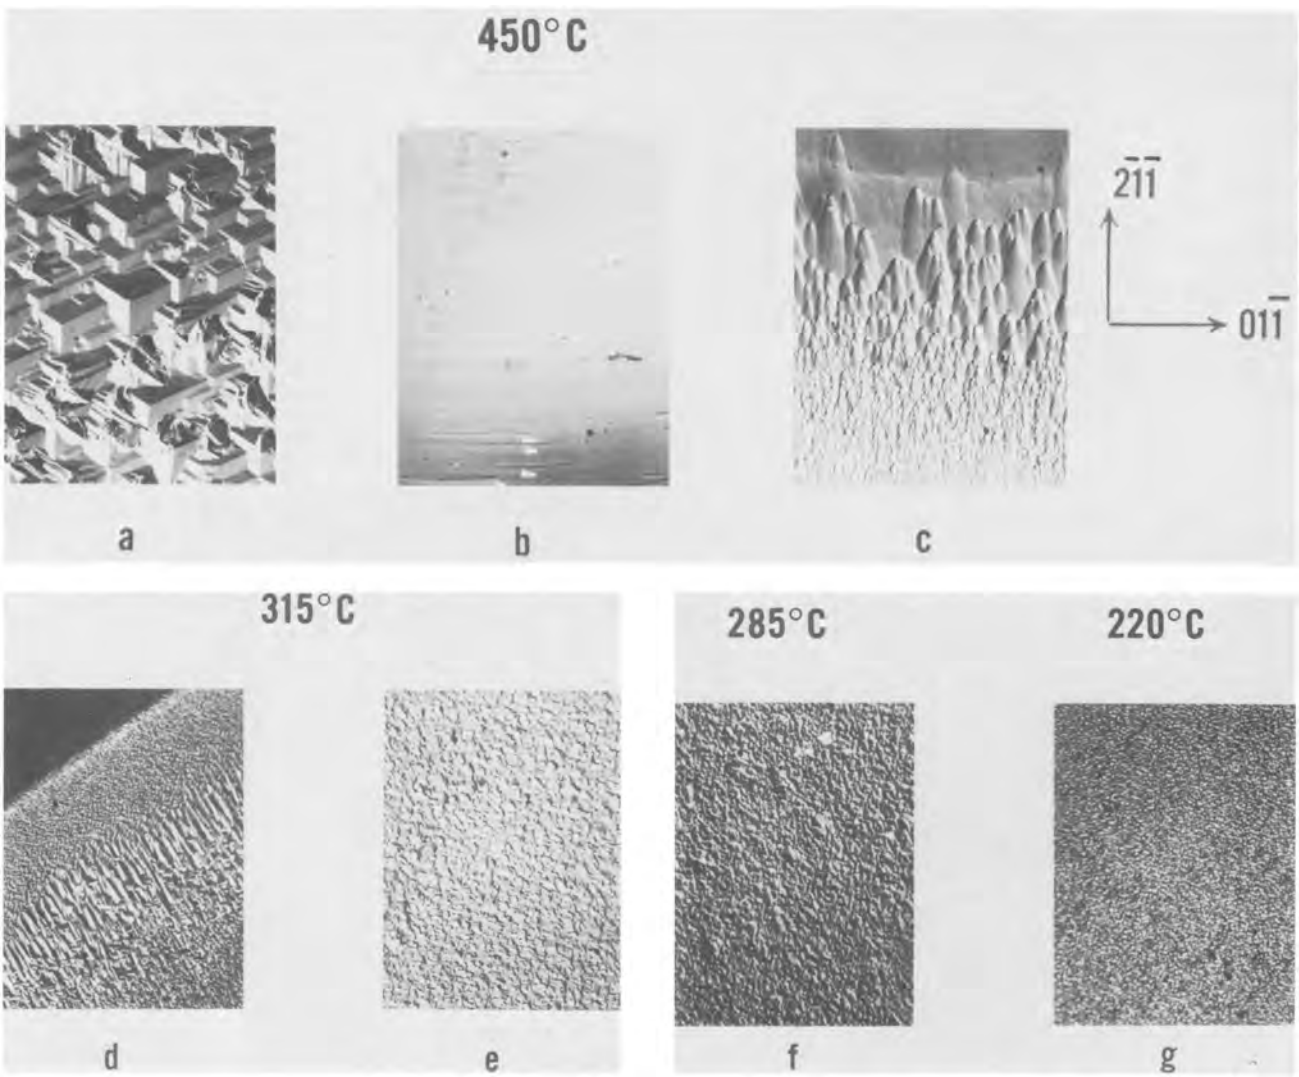

Fig. 6. Nomarski interference-contrast photographs showing details of surface morphology of InP epitaxial layers grown on $(\bar{1}\bar{1}\bar{1})$ face at various substrate temperatures, T_S. (a) Center region of layer shown in Fig. 5 (T_S = 450°C), 128×. (b) "Smooth" region near top edge in Fig. 5, 128×. (c) "Roof-shingle" region near bottom edge in Fig. 5, 200×. (d) Near edge of layer grown at T_S = 315°C, 256×. (e) Central region of layer in (d), 1000×. (f) T_S = 285°C, 1000×. (g) T_S = 220°C, 1000×.

smooth to the eye. Under interference contrast they are devoid of any features except parallel smooth steps which are observable only at maximum contrast. This region is shown under higher magnification in Fig 6b. The step height is estimated to be no greater than several hundred angstroms. The band at the top of Fig. 5 (12 o'clock position) is tilted off the $(\bar{1}\bar{1}\bar{1})$ by $\gtrsim 1°$ toward $2\bar{1}\bar{1}$ azimuth. Based on these results, a 1 $\times$ 1 cm square substrate was intentionally tilted off the $(\bar{1}\bar{1}\bar{1})$ by $\sim 2°$ toward the 211 azimuth and an epitaxial layer grown on it at 450°C. Figure 7 shows the central part of the resulting epitaxial layer. Now the smooth band extends almost the full 1 cm length of the sample in the $2\bar{1}\bar{1}$ direction but is only about 1.5 mm wide in the $01\bar{1}$ direction. Along the $2\bar{1}\bar{1}$ direction the tilt of the smooth band surface with respect to the (111) direction varies from 2° to 4°. However, along the $01\bar{1}$ direction the component of the tilt of the smooth band is from $-0.1°$ to $+0.1°$ with respect to the $(\bar{1}\bar{1}\bar{1})$. The limited extent of the smooth band in the $01\bar{1}$ direction is mainly due to the dependence of the morphology on azimuth, as seen in Fig. 5 (disk sample). Figure 7 illustrates the difficulty in growing large featureless layers on $(\bar{1}\bar{1}\bar{1})$ substrates.

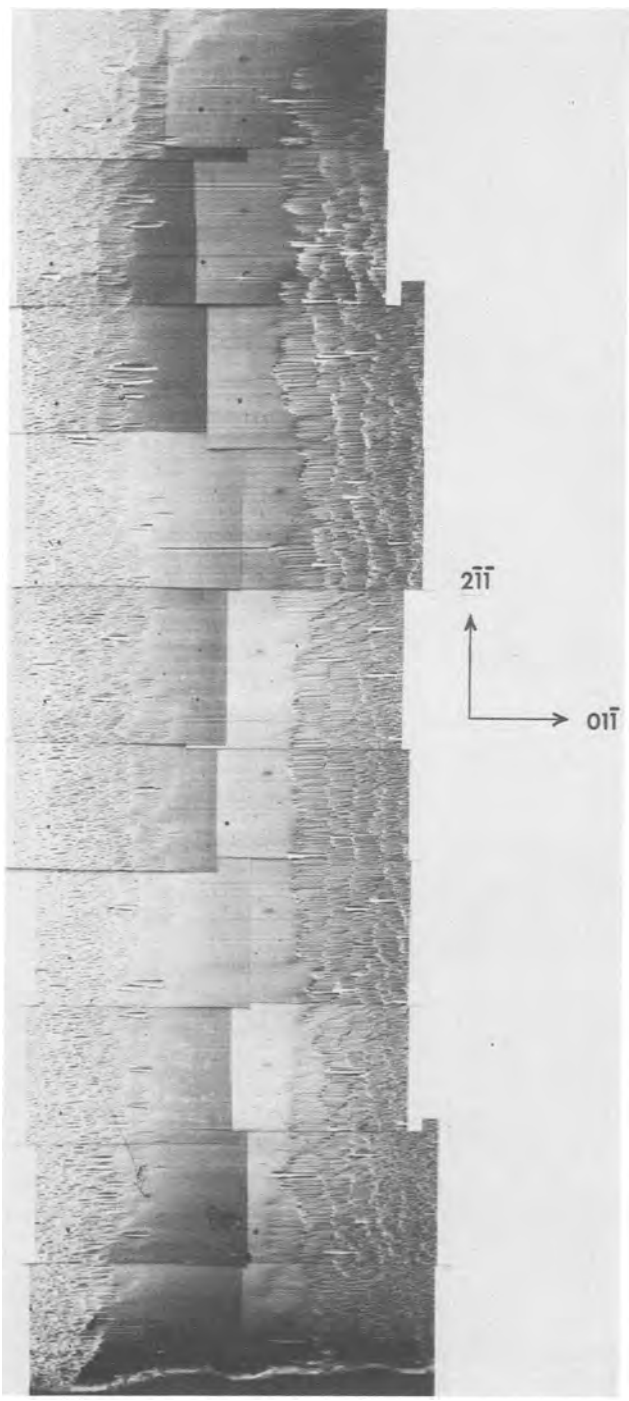

Fig. 7. Nomarski interference-contrast photograph of InP epitaxial layer grown at 450°C on 1 $\times$ 1 cm square InP substrate tilted off $[\bar{1}\bar{1}\bar{1}]$ by $\sim 2°$ toward $2\bar{1}\bar{1}$ azimuth. "Smooth" region extends nearly across whole width of sample.

3. Lying between the three smooth bands are three "shingled" regions separated from the central pyramidal area by a transition belt. Figure 6c shows the shingled area and the transition area in more detail. The distinguishing feature of the shingled region is its twofold nature, as differentiated from the threefold pyramids and one-dimensional steps in the smooth bands.

The morphological features of Fig. 5 can be taken as evidence of the single crystal nature of the epitaxial layer since they show the growth habit of the $(\bar{1}\bar{1}\bar{1})$ face. Furthermore, evidence based on RED, x-ray diffraction, and scanning electron microscopy also shows that the layers grown at 450°C are single crystal. Figure 8a shows the RED pattern of a $(\bar{1}\bar{1}\bar{1})$ epitaxial layer grown at 450°C. The streaked nature of the RED is indicative of relatively smooth single crystal growth. The spacing of the streaks corresponds to the periodicity of the unreconstructed $(\bar{1}\bar{1}\bar{1})$ InP surface for the (110) azimuth. There appears to be no clear evidence of twinning in Fig. 8a. Cho (2, 4) finds that when growing on the $(\bar{1}\bar{1}\bar{1})$ surface of GaAs a $(\bar{1}\bar{1}\bar{1})$-$(19)^{1/2}$ structure appears in the RED pattern for a (110) azimuth and not the unreconstructed $(\bar{1}\bar{1}\bar{1})$ as seen here. In other respects, the InP surface shows the same type of reconstruction as observed in GaAs by Cho. For example, results on epitaxial layers grown on (100) InP show the (100)-C(2$\times$8) surface reconstruction as reported by Cho (12) on the (100) GaAs face. In general, the RED patterns observed from epitaxially grown (100) InP films are sharper and more detailed than those observed from (111) films because of the more smooth and nearly featureless growth obtained for the (100) layers. Details of the RED patterns obtained from (100) epitaxial layers will be the subject of a future publication.

The crystalline nature of the InP epitaxial layers was also studied by x-ray analysis. A cylindrical camera was used in which the primary beam is perpendicular to the cylinder axis. The primary beam was incident on the epitaxial layers $\sim 7°$ from grazing so as to maximize the path length of the x-ray beam through the epitaxial layer. In this way, x-ray scattering from the single crystal substrate was reduced. Nickel-filtered Cu radiation at 25 kV was used. Thus there was a strong CuKα component in the primary beam which would produce Debye-Scherrer rings if randomly oriented crystallites were present in the layers. In addition to the CuKα line, the primary x-ray beam contained a continuous spectrum which would give rise to a Laue diffraction pattern from a single crystal layer. Figure 8b shows the x-ray diffraction pattern obtained from the same sample referred to in Fig. 8a. The notable features in Fig. 8b are the lack of Debye-Scherrer rings and a Laue pattern which is identical to that obtained from a single crystal InP substrate. When this technique was applied to polycrystalline InP films grown on glass substrates, Debye-Scherrer rings and no Laue pattern were observed, indicating completely random orientation of the crystallites. Polycrystalline InP films (grown on single crystal CdS substrates) having some degree of orientation were also examined and showed Debye-Scherrer rings having intensity variations around their circumferences. The absence

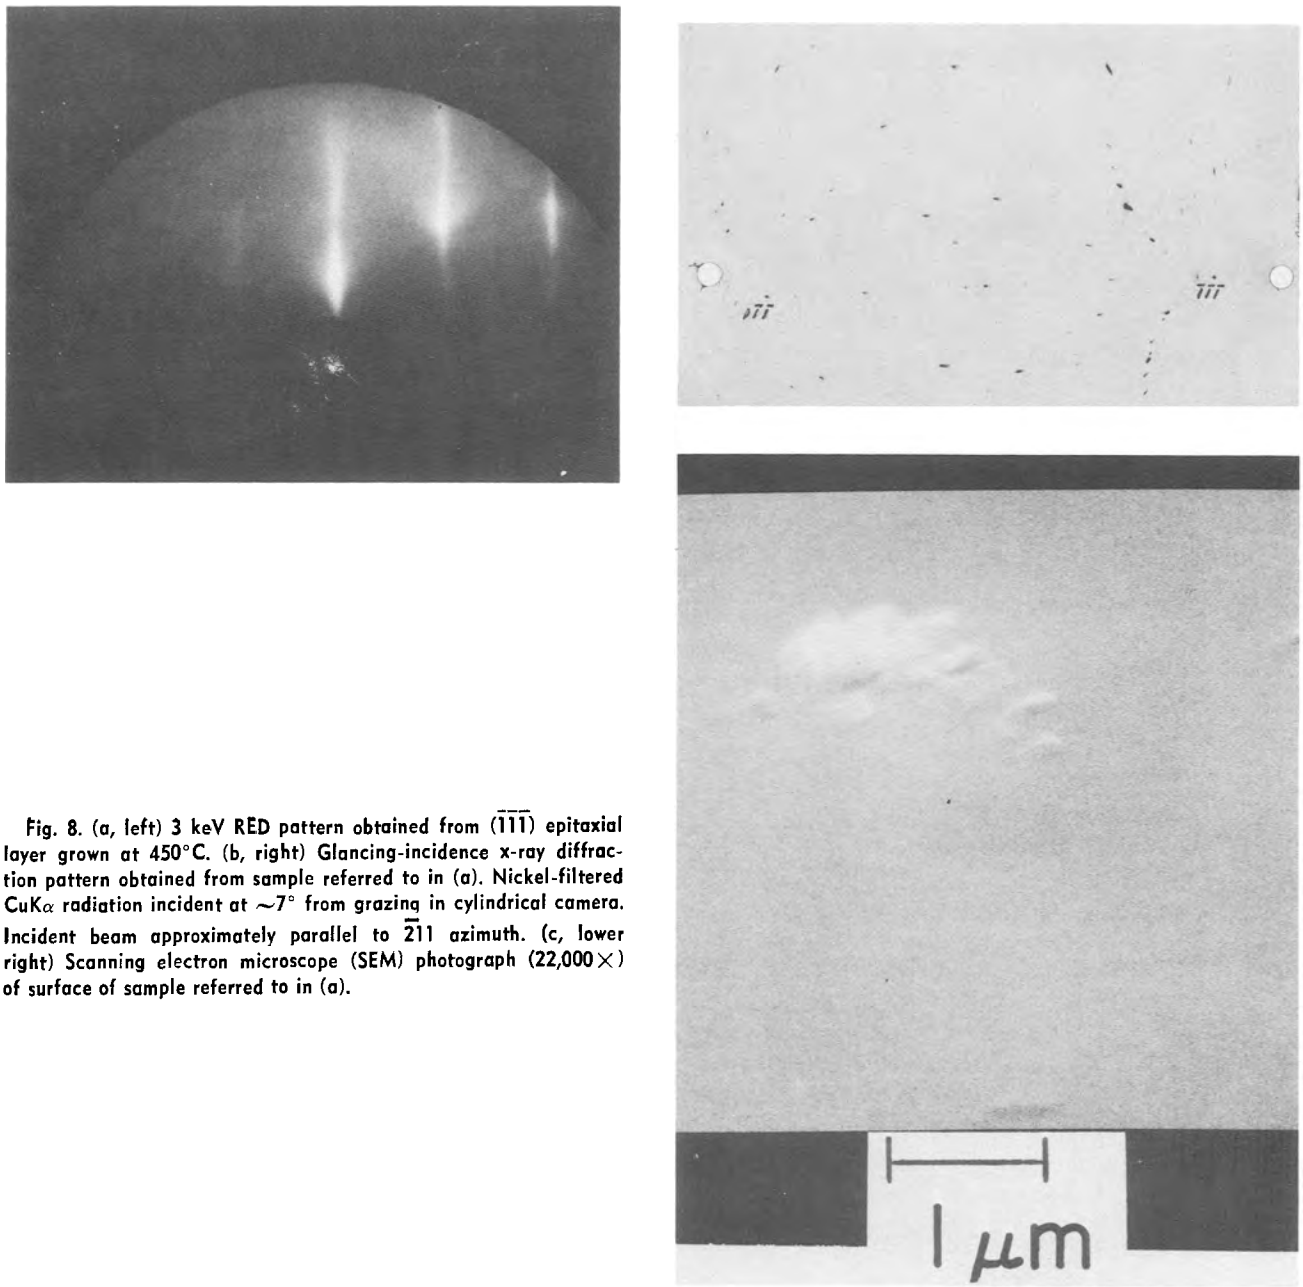

Fig. 8. (a, left) 3 keV RED pattern obtained from $(\bar{1}\bar{1}\bar{1})$ epitaxial layer grown at 450°C. (b, right) Glancing-incidence x-ray diffraction pattern obtained from sample referred to in (a). Nickel-filtered CuKα radiation incident at ~7° from grazing in cylindrical camera. of these features in Fig. 8b indicates the single crystalline nature of this epitaxial layer.

Figure 8c is a 22,000× SEM photograph of the surface of the epitaxial layer grown at 450°C. At this magnification, the surface is essentially featureless and shows no grain boundaries and few surface defects. The large white object at the upper left is a conveniently located dust particle which aided in focusing.

Some additional evidence bearing on the quality of the epitaxial samples grown at 450°C is their electrical and photoluminescent properties which are discussed in the following section.

Properties of epitaxial layers as a function of growth temperatures.—Crystalline properties.—Epitaxial layers were grown at substrate temperatures ranging from 220° to 510°C at a growth rate of 0.5 μm/hr. As the growth temperature is reduced below 325°-350°C, the faceted nature of the surface morphology (as seen in Fig. 5) gradually disappears. Figure 6 contrasts the surface features of epitaxial layers grown at 450°, 315°, 285°, and 220°C on disk-shaped substrates. Figures 6d and 6e show a region near the edge and near the center, respectively, of the epitaxial layer grown at 315°C. In Fig. 6d, only a vestige of the shingle structure seen in Fig. 6c remains. Figure 6e shows a granular surface with only a vestige of the 450°C pyramidal structure (Fig. 6a) remaining. At even lower growth temperatures, the entire surface of the disk becomes completely granular. Comparison of Fig. 6e, 6f, and 6g shows that the grain size decreases as the growth temperature is lowered. Using the SEM, the layers shown in Fig. 6e, 6f, and 6g were examined under higher magnification (20,000×) as seen in Fig. 9. The surface appears to divide into regions which range from several microns in size at 315°C growth temperature to a fraction of a micron at a growth temperature of 220°C. The resemblance of Fig. 9a-c to electron micrographs of polycrystalline films (48) and the tendency of grain size to decrease with decreasing growth temperature (48) lead us to believe that the InP layers grown below 325°-350°C are polycrystalline. It is interesting to compare these surfaces grown at less than 325°C to that shown in Fig. 8c, which was grown at 450°C.

Although it appears that films grown below 325°-350°C are polycrystalline, the RED patterns corresponding to 315° and 285°C (Fig. 10a and 10b) indicate that the crystallites are still well aligned, i.e., they are still in orientational registry with the substrate. The RED patterns are still streaked and the spacing of the streaks corresponds to the substrate periodicity. How-

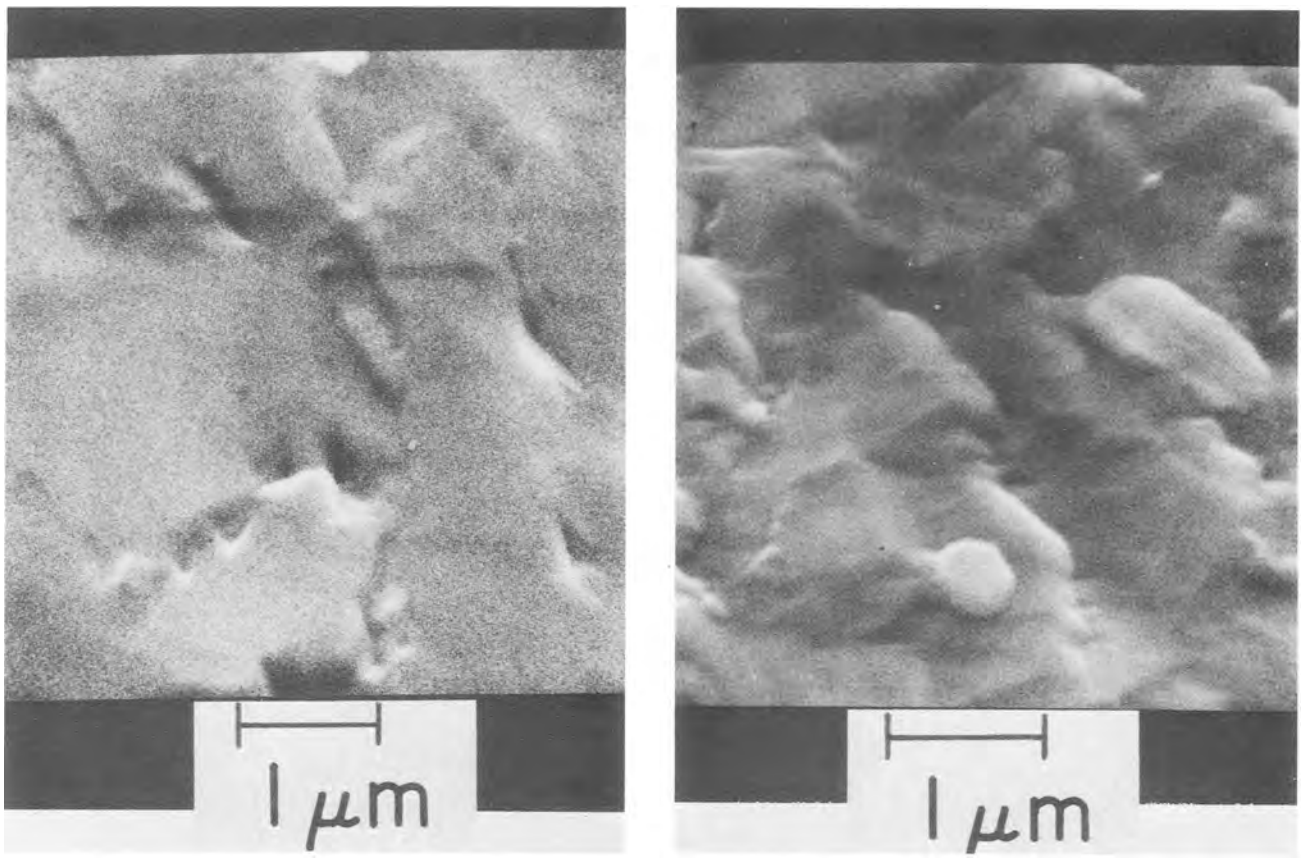

Fig. 9. (a, left) SEM photograph (~20,000×) of surface of epilayer grown at $T_S = 315°C$ (See Fig. 6e). (b, right) SEM photograph (~20,000×) of surface of epilayer grown at $T_S = 285°C$ (see Fig. 6f). (c, lower right) SEM photograph (~20,000×) of surface of epilayer grown at $T_S = 220°C$ (See Fig. 6g).

ever, with decreasing temperature the intensity of the electron diffraction diminishes and the streaked nature tends to disappear; compare Fig. 10a (growth temperature of 315°C) with Fig. 10b (growth temperature of 285°C). In fact, no structure at all could be observed in the RED from the sample grown at 220°C, and for that reason no diffraction pattern corresponding to that temperature is shown here.

The samples grown below 325°-350°C were also examined using the x-ray technique described earlier. Figure 11 shows an x-ray diffraction pattern obtained from an InP layer grown at 220°C. Except for several

very faint Debye-Scherrer rings, this x-ray diffraction pattern is essentially a Laue spot pattern similar to that obtained from the layer grown at 450°C (see Fig. 8b). However, a number of large diffuse Laue spots in addition to the sharper Laue spots are seen in Fig. 11. As the growth temperature is lowered below 325°-350°C, the number of large diffuse spots in the x-ray diffraction patterns tends to increase. On the basis of these x-ray diffraction patterns, it appears that even at a 220°C growth temperature, the polycrystalline InP epitaxial layer consists of well-oriented grains. However, the large diffuse spots in the x-ray pattern indicate some lack of crystalline perfection.

It is possible to grow InP epitaxially in excess of 450°C if the P_4/In ratio is increased in an appropriate fashion (10), analogous to the case of GaAs (2). The only obstacle to growth at higher substrate temperatures is the need for higher P_4 pressure in the vacuum station. At a substrate temperature of 450°C, the P_4 pressure is 1-2 $\times$ 10^{-6} Torr and any sizable increase of P_4 pressure above this level is impractical. Therefore the maximum substrate temperature used to date has been 510°C. Epitaxial layers grown at 510°C are almost identical in all respects (SEM, RED, and x-ray) to those grown at 450°C except for somewhat more pronounced faceting of the surface.

Electrical and optical properties.—Mobilities and carrier concentrations were measured on epitaxial layers approximately 2 μm thick grown on semi-insulating InP using the van der Pauw technique. These epitaxial layers are sufficiently thick (>1 μm) that their electrical properties at 300°K should be characteristic of bulk material (40). Contacts were made by spark-welding Au-2%Sn wires (0.002 in. diam) to the epitaxial layers, affording good ohmic contacts. The room-temperature carrier concentration (n) and mobility (μ) of these unintentionally doped layers is shown in Fig. 12 as a function of growth temperature. One very prominent feature of Fig. 12 is the sudden rise in n below 350°C and sudden drop in μ below 320°C.

Above 350°C, n appears to be nearly independent of growth temperature with a possible slight downward trend with decreasing temperature. Similarly, the mobility above 320°C is nearly constant at a level near that of bulk n-type InP. Typical of this growth temperature region are the electrical properties at 450°C where n (300°K) $\simeq$ 3 $\times$ 10^{16} cm^{-3} and μ (300°K) $\simeq$ 3000 cm^2/Vsec. Hall effect and resistivity measurements were also made at 77°K on a few of the InP epitaxial layers which showed the highest room-temperature mobility. The carrier concentration was observed to decrease by a factor of two at 77°K as compared to

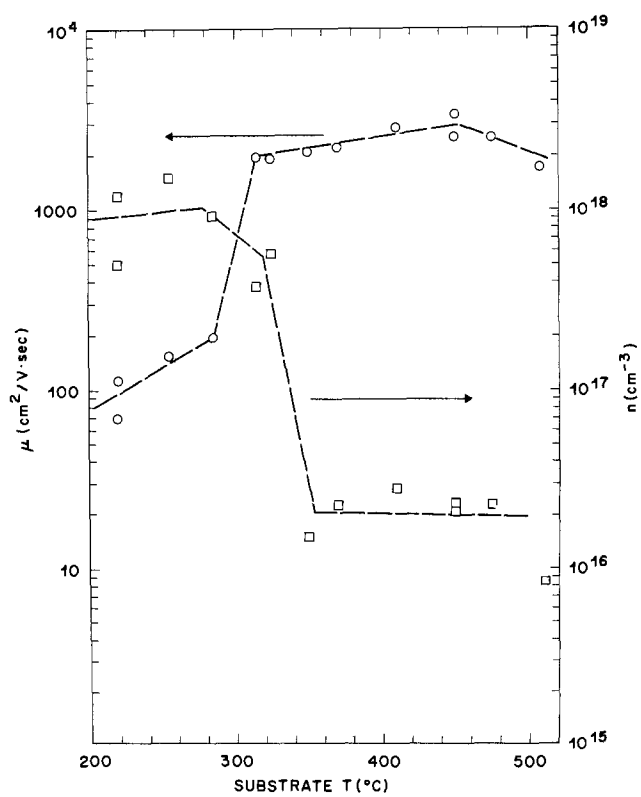

Fig. 12. 300°K carrier concentration ($n \equiv N_D - N_A$) (squares) and Hall mobility (μ) (circles) of ($\bar{1}\bar{1}\bar{1}$) InP epitaxial layers as a function of growth temperature.

300°K, and the mobilities at 77°K were two to four times higher than at 300°K. When compared to Rode's theoretical n *vs.* μ relationship for InP (49), the 77°K data indicate a compensation ratio $(N^+ + N^-)/n \simeq 4$. Also the observed carrier freeze-out indicates the presence of deep levels in these films which, as will be seen below, are not evident in the photoluminescent results.

Below 325°-350°C growth temperature, the 300°K mobility drops abruptly and then continues to decline gradually with decreasing growth temperature, while n is nearly constant at a high level of 10^{18} cm^{-3}. It is obvious from Fig. 12 that the electrical properties of the films deteriorate at the same growth temperatures (325°-350°C) at which the epitaxial layers undergo a transition from single crystal to polycrystal. This suggests that these two phenomena are related.

Photoluminescence measurements on InP epitaxial films offer a nondestructive means of determining their properties and quality. In addition to being able to determine impurity energy levels for the photoluminescence spectra, Joyce and Williams (27) have established the relationship between the half-width of the band-to-band photoluminescent peak at 1.410 eV (77°K) and the carrier concentration. For n-InP, they find a monotonic increase in the half-width as a function of carrier concentration for the range $10^{16} \leq n \leq 2 \times 10^{18}$. Photoluminescence measurements were performed on our epitaxial layers at 300° and 77°K. For this purpose, we used a 4880Å line from an Ar ion laser and a ½m single pass spectrometer whose resolution was 16Å. The power level of the 4880Å beam was accurately monitored in order to properly compare the photoluminescent peak heights from different samples. Figure 13 shows the photoluminescent spectra of the InP epitaxial layers grown from 450° to 285°C. The peak height of each spectrum in arbitrary units is indicated to the right of each peak and has been normalized to 1 mW input power. Each spectrum is plotted on a linear intensity scale, but for clarity of presentation they are displaced vertically by an arbitrary amount.

The spectrum of the layer grown at 450°C shown in Fig. 13a, appears to be very similar to Joyce and Williams' (27) undoped VPE sample where $\mu = 44{,}000$ cm^2 V^{-1} sec^{-1} at 77°K. As in Joyce and Williams' case, the half-width of the 1.410 eV peak is very narrow, characteristic of a carrier concentration $\leq 10^{16}$ cm^{-3}; also there is no evidence of any peaks below 1.410 eV, thus indicating the absence of any compensating acceptors. In their same high mobility sample, Joyce and Williams observed a hint of an exciton peak in the 80°K spectrum at slightly above 1.410 eV, which they attributed to the high quality of their sample. This exciton peak is not observed in Fig. 13a, suggesting that these MBE grown InP layers are not equal in quality to the best VPE material.

For layers grown at temperatures above 450°C, almost no change occurred in the spectrum as compared to Fig. 13a other than a slight narrowing in the half-width of the 1.410 eV peak. In contrast, those samples grown at lower temperatures (Fig. 13b-13e) show an increasing half-width for the 1.410 eV peak as the growth temperature is lowered. In Fig. 14 the half-width $\Delta E/E$ of the 1.410 eV band-to-band photoluminescent peak is plotted as a function of growth temperature. As in Fig. 12, a transition temperature is evident at about 350°C where the half-width increases abruptly with decreasing temperature. In view of the relation between $\Delta E/E$ and carrier concentration, it can be seen from Fig. 12 that the abrupt increase in $\Delta E/E$ is due to the sudden increase of carrier concentration below 350°C. Above 350°C, Fig. 14 indicates a gradual decrease in $\Delta E/E$ with increasing growth temperature, which is clearer evidence of the downward trend of the carrier concentration with increasing temperature as seen in Fig. 12.

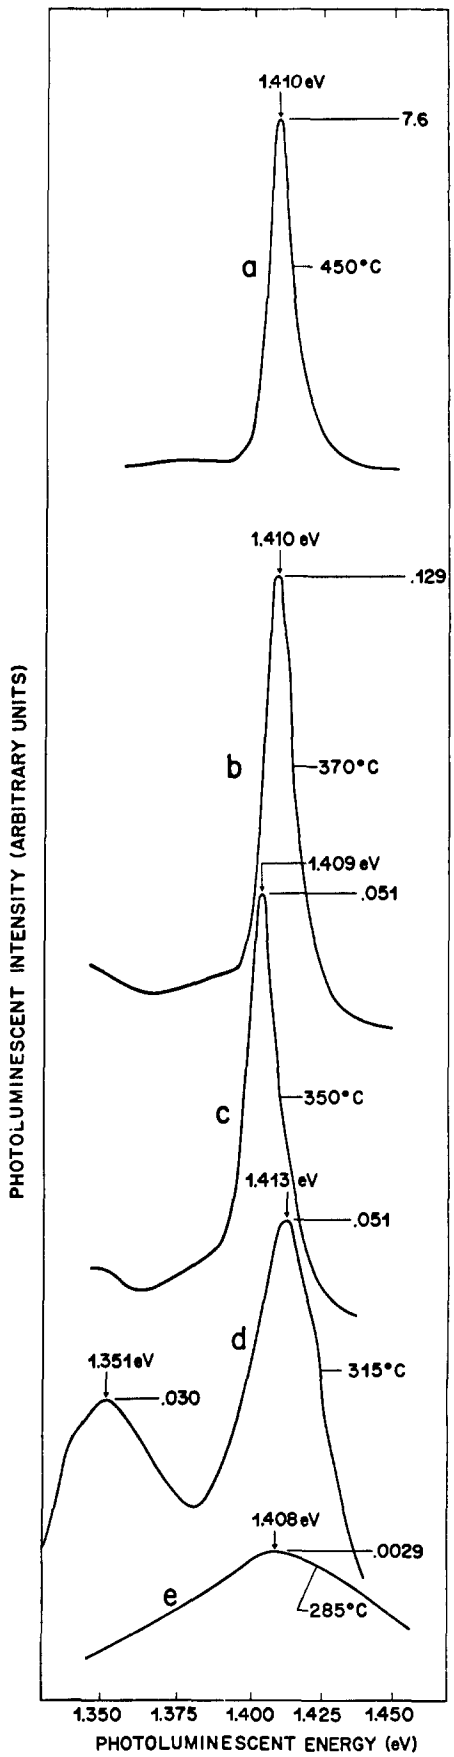

Fig. 13. Photoluminescent intensity spectrum at 77°K of $(\bar{1}\bar{1}\bar{1})$ InP epitaxial layers grown at various temperatures indicated on curves. Intensity scale is linear, but curves are displaced vertically for clarity so they do not overlap. Peak heights are indicated on curves. Argon ion laser line at 4880Å used for excitation.

Referring back to Fig. 13c and 13d, a lower energy peak (at 1.351 eV) appears in the spectrum corre-

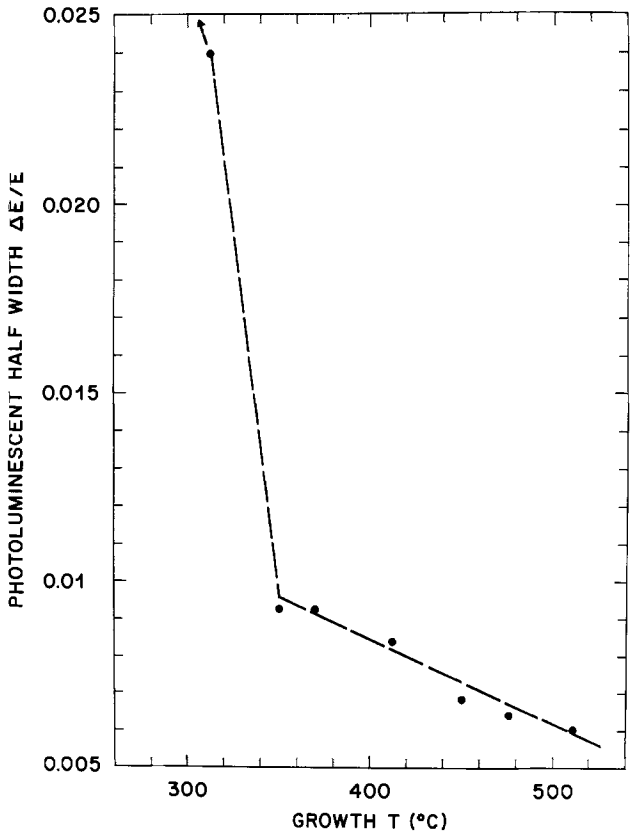

Fig. 14. Photoluminescent half-width ($\Delta E/E$) of InP epitaxial layers as a function of growth temperature. Data taken from Fig. 13.

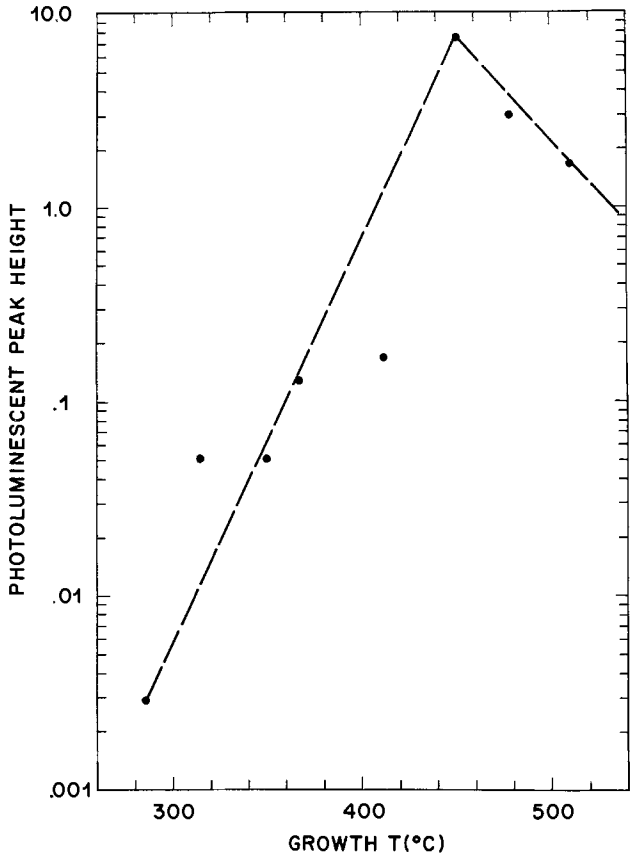

Fig. 15. Photoluminescent peak height (arbitrary units) of InP epitaxial layers as a function of growth temperature. Data taken from Fig. 13.

sponding to a growth temperature of 350°C and becomes pronounced at growth temperature of 315°C. This 1.351 eV peak is quite distinct from the 1.37 eV peak usually reported in the photoluminescence at 77°K for unintentionally doped InP (27-30). Furthermore, this 1.351 eV peak does not correspond to any known impurity level (28) in InP, nor has it been reported in the literature. Therefore, it appears that this 1.351 eV peak may be inherent to the MBE growth process at low substrate temperatures, and can be associated with the presence of defects. Peaks corresponding to defect structures have been seen in the photoluminescence spectrum of GaAs (31). The fact that the 1.351 eV peak is not evident in Fig. 13e (growth temperature of 285°C) may be ascribed to the very low photoluminescent efficiency of this sample and the consequent poor signal-to-noise ratio.

Figure 15 illustrates the dependence of the photoluminescence peak height on growth temperature. Because these results correspond to a constant pump power, Fig. 15 is also a plot of the photoluminescent efficiency *vs.* growth temperature. Although there is considerable scatter in the data due to different surface conditions from one sample to the next, the figure clearly shows a decrease of four orders of magnitude as the growth temperature is reduced from 450° to 285°C. No photoluminescent signal could be detected under any conditions from those samples grown below 285°C. The highest photoluminescent efficiency corresponds to a growth temperature near 450°C.

(111) and (100) Orientations—Preliminary Results

MBE growth of InP on the (111) In face of InP substrates was also studied. As mentioned earlier, a Syton chemo-mechanical polish was necessary in this case in order to prepare the substrate. The epitaxial layer was grown at 450°C at a growth rate of 0.5 μm/hr. An epitaxial layer was also grown on a $(\bar{1}\bar{1}\bar{1})$ semi-insulating substrate at the same time as a control. Tests on the control layer showed it to be typical of a 450°C run, as

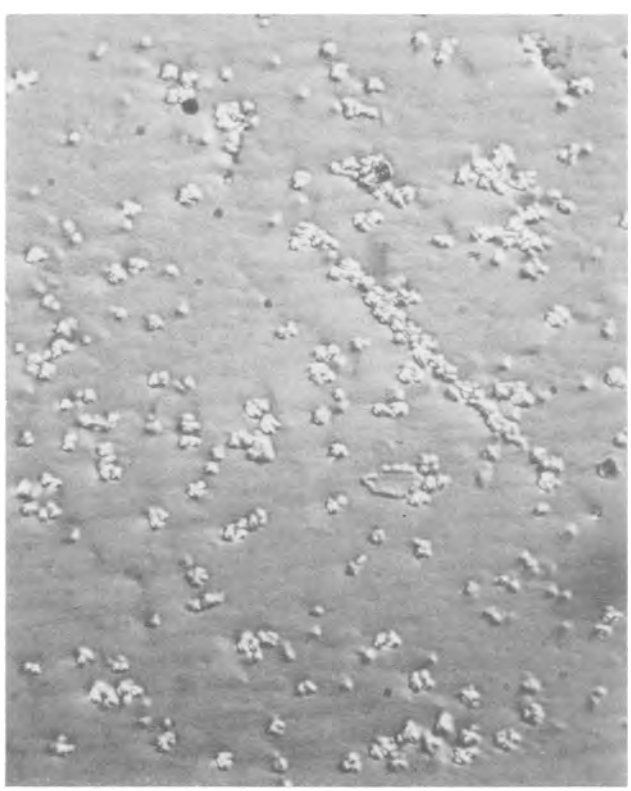

Fig. 16. Nomarski interference-contrast photograph of surface of InP epitaxial layer grown on (111) InP substrate (indium face) at 450°C (500×).

described earlier. Figure 16 is a Nomarski interference contrast photograph (500×) of the surface of the epi-

taxial layer grown on the (111) face. The distinguishing feature of the surface morphology, in this case, is the rather uniform distribution of small point imperfections. Probably these imperfections are associated with substrate damage produced by the chemomechanical surface preparation (32). The underlying surface structure as seen in Fig. 16 is relatively smooth and free of facets as compared to ($\bar{1}\bar{1}\bar{1}$) epitaxial layers (Fig. 6a-6c). It appears, therefore that relatively smooth and uniform epitaxial layers could be grown on the (111) face if a suitable chemical etch (comparable to Br:methanol for the $\bar{1}\bar{1}\bar{1}$ face) were found.

Epitaxial growth on (100) substrates is found to be markedly different than growth on the ($\bar{1}\bar{1}\bar{1}$) face. Orientation-dependent faceting is still observed, but on a much reduced scale. For some choices of substrate orientations near the (100) essentially smooth featureless films are obtained over the entire sample area (0.5 × 0.5 cm) at reduced growth rate.

Discussion

Growth and Morphology

From these results it appears that single crystal epitaxial layers grown on the ($\bar{1}\bar{1}\bar{1}$), (111), and (100) substrates exhibit entirely different morphologies. Highly faceted, orientation-dependent morphology is obtained for ($\bar{1}\bar{1}\bar{1}$) layers, while the (111) layers appear to have a less faceted nature and the (100) layers are relatively featureless. The implication of these facts for device application is that MBE growth on the ($\bar{1}\bar{1}\bar{1}$) face is least promising of the three orientations. The extreme sensitivity of the surface morphology to substrate orientation has been shown in Fig. 5 and 7. On the basis of this we conclude that smooth uniform layers can grow only if the substrate orientation is held within ±5 min over the entire surface. Needless to say, unless smooth layers can be grown, they cannot be used as waveguides, and it is also possible that the surface roughness will have a detrimental effect on their electrical properties. Although the results of MBE growth on the (111) and (100) faces are only preliminary, it appears that they are to be preferred for device applications.

In the case of the ($\bar{1}\bar{1}\bar{1}$) orientation, we have shown the importance of substrate temperature as a parameter in epitaxial growth of InP. All these results refer to a standard flux level corresponding to a growth rate of 0.5 μm/hr. It is well known, however, that the flux level plays an important role in epitaxial growth (33). For this reason, a few layers were grown on ($\bar{1}\bar{1}\bar{1}$) substrates at higher and lower flux levels. At 450°C substrate temperature, the flux level was lowered by a factor of ten with no apparent effect on the epitaxial growth. The flux level was also increased by a factor of four over the 0.5 μm/hr growth rate and a layer grown at a substrate temperature of 400°C. For this run, the P_4:In ratio was maintained at the normal level of ≥10:1 in order to obtain stoichiometric growth. The substrate temperature was chosen to be 400°C to further insure against the buildup of In droplets on the surface. In this case, the morphology of the resulting layer resembled that of the polycrystalline layer shown in Fig. 6d and 6e. However, the layer shown in Fig. 6d and 6e was grown under standard flux conditions (0.5 μm/hr) at 315°C. The 300°K electrical measurements made on this high flux sample give $\mu = 400$ cm^2 V^{-1} sec^{-1} and $n = 6 \times 10^{17}$ cm^{-3}, which corresponds to the electrical properties of a layer grown at about 300°C (see Fig. 12) at the standard flux rate. It appears, therefore, that the effect of growing at a higher flux is to shift the polycrystalline-crystalline transition to higher temperatures. This observed behavior is reasonable on theoretical grounds. Moazed (34) has applied nucleation theory to epitaxial growth and finds that decreasing flux should produce a decrease in the epitaxial temperature, *i.e.*, the temperature corresponding to the transition between epitaxial and randomly oriented growth (polycrystalline growth). In particular, he concludes that at low supersaturation (corresponding to low flux rates) only preferred epitaxial sites will act as nucleation sites, whereas at high supersaturation, random nucleation is more likely. In addition, he concludes that a decrease in substrate temperature lowers the ratio of epitaxial nucleation to random nucleation and therefore epitaxy is not favored at low substrate temperatures. This latter result is also in agreement with our observation. Experimentally, the increase of epitaxial temperature with increased growth rate has also been observed by Cho (35) in the MBE growth of GaP on (111) CaF_2, and by Krikorian and Sneed (36) for the growth of Ge films by evaporation onto (111) Ge and (111) CaF_2 substrates at a background pressure of 10^{-8} Torr.

It is interesting to compare the morphology obtained for epitaxial growth on ($\bar{1}\bar{1}\bar{1}$) InP and ($\bar{1}\bar{1}\bar{1}$) GaAs. In earlier work in the same MBE system, we were able to grow essentially smooth, featureless epitaxial layers of GaAs on ($\bar{1}\bar{1}\bar{1}$) GaAs substrates at 600°C. In other words, no faceting as seen in Fig. 5 for ($\bar{1}\bar{1}\bar{1}$) InP was seen for ($\bar{1}\bar{1}\bar{1}$) GaAs. Smooth, featureless epitaxial ($\bar{1}\bar{1}\bar{1}$) GaAs layers have also been reported by Cho (2, 4) and Gonda *et al.* (5). It is interesting to observe that on (100) GaAs, Gonda *et al.* report pyramidal epitaxial growth at substrate temperatures in excess of 600°C, smooth featureless growth at substrate temperatures of 480°C, and polycrystalline growth at a substrate temperature of 430°C. This suggests that in GaAs there may exist a range of substrate temperatures corresponding to smooth featureless growth lying somewhere between the polycrystalline and faceting temperature regions. If such a region exists for InP, we have been unable to find it in exploring the substrate temperature range from 220° to 510°C in 30° increments. It appears that the mechanism responsible for faceting in InP is markedly different than for GaAs and may be an interesting subject for further study.

Structure of Epitaxial Layers

RED results.—Our RED results on ($\bar{1}\bar{1}\bar{1}$) InP differ in two important ways from those reported by Cho on ($\bar{1}\bar{1}\bar{1}$) GaAs (2, 4). Firstly, Cho's RED pattern obtained from the heated substrate before growth is a spot pattern with prominent Kikuchi lines. In contrast to this, we see the streaked pattern shown in Fig. 4. As noted above, our substrates are routinely sputtered to insure a contamination-free surface prior to growth. According to Cho (46), the substrate RED patterns shown in Ref. (2) and (4) correspond to unsputtered surfaces. Moreover, in agreement with our observations, Cho finds that sputtered substrate surfaces tend to yield streaked RED patterns. A possible explanation of these results is that thermal etching of the substrate prior to sputtering roughens the surface and gives it a three-dimensional aspect. Subsequent sputtering may tend to smooth the surface so that a two-dimensional streaked RED pattern results. A second difference between Cho's GaAs RED results and our RED on InP is that after many monolayers of GaAs are grown on the ($\bar{1}\bar{1}\bar{1}$) GaAs face, a diffraction pattern corresponding to ($\bar{1}\bar{1}\bar{1}$)-$\sqrt{19}$ surface reconstruction is seen by Cho (4), while under similar circumstances for InP we only see the diffraction pattern of the unreconstructed surface (Fig. 8a). The failure to observe the ($\bar{1}\bar{1}\bar{1}$)-$\sqrt{19}$ structure in InP is not understood; however, the difference in surface forces of GaAs *vs.* InP, as well as different impurity reactions, may affect the surface reconstruction differently in these two cases. For example, it is known (47) that the silicon ($\bar{1}\bar{1}\bar{1}$)-$\sqrt{19}$ structure is seen when Ni is present as a contami-

nant, while Cho (4) finds the $(\bar{1}\bar{1}\bar{1})$-$\sqrt{19}$ structure on apparently contamination-free GaAs.

X-ray results.—The x-ray diffraction patterns proved to be very useful in determining the structure of the polycrystalline InP layers grown below 325°-350°C. Referring back to the diffraction pattern of the layer grown at 220°C (Fig. 11), it is seen that the pattern shows a number of large, diffuse Laue spots in addition to sharper Laue spots (37). Analysis shows that the most prominent diffuse spots in Fig. 11 are produced by the intense CuKα component of the primary x-ray beam. These large, intense diffuse spots are not seen in the x-ray diffraction pattern of the single crystal layer grown at 450°C (Fig. 8b). Their presence in Fig. 11 is perhaps due to a slight spread in the orientations of the crystallites in the 220°C InP layer, which allows the Bragg condition to be satisfied in these several directions for the CuKα line. Examination of this same InP layer with white tungsten x-radiation produced a Laue diffraction pattern which was free of the intense diffuse spots. In addition to sharp Laue spots, the tungsten pattern contained a symmetric array of less intense diffuse spots (some of which are evident in Fig. 11). Analysis of the tungsten pattern disclosed that these diffuse spots corresponded to twinning on the $[\bar{1}\bar{1}\bar{1}]$ axis. Furthermore, the angular size of the spots (~2°) indicates a characteristic size of ~60Å for the twinned regions. Such a "microtwin" is a well-known type of stacking fault (38). Examples of various kinds of stacking faults on (111) planes of the fcc lattice are given by Barrett (39). From this point of view, the 60Å characteristic size would correspond to the repeat distance in the stacking fault plane. A general conclusion which may be drawn from the x-ray diffraction data taken on those layers grown below 325°-350°C is that the layers are composed of well-aligned crystallites which have increasing stacking fault density as the growth temperature is lowered. The tendency for stacking fault density to increase with decreasing growth temperature has been observed in VPE Si films (40) and Ge films vapor deposited on CaF_2 under UHV (10^{-9}- 4×10^{-7} Torr) conditions (41).

Electrical and Optical

The most striking feature of the electrical properties of our epitaxial layers (Fig. 12) is the sharp transition which occurs in the mobility and carrier concentration in the 325°-350°C growth temperature range. It is known that the grain size in polycrystalline films can have a strong influence on their mobilities, but the effect does not become pronounced until the grain size falls below 1 μm (40). In Fig. 12, the mobility drops abruptly by an order of magnitude in the temperature range from 315° to 285°C, while the grain size decreases from ~3 to ~1 μm, respectively. For this range of grain size, the largest change in mobility that could be expected from Ref. (40) is a factor of 2 or 3. Furthermore, the large change in carrier concentration which accompanies the mobility transition cannot be ascribed to grain size. One possible cause of the abrupt decrease in carrier concentration for growth temperatures from 300° to 350°C in Fig. 12 may be a decrease of the sticking coefficient with increasing temperature of an unintentional n-type dopant coming from the source materials (In or P), the oven structures, or heated surroundings. However, we recall that the growth run at a substrate temperature of 400°C at four times normal growth rate (2 μm/hr) resulted in a layer where $n = 6 \times 10^{17}$ cm^{-3} and $\mu = 400$ cm^2 V^{-1} sec^{-1}. This result rules out any sticking coefficient explanation because a smaller rather than larger carrier concentration would be predicted for growth at 400°C. The most reasonable explanation of the transition in the electrical properties shown in Fig. 12, as well as the high flux results stated above, involves the appearance of defect structures (42) such as stacking faults with decreasing substrate temperatures. We have already presented x-ray evidence for the presence of stacking faults in those layers grown below 325°-350°C and there is experimental evidence that stacking faults will lead to the kind of electrical behavior shown in Fig. 12. For example, Sloope and Tiller (43) observe an almost identical transition in the electrical properties of (111) Ge (p-type) films grown on CaF_2 as a function of growth temperature. They correlate their results with the presence of defects such as stacking faults or dislocations. According to Sloope and Tiller, the defects may give rise to several acceptor states (singly or doubly ionized) which increase the carrier concentration and act as scattering sites. In our case, the photoluminescent data (Fig. 13) show a peak at 1.351 eV which first appears at a growth temperature of 350°C and is very prominent at 315°C. This occurs just at the transition between crystalline and polycrystalline layer growth and hence it appears that this peak also arises from crystal defects such as stacking faults, etc. In analogy with Sloope and Tiller's proposal, it is suggested that the defects in those InP layers grown below 350°C produce multiple energy levels in the bandgap. In addition to the level (probably an acceptor) at ~60 meV (corresponding to the 1.351 eV peak), there must be a majority of shallow donor levels to account for the increase of n-type conductivity observed in these samples. It should be pointed out that the ~60 meV level we observe in those InP layers grown below 350°C does not correspond to any reported donor or acceptor level in InP (16, 27, 30, 44, 45). The closest acceptor level is Cd at 50 meV, which is highly unlikely in MBE grown layers due to its low sticking coefficient.

Conclusion

We have demonstrated that from elemental molecular beam sources single crystal InP epitaxial layers can be grown on the $(\bar{1}\bar{1}\bar{1})$ face of InP substrates in a temperature range from 350° to 510°C. On the $(\bar{1}\bar{1}\bar{1})$ face, faceting occurs depending on the exact misorientation from the $(\bar{1}\bar{1}\bar{1})$ axis. The quality of the films as determined from the mobility and photoluminescence compares favorably with that of bulk InP. Below 350°C the epitaxial layers become aligned polycrystals with an increasing density of defects, *i.e.*, stacking faults, with lowered growth temperature. Also at these low growth temperatures the carrier concentration becomes very high and the mobility drops due to the increase in the number of crystal defects. The photoluminescence data show a 60 meV level coming in below growth temperatures of 350°C associated with the increase of defects. The observed structural and electrical properties of our layers as a function of growth temperature are in general agreement with the results reported by others for epitaxial deposition of Si, Ge, and GaAs films. Single crystal InP epitaxial layers have also been grown on the (111) and (100) faces of InP and exhibit very little faceting. Relatively smooth and featureless growth has been observed in the (100) face, suggesting that this face may be the most promising for device application. The electrical properties and doping of the layers grown on the (100) face are presently being studied.

Acknowledgments

We would like to thank W. Wiegmann, M. Ilegems, A. Cho, A. Gossard, E. E. Chaban, and J. Robinson, Jr. for help and advice in planning the MBE system. We want to acknowledge the valuable help of E. Buehler in growing the single crystal InP substrates. We also wish to express our appreciation to D. L. Rode for helpful discussions on surface morphology and for measurement of pyramid height and slope on our $(\bar{1}\bar{1}\bar{1})$ epitaxial layers. We would like to especially thank Mrs. A. A. Pritchard for technical assistance.

37. As mentioned previously, the primary x-ray beam was near grazing incidence on the epilayer surface in order to minimize scattering from the substrate. However, the spots to the right in Fig. 11 are forward scattered and therefore correspond to relatively small Bragg angles. Thus many of these spots are produced by short wavelength, highly penetrating components of the primary beam. For this reason many of the sharp spots in the right one-third of Fig. 11 are characteristics of the single crystal substrate. In contrast, the spots to the left in Fig. 11 corresponded generally to strongly absorbed, longer wavelength x-rays, and are characteristic of the grown layer.

Damage Effects in Boron and BF_2 Ion-Implanted p^+-n Junctions in Silicon

B. A. MacIver and E. Greenstein*

General Motors Corporation, Research Laboratories, Warren, Michigan 48090

ABSTRACT

Boron- and BF_2-implanted p^+-n junctions are compared. At 50V reverse bias BF_2-implanted diodes, fabricated in <100> silicon and annealed in a wet O_2 atmosphere, typically exhibited two orders of magnitude lower leakage than B-implanted diodes on the same wafer. The improved reverse I-V characteristics of the BF_2-implanted junctions are related to the BF_2 implant damage. Excessive leakage current in B-implanted diodes is correlated with oxidation-induced defects using scanning electron microscopy. Argon damage implant experiments indicate that an amorphous surface region caused by the BF_2 implant prevents the propagation of defects into the junction region during anneal in a wet oxygen atmosphere.

The annealing behavior of BF_2 implants into silicon has been studied by Müller *et al.* (1). Prussin (2) has related the leakage currents of n^+-p^+ diodes prepared on B- and BF_2-implanted silicon surfaces to oxidation-induced dislocations which he refers to as ternary defects. He has also shown that certain combinations of implant and anneal treatment can minimize ternary defect generation and n^+-p^+ junction leakage. The present work concerns the effects of BF_2 implants on the electrical properties of p^+-n junctions in silicon when BF_2 is substituted for boron to implant the p^+ region.

This paper presents experimental results relating implant damage, annealing atmosphere, and crystal orientation to junction leakage. We found that the leakage current is substantially reduced when large fluences (*i.e.*, $\geq 10^{15}/cm^2$) of BF_2 ions are substituted for B ions for implants into <100> n-type silicon annealed in wet oxygen. Sirtl etching was combined with scanning electron microscopy to correlate residual damage and junction leakage.

Experimental Procedure

Arrays of 1.14×10^{-3} cm^2 circular diodes were fabricated in <100> and <111> oriented, 1-2 Ω-cm, n-type, polished silicon. A 7000Å thick thermal oxide was grown and patterned as a mask for the subsequent implants. One-half of each wafer was implanted with $2 \times 10^{15}/cm^2$ of 50 keV B. The other half was implanted with either 144 keV BF_2 or 50 keV B plus a damage implant of F, Ne, or Ar. The damaging species were implanted with energies of 100, 100, and 144 keV, respectively. The wafers were positioned at 7° from the normal to the beam axis to minimize channeling.

When all implants were completed the wafers were annealed at 1100°C in dry O_2, dry N_2, or sequential dry-wet-dry O_2 for 100 min to activate and redistribute the boron. The sequential anneal consisted of 30 min in dry O_2, then 60 min in wet O_2 followed by 10 min in dry O_2, and is referred to herein as a wet oxidation. The diodes were completed using conventional processing. Aluminum contacts were applied within the diode perimeter and sintered at 500°C for 10 min in forming gas. Diode samples were next probed with 80V reverse bias applied ($V_{BD} \approx 120V$) and the leakage current was measured. Sections of each wafer region were then chemically etched to remove the metal and the oxide. These sections were Sirtl etched for 30 sec and scanning electron micrographs were made of the silicon surface in the junction region.

Results and Discussion

B- and BF_2-implanted diodes.—Fig. 1 shows typical reverse I-V characteristics of B- and BF_2-implanted diodes in <100> silicon that were annealed using the wet oxidation process. The BF_2-implanted diode I-V curve has near ideal slope (≈ 0.6) out to avalanche at just over 100V. The B-implanted diode from the same wafer has a rather soft I-V curve above 10V and at 50V the leakage current is almost two orders of magnitude higher than that of the BF_2-implanted diode.

Scanning electron micrographs of the Sirtl-etched surfaces of diodes of Fig. 1 are shown in Fig. 2. The B-implanted diode (Fig. 2a) has a high density of deep damage dislocation clusters. The BF_2-implanted diode (Fig. 2b) is completely free of gross damage defects although a fine matrix of smaller overlapping defects is evident. Figures 1 and 2 show a correlation between leakage current and dislocation clusters. This is in agreement with earlier reports (3, 4) that precipitates or strain in oxidation-induced defects give rise to excessive leakage in p-n junctions.

Anneal atmosphere and orientation effects.—Diodes prepared by implanting B into <100> silicon and an-

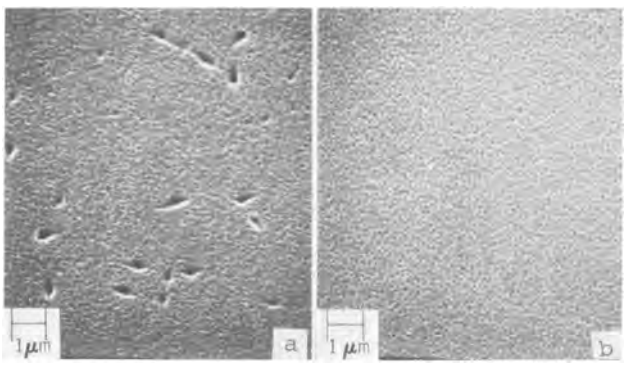

Fig. 2. Scanning electron micrographs of Sirtl-etched surfaces of diodes for which reverse I-V curves are given in Fig. 1. (a) Implanted with 2 × 10^{15}/cm^2 B at 50 keV and (b) implanted with 2 × 10^{15}/cm^2 BF_2 at 144 keV. The diodes were annealed at 1100°C; 30 min dry O_2, 60 min wet O_2, 10 min dry O_2.

nealing at 1100°C for 100 min in dry O_2 or in dry N_2 had low leakage characteristics resembling that of Fig. 1, curve (b). Likewise diodes prepared by implanting B into <111> silicon and subjected to a wet oxidation anneal also exhibited low leakage. Scanning electron micrographs of these Sirtl-etched diode surfaces are shown in Fig. 3.

The dry O_2 and N_2 annealed samples (Fig. 3a and 3b) show none of the damage dislocation clusters that appear in wet O_2-annealed, B-implanted, <100> surfaces (*e.g.*, Fig. 2a). Prussin (5) has shown that wet oxidation enhances defect expansion and Prussin and Fern (6) have shown that a dry N_2 anneal reduces structural defects and n^+-p^+ junction leakage in bipolar transistors with implanted bases. These results suggest that a wet oxidizing anneal atmosphere stimulates the growth of defects that contribute to our p^+-n junction leakage.

The <111> oriented sample annealed using the wet oxidation process (Fig. 3c) shows a large defect density although leakage currents for these diodes were as low as those of BF_2-implanted diodes. Seidel *et al.* (7) have reported less gain degradation due to oxidation-induced defects in bipolar transistors fabricated on <111> silicon than in those fabricated on <100> silicon. They suggest that the differences are associated with either the orientation differences of oxidation-induced defects or their depth distribution. It appears from Fig. 3c, that the low leakages we observe in our B-implanted junctions on <111> silicon may be due to the fact that the defects lie mainly in the <111> plane and do not penetrate the junction.

Damage effects.—To clarify the role of BF_2 in reducing dislocation clusters and leakage current, diodes were prepared by implanting 2 × 10^{15}/cm^2 of 50 keV B together with various fluences or fluorine, neon, or

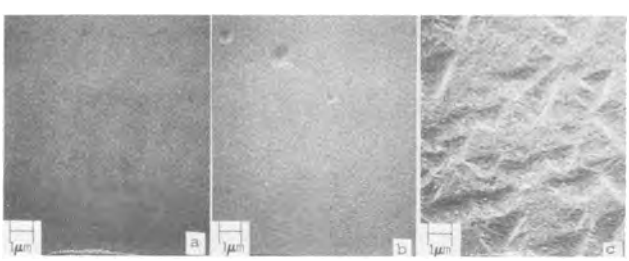

Fig. 3. Scanning electron micrographs of Sirtl-etched boron-implanted diode surface. (a) <100> Silicon, dry O_2 annealed at 1100°C for 100 min, (b) <100> silicon, dry N_2 annealed at 1100°C for 100 min, and (c) <111> silicon, 1100°C anneal, 30 min dry O_2, 60 min wet O_2, 10 min dry O_2.

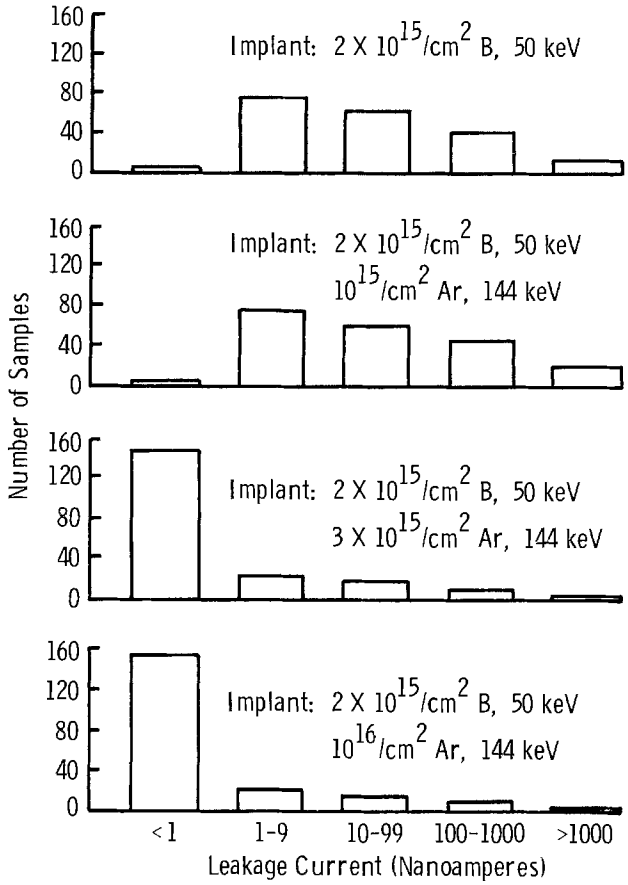

Fig. 4. Histograms of leakage currents at −80V of B-implanted diodes in <100> silicon showing the effect of additional argon damage. The implants were annealed at 1100°C; 30 min in dry O_2, 60 min in wet O_2, 10 min in dry O_2.

argon and annealed using the wet oxidation process. Only the results for 144 keV Ar are discussed here but they apply equally well to 100 keV F and to 100 keV Ne. For leakage current evaluation the diodes were measured at 80V reverse bias.

Histograms of diode leakage current of B-implanted diodes and for B-implanted diodes with selected fluences of implanted Ar are plotted in Fig. 4. These histograms are significant for two reasons:

1. They show that an additional Ar fluence also reduces diode leakage so the reduced leakage observed with BF_2 implants can be assumed to be due to the damage provided by the heavier BF_2 ion.

2. The reduction in leakage current is achieved only when the damage fluence is 3 × 10^{15}/cm^2 or larger. This is close to the 100 keV Si fluence (*i.e.*, 5 × 10^{15}/cm^2) Bauer (8) found necessary to obtain an amorphous layer in silicon implanted with 10^{15}/cm^2 B. These results suggest then, that in order to eliminate dislocation clusters and the attendant excess diode leakage the implant damage must be sufficient to drive the surface amorphous.

Further evidence for the amorphous argument is seen in the scanning electron micrographs of Fig. 5. These are Sirtl-etched surfaces of B-implanted diodes with three different Ar damage fluences. At the 10^{14}/cm^2 Ar fluence level there is little difference from an undamaged diode (see Fig. 2a). At the 10^{15}/cm^2 fluence level dislocation clusters are still clearly evident though not as pronounced. However, at the 10^{16}/cm^2 fluence level dislocation clusters have completely disappeared. Nelson (9) has reported that when a B-implanted silicon surface is driven amorphous and then annealed it is relatively free of crystalline defects.

It should also be noted that the fluence required to drive a silicon surface amorphous has been shown (10) to decrease with increasing flux. In a cursory experi-

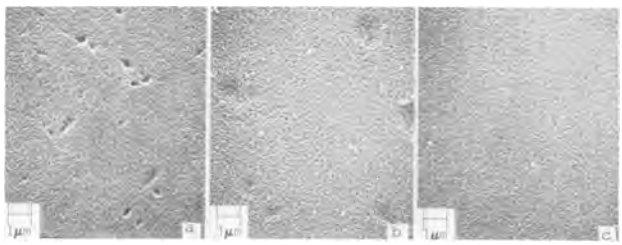

Fig. 5 Scanning electron micrographs of Sirtl-etched boron-implanted diodes with various fluences of argon added. (a) 1×10^{14}/cm^2 144 keV Ar, (b) 1×10^{15}/cm^2 144 keV Ar, and (c) 1×10^{16}/cm^2 144 keV Ar. The diodes were annealed at 1100°C; 30 min dry O_2, 60 min wet O_2, 10 min dry O_2.

ment we found that diodes implanted with 2×10^{15}/cm^2 of BF_2 at a flux of 3 μA/cm^2 had significantly lower leakage than diodes implanted with the same fluence of BF_2 at a flux of 1 μA/cm^2. For all other work reported here B was implanted at 0.2 μA/cm^2 and BF_2 and Ar were implanted at 2 μA/cm^2.

Based on the progressive decrease in dislocation clusters as the Ar damage fluence is increased (Fig. 5) one might expect a continuous decrease in leakage current with increasing damage fluence. The leakage current data of Fig. 4 do not show such a trend. A possible explanation is provided by the work of Ravi *et al.*, who show that diode leakage characteristics depend on the voltage thresholds of individual defects and that these are independent of the size and, to some extent, the density of defects.

Summary and Conclusions

Residual surface damage in B-implanted p^+-n junctions in silicon nucleates dislocation clusters which expand during a subsequent 1100°C anneal in a wet oxidizing atmosphere. If the junction is in <100> silicon the dislocation clusters give rise to excess leakage when the junction is reverse biased. The excess leakage is probably due to strain introduced during the oxidation process or to metal or SiO_2 precipitates on the oxidation-induced defects.

However, when sufficient damage is provided through the implantation of BF_2 or B plus another damaging ion, the silicon surface becomes amorphous. The presence of the amorphous surface layer during subsequent anneal in a wet oxidizing atmosphere inhibits the growth of defects which contribute to the junction leakage current.

Acknowledgments

The authors wish to acknowledge the contributions of others. Mr. T. Schreiber provided scanning electron micrographs. Ms. B. J. Vannoy assisted in device processing. Dr. M. C. Steele supported the work and participated in helpful discussions.

ABSTRACT

The diffusion of randomly implanted boron in silicon during high temperature processing was studied using a $10^{15}/cm^2$ dose of 300 keV boron ions. An anodization-etch sheet-resistance method was used for measuring the diffusion profiles. A computer simulation, utilizing the Crank-Nicolson finite-difference analog, was used to model the diffusions and to aid in interpreting the data. Effects of SiO_2 capping and various ambients (N_2, H_2, and N_2-1% O_2) on boron out-diffusion were investigated. The experiments showed that out-diffusion at 1000°C in N_2 is negligible, but out-diffusion at 1200°C in H_2 is quite significant. A self-capping effect that prevents out-diffusion was observed in the N_2 and N_2-1% O_2 atmospheres at 1200°C.

The use of ion implantation in semiconductor device manufacture is an attractive alternative to conventional diffusion. One advantage of ion implantation is the accurate control of the total number of implanted ions. The implant serves as a predeposition which is then followed by a drive-in diffusion to achieve the desired impurity distribution. The implant concentration profiles of common dopants in silicon are fairly well known (1, 2). When the implant is subjected to heat-treatment, however, the effects of the furnace ambient (3) and the capping material on the impurity distribution (4, 5) obtained in the drive-in step are not as well understood.

The implanted ion dose and the implant profile can be greatly affected if significant out-diffusion occurs at the surface of the silicon during heat-treatment. The amount of out-diffusion depends on the evaporation coefficient, h, which relates the flux in the solid at the surface to the surface concentration (6). In principle, h can vary from zero, implying no evaporation at the surface, to infinity, implying that all the dopant reaching the surface will evaporate. The actual values of h depend upon such factors as temperature and ambient gases. Langer and Goldstein (7) found experimentally that over the temperature range from 1190° to 1380°C the evaporation coefficient of boron from silicon in a hydrogen ambient is given by

$$h = 27.96 \exp(-2.481/kT)\,\text{cm/sec} \qquad [1]$$

The purpose of the present study was to investigate experimentally and theoretically the distribution of implanted boron in silicon after the drive-in diffusion step. The effects of oxide capping and of various ambient atmospheres (N_2, H_2, N_2-1% O_2) upon out-diffusion were studied. Although the impurity profile produced by implantation is often approximated by a Gaussian distribution, in agreement with published data (8) we found that the Gaussian is not an accurate representation of the implanted profile. Therefore, a computer model, using finite-difference solutions to the diffusion equation, was employed to calculate the redistribution of the implanted ions during the drive-in step.

Computer Simulation

The diffusion of boron in silicon can be described by Fick's second law

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(D\frac{\partial c}{\partial x}\right) \qquad [2]$$

where $c(x, t)$ is the concentration of boron and D is the diffusion coefficient. If D is not a function of concentration, Eq. [2] reduces to

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} \qquad [3]$$

This equation has been solved analytically for certain well-behaved initial profiles, but for the case of an implanted profile such a solution is not available. The most useful of the methods for solving differential equations such as the diffusion equation utilize finite-difference techniques. One of these, the Crank-Nicolson finite-difference analog, as described by von Rosenberg (9), is second-order correct with respect to both independent variables and, in addition, stable over a wide range of increments of the variables. We used the Crank-Nicolson method for computer simulation of the diffusion process. Two types of boundary conditions were considered. The first specified an out-diffusion flux at the surface given by

$$hC = -D\frac{\partial c}{\partial x}\bigg|_{x=0} \qquad [4]$$

where C is the surface concentration and $\frac{\partial c}{\partial x}\Big|_{x=0}$ is the concentration gradient at the surface. The second boundary condition specified no out-diffusion, corresponding to $\frac{\partial c}{\partial x}\Big|_{x=0} = 0$.

Experimental Procedure

The experiments were performed on 1¼ in. diam wafers of n-type, (111) silicon with a background phosphorus concentration of approximately 10^{15} atoms/cm^3. Each wafer was implanted with a boron dose of 10^{15} atoms/cm^2 at 300 keV. A random implant was achieved by tilting the sample 7° off the <111> direction about an axis 10° to the [110] flat.

To obtain boron concentration profiles, each sample was anodized and etched (10) to strip away thin layers of silicon and allow the use of differential sheet-resistance measurements. Anodization was performed in a water-cooled bath, at 21°C, which contained an elec-

Key words: implantation, capping, redistribution, annealing, impurities.

trolyte of 1.1g of potassium nitrite in 100 ml of tetrahydrofurfuryl alcohol. A platinum-foil cathode was used and a copper-plated clip held the wafer in the electrolyte. The thickness of the oxide produced was measured by ellipsometry to be 925 ± 50Å. After the oxide film was stripped and the sample rinsed and dried, the sheet resistance was measured in darkness with a linear four-point probe placed at the center of the wafer. No size correction was used since the probe spacing was only 0.040 in. The total concentration profile was measured by removing approximately 400Å of silicon in each of 40 anodization-etch steps.

The data obtained by the profiling were in the form of sheet resistances at known distances from the original surface. The data reduction was performed with a computer program (11) that derives the values of resistivity, $\rho(x)$, from sheet resistance, $\rho_s(x)$, by using the expression (12)

$$\rho(x)^{-1} = \frac{1}{0.4343\,\rho_s(x)} \frac{d}{dx} [\log_{10} \rho_s(x)] \qquad [5]$$

The resistivity profiles were converted to concentration profiles by using a fifth-order approximation to Irvin's data for hole mobility in silicon (13).

The diffusion times and temperatures to be used were calculated with the computer simulation program using a Gaussian distribution as the initial condition. To obtain initial profiles, two of the implanted wafers were annealed to remove the initial damaged regions in 2 liter/min dry nitrogen for 30 min at 950°C in a tube whose cross-sectional area was 24 cm². According to the above calculation, no measurable diffusion of boron should occur during this time period. For profiles at 1000°C, two wafers were diffused in 1 liter/min dry nitrogen for 2 hr 11 min and 14 hr 45 min. Two other wafers were capped with 5000Å of vapor-deposited SiO_2 to prevent out-diffusion. In order to prevent diffusion during capping, the oxide deposition was performed at a low temperature, 420°C, using the following reaction of silane and oxygen

$$SiH_4 + 2\,O_2 \rightarrow SiO_2\ (\text{solid}) + 2H_2O$$

These wafers were then diffused in a 2 liter/min ambient of 99% nitrogen-1% oxygen at 1200°C, one for 30 min and the other for 60 min. As controls, two uncapped implanted wafers were diffused under the same conditions. Three other uncapped samples were diffused at 1200°C for 60 min in the following ambient atmospheres: pure H_2 at 20 liter/min, 99% nitrogen-1% oxygen at 2 liter/min, and pure N_2 at 4 liter/min.

Computer calculations of boron concentration profiles were performed for the same times and temperatures as the experimental runs. A comparison of calculated and measured profiles was then made. The values used for the diffusion coefficient of boron in silicon were calculated from the expression given by Kendall and DeVries (14) with $D_o = 1.4$ cm²/sec and $Q = 3.5$ eV, which yields $D_{1000°C} = 1.83 \times 10^{-14}$ cm²/sec and $D_{1200°C} = 1.40 \times 10^{-12}$ cm²/sec.

Results and Discussion

The initial profile for boron, measured after the sample was annealed at 950°C for 30 min in a 2 liter/min dry N_2 ambient to activate the boron acceptors, is shown in Fig. 1. The curve is Gaussian but it does exhibit a high surface concentration. This effect was observed for both the initial profile samples. Because of some inconsistencies in the sheet-resistance data within the first quarter micrometer, the concentration data were smoothed in this region. The smoothing led to an error under 50% in the surface concentration and had no effect on the final computed profiles. A high surface concentration has been reported by Davies (17), who used junction depth measurements for measuring implanted boron profiles. Values of the range, R, and straggle, σ, were 7000 and 1000Å, respectively, and compare favorably within experimental limits to the LSS

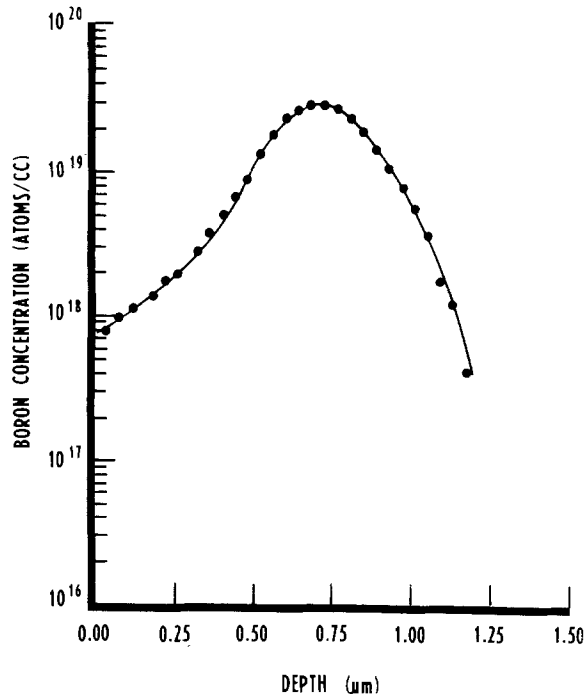

Fig. 1. Initial boron profile obtained after 950°C anneal for 30 min. Solid line is computer fit to experimental points.

(15) values, calculated using Eisen's corrections (2), of 6800 and 1000Å, respectively.

The profiles measured after annealing at 1000°C in N_2 for 2 hr 11 min and for 14 hr 45 min are shown in Fig. 2 and 3, respectively. Computer simulations using h values of 0 cm/sec and 10^{-9} cm/sec are also plotted. It is impossible within the resolution limits of the experiment to determine the value of h for best fit from the 2 hr 11 min curves. It is, however, evident from the 14 hr 45 min curves that the value of h is much smaller than 10^{-9} cm/sec. A good fit is obtained with $h = 0$ and is indistinguishable from that obtained for $h \leq 10^{-10}$ cm/sec, indicating that for these conditions no out-diffusion occurs. No oxide or nitride was observed on the sample surfaces after diffusion.

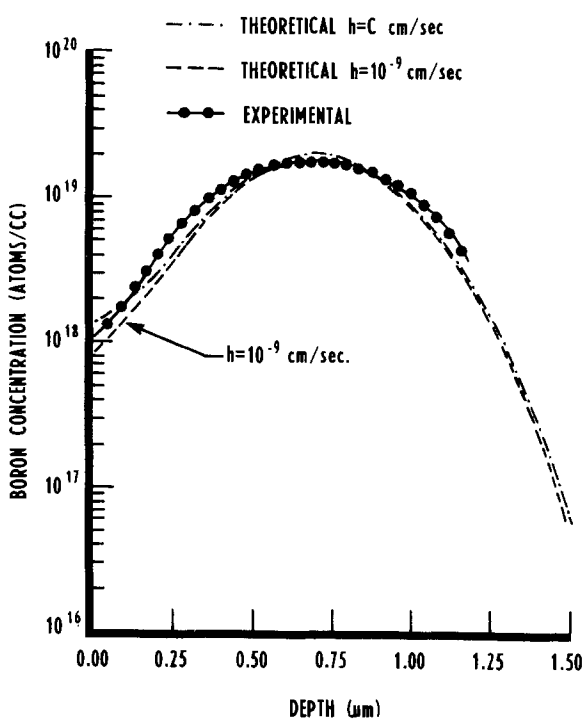

Fig. 2. Boron profile after diffusion at 1000°C for 2 hr 11 min in N_2. The parameter h is the evaporation coefficient.

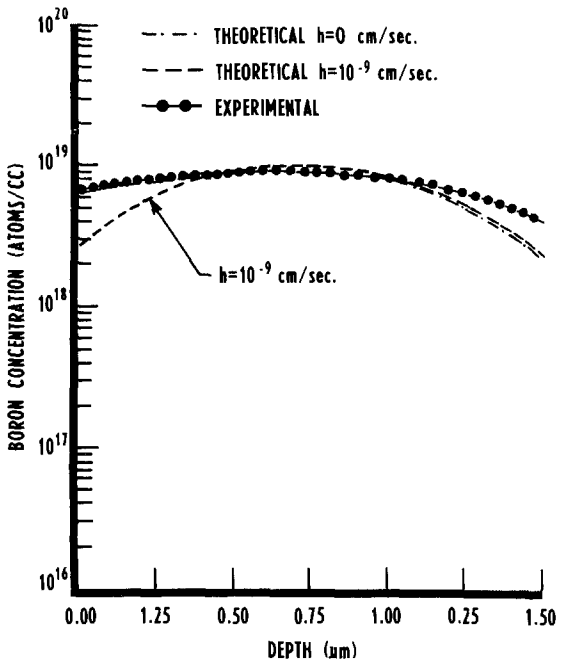

Fig. 3. Boron profile after diffusion at 1000°C for 14 hr 45 min in N_2.

The curves in Fig. 4 show the profiles obtained for the diffusions at 1200°C in a 2 liter/min N_2-1% O_2 ambient. The experimental points for 30 and 60 min diffusion times for the uncapped samples and for the samples capped with 5000Å SiO_2 are shown along with the theoretical simulation curves for $h = 0$ cm/sec. The agreement between the calculated and experimental results for the capped samples is within the experimental accuracy. The close correspondence with the theoretical curves for $h = 0$ in the case of the uncapped samples indicates that no out-diffusion took place in the samples in spite of the lack of an applied capping material. Although these results suggest that an oxide forms on the silicon surface during diffusion in N_2-1% O_2 at 1200°C, no oxide layer was visible on the samples after diffusion. However, a layer of SiO_2 less than 800Å in thickness is not generally visible to the eye. Therefore, to check the possibility of oxide growth an additional sample was diffused at 1200°C for 60 min in 2 liter/min of N_2-1% O_2. An oxide layer about 700Å thick was detected and measured using the fact that a buffered HF solution will etch SiO_2 at a constant rate until the wafer finally becomes hydrophobic. A similar diffusion was done in 4 liter/min N_2 to check for silicon nitride formation at 1200°C. In this case, a layer could be seen on the surface but it was not an oxide since it did not etch in buffered HF. Possibly the layer may have been silicon nitride. The differences between the measured and calculated profiles for the 60 min diffusions at 1200°C in N_2-1% O_2, while within the estimated limits of experimental error, are significantly greater than those for the other diffusions in N_2-1% O_2 and N_2. The reason for this is not understood. The process of boron transfer from silicon to the SiO_2 surface layer (5) is not expected to play a significant role in the redistribution of boron in these experiments since the amount of SiO_2 thermally grown was small. In the case of the capped samples, the effect was assumed to be negligible since no thermal oxide was grown on the samples.

The calculated boron profiles after diffusion lie below the measured ones at the larger distances from the surface. A larger value of D would give a better fit but no attempt was made to adjust D since this would not have contributed significantly to a better understanding of the behavior of boron at the ambient-wafer interface.

Figure 5 shows the profile obtained after diffusion in 20 liter/min of pure H_2 for 60 min at 1200°C. Curves for the computer simulation using Langer and Goldstein's (7) experimental value of $h = 9.1 \times 10^{-8}$ cm/sec and a value of $h = 10^{-8}$ cm/sec are shown for comparison. Values of $h > 10^{-7}$ cm/sec give curves that have a greater drop near the surface and lie generally below the measured values. Values of $h < 10^{-9}$ cm/sec result in curves which closely approximate $h = 0$. A considerable amount of out-diffusion took place in the hydrogen sample, in marked contrast to the negligible amount noted for the N_2-1% O_2

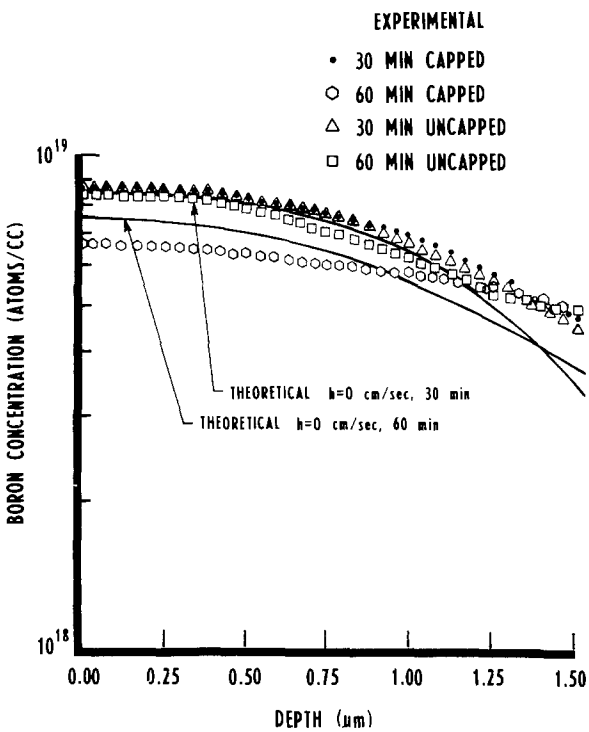

Fig. 4. Boron profiles after copped and uncapped diffusions at 1200°C in 99% N_2-1% O_2.

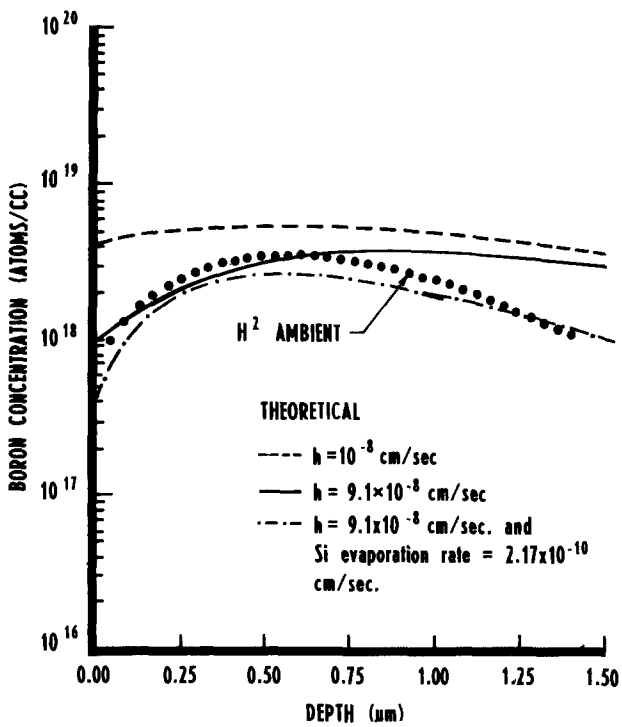

Fig. 5. Boron profile after diffusion at 1200°C for 60 min in H_2

samples (Fig. 4). In one computer calculation allowance was made for the silicon evaporation that occurs at 1200°C in hydrogen according to Tung (16). The rate of evaporation used in this moving boundary simulation was 2.17×10^{-10} cm/sec, as determined experimentally by Langer and Goldstein (7). The profile for the hydrogen diffusion is well approximated by this theoretical curve, as expected, because the hydrogen allowed no oxide or nitride growth. The effect of this out-diffusion is considerable, resulting in nearly twice the value of sheet resistance measured for the capped samples.

The results reported here are subject to the following experimental errors. The anodization step could result in an error of ±2% max in the oxide thickness. This is insignificant for any one step but could become sizable after a large number of steps. The sheet resistance measurement by four-point probe was found to yield a ±5% variation for multiple readings on the same spot. The data reduction technique, being primarily analytical in nature, has only those errors normally introduced by computer calculations associated with it. An error can be associated with the use of Irvin's mobility data, particularly in high concentration regions ($>10^{18}$ atoms/cm^3) (3). Due to the use of an electrical measurement technique, a loss of resolution occurred in two areas. For those samples which had low surface concentrations, the resistivity method of measurement introduces data scatter because of a lack of impurities at the surface. Near the interior p-n junction a large degree of inaccuracy can occur since the sheet resistance approaches the junction asymptotically. A direct measurement of the impurity concentrations would allow more accurate profiles to be taken. This is particularly true for the as-implanted profile, which cannot be found by electrical measurements because annealing is required to activate the impurities.

Acknowledgments

The authors wish to thank Paul Langer, Bell Laboratories, Allentown, for his assistance with the hydrogen diffusion and the data reduction. They would also like to thank C. M. Drum, Bell Laboratories, Allentown, for the implants and C. A. Adams, Western Electric Engineering Research Center, Princeton, for the anodization apparatus. This paper was submitted by Robert P. Ricco as a partial requirement for the M. S. degree Lehigh University (May 1973).

Manuscript submitted Sept. 4, 1974; revised manuscript received Sept. 22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the Western Electric Company, Incorporated.

Ionic Conductivity of Doped Cerium Trifluoride

Takehiko Takahashi,* Hiroyasu Iwahara, and Toyomi Ishikawa

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya 464, Japan

ABSTRACT

The electrical conductivities of the tysonite-type fluorides based on CeF_3 in the sintered state were measured for various aliovalent cation dopants. Doping of difluoride such as CaF_2, SrF_2, or BaF_2 up to 5 mole percent made the conductivity increase while the doping of tetrafluoride such as ThF_4 led it to decrease. These facts together with the experimental results of electrolysis indicated that the specimens were fluoride ion conductors resulting from the easy movement of fluoride ion vacancies. The activation energies for conduction at the high temperature range above 250°C were, in general, about 0.25 eV irrespective of divalent dopant species, while those at lower temperatures were 0.28 ~ 0.50 eV depending on the dopant species. Their conductivities are, in general, higher than those of the LaF_3-based electrolytes which are also the tysonite-type fluorides. $(CeF_3)_{0.95}(CaF_2)_{0.05}$ had the highest conductivity among the tysonite-type fluorides ever examined.

Some of the solid fluorides with large cations have been known to be fluoride ion conductors. They hold considerable promise for use as solid electrolytes; for example, LaF_3 has been used in fluoride ion selective electrodes (1), and CaF_2 as the electrolyte in galvanic cells used in the thermodynamic study of fluorides, carbides, and oxides at high temperatures (2). Besides, Baukal has recently called attention to the potentiality of high power batteries using solid fluoride electrolytes (3). It is, in general, desirable for the electrolyte to have the highest conductivity possible for practical use. The solid electrolytes discovered currently, however, do not always satisfy this demand.

The fluoride electrolytes can be classified into two categories by their crystal structures: The first is the fluorite-type which covers many difluorides of Group II in the Periodic Table and the second is the tysonite-type which includes trifluorides of rare earth metals. While there are a number of studies on the conductivity of the former group, the conductivity studies of the latter group are few and have been almost entirely limited to those on LaF_3 (4-9) because of the rare occurrence of these materials.

Recently, Nagel and O'Keeffe (10) measured the conductivities of tysonite-type CeF_3 as well as of LaF_3, and found that conductivities of the former were one order of magnitude higher than those of the latter over a wide range of temperature. They also measured the conductivities of $La_{0.95}Sr_{0.05}F_{2.95}$, a derivative of tysonite-type LaF_3, and observed that the conductivites were more than ten times higher than those of pure LaF_3. These results suggest that fluoride ion conduction in tysonite-type compounds may be concerned with fluoride ion vacancies, and that, if such defects can be formed in CeF_3 in an appreciable amount by adding some aliovalent fluoride, higher conductivities than that of $La_{0.95}Sr_{0.05}F_{2.95}$ can be expected.

To examine these, we prepared some solid solutions based on CeF_3 and measured their conductivities as well as their electrolytic properties. CaF_2, SrF_2, BaF_2, and ThF_4 were examined as aliovalent dopants. Because of the difficulties of obtaining single crystals with the desired composition and size, all of the specimens examined were polycrystalline sinters.

Experimental

Preparation of the sintered specimens.—In order to eliminate the ammonium fluoride included in the reagent, the cerium trifluoride (purity above 99%) obtained from Katayama Kagaku Company Limited was subjected to preliminary heating at 400°C in an argon stream which was dried with phosphorus pentoxide. The resultant powdery fluoride was mixed with calcium, strontium, barium, or thorium fluoride at a designated ratio and hand-pressed into pellets. The pellets were calcined at 750°C for 4 hr. Then, they were crushed into powder and ground finely in an agate mortar. The powder was pressure-molded hydrostatically under 3 ton/cm^2 into cylindrical shapes (diameter 4 ~ 5 mm, length 5 ~ 7 mm) or disks (diameter 10 mm, thickness 1 ~ 1.5 mm), and sintered at 870° ~ 900°C for 4 hr. The calcining and sintering were performed in argon which had been passed through heated spongy titanium metal and phosphorus pentoxide to eliminate oxygen and water, respectively.

X-ray diffraction and density measurements.—The sintered fluorides thus obtained were subjected to x-ray diffraction analysis to make sure of the formation of solid solutions and to determine the lattice parameters. A Rigaku-Denki x-ray diffractometer with CuKα irradiation source was used for the determination of the lattice parameter at a scanning rate of 0.25 deg/min adopting CaF_2 as an internal standard.

The theoretical densities of the specimens were calculated from the lattice parameters thus obtained and compared with powder densities measured with the normal pycnometric method using n-butanol at 25°C.

Conductivity measurements.—The cylindrical-shaped specimens were used for conductivity measurements. Graphite was smeared on both ends of the specimen rod for electrodes, and it was inserted between graphite disk current collectors in the furnace. The furnace was gastight and argon gas dried with phosphorus pentoxide was flowed through it. The conductivity was measured by an a-c bridge (Ando Denki LCR-6) with a capacity compensator. A measuring frequency of 10 kHz was adopted, in the vicinity of which the dependence of conductivity on the frequency was fairly small. Other electrode materials such as silver paste and graphite paste were also tried, but they were not as stable and independent of frequency as the smeared graphite electrode.

In order to clarify the charge carrier in the specimen, electrolysis by Tubandt's method was performed by contacting three disk-shaped specimens face to face and by adopting the smeared graphite electrodes on both end faces of the pile. The electrolysis products were identified by x-ray diffraction with each surface of the anolyte and the catholyte.

Results

The sinters.—The sintered specimens thus prepared were hard and dense; the porosities calculated from

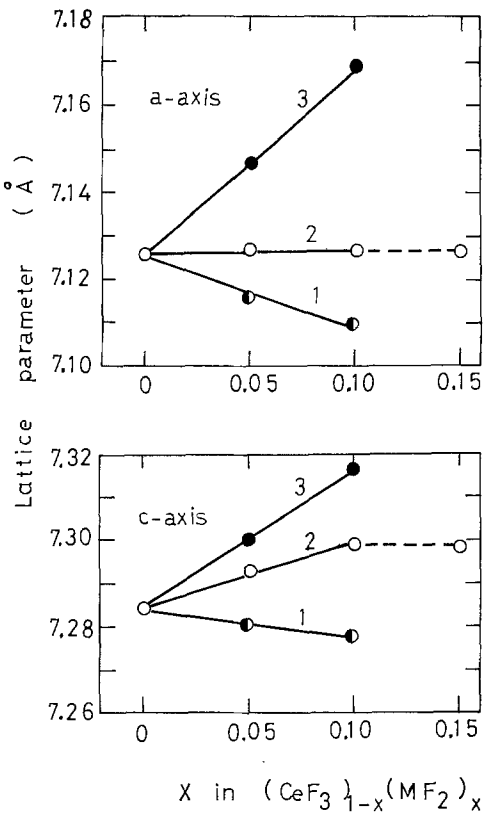

Fig. 1. Lattice parameters of tysonite-type solid solutions based on CeF_3. 1, M = Ca; 2, M = Sr; 3, M = Ba.

powder density and apparent density of the sintered block were less than 5%.

X-ray diffraction patterns of the difluoride-doped specimens $(CeF_3)_{1-x}(MF_2)_x$ showed tysonite-type phase only when the dopant concentrations were less than 10 mole percent (m/o) ($x \leq 0.1$). Figure 1 shows the lattice parameters of pure and doped samples. They obeyed Vegard's rule at least up to 10 m/o, and the larger the radius of the doped ion, the larger the lattice parameter became for both the a- and c-axis. These results indicated that the tysonite-type solid solution formation ranged in these systems up to, at least, 10 m/o MF_2. The specimen doped with 15 m/o SrF_2 gave small diffraction lines of SrF_2 indicating that the solubility of SrF_2 was less than 15 m/o.

In Table I the observed powder densities are compared with the theoretical values calculated from lattice parameters assuming that either fluoride ion vacancies or cation interstitials were formed on doping 5 m/o of MF_2 to CeF_3. The observed values were in good agreement with the values calculated based on the former assumption, suggesting that the fluoride ion vacancies were formed by adding MF_2 as a result of charge compensation.

An x-ray diffraction pattern of 5 m/o ThF_4-doped specimen gave additional lines to the original pattern indicating that the solubility was less than 5 m/o. However, diffraction lines of the tysonite phase at high angle were shifted slightly suggesting a little solubility.

Though the fluoride samples were hydrolyzed to form CeO_2 in wet air at high temperatures, they were stable in dry air (dried with P_2O_5) even at 300°C.

Table I. Comparison of observed density with calculated densities assuming that fluoride ion vacancies or cation interstitials are formed on doping MF_2 to CeF_3

Specimen	Calculated density (g/cm³)		Observed density (g/cm³)
	Anion vacancy	Cation interstitials	
CeF_3	6.13		6.16 ± 0.05
$(CeF_3)_{0.95}(CaF_2)_{0.05}$	5.97	6.07	5.95 ± 0.03
$(CeF_3)_{0.95}(SrF_2)_{0.05}$	6.01	6.12	5.98 ± 0.03
$(CeF_3)_{0.95}(BaF_2)_{0.05}$	6.05	6.16	6.00 ± 0.03

Conductivity.—Arrhenius plots of conductivity of $(CeF_3)_{1-x}(CaF_2)_x$ are presented in Fig. 2 for various compositions. The conductivity of pure CeF_3 above 200°C was close to that of the single crystal reported by Nagel *et al.* (broken line) (10). The conductivities increased by adding CaF_2 to CeF_3 and maximum conductivity lay at 5 m/o CaF_2 compositions. The conductivity of this fluoride was about one order of magnitude higher than that of pure CeF_3, and the value at 200°C (1×10^{-2} Ω^{-1}-cm^{-1}) was several times higher than that of $La_{0.95}Sr_{0.05}F_{2.95}$ reported by Nagel *et al.* (10) (see Fig. 8). In this system, each Arrhenius plot consists of two regions, that is, the lower slope at higher temperatures and the higher inclination at lower temperatures. The change in slope takes place at about 200°C.

As shown in Fig. 3, the conductivities of the CeF_3-SrF_2 system also increased with increasing content of SrF_2 up to 5 m/o. At a higher content of SrF_2 than this, the dependence of conductivity on composition became ambiguous. The conductivity of 5 m/o SrF_2-doped sample at the high temperature range was almost the same as that of $(CeF_3)_{0.95}(CaF_2)_{0.05}$. The Arrhenius plots are also divided into two regions in this case.

As shown in Fig. 4, the relation between the conductivity and the composition in the CeF_3-BaF_2 system was not as regular as the previous two systems. The change in slope at about 200°C is not significant. The maximum conductivity, however, was also observed at 5 m/o of dopant content.

In contrast to the case of difluoride doping, the conductivities decreased by adding ThF_4 to CeF_3 as shown in Fig. 5. It should be noticed in this case that the solubility of ThF_4 was lower than 5 m/o. Nevertheless, this result may indicate that even a small amount of doping caused the conductivity to decrease remarkably. Besides this, the slope of Arrhenius plot differed conspicuously from those for MF_2-doped specimens; in

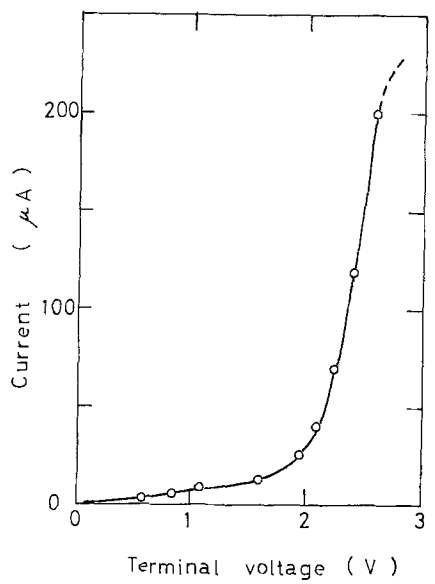

Fig. 6. Electrolysis curve of $(CeF_3)_{0.95}(CaF_2)_{0.05}$ at 300°C in dry air. (The electrodes are smeared graphites. Specimen size, 0.78 $cm^2 \times 0.1$ cm.)

the latter case, the slope at high temperatures is lower than that at low temperatures, whereas in ThF_4-doped specimens, the slope at high temperatures is rather steep compared to that at low temperatures.

Electrolytic properties.—Figure 6 shows the terminal voltage-d-c current curve for $(CeF_3)_{0.95}(CaF_2)_{0.05}$ using smeared graphite electrodes under dry air at 300°C. A decomposition voltage of about 2.0V is considerably lower than that expected from the free enthalpy of formation for the fluoride. When the same measurement was performed in a vacuum, the decomposition current could not be measured clearly at least up to 10V because of the instability of the current with time. X-ray diffraction patterns of the surfaces of the anolyte and catholyte after electrolysis in dry air at 300°C using the smeared graphite electrodes were recorded. The catholyte surface gave the diffraction patterns of CeO_2, while the anolyte surface remained unchanged showing the initial pattern of the tysonite. When the electrolysis was carried out in a vacuum, the resultant x-ray diffraction pattern of the catholyte surface was somewhat broad retaining the initial pattern of the tysonite. However, this catholyte surface was recognized to change to CeO_2 after exposure to air at room temperature for a few days, suggesting that the catholyte surface was reduced to metallic cerium by electrolysis in vacuum.

If oxygen gas is involved electrochemically with the cathode reaction, one of the possible reactions at the cathode may be

$$CeF_3 + O_2 + 3e^- = CeO_2 + 3F^- \quad [1]$$

and the corresponding anode reaction would be

$$3F^- = \frac{3}{2}F_2 + 3e^- \quad [2]$$

thus the over-all reaction may be

$$CeF_3 + O_2 = CeO_2 + \frac{3}{2}F_2 \quad [3]$$

The decomposition voltage estimated from the free energy change of Eq. [3] is 1.8V. Therefore, an observed decomposition voltage of 2.0V in air may be rational considering an additional overvoltage of about 0.2V.

In order to ascertain the charge carrier in the electrolyte, the changes in weight of the anolyte, bulk, and catholyte were measured after electrolysis in dry air at 300°C using smeared graphite electrodes. The results are given in Table II for $(CeF_3)_{0.95}(CaF_2)_{0.05}$. In this table, the calculated weight changes are based on the assumption that the oxides were formed as a result of the cathode reactions such as Eq. [1] or as a result of the reactions of movable cations with oxygen such as

$$Ce^{3+} + O_2 + 3e^- = CeO_2 \quad [4]$$

or

$$Ca^{2+} + \frac{1}{2}O_2 + 2e^- = CaO \quad [5]$$

and that fluorine generated at the anode was caught by smeared graphite or dissolved into the anolyte. The observed changes in weight are in good agreement with the values assumed as fluoride ions being charge carriers

Discussion

The doping of divalent fluoride up to 5 m/o makes the conductivity increase in all cases examined, whereas the addition of tetravalent fluoride makes it decrease. A representative example for this can be seen in Fig. 7, in which the isothermal conductivities were plotted against the dopant content for a CaF_2-doped sample (toward the right-hand side along the abscissa) together with ThF_4-doped one (toward left-hand side along the abscissa). This fact suggests that the ionic current is carried by mobile fluoride ion vacancies, and that the vacancy concentration increases by doping difluoride and decreases by doping tetrafluoride as shown in the following equations

$$CaF_2\ (CeF_3) \rightarrow Ca'_{Ce} + 2F^x_F + V^{\cdot}_F \quad [6]$$

$$ThF_4\ (CeF_3) + V^{\cdot}_F \rightarrow Th^{\cdot}_{Ce} + 4F^x_F \quad [7]$$

The formation of fluoride ion vacancies by doping of the difluoride was also supported by the result of density measurements shown in Table I. However, the effect of doping on conductivity is not as remarkable as in the case of the solid solution based on fluorite-type fluoride such as NaF-doped CaF_2 (11), in which doping

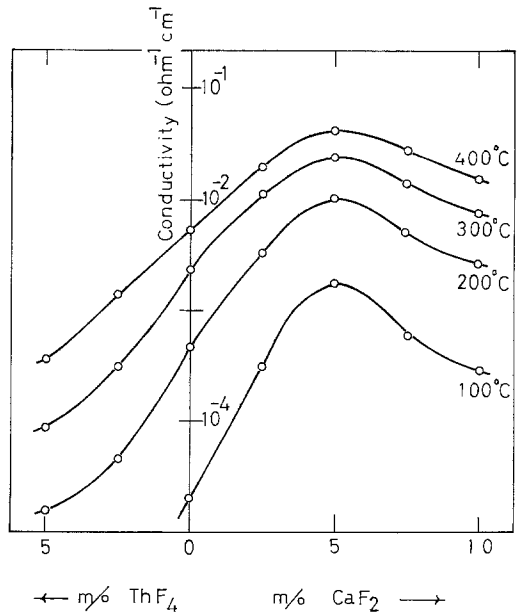

Fig. 7. Isothermal conductivity plots of CaF_2- and ThF_4-doped CeF_3.

of 1 m/o dopant makes the conductivity increase by more than three orders of magnitude. The decrease in conductivity by adding ThF_4 can be explained by a decrease in the concentration of the vacancies which are present in pure CeF_3 as intrinsic defects. The high conductivity of pure CeF_3 compared to pure CaF_2 and its considerable decrease by adding ThF_4 suggest that the concentration of intrinsic vacancies is appreciably high like that in LaF_3, in which the intrinsic defects are reported to be the Schottky type (4).

Arrhenius plots shown in Fig. 2-5 consist, in general, of two regions: the low slope region at high temperatures and the steep slope range at low temperatures. A similar form was also reported by Sher *et al.* in the case of LaF_3 (4). According to them, the activation energy for conduction in LaF_3 crystal was 0.46 eV in the low temperature range (<350°K), whereas in the high temperature range above 400°K, it was only 0.08 eV in spite of the fact that there existed no phase transition between the two regions. The reason for this has not been fully explained. However, according to the NMR study by Lee (12), there exist three kinds of nonequivalent fluoride ion sites in the CeF_3 crystal. At 285°K, fluoride ions in only one of these are mobile whereas at 520°K fluoride ions in all kinds of fluoride ion sites are mobile; the activation energy for motion in this case being 0.13 eV. Table III summarizes the activation energies for conduction calculated from the slope of Arrhenius plot for 2.5 or 2.0 m/o doped specimens. In the high temperature range, the activation energies are low and show almost the same values independent of doped species (except Th^{4+}). This suggests that the conduction mechanism may be the same in this region irrespective of the

Table III. Activation energy for conduction in CeF_3-based fluorides

Dopant	Activation energy (eV)	
	High temperature range, >250°C	Low temperature range, <200°C
Pure	0.26 (>300°C)	0.50
CaF_2	0.25	0.37
SrF_2	0.25	0.42
BaF_2	0.24	0.28
ThF_4	0.54	0.45

At nearly equal dopant content (0.02 ~ 0.025 m/o).

doped species although the value of activation energy (about 0.25 eV) is higher than the 0.13 eV reported from the NMR study at 520°K. The activation energies in the low temperature range are higher than those in the high temperature region, and the values differ somewhat from each other, suggesting that these quantities may be related to defect interaction, for example, to the association of fluoride ion vacancies with dopant cations. In the system CeF_3-ThF_4, the concentration of fluoride ion vacancies is small according as Eq. [7]. The high activation energy for conduction in this system may be ascribed to the intrinsic (thermal) defect conduction and/or to the strong association force between the fluoride ion and the dopant cation Th^{4+} which has larger positive charge than that of the host cation Ce^{3+}. However, quantitative discussions should not be made here, since the specimens examined were not single crystals but sintered polycrystalline samples.

The small electronic conductivity in the specimens was not quantitatively studied in this work. However, estimating from the residual current in the electrolysis curves (*e.g.*, Fig. 6), the electronic conductivities were less than 10^{-3} times smaller than the ionic conductivities in all cases examined. A preliminary experiment using Wagner's polarization method showed that the electronic conductivity of $(CeF_3)_{0.95}(CaF_2)_{0.05}$ was the order of 10^{-7} Ω^{-1}-cm^{-1} at 300°C when using graphite as a blocking electrode and a mixture of graphite and carbon fluoride ($C:CF_{1.00} = 1:1$ in weight) as the counterelectrode. This result, however, had some uncertainty because the slope of the potential *vs.* logarithm of current curve deviated from the theoretical value, the reason for this is still under investigation. Negligibly small electronic conduction was also proved by the fact that the galvanic cell constructed as

$$Pb,PbF_2/(CeF_3)_{0.95}(CaF_2)_{0.05}/Bi,BiF_3$$

gave the theoretical value calculated from the free energy change of the following reaction

$$3PbF_2 + 2Bi = 2BiF_3 + 3Pb$$

The details of this experiment are to be reported elsewhere.

Finally, if attention is focused on the magnitude of the conductivity as a fluoride ion solid electrolyte, CeF_3-based sinters can be said to belong to the highest conductors together with KF-doped β-PbF_2 (13). Their conductivities are higher than those of LaF_3-based solid electrolytes as shown in Fig. 8, which compares conductivities for various fluorides (note that the longitudinal axis does not represent log σT but conductivity itself). $(CeF_3)_{0.95}(CaF_2)_{0.05}$ has the highest conductivity among the tysonite-type fluorides.

Conclusion

It has been shown that the doping of difluoride to the tysonite-type trifluoride CeF_3 makes the conductivity increase up to 5 m/o of dopants, while the doping of tetrafluoride leads it to decrease. These facts together with the experimental result of electrolysis indicate that the specimens are fluoride ion conductors resulting from easy movement of fluoride ion vacancies. Though the CeF_3-based electrolytes are stable in dry air at moderate temperature (up to at least 300°C), they change to oxides at the cathode quantitatively when they are subjected to electrolysis.

As to the fluoride ion conductivity the CeF_3-doped electrolytes are, in general, higher than the LaF_3-based ones which are the same tysonite-type fluoride as

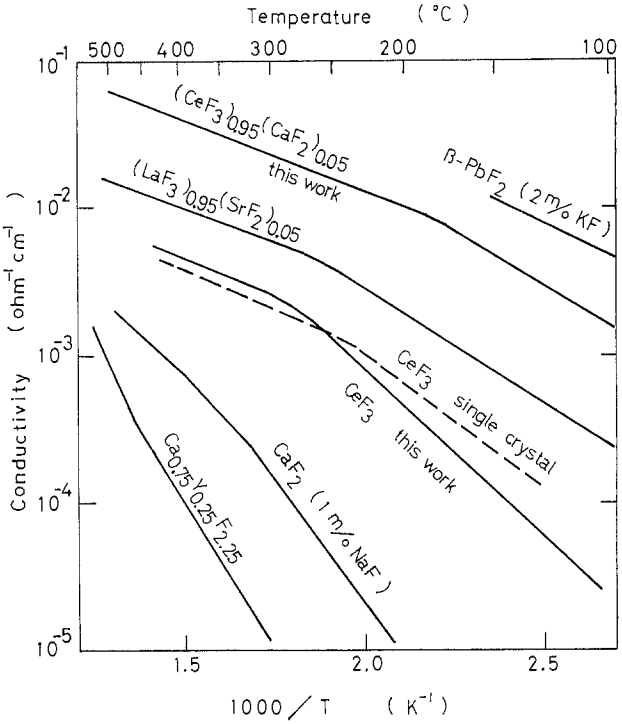

Fig. 8. Comparison of conductivities for various fluoride electrolytes [Ref. (10, 13)].

CeF_3. The highest conductivity was observed in the $(CeF_3)_{0.95}(CaF_2)_{0.05}$ sintered specimen.

Formation and Properties of Porous Silicon Film

Yoshinobu Arita and Yoshio Sunohara

Electrical Communication Laboratories, Musashino-shi, Tokyo, Japan

ABSTRACT

Porous silicon film (PSF) on silicon was formed by anodic reaction in 50 weight percent (w/o) hydrofluoric acid. Effects of parameters on the PSF formation rate, density, crystalline structure, and cross section structure have been studied. Current density and acceptor concentration in p-type silicon PSF formation, as well as current density, illumination light intensity, and donor concentration in n-type silicon PSF formation, were mainly found to play important roles in determining the PSF crystalline and porous structure. The surface crystalline structure in the p-type silicon PSF changes from the clean Kikuchi pattern to a broad pattern when acceptor concentration decreases. In the n-type silicon PSF, the crystalline structure tends to change from single crystal to amorphous as current density becomes smaller, donor concentration decreases, illumination light intensity becomes strong, and reaction time is longer. The cross section, in the p- and the n-type silicon PSF, is virtually dense at a very thin layer close to the surface, becoming more porous at the inner region compared with the surface. The holes injection effect on the PSF formation in n-type silicon has been investigated. It is found that PSF formation without holes injection occurs uniformly at anodic reaction after the order of 0.1 μm thick PSF is formed with holes injection. It is thought that anodic dissolution occurs at the local silicon surface under anodic conditions by which the single crystal PSF is obtained. It was found that the PSF composition consists mainly of silicon and a small amount of hydrogen, oxygen, and fluorine.

PSF was found by Uhlir (1) and Turner (2) when an electropolishing experiment was conducted below about 10% HF concentration. PSF was formed by anodic reaction in the concentrated HF. It has been shown that such films have very chemically active properties, and that the composition of such films consists mainly of silicon, fluorine, and hydrogen (2-4). No detailed investigation made on the PSF composition has been reported in previous literature (2-4).

Models of the PSF formation mechanism have been proposed by Turner (2), and subsequently by Memming and Schwandt (5). Based on these models, anodic dissolution has been suggested as occurring over the entire silicon surface in reaction to the anodic conditions under which the PSF crystalline structure becomes amorphous. Theunissen (6) reported that single crystal PSF was anodically formed in 5% HF.

No studies have been reported so far with respect to the PSF crystalline and cross section structure, the PSF nature, and the effects of anodic reaction parameters on these factors.

Recently, application to isolation of integrated circuits was investigated, using the chemically active nature of the PSF (7).

In this paper, the formation and properties are studied in detail. Initially, the relationship between the electrode potential and the current density varying with p- and n-type silicon resistivity is discussed. Effects of the anodic reaction parameters on the formaton rate, density, crystalline and cross section structure in the p- and the n-type silicon PSF, and the properties are clarified. The holes injection effect is investigated after silicon surface changes into PSF with a certain thickness. A model is proposed based on Turner's investigation (2) to account for the experimental observation that a single crystal PSF is obtained. Finally, the composition of PSF made in this work is determined.

Experimental Procedures

Wafer preparation.—Silicon wafers used for this work consisted of 0.006 Ω-cm, 7 Ω-cm p-type (boron doped), and 0.007 ohm-cm n-type (antimony doped) made by the Czochralski method. Etch pit density was less than 500 per square centimeter. Most of this study with higher specific resistivity was performed by using epitaxial silicon wafers described as follows. In the p-type case, p on p^+ epitaxial silicon was used, whose layer thickness and dopant were 20 μm and boron, respectively. Resistivity was over a wide range (6.2-0.28 Ω-cm). Substrate thickness, dopant, and resistivity were 200 μm, boron, and 0.006 Ω-cm, respectively. On the other hand, in the n-type case, n on n^+ epitaxial silicon was used whose layer thickness and dopant were 20 μm and phosphorus, respectively. Resistivity was over a wide range (5.5-0.09 Ω-cm). Substrate thickness, dopant, and resistivity were 200 μm, antimony, and 0.007 Ω-cm, respectively. Crystal orientation of all types of silicon used was on the (111) plane.

PSF formation.—The electrolytic cell for PSF formation by anodic reaction has been given in a previous paper (8). Anodic reaction was performed by xenon lamp (300 and 500W) illumination to generate holes in the n-type silicon but without illumination for the p-type silicon. Unless otherwise noted, 50 w/o HF was used. The silicon wafer was covered with acid-proof wax (Apiezon wax) to perform anodic reaction selectively in the wafer. The anode and cathode were connected to the silicon wafer and gold wire, respectively. A constant current source was used as electric power.

The ultrasonic oscillator source was used immediately to remove H_2 bubbles that evolve at a porous silicon surface under the anodic reaction. Imperfection in bubble removal under the anodic reaction causes PSF thickness nonuniformity and the PSF surface comes off locally, especially when the PSF becomes thicker.

All experiments were performed without electropolishing.

Electrode potential and current.—The potential of the silicon electrode was controlled with a potentiostat (TOA Electronics Limited PGS-70A) in conjunction with a slow linear potential sweep scanner and an X-Y plotter to record the relationship between current-potential data. The reference electrode was a saturated calomel electrode (SCE). The SCE capillary tip end was dipped in HF and positioned at one corner of the silicon wafer to perform anodic reaction.

Physical and chemical characterization.—A cross

Key words: anodic dissolution, porous silicon film, hydrofluoric acid electrolyte, hole generation center.

section obtained by lapping within a plane inclined from the PSF surface (angle lapping method) shows a clean boundary between the anodic reaction layer and the silicon substrate in the p-type silicon. Therefore, the PSF thickness was determined as that between the PSF surface and the boundary. On the other hand, the angle lapping PSF surface was etched lightly in an etchant (60 HNO_3:1HF or 20 HNO_3:1HF) to determine the PSF thickness in the high resistivity n-type silicon. The PSF density was obtained by measuring the weight difference before and after anodic reaction, and the actual volume of the PSF. The PSF thickness to be etched off in NaOH solution was measured by a Talystep instrument. SiO_2 film was chemically deposited on the PSF surface to be etched off to prevent scratches by Talystep tracing. The PSF crystalline structure was studied by reflection electron diffraction (ED) and by x-ray diffraction. Surface features of the as-grown PSF and the etched PSF surface were examined by the two-stage replication method, using an electron microscope (EM). A cross section by the angle lapping method was etched lightly in HNO_3-HF system reagent and was then examined by a scanning electron microscope (SEM). The PSF composition and atomic bonds were investigated by infrared and sparked mass spectroscopy.

Results and Discussion

Relationship between electrode potential (η) and current density (J), and reaction time (t).—Current-potential curves for two specific resistivities in the p-type silicon are presented in Fig. 1. The Tafel relationship was obtained only over a short range of minus potential (curve 2 in Fig. 1). Curve 1 increases exponentially with increasing η, and curve 2 increases slowly with increasing η in the anodic region. Illumination has no significant effect on PSF formation of the p-type silicon. On the other hand, similar curves for the n-type silicon are shown in Fig. 2 and 3. When resistivity is high in the anodic region, initial J increases with increasing η, and then J saturates with increasing η due to hole diffusion, finally increasing rapidly with increasing η. The J saturation tendency becomes obscure as resistivity decreases from about 5 to about 0.007 Ω-cm. The PSF surface comes off locally at a region where J increases sharply with increasing η. As shown in Fig. 2, this phenomenon occurs at the η indicated by the arrow. Saturation J increases with increasing illumination light intensity (I_p) and with decreasing resistivity. As observed later, PSF structure in the thickness direction changes largely due to the J value in the anodic reaction.

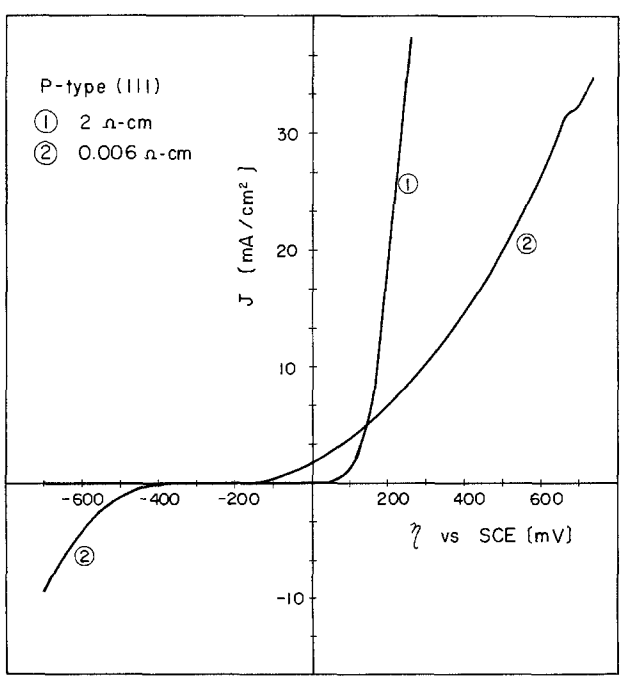

Fig. 1. Potentiostatic current potential curves of p-type silicon anodic reaction.

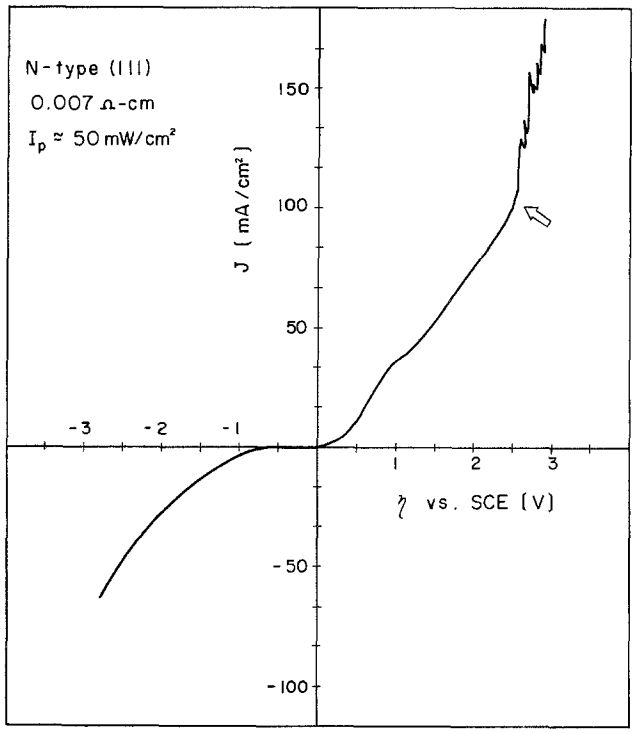

Fig. 2. Potentiostatic current potential curves of n-type silicon anodic reaction.

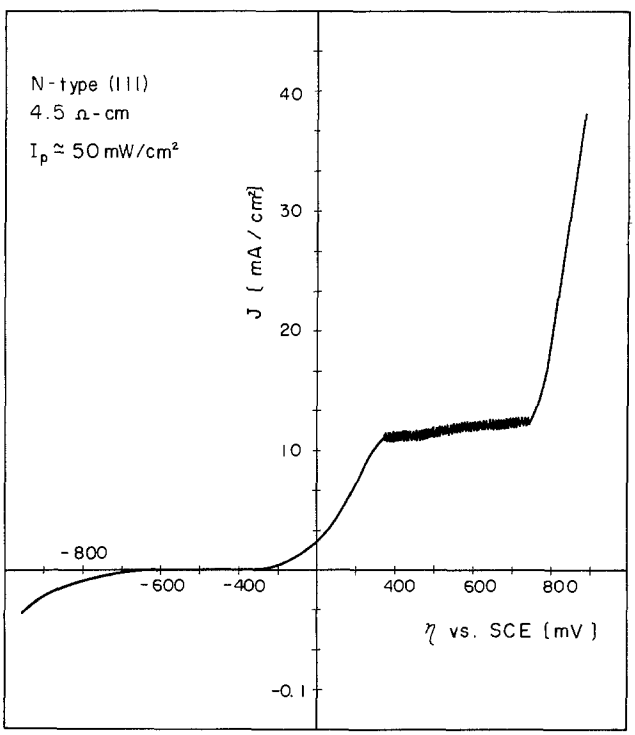

Fig. 3. Potentiostatic current potential curves of n-type silicon anodic reaction. Note that the longitudinal axis plus region scale is ten times that of the minus region scale.

Hysteresis is observed between the ascending and descending curves of η *vs.* J relationships in both the p- and the n-type silicon. It is considered that hysteresis was due to a decrease of the effective dissolution area and to a difference between the state of the silicon surface caused by anodic dissolution and the state of PSF surface at η decrease, because SiF_4, free

Si, and H_2 produced by anodic dissolution remain in the PSF. Consequently, H_2 gas evolution during anodic dissolution is one of the reasons for this phenomenon. J decreases compared with an earlier J to the same η, when cyclic measurement of the η *vs.* J curve is effected. This decrease tendency of J becomes marked with the increasing resistivity of silicon.

The relationship between η and t in anodic reaction of the p-type silicon is shown in Fig. 4. η of silicon is about -0.2V when immersed in HF solution for a long time. At the start of anodic reaction, η increases rapidly and then decreases to a steady-state value.

PSF thickness (T_h)-reaction time (t) relationships and surface color.—T_h (determined from the angle lapping methods) increases with increasing t (see Fig. 5). The slope increases with increasing J. This linear relationship is not established as the t becomes still longer (7) and T_h is proportional to the square root of t at the first approximation. The shift from linear relationship is dependent on the anodic conditions.

Repetitive interference colors can be observed earlier in the PSF formation. The visual surface color of PSF of high resistivity, p-type silicon is a deeper black compared with that of the low resistivity, p-type silicon, and repetitive interference colors cannot be observed when T_h becomes the thickness. On the other hand, the anodic reaction for PSF of high resistivity, n-type silicon remains as a certain interference color, even when T_h becomes more than several microns thick. This result seems to be due to the PSF refraction index difference between a layer near the PSF surface and the inner region. The surface color of the lower resistivity, n-type silicon PSF is found to be similar to that of the p-type silicon PSF.

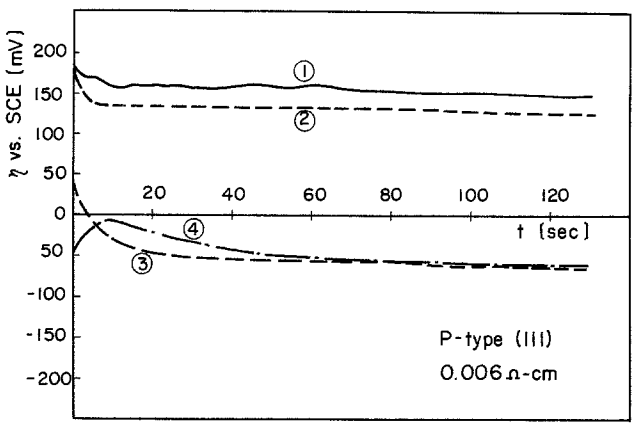

Fig. 4. Electrode potential *vs.* reaction time curves for p-type silicon. ① $J = 10$ mA/cm², ② $J = 5$ mA/cm², ③ $J = 0.4$ mA/cm², ④ $J = 0.04$ mA/cm².

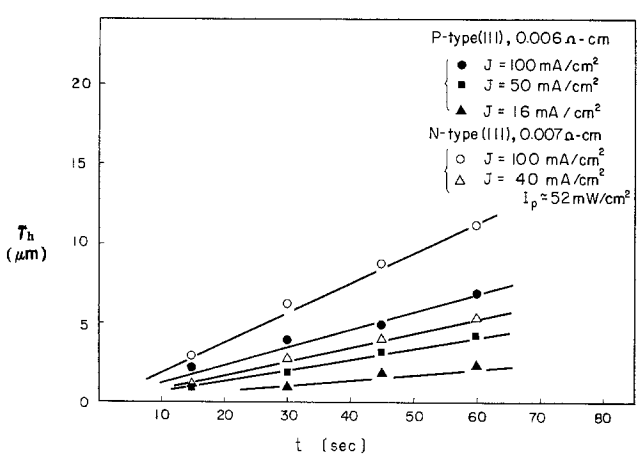

Fig. 5. PSF thickness (T_h) and anodic reaction time (t) relationship.

A convex surface is observed visually, immediately after anodic reaction, when the PSF becomes about 100 μm thick. Radius of the PSF curvature decreases with increasing T_h and with increasing time kept in the air. It is thought that a convex surface is apparently caused by oxidation of the PSF.

Formation rate.—Effects of HF concentration (n_{HF}) and of HF temperature (T) on the formation rate was determined within a range where T_h is proportional to t. It is evident that the formation rate increases linearly with increasing HF concentration. Increasing J on the anodic reaction results in a rapid increase in the formation rate (f_{nHF}) on n_{HF}. When J is small, n_{HF} seems to have little influence on f_{nHF}. A little electropolishing was observed in Fig. 6 when n_{HF} is 15% HF at 100 mA/cm² and 5% HF at 30 mA/cm². In general, the critical current density which electropolishing caused increases with the increasing n_{HF} (see Fig. 6).

The formation rate does not change very greatly with increasing T over a range of from 5° to 65°C (see Fig. 7). The HF temperature seems to have little influence on the formation rate.

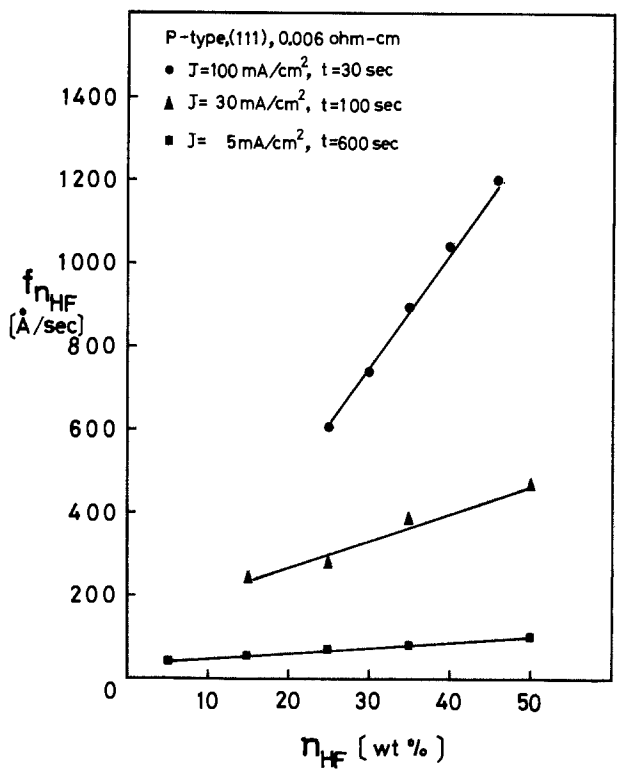

Fig 6. HF concentration (n_{HF}) effect on the PSF formation rate

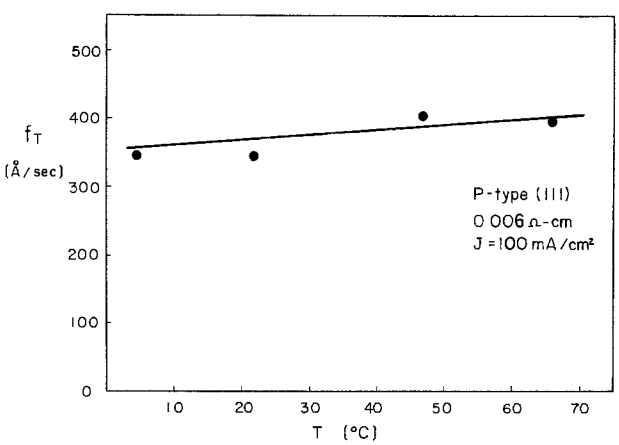

Fig. 7. HF temperature (T) effect on the PSF formation rate

Dependence of the formation rate upon J is shown in Fig. 8 over the 20-100 mA/cm² range for the p- and the n-type silicon PSF. Increasing J results in a linear increase of the rate for the p-type silicon PSF. For the n-type silicon PSF, the rapid initial formation rate is followed by a slower increase with J. The formation rate increases slowly with increasing J, when I_p becomes weaker. It should be noted that the formation rate decreases with increasing I_p below about $J \simeq 40$ mA/cm², and increases with increasing I_p above about $J = 40$ mA/cm². The PSF surface crystalline structure tends to become amorphous below about 40 mA/cm² with increasing I_p. On the other hand, the PSF surface crystalline structure becomes a single crystal structure above about 40 mA/cm² with increasing I_p.

The formation rate as a function of I_p, at 30 and 150 mA/cm², is shown in Fig. 9. The results reveal two characteristics: (*i*) the formation rate decreases slowly with increasing I_p at 30 mA/cm²; (*ii*) on the other hand, the initial formation rate increases rapidly with increasing I_p, and will not increase further even if I_p increases at 150 mA/cm². From the study of relation between η and J, η decreases with the increasing I_p at 30 mA/cm², but a little η decrease occurs when I_p increases at 150 mA/cm²; thus the η decrease corresponds to a decrease of the PSF formation rate. The results shown in Fig. 9 may account for the above-mentioned fact.

Variation in the formation rate with dopant concentration (N_A, N_D) at 30 and 150 mA/cm² is shown in Fig. 10. That of the p-type silicon PSF increases with increasing N_A; *i.e.*, hole concentration. On the other hand, there is a significant difference in the profile of curves for the n-type silicon PSF, whose maximum is between 10^{16} and 10^{17} cm^{-3} in donor concentration, compared with that of the p-type silicon PSF. A sharp curve with the maximum is observed with the increasing J, and a curve with the maximum becomes broad with decreasing J.

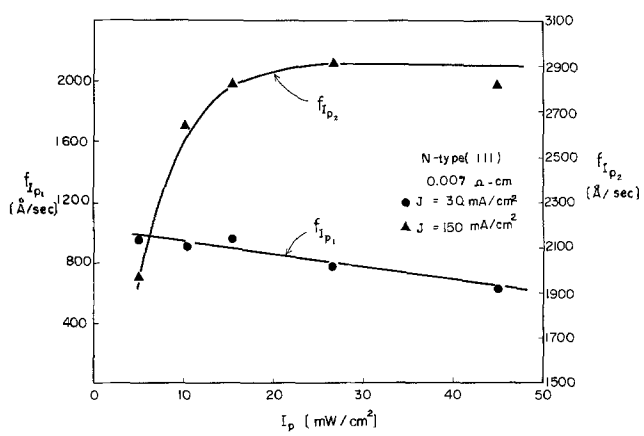

Fig. 9. Illumination light intensity (I_p) effect on the PSF formation rate.

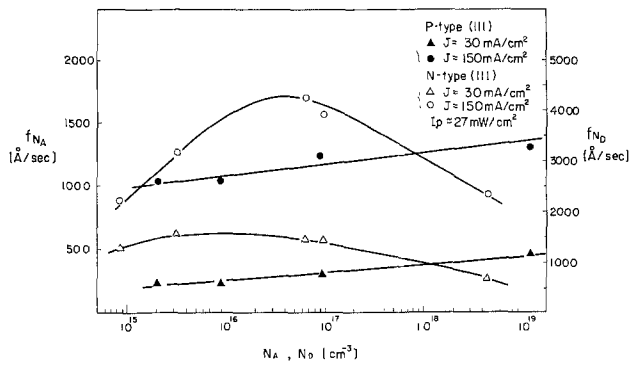

Fig. 10. Acceptor concentration (N_A) and donor concentration (N_D) effects on the PSF formation rate.

Illumination interception effects.—Supplying holes is necessary for PSF formation of the n-type silicon. The illumination interception effect on T_h is shown in Fig. 11. Q is a charge flowing through a cell. When the over-all anodic reaction is performed with illumination, T_h increases linearly with increasing Q. When the first anodic reaction was carried out under the conditions of $J = 100$ mA/cm², $Q = 0.2$ C/cm², $I_p = 50$ mW/cm² and the second anodic reaction was performed under the conditions of $J = 100$ mA/cm², $I_p = 0$, it was found that PSF was formed. This result was observed in spite of n-type silicon resistivity. Theunissen reports that a brownish black, pitted surface was formed in 5% HF for impurity concentrations between 2×10^{18} and 2×10^{16} cm^{-3}, and in the range below about 2×10^{16} cm^{-3} no measurable dissolution occurred and no channels were detected (6). When donor concentration and the depletion layer voltage are 10^{15} cm^{-3} and 10V, respectively, the calculated maximum electric field is lower than the value of the breakdown field. When PSF is formed below 10V in 50% HF for a specimen of donor concentration 10^{15} cm^{-3} without

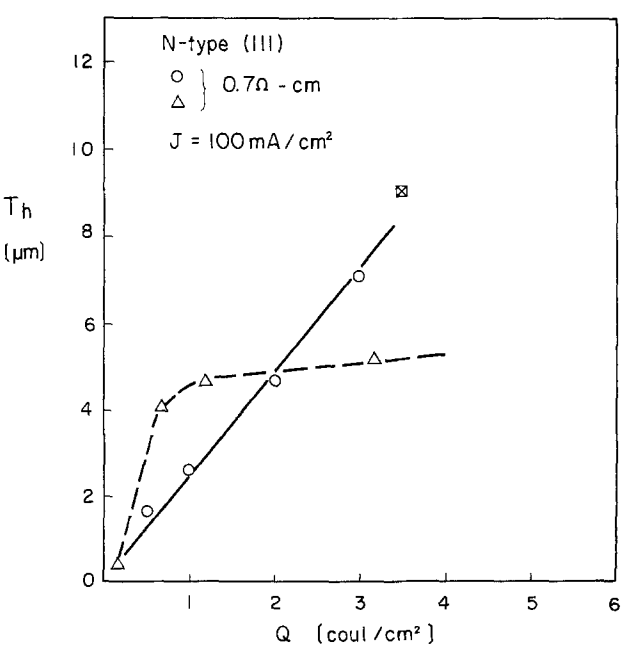

Fig. 11. I_p effect on T_h: ○ illumination during the entire anodic reaction, △ two-step reactions.

illumination, an etch channel is locally formed in the wafer. However, PSF is uniformly formed in the wafer without illumination after the thin silicon surface layer changes to PSF with illumination. From these results, the anodic reaction in high resistivity, n-type silicon is considered as follows. Assuming that hole generation centers are produced at the boundary between the silicon substrate and the PSF formed by first reaction with illumination, second anodic reaction proceeds uniformly and self-catalytically due to hole generation at the boundary without illumination.

Symbol ⊠ in Fig. 11 shows T_h formed by the following process through two step reactions. Initially, anodic reaction is effected at $J = 100$ mA/cm^2, $Q = 0.5$ C/cm^2, $I_p = 50$ mW/cm^2 and secondary at $J = 100$ mA/cm^2, $Q = 3$ C/cm^2 without illumination. These results indicate that T_h increases in the second reaction, compared with a small Q in the first reaction, when Q in the first anodic reaction becomes larger. Figure 12 shows photographs of a cross section of the sample described above. The cross section surface is etched off in 20 HNO_3:1HF for about 2 sec. Figure 12, a and b, indicates samples made by first and second anodic reaction, respectively. It was found that the PSF formation without holes injection occurs after PSF of an order of about 0.1 μm thickness is formed with holes injection, in spite of the n-type silicon resistivity.

Weight loss (ΔW) and PSF density (ρ_{por}).—The amount of silicon dissolution into HF was measured by ΔW before and after anodic reaction. N_A and N_D dependence on ΔW are shown in Fig. 13. Experimental run time is about 10 min. Regarding the p-type silicon, ΔW is nearly constant below about 10^{16} cm^{-3} in N_A and becomes smaller above 10^{16} cm^{-3}. On the other hand, regarding the n-type silicon, ΔW has a minimum at approximately 10^{16} cm^{-3} in N_D. The fact that as-grown PSF had a very active property made it difficult to obtain data that had little scatter. However, it was possible to obtain data that had no scatter by maintaining the process between before ΔW measurement and after PSF formation. The relation between PSF density and dopant concentration is obtained by using the curves in Fig. 13. This result is shown in Fig. 14. ρ_{por} of the p-type silicon with increasing N_A remains constant up to about 10^{16} cm^{-3}; then it increases rapidly. At $J = 150$ mA/cm^2, the relation between ρ_{por} and N_A is nearly the same as that at $J = 30$ mA/cm^2, but only the ρ_{por} value decreases. In the n-type silicon, ρ_{por} up to about 10^{16} cm^{-3} increases with increasing N_D, reaches a maximum, and then decreases. ρ_{por}, at $J = 30$ mA/cm^2, does not decrease markedly below about 10^{16} cm^{-3} in N_D compared with that at $J = 150$ mA/cm^2. ρ_{por} is determined by the amount of the local anodic dissolution point, the amount of dissolution silicon at the same point, and pore distribution in the thickness direction. It was noted that curves of ρ_{por} *vs.* dopant concentration are found to be similar to the formation rate *vs.* dopant concentration curves (see

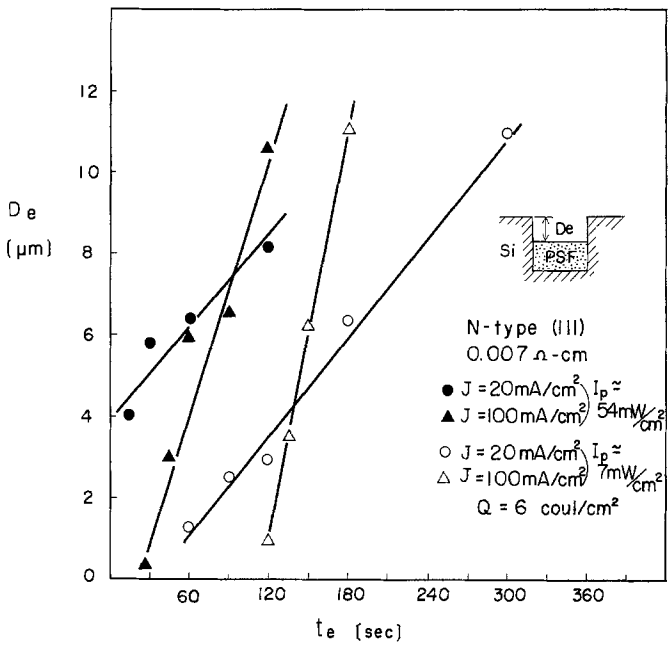

Fig. 16. Relationship of thickness (D_e) to be etched off in 20% NaOH solution (at 22°C) and etching time (t_e).

Fig. 10). It is considered that there is a certain correlation between the formation rate and ρ_{por}. Note that ρ_{por} of the p-type silicon changes markedly with N_A in comparison with that of the n-type silicon with N_D.

ρ_{por} of the p- and the n-type silicon, as a function of J, is shown in Fig. 15. That of the p-type silicon decreases linearly with increasing J. On the other hand, that of the n-type silicon first increases with increasing J against strong I_p, reaches a maximum, and then decreases. At I_p = 52 mW/cm², electropolishing begins to occur below about 20 mA/cm². At weak I_p (22 mW/cm²), the density peak is not reached and ρ_{por} decreases with increasing J. The reason that the ρ_{por} maximum appears seems to be due to the fact that, as will be revealed later from the PSF cross section structure, the average diameter of the void increases with decreasing J and the amount of the effective void increases with increasing J.

PSF structure examination in the thickness direction by chemical etching.—The relation between the PSF thickness (D_e) to be etched off in 20% NaOH solution at 22°C and the etching time (t_e) is shown in Fig. 16. D_e increases abruptly with increasing t_e for PSF formed at a strong I_p and a small J. D_e increases with increasing I_p for the same J and with increasing J for the same I_p. Surface structure of PSF formed at a strong I_p and a small J seems to be rough, while that of PSF formed at a weak I_p and a large J seems to be dense. From these results, it is revealed that variation of the PSF structure in the thickness direction is strongly dependent on I_p and J magnitude. On the other hand, the etching rate of single crystal silicon, for the same etchant as described above, is nearly zero. The reason that the PSF etching rate is very high is considered to be that PSF has a large surface area, weak bonding of silicon at the residual single crystal silicon surface, and various crystal orientations due to the porous structure.

PSF crystalline and cross section structure.—A reflection ED pattern, an EM photograph of as-grown PSF, a SEM photograph of a PSF cross section etched off in 60 HNO_3:1HF for 5 sec, and a PSF cross section photomicrograph are shown in Fig. 17a, b, c, and d, respectively. The p-type silicon resistivity used was 0.006 Ω-cm. Anodic reaction was performed under the conditions of J = 150 mA/cm², t = 60 sec. The ED

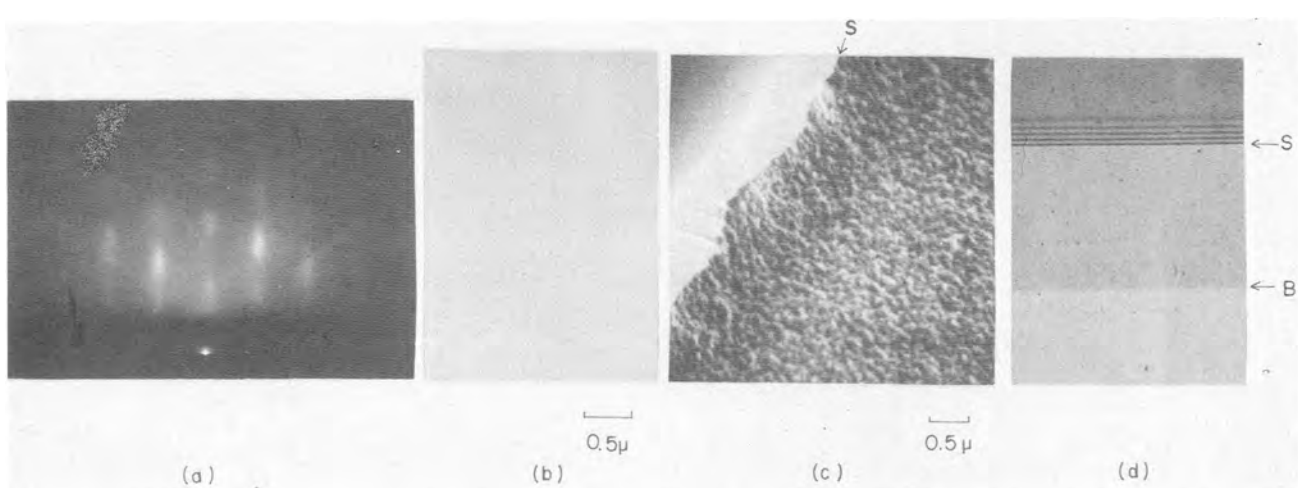

Fig. 17. Crystalline and cross section structure of the low resistivity, p-type silicon PSF: (a) ED pattern, (b) EM photograph, (c) SEM photograph, (d) photomicrograph.

pattern shows a weak halo pattern superimposed on the Kukuchi pattern. This halo pattern becomes stronger with increasing air drying time at room temperature. The surface feature is visually quite smooth and mirror surfaced. A very thin layer close to the PSF surface is dense and the inner region is rough. The boundary between PSF and the silicon substrate is clear.

The crystalline structure and feature in the thickness direction are shown in Fig. 18, A-E. The silicon used is the same as that shown in Fig. 17. Anodic reaction was performed under the conditions of $J = 100$ mA/cm^2, $t = 60$ sec. Figures 18a and b are an ED pattern and an EM photograph, respectively. Figure 18A is rinsed in 50% HF after air drying at room temperature for several hours. Figures 18B, C, D, and E are etched off in 60 HNO_3:1HF for 2, 3, 10, and 60 sec, respectively. In Fig. 18A, the crystalline structure is a single crystal and the surface feature is very smooth, but it is evident that many pits appear. Average diameter of the pits is approximately several hundred angstroms. The amount of pits increases with increasing air-drying time at room temperature. An evolution of many bubbles on the PSF surface was observed during rinsing in 50% HF. The location of bubble evolution seems to coincide with the PSF surface pits. These pits cannot be observed when as-grown PSF is rinsed in 50% HF for several hours after the anodic reaction, and also when they are immersed in H_2O for several days after the anodic reaction. The reason that many bubbles evolved locally at the PSF surface seems to be that amorphous silicon or SiF_2 (which formed locally during the anodic reaction) is oxidized, and finally H_2 gas evolved when the oxide dissolves in the HF. These considerations lead to the following two possible reactions

$$2SiF_2 + O_2 = SiO_2 + SiF_4 \quad [1]$$

or

$$\underset{\text{(amorphous)}}{Si} + O_2 = SiO_2 \quad [2]$$

From Fig. 18B, C, D, and E it is shown that the ED pattern, with increasing etching time, changes from the single crystal pattern to a polycrystal pattern of silicon superimposed on a mosaic pattern. Next, a study was made as to whether the polycrystal silicon ring pattern is due to intrinsic PSF structure or the appearance of an extrinsic effect caused by the chemical etching treatment. As will be seen later herein, PSF crystalline structure in the thickness direction obtained by x-ray diffraction is the single crystal. Thus, it seems that this ring pattern is due to the extrinsic effect. The etched surface pit changes from random distribution to distribution along a grainlike boundary with increased etching time. The PSF crystalline structure formed under the condition of $J = 1$ mA/cm^2 is nearly the same as that of $J = 100$ mA/cm^2.

X-ray diffraction of PSF about 100 μm thick is shown in Fig. 19. It is revealed that PSF has a single crystal structure. Consequently, this result indicates that anodic reaction by Turner's model (2) occurs at local points on an atomic scale, leaving the crystal orientation.

An ED pattern, an EM photograph of the as-grown PSF surface, an SEM photograph of a PSF cross section, and a PSF cross section photomicrograph are shown in Fig. 20a, b, b*, c, c*, and d, respectively. The p-type silicon resistivity used was 1.5 Ω-cm. Anodic reaction was performed under the conditions of $J = 100$ mA/cm^2, $t = 60$ sec for Fig. 20a, b, b*, c, d, and of $J = 30$ mA/cm^2, $t = 360$ sec for Fig. 20c*. b* and c, c* in Fig. 20 were etched off in 5% NaOH solution for 3 sec and in 60 HNO_3:1HF for 5 sec, respectively. The ED pattern becomes broad, compared with that of Fig. 17. Distortion of the PSF surface crystalline structure occurs when the p-type silicon resistivity becomes higher as anodic reaction is performed under the same condition. The PSF crystalline structure, in the inner region, is a mosaic pattern. The surface feature is nearly the same as that of Fig. 17 (see b in Fig. 20). Grainlike boundaries are observed on the PSF surface

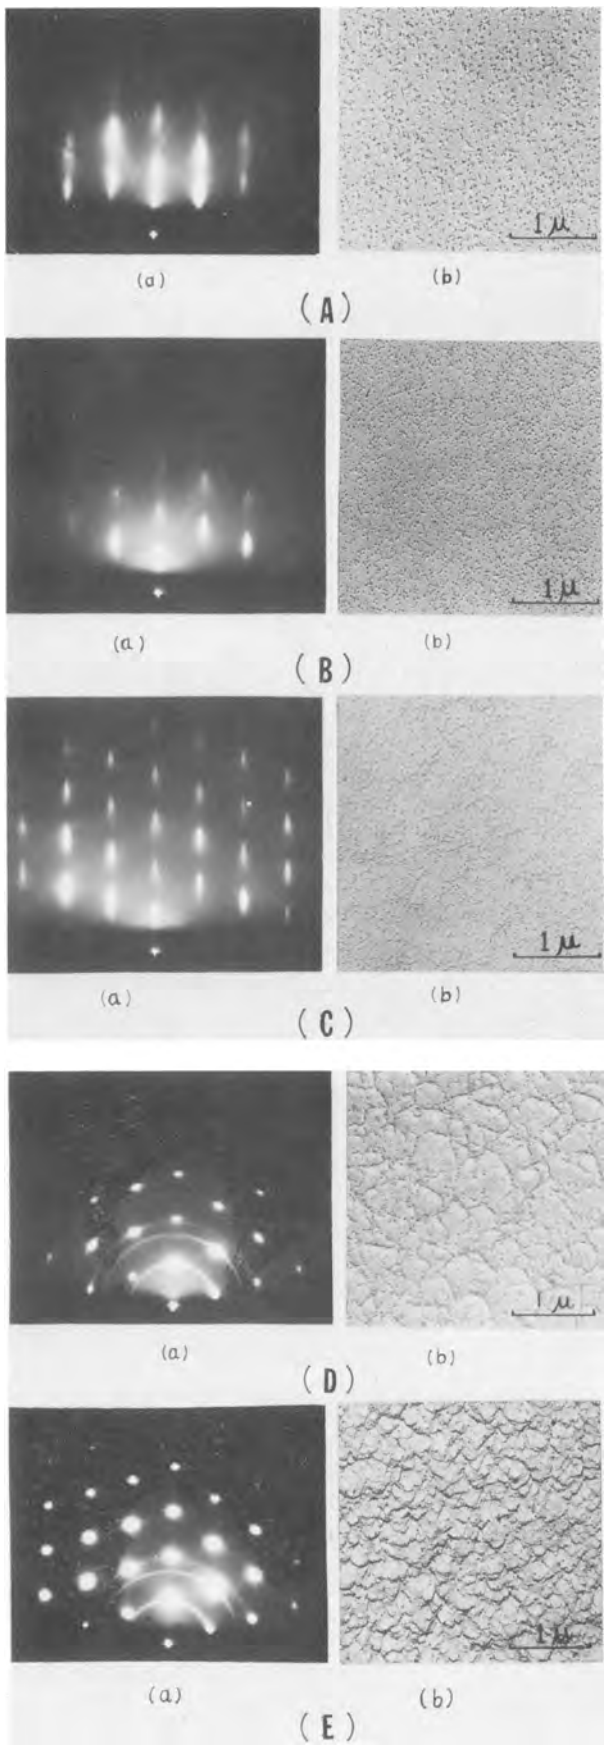

Fig. 18. Variation of crystalline structure and feature in the PSF thickness direction.

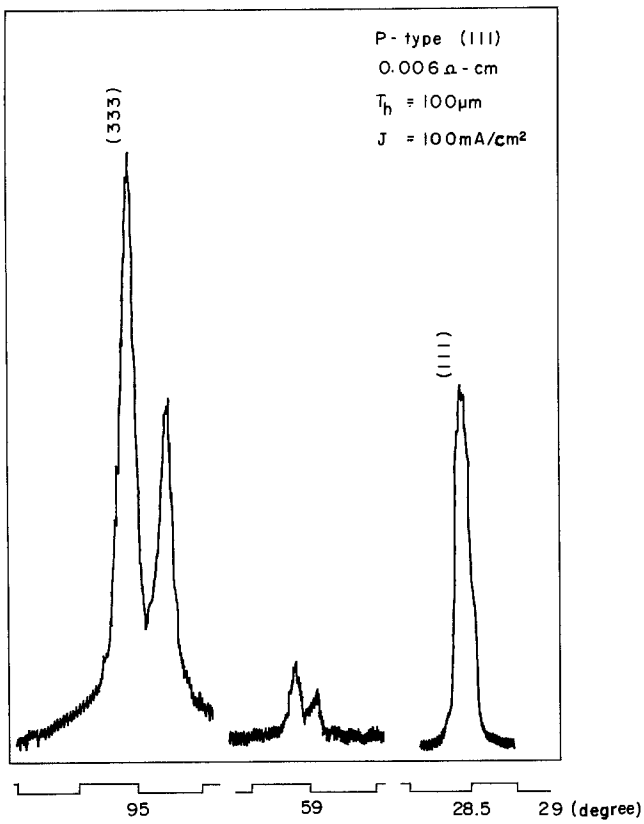

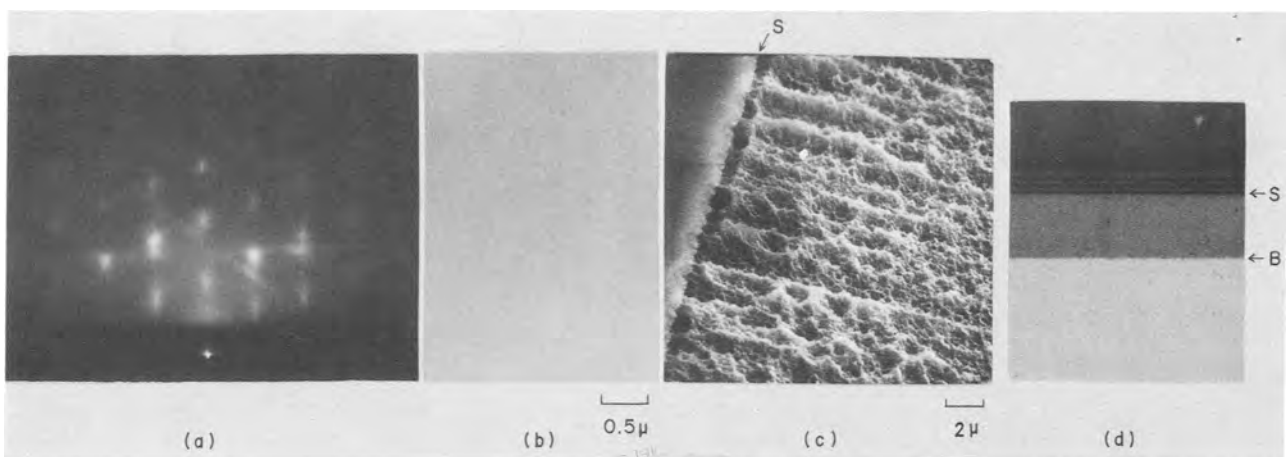

Fig. 19. (111) oriented p-type silicon PSF x-ray diffraction spectrum.

etched off (see b* in Fig. 20). The PSF cross section, except for the PSF surface, becomes rough structured with increasing J, compared with c and c* in Fig 20, and also with decreasing N_A. The PSF surface is virtually dense, as well as that in Fig. 17. As is evident from Fig. 20d, there is a small irregularity of the boundary line between PSF and the silicon substrate compared with that of 0.006 Ω-cm resistivity. It seems that this irregularity correlates with the distribution of acceptor atoms. The visual color of the PSF cross section is a deeper black, the same color as the PSF surface.

An ED pattern, an EM photograph of the as-grown PSF surface, an SEM photograph of the angle lapping surface to be etched off in 60 HNO_3:1HF for 5 sec, and a cross section photomicrograph are shown in Fig. 21a, b, c, and d, respectively. The n-type silicon resistivity used was 0.007 Ω-cm. Anodic reaction was performed under the conditions of $J = 100$ mA/cm², $t =$ 60 sec, $I_p = 54$ mW/cm². The crystalline structure of the as-grown PSF is single crystal, having a mosaic pattern over the inner region, as well as that of Fig. 18 (5). The PSF cross section structure is dense at the surface and rough in the inner region, and is similar to that formed by high N_A silicon.

An ED pattern, an EM photograph of the as-grown PSF surface, an SEM photograph of the angle lapping surface to be etched off in 60 HNO_3:1HF for 5 sec, and a cross section photomicrograph are shown in Fig. 22a, b, c, c*, and d, d*, respectively. Layer resistivity of the n-type epitaxial silicon used was 0.6 Ω-cm. Anodic reaction was performed under the conditions of $J = 100$ mA/cm², $t = 60$ sec, $I = 54$ mW/cm² for Fig. 22a, b, c, d, d*, and of $J = 30$ mA/cm², $t = 50$ sec, $I_p = 27$ mW/cm² for Fig. 22c*. d* in Fig. 22 was etched off in 60 HNO_3:1HF for 5 sec. The ED pattern indicates a weak halo pattern superimposed on the Kikuchi pattern at the PSF surface and the mosaic pattern in the inner region. The feature of the as-grown PSF surface is very smooth, although local pits are evident. The PSF cross section structure is virtually dense at the surface and rough in the inner region. Local voids of large diameter are observed at $J = 30$ mA/cm². No boundary can be observed between PSF and the silicon substrate

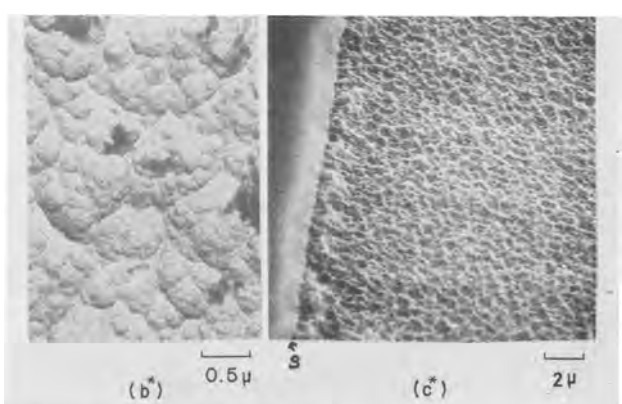

Fig. 20. Crystalline and cross section structure of the high resistivity p-type silicon PSF: (a) ED pattern, (b), (b*) EM photographs, (c), (c*) SEM photographs, (d) photomicrograph.

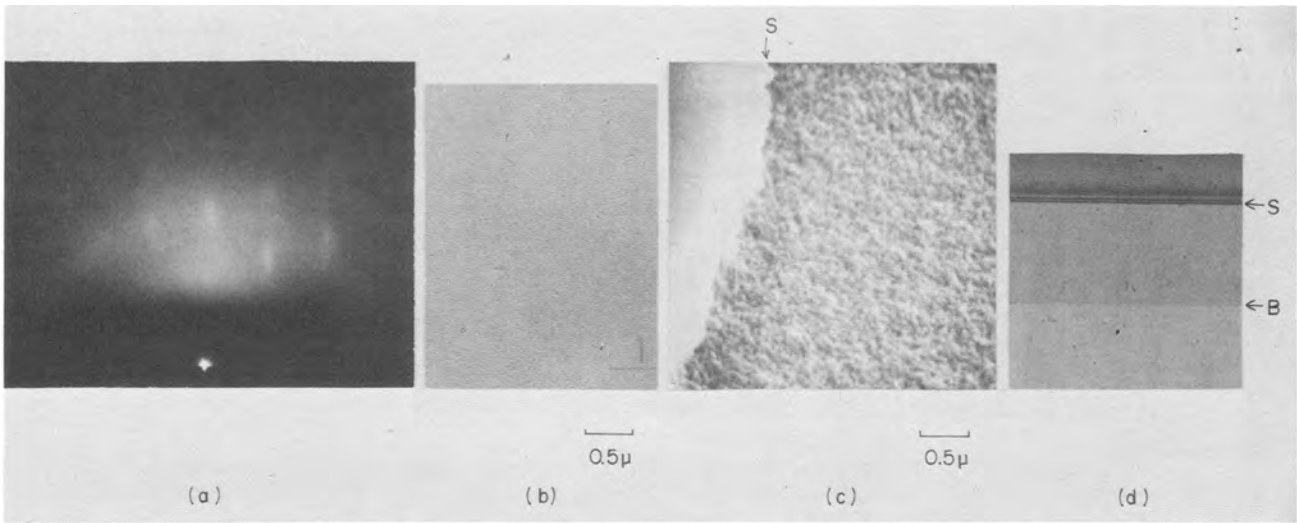

Fig. 21. Crystalline and cross section structure of the low resistivity, n-type silicon PSF: (a) ED pattern, (b) EM photograph, (c) SEM photograph, (d) photomicograph.

(see Fig. 22d). This result is caused by the fact that the PSF density is close to that of the silicon. A porous silicon layer becomes clearly observable by etching the angle lapping surface (see Fig. 22d*).

From the above results, the PSF surface crystalline structure change is investigated, while varying the main anodic reaction parameters (N_D, I_p, J, t). When N_D becomes lower and I_p becomes stronger, and when

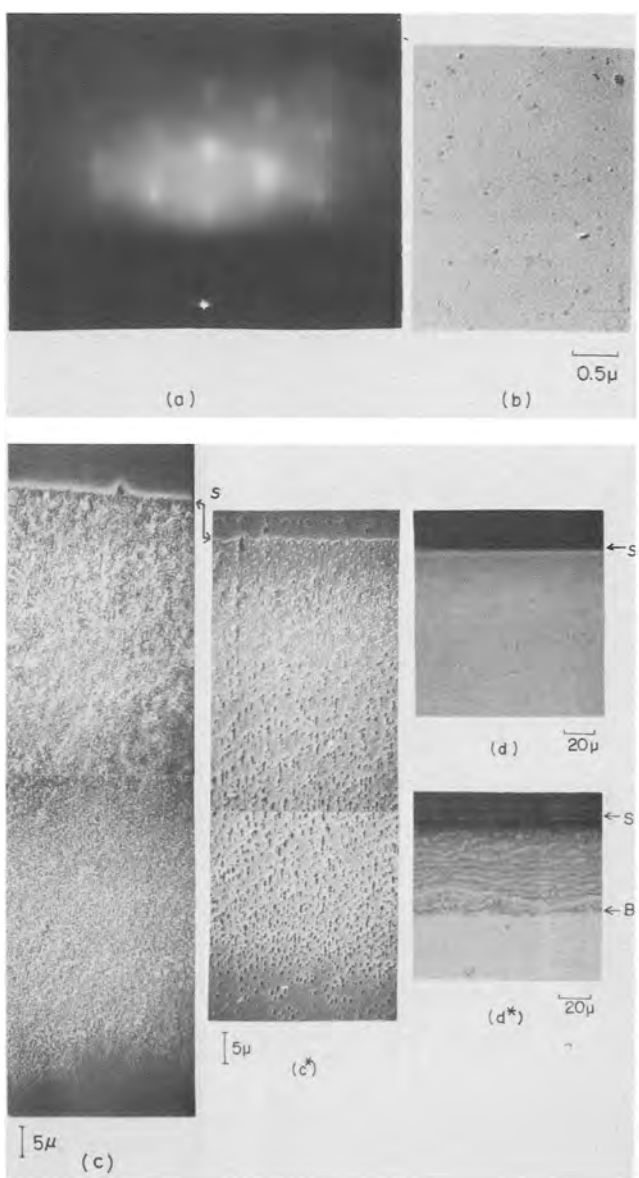

Fig. 22. Crystalline and cross section structure of the high resistivity, n-type silicon PSF: (a) ED pattern, (b) EM photograph, (c), (c*) SEM photographs, (d), (d*) photomicrographs.

J becomes smaller and t becomes longer, the ED pattern of the PSF crystalline structure changes from the Kikuchi pattern to a very weak broad silicon pattern superimposed on a halo pattern, and finally to a halo pattern, and electropolishing begins to appear. This halo pattern seems to be caused by PSF surface oxidation in air drying and amorphous silicon formed under the anodic reaction. The crystalline structure is a mosaic pattern in the PSF inner region, even when it is amorphous at the PSF surface. The relation between the crystalline structure of the PSF surface and the anodic reaction parameters (N_D, I_p, J, t) is qualitatively unified in Fig. 23. The boundary between the single crystal and the amorphous region has a broad line. The amorphous region enlarges when t becomes longer and N_D decreases.

Effects of Ip and J on the PSF cross section structure are shown in Fig. 24. The layer resistivity of the n-type epitaxial silicon used was 2.5 Ω-cm. Figures 24a, b, c, d, and e are photomicrographs of a PSF cross section. Figures 24b* and c* are SEM photographs of cross sections shown in Fig 24b and c, respectively. Anodic

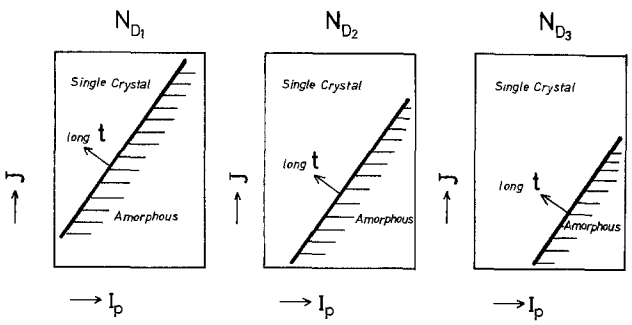

Fig. 23. Illustration of anodic conditions dependence on the n-type silicon PSF surface crystalline structure. Where, $N_{D_1} < N_{D_2} < N_{D_3}$.

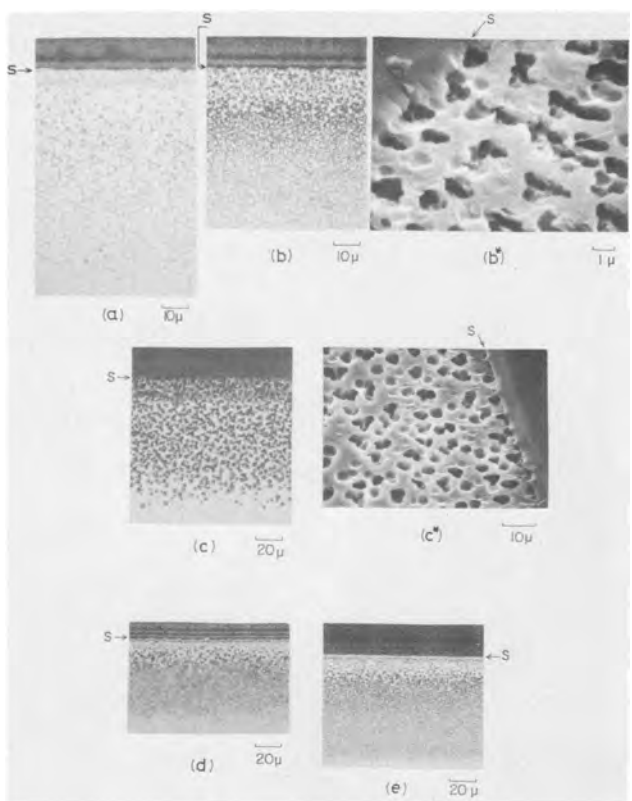

Fig. 24. I_p and J effects on PSF cross section structure with n-type silicon 2.5 Ω-cm resistivity: (a), (b), (c), (d), and (e) are photomicrographs; (b*) and (c*) are SEM photographs.

reaction conditions of Fig. 24a, b, c, d, and e were $J = 30$ mA/cm², $I_p = 7$ mW/cm², $t = 120$ sec; $J = 30$ mA/cm², $I_p = 27$ mW/cm², $t = 120$ sec; $J = 30$ mA/cm², $I_p = 54$ mW/cm², $t = 120$ sec; $J = 150$ mA/cm², $I_p = 7$ mW/cm², $t = 30$ sec; and $J = 150$ mA/cm², $I_p = 27$ mW/cm², $t_p = 30$ sec, respectively. All PSF cross sections were etched in 60 HNO_3:1HF for 5 sec. The cross section feature indicates that the region close to the PSF surface is dense compared with the inner region of PSF. Many voids appear clearly along the (100) direction by etching when the n-type silicon resistivity becomes higher. When I_p increases, the voids in the layer close to the PSF surface tend to increase and the effective diameter of the voids increases. On the other hand, when J increases, the amount of voids in PSF increases.

Anodic dissolution points seem strongly dependent on the dopant atom position. At a lower dopant concentration, it is considered that local dissolution occurs, compared with the anodic dissolution of silicon with a high dopant concentration.

PSF atomic bonds and composition (8).—A typical infrared absorption spectrum from as-grown PSF reveals that the atomic bonds in PSF are Si-H, Si-Si, and Si-O. The characteristic infrared absorption peak of as-grown PSF is unstable Si-Si bonds at approximately 16 μm.

The existence of a few percent of fluorine atoms in as-grown PSF was confirmed by sparked mass spectroscopy, although the existence of those atoms was not confirmed by infrared absorption spectroscopy. The same result was obtained for both the p- and the n-type silicon PSF.

Summary

1. When t is short, T_h is nearly proportional to t. This linearity shifts when t becomes longer.

2. In the p-type silicon with high resistivity, J increases exponentially with increasing η. J, however, increases slowly with increasing η when the resistivity is very low. In the n-type silicon with high resistivity, first J increases with increasing η, saturates, and finally increases rapidly. The PSF structure varies largely in each region. As for the n-type silicon with low resistivity, current saturation becomes obscure.

3. The formation rate is strongly dependent on J, N_A, and η_{HF} in the p-type silicon PSF, and increases with increasing J, N_A, and η_{HF}. In the n-type silicon PSF, the formation rate is strongly dependent on N_D, J, I_p, and η_{HF}. It has a maximum at about 10^{16} cm^{-3} in N_D. The rate initially increases rapidly with increasing J and is then nearly saturated. It increases with increasing I_p at a large J and decreases with increasing I_p at a small J.

4. ρ_{por} of p-type silicon PSF increases with an increasing N_A and decreases linearly with increasing J. ρ_{por} of the n-type silicon PSF has a maximum at about 10^{16} cm^{-3} in N_D. ρ_{por} has a maximum at about 50 mA/cm² in J when I_p becomes stronger. When I_p becomes weaker, no ρ_{por} maximum appears and ρ_{por} decreases with increasing J. ρ_{por} decreases with increasing I_p. The degree of density variation with dopant concentration of the p-type silicon PSF is larger than that of the n-type silicon.

5. Electropolishing under illumination was observed in the n-type silicon PSF when anodic reaction was effected under conditions of a very small J and a strong I_p.

6. When the silicon surface order of 0.1 μm thickness changes to PSF under hole injection, PSF formation continues without hole injection, in spite of resistivity in the n-type silicon.

7. PSF is very rapidly etched by alkali solution etchant at room temperature.

8. Crystalline structure of the p-type silicon PSF surface is single crystal and the PSF inner region has a mosaic pattern. The single crystal pattern is de-

formed when N_A is lower. That of the n-type silicon PSF surface varies from a single crystal pattern to amorphous according to the anodic conditions (N_D, I_p, J, t). The crystalline structure of the PSF inner region indicates a mosaic pattern even when that of the PSF surface is amorphous.

9. The cross section structure of the p-type silicon PSF is nearly uniform, except for a very thin layer close to the surface, and the surface layer is dense compared with an inner region. That of the n-type silicon PSF is strongly dependent on N_D, J, and I_p. The structure difference between the PSF surface layer and an inner region is remarkable when N_D is lower, I_p is strong, and J becomes lower. The PSF surface layer is dense and an inner region is rough.

10. Anodic dissolution occurs at local points of the silicon surface under the anodic condition by which the single crystal PSF is obtained. The PSF formation model proposed by Turner (2) is applicable under the anodic condition by which anodic dissolution occurs at local points.

11. It is revealed that the PSF composition mainly consists of silicon, with a very small amount of fluorine, hydrogen, and oxygen.

Acknowledgments

We thank Dr. H. Toyoda for kindly providing encouragement during the course of this work. We also thank Dr. K. Ono for his helpful suggestions on electron diffraction analysis. We gratefully acknowledge the contribution of S. Hirota, who made observation by electron microscope and by reflection electron diffraction. Further, we appreciate the helpful comments on PSF formation made earlier in this work by Y. Watanabe and Y. Igarashi.

Manuscript received July 7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the Nippon Telegraph and Telephone Public Corporation.

Preparation of Nitrides by Active Nitrogen[1]

II. Si_3N_4

M. Shiloh and B. Gayer

and F. E. Brinckman

National Bureau of Standards, Washington, D.C. 20234

ABSTRACT

A general method for the preparation of nitrides is described by which active nitrogen, excited in a microwave cavity, is subsequently reacted with SiI_4 vapors formed *in situ* by passing iodine vapors over heated silicon powder. The temperature dependence of the deposition of Si_3N_4 on polished Si wafers was measured and compared with calculated thermodynamic data of similar reactions with nonactive nitrogen. The kinetic measurements were related to the special flow characteristics of the system. The over-all reaction

$$4(N)_g + 3(SiI_4)_g \rightarrow (Si_3N_4)_s + 6(I_2)_g$$

was found to be exothermic. Two regions of different slopes were obtained from the Arrhenius plot

$$\Delta E_{(280°\text{-}450°C)} = -3070 \text{ cal/mole}$$

$$\Delta E_{(450°\text{-}600°C)} = -8600 \text{ cal/mole}$$

The calculated temperature dependence of the enthalpy change of the corresponding reaction with nonactive nitrogen was shown to be almost constant in the range studied. Similar values of negative activation energy were obtained for the assumed second-order rate-determining reaction: $N + SiI_4 \rightarrow SiN + 2I_2$.

Much work has been done on the preparation of amorphous films of Si_3N_4 on single crystal wafers of silicon, because of the importance of such films in the technology of silicon electronic devices (1-11). The method mainly used is the reaction of SiH_4 with NH_3. Though this reaction is favorable thermodynamically at rather low temperatures, it can be carried out only above 700°C for kinetic reasons (2-4). The problem becomes much more difficult kinetically when NH_3 is replaced by the exceptionally stable N_2 molecule as the nitriding agent.

The main method used to overcome the kinetic barrier is the excitation of the reacting gases by an

Key words: CVD Si_3N_4 films, active nitrogen reactions, activation energy, SiI_4 reactions, flow reactors.

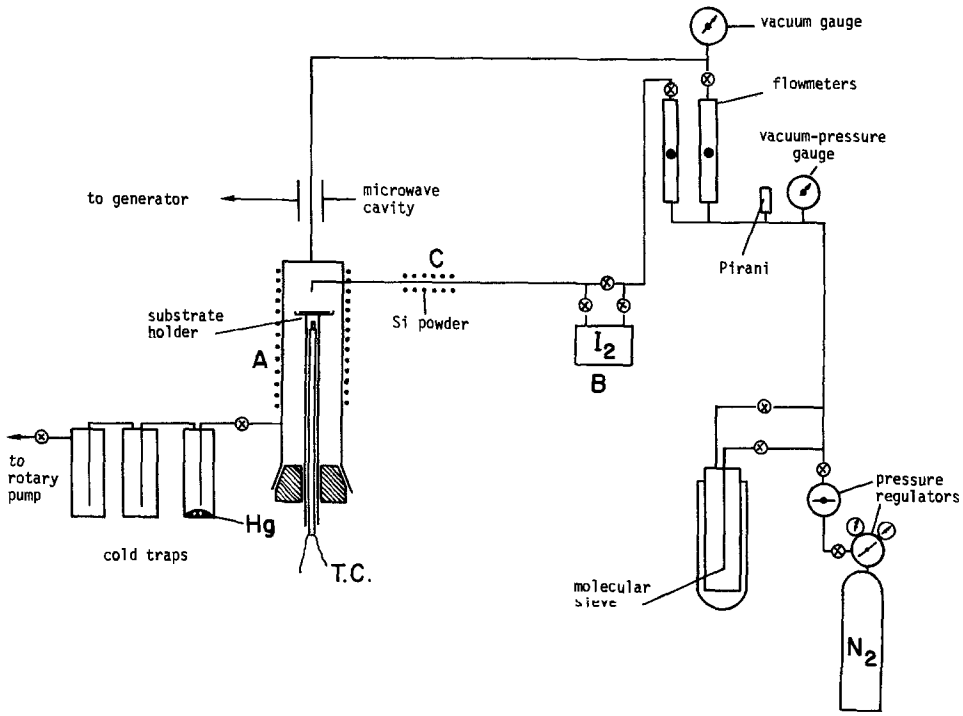

Fig. 1. Schematic diagram of the flow system for preparing nitrides.

electric field produced by d-c or rf power sources. Several works were published on the preparation of Si_3N_4 films by rf or microwave glow discharge excitation, most of them using NH_3 and SiH_4 as the reactants. In all cases both reactants are excited in the vicinity of the substrate (8-14). In a patented method (15) Si_3N_4 films are produced by exciting a mixture of N_2 and $SiBr_4$ vapors by a d-c discharge, forming a plasma in the region of the substrate.

In the present work a general method is described for the preparation of nitrides by microwave excitation of the N_2 reactant alone. The active nitrogen thus produced is then reacted on a substrate with an appropriate volatile compound. The substrate can be maintained at any desired temperature and is not affected by the temperature or other factors in the excitation region. The source of Si is SiI_4 vapor, formed *in situ* by reacting iodine vapor with silicon. Thus, the starting materials for the process are nitrogen, silicon, and iodine which are easier to handle than ammonia, silane, or the silicon halides. Because the substrate and the SiI_4 vapors are not affected by the microwave field in the antenna zone, it is easier to control and analyze the process, especially the temperature dependence of the over-all reaction. The operating pressure used (in the range 5-80 mm Hg) is higher than in previously reported glow discharge methods. This prevents the coating of the reactor walls, which occurs at lower pressures. The reaction that we use is also more favorable thermodynamically at lower temperatures, which is an important advantage in device fabrication. Data on the growth rate of Si_3N_4, produced in this work by the reaction between active nitrogen and SiI_4, are compared with calculated values from available thermodynamic data on reactions with nonactive nitrogen and are related to the flow characteristics of our system.

Experimental

A schematic diagram of the flow system is presented in Fig. 1. The main flow of purified nitrogen is metered to the main reactor (A) after passage through the microwave cavity. A second flow of nitrogen carrier is passed through the iodine reservoir (B) into the SiI_4 reactor (C), which contains silicon powder at 600°-700°C. SiI_4 vapor is formed by reaction with iodine and is carried to the main reactor through a nozzle in the center. The parallel streams of active nitrogen and SiI_4 vapor flow perpendicular to a polished silicon wafer and deposit Si_3N_4 on its surface. The temperature of the tube connecting reactor (C) to the main reactor (A) was about 200°C.

The main reactor is described in Fig. 2. The pressure in the reactor is controlled by the pumping speed of the rotary pump and the setting of the inlet needle-valve of the active nitrogen stream. The upper limit of the pressure is determined by the ability to sustain the discharge in the microwave cavity. In our system we could reach up to about 80 mm Hg. The outlet stream from the reactor, which contains iodine, is passed through mercury and liquid nitrogen cold traps before it enters the rotary pump. The reactor is made of quartz and resistively heated. Teflon valves and Viton O-rings were used in sections which are in contact with iodine vapors.

Matheson oxygen-free nitrogen was used after being further purified by passage through a 5A molecular sieve trap to remove moisture. Iodine and silicon powder were of analytical reagent grade. The polished silicon wafers, after cleaning with T.C.E., HF, and deionized water, were placed on a quartz pedestal equipped with a thermocouple to measure the reaction temperature. The wafers used were 200μ thick, which permitted *IR* transmission measurements. The flow rate of both streams was measured by rotameters at atmospheric pressure. The microwave source was a Raytheon 100W 2540 MHz generator. The entire system was helium leak tested to meet high vacuum requirements. The deposition rate was determined by weighing the Si_3N_4 films formed on the wafers at measured time intervals (usually 30 min). Density of 3.2 g/cm^3 (24) was used to calculate the thickness. Agreement within 5% with Talysurf measurements was found. The refractive index values were in the range 1.9-2.0 measured by reflected light interference) which correspond to the density value used (24) and serve as an indication to the purity of the film. The purity of the Si_3N_4 films was checked by examining the *IR* transmission spectrum. A typical *IR* spectrum is shown in Fig. 3. It shows the same characteristic absorption band of Si-N bonds measured for Si_3N_4 films formed by CVD from SiH_4-NH_3 or sputtering of Si in N_2 (24). Traces of water cause the formation of NH_4I and the appearance of the characteristic absorption peak of NH_4^+ near 1400 cm^{-1}. The flow rates of both the main stream and the iodine carrier were kept constant at 300 and 15 cm^3/min (STP), respectively. The total pressure in the

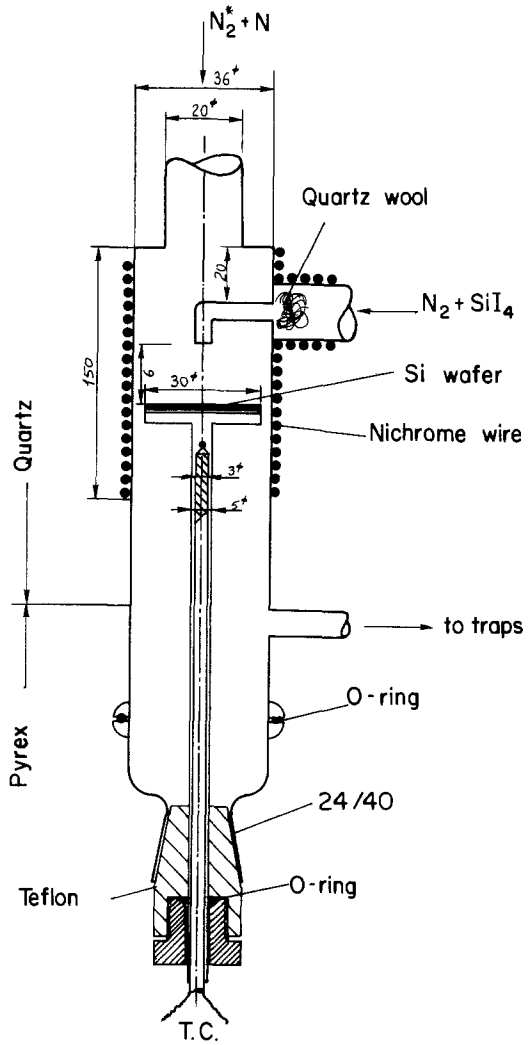

Fig. 2. Schematic diagram of the main reactor

reactor was maintained at 7 mm Hg. The temperature of the iodine reservoir was held at 22°C, corresponding to 0.24 mm Hg of I_2 (17). The low flow rate of the iodine carrier insured sufficient contact time for equilibration in both the iodine reservoir (B) and the silicon iodide generator (C). No free iodine was found in the nonactive nitrogen carrier leaving reactor (C). The amount of iodine carried to the reactor by a stream of nitrogen was measured at known time intervals and was found to correspond to saturation of the carrier stream.

When the carrier stream, containing SiI_4 vapors, meets the yellow afterglow of active nitrogen an intense blue stream of excited iodide vapor is observed. Under the flow conditions of our system the diameter of the blue flame was about the same as that of the nozzle, *i.e.*, 2 mm, with gradual broadening towards the substrate. The reaction between SiI_4 and active nitrogen, under the conditions studied, was heterogeneous and Si_3N_4 was deposited only on the silicon wafer. Because of the large diameter of the wafer (30 mm) compared with the distance to the nozzle (6 mm), all the Si_3N_4 was deposited in a circular area of about 20 mm in diameter. By observing the shape of the blue zone it was possible to adjust the flow rates and the distance from the nozzle in preliminary experiments to insure that deposition occurs only within the wafer area. Interference fringes were observed only at the circumference of the deposition area, within 2 mm of the edge.

Results and Discussion

Thermodynamics of the reaction between SiI_4 *and nitrogen.*—Plot (a) in Fig. 4 shows the temperature

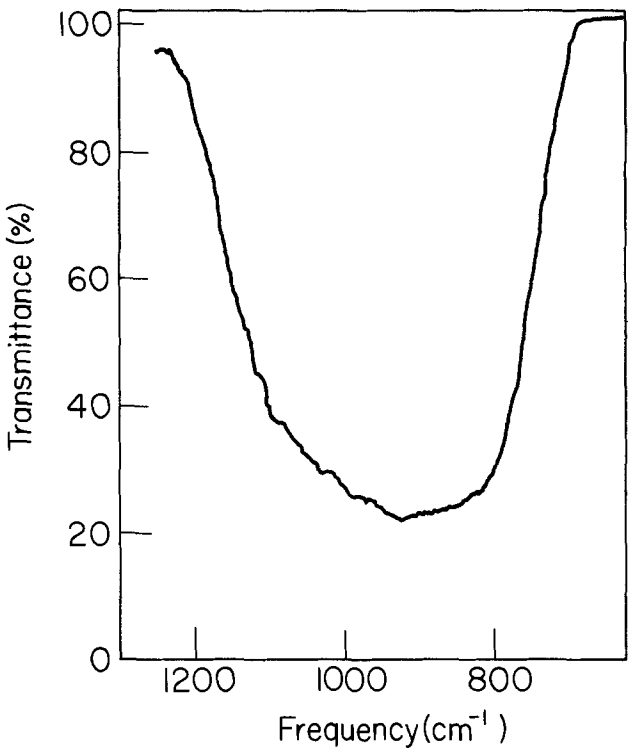

Fig. 3. Typical *IR* spectrum of Si_3N_4

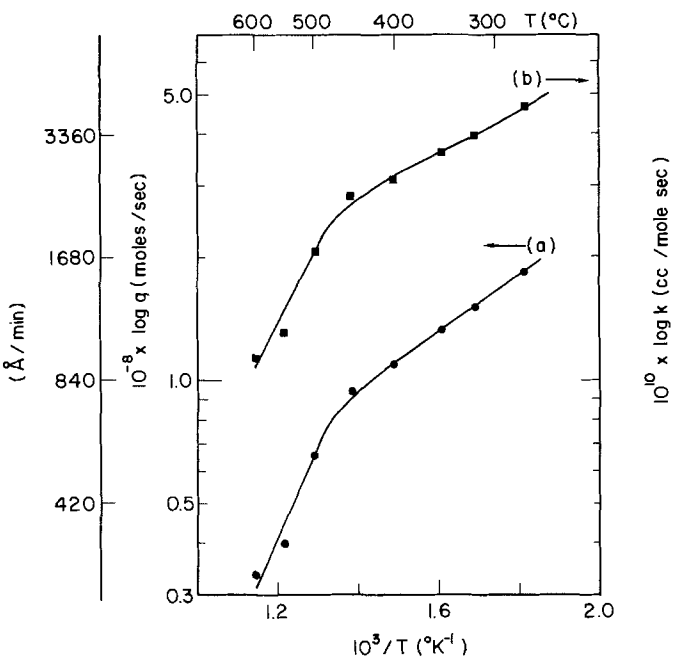

Fig. 4. Temperature dependence of deposition rate of Si_3N_4 by reaction of SiI_4 and active N_2. (a) Measured deposition rate; (b) calculated second-order rate constant, according to Eq. [4].

dependence of the deposition rate of Si_3N_4 from the reaction between SiI_4 and active nitrogen, as obtained in this work. Assuming N atoms to be the main reactant in active nitrogen (23), the deposition may be described by the following over-all reaction

$$3SiI_4 + 4N \rightarrow Si_3N_4 + 6I_2 \qquad [1]$$

Plot (b) in Fig. 4 shows the temperature dependence of the calculated second-order rate constant, assuming the following rate-determining bimolecular reaction

$$SiI_4 + N \xrightarrow{k} SiN + 2I_2 \qquad [2]$$

where k is the constant in the following rate equation

$$\frac{d[\mathrm{SiN}]}{dt} = k[\mathrm{N}][\mathrm{SiI_4}] \qquad [3]$$

It is assumed that breaking Si-I bonds and forming Si-N bonds as in Eq [2] would be much slower than the further reaction of Si-N with N atoms (both are unstable species) to form the stable phase of Si_3N_4. The reaction is assumed to occur mainly on the surface of the substrate, which serves, as a third body, to absorb the excess of energy released by the reaction. The integrated form of Eq. [3] is given by

$$k = 2.3 \log \frac{[\mathrm{SiI_4}]_i[\mathrm{N}]_f}{[\mathrm{SiI_4}]_f[\mathrm{N}]_i} \Big/ \; t([\mathrm{N}]_i - [\mathrm{SiI_4}]_i) \qquad [4]$$

(for $[\mathrm{N}]_i \neq [\mathrm{SiI_4}]_i$). The initial ($i$) and final ($f$) concentrations of the reactants in Eq. [4] after the time interval t (which is the contact time of the flowing reactants with the wafer) are calculated as follows

1. $[\mathrm{SiI_4}]_i = \dfrac{\dot{n}_1}{\Sigma \dot{n}_i} \times \dfrac{P}{RT}$ moles/cm^3

where: $\dot{n}_1$ is the inlet flow rate of SiI_4 in the carrier stream; $\Sigma \dot{n}_i$ is the total flow rate of the carrier stream; P is the total pressure in the reactor

2. $[\mathrm{N}]_i = \dfrac{2X_dP}{RT}$ moles/cm^3

where X_d is the degree of dissociation of N_2.

3. $[\mathrm{SiI_4}]_f = \dfrac{(\dot{n}_1 - 3q)}{\Sigma \dot{n}_1} \dfrac{P}{RT}$ moles/cm^3

where q is the deposition rate of Si_3N_4. The rate of consumption of SiI_4 by reaction [1] is $3q$.

The values of the known parameters in our experiments are: $R = 82$ atm cm^3/°K mole, $P = 0.92 \times 10^{-2}$ atm, $\dot{n}_1 = 1.92 \times 10^{-7}$ moles/sec (corresponding to $P_{SiI_4} = 0.12$ Torr), $X_d = 0.01$ (Ref. 18), $\dot{n}_2 = 44.6 \times 10^{-7}$ moles/sec (flow rate of N atoms corresponding to $X_d = 0.01$), $\Sigma \dot{n}_i = 112 \times 10^{-7}$ moles/sec, $t = 1.2 \times 10^{-2}$ sec (calculated from the linear velocity of the main stream, 124 cm/sec, and the wafer radius, 1.5 cm).

As can be seen $\dot{n}_2 >> \dot{n}_1$ in these experiments. We can therefore assume that the change in concentration of atomic nitrogen after reacting with SiI_4 is very small and therefore, $[\mathrm{N}]_i \approx [\mathrm{N}]_f$. Inserting the above expressions and data in Eq. [4] one obtains

$$k = 5.69 \times 10^8 \times T \times \log \left(\frac{1.92 \times 10^{-7}}{1.92 \times 10^{-7} - 3q} \right) \text{cm}^3/\text{mole sec} \qquad [4a]$$

Equation [4a] relates the second-order rate constant of reaction [2] to the reaction temperature (T) and the deposition rate of Si_3N_4 (q). The Arrhenius plot of k is shown in Fig. 4 as plot (b).

The experimental results as represented in Fig. 4 show that the deposition rate, in the range 280°-600°C, increases with decreasing temperature, which indicates that reaction [1] is exothermic. As the deposition occurred entirely within the wafer area, deposition is assumed to be completed while the reactants are in contact with the substrate. Therefore, it is reasonable to assume that steady-state conditions prevail near the surface.

Two regions of different slopes are seen in the Arrhenius plot (Fig. 4), with that above 450°C having about twice the negative value of the activation energy. Plots (a) and (b) exhibit very similar shapes and slopes. Values of activation energy for the deposition reaction derived from the plots are given in Table I. In order to compare reaction [1] with the corresponding reaction with nonactive nitrogen, the temperature dependence of $\Delta G°$ and $\Delta H°$ for nonactive nitrogen was derived from available data. The corresponding functions for $SiCl_4$ were also compared. [SiH_4 was excluded because it has been reported that no condensable product is formed by reaction with active nitrogen (23).]

Table I. Activation energy for reaction of SiI_4 with active N_2

Temperature range (°C)	ΔE_a (cal/mole)	ΔE_b (cal/mole)
280-450	−3070	−2550
450-600	−8600	−7670

$\Delta G°(T)$ for the formation of $(SiCl_4)_g$ and $(Si_3N_4)_s$ from the elements are given in Ref. (17)

$$(\mathrm{SiCl_4})_g = (\mathrm{Si})_s + 2(\mathrm{Cl_2})_g \qquad [5]$$

$$\Delta G° = 155{,}600 + 3.64T \log T - 43.9T \text{ (cal/mole)} \qquad [5a]$$

$$(\mathrm{Si_3N_4})_s = 3(\mathrm{Si})_s + 2(\mathrm{N_2})_g \qquad [6]$$

$$\Delta G° = 177{,}000 + 5.76T \log T - 96.3T \text{ (cal/mole)} \qquad [6a]$$

$\Delta G°(T)$ for the formation of $(SiI_4)_g$ was derived from $C°_P(T)$ functions for $(Si)_s$, $(I_2)_g$, and $(SiI_4)_g$ from Ref. (19), and $\Delta H°_{298}$ and $S°_{298}$ values from Ref. (17, 20, 21)

$$(\mathrm{SiI_4}) = (\mathrm{Si})_s + 2(\mathrm{I_2})_g$$

$$\Delta H°_{298} = +59.0 \text{ (kcal/mole)}$$

$$\Delta S°_{298} = +21.0 \text{ (cal/mole °K)}$$

$$\Delta C°_p = 1.99 - 0.74 \times 10^{-3}T - 0.06 \times 10^5 T^{-2} \text{(cal/mole °K)} \qquad [7]$$

Inserting these values in the general equation for $\Delta G°$ (17) the following expression is obtained

$$\Delta G° = 59{,}580 + 4.57T \log T - 44.1T \text{ (cal/mole)} \qquad [7a]$$

From [5a], [6a], and [7a] the following relations are obtained

$$3(\mathrm{SiI_4})_g + 2(\mathrm{N_2})_g = (\mathrm{Si_3N_4})_s + 6(\mathrm{I_2})_g \qquad [8]$$

$$\Delta G° = 1800 + 7.97T \log T - 36.1T \text{ (cal/mole)} \qquad [8a]$$

$$3(\mathrm{SiCl_4})_g + 2(\mathrm{N_2})_g = (\mathrm{Si_3N_4})_s + 6(\mathrm{Cl_2})_g \qquad [9]$$

$$\Delta G° = 289{,}000 + 5.16T \log T - 35.4T \text{ (cal/mole)} \qquad [9a]$$

It is seen that reaction [6] is strongly endothermic and reaction [5] is almost independent of temperature (very slightly exothermic). From [8a] one obtains, for reaction [8]

$$\Delta H° = 1800 - 3.47T \text{ (cal/mole)} \qquad [10]$$

which gives, in the temperature range of our experiments 280°-600°C

$$-190 \text{ cal/mole} > \Delta H > -1230 \text{ cal/mole}$$

In Fig. 5 $\log K_p(T)$ is compared for these reactions. It is clear that for a favorable process at low temperatures SiI_4 should be chosen as the reactant. The experimental values of activation energy for reaction [1] given above show that the reaction with active nitrogen is more exothermic than the corresponding reaction with nonactive nitrogen, as expected

Flow characteristics of the process.—The geometry of the main reactor (A) is shown in Fig. 2. Under our experimental conditions the flow of both streams was laminar. The linear velocity of the main stream (containing the active nitrogen) was $v_2 = 124$ cm/sec and that of the SiI_4 carrier at the exit from the nozzle was $v_1 = 2010$ cm/sec

The flow conditions of this process are basically different from those existing in systems with a turbulent flow at atmospheric pressure, on the one hand, and vacuum systems controlled by molecular flow mecha-

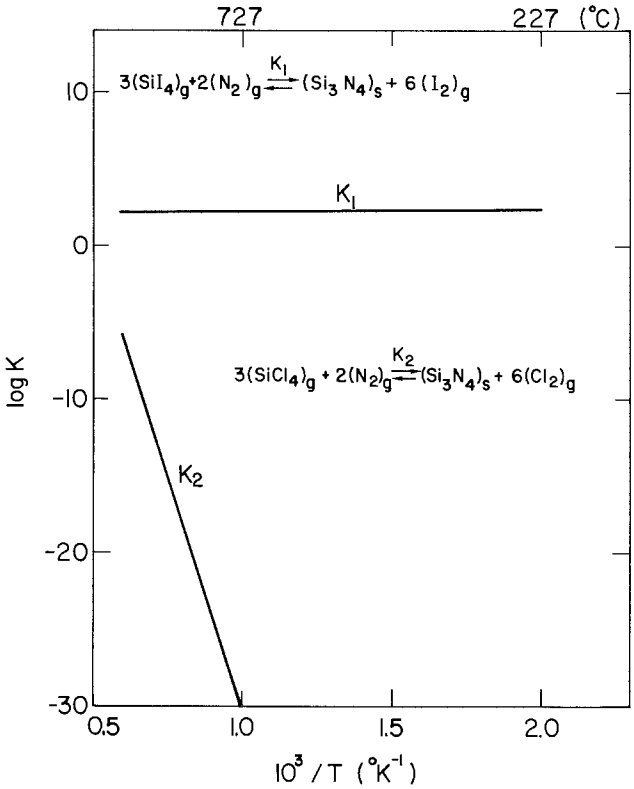

Fig. 5. Temperature dependence of equilibrium constants for the formation of Si_3N_4 from SiI_4 or $SiCl_4$ and nonactive N_2.

nisms on the other. The flow in the present system is not very far from the transition range between the viscous and molecular flow, as defined by the transition pressure P_t (22)

$$P_t = 95.7\sqrt{\frac{T}{M}\frac{\eta}{D}} \qquad [11a]$$

$$P_t = 8.59\sqrt{\frac{T}{M}\frac{\eta}{\lambda_t}} \qquad [11b]$$

where T is temperature, M is molecular weight, η is viscosity, D is reactor diameter, λ_t is mean free path in the transition range. The transition range is defined between $P_u = 10P_t$ as the upper limit and $0.1P_t$ as the lower limit. For our system at 873°K, $P_u = 0.54$ Torr. Accordingly, at 7 Torr, as in our experiments, the pressure is in the viscous flow region. λ_u, from [11b] is 3.23×10^{-2} cm compared with the mean free path of 2.94×10^{-3} cm at 873°K and 7 Torr.

We found experimentally that below 3 Torr, when diffusion becomes the controlling mechanism, the stream of SiI_4 carrier expands and diffuses into the main stream of active nitrogen so that the reactor wall is also coated with Si_3N_4. The observed blue glow results from excitation of SiI_4 by its mutual diffusion with active N_2. At 7 Torr the cross section of the SiI_4 stream is circular. The outward diffusion of SiI_4 causes the broadening of the blue glow towards the substrate, this effect being less pronounced at higher linear velocities of the carrier.

The total inlet flow rate of SiI_4, $\dot{n}_1$, as calculated from the carrier flow rate and known vapor pressure of I_2, was 1.92×10^{-7} moles/sec. The total inlet flow rate of atomic nitrogen, calculated from the main stream flow rate and measured degree of dissociation, $X_d = 0.01$, from Ref. (18) was 44.6×10^{-7} atoms/sec.

Although atomic nitrogen is introduced in excess of SiI_4 only part of it is mixed with SiI_4 by diffusion The linear velocity of the SiI_4 stream is about 16 times that of the main stream, containing atomic nitrogen, so that in the short distance between the nozzle and the wafer the main stream can be considered as a static medium into which the SiI_4 stream is injected. Using the following general equation of diffusion rate (21), the material transport velocities by diffusion and convection of the gas stream can be compared

$$\dot{n}_A = D_o \times \frac{A}{L} \times \frac{\Delta P_A}{P_t} \times T^{0.8} \times 0.5 \times 10^{-7} \text{ moles/sec} \qquad [12]$$

where A is cross section of diffusion path (cm^2), L is length of diffusion path (cm), D_o is diffusion coefficient at STP (cm^2/sec), P_t is total pressure, ΔP_A is partial pressure difference of transported material.

Inserting the data related to the diffusion of SiI_4 from the nozzle to the wafer into a carrier beam with a diameter of $d = 2$ mm gives, at 873°K, $(\dot{n}_1)_D = 6 \times 10^{-10}$ moles/sec compared with 1.92×10^{-7} moles/sec by convection. On the other hand the rate of diffusion of atomic nitrogen into the SiI_4 carrier beam is much more pronounced. Inserting into Eq. [12] the following factor, $A/L = 2\pi dL/d$, where L and d are the length and diameter of the SiI_4 beam, respectively, one obtains

$$(\dot{n}_2)_D = D_o \times 2\pi L \times \frac{\Delta P_2}{P_t} \times T^{0.8} \times 0.5 \times 10^{-7} \text{ moles/sec} \qquad [13]$$

for the rate of diffusion of atomic nitrogen into the carrier beam. ΔP_2 is the partial pressure difference of atomic nitrogen across the diffusion path.

It is seen from Eq. [13] that under steady-state conditions the diffusion rate of atomic nitrogen into the SiI_4 beam does not depend on the diameter of the beam (or of the nozzle) but only on the distance from the nozzle to the wafer. Thus, when the nozzle diameter is changed and the other parameters are kept constant, the rate of mixing of the reactants by diffusion is not affected. On the other hand, the rate of mixing by diffusion increases linearly with the distance (or time interval) between nozzle and wafer. Inserting the data obtained in our experiments ($D_o = 0.1$ cm^2/sec, $P_t = 0.92 \times 10^{-2}$ atm, $\Delta P_2 = 1.84 \times 10^{-4}$ atm, $T_{max} = 873$°K, $L = 0.6$ cm) one obtains

$$(\dot{n}_2)_D = 0.844 \times 10^{-7} \text{ atoms/sec}$$

Thus, at least 33% of the N atoms required for complete reaction with SiI_4, *i.e.*, 2.56×10^{-7} atoms/sec, are mixed with the carrier beam before it reaches the wafer. The SiI_4 stream is spread on the wafer to a thickness of 0.5 mm (assuming that it slows down to the linear velocity of the main stream) so that complete reaction with N atoms on the surface is insured. With the pressure used in our experiments, the barrier of a stagnant film, as in flow systems at atmospheric pressure, is not significant.

Ionic Conductivity in Pure and Cadmium-Doped Cuprous Iodide

Tsuneo Matsui and J. Bruce Wagner, Jr.*

Materials Research Center and Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois 60201

ABSTRACT

The ionic conductivity of CuI has been measured as a function of temperature between 100° and 470°C using the a-c method. The measurements have been made on a pure sample and also on samples doped with CdI_2 in concentrations between 0.02 and 0.50 mole percent (m/o). The results have been analyzed using Koch and Wagner's method (1) as applied by Teltow (2) to obtain the values of the energies of formation and migration, the concentrations and mobilities of the copper interstitial ions ($Cu^{\cdot}_i$) and copper vacancies (V'_{Cu}). The curvature in the temperature dependence of conductivity is discussed. In the low temperature extrinsic region of CuI doped with 0.50 m/o CdI_2, the data yield the migration energy for copper vacancies and also the association energy between cadmium ions and copper vacancies. The two phase transitions of solid CuI have been also studied by conductivity measurements. At both transitions (369° and 407°C), the abrupt jumps in the conductivity curves are discussed in relation to entropy changes.

The predominant lattice defects in ionic crystals can be conveniently investigated by measuring the ionic conductivity of crystals containing known concentrations of aliovalent cations (1-5). These dopants change the concentration of lattice defects, preserving charge neutrality and chemical equilibrium. The values of the energies of formation and migration, the concentrations, and the mobilities of the two species of charge carriers have been obtained from such studies. This technique was originated by Koch and Wagner (1) and has been developed by Teltow (2, 3) and is reviewed by Lidiard (6).

Many measurements have been made on crystals having the NaCl structure [AgCl, AgBr (1-4), alkali halides (4, 7-9)], but not many have been made on copper halides. Unlike AgBr and AgCl which have the NaCl structure, copper halides exhibit two structures, one is the zinc blende structure and the other is the wurtzite structure. Several different investigations (6, 10, 11-13) indicate that the predominant intrinsic defects in copper halides are Frenkel cation pairs (copper interstitials, $Cu^{\cdot}_i$, and copper vacancies, V'_{Cu}).

In this paper we report an investigation of the total conductivity of pure CuI and CuI doped with CdI_2. The experimental results are analyzed to obtain information about the value of the energies of formation and migration, the concentrations, and the mobilities of $Cu^{\cdot}_i$ and V'_{Cu}, respectively, by using Koch and Wagner's method (1).

* Electrochemical Society Active Member.
Key words: mobility, copper interstitials, copper vacancies, defect concentration.

Theory

The formula for the conductivity of a crystal containing a molar fraction, C, of some aliovalent ion is derived by Teltow (2) and by Lidiard (6).

In predominantly ionic conductors such as copper iodide, the ionic conductivity, σ, may be written as

$$\sigma = Nq\ (x_v u_v + x_i u_i) \qquad [1]$$

where N is the number of copper ions per unit volume, u the mobility, q the electronic charge, x the molar fractions of defects, and the subscripts v and i refer to copper vacancies and interstitial copper ions, respectively. The reaction equation and the law of mass action for a Frenkel defect[1] may be written as

$$Cu_{Cu} + V_i = V'_{Cu} + Cu^{\cdot}_i \qquad [2]$$

and

$$x_v \cdot x_i = K^{-1} \equiv x_o^2 \qquad [3]$$

where x_o is the molar fraction of the intrinsic defects. By doping CdI_2 into CuI, copper vacancies are produced as follows

[1] The notation of Kroger and Vink is used (14).

$$CdI_2 = Cd^{\cdot}_{Cu} + V'_{Cu} + 2I_I \quad [4]$$

The electroneutrality condition requires that

$$x_v = C + x_i \quad [5]$$

where C denotes the molar fraction of CdI_2 added and hence the concentration of cadmium ions on copper ion sites according to Eq. [4]. Hence Eq. [3] becomes

$$x_v(x_v - C) = x_o^2 \quad [6]$$

or

$$x_v = \frac{C}{2}\left\{1 + \left(1 + \frac{4x_o^2}{C^2}\right)^{1/2}\right\} \quad [7]$$

Substituting Eq. [3] and [7] into [1], we have

$$\sigma = Nqx_o(u_v + u_i)\left[\sqrt{\left(\frac{C}{2x_o}\right)^2 + 1} - \left(\frac{C}{2x_o}\cdot\frac{\phi - 1}{\phi + 1}\right)\right] \quad [8]$$

where

$$\phi = u_i/u_v \quad [9]$$

For the pure crystal, the intrinsic conductivity is written as

$$\sigma_o = Nqx_o(u_v + u_i) \quad [10]$$

Thus, the conductivity isotherm is expressed by

$$\frac{\sigma}{\sigma_o} = \sqrt{\left(\frac{C}{2x_o}\right)^2 + 1} - \left[\frac{C}{2x_o}\cdot\frac{\phi - 1}{\phi + 1}\right] \quad [11]$$

There is a minimum in the σ/σ_o *vs.* C curve at

$$(C)_{min.} = \frac{x_o(\phi - 1)}{\sqrt{\sigma}} \quad [12]$$

$$(\sigma/\sigma_o)_{min.} = \frac{2\sqrt{\phi}}{1 + \sigma} \quad [13]$$

Experimental

The samples used in this study were sintered pellets of pure CuI and CuI doped with CdI_2. For pure CuI, ultrapure anhydrous CuI powder (99.9998% Alfa Products, Ventron Corporation) was used without further purification. Doped specimens were made by mixing the ultrapure CuI powder with the appropriate amount of CdI_2 powder (99.0% Alfa Products, Ventron Corporation), from which some of the water had previously been removed by heating at about 110°C in a Pyrex glass tube connected to a vacuum pump. The CdI_2 was added in concentrations of 0.02, 0.05, 0.10, 0.20, 0.30, 0.40, and 0.50 mole percent (m/o). Herrmann (15) has reported that CdI_2 is soluble in CuI in all concentrations. These pure and doped powders were pressed at 50,000 psi in a 0.319 in. diameter steel die. The freshly prepared pellets were sintered at 375°C for 16 hr and then at 550°C for 30 hr under a slow flow rate of purified argon gas (about 0.1 cm/sec). The argon gas was purified by passing first over heated copper turnings at about 400°C, and then through a tube of silica gel to remove water vapor. After sintering the size of pellets was about 8 mm in diameter and about 2 mm long, and the density was 92-93% of the theoretical value of pure CuI. The pellets were then polished and washed successively in acetone.

To make the conductivity measurements, the sample was sandwiched between the reversible copper electrodes which were 99.999% pure copper rod obtained from American Smelting and Refining Company, and electrical contact was ensured by applying a slight pressure by means of springs. The sample was annealed at 500°C for 2 hr prior to measurements to ensure a good interface contact. Copper halides, when equilibrated with copper electrodes exhibit virtually 100% ionic conduction (10), like the silver halides equilibrated with silver electrodes (16). A Marshall resistance furnace was used in a horizontal position. The temperatures were controlled to ±1°C by a Leeds and Northrup Electromax controller and the temperature was measured by Doric digital voltmeter using Chromel-Alumel thermocouples. The phase transformations provided a check on the temperature. The electrical conductivity was measured using a General Radio a-c bridge (1650A) at 1000 Hz.

Results and Discussion

Measurements of the total electrical conductivity of a pure CuI sample and seven doped samples containing different concentrations of CdI_2 were carried out in the temperature range of 100°-470°C. The results are shown in Fig. 1 and 2. The previous data on partial electronic hole conductivity of CuI by Wagner and Wagner (10) are also shown in Fig. 1 and 2. Comparing values of the total electrical conductivity and the electronic hole conductivity of CuI, it follows that the electronic conduction makes only a small contribution to the total conductivity of samples equilibrated with copper above 300°C. Thus the total conductivities reported in this study are essentially ionic conductivities above 300°C. On a given sample, the experimental error in the conductivity measurements is about ±3% above 300°C, but is ±6% below 300°C.

Typical curves of the relative conductivity *vs.* molar percentage of cadmium iodide are shown in Fig. 3 for the α-, β-, and γ-phases at 440°, 390°, 325°C, respectively. Table I gives the values of concentration and mobility calculated from the data of Fig. 1, 2, and 3, on the basis of Eq. [10], [12], and [13] for various temperatures. The mobilities of copper vacancies and interstitials, thus obtained, are shown as a function of temperatures in Fig. 4. The temperature dependence of the concentrations of Frenkel defects is also shown

470	0.215	0.620	(8.48 ± 0.10)	(3.62 ± 0.05) × 10^{-3}	(3.01 ± 0.10) × 10^{-2}

Table II. Values of migration energy and formation energy

Phase (temperature range, °C)	Formation energy for Frenkel defects (kcal/mole)	Migration energy for copper vacancy (kcal/mole)	Migration energy for copper interstitial (kcal/mole)
α-CuI (420-470)	1.91 ± 0.10	4.39 ± 0.50	2.74 ± 0.50
β-CuI (390-400)	34.0 ± 0.50	25.7 ± 0.50	—
γ-CuI (325-350)	9.70 ± 0.50 (apparent)	37.2 ± 0.50 (apparent)	28.8 ± 0.50 (apparent)
(160-200)	—	5.30 ± 0.50	—

in Fig. 5. The migration energies and formation energies calculated from the data of Fig. 4 and 5, respectively, are summarized in Table II. In Table II, the migration energy and formation energy for the γ-phase are "apparent values," because the temperature dependence of the conductivity in the γ-phase cannot be fitted by a single straight line but a curved line, and thus the temperature dependence of the mobility, and concentrations do not yield a straight line. An apparent straight line portion of the curve is exhibited over only a short temperature range. The small values of the formation energy of ionic defects in the α- and γ-phase [the crystal structure of these two phases is the zinc blende structure, on the other hand the β-phase is the wurtzite structure (17)] are due to the saturation of the concentration of defects created by thermal energy at high temperatures. The small values of migration energies for copper interstitials and copper vacancies in the α-phase are due to the random positions of the cations as obtained from time-average structure determinations (17). The large values of the "apparent" migration energies for copper vacancies and copper interstitials in the γ-phase cannot be easily explained, but probably are due to the weakness of lattice structure, as is described briefly later.

In Fig. 2, a small linear slope for the variation of the conductivity with temperature between 160° and 200°C is observed with the highest doped sample containing 0.50 molar percentage of CdI_2. This region is the extrinsic region (18, 19), where the concentration of copper ion vacancies produced by the introduction of CdI_2 (whose reaction is expressed by Eq. [4]) is high compared to the concentration of intrinsic defects (for example even at 325°C, the concentration of the intrinsic defects is 0.024 m/o). By using the extrinsic vacancy region, we can calculate the migration energy and the mobility of copper vacancies, and these data are shown in Table II and Fig. 6, respectively.

At still lower temperatures than those in which the vacancies are presumably not associated, the conductivity data of the doped crystal containing 0.50 m/o

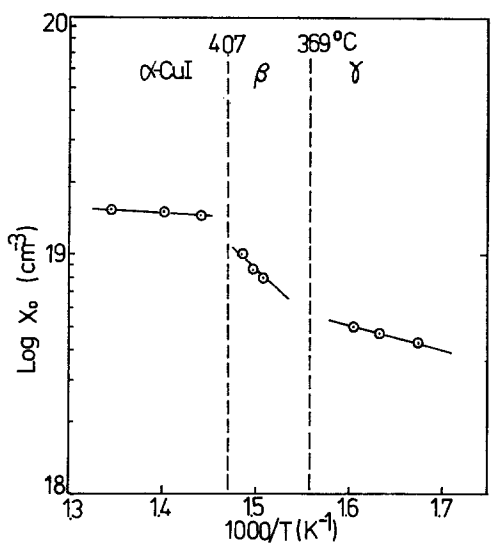

Fig. 5. The temperature dependence of the concentrations of Frenkel defects in CuI.

CdI_2 increase in slope. This region may be taken to be the association region (18, 19). In conjunction with the value of the migration energy of copper vacancies obtained above, this slope yields an energy of association between $(Cd_{Cu}^{\cdot} \cdot V'_{Cu})$ of 8.53 ± 0.46 (kcal/mole). This association energy is similar to the values, 8.76 (kcal/mole) for $(Cd_{Na}^{\cdot} \cdot V'_{Na})$ and 7.38 (kcal/mole) for $(Cd_{K}^{\cdot} \cdot V'_{K})$, calculated by Bassani and Fumi on the basis of the Born-Mayer model (20). In the con-

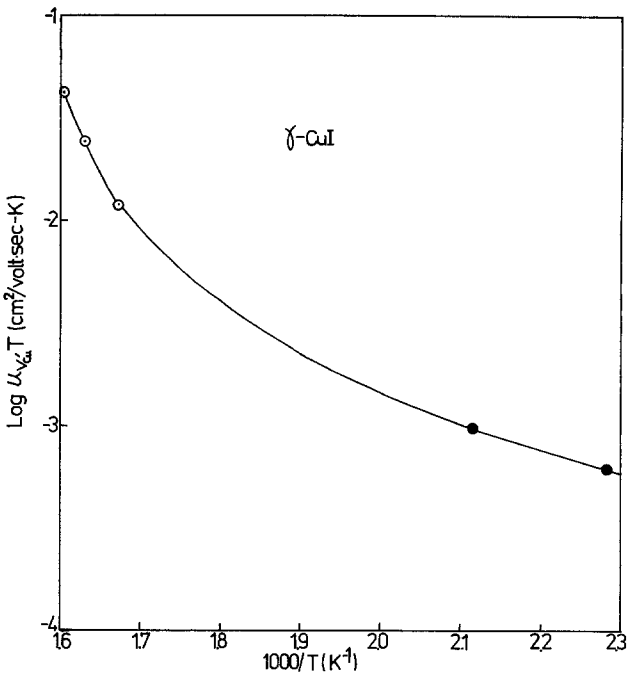

Fig. 6. The temperature dependence of the mobility for copper vacancies in γ-CuI.

ductivity curve of the doped crystals with 0.20, 0.30, and 0.40 m/o CdI_2, a little steeper slope is also seen below about 200°C, but the data are not sufficient for a calculation of the association energy.

Generally in the pure alkali and silver halides a knee in the conductivity curve is exhibited at a low temperature, below which the conductivity is affected by impurities (extrinsic region) which are accidentally present or by grain boundaries (5-9, 18-19). No such well-defined knee is seen in the temperature dependence of the conductivity of our pure CuI down to a temperature as low as 100°C, but a curved line is obtained for all temperatures from 100° to 369°C in the γ-phase. This curvature cannot be explained only by considering the contribution of the copper vacancies in addition to predominant copper interstitials. This behavior is the same as the previous results of Wagner and Wagner (10). Such a concave upward curvature in the high temperature region is also observed for AgBr (1, 2, 4), NaCl (7), and LiF (8).

Various explanations suggested previously for the curvature in AgBr are reviewed by Lawson (21). The curvature may be explained by two contributions: One is the rapidly increasing Schottky defects in addition to the predominant Frenkel defects, and the other is the weakness of lattice structure. The first suggested explanation for the anomalous conductivity at high temperatures has been put forth on the basis of the analysis of the pressure variation of the conductivity by Kurnick (4). The second suggestion is due to Lidiard (6, 22, 23) who rephrased the idea in terms of an effect due to a rapidly increasing dielectric constant on the Debye-Hückel terms in the free energy. The rapid increase in dielectric constant for AgBr has been observed by Everett, Lawson, and Smith (24). The upward bend in the variation of the thermal expansion coefficient for AgBr with temperature has been also observed by Zieten (25).

In the case of CuI, however, there are no such data with the exception of the x-ray diffraction study by Miyake, Hoshino, and Takenaka (17). They have measured the intensity change of diffraction lines with temperature in detail and from which the temperature dependence of the Debye-Waller factors for Cu and I ion have been calculated They found that the crystal structure of the γ-phase begins to change anomalously

at about 130C, and finally transforms to the high temperature structure of the α-phase having a disordered structure (an average structure). The Debye-Waller factor can be related to the mean square displacement of ions, and thus the mean square displacement for copper ions already increases abruptly from about 130°C showing the effect of anharmonicity, although the mean square displacement for iodine ions varies linearly with temperature (17, 26). From these x-ray data, it was inferred that the mobility for copper ions increases abruptly with increasing temperature in the γ-phase. This corresponds to our mobility data shown in Fig. 4 and 6. In summary, the curvature in the conductivity of the γ-phase may be due to the anomalous lattice weakening change with temperature. To clarify the mechanism of this curvature in γ-CuI, other extensive measurements are required.

Miyake, Hoshino, and Takenaka (17) have also studied the phase transitions in CuI by x-ray and calorimetric measurements. According to their data, copper iodide crystal undergoes two phase transitions, one at 369°C from the γ-phase with the zinc blende structure to the β-phase with the wurtzite structure, and the second at 407°C from the β-phase to the α-phase, again with the zinc blende structure. These transitions are of the first order and the transition entropies calculated from the specific heat measurements are 2.64 cal/mol · deg at the γ-β transition and 1.13 cal/mol · deg at the β-α transition.

As shown in Fig. 1, an abrupt jump in the electrical conductivity curve was observed at both the γ-β and the β-α transitions. The jump at the transition may be related to the entropy change at the phase transition (27). This jump width J is written as

$$J = \log \sigma_h(Tr) - \log \sigma_l(Tr) = \log \left[\frac{\sigma_h}{\sigma_l} \right]_{Tr}$$

$$= \log \frac{x_h(u_i + u_v)_h}{x_l(u_i + u_v)_l}$$

$$\simeq \log \frac{x_h u_{i,h}}{x_l u_{i,l}} \qquad [14]$$

because

$$u_i >> u_v \qquad [15]$$

where σ is the electrical conductivity at the transition temperature (Tr), and subscripts h and l are for high and low temperature phases, respectively.

The mobility, u, can be related to the diffusion coefficient D by using the Nernst-Einstein relation as follows (28)

$$u = qD/kT \qquad [16]$$

$$D = \lambda d^2 \nu \exp(-\Delta G/RT) = \lambda d^2 W \qquad [17]$$

where q is the charge of an electron, λ the geometric factor, d the diffusion length, ν the ion jump frequency at $T = \infty$, ΔG the change in Gibbs free energy for ionic migration, and W the probability for ionic migration. From Eq. [14], [16], and [17], the following equations are derived

$$J = \log \left[\frac{x_h \lambda_h d_h^2 \nu_h \exp(-\Delta G_h/RTr)}{x_l \lambda_l d_l^2 \nu_l \exp(-\Delta G_l/RTr)} \right] \qquad [18]$$

$$= \log \left[\frac{x_h \lambda_h d_h^2 W_h}{x_l \lambda_l d_l^2 W_l} \right] \qquad [19]$$

The entropy is related to the probability for ionic migration as follows

$$S = R \ln W = R \ln [\nu \exp(-\Delta G/RT)] \qquad [20]$$

Then we have

$$\Delta S = R \ln \left[\frac{W_h}{W_l} \right] \qquad [21]$$

$$= 2.303R \log \left[\frac{\nu_h \exp(-\Delta G_h/RTr)}{\nu_l \exp(-\Delta G_l/RTr)} \right] \qquad [22]$$

and thus

$$J = \log \left[\frac{x_h \lambda_h d_h^2}{x_l \lambda_l d_l^2} \right] + \frac{\Delta S}{2.303R} \qquad [23]$$

Equation [23] indicates that the difference between the jump width, J, and the entropy change at the phase transition depends on the nature of phase transition, especially the change of crystal structure, since λ and d depend on crystal structure.

The jump widths, J, in the conductivity curve at the γ-β transition and at the β-α transition of CuI are 0.465 and 0.0792, respectively. The difference between jump width and entropy change of the same transition can be calculated from Eq. [23] as follows

$$J - \frac{\Delta S}{2.303R} = \log \left[\frac{x_h \lambda_h d_h^2}{x_l \lambda_l d_l^2} \right]_{\gamma\text{-}\beta} = -0.112$$

so that $[x_h \lambda_h d_h^2 / x_l \lambda_l d_l^2]_{\gamma\text{-}\beta} = 0.77$ for the γ to β transition. For the β to α transition

$$J - \frac{\Delta S}{2.303R} = \log \left[\frac{x_h \lambda_h d_h^2}{x_l \lambda_l d_l^2} \right]_{\beta\text{-}\alpha} = -0.168$$

so that $[x_h \lambda_h d_h^2 / x_l \lambda_l d_l^2]_{\beta\text{-}\alpha} = 0.68$.

The phase transition and the crystal structures of the three modifications in cuprous bromide (CuBr) have also been studied by x-ray and calorimetric measurement (29). Cuprous bromide crystals undergo two phase transitions, one at 385°C from the γ-phase with the zinc blende structure to the β-phase with the wurtzite structure, and the second at 470°C from the β-phase to the α-phase with body-centered structure similar to α-AgI which closely resembles the "average" structure of α-CuI (29). These transitions are also first order and the transition entropies are 2.1 cal/mole deg at the γ-β transition and 0.9 cal/mole deg at the β-α transition. Accordingly it may be expected that CuBr is an analog to CuI.

The electrical conductivity of CuBr has also been measured between 150° and 450°C by Wagner and Wagner (10). From their data, the jump width is 0.346 for the γ-β transition in CuBr. The same calculation for CuBr as for CuI is made as follows

$$J - \frac{\Delta S}{2.303R} = \log \left[\frac{x_h \lambda_h d_h^2}{x_l \lambda_l d_l^2} \right]_{\gamma\text{-}\beta} = -0.113$$

This value is in good agreement with that for the γ-β transition in CuI, indicating the validity of the Eq. [23]. We can estimate the jump width in the electrical conductivity of CuBr at the β-α transition by using Eq. [23] and the value of entropy change at the β-α transition, assuming the same correspondence between the β-α transitions in CuBr and in CuI as the γ-α transition in CuBr and in CuI. The jump width is 0.0286 and the ratio between the electrical conductivity of the α- and β-phase is 1.07.

It is seen from Fig. 5 that the ratios of the concentration of copper interstitials are $[x_h/x_l]_{\gamma\text{-}\beta} \simeq 1.0$ at the γ-β transition and $[x_h/x_l]_{\beta\text{-}\alpha} \simeq 1.3$ at the β-α transition. Using these values, $\lambda_h d_h^2/\lambda_l d_l^2$ can be calculated to be 0.77 for the γ-β transition and 0.52 for the β-α transition, respectively. Assuming the copper interstitial diffusion mechanism in the zinc blende (fcc) structure of the γ-phase, the geometric factor λ and the diffusion length d are 4 and 6.11/2Å[2] (half of the lattice constant), respectively, and also assuming the copper interstitial mechanism only along the a-axis in the hexagonal wurtzite structure of the β-phase, the value of λ and x are 3/2 and 4.32Å[2], respectively. Using these values, we can calculate the ratio $[\lambda_h d_h^2/\lambda_l d_l^2]_{\gamma\text{-}\beta}$ to be 0.75, which is in good agreement with the value 0.77 calculated from J and ΔS.

[2] 6.11 and 4.32A are the lattice constants of the γ- and β-phase at the γ-β phase transition (369°C), respectively (17).

Since the lattice constant of the β-phase at the β-α transition has not been reported, we cannot estimate the value of $[\lambda_h d_h^2/\lambda_l d_l^2]_{\beta\text{-}\alpha}$, but this small value 0.52 may be due to the very small value of d in the α-phase which is the "average" structure of copper ions.

Summary

From the measurements of ionic conductivity on pure CuI and CuI doped with different concentrations of CdI_2, the concentrations of intrinsic defects, mobilities, and the energies of formation and migration of copper vacancies and copper interstitials were calculated on the basis of Koch and Wagner's theory. The association energy between cadmium ions and copper vacancies calculated using the data of CuI doped with 0.50 m/o CdI_2, was 8.53 ± 0.46 (kcal/mole). The difference between jump width in the conductivity curve at the phase transition in the present study and entropy change of CuI (17) was calculated, and was in good agreement with that of CuBr at the same type of transition.

Effect of Metallic Impurities (Ag, Mn) on the Kinetics of the Reaction of Zinc with Gaseous Phosphorus

Yoshinori Sasaki and Shiro Ueda

Department of Synthetic Chemistry, Chiba University, Yayoi-cho, Chiba 280, Japan

ABSTRACT

A study was undertaken on the kinetics and mechanism of the phosphidation of zinc and zinc containing one atomic percent (a/o) of silver or manganese at 390°C in phosphorus vapor of 1 atm. The phosphidation reactions were parabolic and therefore rate limited by a diffusion process. A marker experiment indicated that zinc was the component that diffused. An x-ray and electron microprobe analysis showed that at the phosphide-metal interface the compound Zn_3P_2 was formed, and that at the outer layers solid solutions of phosphorus in the Zn_3P_2 matrix were formed. The rate of phosphidation of Zn-Mn (1 a/o), Zn and Zn-Ag (1 a/o) decreased in that order. It is postulated that silver decreased the cation vacancy concentration in the phosphide layer and manganese increased it because their valences, respectively, are smaller than and larger than that of zinc. Consequently, the mechanism of phosphidation of zinc appears to be controlled by diffusion of zinc ion in the phosphide lattice.

The phosphidation of zinc has been extensively studied by many workers. The two phosphides are known: ZnP_2 and Zn_3P_2. The crystal structures of ZnP_2 (1, 2) and Zn_3P_2 (3) have been studied in detail and their thermodynamic data (4, 5) also given. The polymorphic transition (6, 7) in ZnP_2 at high temperatures and high pressures, and the kinetics (8) of reaction of zinc with phosphorus at high pressures have been investigated.

Key words: zinc phosphide (Zn_3P_2), phosphidation kinetics, mechanism, diffusion, cation vacancy.

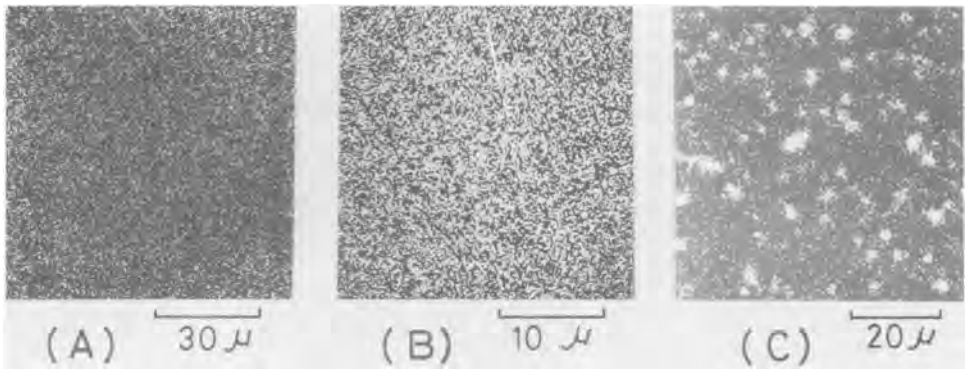

Fig. 1. X-ray images showing distributions of impurities in metallic zinc: (a) AgL_α from Zn-Ag (1 a/o); (b) MnK_α from Zn-Mn (1 a/o); (c) GaL_α from Zn-Ga (1 a/o).

The great majority of work on zinc phosphides has dealt with their preparation (9, 10) and crystal structures. The present study was undertaken to elucidate the mechanism of the reaction between metallic zinc and gaseous phosphorus.

Experimental

A zinc ingot with a purity of 99.999%, made by the Mitsui Mining & Smelting Company Limited, was cut into rectangles of approximately 20 × 5 × 2 mm. According to an analysis by the manufacturer, the impurity level of the zinc was as follows: Pb = 0.3 ppm, Cd, Cu, and Fe = 0.5 ppm. The coupons were abraded with a 0/9 emery paper, then washed with a refined toluene. Their geometric surface areas and weights were measured.

A zinc-silver alloy was prepared by heating the metallic mixture of an atomic ratio Zn/Ag = 99.00 at 960°C for 3.5 hr in an evacuated-sealed silica tube. Silver having a purity over 99.9%, made by the Kojima Kagaku Yakuhin K. K., was used. Quantitative analysis of silver in this alloy by Volhard's method indicated 1.0 a/o. A zinc-manganese alloy also was obtained in the same way with conditions of 1000°C and 8 hr. The manganese had a purity over 99.99% and was made by Johnson Matthey Chemicals Limited. According to colorimetric analysis of MnO_4^{-1} ion obtained by oxidizing the manganese in this alloy, the content of manganese was 1.0 a/o.

In order to examine the homogeneity of the alloys prepared, their x-ray images (Fig. 1) were obtained with a scanning electron microscope (JSM-U3, Japan Electron Optics Laboratory Company Limited).

Since metallic zinc and gallium are mutually insoluble, an example of their heterogeneous alloy is given for reference in the same figure. Figure 1 shows both silver and manganese to be uniformly dispersed respectively in metallic zinc.

Purification of red phosphorus was similar to that described previously (11).

The reaction apparatus consisted of a porcelain tube maintained in two temperature zones, the first zone being used to heat the sample sheet in an evacuated-sealed glass tube, and the second zone, to control the vapor pressure of phosphorus in this glass tube. The apparatus and experimental methods employed in this study are described in detail in a previous paper (11).

Results and Discussion

Kinetic results are shown in Fig. 2 on phosphidation of the sample sheets exposed to phosphorus vapor of 1 atm at 390°C. At this temperature, gaseous phosphorus consists of a P_4 molecule. Because a sealed tube was used to contain the phosphorus vapor, it was not possible to make continuous measurements of weight change. Each point represented here was obtained by phosphidizing an individual specimen. The phosphidation kinetics followed a parabolic rate law under the experimental conditions used; hence, the rate-determining step was apparently a diffusion or a transport process of zinc or phosphorus. It had been confirmed beforehand that metallic silver and manganese also react with phosphorus vapor at 390°C.

Values of the parabolic rate constants were 9.1 ± 1.1, 14.6 ± 1.6, and 19.6 ± 1.2 $mg^2cm^{-4}hr^{-1}$ for Zn-Ag (1 a/o), Zn, and Zn-Mn (1 a/o), respectively.

Figure 3 illustrates the x-ray diffraction patterns of the powder, surface, and reverse side of the phosphide film, employing nickel-filtered copper radiation. These patterns reveal the products to be composed of Zn_3P_2.

The Kirkendall effect relating to the diffusion process was examined for the phosphidation of zinc with use of a glass fiber as a marker. The specimen phosphidized was embedded in a polyester resin, and its cross section was polished with finely divided chromium oxide powder. Figure 4a shows a cross section of the scale and the position of the glass fiber marker. This was confirmed in the SEM by SiK_α radiation as shown in Fig. 4b. Since the marker is situated in the neighborhood of the phosphide-metal interface, the reaction is controlled by diffusion of zinc through the phosphide layer.

The distribution of phosphorus in this scaling film, obtained with the SEM, is given in Fig. 4c, which shows that the content of phosphorus in the scale decreases toward inner scale layers. It must be noted that a plateau having a certain constant content of phosphorus is present in the bulk phosphide. The composition of this plateau should correspond to Zn_3P_2 from the x-ray

diffraction pattern. Since the x-ray diffraction studies show that ZnP_2 is not formed even at the outer surface of the scale, it is assumed that the observed higher concentration of phosphorus represents a solid solution of phosphorus in the Zn_3P_2 matrix.

The reactivity of Zn-Mn (1 a/o), Zn, and Zn-Ag (1 a/o) with phosphorus decreased in that order, as mentioned above. It is noteworthy that the added small amounts of silver hinder the phosphidation of zinc, whereas the added manganese, on the contrary, promotes it. Because silver has a lower valence than zinc, we presume that the addition of silver causes a decrease in the cation vacancy concentration in the phosphide lattice, and, on the other hand, manganese having an equal or higher valence causes an increase in the concentration of cation vacancies in the scale. Consequently, the following equations might be expected

$$\tfrac{1}{2}P_4 \rightleftharpoons Zn_3P_2 + 3Zn\square'' + 6\oplus$$

$$2Ag_3P + 3Zn\square'' \rightleftharpoons 6Ag\bullet'(Zn) + Zn_3P_2$$

$$2MnP \rightleftharpoons Zn\square'' + 2Mn\bullet\cdot(Zn) + Zn_3P_2$$

where $\oplus$ denotes an electron hole. A black circle was used as the symbol for the substitution of cation into the lattice. A dot and prime denote the excess and deficient positive charge, respectively.

Figures 5 and 6 show the distribution profiles of zinc, phosphorus, silver, and manganese in the scale layers. It is obvious from Fig. 5 that the silver was concentrated in the metal alloy side near the phosphide-alloy interface, while its content in the scale was decreased. This could be explained by assuming that the reactivity of zinc with phosphorus is larger than that of silver with phosphorus. The addition of silver to zinc seems to cause the delay of the phosphidation of zinc, because not only the cation vacancy was decreased but silver hindered the diffusion of zinc on the phosphide-metal interface.

On the other hand, Fig. 6 shows that the manganese added was approximately uniformly dispersed in both

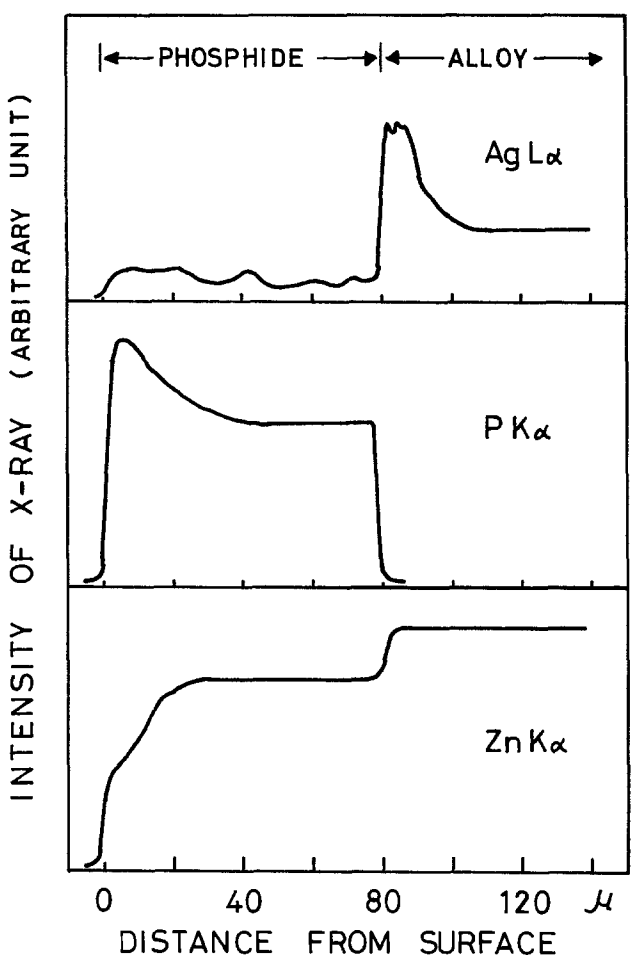

Fig. 5. Distribution profiles of silver, phosphorus, and zinc in the phosphide layer and the alloy phase.

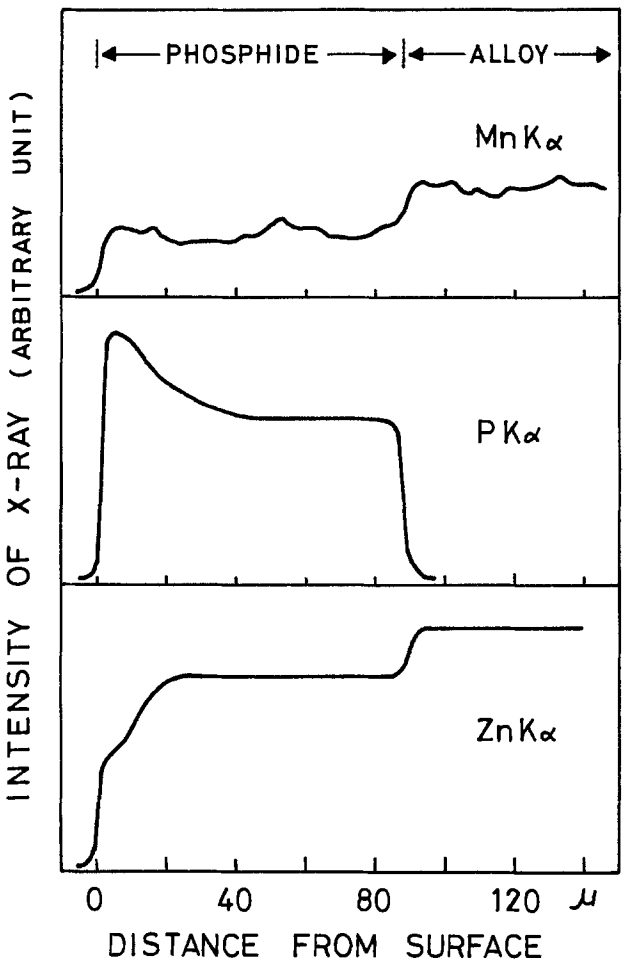

Fig. 6. Distribution profiles of manganese, phosphorus, and zinc in the phosphide layer and the alloy phase.

the phosphide phase and the alloy phase during the phosphidation.

Although it cannot necessarily be concluded that the diffusion process of phosphidation of metals is generally based on such a mechanism, the possibility of lattice diffusion such as the above for the phosphidation mechanism is reasonable.

Acknowledgments

The authors wish to thank Professor E. Kawai for his permission to use the SEM, Mr. K. Oda and Mr. N. Misono for their SEM measurement, and Mr. T. Sato for his assistance in the experimental work.

Energy Transfer Between Rare Earth Ions in a Potassium Feldspar Glass

G. Baran, T. Y. Tien, and W. J. O'Brien

The University of Michigan, Ann Arbor, Michigan 48109

ABSTRACT

Nonradiative energy transfer was observed between rare earth ions in a potassium feldspar glass. Observation was made of the quenching of terbium fluorescence through interactions with dissimilar lanthanide ions. The severity of quenching is dependent on the energy gap between the fluorescing level of terbium and the closest lower lying level of another lanthanide ion and a numerical constant characteristic of the host. The value of this host constant, 2246 cm^{-1}, is indicative of a high probability of phonon-assisted energy transfer. Energy transfer was also observed between dysprosium and samarium when 405 and 425 nm radiation was used for excitation. The site symmetry of Eu^{3+} in potassium feldspar glass was evaluated through analysis of the emission spectrum and appears to be C_s.

The phenomenon of energy transfer between rare earth ions in various hosts has been studied by several investigators. Transfer of energy by radiative means, when emission by one ion is absorbed by another ionic species, has been observed by Nakazawa and Shionoya (1) in glasses containing dysprosium and neodymium. Nonradiative energy transfer between dissimilar ions was investigated by Dexter (2). It was found that energy transfer could occur if the overlap between the emission band of the sensitizer ion and the absorption band of the activator ion was large, *i.e.*, the two levels were in resonance with one another. The dependence of nonradiative transfer on the distance between sensitizer and activator ions was summarized by Blasse and Bril (3). The limiting distance between ions in a host in order for transfer by coulomb interaction to occur was found to be 27Å. Reisfeld (4) observed nonradia-

Key words: fluorescence, rare earths, energy transfer, glass.

tive energy transfer in glasses between thulium and erbium and between terbium and gadolinium. The energy levels participating in the transfer were not strictly in resonance with each other. Therefore, it was proposed that the transfer was made possible by the presence of lattice phonons which served to bridge the energy difference. Resonant energy transfer from terbium and europium in a tungstate host to other rare earth ions was investigated by Van Uitert and Iida (5). They found that the emission of terbium from the $^5D_4$ level was quenched by energy transfer from that level to the closest lower lying level of a dissimilar rare earth ion. The probability of transfer was dependent on the energy difference between the two levels and a constant equal to the vibrational constant of the tungstate group.

The fluorescent spectral character of rare earths is dependent to some degree on the host structure. The effect of nearest neighbor ions may result in a shift of the excited rare earth ion energy levels several hundred cm^{-1}, causing energy transfer paths between dissimilar ions to vary with different hosts. Feldspar glass is of interest as it is a host containing no nonbridging oxygen ions which should favor phonon-assisted energy transfer. Also, this composition is used in porcelains.

The chemical formula for potassium feldspar is $K_2O \cdot Al_2O_3 \cdot 6SiO_2$. Aluminum and silicon oxygen tetrahedra make up the continuous framework structure, with potassium occurring in the interstitial sites with 6-9 nearest neighbor oxygen ions (6). It has been reported that the entropy of fusion of crystalline feldspars is low and that short-range order in the glassy state should be similar to that in the disordered crystalline phase sanidine (7).

The dependence of Eu^{3+} emission spectra on site symmetry was observed by Blasse and Bril (8). The presence of an inversion center at the site caused the transition $^5D_0$-$^7F_2$ to be very weak. Jorgensen and Judd (9) identified that transition as a "pseudoquadrupole" which would only occur if the europium ion was located in certain sites. Reisfeld (4) found that europium sites in phosphate glasses were characterized by C_s symmetry. In order to further characterize the structure of feldspar glass, the emission of Eu^{3+} ions was studied to identify the ionic site symmetry.

Experimental Procedure

The starting materials used for preparation of the glasses were aluminum hydroxide, silicon dioxide, and potassium carbonate hydrate. The rare earth oxides used were Dy_2O_3, Eu_2O_3, Tb_4O_7, Tm_3O_3, and Sm_2O_3. The materials for the glasses were all reagent grade, while the rare earth oxides were luminescent grade. The concentrations of the rare earth ions in the glasses were maintained at 0.1, 0.5 and 1.0 mole percent (m/o). Prior to formulation, weight loss factors were determined for the aluminum hydroxide and the potassium carbonate hydrate and appropriate corrections were made. The charge balance was maintained by substituting the potassium ions with rare earth ions on a 1:3 atomic ratio.

Appropriately weighed quantities of the host materials were ground under acetone and air dried. They were then placed in platinum crucibles, calcined at 800°C for 8 hr and reground. The rare earth ions were added as nitrate solutions to the powder, dried at 90°C, and reground. The dry powder was then fused by an oxygen-natural gas flame with a pure silica rod used to support the molten mass. Due to the high viscosity and melting point of the glass (1540°C), it proved impossible to pour the glass into a standard size and shape. Therefore, specimens were made as large as possible then ground with silicon carbide to assume a suitable shape for spectroscopy.

The instrument used for fluorescent analysis was a spectrophotofluorimeter.[1] The excitation source was a xenon lamp and the detector a photomultiplier tube with S-20 response characteristics. The selection of aperture and slit width yielded resolution within 6 nm. Calibration of the emission monochrometer was done using a mercury lamp, while calibration of the excitation monochrometer was done using a quinine sulfate standard solution.

The spectral data were digitized and treated by a computer program. The main purpose of the program was to correct the intensity values for lamp output variability and photomultiplier tube response characteristics. In this manner direct comparison of relative intensities was possible.

Results and Discussion

Energy transfer.—The quenching of terbium fluorescence due to the $^5D_4$-$^7F_5$ transition at 545 nm (Fig. 1) was studied in samples with 0.5 m/o Tb^{3+} and 0.5 m/o of Tm^{3+} or Dy^{3+} or Pr^{3+}. The $^5D_4$ level of terbium was excited directly with 488 nm radiation in order to avoid energy losses at higher levels. The three coactivating ions have similar ground state spin configurations. The results are presented in Fig. 2, where the intensity value of 1.0 represents the intensity of terbium emission when it alone is the activator and the relative intensity of the peak at 545 nm when coactivating ions are present are plotted against ΔE, the difference in energy between the $^5D_4$ level of Tb^{3+} and lower lying levels of the other ions. The intensity of terbium emission is seen to decrease as the energy difference ΔE decreases. The values for ΔE were taken from crystal spectra documented by Dieke (10). The nearest lower lying levels of the coactivating ions are the $^6F_{1/2}$ level of dysprosium, the $^3F_2$ level of thulium, and the $^1D_2$ level of praeseodymium. The energy difference between the $^5D_4$ level of terbium and the abovementioned levels of the coactivator ions was found to be critical in determining the probability of resonant energy transfer which would lead to quenching of terbium fluorescence.

The quenching of terbium emission by coactivating rare earth ions may be used to draw conclusions regarding the ease with which lattice phonons may bridge energy differences between energy levels of dissimilar ions. The slope of the line in Fig. 2 yields a parameter $\Delta E/2246$ cm^{-1} and the constant 2246 cm^{-1} is interpreted as a host material constant. It happens to be equal to about twice the fundamental vibrational

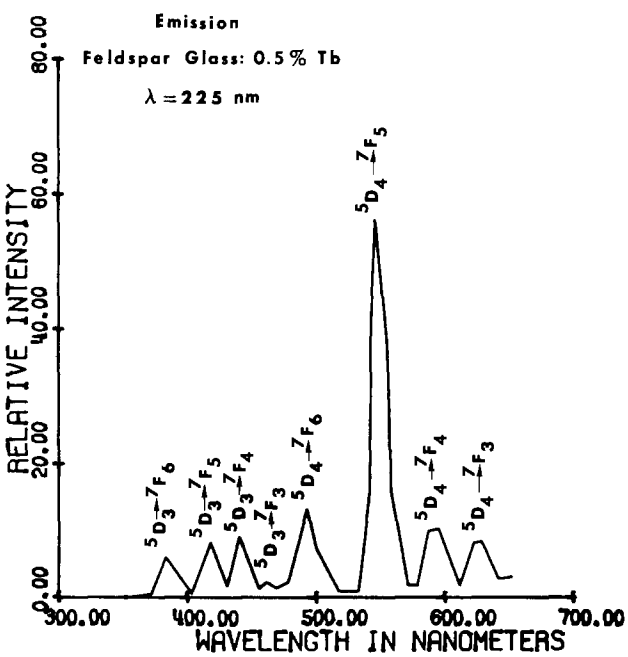

Fig. 1. Emission spectrum of 0.5% Tb^{3+} in potassium feldspar glass with excitation wavelength of 225 nm.

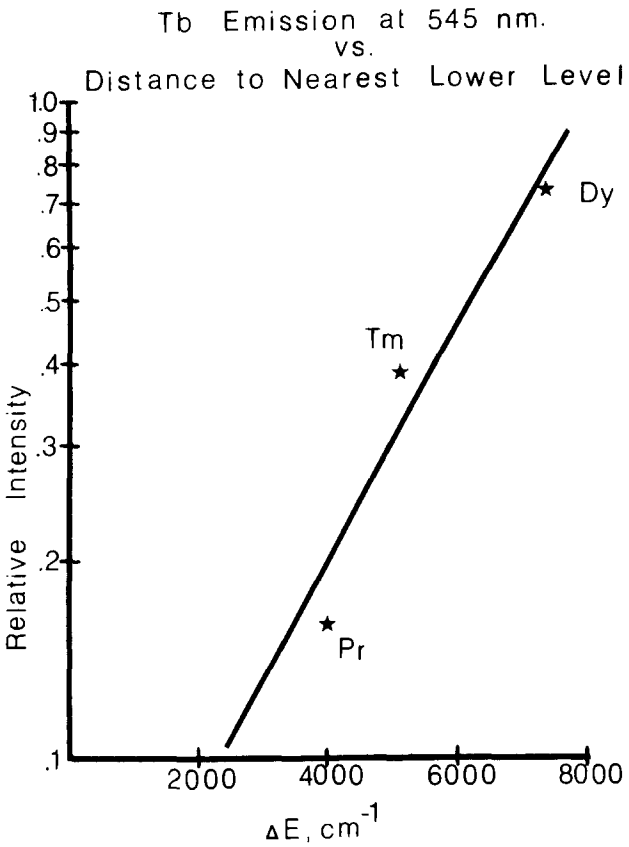

Fig. 2. Quenching of the $^5D_4$-$^7F_5$ transition of Tb^{3+} in potassium feldspar glass by equal concentrations of Tm^{3+}, Dy^{3+}, and Pr^{3+}.

constants of Si-O and Al-O bonds (1000-1130 cm^{-1}). According to Miyakawa and Dexter (11), the probability of phonon-assisted energy transfer "W" may be described by: $W = W(0) \exp(-\beta \Delta E)$, where $W(0)$ is the energy transfer probability when no phonon lines overlap, ΔE the energy gap between the levels of the sensitizer and the activator ions, and β a constant determined by the lattice. The quantity $|1/\beta|$ is therefore comparable to the constant derived in this work which is 2246 cm^{-1} for potassium feldspar glass.

The parameter $\Delta E/2246$ cm^{-1} is indicative of the "number" of phonons needed to bridge the energy gap ΔE between two levels of dissimilar rare earth ions in potassium feldspar glass. The high numerical value of this energy constant, compared to ~850 cm^{-1} in a tungstate host, is an indication of good vibronic coupling between the rare earth ion and the host. This result supports the view of the feldspar structure as being a highly interconnected one with few nonbridging oxygen ions. It is therefore expected that potassium feldspar glass may serve as a good host for observation of resonant, phonon-assisted energy transfer.

The presence of energy transfer was found in the sample containing 0.5% Dy^{3+} and 0.5% Sm^{3+}. With these concentrations, the average distance between Dy^{3+} and Sm^{3+} ions is approximately 26.5Å, a distance low enough so that energy transfer by coulomb interaction may occur. Excitation of this sample by 352 nm radiation to the upper levels of Dy^{3+} caused no energy transfer to occur. Transfer did occur under excitation by 425 and 405 nm radiation. For comparison, typical excitation and emission spectra of Dy^{3+} and Sm^{3+} are shown in Fig. 3-6.

Excitation by 425 nm radiation of the sample containing 0.5% Dy^{3+} and 0.5% Sm^{3+} results in the appearance of new Sm^{3+} peaks at 685, 702, and 730 nm (see Fig. 7). As samarium shows no absorption at 425 nm, the inference is that energy transfer occurs from dysprosium to samarium. The proposed path is from the $^4G_{11/2}$ level of Dy^{3+} to the $^4F_{5/2}$ level of Sm^{3+},

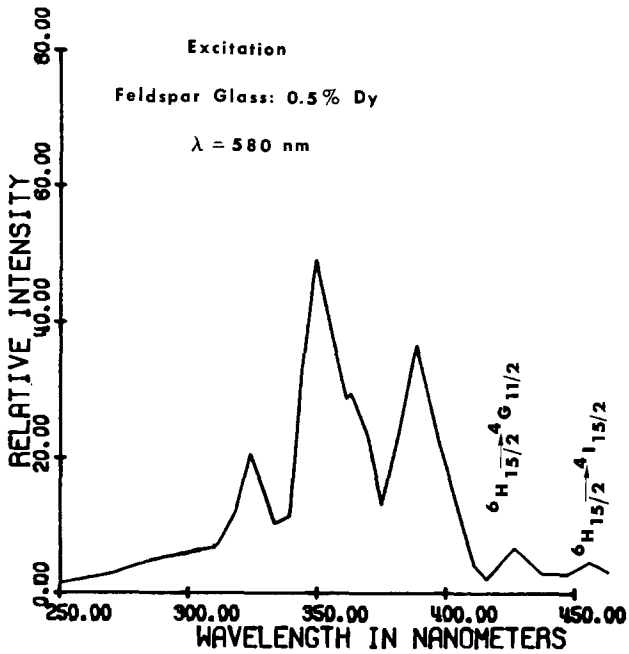

Fig. 3. Excitation spectrum of 0.5% Dy^{3+} in potassium feldspar glass with emission wavelength of 580 nm.

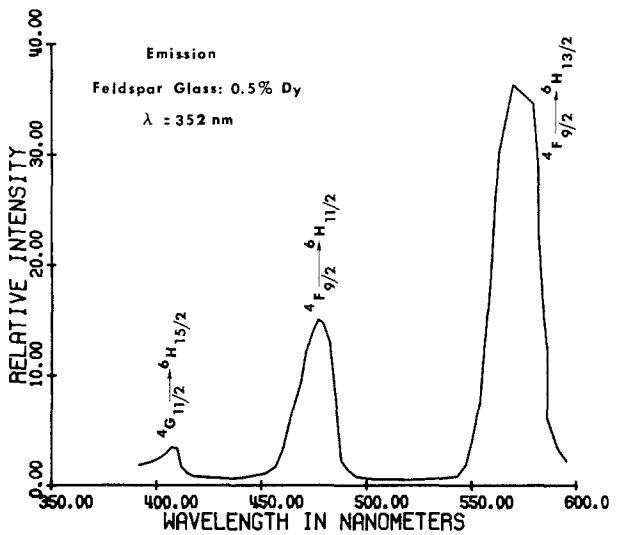

Fig. 4. Emission spectrum of 0.5% Dy^{3+} in potassium feldspar glass with excitation wavelength of 352 nm.

subsequent nonradiative decay of Sm^{3+} to the $^4I_{13/2}$ and $^4G_{5/2,7/2}$ levels and radiative transitions from these levels.

The emission spectrum which results when 405 nm radiation is used for excitation is more difficult to interpret (see Fig. 8). Certainly the peaks at 702 and 730 nm correspond well to samarium transitions. However, the peak at 685 nm may be due to either the $^4I_{15/2}$-$^6H_{9/2}$ transition of Dy^{3+} or the $^4I_{13/2}$-$^6F_{5/2}$ transition of Sm^{3+}. This peak does not occur in the spectrum of either ion alone, so it is evident that some energy transfer must be occurring, else the 702 and 730 nm Sm^{3+} peaks would not occur. Future work will be done in an effort to identify the transition responsible for the peak at 685 nm when 405 nm radiation is used for excitation.

Site symmetry.—The emission spectrum of Eu^{3+} is presented in Fig. 9. The excitation radiation used (393 nm) excited the ion to the $^5L_6$ level at 25,400 cm^{-1}. The site symmetry could be characterized with respect to the presence of an inversion center by examining the spectrum for the appearance of magnetic dipole transi-

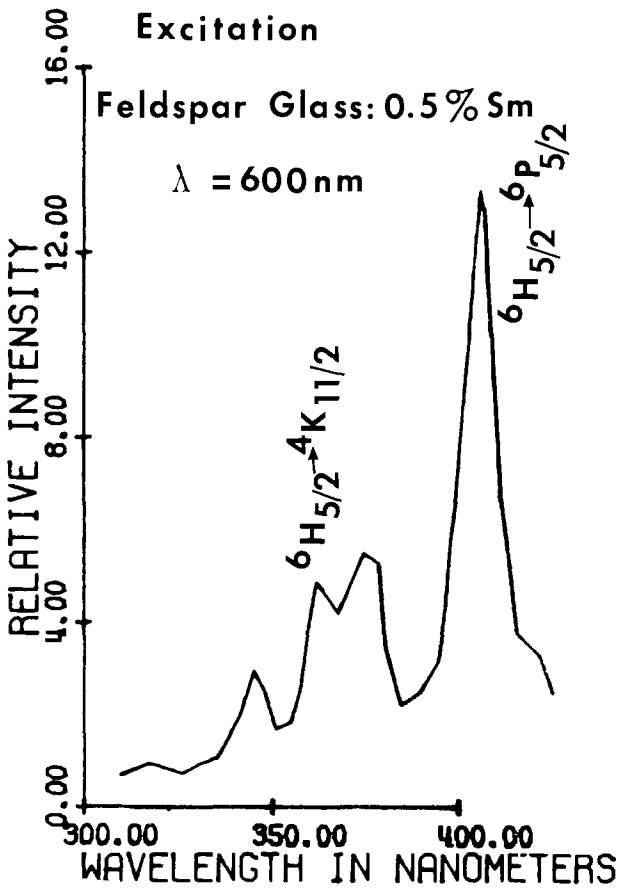

Fig. 5. Excitation spectrum of 0.5% Sm^{3+} in potassium feldspar glass with emission wavelength of 600 nm.

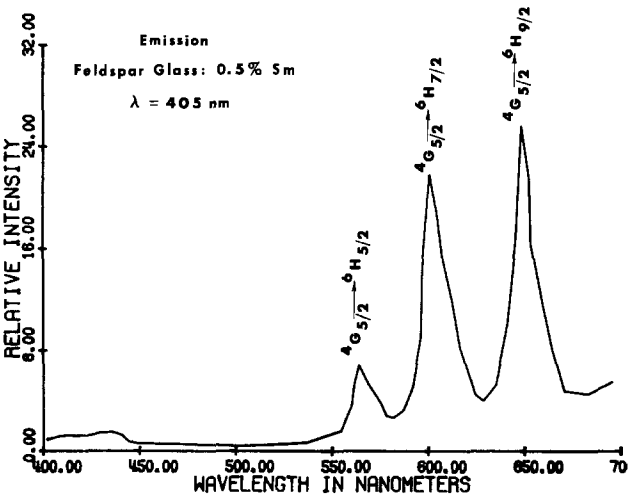

Fig. 6. Emission spectrum of 0.5% Sm^{3+} in potassium feldspar glass with excitation wavelength of 405 nm.

tions. In the case of Eu^{3+}, the $^5D_0$-$^7F_1$ transition is a magnetic dipole transition with $\Delta J = 1$. The $^5D_0$-$^7F_2$ transition is a pseudoquadrupole transition and is hypersensitive to the presence of an inversion center at the Eu^{3+} site. The greater intensity of this transition when compared with the intensity of the magnetic dipole indicates that no center of inversion is present at the eruopium ion site.

The $^5D_0$-$^7F_2$ hypersensitive transition of Eu^{3+} may only occur in a site having one of the following symmetries: C_s, C_1, C_2, C_{2v}, C_{3v}, C_{4v}, and C_6. The highly symmetric groups (the latter four) may be eliminated from consideration due to the low probability of occurrence of such a site in glass. The C_s site for Eu^{3+} in phosphate glass proposed by Reisfeld was formed

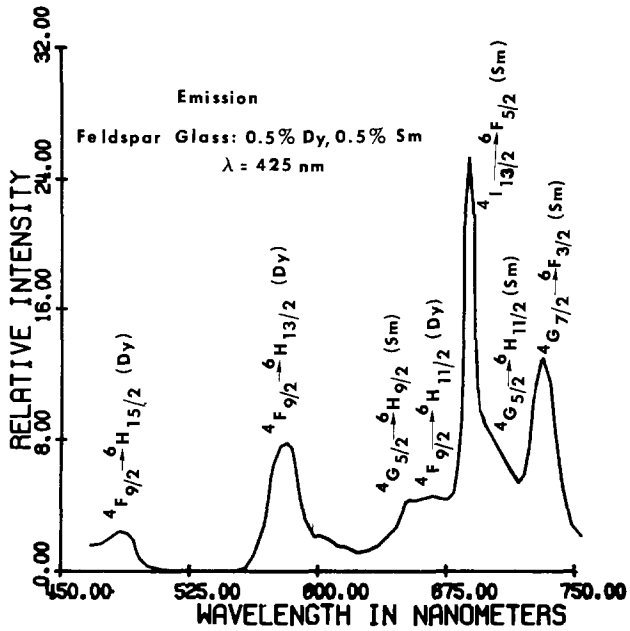

Fig. 7. Emission spectrum of 0.5% Dy^{3+} and 0.5% Sm^{3+} in potassium feldspar glass with excitation wavelength of 425 nm.

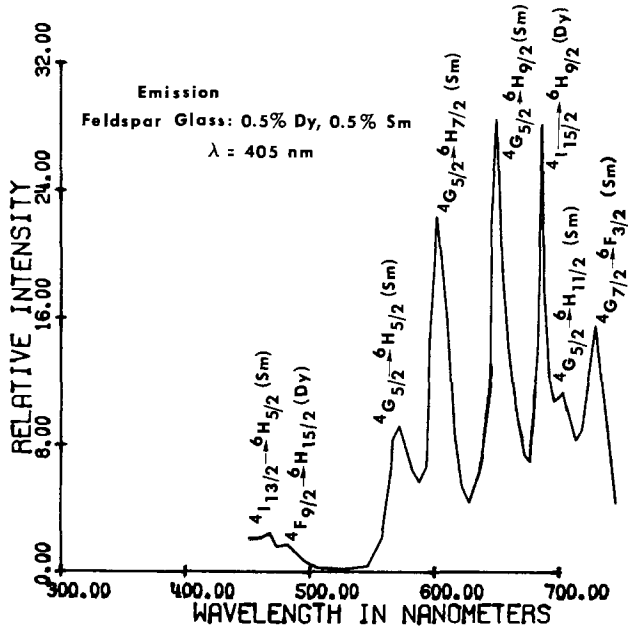

Fig. 8. Emission spectrum of 0.5% Dy^{3+} and 0.5% Sm^{3+} in potassium feldspar glass with excitation wavelength of 405 nm.

with eight oxygen ions located at cube corners with the rare earth ion located at the center of the cube. An eightfold site is possible in potassium feldspar, as the alkali ion in sanidine, a disordered crystalline potassium feldspar, has between 6 and 9 nearest neighbor oxygen ions. The substitution of the rare earth ions for potassium ions in this glass should make it probable that the rare earth ion also has between 6 and 9 nearest neighbor oxygen ions. It is therefore possible that the europium ion is in a site with C_s symmetry in potassium feldspar glass as well. If the rare earth ion is located in a "half" of a sanidine unit cell, which may be composed either of the group 4Al + 4Si or of the group 2Al + 6Si (7), the reflection plane present in C_s symmetry would cut through the cube made up of oxygen ions with aluminum tetrahedra lying directly opposite each other on both sides of the mirror plane. If a totally random distribution of silicon and aluminum tetrahedra surround the rare earth ion, the site symmetry will be C_1. The vibronic coupling between the rare earth ion and the host may then occur through

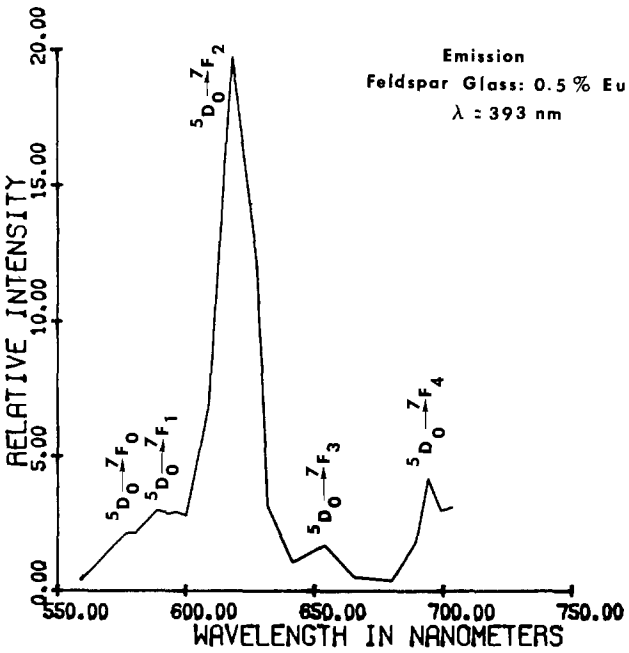

Fig. 9. Emission spectrum of 0.5% Eu^{3+} in potassium feldspar glass with excitation wavelength of 393 nm.

bonded interactions with the excess negative charges which exist due to oxygen ions belonging to aluminum tetrahedra.

Neutron transmutation doping is a very promising method for the production of high quality n-type silicon for high power devices such as thyristors and diodes (1-5). The homogeneity of the distribution of ^{31}P produced is governed by the irradiating neutron flux distribution. Usually, a silicon rod to be irradiated is inserted into a vertical irradiation port in a reactor core and rotated with some mechanical device. Thus, we can reduce the effect of the inhomogeneity of the flux along the radial direction. In contrast to this, the effect of the inhomogeneity along the axial direction cannot be reduced by rotating. The distribution of ^{31}P along the axis is directly proportional to that of neutron flux, which is lower in the top and bottom regions of the core. Then, we must carefully select a portion of the port appropriate to homogeneous doping. Since the flux distribution depends upon the geometry of the core assembly which changes frequently, a method for the rapid determination of the flux distribution is required. We report in this note upon a suitable method in which β-radiation from ^{31}Si produced by neutron irradiation is measured.

The neutron activation cross section is a function of the neutron energy, and hence the energy spectrum of neutrons affects the amount of neutron transmutation. This effect is remarkable, when a concerned nucleus

Key words: neutron transmutation doping, β-activity of silicon, neutron-flux distribution.

has a resonance absorption peak in the region of the epi-thermal neutron, as is the case with ^{59}Co and ^{197}Au. Hence, a neutron monitor of such a material must be carefully used in the silicon transmutation doping. In some cases, troublesome calibration might be required, but the silicon monitor presented herein can be used without any such trouble.

^{31}Si decays and transforms to ^{31}P with a half-life of 2.62 hr, emitting β-radiation of 1.47 MeV. We measured this β-radiation with a solid-state detector of the catheter type (Type-CASRAD, Toshiba Electric Company) which is designed to detect β-radiation of 1.7 MeV from ^{32}P in biological systems (6). The detector head consisted of a p-n junction of Si with a diameter of 2.3 mm, and was held in a nickel collimeter sheath of 3.2 mm diam. Such a compact geometry as this enabled us to measure a concentration of β-emitters contained in a very narrow region. A reverse bias of *ca.* 40V was supplied to the detector from a dry battery. The counting system used was of a conventional type, consisting of a charge sensitive preamplifier, linear amplifier, single channel pulse height analyzer, and scaler. Selecting an appropriate discrimination level for noise, the background counting rate was reduced to less than 2 cpm. The conditions of the measurements were chosen so that the total counts measured in a pregiven counting time of 24 sec were not less than 20,000 counts. Such a short counting time as this was necessarily required to obtain as many data as possible with a given silicon sample. The total counts of 20,000 are subjected to a statistical error of about 0.7%.

The silicon sample irradiated was etched with mixture of 3 parts conc HNO_3 and 1 part conc HF to remove surface contaminations, washed with water, and then set on a traveling plate of a X-Y stage. In the course of successive measurements, it took 30 sec to position a given point of the sample just beneath the detector head by operating the X-Y stage. Thus, we could obtain experimental data at a rate of one point per minute. If we measure the β-activity of a silicon sample giving an initial counting rate of 40,000 counts per 24 sec until it decreases to 20,000 counts per 24 sec, about 150 experimental points can be obtained. A short irradiation for silicon of about 10 min gives the above activity even in a small reactor with a power of 100 kW. Thus, we can

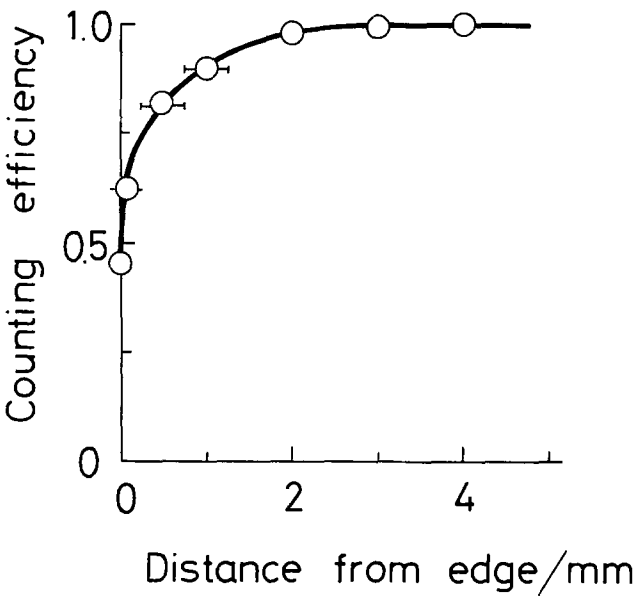

Fig. 1. Effect of the sample edge on the β-radiation counting efficiency of the solid-state detector.

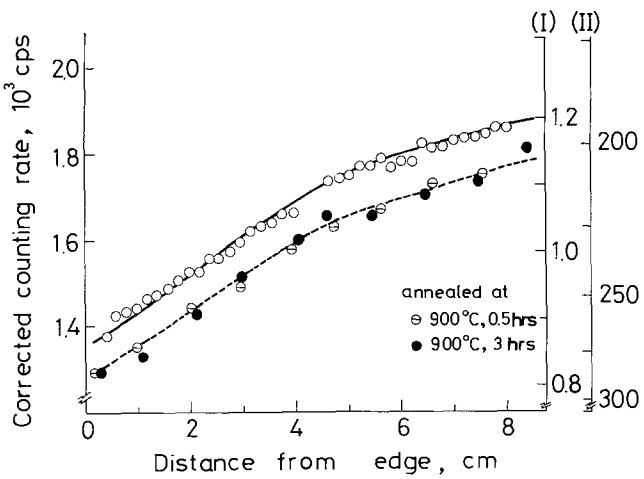

Fig. 2. Profile of the activity of ^{31}Si along the rod axis. The solid curve refers to the counting rate of β-radiation from ^{31}Si; the dotted curve refers to the neutron flux density deduced from the resistivity of the irradiated silicon. Units of right-hand side ordinate: (I), 10^{12} $n \cdot cm^{-2} \cdot sec^{-1}$; (II), Ω cm.

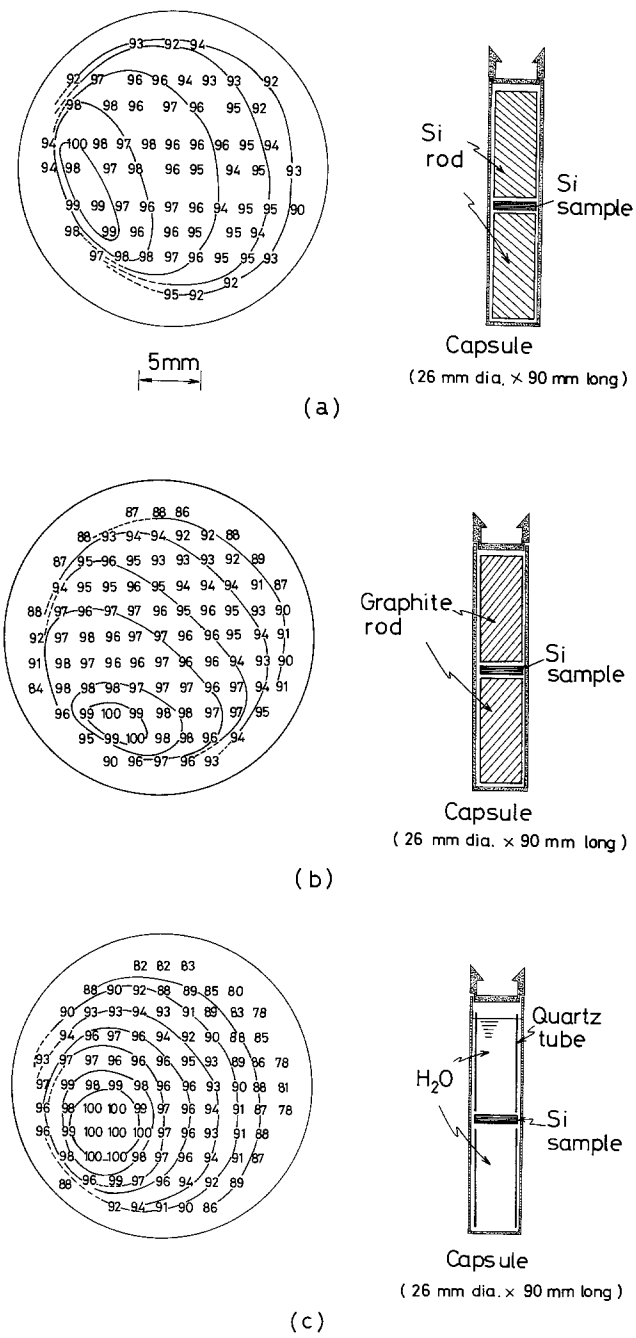

Fig. 3. Some examples of the relative distribution of ^{31}P in the plane of a silicon wafer irradiated under the conditions: (a) perturbed by silicon; (b) perturbed by graphite; (c) perturbed by light (natural)-water.

construct a distribution map of the neutron flux in the irradiation facility, within 3 hr.

The effect of the sample edge on the counting efficiency was investigated by the use of a silicon plate, 1 mm thick, which was homogeneously neutron irradiated. The calibration curve is shown in Fig. 1. No edge effect could be detected at a point located 2 mm inside the edge.

A silicon rod (25 mm diam × 80 mm long) was irradiated in a Triga-Mark II reactor of Rikkyo University. The neutron fluence amounted to about $1.4 \times 10^{17} n \cdot cm^{-2}$. The activity of ^{31}Si contained in the sample was measured along the orientation flat, and is shown in Fig. 2. The ordinate in the left-hand side expresses, in a relative scale, the counting rate which is corrected for the decay of the activity, and that in the right-hand side the neutron flux density deduced by the following procedure.

The concentration of ^{31}P produced, $[^{31}P]$, and the neutron flux density F are mutually related by the simplified equation

$$[^{31}P] = N(^{31}Si) = [^{30}Si]\,\sigma \int_0^\tau F\,dt \qquad [1]$$

where $N(^{31}Si)$ denotes the integrated total amount of ^{31}Si produced by the reaction, $^{30}Si(n, \gamma)\ ^{31}Si$. $[^{30}Si]$ designates the concentration of ^{30}Si ($1.54 \times 10^{21} cm^{-3}$), σ the cross section for the reaction (0.107 barns), and τ the irradiation time. To complete the map of the flux distribution by applying the one-point calibration method, the value for F at some point must be determined. We adopted the value of F determined previously from β-γ coincidence measurements of an irradiated gold foil. On the other hand, one can determine the absolute value of F from measurements of the electric resistivity, ρ, of an irradiated and annealed silicon sample. In this case the irradiation requires a longer time. If the sample is so highly pure that almost all of the carriers are supplied from the ^{31}P produced, the values of $[^{31}P]$ and hence that of F are easily determined from ρ measurements. Silicon wafers (25 mm diam × 1 mm thick) were cut from the irradiated silicon rod and annealed at 900°C for 0.5 and 3 hr in a nitrogen and oxygen stream, respectively. Their resistivities were measured with a four-point probe placed on the center of the wafers and are shown in Fig. 2. The two methods gave somewhat different values, as can be seen in the figure. Let us designate by subscripts c and ρ the values deduced from the first and second method, respectively. Then, we get empirically

$$F_\rho = 0.95 F_c.$$

Uncertainties in our measurements are ±5% for the absolute value of the resistivity, and ±6% for that of the neutron flux determined by the β-γ coincidence measurement method. Hence, the factor 0.95 in the above relation is a reasonable one. By the use of the present method, we can determine easily the distribution of ^{31}P in the plane of a silicon wafer irradiated under various conditions. Some examples are shown in Fig. 3. These samples, of course, were not rotated during irradiation. If the hills in the maps of Fig. 3. were located at the center, the rotation of the silicon rod might not reduce the inhomogeneity in the distribution of ^{31}P. These maps may be used to estimate the effectiveness of the rotation in the homogeneous doping.

Acknowledgment

The present authors would like to thank T. Sugita of Toshiba Electric Company who kindly furnished the solid-state detector.

Origin of the Fixed Charge in Thermally Oxidized Silicon

Herbert Goronkin

Varian Associates, Beverly, Massachusetts 01915

The thermal oxidation of silicon under ultraclean conditions gives rise to a net positive fixed charge, Q_{ss}, which is believed to be located in the oxide near the oxide-silicon interface region. The magnitude of Q_{ss} determines several important electrical parameters such as MOS threshold voltages and junction breakdown voltages. It is important in device fabrication that Q_{ss} be both minimized and reproducible. Therefore, a great deal of attention has been paid to process parameters affecting Q_{ss}.

It is well established that, following thermal oxidation, anneals between 900° and 1200°C in inert gas ambients will result in a reduction in Q_{ss}. The decrease can be as great as an order of magnitude. Recently, there have been reports of Q_{ss} slowly increasing with time following the relatively more rapid initial decrease (1, 2). Figure 1 shows some of the reported behavior. The existence of the positive $Q_{ss}(t)$ slope shows that the anneal cannot proceed for unlimited times to minimize Q_{ss}; there appears to be an optimum time that depends on the anneal temperature and ambient.

Deal *et al.* (3) suggested that excess silicon in thermally grown SiO_2, near the silicon surface, may be ionic and could be the source of Q_{ss}. It has been suggested (1) that the increase in Q_{ss} during inert gas anneal arises from the breaking of Si-Si or Si-O bonds in the strained interface region. The strain in this transition region would have to help ionize Si or SiO_2 at the anneal temperatures and maintain the charged state after return to thermal equilibrium. The breaking of bonds at elevated temperatures can be accompanied by reorientation of molecular clusters in the transition region which can give rise to either a net positive or negative change in oxide charge magnitude. Resulting Q_{ss} would not be monotonic with

Key words: silicon oxide, fixed charge, surface states, silicon diffusion.

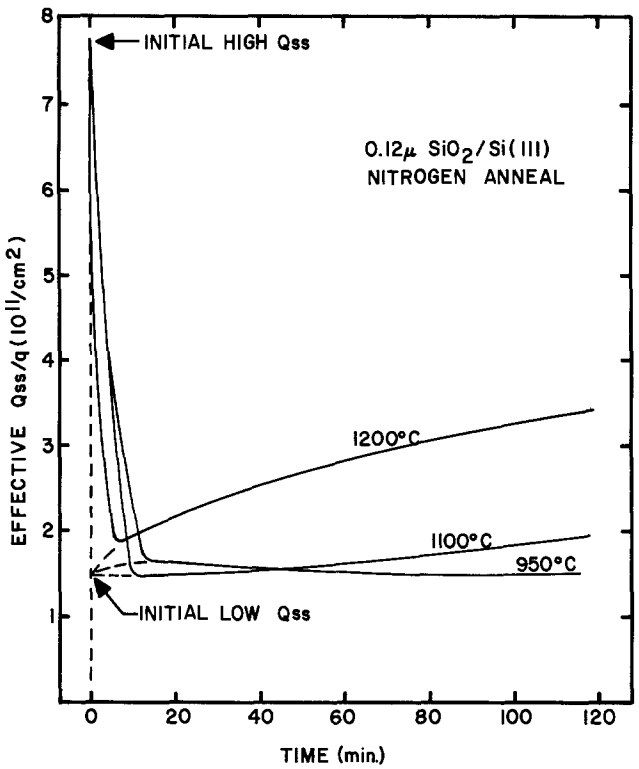

Fig. 1. Dependence of effective Q_{ss}/q on anneal in nitrogen for times of 0-120 min at various temperatures from Ref. (1).

time which is contrary to observations. It seems more probable that there is an introduction of additional charge into the interface region.

We propose that via diffusion of silicon atoms, the diffusion of ionic silicon into the transition region would provide a source of positive charge causing Q_{ss} to increase monotonically with time. It was the purpose of this work to see if the concept of solid-state diffusion could explain the observed variation of $Q_{ss}(t)$.

Theory

We consider SiO_2 grown in dry oxygen and subsequently annealed in an inert ambient. The resulting experimental curve of $Q_{ss}(t)$ is regarded as consisting of two contributions, a term $Q_{ss}^-(t)$ which decreases in magnitude with time and $Q_{ss}^+(t)$ which increases. In the simple theory presented here, excess silicon is the origin of Q_{ss} and each excess silicon atom is singly ionized.

The nature of the two terms are described in the following assumptions.

1. The postoxidation value of the interface region width is x_{io} and the average density of excess silicon ions therein is N_{si}. The initial value of fixed charge is related to N_{si} by

$$Q_{sso} = N_{si}\, x_{io} \qquad [1]$$

The neutral ambient post oxidation anneal reduces $Q_{ss}(t)$ to a minimum value. The corresponding interface region width is x_i and the minimum observed value of Q_{ss} is given by

$$Q_{ssm} = N_{si}\, x_i \qquad [2]$$

The maximum reduction in Q_{ss} arising from neutralization of ionic silicon by excess oxygen in the oxide is given by

$$\Delta Q = N_{ox}\, x_o \qquad [3]$$

where N_{ox} is the solid solubility of oxygen in SiO_2 at the growth temperature and x_o is the oxide thickness.

This assumption is based on the idea that, should oxidation of a silicon surface suddenly cease by either elimination of the source or reduction in temperature, there will be a nearly uniform distribution of oxygen throughout the oxide. Subsequent high temperature annealing in an inert ambient allows diffusion of the unreacted oxygen. That portion diffusing to the interface oxidizes elemental silicon which can no longer contribute to Q_{ss}^-. Since the rate of change of Q_{ss}^- will depend on the amount of charge present, we can write

$$\frac{d\,Q_{ss}^-(t)}{dt} = -\frac{Q_{ss}^-(t)}{\tau} \qquad [4]$$

where τ will depend on temperature and the diffusion constant of oxygen in silicon dioxide. Using Eq. [1], [2], and [3], the solution to Eq. [4] is

$$Q_{ss}^-(t) = (N_o\, x_o + N_{si}\, x_i)\, e^{-t/\tau} = (Q_{sso})\, e^{-t/\tau} \qquad [5]$$

2. Measurements (4) have indicated that the width of the interface region between silicon and thermally grown silicon dioxide is on the order of 25Å. Across this transition region, the concentration of elemental silicon changes is from about 5×10^{22} cm^{-3} to zero. This gives a concentration gradient of about 10^{29} cm^{-4}. There is a difference in bonding energies from the 1.84 eV Si-Si bonds on one side of the transition region to the 2.9 eV Si-O bonds on the other. At elevated temperatures, the strain due to unrelaxed bonds and the difference in chemical potential of silicon on the silicon side of the transition region and silicon on the oxide side combine to produce a driving force for diffusion from the silicon region towards the SiO_2 region. Then $Q_{ss}^+(t)$ can be defined as

$$Q_{ss}^+(t) = \int_0^{x_i} N_s(x)\, dx \qquad [6]$$

where x_i is the width of the interface region. $N_s(x)$ is the density of silicon atoms in the interface region and arises from the diffusion of silicon according to the relation

$$N_s(x) = N_{so}\, \mathrm{erfc}\, \frac{x}{2\sqrt{Dt}} \qquad [7]$$

which is analogous to the redistribution of impurities during epitaxial growth. D is the diffusion constant of silicon in the transition region and t is time. N_{so} is the volume density of silicon in the substrate within a diffusion length of x_i.

Equation [6] is solved, using Eq. [7], to give

$$Q_{ss}^+(t) = N_{so}\{x_i\, \mathrm{erfc}\, (x_i/2\sqrt{Dt}) + 2\sqrt{Dt/\pi}\,(1 - \exp[-(x_i^2/4\,Dt)])\} \qquad [8]$$

$Q_{ss}(t)$ is found by adding the two contributions to give

$$Q_{ss}(t) = Q_{ss}^-(t) + Q_{ss}^+(t) \qquad [9]$$

For $x_i << 2\sqrt{Dt}$, $Q_{ss}^+(t)$ approaches zero. For $x_i >> 2\,Dt$, $Q_{ss}^+(t)$ behaves as $2N_{so}\sqrt{Dt}$.

Experimental

The wafers used in this investigation were 4-6 Ω-cm phosphorus-doped silicon with <111> orientation. They were cleaned with an ammonium fluoride-HF solution, an HF dip, several water rinses, and spun dry. Oxidations were performed at 1000°C using dry oxygen in a fused quartz tube with a high purity liner. After 1300Å of oxide was grown, the wafers were withdrawn (push and pull rates were about 3 min) and annealed in a similar furnace at 1100°C in dry nitrogen for various times up to 140 hr. Aluminum dots were deposited through an evaporation mask on the oxide. Oxide from the back side of the wafer was removed and aluminum deposited thereon. The wafers were sintered at 495°C in N_2 for 30 min.

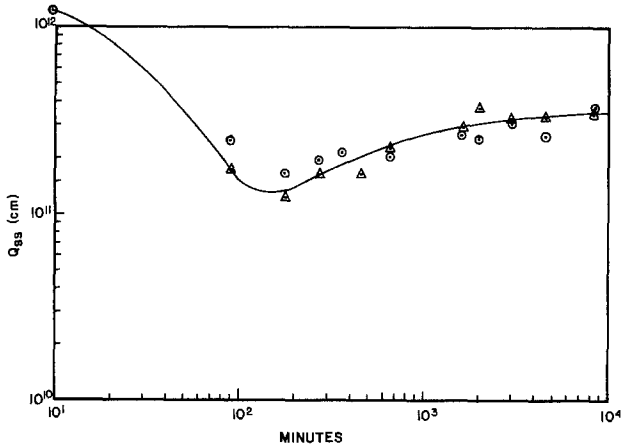

Fig. 2. Variation of Q_{ss} with time in dry N_2 at 1100°C. x_o = 1300Å. Solid curve = theory.

The oxide thickness, x_o, was measured with a Rudolph Routine 100 ellipsometer. The value of Q_{ss} was determined from the relation

$$\frac{Q_{ss}}{q} = \frac{2.13 \times 10^{10}\ (-V_{FB})}{x_o(\mu)}\ \text{charge/cm}^2 \qquad [10]$$

where V_{FB} is the flatband voltage. The mobile ion charge density was determined from the shift in the C-V curves using bias-temperature stress of 300°C, 5 min, +15V to be less than 3×10^{10} cm^{-2}.

Results and Discussion

Figure 2 shows variation of $Q_{ss}(t)$. The circles and triangles are experimental data. The solid curve is theory. Table I gives the values of parameters used in the theoretical curve.

Although the exponential dependence of $Q_{ss}^-(t)$ gives a reasonable fit to the data, there are not enough data points for $t < 90$ min to rule out other functions. Because of the limited number of oxygen molecules available for reaction at the interface, a Gaussian dependence might be more appropriate.

The value of τ was determined from the curve in Fig. 2. Using Eq. [1], [2], and [3], N_{ox} is found to be 7.3×10^{16} molecule/cm^3 which is in good agreement with the published value of 5×10^{16} molecule/cm^3 for the solubility of O_2 in SiO_2 at 1000°C (5). Using Eq. [1] and [2], the data give a value of about 10 for the ratio of initial to final transition layer thickness. Almost 90% of the excess silicon in the transition layer following oxidation was consumed by unreacted oxygen in the first 130 min of inert ambient anneal. At the minimum of $Q_{ss}(t)$, the rate of silicon consumption equals the rate of silicon replenishment via outdiffusion from the substrate.

The results for $Q_{ss}^+(t)$ show that the association of diffused silicon atoms with Q_{ss} predicts the observed behavior. There are only two adjustable parameters in $Q_{ss}^+(t)$. N_{so} is simply a constant of proportionality. It was found by shifting the $Q_{ss}(t)$ curve along the Q axis to obtain the best fit to the data. Its magnitude is considerably less than the bulk density of silicon atoms (5×10^{22} cm^{-3}), and corresponds to the density of silicon atoms within a diffusion length of the transition region that have sufficiently low binding energy to diffuse due to termination of the periodic lattice.

Table I.

Parameter	Value at 1100°C
τ	30 min
D	5×10^{-19} cm^2/sec
x_i	2.5×10^{-7} cm
N_{si}	4×10^{17} cm^{-3}
N_{so}	1.7×10^{18} cm^{-3}

The other parameter is the diffusion constant which, when varied, shifts $Q_{ss}^+(t)$ along the time axis of Fig. 2. A change of half an order of magnitude in D will shift the curve by about the same amount in time. The best fit can be found without knowledge of N_{so}. The value of D at 1100°C is several orders of magnitude less than that for some of the common silicon dopants in SiO_2 and accounts for the small magnitude of the transition region width.

The diffusion constant found here may only be valid for silicon diffusing through the transition region. The small value of x_i and the analytical technique described above show that far larger times are required for measurable concentrations of silicon to diffuse past the transition region and well into the oxide lattice.

The shape of Q_{ss} in the region where $Q_{ss}(t)$ increases is a sensitive function of the value of x_i. For $x_i \geq 160$Å, Q_{ss} increases as the square root of time to 10^4 min. For $x_i = 10$Å, Q_{ss} saturates at about 10^3 min.

The value found for x_i must represent an average value since $Q_{ss}(t)$ continued to increase throughout the anneal. If silicon diffusion is the primary mechanism for increasing $Q_{ss}(t)$, a saturation in Q_{ss} would imply an equilibrium value for x_i.

The data indicate that $Q_{ss}^+(t)$ can be associated with ionic silicon. The presence of elemental silicon diffusing into the interface region and leaving a charged vacancy in the periodic lattice can explain many of the effects that anneal ambients have on Q_{ss}. For example, anneals in oxygen should decrease Q_{ss} by an amount which is approximately the solubility of molecular oxygen in SiO_2 multiplied by the oxide thickness. This agrees with the Q_{ss}-oxygen triangle (3) which relates final Q_{ss} to the final oxidation temperature and ambient. The decreasing Q_{ss} with temperature for the oxygen leg implies an increasing concentration of molecular oxygen with increasing temperature which is in the same direction as the expected increase in solubility with increasing temperature. It follows that in order to decrease Q_{ss}, the concentration of excess oxygen in the oxide should be increased in order to increase the reaction rate with excess silicon.

The value of Q_{ss} obtained from Eq. [10] is ambiguous since it can contain contributions from N_{ss}, the density of fast states which are located at the interface. The two can be separated by measuring the flatband shift in the C-V curve between room and liquid nitrogen temperatures (6). The model described here can be used to explain these properties. The increase in N_{ss} after annealing in inert ambients probably arises from the diffusion of silicon into the silicon side of the transition region. The decrease in N_{ss} with hydrogen anneal is seen as neutralization of Si ions by formation of Si-H molecules.

Summary

The fixed charge and fast states in thermally grown silicon oxides have been associated with silicon which has diffused into the transition region from the surface region of the single crystal substrate. The diffusion follows the complementary error function dependence. A value for the diffusion constant of silicon in the transition region of 5×15^{-19} cm^2/sec at 1100°C was found. The density of silicon atoms that can diffuse is four orders of magnitude less than the bulk density and provides a measure of the thickness of the surface region of the terminated silicon lattice. The magnitude of fixed charge at the end of oxidation or oxygen anneals has been associated primarily with unreacted oxygen and excess silicon in the oxide.

Brief Communications

Contacts to p-Type InP

F. A. Thiel, D. D. Bacon, E. Buehler, and K. J. Bachmann*

Bell Laboratories, Murray Hill, New Jersey 07974

Contacts to p-type InP have recently gained some interest in the context of near-infrared LED's (1) and n-CdS/p-InP solar cells (2). Pure In metal (3) and Au-Zn alloys (4) have been described thus far as suitable materials for making contacts to p-InP. Electroplated Au/Zn/Au contacts sintered into the InP result in excellent ohmic contacts with a resistance $\leq 10^{-3}$ Ω cm² to moderately resistive InP (1-10 Ω cm material) (4). However, in the process of sintering Au-alloy contacts it is difficult to control the depth of penetration into the InP. Also, for large-area InP/CdS solar cells it would be desirable to find an inexpensive contact material that could be applied after the deposition of the InP film without interrupting the production process. In-contacts to thin films of InP on CdS would be a natural choice under fabrication conditions where In metal is reacted with PH_3(5). However, as shown in Fig. 1, pure In does not result in an ohmic contact to moderately resistive p-InP and we evaluate, therefore, In-Zn and In-Cd alloys as possible alternatives for contacting p-InP and compare them with Au-Zn and Au-Cd contacts.

The metal alloys were applied as sputtered films or ball contacts on slabs of p-InP of typical dimensions 0.5 × 2 × 15 mm. The contacts were sintered on a carbon strip heater in forming gas and the contact area was measured by microscopic examination (typically 0.5 mm diameter). Also, we sintered 0.05 mm diameter Au-2% Zn and Au-2% Cd wire contacts to the InP slabs. All contacts were evaluated on polished surfaces since rough surfaces or etched surfaces required considerably higher sintering temperatures leading to inferior contact properties. *I-V* curves were measured between two contacts of the same size. The bulk resistivity of the InP was determined by four-point probe measurements. The optimum sintering temperature was between 400° and 450°C for typically 5 min.

Figure 1 shows *I-V* characteristics obtained for various contact materials. In and In-5% Cd contacts have rectifying characteristics. Approximately linear *I-V* characteristics are observed for AuCd, AuZn, and In-5% Zn contacts, with the lowest contact resistance ($<10^{-2}$ Ω cm²) obtained for the Au-2% Cd contacts.

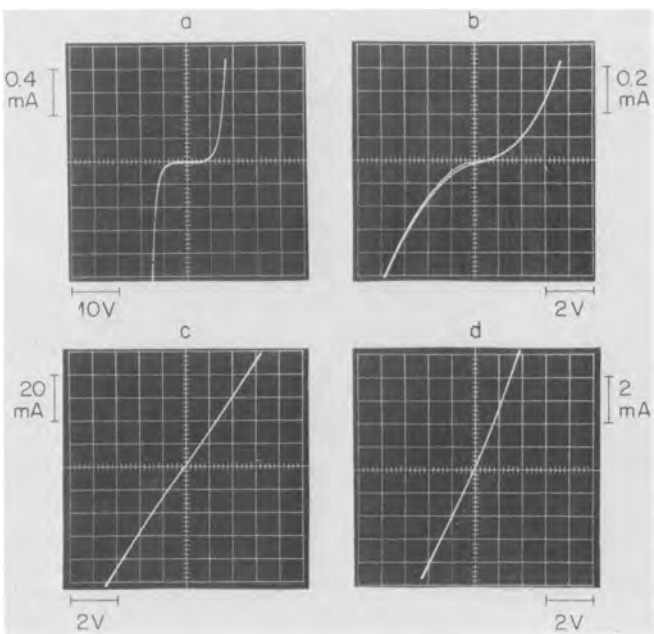

Fig. 1. Two-point *I-V* curves for (a) In, (b) In-5% Cd, (c) In-5% Zn, and (d) Au-2% Zn contracts to p-type InP (N_A-N_D = 5 × 10^{16} cm^{-3}, μ_h = 78 cm²V^{-1}sec^{-1}, ρ = 1.65 Ω cm). Contact area (cm²): (a) 1.7 × 10^{-3}, (b) 2.0 × 10^{-3}, (c) 2.4 × 10^{-3}, (d) ~10^{-4}. Bulk resistance between contacts (Ω): (a) 183, (b) 47, (c) 60, (d) 60. Contact resistance (Ω cm²): (a) ~10^3, (b) 60, (c) 0.02, (d) ~0.01.

Since InZn, but not InCd, results in an ohmic contact and the primary difference in the properties of Zn and Cd acceptor impurities in InP is the considerably faster diffusion of Zn, we believe that diffusion plays an important role in the formation of the contact. The properties of the best InZn contacts are similar to those of our AuZn contacts that have a contact resistance of ~0.01 Ω cm². In view of the results of Ref. (4), electroplating produces evidently a better contact than sputtered or mechanically attached metals sintered

Rare Earth Cobaltites as Oxygen Electrode Materials for Alkaline Solution

T. Kudo, H. Obayashi, and M. Yoshida

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

The perovskite-type compounds $Ln_{1-x}M_xM'O_3$ (Ln = lanthanoid element, M = alkaline earth element, M' = transition metal element) are examined as oxygen electrode materials for an alkaline solution. A porous sintered electrode consisting of a compound like $Nd_{1-x}Sr_xCoO_3$ ($x = 0.2$) is satisfactory in both polarization characteristics and stability under working conditions. However, a polytetrafluoroethylene (PTFE) bonded type electrode barely functions as an oxygen electrode even at a current density as low as 10 mA/cm^2. The electrode oxide undergoes reduction instead of acting as a reduction catalyst for gaseous oxygen to hydroxy ions. From a practical point of view, the sinter-type electrodes are promising as metal-air secondary battery cathodes because they are stable to anodic oxidation during charge periods.

The perovskite-type compounds like $La_{1-x}Sr_xCoO_3$ exhibit high electrical conductivity ($\simeq 10^4\ \Omega^{-1}$-cm^{-1}) at room temperature (1, 2). These compounds have been investigated as cathode materials for high temperature fuel cells (3). However, they have become the subject of renewed attention as oxygen electrode materials for alkaline solution working at moderate temperatures, not only due to their large electrical conductivity but also to their electrocatalytic activity which rivals that of platinized platinum (4).

The authors have studied the electrochemical behavior of $Nd_{1-x}Sr_xCoO_3$ in an aqueous alkaline solution (5). The oxygen ion diffusivity in these compounds is extraordinarily large ($D \simeq 10^{-11}$ cm^2/sec for $x = 0.2$ at 25°C) when compared with ordinary oxides. Their electrochemical redox reaction takes place reversibly in an alkaline solution as

$$O^{2-}(\text{lattice}) + 2Co^{4+} + H_2O + 2e \leftrightharpoons V_O^{\cdot\cdot} + 2Co^{3+} + 2\,OH^- \quad [1]$$

where $V_O^{\cdot\cdot}$ is a doubly ionized oxygen ion vacancy. One of the purposes of this study is to further investigate the reduction of oxygen to hydroxy ions on these compounds in connection with the above results. Another is to examine these compounds as possible oxygen electrode materials. From a practical point of view, the oxygen electrodes obtained here are useful in metal-air secondary batteries, not only because their performance is as good as that of platinized platinum electrodes, but also they are resistive to anodic oxidation during metal electrode chargings.

Experimental

PTFE-bonded type electrode.—A powder of the complex oxide compounds was prepared by sintering a homogeneous mixture of the component metal acetates at 800°C in air for 2 hr. The details of sample oxide preparations can be found in a previous paper (2). X-ray analyses showed only the diffraction pattern of the perovskite structure. The BET specific surface area of the powder was about 5 m^2/g. A complex oxide paste was prepared by adding a PTFE suspension (Mitsui Fluoro Chemical Company, 14.5% solid content) to the oxide powder together with deionized water and vigorously stirring. The amount of PTFE suspension was 0.7 ml/g of the oxide powder. To facilitate the separation of the water and the paste, acetone was added after the agitation was stopped. Then, the paste was spread on a nickel screen (60 mesh, 20 × 30 mm) so that its bulk density was about 75 mg/cm^2. The pasted screen was then pressed with a sheet of nonwoven PTFE on one side by applying a 500 kg/cm^2 pressure and was sintered at 250°C for 30 min in air to enhance its water repellency. The final electrode thickness was about 0.07 cm.

Sinter-type electrode.—Methyl cellulose (1% aqueous solution) was added to the oxide powder as a binder and it was pressed in a die (12 mmϕ or 30 × 35 mm rectangular) applying a 100 kg/cm^2 pressure to give a 2 mm thick disk (or plate). This disk was sintered at 900°C in air for 2 hr. The sintered disk showed about 60% porosity. As a current collector, a piece of platinum net was attached on one side of the disk by baking at 700°C with gold paste (Tokuriki Chemicals). Then, the disk was impregnated with a solution of fluorinated polyacryloester (FC-706, 3M Company) and dried at a temperature of approximately 100°C. Fluorinated polymer was used as a hydrophobant because it dissolves thoroughly in hexafluorinated xylene. In this way, the fluorinated polymer easily penetrates into pores of the electrode, in contrast with the very limited penetration of a PTFE suspension. After being dried at room temperature, the disk was mounted with an epoxy resin on an acryl case and oxygen or air was introduced into the gas compartment at the back of the electrode, while the front surface was in contact with a KOH solution.

Key words: air electrode, perovskite-type oxide, metal-air battery, rare earth cobaltite.

Measurements.—The electrode potentials were measured *vs.* a Hg/HgO reference electrode using a potentiometric recorder (QPD54, Hitachi). Constant rate potential sweep measurements were conducted employing a Type NL-101 potentiostat (Nichia Keiki Company). As a constant current d-c source, a Metronix 621 power supply was used. Temperatures of the electrolyte were controlled to 25° ± 1°C. The specific conductivity of the mixed oxides was measured by a d-c four-probe method, the details of which were reported in previous works (2, 6).

Results and Discussion

The results of potential sweep measurements of a PTFE-bonded type $La_{1-x}Sr_xCoO_3$ ($x = 0.1$) oxygen electrode, are shown in Fig. 1. When the potential is swept starting at a more anodic value ($E = 0.65$V *vs.* Hg/HgO) than that for oxygen evolution (point A in Fig. 1) toward the cathodic direction at a constant sweep rate of 50 mV/min, a cathodic current starts at $E = 0.12$V (point B). This current may be considered as resulting from the reduction of oxygen

$$\tfrac{1}{2}\,O_2 + H_2O + 2e = 2\,OH^- \qquad [2]$$

and/or by the reduction of the electrode itself (5) expressed in Eq. [1]. However, if the oxygen ion diffusion rate in the crystal lattice is sufficiently large, oxygen ions consumed by the reaction in Eq. [1] may be supplied without delay by the reaction

$$\tfrac{1}{2}\,O_2 + V_O^{\cdot\cdot} + 2e = O^{2-}\,(\text{lattice}) \qquad [3]$$

at the gas/electrode interface. Thus, the total reaction would be expressed by Eq. [2], even if the reaction of Eq. [1] takes place. This situation should be true when the cathodic current density is small. However, the reaction expressed by Eq. [1] seems to prevail with an increase in the current density as a result of the delay in oxygen diffusion through the oxide. It has been ascertained that the increase in nonstoichiometry of compounds like $La_{1-x}Sr_xCoO_{3-\delta}$ reduces their conductivity (2). In this respect, the current decrease between points C and D in Fig. 1 may be attributed mainly to the resistivity increase resulting from the reduction of the electrode according to Eq. [1]. When the potential reached −1.2V (point E) where hydrogen began to evolve with the decomposition of the oxide, the sweeping direction was reversed. The cathodic current decreased showing a marked hysteresis, with the anodic current beginning at +0.15V (point F). Since this is much more cathodic than the oxygen evolving potential, an electrochemical reoxidation of the electrode oxide has taken place.

Figure 2 shows the polarization characteristics of $Nd_{1-x}Sr_xCoO_3$ air electrodes *vs.* current densities at their early stages. The PTFE-bonded type electrode was not able to give a stationary potential when the current density exceeded 10 mA/cm² (dotted line). On the contrary, the sinter-type electrode (in the case of $x = 0.2$) showed flat I-V characteristics and gave very stable potentials. No increase in the polarization was observed after a 100 hr test at 20 mA/cm².

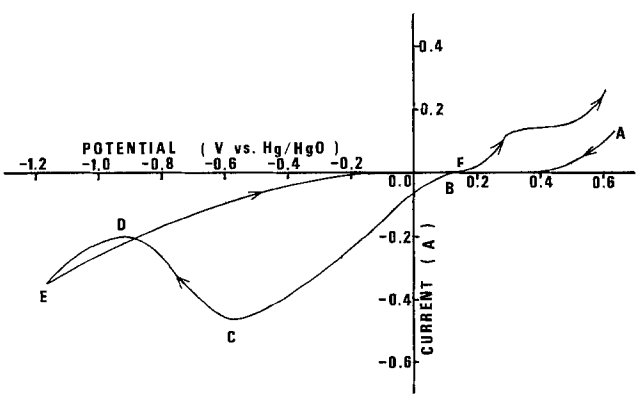

Fig. 1. Potential sweep of a PTFE-bonded $La_{0.9}Sr_{0.1}CoO_3$ in a 30% KOH solution. Sweep rate 50 mV/min.

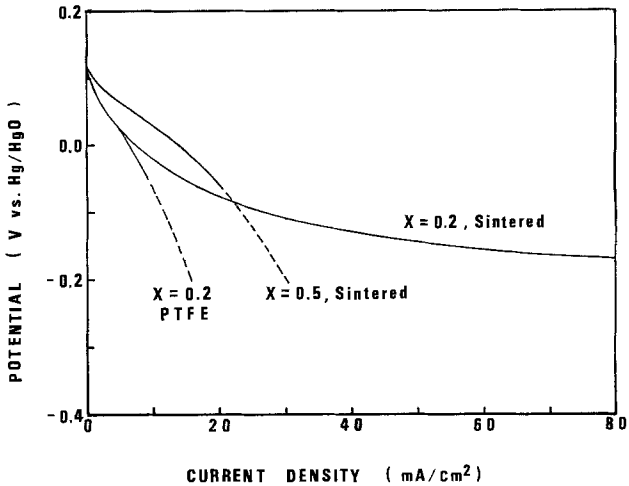

Fig. 2. Comparison of cathode polarization characteristics of various $Nd_{1-x}Sr_xCoO_3$ air electrodes at 25°C.

To explain the difference between the two electrodes, the ohmic polarization in the PTFE-bonded type electrode was measured as a function of discharge time using the current interruption technique. The result shown in Fig. 3 indicates that an increase in polarization can possibly be attributed to the increase in the resistivity in the electrode rather than to other polarizations such as activation. In the PTFE-bonded type electrode, electrical contact is due to the mechanical contact among oxide particles, making its resistivity rather high. Thus, the local current density in the vicinity of the current collector (Ni net) is much higher than the geometrically calculated average value. As a result of this high local current density, the oxide undergoes reduction as shown in Fig. 1 and this results in a drastic increase in electrode resistivity.

In the case of the sintered electrodes, in which particles of the oxides are in closer contact with each other, deterioration of the above kind cannot easily take place. However, a similar decline in the polarization characteristics with time was observed with sintered electrodes of a different Sr content ($x = 0.5$), when the current density exceeded 20 mA/cm² (Fig 2). This is probably due to the delay of oxygen supplied to the electrode/electrolyte interface from the gaseous phase. There may be three possible paths for oxygen to diffuse to the interface, *i.e.*, (*i*) through the electrolyte, (*ii*) over the oxide particle surface, and (*iii*) through the bulk of the oxide particles (as O^{2-} in this case). It is reasonable to assume that diffusion through

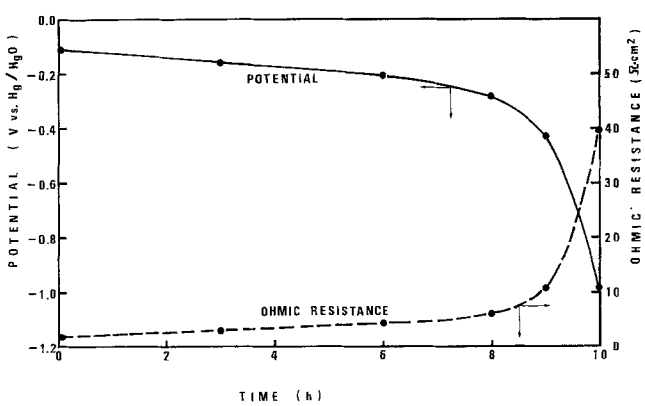

Fig. 3. Correlation of electrode potential and ohmic resistance for a PTFE-bonded $La_{0.9}Sr_{0.1}CoO_3$. Potentials were recorded during a constant current discharge of 15 mA/cm² and resistance was measured by the current interrupter method.

the bulk of the oxide plays the most important role in the case of the relevant oxygen electrodes, because those in which $x = 0.2$ and 0.5 show quite different characteristics in spite of their similarities in pore distributions and surface area. In fact, according to our previous study (5), the oxygen ion diffusion constant for $Nd_{1-x}Sr_xCoO_3$ ($x = 0.5$) is 7.6×10^{-14} cm²/sec at 25°C, which is a hundredth of that for $x = 0.2$. To sum up, the poor characteristics observed in the electrode consisting of $Nd_{1-x}Sr_xCoO_3$ ($x = 0.5$) core is attributed to the relatively small oxygen ion diffusivity.

Figure 4 shows the relationship between the polarization characteristics and x in $Nd_{1-x}Sr_xCoO_3$ for the sintered electrodes. In the range between $x = 0.0$ and 0.2, the polarization characteristics improve with the increase in x, resulting mainly from the decrease in specific resistivity in the x's range (7). The initial characteristics of the electrode in which $x = 0.3$ were almost the same as those in which $x = 0.2$, but the former potential gradually decreased in this case and it became conspicuous after 20 hr testing at 20 mA/cm², while no change in the polarization was observed for more than 100 hr in the case of $x = 0.2$. In the case of $x = 0.4$, however, stationary potentials were not observed at higher current densities. For $x = 0.5$, the stationary potentials were not observed even at a current density as small as 1 mA/cm². Results represented in this figure further support our interpretation that the I-V characteristics are the cumulative effects of the internal resistivity of the electrodes (resistivity of the oxides) and their bulk oxygen ion diffusivity.

In Fig. 5 polarization characteristics of the electrodes consisting of $Ln_{1-x}Sr_xCoO_3$ (Ln stands for La, Pr, Nd, and Sm; $x = 0.2$) are shown. Only these rare earth elements gave a single phase compound when the present preparation method was employed. The order of the polarization characteristics (La > Nd > Pr > Sm) agrees with that of the electrical conductivity data with the exception of Pr, which has a rather stable +4 valence state besides +3, whereas the others have predominantly stable +3 valency. The polarization of all Ln-type electrodes does not change in the first several hundred hours. Although deteriorations in the characteristics after that period resulted not only from the properties of these oxides but also from other factors such as the water repellency treatment, the order of the electrode life was represented as Nd > Pr ≃ Sm > La. The lifetime at 20 mA/cm² was more than 400 hr for Ln = Nd, but it was only about 200 hr for Ln = La.

The electrodes in which the A-site of the perovskite-type crystal lattice has been substituted by other alkaline earth elements than Sr, showed considerably different characteristics as shown in Fig. 6.

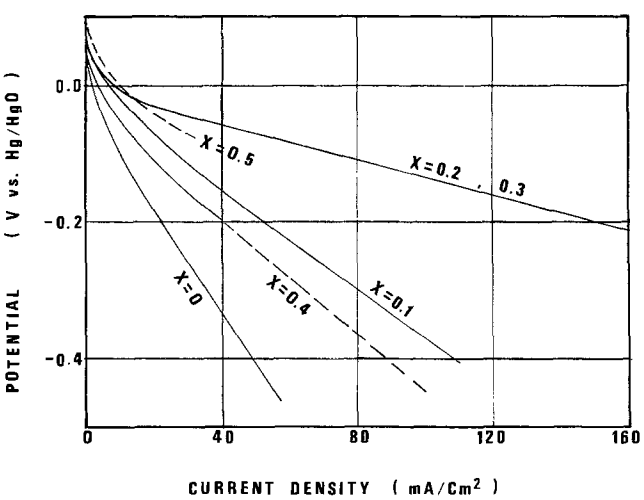

Fig. 4. Electrode potentials of $Nd_{1-x}Sr_xCoO_3$ oxygen electrodes during discharge with different Sr contents at 25°C.

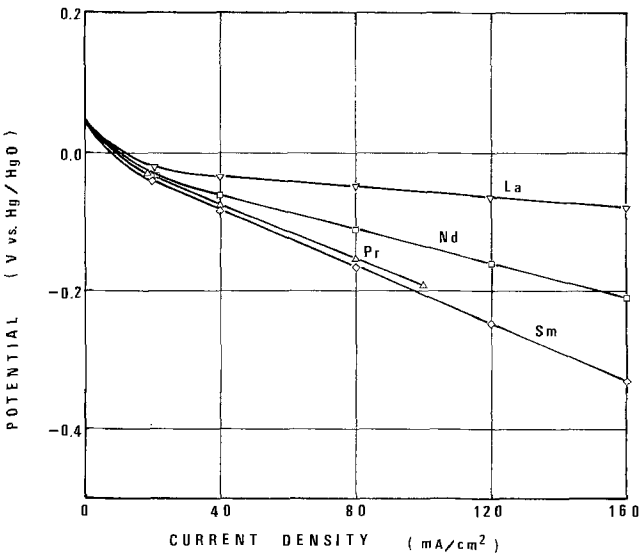

Fig. 5. Electrode potentials of $Ln_{0.8}Sr_{0.2}CoO_3$ oxygen electrodes during discharge at 25°C. Lifetimes of electrodes were in the order of Nd > Pr ≃ Sm > La.

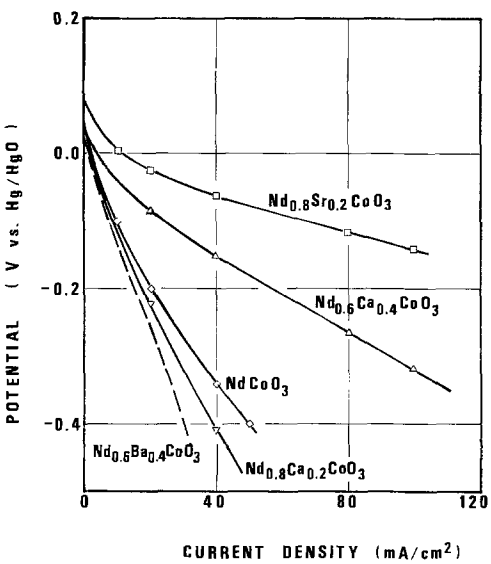

Fig. 6. Electrode potentials of (Nd, M)CoO_3 (M = Ca, Sr, and Ba) showing the effects of A-site substituting alkaline earth elements.

Among the substituting elements tested, potentials were the highest in the case of Sr, Ca, and Ba in that order. Whereas the Sr-substituted compounds showed monotonous increase in potential up to $x = 0.3$, the Ca-substituted compounds showed a decrease in potential when $x = 0.2$ ($Nd_{0.8}Ca_{0.2}CoO_3$), and when $x = 0.4$, its behavior was greatly improved. Thus far, this kind of change in performance is not readily explained. It is noteworthy that in the Ca-substituted electrodes, the polarization increase was not observed for 300 hr even when x was as large as 0.4. This fact is economically important since the use of expensive rare earth elements can be minimized by using these compounds. In the Ba case, the electrode potential was not very much improved and the electrode comprising $Nd_{0.6}Ba_{0.4}CoO_3$ was unable to show a stationary potential.

The effects of substitution of A-sites by these elements are twofold; *i.e.*, to increase the conductivity of the oxides and to modify their crystal structure. Of these, the doping of all three alkaline earth elements has a similar effect on the first point. However, the crystal structure is much affected by different ion dopings and we suspect that the difference in electrode

performance is attributable to some extent to their different crystal structures.

The final approach to improve the electrode characteristics by materials research is to substitute the B-site, *i.e.*, sites for Co^{3+} or Co^{4+} with an element which has an appropriate ionic radius and valence state. The elements Al, V, Cr, Mn, Fe, and Ni were picked as possible ones. Of all these elements, only Mn and Cr form the compounds $Nd_{1-x}Sr_xCo_{1-y}M'_yO_3$ ($x = 0.2$, and M' = Mn and Cr) in the full range of y which lies between 0 and 1, as long as the synthetic method is the one previously described. For other elements, the solubility limit is approximately $y = 0.1$. Representative results for sinter-type oxygen electrodes in which $x = 0.2$ and $y = 0.1$ or 0.2 are shown in Fig. 7. All B-site substituted electrodes exhibited poorer characteristics than nonsubstituted ones. This is mainly due to poorer electronic conductivity values than those of B-site nonsubstituted compounds. Nevertheless, it should be noted in connection with lifetime that Ni-substituted ($y = 0.1$) electrodes do not show any increase in polarization for more than 600 hr.

A life test using air instead of oxygen shows the advantage of Ni-substituted electrodes (see Fig. 8). The lifetimes of the electrodes in this study are more heavily influenced by oxygen partial pressures than ordinary ones because the electrode oxides undergo

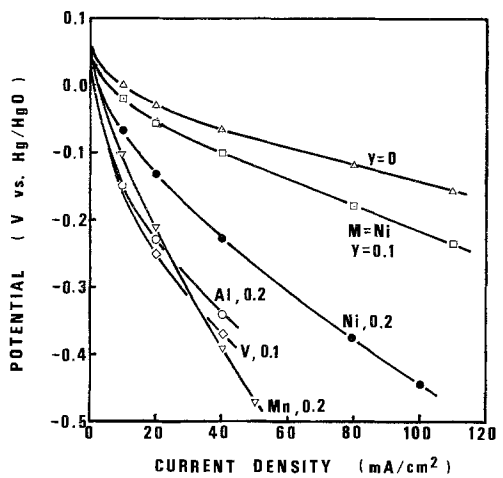

Fig. 7. Electrode potentials of $Nd_{0.8}Sr_{0.2}Co_{1-y}M'_yO_3$ (M' = Al, V, Mn, and Ni) showing the effects of B-site substituting transition metal elements.

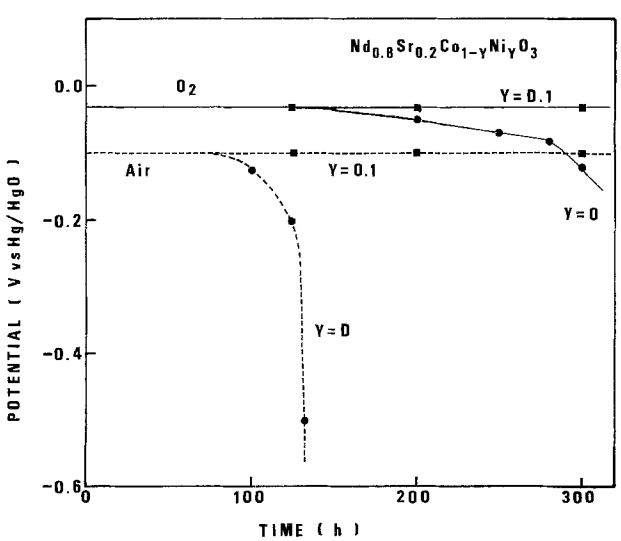

Fig. 8. Comparison of lifetimes of Ni-substituted and nonsubstituted $Nd_{0.8}Sr_{0.2}Co_{1-y}Ni_yO_3$ ($y = 0$ and 0.1) compounds for oxygen and air electrodes. Prolonged life is more clearly shown for Ni-substituted cobalites in air electrode performance.

reduction and decomposition unless sufficient oxygen (or oxygen ion) is supplied to the reaction zone. Although the electrode consisting of $Nd_{1-x}Sr_xCoO_3$ ($x = 0.2$) gives a stable potential for more than 400 hr at 20 mA/cm² if pure oxygen is used as a depolarizer, its lifetime is shortened to 130 hr if air is used. However, the Ni-substituted electrode keeps its initial characteristics for 550 hr even if air is used. It is hard to give a detailed explanation on the effect of doped Ni, but we believe this may be attributed to the enhancement of the oxygen ion diffusivity in the crystal lattice by Ni^{3+}.

Let us now consider the application of these electrodes to secondary batteries like a Zn/air battery. The present study was undertaken in an attempt to obtain an electrode with a resistance to anodic oxidation. Conventional electrodes such as carbon matrix type ones have the disadvantage that they would become corroded by anodic oxidation if they were used as counterelectrodes for charging a metal electrode. Thus, it is necessary to equip a metal/air battery with an auxiliary charging electrode. This has been one of the main drawbacks to the development of these secondary batteries.

As reported previously (5), the oxides used in the present electrodes undergo a reversible redox reaction within the range of $0 \leq \delta \leq x/2$, where δ represents a nonstoichiometric parameter in $Ln_{1-x}Sr_xCoO_{3-\delta}$. When $\delta = 0$ has been established, further passage of anodic current to these compounds only results in the evolution of oxygen from the electrolyte and the oxides themselves remain stable.

A charge-discharge life test has been conducted using a Cd/air cell in which the Cd electrode is charged using the air electrode as a counterelectrode. Figure 9 shows the I-V characteristics of $Nd_{0.9}Sr_{0.1}Co_{0.9}Ni_{0.1}O_3$ air electrodes at several stages during the life cycle tests. In this case, potentials were measured using a reference Zn electrode. The charge and discharge periods were 4 hr, respectively, and the current density employed in each period was 20 mA/cm².

The improvement in the I-V characteristics at earlier stages (between 20th and 80th cycles) may be due to an increase in the electrode/electrolyte interfacial area, resulting from weakening of the water repellency of the electrode. On the other hand, the deterioration observed after the 80th cycle may be considered to be the result of a decrease in the air/electrode interface, resulting also from the decomposition of the hydrophobant. Although the hydrophobant used in this study inevitably undergoes hydrolysis in alkaline solutions, the lifetime of the electrode is not solely controlled by its decomposition rate. The fact that the electrode keeps fairly good characteristics even after

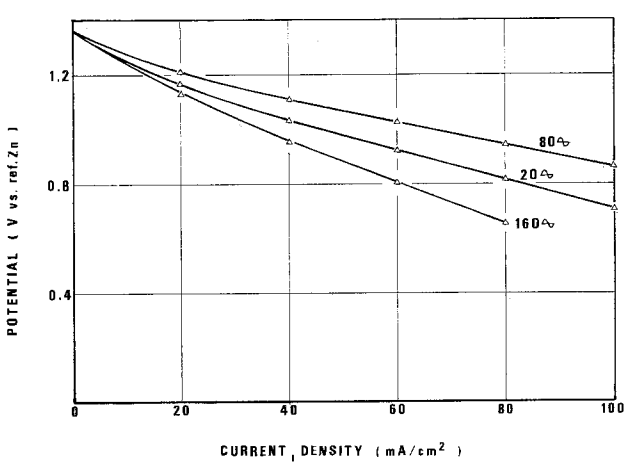

Fig. 9. Electrode potentials of a $Nd_{0.9}Sr_{0.1}Co_{0.9}Ni_{0.1}O_3$ air electrode at several stages of a charge-discharge cycle test. Test conditions are 4 hr/4 hr charge/discharge and 20 mA/cm² constant current density.

1200 hr (corresponding to 160 cycles) in the case of the cycle test while the electrode with the same composition has a lifetime as short as 550 hr in the case of the continuous discharge test seen in Fig. 8 suggests that the deterioration advances very slowly during the charge periods. In fact, it has been revealed by another experiment that an electrode undergoing the continuous charge extending for 500 hr shows almost the same I-V characteristics as the initial ones. These experimental results suggest that the deterioration is advanced by the self-aggravating cycle, namely, (*i*) wetting caused by the decomposition of the hydrophobant, (*ii*) lack of oxygen supply by (*i*), (*iii*) reduction of oxide by (*ii*), (*iv*) increase of resistivity and resulting current concentration by (*iii*), and acceleration of wetting by (*iv*).

Thus to obtain an electrode with a longer lifetime, it is necessary to search for a hydrophobant which is stable in alkaline solutions and has good penetrability into the electrode as well. If a suitable hydrophobant can be found, these types of air electrodes would be promising for metal/air batteries because of their excellent resistivity to anodic oxidation.

A New Niobium Selenide Cathode for Nonaqueous Lithium Batteries

D. W. Murphy,* F. A. Trumbore,* and J. N. Carides

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The γ-"$NbSe_4$" phase, with a single phase composition range $NbSe_{4.0}$ to $NbSe_{4.5}$, is shown to behave as an electrochemically active, reversible cathode material in nonaqueous lithium cells. The cell data, together with the results of n-butyl lithium reaction studies, indicate a topotactic reaction to give an Li_4NbSe_{4+x} (x = 0-0.5) discharge product. Cycle data are presented for nonaqueous lithium cells with cathodes of either $NbSe_4$ containing small amounts of fibrous $NbSe_3$ or hot-pressed composites of $NbSe_{4+x}$ with graphite and polyethylene.

As part of a continuing program on transition metal chalcogenide cathodes in nonaqueous secondary cells, we report here on the use of the γ-"$NbSe_4$" phase first prepared by Selte and co-workers (1, 2), who claimed three different "$NbSe_4$" phases. Meerschaut and Rouxel (3) identified one of these phases (β) as $NbSe_3$ by single crystal x-ray determination. Its use as a reversible cathode material in nonaqueous lithium cells has been described (4-7). The γ-phase was reinvestigated by Guemas *et al.* and found to have the limiting composition $NbSe_{4.5}$ (8, 9). Unit cell parameters were reported, but as yet the full structure has not appeared.

In view of the reversibility of $NbSe_2$ (10-12)[1] and $NbSe_3$ (4-7) in nonaqueous lithium cells, we investigated these limiting compositions of this higher selenide as cathode materials.

Experimental

Materials.—Niobium powder (30 μm, 99.95% purity), selenium shot (5*N* purity), graphite powder (325 mesh), lithium foil (Foote Mineral Company), n-butyl lithium (Alfa Inorganics), and polyethylene powder (Microthene 500 U.S. Industrial Chemicals) were used as received. Propylene carbonate (PC) and tetraglyme were vacuum distilled from lithium while lithium perchlorate (Alfa Inorganics) was vacuum dried at ~ 150°C. Separator bags were made from 1 mil thick polypropylene (Celgard KKX-2, Celanese Plastics Company).

Niobium selenide preparation.—Single phase niobium selenide powder samples in the composition range $NbSe_{4.0}$ to $NbSe_{4.5}$ were prepared by heating the appropriate amounts (~ 6g, total weight) of Nb and Se in sealed, evacuated fused quartz ampuls. The ampuls were heated from 400° to 500°C ($NbSe_{4.0}$) or to 550°C ($NbSe_{4.5}$) at a rate of about 25°/day and then held at the higher temperature for 2-3 days.

When Nb-Se mixtures of nominal composition $NbSe_{4.0}$ were directly heated to 550°C for 3 days, the result was a mixture of predominantly $NbSe_{4+x}$ plus small amounts of $NbSe_3$ fibers as shown by the scanning electron microscope (SEM) photograph in Fig. 1.

Construction of test cells.—With one exception, all of the test cells were constructed by sandwiching the appropriate selenide cathodes between two 15 mil thick Li anodes of the same shape, all three electrodes being contained in polypropylene separator bags wet with tetraglyme. The electrodes were placed in a glass vessel, 1*M* $LiClO_4$ in PC added as the electrolyte and the cell evacuated in the port of a Vacuum Atmospheres dry box. All cells were constructed in this dry box

* Electrochemical Society Active Member.

Key words: chalcogenide cathodes, secondary batteries, topotactic reactions.

[1] In Ref. (10) $NbSe_2$ was reported to be a host material for iodine. The electrochemical activities of the analogous compounds NbS_2 (11) and TiS_2 (12) were demonstrated, probably accounting for the two plateaus (one due to I_2 and one to $NbSe_2$) in the original discharge curves of this reference.

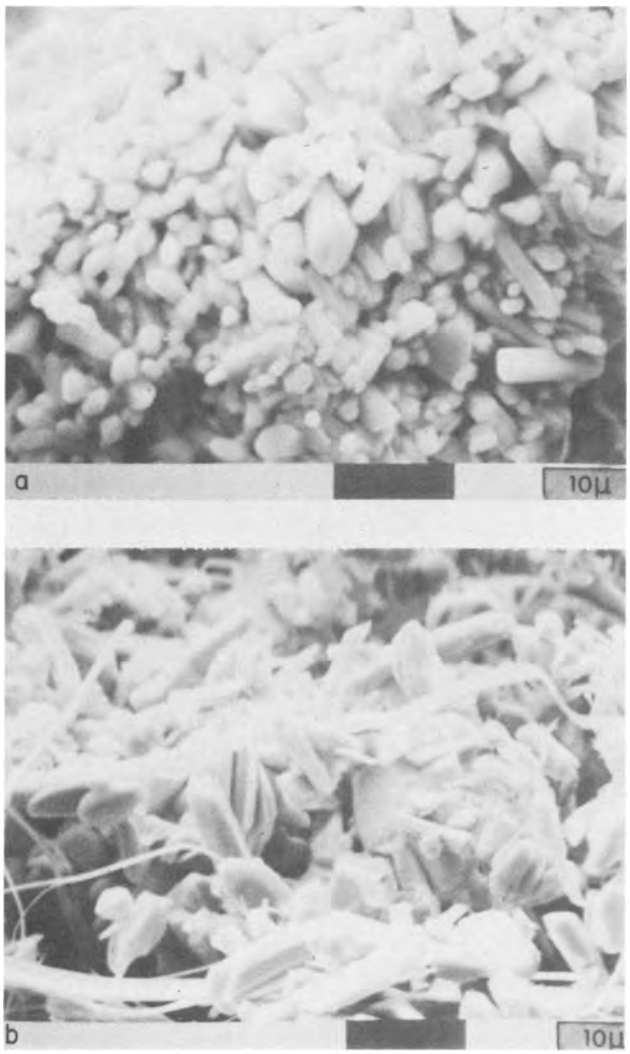

Fig. 1.(a) SEM photograph of single phase $NbSe_{4.5}$. (b) SEM photograph of "nominal" $NbSe_{4.0}$ containing a small amount ($\lesssim$5%) of fibrous $NbSe_3$.

under argon. The cells were placed in Mason jars with electrical feedthroughs and removed from the dry box for charge-discharge cycling.

Single phase $NbSe_{4+x}$ was formed into "composite" cathodes by hot pressing, typically, 65 weight percent (w/o) $NbSe_{4+x}$ powder (150 mesh), 30 w/o graphite, and 5 w/o polyethylene. After rolling this mixture in a ball mill for $\sim$ 16 hr, it was pressed to 6500 psi at 130°C for 3 min onto an expanded nickel screen which serves as a current collector. A typical composite cathode was 3 cm × 3 cm × 0.6 mm weighing 1.6g (exclusive of the nickel screen). A convenient test cell arrangement for the composite cathodes was found to be one in which the anode-cathode-anode sandwich was placed horizontally in a Petri dish containing $\sim$ 8 cm^3 of electrolyte solution. A Teflon block served as a weight on top of the sandwich to promote uniform contact of the electrodes.

A "pocket" cathode of "nominal" $NbSe_{4.0}$ (containing electrically conducting $NbSe_3$ fibers) was prepared by placing slices of the $NbSe_4$ in a nickel pocket (1 × 3 × 0.1 cm), obtained by forming and welding 5 mil perforated nickel sheet. The corresponding "pocket" cell was of a conventional geometry with the electrode sandwich placed vertically in a rectangular glass vessel.

Cycling of cells.—The above cells were tested using essentially two different cycle modes. In the "float" mode the cells were cycled at constant current for selected charge and discharge times, with the charging taking place potentiostatically at 2.7V after the cell reached this upper voltage limit. In the "voltage-limited" cycle mode, the cell was cycled at constant current between 2.8 and 1.0V using a solid-state cycling apparatus which immediately switches from charge to discharge (or vice versa) on reaching the upper (lower) voltage limit.

Results

Unlike the lower selenides of niobium which show metallic conductivity, the $NbSe_{4+x}$ phase was found to be a relatively poor electronic conductor ($\rho \approx 30$ Ω-cm) (13). Hence, composite cathodes, with graphite added to increase conductivity, were used to a large extent. However, a "nominal" composition $NbSe_4$ containing small amounts of $NbSe_3$ (barely detectable by x-ray powder patterns) fibers (see Fig. 1) could be formed (by appropriately varying the growth conditions). This small amount of $NbSe_3$ served to bind the sample together in an open structure much like felt and to impart good conductivity to the entire sample.

A cell[2] consisting simply of a Li anode and a small fiber matte cathode (79 mg) of "nominal" $NbSe_4$ immersed in 1*M* $LiClO_4$ in PC was slowly discharged to determine the capacity of the cathode and the approximate shape of the equilibrium discharge curve (Fig. 2). The capacity corresponded to essentially four (3.8) Li per Nb or one Li per Se. These values compare favorably to those for $NbSe_2$ and $NbSe_3$ which have theoretical capacities of one and three Li per Nb, respectively (14-17). This small $NbSe_4$ cell was over 96% rechargeable.

Pocket cells using the same nominal $NbSe_4$ were prepared from a collection of sliced sections ($\sim$ 50 mil thick) of the fiber matte placed in perforated nickel pockets as described in the experimental section. Cycle data obtained in the voltage-limited mode for a typical pocket cell are shown in Fig. 3. This cell failed after 28 cycles due to Li anode failure. The decrease in capacity on cycling is attributable to at least three factors, namely, (*i*) an inherent decrease in capacity of the cathode after the first cycle or so, (*ii*) higher resistance due to buildup of particulate Li, and (*iii*) smaller charge acceptance in the voltage-limited mode as compared to the float mode. The voltage-limited mode leads

[2] This cell was the only test cell which did not fall into the composite or pocket cell categories described in the experimental section. The loose structure of this matte provided a large surface area exposed to the electrolyte. Pocket cell material was much more densely packed.

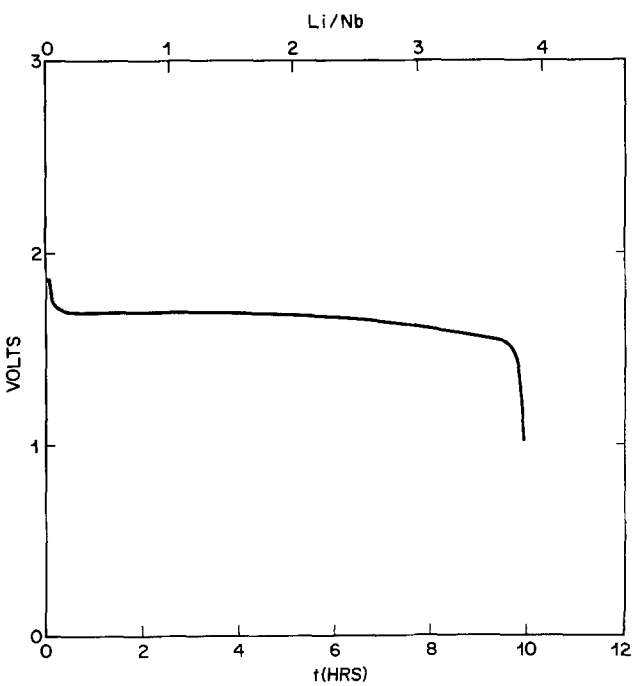

Fig. 2. Semiequilibrium discharge curve for a Li/1M $LiClO_4$ in PC/"nominal" $NbSe_{4.0}$ (79 mg) cell showing the reaction of essentially four equivalents of Li per $NbSe_4$. i_D = 2.0 mA.

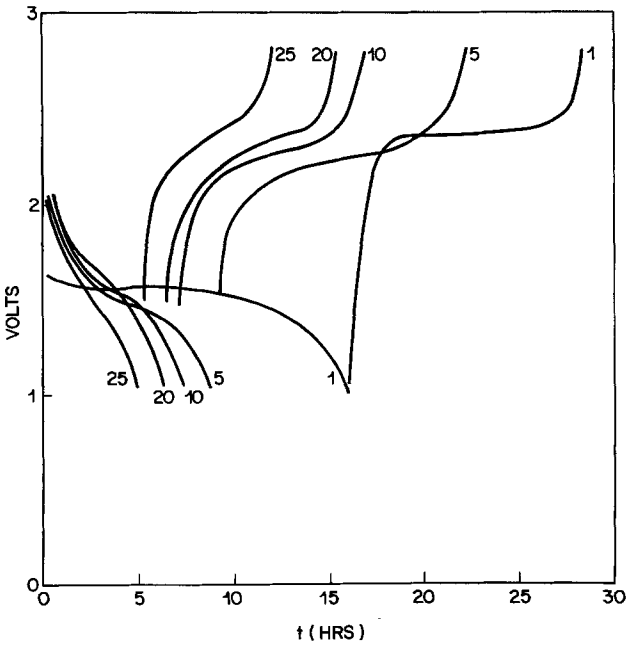

Fig. 3. Cycle behavior of a Li/1M $LiClO_4$ in PC/"nominal" $NbSe_{4.0}$ (314 mg) pocket cell cycled between 2.8 and 1.0V in the voltage-limited mode. $i_D = i_C = 5$ mA (cycles 1-4); $i_D = 5$ mA, $i_C = 3.6$ mA (cycles 5-25); $j_D = 16$ mA/g $NbSe_4 = 1$ mA/cm^2.

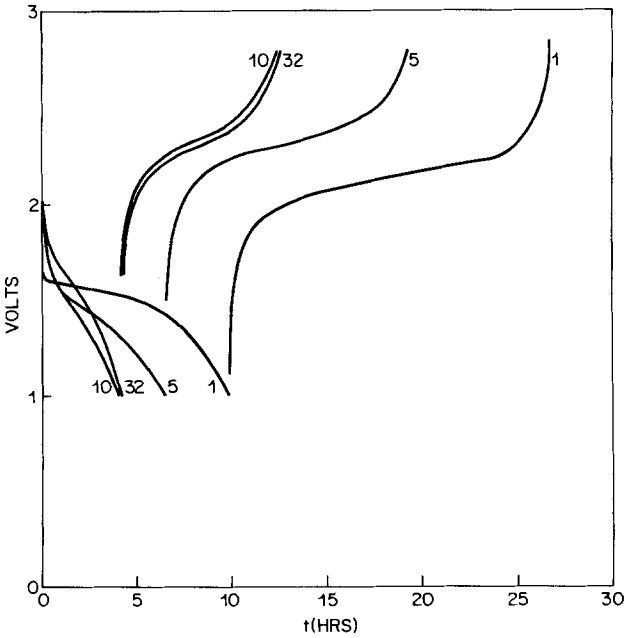

Fig. 5. Cycle behavior of a Li/1M $LiClO_4$ in PC/$NbSe_{4.0}$ (1.01g) composite cathode cell cycled between 2.8 and 1.0V in the voltage-limited mode. $i_D = 10$ mA, $i_C = 5$ mA, $j_D = 9.9$ mA/g $NbSe_{4.0} = 0.55$ mA/cm^2.

to a shallower average depth of discharge (percent of theoretical capacity) of the cathode than does the float mode. At any rate, Fig. 3 demonstrates the reversibility of the nominal $NbSe_4$.

Cycle data for typical cells employing the composite hot pressed cathodes (single phase $NbSe_{4+x}$-graphite-polyethylene) and cycled in the voltage-limited mode are shown in Fig. 4 and 5. It appears from the data presently available that cells employing $NbSe_{4.5}$ cathodes fail sooner than those cells in which $NbSe_{4.0}$ cathodes are used. For the $NbSe_{4.5}$ cells discharged to 1V, failure has occurred by cracking of the composite often leading to complete lift-off from the nickel screen. The increasing steepness and voltage of the charging curves (Fig. 4) is consistent with a higher resistance and nonuniform current distribution associated with cracking and/or lift-off and is indicative of incipient cathode failure, as confirmed by reconstruction with new lithium and electrolyte. Better results are evident for the composite $NbSe_{4.0}$ cell as shown in Fig. 5. Here we see a leveling off of discharge capacity (actually an improvement from the 10th to 32 cycle!) typical of the voltage-limited cycling mode. In addition, the charging curves do not show the pronounced steep slope shown by the $NbSe_{4.5}$ cell in Fig. 4. The $NbSe_{4.0}$ cell failed after $\sim$ 50 cycles due to lithium failure. Reconstruction of this cell with fresh Li returned the capacity to $\sim$ 40 mA-hr at 10 mA discharge current and $>$ 100 mA-hr at 5 mA.

The behavior of $NbSe_{4.5}$ and $NbSe_{4.0}$ composite cells cycled in the float mode to a depth corresponding to only one Li per $NbSe_{4+x}$ is shown in Fig. 6 and 7. Limiting the depth of discharge helped alleviate the

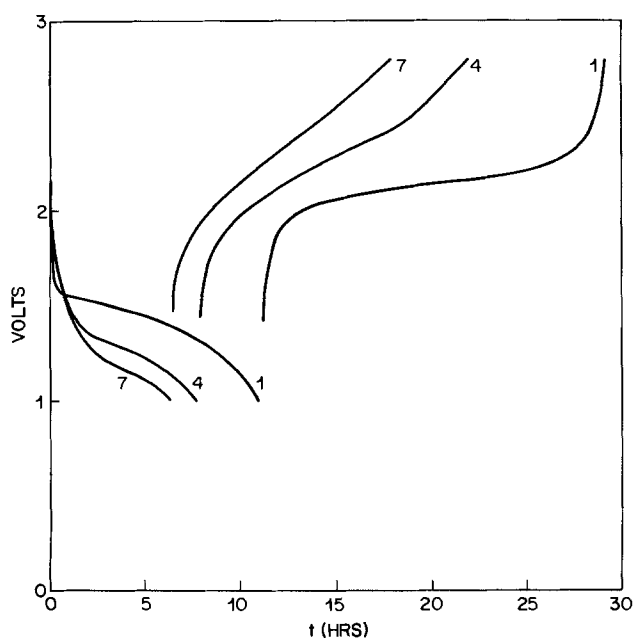

Fig. 4. Cycle behavior of a Li/1M $LiClO_4$ in PC/$NbSe_{4.5}$ (1.05g) composite cathode cell cycled between 2.8 and 1.0V in the voltage-limited mode. $i_D = 10$ mA, $i_C = 5$ mA, $j_D = 9.5$ mA/g $NbSe_{4.5} = 0.55$ mA/cm^2.

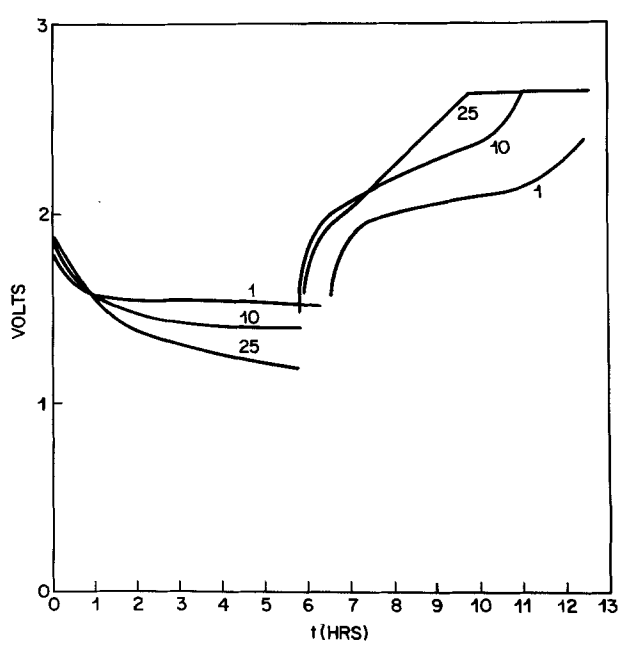

Fig. 6. Cycle behavior of a Li/1M $LiClO_4$ in PC/$NbSe_{4.5}$ (472 mg) composite cathode cell cycled in the float mode at a depth corresponding to one Li per $NbSe_{4.5}$. $i_D = i_C = 5$ mA, $j_D = 10.6$ mA/g $NbSe_{4.5} = 0.4$ mA/cm^2.

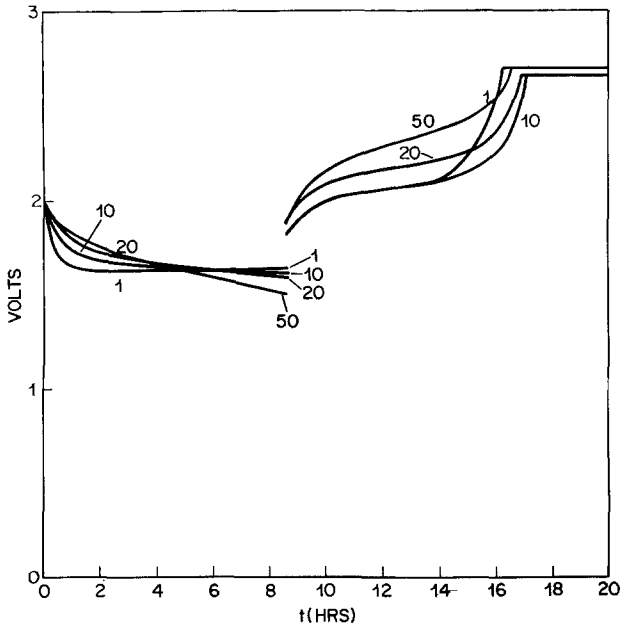

Fig. 7. Cycle behavior of a Li/1M $LiClO_4$ in PC/$NbSe_{4.0}$ (212 mg) composite cathode cell cycled in the float mode at a depth corresponding to one Li per $NbSe_{4.0}$. $i_D = i_C = 1.5$ mA, $j_D = 7.1$ mA/g $NbSe_{4.0} = 0.33$ mA/cm^2.

mechanical breakup of the cathodes. In the case of $NbSe_{4.5}$ composite cells, there was some beneficial effect but the decrease in end-of-discharge voltage and increasing steepness of the charging curve (see Fig. 6) with continued cycling show that the resistance problem remains. Reconstructing the cells with new lithium and new electrolyte did not improve the charge-discharge behavior, confirming that the increased resistance was in the cathode and probably was due to cracks not sufficiently extensive to cause complete failure. On the other hand, consistent with the results of voltage-limited cycling, the $NbSe_{4.0}$ composite cells suffered only slightly on float-mode cycling as shown in Fig. 7. Here, there is only a slight decline in end-of-discharge voltage after 20 cycles while the charge curve, though at a higher voltage, is reasonably flat.

We have used n-butyl lithium to mimic cell discharge (18) on pure samples in order to elucidate the products of cell discharge. With excess n-BuLi, $NbSe_{4.0}$ and $NbSe_{4.5}$ consumed 6.4 and 7.5 moles, respectively. X-ray powder patterns (see Fig. 8) of these products clearly showed the presence of Li_2Se, but no niobium selenide products could be identified. When four equivalents of n-BuLi were used, no Li_2Se was observed and the x-ray powder patterns were very similar to the pure $NbSe_{4+x}$, although weaker. A small amount of Li_2Se appears to be present with 5 moles of n-BuLi. $NbSe_{4+x}$ is triclinic, making a determination of the unit cell in Li_4NbSe_{4+x} impossible from our data.

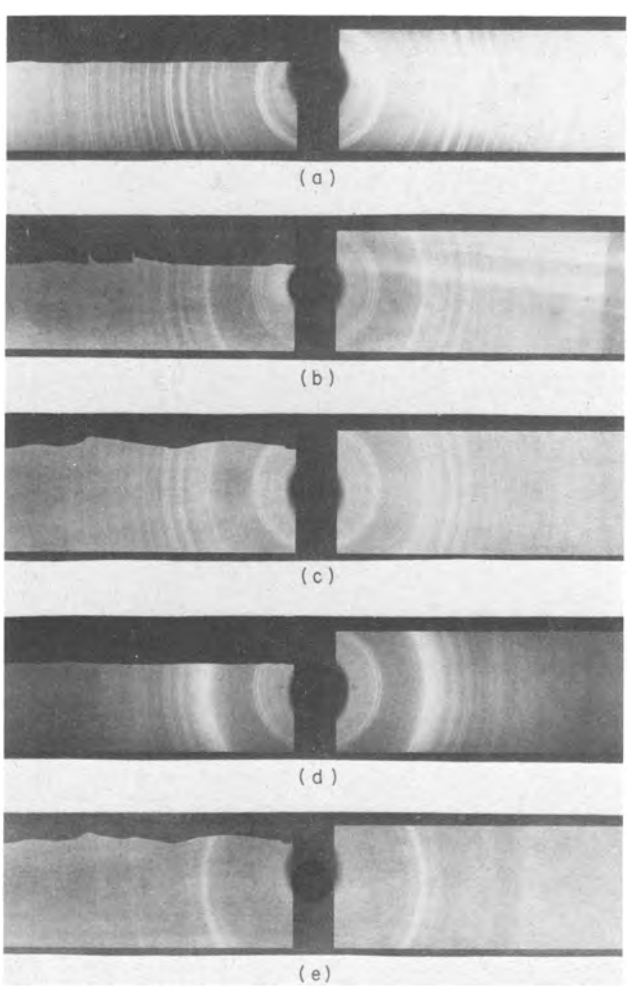

Fig. 8. X-ray powder patterns of $NbSe_{4+x}$ and various compounds with lithium. (a) $NbSe_{4.0}$, (b) Li_4NbSe_4, (c) $Li_4NbSe_{4.5}$, (d) $NbSe_{4.5}$ + 5 n-BuLi, and (e) $NbSe_{4.5}$ + excess (7.4 n-BuLi).

Discussion

The similarity in powder patterns of $NbSe_{4+x}$ and Li_4NbSe_{4+x} suggests that the cell discharge reaction is a topotactic incorporation of Li as found in $NbSe_3$ (17) and several other systems (19). Even though the detailed structure of the $NbSe_{4+x}$ phase is unknown, some reasonable guesses may be made from closely related systems and our results here. $NbSe_3$ may be thought of as $Nb^{4+}Se^{2-}(Se_2)^{2-}$ and replacement of the Se^{2-} by another Se_2^{2-} would give $Nb^{4+}(Se_2^{2-})_2$. Such a structure (see Fig. 9) is found in VS_4 (20), NbS_2Cl_2 (21) (two Cl^- are isoelectronic with an S_2^{2-} unit), and $NbTe_4$ (22). VS_4 and NbS_2Cl_2

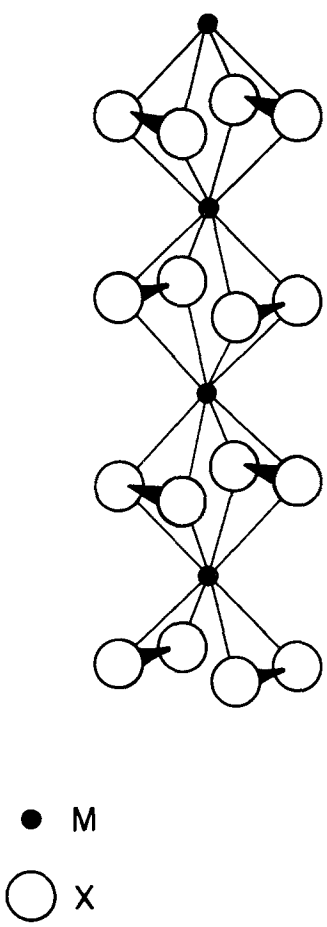

Fig. 9. The chain structure of VS_4

are van der Waals bonded chain compounds, while $NbTe_4$ has substantial Te-Te bonding between chains. We feel that the $NbSe_4$ structure is closely related to this structure type but more complex, as indicated by the triclinic unit cell (VS_4 is monoclinic) and by the ability to incorporate more Se. It is tempting to consider $NbSe_{4.5}$ as $Nb^{5+}(Se_2^{2-})_2Se_{0.5}^{2-}$. Whatever the detailed structure, we feel the essential features $NbSe_4$ will contain are two Se_2^{2-} units and an open structure through which Li may diffuse. We also speculate that the greater tendency of $NbSe_{4.5}$ cathodes to crack may be due to the crowding of 4 Li into the $NbSe_{4.0}$ structure, already containing the additional 0.5 Se, resulting in a greater expansion than for $NbSe_{4.0}$ cathodes.

The flatness of the discharge curve (Fig. 2) for "nominal" $NbSe_4$ suggests either a two-phase system or formation of a ternary phase in which the free energy of formation is nearly constant over the entire range. Although the first is more common, the latter explanation is possible in this case with the energy equivalence owing to the cleavage of Se-Se bonds, the energy of each being nearly independent of the integrity of other Se-Se bonds.

We conclude that the topotactic nature of the cell discharge reaction is responsible for the reversibility of the cell reaction. This type of topotactic reaction has been demonstrated now in a number of secondary lithium cells containing cathodes of certain transition metal dichalcogenides and $NbSe_3$, V_2O_5, and MoO_3 (19). Cell degradation, where not due to Li failure, is believed to be caused by mechanical breakup of the cathodes, rather than any chemical irreversibility.

The main objective of this work was to demonstrate the electrochemical reversibility of the $NbSe_{4+x}$ cathode reaction, rather than to optimize the fabrication of the electrodes themselves. This reversibility has been demonstrated now for the series $NbSe_2$, $NbSe_3$, and $NbSe_{4+x}$.

Ionic Conductivity of Monocrystals of the Gallium Analogs of β- and β''-Alumina

G. V. Chandrashekhar and L. M. Foster*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A-C and d-c conductivities of monocrystals of the gallium analogs of β- and β''-alumina were measured over the temperature range from room temperature to 350°C, using both reversible and ion-blocking electrodes. Conductivities of the gallates are substantially higher than those of the corresponding aluminates, and Na-β''-gallate has the highest conductivity [$\simeq$ **1** $(\Omega\text{-cm})^{-1}$ at 300°C] that has been reported for any alkali ion conductor. The transport number for electrons in the gallates is less than 10^{-6} at 300°C.

The layered sodium aluminates, β- and β''-alumina, have analogs in the Na_2O-Ga_2O_3 system (1, 2). Since these gallium analogs share many of the properties of the aluminum prototypes and, in particular, exhibit fast ion conduction (3) and easy exchange of the alkali ion (4), it is apparent that they have highly defective structures similar to those of β- and β''-Al_2O_3.

Chicotka (3) and Brinkhoff (5) reported preliminary measurements of the conductivity of incompletely characterized, sintered, and polycrystalline Na-gallate

* Electrochemical Society Active Member.
Key words: solid electrolyte, ionic conductor, gallium oxide.

specimens. We have now prepared monocrystals up to about 1 cm^2 in area of both the β- and β''-phases (6), and in this paper we report the electrical conductivity of these optimized samples, using both reversible and ion-blocking electrodes to separate the ionic and electronic contributions.

Experimental

Monocrystals of the β- and β''-phases were prepared in separate experiments by Na_2O vaporization from soda-rich melts held at the temperatures appropriate for the growth of each product. The crystal growth procedure is reported elsewhere (6). The sodium content of the samples was determined spectrophotometrically by comparison with suitable standards. The gallates dissolve readily in hot HCl and the analysis is straightforward. The compositions were $Na_2O \cdot 6.2Ga_2O_3$ and $Na_2O \cdot 5.7Ga_2O_3$ for the β- and β''-phases, respectively.

The crystals could be cleaved quite easily along c-planes into slabs about 1 mm thick. The conductivity in these sections is parallel to c-faces. These pieces were prepared for conductivity measurements by cutting with a low speed diamond saw into rectangular shapes about 8 × 3 mm, using kerosene as the coolant. They were cleaned with benzene and acetone prior to contacting, and stored in a desiccator. These gallates, like their aluminum analogs, are susceptible to moisture (7), and all of the operations involved in sample preparation must be carried out in a dry environment.

In order to apply ion-blocking electrodes, a specimen was sputter etched in argon at $\simeq 10^{-3}$ Torr, then a thin film of gold was applied by sputtering *in situ* to opposite ends of the bar.

Reversible electrodes consisted of pads of glass fiber filter mat, saturated with molten $NaNO_3$-$NaNO_2$ eutectic. The specimen bar was held by pressure between two such pads held in turn between gold pressure blocks to which gold lead wires were welded.

It was generally not possible to remove one type of contact from a specimen and contact it again with the other type. Therefore, the two contacting procedures were employed with different samples cut from the same crystal or from crystals prepared in duplicate runs.

The contacted specimen was contained in a small furnace and resistance measurements were made as a function of temperature from room temperature to 300°C with the blocking electrodes, and from 225° to 350°C with the reversible electrodes.

The contribution to the measured resistance from the cell itself was investigated by measuring Na-β-Al_2O_3 monocrystalline samples[1] of identical cross section but of different lengths, and extrapolating the resistance to zero length. The cell resistance was found to be only about 1% of the sample resistance for both types of electrodes, and was disregarded.

Resistance measurements were made as a function of temperature at a frequency of 5 × 10^5 Hz. Chicotka (3) had previously shown that the resistance of polycrystalline ceramic sodium gallate samples was insensitive to frequency above 10^5 Hz and, in fact, decreased by less than 5% from 2 × 10^4 to 10^5 Hz. A General Radio Corporation Type 1606-A radio frequency bridge and a Tektronix Type 190-A constant amplitude high frequency signal generator were used. A General Radio Corporation Type 1650-A impedance bridge was used for d-c measurements.

Results and Discussion

The conductivity was measured for several crystals of β- and β''-Na-gallate and β-Al_2O_3. Good agreement was obtained in duplicate measurements with each material. Results for typical cases are shown in Fig. 1. It is seen that the data produce a linear relation between the log of the conductivity-temperature product, σT, and $1/T$ over the entire temperature ranges investigated (generally 225°-350°C, but from 350°C down to room temperature with the samples of β''-gallate and β-aluminate with blocking electrodes). This is consistent with the general relation

$$\sigma = (\sigma_0/T)\exp(-E/kT)$$

and suggests that a single ion migration mechanism predominates over the entire range, though admittedly the range is short. Moreover, the slopes of the plots are sufficiently similar to suggest that the conduction mechanism is the same for all three of the materials studied, although this would be surprising in view of the differences in structure of the conducting plane in the hexagonal β- and rhombohedral β''-phases. It is apparent, at any rate, that the disparity among activation energies for the layered conductors that was reported in the early literature resulted from spurious effects and reflected sample history, contact problems, etc., rather than fundamental differences between materials.

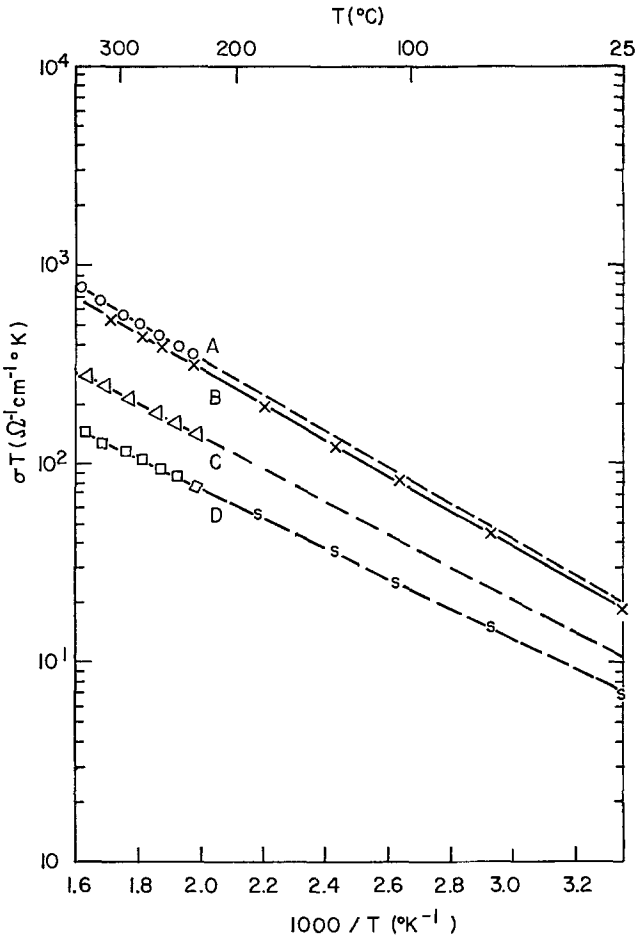

Fig. 1. Log(σT) vs. $1/T$ for aluminum and gallium fast ion conductors. o-o-o β''-Na-gallate (reversible electrodes); x-x-x β''-Na-gallate (blocking electrodes); △-△-△ β-Na-gallate (reversible electrodes); □-□-□ β-Na-aluminate (reversible electrodes); s-s-s β-Na-aluminate (blocking electrodes).

Table I gives the measured values of conductivity at 300°C and the measured and extrapolated values at room temperature for the various samples, as well as the activation energies calculated from the plots of Fig. 1. For comparison, values for monocrystalline Na-β-alumina reported by Fielder *et al.* (8) and by Whittingham and Huggins (9) are included. The sample measured by Fielder *et al.* was from a Czochralski-grown boule that was obtained from the same source as ours and so can probably be considered a duplicate. It is seen that our results agree very well with theirs. The

[f] Ford Motor Company contract report, Ref. (15). (Other activation energies reported as high as 0.208 eV, depending on sample history.)

sample measured by Whittingham and Huggins was obtained from the Carborundum Company and had possibly been cleaved from a larger cast mass. Their sodium tungsten bronze electrodes were shown to be reversible to sodium ions from 820° to −150°C, and the single activation energy applied over the entire range. The somewhat lower conductivity for that sample can undoubtedly be attributed in part to the lower sodium content ($Na_2O \cdot 9.5Al_2O_3$).

It is also seen from Table I that the two-probe d-c measurement on Na-β″-gallate, using the molten salt electrodes and small currents to minimize polarization, agrees reasonably well with the a-c measurement at 5×10^5 Hz.

It is obviously important to determine if electronic conductivity contributes to charge transport in the gallate materials. It had previously been shown to be negligible in Ag-β-Al_2O_3 (10), and since this property should not be affected by substitution of single valency ions in the ionic conducting plane, Na-β-Al_2O_3 was also considered to be purely ionically conducting. Because of the greater likelihood of multivalency occurring in gallium than in aluminum, electronic conduction cannot be ruled out *a priori* in the gallates. However, Lorenz *et al.* (11) and Harwig *et al.* (12) showed that Ga_2O_3 crystals grown under oxidizing conditions were insulating ($\rho > 10^6$ Ω-cm). Our crystals were grown in 1 atm of air, which was comparable to their growth environments. For our own investigation of electronic conductivity, a two-probe d-c measurement was made on a Na-β″-gallate sample at 300°C with ion-blocking gold electrodes. After an initial rapidly decaying current transient, the conductivity fell to $<10^{-6}$ of the a-c conductivity for the same sample.

We accept the a-c measurements with molten salt electrodes (curves A, C, and D, Fig. 1) as giving the correct sodium ion conductivity of these materials. However, since the much simpler sputtered gold contacts on sputter-etched surfaces provide sufficiently equivalent results when employed at high frequency, we recommend their use.

Conductivity data for monocrystalline Na-β″-Al_2O_3 are not available and there is some question whether that material can be prepared in the pure form (*i.e.*, without MgO or Li_2O stabilization) (13). The Na-β″-Al_2O_3 data in Table I are for high density, sintered, Li_2O-stabilized bodies reported in recent Ford Motor Company contract reports (14).

It is seen that the sodium gallates are severalfold better ionic conductors than their aluminum counterparts. Severalfold difference in conductivity between two samples of a substance where the conductivity is entirely electronic, such as a semiconductor, is not considered significant, and might be encountered between two independent measurements of the same sample because of nonohmicity of contacts, introduction of low concentrations of trapping centers by heating, etc. In ionic conductors, on the other hand, ion mobility is determined almost entirely by crystal structure and is relatively insensitive to trace impurities and sample history. Severalfold difference in conductivity in this case between two materials implies either a major difference in structure, or a severalfold difference in concentration of the conducting species.

Since in the ionic conductors of the β-alumina type the crystal defects that permit ion migration are "built-in," *i.e.*, not thermally generated, all of the activation energy is presumably involved in determining the ion mobility

$$\mu = (q\nu a^2/kT) \exp(-E/kT)$$

while the number of carriers remains fixed, and the conductivity is

$$\sigma = nq\mu = (nq^2\nu a^2/kT) \exp(-E/kT)$$

Since the activation energies are similar in the three materials of Fig. 1, the differences in specific conductance are principally in the preexponent $\sigma_0 = nq^2\nu a^2/k$.

It is first necessary to see if the differences in conductivity can be explained by differences in sodium concentration, n. Densities were calculated for the three materials from the volumes of their unit cells calculated from the x-ray lattice parameters, assuming that each surplus Na atom beyond one atom per plane is accompanied by a half-oxygen atom for charge compensation. This may be an oversimplification of the real situation, but the error introduced cannot be large. The densities are: β-$Na_2O \cdot 9Al_2O_3$, 3.256 g/cm³; β-$Na_2O \cdot 6.2Ga_2O_3$, 5.335 g/cm³; β″-$Na_2O \cdot 5.7Ga_2O_3$, 5.236 g/cm³. From these densities, and the specific conductances at 300°C from Table I, equivalent conductances were calculated as 32.2, 42.4, and 110.1 (cm²/Ω-equiv.), respectively. This wide spread between the materials shows that the conductivity differences cannot be accounted for to any significant degree by differences in total sodium content and thus, if all of the Na is active in carrying current, must reside largely in the remaining variables in the preexponent: the attempt frequency, ν, and/or the jump distance, a. Taking a as the distance from a Beevers-Ross site to a mid-oxygen position in the two β-phases (1.62Å for β-Al_2O_3; 1.68Å for β-gallate), and from a normal Na site to a mid-oxygen position in the β″-phase (1.68Å for β″-gallate), attempt frequencies of 1.47×10^{12}, 1.98×10^{12}, and 7.30×10^{12} sec^{-1} are calculated at 300°C, and 1.56×10^{12}, 2.07×10^{12}, and 7.47×10^{12} sec^{-1} at room temperature for the β-aluminate, β-gallate, and β″-gallate, respectively. This choice of jump distance assumes that the mid-oxygen position is a possible site for sodium, as was shown to be the case in β-Al_2O_3 (13). Alternatively, a can be taken as the entire distance between the Beevers-Ross and anti-Beevers-Ross sites in the β-phase materials, or between two normal Na sites in the β″-phase, in which case the calculated attempt frequencies becomes one-fourth of the values above.

No physical significance can be claimed for these attempt frequencies until corroborating experiments can be performed, and it is recognized that the calculations are sensitive to the choice of model for the diffusion process as well as to the choice of the jump distance. Their magnitude appears to be reasonable, however. Our choice of the jump distance (being only the distance from the usual sodium site to a mid-oxygen position $a/(4 \cos 30°) = 1.68$Å away) arose from the difficulty in accounting for the high conductivity of β″-Na-gallate if only the two "normal" Na sites per plane are considered. With the composition $Na_2O \cdot 5.7Ga_2O_3$, 1.93 of the two equivalent sites are filled ac-

cording to the view that all of the Na is in the conducting plane (actually two equivalent planes very slightly separated in the β''-structure). A hopping mechanism involving only the 0.07 remaining empty sites would not seem to be very efficient, especially if the charge on the surplus Na^+ is compensated by additional bridging oxygens which would greatly restrict Na^+ movement in some directions. If the mid-oxygen positions are also possible Na^+ sites, a considerably larger fraction of sites are vacant.

An alternative explanation of the high conductivity of β''-Na-gallate would be that part of the sodium is involved in forming oxygen bridges [playing the role of Mg in MgO-stabilized β''-Al_2O_3, (13) for example] and thus is not involved in conduction, but provides more empty Na^+ sites in the conduction plane to assist in the hopping process. Precise location of the sodium in β''-Na-gallate is obviously an important experiment to be performed. This work is underway and will be reported later.

It is instructive to compare the conductivity of the sodium gallate with that of the excellent Ag^+ ion conductor α-AgI. The specific conductance of β''-Na-gallate at 300°C is about one-half that of α-AgI (16). All of the Ag^+ is assumed to be conducting in α-AgI, and its equivalent conductance is $\simeq$78 (cm^2/Ω-equiv.). On a similar basis, the equivalent conductance of β''-Na-gallate is 110 (cm^2/Ω-equiv.), or still greater if only part of the Na^+ is available for conduction. As pointed out by Whittingham and Huggins (9), it is the equivalent conductance, which is proportional to the mobility of the conducting species, that is important when studying the processes that occur in fast ion conductors.

Why Alkaline Cells Leak

Michael N. Hull* and Herbert I. James[1]

ESB Incorporated, Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

The creepage of alkaline electrolytes along negatively polarized electrodes has been studied experimentally and theoretically. One driving force for this phenomenon is the production of OH^- ions arising from the electrochemical reduction of oxygen and/or the evolution of hydrogen occurring in a thin reaction zone above the observed electrolyte meniscus. Movement of water into this zone causes it to thicken and increase in conductivity with the result that the reaction zone moves along the electrode.

A problem is defined.—Alkaline cell leakage may be divided into (*i*) "nonelectrochemical leakage," and (*ii*) "electrochemically driven creepage." In the former case, leakage arises from physical factors such as an improperly sealed cell, separator fibers or scratches in the seal interface, etc. and can appear at either electrode. We shall address ourselves to the second case, *viz.*, electrochemically driven creepage which manifests itself in the movement of the electrolyte along the negative electronically conducting surface abutting the seal.

Although the cell voltage can be the sole source of the power that causes electrolyte creepage (1), it can be shown that creepage may be driven along a single electrode poised at a sufficiently negative potential. For example, if 1.5V are applied between two nickel electrodes in an alkaline electrolyte, the negatively polarized electrode will exhibit creepage. However, one may produce an equivalent effect by shorting a nickel electrode to an electrode of zinc. In this case, the voltage is zero yet creepage will be observed to occur up both electrodes and, on breaking the connection, will continue only along the zinc. Ergo, electrochemically driven creepage is an electrode potential dependent phenomenon rather than voltage dependent. The questions to be answered are therefore these: Why does an alkaline solution creep along a negatively charged metallic substrate? What factors influence the rate and what steps can be taken to stop the movement?

Electrocapillarity: a partial explanation.—The term "electrocapillary drive" arises frequently as an explanation for creepage, suggesting that the charged surface by being more easily wetted by the electrolyte will

draw up the liquid. The magnitude of this effect is comparatively small in that the meniscus height (h) at an uncharged metal surface is approximately 0.1 cm while that at a surface with a large excess positive or negative charge is ~0.3 cm (2-4). Again, the above effect is static in that a change of electrode potential will cause a simultaneous change in the interfacial tension of the system to a new equilibrium value and the system will return to a state of rest. Electrolyte creepage in contrast is dynamic since no equilibrium state appears to be reached and liquid movement continues indefinitely until the whole surface is covered.

Electrocapillarity: a longer look.—As shown in Fig. 1 and described above, the application of a negative potential will cause the meniscus height (h) to readjust to a new value. Further, the system within a matter of minutes will return to a state of rest. However, if observation of the strip is continued over a period of several hours, it becomes apparent (especially in the presence of oxygen or air) that a thin liquid film (Δ) is growing up the strip above the meniscus. The film thickens slowly with time and after several days it has grown to a length of several centimeters compared to the initial meniscus change which was of the order of 2-3 mm. Some driving force in addition to that of simple electrocapillary action is clearly operative and the problem is reduced to determining the source of power for this process.

Experimental Arrangement—The Cell and Circuitry

The experimental arrangement shown in Fig. 2 incorporated the following features. (*i*) A sealed glass cell with provision for controlling the atmosphere above the KOH electrolyte. (*ii*) A partially immersed test strip the surface of which could be viewed through a traveling microscope mounted externally to the cell. The test strip was lowered into the solution so that the bottom of the strip just touched the surface of the liquid and permitted the meniscus to form. This particular positioning of the strip insured that the total current flow to or from the strip would be the result of electrochemical reactions that occurred in the metal-liquid meniscus layers and not include a current component arising from electrochemical reactions proceeding at a part of the metal surface immersed in the bulk electrolyte. (*iii*) An electrical arrangement consisting of a potentiostat A, d-c voltage source, Hg-HgO reference electrode, and platinum counterelectrode whereby the electrode potential of the metal strip could be continuously controlled at specifically desired

values. The electrode potential and current flow to the strip were monitored by means of voltmeters V_1 and V_2, respectively, and the length of the creep above the meniscus (Δ) was concurrently recorded by means of the calibrated microscope.

In Fig. 1, the visual appearance of creepage is also illustrated. The observed sequence of events was: spots would begin to form above the meniscus; as these spots enlarged in volume, they would coalesce into a solid film of creepage and new spots would begin to form ahead of the solid front. Measurements of the position of both the solid and the spot fronts were recorded.

Experimental Results

The influence of potential and oxygen.—When a nickel strip is placed in 1M KOH in the presence of oxygen at an applied electrode potential of −0.9V *vs.* Hg-HgO (this is approximately the potential of a cadmium electrode in alkaline solution), a reduction current is observed to flow. Further, as time progresses, the reduction current is observed to increase proportionately to that of the area of the climbing creepage film as shown in Fig. 3. Removal of the oxygen, by flushing the cell with argon, will cause the current to drop precipitously and the rate of climb of the creepage to decrease markedly. It may be concluded, therefore, that at this particular potential, the electroreduction of oxygen is the reaction which gives rise to the current flow. In view of the electrode placement, it is evident the whole of this current flow is concentrated in the meniscus and creepage layer on the nickel surface. Furthermore, one may deduce that the rate of oxygen reduction is limited only by the available surface area for reaction.

In contrast to the above, electrodes such as silver which are extremely active catalysts for the reduction of oxygen, show a rapid current climb to a very high value and thereafter the current is limited to this value, even though the creepage height is continually increasing (Fig. 3). The source of this current limitation appears to be resistance polarization losses in the creepage film, that is, IR drop. This may be confirmed by variation of the applied electrode potential between the point at which O_2 reduction commences (0.0V) and that for the onset of visible hydrogen evolution (~ −1.3V). As shown in Fig. 4, a linear variation of the current with potential results. Thus in the case of electrodes such as nickel, which exhibit moderate overpotential for the electroreduction of oxygen, the rate of production of hydroxyl ions by the reaction

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \qquad [1]$$

is controlled by the area of the electrode covered by a film of electrolyte. Conversely, low overpotential electrodes, such as silver, exhibit such high current

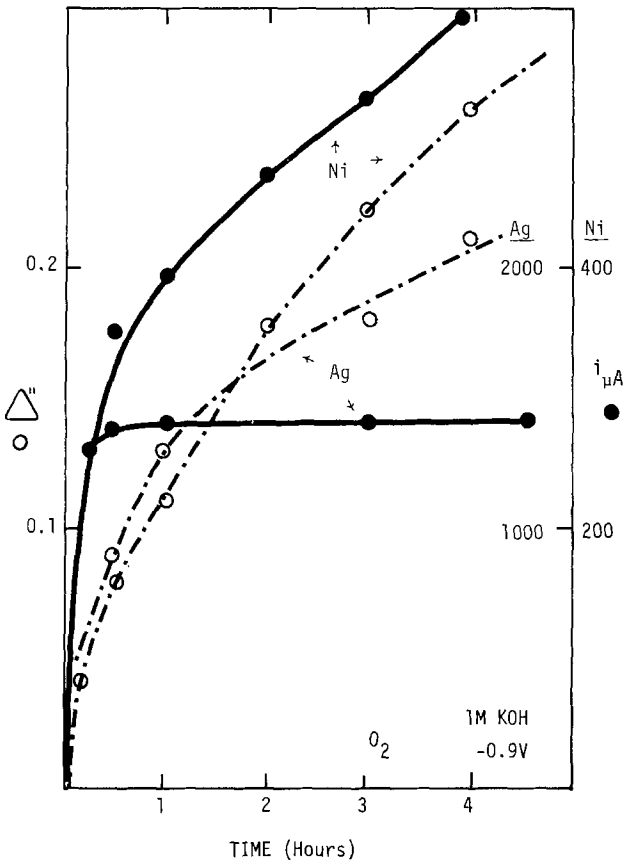

Fig. 3. Reduction current (i) and creepage height (Δ) as a function of time. 0.25 in. wide nickel and silver strips just touching electrolyte surface. 1M KOH, O_2, $E_{App} = -0.9V$ (Hg-HgO).

densities that the electrolyte conductivity in the meniscus and creepage layers becomes the rate-controlling parameter in a short time after reduction is commenced.

The dependence of the rate of creepage on the electrode potential and the gaseous atmosphere surrounding the test strip is detailed in Fig. 5. Oxygen or nitrogen was presaturated with moisture to the relative humidity level present above the test electrolyte and the height of the creepage was measured after 24 hr at a fixed electrode potential. We may divide the figure into two separate potential ranges by a vertical line that indicates the point above which hydroxyl ions can be produced (in addition to those from O_2 reduction) by the evolution of H_2 in the meniscus and creepage layers according to

$$2H_2O + 2e^- \rightarrow 2\,OH^- + H_2 \qquad [2]$$

The figure shows that, for electrode potentials in the range -0.2 to -0.9V, the amount of creepage in the presence of oxygen increases with increasing negative electrode potential. Removal of the oxygen leads to a situation in which practically no creepage will be observed within a 24 hr period. In the potential range more negative than -0.9V, even in the absence of oxygen, a sharply increasing amount of creepage is observed with increase in the potential. This sharp increase corresponds to the onset of hydrogen evolution through reaction [2]. Thus the amount of creepage observed at the cadmium electrode potential (~ -0.9V) is extremely sensitive to the availability of oxygen while that at the zinc electrode potential (~ -1.35V) is somewhat less. In this latter case, particularly if oxygen access to the strip is hindered, creepage will still occur in an amount proportional to the rate at which reaction [2] is occurring in the creepage film.

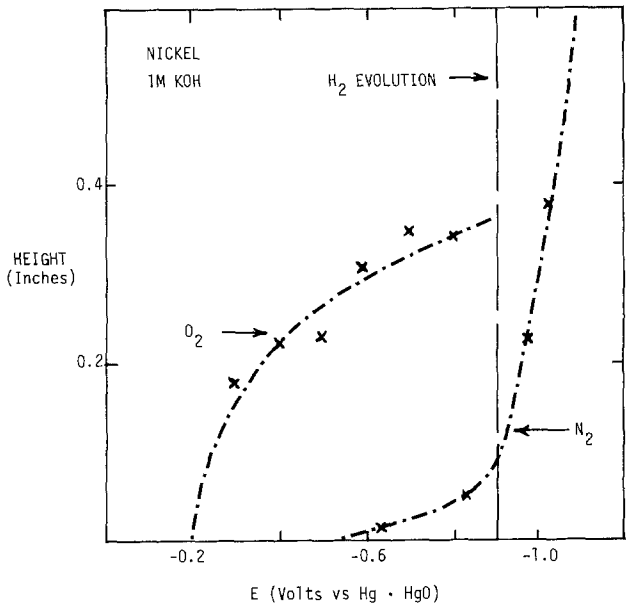

Fig. 5. Height of the solid creepage front for nickel in 1M KOH after 24 hr in O_2 or N_2 as a function of electrode potential.

The influence of electrolyte concentration.—Under all experimental conditions, the creepage rate (and current flow to the strip) declines as the electrolyte concentration is increased. This point is illustrated in Fig. 6 for silver in 5 and 10M KOH. The creepage rate is linearly related to the relative viscosity of the particular KOH electrolyte used as shown in Fig. 7. (The points plotted for 1M NaOH and 1M LiOH will be discussed presently.) As the KOH concentration rises, the viscosity increase becomes much more rapid and, consequently, the rate of creepage is increasingly slowed. Each incremental increase in electrolyte concentration becomes progressively more significant in decreasing the rate of increase of Δ.

The cations: Li^+, Na^+, K^+, and their ionic mobilities.—In the previous section, consideration of sodium and lithium hydroxides was deferred because differences between the relative viscosities of the equimolar concentrations of KOH, NaOH, and LiOH shown in Fig. 7 were evidently too small to explain the large decrease in the creepage rate as the cation was changed from

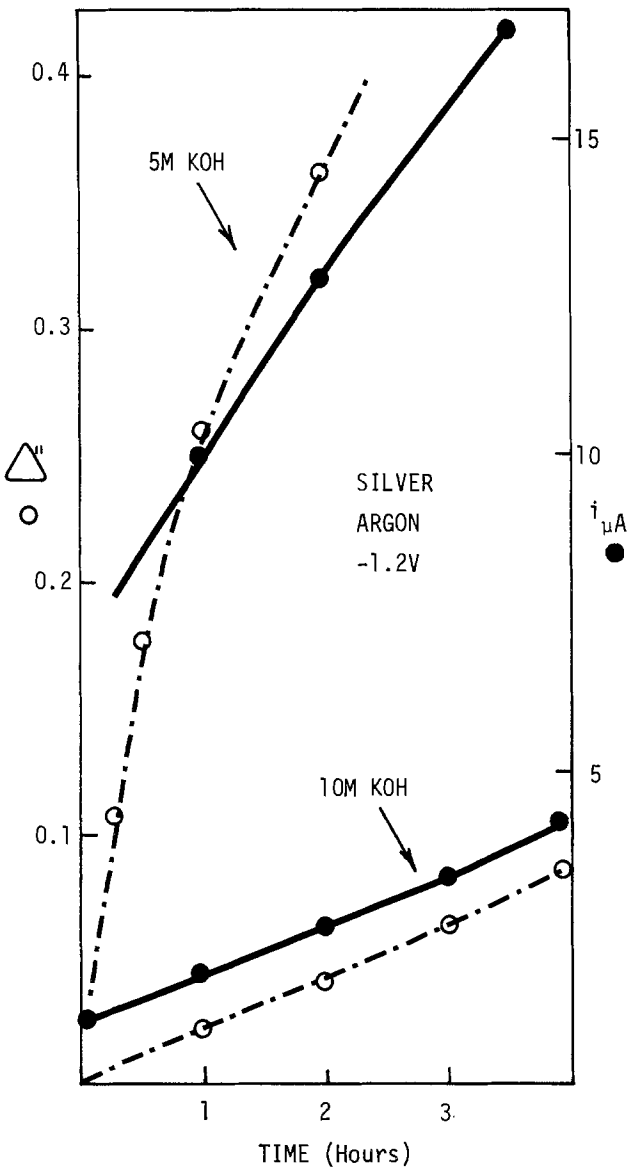

Fig. 6. Reduction current and creepage height as a function of time on a 0.25 in. wide silver plate in 5 and 10M KOH · argon; $E_{App} = -1.2V$.

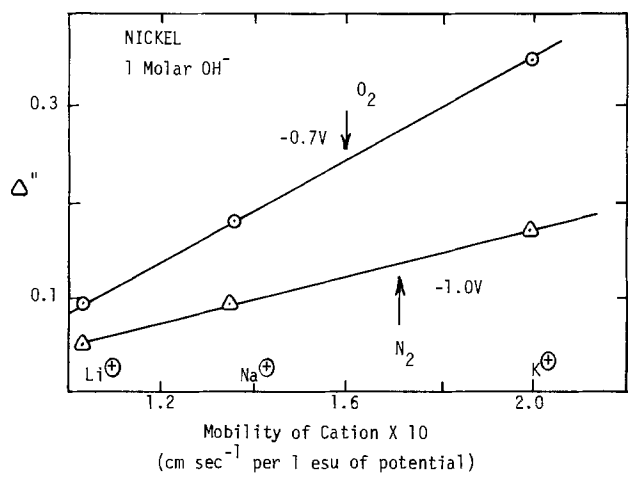

Fig. 8. Variation of Δ in O_2 at $-0.7V$ and N_2 at $-1.0V$ for a nickel strip as a function of the cation ionic mobility.

K^+ to Na^+ to Li^+. The reason for this difference lies partly in the effect of the cation mobility on the creepage rate. The experimental results are that the cation mobility shows a linear relationship to Δ under a variety of conditions (Fig. 8). The decrease in mobility $K^+ > Na^+ > Li^+$ is due to the greater degree of hydration which becomes associated with an ion as the ionic radius is decreased.

The two factors of increase in viscosity of the electrolyte and decrease in the cation mobility lead to a reduction in the rate of alkaline electrolyte creepage. As we have seen from Fig. 7, at a concentration of 1M, the difference in creepage rate between the three electrolytes was solely a question of mobility. At higher concentrations, however, equimolar concentrations of KOH and NaOH and LiOH differ also quite markedly in their relative viscosities. Thus, for example, at a concentration of 8M, a sodium hydroxide solution has nearly three times the relative viscosity of potassium hydroxide. At these high concentrations, both the relative viscosity and relative cation mobility effects play a serendipitous role in lowering the creepage rate of a NaOH or LiOH electrolyte when compared to an equivalent electrolyte of KOH.

The effect of substrate: chemical and physical differences.—A number of metals and alloys were used as substrates in the "as-received" condition and a wide variation in their relative creepage rates was observed as shown in Fig. 9. There are a number of chemical and physical reasons why such differences should appear. On the "chemical" side, one would anticipate that differences in the oxygen reduction overpotential and/or differences in the hydrogen evolution overpotential would lead to different rates in the production of OH^- and, consequently, in the rate of creep. On the "physical" side, the presence of surface scratches or different types of surface oxide layers that wick up electrolyte by capillary action are of utmost importance. This is well demonstrated by the plots presented in the figure for the two strips of Inconel 600 which were tested; one of which had been abrasively cleaned with a detergent while the other had been washed gently in organic solvents. A difference in the rate of creepage was produced between the two samples that was as wide as the whole range of differences of the individual metal and alloy samples tested in the as-received condition, that is, with just a gentle organic solvent wash to remove surface grease.

To clarify the role played by overpotential differences between the different metals and alloys, it would be necessary to polish each of the samples to a common degree of surface roughness and repeat the creepage rate determinations. For materials we tested in the

form received, the order from best to worst alkaline electrolyte creepage is:

1. Inconel 600
2. Nickel 200
3. Inconel 601
4. Nickel alloy 440
5. Monel
6. SS 201
7. SS 301

Theoretical Discussion and Experimental Analysis

Two electrochemical reactions that can proceed at a negative electrode in alkaline solution and produce hydroxyl ions are

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \qquad [1]$$

if $E > 0.0$V *vs.* Hg-HgO and

$$2H_2O + 2e^- \rightarrow 2\,OH^- + H_2 \qquad [2]$$

if $E > -0.9$V. No corresponding electrochemical reactions can be written for a positive electrode, under otherwise identical electrolyte conditions, supporting the hypothesis that these reactions are responsible for negative electrolyte creep. A further interesting observation is that the reduction current has a tendency to increase with increase in the electrode area covered by the creepage film. This is one of the basic principles utilized in the operation of porous electrodes in fuel cells (in these, the porous electrode maximizes the available wetted electrode surface exposed to the gaseous reactant) and is a phenomenon that has been studied by a large number of people (5-12). Their conclusions may be summarized by examining how a reaction, such as the electroreduction of oxygen, will proceed at an electrode immersed in bulk electrolyte compared to one covered by a thin layer of electrolyte, only microns thick. Figure 10 depicts a metal strip which was completely immersed in KOH through which a stream of pure O_2 is being bubbled. An insulated wire is connected to the strip by means of which

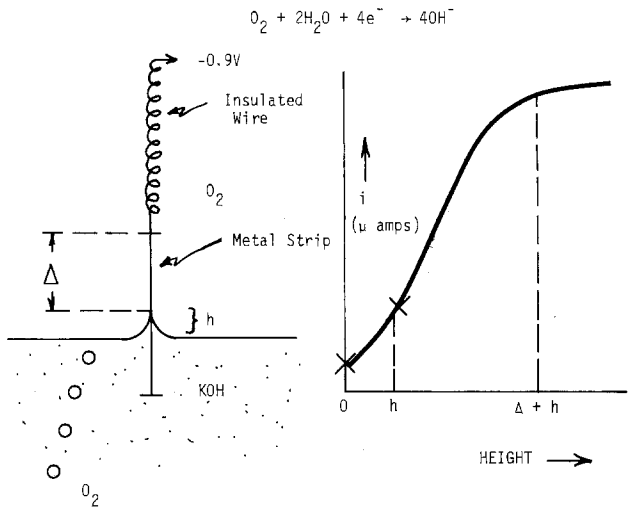

Fig. 10. Diagrammatic representation of the current flow to a metal strip in O_2 saturated KOH at $E_{App} = -0.9$V under various degrees of immersion.

an electrode potential of −0.9V (Hg-HgO) is imposed on the strip. How will the reduction current vary as the metal strip is withdrawn from the electrolyte, that is, as one transposes from a strip covered by bulk electrolyte to one covered only by a thin electrolyte film?

In the totally immersed condition, a steady-state current will be observed whose magnitude is controlled by the rate of diffusion of dissolved oxygen to the electrode surface through the bulk solution. This current is represented by the "X" on the current-height plot corresponding to a height of the strip above the electrolyte surface of zero. When the electrode has been withdrawn to a point which is just sufficient to form the maximum meniscus, (h), a pronounced increase in the reduction current is observed. Diffusion of O_2 present above the electrolyte to the electrode surface in the meniscus region has become quite fast because of the thinning of the liquid layers in the region. Thus, although the electrode surface exposed in the meniscus region is very small compared to that remaining completely immersed in the bulk electrolyte, the current density in the meniscus region undergoes a marked increase. Thus most of the current flowing to the strip arises from the electrochemical reaction proceeding in the meniscus region.

Further withdrawal of the metal strip from the solution leads to a quite unexpected phenomenon. Instead of the current attaining a maximum value at the point (h) where the maximum meniscus height is developed, a limiting value is not reached until the strip is withdrawn to a height of ($\Delta + h$) from the electrolyte. At this point, the greatest fraction of the total current now flowing is concentrated in a zone of width Δ above the visible meniscus. There exists, therefore, an extremely thin electrolyte layer on the electrode above the meniscus across which extremely rapid passage of oxygen occurs.

The idea developed above may now be applied to understanding the magnitude and the spatial relationship of the electrochemical reactions [1] and/or [2] occurring at a partially immersed metal plate. In Fig. 11, a situation is shown in which a metal strip has been partially immersed in a KOH electrolyte and to which a potential of −0.9V is being applied. If the relative humidity above the solution is high, a film of moisture will be present on the electrode surface above the meniscus. Both O_2 reduction and H_2 evolution will tend to yield the highest current density where the diffusive transport of O_2 to the surface or of H_2 away from the surface is kinetically easiest, that is, in the moisture film just above the visible electrolyte meniscus. Accordingly, the current magnitude at each segment of the electrode surface can be spatially depicted by the dotted trace on the left-hand side of

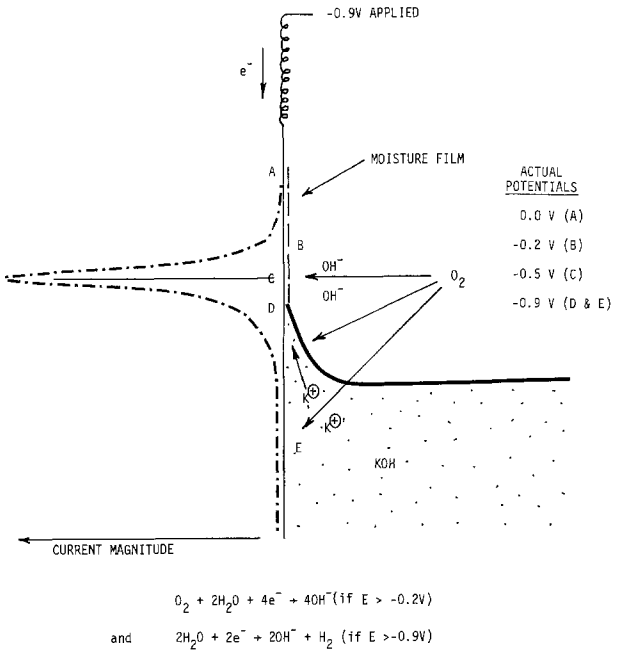

Fig. 11. Spatial distribution of the current density and electrode potential at a partially immersed metal plate in KOH solution and O_2 at −0.9V.

Fig. 11. Hydroxyl ions are being rapidly produced above the meniscus and in order that electroneutrality conditions be preserved, these hydroxyl ions must migrate toward the bulk electrolyte, potassium ions must migrate toward the meniscus top, or some balancing combination of these two migration requirements must concurrently occur. (Under bulk electrolyte conditions, both the hydroxyl and potassium ions are mobile and the potassium hydroxide concentration tends to rise at the site of the reduction reaction.)

The rapid rise in the current magnitude, as one passes from the bulk electrolyte to the meniscus and into the thin electrolyte layer, does not continue indefinitely. Rather, as shown in Fig. 11, a peak value is attained beyond which the current decays back to zero since the tendency for the current to increase, due to the thinness of the electrolyte layer, is opposed by the high electrolyte resistance of this layer to ionic migration. The further up the strip above the meniscus that one measures, the greater becomes the electrolyte resistance and hence the greater the *IR* polarization loss. Due to this *IR* loss, the actual potential driving the electroreduction of oxygen (or evolution of H_2) in the thin film region falls off spatially as shown on the right-hand side of the figure. At the top of the meniscus, the whole of the −0.9V is present to drive the electrode reaction, but the presence of a current flow in the thin layer above the meniscus causes an increasingly greater degree of *IR* drop to be produced in the higher electrode regions until a point is reached (0.0 to −0.2V) above which there is no driving force for O_2 reduction remaining. At this point, the current density has fallen to zero.

There thus exists a "reaction zone" on a partially immersed metal plate which exists from a point within the meniscus region to a point several millimeters above the visible top of the meniscus. In Fig. 11, this reaction zone encompasses that portion of the electrode surface beneath the current peak.

The primary point which has been established is that at the negative electrode of alkaline cells, two electrochemical reactions are possible which lead to the production of hydroxyl ions. Further, it has been established that these reactions take place preferentially in a reaction zone which lies above the visible electrolyte meniscus. In this zone, the hydroxyl ion concentration rises to a value greater than the bulk electrolyte. For this to occur, a counterbalancing movement of positive ions must migrate into the zone and since the ionic mobility of K^+ exceeds that of Na^+, which, in turn, exceeds that of Li^+, this concentration increase occurs at a rate proportional to these mobilities.

This lack of equilibrium between the concentration of KOH in the reaction zone and in the bulk electrolyte must be opposed either by the diffusion of KOH from the high to the low region of concentration or by a movement of water into the reaction zone which will tend to dilute the concentration of alkali there and return it to a state of equilibrium with the bulk electrolyte. The experimental observation is that the reaction zone thickens and moves up the semi-immersed plate. Accordingly, it must now be determined by what mechanism the water is made to move toward the reaction zone.

Of the species involved in reactions [1] and [2], all except the water has a specifically defined source and path to the reaction zone. Taking reaction [1] as an example, it is clear that O_2 arrives from the gaseous phase, the OH^- ions are generated *in situ* and the K^+ ions arrive from the bulk electrolyte by the process of electromigration. The source and path by which water arrives in the reaction zone is, at first glance, not self-evident as both the liquid and the gaseous phases (especially if the relative humidity is high) are potentially capable of providing the required amount. Nor is it certain that each phase does not supply a fraction of the total amount of water. Accordingly, we shall consider two main scenarios which cover the most probable mechanisms for the transport of the water.

The first of these involves electro-osmotic movement of the electrolyte along the negatively charged metal surface. Above the meniscus, the electrode surface is covered with a monolayer of water, especially if the relative humidity conditions are high, *i.e.*, the reaction zone initially consists of a very thin layer of extremely dilute electrolyte. There will thus exist a significant diffuse double layer of positive charge in this region generated by the net negative charge on the metal surface. Should one now apply a potential gradient along such a solution, electro-osmotic movement of the liquid will occur as illustrated in Fig. 12. In this, a negatively charged capillary contains a dilute electrolyte with a positively charged diffuse layer. If now a current is caused to flow through the solution from a zinc electrode undergoing oxidation at one end to a nickel electrode on which oxygen reduction (or hydrogen evolution) is proceeding at the other, there will be a pressure drop produced along the capillary of a magnitude proportional to the driving voltage (and thus the current passing) and the liquid will move toward the cathode. Clearly, the greater the mobility of the positive ion, the faster it will travel from one electrode toward the other and hence the greater will be the resultant pressure "push" and the faster the movement of the bulk liquid. Again, as the viscosity is increased, the resultant pressure push will cause a decreasing volume of electrolyte to flow along the

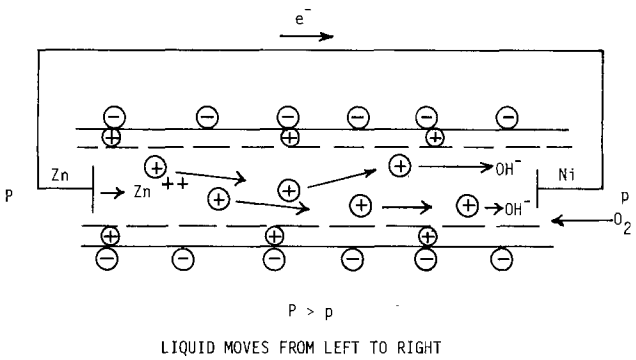

Fig. 12. Electroreduction of O_2 and oxidation of zinc in a dilute electrolyte adjacent to a negatively charged surface.

tube in the stipulated unit of time. (In this example, only the excess charge in the dilute electrolyte is depicted for simplicity.)

Figure 13 summarizes how electro-osmotic movement of the electrolyte thus forces the solution between the negative terminal and the seal. Analogously to the situation described in Fig. 12, the cathodic reduction of oxygen (or evolution of hydrogen) occurring in the reaction zone is driven by dissolution of the negative anode material. The net negative charge present on the terminal substrate in the seal area leads to the establishment of a net positive charge in the reaction zone. Production of hydroxyl ions in the reaction zone leads to electromigration of positive ions into the zone, some of which are part of the net diffuse layer charge. A differential ΔP thus exists between the meniscus and the reaction zone forcing movement of liquid toward the reaction zone and, hence, eventually out of the cell.

A second source of water for the reaction zone is the water vapor present above the surface of the bulk electrolyte. As electroreduction proceeds in the reaction zone and the concentration of the zone increases, the equilibrium relative humidity of the vapor phase above the zone declines to a value lower than that in equilibrium with the bulk electrolyte. As shown in Fig. 14, the relative humidity above a 30% KOH bulk electrolyte is approximately 58%. (The atmosphere introduced into the vicinity of the electrolyte could, of course, have a higher relative humidity than this, but for discussion purposes we will assume equilibrium between the bulk electrolyte and the vapor phase.) If a steady-state concentration of, say, 40% KOH is maintained in the reaction zone by the electroreduction reactions, there will be an equilibrium relative humidity above this zone of only 35%. Thus a transfer of water from the vapor phase to the liquid phase in the reaction zone by the process of condensation will occur. The volume of liquid will thus tend to be expanded both in volume and in surface area coverage of the partially immersed electrode and this process will continue until the electrochemical reactions cease and the reaction zone electrolyte is equilibrated to that of the bulk solution.

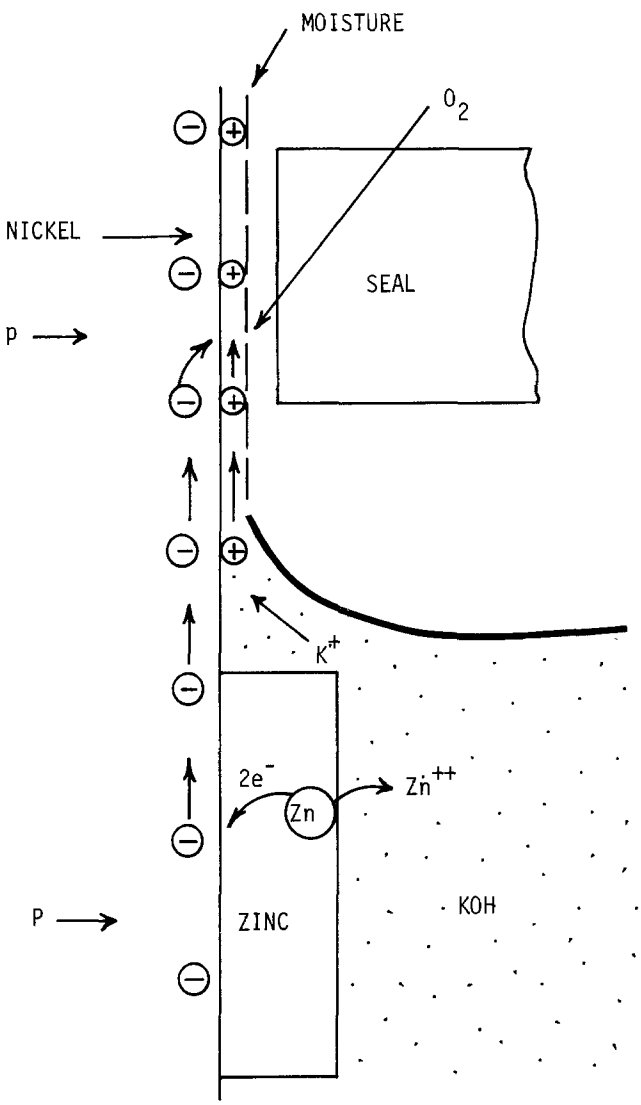

Fig. 13. Spatial separation of the electrochemical reactions proceeding at an idealized metal-seal interface in the presence of zinc, O_2, and KOH.

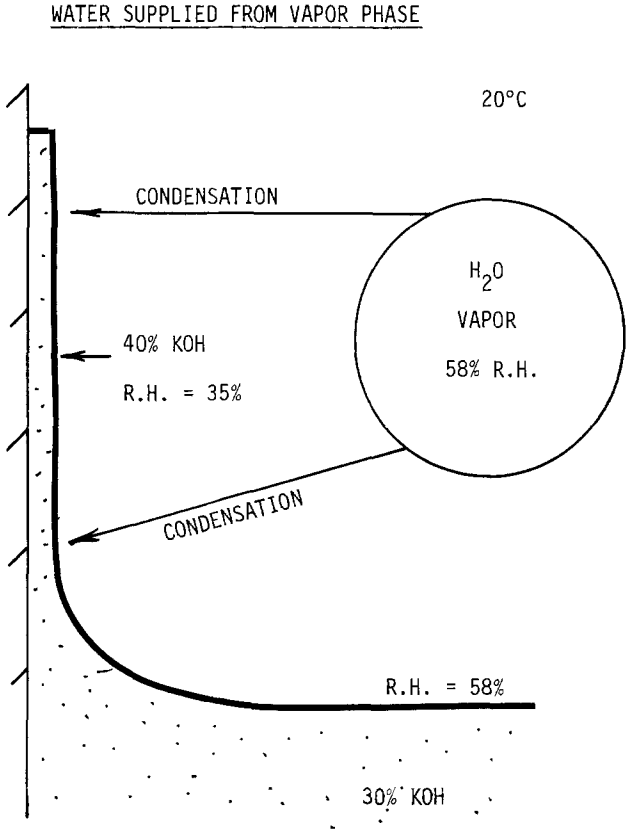

Fig. 14. Equilibrium relative humidities (and direction of water transport) above a bulk electrolyte and in the presence of a partially immersed metal plate exhibiting creepage.

This process of ingress of water to the reaction zone from the vapor phase occurs at a rate that is proportional to the existing relative humidity of the gaseous phase (more correctly, to the RH difference between the reaction zone and the bulk electrolyte but one may assume that the steady-state concentration in the reaction zone reaches a constant value and hence to the equilibrium RH above the zone). Thus, since the bulk electrolyte equilibrium relative humidity decreases as the concentration is increased, the driving force for transfer of water from the bulk electrolyte to the vapor phase and then to the reaction zone where it is observed visually as "creepage" also decreases with concentration.

Two ways by which water can be brought to the reaction zone have now been considered in some detail. The probability is that both mechanisms operate to some degree but that one or the other predominates under the particular ambient conditions present at any particular time. The result is, however, that the reaction zone increases in volume and one must now proceed to a consideration of the effects this volume change will produce on the resistivity of the liquid layer and hence on the spatial distribution of the *IR* polarization losses in the reaction zone.

The result of the increase in the electrolyte concentration of the reaction zone is that the resistance to ionic current flow decreases in the zone and hence the

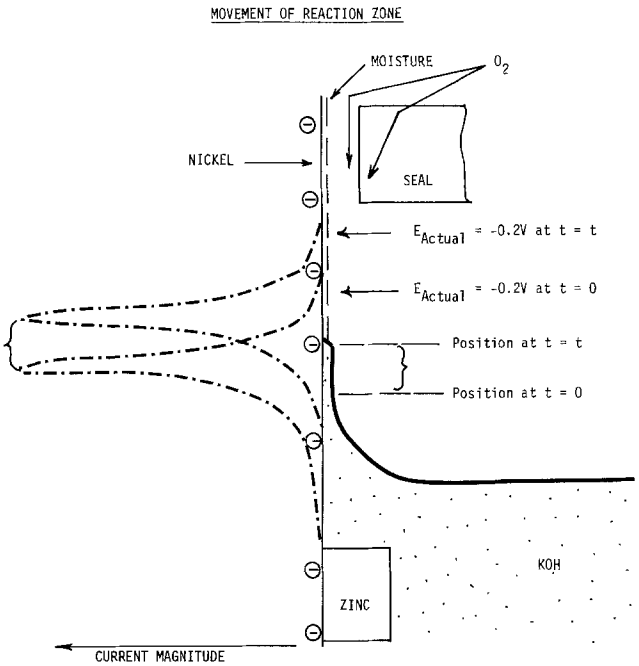

Fig. 15. The spatial distribution of the reaction zone and the concurrent minimum electrode potential for O_2 evolution as a function of time at a partially immersed metal plate exhibiting creepage.

IR polarization begins to fall. Consequently, current flow can commence at a slightly higher part of the partially immersed strip where previously, because of the *IR* polarization, there was an insufficient potential to drive the electroreduction reactions. The reaction zone thus maintains a fairly constant width, but its position moves ahead of the thickening creepage layer at a rate determined by the rate at which the electrolyte layers below it are decreasing in ionic resistance. For example, as shown in Fig. 15 between times $t = 0$ and $t = t$, the position of the creepage front, through electroreduction of O_2 and transport of water into the initial reaction zone, has moved appreciably. The sharp drop in the *IR* polarization loss of the creepage layer between these two positions has permitted the leading edge of the reaction zone to progress up the strip by an equivalent amount. Thus the reaction zone moves inexorably toward the seal and to a limitless supply of O_2 and moisture and cell failure due to electrochemically driven creepage.

Conclusions

Negatively charged electrodes in alkaline electrolytes will tend to reduce oxygen according to

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \qquad [1]$$

and if the potential is sufficiently negative to liberate H_2 according to

$$2H_2O + 2e^- \rightarrow 2\,OH^- + H_2 \qquad [2]$$

Both [1] and [2] produce alkalinity at the site of reaction and this "site of reaction" localizes preferentially in a reaction zone above the meniscus since oxygen diffusive transport to the electrode surface and hydrogen transport away occur at their fastest rates on regions of the surface where the electrolyte is thinnest. Concentration of the electrolyte in the reaction zone increases the conductivity of this region and the driving negative potential can then extend to points further along the electrode surface. The preferential reaction zone thus is caused to move along the electrode and electrolyte creepage is the result.

The prevention of electrolyte creepage caused by reaction [1] is easily accomplished if adequate sealing with respect to oxygen access to the reaction zone region is provided. Reaction [2] is more difficult to prevent since most alkaline cells operate at negative electrode potentials that lie outside the stability region of water. Since water itself is the reactant in this case, it is consumed and must be provided to the reaction zone if creepage is to continue. There are several distinct sources for this water supply; an important one is water vapor from the atmosphere. Under conditions of high relative humidity and inadequate sealing of the cell with respect to water vapor transmission through the seal material itself or along the interface between the electrode surface and the seal, an accelerated rate of creepage will result.

Electrolyte creepage by reactions [1] and [2] is the result of cathodic reactions proceeding above the meniscus at a partially immersed electrode driven by a corresponding anodic reaction (*e.g.*, oxidation of zinc to form zinc hydroxide or zincate in the case of alkaline cells with zinc anodes) proceeding on the submerged part of the same electrode. Such cathodic reactions can, however, be driven by an anodic reaction occurring on a spatially separated second electrode provided an electrolyte bridge exists between the two electrodes. Thus, in the presence of high humidity, an electrolyte bridge can form between the anode and cathode terminals of a cell and the cell voltage will then produce hydrogen evolution and O_2 reduction at the negative terminal (with increase in alkalinity) and O_2 evolution or anodic corrosion of the positive terminal. This voltage-dependent mechanism of negative seal failure will be discussed in a subsequent publication.

Adsorption of n-Decylamine on Zinc from Acidic Chloride Solution

H. B. Rudresh and S. M. Mayanna

Department of Chemistry, Central College, Bangalore University, Bangalore 560 001, India

ABSTRACT

The adsorption of n-decylamine on zinc from acidic chloride solution has been studied using the corrosion technique. The corrosion rates of zinc in acidic chloride solution containing n-decylamine are measured as a function of n-decylamine concentration. The degree of surface coverage as calculated from the corrosion rates is used to calculate the free energy of adsorption of n-decylamine. The variation of negative free energy of adsorption with surface coverage is interpreted in terms of change in the mechanism of inhibitor action of n-decylamine with concentration. The synergistic effect of n-decylamine and chloride ions is discussed from the viewpoint of adsorption models.

Despite the extensive use of inhibitors in the corrosion process, little is known of their function because of the complexity of the process. Understanding of the inhibitive action during corrosion requires a knowledge of the adsorption of inhibitor at the electrode-solution interface (1). Adsorption isotherms of the inhibitors for the corrosion process have been discussed (2-4). Adsorption of n-decylamine on several metals from solution has been studied (5). Zinc is an industrially important metal and is corroded by several corrosive agents of which the aqueous acids are the more dangerous. Results on the corrosion of zinc, reported in earlier work, make use of rough and etched surfaces. This investigation examines the adsorption of n-decylamine (n-DA) on an electropolished zinc surface from acidic chloride solution.

Experimental

Solutions were prepared from freshly distilled, preelectrolyzed hydrochloric acid (AR) and recrystallized potassium chloride (AR) using triply distilled water. Zinc (99.999%) was fixed in Tygon tubing and it was mechanically polished on 4/0 emery paper using ethanol as lubricant. The crystal surface was electropolished in a stirred solution of ethanol containing 35% of orthophosphoric acid at a cell potential of 3.5V for 8 min using a stainless steel cathode (6). The chemical and anodic dissolutions were carried out up to 1 hr at 30° ± 0.1°C in a three-necked Pyrex glass cell containing the stirred acidic chloride solution (0.99M KCl + 0.01M HCl) with the desired amount of n-DA (Fluka AG). n-DA in solution up to 10^{-3}M did not alter the pH of the acidic chloride solution. Zinc in solution after chemical dissolution was estimated polarographically and the dissolution rate (milligrams per square centimeter per hour) was evaluated. A 90V battery in series with a variable resistance was used as a constant current source. A saturated calomel electrode and a platinized platinum electrode were used as the reference and auxiliary electrodes, respectively. The corrosion potential and overpotentials were recorded using d-c VTVM with an accuracy of ± 5 mV.

Results

Zinc was dissolved in a stirred acidic chloride solution containing various concentrations (10^{-8}-10^{-3}M) of n-DA at 30°C and the dissolution rates were evaluated. n-DA was found to have a significant effect on the dissolution rate. The dissolution rate decreased gradually with the increase in concentration of n-DA and decreased markedly when the concentration was above 10^{-4}M. At each concentration of n-DA, inhibitor efficiency was calculated using the equation

$$\%p = \left(\frac{\gamma_o - \gamma_i}{\gamma_o}\right) \times 100$$

where p is protection and γ_o is the uninhibited and γ_i the inhibited corrosion rate. The maximum inhibitor efficiency (90%) was observed at 10^{-3}M n-DA. The variation of dissolution rate and inhibitor efficiency, with concentration of inhibitor, is shown in Fig. 1.

The corrosion potential both in the acidic chloride solution and in the presence of n-DA slightly decreased with time to a steady value. However, the steady corrosion potential values were always higher in the presence of n-DA. The anodic overpotential on zinc in the acidic chloride solution was found to be dependent on the n-DA concentration. The anodic overpotential of zinc in the acidic chloride solution at various concentrations of n-DA is shown in Fig. 2. An increase in the concentration of n-DA shifted the polarization curves toward more positive potentials. An anodic Tafel slope of 29 ± 5 mV sec was obtained with and without n-DA.

The surface coverage (θ) of n-DA at different concentrations of n-DA was calculated using the equation (2)

$$(1 - \theta) = \left(\frac{\gamma_i}{\gamma_o}\right)$$

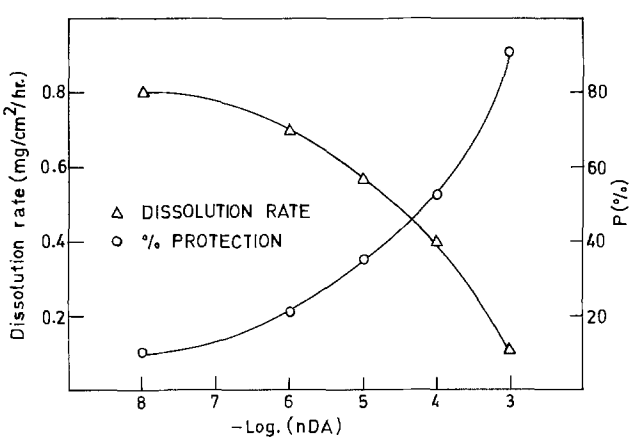

Fig. 1. Variation of dissolution rate and %p with n-DA concentration.

Key words: surface coverage, inhibitor, free energy of adsorption, synergistic effect.

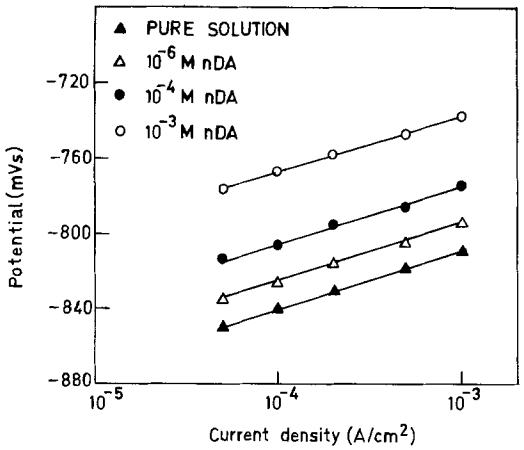

Fig. 2. Effect of n-decylamine on the anodic polarization of zinc in acidic chloride solution.

One could calculate the apparent free energy of adsorption of the inhibitor from θ-values using the equation (5)

$$\Delta G^{o}_{a} = -2.303\,RT \log \left[\frac{55.4\theta}{C_o\,(1-\theta)^n} \cdot \frac{\{\theta + (1-\theta)n\}^{n-1}}{n^n} \right]$$

where C_o is the concentration of inhibitor in the bulk of the solution and n is the size factor. Using the above equation, with $n = 9$ for flat adsorption of n-DA on the surface and $n = 3$ in the perpendicular direction to the surface, the apparent free energies of adsorption (ΔG^{o}_{a}) were calculated. Figure 3 gives the variation of ΔG^{o}_{a} of n-DA with θ. The negative ΔG^{o}_{a} decreased with increase of θ but increased markedly when θ was above 0.6. There is a slight change in the ΔG^{o}_{a} value with change in the n value from 9 to 3. However, the same trend in the variation of ΔG^{o}_{a} with θ is noticed for different n values.

It is shown in Fig. 1 that the effective concentration range of n-DA lies above 10^{-4}M. Hence, the dissolution of zinc in acidic chloride solution with various concentrations of n-DA ($>10^{-4}$M) at different temperatures was also carried out. At each temperature, for a given concentration of n-DA, ΔG^{o}_{a} was calculated. The entropy of adsorption ΔS^{o}_{a} was evaluated from the relation between ΔG^{o}_{a} and T (Fig. 4). From the values of ΔG^{o}_{a} and ΔS^{o}_{a}, the heat of adsorption

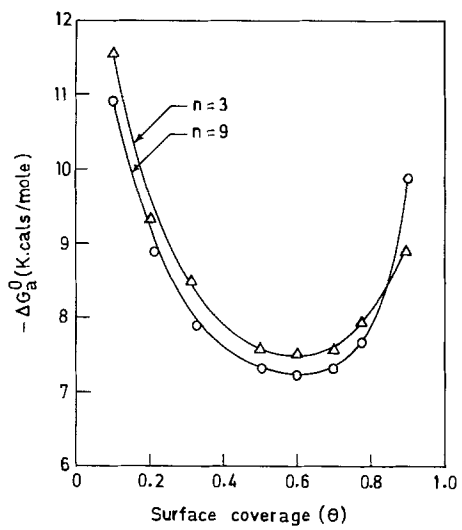

Fig. 3. ΔG_a^{o} for n-decylamine on zinc as a function of surface coverage (θ).

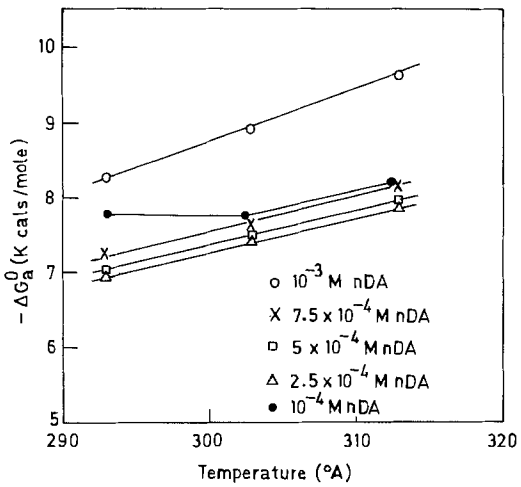

Fig. 4. Relation between ΔG_a^{o} and T at different concentrations of n-DA.

ΔH^{o}_{a} was calculated. Table I gives the values of ΔH^{o}_{a} and ΔS^{o}_{a} at different concentrations of n-DA. The values of ΔH^{o}_{a} and ΔS^{o}_{a} are positive, which increased on increasing the concentration of n-DA.

Discussion

The mechanism of the anodic dissolution reaction of zinc in acidic chloride solution is as follows (7)

$$Zn \longrightarrow Zn^{+} + e$$

$$Zn^{+} \xrightarrow[\text{rds}]{} Zn^{++} + e$$

The results observed (Fig. 2) with and without n-DA indicate the inhibition of the dissolution process without affecting the mechanism. The dissolution reaction initiates on the surface of the metal at the reaction sites (surface defects). Due to adsorption, n-DA perhaps prevents the removal of zinc ions from the reaction sites on the surface. This is usually observed by the increase in the dissolution potential (8), which depends on the concentration of the inhibitor or θ. This is in accordance with the observed results (Fig. 5) that the dissolution potential increases linearly with θ.

Chloride ions are known to adsorb on the metal surface (9). Amines are able to adsorb on the metal surface even at a high concentration of chloride ions (10). Chloride ion has slight effect on the corrosion of zinc in acidic solution (7). The synergistic effect of chloride ions and n-DA in acid corrosion inhibition of steel has been reported (11). The synergistic effect is a complex phenomena and no single mechanism accounts for all observations.

The variation of ΔG^{o}_{a} with θ (Fig. 3) indicates the change in the mechanism of inhibitor action with n-DA concentration. From Fig. 1, it is clear that n-DA is not a film-forming inhibitor on the zinc surface. On the basis of the earlier works (10-12), and observed results, the following models for n-DA adsorption are proposed

Table I. Heat of adsorption (ΔH^{o}_{a}) and entropy of adsorption (ΔS^{o}_{a}) of n-DA at different concentrations

Concentration of n-DA (M)	Heat of adsorption (ΔH^{o}_{a}) (kcal/mole)	Entropy of adsorption (ΔS^{o}_{a}) (cal/deg/mole)
2.5×10^{-4}	9.8	45
5×10^{-4}	10.6	52
7.5×10^{-4}	11.3	65
1×10^{-3}	12.8	75

Cl^- R^+	Cl^- R^+	R^+ Cl^-
Model I	Model II	Model III

Adsorption from solution is influenced by several interactions between the metal and the components both on the surface and in the bulk of the solution. At very low concentration (10^{-8}M), n-DA cations (R^+) from solution gather around the chloride ions, previously adsorbed on the zinc surface, and as a result tend to be weakly bound to the chloride ions (model I). In the case of rather weak adsorption of chloride ions, R^+ at high concentration tends to withdraw the chloride ions on the surface into the solution (12). Hence, on increasing the concentration of n-DA from 10^{-8} to 10^{-4}M, coadsorption of cations and chloride ions is possible (model II). The extent of desorption of chloride ions from the surface depends on the extent of adsorption of R^+, which is a function of the concentration of n-DA. When the concentration of n-DA is increased above 10^{-4}M, the chloride ions on the surface provide a better electrostatic condition, which promotes a direct adsorption of cations on the surface through its polar group ($n = 3$). This is probably seen in the nonlinear relation between ΔG°_a and T at 10^{-4}M n-DA (Fig. 4). This is also in accordance with the increase in negative ΔG°_a with θ above 10^{-4}M n-DA, which is the characteristic feature of lateral interaction between adsorbed n-DA molecules on the surface (5). The positive values of ΔH°_a and ΔS°_a can be explained as a result of the occurrence of the replacement process (13, 14) during adsorption of n-DA on the surface.

Search for Gold Cyanide Inclusions in Cobalt-Hardened Gold Electrodeposits

R. L. Cohen, K. W. West, and M. Antler[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We have studied samples of cobalt-hardened gold electrodeposits via Mössbauer spectroscopy to search for microprecipitates of gold compounds *in situ*. Plated layers were found to contain no detectable AuCN, $KAu(CN)_2$, or $KAu(CN)_4$. The upper limits determined for the presence of these phases exclude the possibility that all the carbon found in this hard gold plate could be incorporated in the deposit in these forms. We have determined the recoil-free fraction for $KAu(CN)_2$ and $KAu(CN)_4$.

Gold electrodeposits containing small amounts of other metals are widely used as contact materials in separable electronic connectors and in relays for low energy switching applications. Cobalt or nickel, from *ca.* 0.3-1.6 atom percent (a/o) [0.1-0.5 weight percent (w/o)], are the most used hardeners and are deposited in the gold from buffered acid solutions of $KAu(CN)_2$. This small metal addition raises the hardness of the plated layer to 140-220 kg/mm^2 and produces surfaces

[1] Bell Laboratories, Columbus, Ohio 43212.

which have low and stable contact resistance and good wear resistance (1). However, a considerable amount of carbon, nitrogen, and hydrogen are also deposited in the plated layer (2-7). The presence of these impurities reduces the observed density of plated layers below that of pure gold, may result in bubbling or cracking of the surface due to gas evolution on heating, and may have deleterious effects on its solderability and ultrasonic bondability (6,8,9).

In 1969, it was reported (8) that some of these impurities could be directly observed by dissolving out the gold (using aqua regia) from the hard gold plate. The carbonaceous material was often found to retain the shape of the original piece of gold plate, and was given the name "polymer." Because of the economic importance of these hard gold plates, many studies have been carried out to determine the quantity and nature of the carbonaceous impurities (2-6). The metallic character of the gold layer makes it effectively impossible to use the standard techniques of optical and infrared spectroscopy or magnetic resonance to study the carbonaceous impurities. As discussed above, some attempts have been made to dissolve out the gold matrix, leaving behind the impurities to be studied. Unfortunately, there is no guarantee that the extracted impurities are unchanged by this processing.

We have used the technique of Mössbauer spectroscopy (10) to study the composition of cobalt-hardened gold in a completely nondestructive way. This paper discusses the search for Au compounds in the plated layer.

Mössbauer spectroscopy is a technique based on γ-ray resonance absorption by nuclear levels. The energy of an excited level of an atomic nucleus is altered slightly ($\sim 10^{-7}$ eV) by the surroundings of the ion. These changes may be detected and measured via Mössbauer spectroscopy. Comparison of the measured spectra with those of known compounds can then be used to determine the composition of the material under study.

For the Au^{197} nucleus used here these perturbations result from (*i*) the electronic density at the nucleus, which leads to the "isomer shift," a change in the energy levels, and (*ii*) the quadrupole coupling, which leads to a splitting of the nuclear energy levels, and thus a symmetric doublet spectrum. The field gradient which produces the quadrupole splitting arises from asymmetric disposition of the ligand ions, and is identically zero in the ideal fcc structure. Any configuration of ligand ions leads to a particular, distinct value of isomer shift and quadrupole splitting of the gold nuclear resonance, and these parameters are observed via the Mössbauer effect. In the research reported on here, we compare the Mössbauer spectra of plated samples with spectra of known gold compounds to search for the presence of particular impurities in the electrodeposits.

In these experiments, only the Au nuclei contribute to the resonance absorption observed.

There are two important advantages to this approach: First, the radiation used here, the 77 keV γ-ray of Au^{197}, will penetrate through $\sim$0.5 mm of gold, so that plated layers can be studied without thinning or special treatment. The total radiation dose received by the sample is at least 1000 times less than that in an x-ray diffraction experiment, so radiation damage should not be significant. Second, the "Mössbauer parameters" characterizing a given compound are determined almost entirely by the first and second nearest neighbor shells around the atom being studied. Thus, microprecipitates containing only a few molecules of a substance exhibit Mössbauer spectra like those of the bulk material.

In view of the relative novelty of the Mössbauer spectroscopy technique for investigations like these, it is worthwhile to discuss some of the previous studies on very fine particles. For gold microcrystals of about 60Å diameter, Schroeer *et al.* (11) found the isomer shift to be less than 0.1 mm/sec different from that of bulk gold. For the same particles, Marshall and Wilenzick (12) found a small increase (about 5%) in the recoil-free fraction (efficiency with which the Mössbauer effect is observed) over that of bulk gold. For granular tin of 45Å mean particle size, Akselrod *et al.* (13) found no changes in the isomer shift or line width from bulk tin values, and a small (less than 2%) decrease in the recoil-free fraction. Akselrod *et al.* also found that for the intergranular SnO phase, with an estimated grain size of 20Å, the isomer shift, quadrupole coupling, and resonance line width were identical with the corresponding values for bulk materials. Cohen *et al.* (14) made measurements on colloidal sols of Pd-Sn alloy which showed that for $\sim$20Å particles, the Mössbauer line was essentially the same as that of the bulk alloys. Mössbauer measurements in iron-containing biological molecules are routinely made using samples in which the individual molecules are isolated in a frozen matrix (*i.e.*, "clusters" consisting of a single molecule are studied) and sharp and well-defined spectra are obtained (15). These experiments, plus many others on "glassy" systems where there is no long range order, demonstrate that the Mössbauer spectra can be used with high reliability to characterize the local environment of the atom (in this case, Au) being studied, even when the particle size is extremely small.

In general, detection of second phases via x-ray diffraction is limited to cases where at least 2-5% of the material is in the second phase (16). The sensitivity is much poorer if the second phase is very finely divided or of poor crystallinity, conditions which we would expect here. In fact, Okinaka and Nakahara (17) have recently reported high concentrations of voids or inclusions in the 20Å size range in cobalt-hardened gold; inclusions of this size would yield such broad x-ray lines as to be almost undetectable.

Experimental Technique

The samples studied were approximately 33 μm (1.3 mil) thick layers of production cobalt-hardened gold plated on copper coupons from an Autronex Cl[2] bath that had been replenished many times with gold and hardener materials. The bath was thus representative of those actually used in manufacturing plants. The current density and temperature during plating were 1 A/dm^2 and 32°C. Analysis of adjacent material showed the cobalt content to be 0.80 a/o, potassium 0.28 a/o, and carbon 3.45 a/o. The copper backing was etched off with ammonium persulfate, and 10 of the hard gold layers were stacked to make a single absorber 330 μm thick to accentuate saturation effects (see below).

Measurements were made in transmission geometry with a drive which has already been described (18), with data collection by up-down multiscaling. The γ-rays were emitted from Au^{197} produced by the decay of Pt^{197}, made by neutron irradiation of Pt^{196} metal. The absorber was maintained at 4°K and the source at about 8°K during the measurements.

Results and Data Analysis

The absorption spectrum of the 10 layer absorber is shown in Fig. 1. The line has approximately the shape and position expected for Au metal (19) or a dilute alloy of cobalt in gold. Figure 1 also shows the line positions reported (20) for three possible Au cyanides. All those compounds have symmetric doublets for their Mössbauer spectra; the spectrum of Au-Co alloy should be a slightly broadened singlet. Although the left-hand line of each of the gold cyanides is close to the main Au line and would not be resolvable, the right-hand lines are reasonably far from the Au peak, and we have looked only for them in the computer analysis of the data. The spectrum of Fig. 1 shows

[2] TM SelRex Company, Division of Oxy-Metal Industries, Nutley, New Jersey.

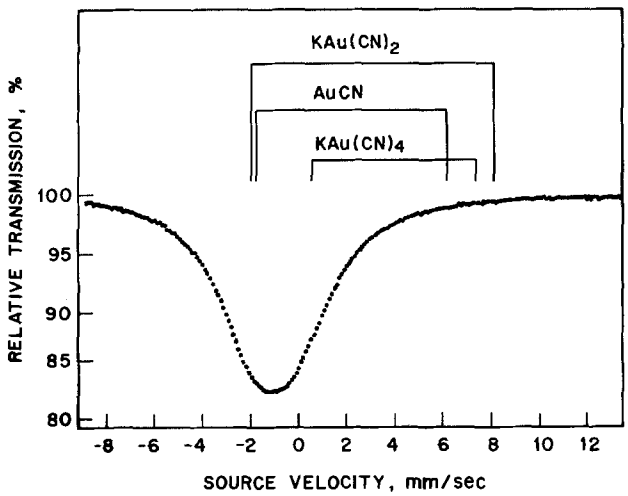

Fig. 1. Mössbauer spectrum of the gold plate sample studied in these experiments, using a source of Pt^{197} in Pt. Known line positions for the doublet spectra of the gold cyanides are shown. Data described as "run 1" in Table I are shown. On this scale, point-to-point variations from counting statistics are invisible. (Five million counts/channel.)

immediately that large quantities of the gold cyanides are not present. Processing of the data by computer least squares fitting is necessary to extract all of the possible information, however.

One possible approach to this problem would be a detailed line shape analysis, starting with the inherent Lorentzian line profile of the Mössbauer resonance, and inserting additional terms for the thickness (saturation) broadening, dispersion (21), and cobalt alloying. Aside from the obvious complications of this approach, the relatively poorly characterized nature of the deposit itself makes it very difficult to accurately describe the alloy. Thus we have chosen the empirical technique of taking the right-hand shoulder of the line (where the distinctive peaks of the cyanides lie) and least squares fitting that with a shoulder of Lorentzian line shape as shown in Fig. 2. For the limited velocity range used, this function represents an adequate fit to the data. The greatly magnified spectrum (Fig. 2A) still shows no obvious peaks where they would be expected for the gold cyanides.

To demonstrate that the technique is in fact sensitive to the small amounts of AuCN which might be present, we have superimposed on the data of Fig. 2 a calculated line showing the spectrum which would be obtained if the sample contained 2 mole percent (m/o) AuCN (see below). The curve has been calculated from the known (20,22,23) width, position, and intensity of the AuCN resonance lines. The data clearly exclude this interpretation.

We have further refined the analysis by constraining the least squares fitting routine to search for Lorentzian lines of width 2.2 mm/sec (this value typical of Au compounds) and positions expected for the gold cyanides in the experimental spectrum. Results of this analysis have been compared with line shapes of a pure solid solution of 0.67 a/o Co in Au, prepared by melting, and then annealing the elements at 800°C in H_2. The results of this analysis for two different sets of measurements on the same absorber are shown in Table I. All of the least squares fits showed χ^2 consistent with there being only statistical deviations between the data and fitted model.

This approach yields the line intensities (in counts) for the anticipated impurities. The following factors must be considered to infer the mole percentage limits of the impurities from the line intensities:

1. Line intensities must be doubled to allow for the other line of the doublet, since the resonance absorption is divided into two lines of equal intensity.

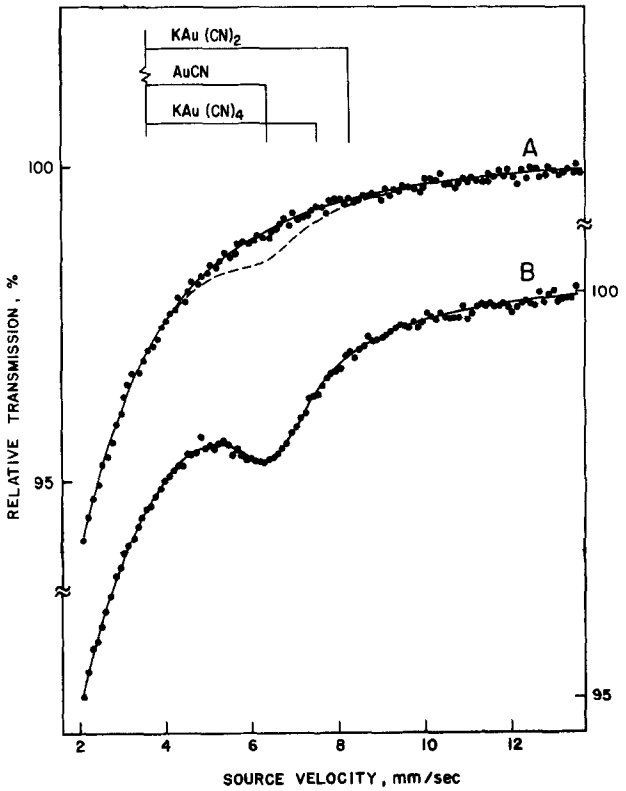

Fig. 2. A. Expanded view of the right-hand shoulder of the line shown in Fig. 1, with a least squares fit line describing a Lorentzian shoulder. The dashed line, determined as described in the text, shows the spectrum that would be obtained if 2% of the Au were in the form of AuCN. Line positions for the right-hand lines of the other gold cyanides are also shown. B. Expanded view of the right-hand shoulder of the Mössbauer resonance obtained with a composite absorber consisting of 627 mg/cm^2 of Au metal and 35 mg/cm^2 of Au as AuCN. The least squares fit line (shoulder of Lorentzian, plus AuCN line at appropriate position) is shown.

2. The relative Debye-Waller factors (recoil-free fraction, or f value) of the cyanides to that of the Au alloy must be considered. From Ref. (23), we find f/f_{Au} for AuCN and $KAu(CN)_2$ to be 0.5 and 0.08, respectively. We have also measured f/f_{Au} for $KAu(CN)_4$[3] and $KAu(CN)_2$ to be 0.31 and 0.08, respectively, with an estimated accuracy of ~15%. These relative f values are listed in Table I and used in the calculations. Using the determination (24) that $f_{Au} = 0.19$ at 4°K, absolute f values at 4°K for AuCN, $KAu(CN)_2$, and $KAu(CN)_4$ are 0.10, 0.015, and 0.06, respectively.

3. The absorber has intentionally been made very "thick" to increase saturation effects, which make the observed size of the resonance absorption increase only slowly for thick absorbers. Since the absorber is "thin" in terms of the gold cyanide, the gold cyanide

[3] We are indebted to Ms. Winifred Heppler, Dr. M. O. Faltens, and Prof. D. A. Shirley for providing us with a sample of this material.

Table I. Least squares fit results for gold cyanide compounds in cobalt-hardened gold

Compound, x	Run	Resonance absorption counts* Au	x	f_x/f_{Au}	x/mole Au*
AuCN	1	868 × 10^3	−159 ± 1447		−0 0001 ± 0.0011
	2	152 × 10^3	662 ± 510	0.5	0 003 ± 0.002
$KAu(CN)_2$	1	868 × 10^3	−818 ± 959		−0.004 ± 0 005
	2	152 × 10^3	60 ± 360	0.081	+0.001 ± 0.006
$KAu(CN)_4$	1	868 × 10^3	−429 ± 1184	0.31	−0.0005 ± 0.0015
	2	152 × 10^3	733 ± 387		0.005 ± 0.003

* Stated error limits are one standard deviation.

lines increase in intensity almost linearly with absorber thickness, while the main gold line increases only slowly. Thus, the use of a thick absorber increases the intensity of the impurity lines relative to the main line. For the value of $t = 10$ we use here, this magnification factor can be estimated from Ref. (22) to be 6.1. Saturation effects also produce broadened lines and are responsible for the excess (over the 2.2 mm/sec mentioned) linewidth observed in Fig. 1.

Although all of these effects are well established theoretically and widely confirmed experimentally, we have also validated the over-all approach and size of the saturation corrections by making a measurement on a compound absorber consisting of 627 mg/cm^2 of Au metal plus 35 mg/cm^2 of Au in the form of AuCN. The spectrum of this composite absorber is shown in Fig. 2B, with the right-hand line of the AuCN clearly visible. Least squares fitting of these data according to the procedures used for the CI samples, using the parameters shown in Table I, gave a value of 31 mg/cm^2 for the amount of gold in the AuCN phase. This confirms the validity of the analysis.

Table II shows the weighted average of the results of Table I for the various gold cyanides. For each material sought, the Mössbauer results are consistent with complete absence of that phase. Also shown are the upper limits for the mole percentage of the potassium gold cyanides obtained from the analysis for potassium.

Discussion

The main conclusion from this research is that the quantity of gold cyanides observed is far too small to account for the amount of carbon in this material. Analysis on other sections of this plated sample showed that 3.5 m/o C was present. Raub *et al.* (2) have reported N/C = 0.5-0.6 for Au-Co samples plated from similar baths under similar conditions. Thus, if we assume that their results describe our samples, and that all the N is present as CN, there would be about 2 m/o CN present.

Table II shows the amounts of the various cyanides that would be found if all of this cyanide were combined with the gold. It can be seen that the Mössbauer results exclude the possibility that a large fraction of the CN could be present as AuCN. Both the Mössbauer results and the potassium analysis show that at most 30% of the CN could be present as $KAu(CN)_2$.

Thus, our main conclusion is that the large amounts of CN observed in hard gold plates are either combined with the (Co) hardener, or occluded in the plate structure without forming well-defined gold cyanides. Forthcoming papers will discuss these possibilities.

Our conclusions are in disagreement with recent suggestions (2), but are based on specific tests sensitive to the microscopic structure of the deposit. There is, of course, always the possibility that sample-to-sample variations play some role in the differing interpretations.

Table II. Limits on presence of gold cyanides

Compound, x	From Mossbauer analysis, m/o	From potassium analysis, m/o	If all CN were in form x, m/o
AuCN	0.06 ± 0.1	—	2
$KAu(CN)_2$	-0.2 ± 0.4	0.28	1
$KAu(CN)_4$	0.1 ± 0.1	0.28	0.5

Tin (IV) Sensitizer for Photoselective Metal Deposition of Cobalt and Nickel from Alkaline Baths

B. K. W. Baylis, N. E. Hedgecock, and M. Schlesinger*

Department of Physics, University of Windsor, Windsor, Ontario, Canada N9B 3P4

ABSTRACT

Sn(IV) sensitizer can be used to achieve electroless plating in either basic Ni or Co metallizing baths, but only if an additional reducing bath is used between the activation step and the last rinse. Irradiation with ultraviolet light before this reduction step prevents subsequent plating for both Ni and Co. When irradiation follows reduction it inhibits Ni plating. The effects of different reducing agents on the subsequent plating from acidic Ni, basic Ni, Co, and Cu baths are reported. Possible mechanisms for ultraviolet inhibition of metal plating are discussed.

In a previous publication (1) we showed that an aged Sn(IV) chloride solution can serve as a sensitizer for electroless copper plating and for nickel plating from an acidic bath. Ultraviolet irradiation of the substrate after Sn(IV) sensitization and Pd(II) activation was shown to have a marked effect on subsequent metal plating. In a copper bath, plating occurred only on the irradiated surface, producing a clear, sharp negative image, which we call a "stimulated" negative [see Ref. (2)]. In an acidic nickel bath, plating occurred only on the nonirradiated surface, producing a clear, sharp positive image of the photomask.

In the light of these results, the performance of this sensitizing system with other metal plating baths was studied. This paper describes results obtained using alkaline nickel (3) and cobalt (3, 4) baths, both using hypophosphite as reducing agent.

Experimental

All chemicals were of A.C.S. reagent grade, supplied by Fisher or Canlab, and were used without further purification.

Sensitizer.—The preparation of this bath is described in detail in Ref. (2).

Activator, acidic nickel bath, and copper bath.—The preparation of these baths is described in Ref. (1).

Exposure system and procedure.—These were described in Ref. (1) except that rinse times were shortened to 1 min and that an infrared lamp was usually used to dry the samples after activation.

Alkaline nickel and cobalt baths and reducing baths.—The composition of these baths are listed in Table I. Except as noted, all baths were used at room temperatures.

Substrate.—All samples were prepared on Esco precleaned microscope slide glasses. These were wiped with paper tissues before use.

Results

All samples in the present study were dipped in aged Sn(IV) sensitizer, rinsed, dipped in Pd(II) activator, and dried. The designation [Sn(IV) · Pd(II)] refers to the catalytic substance present on the substrate after these steps are completed.

The procedure described in Ref. (1) for obtaining selective deposition of Ni (from acidic solution) and of Cu involves the above steps, followed by the sequence: u.v. irradiation, rinse, metallization.

Plating from basic Ni and Co baths.—Using alkaline Ni and Co baths, no plating is obtained with the above procedure on either the irradiated or nonirradiated surface. However, if the catalytic surface is immersed in an acidic hypophosphite reducing bath before the metallization step, plating does occur in either metallizing bath.[1] [The reduction step is also necessary to give plating from an alkaline Ni-B bath of the type used by Gorbunova (5).] Ultraviolet light inhibits Ni-P plating, whether irradiation precedes or follows the reduction step. Co plating is inhibited only if reduction follows u.v. irradiation.

Various hypophosphite reducing baths were used, based upon the metallizing baths. (For two examples, see Table I). These reducing baths were all successful if the *p*H had been lowered to between 5.3 and 5.9. The reducing agent in the copper bath, formaldehyde in strong base, proved also effective as a reducing bath, but only when fresh and concentrated [undiluted solution "B" used in making Cu plating baths, Ref. (1)] or when the glass slide was hot when immersed in the reducing bath. If u.v. irradiation follows reduction, the results with formaldehyde are substantially the same as those with acidic hypophosphite, although with poor reliability. For instance, the amount of cobalt plating in the irradiated area varied from being the same as that on the nonirradiated section to being much more, giving enhanced negative images of the photomask. If irradiation precedes reduction in hot formaldehyde, however, both Ni and Co plating occur on the irradiated surface.

Heating the reduced catalyst does not noticeably affect subsequent Co plating, but impairs Ni plating. Hence the drying step prior to u.v. irradiation is accomplished by draining at room temperature, indicated by D in Table II.

[1] It was possible to obtain Co plating using Sn(IV) sensitizer without the reduction step if the metallizing bath temperature was raised to 80°C, once the *p*H of the bath had fallen to about 6 due to ammonia evolution. If the sample had been irradiated with u.v. light, the irradiated areas did not plate, giving rise to a positive image of the photomask.

Table I. Composition of baths

(Quantities given for 1 liter of solution)

	Ni	Co	Reducing bath No. 1	Reducing bath No. 2
$CoSO_4 \cdot 7H_2O$		35g		
$NiSO_4 \cdot 6H_2O$	30g			
$NaH_2PO_2 \cdot H_2O$	10.6g	40g	40g	17.5g
Na_3 citrate	100g	35g	35g	
NH_4Cl	53.6g			
$(NH_4)_2SO_4$		70g	70g	
Na_2 succinate				14.5g
Succinic acid				1.0g
*p*H (adjusted with NaOH)	8.3-8.6	8.8-9.0		
*p*H (adjusted with HCl)			5.3-5.9	As made

* Electrochemical Society Active Member.

Key words: electroless, sensitizer, tin (IV), photoselective nickel, cobalt, copper.

Table II. Effect of additional reduction step on photoselective deposition from alkaline plating baths

Sequence*					Metal bath	Irradiation U.V.	Irradiation No u.v.	Image type
S R_1 A IR	UV	R_2	—	—	Co or Ni	No	No	—
	UV	R_2	F	R_3	Co or Ni	Yes	Yes	—
	UV	R_2	P	R_3	Co or Ni	No	Yes	Positive
	F or P	D	UV	R_3	Co	Yes	Yes	—
	F or P	D	UV	R_3	Ni	No	Yes	Positive
	UV	R_2	—	—	Cu	Yes	No	Stim. negative
	UV	R_2	P or F	R_3	Cu	Yes	Yes	—
	F or P	IR or D	UV	R_3	Cu	Yes	Yes	—

* S refers to Sn(IV) sensitizer bath (2 min), R_1 = first rinse (1 min), A = Pd(II) activator bath (2 min), IR = infrared lamp (3-5 min), UV = ultraviolet lamp (6 min), R_2 and R_3 = second and third rinses (usually running distilled water), P = acidic hypophosphite solution (1 min), F = fresh, concentrated, basic formaldehyde bath (1 min), Ni = basic Ni bath (11 to 40 min), D = room temperature drain to dryness (about 20 min), Co = basic cobalt bath (8-30 min), Cu = basic copper bath (about 1 min).

Plating from the acidic electroless Ni bath.— The effects of the additional reducing baths on acidic Ni plating (1) were also studied. The only effect of the additional hypophosphite bath is to somewhat slow the rate of plating. This applies whether the reduction step is carried out before or after the u.v. irradiation.

If basic formaldehyde is used as the reducing bath, a positive image is again obtained whether the reduction step precedes or follows u.v. irradiation. Thus the formaldehyde does not appear to affect subsequent plating in an acidic nickel bath. (Positive images were also obtained using an acidic Ni-B bath. No noticeable effects of a reduction step, using dimethyl amine borane, were found.)

Plating from the electroless copper bath.—The acidic hypophosphite reduction step causes subsequent copper plating to occur both on the irradiated and on the nonirradiated areas (that is, full plating), whether the reduction step precedes or follows the u.v. irradiation. Prereduction with concentrated basic formaldehyde, either before or after u.v. irradiation, results in full plating only if the slide is hot when placed in the formaldehyde solution or when the sample is heated afterward.

All these results are summarized schematically in Table II.

Discussion

In Ref. (1) we suggested that the reason that the tin (IV) sensitizer is effective for Ni plating from the acidic bath, but not for Cu plating, is that the hypophosphite (in the Ni bath) can reduce the attached Pd(II) to Pd(O), but formaldehyde (in the Cu bath) cannot. Our present results strongly suggest that a reduction of the catalyst [Sn(IV) · Pd(II)] does occur prior to Ni and Co plating, and that this reduction can proceed in acidic hypophosphite, but not in neutral or basic hypophosphite.

Remembering that the copper bath is strongly basic, it becomes plausible that it is the change in *p*H rather than the change in reducing agent or metal ion that determines whether reduction of Pd(II) and hence plating occurs onto the catalyst. The effect of raising *p*H on hypophosphite is, however, to increase its reduction potential [for example, see Ref. (6)] so that the above results cannot be explained just on the basis of the change in *p*H on the hypophosphite. Moreover, Pd(II) is much harder to reduce in basic solution than in acid because it forms $Pd(OH)_2$, which has a lower reduction potential than $PdCl_2$. Therefore, one reason that no plating occurs on nonirradiated [Sn(IV) · Pd(II)] in basic plating baths, is that $Pd(OH)_2$ forms which cannot be reduced and cannot catalyze metal plating. However, if the glass slide is hot or the formaldehyde solution used in making the copper bath is very fresh, copper plating does occur on the nonirradiated catalyst. This shows that basic formaldehyde is very nearly capable of reducing nonirradiated [Sn(IV) · Pd(II)], and that concentration, temperature, and freshness are critical.[2]

[2] This fact has been exploited to eliminate background in the stimulated copper negative images by always using for the copper baths formaldehyde solutions that are at least one day old.

Meek (7) has suggested that some time in the metallizing bath is necessary before the material present on the substrate after Sn(II) sensitization and Pd(II) activation is capable of catalyzing Cu plating. This may indicate that even for the [Sn(II) · Pd(II)] system, reduction in the metallizing bath is a necessary step in producing an active catalyst.

In our case, the catalyst is reduced in the reducing bath to a form which we designate [Sn(IV) · Pd(O)] which is capable of catalyzing plating from all four of the metallizing baths studied so far. It is also capable of catalyzing the decomposition of hypophosphite, resulting in hydrogen evolution. Ultraviolet irradiation at this point changes the catalyst in a way which prevents subsequent Ni plating from either bath, but which does not prevent Co or Cu plating. It was observed that simply heating the sample after reduction had a similar but less pronounced effect on the catalyst in that decreased Ni plating was observed, but Co and Cu plating were not affected. These facts suggest that the effect of u.v. light on reduced catalyst, [Sn(IV) · Pd(O)], is to decrease in some way the number of active catalytic sites. Such an interpretation was given by Kelly and Vondeling (8) to their result that longer irradiation times rendered [TiO_2 · Pd(O)] catalytic sites inactive for Ni, but not for Ag or Cu, which plated even on "overexposed" catalyst. They also estimated that the minimum amount of Pd(O) required to initiate Ag deposition is 8-16 × 10^{12} atoms/cm^2, whereas the minimum for Ni plating is nearer 32 × 10^{12} atoms/cm^2. Their results suggest that the threshold amount of Pd(O) necessary to catalyze metallization is similar for Ag and Cu. Our results, if u.v. light is presumed simply to decrease the number of active sites, indicate that the threshold for Cu is lower than that for Ni, and furthermore, that the threshold for Co is intermediate.

The effect of u.v. light on [Sn(IV) · Pd(II)] is not understood at this time. It has been shown here that u.v. renders [Sn(IV) · Pd(II)] capable of catalyzing

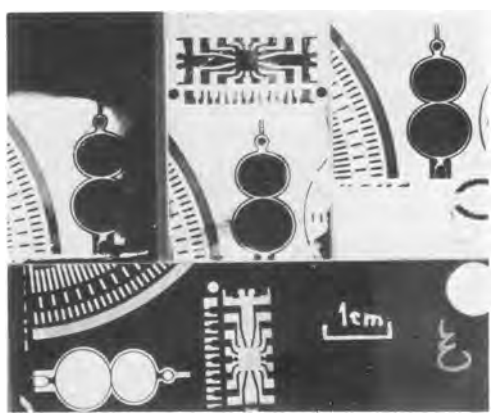

Fig. 1. Contact print of glass slides with imaged deposits obtained from various electroless metallizing baths. Left to right: Co-P (80°C), alkaline Ni-P, acidic Ni-P; below: Cu.

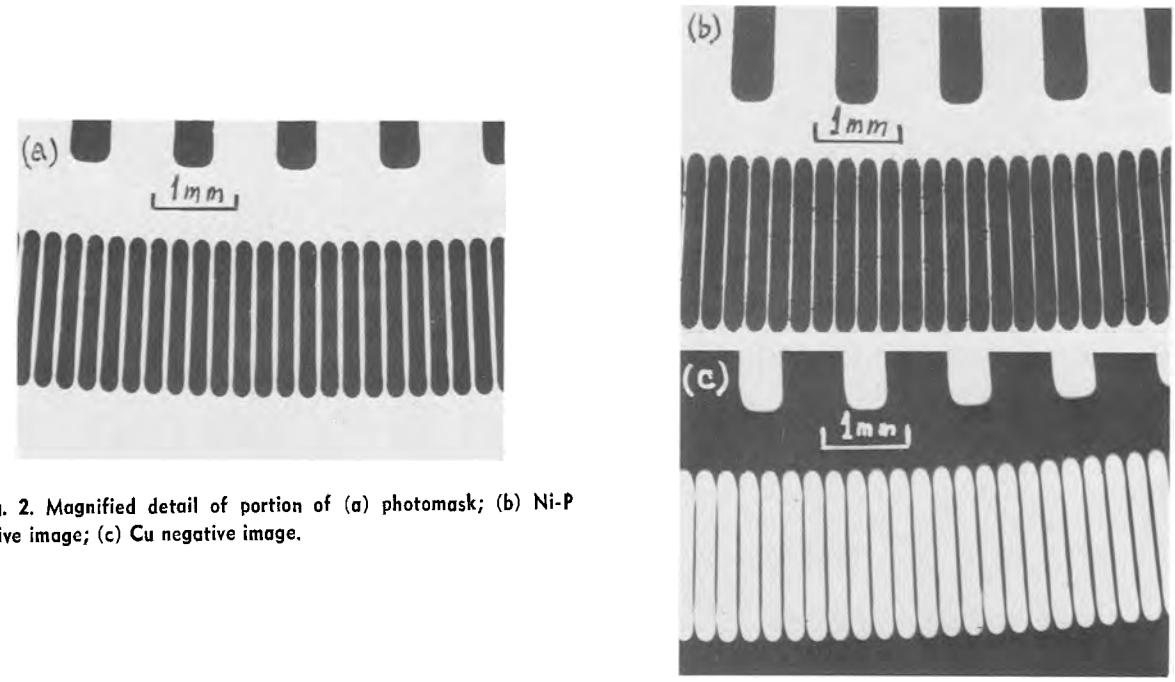

Fig. 2. Magnified detail of portion of (a) photomask; (b) Ni-P positive image; (c) Cu negative image.

Cu plating, but not Ni or Co plating. This could be explained by assuming that the u.v. light initially reduces [Sn(IV) · Pd(II)] to [Sn(IV) · Pd(O)] [as suggested by Kelly and Vondeling (8) for the [TiO_2 · Pd(II)] system] and then decreases the number of active catalytic sites below the threshold necessary for Ni and Co. If this were the case, irradiation times shorter than some minimum should result in more efficient plating for all three metals. No such minimum was found in the present work, however; indeed for copper plating the longer the irradiation time, the faster the plating.

In Table II it is noted that if the irradiated catalyst is reduced with hot formaldehyde, Co and Ni (alkaline) plating will occur. No plating will occur if the reducing agent is hypophosphite, acidic or basic. This result shows that formaldehyde interacts with irradiated [Sn(IV) · Pd(II)] to form a catalyst for basic plating baths, and that hypophosphite does not. This selectivity shows that irradiation of [Sn(IV) ·Pd(II)] results in more than just a decrease in the density of active [Sn(IV) · Pd(O)] sites.

It is possible that one effect of irradiation is to affect the crystallinity of the catalytic material. This was found (9) to be the case with the catalyst based on Sn(II) sensitizer. Attempts to investigate this by electron diffraction have so far been inconclusive.

The catalytic status of the tin-palladium material at various stages of the process can be seen in the following schematic chart:

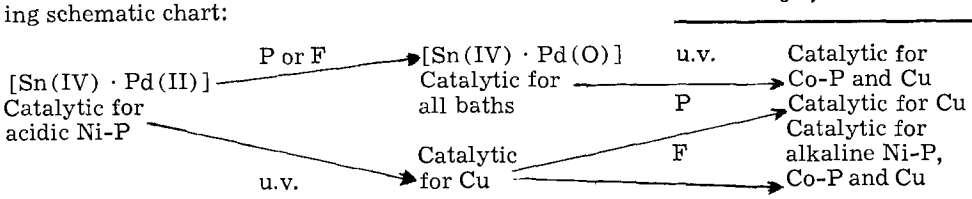

Image quality.—The quality of both the nickel positive and copper negative images is high with respect to both contrast and definition. Figure 1 shows examples of images obtained from the metallizing baths discussed in this paper. The highest quality so far has been obtained using the acidic nickel bath and the copper bath, with which most of our work has been done (1).

In Fig. 2 the finest detail on the photomask and corresponding areas on a nickel positive and copper negative are shown. It should be taken into account that the images are distorted due to the nonparallel light passing through the photomask in our simple optical arrangement.

Conclusion

These results indicate that it should be possible to use Sn(IV) as a sensitizer for quite a range of metallizing baths, and thus take advantage of the sharp images Sn(IV) produces. Basic metallizing baths may require a preliminary acidic reducing bath.

Our best procedure to date for the production of positive images from the basic Ni-P bath is as follows: A clean dry microscope slide is immersed for 2 min in a long-lived Sn(IV) sensitizer bath [see Ref. (2)]. After rinse and activation, the slide is dried under an infrared lamp and then immersed in an acidic hypophosphite bath for 1 min. After the slide is rinsed and allowed to drain to dryness, it is irradiated through an appropriate mask for 6 min with u.v. light. After another rinse the slide is immersed in the alkaline Ni bath described in Table I.

Manuscript submitted June 23, 1976; revised manuscript received Sept. 24, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the University of Windsor.

Ligand Effects in Electroless Copper Deposition

Milan Paunovic*[1]

Kollmorgen Corporation, Photocircuits Division, Research and Development Laboratory, Glen Cove, New York 11542

ABSTRACT

The induction period and cathodic processes in electroless deposition of copper have been studied by galvanostatic, chronopotentiometric, and potential sweep methods. It is shown that the factors which determine the duration of the induction period are the type and concentration of the ligand that is complexing the copper ions. The rate-determining factor is the rate of establishment of the potential of the partial anodic process. Dissociation of a copper complex preceding the charge transfer in the electrochemical and electroless deposition of copper has been studied by chronopotentiometry and potential sweep method. Chronopotentiometric $i\tau^{1/2} = f(i)$ and potential sweep $i/v^{1/2} = f(v)$ functions have been used to estimate the relative rates of dissociation. The properties of the complexes of Cu(II) with ethylenediaminetetraacetic acid (EDTA), N,N,N',N'-tetrakis-2 (2-hydroxypropyl)ethylenediamine (Quadrol), cyclohexane-1, 2-diamine-N,N,N',N'-tetraacetic acid (CDTA), and tartaric acid have been studied. The galvanostatic transient technique has been used for kinetic studies of copper deposition. A definite correlation has been established between the rate of dissociation of the complex and the rate of metal deposition. The rate of deposition of copper and the rate of dissociation of complex as a function of a ligand increase in the order: tartrate, EDTA, Quadrol, CDTA complex.

In a previous paper electroless deposition of metals was interpreted on the basis of the mixed potential theory (1). The mixed potential theory interprets the over-all process of the electroless deposition of metals in terms of electrochemical parameters of the partial electrode processes: reduction of the metal ions and oxidation of the reducing agent (1-4). Upon immersion of a piece of a metal into a solution capable of electrolessly depositing metal, each of these partial reactions strives to establish its own equilibrium potential. The result of this process is establishment of a steady state with the resultant potential, the steady-state mixed potential, E_{MP}. These nonsteady-state processes that lead to the establishment of the steady-state mixed potential represent the initial period in the electroless deposition of metals called the induction period (5). In the steady-state deposition the metal substrate is considered to be statistically divided into cathodic and anodic areas with corresponding processes of oxidation and reduction occurring simultaneously and spatially separated. Since these cathodic and anodic areas are part of the same piece of the metal, they are "short-circuited" and there is a flow of electrons between these areas. Thus, on the basis of the mixed potential theory there are two types of processes in electroless deposition of metals: (*i*) nonsteady-state processes and (*ii*) steady-state processes. Our primary interest here is the induction period and partial cathodic processes under steady-state conditions.

Induction period.—We define the induction period as the time necessary to reach the mixed potential E_{MP} at which the steady-state metal deposition occurs. In the present report we are interested in the basic characteristics of the nonsteady-state processes that lead to the establishment of the steady-state mixed potential, E_{MP}, and the factors that determine the duration of the induction period in the electroless deposition of metals. Induction period phenomena have been detected in the case of electroless deposition of copper and nickel on Pt, Cu, and Ni substrates (5). An interesting case of induction period was reported by Dumesic, Koutsky, and Chapman (6). These authors have recorded the rates of electroless deposition of copper on a silver activated glass substrate and have detected three distinct growth regions: the initial rate region, "the transition point," and the final rate region. In the first region electroless deposition of copper occurs on the silver substrate and in the third region on the copper substrate. The second region corresponds to the induction period for deposition of copper on a copper substrate as discussed in this report. Initial stages of electroless deposition of copper, up to the thickness of 1000Å, have been studied by Sard (7) and it was concluded that development of the copper film proceeds by repeated three dimensional nucleation. The type of deposited copper, its physical and morphological properties, and adhesion to the substrate, depend, in the great extent, upon these first layers deposited at the very beginning of deposition. Knowledge of the mechanism of formation of these first layers is of practical and fundamental interest.

Partial cathodic processes.—The partial cathodic process is the reduction of the complexed copper ions. One of the fundamental problems is electrochemical deposition of metals from complex ions, and also in electroless deposition of metals, is the problem of the electroactive species. The electroactive species can be the complexed or the noncomplexed metal ion. In the first case the kinetic scheme of the process of metal deposition is one of simple charge transfer. In the second case the kinetic scheme is of charge transfer preceded by the dissociation of the complex (8).

The primary purpose of this section of study is the investigation of the mechanism of the cathodic proc-

Key words: copper, formaldehyde, electroless plating, induction period, mixed potential.

esses, and the role of the dissociation of a copper complex, in the electroless deposition of copper. The significance of these studies is that they introduce additional factors that have to be considered in (*i*) describing parameters and (*ii*) in selecting ligands for electroless deposition of metals.

Dissociation of a complex metal ion prior to the charge transfer has been studied electrochemically by polarography, chronopotentiometry, and potential sweep methods. In our approach we have used both chronopotentiometry and potential sweep methods.

For the single reversible and irreversible electrochemical reaction the $i\tau^{1/2}$ chronopotentiometric function is a constant value for constant concentration and independent of the current density (τ, the transition time). In the case when an electrochemical reaction is preceded by a chemical reaction $i\tau^{1/2}$ is a function of the current density, equilibrium constant, and the rate constants of the preceding chemical reaction (8). The potential sweep current function related to our problem is the $i_p/v^{1/2}$ function where i_p is the peak current and v the rate of potential scan. In the case of the single-step electrochemical reaction $i_p/v^{1/2}$ is a constant value for constant concentration and independent of the potential scan. When an electrochemical reaction is preceded by a chemical reaction, the i_p function and the $i_p/v^{1/2}$ function, depend on K, k_f, and k_b (9).

Partial anodic processes.—The partial anodic process is the oxidation of formaldehyde. The mechanism of the anodic oxidation of formaldehyde was studied by Buck and Griffith (10) and Saito (11). On the basis of these studies the most important characteristics of the kinetic scheme for anodic oxidation of formaldehyde are: (*a*) the electroactive species is the methylene glycolate anion; (*b*) the electrochemical reaction is preceded by dissociative adsorption of the electroactive species, *i.e.*, the surface dehydrogenation reaction; and (*c*) the rate-determining step is the electron transfer involving the adsorbed species. The possibility of the direct oxidation of the methylene glycolate anion without an adsorbed intermediate state is not ruled out.

Experimental

For our studies we have chosen four ligands: tartaric acid, EDTA, Quadrol (BASF Wyandotte Corporation), and CDTA (Fig. 1). We have chosen these ligands because they show significant differences in the rate of electroless deposition of copper and thus are good examples for comparison. We have studied corresponding complexes of copper at concentrations of 0.05M $CuSO_4$, 0.06 and 0.15M ligands at 25°C, pH = 12.50 in an argon atmosphere. For the study of the polyelectrodes, 2.5 g/liter of paraformaldehyde has been added to the solution.

We have used two types of all-glass electrochemical cells: a one-compartment and a three-compartment cell. Electrodes have been prepared as described previously (1).

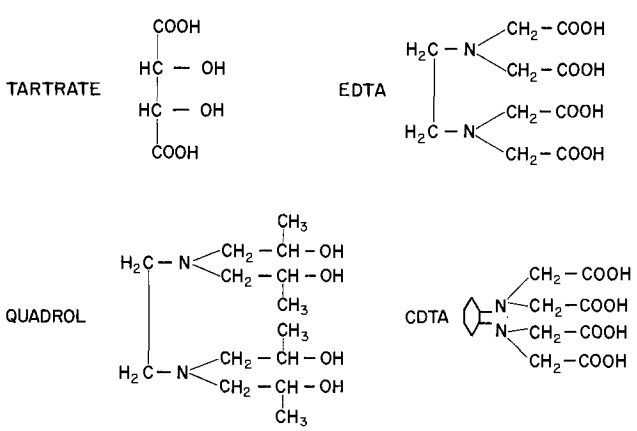

Fig. 1. Structures of the ligands used in this work

A transistorized constant current power supply made in our laboratory has been used as a current source in galvanostatic and chronopotentiometric measurements. A Tacussel (Lyon, France) potentiostat Type PIT 20-2A and function generator Type GSTP 2 have been used in potential sweep and potentiostatic measurements. The current potential or potential time curves have been recorded on (*i*) the Tektronix 564 B storage oscilloscope with plug-in units: Type 3A6 dual-trace amplifier; Type 2B67 time base and Type 2A63 differential amplifier, or (*ii*) Hewlett Packard 7004A recorder with plug-in units: d-c coupler Model 17170A; d-c preamplifier Model 17171A; time base Model 17172A and d-c offset Model 17174A. Oscilloscope traces were photographed with the Polaroid camera C-27.

Results

Induction period.—The over-all process.—The study of the induction period starts with a very simple experiment in which a piece of metal is immersed in a solution for electroless deposition of a metal and the potential of the metal recorded from the time of immersion (or the time of addition of the reducing agent), *i.e.*, the time zero, until the steady-state mixed potential is established. A typical recorded curve for the electroless deposition of copper on copper substrate is shown in Fig. 2. The curve has been recorded for the system in an argon atmosphere. For an air atmosphere, and in the presence of additives in the solution, the duration of the induction period can be considerably longer. For example, for electroless deposition of copper on the copper substrate from the electroless solution that is 0.2M in EDTA and 0.1M in $CuSO_4$ with 0.5 g/liter paraformaldehyde at pH 12.50 and 25°C, the induction period in the argon atmosphere is 140 sec but in the air atmosphere it is 350 sec. For practical plating solutions operated in an air atmosphere and containing additives, induction periods of 30 min to 1 hr are not unusual. This gives rise to another important reason for studying induction period phenomena. For example, in practical operations in the production of printed circuit boards for the electronics industry this induction time represents a loss of production time

Partial processes.—The problem of the induction period for the over-all process can be decomposed into problems of the open-circuit potentials (5) of the oxidation and reduction partial reactions, *i.e.*, individual induction period for each process.

A typical curve representing the change of the open-circuit potential (OCP) with time, for the reducing agent, is given in Fig. 3. The OCP for the Cu/Cu^{+2} system is reached instantaneously, within instrumentation limits. From a comparison of these OCP curves one can conclude that the rate of establishment of the OCP of the reducing agent, CH_2O, is the rate-determining partial reaction in the establishment of the steady-state mixed potential (5).

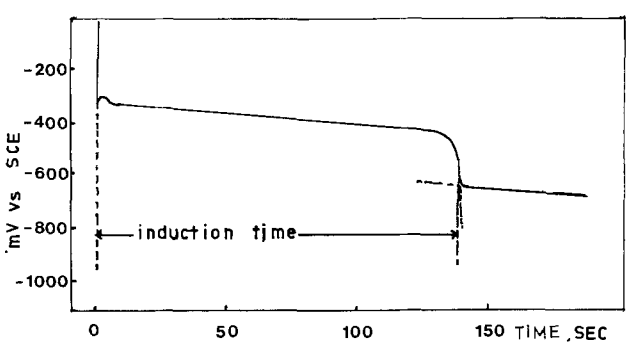

Fig. 2. Induction period for the solution 0.3M EDTA, 0.05M $CuSO_4$, pH 12.50, 2.5 g/liter paraformaldehyde, Cu electrode 2.2 cm^2, 25°C, SCE reference electrode, argon atmosphere.

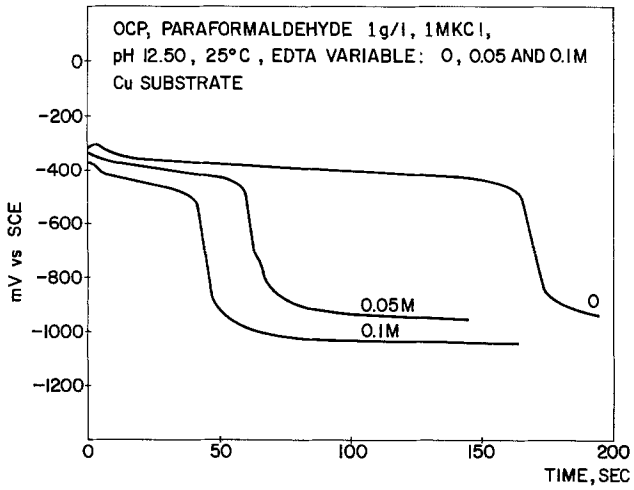

Fig. 3. Open-circuit potential for the solution 1 g/liter paraformaldehyde, pH 12.50. 25°C, Cu electrode, SCE reference electrode.

Major factors that determine the time necessary to reach the rest potential of the reducing agent are type and concentration of the ligand present.

The influence of the type of ligand present can be illustrated with the following example. In a supporting electrolyte that is 1M KCl, pH 12.50, 25°C and with 1 g/liter of paraformaldehyde, the t_{OCP} in the absence of a ligand is 210 sec. Addition of 0.1M tartrate or 0.1M EDTA to the electrolyte gives t_{OCP}'s of 240 and 45 sec, respectively. The influence of concentration of the ligand is illustrated in Fig. 3. For 0.2 and 0.3M EDTA the values are the same as for 0.1M EDTA.

Partial cathodic processes.—Single electrode: reduction of Cu(II) EDTA.—If a triangular wave is applied to the single electrode in the solution of Cu(II)EDTA complex a current potential curve with two peaks is obtained, Fig. 4. These two peaks appear at all compositions of the solution. The first peak we will designate the prewave and the second the main wave. At some ligand/Cu(II) ion ratios and at certain scan rates there is a small third cathodic wave at more positive potentials. Since this wave appears only under specific conditions we will not discuss it here.

Reduction of Cu(II) EDTA complex was studied for the solution that was 0.05M $CuSO_4$, 0.006M EDTA, pH = 12.50 at 25°C, in an argon atmosphere.

Prewave.—Our first analysis of the prewave consists of the analysis of the transition time values at different current densities and of the plot of the $i\tau^{1/2}$ *vs.* current density. The result of one of these plots is shown in Fig. 5. The observed increase of the function $i\tau^{1/2}$ with an increase in the current density [the diagnostic criterion (8)] indicates the adsorption of the electroactive species. The same conclusion is obtained from an analysis of the potential sweep functions as shown

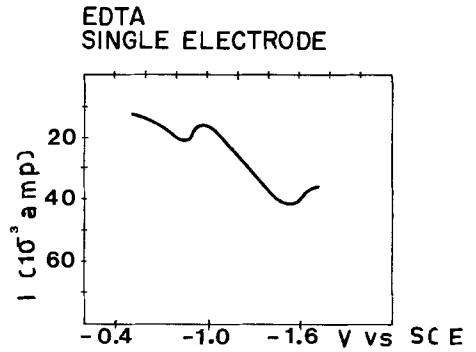

Fig. 4. Current potential curve for the single electrode, $A = 0.680$ cm^2; $v = 2.0$ Vsec^{-1}.

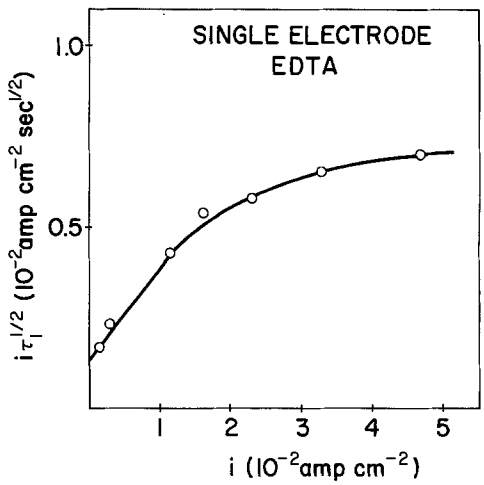

Fig. 5. Chronopotentiometric function for the first transition time

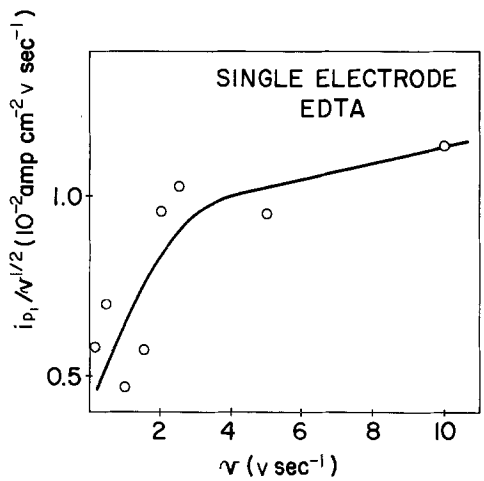

Fig. 6. Potential sweep function for the first wave

in Fig. 6. The function $i_p/v^{1/2}$ *vs.* v shows characteristics of the reduction of the adsorbed electroactive species (9).

Thus, both methods, chronopotentiometric and potential sweep, show that the prewave is due to the reduction of the adsorbed species. In order to identify this wave further we have used the potential sweep method; in one case varying concentration of the supporting electrolyte, and in another case varying concentration of the Cu(II) complex. Results of the analysis are shown in Table I. It is seen from the table that the peak current of the first wave changes with the change of concentration of the supporting electrolyte and that of the second wave does not. Varying the concentration of the Cu(II) complex in the solution does not change the peak current of the first step. On the basis of these results one can conclude that the

Table I. Potential sweep data for the first and second wave for single electrode

ELECTRODEPOSITION OF Cu FROM Cu (II) COMPLEX IOMS

Cu TARTRATE $i_p = f(\phi_2)$

	0.0 KCl	0.1MKCl	1.0MKCl	
i_{p_1}, 10^{-3}amp cm^{-2}	1.32	1.62	2.12	X_2 PLANE
i_{p_2}, 10^{-3}amp cm^{-2}	8.60	8.76	8.60	OUTSIDE X_2 PLANE

Cu EDTA $i_p = f(C^S)$

Cu EDTA	i_{p_1} amp cm^{-2}
5mM	1.03×10^{-3}
50mM	1.04×10^{-3}

first step is due to the reduction of Cu(II) ions in the X_2 plane of the double layer, and in the second step the reduction of ions outside of the X_2 plane (12).

Main wave.—The main wave has been analyzed in the same way as the prewave. Figure 7 shows the change of the $i_p/v^{1/2}$ *vs.* the scan rate. A decrease of $i_p/v^{1/2}$ with the increase of the scan rate is a diagnostic criterion for the kinetic scheme where the charge transfer is preceded by a chemical reaction (9). Chronopotentiometric results shown in Fig. 8 lead to the same conclusions (8).

Thus, both methods show that the reduction of the Cu(II) EDTA complex is preceded by the dissociation of the complex.

Single electrode: reduction of tartrate, Quadrol, and CDTA complexes of Cu(II).—All these complexes have been analyzed in the same way as the Cu(II) EDTA complex. The experimental conditions were: 0.05M $CuSO_4$, 0.06M ligand, pH = 12.50 at 25°C in the argon atmosphere. Results are shown in Fig. 9. One can conclude that in all cases studied the charge transfer is preceded by the dissociation of the complex. It is interesting to observe, however, that the slopes of the linear portions of the curves are considerably different.

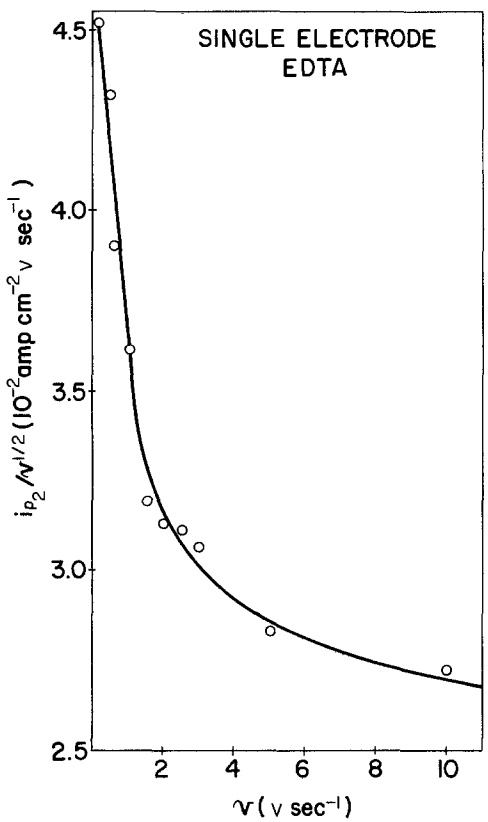

Fig. 7. Potential sweep function for the second wave

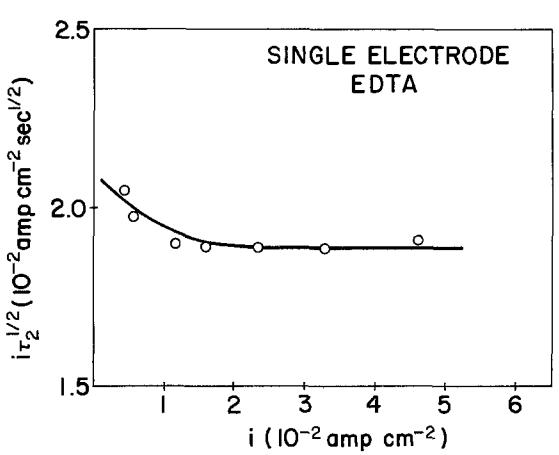

Fig. 8. Chronopotentiometric function for the second transition time

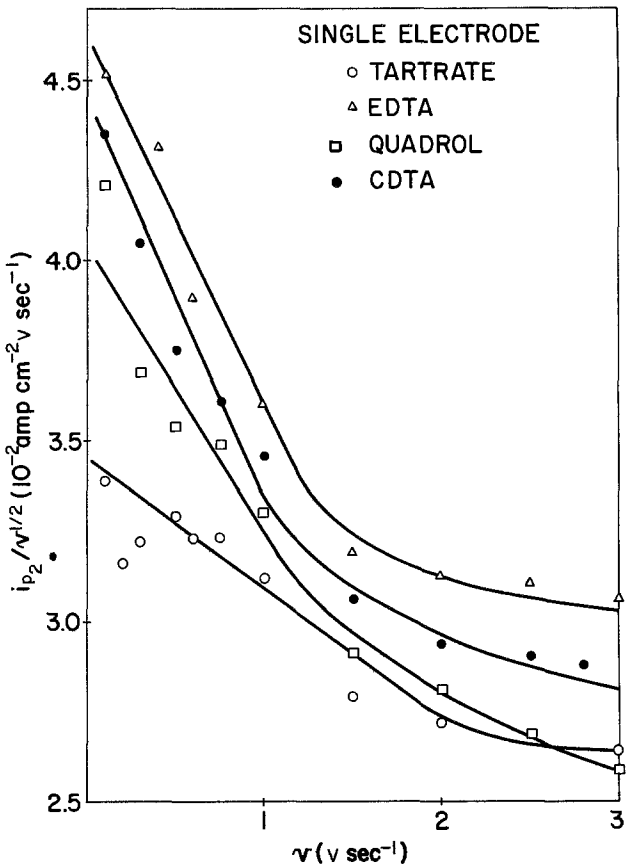

Fig. 9. Potential sweep function for the second wave

Polyelectrode.—Current potential curves for the polyelectrodes show only one peak in the studied potential range. The value of the peak current is of the same order of magnitude as the peak current of the main wave for the single electrode. Chronopotentiometric curves and potential sweep curves are shown in Fig. 10 and 11. It is seen that the same kinetic scheme, complex dissociation, is valid for the polyelectrode as for the main wave of the single electrode.

Rate of electroless deposition and the rate of dissociation of the complex.—The rate of electroless deposition of copper has been determined electrochemically and gravimetrically. The rate expressed electrochemically, *i.e.*, the deposition current, is obtained from the cathodic polarization curve for the polyelectrode. Both methods are in agreement in the limits reported previously. Results are compared in Tables II and III. The first conclusion from these tables is that there is a direct proportionality between the rate of deposition and the rate of dissociation of the complex as indicated by the slope of the curves $i_p/v^{1/2}$ *vs.* v. The plot of the i_{dp} *vs.* the slope is a straight line.

Discussion

Partial cathodic processes.—Kinetic scheme.—From our studies of the single electrode one can conclude that the reduction of the studied metal complexes proceeds simultaneously from the species adsorbed at the

Table II. Deposition current (i_{dp}) and the rate of dissociation of the complex R = ligand/Cu^{2+} = 1.2

electrode and the species resulting from the dissociation of the complex.

Since the prewave shows characteristics of the process involving reduction of adsorbed species, and since the deposition current increases with the increase of the ligand/copper(II) ratio from 1.2 to 3.0, one can conclude that the mechanism of the first wave is the catalytic mechanism of the type proposed and studied by Mark *et al.* (13). According to this theory the ligand is interposed between the electrode and the metal ion and forms the surface complex. This can be taken at least as a temporary explanation until further studies are available.

Table III. Deposition currrent (i_{dp}) and the rate of dissociation of the complex R = ligand/Cu^{2+} = 3.0

Cu(II) complex with the ligand	E_{MP_2} −mV *vs.* SCE	i_{dp} 10^{-3} A/cm^2	Single electrode $\partial(i_{p2}/v^{1/2})/\partial v$ 10^{-2}

CDTA	685	5.4	1.12

The reaction of dissociation of the complex occurs in the reaction layer which can be in the first approximation taken as the outer Helmholtz plane, as compared to the prewave reaction which takes place in the X_2 plane.

Rate of deposition and the rate of dissociation of the metal complex.—We have discussed the relationship between the rate of dissociation of the complex and the deposition current. Another desirable aspect of the discussion of the rate of deposition is one that will include the stability constant of the complex. This aspect cannot be discussed now since there is not enough data on the composition of the solutions used in electroless deposition of copper. To give just one example of the complexity of this problem let us mention that at *p*H higher than 11 there are at least three simultaneously existing complexes in the solution of Cu(II) ions and EDTA: CuEDTA, Cu(OH)EDTA, and $Cu(H_2O)$EDTA. The stability constant of the CuEDTA complex is $10^{18.8}$ and that of Cu(OH)EDTA is 10^2.

We would like to point out some of the factors one has to take into account when trying to compare different complexes with respect to the rate of deposition and the stability constant of the complex. The two most important factors are as follows: (*a*) simultaneous existence of the complex where the metal ion is fully coordinated by the ligand and the complexes where the metal ion is partially coordinated by the ligand, and (*b*) division of functions between different complexes. By this we mean the possibility of the situation when one complex species is controlling the bulk properties and the other species is controlling the electrochemical activity at the electrode.

Since we have established correlation between the rate of electroless deposition of metal and the rate of dissociation of the metal complex it is important to consider dissociation and formation kinetics of metal complexes in order to interpret differences found in the rate of dissociation and in order to find a basis for selection of the ligand which could be used in electroless plating. Additional information, besides the knowledge of a set of elementary steps in the kinetic scheme, is needed in order to understand kinetics and mechanism of deposition at the molecular level.

By comparing rates of dissociation of examined complexes we expect to determine the factors that control the kinetics of reactions. Assuming that the formation and dissociation of the bonds beyond the second are fast in comparison with the two first bonds we can base our discussion on the kinetics of ligands forming two bonds only, *i.e.*, bidentate ligands.

The general dissociative mechanism proposed by Eigen (14) expresses the reaction between hydrated metal ions with the bidentate ligand, *e.g.*, with two nitrogen donor atoms, by the following scheme

$$M(H_2O)_6^{a+} + \begin{matrix} N^{b-} \\ | \\ N \end{matrix} \overset{K_{os}}{\rightleftarrows} M(H_2O)_6^{a+} \cdots \begin{matrix} N^{b-} \\ | \\ N \end{matrix} \qquad [1]$$

$$M(H_2O)_6^{a+} \cdots \begin{matrix} N^{b-} \\ | \\ N \end{matrix} \overset{k_2}{\underset{k_{-2}}{\rightleftarrows}} (H_2O)_5M \begin{matrix} N^{a-b} \\ | \\ N \end{matrix} \qquad [2]$$

$$(H_2O)_5M \begin{matrix} N^{a-b} \\ | \\ N \end{matrix} \overset{k_3}{\underset{k_{-3}}{\rightleftarrows}} (H_2O)_4M \begin{matrix} N^{a-b} \\ | \\ N \end{matrix} \qquad [3]$$

where K_{os} is the equilibrium constant for the formation of an outer sphere complex (the association constant); k_2 and k_{-2} are the rate constants for the first metal-nitrogen bond formation and rupture, respectively; k_3 and k_{-3} are the rate constants for second metal-nitrogen bond formation and rupture, respectively, or closing and opening the ring. The over-all dissociation

rate constant k_d^{ML} (L, ligand) for the above kinetic scheme is given by (15)

$$k_d^{ML} = \frac{k_{-2}k_{-3}}{(k_{-2} + k_3)} \quad [4]$$

and if $k_3 >> k_{-2}$ as is usually the case

$$k_d^{ML} = \frac{k_{-2}k_{-3}}{k_3} \quad [5]$$

Many experimental results can be interpreted by assuming that (15-21) the rate of dissociation of a complex is sterically controlled by the formation step k_3, Eq. [5].

According to Eq. [5] a decrease in the rate constant k_3 produces an increase in the dissociation rate constant k_d^{ML}. Dissociation of tartrate, EDTA, Quadrol, and CDTA complexes of copper can be compared in terms of k_3 rate constants. Since k_3 is the formation rate constant one should briefly consider factors that determine the rate of formation of a complex. According to the general dissociative mechanism the first step is formation of the outer-sphere complex. The second step involves rupture of metal-water bond, formation of the intermediate with the lower coordination number (5 for copper), and insertion of the ligand into the inner coordination sphere. With the polydentate ligand having different donor atoms in the same molecule, in our case N and O, the initial bonding can be to a nitrogen donor (mechanism I) or to an alcoholic oxygen donor atom (mechanism II). Tartrate, EDTA, Quadrol, and CDTA have two alternative mechanisms for formation of the first metal-ligand bond. Both of these mechanisms involve steric hindrance (17, 18). Steric factors in k_2 or k_3 reflect the fact that majority of possible ligand configurations in the outer-sphere (for k_2) or in the single-bonded ligand (k_3) have to have a configuration suitable for bonding or configurational change has to occur. Configurational changes of complexes used in this work involve rotational barriers around a single bond and the barrier for boat-chair configurational change (CDTA). Since the rotational barrier increases with the size of substituent (—CH_2COOH, —$CH_2CH[OH]CH_3$) and since barrier for the boat-chair change is larger than the rotational barrier (22) it follows that the steric hindrance increases in the following order: tartrate, EDTA, Quadrol, CDTA. The rate constants k_3 decrease in the same order. According to Eq. [5] the decrease in k_3 results in an increase of k_d^{ML}. Thus, k_d^{ML} increases in the order: tartrate, EDTA, Quadrol, CDTA. Thus the steric hindrance in the rate constant k_3, with Eq. [5], explains complex dissociation rate results obtained in this work. This discussion in terms of the general dissociative mechanism for the metal complexes can provide basis for selection of ligands in electroless deposition.

Above results point to k_3 steric control in the dissociation of metal complexes. One should also take into account that the internal conjugate base mechanism (ICB) can mask part of the steric effect due to enhancement of the rate of formation (17). Future work in selection of ligands for electroless deposition of metals should consider also steric effects (15) on k_{-2} and k_{-3}.

Acknowledgments

I am pleased to thank Dr. Robert Lippman, Adelphi University, Chemistry Department, for valuable comments during the preparation of the manuscript. Particular thanks are due to Dr. Karl Egerer, the Vice-President, and John McCormack, Director of Research, Photocircuits, for the permission to publish this paper.

Manuscript submitted June 11, 1976; revised manuscript received Oct. 6, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1977 JOURNAL. All discussions for the December 1977 Discussion Section should be submitted by Aug. 1, 1977.

Publication costs of this article were assisted by the Kollmorgen Corporation.

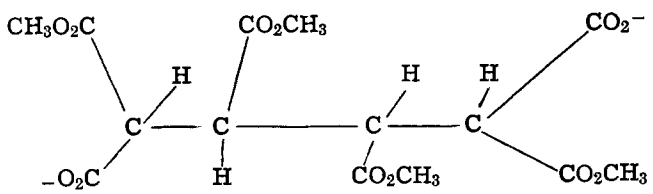
Electrocarboxylation Reactions

Rotating Ring-Disk Electrode, Voltammetric, and Electron Spin Resonance Studies of Dialkyl Fumarates and Maleates



Lun-Shu R. Yeh* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The reduction of the diactivated olefins dimethyl fumarate (DMeF), diethyl fumarate (DEF), di-n-butyl fumarate (DBF), dimethyl maleate (DMM), diethyl maleate (DEM), and di-n-butyl maleate (DBM), in N,N-dimethylformamide-tetra-n-butylammonium iodide solutions saturated with dissolved carbon dioxide at a platinum electrode has been studied by rotating ring-disk electrode and cyclic voltammetry and *in situ* electron spin resonance spectroscopy. The results indicate that the rate-determining step for each compound is the reaction of the radical anion with CO_2; the radical anions are also involved in the dimerization and (for maleates) isomerization reactions which occur in the absence of CO_2. The coupling of the carboxylated radical to dimeric carboxylate is rapid. The rate constants for the reaction of the radical anions with CO_2 were faster for maleates than for fumarates; pseudo-first order rate constants for a saturated CO_2 solution (*ca.* 0.2*M*) are DMeF, 1.5 sec^{-1}; DEF, 0.47 sec^{-1}; DBF, 0.35 sec^{-1}; DMM, 32.0 sec^{-1}; DEM, 19.4 sec^{-1}; and DBM, 18.0 sec^{-1}.

There have been numerous studies of the reactions of electrogenerated radical anions of diactivated olefins (1-12). Hydrodimers are the major product for reductions in aprotic solvents such as N,N-dimethylformamide (DMF), formed by coupling of radical anions followed by protonation. Thus for dialkyl fumarates (abbreviated throughout as F) the reaction sequence is

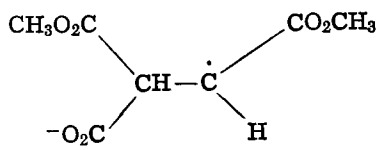
1 or $^{-}O_2CDCO_2^{-}$

$$F + e \rightarrow F^{\cdot -} \quad [1]$$

$$2F^{\cdot -} \xrightarrow{k_{2F}} D^{2-} \quad [2]$$

Recent studies (12, 13) show that the *cis*-forms (maleates or M) follow a similar reaction scheme

$$M + e \rightarrow M^{\cdot -} \quad [3]$$



$$2M^{\cdot -} \xrightarrow{k_{2M}} D^{2-} \quad [4]$$

but that the coupling rate for the radical anions derived from the maleates is about 2000 times that of the fumarate anions. Moreover, isomerization of $M^{\cdot -}$ also occurs

$$M^{\cdot -} \xrightarrow{k_1} F^{\cdot -} \quad [5]$$

Cross-coupling between $M^{\cdot -}$ and $F^{\cdot -}$ is also possible, but this rate is apparently slow compared to the reaction of two $M^{\cdot -}$'s (12).

Carbon dioxide has been shown to react with organic anionic intermediates generated electrochemically in aprotic media (14-17). Recently, Tyssee and Baizer (18, 19) studied the reduction of diactivated olefins in the presence of CO_2. For dimethyl maleate (DMM), production of the carboxylated dimer (**1**), 1,2,3,4-tetramethyl-1,1,2,3,4,4-butanehexacarboxylate, was demonstrated. These authors suggested

2 or $MCO_2^{\cdot -}$

two possible reaction paths leading to **1**: dimerization of $M^{\cdot -}$, [4], followed by reaction with CO_2

$$D^{2-} + 2CO_2 \rightarrow {}^{-}O_2CDCO_2^{-} \quad [6]$$

or reaction of $M^{\cdot -}$ with CO_2 to form the carboxylated radical anion (**2**) followed by dimerization

$$M^{\cdot -} + CO_2 \xrightarrow{k_M} MCO_2^{\cdot -} \quad [7]$$

$$2MCO_2^{\cdot -} \rightarrow {}^{-}O_2CDCO_2^{-} \quad [8]$$

An alternate path would involve coupling of $MCO_2^{\cdot -}$ with M followed by reduction and carboxylation, but the independence of yield of **1** with initial concentration of maleate makes this route less likely (19). An additional reaction path involves the ECEC sequence, [3], [7], followed by further reduction of **2**

$$MCO_2^{\cdot -} + e \rightarrow MCO_2^{2-} \quad [9]$$

$$MCO_2^{2-} + CO_2 \rightarrow {}^{-}O_2CMCO_2^{-} \quad [10]$$

3

where **3** is 1,2-dimethyl 1,1,2,2-ethanetetracarboxylate (18). The reduction in [9] occurs at somewhat more negative potentials than that in [3], so that this path is not significant at potentials of the first reduction wave.

In the work described here, the rate constants for the reaction of the radical anions with CO_2 were determined and the reaction paths of the carboxylated intermediates investigated. The reaction scheme for the maleates is quite complicated, since the rather rapid coupling and isomerization reactions [(for DMM, k_{2M}

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
Key words: reductive coupling, rotating disk electrode, *cis-trans*-isomerization, carboxylation.

$= 1.9 \times 10^5\ M^{-1}\ sec^{-1}$ and $k_1 = 2.2\ sec^{-1}$ (12)] occur in addition to the carboxylation reactions. The fumarates have a slower coupling reaction, and diethyl fumarate (DEF) and di-n-butyl fumarate (DBF) show no appreciable coupling on the RRDE time scale [for DEF and DBF, $k_{2F} = 44\ M^{-1}\ sec^{-1}$ and $25\ M^{-1}\ sec^{-1}$, respectively (5)]. Thus in the absence of CO_2 both DEF and DBF show the theoretical collection efficiency, N, for generation of radical anions at the disk and collection at the ring electrode. Here, changes in the collection efficiency upon addition of CO_2 for different concentrations of DEF and DBF can be used to study the reaction of $F^{\cdot -}$ and CO_2. The study was also extended to the maleates, taking account of their inherent reactions using rate constants determined previously (12), so that a comparison of the reactivity of the radical anions derived from the *cis-* and *trans-* forms of the same species could be made.

Experimental

The reagents, purification schemes, apparatus, and techniques were the same as those previously described (12). The CO_2 was instrument grade 99.99% from Big Three Industries, Incorporated. The RRDE with platinum disk and ring electrodes, constructed by Pine Instrument Company (Grove City, Pennsylvania), had $r_1 = 0.187$ cm, $r_2 = 0.200$ cm, and $r_3 = 0.332$ cm with a collection efficiency of 0.555.

In carboxylation experiments, CO_2 was bubbled through the solution for at least 30 min before the trials, and CO_2 was passed over the solution surface during the experiments. The cell was as used previously (12) with a Pt wire spiral auxiliary electrode in a separate compartment and a silver wire pseudo-reference electrode (Ag RE) also in a separate chamber connected to the RRDE chamber by sintered-glass disks. The electron spin resonance (ESR) measurements, carried out with a Varian Associates (Palo Alto, California) Model E-9 spectrometer at 100 kHz field modulation, followed the usual arrangement for *intra muros* electrochemical methods (20) with a Varian electrolytic cell accessory. The electrolysis current was maintained at a low level so that the working electrode potential was at the foot of the first reduction wave. Nitrogen was continually being bubbled in the solution reservoir before and during the experiments when they were conducted in the absence of CO_2. The flat cell was flushed with nitrogen before oxygen-free solution containing DMF, TBAI, and sample was introduced into it. The same solution in the reservoir was then continually bubbled with CO_2 before and during the experiments involving reactions with CO_2. The flat cell compartment was then flushed with an excess amount of CO_2-saturated solution to rinse it before a new experiment was conducted.

The concentration of dissolved CO_2 in the 0.1*M* TBAI-DMF solution was determined by adding 13 ml of 0.1*M* TBAI-DMF solution to a 25 ml volumetric flask followed by the placement of loosely packed glass fiber in the neck of the flask. CO_2 was slowly bubbled through this solution for 20 min and an increase in weight of 115 mg was observed. This corresponds to 0.2*M* dissolved CO_2 in the solution at room temperature (*ca.* 24°C) (neglecting any loss of DMF); the literature value for pure DMF at 20°C is 0.228*M* (21).

Results and Discussion

Dimethyl fumarate (DMeF), Diethyl fumarate (DEF), and Di-n-butyl fumarate (DBF).—Cyclic voltammograms for 0.1*M* TBAI-DMF solutions of DEF in the absence and presence of CO_2 are given in Fig. 1; the results for DMeF and DBF are very similar. The large decrease in the reversal anodic peak height indicates the consumption of $F^{\cdot -}$ by CO_2. The cathodic peak height does not change upon addition of CO_2, showing that the ECE route leading to **3** is not significant on this time scale (at these potentials). No additional oxidation peaks were observed suggesting that the $FCO_2^{\cdot -}$ formed is rapidly consumed in a following reaction.

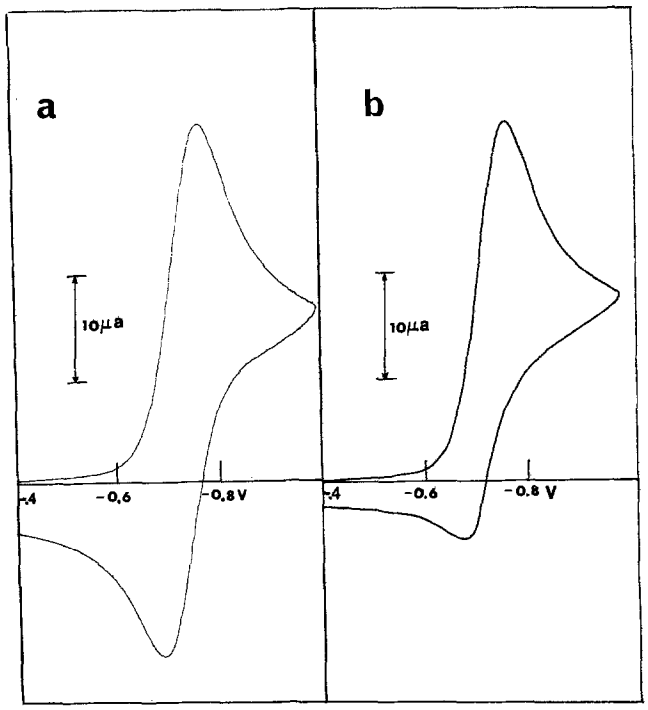


Fig. 1. Cyclic voltammograms (v = 100 mV/sec) of 0.1M TBAI-DMF solutions of 1.22 mM diethyl fumarate (a) without and (b) saturated with CO_2.

Rotating disk electrode (RDE) voltammograms (i_d *vs.* E_d) taken in the absence of CO_2 for millimolar solutions of DMeF and DEF exhibit a reduction wave at $E_{1/2} = -0.75$V *vs.* Ag-RE followed by a dip (at *ca.* −1.60V) in i_d after development of a well-defined plateau (22,23). This dip develops into a second reduction wave on addition of water or acid. In the presence of CO_2, the reduction potential of the first wave of these compounds shifted slightly (10-20 mV) to less negative potentials and the dip disappeared. This disappearance can be attributed to the reaction of F^{2-} with CO_2 thus decreasing the extent of the F^{2-}/F reaction which produces the dip (22). This effect was not investigated further and the discussion here is limited to processes occurring at the first reduction wave. Typical RDE data for the fumarates and values of the Levich constant $i_{d,l}/\omega^{1/2}C$ (where $i_{d,l}$ is the limiting disk current, ω is the angular velocity, and C the concentration) are given in Table I. For DBF this constant is essentially independent of ω and C. For DEF and DMeF a slight decrease in the Levich constant with increasing C is observed, perhaps caused by a small contribution of polymerization reaction consuming parent material. To obtain information about the rate of the $F^{\cdot -}/CO_2$ reaction and the mechanism of the reaction, RRDE experiments were undertaken, and the variation of the kinetic collection efficiency, N_k, expressed as the ratio of the ring current, i_r, to the disk current, i_d

$$N_k = |i_r/i_d| \qquad [11]$$

as a function of the disk current parameter *CONI* (4), where

$$CONI = |i_d/i_{d,l}| \qquad [12]$$

at different values of ω and C was determined. These N_k values were compared to working curves obtained by digital simulation (24) assuming the following reaction

$$F^{\cdot -} + CO_2 \xrightarrow{k_F} FCO_2^{\cdot -} \qquad [13]$$

was rate determining. This reaction can be considered as a pseudo-first-order one, since the concentration of CO_2 in a saturated solution is 50-100 times that of the $F^{\cdot-}$. As in previous studies (4, 24), the dimensionless kinetic parameters XKT (first-order reactions) and $XKTC$ (second-order reactions), defined as

$$XKT = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}\omega^{-1}k_1 \quad [14]$$

$$XKTC = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}\omega^{-1}Ck_2 \quad [15]$$

were employed.

Typical RRDE results for DMeF, DEF, and DBF are shown in Table II. In the absence of CO_2, $N_k = N$, the theoretical collection efficiency (0.555), for both DEF and DBF. In the presence of CO_2, N_k is appreciably smaller than N for both compounds, showing a significant extent of reaction between the radical anion and dissolved CO_2 on the RRDE time scale. The independence of N_k with concentration and $CONI$ for these two compounds agrees very well with an uncomplicated pseudo-first-order mechanism. Typical results for DMeF are shown in Fig. 2. The slight dependence of N_k on $CONI$, can be attributed to the simultaneous occurrence of the $F^{\cdot-}$ dimerization reaction (12). However, the N_k values are considerably smaller than those under identical conditions but without dissolved CO_2.

The experimental points in Fig. 2 were fit by using the known dimerization parameter, $XKTC$, and adding the pseudo-first-order reaction parameter XKT for k_F. Values of k_{2F} were obtained previously (12); for

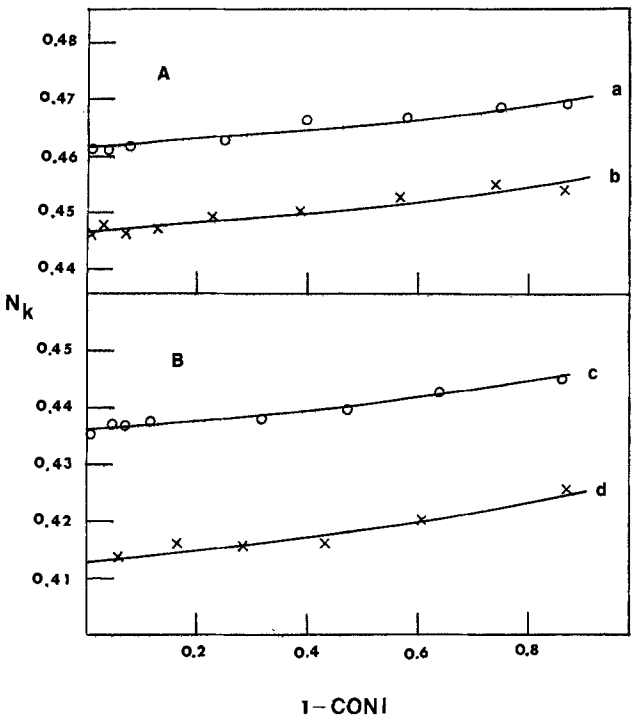

Fig. 2. Collection efficiency (N_k) vs. 1-*CONI* for dimethyl fumarate in presence of CO_2. Experimental points: (x) $\omega = 109$ sec^{-1}, (o) $\omega = 157$ sec^{-1}, (A) 0.83 mM DMeF, (B) 1.37 mM DMeF. Theoretical lines correspond to (a) $XKTC = 0.0086$, $XKT = 0.135$; (b) $XKTC = 0.0127$, $XKT = 0.16$; (c) $XKTC = 0.0144$, $XKT = 0.18$; (d) $XKTC = 0.0208$, $XKT = 0.22$.

DMeF $k_{2F} = 110$ M^{-1} sec^{-1}. *XKTC* values were calculated for the various concentrations and rotation rates used in this work. For example, line a in Fig. 2 was generated by digital simulation using $XKTC = 0.0127$ and $XKT = 0.16$ for $C = 0.83$ m*M*. These lines fit the experimental points quite well. Values of *XKTC* for DEF and DBF were negligible compared to *XKT*. Values of *XKT* and k_F for these three compounds obtained by this method at different *C* and ω values are given in Table III. The average values of k_F are DMeF, 1.5, DEF, 0.47, and DBF, 0.35 (sec^{-1}). The fit of the data to this pseudo-first-order mechanism is persuasive evidence for the reaction sequence [13] and [16] with rapid coupling of the $FCO_2^{\cdot -}$

$$2FCO_2^{\cdot -} \rightarrow {}^-O_2CDCO_2^- \qquad [16]$$

In an attempt to detect $FCO_2^{\cdot -}$, several ESR experiments were undertaken. A 10 m*M* DEF solution was reduced with a constant current of 20 μA in a flat cell inside the cavity of the ESR spectrometer. The steady-state spectrum which resulted after about 1 min of electrolysis was essentially the same as those previously reported (20, 25). The spectrum obtained in a saturated CO_2 solution was the same as that from a CO_2-free system. The ESR spectrum of $FCO_2^{\cdot -}$ would be different than that of $F^{\cdot -}$, since the added CO_2 would change the symmetry and the proton hyperfine coupling constants. Hence the $FCO_2^{\cdot -}$ species must be too short-lived to detect by this method. The reaction of $F^{\cdot -}$ and CO_2 can be seen, however, from the time dependence of the spectra (Fig. 3). After steady-state signals were generated, the constant current responsible for generating the radical anion was turned off and the spectrum was recorded immediately at a

[a] The solutions were all 0.1*M* TBAI in DMF. The RRDE had $r_1 = 0.187$ cm, $r_2 = 0.200$ cm, and $r_3 = 0.332$ cm.
[b] *XKTC* is digital simulation parameter for dimerization of the anion radicals $2F^{\cdot -} \rightarrow D^{2-}$ with reaction rate constant k_{2F} from Ref. (4).
[c] $XKTF = (0.51)^{-2/3} \nu^{1/3} D^{-1/3} \omega^{-1} k_F$, $\nu = 0.00849$ cm^2/sec for the reaction of the radical anion with saturated CO_2, $F^{\cdot -} + CO_2 \xrightarrow{k_F} FCO_2^{\cdot -}$ as a pseudo-first-order reaction.
[d] Negligible dimerization reaction on the RRDE time scale, data from Ref. (5).

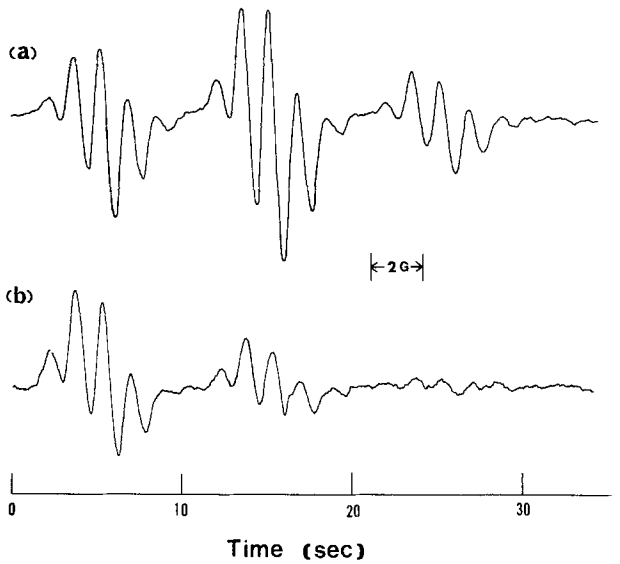

Fig. 3. ESR spectra of 10 mM diethyl fumarate in 0.1M TBAI-DMF electrolyzed at 20 μA in (a) absence and (b) saturated with CO_2. Scan rate 40 G/min.

high scan rate (40 G/min). At this scan rate, good resolution was sacrificed but any differences in signal intensities with time were recorded. In the presence of CO_2 (Fig. 3b) the ESR signals decayed almost to zero 30 sec after the current was turned off. On the other hand, ESR signals still remained reasonably strong in the absence of CO_2 (Fig. 3a) when the generating current was turned off after the same period of time.

Dimethyl maleate (DMM), diethyl maleate (DEM), and di-n-butyl maleate (DBM).—The analysis of the behavior of the maleates parallels that of the fumarates, but is more complicated because of the rapid isomerization and coupling reactions of $M^{\cdot-}$. In the presence of CO_2 the voltammetric reduction waves at the RRDE (at −1.0V *vs.* Ag-RE) are shifted slightly (10-20 mV) toward less negative potentials with essentially no change in the Levich constant (Table I) compared to solutions without CO_2. Variation of N_k with *CONI* [(defined as in (12)] was determined at several values of C and ω; typical results are given in Fig. 4. For determinations of N_k, E_r was adjusted to −0.8V *vs.* Ag-RE, on the plateau of the fumarate reduction wave (where F is reduced to $F^{\cdot-}$ and $M^{\cdot-}$ is oxidized to M). Under these conditions the contribution of $M^{\cdot-}$ oxidation to the ring current can be determined, as discussed previously (12). The N_k values so obtained were used to determine the pseudo-first-order rate constant, k_M (or *XKT*), using the values of k_1 and k_{2M} measured in the absence of CO_2 and digital simulation methods. The solid lines in Fig. 4 are such simulated curves and results for maleates are given in Table IV. Note that carboxylation of $F^{\cdot-}$ (resulting

from isomerization of $M^{-\cdot}$) does not enter into this calculation, since E_r is such that $F^{-\cdot}$ is not oxidized at the ring, and $FCO_2^{-\cdot}$ is too short-lived to be detected. The values of k_M so calculated are: DMM, 32; DEM, 19; and DBM, 18 (sec^{-1}).

Conclusions

The carboxylation reactions of the *cis-* and *trans-*radical anions in general follow previously reported behavior (12, 13). The reaction rate constants decrease slightly as the alkyl group becomes more bulky, because of steric hindrance. The maleate radical anions are much more reactive toward CO_2 than the corresponding *trans-* species, as has previously been seen for radical ion coupling and for reaction with acrylonitrile. This has been attributed to greater electron density at the central ethylenic carbon atoms because of charge repulsion of the neighboring carbonyl groups.

The Ag^+-Ag Exchange Reaction in Aqueous Acidic Nitrate Electrolyte

and N. Hackerman*

Department of Chemistry, Rice University, Houston, Texas 77001

ABSTRACT

The exchange reaction at polycrystalline silver electrodes has been investigated for the system Ag-$AgNO_3$-KNO_3 using a faradaic impedance method. The exchange reaction was determined to be adatom diffusion controlled and the exchange current was found to be dependent on pH. It is suggested that H_3O^+ inhibits the exchange reaction through an adsorption process which blocks the crystal growth sites.

Few investigations have been made of the exchange mechanism for the system

$$Ag^+_{(soln)} + e \rightleftharpoons Ag_{(s)} \qquad [1]$$

in aqueous solutions. This is surprising as silver would not be expected to suffer, to the same degree, from the formation of oxide or hydroxide films on the electrode surface as do many other more extensively studied metals, *i.e.*, the exchange reaction should not be complicated by the possibility of chemical and electrochemical reactions of the type

$$M(H_2O)^{n+}_{y(soln)} \rightleftharpoons M(H_2O)^{n+}_{y(ads)}$$

$$M(H_2O)^{n+}_{y(ads)} \rightleftharpoons M(OH)_n + nH_3O^+ \qquad [2]$$

$$M(OH)_{n(ads)} + ne \rightleftharpoons M_{(solid)} + nOH^-_{(soln)}$$

The absence of a surface oxide or hydroxide film is further indicated by the large polarizable region exhibited by silver (1) [~0.5 to −1.1V (NHE)]. This

* Electrochemical Society Active Member.

suggests that silver would be a suitable solid metal for investigating the electrode exchange reactions. Previous studies which have been made with this system have, however, yielded quite different values for the kinetic parameters.

In a preliminary investigation, Mehl and Bockris (2), using a galvanostatic technique, showed that the rate-determining step for the exchange reaction in the system Ag-$AgClO_4$-$HClO_4$ (aqueous) was dependent on the overpotential (η). For $\eta < 60$ mV [*i.e.*, low i (current)], the reaction was surface diffusion controlled while at larger overpotential (*i.e.*, high i), the charge transfer reaction was rate determining. Using a value of $i_o = 1 \times 10^{-1}$ A · cm^{-2} (for $[AgClO_4] = 2 \times 10^{-1}$M) where i_o = the exchange current for the charge transfer reaction at the equilibrium potential obtained by extrapolation of the η-log$i$ relation at $\eta < 60$ mV, the surface coverage of the electrode by adatoms was calculated to be $\simeq$10%. Despic and Bockris (3), again, using a galvanostatic technique showed that for the system Ag-$AgClO_4$-$HClO_4$ (aqueous) the rate-controlling step was dependent on the overpotential. This investigation is of interest because of the careful techniques used in solution purification and electrode preparation. Values of i_o varying from 0.04 to 1.8 A · cm^{-2} were obtained and appear to be dependent on the electrode used, electrode preparation, and concentration of $AgClO_4$ (concentrations of $AgClO_4$ used were 3.64×10^{-1}, 7.24×10^{-2}, and 1.21×10^{-3}M). The adatom concentration at equilibrium (C^o_{ad}) was calculated and values in the range 3×10^{-11} to 1.6×10^{-9} mole · cm^{-2} were reported which also appear to be dependent on the electrode used and the electrode preparation. In addition, a value of $\sim$76 μF · cm^{-2} for the double layer capacitance of the silver electrodes was given. Gerischer and Tischer (4) using a potentiostatic jump and double impulse methods studied the system Ag-$AgNO_3$-$HClO_4$ and reported exchange currents $i_o = 0.15$ A · cm^{-2} (for $[Ag^+] = 10^{-3}$M) and $i_o = 4.5$ A · cm^{-2} (for $[Ag^+] = 10^{-1}$M) for the charge transfer process from which a "standard exchange current" ${}^oi = 24$ A · cm^{-2} was calculated by normalizing the concentrations to $Ag^+ = 1.0$M using the relationship

$$i_o = {}^oi \left[\frac{[Ag^+]}{[Ag^+]_o} \right]^\alpha$$

where α = transfer coefficient, $[Ag^+]_o = 1.0$M, and $[Ag^+]$ = experimental silver concentration. In addition, they showed that the adatom concentration at the electrode surface was dependent on current density and that the lattice incorporation process was the slow step in the reaction. Gerischer (5), in a further study using a galvanostatic technique, investigated the system Ag-$AgClO_4$-$HClO_4$ and concluded that the adatom layer is an intermediate product of the over-all reaction which covers at least 1% of the surface at 25°C with an enthalpy of formation of $\sim$10.5 kcal · $mole^{-1}$. The bonding of the layer showed 30-40% ionic character. Lorenz (6), using an impedance technique, studied the system Ag-$Ag(NH_3)_2^+$ and reported that the crystalline growth is determined by surface diffusion rates as predicted by theory. Canagaratna and Karunathilaka (7), using a faradaic impedance method, studied the system Ag-$AgNO_3$-KNO_3. Unfortunately, their method of electrode construction and apparent lack of any attempt to purify their solutions makes it likely that their electrodes were "poisoned" by organic surfactants. This is indicated by their impedance plots which, in one of our (D.L.) previous experiments are typical of plots obtained in "impure" solutions. Recently, Cachet *et al.* (8) studied the system Ag-$AgNO_3$-KNO_3 using both polycrystalline and single crystal (100), (110), and (111) silver electrodes. They suggest the possible interaction of the nitrate anions with silver ions to form adsorbed species on the electrode surface of the type $Ag(NO_3)_{ads}$.

Previously, one of us (D.L.) has had some success in studying solid metal systems in ultrapure electrolytes. The present paper represents our results obtained with polycrystalline silver electrodes under similar conditions using the faradaic impedance method.

Experimental

Electrode construction.—Silver wire (supplied by Materials Research Corporation, Marz grade 5*N*) was covered with polyethylene film and sealed into a glass tube. (The polyethylene film was produced by covering the silver electrode with polyethylene powder and gently heating until a thick layer of polyethylene was built up.) This material has been shown previously to be nonsurfactant by observing its effects over a period of time on the double layer capacitance of a sitting mercury drop electrode; no decrease in capacitance was noted. The polyethylene sheath was then cut laterally to expose a cross section of the silver wire. The nominal area of the silver electrode was 4×10^{-3} cm^2.

Electrode preparation.—The silver electrode was first polished on roughened glass using bidistilled water as a lubricant, then etched electrochemically in 10% v/v nitric acid at 100 μA (per electrode area) for 30 sec and then allowed to etch chemically for 30 sec. The electrode was washed immediately with bidistilled water and transferred to the electrolytic cell. After each measurement, the electrode was polished back on roughened glass to expose an essentially new electrode surface. A reoccurring problem with this method of electrode preparation was that after repeated use the etching solution appeared to "age" and produced electrodes which behaved erratically. The reason for this could not be ascertained; use of a new etching solution invariably solved the problem.

Electrolytic cell.—The electrolytic cell consisted of three compartments; one containing a reference electrode (mercurous sulfate/mercury) separated by a potassium nitrate (1.0M) salt bridge from the other two which were connected via a coarse frit and contained, respectively, a platinum gauze counterelectrode (nominal area 100 cm^2) and the test electrode. The electrolyte solution was under an atmosphere of oxygen-free nitrogen and purified by continuous circulation through purified (12) activated charcoal. Silver solutions are well known to be light sensitive and because of the long purification times needed (see below) these cell solutions needed to be shielded from light. The cell was therefore constructed from Pyrex glass and then all outside surfaces of the cell were covered with a dark brown stain which was "fired" into the glass in an annealing oven. The stain penetrated a small distance into the glass but did not diffuse through the glass to the inside surfaces of the cell. This technique was very successful and, once in the cell, no deterioration of the silver solutions was noted even after long periods of time (many weeks).

All solutions were prepared using ACS grade reagents and bidistilled water. The solutions were kept at a constant NO_3^- concentration (1.0M) throughout all the experiments.

Electrical circuit.—All measurements were made using a Schering bridge (frequency range 20 Hz-20 kHz) of essentially the same design as described by Farr and Hampson (9). The analysis of the data was performed by an iterative technique which has been used in a number of previous papers (10, 11) and was first described by Farr and Hampson (9). This method was modified to enable the computer to select the best fit of R_L (the frequency-independent resistive component) and C_L (the frequency-independent capacitive component) of the electrode impedance; previously these were selected by inspection.

Results

Satisfactory impedance behavior was obtained only after exhaustive purification. The criterion adopted was

Table I. Values of R_D at differing $[Ag^+]$ concentrations, pH = 2.40; $[NO_3^-] = 1.0M$

	—	—	3.9	—	3.8	—
	—	—	—	—	4.2	—
Average value of R_D in ohms	3.9 ± 0.2	3.9 ± 0.3	3.7 ± 0.3	4.0 ± 0.3	3.8 ± 0.2	3.9 ± 0.3

that a steady value of R_D (the exchange resistance) was obtained over a period of at least 3 days. Continuous circulation of the solution through activated charcoal for a period of 10 days was generally adequate to achieve this. Initially, even in purified solutions, stable values for R_D were not obtained until 24 hr after etching and placing in the electrolytic cell. Figure 1 shows typical time-dependent behavior of the electrodes. The time to reach a constant value was independent of $[Ag^+]$ concentration and pH. Electrodes reached a stable value of R_D after ~24 hr and this value was constant for many days.[1] Figure 2 shows typical impedance plots of R_R and $1/\omega C_R$ *vs.* $\omega^{-1/2}$ for varying concentrations of $[Ag^+]$ at constant pH. Table I gives values of R_D obtained at different $[Ag^+]$ concentrations. Each value is for an essentially new electrode surface (see electrode preparation above for details). Table II shows typical values of R_D obtained at constant $[Ag^+]$ concentrations and varying pH. The same criteria for each value of R_D in Table II holds as for Table I. Figure 3 shows the variation of R_D and C_L (the frequency-independent capacitive component of the electrode impedance) as a function of pH. There was no variation in R_L (the frequency-independent resistive component of the electrode impedance).

The electrode potential *vs.* mercurous sulfate/mercury reference electrode was measured as a function of $[Ag^+]$ concentrations and showed good nernstian behavior with $n = 1.05$.

Discussion

The Schering bridge was found to operate satisfactorily over a frequency range 20 Hz-20kHz; the lower limit being set by the null detector and the upper limit

[1] Constant values for R_D for periods up to 1 week were recorded.

by the increasing effect of random phase shifts introduced by the nonideality of the circuit components. However, from Fig. 2, it can be seen that impedance measurements are not reported below a frequency of

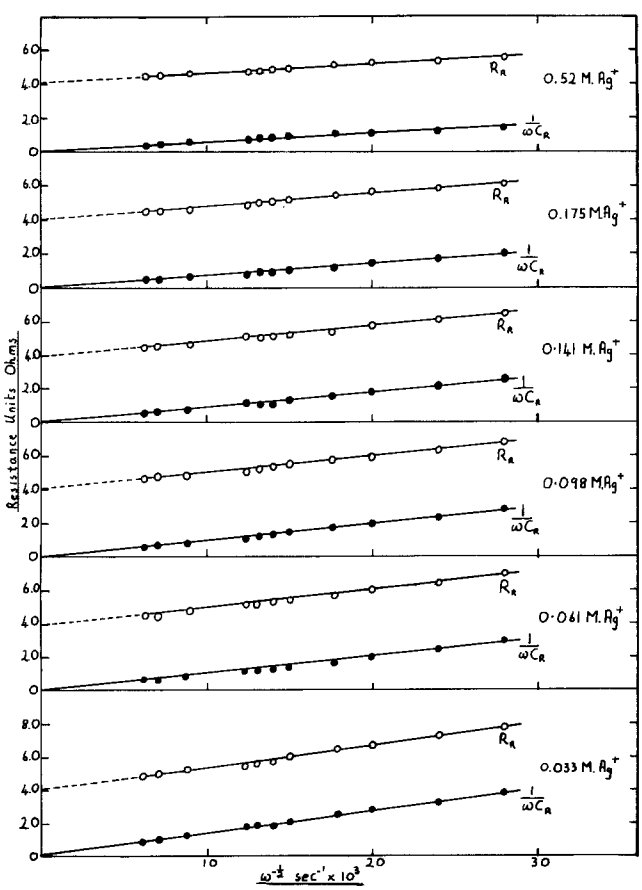

Fig. 2. Plots of R_R and $1/\omega C_R$ vs. $\omega^{-1/2}$ at differing $[Ag^+]$ concentrations, pH = 2.40.

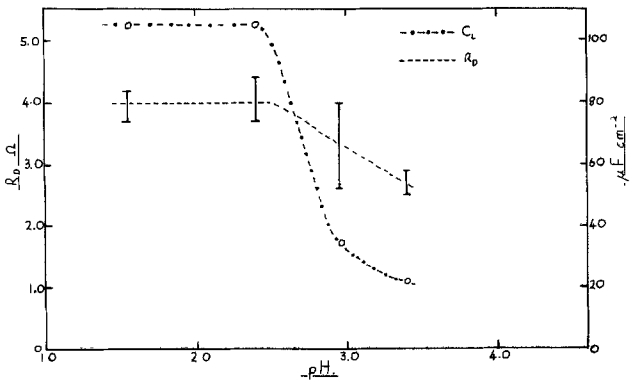

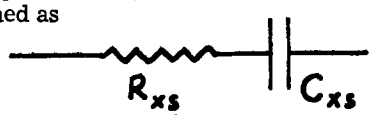

Fig. 3. Plots of R_D and C_L vs. pH, $[Ag^+] = 0.033M$, $[NO_3^-] = 1.0M$.

100 Hz. Experimentally, the total electrode impedance is determined as

where $1/C_{xs} = 1/C_{(ref)} + 1/C_{(test)}$, $C_{(ref)}$ = the capacitance of the platinum auxiliary electrode, and $C_{(test)}$ = the capacitance of the test electrode, as long as $C_{(ref)} >>> C_{(test)}$ then $1/C_{xs} \simeq 1/C_{(test)}$. For experimental systems, where large exchange currents are being measured, $C_{(test)} \simeq C_{(ref)}$ and the above approximation becomes invalid. For the data presented here at frequencies <100 Hz, $C_{(test)} \simeq C_{(ref)}$ which resulted in deviations from linearity for the plots of R_L and $1/\omega C_L$ *vs.* $\omega^{-1/2}$ at frequencies <100 Hz.

The analysis of our impedance data depends on C_L being frequency independent. However, C_L contains as one of its components the double layer capacitance C_{dl} (discussed below) which while theoretically independent of frequency can, in fact, vary with frequency because of frequency dispersion effects. In our present work these frequency dispersion effects do not appear to be significant as they would be expected to cause a deviation from linearity in our impedance plots. It can be seen from Fig. 1 that such effects, due to this process, were not observed and therefore any frequency dispersion effects of C_{dl}, if present, must contribute an error no greater than other experimental errors in our measurements.

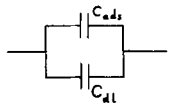

Figure 1 shows typical time dependent behavior of silver electrodes after introduction into the electrolytic cell. The time to reach a steady value of R_D was ~24 hr and was independent of $[Ag^+]$ concentration and pH. This time-dependent behavior has been discussed previously (13, 14) and is considered to be due to an equilibration process between the electrode surface and the solution with which it is in contact. The exchange current i_o calculated from the relationship

$$R_D = \frac{RT}{zFi_o}$$

gave an average value of 3.8 ± 0.2 A · cm^{-2} at pH values of ~2.4 and less while at greater values of pH this rose to a value of 5.5 ± 0.2 A · cm^{-2}. These values are larger than those reported by previous workers (2, 5, 7) which we attribute to the stringent purification technique used in this study. Consequently, the values of i_o reported here are probably more representative of the "true" value of the exchange current for the Ag^+-Ag reaction.

Table II shows that, within experimental error, at pH 2.4, the exchange current is independent of $[Ag^+]$ concentrations. This result is consistent with a rate-controlling step of adatom diffusion across the electrode surface and is in agreement with the results reported in previous studies (2-5).

Figure 3 shows that the value of R_D decreases at pH values larger than ~2.4 and is paralleled by a decrease in the value of C_L, the frequency-independent capacitive component of the electrode impedance. The value of C_L at pH 3.40 is that of the double layer capacitance of a polycrystalline silver electrode at a similar electrode potential (1). At pH values less than ~2.4, C_L can be considered as composed of two capacitances in parallel

C_{dl} = double layer capacitance, C_{ads} = capacitance due to an absorbed species at the electrode surface, where

$$C_L = C_{dl} + C_{ads}$$

It is suggested that the absorbed species is probably the hydronium ion (H_3O^+). At pH values ~2.4 and less, H_3O^+ is absorbed on the surface while at greater values of pH, H_3O^+ desorbs and, consequently, $C_{ads} \rightarrow 0$ and $C_L \rightarrow C_{dl}$. The effect reported here appears small and we suggest, therefore, that the H_3O^+ absorption is weak and that it may compete with other adsorbed species (*e.g.*, NO_3^- which has been suggested by Cachet *et al.* (8) to be absorbed at silver electrodes). The decrease in the value of R_D which accompanies the desorption of H_3O^+ suggests that H_3O^+ is inhibiting the Ag^+-Ag exchange reactions. As reported here and elsewhere (2-5), adatom diffusion is the rate-determining step, thus it appears that H_3O^+ may block the crystal growth sites on the silver metal electrodes, thereby inhibiting the reaction. At larger values of pH, H_3O^+ is desorbed and a corresponding increase in the exchange current is observed.

Electrochemical Synthesis of Tetrapropyl and Tetrabutyl Derivatives of Lead and Tin Via Alkyl-Zinc Intermediates

Giuliano Mengoli

Laboratorio di Polarografia ed Elettrochimica Preparativa, C.N.R., C.P. 1075, 35100 Padova, Italy

ABSTRACT

A novel electrochemical route, which gives favorable results for the synthesis of tetraethyl compounds of lead and tin, has been successfully applied to the preparation of higher tetraalkyl derivatives of the same metals. This synthesis may be accomplished by electrolyzing an alkyl halide between a zinc cathode and a lead or tin anode in an undivided cell. DMF and DMSO are suitable solvents and an alkaline salt may be used as the supporting electrolyte. The features of the synthetic process are mainly determined by cathodic zinc alkylation, which supplies the zinc alkyl intermediates for the anodic reaction. Thus tetraalkyl compounds of lead and tin are easily synthesized at room temperature when alkyl iodides are utilized, whereas poor yields are obtained when alkyl bromides are used as the alkylating material. However, it was found that by selecting suitable experimental conditions and by adding catalytic amounts of a lower alkyl iodide to the alkyl bromides, these halides too may be satisfactorily employed in the synthetic process.

Although industrial interest in electro-organic syntheses has been claimed repeatedly, few processes have so far found any practical application (1, 2).

However, because of their technological importance, the electro-organic syntheses of organometallic compounds, mainly the alkyl derivatives of lead and tin, exhibit some favorable features.[1] Indeed, the traditional chemical routes to these compounds often suffer from unsatisfactory yields, hazardous manufacturing operations, and can cause considerable pollution problems.

In such processes the electrodes may replace chemical reagents of high energy content, *i.e.*, sodium or potassium alloys and Grignard compounds (3) and because the molecular weights of the products are relatively high, satisfactory amounts of material are produced for each faraday of electricity consumed.

Useful results have been obtained for the syntheses of tetraethyl lead by the electrolysis of aluminum and magnesium ethyl derivatives at a lead anode, or by the reduction of ethyl halides at a sacrificial lead cathode (4-6).

However, the results were less satisfactory for the preparation of tin compounds as passivation of the tin anodes often occurred (5) whereas only for tetramethyl tin could good yields be obtained by the sacrificial reduction of alkyl halides (7-9).

Butyl chloride can be reduced at a tin cathode with the formation of butyl tin derivatives (10); the process although very interesting gives only tin compounds of low degrees of alkylation; the same syntheses fail at lead cathodes.

An alternative electrochemical route to the lower tetraalkyl derivatives of lead and tin has been recently devised in the author's laboratory: this synthesis basically consists in the electrolysis of an alkylating agent, alkyl halide (11, 12) or alkyl sulfate (13), between a zinc cathode and a lead or tin anode in an undivided cell. Good electrochemical solvents as dimethylformamide and dimethylsulfoxide are employed and cheap alkaline supporting electrolytes may be utilized.

The aim of this paper is to test the effectiveness of the method for synthetizing some higher tetralkyl derivatives of lead and tin: The contribution of the cathode and anode reactions to the process are examined and discussed.

[1] The manufacture of tetramethyl lead and tetraethyl lead by electrochemical methods has been run commercially for the past 10-15 years by the Nalco Chemical Company, Freeport, Texas (R. M. Hurd, Private communication).

Experimental

Materials.—The alkyl halides utilized in this work were commercially available reagent grade chemicals and were used as supplied. The supporting electrolytes, $NaClO_4$ and tetrabutylammonium perchlorate (TBAP), were dried at 70°C in a vacuum oven before use. The electrolytic solvents, dimethylformamide (DMF) and dimethylsulfoxide (DMSO), were dried by $CaCO_3$ and CaH_2, respectively, and distilled before use. Zinc, lead, and tin, 99% purity grade, were used for the electrodes. Nitrogen, 99.8% purity, was used for degassing the electrolytic cells.

Apparatus and procedure.—Lead and tin organocompounds were prepared by electrolyzing amperostatically (100 mA) 25 ml of solution placed in the simple undivided cell shown in Fig. 1. This consisted of a glass cylinder, a, equipped with a thermostated jacket, b; the cell was sealed at the top by a Teflon plug, c, bearing two glass tubes, d, for degassing the solution by nitrogen and two copper wires, e, for making the electrical contact with the electrodes. The cathode, f, was a zinc sheet rolled in the form of a cylinder (immersed area $\simeq$18 cm^2). The anode, g, was a lead or tin rod placed at the center of the zinc cylinder (immersed area $\simeq$5 cm^2). The distance between the electrodes was 0.5 cm.

Microscale experiments for elucidating the cathode and anode processes were performed by examining

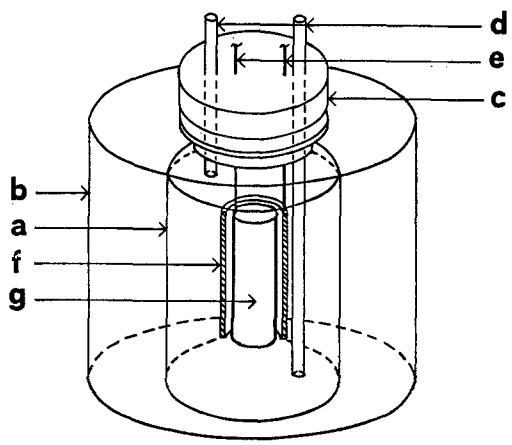

Fig. 1. Electrolytic cell used for the preparation of lead and tin tetraalkyl derivatives.

each electrode reaction separately using a steady-state potentiostatic technique.

Thus the reduction of alkyl halides at zinc was studied in a divided cell equipped with the following electrodes: the working electrode was a zinc disk (area $\simeq 0.2$ cm^2) which was sealed into a Teflon sheath; the secondary electrode was a platinum net which was separated from the cathode compartment by a N2 sinter glass. The reference electrode was an aqueous SCE and was separated from the working electrode by a Luggin capillary and a tap.

The same cell was used for investigating the anode reaction: the zinc electrode was thus substituted by a lead (or tin) microanode (area $\simeq 0.2$ cm^2) and some zinc alkyls were produced *in situ* by heating (or polarizing cathodically) a zinc sheet placed in the same compartment in the presence of suitable concentrations of alkyl halide. The amount of zinc alkyls formed was estimated from the weight loss of the zinc sheet.

The basic electric equipment used for the experiments was a 557 Amel potentiostat.

Analysis.—At the end of each preparative run the weight loss of both electrodes was determined, and the organolead (or organotin) compounds were recovered by extraction with n-hexane from the reaction mixture diluted with water. Their identification was made by gas chromatographic analysis using known standards: tetrapropyl and tetrabutyl derivatives were commercially available whereas the other organocompounds were prepared using published methods (3).

A Perkin Elmer Model 3920 gas chromatograph was used: it was equipped with a 2m column, $\phi = 2$ mm, packed with 8% bis(m-phenoxyphenoxy) berine + 2% Apiezon L on Chromosorb (80-100 mesh). The column temperature ranged from 100° to 160°C; the gas carrier (nitrogen) had a flow rate = 50 ml/min.

The presence of minor amounts of alkyl tin compounds was ascertained in a few instances by submitting the electrolysis products to mass spectrometric analysis, using a Hitachi-Perkin Elmer Model RMU 6 mass spectrometer.

Results

Synthesis of tetrapropyl lead and tetrapropyl tin.—Table I shows the experimental conditions and the results for the synthesis of tetrapropyl lead and tetrapropyl tin.

The runs were performed at 25°C using propyl iodide as the alkylating material and $NaClO_4$ as the supporting electrolyte.

The synthesis was studied in terms of the dependence on the propyl iodide concentration and the quantity of electricity passed. In addition to the variation of these parameters in the runs of Table I the weight loss of the electrodes, the number of faradays passed per gram atom of anode dissolved is reported together with the yield of organoderivative based on both the quantity of electricity passed and the loss in weight of the anode. The current yields were computed by assuming that 4**F** are necessary for producing 1 mole of tetraalkyl derivative.

It is clear that the process is based on the production of zinc alkyl intermediates at the cathode which are converted into organolead or organotin compounds at the anode. The formation of zinc alkyls (deducible from the cathode loss) consequently controls the efficiency of the whole synthetic process. Although a negligible weight loss occurred when using the same conditions as in Table I for unpolarized zinc sheets, the cathode dissolution of the runs (Tables I-II) cannot only be related to current effects but is largely determined by the concentration of propyl iodide in the system.

Additionally, the weight loss of the anode does not follow a constant stoichiometry with the quantity of electricity passed, to a first approximation the number of faradays required for the dissolution of one gram atom decreases from 4 to 2 as the propyl iodide concentration increases. For this reason the yields of tetraalkyl derivative based on the current may exceed 100% and often result in double those based on anode loss.

It has to be noted that the anode metal not converted to tetraalkyl derivative is generally present in solution

at some lower degree of alkylation, the mass spectroscopic analysis moreover gave evidence of the presence of higher molecular weight organotin compounds containing the Sn-Sn bond.

Synthesis of tetrabutyl lead and tetrabutyl tin.—Table II reports data which refer to the synthesis of tetrabutyl lead and tetrabutyl tin.

The experimental conditions of the runs were similar to those adopted for the synthesis of tetrapropyl derivatives: the concentration of the alkyl iodide is the main parameter which still affects the sacrificial loss of both the electrodes and the yields of the tetraalkyl derivative. The remarks above are again valid for a preliminary consideration of these data.

Synthesis of tetraisoamyl tin.—The experimental conditions and the results obtained for the synthesis of tetraisoamyl tin by using 1-iodo-3-methylbutane as alkylating material are reported in Table III.

At room temperature the sacrificial dissolution of the zinc caused by cathodic polarization is low when compared with the losses of Tables I and II, and the yield of organotin is very poor. However, an increase of temperature leads to active dissolution of the polarized zinc with a parallel greatly increased formation of tetraisoamyl tin.

The last column of Table III shows the extent of the zinc dissolution for unpolarized sheets (under the same conditions) caused by purely chemical reaction at various temperatures; it can be deduced that during the electrolytic process the spontaneous reaction is negligible below 50°C in comparison with that cathodically promoted: In contrast the zinc alkyl formation appears to mainly follow a chemical route at the highest temperatures.

In some instances (runs No. 35-37) the electrolyses were carried out using high concentrations of 1-iodo-3-methylbutane in the presence of small amounts of ethyl iodide: No substantial increase of yield was obtained in DMF (run No. 36), but the runs performed in DMSO (No. 35, 37) exhibited some ethyl iodide catalytic effect on the formation of tetraisoamyl tin and mixed isoamyl ethyl tin compounds.

Synthesis of tetrapropyl tin and tetrabutyl tin using alkyl bromides as alkylating agents.—When different concentrations of propyl bromide in DMF were electrolyzed between a zinc cathode and a tin anode, low yields of tetrapropyl tin and propyl tin bromides were generally obtained. Better results were accomplished by electrolyzing propyl bromide containing TBAP (2%) but in the absence of any solvent: The related runs are reported in Table IV (No. 38, 39).

Very poor yields of tin butyl derivatives were also obtained in DMF at room temperature for various butyl bromide concentrations, whereas the results improved when the temperature was raised to 110°C.

However, the process could reach its optimum yield when high concentrations of butyl bromide containing small amounts of DMSO and catalytic concentrations of ethyl iodide were electrolyzed between 100° and 110°C (runs 42-46). Under these conditions, when considering the formation of mixed butylethyl tin compounds (not reported in Table IV), more than 80% of the dissolved tin was alkylated.

By adopting a similar procedure (*i.e.*, DMSO solvent, ethyliodide catalyst, and high concentrations of propyl bromide) and selecting an electrolysis temperature in the range 55°-80°C, results comparable to those obtained with propyliodide were reached for the synthesis of tetrapropyl tin too.

For instance, on electrolyzing at 78°C 25 ml of a DMSO solution containing 7.68M propyl bromide and 0.249M ethyl iodide, after 400C the yields (based on

the dissolved tin) were: 66.8% for tetrapropyl tin and 21.0% for mixed propyl-ethyl compounds.

Use of butyl chloride as alkylating material.—After electrolyzing butyl chloride (70%), DMSO (28%), ethyl iodide (2%) between a zinc cathode and a tin anode at 100°C, no appreciable amount of tetrabutyl tin was detected by gas chromatography, however some moiety attributable to butyl tin halides was detected by mass spectrometric analysis.

Reduction of alkyl halides at zinc.—Steady-state current-potential curves were obtained for the reduction of different concentrations of propyl iodide, butyl iodide, and 1-iodo-3-methylbutane at zinc in DMF at 25°C, using $NaClO_4$ (2%) as the supporting electrolyte. The typical curves shown in Fig. 2 and 3 were plotted by points, on recording for each potential the stationary current after ≧3 min of potentiostatic electrolysis.

Propyl iodide and butyl iodide (Fig. 2) are reduced very easily at zinc; indeed, for both the halides the reduction potential is very close to that for zinc dissolution (the dotted part of the curves), for similar concentrations the limiting currents are lower for butyl iodide than for propyl iodide.

The potential shift from the zinc dissolution shown in Fig. 3 for the reduction of 1-iodo-3-methylbutane probably indicates some different pathway followed by this reaction: in addition the limiting currents obtained with this halide are substantially lower than for other alkyl iodides.

The steady-state current-potential curves obtained for the reduction of propyl bromide and butyl bromide using TBAP (2%) as the supporting electrolyte are shown in Fig. 4. In contrast with the previous results one can observe the very negative potentials necessary for obtaining appreciable reduction currents.

Oxidation of zinc alkyls at lead and tin.—Figures 5 and 6 show the steady-state current-potential curves referring to the various systems which may oxidize lead and tin during the synthetic process: the curves were obtained in DMF at 25°C using TBAP (2%) as the supporting electrolyte.

The most anodic curve of Fig. 5 refers to the system TBAP/DMF in the absence of any depolarizer: since the macroscale electrolysis gave no practical metal dissolu-

tion under these conditions, the process may likely be ascribed to solvent oxidation, products of which are probably responsible for anode passivation at increasing potentials.

The full points of Fig. 5 refer to the anode reaction obtained in the presence of iodide ions (0.315M): the dissolution of the anode with a 2 F/g at. stoichiometry by macroelectrolysis suggests that in this case the lead oxidation is catalyzed by I^- ions.

These results were not appreciably affected when minor amounts of alkyl iodides were added to the systems above.

The subsequent curves of Fig. 5 were recorded in the presence of propyl and butyl zinc derivatives (probably a mixture of mono and dialkyl zinc compounds). For zinc propyls the resulting anodic process (triangles in Fig. 5) practically overlaps with the full points curve, but the direct oxidation of zinc butyls may be deduced from the shift of the electrode process (square in Fig. 5) to more cathodic potential and the substantial current increase.

For similar experimental conditions the oxidation data obtained at tin anode reproduce the behavior described above as can be seen from Fig. 6.

Discussion

The low reactivity at 25°C of unpolarized zinc sheets with propyl and butyl iodides indicates that the possible intervention of either the chemical reaction

$$RI + Zn \rightarrow RZnI \qquad [1]$$

or a spontaneous corrosion process

$$\text{anodic } Zn \rightarrow Zn^{2+} + 2e^-$$

$$\text{cathodic } RI + Zn + e^- \rightarrow RZn^{\cdot} + I^- \qquad [2]$$

which could be important with lower alkyl iodides, is not substantial under the experimental conditions of Tables I-II.

On the other hand, as was previously observed, the cathodic process cannot be explained by a simple electrochemical reaction, since the weight loss of the polarized zinc largely exceeds the provisions of Faraday's law for a sacrificial reduction of the type

$$2RX + 2e^- \xrightarrow{Zn} R_2Zn + 2X^- \qquad [3]$$

where X = I or Br. Consequently, a catalytic process promoted by the electrode potential would appear to be operating; the catalyst is probably a monoalkylate zinc,[2] which once produced at the cathode initiates the formation of zinc alkyls by a chain mechanism similar to that suggested for the reduction of benzyl iodides at mercury (15)

$$RI + e^- \xrightarrow{Zn} RZn^{\cdot} + I^-$$

$$RZn^{\cdot} + RI \rightarrow RZn^+ + I^- + R^{\cdot} \qquad [4]$$

$$R^{\cdot} + Zn \rightarrow RZn^{\cdot}$$

Assuming that this mechanism is valid provides a satisfactory explanation not only for the excessive zinc loss observed in the preparative runs but also for the results of the steady-state experiments. It is apparent that during the reduction of propyl and butyl iodide at zinc, a mixed potential is established mainly as RZn^+ is reduced: under these conditions the reversibility of the reduction curves with the anodic dissolution (see Fig. 2) is readily understood and the decrease in the limiting current when passing from propyl to butyl iodide is explained by a decreased activity of the autocatalytic cycle [4] as the size of the alkyl group is increased.

In the case of 1-iodo-3-methylbutane (Fig. 3), the shift of the reduction to a more cathodic potential (0.5V at 25°C) cannot be due to any great extent to a lower reducibility of the R-I bond for this compound but is probably due to the absence of catalytically produced RZn^+ species. This fact is supported by the loss of polarized zinc at room temperature (Table III, No. 25) which is not far from the provisions of the sacrificial reaction [3].

It is clear that the outline above may be considerably changed when some energy is fed into the system by heating: According to the data of Table III, the catalytic cycle [4] may be activated by a temperature increase, the purely chemical processes of type [1] and [2] become prevailing at 80°C.

The sacrificial route probably occurs during the reduction of alkyl bromides (Fig. 4): In this case the very negative potentials necessary for the cleavage of the R-Br bond decrease the yields of reaction [3] since the free radical intermediates may be further reduced to produce the corresponding hydrocarbons (5). Here the ability of minor amounts of ethyl iodide to cause an excess of butyl bromide to be converted into zinc butyl (Table IV, runs No. 42-46) further underlines the existence of some catalytic process thus emphasizing the occurrence of the radical exchange reactions described by mechanism [4].

It may be noted finally that the reduction of Zn^{2+} ions, either liberated at the anode (discussed at the beginning of this paper) or formed by disproportionation of zinc alkyl iodides (16), may support the cathodic reaction at some stage of the process. When alkyl iodides are used as alkylating agents, this fact does not decrease zinc alkyl formation which only requires the catalytic intervention of the cathode: On the contrary, the reduction of Zn^{2+} ions may conveniently recycle some zinc. On the other hand, when alkyl bromides are used under galvanostatic conditions, as the concentration of Zn^{2+} increases sacrificial reaction [3] may be inhibited, this inconvenience is however eliminated when minor amounts of an easily reduced alkyl iodide are added to the alkyl bromides.

Anodic process.—As was mentioned above, the current yields for the synthesis of lead and tin tetraalkyl derivatives were computed on the basis of the following anodic process

$$4RZnI - 4e^- \xrightarrow{Me} MeR_4 + 4Zn^{2+} + 4I^-$$

$$2R_2Zn - 4e^- \xrightarrow{Me} MeR_4 + 2Zn^{2+} \qquad [5]$$

where Me = Pb or Sn.

This reaction scheme (when substituting Mg for Zn) is usually suggested for Grignard electrosynthesis on the assumption that magnesium alkyls directly oxidize

[2] The peculiarities of lead cathodic alkylation were explained by the catalytic intervention of the monoalkylated species EtPb (14).

to alkyl-free radicals which in turn react with the anode metal (4-6). Indeed, Fleischmann *et al.* found that the oxidation of magnesium ethyl compounds at a lead anode in THF gives current-potential curves with well-formed waves and current plateaus, but the formation of lead-carbon bonds during the electrode process was only inferred from the fact that the oxidation of magnesium ethyls occurs much less readily on an inert electrode (17).

On the other hand, the early observations of Kondyrev (18) show that lead and tin anodes dissolve according to a 2 **F**/g at. stoichiometry in ethereal solutions of Grignard compounds: Furthermore in the Grignard anodic synthesis of tetramethyllead and tetraethyllead the current yields computed on the basis of the above stoichiometry (reactions [5]) often give results close to 200% (6).

The same disconcerting picture is offered here by the steady-state data and from the preparative runs here reported. Thus it seems likely that the formation of lead and tin tetraalkyl derivatives does not follow a single route.

When the potential of the polarization curves of zinc alkyls are a few millivolts less positive than the direct anode oxidation catalyzed by I^- ions (or when the two processes are overlapping as happens for zinc propyls), the anodic reaction in part provides the required oxidized form (Pb^{2+} or Sn^{2+}) of the recipient metal.

Tetraalkyl derivatives are consequently formed by the following reactions

$$Me^{2+} + 2RZnI \rightarrow MeR_2 + 2Zn^{2+} + 2I^-$$

$$2MeR_2 \rightarrow MeR_4 + Me \qquad [6]$$

where Me = Pb or Sn, which may take place homogeneously in the solution. Alkylation of more than 50% of the dissolved anode is accomplished by processes of the type

$$MeR_2 + RI \rightarrow R_3MeI$$

$$R_3MeI + RZnI \rightarrow MeR_4 + Zn^{2+} + 2I^-$$

$$Me + ZnR_2 + 2RI \rightarrow MeR_4 + Zn^{2+} + 2I^- \qquad [7]$$

which most probably occur in the chemical synthesis of lead and tin organoderivatives (3, 19).

On the other hand, when the size and the electron density of the zinc alkyls make their direct oxidation possible at the anode (as for zinc butyls) formation of tetraalkyl derivatives may proceed by reaction [5].

However, the data of the preparative runs suggest that at high zinc alkyl concentration, their direct oxidation again agrees with a two-electron reaction, which would mean that in this case also dialkyl lead (or dialkyl tin) is the main product of the process

$$2RZnI - 2e^- \xrightarrow{Me} MeR_2 + 2Zn^{2+} + 2I^-$$

whereas further alkylation of the unstable MeR_2 species may take place homogeneously by the reactions discussed above.

The Kinetics of the Potentiostatic Oxidation of Lead Sulfate Films on Lead in Sulfuric Acid Solution

E. M. L. Valeriote* and L. D. Gallop
Defence Research Establishment Ottawa, Ottawa, Ontario, Canada K1A, 0Z4

ABSTRACT

Models, proposed by Pavlov and Ruetschi to describe the multiphase electrode structure of anodically oxidized lead/sulfuric acid solutions, have been quantitatively tested, modified, and elaborated in accordance with the experimental evidence. The current, during oxidation at constant potential in the region of lead dioxide formation, is shown to be controlled sequentially by at least three diffusion processes, followed by at least two electrocrystallization stages and further intervals of diffusion control. The natures and concentrations of the diffusing species are quantitatively characterized on the basis of kinetic and thermodynamc data. The corresponding values of *p*H in the electrode pores are calculated. A reversal of the *p*H gradient in the pores apparently occurs in close association with the onset of β-PbO_2 production. It is following this stage of the anodic oxidation that the charging kinetics become qualitatively dependent on temperature. At normal temperatures, growth of β-PbO_2 at the expense of lead sulfate occurs. At very low temperatures this process is blocked, resulting in poor subsequent charge acceptance.

Substantial progress has been made during the past ten years (1-12) in characterizing the composition of anodic films on lead in sulfuric acid solutions and in developing theoretical models (5, 7, 9-11) to explain the formation and stability in these films, of divalent lead compounds thermodynamically impossible in an acidic environment. Although the existence and conditions of formation of these compounds are now reasonably well established, only a small amount of semiquantitative work, most notably by the Pavlov school, has been done to study the kinetics of the processes taking place and to determine the relative importance of some of the several mechanisms proposed (5, 6, 9).

In a previous paper (13) the results of a number of electrochemical techniques, applied to the study of anodic oxidation of $PbSO_4$ at temperatures from $-50°$ to 0°C, were discussed. Potentiostatic transient data were found to fit a mathematical model in which current was controlled by two-dimensional nucleation and growth of PbO_2. The quantitative agreement of the data with either a model for progressive nucleation or for instantaneous nucleation was particularly good at low temperature ($\leq -20°C$) over a wide range of overpotentials. Several diffusion-limited processes precede and follow the nucleation and growth period, however, which were discussed (13) without any firm conclusions being reached.

In the present paper a quantitative treatment of potentiostatic current-time transients is presented for all the stages of anodic oxidation of divalent lead in 35% sulfuric acid at normal room temperatures up to the beginning of the formation of β-PbO_2 and oxygen evolution. Data obtained at lower temperatures and by potentiodynamic and other methods will not be discussed in detail except for purposes of comparison, since the thermodynamic data required for their quantitative treatment are not all available.

Experimental

The electrochemical measurements were made using a PAR® Model 170 electrochemistry system (Princeton Applied Research Corporation, Princeton, New Jersey) with auxiliary high impedance recorders and digital meters to facilitate simultaneous determination of current, charge, electrode potential, and other relevant electrochemical parameters.

A rotating disk electrode (RDE) of 0.441 cm^2 area was inserted through a loosely fitting Teflon cap into the main part of the Pyrex three-compartment electrochemical cell. The RDE was rotated only to elaborate certain results obtained when the electrode was stationary. Side compartments, containing counterelectrode (platinized Pt) and reference electrode (Hg/Hg_2SO_4/35% H_2SO_4), were connected to the main cell through 1-2 mm capillary tubing. The connection from the reference compartment entered the main cell at bottom center and narrowed down to a fine capillary tip about 1 mm below the center of the RDE. The lead disk (> 99.995% purity, Cominco, Trail, British Columbia, Canada) was chemically and mechanically polished using standard techniques and electrochemically oxidized to lead sulfate in 35% reagent grade sulfuric acid. Except as otherwise stated, experiments were carried out beginning with a well-cycled electrode maintained at least 1V above the $Pb/PbSO_4$ potential for several days prior to the acquisition of quantitative results. The current was measured as a function of time during a series of potential steps to various constant oxidation potentials. Each charge step was preceded by a constant potential discharge at 0.4V, until the net reduction current had decayed to 3.0 μA.

In order to obtain reproducible current-time transients, care was taken to terminate each charging experiment before the decreasing current, following the nucleation and growth period, had begun to increase substantially once more at the onset of β-PbO_2 formation and oxygen evolution.

Further experimental details have already been reported (13) or are described below where necessary.

Results and Discussion

Theoretical treatment.—For an electrode reaction under potentiostatic control, the current density i, with charge transfer and diffusion rate control, is a function of time according to the relationship (14)

$$i = i(o)\exp(\lambda^2 t)\,\mathrm{erfc}(\lambda\sqrt{t}) \qquad [1]$$

where

$$\lambda = \frac{i_o}{ZF}\left[\frac{1}{C_r D_r^{1/2}}\exp\left(\frac{\alpha ZF}{RT}\eta\right) + \frac{1}{C_o D_o^{1/2}}\exp\left(\frac{-(1-\alpha)ZF}{RT}\eta\right)\right] \qquad [2]$$

and $i(o)$, the current density at $t = 0$ is given by

$$i(o) = i_o \cdot \left[\exp\left(\frac{\alpha ZF}{RT}\eta\right) - \exp\left(\frac{-(1-\alpha)ZF}{RT}\eta\right)\right] \qquad [3]$$

* Electrochemical Society Active Member.
Key words: models, charging, diffusion, basic sulfates, oxides.

Under normal potentiostatic conditions, λ (as defined by Eq. [2]) is a constant which depends on the electron exchange and mass transfer parameters, whereas $i(o)$ is independent of mass transfer.

The current density is thus determined by the time t, the overpotential η, the exchange current density i_o, the transfer coefficient α, the charge transfer valency Z and the equilibrium concentrations C_o, C_r and diffusion coefficients D_o, D_r of the oxidized and reduced species.

In the limit of very small time, the current density is proportional to $\sqrt{t}$ according to

$$i = i(o)\,[1 - 2\lambda t^{1/2}/\pi^{1/2}] \text{ for } \lambda t^{1/2} << 1 \qquad [4]$$

At large values of time the current becomes proportional to $t^{-1/2}$

$$i = i(o)/\lambda\sqrt{\pi}t^{1/2} \text{ for } \lambda t^{1/2} >> 1 \qquad [5]$$

Although λ and $i(o)$ are dependent on i_o and α, the combination $i(o)/\lambda$ is not and is given by

$$\frac{i(o)}{\lambda} = \frac{ZFC_oC_r\sqrt{D_oD_r}\cdot[1 - \exp(-ZF\eta/RT)]}{C_o\sqrt{D_o} + C_r\sqrt{D_r}\exp(-ZF\eta/RT)} \qquad [6]$$

At high positive overpotentials, $i(o)/\lambda = ZFD^{1/2}C$ where $C_r\sqrt{D_r}$ has been replaced by $D^{1/2}C$ for the purposes of this study. Thus, using the slope and intercept of the linear i-$\sqrt{t}$ dependence one obtains from Eq. [4]

$$D^{1/2}C = -2i(o)^2/ZF\sqrt{\pi}(di/dt^{1/2}) \quad \text{for} \quad \lambda t^{1/2} << 1 \qquad [7]$$

and for the linear i-$t^{-1/2}$ dependence from Eq. [5]

$$D^{1/2}C = \frac{\sqrt{\pi}}{ZF}\left(\frac{di}{dt^{-1/2}}\right) \quad \text{for} \quad \lambda t^{1/2} >> 1 \qquad [8]$$

These equations were applied to the analysis of the diffusion-controlled portions of potentiostatic current-time transients obtained at various temperatures from $-50°$ to $+25°$C.

A current-time transient for a selected run at 25°C is given in Fig. 1 to illustrate the general dependencies observed at all temperatures. This particular run was obtained at a potential of 1.1V with respect to the Hg/Hg_2SO_4/35% H_2SO_4 reference electrode, to which all potentials in this paper are referred, and is plotted against two time scales in order to indicate all of the time intervals analyzed. Intervals A to I are labeled on the more sensitive time scale (0-20 sec) and I to J are labeled for longer times.

Pre-nucleation-and-growth diffusion-limited currents.—In interval A, where $t \leq 0.1$ sec, no data were extracted due to the limitations of recorder response time. During this period, double layer charging and the charge transfer reaction would be expected to control the current. Because of the high electrode resistance (13), at $t = 0$ the time constant for double layer charging is appreciable (~ 0.01 sec) but the process is complete well before $t = 0.1$ sec.

For $t \geq 0.1$ sec, the linear relationships between i and $\sqrt{t}$ (interval B) were obtained at potentials from 0.9 to 1.4V (Fig. 2a, inset). Values of $i(o)$ and λ were extracted using Eq. [4] and the region of linearity was found to extend up to values of $\lambda t^{1/2} \leq 0.36$.

Two linear i-$t^{-1/2}$ regions were obtained during intervals C and D (Fig. 2b). The first (C, right-hand side of Fig. 2b) had a slope very nearly twice that of the second segment (D), suggesting a sudden halving of the value of Z or $D^{1/2}C$ (Eq. [8]). The linearity occurred for values of $1 > \lambda\sqrt{t} \geq 0.3$, assuming a value of λ derived from the i-$t^{1/2}$ plots. However, Eq. [8] is only valid for $\lambda\sqrt{t} >> 1$. Values of λ in the range 0.45-0.84 were obtained from the i-$\sqrt{t}$ plots. For these values of λ, t must be greater than 35 sec in order that

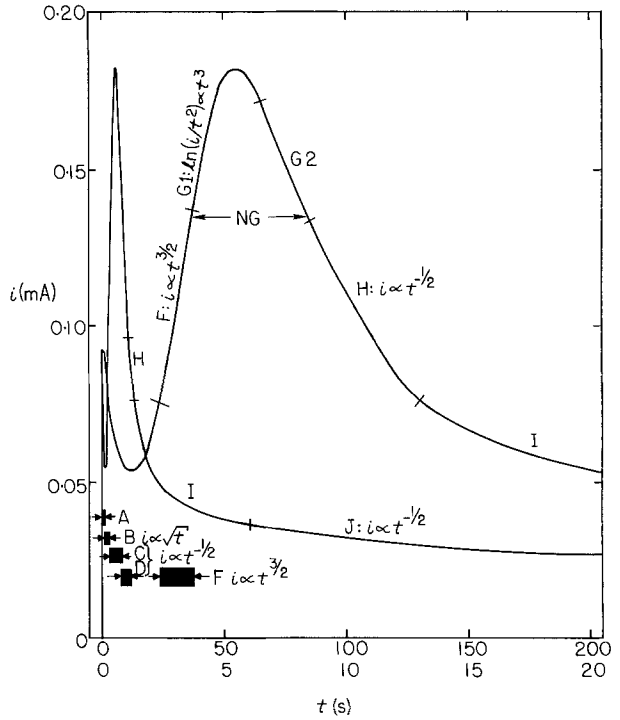

Fig. 1. Potentiostatic anodic transient at 25.0°C, 1.1V (Hg/Hg_2SO_4), for 0.44 cm^2 "lead sulfate" disk electrode in 35% sulfuric acid solution, following a 0.4V discharge to 3.0 μA reduction current. Current-time dependencies were determined as indicated on the curve plotted on the more sensitive (0-20 sec) time scale for intervals B-H. The same transient, showing interval H-J, is also plotted on the 0-200 sec time scale.

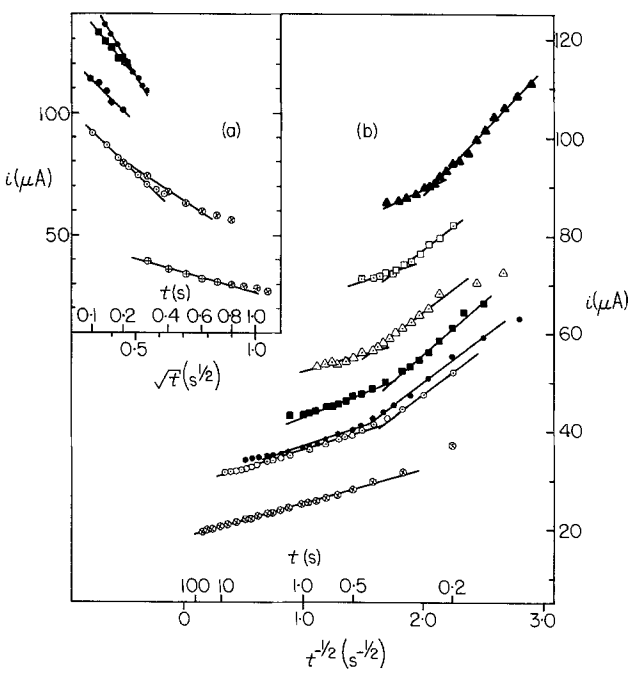

Fig. 2. Current vs. (a) $\sqrt{t}$ (inset) and (b) $t^{-1/2}$ dependencies for intervals B, C, and D of Fig. 1 at various charging potentials: ⊕, 0.9V; ⊗, 1.0V; ⊙, 1.1V; ●, 1.2V; ■, 1.3V; ⧋, 1.4V; □, 1.5V; ▲, 1.6V.

$\lambda\sqrt{t}$ be greater than 5 and therefore the linearities of i *vs.* $t^{-1/2}$ observed at $t < 35$ sec must correspond to diffusion processes involving different species than that responsible for the linearity of i *vs.* $\sqrt{t}$, or to drastically different conditions of concentration or electroactive area. For the i-$t^{-1/2}$ lines, the value of λ must be greater than 12 in order to satisfy $\lambda\sqrt{t} > 5$ for the linear portions of Fig. 2b. From Eq. [2] at a high value

of overpotential, λ is a function of $D^{1/2}C$ and of the electron exchange parameters i_o and α. To what extent are changes in each of these terms responsible for the increase of λ?

If different electron exchange processes are involved for the linearities observed in Fig. 2a and 2b, the values of i_o would be expected to differ. From Eq. [2], at high overpotentials, a plot of ln λ as a function of electrode potential should give a straight line, the slope of which can be used to calculate the anodic transfer coefficient, α. Although a large scatter was observed, the value of $Z\alpha$ determined by such a plot was 0.04 ± 0.01. Such a value is unusually low in comparison to the value of $\alpha = 0.5$ normally assumed for heterogeneous electron exchange and indicates an oxidation step in which, for $Z = 1$, only about 4% of the applied overpotential is effective in determining the rate of the current-limiting process. Further evidence for low values of α are obtained from the data for intervals C and D (Fig. 2b). Equation [5] requires that the i-$t^{-1/2}$ dependencies have a zero current intercept at infinite time, whereas positive intercepts were always observed. This suggests that either there is spherical or other nonlinear diffusion occurring or that a steady-state oxidation process is taking place in parallel with a linear-diffusion-controlled process. In order that Eq. [5] represent the total observed current, rather than only the diffusion-limited current, a second constant term i_∞ should be added which represents the intercept at $t^{-1/2} = 0$. i_∞ was a function of potential and was found to obey a Tafel relationship with a very large Tafel slope, corresponding to $Z\alpha = 0.10 \pm 0.02$ for interval C and $Z\alpha = 0.06 \pm 0.01$ for interval D.

Low values of α (0.05-0.2) have been reported for some other electrode reactions in which the reactant species is a divalent cation in a nonspecifically adsorbed electrolyte (15). The cathodic transfer coefficients reported for the reduction of Cd(II) in nonspecifically adsorbed electrolytes had values ≤ 0.15. For 0.5M K_2SO_4 at pH = 2, the electrolyte most closely resembling sulfuric acid, an approximate value of 0.08 was obtained. Such low values have been attributed to an electron exchange process in which the slow step is a heterogeneous chemical process. In the case of reduction of Ni^{++} in $NaClO_4$ solutions, for example, values of $\alpha \sim 0.05$ have been attributed to rate control by the partial dehydration of the Ni ion at the interface. Such a very low value as 0.04 could also be due to a slow preceding homogeneous dissociation step (15).

It seems reasonable to consider that the sharp increase in λ at the end of the linear i-$\sqrt{t}$ region is at least partially due to an increase in α. However, an increase of $Z\alpha$ from 0.04 to any value greater than 0.2 would also result in a much stronger dependence of λ on potential, and therefore of the time of the beginning of the linearity of the i-$t^{-1/2}$ plots on potential, than was observed (Fig. 2b). Hence the observed increase in λ by a factor of more than 14 must be principally due either to an increase of i_o or to a decrease of $D^{1/2}C$.

Values of $D^{1/2}C$, calculated from the data for intervals B-D are shown in Table I for duplicate sets of experiments with two electrodes. An electrode area equal to the geometrical area of 0.44 cm^2 and the indicated values of Z (to be justified later) were assumed.

Comparison of $D^{1/2}C$ values in the last two columns of Table I with those in the third-to-last column indicates that the values of $D^{1/2}C$ are 10 to 16 times larger during the i-$\sqrt{t}$ linear region (B) compared to the immediately following linear i-$t^{-1/2}$ region (C). This change of $D^{1/2}C$ could account almost completely for the over fourteenfold increase in λ. Since a substantial increase of α is not indicated, the change in i_o must also be relatively unimportant, suggesting that an equally rapid electron exchange reaction is probably occurring for both values of λ but that the rate-controlling step or the electroactive area has changed.

The $D^{1/2}C$ values, given in Table I, differ by orders of magnitude from any corresponding to species in bulk solution. Furthermore, as at low temperatures (13), the inverse dependence of diffusion current on disk rotation rate was in complete contradiction to a model including current limitation by diffusion from the bulk electrolyte. Therefore, in order to proceed further in interpreting these results, a model representing the physically and electrochemically changing states of the interface must be assumed. Before attempting this interpretation one final note of caution should be made.

The values of $D^{1/2}C$ given in Table I have all been based on the assumption that the electrode area is the same as that of the initially smooth lead substrate. If the real electrode area is larger or smaller than this geometric area, the values of $D^{1/2}C$ calculated will be proportionately smaller or larger, respectively. However, the values calculated for λ are unaffected since the area term cancels out in the ratio $i/i(o)$ in Eq. [4] and [5]. Hence, if the area had changed appreciably, a fortuitously compensating change in i_o would also have had to occur in order to explain the similar magnitudes of the fractional changes in λ and $D^{1/2}C$.

Elaboration of the model.—It is now well established that the interior of anodic films formed on lead in aqueous sulfuric acid solutions, over a wide range of potentials, consists of several chemical species, thermodynamically unstable in acid solutions. An excellent review of the literature up to 1969 has been published by Burbank *et al.* (1), in which many of these species and the approximate electrochemical conditions of formation have been schematically illustrated and discussed. In addition to the electrochemical methods, the identification techniques applied have been x-ray and electron diffraction, optical and electron microscopy, and chemical analysis.

Pavlov model.—More recently, further refinement of a model of the anodic film has become possible based on the previous work and on additional experimental and theoretical studies (2-11). Pavlov and co-workers (2-7,

10) have correlated the composition of the anodic layer, as determined by x-ray diffraction studies of potentiostatically formed films, with measurements of current, charge, applied potential, and electrode capacitance (2, 4). Earlier ambiguities in the assignment of diagnostic diffraction lines were resolved by correlation with chemical analytical determinations (2). Under galvanostatic conditions of formation, the x-ray diffraction results were correlated as a function of time with electrode potential, capacitance, resistance, and electron microscopic observations (3). Phase compositions were also determined at the surface and over cross sections of positive plates (6) and of negative plates (7) using the electron microprobe and these were related to measurements of the density of the sulfuric acid, x-ray diffraction intensities, porosity, and surface pore size distribution as a function of time. As a result of this work, the potential interval lying between the equilibrium potential of the $Pb/PbSO_4$ electrode (−956 mV with respect to the $Hg/Hg_2SO_4/1N$ H_2SO_4 reference electrode) and the onset of appreciable oxygen evolution (by about +1400 mV) can be divided into three major regions (2, 4, 6):

1. −956 to −400 mV where the anodic film consists of $PbSO_4$ deposited on the lead substrate.

2. −400 to ~ +900 mV where the film consists predominantly of tetragonal PbO together with small amounts of the basic sulfates of lead, of $5PbO \cdot 2H_2O$ or orthorhombic PbO and of α-PbO_2 beneath a layer of $PbSO_4$. The PbO-tet is commensurate in quantity with the $PbSO_4$ which protects the PbO from attack by the acid electrolyte. The composition of the interior of the film as a function of applied potential could be further subdivided, although with some loss of accuracy. Diffraction lines for monobasic lead sulfate, $PbO \cdot PbSO_4$, appeared at potentials more positive than −400 mV (2). This diffraction line (at 2.95Å) was later (6) reassigned to $2PbO \cdot PbSO_4$ on the basis of comparison with other diffraction lines, but no confirmatory evidence for the reassignment has been published. Tetragonal PbO appeared at −300 mV. At −200 mV the amounts of PbO-tet and mono (or di) basic lead sulfates remained small compared to $PbSO_4$ even after 70 hr of oxidation and tribasic sulfate was detected. Diffraction lines due to either $5PbO \cdot 2H_2O$ or to PbO-orth were obtained at potentials $\geq$ 0. At +300 mV PbO-tet and $PbSO_4$ were present in approximately equal amounts following the initial formation of the protective $PbSO_4$ layer. α-PbO_2 was detected above +500 mV but in very small concentrations below +900 mV.

The existence of hydrated lead monoxide and tribasic sulfate within these films may be the reason for the existence of a chemically bonded form of hydrogen present in electrochemically formed PbO_2 film, which is not present in chemically prepared PbO_2. Caulder *et al.* (16), using DSC, found that this hydrogen was associated with the evolution of water at 180°C and showed, using NMR, that the hydrogen-hydrogen separation exceeded 2Å and was therefore not due to the presence of free water molecules. No suggestions for the chemical nature of the species were offered (16, 17), but the disappearance of this form with increased cycling (17) may be due to the disappearance of hydrated divalent lead compounds. Also relevant to this are the observations by Simon *et al.* (18) that positive plates, formed after high temperature curing, contained a high proportion of electrochemically inactive PbO_2 (and by inference, less of the different form of hydrogen) which formed on an unusually large number of tetrabasic lead sulfate crystals. Hydrated lead monoxide as $5PbO \cdot 2H_2O$ is not stable at temperatures above 60°C and tribasic sulfate above 80°C (19), but instead form tetrabasic sulfate or other anhydrous compounds.

3. > 900 mV where the content of divalent lead species decreases with increasing potential and that of α-PbO_2 increases in the interior of the film. The composition depends strongly on oxidation potential and oxidation time. The major component of the anodic layer beneath the $PbSO_4$ is α-PbO_2 at 1000 mV. At potentials $\geq$ 1200 mV, the $PbSO_4$ is oxidized to β-PbO_2 in an acidic environment near the electrode surface following the prior formation of α-PbO_2 in the alkaline interior.

Pavlov-Ruetschi model.—Theoretical models to explain the creation and maintenance of an alkaline interior, which is necessary for the formation of the basic sulfates, lead monoxide, and α-PbO_2, have been developed (5, 7, 9-11). In the model developed by Ruetschi (11), when the lead sulfate layer, formed anodically or by corrosion, becomes sufficiently thick (> 1 μm), macropores (or intercrystalline spaces) become practically closed. Experimental evidence was presented (11) to show that the lead sulfate then becomes essentially impermeable to $SO_4^=$, HSO_4^-, and Pb^{++} but remains permeable to H^+, OH^-, certain other ions, and probably H_2O. Corrosion of Pb beneath the $PbSO_4$ layer, or precipitation of anodically generated Pb^{++}, results in migration of H^+ away from the electrode interface due to the hindered diffusion of other ions. This creates a basic environment in the interior of the electrode, between the lead substrate and the protective lead sulfate, and generates a considerable diffusion potential across the lead sulfate layer.

Values of *p*H equal to that of the bulk solution, pH_s, were assumed (11) in the case of potential-determining sites at the electrode surface, where reactant species enjoy unhindered access to the electrolyte. In this case, no diffusion potential exists across the $PbSO_4$ layer and electrode potentials can be calculated directly from the potential-determining electrochemical couple.

When the electrochemical reaction occurred beneath the $PbSO_4$ layer, in the electrode interior, a value of pH_i was calculated by consideration of equilibria between species known to be present. Two cases were considered: (*i*) the equilibrium conditions for coexistence of $PbSO_4$ and $PbO \cdot PbSO_4$, which yielded a value of $pH_i = 6.35$ and a value of diffusion potential, E_d, of 0.405V for 4.2M H_2SO_4 bulk electrolyte; (*ii*) the equilibrium corresponding to minimum solubility of PbO (20), which results in a value of $pH_i = 9.34$ and $E_d = 0.581$V.

Whether PbO exists in the form PbO-tet, PbO-orth, $Pb(OH)_2$, or $5PbO \cdot H_2O$ has no significant quantitative effect on the calculation of electrode potentials or *p*H. Hence the use here of the general term PbO implies that no distinction is being drawn between these polymorphs.

The potential between the lead substrate and a reference electrode at the electrode/solution interface, E_r, includes the diffusion potential, which must be added to a calculated reversible potential, E, for an assumed electrochemical couple, in order to make a comparison with experimentally observed reversible potentials. Assuming that E was controlled by the equilibria between Pb or PbO_2 and $PbSO_4$, basic sulfates or PbO, Ruetschi (11) calculated $E_r = E + E_d$, and compared these values with experimental arrest potentials, observed during open-circuit discharge of anodic films, formed potentiostatically on lead. Good agreement was reported between the calculated and observed potentials.

There seems to be no fundamental reason for Ruetschi's choice of a value of $pH_i = 9.34$, corresponding to minimum solubility of PbO. Solid PbO may coexist in equilibrium with its saturated solution and basic lead sulfates over a range of *p*H. Although the experimental evidence supports the assumption of case (*i*) above, with $pH_i = 6.35$, it does not necessarily support case (*ii*) with $pH_i = 9.34$. As duly noted (11), the electrochemical reactions of PbO with both Pb and PbO_2 have a potential dependence, E, of 59 mV/*p*H unit, thus

exactly canceling the dependence of E_d on pH_i. Although the choice of pH_i determines the calculated value of E_d, it has no effect on the calculated value of E_r for the reactions involving PbO. Hence the reported agreement with experiment would not have been altered by a choice of values of pH_i based on other meaningful assumptions. It might be more correct to replace assumption (*ii*) above by one based on the conditions for coexistence of equilibria between $PbSO_4$ and $3PbO \cdot PbSO_4 \cdot H_2O$ or PbO with constituents of the pore solution. Hence, in a similar manner as for case (*i*) above, values of pH_i can be calculated, based on equilibrium solubility-pH (19) or potential-pH (12) relationships, for the coexistence of $PbSO_4$ and basic sulfates or PbO, at a sulfate ion activity, corresponding to the solubility product of $PbSO_4$ ($a_{Pb^{++}} = a_{SO_4^{=}} = 10^{-3.9}$ mole liter^{-1}). Such calculated pH_i values, which are thus average values corresponding to mixed potentials, are given in Table II.

The values of pH in Table II were calculated using the equations of Ruetschi and Angstadt (9) and Pavlov (12). The small concentration gradients of hydroxyl and sulfate ions, which must exist in the solution between the phases (except for the first entry), have been neglected. The calculation of $PbOH^+$ concentration is discussed in a later section. It should be noted that the first value of pH 6.7 for the coexistence of $PbSO_4$ and $PbO \cdot PbSO_4$ disagrees with the value of pH 6.35 calculated by Ruetschi (11) because Ruetschi used the equations of Bode and Voss (19) based on somewhat different thermodynamic data. If one uses the thermodynamic data of Ruetschi and Angstadt (9) and a value of $\Delta G^\circ(Pb^{++}) = -5.81$ kcal/mole, corresponding to $E^\circ = -0.126$V (21), to calculate the expressions given in Bode and Voss's Table 3, different constants are obtained for all the equations containing $a_{Pb^{++}}$ [Eq. [2], [4], [6], and [8], Ref. (20)]. However, the remaining equations appear to be consistent. Combinations of the equations of Ruetschi and Angstadt with the equilibrium equation: $Pb^{++} + 2e = Pb$; $E = -0.216 + 0.0296 \log a_{Pb^{++}}$ gives the same revised values of the constants as are obtained from the thermodynamic data. The errors in the Bode and Voss calculations appear to be due to inconsistent thermodynamic data. Accordingly, the more consistent data (9) were used for the calculated values shown in Table II. Values of pH_i, corresponding to coexistence of $PbO \cdot PbSO_4$ and $3PbO \cdot PbSO_4 \cdot H_2O$, in equilibrium with the pore solution were similarly calculated and have also been included in Table II.

Possible supporting evidence for the existence of such pseudoequilibrium pH_i values, lower than the value of 9.34, assumed by Ruetschi, is presented below. However the choice of pH_i value does not qualitatively alter the conclusions of Ruetschi (11), and would have only a minor quantitative effect on the thermodynamical arguments presented in support of a detailed multiphase model of the lead acid electrode structures.

This model is essentially similar to that proposed earlier by Pavlov (12) and others (1, 19) but differs in the assignment (3, 10) of the equilibria determining open-circuit and galvanostatic arrest potentials. Thus Pavlov presented similar thermodynamical arguments (12) for the case of an alkaline interior of pH 7.8-9.2 in 1*N* H_2SO_4, but the diffusion potential across the lead sulfate layer was not considered. The Pavlov school also presented much more detailed analytical evidence and interpretation of the mechanisms of the electrode reactions (5-7) and attempted a finer discrimination between the roles of the basic sulfates of lead.

Since the models are generally compatible, differing principally in the detail of interpretation of experimental results, use of both models will be made as the basis for further interpretation of the present experimental results.

Interpretation.—Prenucleation-and-growth processes in order of appearance.—For the experiments described, the electrode potential had been previously maintained well above the $Pb/PbSO_4$ potential for several days or weeks. It may, therefore, be assumed that the protective lead sulfate layer had essentially attained its maximum thickness. Prior to each potentiostatic oxidation step, the electrode was maintained at 0.4V until the reduction current had decayed to 3.0 μA. At 0.4V, following prior oxidation to PbO_2, the observed net reduction current consists of a current component for PbO_2 reduction, superimposed on a smaller background oxidation current due to anodic corrosion of lead. Eventually except at low temperatures, a net oxidation current may be observed if the potential is held at 0.4V for a long period of time According to Ruetschi's model (11), immediately before application of the potential step the electrode should consist of a thick layer of PbO ($\sim$ 1 μm) on the lead substrate (with possible traces of α-PbO_2) covered by a relatively thin layer of basic sulfates, increasing in $PbSO_4/PbO$ ratio toward the electrolyte surface, and finally a thick ($\sim$ 1 μm) layer of $PbSO_4$. The initial pH of the solution in contact with PbO at the reaction site in the electrode pores will be taken as 8.5, and the $a_{SO_4^{=}}$ as $10^{-3.9}$ (Table II). These activities arise partly as the result of consumption of acid and production of water during the immediately preceding discharge. They are also due to the chemical corrosion and electrochemical background oxidation of the lead substrate under conditions of hindered diffusion of lead and sulfate ions (11, 12) out of and into the $PbSO_4$ pores, respectively. In order to maintain electroneutrality in the pores, some of the corrosion current must be carried by the more mobile H^+ or OH^- ions leading to alkalinization of the pore solution. A zone of crystallization of $PbSO_4$ will be established in the pores at some distance from the metal (10) and a solution supersaturated with respect to $PbSO_4$ will be established in the region where the opposite Pb^{++} and $SO_4^{=}$ ionic flows meet one another. The alkalinization will occur on the metal side of this precipitation zone where $C_{Pb^{++}} > C_{SO_4^{=}}$ (10).

In alkaline solutions, reaction between Pb^{++} and OH^- ions favors the formation of ionic hydroxy complexes such as $Pb(OH)^+$, $Pb(OH)_3^-$, and $HPbO_2^-$ in addition to the solid phases (10) already described. Thermodynamic calculations, based on stability constants (22 a-f) or other thermodynamic data (11, 19), indicate that for pH $\leq$ 9, the concentrations of $HPbO_2^-$ and of $Pb(OH)_3^-$ ($\leq 10^{-5}$M) are insignificant in comparison to that of Pb^{++} or $PbOH^+$ and can reasonably be neglected even at pH 10. Values of stability or hydrolysis constants for $PbOH^+$ at 25°C have been variously reported, with stability constants ranging from $10^{6.1}$ (22b) to $10^{7.8}$ (22a). An intermediate value of $10^{6.9}$, obtained polarographically (22c), was arbitrarily assumed in order to calculate $[PbOH^+]$, already given (Table II). The concentration of $PbOH^+$ exceeds that of Pb^{++} for pH > 7.1, independently of the $a_{SO_4^{=}}$ and, hence, $PbOH^+$ must be considered in interpreting the experimental data.

A value of $C = [Pb(OH)^+] = 3.2 \times 10^{-3}$M at pH = 8.5 (Table II) can be used to determine a value of the diffusion coefficient from the values of $D^{1/2}C$ in Table I corresponding to the linear i-$\sqrt{t}$ region of Fig. 2a, obtained in interval B between 0.1-0.5 sec fol-

Table II

Coexisting phases in aqueous H_2SO_4 solution	log $a_{Pb^{++}}$ = −3.9 mole/liter; log $a_{SO_4^{=}}$ = −3.9 mole/liter: Equilibrium pH_i	[$PbOH^+$] (M)
$PbSO_4/PbO \cdot PbSO_4$	6.7	5.0×10^{-5}
$PbSO_4/3PbO \cdot PbSO_4 \cdot H_2O$	6.9	7.9×10^{-5}
$PbO \cdot PbSO_4/3PbO \cdot PbSO_4 \cdot H_2O$	7.3	2.0×10^{-4}
$PbSO_4/4PbO \cdot PbSO_4$	8.0	1.0×10^{-3}
$PbSO_4/PbO$	8.5	3.2×10^{-3}

lowing application of the potential step. An average value of $D \sim 3 \times 10^{-6}$ cm^2 sec^{-1} was thus obtained. At pH = 8.0, potential-dependent values of $D = 0.8 \times 10^{-5}$ to 9.9×10^{-5} cm^2 sec^{-1} were obtained with an average of 3×10^{-5} cm^2 sec^{-1}, a reasonable value for the diffusion of a monovalent cation in aqueous solution. In view of the uncertainty in the choice of the stability constant used to calculate [Pb(OH)$^+$], the uncertainty in the calculated diffusion coefficient is at least one order of magnitude. Thus it is possible to deduce only an approximate average pH under the experimental conditions for which Eq. [7] is valid. The experimental values of $D^{1/2}C$, however, were determined much more accurately, so that the potential dependence of $D^{1/2}C$ clearly indicates that pH_i differed as a function of the constant applied potential. If one proceeds from the opposite point of view, therefore, and assumes a particular value of D, which is a constant characteristic of the PbOH$^+$ ion, and uses the experimental values of $D^{1/2}C$, a much more accurate estimate of [PbOH$^+$] can be made. From this, pH values can be calculated with a large but constant uncertainty ($\sim$ 0.5 pH units), but the relative variation of pH with potential can be determined with the higher accuracy of the experimental $D^{1/2}C$ values. A value of $D = 2 \times 10^{-5}$ cm^2 sec^{-1} [*cf.* monovalent ions of comparable size (21)] was thus assumed in order to obtain the results given in Table III.

Although there may be a constant correction for each of the values of pH in Table III, the differences will be relatively accurate. There thus appears to be a definite increase in the pH within the pores as a function of electrode potential during this diffusion-limited period. If the pH was initially controlled at pH = 8.5 (Table II) or greater, some decrease of pH may have taken place during the prior double layer charging interval. Since the linear i-$\sqrt{t}$ region begins later and lasts for a longer time at lower overpotentials and since the currents are smaller, a larger decrease of pH can occur as PbO is consumed, and more nearly equilibrium values of pH exist.

Immediately following this process, the two linear i-$t^{-1/2}$ regions (Fig. 2b) which were observed must correspond to different processes, as discussed earlier. During the first of these processes ($t \lesssim 0.4$ sec), the slope observed showed no significant potential dependence. An oxidation state of $Z = 2$ was postulated. Assuming that this species is Pb^{++} at a concentration of $10^{-3.9}$M, a value of $D = 1.1(\pm 0.1) \times 10^{-5}$ cm^2 sec^{-1} was calculated from the values of $D^{1/2}C$ of Table I. This is in good agreement with the published (21) value of 0.98×10^{-5} for Pb^{++} at infinite dilution.

The second linear i-$t^{-1/2}$ region in Fig. 2b, has a slope, again with no significant potential dependence, of one-half that of the first region. A diffusing species with $Z = 1$ and $D = 2 \times 10^{-5}$ cm^2 sec^{-1} was therefore assumed, and a value of $C = 8.1(\pm 1.1) \times 10^{-5}$M was calculated from the $D^{1/2}C$ values of Table I. If this species is again assumed to be PbOH$^+$, a pH of 6.9 can be calculated, as before. Inspection of Table II suggests that during this interval the pH is controlled at a fairly constant value by equilibria involving $PbSO_4$ and $3PbO \cdot PbSO_4 \cdot H_2O$ and/or $PbO \cdot PbSO_4$.

A problem of interpretation arises in attempting to explain why diffusion control should shift from PbOH$^+$ to Pb^{++} and then back again to PbOH$^+$ at potentials greater than 1.0V. According to the processes of formation postulated by Pavlov and Iordanov (4), at 0.4V, before application of the potential step, the spaces beneath the lead sulfate are filled with basic sulfates and PbO. The latter covers the underlying lead (see Fig. 6a). Immediately following application of the potential step, and double layer charging, we may postulate that the current is limited by the rate of dissolution of PbO or $Pb(OH)_2$ at the lead surface. This would explain the very low value of $Z\alpha$, for the electron exchange reaction, as being due to this preceding slow chemical dissolution.

Table III

Charging potential (V)	$D^{1/2}C \times 10^9$ (Table I)	C = [PbOH$^+$] ($D = 2 \times 10^{-5}$ cm^2 sec^{-1}) (M)	pH_i ($a_{Pb^{++}} = 10^{-3.9}$)
0.9	2.78	6.20×10^{-4}	7.8
1.0	4.62	1.03×10^{-3}	8.0
1.1	3.96	8.9×10^{-4}	7.9
1.2	5.42	1.21×10^{-3}	8.1
1.3	6.72	1.50×10^{-3}	8.2
1.4	9.96	2.2×10^{-3}	8.3

Bode and Voss (23) have pointed out the close similarities in the structures of lead, tetragonal PbO, and α-PbO_2. Thus we might expect that the α-PbO_2 formed could easily deposit on either the exposed lead or on the PbO surface. Initially the deposition should begin on the only available electronically conducting phase, the lead. During the linear i-$\sqrt{t}$ region, diffusion of PbOH$^+$ to the lead therefore becomes rate controlling. The amount of charge passed up to the end of interval B corresponds to less than a monolayer of Pb covered by PbO_2. Since PbO_2 is electronically conducting, the electron exchange sites may now shift from the lead to the PbO_2 and the latter can extend itself further into the PbO deposit as isolated growing filaments. This process, as has been shown, is limited at first by diffusion of Pb^{++} ions at potentials $\geqq$1.1V, then by diffusion of PbOH$^+$ ions. The absence of a Pb^{++} intermediate diffusion mechanism at 0.9 and 1.0V may be due to a greater degree of lateral spreading or isolated nucleation of the α-PbO_2 deposit on the Pb surface to which diffusion of Pb^{++} ions from the pores in the lead sulfate is more difficult. During the last diffusion interval (D) before the current minimum, the PbO_2 reaction sites have apparently grown up toward the basic sulfate zone, decreasing the electrode resistance by the formation of α-PbO_2. The capacitance remains unchanged (13) since the latter is determined by the PbO_2 accessible to the electrolyte in the pores, in parallel with the $PbSO_4$ surface, and the area of the former is still insignificantly small.

The end of this linear region corresponds to the first minimum in the potentiostatically controlled current. The current rise following this minimum culminates in a maximum [with coordinates (t_m,i_m)] which may be followed by other extrema at certain potentials at temperatures $\geqq -10$°C. At low temperatures only a single maximum is observed, which previously has been quantitatively shown (13) to be due to a current-limiting process of two-dimensional nucleation and growth of PbO_2. In a previous paper (13), a divergence of the experimental data from the model was noted to occur during the early part of the current rise. This was tentatively attributed to the large and rapid change in electrode resistance which occurs during this stage of the charging process. It appears now, however, that it is more likely due to mixed current control by diffusion and three-dimensional progressive nucleation and growth (see Fig. 6b), as evidenced by the data of Fig. 3.

Such mixed control leads to a linear dependence of current on $t^{3/2}$ (24), as observed in the present work with the thick $PbSO_4$ film and elsewhere (25) during the direct anodic oxidation of polished lead in sulfuric acid solutions. To a first approximation, the slopes of the lines shown in Fig. 3 are proportional to the cube of the diffusing reactant concentration (24) and to $t_m^{3/2}/i_m$. Hence the slopes are very sensitive to reactant concentration. Since the proportionality constant is not known, it can only be said from Fig. 3 that the value of C is approximately 35 times smaller at 0.9V and 6 times smaller at 1.0V than the average values for the higher potentials. The amount of charge passed by the beginning of the linear i-$t^{3/2}$ region was greater at the lower potentials and the height of the two-dimensional nuclei formed later was significantly less at 0.9V (13).

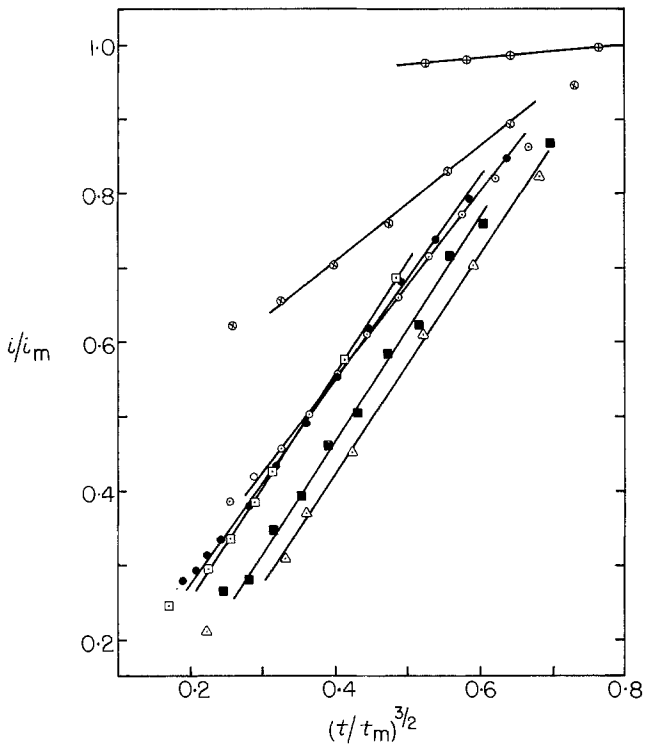

Fig. 3. Current (units of i_m) vs. time$^{3/2}$ (units of $t_m^{3/2}$) for interval F of Fig. 1. Values of (t_m, i_m) are indicated for each potential: ⊕, 0.9V (21.5 sec, 18.5 μA); ⊗, 1.0V (7.4 sec, 70.8 μA); ⊙, 1.1V (5.5 sec, 182 μA); ●, 1.2V (2.57 sec, 481 μA); ■, 1.3V (1.40 sec, 758 μA); △, 1.4V (0.71 sec, 1.460 mA).

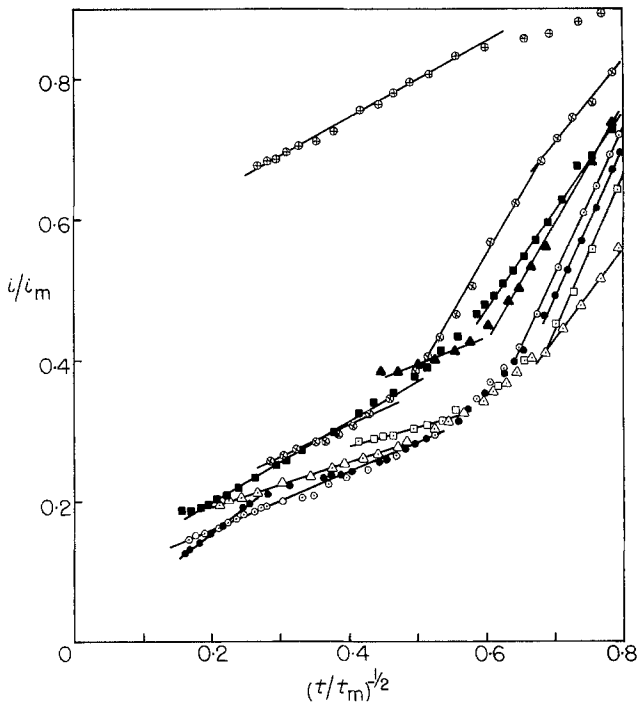

Fig. 4. Current vs. time$^{-1/2}$ (units of i_m, $t_m^{-1/2}$) at various potentials during diffusion-limited intervals H-J (Fig. 1), following nucleation-and-growth interval NG. Values of (t_m, i_m) are indicated for each potential: ⊕, 0.9V (21.5 sec, 18.5 μA); ⊗, 1.0V (7.4 sec, 70.8 μA); ⊙, 1.1V (5.5 sec, 182 μA); ●, 1.2V (1.97 sec, 467 μA); ■, 1.3V (1.72 sec, 583 μA); △, 1.4V (0.71 sec, 1.460 mA); ◙, 1.5V (0.69 sec, 2.07 mA); ▲, 1.6V (0.40 sec, 3.27 mA).

Thus it would appear that a larger number of smaller nuclei are formed near the Pb/PbO interface at 0.9V than at higher potentials and that, as a consequence, the reactant ions, originating further up the pores, have less accessibility to the reaction site. The pores leading to the reaction zone must become smaller since the formation of PbO_2 from Pb or PbO-tet involves an increase in molar volume (26) which would initially tend to restrict the pores.

As the growth of α-PbO_2 proceeds during region F however, mechanical stresses will be set up in the PbO layer (4) due to this volume increase which may physically force crystals apart and create porous intercrystalline spaces. Furthermore, the volume change for the formation of PbO_2 from the basic sulfates is negative (26). These two effects should combine to increase the pore volume and α-PbO_2 network exposed to the pore solution during region F. At −20°C most of the resistance decrease and the initial capacitance increase occurred during this interval (13) and may be attributed to the increase in pore volume and α-PbO_2 surface area.

During the subsequent interval (region NG) the current has been shown (13) to be controlled by two-dimensional nucleation and growth as the α-PbO_2 spreads laterally beneath the lead sulfate causing a strong capacitance increase, and forming a dense anodic layer (see Fig. 6c), and possibly more intercrystalline spaces in the protective lead sulfate layer. Although the fit to the nucleation and growth model was only valid for region G1 for the particular run shown in Fig. 1, the range of validity increased as temperature decreased and typically included all of interval NG at low temperatures and often even a wider range, extending to both sides of NG.

Post-nucleation-and-growth diffusion currents.—Following interval NG, further linearities between i and $t^{-1/2}$, indicating diffusion-limited oxidation steps, were observed (13) during intervals H, I, and J (Fig. 4). The slopes of interval H correspond to values of pH = 8.9-9.5, increasing with potential from 1.1 to 1.6V, if the diffusing species is assumed to be $PbOH^+$, or to values of pH = 2.4-1.8, decreasing with potential over the same potential range, if the diffusing species is assumed to be H^+ at a pH controlled by the sulfate-bisulfate equilibrium (9). However the linearities in interval H, when extrapolated, gave a negative current intercept at infinite time, in contradiction to the zero current intercept required by Eq. [5]. A probable explanation for such negative intercepts is that the diffusion-limiting process did not begin at $t = 0$, as required for the validity of Eq. [5], but at some later time, t_o. Reasonable choices for t_o should lie in the range of t_o = 1.2-1.7 t_m, *i.e.*, near the completion of nucleation-and-growth control. In fact, it was found that zero or positive intercepts were obtained for $t_o \geq 1.3\ t_m$ and that, furthermore, the range of linearity was increased so that a single linear i-$t^{-1/2}$ dependence was obtained for most of an interval combining H and I and, in some cases, part of J. The results of transforming the data from a time scale with $t_o = 0$ (Fig. 4) to $t_o = 1.5\ t_m$ are shown in Fig. 5. The intervals H, I, and J indicated refer only to the data for 1.1V, for comparison with Fig. 1. Larger values of t_o do not appreciably extend the linearity to longer times but result in a reduction of the linear range at short times. It appears from Fig. 5 that a diffusion-controlled process begins at $t_o \simeq 1.5\ t_m$; that a linear i-$t^{-1/2}$ interval begins at $t \simeq 2t_m$, extending for several multiples of t_m and that at very long times (corresponding roughly to interval J of Fig. 1), a second diffusion-limited process begins to control the current. Since the current intercepts are almost all small and positive, some contribution to the total current by a steady-state parallel process, such as a corrosion reaction, is suggested.

The values of $ZD^{1/2}C$ obtained from the linear i-$t^{-1/2}$ intervals (Table IV) are of the same order of magnitude as those for interval B and at least one order of magnitude larger than those for intervals C and D (Table I). As had been the case for the previous diffusion processes, reasonable values for D could not be

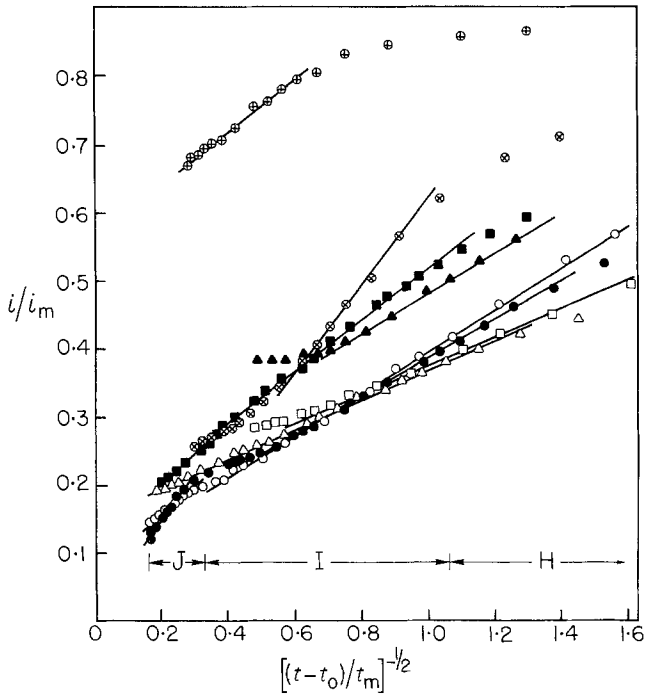

Fig. 5. Current *vs.* time$^{-1/2}$ (units of i_m, $t_m^{-1/2}$) for $t_0 = 1.5\ t_m$. Symbols and data are identical to Fig. 4. Intervals H, I, and J are indicated for the run at 1.1V (Fig. 1).

obtained from $ZD^{1/2}C$ for any values of ZC corresponding to the species present in bulk solution.

It is difficult to predict whether the next stage of oxidation, following interval NG, should involve further oxidation of unconsumed PbO beneath the α-PbO_2 layer (Fig. 6d) or oxidation of $PbSO_4$ above it. Only three plausible diffusion processes could be envisioned which could correspond to values of $ZD^{1/2}C$ within one order of magnitude of those obtained.

1. From the amount of charge passed, it is unlikely that all of the PbO in the electrode interior has been consumed up to this stage of the oxidation. Furthermore, Ruetschi's self-depassivation results (11) and x-ray analyses of the composition of positive plates during formation (6) indicate that PbO continues to be present in positive electrodes after substantial oxidation times. Once the layer of basic sulfates has been oxidized, further oxidation of PbO, which had temporarily been short circuited by α-PbO_2, might occur (Fig. 6d) Values of $[PbOH^+]$ and the thermodynamic values of *p*H corresponding to $[PbOH^+]$ values (assuming $[Pb^{++}] = 10^{-3.9}$M) were calculated as before. The calculated values of *p*H (Table IV) were found to increase with potential but lie within the range of values of PbO stability. Proportionately lower values of *p*H would have been obtained if the $[Pb^{++}]$ was greater than that assumed. Values of $[Pb^{++}]$ calculated assuming that this was the diffusing species are higher than those corresponding to lead sulfate dissolution and would correspond to highly supersaturated solutions. At higher potentials the concentrations of $[PbOH^{++}]$, and thus *p*H, might be expected to be higher, as observed, since the later commencement of diffusion control at lower potentials suggests a greater degree of prior consumption of basic material.

2. If the unconsumed PbO becomes isolated (or permanently short circuited by the α-PbO_2) during the nucleation and growth period, the reaction zone within the pores should begin to advance into the $PbSO_4$ layer. Chemical processes involving the dissolution of unconsumed PbO and basic sulfates may continue with deposition of $PbSO_4$ crystals on the outwardly advancing PbO_2 zone (5, 6). When the available $PbO/PbSO_4$ ratio has become sufficiently small, the *p*H will be expected to decrease quickly, due to the acid production which accompanies oxidation, and formation of β-PbO_2 will begin to take precedence over α-PbO_2 formation. During the transition from an alkaline interior to that of bulk electrolyte, a stable *p*H plateau might be expected near *p*H 2 due to the buffering action of the bisulfate-sulfate equilibrium (9). If one assumes $D = 9.34 \times 10^{-5}$ cm^2 sec^{-1} (21) for the H^+ ion, the values of *p*H shown in the second-to-last pair of columns of Table IV are obtained. These values are substantially less than the *p*H = 1.9 expected for maximum buffering capacity and tend to rule out the hypothesis of such a mechanism for *p*H stability within the pores unless the electroactive surface area is less than 10% of the assumed geometric area.

3. Whether or not the *p*H is arrested near *p*H = 2 by the sulfate-bisulfate equilibrium, it should continue to decrease as oxidation progresses. At lower *p*H, Pb^{4+} (or possibly some other complex tetravalent lead ion) becomes increasingly stable according to the equation (20)

$$\log a_{Pb^{+4}} = -7.10 - 4.00\,pH \qquad [9]$$

Values tabulated in the final two columns of Table IV were derived by assuming $Z = 4$ and $D \simeq 10^{-5}$ for the Pb^{+4} ion and calculating *p*H from the above equation, using the value of $C_{Pb^{+4}}$ obtained from $ZD^{1/2}C$. A more recent equation (27), $\log a_{Pb^{4+}} = -8.26 - 4.00$ *p*H, would result in values of *p*H 0.3 units more negative than those shown in Table IV.

According to these calculations, the *p*H must be of the order of -1 to permit an interpretation based on diffusion limitation by the Pb^{+4} ion. Acid is being continually produced at the reaction site and such a value is not unrealistic since the *p*H of the bulk electrolyte is approximately -0.5 and there are no longer any mechanisms for the consumption of acid in the pores. Thus a steady-state acid concentration in the pores more acidic than that of the bulk electrolyte would not be surprising. The acidity excess would be greater at higher potentials (*i.e.*, higher current densities), as observed (Table IV), since the *p*H would not be controlled thermodynamically but by a steady-state process involving production and diffusion of acid.

Evidence exists to support this reversal of acid diffusion during the formation of both positive (3) and negative (7) plates. For approximately the first one-third of constant current charging, the density of bulk

electrolyte decreases during positive plate formation (5). Thereafter it increases for the duration of the charge. If the changes in electrolyte density are due to diffusion of acid into and out of the plate, the plate interior must be less acidic initially and become more acidic than the bulk electrolyte when about one-third of the plate capacity has been accepted.

Pavlov and Iordanov (4) also concluded that, since the amount of β-PbO_2 formed at potentials above 1.0V was substantially larger than that of oxidized $PbSO_4$ and tet-PbO (as determined by x-ray diffractometry), an ionic current of Pb^{4+} must pass through the anodic layer to form β-PbO_2 at the solution interface prior to oxygen evolution. It is during this final diffusion-limited region that the formation of β-PbO_2 at the surface appears to begin.

Correlation of faradaic and a-c components.—In order to gain further information about the surface state of the electrode, potentiostatic measurements of the components of a superimposed 10 Hz alternating current were made at several temperatures. Although no detailed quantitative correlations between the a-c components and the faradaic current were made at 25°C, such detailed comparisons were made at lower temperatures (13). Except as noted below, the behavior of these parameters, under the conditions of the potential step experiments, were very similar at all temperatures until the end of the final diffusion-limited region. Using the previously published results (13), it is possible to gain some insight into the changes taking place at the electrode/electrolyte interface during this stage of oxidation. At temperatures ≥ -30°C a regular oscillation in current and differential capacity was observed during the final diffusion interval (J). The passage of charge during one period corresponded to the deposition or dissolution of approximately one or two monolayers. Thus it was suggested (13) that no appreciable roughening of the surface had yet occurred. At −20°C and 1.3V, oscillations first appeared in the capacitance at a time $(t/t_m)^{-1/2} = 0.6$ but the oscillations did not become regular in amplitude until $(t/t_m)^{-1/2} = 0.28$, almost precisely at the beginning of the final diffusion region. Prior to the commencement of the oscillations, the differential capacitance showed a pronounced shoulder at $(t/t_m)^{-1/2} = 0.8$, coinciding with the beginning of the diffusion process of interval H. Although the capacitance had been increasing strongly during the prior nucleation and growth region, the rate of increase dropped following the shoulder, by a factor of more than 50.

It would thus appear that a sharp decrease in the rate of PbO_2 surface formation by consumption of the basic sulfate layer (Fig. 6c) at the base of the $PbSO_4$ pores occurs at $(t/t_m)^{-1/2} = 0.8$. Following consumption of further PbO, beneath the newly completed α-PbO_2 layer, controlled by the diffusion of $PbOH^+$, the *p*H decreases rapidly as $(t/t_m)^{-1/2}$ approaches 0.28 (beginning of interval J). The capacitance data suggest only a slow growth of PbO_2 surface during and following this transition. However, it is possible that the site of the electrochemical process changes from the PbO_2 surface to that of $PbSO_4$ forming the pore walls, where Pb^{4+} ions may be generated which can diffuse to the PbO_2 and chemically deposit. In this case the active electrode area may be expected to change. The sign of this change is difficult to predict: although the pore walls probably represent a larger area than that of PbO_2 at the pore base, it is likely that only the $PbSO_4$ near the pore base can become active due to its high resistivity. The charges passed between current and capacitance oscillations suggest that no large change in active area has occurred. If this conclusion is incorrect, however, the rejection of other current-limiting diffusing species, on the basis of the $ZD^{1/2}C$ values, may be invalidated. If the change in the active area is small, the pH need be only slightly different than shown in Table IV to support the postulated diffusion control by Pb^{4+} ions. This point is extremely germane to the problem of poor charge acceptance of the lead acid battery positive plate at very low temperatures. It is during this last interval of diffusion control studied, that significant qualitative differences appear between charging currents at very low and at normal temperatures. Except at very high overpotentials, the current during this period, plotted against $t^{-1/2}$, can be extrapolated to zero at very low temperatures. At normal temperatures it begins instead to markedly increase as β-PbO_2 growth occurs and roughening of the electrode surface takes place.

The oscillations in capacitance and current may be due to the repetitious accumulation of Pb^{4+} ions, to form a saturated or supersaturated solution, followed by surface nucleation of PbO_2 and growth of a new monolayer. The sequence of oxidation steps apparently does not reach this stage at temperatures below −30°C. At −50°C the capacitance continued to increase and no oscillations were observed to the termination of the experimental run at $t > 30\ t_m$, by which time the charge passed was about one-half, but the capacitance less than 10%, of the corresponding values at −20°C (13). [Note, the scale for Q is incorrectly labeled in Fig. 2(a) of Ref. (13). The ordinate scale should be multiplied by 10 to obtain Q in $n\mathbf{F}$.] The temperature dependence will be discussed in more detail in a later paper. The mechanism proposed during this interval consists firstly of electrochemical generation of Pb^{4+} from $PbSO_4$ in close proximity to the PbO_2 at the bottom of the lead sulfate pores. This may also be accompanied by some chemical dissolution of α-PbO_2 to form Pb^{4+}. The Pb^{4+} ions can then diffuse down the pores toward the bulk electrolyte along a gradient of decreasing H^+ concentration. As a consequence of the increasing *p*H, a zone of precipitation of β-PbO_2 onto $PbSO_4$ by chemical reaction of Pb^{4+} with H_2O will be established, advancing toward the mouth of the pore, until reaching the exterior surface in contact with bulk electrolyte. The current and capacitance oscillations observed may be associated with the deposition of monolayers at the electrode/solution interface. Initially, the β-PbO_2 thus chemically formed near the surface may be electronically isolated from the PbO_2 at the base of the pores so that oxygen evolution cannot occur, except on the PbO_2 deep within the pores. At the same time cavities will be developing at the bottom of the $PbSO_4$ layer due to the dissolution and oxidation of $PbSO_4$ and β-PbO_2 may be depositing on the α-PbO_2 base by the oxidation of Pb^{++} ions. Once this deposit grows sufficiently to come into contact with any isolated β-PbO_2 already formed near the surface, or grows to the surface, the mechanisms should change once again. Oxidation of $PbSO_4$ will create a porous network of β-PbO_2, due to the smaller molar volume of the latter, accompanied by increased PbO_2 surface area and a sharply rising current. The kinetics controlling this current increase have already been studied (28) and shown to be three-dimensional nucleation and growth of PbO_2 on $PbSO_4$. The tetravalent lead ion diffusion may be a precursor to the three-dimensional nucleation and growth, in the same way as intervals B to F appeared to create the conditions to initiate two-dimensional growth. An increase of oxygen evolution should then accompany further increase of PbO_2 surface area.

Effect of film age.—As has been noted, most of the potential oxidation steps were carried out beginning with a well-established lead sulfate layer. In order to determine the effect of the lead sulfate history, these experiments were repeated using newly formed, or relatively young, films. Potential step experiments were done on lead sulfate electrodes which had been formed on lead within the previous 48 hr. Some cycling preceded the experimental runs to improve reproducibility. When held at 0.4V following oxidation, the current decayed to an oxidation current of approximately

30 μA, indicating that passivation of the underlying lead was not yet complete. Although the oxidation steps were begun, as before at a potential of 0.4V and when the net reduction current had decayed to 3.0 μA, discharge of the PbO_2 was expected to be less complete than observed for thicker films due to the oxidation component contained in the net reduction current.

At 25°C a very short period of conditioning preceded the series of experimental runs. A newly polished lead electrode was allowed to stand overnight at 0.8V in fresh electrolyte and a few potential step charges and discharges were carried out before the acquisition of quantitative data. Under these conditions, no appreciable diffusion-limited current was observed before the nucleation and growth phase, confirming the expected less complete discharge of PbO_2 in the PbO layer. Following nucleation and growth, $ZD^{1/2}C$ values were obtained, somewhat larger than for the thick films (by a factor of 3 to 15) during the first diffusion-limited period, corresponding to pH values of 8.5-9.6. These remain within the range of PbO stability assuming $PbOH^+$ diffusion, and suggest a higher rate of anodic lead corrosion. In the last diffusion-limited region, $ZD^{1/2}C$ values were almost identical for the thick and the thin films.

At 15°C, a longer preconditioning period was employed (40 hr in the electrolyte and several hours of cycling between 0.6 and 1.8V), although the lead sulfate film was still expected to be less completely developed than for the standard runs. In this case two linear i *vs.* $t^{-1/2}$ regions were observed before nucleation-and-growth control at potentials $\leq$1.3V during some runs but the first was poorly reproducible and had a slope less than twice that of the second. At potentials >1.4V no current minimum occurred before nucleation and growth. From the second, well-defined linear region, values of $D^{1/2}C$ as a function of potential, assuming $Z = 1$, had values very nearly the same as those shown in Table III, corresponding to pH values ranging from 7.8 at 1.0V to 8.2 at 1.3V.

In the post-nucleation-and-growth diffusion regions, values of $ZD^{1/2}C$ were obtained which were intermediate to those for thick and thin films at 25°C for the first linear region, and the same for the final, as expected. At much lower temperatures, experiments were carried out to determine the effect of a longer, deeper prior discharge (but still at 0.4V) on the diffusion characteristics. These results are discussed in another paper (29).

Conclusions

Borrowing from the models of Pavlov and Iordanov (4) and Ruetschi (11), the anodic layer at 0.4V, before application of the potential step, will have a structure such as schematically illustrated in Fig. 6a. Basic lead sulfates fill the macropores, formed from the $PbSO_4$ intercrystalline spaces, and the $PbSO_4$/PbO interface consists of basic lead sulfates with a graduated $PbO/PbSO_4$ ratio. The micropores and the pore electrolyte are not shown.

Upon application of the potential step, PbO is hydrolyzed, or $Pb(OH)_2$ dissociates, to produce $PbOH^+$ and OH^- ions. The $PbOH^+$ diffuses to the lead surface where it is oxidized at a local pH of about 8 to produce α-PbO_2 nuclei and H^+ ions. Since the overlying $PbSO_4$ is impermeable to Pb^{+2} and $SO_4^=$, migration of the H^+ or OH^- ions through the $PbSO_4$ must occur to carry the current. Upon deposition of less than a monolayer, the α-PbO_2 begins to grow as filaments, perhaps of about molecular diameter, at a rate limited by diffusion of Pb^{2+} ions dissolved from the base of the lead sulfate layer and/or formed by anodic corrosion of lead. When these filaments reach the zone of basic lead sulfates where the pH is about 7, the basic sulfates may begin to dissolve to produce $PbOH^+$, OH^-, Pb^{++}, and $SO_4^=$. The latter two diffuse to and precipitate on the lead sulfate and the current-limiting

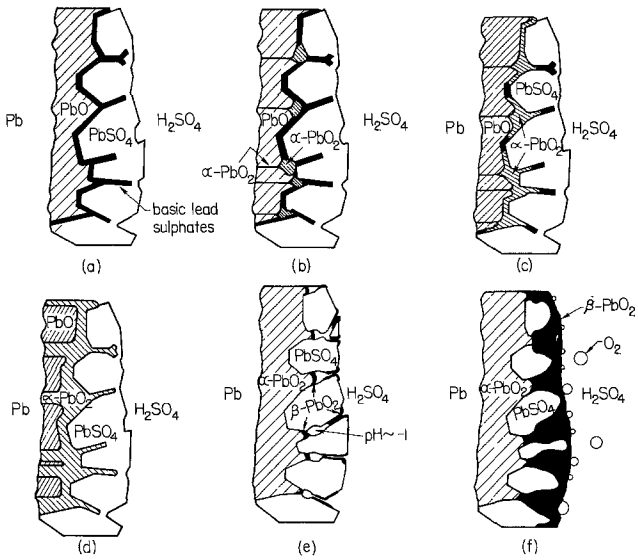

Fig. 6. Models schematically illustrating the progressive growth and composition of an anodic deposit on lead in sulfuric acid solutions following formation of a thick lead sulfate layer (see text).

diffusing species becomes $PbOH^+$ once again. Dissolution of basic sulfates results in the creation of microvoids and pore enlargement around the ends of the PbO_2 filaments due to the large associated decrease in molar volume. These spaces provide "growing room" first during the subsequent three-dimensional growth with slow diffusion (Fig. 6b), then during the two-dimensional lateral growth of α-PbO_2 into the basic sulfate layer (Fig. 6c).

During the first diffusion-limited interval following control by two-dimensional growth, formation of α-PbO_2 proceeds at the expense of underlying PbO (Fig. 6d). Following consumption of the basic reactants, the pH rapidly decreases. At sufficiently low pH, the diffusion of Pb^{4+} ion generated at the α-$PbO_2/PbSO_4$ interface, limits the rate. The diffusing tetravalent lead may react with water and deposit on the α-PbO_2, (or with less likelihood on the $PbSO_4$) at the pore bases. At potentials less than 1.1V, this reaction will cease or may never occur if the pores are sufficiently large to maintain or reduce the internal acidity below or equal that of bulk electrolyte and only the background oxidation of PbO to α-PbO_2 and Pb to PbO will continue. At higher potentials diffusing tetravalent lead may continue to deposit on the β-PbO_2, thus growing toward the electrode surface. If nucleation onto the $PbSO_4$ does not require too great an activation energy, the Pb^{4+} ions might diffuse much further down the pores before reaching a state of supersaturation (as bulk electrolyte pH is approached) and depositing near the electrode surface (Fig. 6e). The observed current and capacitance oscillations are attributed to such a mechanism. Once the two zones of β-PbO_2 join together, $PbSO_4$ is oxidized to form a porous PbO_2 layer at normal temperatures (Fig. 6f), following a three-dimensional nucleation and growth law, and simultaneous oxygen evolution can occur. At very low temperatures, the development of the porous PbO_2 layer is somehow inhibited. This inhibition may be due to preferential persulfate formation (30), pore blockage by $PbSO_4$ and PbO_2 precipitation or ice formation, or some other unknown mechanism. At present it is difficult to state the precise cause with the available data. Further experimental studies at low temperatures will be reported (29) and work, similar to that of the Pavlov school, has been commissioned in order to obtain the necessary additional information to resolve this question.

Low Temperature Oxidation Kinetics of Anodic Films on Lead in Sulfuric Acid Solution

E. M. L. Valeriote* and L. D. Gallop

Defence Research Establishment Ottawa, Ottawa, Ontario, Canada K1A 0Z4

ABSTRACT

A multiphase model of anodic films on lead in sulfuric acid, previously developed to describe the oxidation of lead at room temperature, has been applied to potentiostatic transient data at very low temperatures (0° to −50°C). Freezing of the dilute pore electrolyte is proposed, such that ionic diffusion and equilibria must occur in a thin layer of adsorbed water between the ice and pore walls The experimentally determined activation energies and entropies of diffusion indicate that desorption of water or dehydration of ions plays an important role in the activation process. Except for the effects of the more limited electrolyte volume within the pores upon freezing, the electro-oxidation processes follow a similar sequence above and below the freezing point. However, eventual reactant depletion, due to kinetically hindered equilibria and reduced electrolyte volume in the pores, leads to cessation of charge acceptance at very low temperatures, before appreciable β-PbO_2 formation can occur.

Results of a study of the oxidation of thick divalent lead films, in 35% aqueous sulfuric acid at low temperatures, have previously been discussed (1). The initial potentiostatic oxidation kinetics were found to obey a two-dimensional nucleation-and-growth law particularly well at temperatures below −20°C. As the temperature is increased, the range (in terms of both time and applied potential) of the model's validity decreased. Several diffusion-limited processes preceded and followed the nucleation and growth interval. Rate laws were found, which described very well the sequence of processes governing the oxida-

Key words: diffusion, activation, freezing, pores, charging.

tion, from the time of application of the potential step, until the time at which a qualitative dependence of the rate on temperature became apparent. The results of potentiostatic transient experiments at 25°C were discussed quantitatively (2) in terms of a model based on those developed by Ruetschi and Pavlov *et al.* (3-7). The model was elaborated, describing the formation of α-PbO_2 beneath a protective lead sulfate film. Evidence was presented for current control by the sequential processes of $PbOH^+$ and Pb^{++} diffusion, three-dimensional and two-dimensional electrocrystallization, and $PbOH^+$ ionic diffusion, before the formation of β-PbO_2 begins. A reversal of the pH gradient in the pores apparently occurs in close association with the onset of β-PbO_2 production, which results in a small oxidation current, limited by diffusion of tetravalent lead. Following or during this stage of the anodic oxidation, the charging kinetics become qualitatively dependent on temperature.

In the present paper, the potentiostatic transient data, obtained at lower temperatures (0°C to −50°C), are discussed in terms of the same model in order to elucidate the reasons for poor low temperature charge acceptance of positive electrodes in the lead acid battery.

Experimental

The electrochemical measurements were made using a PAR® Model 170 electrochemistry system (Princeton Applied Research Corporation, Princeton, New Jersey) with auxiliary high impedance recorders and digital meters to facilitate simultaneous determination of current, charge, electrode potential, and other relevant electrochemical parameters.

A rotating disk electrode (RDE) of 0.441 cm^2 area was inserted through a loosely fitting Teflon cap into the main part of the Pyrex three-compartment electrochemical cell. The RDE was rotated only to elaborate certain results obtained when the electrode was stationary. Side compartments, containing counterelectrode (platinized Pt) and reference electrode ($Hg/Hg_2SO_4/35\%$ H_2SO_4), were connected to the main cell through 1-2 mm capillary tubing. The connection from the reference compartment entered the main cell at bottom center and narrowed down to a fine capillary tip about 1 mm below the center of the RDE. The lead disk (>99.995% purity, Cominco, Trail, British Columbia, Canada) was chemically and mechanically polished using standard techniques and electrochemically oxidized to lead sulfate in 35% reagent grade sulfuric acid. Experiments were carried out with a single well-cycled electrode maintained at least 1V above the $Pb/PbSO_4$ potential at all times and temperatures during the acquisition of quantitative results. The current was measured as a function of time during a series of potential steps to various constant oxidation potentials and at 10°C intervals from −50° to 0°C. Each charge step was preceded by a constant potential discharge at 0.4V, until the net reduction current had decayed to 3.0 μA.

In order to obtain reproducible current-time transients, care was taken to terminate each charging experiment before the decreasing current, following the nucleation and growth period, had begun to increase substantially.

Further experimental details have already been reported (1) or will be described below where necessary.

Results

When the experiments were carried out in the standard way, *i.e.*, constant potential charging following discharge to 3.0 μA at 0.4V, three diffusion-controlled currents were observed at 25°C prior to the first current minimum followed by nucleation-and-growth control (2). The slopes of the two linear segments of the i *vs.* $t^{-1/2}$ plots were in the ratio 2:1. It was argued (2) that the currents were limited

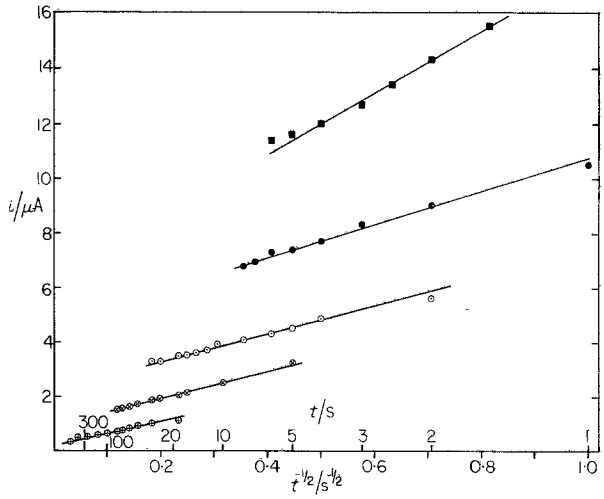

Fig. 1. Current-time characteristics for the early stage of potentiostatic oxidation of an anodic film on lead in 35% sulfuric acid at −40°C. The disk electrode of 0.44 cm^2 area was previously discharged at 0.4V to a reduction current of 3.0 μA. Charging potentials (relative to the Hg/Hg_2SO_4 reference electrode) were: ⊕, 0.9V; ⊗, 1.0V; ⊙, 1.1V; ●, 1.2V; ■, 1.3V.

during these two intervals by the diffusion of Pb^{++} and $PbOH^+$ which were present at approximately equal concentrations in the slightly alkaline pore electrolyte beneath the $PbSO_4$. At temperatures ≤0°C, only one unambiguously diffusion-limited interval was observed. A typical example of the linear i-$t^{-1/2}$ dependence is given in Fig. 1 for data obtained at −40°C and at various applied potentials. During some experimental runs at −50°C there were indications of an earlier diffusion-limited interval at times of less than 1 or 2 sec following application of the potential step. An oscillographic recording method would have been useful to obtain accurate enough data to quantitatively discuss this earlier interval. As an alternative, the electrode was discharged more deeply prior to the charging step. The data obtained following discharge at the same potential (0.4V) as during the standard experiment, but for a longer period of time (until the current decayed to values between 40 and 70 nA), are displayed in Fig. 2. As in the

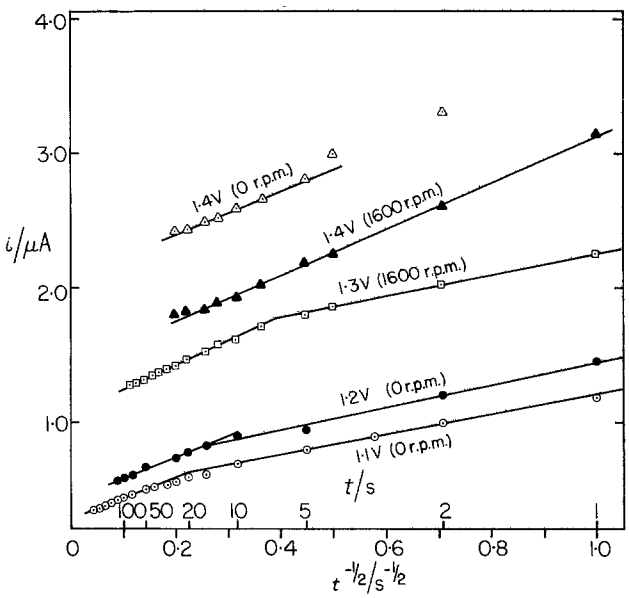

Fig. 2. Current-time characteristics for 35% sulfuric acid at −40°C, as in Fig. 1, but following discharge at 0.4V to reduction currents of 40-70 nA. Potentials and angular speed of electrode are indicated on the graph.

experiments at 25°C under the standard regime, two linear i *vs.* $t^{-1/2}$ dependencies were observed, with slopes in the ratio of 1:2, separated by a very sharp change of slope. However, the order was reversed, *i.e.*, the slope of the earlier linear segment at −40°C, following deep discharge, was smaller than that of the latter by a factor of two at potentials of 1.1-1.3V. No significant dependence of slope on rotation rate of the disk electrode was observed, although the current was higher for a stationary electrode, than for one which was rotating as was also observed during linear scan voltammetry experiments (1).

During the interval following control by nucleation and growth, similar dependencies of potentiostatic current on time were observed at all temperatures. At least two linear i *vs.* $t^{-1/2}$ intervals are observed before the current either approaches zero or reaches a minimum, depending on temperature and potential. The results have already been reported for temperatures of −50°C (1) and 25°C (2).

Discussion

Calculation of diffusion parameters.—From the slopes of the linear i-$t^{-1/2}$ segments, values of $ZD^{1/2}C$ are obtained (2) where Z is the charge on the diffusing species of concentration C. Assuming that the diffusion coefficient D obeys on Arrhenius-type equation and that Z and C are independent of temperature, values of the activation energy of diffusion, $\Delta H^{\neq}$, can be obtained from the slope of log $(ZD^{1/2}C)$ plotted as a function of $1/T$. Values of $\Delta H^{\neq}$ for the post-nucleation-and-growth diffusion-limited intervals of approximately 40 kJ/mole (10 kcal/mole) were previously reported (1).

The assumption of a temperature-independent concentration is of unlikely validity, however. Furthermore, correct values of Z and C must be assigned at each temperature in order to obtain valid estimates of the preexponential factor in the Arrhenius equation and hence of the entropy of activation of the rate-limiting process.

At 25°C values of Z and C and the nature of the diffusing species were inferred from the data, using available kinetic and thermodynamic parameters for a multiphase model of the electrode (2). Values for relevant parameters at low temperatures are generally unavailable however and so have had to be estimated by relying on the following assumptions.

1. The same sequence of processes occurs at all temperatures up to the beginning of the formation of β-PbO_2. This assumption is based on the similarity of the potentiostatic transients at all temperatures studied (2).

2. The equilibrium concentration of the current-limiting diffusing species can be accurately estimated as a function of temperature by assuming a temperature-independent ΔH for the concentration-determining equilibria and that the integrated form of the van't Hoff equation (8) applies, *i.e.*, that

$$\ln\left(\frac{K_2}{K_1}\right)=\frac{-\Delta H}{R}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)$$

where K_2 and K_1 are the equilibrium constants at temperatures T_2 and T_1, respectively.

3. Near-equilibrium conditions prevail during charging so that the equilibrium concentrations thus calculated can be identified with the quantity C in the values of $ZD^{1/2}C$ extracted from the kinetic data. This assumption may be the least tenable at the lowest temperatures and when there is appreciable current flow.

In order to obtain the temperature dependence of D, values of C were calculated for the diffusion-limited charging stages for which values of $ZD^{1/2}C$ had been obtained at most temperatures. It was assumed that the same diffusing species limited the current as at 25°C (2). The bisulfate-sulfate equilibrium was also considered, although previously judged unlikely (2). Accordingly, the van't Hoff equation was applied to the following equilibria

$$PbSO_4 = Pb^{++} + SO_4^{=} \quad \Delta H = 3.0 \text{ kcal/mole} \quad [I]$$

$$Pb^{++} + OH^- = PbOH^+ \quad \Delta H = -7.6 \text{ kcal/mole} \quad [II]$$

$$HSO_4^- = H^+ + SO_4^{=} \quad \Delta H = -5.2 \text{ kcal/mole} \quad [III]$$

In the case of [I], the value of ΔH was estimated from the solubility of $PbSO_4$ in water at 25° and 0°C (9) and from tables of thermodynamic data (10). Values of C as a function of T were thence obtained assuming that $C = [Pb^{++}] = [SO_4^{=}] = \sqrt{K_{sp}}$, *i.e.*, that the concentration of Pb^{++} is controlled by the solubility of $PbSO_4$ in near-neutral pore electrolyte solution (2, 3).

In the case of [II], ΔH was estimated from reported stability constants (11) of $10^{7.51}$ at 25°C (11a) and $10^{6.39}$ at 100°C (11b), determined by similar methods. Values of $C = [PbOH^+]$ could then be calculated as a function of temperature and pH using the value of $[Pb^{++}]$ obtained from [I]. For the bisulfate-sulfate equilibrium [III], ΔH was estimated from tables of thermodynamic data (10) and from values of the equilibrium constant determined over the range 5°-55°C (12).

The values of C thus calculated are given as a function of temperature in Table I. At 25°C the values of $D^{1/2}C$ for Pb^{++} and for $PbOH^+$ at pH = 7 are approximately equal. Thus the observed ratio of slopes $(ZD^{1/2}C)$ of 2:1 at 25°C previously discussed (2) supported the ratio of Z values of 2:1. It was, therefore, inferred that the last diffusing species to limit the current, before the first current minimum, was $PbOH^+$, and further that this stage was immediately preceded by limiting Pb^{++} diffusion. The ratio of slopes of 1:2 at −40°C, following deep discharge (Fig. 2), still supports the same sequence of rate limitation in spite of the apparent reversal in time of the ratio of slopes. This is explained by the much lower value of $[Pb^{++}]$ in comparison to $[PbOH^+]$ at −40°C. Thus, in order to interpret the single diffusion-limited interval observed following the standard discharge at −40°C (Fig. 1) and other low temperatures, the most probable assignment of diffusing species is the $PbOH^+$ ion.

Using the values of $C = [PbOH^+]$ at pH = 7 from Table I, values of D were calculated from the experimental data at each temperature and an Arrhenius plot was constructed (Fig. 3). At potentials below the reversible potential (in 35% sulfuric acid) of 1.087V, *i.e.*, at 0.9 and 1.0V, a linear relationship between log D and $1/T$ was obtained over most of the temperature range investigated. If the diffusion coefficient is given by

$$D = D_0 \exp(-\Delta H^{\neq}/RT)$$

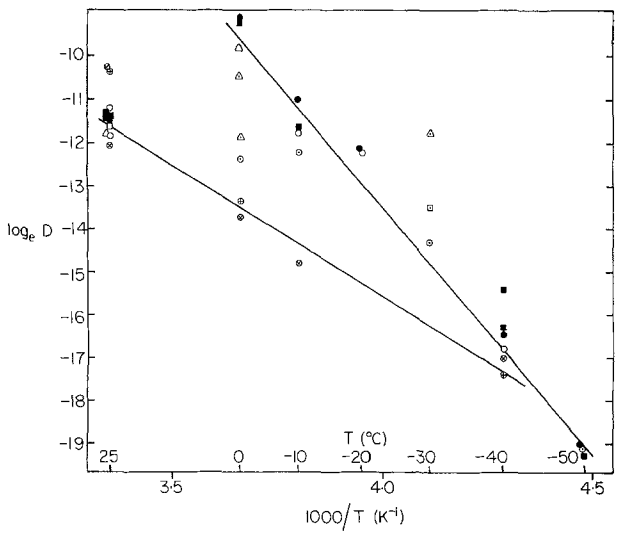

Fig. 3. Arrhenius plot for prenucleation-and-growth-peak diffusion-limited interval, assuming that the diffusing species is $PbOH^+$, pH = 7 (see text). Applied potentials were: ⊕, 0.9V; ⊗, 1.0V; ⊙, 1.1V; ●, 1.2V; ■, 1.3V; △, 1.4V; □, 1.5V.

values of $\Delta H^{\neq} = 11.4 \pm 0.9$ kcal/mole and log $D_o = 3.1 \pm 0.7$ describe the dependence of the diffusion coefficient on temperature. It is of interest to note that the values of D at 25°C and at higher potentials also fall on the same line. However, at higher potentials the linear dependence of log D on $1/T$ was not observed above 0°C. For the range of −50°-0°C, values of $\Delta H^{\neq} = 23.4 \pm 1.6$ kcal/mole and log $D_o = 14.6 \pm 1.5$ were determined for charging potentials of 1.1-1.5V. If it is assumed instead that the diffusing species is Pb^{++}, values of $\Delta H^{\neq} = 9 \pm 1.5$ and log $D_o = 3.5 \pm 1.1$ are obtained for the same range of temperature and potentials, but no unambiguous linear region is found at 0.9 and 1.0V.

Such high values of $\Delta H^{\neq}$ and D_o were also obtained from analysis of the diffusion-limited currents in the intervals following the nucleation and growth peak. Accordingly, the significance of such values will not be discussed until the derived results for the later intervals have been presented.

From the results at 25°C (2), it was concluded that the first diffusion-limited interval following nucleation-and-growth control was due to $PbOH^+$ diffusion at pH values increasing from 8.1 at 1.0V to 8.8 at 1.6V. In order to remain consistent with the semi-infinite linear diffusion model, it was concluded that this diffusion process could not begin until two-dimensional nucleation and growth were virtually complete. If the coordinates of the nucleation and growth peak were (t_m, i_m), this occurred at $t_o \simeq 1.5\ t_m$ for all potentials. If there had been some other explanation for the apparent inconsistency (negative current intercepts at infinite time) with the model and the diffusion processes began instead at $t_o = 0$, the diffusing species could have been either $PbOH^+$ at pH = 9.0 ± 0.5, or H^+ at pH ≃ 2, controlled by the sulfate-bisulfate equilibrium.

The reduced variable plots for the postnucleation-and-growth interval at −20°C are shown in Fig. 4. Similar results have previously been published for data obtained at −50°C (1) and at 25°C (2). As at 25°C, the intercept of the first linear i-$t^{-1/2}$ interval in the range $0.6 < (t/t_m)^{-1/2} < 0.8$ yields a negative current intercept at infinite time. If it is assumed that the diffusion process does not begin at $t_o = 0$, but after completion of the two-dimensional nucleation and growth process at $t_o \gtrsim 1.5\ t_m$, negative current intercepts (although less negative) were still obtained at all temperatures below 0°C, except at

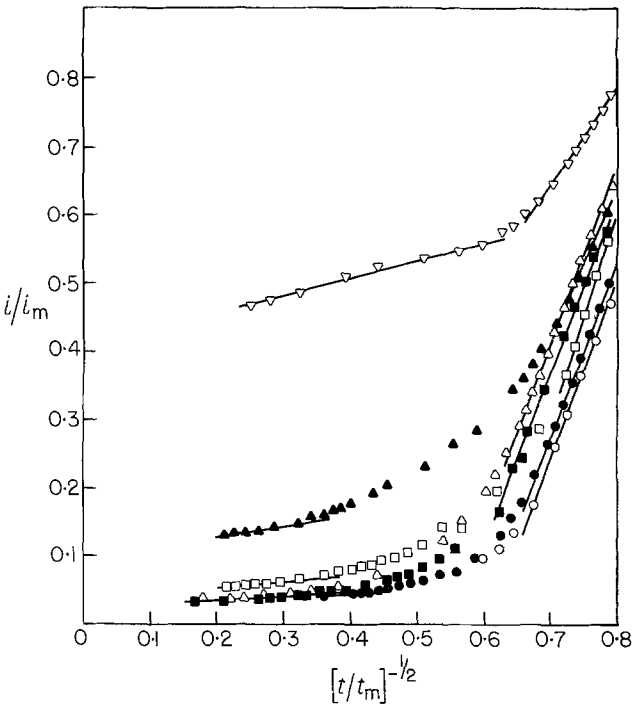

Fig. 4. Reduced variable plot of current vs. $t^{-1/2}$ for potentiostatic transients at various potentials and at −20°C, for postnucleation-and-growth interval. Values of (t_m, i_m) are indicated for each potential: ⊙, 1.1V (250 sec, 36.6 μA); ●, 1.2V (78 sec, 124 μA); ■, 1.3V (31.0 sec, 244 μA); △, 1.4V (14.55 sec, 473 μA); □, 1.5V (13.0 sec, 680 μA); ▲, 1.6V (10.45 sec, 898 μA); ▽, 1.7V (7.9 sec, 1.120 mA).

high potentials (≧ 1.5V for $t_o = 1.5$-$2.0\ t_m$) and at underpotentials (0.9 and 1.0V). This is illustrated for the same −20°C data in Fig. 5 for $t_o = 1.5\ t_m$.

It is apparent that some other or additional explanation is required for the negative intercepts at low temperatures. The shapes of such reduced variable plots are so little dependent on temperature that it is difficult to believe that different mechanisms for oxidation are operative at 25°C from those at temperatures below 0°C. What further effects could cause

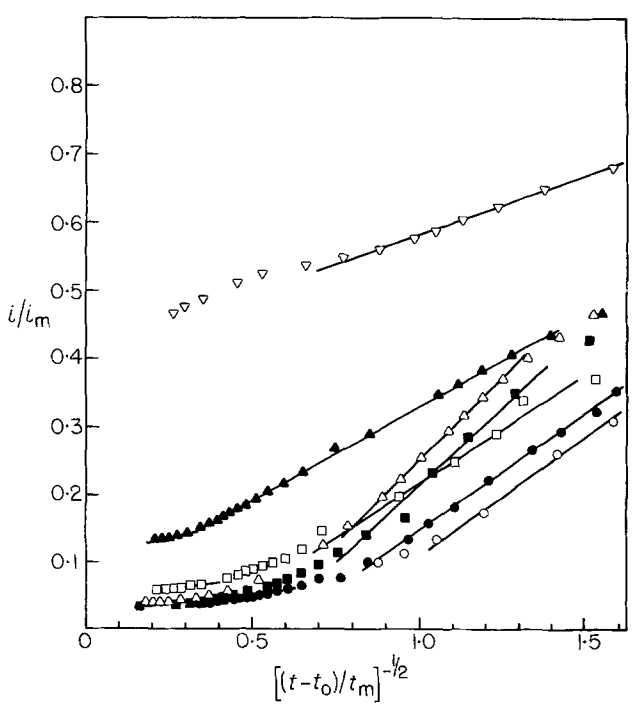

Fig. 5. Current vs. time$^{-1/2}$ (units of i_m, $t_m^{-1/2}$) for $t_o = 1.5\ t_m$. Symbols and data are identical to those of Fig. 4.

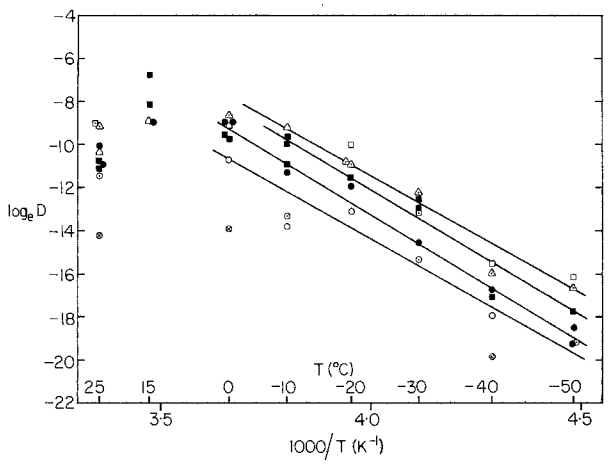

Fig. 6. Arrhenius plot for first diffusion-controlled postnucleation-and-growth-peak interval, assuming that the diffusing species is $PbOH^+$, pH = 9 (see text). Symbols have same significance as in Fig. 3.

the current to decrease more quickly at low temperatures than predicted by the diffusion model? One possibility is that, because of the longer time scales (*i.e.*, larger values of t_m) for oxidation at low temperatures, the diffusion layer begins to approach the dimensions of the film during the postnucleation-and-growth period, except at high overpotentials, where the values of t_m are still relatively small; *e.g.*, at 1.7V, t_m = 4-8 sec with no appreciable temperature dependence from 0° to −50°C [but note (2) that t_m was smaller by more than a factor of 10 at 25°C]. If the diffusion layer exceeds the film dimensions, erroneous application of the model would yield "virtual" concentrations, larger than the true concentrations at the source of the diffusing ions, and therefore high values of $ZD^{1/2}C$, *i.e.*, high i-$t^{-1/2}$ slopes. This explanation, however, fails to account for the more normal diffusionlike dependence of i on $t^{-1/2}$ at very long times. Furthermore, it would not be expected that the linearity of the i-$t^{-1/2}$ plots would be retained because the "virtual" concentration would be increasing with time so that the slope would also be expected to increase with time.

An alternative explanation is that depletion of the reactant species occurs at low temperatures due to partial blockage of the pores (discussed below) so that only a limited quantity of reactant is available for oxidation. As reactant is progressively consumed, the current would have to fall more quickly than predicted by the semi-infinite linear diffusion model. Such an effect might not necessarily predict a linear dependence of i on $t^{-1/2}$, but the deviation from linearity at longer times would be in the direction observed.

From data, such as given in Fig. 4, and the temperature dependence of concentration from Table I, values of diffusion coefficients were calculated as a function of temperature assuming that $C = [PbOH^+]$ at pH = 9. Very similar values were also obtained for $C = [H^+]$. The results are given in Fig. 6, where a linear dependence of ln D on $1/T$ can be observed at potentials of 1.1-1.4V over the temperature range of −50°-0°C. The parameters of the fitted lines are given in Table II for each potential and are of the order of $\Delta H^{\neq} = 23$ kcal/mole and $D_0 = 10^{-14}$. Although a somewhat more rigorous treatment would have been obtained by using the slopes of data plotted in the manner of Fig. 5, the values of the parameters of Fig. 6 would not be appreciably altered.

During the final diffusion-limited interval at 25°C, it was postulated (2) that the current was limited by the diffusion of tetravalent lead ions and that the internal acidity of the electrolyte in the pores of the electrode was greater than that in the bulk electrolyte. Following or during this interval the charging behavior at low temperatures appeared to become qualitatively different than at temperatures ≥ 0°C. Values of $ZD^{1/2}C$ yielded $D \geq 10^{-5}$ cm²/sec for $C \leq 10^{-5}$M. If $C = [Pb^{4+}]$, a pH of the order of −1 was necessary to obtain reasonable values of $D \simeq 10^{-5}$ cm²/sec. This local pH appeared to be determined by kinetic factors, not thermodynamic ones. Therefore, no estimate of the dependence of pH or of $[Pb^{4+}]$ on temperature is possible. Furthermore, the diffusing species may well be different at low temperatures than at 25°C. To obtain the activated diffusion parameters for this interval, a constant value of $C = 10^{-6}$ mole/cm³ was assumed (this corresponds to a temperature-independent local pH of −1.2 if a further assumption is made that Pb^{4+} is the diffusing ion) and the resulting Arrhenius plots are given in Fig. 7. Values of $\Delta H^{\neq}$ of the order of 10 kcal/mole (see Table II) were obtained for potentials ≥ 1.2V. At 1.1V, the slope was substantially smaller, corresponding to $\Delta H^{\neq} = 3.5 \pm 1$ kcal/mole.

Calculation of parameters of the activated state.— The theory of absolute reaction rate predicts that the diffusion coefficient can be described by an equation of the form (13)

$$D = e\lambda^2\left(\frac{kT}{h}\right)\exp(\Delta S^{\neq}/R)\exp(-\Delta H^{\neq}/RT)$$

where e is the base of the natural logarithms and λ, the "jump distance," is the distance between successive

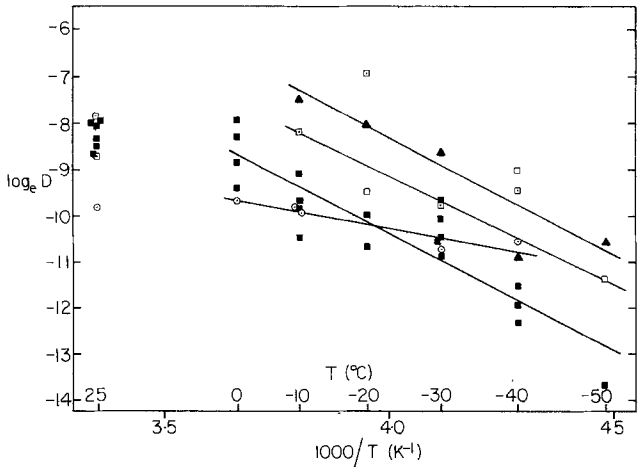

Fig. 7. Arrhenius plot for last diffusion-limited interval, assuming a temperature-independent diffusion-limiting species of concentration C = 10^{-6} mole cm^{-3}. Applied potentials were: ⊙, 1.1V; ■, 1.2-1.4V; ⊡, 1.5V; ▲, 1.6V.

equilibrium positions of the diffusing species. $\Delta S^{\neq}$ and $\Delta H^{\neq}$ are the molar activation entropy and energy, respectively, and the remaining constants have their usual significance.

From the experimental data one obtains a relationship of the form

$$D = D_0 \exp(-\Delta H^{\neq}/RT)$$

Thus, assuming an appropriate value for λ, $\Delta S^{\neq}$ can be obtained from the values of D_0 using the equation

$$\Delta S^{\neq}/R = \ln D_0 - \ln(e\lambda^2 kT/h)$$

For the values of $\Delta S^{\neq}$ given in Table II, it was assumed that $\lambda^2 \simeq 10^{-15}$ cm^2, *i.e.*, that λ was of the order of magnitude of the diameter of one water molecule. T was taken as the temperature at the middle of the linear range. The calculated values of $\Delta S^{\neq}$ are relatively insensitive to the value of the last term of the last equation above, for the large values of D_0 observed. Thus the choices of λ^2 and T do not become very important until log D_0 becomes less than 3 (at which point the error in $\Delta S^{\neq}$ becomes 10% for an error in $\lambda^2 T$ of a factor of 2). Included in Table II, for comparison with $\Delta S^{\neq}$, are values of $\Delta H^{\neq}/T$, calculated using the same average value of T as used for calculating $\Delta S^{\neq}$.

Interpretation.—The experimental results at 25°C were found to fit a multiphase model of the positively polarized lead electrode in sulfuric acid solution (2). The major feature of the model was a slightly alkaline (pH = 7-9) electrolyte in the pores between a protective lead sulfate layer and the lead substrate. The electrode material in this interior part of the electrode consisted of PbO, α-PbO_2, and basic sulfates of lead.

Such a dilute pore solution (as was required to fit the model) would certainly have been frozen if in the bulk state. In the pores a significant fraction of the water might be expected to be adsorbed on the pore walls or to be influenced by the short-range orienting forces of such adsorbed water.

A number of questions need to be answered in order to interpret the data presented. Some such questions are: Does the pore solution freeze at low temperature? If so what effects would such freezing have on the transport properties of the pore electrolyte constituents? Do the same diffusing species control the charging current at temperatures below the freezing point as at 25°C? If freezing does not occur, why not?

The similarity of the potentiostatic transients at all temperatures suggests that freezing does not occur. However, the sharp break in the Arrhenius plots at temperatures of 0° to −10°C suggests that it does. There are other such apparently conflicting phenomena and not only in this particular electrochemical system. In the case of water adsorbed on clays, for example, dielectric relaxation experiments, carried out in the microwave frequency range, indicated that below −10°C all water in excess of about two layers between the clay plates had formed ice (14). When the same experiments were done at radio frequencies, a dispersion in the two-layer-thick films of adsorbed water was observed. The unfrozen film of water decreased in thickness as the temperature was lowered from 0° to −10°C and then decreased no further below −10°C to below −50°C. The unfrozen water film must be strongly bound to the clay surface to resist freezing even at temperatures below −50°C.

Some idea of the type and strength of bonding of water on solids more similar to the lead electrode than clay can be deduced from thermal desorption studies of water on metal oxide surfaces. Studies of the adsorption of water vapor on PuO_2 (15) yielded desorption energies of 68 and 20 kcal/mole for the first and second adsorbed water layers, respectively, corresponding to 58 and 10 kcal/mole, respectively, for desorption to the aqueous phase. These may be compared to values (similarly converted to aqueous phase/solid phase adsorption) of 30 and 5 for ThO_2 (16), 19 and 9 for TiO_2 (17), and 50 and 10 for MgO (18) and W (15). It was proposed (15) that the larger adsorption energy corresponded to a dissociative chemisorption of water on the solid oxide, whereby one water molecule dissociated and reacted with one surface oxygen to produce two hydroxyl groups, each bound to a surface metal atom. The smaller adsorption energy was due to the "quasi chemisorption" of a second water layer onto the hydroxylated surface by hydrogen bonding. Beyond this second layer bulk water characteristics were quickly reached.

Such values, particularly for the case of TiO_2 (17) are similar to the activation energies given in Table II. Values of $\Delta H^{\neq} \gtrsim 13$ kcal mole^{-1} for PbO_2 formation have also been obtained from cyclic voltammetry measurements (19). An exception is the 3.5 kcal mole^{-1} activation energy for the last diffusion interval at 1.1V, which is characteristic of diffusion in bulk electrolyte.

The values of $\Delta H^{\neq}$ are therefore consistent, for the most part, with a model of the electrode in which the electrolyte in the pores is frozen, except for two or three layers of adsorbed water on the pore walls. The concentration-determining chemical equilibria and diffusion processes must therefore take place within an adsorbed film between the ice and pore walls (except for proton conduction which occurs very well in ice). Under such conditions, the dielectric constant of the aqueous film would be reduced, therefore favoring the formation of less highly charged (Z = 0 or 1) species than in bulk solution. Other changes in transport properties (*e.g.*, viscosity, diffusion) and thermodynamic properties (*e.g.*, equilibrium constants, activity coefficients) would also be expected to occur. It may be that such changes invalidate the rather simple-minded estimation of concentrations used here and that species other than those postulated on the basis of the 25°C experiments are the diffusing ions. Furthermore, it may be that the chemical reactions controlling the reactant concentrations are much further from equilibrium at low temperatures than at 25°C. No answers can be given to these objections at the present time except to explore further the consistency between the experimentally derived results and the model.

The values of $\Delta S^{\neq}$ (Table II) calculated from D_0 are unusually large for activated diffusion. Although

the large values of $\Delta H^{\neq}$ (~23 kcal/mole) might be interpreted as due to solid-state diffusion (1), this interpretation becomes less tenable in view of the concomitantly large values of $\Delta S^{\neq}$. The latter suggest the participation of desorption and/or desolvation processes during formation of the activated complex. Furthermore, the similar magnitudes of $\Delta S^{\neq}$ and $\Delta H^{\neq}/T$ suggest the possibility of a phase change such as desorption. Further evidence relevant to the role of desorption (or desolvation) was obtained at 25°C (2) where unusually low values of the transfer coefficient, near the beginning of the potentiostatic charge interval, were obtained. Such low values of α may have been due to rate control by the partial dehydration of the reactant ion or by a slow preceding homogeneous dissociation step.

Calculation of absolute values of the standard ionic entropies of solution (or hydration) is approximate because of the difficulties of determining an acceptable value for the reference ion (20, 21). The most recent, and probably most reliable, compilation (21) estimates values of $-\Delta S^{\neq}$ (hydration) of the order of 30 cal mole^{-1} °K^{-1} for small monovalent cations. For Ba^{++} and Sr^{++}, the ions most similar to Pb^{++} in size and charge, values of $-\Delta S \simeq 60$ cal mole^{-1} °K^{-1} are given (20).

If ionic diffusion occurs through, or within the influence of, layers of adsorbed water, desolvation (at least in part) of the diffusing ion probably is included in the activation process. In order for diffusion to occur to or from a reaction site, desorption of adsorbed water is also likely to be necessary. Values of ΔS for desorption from the charged electrode surface are expected to be of the same order of magnitude as from an ion, *i.e.* $\Delta S > 0$ and several tens of entropy units in magnitude.

Thus the model which emerges, for diffusion at low temperatures, is that of a near-surface diffusion process in the water layer between the pore walls and ice activated by partial ionic desolvation and/or electrode desorption processes. For those processes having values of $\Delta H^{\neq} \simeq 10$ kcal mole^{-1} and $\Delta S^{\neq} \simeq 28$ cal mole^{-1} °K^{-1}, the activation may involve desorption of the second "pseudochemisorbed" water layer from the electrode, or partial desolvation of the diffusing ion. For the values of $\Delta H^{\neq} \simeq 23$ kcal mole and $\Delta S^{\neq} \simeq 75$ cal °K^{-1} mole^{-1}, activation may involve desorption of the chemisorbed (hydroxylated) layer of surface water or both desorption and partial desolvation processes. Some part of the value of $\Delta S^{\neq}$ may be due to irreversibility but since this is impossible to estimate it is difficult to be more specific about the details of the activation process.

One experimental value that was obtained for the final diffusion process at 1.1V does not fall into either of these categories. In this case the values of the activation parameters were typical of diffusion in bulk aqueous solution. However, it is possible that the potentiostatic transients for the experiments at 1.1V were not followed for a long enough period of time and that the results obtained at this potential are characteristic of fortuitous linearities in the intermediate time interval following nucleation and growth previously mentioned (2). Examination of the i/i_m *vs.* $(t/t_m)^{-1/2}$ plots for the data at −40°C suggests that the experiment was terminated too soon, *i.e.*, at too large a value of $(t/t_m)^{-1/2} \simeq 0.45$, and that at least one more linear region might have been expected to occur had the experiment been continued. At −50°C the experiment had definitely been terminated prematurely. Hence the activation parameters calculated for 1.1V applied potential may be spurious.

The values obtained for $\Delta H^{\neq}$ and $\Delta S^{\neq}$ depend on a number of stated but unproven assumptions. The values of D_0 and hence $\Delta S^{\neq}$ will also be sensitive to the electrode roughness factor and to the slope of the Arrhenius plots, *i.e.*, to $\Delta H^{\neq}$. The latter term is independent of electrode area but sensitive to changes of roughness factor or values of ZC with temperature, terms which are used to calculate the temperature dependence of D. Even if these assumptions are seriously wrong, however, the calculated values of $\Delta S^{\neq}$ still would be larger than expected for diffusion in bulk electrolyte, unless the dissociation reactions which determine reactant concentrations have very large and positive values of ΔH, or the concentrations decrease much more strongly with temperature than calculated, for other reasons. Furthermore, very large roughness factors would have to be obtained to seriously alter the interpretation of the large $\Delta S^{\neq}$ values.

In view of the number of assumptions required to interpret the experimental results in a consistent manner, it would be unreasonable to claim that solid-state diffusion has been completely disproven, or that the sequence of rate-limiting diffusion processes proposed is correct in all its details. However, whether or not all of the diffusing species have been correctly identified, it is possible to construct a model of the kinetics of the constant potential charging process consistent with all of the quantitative results presented here and in the previous paper (2). The conclusions, based on such a model, are summarized as follows.

Conclusions
