(Received 17 March 1994; revised version received 18 January 1995; accepted 26 January 1995)

Abstract

Two hot-pressed, dense, silicon nitride materials have been exposed to the flue gases of an aluminium smelting furnace heavily contaminated with Al, Ca and K-containing dust and vapours. Transmission electron microscopy (TEM) has been used to examine microstructural changes occurring in the silicon nitride at the interface between corroded and uncorroded material. Extensive diffusion of contaminant metal into the intergranular glass of the silicon nitride occurs, associated with physical and chemical changes in the intergranular regions, and a marked loss of mechanical strength.

1 Introduction

Silicon nitride ceramics are being considered for use as structural components in heat-exchangers in a range of industrial processes. One example is the aluminium remelting furnace where waste heat recovery would be expected to lead to significant energy savings. During the refining operation considerable amounts of a fluoride and chloride flux are added to the metal to form slags. The flue gases can thus contain high concentrations of salts, and silicate byproducts, and they are highly corrosive towards the non-oxide ceramics such as silicon carbide and silicon nitride. Most reported high temperature corrosion studies on silicon nitride have been carried out under closely defined and simplified laboratory conditions. A small number of studies have also been made involving the exposure of silicon carbide and silicon nitride materials to high temperature working industrial environments.[1–3] The work reported here was part of a study carried out to identify the major consequences of corrosive degradation of dense multiphase silicon nitride materials under severe industrial conditions.

Previous detailed studies on silicon nitride[4–8] have concentrated attention on the mechanism of surface oxidative corrosion with relatively thin (~20 μm) layers of corrodent oxide, or with continuous supplies of volatile corrodent at low vapour pressure. It has been shown that surface reactions, and phase equilibrium relationships, involving silicon dioxide and the oxide components of the corrosion film of the type:

$$M_aO_{b(s)} + SiO_{s(s)} = M_aSiO_{(2+b)(l)}$$

are of importance in controlling the rate of corrosion. Surface equilibria can also determine the extent of corrosion caused by a specific amount of corrodent oxide. Liquid silicates of composition not in thermodynamic equilibrium with silicon dioxide (SiO_2) are effectively solvents for SiO_2 and thus prevent the formation of potentially protective films on the silicon nitride surface. These laboratory studies have shown the importance of actual or incipient SiO_2 films at the silicon nitride–silicate film interface as oxygen transport barriers,[9] and therefore able to provide resistance against corrosion. The oxygen conductivity of pure SiO_2 in amorphous and crystalline form is low: silicate glasses and liquids are markedly more permeable towards oxygen.[10]

Detailed attention has not been paid to processes occurring in the silicon nitride beneath the surface oxide film during high temperature corrosion, and under conditions where the formation of a protective SiO_2 layer may be difficult. The microstructure of the silicon nitride is an important factor, and in particular the presence of the interconnecting siliceous intergranular glass. Intergranular cations are particularly important during oxidation in that they are able to diffuse from the intergranular phase to the surface oxide film to react to form silicates. The outwards diffusion of metal cation then becomes an important component of the rate controlling process.[11] However,

*To whom all correspondence should be addressed.

during high temperature oxidative corrosion under conditions where high concentrations of metal cations are deposited on the outer surface of the nitride, inwards diffusion of these cations into the intergranular glass will also occur. One consequence will be a change in composition of the glass, to one richer in contaminant metal oxide and of lower viscosity,[12] and resulting in the silicon nitride having lower high temperature strength and creep resistance. There exists also the possibility of internal oxidation through the rapid transport of oxygen to the silicon nitride grains through the more conductive intergranular glass or liquid. The implications for the long term structural stability and load-bearing capability of the component are thus considerable.

The object of the study reported here was to detect the existence of such inwards diffusion processes by examination of the intergranular regions of the silicon nitrides close to the surface corrosion product film, using transmission electron microscopy (TEM) on thinned foils. Two dense commercial grades of hot-pressed silicon nitrides were used for this study: one (designated SN1) had been densified using yttrium oxide (Y_2O_3); the other (SN2) had been formed using magnesium oxide (MgO). Both contained iron (the SN1 less than the SN2) which had been used possibly either as a silicon nitridation catalyst in the production of the silicon nitride powder, or as a densification aid.[13] The microstructure of the MgO-densified SN2 has already been discussed with regard to the function of iron during the hot-pressing densification stage.[14]

These materials were mounted in refractory concrete holders in an industrial continuous operation aluminium scrap remelting furnace, and exposed for extended times to the flue waste gases at temperatures in the region of 1050°C.

2 Experimental

The chemical compositions of the two commercial hot-pressed silicon nitrides (Feldmühle, Plochingen, Germany), expressed in terms of weight % of oxide constituent (or the equivalent), are given in Table 1.

Small test bars of material, of dimension 14 × 7 × 7 mm^3, were partly embedded in a block of refractory concrete and mounted in the wall of the flue gas duct of a standard large aluminium remelting furnace (Aluminium Foundries, R. Claeys, Lichtervelde, Belgium) fired by three natural gas burners. Two thermocouples were fixed to the concrete blocks with their tips close to the silicon nitride bars. The furnace was operated normally for times up to 1000 h during which time

the temperature fluctuated between 1000 and 1100°C with a mean of 1050°C. Flue gases were contaminated with chlorides and fluorides used as slag-forming fluxes in earlier furnace operating cycles. Exposed bars were removed, and sectioned for examination across the regions which had been fully in the flue gas flow. Scrapings of deposit from corroded surfaces were milled and analyzed by X-ray diffraction (XRD).

TEM examinations (JEOL 200CX equipped with a LaB_6 filament operating at 200 kV) were made of ion-beam thinned discs cut from as-received, and exposed, plates of material 7 × 14 × 0·5 mm^3. The more loosely adhering surface scale was carefully brushed away from each oxidised plate, and the silicon nitride mechanically ground from the unreacted side of the plate to give a maximum thickness of 150 μm. Discs 3 mm in diameter were drilled from the thinned plate and dimpled from both sides until the corrosion layer–bulk material interface was barely visible. Uncorroded materials were prepared in the standard way. Discs were then further ion-milled to perforation in a Gatan 600 dual ion mill using argon ions at 6 kV with a 15° incidence angle, and were finally coated with a 20 nm carbon film to prevent charging in the electron beam. The samples of corroded silicon nitride used for TEM examination were therefore planar sections approximately parallel to the corroded surface (rather than sections normal to the external surface) in the vicinity of the interface between uncorroded, and corroded, material.

The mechanical strengths in four-point bend (Instron Universal test equipment) of as-received and corroded materials were measured before and after exposure to flue gas, using a self-aligning fixture (span 40/20 mm) and a crosshead speed of 6 μm s^{-1}.

3 Results

3.1 The corrosion environment

Two typical random analysis of the flue gases during the course of normal corrosion tests are given in Table 2. These showed that while the tempera-

ture and gas flow rates remained constant, changes in the combustion air/gas ratio could lead to swings in condition from a high excess oxygen level to marginally oxidising. However, the residual oxygen, together with the oxygen partial pressure arising from the CO_2 and H_2O levels, would have been adequate to ensure stability of the SiO_2 in the oxide film and suppress loss as silicon monoxide (SiO) vapour.

SEM X-ray microspectroscopy (XMS) analyses of flue dust particles showed them to contain predominantly K, Cl, Si, Al and Ca, with lesser amounts of Na, Zn, S, Mn, Ti, Cr, and Fe. Between 70 and 95% of the particles were water soluble, and were mainly the fluorides and chlorides of K, Na, Al, and Ca; there were insoluble silicates of Al and Fe.

The surfaces of the corroded silicon nitride bars were covered with thick deposits of severely blistered material, most probably the result of nitrogen evolution from the underlying silicon nitride. The blisters appeared to consist of a glassy material, which had been liquid at the corrosion temperature, and one or more crystalline phases. XMS elemental analysis of material obtained from the blisters showed that they contained K, Si, Ca, Al, and Cl, and lesser amounts of Zn, S, and either Y, or Fe and Mg, depending on the base silicon nitride composition (Y for SN1, Fe and Mg for SN2). It appeared that the glasses were predominantly a potassium aluminosilicate, and that the crystals, on the bases of XMS analyses, were either a calcium yttrium silicate (SN1), or calcium magnesium silicate (SN2), together with the potassium aluminosilicate, $KAlSiO_4$: strong peaks for sodium potassium sulphate were identified by XRD.

3.2 Corroded SN1

XRD examination showed that the SN1, yttrium oxide-densified, silicon nitride contained β-silicon nitride as the major crystalline phase together with the intergranular yttrium-containing phases, SiY, $Y_2Si_3O_3N_4$ and $YNSiO_2$. A general microstructural

overview of uncorroded SN1 silicon nitride at the corrosion layer interface with unattacked material, and in a plane parallel to the external exposed surface, is provided by the TEM micrograph in Fig. 1. The light regions are β-silicon nitride grains; pockets of a yttrium-rich intergranular phase, which also contained Fe, are shown clearly as the dark regions (arrowed) at higher magnification coupled with XMS analysis (Fig. 2). Many of the yttrium-rich regions appeared to be interconnected. These micrographs are not distinguishable form those of uncorroded material. Figs 3 and 4 show planar sections, but now just within the corroded zone. Figure 3 illustrates the changes taking place in the intergranular region, with the appearance of 100–200 nm dimension regions of foamed glass (liquid at high temperature) at points where the (lighter) silicon nitride grains come into contact with wetting liquids. Because this figure shows a planar section at the corrosion front there is the likelihood that some of the grain boundaries seen are those of uncorroded material. There is here, however, an indication of penetration of a liquid-forming phase at the silicon nitride grain

Fig. 2. Corroded SN1 at high magnification: XMS analysis of dark regions showing the presence of Y and Fe.

Fig. 3. Corroded SN1: 100 to 200 nm regions of foamed intergranular glass at a Si_3N_4 grain, and (smaller arrows) indications of general intergranular attack.

boundary (both features arrowed). At higher magnification (Fig. 4(a)) ~10 nm dimension microvoid formation at a silicon nitride–silicon nitride grain boundary can be seen, leading in extreme cases to the complete grain face separation in Fig. 4(b). On the basis of the lighter colour of the void regions of Fig. 4(b) it is believed that they do not contain glass: whether the nm dimension, more spherical, regions of Fig. 4(a) are voids or glass microspheres is not so certain, but it is assumed that they are again gas-filled bubbles. The very fine scale of all these regions made reliable XMS analyses impossible.

3.3 Corroded SN2

The more heavily iron-contaminated and glassy SN2 silicon nitride also contained predominantly β-Si_3N_4, together with intergranular FeSi, $FeSi_2$, Si_2N_2O, and the Olivine $(Mg,Fe)SiO_4$ forsterite structure solid solution; glass was present at many three grain junctions, and identification of the Mg-containing secondary phase was assisted by XMS analysis. Figs 5(a) and (b) show typical regions of material at the corrosion zone interface after corrosion for 800 h. The MgO-containing silicon nitride was more severely degraded during corrosion than the SN1, Y_2O_3-densified silicon nitride. A marked feature of the microstructure of this material (arrowed) is the regions which appear to be completely depleted of glass, bounded by silicon nitride grains. These are not seen in uncorroded material and suggest the large-scale loss of a liquid (of lowered viscosity) from these regions. Figure 6 shows (arrowed) a crystalline

Fig. 5. Corroded SN2: typical planar view regions at the corrosion zone interface after corrosion for 800 h; arrows indicate intergranular voids foreign to the uncorroded microstructure.

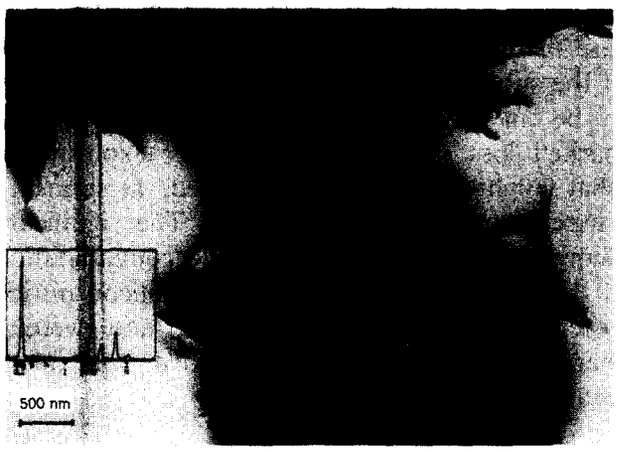

Fig. 6. Corroded SN2 at higher magnification: Fe-rich inclusions and evidence of extensive Zn contamination.

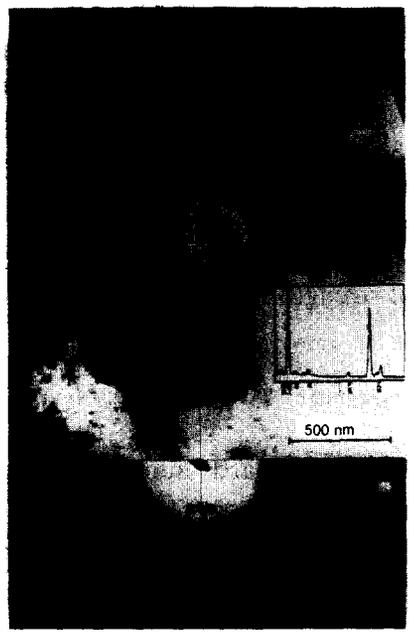

Fig. 7. Corroded SN2: proximity to the corroded external surface; arrowed phase identified by selected area diffraction as β-cristobalite.

Fe-rich intergranular phase, together with the corresponding XMS spectrum, suggesting that it is an iron silicide inclusion, which from the contacting angle with the bounding silicon nitride grains appears to be non-wetting. There is evidence from the XMS spectrum of significant penetration of flue gas Zn into this region of the material. This photograph also shows small neighbouring regions which appear to be devoid of glass.

Figure 7 shows a section of material nearer still to the surface. The arrowed phase was identified by SAD as predominantly β-cristobalite although some reflections could not be indexed. What may be relics of hexagonal symmetry silicon nitride grains are visible in the vicinity, and the appreciable amounts of S present in this film, in association with K and Zn, suggest the presence of sulphates.

Table 3. Strength and residual strength, after exposure at ~1050°C for 100 h

	4-point bend strength/MPa		
Material	*Uncorroded*	*Corroded*	*% loss*
SN1	610 ± 39 [20]	437 ± 62 [8]	28
SN2	610 ± 54 [10]	282 ± 38 [8]	54

3.4 Strength measurements

Bars of both materials, uncorroded and after corrosion for 100 h, were cut from the plates and broken in 4-point bend. The mean strengths and standard deviations, and the numbers of bars used for each series, are shown in Table 3. While both materials lost strength, the more glassy, magnesium oxide densified SN2 material was the most strongly affected by corrosion.

4 Discussion

These examinations using TEM showing details of the silicon nitride oxidative corrosion process under real industrial conditions, and the nature of some of the sub-surface events, indicate the usefulness of this technique for analysis of aspects of the high temperature corrosion of multiphase silicon nitride ceramics. A number of features of interest are revealed, the interpretation of which requires at this stage some speculation. The views put forward in this report are therefore regarded as tentative, but it is hoped that they will stimulate continued and more detailed examination of this type of reaction interface, and lead to a more complete identification of the complex processes occurring.

Analyses of the outer corrosion layer show that the surface at temperatures in the region of 1050°C was predominantly a low viscosity liquid potassium aluminosilicate. The susceptibility of the intergranular glass to reaction with corrodent metal oxide such as Al_2O_3 and K_2O is marked. This effect is seen most strongly with the glassy, MgO-densified, silicon nitride, although there is also very clear evidence for sub-surface attack in the more crystalline material hot-pressed with Y_2O_3 addition. Of significance is the evidence for the inwards diffusion of impurity cations into the intergranular phase of the silicon nitride, where they alter markedly the chemical and physical characteristics of the glass, and in particular its permeability towards oxygen.

The localised, uniform 10–15 nm dimension intergranular spherical features shown in Fig. 4(a) seem most probably to be nitrogen-filled bubbles generated by oxidation of the silicon nitride by

oxygen diffusing through an intergranular film. At this bubble dimension, and assuming a liquid–gas interfacial energy of ~300 mJ m^{-2}, the equilibrium internal gas pressure would be of the order of 600 bar. This is high, but is still insignificant by comparison with the theoretical nitrogen pressure in equilibrium with silicon dioxide and oxygen at 0·2 bar pressure at this temperature, which, on the basis of a standard Gibbs function of reaction at 1400 K of ~–1703 kJ mol^{-1}, would theoretically be of the order of 10^{30} bar. This pressure is clearly an unrealistic one from any practical point of view; the value is of interest in that it serves to indicate the marked tendency for nitrogen to be generated in these regions, and for it to be able to build up a considerable pressures. The internal gas pressure might then be able, in effect, to prise grains apart. This interpretation is, however, clouded by the possibility that internal stresses will be generated also by the considerable volume expansion (~86%) caused by oxidation of silicon nitride to SiO_2, and these stresses will add to those caused by nitrogen generation. The larger voids seen in Fig. 4(b) suggest that with time individual bubbles have indeed linked to form continuous cavities, from which liquid silicate has been expelled by the continuing generation of nitrogen. In the case of the more glassy SN2 material, giving on corrosion much larger liquid-free regions, the process appears to have occurred more extensively. That liquid mobility on this scale should occur at the relatively low temperature of 1100°C would require a very low viscosity, but this would be readily attained by the incorporation of K_2O into the intergranular phase.

Thus, the overall action of the liquid phase assisted corrosion process in generating the intergrain cavities is postulated to be a combination of enhanced oxygen permeation and therefore internal oxidation, and a lowered silicate liquid viscosity associated with K_2O enrichment. That the effect seems to be more marked in the case of the MgO-containing silicon nitride would be explicable partly in terms of a stronger effect of the Mg^{2+} ions on the liquid viscosity, by comparison with the trivalent Y^{3+}, but also because (on the basis of the XRD data) only part of the Y is incorporated into the intergranular glass. Evidence for the greater susceptibility of the MgO-densified silicon nitride to corrosion is provided also by the greater loss of strength of this material after exposure to the flue gas.

It may be speculated therefore that one of the important consequences of the intergranular oxidation of silicon nitride, as shown by this series of TEM photographs, is the loss of bonding of individual silicon nitride grains in the sub-scale region, and thus their incipient detachment. In the case of fully densified materials this deterioration of the sub-surface microstructural quality is likely to be an important factor responsible for the marked loss of strength seen after exposure to what might otherwise be regarded, in terms of temperature, as mild conditions. The significant changes during exposure to oxide contamination of the intergranular liquid in these silicon nitride systems, in composition, fluidity, and wetting characteristics, thus merit extended, and more detailed investigation.

5 Conclusions

Penetration of the intergranular phase of silicon nitride materials by the more mobile cations of a corrodent surface film leads to significant compositional changes in the subsurface intergranular liquid phase, to the development of nm dimension voids within the intergranular phase, and ultimately to local complete loss of contact between adjacent silicon nitride grains. This is postulated to be an important factor leading to the loss of mechanical strength in corroded materials.

Abstract

Methylcyclosiloxanes and methylcyclosilazanes prepared using dichloromethylsilane have been reacted together to prepare a copolymer which was pyrolysed to give a ceramic powder. The copolymer was characterized using proton nuclear magnetic resonance spectroscopy (^1H NMR) and Fourier transform infra-red spectroscopy (FT-IR). Thermogravimetric analysis of the pyrolysis process and reactions which could occur during conversion of the copolymer to the ceramic are discussed. The product, which was found to be amorphous, was also studied using FT-IR, crystallized by re-heating and characterized using FT-IR, X-ray techniques and scanning electron microscopy. It was identified as α-silicon nitride and its characteristics are compared with a conventionally prepared, widely used, commercially available grade of silicon nitride. The α-silicon nitride synthesised in the present work contains a wide range of particle morphologies, varying from needles (500 nm in length and 100 nm in width) to equiaxed agglomerates (200–500 nm in size with a substructure in the size range 50–120 nm).

1 Introduction

Strength retention at high temperature, high thermal shock, corrosion and wear resistance makes silicon nitride (Si_3N_4) a rapidly emerging engineering material, especially useful for structural applications such as components in advanced engines.[1,2] However, there are several difficulties that must be overcome before the full market potential of Si_3N_4 is realized. A major issue is the lack of suitable Si_3N_4 powder from which ceramic components can be fabricated. Currently, Si_3N_4 powders are manufactured by three main methods:[3]

(1) Nitridation of silicon: $3Si + 2N_2 \rightarrow Si_3N_4$.

(2) Ammonolysis (in the gas phase) of silicon tetrachloride: $3SiCl_4 + 4NH_3 \rightarrow Si_3N_4 + 12HCl$.

(3) Carbothermic reduction of silicon dioxide $3SiO_2 + 6C + 2N_2 \rightarrow Si_3N_4 + 6CO$.

These conventional routes produce powders with the following drawbacks:[4]

(1) Lack of control over crystal structure, phase chemistry and impurity levels, resulting in glass formation at grain boundaries which drastically lower the strength of the materials, especially at high temperatures.

(2) A large average particle size, >1–10 μm, with some powder particles in the 20–100 μm range, thereby giving rise to poor sintering and large grains in the final microstructure.

(3) Irregular morphologies which reduce the packing efficiency during fabrication of components.

(4) A high degree of agglomeration which result in micro-defects in the final microstructure.

Some of the above-mentioned difficulties have been overcome by process modifications, e.g. the use of laser-driven, gas phase reactions which produces finer powders,[4] but it is increasingly acknowledged that chemical processing of ceramic materials could provide the stoichiometry, purity and microstructural control required.[5,6] One such processing method is the pyrolytic conversion of organometallic molecules and polymers to ceramics to produce powders, fibres, coatings and even ceramic artefacts,[7–10] as postulated by Chantrell and Popper[11] in 1964. However, it must be noted that this processing route produces amorphous Si_3N_4 and further heating is necessary to form a crystalline product.

Pioneering work on the synthesis of Si_3N_4 from polymeric precursors was carried out by Seyferth and coworkers[12] who reacted dichlorosilane (H_2SiCl_2), a potentially hazardous material, with NH_3 to produce silazane oil which, when pyrolysed in N_2 at 1150°C, produced α-Si_3N_4 with Si as

*To whom correspondence should be addressed.

an impurity. The yield obtained was approximately 70%wt. Subsequently, Seyferth and Wiseman[13] reported the use of dichloromethylsilane (CH_3SiHCl_2) which was reacted with NH_3 to produce polysilazanes and these were pyrolysed in N_2 at 1420°C to produce ceramics. However, the product was a mixture of Si_3N_4, silicon carbide (SiC) and C (yield of ceramics 80–85%wt.). Further work[14] on mixtures of CH_3SiHCl_2 and $CH_3(CH_2 = CH)SiCl_2$, and CH_3SiHCl_2 and $CH_3(CH_2 = CHCH_2)SiCl_2$, which were ammonolysed to prepare several polysilazanes and pyrolysed in Ar or N_2 at 1000°C, produced a slightly higher yield of ceramics (up to 86%wt.) but still contained a mixture of Si_3N_4 and SiC (about 68%wt. Si_3N_4). In fact, most investigations in this area of research report the preparation of several preceramic polymers which on pyrolysis produce Si_3N_4–SiC mixtures rather than Si_3N_4.[15] Improvement of the Si_3N_4 content was achieved by increasing the N content of the preceramic polymer, e.g. by using mixtures of CH_3SiHCl_2 and H_2SiCl_2 for ammonolysis,[14] and by pyrolysing the precursor in a reactive gas such as NH_3 rather than N_2 or Ar.[14] The first strategy seems to be case-specific as Seyferth and coworkers[14] have also used other types of commercially available $RSiCl_3$ compounds which were mixed with CH_3SiHCl_2, but, overall, there was no appreciable increase in the Si_3N_4 content. Pyrolysis in NH_3 produced Si_3N_4 with 0·29%wt. of C but the phase chemistry of the ceramic obtained is not discussed.

Many other subsequent investigations[16,17] used pyrolysis in NH_3 for the synthesis of nitrogen ceramics, mainly Si_3N_4. In particular, Blum and coworkers[16] give detailed chemical analyses of several ceramic products obtained using different polymers and these clearly indicate that pyrolysis in NH_3, compared with that in N_2, reduces the molar ratio of C by an order of magnitude. Yu and Mah[18] reported the use of a mixture of poly-siloxanes and polysilazanes to produce a 'living' polymer which can be pyrolysed in NH_3 at 1000°C to produce silicon oxynitride (Si_2ON_2). It is worth noting that if the 'living' polymer was pyrolysed in N_2 or Ar, the product obtained was a mixture of Si_3N_4 and SiC.[14] Laine and coworkers[19] report a dehydrocoupling reaction (with an Ru catalyst) to polymerise a silazane oligomer to give a high molecular weight ($\bar{M}_n > 8000$) precursor which can be pyrolysed in NH_3 to produce approximately 97%wt. pure Si_3N_4 with a > 80%wt. yield.

Only a few investigations indicate the phase chemistry of the Si_3N_4 prepared and the product has been mainly a mixture of α-Si_3N_4 and β-Si_3N_4. Burns and Chandra[20] have reported the pyrolysis of several cross-linked polycarbosilanes, polysilanes and polysilazanes in N_2 or NH_3 at 1200°C to produce amorphous Si_3N_4 with a yield of 81–93%wt. but the crystallized product contained only 56%wt. α-Si_3N_4. Schwab and coworkers[21] have also used polysilazanes to produce Si_3N_4 fibres but the product contained a mixture of α-Si_3N_4 and β-Si_3N_4. Recently, Funayama and coworkers[22] used a polyborosilane but pyrolysis in NH_3 and subsequent crystallization in N_2 produced a mixture of α-Si_3N_4 and β-Si_3N_4. Interrante and coworkers[23] report the preparation of α-Si_3N_4 and free C as the main products of pyrolysis of silicon tetradiethylamide produced by condensation polymerisation but no further details are given.

Reports of investigations on the synthesis of ceramics by the pyrolysis of polymeric precursors suffer from the fact that information on polymer synthesis, pyrolysis reactions and the phase and powder characteristics of the ceramic produced are not presented together. In the present work we pyrolyse a copolymer, prepared from methylcyclosiloxanes and methylcyclosilazanes, which have been produced using dichloromethylsilane (CH_3SiHCl_2), in N_2 to synthesise amorphous Si_3N_4 which is heat treated to form crystalline α-Si_3N_4. The copolymer used is a precursor which is suitable for the synthesis of several nitrogen ceramics, as discussed above. Reactions which can occur during pyrolysis are discussed and the resulting crystalline Si_3N_4 powder synthesised is characterized and compared with a conventionally prepared, commercially available grade of Si_3N_4.

2 Experimental Details

2.1 Starting materials

CH_3SiHCl_2 was obtained from Aldrich Chemical Co. (Poole, UK). The middle cut from the distillation of CH_3SiHCl_2 over Mg metal under dry N_2 was used to prepare methylcyclosiloxanes by hydrolysis and methylcyclosilazanes by ammonolysis. Details of these methods and products have been fully described earlier.[24,25]

2.2 Copolymerization

The reaction conditions and procedure described below have been deduced from a detailed investigation on the copolymerization of methylcyclosiloxanes and methylcyclosilazanes.[26] Methylcyclosiloxanes (0·5 g) were added to a THF solution of the methylcyclosilazanes (90 ml, containing 1 g of the silazanes) in a round bottom flask containing a magnetic stirrer. The catalyst/initiator, KH (0·05 g) was added and the reaction was carried out at

60°C for approximately 30 h. Chloromethylsilane (0·2 ml) was injected into the flask to terminate the reaction and about 3 min later a white precipitate appeared. The system was stirred for 3 h and then left for 5 h. Subsequently, the solution was taken in a dry flask and the solvent was evaporated under high vacuum. A redissolvable white solid (the copolymer) was thus obtained.

2.3 Pyrolysis

The copolymer was placed in an alumina holder and pyrolysed in a tube furnace (Lenton Thermal Designs Ltd., Market Harborough, UK) in the presence of flowing N_2 (flow rate approximately 250 ml min^{-1}). The furnace tube was at 120°C when the copolymer was inserted (to minimize any effects of moisture) and heating to 1000°C was carried out at 100°C h^{-1} followed by soaking at this temperature for 2 h. Subsequently, the furnace was switched off and allowed to cool to room temperature. The copolymer was also pyrolysed in a Perkin-Elmer TG2 thermogravimetric balance under similar conditions but at a faster heating rate (20°C min^{-1}).

2.4 Crystallization

The residue after pyrolysis was ground to a fine powder using a mortar and pestle and pressed into a disc shape, (8 mm diameter and a few mm thick). It was encapsulated in a commercially available sub-micrometer size silicon oxynitride powder (supplied by Mandoval Ltd., Surrey, UK) and further pressed to produce a thicker disc which was heated in the tube furnace used for pyrolysis in the presence of flowing N_2 (flow rate approximately 200 ml min^{-1}) to 1600°C at 60°C h^{-1}, soaked at this temperature for 2 h and subsequently cooled to room temperature at 60°C h^{-1}. This encapsulation was carried out to prevent the pyrolytic residue from reacting with any O_2 present in the N_2 during heat treatment at high temperature. Subsequently, the 8 mm disc was separated carefully from the thicker disc and characterized as described below. Crystallization experiments were also carried out at other temperatures (< 1600°C) using a similar temperature ramp.

2.5 X-ray and microscopical characterization

The crystallized ceramic powder and a commercially available Grade LC12 Si_3N_4 powder (supplied by Hermann C. Starck Berlin, Goslar, Germany) were characterized by X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and scanning electron microscopy (SEM). For the last technique the samples were sputter coated with gold before examination to avoid charging effects.

2.6 FT-IR spectroscopy

A sample of the solution (mentioned in Section 2.2) was taken before the solvent evaporated and used for FT-IR spectroscopy. It was placed on a KBr disc and the solvent was allowed to evaporate under dry N_2. A Nicolet 710 FT-IR spectrometer was used to obtain a spectrum in the range 4000 cm^{-1} to 400 cm^{-1} with a resolution of 4 cm^{-1}. The pyrolytic residue, the crystallized ceramic powder and LC12 Si_3N_4 powder were also investigated using a Nicplan FT-IR microscope to obtain the FT-IR spectrum in the range 4000 cm^{-1} to 600 cm^{-1} with a resolution of 4 cm^{-1}.

2.7 ^{1}H NMR spectroscopy

A JEOL FX200 spectrometer was used and a 10%wt./vol. solution of the copolymer in $CDCl_3$ was studied at 200 MHz. A delay time of 6–10 s was used to ensure that the proton signals were completely relaxed between pulses. Tetramethylsilane (TMS) was used as the internal reference.

3 Results and Discussion

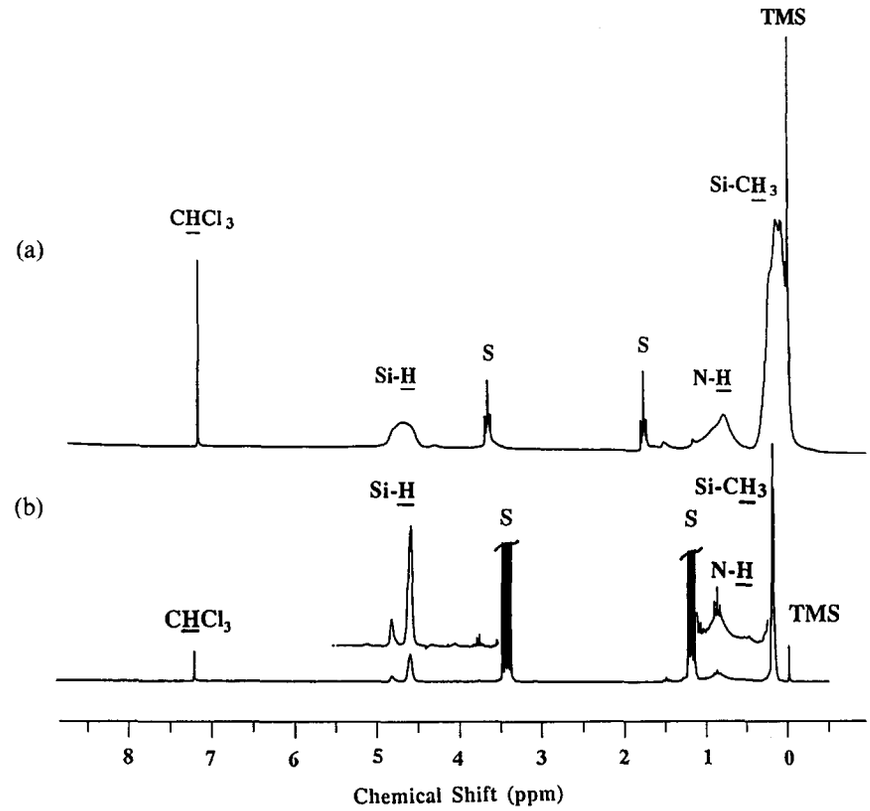
3.1 Copolymer

The molar ratio of Si–H: N–H: Si–CH_3 of the copolymer (from Fig. 1(a)) is equal to 1 : 1·2 : 7·6. We have shown previously[26] that the reaction between methylcyclosiloxanes and methylcyclosilazanes result in a block copolymer dominated by silazane blocks and therefore it is reasonable to compare the ^{1}H NMR spectrum of the copolymer with that of methylcyclosilazanes used in the copolymerization reaction (Fig. 1(b)). The molar ratio of Si–H: N–H: Si–CH_3 of the methylcyclosilazanes (Fig. 1(b)) is 1 : 1 : 3·2. Therefore, it can be concluded that the copolymer contains a much higher concentration of Si–CH_3 groups. Also, comparison of Figs 1(a) and 1(b) shows that the peaks in the former (copolymer) are broader, indicating the complex nature of its chemical structure.

The FT-IR spectra also show the same trends. The relative intensities of Si–CH_3, Si–H and N–H bands of the copolymer (Fig. 2(a)) are compared with similar bands in the reactant methylcyclosilazanes (Fig. 2(b)). Clearly, the relative intensity of the Si–CH_3 bands in the copolymer have increased in comparison with the Si–H and N–H bands. Fig. 2(a) also indicates the presence of Si–NH_2 groups in the copolymer (3450 cm^{-1} for NH_2 stretching and 1540 cm^{-1} for NH_2 deformation, respectively).

3.2 Pyrolytic residue

The pyrolysis of the copolymer results in approximately 70%wt. of residue (Fig. 3). Pyrolysis of



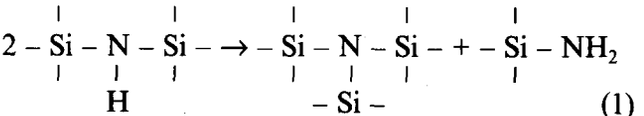


Fig. 1. ^{1}H NMR spectra of (a) the copolymer and (b) the methylcyclosilazanes used to prepare the copolymer (after Refs 25 and 26). TMS and S refer to tetramethylsilane and solvents respectively.

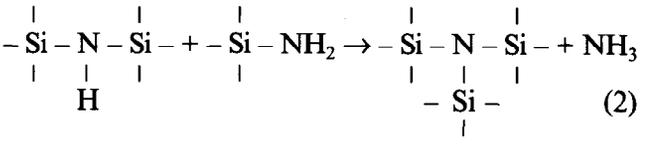
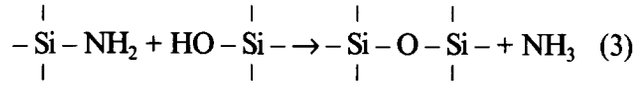


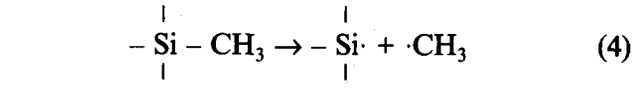
larger quantities in the tube furnace also resulted in the same yield. The residue contained 11·20%wt. C, 21·90%wt. N, and H was not detected (chemical analysis performed using a CHN Elemental Analyser, Carlo Erba, Italy. Chemical analysis to assess Si was not carried out, hence the O content is not reported here). XRD does not show any peaks and therefore the residue is amorphous. The FT-IR spectrum of the residue (Fig. 4(a)) shows the characteristics of Si_3N_4.

The thermogravimetric trace (Fig. 3) indicates that pyrolysis takes place mainly in two stages. The first occurs between approximately 120 and 440°C when about 20%wt. is lost. This is followed by an approximately 10%wt. loss between 440 and 900°C which takes place at a slower rate. The shape of the TGA curve and the %wt. of residue left did not change significantly with variations in the rate of heating, suggesting that cross-linking during pyrolysis is quite fast compared with the thermal degradation of (vinyl SiHNH)$_x$ (MeSiHNH)$_y$ polymers studied by Bahloul *et al.*[27] In a previous paper[28] we used thermogravimetric-Fourier transform infra-red spectroscopy (TG-FTIR) to suggest reactions that take place when a copolymer, very similar to the one used in the work discussed here, is pyrolysed in N_2. However, the resulting ceramic was not identified at that time[28] and we were unable to fully justify the entire scheme of reactions. We can now propose, using the results of the present work, a full scheme of reactions as described below.



The first stage of weight loss is largely transamination, similar to that occurring during the pyrolysis of polymers of silazanes,[27,29,30] resulting in the formation of the –Si–N–Si– structure according to reaction 1. In addition, –Si–NH_2 and HO–Si– groups are removed according to Reactions 2 and 3, respectively.

(1)



(2)

(3)

These reactions are accompanied by the release of NH_3 as shown by TG-FTIR studies.[28] The second stage of weight loss is accompanied by the evolution of CH_4, as indicated by TG-FTIR studies,[28] and this can occur due to reactions 5 and 6. The $\cdot CH_3$ can be produced initially by Reaction 4.

(4)

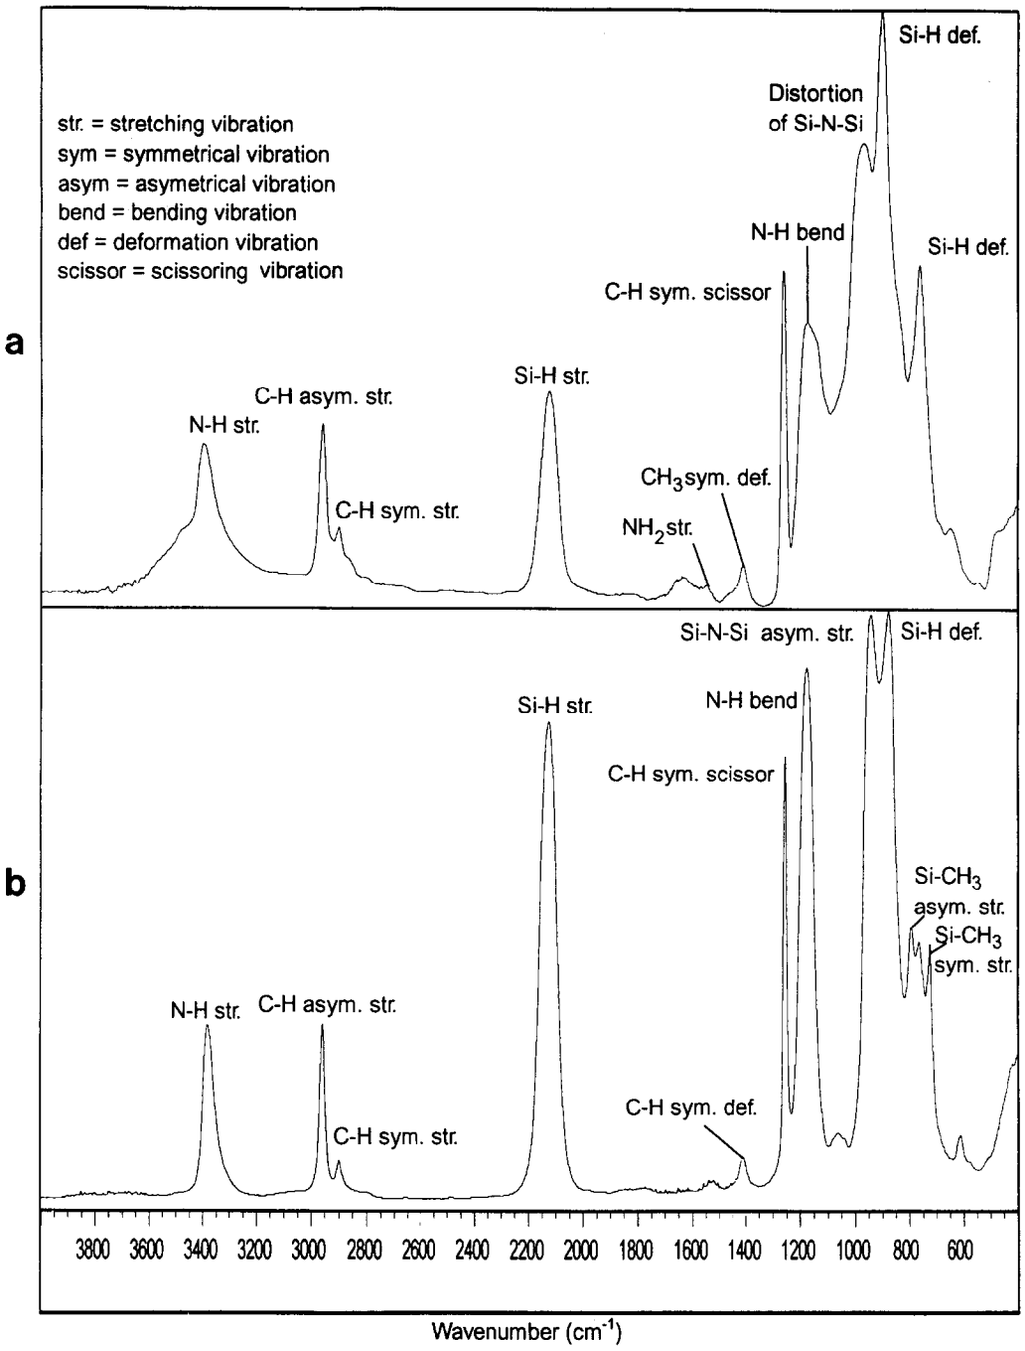


Fig. 2. FT-IR spectra of (a) the copolymer and (b) the methylcyclosilazanes used to prepare the copolymer (after Refs 25 and 26).

$$-\underset{|}{\overset{|}{N}}-\underset{|}{\overset{|}{Si}}-\text{ or }-\underset{|}{\overset{|}{O}}-\underset{|}{\overset{|}{Si}}-+\cdot CH_3 \rightarrow -\underset{|}{\overset{|}{Si}}\cdot + CH_4 \qquad (5)$$

$$-\underset{|}{N}-H + \cdot CH_3 \rightarrow -\underset{|}{N}\cdot + CH_4 \qquad (6)$$

Reaction 7 can also produce CH_4 and –Si–CH_2–Si– groups which have been detected in a recent study where silicon oxynitride was synthesised from a preceramic polymer.[31]

$$2-\underset{|}{\overset{|}{Si}}-CH_3 \rightarrow -\underset{|}{\overset{|}{Si}}-CH_2-\underset{|}{\overset{|}{Si}}- + CH_4 \qquad (7)$$

The products of Reactions 5 and 6 will enable Reaction 8 to take place forming –Si–N–networks.

$$-\underset{|}{N}\cdot + \cdot\underset{|}{\overset{|}{Si}}- \rightarrow -\underset{|}{N}-\underset{|}{\overset{|}{Si}}- \qquad (8)$$

The decomposition of the copolymer can also result in the formation of free C.[32] At higher temperatures (>850°C) C reduces the –Si–O–Si– groups, which are present in the polymer or are formed in reaction 3, eliminating oxygen in the residue and producing both CO and CO_2. In fact in our previous work,[28] TG-FTIR analysis showed that the relative intensities of the CO and CO_2 peaks increased between 850 and 980°C. If the C content available is sufficiently high most of the O should

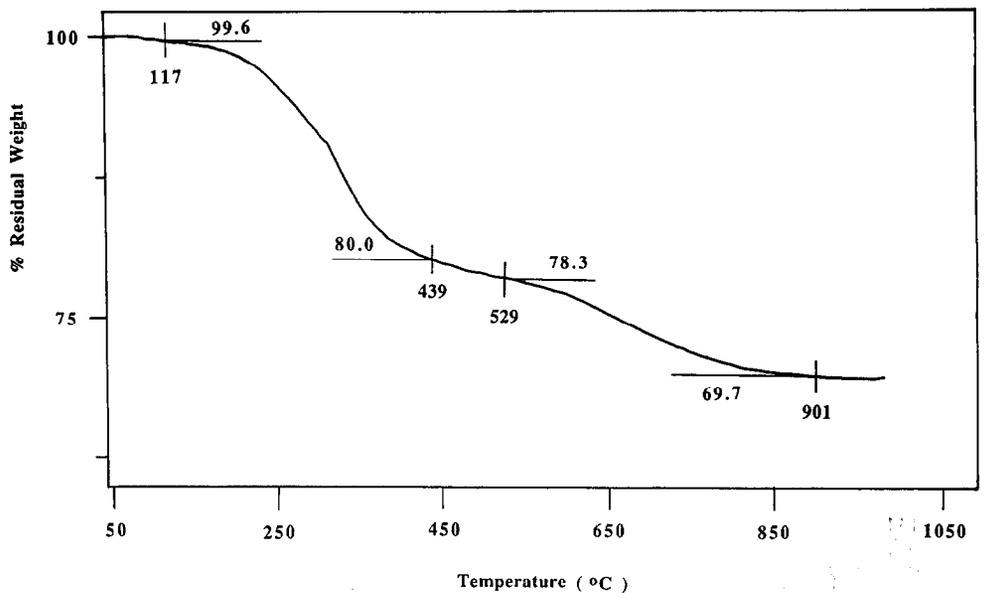

Fig. 3. Thermogram for the degradation of the copolymer in N_2 at a heating rate of 20°C per minute.

be removed and Si_3N_4 with residual O and C is produced as in the present work. The presence of a lower C:O ratio at higher temperatures (>850°C) during pyrolysis will result in a –Si–O–N– ceramic (silicon oxynitride) as observed recently.[31] This confirms the important role C would play during pyrolysis, especially during the final stages of pyrolysis.[33] However, the C content can be controlled by changing the pyrolysis atmosphere.[31]

3.3 Crystalline ceramic

The FT-IR spectra of the crystalline product (Fig. 4(b)) and LC12 Si_3N_4 (Fig. 4(c)) both show the characteristic peak of α-Si_3N_4 at approximately 1100 cm^{-1}. It is well known that Si_3N_4 synthesised from polymeric precursors are amorphous and when heated above 1200°C undergo a diffusion controlled transformation to the crystalline form.[34] In the present work, XRD of the pyrolysis residue heated to various temperatures first showed peaks

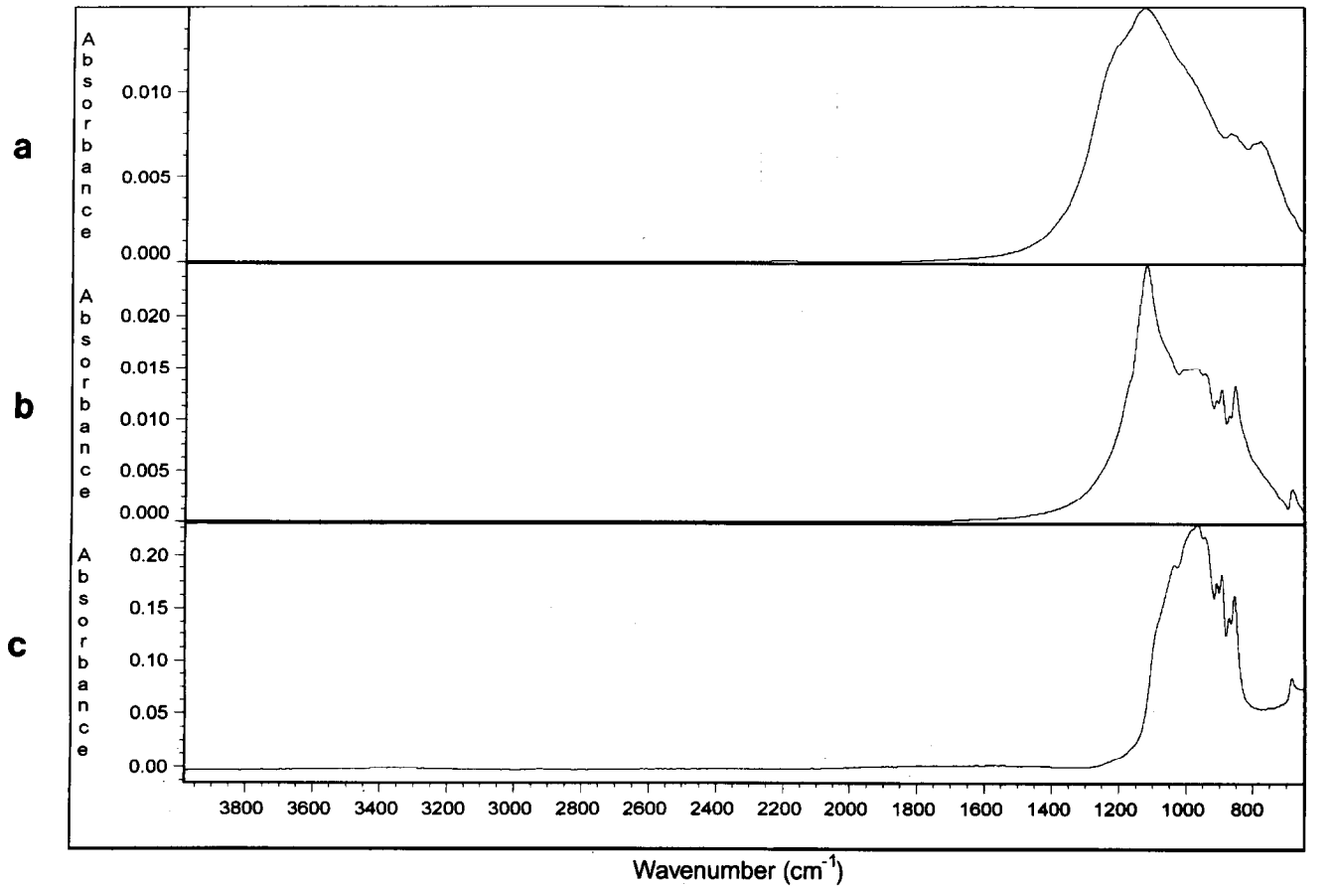

Fig. 4. FT-IR spectrum of (a) the pyrolytic residue, (b) the crystallised Si_3N_4 synthesised in the present work and (c) LC12 Si_3N_4.

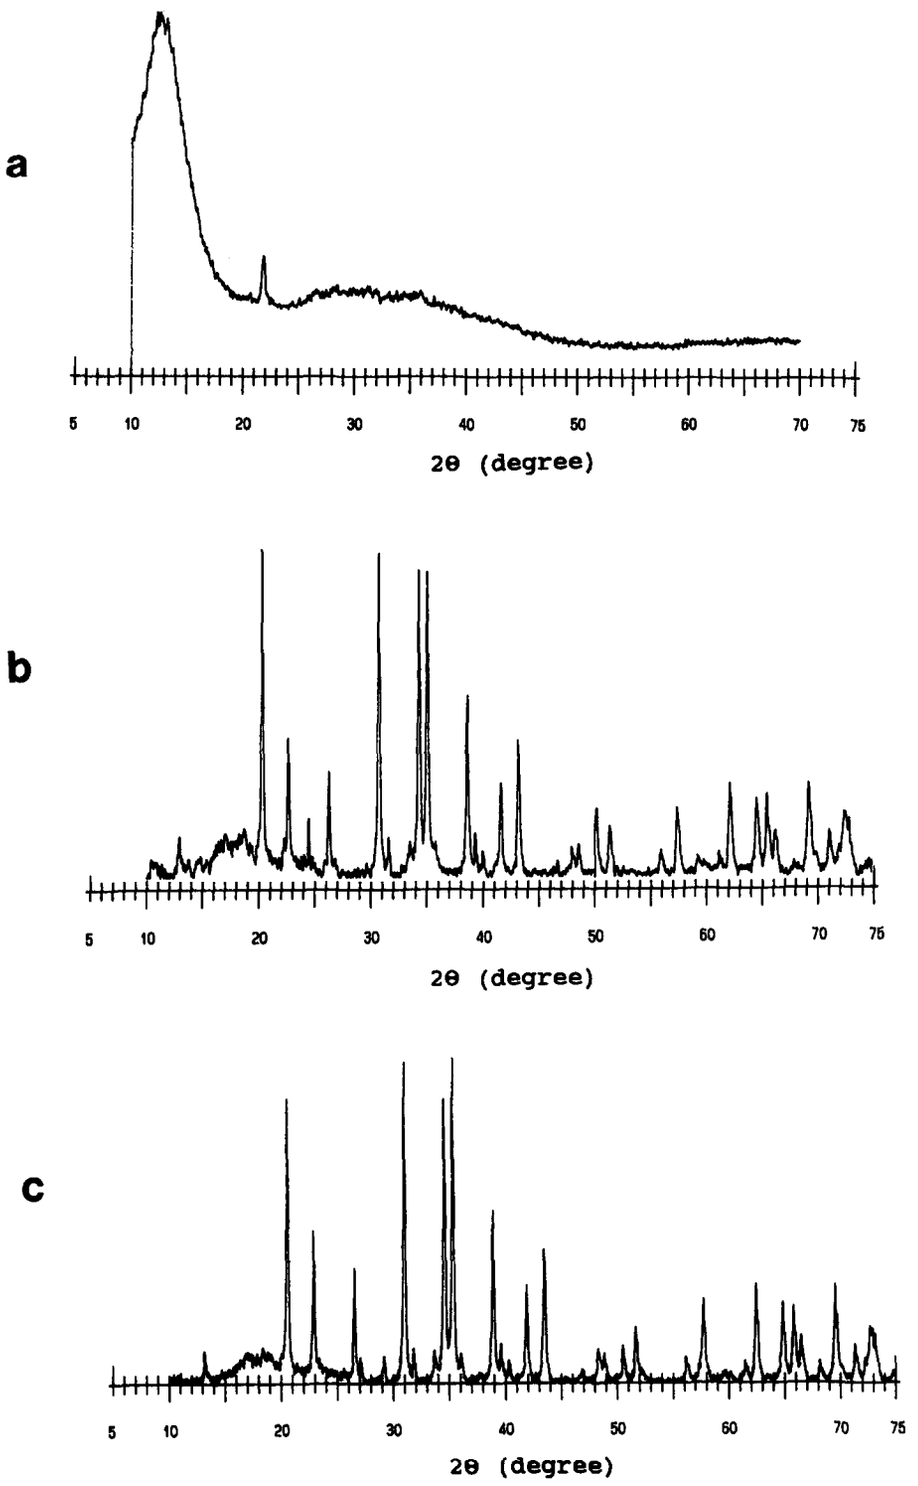

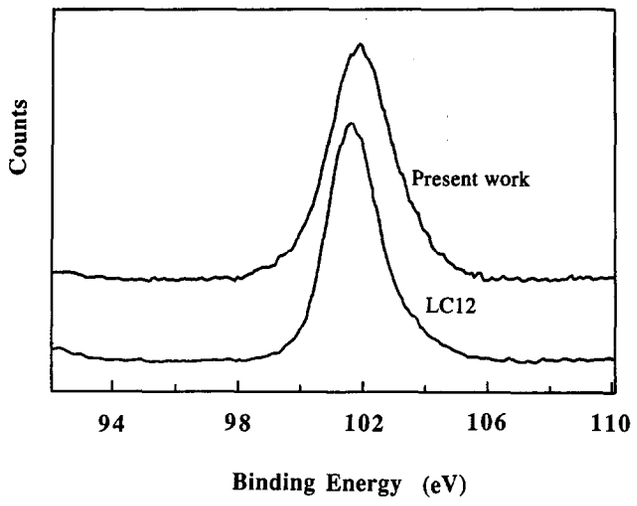

Fig. 5. X-ray diffraction pattern of (a) the pyrolytic residue heated to 1400°C for 5 h, (b) crystallised Si_3N_4 sample synthesised (heated to 1600°C for 2 h) in the present work and (c) LC12 Si_3N_4. A Philips X-ray diffractometer (CuKα radiation of wavelength 0·154 nm and a Ni filter) was used. The step size and scan speed were 0·021° and 0·005° s^{-1} for (a), 0·021° and 0·02° s^{-1} for (b) and 0·01025° and 0·005° s^{-1} for (c).

in the sample heated to 1400°C for 5 h (Fig. 5(a)). Therefore, the crystallization temperature required in the present work was much higher. XRD results of the crystallised product† (after heating to 1600°C for 2 h) are shown in Fig. 5(b). The peaks in Fig. 5(b) correspond to α-Si_3N_4. β-Si_3N_4 and Si were not detected but the diffraction trace shows that some residual C is present. In comparison, LC12 Si_3N_4 was predominantly α-Si_3N_4 containing β-Si_3N_4 and cubic silicon (Fig. 5(c)). The α/β ratio influences sintering behaviour[35] and a high value, as in the powder synthesised in the present work, is a pre-requisite for high technology applications.[36,37]

XPS results of the two samples of Si_3N_4 are shown in Figs 6(a) and (b) where the similarity of

†Recent TEM studies, not reported here, show that complete conversion to the crystalline product was achieved.

Table 1. Summary of XPS results of Si_3N_4 powders. The published binding energy values for Si_{2p} and N_{1s} for Si_3N_4 are 101·9 eV and 397·7 eV, respectively. The area under each curve (given below) is after charge correcting all spectra relative to the C_{1s} peak

	Peak Identity	*Binding Energy (eV)*	*Area*	*Atomic%*
Present work	Si_{2p}	101·9	10·08	32
	N_{1s}	397·5	10·82	34
	O_{1s}	532·4	7·84	25
	C_{1s}	284·6	2·85	9
LC12	Si_{2p}	101·6	15·09	33
	N_{1s}	397·3	18·49	40
	O_{1s}	532·3	8·96	19
	C_{1s}	284·6	3·51	8

the band shape suggest that they exhibit similar chemical binding. Using a full spectrum scan, a summary of all bands present in the two samples are given in Table 1. Both samples contain C and O impurities but the powder prepared in the present work contains a slightly higher level of O. The latter feature is beneficial for sintering[38,39] but the presence of C is not helpful as it can remove O during sintering.[35]

Figure 7 shows that a wide range of particle morphologies, varying from needles to equiaxed lumps, are present in the Si_3N_4 synthesised from the copolymer. The needles are approximately 500 nm in length and 100 nm in width. The lumps are agglomerates, having diameters in the range 200–500 nm. The sub-structure in the agglomerates are in the range 50–120 nm. The particle characteristics of the LC12 Si_3N_4 are well documented.[40] The particles are in the size range 150–1500 nm with a median particle size of 500 nm and these particles are equiaxed in shape and

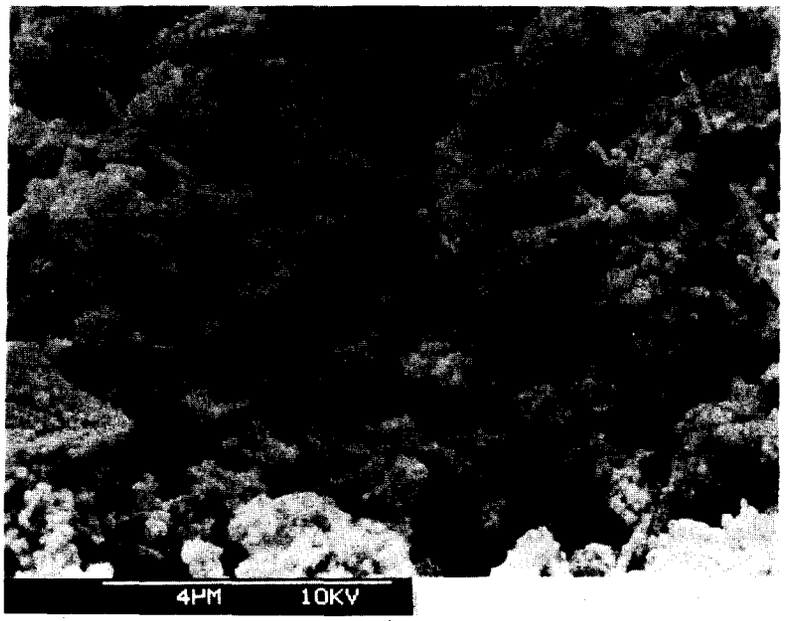

Fig. 7. A scanning electron micrograph of the Si_3N_4 powder in the crystalline form synthesised in the present investigation. A very wide range of particle morphologies is seen. The micrograph was taken using secondary electrons at 10 kV.

appear to be agglomerated to a lesser extent. Clearly, the mixed morphology of the Si_3N_4 prepared using the polymeric precursor indicates that by suitably varying and controlling the pyrolysis and crystallization heat treatments of the amorphous product various particle morphologies can be developed. Strutt *et al.*[41] have synthesised polymerized preceramic nanosized Si_3N_4 by laser irradiation of metalorganic precursors. A near spherical Si_3N_4 powder with a bimodal size distribution corresponding to median diameters of 45 nm and 120 nm was produced and the larger size was thought to be agglomerates. However, the yield of the ceramic powder from the metalorganic powder was about 54%wt. Our yield was approximately 70%wt., typical from the pyrolysis of preceramic polymers in N_2 but higher yields are reported for Si_3N_4 produced by pyrolysis of polymeric precursors in NH_3[14].

4 Conclusions

Crystalline Si_3N_4 powder has been synthesised from a copolymer prepared from methylcylosiloxanes and methylcyclosilazanes.

The complex structure of the copolymer contains a higher concentration of $Si–CH_3$ groups, compared with the reactants. Weight loss in the copolymer occurs mainly in two stages. Between 120 and 440°C the most likely reactions produce –Si–N–Si–, $–Si–NH_2$ and –Si–O–Si– groups and NH_3, which results in about a 20% wt. loss. In the second stage, between 440 and 900°C during which about a 10%wt. loss occurs, release of CH_4 is accompanied by the formation of –Si· and –N· groups. These groups react to produce the –Si–N– structure and hence Si_3N_4. However, the C:O ratio at temperatures > 850°C is a crucial factor in determining the type of ceramic product. A high C:O ratio supports the formation of Si_3N_4.

The product is amorphous and has been crystallised by heat treatment and identified as α-Si_3N_4 containing 9 atomic% of carbon and 25 atomic% of oxygen. The α-Si_3N_4, crystals produced have a wide range of morphologies ranging between 500 nm × 100 nm size needles to 200–500 nm size agglomerates containing 50–120 nm size particles. Comparison of the Si_3N_4 thus produced with conventional, commercially available LC12 Si_3N_4, shows that the former is superior in that it does not contain undesirable β-Si_3N_4 and is free from coarse particles (> 1 μm). Also it has slightly higher oxygen which will aid sintering. However, the LC12 particles are predominantly equiaxed in shape and agglomerated to a lesser extent.

The results of the present investigation show clearly that both the pyrolysis and crystallization process conditions are related closely to the characteristics of the final product. Changes in these process variables seem to determine the type of Si_3N_4 produced. In fact, it should be possible to produce Si_3N_4 with a certain predetermined morphology (needles or equiaxed particles) and this could be of vital importance in the preparation of ceramic composites.

Acknowledgements

The authors are very grateful to S.E.R.C. for financial support of this research (Grant No. GR/H 09904). Dr. S. Woodisse is thanked for help in the X-ray diffraction studies. The staff at the Experimental Techniques Centre at Brunel University are thanked for help with characterization. Mrs Kathy Goddard is thanked for typing the manuscript.

(Received 16 May 1994; revised version received and accepted 10 November 1994)

Abstract

A low temperature process for the manufacture of non-oxide monolithic ceramic bodies is presented. This process is based on the pyrolysis at temperatures between 1000 and 1400°C of the polysilazane precursor.

The different steps of the process are precisely described. The physical (porosity, density, crystalline phases) and mechanical properties (flexural strength, Young's modulus, toughness and hardness) of the bodies obtained are studied versus the maximum temperature of the pyrolysis. The high temperature oxidation resistance in air is also presented.

1 Introduction

Non-oxide monolithic ceramic bodies, (e.g. SiC, Si_3N_4...) generally result from powders sintering. Materials obtained by this process show interesting mechanical characteristics (e.g. 600–700 MPa for sintered Si_3N_4). However, the very high temperatures (1700°C–2500°C) required to densify ceramic bodies imply expensive energy costs. The homogenisation of the initial slurry (powder + additives) presents difficulties on what effects on the flaw distribution in the final ceramic.

Another way to obtain non-oxide ceramics is the use of organometallic precursors. Indeed, polycarbosilane and polysilazane which lead to SiC or Si_3N_4 derived ceramics, respectively, are frequently used for the manufacture of non-oxide matrix composites. However, only a few experiments have been performed on the elaboration of monolithic bodies from these products.

Such processes may present some interests. The temperatures relative to the precursor's pyrolysis are significantly lower (1000–1400°C) than those required for powder sintering (1700–2500°C). Moreover, powder sintering imposes the use of organic additives which have to be eliminated by heat treatment before sintering. In the present process, no additives are used, therefore very few impurities are present in the final ceramic.

ELF ATOCHEM† has recently developed the synthesis of the polysilazanes PYROFINE PV‡ and PYROFINE PM.[1,2] Research performed on the manufacture of ceramic matrix composites from PYROFINE PV,[3,4] required the optimisation of the ceramic characteristics versus the pyrolysis parameters.[5] The study of mechanical properties needing dense samples, the following process has been developed.

2 The Polysilazane

The following information is more detailed in Refs. 1 and 2.

At room temperature the polysilazane is a highly viscous liquid. Its density is about 1 and its typical elemental composition is given in Table 1 (oxygen originates from the hydrazine used for the synthesis).

Its viscosity decreases with an increase in temperature up to 200°C (Table 2).

The structure of this polymer is cyclic and is shown in Fig. 1.

Upon heating up to 300°C under nitrogen, the opening of the vinyl groups allows the precursor cross-linking. The product obtained is solid, unmeltable and insoluble.

Above 300°C mineralization starts and changes the precursor into an amorphous ceramic. The typical elemental composition of the ceramic obtained after

wt.%	47·5	23·6	21·5	7·4

pyrolysis at 1000°C is given in Table 3. Its absolute density is 2·13 g/cm^3 (measured by He picnometry).

At 1000°C, the ceramic yield is 60–65 wt.%, depending on the heating-up rate used during the cross-linking.[2] The volumetric yield of the transformation is about 30%.

3 Manufacture of Monolithic Ceramic Samples

Due to the foaming of the precursor during pyrolysis,[2] conventional pyrolysis leads in the best case to a ceramic having about 1 g/cm^3 apparent density corresponding to more than 50% porosity.

Such samples cannot be used for the physical and mechanical characterisation of the ceramic, and a specific process has been developed to obtain relatively dense ceramic samples.

3.1 Principle

The basic idea of this process is first to manufacture a mixture of powder and precursor, press it and then pyrolyse it (Fig. 2).

The powder is obtained by heat treatment and milling of the precursor.

To reduce the viscosity of the precursor and to obtain a good homogeneity, toluene is added to the mixture following the ratio a volume toluene per volume precursor. The solvent is then evaporated at 60°C under 500 Pa for 2 h.

Finally the mixture is pressed in a die with a pressure of 150 MPa before proceeding to the pyrolysis.

3.2 Use of ceramic powder

For the first attempts the powder used was obtained by milling the ceramic residue issued from the precursor pyrolysis at 1000°C. The absolute density of this powder is 2·13 g/cm^3 (determined by He picnometry).

The powder alone, pressed under 150 MPa forms a green body having 60% of the absolute density. Therefore the mixture is manufacture in order to obtain a precursor/powder ratio of 40/60 in volume (12/88 wt.%) after toluene evaporation.

The green body obtained after moulding is pyrolysed following the temperature schedule given in Table 4.

The samples obtained have about 30% porosity (apparent density 1·5 g/cm^3) corresponding to the theoretical calculation (28%) based on the volume

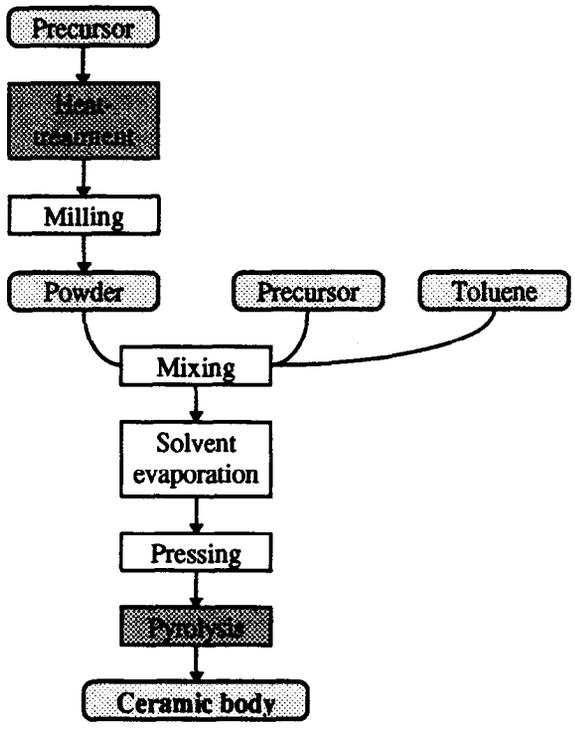

Fig. 2. Elaboration of monolithic ceramic bodies (first process).

5	130–300	0
50	300–1000	4

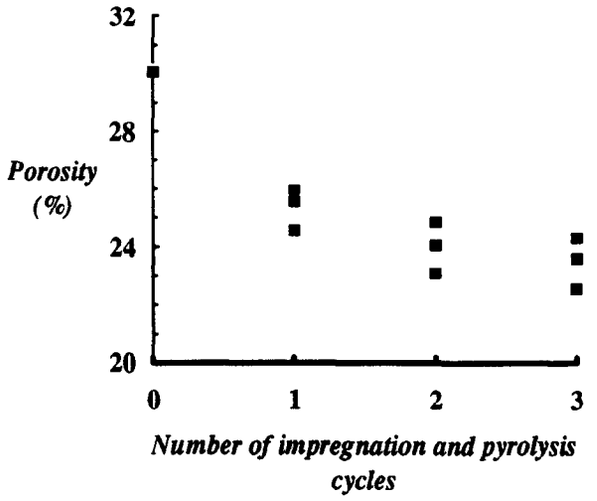

Fig. 3. Variation of porosity of the monoliths versus the number of impregnation and pyrolysis cycles.

ratio of the components, and the volume yield of the precursor to ceramic transformation (about 30 vol.%).

The porosity can be reduced by successive impregnation and pyrolysis cycles with the precursor. However, the larger part of the porosity is closed and a porosity lower than 20–25% cannot be achieved (Fig. 3).

On the other hand numerous cracks are present on the sample surface due to the difference of shrinkage between the precursor (about 70 vol.%) and the ceramic powder (no shrinkage).

To avoid these phenomena and to achieve a lower porosity, new experiments have been completed using a cross-linked precursor powder in place of the ceramic powder.

3.3 Use of cross-linked precursor powder

3.3.1 Theory

A cross-linked precursor powder results from heat treatment under nitrogen at 300°C of the polysilazane. After milling (mortar) the size of the powder grains is about 100–1400 μm in diameter (Fig. 4).

The absolute density of this powder is approx. 1·13 g/cm^3. After pyrolysis at 1000°C its ceramic yield is 72 wt.% corresponding to 38 vol.%.

The powder alone, pressed under 150 MPa,

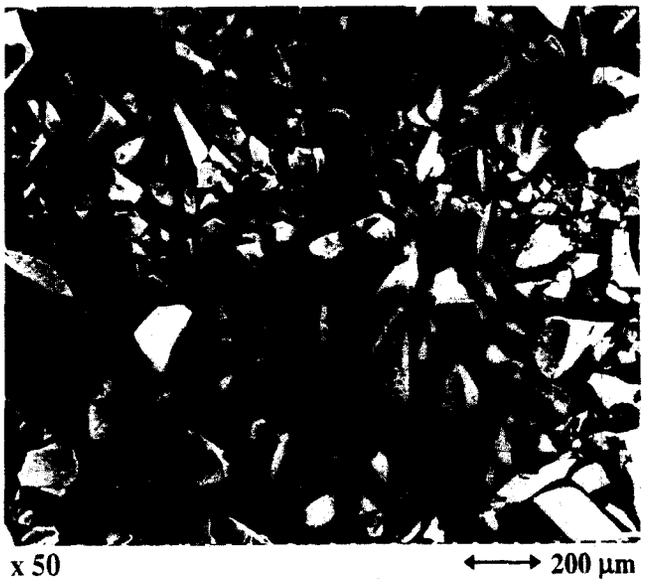

Fig. 4. SEM observation of the cross-linked precursor powder.

forms a green body having 70% of the absolute density. Assuming an apparent sample shrinkage during the pyrolysis equal to that of the precursor powder (about 62 vol.%), the porosity of the ceramic samples would be only 7–8%.

3.3.2 Experiment

(a) Manufacture of the initial mixture

The mixture is obtained following the same process as when using the ceramic powder (see 3.2).

The relative density of the powder in the sample (powder volume/apparent volume of the sample) depends on the precursor amount added (Fig. 5).

As this one remains below 22 wt.%, the relative density of the powder in the sample is equal to the green density of the powder (about 70 vol.%). The precursor fills the spaces separating the powder grains without disturbing their arrangement.

Above 22 wt.% the powder cannot be compacted properly and the relative density of the powder in the sample significantly decreases.

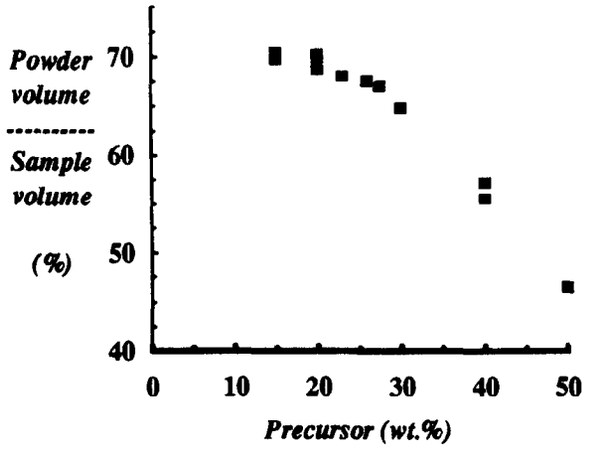

Fig. 5. Variation of the ratio powder volume/sample apparent volume versus the precursor amount added.

Table 5. Cross-linking temperature schedule

Heating rate	*Temperature*	*Holding time*
(°C/h)	(°C)	(h)
100	20–130	0
5	130–300	1

(b) Cross-linking

Using the optimal precursor/powder ratio previously determined, (22/78 wt.%), samples were pressed and cross-linked following the temperature schedule given in Table 5.

After heat treatment, an increase in the apparent volume of the samples is ascertained. This may be due to the precursor 'foaming'.[2] This phenomenon occurs as the precursor amount is higher than 15 wt.%. This value is significantly lower than that corresponding to a complete filling of the intergranular spaces (precursor/powder ratio = 27·5/72·5 wt.%, 30/70 vol.%).

(c) Pyrolysis

Using mixtures having various precursor/powder ratios, samples were pressed, cross-linked and then pyrolysed following the temperature schedule given in Table 4.

The shrinkage of the apparent volume of the sample after cross-linking and after pyrolysis is approximately 60 – 62%, as expected.

The lowest porosity measured is about 24% and corresponds to an initial precursor/powder ratio: 15/85 wt.% (Fig. 6).

This result is not as low as expected due to the apparent volume increase during the cross-linking as the precursor/powder ratio of the initial mixture is high. To avoid this problem and to obtain lower porosity a new step has been added to the process (Fig. 7).

A cross-linked precursor preform is manufactured by moulding and cross-linking the precursor

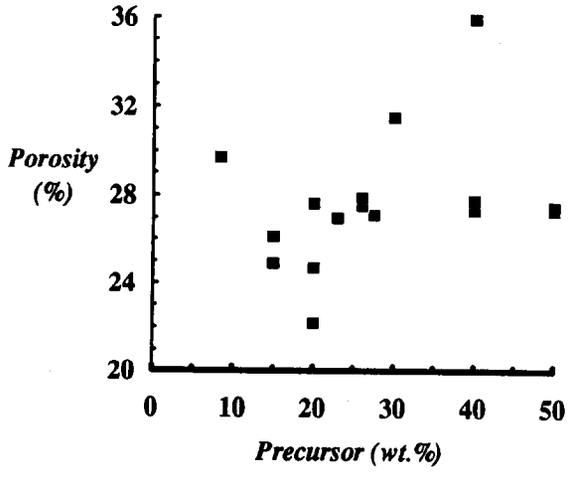

Fig. 6. Porosity of the ceramic monolith versus the initial precursor content.

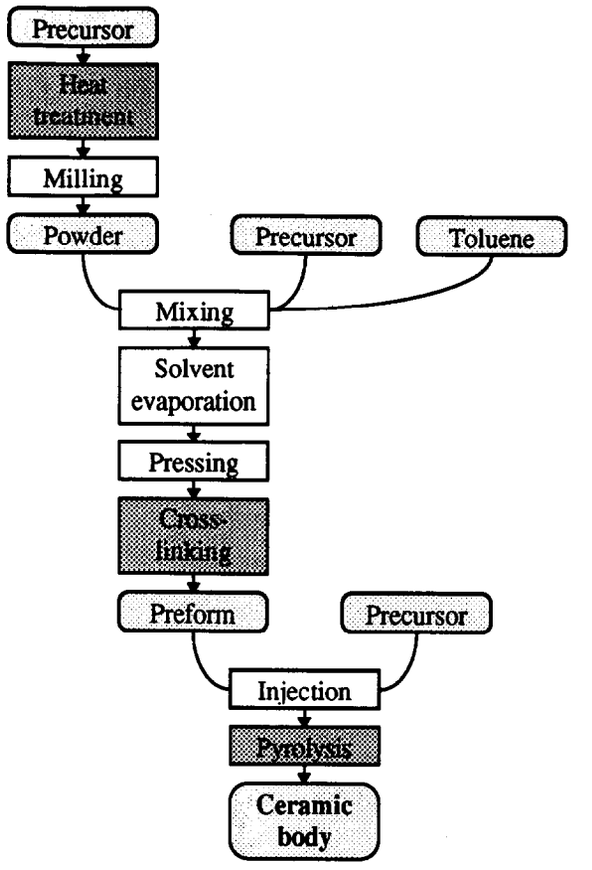

Fig. 7. Elaboration of monolithic ceramic bodies (second process).

+ cross-linked precursor powder mixture. The precursor/powder ratio used is 5/95 wt.% in order to avoid the apparent volume increase of the samples during the cross-linking (see 3.3.2 (b)) and to favour open porosity.

The preform obtained after cross-linking is solid. The high porosity of this preform (about 27%) is filled by precursor impregnation. The preform is charged into a reactor (Fig. 8) and degassed under dynamic vacuum (500 Pa) at 150°C for 2 h.

The precursor, preheated at 150°C to reduce its viscosity, is then injected into the preform by means of the pressure gradient between the outside

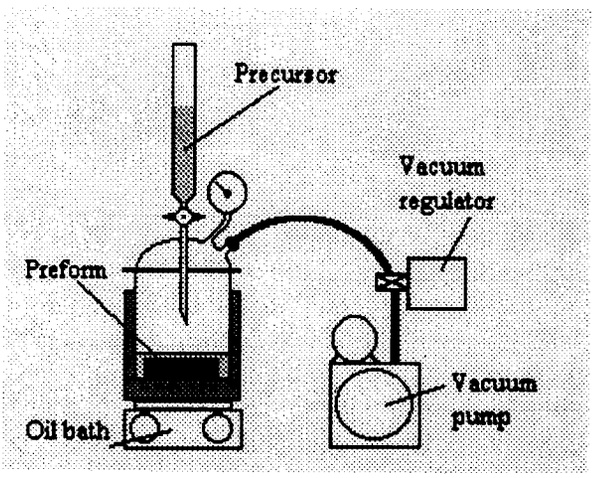

Fig. 8. Diagram of the device used for the precursor injection.

(Nitrogen atmospheric pressure) and the inside of the reactor. After injection the preform is soaked in the precursor for 2 h at 150°C under nitrogen before being removed and placed in the pyrolysis furnace.

The weighing of the performs after the precursor injection and before the pyrolysis indicates that 3–4% of the porosity is not filled. Therefore, the porosity of the monolith obtained after pyrolysis is about 12% instead of 8% as expected from the theoretical calculation.

4 Characterisation of the Monolith Bodies

Seven samples (45 × 40 × 10 mm^3 after pyrolysis) were manufactured using pyrolysis temperatures from 1000°C to 1600°C.

The large size of these samples imposed a very slow heating rate (10°C/h) above 300°C to avoid the crack formation during pyrolysis.

4.1 Porosity

After pyrolysis, the porosity of the monoliths was determined from the ratio between the apparent and absolute density (The absolute density was determined by He picnometry on samples after milling).

A minimum in porosity, about 10–11%, is observed for pyrolysis at 1400°C (Fig. 9).

4.2 Mechanical properties

Ten test bars (40 × 3·5 × 8 mm^3) were cut in each sample. Room temperature flexural strengths were measured in three-point bending on a Schenk RM-T 25 kN using a support span of 50 mm and a crosshead speed of 0·5 mm/min.

Young's modulus was determined from the load/displacement curves. The toughness was determined by the single edge notched beam technique (S.E.N.B.) with $a/w = 0{\cdot}5$ (a = initial crack length; w = thickness of the test bar).

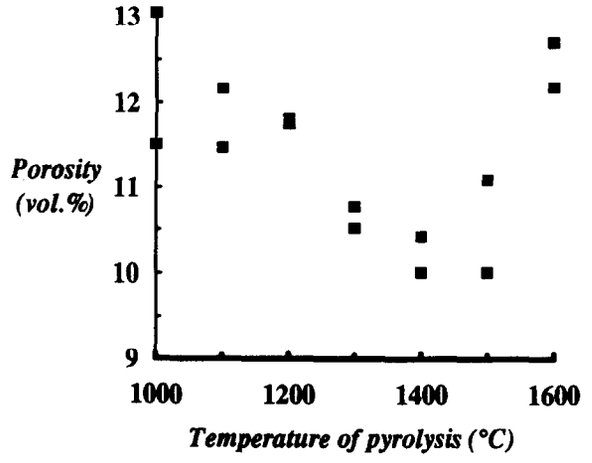

Fig. 9. Porosity of the monoliths versus the highest temperature of the pyrolysis.

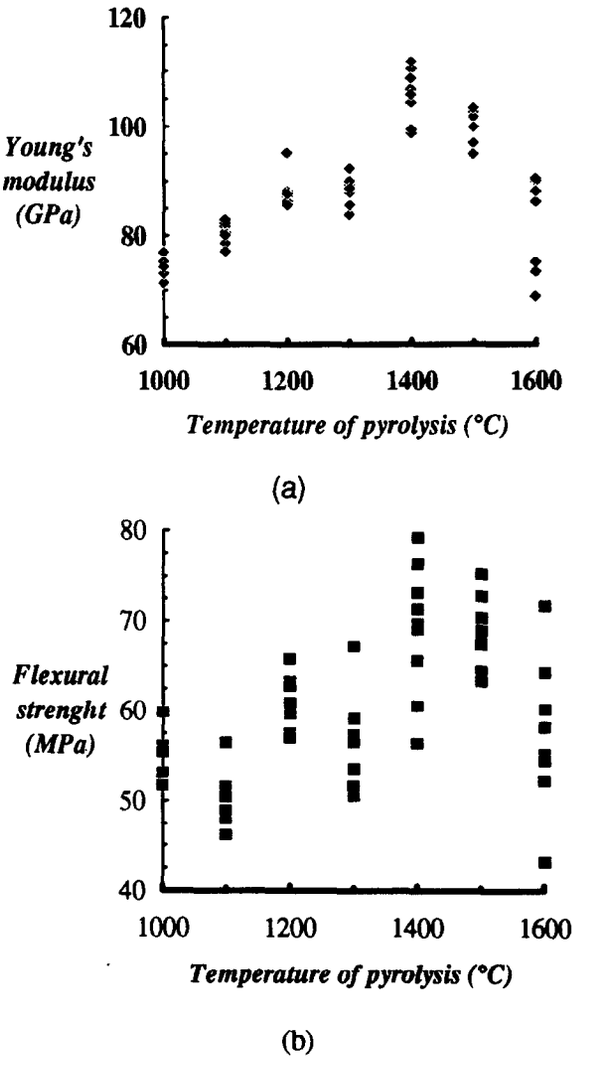

Fig. 10. Evolution of the flexural strength (a) and of the Young's modulus (b) versus the maximum of the pyrolysis.

Highest flexural strength and Young's modulus are observed after pyrolysis at 1400°C corresponding to the minimum in porosity (Figs. 10(a) and (b) and Table 6).

4.3 X-ray diffraction

After milling, the samples were characterised by X-ray diffraction.

Only weak diffractions of SiO_2 are detected on the monoliths pyrolysed at temperatures lower than 1400°C. This SiO_2 is probably polution originating from the milling process and does not belong to the ceramic itself.

On samples pyrolysed at 1500 and 1600°C the X-ray diffraction spectra exhibit signals corresponding to α SiC and α Si_3N_4.

The SEM observation shows the formation of whiskers in the porous volume and of a layer, looking like a skin, on the pore surface (Fig. 11).

This crystallisation may cause the decrease in mechanical properties observed for pyrolysis temperatures higher than 1400°C.

Table 6. Mechanical properties of the composites

Highest temp. (°C)	*Apparent density* (g/cm^3)	*Absolute density* (g/cm^3)	*Porosity* (%)	*Young's modulus* (GPa)	*3-point flexural strength* (MPa)	*Vickers hardness* (MPa)	*Toughness* K_{IC} ($MPa.\sqrt{m}$)

1600	2·12 ± 6	2·48	12	69 ± 22	52 ± 20	965 ± 20	—

Fig. 11. SEM observation of the monoliths pyrolysed at 1600°C.

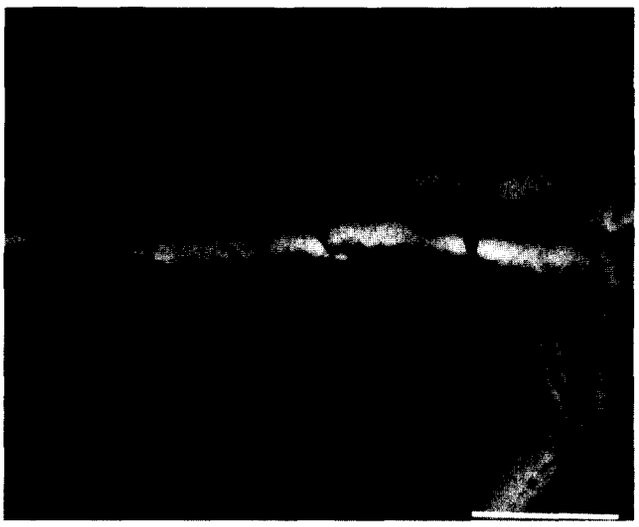

Fig. 13. SEM observation of the surface of the monoliths after 6 h in air at 1400°C.

4.4 Oxidation resistance

The study of the thermal oxidation behaviour by thermogravimetric analysis in air at 1000, 1200 and 1400°C (Fig. 12) shows the high resistance of the ceramic.

After 6 h, no weight deviation is observed at 1000°C and a very low and asymptotic increase is seen at 1200 and 1400°C (respectively + 0·17 wt.% and + 0·28 wt.%).

The SEM observation (Fig. 13) shows that the weight increase observed at 1200 and 1400°C corresponds to the formation of a coating, probably composed of SiO_2, on the sample surface. This coating slows down the oxidation reaction thereby explaining the asymptotic appearance of the TG curves.

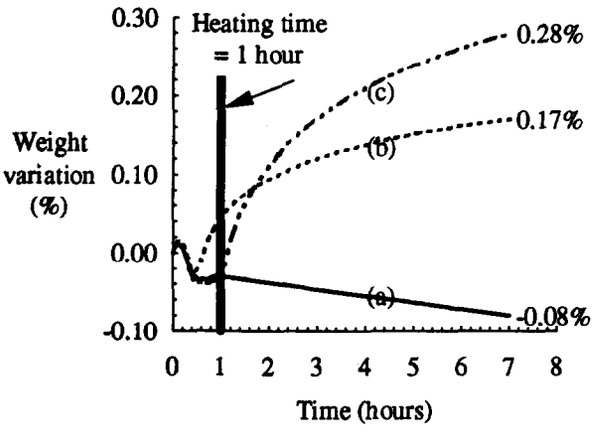

Fig. 12. TGA curves in air at 1000°C (a), 1200°C (b), 1400°C (c) on monoliths pyrolysed at 1000°C (a), 1400°C (b,c).

5 Conclusion

A new process route for ceramic bodies has been developed. Ceramic monoliths with less than 12% porosity can be obtained. As compared to ceramics obtained by sintering of powders, such values are high, but they are relatively good for a liquid precursor processing route. Moreover, the structure of the samples shows no apparent cracks.

The maximal flexural strengths measured in 3 point bending are approximately 70 MPa and Young's modulus 105 GPa. These results are low, but could possibly be improved by a decrease in the pore sizes. Such decrease could be obtained by the use of a cross-linked precursor powder having a lower grain size.

The maximum in mechanical properties is

obtained after pyrolysis at 1400°C, and correspond to the samples having the lowest porosity (about 10%). The decrease observed as the pyrolysis is operated as higher temperatures is probably due to the beginning of the α SiC and α Si_3N_4 crystallisation.

The TGA operated in air at temperatures between 1000–1400°C show the high oxidation resistance of such ceramics due to the formation of a coating (probably SiO_2) on the surface of the samples.

Carbothermal Preparation and Characterisation of Ca-α-sialon

J. W. T. van Rutten, R. A. Terpstra, J. C. T. van der Heijde, H. T. Hintzen & R. Metselaar

Centre for Technical Ceramics, P.O. Box 595, 5600 AN Eindhoven, The Netherlands

(Received 20 September 1994; revised version received 14 December 1994; accepted 10 January 1995)

Abstract

Ca-α-sialon can be synthesised by simultaneous carbothermal reduction–nitridation of a mixture of fine SiO_2, Al_2O_3, $CaSiO_3$ and carbon black powder at 1500°C. For the first time a single phase material is obtained in a one step process. The main intermediate product in these processes is a β-sialon with a low z*-value (z < 1·2). After formation of this β-sialon the calcium is incorporated in the lattice to form the Ca-α-sialon.*

1 Introduction

Si_3N_4 and Si_3N_4 based ceramics like sialon materials are interesting for high temperature engineering applications. These materials have very good thermal shock behaviour, high wear resistance, good corrosion resistivity, oxidation resistance and high strength.[1–4] The preparation of the sialon materials, either α or β, can be performed in several different ways. Reaction sintering is the most widely used method among them. The disadvantages are the relatively expensive starting materials and the limited possibilities to produce complex shapes of fully densified materials. An alternative way of producing sialon starting with relatively inexpensive materials is the route of carbothermal reduction and nitridation of oxide materials. The carbothermal reduction and nitridation of kaolin clay is well known for the synthesis of β-sialon.[5–7] The overall reaction for the production of β-sialon ($Si_{6-z}Al_zO_zN_{8-z}$) when $z = 3$ is:

$$3\,(2\,SiO_2\,Al_2O_3\cdot 2\,H_2O) + 15\,C + 5\,N_2 \rightarrow 2\,Si_3Al_3O_3N_5 + 15\,CO + 6\,H_2O \quad (1)$$

This reaction can be separated into several stages. Some of the intermediate products are mullite and SiC.[5,6]

As mentioned, besides the β-sialon α-sialon also exists. The structure of these latter materials is stabilised by a modifying cation such as Y, Li, Mg and Ca. The general formula for α-sialon is $Me_{m/val}Si_{12-(m+n)}Al_{(m+n)}O_nN_{16-n}$ where m and n indicate the replacement of (Si–N) by (Al–O) and *val* is the valency of the metal ion. The synthesis of α-sialon materials by reaction sintering is widely used, especially for the Y-α-sialon materials which are intensively studied.The carbothermal reduction, however, is hardly ever investigated and reported about. In this paper, the possibility is investigated of preparing Ca-α-sialon by carbothermal reduction in a single step from oxidic starting powders. To determine the most convenient starting materials, it is important to know what kind of intermediate products are formed. This is one of the reasons why the mechanism of the carbothermal reaction has been studied here.

The composition chosen is $Ca_{0.8}Si_{9.2}Al_{2.8}O_{1.2}N_{14.8}$. Starting with $CaSiO_3$ the overall reaction is as follows:

$$0{\cdot}8\,CaSiO_3 + 8{\cdot}4\,SiO_2 + 1{\cdot}4\,Al_2O_3 + 22{\cdot}2\,C + 7{\cdot}4\,N_2 \rightarrow Ca_{0.8}Si_{9.2}Al_{2.8}O_{1.2}N_{14.8} + 22{\cdot}2\,CO \quad (2)$$

This composition has been chosen for practical reasons because it is well within the single phase area of Ca-α-sialon,[8] and single phase material is likely to be obtained.

Some years ago, Mitomo *et al.*[9] prepared α-sialon (Ca and Y) by carbothermal reduction and nitridation. In that study relatively expensive starting materials such as tetraethyl–orthosilicate, aluminium–isopropoxide, calcium–ethoxide and yttrium nitrate were used. These were mixed with carbon black, precipitated and fired at different temperatures. This study showed that α-cristobalite, mullite, Si_2N_2O and β-Si_3N_4 were the main intermediate crystalline products. These were obtained, next to some amount of α-sialon, after firing at temperatures at 1450°C or lower. In a second step the material was transformed to single phase α-sialon by firing it at higher temperatures.

2 Experimental Methods

2.1 Preparation

Pure oxide materials were used to investigate the formation of single phase Ca-α-sialon. The starting materials were SiO_2 (Aerosil OX50, Degussa), C (Elftex 125, Cabot, stoichiometric amount according to reaction eqn (2)), Al_2O_3 (grade 'C', γ + δ Al_2O_3, Degussa) and $CaSiO_3$ (Wollastonite SG, Rheinische Kalksteinwerke). In some experiments $CaCO_3$ (Merck p.a., purity > 99%) or CaO (decomposed $CaCO_3$) were used as a source for calcium. The SiO_2 and Al_2O_3 powders have a high specific surface area (± 50 m^2/g). This means a high reactivity which can cause sintering of particles during the powder preparation.

An important parameter in carbothermal processes is the mixing of the powders to improve the contact between reactants and reduce the diffusion path length. Wet mixing and dry mixing were the two methods that were used. They are described briefly below.

2.2 Wet mixing

The starting powders are dispersed in water or isopropanol in a polyethylene bottle with Si_3N_4 milling balls on a roller bench for ± 48 h. The next stage is evaporating the isopropanol, pressing tablets of the powder, or slip casting the aqueous suspension. For slip casting tablets, the suspension has to meet certain requirements. The powder particle size distribution should be narrow and if possible the particle size should be below 1 μm. It is important that the suspension is stable and not too viscous. To obtain a stable suspension with SiO_2 and Al_2O_3, the pH should be either below pH = 2 (otherwise the SiO_2 and Al_2O_3 will form a gel) or above 9. However in the latter case, a very small amount of the SiO_2 will dissolve and the ionic strength will increase, which will flocculate the suspension. In order to check these properties sedimentation experiments were done in all cases. For dispersing the carbon a surfactant is required. Several surfactants were tried and among these CG-6 (i.e. ammonium salt of poly acrylic acid) supplied by ICI worked best for this system. It also helped to disperse the other powders. The suspensions which were used for slip casting had a pH < 2 because the surfactant worked better at this pH than at higher pH-values. After mixing, the suspension was ultrasonically treated to break the agglomerates and then slip cast in a plastic ring (ϕ 45 mm) placed on a gypsum plate.

2.3 Dry mixing

Pelletising is another way to produce green bodies which can be fired. The starting powders are dry mixed in an Eiger mixer (Labor Mixer R02) until the mixture looked homogeneous. Then water is sprayed on the powder which caused agglomeration of the powder. The size of the pellets obtained is related to the amount of water added and the speed of the mixer (typical values 5–10 mm). These pellets are dried at 100°C and can be used for the synthesis of Ca-α-sialon.

The density of the tablets and pellets are roughly estimated by measuring the weight and volume (pellets = 1·0 g/cm^3, tablets = 0·7 g/cm^3). The slip cast tablets are less dense and more porous than the pellets, so the influence of porosity on the reaction can be observed.

2.4 Synthesis

The different experiments and conditions are summarised in Table 1. For these experiments a constant amount of slip cast tablets were used in a horizontal tube furnace with flowing nitrogen. The exceptions were Experiment A, during which pieces of mixed starting powder bonded with binder were used. (These can be considered as pellets; agglomerates are formed after evaporation of isopropanol) and Experiment E in which pellets were used. The experiments with starting mixtures A–D were carried out in a horizontal tube furnace with a diameter of 25 mm. Experiment E was carried out in a tube furnace with a diameter of 50 mm. The amount of pellets used was 200 g and the bed length was 20 cm. The temperature was in the range 1350 – 1650°C for 3 – 65 h. The progress of the reaction was followed by measuring the CO content in the exhaust gas mixture with a CO-monitor (Defor Gas Analyser, Maihak).

Additionally some of the tablets were refired for 1 or 2 h between 1550 and 1700°C in a graphite resistance furnace in a static nitrogen atmosphere to see if the amount of α-sialon would increase. The tablets were embedded in a mixture of BN, Si_3N_4 and AlN powder to prevent dissociation at these relatively high temperatures. The influence of a milling step between the first and second firing was investigated as well. The milling could be performed in a mortar, because the material was not very hard. This powder was pressed uniaxially followed by isostatic pressing.

To get some insight into the mechanism of the carbothermal reduction, several experiments were carried out at 1500°C as a function of the firing time. In these experiments pellets were used and all the reaction parameters were kept constant, except for the time, which varied from 20 to 1000 min. The volume of the reaction bed in the horizontal tube furnace (ϕ 25 mm) was 10 ml and the N_2 flow was 12·5 l/h.

Table 1. Approximate phase composition after the first firing of a mixture of SiO_2, Al_2O_3, $CaSiO_3$ and C in N_2 at different temperatures

Starting materials	*Temperature [°C]*	*Time [h]*	*N_2-flow [l/h]*	*α/β ratio*	*Composition**
A	1450	14	12	0·27	α-sialon, β-sialon

(A) SiO_2, Al_2O_3, CaO + C in isopropanol with binder.
(B) SiO_2, Al_2O_3, $CaSiO_3$ + C in water.
(C) SiO_2, Al_2O_3, $CaSiO_3$ + C in water, lower mass content.
(D) Same as B but excess of $CaSiO_3$ (2×).
(E) SiO_2, Al_2O_3, $CaSiO_3$ + C, pelletised.
(*) Amorphous and secondary phases neglected.
(+) No cooling inbetween.

3 Characterisation

To investigate the phase compositions in the product material, X-ray diffraction was applied (Rigaku Geigerflex diffractometer) using Cu–Kα radiation. To determine the ratio of α-sialon to β-sialon the following equation was used:[10]

$$\alpha/\beta = [I_{\alpha(102)} + I_{\alpha(210)}] / [I_{\beta(101)} + I_{\beta(210)}] \quad (3)$$

This equation is applicable in the case of pure α and β Si_3N_4 and is assumed to be valid for sialon materials too, because the structures are very similar. To estimate the α-sialon content only α and β sialon phases were taken into account. Amorphous phases and (traces of) secondary phases were neglected. Therefore in Table 1 only an indication is given of the compounds present in the sample; the concentration for each component is not calculated. The lattice parameters of the materials were determined from slow scans (0·0125°/s). The ten strongest reflections observed were applied to calculate the lattice parameters using a computer program based on the SIMPLEX method.[11]

To determine the relation between the nitrogen content and the content of α-sialon the nitrogen content was determined by a reverse Kjelldall titration.[12] The sample is destructed with molten lithium hydroxide, the formed NH_3 is dissolved in boric acid which was titrated with hydrochloric acid to determine the nitrogen-content. Particle size was determined by sedigraph measurements (Micromeritics Sedigraph 5100). The powder was suspended in water and ultrasonically treated to break agglomerates before the measurements.

4 Results and Discussion

4.1 Synthesis of Ca-α-sialon

The conditions of the experiments and the results are displayed in Table 1. As can be seen, the applied conditions at 1450°C or lower temperatures are not appropriate for preparing single phase α-sialon from the starting SiO_2, Al_2O_3 and $CaSiO_3$ powders. The main products in this range of temperatures are α-sialon and a β-sialon when these starting powders are used. Even after a very long time the composition of the samples does not differ significantly. In all samples an amorphous phase is present. This phase cannot be characterised by X-ray diffraction; the phase is assumed to consist of aluminates and silicates. Evaporation of SiO influences the yield of the sialon material. When the reaction time is longer the silicon loss increases. This explains the higher ratio after 6 h compared to the ratio after 14 h (Experiments 2 and 3). Although the circumstances were the same in Experiments 3 and 4, the results were quite different. This is probably due to the fact that two different batches of tablets were used. Apparently one batch was not as homogeneously mixed as it should have been. This could explain the large difference in the α/β ratio. According to the results

of Experiments 13 and 14 (main products SiO_2 and Si_2ON_2) the temperature of 1350°C is not sufficient for the reaction to have proceeded far enough for the sialon materials to be detected. SiO_2 and Si_2ON_2 are well known intermediates in the formation of β-sialon too.[6] In Experiment 14 the N_2-flow is too low to supply a sufficient amount of nitrogen in 6 h to form sialon material. In the samples reacted for a short time there were remains of starting materials present. The z-values of the formed β-sialon material in the samples fired below 1500°C vary between approximately 0·4 and 1·2. A value of 1·4 at the most can be expected from the starting composition. At a temperature below 1500°C the highest content of α-sialon is about 40%, both for the slip cast tablets and pelletised starting material. Increasing the temperature to 1500°C resulted in an almost single phase Ca-α-sialon (> 95 wt%). The rest (5 wt%) is uncertain because of the detection limit of the X-ray diffraction analysis. However, when the holding time at 1500°C is not long enough, a significant amount of residual carbon is left in the mixture. The mixture contains hardly any sialon material (at least not above the detection limit). When the temperature is raised to 1650°C the main product is SiC instead of α-sialon. Refiring the tablets, which were fired at temperatures below 1500°C, at elevated temperatures (1550–1700°C) resulted in a decrease of the α-sialon content. On the contrary, milling and pressing tablets and refiring these tablets in the same temperature range results in products with high α-sialon content. α-sialon contents of up to 95 wt% are achieved (see Table 2).

This means that on the one hand it has been confirmed that Ca-α-sialon can be obtained in a two step process,[9] but on the other hand it has been shown in this paper that it is possible to use a single step process.

Table 2 shows the influence of porosity on the conversion to α-sialon. From this it can be seen that porosity has little or no effect on the reaction (at least in this range of porosity).

Figure 1 shows the transformation percentage to α-sialon after milling and a second firing at higher temperatures. The highest amount of Ca-α-sialon was obtained at 1700°C. No SiC could be detected, indicating a complete consumption of carbon in the first step.

Table 2. Comparison of α-sialon content between first and second firing of tablets and pellets with intermediate grinding. (The numbers are averages)

	First firing (1450°C)	*Second firing (1700°C)*
Tablets	30% α-sialon, 70% β-sialon	> 95% α-sialon
Pellets	35% α-sialon, 65% β-sialon	> 95% α-sialon

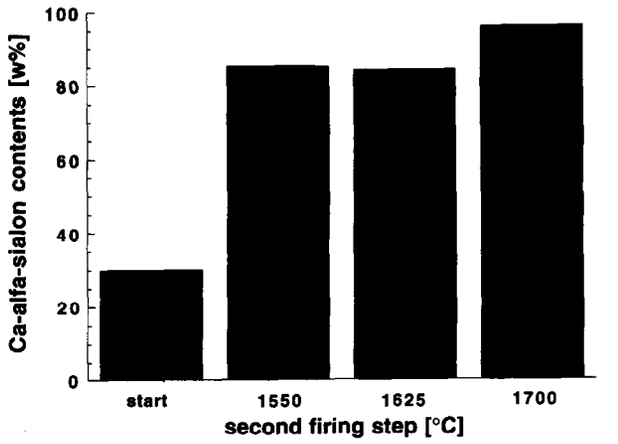

Fig. 1. Transformation to α-sialon after the second firing. (Start = initial amount of Ca-α-sialon before the second firing).

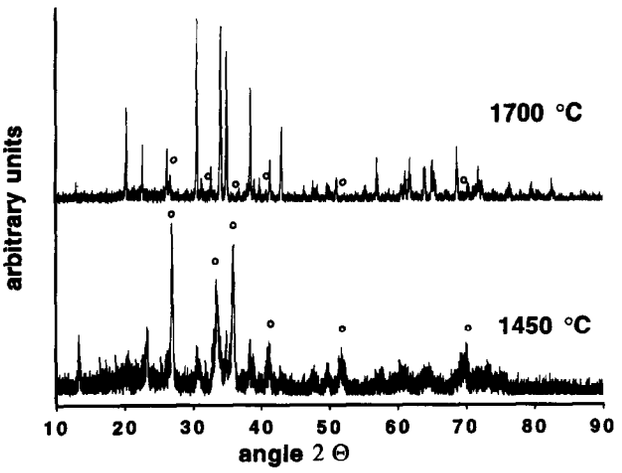

Fig. 2. X-ray diffraction patterns of material after first firing at 1450°C (bottom) and firing at 1700°C (top).The circles indicate peaks of β-sialon.

The phase change during the refiring process is shown in Fig. 2. The lower part presents a diffractogram of a sample fired at 1450°C. According to the baseline (which is not straight) a significant amount of amorphous phase is still present after firing at 1450°C. The diffractogram in Fig. 2 after refiring at 1700°C shows narrow and sharp peaks and a straight baseline. The unit cell dimensions of α-sialon calculated from this diffractogram are a = 0·784 and c = 0·571 nm. From these lattice parameters an m-value in the general formula for α-sialon of ± 1·4 can be estimated. This means that most of CaO is incorporated in the crystalline material and the rest is present in the amorphous or unidentified phase. The powder which is obtained after firing twice is more difficult to mill than powder which is synthesised at 1500°C. The particle size (agglomerate size) of this powder as synthesised is approximately 5–8 μm while the agglomerate size of the refired powder is about 10–20 μm.

4.2 Reaction mechanism

The results from the experiments concerning the investigation of the mechanism of the reaction are presented in Fig. 3 and discussed in the next paragraph. In a relatively short time the sialon products are formed. From X-ray diffraction patterns it follows that in the beginning of the reaction a significant amount of amorphous phase is present. This complicates the identification and quantitative determination of several components during this initial period. The main intermediate product is β-sialon material with low z-values ($z < 1{\cdot}2$). In shortly reacted samples some SiC seems to be present. Sometimes the samples contain O'-sialon. Calcium aluminates or silicates were hardly found except the starting $CaSiO_3$. The intermediate products are consumed very fast otherwise there should have been a plateau at a certain level in the curves.

To monitor the progress of the reaction the cell parameters of Ca-α-sialon are calculated. The values are shown in Table 3. These show that the further the reaction proceeds the smaller the cell parameters become. The cell parameters of the α-sialon converge to the values of the desired product. As expected, if the amount of nitrogen increases the cell parameters will decrease.[13]

In Fig. 4, the data from the nitrogen determination are plotted, showing that even at a low (40 wt%) Ca-α-sialon concentration the nitrogen content is high. This means that nitridation has proceeded so far that most of the nitrogen required for the formation of the Ca-α-sialon is available in the sample. Approaching 100 wt% of Ca-α-sialon the nitrogen content rises up to almost the theoretical value (35·0 wt%)

On the basis of the results mentioned previously the following mechanism of the formation of Ca-α-sialon is proposed. The first step is the formation of a β-sialon with a z-value of 1·2 (Theoretically $z = 1{\cdot}4$, because it was aimed at

Table 3. Cell parameters of Ca-α-sialon calculated during progress of the reaction.

Time [min]	a *[nm]*	c *[nm]*
100	0·787	0·572
125	0·785	0·568
250	0·784	0·569
500	0·785	0·569
750	0·784	0·569
1000	0·784	0·568

$Si_{9.2}/\ Al_{2.8}$). The theoretical value of the nitrogen content of a β-sialon is 33·8 wt% if the z-value is 1·2. In Fig. 4 it is shown that with a low (40 wt%) Ca-α-sialon concentration combined with a high content of β-sialon (60 wt%) the nitrogen content nearly reaches the theoretical value for a β-sialon material with a z-value of 1·2. The end of the curve shows that the nitrogen content rises to the theoretical value of Ca-α-sialon which is 35·0 wt%. The molar concentration of nitrogen is increased from 13·2 to 14·8 (see eqns 4 and 5). In summary, the first step is:

$$4{\cdot}6\ SiO_2 + 0{\cdot}7\ Al_2O_3 + 9{\cdot}9\ C + 3{\cdot}3\ N_2 \rightarrow \underset{(\beta\text{-sialon})}{Si_{4.6}Al_{1.4}O_{1.4}N_{6.6}} + 9{\cdot}9\ CO \quad (4)$$

In the second step calcium and the extra nitrogen are being incorporated:

$$0{\cdot}8\ CaO + 2\ Si_{4.6}Al_{1.4}O_{1.4}N_{6.6} + 2{\cdot}4\ C + 0{\cdot}8\ N_2 \rightarrow \underset{(\alpha\text{-sialon})}{Ca_{0.8}Si_{9.2}Al_{2.8}O_{1.2}N_{14.8}} + 2{\cdot}4\ CO \quad (5)$$

It is assumed that an eutectic liquid of $CaSiO_3$ (providing CaO) and β-sialon promotes the formation of Ca-α-sialon. During this formation it is expected that Si–N as well as Al–O bonds have to be broken but how exactly the formation takes place is not in the scope of this work and is

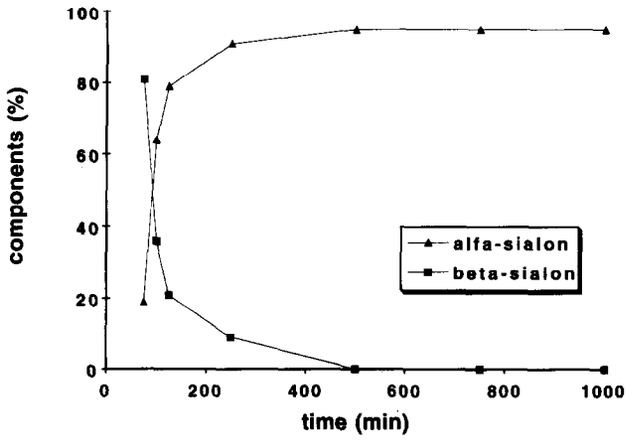

Fig. 3. The α and β sialon content of the mixture after firing at 1500°C for different times.

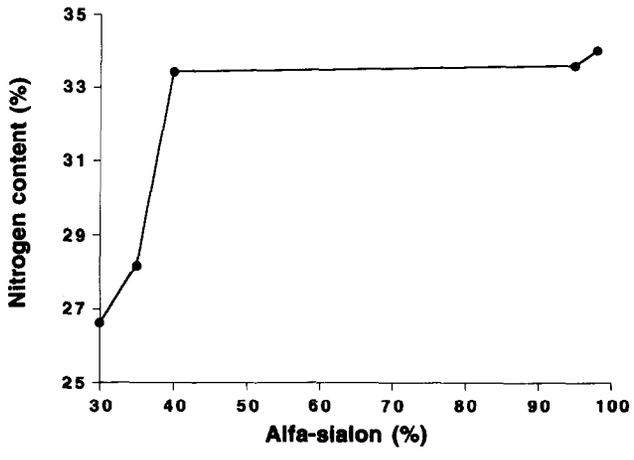

Fig. 4. Relation between nitrogen content and Ca-α-sialon content in the mixture. Experiments were carried out in a large horizontal tube furnace (ϕ 50 mm, 200 g pellets, 30 l/hr N_2-flow, 1500°C).

not investigated. The conversion of the mixed α/β-sialon which was obtained after firing at a temperature lower than 1500°C to a single phase α-sialon by firing it at a higher temperature can be compared to reaction sintering.[13] The carbon was fully consumed in the first step due to complete nitridation. Ca is then incorporated into the material in the second step at a higher temperature without further nitridation, different from the second step of the carbothermal reaction given by eqn (5).

5 Conclusions

The carbothermal reduction and nitridation of oxidic powder precursors is a possible route to prepare single phase Ca-α-sialon in a relatively inexpensive way. There are two methods to obtain single phase material. The first way is firing first at 1450°C, milling the obtained α/β mixture and refiring it at 1550–1700°C. Results from this route are comparable with the results found in Ref.[9] The second way is firing at 1500°C where the reaction can be completed in *one* step to form single phase materials. The main intermediate product in the carbothermal reduction of the oxides is β-sialon with a low z-value ($< 1{\cdot}2$). A proposal for the formation mechanism of single phase Ca-α-sialon has been made. Firstly, a β-sialon with low z-value is formed, followed by the incorporation of the Ca-ions. Nitrogen content determination and calculation of the cell parameters support this proposed mechanism. In contrast with the formation of β-sialon, SiC is not a major intermediate product.

The Barrier Height Formation in ZnO Varistors

P. Q. Mantas & J. L. Baptista

Dep^{to} Eng.^{a} Cerâmica e do Vidro (INESC), Universidade de Aveiro, 3800 Aveiro, Portugal

(Received 2 June 1994; revised version received 27 January 1995; accepted 31 January 1995)

Abstract

The electrical characteristics of ZnO ceramic varistors are interpreted as being due to the existence of potential barriers at the grain boundaries. The two main models describing the origin of these barriers, surface states at the interface, and surface oxidation, are discussed in this work, where the microstructure and the electrical properties at various temperatures (up to 160°C) of a standard varistor composition, are used in an attempt to separate both contributions. The temperature dependence of both the distribution of surface states and the Fermi level, when extrapolated to high temperatures, indicates that the surface states control mainly the shape of the I–V curves, and that the surface oxidation contribution to the barrier, although as high as 0·25 eV, is not sufficient to account for the total energy of the barrier. Values for the density of carriers calculated using the dependence of the Fermi level on temperature, were in good agreement with reported values determined by other techniques.

1 Introduction

The electrical characteristics of ZnO varistors are interpreted as due to potential barriers formed at the grain boundaries of the ceramic material. There are two main models describing the origin of these barriers: (i) surface states at the interface, and (ii) surface oxidation. In the first model, it is considered that the junction between two semiconducting ZnO grains (n-type semiconductor at room temperature) behaves as a p-type semiconductor, and, for the thermodynamic equilibrium, i.e. the equalisation of the Fermi level throughout the junction, a process of charge transfer between the grains and the interface is necessary.[1,2] As a consequence of this process, donors in the grains nearby the interface are ionized, giving electrons to the interface states, which also become ionized. The region near the junction is depleted of charges, and therefore, a potential barrier appears. In equilibrium, there is a simple relation between these three entities, the barrier height, Φ_{Bo}, the ionized donors, N_D, and the ionized charge at the interface, Q_{io}: $\Phi_{Bo} \propto Q_{io}^2/N_D$. Since two opposite Schottky type barriers are formed, this model is also called the Double Schottky Barrier (DSB) model.

In the second model, it is considered that the regions of the ZnO grains near the grain boundaries are much more resistive than the bulk of the grains. The difference in resistivities is due to a non-equilibrium defect chemistry process, arising during the cooling down period. At the sintering temperature (>1200°C), all the material can be considered in thermodynamic equilibrium, and so there is a great concentration of defects, namely those of the Schottky type. When the sample is cooled, these defects must diffuse from the bulk of the grains to the surface where they will be annihilated. Because both the defect formation and the defect diffusion are thermally activated, only the defects near the grains surface are able to reach the interface to be annihilated, the others being frozen in the bulk. The bulk of the grains remains with a high concentration of defects (giving the n-type semiconductor nature), while the interface becomes stoichiometric, i.e. highly resistive (the forbidden band in ZnO at room temperature is about 3·2 eV). For the electron flow across such a junction, a potential barrier is therefore present.[3,4]

Both models, n–p–n and n–i–n, reasonably describe the I–V curves of these materials, if the varistor quality factor α is less than ~25.[5] For higher α values, they need to incorporate other mechanisms of electron flow, based on impact ionization[6–9] or electron tunneling from one grain to the other.[10,11]

In this work we used ZnO varistor samples to measure their electrical characteristics at several temperatures, up to 160°C, and used these experimental results to theoretically derive the distribution of surface states above the equilibrium Fermi level, in an attempt to differentiate the contributions from the two mechanisms for the formation of the varistor potential barriers.

2 Experimental

Varistor samples prepared via a normal ceramic processing route, and sintered at 1300°C, 1 h, in air, were used. The chemical composition of these samples was: 97·0 mol% ZnO and 3·0 mol% of Bi_2O_3, Sb_2O_3, Co_2O_3, MnO_2 and Cr_2O_3, with the molar proportion of 1:2:1:1:1. Samples were used for SEM observation, after polishing and chemically etching the surfaces. Mean grain size was determined by the interseption method, using a computer aided system. Samples used for electrical measurements were sputtered on opposite faces with gold electrodes, after lapping. Electrical measurements were preformed in an oven, heated via an electrically heated wire double wound around a supporting tube. A wire net was used to shield the sample from the tube. Temperatures were controlled with the aid of a programable controller, using cromel–alumel thermocouples. Before electrical measurements, the temperature in the oven was stabilized for 30 min.

I–V measurements were made with a current source (Keithly 225 Current Source), and an electrometer (Keithly 616 Digital Electrometer), up to 100 V. At room temperature, for higher voltages, a pulsed source (AMBO, with 60 μs pulse duration, 13 Hz, up to 1 kV) was used. C–V measurements were done with an ac bridge (Hewlett-Packard 4280A 1MHz C Meter/C-V Plotter), at a fixed frequency of 1 MHz, up to 40 V dc applied voltage.

3 Results and Discussion

3.1 Microstructure

Figures 1 and 2 show the microstructure of the varistor; it can be seen that three phases are present: large ZnO grains, inter/intragranular spinel particles, and a third minor phase, brighter than the other two, that is possibly the reported pyrochlore type phase.[12–18] By EDS, we could hardly detect the presence of Co as the only dopant inside the ZnO grains (Fig. 3(a)). The spinel phase is doped with Co, Mn, and Cr (Fig. 3(b)). The third phase is composed by Zn, Sb, and Bi (Figs 3(c) and 2). This type of microstructure is the one that could be expected from the chemical composition of the sample and the sintering schedule used, as reported by Inada.[13–15] However, it must be

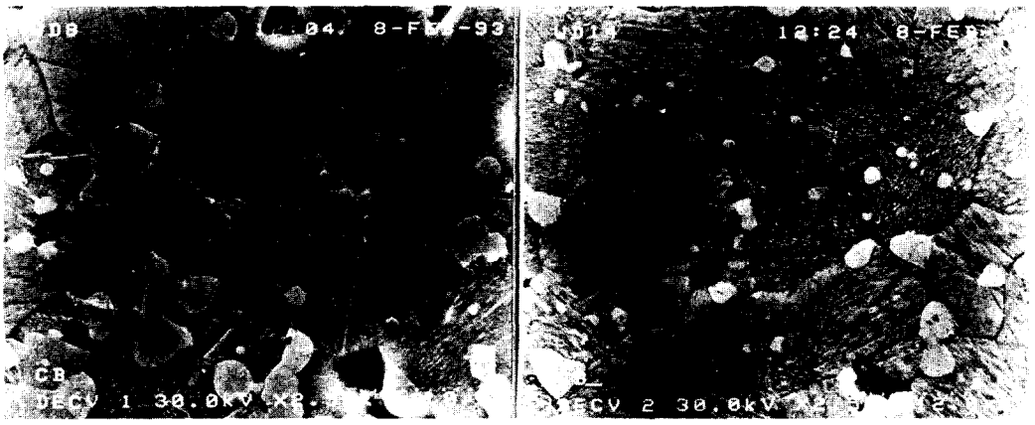

Fig. 1. SEM micrograph of polished and chemically etched sample. The spinel like phase (A) is normally located at the grain boundaries of the ZnO grains with some finer particles inside the grains. A brighter phase (B) can be found near the spinel like phase, and is probably the reported pyrochlore type phase.

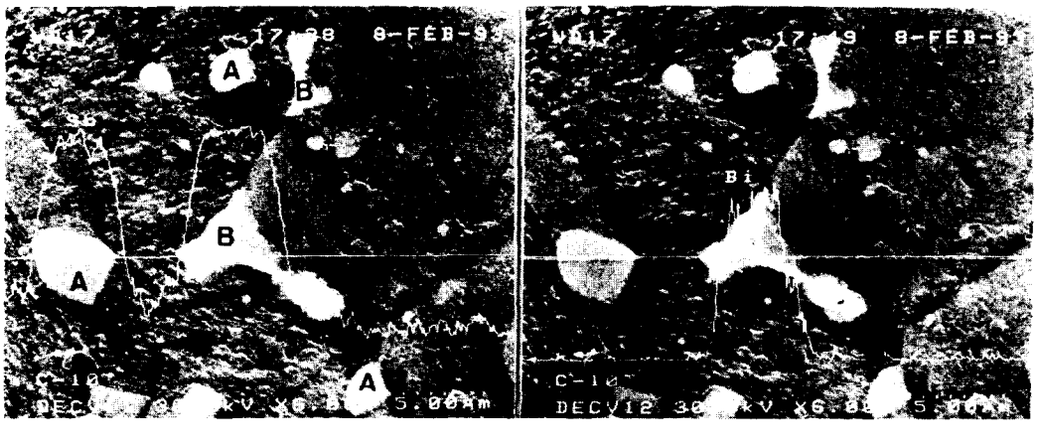

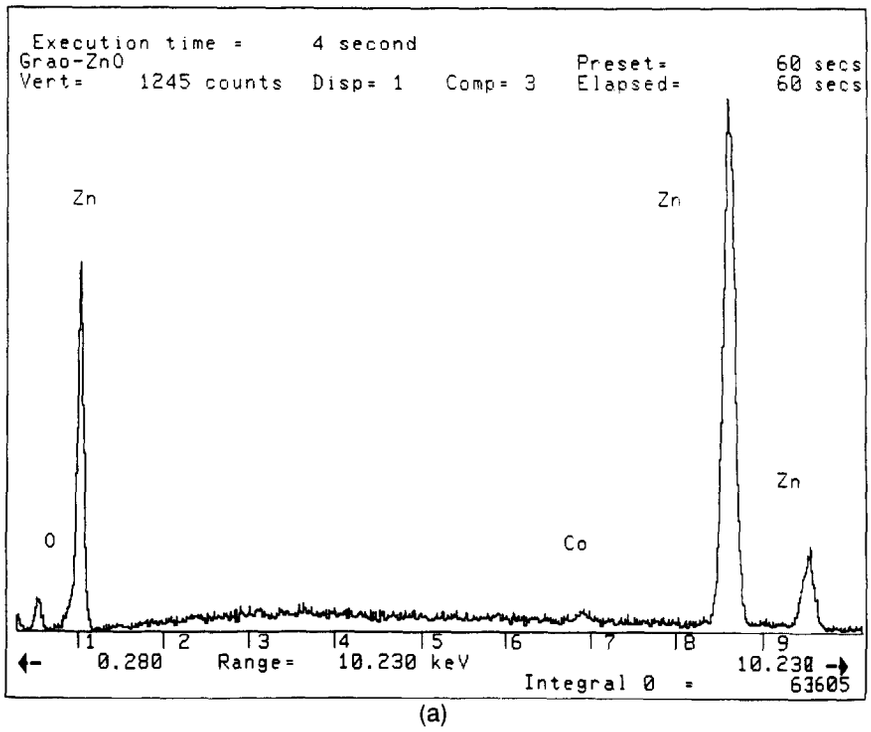

Fig. 2. Antimony and bismuth profiles (by EDS attached to the SEM) of the three phases present in the sample microstructure. Both the spinel like phase (A) and the brighter phase (B) contain Sb, while Bi is only present in the brighter phase.

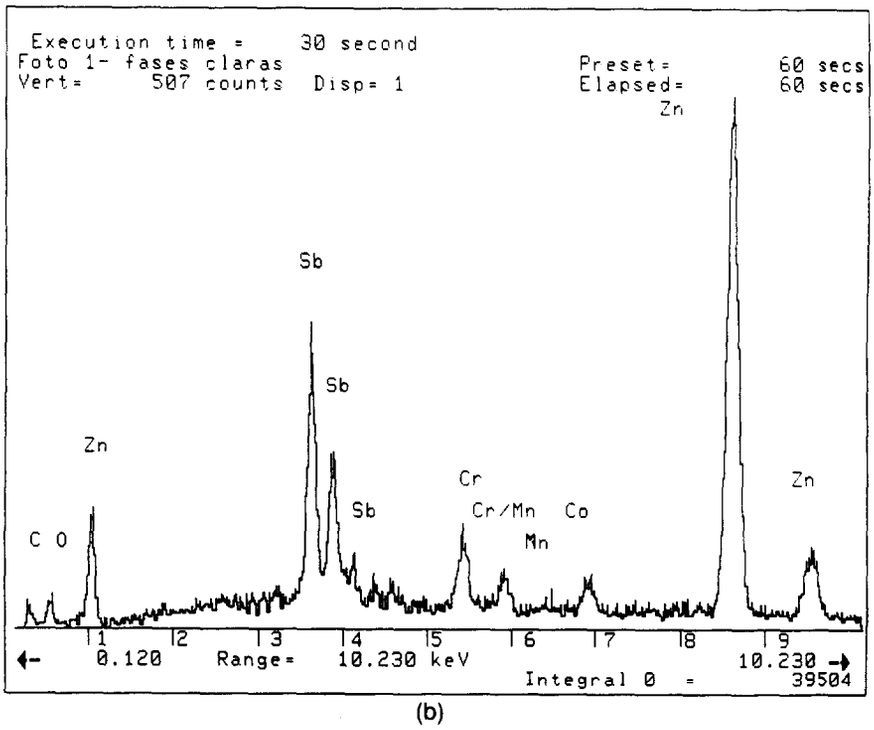
emphasized that Co, Mn or Cr, were not detected in the third phase. If this phase is the pyrochlore type phase, then it comes with ZnO from the reaction between the spinel like and the Bi-rich liquid phases, during the cooling down of the sample[13–15]



$$3Zn_7Sb_2O_{12}(SP) + 3Bi_2O_3(Liq.) \xrightarrow{950°C} 4Bi_{3/2}ZnSb_{3/2}O_7(PY) + 17ZnO \quad (1)$$

where SP is spinel and PY pyrochlore.

Since the third phase does not contain Co, Mn or Cr, it is possible that these dopants were incorporated in the newly precipitated ZnO. Einzinger[3,4] and Schwing and Hoffmann,[10,11] proposed the build up of the potential barrier in the ZnO grain boundaries as being due to the presence of Co in the grain boundary. For these authors, this mechanism is important for the build up of the potential barrier in the grain boundaries, since foreign atoms segregated near the interface will shift the relative concentrations of zinc and oxygen vacancies. Donor cations (Co, Mn or Cr) will decrease the oxygen vacancy concentration relative to that of zinc vacancy and, consequently, the Fermi level at the interface will be lower in energy, relative to the conduction band edge, than in the bulk of the material; this means that a potential barrier is formed at the interface. The above results could support this mechanism, since a high concentration of these dopants would be in the

(a)

(b)

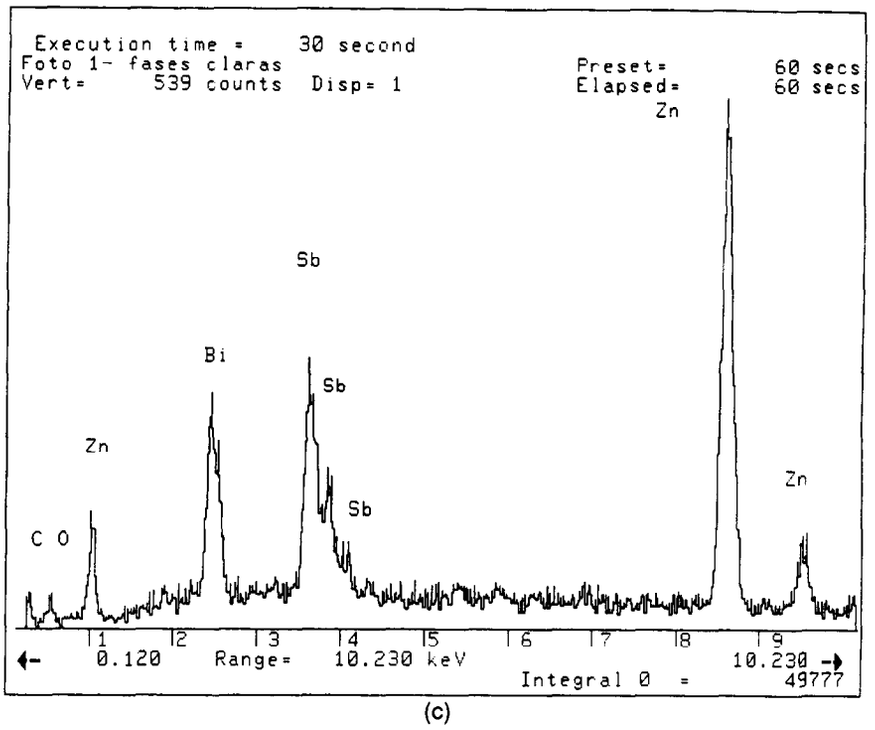


Fig. 3. EDS spectra of the three phases present in the sample microstructure: (A) ZnO phase, showing faintly the presence of Co; (B) spinel like phase, doped with Cr, Co, and Mn; and (C) the brighter phase, composed by Zn, Sb, and Bi, without clear evidence of the dopants.

freshly precipitated ZnO layer. However, in this temperature range (~950°C), most of the ZnO–ZnO grain boundaries are already formed and the material already presents varistor characteristics,[19] and so some doubts can be put on accepting this mechanism as the main contribution to the formation of the potential barriers. It was decided, therefore, to pursue this matter in some detail, and see if there was consistency between the DSB model and the formation mechanism of the potential barriers.

3.2 Varistor parameters

3.2.1 The method used to determine the density of surface states (DOS)

In this work, we firstly determined the equilibrium Fermi level at the interface, E_{Fo}, and thereafter the density of surface states (DOS), at various temperatures, ranging from room temperature up to 160°C. Both parameters, E_{Fo} and DOS, were calculated from each experimentally determined I–V curve, using the double Schottky barrier model (DSB). The procedure was made by successive fittings of the theoretically calculated I–V curves to the experimental ones, until a good fitting between both curves was found. In the following, we describe this procedure step by step.

Using the DSB model, there are two main steps to obtain the electrical parameters that allow the derivation of the I–V curves: in the first step, the relation between the barrier height, Φ_B, and the applied voltage across one junction, V, is found; in the second one, these two parameters are related with the electron flux, J_{DC}. Once the I–V curve is obtained for one junction, it is necessary to relate it to the polyjunction system describing the polycrystalline material. We shall return to this last relation later in this section.

To accomplish the first step, it is necessary to know the density of charge in the junction, $\rho(x)$, and solve the Poisson equation for that case. This has been done by Blatter and Greuter[20,21] who have found a relatively simple relation between the barrier height and the applied voltage

$$\Phi_B = \frac{V_C}{4}\left(1 - \frac{V}{V_C}\right)^2 + \sum_{\nu=1}^{n} N_\nu(\epsilon_\nu - \epsilon_\xi)\left(e\sum_{\nu=0}^{n} N_\nu\right)^{-1} \quad (2)$$

In this equation, the critical voltage, V_C, is related to the accumulated charge at the interface, Q_i, and to the concentration of donors in the grains, N_ν, by the equation

$$V_C = Q_i^2\,(2\epsilon\epsilon_o e\sum_{\nu=0}^{n} N_\nu)^{-1} \quad (3)$$

where ϵ is the relative permitivity of the material, ϵ_o the vacuum permitivity, and e the electron charge. Each donor species, ν, with density N_ν, is in the energy level $E_g - \epsilon_\nu$, where E_g is the forbidden band of the semiconductor; $E_g - \epsilon_\xi$ is the Fermi level in the bulk of the material. The second term of the right hand side in eqn (2), is the contribution of deep donor levels to the barrier height. These

deep levels tend to decrease the barrier height, and have some effect in the I–V curves for high voltages (normally in the breakdown region). As has been pointed out,[20,21] for normal densities of deep levels in ZnO varistors (ca. 10% of the density of shallow donors), the barrier height is reduced by ~0·10 eV, which only represents 10%–20% of the total barrier height; moreover, experimentally it is difficult to observe any smooth change of the I–V curve at high voltages, especially in the breakdown region. Because of that, we have neglected this type of contribution, and so eqn (2) reduces to quite a simple one

$$\Phi_B = \frac{V_C}{4}\left(1 - \frac{V}{V_C}\right)^2 \tag{4}$$

The accumulated charge at the interface, Q_i, represents the total amount of trapped charge,

$$Q_i = e\int_{\xi_i^n}^{n} N_i(E) f_i(E)\,dE \tag{5}$$

where ξ_i^n is a fictitious Fermi level describing the neutral interface, $N_i(E)$ the density of surface states, and $f_i(E)$ their probability of being occupied. Upon the application of the voltage, some of the surface states are ionized, and so the Fermi level at the interface shifts upwards in energy. The voltage dependent barrier height is defined by eqn (2) (or (4)) and by $e\Phi_B(V) = E_g - \epsilon_\xi - E_F(V)$; so any pair of ($\Phi_B$, V) values must be found in a self-consistent way.[20,21]

In the second step for the determination of the I–V curve, it was assumed that the electron flux over the barrier corresponds to the thermionic emission mechanism.[1,2,20,21] It has been shown by Pike[22] that a diffusion mechanism will give similar results, so both mechanisms can be applied to describe the system. Other mechanisms, like the field emission, used by other authors,[23] were not considered here. According to the thermionic emission mechanism, the electrical density across a junction has the form

$$J_{DC} = A^*T^2\exp(-(e\Phi_B(V)+\epsilon_\xi)/kT)(1-\exp(-eV/kT)) \tag{6}$$

where A* is the Richardson constant, T the absolute temperature, e the electron charge, and k the Boltzmann constant; [1– exp(–eV/kT)] corresponds to the net electron flux crossing the junction.[1,2,20,21] In a more accurate description, the electron capture probability must also be taken into consideration in this equation, but since this is a rather minor correction, we have neglected it.[20,21]

Having defined the relation between applied voltage and current density for one junction, i.e. the I–V curve, it is important to relate this to the material characteristics. It is normally accepted that the I–V properties of the material can be described by an equivalent electrical circuit composed of a network or resistors. It is also known that some of the grain boundaries in the material are not electrically active, i.e. they don't have varistor properties. It has been proposed[24] that in such equivalent circuits, it is only necessary to have ~30% of good electrical junctions for the material to behave as a varistor. In view of this result, one can consider that the material is composed of a series of resistors between the electrodes, whose number, m, can be readily calculated by $m \approx d/G$ (d being the sample thickness, and G the mean grain size of the material). This type of approximation can give values of 2–3 volts per grain boundary (V/GB) for the breakdown voltage. If, experimentally, a varistor has α values greater than 25, it is necessary to incorporate a mechanism of impact ionization, or a tunneling mechanism, as already pointed above. For these mechanisms to operate, the breakdown voltage must be ≥3·2 V/GB. This value has been found experimentally for one junction, using microcontacts over a polished surface;[25–28] besides, it is the threshold voltage for the mechanism of impact ionization, also found experimentally.[7] This means that the approximation used for the determination of m, where every grain boundary was counted, can give unrealistic results. However, in these situations where $\alpha \geq 25$, the number of electrically active grain boundaries, m', can be easily found by assuming that the 3·2 V/GB have been reached for these samples, which allows the use of the relation $V_{breakdown}/m' \approx 3{\cdot}2$ V/GB. Once this value has been found, it is thus possible to compare the theoretically calculated (J_{DC}, V) curve with the experimental (J_{DC}, V_{exp}/m') one.

Knowing the relevant electrical parameters for each case, it is then possible to fit a theoretically calculated I–V curve to the experimental one, by manipulating only the distribution of the surface states. In this work, we made this approach with the aid of a computer program, in which the density of surface states (DOS) was introduced as a set of Gaussian distributions. In practice, the type of distribution used is not important, since we could input any number of Gaussians and integrate them to fit the curves.

Since we neglected the contribution of deep donors to the barrier height, N_ν reduces to N_0 (ν = 0). For the density of ionized donors. N_0, we used the values determined by the known relation:[29]

$$\left(\frac{1}{C} - \frac{1}{2C_0}\right)^2 = \frac{2(\Phi_B + V)}{e^2\epsilon\epsilon_0 N_D} \tag{7}$$

where C and C_0 are the capacitance at V and $V = 0$

applied voltage, respectively, and N_D the total density of ionized donors. We assumed that $N_0 \equiv N_D$, since this relation was used with results obtained at a fixed frequency of 1 MHz.[1,3,20,21]

3.2.2 Electrical characteristics

To plot the I–V curves, V/GB was determined by $V_{applied}/m$, where $V_{applied}$ is the voltage applied to the sample, and m is the total number of grain boundaries between the electrodes, m = 189 (with G = 9·8 μm). For this value of m, at a current density of 0·5 mA/mm^2, which is the current density normally accepted for the onset of the breakdown regime,[30] V/GB $\approx$ 2·6 V, and the α value is greater than 25, $\alpha \approx 35$. As already said, for such a high value of α, the voltage applied to each grain boundary exceeds 3·2 V. The calculated value, 2·6 V, is lower than this one, and we can presume that not all the grain boundaries are electrically active. Assuming that this value must be at least 3·2 V, then the number of electrically active grain boundaries is m' = 152. Figure 4 shows the I–V curves, plotted as ln(J) versus ln($V_{applied}/m'$), where J is the current density, for the various temperatures. In this figure m' = 152, which corresponds to ~80% of good junctions in the material and is far above the minimum required for the varistor action. This fraction of good junctions in the material seems to be too high to correspond to the mechanism of segregation of dopants in the ZnO–ZnO boundaries via the formation of the pyrochlore phase by eqn (1), since this phase is a rather minor one, and most of the ZnO grain boundaries must be already formed at ~950°C.[19]

The next step is the determination of the energy of the equilibrium Fermi level at the interface, E_{Fo}, at each temperature. At zero bias, i.e. for lim J_{DC} (V→0) in eqn (6)

$$\sigma = ek^{-1}A^*T\exp[-(e\Phi_{Bo} + \epsilon_\xi)/kT] \qquad (8)$$

and the conductivity, σ, of the material depends essentially on the exponential part of eqn (8). Since $E_{Fo} = E_g - (e\Phi_{Bo} + \epsilon_\xi)$, then E_{Fo} determines the conductivity of the material at each temperature. Assuming a reasonable value for the bulk Fermi energy, ϵ_ξ, E_{Fo} can be calculated for each temperature by simply fitting the ohmic highly resistive part of the I–V curve to the theoretically calculated one. We assumed that ϵ_ξ = 0·05 eV for all the tested temperatures; it is a reasonable energy for the semiconductor, although not necessarily constant for all temperatures. The choice of this energy is to be checked in the following.

Figure 5 represents the variation of E_{Fo} with temperature. It is an almost straight line, with slop $dE_{Fo}/dT = -2{\cdot}3 \times 10^{-3}$ eV K^{-1}. Rossinelli *et al.*[31] have found a similar value for the $SrTiO_3$ based varistors ($-2{\cdot}0 \times 10^{-3}$ eV K^{-1}), and in view of the two quite different chemical systems, it is expected that they have the same physical origin. During heating, the width of the ZnO forbidden band is also decreasing, $E_g = E_{go} - \beta T$, with β = 9·5 × 10^{-4} eV K^{-1}.[32] Instead of calculating the absolute change of E_{Fo} with temperature, we have calculated the relative change of E_{Fo} to E_g with temperature. For each temperature we plotted E_{Fo}/E_g–vs–T, and have then calculated the slope of the obtained curve. We found $d(E_{Fo}/E_g)/dT = -5{\cdot}2 \times 10^{-4}$ K^{-1}. Such temperature dependence can be

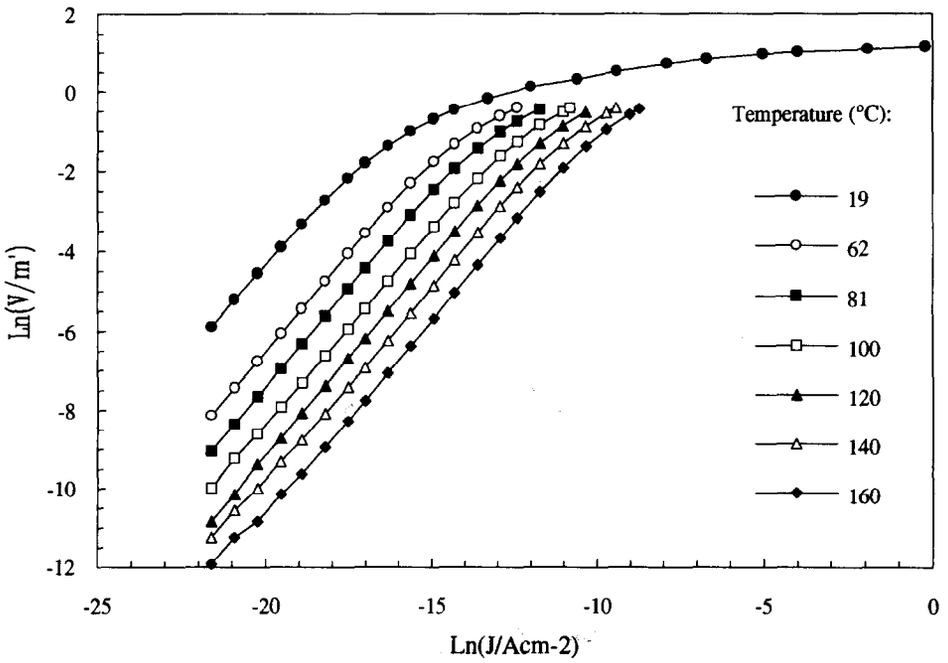

Fig. 4. I–V curves of the samples at the studied temperatures (legend inside the figure). In this Figure, V/GB was determined by $V_{applied}/m'$, where m' = 152 is the number of good junctions (see text).

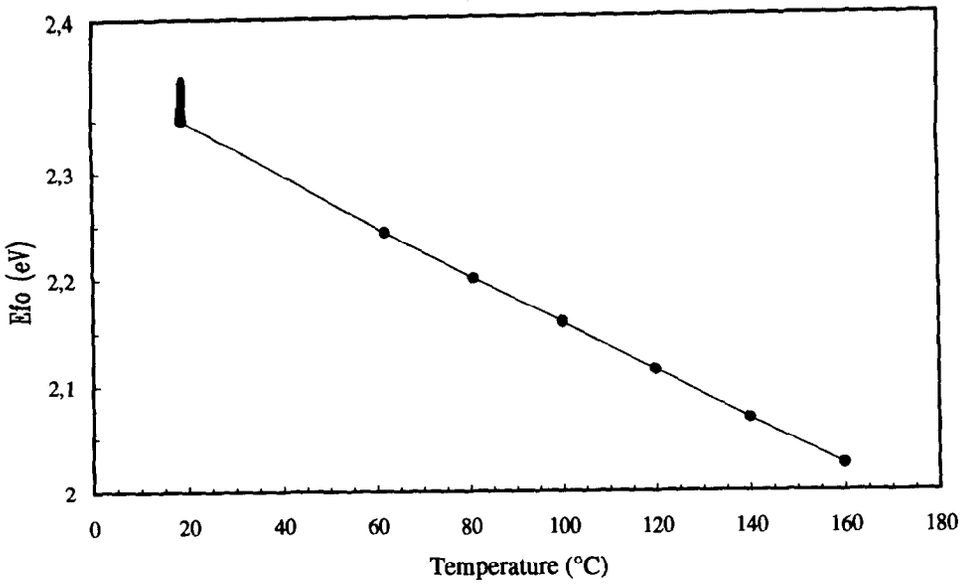

Fig. 5. Variation of the equilibrium Fermi level at the interface, E_{Fo}, with temperature.

assigned to the variation of the bulk Fermi level, assuming that the density of carriers in the ZnO conduction band, in this temperature range, is controlled by donor defects (either intrinsic, like the zinc interstitial, Zn_i, or the oxygen vacancy, V_O, or extrinsic, e.g. due to the presence of Co). As a first approximation, the density of carriers, n, can be considered constant,[33] and ϵ_ξ can be determined by adjusting the n value in the following eqn (9), until it has the same temperature dependence as E_{Fo}/E_g

$$\epsilon_\xi = kT\ln\left(\frac{N_C}{n}\right) \tag{9}$$

where $N_C = 2(2\pi m_e^* kT/h^2)^{3/2}.m_e^*$ is the electron effective mass in ZnO, taken as $m_e^* = 0{\cdot}25m_o$, and h is Planck's constant. Equation (9) is, of course, not entirely correct, since the exact structure of the system is not known (type of donor species, its energy and concentration). However, it gives quite reasonable values for n and for ϵ_ξ: (i) the adjusted n value, $n = 4{\cdot}5 \times 10^{16}$ cm^{-3}, is in close agreement with values determined by other techniques (infrared spectroscopy,[34] high current and high frequency measurements[35]) on commercial varistor samples, $n \sim 1 \times 10^{17}$ cm^{-3}, and (ii) the value of the bulk Fermi level, ϵ_ξ, ranges from 0·10 eV, at room temperature, up to 0·18 eV, at 160°C, values which fall in the range of 0·066 eV[20,21] to 0·32 eV.[36] Knowing the values of E_{Fo} and ϵ_ξ for each temperature, we are now able to calculate the density of states (DOS).

To calculate the DOS we used the parameters listed in Table 1. Figure 6 shows the DOS as a function of the energy at the interface, for all the tested temperatures. For these calculations we introduced four Gaussian curves for each temperature. One of these curves, E_1 in Table 2, corresponds mostly to the ionized surface states in equilibrium, i.e. to Q_{io}. Although the density and distribution of the DOS below the equilibrium Fermi level cannot be known be this method, it is however necessary to use Gaussian curves that extend below the equilibrium Fermi level in order that the DOS very close to it (above and below) can be computed to correctly calculate the DOS for higher energies. This is the reason why this Gaussian curve is shown in Table 2. The Table also shows the parameters of the Gaussian curves, E_i, σ_i, and N_i, representing the energy level, the standard deviation, and the total surface states, respectively, for each tested temperature. It must

Table 1. Used and calculated electrical parameters for the determination of the DOS: the energy of the band gap, E_g, bulk Fermi level, ϵ_ξ, and the concentration of donor species, N_D, were used to calculate the equilibrium values for the interface Fermi level, E_{Fo}, barrier height, Φ_{Bo}, and trapped charge at the interface, Q_{io}. Other important parameters are: electrical permitivity, 8·5, effective mass, $0{\cdot}25m_o$, grain size, 9·8 μm, grain resistivity, 1 Ω cm, and Richardson constant, 30 A cm^{-2}K^{-2}

Temperature (°C)	$E_g(eV)$	$\epsilon_\xi(eV)$	$N_D(m^{-3})$	$E_{Fo}(eV)$	$\Phi_{Bo}(eV)$	$Q_{io}(m^{-2})$
19	3·206	0·103	$1{\cdot}432 \times 10^{24}$	2·349	0·754	$3{\cdot}176 \times 10^{16}$
62	3·165	0·124	$1{\cdot}441 \times 10^{24}$	2·243	0·798	$3{\cdot}278 \times 10^{16}$
81	3·147	0·134	$1{\cdot}542 \times 10^{24}$	2·199	0·814	$3{\cdot}426 \times 10^{16}$
100	3·129	0·144	$1{\cdot}804 \times 10^{24}$	2·158	0·827	$3{\cdot}736 \times 10^{16}$
120	3·110	0·154	$2{\cdot}223 \times 10^{24}$	2·114	0·842	$4{\cdot}184 \times 10^{16}$
140	3·091	0·165	$2{\cdot}084 \times 10^{24}$	2·068	0·859	$4{\cdot}090 \times 10^{16}$
160	3·072	0·175	$2{\cdot}395 \times 10^{24}$	2·025	0·872	$4{\cdot}419 \times 10^{16}$

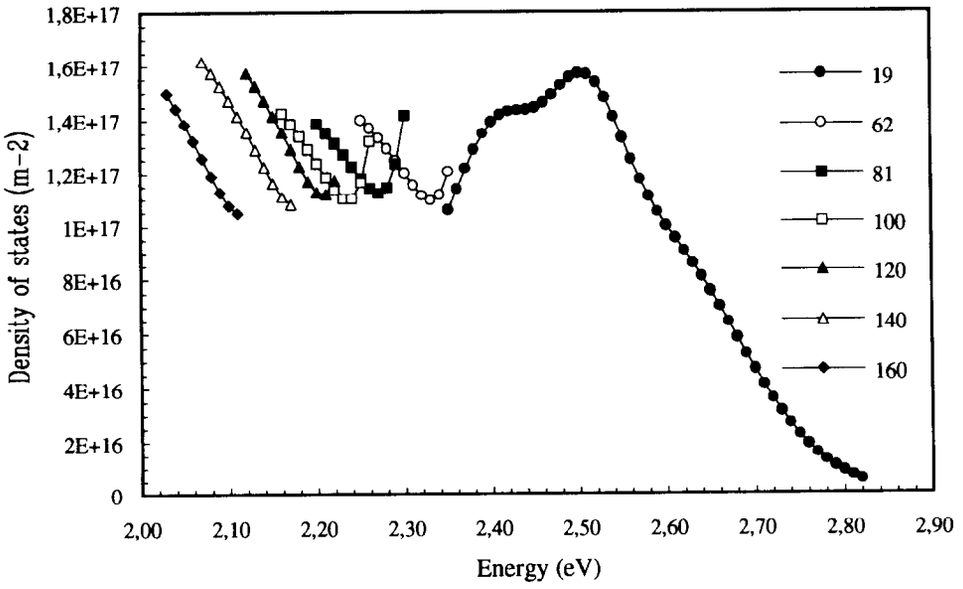

Fig. 6. Energy distribution of surface states (DOS) at various temperatures.

be emphasized that these are guideline parameters and not absolute ones, as pointed out above. The DOS curves in Fig. 6 start at the interface equilibrium energy, E_{Fo}, and end at the energies corresponding to the last experimental point of the I–V curves. Because of this, the room temperature DOS curve is the one with more complete information about the energy distribution. This curve is composed of three main relative peaks, E_2, E_3 and E_4, in Table 2. Their origin is not discussed here, and will be the subject of a forthcoming paper. Although not evident in Fig. 6, with rising temperature, the peaks shift their energy position to lower energies at different rates, and tend to merge together (see Table 2). However, their magnitudes remain unchanged. This observation, together with the linear decrease of E_{Fo}, explains why the values of N_D (Table 1) increase slightly with temperature: as the temperature is rising, some more surface states are being ionized, since they are now below the equilibrium Fermi level, and, to maintain the electrical neutrality condition, eqn (2), N_D must increase. If this behaviour can be extrapolated for higher and lower temperatures, one would expect the following situations:

(i) for higher temperatures, one should see the decrease of the non-ohmic behaviour, since the unionized surface states tend to decrease, and, for some very high temperatures, the system should be ohmic. This behaviour has been experimentally described in the literature;[30,37]

(ii) for lower temperatures, more surface states will be above the equilibrium Fermi level, that is, the sample will show more pronounced varistor characteristics. Concomitantly, there is a higher probability of minor carrier generation by the impact ionization mechanism (or tunneling of electrons from one grain to the other, at the junction). This corresponds to a 'cut-off' of the higher energy surface states, giving the origin of a 'knee' in the I–V curve, or a sharp transition to the breakdown regime. This, in fact, corresponds to much higher α values, that is, the varistor will show α values higher than one could predict *a priori*.[38]

Table 2. Parameters used for the Gaussian curves that describe the DOS for each temperature: E_i, σ_i, and N_i, are the energy level, the standard deviation, and the total surface states, respectively. E_i shift their energy and tend to merge together, while σ_i and N_i remain constant throughout the temperature range. The E_i energies are related to the top of the valence band edge ($E_{VB} = 0$)

Temperature (°C)	*E_1(eV)*	*E_2(eV)*	*E_3(eV)*	*E_4(eV)*
19	2·12	2·41	2·51	2·58
62	2·07	2·28	2·40	2·46
81	2·05	2·21	2·34	2·40
100	2·01	2·14	2·25	2·34
120	1·97	2·05	2·17	2·25
140	1·94	2·00	2·13	2·20
160	1·89	1·92	2·08	2·15
σ_i(eV)	0·15	0·07	0·03	0·10
N_i(m^{-2})	$2{\cdot}9 \times 10^{16}$	$1{\cdot}9 \times 10^{16}$	$4{\cdot}0 \times 10^{15}$	$2{\cdot}3 \times 10^{16}$

It is important to have these observations in mind when attempting to characterize the DOS. In one hand, it is necessary to go to lower temperatures to split the relative peaks of the DOS; on the other hand, at low temperatures some of the DOS will not be 'detected' by the method, namely those at the highest energies. So, the characterization of the DOS is not a straightforward task.

Another important result is the observation that the concentration of donor species in the bulk of

the ZnO grains, is controlling the equilibrium Fermi level at the interface, at least in the temperature range of this work. It is expected that the higher the bulk donor concentration, the lower the temperature coefficient of E_{Fo}, and, since dE_g/dT is constant, this situation leads to a decrease of $E_A = \epsilon_\xi + \Phi_{Bo}$ (E_A is normally determined by the variation of the low voltage ohmic resistivity with temperature, i.e. $\rho = \rho_0 \exp(E_A/kT)$). This means that, unless two different systems are equivalent in their bulk donor concentration, there is no reason to compare the experimentally determined E_A energies in different varistor systems. This is the reason why there is a large range of the determined values for E_A in the literature, $0{\cdot}35 \leq E_A \leq 0{\cdot}94$ eV,[30,39] all of them corresponding to acceptable varistor characteristics.

If the change of E_{Fo} with temperature is only due to the simultaneous variation of E_g and ϵ_ξ, one can extrapolate this result to higher temperatures, and predict what would happen after E_{Fo} reaches the middle of the energy gap, $E_g/2$. For our sample, this situation would happen at ~450°C. Two hypotheses can be considered, either the energy of E_{Fo} continues to decrease after this temperature has been reached, and will be now under the $E_g/2$ value, or E_{Fo} stays at the energy of $E_g/2$.

The first hypothesis would then correspond to a situation where the interface is best described as a p-type semiconductor, while the bulk of the material is still a n-type semiconductor. The junction would then be of the n–p–n type, and, consequently, it would show varistor properties, even at very high temperatures. This is contrary to what has been experimentally observed and reported in the literature.[30,37] The prevision was, of course, a forced one, because even in a p-type semiconductor, at very high temperatures, the Fermi level will tend towards the middle of the band gap, especially if the acceptor concentration is low. However, it must be pointed out that to achieve a p-type conductivity in ZnO, it is necessary to sinter the material at very high oxygen partial pressures,[40,41] or to dope the material with acceptor species. The first condition is not observed in practice, even if one assumes that the Bi-rich liquid phases are good oxygen carriers,[42] since the maximum attainable oxygen partial pressure is *a priori* established by the ambient atmosphere. The second condition can only be observed if the acceptor species are intrinsic in origin, since all the normally used dopants are of the donor type (three- or four-valent cations). The possible intrinsic acceptor species are the interstitial oxygen or the zinc vacancy, the later being invoked, since at the sintering temperatures the Schottky pairs are the predominant defects.[43,44] A surplus of zinc vacancies, or, equivalently, a depression of oxygen vacancies, can arise by the doping process via

$$M_2O_3 \xrightarrow{ZnO} 2M^{\bullet}_{Zn} + 3O_O + V''_{Zn} \qquad (10(a))$$

or

$$M_2O_3 + V_O^{\bullet\bullet} \xrightarrow{ZnO} 2M^{\bullet}_{Zn} + 3O_O \qquad (10(b))$$

(where V_{Zn}'' and $V_O^{\bullet\bullet}$ are the zinc and oxygen vacancy, respectively, both completely ionized, $M_{Zn}^{\bullet}$ is the substitution of a zinc site by the dopant cation, and O_O is an oxygen in its normal site in the ZnO matrix) that is, if the dopants are segregated to the grain boundaries (e.g. M = Bi), it is possible that the interface acts like a p-type semiconductor.

A second hypothesis to consider after E_{Fo} has reached the middle of the band gap, is that it stays at this position when the temperature increases. The interface would then be best described as a n–i–n type junction, where i denotes intrinsic electrical behaviour, or, since the density of majority carriers (electrons) is lower at the interface, it could also be described as a n–insulator–n junction. This model predicts that, at sufficiently high temperatures, the energy difference between the Fermi level and the bottom of the conduction band in both the interface and the bulk of the material, i.e. the barrier height, tends to disappear, and the material will show ohmic behaviour. This is what has been experimentally observed.[30,37] To have intrinsic behaviour at the interface, it is necessary that the material has neither donor nor acceptor levels, or that the net balance of them is null. It is quite unreasonable that there are no defect levels at the interface, since dopants are segregated there from the very beginning of the cooling of the samples.[19] At the sintering temperatures, the Schottky pairs dominate the defect chemistry of the system,[43,44] and, if eqns (10(a, b)) is valid for the formation of associated defects, $(M^{\bullet}_{Zn} - V''_{Zn} - M^{\bullet}_{Zn})^x$, rather than for unassociated species, the condition of net null charge at the interface only requires the annihilation of both oxygen and zinc vacancies following their chemical reaction (Schottky pair equation), during cooling. The elimination of both defects at the interface during cooling, has been the basis for the surface oxidation process.[3,4] Although the formation of the above mentioned associated defects is speculative, it must be emphasized that they could limit the density of unpaired species to a certain extent, which would explain the discrepancy between the density of charged interface defects (10^{12}–10^{13} cm^{-2}) and the concentration of foreign atoms at the interface (~10^{15} cm^{-2}, for Bi atoms), as pointed out by Greuter and Blatter.[20,21]

The second hypothesis discussed above, would

mean that there could be a significant contribution of the surface oxidation process for the barrier height formation. Mahan[42] concluded that the contribution of this process is negligible, ~0·10 eV, which is 10–20% of the total barrier height. Taking his own results (pure ZnO), we have calculated the temperature in which the bulk defects should be frozen, to give $n = 4{\cdot}5 \times 10^{16}$ cm^{-3} at room temperature, and found $T \approx 1050$°C. This seems to be a rather low temperature, since samples quenched from higher temperatures already show varistor characteristics.[19] Taking into consideration that these calculations are reported for pure ZnO, we also calculated the concentration of carriers, n, at the interface, for a frozen temperature of 450°C (temperature at which E_{Fo} in cooling separates from the middle of the band gap), and found $\Delta E_F = kT\ln(n(450°C)/n(1050°C)) \approx 0{\cdot}25$ eV. This contribution can no longer be neglected. Although the contribution of the surface oxidation process, the n–i–n model, to the barrier height formation could then have a significant value, it must be considered that the same type of defect equations (eqns 10 (a, b)) can also be used to explain the contribution to the barrier height formation from a n–p–n model. Subtle differences will be hard to clarify experimentally.

4 Conclusions

Varistor samples sintered at 1300°C in air, developed a microstructure in which the distribution of dopants seemed to indicate that their chemical segregation at the ZnO grain interfaces could be the origin of the electrical potential barrier present in these devices. This type of barrier height formation mechanism should be operative at temperatures below ~950°C, the temperature at which the remaining Bi-rich liquid phase reacts with the spinel phase to give the pyrochlore and ZnO. However, before this temperature most of the ZnO–ZnO grain boundaries are already formed, and the material shows varistor characteristics. Consequently, the contribution of the surface oxidation mechanism to the barrier height formation should only be important at high temperatures, where the diffusion coefficients still allow the migration of the species to the surface of the grains. For temperatures below 950°C, another type of barrier height formation mechanism should then be present.

Taking the double Schottky barrier (DSB) model, we have calculated the distribution of surface states (DOS) above the equilibrium Fermi level for various temperatures, ranging from room temperature up to 160°C. In this temperature range, the equilibrium Fermi level at the interface, E_{Fo}, linearly decreases with temperature, independent of the DOS changes. This variation in relation to the band gap of the semiconductor was assigned to the change of the bulk Fermi level, and so it was possible to derive the density of carriers in the semiconductor conduction band, n. The calculated value, $n \sim 4{\cdot}5 \times 10^{16}$ cm^{-3}, is in good agreement with values, $\sim 1 \times 10^{17}$ cm^{-3}, experimentally determined using other techniques. This procedure can thus be used in any other system, and it also permits the determination of the bulk Fermi level at any temperature. Since the bulk Fermi energy depends on the defect concentration inside the ZnO grains, it is related to the processing of the ceramic, namely to the type and concentration of additives and to the sintering schedule. Consequently, it is expected that each varistor system and processing procedure will give different energy values determined by electrical measurements, which explains the large range of the barrier energy values reported in the literature.

It was also shown that during heating of the samples, the DOS peaks tend to lower energy values, at different rates. This behaviour explains why the interface defect energies also have a large range of reported values. An extrapolation of this behaviour at low temperatures, lead us to the conclusion that the material should show non-linear exponent α at these temperatures, higher than one could predict *a priori*; and also, extrapolating to high temperatures, that the material should show ohmic behaviour.

The temperature dependence of both the band gap of the semiconductor and the energy of the Fermi level, was used to predict the electrical behaviour of the material at high temperatures. The contribution of the surface oxidation mechanism to the formation of the potential barriers, was estimated from the above considerations, and it can be as high as 0·25 eV. According to the results obtained up to now, it seems that the surface states control mainly the shape of the I–V curves. Other contributions to the energy barriers can probably be elucidated by expanding the experimental range of temperatures used to determine the varistor parameters. This is going to be addressed in further publications.

(Received 11 October 1994; revised version received 27 January 1995; accepted 31 January 1995)

Abstract

The micro-electrical properties of $BaTiO_3$ have been studied using the remote electron beam induced current technique. Difficulties associated with applying this technique to low resistance, inhomogeneous ceramics are discussed and illustrated with the example of PTCR materials. At temperatures above the Curie temperature, contrast steps corresponding to resistive interfaces are observed with differing sensitivities according to the imaging conditions used. The image noise decreases and the current sensitivity increases with the sample resistance. Remote electron beam induced current contrast in $BaTiO_3$, showing the high resistivity transition does not occur uniformly as a function of temperature across all grain boundaries.

Introduction

Semiconducting barium titanate and related phases are important electroceramic materials which have been used for their positive temperature coefficient (PTC) of resistance properties in applications such as over-temperature protection and current limiting devices for over thirty years,[1] and are still very important technologically.[2] The most widely accepted model of the PTC effect, due to Heywang,[3] is of back to back Schottky barriers at grain boundaries due to a build up of negative interface charge. This gives rise to a potential barrier whose height depends on the dielectric constant. Since the dielectric constant changes abruptly at the phase transformation, the barrier height and resistivity change accordingly. This model was extended by Jonker who also considered ferroelectric effects below T_c, where spontaneous polarisation reduces the expected potential barrier height.[4]

However, while the gross behaviour is well explained by these models, sensitive structure averaging techniques such as impedance measurements reveal that they do have some shortcomings.[5–7] The introduction of modified models, such as that of Daniels and Wernicke[8] have caused a parallel search for explanations of the PTC effect at the grain level due to the strong effect of heterogeneity on the electrical properties.[9] TEM investigations clearly show the ferroelectric domains below T_c and also that there is no intergranular phase present of width greater than 2–10 nm.[10] Cathodoluminescence microscopy has been used to observe grain boundary potential barriers in PTC material.[11] EBIC has also been used to view the domains and grain boundaries.[12] However, none of these studies offered direct observation of the resistive properties of such materials.

In this paper we discuss the practicalities of the application of a little used variant of the EBIC technique which allows direct observation of the resistivity changes of individual grain boundaries as the resistive transition progresses, allowing detailed determination of device homogeneity.

EBIC Phenomenology in Ceramics

The well-known charge collection imaging mode of the scanning electron microscope (SEM) is often applied to the microcharacterisation of semiconductors. In this mode the impinging electron beam generates a multitude of electron–hole pairs which can then be separated by built-in fields such as those at pn-junctions. By using a suitable contact geometry, charge collection currents several orders of magnitude larger than the beam current

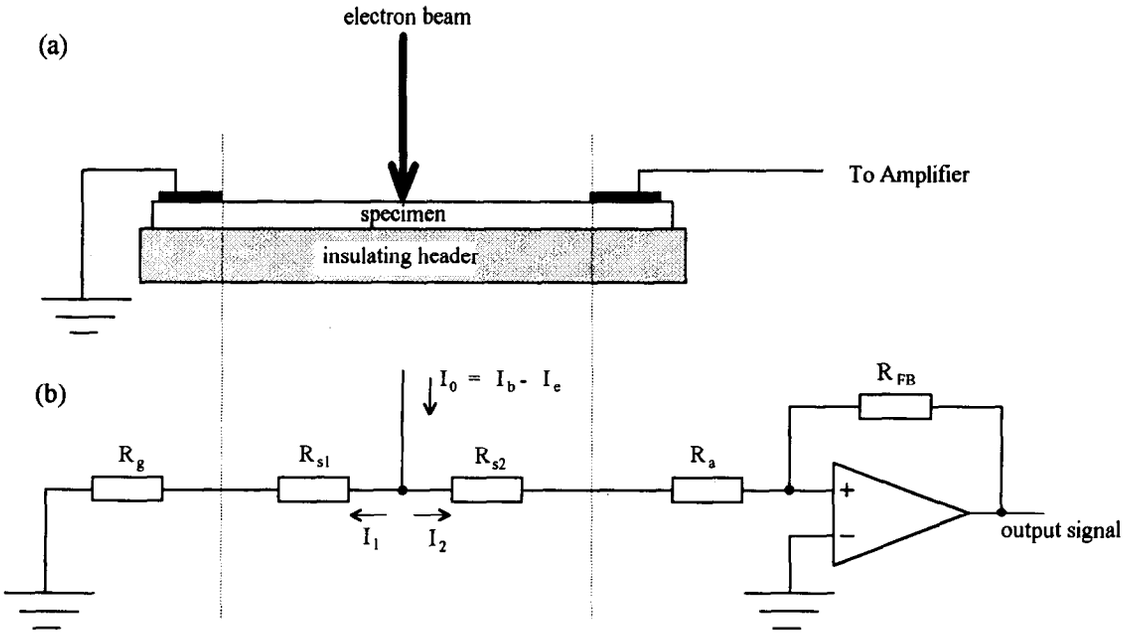

Fig. 1. (a) Specimen configuration and (b) equivalent circuit for REBIC mode imaging. R_g is the resistance from the left of the sample to earth, R_a is from the right of the sample to the amplifier input, I_b is the beam current, I_e the total emitted current, R_{s1} and R_{s2} are the specimen resistances to the left and right contacts from the beam impact point, and $R_{s1} + R_{s2} = R_s$, the specimen resistance. The amplifier is shown schematically, with feedback resistance RFB.

can be obtained in a technique called electron beam induced current (EBIC).[13] In the case of less-well characterised materials such as electroceramics, the absence of suitable built-in fields, and much larger recombination centre densities mean that the usual charge collection mode geometries do not always work as effectively, or at all. However, a technique first used by Matare and Laakso[14] and subsequently termed remote electron beam induced current (REBIC) by Bubulac and Tennant[15] can be employed.

If the specimen has two closely separated contacts as shown in Fig. 1(a), it will have an equivalent circuit as shown in (b), where R_g represents all resistances between the scanned region of the inter-electrode observation area and earth via the earth electrode, and R_a all resistances between the scanned area and earth via the amplifier. R_{s1} and R_{s2} are the components of the scanned area resistance (total R_s) immediately to the left and to the right of the impinging beam. The specimen acts as a current divider with the net current injected by the electron beam flowing either directly to earth through the left contact or to the right through the low input impedance current amplifier. The proportion of I_b reaching the amplifier is used to modulate the signal on the viewing screen and results in a contrast gradient. In some ceramics, electrically active regions cause charge collection contrast due to separated electron–hole pairs. Such contrast would be superimposed on the resistive baseline,[16] and has been observed in ZnO varistor material, for example,[17] where the presence of grain boundary barriers can be satisfactorily explained by grain boundary EBIC models.[18] However, frequently such contrast is not seen and only effects due to the passive resistance component of the interfaces are observed. In this case the imaging method can be referred to as resistive contrast imaging (RCI).[19]

The RCI quality is affected by four factors, as described below.

Current sensitivity

If we consider the case when the scanned area is the total width of sample between the contacts, it can simply be shown, using the terminology of Fig. 1 that the currents which flow through the amplifier when the beam impinges on the sample adjacent first to the left and then the right contact are given by

$$I_{left} = I_o \frac{R_g}{R_g + R_s + R_a} \quad (1)$$

$$I_{right} = I_o \frac{R_g + R_s}{R_g + R_s + R_a} \quad (2)$$

In the case of $BaTiO_3$ the sample resistance, R_s varies widely with temperature, which causes the imaging characteristics to vary. We can define a quantity called the current sensitivity, S,

$$S = \frac{I_{right} + I_{left}}{I_b} \quad (3)$$

where I_b is the beam current. The current sensitivity describes the possible current variation, and hence

contrast, across the sample as a fraction of the beam current, and must be larger than the noise floor for meaningful images to be observed. Although the noise generated by a typical amplifier may only be of the order of picoamperes, as will be seen later, the observed noise can be affected greatly by the sample resistance. It is thus often necessary to work with beam currents of several nA and larger which in turn limits the spatial resolution. The effect of noise is much more important than in charge collection imaging of semiconductors, in which charge multiplication causes a gain of about 1000 over the beam current level. In contrast, RCI of electrical ceramics leads to signals of the order of the beam current. In the case of $BaTiO_3$ PTCR material, a typical sample mounted in the SEM may vary in resistance from 30Ω below the Curie temperature to 30 kΩ above it. From eqns (1–3), using $R_g \approx 10\Omega$, $R_a = 40\Omega$ and $I_o/I_b \approx 0{\cdot}8$ this gives S values of 0·3 and 0·8. Thus the current sensitivity is changed by a factor of 2·7, as is the image contrast, on crossing the phase transition.

Geometrical effects

For a given specimen the largest current sensitivity, and hence the largest current contrast, will be seen if the electrodes are at the image edges. If the field of view spans only part of the electrode separation, the current resolution will be reduced proportionately, i.e. neglecting contact resistances

$$S' = S\frac{w}{D} \tag{4}$$

where w is the image field-width and D the inter-electrode spacing. Thus it is important in detailed work to locate the electrodes as close together as possible. Unfortunately this configuration limits flexibility in aereal imaging and reduces the overall resistance of the sample which gives rise to further difficulties as described in the next section.

Amplifier limitations

For specimen resistances which are small compared with the input impedance of the detecting amplifier, both amplifier noise and the input offset voltage which appear at the inputs of the operational amplifier are magnified in effect. The equation describing the noise amplification is of the form

$$V_{\text{output noise}} = V_{\text{input noise}}\left(1 + \frac{R_{FB}}{R_g + R_s + R_a}\right) \tag{5}$$

where R_s is the sample resistance and R_{FB} is the amplifier feedback resistance (Fig. 1(b)). The value of R_{FB} fixes the amplifier gain, and a typical value for R_{FB} under our experimental conditions would be 100 MΩ. Thus, for the case of the PTCR described previously, the output noise increases by a factor of 1000 in the low temperature, low resistance state compared with its high temperature variant. A similar relationship exists for the amplifier input offset voltage which changes as the sample resistance changes. Although the latter can, in principle, be corrected by applying an appropriate back-off current, in practice for PTCR materials undergoing the phase transformation, the steepness of the change of resistance with temperature means that the signal drifts over a large range with small variations in the sample temperature leading to excessive signal instability.

One way to circumvent this is to add a resistor in series with the sample which will reduce the noise and signal instability. Additionally, this will decrease the total current sensitivity by making the specimen a smaller part of the overall current divider circuit. For example, whilst reducing the noise substantially, adding a 1 kΩ resistor would change the current sensitivity values from 0·3 and 0·8 to 0·022 and 0·77 using the sample resistance values previously cited. It is thus possible to extend downwards the range of sample resistances for which useful images can be obtained. However, because of the close interdependence of the noise and sensitivity, the optimal resistance value required is usually a compromise.

Backscattering contrast effects

On average, around 20% of the beam current is lost from the sample by re-emission as backscattered or secondary electrons. The RCI current will be reduced in regions where a large proportion of the incident beam current is lost. Grains with different backscattering coefficients will, as a consequence, show different contrast in the RCI image for which a correction must be made. This can in principle be achieved by taking a specimen current image (by removing the earth contact so that all the absorbed current must flow to earth through the amplifier) and using it to adjust the measured RCI signal intensity at each point according to

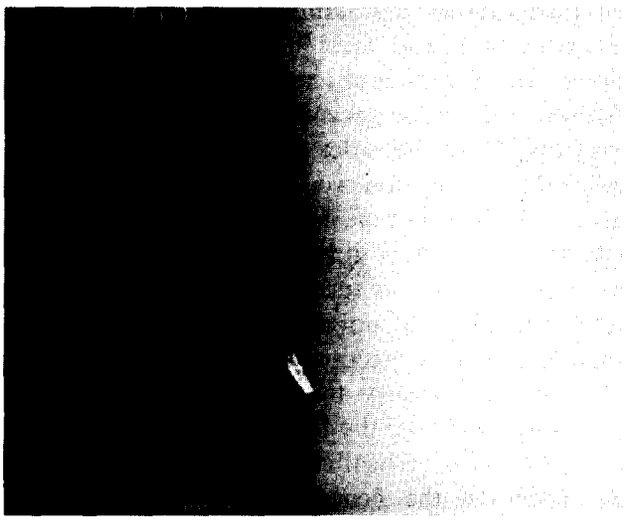
$$I_R = \frac{I'_R}{I_s} \tag{6}$$

where I_R and I_R' are the true and measured RCI currents respectively, and I_s is the local specimen current. Such corrections are small for materials which are predominantly single phase.

Experimental

Polished samples with a 3 mm electrode spacing were prepared from a commercial PTC thermistor device with a Curie temperature of 80°C. These

specimens were mounted on an Oxford Instruments H1001 heating stage, and electrical connections were made using a micromanipulator with fine tungsten probes. A Matelect ISM5 EBIC amplifier was used to amplify the input signal for the SEM.



Subsequently the current sensitivity was increased for higher magnification imaging by reducing the contact separation. This was achieved by producing an array of closely spaced ohmic contacts on the sample surface by careful cleaning and evaporation of aluminium onto a polished sample using a fine TEM grid as a mask.

Results and Discussion

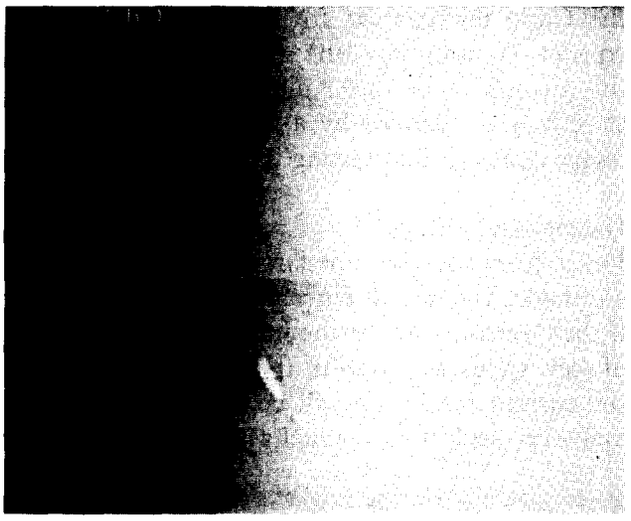


Fig. 2(a) is an RCI image of a region of the polished sample taken with the sample heated to well above the Curie temperature. The inter-electrode spacing is approximately 3 mm left–right in the image. The contrast gradient from left to right is clearly visible, as are the resistive interfaces where abrupt steps in the signal occur. The width of the steps is much larger than the grain size and so at this sensitivity we see clusters of grains of similar grey-level bounded by interfaces with intensity steps. This effect is sometimes referred to as terrace contrast.

As the imaging temperature is decreased, the substantial decrease in sample resistance results in the image becoming more noisy as predicted, along with a parallel decrease in the current sensitivity. However, once this decrease in current sensitivity (Fig. 2(b)), is corrected for, the terraced microstructure can be seen to persist to quite low temperatures until it is lost ultimately in the noise floor. It is thus not clear whether the terraced structure disappears altogether at lower temperatures, or it is simply beyond the capabilities of the imaging technique to observe it. Thus the terrace structure imaged in this way is not necessarily related to the PTCR effect, but may be linked to some intrinsic microstructural feature, such as relics of powder agglomeration prior to sintering.[20] It can be seen from Fig. 2(c) that on increasing the magnification, using this specimen configuration little extra information is seen; contrast is poor with effects only visible at some interfaces. This is due to the lack of current sensitivity when observing a small region between widely spaced contacts (see eqn (4)).

Figure 3 shows the results of a further examination of the same material at higher magnification and higher current sensitivity. This was achieved by using more closely spaced contacts as previously described. A sequence of reproducible

(a)

(b)

(c)

Fig. 2. (a) RCI image between widely separated contacts on $BaTiO_3$ at 140°C showing terrace contrast. (b) is the same area at 110°C where the contrast of the lower half of the image has been scaled to allow for the decreased current sensitivity. The image also shows the increased noise associated with the lower sample resistance. (c) is a higher magnification image of a region from (a). Scale bar (a) and (b) = 100 μm, (c) = 10 μm.

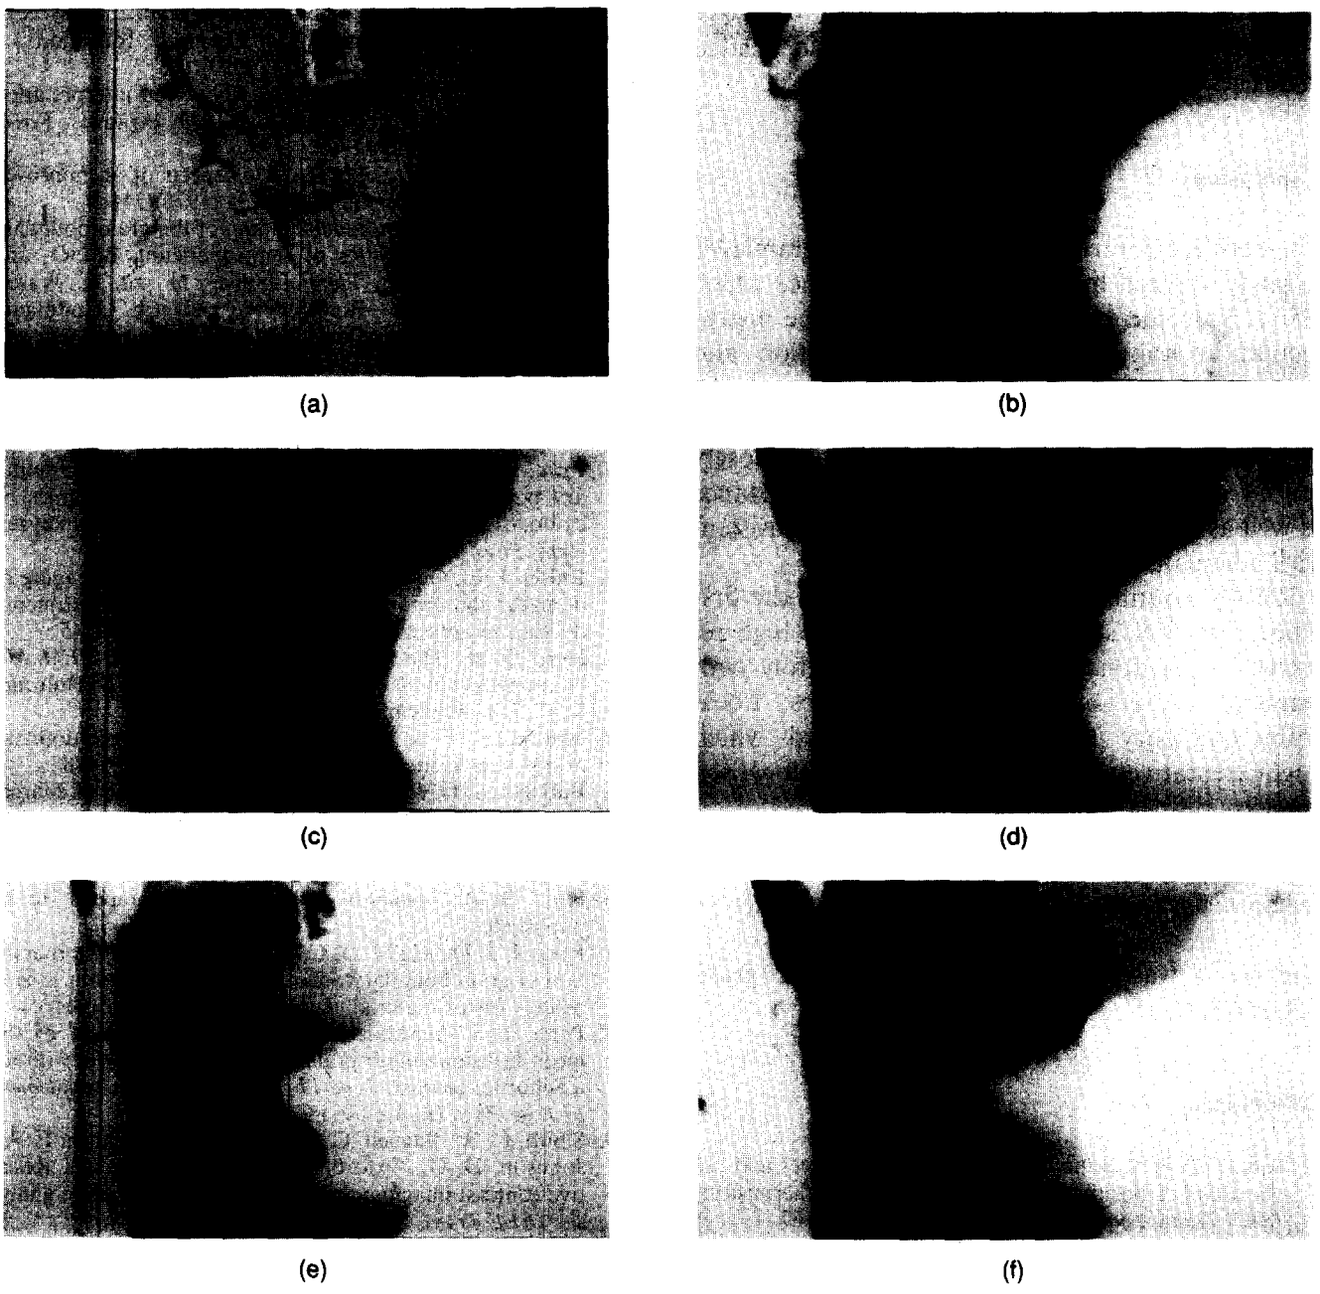

Fig. 3. (a) Secondary electron image showing the grain structure, with the contacts labelled 'L' and 'R'. The left contact is partially covered by a probe. (b–f) are a series of resistive contrast images at 110, 120, 130 and 140°C respectively. In (f) 'A' is an example of a resistive barrier, while 'B' denotes extended regions surrounding grain boundaries also visible in the other images. Scale bar = 10 μm.

images taken in the temperature range 110°C–140°C, where the PTCR effect is active is shown. Figure 3(a) is the corresponding secondary electron image, showing the grain structure and the positions of the two contacts 'L' and 'R', of which the former is covered by one of the micromanipulator probes. Several features are evident.

The REBIC images in Fig. 3(b–f) show that as the temperature increases the image becomes less noisy, and the contrast gets stronger, in accordance with the earlier discussion. This is most clearly evident by comparing (b) and (f).

Each grain boundary that increases its resistance leads to a new contrast step (such as that labelled 'A' Fig. 3(f)) between the contact pads and a slight readjustment of the overall intensity gradient, which is always from approximately left to right. In the later images of the Fig. 3(b–f), more high resistance grain boundaries are introduced compared with the earlier micrographs. It is clearly seen that different barriers become highly resistive at different temperatures, as evidenced by the change in the steps of the contrast profile across the centre of the images with increasing temperature.

Extended regions bounded by resistive barriers spanning grain boundaries occur on the two vertical grain boundaries at the bottom of each image (labelled 'B' in Fig. 3(f)). Backscattered channelling pattern analysis showed that these regions are not crystallographically distinct. Their origin is

unclear, but they might be related to broad impurity diffusion zones as observed in related materials.[21,22]

Conclusions

The resistive contrast shown by electroceramics is strongly affected by the specimen resistance which affects both the current sensitivity and the instrumentation noise. The electrode separation and backscattered electron current loss also need to be taken into consideration. Imaging conditions can be optimised by using specially fabricated, closely spaced electrodes and additional series resistance as well as using the largest beam current consistent with adequate spatial resolution.

REBIC contrast has been observed for the first time in $BaTiO_3$, showing directly that the high resistivity transition does not occur uniformly with temperature across all grain boundaries. Local grain boundary features were observed which might (tentatively) be attributable to a delocalised impurity diffusion phenomenon.

(Received 7 April 1994; revised version received 31 January 1995; accepted 7 February 1995)

Abstract

Modifications of the X-ray diffraction line profiles by die pressing of fine grained powders of barium titanate have been studied. Two main parameters have been considered: the forming pressure and the mechanical characteristics of the binder. The higher the forming pressure, the greater the modifications of the line profiles. Furthermore, the phenomena seems to be related to pressing only; no significant effect related to the nature of the binder has been shown.

The modifications of the diffraction line profiles are interpreted by considering a reduction of the size of the ferroelectric domains during pressing. In order to confirm this interpretation, the behaviour of the domain structure of a $BaTiO_3$ single crystal under local compression has been studied. The average size of the domain is dramatically reduced by applying local pressure. Moreover, the domain structure modifications produced by the high stress state are largely preserved under a rather low residual pressure. There is a kind of hysteresis as a function of the pressure. This observation may explain the remanent modifications of the line profiles recorded after pressure relaxation.

Introduction

The X-ray diffraction line profiles of fine grained barium titanate powders are modified after the formation of green parts.[1] The effects of the different steps of the green part preparation on the line profile modifications have been determined within an experimental design approach.[2] The forming step is by far the parameter which has the largest influence. Indeed, the line profiles are closely dependent on the forming step and none of the other studied parameters seems to have any direct influence on the profile modifications. Forming was performed by slip casting or die pressing. Thus, the mechanical stress applied during the forming step is responsible for the studied phenomenon.

It is well-known that the line profiles of $BaTiO_3$ powders are quite dependent on the granulometric characteristics.[3–7] It has recently been shown that the diffraction diagram of a fine grained barium titanate is also dependent on the ferroelectric domain structure.[8,9] Thus, a full interpretation of the diffraction line profiles requires consideration of the ferroelectric domain structure with respect to the diffracted intensity.[1,10,11]

The influence of the die pressing pressure on the diffraction line profiles of a micronic barium titanate powder is studied in this paper. In order to fully evaluate the effect of residual stress, the mechanical characteristics of the binder are also considered.

Experimental

1 Sample preparation

A pure $BaTiO_3$ powder, with a narrow grain size distribution ($\varnothing_{10}$ = 1·0 μm, $\varnothing_{50}$ = 2·4 μm, $\varnothing_{90}$ = 4·9 μm), has been used in order to get well separated 002 and 200 diffraction lines (Fig. 1).

Two slips were prepared in organic media with two binders presenting quite different mechanical characteristics (Poly Vinyl Butyral PVB and paraffin 46–48°C). After slip drying and preparation of granules, two sets of discs were formed by die pressing. In both cases, the forming pressure range was 100–1000 MPa.

2 X-ray diffraction characterization

The samples were characterized after die forming by X-ray diffraction using a diffractometer fitted out with an INEL Curved Position Sensitive Detector (CPS120). Cu $K\alpha_1$ radiation has been selected with a focusing quartz monochromator. For each diagram, a 120° 2θ zone was recorded over 8196

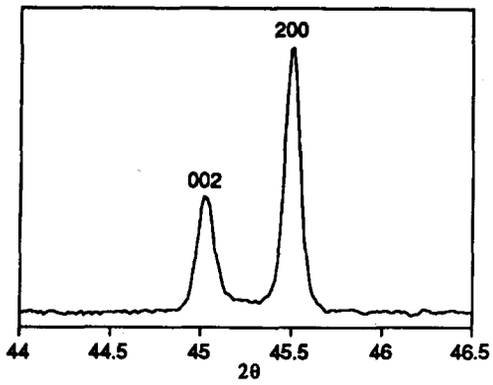

Fig. 1. 002 and 200 X-ray diffraction lines of the $BaTiO_3$ powder used for the sample preparation.

channels during one hour. All the lines of the diagram were fitted.

- The cell parameters' refinement has been carried out with the CELREF Software.
- The mean apparent crystallite size and the mean apparent amount of crystalline lattice distortion have been performed according to the Williamson and Hall[12] method. For this, the half widths (F.W.H.M.) of the 111 and 222 diffraction lines have been determined. They were corrected from the instrumental broadening by considering a Lorentzian approximation of the line profiles. The instrumental broadening approximation for the 111 and 222 lines were the half widths of the two corresponding lines of a well crystallized $BaTiO_3$ previously used as a broadening reference.[1]
- The diffracted intensity profile around the 002 and 200 lines was previously considered for the determination of both the distribution of the cell parameters[5] and the size of the 90° ferroelectric domains.[1,10,11] In the present study, only the two intensity maxima and the minimum of the diffracted intensity between the peaks have been carefully measured.

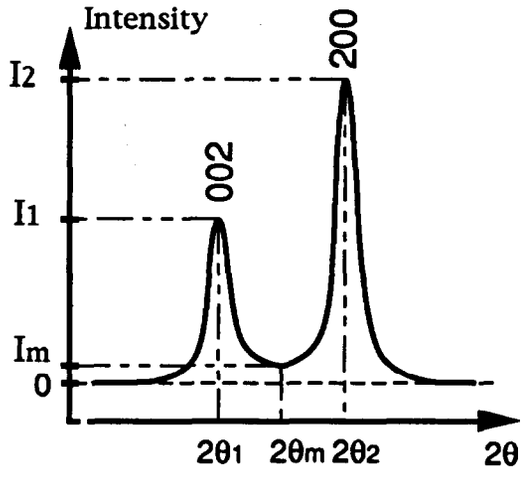

Fig. 2. Characterization by a relative number R of the diffracted intensity between the 002-200 lines.

From these intensities, the R ratios have been calculated in order to characterize the relative intensity between the two lines by a number.

$$R = \frac{(I_m)}{1/2(I_1 + I_2)_{sample}} \Big/ \left(\frac{(I_m)}{1/2(I_1 + I_2)}\right)_{powder}$$

These numbers were normalized by using the corresponding intensities of the initial powder diagram as a reference (Fig. 2).

Results

1 Evolution of the diffracted intensity profile around the 002-200 lines

The 002-200 line profiles obtained with the samples of each of the two sets display the same evolution. Some profiles of various samples prepared with PVB binder are presented in Fig. 3: the diffracted intensity between the two peaks increases with increasing forming pressure.

This first observation of the profiles evolution is numerically shown with the evolution of the R ratio. Figure 4 illustrates the evolution of R as a function of the forming pressure for the two sets of samples. The evolution of R is almost linear with the pressure and on the same straight line whatever the nature of the binder. The binder has no significant influence on the modifications of the line profiles.

Moreover, intensity appears on the two external sides of the line profiles. The two observed modifications are evident in Fig. 5 which presents the superposition of two 002-200 line profiles corresponding to the initial powder and a sample after pressing at 1000 MPa, respectively.

2 Evolution of the cell parameters

The results are presented in Fig. 6. The a parameter does not seem to present any variation whereas the c parameter is slightly decreasing with the forming pressure. The resulting c/a ratio shows a diminution of the cell tetragonality. This is the typical behaviour of a $BaTiO_3$ single crystal under hydrostatic pressure.[13] That means, from a macroscopic point of view, that the uniaxial pressing induces on the powder the same structural modifications as does hydrostatic pressing. This is due to the reaction forces of the die during the pressing and to the fact that the zones of contact between grains are not necessarily oriented perpendicularly to the pressing direction.

3 Evolution of the broadening of the 111 and 222 lines

The 111 line of $BaTiO_3$ and its harmonics are not affected by the tetragonal deformation of the

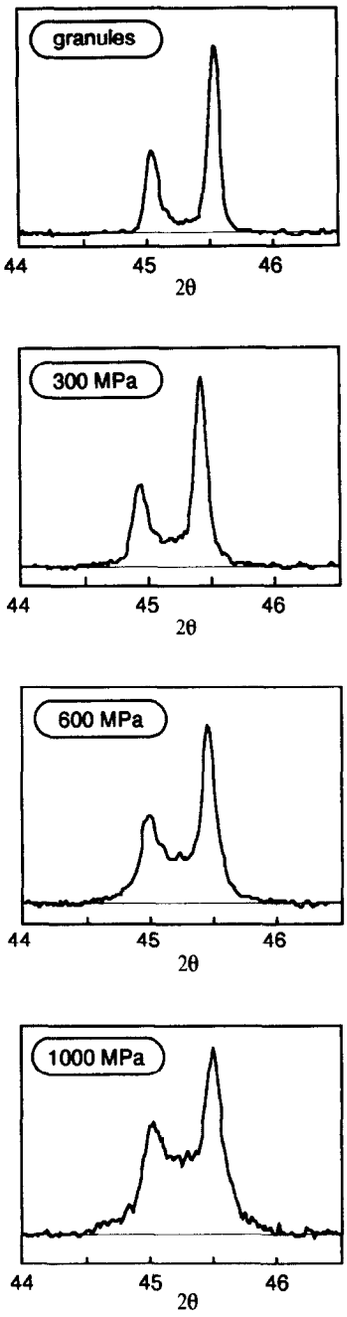

Fig. 3. 002-200 line profiles recorded on granules and discs formed at different pressures (samples prepared with PVB binder).

perovskite structure. Thus, 111 and 222 are the only true single lines of the $BaTiO_3$ diagram at room temperature. These lines were used to study the broadening involved by the pressing.

In Fig. 7, the widths of the 111 and 222 lines — corrected from the instrumental broadening — are reported as a function of the forming pressure. The higher the forming pressure, the broader the lines. Moreover, the broadening of the 222 line increases more rapidly than that of the 111 line. This is thought to be attributed to the formation of a kind of lattice distortions in the material.

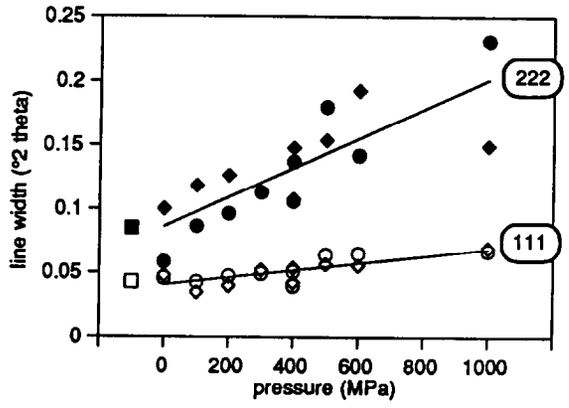

Fig. 7. Evolution of the 111 and 222 line widths with the forming pressure: □■ initial powder; ◇ ◆ samples prepared with PVB binder; ○● samples prepared with paraffin binder.

The Williamson and Hall method has been used to go further with this observation. In this representation, the harmonic lines describe a straight line which the origin ordinate corresponds to the size effect broadening and which the slope is due to the lattice distortion effect broadening. The origin ordinate and slope of each Williamson and Hall straight line are presented in Figs 8 (a) and (b) respectively. The origin ordinate does not exhibit any significant variation, whereas the slope increases with the forming pressure. Therefore, the modifications of the structure involved by the forming are seen as an increase in the lattice defects along the [111] axis without any variation of the size of the coherence domains.

Discussion and Further Results

1 Diffraction line profiles and organization of the material into ferroelectric domains

At room temperature, the $BaTiO_3$ grains are usually divided into ferroelectric domains which size is commonly correlated to the grain size.[14] This division allows a minimization of the overall deformation and polarisation induced during the paraelectric to ferroelectric transition.

The division into ferroelectric domains has an influence on the X-ray diffraction diagram of $BaTiO_3$ powders.[8,9] In particular, it has been shown that the size of the ferroelectric domains is partly responsible for the broadening of the line profiles:

— The subdivision of the $BaTiO_3$ crystallites into domains at 90° induces a broadening of the 002-200 lines related to the ferroelectric domain size. Moreover, decreasing the domain size increases a particular contribution to the diffracted intensity between these two lines. A model of the 002-200 line profile in relation to the ferroelectric domain size has been proposed.[1,10,11] Figure 9 shows the line profiles obtained with a rough model of a single crystalline grain containing two 90° domains for two different domain sizes.[11] From this figure, the reduction of the domain

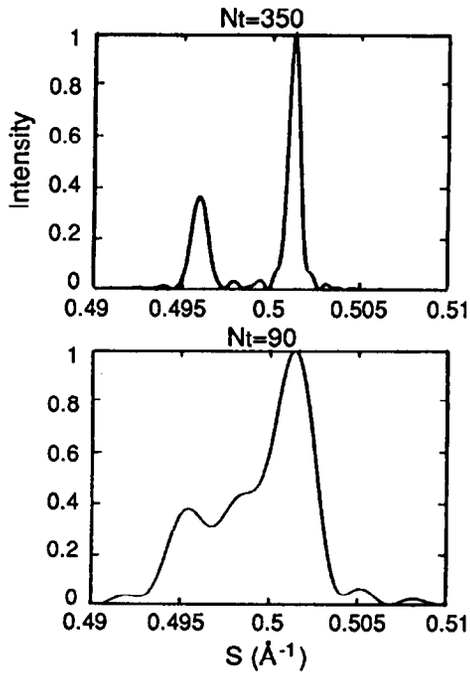

Fig. 9. 002-200 line profile performed with a two 90° domains model for the ferroelectric grain: Nt is the number of 002 and 200 planes in the considered direction.[11]

size involves an increase in the intensity of the middle zone and of the external sides of the line profiles.

— On the contrary, the subdivision of the crystallites into ferroelectric domains does not involve any size effect broadening for lines such as 111 and 222. The division into domains also involves a broadening of these lines but now due to a lattice distortion effect. In fact, along the [111] axes, the lattice periodicity is almost completely preserved from one domain to another. Thus, the diminution of the domain size without any evolution of the grain size involves an increase in the lattice defects content along the [111] axis. Such a modification of the structure should induce a very particular evolution of the Williamson and Hall straight lines built with the 111 and 222 lines: the origin ordinate would be constant while the slope would increase.

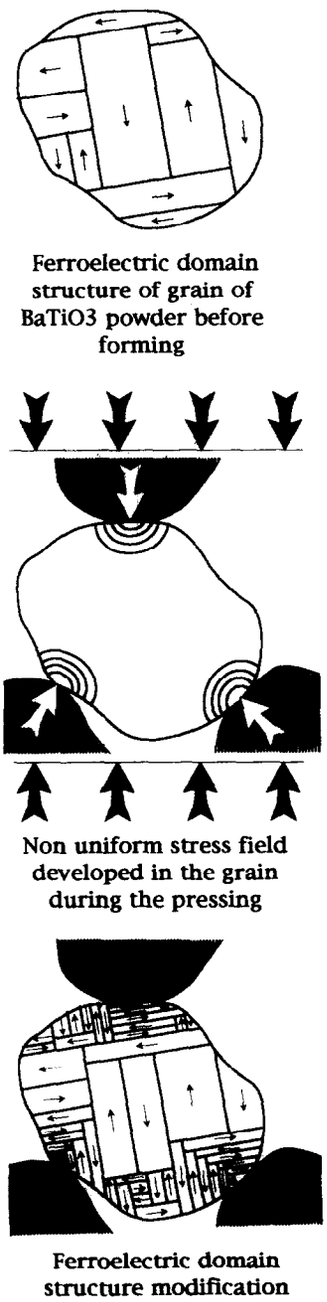

Fig. 10. Proposition for a mechanism of ferroelectric domains fragmentation during the pressing.

2 Influence of the forming pressure on the ferroelectric domains organization of the grains of powder

The Williamson and Hall analysis of the present study has shown that the increase in the forming pressure involves an increase in the apparent lattice defects content while the apparent size of the coherence domains does not vary. This is the expected evolution of the 111 and 222 line profiles in the case of a reduction of ferroelectric domain size. Furthermore, the evolution of the 002-200 line profiles, as a function of the forming pressure, is very similar to that observed with the model of a two domains grain. This is evident by the comparison of Figs 5 and 9.

These observations allow us to interpret the line profile modifications as a reduction of the domain size induced by the pressing of the grains. Figure 10 proposes a diagrammatic mechanism of domain fragmentation. During forming, the grains of the powder develop small zones of contact through which the stress is transmitted. Therefore, the non-uniform stress field developed inside each grain involves local deformations. Since the material plasticity is low, the domain reorganization favours the deformation. These rearrangements are more efficient when increasing the number of domains, thus when the domain size is reduced. The fragmentation into ferroelectric domains allows the minimization of the mechanical energy of the material during forming. A similar mechanism has been proposed by Hennings[15] to explain the grain size dependency on the domain size in fine grained $BaTiO_3$ ceramics.

Nevertheless, this proposition of interpretation is not sufficient to account for the fact that the structural modifications are observed after the forming of the samples. Thus, this mechanism is only valid if the modifications of the domain structure involved during pressing are totally or partially kept after the pressure relaxation.

3 Macroscopic evidence of the pressing influence on the ferroelectric domains

In order to confirm this domain fragmentation, the behaviour of the domain structure of a $BaTiO_3$ single crystal under local compression has been studied. The domain walls of a polished crystal were observed with an optical microscope. Figure 11 shows the special device achieved for studying the local compression of the crystal. A metallic awl is kept in contact with the crystal and applies a compressing force adjusted with a

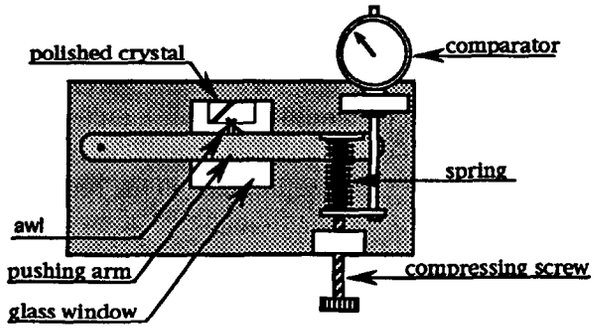

Fig. 11. Diagram of the special device realized for studying the influence of the local compression on the ferroelectric domains of $BaTiO_3$ single crystals.

spring. The compression of the spring is realized with a screw and controlled with a comparator. The calibration of the spring allows the calculation of the force applied on the crystal. This device was placed under an optical microscope to follow the evolution of the domain structure under local pressing.

Figure 12 displays the photographs taken with the microscope during a cycle of increase and decrease in the compressive force. It shows that the pressing of the crystal involves an increase in the density of domain walls around the awl; the higher the force, the broader the zone of high wall density.

Furthermore, the comparison of the pictures relative to the same stress states shows that the domain wall density is not identical depending on whether the pressure is increasing of decreasing. The structure involved under a 12 N force is almost entirely kept right down to a 4 N force. Thus, there is an hysteresis relation between the local pressure and the ferroelectric domain structure. This is in all likelihood due to the ferroelastic properties of $BaTiO_3$. This hysteresis is shown with the curve of Fig. 12 which presents a visual estimation of quantity of domain walls as a function of the force applied on the crystal.

So, a structure generated at high pressure is largely preserved with a rather low residual stress. This might explain the fact that the modifications appearing during the pressing of the $BaTiO_3$ powders are observed after the forming. These last experiments tend to confirm the hypothesis of a fragmentation of the ferroelectric domains during the pressing of the powder.

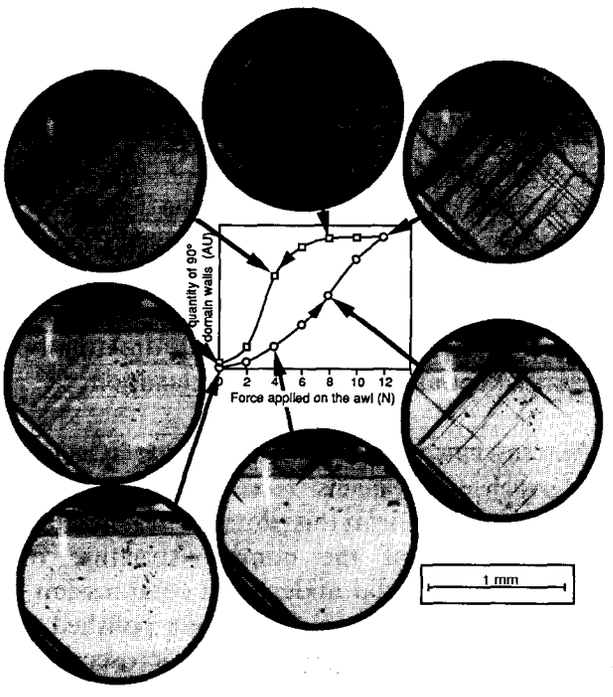

Fig. 12. Optical microscopy photographs of a $BaTiO_3$ single crystal during increase and decrease in the local applied pressure; visual estimation of the quantity of new domain walls as a function of the pressure.

Conclusion

This study has shown that the modifications of the line profiles of barium titanate powders involved during the forming of pellets are essentially due to the pressure applied for the die forming. The nature of the binder, which was suspected to have some influence on this phenomenon, seems to have no noticeable effect. The different results obtained with the X-ray diffraction analysis let us think that a reduction of the ferroelectric domain size inside the material is responsible for these line profile modifications. The mechanism of domain fragmentation proposed is supported by the observation of the domain structure of a $BaTiO_3$ single crystal under local compression. Moreover, this last experiment shows that the modifications involved during the forming may be preserved after the pressure relaxation.

The present results are a new illustration of the influence of the domain structure of barium titanate powders on the X-ray diffraction line profiles. Moreover, this study points out the fact that the granulometric characteristics of the powder are not sufficient to define the domain structure of the grains, the mechanical history of the material has also to be considered.

Abstract

The citric resin method is used to prepare stoichiometric, homogeneous and fine barium titanate powders. The elaboration process is described in detail. Powders are characterized by several methods such as R-ray diffraction, scanning and transmission electron microscopy, thermogravimetric measurements and infra-red absorption and X-photoelectron spectroscopies. Residual carbon content is quantified by nuclear technics and Rosemount method, Raw powders contain small quantities of barium carbonate and residual carbon.

1 Introduction

Today's leading trend in the electronic ceramic industry is to develop component miniaturization. The application of multilayer capacitors implies an increase of the volume efficiency C_v which may be obtained by:

(i) an increase of the relative permittivity ϵ': it may be obtained by grain size control: the dielectric properties are greatly influenced by the grain size; Caboche *et al.*[1] showed that a maximum of ϵ' is observed at room temperature for ceramics having a grain size of about 0·8 μm. The manufacture of such ceramics needs the use of fine powders.
(ii) a decrease of the thickness of the dielectric layers; the production of thin layers again needs fine barium titanate powders.

A wet chemical route to prepare fine and homogeneous powders is interesting compared to conventional solid state reaction processing. In this work, $BaTiO_3$ powders were elaborated by the thermal decomposition of an organic resin produced from a mixed citrate obtained by a method previously described.[2,3] This chemical route allows one to control the Ba/Ti = 1 ratio and the powder morphology and to fix the aggregate size. The Ba/Ti ratio is an important parameter which may dramatically influence microstructural development in high-purity $BaTiO_3$. An excess of BaO involves the formation of Ba_2TiO_4 which inhibits grain growth during sintering and an excess of TiO_2 leads to the formation of an eutectic melt which affects the sintering behaviour because of liquid phase formation at grain boundaries.[4–7]

Different characteristics such as structure, microstructure and residual carbon content must be precise and have been investigated by several methods: transmission electron microscopy (TEM), scanning electron microscopy (SEM), X-ray diffraction (XRD), thermogravimetric analysis (TGA), infra-red (IR) and X-ray photoelectron (XPS) spectroscopies, nuclear analyses, etc.

2 Experimental Procedure

$BaTiO_3$ powders were obtained from a citric resin method, described in previous papers.[2,3] The mixed citrate $BaTi(C_6H_6O_7)_3,6H_2O$ was first prepared, then dissolved in a citric acid, ethylene glycol and water mixture so that the R = $BaTiO_3$ mass/solution mass ratio was 1%. This solution was calcined at 700°C in static air and $BaTiO_3$ powders were produced after 2 h.

The deagglomeration step was performed in two steps:

(i) first the powder was roughly deagglomerated by attrition: the powder was mixed with ZrO_2 balls in isopropanol in the 1/3 balls, 1/3 isopropanol and 1/3 solid phase ratio and shaken for 12 h.
(ii) the powder was then deagglomerated by ultrasonic dispersion. This step was especially studied. Several factors were investigated, for example sonication time (15–30 min), volume of the suspension (20–50 ml) for a solid weight fraction of 1 g. Optimal condi-

tions were found to be 30 min ultrasonication (100 W power) with 30 ml isopropanol per gram of solid phase. After sedimentation, the suspension was dried in a rotovapor and calcined at 700°C for 4 h before yielding raw $BaTiO_3$ powders.

X-Ray diffraction experiments were performed on a Philips PW 1729 diffractometer with the CuK_α wavelength, at room temperature.

Thermogravimetric measurements were made with a Setaram thermobalance, under a flowing oxygen atmosphere. Approximately 100 mg of powder were accurately weighed in a platinum crucible. The temperature was raised from room temperature up to 1000°C at 10°C min^{-1} and then from 1000 to 1400°C at 5°C min^{-1}.

FT-IR absorption spectra were recorded with a Brucker IFS 113+88 interferometer between 4000 and 400 cm^{-1} at room temperature on a sample containing 2 mg of $BaTiO_3$ dispersed in 200 mg of KBr and pressed into pellets.

Carbon analysis: the carbon concentration was determined by two methods:

(i) the Rosemount carbon analysis consisted of heating a weighted sample by flowing O_2 up to 1800°C and analysing the CO_2 evolved with an infra-red detector. This technique gives the volumic carbon content but is not precise enough at ppm levels.

(ii) the $^{12}C(d,p)^{13}C$ nuclear technique using deuterons from the C.E.R.I.'s[1] van de Graaff accelerator. The method has been described in different articles.[8–11] The measurements were performed at 950 keV deuteron energy in a UHV chamber under a vacuum of about 10^{-9} mbar obtained with a cryogenic pumping system on pellet-shaped samples of 4 mm thickness and 13 mm diameter, isostatically pressed at 250 MPa. The detector was a PIPS silicon diode with 100 mm^2 active surface protected by an aluminium foil of 10 μm thickness, situated 64 mm from the sample position with a $\theta = 150°$ detection angle. The beam current was about 10 nA and the counting time was about 2000 s. A theoretical proton spectrum of a material containing C in the bulk with a C-rich surface layer is given in Fig. 1. It can be seen that the shape of the peak gives information about the C content in the surface layer and in the bulk. In the experimental conditions used, taking account of the differential cross-section[12] and the density of the compacted material (50% of the theoretical density of $BaTiO_3$), the surface layer may be estimated about 0·7 μm and the maximal penetration depth about 1·7 μm. This technique is sensitive down to ppm levels.

[1]C.E.R.I. Centre d'Etude sur les Radiations Ionisantes, CNRS Orléans.

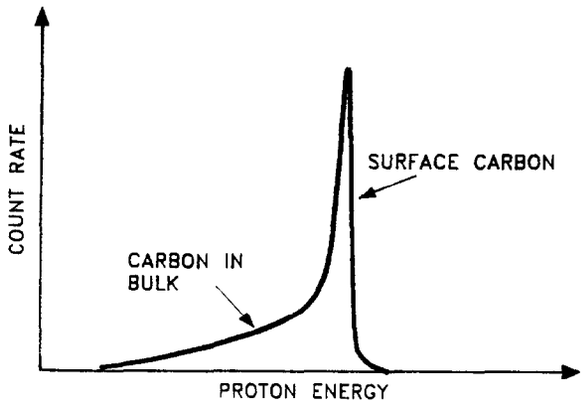

Fig. 1. A theoretical proton spectrum of material containing C with a C-rich surface layer.

X-Ray photoelectron spectroscopy (XPS) analyses were made with an Escalab MK2 of Vacuum Generator system spectrometer using Mg K_α line. The measurements were performed under a vacuum of about 10^{-9} mbar. Samples were obtained by spraying citric precursor on a silica substrate and firing at 700°C. The signal curves were fitted using Gaussian peaks summation and baseline subtraction. Charge compensation was performed using the C_{1s} peak at 284·6 eV.

The SEM images were obtained with a Cambridge stereoscan 100 microscope on samples previously metallized with platinum.

The TEM images were obtained with a JEOL 100 CX microscope on microtomic sections.

3 Results and Discussion

The microstructure is a very important factor which must be controlled during the elaboration of the powder. Figure 2 shows the different agglomeration states of the powder using TEM and SEM techniques. The sample microstructure can be described by (i) microcrystallites of 25–30 nm size (Fig. 2(a)), (ii) crystallites associated into 150 nm spheroid aggregates (Fig. 2(b)) and (iii) aggregates linked in larger agglomerates (platelets about 60 μm in size) (Fig. 2(c)).

Several characterisation methods were used such as XRD, IR absorption and TGA to detect the presence of impurities such as $BaCO_3$. By XRD only one crystalline phase was observed at room temperature, cubic $BaTiO_3$ with cell parameter $a = 4·007$ Å instead of a tetragonal phase as predicted from the phase diagram.[13] This phe-

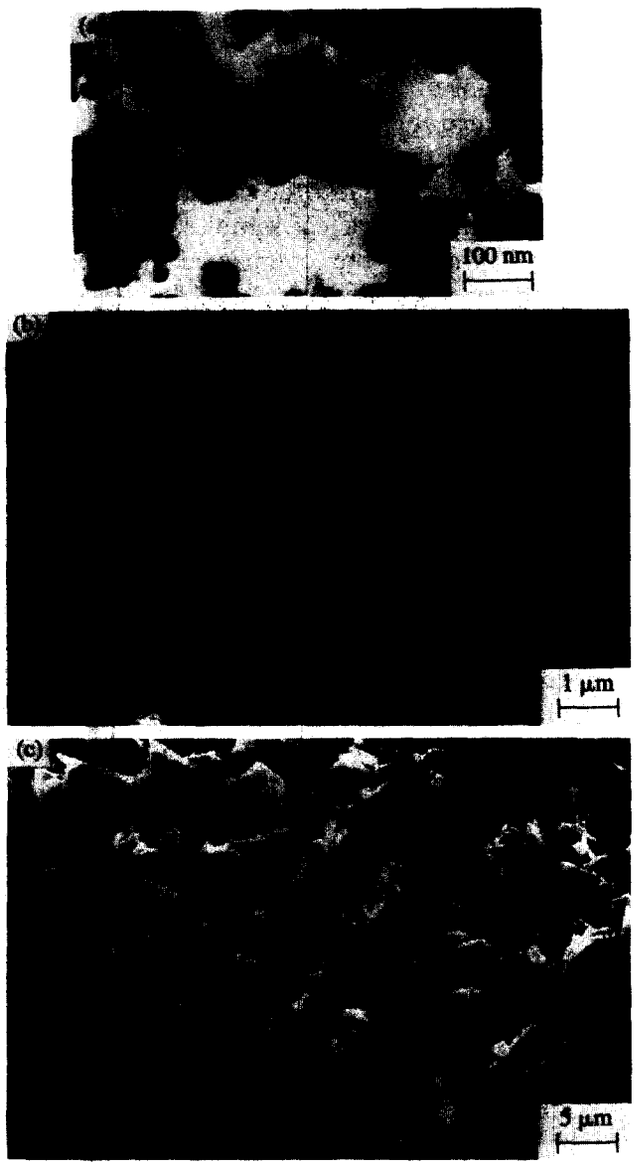

Fig. 2. Microstructure of $BaTiO_3$ powders (a) TEM of ultra-thin sections, (b) SEM of deagglomerated powders, (c) SEM of non deagglomerated powders.

nomenon was already described by Caboche *et al.*[1] They have shown that barium titanate crystallizes at room temperature either in a cubic or a tetragonal phase depending, as well as on cell parameter(s),

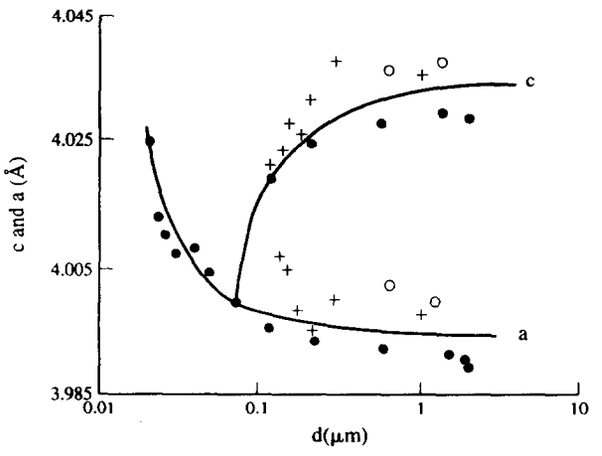

Fig. 3. Variation of cell parameters of fine $BaTiO_3$ powders given by Caboche *et al.*.[7]

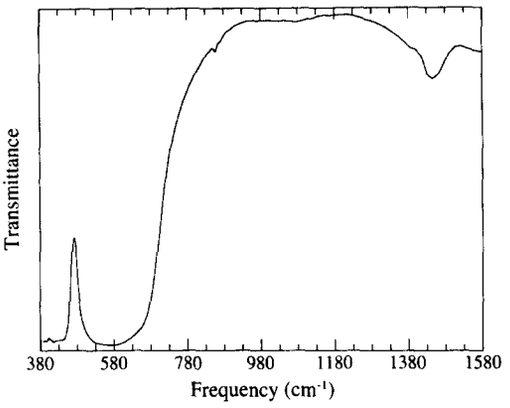

Fig. 4. IR absorption spectra of raw $BaTiO_3$ powders.

on the elementary single crystalline grain size. The cubic cell parameter decreases with this grain size up to a limit of 0·07 μm. Above this limit the crystal cell becomes tetragonal as represented in Fig. 3. Microscopic studies (Fig. 2(a)) have shown that the single crystalline grain size was about 30 nm. According to Caboche *et al.*[1] (see Fig. 3), for such a grain size the powder crystallises in a cubic phase with a cell parameter of about 4·008 Å. Thus, our results are in good agreement with those of Caboche.

The IR absorption spectra recorded at room temperature are presented in Fig. 4 in the 2200–400 cm^{-1} range. The two main absorption bands are characteristic of the vibration frequencies of the TiO_6 octahedra. Two other weak absorption bands, at 1430 and 875 cm^{-1}, reveal $BaCO_3$ traces.

These results are in good agreement with those obtained by XPS. The photoelectron peaks of Ba, Ti and O elements were carefully investigated:

(i) the Ti_{2p} line consists of a single narrow Gaussian peak, meaning that titanium was only present in a single chemical state, $BaTiO_3$.

(ii) the study of the 770–800 eV range shows the presence of two barium types (Fig. 5(a)). The two main peaks at 779·5 and 795 eV after calibration of the charge-shifted energy scale can be associated with barium environment in $BaTiO_3$. The third peak at about 785·5 eV can be assigned to barium environment in $BaCO_3$.[14]

(iii) on the oxygen range (Fig. 5(b)) the first peak at 526·5 eV corresponds to the titanate environment and the second one at 527·5 eV may be due to the carbonate.[14] The XPS results confirm the existence of $BaCO_3$ traces.

More quantitative methods were thus necessary to give the residual carbon content in the form of barium carbonate or other carbonaceous species

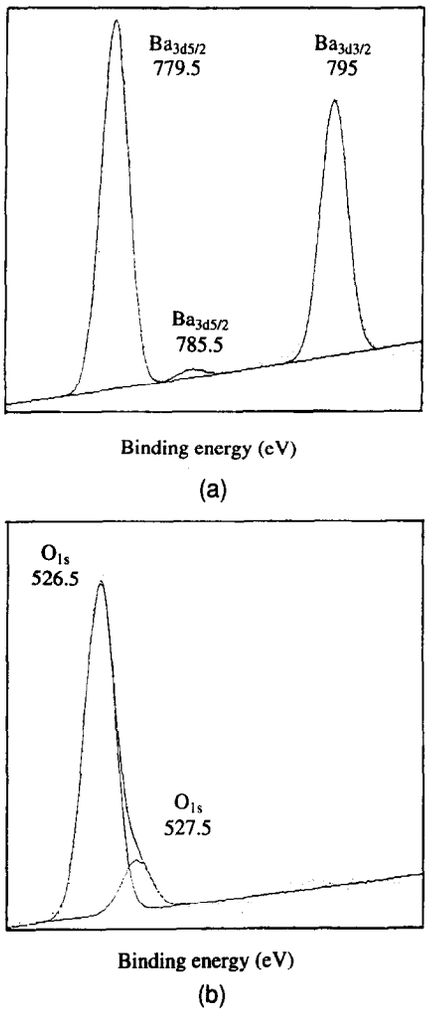

Fig. 5. XPS spectra from raw $BaTiO_3$ powders (a) $Ba_{3d5/2}$ and $Ba_{3d3/2}$, (b) O_{1s}.

more precisely. TGA measurements carried out under flowing oxygen atmosphere gave a curve (Fig. 6) with two weight losses, the first one near 80°C resulting from adsorbed water removal and the second one between 400 and 1100°C which can be due to the CO_2 released during $BaCO_3$ decomposition. Demartin *et al.*[15] and Fang *et al.*[16] have shown that the CO_2 comes mostly from the $BaCO_3$ calcination and that its evolution is observed between 600 and 1300°C on the TGA

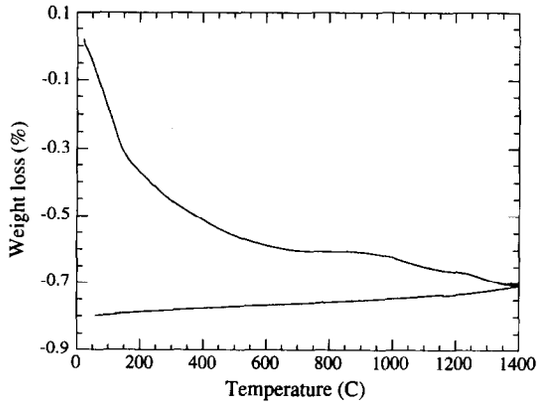

Fig. 6. ATG curve of raw $BaTiO_3$ powders.

curves. In our case the corresponding weight loss was estimated about 0·12%.

The amount of residual carbon in the raw powder determined by the Rosemount method was about 0·25% of the volume.

By nuclear techniques, the carbon content was determined in compacted samples. The surface layer (0·7 μm) of the compacted raw powder exhibits a carbon content of 1·4%. In the volume the C content was estimated at roughly 0·3%.

The results obtained of the volume C content by the two techniques are in very good agreement. The high value of the surface C concentration may be due to the contamination.

If the amount of released CO_2 detected by TGA only originates from the $BaCO_3$ decomposition, we can estimate the $BaCO_3$ concentration at 0·5%. This result is coherent with the XRD results which did not reveal the presence of $BaCO_3$ and the infra-red spectra which displayed two bands of weak intensity assigned to carbonate ions. The carbonate concentration found is low in comparison with those given by different authors for $BaTiO_3$ powders prepared by wet chemical route or hydrothermal synthesis.[14,15,17]

Comparing the results obtained by TGA and carbon content determinations, it can be concluded that the raw powder contains a noticeable residual carbon content in other chemical states than the carbonate one. They could not be found on IR spectra and studies of the XPS C_{1s} peak are now in progress in order to characterize these chemical states.

4 Conclusions

The citric resin method is an interesting way to prepare stoichiometric, homogeneous and fine barium titanate powders. Cubic powders with microcrystallites of 30 nm size were obtained: they contain small quantities of $BaCO_3$ (about 0·5%) which is thermally decomposed between 600 and 1300°C to release CO_2. The total C residual content has been estimated at 00·25–0·30%. Thus a part of the C is in another chemical form than carbonate. Further studies are now in progress to elucidate this point. This synthesis optimization should allow one to obtain dense ceramics with satisfactory bulk capacity.

Abstract

Spinel coatings on steel substrates have been obtained by a thermal spraying process. The projection has been done on cold or hot substrates. A further thermal treatment has been performed on some coatings formed on cold substrates. A good adhesion has been observed only on steels rich in oxidizable elements (Z38 CDV5). These coatings have been characterized and tested in a foundry. Adhesion tests have been done by the pulling method and by indentation. The concentration profiles of the most important elements from the metal/oxide interface to the bulk have been determined by EPMA analysis. This set of results has allowed us to show the importance of the coating microstructure and of the diffusion processes on the metal/ceramic bond strength and of the coating stability in contact to Al/Si melted alloys. Such coatings are then good candidates to be used in a foundry to protect the casting tools, mainly when they are performed on heated surfaces.

1 Introduction

Due to the high chemical inertness of ceramics and to the possibility of connecting them to metals, they are increasingly being used as coatings to protect metals in corrosive environments. Some ceramic coatings can also act as thermal barrier. They can both insulate and protect the metal which can then endure extreme thermal cycling under hostile environments. The requirement that the coating must fulfil is dictated by the functions of the device. Nevertheless, its limitations are not due generally to the coating itself but rather by the adhesion quality which is reflected by the fracture resistance of the metal/ceramic interface. Of course, the strength of the metal–ceramic bond is directly linked to the way of formation of the metal/ceramic bonding and to the nature of the material couples but it is also linked to the presence of active species which influence the thermodynamic properties of the interfacial region. Calculating bond strengths is theoretically possible, but at present, results are not available for complex metal/ceramic interfaces. To optimize the metal/ceramic bonding it is then important to have a complete characterization of the interfacial region and to understand as much as possible the correlations between the atomistic configurations and the macroscopic properties.

In the present work, a melted ceramic oxide (Al_2O_3, MgO 70/30 in wt) has been projected in air, using an oxyacetylene flame wire gun fed by a flexible cord, onto previously sanded chromium/molybdenum steels. The spraying has been done on a cold substrate, or on a cold substrate followed by a thermal treatment, or on a hot substrate. Different tests have been performed to characterize these coatings. The adhesion has been controlled by adherence and indentation tests. The metal/ceramic interface has been characterized by EPMA analysis. Furthermore, the coating behavior in contact with Al/Si melted alloys has been studied because such coatings could be used in foundry to protect the casting tools. The set of data obtained has allowed us to identify the main parameters that govern the adhesion and the properties of the coatings.

2 Materials and Coating Procedures

The substrates considered are chromium and molybdenum steels containing different amounts of oxidizible elements (Table 1). They have been coated by the spinel $MgAl_2O_4$ (Al_2O_3/MgO ≈70/30 in wt). The samples for the adhesion tests

and EPMA analysis were disks of 50 mm diameter and 3 mm thickness. Those for the foundry tests were cylinders of approximately 50 mm thickness and 50 mm diameter, in order to be able to insert them at the bottom of a casting mould (Fig. 1). All the samples were sandblasted immediately before coating. This allows both cleaning of the substrate surface and creation of surface irregularities giving better adhesion of the coating during the projection (mechanical adhesion).

The projections were performed in air with an oxyacetylene thermal spray flame gun (CYBER-JET model) on which was fitted a ceramic supple string 'SFECORD'. The coating material is melted in the flame and then thrown with a high velocity onto the previously cleaned surface of the substrate. During spraying, the samples were maintained by a steel support. The thickness of the coatings was between 0·1 and 0·2 mm, according to the spraying conditions.

The spinel coatings have been performed on XC 38 and Z38 CDV5 steels, which contain different amounts of oxidizible elements. Three types of coatings have been performed:

- — coatings on cold substrates — samples called IS
- — coatings on cold substrates followed by a thermal treatment under a vacuum of $0{\cdot}5 \times 10^{-2}$ Torr at 800°C, for 100 h — samples called IIS.
- — coatings on a substrate heated at a controlled temperature close to 650–700°C — samples called IIIS

For the coatings IIIS, the temperature of the substrate was controlled with a chromel/alumel thermocouple placed in a radial cavity, as shown in Fig. 1. The heating was performed with an enveloping flame and was maintained during the projection. For the smaller samples an assisted cooling was performed up to 300°C, i.e. for 8 min, in order to prevent thermal shocks. The samples for the foundry (Fig. 1) have a higher calorific capacity. Their temperature decreases naturally from 700 to 300°C, in approximately 17 min.

3 Results

Whatever the type of projection, the coatings on the XC 38 steels crumbled after the projection, during the cooling of the sample. The concentration of oxidizible elements is one of the main differences between the XC38 and the Z38 CDV5 steels. These elements seem to be active species during the projection, performed in air. They can lead to the formation of oxides on the metal surface, in an oxidising atmosphere. These oxides can then react with the coating and create chemical bridges between the metal and the ceramic. The beneficial effect caused by such reactions, due both to the dissolution and to the diffusion of the active species near the metal/ceramic interface, are known in the literature.[1,2] McDonald and Eberhart[1] have found that impurities that are highly oxygen-active can make a major contribution to the adhesion at the interface. Characterizations of the coatings performed on the Z38 CDV5 steel have then been done, in order to establish the main parameters responsible of the adhesion and to check the influence of the oxidizible elements.

3.1 Adhesion tests

The coating adherence is often taken as a criterion which allows definition of the best coating conditions.[3] In the following, two adherence testing methods have been used, in order to compare the adhesion resistance of the spinel coatings on the Z38 CDV5 steels.

3.1.1 Pulling out tests

The adhesion resistance is measured with a traction machine, INSTRON model 1185. The pull

Table 2. Pulling out tests

Sample	Pull out strength (N)	Pull out surface (mm^2)	Adherence (MPa)	Observations
IS	2050	41	50·0	Detachment between the coating and the substrate, in the middle of the sample
	2150	138	15·6	Detachment between the coating and the substrate, from a corner
	2250	103	21·8	Detachment between the coating and the substrate, from an edge
IIS	2550	166	15·4	Coating pulling out
	2750	10	275	The pulling out occurs in the coating thickness
	2850	120	23·8	Coating pulling out
IIIS	3400	130	26·2	The pulling out occurs in the coating thickness
	3950	25	158	Detachment between the coating and the substrate from a corner and partial pulling out of the coating
	4750	20	238	Detachment between the coating and the substrate from a corner and partial pulling out of the coating

rate is equal to 0·5 mm/min. The strength leading to the break at the metal/oxide interface allows the adhesion quality to be known. It is a critical value generally called 'adherence' of the ceramic coating. The results reported in Table 2 show that the adherence is higher for the coatings thermally treated and the best results are obtained for the coatings performed on heated metal substrate (coatings IIIS). Nevertheless, a break sometimes occurs in the thickness of the coatings IIIS. This may be due to changes in temperature during the projection, leading to thermal stresses in the ceramic.[4] Indeed, it is difficult to keep exactly the same experimental conditions from one experiment to the other, with our experimental arrangement. An improvement of the thermal treatment conditions with a better control of the temperature of both the substrate and the coating during the projection can then give promising results. Nevertheless, it may be pointed out that the main use of these coating is to protect steel against corrosion. Therefore, the break inside some coatings observed during the tests does not change the corrosion-preventing performances of the ceramic in service conditions.

3.1.2 Vickers indentation tests

Vickers indentation tests have been performed with a micro-durometer Leitz (HPO-250) at the interface zone of the coatings IS and IIIS. Different loads have been applied on the indenter and the results are in agreement with the pulling out tests. Indeed, we have observed that cracks start to appear for an indenter load of 2 kg for the coatings IS and of 10 kg for the coatings IIIS. Figure 2 shows micrographs of indented samples under a load of 5 kg, applied for 15 s. It illustrates clearly the strong dependence of the coating processing conditions on the mechanical properties of the samples. Indeed, the indentation zone is smaller when the coating is performed on a heated surface (coatings IIIS) and a crack, propagating along the metal/oxide interface, is observed only for the coating IS.

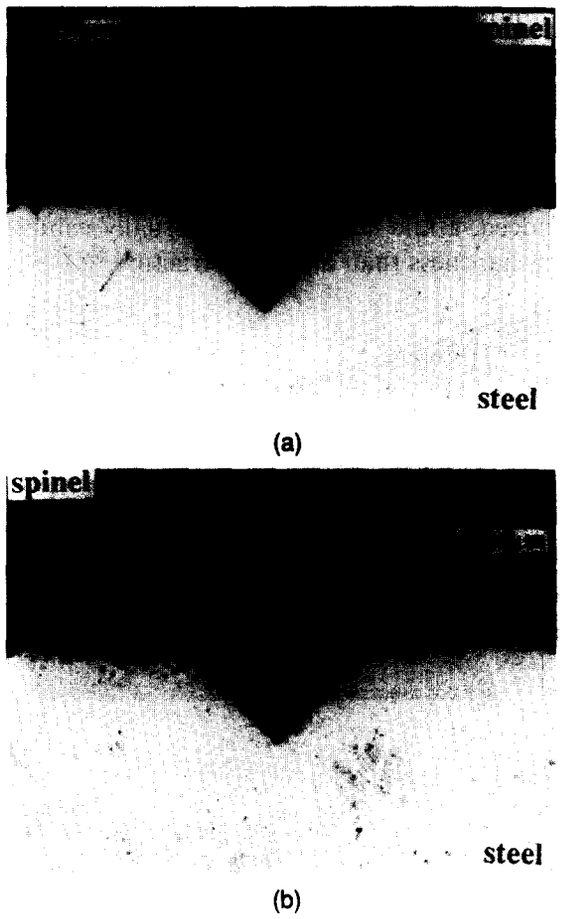

Fig. 2. Spinel coated steel (Z38 CDV5) indented in the interface region (indenter load 5 kg during t = 15 s). (a) Spinel sprayed on an unheated substrate. Note that cracks propagate along the metal/ceramic interface. (b) Spinel sprayed on a heated substrate. Note that the indentation zone is smaller.

3.2 Optical microscopy

Typical cross sections of coatings IS and IIIS on Z38 CDV5 steel are reported in Fig. 3. These micrographs show that the coatings IIIS have a fine microstructure while those performed on an unheated surface (coatings IS) are less dense and microcracks are observed between the particles. Similar observations have been done by Claes and Helgesson[4] who have studied the appearance of alumina droplets sprayed onto cold (20°C) or preheated (600°C) metal substrates. When a droplet hits a cold substrate, it scatters leading to the formation of irregular shape droplets.[4] Indeed, the temperature being too low, the surface tension does not allow them to coalesce and to have a spherical shape. Consequently, they are less mobile and cannot flow into the irregularities of the substrate or of the previous layers. This leads to a porous coating with many interfaces and therefore to a coarse microstructure (Fig. 3(a)). On the contrary, when the droplets hit a preheated substrate they can come together and have time to flow into the irregularities. A more dense coating is then obtained, as shown in Fig. 3(b). It may be pointed out that these microstructural observations are consistent with the indentation tests (Fig. 2). Indeed, a fine microstructure usually exhibits a higher hardness than a coarse structure.[5]

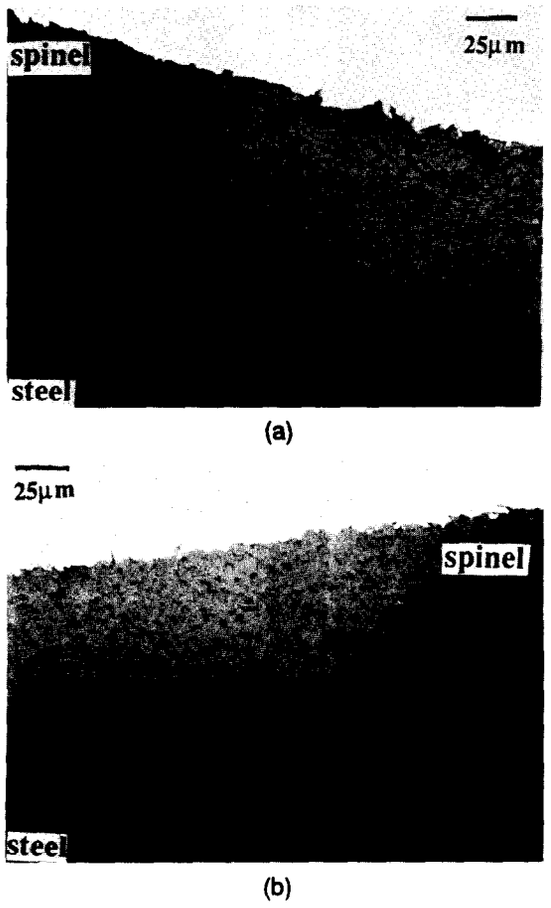

Fig. 3. Cross section micrographs: (a) spinel sprayed on an unheated substrate, (b) spinel sprayed on a heated substrate. Note the perturbation of the metal/oxide interface and the fine microstructure of the coating performed on a heated substrate.

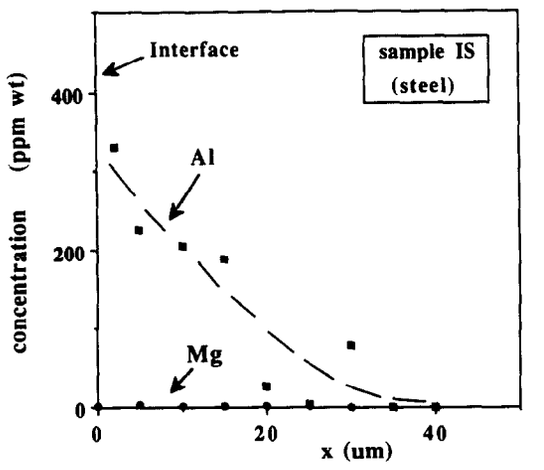
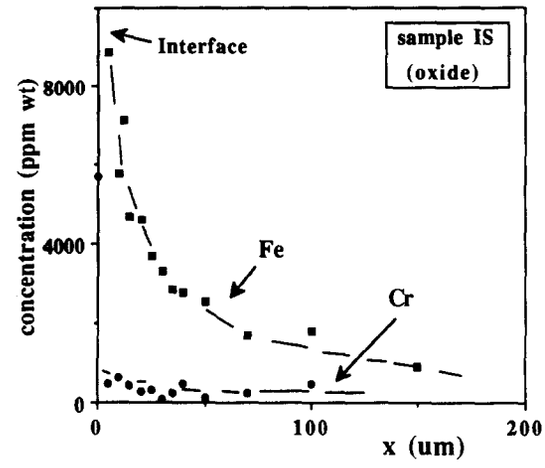


Furthermore, we have observed that the coating IS interface stays planar, whereas at the coating IIIS interface (Fig. 3) perturbations occur in places. Of course, such instabilities have a beneficial effect on the coating adhesion. The initial surface perturbations increase in amplitude when a diffusion process takes place.[6] Consequently, such interface morphologies are consistent with the formation of a 'diffusive coating' when the ceramic is sprayed on heated surfaces.

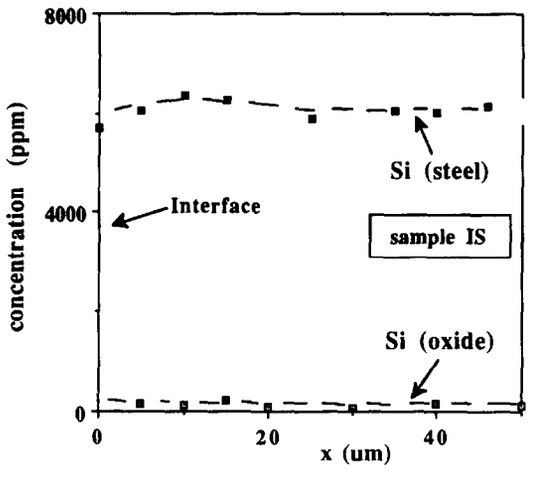


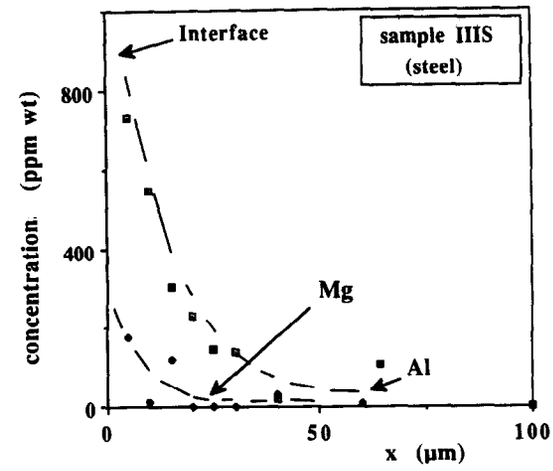
3.3 Electron probe microanalysis

The concentration profiles of the most important elements from the metal/oxide interface to the bulk have been determined by EPMA analysis, in samples IS and IIIS. Typical concentration profiles of Fe, Cr and Si in the oxide and of Al and Mg in the substrate, are reported in Fig. 4. They show clearly the increase of the diffusion zones in the heated coatings. The amount of Fe and Cr close to the interface are nearly the same in samples IS and IIIS. These values seem to be controlled by the solubility limit of these elements in the oxide. The Fe and Cr profiles are very steep in samples IS, whereas they are more extended when the coating is performed on a heated surface (samples IIIS). For silicon, the concentration in the metal seems not to be affected near the interface when the coating is deposited on an unheated substrate and the amount in the oxide is close to the limit of detectability (Fig. 4(a)). In the heated substrate, the silicon concentration increases near the interface both in the metal and in the oxide, due probably to an interfacial reaction between Si and $MgAl_2O_4$ (Fig. 4(b)). For V, Mn and Mo, their amount in the oxide is generally below the limit of detectability.

3.4 Behaviour of the coatings in foundry in contact with an Al/Si melted alloy

The three types of coatings have been studied. The samples (Fig. 1) have been inserted at the bottom of the mould which receives the Al/Si melted alloy, at 700°C. The coating is then subjected to different simultaneous degradations: liquid alloy impact, erosion by the liquid current, thermal shock, thermal stresses and liquid alloy corrosion. The behaviour of the coatings after several casting cycles are described in Table 3. Only the 'diffusive coatings', performed on heated substrate, are very stable. After several casting cycles we have not observed a surface degradation of the ceramic while a scaling is detected, from the first casting cycles, for the coatings performed on unheated substrates. These results are consistent with both the fine microstructure of the coatings IIIS and the strong adherence. Nevertheless, an increase of the quality of the coatings IS is observed after a thermal treat-





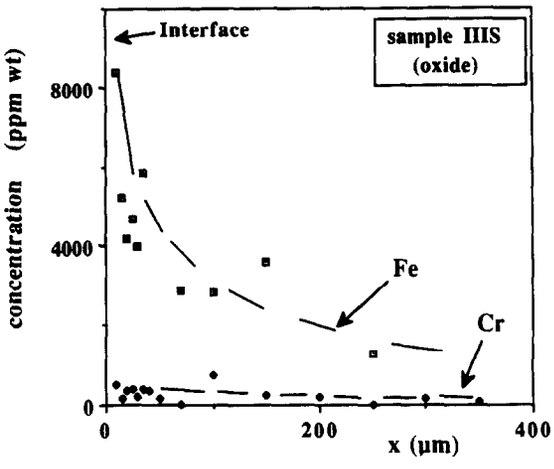


Fig. 4(a). Concentration profiles from the steel/spinel interface of Fe, Cr and Si in the oxide and Al, Mg and Si in the unheated steel.

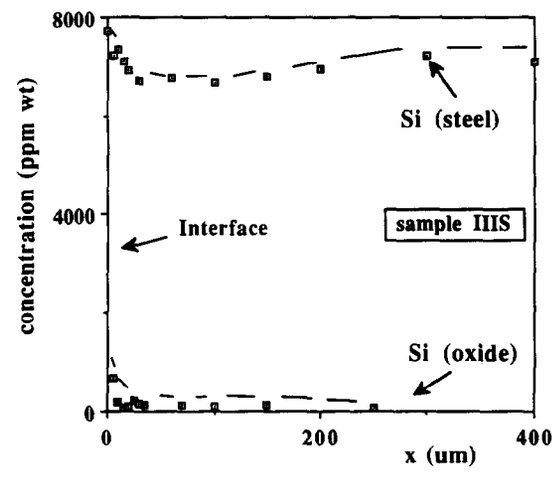

Fig. 4(b). Concentration profiles from the steel/spinel interface of Fe, Cr and Si in the oxide and of Al, Mg and Si in the heated steel.

ment at 700°C (samples IIS). These results show that the degradation of the coating IIS, while continuous, is low (Table 3). An improvement of the coating IS can then be expected by changing the thermal treatment conditions (Section 2).

4 Conclusion

In this work we have first shown the importance of the steel composition on the metal/ceramic bond strength of thermal sprayed coatings. Spinel coatings deposited on XC38 steels crumbled after the projection while spinel coatings on Z38 CDV5 steels are stable. This behaviour has been attributed to the higher amount of oxidizible elements in the Z38 CDV5 steels. Optimization of the properties of the spinel coatings deposited on Z38 CDV5 steel substrates, for use in foundry to protect casting tools against the severe erosion–corrosion conditions encountered when the mould receives the melted alloy, have been performed. The lifetime of the coating deposited on cold substrates increases

Table 3. Coating behaviour in contact with Al/Si melted alloys, after several casting cycles

Spinel coating type	IS	IIS	IIIS
Casting cycles	50	50	730
Observations	Coating scaling from the beginning of the test The interfacial adhesion seems correct	Low and continuous degradation of the coating The interfacial adhesion seems correct	The coating quality widely satisfied the purpose of the test
Coating quality conclusions	Medium	Medium	Satisfactory

when it has been thermally treated at 700°C after deposition, while more promising results have been obtained with coating deposited on heated substrates. Adherence tests, EPMA analysis and microscopical observations have identified the main parameters responsible of the protective properties of the coatings. The fine microstructure, which increases the toughness against the erosion by the melted alloy impact, and the strong metal/ceramic bond contribute to the protective performances of the coatings performed on heated substrates. These properties are in part due to the diffusion processes at the metal/oxide interface as well as the surface instabilities which have a beneficial effect on coating adherence.

Creep Crack Growth in Alumina with a Glassy Phase

G. Martin, T. Fett & D. Munz

Forschungszentrum Karlsruhe, Institut für Materialforschung II and Universität Karlsruhe, Institut für Zuverlässigkeit und Schadenskunde im Maschinenbau, Karlsruhe, Germany

(Received 22 September 1994; revised version received 19 January 1995; accepted 31 January 1995)

Abstract

Creep-induced crack growth can be described with the C-integral as the relevant load parameter. Several possibilities of evaluating the C*-integral in single specimen tests are discussed, and the constant load and the constant loading-rate are applied to an alumina ceramic containing a glassy phase. The crack-growth rate as a function of the C*-integral is described by a power-law relation with an exponent which agrees very well with the theoretical value.*

1 Introduction

Fracture at elevated temperatures may be caused by subcritical crack propagation, which starts from existing flaws or from creep-induced damage caused by the formation and coalescence of pores. Whereas in the range of subcritical crack growth, which can be described by linear–elastic fracture mechanics, the stress intensity factor is the stress variable at the crack, this is the C^*-integral in the range of noticeable creep.[1] Creep-induced crack growth has very often been studied for metals, but investigations into ceramic materials are sparse.[2–4] It is the aim of this investigation to determine the crack-growth rates as a function of the C^*-integral for macroscopic cracks.

The C^*-integral — proposed by Landes and Begley[1] — is a path-independent energy-rate line integral. In the two-dimensional case (see Fig. 1) it is defined as

$$C^* = \int_\Gamma W^* \mathrm{d}y - T_i \frac{\partial v_i}{\partial x} ds \tag{1}$$

$$W^* = \int_0^{\epsilon_{ij}} \sigma_{ij} \mathrm{d}\epsilon_{ij} \tag{2}$$

where W^* is the strain-energy density rate, T_i is the traction vector, v_i is the displacement vector, and ds is a line length increment along the contour Γ.

The C^*-integral governs the stresses and strains in front of a crack tip. A premise for the applicability of the C^*-integral as a loading parameter is the occurrence of secondary creep, which may be described by a Norton power law

$$\dot{\epsilon}_s = D\,\sigma^n \tag{3}$$

Under this condition, an HRR-stress field occurs ahead of the crack tip.[5,6] The stresses and strain rates are given by

$$\sigma_{ij} = \left(\frac{C^*}{I_n D r}\right)^{\frac{1}{n+1}} \tilde{\sigma}_{ij}(\theta) \tag{4}$$

$$\dot{\epsilon}_{ij} = \left(\frac{C^*}{I_n D r}\right)^{\frac{n}{n+1}} \tilde{\sigma}_{ij}(\theta) \tag{5}$$

where $\dot{\epsilon}$ is the strain rate and $I_n(n)$ and $\tilde{\sigma}_{ij}(\theta)$ are the dimensionless functions, which can be taken from Ref. 6.

Under creep conditions, the application of a load instantly yields an elastic strain reaction. This elastic strain is superposed by creep strains. In the vicinity of the crack tip eqn (5) is immediately valid, but under non-steady-state creep conditions the parameter C^* has to be replaced by the time-dependent parameter $C(t)$.[7]

For very short times after load application, the stress intensity factor K is the relevant loading parameter, which describes the stresses at the crack tip

$$\sigma_{ij} = \left[\frac{\alpha K_I^2}{I_n D r (n+1)\, tE'}\right]^{\frac{1}{n+1}} \tilde{\sigma}_{ij}(\theta) \tag{6}$$

where $E' = E/(1-\nu^2)$ (E = Young's modulus, ν = Poisson's ratio). The numerical factor α is given in Ref. 7 as $\alpha \simeq 1$. With increasing size of the creep zone, the stress field is firstly governed by $C(t)$ and tends asymptotically to the C^*-controlled state. Since

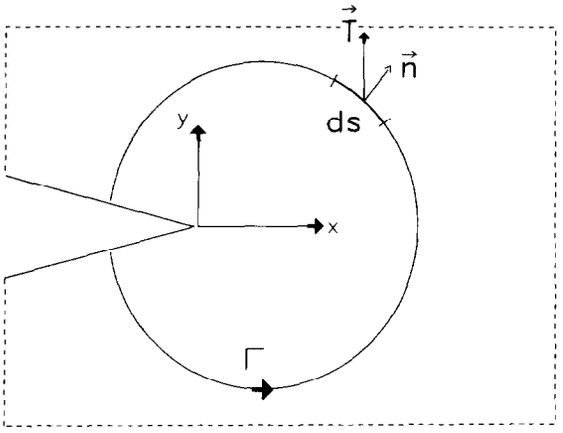

Fig. 1. Definition of the C^*-integral.

$$C(t) \to \frac{\alpha K_1^2}{(n+1)\, t\, E'} \text{ for } t \to 0 \tag{7}$$

and

$$C(t) \to C^* \text{ for } t \to \infty \tag{8}$$

Riedel[7] proposed the interpolation formula:

$$C(t) = \left(1 + \frac{t_1}{t}\right) C^* \tag{9}$$

for the region $t \simeq t_1$ with the characteristic time

$$t_1 = \frac{K_1^2}{(n+1)\, E' C^*} \tag{10}$$

In cases where primary creep dominates an additional integral quantity denoted C_h^* has to be applied. In this investigation we restrict our considerations to C^*.

2 The Experimental Determination of C^*

C^* can be expressed by the power difference of two identically loaded structures containing cracks of depths a and $a + da$, respectively, i.e.

$$C^* = -\frac{1}{B}\frac{dU^*}{da}, \quad U^* = \int_0^{\dot\delta} F\, d\dot\delta \tag{11}$$

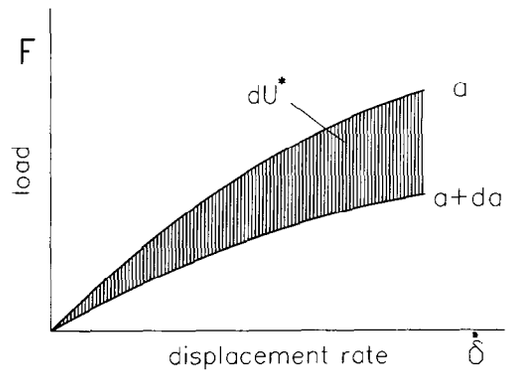

Fig. 2. Increment of energy rate dU^* for two cracks with crack lengths a and $a + da$.

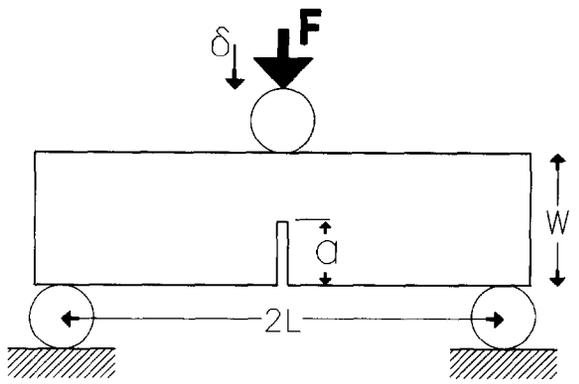

Fig. 3. Geometrical and loading quantities.

(B = specimen thickness). This relationship offers the possibility to determine C^* experimentally. The quantities entering eqn (11) are explained by Fig. 2. Equation (11) is the basis for a number of procedures for determination of C^*. The experimental data necessary for the evaluation of eqn (11) are the force F, the displacement rates $\dot\delta$ of the load application points, and the crack length a.

2.1 Single-specimen evaluation

The application of C^* as the crack-tip parameter was proposed by Landes and Begley[1] in analogy to the J-integral, the loading parameter in case of plastic material behaviour. J-integral solutions are available for numerous types of specimen and loading. In the EPRI-handbook[8] a number of FE-solutions are reported. Due to the analogy between Norton-like creep and strain-hardening plasticity,[9] the data of the EPRI-handbook can be used also for the computation of C^*. By introducing the net stress

$$\sigma_{\text{net}} = \frac{F}{B(W-a)} \tag{12}$$

Riedel[7] proposed the simple relation

$$C^* = aD\sigma_{\text{net}}^{n+1}\, g_1 \tag{13}$$

It should be noted that eqn (13) is only valid if the creep behaviour is correctly described by a Norton-relation. The geometric function $g_1(a/W,n)$ depends on the stress state and differs for plane-stress and plane-strain conditions. A second possibility to determine C^* — also proposed by Riedel[7] — is based on the measurement of the displacement rate at the load-application points

$$C^* = \sigma_{\text{net}}\, \dot\delta\, g_2 \tag{14}$$

with g_2 dependent on a/W and n. Based on the formulation eqn (11), Webster[10] derived

$$C^* = \frac{F^{n+1}}{B(n+1)}\frac{dC_n}{da} \tag{15}$$

with the creep-compliance

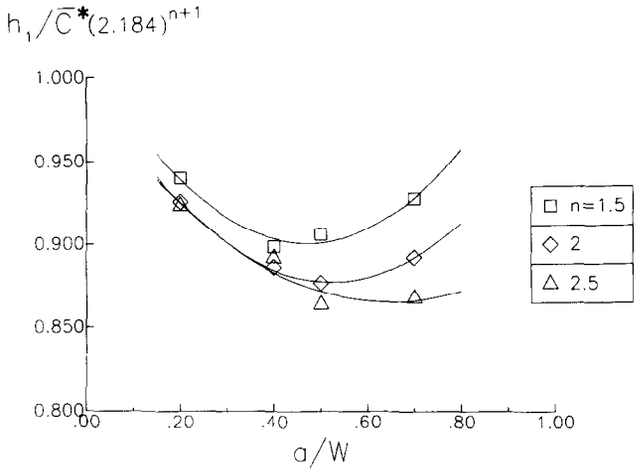

Fig. 4. Ratio of geometric functions from Walz[13] and the EPRI-handbook.[8]

$$C_n = \frac{\dot{\delta}}{F^n} \tag{16}$$

For a static test it results

$$C^* = \frac{F\dot{\delta}}{BW}\left[\frac{W}{n+1}\,\frac{1}{\dot{\delta}}\,\frac{d\dot{\delta}}{da}\right] \tag{17}$$

and in the dynamic loading case with constant displacement rates at the load application points

$$C^* = \frac{F\dot{\delta}}{BW}\left[-\frac{n}{n+1}\,\frac{W}{F}\,\frac{dF}{da}\right] \tag{18}$$

Based on the integral formulation of C^*, Harper and Ellison[11] derived for the static test (F = constant)

$$U^* = \frac{1}{n+1} DL \left(\frac{F}{m_{pl}BW}\right)^n F \tag{19}$$

and in case of constant displacement rates

$$U^* = \frac{n}{n+1} DL \left(\frac{F}{m_{pl}BW}\right)^n F \tag{20}$$

where L is the specimen length, for example the supported length of a bending bar and F is the applied load. m_{pl} is the ratio of the loads necessary to plastify the specimen with and without crack for ideal plastic material behaviour. Consequently, C^* results

$$C^* = -\frac{n}{n+1} DL \left(\frac{F}{m_{pl}BW}\right)^{n+1} \frac{dm_{pl}}{d(a/W)} \tag{21}$$

2.2 Multiple-specimen evaluation

The procedure of Landes and Begley comprises several steps. The detailed description is given in the original paper.[1]

(1) In the first step the load F is plotted as a function of the crack length a and the displacement rate $\dot{\delta}$. The area below the resulting curves gives the energy rate $U^*(a,\dot{\delta})$.

(2) The representation $U^* = f(\dot{\delta}, a)$ provides the derivative $\partial U^*/\partial a$ as a function of $\dot{\delta}$.

(3) From eqn (9) C^* is calculated and plotted versus $\dot{\delta}$.

(4) The basic data directly give $da/dt = f(a, \dot{\delta})$ and, finally, the combination of steps 3 and 4 results in the da/dt versus C^* curve.

This procedure has been applied successfully to Al_2O_3 which contains a glassy phase.[2,4] A further possibility to determine C^* has been proposed by Kanninen and Popelar.[12] Their procedure is based on tests with constant load where the crack length is determined as a function of time. The further procedure is identical with the evaluation according to the procedure proposed by Landes and Begley.[1]

In the present investigation the evaluation of single tests will be applied.

3 Determination of C^* in 3-point bending tests

The procedure of Landes and Begley, Kanninen and Popelar, Harper and Ellison and Webster are directly applicable in 3-point bending. With the relationships proposed in Ref. 7 also the J-integral solutions for bending tests can be used for the determination of C^*. The geometric functions g_1 and g_2 can be written in terms of the h-parameters h_1 h_2 tabulated in:[8]

$$g_{1b} = \left(\frac{W}{a} - 1\right) h_1 \left(\frac{L}{0{\cdot}728\,(W-a)}\right)^{n+1} \tag{22}$$

$$g_{2b} = \frac{h_1}{h_3}\,\frac{L}{0{\cdot}728a} \tag{23}$$

where the subscript b stands for bending. The geometric quantities L, a and W can be seen from Fig. 3. The C^*-integral can also be computed from

$$C^* = D(W-a)\, h_1 \left(\frac{FL}{0{\cdot}728B(W-a)^2}\right)^{n+1} \tag{24}$$

The h-parameters of the EPRI-handbook may be expressed by the following approximations for the range $2 \le n \le 7$

$$h_1 \simeq \alpha \left[1{\cdot}26 + \sum_{\nu=1}^{4}\sum_{\mu=1}^{3} A_{\nu\mu}\,(1-\alpha)^\nu n^{\mu/5}\right]^2 \tag{25}$$

$$h_3 \simeq \frac{1}{\alpha}\left[\sum_{\nu=0}^{3}\sum_{\mu=0}^{2} A_{\nu\mu}\,(1-\alpha)^\nu n^\mu\right]^2 \tag{26}$$

with $\alpha = a/W$ and the coefficients $A_{\nu\mu}$ listed in Table 1 for h_1 and in Table 2 for h_3

It is a well-known fact that ceramics containing a glassy phase exhibit non-symmetry in their creep behaviour. The creep rates under tensile stresses may be substantially higher than under compressive

Table 1. h-parameters. Coefficients for eqn (25)[4]

	$\mu = 1$	2	3
$\nu = 1$	4·4451	−4·552	0·1232
2	8·9083	−9·312	3·9838
3	−23·27	20·225	−3·790
4	13·543	−6·597	−1·333

Table 2. h-parameters. Coefficients for eqn (26)

	$\mu = 0$	1	2
$\nu = 0$	2·1204	−0·196	0·0153
1	−0·809	−0·287	−0·025
2	0·2307	0·7110	0·0519
3	0·4596	−0·326	−0·046

stresses. This behaviour affects heavily the bending creep test in which tension and compression occur. Very often, the non-symmetry is related only to the state of secondary creep. This seems to be the case e.g. for MgO-doped hot-pressed silicon nitride (HPSN).[14] If we take into consideration this non-symmetry, the Norton power law may be modified as

$$\dot{\epsilon}_s = \lambda\, D|\sigma|^n \tag{27}$$

with

$$\lambda = \left\{ \begin{array}{l} 1 \text{ for } \sigma > 0 \\ \dfrac{-1}{\gamma^n} \text{ for } \sigma < 0 \end{array} \right\} \tag{28}$$

and $\gamma > 0$.

In a Finite-Element study Walz[13] determined the C^*-integral in 3 point bending for a number of n-values and γ = 1, 5 and 10. The results are expressed by a geometric function C^* defined as

$$C^* = DW(1 - a/W)^{-(2n+1)}\bar{C}^*\,\sigma^{n+1} \tag{29}$$

where σ is the elastically calculated outer fibre bending stress. In case of symmetric creep behaviour (γ = 1), the geometric functions obtained by Walz[13] can be compared with the C^*-values according to eqn (24). From eqn (24) and eqn (29) one obtains

$$\bar{C}^* = \frac{h_1}{2{\cdot}184^{n+1}} \tag{30}$$

Figure 4 illustrates the quantity $h_1/\bar{C}^*2{\cdot}184^{n+1}$ as a function of α for several n-values. The deviations from the expected value 1 are caused by different values chosen for L/W. Whilst in the EPRI-handbook[8] L/W = 2 is used, the calculations of Walz[13] were performed with L/W = 4·4, as usual for ceramic bending bars. From the computations of Walz the geometric functions C^* were obtained, as listed in Tables 3 and 4.

4 Experiments

4.1 Material and measurements

The tested material was an Al_2O_3 containing a glassy phase. Short characterisation of the material used: density 3·75 g/cm^3, mean grain size 5 μm, composition 96% Al_2O_3 (2·7% SiO_2, 1·3% MgO, 0·02% CaO, 0·02% Fe_2O_3), fracture toughness 20°C: 3·4 MPa $\sqrt{m}$, 1100°C: 4·1–5·2 MPa $\sqrt{m}$, 1200°C: 3·1–5·0 MPa $\sqrt{m}$, elasticity data at 20°C E = 325 GPa, ν = 0·24. In 4-point bending creep tests the parameters of secondary creep were determined as:[4] n = 2·25, $D = 1{\cdot}4 \times 10^{-8}$ (in MPa, h), γ = 5·1. Bending specimens, 3·5 × 4·5 × 45 mm in size, were diamond machined and then annealed in the vacuum for 5 h at 900°C. Then the specimens were damaged by introducing narrow saw cuts of 50 μm width. A second series of bending bars was precracked using the bridge indentation method. The static and dynamic tests were performed in a testing device as used in creep tests.[14] With this device the displacements can be measured within the inner roller span where the bending moment is constant. The 3-point bending tests were carried out with a modified device where the outer displacement pick-ups were applied directly under the outer rollers. All bending tests were performed with $2L$ = 40 mm. The experimental input for the determination of C^*

are the load–displacement curves and the crack-length data which are determined from partial unloadings. During the periodical partial unloadings the displacements are recorded. An example is shown in Fig. 5. The slopes of the partial unloadings decrease with increasing crack length. During partial unloading and reloading hysteresis effects were observed. Therefore, the usually applied linear–elastic compliance relationship could not be applied. Dynamic bending tests were interrupted in different states and the specimens were broken at room temperature. Then it was possible to measure the crack size on the fracture surface, and one point of the relationship slope of the hysteresis = $f(a)$ has been determined. A series of such tests then yielded the complete calibration curve. The result of a single cynamic bending test performed with a bar containing a saw-cut of 50 μm width and $a/W \simeq 0{\cdot}5$, with a displacement rate $\dot{\delta} = 2$ μm/h, is shown in Fig. 6. The crack starts propagating approximately when the maximum load is reached, and the following crack growth is nearly proportional to the time.

4.2 Evaluation of constant load tests

The loading-point displacements occurring in a creep-crack-growth test consist of three contributions:

- the creep deformations δ_c caused by the singular stress field close to the crack tip;
- the share of global creep deformation occurring in the remote parts of the specimen, δ_{nc}, and
- the contribution caused by an increase in compliance due to crack extension δ_{el}.

The measurable total displacements are

$$\delta_{meas} = \delta_c + \delta_{nc} + \delta_{el} \tag{31}$$

Due to the change of crack length during creep crack growth, an elastical displacement rate $\dot{\delta}_{el}$ occurs. In order to consider only creep effects, the elastic part has to be eliminated, i.e.

$$\dot{\delta} = \dot{\delta}_{meas} - \dot{\delta}_{el}, \quad \dot{\delta}_{el} = F \frac{\partial C}{\partial a} \dot{a} + C\dot{F} \tag{32}$$

or it has to be ensured that the elastic part can be neglected. Displacement rates obtained in a constant load test are plotted in Fig. 7. Whereas the total displacement rate $\dot{\delta}_{meas}$ was experimentally determined, the quantity $\dot{\delta}_{nc}$ was measured in a separate test with an unnotched specimen and $\dot{\delta}_{el}$ was computed from the time-dependent increase in crack length.

As a premise for the correct determination of dU^*/da it has to be ensured that crack propagation had taken place and that the minimum displacement rate in a test has been reached. In Fig. 8 the crack-growth initiation times — the time span between the moment of load application and

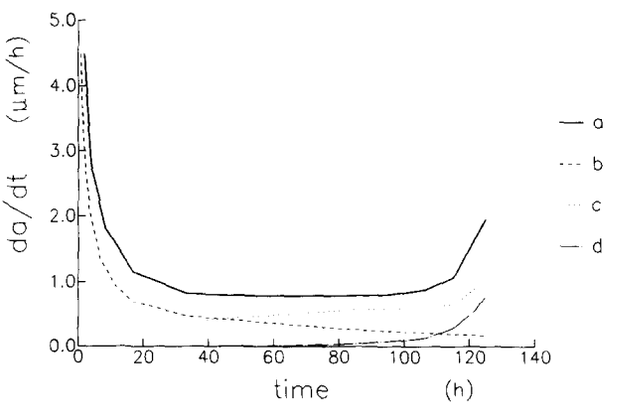

Fig. 7. Displacement rates in a constant load test.; (a) $\dot{\delta}_{meas}$; (b) $\dot{\delta}_{nc}$; (c) $\dot{\delta}_c$; (d) $\dot{\delta}_{el}$.

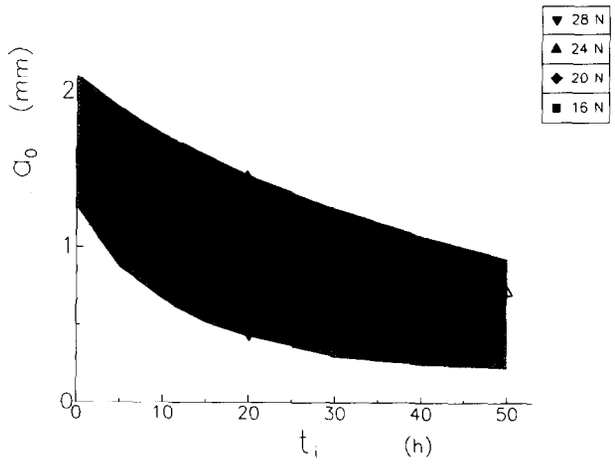

Fig. 8. Initiation times for creep crack growth tests under static load as a function of the initial crack length a_o; solid symbols: cracks introduced by a saw-cut of 50 μm width, open symbols: pre-cracked by the bridging method.

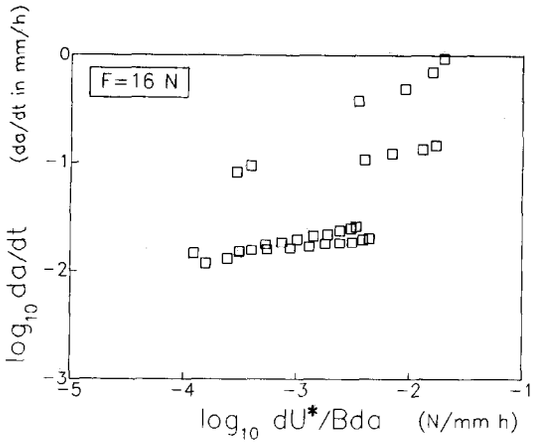

Fig. 9. Crack-growth rate as a function of dU^*/da.

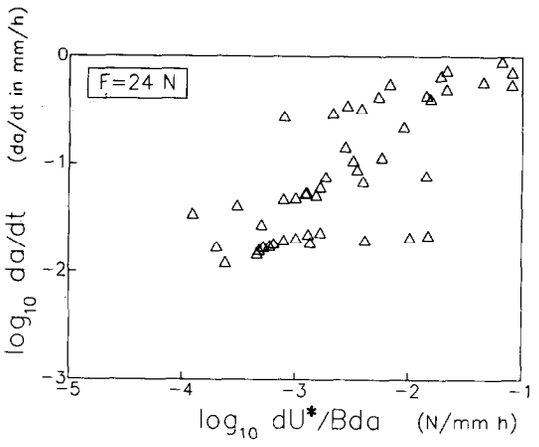

Fig. 11. Crack growth rate as a function of dU^*/da.

the first detectable crack extension — are plotted as a function of the initial crack length a_0.

It can be seen that no significant difference exists between specimens with saw-cut and with precrack. The tendency of decreasing crack-growth initiation time with increasing initial crack size is perceptable and has been expected.

Several series of static bending tests were evaluated with the method proposed by Webster,[10] eqn (17). The change of creep power with crack length was determined for test times $t > 20$ h at 8 h intervals and for times $t < 20$ h in time steps of 1–2 h until the specimens failed or the tests were suspended. All test durations were within 5 h and 340 h. The results are plotted in Figs 9–12.

4.3 Determination of C^*

The values dU^*/da determined in the experiments have to be examined out whether or not they represent valid C^*-values. In order to decide this, we have to compute the characteristic times t_1, using eqn (10). For times $t > 10\ t_1$ we expect the results to be valid C^*-values. Figure 13 shows the results of the constant load tests. The data undergo much scatter. There is some evidence that the very low crack-growth rates may be caused by R-curve effects. The R-curve behaviour shields the crack-tip region from the externally applied loads which results in lower crack-tip loading and, consequently, lower crack-growth rates. A clear indication is the reduction of the scatter band if only the first C^*-data of each test is considered. These data are introduced in Fig. 13 as solid symbols. For these tests the R-curve, for instance caused by crack-bridging effects, does not influence the result since $\Delta a = a - a_0 \to 0$. Fitting the solid symbols we find the power-law relation of creep-crack growth

$$\frac{da}{dt} = 6{\cdot}9\ \frac{\text{mm}}{\text{h}}\ C^{*0{\cdot}77} \tag{33}$$

(C^* in N/mm h). The corresponding straight line is entered in Fig. 13. Figure 14 shows the data resulting from times $t_1/10 \le t \le 10\ t_1$ evaluated according to eqn (9). These data can be expressed by

$$\frac{da}{dt} = 4{\cdot}4\ \frac{\text{mm}}{\text{h}}\ C(t)^{0{\cdot}71} \tag{34}$$

($C(t)$ in N/mm h). For identical crack-growth rates $C(t)$ is slightly lower than C^*. Riedel[7] has shown that the exponent of the creep-crack growth relation should be a simple function of the Norton creep exponent, namely

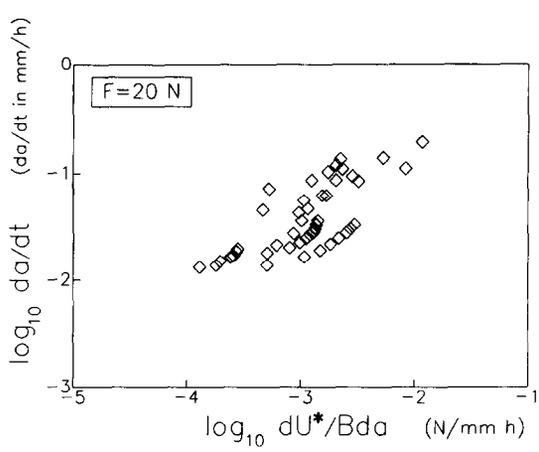

Fig. 10. Crack-growth rate as a function of dU^*/da.

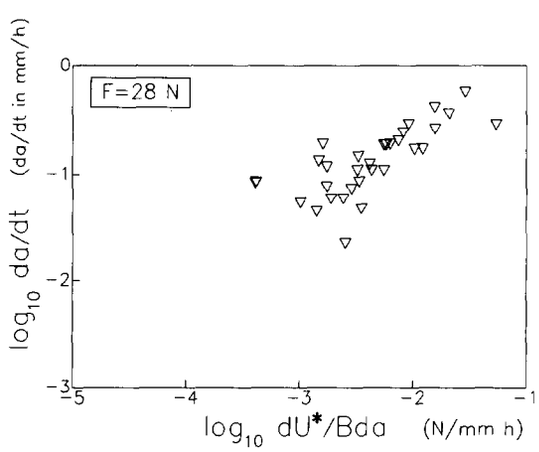

Fig. 12. Crack-growth rate as a function of dU^*/da.

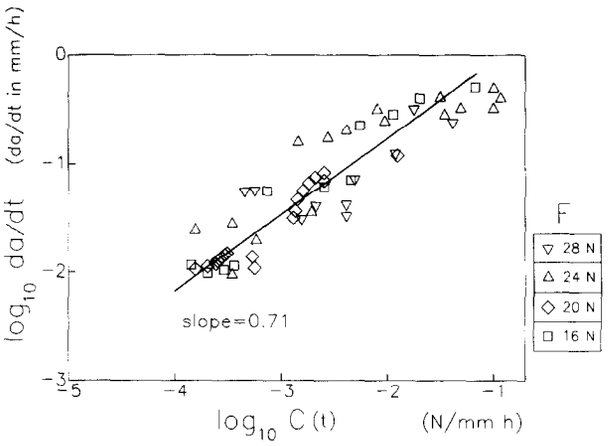

Fig. 14. Crack-growth rate as a function of $C(t)$ from static tests.

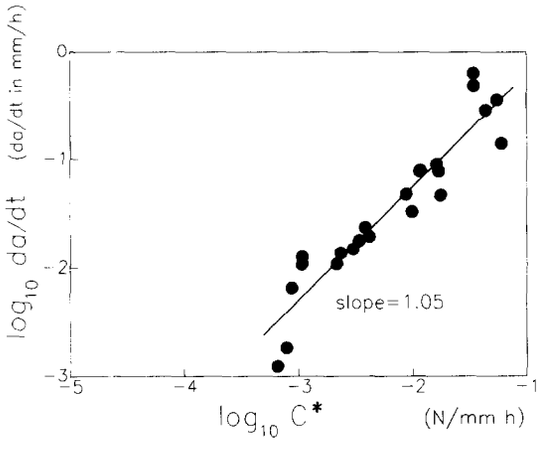

Fig. 15. Crack-growth rate as a function of C^* from dynamic tests.

$$\frac{da}{dt} \propto C^{*n/(n+1)} \tag{35}$$

leading for the investigated material ($n = 2{\cdot}25$) to an exponent of 0·69. This expected value is in very good agreement with the experimental result.

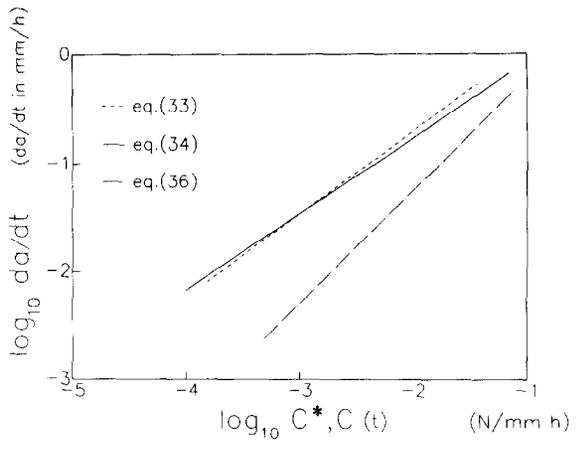

Fig. 16. Intercomparison of the crack-growth relations.

4.4 Evaluation of dynamic bending tests

The single-specimen evaluation from the dynamic tests (tests with constant displacement rates) was performed with eqn (18). It was assumed that in the range of decreasing load steady-state creep conditions are sufficiently fulfilled. The tests were performed with displacement rates in the range from 0·2 μm/h to 10 μm/h. The initial crack sizes were in the range 1 mm $\leq a_0 \leq$ 2·3 mm. In the region where the tests were evaluated the corresponding loads were between 8 and 22 N. Since, unfortunately, the crack-growth rates in the range of decreasing load were found to be highly constant in each test, it was only possible to determine one single C^*-value for one da/dt-value. Figure 15 shows the data obtained. Also in these tests a power law was found

$$\frac{da}{dt} = 6{\cdot}9 \ \frac{\text{mm}}{\text{h}} \ C^{*1{\cdot}05} \tag{36}$$

(C^* in N/mm h). The slightly increased exponent of 1·05 may be caused by R–curve influences. In case of the dynamic tests, the cracks had strongly grown by about 1·4 mm to attain the range of decreasing load. In the static tests the mean crack extension was only $\simeq$ 0·3 mm. Consequently, R–curve effects are stronger in the dynamic tests since $\Delta a \not\to 0$.

A comparison of the crack-growth relations, eqns (33), (34) and (36), is given in Fig. 16.

5 Summary

The paper deals with the determination of the loading quantities C^* and $C(t)$ for creep-crack growth. Different possibilities of evaluating the C^*-integral in single-specimen tests were listed, and the constant load test and the constant loading-rate test were applied to an alumina ceramic

containing a glassy phase. It was found that:

- the crack-growth rate as a function of the loading quantities C^* and $C(t)$ can be described by a power-law relationship;
- the exponents in static tests are about 0·75 and agree very well with the theoretical value (here: 0·69) proposed by Riedel;[7]
- the exponent resulting in tests with constant displacement rate is slightly higher, possibly influenced by R–curve effects.

Acoustic Emission Monitoring of Damage Evaluation in Ceramics Submitted to Thermal Shock

F. Mignard, C. Olagnon & G. Fantozzi

Laboratoire GEMPPM, URA CNRS 341, bât. 502, INSA de Lyon, 20 bd. A. Einstein, 69621 Villeurbanne Cedex, France

(Received 27 September 1994; revised version received 3 February 1995; accepted 7 February 1995)

Abstract

In studies conducted on two ceramic materials, namely a porous alumina and a dense zirconia, it is shown that a simple acoustic emission experiment can provide valuable information on the processes of thermal shock degradation in the materials.

Acoustic emission technique for thermal shock damage evaluation of ceramics is particularly attractive because it is non-destructive and it gives *in-situ* information. However, the complexity of the acoustic emission (AE) response of a material makes the quantitative analysis difficult to achieve.[1] Konsztowicz[2,3] used AE for detecting the damaging of refractory or high thermal shock resistance ceramics quenched in silicon oil, but he has not made any direct correlation between the acoustic emission activity and the number of cracks formed. He has also pointed out that not all the signals recorded could be directly related to strength degradation. AE was also used in rising thermal shock by laser irradiation in order to monitor the degradation of thermal barrier coating.[4]

The goal of this work is to show direct relations between AE and thermal shock degradation on relatively dense material, in order to use this technique for monitoring a thermal shock apparatus.

For this purpose thermal shock tests were conducted on two commercial ceramic materials, a coarse grain porous alumina (grade AL24, Degussa, Germany) and a magnesia partially stabilised zirconia (grade Z500, Morgan Matroc, UK). Thermal shock tests consisted of heating the specimens to various high temperatures and to cool them by jet air as described elsewhere.[5] Acoustic emission response of the specimen was recorded with piezoelectric sensor (Bruel & Kjaer sensor, model 8313, resonance frequencies: 250 kHz) connected to a pre-amplifier (Bruel & Kjaer sensor, model 2637, fixed gain: 40 dB) and a main amplifier (Bruel & Kjaer sensor, model 2638, variable gain: 20 dB chosen) leading to a total gain of 60 dB, as described by Peigné.[6] The AE transducer is clamped at the end of a wave guide which plays also the role of a specimen holder (Fig. 1). The envelope of the AE signals delivered by the amplifier is sampled at a frequency of 10 kHz by means of digital/analogical converter driven by a micro-computer. Rectangular flexure specimens of dimensions $4 \times 6 \times 40$ mm^3 were used. The specimens were cooled during 6 s at room temperature by 2 jet air nozzles. This cooling time was shown to be longer than the degradation duration. During the cooling, the acoustic emission was recorded. Alumina specimens were tested as ground and zirconia specimen were polished at 3 μm. Special care regarding subeutectoid ageing treatment was accorded to enhance mechanical properties of Mg—PSZ and to remove residual stresses. The resistance to thermal shock was evaluated in terms of elastic modulus variations and retained strength as shown in Fig. 2. At a critical thermal shock temperature ΔTc, both elastic modulus and retained strength decrease. The number of acoustic emission events is also reported in Fig. 2. Note that the apparition of the first acoustic emission event takes place for the critical thermal shock temperature. This suggests that the degradation is effectively correctly recorded and that it occurs by unstable crack propagation. The number of acoustic peaks increases linearly when increasing the severity of the thermal shock. The critical thermal shock temperature difference is found to be $\Delta Tc = 670$°C for Mg–PSZ and $\Delta Tc = 700$°C for alumina. Thermal, elastic and mechanical properties of these two materials are quite different but their combination leads to similar ΔTc values. It is worth noting that the thermal shock behaviour of the alumina is quite different from that of the Mg–PSZ. After ΔTc, the retained strength of the alumina material is about 0·5 σ_R which is higher than the 0·15 σ_R retained strength measured in Mg–PSZ. The elastic modulus

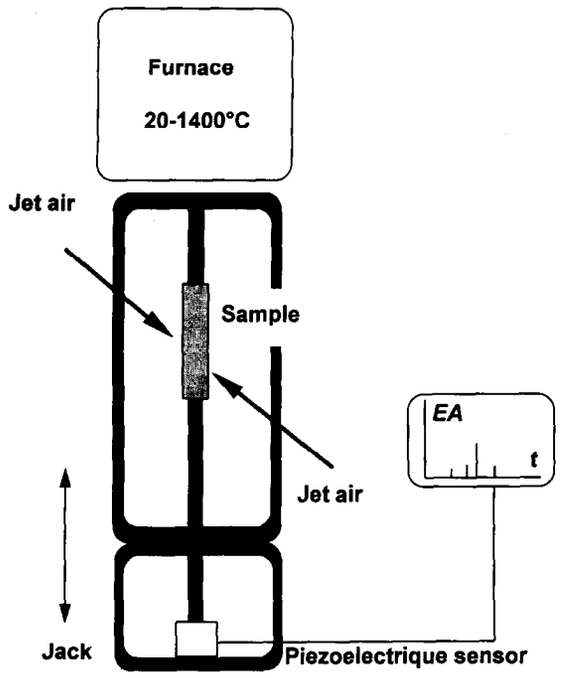

Fig. 1. Thermal shock device.

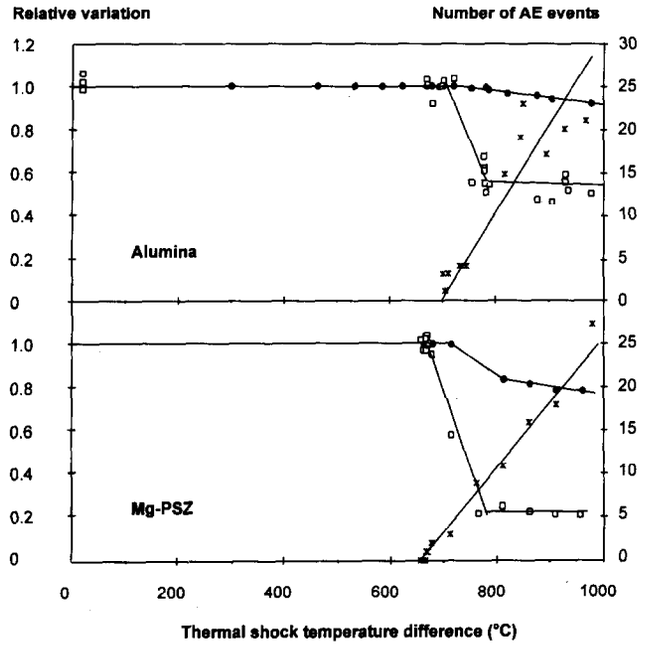

Fig. 2. Relative variation of retained strength (□), modulus of elasticity (●) and number of AE events (×) as a function of thermal shock temperature difference for alumina and Mg–PSZ materials.

exhibits the same phenomena and its decrease with temperature is lower for the alumina than for the zirconia material. This means that the studied alumina behaves like a refractory material.

It is to be recalled that the thermal stress field is such that tensile stresses arise parallel to the surface, which leads to crack initiations from the surface. They could be easily observed by dye penetrant on the nearly dense zirconia material but the high amount of porosity in alumina material did not allow direct crack observation. In the case of zirconia specimen the number of acoustic emission events could be correlated with the number of cracks at the surface of the body. The number of cracks induced by a thermal shock temperature near the critical temperature is low and easy to count. For higher thermal shock temperature differences the number of cracks strongly increases and the counting is difficult to achieve. Pictures were therefore taken from each side of the specimen and assembled together in order to represent a projection of the whole surface and to make the counting easier (see Figs 3(a) and (b)). The number of events in an acoustic emission response was counted with a computer treatment. The surface projection of a Mg–PSZ sample subjected to a thermal shock temperature of 714°C is represented in Fig. 3(a), and its associated acoustic emission response is represented in Fig. 4(a). Note that each crack corresponds to an AE peak. Figures 3(b) and 4(b) show the same phenomena but for a thermal shock temperature of 961°C leading to a higher crack density. Figure 5 shows the correlation between the number of cracks and the number of AE events for all the tested thermal shock temperatures. It appears clear that each crack propagation is associated to an AE peak; the error for the highest thermal shock temperature resulting from the way to count the cracks. This result suggests that the simple AE treatment conducted here can precisely enable us to record the degradation occurring during thermal shock. It might be especially useful for porous material

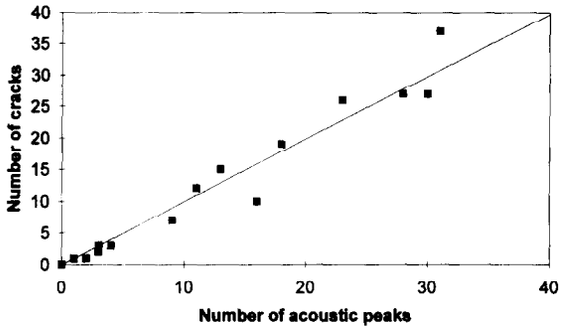

Fig. 5. Correlation between the number of AE peaks and the number of counted cracks in various Mg–PSZ specimens.

such as the alumina studied here and could also be extended to refractory materials.

It is also important to note that AE reflects particular cooling instants that can be associated to damage events. This is of major interest for such a transient problem where only final degradation is otherwise observed.

AE method which gives *in situ* information can be advantageously used for thermal fatigue where the cycling device can be automatically stopped from the apparition of an AE event.

Mechanical Behavior of Porous Glasses Produced by Sintering of Spherical Particles

Savitha C. Nanjangud & David J. Green

Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania 16802, USA

(Received 10 September 1994; revised version received 27 January 1995; accepted 31 January 1995)

Abstract

Young's modulus and biaxial flexure strength were measured for compacts of spherical glass particles sintered to various densities. The aim of the work was to relate the mechanical properties to the sintering process. In particular, changes in the interparticle neck sizes during the sintering process were measured from fracture surfaces. It had been postulated previously that the elastic moduli directly depend on the neck radius to particle radius ratio and such measurements allow the elastic behavior to be directly related to the sintering kinetics. The experimental results were consistent with both the mechanical and sintering models. There was also found to be a strong correlation between Young's modulus and strength of the porous glass bodies.

1 Introduction

One of the aims of the study of sintering science is the development of techniques that allow the experimentalist to characterize the geometric changes that occur in the powder compact as it undergoes sintering. A variety of characterization techniques, such as mercury porosimetry, surface area measurements, small angle neutron scattering etc., have been utilized. In other studies,[1,2] however, it was suggested that the elastic behavior of a porous body could be used to characterize the sintering process. For the case of partially sintered alumina, elastic moduli were measured for specimens that had been subjected to the initial stage of sintering. In this material, there was a rapid increase in the elastic moduli with minimal densification and it was suggested[1,2] that this behavior could be understood by the interparticle neck growth process, and particularly by surface diffusion. An attractive feature of utilizing the elastic behavior of a material to characterize the sintering process, is that the elastic constants can be measured to a high accuracy using nondestructive techniques, such as dynamic resonance or sound velocity measurements.

The aim of the current study was to determine the changes that occur in the mechanical properties of partially sintered glass and to relate these to the changes in the microstructure that occur during the sintering process. In order to simplify the compact geometry, a model system of spherical glass particles was utilized.

2 Background

There has been considerable scientific effort in predicting the elastic behavior of porous materials. In such analyses, the theoretical relationships for the elastic moduli are often expressed solely as functions of the fraction of porosity. In other cases, it has been suggested that pore geometry may play an important role and factors, such as pore shape, have been incorporated into some of the analyses. For materials with moderate or high fractions of porosity, it can be quite difficult to describe the complex nature of the pore structure, especially for materials produced by the sintering of powder compacts. As an alternative approach, Green *et al.*[1,2] have suggested it may be useful to consider the elastic behavior in terms of the interparticle neck growth process and the coordination of the particles. For example, for spherical particles subjected to the initial stage of sintering, it was suggested that[1]

$$\frac{B}{B_o} = \frac{3Nr(1-2\nu_o)}{8kR(1-\nu_o^2)} \tag{1}$$

where B is the bulk modulus of the porous compact, B_o and ν_o are the bulk modulus and Poisson's ratio of the particle, r is the neck radius, N the particle coordination number, R is the radius of the particle and k is an empirical geometric constant. For a given material, eqn (1) can be simplified to obtain

$$\frac{B}{B_0} = CN\left(\frac{r}{R}\right) \quad (2)$$

where C is an empirical constant that can be obtained by comparison with experimental data for a given material. Although the theoretical approach to obtain eqn (2) was considered to be only approximate, the dependence of the elastic constants on the particle coordination number and the ratio of the neck and particle radii is intuitively appealing. The idea of relating the interparticle neck size to the mechanical behavior of porous materials has also been put forward by other researchers[3,4] and in a related idea, Cytermann[5] has postulated that the Young's modulus is directly dependent on the contiguity of the porous solid.

As eqn (2) predicts a dependence of the bulk modulus on (r/R), this allows the sintering theories concerning neck growth in powder compacts to be directly related to the elastic behavior. For example, Frenkel[6] proposed that the sintering mechanism in glass is by viscous flow and derived an expression for the rate of neck growth for glass spheres, i.e.,

$$\left(\frac{r}{R}\right)^2 = \frac{3\gamma t}{R\eta} \quad (3)$$

where γ is the surface energy, η is the viscosity, r is the radius of the neck, R is the radius of the particle and t is the sintering time. Experimental studies by Kuczynski[7] and Kingery and Berg[8] on the sintering of glass beads were in agreement with Frenkel's analysis.

3 Experimental Procedure

Soda–lime–silica glass beads were obtained from a commercial source (Potters Industries Inc., Parsippany, NJ). The average particle size was determined to be 58·6 μm from microscopic observation (750–1000 particles).

3.1 Sample preparation

Twenty grams of the glass powder were mixed with 4 wt% polyethylene glycol (organic binder) which had been dissolved in 20 ml of ethanol at 50°C. The mixture was stirred and the ethanol was removed, by drying at the same temperature for about 6–8 h. The dried powder was crushed to obtain a free flowing glass powder, which was subsequently uniaxially pressed into pellets of 25·4 mm diameter, at a pressure of ~90 MPa. The theoretical density of the glass powder was determined with a helium pycnometer (Multivolume Pycnometer 1305, Micromeritics, Norcross, GA) and found to be 2420 kg m^{-3}.

The glass samples were sintered in two steps. The first step involved binder burnout at 300°C. In the second step, the samples were sintered at various temperatures, ranging, from 620 to 655°C for 2 h and at 625 and 645°C for various times, between 0·5 and 10 h. The density of the samples was calculated from their measured dimensions and weights.

3.2 Mechanical properties

The strength of the glass samples was measured by the biaxial flexure method[9] using a mechanical testing machine (Instron Corporation, Canton, MA). The strength was calculated assuming a constant value of 0·2 for the Poisson's ratio. A 10% error in the Poisson's ratio value gives rise to an error of 4% in the flexural strength value, and this was considered acceptable for the current study.

The Young's modulus of the samples was measured by determining the longitudinal sound velocity.[10] Ultrasonic transducers (2 MHz, Ultran Laboratories, Boalsburg, PA) were used to transmit and receive the signals and no liquid couplant was used between the transducers and the samples. The sound velocity was measured through the thickness of the glass samples and Young's modulus was calculated using[10]

$$E = \frac{V^2\rho(1-2\nu)(1+\nu)}{(1-\nu)} \quad (4)$$

where V is the longitudinal sound velocity, ρ is the density and ν is the Poisson's ratio. As mentioned earlier, a constant value of 0·2 was used for the Poisson's ratio. For typical values of ν, a 10% error will give a ~4% error in the Young's modulus value.

3.3 Microstructural analysis

Neck radius measurements were made on samples sintered in the range 625–645°C and at 625°C for 4, 6, 8 and 10 h. These measurements were accomplished by obtaining a series of micrographs (scanning electron microscope) of the fracture surfaces of four different samples for each of the chosen conditions. For these conditions, the materials fail primarily by the crack passing through the necks. The neck sizes were measured from the micrographs using an image analyzer (ZIDAS, Carl Zeiss, Inc., Thornwood, NY). About 100 necks were measured for each experimental condition and the values were arithmetically averaged to obtain the mean contact radii.

4 Results and Discussion

The average green density of the compacts was determined to be ~64% of the theoretical density.

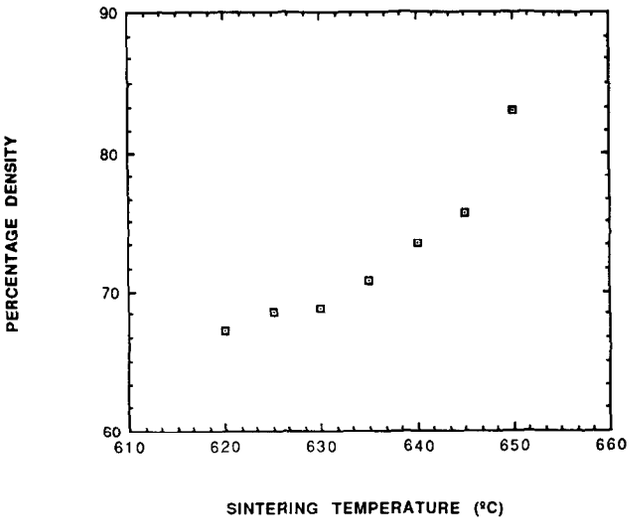

Fig. 1. Density of glass specimens after sintering at various temperatures for 2 h.

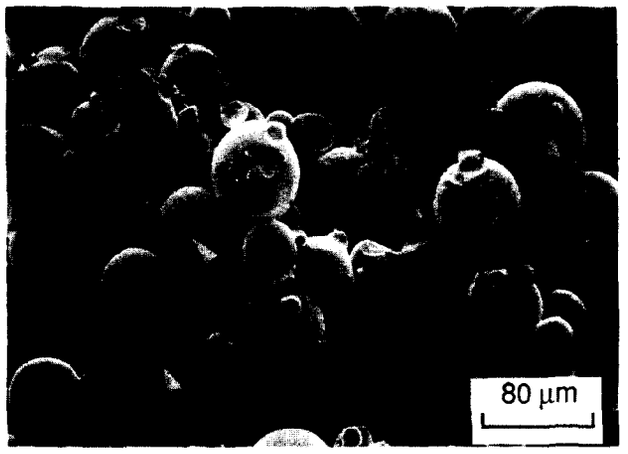

Fig. 3. Fracture surface for a specimen sintered at 620°C (4 h), showing the failed interparticle necks. Some of these necks are indicated by arrows.

The sample densities are shown in Fig. 1 as a function of the sintering temperature. The room temperature Young's modulus values obtained for these specimens are shown in Fig. 2 as a function of the % theoretical density. The Young's modulus values increase continuously with relative density, as expected. This behavior does, however, contrast strongly with the rapid increase in Young's modulus observed in partially sintered alumina.[1,2] For glasses, neck growth is expected to occur by viscous flow with densification, whereas for alumina, in which surface diffusion is prevalent at the lower sintering temperatures, the changes in the elastic moduli should occur without densification. If one considers the Young's modulus of dense soda lime silica glass is ~70 GPa, the data in Fig. 2 is also consistent with the recent analysis of Lam *et al.*,[11] in which the Young's modulus is predicted to be directly dependent on the degree of densification.

The fracture surfaces of the glass samples showed fractured necks which could be seen as small, almost perfect circles on the particles. Figure 3 shows the fracture surface for a glass sintered at 620°C for 4 h and the fractured necks, some of which are arrowed, are small but clearly visible. Transparticle fracture becomes more prevalent in samples sintered at higher temperatures or for longer times, making the neck size measurements more difficult. For example, Fig. 4 shows the fracture surface for a sample sintered at 620°C for 10 h. The ratio of the neck radius to the particle radius was calculated using the average particle size of the glass spheres. The presence of the transparticle failure complicated the current study, in that it may lead to a bias in the measured r/R values. For example, particles with the larger neck sizes may be obscured if the particles fail rather than the necks.

The model by Green *et al.*[1] predicts that the bulk modulus of a partially sintered sample is directly proportional to the product of the coordination of the compact and the radius ratio.

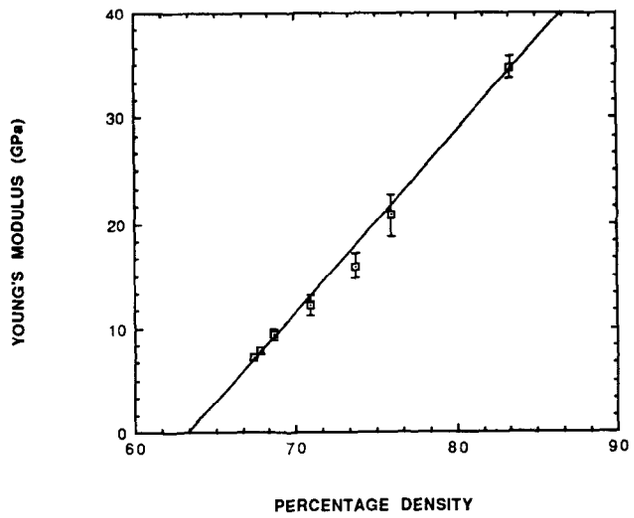

Fig. 2. Room temperature Young's modulus values for porous glass specimens after sintering to various temperatures. The error bars indicate the standard deviation in the data.

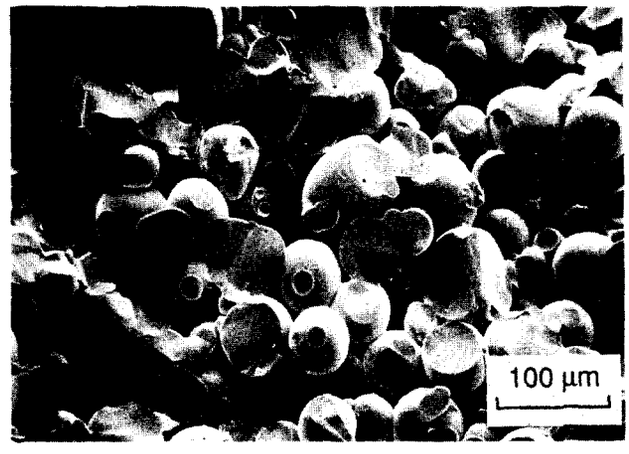

Fig. 4. Fracture surface for a specimen sintered at 620°C (10 h), showing the increase in transparticle failure for the longer sintering times.

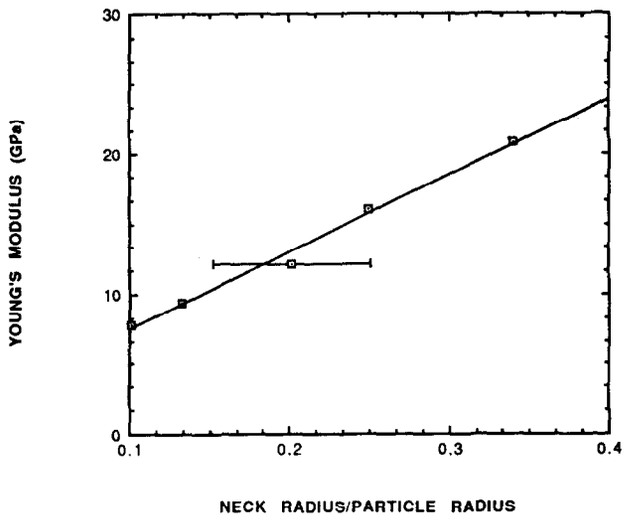

Fig. 5. Young's modulus values for porous glass specimens as a function of the neck to particle radius ratio. The error bar is a typical value of the standard deviation seen in the contact radius measurement.

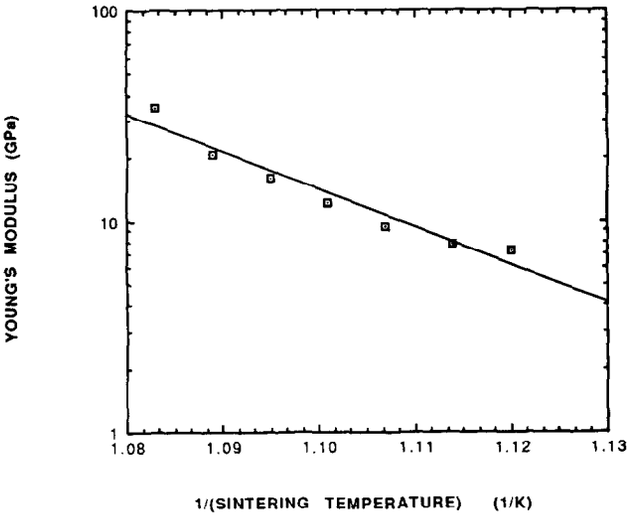

Fig. 6. Arrhenius plot for the (log) Young's modulus values for porous glass specimens as a function of the inverse sintering temperature.

In particular, eqn (2) predicts a linear relationship between the bulk modulus and r/R, assuming there is no change in particle coordination number. If one assumes that the value of Poisson's ratio for the porous glasses does not change significantly with densification, the same linear relationship will be obtained for the relative Young's modulus. To verify this prediction, the Young's modulus values of the porous glasses were plotted as a function of the radius ratio (r/R), as given in Fig. 5. Although the model was derived only for very small contact areas, a linear dependence on r/R is seen to not be unreasonable. From the data in Fig. 5 and eqn (2), if one assumes $(B/B_0) \approx (E/E_0)$ and $E_0 = 70$ GPa, one finds $CN \approx 1$.

In order to relate the elastic behavior to the sintering kinetics, one can combine eqns (2) and (3) to obtain,

$$\frac{E}{E_o} = CN\left(\frac{3\gamma t}{R\eta}\right)^{1/2} \tag{5}$$

where E and E_0 are the Young's moduli of the porous body and the spheres and η is the viscosity of glass at the sintering conditions. In addition, the viscosity is temperature dependent and can be written in the form of an Arrhenius equation near the glass transition temperature, i.e.

$$\frac{\eta}{\eta_o} = \exp\left(\frac{Q}{\mathrm{R}'T}\right) \tag{6}$$

where η_0 is a constant that depends on the glass composition, Q is the activation energy for viscous flow, R' is the universal gas constant and T is the absolute temperature. Substituting for η in Eqn (5), one obtains the following relationship between the Young's modulus and the sintering temperature

$$\frac{E}{E_o} = D\exp\left(-\frac{Q}{2\mathrm{R}'T}\right) \tag{7}$$

where $D = CN(3\gamma t/R\eta_0)^{1/2}$ The results of the analysis are shown in Fig. 6 and the activation energy for viscous flow was calculated from the slope and found to be 690 kJ mol^{-1}. This value is very close to 703 kJ mol^{-1}, which is the activation energy reported in literature[12] for soda lime silica glass in the temperature range 492–541°C.

The biaxial flexure strengths of the porous glasses are given in Fig. 7. The trend in the flexural strength data is very similar to that in the Young's modulus data, suggesting a similar dependence on the compact structure.

The densities of samples sintered at 625 and 645°C for various times are shown in Fig. 8. The density of samples sintered at 645°C increases more rapidly, reflecting the lower viscosity of the glass at this temperature. The Young's modulus and

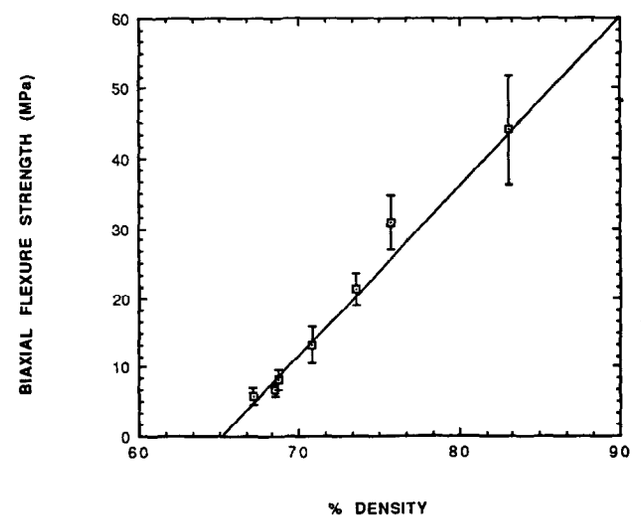

Fig. 7. Room temperature biaxial flexure strength values for porous glass specimens after sintering to various temperatures. The error bars indicate the standard deviation in the data.

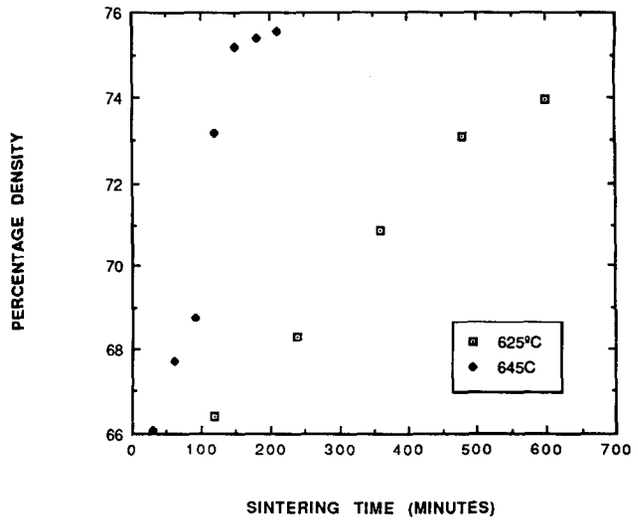

Fig. 8. Density of glass specimens after sintering at 625 and 645°C for various times.

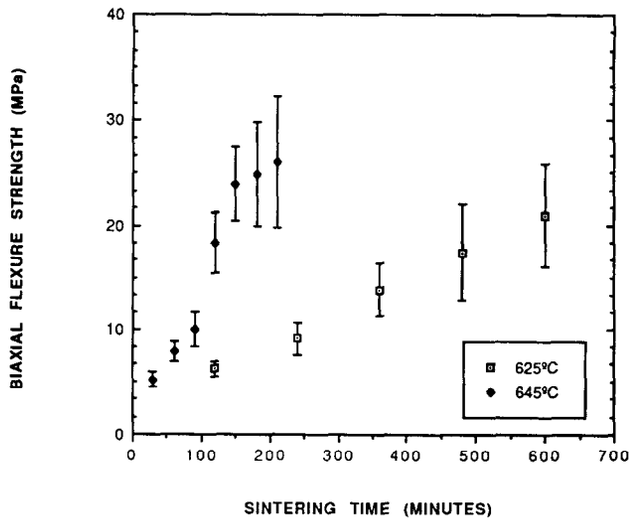

Fig. 10. Biaxial flexure strengths values for porous glass specimens after sintering at 625 and 645°C for various times.

flexure strength of these samples are presented in Figs 9 and 10, and in a similar fashion to the earlier data, show a strong correlation with each other.

From eqn (3), the neck/particle radius ratio is predicted to increase with sintering time with a time exponent of 0.5 and this can be tested using the measured r/R values. Figure 11 shows the data for the samples sintered at 625°C and although the data is rather scattered, a time exponent of 0·51 was obtained, in excellent agreement with the theory and with previous studies.[6,13,14] The data in Fig. 11 can also be used to estimate the glass viscosity at 625°C. From eqn (3), the square of the radius ratio can be plotted as a function of time and the viscosity can be obtained from a linear regression analysis. Using a value of 0·3 J m^{-2}, as suggested by Scherer,[15] the viscosity was calculated to be 10 GPa s. This value is in fair agreement with the value of 1·52 GPa s, reported by Hagy.[16]

The Young's modulus data on samples obtained from the isochronal and isothermal experiments have been combined in Fig. 12 to show the dependence on r/R. One would expect the two data sets to fit a single linear function, assuming there is no change in particle coordination. It appears, however, there is a significant difference between the two data sets. The reason for this difference could be that the particles undergo rearrangements during sintering, thus altering the coordination number and structure of the compact. The extent of these rearrangements may be different at the various sintering temperatures due to the differences in glass viscosity. Alternatively, it should be remembered that the model was only derived for small r/R values; therefore one would expect the agreement to be poor at large r/R values. Thus, although the model tested in this work seems be a reasonable first approximation, it is suspected that further refinements in the model are needed.

5 Conclusions

The Young's modulus and strength were determined for spherical glass particle compacts sintered under various conditions. These properties both increased with increasing density and the changes in the two properties were strongly correlated. The Young's modulus data were also analyzed in terms of the changes in the neck radius/particle radius ratio and an approximate linear relationship was confirmed, in agreement with earlier theoretical predictions. It was also possible to link the sintering kinetics to the elastic behavior and good agreement with the theory was found. Overall, it was found that elastic constant measurements are a very useful approach for characterizing porous ceramic bodies produced from powder compacts and gives insight into the sintering process.

(Received 29 September 1994; revised version received 2 February 1995; accepted 7 February 1995)

Abstract

Ultrafine aluminium-nitride (AlN) powders with primary particle sizes of 10–20 nm were prepared by a metal–organic chemical vapour deposition (MOCVD): trimethylaluminium ($Al(CH_3)_3$), triethylaluminium ($Al(C_2H_5)_3$) and triisobutylaluminium ($Al(i\text{-}C_4H_9)_3$)-vapours were reacted with ammonia (NH_3) at 1050°C. The sintered compacts with relative densities of ~95% could be fabricated by firing these compressed powders at temperatures as low as 1600°C. The relative densities of the $Al(CH_3)_3$-derived and $Al(C_2H_5)_3$-derived compacts fired at 1800°C for 10 h attained ~98%. The oxygen contents of these compacts were 1·8 and 4·7%, respectively.

1 Introduction

Aluminium-nitride (AlN) ceramics have high thermal conductivities (theoretical value; 320 $Wm^{-1} \times K^{-1}$)[1] and low thermal expansion coefficients (4·4 $\times 10^{-6}°C^{-1}$; 25–400°C) close to that of silicon.[2] By making use of these properties, AlN ceramics have started to be used as a high-performance ceramic substrate and packaging material. To date, (i) the preparation of high-purity AlN powder and (ii) the fabrication of high-density AlN ceramics with and without a sintering aid have been examined by many researchers.

The high-purity AlN powder may be prepared either by a direct nitridation of metallic aluminium (Al) or by a carbothermal reduction of Al_2O_3.[2,3] Recently, much attention is being devoted to the preparation of high-purity and ultrafine AlN powder by a chemical vapour deposition (CVD), because this AlN powder has a potential application in the fabrication of high-density AlN ceramics without a sintering aid. Various vapourization sources have been proposed by many researchers: metallic Al,[4–8] aluminium chloride ($AlCl_3$)[9–13] and alkylaluminium.[14–16] Among these sources, the vapourization rate of alkylaluminium may be controlled more strictly than those of solid sources, because the commercially available alkylaluminiums: trimethylaluminium ($Al(CH_3)_3$: TMAL), triethylaluminium ($Al(C_2H_5)_3$): TEAL) and triisobutylaluminium ($Al(i\text{-}C_4H_9)_3$: TIBAL) are not solid but liquid at room temperature. The properties of TEAL-derived AlN powder have been reported by Wakimura and Hiai,[15] and Adjaottor and Griffin;[16] those of TIBAL-derived AlN powder by Tsuchida *et al.*[14] But the properties, especially sinterabilities, of AlN powders prepared by the vapour-phase reactions of alkylaluminiums with ammonia (NH_3) have never been examined systematically.

The present authors[8] have examined the properties of AlN powder prepared by a low-pressure CVD (LP-CVD), using metallic Al and NH_3–nitrogen (N_2) gas. This paper deals with: (i) the preparation of AlN powder by a metal organic CVD (MOCVD); (ii) the evaluation of the powder properties and (iii) the comparison of the present data with those of our previous LP-CVD.

2 Experimental Procedure

2.1 Starting materials and reaction apparatus

Three kinds of alkylaluminiums available from Aldrich Chemical Company (Milwaukee, WI, USA) were used as starting materials: (i) TMAL; (ii) TEAL and (iii) TIBAL.

The schematic diagram of the reaction apparatus assembled by ourselves is shown in Fig. 1. The apparatus consisted of: (i) a reacting zone ((a)–(e)); (ii) a collecting zone ((f)–(h)), and (iii) an evacuating

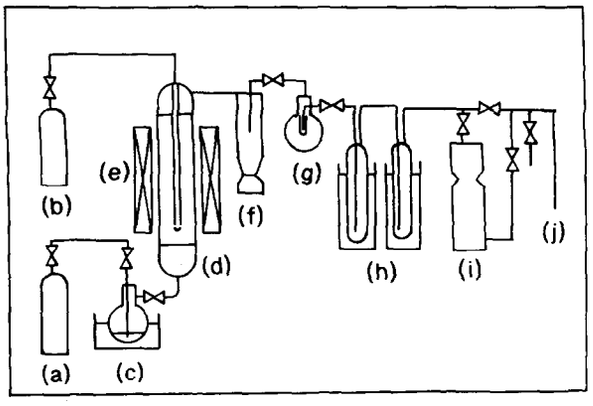

Fig. 1. Schematic diagram of the reaction apparatus: (a) N_2 cylinder (purity: 99·9995%); (b) NH_3 cylinder (purity: 99·99%); (c) Evaporation flask; (d) Mullite tube (diameter: 3 cm, height: 60 cm); (e) Electric furnace (heating zone: 30 cm); (f) Cyclone; (g) Test-tube type filter; (h) Trap; (i) Oil-diffusion pump and (j) Rotary pump.

Table 1. Preparation conditions of AlN powders

(Evaporation)		*(Flow rate)*	
Alkylaluminium	*Temperature (°C)*	*NH_3 gas (dm^3 min^{-1})*	*Carrier gas (N_2) (dm^3 min^{-1})*
$Al(CH_3)_3$	30	50–100	50
$Al(C_2H_5)_3$	110	50	50–100
$Al(i\text{-}C_4H_9)_3$	100	50	100–200

zone ((i)–(j)). The reaction apparatus was first evacuated using the rotary and oil-diffusion pumps. Then alkylaluminium vapour with the partial pressure of 15 mmHg, which was formed by controlling the heating temperature of the liquid alkylaluminium, was introduced into the reaction tube heated at 1050°C, using a carrier gas of nitrogen (N_2) with purity of over 99·9995%; NH_3 gas with purity of 99·99% was simultaneously introduced into the reaction tube. The evaporation conditions of alkylaluminium and the flow rates of NH_3 and N_2 are listed in Table 1. The resulting powder was collected by a cyclone filter and a test-tube type filter. The yield of the powder was ~80% of the theoretical yield.

2.2 Phase identification and quantitative analysis

The crystalline phase of the resulting powder was examined using an X-ray diffractometer with $CuK\alpha_1$ radiation operated at 40 kV and 25 mA (Model Rad IIA, Rigaku, Tokyo). The aluminium content of the resulting powder was determined using an X-ray fluorescence apparatus (Model SXF-1200, Shimadzu, Kyoto); the nitrogen and oxygen contents were determined using a simultaneous nitrogen/oxygen analyser (Model EMGA-550, Horiba, Kyoto).

2.3 Evaluation of powder properties

The specific surface area of the resulting powder was measured by BET technique, using nitrogen (N_2) as an adsorption gas. The particle shape was observed using a transmission electron microscope (TEM; Model H-800; accelerating voltage 200 kV, Hitachi, Tokyo). The particle-size distribution was measured by a laser scattering/diffraction apparatus (Model LA-700, Horiba, Kyoto).

2.4 Evaluation of sinterability

Two kinds of the compacts were fabricated to evaluate the sinterability of the resulting powder; each compact with a diameter of 10 mm and thickness of 10 mm for the dilatometric evaluation was fabricated by pressing ~1·3 g of the powder uniaxially at 50 MPa; each compact with a diameter of 10 mm and thickness of ~3 mm for the measurement of density and microstructural observation was fabricated by pressing ~0·3 g of the powder uniaxially at 50 MPa.

The densification behaviour of the compact was evaluated using a dilatometer from room temperature up to ~1600°C at the heating rate of 5°C min^{-1}. The relative density (bulk density/true density) of the compact fired at a temperature between 1400 and 1800°C for 3 or 10 h, in N_2 flowing at the rate of 2 dm^3 min^{-1}, was calculated using the data on dimensions and weight of the compact; the heating rate from room temperature up to the desired temperatures was 10°C min^{-1}. The fractured surfaces of the sintered compact were observed using a scanning electron microscope (SEM; Model S-430, Hitachi, Tokyo).

3 Results and Discussion

3.1 Crystalline phase of the resulting powder

The powders were deposited not only on the walls (upper parts) of the reaction tube but also on the cyclone and test-tube type filter. The resulting powders were white.

Typical XRD patterns of the powders collected from the cyclone and filter are shown in Fig. 2. Only AlN[17] was detected from the powders, irrespective of the difference in the kind of alkylaluminium. The crystallinities of these powders were almost the same as those collected from the cyclone and filter.

The analytical results of the present powders are listed in Table 2. The molar ratios of Al to N were in the range of 1·00–1·08. The oxygen content varied from 4·6 to 9·9%, according to the kind of alkylaluminium.

The reaction routes of TMAL, TEAL and TIBAL with NH_3 have been examined by several researchers.[14,15,18] Details will be described below:

(i) Reaction route of TMAL with NH_3[18]

$$Al(CH_3)_3 + NH_3 \rightarrow Al(CH_3)_3{\cdot}NH_3 \quad (1)$$

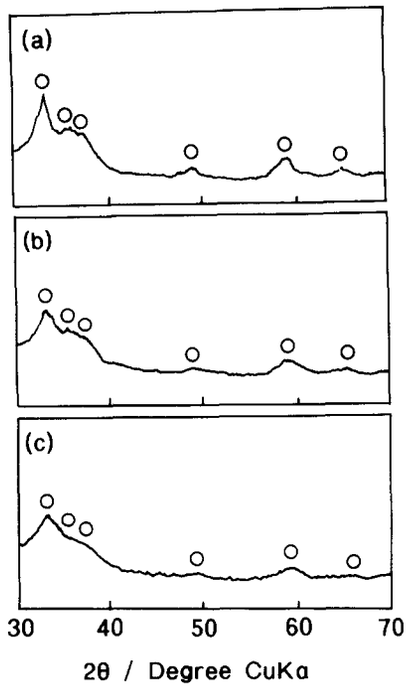

Fig. 2. X-ray diffraction patterns of (a) TMAL-derived powder; (b) TEAL-derived powder and (c) TIBAL-derived powder. ○ AlN — Reaction temperature: 1050°C.

Table 2. Analytical results of the powders and molar ratios of Al to N. Reaction temperature: 1050°C

Alkylaluminium	*Al (wt%)*	*N (wt%)*	*O (wt%)*	$\frac{Al}{N}$
$Al(CH_3)_3$	63·5	31·9	4·6	1·03
$Al(C_2H_5)_3$	61·1	31·7	7·2	1·00
$Al(i\text{-}C_4H_9)_3$	61·0	29·1	9·9	1·08

$$Al(CH_3)_3{\cdot}NH_3 \rightarrow Al(CH_3)_2NH_2 + CH_4 \quad (2)$$
$$Al(CH_3)_2NH_2 \rightarrow AlCH_3NH + CH_4 \quad (3)$$
$$AlCH_3NH \rightarrow AlN + CH_4 \quad (4)$$

(ii) Reaction route of TEAL with NH_3[15]

$$Al(C_2H_5)_3 + NH_3 \rightarrow Al(C_2H_5)_2{\cdot}NH_2 + C_2H_6 \quad (5)$$
$$Al(C_2H_5)_2{\cdot}NH_2 \rightarrow (1/n)\,(AlC_2H_5NH)_n + C_2H_6 \quad (6)$$
$$(AlC_2H_5NH)_n \rightarrow nAlN + C_2H_6 \quad (7)$$

(iii) Reaction route of TIBAL with NH_3[14]

$$Al(i\text{-}C_4H_9)_3 + NH_3 \rightarrow Al(i\text{-}C_4H_9)_3{\cdot}NH_3 \quad (8)$$
$$Al(i\text{-}C_4H_9)_3{\cdot}NH_3 \rightarrow AlN + 3(i\text{-}C_4H_{10}) \quad (9)$$

The upsurges of the X-ray baseline spectra in the range of 30–40° suggest the presence of some amorphous material. The composition of such amorphous material appears to be Al–O–N system, partly because 4·6–9·9% of oxygen are included in the powder, and partly because Al/N ratios above unity indicate somewhat lower nitrogen contents than stoichiometry.

The oxygen may come to be included in the powder during the handling in air.[19] The present oxygen contents (4·6–9·9%) are, however, much smaller than those reported previously; the previous data showed that TEAL-derived and TIBAL-derived powders contain 15–20% of oxygen.[14–16]

3.2 Powder properties

The properties of the resulting powders were examined from the viewpoints of specific surface area, particle shape and particle size.

The specific surface areas of the resulting powders were arranged in the following order: TIBAL-derived powder (175 m^2g^{-1}) > TEAL-derived powder (145 m^2g^{-1}) > TMAL-derived powder (95 m^2g^{-1}). The primary particle sizes calculated on the basis of the surface areas were arranged as follows: TMAL-derived powder (19 nm) > TEAL-derived powder (13 nm) > TIBAL-derived powder (11 nm).

The TEM micrographs and histograms for particle-size distributions of the resulting powders are shown in Fig. 3. The TEM micrographs of TMAL-derived and TEAL-derived powders (Fig. 3(a) and (b)) showed that the polyhedral particles with sizes of < 0·05 μm (50 nm) were adhered to form agglomerates; the histograms for the particle-size distribution indicated that the particles with sizes of < 0·5 μm and with sizes of 1 to 30 μm were present in the powder. The TEM micrograph of TIBAL-derived powder (Fig. 3(c)) showed that the polyhedral particles with sizes of < 0·05 μm (50 nm) were linked to form agglomerates; the histogram for the particle-size distribution revealed that the particle sizes were distributed in the ranges of 0·1–0·2 μm and of 2–30 μm.

The individual particles observed by TEM correspond to primary particles, because the particle

sizes (< 50 nm) observed by TEM are in accord with the primary particle sizes of 10–20 nm. These primary particle sizes are smaller than those (30–50 nm) prepared by LP-CVD[8] and those (20–80 nm) by rf plasma.[6]

The particles with sizes of < 0·5 μm correspond to secondary particles where the primary particles are adhered to one another; the particles with sizes of 1–30 μm correspond to ternary particles which are formed by the agglomeration of the secondary particles. The secondary and ternary particles may form spontaneously to lower the excess surface energy which the ultrafine primary particles possess.

3.3 Sinterability

Before we fabricated the high-density AlN ceramics, we examined the linear shrinkages of these compacts during heating. Results are shown in Fig. 4. The shrinkage of TMAL-derived compact proceeded with temperature and was promoted at temperature exceeding 1200°C. The shrinkage of TEAL-derived compact was similar to that of TMAL-derived compact but was slightly shifted toward the higher temperature side. The shrinkage of TIBAL-derived compact started to occur at ~200°C and was promoted above 1400°C.

The shrinkages during the heating of TMAL-derived and TEAL-derived compacts below ~1200°C and during the heating of TIBAL-derived compact below ~1400°C may be attributed to (i) the elimination of residual carbon formed by the decomposition of alkyl groups and (ii) the elimination of oxygen and H_2O adsorped on the AlN particles. The weight loss (~10%) of TIBAL-derived compact before and after the dilatometric measurement is more appreciable than the weight losses (~5%) of TMAL-derived and TEAL-derived compacts.

As shown above, the rapid shrinkages during the heating of these three compacts above 1200–1400°C indicate the initiation of the mass transfer due to the sintering of AlN particles. On

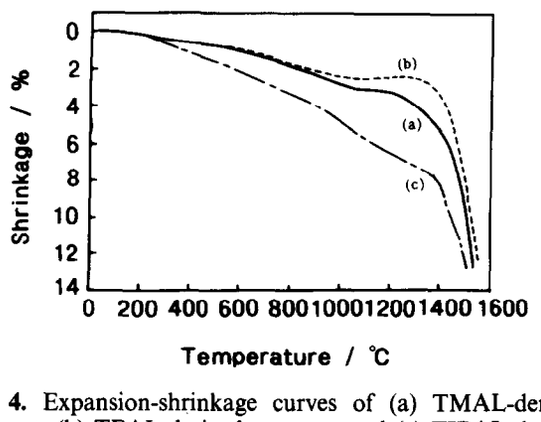

Fig. 4. Expansion-shrinkage curves of (a) TMAL-derived compact; (b) TEAL-derived compact and (c) TIBAL-derived compact. Heating rate: 5°C min^{-1}.

the basis of this information, we decided to fire the compacts at 1400°C or at a higher temperature. The relationship between firing temperature and relative density is shown in Fig. 5. The relative densities for these compacts varied from 60 to 67% at the firing temperature of 1400°C; however, they increased with increasing temperature and attained 95–96% at and above 1600°C.

Although the sintering temperatures of the conventional pure AlN powders with the surface areas of 1–5·3 m^2g^{-1} usually need to be 1850°C or higher,[2,20] those of the present AlN powders with the surface areas of 95–175 m^2g^{-1} are as low as 1600°C. This sintering temperature is in accord with that of AlN powder with the surface area of 92 m^2g^{-1} prepared by rf plasma.[6] Thus, the difference in sintering temperature between conventional pure and present ultrafine AlN powders can be attributed to the surface area or the primary particle size. Moreover, the oxygen in AlN powder may create the cation vacancies to promote the mass transfer during sintering;[19] however, Kuramoto and his coworkers[2,20] state that the particle-size effect, i.e. small particle size and narrow particle-size distribution, contributes much more to the densification of the AlN compact than the oxygen effect does. In actual fact, the relative densities of these sintered compacts are all in the range of 95–96% at and above 1600°C, regardless of the differences in oxygen contents among the starting powders.

The crystalline phases of the compacts fired at 1800°C for 3 h were examined by XRD. Although the data were omitted in this paper, the XRD patterns of these sintered compacts showed that the crystalline phases were not only AlN but also $Al_{(8/3+x/3)}O_{4-x}N_x$[21] (trace).

The oxynitride or $Al_{(8/3+x/3)}O_{4-x}N_x$ results from the reaction of AlN with H_2O and/or O_2 during firing. Although the sintering of AlN powder is promoted by the presence of oxygen,[2] the thermal

Table 3. Some properties of the compact fired at 1800°C for 10 h.

Alkylaluminium	*Relative density (%)*	*Phase*[a]	*Oxygen (%)*
$Al(CH_3)_3$	97·9	AlN	1·8
$Al(C_2H_5)_3$	98·2	AlN	4·7
$Al(i\text{-}C_4H_9)_3$	95·1	AlN	5·2

[a] Identified by X-ray diffractometry.

conductivity lowers with increasing oxygen content.[2,22] The oxygen content may be reduced by firing the compact in nitrogen atmosphere.[23] In order to: (i) reduce $Al_{(8/3+x/3)}O_{4-x}N_x$ content and (ii) increase the relative density over ~95%, the firing time was prolonged from 3 to 10 h at the fixed temperature of 1800°C. We examined the crystalline phases of the compacts by XRD. As a typical case, the XRD pattern of TMAL-derived compact is shown in Fig. 6. Only AlN was detected from the sintered compact.

The relative density, crystalline phase and oxygen content are listed in Table 3. The relative density of TIBAL-derived compact was limited to be 95·1%; however, the relative densities of TMAL-derived and TEAL-derived compacts attained ~98%. The crystalline phase was only AlN. The oxygen contents were in the range of 1·8–5·2%.

The SEM micrographs of these sintered compacts are shown in Fig. 7. The SEM micrographs of TMAL-derived and TEAL-derived compacts (Fig. 7(a) and (b)) showed that the grains with sizes of 1–4 μm were closely arrayed. The SEM micrograph of TIBAL-derived compact (Fig. 7(c)) showed that the grains with sizes of < 1 μm were present among the grains with sizes of 2–4 μm.

The fabrication of high-density AlN ceramics without a sintering aid has been examined chiefly by Kuramoto and his coworkers: the relative density of AlN compact fired at 2000°C for 3 h is 93%;[2] the firing of doctor-bladed powder compact at 1850°C for 7 h raises the relative density to 98·7%.[20] Since the relative densities of TMAL-derived and TEAL-derived compacts achieve ~95% at 1600°C for 3 h and ~98% at 1800°C for 10 h, these AlN powders prove to have excellent sinterabilities.

The SEM micrographs (Fig. 7) shows that the uniform-sized grains are closely arrayed, reflecting the high densities (95–98%) of the sintered compacts. Such microstructures demonstrate that the homogenous sintering may proceed among the ultrafine, uniform-sized and weakly-agglomerated AlN particles.[20]

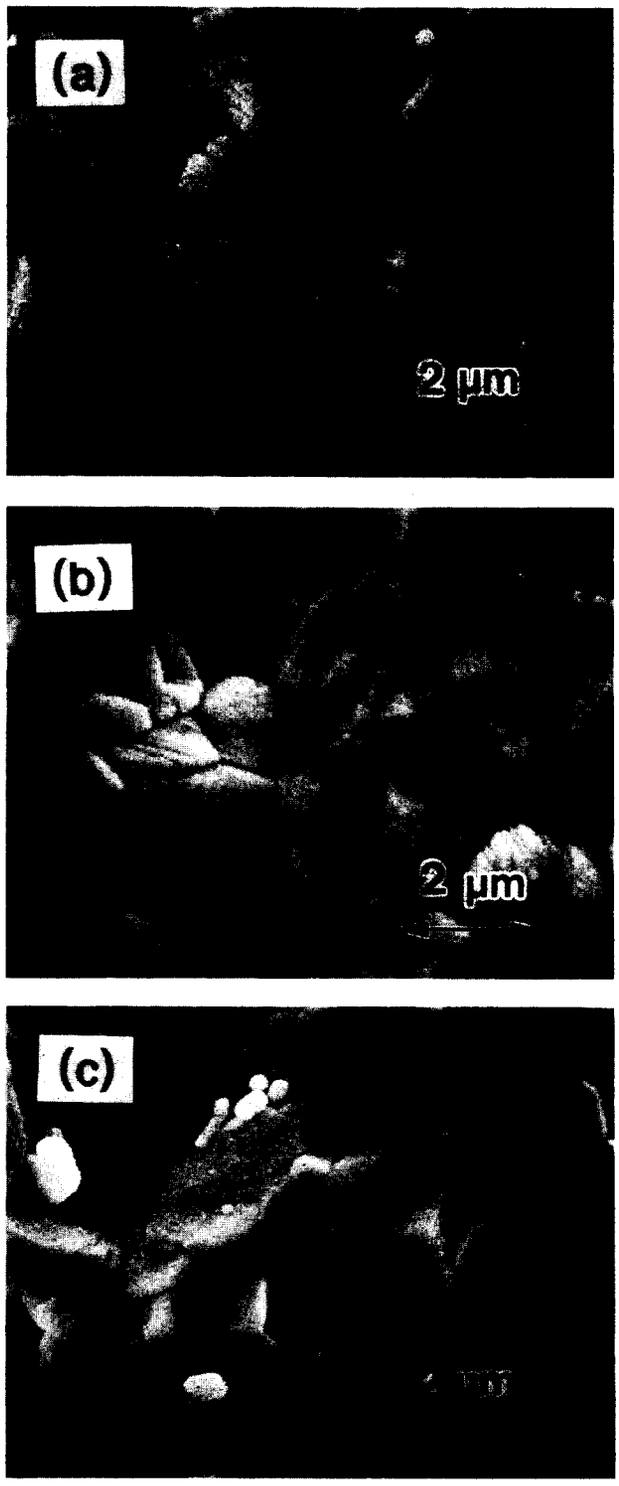

Fig. 7. SEM micrographs of (a) TMAL-derived compact; (b) TEAL-derived compact and (c) TIBAL-derived compact. Firing conditions: 1800°C, 10 h.

4 Conclusion

The aluminium-nitride (AlN) powders were prepared by the metal–organic chemical vapour deposition (MOCVD), i.e. the vapour-phase reactions of trimethylaluminium ($Al(CH_3)_3$: TMAL), triethylaluminium ($Al(C_2H_5)_3$: TEAL) and triisobutylaluminium ($Al(i\text{-}C_4H_9)_3$: TIBAL) with ammonia (NH_3). The properties of the resulting powders are summarized as follows:

(1) The specific surface areas of the resulting powders were 95–175 m^2g^{-1}; the primary particle sizes were in the range of 10–20 nm.

(2) The sintered compacts with the relative densities of ~95% could be fabricated by firing these powders at temperatures as low as 1600°C. When these compacts were fired at 1800°C for 10 h, the relative densities were 98·2% (TEAL-derived compact) > 97·9% (TMAL- derived compact) > 95·1% (TIBAL-derived compact).

(3) After the firing of the compacts at 1800°C for 10 h, only AlN was detected from the sintered compacts; the oxygen contents were 1·8% (TMAL-derived compact) < 4·7% (TEAL-derived compact) < 5·2% (TIBAL-derived compact).

Abstract

Various Si_3N_4 powders, produced by different procedures, were characterized by imaging (TEM) and analytical methods (EDS, FT-IR, XPS) in the as-received state as well as after doping with a metal oxide (MgO). For the doping, an alternative procedure to the usual methods, was applied, which is based on soluble organometallic compounds. Analytical transmission electron microscopy combined with lateral resolution element analysis and XPS measurements was used for morphological, structural and analytical characterization. The distribution of the dopant was deduced from measurements of XPS sputter depth profiles. These investigations were supplemented by FT-IR measurements in order to determine qualitatively and semi-quantitatively the reactive groups on the particle surfaces of the as-received powders.

For comparison, measurements were performed with Si_3N_4 powders which were doped by the above chemical procedure and by mechanical mixing. The results of the various characterization methods are interpreted in the form of a model display for surface reactions of organometallic doping reagents on the surfaces of ceramic particles. The results show that Si_3N_4 powders with high concentration of OH groups on their particle surface reveal very good distribution of the fluxing element (layer-like coating).

1 Introduction

It is well known that the improvement of homogeneity, reproducibility and sinter activity is an essential objective in the development of structural ceramics. In that context the surface chemistry and structure of sintering powders, which have been developed with even smaller particle sizes and in higher purity degrees, play an important role. Moreover, the distribution of sintering additives in the matrix material has to be improved, which can make it possible to reduce the additive concentration and to enhance the high-temperature properties. Consequently, investigations are necessary to improve the doping techniques, the characterization of the highly sinter active powders, and the homogeneity of (powder + sintering additive)-mixtures.[1] Up to now several techniques, such as mixing/milling processing, the sol-gel method, the precursor route and doping with inorganic metal compounds, have been used in order to introduce inorganic sintering additives (metal oxides).

In the mixing/milling processing frequently used, the raw materials are ground (homogenized) with the sintering additive (mostly metal oxides) in a milling device. Using this technique, the homogeneity of the additive distribution is limited by the particle size distribution (μm-range) of the starting powder and of the dopant. This method is not suited for the doping of silicon nitride powders with small amounts of sintering additives. Additionally, the mixture may be contaminated by abrasion materials.

The sol-gel method is based on the hydrolysis of multivalent metal alkoxides. The gel is subjected to a drying process in order to obtain the material in the powder state.[2,3] Another technique, which is also based on the use of chemical pre-products, is the liquid precursor route. Non-oxide powders have been produced by reaction pyrolysis of inorganic polymers.[4–6] However, both techniques are very expensive.

The disadvantages of inorganic metal compounds is the possibility of forming crystalline phases[7] and the contamination of the powder particles by additional elements from the counterions (N from nitrates, Cl, Br, I from halogenides, P from phosphates, S from sulfates etc.) which may have a detrimental effect particularly on high-temperature properties.[8] Therefore, these elements have to be removed during heating (formation of nitric oxide, sulfur dioxide, halogenic acids etc.).

In the present investigation another method is

used to dope the mostly commercially available powders through soluble organometallic compounds based on Mg as model substance. This method provides several advantages compared to the procedures mentioned above.[9,10] By using Mg-methoxide as the organometallic compound, for example, which can act as the dopant compound, only those elements (in small amounts) are introduced in the matrix powder, which are anyhow incorporated into the raw material through organic additives (carbon, hydrogen and oxygen). This method allows a homogeneous introduction of doping elements even at low concentrations. The development of a chemical bonding between particle surface and organometallic compound suppresses the formation of a separate phase of the dopant metal.

2 Experimental Procedure

Organometallic chemistry was carried out in non-aqueous and water-free solvents; whereby magnesium methoxide as organometallic compound was used. During the mixing process of this solution with a suspension of the raw material in the same liquid, (alcohol), the surface groups of the Si_3N_4 powders act as polar reagent to which the metal alkoxide can be directly bonded generating an alcohol molecule ($Si–OH + (CH_3O)_2Mg \rightarrow Si–O–Mg–O–CH_3 + CH_3OH$). As a result, an excellent distribution of the sintering aids (in solution) may be assumed, which will subsequently be transferred to the particle surfaces in accordance with the distribution and density of the OH-groups. Thus, these are decisive parameters for the homogeneous distribution of the inorganic additives.

The infrared spectroscopy is an ideal method to achieve information about functional groups of molecules[11] through the vibrational excitation. To detect the functional surface groups, powder analysis was performed in the so called Barnes cell (Spectra Tech. Inc.) of an FT-infrared-spectrometer (Digilab FTS 15/80) in the reflection mode, wave numbers ranging from 4000 to 600 cm^{-1}. In the range of 4000–3000 cm^{-1} the stretching vibrations of the surface-OH-groups, which are important for the chemical dopant used here, can be determined. In the range of about 1000 cm^{-1}, the backbone vibrations of the lattices were observed.[12,13]

The silicon nitride powders investigated — either commercially available or special grades from industry — were produced by different procedures (Table 1). These powders were analyzed in the as-received state and after doping with magnesium methoxide with various concentrations between 0·5 and 2 wt% of Mg related to Si_3N_4. Analysis of the dopant reaction concerning the homogeneity of the element distribution was performed by transmission electron microscopy (Philips EM 430; accelerating voltage 300 kV; lateral resolution about 0·2 nm, equipped with EDS, Tracor) and X-ray-photoelectron-spectroscopy (Perkin Elmer PHI 5600). For comparison purposes, a powder mixture (Si_3N_4 grade UBE SN-E10 + 2 wt% MgO grade p.a. Merck) was produced by mixing the powders in a non-aqueous liquid.

Table 1. Oxygen content and specific surface area of the silicon nitride powders most investigated. Additionally, FT-IR measurements were performed with the following powders: HCST S1, Denka SN-9S, HCST LC10-S, HCST LC10-N, Bayer DF0014, HCST LC12-SX, HCST 3918 LC12 (special grade with 3 wt% oxygen), HCST GP, TOSOH TS10.

3 Results and Discussion

3.1 FT-infrared spectroscopy

The infrared spectrum analysis of the silicon nitride powders investigated provides information about the surface bonded molecules. The height of

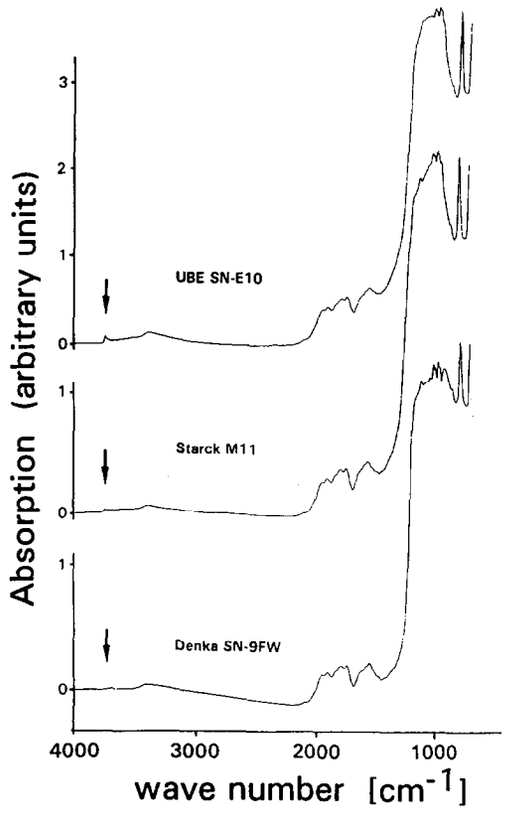

Fig. 1. FT-infrared spectra of various silicon nitride powders investigated (UBE SN-E10, Starck M11, Denka SN-9FW).

the absorption peak of the OH-stretching vibration at 3750 cm^{-1} indicates the amount of the OH-surface groups (Fig. 1). An increasing peak height was found spectroscopically in the sequence of the silicon nitride powders Denka SN-9FW, Starck M11, UBE SN-E10 (see arrows in Fig. 1); in other silicon nitride powders investigated, the intensity of the OH-vibration band increases in the following sequence: HCST Sl (low), Denka SN-9S, HCST LC10-S, HCST LC10-N, Bayer DF0014, HCST LC12-SX, HCST 3918 LC12 (special grade with 3 wt% oxygen), HCST GP, TOSOH TS10 (high). In the range of about 1000 cm^{-1} the backbone vibrations (Si–N–Si, Si–O–Si) of the lattices can be observed (a detailed association of each maximum of the overlapping vibration bands in this so-called 'fingerprint' region is not discussed in connection with the dopant reaction used here).

The silanol groups are used as reactive surface groups for the organometallic compounds. Measuring the extent of the OH-stretching vibrations at 3750 cm^{-1} allows an estimation of the surface occupation of these groups which is not strongly correlated to the total oxygen content of silicon nitride powders (compare Fig. 1 with the total oxygen content in Table 1). Thus, the variation in the intensities of the OH-vibrations gives an indication of suitability and potential for the chemical dopant reaction of each powder.

3.2 Photo-electron spectroscopy

Photo-electron spectroscopy (XPS) is an important analytical technique for surface and thin film characterization of solid materials. It provides qualitative and quantitative information relating to the outermost atom or molecule layers. The depth of information or the thickness of the analyzed surface layer ranges from 1 to 3 nm. This mainly depends on the kinetic energy of the photo-electrons. Sputter depth profiling is applied if concentration variations within a thick surface layer are of interest. The XPS spectra are commonly initiated by Mg K_α or Al K_α radiation. The resulting photo-electron lines can be correlated with the binding energy of the core level states of the atoms. That energy can respond sensitively to a charge transfer between neighbouring atoms. It provides a direct insight into chemical bonding

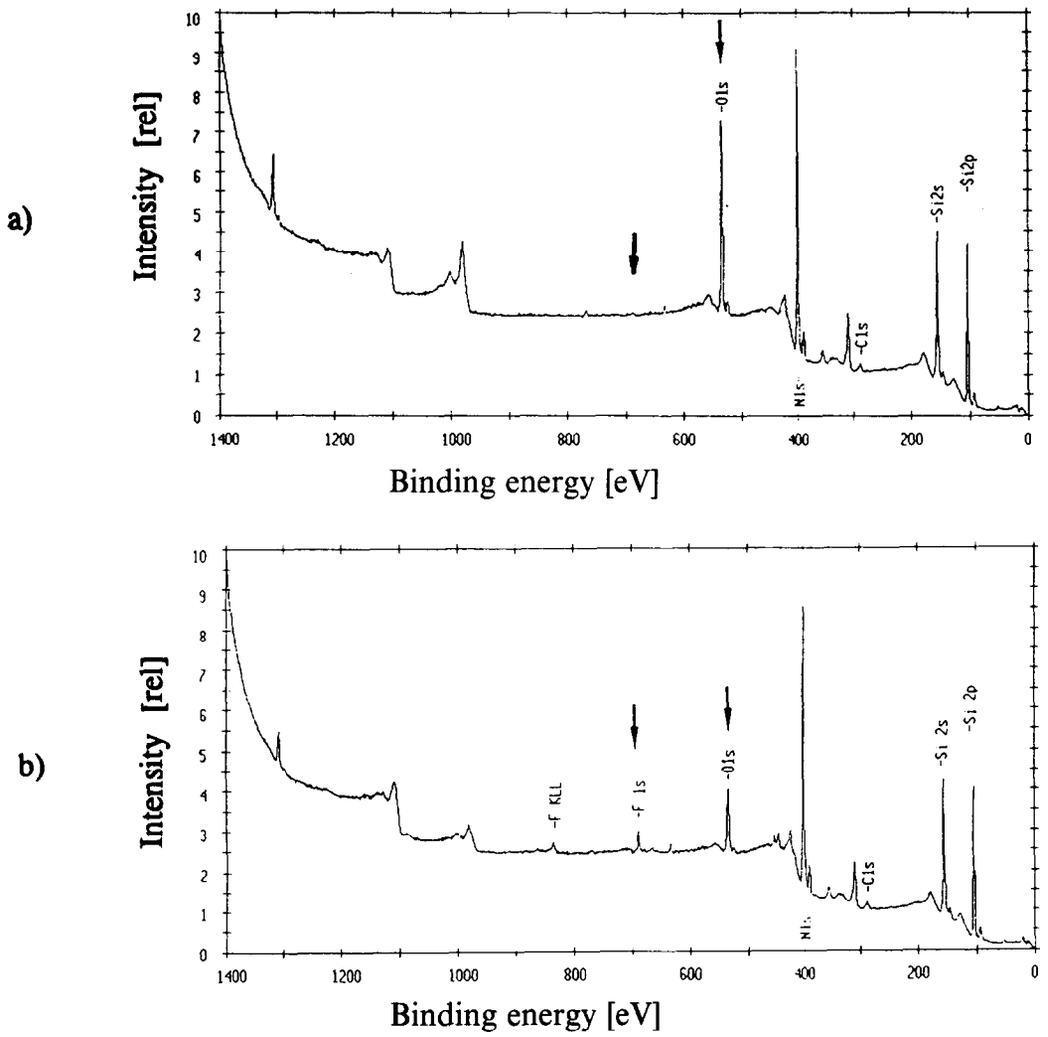

Fig. 2. XPS spectra of two silicon nitride powders with (a) high (UBE SN-E10) and (b) low (Denka SN-9FW) oxygen content.

parameters (chemical shift). XPS is therefore a powerful tool for the identification of chemical compounds and the modification of the electronic structure. A limitation, however, is the overlapping of several bonding states of different compounds.

In the case of the Si_3N_4 powders, a correlation between the XPS data and the TEM studies was found (Figs 2 and 3). The Denka powder SN-9FW reveals a lower oxygen concentration at the surface compared to the powder UBE SN-E10. The low oxygen content connected with the detection of fluorine is obviously caused by HF treatment of the powder. The result coincides with the thickness of the amorphous oxide layer in Fig. 3. The evaluation of the silicon peak in Fig. 4 shows the amount of oxidized Si (SiO_2 at 104·4 eV) in reference to the nitrogen bonded Si (Si_3N_4 at 102·8 eV). This proves that the Si_3N_4 powder synthesized by diimide precipitation has a higher amount of an oxidized phase on the particle surface compared to the Si_3N_4 powder synthesized by direct nitridation (followed by HF treatment). The essential point is that (because of the reaction of HF with the silanol groups) high fluorine contents cause a reduction in the number of OH groups.

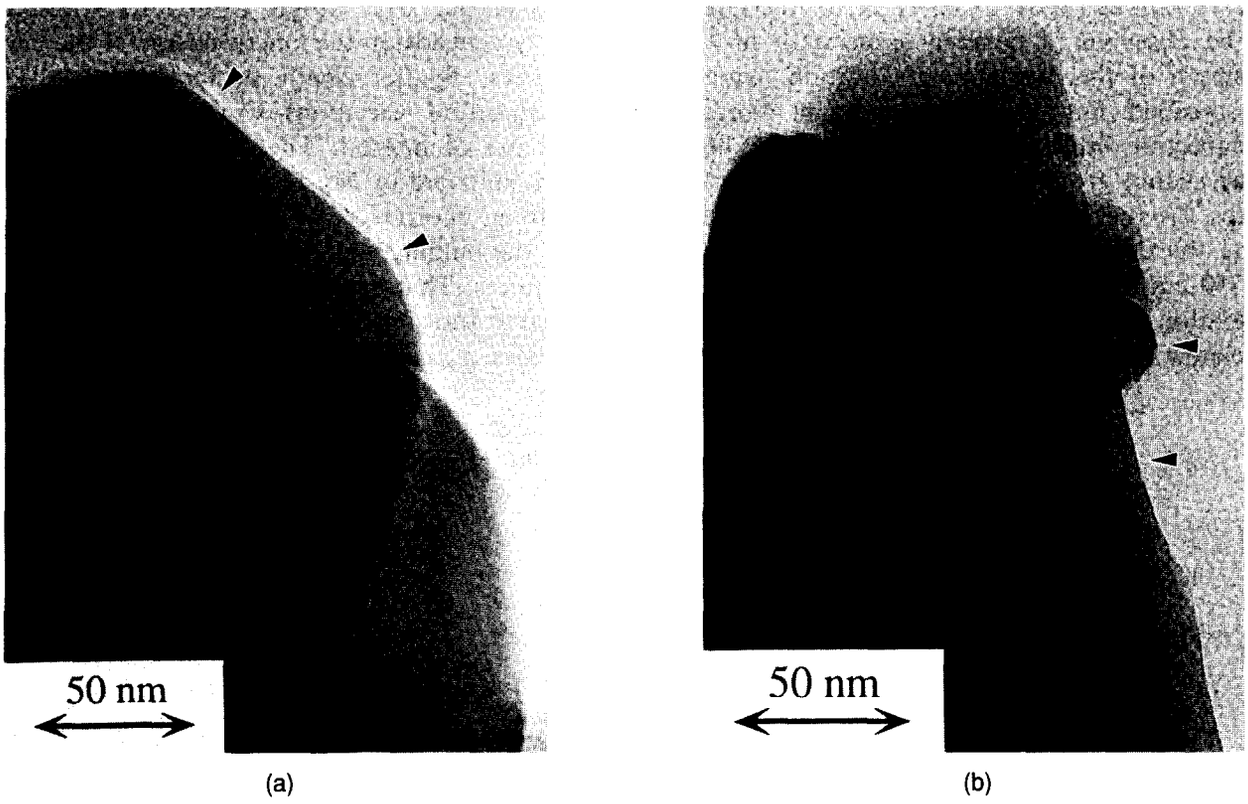

Fig. 3. TEM micrographs of Si_3N_4 particles with (a) a relatively thick and (b) a thin amorphous surface layer. The Si_3N_4 powders are synthesized by (a) diimide precipitation and by (b) direct nitridation.

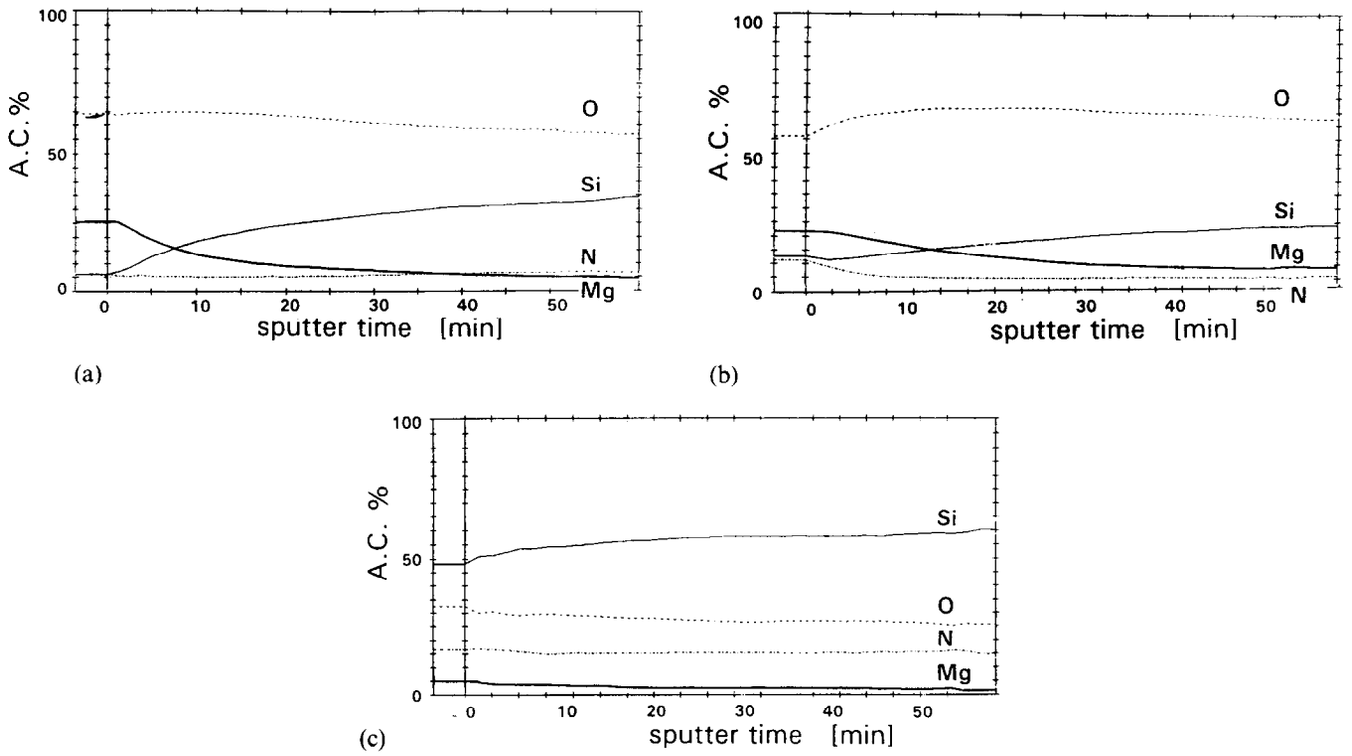

Fig. 5. XPS sputter depth profile measurements (concentration of Si, O, N and Mg as a function of sputter time) of Si_3N_4 powders doped with 2 wt% Mg: (a) chemically doped UBE SN-E10 (high number of OH groups); (b) chemically doped Denka SN-9FW (low number of OH groups); (c) mechanically doped UBE SN-E10.

In Fig. 5, the results of the XPS sputter depth profile measurements of silicon nitride powders, which are chemically and mechanically doped, are presented indicating the Mg-, Si-, O- and N-concentrations. The variation of the element concentration versus sputter time is different for the three

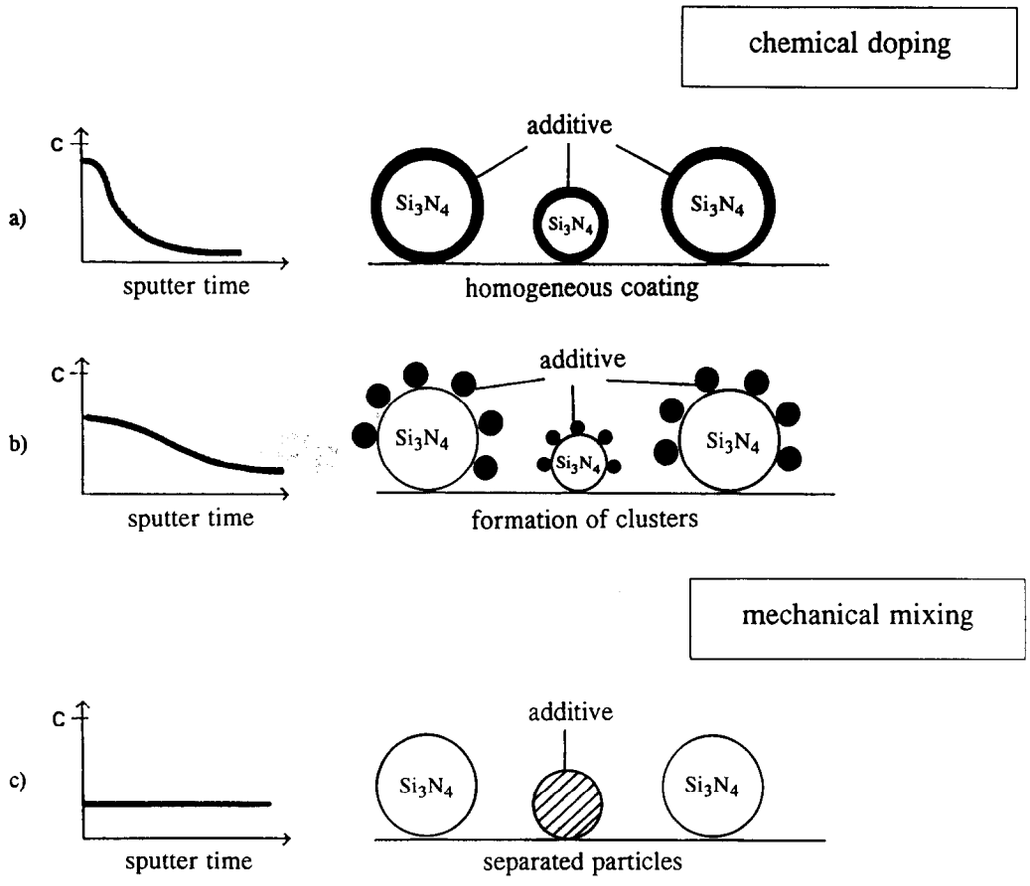

Fig. 6. Model of (a) layer-distribution (additive-coated Si_3N_4 particles), UBE SN-E10; (b) cluster-distribution (additive clusters on Si_3N_4 powder surface), Denka SN-9FW; (c) particle-distribution (additive-particle and Si_3N_4 particles), based on the sputter depth profiles of the dopant element (here schematic; experimental results see Fig. 5).

powder mixtures. From these results, information about the additive distribution in the three systems may be deduced (Fig. 6): a layer distribution (Fig. 6(a)), a particle–particle distribution (Fig. 6(c)) or, as a transition stage between these two, a cluster-like distribution of the dopant element at the powder surfaces (Fig. 6 (b)). For the mechanical doping of raw materials with metal oxide particles, the element concentrations remain mainly unchanged during sputter depth profile measurements because of the simply mixed particles. Powders doped with magnesium methoxide show in the surface-near region a higher magnesium content compared with the added total concentration.

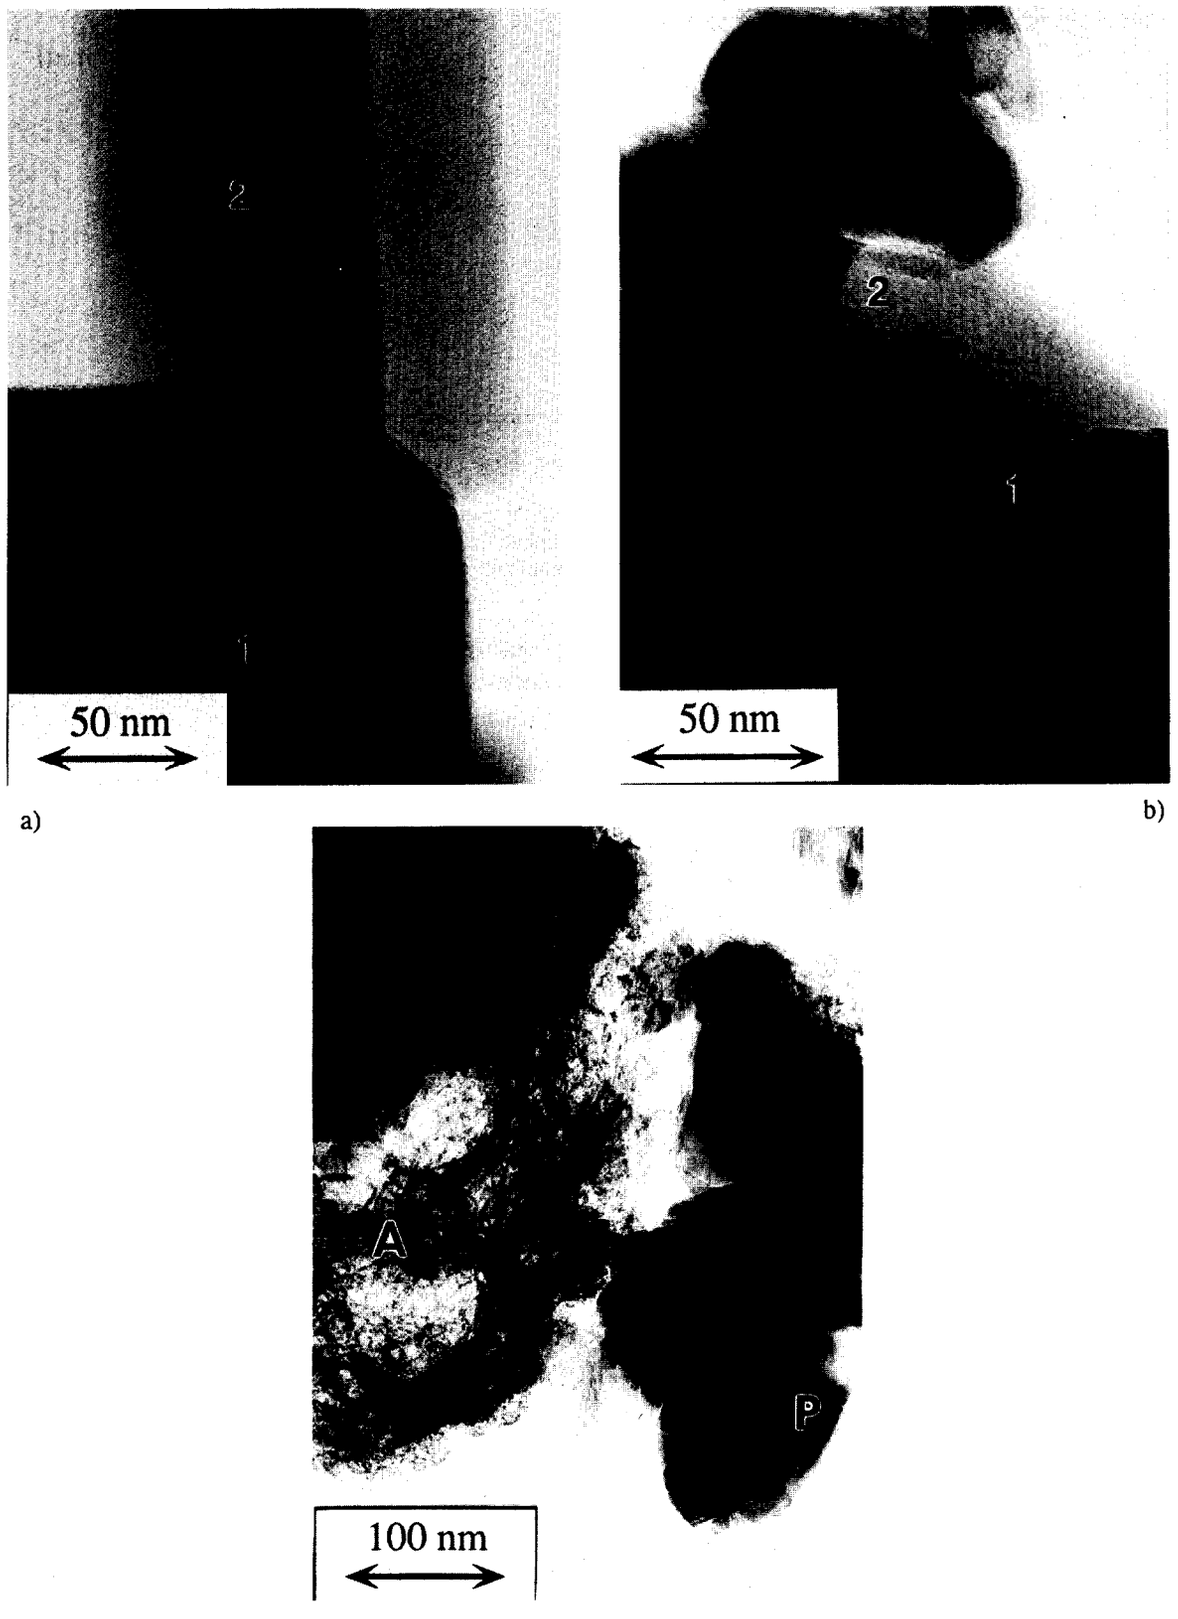

Fig. 7. TEM micrographs of various silicon nitride powders doped with 2 wt% Mg: (a) Si_3N_4 UBE SN-E10, particles 1 and 2; (b) Si_3N_4 HCST M 11, particles 1 and 2; (c) Si_3N_4 Denka SN-9FW, amorphous region A and particle P.

The magnesium concentration decreases with increasing sputtering time. This behaviour may be interpreted in terms of a layered coating or cluster-like doping of the single powder particles with the dopant metal. The higher the slope of the curve Mg = f (sputter time) the more the doping is approaching the layer-like coating.

The results show that the powder UBE SN-E10 with a higher amount of surface-OH-groups reveals a stronger decrease of the magnesium intensity compared to the powder Denka SN-9FW with a lower fraction of surface-OH-groups (see Figs 1 and 5), indicating the desired layer-like doping of each particle.

3.3 Analytical transmission electron microscopy

High resolution and analytical transmission electron microscopy (TEM) offers with extreme lateral resolution the unique possibility for structural, morphological and analytical characterization of powders.[14,15] By using TEM and EDS the local amount of magnesium in the powders was analyzed. Figure 7 shows TEM-micrographs of various silicon nitride powders doped with 2 wt% magnesium; Fig. 8 gives the results of EDS measurements. In the case of the Denka SN-9FW powder doped with 2 wt% Mg, a much higher content of magnesium was found in the amorphous regions (precipitated Mg compound) compared to the Si_3N_4 powder particles (see Figs 7(c) and 8(c)). In contrast to the Denka powder no amorphous region between the particles was observed in the powder mixtures of Si_3N_4-Starck M11 and Si_3N_4-UBE SN-E10 doped with 2 wt% Mg (see Figs 7(a) and 7(b) as well as Figs 8(a) and 8(b)). In these cases, particularly for UBE SN-E10,

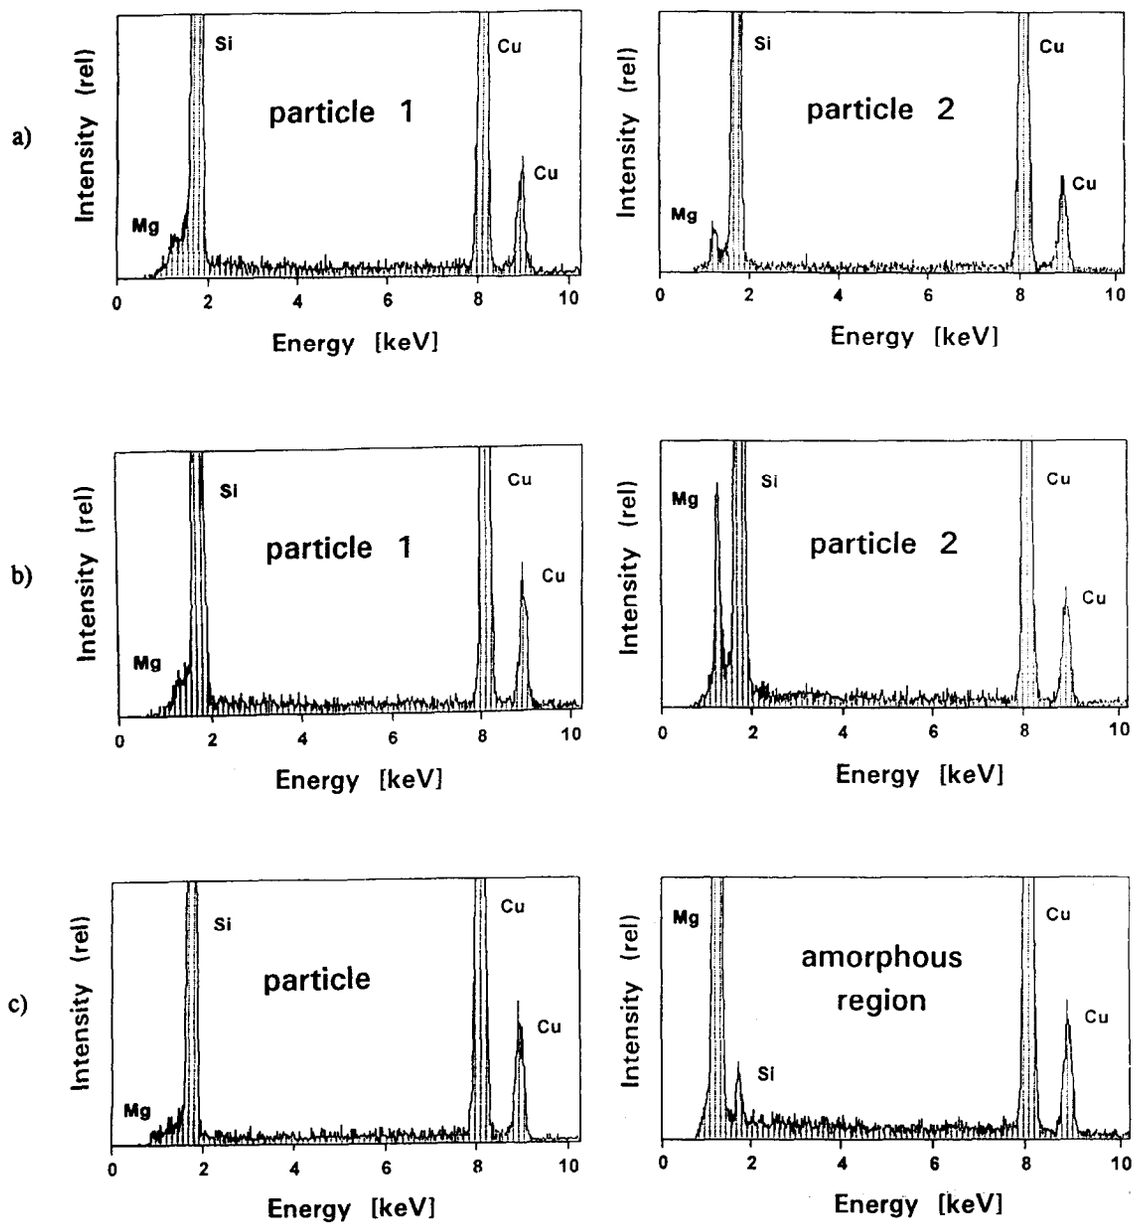

Fig. 8. EDS spectra on local sites of silicon nitride particles doped with 2 wt% Mg (Cu from copper grid): (a) Si_3N_4 UBE SN-E10; (b) Si_3N_4 Starck M 11; (c) Si_3N_4 Denka SN-9FW.

a more homogeneous distribution of the sintering aid was obtained. The reason is the relative high number of silanol groups on the surface as indicated in the FT-infrared spectra (see Fig. 1).

4 Conclusions

The dopant-technique involving organometallic compounds (strong alkaline reagents) provides a more homogeneous distribution of additives like magnesium. The use of analytical transmission electron microscopy, photoelectron spectroscopy and infrared spectroscopy allows an improved characterization of ultra-fine and doped sintering powders. The correlation of the results of the different analytical methods permits an interpretation about the quality of the distribution of sintering aids in ceramic raw materials. From the variation of the element concentration versus sputter time the distribution of the additives in the powder mixtures can be deduced, e.g. layer-like distribution, particle–particle distribution or a transition stage between these two cases, a cluster-like distribution of the additive on the powder surface.

The degree of homogeneity that can be achieved with the aim of eventually producing continuous thin coatings is strongly dependent on the number of OH groups (silanol groups, adsorbed water) on the powder particle surface which are controlled by the type of the Si_3N_4 powder and the pre-treatment as well as the amount of sintering additives. The number of silanol groups cannot be strongly correlated to the total oxygen content in the powders. However, a large specific surface area of the powders and a relatively high amount of oxygen at the particle surface is in general an advantage. In this connection it is important to note that fluorine (because of the reaction of HF with the silanol groups) results in a reduced number of silanol groups.

Based on the character of element distribution as a function of the number of surface groups, the dopant content and the test parameters, three idealized basic models may be deduced:

- a high number of OH-surface groups and low dopant content for dry powders and water-free suspension media result in a layer-like distribution of the sintering additive which is desirable;
- a low number of OH-surface groups and high dopant content for dry powders and water-free suspension media lead to amorphous precipitation of the dopant;
- a number of OH-surface groups nearly equal to the dopant content results in a domain structure of the additives.

In this scope it should be mentioned that in the case of a low number of OH groups relative to the amount of the dopant compound, and small amounts of water in the suspensions (powders with adsorbed water and/or water-containing suspension media) a domain structure of additives is enhanced.

The methodology is not restricted to the described powders, but also appreciable for other oxidic and non-oxidic raw materials. Moreover, it is suited for doping with more than one metal component, especially for low concentrations.

Abstract

The structural evolution of SiC precursors prepared from tetramethoxysilane (TMOS) and phenol resin by H_2O polymerization and heat-treated between 80 and 1400°C was investigated by X-ray diffractometry (XRD), large-angle X-ray scattering (LAXS), transmission electron microscopy (TEM), and by ^{29}Si and ^{13}C nuclear magnetic resonance spectroscopy (NMR).

After hydrolysis and drying at about 80°C, the samples structurally consist of domains of partially hydrogenated silica and of coexisting phenol resin. Heat-treatments carried out on the predried material yield different stages of structural evolution, though the precursor is non-crystalline throughout the whole temperature field investigated:

— Stage I (≤500°C): gradual temperature-dependent decomposition of phenol resin and simultaneous dehydrolysis of silica.

— Stage II (≥500–≤1400°C): breakdown of the local structural order of phenol resin and formation of C domains with graphite-type short-range-order. C coexists with non-crystalline SiO_2 containing low amounts of OH-groups. The C and SiO_2 domains up to ≈ 1000°C are extremely small (≤1 nm). At higher temperatures, C and SiO_2 domains become larger (≈ 2–3 nm at 1400°C) and develop partial ordering of the short-range structure.

1 Introduction

Different routes have been used to produce SiC, starting with metal organic materials. In an early work Prochazka[1] synthesized β-SiC powders by vapor phase decomposition of halogenated silanes. SiC synthesis by laser or plasma driven CVD methods have also been reported.[2,3] The most widely studied SiC synthesis process using metal organic starting materials is pyrolysis of polysilanes and polycarbosilanes.[4–6] Zhang *et al.*[7] mentioned in a recent paper that the thermal decomposition of polymethylsilane to polycarbosilane takes place at 400°C. Above this temperature a hydrogenated non-crystalline SiC-phase is being formed, transforming to β-SiC at about 1000°C with some small amount of coexisting α-SiC. β-SiC powders can also be processed from tetramethoxysilane and phenol resin by H_2O polymerization.[8] The reaction is believed to take place through an intermediate non-crystalline precursor stage consisting of SiO_2 plus C. Reaction of SiO_2 with C to SiC was observed above about 1200°C. The present study provides additional information on the structural development of the latter precursor prior to SiC crystallization. Nuclear magnetic resonance spectroscopy, X-ray diffraction, transmission electron microscopy, and the large-angle X-ray scattering methods have been used to solve the problem.

2 Processing Conditions

SiC precursors were prepared from tetramethoxysilane ($Si(OCH_3)_4$, TMOS Trichemical Co., Japan), and resol-type phenolic resin (phenol formaldehyde condensate, J-325, Dainippon Ink and Chemicals, Inc., Japan). The molar ratio of water to alkoxide in the starting admixture was 1. The TMOS is 6 N pure and yields SiO_2 after polymerization. The phenolic resin has a molecular weight of 600–650 g/mol. It is thermally set to

polymer resin below 80°C and it transforms to an amorphous carbon at temperatures higher than about 500°C. The carbon yield from the phenolic resin is 35·4 wt% after heat-treatment at 1000°C in N_2 atmosphere. TMOS and phenolic resin were mixed with H_2O and ethyl alcohol, with a weight ratio of TMOS and phenol resin of 1:0·76 to form a gel. After forming a gel by polymerization, the admixture was dried at about 80°C in a laboratory furnace. The resulting product (designated as 'as-received material') appears as a dark brown transparent solid.

The as-received material was heat-treated for 30 min in the temperature range between 300 and 1750°C in flowing N_2 gas. A tabulation of investigations carried out with various samples is given in Table 1.

The plot of weight losses versus heat-treatment temperatures shows that there are 3 distinctive stages leading to SiC formation. During the first stage, from the as-received state to about 500°C,

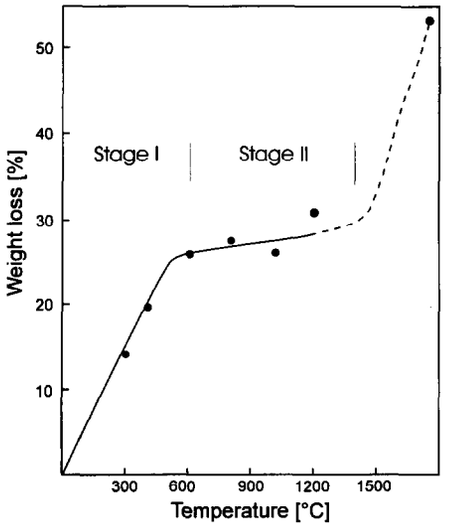

Fig. 1. Weight loss of the as-received SiC precursor material plotted against heat-treatment temperature.

the weight loss increases gradually with temperature. There is no change during the second stage between 500– ≈1400°C. The third stage between 1400 and 1750°C shows again a strong temperature dependency of weight loss (Fig. 1).

3 Experimental Procedure

3.1 X-ray diffractometry (XRD)

Powder XRD studies were carried out at room temperature with a computer–controlled Siemens D5000 powder diffractometer (CuK_α-radiation). The diffractograms were recorded in the 10 to 80° 2θ-range in the step-scan mode (5 s/0·01°, 2θ).

3.2 Large-angle X-ray scattering (LAXS) measurements

The diffuse spectrum scattered by the sample irradiated with graphite-monochromatized molybdenum K_α radiation was obtained by using an automatic diffractometer.[9] 500 intensities corresponding to equidistant s points ($s = 4\pi(\sin\theta/\lambda)$, $\Delta s = 0{\cdot}035363$) were collected in the range $2° < \theta < 65°$ (2θ = diffraction angle). The stability of the X-ray flux and of the sample was checked by frequent repetition of measurements at angles conveniently spread out in the θ range. All measurements were carried out at 22°C.

Scattered intensities were corrected for polarization and absorption effects (namely $I_c(s)$), then normalized by comparison, in the vicinity of high θ angles, with the sum of coherent and incoherent independent intensities. The normalization factor K derived from this data treatment is in good agreement with those determined from Norman's[10] and Krogh-Moe's[11] methods. Atomic scattering factors, $f_i(s)$ for all the atoms, were those proposed by Cromer and Waber.[12] Compton diffusion factors were taken from tables published by Cromer.[13]

Reduced intensities, $I(s)$, were calculated as follows:

$$I(s) = KI_c(s) - \Sigma_i n_i [(f_i(s) + \Delta f'_i)^2 + \Delta f''^2_i + I_{i(inch)}(s)]$$

where K is the normalization constant, $I_c(s)$ is the corrected intensities, n_i is the number of atoms f_i in the chosen unit volume, $f_i(s)$ is the atomic scattering factor, $\Delta f'_i$ and $\Delta f''_i$ are the real and imaginary parts of the anomalous dispersion, and $I_{(inch)}(s)$ is the total incoherent radiation for the atom i.

The radial distribution $D(r)$ is then expressed under the form:

$$D(r) = 4\pi r^2 \rho_o + 2\tau\pi^{-1} \int_i^s si(s)M(s) \sin(rs)\, ds$$

where ρ_o is the average electronic density of the sample and $M(s)$ is a modification function defined by $f^2_{ni}(O)/f^2_{ni}(s)\exp(-s^2/100)$.

All calculations were performed by using our

LASIP program[13] the structure of which is similar to the KURVLR program of Johansson and Sandström.[14]

3.3 Nuclear magnetic resonance (NMR) spectroscopy

MAS NMR measurements were carried out using a Bruker MSL 300 spectrometer operating at 75·4 MHz (^{13}C), and 59·4 MHz (^{29}Si).

^{13}C CP TOSS (CP = Cross polarization, TOSS = Total suppression of spinning sidebands) NMR spectra were acquired with typical cross polarization times of 1 ms and recycle delays of 1 s. About 300 scans were accumulated. The MAS frequency was 3·2 kHz. Additionally, single pulse ^{13}C experiments were carried out for the sample heat treated at 800°C (repetition time: 20 s, number of scans: 1500).

Similar conditions were applied to ^{29}Si measurements. ^{29}Si CP TOSS investigations, and, additionally, a series of single pulse spectra were taken in order to estimate the relative amounts of silica in the different Q^n units. Chemical shifts are referenced to TMS both for ^{13}C and ^{29}Si NMR.

3.4 Transmission electron microscopy (TEM)

TEM was performed with a Philips EM430 analytical microscope (300 kV accelerating voltage, LaB_6 filament). Thin foils were prepared using a tripod polisher and subsequent ion beam milling.

4 Results

4.1 X-ray diffractometry (XRD)

The XRD patterns of the SiC precursors show that up to 1400°C the material is non-crystalline. At 1750°C (ST16-17, Table 1) it consists of β-SiC and a trace of graphite.

Despite being non-crystalline, the XRD diagrams of the SiC precursors below 1400°C exhibit very broad diffraction maxima near 3·95 Å. Another very broad and low intense diffraction maximum appears near 2·08 Å. It gradually becomes more intensive with the increase of the annealing temperature.

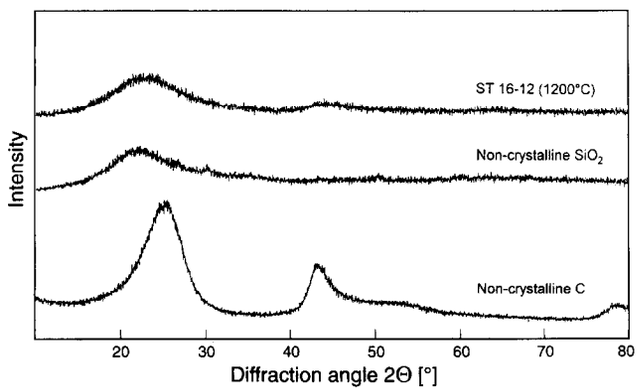

Fig. 2. XRD diagrams of precursor sample ST16-12, heat-treated at 1200°C (Table 1). The XRD patterns of non-crystalline SiO_2 and C are given for comparison.

4.2 Differential radial electron distribution functions (Rdf)

LAXS raw intensity curves of the as-received powder (ST16) and of the sample heat-treated at 1200°C (ST12, Table 1) are drawn in Fig. 3. The LAXS patterns yield strong and broad peaks near 3·95 Å, and weak signals near 2·08 and 1·22 Å. The intensity of the latter peaks increases with temperature. Rdf curves of the as-received and of

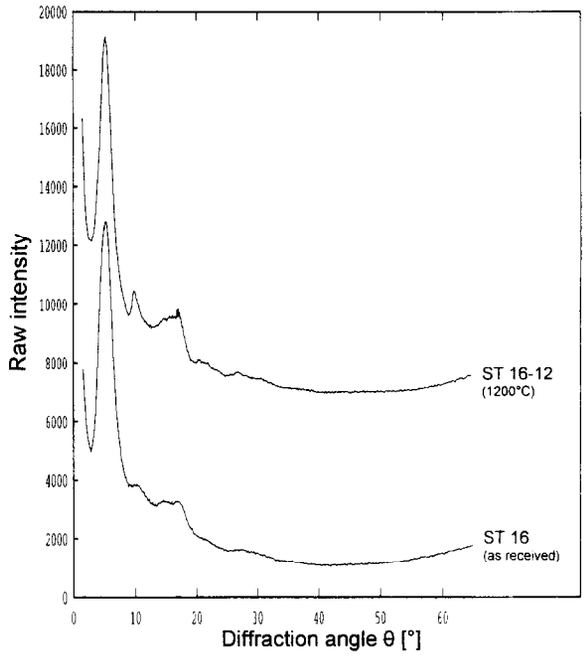

Fig. 3. LAXS raw intensity curves for the as-received sample (ST16) and for the sample heat-treated at 1200°C (ST16-12, Table 1). $Mo_{K\alpha}$ radiation.

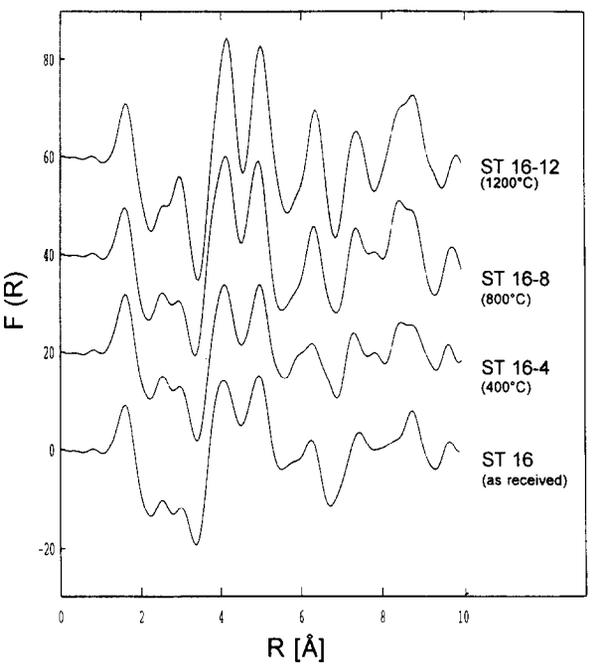

Fig. 4. Differential radial distribution functions (rdf) for the as-received sample (ST16), and for samples heat-treated at 400°C (ST16-4), 800°C (ST16-8), and 1200°C (ST16-12, Table 1).

heat-treated samples show similar features. They can roughly be divided into two domains: below and above R = 5·5 Å (Fig. 4).

- In the first range (R < 5·5 Å), the peaks can readily be assigned to Si–O (1·6 Å), O–O (O_1-Si_1–O_2, 2·6 Å), Si_1–Si_2 (Si_1–O_1–Si_2, 3·3 Å), Si–O_2 (Si_1–O_1–Si_2–O_2, 4·1 Å), and Si_1–Si_3 (Si_1–O_1–Si_2–O_2–Si_3, 5·0 Å). These peak positions lie very close by to those observed for a pure SiO_2 glass.[15-16] The first peak can be taken as internal standard in order to compare the signal intensities, because it always corresponds to the SiO_4 contribution. The peaks at 4·1 Å and 5·0 Å have considerably higher intensities in our samples than in pure SiO_2 glass, except for the samples heat-treated at T ≤ 400°C (samples ST16 and ST16-4, Table 1). This indicates that the short-range-order of the SiO_2 compound is much more regular in our sample as compared to SiO_2. The increase of the intensity of the Si_1–Si_2 peak at 3·3 Å, especially between 800 and 1200°C (samples ST16-8 and ST16-12, Table 1), corresponds to an increase in the size of the partially ordered SiO_2 domains, or to a more narrow distribution of the O–Si–O bonding angles.
- The second range (R > 5·5 Å) in the rdf curves is more difficult to understand, since the peaks cannot be assigned to a specific interaction, but correspond to superpositions of different contributions. However, the main features are also very similar to those observed for pure SiO_2 glass. The samples heat-treated at 800 and 1200°C show an increase of the peak intensities corresponding either to a more regular middle-range-order or to an enlargement of the ordered domains.

4.3 Transmission electron microscopy (TEM)

Bright-field micrographs of samples heat-treated between 1000 and 1400°C appear almost featureless. Dark-field images, however, obtained by a section of the d = 2·08 Å diffraction ring corresponding with non-crystalline carbon (Fig. 5) exhibit remarkable differences between the 1000°C-sample and specimens heat-treated at higher temperature. The latter show domains of few nanometres (Fig. 5), which are assumed to correspond with areas of carbon enrichment. The domain size does not increase significantly from 1200 to 1400°C. No domain-like contrast is detectable in dark field images of samples heat-treated at 1000°C leading to the assumption that carbon clusters, if they exist, are smaller than 1 nm.

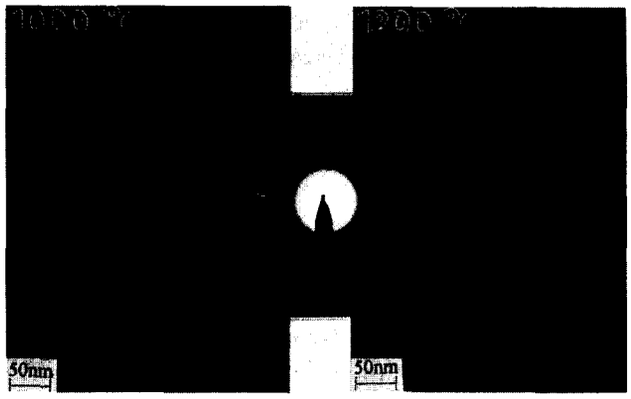

Fig. 5. Dark-field transmission electron micrographs of SiC precursor heat-treated at 1000°C (left) and 1200°C (right) generated by the diffraction ring of d = 2·08 Å (arrow). Bright areas correspond with carbon clusters.

4.4 Nuclear magnetic resonance spectroscopy (NMR)

Figure 6 shows the ^{13}C CP TOSS spectrum. The ^{13}C resonances of the sample ST16 (as-received) and that heat-treated at 300°C (ST16-3, Table 1) can be assigned quite easily using the results of Sojka *et al.*.[17] The signals originate from phenol resin which was used to prepare the samples. Only the low intensity components between 60 and 70 ppm (indicated by stars in Fig. 6) are not yet fully

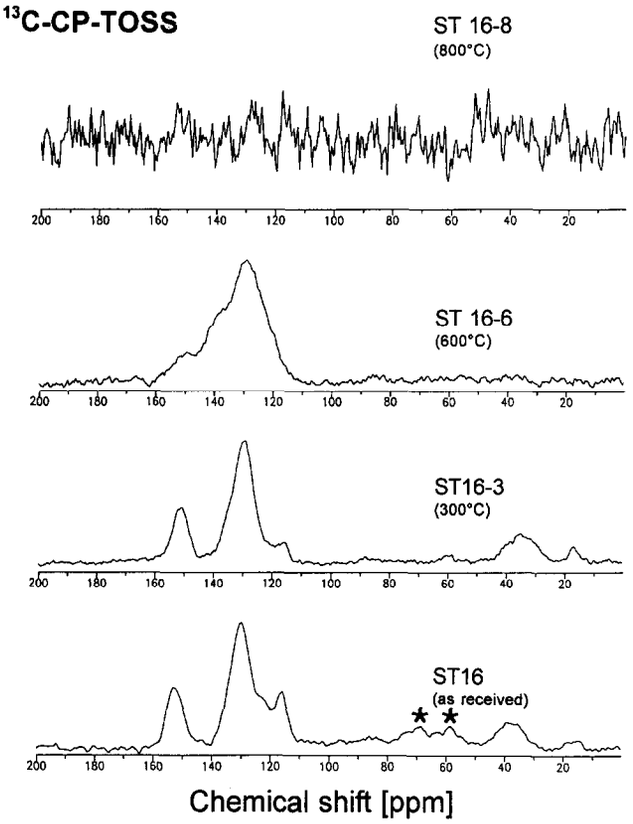

Fig. 6. ^1H–^{13}C CP TOSS NMR spectra (^1H–^{13}C Cross polarization spectra with total suppression of spinning sidebands) of various ST16 samples (Table 1). The spectrum at the bottom corresponds to that of phenol resin (only the two low intensity resonances marked by the stars are not identified as yet, see also text). Phenol resin is decomposed at temperatures above 300°C. At 600°C only sp^2-hybridized C is found. Cross polarization of the sample dried at 800°C gives no signal at all. Hence, there are no CH_x units left.

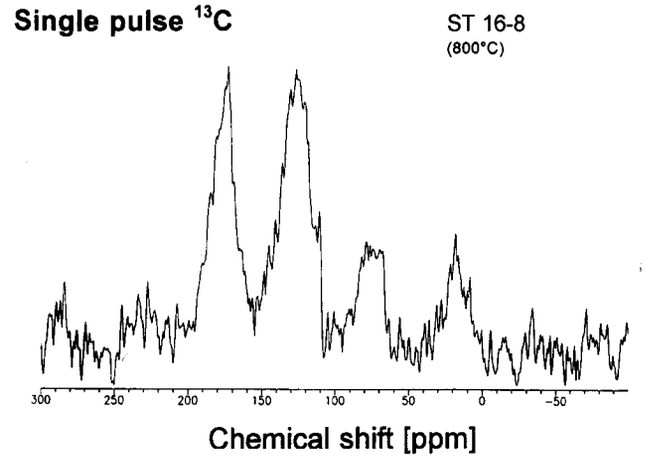

Fig. 7. Single pulse ^{13}C MAS NMR spectrum of sample ST16-8, heat-treated at 800°C (Table 1). The lineshape consists of only one resonance (δ_{iso} = 130 ppm) referring to sp^2-hybridized C with a series of spinning sidebands centered at 180, 75 and 20 ppm.

understood. It is likely that they represent CH_2–O and CH–O units. Heat-treatment of the samples up to 600°C (ST16-6) causes the phenol resin to decompose. A broad resonance at about 130 ppm is found, indicating sp^2-hybridized C. The C is still cross polarized by residual H atoms. However, after heat-treatment of the samples at 800°C (ST16-8) no CP signal is detected, which means that the remaining protons are not associated with C. Single pulse ^{13}C measurements of that sample give only a resonance signal for sp^2-hybridized C with the MAS center band at 120 ppm. The other lines are the spinning side bands equally spaced by the MAS spinning frequency of 4 kHz. They reflect the typical chemical shift anisotropy of about 200 ppm of non-protonated sp^2-hybridized carbon (Fig. 7). There is no hint for sp^3-hybridized carbon.

The situation is different for ^{29}Si NMR. The CP spectra shown in Fig. 8 reveal three different structural units: Q^4 (–112 ppm, SiO_4), Q^3 (–102 ppm, SiO_3OH), and to a minor extent Q^2 groups (–92 ppm, $SiO_2(OH)_2$). In contrast to ^{13}C NMR there is still a CP signal at an annealing temperature of 800°C (ST16-8, Table 1). This indicates that apparently some trace of H atoms is incorporated in the SiO_2 network, forming Q^3 units. The major amount with Q^4 groups, of course, is not cross-polarized. This can clearly be identified by single pulse experiments as shown in Fig. 9 for samples heat-treated at 300 and 800°C. Spectra of single pulse experiments are difficult to deconvolute into three Gaussian lines. But clearly a continuous decrease of the ratios $Q^2:Q^3:Q^4$ is found with increasing temperatures. Estimated ratios are

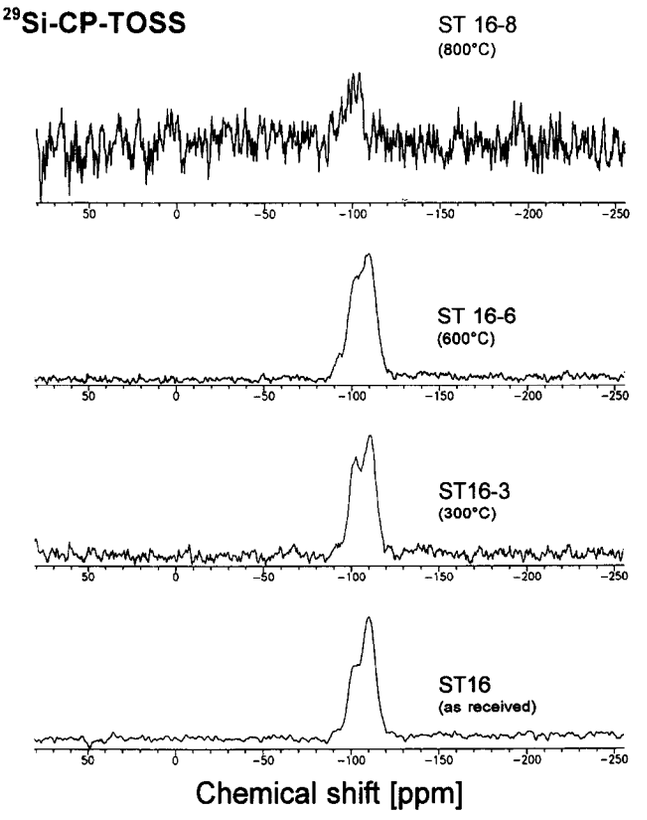

Fig. 8. ^{1}H–^{29}Si CP TOSS NMR spectra (^{1}H–^{29}Si Cross polarization spectra with total suppression of spinning sidebands) of various ST16 samples (Table 1). The spectra for the as-received sample and for the sample heat-treated at 600°C are similar and show Q^4 (SiO_4), Q^3 (SiO_3OH), and a small Q^2 ($SiO_2(OH)_2$) signals (for details see text). At the highest temperature (800°C, ST16-8) only a very weak Q^3 signal is found.

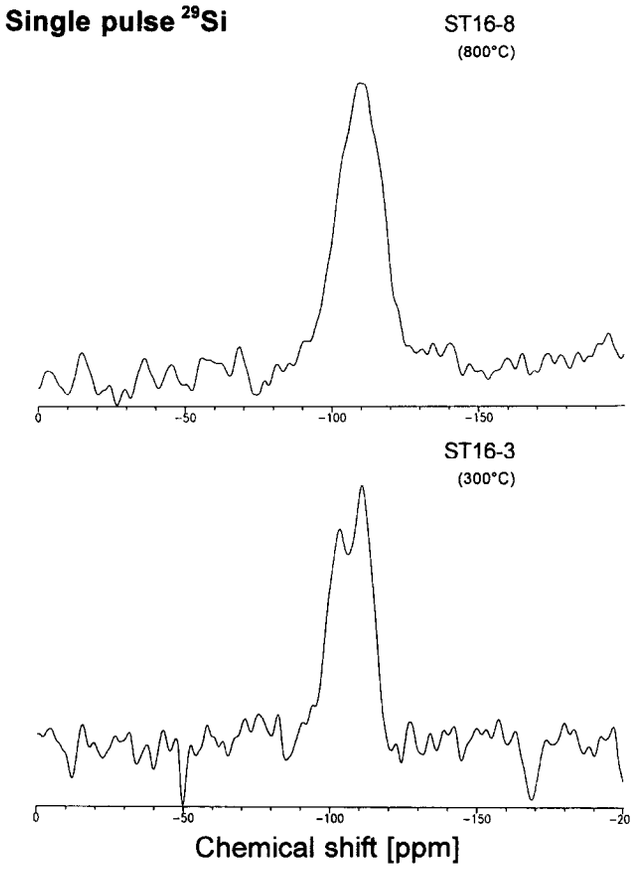

Fig. 9. Single pulse ^{29}Si MAS NMR spectra of the samples ST16-3 and ST16-8 heat-treated at 300 and 800°C, respectively (Table 1). The spectrum at the bottom clearly shows Q^3 (SiO_3OH) and Q^4 (SiO_4) groups in almost equal amounts, whereas only Q^4 units are present after heat-treatment at 800°C.

10:45:45, 5:30:65, and 0:10:90, for the 300, 600, and 800°C samples.

5 Discussion

The Si source material tetramethoxysilane (TMOS) transforms upon hydrolysis and drying at about 80°C to partially hydrogenated SiO_2 (ST16, Table 1). According to the ^{29}Si NMR spectrum, which is very similar to that of dried silica gels,[18] Si occurs as SiO_4 (Q^4), $SiO_3(OH)$ (Q^3) with isolated OH groups, and SiO_2 $(OH)_2$ (Q^2) with two OH groups.[19] There remains the question, whether OH groups are only located in the surface or if they also occur in the bulk of the material. We believe that OH groups are located at the surface and in the volume of the SiO_2 compound.[18] ^{13}C NMR spectra of the sample dried at about 80°C (ST16, Table 1) exhibit peaks which are attributed to phenol resin. Obviously there is no drastic change of the structural short-range-order of the C compound upon hydrolysis and drying the material.

Heat-treatment of hydrolized and dried as-received samples up to 1400°C exhibits 2 different stages in the structural development of the precursors, though all of them are non-crystalline throughout the temperature field investigated (Fig. 2).

Stage I (≤500°C)

Heat-treatment of the as-received material at temperatures to ≤500°C produces strong weight loss (Fig. 1), which is likely due to the gradual decomposition of the phenol resin. This is supported by ^{13}C NMR spectra which gradually and considerably change in this temperature region (Fig. 6). It is especially striking to note that the peaks previously present at about 18 and 35 ppm gradually disappear leaving a rather broad resonance pattern between 120 and 150 ppm in samples heat-treated at 600°C. Rdf curves of the SiC precursor heat-treated at 400°C (ST16-4, Table 1) can also be interpreted in a similar way. Intensities of all rdf peaks, except those at 2·5 and 3·3 Å, become weaker than the peaks of the as-received material (Fig. 4), indicating gradual decomposition of the local structural order in phenol resin.

^{29}Si NMR data (Fig. 8) indicate dehydrolysis of the SiO_x $(OH)_{4-x}$ network to take place. This is evidenced by the deconvolution of the spectra, exhibiting gradual disappearance especially of Q^2 $(SiO_2(OH)_2)$ units.

Stage II (≥500 – ≤1400°C)

Heat-treatment of the SiC precursor in the temperature range of reaction Stage II yields only little weight loss (Fig. 1). ^{29}Si NMR spectra (Figs 8 and 9) and rdf curves (Fig. 4) suggest that non-crystalline SiO_2 is a major compound of the precursors. According to ^{29}Si NMR data (Fig. 8) at 600°C some of the Si bonds are saturated by OH groups distributed throughout the SiO_2 network ('network modifiers'). At 800°C the occurrence of network modifying OH ions becomes less frequent, while at 1200°C the SiO_2 network is OH-ion free. The high intensity of short distance ($R < 5{\cdot}51$ Å) rdf peaks near 4·1 and 5·0 Å suggest that the SiO_2 domains above 400°C have a higher level of structural order than pure fused SiO_2 glasses. The increase of peak intensities in the far distance region ($R > 5{\cdot}5$ Å) of the rdf diagram is interpreted of gradually increasing middle-range-order and of growing sizes of the SiO_2 domains.

^{13}C NMR spectra samples heat-treated at temperatures ≥500°C (Figs 6 and 7) exhibit a complete breakdown of the remaining local structural order of phenol resin and formation of non-crystalline C with sp^2-hybridized graphite-like short-range-order. According to transmission electron microscopic observations the C domains are randomly distributed throughout the SiO_2 matrix (Fig. 5). At 1000°C C domains are below the microscopical resolution (≤1 nm). At 1200°C domain sizes become larger (2–3 nm) though no further increase is observed between 1200 and 1400°C.

Processes taking place at temperatures > 1400°C are beyond the scope of the present study. Referring to weight loss measurements (Fig. 1) and to literature data SiC is formed by reaction of C and SiO_2.[20] The homogeneous mixture of the highly reactive C and SiO_2 compounds yields high SiC formation rates. Ceramics produced from such SiC powders exhibit homogeneous and dense microstructures with favorable fracture toughness, especially in the presence of some finely dispersed graphite particles.[8]

(Received 6 October 1994; revised version received 3 February 1995; accepted 7 February 1995)

Abstract

This paper reports the ability to use a commercial polysilazane† as matrix precursor for the manufacture of ceramic matrix composites.

By pyrolysis under nitrogen in the temperature range 1000–1400°C this polysilazane leads to an amorphous silicon carbonitride with a ceramic yield around 65 wt%.

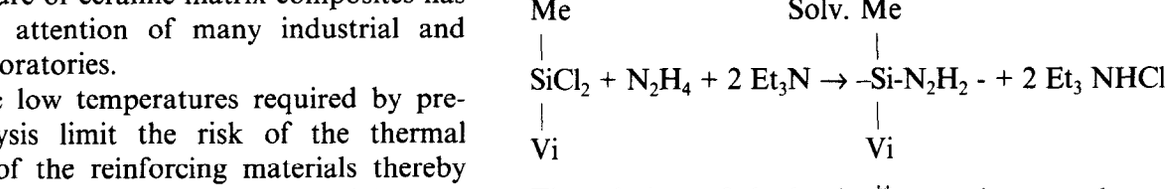
The rheological behaviour and the thermal decomposition of the polysilazane have been studied. Parameters for the impregnation and pyrolysis cycles required by the manufacture of composites are also proposed.

Introduction

For the last 20 years, the organometallic way for the manufacture of ceramic matrix composites has attracted the attention of many industrial and university laboratories.

Indeed, the low temperatures required by precursor pyrolysis limit the risk of the thermal degradation of the reinforcing materials thereby allowing a large panel of potential materials. Low temperatures also induce low energy costs.

Moreover, times required for composites manufacturing (a few days to few weeks depending on the pyrolysis temperature schedules) are significantly shorter than those needed by the Chemical Vapour Infiltration process (many months).



The basic process, using a serial of impregnation and pyrolysis cycles of a fibrous preform by the precursor, appears simple and does not require sophisticated and expensive equipment.[1]

Silicon based ceramics like SiC or Si_3N_4 can be obtained from polycarbonsilanes and polysilazanes.[2] Due to their high mechanical properties and high oxidation resistance, silicon nitride derived materials are interesting as a matrix for thermomechanical composites.[3]

Consequently, research on the synthesis of new polysilazane precursors and the development of a composites manufacturing process using such precursors present a high commercial interest.

1 Synthesis

The synthesis of the polysilazane has already been described in detail by C. Colombier.[4]
PYROFINE PV is a polyvinylsilazane obtained by polymerisation of vinylmethyldichlorosilane with hydrazine in presence of triethylamine.

The choice of hydrazine†† as nitrogen donor instead of ammonia, which is generally used, results in its higher functionality toward vinylmethyldichlorosilane.

For its part, the solvent is chosen among those in which both polysilazane, chlorosilanes and triethylamine are soluble and $(Et)_3NHCl$ is not.

The monomer condenses to form cyclic structures and by further condensation forms high molecular weight cyclic polymers (Fig. 1).

The typical elemental composition of the precursor is given in Table 1, oxygen originating from the hydrazine used for the synthesis:

††Liquide hydrazine, bp: 130°C.

Table 1.

	Si	*C*	*N*	*O*	*H*
wt%	31·5	37·2	20·3	3·2	7·8
at%	8·2	22·7	10·5	1·4	57·2

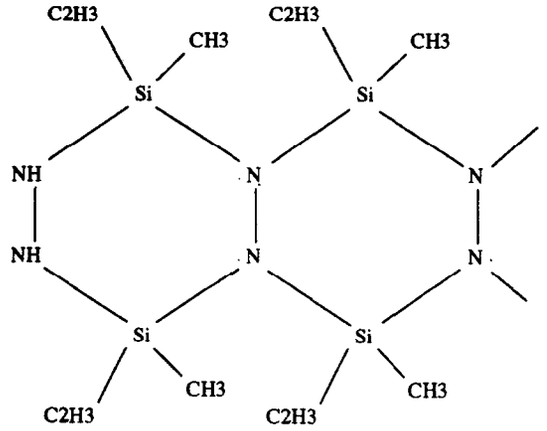

Fig. 1. Structure of the polysilazane.

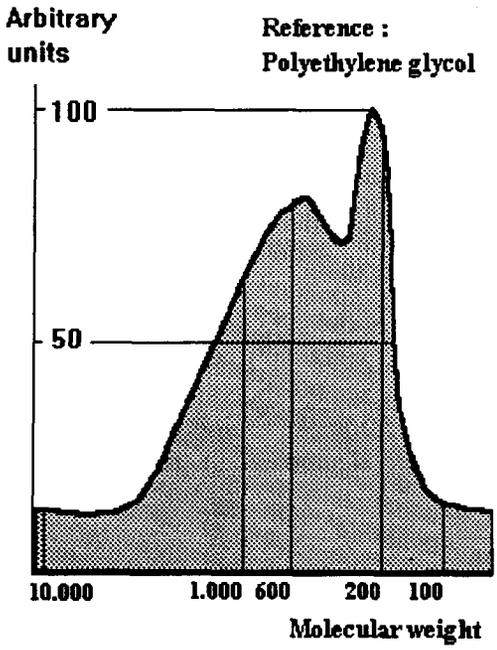

Fig. 2. Molecular weight distribution of the polysilazane.

The gel permeation chromatography shows the large molecular weight distribution of the precursor (Fig. 2). M varies from 0 up to more than 10 000 with a maximum in number between 200 and 1200 corresponding respectively to 1–6 elemental cycles. The average molecular weight in number is 500. A large amount of low molecular weight oligomers ($M < 100$) is also evident.

2 Rheology

At room temperature, the polysilazane is a high viscous liquid with a density close to 1. Upon heating up to 150°C its viscosity decreases with the increase in temperature (Fig. 3) and remains stable during numerous hours (Fig. 4).

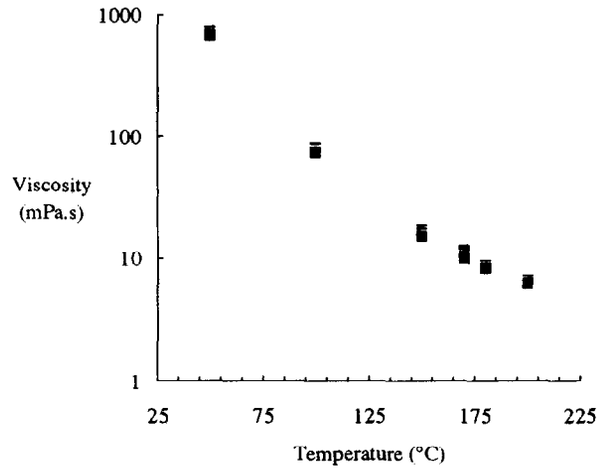

Fig. 3. Variation of the viscosity of the polysilazane versus temperature.

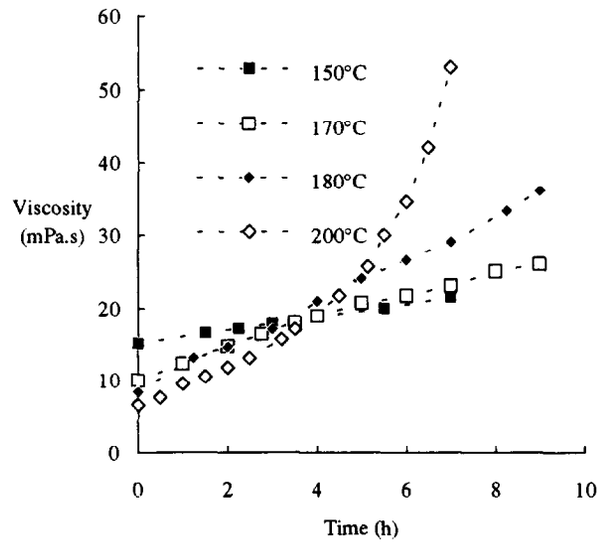

Fig. 4. Variation of the viscosity of the polysilazane versus time at different temperatures.

Above 150°C and up to 220°C, the viscosity still decreases versus temperature but increases quickly versus time. The low molecular weight oligomers may be evaporated or may condense to form longer chains. That increases the average molecular weight of the precursor and consequently, explains the variation of the viscosity versus time.

3 Evolution of the Polysilazane Versus Temperature

3.1 From room temperature up to 300°C

Below 150°C, no weight loss is observed on the TGA curve (Fig. 5, part I). Between 150 and 300°C a 15% weight loss is measured (Fig. 5, part II). The mass spectrometry coupled with the TGA indicates an ammonia release (Fig. 6) which could correspond to the condensation reaction:

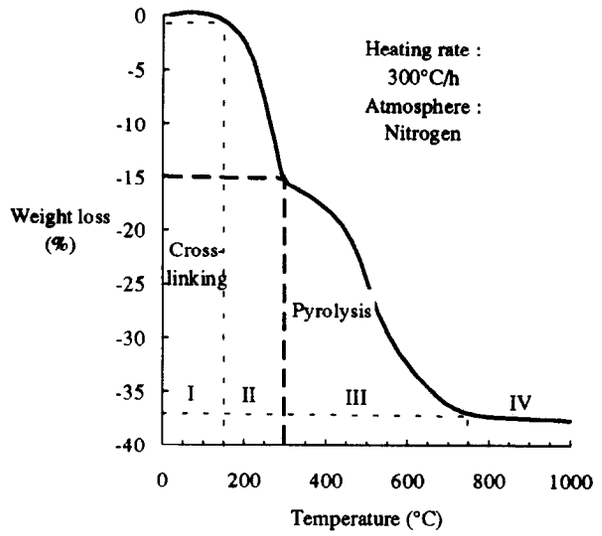

Fig. 5. TGA curve of the polysilazane.

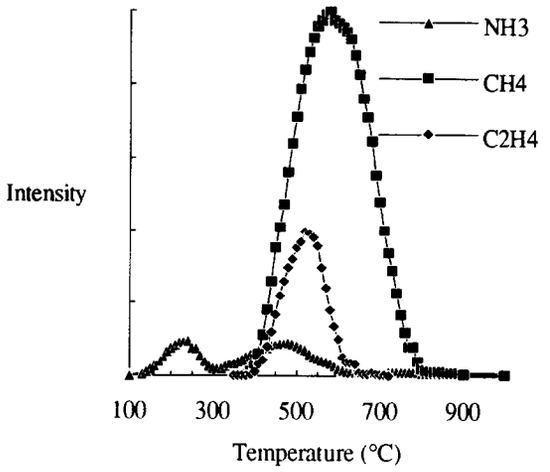

Fig. 6. Mass spectrometry associated to the TGA (Fig. 5).

$$2 \equiv Di\text{–}NH\text{–}NH_2 \rightarrow \equiv Si\text{–}NH\text{–}NH\text{–}Si \equiv + N_2H_4$$

Above 250°C, the hydrazine released may decompose to ammonia and nitrogen with a strong exothermic reaction (–336 kJ/mol):

$$3N_2H_4 \rightarrow N_2 + 4\ NH_3$$

The titrage by reaction in H_2SO_4 of the ammonia generated up to 300°C explains only 1–2% of the 15% weight loss measured by TGA. The evaporation of the light oligomers can explain the bulk of the weight loss. These oligomers are not observed by the mass spectrometry because they condense in the apparatus before the detection.

Between 220 and 300°C the precursor is progressively transformed from a soluble (in toluene) liquid into an unmeltable and insoluble solid.

Table 2.

Heating rate (°C/h)	*Temperatures (°C)*	*Holding time (h)*
100	20–130	0
5	130–*T*°C	1

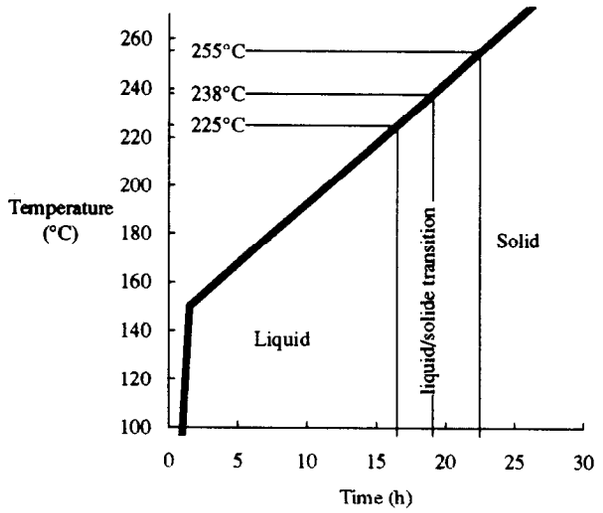

Fig. 7. Temperature range of the precursor cross-linking.

That is evidenced by successive heat treatments on the precursor using the following temperature schedule (Fig. 7 and Table 2):

T = 225°C; the product obtained is a high viscous liquid soluble in toluene.

T = 238°C; the product is solid, soluble in toluene, its melting point is about 100°C. Bubbles are observed on the surface of the sample.

T = 255°C; the product is solid, unmeltable and insoluble. Numerous bubbles are observed in the cross-section of the sample.

The ^{29}Si solid NMR confirms that the cross-linking is due to the opening of the vinyl groups.[5]

$\equiv Si\text{–}CH{=}CH_2$ transforms to $\equiv Si\text{–}CH\text{–}CH_2$

The liquid to solid conversion corresponding to the vinylic cross-linking combined with the generation of gases due to the condensation reaction and the oligomers evaporation, which leads to the

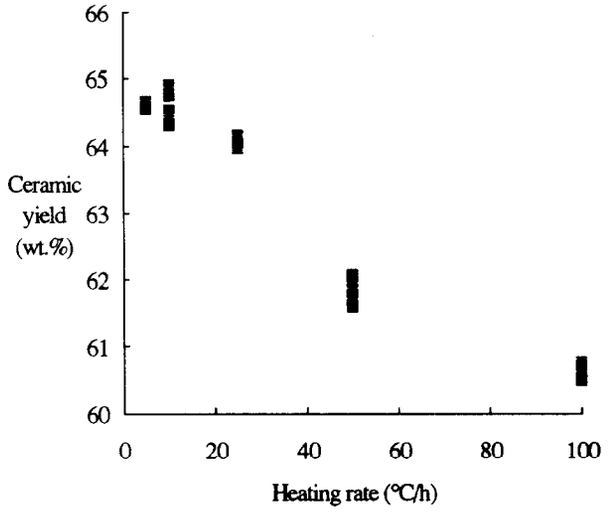

Fig. 8. Variation of ceramic yield at 1000°C versus the heating rate used during the cross-linking (temperature range 130–300°C) the heating rate used from 300–1000°C being 1000°C/h.

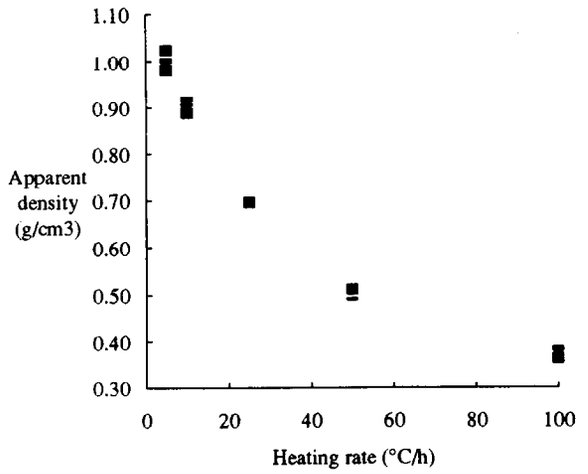

Fig. 9. Apparent density of the ceramic obtained after pyrolysis at 1000°C versus the heating rate used during the cross-linking (temperature range 130–300°C) the heating rate used from 300–1000°C being 100°C/h.

formation of foam, and after pyrolysis to high porous volume ceramics.

As it has previously been shown, the major part of the gas generated arises from the evaporation of the low molecular weight oligomers. This evaporation can be controlled by the heating rate used before and total solidification of the precursor. Indeed, using various heating rates between 130 and 300°C and then achieving the pyrolysis at 100°C/h between 300 and 1000°C we noted that the ceramic yield is higher, when the heating rate used is low.[6] (Fig. 8).

The decrease of the gas released during the solid liquid transition also reduces the foaming and then increases the apparent density of the ceramic residue (Fig. 9).

3.2 Above 300°C

Above 300°C the mineralisation starts. The weight loss between 300 and 800°C is 20–25% (Fig. 5, part III) and the gas release is maximum around 500°C. In the early stage of this step, the ammonia release remains high (Fig. 6) and could be explained by transamination reactions.[5,6]

$$\equiv Si\text{–}NH\text{–}NH\text{–}Si\equiv + \equiv Si\text{–}H \rightarrow \equiv Si\text{–}\underset{\displaystyle Si\equiv}{\overset{|}{N}}\text{–}Si\equiv + NH_3$$

Up to 600°C mainly methane but also methylene, propene and other unsaturated hydrocarbons are generated (Fig. 6).

Methane may originate from the decomposition of the methyl groups.[6]

$$\equiv Si\text{–}CH_3 \rightarrow \equiv Si^* + {}^*CH_3$$

$${}^*CH_3 \xrightarrow{\text{H abstraction}} CH_4$$

The unsaturated hydrocarbon released could arise from the decomposition of isolated vinyl groups which are not in a position to react with another vinyl group.

$$\equiv Si\text{–}CH{=}CH_2 \rightarrow \equiv Si^* + {}^*CH{=}CH_2$$

The $^*CH{=}CH_2$ groups may react with *H, $^*CH_3$ or with another $^*CH{=}CH_2$:

$$^*CH{=}CH_2 + {}^*H \rightarrow C_2H_4$$

$$^*CH{=}CH_2 + {}^*CH_3 \rightarrow C_3H_6$$

$$^*CH{=}CH_2 + {}^*CH{=}CH_2 \rightarrow C_4H_6$$

Above 600°C and up to 800°C only methane is detected. Hydrogen may also be generated from the cleavage of the Si–H, N–H bonds but not detected by mass spectrometry. At higher temperatures the cleavage of the Si–C bonds leads to the formation of Si–N and graphite which is evidenced by ^{13}C solid state NMR after heat treatment at 1000°C. The typical elemental composition of the ceramic obtained after pyrolysis at 1000°C is given in Table 3:

Table 3.

1100	2·18
1200	2·27
1300	2·31
1400	2·35
1500	2·38
1600	2·48

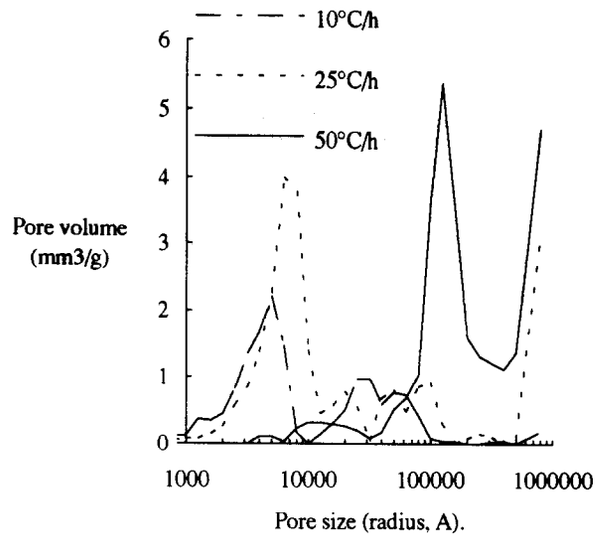

Fig. 11. Pore size distribution in the ceramic samples versus the heating rate between 300 and 1000°C.

The true density of the ceramic has been determined by He picnometry on milled samples. The densities measured depending on the maximum temperature of the pyrolysis as shown (Fig. 10 and Table 4).

3.3 Crystalline structure

Up to 1400°C the ceramic residue remains almost totally amorphous. Only a low signal corresponding to SiO_2 is detected by X-ray diffraction.

Above this temperature, peaks corresponding to α SiC and α Si_3N_4 appear on the graph.[7] It has already been shown that the crystallisation corresponds to the formation of whiskers and of a coating at the pores' surfaces. This leads also to a decrease in the mechanical properties of the ceramic.[8]

3.4 Influence of the heating rate during the mineralisation

Using a specific process for the manufacture of monolithic bodies,[8] ceramic samples were realised using various heating rates (50, 25 and 10°C/h) during the mineralisation step.

After pyrolysis at 1000°C, the true and apparent densities of the samples are similar; 1·91 and 2·15 respectively and correspond to 12–13% porosity. On the other hand, the pore size distribution determined by mercury porosimetry is significantly different versus the heating rate used (Fig. 11). A low heat rate (10°C/h) leads to pores having 2–10 μm radius whereas a faster heating rate (50°C/h) creates pores having more than 20 μm radius.

Moreover, the pores studied by mercury porosimetry correspond to the opened porosity. The porous volume measured on the samples pyrolysed at 10°C/h is significantly lower than that of the samples pyrolysed at 50°C/h. The total porous volume being the same, the ratio open porosity/closed porosity increases as the heating rate is high.

Conclusion

The polysilazane studied appears as an interesting precursor for the manufacture of ceramic matrix composites. Indeed its low viscosity, about 10 mPas at 150°C, and its high stability versus time at this temperature make it particularly suitable for the infiltration of fibrous or particulate preforms.

Moreover, the ceramic yield is high, about 60–65 wt% (About 30 vol%) after pyrolysis at 1000°C, then the number of impregnation and pyrolysis cycles required to obtain low porosity composites would be low. The low true density of the ceramic (2·13 g/cm^3 after pyrolysis at 1000°C) is also interesting.

However, a gas generation, mainly due to the evaporation of low molecular weight oligomers, and taking place simultaneously to the precursor cross-linking leads to the formation of a foam and consequently to a high porous volume in the ceramic after pyrolysis. A low heating rate, 5°C/h, between 130°C–300°C reduces the evaporation of the low molecular weight oligomers and then increases the ceramic yield and the apparent density of the ceramic. Nevertheless in the best case the porosity remains higher than 50%.

Above 300°C the heating rate does not influence the porosity amount in the ceramic but has significant consequences on the pore size distribution. A low heating rate leads to finer pores but creates more closed porosity than a higher one. Therefore, as successive impregnation and pyrolysis cycles will be required, a mean heating rate, about 25°C/h would be used. The ceramic residue remains amorphous up to a pyrolysis temperature of 1400°C. Above this temperature the αSiC and αSi_3N_4 crystallisation leads to a decrease in the mechanical properties of the ceramic.

(Received 28 September 1994; revised version received 12 January 1995; accepted 31 January 1995)

Abstract

The solubility of aluminium in the nitrogen-containing melilite structure has been studied by preparation of specimens of the general formula $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ with R = Nd, Sm, Gd, Dy and Y by hot pressing and pressureless sintering techniques in the temperature interval 1600–1750°C. For elements with large ionic radii, i.e. R = Nd and Sm, up to one Si can be replaced by Al, but the solubility limits in melilite solid solutions decrease with decreasing the ionic radii. Consequently, yttrium–melilite had the lowest observed aluminium solubility ($x \approx 0{\cdot}6$) in rare earth elements–melilite solid solutions.

1 Introduction

Nitrogen-containing melilite phases comprise compounds based on the general melilite composition $Si_3N_4{\cdot}R_2O_3$ with R = Y, and rare earth elements such as Nd, Sm, Gd and Dy, and these compounds have been shown to be refractory and stable ceramics in non-oxidising environments. Yttria and rare earth oxides are frequently used as a sintering aid in the preparation of Sialon ceramics. Consequently nitrogen-containing melilite phases are frequently occurring as a grain boundary phase in α-Sialon and mixed α–β-Sialon ceramics.[1,2] This is expected from phase relationships of the R–Si–Al–O–N systems[3,4] and, apart from the α-Sialon phase, these phases contain more nitrogen than any other phase in these quinary systems. By the formation of crystalline nitrogen-containing rare earth element–melilite (abbreviated R–M below) and/or aluminium and nitrogen-containing rare earth element–melilite solid solution (abbreviated R–M' below) phases, the amount of glassy phase at the grain boundary is reduced and eventually totally eliminated. The ability of the various R–M' phases to act as 'element sink phases' will be discussed below.

The properties of Sialon ceramics at high temperatures are mainly determined by the deterioration of the grain boundary phase. The presence of Y–M in silicon nitride based ceramics has been avoided. Y–M is known to oxidise rapidly at low temperatures (around 1000°C) whereby cristobalite and yttrium disilicate is formed and this process is accompanied with a drastic increase in the specific volume. The specific volume of the latter phases is thus approximately 30% larger than that of Y–M resulting in cracking of the specimen and spalling of the protective oxide layer formed upon oxidation.[5] Thus, although the melting point of Y–M itself is very high (>1850°C) these materials have failed in high-temperature application due to their poor oxidation resistance.[6] Aluminium melilite solid solutions $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$(R–M') are expected to have an improved stability against oxidation because when Si–N is replaced by Al–O a much smaller relative increase in specific volume of the formed oxidation products is expected and can be used as the best high temperature grain boundary phases for mixed α–β-Sialon ceramics because of their high melting points. Sialon ceramics containing crystalline R–M' phases at the grain boundaries are thus expected to exhibit better oxidation properties than the corresponding materials containing crystalline R–M phases.

The aluminium solid solution range in the Nd–M' system is reported to extend from $Nd_2Si_3O_3N_4$ to around $Nd_2Si_2AlO_4N_3$.[6,7] This range is very similar to the one reported for the Sm–M' system where, also, up to one Si can be replaced by one Al.[8] In order to understand the characteristics of the oxidation behaviour of various R–M' phases, it is necessary, at the first stage, to study

the extension of solubility range of the R–M' phases and the microstructure of the formed compacts and this is reported below.

2 Experimental

The starting powders used were silicon nitride (LC12, H. C. Starck, Berlin) and aluminium nitride (prepared at Shanghai Institute of Ceramics) while R_2O_3 with R = Nd, Sm, Gd, Dy and Y (99·9% pure) were all the products of Yaolung Chemical Works, China. Powder mixtures with the overall nominal composition $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ with R = Nd, Sm, Gd, Dy and Y and $0 \leq x \leq 1{\cdot}5$, taking into account surface oxygen of the particles of both Si_3N_4 (1·8 wt%) and AlN (2·0 wt%), were prepared. The powders were mixed in absolute alcohol and milled in an agate mortar for 1·5 h. The compacted samples were fired at the different temperatures in the interval 1600–1750°C for 1 h or 2 h depending on the nominal composition of R–M' to have the samples synthesized, applying both hot-pressing or pressureless sintering techniques in a graphite-resistance furnace in a flowing nitrogen atmosphere.

The phase analysis of the prepared samples was based on X-ray diffraction data obtained in a Guinier–Hägg camera with use of Cu $K\alpha_1$ radiation and Si as the internal standard. The obtained photographs were evaluated with a computerised scanner system and the cell parameters were refined with use of the program PIRUM.[9] The Al content of the prepared R–M' phases were determined from element analysis using either an SEM (Jeol JSM 820) and a TEM (JEM 200CX), both equipped with energy dispersive spectrometers, or an electron probe instrument (8705 QH2). The Si and Al content given below is an average of several (10 or more) spot analysis determinations. The micrographs were obtained in an SEM (Jeol JSM 820) operating in the back scattering mode. The detailed microstructural studies of Sm–, Gd– and DY–M' samples were made in a TEM (JEM 200CX).

3 Results and Discussion

3.1 Phase analysis

The observed crystalline phases in the prepared samples are given in Table 1. The results are given

Table 1. A summary of the phases present in $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ compacts according to the X-ray analysis

HP = hot pressing; PLS = pressureless sintering; J = $R_4Si_2O_7N_2$; K = $R_3Si_3O_6N_3$; H = $R_{10}(SiO_4)_6N_2$; S = $R_2Si_2O_7$; I = $RAlO_3$; Y = $Al_5Dy_3O_{12}$; A = AlN-polytypoid.

as a function of the x value of the overall compositions $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ with R = Nd, Sm, Gd, Dy and Y and $x \leq 1{\cdot}5$ and as expected the R–M phase or the R–M' phase was found to be the main phase in all samples, but the formed samples contained other phases as well. Thus minor amounts of $Nd_3Si_3O_6N_3$ (Nd–K phase) and $Sm_2Si_2O_7$ was found for $x = 0$ in these systems and trace amounts of $Nd_{10}(SiO_4)_6N_2$ appeared in the Nd–M' system. The J phase, $R_4Si_2O_7N_2$ (or corresponding J'-phase), was found in most other samples. For a given nominal composition, the amount of J phase increased with decreasing the ionic radii of the rare earth element. Finally, the synthesis of Yb–M with the composition $Yb_2O_3{\cdot}Si_3N_4$ was tried by hot-pressing at 1700°C for 1 h and the sample contained the Yb–J phase, $Yb_4Si_2O_7N_2$, as a major component and only minor amounts of Yb–M, which in turn suggests that the R–M' phase is more easily formed for the high ionic radii (low Z) rare earth elements.

In addition, $RAlO_3$ was observed in samples of Nd–M', Sm–M' and Gd–M' with $x > 1{\cdot}0$ while $Al_5Dy_3O_{12}$ was found in samples of Dy–M'. Small amounts of AlN-polytypoid (27R or 2H[6]) appeared in the Y–M' material for $x \geq 1$, which was also confirmed by the SEM/EDS studies (see below).

The occurrence of small amounts of additional phases in samples with $x = 0$ might be attributed to the presence of surface oxide on the silicon nitride powder, which cannot be compensated for at this specific composition. However, we have not been able to prepare monophasic R-M' phases, although these compositions have been compensated for surface oxides on the nitride particles. This can be understood for two reasons. Firstly, the densification process of melilite phase would be the same as Si_3N_4-based ceramics because its composition consists of Si_3N_4 and R_2O_3, i.e. the formation of an oxynitride liquid due to the reaction of rare earth oxides with the silica present on the starting nitrogen-containing powder is an important feature of the densification process, which results in the occurrence of amorphous or crystalline intergranular phases after sintering in R–M/R–M' samples. Secondly, the overall compositions might still be in an oxygen-rich multiphase region, especially for the compositions with high x values. According to the phases analysis, the nominal R–M' compositions with $x > 1{\cdot}0$ and with R = Nd, Sm and Gd might be located in the phase compatible region R–M' – R–J – $RAlO_3$ and for R = Dy in the region R–M' – R–J – $Al_5Dy_3O_{12}$. It is known that in the pseudo-binary systems R_2O_3 – Al_2O_3 (R = rare earth elements), the aluminate phase $RAlO_3$ is formed for low and middle Z rare earth elements, whereas the phase $Al_5R_3O_{12}$ is formed only for Dy and higher Z rare earth elements.[10,11] This is in analogy to the phases found in the present R–M' samples with $x > 1{\cdot}0$. It can also be noted that in spite of the fact that the ionic radii of Y^{3+} is similar to that of Dy^{3+}, $Al_5Y_3O_{12}$ is not formed but AlN-polytypoids are.

3.2 Solid solubility range of R–M' phases

The variations of the a- and c-axis parameters of the tetragonal unit cell of the formed R–M' phases are given as function of the x values of the $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ samples in Table 2. The lattice dimensions increase with increasing x-values up to a certain x-value for respective R–M' phases. However, these x-values do not necessarily represent true solubility limits as all samples contained additional phases some of which are rare earth rich. It can, however, be noted that the c/a ratios are almost constant with increasing x-value for each R–M' phase which indicates that the structural changes introduced when Si–N pairs are replaced by Al–O ones are isotropic in all R–M'-phases studied.

SEM-EDS studies have been used to estimate the solubility limits of Al in the various R–M' phases. The findings are compiled in Table 2 and Fig. 1. The maximum Al-content in the various R–M' phases were x = 0·98, 0·90, 0·78, 0·71 and 0·57 for R = Nd-, Sm-, Gd-, Dy- and Y, respectively. Thus, in Nd–M' and Sm–M' systems we find that one Si–N pair per formula unit can be replaced by one Al–O pair in accordance with previous findings[6–8] while the true solubility limits in the Gd–M' and Dy–M' systems seem to be somewhat less (0·75) and even the smaller in the Y–M' system (0·60). The maximum Al-content in the R–M'-phases clearly decreases with the ionic radii[12] of the R-element (see Fig. 2).

The substitution of Si–N by Al–O in the R–M structure produced a lattice expansion. The maximum value of latice expansion is found in the Nd–M' system (1·66%) and the minimum one in the Y–M' system (0·70%) which in turn is due to the fact that these systems exhibit different solid solubility ranges. The slopes of the curves of cell parameters versus the x-value are slightly different for different dopings as shown for Y– and Sm–M' in Fig. 1.

Although the small number of additional phases occurs in the formed samples as mentioned above, the measurements of cell parameters and SEM-EDS studies can be done without difficulty because R–M/R–M' phases were found to be the main phases in all samples and the additional phases can be easily separated from the melilite phase in the back scattering mode of SEM.

In order to understand why the solid solubility decreases with decreasing ionic radii of the R

element one needs more detailed structural information concerning the metal – non-metal distances of the various R–M' phases. It can, however, be noted that when Si–N is replaced by Al–O the unit cell volume is increased implying that the voids, which accommodate the R element, become larger and eventually they are or will become too large to accommodate the used R element.

3.3 Microstructural studies of compacts containing R–M' phases

The microstructures of R–M' samples containing different amount of Al were studied in an SEM operated in back scattering mode. The micrographs clearly show the multiphase nature of the prepared samples (see in Figs 3 and 4). It is thus clearly seen that large crystals with sharp edges are formed and these crystals are surrounded by a significant

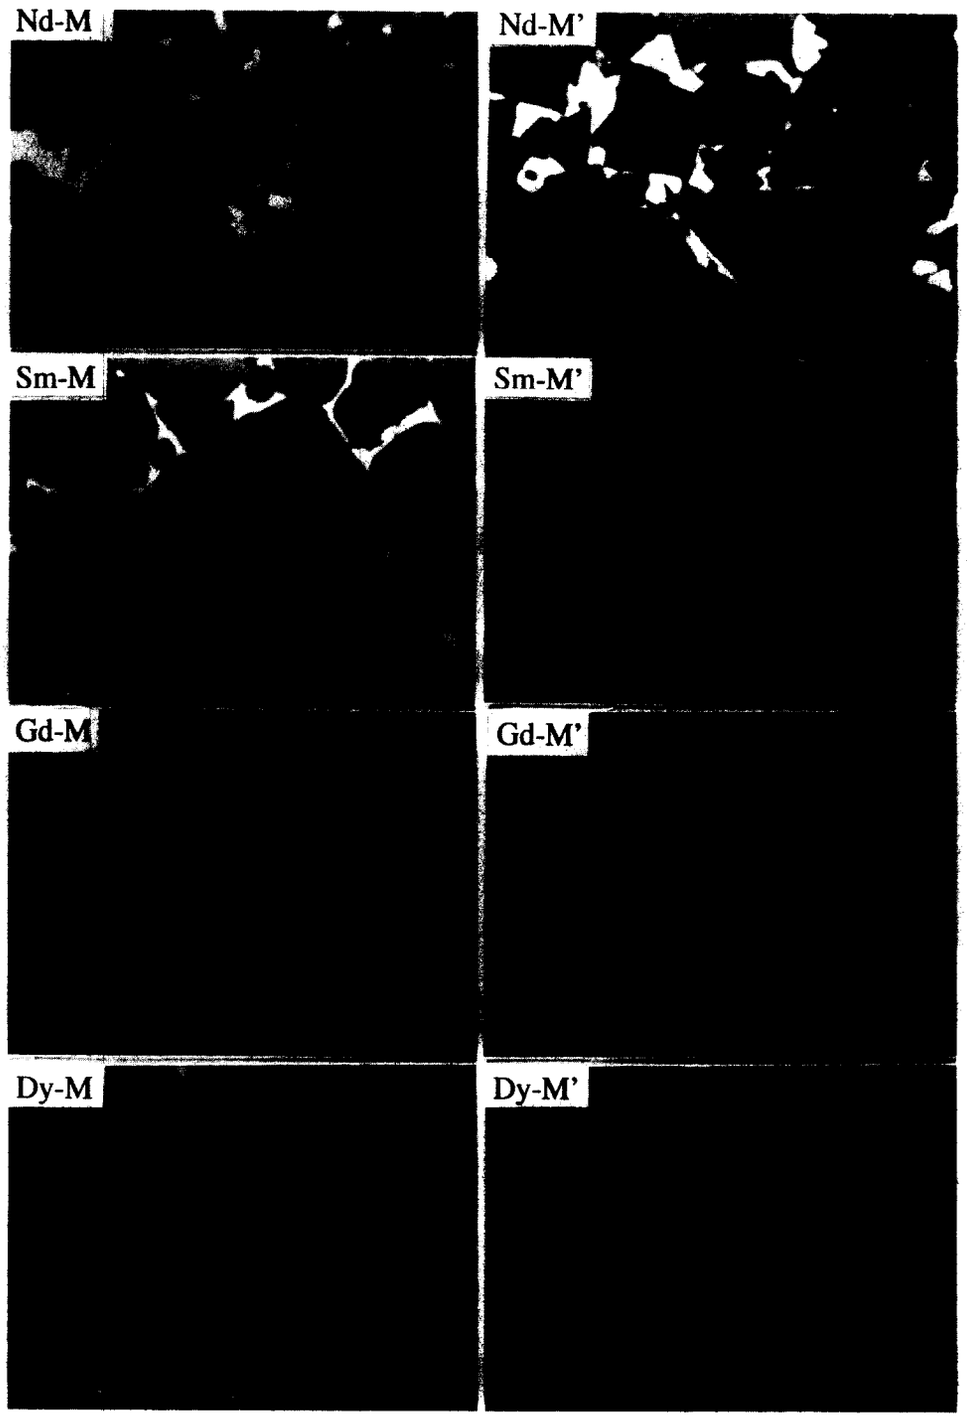

Fig. 3. SEM micrographs of $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ with R = Nd, Sm, Gd and Dy and with (a) $x = 0$ and (b) $x = 0{\cdot}5$. The dark grey area represents the R–M' phase and the light grey one the J phase.

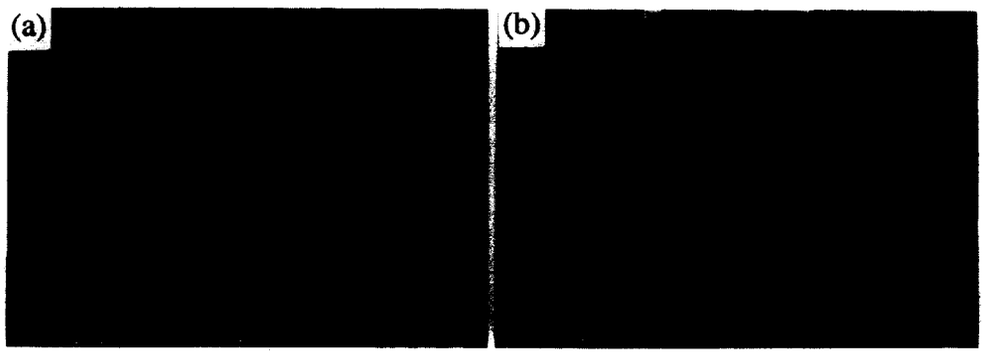

Fig. 4. SEM micrographs of $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ with R = Y and with (a) $x = 1{\cdot}0$ and (b) $x = 1{\cdot}25$. The dark grey contrast represents the melilite phase and the light grey one the J phase. The flake and needle-like crystals with black contrast are AlN-polytypoids containing no yttrium.

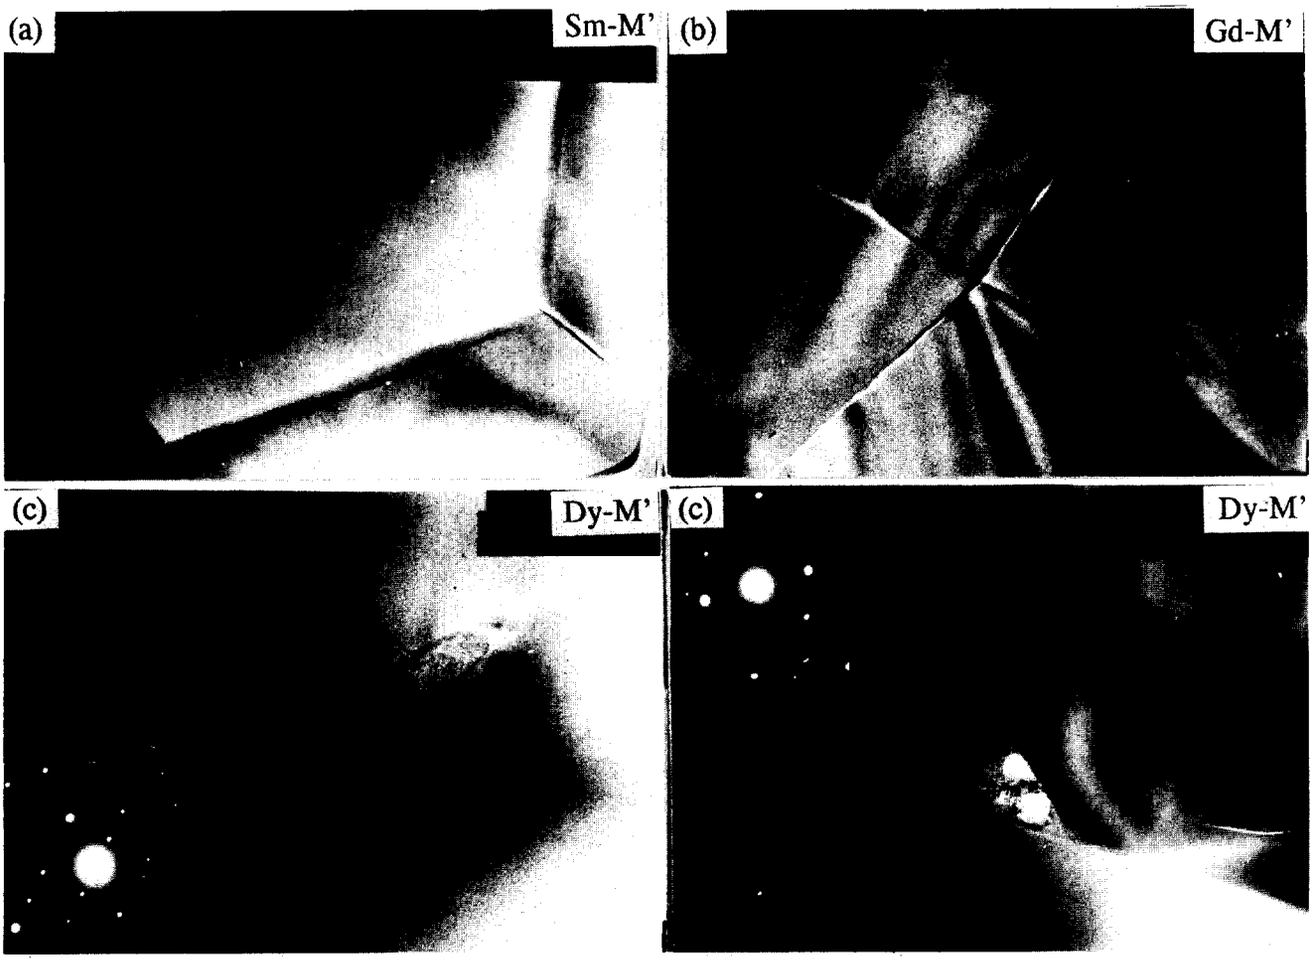

Fig. 5. TEM micrographs of $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ samples with (a) R = Sm and x = 0·75, (b) R = Gd and x = 0·5 and (c) R = Dy and x = 0·4.

amount of a rare earth rich grain boundary phase and that the crystallographic morphology of the melilite phase is developed when Si–N are replaced by Al–O in the R–M' samples. This can be understood in terms of the added Al_2O_3 reacting with the silicon oxide on the surface of the nitride particles and with increasing x-value, an increasing amount of liquid phase is formed which in turn promotes the grain growth of the melilite phase.

The SEM micrographs in Fig. 4 show the morphologies of Y–M' phase (dark grey) and J phase (with light grey contrast) in the samples of Y–M' (x = 1·0 and 1·25). The flake and needle-like dark crystals are different AlN-polytypoids containing no yttrium, probably the $2H^{\delta}$ and the 27R modifications respectively. The micrographs also show that the amounts of the J-phase and AlN-polytypoid phases are larger in the sample with x = 1·25 than that of x = 1·0, which agrees with the results of the XRD analysis. The SEM micrographs have revealed that a rare earth element rich grain boundary phase is present in all samples, but more so in the Al containing materials. The XRD analysis has shown that most of it comprises crystalline phases, but the presence of a glassy phase can not be excluded.

TEM studies of triple-grain boundaries in the Sm–M'–(x = 0·75), Gd–M'–(x = 0·5) and Dy–M'–(x = 0·4) samples showed that:

(i) materials prepared with the largest ionic radii element, Sm, exhibited many triple-grain boundaries almost free of any additional phase. Typical triple-grain boundary junctions in this sample are shown in Fig. 5(a);
(ii) in the Gd–M' sample the number of glassy phases in the triple-grain boundaries was increasing but occasionally some multi-grain junctions were observed with no intergranular of glassy phase at all, as shown in Fig. 5(b);
(iii) a mixture of crystalline and glassy phases was always found in the triple-grain boundaries of the Dy–M' material illustrated in the micrographs and electron diffraction patterns given in Fig. 5(c).

These observations are in agreement with the SEM and XRD studies which showed that the homogeneity range of the R–M' phases is largest for the R elements with the largest ionic radii, i.e. these R–M' phases exhibit the best possibility to act as an 'element sink-phase' whereby the amount of glassy phase at the junctions is reduced.

4 Conclusions

The solubility of Al in nitrogen-containing melilite solid solutions according to the formula $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ with R = Nd, Sm, Gd, Dy and Y has been studied. The SEM and XRD studies showed that the extension of solid solubility range of the various R–M' phases was largest for the R element with largest ionic radii (Nd and Sm). The TEM studies revealed that the R–M' phase with R = Sm acted as a better 'element sink phase' than R–M' phases containing R elements with smaller ionic radii.

Abstract

The mechanical properties of hot-pressed 12H polytypoid phase with YAG as the sintering additive have been studied. The results showed that small amounts of YAG can greatly increase high temperature strength. At room temperature, the 12H with 2·5 wt% YAG possesses a flexural strength of 367 ± 18 MPa, but its high temperature strength can reach above 500 MPa in the temperature range from 1000 to 1300°C. The fracture mechanism has been discussed on the basis of the fracture morphology observed by SEM.

Introduction

It is well known that Sialon ceramics are a family of materials which possess high performance properties at elevated temperatures. In the Si–Al–O–N system, at compositions between β-sialon and AlN, there are six polytypoid phases (8H, 15R, 12H, 21R, 27R and $2H^{\delta}$) with wurtzite-type structures having compositions represented as M_mX_{m+1}.[1-2] These are built up by MX double layers of metal (M) and non-metal (X) atoms stacked with variants of AB and ABC sequences, as in silicon carbide and with MX_2 layers at periodic intervals to account for the different stoichiometries and structures. The crystal structures of AlN-polytypoids have been examined in detail,[3-4] but studies concerning their fabrication and mechanical properties are scarce.[5-6] Komeya[6] studied the formation and mechanical properties for 27R polytypoid and indicated that pure 27R can only be densified by 2000°C presintering and subsequent 2100°C hot-pressing; the ceramics show approximately constant strength values at room temperature to 1700°C(380–470 MPa prepared under the best conditions). This high refractoriness of the 27R polytypoid suggests that other polytypoids such as 21R, 12H and 15R would be also highly refractory. The phase relationships in the Y–Si–Al–O–N system[7] indicate that all AlN–polytypoids are compatible with β-sialon (except 8H), α-sialon (except 8H, 15R) and YAG ($3Y_2O_3{\cdot}5Al_2O_3$). This offers the possibility to incorporate polytypoid phases into α- and/or β-sialons forming composite ceramics simultaneously with YAG as the grain boundary phase. Since AlN-polytypoid phases possess fibre-like or prismatic morphology,[8] it would be interesting to document whether an *in situ* strengthening and toughening effect could be achieved in these composite ceramics. Therefore, the fabrication and mechanical properties of monolithic AlN-polytypoid ceramics prepared under the normal temperatures for nitride ceramics are worth exploration. The sinterability of sialon ceramics strongly depends on the nitrogen content in the starting compositions. In general, the more nitrides in the overall compositions, the more difficult the materials are to be densified. 12H phase contains the lowest nitrogen content among the polytypoids which are compatible with both α-sialon and β-sialon phases and therefore, it poses the greatest attraction among all AlN-polytypoid phases to be studied.

Recently, we studied monolithic 12H ceramics and α'-12H ceramics both with YAG as the sintering additive. A preceding paper[9] has described the effect of YAG on the densification and reaction sequence. The present paper reports the mechanical properties of 12H ceramics. The work on the α'-12H composite ceramics has appeared elsewhere.[10]

Experimental

As indicated in the Si–Al–O–N phase diagram, each AlN-polytypoid phase (M_mX_{m+1}) occurs along a certain line with $M:X$ equal to m:(m + 1). The nominal composition of 12H can be taken as $SiAl_5O_2N_5$. The starting materials used were Si_3N_4(LC12, Stark), AlN(1–2 μm, 1·2 wt% oxygen, (Zhuzhou Institute of Hard-Metals, China), Al_2O_3(99·99%) and Y_2O_3(99·9%). The mixed powder was ball-milled with absolute alcohol for 24 h,

dried and passed through a 120-mesh screen, and then hot-pressed at 1750°C for 1 h in a graphite-resistance furnace under 25 MPa in a flowing N_2 atmosphere. The specimens used for high temperature property determinations were heat treated at 1250°C for 24 h. The phases were identified by X-ray diffraction technique. Hardness and indentation fracture toughness were measured by using a Vickers diamond indenter under a load of 100 N. Flexural strength was tested at room temperature and high temperatures (1000–1400°C) in air by three-point bending with a 30 mm span (20 mm for high temperature test) and a cross-head speed of 0·5 mm/min. A boiling solution of $K_3Fe(CN)_6$ was used for etching the polished specimens. Both polished and fracture surfaces were observed by SEM. TEM study was also performed for revealing the grain boundary structure.

Results and Discussion

1 The effect of YAG on mechanical properties

Table 1 shows the starting compositions and their phase compositions present after hot-pressing and further heat treatment. The room temperature mechanical properties — Vickers hardness, indentation fracture toughness and the flexural strength are shown in Figs 1–3 respectively, and high temperature flexural strength is shown in Fig. 4.

At room temperature, as shown in Figs 1–3, when YAG is below 5 wt%, the flexural strength

and fracture toughness are not sensitive to YAG content and the Vickers hardness decreases with the amount of YAG, but with further increase of YAG, all these mechanical properties become poorer. At high temperatures, as shown in Fig. 4, the effect of YAG on the flexural strength becomes more complex. The flexural strength of 12 H with 2·5 wt% YAG is much higher at high temperatures than at room temperature with an increment of 45 and 37% at 1000 and 1300°C respectively. However, when 5 wt% of YAG is added, the flexural strength decreases gradually with temperature rise.

The grain boundary phases in the 12H materials are YAG and glassy phase as revealed by TEM and X-ray diffraction technique. YAG as a sintering additive in 12H ceramics is more easily crystallized out than in β-sialon where YAG can only be obtained through post heat treatment. Fig. 5 is a TEM grain boundary micrograph of as fired 12H with 2·5 wt% YAG showing YAG with glassy phase existing at the triple grain junction. The microstructures of the compositions with different YAG contents are shown in Fig. 6. With increasing YAG, the content of grain boundary phase composed of both the glassy phase and YAG (white contrast) increases, and the grain size becomes smaller. The grain size change might be the result of having more nucleation sites being developed because of more liquid phase present during hot pressing. Clearly, the variation in the microstructure should be reflected in the mechanical properties. It has been known that the grain size has an obvious effect on the work of fracture in ceramic materials with non-equiaxed grains. The fracture energy can be improved through increasing the grain size.[11,12] Therefore, the higher fracture toughness of 12H materials with smaller amount of YAG addition can be attributed to the smaller quantity of grain boundary phase and to the relatively large grain size. The decreasing hardness in the compositions with higher YAG content can be envisaged by similar reasoning. In the composition with 10 wt% YAG, as indicated in Table 1, there still exists a small amount of 15R(an AlN-polytypoid containing less nitrogen than 12H) which is a transitional phase in the formation of 12H.[9] Whether the small amount of 15R has some effect on the mechanical properties is not clear, but it probably has slightly worse mechanical properties than 12H because of the lower N content in the composition.

The big difference in high temperature flexural strength caused by the amount of YAG must have some indication in their fracture morphology. In general, the glassy phase adversely affects high temperature mechanical properties more severely than at room temperature. But for the composition with 2·5 wt% YAG, the material behaves diff-

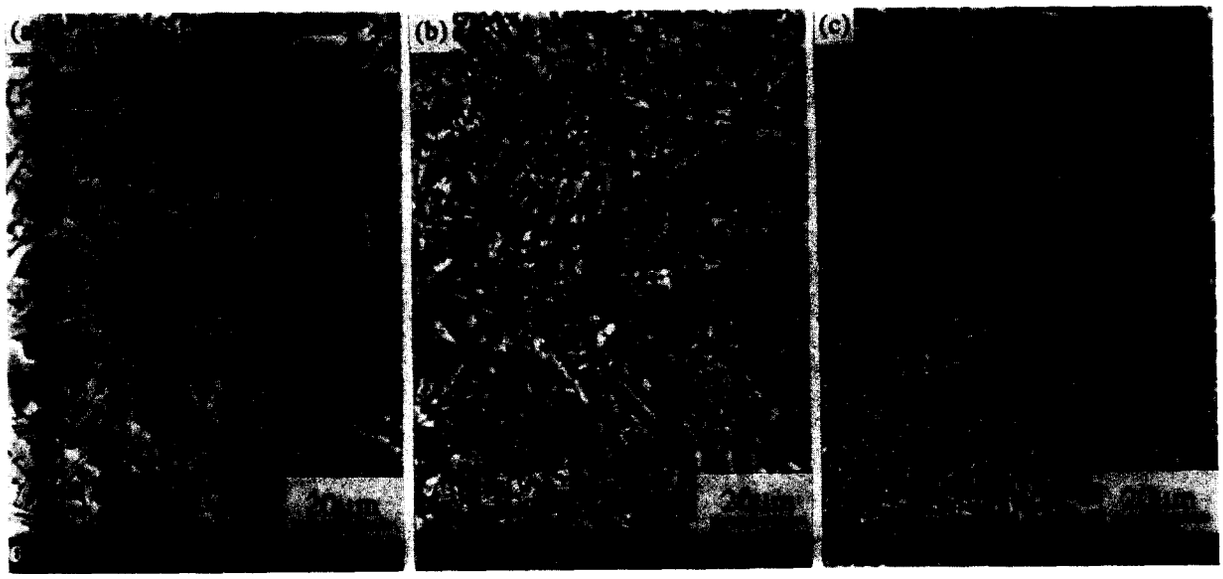

Fig. 6. SEM micrographs of 12H densified with (a) 2·5; (b) 5·0 and (c) 10 wt% YAG.

erently. There must be some strengthening mechanism occurring at high temperatures and this may be found through observing the fracture morphology.

2 The characteristics of fracture morphology

The micrograph of the fracture surface at room temperature for the composition with 2·5 wt% is shown in Fig. 7(a). As observed, 12H materials fractured in a transgranular mode. Some cracks propagated within the 12H grains with a stepwise fracture surface. The transgranular fractural mode is thought to be associated with the interlocking arrangement of 12H grains and their relatively poor strength. The step-like morphology is apparently related to the crystal structure of 12H. The hexagonal AlN-polytypoid phases prefer to grow along the a-dimension, and the width of the grains corresponds to the c-dimension, along which the MX and MX_2 layers stack up. Therefore, the strength of 12H grains varies with their orientation and is weaker along their width due to the poor cleavage strength between structural layers. Consequently, when 12H materials are fractured, the cracks propagate more easily along the c-dimension.

The micrographs of high temperature fracture surfaces are shown in Figs 7 (b–c) and 8 (a–c). In the composition with 2·5 wt% YAG, some grain pull-out or partial pull-out at 1000°C was observed, as indicated in Fig. 7(b). The additional energy consumed by the pull-out would increase fracture energy thus resulting in an increase in flexural strength. At 1300°C, microcracks on the fracture surface were observed, as shown in Fig. 7(c). The formation of microcracks also provides an additional contribution to the energy dissipation, thus improving the strength. Therefore, in the composition with less YAG content, the possible mechanism for the increment of high temperature strength are thought to be grain pull-out and the formation of microcracks. However, when

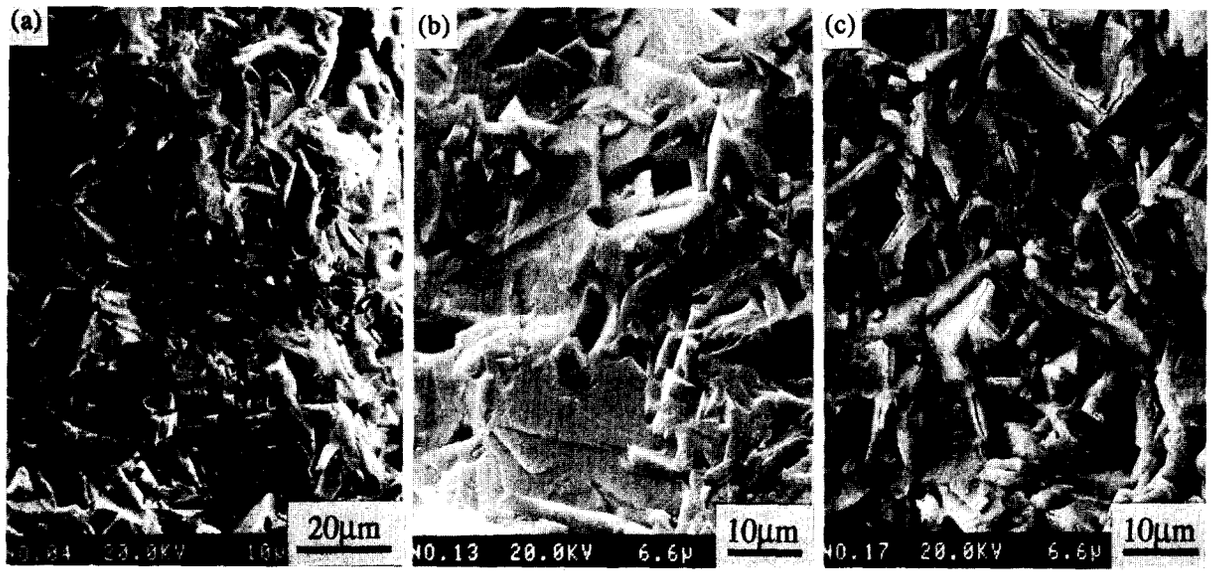

Fig. 7. Micrographs of fracture surface of 12H with 2·5 wt% at (a) room temperature, (b) 1000°C and (c) 1300°C.

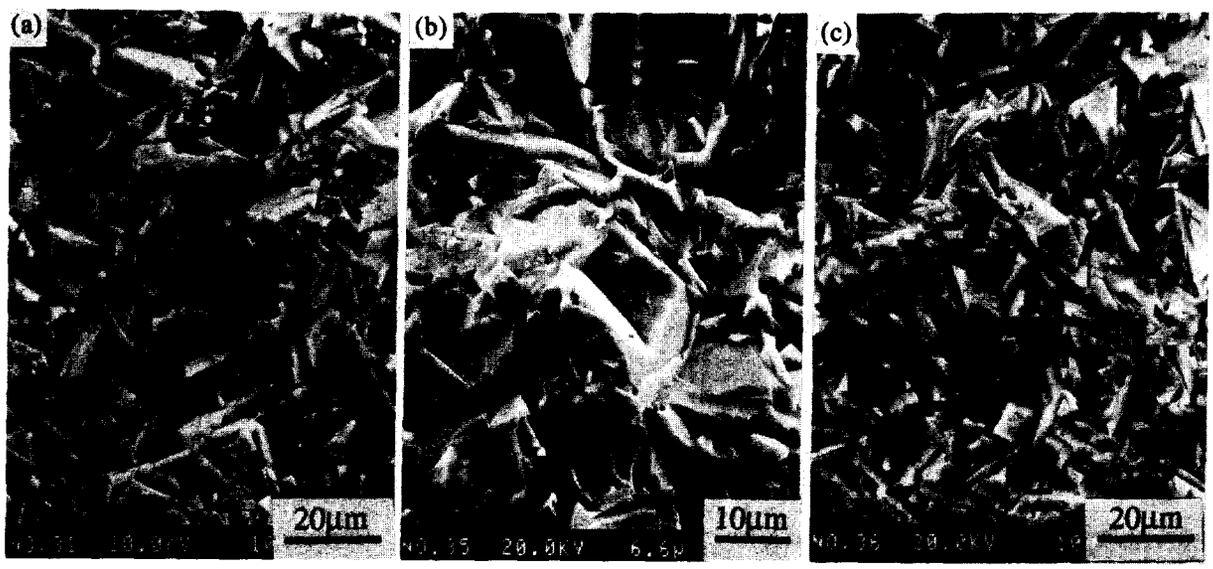

Fig. 8. Micrographs of fracture surface of 12H with 5·0 wt% YAG at (a)1000°C, (b) 1300°C and (c) 1400°C.

more YAG was added, no grain pull-out was observed and the grain boundaries appear to be less sharply defined, as shown in Fig. 8(a–c). The formation of this morphology can be attributed to more glassy phase present at the grain boundaries. Therefore, high temperature mechanical properties are more sensitive to the amount of YAG in the microstructure and better mechanical properties can be obtained through careful control of the grain boundary phases.

Conclusion

YAG as the sintering additive for 12H ceramics plays a decisive role in determining the mechanical properties of the material, especially at high temperatures. The composition with a small amount of YAG (about 2·5 wt%), gives a substantially higher flexural strength at temperatures between 1000 and 1300°C than its room temperature strength. Grain pull-out at 1000°C and microcracks formed in the 12H grains at 1300°C as manifested on the fracture surfaces are supposedly the main mechanisms for the strengthening effect at low additive level of YAG.

Abstract

The synthesis and processing of dense silicon-based bulk ceramic materials derived from the thermal decomposition of preceramic organosilicon polymers such as polysilazanes and polysilanes was achieved by three different routes A, B, and C. Additive-free silicon carbonitride bodies of the composition $Si_{1.7}C_{1.0}N_{1.6}$ were produced according to route A, with up to 94% relative density by the pressureless pyrolysis of compacted infusible polysilazane powders at low processing temperatures (1000°C). The resulting silicon carbonitride was single-phase and amorphous according to X-ray- and TEM-investigations and exhibited a low solid-phase density of 2·33 g/cm³. The maximum room temperature fracture strength of additive-free silicon carbonitride was 370 MPa. Crystallization of the as-synthesized silicon carbonitride bulk samples occurred at temperatures exceeding 1400°C.

In a second process, route B, densification of polysilazane-derived amorphous silicon carbonitride powder was achieved by liquid phase sintering with alumina and yttria as sintering additives in nitrogen atmospheres and at temperatures up to 1900°C. This process resulted in the formation of dense polycrystalline β-Si_3N_4/β-SiC-composites. The average room temperature fracture strength and fracture toughness of the gas pressure sintered composite were in the range of 650 MPa and 10·2 MPa$\sqrt{m}$, respectively.

Polycrystalline Si_3N_4/SiC-composites were obtained in a third process, route C, by the pyrolysis and subsequent sintering of α-Si_3N_4-powder/polysilane blends. The Si_3N_4-powder serves as an inert filler reducing the volume shrinkage associated with the polymer-to-ceramic transformation. Dense Si_3N_4 and Si_2N_2O bulk ceramics were formed according to route B by the liquid phase sintering of amorphous silicon nitride powder synthesized by the polysilazane pyrolysis under ammonia.

1 Introduction

Advanced non-oxide Si-based materials such as Si_3N_4 or SiC are commonly produced by inorganic solid state reactions at high temperatures. Thus, SiC is synthesized by the reaction of silica with carbon according to the Acheson process at $T \geq 2000$°C. Silicon nitride is fabricated either by the reaction of the elements or by the nitridation of silica in the presence of carbon at $T = 1500$°C. Due to their predominantly covalent nature, high sintering temperatures in the range of 1700–2100°C and the addition of sintering aids have to be used to enhance the densification of compacts prepared from these materials. Since the work of Verbeek *et al.* and of Yajima *et al.* in the mid 1970's, it is known that these ceramics can be produced at unusually low temperatures, i.e. in the temperature regime of 800–1200°C, by the thermal decomposition of organosilicon preceramic polymers.[1,2] This process is known as preceramic polymer pyrolysis and involves the following reaction steps as demonstrated by Seyferth and Wiseman for the formation of Si_3N_4 or Si_3N_4/SiC-composites from polysilazanes.[3,4]

(1) Synthesis of Si-based oligomers or polymers from low molecular weight compounds:

$$RHSiCl_2 \xrightarrow{NH_3} [RHSiNH]_n + 2\ NH_4Cl \quad R = \text{alkyl}$$

(2) Enhanced chemical or thermal cross-linking of the as-synthesized polymers giving high

*Present address: Material-und Energiesysteme, Filderhauptstr. 23, D-70599 Stuttgart, Germany.

molecular weight compounds suitable for polymer-to-ceramic transformation with high yields:

$$[RHSiNH]_n \xrightarrow{\text{strong base}} [RHSiNH]_{n-m}[RSiN]_m + m\ H_2$$

(3) Finally, pyrolysis of the cross-linked polymer providing the desired ceramic material:

$$[RHSiNH]_{n\ m}[RSiN]_m \xrightarrow{1000°C/Ar} Si_xC_yN_z + H_2 + RH$$

$$[RHSiNH]_{n\ m}[RSiN]_m \xrightarrow{1000°C/NH_3} Si_3N_4 + H_2 + RH$$

The preceramic polymer pyrolysis process has been intensively investigated with respect to the production of Si-based non-oxide fibers[2,5] and is already utilized commercially for the fabrication of SiC-, Si_3N_4-, and Si–C–N-fibers. Further potential applications such as infiltration of porous substrates, preparation of ceramic coatings, and joining of ceramics are under research.[6] However, the high potential of molecular preceramic compounds for the production of ceramic powders and bulk materials has been only sporadically demonstrated in the literature. Recently, great interest has been focussed on the *in situ* formation of β-Si_3N_4/β-SiC ceramic micro/nano-composites prepared by the densification of amorphous Si–C–N-powders at $T \gg 1000°C$.[7,8] The amorphous ceramic powders were produced either by the gas-phase decomposition of hexamethyldisilazane $((CH_3)_3Si)_2NH$[8] or by the solid-phase pyrolysis of poly(methyl)silazanes.[3,7,9] Hot-pressing of the Si–C–N-powders can result in β-Si_3N_4/β-SiC-composites which exhibit extraordinary high mechanical strength values ($\geq$1500 MPa)[8] or superplasticity at 1600°C.[10] According to a novel route, Si-containing polymers such as polysilazanes and polycarbosilanes can be processed directly to near dense monolithic ceramic bodies at low temperatures (1000°C) and without using additives by the thermolysis of inorganic polymer powder compacts.[11,12]

Besides the Si-based materials, other non-oxide ceramics such as AlN, BN, B_4C or TiN have also been synthesized by the pyrolysis of appropriate molecular compounds.[13,24] Some representative examples are listed in Table 1. In general, molecular compounds containing more or less direct polar bonds $M^{\delta+} - C^{\delta-}$ between the metal M and carbon are denoted as organometallics. In order to include for consideration the Si-containing polymers, the term organoelement polymer is used for the classification of materials such as polysilanes, polycarbosilanes, polysiloxanes, or polysilazanes.[25]

Generally, preceramic polymer pyrolysis is a process effective at relatively low temperatures and forming in many cases completely amorphous ceramic materials. Polymer-derived multi-component ceramic systems like Si–B–C–N start crystallizing at temperatures exceeding 1600°C, which makes the amorphous ceramics interesting materials for high temperature applications.[26] The controlled crystallization of the amorphous phases can itself be utilized for the synthesis of nano-structured ceramic monoliths or powders. However, the formation of ceramic bulk materials other than fibers starting from preceramic polymers is difficult owing to the fact that the release of the reaction gases formed during the thermolytic conversion of the polymer to the ceramic is associated with a high volume shrinkage, which can lead to crack formation. Furthermore, the use of meltable polymers can result in foaming and bloating of the material during the pyrolysis process. The present work has been undertaken to investigate the processing of organoelement compounds into dense bulk ceramics with the objective of avoiding these problems.

Table 1. A choice of preceramic molecular compounds for the synthesis of non-oxide ceramics

Preceramic molecular compound	*Ceramic product*	*Reference*
$[RAlNH]_n$	AlN	13
$[Cl_2Al\text{-}N(H)Si(CH_3)_3]_2$	AlN	14

In the present study, dichloro(diorgano)silanes of the general formula $RR'SiCl_2$ with R = H or CH_3 and R' = CH_3 or R = CH_3 and R' = C_6H_5 have been used as the starting materials for the synthesis of the silicon-based polymers and ceramic materials. Dichloro(diorgano)silanes are produced in large quantities by the Rochow synthesis[27] and are commonly used for the preparation of silicones which are produced on the order of 700,000 tons per year.

The organopolysilazanes of the form $[RR'SiNH]_n$ used in this work were synthesized by the reaction of chlorosilanes with ammonia and by subsequent cross-linking of the ammonolysis product with strong bases such as potassium hydride, KH, or with dichloromethylsilane, CH_3SiHCl_2.[3,28] Poly(organo)silanes were obtained by the Wurtz–Fittig analogous reaction of R_2SiCl_2 with Na/K alloys.[20,29] Pyrolysis and subsequent processing of the polysilazanes resulted in the formation of the ceramic materials $Si_xC_yN_z$ (silicon carbonitride),

Si_3N_4 or Si_2N_2O, whereas the thermal decomposition of the polysilanes provided SiC_{1+x}.

In Part I, we report on the synthesis of dense or near dense Si-based bulk ceramics other than fibers from the above organosilicon polymers. Some of the mechanical properties of the materials produced are discussed. In Part II, the polymer-derived bulk ceramic microstructures developed during thermolysis and sintering are investigated by analytical transmission electron microscopy.

2 Experimental

The preparation of various Si-based ceramic bulk materials starting from organoelement polymers was accomplished first by the direct pyrolysis of polymeric shapes (route A) and secondly by the pressureless sintering of polymer-derived amorphous ceramic powders with addition of sintering aids (route B). In a third process, route C, α–Si_3N_4-powder containing Al_2O_3 and Y_2O_3 as sintering additives was mixed with a SiC-forming precursor, pressed and finally sintered. The principal reaction paths used for the synthesis of the organosilicon polymers and the ceramic products derived therefrom are shown in Fig. 1. The different routes applied for the processing of the preceramic polymers to dense bulk ceramics are denoted as A, B, and C as illustrated in Fig. 2. Generally, synthesis and all manipulations of the organoelement polymers were done in glass vessels under Ar. The pyrolysis reactions were conducted in quartz tubes in flowing atmospheres (Ar (99·999% purity) or NH_3 (99·996% purity))[1] with heating rates of 0·5 to 5°C/min.

2.1 Characterization of the polymer-derived ceramics

The chemical analysis of the synthesized ceramic materials was performed by conventional analytical methods.[2]

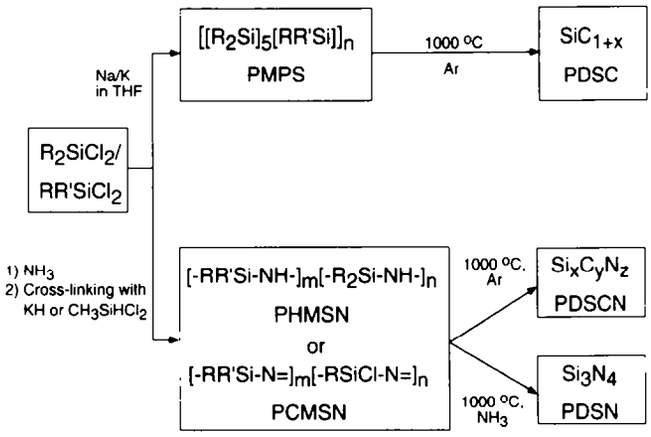

Fig. 1. Synthesis of Si-based polymers and the ceramic products obtained after pyrolysis in different atmospheres. R = CH_3, R' = H (reaction with NH_3) or C_6H_5 (reaction with Na/K); PMPS = poly(methylphenyl)silane; PHMSN = poly(hydridomethyl)-silazane; PCMSN = poly(chlorohydridomethyl)silazane; PDSC = polymer derived SiC; PDSCN = polymer derived silicon carbonitride; PDSN = polymer derived silicon nitride.

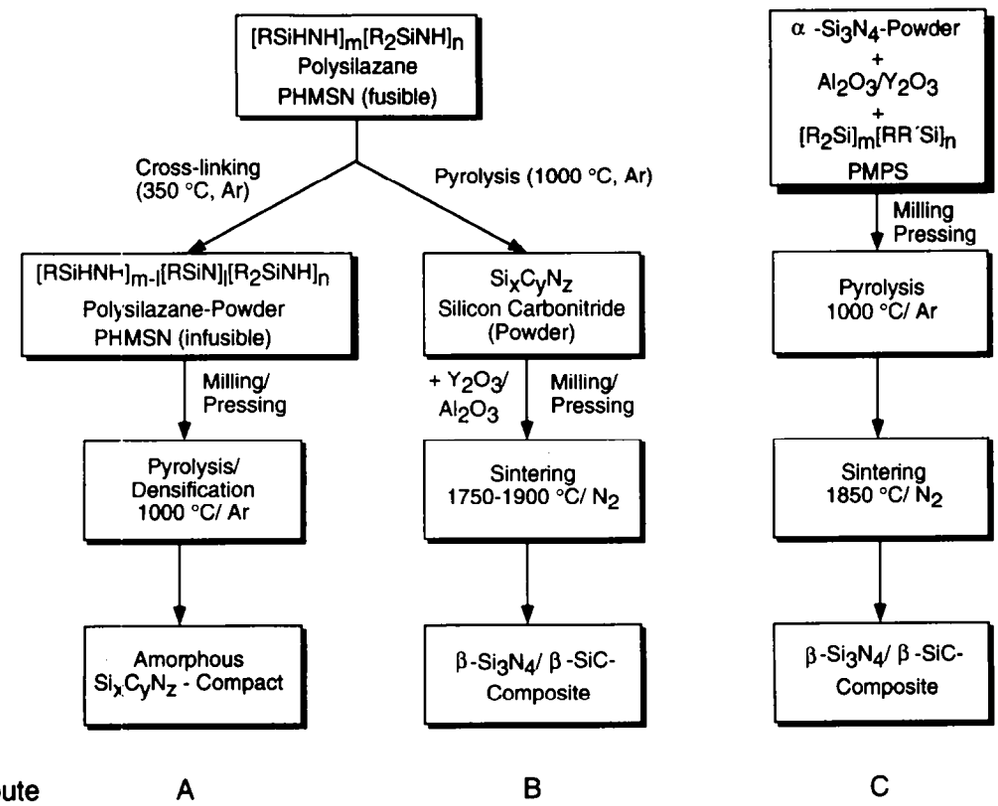

Fig. 2. Flow chart representing the processes A, B and C applied for the preparation of Si-based bulk ceramics derived from organoelement precursors. R = methyl (CH_3); R' = phenyl (C_6H_5H).

Phase compositions were determined by X-ray powder diffraction using monochromated CuK_α radiation (wavelength 154·178 pm).

For the determination of the ceramic solid-phase densities, the densified bulk samples were ball milled to powders. The solid-phase densities of the powders were then measured in a pycnometer using water as the liquid. Silicon carbonitride produced according to route A was analyzed in terms of BET surface area and pore size distribution by the measurement of the adsorption and desorption isotherms using N_2 or Ar as the adsorbing gas to ascertain the influence of possible nanoporosity on the solid-phase density. The solid-phase density of annealed and infusible polysilazane powder (PHMSN) was evaluated by pycnometry with n-hexane as the liquid. The bulk densities were determined by the water displacement method or, in the case of samples with open porosity, by mercury-pressure porosimetry. Relative densities were either based on theoretical densities calculated according to the rule of mixtures or on the ascertained solid-phase densities.

The amorphous silicon carbonitride was analysed by ESCA using Mg-K_α irradiation (1253·6 eV) as the X-ray source.[3] In order to avoid a charge shift due to the low electrical conductivity of the silicon carbonitride, the powder samples were mixed with Cu or Al powder (80 vol%) and uniaxially pressed to tablets.

Flexural strength was determined by the 4-point bend test[4] with an outer and inner span of 40 and 20 mm respectively in the case of room temperature testing and of 20 and 12 mm respectively in the high-temperature case. The flexural strength is given as the mean value calculated from eight specimens. Fracture toughness (K_{IC}) was evaluated by the indentation crack length method (ICL) according to Anstis *et al.*[30] The thermal decomposition of polysilazane-derived silicon oxynitride, Si_2N_2O, was investigated by TGA-MS.[5]

2.2 Synthesis and processing of the materials

2.2.1 Synthesis of additive-free monolithic silicon carbonitride (route A)

The starting material, poly(hydridomethyl)silazane (PHMSN) with the composition $[CH_3SiHNH]_m$ $[(CH_3)_2SiNH]_n$, was commercially available[6] and was used without purification.

In a typical experiment, 50 g of PHMSN were further cross-linked by thermally induced polycondensation for 100 min at 350°C in 0·1 MPa Ar and subsequently for 80 min in vacuum (2×10^{-3} Torr) at the same temperature. During the heat-treatment, a colourless liquid was distilled off and the overall mass loss was determined to be 12 wt%. The annealed PHMSN was infusible and insoluble in organic solvents such as toluene, THF or n-hexane. A solid-phase density of 1·22 g/cm^3 for the infusible polymer was evaluated. The polycondensation was investigated by simultaneous thermo-gravimetric and mass spectrometric (TGA–MS) measurements.[7] The material was then ball milled for 1 h with ZrO_2-balls, sieved through a 32 μm screen and finally compacted by cold isostatic pressing at 640 MPa into cylindrical samples 14 mm in diameter and in height or into rectangular bars having dimensions of 60 × 22 × 14 mm.[3] The relative green densities of the polymer green bodies were in the range of 84–89%. The main part of the pore volume exhibited pore radii of less than 100 nm, as determined by Hg-pressure porosimetry.[8] A minor amount of porosity with radii in the range of 10 μm was also detected. Subsequently, the polymeric green body was heated to 1000°C with a heating rate of 0·5–1°C/min in flowing Ar. Relative linear shrinkages of 25 up to 28% were detected and the overall yield of the black polymer-derived silicon carbonitride was found to be 68% relative to the PHMSN used. According to chemical analysis, the material contained 57·8 wt% Si, 14·3 wt% C, and 26·0 wt% N. From these values, an empirical formula $Si_{1·7}C_{1·0}N_{1·6}$ was derived for the synthesized silicon carbonitride (Table 2). The sample handled in air was contaminated with 0·8 wt% 0. Contamination of the ceramic residues with Zr stemming from the processing of the cross-linked polymer powder with ZrO_2 balls could not be detected. The as-pyrolyzed compacts exhibited relative bulk densities of 90–94% corresponding to a solid-phase density of 2·33 g/cm^3 and to open porosities in the range between 10 and 6% as found by Hg-pressure porosimetry (Table 3). The solid-phase density of PHMSN-derived silicon carbonitride (2·33 g/cm^3) deduced from Hg-pressure porosimetry was in good accordance with that determined by water

[c]Calculated according to the rule of mixtures assuming SiC and C as the phases formed during pyrolysis.

pycnometry of $Si_{1.7}C_{1.0}N_{1.6}$-powder (2·30 g/cm³). In addition, gas adsorption measurements of the as-synthesized silicon carbonitride powder revealed a BET surface area of 5·5 m^2g.Thus, it can be concluded that the pyrolysis of the polysilazane PHMSN gives fully dense amorphous silicon carbonitride powder particles without any detectable nanoporosity.

Pyrolysis of PHMSN-powder in NH_3 up to 900°C provided X-ray amorphous, white silicon nitride in 65% yield. The silicon content was measured to be 60·2 wt% (theoretical value for crystalline Si_3N_4: 60·0 wt%). Due to manipulation of the material in air, an oxygen contamination of 4 wt% was detected. The residual carbon content was below the detection limit of 0·3 wt%.

2.2.2 Synthesis and sintering of polysilazane derived Si-based ceramic powders with additives (route B)

Amorphous polysilazane-derived Si-based ceramic powders were obtained by the pyrolysis of poly(chlorohydridomethyl)silazane PCMSN in flowing Ar or in flowing NH_3. The synthesis of PCMSN is based on the reaction of oligomeric silazanes $[CH_3SiHNH]_n$ with dichlororganosilanes CH_3SiHCl_2[28] and is shown by the following simplified reaction equations:

$$RR'SiCl_2 \xrightarrow{NH_3} [-RR'Si-NH-]_n / R = H;\ R' = CH_3 \quad (1)$$

$$[-CH_3SiH-NH-]_x + yCH_3SiHCl_2 \xrightarrow[H_2/HCl]{30\text{–}300°C} [-CH_3SiH-N=]_m[-CH_3SiCl-N=]_n \quad (2)$$

Pyrolysis of PCMSN in argon at 1000°C gave a black X-ray amorphous silicon carbonitride powder with an empirical composition $Si_{1.7}C_{1.0}N_{1.5}$ and 72 wt% yield (Table 2). Decomposition of PCMSN in ammonia at 1000°C resulted in the formation of X-ray amorphous silicon nitride with 68 % yield. The nitrogen content was measured to be 35·2 wt%. The product was contaminated with 3·1 wt% oxygen and the residual carbon content was less than 0·5 wt%.

Prior to sintering, the different amorphous polymer-derived powders were attrition milled at 1000 rpm either in air or under Ar for 3 h after addition of Al_2O_3 and Y_2O_3 in various amounts. Isopropanol was used as the suspension medium and Si_3N_4-balls as the milling medium. After evaporation of the alcohol, the powder was sieved through a 160 μm-screen and subsequently cold-isostatically pressed at 640 MPa to form green compacts (cylinders 10 mm in length and 15 mm in diameter or rectangular strength-test bars 55 × 25 × 15 mm^3).

A graphite furnace[9] was used for the sintering experiments. Heating rates of 5 and 10°C/min were applied for all samples; the final temperatures were 1750 or 1850°C in 0·1 MPa nitrogen atmosphere.

Besides pressureless sintering of oxide-doped PCMSN-derived silicon carbonitride powder, post-gas-pressure sintering at 1900°C and 10 MPa N_2-pressure[10] was applied to yield polycrystalline Si_3N_4/SiC-composites.

2.2.3 Synthesis and sintering of α-Si_3N_4-powder/ 20 wt% PMPS-blends (route C)

The reaction of a mixture of 5 mol $(CH_3)_2SiCl_2$ and 1 mol $CH_3(C_6H_5)SiCl_2$[11] with Na/K-alloy in THF as the solvent provided poly(methylphenyl)-silane PMPS as shown in eqn 3.

$$5\ R_2SiCl_2 + RR'SiCl_2 \xrightarrow[-NaCl/KCl]{Na/K\text{–}alloy} [[R_2Si]_5[RR'Si]]_n \quad / R = CH_3;\ R' = C_6H_5 \quad (3)$$

Before the preparation of the ceramic-powder/ polymer-blends, as-synthesized PMPS was first heat-treated at 500°C for 5 h under Ar. The resulting product was an amber-coloured polysilane soluble in organic solvents and having a melting range of 100–120°C.

[9]Furnace GERO GmbH, Neuhausen, Germany.
[10]Furnace GERO GmbH, Neuhausen, Germany.
[11]The organochlorosilanes obtained from Merck, Darmstadt, Germany were used without further purification.

Attrition milled α-Si_3N_4-powder[12] containing 2·8 wt% AlN, 7·8 wt% Y_2O_3 and 1·4 wt% Al_2O_3 as sintering additives was mixed with 20 wt% annealed PMPS dissolved in THF. Subsequent evaporation of the solvent THF gave α-Si_3N_4-powder homogeneously coated with the polysilane PMPS. The α-Si_3N_4-powder/PMPS-blend was then cold-isostatically pressed at 640 MPa. Finally, pyrolysis and sintering of the cold-isostatically pressed polymer-powder mixture was conducted under 0·1 MPa Ar at temperatures up to 1000°C in a quartz tube and under 0·1 MPa N_2 up to the final sintering temperature of 1850°C in a graphite furnace.[8]

3 Results and discussion

3.1 Synthesis and processing of the materials

The chlorosilanes were reacted either with Na/K-alloy or with NH_3 providing various types of organoelement ceramic precursors (Fig. 1). Basically, polymers with a high viscosity and a low volatility have to be synthesized to produce dense bulk ceramic materials. Best results, i.e. the highest ceramic yields, are obtained using infusible polymers.[13]

The following different polymer processing routes (A, B, and C) were used to produce dense or near dense bulk ceramics (Fig. 2).

Route A in Figure 2

During the proceeding polycondensation of fusible PHMSN at 350°C, mainly ammonia and hydrogen were evolved as could be determined by simultaneous thermal gravimetric and mass spectrometric (TGA–MS) investigations. The evolution of H_2 indicates that the thermal cross-linking proceeds via the formation of three-dimensional bridging [RSiN]-units:

$$[RSiHNH]_m[R_2SiNH]_n \xrightarrow{350°C/-H_2} \begin{matrix}[RSiHNH]_{m-l}[RSiN]_l \\ [R_2SiNH]_n\end{matrix} \quad (4)$$

Ammonia is formed during the heat-treatment due to condensation of H_2N-polymer end groups. An infusible polysilazane PHMSN was isolated as the reaction product (Fig. 2). The subsequent thermolysis of the compacted infusible polysilazane powder at 1000°C in Ar gave amorphous, additive-free silicon carbonitride compacts with dimensions of 42 × 16 × 10 mm^3. According to our studies, the crack-free polymer to ceramic transformation process succeeds if the following requirements are met:

- The organoelement polymer has to be infusible to enable the compact to shrink while retaining its shape during the heat-treatment.
- After shaping of the polymer-powder, a transient open porosity has to be present to allow the volatile reaction gases to be released without forming cracks and gas bubbles.
- Finally, during ceramisation, the original polymer particles have to form a continuous three-dimensional network by the formation of new covalent bonds between the individual polysilazane powder particles.

Route B in Figure 2

The infusible polysilazane powder was first pyrolyzed in Ar to an amorphous Si–C–N ceramic powder and then processed into dense polycrystalline β-Si_3N_4/β-SiC-composite ceramics by liquid phase sintering at higher temperatures (Fig. 2). Using ammonia instead of Ar during pyrolysis of the polysilazane powders PHMSN and PCMSN results in the formation of X-ray amorphous Si_3N_4-powder (Fig. 1). During attrition milling in wet isopropanol, the reactive amorphous Si_3N_4-powder takes up oxygen by hydrolysis or by alcoholysis in such amounts that pure polycrystalline silicon oxynitride, Si_2N_2O, is formed after densification at 1600°C in 0·1 MPa N_2 when Al_2O_3 and Y_2O_3 were added to this powder. Accordingly, the oxygen content increased from 3·1 wt% in the as-pyrolyzed (NH_3) material to 14·8 wt% in the attrition milled powder. The oxygen content of crystalline Si_2N_2O is calculated to be 14·0 wt%. The oxygen contamination can be reduced to 6·7 wt% by the use of dried isopropanol as the suspension medium and by attrition milling under an Ar atmosphere. In contrast, the oxygen content of the carbon containing silicon carbonitride powder attrition milled in wet isopropanol in air was significantly lower (4 wt%) owing to a strongly decreasing sensitivity of these powders towards moisture.

Route C in Figure 2

Pyrolysis of polysilane PMPS in Ar at 1000°C resulted in the formation of X-ray amorphous SiC_{1+x} with $x = 1$[29] (Fig. 1). In the present investigation, we used PMPS for the *in situ* formation of inter- and intragranular SiC dispersions in a Si_3N_4 matrix.

The ceramic yields, elemental composition and solid-phase densities of the pure organosilicon polymer-derived ceramics are listed in Table 2. Details of the processing of the polymers to dense bulk ceramics and some characteristic data of the densified products such as density, porosity and phase composition are summarized in Table 3.

[12]LC 12 H.C. Starck, Germany.

[13]In contrast, meltable and soluble polymers with lower viscosities are suitable for infiltration processes, for fiber preparation, and for the formation of coatings.

3.2 Characterization of the polymer-derived ceramics

3.2.1 PHMSN-derived monolithic silicon carbonitride (route A)

Generally, the volume shrinkage caused by the thermal decomposition of a polymeric compound (*P*) into a ceramic (*C*) with the simultaneous formation of gaseous reaction products (*R*) according to eqn (5)

$$P_{(s,l)} \rightarrow C_{(s)} + R_{(g)} \tag{5}$$

depends on the change in the density of the contributing phases and on the ceramic yield α (≤ 1). The yield α is defined as the ratio of the mass of the polymer-derived ceramic (M_C) to that of the applied polymer (M_P):

$$\alpha = \frac{M_C}{M_P} \tag{6}$$

The overall change in the volume (ΔV) can then be expressed in terms of the mass (M) and solid-phase density (D) of the condensed phases considered in eqn (5):

$$\Delta V = \frac{M_P(D_C - \alpha D_P)}{D_P D_C} \tag{7}$$

or:

$$\Delta V\,[\%] = \frac{D_C - \alpha D_P}{D_C} 100 \tag{8}$$

The polymer to ceramic transformation of shaped PHMSN bodies according to route A in Fig. 2 provided silicon carbonitride compacts with up to 94% rel. density and with the composition $Si_{1.7}C_{1.0}N_{1.6}$. In this case, the densities D_P, D_C, and the ceramic yield α were determined to be 1·22 g/cm³, 2·33 g/cm³, and 77%. From this, the calculated value ΔV of 59·7, however, is about 5% lower than the experimentally determined relative volume shrinkage of 65%. This finding suggests that additional densification processes occur during pyrolysis that enable the porous polymeric body to form dense ceramic materials, even at these low reaction temperatures (800–1200°C).

The SEM micrograph of a polished surface of PHMSN-derived silicon carbonitride bulk sample is shown in Fig. 3. It is evident that pore sizes up to 10–15 μm are present which is in accordance with the pore size distribution measurements from Hg pressure porosimetry.

In order to evaluate the microstructural features of amorphous silicon carbonitride, $Si_{1.7}C_{1.0}N_{1.6}$ obtained after pyrolysis of PHMSN at 1000°C in Ar, ESCA and analytical TEM investigations were performed. The ESCA results support a single phase amorphous material. The ESCA Si(2p)

Fig. 3. SEM micrograph of a polished surface of PHMSN-derived silicon carbonitride bulk material prepared according to route A.

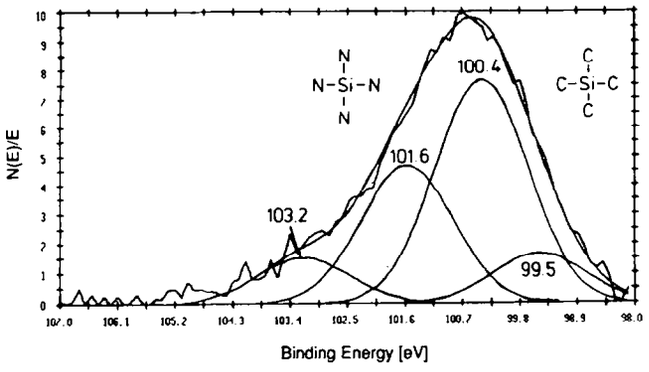

Fig. 4. ESCA Si(2p) spectrum of PHMSN-derived amorphous silicon carbonitride.

spectrum has to be deconvoluted using at least four Gaussian functions as shown in Fig. 4 indicating the presence of Si–N and Si–C bonds in the polysilazane derived material. The bonding energy at 99·5 and at 101·6 eV are associated with SiC_4- and SiN_4-units, respectively, whereas that at 100·4 eV is due to $SiN_{4-x}C_x$-units. The bonding energy located at 103·2 eV is related to the presence of oxygen contamination in the form of silica or silicon oxynitrides. Additionally, no SiC-shoulder can be assigned in the ESCA Si(2p) spectrum in contrast to reports for a mechanical Si_3N_4/SiC mixture.[31] The measured binding energy curve of the N(1s) electron can be deconvoluted into at least two Gaussian peaks with maxima located at 397·4 eV and 398·6 eV corresponding to N–Si and N–C bonds, respectively. The deconvoluted C(1s) peaks clearly indicate the presence of C–C (284·2 eV), C–N (286·4 eV), and Si–C bonds (282·7 eV).

Analytical TEM investigations revealed that the pure silicon carbonitride is completely amorphous and a single phase material. No segregations of C, SiC or Si_3N_4 could be found by the evaluation of the microstructure by means of electron spectroscopic imaging (ESI) in an energy filtering TEM.[32] Even after long annealing times in the order of 50 h under 0·1 MPa N_2 at 1000°C, the material remained amorphous without any phase partitioning. Accordingly, the synthesized silicon carbonitride can be considered as a metastable solid solution. It is worth to mention that such a material cannot be produced by conventional synthesis, i.e. by mixing and heat-treating of SiC and/or C with Si_3N_4.

The determined solid-phase density D_C = 2·33 g/cm^3 of the silicon carbonitride is significantly lower than that of the thermodynamically stable phases of $Si_3N_4$and SiC ($\rho \sim 3{\cdot}2$ g/cm^3). According to the rule of mixtures, solid-phase densities between 2·97 and 3·14 g/cm^3 were expected if the sample is considered to contain amorphous and/or crystalline Si_3N_4, SiC and C (graphite). The low density cannot be explained by nanoporosity since gas adsorption measurements clearly indicated the formation of fully dense silicon carbonitride powder. This phenomenon is associated with a highly disordered solid-phase structure and is in part caused by residual Si–H and C–H bonds which are still present in the material pyrolyzed at 1150°C in Ar as determined by infra-red investigations. In the infra-red spectrum, silicon carbonitride reveals broad vibration bands located at 1250–720 cm^{-1} and 600–415 cm^{-1} indicating the presence of Si–N- and Si–C-bonds. In addition, sharp absorption bands located at 2950–2850 cm^{-1} and at 2164 cm^{-1} are due to aliphatic C–H- and Si–H bonds. The relative openness of amorphous SiC-based ceramics prepared by polymer pyrolysis has also been reported by Soraru *et al.*[33] The solid-phase density of the silicon carbonitride increased from 2·33 g/cm^3 at 1000°C to 2·40 g/cm^3 at 1400°C and is related to the successive loss of residual hydrogen.

The Vickers Hardness, HV, of silicon carbonitride synthesized at 1150°C was determined to be 10 GPa in a sample with 6% open porosity. The median value of the fracture strength σ_B is of the order of 170 MPa with a maximum value of 370 MPa.

Crystallization of $Si_{1{\cdot}7}C_{1{\cdot}0}N_{1{\cdot}6}$ started at temperatures exceeding 1400°C and gave α-Si_3N_4 and α/β-SiC. In contrast, amorphous Si_3N_4 obtained by the mineralization of PHMSN under NH_3 was completely crystallized to α-Si_3N_4 at 1200°C and 30 min soaking time. This behavior reveals a significantly higher thermal stability of the compositionally more complex ternary system Si–C–N. The high thermal stability of precursor-derived Si–C–N ceramics was also observed by D. Mocaer *et al.*[34] The crystallization was accompanied by a weight loss reaching 10·3% after 50 h annealing of the silicon carbonitride bulk material at 1600°C in nitrogen and is associated with the solid state reaction of carbon with silicon nitride partitioned during the course of heat-treatment. Thermodynamically, the excess carbon reacts at temperatures exceeding 1440°C with the Si_3N_4-particles under 0·1 MPa nitrogen pressure according to the following reaction:[35]

$$Si_3N_4 + 3C \rightarrow 3SiC + 2N_2 \qquad (9)$$

3.2.2 PCMSN-derived β-Si_3N_4/24 wt% β-SiC-composites and Si_3N_4-ceramics (route B)

Silicon carbonitride powder with the composition $Si_{1{\cdot}7}C_{1{\cdot}0}N_{1{\cdot}5}$ derived from PCMSN was liquid phase sintered according to route B (Fig. 2, Table 3) with Al_2O_3 and Y_2O_3 (weight ratio = 1 : 2) as sintering aids and at 0·1 MPa N_2-pressure resulting in the in situ formation of β-Si_3N_4 and β-SiC polycrystals as the matrix phase. During the course of densification, β-Si_3N_4- and Si_2N_2O-particles crystallized first as could be determined by

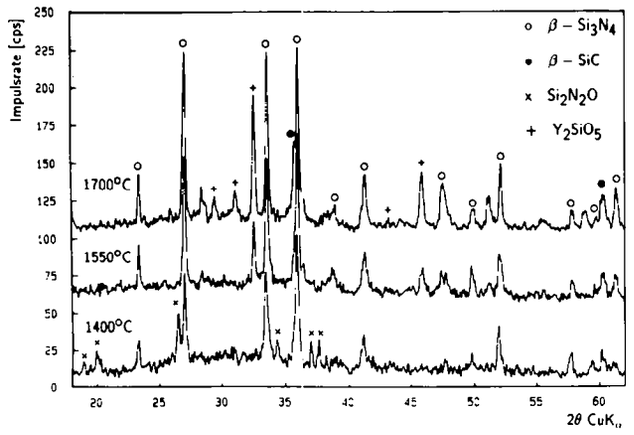

Fig. 5. X-ray diffractograms of cold-isostatically pressed PDSCN powder heat-treated at various temperatures in N_2 without isothermal hold in the presence of 10 wt% Y_2O_3 and 5 wt% Al_2O_3 according to process B.

sintering the cold-isostatically pressed silicon carbonitride powder samples without any holding time at various temperatures. The X-ray diffractograms shown in Fig. 5 clearly show that β-SiC begins to crystallize at temperatures above 1500°C, whereas β-Si_3N_4 is identified at $T \leq 1400$°C. The intermediate generation of silicon oxynitride Si_2N_2O evident at 1400°C cannot be observed at higher temperatures. Crystallization of a part of the amorphous oxide phase in the form of Y_2SiO_5 was also observed in the material annealed at $T \geq 1550$°C. The sintering of the amorphous Si-, C-, and N-containing starting powder has been proposed to proceed via a particle disintegration mechanism.[7] These findings are in accordance with the TEM studies of the microstructure developed at different final temperatures during liquid phase sintering of silicon carbonitride powder.[32]

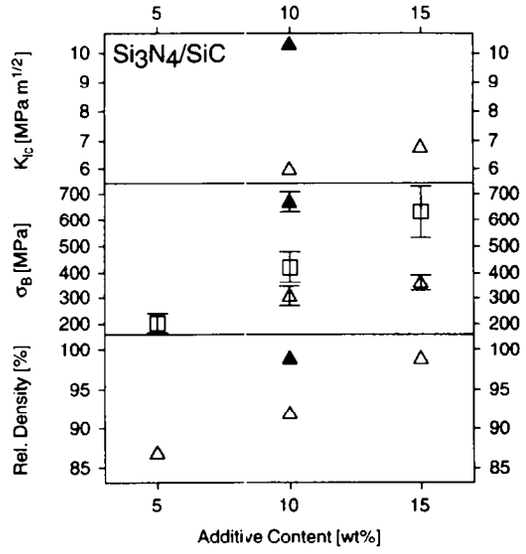

Fig. 6. Sintering densities, fracture strength and toughness (average values) of PCMSN-derived Si_3N_4/SiC-composite versus additive content (Y_2O_3/Al_2O_3 = 2:1). Δ = samples liquid phase sintered at 1850°C and 0·1 MPa N_2-pressure for 1 h according to process B; the filled triangles represent the values of samples which have been subsequently gas-pressure sintered at 1900°C and 10 MPa N_2-pressure for 1 h; □ = fracture strength values measured at 1000°C in air.

In Fig. 6, relative densities and some mechanical properties of the densified samples are shown as a function of additive content. The highest relative density was obtained by the addition of 15 wt% oxides. In the case of 10 wt% sintering aids, similar high densities were measured after gas-pressure sintering of presintered samples. The flexural strength significantly increased from 320 MPa at room temperature to 635 MPa at 1000°C. A maximum value of 700 MPa was attained. This phenomenon may be associated either with the reduction of internal stresses at elevated temperatures or with the reduction of surface defects owing to crack blunting via oxidation during the measurements in air. At temperatures exceeding 1100°C, the strength value strongly decreased due to the beginning of softening of the glassy phase. The room-temperature strength was improved from 280 to 650 MPa for the gas pressure sintered sample. The K_{IC} value was determined to be 10·2 MPa$\sqrt{m}$ which is nearly twice the fracture toughness measured in the presintered material (5·8 MPa$\sqrt{m}$). In Fig. 7, the resulting microstructure and the crack path induced by a Vickers indenter are shown. Due to gas-pressure sintering at a relatively high temperature (1900°C) large rod-like grain sizes up to 40 μm in length were found in

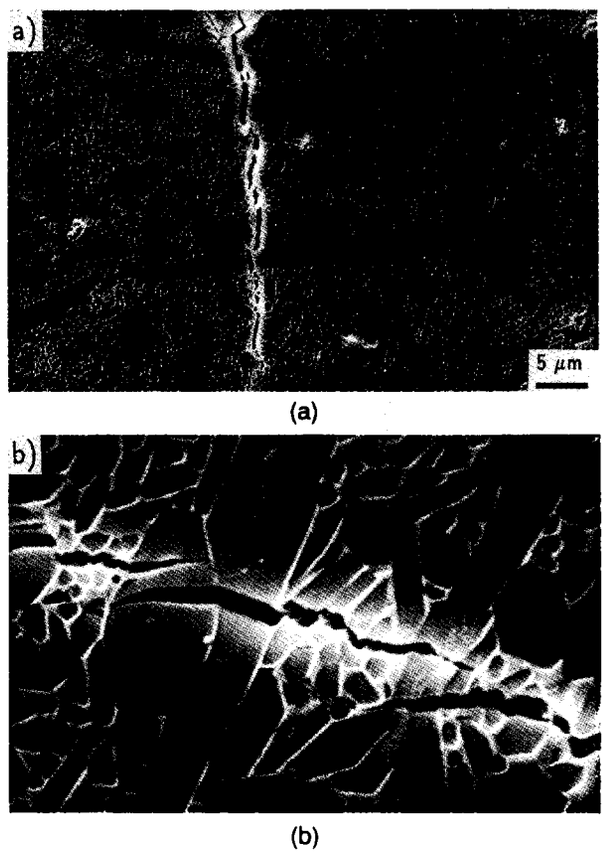

Fig. 7. (a) SEM micrograph of the microstructure of gas pressure and liquid phase sintered β-Si_3N_4/β-SiC composite according to route B (polished and plasma etched surface). The crack has been induced by a Vickers indenter. The micrograph (b) shows a section at higher magnification indicating the occurrence of crack branching. For sintering conditions see Fig. 6.

the β-Si_3N_4/β-SiC microstructure. The rod-like growth is typical for β-Si_3N_4 sintered with 15 wt% additives in the weight ratio Y_2O_3/Al_2O_3 = 2:1.[36] Besides these large, elongated particles, small crystallites in the range of 0·5 μm to several microns were also present.

The crack path induced by a Vickers indenter in the gas pressure sintered sample exhibited both intergranular and transgranular fracture modes as can be seen in Fig. 7. In addition, the crack path reveals the presence of crack branching (Fig. 7(b)) and indicates microcracking causing the relatively high fracture toughness measured. The distance between two crack branches is estimated to be about 5 μm. It is evident that the cracks always stop in a region consisting of small grains as can be also seen in Fig. 7(b). Further investigations on the toughening mechanism operating in the polymer-derived Si_3N_4/SiC-composites are in progress.

The ammonolysis of PCMSN at 1000°C resulted in the formation of amorphous silicon nitride (Fig. 1). Densification of the PCMSN-derived amorphous Si_3N_4-powder (PDSN) containing yttria and alumina as the sintering aids gave dense polycrystalline Si_3N_4-ceramics. X-ray diffraction patterns of the densified samples revealed the presence of the β-modification of Si_3N_4 exclusively. The final densities and mechanical properties vs. the additive content of the sintered PDSN-powder are given in Fig. 8. Figure 9 shows a typical microstructure of the sample densified at 1750°C containing 15 wt% additives. A crack path induced by a Vickers indenter reveals predominant intergranular fracture mode as is represented in Figure 9(b).

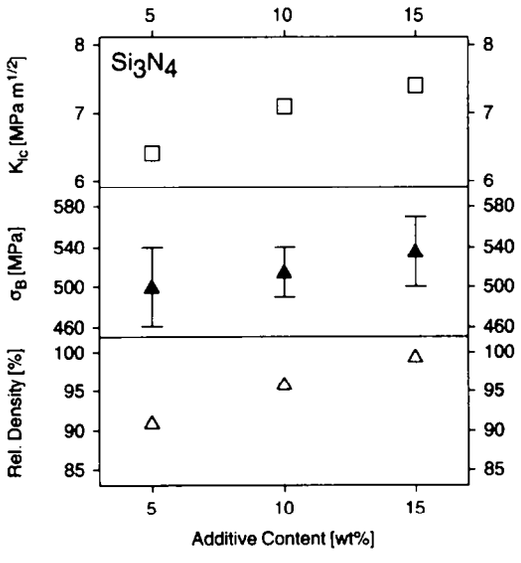

Fig. 8. Mean values of sintering densities, fracture strength and toughness of PCMSN-derived Si_3N_4-ceramic versus additive content (Y_2O_3/Al_2O_3 = 2:1). Sintering was conducted according to process B at 1750°C for 1 h under 0·1 MPa N_2.

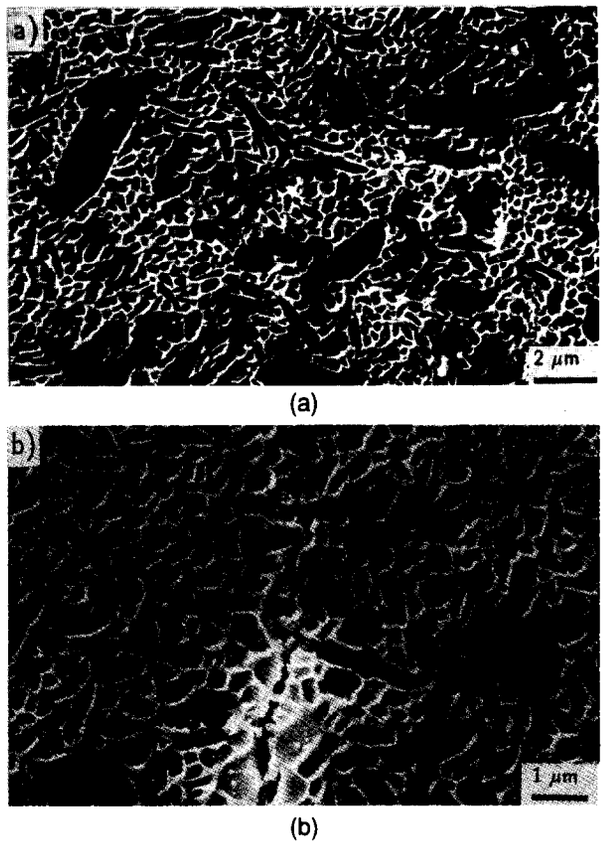

Fig. 9. (a) SEM micrograph of a polished and plasma etched section of the PCMSN derived Si_3N_4 microstructure. The micrograph (b) shows the fracture path induced by a Vickers indenter. The sample was liquid phase sintered after route B at 1750°C for 1 h and 0·1 MPa N_2 pressure with 10 wt% Y_2O_3 and 5 wt% Al_2O_3 as sintering additives.

3.2.3 PCMSN-derived Si_2N_2O (route B)

Besides SiC and Si_3N_4, Si_2N_2O is a potential material appropriate for high-temperature engineering applications. Thermodynamic calculations indicate a superior stability in oxidizing environments,[37,38] compared to Si_3N_4 and SiC. Generally, the pressureless densification of Si_2N_2O-powders is difficult due to its decomposition[39] at temperatures above 1580°C according to eqn (10)

$$3Si_2N_2O \rightarrow 3SiO + Si_3N_4 + N_2 \qquad (10)$$

Therefore, Si_2N_2O-materials with relative densities higher than 95% can only be obtained by hot or hot isostatic pressing of Si_3N_4 and SiO_2 powders at temperatures greater than 1800°C.[38] The use of double oxide sintering aids such as a combination of Al_2O_3 with Y_2O_3 lowers the eutectic temperature and ensures liquid phase sintering yielding final relative densities up to 93%.[39]

We found that PCMSN-derived amorphous silicon oxynitride can be densified at 1600°C in 0·1 MPa nitrogen atmosphere up to 97 and 99% of relative density in the presence of 10 and 15 wt% oxide additives (Figs 10 and 11), respectively. According to X-ray diffraction analysis of the

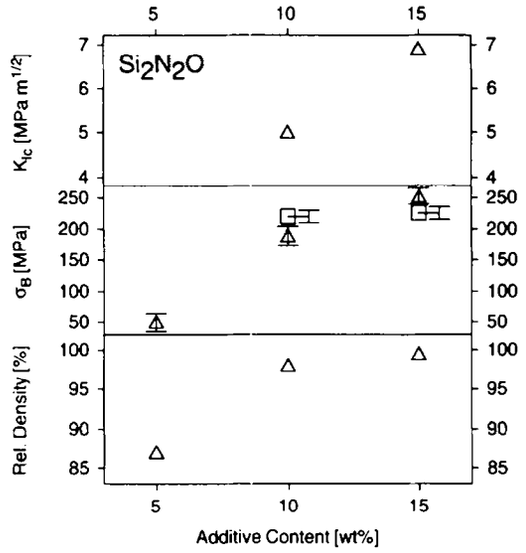

Fig. 10. Average values of sintering densities, fracture strength and toughness of PCMSN-derived Si_2N_2O-ceramic versus additive content (Y_2O_3/Al_2O_3 = 2:1) prepared after process B. Δ = samples sintered at 1600°C for 1 h and 0·1 MPa N_2-pressure; □ = fracture strength values measured at 1000°C in air.

densified sample, the amorphous powder crystallizes to Si_2N_2O, exclusively. No diffraction lines due to silicon nitride polymorphs, indicating the decomposition of the oxynitride phase, could be detected up to 1600°C (Fig. 12). At higher temperatures, β-Si_3N_4 is generated as the crystalline phase. Thermal gravimetric investigations in combination with a mass spectrometer (TGA–MS) of amorphous Si_2N_2O under 0·1 MPa He pressure revealed that the evolution of SiO with m/e = 44 was already detected in small amounts at $T \geq 1400$°C indicating the starting decomposition of the material. Owing to the reduced nitrogen pressure under these conditions, the decomposition of Si_2N_2O occurred at lower temperatures.

The diagrams depicted in Fig. 10 show the relative densities, the mechanical strength, and the K_{IC}

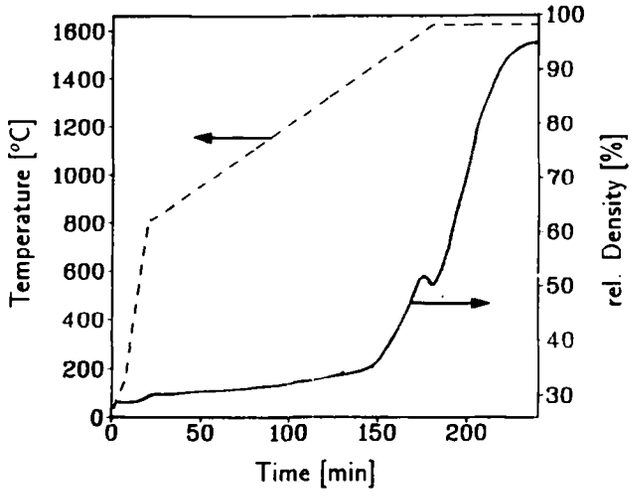

Fig. 11. Density and temperature versus time during sintering according to route B under 0·1 MPa N_2 of PCMSN derived amorphous Si_2N_2O-powder. 10 wt% Y_2O_3 and 5 wt% Al_2O_3 have been used as sintering additives.

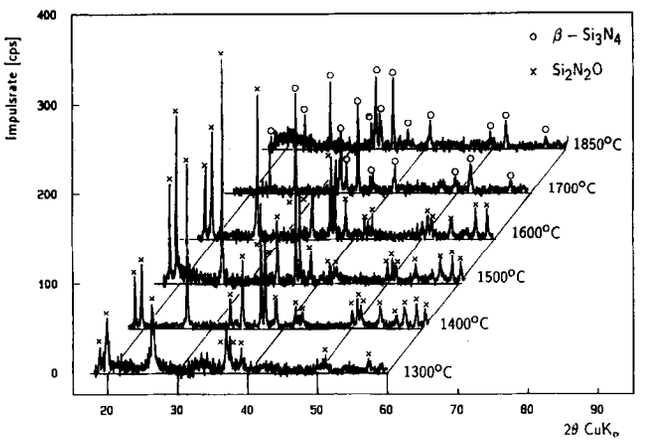

Fig. 12. X-ray diffractogramms of amorphous Si_2N_2O heat-treated for 15 min at various temperatures in the presence of 6·66 wt% Y_2O_3 and 3·33 wt% Al_2O_3 under 0·1 MPa N_2.

values of the sintered Si_2N_2O-material versus the amount of sintering aids. Depending on the final density, the mechanical strength values at room temperature are in the range of 205 (ρ = 97%, 10 wt% additives) and 230 MPa (ρ = 99%, 15 wt% additives) and are retained up to 1000°C. At higher temperatures, the fracture strength rapidly decreases.

3.2.4 α-Si_3N_4-powder/20 wt% PMPS-blend (route C)
The high linear shrinkage of up to 28% found during polymer to ceramic transformation of compacted polysilazane powders (route A in Fig. 2) can be significantly reduced by mixing the polymeric fraction with inreactive powders. Thus a α-Si_3N_4-powder/20 wt% PMPS-mixture prepared according to route C in Fig. 2 and pyrolysed at 1000°C in Ar showed a linear shrinkage of up to 3–4%. The sintered composite sample contained 10 wt% SiC in situ generated from the polysilane PMPS used as determined by chemical analysis (Table 2).

According to TEM studies, the resulting microstructure of the liquid phase sintered samples revealed the presence of SiC crystallites with grain sizes in the range between 20 and 200 nm embedded either intra- or intergranular in the Si_3N_4 matrix; the structure is described in detail in Part II.[32]

Pyrolysis of pure PMPS at 1000°C in Ar without Si_3N_4-powder and without additives gave a ceramic with a molar composition $SiC_{2.0}$. Crystallization started at $T \geq 1200$°C forming nano-sized β-SiC as the crystalline phase.[40] The median crystallite size was derived from the line broadening of the SiC(100)-reflexions in the X-ray powder diffractogram and is plotted versus temperature in Fig. 13. As can be seen in Fig. 13, the grain size of β-SiC heat-treated between 1200 and 2000°C is in the nm-range. Consequently, the β-SiC grain

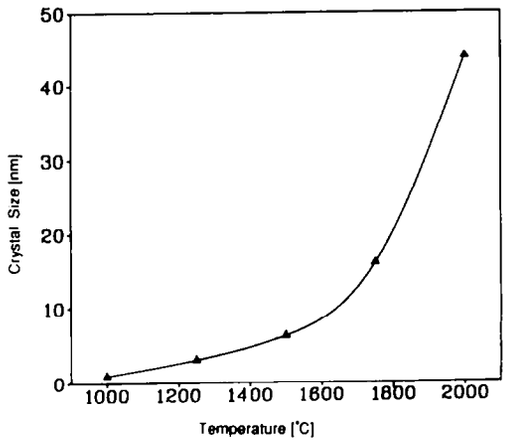

Fig. 13. Temperature dependence of the PMPS-derived β-SiC crystallite size. Isothermal hold at each temperature = 1 h in Ar.

growth is retarded which is related to the excess carbon content present in the polysilane derived SiC (Table 2). In addition, no phase transformation from the β- to the α-modification was observed even by annealing the sample at 2000°C in Ar.

4 Conclusions and outlook

The present studies have shown that dense or near dense silicon-based non-oxide bulk ceramic materials can be synthesized from organosilicon compounds under the following conditions:

(1) The synthesis of crack-free silicon carbonitride ($Si_{1.7}C_{1.0}N_{1.6}$) ceramic parts with 94% rel. density by the direct polymer to ceramic transformation process was demonstrated. An infusible polysilazane prepared by the thermal cross-linking of a commercially available organoelement polymer was used as the starting material. The annealed polymer is ball-milled and sieved, isostatically pressed to polymer green bodies and finally pyrolyzed in Ar. The method is especially suitable for the fabrication of bulk ceramics other than fibers. The main advantages of this novel process compared to the conventional method for the production of Si_3N_4- and SiC-based ceramics are:
- low processing temperature of about 1000°C
- densification without sintering aids,
- low solid-phase density (2·33 g/cm^3) of the resulting ceramic, and
- synthesis of metastable solid solutions in the ternary system Si–C–N.

As-synthesized silicon carbonitride bulk ceramic was amorphous and single phase. The material produced was thermally stable in nitrogen up to 1400°C, had a hardness, HV, of 10 GPa, and a maximum bending strength value of 370 MPa determined in samples with 6% open porosity. Additive-free silicon carbonitride is expected to be a candidate material with high temperature creep resistance.

(2) Bulk ceramics based on crystalline polymorphs comprised of SiC, Si_3N_4, and Si_2N_2O were prepared by the liquid phase sintering of polymer-derived amorphous ceramic powders. Pyrolysis of polysilazanes at 1000°C in Ar gave metastable silicon carbonitride powders with homogeneous distribution of the constituents Si, C and N. During the course of the sintering of these powders attrition milled in isopropanol with Al_2O_3 and Y_2O_3 as oxide additives, the thermodynamically stable phases, β-Si_3N_4 and β-SiC, were formed *in situ* and dense Si_3N_4/SiC-composites were obtained. Similarly, dense Si_3N_4 and Si_2N_2O bodies were produced by the liquid phase sintering of amorphous Si_3N_4 powders obtained by pyrolysis of polysilazane in ammonia.

(3) Polysilane/silicon nitride powder blends have been used to reduce the high shrinkage associated with the density increase from the Si-polymer (ca. 1·1 g/cm^3) to the Si-ceramic (ca. 3·2 g/cm^3) during pyrolysis. The polysilane PMPS used in this work resulted in the *in situ* formation of $SiC_{2.0}$. During liquid phase sintering of the PMPS/Si_3N_4-powder mixture, β-SiC crystals were formed and were embedded inter- and intragranular in the Si_3N_4-matrix.

Due to the fact that Si-based polymers such as polysilanes and polysilazanes are now commercially available, the polymer pyrolysis process can be considered as an alternative method, with respect to the traditional technology, for the production of various Si-based non-oxide ceramics in large quantities. In addition, novel type of non-oxide ceramic materials such as the solid solutions of silicon carbonitrides and *in situ* crystallized Si_3N_4/SiC micro-, nano- and micro/nano-composites can be synthesized.

Abstract

The microstructure of polymer-derived Si-based ceramic materials was characterised with elemental distribution images produced by electron spectroscopic imaging. Depending on the processing conditions, a variety of different microstructures were obtained from the same precursor: without sintering additives, amorphous silicon carbonitride which is stable against crystallisation up to 1400°C is formed. In the presence of Al_2O_3 and Y_2O_3 as sintering additives, Si_3N_4/SiC-composite materials and Si_2N_2O ceramics are produced. Sintering a mixture of Si_3N4 powder with additional polysilane leads to a Si_3N_4/SiC-composite comprising nano-sized SiC inclusions in the Si_3N_4 grains. The development of the microstructure of the Si_3N_4/SiC composite materials was investigated as a function of the sintering temperature and of the concentration of the sintering additives. The observed microstructural changes lead to conclusions on the processes which occur during the sintering of the materials.

1 Introduction

A primary aim in the development of structural ceramics is to obtain control over both the mechanical properties and the macroscopic shape of the ceramic component. The mechanical properties of any material are governed by the microstructure. It is thus desirable to be capable of influencing the microstructure, via the starting material and the processing conditions, and to 'know' the result, via an efficient characterisation technique. In Part I[1] of our studies we have shown that preparing ceramic materials from polymer precursors potentially offers control of both the shape of the final ceramic product and of a variety of microstructural parameters, ranging from the synthesis of monolithic ceramics at low temperatures to the design of composite microstructures with several different phases.

In this paper we report on the results of our microstructural investigations on the polymer derived ceramic materials. In a systematic way we aim to gain insight into the relationships between microstructure and processing parameters. For characterisation, a new technique in transmission electron microscopy was used: electron spectroscopic imaging, (ESI).[2] With ESI, images showing the distribution of various elements in large specimen areas (several μm^2) at high resolution (2–3 nm) can be produced within short times (less than 1 min for one element). ESI is based on the use of an imaging energy filter and makes it possible to image the distribution of a certain element via the characteristic energy losses which an electron beam may suffer in inelastic scattering processes with the atoms in the sample. Hence, Energy Filtering Transmission Electron Microscopy (EFTEM) has become an important tool for the microstructural characterisation of composite microstructures.

In the last ten years considerable research has been devoted to the evaluation of microstructures in Si_3N_4 and SiC ceramics. For the sintering of Si_3N_4 ceramics, Al_2O_3 and Y_2O_3 are used as sintering additives in most cases. Sintering occurs via a liquid phase mechanism in which the solution of α-Si_3N_4 and reprecipitation of β-Si_3N_4 play an important role. Systematic studies with various

*Present address: Kernforschungszentrum Karlsruhe, IMF 3, Postfach 3640, D-76201 Karlsruhe, Germany.

amounts of sintering additive were carried out by Hayashi *et al.*[3] They found that diffusion through the liquid phase is the rate-limiting step in the growth of the Si_3N_4 crystals. Boberski *et al.*[4] investigated the intermediate sintering stages by quenching samples during the sintering process and found that the major densification step is correlated with the melting of the sintering additives at 1389°C and the $\alpha \rightarrow \beta$ transition occurring at 1615°C. Sintering of SiC with Al_2O_3 and Y_2O_3 as sintering additives has first been reported by Omori and Takei.[5] In a systematic TEM study, Kleebe[6] compared SiC and Si_3N_4 ceramics sintered with Al_2O_3 and Y_2O_3 and found that, in contrast to Si_3N_4, the SiC grains are not wetted by the liquid phase formed by the sintering additives. The microstructure of Si_3N_4/SiC-composite materials was investigated by several different groups.[7-11] The densification which can be obtained is significantly influenced by the amount of SiC added.[8] Higher contents of SiC particles inhibit complete densification and a number of pores remain in the final material. Indications for solution and reprecipitation of the SiC particles could only be found at temperatures above 1700°C. Under special conditions, inclusion of the SiC particles in the Si_3N_4 grains could be observed[9-11] which leads to an improvement of the mechanical properties. In the present paper we report on the sintering mechanisms observed in the Si_3N_4/SiC-composite materials prepared from polymer precursors. The temperature dependence of the sintering processes was studied by varying the maximum temperature. The dependence of the microstructure on the concentration of sintering additives was investigated by varying the amount of Al_2O_3 and Y_2O_3 which was added.

2 Experimental

2.1 Energy filtering TEM

In analytical electron microscopy the two methods mainly used, electron energy loss spectroscopy (EELS) and energy dispersive X-ray analysis (EDX), are based on focusing the probe on a small area of interest. The spectroscopic data are then analysed for each probe position. Two-dimensional chemical information can only be obtained by stepping the probe across the sample. For the light elements, EELS analysis is preferable because it offers a much higher detection efficiency. In principle, any EELS spectrometer can be treated as being part of the electron optical system of a TEM with the important property that the information on the image or diffraction pattern of the illuminated sample area is not completely lost but only heavily distorted while the electrons pass through the spectrometer. Within the past ten years, successful attempts have been made to correct these distortions electron-optically. One possibility is to combine four magnetic prisms in an Omega-like geometry where most of the electron optical aberrations are corrected by symmetry.[12] A different approach is to correct the distortions caused by one sector-magnet with an appropriate number of quadrupole and sextupole corrector elements.[13]

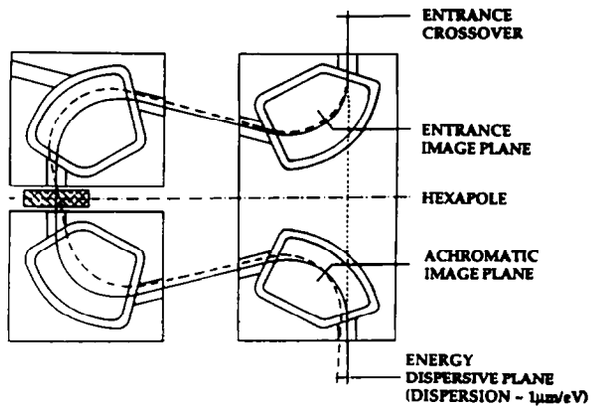

Fig. 1. Schematic drawing of the Omega filter. Through the symmetrical arrangement of magnetic prisms an image is transferred from the entrance image plane to the achromatic image plane. An energy loss spectrum of the illuminated sample area is formed in the energy dispersive plane.

In the present studies we have used a Zeiss EM 912 Omega which is the first commercially available EFTEM with an imaging Omega filter.[14] The design of the Omega filter is schematically shown in Fig. 1. An imaging filter combines two properties: (1) The symmetrical arrangement of prisms transfers an image without distortions to the achromatic image plane. (2) The energy dispersion of the whole arrangement of prisms causes the paths of electrons with different energies to separate and to form an energy loss spectrum at the exit surface of the Omega filter. In this energy dispersive plane, electrons within a defined energy loss interval $\Delta E_1 < \Delta E < \Delta E_2$ can be selected by inserting an energy selecting slit. Only these electrons will contribute to a magnified 'ESI' image which can be produced by focusing the following lenses of the projector system to the achromatic image plane.

2.2 Electron Spectroscopic Imaging (ESI)

Inner-shell excitation of the atoms by the beam electrons leads to characteristic edges in the energy-loss spectrum (Fig. 2). For energy losses above 100 eV the edges are located on top of a nearly exponentially decreasing background and the onset energies of each edge can be used to identify the individual chemical elements. The concentration of an element can be determined from an EELS spectrum if the pre-edge background is extrapolated and subtracted from the signal

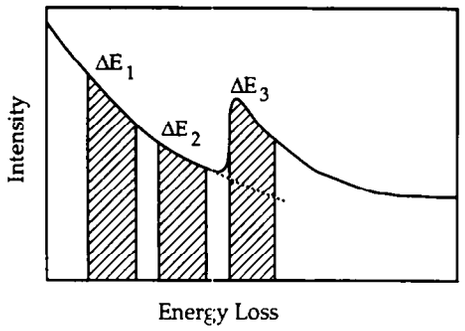

Fig. 2. Illustration of the three-window technique used to produce elemental distribution images. With the two ESI images acquired in front of the edge, an extrapolated background can be calculated and subtracted from the third image containing the element specific signal.

obtained above the edge. In ESI images this has to be done for each individual pixel. The easiest method for background subtraction, the three window technique, is illustrated in Fig. 2. Two ESI images are acquired in the background region before the edge and the extrapolated background is then subtracted from the ESI image containing the signal above the edge. As a result the difference image only contains intensity in the areas where the corresponding element is present in the sample and thus maps the distribution of this element. In the three window technique, however, the intensity in the difference image is not only depending on the concentration of the element but may also vary with thickness or the Bragg orientation of crystalline grains. Owing to the low intensity of the individual ESI images (up to a factor of 100–1000 less than the corresponding bright field image) the difference image will also contain considerable noise which makes it impossible to detect elements in very small concentrations (below 1 at%). The noise in the elemental distribution images can be reduced by special image processing techniques, which may result in a loss of resolution. The detection limits in elemental distribution images are as low as 1–2 monolayers, e.g. for segregants at grain boundaries.[15] The resolution limits are in the order of 2–5 nm, depending on the element and its concentration.

In the three window technique, the optimum position of the energy windows and their width depends on several parameters: (1) the intensity in the energy loss spectrum which decreases strongly with increasing energy loss; (2) the shape of the edge which only shows a sharp onset for the light elements, and (3) the width of the unstructured background region before the edge. The width and positions of the windows which we have used have been determined in an empirical way and are listed in Table 1. In the case of the Si–K edge at 1836 eV the slope of the decreasing background is so small that it can be extrapolated by a horizontal line. In this case, only one background image has to be acquired which is then simply subtracted from the image containing the signal.

Table 1. List of elements investigated by ESI. The energy losses of the edges, ΔE, and the centre of the windows, $\Delta E_1 ... \Delta E_3$, are given in eV.

Element	*Edge*	ΔE	ΔE_1	ΔE_2	ΔE_3	*Window width* ∂E
C	K	284	255	275	295	15
N	K	401	370	390	410	15
O	K	532	500	520	540	15
Si	K	1836	1740	1810	1880	50
Si	K	1836	—	1800	1880	50
Si	L	199	180	194	208	10

In most of the cases, the distribution of several elements will be studied in one sample area. The resulting elemental distribution images can be combined in one image by using different colours for each element and overlaying the individual images. If two or more of the elements under investigation are present in one sample area mixed colours will occur. Mixed colours thus reveal important information on the occurrence of phases which contain more than one of the elements under investigation.

2.3 High-resolution TEM

For some of the materials analysed, high-resolution TEM has been employed in order to distinguish between structurally amorphous and microcrystalline material. These studies were performed on a Jeol 4000 EX operated at 400 kV.

2.4 TEM specimen preparation

The samples sintered at lower temperatures or at a lower concentration of the sintering additives exhibit extremely high brittleness and thus low mechanical stability. Self-supporting TEM specimens could not be made out of these brittle samples and a special technique had to be applied. The method is based on the use of special cylindrical holders which are made out of alumina. The holders contain a slit into which a thin slice of the material (200–300 μm thick) is glued which gives the necessary mechanical support to the brittle material. Subsequently the holders are sectioned into thin discs from which TEM samples are made in the conventional way by polishing, dimpling and ion milling. Details of the technique were published elsewhere.[16]

3 Results and Discussion

As described in Part I of this work,[1] the Si-based materials produced by pyrolysis of Si-containing

polymer precursors can be classified according to the resulting microstructure. Monolithic silicon carbonitrides which consist entirely of an amorphous phase can be produced directly by pyrolysis of the compacted polymer. Dense ceramic composites formed by the crystalline phases Si_3N_4, Si_3N_4 containing SiC, or Si_2N_2O can be produced by adding sintering additives prior to pyrolysis. Both the chemistry of the metal–organic precursors and of the oxidic sintering additives can be varied in wide ranges with resultant changes in the microstructure. For the different precursors the following abbreviations will be used: poly(hydridomethyl)-silazane = PHMSN, poly(chlorhydridomethyl)silazane = PCMSN, poly(methylphenyl)silane = PMPS. The chemical formulae of the polymers have been derived from analytical investigations and are summarised in Table 2. A mixture of Al_2O_3 and Y_2O_3 in various amounts has been used as sintering additives in all cases.

3.1 PHMSN-derived monolithic Silicon Carbonitride

The monolithic silicon carbonitride was prepared by pyrolysis of the shaped infusible polysilazane precursor (PHMSN) at 1000°C under argon. Details of the preparation and characterisation of the material in terms of density and porosity are described in Part I. The TEM investigations showed that the sample material contains pores with diameters between 100 and 1000 nm. By SEM the existence of some larger pores with diameters of up to 10 μm could be seen. By electron diffraction in the TEM it could be verified that the samples are completely amorphous. The analysis of EELS spectra confirmed the presence of Si, N and C in the amorphous ceramic material while oxygen was below the detectivity limit (< 1 at%).

In Fig. 3, a TEM bright field image of the amorphous silicon carbonitride is compared with the ESI images obtained for C and N. The intensity variation in both ESI images is caused by the thickness changes visible in Fig. 3(a). In very thin areas of the specimen, e.g. close to the edge of the sample, the ESI image intensity is low due to the small number of atoms present. For increasing thickness, but below the mean free path for inelastic scattering, the intensity in the ESI images increases. Finally, for thicknesses above 20–30 nm, the intensity decreases again due to the occurrence of multiple inelastic scattering, which increases the background but decreases the intensity gain at the onset energy of an edge in the energy loss spectrum. However, in Figs 3(b) and (c) the same intensity ratio is always obtained for areas of constant thickness. Thus, the distribution of C and N in the amorphous material is homogeneous down to the resolution limit of about 2 nm. No indication for the precipitation or nucleation of Si_3N_4, SiC or pure carbon and elemental silicon was found. According to these electron microscopic findings, the polysilazane-derived silicon carbonitride can be described as a silicon-based amorphous ceramic containing $SiN_{4-x}C_x$ units with $0 < x < 4$.

Finally, quantitative elemental analytical investigations (for experimental details see Part I,[1]) yielded molar ratios which can be represented by the empirical formula $Si_{1.8}N_{1.6}C_{1.0}$ for the PHMSN

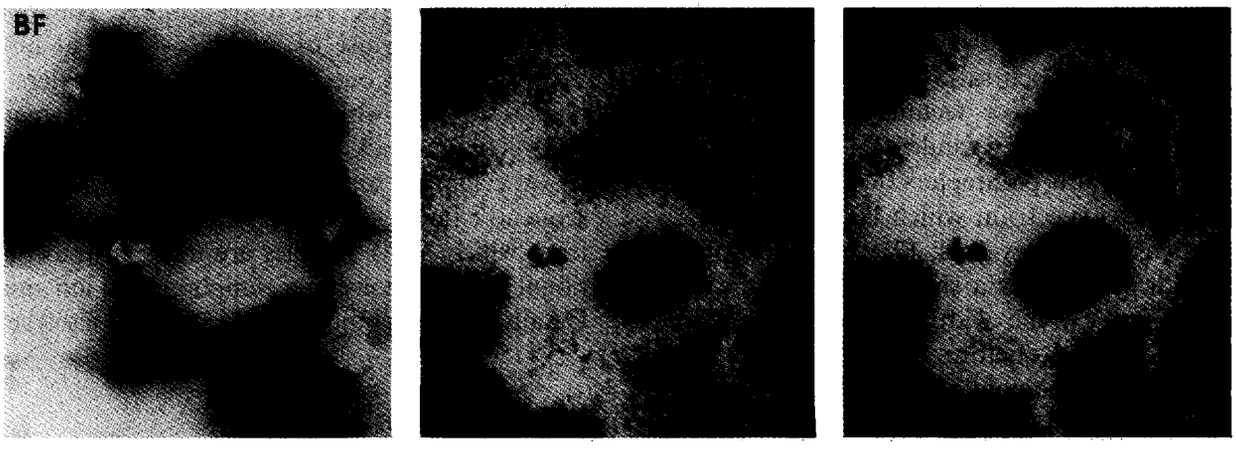

Fig. 3. Monolithic silicon carbonitride after pyrolysis at 1000°C. Comparison between bright field image and the elemental distribution images obtained for carbon and nitrogen. The thickness dependent intensity variation is the same in both distribution images confirming that C and N are distributed homogeneously in the material.

derived silicon carbonitride. Pyrolysis of PCMSN under the same conditions results in a silicon carbonitride with the composition $Si_{1.7}N_{1.5}C_{1.0}$.

3.2 PCMSN-derived Si_3N_4/SiC-composite

Polycrystalline Si_3N_4/SiC composites were produced by sintering of the amorphous PCMSN derived silicon carbonitride at different temperatures under nitrogen atmosphere. Various amounts of Y_2O_3 and Al_2O_3 were added as sintering additives prior to pyrolysis. Details of the processing conditions are described in Part I.[1]

In order to obtain insight into the formation of the microstructure during the sintering process, two series of experiments were carried out. The evolution of the microstructure with increasing sintering temperature and constant additive content was studied at four different temperatures between 1400°C and 1850°C. The dependence of the resulting microstructure on the concentration of the sintering additives at constant sintering temperature was investigated by varying the amount of sintering additives between 5 and 15 wt%. In the following, the microstructure obtained after heat treatment at the highest sintering temperature (1850°C) will be discussed first in order to facilitate comparison with the results obtained in the intermediate stages.

3.2.1 Microstructure after sintering at 1850°C

By sintering the material with 15 wt% sintering additives at 1850°C for 1 h, a ceramic composite with high density and low porosity is obtained. In Fig. 4, a bright field image of a thin area of the TEM specimen is shown. The microstructure consists of crystalline particles with grain sizes ranging from 50 nm to 1 μm and an oxidic glassy phase. The phase composition is revealed by the ESI image in Fig. 4(b). The elemental distribution of C, N and O is imaged in red, green and blue colour, respectively. The corresponding phases are SiC, Si_3N_4 and the amorphous oxide, which can thus clearly be identified. The average size of the SiC grains is generally smaller and less uniform than the size of the Si_3N_4 grains. The ESI images show that there is a tendency of the SiC grains to form clusters. In the material with 15% sintering additives, the Si_3N_4 grains and the individual or clustered SiC grains are separated by extended areas containing the amorphous oxide. X-ray investigations revealed that both crystalline phases are formed in the β-modification, i.e. the materials consist of β-Si_3N_4 and β-SiC.

3.2.2 Evolution of microstructure with temperature

By X-ray diffraction of the heat treated materials (see Part I[1]) it could be shown that, at temperatures below 1400°C, no changes in the phase composition occur and that the amorphous phase produced by the pyrolysis at 1000°C does not start to crystallise nor to react with the sintering additives. At temperatures around 1400°C, however, a rapid onset of crystallisation could be detected. This is presumably caused by the formation of a liquid phase by melting of the sintering additives.

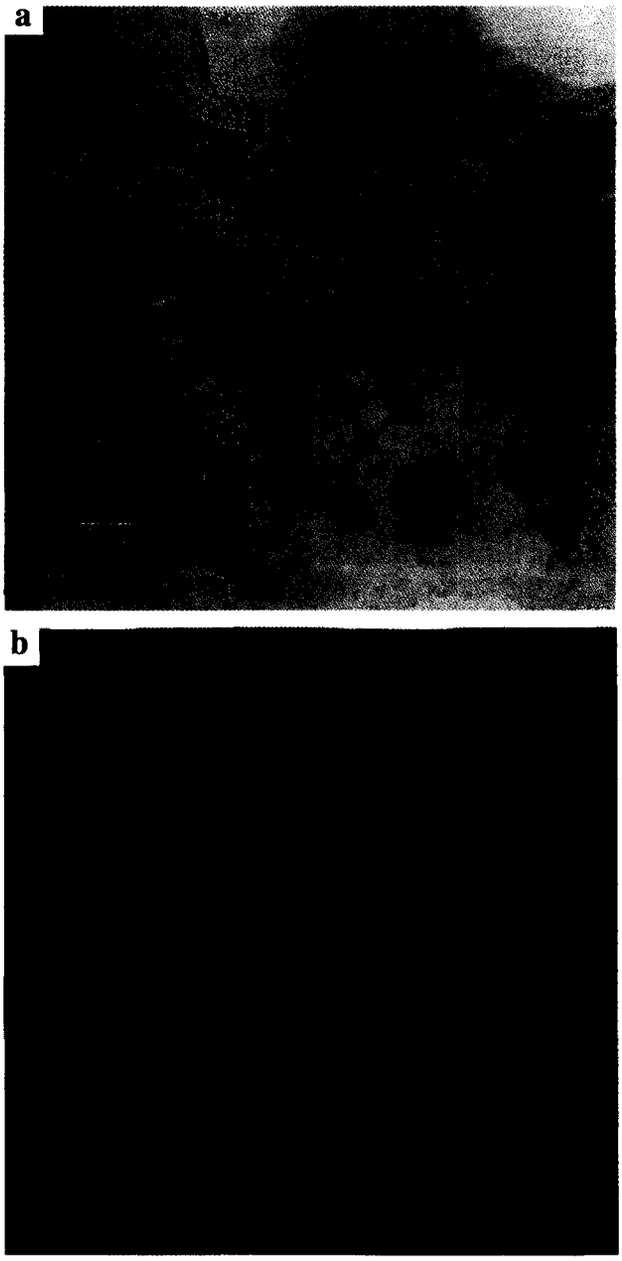

Fig. 4. Si_3N_4/SiC-composite material after sintering for 1 h at 1850°C. (a) Bright field image showing the microstructure; (b) Combined elemental distribution image for carbon (red), nitrogen (green) and oxygen (blue), showing the distribution of the SiC, Si_3N_4 and the amorphous oxide, respectively.

The microstructure which was obtained after a heat treatment of 1 h at 1400°C is shown in Fig. 5 (a). Irregularly shaped grains with dimensions between 50 and 300 nm can be observed. The grains are embedded in a matrix formed by a glassy phase. These areas can clearly be distinguished

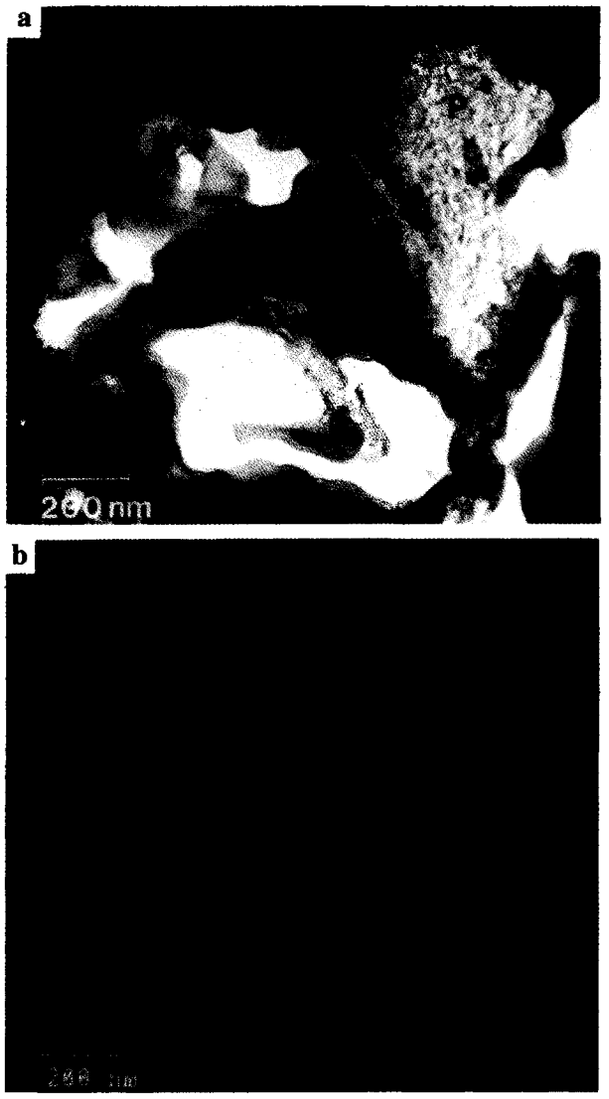

Fig. 5. (a) Microstructure of the material sintered at 1400°C. (b) The elemental distribution image shows that all the carbon (red) remains in pockets (denoted by P), while all the nitrogen (green and light blue) crystallises with an equivalent amount of Si and forms Si_3N_4 grains which are embedded in the glassy phase (dark blue).

from a large number of pockets (denoted by P in Fig. 5(a)) which show fine speckle contrast and have a diameter between 0·5 and 1 μm. Qualitatively, the chemistry of these two morphologically different parts of the microstructure could be clarified by ESI (Fig. 5(b)). The larger irregularly shaped grains all consist of Si_3N_4. The Si_3N_4 grains in the 1400°C material reach about half of the final grain size observed in the 1850°C composite.

Occasionally needle-like grains occur which contain both N and O and presumably consist of Si_2N_2O. They are also embedded within the glassy phase formed by the sintering additives. The pockets (P in Fig. 5(a)) are filled with a material showing speckle contrast and consisting mainly of Si and C. EDX and EELS analysis revealed that small amounts of Al, Y (less than 1 at%) and O

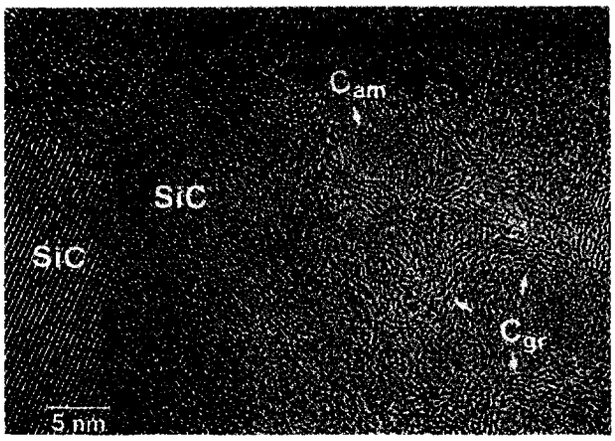

Fig. 6. High resolution image showing the atomic structure of the material contained within the pockets (P in Fig. 5). Nanocrystalline SiC can be identified by the corresponding lattice fringes. The SiC particles are embedded in graphitized and amorphous carbon.

(less than 5 at%) are also present. Electron diffraction patterns from these areas show Debye–Scherrer rings indicating that most of the material is nanocrystalline and that small SiC crystallites exist. In high resolution micrographs (Fig. 6) the SiC grains can be identified by their lattice fringes. Besides these, bent lattice fringes characteristic for graphitized carbon are also present. Both types of precipitate are embedded in amorphous carbon. The observed phase separation in the pockets is in agreement with the phase diagram of the binary Si–C system.[17]

Our microstructural results thus show that during the crystallisation at 1400°C a distinct phase separation takes place which leads to a demixing of the initial silicon-carbonitride into: (1) areas containing crystalline Si_3N_4 and Si_2N_2O grains which are embedded in the glassy phase formed by the sintering additives, and (2) pockets containing all the carbon in the form of nanocrystalline SiC and residual amorphous or graphitized carbon. It is important to note that, in the presence of the sintering additives, the initially amorphous silicon carbonitride has almost completely crystallised at 1400°C (even though the SiC is only nanocrystalline). In contrast to this, the monolithic silicon carbonitride (i.e. without sintering additives) remains amorphous at 1400°C even after 60 h of heat treatment. At 1400°C the sintering additives thus very effectively promote the crystallisation of the amorphous starting material. In the preparation of ceramic composites from polymer precursors the sintering additives are therefore not only required for densification but mainly to promote the crystallisation of the phases forming the composite.

The rapid onset of crystallisation at temperatures between 1300°C and 1400°C can be explained by the melting of the sintering additives.

The microstructure of the material at temperatures below 1300°C presumably consists of large amorphous silicon carbonitride particles which are mixed with crystalline Al_2O_3 and Y_2O_3 particles. In addition the SiNC particles are surrounded by an amorphous SiO_2 layer. In the system SiO_2 + Al_2O_3 + Y_2O_3 a deep eutectic exists at temperatures slightly above 1300°C. Between 1300 and 1400°C the sintering additives thus melt and the SiCN particles are embedded in a liquid phase. The crystallisation of the Si_3N_4 and Si_2N_2O phases is achieved by dissolution of Si and N in the liquid phase and reprecipitation of the crystalline phases. At a temperature of 1400°C only Si and N, but not carbon, diffuse out of the SiCN-particles and dissolve into the liquid phase which explains the observed phase separation into areas containing only Si_3N_4 and Si_2N_2O grains and remaining pockets consisting of nanocrystalline SiC and amorphous C. This result is also in agreement with the observation that sintering of SiC with Al_2O_3 and Y_2O_3 requires much higher temperatures before a solution–reprecipitation mechanism becomes operative.[5,6,8]

At temperatures above 1400°C further reactions are mainly expected in the pockets containing Si and C. At 1550°C grain coarsening occurs in the pockets and clusters of SiC grains form which are surrounded by pure carbon (Fig. 7). The existence of residual carbon can be explained by a surplus of carbon in the initial silicon carbonitride $Si_{3+x}N_4C_{x+y}$ with respect to the formation of stoichiometric Si_3N_4 and SiC. The transformation can be described by the reaction:

$$Si_{3+x}N_4C_{x+y} \xrightarrow{1400°C} Si_3N_4 + (x\ SiC_{nano} + y\ C)_p \xrightarrow{1550°C} Si_3N_4 + x\ SiC + y\ C^{(\uparrow)} \quad (1)$$

The first part of this reaction represents the initial silicon carbonitride, the second part the reaction product at 1400°C, in which the pockets P are filled with a mixture of nanocrystalline SiC and graphitized or amorphous C, and the third part the product at 1550°C, where the pockets are filled with precipitated SiC grains and amorphous carbon. At these temperatures the residual carbon obviously acts as a sintering aid for the SiC grains. At 1550°C the SiC does not seem to be wetted by the liquid phase formed by the sintering additives. Areas containing Si_3N_4 are still well separated from areas containing C and SiC. At 1550°C the residual carbon starts to disappear by forming gases. First indications for the onset of a reaction of the residual carbon with both the oxide phase and the Si_3N_4 grains are given by the gaps between the Si_3N_4 grains and the carbon rich areas. Three chemical reactions can be responsible for this:[18,19]

$$C + SiO_2 \rightarrow SiO\uparrow + CO\uparrow \quad (2)$$

$$3C + SiO_2 \rightarrow SiC + 2\ CO\uparrow \quad (3)$$

$$3C + Si_3N_4 \rightarrow 3SiC + 2\ N_2\uparrow \quad (4)$$

Reactions (2) and (3) lead to a decrease of the oxygen concentration of the material. Thermodynamically, the occurrence of reaction (4) is also expected.[19]

During sintering at 1700°C the amorphous carbon disappears completely. The SiC grains still occur mainly in clusters and the average grain size varies between 10 and 100 nm (Fig. 8). However,

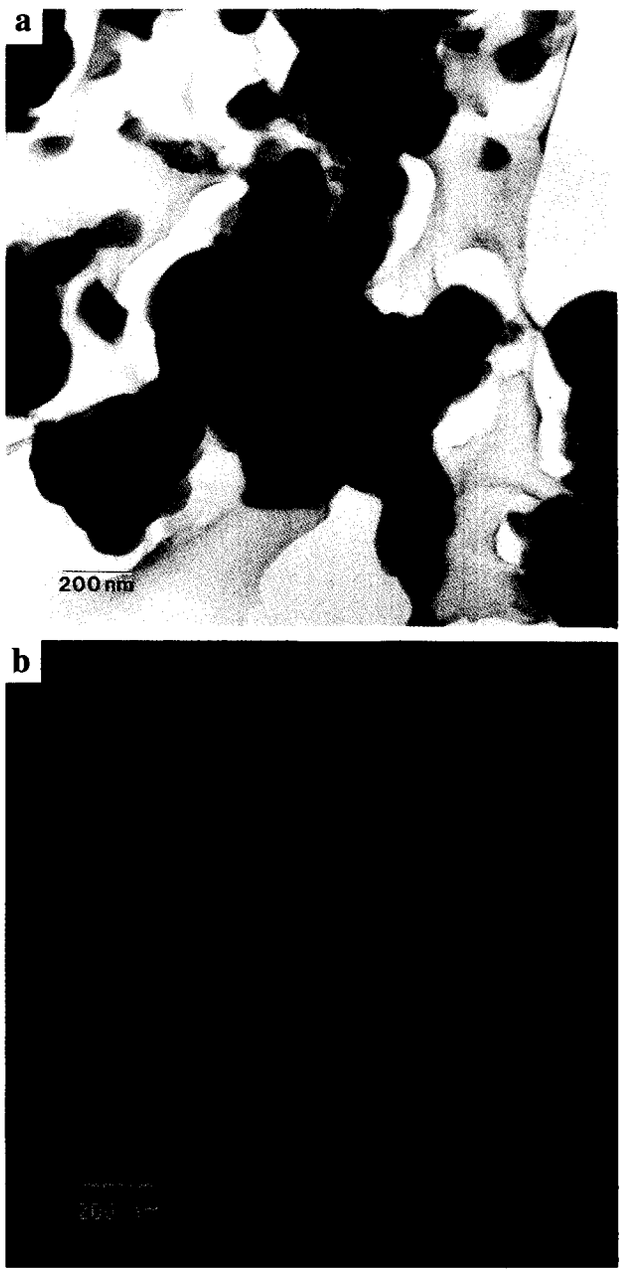

Fig. 7. Bright field (a) and elemental distribution image (b), carbon: red, nitrogen: green, and oxygen: blue) of the material sintered at 1550°C. Grain coarsening of the SiC within the residual C can be observed. At the same time, the residual carbon starts to react with the Si_3N_4 grains and the oxide phase which leaves gaps at the interfaces.

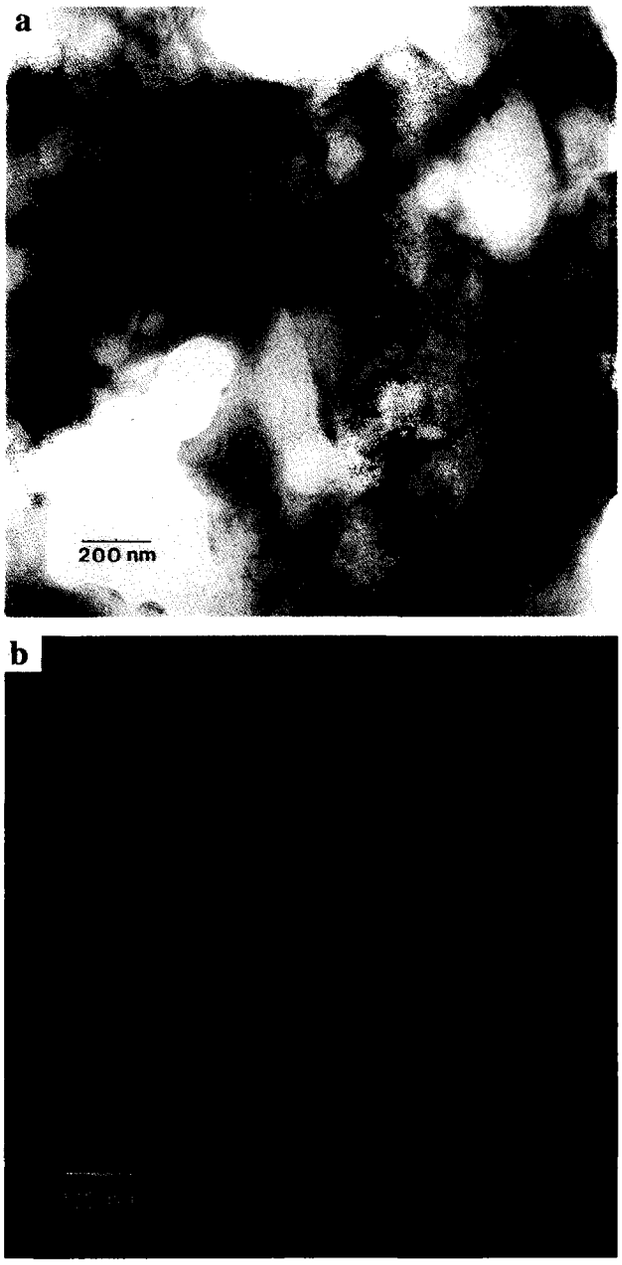

Fig. 8. Bright field (a) and elemental distribution image (b) carbon: red, nitrogen: green, and oxygen: blue) showing the microstructure of the material sintered at 1700°C. Clustering of the SiC particles (red) is still visible and most of the SiC particles have not reached the final grain size observed at 1850°C.

Fig. 8 shows that the SiC grains are now embedded within the glassy phase. From this we conclude that wetting of the SiC grains by the liquid oxides starts between 1550 and 1700°C. At 1700°C no more Si_2N_2O could be observed. This is in accordance with the thermal decomposition of the Si_2N_2O at temperatures above 1600°C:

$$3Si_2N_2O \rightarrow Si_3N_4 + 3SiO\uparrow + N_2\uparrow \qquad (5)$$

Between 1550 and 1700°C the reactions ((2)–(5)) lead to the production of gases which slow down densification.

After the disappearance of the amorphous carbon and the Si_2N_2O at 1700°C only the phases observed in the final product at 1850°C remain, i.e. SiC, Si_3N_4 and the oxidic glassy phase. An increase of the temperature to 1850°C thus only leads to gradual changes in the microstructure. These changes mainly are: a further grain growth of the SiC grains and a further densification. At 1850°C the grain growth of the SiC grains may also involve a solution/reprecipitation mechanism through the liquid phase. This results in an increasing intermixing of the SiC and Si_3N_4 grains leading to the final product described in 3.2.1.

3.2.3 Dependence on concentration of sintering additives

In the preceding section it has been shown that the sintering additives play an important role during the crystallisation of the amorphous silicon carbonitride. Therefore it can be expected that the concentration of the sintering additives also influences the resulting microstructure. In order to investigate this, composites were prepared with 5, 10 and 15% sintering additives under otherwise identical conditions (sintering for 1 h at 1850°C in 0·1 MPa N_2).

In the material with 5 wt% sintering additives, a large amount of open porosity is still present after sintering. This porosity can only be reduced by adding a larger amount of sintering additives, and at 15 wt% an almost completely dense material is obtained. These microstructural observations are in good agreement with the relative densities measured by porosimetry.[1]

In the samples sintered with 5 and 10 wt% sintering additives, a small number of Si_2N_2O grains are still present (Fig. 9). This observation is in contrast with the thermal decomposition of Si_2N_2O above 1600°C (Reaction (5)). However,

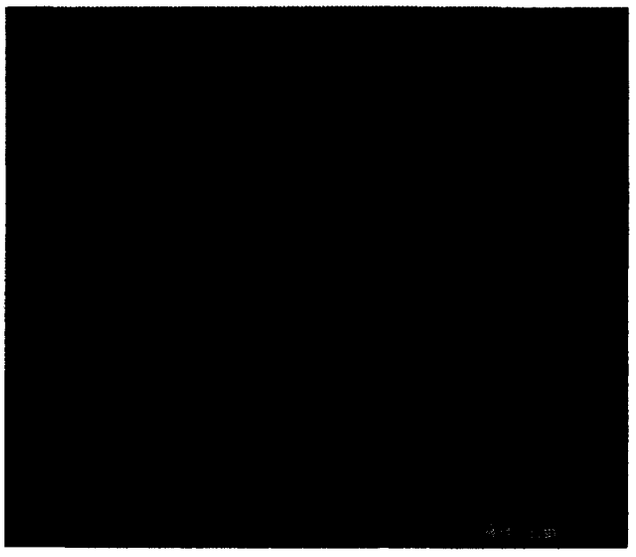

Fig. 9. In the samples sintered with 10 wt% sintering additives at 1850°C the microstructure consists of Si_3N_4 (green), SiC (red) and the amorphous oxide (blue). Occasionally Si_2N_2O grains could be observed, which in the ESI images are characterised by their mixed colour (here: mixed blue and green).

owing to the short annealing time of only 1 h, the Si_2N_2O grains may have survived for kinetic reasons and will disappear after longer heat treatments. The fact that Si_2N_2O is not found in the material sintered with 15% sintering additives indicates that the concentration of sintering additives and thus solution and reprecipitation processes play an important role in the thermal decomposition of Si_2N_2O.

From Fig. 9 it is also evident that the grain sizes of both SiC and Si_3N_4 are smaller in the material sintered with 5 or 10 wt% than in the reference material prepared with 15% additives. Hence, the rate at which the individual grains grow also shows a dependence on the concentration of the sintering additives. This can easily be understood for the Si_3N_4 while the fact that this grain size dependence is also observed for SiC indicates that solution/reprecipitation dominates the grain growth of SiC at 1850°C.

3.3 Sintered PCMSN-derived Si_2N_2O-ceramic

As discussed in Part I,[1] using ammonia during pyrolysis of the PCMSN results in the formation of amorphous silicon nitride powder. By attritor milling in wet isopropanol the reactive amorphous silicon nitride takes up oxygen in such an amount that during the subsequent sintering step polycrystalline Si_2N_2O can be produced. The sintering has to be performed at 1600°C because at higher temperatures Si_2N_2O decomposes according to Reaction (5). A mixture of Al_2O_3 and Y_2O_3 was used as sintering additives in concentrations of 3, 5,10 and 15 wt%.

In the TEM investigations submicron-size pores between the grains could be observed in the samples with 3 and 5% sintering additives. In these materials the low amount of sintering additives is not sufficient to close the pores during pressureless sintering. The individual Si_2N_2O grains are characterised by their elongated shape with an aspect ratio of 3–10 and by the high number of parallel stacking faults. In the materials with 3 and 5 wt% sintering additives only Si_2N_2O grains but no Si_3N_4 grains were found. In the ESI images the Si_2N_2O grains are characterised by their mixed colour (yellow) which is obtained by the superposition of the intensity which is present in both elemental distribution images (nitrogen: red and oxygen: green) (Fig. 10(a)). The oxidic glassy phase between the individual grains is characterised by the green colour.

At a concentration of 10 and 15 wt% of the sintering additives no more pores between the grains could be found. In the 10 wt% material occasionally Si_3N_4 grains could be observed and in the 15 wt% material the Si_3N_4 grains were present more frequently reaching concentrations of up to 10

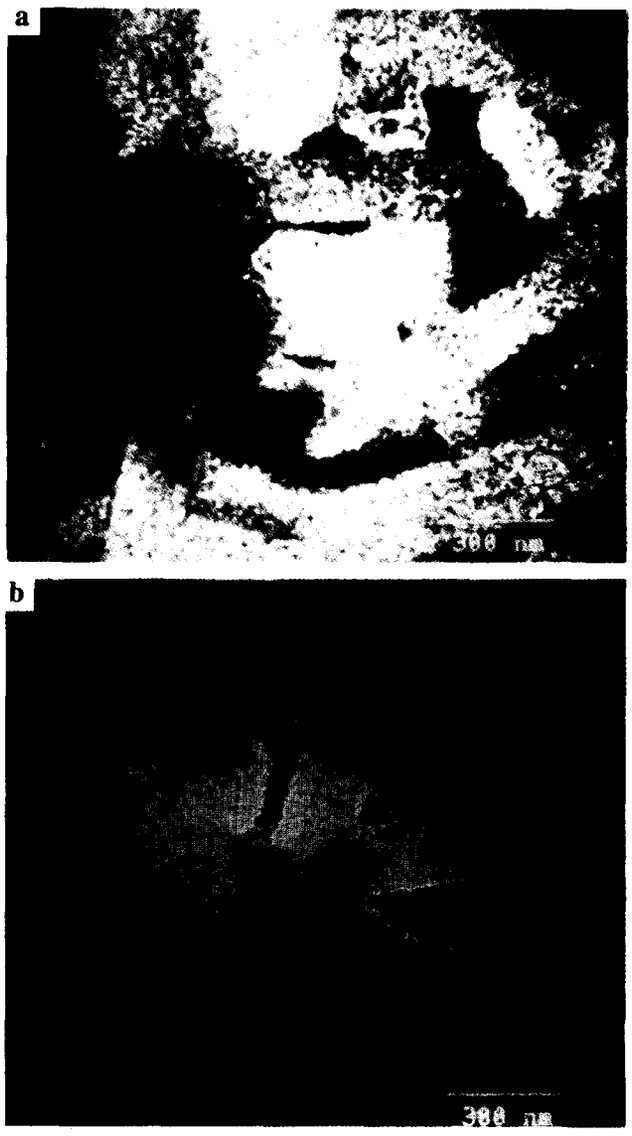

Fig. 10. The microstructure of the Si_2N_2O materials sintered with 3 wt% (a) and 15 wt% (b) sintering additives. In the images the nitrogen distribution is shown in red, the oxygen distribution in green. The Si_2N_2O grains are characterised by their mixed colour (red + green = yellow). At 3 wt% unfilled pores remain. In the 15 wt% samples the microstructure is dense but Si_3N_4 grains were present (red).

vol% (Fig. 10 b). The occurrence of Si_3N_4 grains is thus clearly dependent on the concentration of the sintering additives. This can be understood if it is assumed that during sintering the amorphous silicon nitride at least partly has to be dissolved in the liquid phase formed by the sintering additives. As discussed in the previous section the solution/reprecipitation mechanism may lead to a decomposition of Si_2N_2O into Si_3N_4, therefore increasing the amount of sintering additives increases the probability of Si_3N_4 precipitation.

3.4 Si_3N_4 sintered with 20 wt% Polysilane (PMPS)

According to the results described in Part I[1], an alternative way to produce Si_3N_4/SiC-composites is to mix Si_3N_4 powder with the polysilane PMPS

and an adequate amount of sintering additives. In our studies, 20 wt% of the PMPS and 12 wt% of sintering additives comprising 2·8 wt% AlN, 7·8 wt% Y_2O_3 and 1·4 wt% Al_2O_3 were used.

The resulting microstructure obtained after pyrolysis and sintering of the polymer-powder compact is shown in Fig. 11(a). Large grains with average grain sizes of 0·5–1 μm can be identified. Smaller particles with diameters of 20–200 nm surround these grains (intergranular) but are also embedded within the grains (intragranular). These particles are comprised of SiC as is clearly revealed by the ESI image (Fig. 11(b)). The larger grains consist of β-Si_3N_4. Therefore, besides the intergranular SiC, small intragranular SiC nanoprecipitates in the Si_3N_4 crystals could be detected in our material. A similar composite microstructure belonging to this mixed intra- and inter-type was first reported by Niihara *et al.*.[20] It was found that the fracture strength of these materials is considerably higher than the strength of Si_3N_4/SiC composites without intragranular SiC-precipitates.[9]

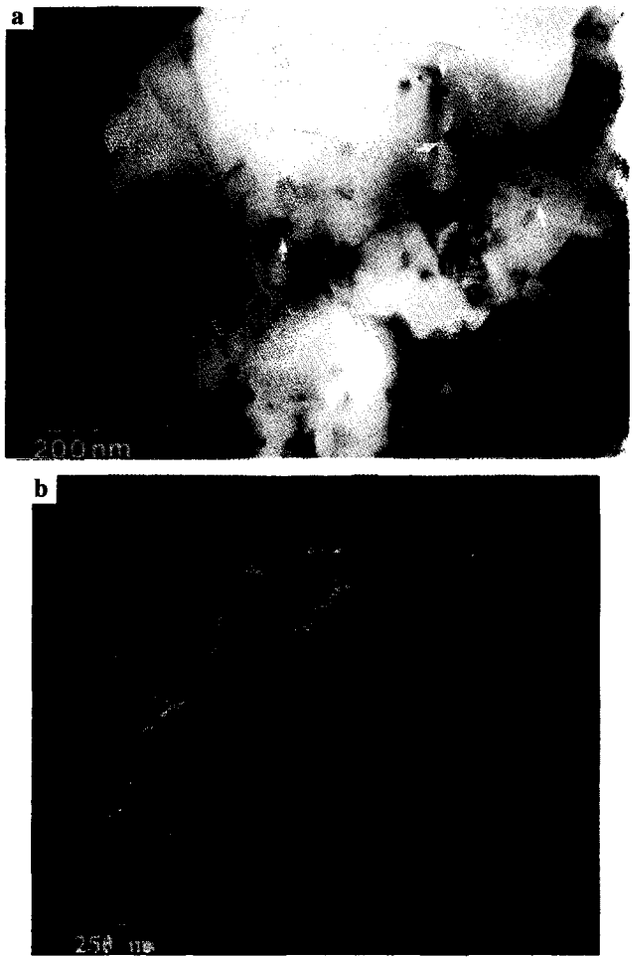

Fig. 11. Si_3N_4/SiC-composite material produced by sintering Si_3N_4 powder with 20 wt% of the PMPS precursor. In the bright field image (left) a number of precipitates can be observed in the large Si_3N_4 grains. The ESI image reveals that these precipitates consist of SiC nanoparticles (red). The Si_3N_4 grains are shown in green, the amorphous oxide in blue.

The results obtained on the Si_3N_4/SiC-composites produced from the polysilazane precursor (see Section 3.2.2) indicate that during sintering considerable amounts of the Si and N present in the starting material are dissolved in the liquid phase. In the material produced from the Si_3N_4-powder/polysilane mixture this solution–reprecipitation process will also take place leading to the growth of larger Si_3N_4 grains. During the reprecipitation of Si_3N_4 from the liquid phase, small polysilane derived SiC particles might become enclosed by the growing Si_3N_4 grains leading to the observed microstructure. The fact that this is not observed in the Si_3N_4/SiC-composites produced from polysilazane as described in Section 3.2.2 could be due to the observed phase separation into regions containing Si_3N_4 grains embedded in the glassy phase and regions containing SiC and residual C. Even though Si_3N_4 might dissolve and reprecipitate at higher temperatures, the SiC is well enough separated from the growing Si_3N_4 crystals and no enclosure is possible.

4 Conclusions

The processing of ceramic composites from polymer precursors involves a complicated sintering mechanism for which we have studied the dependence on the starting material and the processing conditions. The mechanism is based on the formation of a liquid phase from the sintering additives which, by surrounding the amorphous starting material, serves several purposes: (1) the onset of crystallisation occurs much faster and at lower temperatures; (2) the chemical reactions which lead to the formation of the stable, stoichiometric crystalline phases are accelerated by the diffusion through the liquid phase, and (3) complete densification of the material can only be achieved with sintering additives. Based on the results of our microstructural characterisation, a model of the processes occurring during sintering can be proposed (Fig. 12): β-Si_3N_4 grains and Si_2N_2O grains start to form by a solution–reprecipitation mechanism immediately after formation of the liquid phase (1400°C). An increase in temperature leads to grain coarsening by the same mechanism. SiC and C, at least at the lower temperatures, are not dissolved by the liquid phase and are left in pockets which are remnants of the initial SiCN particles. Nucleation and grain coarsening of the SiC grains at the lower temperatures only occurs within the residual carbon matrix. The phases formed are the thermodynamically stable phases β-Si_3N_4 and β-SiC. Chemical reactions at intermediate sintering temperatures result in the disappearance of the

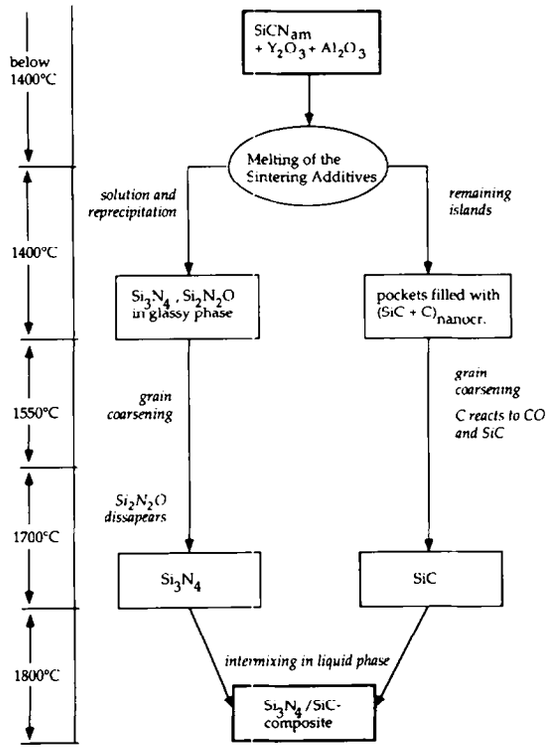

Fig. 12. Schematic diagram showing the processes occurring at increasing sintering temperatures in the Si_3N_4/SiC-composite material.

Si_2N_2O grains and the residual carbon. The gases produced during these reactions slow down densification. Further grain coarsening and rearrangements of the particles at the higher sintering temperatures lead to the final microstructure observed at 1850°C. In the final product the clustering of SiC grains is less pronounced than in the materials obtained at lower temperatures. We attribute this to a solution and reprecipitation reaction which at 1850°C also becomes operative for the SiC and leads to a redistribution of the SiC grains.

In our studies, elemental distribution images obtained with the ESI technique have proven to be a very efficient tool for the analytical characterisation of ceramic microstructures. A comparison with the phases identified by X-ray diffraction (see Part I of our studies[1]) confirms that our TEM results are representative for the overall micro-structure of the materials investigated. However, details of the microstructure, for example the inclusion of SiC precipitates in Si_3N_4 grains which is important for the mechanical behaviour of the resulting composite, could only be identified in the TEM studies.

Abstract

Large ceramic injection mouldings were prepared using a SiC composition with polycarbosilane and paraffin wax. The material sustained mixing and injection moulding at temperatures up to 230°C. Conventional, modulated pressure and heated sprue techniques were used to produce large sections, some of which were subsequently pyrolysed and sintered. Fired relative densities of 97% were obtained under conditions where the dry compacted powder sintered to 90%.

1 Introduction

Previous work[1] has identified modifications to a ceramic polymer composition suitable for injection moulding in which a transient organic binder is replaced with a polymer which decomposes to silicon carbide. The idea of using polycarbosilane as a binder for silicon carbide was proposed by Yajima[2] and hypostatised by Mutsuddy for extrusion.[3] In the same way Sugawara[4] added polycarbosilane at approximately 40 vol.% to a binder system of ethylene vinyl acetate, wax, dibutyl phthalate and a fatty acid ester for injection-moulding silicon carbide powder. Similarly, Okumara[5] blended polycarbosilane with stearic acid to provide a moulding composition for SiC powder.

By incorporating paraffin wax into the composition, the viscosity is reduced and the danger of temperature-induced crosslinking in the machine is avoided.[1] In the present work, this approach was followed up by using the composition previously developed in an injection-moulding machine to make several components and hence examine the behaviour of the material in the mould-filling and solidification stages.

2 Experimental Stages

The silicon carbide was grade 059S from Superior Graphite Co., Chicago, USA. The powder is shown in Fig. 1 and was equiaxed with irregular shape, with a mean particle size of 0·8 μm. Polycarbosilane (PCS) was supplied by Changsha Institute of Technology, People's Republic of China.

The wax was grade 130/135 from Shell Chemicals UK. The mixture prepared contained 56 vol.% SiC and the composition was 80% SiC, 14% PCS and 6% wax by weight.

Mixing was carried out using a Betol (Luton, Beds, UK) TS40 twin-screw extruder running at 60 rpm with barrel temperatures 190–200–220–210°C feed to exit. When cold, the extrudate was granulated by passing it through the unheated rolls of a twin-roll mill to produce feedstock for the injection-moulding machine.

Viscosity was measured with a Davenport Capillary Rheometer fitted with a 2-mm diameter, 40-mm long die and a 5000 psi pressure transducer. A temperature of 226°C was used and shear rates from 20–150 s^{-1} were studied.

Injection moulding was done on a Negri-Bossi NB90 SM290 machine modified for ceramics use. Three moulds were used producing (i) a centre-gated rectangular bar measuring 15 mm × 10 mm × 113 mm, (ii) an axially gated cylinder measuring 40 mm diameter and 60 mm in length and (iii) a straight-bladed rotor having a diameter of 94 mm with a solid hub. The injection speed was 6·7 × 10^{-5} m^3/s. The injection moulding variables are given in Table 1. Examples of these mouldings made with the SiC–PCS blend are shown in Fig. 2.

The bars were made using conventional static pressure moulding with a sprue bush having a minimum diameter of 10 mm. The cylinders were made using a heated sprue which has been described previously.[6,7] The sprue was heated to 210°C before injection and held at that temperature for 300 s which was calculated[8] to be greater than the time needed for the centre of the cylinder to solidify in a mould at 40°C. The rotors were made using either static pressure or modulated pressure at various pressure amplitudes using the procedure described previously.[9]

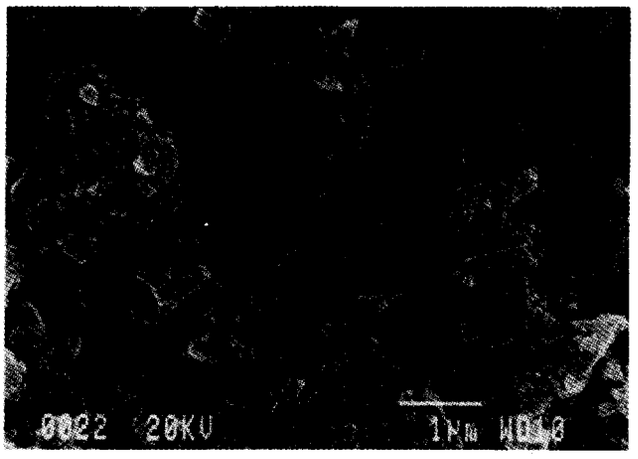

Fig. 1. Scanning electron micrograph of the silicon carbide powder.

The injection-moulding machine was operated with barrel temperatures 210–220–230–230°C feed to nozzle. The mould temperature was varied from 20°C to 50°C and the pressures, which are discussed in Section 3, were varied as shown in Table 1.

Partial pyrolysis of mouldings was carried out in an oxygen-free nitrogen flow of 30 litres/h up to a maximum temperature of 500°C.

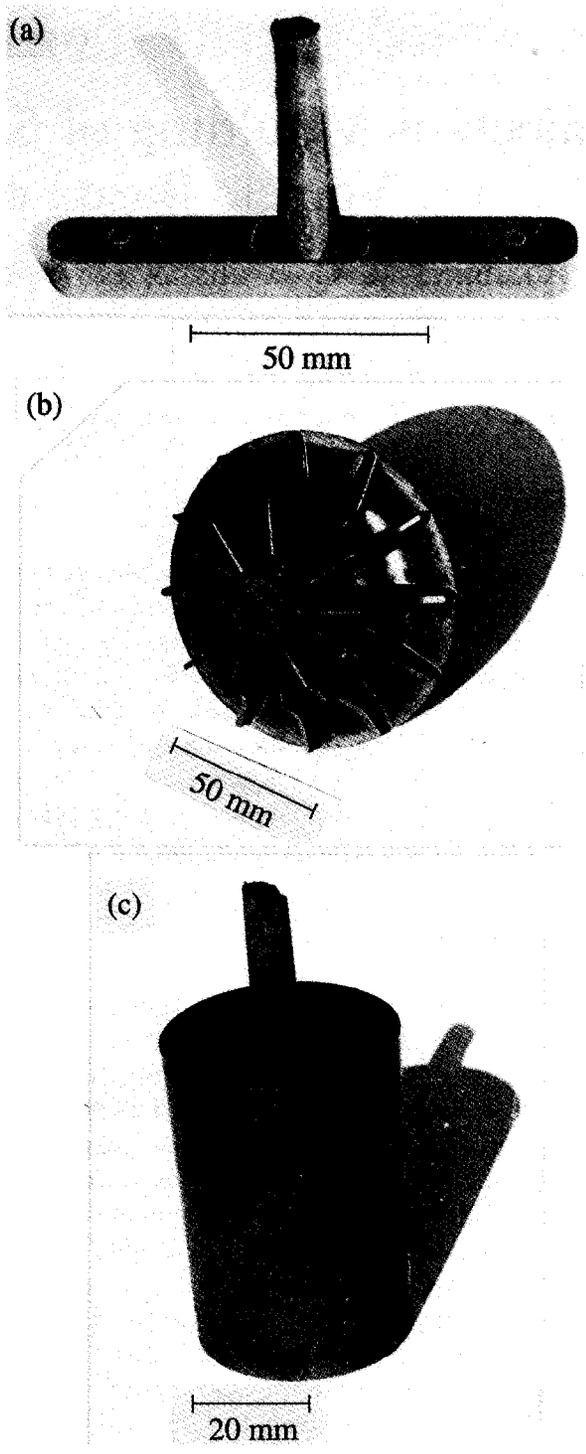

Fig. 2. Injection moulded components: (a) centre-gated rectangular bar, (b) straight-bladed rotor, (c) cylinder.

After initial pyrolysis to 500°C, samples were sintered in a carbon resistance furnace (Jones Vacuum Ltd., Bury, Lancs, UK). The heating rate was 10°C/min to 900°C followed by 5°C/min to 1500°C and a one-hour dwell under vacuum. An argon flow was then established and the temperature was raised to 2050°C at a 5°C/min rate and a 30 min dwell at 2050°C ensued. The density of sintered samples was measured by the Archimedes method in distilled water with a drop of surfactant added.

The sintering behaviour of the pyrolysed bars was compared with that of pressed components of

the SiC powder without organic additives. Rectangular bars (8 × 8 × 51 mm) were made by single-ended die pressing at 70 MPa. Bars of the same size were cut from the pyrolysed injection-moulded material. Pairs of bars were companion-fired in a graphite element vacuum furnace (Lenton, Leics, UK) at 15°C/min to 2000°C and held for 0·5 h and 4 h. An argon flow rate of 0·5 litres/min was maintained. Fracture surfaces were examined in a Cambridge S250 scanning electron microscope.

3 Results and Discussion

3.1 Injection moulding

When mixed in the proportions tested previously,[1] the suspension had a higher viscosity at the same powder volume loading. This indicates a slightly higher molecular weight for the new sample of PCS, which is made in the laboratory in batches and is not a commercial product.

The composition of the organic vehicle was therefore changed from that used previously so that the ratio of PCS to wax was 7:3 instead of 4:1 and this gave an apparent viscosity at 121 s^{-1} of 800 Pa s and a flow behaviour index of 0·7 at 226°C. Thus the increase in wax fraction had the effect of making the suspension slightly more Newtonian.

In the previous work,[1] mixing was carried out in solvent. The large quantities of material required for injection moulding favoured mixing by twin-screw extrusion at high temperatures. The success of this process shows that the suspension, based on polycarbosilane, can be compounded in plastics processing machinery. This is a necessary but not sufficient condition for admitting a new material to the injection-moulding machine barrel. The other condition is that the apparent viscosity in the region of 100 s^{-1} should be less than about 1000 Pa s.

The mixture had a low softening point of ≈50°C[1] and this meant that shrinkage in the solid state was low. Although this should mean that residual stresses are reduced, it also leads to the tendency to resist ejection. This was a particular problem with the rectangular bars, 50% of which fractured on ejection because of failure to release the sprue when high hold pressures or mould temperatures were used. Rectangular bars made by conventional moulding with a hold pressure of 54 MPa in a mould at 35°C were free from macroscopic defects in the polished section after moulding (Fig. 3). The dimensional reproducibility of the moulded bars is reflected in the coefficient of variation for the length of the bar, which was 0·1%.

Rotors made by conventional moulding were replete with defects over a range of injection and hold pressures as generally observed.[9,10] Figure 4(a) shows the arrangement of defects in a rotor made with a hold pressure of 54 MPa in a mould at 38°C. Variation of the injection pressure did not influence the incidence of defects, which are attributed to the solidification rather than the mould-filling stage. High hold pressures made it very difficult to eject the rotor mouldings without fracture of blades. Modulated pressure rotors with pressure amplitudes in the region 71–92 MPa were free from macroscopic defects in the polished section (Fig. 4(b)) but when the pressure amplitude was increased to 99–120 MPa, large cracks perpendicular to the axis appeared in the hubs of rotors after moulding (Fig. 4(c)). In some cases it was possible to hear and sense the cracking as the rotors were held in the hand after removal from the mould. This phenomenon, attributed to over-packing, has also been reported previously for other systems.[9]

In the frequency region 0·7–1·0 Hz, the frequency had no effect on the appearance of defects. When the frequency was lower than 0·7 Hz, voids appeared even at pressure amplitudes of 120 MPa, an effect that has been attributed to wasted time at the top and bottom of dead centre of piston travel.[11]

Large axially centre-gated cylinders, 40 mm in diameter were made by heated sprue moulding. This method allows large sections to be made without voids at very low pressures. Figure 5 shows the polished section of a cylinder made with a hold pressure of 15 MPa. The sprue was kept molten until the centre of the cylinder was solid. However, the heated sprue process is not yet fully understood and approximately 50% of mouldings showed cracks perpendicular to the axis of the cylinder either on ejection or shortly afterwards. An example is shown in Fig. 6. A similar experience with large heated sprue mouldings with an alumina– polypropylene based system

has been reported.[7] It is suggested that this type of cracking arises from the continuing restraint on shrinkage provided by pressure in the liquid core.

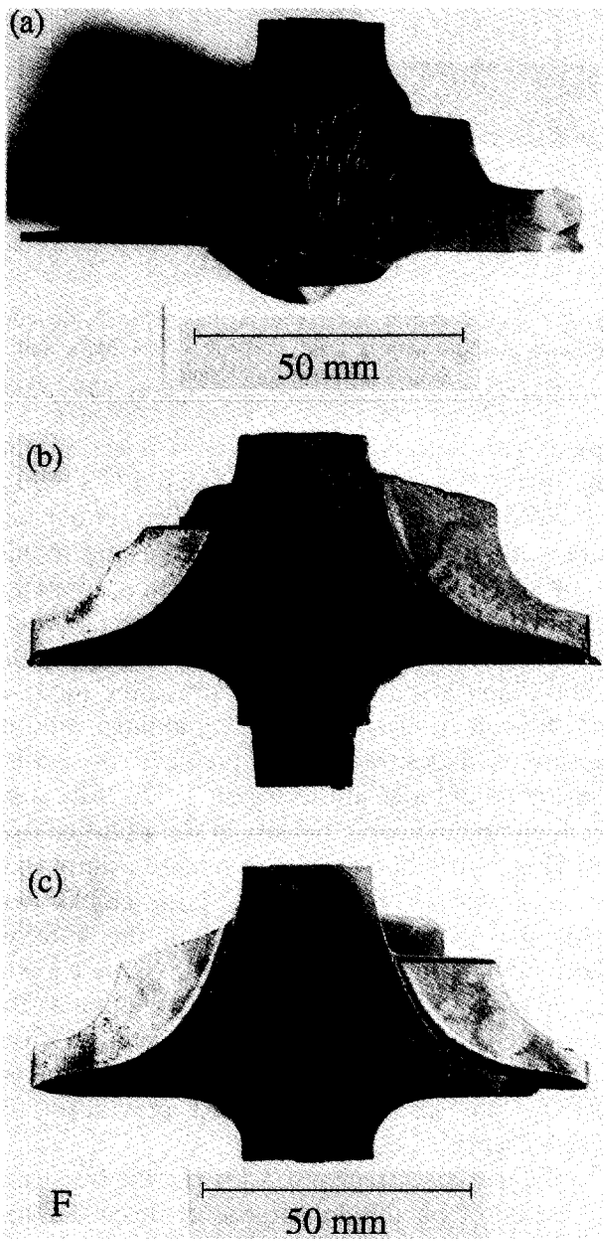

Fig. 4. Polished sections of as-moulded rotors: (a) static pressure 54 MPa, (b) modulated pressure 92 MPa, (c) modulated pressure 120 MPa. The defects are revealed by oblique illumination; no dye was used.

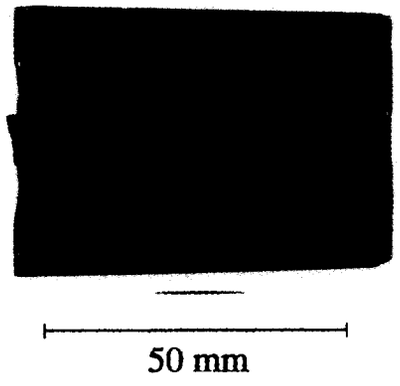

Fig. 5. Section of cylinder made by heated sprue moulding with a 15 MPa hold pressure and mould temperature 30°C.

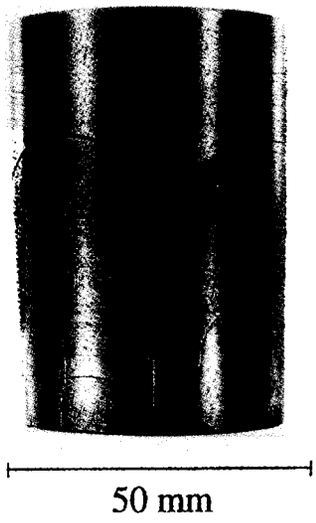

Fig. 6. Cracking in some cylinders made by heated sprue moulding under the same conditions as that in Fig. 5. Flow lines from the axial gating system are also clearly seen in the surface.

3.2 Pyrolysis and sintering of mouldings

Initial pyrolysis was carried out in the temperature range 20–500°C. For the rectangular bar mouldings, the schedule was 60°C/h to 150°C, followed by 2°C/h to 500°C. This produced a weight loss, W_1, of 9·3 ± 0·1 wt%. The bars, which were free from external signs of cracking after moulding, now showed cracks at the junction with the gate. Since the gate had nearly the same diameter as the width of the bar, this region represents the largest overall section. These bars were then broken in half and the sprue was removed before sintering.

Problems were also encountered with the rotor mouldings, which have a much greater section thickness in the hub. These produced a few radial cracks on initial pyrolysis, even at heating rates of 0·5°C/h, which then act as fast transport paths for degradation products. The thinner sections appeared to be sound. A sintered rotor is shown in Fig. 7. There were no external signs of additional defects caused by sintering.

Clearly the overall shrinkage which the component undergoes from the moulded to the sintered state is influenced by the incorporation of a

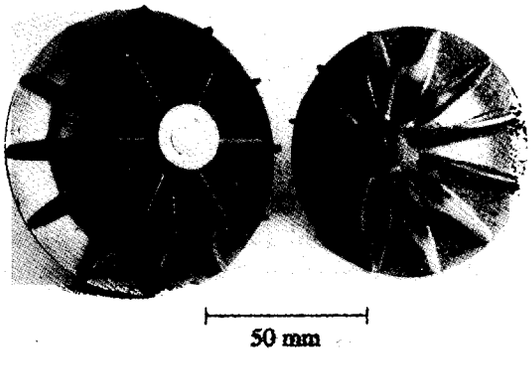

Fig. 7. Rotors, as-moulded (left) and after sintering. Radial cracks appear after pyrolysis of the large section (note the crack at 2 o'clock).

ceramic precursor as binder and by the various weight losses that occur throughout the process. In view of mould tooling costs it is useful to see how well overall shrinkage can be predicted from thermogravimetry.

The average weight loss, W_2, on sintering is made up mainly of the final stage of pyrolysis of the binder, the wax having been expelled earlier. This was 4·1 ± 0·1 wt% measured on 16 samples. The overall weight loss, W_L, is given in terms of the two stages of fractional weight loss by

$$W_L = W_1 + W_2 - W_1 W_2$$

and was 13·0%.

Two stages of shrinkage accompany these processes. The average linear shrinkage after initial pyrolysis was 0·82% measured on the rectangular bar mouldings. The shrinkage attributable to sintering measured on the thickness and width of rectangular bars was 14·0% and 13·8%, respectively. The average overall shrinkage from moulding to sintered body was thus 14·6%.

For samples fired in the Jones furnace, measurement of the sintered density by the Archimedes method in water on 17 bars gave an average of 3122 kg/m^3 with 95% confidence limits based on a 't' distribution of ±10 kg/m^3.

Using the crystallographic density of 3218 kg/m^3 for silicon carbide[12] and assuming the sintered body is free of excess carbon or silica, this corresponds to a relative density of 97%, the same value as that obtained by Mutsuddy.[3]

Since the volume of the moulded material accommodates silicon carbide, wax and PCS exclusively, its specific volume is given by

$$V_0 = \sum_{i=1}^{i=3} W_i/\rho_i$$

where W and ρ are weight fractions and density, respectively, giving $V_0 = 4{\cdot}45 \times 10^{-4}$ m^3/kg.

After sintering, the volume is occupied by silicon carbide and voidage, and

$$V_1 = \frac{(1 - W_L)}{\rho_s}$$

where ρ_s is the apparent density of the sintered body and W_L is the overall fractional weight loss. This gives $V_1 = 2{\cdot}787 \times 10^{-4}$ m^3/kg. The overall volumetric shrinkage is therefore 37·4% and since

$$\frac{\Delta L}{L_0} = 1 - \left(1\frac{\Delta V}{V_0}\right)^{1/3}$$

the linear shrinkage predicted from weight loss and density measurements is 14·5%. This agrees well with the 14·6% measured from the dimensions of bars.

Table 2. Densities and weight losses for companion-fired injection-moulded and pressed SiC (each value is the average for 2 samples)

		Pressed	*Injection-moulded*
Prefired density (%)		54·3	65·7
Sintered 0·5 h	Weight loss	2·2	4·5
	Density	85·9	93·0
Sintered 4 h	Weight loss	1·7	4·0
	Density	90·0	96·8

The overall weight loss is made up of the 6 wt% and the weight loss on pyrolysis of the PCS. Since the overall loss was 13 wt%, the latter represents 50 wt% based on the initial weight of PCS. This is somewhat larger than the 34 wt% loss from PCS noted previously.[1] However, this excludes weight loss of, for example, native silica from the submicron powder on sintering. A weight loss based on the powder of 1·8 wt% would account for this discrepancy and experience shows that losses from this powder are typically 1–2 wt%. Table 2 shows that the weight losses obtained from sintering compacts of this powder without organic additives were 1·7–2·2%.

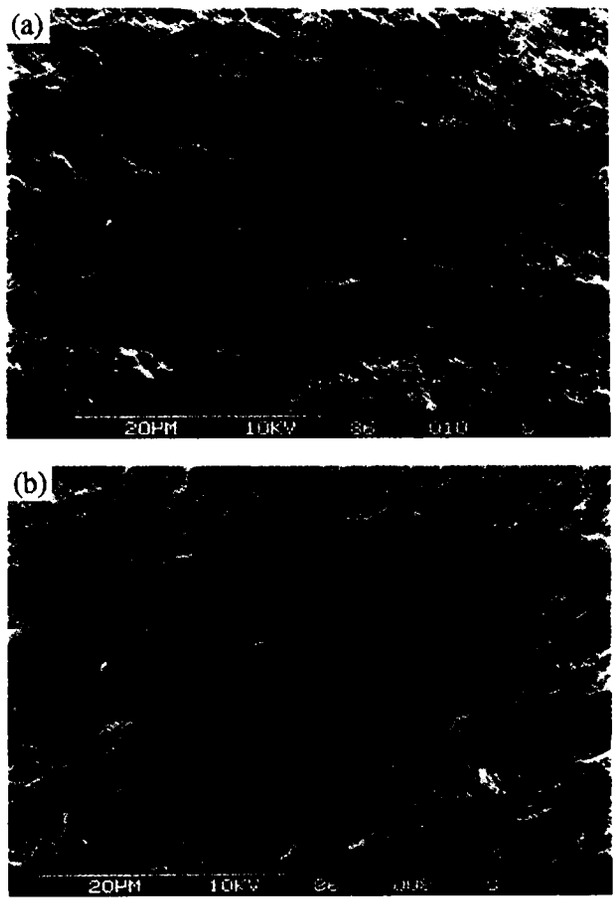

Fig. 8. Scanning electron micrograph of the fracture surfaces of bars companion-fired at 2000°C for 4 h in the Lenton furnace: (a) compacted powder (b) injection-moulded with PCS.

The sintering behaviour of the injection-moulded and pyrolysed bars is compared with that of the die-pressed bars in Table 2. The injection-moulded bars started at a much higher prefired density and reached 97% relative density after 4 h at 2000°C in the Lenton furnace, while pressed bars, fired as companions, reached only 90% relative density. The fracture surfaces of companion-fired bars of both types were examined principally to establish any differences in grain size. Figure 8(a) shows the more extensive porosity in the compacted sample compared with the injection-moulded one (Fig. 8(b)). In both cases, the exaggerated grain growth typical of many silicon carbide artefacts is seen, but there was no evidence of a higher grain size in the sample which had contained PCS.

4 Conclusions

An injection-moulding suspension incorporating a polymeric precursor to silicon carbide diluted with wax can be melt-compounded and injection-moulded at temperatures up to 230°C without premature crosslinking in the machine. Subsequent pyrolysis of large moulded sections produced the same defects that are seen with conventional binder systems, while small sections did not show macroscopic defects. Sintered density was 97% of theoretical and the weight loss and shrinkage were accounted for by the expected SiC residue from the polycarbosilane. Injection-moulded bars, which were companion-fired with compacted bars of the same powder, showed a higher relative density (97%) than the compacted samples (90%). Both samples showed evidence of discontinuous grain growth, but there was no significant difference in grain size.

Synthesis and Densification Behaviour of Bi-Based Superconducting Powder by Organic Precursor

A. Tampieri & G. Celotti

Research Institute for Ceramic Technology (IRTEC-CNR), via Granarolo 64, 48018 Faenza, Italy

(Received 4 July 1994; revised version received 7 February 1995; accepted 14 February 1995)

Abstract

BSCCO (2223) phase superconducting powder was synthesized by pyrolysis of a solution of citrates containing cations in the relative amounts required to prepare compounds with the nominal composition $Bi_{1.84}Pb_{0.35}Sr_{1.9}Ca_{2.1}Cu_3O_x$. *Starting from the pyrolysed precursor, the preparation of (2223) monophasic powder is realized in very short processing time of only 24 h. Reactions among components were investigated by thermogravimetric and differential thermal analysis; the products obtained on treating powders at various temperatures in the range 500–950°C were defined by XRD. The identification of the reaction intermediates that play a crucial role in the synthetic process was systematically performed, and a comparison with the solid-state reaction method was carried out. Hot pressing was performed in order to prepare highly dense superconducting materials. The densification behaviour of the powder obtained by the citrate route was studied in comparison with the solid-state reacted one.*

1 Introduction

Several studies reported the existence of many difficulties in preparing Bi-based superconducting phases, mainly regarding the isolation of the high-T_c phase (2223) as a single phase. Indeed, incomplete reaction, compositional inhomogeneity, very large particle size and long sintering treatment are still typical trademarks of the conventional BSCCO solid-state synthesis. The use of the solution method to prepare organic precursor by pyrolysis overcomes these problems, producing highly homogeneous mixing with good stoichiometric control and constituted by active submicronic particles, characterized by a greater degree of reproducibility.[1,2] It is already known[3] that the pyrolysed precursors and classical mixture of oxides and carbonates, subjected to the same thermal treatments, run along different routes, characterized by different kinetics and generating peculiar reaction intermediates in the two cases.

The present work examines the reactions involved when the pyrolysed precursors are thermally treated and discusses the fundamental role of the Bi–Ca phases as reaction intermediates highly affecting the superconducting phase synthesis rate. Evaluation of the densification behaviour and the sintering efficiency of the citrate powder compared to the solid-state reacted one, during hot pressing, has been performed. Microstructural and electrical characterization of dense materials, produced with the pyrolysed powder, were also carried out.

2 Experimental Procedure

The detailed procedure for powder preparation with a nominal composition $Bi_{1.84}Pb_{0.35}Sr_{1.9}Ca_{2.1}Cu_3O_x$ using a citrate method is reported elsewhere.[1] The obtained powder was calcined at 800°C for 6 h, then fired at 846°C for 5 h and at 858°C for 13 h, with three interposed grindings. The intermediate reaction products obtained after each step were determined by careful interpretation of XRD spectra.

Differential thermal analysis (DTA) and thermogravimetric analysis (TGA) were carried out on the pyrolysed mixture up to 1000°C. To investigate the DTA curve, various thermal treatments up to temperatures in the range 580–930°C were also performed and the products examined by XRD analysis using graphite monochromatized CuK_α radiation.

Morphology of powders and dense samples was investigated by means of Scanning Electron Microscopy (Leica Cambridge Ltd).

The obtained powders were hot-pressed in air using an alumina die with a pressure of 10 MPa; the sintering temperatures were 790 and 800°C and the sintering time under pressure was 2 h. Shrinkage was continuously recorded during sintering and the obtained density reported versus

time. Sample densities were measured by Archimedes' method. The degree of (001) texture orientation (Lotgering factor) in dense samples was also determined by XRD analysis. Electrical resistance of the dense samples was measured by means of the four-probe method with Ag paste contacts which were dried and hardened at 100°C for 10 min.

3 Results and Discussion

Micrograph in Fig. 1 shows spongy agglomerates as the product of the pyrolysis process, consisting of spherical submicronic primary particles (0·2–0·4 μm in diameter) connected to each other by necks partially sintered during the combustion process. Some of these agglomerates are rich in amorphous phases that, hardly detectable even by XRD, are revealed by thermoanalytical investigations.

In Fig. 2 the TG and DTA curves reveal that the precursor powder starts to react at about 500°C and the reaction develops via a complex process. The first step in the TG curve is attributed to the decomposition of $Ca_{0.33}Pb_{0.67}(NO_3)_2$, mainly present in the amorphous state (thus undetectable by XRD), followed by the decomposition of $CaCO_3$, between 580 and 780°C, present with different degree of crystallinity.

Fig 1. SEM micrograph of as-pyrolysed BSCCO powder.

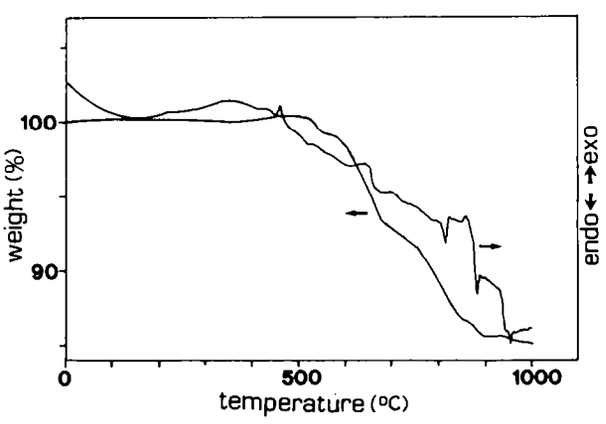

Fig. 2. Thermogravimetric and differential thermal analysis of pyrolysed powder.

The weight loss starting at 780°C is due to the beginning of $SrCO_3$ decomposition that runs out at $T \approx 930$°C. The DTA peaks clearly evident during the thermal analysis of the carbonate and oxide mixing used as a precursor of the solid-state reaction procedure,[4,5] are smoothed and broadened in the thermoanalytical curve of the pyrolysed precursor due to their low crystallinity. The DTA peaks between 630 and 730°C are attributable to various Bi–Ca phase formations and their interconversion from one form to another more stable one.[6] At 730°C, the $Bi_6Ca_4O_{13}$ phase starts to form, in equilibrium with traces of $Bi_6(Ca,Sr)_5O_{14}$; the DTA peak at 815°C is attributed to the transformation of the orthorhombic $Bi_6Ca_4O_{13}$ phase into monoclinic $Bi_6(Ca,Sr)_5O_{14}$. As the decomposition of $SrCO_3$ advances at $T > 820$°C, the CuO species is contemporarily engaged to form $(Ca,Sr)CuO_2$. Taking into account that the methodology used to identify the phases at different temperatures permits only the detection of products of irreversible reactions, it is, however, possible to attribute to the various Ca–Bi phases, and mainly to the 'O_{14}' phase, a dominant role in the superconducting phase formation process.

Table 1 shows the phase evolution, determined by XRD, in the pyrolysed powder, during the various steps of the 24 h processing to obtain 98% pure (2223) phase, as far as the phases belonging to Bi–Sr–Ca–Cu–O system are concerned, the exact amounts of Ca_2PbO_4 and Ca_2CuO_3 cannot be specified, their scattering powders being unknown referred to α-Al_2O_3 standard, but in any case the involved quantities are limited.

The high concentration of 'O_{13}' and especially of 'O_{14}' phases after the calcination treatment is a distinctive factor of the pyrolysed precursor synthetic process with respect to the conventional mixture of oxides and carbonates. The formation and dynamic equilibrium of the $Bi_6Ca_4O_{13}$ and $Bi_6(Ca,Sr)_5O_{14}$ phases cause a retardation in (2212) formation; as a consequence, the phase concentration starts to increase substantially only after the first firing step at 858°C, while the solid-state reacted powder already after calcination exhibits over 80% of (2212) phase. The slackened (2212) formation involves a delay in its grain growth at the considered stage. Taking into account the (2223) formation mechanism proposed by Wang *et al.*,[7] in which after a nucleation on the (2212) particle surface the (2223) growth process is controlled by diffusion, the accelerating effect of the smaller (2212) grain size, typical of calcined pyrolysed powder, becomes clear.

Moreover, the starting submicronic dimension of the pyrolysed precursor grains, promoting the

solid-state diffusion process, stimulates the interfacial reactions responsible for any intermediate and/or final phase growth.[7]

Micrographs in Fig. 3(a,b) show morphology differences between the two completely reacted powders: the one obtained by organic precursor is characterized by reduced average dimension of grains (0·7 μm against 3·5 μm) and definitely less anisotropic shape. These features can explain the differences in green packing of the two powders: the powder by organic precursor shows significantly lower density values of green bodies compared to the solid-state reacted one. This reflects in the different starting points (time = 0) of the densification curves reported in Fig. 4, which shows the densification behaviour of the two powders during hot pressing at different temperatures.

It is evident that the densification rate increases with temperature and at 800°C the density value approach 100% after 2 h. The curves at 790°C were mathematically analysed on the basis of Brook's theory[8] in order to establish the firing behaviour of the two powders in terms of the attainment of high density and the limitation of grain growth. Thus a parameter that relates the

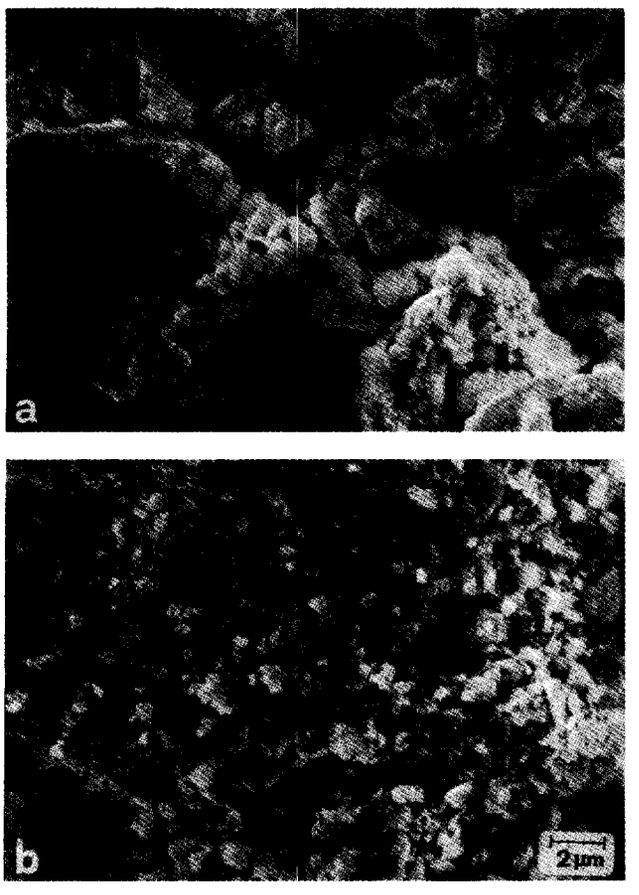

Fig. 3. SEM micrographs of BSCCO completely reacted powders ((2223) phase >95%): (a) solid state (96 h thermal treatment), (b) organic precursor (24 h thermal treatment).

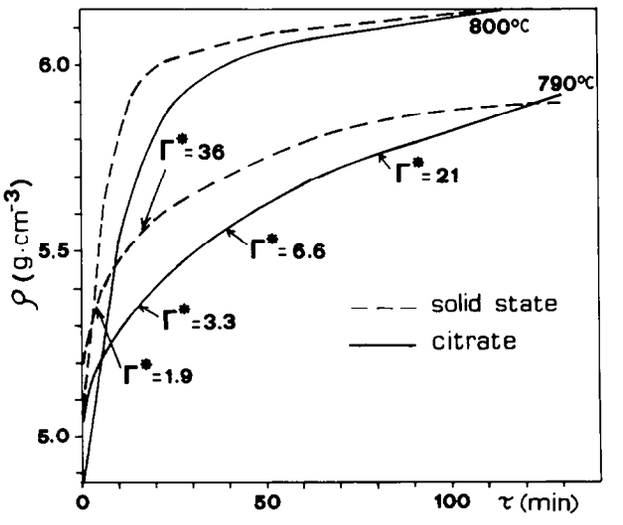

Fig. 4. Densification curves of solid-state reacted and citrate precursor powder; calculated figures of merit Γ^* are reported for some particular density values.

rate of grain growth and the densification rate is a figure of merit defined as:

$$\Gamma^* = -(1/3)\,\dot{\rho}^{\bullet}\,\rho/\dot{\rho}^2$$

where $\dot{\rho}$ is the densification rate and $\dot{\rho}^{\bullet}$ is the densification acceleration. The Γ^* values calculated at different densities along the densification curve (Fig. 4) evidence the behaviour of the two powders: the solid-state reacted powder, which starts the isothermal stage with better particles packing, densifies very rapidly up to 15 min and Γ^* is characterized by a low value, as expected for powders with high densification tendency (and low grain growth rate). At higher densities, Γ^* is lower for organic precursor powder, with respect to solid-state reacted one; in fact, the densification rate of the former increases, leading to the attainment of higher-density values over 120 min of hot-pressing treatment. Γ^* values also show that grain growth in the solid-state reacted powder (highly anisotropic in this case) is markedly enhanced (for densities higher than 80%), causing a reduction in the densification rate. Contemporarily, however, the more anisotropic grain growth allows the attainment of a higher degree of texture orientation (the orientation factor F in this case is $\approx$ 48%, to be compared with 35% for dense sample obtained by organic precursor powder). The citrate powder, characterized by a lower green packing, but able to achieve a higher density in long hot-pressing treatments, produces dense material with a low Lotgering factor, owing to the larger randomness in orientation of less anisotropically grown grains.

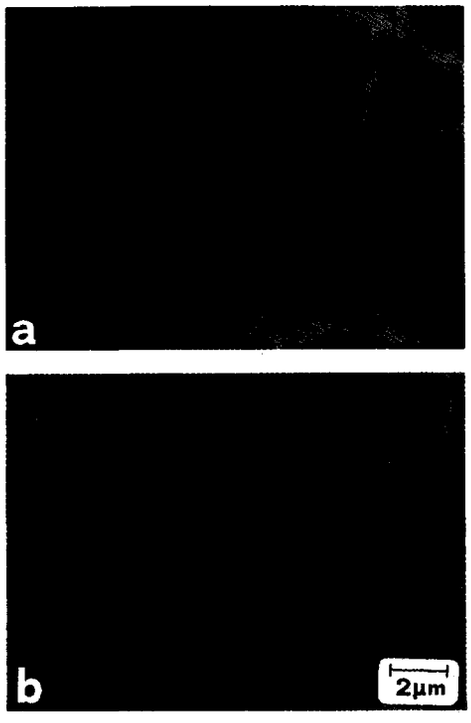

Fig. 5. SEM micrographs of fracture surfaces showing the morphology of hot-pressed dense samples obtained by (a) solid-state reacted powder, (b) citrate precursor powder.

Table 2. Properties of dense samples obtained by pyrolysed powder

Sample	*Sintering temperature (°C)*	*RD (%)*	*F (%)*	$T_{c\ onset}$ *(K)*	$T_{c\ offset}$ *(K)*
1	790	94	35	110	92
2	800	98	38	115	106

In Fig. 5(a,b) the morphology of hot-pressed samples is reported, showing the reduced average dimension of grains (about 2/5) of the sample prepared by organic precursors with respect to that obtained by solid-state reacted powder.

The properties of the hot-pressed samples are reported in Table 2. Critical temperature evaluated on dense samples showed Tc_{onset} values $\approx$ 110 K, proving the substantial (2223) phase purity of the bulk.

The presence of a tailing phenomenon on Sample 1,[9,10] lowering the Tc_{offset} (Table 2), is attributed to the still incomplete densification in comparison with Sample 2 and to the low oxygen income during densification itself. Indeed, it is well known[11] that a scarce diffusion of oxygen into the inner part of the sample causes a lowering of T_{c0} in the (2223) phase: actually the critical temperature of Sample 2 (as densified) was for this second reason very low ($T_{c0} \approx$ 80 K).

Since an oxygen decrease in formula stoichiometry, typical of highly dense materials, could be supposed on the basis of cell parameters evaluated by XRD analysis, Sample 2 was annealed at 820°C for 40 h in flowing air in order to restore the cell parameters themselves, and T_{c0} increased up to 106 K.

4 Conclusions

The citrate solution pyrolysis as an alternative method of preparing precursors for synthesis of BSCCO (2223) superconducting phase was performed and analysed, and inherent differences in comparison with traditional solid-state mixtures of oxides and carbonates were found: intermediate Bi–Ca phases play a determinant role in the organic precursor transformation, retarding the (2212) appearance and allowing the formation of (2223) phase in a total heat-treatment time at least four times shorter.

As expected, grain development is smaller for citrate precursor powder, and their shape is clearly more isotropic; densification exhibits a rather slow rate at the beginning, but within two hours powders by citrates reach and even exceed density values typical of solid-state reacted powders.

Critical temperatures result not too far from

those obtained with solid-state reacted powders, though lesser orientation factors attained by citrate precursor powders point to presumably lower transport current values; anyway, the probable compensating effects of different pinning centre concentrations deserve further investigation.

Binder Distribution in Green Ceramic Foils

G. P. van der Beek, U. Gontermann-Gehl & E. Krafczyk

Philips GmbH Forschungslaboratorien, Weisshaustrasse 2, D-52066 Aachen, Germany

(Received 7 November 1994; revised version received 10 February 1995; accepted 14 February 1995)

Abstract

Green ceramic foils with a thickness of 20 μm were tape cast on a doctor-blade machine from an aqueous dispersion of barium titanate powder, containing poly vinyl alcohol, PVA as a binder and triethylene glycol, TEG as a plasticizer. After casting, the wet foils were dried in an oven. The specific aim of this study was to characterize the binder distribution in green foils and to find parameters that affect this distribution. Mercury Intrusion Porosimetry and Nitrogen Adsorption (B.E.T.) were used as techniques to analyse the binder distribution. Experiments were carried out with foils containing either a coarse (d_{50} = 0·75 μm) or a fine barium titanate powder (d_{50} = 0·2 μm). The moment in the drying process of foils, that the binder gets fixed in the ceramic structure determines the binder distribution in green foils. The earlier the PVA fixation process takes place, the more homogeneous is the binder distribution. The plasticizer triethylene glycol (TEG) promotes fixation of PVA by a gelation process. More TEG in the slip leads to a more homogeneous binder distribution in foils. In the case of a low TEG amount, small pores are preferentially filled with binder over large ones and the lower side of foils is enriched with binder. Less hydrolysed PVA types are less susceptible to gelation with TEG, resulting in a more heterogeneous binder distribution.

1 Introduction

Thin green ceramic foils are used for the preparation of several laminated components, e.g. ceramic multilayer capacitors (CMCs)[1–3] and multilayer actuators (CMAs),[4] solid oxide fuel cells (SOFC),[5] heat exchangers,[6] ceramic superconducting elements[7] and laminated composites.[8]

Green ceramic foils consist of inorganic particles, organic substances (binder, plasticizer, dispersants, etc.), air (porosity) and moisture or organic solvent rests. The binder, which is a polymeric substance, has an adhesive function for the ceramic particles within green tapes. The binder is present during a large part of the whole processing route for ceramic components. In most cases, ceramic components are built and shaped in the green state. After that, the binder is burnt out and finally the components are sintered. The constitution and distribution of the binder within green foils influence or determine foil properties that are important for the processing of laminated ceramic components: mechanical characteristics,[9] stress sensitivity, lamination behaviour, porosity and pore sizes. The binder distribution may have a large effect on the mass and heat transfer resistance during thermolysis of green components.[10] These parameters are of crucial importance to prevent crack and defect formation. The amount of binder and the binder distribution in green foils may also affect the porosity in sintered products. Porosity in green bodies can be reduced by pressing; porosity after binder burn-out can only disappear by the sintering procedure. A high local binder content in the pressed green state leaves such a high porosity after binder removal that it cannot be sintered any more to a dense ceramic. Considering all the effects described above, the binder distribution in green foils may have a significant impact on the structural integrity of laminated green components and, eventually, on that of sintered ones as well.[11,12]

The specific aim of this study is to characterize the binder distribution in foils and to determine parameters that affect this distribution. The techniques used for this purpose are Nitrogen Adsorption (B.E.T.) and Mercury Intrusion Porosimetry.

To investigate the binder distribution, as a function of particle size (or pore size), we have analysed foils made from both coarse and fine powders. As a powder system we have taken barium titanate, which is an important material for dielectric layers.[13,14] The influences of the binder concentration, the binder type and the plasticizer content in the slip, on the binder distribution in foils have also been studied. Apart from the materials, the processing conditions (i.e. drying procedure) affect the binder distribution as well.

We will start this paper with a brief description of the drying mechanism of ceramic foils and discern the important parameters for drying. This description appears to be helpful for the interpretation of the results obtained in this study.

2 Theory of Drying

A number of studies on drying of ceramic bodies have been issued over the last few years.[15-21] An excellent paper on this issue has been written by Scherer.[17]

Several stages can be distinguished during drying of ceramic bodies. The drying mechanism, the rate-controlling factors, the stresses that may develop and the dimension changes may all be different in these stages of drying.[17-19] Each stage depends, in a particular way, upon external factors (temperature, air flow and ambient vapour pressure) and on internal factors (such as body geometry, particle packing, pore sizes). For a good controlled drying procedure, the drying conditions have to be set separately for each stage.

The first drying stage is called the *constant rate period* (CRP). Under constant external conditions, the rate of evaporation per unit surface area is independent of time and moisture content in the drying body. During the CRP, the shrinkage of the drying body is equal to the volume of liquid evaporated. The meniscus remains at the exterior surface.

The drying rate during this stage depends upon the external conditions such as ambient vapour pressure, temperature, draught and geometry of the system. In the constant rate period, the evaporation process is by definition the rate-limiting step and not the liquid transport in the green body. Evaporation is an endothermal process and has, therefore, a cooling effect. A reduced temperature upon evaporation leads to a lowering of the drying rate. This feedback process equilibrates when the drying surfaces reach the so-called *wet bulb* temperature. Hence, the drying temperature of water-based ceramic foils is determined by the humidity, the ambient temperature and the air flow.

Liquid from the interior of the green body is transferred to the evaporation surface by flow due to pressure gradients (capillary pressure) as well as by diffusion due to concentration gradients. The flow flux is the most important one in this stage.

The constant rate period ends at the so-called *critical point* where shrinkage virtually stops. At this point, the ceramic structure has been built and further drying occurs by replacing liquid in the ceramic network by air.

A phenomenon often observed during drying of ceramic tapes is the so-called *skin effect*. In such a case, the evaporation process is so fast that the concentration of binder at the surface becomes very high because the diffusion rate is too small. The binder may then precipitate or gelate to an impermeable layer which hinders the transport of the underlying liquid to the evaporation surface. The drying rate may then reduce drastically and the constant rate period is ended by definition. Skin-forming can be prevented by lowering the evaporation rate and/or increasing the diffusion flux. A reduction of the ambient temperature decreases the evaporation rate but also decreases the diffusion flux and is therefore not very effective to counteract binder segregation. Increasing the humidity and/or reducing the air flow lowers the evaporation rate. The diffusion rate may eventually be enlarged because the wet bulb temperature increases due to a lowered evaporation rate. Hence, to overcome the skin effect it is much more effective to reduce the difference between the ambient and equilibrium vapour pressures than to lower the ambient temperature. The skin-forming effect becomes less important for thinner foils because the diffusion distances are smaller.[20]

After the critical point the second drying stage sets in. This stage is called the *first falling rate period* (FRP1). The vapour/liquid interface recedes into the green body and the drying surface may begin to lose its translucency. The drying rate decreases and the temperature of the surface rises above the wet bulb temperature during this stage. Although the meniscus retreats into the green body, most of the evaporation still occurs at the exterior surface due to the fact that the liquid in the pores near the surface is in a funicular condition (i.e. continuous thin liquid pathways along the flow is still possible). Therefore, the temperature of the surface remains under the ambient temperature and the drying rate is still sensitive to external factors as temperature and vapour pressure. The liquid flux from the interior to the surface becomes, however, more and more rate-controlling. At the same time, some liquid evaporates in the unsaturated pores and the vapour is transported by diffusion.

The drying front becomes irregular in instances where different pore sizes are present. At the critical point, the radii of the menisci in different pores are equal and therefore the capillary pressures are equal. Upon further drying, the meniscus radii of the small pores get smaller than those of the large pores. This leads to different capillary pressures in large and small pores. As a consequence, liquid flows from large pores to smaller ones. Hence, large pores are emptied before the small ones.

In the last drying stage, the *second falling rate period* (FRP2), the flux of the liquid is very slow.

Eventually, the flow to the surface stops, the liquid is isolated in pockets (mainly the small pores) and can only be removed from the green body by vapour diffusion. This diffusion process controls the drying rate, which is therefore less dependent upon external factors, and the evaporation process takes place completely inside the body. The temperature of the surface approaches the ambient temperature.

3 Preparation of Foils

Both ceramic foils containing coarse barium titanate powder and foils containing fine barium titanate powder were made and analysed in this study. These foils were prepared by tape casting on a doctor-blade machine.[22-24] The conducted procedure was as follows. Dielectric powder was dispersed into water with the help of a dispersant. The amount of dispersant added was equal to that needed for a minimum value of the yield value and of the viscosity. Of course, more dispersant per weight unit of solid material had to be added to the fine barium titanate powder because of the larger specific surface area (due to smaller particles). The obtained dispersion, which is called a slurry, is then de-agglomerated by ultrasonification (15 min in a US bath of 200/400W) and milling (Attritor-mill filled with 2 mm ZrO_2 balls at 500 rpm; 20 min milling for the fine powder and 40 min for the coarse powder sample). The average diameter of the coarse barium titanate particles in the slurry was about 0·75 μm (= d_{50} as measured by X-ray absorption in a sedimentation experiment using the Micromerites Sedigraph 5000D). This value was equal to 0·2 μm for the fine barium titanate sample. After sieving the slurry, the constituents listed below are added and the suspension is then called a *slip*.

- The binder poly vinyl alcohol, PVA. The rheological behaviour of the slip, which is important for the casting process, may be adjusted by the amount and/or type of binder. When the solvent evaporates after tape casting, the ceramic particles within the foil are held together by the binder. In our study, we used different PVA samples, which are given in Table 1.
- The plasticizer triethylene glycol, TEG. In general, the plasticizer structurally expands the binder and improves the distribution of the binder in the slip. The flexibility of green foils may be increased by the addition of a plasticizer, which lowers the glass transition point, T_g of the binder.

Table 1. Poly vinyl alcohol samples used in this study

PVA sample	$\overline{M_w}$ *(g mol^{-1})*	*hydrolysis ratio*[a] *(mol%)*
PVA 31-88	31 000	87·7 ± 1·0
PVA 27-98	27 000	98·4 ± 0·4
PVA 125-98	125 000	98·4 ± 0·4
PVA 205-88	205 000	87·7 ± 1·0

[a]Poly vinyl alcohol is made from poly vinyl acetate. The hydrolysis ratio is the percentage of acetate groups hydrolysed to alcohol groups.

- Small amounts of an anti-foam agent (to counteract foam formation during mixing), a wetting agent (to have a good wetting behaviour of the slip on the tape casting carrier) and a release agent (to release the green foil from the carrier).

Concentrations of PVA and TEG are always expressed in wt% relative to the solid material throughout this study. After all these additions, the resulting slip was finally degassed before tape casting took place to prevent holes in the foil caused by enclosed air bubbles. Care was taken to prepare the slurry and slip always in the same way in order to be able to compare the foil properties properly.

In this study, 20 μm green foils (unless otherwise stated) were cast from a slip with the help of a doctor-blade machine and subsequently dried in an oven (without air circulation). Because the drying procedure may affect the foil properties, results presented in this study are all based on foils which were dried in the same way, i.e., at 60°C for 30 min. After drying, the foils were carefully released from the substrate.

The binder content and plasticizer concentration in slips are varied in this study. Changes in these concentrations were always compensated for by the amount of water added. In this way, the solid content of all slips could be kept the same (i.e. 45·6 wt%). Variation in the solid content leads to a different drying procedure, which may influence the foil characteristics.

4 Measuring Methods

Both Nitrogen Adsorption (B.E.T.) and Mercury Intrusion Porosimetry may yield information about the binder distribution within a green ceramic foil. Neither of these methods gives, however, a real binder concentration profile over the thickness of the foil.

4.1 B.E.T. nitrogen adsorption

Gas adsorption onto solid phases was first

described by Brunauer, Emmet and Teller (B.E.T.). They derived the following adsorption isotherm:

$$\frac{V}{V_m} = \frac{C(P/P_0)}{[1-(P/P_0)]\,[1 + (C-1)\,(P/P_0)]}$$

where V_m is the volume of one adsorbed monolayer, P is the vapour pressure of the adsorbate and P_0 is the saturated vapour pressure at the temperature of adsorption. The constant C is a measure for the affinity of the adsorbate molecules for the surface. A large C value indicates a strong interaction of the adsorbing molecules to the substrate (so-called 'high energy' surface). Hence, the form of the isotherm depends upon the substrate material. Isotherms with C-values between 1 and 100 are quite usual. Inorganic oxide surfaces have a high C-value most of the time.

The specific surface area (S) can be calculated from the V_m value using the molecular dimension of the adsorbate molecules. Because V_m stays explicitly in the equation of the adsorption isotherm, S can be determined from the experimental adsorption data.

Adsorption hysteresis is frequently found for gas adsorption onto porous media. This hysteresis effect can be explained by capillary condensation. Small pores will be filled with adsorbate at a high vapour pressure, forming a concave adsorbate meniscus. According to Kelvin's law, the evaporation from a flat liquid surface and a concave liquid surface as a function of the vapour pressure is different. Hence, the desorption isotherm will be influenced by capillary condensation. This hysteresis effect is, of course, dependent upon the size of pores. A pore size distribution can, in principle, be determined from the hysteresis effect. Obviously, only small pores (2 nm $\leq d_{pore} \leq$ 50 nm) can be detected in this way.

4.1.1 Analyses

Ceramic foils, with and without binder (after binder burn-out), as well as the ceramic powders were analysed using the ASAP 2000 B.E.T. apparatus from Micromeritics. Nitrogen gas was used as an adsorbate. Before each measurement, the sample was degassed under vacuum at 50°C for about 15 h. The surface affinity to nitrogen adsorption was determined by calculating the C-value from the adsorption isotherm. Changes in the chemical nature of the surfaces inside pores may be detected with the help of this parameter.

As already described in the previous section, small pores can be determined by the B.E.T. adsorption technique. However, we did not pay very much attention to this feature of the B.E.T technique for the following two reasons:

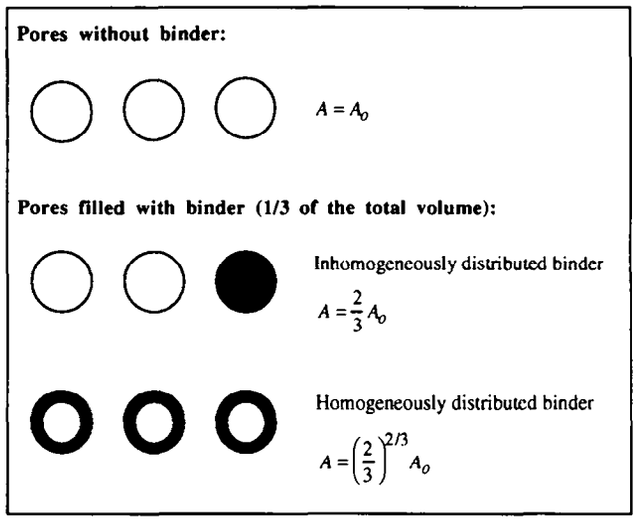

Fig. 1. Surface areas of spherical pores differently filled with binder.

(1) the pore size distribution of most of the foils goes beyond the detection limit of this technique,
(2) the pore size distribution can be measured more accurately by Mercury Intrusion Porosimetry (see next section).

The specific surface area of a green foil depends upon (i) the primary particle size, (ii) the ceramic structure, (iii) the total amount of binder and (iv) the binder distribution. An example of the correlation between the specific surface area of foils and the binder distribution is given in Fig. 1. A foil with an inhomogeneous binder distribution always has a lower surface area than a foil containing a homogeneously distributed binder.

4.1.2 Relationships between the surface area and the binder distribution in foils

Theoretical dependencies of the surface area on the total amount of binder in foils are derived in the Appendix for four special cases. These instances differ in pore geometry and/or binder distribution. The formulas belonging to these different cases are given below. The parameters used in these formulas are:

A_0 The specific surface area of a foil without binder
A The specific surface area of foils containing a certain amount of binder
P_0 The total porosity of foils without binder (not to confuse with the saturated vapour pressure in the B.E.T. adsorption isotherm)
V_i The amount of organic substances (binder, dispersant, etc.), expressed in vol.% with respect to the ceramic material.

4.1.2.1 Spherical pores filled homogeneously with binder. In this case, the added amount of binder with respect to the ceramic is assumed to affect only the radius of the pores (see Fig. 1).

$$A = A_0\left[1-\frac{1-P_0/100}{P_0}V_i\right]^{2/3} \quad (1)$$

4.1.2.2 Pores filled inhomogeneously with binder. In this instance, the amount of added binder with respect to the ceramic is assumed to affect only the number of filled and unfilled pores. This dependency is invariant of the pore geometry. The same relationship holds also for cylindrical pores that are filled from the bottom to the top (the filling height of the cylinders changes with the amount of binder).

$$A = A_0\left[1-\frac{1-P_0/100}{P_0}V_i\right] \quad (2)$$

4.1.2.3 Cylindrical pores filled homogeneously with binder. In this case, the amount of added binder with respect to the ceramic is assumed to affect only the diameter of the cylinder.

$$A = A_0\left[1-\frac{1-P_0/100}{P_0}V_i\right]^{1/2} \quad (3)$$

4.1.2.4 Small spherical pores preferentially filled with binder over large ones. The previous relationships were all based on the assumption that pores are filled equally over the size distribution. Suppose that three different pore sizes (spheres with radii of $0{\cdot}5R$, R, and $2R$) exist in a ceramic foil without binder. The number of pores, for each type, is chosen such that the volume of each class of pores is equal to one third of the total porosity. An inhomogeneous binder distribution is assumed, i.e. pores are filled one by one by the binder. Suppose that first the small pores are filled with binder, then the medium sized ones, and finally the big ones. The total surface area as a function of the amount of binder is then described by the following set of relations:

$$A = A_0\left[1-\frac{12}{7}\left(\frac{1-P_0/100}{P_0}\right)V_i\right] \quad (4a)$$

$$\text{for } 0 \le V_i \le \frac{1}{3}\frac{100P_0}{(100-P_0)}$$

$$A = A_0\left[\frac{5}{7}-\frac{6}{7}\left(\frac{1-P_0/100}{P_0}\right)V_i\right] \quad (4b)$$

$$\text{for } \frac{1}{3}\frac{100P_0}{(100-P_0)} \le V_i \le \frac{2}{3}\frac{100P_0}{(100-P_0)}$$

$$A = A_0\left[\frac{3}{7}-\frac{3}{7}\left(\frac{1-P_0/100}{P_0}\right)V_i\right] \quad (4c)$$

$$\text{for } \frac{2}{3}\frac{100P_0}{(100-P_0)} \le V_i \le \frac{100P_0}{(100-P_0)}$$

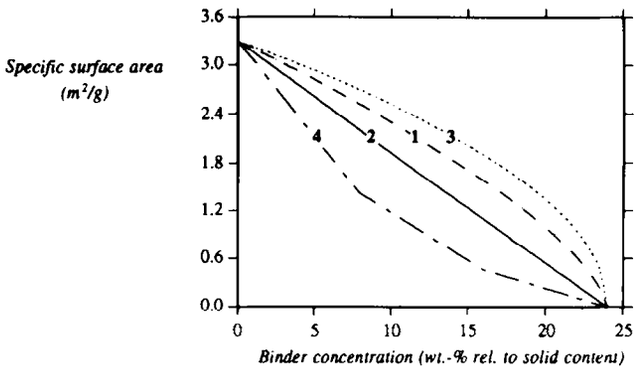

Fig. 2. Theoretical relations between the specific surface area and the amount of added binder relative to the ceramic for foils containing the coarse barium titanate. The numbers correspond to the different cases described above. The following parameters were used for the calculations: P_0 = 55%, A_0 = 3·3 $m^2.g^{-1}$, ρ_{binder} = 1·2 $g.cm^{-3}$, $\rho_{ceramics}$ = 5·9 $g.cm^{-3}$.

All the dependencies given above are visualised by the curves given in Fig. 2. As can be seen in this figure, a high surface area corresponds to a homogeneous binder distribution (cases 1 and 3). Surface area values lower than those given by case 2 can, in principle, only occur if small pores are filled preferentially over large ones.

In order to be able to compare binder distributions of different systems by measuring the specific surface area, we have defined a so-called *binder distribution index*, X:

$$X = \frac{A - A_0\left[1-\frac{1-P_0/100}{P_0}V_i\right]}{A_0\left[1-\frac{1-P_0/100}{P_0}V_i\right]^{1/2} - A_0\left[1-\frac{1-P_0/100}{P_0}V_i\right]} \quad (5)$$

This index is 0 for specific surface areas corresponding to line 2 in Fig. 2, and 1 for values corresponding to curve 3. Hence, the larger the index X, the more homogeneously is the binder distributed. We have to note, however, that high X-values can, in principle, also be due to the fact that large pores are preferentially filled with binder over small ones. In practice, this will rarely occur because large pores are emptied first during drying (by capillary action). On the other hand, negative X values are more probable because of the tendency that small pores are preferentially filled with binder.

4.2 Mercury intrusion porosimetry

The principle of Mercury Intrusion Porosimetry is based on the fact that mercury behaves as a non-wetting liquid towards most substances. Consequently, it does not intrude into the pores of these substances without applying pressure. Mercury porosimetry measurements are conducted by measuring a series of pressures with corresponding

volumes of mercury intruded into the porous body. The pore radius (r) can be calculated from the applied pressure (ΔP), the surface tension of mercury (γ_{LV}) and an assumed wetting angle (θ), using the Washburn equation:

$$\Delta P = \frac{2\gamma_{LV}\cos\theta}{r} \quad (6)$$

The total amount of pores with a certain radius is simply calculated from the volume of intruded mercury at the pressure corresponding to that pore size.[25–28] The total pore volume can be determined if all pores have been filled at the maximum pressure of the equipment. The porosity can then be calculated if the total volume of the sample is known.

A few things should be taken care of using Mercury Intrusion Porosimetry. These items can be summarized as follows:

1. Mercury Intrusion Porosimetry often displays hysteresis phenomena. The pressure-volume relationship is different for penetration and retraction of the mercury. A certain amount of mercury may remain in the porous medium after complete reduction in the pressure. Two causes are mainly responsible for this phenomenon:
   - — The advancing contact angle is often different from the receding one. Different penetration and retraction curves will then be obtained.
   - — Structural hysteresis refers to the presence of the so-called *ink-bottle* pores (i.e. pores with a small opening). During penetration, one big ink-bottle pore is measured as a number of small ones with radii equal to that of the opening of the big pore. In general, the effect of structural hysteresis will be less if the porosity is higher. However, the details of this phenomenon will depend upon the particular geometry of the pore space.
2. If a number of hysteresis loops are recorded, the first penetration curve is different from subsequent ones. A difference in contact angle for a fresh surface and a surface that has already been in contact with mercury may be the reason for this phenomenon.
3. For easily deformable samples, geometrical and pore size changes may occur by the applied pressure (compression).

Assuming that the pores are series of cylinders of different diameters, the surface area can be calculated by integrating the volume–diameter curve. Specific surface areas determined in this way are, in most cases, higher than those obtained from sorption isotherms (B.E.T.) due to the presence of *ink-bottle* pores. We do not use this feature of Mercury Intrusion Porosimetry because the determination of the specific surface area by this technique is less reliable than that of B.E.T. measurements.[25, 28]

4.2.1 Measurements

The measurements were conducted with a Porosimeter 2000 from Fa. Carlo Erba Instruments. Samples that were both analysed by nitrogen sorption and porosimetry were first used for the specific surface area measurement and afterwards put into the porosimeter vessel. Samples of about 15 cm^3 were evacuated for about 1 h before immersing in mercury at a low pressure (0·1 MPa). The Hg-pressure was increased step-wise. The pressure was enlarged only if the volume of intruded mercury had become constant. After a complete reduction in the pressure, a second run was started. All measurements were carried out at room temperature.

We used the following values for the parameters needed to calculate the pore sizes: γ_{LV} = 0·485 N m^{-1} and θ = 140°. For comparison of the porosity and pore sizes between samples of the same nature, it is not really necessary to know the exact values of these parameters. The pore size distribution is indicative of binder distribution in a foil, as can be seen in Fig. 1. Only the number of large pores is diminished for a very inhomogeneous binder distribution. The pore sizes remain unchanged in such a situation. In the case of a homogeneously distributed binder, the pore sizes get smaller with respect to pores in foils without binder.

5 Results

Results from measurements, as mentioned above, are described in this section. Firstly, analyses of the ceramic powders used to process the foils in this study are given. Then the results of foils released from binder are reported, and lastly the characterization of green foils is described. The interpretation and discussion of the results is partly done in a separate paragraph (Section 6).

5.1 Powders

For a correct analysis of green ceramic tapes, characterization of the powders, from which these foils were made, is needed. Porosity measurements were only possible when powders were pressed (or centrifuged) to a coherent pill. The results of the powder analyses are summarized in Table 2.

Table 2. Powder analyses

System	*C*	*B.E.T. surface* ($m^2 g^{-1}$)	*Porosity* (%)	d_{50} *pore size (nm)*
Coarse barium titanate #1:				
Without pre-treatment	103·3	2·91		
Isostatically pressed at 320 MPa	97·7	3·24		
Slurry, 40 min milled, dried	78·5	3·32		
Slurry, 40 min milled, centrifuged	62·3	3·20	37·6	181
Slurry, 40 min milled, dried, pressed at 320 MPa	64·0	3·40	36·1	152
Coarse barium titanate #2:				
Without pre-treatment	108·6	2·87		
Powder-PVA granules	40·4	1·19		
50 wt% powder-PVA granules + 50 wt% powder	76·7	2·14		
Fine barium titanate:				
Without pre-treatment	106·1	9·09		
Isostatically pressed at 3·2 kbar	113·3	9·83	37·9	61
Slurry, 20 min milled, dried	78·7	9·34		
Slurry, 20 min milled, centrifuged	78·6	9·36	38·9	56
Slurry, 20 min milled, dried, pressed at 320 MPa	75·4	9·27	37·6	50
PVA 125-98:				
Crushed granules, dried at 50°C	20·1	–	–	–

5.1.1 B.E.T. analyses

The specific surface areas of the fine and coarse powders without any special treatment are equal to 9·1 $m^2 g^{-1}$ and 2·9 $m^2 g^{-1}$, respectively. No significant difference was found between two different batches of the coarse sample (batch #1 and #2 in Table 2). As expected, the specific surface area of the fine powder sample is much higher than that of the coarse powder due to the smaller particles.

As can be seen in Table 2, the *C*-values of the powders without any pre-treatment are equal to about 105, indicating 'high energy' surfaces. Just isostatically pressing the powders does not change the B.E.T. values very much. The specific surface area seems to increase a little upon this treatment.

We also analysed the powders from the slurries made as described in Section 3. The powders were separated from the slurries either by simply drying or by centrifugation and subsequently drying the centrifuged cake. The specific surface areas of the powders from the slurries are slightly higher than those of the ones without any pre-treatment because of the milling procedure used for the preparation of slurries. This effect is not very large because the surface area of particle aggregates is not very different from that of separated particles. The *C*-values of the slurry powders are all about 75, which is significantly lower than those found for untreated powders. This effect is caused by the adsorption of the dispersant onto the particle surfaces. The chemical nature of the surface, and hence the affinity to nitrogen adsorption, have been changed by this adsorption process.

In order to investigate the influence of the poly vinyl alcohol on the *C*-parameter, we dispersed coarse powder (batch #2) into a PVA solution. The binder concentration with respect to the ceramic material was of the same order as that used in slips (i.e. 8 wt%). Thin films of this dispersion were dried in a oven at 60°C. The product obtained in this way was analysed by the B.E.T. technique. The *C*-value of these powder-PVA granules was equal to 40·4. A mixture of 50 wt% of this product and 50 wt% of untreated powder gave a *C*-value of 76·7 (mixing was done in the dry state). Hence, the B.E.T. technique is sensitive to the degree of powder particle coating with PVA. This effect is graphically shown in Fig. 3.

Finally, we have measured the *C*-value of pure PVA 125-98. This turned out to be about 20, i.e.

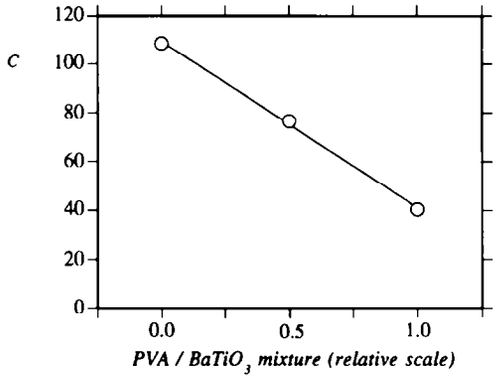

Fig. 3. Surface affinity to nitrogen adsorption (*C*-value) of coarse $BaTiO_3$/PVA mixtures as a function of the PVA concentration: 0.0, pure $BaTiO_3$ powder; 1.0, PVA/$BaTiO_3$ granules (8·0 wt.% PVA with respect to barium titanate); 0·5, pure $BaTiO_3$ powder mixed with the same PVA/$BaTiO_3$ granules as in 1·0 in a weight ratio of 1:1.

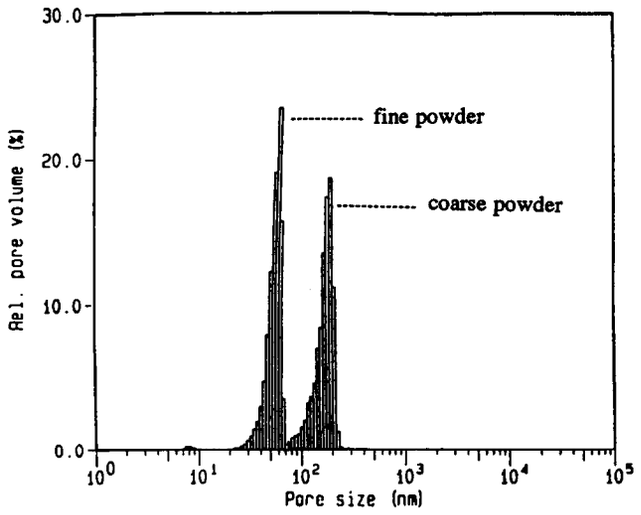

Fig. 4. Pore size diagrams of pills centrifuged from slurries containing the two grades of powder.

the lowest value found so far. Apparently, the nature of the ceramic powder in the dried PVA/$BaTiO_3$ mixture (C = 40) was not fully masked by PVA. The powder particles were, probably, not completely or sufficiently wetted (coated) by the PVA in the dispersion.

5.1.2 Porosimetry

The pore size distributions of powders centrifuged from slurries to a coherent tablet are given in Fig. 4. As can be seen in this figure, the pore sizes for the finer powder batch (d_{50} pore size ≈ 60 nm) are much smaller than for the coarser sample (d_{50} pore size ≈ 190 nm).* A measure of the particle packing is the d_{50} pore size divided by the d_{50} particle size. These numbers lay between 0·20 and 0·30 for both powders. Values of about 0·14 (= 1/7) are found for an ideally closed packed system of monodisperse particles. Hence, both powder pills have the same fairly close particle packing. This is supported by the total porosity measurements. The total porosity for the coarse powder system and the fine powder system are the same, i.e about 37%. For comparison, the porosity of a closed packed system of monodisperse particles is equal to 26%. Apparently, the slurries did not contain large aggregates.

5.2 Foils

A green foil can be conceptualized as a ceramic structure containing organic material. First, the ceramic structure of foils will be discussed. Paragraph 5.2.2. deals with the distribution of organic material within the ceramic structure.

5.2.1 Foils released from organic material

Green foils were released from the organic substances by heating in air at 550°C for 1 h. Both foils consisting of coarse and fine powder were analysed. The influences on the ceramic structure of the binder type, binder concentration and the amount of plasticizer added to the slip have been studied. All results of these measurements are summarized in Table 3.

The C-values and the specific surface areas measured for these burned foils come close to those found for the untreated powders in Table 2.

*The d_{50} value is the pore size at which half of the total porosity is filled with mercury.

Table 3. Analyses of foils released from organic material

PVA type and concentration present in the foils before binder removal	*TEG conc. in the slip (wt%)*	*B.E.T. results*		*Porosity (%)*	*d_{50} pore size (nm)*
		C	*S ($m^2 g^{-1}$)*		
Coarse barium titanate:					
6·5 wt% PVA 205-88	0	83	3·46	55·9	380
6·5 wt% PVA 125-98	0	109	3·63	53·1	364
6·5 wt% PVA 205-88	2·6	96	3·34	55·7	372
6·5 wt% PVA 125-98	2·6	108	3·40	56·5	390
8 wt% PVA 205-88	0	140	3·30	53·6	457
8 wt% PVA 125-98	0	86	3·25	56·9	466
6·5 wt% PVA 205-88 + 1·5 wt% PVA 27-98	0	88	3·38	–	...
6·5 wt% PVA 125-98 + 1·5 wt% PVA 31-88	0	138	3·35	55·7	417
6·5 wt% PVA 125-98 + 1·5 wt% PVA 27-98	0	119	3·33	54·0	463
8 wt% PVA 205-88	3·2	107	2·99	55·0	383
8 wt% PVA 125-98	3·2	118	3·32	52·0	390
6·5 wt% PVA 205-88 + 1·5 wt% PVA 27-98	3·2	108	2·92	55·1	393
6·5 wt% PVA 125-98 + 1·5 wt% PVA 27-98	3·2	117	3·27	56·1	439
12 wt% PVA 125-98	1·6	87	3·13	52·2	408
Fine barium titanate:					
6·5 wt% PVA 20/98	3·2	107	9·27	55·1	136
8 wt% PVA 20/98	1·6	113	8·97	54·0	132
8 wt% PVA 20/98	3·2	109	8·48	55·3	147

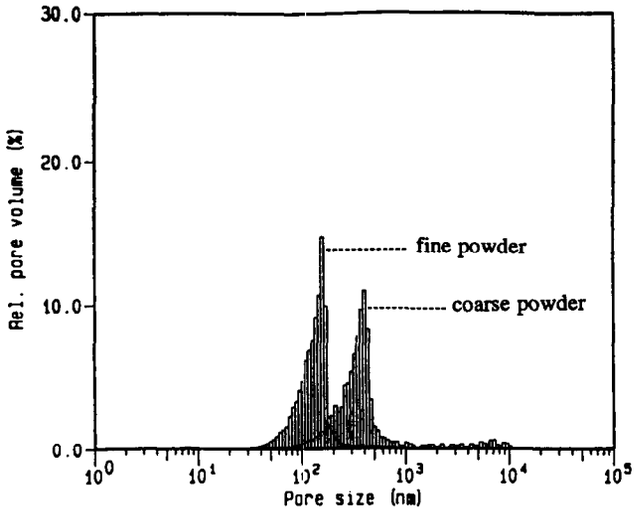

Fig. 5. Pore size diagrams of foils without binder. One foil consists of the fine powder, the other one of the coarse powder.

However, the spread in the *C*-values is quite large. Apparently, the powder surface is not left in a completely reproducible condition after the removal of the organic species. This can possibly be caused by the presence of carbonaceous residues.

As can be seen in Table 3, there is no significant change in either the total porosity or the pore sizes as a function of the slip parameters mentioned above. Hence, the ceramic structure is independent of the PVA type, the PVA concentration, and the TEG concentration within the ranges used in this study. The pore size distributions of a coarse powder and a fine powder foil without organic material are given in Fig. 5. The d_{50} pore sizes in burned foils containing either coarse or fine ceramic powder are 410 nm and 140 nm, respectively.

Both foil types without binder exhibit the same porosity (i.e. about 55%). The average values of the ratio of the d_{50} pore size over the d_{50} particle diameter are equal to 0·54 and 0·69 for the coarse and fine powder foils, respectively. Although this ratio is somewhat larger for fine powder foils than for coarse powder foils, it is questionable whether or not this difference is significant.

Both the porosity and the ratio of pore size to particle size show, however, that the powder particles are less well packed in the foils than in the centrifuged pills. This indicates that the colloidal system in the slip, during the settlement of the powder particles, was most probably not stable. This may be caused by depletion flocculation of particles in the slip due to the presence of the relatively high amount of polymer.

5.2.2 Binder distribution in green foils

The porosimetry and B.E.T. results for green foils, as a function of the binder system, are directly indicative of the distribution of the organic matter in the foils because the ceramic structure is not significantly affected by the constitution of the binder system (see previous section). The influences of the TEG content in the slip, and the PVA type and concentration, on the binder distribution in both coarse powder and fine powder foils are described in the following sections.

5.2.2.1 TEG concentration. Triethylene glycol is a relatively small molecular weight plasticizer which is not very compatible with PVA.[29] As a consequence, TEG can be removed quite easily from thin green foils. Foils may even lose TEG during storage. For instance, most of the TEG can be removed by putting thin green foils between sheets of paper for about 10 days (no plasticizing effect could be observed any more after such storage). The TEG diffuses out of the foils into the paper. All foils used for the experiments described in this section were stored between paper for at least 10 days. Moreover, the foils were evacuating at 50°C or 150°C in the B.E.T. apparatus before a measurement was carried out. So, we can assume that almost no TEG was present any more in the foils during the measurements. This is supported by Fig. 6, which shows porosities of foils prepared with different amounts of TEG. The lines given in

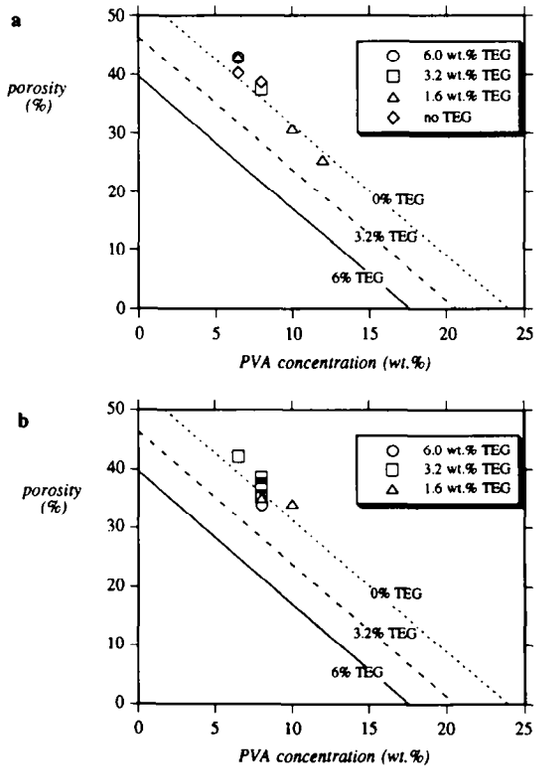

Fig. 6. The porosity of coarse particle green foils (a) and fine particle green foils (b) as a function of the PVA concentration (in wt.-% relative to the ceramic content). The given lines were calculated from the porosity of foils without binder and the densities of the organic substances, the symbols are measured values. Parameters used for the porosity calculation: P_0 = 55%, ρ_{BaTiO_3} = 5·9 g.cm^{-3}, ρ_{TEG} = 1·1 g.cm^{-3}, ρ_{PVA} = 1·2 g.cm^{-3} and 0·4 wt.% other organic substances.

this figure show porosities calculated as a function of the PVA concentration, based on a porosity of the ceramic structure of 55%. These calculations were done for different amounts of TEG present in the foils. The TEG concentrations chosen are equal to those used in several slips. A constant amount of dispersant and other substances is also taken into account (i.e. 0·4 wt% with respect to the ceramics). The measured porosities of foils are compared to calculated values. All the measured porosities (both for the fine and the coarse foils) fall around the line calculated for the case where no TEG is present in the foils. This means that TEG has indeed left the foils and that a direct influence of TEG on the pore size distribution and the specific surface area of foils can be neglected.

Pore size distributions of foils made from slips containing different amounts of TEG are given in Fig. 7. The same trend can be observed for both coarse and fine particle foils. The pore size distribution changes as a function of TEG concentration in the slip. Hence, TEG influences indirectly the binder distribution in foils. In the case where no TEG was used, a fairly thin peak could be found at the same position as the one observed for foils released from binder (see Fig. 5). In the presence of TEG, a second peak at a smaller pore size appears. Sometimes a third very small peak can be observed, especially for coarse foils (position around 1 μm). This peak is, however, independent of the TEG concentration. Whether this peak corresponds to pore sizes with these dimensions or not is doubtful.

We have to note that all pore size diagrams presented in this paper are volume distributions. Hence, one big pore has a much larger contribution to the peak area than one small pore. For a number distribution, the amount of large pores would be much smaller and that of the small pores much larger.

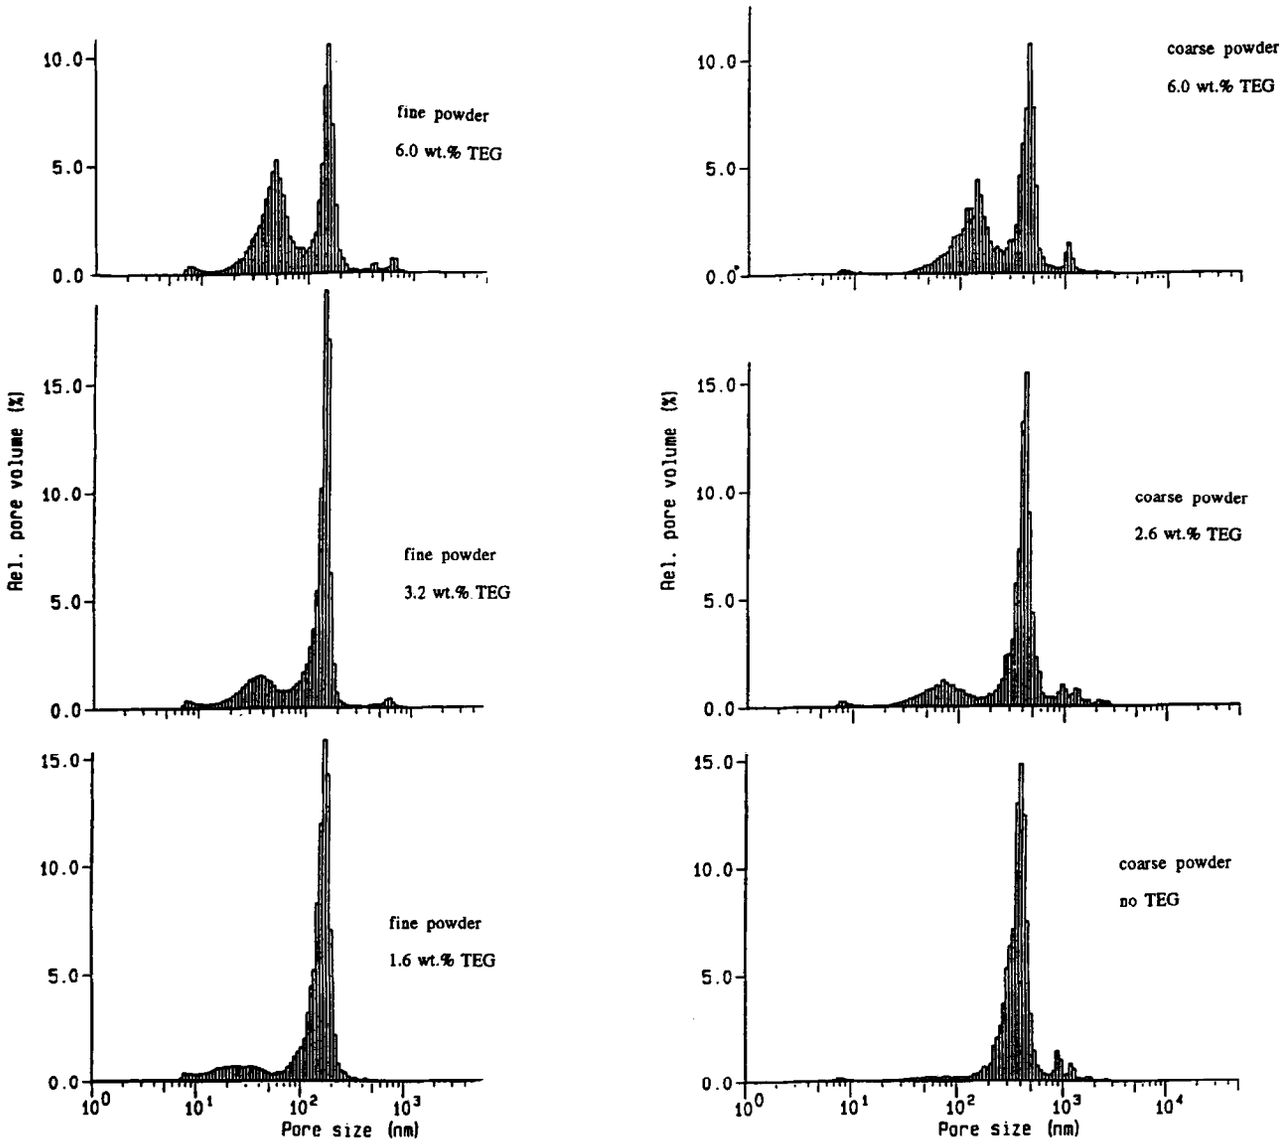

Fig. 7. Pore size distributions of coarse and fine particle green foils as a function of the amount of TEG used in the slip. The TEG concentrations are indicated in the figure (expressed in weight ratio). The PVA 125-98 concentrations were 6·5 wt.-% and 8·0 wt.-% with respect to the solid content for the coarse and fine particle foils, respectively.

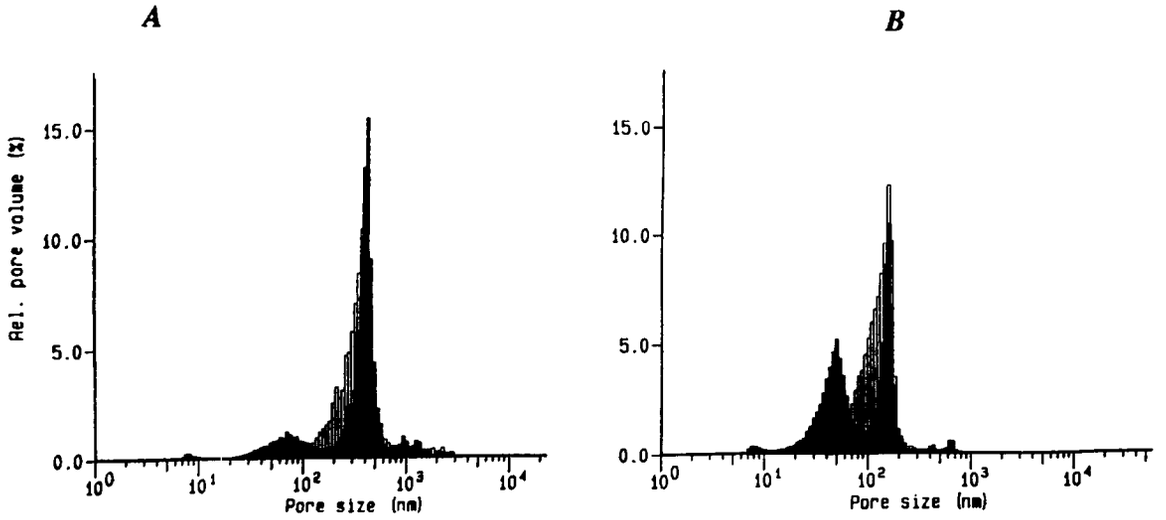

Fig. 8. Pore size distributions of foils with and without binder. A, coarse particle foil made with 6.5 wt.-% PVA 125-98 and 2.6 wt.-% TEG with respect to the ceramic powder (black) and a coarse particle foil released from organic material (white); B, fine particle foil made with 8.0 wt.-% PVA 125-98 and 6.0 wt.-% TEG with respect to the ceramic powder (black) and a fine particle foil released from organic material (white).

Figure 1 is quite helpful for the interpretation of the results of Fig. 7. The large pores (large peak) found in green foils are more or less empty ones and the peak for smaller dimensions are pores partly filled with binder. In the case of no TEG, only large pores exist. This means that some pores are filled completely with binder and others are not filled at all, i.e. there is an inhomogeneous binder distribution. Foils made in the presence of TEG show a more homogeneously distributed binder.

Remarkable is that the peaks of the large pores in the green foils are fairly thin, whereas those found in foils without binder are much broader. Figure 8 compares these two peaks with each other. The peaks of the green foils are drawn in black. It can be seen very clearly that smaller pores are preferentially filled with binder over the larger ones.

In this study, we have used the ratio of the intruded mercury into small pores over that into large pores as a measure of the binder distribution. A larger peak ratio means a more homogeneous binder distribution by this definition. Peak ratios, as a function of TEG concentration in the slip, are given in Fig. 9 for three different types of foil. As can be seen in this figure, the peak ratio increases strongly for larger TEG contents, which indicates a better-distributed binder. The data of the foils presented in Fig. 9 can be more or less described by one single exponential curve.

As already stated in Section 4.2., differences may be found when the same sample is measured for the second time (second run). Figure 10 shows the differences between a first and a second run for both a coarse powder and a fine powder foil. The peak of the small pores is hardly influenced, while the peak of the large ones is quite suppressed in the second run. As a consequence, the peak ratios of the second run are always somewhat larger than those of the first one. This can also be clearly seen in Fig. 9. Both peak ratios determined from the first run and those from the second run are plotted in this figure. The positions of the peaks, however, do not change whether the measurement is carried out the first time or the second time. Not only the height of the peak at small pore dimensions is influenced by the TEG content in the slip but also the position is affected. Figure 11 shows the relative position of the maximum of the peak as a function of the TEG content for different types of foil. The relative position is defined as the pore size at the maximum of the peak divided by the d_{50} pore size of the same foil without binder. The peak maximum of the small pores shifts to larger sizes as the TEG content in the slip becomes higher. Remarkably,

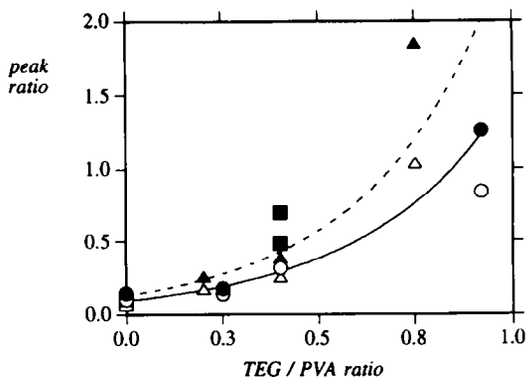

Fig. 9. Peak ratios as a function of the TEG/PVA weight ratio in the slip: circles, coarse particles foils with 6.5 wt.-% PVA 125-98; squares, coarse particle foils with 8.0 wt.-% PVA 125-98; triangles, fine particle foils with 8.0 wt.-% PVA 125-98; open symbols (solid line), data from a first run; filled symbols (dotted line), data from a second run.

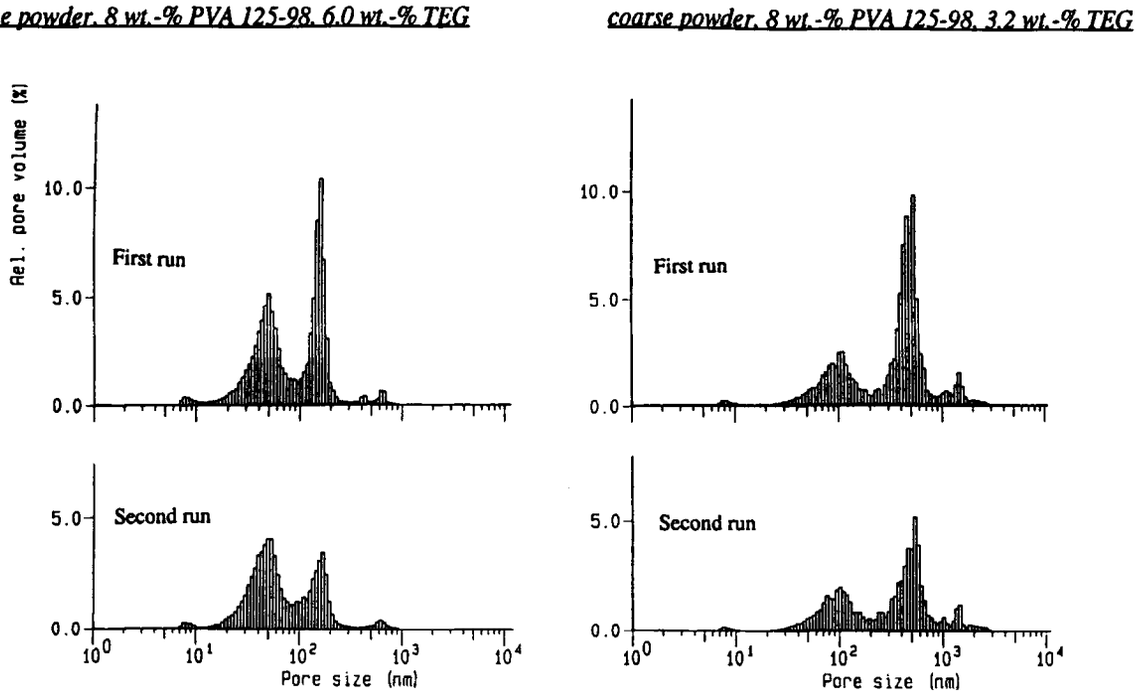

Fig. 10. Pore size distribution differences between a first measuring run and a second one.

the relative positions of these peaks fall on the same curve for both coarse and fine particle foils. Hence, the influence of TEG on the pore sizes in green foils seems to be the same for foils consisting of these two particle sizes.

The B.E.T. results of foils made with different amounts of TEG are given in Fig. 12. The binder distribution index X (see Section 4.1.1) increases with TEG concentration, indicating a more homogeneous binder distribution with increasing TEG content. The X index is negative for low TEG contents, which suggests that small pores are preferentially filled with binder over large ones. The X index reaches a value of unity at a TEG/PVA ratio of about 0·8. Based on the model described in Section 4.1.1, this means a fairly homogeneously distributed binder. The same effect could be seen for the porosity measurement results shown in Fig. 9. The peak ratio increases sharply at TEG/PVA ratios of about 0·8, also indicating a homogeneous binder distribution. Remarkable in Fig. 12 is that the binder distribution index is somewhat lower for the fine particle foils than for coarse particle foils.

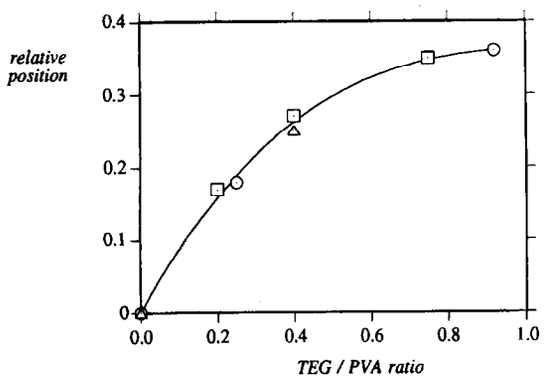

Fig. 11. The relative position of the peak of small pores (i.e. pore size at the maximum of the peak divided by the d_{50} pore size of the same foil without binder) as a function of the TEG/PVA weight ratio: ○, coarse particle foil, 6.5 wt.-% PVA 125-98; Δ, coarse particle foil, 8.0 wt.-% PVA 125-98; □, fine particle foil, 8.0 wt.-% PVA 125-98.

5.2.2.2 PVA type. All the results given above are based on foils made with PVA type 125-98. Do these results also hold for other types of binder? Tables 4 and 5 compare the binder distribution in foils containing either PVA 125-98 or PVA 205-88. Just as in the case of PVA 125-98, foils with PVA 205-88 get a more homogeneous binder distribution when more TEG is used in the slip. The peak ratios from the porosity measurements, as well as the binder distribution indices determined by B.E.T. measurements show,

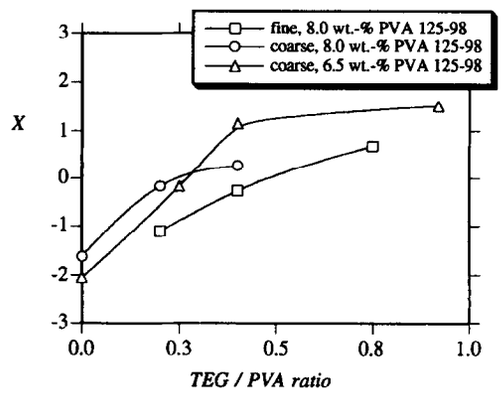

Fig. 12. The binder distribution index as a function of the TEG/PVA weight ratio in the slip.

Table 4. Peak ratios from porosity measurements as a function of the binder type in coarse particle foils

PVA conc. (wt%)	*TEG conc. in the slip (wt%)*	*Peak ratio[a] for PVA 205-88*	*Peak ratio[a] for PVA 125-98*
6·5	0	0·00/0·03	0·10/0·14
6·5	2·6	0·14/0·14	0·31/0·47
8	0	0·06/0·05	0·08/0·10
8	3·2	0·28	0·48/0·70
8 (6·5 + 1·5 PVA 27-98)	3·2	0·25/0·16	0·52

[a]The first number is from a first run, the second is from a second run.

Table 5. The binder distribution index (X) as a function of the binder type in coarse particle foils

PVA con. (wt%)	*TEG conc. in the slip (wt%)*	*X for PVA 205-88*	*X for PVA 125-98*
6·5	0	−2·27	−2·05
6·5	2·6	−1·17	1·15
8	0	−2·16	−1·62
8	3·2	−1·40	0·27
8 (6·5 + 1·5 PVA 27-98)	3·2	−1·42	0·86

however, that at a given TEG concentration in the slip, PVA 205-88 is less homogeneously distributed in foils than PVA 125-98. Even for foils made without TEG, PVA 205-88 is less well distributed. PVA 205-88 differs from PVA 125-98 in two ways, i.e. the molecular weight of PVA 205-88 is higher and the hydrolysis ratio is lower. Which of these properties is responsible for the differences observed? We have plotted the binder distribution index as a function of the relative amount of less-hydrolysed binder in a two-component binder mixture in Fig. 13. As can be seen, the binder distribution index becomes consistently lower for a higher amount of less-hydrolysed PVA types. Hence, most probably, the hydrolysis degree is responsible for the differences found for PVA 125-98 and for PVA 205-88. It is known that some physical properties of PVA (for instance, dissolution behaviour, viscosity, melting point, glass transition temperature) change (drastically) if the hydrolysis ratio reaches 100%.[29]

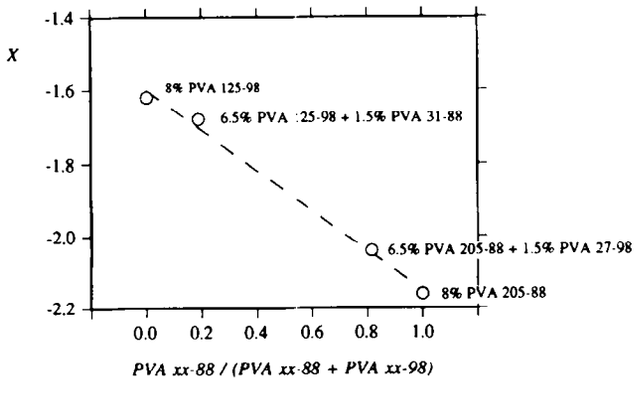

Fig. 13. The binder distribution index as a function of the relative amount of 88% hydrolysed PVA (see Table 1). Foil system: coarse $BaTiO_3$ with 8·0 wt.-% PVA, and no TEG.

5.2.2.3 PVA concentration. The binder distribution index X calculated from the specific surface area of foils is defined in such a way that a comparison between foils containing different amounts of PVA is possible. Table 6 gives X-values for coarse particle foils containing either 6·5, 8·0, 10 or 12 wt% PVA 125-98 with respect to the ceramic material.

The TEG content in the slip is kept constant with respect to the ceramic powder (i.e. 1·6 wt%). This means, however, that the TEG/PVA ratio decreases with increasing amounts of PVA. Hence, a decreasing effect on the binder distribution index may be expected because of a decreasing TEG content with respect to the binder concentration. As can be seen in Table 6, the X-value is negative for the relatively low PVA concentrations and positive for the higher ones. A relatively large difference in binder distribution is found for foils with 8·0 and 10 wt% PVA. To be conclusive, a higher PVA concentration with respect to the ceramic content also leads to a better-distributed binder in the foil.

Table 6. Binder distribution index as a function of binder content in green coarse particle foils; in all cases, the TEG concentration was equal to 1·6 wt% with respect to the ceramics

PVA 125-98 conc. (wt%)	*TEG/PVA (wt/wt)*	*X*
6·5	0·25	−0·17
8·0	0·20	−0·17
10	0·16	0·84
12	0·13	0·57

6 Interpretation/Discussion

In this section, we will try to elucidate the mechanism of how binder is distributed over the foil during drying. Especially, the results obtained for green foils in the previous sections and the drying model as described in Section 2 will be the keys for understanding this mechanism.

Important for the distribution of binder over green foils is the moment in the drying process (i.e. at which part of which drying stage) that the binder gets fixed in the ceramic structure by precipitation, gelation or whatever. Factors that influence this fixation process affect also the binder distribution in foils. Other kinds of factors, such as parameters that influence the accumulation of binder molecules onto ceramic particles due to physical (chemical) interactions, may have also an effect on the binder distribution.

As shown in the previous chapter, several parameters affect the PVA distribution in foils. All of these parameters, however, do not alter the ceramic structure of foils. The porosity of the ceramic structure is even independent of the particle size. The ceramic structure of foils has been built at the end of the constant rate period, i.e. the critical point. This suggests that the binder is not precipitated, gelated or whatever during the constant rate period for the systems analysed in this study. Otherwise, an effect on the ceramic structure of the parameters that influence the fixation process of the binder would have been observed. The supposition that the binder is not yet fixed at the end of the constant rate period is supported by the fact that after complete drying, smaller pores appears to be preferentially filled with binder over the larger ones. This can be explained by the difference in capillary pressures of large and small pores during the first falling rate period. Solution with binder is transferred from large pores to small ones due to this pressure difference. If the totality of the binder had already been fixed in this stage, the binder could not have been transferred in this way. The fact that in some cases binder is observed at the lower side of the foil (the side that has made contact with the carrier) also suggests that the binder is still in solution as the drying process enters the first falling rate period (FRP1). In the FRP1 stage, pores at the upper side of the foil are emptied first and pores that are still filled with solution are enriched with binder by diffusion. This diffusion process is only possible if an amount of the binder is still solved. Hence, for the systems described in this report, the fixation of binder does not notably take place before the critical point is reached.

A very homogeneous binder distribution in green foils will probably be established if the fixation of the binder occurs just at the critical point. In this situation, all pores are still filled with solution with the same binder concentration. The later the point of fixation in the drying process, the less homogeneous is the binder distribution. Binder will then be found more and more in the smaller pores and at the bottom of the foil. This corresponds with very low (negative) X-values.

As shown in the previous section, the binder distribution in foils is influenced by the concentration of TEG and the amount of PVA in the slip. Obviously, the more organic material in the system, the sooner this material is fixed after the critical point in the drying process. However, this certainly does not explain all the results reported in this paper. The binder type also has an influence on the binder distribution. Although not shown in this paper, the drying conditions (external factors) appear to affect the binder distribution in foils as well. Triethylene glycol is known to gelate PVA (one piece of gel may be formed after mixing of PVA and TEG in the appropriate concentrations and waiting for a certain time). With more TEG in the slip, the gelation process will set in earlier, resulting in a more homogeneous binder distribution. PVA types with lower degrees of hydrolysis are somewhat less susceptible to gelation by TEG. These polymers are also better solvable in water than fully hydrolysed ones.[29] Hence, the fixation point is postponed for less-hydrolysed PVA types and, as a consequence, the binder is more heterogeneously distributed.

The external factors for the drying process (air flow, ambient temperature and vapour pressure) can also be expected to have an influence on the fixation process of the binder by TEG. The wet bulb temperature and the speed of drying, which are controlled by these factors, influence the gelation process. Gelation will be set in later when the wet bulb temperature is higher (i.e. a higher ambient temperature and a higher degree of humidity). Most gelation processes are kinetically not very fast. That means that if the drying speed is lowered, the gelation has more time to proceed. Effectively, the gelation point will then be found earlier in the drying process.

The concentration of the binder and that of the plasticizer (provided no plasticizer has been evaporated during drying) at the critical point can be simply calculated using the porosity of foils released from binder, the solid content of the slip and the PVA and TEG concentrations in the slip. The solid content of the system at the critical point can be calculated from the porosity of foils released from binder. The difference in solid content of the slip and that of the system at the critical

point yields the factor with which the concentrations of the organic species have been concentrated at the critical point. In our case, this turns out to be about 5·5. So, the concentrations for gelation at the drying conditions used are probably higher. In principle, an estimate of the gelation concentrations can be made from the peak positions in the pore size distribution diagrams. The volumetric filling percentage of pores with binder can be calculated from the dimensions of an empty pore and those of a filled one. This percentage is then easily transformed into the PVA and TEG concentration at binder fixation, knowing the relative PVA and TEG concentration in the slip. The following uncertainties make this estimate, however, too unreliable:

1. the pore geometry,
2. the way a pore is filled with binder,
3. whether or not TEG has been evaporated before the fixation point is reached during the drying process,
4. the filling degree of pores filled with binder solution when fixation starts,
5. the size of the empty pore (this is not well defined because large pores are emptied firstly during drying).

The peak in the pore size diagram at the small pore size shifts to a larger size when more TEG is used in the slip (see Fig. 11). Two causes may be responsible for this effect:

1. The fixation of the binder starts at a lower PVA concentration in the pores when more TEG is used. After complete drying, less PVA has been left in the individual pores and therefore the open space in pores is larger.
2. When more TEG is used, more TEG will be present in the pores at the fixation point. After removal of TEG from the foil by evaporation or diffusion, more open space will be left.

Another point to remark on is that although a binder distribution may be very inhomogeneous, the *C*-values found were still very close to that of pure PVA. This means that all particles are at least coated with a very thin layer of PVA, even the particles forming empty pores. This may be caused by adsorption of PVA onto the particles. However, the particles are already coated with an adsorption layer of dispersant. Hence, that would mean that PVA adsorbs onto this dispersant layer (displacement is not probable[30]). The effect of a low *C*-value may also be related to the fact that in the first falling rate period, most of the evaporation still occurs at the exterior surface due to continuous thin liquid pathways in pores, along flow is still possible (funicular condition).

We have noticed, that in many cases, the *X*-values for fine particle foils are somewhat smaller than for coarse particle foils, using the same recipe and processing conditions. This may be explained by the differences in capillary pressure that occur within the foil during drying. Pore sizes and the width of the pore distribution are, of course, important in this respect.

7 Conclusions

Both B.E.T. and Mercury Intrusion Porosimetry measurements are useful to characterize the binder distribution in green foils. The results obtained using both techniques are fully in agreement with each other.

Ceramic foils consisting of either a coarse $BaTiO_3$ powder (d_{50} = 0·75 μm) or a fine $BaTiO_3$ powder (d_{50} = 0·20 μm) could be made with the same porosity. The pore sizes in the foils scaled with the particle sizes of the respective powders.

The binder and plasticizer concentrations in the slip used in this study do not change the ceramic structure of foils. Only the binder distribution is influenced by these parameters.

The moment in the drying process of foils that the binder gets fixed in the ceramic structure determines the binder distribution in foils. Factors influencing this fixation process affect the binder distribution. The plasticizer triethylene glycol (TEG) promotes fixation of PVA by a gelation process. More TEG in the slip leads to a more homogeneous binder distribution in foils. In the case of little TEG in the slip, small pores are preferentially filled with binder over large ones and the lower side of foils is enriched with binder. Less-hydrolysed PVA types are less susceptible to gelation with TEG, resulting in a more heterogeneous binder distribution.

All powder particles are covered with PVA molecules, both in foils with a homogeneous binder distribution and in ones with a very heterogeneous binder distribution.

Appendix: Relationships between the surface area and the binder distribution in foils (eqns (1)–(4))

A1 Spherical pores filled homogeneously with binder

Suppose a porous system has N equal spherical pores of radius R. The empty porous system has a surface area A_0 and a volume V_0 which are given by

$$A_0 = 4\pi R^2 N \tag{A1}$$

$$V_0 = \frac{4}{3}\pi R^3 N \tag{A2}$$

Filling the porous system proceeds in such a way that the radii of all pores decrease equally. The surface area of a system filled with a certain amount of binder is then equal to

$$A = 4\pi r^2 N \quad \text{with } 0 \le r \le R \tag{A3}$$

The volume of added material, V_a, can be expressed in the following way

$$V_a = \frac{4}{3}\pi(R^3 - r^3)N \quad \text{with } 0 \le r \le R \tag{A4}$$

Combining relations (A1)–(A4) yields eqn (A5)

$$A = A_0 \left[1 - \frac{V_a}{V_0}\right]^{2/3} \tag{A5}$$

The volume of the empty porous system, V_0, can also be expressed in terms of the porosity P_0 and the total volume V_{tot} of the system without additions

$$V_0 = \frac{P_0}{100} V_{tot} \tag{A6}$$

In the same way, the volume of the ceramic material is given by

$$V_{cer} = \frac{(100 - P_0)}{100} V_{tot} \tag{A7}$$

A definition of the amount of added organic substances (V_i), expressed in vol.% with respect to the ceramic material, is given in eqn (A8)

$$V_i = \frac{V_a}{V_{cer}} 100 \tag{A8}$$

The factor V_a/V_0 in eqn (A5) can be expressed in the following way, using eqns (A6)–(A8)

$$\frac{V_a}{V_0} = \frac{(1 - P_0/100)}{P_0} V_i \tag{A9}$$

Because the maximum value for the ratio V_a/V_0 is 1, V_i can by definition not be larger than $P_0/(1 - P_0/100)$.

Substitution of the last equation into (A5) yields the following formula, which is identical to eqn (1):

$$A = A_0 \left[1 - \frac{1-P_0/100}{P_0} V_i\right]^{2/3} \quad \text{(A10)}$$

Usually, the concentrations of organic substances in slips and foils are given in wt% with respect to the solid content. The parameter V_i can easily be calculated from the concentrations defined in this way using eqn (A11)

$$V_i = C_i \frac{\rho_{cer}}{\rho_i} \quad \text{(A11)}$$

with ρ_i the specific density of substance i, C_i the concentration of substance i in wt% with respect to the ceramics and ρ_{cer} the density of the ceramic material.

A2 Pores filled inhomogeneously with binder

In this case, filling of the porous system proceeds by lowering the number of empty pores. Pores are completely filled one by one. The number of filled pores is equal to n. The surface area and the volume of one pore are a_0 and v_0, respectively. Relations (A12)–(A15) are of the same kind as eqns (A1)–(A4).

$$A_0 = a_0 N \quad \text{(A12)}$$

$$V_0 = v_0 N \quad \text{(A13)}$$

$$A = a_0(N-n) \quad \text{with } 0 \le n \le N \quad \text{(A14)}$$

$$V_a = v_0 n \quad \text{with } 0 \le n \le N \quad \text{(A15)}$$

Combining the last four equations gives

$$A = A_0 \left[1 - \frac{V_a}{V_0}\right] \quad \text{(A16)}$$

The link between eqns (A16) and (A17) is the same as in the previous case, and

$$A = A_0 \left[1 - \frac{1-P_0/100}{P_0} V_i\right] \quad \text{(A17)}$$

Because we did not assume any pore geometry for the derivation of eqn (A17), this dependency is invariant for the pore geometry!

A3 Cylindrical pores filled homogeneously with binder

In this case, the porous system is modelled as a body containing N cylindrical pores of length z. Addition of organic material reduces the diameter of all cylinders, i.e. this is a homogeneous filling. The same kind of formulas are derived as in the previous cases

$$A_0 = 2\pi R z N \quad \text{(A18)}$$

$$V_0 = \pi R^2 z N \quad \text{(A19)}$$

$$A = 2\pi r z N \quad \text{with } 0 \le r \le R \quad \text{(A20)}$$

$$V_a = \pi(R^2 - r^2) z N \quad \text{with } 0 \le r \le R \quad \text{(A21)}$$

These equations lead to

$$A = A_0 \left[1 - \frac{V_a}{V_0}\right]^{1/2} \quad \text{(A22)}$$

and

$$A = A_0 \left[1 - \frac{1-P_0/100}{P_0} V_i\right]^{1/2} \quad \text{(A23)}$$

A4 Small spherical pores are preferentially filled with binder over large ones

In the previous cases, we have modelled the porous structure as a body containing a number of equally sized pores. Equations (A10), (A17) and (A23) also hold for ceramic structures containing different pore sizes, but the added organic material must then be distributed equally over the size distribution. In this instance, the added organic material is not distributed equally over the size distribution. We assume three different spherical pores with radii $0{\cdot}5R$, R and $2R$. These pore types are denoted in the following relations with one prime, two primes and three primes, respectively. The number of each type of pore is chosen such that the volume of each class of pores is equal to 1/3 of the total volume of pores. Hence,

$$V'_0 = \frac{1}{3} V_0 = \frac{4}{3}\pi (0{\cdot}5R)^3 \frac{64N}{73} \quad \text{(A24)}$$

$$V''_0 = \frac{1}{3} V_0 = \frac{4}{3}\pi R^3 \frac{8N}{73} \quad \text{(A25)}$$

$$V'''_0 = \frac{1}{3} V_0 = \frac{4}{3}\pi (2R)^3 \frac{N}{73} \quad \text{(A26)}$$

The surface area of each class of pore without organic material is given by the following three formulas

$$A'_0 = a'_0 \frac{64N}{73} = \frac{4}{7} A_0 \quad \text{(A27)}$$

$$A''_0 = a''_0 \frac{8N}{73} = \frac{2}{7} A_0 \quad \text{(A28)}$$

$$A'''_0 = a'''_0 \frac{N}{73} = \frac{1}{7} A_0 \quad \text{(A29)}$$

Now added material is not the distributed equally over pores of different sizes. Firstly the small pores are filled, then the medium sized ones and finally the pores with the largest radii. Filling of the porous system proceeds in such a way that the number of pores decreases with the added amount (i.e. inhomogeneous distribution). The surface area A and the added amount of material V_a as a function of the number of occupied pores n are given by the follows equations:

$$\begin{cases} A = A_0 - a'_0 n \\ V_a = v'_0 n \end{cases} \quad \text{for } 0 \le n \le \frac{64N}{73} \tag{A30}$$

$$\begin{cases} A = \frac{3}{7} A_0 - a''_0 (n - \frac{64N}{73}) \\ V_a = \frac{1}{3} V_0 + v''_0 (n - \frac{64N}{73}) \end{cases} \quad \text{for } \frac{64N}{73} \le n \le \frac{72N}{73} \tag{A31}$$

$$\begin{cases} A = \frac{1}{7} A_0 - a'''_0 (n - \frac{72N}{73}) \\ V_a = \frac{2}{3} V_0 + v'''_0 (n - \frac{72N}{73}) \end{cases} \quad \text{for } \frac{72N}{73} \le n \le N \tag{A32}$$

In the same way as in the previous cases, these equations lead to

$$A = A_0 \left[1 - \frac{12}{7} \left(\frac{1-P_0/100}{P_0}\right) V_i\right] \quad \text{for } 0 \le V_i \le \frac{1}{3} \frac{100P_0}{(100-P_0)} \tag{A33}$$

$$A = A_0 \left[\frac{5}{7} - \frac{6}{7} \left(\frac{1-P_0/100}{P_0}\right) V_i\right] \quad \text{for } \frac{1}{3} \frac{100P_0}{(100-P_0)} \le V_i \le \frac{2}{3} \frac{100P_0}{(100-P_0)} \tag{A34}$$

$$A = A_0 \left[\frac{3}{7} - \frac{3}{7} \left(\frac{1-P_0/100}{P_0}\right) V_i\right] \quad \text{for } \frac{2}{3} \frac{100P_0}{(100-P_0)} \le V_i \le \frac{100P_0}{(100-P_0)} \tag{A35}$$

Abstract

Four kinds of zirconia powders are prepared in different ways. Their compaction and sintering behaviour are studied extensively. During compaction, the agglomerates or granules present in the powder are broken and/or undergo plastic deformation. The behaviour depends essentially on the strength of links between the particles.

The sol-gel powders are more sensitive to the formation of hard inter-particle links during the synthesis process. So careful control is needed in order to avoid the formation of aggregates, because they favour the presence of large pores which lead to differential sintering and grain coarsening.

In other cases the sintering can also be inhibited by the presence of residual impurities. A powder which has rod-like shaped agglomerates is sintered to regular microstructure.

Introduction

Uniaxial dry pressing is the most common forming process used to obtain green ceramic bodies in technology today. This process is of great interest technologically because it conditions the quality of fired ceramic bodies, which are influenced by the characteristics of the starting powders.

The presence of hard agglomerates in the powders was reported to be the main source of microstructural inhomogeneities in green ceramic bodies.[1–3] They are formed during the synthesis of the powder.

The purpose of this work was to compare the compaction and sintering behaviours of zirconia powder prepared by several laboratories with a commercial zirconia powder P1.† The following synthesis methods were used:

- Sol–gel process[4] was used for the first batches of powder, (P2, P3).
- Drying of amorphous gelatinous precipitates obtained by hydrolysis of solutions containing both zirconium and yttrium acetates[5] for the second batch, (P4).
- Reaction of both zirconyl and yttrium chlorides in molten salt[6] for the final batch, (P5).

The comparison was likely to give some information about the respective processes involved and could help to optimize the physico-chemical parameters in order to produce high quality zirconia powders.

Experimental procedure

The synthesis processes used to prepare the five batches of zirconia are summarized in Fig. 1.

The powder, P1, was prepared by hydrolysis of a solution containing zirconia and yttria chlorides. It was obtained from calcinated gel. It was then milled and atomized.

The powder, P2, was prepared from a solution containing both zirconia and yttria salts. Ammonia was used as the neutralising agent. The gel was first washed using water, then dried using hexanol. The obtained spheroidal xerogel particles were finally calcinated at 700°C.

The powder, P3, was obtained by coprecipitation of gel. This was later prepared from zirconia and yttria chlorides. The gel was washed three times using water, then three times using pure ethanol. It was then, dried at 110°C and calcinated at 600°C.

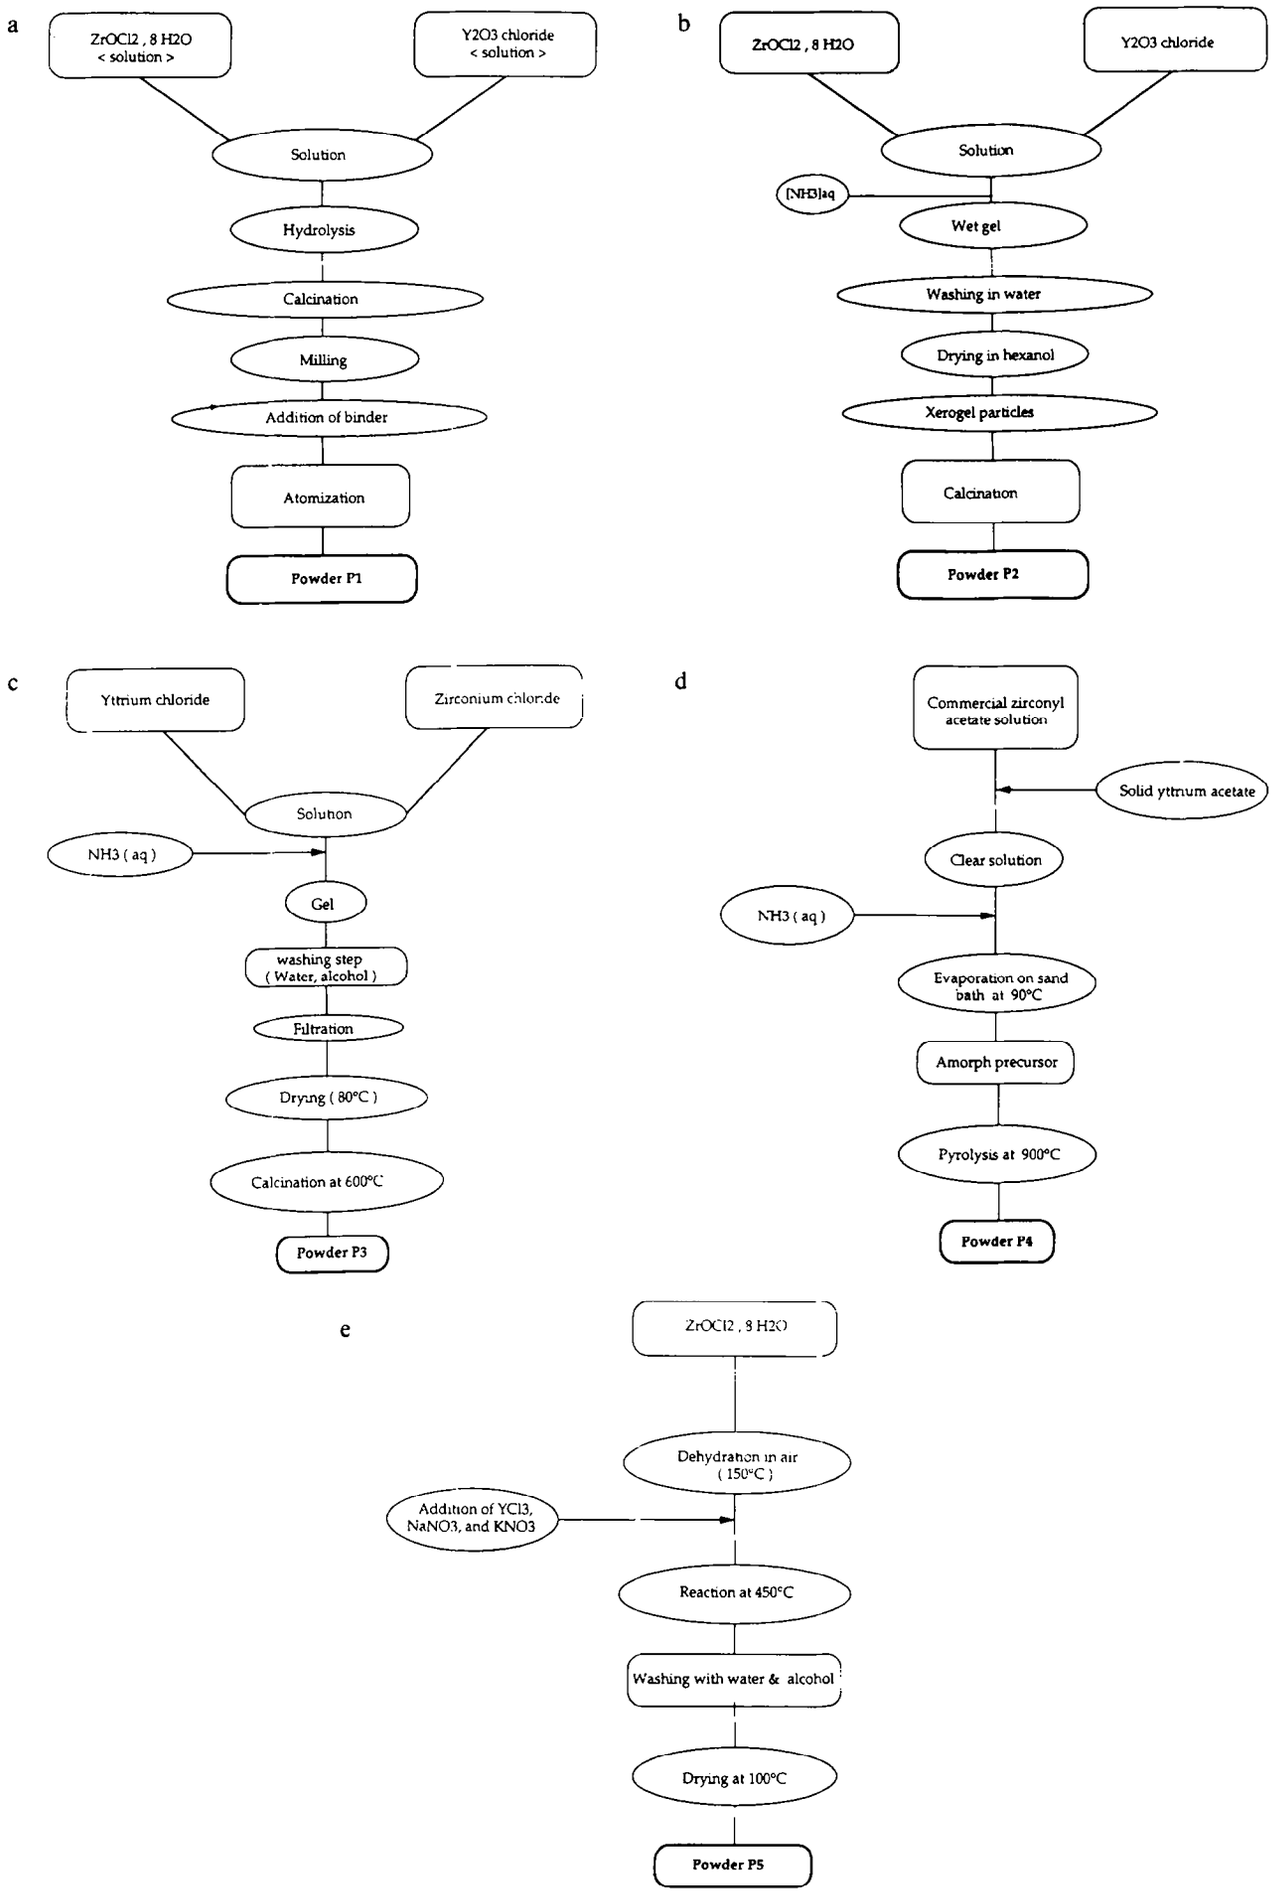

Fig. 1. Flowcharts of synthesis processes involved to prepare the five zirconia powders. (a) Synthesis process of the powder P1; (b) synthesis process of the powder P2; (c) synthesis process of the powder P3; (d) synthesis process of the powder P4; (e) synthesis process of the powder P5.

Table 1. Sample characteristics

Sample	*Synthesis route*	*Y_2O_3 (mol%)*	*Specific surface area (m^2/g)*	*Agglomerates mean size (μm)*	*Crystallite mean diameter (nm)*
P1	—	3	17	53·3	93
P2	Sol–Gel	3·6	100	34	9
P3	Sol–Gel	2	80	12·5	9
P4	Hydroxyacetate	3	6	100	25
P5	Molten salts	3	120	1·7	10

The powder, P4, was prepared from acetates. Solid yttrium acetate was dissolved in commercial zirconyl acetate solution. Then, the clear solution was neutralized by adding ammonia. The wet gel obtained was dried on a sand bath at 90°C and finally calcinated at 900°C in order to obtain white zirconia.

The powder, P5, was prepared by reacting both zirconia and yttria chlorides in molten salts at 450°C.

All the powders are yttrium stabilized zirconia, the amount of Y_2O_3 varying from 2·0 to 3·6 mol% (see Table 1).

The granulometric distribution of the different batches was obtained using a laser particle size analyser† and their morphology was investigated by scanning electron microscopy (SEM). The mean diameter of crystallites was determined from X-ray diffraction line broadening (XRD-LB) using the Scherrer formula for the calculation:

$$D = 0{\cdot}89\ \lambda/(\beta\ \mathrm{Cos}\theta)$$

where D is mean diameter of crystallites, λ the wave length of the X-ray (Cu–Kα), θ is the Bragg angle and β is the calibrated width of the diffraction peak at half maximum at selected 2θ. The proportion between the phases (monoclinic and tetragonal zirconia) was estimated using the empirical equation given by Toraya *et al.*[7] The specific surface area was evaluated by Brunauer–Emett–Teller (BET) nitrogen adsorption method.

Compaction tests were carried out on a mechanical testing machine‡ from 0 to 200 MPa with a crosshead rate of 0·5 mm/min so as to avoid the influence of loading rate.[8] In order to minimize the influence of moisture,[9,10] samples were oven dried at 110°C before compaction. Density variation during pressing was deduced from the crosshead continuous displacement. Deviation due to the elastic deformation of the die and the loading cell was taken into account with a blank test.

Porosity of the green samples was characterized by mercury penetration inside cold isostatic pressed pellets (400 MPa). The open porosity distribution could thus be quantified. Microstructure was also investigated by SEM.

The sintering schedule was optimized by performing dilatometric tests on samples isostatically pressed at 400 MPa; the temperature was raised up to 1500°C, at a rate of 1°C/min and samples were held at this temperature for 2 or 3 h. The porosity and microstructure of sintered samples were also examined.

Results and discussion

The sample characteristics are shown in Table 1. From these results it is shown that:

- Powders P2 and P3, (sol-gel) and P5, (molten salt) exhibit much higher surface areas than powders P1, (commercial) and P4, (hydroxyacetate).
- The crystallite mean diameter of the commercial powder, P1 is consequently larger than that of the other powders.

The X-ray patterns of these powders (Fig. 2) indicates that powders P2, P3, P4 and P5 are fully

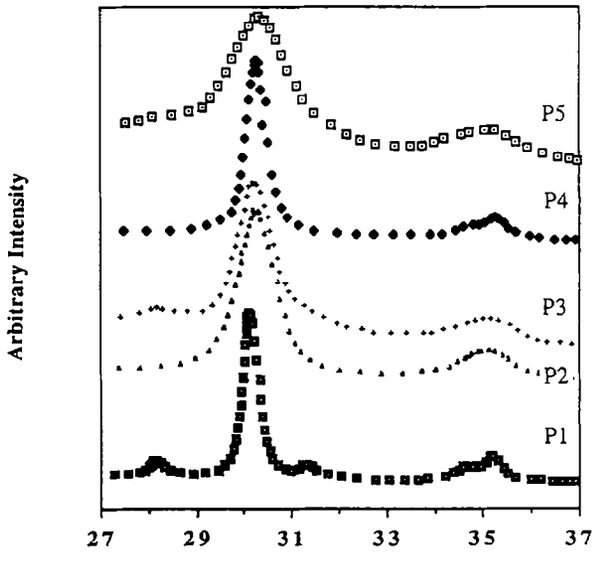

Fig. 2. X-ray patterns of the powders.

†Malvern particle size analyser 2000/3000.
‡Instron Ltd 1195.

stabilized into the tetragonal phase whereas the commercial powder, P1, contains a very low amount of monoclinic zirconia, about 3 vol%.

The SEM micrographs (Fig. 3) can divide the samples into three groups according to the shapes of the agglomerates: spheroidal (P1, P2 and P3), rod-like (P5) and irregular (P4).

The compaction plots (Fig. 4) of all the powders, density versus applied pressure, shows two linear regions separated by a transition zone. The first linear region, localized at low pressures and characterized by a low slope, is consistent with a rearrangement of the agglomerates in the die. This stage is controlled by particle–particle friction,

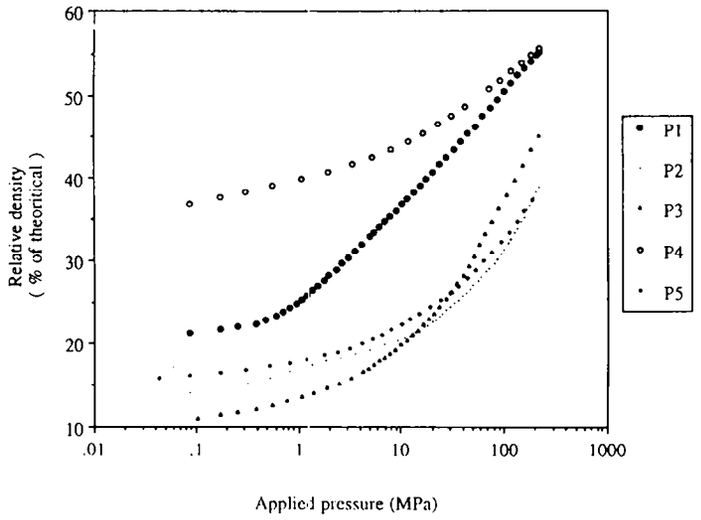

Fig. 4. Compaction behaviour of the five zirconia batches.

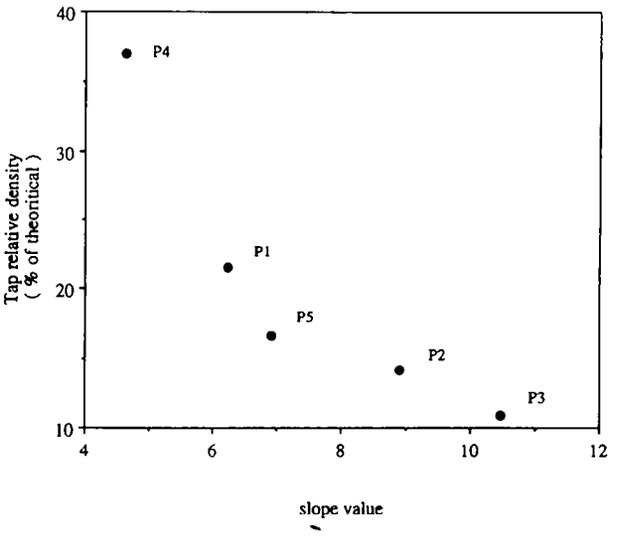

Fig. 5. Plot showing the compaction slope versus tap density. The slope was calculated for each powder in high pressure linear region according to Zheng.

Table 2. Compaction characteristics of the samples

Sample	*P1*	*P2*	*P3*	*P4*	*P5*
Tap density	21·45	14·16	10·83	37·08	16·66
Slope value	6·23	8·90	10·46	4·62	6·90
Pj (MPa)	1	30	11	11	15

until they are on fixed positions to each other.[7,11] The second linear region occurs at higher pressure having a more significant slope, corresponds to the elimination of the interagglomerate porosity.[7,11] The transition zone exhibits a particular pressure value *Pj* for each powder, known as the 'yield point.'[7,11,12] This threshold pressure corresponds to the beginning of the agglomerate deformation and/or crushing. It indicates a transition from discrete agglomerate structure to a coherent compact structure. Compared to the commercial powder, P1, the tap density of powder P4 is about 50% higher whereas for powders P2, P3 and P5 it is lower. For powder P4, even if the shape of agglomerates is irregular, their high density and large size (100 μm) allows this high tap density. For P1 powder, exhibiting the same shape of agglomerates as for the powders P2 and P3, the high tap density is favoured by the large size (53·3 μm) and density of agglomerates. This later allows easy rearrangement in the die. On the contrary, the small size of P2 and P3 agglomerates (mean size 34 and 12·5 μm respectively) and also their porous morphology in the case of the powder P3 favours low tap density. For the powder P5, the rod-like shape of agglomerates involves a bad flowability and consequently a weak green density.

The slopes of the curves in the high pressure linear region have been calculated (Table 2), and plotted versus taped densities (Fig. 5) in the same

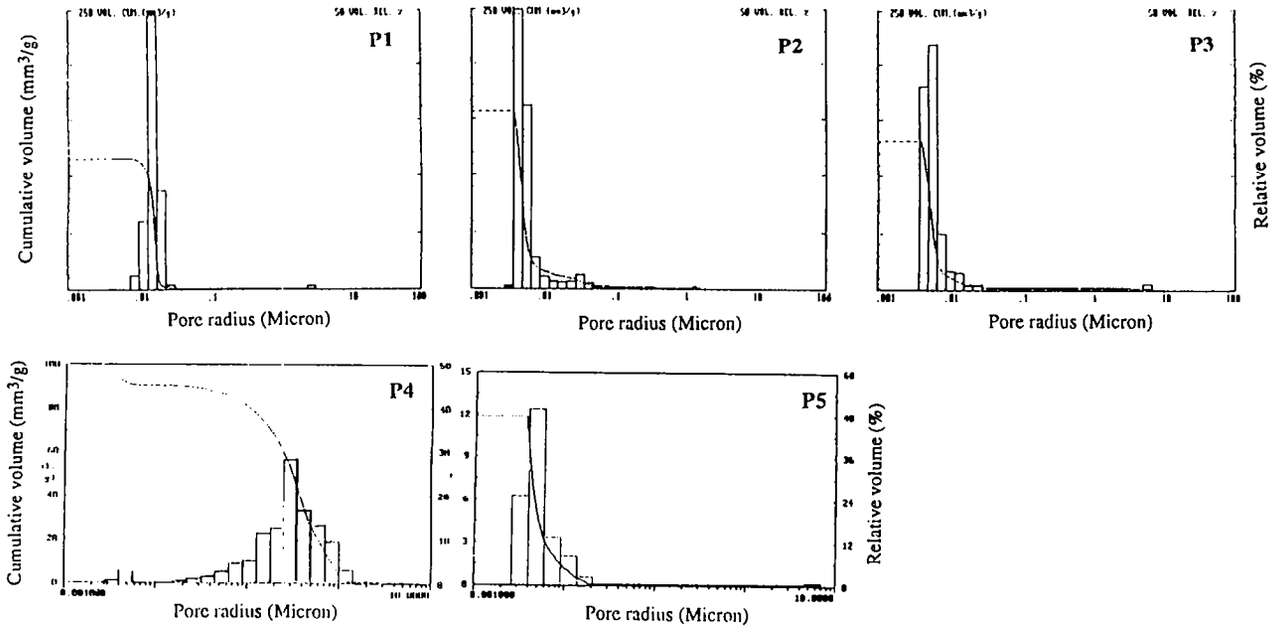

Fig. 6. Pore size frequency distribution in dry isostatically pressed compacts (400 MPa).

way as Zheng and Reed.[13] The compaction rate varies inversely to the powder tap density. The more the powder is constituted of large and dense agglomerates, the more the agglomerates are difficult to deform and/or to crush.

For the powder P1, the yield pressure is about 1 MPa, whereas for the laboratory prepared powders, P2, P3, P4 and P5 it is close to 10 MPa. The difference could be explained by the presence of a binder/plasticizer system in powder P1, allowing

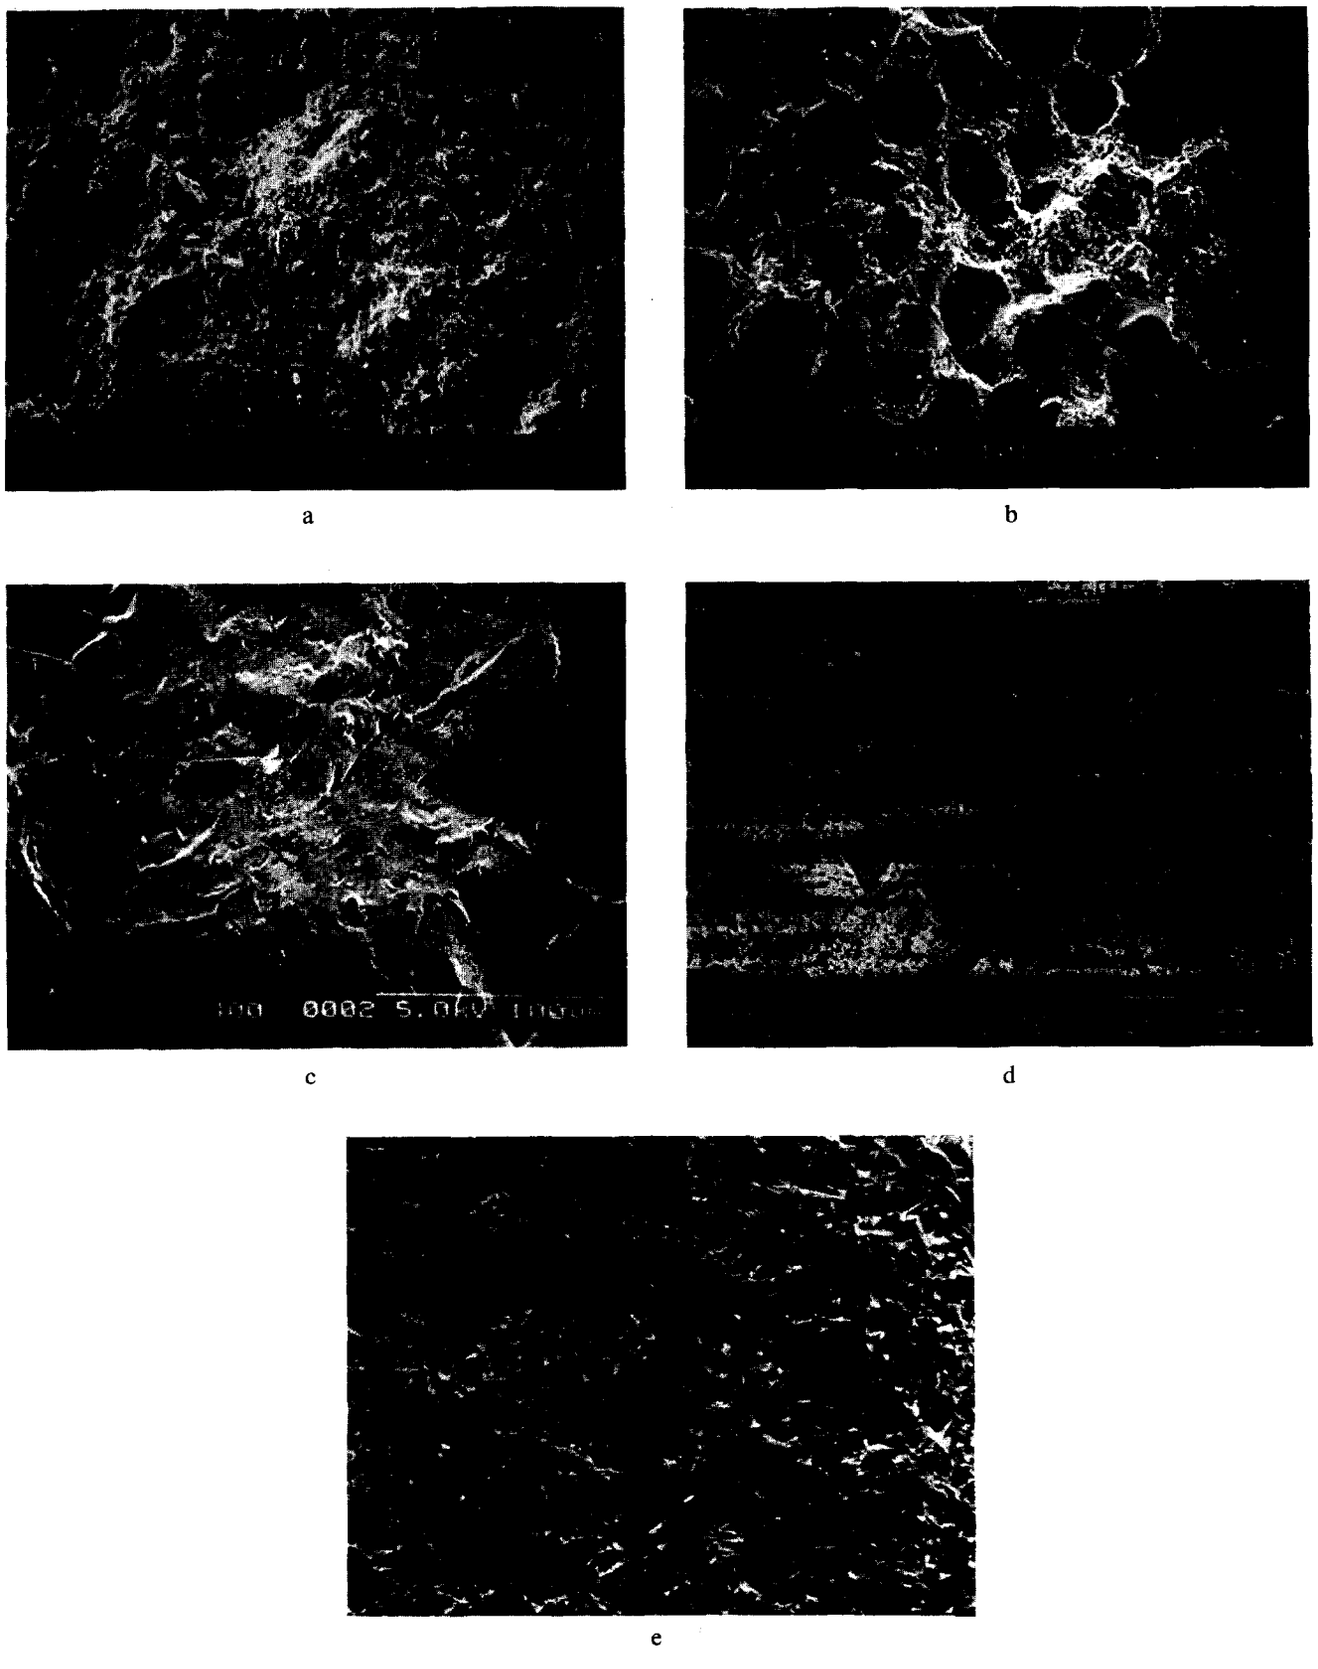

Fig. 7. Series of scanning electron micrographs showing fractured surfaces of green bodies isostatically compacted up to 400 MPa. (a) Fractured surface of green compacted P1; (b) fractured surface of green compacted P2; (c) fractured surface of green compacted P3; (d) fractured surface of green compacted P4; (e) fractured surface of green compacted P5..

easy plastic deformation of agglomerates at low applied pressure. Then, they crush easily and the particles slide onto each other, favouring inter and intra-agglomerate porosity elimination and thus better compaction.

Mercury porosimetry data (Fig. 6) shows a pore distribution radii in the range 0·01–10 μm for all samples isostatically compacted at 400 MPa. The maximum porous volume is localised in the low value side for P1, P2, P3 and P5 (near 0·01 μm) and at the larger side value for P4 (near 0·7 μm). If the pore mean diameter of each powder is compared to crystallite mean diameter obtained from X-ray patterns, we can easily notice that the samples P1, P2, P3 and P5 exhibit mainly intercrystallite porosity. In addition, a very small interaggregate porosity is noticed for samples P2 and P3 with pore radii more than 0·01 μm. On the contrary, the sample P4 exhibits essentially large interaggregate pores. Very weak intercrystallite porosity is also seen at about 5 nm. So, this powder is essentially formed of dense aggregates.

The SEM characterization of green bodies (Fig. 7) shows that:

- The compaction process of powders P1, P3 and P4, at pressures higher than *Pj*, is controlled by a crushing phenomenon of their agglomerates.
- For powder P5, it is also controlled by the crushing of agglomerates but some rod-like shaped agglomerates remain after pressing.
- For powder P2, the integrity of agglomerates is conserved even after pressing up to 400 MPa. Consequently large pores are still present in the green bodies.

The shrinkage of P2, P3 and P5, characterized by a high specific surface area (close to 100 m^2/g),

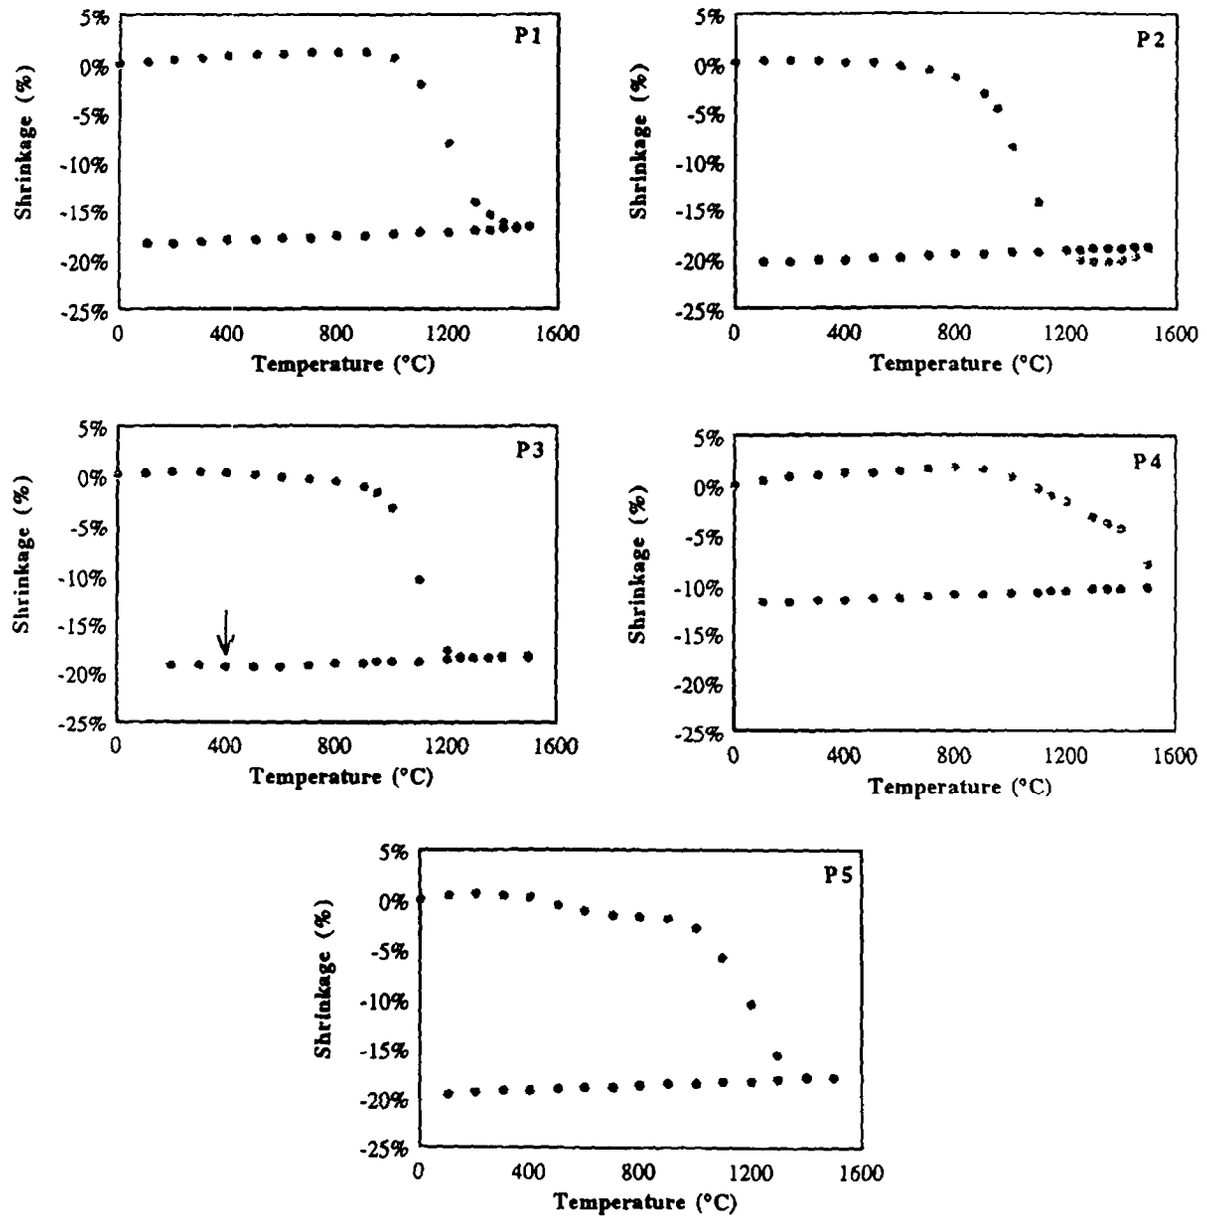

Fig. 8. Dilatometric curves of samples isostatically packed up to 400 MPa and sintered up to 1500°C with a heating rate of 1°C/min.

starts at 400°C and reaches about 20%. Shrinkage is also significant for the powder P1 but begins only at 850°C. Powder P4 has the lowest surface area and shrinkage starts at 850°C and does not exceed 12%, (Fig. 8). Thus, the reactivity of the powders P2, P3 and P5 allows a good densification during the sintering stage, though they have a low green density. The sintering stage of powder P4 is largely delayed by the presence of a large porosity, which is difficult to eliminate at 1500°C

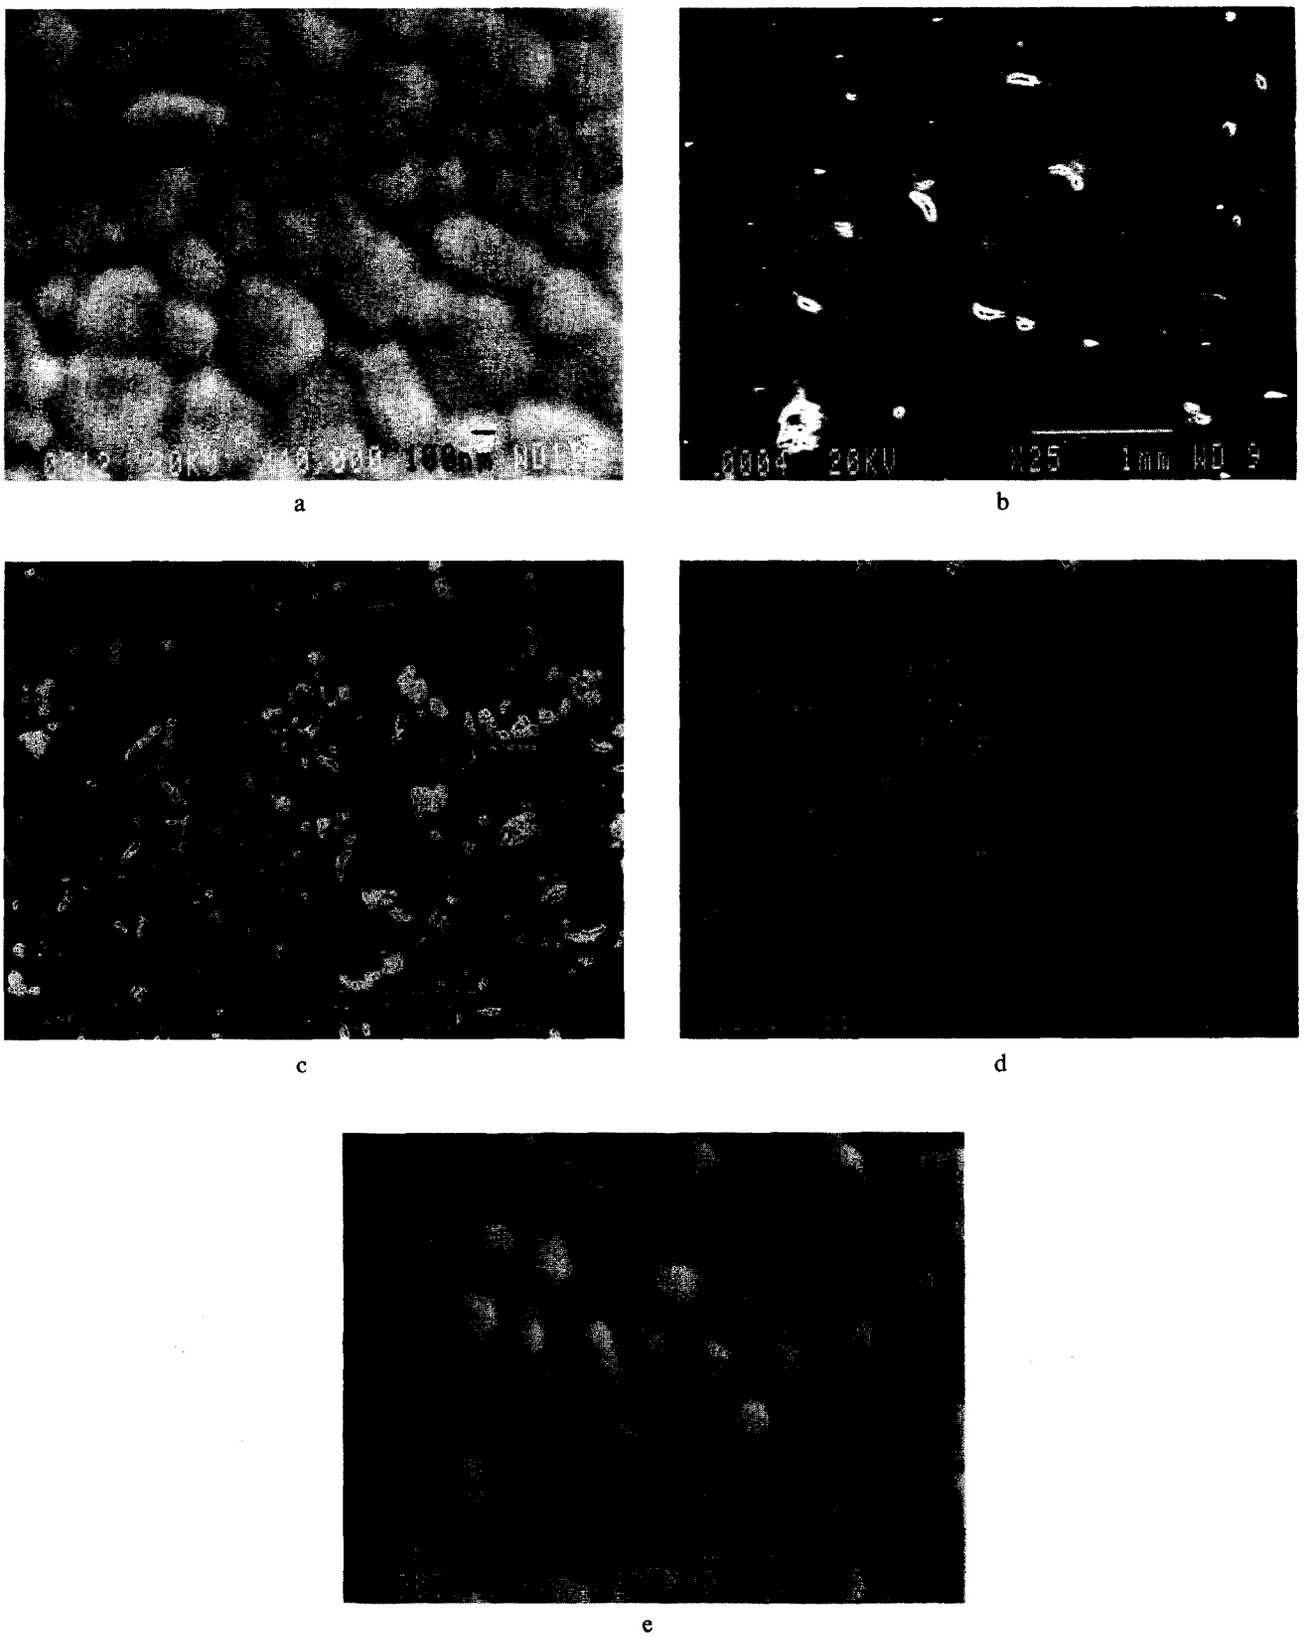

Fig. 9. Series of scanning electron micrographs of sintered (1500°C) pellets made from the powders compacted up to 400 MPa. Table 3. Density of green and sintered samples, % of theoretical

Sample		*P1*	*P2*	*P3*	*P4*	*P5*
Green		54·67	46·78	49·09	58·52	52·17
Sintered	1350°C	—	96·16	94·09	—	—
	1500°C	99·83	88·44	91·99	79·01	98·7

probably owing to the hardness of agglomerates which have not been crushed during pressing. Dilatometric curves of sol–gel powders P3 and principally P2 show a dedensification above 1350°C as previously observed in earlier work.[14,15]

Dilatometric data are confirmed by the measurement of the density of sintered pellets using Arthur's method[16] (Table 3). A density close to 95% of theoretical is reached for samples P2 and P3 sintered at 1350°C. The marked density decrease for the pellets sintered at 1500°C can be explained both by the opening of large pores and the presence of microcracks as shown in SEM micrographs (Fig. 9). Microcracks seen on the micrograph of sample P3, are induced by an increase in monoclinic zirconia content due to grain growth which causes lower density. The tetragonal to monoclinic transformation occurs during the cooling stage as is evident from a dedensification mentioned by the arrow on the dilatometric curve, (Fig. 8) and the presence of monoclinic zirconia on XRD patterns, (Figs 10 and 11).

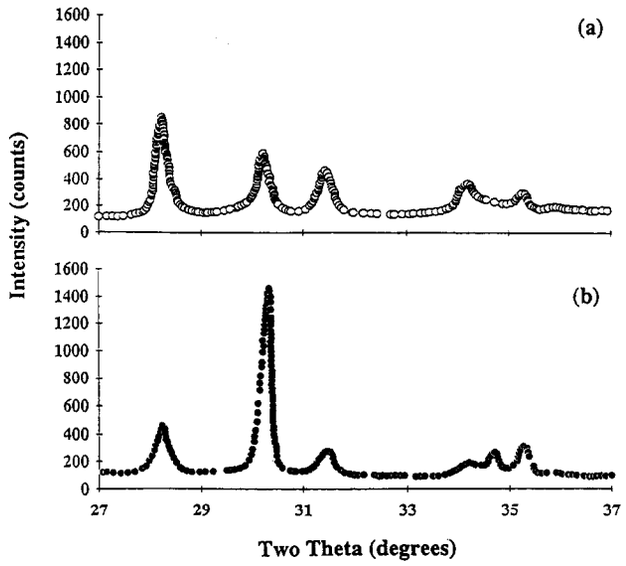

Fig. 11. XRD patterns of P3 sintered (a) at 1500°C, (b) at 1350°C pellets.

The pattern of the other sintered samples indicates only the presence of tetragonal zirconia (Fig. 10). This difference of behaviour is interpreted as a consequence of a lower amount of Y_2O_3 in sample P3. The dedensification phenomenon of sample P2 is a consequence of differential sintering leading to circumferential cracks around hard granules.[17]

A density close to 99 and 98% of theoretical is reached respectively for samples P1 and P5 exhibiting a regular microstructure. The SEM micrograph of sample P4 shows a large porosity which can not be eliminated below 1500°C. TGA experiments (Fig. 12) coupled with gas release

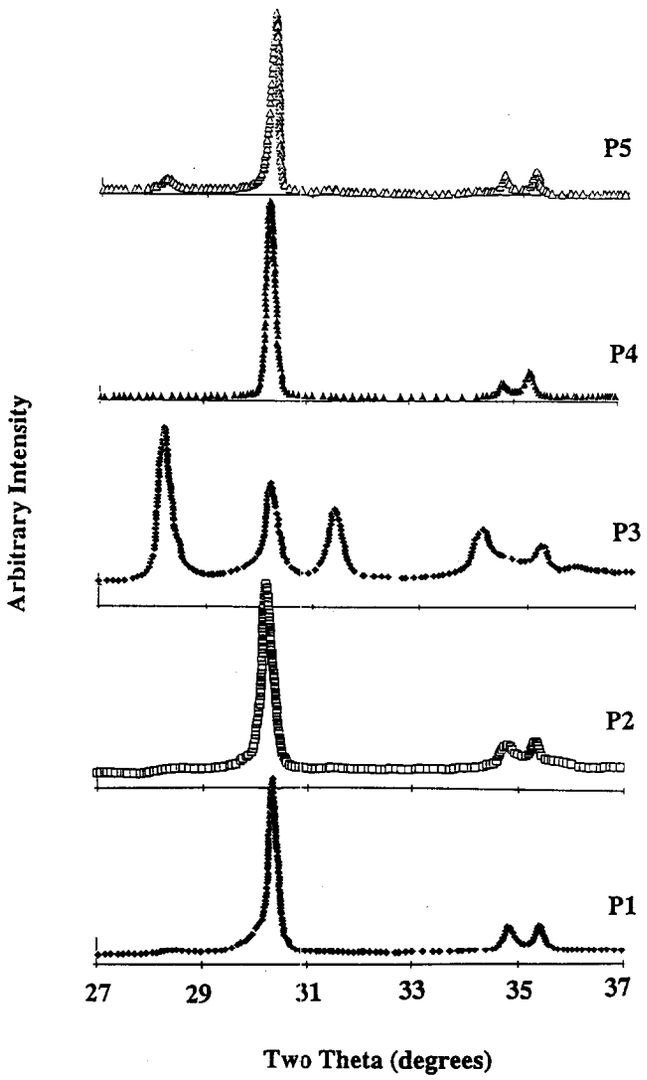

Fig. 10. XRD patterns of compacts sintered at 1500°C.

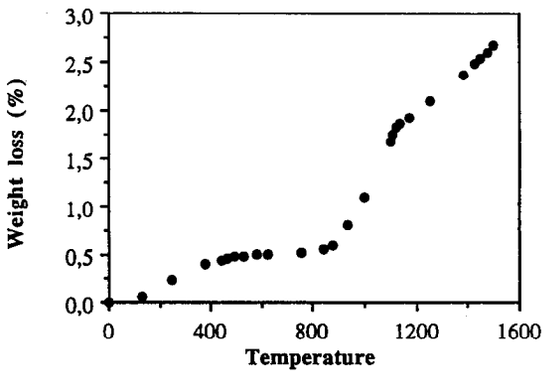

Fig. 12. Thermogravimetric data (TGA) of the sample P4 isostatically packed (400 MPa).

analysis show that the decomposition of residual carbon may be in the form of carbonate or oxycarbonate groups beginning beyond 900°C and not finished at 1500°C. So, a density of 78% of theoretical isn't exceeded.

Conclusions

The commercial powder has a higher mean crystallite size, it sinters quite well and a regular microstructure is obtained. This is due to plastic behaviour of the granules during the compaction stage. The binder favours compaction and allows an earlier crushing of the agglomerates at very low applied pressures. Then, narrower porosity distribution in the green samples leads to good densification.

The reactivity and the fine grain size of sol–gel powders allows a very low sintering temperature. The granulation process involves very good flowability, but it must be controlled carefully to avoid the formation of hard agglomerates. This could be achieved by lowering the calcination temperature down to 400–500 as proposed by Van de Graaf *et al.*[15]

The presence of residual carbon in the form of carbonate or oxycarbonate groups in the sample P4 inhibits the sintering of this powder. Their decomposition begins beyond 900°C and is not finished at 1500°C. Also the presence of aggregates is the second major inconvenience which inhibits the sintering stage.

The molten salt route is interesting because sintered bodies reach the theoretical density. The morphology of this powder must be optimized by changing synthesis parameters so as to enhance flowability.

Abstract

An experimental investigation was performed to understand the mechanical properties of alumina with moderate amounts of porosity (~20–40%). Young's modulus, strength and fracture toughness showed similar behavior as a function of the degree of sintering. For low sintering temperatures (<1050°C), the mechanical properties were found to change significantly with only minimal densification, and this was considered to be due to neck growth by surface diffusion. At these temperatures, increases in sintering time resulted in further increases in Young's modulus. The Young's modulus and fracture toughness data agreed well with modifications to a recent theory. The critical crack size in these porous materials calculated from the strength and fracture toughness data was found to increase slightly as the sintering temperature was increased. It was concluded that significant improvements in the mechanical properties of porous ceramics can be obtained by control of the sintering process, and in some cases these improvements can be made with minimal densification.

1 Introduction

There are many technological applications in which porous ceramic materials are utilized. For example, high-porosity cellular ceramics can be used for molten-metal filters, radiant burners, lightweight cores for sandwich panels, etc. In other cases, ceramics with moderate amounts of porosity are needed, e.g. as particle filters, catalyst supports and sensors. For structural components, the presence of porosity may be useful in reducing the weight of the component, whereas for non-structural components, porosity may be essential for other functions, such as permeability or a high-surface-area substrate. For both structural and non-structural applications, however, improvements in the mechanical properties and control of strength variability are expected to increase the overall reliability of the material. In order to accomplish this goal, the interrelationship between processing, structure and mechanical properties of porous materials must be understood. The most common way of processing moderately porous ceramic materials is by sintering powder compacts to a fixed degree of densification. During this process, the particles coalesce by the formation of necks, and the particles usually undergo grain coarsening and other geometric changes. The aim of the current study was to measure the room-temperature mechanical properties of a partially sintered alumina, i.e. Young's modulus, fracture toughness and strength, and relate these properties to the sintering process.

2 Background

In order to understand the effect of porosity on mechanical properties, researchers have usually emphasized the volume fraction and geometry of the porosity. In some recent studies,[1–7] however, there has been an attempt to relate the mechanical properties to the microstructure of the *solid* phase, linking the properties to neck growth, particle coordination, solid phase contiguity, etc. Green and coworkers[2,6] have demonstrated a dramatic increase in the strength and elastic moduli of alumina with no change in pore volume. This sharp increase in stiffness with minimal increase in density was attributed to neck growth by surface diffusion, the dominant mechanism in the sintering of alumina at temperatures below ~1000°C. Using a simple model for the initial stages of neck growth that emphasizes the solid microstructure, Green *et al.* suggested[1,2]

$$(B/B_0) = [3Nr(1-2\nu_0)]/[8kR(1-\nu_0^2)] \quad (1)$$

where B is the bulk modulus of the porous compact, B_0 and ν_0 are the bulk modulus and Poisson's ratio of the particle, r is the neck radius, N is the particle coordination number, R is the radius of the particle and k is a geometric constant. According to this model, for a given material the

relative bulk modulus is proportional to the coordination number and the neck-to-particle radius ratio (r/R). By combining eqn (1) with the established relationships for neck growth, it is then possible to relate the elastic moduli of a porous material to the sintering mechanism.[2,7] For the case of alumina, the elastic constants were found to be consistent with the sintering mechanism of surface diffusion at the lower sintering temperatures and volume diffusion at the higher.[2] The increase in strength for alumina without any densification[6] is particularly intriguing, as it implies that one can control the strength of a porous material through manipulation of the sintering process.

In order to obtain further support for eqn (1), Nanjangud and Green[7] measured r/R for partially sintered glass spheres from observations of the fracture surface. The study demonstrated that a linear relationship between Young's modulus and the radii ratio was not unreasonable. Moreover, the study again showed that the elastic properties could be related to the sintering mechanism (viscous flow) and good agreement was obtained between the viscosity data obtained in this manner and previous literature data.[7] In order to understand the strength behavior of a porous material, information is needed on the fracture toughness behavior, and obtaining such data was the primary focus of the current study.

Mechanical property data on porous alumina has recently been gathered by Lam *et al.*[8] and they suggested the elastic constants and fracture toughness should be directly proportional to the degree of densification, i.e.

$$\frac{E}{E_0} = \frac{K_{IC}}{K_{IC}^0} = \left(1 - \frac{P}{P_I}\right) \tag{2}$$

where E and E_0 are the Young's modulus values of the porous and theoretically dense materials, respectively, K_{IC} and K_{IC}^0 are the fracture toughnesses of the porous and dense materials, respectively, P is the fractional porosity and P_I is the fractional porosity in the green state. By postulating an equation for the change in the crack size that initiates failure in these materials, Lam *et al.*[8] also put forward a theoretical relationship for the strength behavior of porous materials. Equation (2) clearly runs into difficulties for materials that undergo sintering without densification, and thus it was suggested recently[7] that the theory for the Young's modulus can be modified to

$$\left(\frac{E - E'}{E_0 - E'}\right) = \left(1 - \frac{P}{P_I}\right) \tag{3}$$

where E' is the Young's modulus at the onset of densification.

3 Experimental Procedure

Porous samples were processed by the partial sintering of powder compacts to various temperatures using a commercially available alumina (Malakoff Industries, TX., >99·99% purity, median particle size = 0·38 μm).

3.1 Sample processing

Bar specimens were used for the Young's modulus and fracture toughness determinations and ~10 individual bars were uniaxially dry-pressed at a pressure of 17 MPa for each batch. The specimens were also isostatically pressed to a pressure of 172 MPa. The specimen dimensions were typically 7 mm × 4 mm × 45 mm. The various batches of material were sintered to different temperatures ranging from 800 to 1600°C. The sintering was conducted in air with a heating rate of 10°C/min and a dwell time of 2 h at the maximum temperature. At the end of the isothermal hold, the samples were allowed to cool at a rate of about 5°C/min. Some isothermal sintering experiments were also conducted at temperatures of 900, 1050, and 1200°C for times up to 78 h.

Specimens for Young's modulus and strength testing were in the form of discs. Powder was introduced into a steel die with a diameter of 25·4 mm and uniaxially pressed to a stress of 45 MPa, but these samples were not isostatically pressed. The sintering procedure was identical to that for the bars. The densities of the bars and discs were both calculated from simple volume and mass measurements and the densities within the batches varied by less than 1%.

3.2 Young's modulus measurements

The Young's modulus of the bars was determined using a dynamic resonance technique from[9,10]

$$E = 0{\cdot}94642C\rho\left(\frac{L^2 f}{h}\right)^2 \tag{4}$$

where E is Young's modulus, L is the sample length, f is the fundamental flexural resonance frequency, h is the beam height, ρ is the density and C is a shape factor. The parameter C is dependent upon Poisson's ratio and values for a porous alumina were taken from a previous study.[2] This approach was considered to be acceptable as Poisson's ratio has only a small effect on the magnitude of C.

The Young's moduli of the discs were determined by an ultrasonic sound velocity technique. Longitudinal sound waves were transmitted through the thickness of the discs by means of a wave pulser and a 12·7-mm diameter, dry contact, 10 MHz transducer (Ultran Laboratories, Boals-

burg, PA). The transit-time measurement was made in the pulse-echo mode and E was calculated using

$$E = \frac{v^2[\rho(1 + \nu)(1 - 2\nu)]}{(1 - \nu)} \quad (5)$$

where v is the longitudinal sound velocity, ρ is density and ν is Poisson's ratio. The Poisson's ratio values for porous alumina were obtained from the literature.[2] Ten samples for each sintering temperature were measured, and the average Young's modulus values were calculated.

3.3 Strength testing

The strengths of the discs were measured using a 'piston on three ball' biaxial flexure test.[11] The load was applied using a commercial mechanical testing machine (Instron Corporation, Model 4200, Canton, MA.). The equation for calculating strength depends on Poisson's ratio, and again values were obtained from literature.[2] The fracture strength for each batch was taken as the average of the strengths of the individual samples. The discs broke into three or four pieces with the cracks originating from the center of the tensile side of the specimens.

3.4 Fracture toughness measurements

Fracture toughness values (K_{IC}) were measured using a four-point bend chevron-notch test.[12,22] This method was chosen to ensure the introduction of sharp cracks in these fragile porous materials. The details of the notching procedure are given elsewhere.[23] Fracture toughness values were determined using the analysis of Munz *et al.*[12] The major and minor spans of the bend fixture were 38·1 and 12·7 mm, respectively, and the crosshead speed was 0·05 mm/min. In the chevron-notch test, crack growth must proceed stably through the maximum load and the presence of stable crack growth was confirmed by the shape of the load–displacement curve obtained for each specimen. If stable growth occurred, the top of the curve would be rounded, whereas a catastrophic failure would give an instantaneous drop in load.

3.5 Microstructural characterization

Scanning electron microscope observations were made on planar sections of the samples to study the microstructural changes as a function of the degree of sintering. It is difficult to polish porous samples without damage, so vacuum impregnation with a cold-mounting epoxy (Epofix HQ, Struers, Westlake, OH) was used to fill the pores and strengthen the samples for polishing. The epoxy was heated to 50°C to reduce the viscosity, and then pieces of the broken discs were dropped into the epoxy in a vacuum chamber. The vacuum was released after 15–30 s to prevent the epoxy from vaporizing. The samples were then mounted for polishing in a different epoxy (M135 Fast Cure Epoxy, Metlab, Niagara Falls, NY). The infiltrated samples were polished to a 0·2-μm diamond paste finish. After polishing, the samples were heated on a hot plate and removed from the softened epoxy. The samples were then heated to 500°C to remove the infiltrated epoxy and, as a final step, were cleaned in acetone prior to microscopic observation.

4 Results and Discussion

Figure 1 shows the changes in the relative density of the alumina bars with sintering temperature. The densities of samples sintered to < 1100°C are relatively unchanged and densification occurs at the higher temperatures. The Young's modulus

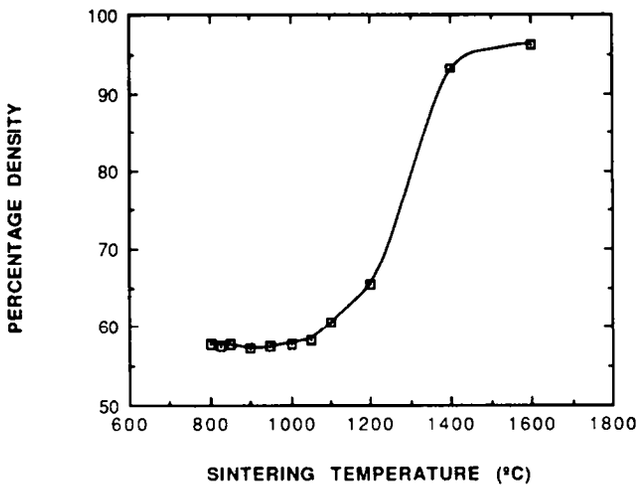

Fig. 1. Density of glass specimens after sintering at various temperatures, showing the onset of densification at ~1050°C.

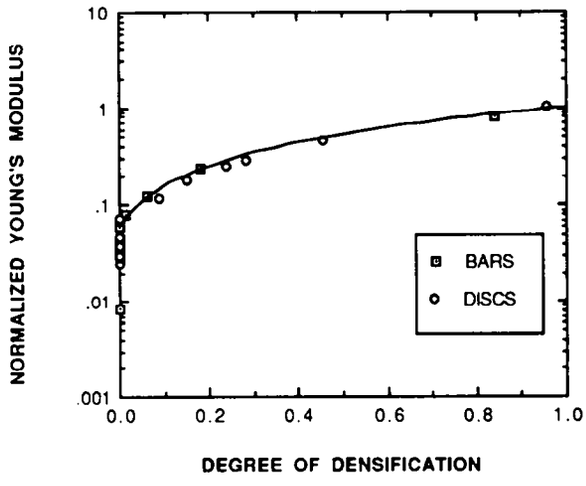

Fig. 2. Comparison of the room temperature Young's modulus values for porous alumina specimens after sintering to various temperatures as a function of the degree of densification with eqn (3).

data for the bars and discs are given as a function of the degree of densification in Fig. 2, i.e. $D = 1 - (P/P_I)$. As with the earlier studies,[2,6] there is a dramatic increase in the Young's modulus for specimens subjected to the initial stages of sintering with very little increase in density, reflecting neck growth by surface diffusion. It is also important to note the E data for both bars and discs fit a single function, even though there was a difference in their respective green densities, i.e. 58% and 54% theoretical density. In terms of eqn (3), the data show an excellent fit, using $E'/E_0 = 0{\cdot}06$. It would appear that the modification to eqn (2) is very useful, but it is still incapable of describing the changes in modulus that occurs for $D = 0$. For these cases, in which non-densifying sintering mechanisms are active, approaches such as that outlined in eqn (1) show more promise, but information on the changes in the r/R ratio and coordination number is difficult to obtain, especially when using sub-micrometer powder as a starting material.

Isothermal sintering was conducted at 900, 1050 and 1200°C and the Young's modulus data are shown in Fig. 3 as a function of the sintering time. For the 900°C and 1050°C sintering schedules, the modulus was substantially increased with no significant change in density (< 1%). This effect could be of technological interest in that Young's modulus can be doubled for this range of sintering times. For the 1200°C specimens, the modulus increased more dramatically, but the density was found to increase at a similar rate. As with the earlier study,[2] the variation in the elastic constants observed in the current study is consistent with a change in the dominant sintering mechanism, i.e. from surface diffusion to volume diffusion at ~1050°C.

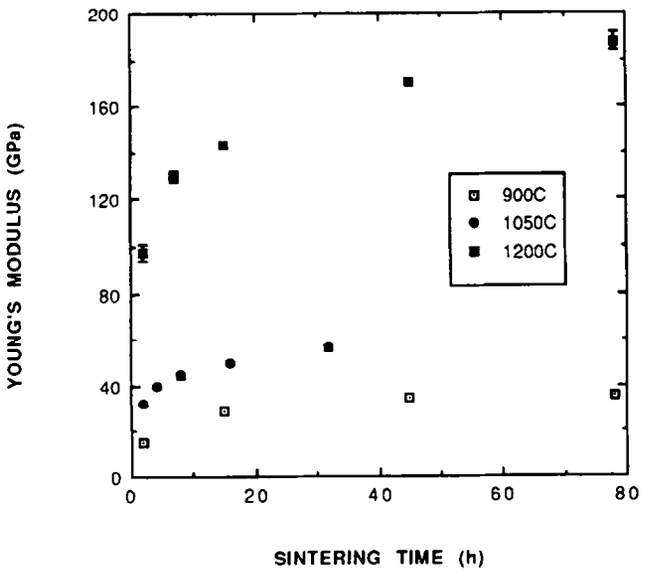

Fig. 3. Room-temperature Young's modulus values for porous alumina specimens after sintering at 900, 1050 and 1200°C for various times. These changes occur without significant densification at the two lower temperatures.

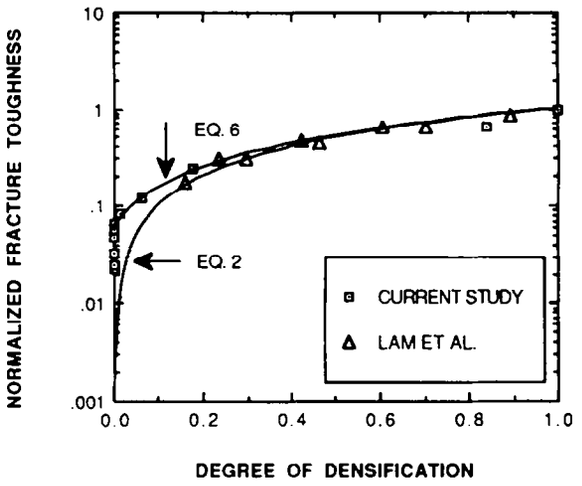

Fig. 4. Room-temperature fracture toughness values for porous alumina specimens after sintering to various temperatures as a function of the degree of densification. For small D, there is significant deviation from the theory of Lam *et al.*[8] Improved agreement is obtained using the proposed modification of eqn (6).

Mode I fracture toughness values (K_{IC}) are given as a function of D in Fig. 4 and are compared with eqn (2). The experimental data of Lam *et al.*[8] is also included in Fig. 4 and comparison with the theory for both data sets shows good agreement for $D \geq 0{\cdot}1$. The growth of the necks for $D = 0$ leads to a significant increase in fracture toughness and shows a strong similarity to the elastic constant data. For a density of 65·4% theoretical, the fracture toughness has increased to 1·06 MPa $\sqrt{m}$, which is a relatively significant value. To place this value in perspective, one should note that the value exceeds that of dense soda-lime-silica glass (~0·7 MPa $\sqrt{m}$). The discrepancy with eqn (2) for small D suggests that eqn (2) for fracture toughness could be modified in the same fashion as the equation for Young's modulus (eqn (3)), i.e.

$$\left(\frac{K_{IC} - K'_{IC}}{K^0_{IC} - K'_{IC}}\right) = \left(1 - \frac{P}{P_I}\right) \qquad (6)$$

where K'_{IC} is the fracture toughness at the onset of densification. The modification to the theory is shown in Fig. 4 using $K'_{IC}/K_{IC}{}^0 = 0{\cdot}06$, and the fit is excellent. A model has been developed that considers the fracture toughness of a partially sintered body in terms of particle neck failure.[23] Such a model would be supported by the increase in fracture toughness seen in Fig. 4 for $D = 0$, similar to the way in which the elastic data in Fig. 2 supports eqn (2). An important difference with the elastic problem is that failure may not necessarily pass through the interparticle necks.[7] For the current work, there was not enough direct evidence to test and support the model.

The biaxial flexural strengths of discs are plotted against relative density in Fig. 5. As with

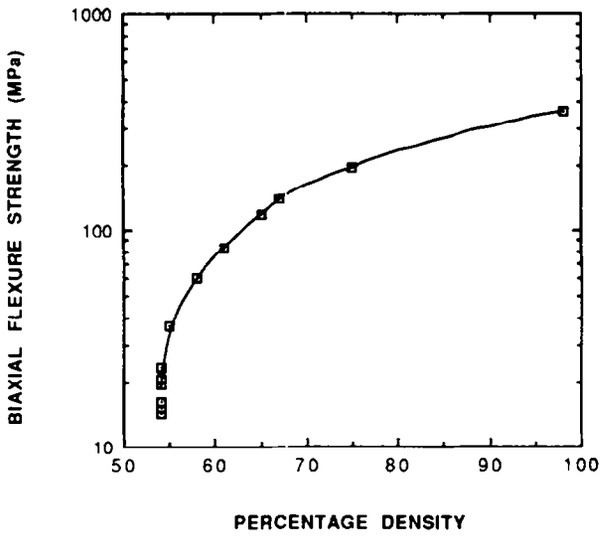

Fig. 5. Room-temperature biaxial flexure strength for porous alumina specimens after sintering to various temperatures as a function of the percentage theoretical density.

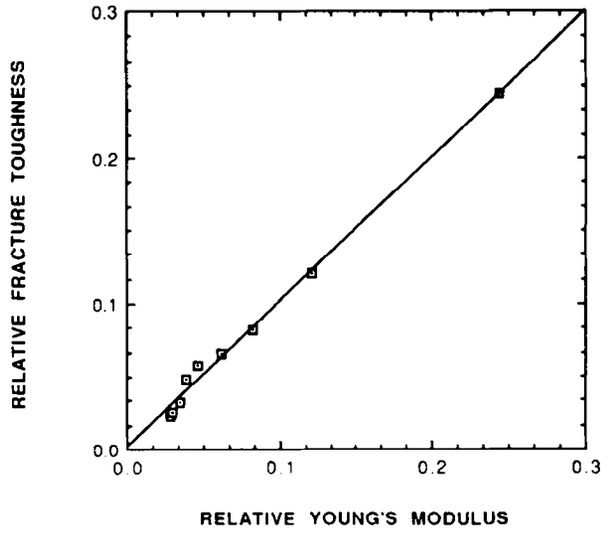

Fig. 6. Correlation between the relative Young's modulus and the relative fracture toughness for bar specimens.

Young's modulus and fracture toughness, there is a relatively large increase in strength for specimens sintered at temperatures below 1100°C. These data show that significant gains in strength of porous ceramics can be obtained with minimal densification. This flexural strength data, along with the Young's modulus and fracture toughness data, is very encouraging in that it demonstrates that the mechanical properties of a porous material can be enhanced at a particular density by control of the sintering mechanism.

The relationship between the strength of a brittle ceramic and its mode I fracture toughness is given as

$$\sigma_f = \frac{K_{IC}}{Y\sqrt{c}} \tag{7}$$

where σ_f is fracture strength, Y is a geometric constant and c is the critical crack length. Thus, the critical crack size can be calculated if σ_f and K_{IC} are known for a given material, and this gives insight into the failure process. In the present study, both σ_f and K_{IC} were measured, but not for the same sample geometry. The fracture toughness tests were conducted on bars, whereas discs were used for the biaxial flexure strength measurements. The difficulty in performing the crack size calculation was that the difference in specimen geometry for the toughness and strength tests gave rise to slight differences in green density. As Young's modulus was measured for both specimen types, it was postulated that K_{IC} could be empirically determined for the strength specimens from the correlation between K_{IC} and E. Equation (2) suggests that $(E/E_0) = (K_{IC}/K_{IC}^0)$ and as shown on Fig. 6, this approach gives a strong correlation even when $D = 0$. Higher-degree polynomials could be used in this fitting procedure, but this was found not to have a strong influence on the crack size calculation. Thus, the fracture toughness of the specimens used in the strength testing was estimated from the E values. The critical crack size, as calculated from eqn (5), is shown in Fig. 7 as a function of the sintering temperature. The value of $Y = 2/\sqrt{\pi}$ was used in the calculation, i.e. the value established for circular cracks of radius c. The critical crack size increased from about 45 to 70 μm as the degree of sintering progressed. At these high porosity levels, it is assumed that the major flaws are interconnected pores and it has been shown previously that pore sizes are expected to increase in alumina during the initial stages of sintering.[24] The data in Fig. 7 contrast strongly with the idea that the critical crack size decreases with increasing D, as suggested by Lam *et al.*[8] One suspects that the critical flaw evolution process may be rather complex and it may be

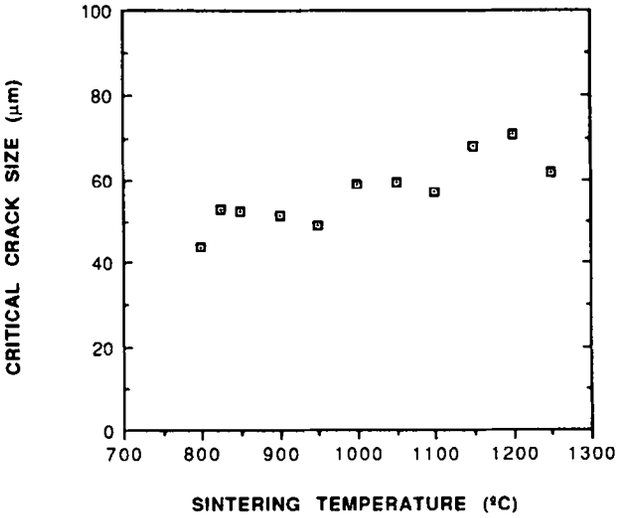

Fig. 7. Critical crack sizes calculated from the biaxial flexure strength and estimated fracture toughness data, assuming a circular flaw geometry, as a function of the sintering temperature.

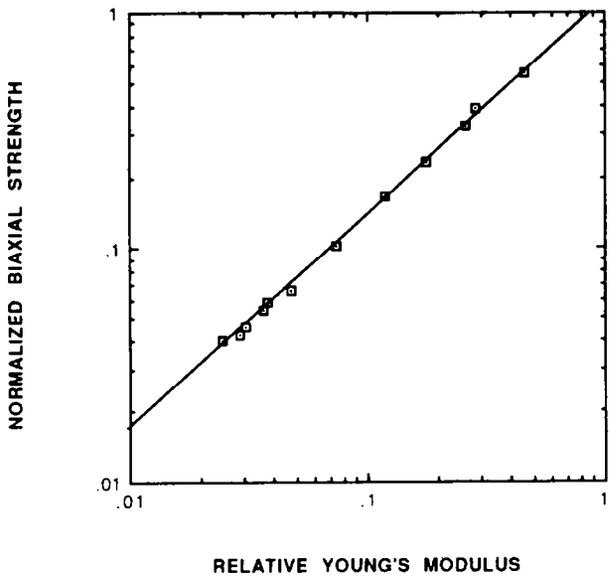

Fig. 8. Empirical correlation between biaxial flexure strength and relative Young's modulus. The strengths were normalized by the strength at the highest density, 357 MPa.

preferable to measure both strength and fracture toughness and obtain empirical information on the changes in critical crack size. For the current work, the critical crack sizes show a fairly smooth variation with increased sintering and as there is a strong correlation between fracture toughness and Young's modulus, one also finds a strong correlation between strength and Young's modulus, as shown in Fig. 8.

Figure 9 shows micrographs for samples sintered at 800, 1000, 1100 and 1200°C. Up to 1050°C, there is no obvious change in particle size or coordination, but some neck growth can be discerned. Above 1050°C, the increased density of the structure becomes apparent as clusters of particles coalesce into a chain-like morphology.

5 Summary and Conclusions

The Young's modulus, strength and fracture toughness of alumina with moderate amounts of porosity (~20–40%) showed similar behavior as a function of the degree of sintering. For low sintering temperatures (< 1050°C), these mechanical properties change with only minimal densification and this was considered to be due to neck growth by surface diffusion. At these temperatures, increases in sintering time can also be used to increase Young's modulus. Modifications to a recent theory that considers the relative Young's modulus and relative fracture toughness to be dependent upon the degree of densification showed very good agreement with the experimental data after densification had initiated. For the present

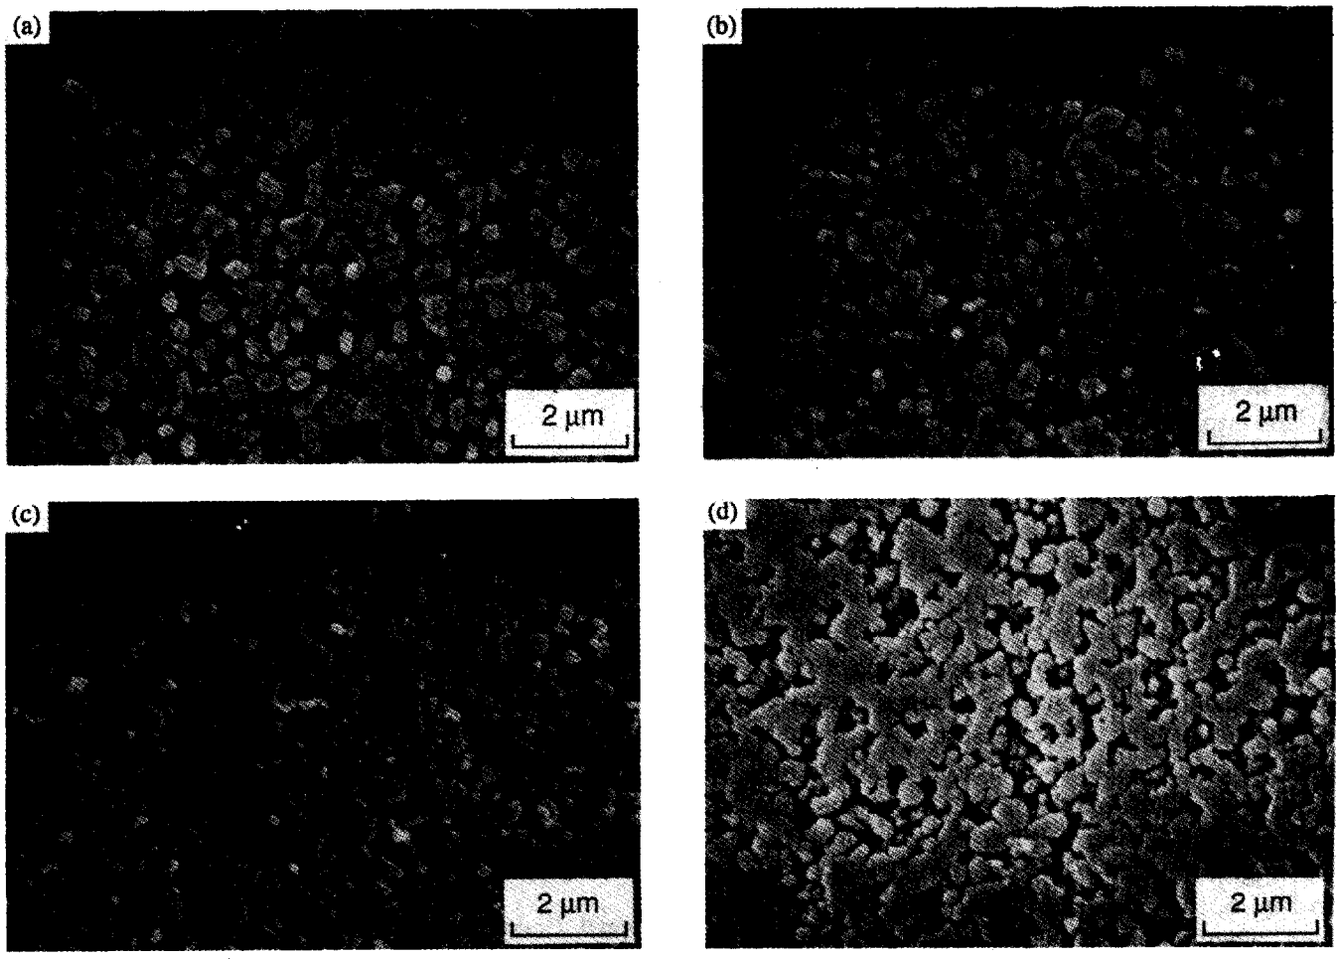

Fig. 9. Scanning electron micrographs showing specimens sintered at (a) 800°C, (b) 1000°C (c) 1100°C and (d) 1200°C.

study, the critical crack size in these porous materials was found to increase slightly as the sintering temperature was increased. Overall, this work shows that significant improvements in the mechanical properties of porous ceramics can be obtained by control of the sintering process and in some cases, with minimal densification.

The Interrupted Static Fatigue Test for Evaluating Threshold Stress Intensity Factor in Ceramic Materials: A Numerical Analysis

Vincenzo M. Sglavo & David J. Green

Department of Materials Science and Engineering, The Pennsylvania State University, University Park, PA 16802, USA

(Received 1 August 1994; revised version received 7 February 1995; accepted 14 February 1995)

Abstract

The interrupted static fatigue (ISF) test can be used to evaluate the threshold for sub-critical crack growth, K_{th}. A critical theoretical analysis of this technique is presented in order to elucidate its advantages and limitations and to furnish some suggestions for a more definitive procedure for evaluating K_{th}. It was concluded that a critical parameter in the ISF procedure is the duration of the static hold time. In particular, one should demonstrate that the calculated value of K_{th} does not change when this holding time is increased. Moreover, the applied stress must be chosen such that a significant fraction of samples fail in the hold period. Two different approaches are suggested for calculating the value of K_{th} from experimental data. The first approach is considered preferable for materials with larger Weibull moduli and the threshold is determined from the applied stress intensity factor at which 50% of samples fails during the stress hold. In the second approach, the stress intensity factor applied to the weakest specimen during the stress hold is calculated for various hold times. Once this value becomes independent of hold time, it is equivalent to the threshold.

1 Introduction

The use of glasses and ceramic materials in structural applications can be limited by the phenomenon known as sub-critical crack growth. For ceramics that exhibit this fatigue behaviour, strength becomes dependent upon time and environmental conditions. The design of structural components consisting of materials that exhibit fatigue behaviour must proceed by the estimation of a design stress, which corresponds to a required minimum failure time.

Some studies on sub-critical crack growth in glasses and ceramics have shown that this phenomenon seems to have a lower limit in the sense that crack propagation velocities tend to zero for some particular value of the applied stress intensity factor, K_{th}. This is termed the fatigue limit or the threshold stress intensity factor.[1–15] From an engineering design point of view, the existence of a fatigue limit turns out to be extremely desirable, as it allows an applied stress to be defined, below which delayed failure does not occur.

In spite of the importance of the fatigue threshold, no comprehensive test methodology has been presented for its determination. In early works on sub-critical crack growth in glasses and ceramics, specimens, usually pre-cracked, were loaded at different stress levels and the lifetime was determined.[1–7,9] The 'endurance limit' was defined as the stress at which the fatigue curve shows an asymptotic limit. For glass in a moist environment, values ranging from 0·2 to 0·4 times the strength measured in liquid nitrogen were obtained.[5] The same approach has also been used in more recent works.[16–18]

Studies devoted to sub-critical crack velocity determination as a function of the applied stress intensity factor showed, in some cases, the existence of a threshold below which crack motion did not occur. In these cases, fracture mechanics specimens such as the double cantilever beam (DCB) and double torsion geometries were used and crack advancement was measured as a function of time.[8,10,13,14,19–21]

The difficulty with the methodologies described above is that extremely long experimental times are necessary to evaluate the crack growth at these low stress levels. In fact, the fatigue limit is usually extrapolated from stress or stress intensity factor data to obtain information at long times.

The difficulties, outlined above, can be by-passed by using some indirect methods. For example, in the work of Michalske, DCB glass specimens were loaded in water at a stress intensity factor value of

0·225 MPa √m and aged in this state for fixed periods.[22] The stress intensity factor was then raised and crack motion as a function of time was recorded. The existence of a stress corrosion limit in glass, postulated to be the result of crack tip blunting, was exhibited by observing a delay in the crack growth upon reloading. A fatigue limit $<0{\cdot}25$ MPa √m in soda lime silicate glass was proposed.[22]

An approach that is experimentally easier was presented by Dutton and Rogowski[23] and Wilkins and Dutton.[24] In their studies, alumina and glass samples were loaded in a 'corrosive' environment and the load was maintained for times of the order of a few hours. The strength was then measured and compared to the initial strength. This has been termed the interrupted static fatigue (ISF) test. The same technique has been used by Hayashi *et al.* to measure the fatigue limit of borosilicate glass rods in water.[25]

Tressler and coworkers[26–29] have further developed the approach proposed by Dutton and Rogowski.[23] In studies on silicon carbide and silicon nitride ceramics at high temperatures, they measured the average strength of samples aged under different loads. The threshold stress intensity factor was calculated from the stress level above which samples failed during the static hold part of the test. Nevertheless, the lack of a solid theoretical background sometimes made the interpretation of the data difficult.[26–29] Tanaka and Pezzotti pointed out that some of the data proposed by Tressler and coworkers do not represent the real fatigue limit but are the result of a typical time-to-failure test.[30]

In the following study, a theoretical analysis on the interrupted static fatigue test is presented. The behaviour of silicon carbide at high temperatures and of glass in water is simulated using fracture mechanics so that the conditions for the correct evaluation of the fatigue limit can be highlighted. The results of the theoretical analysis allow some suggestions regarding the methodology for threshold stress intensity factor determination to be proposed.

2 Theoretical Approach

In order to describe the strength degradation that occurs in the interrupted static fatigue test, a function describing the sub-critical crack propagation velocity is required. The crack growth behaviour is usually expressed as a power function of the stress intensity factor K and can be written as follows:

$$v = \frac{dc}{dt} = v_0 \left(\frac{K}{K_c}\right)^n \quad \text{if } K > K_{th} \tag{1a}$$

$$v = 0 \quad \text{if } K < K_{th} \tag{1b}$$

where K_c corresponds to the fracture toughness, v_0 and n are constants which depend upon the material and the environment, K_{th} is the threshold for sub-critical crack growth and c is the crack length.

The stress intensity factor K, associated with a 'crack-like' flaw subjected to an applied stress σ, is given by

$$K = \sigma \Psi \sqrt{c} \tag{2}$$

where Ψ is the geometric factor that includes the effect of flaw shape, boundary interactions and loading geometry. In the absence of residual stress fields, the strength S, associated with a crack of length c, can be written as

$$S = \frac{K_c}{\Psi \sqrt{c}} \tag{3}$$

According to eqn (1a), when a constant stress, σ_h, is applied for a time t and $K > K_{th}$, the flaw size increases from the initial value c_0 to a final value c_1. Correspondingly, strength decreases from S_0 to S_1. Substitution of eqn (2), with $\sigma = \sigma_h$, into eqn (1) and subsequent integration allows one to evaluate S_1 as a function of hold time t as

$$S_1 = \left(S_0^{n-2} - \frac{\sigma_h^n t}{B}\right)^{1/(n-2)} \quad \text{if } K > K_{th} \tag{4a}$$

$$S_1 = S_0 \quad \text{if } K < K_{th} \tag{4b}$$

where

$$B = \frac{2K_c^2}{(n-2)\Psi^2 v_0} \tag{5}$$

When n is a real number, eqn (4a) is not defined for $\sigma > \sigma^* = (B\, S_0^{n-2}/t)^{1/n}$, the condition for which $S_1 = 0$.

Equation (4) can also be expressed in terms of the stress intensity factor K_h, applied at the start of the static hold. From eqns (2) and (3),

$$\sigma_h = S_0 \frac{K_h}{K_c} \tag{6}$$

and thus, for $K_h > K_{th}$, eqn (4a) becomes

$$S_1 = S_0 \left(1 - \frac{S_0^2 K_h^n t}{K_c^n B}\right)^{1/(n-2)} \tag{7}$$

In this case, S_1 is not defined for $K_h > K^* = K_c\,[B/(S_0^2 t)]^{1/n}$. The importance of this condition resides in the fact that, when a stress intensity factor larger than K^* is applied for a time t, the final strength S_1 is zero. This condition can also be defined in terms of the ratio $\kappa = K_h/K_c$, as

$$\kappa^* \left(\frac{2c_0}{(n-2)tv_0}\right)^{1/n} \tag{8}$$

3 Simulation Results

On the basis of the theoretical background developed in the previous section, the behaviour of silicon carbide at 1400°C and soda-lime silicate glass in water at room temperature was simulated. The properties used in the calculations are given in Table 1.[31,32] In these initial calculations, average strength values were used. The effect of strength variability will be explored later.

Figure 1 shows the strength of SiC after the ISF test as a function of the applied stress for three different holding times, as calculated from eqn (4), in the absence of a threshold. Sub-critical crack growth is responsible for the strength decrease that occurs over a small range of applied stress values. This behaviour demonstrates that, even in absence of a threshold for fatigue, strength remains practically constant for most of the lifetime of the sample. It can also be observed that the stress value (σ^*) at which strength 'drop-off' occurs, decreases for increasing hold time.

Diagrams such as Fig. 1 can also be given in terms of the stress intensity factor (eqn (7)), as shown in Fig. 2. In this case, the threshold for sub-critical crack growth was assumed to be 1 MPa $\sqrt{m}$.[31] A distinct strength drop-off is still evident and K^* decreases for increasing hold times until the threshold is reached. At this point, further increases in hold time do not have any influence on the stress intensity factor corresponding to the strength drop-off.

Figures 1 and 2 illustrate some important features regarding threshold measurement by the ISF test. When S_1 is measured to be equal to the initial strength S_0, it is not possible to definitely conclude that this is the effect of K being lower than the threshold. In addition, as shown in Fig. 2 for SiC at 1400°C, hold times during the ISF test must be longer than 44·2 h in order to guarantee that the strength degradation is only a result of the stress intensity factor being above the threshold.

Table 1. Properties of SiC and soda-lime glass considered in this study[31,32]

S_0 (MPa)	K_c (MPa $\sqrt{m}$)	n	B (MPa^{2}s)
470	2·7	21	14·23
130	0·75	19·3	0·19

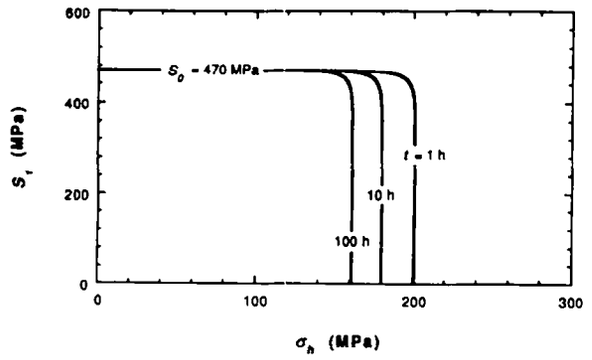

Fig. 1. Strength S_1 of SiC after the ISF test as a function of the applied stress σ_h for three different holding times.

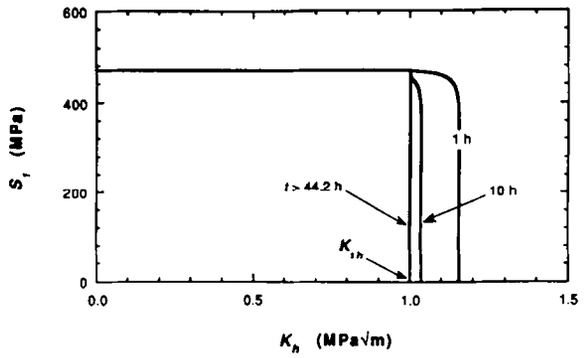

Fig. 2. Strength S_1 of SiC after the ISF test as a function of the applied stress intensity factor K_h for increasing holding times. A fatigue threshold equal to 1 MPa $\sqrt{m}$ was assumed.

The importance of the hold time on the performance of the ISF test can be highlighted further by Fig. 3, in which the stress intensity factor at which strength drop-off occurs (K^*) is plotted as a function of t. It is clear that if the material possesses a threshold, it is critical to ensure the strength loss due to sub-critical crack growth is occurring at the threshold conditions. Diagrams in Fig. 3 were calculated starting from initial strength values of 470, 149 and 47 MPa. The first of these values was that used in Table 1 while the other two were calculated by assuming that the initial crack size was 10 and 100 times larger. Such behaviour would be obtained if cracks were purposely introduced into the test specimens. The behaviour in Fig. 3 indicates that the presence of larger flaws leads to an increase in the time necessary for defining the threshold behaviour in the ISF test. Indeed, the introduction of artificial larger cracks, in order, for instance, to reduce the strength scatter, has a negative impact on the efficiency of the test methodology in terms of time management.

Calculations similar to those presented for SiC at 1400°C were also performed for soda-lime silicate glass in water at room temperature. The most

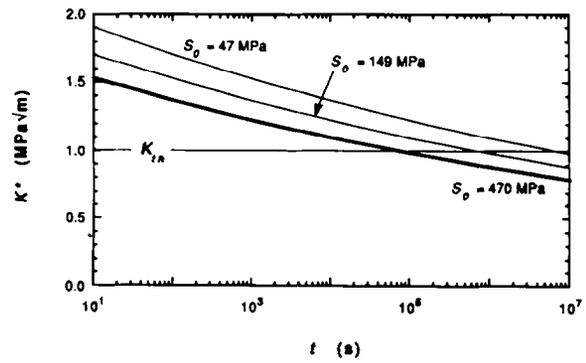

Fig. 3. 'Drop off' point K^* for SiC as a function of the holding times for different initial strengths S_0.

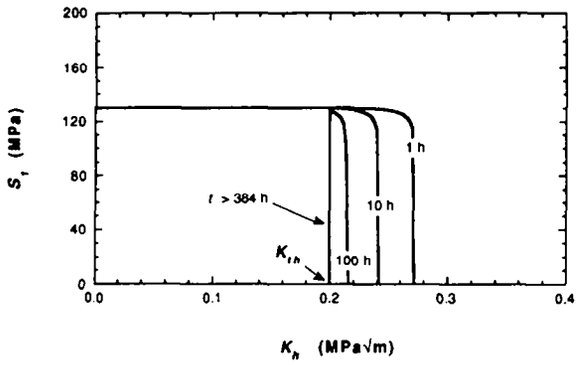

Fig. 4. Strength S_1 of soda-lime silicate glass after the ISF test as a function of the applied stress intensity factor K_h for increasing holding times. A fatigue threshold equal to 0·2 MPa √m was assumed.

significant result is shown in Fig. 4, where the strength after holding under constant stress is plotted as a function of K, for different dwell times. In this case a threshold for sub-critical crack growth was assumed to be 0·2 MPa √m.[11] For this case, hold times in excess of 384 h were found to be necessary to ensure the threshold is being measured properly for soda-lime silicate glass. Clearly, lower values of the ratio K_{th}/K_c would further increase the necessary hold times for threshold detection.

Simulation of the strength degradation behaviour of soda-lime glass was analysed further in order to point out the influence of an interrupted static fatigue test on the strength distribution. Thus far, calculations were developed by considering only the average strength (Table 1). Due to the typical large scatter shown by the strength of ceramic materials, a complete analysis should not leave out of consideration the variation in the initial crack sizes. This is an important feature as it implies a variability in K_h.

Glass strength was assumed to follow a Weibull distribution, as defined by the relationship[33]

$$F = 1 - \exp\left[-A\left(\frac{S}{\sigma_0}\right)^m\right] \tag{9}$$

where F is the failure probability, A is a constant depending on the geometry of the specimen and of the test, while σ_0 and m represent the scale parameter and the shape factor, or Weibull modulus, respectively. The constant A was assumed to be equal to 1 for easier calculation, but this does not compromise the generality of the analysis. The strength distribution was generated by assuming a mean strength S_m and a Weibull modulus equal to 130 MPa (Table 1) and 5, respectively.[33] The scale parameter σ_0 was determined by the relation[33]

$$\sigma_0 = \frac{S_m}{\Gamma(1 + 1/m)} \tag{10}$$

where Γ is the gamma function. Two situations, corresponding to a number of test specimens (N) equal to 10 and 100, respectively, were considered. Failure probability was calculated as $F = j/(N + 1)$, j being the rank in the ascending strength distribution.[33] Discrete values of the strength were obtained from eqn (9). The simulation of strength distribution variations after ISF testing was performed by considering holding times (t) ranging from 1 to 1000 h and applied stresses (σ) of 15, 30, 45 and 60 MPa. As earlier, a threshold stress intensity value of 0·2 MPa √m was assumed. Each element of the initial strength distribution S_{0j} (j = 1,N) was associated with a particular initial flaw size c_{0j}. This value was used to evaluate the stress intensity factor K_j applied to each specimen by eqn (2), once the hold stress was defined. Depending on the K_j value, the strength S_{1j} was calculated by eqn (4) as a function of hold time and applied stress.

Figure 5(a) shows the Weibull plot of the strength distributions after the holding at different stress levels for 1 h, for N = 100. The failure probability of specimens surviving the static hold were calculated as a censored distribution. The initial distribution, corresponding to an applied stress equal to 0, is obviously represented by a straight line.[33] Increased values of σ lead to significant changes in the strength distribution. This appears

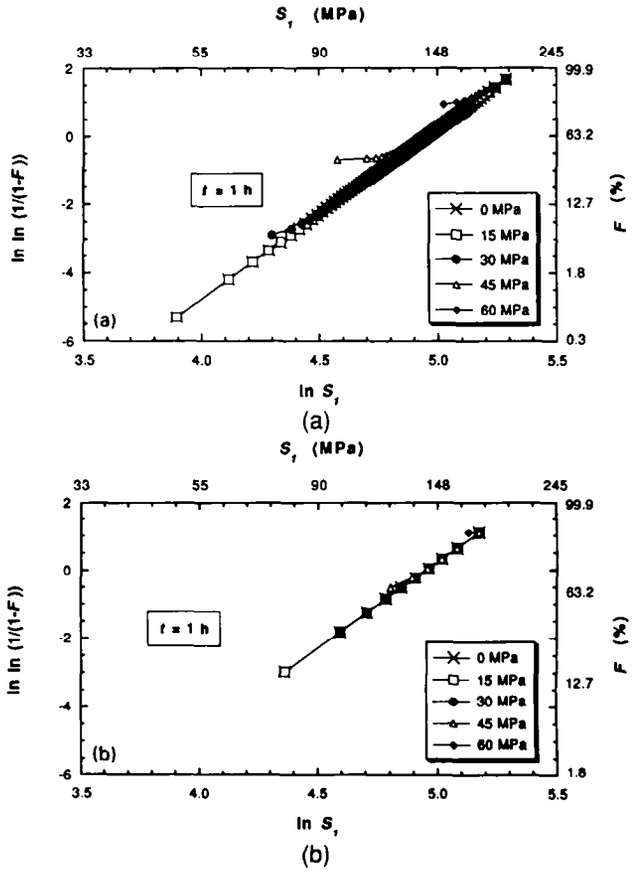

Fig. 5. Weibull plot of the strength distribution of soda-lime silicate glass after the holding at different stress levels for 1 h. The initial strength distribution corresponds to the applied stress of 0 MPa. (a) Number of specimens, N = 100, (b) N = 10.

as a 'twist' in the distribution, which is truncated for specimens that fail during the static hold. Sub-critical growth accounts for these effects. The larger the defect, the higher the stress intensity factor applied during the hold and this increases the amount of sub-critical crack growth. Thus, larger flaws can grow significantly or even fail during the constant stress period. Similar trends were also observed when $N = 10$, although the 'twisting' becomes more difficult to distinguish, as shown in Fig. 5(b). Clearly, the behaviour in a real experimental test would be further complicated by the actual scatter in the c_0 values and statistical sampling effects.

The effect of increasing hold time is shown in Fig. 6, for $N = 100$ and, as expected, a larger number of specimens fail during the stress hold for a given applied stress (all specimens fail when $\sigma = 60$ MPa and $t \geq 100$ h). A limit is reached when an increased hold time does not affect the distributions further, i.e. the twist in the distribution disappears, as shown in Fig. 6(c) and (d). This implies that all the specimens that fail in the hold had K values above the threshold, while those that survived were below the threshold. The same behaviour was also observed for $N = 10$.

Changes in strength distribution after specimens have been held at particular stress levels have been used in some previous studies as a means to identify the threshold for sub-critical growth in glass.[24,25] For example, Wilkins and Dutton[24] and Hayashi *et al.*[25] determined K_{th} for soda-lime glass at 400°C and for borosilicate glass in water at room temperature, respectively. In these studies the threshold was defined as the point in the strength distribution at which the 'twisting' starts. This approach is based on the assumption that the element of the distribution from which 'twisting' starts corresponds to the specimen subjected to a stress intensity factor equal to or lower than the threshold. If the data output used to draw Figs 5 and 6 are considered, the elements subjected to $K = K_{th}$ can easily be identified. The points corresponding to these specimens are marked with the letter X in Fig. 7, which shows three of the distributions presented in Fig. 5(a). It is evident that the points denoted as X_1 and X_2 are not the same as the points at which the twisting becomes significant. As already pointed out in the earlier analysis, specimens that do not show any strength degradation may not have been subjected to a stress intensity factor value lower than K_{th} (Fig. 1). When experimental data are considered, detection of the points denoted as 'X' in Fig. 7 is an even more formidable task as the current analysis did not include the type of scatter seen experimentally. If points like those marked with 'Y' in Fig. 7, are considered in place of 'X', this leads to an overestimation of the fatigue limit. For example, the use of points Y_1 and Y_2 leads to threshold estimates of

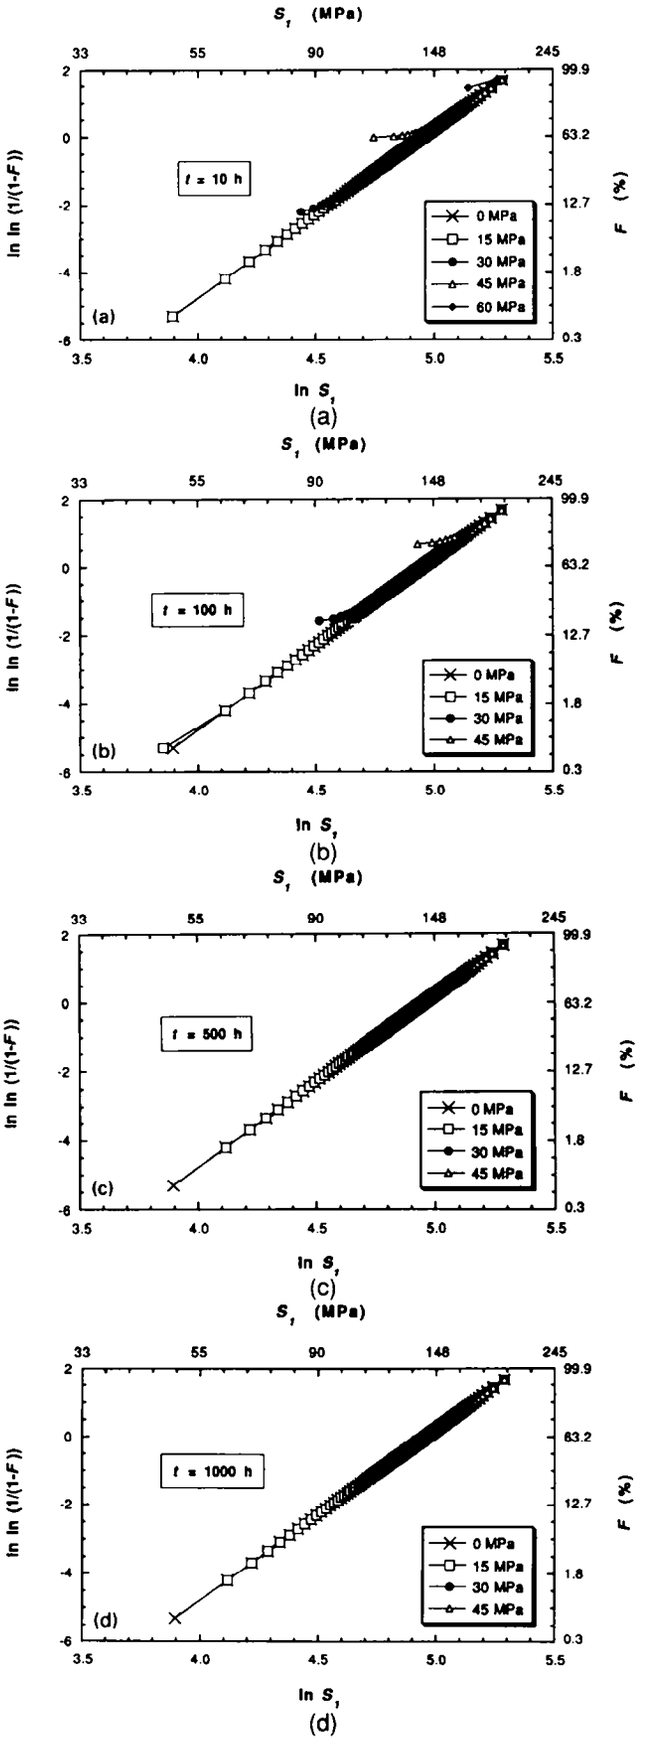

Fig. 6. Weibull plot of the strength distribution of soda-lime silicate glass after the holding at different stress levels for (a) 10 h, (b) 100 h, (c) 500 h and (d) 1000 h. The initial strength distribution corresponds to an applied stress of 0 MPa.

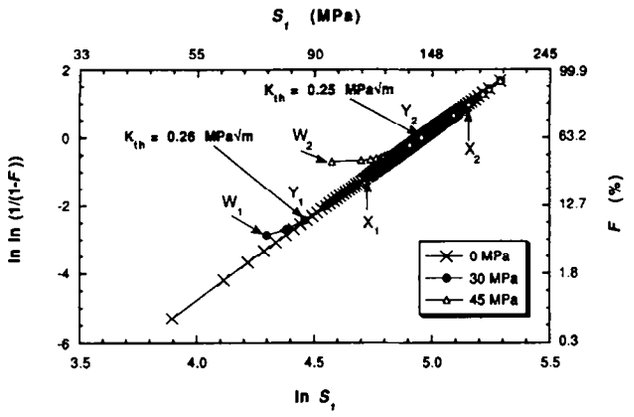

Fig. 7. Weibull plot of the strength distribution after the holding at two different stress levels for 1 h (Fig. 5(a)). The initial strength distribution corresponds to the applied stress of 0 MPa. Some elements of the distributions were removed around points marked with 'X' and 'Y' for better clarity. Explanation of points 'X', 'Y' and 'W' is given in the text.

0·26 and 0·25 MPa √m, respectively, instead of the value assumed in the analysis (0·2 MPa √m).

On the basis of the presented simulation (Figs 5 and 6), a different approach to threshold estimation is proposed. If the weakest specimen of the distribution (marked as 'W' in Fig. 7) is considered, the corresponding stress intensity factor K_W tends to, and then equals, the threshold, as the holding time is increased, as shown in Fig. 8. This shows that calculated K_W values correspond to the previously assumed fatigue limit (0·2 MPa √m) for $t \geq 500$ h, when $N = 100$. One would expect that the number of specimens used for each test condition would be important, as this increases the range of K_h values (Fig. 5); that is, one is more likely to obtain $K_h < K_{th}$ and more specimens would break during the constant stress phase. Clearly, using a larger number of specimens influences both economics and duration of the experimental work.

A final step in the simulation was performed by using data shown in Fig. 6 in order to plot the strength as a function of the applied stress intensity factor. Average values (K_{av}) of the stress intensity factor applied during the hold were calculated from the initial average strength from eqn (6). The average strength after holding, and

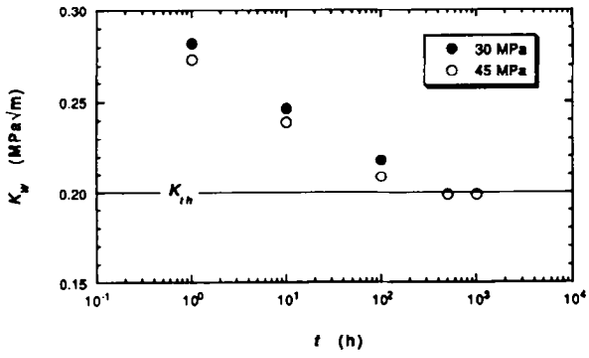

Fig. 8. Stress intensity factor K_w corresponding to the weakest sample of the strength distributions after the ISF test at stress levels of 30 and 45 MPa (Figs. 5(a) and (6)) as a function of the holding time t. Symbols at t equal to 500 and 1000 h are overlapped.

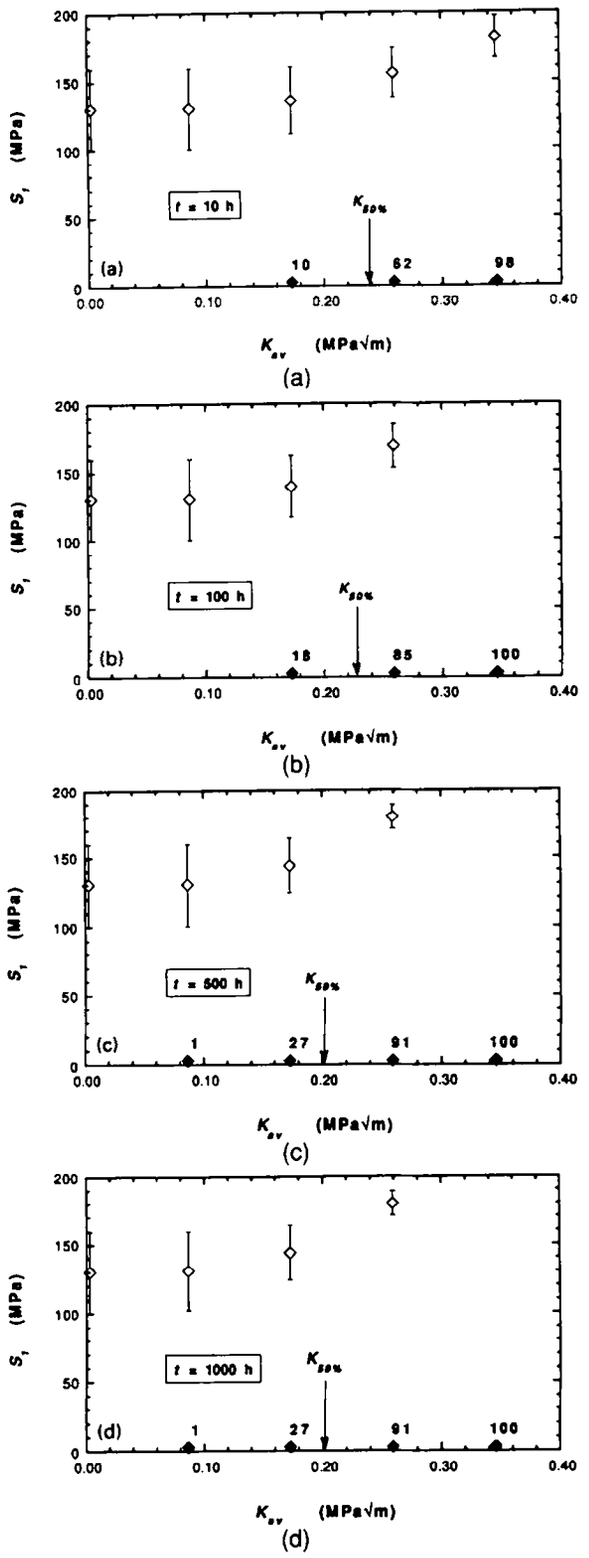

Fig. 9. Average strength S_f after the holding at different stress levels as a function of the applied stress intensity factor K_{av} for holding times of (a) 10 h, (b) 100 h, (c) 500 h and (d) 1000 h. The initial strength is shown at $K_{av} \approx 0$ MPa √m. Both S_f and K_{av} were calculated on the basis of results shown in Fig. 6. The numbers close to the solid symbols represent the number of specimens failing during the hold. The stress intensity factor $K_{50\%}$ corresponding to failure of 50% of the specimens during the hold, was calculated by linear interpolation.

corresponding standard deviation, were determined from data in Figs 5 and 6. Figure 9 shows the results for $N = 100$. The number of samples failing during the stress hold is also shown and the stress intensity factor ($K_{50\%}$) corresponding to the failure of 50% of the specimens during the hold is shown. $K_{50\%}$ is meant to represent the value of the stress intensity factor at which the average of the strength S_1 tends to zero in eqn 4(a). In Fig. 9, $K_{50\%}$ was calculated, by linear interpolation, as the stress intensity factor at which 50 specimens failed. As was previously pointed out, it is evident that $K_{50\%}$ tends to, and then equals, the fatigue limit as t increases. These calculations suggest a second approach to threshold determination, i.e. design the ISF test such that specimens break during the hold time and then increase the hold time.

4 Suggestions for a Correct Procedure for the ISF Test

The results presented in the last section suggest appropriate procedures for the measurement of the fatigue limit for sub-critical crack growth.

Two different approaches have been suggested. The first one is related to the determination of the strength distribution changes for specimens that survive the hold period, while the second one considers the changes in the average strength values. Suggested procedures for these two approaches are given below.

4.1 Strength of weakest specimen approach

The initial strength distribution (S_{0j}) must be determined in an inert environment. Samples are then subjected to the ISF test using constant stress σ for a time t. Knowledge of the fatigue parameters n and B from dynamic fatigue experiments is very useful as it allows one to estimate σ^* and K^* values from eqns (4) and (7). If an estimated value of the threshold is available, σ and t can be decided on the basis of σ and K^*, such that some failures will occur during the static hold. Strengths are also measured in the inert environment after the ISF test to obtain the distribution S_{1j}. A strength of zero is assigned to samples that fail during the stress hold and this allows one to obtain the censored distributions such as those illustrated in Figs 5 and 6. The weakest sample is identified and its rank in the strength distribution allows its strength (S_{0w}) to be defined from the previously determined initial strength distribution. The stress intensity factor K_w applied to this weakest sample can then be calculated as:

$$K_w = K_c \left(\frac{\sigma}{S_{ow}} \right) \tag{11}$$

Knowledge of the toughness K_c is essential for a precise definition of K_w. The value of K_w is then determined at the same hold stress but with increasing hold times. When K_w becomes invariant with hold time, $K_w = K_{th}$.

This first approach is considered to be preferable for materials with lower Weibull moduli. In fact, due to the large strength scatter when m is low, only a few trials are necessary to identify the stress and times required for the hold periods. Conversely, for very narrow strength distributions, several trials could be necessary before the optimal applied stress value can be identified.

It has been outlined that the strength measurement should be performed in an inert environment. Determination of K_w from eqn (11) requires the inert strength to be known. Unfortunately, inert conditions are sometimes difficult to obtain, especially when the behaviour of materials at high temperatures is considered. When the strength is measured in an active environment, it is usually lower than the inert value and this results in an overestimation of the threshold.

4.2 Hold period failure approach

In this alternative approach, the average initial strength S_{0av} is measured. Then samples are subjected to some ISF tests in which different stress levels are used for a certain time t. In this case, values of σ and t can be a decided on the basis of the assumption of a particular value for the threshold and from a knowledge of n and B. The number of samples failing during the hold at each stress level is recorded and the applied stress corresponding to 50% of samples failing during the hold ($\sigma_{50\%}$) can be calculated by easy linear interpolation. The corresponding stress intensity factor is given by

$$K_{50\%} = K_c \left(\frac{\sigma_{50\%}}{S_{0av}} \right) \tag{12}$$

As in the previous case, the hold time is increased and, once $K_{50\%}$ becomes invariant with hold time, $K_{50\%} = K_{th}$.

This second approach is considered to be appropriate for materials with large Weibull moduli. First of all, the precision of the average strength and of the number of samples failing during the hold is higher for larger values of m. In addition, several trials could be necessary to determine $\sigma_{50\%}$ precisely for wider strength distributions. Interestingly, in this approach, determination of the strength after the holding is not even necessary unless the purpose of the study is also to detect some strengthening effect taking place during the hold, for instance a strength increase could be correlated to crack tip blunting.[34–37]

5 Conclusions

A theoretical simulation of the interrupted static fatigue (ISF) tests, used for the evaluation of the fatigue threshold K_{th}, was presented. The behaviour of SiC at 1400°C and soda-lime glass in water at room temperature was analysed using fracture mechanics principles. The analysis considered changes in both the average strength values and strength distribution as a result of a period of constant stress. The duration of the ISF test and the applied stress turned out to be extremely important for a correct evaluation of the threshold. Optimal values for these two parameters can be calculated *a priori* from the fatigue parameters n and B, and from the assumption of a particular value of K_{th}. Two different approaches were proposed for fatigue limit determination. In the first case, a stress level is applied in order to obtain some failures during the hold, which then allow the 'interrupted' strength distribution to be determined. The stress intensity factor corresponding to the weakest sample that survives the hold is calculated as the estimate for K_{th}, and this value is then determined as a function of increased hold time. In the second approach, sample sets are subjected to various stress levels. The stress intensity factor corresponding to 50% of failures occurring during the stress hold is assumed as the estimate K_{th}. The value of K_{th} is than re-determined as a function of hold time until it becomes invariant. The two approaches outlined above were considered to be preferable for materials with lower and higher Weibull moduli, respectively.

Abstract

The potential for preparing a ZrO_2-containing ceramic composite based on barium feldspar ($BaAl_2Si_2O_8$) using the reaction sintering of zircon has been investigated. It is demonstrated that, through the reaction of $ZrSiO_4$, Al_2O_3 and $BaCO_3$ above 1400°C, a distribution of ZrO_2 particles in a $BaO{\cdot}Al_2O_3{\cdot}2SiO_2$ matrix can be achieved. A glassy phase rich in Si and Ba surrounds the zirconia particles and infiltrates the grain boundaries of the polycrystalline feldspar matrix. The tendency of the ZrO_2 particles to agglomerate within the matrix can be reduced by incorporating additional silica into the reaction, while limited stabilisation of tetragonal ZrO_2 can be achieved by additions of Y_2O_3 which partition between the ZrO_2 and the glassy boundary phase.

Introduction

Zircon ($ZrSiO_4$) is a natural mineral resource known to react with certain oxides to produce a dispersion of zirconia particles within ceramic or glass–ceramic matrices. The reaction of zircon with alumina results, for example, in a ZrO_2–mullite composite material, while the reaction of zircon with alumina and magnesia or alumina and calcia produces ZrO_2-containing cordierite and anorthite, respectively.[2–5] These composite materials, obtained by the reaction sintering method in which consolidation of individual particles is accompanied by a chemical reaction, have often been shown to possess high thermal stability and improved fracture toughness, the latter being a direct consequence of the transformation toughening effect associated with the included ZrO_2 particles.[7]

Barium aluminosilicates, particularly the celsian polymorphs of $BaO{\cdot}Al_2O_3{\cdot}2SiO_2$, display oxidation resistance and refractory characteristics commensurate with the properties required of high temperature materials.[8–10] The orthorhombic (α) and hexagonal (β) phases of hexacelsian ($BaAl_2Si_2O_8$) possess thermal expansion coefficients of $7{\cdot}1 \times 10^{-6}$/°C and $8{\cdot}0 \times 10^{-6}$/°C, respectively,[11] while the monoclinic phase, simply termed celsian, has a melting point of 1760°C and a thermal expansion coefficient as low as $2{\cdot}29 \times 10^{-6}$/°C.[11] Zirconia has a thermal expansion coefficient of $6–10 \times 10^{-6}$/°C[12] which is comparable to that of the hexacelsian polymorphs and is therefore expected to minimise the thermal expansion mismatch within a composite material comprised of hexacelsian and zirconia. Such thermal properties, coupled with the high melting point of ZrO_2 (2680°C) suggest that barium aluminosilicates and zirconia are an ideal combination from which to fabricate high temperature materials. A recent study has indicated that a barium aluminosilicate containing up to 40 mol% ZrO_2 can be prepared via a sol–gel process.[13] However, the desire to utilise a natural resource in the form of zircon in the present work has led to the choice of reaction sintering as an alternative processing route. Reaction sintering is becoming increasingly attractive as a ceramic processing technique because of its simplicity and cost efficiency, and reaction sintering of zircon is a particularly effective means of dispersing zirconia grains into ceramic matrices. The current work was undertaken to investigate the possibility of forming a zirconia-containing barium feldspar composite material using the reaction sintering of zircon and assuming the following stoichiometric reaction:

$$2ZrSiO_4 + BaCO_3 + Al_2O_3 \rightarrow 2ZrO_2 + BaO{\cdot}Al_2O_3{\cdot}2SiO_2 + CO_2 \uparrow \quad (1)$$

Experimental Procedures

The starting powders used were $ZrSiO_4$ (Cerac 99% pure, average particle size approximately 3·5 μm), $BaCO_3$ (AJAX Chemicals, 99% pure), SiO_2

* To whom correspondence should be addressed.

(AJAX Chemicals, precipitated) and Al_2O_3 (AJAX Chemicals). Stabilisation of ZrO_2 was achieved through the addition of Y_2O_3 (Cerac 99·9% pure). The powders were hand-mixed for 20 min in an alumina mortar and pestle with a small amount of isopropanol added for lubrication. Batches of about 2·5 g were compressed uniaxially in a compaction die to produce pellets approximately 14 mm in diameter. The pellets were placed in a high purity alumina crucible and fired in a rapid heating furnace in which temperatures of up to 1600°C could be achieved in 80 min, and a cooling rate of 20°C/min was employed. The mercury displacement method was used to determine the bulk density of sintered samples.

Phase identification for the sintered samples was carried out using X-ray diffraction (XRD) on a Rigaku Geigerflex diffractometer with Cu K_α radiation and a Ni filter. Samples for scanning electron microscopy (SEM) were mounted, ground on SiC paper and polished prior to being carbon coated and examined in a JEOL JSM840A scanning electron microscope operating at 20 kV. Samples for transmission electron microscopy (TEM) were cut, polished, ion-beam milled to perforation, carbon coated and then examined in a Philips EM420 TEM operating at 120 kV and equipped with an EDAX PV9900 energy dispersive X-ray spectrometer.

Results and Discussion

Sample preparation

Initial nominal compositions of the samples prepared are shown in Table 1. The progress of reaction sintering, the densification behaviour of the samples and the microstructures produced were studied in detail using a variety of techniques.

Crystalline phases

The reaction sequence of the system was studied by obtaining XRD spectra from samples sintered for 2 h at temperatures of 1000–1600°C at 100°C intervals. The positions of characteristic peaks at each of the given temperatures allowed for the identification of phases as the reaction progressed. With changes in the sintering temperature the starting powders reacted to form intermediate phases as well as the final products. By comparing the intensities of peaks corresponding to the reactants it was possible to obtain an indication of when these phases disappeared. Similarly, the emergence of new phases could also be monitored as the reaction progressed, and the relative intensities of corresponding characteristic peaks were used to define approximately the proportions of the phases as a function of sintering temperature. Representative XRD spectra of samples sintered for 2 h at 1300 and 1600°C are shown in Fig. 1(a) and (b), respectively, while the results in Fig. 2 illustrate the relative proportions of phases detected at different sintering temperatures.

The onset of zircon dissociation is evident at approximately 1100°C. This compares favourably

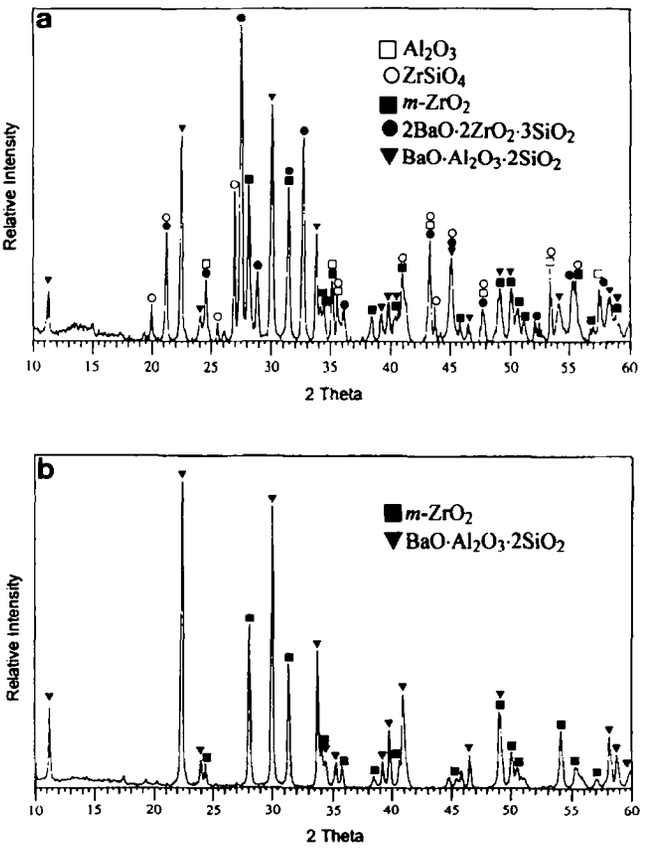

Fig. 1. XRD traces of samples sintered for 2 h at (a) 1300°C and (b) 1600°C.

Table 1. Nominal compositions of samples prepared (wt%)

Sample	*$ZrSiO_4$*	*Al_2O_3*	*$BaCO_3$*	*SiO_2*	*Y_2O_3*
1—Reaction 1	55·1	15·3	29·6	—	—
2—Reaction 2	33·8	18·9	36·4	11·1	—
3—Yttria stabilised (4%)	54·2	15·0	29·2	—	1·5
4—Yttria stabilised (8%)	53·3	14·8	28·7	—	3·1
5—Yttria stabilised (12%)	52·4	14·6	28·2	—	4·8

Reaction (1) is defined by the stoichiometric equation while reaction (2) incorporates additional silica into the reaction. Compositions 1 and 2 correspond to reactions (1) and (2), respectively, while compositions 3, 4 and 5 are free of additional silica and lead to sintered products in which the Y_2O_3 concentration corresponds to 4, 8 and 12 wt% of the anticipated ZrO_2 content.

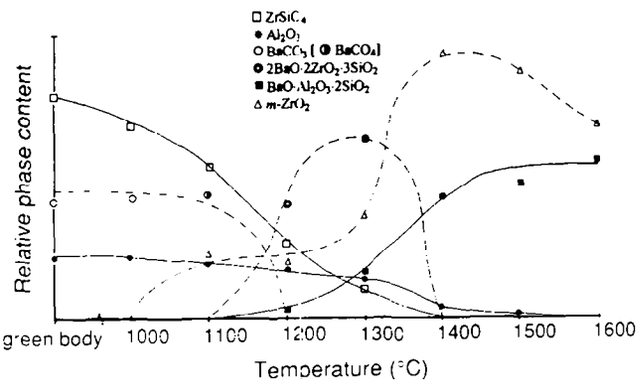

Fig. 2. Reaction sequence showing approximately the relative proportion of major phases present as a function of sintering temperature.

with the dissociation temperature of pure zircon of 1670°C, indicating that the presence of the other components significantly lowers the temperature at which the constituents, ZrO_2 and SiO_2, are obtained. The dissociation of zircon at 1100°C is accompanied by the appearance of monoclinic zirconia, m-ZrO_2. The SiO_2 obtained from the dissociation is not detected as a crystalline phase and is thus assumed to exist in an amorphous state. At this temperature, barium carbonate has undergone a structural change from $BaCO_3$ to a phase identified as $BaCO_4$,[14] but no evidence of decomposition of this phase was observed.

At 1200°C, the zircon content has further diminished and the barium carbonate has completely decomposed. The ZrO_2 and BaO thereby attained manifest themselves in the formation of an intermediate phase, $2BaO{\cdot}2ZrO_2{\cdot}3SiO_2$,[15] which also utilises the SiO_2 formed at lower temperatures. Furthermore, a slight reduction in Al_2O_3 is observed at this temperature, a barium aluminosilicate phase (hexacelsian) starts to emerge and a barium silicate phase, $2BaO{\cdot}3SiO_2$,[16] is also detected. However, since the latter phase was only observed at 1200°C it is not represented by a separate curve in Fig. 2.

At 1300°C, the Al_2O_3 and $ZrSiO_4$ contents continue to decrease, the transitory barium silicate phase has disappeared and the proportions of m-ZrO_2, hexacelsian and $2BaO{\cdot}2ZrO_2{\cdot}3SiO_2$ have increased. On heating to 1400°C, the decomposition of $ZrSiO_4$ is essentially complete and the Al_2O_3 content shows a marked reduction. This coincides with a maximum in the ZrO_2 content and increasing formation of hexacelsian. These observations may be explained by the complete dissociation of the barium zirconium silicate ($2BaO{\cdot}2ZrO_2{\cdot}3SiO_2$), which reacts with Al_2O_3 and thereby allows for the formation of hexacelsian.

At 1500°C only a trace of Al_2O_3 is detected, with the dominant phases being the reaction products, hexacelsian and ZrO_2. Zirconia is present only as the monoclinic phase since no stabilising oxide has been added at this stage to allow for the stabilisation of tetragonal zirconia. It is noted that a reduction in the ZrO_2 content occurs and this may be explained by the dissolution of ZrO_2 in the residual liquid. The solubility of ZrO_2 increases with increasing temperature and hence a further reduction in ZrO_2 is observed at 1600°C. By 1600°C, the initial powders have completely reacted to form hexacelsian and m-ZrO_2.

The detection of hexacelsian in these samples is interesting and perhaps raises questions concerning the existing understanding of this material. It is commonly reported that the barium aluminosilicate of composition $BaAl_2Si_2O_8$ may exist as one of three crystallographic phases: α-hexacelsian (orthorhombic), β-hexacelsian (hexagonal) and celsian (monoclinic).[8–11] Monoclinic celsian is stable thermodynamically below 1590°C, whereas β-hexacelsian is stable above 1590°C. However, the transformation between β-hexacelsian and celsian occurs sluggishly, so that β-hexacelsian may persist as a metastable phase below 1590°C.[8] Furthermore, it has been reported that at approximately 300°C, β-hexacelsian undergoes a rapid, reversible displacive transformation to metastable orthorhombic α-hexacelsian and that this transformation is accompanied by a 3–4% volume expansion, which is large enough to potentially cause deterioration of the material during cooling.[17] The α and β forms of hexacelsian are based on similar lattices and, given the similarity in interplanar spacings for the two phases, it proved impossible to distinguish between them in the current samples using X-ray diffraction.[18] However, there was little metallographic evidence of significant cracking in the matrix of the sintered samples suggesting that the β-hexacelsian may have been retained as a metastable phase, and that the transformation to orthorhombic α-hexacelsian may have been suppressed on cooling to room temperature.

The preferential formation of metastable hexacelsian rather than monoclinic celsian has previously been ascribed to structural differences.[8] The high symmetry hexagonal and orthorhombic forms may be described in terms of infinite two-dimensional hexagonal sheets consisting of two layers of $(Si,Al)O_4$ tetrahedra, whereas the low symmetry celsian consists of a three-dimensional structure in which the four vertices of the tetrahedra are shared. In both structures, some substitution of Al for Si occurs in the tetrahedra and charge compensation by Ba is provided through its location either between the sheets, in the case of hexacelsian, or in the larger interstices of the celsian structure. The

two-dimensional high symmetry forms therefore have lower kinetic barriers for nucleation and are consequently formed first. Nevertheless, with a suitable additive it may be possible to stabilise monoclinic celsian in these materials.[19]

Densification

The sintering behaviour was further monitored by measuring the density of the sintered samples as a function of temperature and the results are presented in Fig. 3. The initial reduction in the density up to 1200°C may be the result of the decomposition of $BaCO_3$. The CO_2 gas evolved during this decomposition will, if trapped in the sample, expand with further heating, and thereby cause an expansion of the specimen. With continued heating, chemical reaction begins accompanied by particle coalescence and sample shrinkage occurs. A significant increase in the rate of densification is observed above 1300°C and a maximum density of 3·52 g/cm^3 is obtained at 1500°C. It is thought that the melting of the intermediate phase ($2BaO{\cdot}2ZrO_2{\cdot}3SiO_2$) above 1300°C provides a low temperature eutectic liquid which facilitates the rapid densification. The relatively lower density measured at 1600°C is attributed to the bloating effect prevalent in these samples, a phenomenon which may be a result of the instability of the low temperature eutectic liquid phase. In addition, the transformation of zirconia from tetragonal to monoclinic symmetry on cooling produced cracks in samples sintered above 1200°C and this may also have contributed to a reduction in the measured density. The trends observed in the densification process were substantiated by dilatometry measurements, although the results obtained are not presented here.

Scanning electron micrographs were obtained at various stages of the reaction sequence to illustrate particle arrangement and distributions at each temperature. Since little microstructural change occurred on sintering below 1300°C, only those samples prepared at the higher sintering temperatures ($T \geq 1300$°C) where the most significant changes occurred, are represented in Fig. 4.

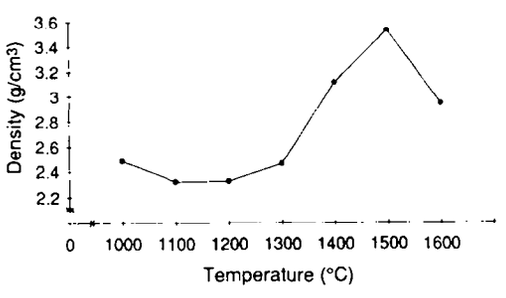

Fig. 3. Density as a function of temperature for samples prepared according to reaction 1. Rapid densification is seen to take place at temperatures immediately above 1300°C.

The emergence of a liquid phase occurs at 1300°C (arrowed, Fig. 4(a)); however, since only a small amount of this phase is formed, no significant densification is achieved at this temperature. At 1400°C, Fig. 4(b), there are significant pores present but individual grains of starting powder are no longer distinguished. The lighter contrast regions in Fig. 4(b) are ZrO_2-rich and comprise clusters of small spheroidal grains with a morphology typical of a product forming in the presence of a liquid phase. The microstructural observations are consistent with both density and X-ray results which suggest that chemical reaction and densification are significantly accelerated between 1300 and 1400°C. At 1500°C, Fig. 4(c), the dispersion of ZrO_2 particles is clearly evident, although the tendency to form agglomerates is common. At 1600°C, Fig. 4(d), the reaction is essentially complete and spherical ZrO_2 particles, between 1 and 3 μm in diameter, remain as agglomerates within the feldspar matrix.

The results to this stage support the feasibility of using a reaction sintering approach to fabricate a ZrO_2/hexacelsian composite material. A significant porosity is observed in all samples and the ZrO_2 particles remain in localised clusters, often in association with pores. In addition, as a result of the tetragonal (*t*) to monoclinic (*m*) transformation within the ZrO_2 grains on cooling, these particles are of monoclinic symmetry with the ensuing cracks in the samples being a direct consequence of the volume expansion associated with this transformation.

Stabilisation of ZrO_2

In order to prevent cracking of the samples, it was necessary to suppress the spontaneous *t* to *m* transformation in the ZrO_2 particles on cooling through the addition of a suitable stabilising oxide. As shown in Table 1, the compositions were adjusted to incorporate additions of Y_2O_3 corresponding to 4, 8 and 12 wt% of the expected ZrO_2 content, and subsequent sintering was performed at 1500°C for 2 h. According to the ZrO_2–Y_2O_3 phase diagram,[20] at 1500°C the 4 wt% composition is located in the tetragonal phase field; the 8 and 12 wt% compositions lie in the tetragonal/cubic phase field. Provided that the Y_2O_3 partitions to the ZrO_2 during reaction sintering, the precipitation of transformable metastable *t*-ZrO_2 might therefore be expected on cooling and hence phase transformation toughening may become possible at room temperature.

In contrast to the yttria-free samples, all the samples with additional yttria displayed negligible cracking after sintering. As shown in Table 2, X-ray diffraction suggested that increasing fractions

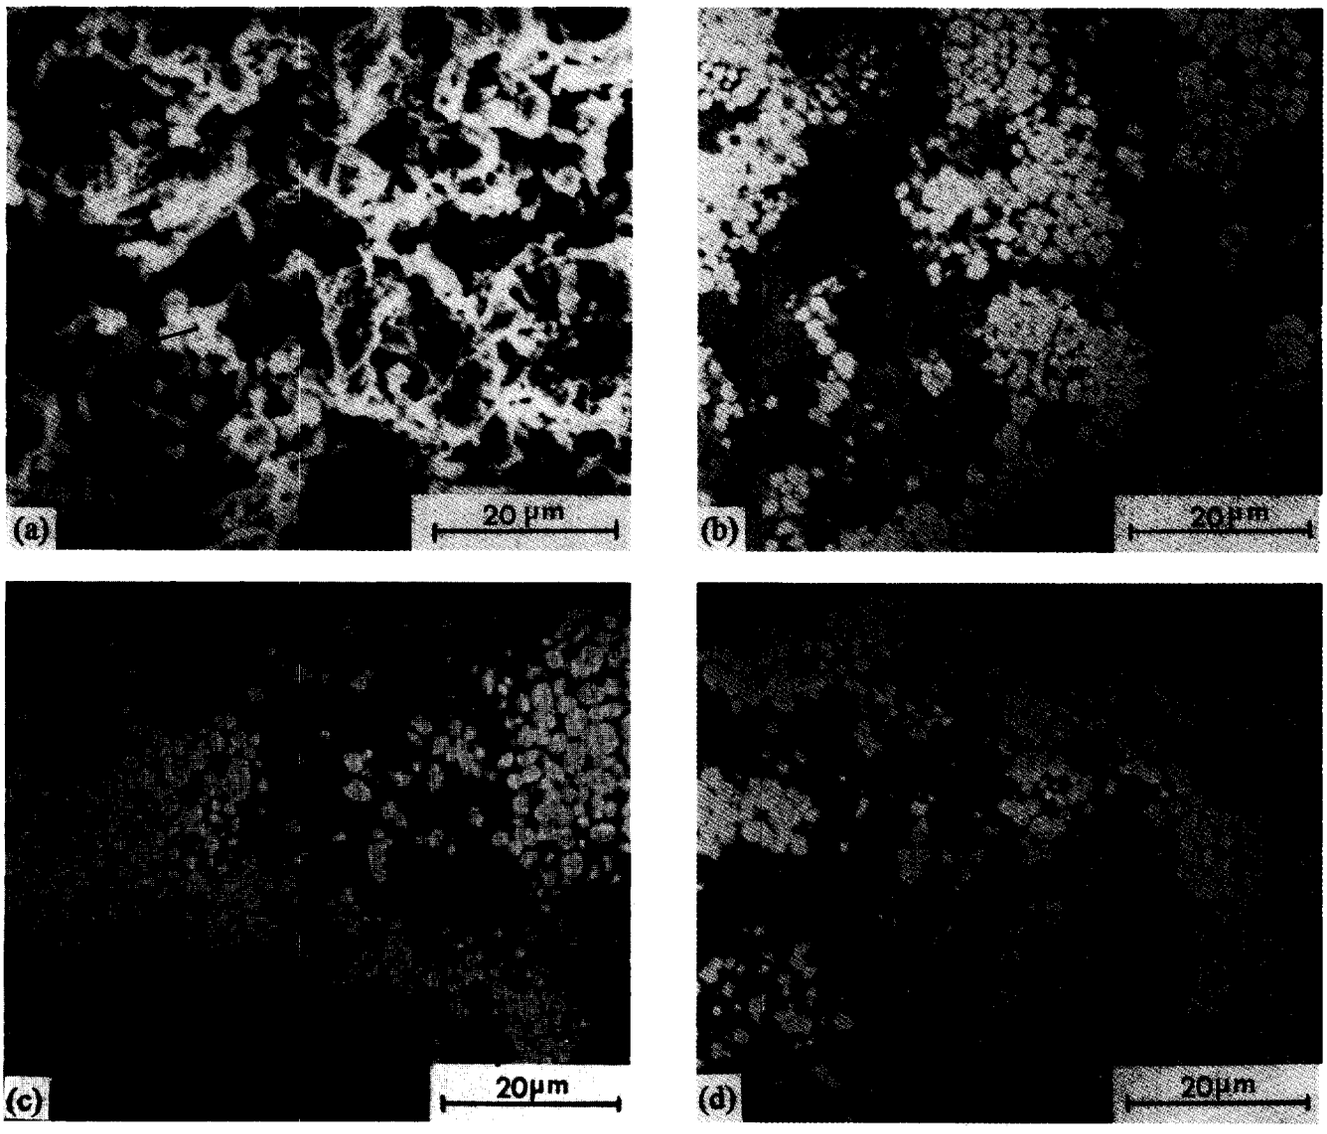

Fig. 4. SEM images depicting the microstructures obtained when sintering for 2 h at (a) 1300°C (b) 1400°C (c) 1500°C and (d) 1600°C.

of zirconia were stabilised as tetragonal phase with increasing yttria content. Moreover, in samples containing 4 and 8 wt% Y_2O_3, the ratio of monoclinic to tetragonal zirconia was found to be increased after grinding the samples to a fine powder using a mortar and pestle, see Table 2. Since the mechanical stresses associated with this grinding are comparable to the stresses located around a crack tip, these results are indicative of the potential for a toughening increment to be achieved through the stress-induced transformation of zirconia dispersed within the composite. It is noted that analysis of the XRD data was complicated by overlap between the (111) t-ZrO_2 peak and what is either the (112) peak of α-hexacelsian or the (102) peak of β-hexacelsian. However, a comparison of peak intensities corresponding to m- and t-ZrO_2 is still useful, since the intensity of the feldspar peaks should be unaffected by grinding and any changes in the peak intensity at this location can be attributed entirely to changes in the fraction of t-ZrO_2.

Table 2. Ratio of monoclinic to tetragonal zirconia in the yttria-modified samples before and after grinding. Samples were sintered for 2 h at 1500°C

Y_2O_3 content	$I_m(11\bar{1})/I_t(111)$ before grinding	$I_m(11\bar{1})/I_t(111)$ after grinding
4%	29/100	41/100
8%	0/100	9/100
12%	0/100	0/100

Microstructural observation

A sample containing 4 wt% Y_2O_3 and sintered at 1500°C for 2 h was further characterised using transmission electron microscopy and energy dispersive X-ray spectroscopy (EDXS). As shown in Fig. 5(a), the microstructure contained local clusters of spheroidal ZrO_2 particles dispersed in an amorphous matrix. The domain substructure of the particles and the corresponding selected area diffraction pattern, Fig. 5(b), confirm that they are m-ZrO_2. The substructure of approximately twin-related domains arises during the displacive t to m transformation, in order to accommodate the shear

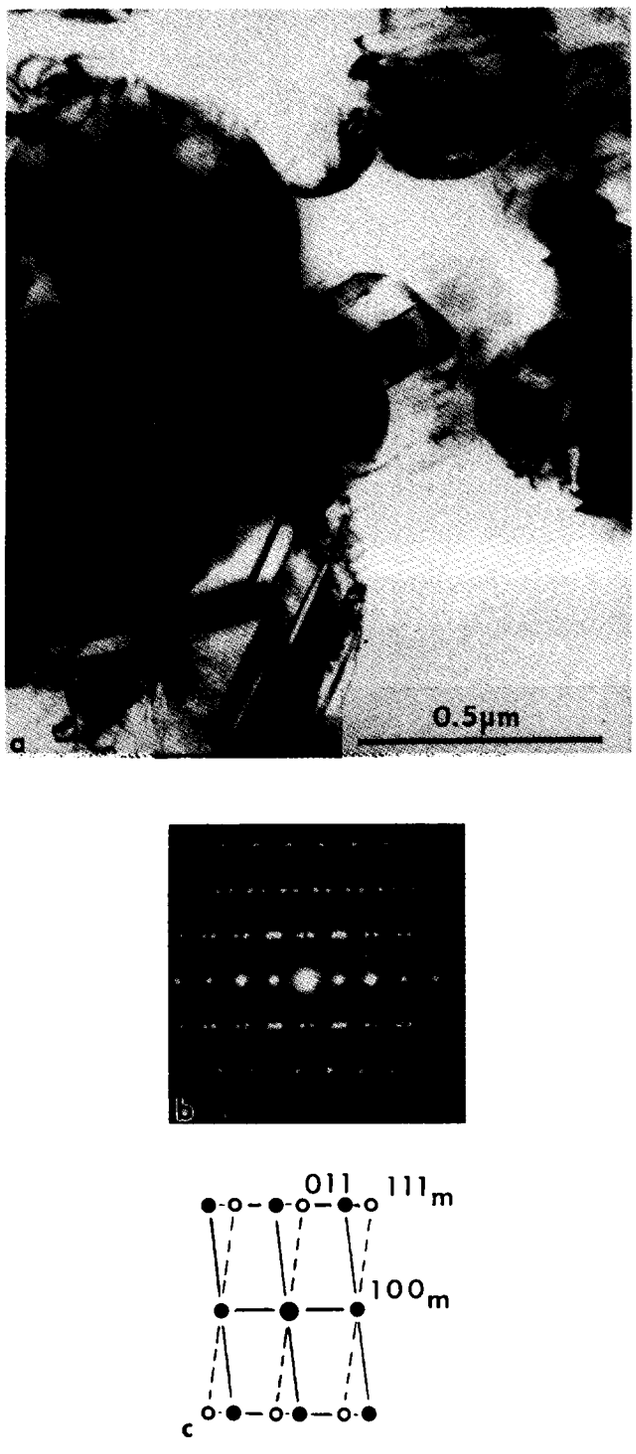

Fig. 5. (a) Bright field TEM micrograph of a sample containing 4 wt% Y_2O_3 and sintered for 2 h at 1500°C; (b) corresponding SAED pattern from single ZrO_2 particle, and (c) schematic solution to pattern containing two variants of the monoclinic phase twin-related about $(100)_m$. The zone axis is $[0\bar{1}1]_m$.

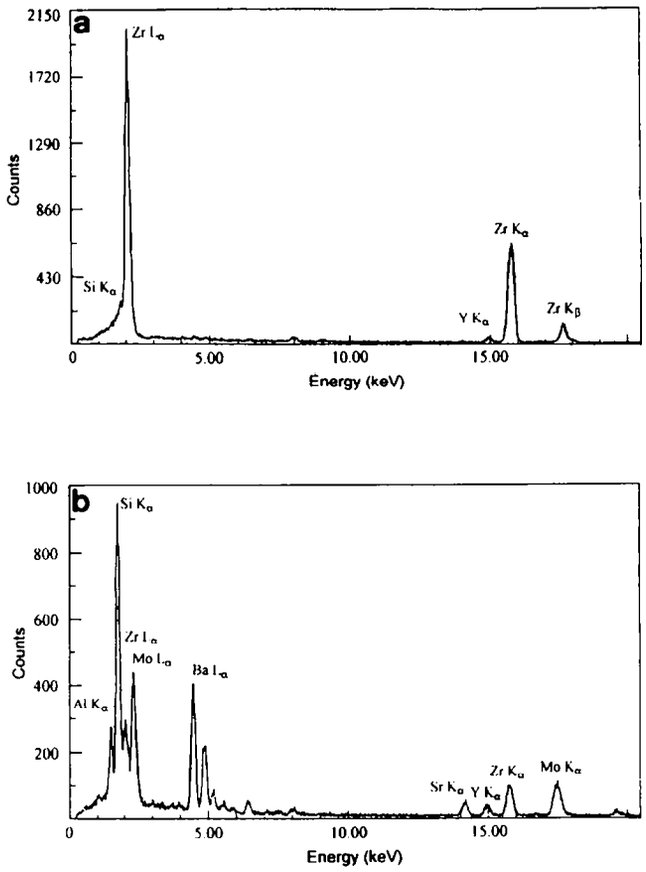

Fig. 6. EDX spectra from a sample containing 4 wt% Y_2O_3, sintered for 2 h at 1500°C. Spectra were recorded from (a) a zirconia grain shown in Fig. 5(a) and; (b) the glassy region seen in Fig. 5(a). The molybdenum recorded in Figure 5(b) is a contaminant resulting from ion-beam milling.

component of transformation. The absence of extensive microcracking around the particles indicates that the residual misfit strains around the particles may be accommodated by the glassy matrix.

X-ray microanalysis, Fig. 6(a), indicated that detectable concentrations of Y_2O_3 were present within the ZrO_2 grains. However, there was also a significant concentration of Y_2O_3 in the surrounding amorphous phase, indicating that an excess of Y_2O_3 may be necessary to stabilise the ZrO_2 as tetragonal phase. The detection of a significant fraction of tetragonal phase in X-ray diffraction patterns from this sample, and the failure to observe tetragonal phase in thin foil specimens, can probably be attributed to the tetragonal to monoclinic transformation occurring during preparation of the thin foil specimens upon relaxation of matrix constraint.

Figure 7 includes bright field images recorded from matrix regions of the same sample. In this case the structure is polycrystalline and the mixture of elongated and equiaxed grains were identified as metastable hexacelsian using electron microdiffraction. However, the diffraction patterns recorded from such grains, Fig. 8, could commonly be interpreted as being from either the high temperature hexagonal β form or the low temperature orthorhombic α phase. The pattern in Fig. 8(a) may, for example, be indexed as representing either a hexagonal $[2\bar{1}\bar{1}0]$ zone axis pattern or a [100] orthorhombic zone, while that in Fig. 8(b) is either a $[\bar{2}4\bar{2}3]$ zone axis pattern from the hexagonal phase or a $[\bar{2}01]$ pattern from the orthorhombic α. In the absence of detailed information on the crystal structures for the two phases it proved

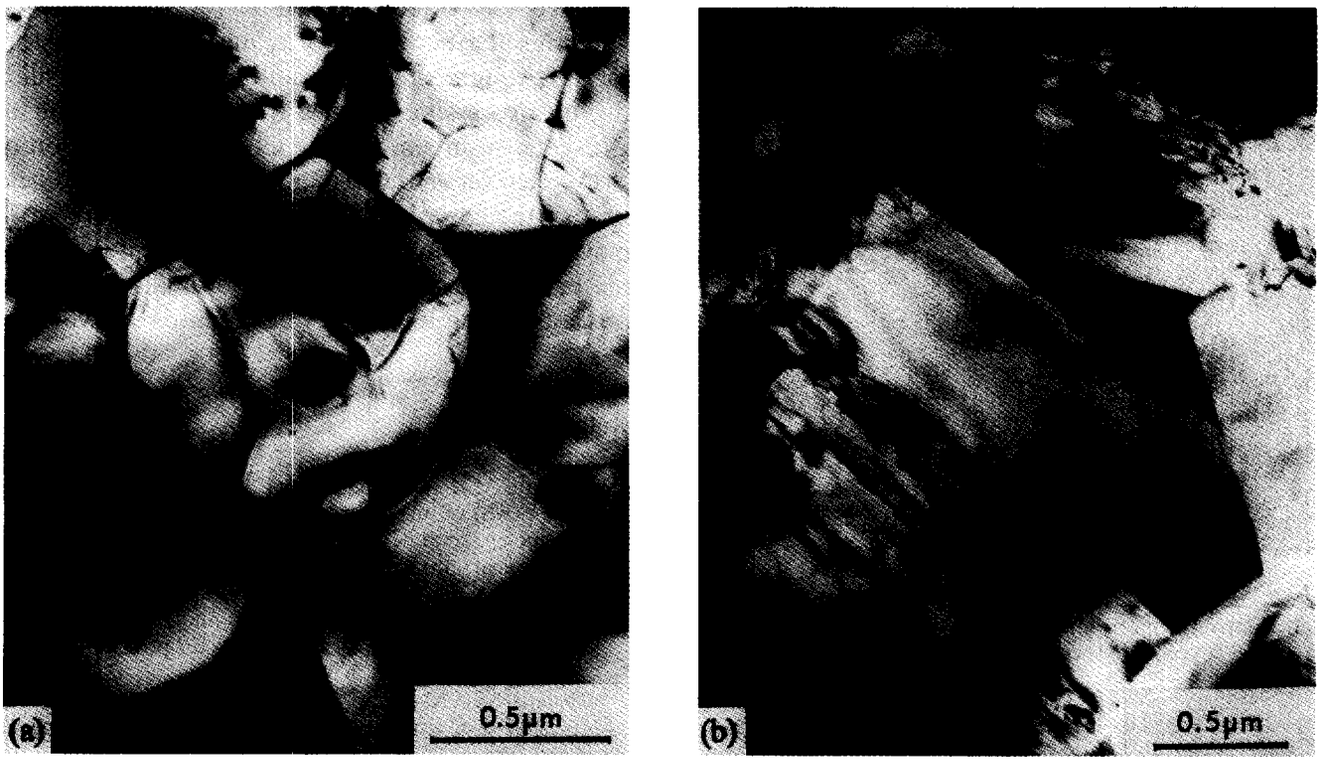

Fig. 7. Bright field TEM images showing (a) equiaxed and (b) elongated grains of hexacelsian.

impossible to identify zone axes for which patterns might be distinguishable for the two structures and thus impossible, in this preliminary study, to distinguish between the phases using electron diffraction. However, there was little or no evidence in the microstructure of the matrix of a solid state displacive transformation to the orthorhombic α-hexacelsian, or of the cracking or microcracking that might be expected to accompany such a transformation involving a 3–4% volume change. It is thus suggested that the hexagonal β-hexacelsian may have been retained as the dominant metastable phase at ambient temperature.

The micrographs of Fig. 7 indicate that the grains of hexacelsian were separated by a thin film of the same glassy phase as that surrounding the zirconia particles, and that there were pockets of glassy phase at grain triple junctions. Diffraction patterns recorded from such triple junctions contained diffuse rings consistent with an amorphous structure, and EDX spectra from such pockets, Fig. 6(b), indicated that the phase was Si-rich, with a high content of Ba. The composition is consistent with a glassy phase that is liquid during sintering to facilitate consolidation and the spheroidal form of the ZrO_2 grains is characteristic of the morphology that would be expected to develop during liquid phase sintering.

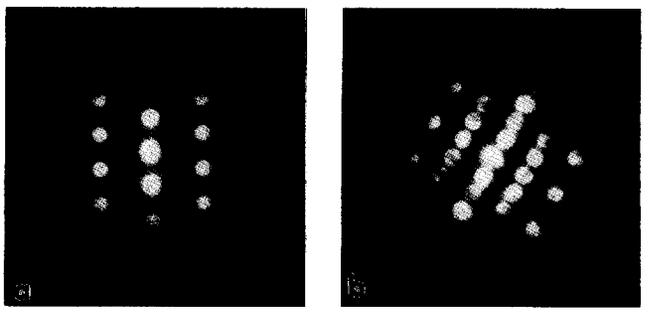

Fig. 8. Electron microdiffraction patterns recorded from hexacelsian grains which may be indexed as representing (a) a hexagonal $[2\bar{1}\bar{1}0]$ zone axis pattern or a [100] orthorhombic zone; and (b) a $[\bar{2}4\bar{2}3]$ zone axis pattern from the hexagonal β phase or a $[\bar{2}01]$ pattern from the orthorhombic α hexacelsian.

Effect of additional SiO_2

The stoichiometric reaction (1) yields a product with a molar ratio of zirconia to feldspar of 2:1. On the basis that the excess zirconia concentration may contribute to the inhomogeneous dispersion of zirconia agglomerates, additional SiO_2 was added in an attempt to improve the sinterability and homogeneity of the composites, assuming a reaction of the form:

$$ZrSiO_4 + BaCO_3 + Al_2O_3 + SiO_2 \rightarrow ZrO_2 + BaO{\cdot}Al_2O_3{\cdot}2SiO_2 + CO_2 \uparrow \quad (2)$$

It was anticipated that addition of SiO_2 would serve to form extra low temperature eutectic liquid phase and a comparatively lower zirconia concentration. A further series of samples was thus prepared under similar processing conditions, but with the composition of Sample 2 given in Table 1.

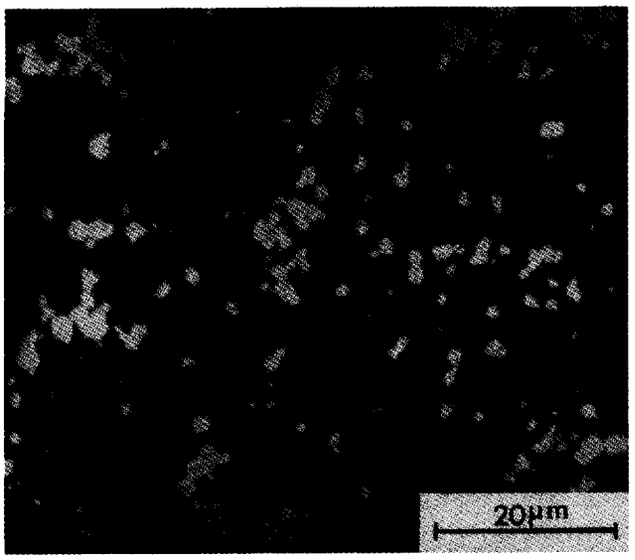

Fig. 9. SEM micrograph of Sample 2 sintered at 1500°C for 2 h, showing a more uniform distribution of ZrO_2 particles compared with that shown in Fig. 4.

The scanning electron micrograph recorded from the resulting sample is shown in Fig. 9 and indicates that the effective reduction in zircon content has resulted in a lower volume fraction and more uniform distribution of zirconia particles within the matrix. However, the improved distribution of the ZrO_2 particles seems to occur at the expense of the densification achieved. In fact, the highest density attained for the silica modified reaction was 2·87 g/cm^3 when sintering was carried out at 1500°C for 2 h. A possible explanation of this effect may lie in the origin of the silica. A finer, more uniform dispersion of amorphous SiO_2 produced from the dissociation of zircon may permit a more uniform formation of liquid phase that in turn facilitates densification more readily.

Conclusions

Reaction sintering of zircon with alumina and barium carbonate produces a composite material comprising distributed ZrO_2 in a continuous barium feldspar matrix. The spheroidal particles of ZrO_2 are in clusters surrounded by an amorphous phase rich in Si and Ba, and there is evidence that this glassy phase also infiltrates the grain boundaries of the polycrystalline feldspar matrix. Electron and X-ray diffraction results suggest that the matrix consists of either hexagonal (β) or orthorhombic (α) forms of hexacelsian ($BaO{\cdot}Al_2O_3{\cdot}2SiO_2$), or a combination of these two phases. Yttria added during processing partitions in part to the ZrO_2 allowing a significant fraction of the ZrO_2 to be retained as tetragonal phase at room temperature and thus the potential for a measure of transformation toughening. The addition of extra silica during processing reduces the volume fraction of ZrO_2 and results in a more uniform distribution of ZrO_2 particles. However, in this case the densification of the composite is less effective. Future work may focus on improving the dispersion of the zirconia particles by the use of attrition milling or other mixing–milling techniques of the initial powders.

Ca-acceptors in Dielectric Ceramics Sintered in Reducive Atmospheres

D. F. K. Hennings & H. Schreinemacher

Philips GmbH, Research Laboratories Aachen, P. O. B. 1980, 52021 Aachen, Germany

(Received 15 November 1994; revised version received 7 February 1995; accepted 14 February 1995)

Abstract

Dielectric ceramics of the system (Ba,Ca)(Ti,Zr)O_3 (BCTZ) have been fired with BaO-excess in reducive atmosphere. By the influence of BaO-excess the Ca^{2+}-ions are shifted from the Ba- to the Ti-sites of the perovskite lattice. The solubility of Ca^{2+} on Ti-sites is largely independent of the firing atmosphere, but shows a pronounced temperature dependence. At 1400°C ≅ 2 at.% Ca can be dissolved on the Ti-sites. Ca-ions on Ti-sites are strong electron acceptors. Highly insulating materials can be thus prepared in reducive atmospheres. The Ca-acceptors are electrically compensated by large numbers of ionized oxygen vacancies. Electromigration of the oxygen vacancies gives rise to ionic conductivity, resulting in low life stability of multilayer capacitors, sintered in reducive atmosphere.

1 Introduction

Up to now most of the dielectric materials used in ceramic multilayer capacitors (MLCs) are based on barium titanate. For a long time the dielectric ceramics have been cofired with inner electrodes of expensive palladium or palladium silver alloys. After decades of research and development[1,2] the manufacturers of MLCs are now capable of replacing the expensive noble metals by cheaper base metals, e.g. Fe, Co, Ni. Base metal electrodes (BME), however, have to be fired in a protective atmosphere of N_2/H_2 or CO/CO_2. In reducing atmosphere the $BaTiO_3$ forms large numbers of ionized oxygen vacancies,[2] $V(o)^{\bullet\bullet}$. Large numbers of conduction electrons then give rise to high electronic conductivity of the dielectric material, according to the reaction

$$V(o)^{x} \rightarrow V(o)^{\bullet\bullet} + 2e.$$

The semiconductance of reducive sintered $BaTiO_3$ ceramics can be, however, very effectively suppressed by addition of acceptor dopes. Classical acceptor dopes[1] for $BaTiO_3$ are the ions of Al, Cr, Mn, and Fe. These ions enter the B-sites (Ti-sites) of the perovskite lattice, forming there acceptor-type point defects, like $[Mn^{2+}{}_{(Ti)}]''$, $[Fe^{3+}(Ti)]'$ which strongly trap the conduction electrons.[3] Highly insulating dielectric materials can be thus prepared in reducing atmosphere. BME capacitors, made from acceptor doped $BaTiO_3$ dielectrics exhibit very high insulation resistances (IR) of $\geq 10^{12}\Omega$.[4]

One of the principal problems of transition metal acceptors is the valence instability of transition metal ions, e.g. Cr^{3+}, Mn^{2+}, Fe^{3+}, at a change of the oxygen partial pressure during heat treatment of the MLCs. For this reason manufacturers of BME–MLCs make use of calcium ions on Ti-sites, $[Ca^{2+}{}_{(Ti)}]''$, which have been reported as being very strong acceptors.[5,6] Chan *et al.*[7] found that Ca^{2+}-ions which are well known as A-site substituents may also enter the B-sites of $BaTiO_3$. In the case of BaO-excess a certain number of the Ca^{2+}-ions is shifted from the Ba- to the Ti-sites. Zhuang *et al.*[8] studied the effect of Ca-acceptors on the conductivity and dielectric properties of $BaTiO_3$. They observed a decrease of the tetragonal distortion (c/a) of the perovskite unit cell and a lowering of the Curie point, T_C, at the incorporation of $[Ca^{2+}{}_{(Ti)}]''$ in $BaTiO_3$. Zhang *et al.*[9] reported a maximum solubility of ≅ 5% $[Ca^{2+}{}_{(Ti)}]''$ in $BaTiO_3$.

High-permittivity dielectrics of the temperature specification Y5V are usually prepared from ceramic mixed crystals of the system $(Ba_{1-x}Ca_x)[Ti_{1-y}Zr_y]O_3$ (BCTZ). In BCTZ the Ca^{2+}-ions strongly prefer the Ba-sites of the perovskite lattice,[10] too. At 1300°C a maximum solubility of ≅ 20% $[Ca^{2+}{}_{(A)}]$ was found in $BaTiO_3$.[11] Incorporation of Ca^{2+} on the A-sites yields only slight changes of the lattice parameters and Curie point of $BaTiO_3$.

1.1 Aim of the investigation

The solubility of Ca on the Ti-sites of BCTZ is not yet known. Changes of the Curie point and

the unit cell volume will be therefore studied as function of the concentration of $[Ca_{(Ti)}]''$ in BCTZ. Subject of investigation are further the temperature dependence of the solubility of $[Ca_{(Ti)}]''$ and a possible change of the Ca^{2+}-ions from the B-sites back to the A-sites, $Ca_{(Ti)} \rightarrow Ca_{(Ba)}$, in CO_2 or oxidizing atmosphere. The insulation resistance and life stability of reducively sintered BCTZ is studied, using accelerated life tests (ALT).

2 Experimental

2.1 Preparation of BCTZ

The standard experimental material was BCTZ of the composition $(Ba_{0.95}Ca_{0.05})[Ti_{0.88}Zr_{0.12}]O_3$. The atomic ratio of A-site (Ba, Ca) and B-site ions (Ti, Zr) was carefully fixed by analytical means (XFA) at $A/B = 1 \pm 0.0015$. For this the raw materials TiO_2 ('TM1', Fuji Titanium Industries, Ltd, Osaka, Japan) and ZrO_2 ('EF-ULTRA', Z-Tech, Bad Homburg, Germany) had to be analysed for impurities, using ICP analyses and heated for 1 h at 1000°C in O_2 to remove slight oxygen deficits and traces of water. $BaCO_3$ and $CaCO_3$ (both analytical grade, Merck Darmstadt, Germany) were heated for 1 h in a CO_2 stream at 500°C. The small Sr-content of $\cong$ 0·2 wt% of the $BaCO_3$ was also considered at weighing in. The raw materials were mixed in isopropanole, using an agate ball mill and then calcined to perovskite at 1200°C (6 h) in air.

2.2 Sintering of ceramics

The atomic ratio A/B of the BCTZ was systematically varied by addition of appropriate amounts of TiO_2 or $BaCO_3$ in the range 0·005 mol TiO_2 to 0·15 mol $BaCO_3$. TiO_2 and $BaCO_3$ additives were finely distributed over prereacted BCTZ by wet milling in isopropanole, using 2 mm∅ ZrO_2 balls. Because of the poor sintering behaviour at $A/B > 1$ the powders must be intensively milled to $d_{50} \cong 0.4$ μm. The powders were uniaxially pressed at 3 kbar to discs of 6 mm diameter and 600 μm thickness. The predensified samples were fired for 2 h at 1400°C in a reducing atmosphere of moist (H_2O-20°C) N_2H_2-95/5. Theoretical densities were determined, using the lattice constants of sintered ceramics. Relative densities of 96–99% of the theoretical value were observed. The highest densities (≥99%) were found at the atomic ratio $A/B \cong 1$. With increasing $BaCO_3$ additions the densities decreased. After sintering the diameter of the discs was $\cong$ 5 mm and the thickness $\cong$ 500 μm.

2.3 XRD experiments

The lattice parameters of BCTZ ceramics were determined by means of X-ray diffraction (XRD), using Cu–K_α radiation. Due to the large size difference between Ca^{2+}- and Ti^{4+}-ions, strong changes of the lattice parameters are expected to occur at the incorporation of Ca^{2+} on the B-sites. The solubility of Ca on the B-sites was thus determined from the change of the unit cell volume in dependence of the molar amount of added $BaCO_3$.

2.4 Electrical measurements

For electrical measurements 500 μm thick ceramic discs were evaporated with CrNi–Au electrodes. The temperature dependence of the relative dielectric constant K was studied in the range -50°C to +150°C, using an automatic capacitance bridge (HP 4278 A). Similar to the lattice parameters also the Curie point T_C of BCTZ is assumed to change with the number of Ca-ions on B-sites. Hence, the solubility of $[Ca^{2+}{}_{(Ti)}]''$ was also determined from T_C changes as function of the BaO-excess in BCTZ.

The life stability of dielectric materials is commonly evaluated from long time measurements of the insulation resistance (IR) under electric field and temperature stress. The long time measurements were abbreviated by employing so-called accelerated life tests (ALT) under specially high temperature stress. The IR of such tested ceramics then breaks down after rather a short time. ALT experiments on BCTZ discs were performed at 250 V and 200°C.

2.5 Thermogravimetric (TGA) experiments

The incorporation of Ca on the B-sites of BCTZ was thermogravimetrically studied on powders, containing various additions of $BaCO_3$. $BaCO_3$-excess pushes the Ca^{2+}-ions from the A- to the B-sites, according to the reaction:

$$(Ba_{1-x}Ca_x)[Ti_{1-y}Zr_y]O_3 + z\ BaCO_3 \quad (1)$$

$$\rightleftharpoons$$

$$(Ba_{(1+z-x)}Ca_{(x-\frac{z}{2})})\ [Ti_{(1-y)}Zr_yCa_{\frac{z}{2}}]O_{3+z} + z\ CO_2$$

From eqn (1) it can be derived that for each Ca on B-sites two extra Ba-ions have to be incorporated on the A-sites. Thus, formation of $z/2$ $[Ca_{(Ti)}]$ corresponds to the addition of z $BaCO_3$. The weight loss due to evaporation of z CO_2 at the incorporation of z $BaCO_3$ was determined by means of TGA. One of the important questions to be answered by TGA were the extent and the reversibility of reaction (1) in different atmospheres.

According to reaction (1) the total number of perovskite unit cells increases by $z/2$ new units at the addition of z BaO to BCTZ. For $z/2$ new perovskite units a corresponding number of $3/2z$ oxygen ions would be necessary to fill up the oxygen sublattice. However, only a number of z O^{2-} is

available at the incorporation of z BaO. Hence, at the incorporation of z BaO a corresponding number of $z/2$ oxygen vacancies (V(o)) is generated. For each Ca^{2+} on B-sites therefore one oxygen vacancy is formed. In $BaTiO_3$ the Ca-acceptors are compensated by doubly ionized[3] oxygen vacancies.

$$[Ca^{2+}{}_{(B)}]'' \cong [V_{(o)}]^{\bullet\bullet} = z/2$$

The actual composition of BCTZ, containing Ca on A- and B-sites and oxygen vacancies is:

$$(Ba_{(A)1-x}Ca_{(A)x})[Ti_{(B)1-y-z}Zr_{(B)y}Ca_{(B)}{}''_z]O_{3-z}V_{(o)}{}^{\bullet\bullet}{}_z \quad (2)$$

After saturation of the B-sublattice with $[Ca^{2+}(B)]''$ an orthotitanate 2nd phase, similar to Ba_2TiO_4, is most probably formed on further addition of δ $BaCO_3$. The formation of orthotitanate is assumed to be analogous to the known reaction in $BaTiO_3$:

$$BaTiO_3 + \delta\ BaCO_3 \Leftrightarrow \delta\ Ba_2TiO_4 + (1-\delta)\ BaTiO_3 - \delta\ CO_2 \quad (3)$$

In BCTZ most probably a mixed crystal of $(Ba,Ca)_2TiO_4$ is formed.

For TGA experiments mixtures of BCTZ and z mol $BaCO_3$ in the range $z = 0{\cdot}01$ to $z = 0{\cdot}15$ were prepared. The powder mixtures were prereacted for 2 h at 1400°C in moist (H_2O-20°C) N_2/H_2-95/5. In the thermobalance the crushed powders were several times heated to 1250°C and cooled down to room temperature in streaming CO_2 ($\cong$ 1 bar). The weight changes due to uptake or loss of CO_2 were thus repeatedly measured.

3 Results

3.1 Unit cell volume

Corresponding to the expected shift of Ca^{2+} from A- to B-sites the unit cell volume strongly increased at the incorporation of BaO in BCTZ, see Fig. 1. Up to $BaCO_3$ additions of $z = 0{\cdot}05$ the volume of the perovskite unit cell almost linearly increased (Végards law). The volume increase did not directly start at $z = 0$, but at $z \cong 0{\cdot}005$, indicating a small impurity excess of $\cong$ 0·5% on the B-sites of BCTZ which had to be balanced by the corresponding amount of $\cong$ 0·5% $BaCO_3$. The slight B-excess most probably results from the wear of ZrO_2 milling balls. By interpolation of the Végard lines a maximum solubility of $z = 0{\cdot}045$ BaO in BCTZ was derived.

The XRD diagram of BCTZ fired with $z = 0{\cdot}06$ mol $BaCO_3$ exhibited weak reflexions of a 2nd phase which were almost identical to those of $BaCaTiO_4$.[12] Thus, at $z = 0{\cdot}06$ orthotitanate is formed, analogous to reaction (3). The BCTZ is most probably saturated with BaO already at $z < 0{\cdot}06$. From the value of $z = 0{\cdot}045$ the slight B-excess due to $\cong$ 0·005 mol ZrO_2 wear has to be subtracted. Thus, a maximum solubility of $z \cong 0{\cdot}040$ mol BaO in BCTZ results at 1400°C.

According to eqn (1), the maximum solubility of Ca^{2+} on the B-sites of BCTZ is $z/2 \cong 2$ at.% at 1400°C. This value is considerably lower than the $\cong$ 5 at.% $[Ca^{2+}{}_{(B)}]''$ reported for pure $BaTiO_3$ by Zhang *et al.*[9] In samples containing 0·5% TiO_2-excess, the maximum solubility of Ca^{2+} on the A-sites of BCTZ was found to lie at $[Ca^{2+}{}_{(A)}] \cong$ 16% at 1400°C, see Fig. 2.

3.2 Curie point changes

Similar to the observed changes of the unit cell volume the Curie point T_C is also strongly shifted towards lower temperatures by the incorporation of BaO, see Fig. 3. Due to the slight ZrO_2 wear, the T_C shift starts at $z \cong 0{\cdot}005$ again. The T_C of BCTZ is almost linearly decreasing from +75°C at $z = 0$ to −35°C at $z = 0{\cdot}045$. From this a maximum

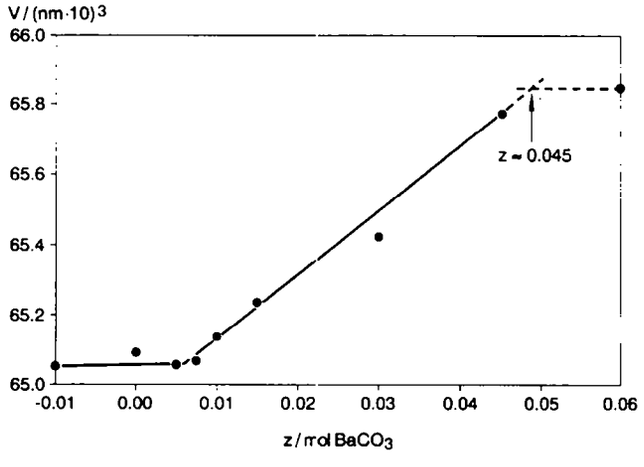

Fig. 1. Change of the unit cell volume of $Ba_{0.95}Ca_{0.05}(Ca_{0.88}Ti_{0.12})O_3$ (BCTZ) at the addition of z mol $BaCO_3$ to 1 mol BCTZ; 1400°C, moist (H_2O-20°C) N_2/H_2-95/5.

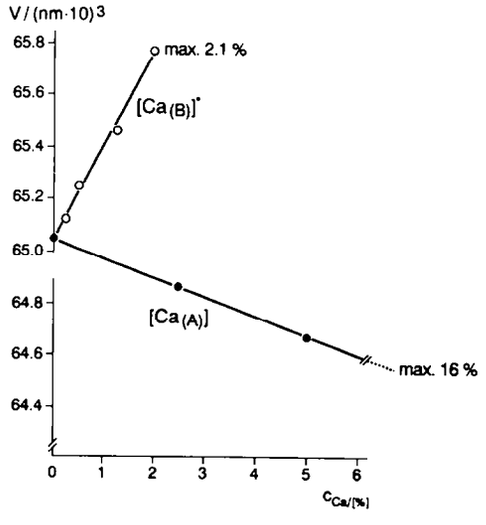

Fig. 2. Change of the unit cell volume of $Ba_{0.95}Ca_{0.05}(Ca_{0.88}Ti_{0.12})O_3$ as function of the Ca concentration on A- and B-sites of the perovskite lattice (1400°C).

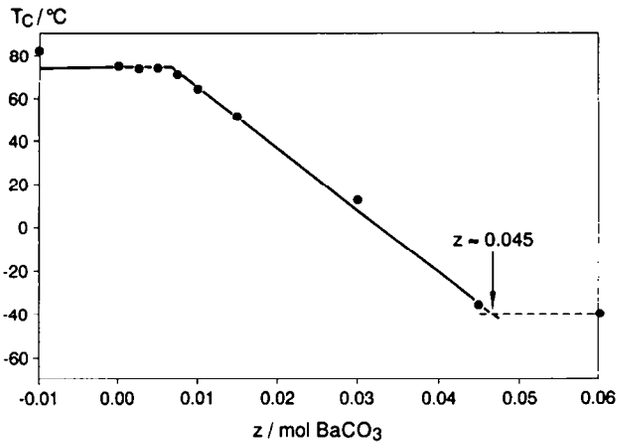

Fig. 3. Curie point shift of $Ba_{0.95}Ca_{0.05}(Ca_{0.88}Ti_{0.12})O_3$ at the addition of z mol $BaCO_3$ to 1 mol BCTZ; 1400°C, moist (H_2O-20°C) N_2/H_2-95/5.

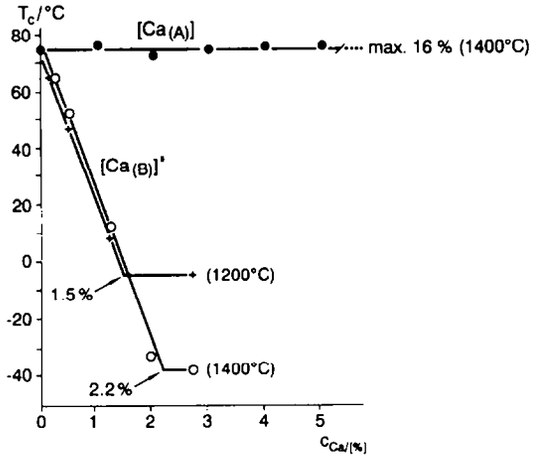

Fig. 4. Curie point shift of $Ba_{0.95}Ca_{0.05}(Ca_{0.88}Ti_{0.12})O_3$ as function of the Ca concentration on A- and B-sites of the perovskite lattice; 1200°C and 1400°C.

solubility of $\cong$ 2% [Ca^{2+}(B)]" at 1400°C was again evaluated, see Fig. 4. The maximum solubility of [Ca^{2+}(B)]" decreased to $\cong$ 1·5% after annealing the samples for 2 h at 1200°C. Firing of the samples at various partial pressures of oxygen, (N_2/H_2-95/5 to ~99·9/0·1, air and pure O_2) had no measurable influence on T_C. Incorporation of Ca^{2+} on the A-sites of BCTZ had in accordance to the known phase diagrams[10] negligible influence on T_C, see Fig. 4.

3.3 TGA results

The TGA experiments were carried out with pre-reacted mixtures of BCTZ and $BaCO_3$ in pure CO_2 at 1250°C. At a partial pressure of 1 bar CO_2 the orthotitanate phase Ba_2TiO_4 begins to decompose into $BaCO_3$ and $BaTiO_3$ at temperatures of $T \leq 1135$°C.[13] The decomposition of $(Ba,Ca)_2TiO_4$ into $BaCO_3$, $CaCO_3$ and $(Ba,Ca)TiO_3$ is expected to occur at comparable temperatures.

The TGA experiments revealed negligible weight changes for a BaO excess of $z \leq 0{\cdot}03$, see Fig. 5. At

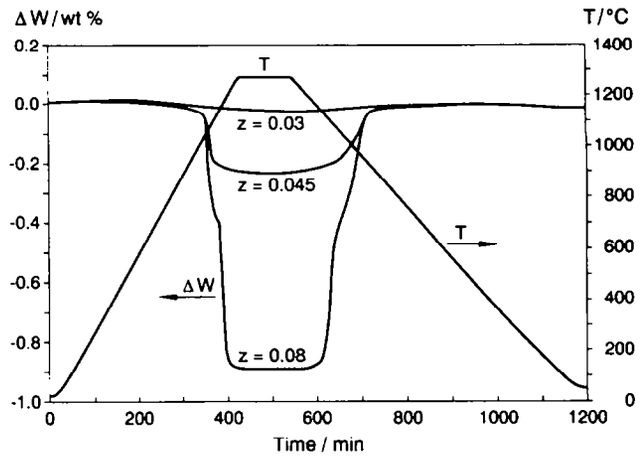

Fig. 5. TGA of $Ba_{0.95}Ca_{0.05}(Ca_{0.88}Ti_{0.12})O_3$ at the addition of z = 0·03, z = 0·045, and z = 0·08 mol $BaCO_3$; 20–1250°C, CO_2 atmosphere.

larger BaO-excess ($z > 0{\cdot}03$) a reversible uptake and loss of CO_2 was observed at *ca* 1050°C due to formation of orthotitanate. The lower equilibrium temperature of 1050°C, compared to 1135°C of pure Ba_2TiO_4, suggests a modification of Ba-orthotitanate by dissolved Ca and Zr. With increasing BaO-excess in BCTZ, the weight changes due to uptake and loss of CO_2 also become larger and larger, see Fig. 5. The TGA experiments revealed an irreversible incorporation of Ca^{2+}-ions on the B-sites of BCTZ for $z \leq 0{\cdot}03$, even in CO_2 at $T \leq$ 1250°C. The (Ba,Ca)-orthotitanate phase formed at larger $BaCO_3$ additives, $z > 0{\cdot}03$, is obviously in equilibrium with $(Ba,Ca)CO_3$ and BCTZ at $T \cong$ 1050°C and $p(CO_2) \cong 1$ bar.

The reversible weight change Δw, due to the uptake or loss of CO_2 in BCTZ + z $BaCO_3$ at 1250°C was plotted as function of z, see Fig. 6. Most of the measured values of Δw lie on a straight line which becomes $\Delta w = 0$ at z = 0·035. Considering a ZrO_2 wear of $\cong$ 0·5%, a maximum solubility of z = 0·03 mol BaO of $\cong$ 1·5% Ca^{2+} on the B-sites of BCTZ was derived for 1250°C. The

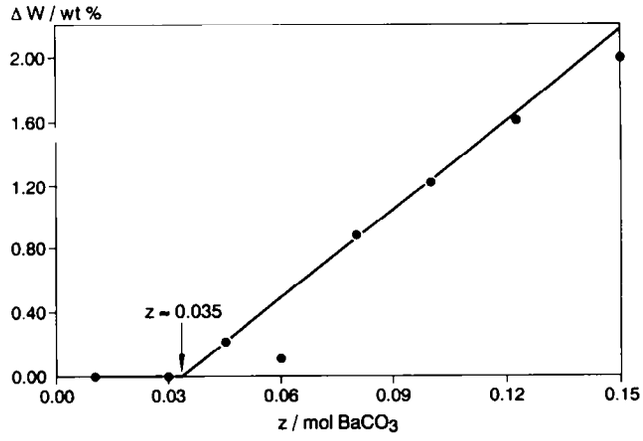

Fig. 6. Reversible weight change of $Ba_{0.95}Ca_{0.05}(Ca_{0.88}Ti_{0.12})O_3$ at the addition of z mol $BaCO_3$ in CO_2 atmosphere; 20–1250°C.

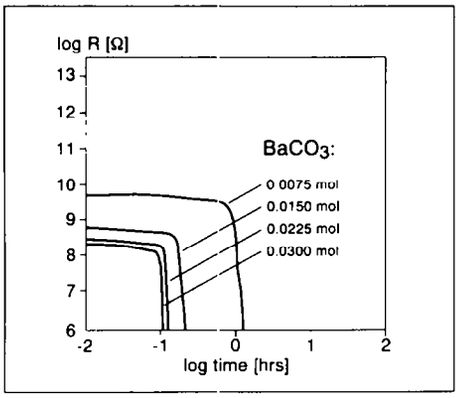

Fig. 7. Life stability at 200°C, 0·5V/μm of $Ba_{0.95}Ca_{0.05}(Ca_{0.88}Ti_{0.12})O_3$ containing various $BaCO_3$ additives, fired at 1400°C in moist (H_2O-20°C) N_2H_2-95/5.

lower solubility of [Ca(B)]" determined at 1250°C confirms the temperature dependence of the solubility of $[Ca^{2+}{}_{(B)}]$, already detected by means of T_C measurements.

3.4 Insulation resistance (IR) and life stability

Accelerated life tests (ALT) have been performed on ceramic discs at 200°C and 0·5V/μm, see Fig. 7. The discs have been sintered at 1400°C with various $BaCO_3$ additives of $z = 0{\cdot}0075$ to $z = 0{\cdot}03$ in moist (H_2O-20°C) N_2/H_2-95/5 atmosphere. The insulation resistance of such treated samples show rather high values of IR = 10^8 Ω to 10^{10} Ω at 200°C. The pale yellow colour as well as the high IR indicate the strong electron trapping effect of the Ca-acceptors. Increase of the BaO-excess from $z = 0{\cdot}0075$ to $z = 0{\cdot}03$, however, lowers the IR by more than one decade. This effect can be ascribed to the ionic conductivity, caused by electromigration of charged oxygen vacancies,[14] $[V(o)]^{\bullet\bullet}$.

Electromigration of ionized oxygen vacancies in dc fields was found to be the major reason for the electrical degradation of $BaTiO_3$-based perovskite dielectrics.[15,16] Charged oxygen vacancies, formed for compensation of the Ca-acceptors are thus assumed to be responsible for the rather poor life stability of BCTZ, fired with BaO-excess. As can be seen in Fig. 7, the life time of BCTZ strongly decreases with increasing amount of BaO-excess, z.

4 Summary and Discussion

The investigation of $(Ba_{0.95}Ca_{0.05})(Ti_{0.88}Zr_{0.12})O_3$ (BCTZ) confirmed earlier results obtained on pure $BaTiO_3$, that Ca^{2+}-ions are shifted from the A- to the B-sites by the influence of BaO-excess. Even at 1400°C the maximum solubility of $\cong$ 2% $[Ca^{2+}{}_{(B)}]$ in BCTZ is below that reported for pure $BaTiO_3$[9] (5%). The solubility of Ca^{2+}-acceptors on the B-sites of BCTZ shows a distinct temperature dependence, but was found to be independent of the oxygen partial pressure of the firing atmosphere. It has been also confirmed that $[Ca^{2+}{}_{(B)}]$" is a strong electron-acceptor in BCTZ. Ba-excess (A/B > 1) can be thus successfully employed for suppressing the electronic conduction in BCTZ-based dielectric materials cofired with Ni electrodes in reducive atmosphere. While the electronic conductivity of Ca-acceptor doped BCTZ is very low, a large number of charged oxygen vacancies, $[V(o)]^{\bullet\bullet}$ gives rise to a considerably high ionic conductivity. The mobility of the ionized oxygen vacancies $[V(o)]^{\bullet\bullet}$ in the electrical field is considered as responsible for the rapid degradation of Ca-acceptor doped BCTZ under dc field and temperature stress. Hence, additional dopes are needed to suppress the ionic conduction in BME multilayer capacitors prepared from BCTZ dielectric materials with BaO-excess.

Interfacial Reaction in Carbon Fibre–Sialon Ceramic Composites

P. Dupel & A. Hendry

Department of Metallurgy & Engineering Materials, University of Strathclyde, Glasgow, UK

(Received 7 June 1994; revised version received 10 February 1995; accepted 14 February 1995)

Abstract

Sintering and interfacial reaction have been studied in a composite of sialon matrix with chopped carbon fibre reinforcement. It has been shown that at relatively low temperature (1500°C) there is a little α *to* β *transformation in the reaction sintered matrix, no interfacial reaction (the carbon fibre is unaltered by the firing cycle) and 20% apparent porosity. As the temperature is increased to 1550°C and 1600°C, a corresponding increase in both transformation and density occur but accompanied by significant interfacial reaction. The nature of these changes is quantified and the microstructures determined by electron microscopy. The observations are interpreted in terms of interface chemistry, and transport mechanisms in both the gas and liquid phases are explained. Optimised procedures for fabrication are suggested.*

1 Introduction

The development of silicon nitride engineering ceramics over the last two decades has been devoted to the pursuit of maximum sintered density and therefore to the highest levels of mechanical strength. However, of equal importance is the need for reliability and reproducibility in the fabricated component, and for a means of crack inhibition to improve the relative toughness. Both of these aspects can be addressed through the use of composite action in the ceramic matrix, although this will necessarily lead to some decrease in fracture strength. A number of papers devoted to these aspects of the mechanical behaviour of ceramic matrix composites have been published in recent years and these are best summarised in the proceedings of the conferences at Riso[1] and that specifically devoted to silicon nitride in Stuttgart in 1993.[2]

Before detailed modelling of fracture behaviour can be attempted, however, it is necessary to address the problems of composite fabrication. This is necessary because, in general, the systems of interest are chemically incompatible, i.e. a reaction occurs between the matrix and the reinforcement during high-temperature fabrication or high-temperature use. The specific problem of carbon-fibre-reinforced silicon nitride materials was first discussed by Kyotoku *et al.*[3] where the nature of the interfacial reaction was identified and methods of inhibition or prevention devised. The critical factors are the interaction of the sintering gas atmosphere with the composite in the early stages of sintering when open porosity is present, and the rate of pore closure. However, in that work[3] and in subsequent investigations at Strathclyde, the detailed nature of the carbon–sialon interaction was not elucidated and therefore the micromechanisms at the interface are not known. There are specific requirements for knowledge of (i) the influence of temperature on the interfacial reaction, (ii) the interaction between sintering mechanisms and interfacial reaction, and therefore (iii) the role of the sintering liquid phase on material transport at the interface.

In order to have a simple, rapid densification, it was decided to use hot pressing as the fabrication method and to use a limited range of temperatures, 1500–1600°C, in which it was evident that both sintering and interfacial reaction were relatively rapid. The hot-press environment of a graphite die initially heated in air gives rise to a gas atmosphere with total pressure slightly in excess of one atmosphere with a chemical composition of 35 vol.% CO and 65 vol.% N_2 from the conversion of air to nitrogen and carbon monoxide. An investigation was therefore carried out to determine the answers to the three headings above and to provide guidance on the optimum fabrication routes for strong, reliable composites.

2 Experimental Procedure

The composites were prepared from β'-sialon 201 supplied by Cookson Group and containing un-reacted α-Si_3N_4, 6 wt% Al_2O_3, 8 wt% Y_2O_3 (as a densifying aid) and 10 wt% AlN polytypes. During sintering, this material forms a β'-sialon

of composition $Si_{5.25}Al_{0.75}O_{0.75}N_{7.25}$ (β'; $z = 0.75$). Reinforcing material used was chopped carbon fibre supplied by Osaka Gas Co. and two different proportions of carbon fibre have been added to the matrix : 10 vol.% and 20 vol.% The appropriate quantities of matrix and reinforcement material were wet-mixed for 2 h in propan-2-ol using alumina balls. After evaporating the alcohol, the powder was remixed dry for 1 h. Samples were uniaxially cold-compacted in a steel die to approximately 60% of the theoretical density to produce cylindrical pellets (15 mm diameter × 5 mm; 1·5 g). The pellets were embedded in boron nitride powder and hot-pressed in a graphite die under a stress of 30 MPa at different temperatures (1500, 1550 and 1600°C). Temperature was monitored by a two-colour optical pyrometer. The sintering time used was generally 1 h but lower times have also been used to determine the sequence of the reaction. Samples were subsequently sectioned and polished for micro-examination. Densities were measured by Archemedes' method using distilled water. Crystalline phases present were identified by X-ray powder diffraction using a Hägg–Guinier focusing camera (CuK_α, 50 KV, 20 mA). The microstructure of the samples has been studied by scanning electron microscopy (SEM, Jeol 840) and by transmission electron microscopy (TEM, Philips 400T) equipped with a windowless energy-dispersive X-ray analysis system (EDX).

3 Results

3.1 Density, weight losses and optical observations of the samples

Table 1 gives the densities and weight losses of samples sintered for 1 h at various temperatures and containing 10 or 20 vol.% carbon fibres.

The weight loss and density increase slightly for a given temperature with the amount of fibre in the sample. At 1500°C, the weight loss is negligible and density is very low, while the maximum density is obtained from 1550°C and the weight loss increases slightly with temperature. It should be noted that the percentage of theoretical density is sensitive to the value assumed for theoretical density. The value for density of carbon fibre given by the manufacturer is an overestimate of the true value, and samples fired at 1600°C are effectively fully dense. All weight losses are very small.

Table 1. Sample density and weight loss for various sintering temperatures and carbon fibre loadings

	Vol.% fibre		*Vol.% fibre*	
	10	*20*	*10*	*20*
Temperature (°C)	*Density (% theoretical)*		*Weight loss (%)*	
1500	81	83	0·2	0·4
1550	92	94	1·3	1·7
1600	94	95	2·0	2·5

Accuracy of density ±1%, weight loss ±0·2%.

Samples sintered at 1600°C exhibit a grey colour in contrast to the black colour at lower temperatures. Optical micro-observations show that at 1600°C and 1550°C a reaction has taken place between the matrix and the carbon fibre and at 1600°C an external surface layer is formed as shown in Figs 1a and 1b, respectively.

3.2 SEM observations

Electron microscopy observations of samples sintered for 1 h at 1500°C confirm a weak reaction between fibres and matrix. Cross-sectional and surface appearance of fibres do not reveal any attack, and the matrix appears to be adherent to the fibres as shown in Figs 2a and 2b. At 1550°C with 10 vol.% fibre, two kinds of fibre are observed. First, fibres with a reaction layer between the carbon core and the matrix, as shown in Fig 3. Usually small pores are also present between the matrix and the reaction layer. Second, some fibres do not seem to have reacted with the matrix and

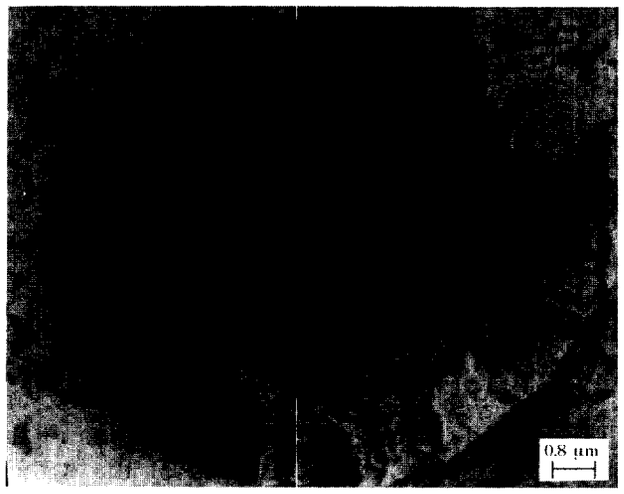

Fig. 2b. SEM micrograph of a cross-section of a fibre in a 10 vol.% fibre composite sintered at 1500°C for 1 h.

show the same appearance as in Figs 2a and 2b. Samples with 20 vol.% fibres and fired at the same temperature exhibit a similar comportment but the reaction between the matrix and the fibre is less extensive. It should also be noted that independent from the fibre loading, fibres near the

Fig. 3. As in Fig. 2 sintered at 1550°C for 1 h.

Fig. 4. As in Fig. 2 and 3 sintered at 1600°C for 1 h.

surface of the pellet appear to be more heavily attacked than at the centre (see also Fig. 1b).

At 1600°C for 1 h with 10 vol.% of fibres, the reaction is more extended and complete for most of the fibres, i.e. the initial structure of the carbon fibre is no longer apparent, as shown in Fig 4. In this case, there is extensive porosity around the fibre and the surface of the fibres exhibit holes due to gas emission, as shown in Fig. 5. There is no difference between the surface and the centre of the pellet after 1 h, but a sample fired at 1600°C for only 5 min reveals a less extensive reaction and a clear difference between the surface and the centre of the pellet. As at 1550°C, samples with 20 vol.% fibres sintered at 1600°C create a less-extended reaction than the 10 vol.% fibres.

3.3 T.E.M. and X-ray analysis

3.3.1 Matrix

Figure 6 shows the X-ray diffraction patterns obtained from samples containing 10 vol.% fibres

and sintered at various temperatures for 1 h. As expected, there is a large variation in the sample composition with temperature since at 1500°C α-Si_3N_4 is the main phase, whereas at 1600°C β'-sialon is in the majority. The z-value of the β' phase calculated from the β' lines of the diffraction patterns presented in Fig. 6 follows the variation with temperature as shown in Table 2. The lower the temperature, the higher the z-value. A variation is also observed with the amount of carbon fibres.

TEM observations of the matrix corroborate the X-ray analysis. At 1500°C, large α-Si_3N_4 grains are surrounded by smaller grains and the

sample exhibits a low density as shown in Fig. 7. Some elongated β'-sialon crystals are also present. At higher temperature, the matrix is more dense and no large α-Si_3N_4 grains are observed, as shown in Fig. 8.

3.3.2 Carbon fibre–matrix interface

At 1500°C, whatever the content of fibre, most of the carbon fibres have not reacted with the matrix. A typical interface between the two components is shown in Fig. 9. The fibre and the matrix are clearly unreacted and the low densification of the matrix is obvious. EDX analysis of the carbon fibre gives only a carbon peak and a small silicon peak (see Fig. 10). However, in some places in the sample, two other features of the fibres can be observed. First, the carbon fibre reveals a weak reaction with the components of the matrix, particularly the liquid phase, giving rise to very tiny grains at the interface or within the fibre, as shown in Fig. 11a. EDX analysis shows that these

Fig. 9. TEM bright field micrograph of a fibre–matrix interface in a 10 vol.% composite sintered at 1500°C for 1 h.

small grains and the fibre itself contain a larger amount of silicon than the unreacted fibre, as shown in Fig. 11b. In rare places, some large pieces of silicon carbide with intergrowths are observed, as shown in Fig. 12.

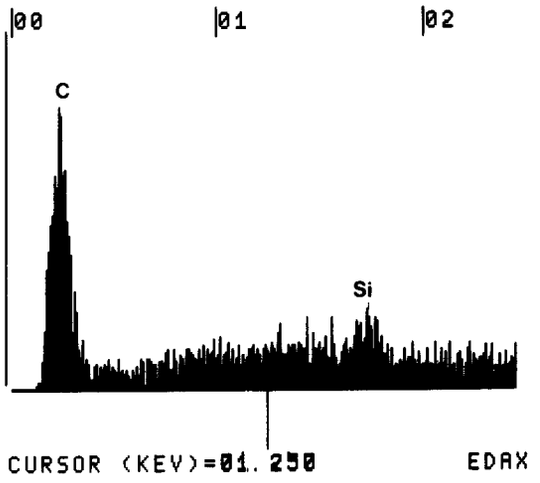

Fig. 10. Energy-dispersive analysis trace of the carbon fibre shown in Fig. 9.

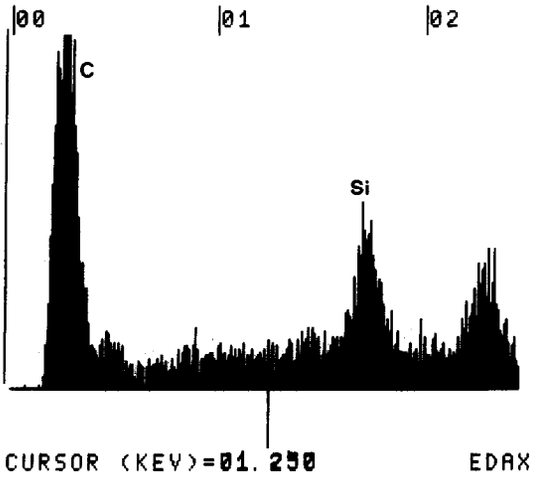

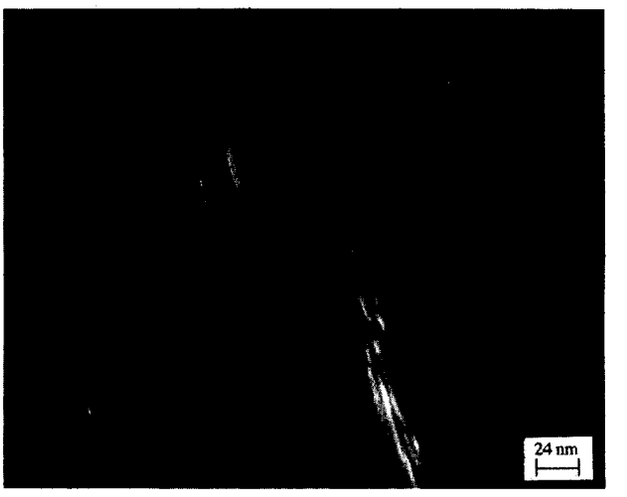

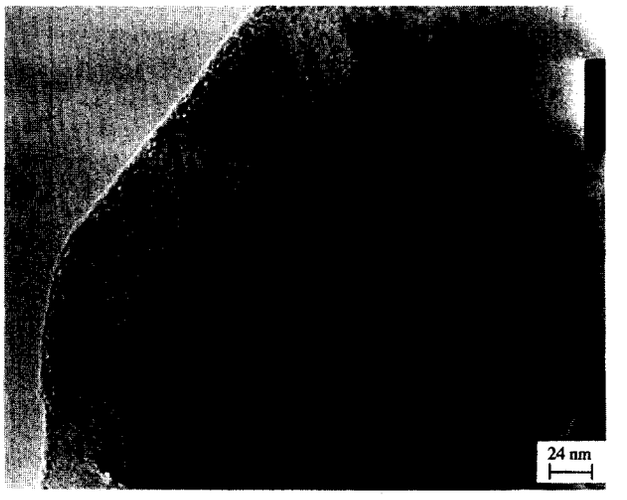

Fig. 11b. Energy-dispersive analysis trace of the carbon fibre shown in Fig. 11a.

A higher temperature, 1600°C, yielded a noticeably different microstructure in that extensive reaction had taken place between matrix and fibre. Two main structures are observed in the samples. First, some net interfaces between the fibre and

the matrix are seen, as shown in Fig 13. As at lower temperatures, the carbon fibre contains silicon. The matrix contains a large amount of liquid phase containing Y, Si, Al and O (see Fig. 14) and small grains are embedded in this solidified liquid as shown in Fig 15a. Generally, few silicon carbide grains are observed in the samples fired at 1600°C for 1 h, and in this case they are located in the matrix or surrounded by the solidified liquid phase (see arrow in Fig. 15a). However, when the sintering time is shorter, 5 min, some large areas containing a lot of SiC grains are found as shown in Fig. 15b (silicon carbide grains are clearly evident from the high incidence of faulting). The second main structure observed is presented in Fig. 16a. This reacted carbon fibre shows a peculiar appearance with very small grains within the structure. The EDX analysis of the carbon fibre shows the presence of silicon and more surprisingly of molybdenum. These products are found again in some other places in the matrix, as shown in Fig. 16b (see arrow). The diffraction patterns of both such areas show that the small grains are SiC. These types of reacted carbon fibre are often observed as a thin film in the matrix, as shown in Fig 17. Whatever the temperature and the carbon content in the sample, some bubbles in the liquid phase are often observed near the fibre–matrix interfaces as, shown in Fig. 18.

4 Discussion

It is clear that temperature affects both sintering of the matrix and reaction between the components of the composite, and that sintering only occurs if the temperature is equal to or higher than 1550°C. The interesting result regarding sintering is the variation of the β'-sialon z-value with temperature and with the fibre content. When temperature increases, z decreases. According to Kim and coworkers,[4] this is due to the transformation of α to β' in the matrix. At the beginning of sintering, the liquid phase and the precipitated β'-sialon grains are very Al rich. Because the aluminium in the liquid phase is consumed with the formation of β'-sialon by reaction of α-Si_3N_4 grains, the liquid contains less and less aluminium as the transformation progresses and the Al content in the β'-sialon grains decrease with time. Moreover, the Al-rich β'-sialon grains precipitated at the beginning of sintering redissolve as the Al concentration in the liquid phase decreases. In short, as α dissolves the z-value decreases, and therefore the average z-value of the β'-sialon in the composites decreases with time and temperature. However, some silicon is also consumed by formation of SiC within the fibres during sintering and there the z-value of the matrix β' is expected to decrease with increasing fibre content. That is, the dependence of z with the amount of carbon fibre in the sample is related to the reaction between the matrix and the fibres. Two factors have to be considered. First, the more carbon fibre in the composite, the less liquid phase is present. Second, silicon is incorporated in the attacked fibres (see Fig. 11). So, at a given temperature, the 20 vol.% composite contains more fibres, less liquid phase and Si reacts partly with the fibres. As a consequence, the ratio Si/Al in the liquid phase is lower, the transformation α to β' slower and the z-value is higher for a given sintering time.

From the results, it is clear that the extent of reaction increases with temperature of sintering and is related to the sintering behaviour in that it is promoted by the presence of liquid phase. At low temperature, the extent of sintering is limited and little α to β' transformation occurs, but the β' which is formed is of higher z-value than expected, as discussed above. There is no reaction at 1500°C and the fibre is unaffected by the sintering process. As the temperature and extent of densification increase, so the z-value of β' decreases and the attack on the carbon fibre becomes more pronounced. Two effects on the fibre are clear from the results. First, there is surface degradation due to the attack at the liquid/fibre interface which results in increased porosity in the fibre (compare Figs 5 and 2a). The second effect is reaction within the fibre, which converts the carbon from an amorphous phase to a micropolycrystalline state and includes formation of silicon carbide (Figs 12a and 16a). At the same temperature, as

shown in Fig. 15, there is reaction within the ceramic phase to form grains of silicon carbide as discreet crystals close to the interface. In the relatively short time duration of the present experiments (1 h) it is unlikely that such effects can be explained by liquid-phase diffusion and therefore gaseous transport must be involved both within the ceramic matrix pore network and in the increasingly porous fibres. The gases involved in the sintering environment are N_2 and CO and these must be involved in the process at the earliest stages when open porosity is present. This behaviour has been discussed by Kyotoku *et al.*[3] and it has been shown that in the presence of a significant CO pressure, the interfacial reaction is inhibited and weight losses are therefore expected to be small, as is found in the gas atmosphere of the hot press used in the present experiments. Similarly, open porosity is necessary for a gas evolution reaction (see weight losses in Table 1) at the fibre surface. In addition, however, the strongly reducing environment at the fibre/matrix interface (solid carbon, gaseous CO and N_2) will lead to carbothermal reduction of the predominantly oxide sintering liquid with formation of silicon monoxide (SiO) and carbon monoxide (CO)

$$SiO_2 + C_{(s)} \Leftrightarrow SiO_{(g)} + CO_{(g)} \quad (1)$$

where SiO_2 represents silica at reduced activity in the liquid phase. By this means carbon is consumed at the fibre surface and silicon is transported into the fibres by gaseous diffusion of SiO within the fibre pore network. This reacts with the fibres producing SiC in the fibre structure:

$$SiO_{(g)} + 2C_{(s)} \Leftrightarrow SiC_{(s)} + 2CO_{(g)} \quad (2)$$

while silicon carbide may be formed in the liquid phase either by direct reduction:

$$SiO_2 + 3C_{(s)} \Leftrightarrow SiC_{(s)} + 2CO_{(g)} \quad (3)$$

or by gaseous reaction with the carbon monoxide

$$SiO_2 + 4CO_{(s)} \Leftrightarrow SiC_{(s)} + 3CO_{2(g)} \quad (4)$$

The latter reaction is unlikely, however, both on thermochemical grounds (at 1600°C) and from electron microscopy, which shows that SiC crystals in the ceramic matrix are only found in the immediate vicinity of the interface, indicating reaction with solid carbon. As sintering proceeds and closed porosity develops, all of the above gas-generating reactions will be inhibited as the internal pore pressures increase and further reaction will not occur. Indeed, it should be noted that weight losses are small (Table 1) and that the above reactions are limited in extent even at the highest temperature studied; this is reflected in the high density achieved at 1550 and 1600°C even when reaction occurs.

In a second, later stage of the sintering process, silicon carbide crystals in the matrix redissolve as the system tends toward chemical equilibrium. At 1600°C and below, silicon carbide is thermodynamically unstable with respect to carbon, β'-sialon and the liquid phase.[5–7] The latter is assumed to be in equilibrium with the crystalline solid β' precipitated from it as part of the reaction sintering process.

The optimum manufacturing conditions for such composites require a rapid sintering process and sufficient time at a temperature high enough to equilibrate β'-sialon/liquid. Therefore, to produce a composite with minimum interfacial reaction, the sintering conditions should be arranged so as to provide rapid pore closure, i.e. a fast heating rate and adequate liquid phase. Prolonged sintering should not affect the reaction but is necessary for maximum density and phase transformation. The results also suggest that the fibre composites can be sintered to maximum density at 1600°C, which is 50–100°C less than that recommended for the monolithic ceramic.

5 Conclusion

The present work has shown that good-quality carbon-fibre-reinforced sialon composites can be prepared with 10 or 20 vol.% of fibre. Interfacial reaction between the constituents only takes place above 1500°C, in the temperature range required for liquid-phase sintering of the sialon matrix. The interfacial reaction therefore accompanies the α to β' transformation. Interfacial reaction involves the liquid phase and results in formation of silicon carbide in the matrix side of the interface at short times, but these redistribute on prolonged sintering times. Gas phase transport by silicon monoxide from the matrix to the fibres results in conversion of part of the amorphous fibre to crystalline silicon carbide.

The data suggests that the optimum sintering procedure for these chopped fibre composites is to use a rapid heating rate to provide fast pore closure, thereby preventing gas phase transport, and a maximum densification temperature of 1600°C for 1 h to give α to β' transformation and complete sintering of the matrix.

Alumina of High Reliability by Centrifugal Casting

W. Huisman, T. Graule & L. J. Gauckler

Nichtmetallische Werkstoffe, ETH Zürich, Sonneggstr. 5, 8092 Zürich, Switzerland

(Received 8 September 1994; revised version received 14 February 1995; accepted 20 February 1995)

Abstract

Centrifugal casting is a powerful colloidal processing route for massive ceramic parts of high strength and high reliability. Aqueous α-alumina slurries with up to 56·8 vol.% solids content with a mean particle size of 0·46 μm were deagglomerated by ultrasonic treatment and subsequent filtration. Consolidation was performed at various centrifugal accelerations. Differential sedimentation during centrifugal casting was studied and found to be negligible for slurries with high solids loadings exceeding 50 vol.%. Green bodies with very good particle packing, showing high green densities of 68%TD (theoretical density), as well as narrow pore size distributions were obtained. High sintered densities (≥99·4%TD) with homogeneous and fine microstructures were achieved at sintering temperatures as low as 1400°C. Four-point-bending tests showed an average strength of 540 MPa with a Weibull modulus m *of 24.*

1 Introduction

Despite the outstanding properties of advanced ceramic materials, their lack of reliability still remains the highest barrier to a wider range of engineering applications.

The lack of plastic deformation in combination with flaws often up to 100 times larger than the average grain size, makes ceramic parts very susceptible to stress peaks. Thus, surface and volume flaws can lead to catastrophic failure of an entire component.[1–3] Critical flaws can be introduced via the starting powder, (e.g. impurities and hard agglomerates), during the formation of the green body (organic or inorganic inclusions, drying-induced cracks)[3,4] or during service of the component via surface damage, as well as slow crack growth.

The homogeneity of the particle packing in the green compact has a great influence on the microstructural evolution during sintering, rather than actual sintering mechanisms.[5–10] For in the case of solid state sintering, inhomogeneous (unreliable) green bodies lead to unreliable fired products. The amount and distribution of large flaws present in the green body are retained throughout the sintering process unless further flaws are introduced, e.g. due to differential shrinkage or due to exaggerated grain growth.[11] In the worst case, this can lead to an undesirably wide strength distribution in a set of ceramic components. The spread of strength values of a batch of samples is expressed by means of the Weibull Modulus m, which, for ceramic compounds (alumina, zirconia (Y-TZP), ZTA) has a value around 10, whereas metallic components show values around 100. Design engineers require values between 20 and 30.[1,2]

Hence the formation of a homogeneous, densely packed green body is one of the most important steps in the manufacturing of engineering ceramics. Average strength and reliability, especially of the low-toughness-type advanced ceramics, which obey the Griffith fracture criterion, will then be strongly increased.[12–14]

In recent years it has become evident that wet processing of powders has many advantages over dry processing in respect of reliability.

The wet processing route provides the possibility of breaking up agglomerates by milling or ultrasonic treatment or by removing them and other flaw sources from the slurry by filtration, decantation or sedimentation.

This route also allows optimal particle packing and thus a minimum in flaw size and number of flaws.[4,6,15,16] Well-known examples are slip casting, pressure filtration and electrophoretic deposition of ceramic slurries. Centrifugal casting, compared with other colloidal-forming methods, has the advantage of producing massive ceramic objects combined with a reduced risk of stress gradients in the formed part.

Stresses during the centrifugal forming process act on every volume element.[13,15,17] During sedimentation the particles move in the direction of gravity, whereas the liquid flows in the opposite

direction. This means that the total volume of liquid in the dispersion does not have to be transported through the sedimented body leaving defects such as filtration channels as in the case of slip casting and pressure filtration.

The drawback of this technology, however, is that particle size separation might occur due to differential settling during the consolidation stage.[16,18,19] There are three approaches to overcome this problem: consolidation of the system (1) in the flocculated state[18] or (2) in the coagulated state,[19] or (3) the use of highly concentrated dispersed slurries.[20] The first two approaches have been successfully used in various single-phase[18,19] and binary powder systems[19] but lead to an open structure showing bimodal porosity (intra-agglomerate: small, inter-agglomerate: large) which is undesirable for subsequent densification[5–10,21,22] because higher temperatures are needed to approach the theoretical density. It is well known that higher sintering temperatures can lead to exaggerated grain growth in the well packed regions which is equivalent to the introduction of new flaws. Several investigations severely questioned the flocculated approach by theoretically and experimentally proving an inhomogeneous density profile in centrifuged sediments from as-prepared slurries.[23–27] The third approach produced very good results for one component system with high solids loadings (≥50 vol.%).[20,28–31] Mass segregation could be avoided by hindered sedimentation in these high-solids-content slurries. Such suspensions with repulsive, nontouching particles led to green bodies with high densities and narrow pore size distributions. They show good sintering behaviour and reach high final densities at much lower sintering temperatures.[6,28–31]

The aim of the present study was to improve the mechanical properties of alumina via centrifugal casting. Of special interest for the production of such high-quality ceramic objects were the processing parameters such as solids loading, suspension conditions, sedimentation velocity and centrifugal acceleration. Green and sintered densities, sintering behaviour and microstructures were studied as well. All these results were compared to those obtained from isostatically pressed α-alumina.

2 Experimental Procedure

A commercial α-alumina powder (Ceralox HPA-0·5 with MgO, Condea, Tucson, USA) was used with a surface area of 9·4 m^2/g (BET method) and an average particle size d_{50} of 0·46 μm (d_{90} = 0·2 μm, d_{10} = 1·3 μm, Malvern Mastersizer). Chemical analysis revealed a purity of >99·97%, with the following major impurities (in ppm): Mg 293, Na 20, Si 17, Fe 13 and Ca 7, according to the supplier.

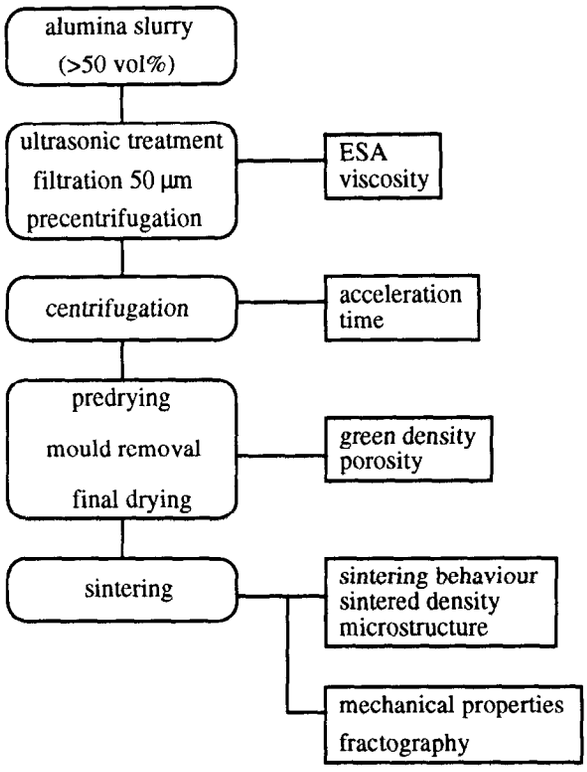

Fig. 1. Flow chart of centrifugal casting process.

Surface charge measurements were performed with 2 vol.% suspensions using an Electrokinetic Sonic Analysis System (ESA) (Matec ESA 8000, Matec Applied Science, USA). The ESA system was calibrated with Ludox TM (DuPont) 33 vol.% solids in water at a value of –3·67 mPa m/V. Viscosities of highly loaded suspensions were studied using a rotational viscosimeter (Rheomat 115A, Contraves AG, Zürich) equipped with a DIN125 testing device which varied the shear rate from 0 to 700 s^{-1} under isothermal conditions at 25°C.

The centrifugal casting process flow chart is shown in Fig. 1. Electrostatically stabilized aqueous suspensions of up to 56·8 vol.% Al_2O_3 were prepared at a pH between 4 and 4·2 using HNO_3, and subsequently dispersed by 50% pulsed ultrasonic cavitation for 8 min at 20 kHz and a power input of 420 W (Vibra Cell VC600, Sonics & Materials Inc., Danbury, USA). As the alumina used in this study is not derived by the Bayer process and therefore it is very low in Na-content, the pH did not change in between the limits given above during the subsequent preparation time. Large agglomerates, which could not be destroyed during ultrasonication, were removed by filtration (50 μm sieve) which led to slurries free of large agglomerates. These slurries were consolidated by cen-

trifugal casting (ZK 510, Berthold Hermle GmbH & Co., D-7209 Gosheim) in aluminum tubes with a diameter of 38·4 mm and a height of 110 mm. Objects with different geometries were cast in anodized aluminium moulds of which the ball-shaped one (d = 45 mm) could be disassembled into two halves along the acceleration axis. Centrifugal acceleration was varied from 150 to 4000 g to give compacts of up to 8 cm height. Centrifugation time to compact a given slurry volume of 90 cm^3 was dependent upon acceleration and ranged from 75 min to 64 h. Standard conditions were chosen, if not otherwise mentioned, with 53·4 vol.% solids content, densified at 4000 g for 90 min. Cast specimens were dried under controlled temperature and humidity conditions and then sintered in air at 1400°C with 6 h holding time. The heating and cooling rate was 1°C/min. Green and sintered densities were measured by the Archimedes principle in both mercury and water. Pore size distributions in green compacts were determined by mercury porosimetry with pressures up to 2000 bar (Hg-Porosimeter 2000, Carlo Erba Strumentazione, I-Milano). For analysis the cylindrical model was used,

Other samples using the same alumina powder were prepared by isostatic pressing at 350 MPa for 3 min. The sintering temperature for those samples was 1500°C with a 2 h holding time. The sintering behaviour in air was monitored with a differential dilatometer (Type 802, Bähr Gerätebau GmBH, D-4971, Hüllhorst), using a sapphire reference.

Bending test specimens of 4 × 3 × 45 mm (width, height, length) were cut out of a sintered cylinder in the direction of the acceleration axis. Strength measurements were performed according to the four-point-bending test method DIN 51 110 (Instron 8652, Instron Ltd., HP12 3SY, England) with 20/40 mm spans and a crosshead speed of 2 mm/min. Microstructures were observed by LM and SEM on polished and thermally etched surfaces. Mean grain sizes were obtained by measuring the intercepts of about 200 grains per sample and multiplying the average value by 1·5.[32] K_{Ic} measurements were performed in air by the Vickers indentation method (Zwick, D-7900, Ulm) using the Evans and Charles approach to evaluate fracture toughness.[33]

3 Results and Discussion

3.1 Suspension stability and viscosity

To avoid preferential segregation during centrifugal casting, highly stabilized dispersed systems with high solids content are required.[19,28–30] It is well known that the stability of suspensions increases with increasing electrokinetic sonic amplitude signal (ESA) which is directly proportional to the Zeta potential. Figure 2 shows the change in ESA signal in the pH range from 3 to 11 for an Al_2O_3 suspension containing 2 vol.% solids. The region of highest ESA signal lies around pH 4 and the isoelectric point at pH 9. Below pH 4 the solubility of Al_2O_3 increases drastically. Since the formation of dissolved Al^{3+} ions has a deteriorating effect on the sintering behaviour of alumina,[31] the plateau region around pH 4 was chosen to stabilize the suspensions.[19,28,29]

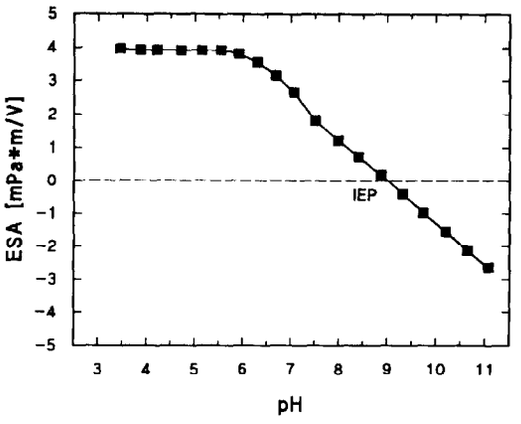

Fig. 2. ESA signal versus pH for a 2 vol.% alumina suspension.

The highest possible powder content is desirable for centrifugal casting in order to prevent separated sedimentation, but also to save space (for supernatant water) and weight (of the moulds) during the centrifugation step. On the other hand, high solids loadings are limited by the increase in viscosity (Fig. 3), and by rising pseudoplasticity. In addition, higher powder contents in the slurry result in increased losses of material during filtration and increased difficulties during mould filling.

In order to explore an optimum solids content of the suspension, slurries with 50·1, 53·4 and 56·8

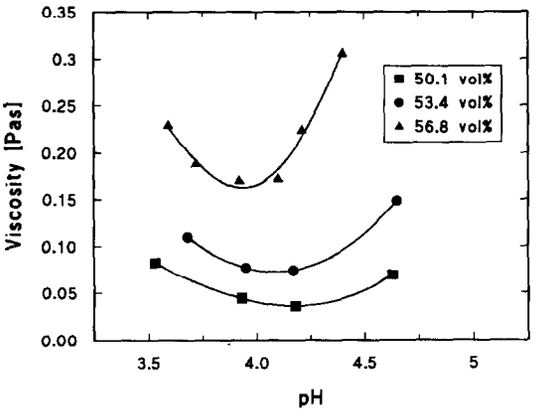

Fig. 3. Viscosity (at shear rate 100 s^{-1}) versus pH for alumina suspensions with different solids loadings.

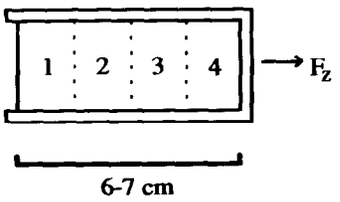

Fig. 4. Segmentation and numbering of cylindrical green compact.

vol.% solids were made at various pH values around pH 4. Figure 3 shows the viscosities at a shear rate of 100 s^{-1} (η_{100}) for slurries with different solids loadings around the optimal pH (≈ 4) found in ESA measurements. With rising powder content, the minimum of lowest viscosity will increase from 3 mPa s (50·1 vol.%, at pH 4·2) to 160 mPa s (56·8 vol.%, at pH 3·95). In addition, the viscosity/pH curve's minima shift slightly to lower pH values while narrowing considerably with augmenting powder content.

3.2 Solids content, green density and porosity

To define the limits of hindered sedimentation, slurries of different powder contents from 36·9 to 56·8 vol.% were cast in aluminum tubes at 4000 *g* for 90 min. All suspensions were stabilized at a pH between 4 and 4·2. The dried compacts were cut into segments of about 1·5 cm height to determine their green density and porosity. The numbering of the segments is shown in Fig. 4. Green densities and average pore radii (r_{50}) are summarized in Table 1.

All top segments show a green density that is lower than that of segments closer to the bottom of the cylinder. This difference is negligible for all parts that were cast from slurries with a powder content higher than 51·7 vol.%. If the solids loading was chosen below this value, a much larger deviation in green density could be measured. Obviously, differential sedimentation occurred in those slurries and finer particles were packed at the top corresponding to smaller pores found as well. Porosimetry measurements revealed a different mean pore size (Table 1), a different cumulative volume and a different surface area for top and bottom parts of compacts made from those low-

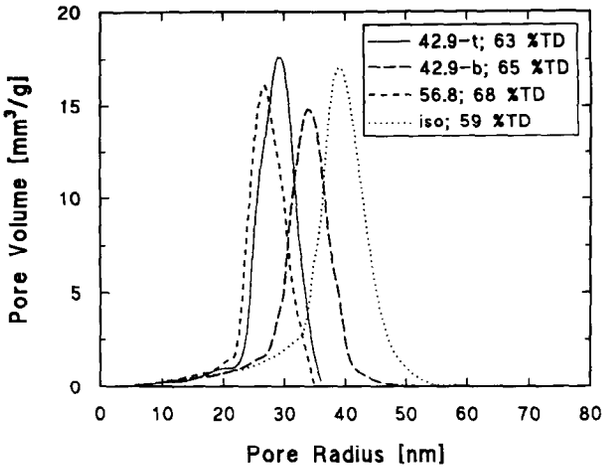

Fig. 5. Porosimetry data of 42·9 vol.%-slurry compact, 56·8 vol.% compact and isopressed compact (segments).

loaded slurries (<50 vol.% powder). It is well known, that monosized particles do pack more homogeneously but lead to lower densities (63 versus 68 %TD) than multisized powders. The change in surface area is due to the fact that larger particles pack at the bottom (smaller BET) and finer ones pack at the top (larger BET) in the case of particle size separation. As can be seen from Fig. 5, the average pore radius decreases from the bottom to the top segment of a 42·9 vol.% slurry-cylinder from 35 to 29 nm. In contrast to these findings, a 56·8 vol.% slurry-compact shows an average pore radius of 28 nm over the entire length of the cylinder, as well as a homogeneous and high green density of 68%TD. This indicates that no separation occurred during the centrifugation process. For comparison reasons, the pore size distribution of an isostatically pressed sample is also displayed. This dry processed sample (59%TD) has a broader pore size distribution than all wet processed samples and the highest average pore radius of 41 nm. Thus, the particle packing of colloidally processed samples is much better (63–68%TD) than that of an isostatically pressed sample (59%TD).

Shih *et al.*[25,27] have elaborated a theoretical approach to predict the density profiles of centrifuged cakes from flocculated suspensions by

Table 1. Green density (GD, in %TD) and average pore size (r_{50}, in nm) of segmented cylinders

Slurry (Vol.%)	*Segment 1*		*Segment 2*		*Segment 3*		*Segment 4*

51·7	65·0	27·5	65·2	29·8	68·5	28·7	67·7	28·8
53·4	65·0	29·3	65·7	30·6	66·7	30·0	66·5	30·0
56·8	67·6	27·5	68·1	28·3	68·3	28·2	68·1	27·5

implementing their experimentally obtained power-law pressure–density relationship[23] into the general differential equations for centrifugation[17] with appropriate boundary conditions. Their calculations were formulated in the equation

$$\frac{\Phi(z)}{\Phi_{max}} = \left[1 - \left(\frac{z}{z_m}\right)\right]^{\frac{1}{(n-1)}} \quad (1)$$

where $\Phi(z)$ is the volume fraction of solids at elevation z (measured from the bottom of the tube), Φ_{max} is the maximum solids volume fraction (measured at $z = 0$) and z_m is the elevation at equilibrium state. The exponent n indicates the flocculation state of a system during compaction. Generally, n decreases as the degree of flocculation increases. Their predictions agreed very well with the pronounced density profiles they measured in cakes that were centrifuged from flocculated alumina and boehmite suspensions. The uniform density profiles found in this investigation can be described by their equation as well. Green densities GD(z) instead of volume fractions $\Phi(z)$ were used for the calculations made in this study. This is, especially for the high loaded suspensions, a tolerable approximation. A linear drying shrinkage of 0·5–1·0% equals a volume reduction of 1·5–3·0%, indicating that the actual volume fraction for a green density of 0·68 would then be 0·67 or 0·66. Due to the high green densities obtained in this investigation, Φ_{max} was set to 0·685 (instead of 0·64 for random packed spheres[25,27]). Green densities of cylinders compacted from a 36·9 vol.% and a 56·8 vol.% slurry are displayed in Fig. 6. Three curves calculated according to Ref. 27 are shown as well. The n values chosen are $n = 9$ for a flocculated suspension[25,27] and $n = 100$ to fit the dispersed suspension with low (36·9 vol%) solids content. Hereby it has to be emphasized that for dilute alumina suspensions, a density gradient is

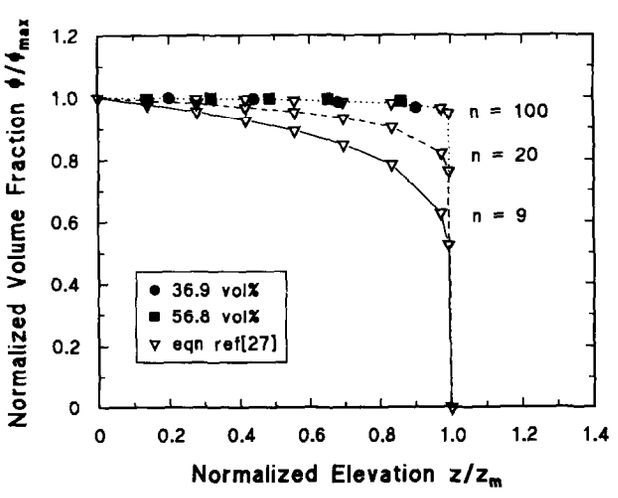

Fig. 6. $\Phi(z)\Phi_{max}$ versus z/z_{max} for green densities of compacts made from 36·9 and 56·8 vol.% slurries. Triangles are calculated values according to Ref. 27.

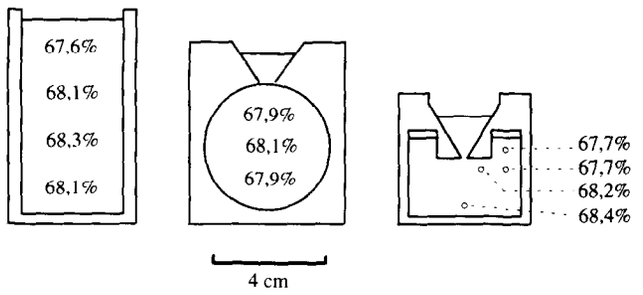

Fig. 7. Green density distribution of compacts shaped in different moulds: (a) cylinder; (b) ball; (c) with extreme constriction (53·4 vol.% slurry).

found due to particle size separation and not due to a pressure gradient in the centrifuged cylinder. For dispersed suspensions containing high volume fractions, the density–elevation relationship can be described if $n = 150$ is applied, which expresses virtually a step function and therefore a negligible density gradient.

Based on the results obtained so far, a solids loading of 53·4 vol.% was chosen for further experiments to be the best compromise between good handling of the suspensions and highest possible powder content.

During centrifugation the centrifugal force on the particles acts radially to the centre of the centrifuge. The question arises as to how a mould with undercuts can be filled properly with solids. Beylier *et al.*[20] have shown that the casting process can properly fill past constrictions in their spool and screw moulds. In order to elucidate the limits of mould filling, a mould containing an extreme undercut (Fig. 7c) was constructed. Centrifugal casting was performed with a 53·4 vol.% slurry. After centrifugation, the undercut was filled up to 65% of its height (10 mm) with alumina, leaving the upper part filled with clear water. The cast undercut was of stable shape and did not flow away after immediate removal of the top part of the mould. There was no evident difference in green density in this highest annular-shaped segment compared to the rest of the compact (Fig. 7(c)). Sintering led to a compact that showed no cracks and a homogeneous density. As can be seen from Fig. 7, high and homogeneous green densities of about 68%TD could be achieved in all moulds used throughout this investigation.

3.3 Mould-filling factor

To study dependence of the velocity of sedimentation upon the maximum applied acceleration, a slurry with 53·4 vol.% solids content was centrifuged at different accelerations for various times. The time t_{eq} to reach the equilibrium-state height z_m of a suspension by centrifugation is proportional to the initial slurry column height H_0

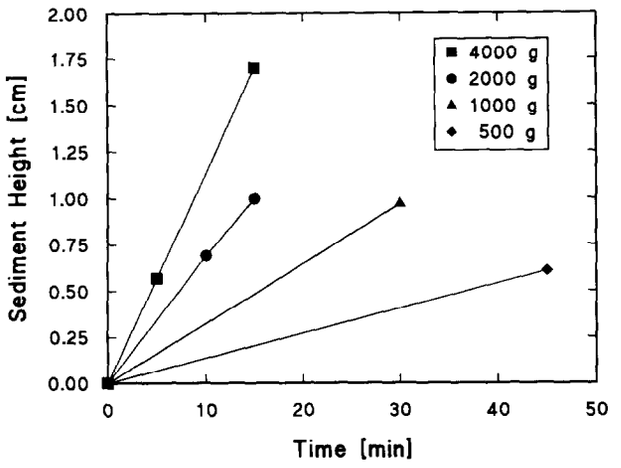

Fig. 8. Sediment height versus centrifugation time of a 53·4 vol.% slurry at various centrifugal accelerations.

and inversely proportional to the centrifugal acceleration $\omega^2 R$ where R is the radius of the centrifuge ($z = 0$).[24]

$$t_{eq} \approx H_0/\omega^2 R \quad (2)$$

At 4000 g the settling rate of the suspension in a cylindrical mould with a diameter of 38·4 mm is 0·12 cm/min, as shown in Fig. 8. To settle down the same amount of slurry and reach the same green density at 500 g, the centrifugation time is 6·6 times longer, and at 150 g, 26 times longer. No evident difference in homogeneity of the compact density was detected. After 15 min centrifugation at 4000 g the body does not show any plastic deformation under its own weight anymore. With lower solids contents, the settling rate will increase but differential sedimentation will occur due to increased inter-particle distances.

3.4 Drying and drying shrinkage

After centrifugation, the supernatant water is removed. Then the centrifuged green bodies still contain between 9 and 11 wt% water, which will evaporate during drying. It is well known that fast evaporation of the liquid during and especially at the end of the constant rate period (CRP) can lead to the formation of cracks in the green body, resulting in a low yield after sintering.[34] To detect the limits of successful, (i.e. crack-free) drying of centrifuged compacts, drying was performed while varying the parameters of temperature and relative humidity (RH). Cast compacts were dried under the following conditions: (1) in an oven at 50°C, (2) at ambient, (3) in a temperature-controlled humidity chamber at 25°C and 97%RH and (4) totally protected from direct convection at 25°C/97%RH. After casting, one-half of the ball-shaped mould was removed immediately after casting and the compacts were dried under the aforementioned conditions. The weight loss of the drying compacts was monitored over time and is displayed in Fig. 9. The final weight (dry body) was subtracted from that of the starting weight (wet body without supernatant) to give the value for the total water content in the cast compact (≡100%, Fig. 9). The fastest drying rates were achieved under oven and ambient conditions, followed by the nonconvection-protected compact under climatized conditions (25°C/97%RH) and with the slowest rate for the full convection-protected ball. As soon as drying rates are faster than 1·5% of the total water content of the green body per hour, the possibility of crack formation in the sintering body will be strongly increased. Compacts dried in the oven or under ambient conditions could not be sintered without cracking. In addition to that, it is important to protect the drying green bodies from direct convection as the CRP drying rate will be decreased with increasing layer of standing air over the compact. Normally, after a drying period of 4–5 days under climatized conditions, compacts could be sintered without cracking.

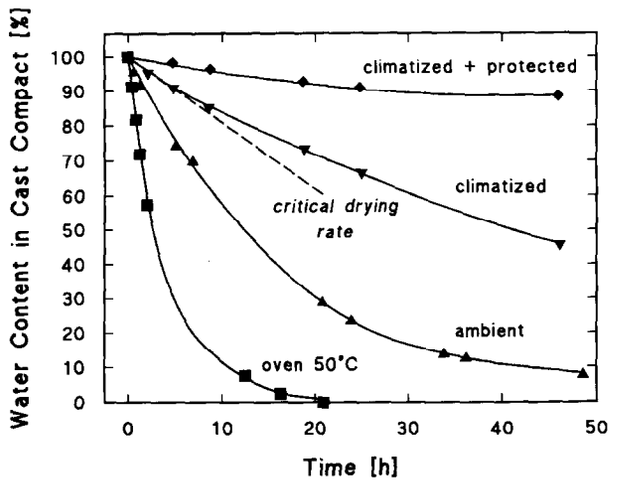

Fig. 9. Drying behaviour of ball-shaped cast compacts under various conditions.

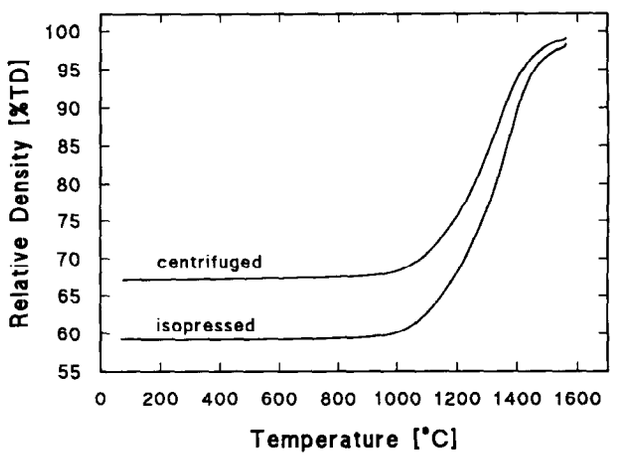

Fig. 10. Sintering curve of isopressed and cast alumina (53·4 vol.% slurry, 4000 g/90 min) at a constant heating rate of 5°C/min.

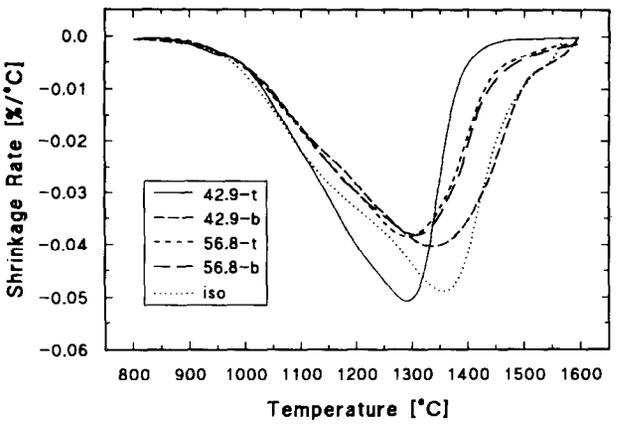

Fig. 11. Shrinkage rates of segments of cast alumina parts produced from 42·9 and 56·8 vol% slurries and of isopressed alumina.

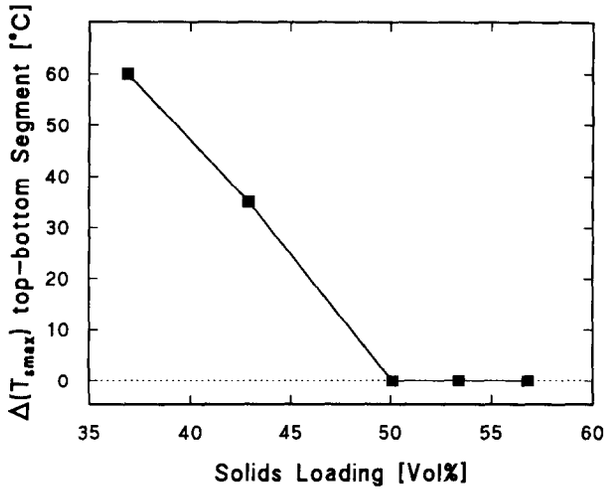

Fig. 12. Influence of solids loading on the difference of temperature of the maximum shrinkage rate $\Delta(T_{smax})$ between top and bottom segments of the centrifuged cylinders.

Linear shrinkage during drying was in the range 0·5–1·0% for compacts produced from high-solids-content slurries. This is equal to a volume reduction of 1·5–3·0% for compacts produced from high-solids-content slurries. Assuming a straight line of average-sized particles, this corresponds to an inter-particle distance of 5 nm in the sedimented wet state which is, according to the DLVO theory, just of the order of the distance of the primary minimum barrier. This calculation model, however, is very simplified and does not take into account the three-dimensional rearrangement behaviour of a drying particle system.

3.5 Sintering behaviour

The change in relative density during constant-heating-rate sintering (5°C/min) is shown in Fig. 10. The wet processed sample, which was produced from a 53·4 vol.% slurry, starts from a higher green density (68%TD) and reaches a higher final density at lower temperature than the dry processed sample (59%TD). This is due to the fact that larger pores disappear or get smaller, reaching an equilibrium size at higher temperatures and at a lower rate than small pores.[22,23] The isopressed part shows a wide pore size distribution from 0 to 60 nm around an average pore radius of 41 nm, whereas the centrifuged part has a smaller r_{50} of 29 nm and a narrow pore size distribution (Fig. 5). This proves that the finer the pores and the narrower the pore size distribution, the faster and earlier ceramic parts will sinter to maximum density.[6] Hence, centrifugal casting leads to a good sintering behaviour due to homogeneous particle packing in the case of high-solids-content slurries.

For a further illustration of the sintering kinetics, the shrinkage rates of three green compacts are compared in Fig. 11. A compact made from a relatively low solids loading slurry (42·9 vol.% Al_2O_3) showed different shrinkage rates at the top (t) and the bottom (b) of the compact. Due to differential sedimentation in this compact, the top consists of finer particles and finer pores (as illustrated in Fig. 5) than the bottom and therefore shows sintering at lower temperatures than the bottom part. This difference becomes negligible in the case of compacts made from high-solids-loading (56·8 vol.%) slurries. Both parts, top and bottom, show identical shrinkage rates over the whole sintering regime (Fig. 11). For comparison reasons, the shrinkage rate of an isostatically pressed sample is shown too. In the beginning (up to 1100°C) well-densified intra-agglomerate regions are responsible for the shrinkage, and the shrinkage rate is very similar to that of the 42·9 vol.% top segment. However, due to the larger inter-agglomerate pores, the temperature for the maximum shrinkage rate is not reached until 1375°C and the final density even at 1600°C is not as high as that of the cast compact (Fig. 10).

The findings from Fig. 11 can be illustrated in a different manner. Fig. 12 shows the influence of solids loading on the difference in temperature of the maximum shrinkage rate for the top and bottom segments of the cylindrical compacts. With rising solids loading, this temperature difference decreases from 60°C in the case of a 36·9 vol.% slurry over 35°C at 42·9 vol.% and becomes negligible for green bodies made from suspensions with solids loadings higher than 50 vol.%. This means that for a solids content above 50 vol.% no differential shrinkage over the length (8 cm) of a compact occurs. These findings agree with the results of the porosity measurements (Table 1), crack formation (Table 2) and the gradient degree in light scattering of polished cross sections (lengthways

Table 2. Density and appearance of sintered cylinders (1400°C/6 h)

Slurry (vol.%)	*Sintered density (%TD)*	*Sintered compact*
36·9	99·72	Cracks, gradient
42·9	99·50	Cracks, gradient

51·7	99·47	OK
53·4	99·40	OK
56·8	99·35	OK

of centrifugation axis) of sintered cylinders produced from slurries containing less than 50 vol.% solids.

3.6 Sintered density

Table 2 shows the differences in sintered density after 6 h at 1400°C for the entire cylinders. Centrifugal casting leads to sintered densities of more than 99·3%TD which are significantly higher than those of isostatically pressed material (98·6 %TD). Highest densities were reached with cylinders made from slurries with low solids contents (36·9 and 42·9 vol.%), but, however, the particle separation led to the formation of cracks during the firing process, as well as to a gradient degree of

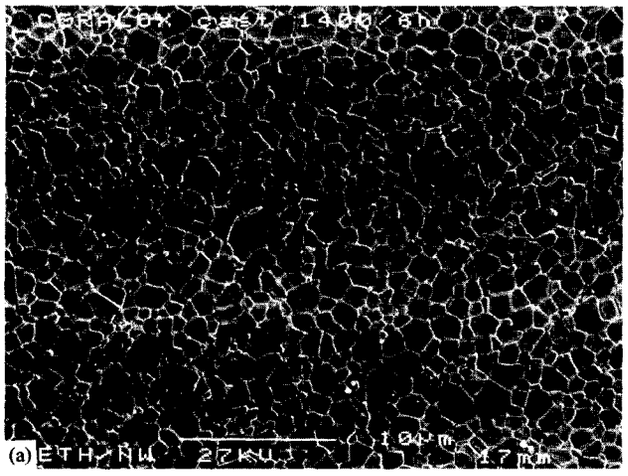

Fig. 13. Microstructures of sintered compacts: (a) centrifugally cast (53·4 vol.% slurry, 4000 *g*/90 min); (b) isostatically pressed.

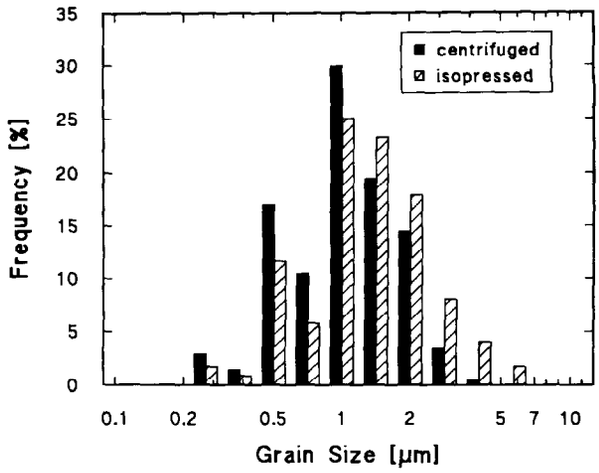

Fig. 14. Statistical evaluation of microstructures of sintered compacts.

light scattering over the length of the cylinder. This is due to the different sintering kinetics of larger and smaller particles (and larger and smaller pores) at the top and bottom part of the cylinder, respectively. Slurries containing more than 50 vol.% solids gave crack-free sintered parts that showed densities of about 99·4%TD and homogeneous light scattering throughout the entire length of a cylinder.

3.7 Microstructure

At the same final density (99·4%TD) a finer and more homogeneous microstructure is achieved by centrifugal casting compared to isopressed samples, as can be seen from Fig. 13. A statistical evaluation of the micrographs is shown in Fig. 14. The average grain size measured was 1·1 μm for the centrifuged samples and 1·6 μm for the isopressed alumina. The most important difference lies in the homogeneity of the microstructure. Isostatically pressed alumina shows grains of up to 10 μm in size, whereas the maximum grain size in cast alumina does not exceed 6 μm. Grain growth can occur in densified regions and its speed is strongly dependent upon the temperature. The lower the sintering temperature to reach a high final density, the better for the microstructural evolution which will be finer and more homogeneous.

3.8 Flaw size distribution

Figure 15 shows polished surfaces of cast and isostatically pressed alumina of comparable density (99·4%TD). By colloidal processing the number and size of larger pores could be drastically reduced. This can be more clearly seen from Fig. 16 which shows a statistical evaluation of the flaw distribution of centrifugally cast and isopressed samples. The largest pores in sintered compacts from cast alumina reach a size of 20–30 μm, which is about 4–5 times smaller than the largest

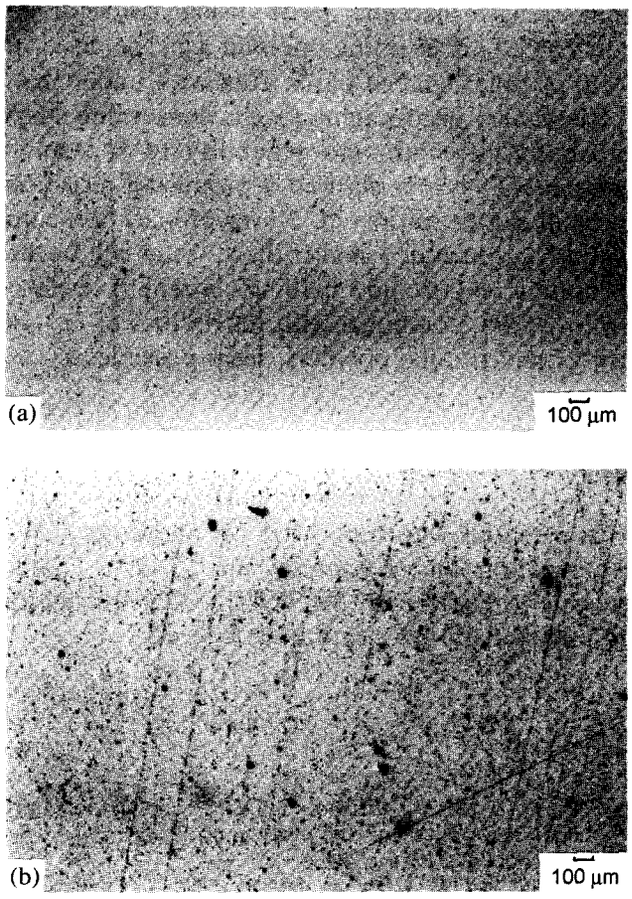

Fig. 15. Polished surfaces of sintered compacts: (a) centrifugally cast (53·4 vol.% slurry, 4000 *g*/90 min); (b) isostatically pressed.

pores found in isopressed material (90–120 μm). The area investigated on both samples was 5·6 mm^2. The total pore volume equals 5 ppm of the total volume.

Fracture surfaces of centrifuged bending test specimens were examined with SEM (Fig. 17) and the fracture origins were recognized to be agglomerates having a size of 20–30 μm. This is typical for the maximum flaw size of the centrifuged compacts of this study and is in accordance with the Griffith relationship for the case of a fracture

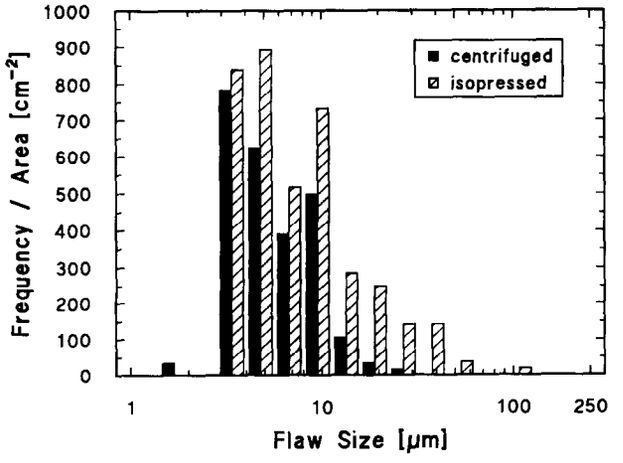

Fig. 16. Statistics of flaw distribution in sintered compacts.

Fig. 17. Typical fracture surface of centrifuged bending test specimen showing the fracture origin.

toughness of 3·8 MPa $\sqrt{m}$ and an average bend strength of 540 MPa, (geometry factor Y-1168).

3.9 Mechanical properties and reliability

The advantages of centrifugal casting are obvious when comparing the mechanical properties, as shown in Fig. 18. These data were acquired from four-point-bending tests of batches of at least 21 specimens. The number of specimens is large enough to give good Weibull statistics.[35] The average strength of cast alumina was 540 MPa; an increase of 60% compared to isostatically pressed material (340 MPa). The Weibull modulus m of the centrifuged material was more than tripled, reaching 23·9. For the statistical calculation, the fracture probability estimator with the largest bias (mean rank value: $P_{if} = i/(n + 1)$) was chosen, leading to the lowest m-values of all known estimators.[36,37] These results prove that centrifugal casting provides the possibility of increasing the reliability of α-alumina ceramics up to the level requested by design engineers.

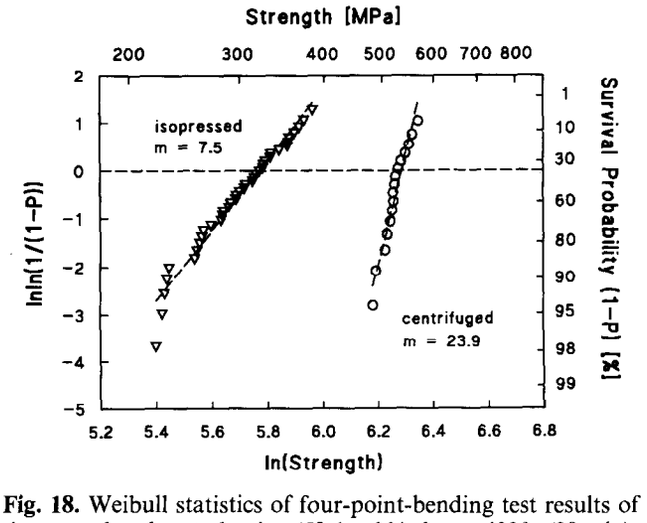

Fig. 18. Weibull statistics of four-point-bending test results of isopressed and cast alumina (53·4 vol.% slurry, 4000 *g*/90 min).

Table 3. Comparison of typical properties for cast and isostatic-pressed compacts

Property	*Centrifugal casting*	*Isostatic pressing*
Green density (%TD)	68	59
Sintered density (%TD)		
1400°C/6 h	99·4	98·6
1500°C/2 h	99·7	99·5
Linear shrinkage (%)	12	17
Average grain size (μm)	1·1	1·6
Maximum grain size (μm)	6	10
Maximum flaw size (μm)	20–30	90–120
Average strength (MPa)	540	340
Weibull modulus m	23·9	7·5

3.10 Comparison of centrifugal casting and isostatic pressing

In Table 3 some properties of compacts made via centrifugal casting and isostatic pressing are shown. The cast sample sinters to ≥99·4%TD at 1400°C with 6 h holding time, whereas the pressed sample requires a sintering temperature of 1500°C and 2 h to reach the same density. Centrifugal casting of high-solids-content slurries provides ceramic parts which have high green densities (15% higher than isopressed) and narrow pore size distributions and therefore closing of the structure is completed at lower temperatures and shrinkage is smaller. Higher green densities in combination with narrow pore size distributions leads to smaller grain sizes due to lower sintering temperatures. The largest flaws in the centrifuged parts are due to agglomerates not eliminated in the slurry preparation sequence. It can be expected that even better slurry preparation combined with smaller sieve size (from 1 to 5 μm) will reduce the maximum flaw size even more, leading to even higher strength values at higher reliabilities.

4 Summary and Outlook

α-Alumina ceramic components showing high reliability at high bend strength levels can be obtained from commercially available powders via centrifugal casting. Wet processing of ceramic powders and subsequent centrifugal casting of high-solids-content suspensions provides a route to producing parts that show better particle packing and a smaller number and size of flaws than dry processed components. High green and sintered densities as well as homogeneous microstructures were achieved by centrifugal casting α-alumina with a four-point-bend strength of 540 MPA and a reliability characterized by a Weibull modulus of m = 23·9 could be obtained. Centrifugal casting of high-solids-loading slurries is a very promising way to form highly reliable, high-strength ceramic parts using conventional powders. This forming method can be used to form complex shaped parts, even with undercuts.

These very encouraging results concerning shape capability, strength and reliability of α-alumina components clearly showed a promising direction, but still can be improved. Slurry preparation eliminating agglomerates smaller than 30 μm will further increase strength and reliability. Strength levels of up to 1 GPa, combined with reliabilities of m = 40 using conventional powders, seem possible.

(Received 19 August 1994; revised version received 21 February 1995; accepted 10 March 1995)

Abstract

Both unreinforced and model filler reinforced aluminium/alumina bodies have been produced by directed metal oxidation from pure aluminium parent metal blocks externally doped with magnesium. It is shown that there are some differences between the growth processes in the two cases and that in particular the presence of the filler in the production of reinforced bodies restricts the supply of oxygen to the reaction front and that an oxygen-depleted atmosphere may arise locally, leading to areas where aluminium nitride is produced rather than alumina.

1 Introduction

The production of ceramic materials by the directed metal oxidation process developed by the Lanxide Corporation, Delaware, USA, has received increasing attention recently. The process involves the oxidation of a bulk molten metal by a gas through a directed growth process to produce an interconnected ceramic reaction product, that may contain several percent of residual metal. Reinforcements may be readily incorporated in the ceramic/metal body by allowing the oxidation reaction product to grow through, and thereby incorporate, a filler material such as ceramic particles, platelets or fibres. Dopants are required to initiate and maintain the growth process and it is this feature that distinguishes it from other reaction bonding processes. Growth is limited by the presence of inert (barrier) powders which may used to define the shape of the desired product.

Much of the published work[1–3] in this area has concentrated on the production of unreinforced Al_2O_3/Al bodies grown from specially prepared aluminium alloys containing both Mg and Si as dopant elements. Nagelberg[4] has studied directed growth from an Al–Mg alloy, but in this case initiation required scratching the initial oxide scale to expose the molten Al alloy directly to the air atmosphere. Xiao and Derby[5,6] have shown that MgO may be used as an external dopant to initiate growth with pure Al.

In this paper, we concentrate on the effects of reinforcement on the production of Al_2O_3/Al bodies from pure Al with Mg as an external dopant element. To this end both unreinforced and model reinforced bodies have been produced. The model reinforced bodies were produced by growth into coarse alumina fillers (this filler could be readily distinguished from the alumina reaction product generated by the oxidation process). The microstructural development and the relationships between the growth mechanisms for both unreinforced and reinforced directed metal oxidation bodies have been investigated and are discussed below in some detail.

2 Experimental Procedure

99·8% pure Al (Alcan) blocks were placed on a bed of fine alumina powder (A17, Alcoa) contained within a mullite crucible. A mullite tube was placed on top of the Al block and further fine alumina was packed round the outside of this tube. Powdered reagent-grade Mg (5 wt%, Fisons) was either placed inside the tube directly on the surface of the Al block as a dopant (in the production of unreinforced bodies) or mixed with coarse tabular alumina (8–14 mesh, Alcoa) and the mixture placed in the tube above the Al block (to produce model reinforced bodies). In either case the tube was then withdrawn leaving the arrangements are shown in Fig. 1.

The prepared systems were heated in air at 200°C per hour in a muffle furnace to a soak temperature of 1180°C. This temperature was maintained for 15 or 24 h, after which the samples were cooled to room temperature inside the furnace.

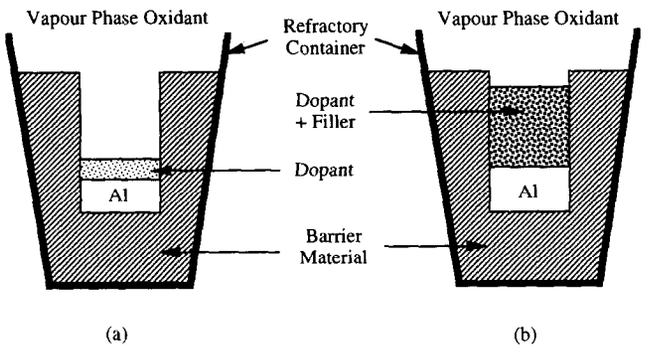

Fig. 1. Experimental arrangements used; (a) unreinforced body system: dopant directly placed on Al block, (b) reinforced body system: dopant mixed with filler and mixture placed above Al block.

Qualitative phase analysis of both the starting materials and fired specimens was undertaken by X-ray diffraction (XRD). Fired samples were sectioned parallel or perpendicular to the growth direction and the different regions analysed by XRD. These samples were subsequently mounted in epoxy resin, ground and diamond-polished to 1 μm, before carbon coating for examination with both scanning electron microscopy (SEM) (Jeol JSM 6400) and energy dispersive spectroscopy (EDS) (Link Analytical 6276).

3 Results

3.1 Unreinforced Al_2O_3/Al composites

After 24 h oxidation at 1180°C, the Al-block was partially consumed; the reaction product had an irregular shape with a smooth surface. Cross sections of this reaction product showed that it contained substantial amounts of aluminium in wide channels 3–5 μm in diameter, it is clear that the oxidation process was not completed. XRD showed that the product was predominantly Al and $MgAl_2O_4$, (magnesium aluminium spinel) with some Al_2O_3 present (Fig. 2).

SEM and EDS indicated the presence of several regions within the sample. The bulk of the sample consisted of unoxidised aluminium interspersed with a ceramic phase that contained both Al and Mg and which was presumed to be spinel (Fig. 3) as XRD failed to detect either Mg or MgO. On the outer surface of the product, there was a denser Mg-containing layer, which was about 10 μm thick; the lack of Mg or MgO detected by XRD indicated that this was also spinel (Fig 4).

3.2 Reinforced Al_2O_3/Al bodies

On heating the system with filler to 1180°C for 15 h, a small amount of growth product was obtained. Macroscopic inspection of a cross-section of the growth product showed that although infiltration of the filler/dopant mixture by the molten metal occurred during the initial stages of the oxidation reaction, it was limited in extent and most of the mixture (filler and dopant) remained unimpregnated by either metal or ceramic. XRD (Fig. 5) showed that the unimpregnated mixture contained Al_2O_3, $MgAl_2O_4$ and MgO but no free Mg. In the growth product, although both α-Al_2O_3 and Al were present, the filler was the main source of α-Al_2O_3; Mg and $MgAl_2O_4$ were also present; again no MgO was detected.

Microanalysis of the oxidised sample provided further confirmation that Al infiltrated into the base of the filler mass close to the metal reservoir (Fig. 6). Within the metallic phase, inclusions containing Al, Mg and O were observed by EDS, which again suggested that they consisted of $MgAl_2O_4$. In the upper region of the growth product, ceramic

particles were developing within the metallic phase. The oxidation front was rather porous and extended over a scale of several particle diameters, with the extent of the reaction product increasing towards the central axis of the sample. It appears that layers of matrix grew outwards from the surface of the filler particles (Fig. 7a). The growth matrix contained unoxidised aluminium channels and was covered by a Mg-containing layer thought to be $MgAl_2O_4$ (Fig. 7b).

By comparison, after 24 h at 1180°C the Al-block was totally consumed, and the resultant reaction product encapsulated the filler particles. It was also observed that, in the completely oxidised sample, the distribution of Al_2O_3 filler particles was quite uniform, although some large holes

were present, especially towards its base. In this case XRD (Fig. 8) showed that Al, α-Al_2O_3 and $MgAl_2O_4$ were all present but there was still no MgO and there was also no longer any free Mg. Significantly, aluminium nitride, AlN, was also detected by XRD in this sample.

Microanalysis of the sample fired for 24 h at 1180°C showed that it consisted of an Al_2O_3/Al matrix with some $MgAl_2O_4$. In the middle of part of the product, AlN instead of Al_2O_3 matrix could be observed (Fig. 9). Three different structures could be clearly distinguished. The first was filler particles; whilst the second, close to the filler, was the matrix growth, which consisted of Al_2O_3 with a surface layer about 5 μm thick, of $MgAl_2O_4$. The third structure which was immediately next to the $MgAl_2O_4$ layer, consists of needles which EDS indicates contain both Al and N and which were

thus identified as the aluminium nitride detected by XRD in this sample.

4 Discussion

In the current work, directed metal oxidation from a pure aluminium block with a surface doping of Mg particles has been studied, rather than growth from an aluminium alloy which has been reported elsewhere. Differences in microstructure between these two types of system have been observed, implying that there are differences in growth mechanism between Al–Mg alloy systems and an externally doped pure Al system.

Some mechanisms have been proposed to explain the directed oxidation of the Al–Mg–Si alloy system.[4,7,11] These are, in general, based on the initiation of the reaction sequence in the aluminium/alumina system by magnesium. For example, Xiao and Derby reported that when pure MgO was placed on the surface of a commercial-purity Al alloy (>99·5%) and oxidised at 1200°C for 7 h, a reaction occurred. Nagelberg[4] pointed out that oxidation product can also be obtained from the Al–Mg alloy; however, the initiation of composite growth required the mechanical disruption of the protective oxide formed during initial heating to the growth temperature.

When aluminium is exposed to oxygen in the atmosphere, a persistent oxide film is soon formed by the following reaction:

$$2Al(s) + \frac{3}{2} O_2(g) \rightarrow Al_2O_3(s). \qquad (1)$$

However, if Mg is present on the surface of the Al-block then, according to the Ellingham diagram,[12] Mg is oxidised first. For example, Bahadur[13] reported that the addition of 0·9 wt% Mg to pure Al at temperatures of more than 500°C caused the formation of MgO at the surface instead of α-Al_2O_3. In addition Al–Mg alloys favour the formation of both MgO and $MgAl_2O_4$ for Mg concentrations above 0·02% and thus Mg is thought to prevent the normal passivation of aluminium by the formation of aluminium oxide film. Haginoya[14] demonstrated by XRD that during the initial oxidation of Al–Mg alloys, the amount of MgO first increased and then decreased with time, while the $MgAl_2O_4$ content increased continuously with time as bulk depletion of Mg in the alloys results in the eventual conversion of nearly all the MgO to $MgAl_2O_4$.

In the present study MgO was not observed, but EDS has shown that most of the Mg was found in regions which also contained Al and these regions are thereby presumed to be the $MgAl_2O_4$ identified by XRD. This is the case even for reaction products formed by heating to 1180°C followed immediately by furnace cooling. Those workers who have observed MgO have air-quenched their samples. This difference in cooling rate implies that $MgAl_2O_4$ is more stable than MgO for alloy compositions containing 5% Mg. This is in agreement with the thermodynamic calculations of Xiao and Derby,[5] which show that spinel ($MgAl_2O_4$) is the most stable oxide in contact with liquid aluminium alloys containing greater than about 0·5 wt% Mg.

Based on these observations the following growth mechanisms for both unreinforced and reinforced bodies are proposed. In the following argument all the thermodynamic data has been calculated using the SGSUB database in the MT-DATA package.

4.1 Unreinforced directed metal oxidation

In this case the system is pure aluminium with a surface layer of 5 wt% of powdered Mg. Initially Mg powder is oxidised by the air to form MgO (this occurs before the aluminium melting temperature is reached):

$$2Mg(s) + O(g) \Leftrightarrow 2MgO(s). \quad (2)$$

An interdiffusion reaction between the MgO so formed and the layer of alumina that will be present on the aluminium surface can then convert the MgO layer to spinel:

$$MgO(s) + Al_2O_3(s) \Leftrightarrow MgAl_2O_4(s) \quad (3)$$

This spinel layer is non-protective and because it is easily wetted by aluminium permits infiltration by aluminium. At the aluminium melt surface, the oxygen partial pressure is determined by the equilibrium between Al and Al_2O_3:

$$Al(l) + \frac{3}{2} O_2(g) \Leftrightarrow \frac{1}{2} Al_2O_3(s)$$

for which $\Delta G = 1{\cdot}21842 \times 10^6$ J mol^{-1} at 1453 K. Thus, assuming that condensed materials have unit activity, the partial pressure of oxygen in this region is fixed and low at about $9{\cdot}064 \times 10^{-30}$ atm. The spinel in this region will be in equilibrium with magnesium and alumina. Considering the following equilibrium:

$$MgAl_2O_4(s) + 2Al(l) + O_2(g) \Leftrightarrow 2Al_2O_3(s) + Mg(g) \quad (4)$$

for which $\Delta G = -7{\cdot}27010 \times 10^5$ J mol^{-1} at 1453 K. Again, taking the condensed materials to be at unit activity, this gives an equilibrium constant of $K = P_{Mg}/P_{O_2} = 1{\cdot}36458 \times 10^{26}$ and thus the partial pressure of magnesium at the aluminium melt interface is $1{\cdot}237 \times 10^{-3}$ atm. This is sufficient to move magnesium away from the melt interface to a region with a higher partial pressure of oxygen, where it will recombine to form magnesia:

$$Mg(g) + \frac{1}{2} O_2(g) \Leftrightarrow MgO(s). \quad (5)$$

At 1453 K $\Delta G = -4{\cdot}33283 \times 10^5$ J mol^{-1} for this reaction, and thus using $\Delta G = -RT\ln K$ the equilibrium constant is:

$$K = \frac{1}{P_{Mg} P_{O_2}^{1/2}} 3{\cdot}76703 \times 10^{15}.$$

Recombination will therefore occur when the magnesium reaches a region where the oxygen partial pressure is greater than $4{\cdot}6068 \times 10^{-26}$ atm. As the partial pressure of magnesium drops, a proportionately higher oxygen partial pressure will be required to cause the formation of magnesia. The magnesia formed by this reaction will subsequently react with the Al that reaches it by penetrating the non-protective spinel layer that lies immediately beneath it.

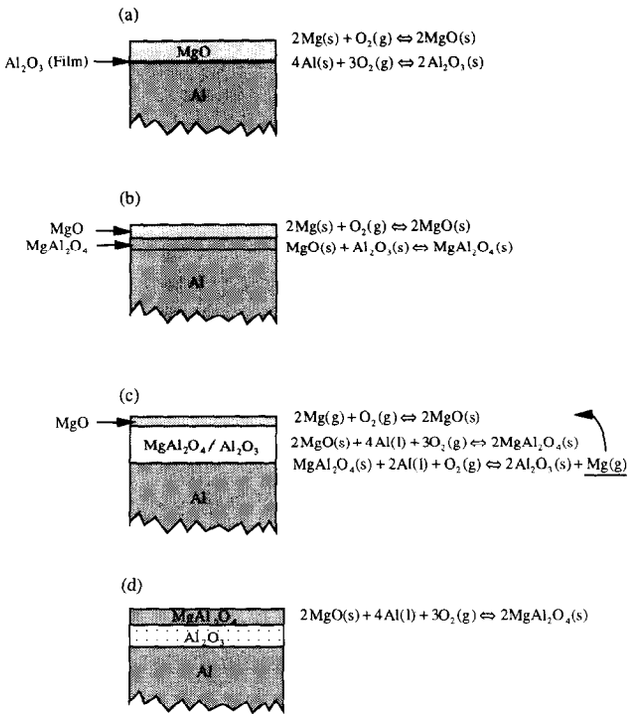

Fig. 10. Schematic diagram of development of cyclic reaction sequence in unreinforced DMOX bodies (time increases from (a)–(d)).

Removal of magnesium from the melt interface will favour the decomposition of the spinel to form alumina and thus a reaction system is set up with a thin magnesia layer overlaying a spinel layer, which in turn overlays an alumina layer. The spinel layer is continually being decomposed at its lower surface to form the next layer of alumina and it is continually being replenished at its upper surface by the reaction of the lower surface of the magnesia layer. The upper surface of the magnesia layer is in turn being replenished. The reaction process, which is shown schematically in Fig. 10, agrees in essence with that given elsewhere.[7,9,10]

Although this reaction sequence implies the existence of a magnesia layer on the growth surface, this was not seen in this work, although it has been reported elsewhere on air-quenched samples. Air-quenching will tend to freeze the sample in the high-temperature state, whereas during furnace cooling there is sufficient time for lower-temperature equilibria, which favour the formation of spinel from magnesia, to develop.

4.2 Reinforced directed metal oxidation Al_2O_3/Al

The introduction of a filler has several effects on both the process reactions and the microstructure of the product. For growth to be possible, the filler must both be wettable by the molten metal

and allow matrix growth through the pores amongst its particles. If there were no wetting of the filler particles by the matrix, the effective reactive surface area of the growing matrix would be reduced in proportion to a volume fraction of the filler. Conversely, if the filler is easily wetted by the growing matrix, the matrix/atmosphere surface area can be increased significantly and this should give enhanced growth rates. The coarse filler used in this work has a very rough surface texture, which according to the Wenzel model implies a high degree of wettability of the filler by molten Al.[15]

In this work, filler particles mixed with magnesium powder are placed on the Al-block. During firing, within the mixture, Mg powder is firstly oxidised to form MgO (reaction (1) above). As well as reacting with the protective alumina layer on the aluminium reservoir surface Mg may also react with the Al_2O_3 filler surface to form $MgAl_2O_4$ by either:

$$MgO(s) + Al_2O_3(s;\ \text{filler}) \Leftrightarrow MgAl_2O_4(s), \quad (6)$$

$$Mg(s) + Al_2O_3(s;\text{filler}) + \frac{1}{2}O_2(g) \rightarrow MgAl_2O_4(s). \quad (7)$$

This is in agreement with the observation of Hitchcock *et al.*[15] who reported that in the wetting of alumina by Al–Mg alloys, the interface was characterised by formation of spinel, which considerably enhanced the wettability of aluminium liquid for alumina.

As described above, the Al-rich melt may also dissolve Mg from spinel to nucleate Al_2O_3 (reaction (4) above), thereby releasing magnesium and thus setting up the same basic reaction sequence that is outlined above. A reaction front will thus gradually propagate through the filler body, leading to the encapsulation of filler in the alumina product.

This time, however, the gas phase reaction between Mg and O_2 can also lead to the deposition of magnesia on the surface of the alumina filler. This magnesia then reacts with the filler to produce spinel. Molten aluminium will react with the spinel layer to produce alumina, thereby freeing magnesium, and the cycle of reactions can proceed locally round each filler particle so that growth proceeds outwards from each filler particle.

This process will, however, deplete oxygen locally; this is especially significant if the filler particles in question are behind the main reaction front. The presence of the filler limits the ingress of oxygen to the growth surface. As a result, when the matrix grows and wetting of the filler proceeds upwards, unreacted regions may remain between filler particles where the oxygen content is very

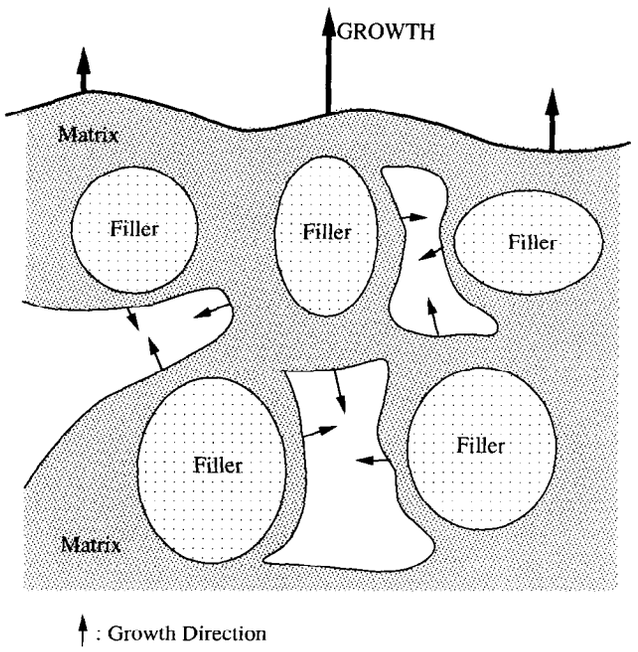

Fig. 11. Schematic diagram of growth mechanism in reinforced DMOX bodies.

low (shown schematically in Fig. 11). If the oxygen content is sufficiently low, with nitrogen (in air) as the diluent, Al liquid reacts with nitrogen to form AlN amongst the filler particles:

$$Al(l) + \frac{1}{2}N_2(g) \Leftrightarrow Aln(s). \quad (8)$$

In fact, high-purity AlN can be prepared by complete nitridation of molten Mg–Al alloys[17] at temperatures above the boiling point of magnesium (1363 K). Scholz and Claussen[17] suggested that magnesium plays a similar role in the nitridation of aluminium as it does in the oxidation, it prevents the formation of a dense nitride layer and thus turns a surface reaction into a volume reaction. For the pure alumina, a threshold oxygen-to-nitrogen ratio exists, above which the oxide and below which the nitride become stable, according to the reaction:

$$2AlN(s) + \frac{3}{2}O_2(g) \Leftrightarrow Al_2O_3(s) + N_2(g). \quad (9)$$

For this reaction at 1453 K $\Delta G = -8{\cdot}94725 \times 10^5$ J mol^{-1} and as long as the $P_{N_2} : P_{O_2}$ ratio is greater than $1 : 3{\cdot}07 \times 10^{-20}$, then the nitride formed by reaction (8) will not be converted to alumina. This condition is achieved because of the tortuous oxygen diffusion path and the removal of oxygen from the local atmosphere within the filler body as either alumina or spinel. Hence both Al_2O_3 and AlN are observed in the central region of the final product. Enough oxygen reaches the top of the reaction product to ensure that only Al_2O_3 or spinel is seen in this region.

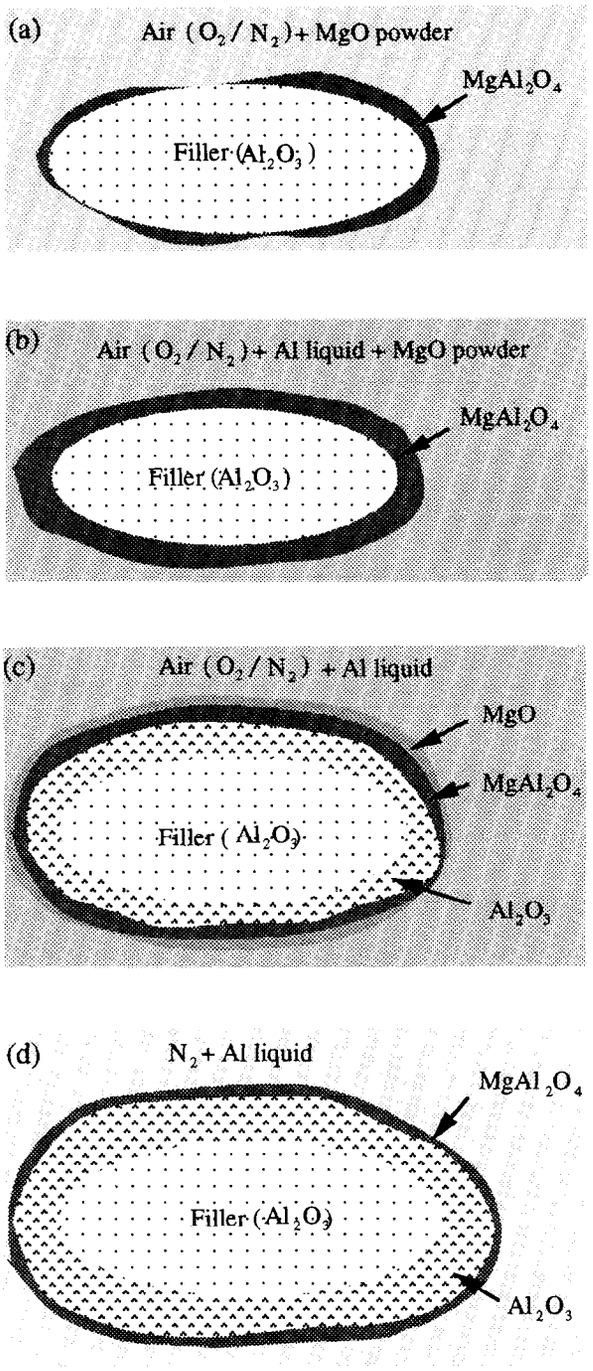

Fig. 12. Schematic diagram of stages of growth with time around filler particles in reinforced DMOX bodies (time increases in going from (a)–(d)).

Thus, although the presence of a filler does not change the overall reaction sequence in the Mg doped Al/Al_2O_3 system, it can give rise to local reaction sequences behind the main reaction front. The local growth mechanism is shown schematically in Fig. 12.

5 Conclusions

The directed metal oxidation growth of both unreinforced and reinforced Al_2O_3/Al bodies from pure Al with an external dopant of Mg has been investigated. The role of the dopant Mg is to promote the formation of a non-protective oxide layer at the surface of the reaction product. This layer is instrumental in developing the subsequent cyclic reaction sequence.

The proposed mechanism is consistent with the experimental results observed, and has the following stages: firstly, $MgAl_2O_4$ is formed via the reaction between MgO which is produced by oxidation of Mg dopant and the passive Al_2O_3 layer which is present on the surface of the Al-block. This ruptures the stable oxide film Al_2O_3; as it thickens, some of the $MgAl_2O_4$ is dissolved by Al melt, and Al_2O_3 is subsequently nucleated. Mg produced via the decomposition of $MgAl_2O_4$ moves to regions of higher oxygen partial pressure, where it forms magnesia and subsequently reacts with Al to reform $MgAl_2O_4$. The cyclic reaction sequence results in the observed product growth.

In the case of reinforced Al_2O_3/Al composite, the filler bed placed on the parent metal affects both reactions and microstructure. With an alumina filler, the magnesia formed during the reaction sequence may react with either aluminium metal or with the filler itself to form spinel. The latter reaction locally consumes oxygen and as the filler limits the ingress of oxygen to oxidation growth reaction fronts that are between the filler particles and behind the main reaction front, oxygen may become locally exhausted, leading to the formation of AlN instead of Al_2O_3. Thus the presence of a filler preform has led to changes in the observed reaction products. The details of such changes obviously depend upon the material used, but they should be considered in the production of ceramic matrix composites by this route.

Acknowledgments

We thank Professor B. B. Argent for his help with calculating the free energy changes in the directed metal oxidation process and for his critical reading of the first draft of this paper. This work was undertaken whilst one of us (X. G.) was in receipt of a scholarship from the University of Sheffield.

Abstract

A study of ion implantation in polycrystalline alumina has been undertaken aimed at two principal areas. Firstly the measurement of the evolution of mechanical properties in the treated surface, such as hardness and fracture toughness, was undertaken using a Vickers indentation method. These properties are very sensitive to the presence of residual stresses and to the surface microstructure. Secondly a physicochemical study of the treated surface using XRD and SEM techniques in order to identify the parameters that influence the mechanical changes was undertaken.

1 Introduction

The thermomechanical properties of structural ceramics depend strongly on their surface state: e.g. fracture in brittle materials is frequently due to the flaws present on the surface Ion implantation is one of the methods currently used to overcome this difficulty, since the method has the advantage that the net shape and dimensions of the samples are preserved even after the treatment. Most of the studies on ion implantation up to now have been carried out on single crystals.[1–3] We report here on a study of ion implanted polycrystalline alumina. In the case of ion implantation with zirconium, an element which readily oxidises to ZrO_2, which is not miscible in alumina, the formation of a zirconia reinforced alumina composite layer has been observed.[4] It is therefore equally interesting to study the case of titanium implantation in alumina since titanium also oxidises very easily to TiO_2 which has considerable solubility in alumina.[5] Earlier studies on the ion implantation of Ti^+ and Y^+ ions in single crystals has revealed that compressive stresses are created in the implanted zone.[6] These stresses provide a possibility of reducing the spreading of radial cracks on the sample surface, which leads to variations in the surface mechanical properties. It is also possible under certain conditions, to form an amorphous surface layer by this technique. In the case of titanium implantation into sapphire, the amorphous layer is not formed until the fluence is less than 10^{17} ions/cm^2 (at room temperature) or until the temperature is lowered to 77 K with smaller doses.[7] The microstructure of the implanted zone depends generally on the fluence level and the ion energy, as well as on the temperature of implantation, the nature of the ion implanted and the state of the substrate surface.[8] A post-thermal treatment could allow the possibility of other changes in the microstructure and in the phases present in the implanted layer which, in turn, could lead to changes in the mechanical properties. It is therefore necessary to understand the processes that follow the thermal treatment of the ion implanted layers.

2 Experimental

2.1 Sample preparation

Polycrystalline alumina samples (MATROC D995 F) of 99·95% purity and a grain size <3 μm was used in this study. The samples were polished rigorously to the same reference level (fixed roughness).

Polishing grinding

The samples were ground to levels of assured planarity by fixing them on rotating metallic disks and using a diamond paste of 6 μm size for a period of about 20 min under a pressure of 1 bar.

Polishing

Final polishing was done on a felt disc using polycrystalline diamond paste of 3 μm, followed by a diamond paste of 1 μm, the different operations led to a surface roughness < 0·02 μm. To reduce the damages induced by polishing, the samples were post annealed in air for 1 h at 1200°C.

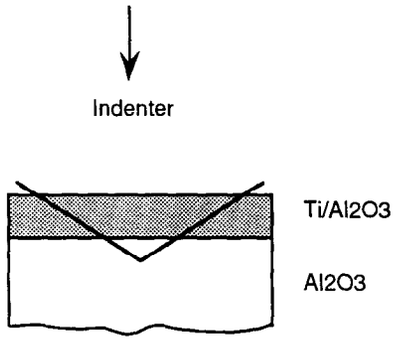

Fig. 1. Indenter into the implanted layer.

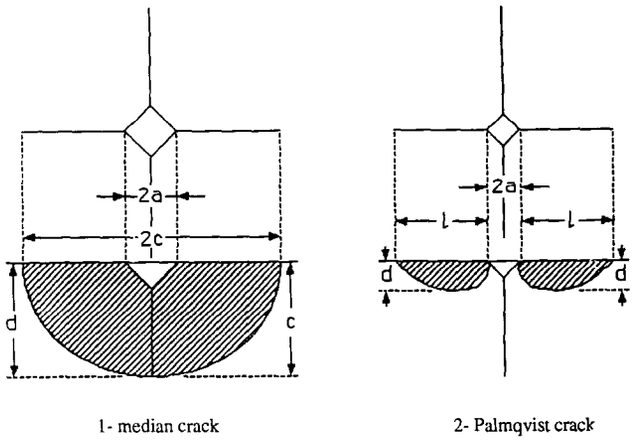

Fig. 2. Crack system.

2.2 Ion implantation

Ion implantation was conducted using monocharged ions produced by an isotopic separator which permits separation of monocharged ions possessing a maximum energy of 110 Kev; doses of 2×10^{16} ions/cm^2 and 10^{17} ions/cm^2 are used in this study. The higher dose is the limit, for this energy, to obtain an implanted layer without amorphisation.[7] During the implantation, the temperature of the target was maintained at the ambient level using a water circulation system for the target holder. After implantation, thermal treatment at three different temperatures 1000, 1200 and 1500°C was conducted for 1 h in air in all cases.

2.3 Vickers hardness

The hardness of the implanted alumina samples was obtained by the ratio of the load to the surface contact area. The Vickers microhardness was measured on a non-instrumented microhardness tester (WOLPERT VTD 11 Type) using loads in the range of 0·1–10 N. The loads were applied to the sample for a period of 30 s in all cases. The unit was fitted with an optical system with two scales of magnification. The samples were subjected to 10 indentations under different loads (0·1, 0·25, 0·5, 1, 2, 3, 5 and 10 N). For the smallest load, the indents were of the order of 3 μm, thus we are unable to observe them accurately. Hence an indirect method has been used, where an optical microscope with its immersion objective attached camera with a high resolution film is used. This permits a magnification of 10000 and increases the possibility of measuring such small indents, without, however, increasing the resolving power of the microscope. The photography enables us to measure the indents with a higher definition (a few %). The implanted layer is about 1000 Å thick and the lowest charge of 0·1 N was used for the indentation, shown schematically in Fig. 1. As stated above, this arrangement indicates the direction of the changes in the hardness value, but not the exact value of the hardness of the implanted layer. If the hardness of the implanted layer increases this increases the measured hardness as well.

2.4 Fracture toughness

The Vickers indentation is particularly suitable to measure the toughness of brittle materials. Recently Liang *et al.*[9] have proposed a unified formula which enables the determination of toughness in both cases of median or Palmqvist's cracks, shown schematically in Figs 2.1 and 2.2.

$$\frac{K_c\Phi}{Ha^{1/2}}\left(\frac{H}{E\Phi}\right)^{0.4}\alpha = \left(\frac{c}{a}\right)^{(c/18\,a)-1.51}$$

$$\alpha = 14\left[1{\cdot}8\left(\frac{4\nu - 0{\cdot}5}{1+\nu}\right)^4\right]$$

where a and c are respectively: the semidiagonal length of indent and the half length of the cracks produced by indentation. Φ is a constant ≈ 3, ν is Poisson's ratio, H the hardness and E the Young's modulus of the material. The load at which the crack is initiated is 2 N. A knowledge of the length of the crack, $2c$, and the hardness of the material, H, would enable the determination of toughness K_{1C}. The polycrystalline material used in this study is an industrial product and possesses a heterogeneous microstructure; this leads to a

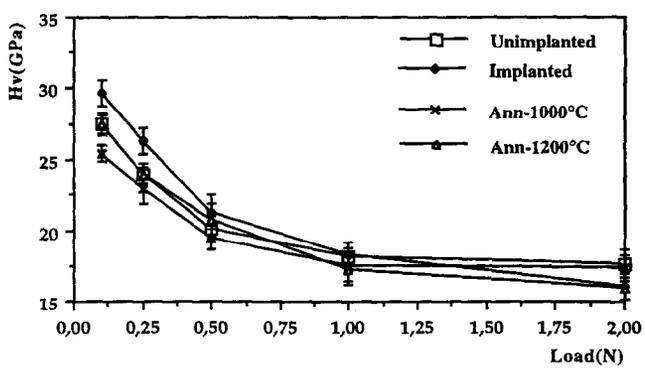

Fig. 3. H_v versus load in Ti^+ implanted Al_2O_3, dose 2×10^{16} ions/cm^2.

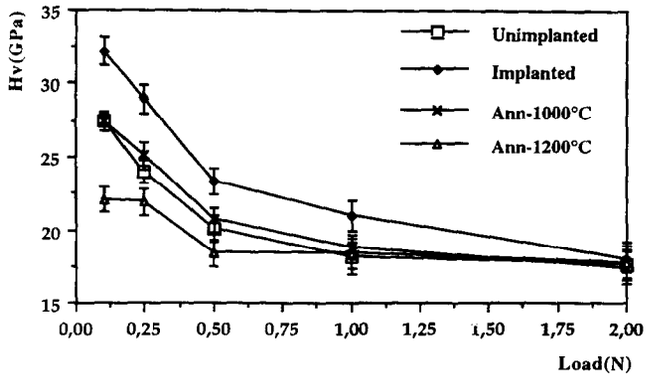

Fig. 4. H_v versus load in Ti^+ implanted Al_2O_3, dose 10^{17} ions/cm^2.

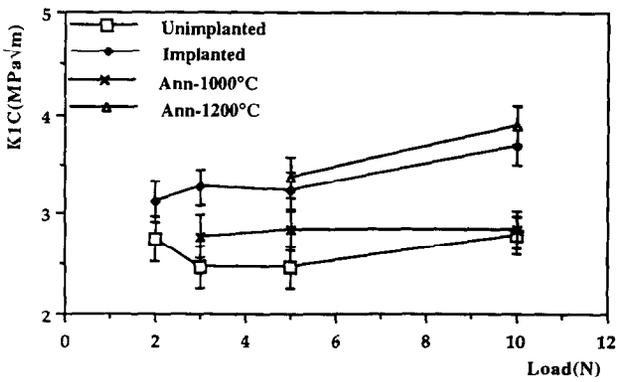

Fig. 6. Variation of K_{1C} as a function of applied load on Ti^+ implanted Al_2O_3, dose 10^{17} ions/cm^2.

dispersion in the measured values of toughness. For this reason, the results showing a large deviation from the mean values are excluded in this study. The mean values derived give an indication of the changes to the material toughness.

3 Experimental Results

3.1 Hardness

The curves of Figs 3 and 4 present the variation of hardness as a function of the load used for different temperatures of annealing and for the two implantation doses mentioned. As stated earlier, the most significant values of hardness are obtained at a load of 0·1 N.

3.2 Toughness

Figures 5 and 6 present the evolution of toughness as a function of load and the temperature of annealing. Cracks occur only after a particular applied load. The K_{1C} values have been calculated for different loads.

3.3 Physicochemical analyses

Figure 7 presents the evolution of the superficial microstructure observed in a scanning microscope at the two implantation dose levels and for different temperatures of annealing. (Fig. 7(a–d)) for the dose 2×10^{16} ions/cm^2 and Fig. 7(e–h) for the dose 10^{17} ions/cm^2 respectively).

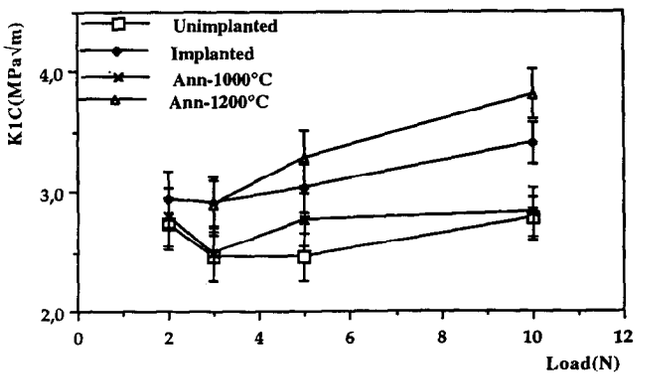

Fig. 5. Variation of K_{1C} as a function of applied load on Ti^+ implanted Al_2O_3, dose 2×10^{16} ions/cm^2.

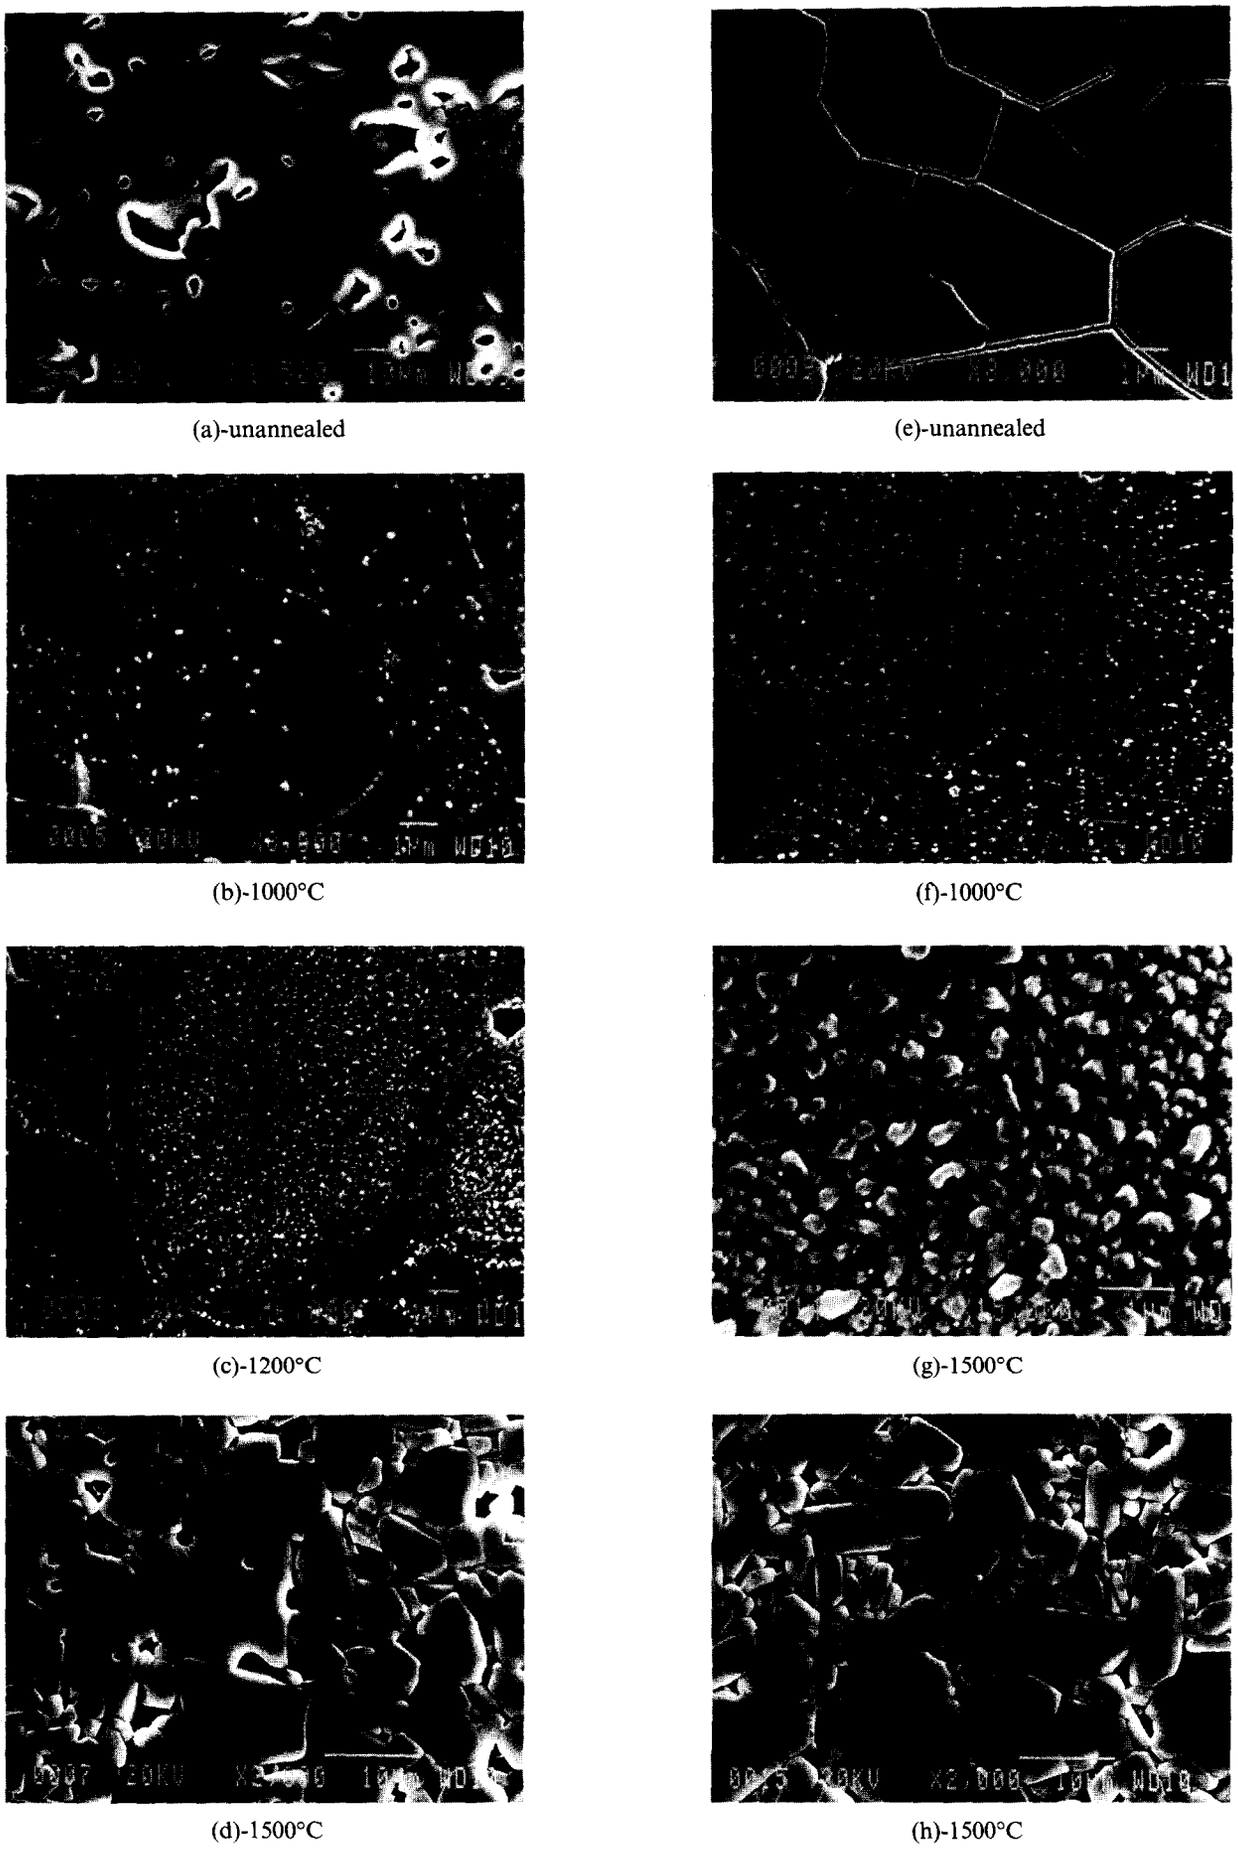

It can be seen that for the unannealed samples the surface is free of precipitates, (Fig. 7(a–e)). These precipitates only appear at 1000°C and grow at 1200°C, (Fig. 7(c–g)). Annealing at 1500°C removes the precipitates so that only the grain boundaries remain, (Fig. 7(d–h)).

Figure 8 presents the X-ray diffraction diagrams at grazing incidence (GXRD) obtained for the implanted sample (Fig. 8(a)) for both doses of 2×10^{16} ions/cm^2 and 10^{17} ions/cm^2 annealed at 1000°C and Fig. 8(b) for both doses of 2×10^{16} ions/cm^2 and 10^{17} ions.cm^2 annealed at 1200°C respectively). The peaks without indices correspond to α-Al_2O_3 and the others indicate the presence of the tetragonal TiO_2 obtained after annealing.

4 Discussion of the Results

The result of titanium implantation into polycrystalline alumina is an enhancement of the hardness of 8 and 18% for dose levels of 2×10^{16} ions/cm^2 and 10^{17} ions/cm^2 respectively. When the implanted samples are thermally annealed at 1000°C, the hardness was found to decrease for both doses. However, while thermal annealing at 1200°C recovers the hardness value to that of the unimplanted alumina in the case of the smaller dose, the hardness value lies much below that of the unimplanted alumina in the case of the higher dose. It should be noted also that changes in the toughness K_{1C} in the case of both doses follow a trend similar to the case of hardness (Fig. 6).

An appreciable increase in the value of K_{1C} could be noticed in the case of both doses (22% for the smaller dose and 32% for the larger dose). Thermal annealing at 1000°C lowers the values of K_{1C} in both cases while thermal annealing at 1200°C finally leads to an increase in the value of toughness (32 and 40% for the small and the high doses respectively).

Fig. 7. Microstructure of the implanted alumina before and after annealing at different temperatures: a–d — dose: 2×10^{16} ions/cm^2 and e–h — dose: 10^{17} ions/cm^2.

The scanning electron microscopic (SEM) studies show that the microstructure of all the implanted alumina samples is similar and the porosities present in alumina are visible (Fig. 7(a)–(b)). Thermal annealing at 1000°C creates precipitates in the grain and on the grain boundaries (Fig. 7(b)). Annealing at 1200°C increases the quantity of precipitates which have a size less than 1 μm (Fig 7(c–g)). At 1500°C, the precipitates disappear and only the grains remain visible (Figs 7(d–h)) the surface becomes irregular and measurement of the indent or cracks dimensions is no longer possible. It is also observed that implantation at the larger dose leads to rupture of the grain boundaries (Fig. 7(e)) as an increase in the size and number of precipitates at the lower dose level (Fig. 7(f–h)).[10]

The principle of X-ray diffraction at grazing incidence is the same as for classical X-ray diffraction studies. The X-ray beams of constant intensity fall on the sample under grazing incidence (a few tenths of 1 or 2 degrees). The penetration of X-ray beams is a function of this angle and the depth of analysis is variable. These diagrams reveal the presence of TiO_2 at 1000 and 1200°C (Fig. 8(a–b)) for both doses. At room temperature and at 1500°C the XRD reveals only the presence of α-Al_2O_3. These X-ray diffraction studies show that the oxidation of titanium occurs during the heat treatment and may be due to the oxygen ions displaced from the substrate by the ion implantation, or an external ingress of oxygen.[11]

On the basis of the XRD and SEM studies, these results can be explained in the following manner:

(i) For the two doses used, the increase of hardness observed on the implanted samples which remain crystalline,[12] could be attributed to the compressive stresses induced by implantation.
(ii) When the annealing temperature is increased, two phenomena are induced simultaneously, namely stress relaxation and TiO_2 formation.

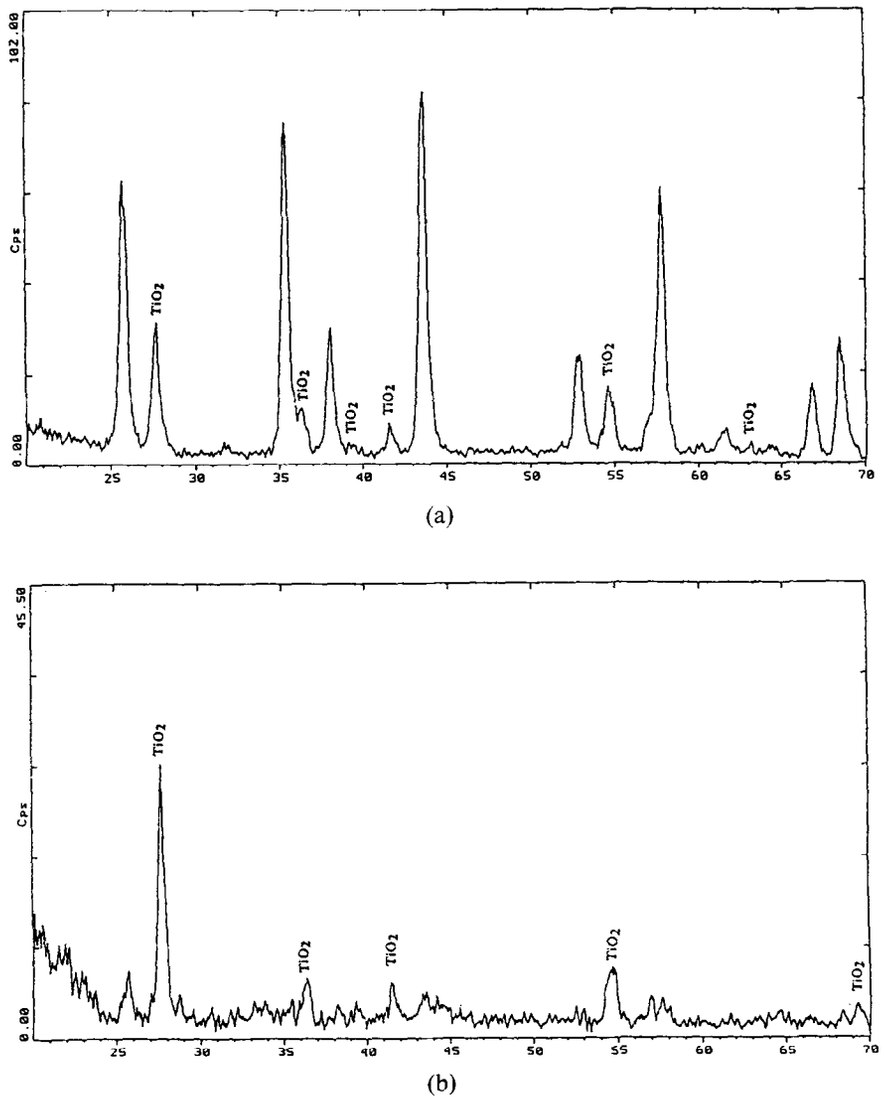

Fig. 8. GXRD patterns showing the effect of annealing for ion implanted alumina. (a) Doses 2×10^{16} ions/cm^2 and 10^{17} ions/cm^2, annealed at 1000°C, (α = 0·3°). (b) Doses 2×10^{16} ions.cm^2 and 10^{17} ions/cm^2, annealed at 1200°C, (α = 0·5°).

One can see that for implantation at the 2×10^{16} ions/cm^2 dose followed by thermal annealing at 1200°C there is very little formation of TiO_2 and the initial hardness of the unimplanted sample is recovered. For the 10^{17} ions/cm^2 dose, the hardness obtained is much less since there is an appreciable formation of TiO_2, whose hardness is less than that of pure alumina. At a temperature which is close to the sintering temperature of alumina (1500°C), the implanted ions are entirely ejected from the implanted surface.

According to Burnett and Page,[6] the residual stresses introduced in the implanted layer are compressive in nature. These stresses were observed by the beam embedding of thin samples method,[13] and also by the measurement of variation of the radial crack length around the Vickers indent. Lawn and Fuller[14] have given a relationship which gives the values of these stresses.

$$1 - \left(\frac{C_0}{C}\right)^{3/2} = \frac{2\Psi\sigma_s\, d^{1/2}}{K_c}$$

where K_c is the substrate toughness, C_0 is the radial crack length at $\sigma_s = 0$, C is the crack length at stress σ_s, and ψ is a constant taken as unity (= 1). In the case where $C < C_0$, σ_s is negative, and the stresses are compressive. The following tables show the values of σ_s (residual stress) obtained for three values of the crack length.

The results obtained with different indentation loads give slightly different values of stress. The method of Lawn and Fuller gives lower values of stress than the method of Krefft and Eernisse.[15]

Generally, implanted samples become amorphous and this leads to the enhancement of the toughness,[10] but the fluences used in this study are not sufficient to amorphise alumina.[6] Hence, we should consider again the idea developed here that the toughness increase for the as-implanted samples is due to the compressive stresses induced by the implantation.

Annealing at 1000°C relaxes these stresses and we obtain a value of toughness close to that of unimplanted alumina. At 1200°C, there is a formation of TiO_2 which gives a toughness value higher than that of alumina. In particular the case where a load of 5 N has been applied, (Figs 5 and 6) an enhancement of 32% for the dose of 2×10^{16} ions/cm^2 and of 36% for the dose of 10^{17} ions/cm^2 is observed. We propose that the residual stresses increase with the implanted dose. This could be attributed to a large concentration of induced defects, point defects and dislocations.[10]

Figure 9 shows a schematic representation of the evolution of the implanted layer composition as a function of annealing temperature and a pictorial representation of the results obtained in the SEM studies.

5 Conclusion

The surface mechanical properties of ceramics could be modified by ion implantation. Such modifications are a result of the change in material microstructure and in the residual stresses produced in the implanted layer.

The specific case of Ti^+ ions implanted in polycrystalline alumina is studied here at 2×10^{16} and 10^{17} ions/cm^2, an increase in hardness due to the effect of compressive stresses is noted at room temperature. These stresses relax with the formation of a layer of TiO_2 when implanted samples are annealed at 1000°C, leading to a decrease of the sample hardness. However, this relaxation effect is compensated by the formation of a large quantity of titanium oxide, in the case of the higher fluence, followed by annealing at 1200°C. Since the toughness of TiO_2 is higher than that of alumina, it is normal that the toughness increases with annealing temperature. At a certain temperature the oxide layer disappears from the implanted layer, which in the present case takes place at 1500°C. Most previous work has been carried out in single crystal alumina and the present work confirms that previous knowledge is equally applicable to polycrystalline aluminas.

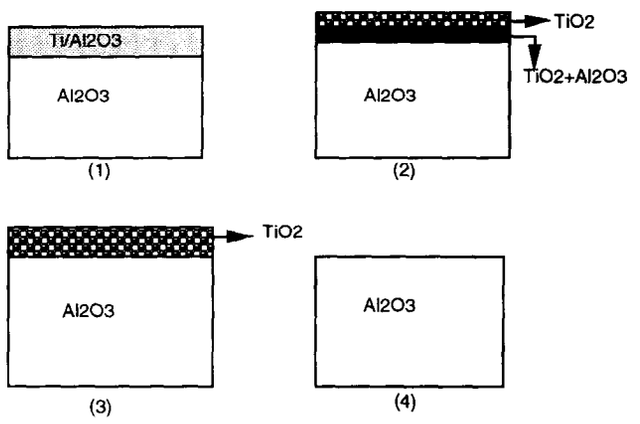

Fig. 9. Schematic representation of the evolution of implanted layer (1) Room-T (2) 1000°C (3) 1200°C (4) 1500°C.

It can therefore, depending on the desired applications, either increase the hardness by implantation, or the toughness by a combination of implantation doses followed by annealing at an optimum temperature. In the last case there is a great possibility of the creation of a third phase. Thus the surface could be suitably treated to obtain surface layers favourable for tribological application.

Abstract

Hot-pressing is the only process to densify alumina–hexagonal boron nitride composites. It must be applied at 1750°C — 40 MPa, under nitrogen, but it does not reduce the porosity lower than 8% for composites with alumina contents lower than 70 vol%, and leads to anisotropic composites due to the orientation of the boron nitride platelets perpendicular to the pressing axis. Furthermore, the composites' behaviour during their use in the continuous steel casting is mainly due to the porosity and anisotropy.

To increase their resistance to oxidation by oxygen and corrosion by molten steel, and to change the effect of their microstructure, some yttrium oxide additions have been used. Yttrium oxide, by helping the alumina sintering, increases the composite's densification and so its mechanical strength, and by increasing the grains cohesion, it allows us to change the hot-pressing programme to obtain a more isotropic composite. Also, by reaction with alumina, it forms yttrogarnet (YAG) which protects the composite from oxidation by forming a protective liquid phase at the surface, following the reaction with boron oxide formed by the boron nitride oxidation. However, this liquid phase is eroded by the molten steel and so, cannot increase the corrosion resistance, but it is possible to stop this corrosion by an addition of neodymium oxide.

1 Introduction

The alumina–hexagonal boron nitride composites have interesting properties used in the continuous casting of low carbon steel, substituting to alumina–graphite. Indeed, boron nitride brings to the composites its good thermal shock resistance and its low wettability by the molten metals.

But it resists poorly to the oxidation and acts as a sintering inhibitor. So, the composite's densification, that needs hot-pressing shaping, does not exceed 92% of the theoretical density for alumina contents lower than 80 wt% (70 vol%). So a considerable porosity is maintained into composites that allows the gas exchanges and so, enhances the oxidation too. For that reason, some yttria additions have been tested to increase the densification of these composites and their oxidation resistance.

This oxide addition was chosen because yttria is a sintering help for alumina by the aluminum vacancies formation, characteristic of an electron donor.[1–5] This effect is attributed to its ionic radius which is larger than the aluminum radius ($r\ Y^{3+}$ = 0·093 nm, $r\ Al^{3+}$ = 0·05 nm) and the phenomenon follows the mechanism:

$$\frac{3}{4}O_2 + 3\,Y_{Al}^{x} \leftrightarrows \frac{3}{2}O_0^{x} + 3\,Y_{Al}^{\circ} + V_{Al}'''$$

Moreover, these vacancies increase the alumina plasticity and so, can help the BN flakes orientation when the pressure is applied during hot-pressing, and limit the vaults formation between these platelets that creates a considerable porosity in the composites.

Also, the Y_2O_3 addition can lead to the appearance of yttrogarnet $Y_3Al_5O_{12}$ (YAG) by *in situ* reaction with Al_2O_3: yttrogarnet whose corrosion resistance in molten steels was shown to be better than BN, W. Sinclair and M B. Trigg.[6–8]

2 Experimental Procedure

Commercial grade powders, 772 SB PECHINEY Alumina and GREPSI Hexagonal Boron Nitride flakes were used to prepare the composites. Starting from a 4 μm homogeneous BN powder after attrition, two slurries were prepared in the 66 vol% methyl ethyl ketone-34 vol% ethanol azeotrope, with specific dispersants, 0·8 wt% phosphate ester for alumina and yttria, and 2 wt% Polyvinyl Pyrrolidone for BN. After 10 min of ultrasonic disintegration, necessary to crumble these powders,

both slurries were mixed together for 42 h by ball-milling and 5 h by a slow attrition before to be dried and sieved.

The powder was hot-pressed at 1750°C and 40 MPa for 30 min in nitrogen atmosphere with a heating rate of 30°C/min.[9-10] All these parameters are controlled by a computer which allows us to obtain the shrinkage rate during sintering.

The properties of Y_2O_3 doped alumina–BN composites were determined: density, flexural strength, SEM observations and XRD analysis. For flexural strength measurements, the crack propagation is parallel to the pressing axis of hot-pressing.

The composites, whose behaviour were studied at high temperatures, were chosen with 60 wt% alumina and 0, 0·5 and 2·5 wt% Y_2O_3 in reference to Al_2O_3 content.

These composites were tested for resistance to thermal shocks. After having been cut into bars of $20 \times 3 \times 4$ mm^3, they were heated in a vertical tube furnace at a chosen temperature and then dropped into agitated oil at room temperature. Then, the samples were broken by the 3 point bending test; the variation of the flexural strength versus the temperature difference ΔT, between the initial hot temperature and the quenching medium, allows to determine the critical value ΔT_c.

The oxidation resistance was studied on cubic samples of $10 \times 10 \times 10$ mm^3 treated in oxygen at 1300°C, by measurements of the oxidized layers depths versus soaking time, for the two main directions, parallel and perpendicular to the pressing axis.

Also, the corrosion resistance was obtained by studying the corroded layers on fingers with dimensions $45 \times 10 \times 10$ mm^3 immersed into liquid steel at 1580°C ± 10°C for 30 min (Fig. 2).[10-11] The steel oxidation is limited by the addition of a slag whose composition is given in Table 1. An erosive condition is maintained by the forced movement of steel due to the furnace induction and the rotation of the samples at the speed of 2 rpm.

The oxidized and corroded samples were studied by SEM observations and XRD analysis.

3 Results and Discussion

3.1 Densification and flexural strength

3.1.1 Undoped composites

Without Y_2O_3, the composite densification is limited to 92% of the theoretical density, for alumina contents lower than 70 wt%, due to vault formations between the BN platelets during hot-pressing[5] (Fig. 3). To reduce this drawback and densify composites, a pressure of 40 MPa must be applied at the soaking temperature which must be at least 1750°C, to achieve a sufficient plasticity of the alumina grains and so to allow orientations of the BN flakes. So, the material has an anisotropic microstructure with BN flakes orientated perpendicularly to the pressing axis and separated by strata of alumina grains between these platelets.

The reference hot-pressing cycle, presented in Fig. 1 and optimized by D. Goeuriot,[9] allows us to minimize the unfavourable orientations of BN platelets. It is divided into three successive segments:

— Heating in N_2 atmosphere at 30°C/min rate under a pressure of 10 MPa to limit the chemical reaction between Al_2O_3 and BN to form AlN and B_2O_3.

— Temperature soaking at 1750°C under a pressure of 40 MPa for 30 min, to allow the BN flakes to orient perpendicular to the pressing axis.

— Cooling to room temperature at 50°C/min rate without applied pressure.

Fig. 3. Fracture faces of an undoped composite with an important porosity due to a bad BN platelets orientation.

3.1.2 Yttria doped-composites

3.1.2.1 Sintering shrinkage of doped-composites. The sintering shrinkage curves, presented in Fig. 4, show differences between the composites' behaviour depending on their boron nitride and yttria contents:

— For composites with alumina content lower than 70 wt%, the curves for Y_2O_3 additions indicate that the beginning of densification and the temperature of the maximum of densification rate are shifted back by about 150°C.[12] Furthermore, these composites are particularly sensitive to the alumina plasticity for the BN platelets orientation. So, with yttria, the vacancies formation in alumina grains increases their plasticity and so allows the BN platelets orientation at lower temperatures.

— For composites containing 80 wt% Al_2O_3, the shrinkage beginning temperature is also decreased by the yttria presence, but the maximum shrinkage rate temperature and that of the end of the 'rapid' step of densification at 1400°C are not changed by yttria additions. For these composites which contain only 30 vol% of BN, the BN flakes dispersion is already sufficient to limit the contacts between them, and the vaults formation is so limited. The flakes orientation is so easy under a pressure of 40 MPa at 1750°C, that the yttria effect does not appear.

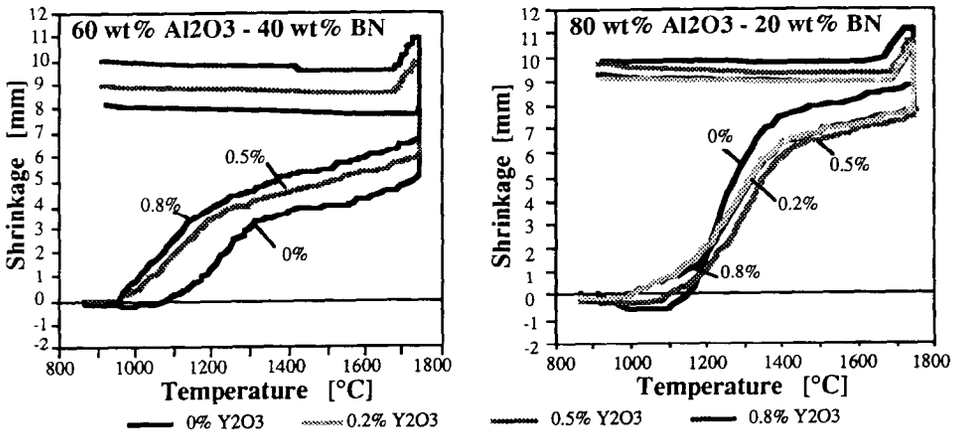

Fig. 4. Shrinkage of the Y_2O_3 doped composites during hot-pressing.

Fig. 5. Fracture faces of 0·5 wt% yttria doped composites (30 wt% BN–70 wt% Al_2O_3). Presence of strata of alumina and BN.

3.1.2.2 Doped composites microstructures. Due to the favourable effect of yttria on alumina sintering, the composites hot-pressed at 1750°C under 40 MPa following the reference cycle of Fig. 1 present a very nice orientation of the BN flakes. The microstructure is so composed by successive strata of BN platelets and alumina grains (Fig. 5).

3.1.2.3 Optimal addition of yttria. Despite the effect of yttria on composite shrinkage (mentioned before), it has a low influence on the final densification at 1750°C. For all alumina contents, the densities of doped composites and hot-pressed composites with the reference cycle, show a maximum increase of their densification of about 1% in comparison with undoped samples (Fig. 6). This increase obtained for additions of 0·5 wt% yttria considering Al_2O_3.

3.2 Hot pressing cycles influence (Fig. 7)

As the shrinkage temperature could be decreased by 150–200°C, different hot-pressing cycles were tested, with soaking temperature reduced to 1550°C and two different moments of pressure rise, at soaking temperature to obtain a favourable orientation of BN platelets, and at 1050°C below the alumina sintering temperature.

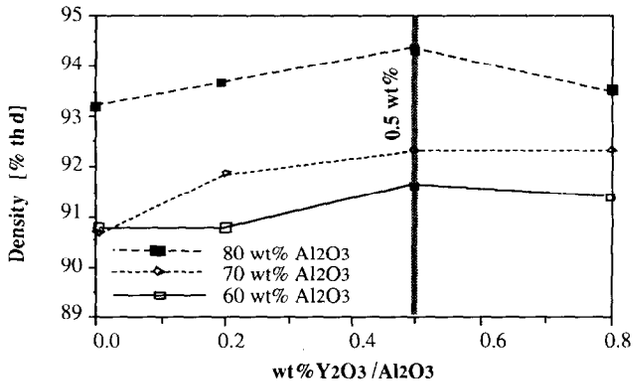

Fig. 6. Y_2O_3 additions effects on the composite densities after hot-pressing at 1750°C–40 MPa for 30 min.

So, four hot-pressing cycles were tested to densify the alumina–BN composites.

- 1750: the reference cycle presented in Fig. 1, with a soaking temperature of 1750°C and a pressure of 40 MPa applied during this temperature soaking.
- 1750–40: 40 MPa pressure is applied at 1050°C, below the soaking temperature at 1750°C.
- 1550: is the same cycle as 1750 with a soaking temperature reduced by 200°C, at 1550°C.
- 1550–40: is the same cycle as 1750–40 with a soaking temperature reduced to 1550°C.

The densification rates and flexural strengths were determined for two Y_2O_3 contents: 0·1 wt% and 0·5 wt% Y_2O_3 in reference to alumina and two alumina contents: 70 wt% and 80 wt%. The results are presented in Fig. 7.

3.2.1 Composites doped with 0·1 wt% Y_2O_3

There is not enough Y_2O_3 to densify the composites with 70 wt% alumina and only the reference cycle, 1750, allows us to obtain the most densified composites with the highest flexural strength.

For this temperature, applying high pressure (40 MPa) before the alumina shrinkage, which happens above 1100°C, leads to a poor orientation of BN flakes. This disorientation remains when the temperature rises and so impedes the densification, so that, the porosity of the sintered composite that follows the 1750–40 cycle is higher and it shows a lower flexural strength.

Samples sintered at 1550°C are less dense and so present lower flexural strengths too.

For the 80 wt% Al_2O_3 composite, there exists no important difference between the cycles in regard to their densification. For this composition, the low content of BN has little effect on the densification, as has been explained in Section 3.1.2.1.

But the flexural strengths are significantly higher if the soaking temperature is 1750°C. This difference is not only due to the porosity, but also certainly to a higher anisotropy of the material at 1750°C owing to a sufficient plasticity of alumina that allows the BN orientation during the pressure application. This plasticity which only occurs above 1100°C, does not allow us to obtain anisotropic composites at 1550°C and corresponding to these composites possess lower strengths.

For this composition also, applying 40 MPa at 1100°C is unfavourable to the BN orientation and so to the flexural strength.

3.2.2 Composites doped with 0·5 wt% Y_2O_3

Hot-pressing with 0·5 wt% Y_2O_3/Al_2O_3, allows us to densify the alumina–boron nitride composites

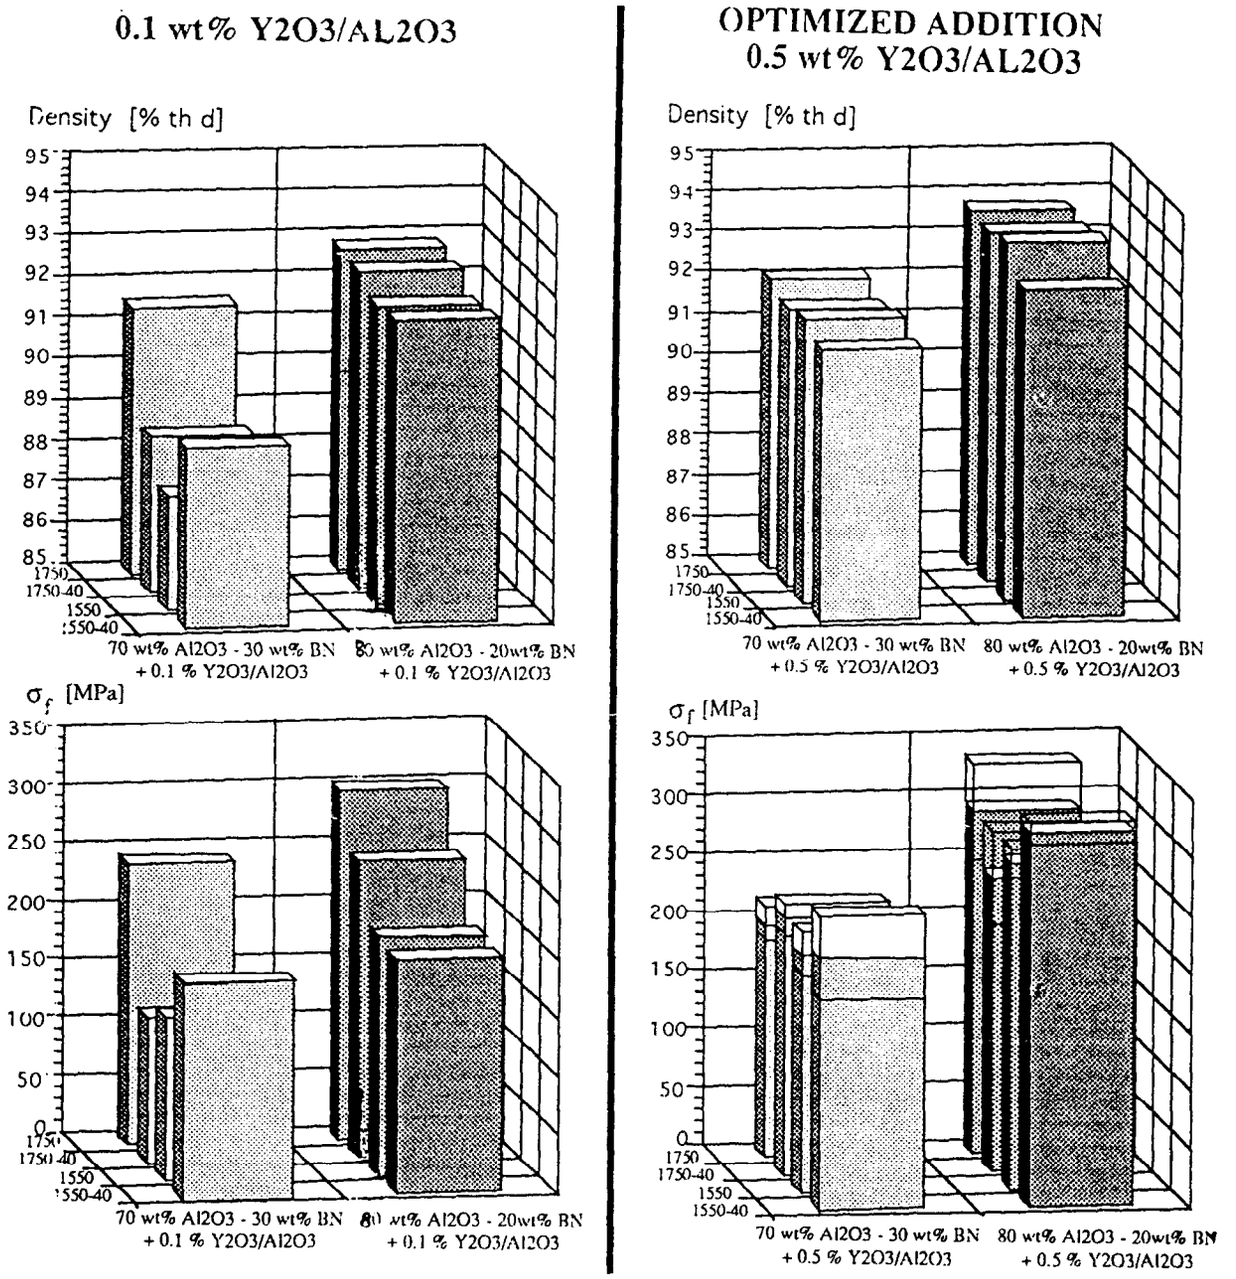

Fig. 7. Densities and flexural strengths of composites with 0·1 and 0·5 wt%/Y_2O_3 considering Al_2O_3.

and even the 70 wt% Al_2O_3 composites. Also, flexural strength is considerably increased by the addition of 0·5 wt% Y_2O_3 for all the applied cycles.

Part of these increments can be due to higher densification. But we can show that the highest strengths are measured for composites for which the pressure was applied at low temperatures, (1750–40 and 1550–40 cycles), even though the densities are a little lower than for the 1750 and 1550 cycles. The yttria addition has a significant favourable effect on the flexural strength of the alumina– boron nitride composites.

3.2.3 Discussion

3.2.3.1 Undoped composites. In the case of a high anisotropic composite formed by strata of alumina between the BN platelets, the fracture is propagating during flexural bending tests perpendicularly to the orientation of the platelets through the alumina boundaries or grains. When the crack meets a BN platelet, it by-passes along the Al_2O_3–BN boundary. This case corresponds to the 'pull-out' phenomenon of reinforcement.

But if the platelets are not perpendicularly orientated to the pressing axis, the fracture can follow it and propagate through this platelet between the 001 crystallographic planes.

So, less energy is spent to limit the fracture propagation, and the flexural strength of the composite is significantly decreased.

So, to reach the highest flexural strengths for undoped composites, BN platelets must be oriented. This needs the reference cycle to be used, with a soak at 1750°C under 40 MPa.

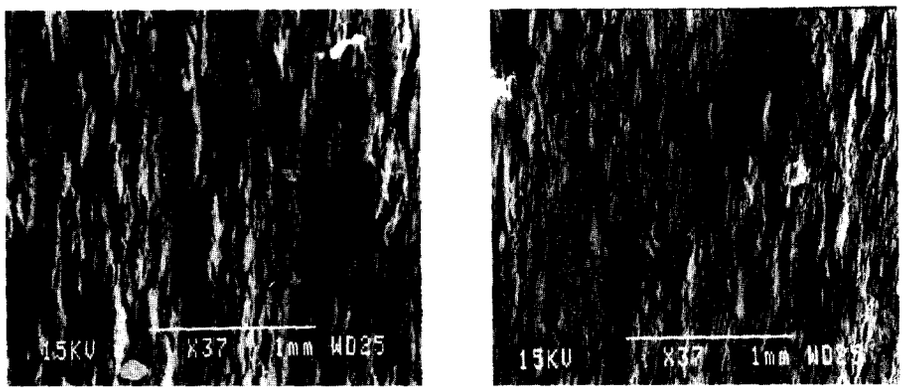

Fig. 8. Fracture faces of hot-pressed (1800°C — 40 MPa) boron nitride: (a) pure boron nitride; (b) BN with 2·3 vol% of Y_2O_3.

3.2.3.2 Doped composites. Samples that have been hot-pressed with a pressure rise at 1050°C (cycles 1750–40 and 1550–40) are considerably more porous due to the formation of vaults between the BN platelets. However, they have higher flexural strength due to the presence of yttrium at the boundaries, increasing the adhesion between alumina grains and BN platelets and cohesion between the BN platelets themselves, as shown on the fracture faces of Fig. 8. The fracture is more transgranular into the doped samples. In fact, the energy, spent to propagate the fracture through the BN flakes is more significant than that of by-passing. A. G. Evans[13] presented his theory (Fig. 9) on the reinforcement of boundaries in composites and the fiber or platelets debonding. There is a critical value of the ratio between the fracture energies of the interface and the platelet, for that, the fracture propagates either along the boundary or through the platelet.

The mechanism of crack deflection also occurs for these high energy boundaries and can thereby increase the flexural strength too (Fig. 10).

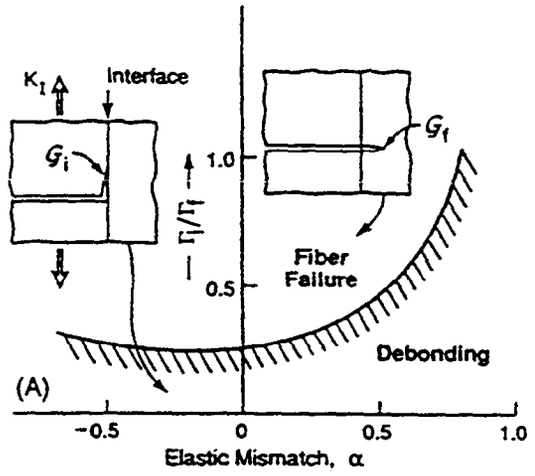

Fig. 9. Conditions of debonding of a fiber, perpendicular to the fracture (Ref. 13).

3.2.4 Conclusions

Without yttria, the alumina–boron nitride composites need to be hot-pressed at least at 1750°C under 40 MPa under nitrogen with a pressure rise during temperature soaking, to reach the highest flexural strengths. So the composites have an anisotropic microstructure constituted by strata of alumina between the BN platelets.

With yttria, composites can also be shaped without orientation of the BN platelets, also having a good flexural strength, and by the reinforcement of boundaries due to the presence of yttrium. So, we can suppose that it is easier to sinter these composites, perhaps by hot isostatic pressing.

3.3 Other properties

With yttria, property studies were performed to find out the composition that seems to be the best compromise on the different properties that composites need for the molten-steel casting, like good resistance to thermal shocks, oxidation and corrosion by the molten metals. This composition is 40 wt% BN and 60 wt% Al_2O_3.

3.3.1 Thermal shock resistance (Fig. 11)

Without yttria, the thermal shock resistance was

Fig. 10. Deflection of cracks into doped composites (30 wt% BN–70 wt% Al_2O_3) hot-pressed following the 1750–40 cycle.

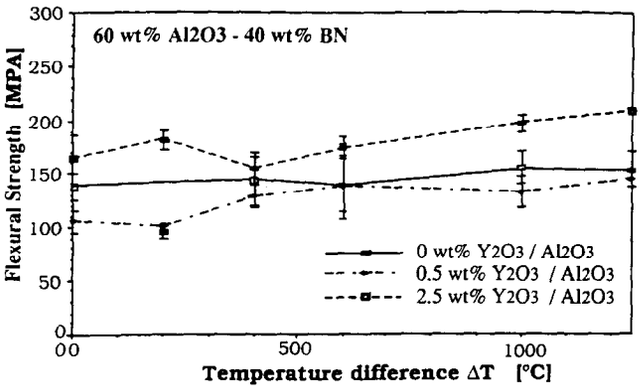

Fig. 11. Thermal shock resistance of yttria doped composites after oil quenching at 25°C.

studied for all the compositions between 50 and 90 wt% alumina contents. No drop of flexural strength in plotting it against temperature difference ΔT was observed, except perhaps for the highest alumina content.

With yttria, in spite of the temperature difference that exceeds 1200°C for some tests, the flexural strength curves of Fig. 11 show no fall, a slight increase can even be noticed for the highest yttria content.

In fact, all these composites have about 8 vol% of porosity, that is favourable to the thermal shock resistance. Moreover, microcracks appear during hot-pressing due to the significant thermal expansion coefficients mismatch between alumina (7–10 × 10^{-6} K) and boron nitride (0·7 × 10^{-6} K in the direction perpendicular to the pressing axis). The initial low flexural strengths prove that the microcrack length and density are high. So, it could be expected that the thermal shocks cause only quasi-static crack propagations. That does not affect the composites' flexural strengths.

So, the alumina–boron nitride composites' properties make them highly resistant to thermal shocks and no deterioration of the mechanical properties could be observed.

3.3.2 Oxidation

3.3.2.1 Undoped composites. Without yttria, composites are readily oxidized above 1100°C, according to the following mechanism, divided into two successive steps:[10,14]

$$2\ BN + 3/2\ O_2\ (g) \rightleftarrows B_2O_3(1) + N_2\ (g)$$

$$9\ Al_2O_3 + 2\ B_2O_3(g)(1) \rightleftarrows 9\ Al_2O_3 \cdot 2\ B_2O_3\ (A9B2)$$

The plotting of the oxidation depth versus time at 1300°C under O_2 (Figs 12 and 13) shows the oxidation kinetics in the two directions, perpendicular and parallel to the pressing axis for anisotropic materials.

3.3.2.2 Perpendicular to the pressing axis. Without yttria, and perpendicular to the pressing axis, the oxygen can migrate between the debonding 001 planes of the hexagonal boron nitride and oxidizes their platelets very quickly and forms significant quantities of B_2O_3. A part of this boron oxide is unable to react with alumina and so migrates to the surface along with the nitrogen formed. There, it forms a protective liquid layer that closes the pores and thereby stops the gas exchange (Fig. 14). So, the oxidation protection is assumed to be that of boron oxide alone and, in this direction, the effect of yttria on the oxidation rate could not be observed.

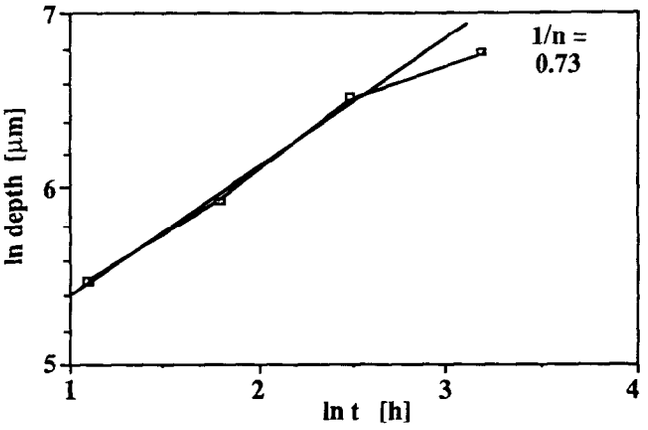

Fig. 13. Evolution of the oxidized layer depth with 0·5 wt% Y_2O_3/Al_2O_3 (parallel to the pressing axis).

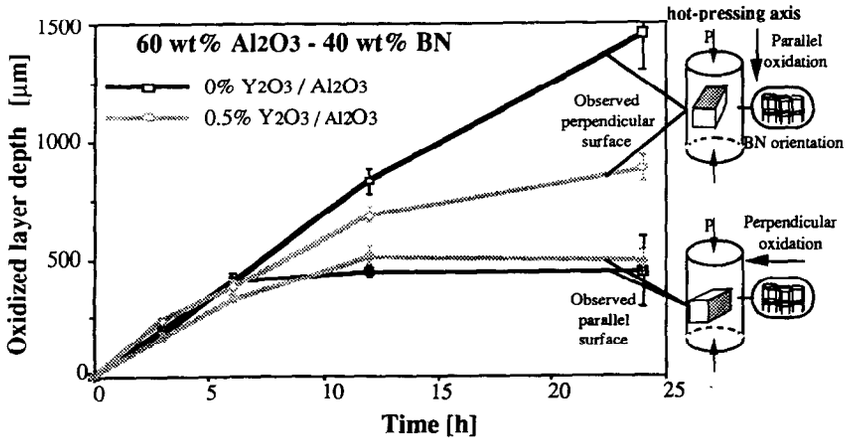

Fig. 12. Evaluation of the oxidized layer depths versus time with and without yttria additions.

Fig. 14. Cross-section of the oxidized scale in the case of oxidation perpendicular to the pressing axis. Presence of a dense liquid layer.

Also, at the surface, above this protective layer, the boron oxide's evaporation leads to enrichment in alumina and A9B2 chimneys can form. This chimney shape is caused by the exhaustion of volatile boron oxides and nitrogen (Fig. 14).

3.3.2.3 Parallel to the pressing axis. Without yttria, the oxidation follows a linear kinetic, that means there is a reaction limiting step:

$$\text{Depth} = kt$$

Following this oxidation direction, oxygen meets the BN flakes oriented perpendicularly and only oxidizes some first 001 planes. So, there is little boron oxide, B_2O_3, formed by oxidation of the boron nitride, that dissolves the alumina grains. Then, there is a crystallization of A9B2 in the form of bars of about $10 \times 0{\cdot}8 \times 0{\cdot}8$ μm^3 in dimension, following the remaining nonoxidized BN planes. So this crystallization occurs perpendicularly to the pressing axis as shown in Fig. 15. Then there is a penetration of the oxygen between these A9B2 bars, and the mechanism happens again.

With Y_2O_3, the mechanism is more complex. The composite is, before oxidation, composed of Al_2O_3, BN and yttrogarnet, $Y_3Al_2(AlO_4)_3$, formed *in situ* by the reaction between Al_2O_3 and Y_2O_3 during hot-pressing. EDS analysis showed the yttrium migration to the surface during oxidation. Then, this material forms at the surface as a protective amorphous layer constituted of Al, B, Y, O, N, present around and under the A9B2 crystals. That allows part of the open pores to close due to the A9B2 crystallization, so limiting the gas exchange and thereby the oxidation rate. But the kinetic law does not follow a parabolic curve as for an O_2 diffusion-controlled mechanism, but this law follows:

$$\text{Depth}^{1{\cdot}4} = k't$$

So the oxidation mechanism with yttria is dual, consists of kinetics of O_2 diffusion mechanism due to the protective layer and of reaction-controlled mechanism.[10,14]

Fig. 15. Oxidized scale for oxidation parallel to the pressing axis: A9B2 crystals and open porosity.

3.4 Corrosion by molten steel

The same samples tested for oxidation were dropped into molten steel covered with a slag containing $34{\cdot}3 \pm 2{\cdot}0$ wt% SiO_2 and $33{\cdot}0 \pm 2{\cdot}0$ wt% CaO, as presented in Table 1. This test combines two corrosive mechanisms.[10–11]

- — oxidation of boron nitride by the dissolved oxygen in iron and by FeO
- — alumina dissolution by the slag which is particularly reactive with Al_2O_3, forming mullite or calcium aluminates with SiO_2 and CaO respectively.

In iron, the yttria-doped composites are oxidized by a mechanism similar to the one in oxygen with the A9B2 crystallization. But there is an erosion of the protective layer observed after the tests of oxidation by the movement of the molten steel. So, although the corroded layer depths with yttria (Table 2) are smaller, the attack is significant as can be observed in Fig. 16, because this liquid layer at the surface is eroded and the alumina grains are carried off along with it.

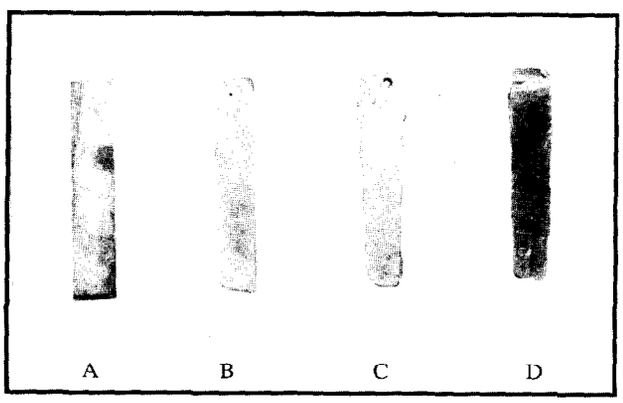

Fig. 16. Corroded samples cross-section: (A) uncorroded sample (reference); (B) 0 wt% Y_2O_3; (C) 0·5 wt% Y_2O_3; (D) 2·5 wt% Y_2O_3.

Table 2. Corroded layer depthes depending on the yttria contents

Sample (60 wt% Al_2O_3–40 wt% BN)	*Corroded layer depth in slag (μm)*	*Corroded layer depth in iron (μm)*
0 wt% Y_2O_3/Al_2O_3	10–20	500–600
0·5 wt% Y_2O_3/Al_2O_3	100	300
2·5 wt% Y_2O_3/Al_2O_3	30	150

In the slag, the corrosive attack is slightly more significant with yttria too. The reaction between yttria and alumina to give YAG, consumes a part of the alumina grains that are smaller and so more reactive to react with the slag.

Moreover, the 2·5 wt% yttria content composite has cracks, mostly longitudinal and 'V' shaped. They indicate that this composite did not withstand the thermal shock induced by immersion in liquid steel. That was not detected in its behaviour during thermal shock at 1250°C. So, either the yttria content must be limited in order to avoid considerable deterioration of the mechanical properties of the composite in contact with iron, or it should be necessary to pre-heat the composite specimen prior to this contact.

Although, yttria addition offers much resistance to oxidation by O_2 resistance, but does not protect the alumina–boron nitride composites from the corrosion by slag and molten steel. But other studies allow us to increase this corrosion resistance by neodymium oxide additions to lead to very inert composites.[10–12]

4 Conclusions

Without Y_2O_3 additions, the improvement of mechanical properties of the Al_2O_3–BN composites is maximum; if the BN platelets are oriented perpendicularly to the pressing axis during hot-pressing. This microstructure is attained by hot-pressing at 1750°C with a pressure rise from 10 to 40 MPa at this soaking temperature.

With 0·5 wt% Y_2O_3/Al_2O_3, it is possible to modify the microstructure by changing the hot-pressing cycle to obtain a more isotropic material by a pressure rise at only 1050°C. This yttria addition allows us to reduce the soaking temperature by 200°C, from 1750 to 1550°C, leading to more densified composites with increased mechanical strengths, due to the more stronger cohesion caused by Y_2O_3.

This 0·5 wt% Y_2O_3 addition increases the oxidation resistance of the composite too, by reaction at the surface between YAG, alumina and B_2O_3, forming a liquid phase that protects the material by closing the pores created by the A9B2 crystallization.

But Y_2O_3 decreases the corrosion resistance to molten steel, because this liquid phase is easily eroded and unable to protect the material. Moreover its concentration should not exceed 0·5 wt%/Al_2O_3, in order to limit the damage caused by the thermal shock during the immersion in liquid steel.

Abstract

This work considers the effect of a thermal treatment, at a temperature equal to or higher than 1200°C, on the physical and chemical characteristics of submicron α-alumina powders, doped with 550 and 1650 ppm in weight of MgO. The powders have been characterized by TEM, SEM, BET, XPS and chemical analysis. TEM observations show that the grains have elongated and rounded forms and exhibit considerable agglomeration. The BET surface area of the powder decreases with increasing annealing time and temperature and increases with the amount of MgO. XPS analysis shows a strong segregation of Mg and this effect is more pronounced when the size of the grains increase. In some cases XPS also detected the presence of Na, Ca and Si in the surface region of the grains.

1 Introduction

The fabrication of reliable, high-performance ceramics is an important industrial challenge, and it has long been recognized that further progress will be made by an increased understanding of the role played by the microstructure and microchemistry of the starting powders. Indeed, the processing of a ceramic generally involves the manufacture of a powder, with a suitable composition and microstructure, followed by its compaction and sintering. The characteristics of powders, such as size distribution, agglomeration, purity and surface area, are of course crucial in controlling the densification and therefore the microstructure of the finished material, which may give rise to specific properties. Nevertheless, in the different processing steps leading to the sintered ceramic, surfaces and interfaces play a critical role. At the macroscopic level, a requirement for densification is that the interfacial energy of the sintered material is lower than the surface energy of the powder. However, at the microscopic level it is the rapid movement of atoms that leads to the closeness of the center of the particles and to the densification. The influence of curved surfaces on these atom fluxes has long been recognized. Local variations in surface curvature give rise to local gas partial pressure differences and this in turn leads to local chemical potential gradients which drive the atom transport. For an atom to move, however, it is necessary that point defects be in close proximity. The point-defect concentration is of course related to the surface curvature, but also depends strongly upon the surface composition and the thermodynamic equilibrium conditions (T and P_{O_2}). Various papers have been devoted to the effect of dopants on the microstructure and characteristics of powders and sintered materials.[1–9] To our knowledge, however, there is a lack of data concerning the microchemistry of the powder and therefore the effect of variations in composition at or near the powder surfaces on the early stages of sintering, controlled mainly by surface diffusion, and ultimately on the ceramic densification. This is mainly due to experimental difficulties encountered until recently in characterizing insulating materials, particular in the form of powders.

In the case of alumina, an intensification of research was observed after the discovery by Coble in 1957 concerning the beneficial effect of magnesia on the alumina sintering. Small additions of MgO allow the theoretical density to be achieved without both abnormal grain growth and pores entrapped within grains. In subsequent studies,[5–9] authors have tried to understand the role of MgO and also to determine how to extend those results to other systems. It is now unquestioned that the presence of impurities, such as CaO or SiO_2, also play an important role in the alumina sintering.[5–9] Nevertheless, difficulties arise in understanding the influence of these additives on the mobility of grain boundaries and pores. The results are generally controversial[7] and it is now

recognized that an improved characterization of powders and compacts,[10] and a better knowledge of the microstructure evolution during densification, would be beneficial for further progress to be made in predicting the influence of dopants on sintering and grain growth.

This study mainly concerns the influence of the thermal treatment conditions on the nanochemistry and microstructure of α-alumina powders doped with magnesia. In previous papers the authors[11–14] have analysed kinetic demixing effects near surfaces in ceramics under a thermodynamical potential gradient or during cooling. They have also examined the segregation of additives (Y, Zr or Mg) and impurities (Si, Ca,...) to the surface of alumina powders and the effect of dopants on both the microstructure of alumina particles and the sintering kinetics.[15] More recently, XPS analysis of alumina powders doped with magnesium have allowed the determination of the extent of magnesium surface segregation as a function of the thermal treatment conditions and of the amount of dopant.[16] In this paper, we report a systematic study of cation redistributions (dopants and impurities) near the surface of alumina powders, in order to try to understand the parameters that play a critical role in the powder microchemistry.

2 Materials

The alumina powders studied have been prepared from the alum. They are doped with MgO: 550 ppm (0·07 at% Mg with respect to the cationic site number) or 1650 ppm in weight (0·21 at%). In the alum method, the dopants are added before the thermal decomposition of the starting materials (sulfates), close to 400°C. The change by a liquid phase promotes a uniform distribution of the additives in the grains because the nascent crystallites of γ-alumina have a high reactivity due to their high surface area. The next calcination occurs at temperatures higher than 1150°C. This

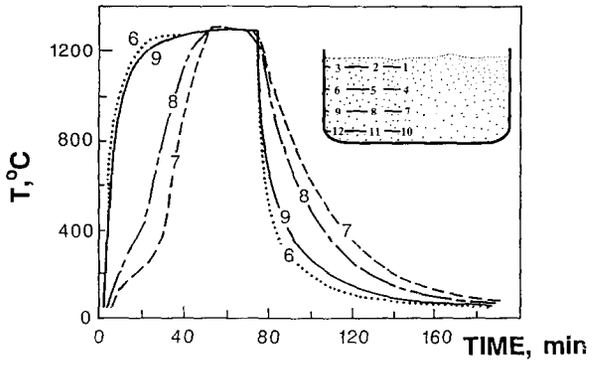

Fig. 1. Position of the thermocouples (1–12) in the silica crucible and thermal history of the powder for positions 6–9.

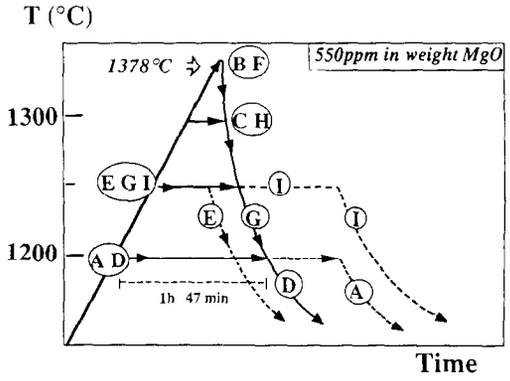

Fig. 2. Thermal history of the powder treated in air in an alumina crucible. Powders B, F, C, D, H, G and D have been maintained for the same time (1 h 47 min) at a temperature equal to or higher than 1200°C and cooled at the furnace cooling rate.

results in the commercial α-alumina. The quality of the powder depends strongly upon this step of the process. Consequently, in the present work we have examined the influence of the conditions of this last thermal treatment on the microchemistry and microstructure of the powder. The calcination was first performed in air at 1300°C, in large silica crucibles which contain approximately 700 g of powder. Pt/Pt–Rh10% thermocouples are placed in the silica crucible, as shown in Fig.1 (positions 1–12), to monitor the thermal history of the powder. As an example, we have reported in Fig. 1 the thermal history of powders from positions 4–9. Chemical analysis, surface area measurements and SEM examinations have been performed on powders taken in the vicinity of the different thermocouples (1–12). Only samples from position 6 and 7, with the largest difference in thermal treatment conditions (Fig. 1), have been analysed by XPS and TEM. Complementary treatments have been carried out between 1200 and 1378°C, in small alumina crucibles containing approximately 7 g of powder, in order to try to separate the role played by different parameters, such as the temperature of calcination, the cooling rate and the size of the grains. Figure 2 shows the thermal history of different samples treated in alumina crucibles and which have been cooled at the furnace cooling rate, i.e. more slowly than the powders treated in the silica crucible.

3 Results and Discussion

3.1 Chemical analysis, surface area measurements (BET), SEM and TEM observations

The main impurities found in the powders by inductive coupled plasma spectrometry (ICPS analysis) are: Si, Na, K, Ca and Fe. Their concentration range is reported in Table 1. Whatever the

Table 1. Concentration range of the main impurities (ppm in weight) found in different α-alumina powders (treated in alumina or silica crucibles) doped with 1650 and 550 ppm (by weight) of MgO (0·21 and 0·07 at% Mg), respectively

Amount of MgO	*Fe*	*Na*	*K*	*Si*	*Ca*
1650	3–12	11–27	8–48	13–120	3–11
550	2–9	12–34	12–33	18–143	3–6

type of treatment (alumina or silica crucible), the repartition of impurities is found to be relatively homogeneous, except for Si and Na. When the powder is treated in a silica crucible, the amount of Si increases in the powder taken near the edges of the crucible (Fig. 3), while the opposite is observed for Na. The amount of Na is generally close to 15 ppm for the powders taken near position 6 and between 22 and 34 ppm for powders near position 7. When the powder is treated in a small alumina crucible, the amount of Si is independent of position, but depends upon MgO content: 27 ppm in weight for powders doped with 550 ppm

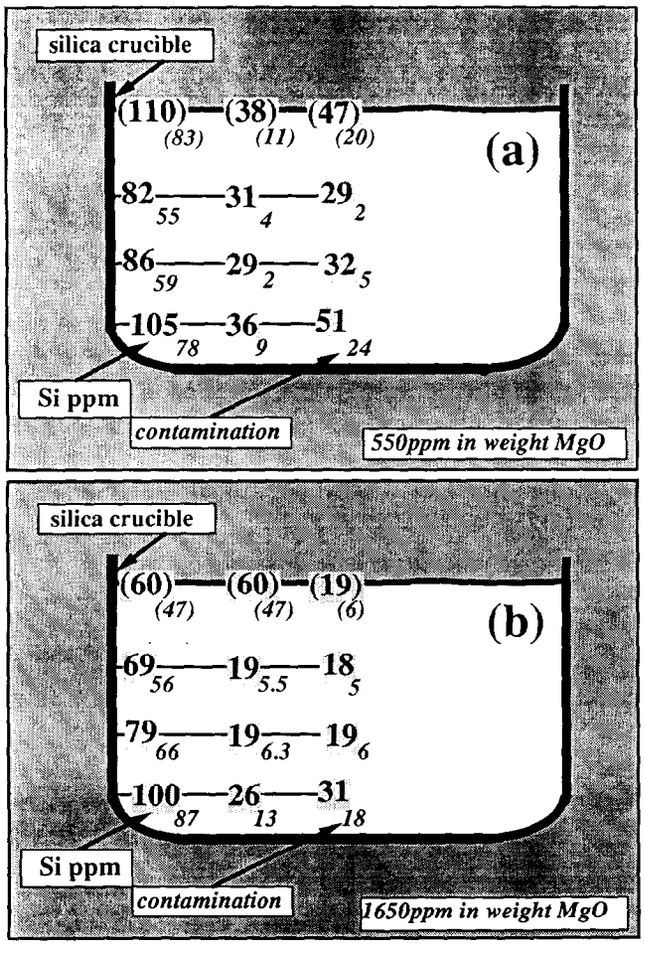

Fig. 3. Amount of silicon in the magnesium-doped alumina powder, as a function of the position in the silica crucible and silicon contamination due to the silica crucible. The surface values are given in parentheses: (a) 550 ppm MgO (average of two experiments); (b) 1650 ppm MgO (average of three experiments).

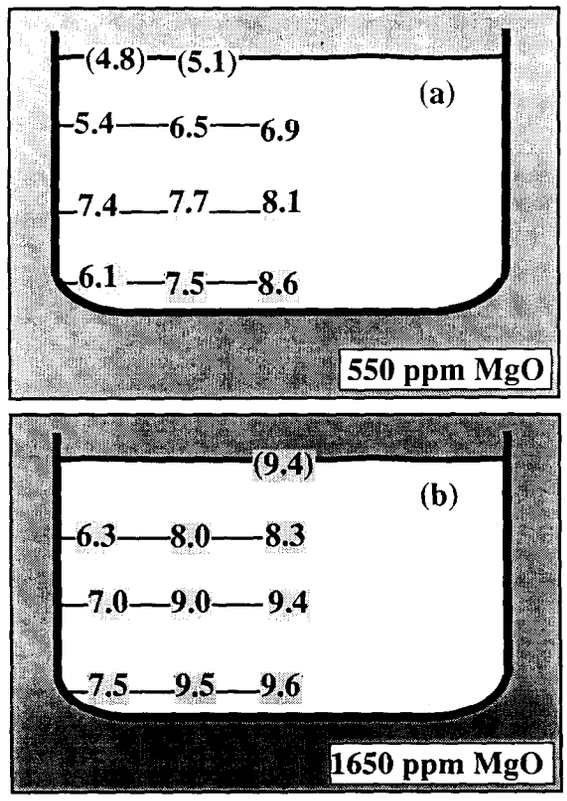

Fig. 4. BET surface area of the alumina powders doped with 550 and 1650 ppm MgO, as a function of the position in the silica crucible. Surface areas of powder near the outer surface are given in parentheses.

MgO and 13 ppm for those doped with 1650 ppm MgO. A comparison of the results of the amount of silicon from samples in the silica crucible (Fig. 1) with those for powders treated in the alumina crucible, allows determination of the amount of additional Si due to the contamination (Fig. 3).

BET analyses have been performed only on powders treated in the silica crucible. The surface area depends upon the position of the powder in the crucible, as shown in Fig. 4. The powders from position 7 have the largest surface area, while those taken near position 6 have the lowest values. One can recall that a decrease in surface area seen by BET corresponds to an increase in the grain size. In agreement with the BET analysis, SEM (JEOL 840 microscope) and TEM (80 kV Zeiss Model 902 electron energy loss (EEL) imaging microscope) observations show that the size of the grains increases with annealing time at 1300°C and when the amount of magnesium decreases (Fig. 5). The TEM observations also show that the grains have elongated and rounded forms and that they are highly agglomerated. Their size is between 50 and 400 nm, depending on the thermal treatment. A texture has been observed at the surface of some grains which may be due to spinel precipitates (cf. XPS analysis) but complementary observations must be performed to better define this texture.

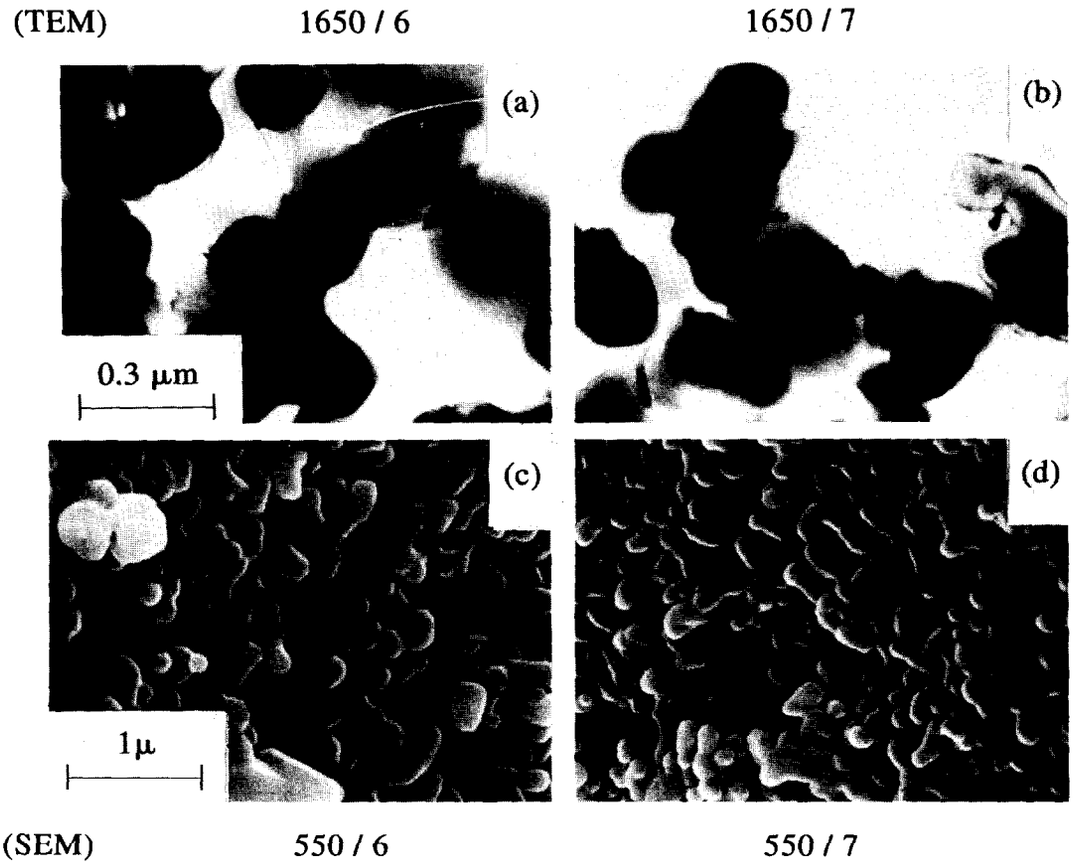

Fig. 5. Influence of the amount of magnesium and thermal treatment conditions on the size and microstructure of the alumina grains. TEM: (a) 1650 ppm MgO/position 6; (b) 1650 ppm MgO/position 7; SEM; (c) 550 ppm MgO/position 6; (d) 550 ppm MgO/position 7.

3.2 Nano-chemical analysis

XPS and EELS analysis has been performed to obtain information concerning the distribution of magnesium near the surface of the grains. Experimental details of these analyses are reported in a previous paper.[16] The trends of the two sets of results are similar. However, the error in quantifying the EELS data is large, and this method allows only an estimate of the magnesium concentration.[16] Consequently, we have concentrated on XPS analysis to examine the surface composition of the powders. Observations have been made on a perfectly flat surface of compacted powder. The results are obtained from a surface area of 0·8 × 0·8 mm. It may be pointed out that it is not possible to distinguish by XPS the Mg segregated in alumina grains from the Mg present in a second phase. Therefore, according to the amount of magnesium we have found, $MgAl_2O_4$ has been used as a standard. By analysing the magnesium lines (Mg_{1s}, Mg_{2s} and Mg_{2p}) it has been possible to obtain information on the total magnesium concentration near the surface of the grains. The escape depth of the Mg_{1s} electrons is about 0·5 nm (kinetic energy = 187 eV), while for the Mg_{2s} and Mg_{2p} electrons (with kinetic energies of 1387 and 1437 eV, respectively) it is about 2·0 nm. The Mg_{1s} signal allows us to determine a mean concentration of magnesium over the first 2 or 3 monolayers at the surface of the grains, while the Mg_{2s} and Mg_{2p} signals give a mean concentration over a depth of about 2·0 nm. The error in quantification is quite large because of the morphology of the samples and can be estimated to be 0·3–0·4 at%. Nevertheless, it should be noted that the reproducibility of the results is generally better than 0·1 at%. Furthermore, the Mg_{2s} peak gives more accurate data than the Mg_{2p} peak, because of peak overlaps.

3.2.1 Powders treated in silica crucibles

The XPS results obtained with the powders treated in the silica crucible (positions 6 and 7) are given in Table 2. They show a high magnesium concentration over the first two or three monolayers (Mg_{1s}) at the surface of the grains and this

Table 2. Amount of magnesium (at%) determined by XPS at the near surface of the alumina powder treated in a silica crucible. These results represent the mean of 6 different experiments. The reproducibility of the data is better than 0·1 at%

Analysis depth / *Sample*	*0·5 nm* (Mg_{1s})	*2 nm* (Mg_{2s})	*2 nm* (Mg_{2p})
Al_2O_3–1650/6	4·7	1·0	0·9
Al_2O_3–1650/7	4·4	1·0	1·0
Al_2O_3–550/6	3·4	1·0	0·7
Al_2O_3–550/7	2·4	0·6	0·5

enrichment is related to both the amount of magnesium in the powder and to its position in the crucible. Less surface segregation is observed in the alumina powder doped with 550 ppm MgO (0·07 at% Mg with respect to the cationic site number), and the powder from position 7 appears to have less segregation than the powder from position 6. The magnesium enrichment factor (atomic surface concentration in Mg divided by the average atomic concentration in Mg) over the first 2 or 3 monolayers calculated from these results is about 30 for the powder doped with 0·21 at% Mg (1650 ppm) and 80 for the powder containing 0·07 at% Mg (550 ppm). It is likely that precipitates of $MgAl_2O_4$ are also present at the surface of the grains, according to the limit of solubility of Mg in alumina.[17]

Figure 6 shows the mean concentration of magnesium in a depth of 2·0 nm (Mg_{2s}) as a function of the mean concentration in the first 2 or 3 monolayers (Mg_{1s}). The data exhibit a straight line whose gradient is 1/4. This value corresponds to the ratio of the analysis depth, and therefore suggests that the magnesium segregated mainly on a depth lower than or equal to 0·5 nm, leading to a Mg-enriched near-surface layer including the precipitation of the spinel phase. Figure 7 shows the different information that can be deduced from Mg_{2s}/Mg_{1s} relationships, according to the position of the experimental results in the graph. When the magnesium segregation increases, a saturation effect occurs near the surface (depth equal to 0·5 nm) and this leads to an increase in the segregation depth. The experimental results deviate then

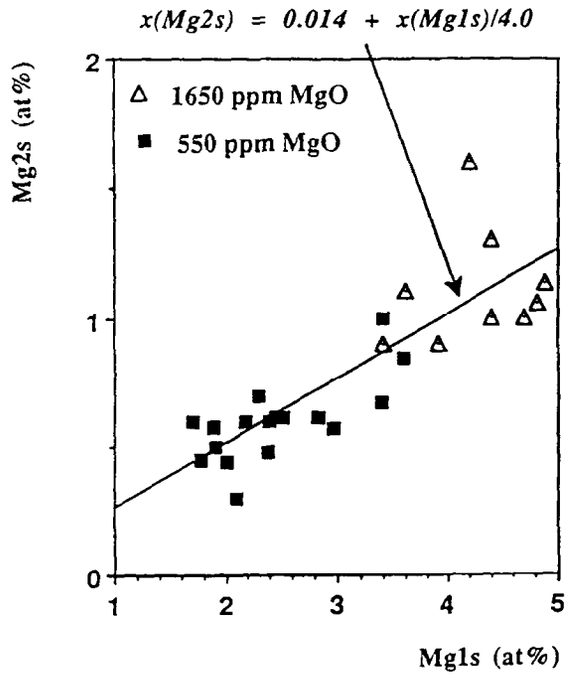

Fig. 6. Concentration of magnesium in a depth of 2·0 nm (Mg_{2s}) as a function of the concentration in a depth of 0·5 nm (Mg_{1s}).

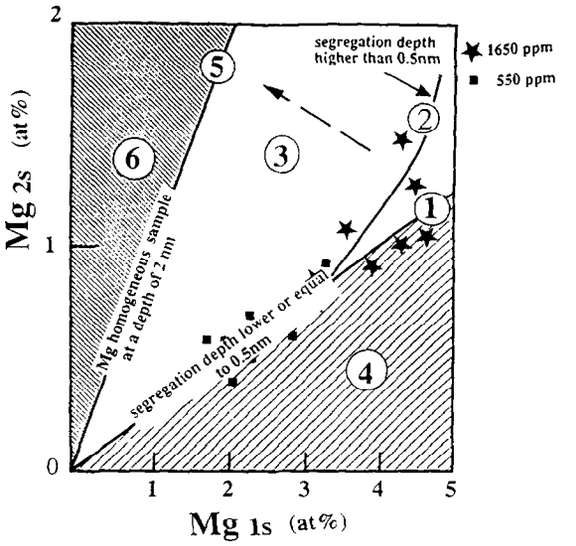

Fig. 7. Information that can be obtained from a representation of the concentration of magnesium in a depth of 2 nm (Mg_{2s}) as a function of the concentration in a depth of 0·5 nm (Mg_{1s}). When the Mg segregation increases, a saturation effect occurs at a depth of 0·5 nm (line 1) and the segregation depth increases (line 2 or in a general way area 3). When the experimental results are in area 6, the concentration of Mg decreases near the surface. The sample is homogeneous on a depth of 2 nm when the experimental results are on line 5.

from the straight line 1, whose gradient is equal to 1/4 (Fig. 7). In agreement with the results reported in Fig. 6 and Table 2, the saturation effect observed at a depth of 0·5 nm is of course more likely when both the magnesium concentration in the powder and the size of the particles increase.

The previous results (Fig. 6) are in agreement with the estimate of the repartition of magnesium in the grains (Fig. 8). Indeed, taking into account the amount of magnesium in the powder and the XPS results, it has been possible to determine the mean concentration of magnesium at a depth of 0·5 and 2 nm, respectively, in the particles assumed to be spherical. Their size has been estimated from

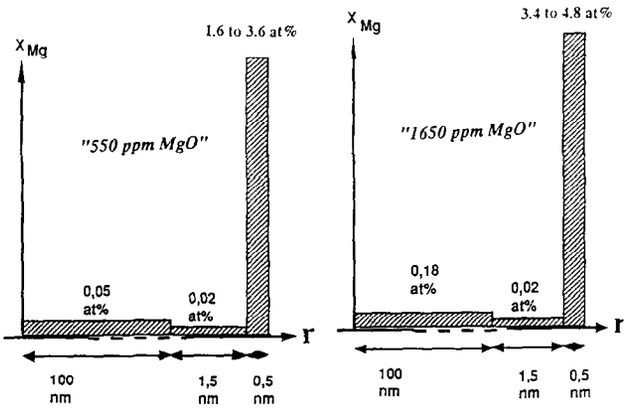

Fig. 8. Distribution profile of magnesium through an alumina grain treated at 1300°C, in a silica crucible for both 550 and 1650 ppm MgO-doped powders. This estimation has been performed assuming the grains to be spherical and taking into account the mean concentration of Mg in the powder (chemical analysis) and the XPS results at 0·5 and 2 nm.

the BET surface-area results. The results reported in Fig. 8 represent schematically the distribution of Mg across the grain. A lowering of the magnesium concentration is observed at a depth higher than 0·5 nm. This observation is consistent with a Mg kinetic demixing during the cooling of the powder. Nevertheless, complementary experiments must be performed to check the influence of this parameter on the Mg redistribution in the alumina grains.

XPS also detected the presence of Na, but the other impurities (Si, Ca, Fe and K) were not found in these powders. It may be noted that the amount of Na in powders from position 6 (0·6 at%) is lower than in powders from position 7 (1·4 at%), in agreement with the chemical analysis reported in the last section.

3.2.2 Powders treated in alumina crucibles

As shown in Fig. 2, samples B, C, D, F, G and H have been maintained for the same time (1 h 47 min) at temperatures equal to or higher than 1200°C, in order that the size of the grains be of the same order of magnitude after the different thermal treatments. They have then been cooled at the furnace cooling rate, i.e. more slowly than the powders treated in the silica crucible. The XPS results reported in Table 3 seem to show a decrease in the magnesium segregation when the maximum temperature of annealing decreases. However, a small increase in the size of the grains seems to occur when the annealing temperature increases (Table 3) and complementary experiments must be performed to substantiate this conclusion, as we shall see in the next section. Concerning the effect of the annealing time, the results at 1250°C are consistent with those obtained in the silica crucible at 1300°C (positions 6 and 7). The segregation of Mg increases when the annealing time increases and the TEM observations show that this effect is accompanied by an increase in the size of the grains.

3.3 Effect of grain size and cooling rate

According to the results reported in Figs 4 and 5 and in Table 3, the size of the grains is strongly related to the thermal history of the powder. Consequently, it was important to check the influence of this parameter on the segregation phenomena. Figure 9 reports the mean concentration of magnesium in the first 2 or 3 monolayers (Mg_{1s}), as a function of the size of the grains, assumed to be spherical. The size has been estimated from the BET surface area measurements. In a few cases this has also been measured on the SEM images. Whatever the amount of magnesium in the powder, the segregation increases with the size of the grains. This effect is so important that it overshadows the influence of the other parameters. It is thus difficult to draw definite conclusions with regard to the influence of annealing temperature and cooling rate on magnesium surface segregation. However, it seems that a decrease in cooling rate favors the segregation of silicon. Indeed, this impurity has been detected by XPS only in powders treated in alumina crucibles, which have a lower amount of silicon (around 13 and 26 ppm in the powders doped with 1650 and 550 ppm of MgO, respectively), than those treated in a silica

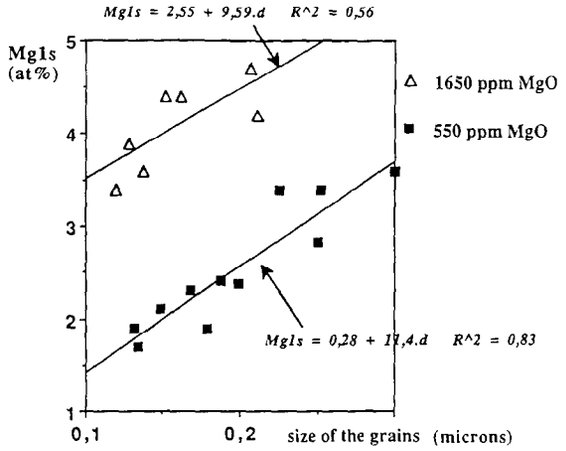

Fig. 9. Influence of the amount of magnesium and of the size of the grains on the magnesium concentration in the first 2 or 3 monolayers (depth 0·5 nm) at the surface of the grains.

Table 3. Amount of magnesium, silicon and sodium (at%) determined by XPS at the near surface of the alumina powder treated in an alumina crucible and cooled at the furnace cooling rate. (Concentration of Si over a depth of 2·4 nm; concentration of Na over a depth of 1·0 nm)

Experiment	*Temperature (°C)*	*Time*	*Grain size (SEM)*	*XPS Mg_{1s} (at%)*	*XPS $Mg_{2s,2p}$ (at%)*	*XPS Na_{1s} (at%)*	*XPS Si_{2s} (at%)*
A1	1200		0·3 μm	3·57	0·85–1·13	2·30	–

F	1378	1 s		2·97	0·57–0·64	0·88	–

crucible (Fig. 1) but which have been cooled more slowly (furnace rate).

It may be pointed out that the results reported in Fig. 9 are consistent with the estimation of the repartition of Mg through the grain, assumed to be spherical (Fig. 8). Indeed, if we take into account that practically all the dopant has segregated at the near surface of the grain, i.e. over a thickness equal to 'e' (0·5 nm, for example), with $e<<R_{grain}$, it is possible to write, for a given amount of dopant: $V_{total}/V_{grain})4\ \pi\ R^2 e\ C_{surf}$ = constant (where V_{total} is the total volume of the powder, C_{surf} the near-surface concentration of the dopant in a thickness 'e' and R is the grain radius). One obtains from this expression:

$$C_{1surf}/R_1 = C_{2surf}/R_2 = \text{constant}$$

Then one can verify that the surface concentration is proportional to the grain radius (R_{grain}).

4 Conclusions

This study has allowed us to illustrate the influence of the thermal treatment conditions on the microchemistry and microstructure of alumina powders doped with 550 and 1650 ppm by weight of MgO. SEM and TEM observations, as well as surface-area measurements, have allowed us to show that the size of the grains is strongly related to the amount of magnesium and to the thermal treatment conditions (temperature and annealing time). Quantitative XPS analysis shows that Mg, Na and Si are segregated at the near surface of the grains. In the case of Mg, this is likely to lead to the formation of $MgAl_2O_4$ precipitates. Furthermore, the results obtained show clearly that the magnesium surface enrichment increases with the size of the grains. However, it is difficult to draw conclusions regarding the influence of the cooling rate, as well as the effect of the temperature and annealing time. These effects are overshadowed by the effect of grain size. Complementary experiments must be performed on powders of the same grain size, in order to eliminate the important influence of this parameter. For Si and Na, their surface concentration seems to increase when the cooling rate decreases.

Finally, this study shows that it is possible to control the concentration of dopants or impurities at the near surface of the grains by changing only the thermal treatment conditions of the powder. Of course, such segregation phenomena, which can lead to the precipitation of a second phase at the near surface of the grains, confer specific properties to the powder. Nevertheless, complementary experiments must be performed in order to obtain a better understanding of the role played by parameters such as the cooling rate and the surrounding atmosphere.

Abstract

Cathodoluminescence (CL) microscopy has been used to investigate the luminescence response of MgO single crystal substrates intended for high T_c *superconductor applications. Wavelength resolved CL spectra have been collected from both the surface and the bulk of the MgO single crystals, under different preparatory treatments. It was found that annealing the MgO resulted in the reduction of luminescent surface defect states present in the as-received and ion milled samples and at sites of surface damage. The surface treatment given to MgO single crystals can significantly affect the electrical properties of high* T_c *superconducting thin films deposited on them.*

Introduction

$YBa_2Cu_3O_{7-\delta}$ high T_c superconducting thin films, produced by laser ablation or sputtering, are frequently grown in an epitaxial relationship on MgO single crystals. The substrate/film lattice mismatch, however, will give rise to coherent or semi-coherent heterophase boundaries that can affect the performance of the thin film. In this respect the surface quality of the substrate is an important parameter in the construction of good epitaxial thin films as any disturbance in the substrate will ultimately be incorporated in the film structure.[1,2] Optimisation of deposition parameters maximises the number of *c*-axis oriented grains.

In a previous study, the observation of CL in the scanning electron microscope (SEM) and the light microscope was applied to the problem of locating and determining the nature of impurity phases within YBCO polycrystalline pellets.[3] Here the technique has been applied to the study of MgO single crystals intended as substrates for the production of superconducting thin films. MgO has a band gap of 7·7 eV[4] which is too big for direct CL emission, but the presence of impurities at parts per million (ppm) levels, local deformation, or defect structures can give rise to extra states in the band gap that allow a number of luminescent emissions to be observed in the visible range via electron beam excitation.

Slip planes in deformed and compressed single crystals display bright contrast in CL emission.[5–8] Datta *et al.*[5] recorded blue emission from the slip planes with a CL band at 466 nm; the undeformed crystal containing two CL bands at 425 nm and 488 nm. Changes in the slip plane luminescence intensity can be brought about by annealing, causing some planes to appear in dark contrast.[8] An excitation peak at 500 nm[7] in compressed crystals is attributed to the generation of F centres.

Vickers indentations in MgO have also been analysed in CL[8–10] and luminescence variations attributed to differences in the density of point defects. Piqueras *et al.*[9] observed CL intensity variation across indentations which appeared dark at the centre and bright at the edge of the deformation band. The dark CL contrast was attributed to a high density of defects at the centre, quenching the CL emission. Annealing caused the centre of the indent to luminesce as a result of the diffusion and annihilation of these point defects.[8] A broad band of emission at 400–420 nm was observed from some of the dislocation etch pits due to the impurities or point defects that surrounded them.[6] Away from the dislocations, two CL peaks were present at 400 and 430 nm. Frictional damage of MgO by 2 mm tungsten carbide balls gave rise to a non-luminescent region within the track with luminescence at the edges due to the highly distorted layer beneath the surface containing defects.[11]

Impurities contained within the MgO, particularly iron, have been shown to play a role in defining both the overall CL intensity and spectral response. Emissions in the red region have been found to increase with higher Fe doping in some cases[5] but not others.[6] Without knowing the precise overall impurity levels within the MgO crystals, correlation between workers'[1] sets of results for the band structure can only be speculative. This occurs because some impurities act to increase luminescence, whilst others can 'quench' or 'kill' emissions. In fact, a non-linear relationship of CL intensity versus concentration can be seen with some impurity atoms where increasing concentrations at first increase CL intensity, but then at some critical defect density, the introduced states interact and CL can be lost.

Other luminescence techniques such as fluorescence, radioluminescence, photoluminescence, thermoluminescence (TL), and gamma irradiation[12–19] have also been used to attempt to correlate the occurrence of certain impurities in MgO with observable peaks in the visible region. Ni^{2+} doping has been related to the emissions at 478, 482, 486, and 491 nm.[12] This idea has been supported by Delgado[14] who proposed the $^1T_{2g}$–$^3A_{2g}$[14,17,19] transition in substitutional Ni^{2+} ions. Chromium ions have been associated with the peaks in the 700 nm region.[15–19] However, there is some controversy about the role of the iron impurities and some suggest[18] that this impurity gives rise to red luminescence as well as chromium. However, Sathyamoarthy *et al.*[19] found in his samples that Fe acts to quench the observed TL intensity. Other impurity elements such as cobalt and copper also reduce the luminescence from MgO, whereas manganese has been seen to increase luminescence with a band at about 600 nm.[19]

For superconducting thin film fabrication, some workers[1,21,22] have considered pre-treatments before deposition. Of these, the most successful has been annealing the MgO at 1273–1473 K either in air or in oxygen. Awaji *et al.*[21] reported the removal of CL spots by annealing suggesting that any contamination layer on the MgO was removed. Moeckly *et al.*[22] concluded that films on annealed MgO substrates produced the higher T_c and J_c response. This finding has also been reproduced in previous work.[23] The reason is connected to improved surface crystallinity in the substrate.

The effect of substrate defects on thin films has been studied by Barkay *et al.*[24] They determined that cleavage slip steps in the substrate, observable by CL, disrupted the thin film. The step defects that they observed were of the order of microns in height and hence should be observable by normal optical microscopy.

This paper describes the CL technique as a method for assessing the surface structure quality of the MgO single crystals prior to superconducting film deposition and addresses the problem of characterising defects too small to be seen by light microscopy, but which are believed to affect the film microstructure.[23]

Experimental Method

MgO single crystals, 99·99% purity, were obtained from PI-KEM. The major impurity was ~5 ppm iron, with all other elements at lower levels than this. A piece of single crystal MgO was cleaved into three strips for each of the following surface treatments:

- annealed at 1273 K for 10 h in O_2 then cooled to RT in oxygen,
- ion milled for 30 h using argon,
- as-received (the control sample).

Using strips from the same MgO sample was necessary to obtain samples with identical impurity contents. This allowed the effect of the treatments on the CL emission to be compared. The samples were cleaned in ethanol using an ultrasonic bath and then rinsed with acetone. A light carbon coat was applied to eliminate charging in the SEM.

Panchromatic CL images of the samples were recorded in colour using a Technosyn Cold Cathode Luminescence stage, model 8200MK11, fitted to a light microscope. This was operated at 15 keV and 200 μA load current, illuminating approximately 1 cm^2 of the sample surface.

Collection of the CL emissions was carried out using an Oxford Instruments CL detector and wavelength resolved by a Bentham monochromator with a slit width of 0·4 mm. The MgO samples were cooled to 77 K which reduced band broadening and increased the overall CL intensity. Higher order diffraction peaks were eliminated by the use of two optical filters at 400 and 700 nm respectively. A linear response GaAs solid state detector with a useful wavelength range of 400–900 nm amplified any emissions. Noise output from the detector was reduced by cooling to 273 K. The secondary electron and CL images were generated in a Jeol JSM 840A scanning electron microscope. For each analysis, the CL collection mirror was optimally focused and accurate beam currents were measured using a Faraday cage. The electron beam conditions ranged from 5 to 20 keV and 3 to 9 nA.

Results

Some variability in CL emission (both chemically and mechanically induced) was noted between as-received MgO crystals from different batches and so obtaining single crystals from the same melt and to a good polished quality is very important in any comparative work.

The colour micrographs in Fig. 1(a) (transmitted light optical) and Fig. 1(b) (CL) demonstrate the benefits of CL microscopy over optical for observing fine surface damage in MgO single crystals. Figure 1(b) clearly shows sharply defined blue lines in CL at the surface of the substrate. No surface damage can be seen in the optical image of Fig. 1(a).

Figure 2(a–c) illustrates the effects on the CL images of ion milling and annealing MgO single crystals. The micrograph in Fig. 2(a) shows dark red lines, possibly at the sites of subgrain boundaries, running throughout the as-received sample. Ion milling the surface (Fig. 2(b)) resulted in a pronounced increase in the light blue excitations generated from the surface layer. Annealing decreased the intensity of these CL excitations which resulted in the sample having strong luminescent emission in the red region. The dark red lines are now unresolved.

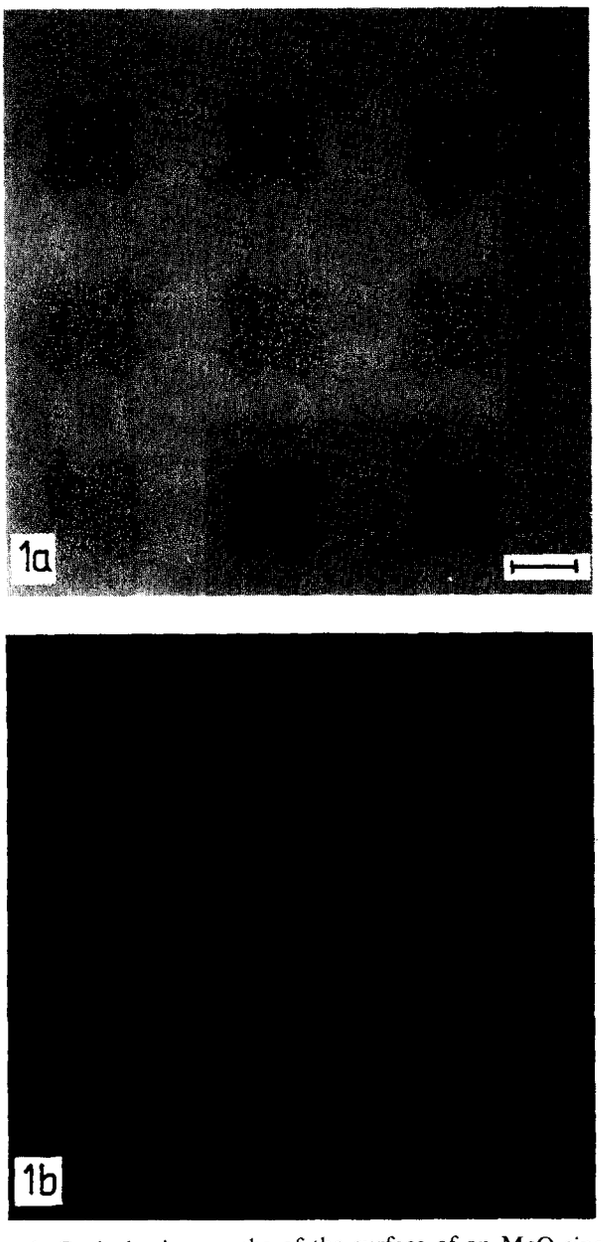

Fig. 1. Optical micrographs of the surface of an MgO single crystal: (a) normal mode and (b) CL mode (scale bar = 200 μm).

Wavelength resolved CL examination of the substrates in the SEM is illustrated in Fig. 3(a–d). The luminescence response generated from the bulk and from the surface were determined by using accelerating voltages of 5 and 20 keV. Using the Kanaya equation[25] 5 keV corresponded to 0·07 μm penetration depth and 20 keV to 0·78 μm depth, for the surface and bulk analysis respectively. On comparing Fig. 3(a) and (c), sharp peaks are observed from the bulk but not the surface around the 480 nm region. The spectra collected at 20 keV in Fig. 3(c) all display sharp peaks at 477, 481, 486 and 490 nm. The low CL emission at 5 keV meant that spectral resolution was poor, and hence no peaks could be resolved in Fig. 3(a).

Comparison of Fig. 3(a) with the colour micrographs (Fig. 2(a–c)), indicate good CL correlation between the systems. Ion milling the surface results in the highest proportion of luminescent defect states at wavelengths above 500 nm, with bands at 540, 560 and 630 nm. The annealed sample had the lowest CL intensity. Consideration of Fig. 3(b) and (d), analysing the surface and bulk luminescence generation respectively, illustrate similar spectra between the ion milled and as-received samples. Several peaks are present in the red region, between 696 and 740 nm. One unusual feature is the presence of a broad excitation band stretching from 750–850 nm. However, the annealed spectrum differs in one major respect from the as-received and ion milled samples, as the peak intensity at 867 nm is greatly reduced.

The wavelength resolved data in Fig. 4(a) and (b) show the effect of surface damage. Using spot mode at 10 keV and 6 nA resulted in the CL signal to noise ratio being sufficient for data collection without appreciable sample damage. In Fig. 4(a), the spectrum collected from the scratch has around 10 times the CL intensity of that from an undamaged area. Numerous luminescent states are generated throughout the visible range demonstrating that the electronic band structure is greatly disrupted. The 540, 560 and 630 nm bands are all clearly visible. However annealing the surface damage (Fig. 4(b)) returns the spectrum close to that of the undamaged surface.

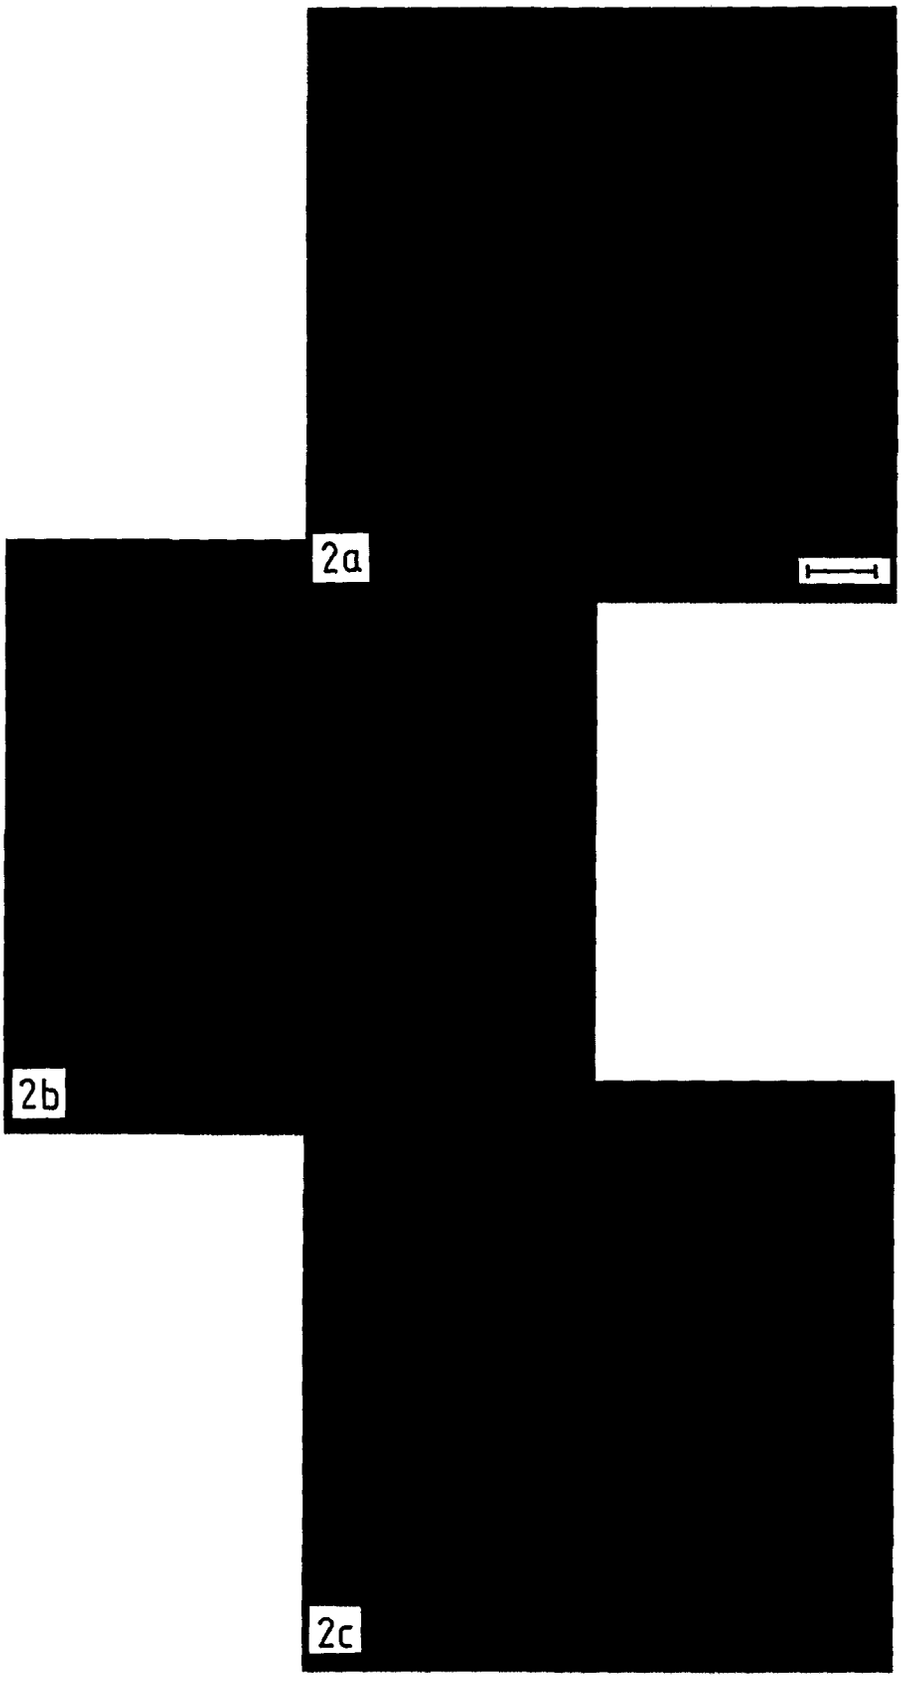

Fig. 2. CL micrographs showing the luminescent emissions of the MgO under the surface treatments of: (a) as-received, (b) ion milled and (c) annealed (scale bar = 200 μm).

Discussion

Assessment of the quality of MgO substrates, suitable for high T_c thin film deposition, can be carried out quickly by optical CL. Surface damage, which greatly affects the quality of epitaxial thin film growth, is easily observed due to local disruption of the electronic band structure at the site of flaws giving rise to bright CL contrast. However, other workers have reported the CL intensity to

be dependent upon the density of defect sites, with a high density giving rise to low CL emission.[8] Analysis of other single crystals, with optically visible surface flaws, confirmed that the surface damage displays a characteristic luminescence emission. Hence, in this study, the sharp blue lines in MgO single crystals are concluded to be due to fine surface flaws, that cannot be resolved using normal light microscopy. The damage observed by CL and described in this paper is much finer than that previously studied[24] and is generally not observable by normal light microscopy. Other researchers have also observed dislocations in CL contrast,[6,24] but were not able to correlate them with red luminescence. It is well documented that substitional Cr^{3+} ions are responsible for the red peaks between 696 and 701 nm. The direct transition is believed to be ^2E–$^4A_2$.[13,18] From the data presented here, it is not easy to judge the true position of the direct electronic transition as no system response correction was made to the data, but it is reported to lie at 698 nm.[13]

The peaks at 710, 718 and 724 nm resemble a direct transition with vibrational side bands. These could be connected to Fe^{3+} ions, but there is no evidence of this in the literature, although it has been suggested that Fe^{3+} gives rise to red luminescence.[18]

The broad blue emissions, in the colour micrographs of the as-received and ion milled samples occur uniformly within the samples. The spectroscopic analysis reveals four distinct excitations (476, 481, 486 and 490 nm), from the bulk (20 kV), which correlate very well with the TL data of Ralph *et al.*[12] for substitutional Ni^{2+} ions undergoing the $^1T_2$–$^3A_2$ transition.[14,17,19] Monochromatic CL imaging in the SEM at 480 and 700 nm was not able to identify the dislocations, because of the detector's small area of focus, hence any differences in the CL excitation spectra at the dark red lines, believed to be sub-grain boundaries, could not be determined.

Spectroscopic analysis of the surface at 5 keV beam energy, however, showed the band attributed to the Ni^{2+} ions together with luminescent transitions giving rise to bands at 540, 560 and 630 nm. The intensity of these emissions was found to be dependent upon the surface treatment suffered by the MgO, with the ion milled surface showing an increased CL intensity compared with the other two. Figure 3(a) shows that the as-received sample also has some defect band transitions. Residual lattice strain in the surface, caused by mechanical polishing prior to their supply, would be expected to alter the electronic band structure. This may be connected to the three luminescent bands. Ion milling appears to have enhanced these defects. The CL spectrum from the annealed specimen shows some recovery of the surface deformation and elimination of defects resulting in the CL intensity of the defect bands being much lower. These bands at 540, 560 and 630 nm are possibly connected to surface defect states associated with atomic scale surface roughness, as the bulk spectra displayed no such bands above noise levels. Annealing would result in the reconfiguration of the surface layers, reducing the density of defect states, thus giving a reduced CL intensity for these bands.

The spectra in Fig. 3(b) and (d) contain two peaks that have not been previously described. The emission at 867 nm is dominant in both, but annealing reduces its intensity considerably. Associated with this are four small peaks at 873, 880 and 886 nm, all of which are removed during annealing. The narrow width of the peak at 867 nm suggests a direct transition, with the small peaks being vibrational side bands. This could possibly be the result of surface contamination, as MgO suffers degradation when exposed to the atmosphere through chemisorption of H_2O and CO_2[20], but for the presence of peaks at 20 keV in the as-received and ion milled samples. Presumably, either the electronic configuration of the MgO is being affected by the anneal, which acts to remove vacancy sites, or an impurity ion is diffusing through the sample.

The presence of surface flaws in the MgO substrate greatly affects the local electronic band structure. Similar defects, albeit larger, from cleavage steps, have been described by Barkay *et al.*[24] However, their use of large excitation volumes (beam energies of 30 keV) meant that CL collection was predominately from the bulk and not from the surface. The spectra in Fig. 4(b) show that the CL intensity is reduced by annealing the substrate. The CL emissions from an annealed flaw are now very similar to that of the undamaged substrate. However, the gross flaws that can be seen optically are not removed by the anneal; only the luminescent defect states associated with the flaw have been removed, whilst the flaw itself remains.

Superconducting thin films of YBCO have been grown onto similarly treated MgO substrates which contain defects, and the film morphologies determined.[23] At the site of a defect, porosity was observed in the film microstructure. For example, the defect width in an YBCO film deposited on an annealed substrate was about 200 nm. Hence it is seen that fine defects in the substrate, not easily observable by optical methods can affect the thin film nucleation and growth processes, resulting in unwanted defects in the final microstructure. This is undesirable for electronic device applications.

Conclusions

The preparation of MgO single crystals has been successfully monitored by the CL technique. The optical and spectroscopic CL systems have enabled the identification of both Ni and Cr impurities, and the assessment of surface quality, with respect to treatment. Annealing has resulted in the removal of surface defect states, which are responsible for the luminescence in both the untreated and ion milled samples. Also luminescent defects states associated with surface scratches are virtually removed on annealing. It is concluded that, with respect to high T_c thin films, the process of annealing results in a marked improvement in the thin film electrical properties.

Abstract

DC electrical conductivity and Seebeck data as functions of temperature and oxygen activity were used to explain the electrical and thermal transport properties of (La,Ca)(Cr,Co)O_3. The electrical conductivity data of La(Cr,Co)O_3 suggested that it depends upon Co content. At Co concentrations less than 20 mol%, Co acted as traps for the carriers and decreased the electrical conductivity of the compositions at temperatures less than 900°C. As the Co concentration increased to above 20 mol%, electrical conductivity increased significantly due to a connecting path of available Co sites. Additional Ca substitution for La increased the electrical conductivity in accordance with Verway's principle. Defect models derived from the electrical conductivity data were found to relate the carrier concentrations to the Ca, Co and oxygen vacancy concentrations. The measured Seebeck coefficients were found to be positive even for the most reducing conditions, indicating that (La,Ca)(Cr,Co)O_3 compositions with Co ≤ 0·3 and Ca ≤ 0·3 were as stable as $LaCrO_3$. The Heikes formula was adopted to interpret the Seebeck coefficient results. These results indicated that electrical conduction in La(Cr,Co)O_3 and (La,Ca)(Cr,Co)O_3 occurs via the non-adiabatic and adiabatic small polaron mechanisms, respectively.

1 Introduction

The demand for materials that possess the chemical stability and electrical conductivity required in high-temperature solid oxide fuel cells (SOFC) and oxygen-separation cells has led to the investigation of the substantially mixed perovskite-type (La,Ca)(Cr,Co)O_3 system.[1,2] The basic perovskite crystal structure is given by the formula ABO_3 in which A, the large cation site, may be an alkali, alkaline earth, or rare earth ion and B represents a transition metal cation. The (La,Ca)(Cr,Co)O_3 system has a pseudo-perovskite crystal structure because its crystal structure deviates from the ideal cubic perovskite structure, (i.e. orthorhombic and rhombohedral). This system is composed of both Cr and Co B-site ions in an attempt to retain the desirable properties found in the end members, (e.g. $LaCrO_3$ — chemical stability in both air and in highly reducing atmospheres at 1000°C, $LaCoO_3$ — high electrical conductivity and sinterability). Ca is substituted for a fraction of the La on the A lattice site, in order to increase the small-polaron carrier concentration according to the Verway controlled ionic valency principle.

Both $LaCrO_3$ and $LaCoO_3$ are believed to show a thermally activated electrical conductivity due to p-type small-polaron hopping among B-site cations. $LaCrO_3$ is chemically stable to high temperatures over a wide range of oxygen activity. $LaCoO_3$ has a significantly greater electrical conductivity than $LaCrO_3$. However, $LaCoO_3$ is not chemically stable under reducing conditions at high temperatures.

The present author's recent results on $La_{1-x}Ca_xCr_{1-y}Co_yO_3$ have shown that compositions with $x \geq 0{\cdot}1$ and $y \geq 0{\cdot}1$ can be sintered to densities above 94% of theoretical in air at 1400°C and below.[1] The electrical conductivity as measured in air from room temperature to 1100°C increased with increasing Co and Ca content. At 1000°C, values from 1·5 S/cm (for $LaCr_{0.9}Co_{0.1}O_3$) to 50 S/cm (for $La_{0.7}Ca_{0.3}Cr_{0.9}Co_{0.1}O_3$) were measured.[2] However, the room-temperature electrical conductivity minima occurs at a Co concentration of approximately 20%. The Seebeck coefficients were positive, indicating p-type conductivity. The substitution of Co for Cr significantly decreased the Seebeck coefficients, indicating that Co substitution for Cr increased the carrier concentration. Additional Ca substitution for La resulted in a further decrease in the Seebeck coefficient.

Seebeck coefficients then exhibited a temperature-independent behavior, indicating that the carrier mobility, rather than carrier concentration, was thermally activated.[2] However, published works regarding the electrical behavior with respect to oxygen activity of $(La,Ca)(Cr,Co)O_3$ ceramics are virtually non-existent.

The objectives of the present paper are to explain the electrical and thermal transport properties of $(La,Ca)(Cr,Co)O_3$ ceramics and provide information on electrical conductivity and Seebeck coefficients as a function of oxygen activity for the material system at 1000°C.

2 Experimental Procedure

Specimens in the $(La,Ca)(Cr,Co)O_3$ system were prepared by a polymer precursor method similar to that first described by Pechini.[3] The starting chemicals were reagent-grade materials and were standardized by thermogravimetric methods to determine the actual cation contents. The desired compositions were prepared by dissolving measured amounts of selected carbonates and nitrates in solutions of citric acid, ethylene glycol, and water. The mixtures were heated on a hot plate at about 95°C until polymerization had occurred. Subsequent heating at higher temperatures resulted in the decomposition of the polymer resin and allowed conversion into the desired oxide. Final calcination was done at 850°C for 8 h. The resulting powders were milled and subjected to X-ray diffraction to ensure that they were single-phase. Samples for electrical conductivity and Seebeck measurements were formed by dry pressing at 2500 kg/cm^2 and then sintering the compacts at 1500°C for 10 h in a SiC heated furnace. Bulk densities of about 95% of theoretical were obtained. Rectangular specimens, usually 0·3 × 0·3 × 2 cm, were cut from the sintered bars. To reduce the effects of barrier layers and non-ohmic contacts, Pt paste was applied to the contact faces of the specimens.

Four-wire DC electrical-conductivity and Seebeck measurements were performed simultaneously in an apparatus that could measure three samples at a time. The specimens were mounted between two platinum blocks, which had type-S thermocouples (Pt versus Pt–10% Rh) as electrical contacts; the Pt wire heater was wound on the lower end of the holder to generate a temperature gradient along the vertical direction. Three sets of specimens and holders were contained in Al_2O_3 tubes within a $MoSi_2$ furnace, where the temperature was controlled by a Eurotherm temperature controller. The oxygen activity over the samples was controlled by using flowing gas mixtures composed of either O_2–N_2 or CO_2-forming gas (10% H_2–90% N_2). A Y_2O_3-stabilized ZrO_2 oxygen sensor was used to monitor the oxygen partial pressure of the gas mixture. Electrical conductivity measurements were made using the two-probe, four-wire Kelvin technique in which two leads carry the test signal (1 mA) and the other two measure the voltage drop. The Seebeck coefficients were determined by measuring temperature gradients and thermal emf's through the common leads of the thermocouples. The measurements were made using a data logger (Hewlett Packard 3497A data acquisition/control unit), which employs a HP-85 computer both as a control and readout device.[4]

3 Results and Discussion

3.1 Temperature dependence

DC electrical conductivity of $La(Cr,Co)O_3$ was measured in air as a function of temperature, with results shown in Fig. 1. The electrical conductivity increased with increasing temperature and Co content. The electrical conductivity of the end members of the $La(Cr,Co)O_3$ series exhibits the activated behavior expected from small-polaron transport over a wide temperature range. Previous investigations[5–7] have indicated that $LaCrO_3$ and $LaCoO_3$ perovskites conduct by the diffusion of p-type small polarons among Cr and Co ions. A small polaron is associated with a particular Cr or Co site if the ion is in the +4 valence state, rather than the stoichiometric +3 valence state.

Transport of the carrier to an adjacent unoccupied site requires transport of the lattice distortion as well. The activation energy is associated with small-polaron transport, and charge migration through the crystal occurs by an activated hopping mechanism. Two different types of small

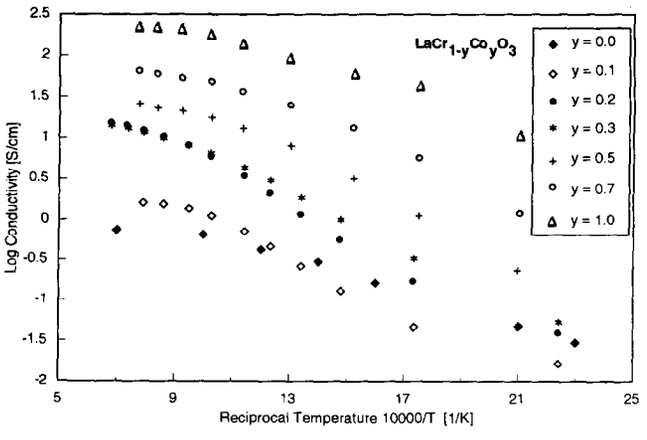

Fig. 1. DC electrical conductivity versus 10 000/T in air for $La(Cr,Co)O_3$.

polaron have been determined. The carrier is always able to jump to an adjacent unoccupied site whenever an atomic displacement favoring the jump occurs, which is called the adiabatic case, while in the non-adiabatic case the carrier can only occasionally take advantage of a favorable atomic configuration and change sites.

The mobility of charge carriers, μ, of adiabatic small polarons is given as[8]

$$\mu = [(1-C)\, e\, a^2 \nu / kT] \exp(-E_A/k/T) \qquad (1)$$

where C is the fraction of available sites occupied by charge carriers, e is the unit charge, a is the lattice spacing, ν is the vibrational frequency, k is the Boltzmann constant, T is absolute temperature, and E_A is the activation energy for hopping. The electrical conductivity, σ, is expressed as

$$\sigma = (NC)\, e\, \mu \qquad (2)$$

where N is the density of available sites. The expression for the temperature-dependent electrical conductivity of an adiabatic small-polaron material becomes

$$\sigma = [NC\,(1-C)\, e^2\, \nu\, a^2/kT] \exp(-E_A/kT) \qquad (3)$$

For materials that obey non-adiabatic small-polaron conduction, the mobility expression is given by

$$\mu = [(1-C)\, e^2\, a^2/kT]\, (4\, \pi^2 j^2/h^2)\, (\pi/4\, kTE_A)^{1/2} \exp(-E_A/kT) \qquad (4)$$

where j is the electron transfer energy and h is Planck's constant. The electrical conductivity of a non-adiabatic small-polaron material becomes

$$\sigma = [NC(1-C)\, e^2\, a^2/kT]\, (4\, \pi^2 j^2/h^2)\, (\pi/4\, kTE_A)^{1/2} \exp(-E_A/kT) \qquad (5)$$

If all of the variables in the pre-exponential term of eqns (3) and (5) are independent of temperature (or slightly temperature-dependent), a plot of log (σT) (for the adiabatic case) or log ($\sigma T^{3/2}$) (for the non-adiabatic case) versus reciprocal temperature should give a straight line, with a gradient proportional to the activation energy associated with small-polaron hops.

Plots of log (σT) versus 10 000/T and log ($\sigma T^{3/2}$) versus 10 000/T for La(Cr,Co)O_3 compositions covering the entire temperature range studied are shown in Figs 2 and 3, respectively. The two plots are very similar, showing substantial linearity for the compositions. Linear regression was applied to calculate the activation energies and evaluate the linearity of plots for the compositions. Calculated values for the activation energies are given for each case in Table 1. The conductivity of the compositions of the La(Cr,Co)O_3 series does exhibit the activated behavior expected from small-polaron transport over a wide temperature range, with $\sigma T^{3/2}$ giving a slightly better fit than σT. Linear regression was used to evaluate the linearity of the plots. The linearity was slightly higher for the non-adiabatic case (Fig. 3) than for the adiabatic case (Fig. 2). R^2 values are included in Table 1 for

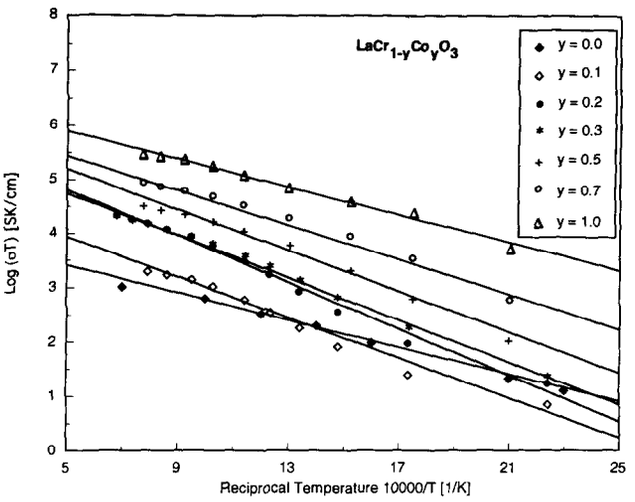

Fig. 2. Log σT versus 10 000/T for La(Cr,Co)O_3.

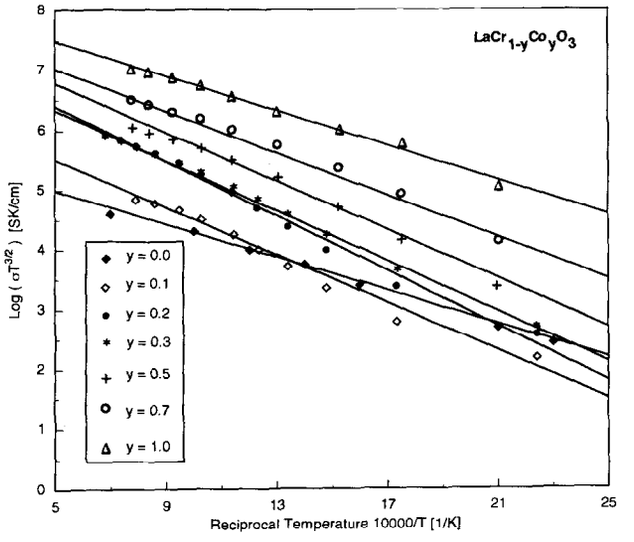

Fig. 3. Log $\sigma T^{3/2}$ versus 10 000/T for La(Cr,Co)O_3.

Table 1. Activation energies for La(Cr,Co)O_3

	Activation energy (eV)			
Composition $LaCr_{1-y}Co_yO_3$	*Adiabatic case*	*Non-adiabatic case*	*Adiabatic case*	*Non-adiabatic case*
$y = 0.0$	0·25	0·28	0·9930	0·9966
$y = 0.1$	0·37	0·40	0·9786	0·9805
$y = 0.2$	0·42	0·46	0·9894	0·9900
$y = 0.3$	0·39	0·42	0·9958	0·9972
$y = 0.5$	0·37	0·41	0·9869	0·9912
$y = 0.7$	0·32	0·35	0·9843	0·9903
$y = 1.0$	0·26	0·29	0·9875	0·9915

both cases. The greater the magnitude of R^2, the better the fit of the data to the linear function. Evaluation of the linearity of plots for compositions in La(Cr,Co)O_3 indicated that the electrical conduction occurs via the non-adiabatic small-polaron mechanism.

Although the activation energies of the end members are similar, $LaCoO_3$ has a high-temperature conductivity value much higher than that of $LaCrO_3$. Despite the larger intrinsic electronic conductivity of $LaCoO_3$, a small substitution of Co for Cr in $LaCrO_3$ resulted in a sharp drop in low-temperature conductivity from that exhibited by either end member (see Fig. 1). This minimum occurs at a Co concentration of 10 mol%. This small substitution of Co also resulted in a strong temperature dependence with increased gradient. The maximum gradient observed occurs in the 20 mol% Co composition and corresponds to an activation energy of 0·46 eV. As can be seen from Table 1, the activation energy increases with Co content to a maximum at 20 mol% and then linearly decreases as Co content increases. The substitution of small amounts of Co for Cr has been found to cause the low-temperature electrical conductivity to drop orders of magnitude below that of either end member and increase in activation energy. This is probably due to the difference in the electronic structure of Co and Cr ions. The Co sites also have lower small-polaron site energies as compared to Cr sites. In the case of a low concentration of Co, the lower-energy Co sites act as traps for carriers diffusing among Cr sites at low temperature. Therefore, the activation energy for conduction is increased from that of $LaCrO_3$. At higher Co concentrations, direct transport among Co sites becomes possible and conductivity increases and activation energy decreases. The electrical conductivity of all compositions increased to an asymptotic value dependent upon the amount of Co present as the temperature was increased. A possible explanation for this involves considering the different spin states of Co. The low spin (s = 0) state is the most stable and predominates at temperatures below 900°C. As the temperature increases, higher spin states of Co^{3+} (s = 1, s = 2) become populated. This transition probably leads to hopping between Co-sites and neighboring Cr-sites. Therefore, the electrical conductivity at higher temperatures increased with Co concentration.

The DC electrical conductivity of $La_{1-x}Ca_xCR_{0.9}Co_{0.1}O_3$ and $La_{1-x}Ca_xCr_{0.8}Co_{0.2}O_3$ (with x = 0·1 and 0·2) was measured in air as a function of temperature, with the results shown in Figs 4 and 5, respectively, as log(σ) as a function of reciprocal temperature. Plots of log (σT) versus 10 000/T and log ($\sigma T^{3/2}$) versus 10 000/T for

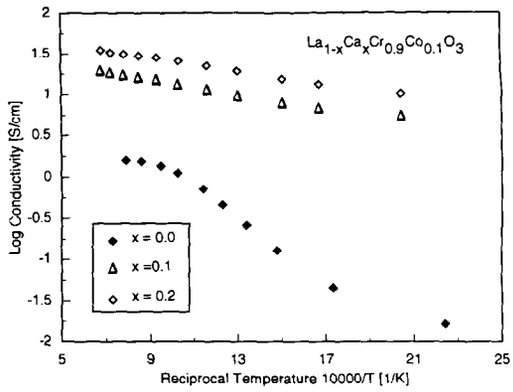

Fig. 4. DC electrical conductivity of $La_{1-x}Ca_xCr_{0.9}Co_{0.1}O_3$ as a function of Ca content and temperature.

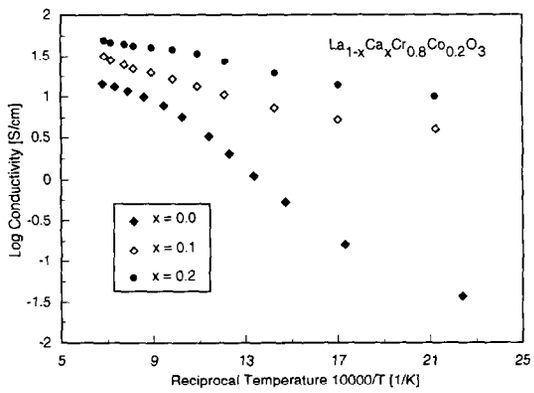

Fig. 5. DC electrical conductivity of $La_{1-x}Ca_xCr_{0.8}Co_{0.2}O_3$ as a function of Ca content and temperature.

$La_{1-x}Ca_xCr_{0.9}Co_{0.1}O_3$ are shown in Figs 6 and 7, respectively. The two plots are very similar, showing slightly higher linearity for the adiabatic case. Thus, for the system $La_{1-x}Ca_xCr_{0.9}Co_{0.1}O_3$, the high linearity of the plots is consistent with the assumption that electrical conduction in these compositions occurs via the adiabatic small-polaron mechanism (see Table 2). Log (σT) versus 10 000/T and log ($\sigma T^{3/2}$) versus 10 000/T for $La_{1-x}Ca_xCr_{0.8}Co_{0.2}O_3$ are also plotted in Figs 8 and 9, respectively. The linearity of the plots are again consistent with the assumption that electrical

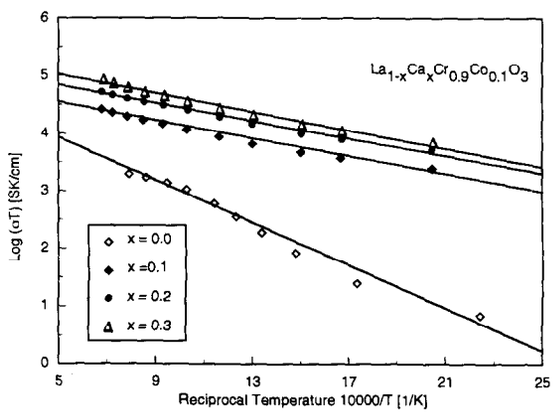

Fig. 6. Log σT versus 10 000/T for $La_{1-x}Ca_xCr_{0.9}Co_{0.1}O_3$.

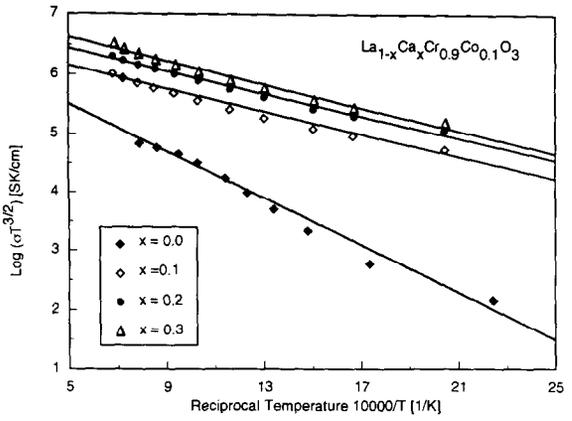

Fig. 7. Log $\sigma T^{3/2}$ versus 10000/T for $La_{1-x}Ca_xCr_{0.9}Co_{0.1}O_3$.

conduction occurs via the adiabatic small-polaron mechanism. There was only one composition (x = 0·1) which had the greater magnitude of R^2 in the non-adiabatic case. This might be due to the experimental error, since the rest of the compositions yielded a better fit of the data to the linear function with the adiabatic small-polaron mechanism.

Activation energies for hopping for adiabatic and non-adiabatic cases were calculated from Figs 6–9 and tabulated in Table 2. The activation energies were slightly higher for the non-adiabatic case than for the adiabatic case. As can be seen, with a

Ca content of 10–30 mol%, all Co-content levels have essentially the same activation energy. The additional substitution of Ca for La in the La(Cr,Co)O_3 eliminated the increase in activation energy that was observed with Co substitution for Cr. The substitution of 10 mol% Ca for La in the La(Cr,Co)O_3 series increased the conductivity by approximately 10%, which was anticipated in view of a carrier density increase of 10% in accordance with Verway's principle. As in the case of $La_{1-x}Ca_xCrO_3$ and $La_{1-x}Ca_xCO_3$, the substitution of Ca for La in La(Cr, Co)O_3 should result in the formation of Cr^{4+} and Co^{4+} in order to preserve the electrical neutrality. Formation of both Cr^{4+} and Co^{4+} increases the small-polaron concentration and decreases the activation energy for conduction.

Thermopower measurements were made to determine the type and concentration of charge carriers. Figures 10–12 show the Seebeck coefficient plotted as a function of temperature for La(Cr,Co)O_3, $La_{1-x}Ca_xCr_{0.9}Co_{0.1}O_3$, and $La_{1-x}Ca_xCr_{0.8}Co_{0.2}O_3$, respectively. In La(Cr,Co)O_3, the substitution of Co for Cr significantly decreased the Seebeck coefficient, indicating that Co substitution for Cr increases the carrier concentration. As the Co content increased, the Seebeck

coefficient showed temperature-independent behavior, indicating that the carrier mobility, rather than the carrier concentration, was thermally activated. According to Heikes' formula, this type of behavior indicates a small-polaron conduction mechanism which agrees with electrical conductivity measurements. In the cases of $La_{1-x}Ca_xCr_{0.9}Co_{0.1}O_3$ and $La_{1-x}Ca_xCr_{0.8}Co_{0.2}O_3$, introduction of Ca significantly decreased the Seebeck coefficient, which became temperature-independent.

3.2 Oxygen-activity dependence

DC electrical conductivity measurements for $La_{1-x}Ca_xCr_{1-y}Co_yO_3$ (x = 0·0, 0·1, 0·2, 0·3 and y = 0·1, 0·2) were made as a function of oxygen activity at 1000°C. The results are shown in Figs 13 and 14. The electrical conductivity data showed similar oxidation–reduction behavior. In the high oxygen-activity region, within the experimental error the electrical conductivity was nearly constant. The electrical conductivity decreased as a function of oxygen activity to the one-quarter power as reduction progressed. The constant electrical conductivity that exists in the high oxygen-activity region may be easily understood if it is assumed that the carrier concentration and electronic compensation predominates. In the low oxygen-activity region, oxygen vacancies are formed and the electrical conductivity begins to decrease as a result of ionic compensation.

The defect chemistry of oxides shows how the defect structure and electrical conductivity change as they equilibrate under various oxygen activities at elevated temperatures. The following model is adopted from the model developed for Mg-doped $LaCrO_3$[5] in order to explain the electrical conductivity of $La_{1-x}Ca_xCr_{1-y}Co_yO_3$ (where y is less than 0·3) as a function of oxygen activity. In the $La_{1-x}Ca_xCr_{1-y}Co_yO_3$, the Co^{3+} substitutes for Cr^{3+}, and Ca^{2+} substitutes for La^{3+}. The acceptor Ca^{2+} substitutes for La^{3+}. The acceptor Ca^{2+} possesses one effective negative charge which can be compensated for either by Cr^{3+}–Cr^{4+} or Co^{3+}–Co^{4+} transitions, or by the formation of oxygen vacancies. If such a substitution is compensated for by the formation of oxygen vacancies, no contribution to the electronic conductivity is anticipated.

Since cations and anions are of comparable size, it can be assumed that Schottky is native defect, and the Schottky reaction (using the Kroger–Vink notations[9]) for this composition is expressed by

$$\text{nill} = V'''_{La} + V'''_{Cr,Co} + 3\ V^{\cdot\cdot}_{O} \quad (6)$$

$$K_s = [V'''_{La}][V'''_{Cr,Co}][V^{\cdot\cdot}_{O}]^3 \quad (7)$$

Since this is a closed system, the cation stoichiometry must remain constant, therefore, $[V_{La}] = [V_{Cr,Co}] = [V_M]$ throughout the entire region.

$$K_s = [V'''_M]^2\,[V^{\cdot\cdot}_O]^3 \quad (8)$$

The p-type non-stoichiometric reaction is given by

$$3/2\ O_2 = V'''_{La} + V'''_M + 6\,\dot{h} + 3\ O_o \quad (9)$$

$$K_9 = [V'''_{La}]\,[V'''_M]\,p^6\,P_{O_2}^{-3/2} \quad (10)$$

When Ca^{2+} is substituted for La^{3+}, the Ca^{2+} will possess one effective negative charge which can be compensated for either by a B^{3+}–B^{4+} transition or by the formation of oxygen vacancies. This leads to the following electrical neutrality condition:

$$2\,[V^{\cdot\cdot}_O] + p = 6\,[V'''_M] + [Ca'_M] \quad (11)$$

At high oxygen activity, assuming that both $[V_O]$ and $[V_M]$ are smaller than the acceptor content, the neutrality condition becomes

$$p = [Ca'_M] \quad (12)$$

and from eqns 8, 10 and 12

$$[V'''_M] = K_9^{1/2}\,P_{O_2}^{3/4}/[Ca'_M]^3 \quad (13)$$

$$[V^{\cdot\cdot}_O] = K_S^{1/3}\,[Ca'_M]^2\,P_{O_2}^{-1/2}/K_9^{1/3} \quad (14)$$

respectively.

At low oxygen activities, oxygen may be lost and ionic compensation takes place through the formation of oxygen vacancies. In this case the electrical neutrality condition becomes

$$p = [Ca'_M] - 2[V^{\cdot\cdot}_O] \quad (15)$$

This condition can be expressed by

$$La_{1-y}Ca'_yM^x_{1-y}M^{\cdot}_yO_3 = La_{1-y}Ca'_yM^x_{1-y+2x}M^{\cdot}_{y-2x}V^{\cdot\cdot}_{Ox}O_{3-x} + \tfrac{1}{2}\,xO_2$$

or

$$O_O + 2\ M^{\cdot}_M = 2\ M_M + V^{\cdot\cdot}_O + 1/2\ O_2 \quad (16)$$

where y is the amount of acceptor and x is the concentration of oxygen vacancies. The equilibrium constant for reaction (16) can be expressed as

$$K_{16} = [M_M]^2\,[V^{\cdot\cdot}_O]\,P_{O_2}^{1/2}/[M^{\cdot}_M]^2 \quad (17)$$

which in terms of mole fractions becomes

$$K_{16} = (1-y+2x)^2\,x\,P_{O_2}^{1/2}/(y-2x)^2 \quad (18)$$

Equation (18) can be solved to yield

$$2x = y - \{P_{O_2}^{1/2}\,[(8y\,K_{16}\,P_{O_2}^{-1/2} + 1)^{1/2} - 1]/4\,K_{16}\} \quad (19)$$

The electrical conductivity for p-type materials is given by

$$\sigma = e\,p\,\mu \quad (20)$$

where e is the electron charge, μ is the mobility, and p is the concentration of carriers which, from the model, is equal to $(y–2x)$. Thus eqn (19) can be rearranged to give

$$\sigma = e\mu P_{O_2}^{1/2}\{[(8\,yK_{16}\,P_{O_2}^{-1/2} + 1)^{1/2} - 1]/4\}K_{16} \quad (21)$$

At the high oxygen-activity region, eqn (19) reduces to $x = 0$ and eqn (21) reduces to $\sigma = e\,y\,\mu$, whereas in the low oxygen-activity region the respective equations are reduced to

$$p = (y\text{-}2x)/y = P_{O_2}^{1/4}/(2y\,K_{16})^{1/2} \quad (22)$$

or

$$\sigma = (e\,\mu\,y^{1/2}\,P_{O_2}^{1/4})/2K_{16} \quad (23)$$

and

$$\sigma/\sigma_R = P_{O_2}^{1/4}/(2y\,K_{16})^{1/2} \quad (24)$$

where σ_R is the electrical conductivity at 1 atm oxygen.

The equilibrium constant K_{16} can be found by combining the electrical conductivity experimental data and eqn (24). The theoretical curves can be generated by using eqn (24) and the calculated values of K_{16}. The individual symbols in Figs 13–14 represent the experimental data, while the lines are the calculated curves. The equilibrium constants used to generate these lines are listed in Table 3. It is clear that the electrical conductivity decreases with decreasing oxygen activity as $P_{O_2}^{1/4}$, as the electrical compensation changes from electronic to ionic. All of the compositions showed the same behavior. The oxygen-activity dependence on conductivity was small at high oxygen activities; as oxygen activity decreased, a break in electrical conductivity at 10^{-10} atm and 1000°C was observed, then the electrical conductivity decreased as $P_{O_2}^{1/4}$. Compositions $La_{1-x}Ca_xCr_{1-y}Co_yO_3$ with x = 0·0–0·3 and y = 0·0–0·2 are stable towards dissociation

Table 3. Equilibrium constants calculated from defect model at 1000°C

in forming gas at 1000°C, even though the electrical conductivity decreases.

Seebeck measurements were also made as a function of oxygen activity at 1000°C. The results for compositions $(La,Ca)(Cr,Co)O_3$ are shown in Fig. 15 . The Seebeck coefficients in all cases were positive, indicating p-type conductivity. Increasing the Co substitution for Cr decreased the Seebeck coefficients. In accordance with the electrical conductivity, the Seebeck coefficient remains constant until the low P_{O_2} region is reached. At this point, the Seebeck coefficient rapidly increases at the transition knee because of its inverse relationship with the carrier concentration. The location of the transition knee shifted to a higher P_{O_2} with increasing Co and Ca concentration in both the Seebeck and electrical conductivity data. For the high P_{O_2} region, the carrier concentration is controlled by the acceptor content p = [Ca'] and electronic compensation predominates. Any temperature dependence of the electrical conductivity is therefore determined by mobility. It should be noted that in eqn (24), the mobility was assumed to be independent of oxygen activity. This is an important feature of the model if the calculated equilibrium constants are to be regarded as correct.

4 Conclusions

The electrical conductivity as measured in air from 100 to 1100°C increased with increasing Co and Ca content. At 1000°C, values from 1·5 S/cm (for $LaCr_{0.9}Co_{0.1}O_3$) to 50 S/cm (for $La_{0.7}Ca_{0.3}Cr_{0.9}Co_{0.1}O_3$) were measured. The Seebeck coefficients were positive, indicating p-type conductivity. The substitution of Co for Cr significantly decreased the Seebeck coefficients, indicating that Co substitution for Cr increased the carrier concentration. Additional Ca substitution for La resulted in a further decrease in the Seebeck coefficient. Seebeck coefficients then exhibited a temperature-independent behavior, indicating that the carrier mobility, rather than carrier concentration, was thermally activated. The results indicated that the electrical conduction in $La(Cr,Co)O_3$ and $(La,Ca)(Cr,Co)O_3$ occurs via the non-adiabatic and adiabatic small-polaron mechanisms, respectively.

At 1000°C the oxygen activity dependence upon conductivity was small at high oxygen activities; as oxygen activity decreased, a break at 10^{-10} atm was observed, at which point the electrical conductivity began decreasing as $P_{O2}^{1/4}$, following the model previously proposed for $LaCrO_3$.

Abstract

In this paper the densification of a cylindrical pore due to a first order heterogeneous deposition reaction on the wall is described. The basic understanding of these mechanisms can aid in the prediction of the infiltration time and composite porosity after densification. The results of the modelling are compared with experimental results which are reported in an additional paper, i.e. Part 2 of this study. The main characteristic parameter that determines the infiltration behaviour is the gas velocity.

1 Scope

The drive to gain 'tough' ceramic material led to the development of the so-called thermal gradient FCVI (TGFCVI) technique some ten years ago.[1–4] With this method, thick walled ceramic component structures can be made. A drawback however, is that for each different sample geometry, a new fixture needs to be developed through which a thermal gradient can be applied across the fibrous preform.

The isothermal FCVI (IFCVI) method does not have this problem, so the fixture can have a much simpler design. For thin walled structures like hot gas filters, heat shields, burner tubes, seal rings and heat exchanger panels, this isothermal method can thus provide a great improvement towards industrial application of the FCVI technique. Optimisation of IFCVI process conditions however is of great importance to be able to homogeneously fill the porous substrate, especially in the direction parallel to the gas flow.

The modelling of both ICVI and FCVI processes is a topic of much effort and a first attempt to optimise conditions rapidly. However, the experimental validation of these models (especially FCVI) is still very limited and a basic insight into the process mechanisms is often arduous. As far as is known, there are no publications on the effect of the different process variables of the FCVI process on the infiltration efficiency in terms of composite density and infiltration time. This study is an attempt to fill this gap and reach a better understanding in the IFCVI process using on one hand a very simple model (*viz.* in Part 1) and on the other hand, experimental validation (Part 2).[5]

2 Introduction

When reactive precursor gas is forced through a heated porous fibrous preform, a chemical reaction takes place on the fibre surface and a solid matrix material is deposited onto the fibres: the forced flow chemical vapour infiltration (FCVI) process.

In this study, silicon carbide (SiC) is deposited onto the fibres as a result of a heterogeneous decomposition of methyl-trichlorosilane (MTS) in hydrogen:

$$SiCH_3Cl_{3(g)} + H_{2(g)} \rightarrow SiC_{(s)} + 3HCl_{(g)} + H_{2(g)}$$

As the material is growing onto the fibres, the density of the preform increases and the pores get smaller. The preform microstructure is thus changing with time.

In principle, the preform can be visualised simply as a cylindrical plate in which cylinder holes (pores) are present. Through these pores the gas flows, due to the pressure gradient that is present across the plate. The diffusion due to concentration gradients along the pore axis can be neglected, because it is much smaller than the mass transport of the species due to the pressure driven convection.

The FCVI process is dependent on two kinds of parameters, i.e. the process conditions such as:

- Temperature of the preform
- Total pressure
- Gas velocity

- Precursor concentration

and the microstructural properties of the starting preform such as:

- Preform permeability
- Preform porosity
- Average pore size and pore size distribution
- Preform thickness
- Pore tortuosity
- Specific surface area available for deposition.

For a complete understanding of the FCVI process it is necessary to know the effect on the infiltration process when one or more of these parameters are varied.

The purpose of this manuscript is to gain more understanding of the infiltration behaviour and this paper describes the effect of the different process conditions and microstructural properties of the preform under isothermal conditions. Although the model presented is a simplification of reality, it can provide insight into the basic principles of the FCVI process.

3 One-dimensional analysis of the isothermal CVI process

The three dimensional raw fibrous preforms used in Part 2 of this study, contain pores of three size ranges and contain an average total porosity of 50 vol%. The smallest pores are smaller than 0·01 μm, bigger pores between 2–30 μm represent the pores within the bundles and large pores with a diameter between 100–1000 μm are the voids between two crossing tows and the pores between the tows.

When it is assumed that the relative contribution in void space of the two smallest pores is negligible, then the porosity will depend on the large pores only. As such, the infiltration time and densification of the preform is dependent on these large pores, since they determine the preform permeability and pressure drop and thus the moment that the process is terminated, i.e. when the pore entrances of these big pores are (almost) closed due to matrix deposition.

For the description of the CVI process. the preform can then be represented simply as a plate with continuous monosized pores of 500 μm in diameter under isothermal conditions. The pores are straight and open on both sides. Such a model preform is visualised in Fig. 1.

Distinction should be made in the way the gas species are transported into the pore cavity using one of the different CVI methods. During isothermal isobaric CVI (ICVI) processing, the gas flows around the model preform and the gas species are transported into the pores by diffusion.

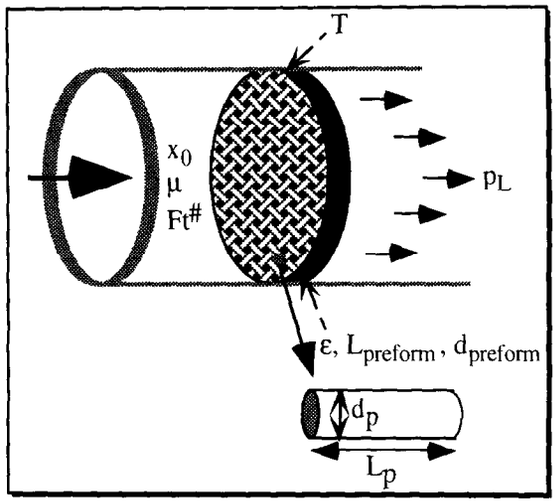

Fig. 1. The cross-section of the reactor tube with a porous model preform consisting of n monosized cylindrical pores. Known initial adjustable process and microstructural parameters are indicated.

On the other hand, in the case of isothermal forced flow CVI (IFCVI), the gas mixture enters the preform from one side and flows in axial direction due to forced convection.

For both ICVI and IFCVI densification, silicon carbide (SiC) is deposited onto the pore wall. The deposition rate of SiC is controlled by either the chemical reaction rate or one of the two mass transport mechanisms.

Two dimensionless numbers, i.e. the mass Peclet number (Pe) and the Damköhler (Da) number[1,2] describe the competition between the chemical reaction rate at the fibre surface and the mass transport rate of the precursor species into the pore.

The Peclet number describes the ratio of mass transport due to convection into the pore relative to diffusive transport. The Damköhler number is the ratio of the chemical deposition rate of the matrix material relative to the rate of mass transport into the pore. For a porous preform consisting of cylinder pores in which deposition takes place, the Pe number for a cylindrical pore is defined as:

$$Pe = \frac{\text{convective mass transport}}{\text{diffusive mass transport}} = \frac{u_p d_p}{D_{eff}} \quad (1)$$

D_{eff} is the effective gas diffusion coefficient ($m^2.s^{-1}$), d_p is the pore diameter (m) at the gas entrance side and u_p is the average superficial gas velocity ($m.s^{-1}$) for laminar flow within a horizontal cylindrical straight pore and will be described later on.

At low Peclet numbers, (i.e. if $u_p d_p << D_{eff}$), diffusion is the mass transport mechanism whereas at large Pe numbers convection is dominant.

The Damköhler number is dependent on the mass transport mechanism and therefore distinction is made between the first and second

Damköhler number Da I and Da II, respectively). For a first order reaction (in MTS) on the pore wall, these are defined as:

$$Da\ \mathrm{I} = \frac{\text{chemical reaction rate}}{\text{convective mass transport rate}} = \frac{4k_s}{u_p} \quad (2)$$

$$Da\ \mathrm{II} = \frac{\text{chemical reaction rate}}{\text{diffusive mass transport rate}} = \frac{4k_s d_p}{D_{eff}} \quad (3)$$

Here, k_s is the first order reaction rate coefficient based on surface area ($m.s^{-1}$).

When the Damköhler numbers are small (i.e. if numerator << denominator), the chemical reaction is rate limiting whereas at large values the rate of mass transport is controlling the SiC growth.

Four idealised, extreme cases can be given:

(1) The growth rate is mass transport limited and mass transport is dominated by:
   (a) gas phase diffusion; Pe small, *Da* II high;
   (b) forced convection; Pe high, *Da* I high.

(2) The chemical reaction rate is limiting the growth and mass transport is due to:
   (a) gas phase diffusion; Pe small, *Da* II small;
   (b) forced convection; Pe high, *Da* I small.

Cases 1(a) and 2(a) are conditions during the ICVI process (isothermal and isobaric CVI, low Pe) and 1(b) and 2(b) (high Pe) are common for FCVI. In the former cases, the gas flows around the substrate and the concentration gradient is the driving force for the diffusion of the precursor gas into the pores. In the latter cases, a pressure gradient across the substrate forces the gas to flow through the pores.

For both situations an equation can be found for the MTS concentration profile (or effectiveness factor ζ) within a cylindrical pore (open on both sides) where gas molecules enter the pore from one side. For ICVI (cases 1(a) and 2(a)), diffusion and reaction the effectiveness factor is given in literature.[3–5]

For FCVI (cases 1(b) and 2(b)), forced convection and chemical reaction in a straight pore, the effectiveness factor is defined as (Appendix A):

$$\frac{C_z}{C_0} = \exp\left(\frac{-4k_s z}{d_p u_p}\right) = \exp\left(\frac{-Da\ \mathrm{I} z}{d_p}\right) \quad (4)$$

The decrease of the layer thickness or precursor conversion (depletion) along the pore axis from opening ($z = 0$) to end ($z = L$) can be represented by Δ, defined as:[4]

$$\Delta = \frac{G_0 - G_L}{G_0} = 1 - \frac{C_L}{C_0} \quad (5)$$

with G being the first order SiC growth rate ($mol.m^{-2}.s^{-1}$) and is:

$$G_{SiC} = k_s\, C_{MTS,z} \quad (6)$$

For FCVI, the deposition layer gradient or depletion can be expressed as:

$$\Delta = 1 - \exp\left(\frac{-4k_s L}{d_p u_p}\right) = 1 - \exp\left(\frac{-Da\ \mathrm{I} L}{d_p}\right) \quad (7)$$

For a uniform deposited layer, Δ equals zero. As the precursor conversion is low, the SiC layer uniformity and composite density will thus be large.

For both ICVI and FCVI this means that respectively *Da* II and *Da* I should be small. Infiltration should therefore be performed in the reaction rate limited growth regime to enhance uniform deposition.

Furthermore, for ICVI a small Δ implies a large diffusion coefficient and pore diameter and small pore length. The modelling of the ICVI process is performed by many[4–8] and is no topic of this study.

4 The Infiltration Behaviour Versus IFCVI Process Conditions. Introduction

In this section, some general relationships are derived that are applicable for the description of the IFCVI process. The FCVI process has been modelled by many, using complex and powerful computer models.[9–12] However, basic insight in the controlling phenomena of the FCVI process is often lost and the model is a black box where a certain input will yield an output that is not well understood. Furthermore, these models are often based upon process variables that are impossible to alter in real experiments. The operator of the IFCVI process is only able to vary four input process conditions, i.e. preform temperature: T, total gas flow rate at STP: $Ft^{\#}$, total pressure at the gas exit side of the preform: p_L and the reactant mole fraction in the gas mixture at the gas inlet side: X_0. Furthermore, the shut off point of the process can be adjusted. The latter is a certain pressure difference between the pressure at the gas inlet side at $t = 0$ and the pressure at the same location after a densification time period.

In the next section, some simple analytical tools are presented[16] that can aid in the prediction of trends in matrix growth rate at the gas inlet and outlet position of the preform. First (Section 4.1–4.3), the effects of the four input process conditions are examined. Subsequently, a correlation of the microstructural parameters of the raw (uninfiltrated) preform on the infiltration behaviour is presented in Section 5.

4.1 General description of the growth rate during FCVI in a cylindrical model pore

The growth rate G_z ($mol.m^{-2}.s^{-1}$) of the solid matrix material SiC in axial direction z in the pore is given by:

$$G_z = C_z k_s = C_0 k_s \exp\left(\frac{-4k_s z}{d_p u_p}\right) \quad (8)$$

As infiltration proceeds, the pore mouth — of diameter d_p (m) (at z = 0) — will become smaller due to deposition, hence:

$$d_{pt} = d_{p0} - \frac{2t_i G_0 m_{SiC}}{\rho_{SiC}} \quad (9)$$

Here, m_{SiC} is the molar mass of SiC = 0·040 kg.mol^{-1} and $\rho_{SiC} = 3{\cdot}2 \times 10^3$ kg.m^{-3}, t_i is the infiltration time (s).

4.2 Kinetically controlled matrix growth

At very large gas velocities (u_p > infinity), eqn 8 reduces to $G_z = C_0 k_s = G_0$, indicative of kinetically controlled growth. Within this growth regime, Δ (eqn 7) equals 0.

$$G_z = k_s C_z = k_0 \frac{X_0 p_0}{Rg\ T} \exp\left(\frac{-Ea}{Rg\ T}\right) \quad (10)$$

with Rg (J.mole^{-1}.K^{-1}) as the gas constant and Ea (J.mole^{-1}) the activation energy of the heterogeneous reaction. Clearly, neither the total gas flow rate does not affect the growth rate within the pore. Increase of total inlet pressure p_0, temperature T or molar fraction of the precursor X_0, will increase the growth of SiC.

Theoretically, compared with kinetically controlled growth during ICVI, FCVI will not allow complete densification of the preform due to the imposed pressure gradient that yields a deposition gradient.

4.3 Forced convection controlled matrix growth

The effect of the process conditions in case of mass transport limited SiC growth, is not as straightforward as for kinetically controlled growth. The gas velocity is the prime parameter that determines the growth rate of SiC along the pore axis.

Gas velocity

Clearly, the gas velocity is of prime importance during convective mass transport. The gas velocity determines the mass transport rate of the MTS and depletion along the pore axis. This pressure driven velocity of the precursor species is represented by the gas velocity u_p of the gas through a pore p of the preform.

As a starting point, the superficial gas velocity u (m.s^{-1}) for a hollow cylinder tube of constant diameter, based on the mass flux of the species is defined as:

$$u = \frac{Ft}{A} = \frac{Ft^{\#}\ T\ p^0}{T^0\ \bar{p}\ A} \quad (11)$$

Here, $Ft^{\#}$ is the total gas flow rate at STP conditions (m^3.s^{-1}), A is the cross flow area of the cylindrical tube and is thus $0{\cdot}25\pi d^2$ (m^2), d is the tube diameter (m), T^0 and p^0 are the standard temperature (273 K) and standard pressure (10^5 Pa) respectively, $\bar{p}$ is the arithmetic mean pressure, averaged across the preform width (Pa). This description of the gas velocity in the reactor tube or pore is linearly dependent on the gas inflow rate Ft.

As a first approximation it is assumed that the pressure within the pore decreases linearly from gas inlet to outlet of the preform and the gas velocity through the pore is the gas velocity based upon the pore mouth diameter. In other words, these assumptions imply that the pore becomes smaller, but remains of uniform diameter.

The average total pressure in the pore $\bar{p}$ is:

$$\bar{p} = \frac{p_0 + p_L}{2} \quad (12)$$

where p_0 is the pressure at the gas inlet side of the preform and p_L the pressure at the gas outlet side (Pa).

The average† gas velocity u_p (m.s^{-1}), according to the Hagen–Poiseuille relationship[1] for a hollow cylindrical straight pore p where laminar flow is present and the gas density is constant (incompressible flow) is given by:

$$u_p = \frac{d_p^2\ \Delta p}{32\ \mu L} \quad (13)$$

Here L (m) is the pore length and equals (in this case, Fig. 1) the preform thickness, μ (Pa.s) is the dynamic viscosity of the gas mixture flowing through the pore, and Δp (Pa) is the pressure drop across the pore or preform:

$$\Delta p = p_0 - p_L \quad (14)$$

The pore gas velocity, (i.e. the average gas velocity through each of the total of n single monosized straight pores) is linked with the superficial gas velocity through a hollow IFCVI reactor tube u, through the preform total porosity ϵ:

$$u_p = \frac{u}{\epsilon} \quad (15)$$

The preform porosity ϵ (volume fraction) is derived from the total pore volume equation. The total pore volume of a preform equals $n \times V_p$ or $\epsilon \times V_{preform}$ and hence the (constant) number of pores n, with constant diameter d_p is:

$$n = \frac{\epsilon d^2_{preform}\ L_{preform}}{d_p^2\ L_p} \quad (16)$$

where $L_{preform}$ can be considered to equal L_p, when the tortuosity of the pore equals one. V_p is the

†The average velocity of the parabolic velocity profile in the hollow tube or pore.

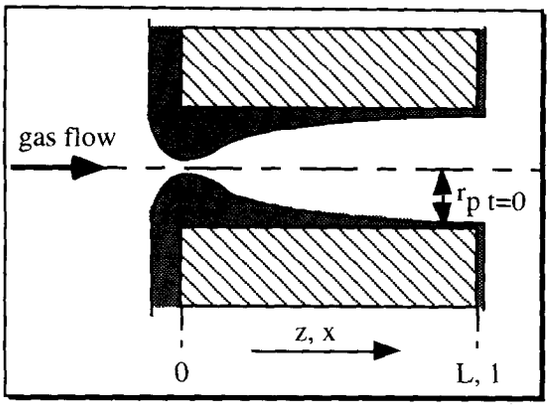

Fig. 2. A cross-section of one cylinder pore.

single raw pore volume (m^3), $V_{preform}$ is the total raw preform volume (m^3) and $d_{preform}$ is the preform disc diameter (m).

The preform diameter remains relatively unchanged whereas the porosity changes during infiltration. Due to deposition on the pore wall and depletion of the precursor from the gas mixture at mass transport limited conditions, the pore diameter gets larger from the gas inlet side ($z = 0$) further down the pore and thus will be dependent on z. This effect is visualised in Fig. 2 (Section 6).

Combination of (11) with (15) gives the velocity through one pore u_p ($m.s^{-1}$):

$$u_p = \frac{Ft}{\epsilon A_{preform}} \tag{17}$$

During the FCVI process, the driving force for the gas flow is dominated mainly by forced convection due to a pressure difference.

The FCVI operator can only adjust the total gas flow rate $Ft^{\#}$ and the outlet pressure p_L to gain a certain u_p setpoint. An expression for the pore gas velocity, similar to the Hagen–Poiseuille relation, in terms of outlet pressure can be derived through combination of eqns 13 and 17:

$$u_p = \frac{d_p^2}{32\mu L} p_L \left\{ \sqrt{1 + \frac{256 Ft^{\#} p^0 T \mu L}{\pi n d_p^4 T^0 p_L^2}} - 1 \right\} \tag{18}$$

Here, the term within brackets times p_L, equals the pressure drop across the pore.

5 Effect of the Preform Microstructure on the Infiltration Behaviour

The effect of the microstructural properties on the infiltration behaviour can be performed through correlation of these properties with the gas velocity. This latter is the prime process parameter for the description of the layer uniformity and thus density during mass transport limited growth.

In the next section, the microstructural properties are presented in detail with their effects on the infiltration behaviour of the preform.

The microstructure of the preform changes with time due to deposition within the pore network. Unless stated otherwise, the initial ($t = 0$) microstructural parameters of the raw preform are meant in all cases.

The total description of the initial preform microstructure is performed through the definition of:

- Preform permeability, indicative of the resistance of the preform for gas flow;
- Preform open porosity, the total open pore volume of the preform that is to be filled with matrix material;
- Diameter of the pores, giving the size of the openings through which the gas flows;
- Deposition area, giving the total surface area available for deposition;
- Preform thickness, the length of the path the gas molecules have to travel;
- Tortuosity, giving the complete path length in case of curved pores.

Preform permeability

The permeability K (m^2) is defined as the fluid conductivity of the porous material.[13,14]

The permeability of a porous system is supposed to be a constant in Darcy's law.

In case the fluid is an incompressible liquid, K is indeed a constant. In the case of gases, the permeability is dependent on pressure at low absolute pressure. (More details about the permeability are given in Part 2 of this study in Section 5). Because of this fact and because the liquid permeability K_l is not a realistic useful FCVI quantity, it is necessary to express the preform microstructure in other more suitable parameters like porosity, pore size, thickness and to be more complete also in terms of tortuosity.

The permeability of the preform is, despite the facts mentioned above, still the sole parameter that gives an impression of the resistance of the structure to the gas flow.

A constraint of infiltration is that the gas permeability of the structure should be sufficiently large to be able to force the gas through it, without having the pressure at the inlet side reaching excessively high values in a short period of time.

Initial preform tortuosity

The tortuosity of a porous material $\tau(-)$, is defined[15] as the square of the ratio of the average distance traversed by a particle of fluid, L_{eff} to the

direct distance through the preform, $L_{preform}$ and hence $(L_{eff}/L_{preform})$.[2] The mean tortuous velocity through the bed u_{bed} (m.s^{-1}) is:

$$u_{bed} = \frac{uo\ \tau}{\epsilon} \tag{19}$$

Where uo is the superficial gas velocity.

It is hard to anticipate what the effect of the tortuosity will be on the density of the composite after infiltration without knowing the exact microstructure. As a first approximation it is anticipated that a preform with $\tau > 1$ can be compared with a thicker preform and that effects are similar. Large tortuosity will yield low density due to larger depletion effects.

As the pores are not straight and uniform in diameter, the section with the largest resistance (small diameter or high angle) can cause early blocking of the pore resulting in early termination of the infiltration process and thus low density.

6 The Relative Composite Density as a Function of Process and Microstructural Parameters

During the densification process, matrix material is deposited onto the pore wall and the layer thickness of the matrix will decrease exponentially with z, see Fig. 2.

Obviously, during the infiltration process, the deposition behaviour changes due to the reduction of the pore size and non-uniform deposition on the pore wall.

Modelling of the infiltration process is therefore more accurate when all conditions and pore dimensions are described both time and position dependent.

The simple equations derived in the previous sections are no longer sufficient. For position dependence, some basic differential equations were derived. This is described in Appendix B.

In summary, for a pore of length L (m) and radius r (m) at temperature T (K) where MTS (denoted with S) reacts at the pore wall, the three principal differential equations are:

$$\frac{\partial p_x}{\partial x} = \frac{-8\ \mu\ L\ K\ Ft^{\#}}{n\ \pi\ p_x\ r_x^4} \tag{20}$$

$$\frac{\partial C_{Sx}}{\partial x} = -2LC_{Sx}\left[\frac{n\ \pi\ k_s\ r_x\ p_x}{Ft^{\#}\ K} + \frac{4\ \mu\ K\ Ft^{\#}}{n\ \pi\ p_x^2\ r_x^4}\right] \tag{21}$$

$$\frac{\partial r_x}{\partial t} = \frac{-m_{SiC}}{\rho_{SiC}} k_s\ C_{Sx} \tag{22}$$

$$\text{with } K = \frac{Tp^0}{T^0}\ (\text{Pa}) \tag{23}$$

and x (–) is the dimensionless axial distance in the pore.

Simultaneous solution of these equations with the variables p_x (Pa), C_{Sx} (mole.m^{-3}) and r_x (m), allows the calculation of the evolution of the pore diameter as a function of time and position in axial direction. After the simulated infiltration process has ended the resulting composite microstructure can be estimated.

The open volume V_0 within the preform after infiltration (m^3) is given by the general expression for a solid of revolution:

$$V_0 = n\pi L \int_0^1 r_x^2\ dx \tag{24}$$

with n the (constant) number of pores in the preform (eqn 16) and r_x represents the pore radius after infiltration.

The mass of the total amount of deposited matrix in the preform M_{in} (kg), is the matrix volume multiplied by the theoretical density of the SiC matrix material ($3{\cdot}2 \times 10^3$ kg.m^{-3}).

$$M_{in} = \rho_{SiC}\ (n\ V_p - V_0) \tag{25}$$

where V_p is the volume of one raw cylindrical pore and equals $\pi r_p^2 L$.

Furthermore, the SiC matrix is not only deposited in the porous preform but moreover, on the front surface of the preform as well. The mass of the deposited SiC on its front side, neglecting the initial surface porosity, can be roughly estimated with:

$$M_{on} = \rho_{SiC}\ \pi r^2_{preform}\ (r_p - r_a) \tag{26}$$

with r_a the radius of the pore mouth after infiltration (m) and r_p the radius of the raw pore (m). The porosity of the preform after infiltration ϵ_c (vol%) is:

$$\epsilon_c = \frac{V_0}{V_{preform}} \tag{27}$$

Here, $V_{preform}$ is the volume (m^3) of the raw preform (without the coating on the front side). The relative bulk composite density is defined here as:

$$\rho_{brel} = 100 - \epsilon_c \tag{28}$$

7 The Model Set-up

General assumptions and model input

In the simulation results described in Section 8, assumptions are made in order to gain a model that can be solved easily and is easy to use and understand. These assumptions are:

(1) Mass transport of the gaseous species takes

place by forced convection in axial direction only. Axial dispersion and radial convection or diffusion (either ordinary or Knudsen) are not taken into account. This model is thus ID.

(2) The forced convection takes place in the viscous laminar flow regime.
(3) The gas behaves ideally.
(4) Stefan flow due to the reaction stoichiometry is neglected since dilution of the precursor compound in the gas mixture is generally large.
(5) The surface kinetics follow a first order relationship with respect to the MTS concentration. The reaction rate coefficient is assumed to be independent of total pressure.
(6) Homogeneous gas phase reactions do not occur.
(7) The initial pores are cylindrical and monosized and the tortuosity equals 1.

The required input parameters for the modelling are:

Initial preform porosity (volume fraction), initial preform thickness (m), diameter of the preform disc (m), activation energy of the first order deposition reaction (J.mole^{-1}), pre-exponential factor (m.s^{-1}), preform temperature (K), outlet pressure (Pa), precursor inlet molar fraction, total gas flow rate at STP (m^3.s^{-1}) and pressure shut off point (Pa). The latter is defined in Part 2 of this study (eqn 10).

The only input microstructural parameter that is required and initially unknown is the pore radius r_p at $t = 0$ (m). Through comparison of experimental infiltration durations and simulation results, this r_p can be fine-tuned to gain a matching between experiments and model.

Calculation algorithm

After input of the process conditions, the constants are calculated: k_s, μ at the selected temperature and the number of pores n (eqn 16). An initial pore diameter is selected and an initial iteration step of 5 s was chosen. At these conditions, the pressure within the pore as a function of position is calculated through numerical integration of eqn 21. Hereto, the total pore is split into 40 equal length segments. Simultaneously, the MTS concentration (eqn 22) within the pore is calculated numerically and allows the estimation of the deposition rate in the pore and the local reduction in pore radius (eqn 23).

With this reduced pore size, a next time step is selected and again the pressure, concentration and growth rate are calculated for each of the 40 segments.

As the inlet pressure starts to increase more rapidly, the time step is reduced to gain higher accuracy. The whole iteration is terminated when the selected shut off pressure drop setpoint is reached. At the final pore dimensions, the relative density or porosity of the preform, the deposited mass of SiC in and on the preform and final pore mouth radius are calculated.

The results of the model calculations as a function of process conditions are presented in Section 8.

8 Modelling Results

Due to the large amount of assumptions and simplifications made, this model can only simulate rough trends in infiltration time and composite density as a function of time and process or microstructural conditions. It is thus not intended to give quantitative information.

Nominal simulation conditions

In the following figures the results are summarised of the simulations performed at nominal process conditions using a standard preform model plate:

Temperature: 1273 K, outlet pressure: 50 torr, total gas flow rate: 1 slm, MTS inlet mole fraction: 0·15, preform porosity: 50%, initial preform thickness: 3 mm, preform diameter 8 cm, initial pore diameter: 500 μm, pressure shut off difference: 100 ± 10 torr, activation energy: 400 kJ.mole^{-1} and pre-exponential factor: $2{\cdot}1 \times 10^{14}$ m.s^{-1} of the first order reaction.[16] The dynamic viscosity of the gas mixture is estimated through: $\mu(T) = 2{\cdot}9 \times 10^{-7} + 4{\cdot}8 \times 10^{-8}T - 1{\cdot}6 \times 10^{-11}T^2 + 3{\cdot}2 \times 10^{-15}T^3$ in Pa·s. Initial iteration step size: 5 s.

IFCVI process as a function of time

As infiltration proceeds and the pores become smaller, the process conditions change.

In Fig. 3, the simulated change in inlet pressure and inlet and outlet MTS concentration are presented.

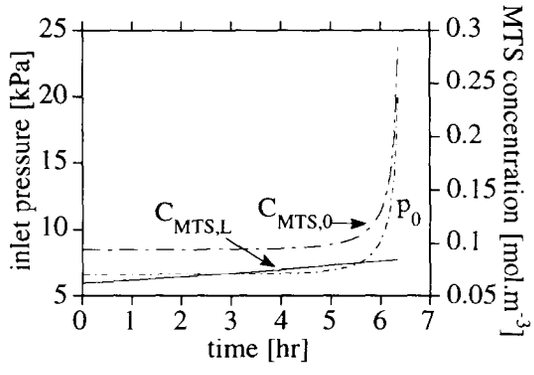

Fig. 3. Simulation result of the inlet pressure, the inlet and outlet MTS concentration (resp. $C_{MTS,0}$ and $C_{MTS,L}$) of a model preform at nominal conditions.

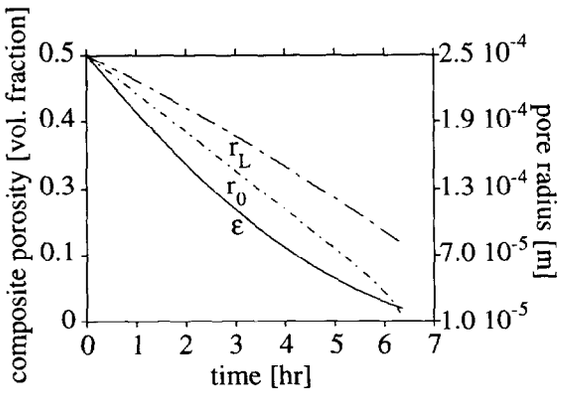

Fig. 4. Simulation result of the inlet and outlet radius (respectively r_0 and r_L and porosity of a model preform at nominal conditions.

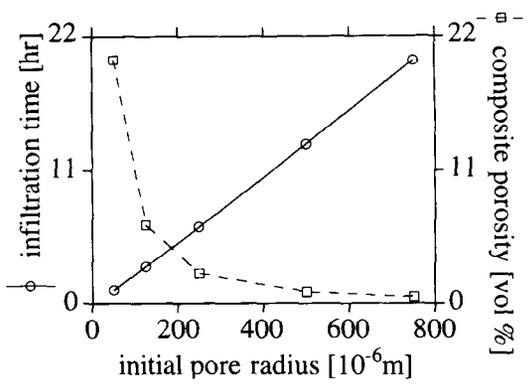

Fig. 6. The simulated infiltration time and composite porosity after infiltration of a model preform at nominal conditions versus initial pore radius.

The outlet pressure remains constant at 6·65 kPa (= 50 torr). Initially the inlet pressure hardly rises, but as soon as a critical pore size is reached, the pressure increases rapidly.

Combined with the increase of the inlet pressure, the inlet concentration and the gas velocity are increasing.

In general, more uniform deposition occurs due to the increase in gas velocity through the pores so that depletion effects are less severe in a later stage of the infiltration process.This effect is demonstrated in Fig. 3 by the increase of $C_{MTS,L}$.

Clearly, as the pore is becoming smaller, the porosity decreases (Fig. 4). At first, decrease is rapid, but due to the reduction of the deposition (pore mantle) area, porosity is only decreasing relatively slowly later on.

Total gas flow rate

Increase in total gas flow rate and thus increase of the mass transport rate, yields a larger matrix growth rate and reduction in infiltration time (Fig. 5). Subsequently, the uniformity of the layer profile is enhanced, since the gas velocity is enlarged.

When the kinetics are becoming rate controlled, further increase of $Ft^{\#}$ no longer has an effect on the layer uniformity, but the increase of the initial pressure drop at large $Ft^{\#}$ will yield a reduction in G_L/G_0 ratio and thus increase the composite porosity. In summary, a minimum will exist in composite porosity.

Initial pore size

When L/d_p is relatively small, matrix growth is limited by the chemical reaction (eqn 8) and thus occurs at large r_p. Increase of r_p as demonstrated in Fig. 6, linearly increases infiltration time, whereas composite porosity decreases through the increase of the gas velocity (eqn 13).

Outlet pressure

Similar to Fig. 5, in Fig. 7 an optimum (at 6·65 kPa outlet pressure) in composite density is found when the outlet pressure is increased from 13·3 to $1{\cdot}0 \times 10^5$ Pa (0·1–760 torr). At high outlet pressure, (i.e. ≥ 20 kPa), the gas velocity is low (eqn 11) so that depletion of the precursor gas is high along the pore length. Non-uniform deposition is the consequence. At low outlet pressure (p_L = 0·133 kPa) and thus at large gas velocity, the pressure drop value across the preform is of similar magnitude as the outlet pressure.

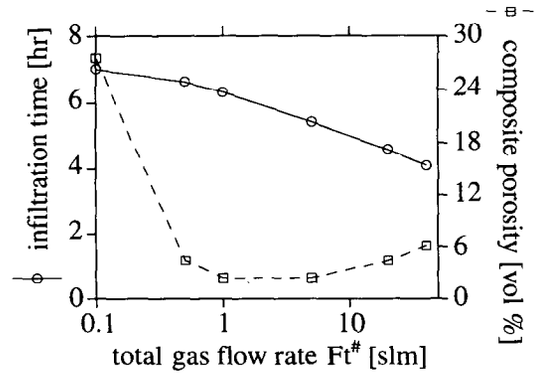

Fig. 5. The simulated infiltration time and composite porosity after infiltration of a model preform at nominal conditions versus total gas flow rate.

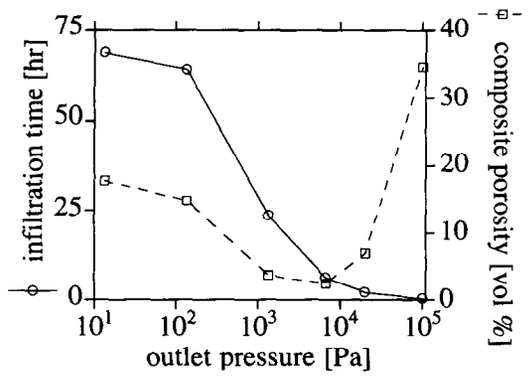

Fig. 7. The simulated infiltration time and composite porosity after infiltration of a model preform at nominal conditions versus total outlet pressure.

The large gas velocity will yield large density, but on the other hand when $p_0 > p_L$ and thus $G_0 > G_L$ uniformity will be poor. It is speculated that growth is limited by the chemical kinetics at these large gas velocities, since mass transport to the surface is very fast. Here, the matrix growth is not dependent on the gas velocity but on the local total pressure only.

Infiltration time is reduced if the total pressure and thus concentration is increased, because matrix growth is enhanced.

Temperature

At low temperature, deposition is kinetically controlled. Increase of temperature decreases infiltration time rapidly, whereas growth becomes mass transport limited infiltration time is less severely reduced (Fig. 8). As stated before, kinetically controlled growth is preferred because depletion (at low T) is low and uniformity is high.

Precursor input mole fraction

Increase of the MTS fraction in the gas mixture has no effect on the relative composite density. In relative terms, the uniformity is not affected by the absolute value of the MTS fraction within the gas mixture, neither in the mass transport limited nor in the kinetically controlled regime, as coincides with theoretical considerations.

However, infiltration time is reduced inversely proportional with the MTS fraction due to the increase of precursor concentration.

Preform porosity

The raw preform porosity is changed by alteration of the amount of pores. The gas stream is split into smaller portions, so that when the porosity is increased it will have to flow through a larger pore area. This reduction in gas velocity (eqn 11) yields a larger composite porosity in an almost linear fashion.

At low mass transport rate (high porosity) infiltration will take more time.

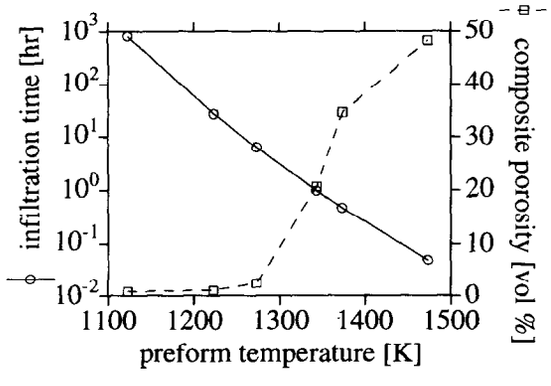

Fig. 8. The simulated infiltration time and composite porosity after infiltration of a model preform at nominal conditions versus preform temperature.

Initial preform thickness

A thicker preform disc will be infiltrated in the same time as a thin disc, as long as the deposition rate in the pore mouth is unaffected, i.e. p_0 remains unchanged.

A thick preform will, however, yield a larger initial pressure drop across the preform as compared to a thin preform at the same flow rate. Depletion of the MTS from the gas mixture is more severely affecting the composite density when the pores are longer.

Preform diameter

As the preform diameter or cross flow area A gets larger, the gas velocity is decreased (eqn 11). Subsequently, composite porosity is increased. As a consequence, the infiltration time will increase since mass transport of the gas species is reduced.

9 Discussion and Conclusions

Despite the better and more comprehensive numerical 2D models used by others, the developed simple ID model gives a good insight in the relative complex FCVI process without using a black box approach. The simulation variables correspond to the process variables that can be adjusted by the operator providing a direct correlation between experiments and model.

The capability of this model is to predict trends in filtration time and composite density that might be expected when process conditions, preform structure or dimensions are varied.

The general model trends are summarised in Table 1.

The simulation results show that uniformity of the matrix deposition can be improved by allowing

Table 1. The infiltration behaviour parameter dependence on initial process conditions and raw preform structure. The matrix growth is either limited by the surface kinetics or the mass transport rate.

*Assuming a first order reaction.

a large pore gas velocity in combination with a low inlet to outlet pressure ratio.

The first Damköhler number should be small. This implies operation where the gas velocity is so fast that matrix growth is just within the kinetically controlled growth regime. This generally occurs at: medium total gas flow rate, medium outlet pressure, low temperature and arbitrary precursor content in the gas mixture (with the constraint however that pure SiC will be formed, so the ratio H_2/MTS must not be too low).

The preform microstructure that is best suited for FCVI processing to gain a large composite density has a low open porosity, is thin and contains pores of large diameter. In general the gas permeability of the porous structure should be sufficiently large to enable the gas to flow through the structure easily. The best starting preform microstructure (without considering mechanical aspects) implies: low porosity, thin walled structures, large pore diameter, straight continuous pores and sufficient permeability.

For economical reasons, the infiltration time required to reach a certain homogeneous density should be kept as low as possible. Obviously, a high matrix growth rate across the entire pore length is essential. Increase of the matrix growth rate can be tailored by increase of the precursor molc fraction in the gas mixture without affecting the uniformity of the deposition profile. Increase of the temperature will also enhance densification rates, but will negatively affect the uniformity of the matrix distribution. Rapid infiltration is also enhanced through increase of the gas velocity. Lowering the total pressure will negatively affect the matrix growth rate and thus increase of the total gas flow rate is more suitable for this purpose.

In summary, the global optimum process settings for both rapid and dense composites are thus:

- high total gas flow rate;
- medium outlet pressure;
- medium temperature;
- high precursor molar fraction;

the best starting preform microstructure implies:

- low porosity;
- thin walled structures;
- straight continuous pores;
- medium pore size;
- sufficient permeability.

Unfortunately, it can be concluded that rapid densification does not coincide with high composite homogeneity and density.

For industrial application of the FCVI process, the real processing optimum depends on the specification of the desired composite material, especially its density. A high density can be achieved, but the time consumption will be large. This extra energy and material consumption should thus be compared with the extract value of the material for the specific application.

Appendix A. Time Dependent Precursor Concentration in a Cylindrical Model Pore

The cylindrical model pore can be assumed to be a steady state plug flow reactor in which forced convection is present and chemical reaction takes place on the pore wall. Stefan flow is neglected since the dilution of the $SiCH_3Cl_3$ in the carrier gas (hydrogen) is high. If it is assumed that the pore gas velocity is constant throughout the pore and independent of axial position, the following simplified analytical solution of the concentration of MTS within the pore can be derived.

The mass balance for a differential element of the pore with volume dV:

$$F_{Sz} = (F_S + dF_S)_z + (-r_S dV) \qquad \text{(A1)}$$

where 'S' denotes $SiCH_3Cl_3$, F_{Sz} the molar flow rate S (moles.s^{-1}) and equals $C_{Sz}\, u_z\, A_z$ since S is heavily diluted in the carrier gas. C_{Sz}, u_z and A_z are respectively the concentration of S (moles.m^{-3}),

the gas velocity ($m.s^{-1}$) and the cross flow area (m^2) at a location in axial direction z within the pore. Also:

$$C_{Sz} = \frac{F_{S0}(1 - Y_{Sz})}{u_z A_z} \tag{A2}$$

where Y_S is the conversion of S.

The reaction rate ($moles.m^{-3}.s^{-1}$) of S on the pore wall is:

$$-r_S = k_v C_{Sz} = \frac{k_v F_{S0}(1 - Y_{Sz})}{u_z A_z} \tag{A3}$$

where k_v is the volumetric reaction rate coefficient for the first order reaction (s^{-1}).

Rewriting A1 yields:

$$-dF_{Sz} = F_{S0}\, dY_{Sz} = -r_S dV \tag{A4}$$

and combination with A3 gives:

$$dY_{Sz} = \frac{-r_S\, dV}{F_{S0}} = \frac{k_v(1 - Y_{Sz})dV}{u_z A_z} \tag{A5}$$

After grouping of the terms and with $dV = A dz$ for a straight pore:

$$\int_0^{Y_{Sz}} \frac{1}{1 - Y_{Sz}}\, dY_{Sz} = \int_0^z \frac{k_v}{u_z} dz \tag{A6}$$

Here, the reaction rate coefficient k_v is based on the volume of the pore. In terms of surface area of the pore k_s ($m.s^{-1}$) is calculated through: $k_v V = k_s A$ with A representing the deposition or mantle area of the straight pore (m^2). k_v is thus $4k_s/d_p$, where d_p is the pore diameter of the straight pore (m).

Equation A6 can be integrated from pore mouth to length z and combined with (eqn A2):

$$1 - Y_{Sz} = \frac{C_{Sz} u_z A_z}{C_{S0} u_0 A_0} \tag{A7}$$

to yield:

$$\frac{C_{Sz} u_z A_z}{C_{S0} u_0 A_0} = \exp\left(-4k_s \int_0^z \frac{1}{u_z d_{pz}} dz\right) \tag{A8}$$

This equation reduces to a simpler one when the pressure across the pore axis is assumed to be linearly decreasing from p_0 towards p_L and the pore is straight so that u_z and d_{pz} are independent of z. At constant pressure and for an incompressible gas, the continuity equation is $\rho_z u_z A_z = \rho_0 u_0 A_0$. A very rough estimation of the concentration profile is:

$$\frac{C_{Sz}}{C_{S0}} = \exp\left(\frac{-4k_s z}{d_p u_p}\right) \tag{A9}$$

where u_p and d_p are based upon the entrance pore diameter conditions ($z = 0$).

Appendix B. Time and Position Dependent Precursor Concentration in a Cylindrical Model Pore

It may be clear that due to non-uniform deposition on the pore wall (as a consequence of depletion and the pressure gradient), the total gas flow rate, total pressure, MTS concentration and pore radius are all a function of position along the pore axis z.

The next section presents the derivations of three differential equations and are: the total gas flow rate, total pressure within the pore, the MTS concentration and the pore radius as a function of position in axial direction. These equations are solved simultaneously using a Mathematica† numerical routine based upon the Runge Kutta method.

Recall the inflow gas velocity (eqn 11):

$$u_{pz} = \frac{Ft^{\#} T p^0}{n A T^0 p_z} = \frac{Ft^{\#} T p^0}{n \pi r_z^2 T^0 p_z} \tag{B1}$$

and the Poiseuille flow eqn 13 as:

$$u_{pz} = \frac{-r_z^2}{8\mu} \frac{\partial p_z}{\partial z} \tag{B2}$$

Rewriting the equations in terms of dimensionless axial distance x: $x = z/L > dz = L dx$, equation B2 becomes:

$$u_{pz} = \frac{-r_x^2}{8\mu L} \frac{\partial p_x}{\partial x} \tag{B3}$$

A combination of (B1) and (B3) yields the position dependent pressure differential equation:

$$\frac{\partial p_x}{\partial x} = \frac{-8\mu\, LK\, Ft^{\#}}{n\pi p_x r_x^4} \quad \text{with } K = \frac{Tp^0}{T^0} \tag{B4}$$

The mass balance for a differential element of the pore with volume dV:

$$F_{Sz} = (F_S + \partial F_S)_z + (-r_S\, \partial V) \tag{B5}$$

where $SiCH_3Cl_3$ is denoted as 'S' and F_{Sz} is the molar flow rate of S ($moles.s^{-1}$).

The first order reaction rate of disappearance of S, r_S ($moles.m^{-3}.s^{-1}$) on the pore wall is:

$$r_S = -k_v C_{Sz} \tag{B6}$$

Here, the reaction rate coefficient k_v is based on the volume of the pore. In terms of surface area of the pore, k_s ($m.s^{-1}$) is calculated through: $k_v V = k_S A$, where A represents the deposition (or pore mantle) area (m^2) and thus $k_v = \frac{2k_s}{r_z}$. Rewriting B5 yields:

$$\partial F_{Sz} = r_S A_z\, \partial z = r_S \pi r_z^2 \partial z \tag{B7}$$

†Mathematica is software of Wolfram Research Inc.

$$\partial F_{Sz} = -k_S\, C_{Sz}\, 2\pi\, r_z\, \partial z \text{ with } \partial z = L\partial x \quad \text{(B8)}$$

$$\frac{\partial F_{Sx}}{\partial x} = -2\,\pi\, k_s\, L\, C_{Sx}\, r_x \quad \text{(B9)}$$

F_{Sx} equals ($C_{Sx}\ u_x\ A_x$) if the dilution of S in the carrier gas is high. C_{Sx}, u_x and A_x are respectively the concentration of S (moles.m^{-3}), the gas (m.s^{-1}) velocity and the cross flow area (m^2) at a location in axial direction within the pore. It is known that:

$$C_{Sx} = \frac{nF_{Sx}}{Ft_x} = \frac{nF_{Sx}p_x}{Ft^{\#}\,K} \quad \text{(B10)}$$

where F_{Sx} is the molar and Ft_x is the volumetric flow rate and equals (u_xA_x) and p_x is the total pressure in the pore as a function of x. Differentiation on both sides yields:

$$\frac{\partial F_{Sx}}{\partial x} = \frac{Ft^{\#}\,K}{n}\ \frac{\partial \dfrac{C_{Sx}}{p_x}}{\partial x} \quad \text{(B11)}$$

and with the chain rule:

$$\frac{\partial F_{Sx}}{\partial x} = \frac{Ft^{\#}\,K}{n}\left[\frac{1}{p_x}\,\frac{\partial C_{Sx}}{\partial x} - \frac{C_{Sx}}{p_x^2}\,\frac{\partial p_x}{\partial x}\right] \quad \text{(B12)}$$

Combination of equations (B9) and (B12) yields:

$$\frac{Ft^{\#}\,K}{n}\left[\frac{1}{p_x}\,\frac{\partial C_{Sx}}{\partial x} - \frac{C_{Sx}}{p_x^2}\,\frac{\partial p_x}{\partial x}\right] = -2\,\pi\, k_s L r_x C_{Sx} \quad \text{(B13)}$$

hence:

$$\frac{1}{p_x}\,\frac{\partial C_{Sx}}{\partial x} = \frac{-2n\pi\, k_s L r_x C_{Sx}}{Ft^{\#}\,K} + \frac{C_{Sx}}{p_x^2}\,\frac{\partial p_x}{\partial x} \quad \text{(B14)}$$

combination with equation (B4):

$$\frac{\partial C_{Sx}}{\partial x} = -2\,L\,C_{Sx}\left[\frac{\pi\, n\, k_s\, r_x\, p_x}{Ft^{\#}\,K} + \frac{4\,\mu\,K\,Ft^{\#}}{n\,\pi\,p_x^2\,r_x^4}\right] \quad \text{(B15)}$$

with the boundary condition that at $x = 0$:

$$C_{S0} = \frac{p_{S0}}{RgT} = \frac{S_{S0\,p0}}{RgT} \quad \text{(B16)}$$

For the change in pore radius due to deposition on its wall:

$$\frac{\partial r_x}{\partial t} = \frac{-m_{Sic}}{\rho_{Sic}}\, k_s\, C_{Sx} \quad \text{(B17)}$$

(B4), (B15) and (B17) and the three principal equations that depend on the three variables p_x, C_x, r_x and can be solved simultaneously as a function of both position x and time t to yield the development of the matrix deposition within a cylindrical pore.

Abstract

The preparation of homogeneously dense fibre reinforced SiC composites in a rapid way was the main objective of this study. Furthermore, densification should proceed as fast as possible. In Part 1 of this study,[1] some theoretical concepts were proposed of the infiltration mechanisms. The simple model was verified qualitatively using the results of experiments as is reported in this manuscript. Model and experiments do generally coincide. The trends predicted and found experimentally during alteration of the process or microstructural conditions appear to justify the theoretical concepts. Optimum infiltration conditions to gain largest density gain in the shortest time frame are 1320 K, outlet pressure of 6·65 kPa, total gas flow rate of 4 × 10^{-5} m^3 s^{-1}, MTS fraction of 16 vol% and pressure shut off point of 10 kPa.

1 Introduction

This paper is the continuation of the study to find the optimum process and microstructural conditions to gain high density ceramic composites using the Isothermal Forced Flow Chemical Vapour Infiltration (IFCVI) technique. In the previous paper, a simple mechanistic model was presented. In this manuscript the results are presented of an experimental study to verify the derived concept of the first paper.

2 Experimental Details

During the IFCVI of a porous carbon fibre preform, a CVD reaction takes place on the hot fibre surface. In this study, methyl-trichlorosilane (MTS) was used as both the silicon and carbon donor for the silicon carbide matrix. In the presence of a large amount of hydrogen it is known to form stoichiometric SiC.[2] The CVD reaction is:

$$CH_3SiCl_{3(g)} + H_{2(g)} \rightarrow SiC_{(s)} + 3HCl_{(g)} + H_{2(g)} \quad (1)$$

Raw materials

Disc shaped substrates with a diameter of 80 mm and a thickness of approximately 3 mm are used for the infiltration experiments. They were manufactured at DASA Aerospace,[3] Germany. They consist of Torayca T-300 (3K) fibres in plain woven layers that are stacked upon each other in a 0/90° orientation and woven together through a tow in the z direction. This orthogonally woven preform thus contains fibres in a 3D configuration.

Since the preform is very sensitive to handling and has a low stiffness, it is prefixed through impregnation with an alkali free liquid phenolic resin and compressed. After pyrolysis of the resin, the plates are cut into discs of 80 mm diameter using a water cutting machine. The carbon fibre content of the preforms varied from approximately 40–55 vol.% with respective thicknesses of 3·2–2·5 mm.

Infiltration experiments

Before infiltration, the preform plate is washed ultrasonically in acetone for 15 min and then positioned on top of a graphite support ring into a graphite holder. This holder is placed on top of a graphite injector tube through which the gases enter the holder and after flowing through the preform mainly axially, exit via the exhaust tube and pump (see Fig. 1). The graphite injector and holder are situated in a vacuum tight reactor chamber which is kept at a constant pressure and temperature by external resistance heating. This reactor is checked for leaks prior to each run. The preform is heated under a flow of nitrogen to 1200 K overnight at a rate of 120 $K.hr^{-1}$ and thereafter ramped to process temperature. After temperature stabilisation of at least 30 min, the process is started through introduction of the CVI gases at the process pressure.

The preform temperature is monitored by a thermocouple that is located in the bottom of the holder. All process settings (temperatures,

pressures, gas flows) during the infiltration are monitored by a data logging system attached to the FCVI apparatus which logs at 5 min intervals.

The methyltrichlorosilane (MTS) precursor flow rate is controlled by a vapour source controller. The MTS bubbler is weighed before and after each run to check the MTS flow rate. The 'weighed' MTS flow is used as the actual MTS flow value. The total amount of hydrogen gas, (i.e. the carrier gas for the bubbler and the bypass) is kept constant during the entire infiltration duration and additional argon is added for obtaining both a constant H_2/MTS ratio and total gas flow rate. The pressures at the injector and outlet side are monitored with two baratrons.

The pressure in the outlet is maintained at a constant value during the entire infiltration experiment. When the pressure in the injector at the start and the pressure at the end exceeds a certain shut off value, the infiltration is terminated and the gas flows are shut off. The preform is cooled to room temperature at 120 $K.hr^{-1}$ under a flow of argon.

In Table 1, the standard IFCVI process conditions are summarised.

Table 1. Standard IFCVI process conditions

Preform temperature (K)	1273
Outlet pressure (kPa)	6·65
MTS bubbler temperature (K)	288
Total gas flow rate (slm)	1
H_2 fraction at inlet (vol.%)	54
Ar fraction at inlet (vol.%)	37
MTS fraction at inlet (vol.%)	9
H_2/MTS ratio at inlet	6
Shut off pressure difference (kPa)	9·44 or 26·6

3 Characterization of the Preform

Raw preform

The outer dimensions and the weight of the disc shaped carbon fibre substrates with an initial diameter of 80 mm and a thickness of approximately 3 mm were measured before and after each run respectively with vernier callipers and an analytical balance. For the calculation of the fibre content V_f (volume fraction) of the preform relation[2] was used in which the small amount of pyrolised resin was neglected.

$$V_f = \frac{M_{preform}}{V_{preform}\,\rho_C} \tag{2}$$

Here, $M_{preform}$ (kg) is the mass of the raw preform and $V_{preform}$ is the volume of the raw preform disc in m^3 and ρ_C is the density of the carbon fibre ($1{\cdot}75 \times 10^3$ $kg.m^{-3}$).

Hereafter, the theoretical ideal density ρ_i ($kg.m^{-3}$) of a densified preform where the total pore volume is completely filled with silicon carbide matrix material ($\rho_m = 3{\cdot}2 \times 10^3$ $kg.m^{-3}$) can be calculated according to:

$$\rho_i = V_f\,\rho_c + (1 - V_f)\,\rho_m \tag{3}$$

The initial deposition area A_{dep} (m^2) is the weight $M_{preform}$ (kg) of the raw preform multiplied by the specific surface area S_C ($m^2.kg^{-1}$) of the carbon fibres (550 $m^2.kg^{-1}$). Assuming that there is no trapped porosity:

$$A_{dep} = S_C M_{preform} \tag{4}$$

Permeability

The preform permeability K, is defined as the conductance of the preform for the gas flow. The

initial permeability of the raw preform is dependent on its microstructure only and thus dependent on its fibre content. The gas permeability K_g (m^2) of a porous structure is given by Darcy's law as:[4]

$$K_g = \frac{uo\ \mu\ L}{\Delta p} \tag{5}$$

where L is the preform thickness (m), uo is the average superficial gas velocity ($m.s^{-1}$), μ is the dynamic gas viscosity (Pa.s) and ΔP is the pressure difference across the preform plate (Pa). This form of Darcy's law has, however, a very narrow range of validity.[5]

The permeability of a porous system is supposed to be a constant by definition. In case the fluid is an incompressible liquid and inertial effects can be neglected,[6] K is indeed a constant. In the case of gases, especially at low total pressure, the fluid does not always stick to the wall of the pores as required in Darcy's law (Poiseuille type flow) and a phenomenon termed 'slip' can occur. This slipping of the fluid along the pore walls gives rise to an apparent dependence of permeability on pressure. This dependence is called the Klinkenberg effect and occurs typically at low total pressure and corresponding Knudsen numbers[7] between 0·1 and 1.

Because the gas permeability is thus dependent on the pressure (drop) and not solely a microstructural constant, for the sake of comparison within the range of a process condition, it is necessary to express the evolution of the preform microstructure during CVI in other parameters like porosity, pore size, fibre diameter, fibre arrangement and wall thickness and to be more complete also in terms of tortuosity. Still, the permeability of the raw preforms is measured as a function of fibre content (and preform thickness), outlet pressure and total gas flow rate to obtain an order of magnitude of the conductance to gas flow. Hereto, argon gas flowed through the raw preform in the IFCVI apparatus at a temperature of 1273 K. The argon flow rate was varied stepwise from 0 to 2 slm at 2·66, 6·65 and 9·31 kPa outlet pressure and the pressure drop across the preform plate was measured using two matched pressure gauges.

Dimensionless numbers

The Peclet and the first Damköhler numbers can aid in the description of the IFCVI process conditions that were used for the experiments. These are defined in Part 1 of this study for a hollow cylindrical pore. For a more realistic definition of the preform the following definitions[9] were applied that are indicative for the raw preform and process conditions at $t = 0$.

$$Pe_{bed} = \frac{u d_f\ \tau^2}{\epsilon\ (1 - \epsilon)\ D_{multi}} \tag{6}$$

$$DaI_{bed} = \frac{4\ k_s\ \epsilon}{\tau\ u} \tag{7}$$

with τ (–) is the tortuosity of the preform and assumed to equal 2, k_s ($m.s^{-1}$) is the first order reaction rate coefficient, ϵ (vol. fraction) is the raw preform porosity, d_f (m) is the fiber diameter = 7×10^{-6} m, D_{multi} ($m^2.s^{-1}$) is the multi component diffusion coefficient.

Infiltrated preform

After the infiltration experiments, the composite discs were weighed to calculate the overall MTS conversion or total yield of MTS: η in the preform into solid matrix material. This η (%) is estimated by:

$$\eta = \frac{M_{m,dep}}{M_{m,max}} \times 100 \tag{8}$$

where $M_{m,dep}$ (kg) is the total deposited mass of matrix material and $M_{m,max}$ (kg) is the mass of matrix material that would be deposited at a complete conversion of MTS. Note that (reaction 1) 1 mol of MTS yields 1 mol of SiC.

This definition of η is very similar to Δ (eqn 5 part 1), whereas the first represents the conversion based upon the whole preform volume and the latter one represents the conversion across the length of a cylinder pore. This similarity implies that large η will yield low composite density due to low uniformity of the deposited matrix in axial direction.

After weighing of the composite preforms, they were cut into bars. Out of each disc, four samples from the middle section were cut, with typical dimensions of $60 \times 10 \times 3$ mm^3 using a diamond blade. The bars were ultrasonically cleaned in ethanol for 15 min and dried at 400 K for at least one night. Since the samples absorb moisture from the air, each bar was weighed directly after drying on an analytical balance. The outer dimensions of each bar were measured with callipers and the percentage of the ideal density expressed as the relative bulk composite density $\rho_{b\ rel}$ (vol.%) was estimated through:

$$\rho_{b\ rel} = \frac{M_b}{V_b\ \rho_i} \times 100 \tag{9}$$

with V_b (m^3) being the bulk volume of the bar and M_b (kg) the weight of the infiltrated bar. The arithmetic mean of the relative density of the four bars indicates the $\rho_{b\ rel}$ of each preform disc.

Analysis of the matrix composition

For the determination of the phase structure of the deposited matrix material, XRD analysis was

used with CuKα radiation at 35 kV and a 2θ diffraction angle between 20 and 80°. The SiC matrix was further analysed using a microprobe (EPMA, Jeol type JXA-8600SX). The composition of the matrix as a function of infiltration temperature, i.e. the silicon, carbon and oxygen content were measured quantitatively using an acceleration voltage of 10 kV. Both sides of the composite discs were measured *viz.* the gas inlet side and gas outlet side.

4 Results and Discussion

The effect of the different process variables such as preform temperature, total gas flow rate, MTS fraction in the inlet gas mixture and the outlet pressure on the infiltration time and composite density was studied. Furthermore, the effect of the fibre content and the densification stage (pressure drop) as a function of infiltration time are presented.

First, the reproducibility of the process and of the characterization methods are tested.

Reproducibility

A blank run was performed in which a preform plate was heated up to the typical process temperature of 1273 K and subjected to a mixture of H_2 and Ar, at a rate of respectively 500 and 100 sccm for 5 h. After cooling according to the normal procedure, the preform dimensions and weight were checked. No significant difference in weight or volume was detected.

So, it can be concluded that the changes of the preform, described hereafter, are solely the consequence of the infiltration procedure.

Before the effect of any process variable was tested, the reproducibility of the IFCVI process was estimated by carrying out twice, three repeated runs, (i.e. three runs under the same conditions). The relative bulk density (average of four bars out of one sample, $n = 4$) varied 0·5%, whereas it varied more when measured with a whole composite disc ($n = 1$), i.e. 2·2%. The latter error is larger, because of the error that is made in the measurement of the composite thickness, due to a radial thickness gradient of the deposited coating on the gas inlet side of the sample of approximately 10%.

Process conditions during the run

The data logging system allows continuous monitoring of the process settings. A typical result is given in Fig. 2. The total hydrogen flow rate is the summation of the hydrogen flow rate through the bubbler and the 'back up' hydrogen flow rate that is added additionally. All process conditions

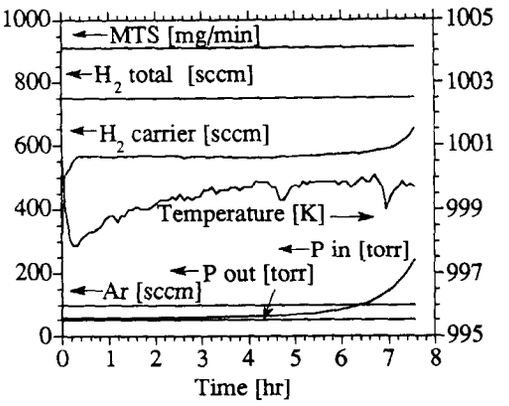

Fig. 2. The process conditions as a function of infiltration time as monitored with the data logging system. 'H_2 carrier' is the H_2 flow through the MTS bubbler. It increases due to increase in injector pressure 'pin'.

remain constant during the run with the exception of the injector pressure. Temperature typically varies ±2 K.

Pressure difference shut off point

During the infiltration process the gas permeability of the preform decreases due to the deposition of the SiC on the pore walls. Consequently, the pressure drop across the preform starts to rise. For comparison of the preforms after the infiltration process and especially of the infiltration time, a shut off point is required.

Therefore, the pressure drop across the preform is used as the shut off quantity and despite changing the process conditions it is kept at a constant shut off value. Its definition is:

$$\Delta p_{\text{shut off}} = (p0_{t=\text{end}} - p0_{t=0}) \qquad (10)$$

For the bulk density estimation, the average of the four bars, cut from the middle section of the composite disc were used, thus $n = 4$. The printed dots in the plots presented hereafter, are the arithmetic means of the relative densities of the four bars from one experiment and the error bars are indicative of the 95% confidence interval, assuming that the data is normally distributed.

Axial uniformity

It is clear that within the goal of achieving homogeneous composite density, the axial gradient of the SiC deposition within the preform plays an important role. The direct quantitative measurement of the uniformity in axial direction with the purpose of comparison of the samples, appeared however to be impossible for these thin samples.

Therefore, the simplest method was used, which is the estimation of the overall bulk density by eqn 9. Due to the fact that the (theoretical) density of the SiC matrix is larger than of the composite

material C/SiC, the relative bulk density of a composite with a thick SiC coating on the gas inlet side will be lower compared to one with a thin layer, assuming that the C/SiC composites without the thin layer have the same density. The relative bulk density is therefore not only a tool for measuring density but in a sense for homogeneity as well.

4.1 Effect of the total gas flow rate

Matrix composition at high flow rate

It was noticed that at high total gas flow rate, (i.e. >1·8 slm) the deposited SiC layer on the gas inlet side had a black appearance. The coatings produced at low gas flow rate had a shiny silvery appearance. The composition of the black deposit was measured using EPMA at an acceleration voltage of 6 kV. Although oxygen free, the Si/C ratio was in the order of 1·5, (i.e. 20 at.% free silicon). It is anticipated that the silicon forms more easily as compared with carbon at this high gas velocity.

Infiltration behaviour

From Fig. 3, it is evident that increase of the total gas flow rate results in a decrease of the infiltration time. As in CVD, it is anticipated that at low total gas flow rates, mass transport limitations— either convective or diffusive — are dominating growth. For clarification, if either convective or diffusive mass transport has been dominating matrix growth, the following concepts were audited.

During FCVI processing, the gas flows through the pores. The transport of the species is driven by convection. A boundary layer develops along the wall of the pores through which diffusive mass transport (low Peclet number) of the gas species occurs.

Consequently,[1] t_i is proportional to the reciprocal of the square root of $Ft^{\#}$. On the other hand, if convection in the remaining pore cavity — surrounded by the boundary layer — is faster than diffusion (large Peclet number), the infiltration time is proportional to exp $(c \times Ft^{\#-1})$.

Unfortunately, on this basis it is not possible to distinguish which of the two transport mechanisms has controlled matrix growth. Therefore, the magnitude of the Peclet number should indicate if either diffusive or convective mass transport has taken place in the regime of low total gas flow rate. Since the calculated Peclet numbers for the packed bed at the process conditions used — indicated in the figure caption of Fig. 3 — are relatively large, i.e. larger than 10^{-3} *viz.* $3{\cdot}8 \times 10^{-3}$, it is assumed that forced convection has been more dominant than diffusion. At large gas flow rates, the growth is limited by the kinetics of the deposition reaction at the fibre surface and becomes independent of flow rate.

The transition between the two growth regimes in Fig. 3, e.g. mass transport (at large Damköhler numbers and low flow rates) towards kinetically controlled growth (at small Damköhler numbers and large flow rates) was estimated by the intersection of the two slopes of the curves of the growth regimes. Surface reaction limitation starts at a rate of approximately 0·8 slm and at a corresponding calculated DaI_{bed} number of approximately 0·06–0·05.

It is anticipated that the infiltration time will decrease until a minimum is reached asymptotically when the growth is totally kinetically controlled, whereas at very low flow rate (close to 0) the infiltration time will reach infinity. Although the error of the measurements presented in Fig. 4 is relatively large, it may be stated that there is an increasing trend in density as a function of total gas flow rate. At zero gas flow rate, beyond the scope of the fire, the bulk density equals the raw relative bulk density of the starting preform (typically 36·5%).

Large total gas flow rates are thus advantageous in achieving large bulk densities. This is not

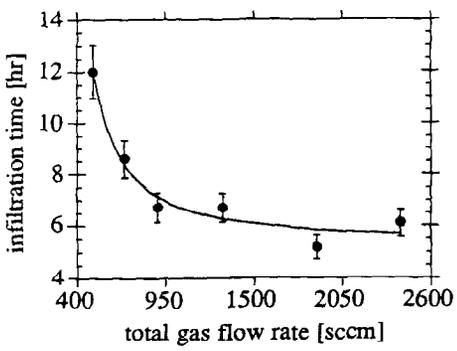

Fig. 3. The infiltration time versus total gas flow rate $Ft^{\#}$. T = 1273 K, H_2/MTS = 6·15, V_f = 51·2 vol%, $L = 2{\cdot}89 \times 10^{-3}$ m, p_L = 6·65 kPa, $\Delta p = 9{\cdot}44 \times 10^3$ Pa $Pe_{bed} = 3{\cdot}88 \times 10^{-3} - 2{\cdot}20 \times 10^{-2}$, $DaI_{bed} = 6{\cdot}81 \times 10^{-2} - 1{\cdot}74 \times 10^{-2}$.

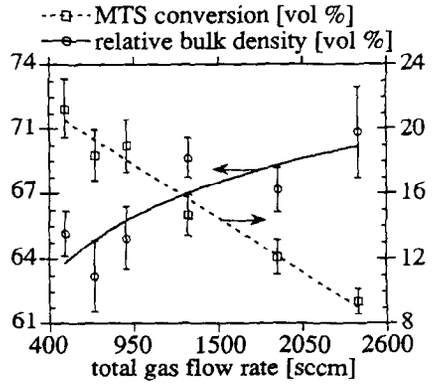

Fig. 4. The relative bulk density and MTS conversion versus total gas flow rate $Ft^{\#}$. T = 1273 K, H_2/MTS = 6·15, V_f = 51·2 vol%, L = 2·89 mm, p_L = 6·65 kPa, $Pe_{bed} = 3{\cdot}88 \times 10^{-3} - 2{\cdot}20 \times 10^{-2}$, $DaI_{bed} = 6{\cdot}81 \times 10^{-2} - 1{\cdot}74 \times 10^{2}$, $\Delta p = 9{\cdot}44 \times 10^3$ Pa.

surprising, considering the fact that through increase of flow rate, the gas velocity within the pores will increase and the uniformity of the matrix distribution will enlarge. At even larger flow rates, i.e. >0·8 slm (Fig. 3), the growth is limited by surface kinetics.

The enhancement of the matrix deposition uniformity is also demonstrated by the MTS conversion that decreases linearly with flow rate. Despite the fact that density is reaching a more or less constant value above 1·5 slm, the MTS conversion is still decreasing. This is explained as follows. During kinetically limited growth only a certain limited amount of molecules can be converted into solid matrix material. The numerator in eqn 8 ($M_{m,dep}$) will remain constant. Larger mass transfer fluxes will, however, increase the denominator $M_{m,max}$. The MTS conversion will decrease until the denominator reaches infinity.

At very large gas velocities, this phenomenon can reach an extreme. When the residence time t_r of the gas in the preform structure gets very short, the critical reaction time t_{cr} can become larger than the residence time of the gas. If so, the MTS has insufficient time to react. This explains the fact that in the centre part of the discs, infiltrated at flow rates exceeding 1·5 slm and/or at outlet pressures ≤1·33 kPa, poor deposition was achieved. The residence time of the gaseous species in the centre of the disc is based upon the Poiseuille gas velocity. On the axis of the preform $u_{bed,ax} = 2u_{bed}$. In general terms as $t_r < t_{cr}$ (s) deposition will be severely hindered and hence in the centre of the preform disc:

$$\frac{\epsilon L_{preform}}{2\,\tau\,uo} < \frac{1}{k_s \times av} \qquad (11)$$

where av is defined[1] as $4 \times d_f^{-1}$. Calculation of t_r and t_{cr} (with assumed tortuosity τ of 2) indicated that at mean gas bed velocities larger than 3 m.s^{-1} this phenomenon can occur.

During kinetically controlled growth, theoretically uniform deposition should occur. However, due to the pressure gradient across the preform, deposition will always be larger at the gas inlet side as compared to the outlet side. Therefore, complete homogeneity can never be reached using the IFCVI technique. Best uniformity can be gained at large flow rates when the process is just kinetically limited. At larger gas flow rates, beyond the scope of the plot, it is anticipated that density can decrease again if the MTS has insufficient time to react at the fibre surface, or due to the following phenomenon.

The pressure drop across the preform is a function of the square root of the total gas flow rate. Experiments performed at high total gas flow rate will consequently start at a high value of the inlet pressure. The corresponding SiC growth rate at the high pressure side will thus be much larger than the growth rate at the opposite side of the preform, i.e. $G_0 >> G_L$ ($t = 0$).

All experiments are finished at the same pressure drop value (eqn 10). Consequently the amount of uniformly deposited matrix will be larger when the flow rate is small ($G_0 \approx G_L$), resulting in a higher density. According to this consideration — that coincides with the model predictions of Part 1 of this study — the relative bulk density presented in Fig. 4 should reach a maximum at the point where growth is kinetically limited and the infiltration process begins at the condition that $p_0 \approx p_L$. These theoretical considerations could not experimentally be verified due to practical limitations. The p_0 over p_L ratio — as measured at the largest experimental flow rate — is 1·6 at the start of the infiltration process and is not sufficient to negatively affect the deposition uniformity.

4.2 Effect of the outlet pressure

In Fig. 5 the results are presented of the study on the effect of outlet pressure on the infiltration time. Increase of the outlet pressure results in decrease of the infiltration time in a non-linear way. It is known that the precursor concentration is a linear function of the total pressure. Increase in (outlet) pressure therefore results in a larger growth rate of the matrix.

The gas velocity is also affected by the total pressure. At low pressure, when the gas velocity is high, it is assumed that chemical kinetics control matrix growth. In the other regime at high total pressure, mass transport governs matrix growth and decrease in infiltration time is less severe.

On the other hand, when diffusive mass transport — across the boundary layer that is present along the pore wall — would control matrix growth, infiltration time would be independent of total pressure.

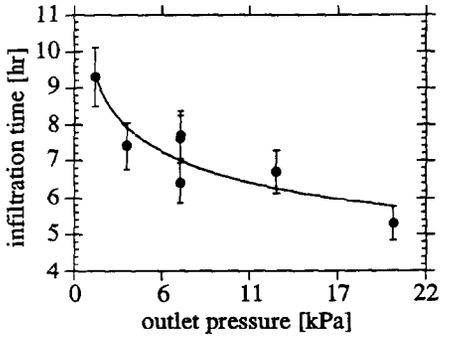

Fig. 5. The infiltration time versus total outlet pressure p_L. T = 1269 K, H_2/MTS = 4·97, V_f = 45·9 vol%, $L = 2{\cdot}96 \times 10^{-3}$ m, $Ft^{\#} = 1{\cdot}67 \times 10^{-5}$ m^3.s^{-1}, $Pe_{bed} = 5{\cdot}03 \times 10^{-3}$, $Dal_{bed} = 1{\cdot}17 \times 10^{-2} - 9{\cdot}50 \times 10^{-2}$, $\Delta p = 2{\cdot}66 \times 10^4$ Pa.

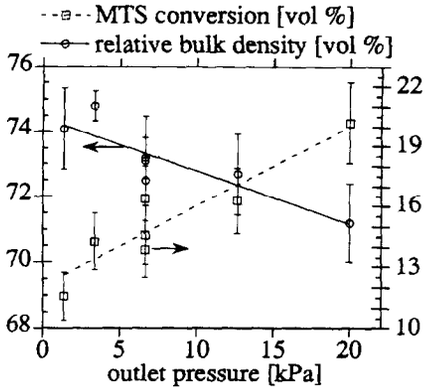

Fig. 6. The relative bulk density and MTS conversion versus total outlet pressure p_L. T = 1269 K, H_2/MTS = 4·97, V_f = 45·9 vol%, L = 2·96 × 10^{-3} m, $Ft^{\#}$ = 1·67 × 10^{-5} $m^3.s^{-1}$, Pe_{bed} = 5·03 × 10^{-3}, DaI_{bed} = 1·17 × 10^2 – 9·50 × 10^{-2}, Δp = 2·66 × 10^4 Pa.

Comparison of these theoretical concepts with the experimental results that are presented in Fig. 5, shows that convection has been the mass transport mechanism at the corresponding Peclet number of 5 × 10^{-3}.

In Fig. 6, the relative bulk density decreases with increasing outlet pressure. When the outlet pressure is increased — during convection controlled growth — the gas velocity through the pores will reduce and the uniformity of the matrix distribution is lowered. This results in a reduction of the relative bulk density and is also demonstrated by the increase in MTS conversion.

One may conclude that the experiments have predominantly been performed within the mass transport limited regime, since density and eventually MTS conversion would remain constant with pressure otherwise. From the effect of the total gas flow rate it is known that transition between the two growth regimes is in between a DaI_{bed} of 0·05 and 0·06. This implies that only the first three data points of the experiments in Fig. 6, have been performed at surface reaction limited conditions where the effect of outlet pressure on relative density is indeed negligible.

4.3 Effect of the preform temperature

Matrix composition

The composition of the SiC matrix of all preform discs on both gas inlet and outlet side were measured using EPMA. The coatings were oxygen and chlorine free, i.e. within the error of the detection limit. The SiC coating on the gas inlet side of all specimens had a shiny silvery appearance. The Si/C ratio varied slightly from 1·0 to 1·1 corresponding to a maximum free silicon content of 5 at.%. No effect of the SiC location (either gas inlet or outlet) was detected.

XRD measurements on both sides of the samples indicated that the coating was crystalline β-SiC and contained mainly cubic crystals. Traces of hexagonal SiC were observed at the gas inlet side of the preform.

Consequently, it is assumed that the density of the matrix material is independent of the deposition temperature and equal to the theoretical density of silicon carbide.

Infiltration behaviour

In Fig. 7 the infiltration time is presented as a function of preform temperature.

At high temperatures, matrix growth is fast. In accordance with theoretical considerations, the infiltration time reduces with increasing temperature due to the Arrhenius behaviour of the deposition reaction. Since the first Damköhler number is smaller than 0·054 within the whole range of experiments, it is anticipated that kinetics have been controlling the formation of SiC.

In Fig. 8 relative composite density is independent of temperature and possibly even positively affected by an increase of temperature. On the other hand, the MTS conversion is a linear increasing function of temperature.

The independence of the relative bulk density on temperature can be explained if chemical kinetics are governing matrix growth. This statement is

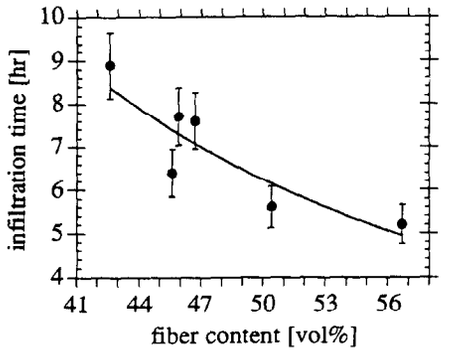

Fig. 7. The infiltration time versus preform temperature T. H_2/MTS = 4·98, V_f = 44·8 vol%, $Ft^{\#}$ = 1·67 × 10^{-5} $m^3.s^{-1}$, L = 3·06 × 10^{-3} m, p_L = 1·33 kPa, Pe_{bed} = 1·32 × 10^{-2}, Δp = 2·65 × 10^4 Pa, DaI_{bed} = 3·49 × 10^{-3} – 5·41 × 10^{-2}.

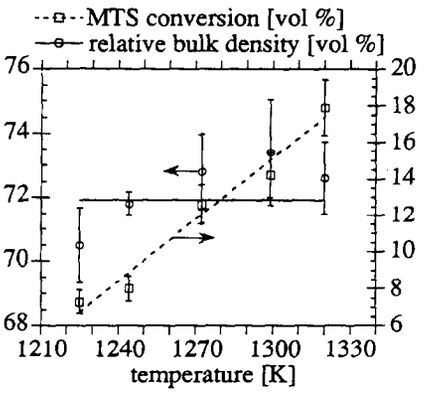

Fig. 8. The relative bulk density and MTS conversion versus preform temperature T. H_2/MTS = 4·98, V_f = 44·8 vol %, $Ft^{\#}$ = 1·67 × 10^{-5} $m^3.s^{-1}$, L = 3·06 × 10^{-3} m, p_L = 1·33 kPa, Pe_{bed} = 1·32 × 10^{-2}, Δp = 2·65 × 10^4 Pa, DaI_{bed} = 3·49 × 10^{-3} – 5·41 × 10^{-2}.

in accordance with the value of $DaI_{bed} < 0{\cdot}05$–$0{\cdot}06$. In general terms, at low temperature, SiC growth is kinetically controlled.

The relative bulk density will remain unaffected as long as the initial pressure gradient ($t = 0$) is not too large, (i.e. $G_0 \approx G_L$).

Depletion effect can be excluded and deposition is uniform. Hereafter, at higher temperatures, density will decrease because mass transport limitations dominate matrix growth and depletion of the MTS — that flows in axial direction through the pores — is rising and the resulting deposition profile is less uniform. At very high temperatures, when the MTS is almost completely depleted from the bulk gas stream, no SiC is deposited deeper into the preform. What remains is an only partially infiltrated preform.

4.4 Effect of the MTS fraction in the gas mixture

Experimental examination of the dependence of the infiltration time as a function of MTS fraction — shown in Fig. 9 — is in accordance with theoretical predictions (see Part 1 of this study). The concentration of the precursor is a linear function of its mole fraction in the gas mixture. The infiltration time is thus proportional with X_{MTS}^{-1}. The input fraction of the MTS has no effect on the resulting relative bulk density.

Theoretical concepts indicate that neither in the mass transport controlled regime nor during kinetically controlled growth is an effect of the MTS fraction on the composite density expected. In Fig. 10 this theory is experimentally verified for the kinetically controlled growth regime since DaI_{bed} is smaller than 0·05 for all experiments. This independence of MTS content in the gas mixture on the composite density is also confirmed by the fact that the first Damköhler number is independent of precursor concentration as long as first order reactions apply.

Depletion of the precursor is independent of absolute concentration and hence the relative density

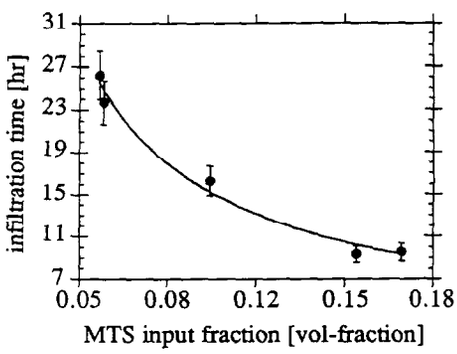

Fig. 9. The infiltration time versus input MTS fraction in the gas mixture x_{MTS}. $T = 1269$ K, $V_f = 44{\cdot}8$ vol%, $L = 3{\cdot}03 \times 10^{-3}$ m, $Ft^{\#} = 1{\cdot}67 \times 10^{-5}$ m^3 s^{-1}, $p_L = 1{\cdot}33$ kPa, $Pe_{bed} = 1{\cdot}33 \times 10^{-2} - 3{\cdot}57 \times 10^{-3}$, $DaI_{bed} = 1{\cdot}22 \times 10^{-2}$, $\Delta p = 2{\cdot}66 \times 10^4$ Pa.

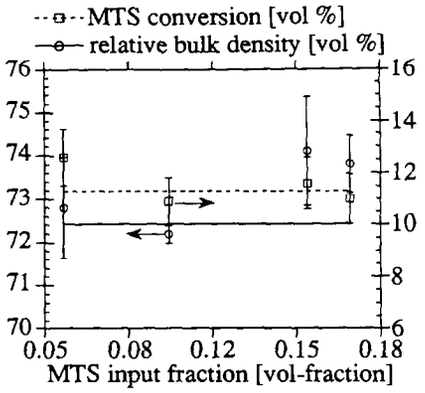

Fig. 10. The relative bulk density and MTS conversion versus input MTS fraction in the gasmixture x_{MTS}. $T = 1269$ K, $V_f = 44{\cdot}8$ vol%, $L = 3{\cdot}03 \times 10^{-3}$ m, $Ft^{\#} = 1{\cdot}67 \times 10^{-5}$ m^3.s^{-1}, $p_L = 1{\cdot}33$ kPa, $Pe_{bed} = 1{\cdot}33 \times 10^{-2} - 3{\cdot}57 \times 10^{-3}$, $DaI_{bed} = 1{\cdot}22 \times 10^{-2}$, $\Delta p = 2{\cdot}66 \times 10^4$ Pa.

is constant. Clearly, the MTS content should be sufficiently high to overcome almost complete conversion of the MTS before the gas has arrived at the other end of the preform.

4.5 Effect of the fibre content and preform thickness

Increase of the fibre content in the preform volume is achieved by exerting higher pressure on the preform during its prefixing stage, resulting in not only larger fibre content per volume (V_f), and tortuosity (τ), but also in lower thickness (L) and smaller average pore size (d_p). These quantities are measured and presented in Table 2 as a function of fibre content. It appears that even the surface area available for deposition (A_{dep}) is increased.

Due to these microstructural changes, the gas permeability of the porous structure K_g will also differ between the samples.

Permeability of the raw preform: experimentally and analytically

The gas permeability K_g (m^2) was measured as a function of raw preform fibre content, outlet pressure and argon flow rate at 1273 K. The details of the raw preforms used for the permeability test are given in Table 2.

The results can be fitted according to Darcy's law (eqn 5) for incompressible fluids, since for a constant outlet pressure, $uo\mu L$ follows a linear relationship with Δp and the slope represents K_g.

However, the data obtained at different outlet

Table 2. Raw preform characteristics for the permeability test at 1273 K under argon flow.

Exp no.	V_f (vol %)	Thickness (m)	A_{dep} (m^2)
52	42·6	$3{\cdot}17 \times 10^{-3}$	6·54
50	45·6	$2{\cdot}95 \times 10^{-3}$	6·66
53	49·4	$2{\cdot}74 \times 10^{-3}$	6·68
51	56·7	$2{\cdot}53 \times 10^{-3}$	6·94

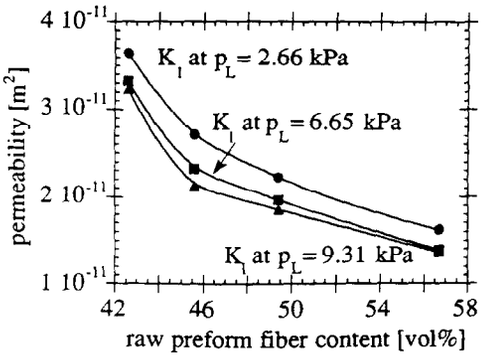

Fig. 11. The permeability K_l versus raw preform fibre content V_f and outlet pressure p_L at 1273 and argon flow.

pressures resulted in different slopes, so that K_g is a function of average pressure. Best fit was achieved with the permeability expression for compressible gas flow with slip.[1] It was found that the experimental data could not be fitted within the whole range of process variables and no complete elucidation of the proper permeability equation was gained. Deviations were noticed at the lowest outlet pressure of 6.65 kPa and are probably due to inertial effects.[7]

From Table 2 and Fig. 11 it can be concluded that permeability decreases with increasing fibre content, due to the less open structure.

Also, it was found that permeability at the low absolute total pressure conditions used, increases linearly with decreasing outlet pressure or increasing pressure drop.

A constraint for proper infiltration is the fact that sufficiently high permeabilities are required to overcome excessive inlet pressures (or Δp) so that infiltration can proceed sufficiently long to be able to grow matrix into the structure. More generally stated, $LA^{-1}K^{-1}$ should be small (eqn 5) with A representing the cross flow area (m^2).

Infiltration behaviour

As illustrated in Fig. 12, when the fibre content of the raw preform is increased, the infiltration time

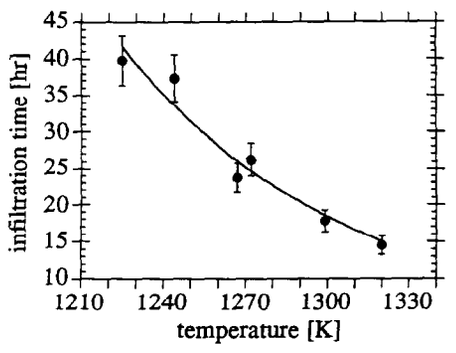

Fig. 12. The infiltration time versus raw preform fibre content. T = 1271 K, H_2/MTS = 5·02, V_f = 42·6–56·7 vol%, $Ft^{\#}$ = 1·67 × 10^{-5} $m^3.s^{-1}$, L = 3·17 × 10^{-3}–2·96 × 10^{-3} m, Pe_{bed} = 5·05 × 10^{-3}, DaI_{bed} = 3·97 × 10^{-2}–3·32 × 10^{-2}, A_{dep} = 6·54–6·94 m^2, Δp = 2·65 × 10^4 Pa.

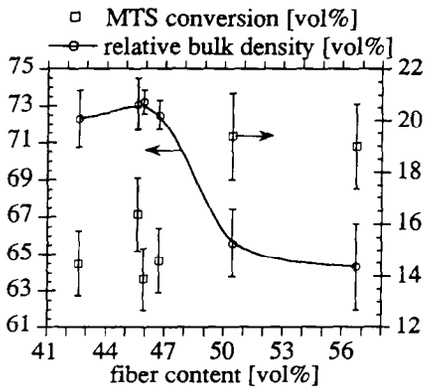

Fig. 13. The relative bulk density and MTS conversion versus raw preform fibre content. T = 1271 K, H_2/MTS = 5·02, V_f = 42·6–56·7 vol%, $Ft^{\#}$ = 1·67 × 10^{-5} $m^3.s^{-1}$, L = 3·17 × 10^{-3}–2·96 × 10^{-3} m, Pe_{bed} = 5·05 × 10^{-3}, DaI_{bed} = 3·97 × 10^{-2}–3·32 × 10^{-2}, A_{dep} = 6·54–6·94 m^2, Δp = 2·65 × 10^4 Pa.

is reduced. Yet, the variation of the raw preform fibre content is a combined effect of more than only one variable. Pore size is reduced, whereas the surface area and tortuosity of the structure is increased (Table 2). So, the filling of the pores is relatively fast at large fibre content. This effect is mainly due to the small pore diameter of the preform of high fibre content.

The relative bulk density of the composite is a decreasing function of the fibre content and is presented in Fig. 13. Apparently, the deposition uniformity is enhanced when V_f is decreased. This effect cannot be explained in terms of decreasing τ or A_{dep} or increasing L, but only in increasing pore diameter d_p.

The pore gas velocity that controls the uniformity of the matrix distribution along the pore axis is a positive function of the pore diameter (eqn 13, Part 1 of this study). And since the mean pore diameter is a decreasing function of the fibre content, the density will thus decrease with increasing V_f.

For achieving the same composite density, a preform with low fibre content and high permeability should be infiltrated up to a lower pressure shut off point as compared with a preform of high fibre content and low permeability. An optimum in density gain, i.e. the largest density in the shortest time is reached at a fibre content of 46 vol.%.

4.6 Apparent reaction rate equation

Introduction

Premature homogeneous decomposition[8] of MTS in the gas phase in front of the preform can rule the kinetic equation. Therefore, the amount of decomposed MTS in the gas phase prior to and in the preform was calculated and appeared to be smaller than 10% for all experiments.[1] It is

therefore assumed that the kinetic equation derived in the following, is caused by the direct reaction of MTS to SiC without prior decomposition.

Experimental results

The overall apparent reaction rate equation within the porous structure that relates the infiltration time with the process conditions within the regime of kinetically controlled growth was quantified. The results of the effect of temperature (Section 4.3) and MTS fraction in the gas mixture (Section 4.4) were used for the estimation of the overall apparent reaction rate equation. First, the activation energy (E_a) of the surface reaction was derived from plotting the logarithm of the matrix growth rate versus the reciprocal temperature in Fig. 14(a).

The matrix growth G_{SiC} (mol.m^{-2} s^{-1}) is calculated according to:

$$G_{SiC} = \frac{M_{m,dep}}{m_{SiC} A_{dep} t_i} \tag{12}$$

where $M_{m,dep}$ (kg) is the weight increase of the preform due to SiC deposition, m_{SiC} is the molar mass of SiC (kg.mole^{-1}), A_{dep} (m^2) is the deposition area (eqn 4) and t_i (s) is the infiltration time. The slope of the plot Fig. 14(a) represents $-E_a/R_g$, from which an apparent activation energy of 135 kJ.mol^{-1} was calculated. The experiments where the MTS input fraction was varied, were used for the estimation of the partial reaction order and pre-exponential factor. In Fig. 14(b) it is demonstrated that the SiC matrix growth follows a first order dependence in MTS.

The slope of the plot equals the partial reaction order, whereas the intercept represents $\ln(k_s)$. From k_s (m.s^{-1}) and the activation energy, k_0 is calculated to equal 16·45 m.s^{-1}.

This results in the overall apparent reaction equation for the silicon carbide growth rate G_{SiC} (mol.m^{-2}.s^{-1}) within a porous structure using MTS in an excess of H_2 and Ar:

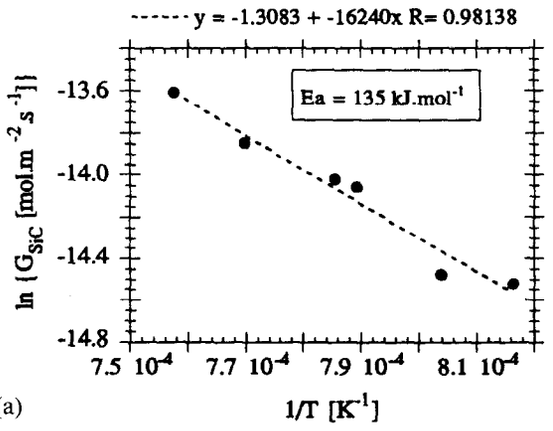

Fig. 14(a). The logarithmic SiC growth rate versus the reciprocal preform temperature; H_2/MTS = 5.

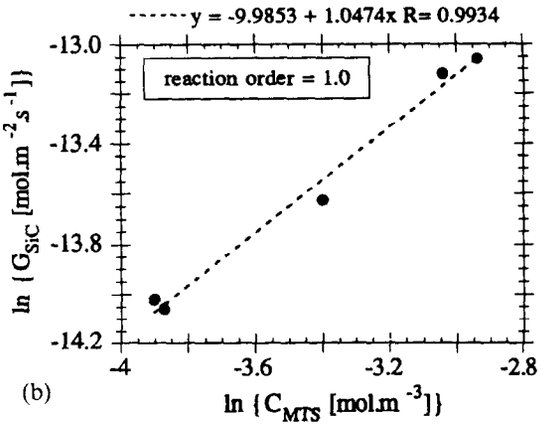

Fig. 14(b). The logarithmic SiC growth rate versus the logarithmic MTS concentration at input.

$$G_{SiC} = 16{\cdot}45 \exp\left(\frac{-135 \times 10^3}{T\ Rg}\right) C_{MTS}^{1{\cdot}0} \tag{13}$$

Because the experiments were performed at $DaI_{bed} < 0{\cdot}054$, it is assumed that surface kinetics have been dominating growth.

4.7 Effect of the shut off pressure drop on the infiltration time and composite density

The effect of the pressure difference across the preform (shut off point) on the infiltration time and the composite density was studied. The results are presented graphically in Figs 15 and 16.

After termination of the experiments, the permeability of the composite at the end of the process was calculated using eqn 5 at the pressure drop shut off point, temperature and gas composition used.

Initially, during the first 4 h of infiltration, the pressure drop across the preform hardly rises *viz.* from 0·13 to 1·2 kPa. After approximately 7 h, the injector pressure (and pressure drop) start rising rapidly, because the pores in the preform reach a critical size. Within approximately an hour the injector pressure rises from 5 to 55 kPa.

In this time lapse hardly any additional matrix is deposited within the small pores (Fig. 16). Here, not

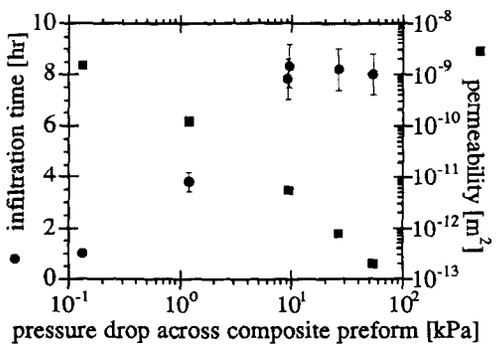

Fig. 15. The infiltration time and composites permeability versus shut off pressure difference. T = 1255 K, H_2/MTS = 6·00, V_f = 47·4 vol%, $Ft^{\#}$ = 2·49 × 10^{-5} m^3.s^{-1}, L = 2·90 × 10^{-3} m, p_L = 1·33 × 10^3 Pa, Pe_{bed} = 5·05 × 10^{-3}, DaI_{bed} = 3·97 × 10^{-2}–3·32 × 10^{-2}, A_{dep} = 6·54 m^2.

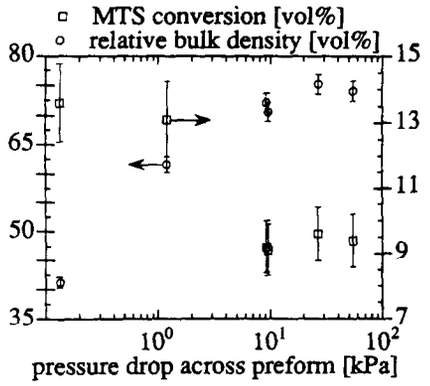

Fig. 16. The relative bulk density and MTS conversion versus pressure difference and infiltration time. T = 1255 K, H_2/MTS = 6·00, V_f = 47·4 vol%, $Ft^{\#}$ = 2·49 × 10^{-5} $m^3.s^{-1}$, L = 2·90 × 10^{-3} m, pL = 1·33 × 10^3 Pa, Pe_{bed} = 5·05 × 10^{-3}, DaI_{bed} = 3·97 × 10^{-2}–3·32 × 10^{-2}, A_{dep} = 6·54 m^2.

only density, but the uniformity expressed in terms of MTS conversion is also constant. It appears that a pressure drop of about 10 kPa is sufficient to reach maximum density at the selected infiltration conditions. Further densification will only yield a thicker coating on the gas inlet side of the sample.

The permeability of the composite is a decreasing function of the pressure drop. Even when composite density is not further enlarged, permeability still decreases. This drop in conductance for the gas flow will, however, be attributed to the deposited coating on the gas inlet side and narrowing of the pore mouth of the sample instead of the whole preform structure. At the point of just reaching maximum density, the permeability of the preform structure is decreased at least two orders of magnitude.

General remarks

The FCVI process can be represented as a two stage process in which both the small pores in a fibre bundle and the bigger pores inbetween the bundles have to be infiltrated. Convection is present in the big pores between the bundles (FCVI), whereas mass transport of the gaseous species into the bundles will be dominated by diffusion since there is no Δp from outer to inner volume of the bundle (this is in fact ICVI).

During the first hours of infiltration, the matrix deposits onto the available surface area and density increases rapidly (Fig. 16). Each filament is coated with a layer of SiC. As soon as a fibre bundle has grown together, the available surface area is greatly reduced and the larger pores between the bundles will become smaller. As a result, density gain is less rapid. During this time lap, a pressure increase is observed. As soon as the resistance for the gas flow is getting too big, the injector pressure increases very rapidly and the experiment is shut off.

5 General Discussion and Conclusions

The results presented above are consistent with the general concepts that are described in Part 1 of this study. For homogeneous densification, matrix growth within the kinetically limited growth regime is preferred. For rapid infiltration, forced convection should control matrix growth.[9]

Comparison with the FCVI model

The infiltration characteristics as a function of process variables were investigated and appear to qualitatively coincide with the FCVI model predictions of Part 1 of this study. Therefore, infiltration trends may be predicted using a 1D cylinder pore approach.

The transition point (x-value) of kinetically controlled towards convective controlled growth conditions of the model and of the experiments coincide (compare Fig. 5 Part 1 with Figs 3 and 4 Part 2, Fig. 7 Part 1 with Figs 5 and 6 Part 2, and Fig. 8 Part 1 with Figs 7 and 8 Part 2).

However, the effect of the preform temperature on the infiltration time as experimentally observed — in the kinetically limited growth conditions — is less pronounced than simulated with the model (Fig. 8 Part 1). The trend that the composite density is unaffected by temperature increase in the kinetically limited growth conditions is in agreement with model predictions. Increase of the total gas flow rate or decrease in outlet pressure — in the mass transport limited growth regime—yields an increase of the gas velocity and hence uniformity of the deposited SiC layer within the pores. The model (Figs 5 and 7 Part 1) and experimental observations are in agreement.

The MTS content in the gas mixture has no effect on the resulting composite density for both model and experiments. The increase of injector pressure with time as experimentally observed and calculated with the model (Fig. 3 Part 1) are in good agreement. Also, when infiltration proceeds densification is rapid initially, but levels off later on.

According to the model, high raw preform porosity yields low composite density. As such, experimental observations indicate the opposite. However, decrease of the raw preform porosity without affecting other microstructural parameters such as tortuosity, pore diameter, preform thickness and deposition area cannot be achieved. In terms of pore diameter, model (Fig. 6 Part 1) and experimental results do coincide.

Experimental observations

It appeared that a Peclet number (for a packed bed) larger than 4 × 10^{-3} corresponds with convective mass transport. $Pe_{bed} < 4 \times 10^{-3}$ and DaI_{bed}

$<5 \times 10^{-2}$ coincide with kinetically limited SiC growth conditions. The apparent overall reaction rate of the heterogeneous controlled conversion of MTS to SiC follows a first order dependence in MTS with an apparent activation energy of 135 kJ.mole^{-1}. The pre-exponential factor equals 16·45 m.s^{-1}.

In principle, for this first order reaction, low first Damköhler numbers and MTS conversion are in agreement with large IFCVI composite density. The highest composite density gained in this study was 75% of the ideal density at a MTS conversion smaller than 15%. Since the determination of the relative bulk density of the composite samples is subjected to many errors and its measurement is even impossible for complete geometries, the simple total MTS conversion appears to be a powerful tool in the estimation of the optimum process conditions.

It should be noted that the transition values of the Peclet and first Damköhler number itself should be treated with care. Their order of magnitude or moreover its transition value is very much dependent on the definition used, especially its characteristic length. The optimum pressure shut off point is dependent on the permeability of the raw preform. A poorly permeable preform structure requires a larger pressure drop to reach the same density as compared to a preform of large permeability. A constraint of the FCVI technique is that only preforms with high permeability without closed porosity are suitable to gain large composite density and strength. More generally stated, $LA^{-1}\ K^{-1}$ should be small.

Optimum infiltration, i.e. the largest density gain for a 80 mm diameter, 3 mm thick preform in the shortest time, occurs with a preform of 46 vol.% fibre, a temperature of 1320 K, outlet pressure of 6·65 kPa, total gas flow rate of 4×10^{-5} m^3.s^{-1}, MTS fraction of 16 vol.% and a pressure drop shut off point of 10 kPa. Clearly, these specific conditions are only applicable for preforms of exactly the same microstructure as the one studied and a first order heterogeneous decomposition reaction at the pore walls.

In general, high composite density is reached at IFCVI conditions of kinetically controlled matrix growth and hence implies: high total gas flow rate, low preform temperature, low outlet pressure, arbitrary precursor fraction in the gas mixture, high pressure shut off difference, low raw preform fibre content and high raw preform gas permeability. A negative effect of the initial pressure drop ($t = 0$) on the composite density was not observed at least as long as $p_0/p_L < 1{\cdot}6$. On the other hand, rapid IFCVI is achieved at mass transport limited matrix growth conditions and generally at: high total gas flow rate, high preform temperature, high outlet pressure, high precursor fraction in the gas mixture, low pressure shut off difference, high raw preform fibre content and low raw preform gas permeability.

Unfortunately, these two criteria — with the exception of the total gas flow rate and MTS fraction in the gas — obviously are contradictory. It should be noted that again a too large gas velocity — typically $u_{bed} > 3$ m.s^{-1} — can lead to poor infiltration, because the residence time of the MTS precursor in the preform is insufficient to cause a deposition reaction at its fibre surface.

Influence of the Debinding Method on the Mechanical Properties of Plastic Formed Ceramics

Thierry Chartier, Marc Ferrato & Jean-François Baumard

LMCTS, URA 320, ENSCI, 47 Av. Albert Thomas, 87065 Limoges, France

(Received 7 June 1994; revised version received 23 February 1995; accepted 10 March 1995)

Abstract

A new method of extraction of organic additives, by a supercritical fluid, is presented. Flexural strengths and Weibull moduli of extrusion molded alumina, debinded by classical pyrolysis and by supercritical CO_2 extraction are compared. Better mechanical properties are obtained after a short time (3 h) of supercritical treatment (σ = 277 MPa, m = 13·7) than after 18 h of pyrolysis (σ = 253 MPa, m = 12·4). The binder extraction from green pieces by supercritical fluids is limited by two factors, solubility and diffusivity of organic compounds. The major factors causing defects in the pyrolytic binder removal, such as binder redistribution in the liquid phase and the outward diffusion of degradation products, do not take place in the supercritical debinding method.

1 Introduction

Ceramic components are made by applying ceramic processing techniques to ceramic materials. One of the main difficulties that structural engineering ceramics have to overcome to find industrial applications lies on the fabrication of shapes from powders. The forming of green pieces is critical, because it affects both final properties of materials, for example because it introduces cracks, and the characteristics of components, for example because it alters the size accuracy of the shapes.

Most high technology ceramic processings require the use of transitory, organic compounds, which are eliminated by subsequent treatments before sintering. A compromise must be found between the ease of shape forming and the necessity of removing the binders. Therefore, the optimization of ceramic processing techniques must take not only the forming method, but also the removal of the organic additives into account.

Plastic forming methods as injection and extrusion-molding are attractive for producing complex shapes of high dimensional accuracy and high uniformity at a rather low cost. These techniques require the use of a large amount of organic compounds in order to confer properties as cohesion, flexibility and workability in the green state.[1] Amounts as large as 50 vol.% of organic are sometimes added to the ceramic powder. A major drawback of these processing methods remains the removal of these organics.

Although thermal decomposition is the method currently used, studies of pyrolytic removal of organic additives in a green ceramic body, are very recent.[2–8] In the last few years, an effort was made to understand the many physico-chemical processes that occur during binder removal. Binder removal by thermal treatment involves: (i) chemical mechanisms with the thermal degradation of organic compounds into volatile species and, (ii) physical mechanisms as the diffusion of these species to the surface as well as the changes in the binder distribution within the green body. Changes in the binder distribution, governed by diffusion and capillary migration, and the magnitude of the mass- and heat-transfer limitations are critical parameters for the design of the efficient heating cycle to prevent stresses and the formation of defects in ceramic parts.[6]

Thermal debinding remains one of the most critical steps of ceramic processing, especially in the case of large size parts for three main reasons: (i) defects are generated which affect properties of the sintered pieces, (ii) it is very time-consuming, the binder removal time being directly proportional to square of the section thickness[2] and (iii) residues of pyrolytic degradation can be detrimental during the subsequent sintering stage.

Alternative techniques are needed to produce defect-free green bodies and to reduce debinding time. In this respect, approaches including chemical degradation, evaporation or sublimation, solvent extraction and capillary action can be beneficial. In the present work, we have used an original

method of extraction of organic compounds based on the unique dissolving characteristics and transport properties of fluids at temperatures and pressures beyond the critical point, i.e. supercritical fluids. While the densities of liquids and supercritical fluids are more or less similar, the diffusion coefficients are expected to be much larger in the later media. The binder extraction by the supercritical fluid is controlled by the solubility and the diffusivity of the polymeric compounds. The largest solubility of a binder in the supercritical fluid can be estimated using solubility parameters and the diffusivity of dissolved organic species in green samples has been modelled.[9]

The purpose of this paper is to compare mechanical properties (flexural strength and Weibull modulus) of extrusion-molded ceramics debinded by classic pyrolysis and by supercritical extraction of organics.

2 Experimental

2.1 Preparation of green samples

Samples with a square section (4 × 4 mm^2) were prepared by extrusion-molding of a mixture containing 86 wt.% alumina, 2 wt.% polystyrene and 12 wt.% paraffin oil (Prolabo, France). The alumina (P172SB, Péchiney, France) was 99·7 wt% purity, 0·6 μm mean particle size and 10 $m^2.g^{-1}$ specific surface area. The molecular weight of the polystyrene (Lacqrene 4801, Elf Atochem, France) was 150000. The green density was 56% of theoretical density.

2.2 Removal of organic compounds

Two routes were used to remove organic compounds: pyrolysis and treatment with a supercritical fluid.

The pyrolysis was carried out with four heating rates up to 550°C; 0·5, 1, 2 and 4·5°C.mn^{-1} without dwell.

Extraction of binders was performed by using carbon dioxide in a supercritical state. Carbon dioxide, which is extensively used in the food or perfume industry, has shown promising possibilities for the extraction of light organic compounds in ceramic forming processes.[10] The main advantages of carbon dioxide lie in a low cost, low critical temperature and pressure (Tc = 31°C, Pc = 7·37 MPa) as well as in absence of toxicity and flammability.

The schematics of the equipment used during the present work are shown in Fig. 1. Green samples to be debinded (7) are introduced in a cylindrical basket (8) fitted with sintered metallic parts at both ends. This basket, located into the extractor (6), acts as a sample holder for the polymer-containing materials, and remains quite permeable to the fluids. Carbon dioxide, taken from a storage tank (1), is cooled down to –10°C by means of a heat exchanger (3). The resultant liquid carbon dioxide is pressurized up to the working pressure, by means of the pump (4). Then, the pressurized liquid is heated up to the working temperature (15–120°C) with a second heat exchanger (5), leading to supercritical carbon dioxide. The carbon dioxide, in the supercritical state, is flowing through the extractor, dissolving binders from the green sample. The dissolved binders are recovered in a collector cylinder (10). The process temperature of the extractor (6) and the temperatures of the two heat exchangers (3 and 5) are regulated by thermostated baths.

2.3 Sintering

The two series of samples, e.g. those submitted to supercritical treatment, thus still containing a low amount of non-soluble binder, and those debinded by pyrolysis, were sintered in an electric furnace with $MoSi_2$ heating elements, with the same heating cycle, i.e. 5°C.mn^{-1} up to 1600°C with a dwell time of 3 h.

2.4 Characterization

The density of sintered samples was measured by the Archimedes method in distilled water.

The room temperature strength was measured by the classical four-point bend test (outer span: 40 mm, inner: 20 mm) at a cross head speed of 0·5 mm.min^{-1}. The tensile face was polished and the edges were bevelled.

The fracture of a homogeneous brittle material depends on the stress necessary to propagate an existing critical flaw or crack present in it. Variable sizes and shapes of flaws in ceramic materials are responsible of the scatter of failure strengths observed when 'identical' specimens are tested under identical loading conditions. The Weibull statistics[11,12] were commonly used in the analysis of strength of brittle materials. This method, based on the 'weakest link of a chain', assumes that the most critical flaw under a given stress distribution leads to failure.

The major defects included in injected molded ceramics, in particular in the case of thick parts with submicrometer particle sizes, can be associated with removal of organic compounds[13,14] The Weibull statistics were used to provide a means of comparison of strength distribution, and then of flaw size distribution, between the two series of samples.

The strength data (N = 20 samples) was analysed using the usual two-parameter empirical formula relating the probability of failure, P_f, to the stress, σ_f:

$$P_f = 1 - \exp\left[-\left(\frac{\sigma_f}{\sigma_0}\right)^m\right] \quad (1)$$

where m is the Weibull modulus and σ_0 a normalizing factor. Flexural strengths were ranked in order and assigned a probability of failure according to the formula:

$$P_f = (i\text{–}0{\cdot}5)/N \quad (2)$$

where i is the i^{th} specimen. The Weibull modulus is the slope of a plot of LnLn $(1/P_f)$ versus Ln σ_f.

3 Results and Discussion

The supercritical treatment of the green pieces was carried out at 88°C under 28 MPa for 3 h. Under these conditions, supercritical CO_2 is a relatively good solvent for paraffin oil, but the high molecular weight polystyrene was not dissolved. The molecular weight distribution of the paraffin used is large, and only 67% of the paraffin introduced, probably corresponding to the lighter backbone, was dissolved. It is noteworthy that a small amount of undissolved polystyrene presents the advantage of maintaining a cohesion of ceramic green bodies, and that it does not seem to affect properties of sintered parts.

Extruded samples pyrolyzed with a heating rate higher than 1°C.mn^{-1} exhibit macro-defects as blistering, bloating and cracking (Fig. 2). Hence, the strength analysis was performed on samples pyrolyzed at rates of 0·5 and 1°C.mn^{-1}.

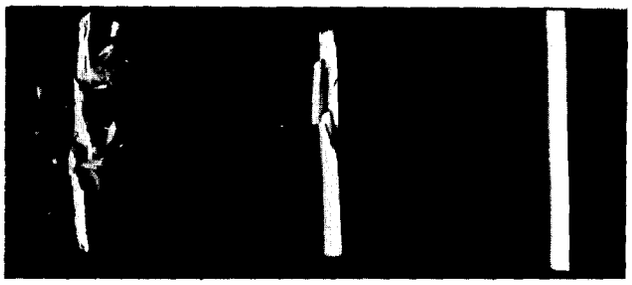

Fig. 2. Samples (4 × 4 mm^2) after removal of the organic compounds by heating at a rate of (a) 4·5°C.min^{-1}, (b) 2°C.min^{-1} and (c) 1°C.min^{-1}.

Weibull diagrams of sintered samples previously debinded by pyrolysis and by supercritical treatment are given in Fig. 3. The relative density of the sintered samples was 97%. Taking into account that testing bars were polished, it can be assumed that critical defects are volumic ones. Samples submitted to thermal and supercritical treatments were prepared using the same forming technique. Hence, differences in strength-controlling defects can be associated with the removal of organic compounds and not with the forming method. The mean failure strengths, in the four-point bend test, were 219, 253 and 277 MPa for samples pyrolysed at rates of 1 and 0·5°C.mn^{-1}, and for samples submitted to supercritical treatment, respectively. The Weibull modulus was low, i.e. 5·4, for samples thermally debinded at a rate of 1°C.mn^{-1}, whereas samples thermally debinded at a rate of 0·5°C.mn^{-1} and those supercritically treated exhibited a larger and similar value of the Weibull modulus, i.e. 12·4 and 13·7, respectively.

A first comment concerns the higher strength of samples debinded by supercritical treatment. This

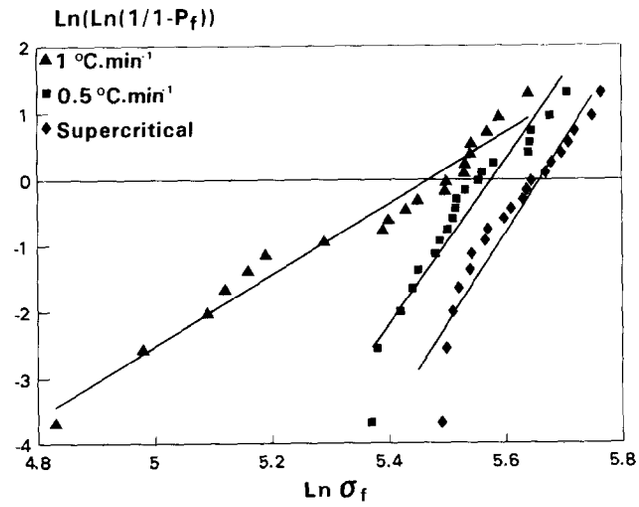

Fig. 3. Weibull diagrams of sintered samples previously debinded by pyrolysis with heating rates of 0·5°C.mn^{-1} (σ = 253 MPa, m = 12·4) and 1°C.mn^{-1} (σ = 219 MPa, m = 5·4), and by supercritical treatment (σ = 277 MPa, m = 13·7).

suggests that this method of binder removal leads to a more homogeneous green state before firing, with smaller critical defects than after classical thermal debinding.

A second comment concerns the higher Weibull modulus of samples debinded with a very slow heating rate and for samples debinded by supercritical treatment. The scatter of failure strengths, hence the scatter of defect sizes and/or shapes, was lower for samples debinded by a supercritical fluid.

As far as the treatment duration is concerned, better mechanical properties were achieved after 3 h of supercritical treatment than after about 18 h of thermal treatment on similar extruded samples. The time parameter then becomes critical for large ceramic parts.

Mutsuddy[15] reported a three-point flexural strength of 260 MPa and Fanelli *et al.*[16] a four-point flexural strength of 309 MPa for injection molded alumina (A16SG, AlCoA, Pittsburgh, PA) after thermal debinding and sintering. This alumina has similar characteristics to the one used in this study. Three-point bend tests generally lead to higher values of flexural strength than four-point bend tests, due to the Weibull effect. Concerning the Weibull modulus, G. D. Quinn[17] reported values ranging between 7 and 13 for nearly fully densified alumina. The values of four-point flexural strength (277 MPa) and of Weibull modulus (13.4), obtained after 3 h of supercritical debinding, are slightly higher than those generally quoted in the literature.

Pyrolytic binder removal is controlled by two main phenomena,[2,18] namely capillary migration in the liquid phase and diffusion in the gas phase. These two mechanisms lead to a redistribution of the binder in the green body, which determines the path length over which molten binder or volatile species must migrate or diffuse.[8,19] Due to capillary forces, molten binder, in the early stage of removal, segregates to the smallest pores of the green body, leading to the apparition of stress gradients. The magnitude of capillary forces depends on the surface tension and of the viscosity of the organic liquid. At higher temperature, cracking occurs if the generation of volatile species produced by thermal decomposition of organics is in excess of the amount removed by outward diffusion and evaporation at the surface.[20] The major factor causing defects was attributed to the diffusion of degradation products in solution in the binder.[3,4] Then, the formation of defects is dependent on balancing the rates of diffusion and degradation/evaporation. The thermogravimetric analysis of extruded samples (Fig. 4) shows that about 10 wt% of organics are removed over a very narrow temperature range during pyrolysis, making kinetics control

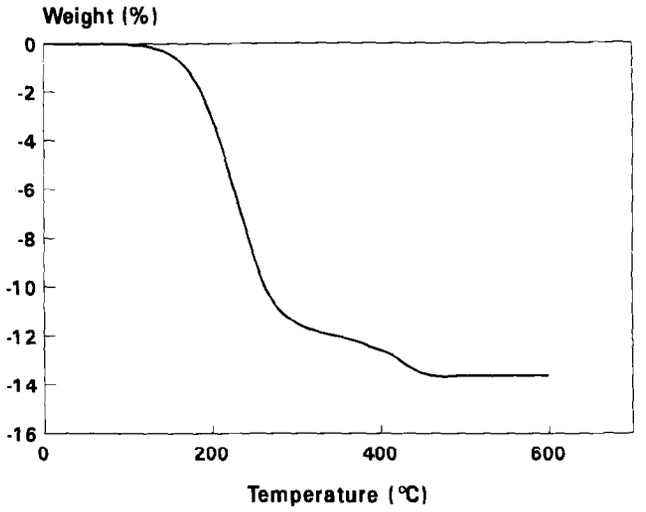

Fig. 4. Thermal gravimetric analysis for alumina–polystyrene–paraffin extruded samples (in air with a heating rate of 5°C.min^{-1}). The total amount of organic compounds is 14 wt%.

difficult. To summarize, chemical kinetics, liquid diffusivity, vapour phase transport and binder redistribution are critical parameters of the pyrolytic binder removal process. These parameters can hardly fulfil requirements together in order to avoid the formation of defects in the green body.

The supercritical debinding method was performed at a rather low temperature, (i.e. lower than 120°C), at which no redistribution of the binder in the green body, due to capillary forces, takes place and at which no degradation of organic compounds occurs. For example, in the case of the polypropylene-based binder system studied by Pinwill,[5] defects occur at temperatures higher than 160°C.

Extraction by the supercritical fluid acts through two steps, namely solubilization of organics without degradation and diffusion of dissolved species through the porous medium. On one hand, the density of the supercritical fluid, which depends on pressure and temperature, leading to the largest solubility of a binder can be estimated using solubility parameters. On the other hand, a model based on diffusion equations was recently developed to estimate diffusivity of dissolved organic species in green samples.[9] Solubility and diffusivity control the binder extraction with opposite pressure and temperature dependencies. The limiting mechanism of supercritical debinding is the diffusion of dissolved species, here soluble paraffin, through the space available between ceramic particles, keeping in mind that a large portion of this space (about 50 vol.%) is still occupied by undissolved binder (non-soluble paraffin and polystyrene). The diffusion coefficient is also reduced by the tortuosity factor.

The small amount of undissolved polystyrene by the supercritical CO_2 maintains the cohesion of the ceramic green body. Organic bridges between ceramic particles are preserved, avoiding the deformation of the green part during and after the extraction of the largest amount of organics. According to calculations based on a diffusion model,[9] the amount of organics which have to be removed, by supercritical treatment, to reach an open and interconnected porosity over the whole sample was evaluated at 42% of the initial organic content. Then volatile species produced during the subsequent pyrolysis can diffuse more freely between ceramic particles and escape to the gas phase without causing large stresses. The supercritical treatment, by itself, allows the extraction of 50 vol.% of binders under the present conditions. Then, it remains possible that the unavoidable pyrolysis of residual organics at a heating rate of 5°C min^{-1} could affect mechanical properties of sintered specimens through the mechanisms involved earlier in this section, and thus a reduced heating rate during the presintering stage could possibly improve the strength to failure and the Weibull modulus to some extent. This is presently under investigation, but nevertheless it is noteworthy that interesting benefits can be expected from a 'soft' technique of binder removal such as supercritical extraction.

4 Conclusions

Organic removal from green ceramic parts is a crucial stage in ceramic processing, especially when large pieces are produced. This work has demonstrated that organic removal by supercritical carbon dioxide leads to plastic formed materials with higher mechanical properties than thermally treated ones. Higher values of strength to failure and Weibull modulus were obtained after 3 h of supercritical treatment (σ = 277 MPa, m = 13·7) than after 18 h of thermal treatment (σ = 253 MPa, m = 12·4).

This original method offers the great advantage of removing binders from ceramic green pieces without melting and without degradation of these organic compounds. Binder redistribution due to capillary forces and outward diffusion of degradation products, which are the major factors causing defects in the pyrolytic binder removal, does not take place during the supercritical extraction. Supercritical debinding involves two mechanisms, namely solubility of organics and diffusion of dissolved species through the porosity created.

The selective solvent properties of supercritical carbon dioxide allow a small amount of high molecular weight binder to be kept in order to maintain the cohesion of the ceramic green bodies after the extraction treatment.

The Accuracy of Failure Predictions Based on Weibull Statistics

S. L. Fok* & J. Smart

Department of Engineering, University of Manchester, Manchester, M13 9PL, UK

(Received 3 October 1994; revised 2 March 1995; accepted 10 March 1995)

Abstract

The mechanical failure of ceramic materials is usually characterised by probability equations based on Weibull's weakest link theory. To evaluate these for components in a varying stress field, postprocessors have been developed by us as well as others. The effect of the errors which arises from the postprocessing on the fractional errors in the nominal failure load, the probability of failure or the probability of survival are found and discussed.

Introduction

The mechanical failure of ceramics is usually considered to be governed by failure laws which are based on the original ideas of Weibull[1] in 1939. Since then the theory has been developed to allow for multiaxial stress fields and for different failure criteria. Essentially, the ceramic is considered to have many small flaws (cracks) distributed throughout the body and failure depends upon the first crack to fail: hence the concept of the weakest link. These small cracks will have different sizes and will be randomly orientated. The largest crack may not cause failure as it may occur in an area of low stress or it may be orientated so that, for example, the stress normal to the crack is small and hence is less likely to fail when compared to the crack which is orientated so that the stress normal to the crack is high.

To account for these variations, the mechanical failure of ceramics is normally described by a probability distribution and typically the failure probability will be described by the equation

$$P_f = 1 - e\left\{-\left(\frac{\sigma_{nom}}{\sigma_0}\right)^m \Sigma_v\right\} \quad (1)$$

where Σ_v is a stress volume integral given by

$$\Sigma_v = \int_v \frac{1}{4\pi} \int_0^{2\pi} \int_0^{\pi} \left(\frac{\sigma_e}{\sigma_{nom}}\right)^m \sin\phi \, d\phi \, d\psi \, dv \quad (2)$$

for a body with a random distribution of crack orientations.

The stress volume integral accounts for the variation of stress throughout the body and also, through σ_e, the different failure criteria. In these equations, σ_0 and m are material properties which correspond to the strength of the ceramic and to the spread in the failure loads and σ_{nom} is a nominal stress. As well as stress volume integrals in which the stress is evaluated over the volume, there are also failure laws based on the stress distribution over the surface of the component.

In order to determine the failure probability of a structure in which the stress varies, the normal procedure is to perform a finite element analysis and then using the data from this analysis evaluate the failure probability using a postprocessor based on (1) and (2). How our postprocessor worked is described in Ref. 2.

To compare the performance of various postprocessors a numerical round robin was performed and the results have been published by Dortmans *et al.*[3] To compare the errors a measure called $\bar{S}_{nom}$ was used. This is the predicted mean nominal stress and is directly related to σ_{nom} in eqn (1). This was chosen as it is not too sensitive to errors in the postprocessor.

However, a designer is probably more interested in properties such as probability of failure or nominal failure stress for a given probability of failure (or survival). The purpose of this paper is to discuss the relationships between these values and the relationship with the errors arising from the postprocessor when evaluating the stress volume (or area) integral.

Theory

The probability of failure as given by (1) can be generalised so that Σ represents either a stress volume, Σ_v, or stress area, Σ_A, integral, i.e.

*Now at Nuclear Electric Plc, Berkeley Technology Centre, Gloucs., UK.

$$P_f = 1 - e\left\{-\left(\frac{\sigma_{nom}}{\sigma_0}\right)^m \Sigma\right\} \quad (3)$$

and for the survival probability

$$P_s = e\left\{-\left(\frac{\sigma_{nom}}{\sigma_0}\right)^m \Sigma\right\} \quad (4)$$

Now, for a particular value of survival probability

$$\sigma_{nom} = \sigma_0 \left(\frac{\ln(1/P_s)}{\Sigma}\right)^{1/m}$$

or

$$\sigma_{nom} \propto (1/\Sigma)^{1/m} \quad (5)$$

This gives a relationship between the nominal failure stress, the stress integral and the Weibull parameter. Now, because of errors in the postprocessing

$$\frac{\sigma^*_{nom}}{\sigma_{nom}} = \left(\frac{\Sigma}{\Sigma^*}\right)^{1/m} \quad (6)$$

where the asterix denotes the numerically derived values. This provides a measure of the error in the nominal failure stress which depends on the Weibull modulus and the numerical error from the postprocessing step in calculating the stress integral. Equation (6) also applies to $\bar{S}_{nom}$.

On the other hand, if the survival probability, P_s, is required then from (4)

$$P_s = e\left\{-\left(\frac{\sigma_{nom}}{\sigma_0}\right)^m \Sigma^*\left(\frac{\Sigma}{\Sigma^*}\right)\right\} = P_s^{*(\Sigma/\Sigma^*)}$$

or

$$\frac{P_s^*}{P_s} = P_s\left(\frac{\Sigma^*}{\Sigma} - 1\right) \quad (7)$$

This now provides a measure of the error in the survival probability which depends on the survival probability and the error in the stress integral.

For the failure probability and using (7) gives

$$\frac{P_f^*}{P_f} = \frac{1 - P_s^{\Sigma^*/\Sigma}}{P_f}$$

or

$$\frac{P_f^*}{P_f} = \frac{1 - (1-P_f)^{\Sigma^*/\Sigma}}{P_f} \quad (8)$$

This provides a measure of the error in the failure probability which depends on the failure probability and the error in the stress integral.

Results and Discussion

Equations (6), (7) and (8) have been evaluated to examine the effect of errors in determining the stress integrals and the results are given in Figs 1, 2 and 3.

For the nominal failure stress, Fig. 1 shows the dependency on the Weibull parameter and that the errors in evaluating the stress integral are reduced when calculating the nominal failure stress, particularly for high values of Weibull modulus. However, as has been shown elsewhere,[3] the errors in evaluating Σ are greater for higher values of m.

From Fig. 2 it can be seen that to evaluate the survival probability accurately, it is important for low survival probabilities that the stress volume integral is evaluated accurately. However, for high survival probabilities, which is the realistic region for design, the errors are smaller.

From Fig. 3 it can be seen that a high failure probability reduces the fractional error of failure probability caused by errors in evaluating the stress integral. The error in the failure probability is always lower than that in the stress integral.

The equations given above have been derived using a 2-parameter Weibull model. However, a

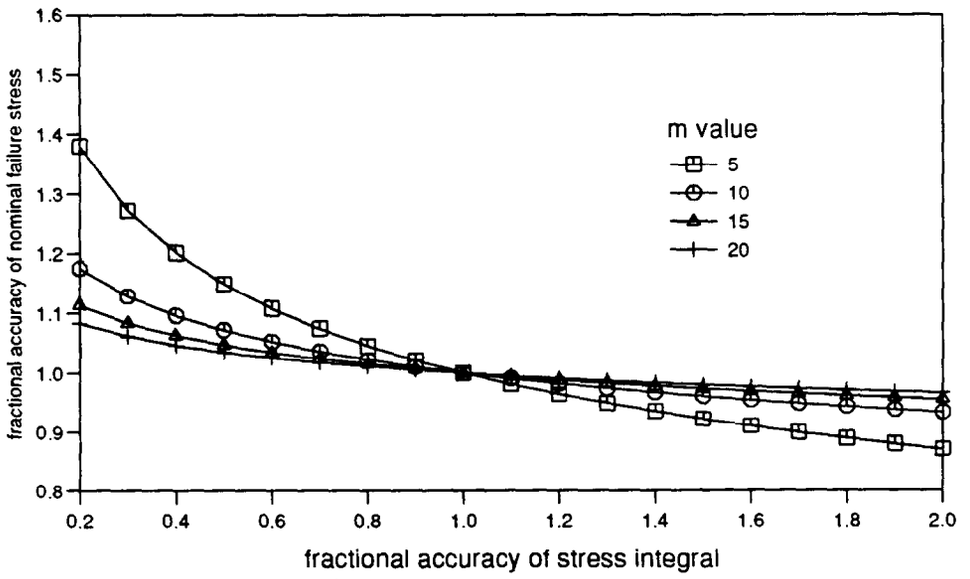

Fig. 1. Accuracy of nominal failure stress.

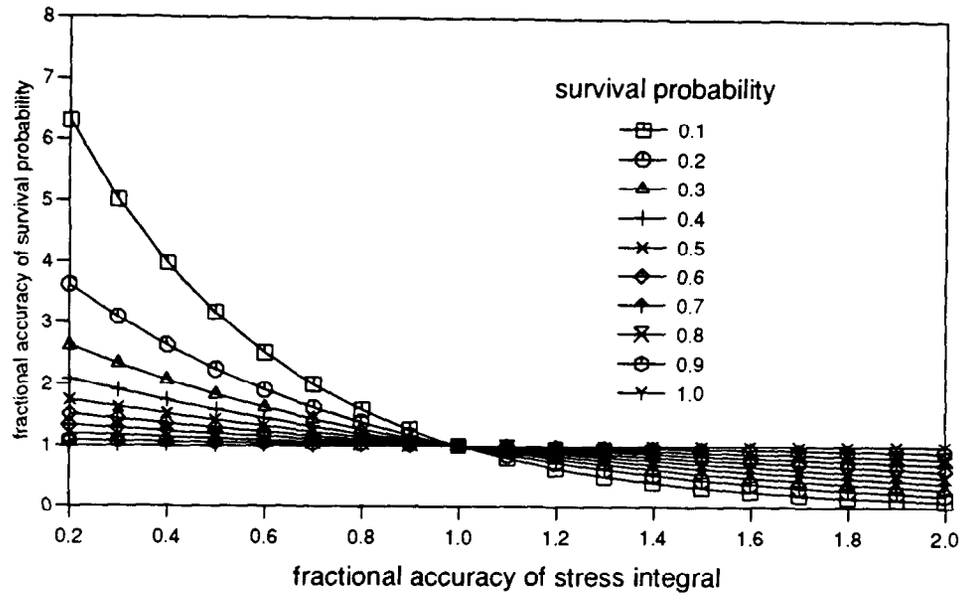

Fig. 2. Accuracy of survival probability.

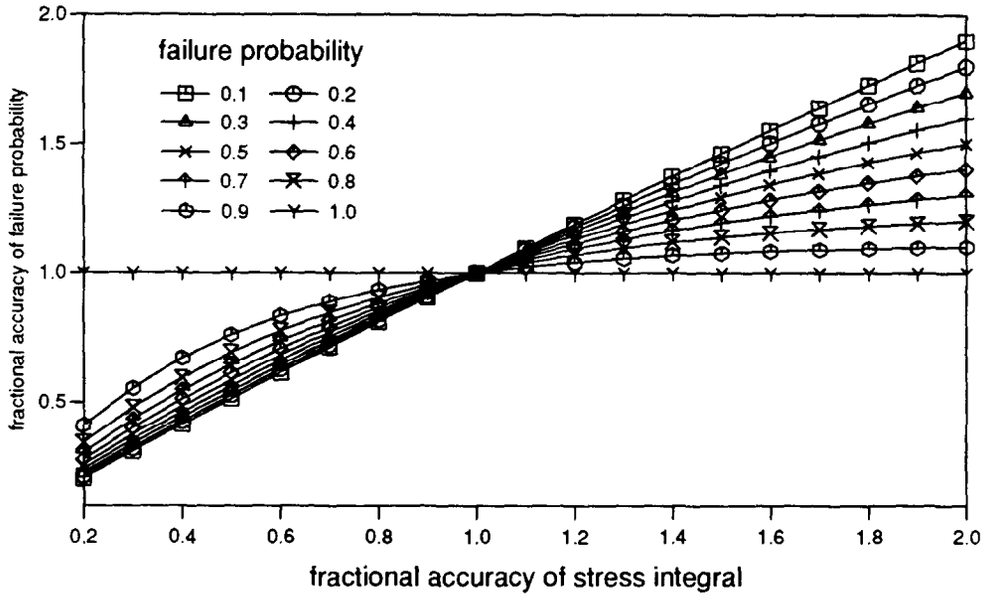

Fig. 3. Accuracy of failure probability.

3-parameter model using a threshold stress is also used in describing the mechanical failure distribution of ceramics. In this case the relationship given by (6) is no longer valid although the relationships (7) and (8) still hold.

A further measure of error is the absolute error, i.e.

$$| P_s^* - P_s | = | P_s^{\Sigma^*/\Sigma} - P_s | \tag{9}$$

Also

$$| P_f^* - P_f | = | (1 - P_s^*) - (1 - P_s) |$$

$$\therefore | P_f^* - P_f | = | P_s^{\Sigma^*/\Sigma} - P_s | \tag{10}$$

It can be seen from (9) and (10) that, not surprisingly, the absolute error in the failure and survival probabilities is the same. This is probably a better indicator of error because, for example, the practical difference between a failure probability of 1×10^{-5} and 2×10^{-5} is negligible even though the fractional error is 50%.

The results of evaluating (9) are shown in Fig. 4 for the region of high survival probability which is the realistic design range.

Equation (10) can be further developed as

$$P_f^* - P_f = (1 - P_f)^{\Sigma^*/\Sigma} - (1 - P_f)$$

For small probabilities of failure and when Σ^*/Σ is approximately 1, then

$$P_f^* - P_f = 1 - \frac{\Sigma^*}{\Sigma} P_f - 1 + P_f$$

$$\therefore P_f^* - P_f = P_f \left(1 - \frac{\Sigma^*}{\Sigma} \right) \tag{11}$$

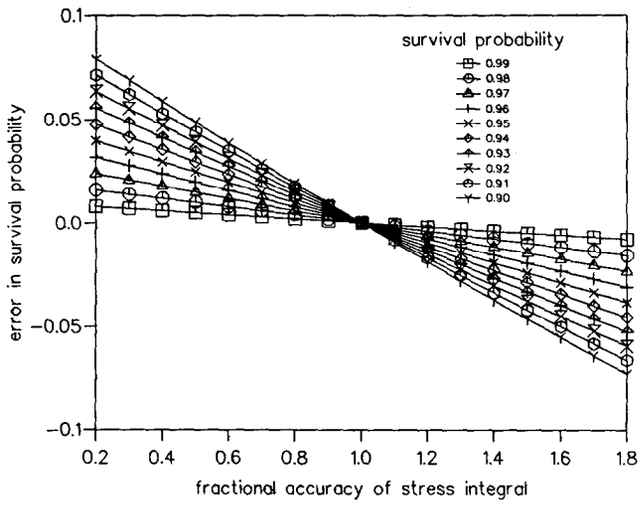

Fig. 4. Error in survival probability.

An examination of Fig 4 shows that this simplified equation is a good representation of the data and will enable the error in the failure probability caused by an error in determining the stress integral to be readily determined.

Conclusions

Relationships have been developed which give the fractional error in the mean nominal failure stress, the survival probability, the failure probability and the error in survival probability caused by errors in evaluating the stress integrals in the Weibull failure laws used for ceramic materials.

These have been evaluated to provide guides for the accuracy required in calculating the stress integrals in postprocessors.

The Efficient Integration of the Orientation Integral in Weakest Link Finite Element Postprocessors

S. L. Fok* & J. Smart

Department of Engineering, University of Manchester, Manchester, M13 9PL, UK

(Received 3 October 1994; revised 2 March 1995; accepted 10 March 1995)

Abstract

In evaluating the failure probability of ceramics it is usually necessary to numerically integrate an orientation integral which accounts for the random orientation of cracks with respect to the stress field. The procedure for performing this efficiently is discussed and recommendations are given.

Introduction

To evaluate the failure probability or nominal failure load of a ceramic component in a varying stress field a postprocessor is normally used. This takes the results from a finite element analysis and evaluates the failure laws which are typically written as[1]

$$P_f = 1 - e\left\{-\left(\frac{\sigma_{nom}}{\sigma_0}\right)^m \Sigma_v\right\} \quad (1)$$

where Σ_v is a stress volume integral given as

$$\Sigma_v = \int \frac{1}{4\pi} \int_0^{2\pi} \int_0^{\pi} \left(\frac{\sigma_e}{\sigma_{nom}}\right)^m \sin\phi \, d\phi \, d\psi \, dv \quad (2)$$

In eqn (2), σ_e and σ_{nom} are the equivalent and nominal stress respectively and the angles ϕ and ψ are defined in Fig 1.

In order to provide some benchmarks and to investigate how various postprocessors work, a numerical round-robin was carried out and a questionnaire circulated by WELFEP.[2] One question asked referred to the numerical integration of (2). Essentially, this equation accounts for the stress variation within the component and for the possibility that a crack may be orientated in any direction with respect to the stress field.

If eqn (2) is examined it can be seen to comprise of 2 parts; an integration over a unit sphere within an integration over the volume of the component. Previously,[1] we have investigated the integration rule within the volume of the component but have not discussed the integration over the unit sphere.

The purpose of this paper therefore, is to discuss the problem of how to efficiently and accurately integrate

$$I = \int_0^{2\pi} \int_0^{\pi} \left(\frac{\sigma_e}{\sigma_{nom}}\right)^m \sin\phi \, d\phi \, d\psi \quad (3)$$

As this is over a unit sphere and is to account for the orientation of the cracks with respect to the stress field it is often called the orientation integral. In the questionnaire,[2] it was found that 'generally Gauss–Legendre integration is applied with 10, 15 or 20 Gauss points'.

However, the question arises, is this the best method?

Theory

If the maximum principal stress, σ_1, is taken as the nominal stress then (3) can be rewritten as

$$I = \int_0^{2\pi} \int_0^{\pi} f\left(\frac{\sigma_2}{\sigma_1}, \frac{\sigma_3}{\sigma_1}, m, \phi, \psi\right) d\phi \, d\psi \quad (4)$$

and if the integration is performed numerically then

$$I = \sum_{i=1}^{N} \sum_{j=1}^{N} f_{ij} W_i W_j \quad (5)$$

where N is the number of sampling points and W_i and W_j are the weighting factors associated with the integration scheme.

For the Gauss–Legendre method, a linear transformation has to be performed to make the limits of integration +1 and −1. The sampling points are non-uniformly distributed and the values of the weighting factors vary.[3]

For the rectangular rule, the weighting factors are constant and the sampling points are evenly distributed through the domain. When integrating in 1-D this is equivalent to dividing the area under the curve into equal strips with the weighting

*Now at Nuclear Electric Plc, Berkeley Technology Centre, Gloucs, UK.

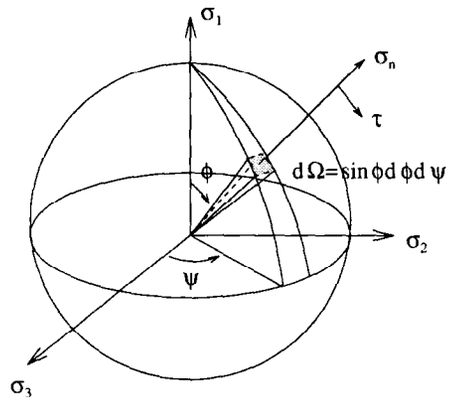

Fig. 1. Unit sphere in principal stress space.

factor the strip width and the sampling point being the centre of each strip. (Often, numerical integration is called quadrature and the Gauss–Legendre method is called Gaussian quadrature).

To investigate the efficiency of the evaluation of the integral both the Gaussian and rectangular rules will be used. Also, as (4) shows that the ratios σ_2/σ_1 and σ_3/σ_1 are important, various cases are considered, i.e.:

(i) uniaxial tension $\sigma_2/\sigma_1 = \sigma_3/\sigma_1 = 0$
(ii) equi-biaxial tension $\sigma_2/\sigma_1 = 1; \sigma_3/\sigma_1 = 0$
(iii) tension-compression $\sigma_2/\sigma_1 = 1; \sigma_3/\sigma_1 = -1$
(iv) equi-triaxial tension $\sigma_2/\sigma_1 = \sigma_3/\sigma_1 = 1$

Results and Discussion

The results are shown in Figs 2–5 for a shear insensitive equivalent stress, i.e. $\sigma_e = \sigma_n$.
In this case

$$\sigma_e = \sigma_1\cos^2\phi + \sigma_2\sin^2\phi\sin^2\psi + \sigma_3\sin^2\phi\cos^2\psi \quad (6)$$

From these figures, it can be seen that the calculated orientation integrals converge with increasing integration order and that, as for the integral over the volume,[1] the higher the Weibull modulus, m, the more sampling points are required for the integral to converge. For both rules, a quadrature order of 10 or less appears to be sufficient for the ranges of m values and stress ratios tested. However, in contrast to the calculation of the stress integrals, the rectangular rule can be seen to give a faster convergence than Gaussian quadrature with the exception being the case of equi-triaxial tension.

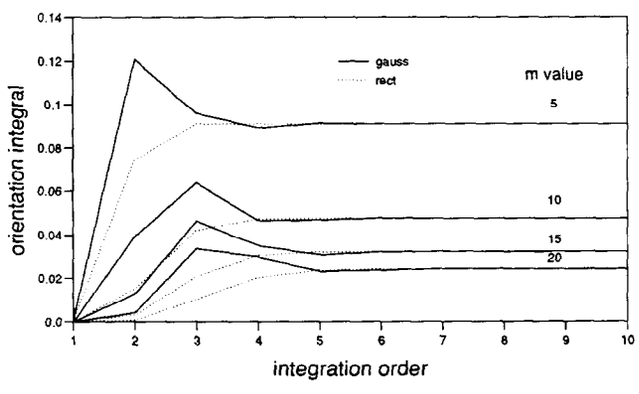

Fig. 2. Convergence of orientation integral for uniaxial tension.

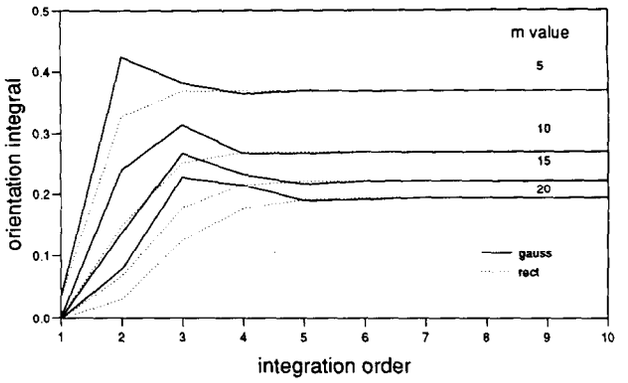

Fig. 3. Convergence of orientation integral for equi-biaxial tension.

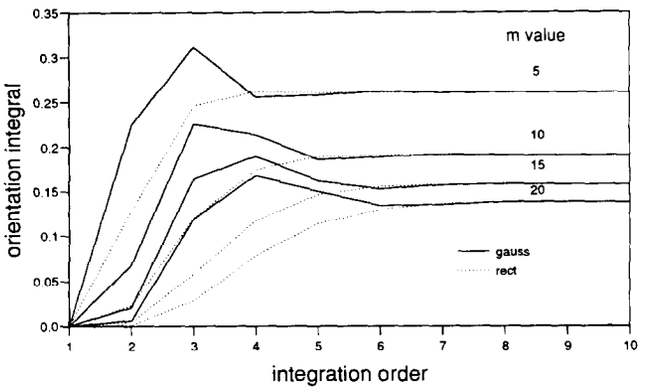

Fig. 4. Convergence of orientation integral for tension–compression.

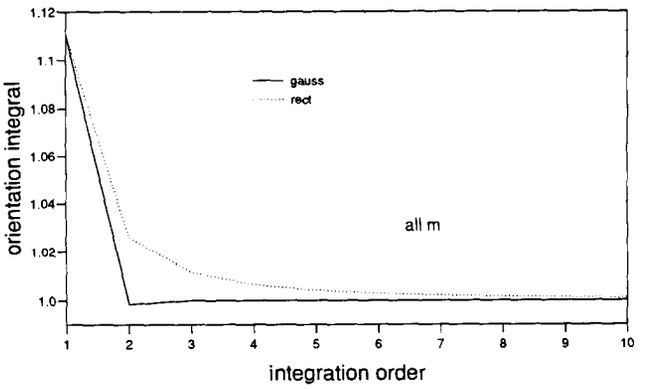

Fig. 5. Convergence of orientation integral for equi-triaxial tension.

At first sight, the results may seem surprising considering the superiority of Gaussian quadrature in evaluating the volume integral.[1] However, if the integral, eqns (3) and (6), is examined it can be found to contain terms such as $\cos^m\phi$ and $\sin^m\phi$ because of the stress transformations. When plotted, these functions have shapes similar to a ramp function as shown in Figs 6 and 7. If the

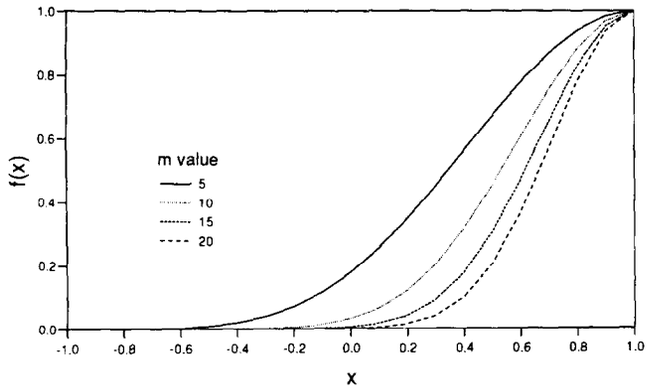

Fig. 6. $f(x) = \sin^m \frac{\pi}{4}(x + 1)$

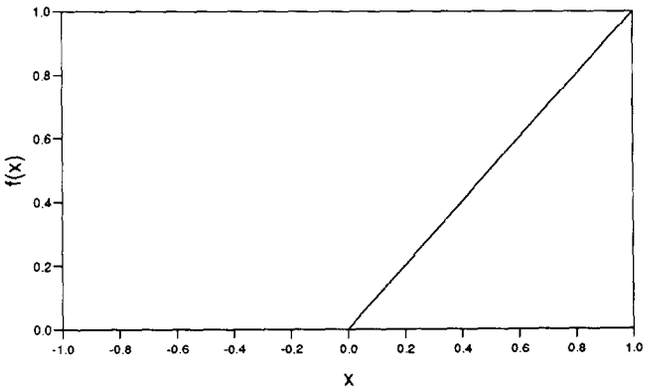

Fig. 7. Ramp function.

rectangular rule is used to integrate the ramp function, the use of 2 or any other even number of sampling points will give the correct answer. On the other hand, when the number of sampling points is odd a higher integration order is required to obtain a converged result. Figs 8 and 9 compare the performance of the rectangular and Gaussian rule in integrating the functions in Figs 6 and 7 and it can be seen that in both cases the rectangular rule is more efficient.

For a shear sensitive criterion, e.g.

$$\sigma_e = (\sigma_n^4 + 6\sigma_n^2 \tau^2 + \tau^4)^{1/4} \qquad (7)$$

similar results are obtained, although the convergence is not so rapid with the value of the orienta-

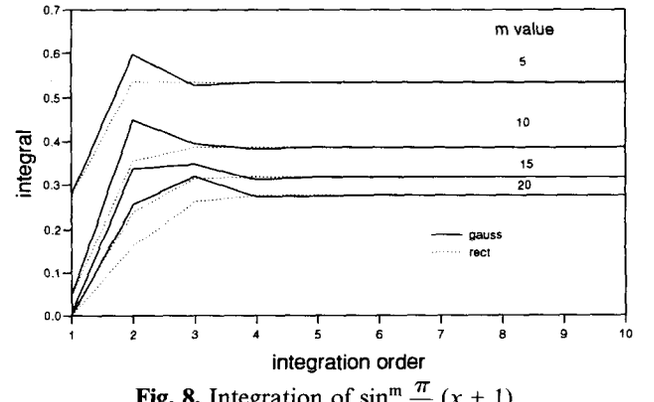

Fig. 8. Integration of $\sin^m \frac{\pi}{4}(x + 1)$

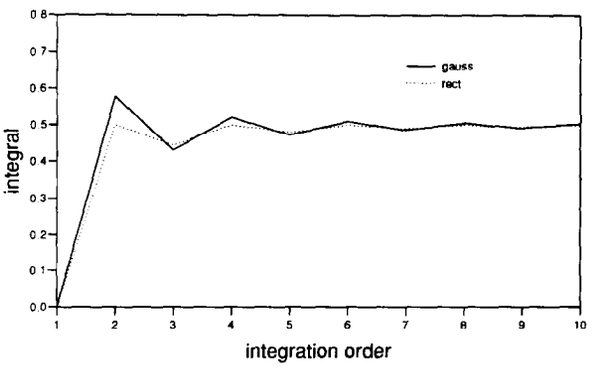

Fig. 9. Integration of ramp function.

tion integral oscillating more before converging. This is particularly so for case (iii), i.e. tension–compression and for $m = 5$. Convergence is also affected by the way in which negative values of stress are treated. If

$$\sigma_e = 0 \text{ for } \sigma_n < 0$$

then convergence is not so good and higher integration orders may be needed.

The effect of any errors in calculating the error in probability of failure, probability of survival or nominal stress has also been examined by the authors.[4] For high survival probabilities, the fractional error in the survival probability is considerably less than the fractional error in the stress integral. It was shown that

$$\frac{P_s^*}{P_s} = P_s\left(\frac{\Sigma^*}{\Sigma} - 1\right)$$

where P_s is the survival probability, Σ is the value of the stress integral and the *superscript denotes the numerically derived values. So, for example, for a fractional error of 10% in Σ, i.e. $\Sigma^*/\Sigma = 1{\cdot}10$, then P_s^*/P_s for a survival probability of 0·99 is 0·999, i.e. a 0·1% error. Alternatively, the absolute error is given as

$$| P_s^* - P_s | = | P_s^{\Sigma^*/\Sigma} - P_s |$$

and the absolute error is 0·000994.

In view of these results, an integration order of 10 is recommended as sufficient for practical applications and there is little difference between Gaussian and rectangular quadrature.

Conclusions

To evaluate the orientation integral in the failure laws for ceramic materials, it is recommended that an integration order of 10 is used. The rectangular rule and Gaussian quadrature give almost identical results.

(Received 20 December 1994; accepted 10 February 1995)

Abstract

The creep behaviour of high-alumina refractories containing increasing amounts of a fused mullite–zirconia aggregate (MZA) of eutectic composition was studied experimentally. The MZA has been added with the intention of improving the work of fracture and the thermal shock resistance through microcrack toughening. The creep resistance was found to decrease with increasing MZA content. This was attributed to the formation of an increasing fraction of a substructure composed of small grains and an amorphous binder phase situated between the large agglomerate particles. Creep deformation mainly occurred within these fine-grained interagglomerate regions, but rate controlled by mullite formation kinetics as an accommodation process. This interpretation is substantiated by the measured values of the stress exponent (n = 1·2–2·7) and the activation energy for creep ($Q \approx$ 720 kJ/mol) and by the finding that the creep rate was distinctly reduced by a preceding heat treatment.

1 Introduction

During the last decade, modern refractories have been developing into a class of highly sophisticated multiphase composite materials. As pointed out recently by Bradt[1] in a review on present day refractories, the manyfold and complex reactions between the constituents of the microstructure which are dynamic and transient in nature must be understood when a critical assessment of the physical and mechanical properties is to be obtained.

Among the mechanical properties of refractories, the deformation behaviour at high temperature under compressive load is of particular interest. Knowledge of the creep data of refractories is a prerequisite for selecting materials that exhibit a minimum of creep in a given application, as well as for establishing engineering design parameters for the construction of stoves and furnaces, as has been clearly demonstrated by Ainsworth and Kaniuk.[2] Furthermore, it has been pointed out by Evans *et al.*[3] that the availability of creep data is an indispensable basis when stresses and strains in refractory components and structures in service are to be calculated. By using the Θ projection concept developed by Evans and Wilshire[4] they demonstrated that the creep strength of refractories under service conditions can be extrapolated from the creep data determined in the laboratory within a limited range of test conditions.[3] Finally, the investigation of basic creep mechanisms is the key for developing new materials of improved creep resistance for use in refractory settings where creep is to be minimized.

A series of experimental creep studies on a variety of refractories of different compositions have been reported in the literature.[2, 5–13] It is generally recognized that creep of refractories is strongly affected by the microstructure. Fundamentally, there are three microstructural features which influence the creep behaviour, i.e. (1) the mineral content (size and distribution of the crystalline aggregates); (2) the flux content (amount, composition and distribution of the glassy phase), and (3) the apparent porosity.

The aim of the work presented here was to evaluate the creep behaviour of an experimental high-alumina refractory particularly designed for high thermal shock resistance.[14] To achieve this, different amounts of a mullite–zirconia aggregate (MZA) were added with the purpose of taking advantage of the zirconia toughening effect on room temperature mechanical properties. In fact, an increase in both the work of fracture and the retained strength after thermal shock was observed as the MZA content was increased, pointing at an increased microcrack density caused by the presence of zirconia particles.[14] Likewise, a pronounced loss of high-temperature strength was found to occur at 1400°C. This was attributed to increasing fractions of glassy phase

introduced by the MZA additive.[14] It was to be expected that the increase in glass phase content should also degrade the creep resistance of the material which was actually found in this paper.

2 Experimental Details

2.1 Materials and sample preparation

Five different high-alumina refractories were tested. These consisted of a basic mixture of a tabular and a calcined alumina to which varying amounts of a fused mullite–zirconia aggregate (MZA) have been added. The pressed bricks were fired at 1510°C for 12 h as indicated in Ref. 14. Table 1 shows the compositions of the materials tested, as well as their grain-size ranges. In the following, these five materials are identified by the weight fraction of their MZA content. Samples for compressive testing having dimensions of 20 × 20 × 40 mm^3 and 12 × 12 × 20 mm^3 were prepared by cutting blocks from the as-fired bricks and grinding them to the final dimensions. Specimens for microstructural examinations were ground and polished using a diamond paste down to a size of 1 μm. Micrographs were obtained by scanning electron microscopy on as-polished microsections.

2.2 Mechanical testing

Experimental techniques used in the literature for generating creep data are: (1) the refractoriness-under-load test (RUL test) where under a constant load and at a constant heating rate the temperature of the onset of plastic deformation is determined, and (2) compressive creep tests under constant load and temperature. Both techniques were applied in the present study. RUL tests were carried out according to DIN 51053 using a heating rate of 5°C/min and a compressive stress of 0·2 MPa.

Creep tests were performed in a constant-load creep machine in air at 1400°C and 3 MPa until failure occurred. Both as-received materials (all compositions) and samples annealed for 10 days at 1400°C (compositions 0, 10 and 30% MZA content) were tested. Stress change tests at 1400°C from 1 to 10 MPa and temperature change tests at 3 MPa from 1300 to 1450°C were made to obtain the stress exponent, n, and the activation energy for creep, Q, respectively (see eqn 1).

3 Results

3.1 Micrographic examinations

The microstructures of the five refractories studied in this work are shown in Figs 1 and 2. Figs 1(a) and (b) compare the materials without MZA and with 20% of MZA at a low magnification. In both micrographs, the large grains of tabular alumina prevail. These particles are considered to be rigid even under creep conditions and therefore do not contribute to the deformation. Between these large crystalline components, there is a substructure consisting of small grains and an amorphous binder phase. A fine-grained interaggregate substructure of similar appearance was also reported by Wiederhorn and Krause[13] in a magnesium–chromite refractory. The comparison of Figs 1(a) and (b) demonstrates that the volume fraction occupied by the interaggregate substructure is increased and that the grain size of the small grains within this substructure is decreased when MZA is added.

In Figs 2(a), (b) and (c), micrographs of the refractories containing 10, 20, and 40% of MZA

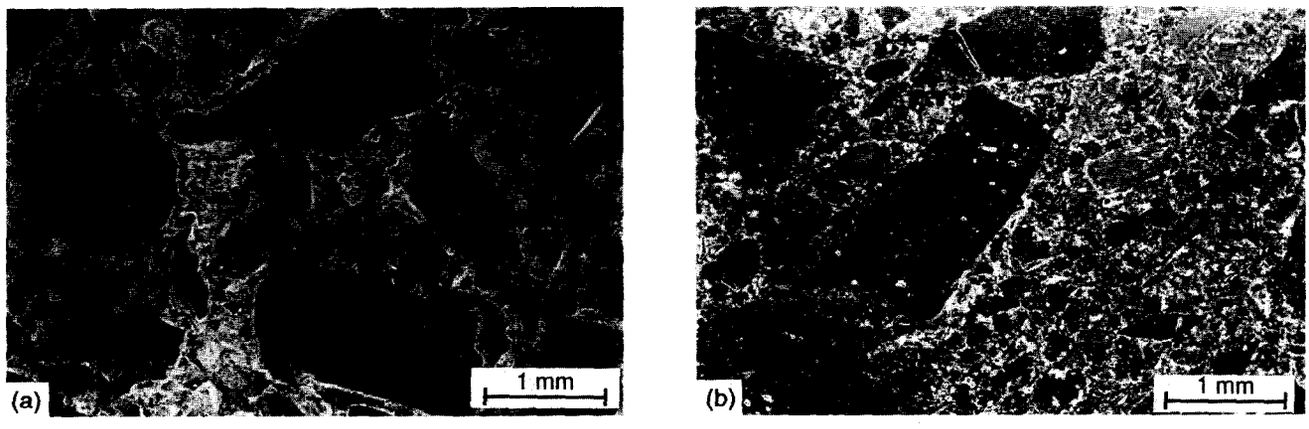

Fig. 1 SEM micrographs of refractories studied: (a) 0% of MZA content; (b) 20% of MZA content.

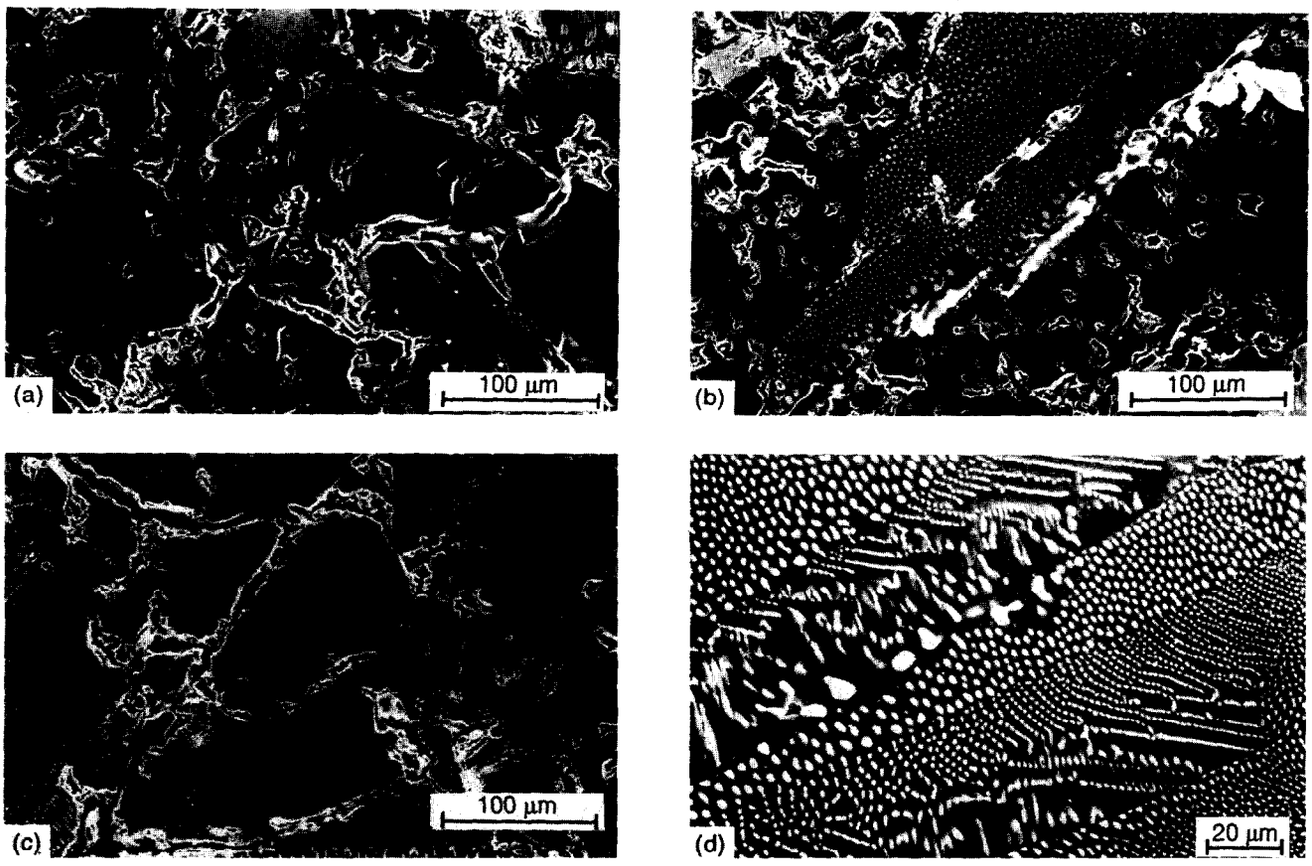

Fig. 2 Microstructure development with an increasing amount of MZA: (a) 10% of MZA content; (b) 20% of MZA content; (c) 40% of MZA content; (d) 20% of MZA content at higher magnification.

are shown at a higher magnification. The microstructure is composed of large particles of tabular alumina and the mullite–zirconia aggregate. These two components represent the major part of the crystalline phase content of the refractories.

The MZA can easily be detected in Fig. 2 by its dotted or striped appearance. The light phase is zirconia and the dark phase is mullite, as was proved by an EDX analysis. It is the mullite–zirconia eutectic which is formed in the Al_2O_3–SiO_2–ZrO_2 phase diagram. It has a eutectic temperature of 1750°C.[15] Within the MZA particles, the zirconia phase has a rod-like shape and forms periodic arrays of parallel orientation which are embedded in the continuous mullite matrix, as is shown in Fig. 2(d). This micrograph also demonstrates that there is a reasonable fit between the two phases of the eutectic since no microcracks can be detected within the MZA particles. However, considering the thermal expansion coefficients of mullite and zirconia, α_M and α_Z, ($\alpha_M = 5{\cdot}3 \times 10^{-6}\ K^{-1}$ and $\alpha_Z = 10{\cdot}0 \times 10^{-6}\ K^{-1}$ [16]), the value for the embedded phase is nearly twice that of the matrix phase. Thus, it may be concluded that thermally induced residual stress is created on cooling. In fact, evidence of microcrack formation at the ZrO_2/mullite interface was obtained on several micrographs.

Beside the rod-like zirconia component, there are also larger zirconia particles present in the micrographs of Figs 2(a), (b) and (c). These particles may be responsible for the toughening effect found in Ref. 14. Figures 2(a), (b), and (c) also show that the aggregate particles are surrounded by small layers of amorphous phase.

3.2 RUL tests

RUL test plots of the compositions 0, 20, and 40% MZA are presented in Fig. 3. The curves show a regime of linear thermal expansion and, at temperatures >1200°C, small deviations caused by the very onset of plastic deformation, the 20 and 40% materials going through a strain maximum at about 1400°C. According to DIN 51053, the upper temperature limit of the test is 1500°C and the softening temperature $T_{0{\cdot}5\%}$ is defined as that temperature where the compressive deformation attains a value of 0·5% with respect to the strain reached at the maximum. As can be seen from Fig. 3, $T_{0{\cdot}5\%} > 1500$°C for all compositions.

Since the sample deformation was very small when the temperature limit of 1500°C was reached the tests were continued at this temperature and stress for an additional 24 h to get a first idea of the creep resistance. By that means, creep curves $\epsilon(t)$ are developed which are also plotted in Fig. 3. From these curves the time $t_{0{\cdot}5\%}$ to reach a deformation $\epsilon = 0{\cdot}5\%$ was taken for each composition

and listed in Table 2. For the material without MZA content, this time is about 4 times that of the two other materials, indicating its superior creep resistance.

3.3 Creep tests

Creep curves plotted as creep rate $\dot{\epsilon}$ versus strain ϵ are shown in Fig. 4 for all materials in the as-received state at 1400°C and 3 MPa. The form of the creep curves is typical of many other ceramics and also refractories, exhibiting a primary, secondary or steady-state and tertiary creep stage. In some cases, no steady-state creep stage was found. The material without MZA had the lowest creep rate and did not exhibit any signs of creep damage up to ϵ = 10% where the test was stopped. The other compositions crept much more readily and exhibited failure by creep rupture at strains between 6 and 9%. Values of rupture strain ϵ_r, rupture time t_r and the steady-state or minimum creep rate $\dot{\epsilon}_s$ are listed in Table 2 for comparison.

The steady-state creep rate of a material is usually described by the equation

$$\dot{\epsilon}_s = A(S) \cdot \sigma^n \cdot \exp\left(-\frac{Q}{RT}\right), \qquad (1)$$

where $A(S)$ is a structure-dependent constant, σ is the stress, n is the stress exponent, Q is the activation energy for creep, and R and T have their usual meaning. To determine n and Q of eqn (1), stress and temperature change tests were performed. Examples of such tests are shown in Fig. 5 (stress changes) and Fig. 6 (temperature changes) for the refractory containing 30% of MZA. The stress exponent is calculated from the height of the $\dot{\epsilon}_s$ steps of Fig. 5 and the activation energy from the step height of Fig. 6. The n and Q values which were thus obtained are listed in Table 2.

The stationary creep rates measured at different stress levels at 1400°C are presented in Fig. 7 in a log–log plot. In this type of presentation, all five materials tested are close together, the difference increasing a little with increasing stress and reaching a factor of 5 at 10 MPa. The stress exponent derived from the slope of the curves has values between 1 and 2 and increases slightly with increasing applied stress level.

Figure 8 is an Arrhenius plot of the creep rates of the five materials at 3 MPa. Straight and nearly parallel lines were obtained which point at an activation energy for creep that is independent of temperature and equal for all compositions.

The effect of the MZA content on the steady-state creep rate at 1400°C and 3 MPa is shown in Fig. 9. It can clearly be recognized that the addition of MZA accelerates the creep deformation process. The maximum increase (by a factor of 25) was observed for the samples containing 20%

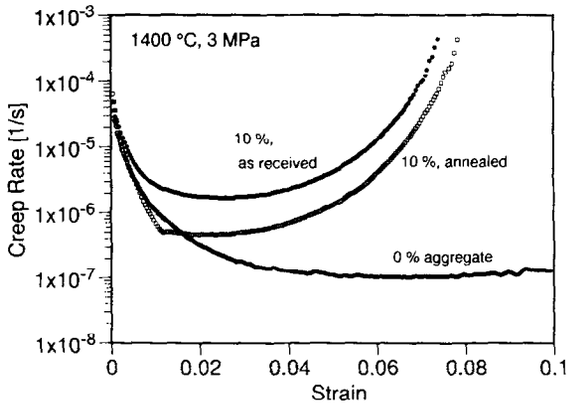

Fig. 10. Effect of heat treatment on the creep behaviour of 10% MZA refractory.

MZA. Figure 9 additionally contains modulus-of-rupture (MOR) data taken from Ref. 14. The MOR data are also listed in Table 2. The comparison of the two curves of Fig. 9 demonstrates that the high-temperature strength is degraded by the MZA addition in the same way that the creep rate is increased. From this finding it may be argued that the two mechanical parameters are controlled by the same microstructural features.

It has been reported by many investigators[5–7,10] that a post-fabrication heat treatment or hard firing condition reduces the creep rates of fired bricks. To examine the validity of this observation for the refractories studied here, compositions of 10 and 30% MZA were annealed at 1400°C for 10 days prior to creep testing. In Fig. 10 the creep curves of 10% MZA materials after the heat treatment and in the as-received state are compared. Minimum creep rate data of the two annealed

refractories are contained in Table 2. It was found that annealing altered the shape of the creep curve considerably, reducing minimum or steady-state creep rate by a factor of 4 in the material containing 10% and by a factor of 2 in the 30% MZA refractory.

4 Discussion

The creep behaviour of fired high-alumina refractories is strongly affected by their microstructure. There exists agreement in the literature that the two most important microstructural parameters are the crystalline phase content and the intergranular glassy phase. The results of the present research will be discussed in terms of these two features.

4.1 Crystalline phase content

According to the silica–alumina phase diagram, the equilibrium phases formed at elevated temperatures are mullite and corundum. Therefore, in high-alumina refractories mullite may be formed from alumina and excess silica by the reaction

$$3Al_3O_3 + 2SiO_2 \rightarrow 3\ Al_2O_3 \cdot 2SiO_2 \qquad (2)$$

The amount and morphology of the mullite phase controls the creep strength of high-alumina refractories since mullite formation increases the fraction of crystalline phases and reduces the amorphous phase content in the microstructure. Clements and Vyse[5] pointed out that best creep resistance is achieved when a three-dimensional network of mullite laths is present. Hulse and Pask[6] arrive at the same conclusion; namely that creep is controlled by the continuous mullite microstructure. Similar observations were made by Burdick and Day[7] and by Matsumara *et al.*[10] who found that all means of accelerating the rate of mullite formation resulted in a decrease of the creep rate. Other crystalline phases, such as large aggregate grains, are thought to be rigid and therefore do not contribute to the deformation. Furthermore, all four of these studies[5–7,10] agree upon the observation that the mullite content and hence the creep resistance of high-alumina refractories is increased through a heat treatment, either during initial firing or afterwards. A further observation concerning the effect of the crystalline phase content on the creep strength of refractories was made by Coath and Wilshire[9] and by Evans *et al.*[11] They reported that the creep rate of CaO/MgO doloma refractories decreased by up to an order of magnitude when the magnesia content was increased by admixing additional MgO powder to the raw material.

There is strong evidence that the creep behaviour of the refractories studied here is controlled by their mullite formation kinetics as well, as may be seen from the following arguments: (1) In metallographic observations a mullite lath network was observed at the interface between large alumina grains and MZA particles[14] where most of the local deformation is likely to occur. (2) The activation energy for creep is nearly the same for all five grades tested (Fig. 6). It has an average value of 720 kJ/mol and is very close to the activation energy for creep of mullite which has been reported to be 740 kJ/mol.[6] On the other hand, creep control by one of the other main constituents of the microstructure, i.e. the glassy phase and the large alumina grains, can be excluded since both of them have activation energies for creep much smaller than the measured figure of 720 kJ/mol. After Hulse and Pask,[6] silica-based glass has an activation energy in the range of 210–340 kJ/mol, whereas that of pure polycrystalline alumina is about 580 kJ/mol.[17] (3) The creep resistance was found to increase after a prolonged heat treatment (Fig. 8). This can be explained by temperature-activated mullite formation and silica consumption according to eqn (2). (4) Creep of the high-alumina refractories studied here is not a merely viscous process that would exhibit a stress exponent of $n = 1$. Instead, n values significantly greater than unity were found (Table 2 and Fig. 5). This finding indicates that the deformation additionally involves an accommodation process which probably actuates at the mullite–mullite and mullite–glass junctions and interfaces and which has a non-linear stress dependence.

4.2 Intergranular glassy phase

Even though the mullite phase is regarded to be rate-controlling in the creep of high-alumina refractories the properties of the glassy phase also affect the deformation behaviour. As pointed out by Hulse and Pask,[6] refractories with a high glass content will have a high deformation rate. Evidence of the effect of glassy phase content on the creep behaviour was also found in this study: (1) The MZA content caused the creep rate to be increased (Figs 2 and 7). This is attributed to an increased fraction of the amorphous phase in the microstructure because it was found in Ref. 14 that the addition of MZA resulted in an increased glass content. (2) In the presence of MZA, tertiary creep was observed to occur (Fig. 2) which is indicative of creep damage formed during deformation. The formation of creep damage generally decreases the rupture time t_r and reduces the ductility ϵ_r as indicated by the respective data in Table 2. It is well known that creep cavitation in

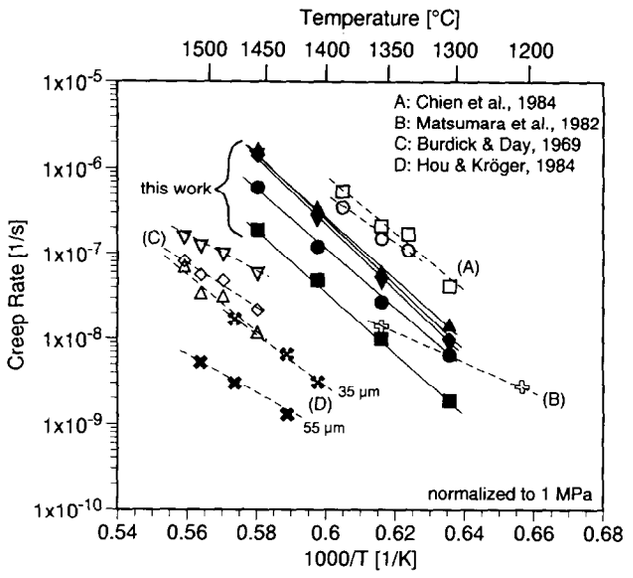

Fig. 11. Comparison of creep data from previous creep studies — data taken from Burdick and Day,[7] Matsumara *et al.*[10] Chien *et al.*,[19] and Hou and Kröger.[20]

structural ceramics is extraordinarily promoted by the presence of an amorphous phase. (3) The increase in creep rate and the decrease of rupture time must have the same origin. This follows from the fact that the $\dot{\epsilon}_s$ and t_r data of the four MZA containing refractories (Table 2) obey the Monkman–Grant relationship:[18]

$$\dot{\epsilon}_s \cdot t_r = \text{const.} \quad (3)$$

The $\dot{\epsilon}_s \cdot t_r$ product of the four data sets of Table 2 is about 0·040. The basic idea of the Monkman–Grant relationship is that, for a given failure mechanism, the strain at rupture is a constant.[18] Thus, if eqn (3) is valid for a given material, both the acceleration of the creep process and the reduction of the failure time are solely two different aspects of the same underlying mechanism. The Monkman–Grant relationship was found to hold for a series of glass-containing structural ceramics.[13]

The role of the intergranular glass phase in the creep of refractories was further elucidated by Wiederhorn and Krause.[13] They recognized that a substructure of small grains plus binder phase is present between the large rigid aggregate particles, and that it is this fine grain-size interaggregate microstructure which represents an easy path for dissolution and mass transport of the rate-controlling crystalline phase. After Ref. 13 the deformation occurs more easily within the fine grain-size bonding structure, leading to an effective interagglomerate viscosity of the bond phase that is smaller than in the absence of the fine interagglomerate grains. In the present investigation, evidence of increasing volume fractions of the fine grain-size interagglomerate microstructure with increasing MZA content were found in metallographic examinations as described in Section 3.1. This observation is taken as a further explanation of the decrease of the creep resistance due to the addition of MZA.

A further experimental result that emphasizes the role of the intergranular amorphous phase in the creep process of refractories is the work of Evans, Wilshire and co-workers.[9,11,12] In both CaO/MgO-based doloma refractories[9,11] and in magnesia refractories[12] it was observed that the creep rate increased drastically (up to a factor of 30) when the impurity level, specifically Fe_2O_3, was increased by intentional doping. It must be supposed that the Fe_2O_3 impurities were dissolved in the silicate-based glass phase. Due to its trivalent state, Fe^{3+} is known to substitute Si–Si bonds, thereby reducing the viscosity of the glass and accelerating the creep process.

4.3 Comparison with previous creep studies

In Fig. 11, the results of the present creep investigation are compared with creep data from previous creep studies. The comparison is limited to materials of similar basic compositions, i.e. other high-alumina refractories. Creep data of such materials were reported by Burdick and Day,[7] Matsumara *et al.*,[10] Chien *et al.*[19] and Hou and Kröger.[20]

To compare the results measured at different applied stresses, the data were normalized to a common stress of 1 MPa before plotting them in Fig. 11. For that, the stress exponent n given in the respective paper was used, or, if no stress exponent was indicated, $n = 1$ was assumed. As can be seen from Fig. 11, the creep data at a given temperature cover a range of about three orders of magnitude.

The spread of the data must be attributed to differences in both the grain size and glassy phase content of the various materials investigated. Unfortunately, the grain size is not reported in most of the papers, with the exception of Ref. 20 where creep rates of three different aluminas having grain sizes of 6, 35 and 55 μm, respectively, were measured. For the comparison of Fig. 11 the data of the 35 and 55 μm grain size material were selected since this figure is close to the lower limit of the grain-size range of the tabular alumina given in Table 1.

The glass-phase content of the high-alumina refractories studied in Refs 19 and 20 was 33–44% and 1%, respectively. For the refractories of the present investigation, a value between 10 and 20% seems to be a reasonable assumption. The creep data of these three studies are ranked in the same sequence in Fig. 11: the data sets of Refs 19 and

20 form the upper and lower boundary of the experimental data whereas the creep data of the present study are intermediate. Thus, it may be concluded that the fundamental microstructural feature that controls the creep rate of these refractories is the volume content of the glassy phase.

5 Conclusions

It was shown previously in Ref. 14 that the addition of a fused mullite–zirconia aggregate results in a considerable improvement of the work of fracture and the thermal shock resistance of high-alumina refractories. Unfortunately, high-temperature mechanical properties such as the strength and creep resistance are deteriorated by increasing amounts of MZA in the microstructure as is demonstrated by Fig. 9. Thus, to take full advantage of zirconia-induced microcrack toughening of the high-alumina refractories studied here, a balance must be achieved between the opposing influences of MZA on the mechanical properties. This may be obtained by optimizing the MZA content for a given application.

Abstract

ZrO_2-free glasses and glasses containing ZrO_2 in the system Y_2O_3–Al_2O_3–SiO_2 have been investigated. Properties of compositions fired in nitrogen at 1600, 1650 and 1700°C have been assessed. The solubility limit of ZrO_2 in yttrium aluminosilicate liquids with a high content of Y_2O_3 at 1700°C was determined to be 6 wt%. The hardness and density of the ZrO_2-containing glasses were slightly increased compared to the ZrO_2-free glass; y-$Y_2Si_2O_7$ (at temperatures <1300°C) and β-$Y_2Si_2O_7$ (at temperatures >1300°C) monoclinic phases are the main products formed during the crystallization. An unidentified intermediate phase rich in Y, Al and Si was observed to undergo a transformation at temperatures ≥1200°C resulting in the formation of the β-$Y_2Si_2O_7$ phase.

1 Introduction

Silicon nitride and sialon ceramics are among the most promising materials for use in structural applications at high temperatures due to their outstanding combination of mechanical, chemical and thermal properties. Processing of these materials to near-theoretical density requires the use of sintering aids to provide a medium for liquid-phase sintering since the low self-diffusivity of Si_3N_4 does not allow densification by solid-state sintering.[1] Among the many oxides studied, Y_2O_3 is one of the most useful as a sintering additive, both in terms of the refractory nature of the resulting microstructures and in terms of its oxidation resistance. Alumina is often added to enhance sinterability. On cooling, these two oxides, together with SiO_2, appearing naturally on the surface of all silicon nitride powders, form a glass.[2] The softening of this glassy phase at high temperatures reduces mechanical strength and the upper-use temperature.

Two possible approaches to eliminate the glassy phase from the final microstructure are: (i) heat treatment to promote crystallization of the amorphous phases and (ii) alteration of the glass composition to increase the ease of crystallization.[3] Two-stage heat treatment, using the temperature of maximum nucleation rate for the first stage, followed by a higher annealing temperature to induce growth, has been suggested.[2] Other parameters also affect crystallization in the intergranular regions of Si_3N_4 ceramics such as the thickness of these regions. While crystallization of the secondary-phase pockets is possible in most systems, glassy material always remains at the grain boundaries with only the exception of special boundaries.[4] Clarke[5] proposed that an equilibrium intergranular film thickness exists for each material composition.

The amorphous grain-boundary phase composition in Si_3N_4 containing yttria and alumina as sintering additives can be simulated by glasses in the Y_2O_3–Al_2O_3–SiO_2 system. The first major study of the Y_2O_3–Al_2O_3–SiO_2 system was reported by Bondar and Galakov,[6] who developed a phase diagram in 1964. Recently Arita *et al.*[2] reviewed the crystallization studies in yttria–alumina–silica glasses. Several investigations have been carried out on other properties of yttria–alumina–silica glasses.[7–15] It was found that the density, refractive index, microhardness and thermal expansion of these glasses vary significantly with the Y_2O_3 content. The yttria–alumina–silica glasses have high thermal expansion considering their high T_g. The high microhardness indicates good abrasion resistance. The chemical durability in distilled water is very high.

Typical glass compositions for sialons are in the ternary eutectic 'trough' of the Y_2O_3–Al_2O_3–SiO_2 system with nitrogen solubility and stable glass-forming ability extending to between 20 and 30 eq.%.[16] The amorphous grain-boundary phase composition in Y-sialon materials can be simulated

by oxynitride glasses in which nitrogen is substituted for oxygen in the Y_2O_3–Al_2O_3–SiO_2 system to produce a more tightly linked glass network. It has been shown that the glassy phase in β-sialon material, with additions of yttria, can be crystallized to yttrium aluminum garnet—YAG—by a post-sintering heat treatment. The YAG crystallization requires either simultaneous Si_2N_2O formation or accommodation of excess Si and N within β-sialon.[17] Crystallization behaviour in oxynitride glasses has been investigated by several researchers. Leng-Ward and Lewis[7] studied glasses having compositions with a constant Y:Si:Al ratio of 1·04:1·27:1·27 with nitrogen contents ranging from 0 to 30 eq.% and reported the replacement of the yttrium disilicate ($Y_2Si_2O_7$) by yttrium aluminum garnet with increasing nitrogen content at 1250°C for 40 h when nitrogen was mainly incorporated into Si_2N_2O. Annealing of the nitrogen glasses at 1100°C produced partial crystallization involving an intermediate phase related to nitrogen-wollastonite ($Y_2Si_2O_4N_2$). Loehman[14] investigated glasses lying on the Y_2O_3–SiO_2–AlN plane of the Y–Si–Al–O–N system and found a general trend to formation of $Y_2Si_2O_7$ as the predominant crystalline phase at 1000, 1100 and 1200°C and longer times. Five intermediate phases (yttrium silicates, yttrium aluminum silicates or nitrogen apatite — $Y_4Si_4O_{11}N_2$) were also observed. Dinger *et al.*[18] studied crystallization of a glass having a composition of $Y_{0.26}Si_{0.30}Al_{0.11}ON_{0.11}$ with the crystallization proceeding by a heterogeneous nucleation mechanism, with intermetallic iron silicides acting as nuclei for the columnar dendritic y-$Y_2Si_2O_7$ species. After secondary crystallization of $YSi_2AlO_4N_2$ in interdendritic regions at 1200°C, the high-temperature polymorph of $Y_2Si_2O_7$ (δ_2–$Y_2Si_2O_7$) formed and became the predominant crystalline phase in glass crystallized at 1300°C and 1400°C. Besson *et al.*,[19] investigating a glass with a similar composition to that of Dinger *et al.*[18] containing 17 eq.% of nitrogen, observed $Y_2Si_2O_7$ in the α form below 1200°C and the β form above this temperature. Crystallization of the YAG phase at 1100°C and $AlYO_3$ with Si_2N_2O at 1250°C and 1300°C was also observed. O'Meara and Dunlop[20] studied crystallization of glass with the composition 53 wt% Y_2O_3, 17 wt% Al_2O_3 and 30 wt% SiO_2 with additions of 8–15 wt% Si_3N_4 at 1200°C for 12 h and found $Y_2Si_2O_7$ (α, β) Si_2N_2O and YAG.

Since nucleation and growth of secondary crystalline phases are unlikely processes in grain boundaries or pockets in Si_3N_4-based ceramics, the full crystallization of the glassy phase in these materials may be difficult. Complete elimination of this glassy phase might be achieved by another mechanism, namely the remaining intergranular phase may form a crystalline solid solution phase. Zirconia provides a good example of this behaviour since its structure can accept considerable amounts of oxides in solid solution. The microstructure of sintered Si_3N_4–$ZrO_2(Y_2O_3)$ ceramics contains extremely small amounts of intergranular phase.[21–25]

Zhao *et al.*[26] found that addition of ZrO_2 to yttria–alumina–silica glasses as a nucleating agent could shorten the incubation period of nucleation and increase the rate of nucleation. Crystallization studies reported by Drummond[3] on three different systems showed that the addition of nucleating agents can result in crystallization of the intergranular phases.

The present study attempts to simulate the intergranular phase in silicon nitride-based ceramics by an yttria–alumina–silica glass with an addition of zirconia. First, three ZrO_2-free powder mixtures were fired at different temperatures to assess their glass-forming tendency on furnace cooling and the obtained glasses were characterized. Following this, the solubility limit of ZrO_2 in a chosen composition at 1700°C was determined by producing a series of glasses with between 0 and 11 wt% ZrO_2. These ZrO_2-containing glasses were characterized. The crystallization behaviour at different temperatures of an appropriate glass with the addition of 6 wt% zirconia was studied.

2 Experimental Procedure

2.1 Sample preparation

The experimental conditions and the composition of all the samples are given in Table 1.

Three powder mixtures in the Y_2O_3–Al_2O_3–SiO_2 system located as indicated in Fig. 1 were fired at 1600, 1650 and 1700°C to determine the glass-forming tendency on furnace cooling (compositions 1A–3C). Samples were prepared from high-purity Y_2O_3, Al_2O_3 and SiO_2 powders (Rhone Poulenc, Alcoa Chemicals, and Johnson Matthey Alfa Products, respectively). The powders were weighed in a precision balance, dry-mixed in polyethylene containers on a Siemens roller mill for 10 h and sieved. Batches of approximately 20 g each were then mechanically compacted into molybdenum crucibles and fired in a nitrogen atmosphere (pressure 0·17 MPa) at temperatures of 1600, 1650 and 1700°C for 3 h. The heating rate up to the firing temperatures was 5°C/min, the cooling rate from the firing temperatures to 1400°C was 20°C/min, from 1400–950°C, 15°C/min and from 950 to 500°C, 10°C/min. The

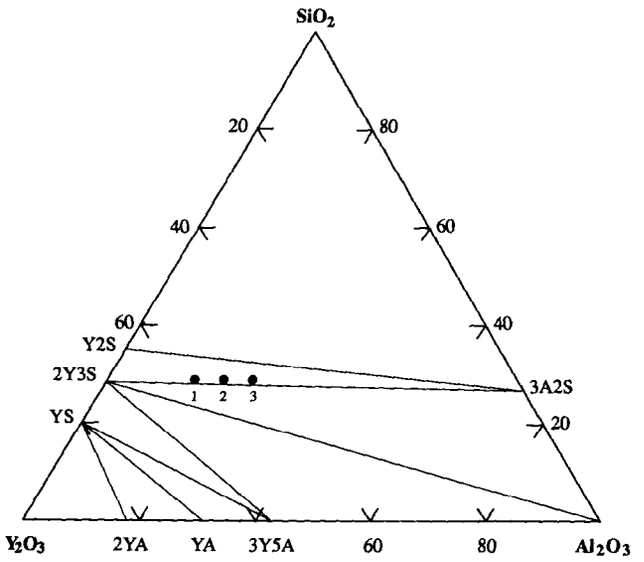

Fig. 1. The Al_2O_3–Y_2O_3–SiO_2 subsolidus phase diagram[6] with the powder mixtures (1, 2, 3) (YS = $Y_2O_3{\cdot}SiO_2$; Y2S = $Y_2O_3{\cdot}2SiO_2$; 2Y3S = $2Y_2O_3{\cdot}3SiO_2$; YA = $Y_2O_3{\cdot}Al_2O_3$; 2YA = $2Y_2O_3{\cdot}Al_2O_3$; 3Y5A = $3Y_2O_3{\cdot}5Al_2O_3$; 3A2S = $3\ Al_2O_3{\cdot}2SiO_2$).

cooling rate was the natural cooling rate of the furnace (cold wall vacuum/pressure furnace with a graphite heater) after it has been switched off. No mass changes were observed.

A glass with composition 4, i.e. with the addition of 8 wt% Si_3N_4 (KemaNord Industrikemi) was prepared at 1650°C using the same procedures as described above; this was used for comparison of the hardnesses of the produced glasses. Glass with composition 5 was prepared in air, also for comparison when subsequently characterizing glasses made in nitrogen. A batch of 20 g was fired in an alumina crucible at 1600°C for 1 h using a rapid high-temperature furnace (maximum temperature of 1600°C).

To evaluate the solubility of zirconia in the yttrium aluminosilicate liquid at 1700°C, increasing amounts of unstabilized zirconia powder (Sigma Chemical) were added to composition 3C to give compositions 6–13 of the type $x ZrO_2$ + (100-x) (46·9 Y_2O_3 · 24·3 Al_2O_3 · 28·8 SiO_2) where x (in

wt%) varied between 0 and 11. The above mixing and firing procedures were used with batches of approximately 10 g each. The firing temperature was 1700°C.

A large 100g batch of composition 8 with 6 wt% of zirconia was also fired applying the same procedures. This glass was used to investigate crystallization of an yttria–alumina–silica glass containing zirconia. To improve the mixing efficiency of such a large batch, propanol was used as the mixing medium.

2.2 Glass characterization

Powder X-ray diffraction (Phillips X-ray diffractometer, CuK_α radiation) was performed on the furnace-cooled specimens to check for crystallization during cooling, to determine the solubility limit of zirconia and to identify crystalline phases in zirconia-containing glass-ceramics after the heat treatment. The lower limit of detectability of the technique lies around 2–5 wt% of a given phase. Differential thermal analysis (DTA) was carried out in a nitrogen atmosphere using an Al_2O_3 powder reference standard and a heating rate 10°C/min. The infrared spectra (IR) were measured using a Perkin-Elmer 1760 X Fourier transform spectrometer equipped with a triglycine sulphate (TGS) detector. The measurements were carried out on discs pressed from powdered samples mixed with KBr. A microhardness tester with a diamond indenter was used to measure Vickers hardness. A load of 200 g was applied for 15 s on the sample whose surface had been polished with a 3-μm spray diamond. At least 10 indentations were made on each sample, the hardness being calculated on the basis of the average length of the indentation diagonals. The density was measured with Archimedes' method, using water as the suspending medium. SEM investigations were carried out using a CamScan S4-80DV electron microscope. The nitrogen contents of the glasses were determined on powdered samples using commercially available equipment, the Leco nitrogen determinator TN-414.

2.3 Crystallization of an Yttria–Alumina–Silica glass containing zirconia

The investigation was carried out on glass composition 8 with 6 wt% of zirconia using an alumina tube furnace with flowing nitrogen. Pieces of approximately 1 g (7 × 7 × 4 mm) were placed in a Si_3N_4 powder bed in alumina–silica boats and heat-treated at 50°C intervals between 950 and 1400°C for 1 h with a heating rate of 250°C/h. After the heat treatment, the samples were removed from the high-temperature zone and cooled rapidly to room temperature in the cold zone, while still in the nitrogen atmosphere.

Table 2. Glass transition temperatures for compositions 3B and 3C from DTA analysis

Composition	*Firing temp. (°C)*	T_g *(°C)*
3B	1650	900
3C	1700	920

3 Results and Discussion

3.1 Yttria–alumina–silica glasses

Table 1 summarizes the results of phase identification of samples furnace-cooled after firing. Only compositions 3B and 3C fired at 1650 and 1700°C gave fully amorphous material (transparent grey-coloured glasses). According to the equilibrium phase diagram,[6] phases expected after cooling from the firing temperatures were yttrium oxide silicates (Y2S = $Y_2O_3.2SiO_2$ and 2Y3S = $2Y_2O_3{\cdot}3SiO_2$) and mullite (3A2S = $3Al_2O_3{\cdot}2SiO_2$). With the exception of Y2S, these phases were not found after the furnace cooling, probably because the cooling conditions were far from equilibrium; it should also be noted that the existence of the 2Y3S phase has not been confirmed and has been questioned.[8,10] In some cases another yttrium oxide silicate phase ($Y_{4.67}[SiO_4]_3O$—JCPDS: 30-1457) was identified instead.

Results from DTA analysis of glasses 3B and 3C are shown in Table 2 and indicate a shift in glass transition temperature. Loehman[13–15] and Ding *et al.*[27] have reported a similar shift of T_g to a higher temperature with increasing nitrogen content.

Hardness of glass can also be an indicator of composition changes. For example, Makishima *et al.*[11] compared the Vickers hardness (200 g, 15 s) of an optical glass containing PbO (4·6 GPa) with an yttria–alumina–silica glass (8·2 GPa). It was found by Hyatt and Day[9] that glasses of high Y_2O_3 content were harder. As shown by Loehman,[13–15] increasing the nitrogen content increases the hardness of the yttria–alumina–silica glasses due to the nitrogen substitution for oxygen in the network to produce a more highly cross-linked structure. Here, the hardnesses of four glasses with the compositions 3B, 3C, 4 and 5 fired under different conditions were examined (Table 3). As expected, the lowest value of Vickers hardness was found for the glass fired in air and the highest for the glass prepared in nitrogen with the addition of Si_3N_4 and containing 1 wt% of nitrogen. Glasses fired in 1650 (≤ 0·1 wt% of

Table 3. Vickers hardness (200 g, 15 s) and density of the selected glasses

Composition	*Firing temp. (°C)*	*VH (GPa)*	*Density (g cm^3)*	*Fired in*
3B	1650	7·69 ± 0·24	3·59	Nitrogen
3C	1700	7·96 ± 0·46	3·63	Nitrogen
5	1600	7·06 ± 0·32	3·54	Air
4	1650	9·22 ± 0·11	3·84	Nitrogen

nitrogen) and 1700°C (≤0·1 wt% of nitrogen) exhibited intermediate values. The results in the present work are therefore comparable to those reported in the above-mentioned studies.[9,11,13–15] Results of the density measurements are also included in Table 3 and are in a good agreement with previously reported data.[27]

The infrared spectra (Fig. 2) of glasses with compositions 3A, 3B, 3C and 5 revealed their structure to be a continuous, closed network. The spectrum of the sample melted at 1600°C (3A) is characterized by the presence of two absorption bands located at 920 and 1100 cm^{-1}. They are associated with the cooperative antisymmetric stretching motion of silica tetrahedra containing bridging Si–O–Si and non-bridging Si–O$^-$ oxygen bonds.[28] The number and sequence of another group of absorption bands (770, 715, 680, 580 and 535 cm^{-1}) can be related to the YAG phase sintered as a standard at 1600°C in air. The spectra of glasses melted at 1650 and 1700°C (3B and 3C, respectively) are characterized by a broad absorption band at 890 cm^{-1}. This broad band is a result of stretching modes of both the Si–O–Si and the Si–O–Al(Y) bonds. These two spectra are very similar to the spectrum of glass melted in air (5). The small shift of this band at 1700°C to 870 cm^{-1} might be related to the contribution of the Si–N bonds,[27,29] but in view of the chemical analysis of the glasses, this contribution to the IR spectrum is

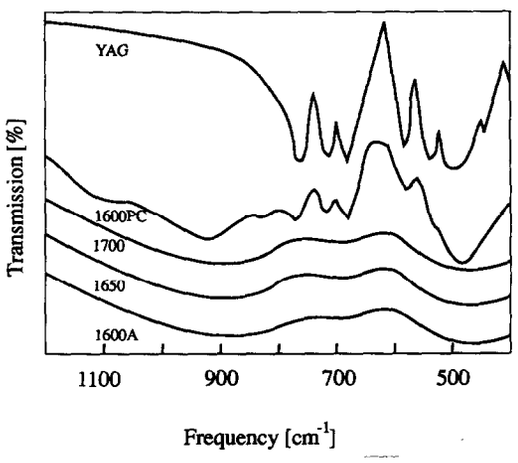

Fig. 2. IR spectra of glasses with compositions 3A, 3B, 3C and 5 prepared at different temperatures and YAG crystalline phases.

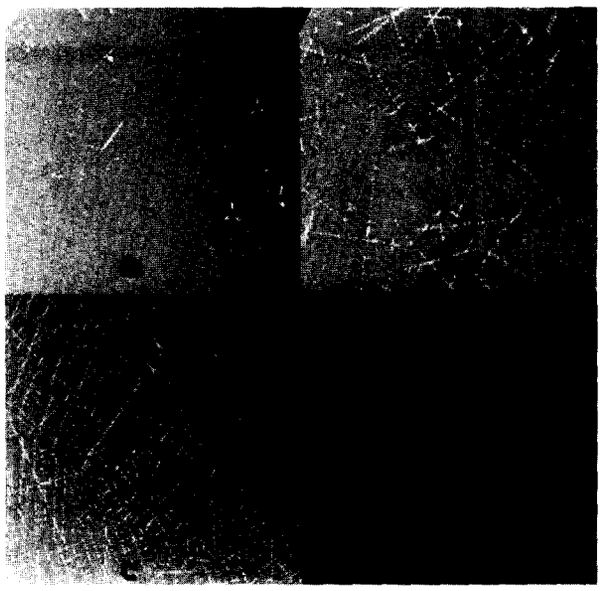

Fig. 3. Microstructures of zirconia-containing yttria–alumina–silica as-quenched glasses (backscatter image — 100×): (a) 7 wt% ZrO_2, (b) 9 wt% ZrO_2, (c) 11 wt% ZrO_2.

probably negligible. However, in general the location of the bond absorption at 870 and 890 cm^{-1} is determined by a strong contribution of Si–O–Al(Y) stretching.

3.2 Addition of zirconia

The X-ray diffraction patterns of compositions 6–8 revealed no crystalline phases to be present. A cubic phase of 'yttria-stabilized zirconia' having a composition of $Y_{0.15}Zr_{0.85}O_{1.93}$ was identified in compositions 9–13 containing more than 6 wt% of zirconia. SEM investigations revealed a dendritic structure of this phase as indicated in Fig. 3.

Results from DTA analysis are shown in Fig. 4. When evaluating the glass transition temperature (T_g) of the ZrO_2-containing glasses, no significant peak above background could be identified on the DTA charts but two endotherms were recorded at 1410 and 1425°C. No mass change occurred in association with the endotherms and therefore they were interpreted as representing melting reactions. The eutectic temperature of the base mixture of oxides without zirconia has been determined as 1430°C (Fig. 4). The lowest endotherm indicates that this eutectic is lowered to 1410°C by the addition of zirconia. The melting process is assumed to proceed as follows:

$$C_1 + C_2 + \ldots \rightarrow L_I + C(\text{compound(s)}) \rightarrow L_{II}$$
$$1410°C \qquad 1425°C$$

This implies that the second melting temperature is due to a monotectic reaction and that consequently liquids L_I and L_{II} are immiscible.[20] Table 4 includes Vickers hardness and density measurements. The densities of samples containing 7 and 8 wt% of zirconia are higher due to the

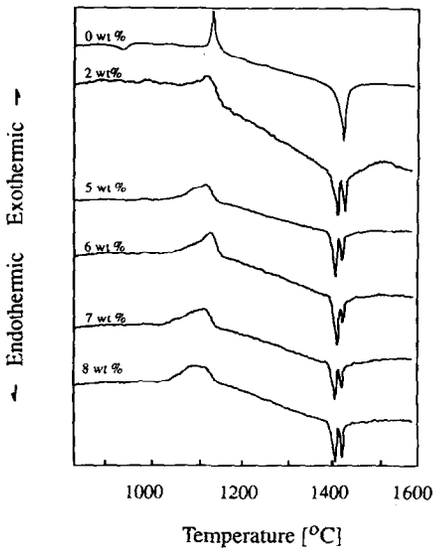

Fig. 4. DTA curves of glasses prepared at 1700°C with different ZrO_2-content.

higher density of the dendritic crystalline phase (5·959 g/cm^3).

3.3 Crystallization of a zirconia-containing glass

Composition 8 with the addition of 6 wt% of zirconia was subjected to heat treatments described in Section 2 in order to investigate the behaviour of ZrO_2 in the glass.

Samples treated at 950 and 1000°C still remained as clear transparent glasses. A sample treated at 1050°C was opaque but no traces of crystalline phases could be detected in its X-ray pattern. Heat treatments at higher temperatures resulted in glass-ceramics with a small amount of glassy phase retained in the structure. Peaks of cubic yttria-stabilized zirconia were found in all of the X-ray diffraction patterns. Other crystalline phases identified by X-ray diffraction analysis are listed in Table 5. They are consistent with those found in previous studies.[2] Yttrium disilicate ($Y_2Si_2O_7$) crystallized from the glass in the form of two polymorphs β (JCPDS-22-1103) and y (JCPDS-32-1448). Small traces of mullite ($Al_6Si_2O_{13}$) were present in all X-ray diffraction patterns.

The Al_2O_3 phase, expected because the existence

1200	y-$Y_2Si_2O_7$, s; β-$Y_2Si_2O_7$, m $Al_6Si_2O_{13}$, vw;
1250	β-$Y_2Si_2O_7$, s; y-$Y_2Si_2O_7$, w; $Al_6Si_2O_{13}$, vw;
1300	β-$Y_2Si_2O_7$, s; y-$Y_2Si_2O_7$, w; $Y_3Al_5O_{12}$, vw; $Al_6Si_2O_{13}$, vw; $Al_6Si_2O_{13}$, vw
1350	β-$Y_2Si_2O_7$, s; y-$_3Al_5O_{12}$, vw; $Al_6Si_2O_{13}$, vw

s is strong, m is medium, w is weak and vw is very weak.

of the 2 $Y_2O_3{\cdot}3SiO_2$ phase has been questioned, was detected neither by X-ray nor SEM analysis, which confirms results by Hyatt and Day.[9] A very small amount of YAG ($Y_3Al_5O_{12}$) was identified after the 1300 and 1350°C treatments by X-ray analysis. It is important to emphasize that the specimens were heat-treated at the elevated temperatures for only 1 h and then quenched very rapidly. Therefore, equilibrium conditions mean reached and consequently some additional, probably intermediate, phases were observed. Although they could not be identified using JCPDS tables, the existence of such phases has been reported in earlier studies.[2,3] Dinger *et al.*[18] reported the existence of a low-temperature, impurity-stabilized y-polymorph of $Y_2Si_2O_7$, that transforms to α-$Y_2Si_2O_7$ upon heating at 1200°C and to δ_1 and δ_2 upon heating above 1200°C. Drummond[3] observed the formation of the β-$Y_2Si_2O_7$ polymorphs when adding zirconia as a nucleating agent. The crystallographic data for the compounds in the Y_2O_3–$NSiO_2$ system have been summarized recently by several investigators (see, e.g. Refs 30 and 31).

SEM investigations in this study revealed that the crystallization of the glass is probably governed by a number of mechanisms acting at different temperatures. The different types of phase transformation observed in the glass can be summarized as follows:

(i) crystallization of β-$Y_2Si_2O_7$;
(ii) crystallization of y-$Y_2Si_2O_7$;
(iii) crystallization of yttria stabilized ZrO_2 (Y–ZrO_2);
(iv) transformation of y-$Y_2Si_2O_7$, to β-$Y_2Si_2O_7$;
(v) transformation of a Y–Al–Si-rich phase to β-$Y_2Si_2O_7$.

At 1100°C, the sample is almost fully crystallized, with only a small amount of retained glassy

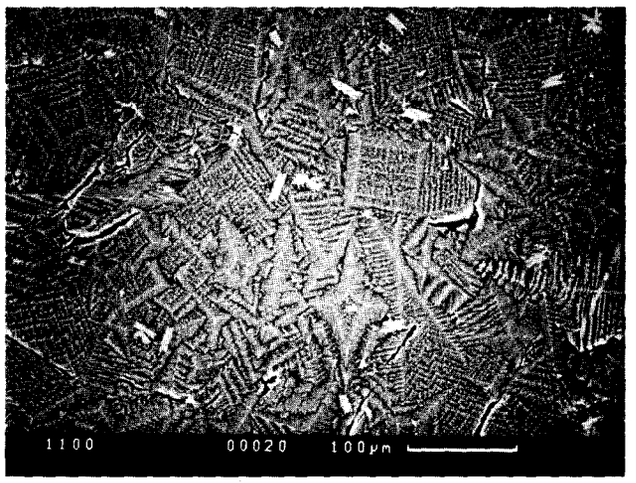

Fig. 5. Crystallization at 1100°C. (backscatter image — 200×).

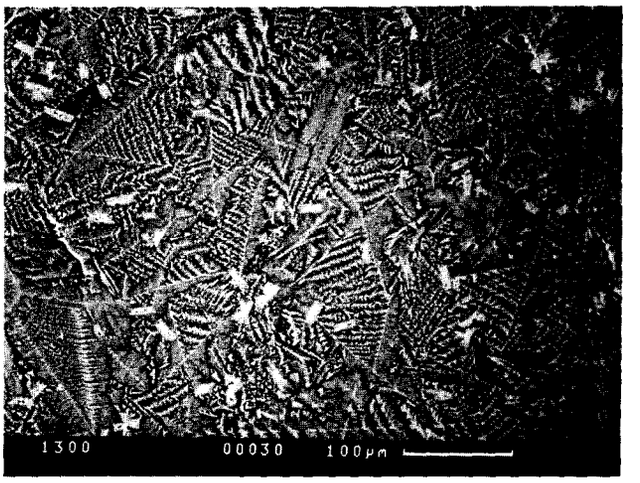

Fig. 7. Crystallization at 1300°C (backscatter image — 200×).

phase (Fig. 5). The y-$Y_2Si_2O_7$ is the dominant phase at this treatment temperature. At 1150 and 1200°C, a Y–Al–Si-rich phase appears in the microstructure and starts to transform to β-$Y_2Si_2O_7$ and probably mullite (Fig. 6). At 1300°C, the β-$Y_2Si_2O_7$ phase begins to dominate the microstructure (Fig. 7) and the y-$Y_2Si_2O_7$ phase also starts to transform to the β-$Y_2Si_2O_7$ phase while the phase transformation of the Y–Al–Si-rich phase continues. At 1350°C, the dominant phase is β-$Y_2Si_2O_7$. The microstructure begins to loose its dendritic appearance and the transformation of the y-$Y_2Si_2O_7$ phase to the β-$Y_2Si_2O_7$ phase continues (Fig. 8).

The transformation of the y- to the α-polymorph was not observed. At higher temperatures the y-$Y_2Si_2O_7$ polymorph starts to transform to the β-$Y_2Si_2O_7$ polymorph (stable at temperatures between 1225 and 1445°C in the binary Y_2O_3–SiO_2 system.[3,10]

4 Conclusions

Properties of yttria–alumina–silica compositions fired in nitrogen at 1600, 1650 and 1700°C have been assessed. The results are consistent with previous studies. ZrO_2 (6 wt%) can be dissolved in the investigated composition of the yttria–alumina–silica liquid at 1700°C. When larger amounts are added, a cubic crystalline phase of 'yttria-stabilized zirconia' with a composition of $Y_{0.15}Zr_{0.85}O_{1.9}$ forms. The hardness and density of the glass increased slightly with addition of ZrO_2·y-$Y_2Si_2O_7$ (at temperatures <1300°C) and β-$Y_2Si_2O_7$ (at temperatures >1300°C) monoclinic phases formed during the crystallization. Very small amounts of mullite in all cases, and yttrium aluminium garnet at 1300 and 1350°C, were also observed. An unidentified intermediate phase rich in Y, Al and Si was observed to undergo a transformation at temperatures ≥ 1200°C, probably resulting in the formation of the β-$Y_2Si_2O_7$ phase.

Thermal Shock Resistance of $KZr_2P_3O_{12}$–$SrZr_4P_6O_{24}$ Ceramics

Biao Zhang & Jingkun Guo

Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai 200050, People's Republic of China

(Received 29 July 1994; revised 7 March 1995; accepted 10 March 1995)

Abstract

The thermal shock resistance of potassium strontium zirconium phosphate (KSZP) ceramics was investigated by quenching in water. The retained strength of the compositions with very low thermal expansion increased greatly after quenching. These compositions can withstand water quench from 1000°C and still retain their strength before quenching. The relationships between thermal shock resistance and strength, Young's modulus, thermal conductivity, thermal stress, and thermal expansion coefficient was discussed. The thermal shock resistance data measured was compared with that of calculated.

1 Introduction

Materials having high thermal shock resistance are needed for high-temperature applications. Generally, there are two principal ways to design and select materials to achieve high thermal shock resistance.[1] The first way involves the avoidance of fracture initiation, and the second is avoidance of catastrophic crack propagation. A figure of merit for thermal shock resistance is given by

$$R = \sigma/\alpha E \propto \Delta T_c \quad (1)$$

where ΔT_c is the maximum step change in temperature without causing fracture, σ the strength of the material, E Young's modulus and α the thermal expansion coefficient. To avoid fracture initiation by thermal shock, the favorable material characteristics include high strength and thermal conductivity (such as Sialon[2]), and low thermal expansion coefficient (such as LAS glass-ceramic and cordierite ceramic). Most of the structural ceramics have a high Young's modulus and a typical catastrophic decrease in the retained strength. However, to minimize the extent of crack propagation, high Young's modulus and low strength are required. These requirements of Young's modulus and strength are just opposite to those necessary for preventing crack initiation.[3] Hence, the microstructures that exhibit both high thermal shock resistance and high thermal shock damage resistance must be carefully designed. In this respect, ceramics with fine grain size, no defects on grain boundary and small porosity (homogenously distributed) are needed for obtaining high thermal shock resistance. In the case of aluminum titanate,[4] Si_3N_4–BN composite,[5] and Y–TZP,[6] low thermal expansion, microcrack, and large grain size are responsible respectively for their high thermal shock damage resistance. High anisotropic expansion induced microcracks at grain boundaries can restrain crack propagation caused by thermal shock. The increase of the contribution of the transformation toughening of large grain size Y–TZP prevent the thermal stress fracture. The present study was concentrated on the effects of thermal expansion on the thermal shock resistance of two KSZP compositions, $K_{1/2}Sr_{1/4}Zr_2P_3O_{12}$ and $K_{1/4}Sr_{3/8}Zr_2P_3O_{12}$, with magnesia (MgO) additions of 0–8 wt%.

2 Materials and Experimental

Compositions of KSZP with 0–8 wt% MgO are given in Table 1. The KSZP powders were synthesized through coprecipitation and the ceramics were prepared by pressureless sintering. Details of the preparation procedure were described in previous papers.[7,8] Sintering conditions and selected properties are shown in Table 1.

Thermal shock tests were conducted by measuring the retained bending strength after quenching samples from successively increasing temperatures into water at 0°C. The specimens were 2·5 × 5 × 25 mm in dimension. The strength and Young's modulus were measured by three point bending over a 20 mm span at a cross-head speed of 0·5 mm/min (Instron 1195). Each number is the mean

result over 5 samples with a maximum dispersion of ±15 MPa.

The measurements for bulk thermal expansion were made on rectangular bars (4 × 4 × 50 mm) using a dilatometer (Model 402-3, Netzsch) from room temperature (RT) to 1000°C at a heating rate of 10°C/min.

The stresses of specimens were determined by using X-ray diffraction method[9] at fixed Ψ (Model D/Max-3A). Strains were determined from 142–143° diffraction angle (2θ) using CrKα radiation at $\Psi = 0°$ and $\Psi = 45°$ on a Φ 40 × 2·5 mm specimen. The total residual stresses (σ_s, includes macrostresses and microstresses) were calculated from the simplified equation:

$$\sigma_s = E \cdot \cot\theta \cdot \Delta 2\theta \cdot \pi/((2(1+\nu) \cdot \Delta \sin\Psi \cdot 180) \quad (2)$$

where Ψ the angle between sample surface and diffraction crystal plane, θ the diffraction angle, $\Delta 2\theta$ the difference of diffraction angle when $\Psi = 0°$ and $\Psi = 45°$, E Young's modulus, and ν Poisson's ratio.

Additionally, thermal conductivities were measured by using a laser heat-conductometer and a differential scanning calorimeter (Model DSC-4, Perkin Elmer).

3 Observations and Discussion

Figure 1 shows the flexural strength of the specimens with various compositions after quenching. The initial strength of K2M5 ceramic is retained up to a critical temperature difference ΔT_c (about 600–800°C) where a sudden decrease in the retained strength occurs. Other ceramics exhibit no instantaneous decline in strength prior to what might be interpreted as a ΔT_c, but do exhibit a more gradual reduction because of microcrack initiation and subcritical crack propagation before ΔT_c is reached. For K2M2 the thermal shock behavior is more complicated.

The retained strength of K2M2 increased markedly after thermal shock. A slight increment of retained strength after thermal shock were observed for K1M2, like that of low thermal expansion aluminium titanate ceramic.[10] It is clear that thermal shock predictions based on so many factors are critically dependent upon the accuracy of that data. The remarkable characteristics of K2M2 ceramic is its low thermal expansion and phase transition. Thermal expansion coefficients of KSZP ceramics are indicated in Table 2. K1 series

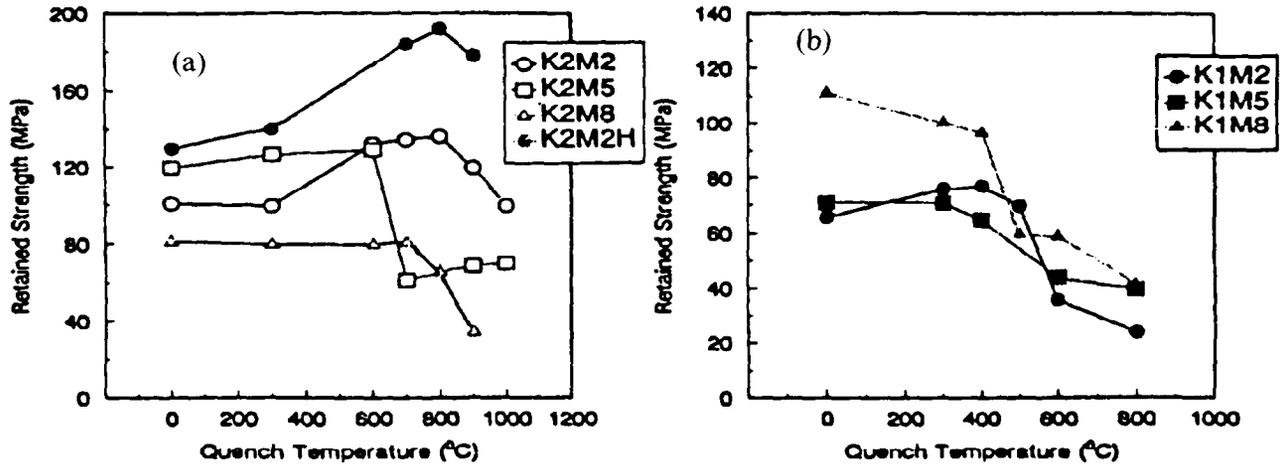

Fig. 1. Thermal shock resistance of (a) K2 series and (b) K1 series of ceramics.

of ceramics exhibit an overall positive and high thermal expansion, while the thermal expansion coefficients of K2 series of ceramics are low or negative below 300°C. The thermal expansion anisotropy of KSZP is low compared with that of KZP.[8]

To clarify the thermal shock fracture behavior of K2 series ceramics, residual stresses after water quench were measured. The results are shown in Fig. 2. The negative value means compressive stress. The more negative the value, the larger the strength. The stress dependence of quenching temperature stand in direct contrast with each other between K2M2 and K2M5. Compressive stress of K2M2, the lower thermal expansion ceramic, increase with quenching temperature increase and has a sharp change from 300 to 600°C, and is in good agreement with strength variation (Fig. 1(a)). Compressive stress of K2M5, the larger thermal expansion ceramic, decrease with quenching temperature increase, and has a gradual decline. It is also corresponding to its thermal shock result.

Residual stress in single-phase polycrystalline ceramics are of two types: macrostresses and microstresses. Macrostresses generally are near the surface because of differences in processing (such as cutting, grading and quenching) between the surface and the interior. Microstresses arise because grains constrain if the grain is anisotropic. Experimental methods to be used for the determination of residual stress should take into account the two types of residual stress as well as the depth over which the method averages the measurements.[11] A method for separating the macrostresses from the microstresses has been developed by Noyan and Cohen.[12] In this work, the stresses were calculated approximately from eqn (2) as total stresses. Although unable to separate macrostresses from microstresses at these moments, the general trend of stress variation is enough to explain the thermal shock behavior.

As illustrated in Fig. 1(a), the pressureless sintered and hot pressed K2M2 ceramics exhibit similar behavior. Under optical and scanning electron microscope, no obvious cracks were observed. The reason why the significant improvement of residual strength of the K2M2 ceramic after thermal shock is that the ceramic has a very low thermal expansion and phase transition. Below 400°C, the ceramic exhibits negative expansion, whereas above 400°C, it is positive. A phase transformation occurs at 600°C in $K_{1/2}Sr_{1/4}Zr_2P_3O_{12}$ ceramic.[8] The cell volume of the high-temperature phase is larger than that of the low-temperature phase. The phase transition still exists in the K2M2

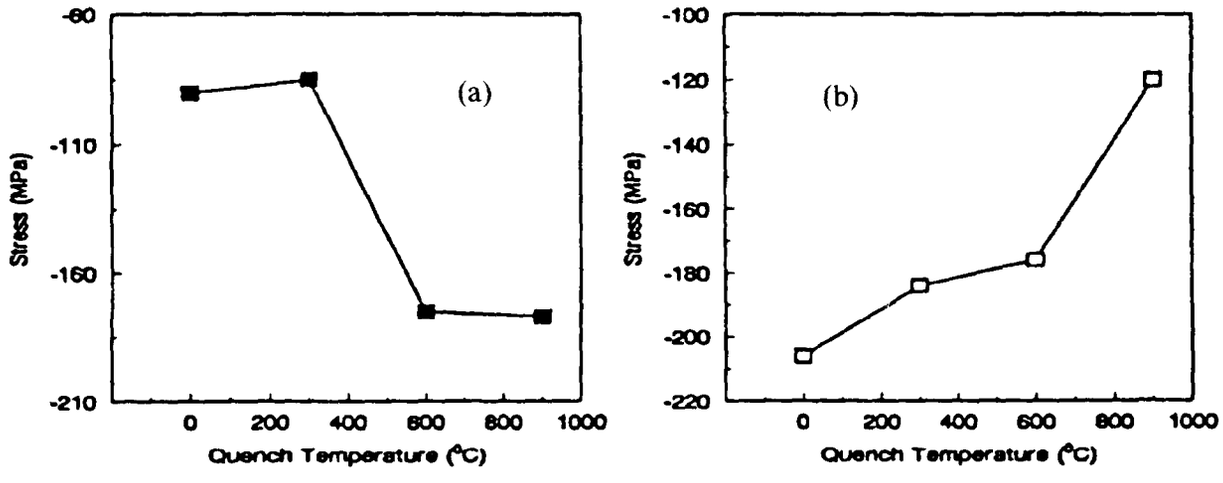

Fig. 2. Total stresses of (a) K2M2 and (b) K2M5 ceramics after water quench from high temperature.

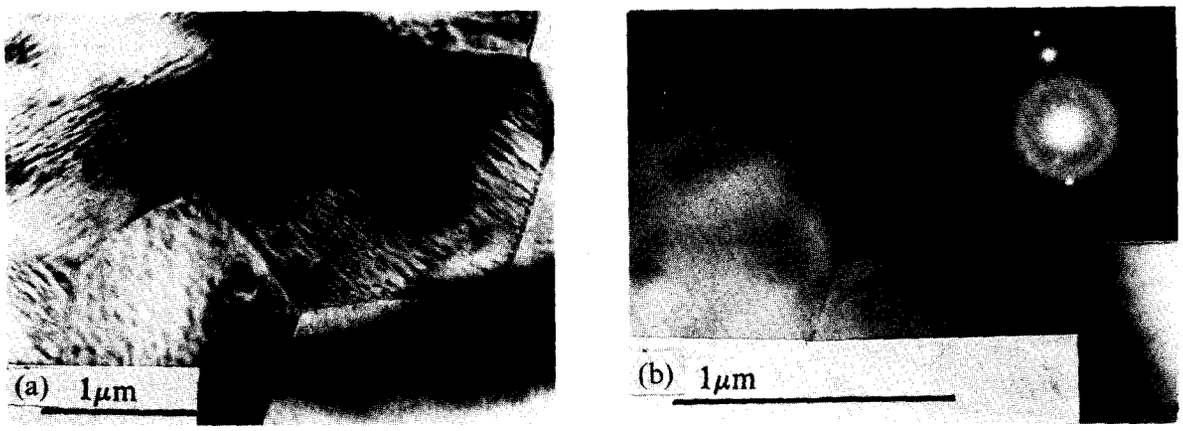

Fig. 3. Microstructure of grain boundaries: (a) bright-field micrograph showing clear boundaries K2M2, and (b) amorphous phase at triple-grain junction and electron diffraction pattern of K2M5 being attached.

ceramic, but it is restrained in K2M5 ceramic. During quenching, the surface region of the specimen cools quickly and shrinks until the temperature reaches 400°C and expands, but the core of the sample cools slowly and still contracts when the surface expands. The surface remains the high-temperature phase and the core transforms to the low-temperature phase. Therefore, the surface is constrained and compressive stresses were formed on the surface. The increment of retained strength occurred just as in strengthened glass. Another reason for high thermal shock resistance of the K2M2 ceramic is no glass phases at the intergranular regions, as suggested by Hoffmann[13] that the ΔT may be connected with the softening of glass phase. TEM micrographs (Fig. 3) show the clear boundaries and junctions of grains for the K2M2 ceramic, but for the K2M5 ceramic, an amorphous phase is observed at triple grain junctions. The residual strength of K2M5 after 1000°C water quenching was a little larger than that of 700°C water quench. This is because that the density of cracks caused by thermal shock increased with increasing ΔT.

For other ceramics, a gradual strength decay is observed. Normally, with most large-grain and large pore ceramics, the retained strength declines slowly when ΔT just exceeds ΔT_c. Relatively, the strength and density of the KSZP ceramics are low and are difficult to sinter, especially for K1 and K2 which have no addition of MgO. For this reason, the thermal shock tests were not conducted on K1 and K2 ceramics.

The application of eqn (1) to KSZP ceramics is shown in Fig. 4(a). The data shows a good fit to eqn (1). Precise theoretical calculations for thermal shock resistance based on material parameters is very difficult. The disagreement between experimental observations and predictions can be attributed to the difference in test methods and inexact property data,[14] especially temperature dependence of mechanical and thermal properties.

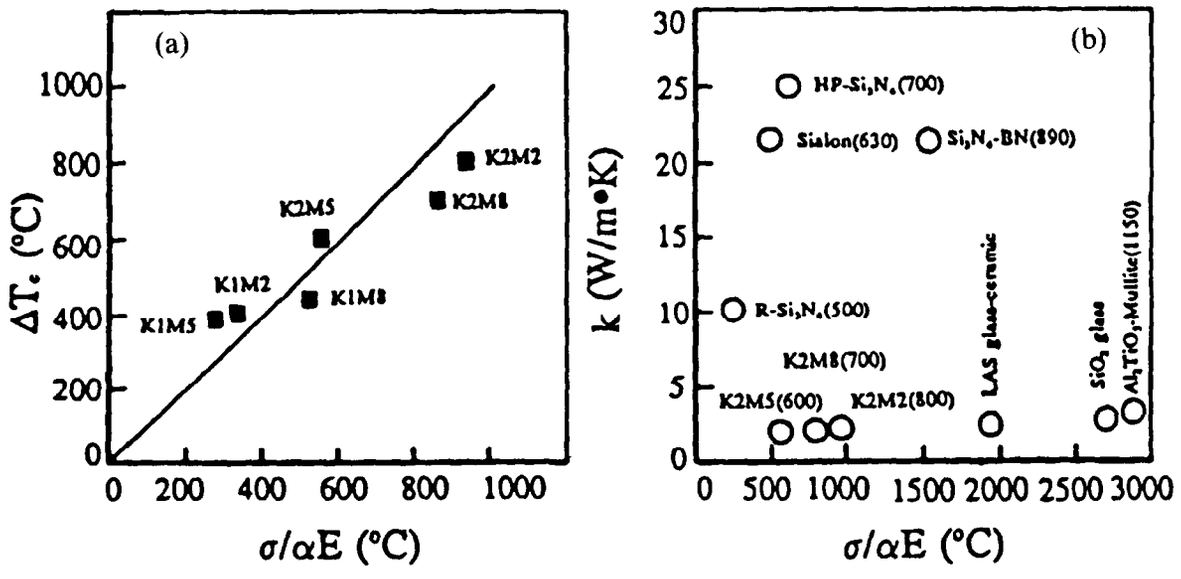

Fig. 4. (a) Thermal shock resistance of KSZP ceramics measured and described in eqn (1), (b) thermal conductivity and thermal shock resistance of SKZP and other ceramics (Refs 2, 5, and 10. The values in parentheses mean ΔT_c).

As is illustrated in Table 2, thermal expansion coefficients, especially low thermal expansion material, are not constant over all the temperature range. They vary significantly in different temperature ranges. It is not clear what an appropriate value for α and σ should be.

Figure 4(b) summarizes the most important properties (k, thermal conductivity, σ, strength, α, the coefficient of thermal expansion, and E Young's modulus) of high thermal shock resistant ceramics. It is indicated that there are two major categories of high ΔT_c ceramics, one with high strength and thermal conductivity, and another with low thermal expansion coefficient. To make an optimum material design and selection of high thermal shock resistant ceramics, guidelines on some factors are needed: high strength, toughness, thermal conductivity, low thermal expansion, less thermal expansion anisotropy resulting in microstructures that can cope with thermal stresses without developing creep cavitation.

4 Conclusions

$KZr_2P_3O_{12}$–$SrZr_4P_6O_{24}$ (0–8 wt% MgO) ceramics possessing low thermal expansion, high thermal shock resistance and high strength have been studied. Thermal expansion coefficients varied in the range of $-4{\cdot}68 \sim 3{\cdot}97 \times 10^{-6}$°C. The thermal shock behavior of low thermal expansion ceramics exhibited some interesting features. The retained strength and compressive stress on the surface of the K2M2 ceramic increased with increasing quench temperature (from 100 MPa at RT to 136 MPa at ΔT = 800°C for pressureless sintered and from 130 MPa at RT to 192 MPa at ΔT = 800°C for hot pressed K2M2 ceramic). The thermal expansion behavior, single phase microstructure, and phase transformation are responsible for its thermal shock behavior. The critical quenching temperature difference varied from 400 to 800°C for KSZP ceramics, which might be used as thermal barrier materials.

Fast Firing of Alumina

D. E. García, J. Seidel, R. Janssen & N. Claussen

Technische Universität Hamburg-Harburg, Advanced Ceramics Group, D-21071 Hamburg, Germany

(Received 2 August 1994; revised version received 16 March 1995; accepted 31 March 1995)

Abstract

Densification behavior and mechanical performance of alumina fast fired at relatively low temperatures were evaluated and compared to those of conventionally sintered alumina. A density of about 99% of the theoretical value and a grain size of 1·2 μm were achieved by firing pure alumina powder compacts at 1350°C for 20 min. Fast fired alumina exhibits room temperature strengths (520 MPa) and Weibull moduli (10·4) nearly comparable to those of conventionally sintered alumina although very high heating/cooling rates were used. A qualitative densification model is presented based on the beneficial effects of transient mismatch stresses.

1 Introduction

Rapid sintering (fast firing), which is known to provide equivalent densities at smaller grain sizes in a less energy-consuming process, has been reported for a number of materials.[1–8] It generally involves rapid insertion of a specimen into a preheated furnace at high temperatures followed by soaking for shorter times than used in conventional sintering. Although the validity of the fast firing concept has been confirmed for several ceramic materials, the mechanism has not been fully identified. Basically the superior densification is attributed to the rapid passage of a specimen through the low temperature regime where grain coarsening dominates into the region where densification mechanisms prevail, resulting in dense products in very short firing times. Using this concept, Johnson[9] modeled rapid initial stage sintering of Ag and found that the heating rate and particle size parameters have a large effect on the sintering behavior. He concludes that rapid sintering and its beneficial effects are uniquely associated to fine particles sizes.

During fast firing, energy is absorbed in the surface of the material which is then transferred into the bulk of the sample by heat conduction. Because thermal conduction takes a finite amount of time, temperature gradients within the sample exist until the sample achieves thermal equilibrium. The importance of temperature gradients in mass transport was stressed by Braudeau *et al.*,[10] and calculations of Searcy[11] suggest that temperature gradients are essential in driving densification during fast firing. Enhanced diffusion is therefore held to be responsible for accelerated sintering in fast firing.

In contrast to these findings, Morgan and Yust,[12] studying the rapid heating of ThO_2 compacts, observed that the increase in densification rate was much greater than the corresponding increase in the diffusion coefficient of the slower diffusing species. They explain their results in terms of material transport by dislocation movement or 'plastic flow'. Furthermore, it is interesting to point out that fast firing and the well known rate controlled sintering concept[13] are somehow in conflict, although both approaches are aimed at the fabrication of advanced ceramics with high density and small grain size. Whereas the first one requires very fast densification rates, the second one is based on the control of densification rates within certain limits through all stages of densification in order to avoid, e.g. premature pore closure, gas entrapment and rapid grain growth.

In the present paper, we focus on fast firing of Al_2O_3 with respect to the benefits in energy savings and production time. Harmer *et al.*[4] have already shown that pure alumina can be fired in 2 min to 95·5% of the theoretical density (T.D.), however, at 1850°C which is a major disadvantage. Therefore, the feasibility of fast firing pure Al_2O_3 at lower temperatures was studied. The intent of the present paper is to further understand fast firing and to compare the mechanical performance of rapidly and conventionally sintered alumina.

2 Experimental Procedure

Commercial Al_2O_3 powder† of high purity (99·99%) and small grain size (~0·2 μm) was used to fabricate bars (4 × 5 × 40 mm) by uniaxial pressing of

†Taimei Chemical Co. LTD, TM-DAR.

the as-received powder at 50 MPa in a steel die followed by cold isostatic pressing at 800 MPa. Green densities of 57% T.D. were attained. The specimens were heated to 200°C prior to firing in order to remove adsorbed water. The fast firing process was carried out at 1350°C using a standard box furnace. To obtain the highest heating rates possible, the samples were introduced rapidly into the preheated furnace. After sintering for various times, the samples were taken out of the furnace and cooled in air. The free cooling to room temperature took about 15 min. Polished specimens cut from samples sintered for 20 min were thermally etched in air at 1300°C for 30 min in order to examine the microstructure and to identify possible strength-determining defects. The average grain diameter was measured using the linear intercept technique.

Fracture strength was measured in 4-point bending according to German standard DIN 51110 but with rectangular bars of reduced length (25 × 4 × 3 mm) and loading spans of 10 and 20 mm. The tensile side was polished to a 3 μm surface finish and the edges were bevelled. The scatter of strength data and Weibull moduli was analyzed as described elsewhere.[14]

3 Results and Discussion

Fast firing of pure alumina by rapid insertion and removal using a preheated furnace includes extremely high heating and cooling rates, and a certain soaking time at maximum temperature. In Fig. 1, final mean densities are summarized as a function of soaking time at 1350°C. A density of 95·4% T.D. was obtained by conventional firing using a heating rate of 15 K min^{-1} and a soaking time of 20 min. Even without densification during the heating period, fast firing yielded final densities of about 99% T.D just by soaking for 20 min. The average grain size is 1·2 μm about 30% smaller than those reported by Seidel *et al.*[14] after conventional sintering using low heating rate (10 K min^{-1}) and soaking for 120 min at 1350°C. The morphology of the microstructure, however, is very close to conventionally sintered pure alumina as shown in Fig. 2. Therefore, the fast firing approach as outlined by Brook *et al.*[4-7] can be used to fabricate highly dense and fine grained alumina within very short periods of time, e.g. cycle time from room temperature to room temperature of ~30 min.

In a strict discussion, however, the density distribution during the initial stages of fast firing must also be considered. For example, Fig. 3 represents a part of the cross section of fast fired alumina after soaking for 8 min at 1350°C showing a dense

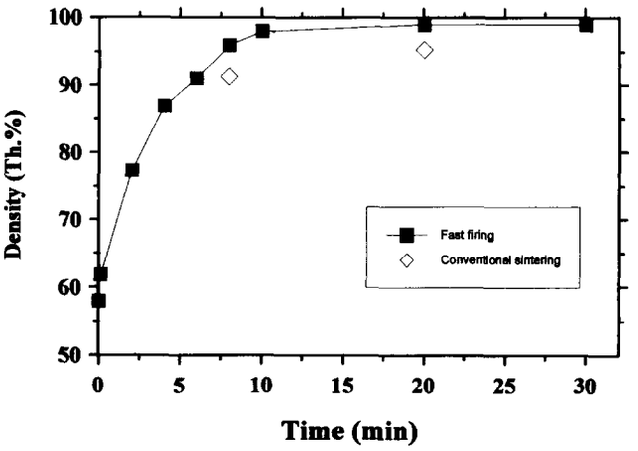

Fig. 1. Average density versus soaking time at 1350°C (note: densities plotted are determined after quenching to room temperature).

Fig. 2. Microstructure of alumina fast fired at 1350°C for 20 min.

outer layer and a porous inner core of the sample as well as a transition from dense to porous within less than 100 μm. Neglecting small gradients within the porous and dense region, the transition can be termed as interface 'porous/dense'. During soaking, this interface migrates from the surface to the center of the sample. Optical microscopy of

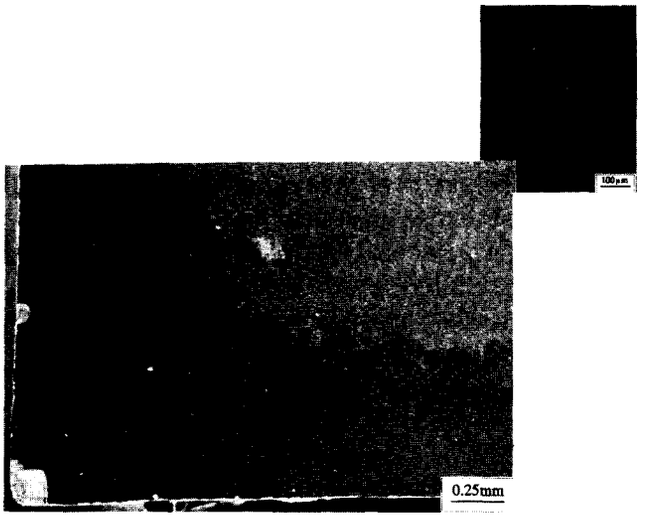

Fig. 3. Cross section of fast fired alumina after 8 min at 1350°C. The interface dense/porous is shown in the upper right at higher magnification.

samples quenched after various soaking times corroborates the evidence for a migrating interface 'porous/dense'. However, micrographic reproduction proved difficult due to low contrast and the small scale of pores and grains. In contrast to fast firing, conventional sintering at 1350°C/8 min using a heating/cooling rate of 15 K min^{-1} results in homogeneous microstructures without density gradient.

It is necessary to point out that the creation of an interface 'porous/dense' in fast fired samples is associated with the formation of transient stresses due to the shrinkage mismatch. Considering these stresses, a schematic of our understanding of the densification progress during fast firing is given in Fig. 4 contrasting the migrating densification front with the transient mismatch stresses during a given fast firing experiment at various times. For simplicity, the interface is considered as infinite. In the following, each situation is discussed in turn.

t_0: The green sample is just inserted into the preheated furnace. The surface of the sample is heated to temperatures close to the temperature of the furnace predominantly by radiation heat transfer, whereas the core remains almost at room temperature (assuming heat conduction as the velocity determining mechanism). However, a notable densification and, therefore, transient stresses caused by shrinkage mismatch are not yet formed. Considering the calculations of Searcy[11] the large

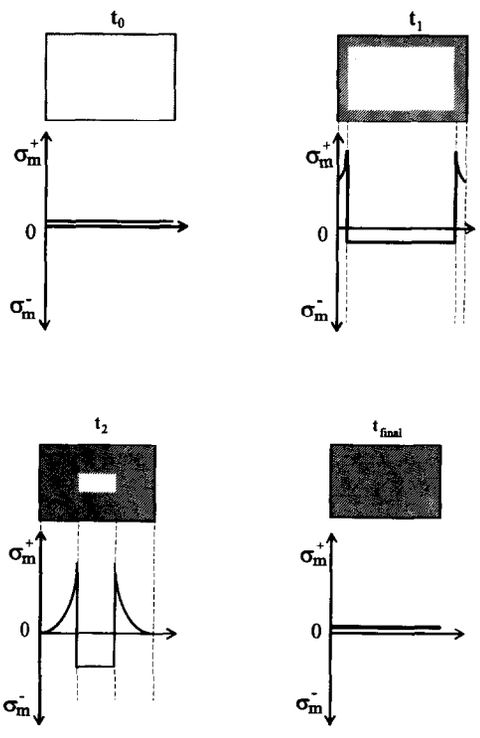

Fig. 4. Schematics contrasting densification progress and transient mismatch stresses during fast firing for the (a) porous compact, (b) initial and (c) medium state during fast firing and (d) final product after prolongated soaking at T_{max}, (note: stress relaxation effects are neglected and the interface is considered as infinitesimal thin).

thermal gradient formed may cause an enhanced mass transport although the following scheme holds also assuming conventional mass transport.

t_1: A small surface layer is densified to a certain extent. Tensile stresses are formed in this layer, however, they are overruled by high sintering potential resulting in a first densification of the outer layer (the rate of densification is neglected for this simplified discussion). The compressive stresses at the interface enhance the densification of the porous region. Due to easy stress relaxation, the stresses are only effective within a small area considering the grain size as characteristic length of microstructure.

t_2: The interface has moved further and, therefore, densification caused by transient stresses proceeds in the interior. The center core, however, is still porous (cf. Fig. 3). The densification already present is associated with volumetric shrinkage of the sample and, therefore, with mass transport from the outer dense to the inner porous part.

t_{final}: The sample is almost fully densified, i.e. after 20 min soaking at 1350°C. Furthermore, transient stresses caused by constrained sintering are diminished due to creep relaxation. The microstructure of the final product (Fig. 2) is similar to conventionally sintered pure alumina.

In summary, besides the densification mechanism mentioned generally for fast firing, transient stresses play an important role improving densification. We should point out that subleties like densification by stress induced diffusion are not included here and may provide an additional effect for the very fast densification observed. Specimen composition and size effects are also not included since these do not effect the basic influence of transient stresses, however, they can be used to improve our understanding of fast firing. For instance, the specimen thickness can be used to calculate the rate of interface movement. Considering the present results (cf. Fig. 1), we can estimate an interface movement of 4 $\times 10^{-6}$ ms^{-1}. For a quantitative analysis, one would have to face for example the rate of heat transfer to the surface, the heat conduction within the sample as well as stress relaxation kinetics. Calculations of heat conductivity, however, are particularly difficult due to non constant parameters during fast firing, i.e. pore size distribution.

Nevertheless, while appreciating that we present a simplified picture of fast firing, the results can be linked to previous work. For instance, Johnson[9] concluded in his review that rapid sintering is a phenomena unique to fine particle sizes. Considering the model presented, it is obvious that reactive fine particles are required in order to overrule the tensile stresses in the dense region by high sintering potential as well as to enhance stress relaxation by creep phenomena.

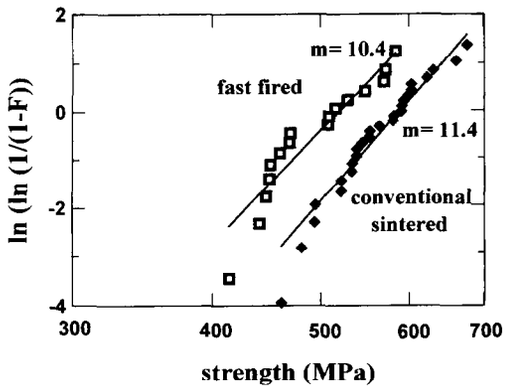

Fig. 5. Bending strength distribution (Weibull plot) of alumina fast fired at 1350°C for 20 min and conventional alumina sintered at 1350°C for 2 h.[14]

The preliminary results of fracture strength of fast fired alumina indicate that there is almost no severe strength degradation when compared to conventionally sintered alumina. Fig. 5 shows the strength distributions of fast fired and conventionally sintered alumina,[14] with an average strength of 520 and 564 MPa and Weibull moduli of 10·4 and 11·4, respectively. The solid lines through the strength data are curves representing the fit on the basis of a two parameter Weibull approach.

Polished surfaces investigated reveal defects of about 10–15 μm in the form of voids, as shown in Fig. 6, probably originating from powder agglomerates in the green compact. However, there is no indication of a change of the defect character when compared to conventional sintering. The small drop in strength and the corresponding increase in flaw size may be attributed to the transient tensile stresses in the surface region during fast firing, resulting in an expansion of flaws already present prior to heat treatment. With this hypothesis, nearly defect-free green bodies as well as further enhanced stress relaxation by creep is required for obtaining high strength alumina by fast firing.

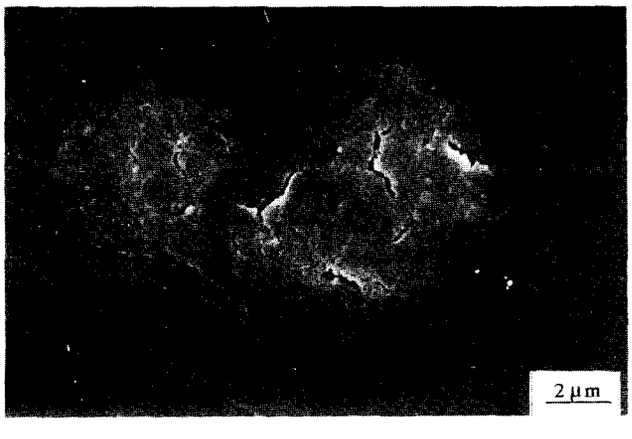

Fig. 6. SEM micrograph of polished surface showing typical defects in fast fired alumina.

4 Conclusions

Using fine reactive powders, the fast firing approach can be used to fabricate alumina within very short production times at low temperature. Transient stresses caused by constrained sintering are formed during fast firing. These stresses accelerate densification and enhance the formation of a dense, fine grained microstructure. The mechanical performance of the final product is, in first approximation, comparable to conventionally sintered alumina.

Effect of Solid Solution Additives on the Sintering of Ultra-fine CeO_2 Powders

M. N. Rahaman[a] & Y. C. Zhou[b]

[a]University of Missouri–Rolla, Department of Ceramic Engineering, Rolla, Missouri 65401, USA
[b]Institute of Metal Research, Academia Sinica, Shenyang 110015, P. R. China

(Received 12 September 1994; revised 6 March 1995; accepted 10 March 1995)

Abstract

Ultra-fine CeO_2 powders (particle size ≈10–15 nm) containing up to 20 at% of various divalent and trivalent cations (Mg^{2+}, Ca^{2+}, Sc^{3+}, Y^{3+} and Nd^{3+}) were prepared by chemical precipitation under hydrothermal conditions. The effects of the cation concentration, size and valency on the densification and grain growth of the compacted powders were examined during sintering at a constant heating rate of 10°C/min. Compared to undoped CeO_2, all of the additive cations caused a shift in the densification curve to higher temperatures. However, the density and grain size achieved after sintering depended significantly on the elemental composition of the additive. When the radii of the additive cations were larger than that of the host Ce^{4+} cation, (i.e. Ca^{2+}, Y^{3+} and Nd^{3}), nearly full density and ultra-fine grain size were achieved. Under identical sintering conditions, lower density (≈93–95% of the theoretical) and larger grain size were achieved when the radii of the additive cations were smaller than that of the host, (i.e. Mg^{2+} and Sc^{3+}). Powders doped simultaneously with two cations, (e.g. Ca^{2+} and Mg^{2+}) showed sintering and grain growth characteristics which were intermediate between those for the powders doped with single cations at the equivalent concentration.

1 Introduction

Materials with ultra-fine grained microstructure (sometimes referred to as nanocrystalline materials) have been the subject of much recent investigation.[1–8] While considerable attention has been devoted towards the preparation of ultra-fine particles and the production of thin films by vapor phase or sol–gel techniques, the production of bulk materials with controlled density and grain size by the sintering of ultra-fine particles has received little attention. Due to their ultra-fine size, typically of the order of 10 nm or so, nanocrystalline powders have a fairly large fraction of molecules residing in the surface of the particles. Nanocrystalline solids also contain a large number of grain boundaries per unit volume. The consequences of these characteristics for sintering and grain growth have not been determined.

An understanding of the sintering behavior of ultra-fine powders is also important for the application of nanocrystalline materials. The driving force for densification increases and the diffusion distance for matter transport decreases with a decrease in the particle size. From the point of view of materials fabrication, a key benefit of ultra-fine powders, therefore, is the reduction in the sintering temperature. Many properties are dependent on the grain size of the fabricated body. Another key benefit is the production of ultra-fine grained microstructures. Such microstructures are of great practical interest for the investigation of structure–property relationships in polycrystalline materials. A problem is that non-densifying processes such as vapor transport and surface diffusion are also enhanced with a decrease in the particle size.[9] These processes lead to coarsening of the microstructure and, consequently, to the reduction in the driving force for densification. The benefits of the ultra-fine particle size for sintering are therefore not clear.

The reduction in the sintering temperature of ultra-fine powders has been observed in a number of studies.[3,7,8] However, the production, by sintering, of materials with high density and ultra-fine microstructure has experienced difficulties. Rapid grain growth in the final stage of sintering has been a common problem so that the achievement of high density has normally been accompanied by relatively large grain size.[3,7]

In an earlier study, the present authors investigated the sintering of ultra-fine CeO_2 powders which were prepared under hydrothermal conditions.[10] Nearly full density and ultra-fine grain size

(less than ≈200 nm) were obtained by careful control of the heating schedule or with the use of powders doped with yttrium. The present paper describes a more detailed study of the preparation and sintering of doped, ultra-fine CeO_2 powders. The effects of substituting cations differing in valency and ionic size were investigated. Of particular interest was the effect of the additive cations on the morphology and chemical homogeneity of the synthesized powders and on the sintering and grain growth of the compacted powders. CeO_2 was considered to be a useful model system for these studies because of its relatively simple cubic fluorite crystal structure[11] and its high solid solubility for many cations.[12] In addition, it does not undergo any known crystallographic transformation during the normal range of heating. The results are expected to be relevant to the general understanding of the sintering behavior of ultra-fine powders and to the elucidation of the role of dopants in sintering. Solid solutions of CeO_2 have also been attracting considerable interest as solid electrolytes with high ionic conductivity for applications in fuel cells.[13,14] The present study may also be useful for the microstructure control of CeO_2 solid electrolytes.

2 Experimental

2.1 Hydrothermal synthesis of CeO_2 powders and doped CeO_2 powders

Powders of undoped CeO_2 and of solid solutions of CeO_2 containing up to 20 at% of Mg, Ca, Sc, Y and Nd were prepared by hydrothermal techniques. The starting materials for the preparation of the powders consisted of Analar Grade nitrate or chloride salts of the appropriate metals with a purity greater than 99.9%: cerium (III) nitrate hexahydrate,* $Ce(NO_3)_3.6H_2O$, magnesium nitrate hexahydrate,† $Mg(NO_3)_2.6H_2O$, calcium nitrate tetrahydrate,† $Ca(NO_3)_2.4H_2O$, scandium nitrate hexahydrate,† $Sc(NO_3)_3.6H_2O$, yttrium chloride hexahydrate,* $YCl_3,6H_2O$, and neodymium nitrate hexahydrate,† $Nd(NO_3)_3.6H_2O$.

In the hydrothermal synthesis of the powders, the appropriate amounts of cerium nitrate (for the undoped CeO_2) or a mixture of cerium nitrate and the desired metal salt, (e.g. yttrium chloride, for the CeO_2 solid solution containing yttrium) were dissolved in distilled water and ammonium hydroxide solution was added, under vigorous stirring, to produce a sol at pH = 10. The gelatinous precipitate was filtered, washed with distilled water and then transferred to a Teflon tube which was sealed with a cap and placed in an autoclave. Hydrothermal synthesis was performed for 4 h at ≈300°C and under a pressure of ≈10 MPa. After rapid cooling, the product was washed with distilled water, dried in air at room temperature and then ground lightly in an agate mortar and pestle. Finally, the powder was calcined at 200°C for 2 h. The preparation conditions were kept almost identical for each powder composition.

2.2 Sintering of the compacted powders

Powder compacts (6 mm diameter by 4 mm) were formed by uniaxial pressing in a die at ≈50 MPa in a tungsten carbide die. The compacts were sintered in air in a dilatometer which allowed continuous monitoring of the shrinkage kinetics. The sample holder and pushrods of the dilatometer were made of high purity alumina. Sintering was performed at a constant heating rate of 10°C/min to 1350–1400°C. The density of the sample at any temperature was determined from the initial density and the measured shrinkage. The final density was checked by Archimedes' method.

2.3 Characterization of the powders and sintered materials

The ultra-fine powders prepared by hydrothermal synthesis were characterized by X-ray diffraction (XRD), thermogravimetric analysis (TGA), differential thermal analysis (DTA) and transmission electron microscopy (TEM). The TGA and DTA analyses were performed at a heating rate of 10°C/min. Analysis of the crystal structure of the powder was performed in a diffractometer (Scintag XDS 2000) using Cu K_α radiation at a scan rate of 2° 2θ min^{-1}. Crystallite size was measured from XRD patterns at a scan rate of 0·5° 2θ min^{-1}. The crystallite size, H, was calculated from the Scherer formula:

$$H = \frac{0{\cdot}9\,\lambda}{\beta \cos\theta} \tag{1}$$

where λ is the wavelength of the X-rays, θ is the diffraction angle, and β is the corrected half width given by:

$$\beta^2 = \beta_m^2 - \beta_s^2 \tag{2}$$

where β_m is the measured half width and β_s is the half width of a standard CeO_2 sample with a crystal size greater than 100 nm. The reflection from the (422) plane, occurring at 88° 2θ, was used for the crystallite size measurement.

Transmission electron microscopy was also used to characterize the powders. Samples were prepared by dispersing the powder in ethanol and then putting a drop of the suspension on a holey

*Aldrich Chemical Co., Milwaukee, WI, USA; †Johnson Matthey, Seabrook, NH, USA.

carbon film and allowing it to dry. The microstructure of the powders was observed in a Philips EM-420 transmission electron microscope. In addition, the microstructure of the CeO_2 powders doped with Y and Ca was observed in a JEOL-2000FXII high resolution electron microscope. The distribution of the dopants in the doped powders were analyzed by energy dispersive X-ray analysis (EDX).

The microstructure of the sintered samples was observed using scanning electron microscopy (SEM) of fracture surfaces. The grain size was measured by the line intercept method. The microstructure of selected samples were also observed in a JEOL-2000FXII high resolution electron microscope. The samples for TEM were prepared by cutting to a thickness of ≈0·5 mm, followed by mechanical polishing to ≈25 μm and finally ion beam milling at 5 kV using an incident angle of 15°. Phase composition of the sintered materials was analyzed by XRD of powder samples at a scan rate of 2° 2θ min^{-1}.

3 Results

The results of the present work allowed an investigation of the effects of solid solution additives on the sintering of compacted CeO_2 powders. Since the characteristics of the synthesized powder can have a significant influence on the sintering behavior, it is important to determine how these characteristics are controlled by the concentration and elemental composition of the additive. Figure 1 shows the effect of dopant concentration on the characteristics of the powder doped with yttrium. The TEM micrographs show powders of undoped CeO_2 (a), and CeO_2 doped with Y^{3+} at concentrations of 6 at% (b), 10 at% (c) and 20 at% (d). The undoped CeO_2 powder consists of polyhedral shaped particles with an average size of ≈12 nm (as measured by X-ray line broadening). The average size measured by TEM was ≈14 nm, which agrees well with the value obtained by X-ray line broadening. The powders doped with 10 and 20 at% yttrium have an average size and shape that are close to that for the undoped powder. However, the powder containing 6 at% Y^{3+} shows a fairly significant difference in size. The average particle size obtained from X-ray line broadening measurements for the powder doped with 6 at% Y^{3+} was 9 nm.

The effect of the elemental composition of the dopant on the characteristics of the synthesized powder is shown in Fig. 2 for undoped CeO_2 powder (a) and for doped CeO_2 powder containing

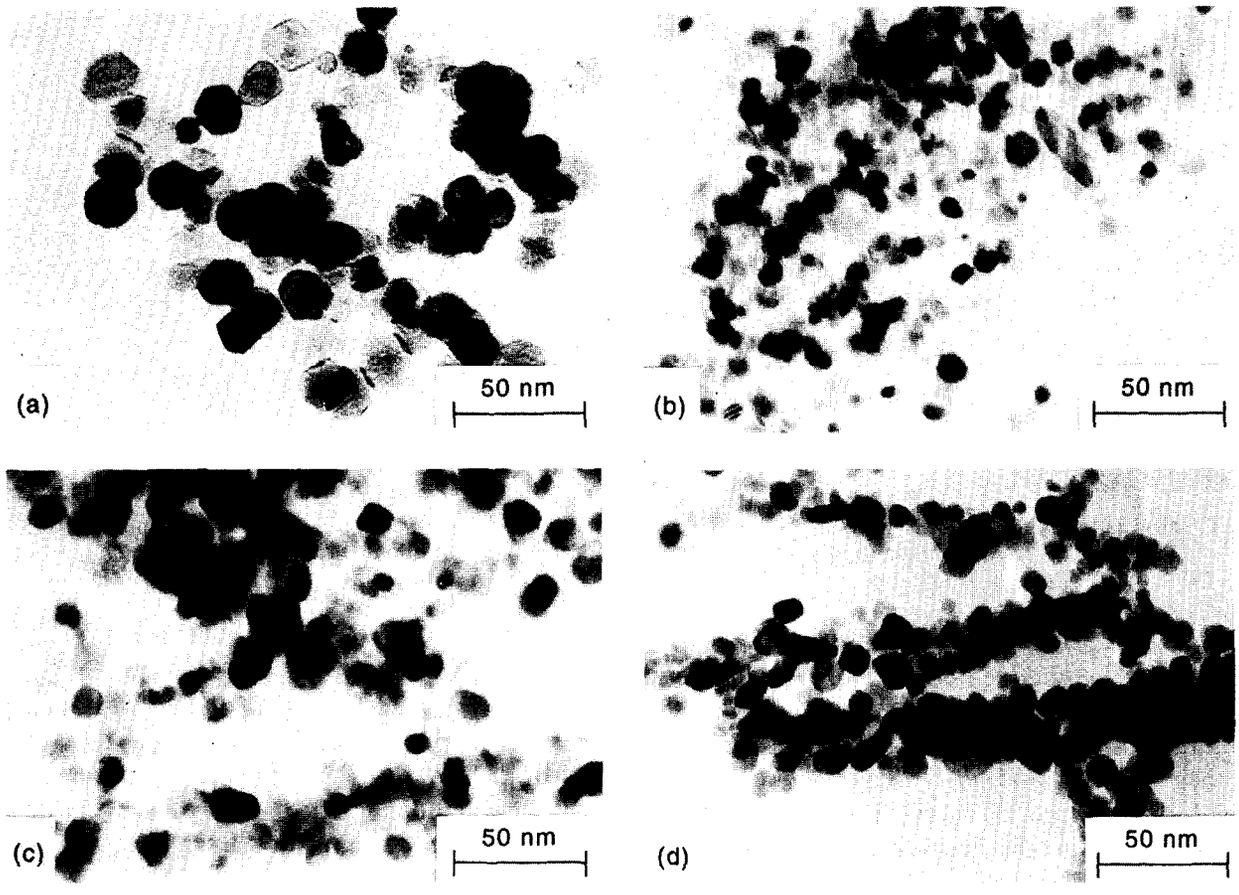

Fig. 1. TEM of the CeO_2 powder doped with Y^{3+} at concentrations of (a) 0; (b) 6; (c) 10 and (d) 20 at% prepared under hydrothermal conditions.

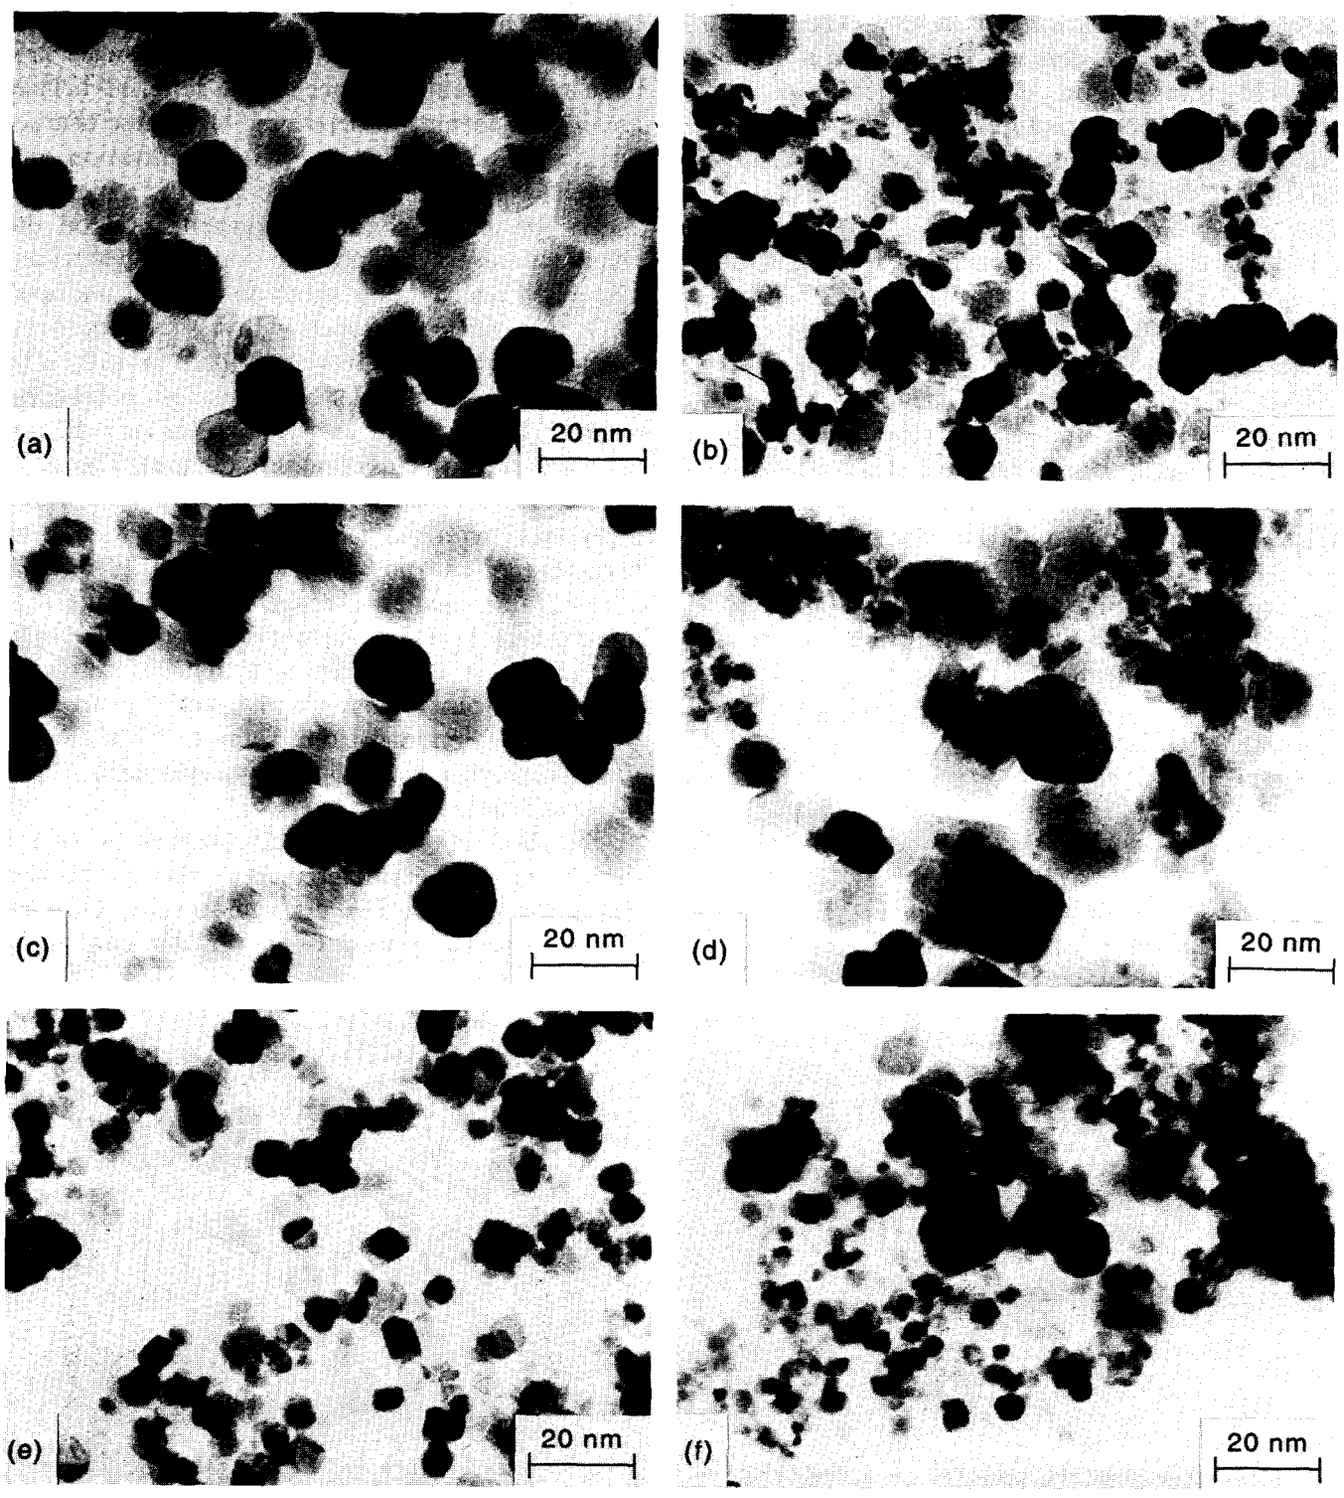

Fig. 2. TEM of the powders prepared under hydrothermal conditions showing (a) the undoped CeO_2 powder and the doped CeO_2 powder containing 6 at% of (b) Mg^{2+}; (c) Ca^{2+}; (d) Sc^{3+}; (e) Nd^{3+} and (f) Y^{3+}.

6 at% of Mg^{2+}, Ca^{2+}, Sc^{3+}, Nd^{3+} and Y^{3+} (b–f) respectively). The undoped powder and the powders doped with Ca^{2+} and Nd^{3+} have a fairly narrow distribution of sizes. However, the powders doped with Mg^{2+}, Sc^{3+} and Y^{3+} have a noticeable bimodal distribution of sizes. The effect of the dopants on the size distribution of the powders is further illustrated in Fig. 3. Particle size distribution histograms determined by measuring maximum diameters of more than 100 particles in TEM micrographs are shown for (a) undoped CeO_2 and CeO_2 doped with (b) 6 at% Ca^{2+} and (c) 6 at% Sc^{3+}. The histogram of the Ca-doped powder is approximately similar to that of the undoped powder. The powder doped with Sc^{3+} has a bimodal distribution of larger particles (average size $\approx$20 nm) and finer particles (average size $\approx$8 nm).

The distribution of the dopant in the particles of the powder may also have important conse-

quences for sintering. Figure 4 shows high resolution TEM micrographs of the synthesized powder doped with 6 at% Ca^{2+}. The particles are observed to have faceted shapes and, within the limits of resolution, fully crystalline. EDX analysis revealed no difference in the chemical composition of the individual particles. As outlined above, the powders doped with Mg^{2+}, Sc^{3+} and Y^{3+} have a bimodal distribution of sizes. High resolution micrographs

of the powder doped with 6 at% Y^{3+} are shown in Fig. 5 for (a) a larger particle and (b) smaller particles in the distribution. The highly crystalline nature of the larger particle is very noticeable. However, for these powders, EDX analysis revealed a significant difference in the dopant

concentration between the larger and smaller particles, with the concentration being significantly greater in the finer particles.

The sintering curves for the undoped and Ca-doped powders are shown in Fig. 6, where the relative density is plotted as a function of the temperature. Dopant concentrations of 2, 6, 10 and 20 at% were investigated. The sintering curve for the powder doped with 2 at% Ca^{2+} was nearly identical to that for sample doped with 6 at% and, to maintain clarity of the figure, was omitted. Each curve is the average of two runs under the same conditions, and the density at any temperature is reproducible to ±0·01. The sintering behavior of the undoped powder has been described in detail elsewhere.[10] The undoped CeO_2 powder starts to sinter at ≈800–900°C and reaches a density of 0·95 of the theoretical at ≈1200°C, after which the density decreases slightly. It is seen that one effect produced by the dopants is a shift of the sintering curves to higher temperature. Furthermore, the sintering curves for the doped powders lie within a narrow band, which indicates that for the range of values investigated (2–20 at%), the Ca^{2+} concentration has a relatively insignificant effect on the densification. It is also seen that the doped samples reach nearly full density below ≈1300°C.

For the Ca-doped powders, the final grain size of the compacts sintered under identical conditions (10°C/min–1350°C) is shown in Fig. 7 as a function of the dopant concentration. It is seen that the dopant concentration has a significant effect on the final grain size. With increasing Ca^{2+} concentration, the final grain size decreases from ≈400 nm for the undoped sample and reaches a minimum value of ≈30 nm at 6 at%, after which it increases to ≈1 μm for a concentration of 20 at%. SEM of the fracture surfaces of the sintered bodies are shown in Fig. 8. The effect of the Ca concentration on the grain size and microstructure is very striking.

Figure 9 shows the effect of yttrium dopant on the sintering of the compacted powders. Dopant concentrations of 2, 6, 10, 14 and 20 at% were investigated but the data for the powder doped with 14 at% Y^{3+} were omitted to maintain clarity of the figure. As observed above for the powders doped with Ca^{2+}, doping produces a shift in the sintering curves to higher temperature. However, the effect of the Y^{3+} appears to be somewhat more complex than that observed for Ca^{2+}. The shift in the curves increases with increasing Y^{3+} concentration so that higher temperatures are required in order to achieve the same final density. The sintering curve for the sample doped with 20 at% Y^{3+} shows a trend which is different from those of the others. No densification occurs below ≈1300°C, after which the curve increases rapidly. Furthermore, the curve shows a small expansion at ≈1200°C. A small expansion was also observed for the powder doped with 14 at% Y^{3+}. The cause of the expansion is not understood clearly at present. As outlined earlier, X-ray analysis and high resolution electron microscopy show no evidence of free Y_2O_3 in the powders. However, electron microscopy shows that the powder doped with Y^{3+} has a bimodal size distribution and that the smaller particles in the distribution have a higher yttrium concentration (Fig. 5). A possibility is that the expansion is caused by a solid state reaction driven by the yttrium concentration difference between the smaller and larger particles in the powder. After the yttrium concentration has equilibrated, densification occurs rapidly.

The effect of the elemental composition of the dopant on the sinterability of the compacted powders is shown in Figs 10 and 11 for a fixed dopant

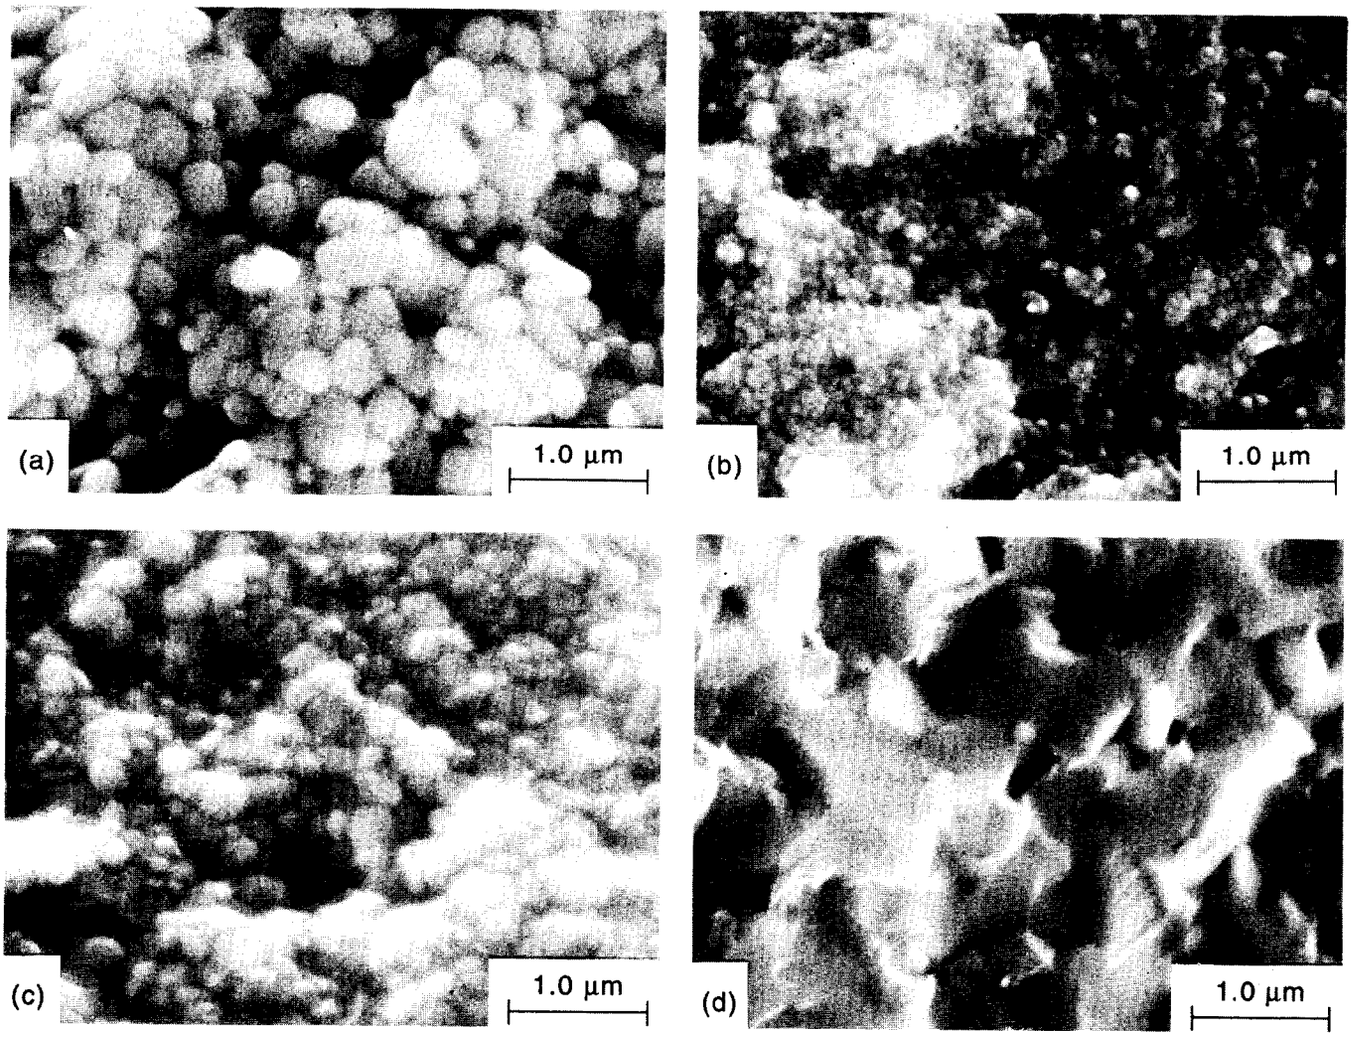

Fig. 8. SEM of the fracture surfaces of the Ca-doped powder compacts after sintering at 10°C/min to 1350°C for Ca^{2+} concentrations of (a) 2; (b) 6; (c) 10 and (d) 20 at%.

concentration of 6 at%. For the divalent cations investigated, i.e. Mg^{2+} and Ca^{2+}, it is seen that both cations lead to a shift of the sintering curve to higher temperature (Fig. 10). However, the final densities obtained under identical sintering conditions are different. The Mg-doped sample reaches a limiting density of ≈95% of the theoretical while the Ca-doped sample reaches almost full density. For the trivalent cations, i.e. Sc^{3+}, Y^{3+} and Nd^{3+}, the shift of the sintering curves to higher temperatures is also observed (Fig. 11).

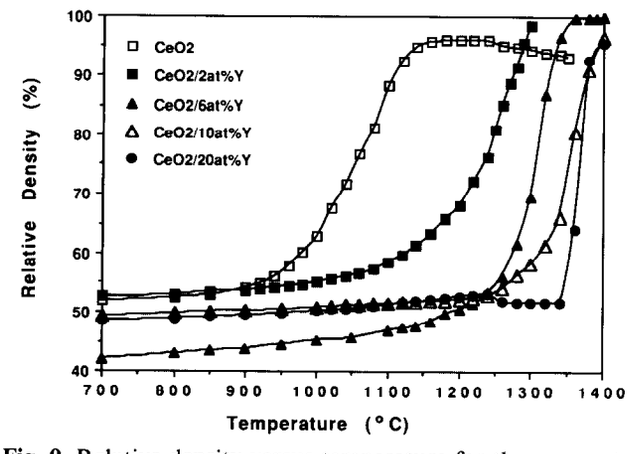

Fig. 9. Relative density versus temperature for the compacted CeO_2 powder doped with 2, 6, 10 and 20 at% Y^{3+} during sintering at 10°C/min.

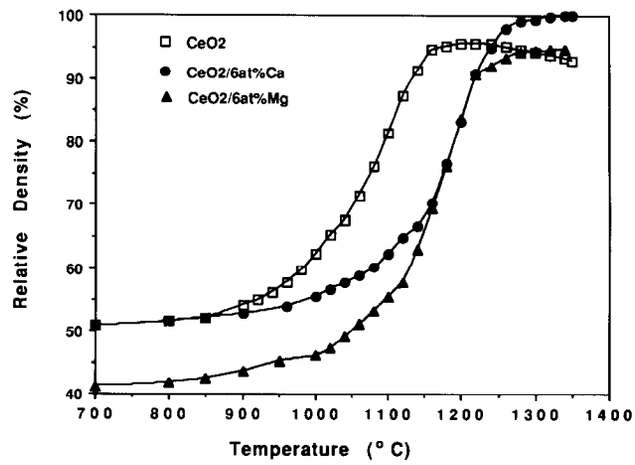

Fig. 10. Relative density versus temperature for the CeO_2 powder compacts doped with 6 at% of the divalent cations, Mg^{2+} and Ca^{2+}, during sintering at 10°C/min to 1350°C. For comparison, the data for the undoped CeO_2 powder compact are also shown.

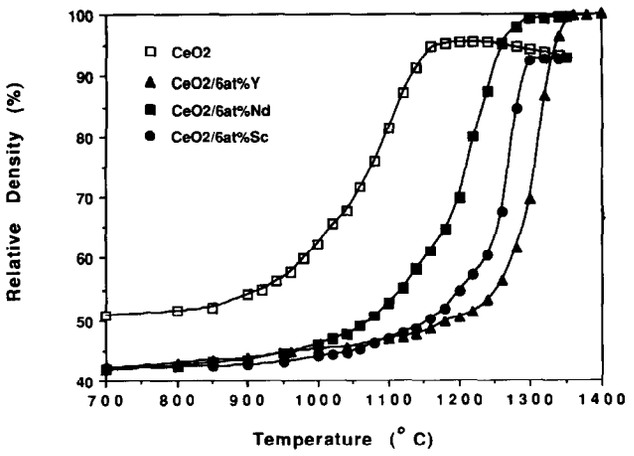

Fig. 11. Relative density versus temperature for the CeO_2 powder compacts doped with 6 at% of the trivalent cations, Sc^{3+}, Y^{3+} and Nd^{3+}, during sintering at 10°C/min. For comparison, the data for the undoped CeO_2 powder compact are also shown.

The extent of the shift is dependent on the elemental composition of the dopant; the smallest shift is caused by Nd^{3+} while Y^{3+} produces the largest shift. As observed for the divalent cations, the final density depends on the elemental composition of the dopant. Almost full density is achieved for the powders doped with Nd^{3+} and Y^{3+} while the powder doped with Sc^{3+} reaches a limiting density of only ≈93% of the theoretical.

SEM of the sintered samples doped with 6 at% of Mg^{2+}, Ca^{2+}, Y^{3+} and Nd^{3+} are shown in Fig. 12. The grain size and microstructure are seen to be highly dependent on the elemental composition of the dopant. Relatively large grain size is obtained with the Mg^{2+} dopant. The microstructure of the Sc-doped sample, not shown here, is close to that for the Mg-doped sample. While Ca^{2+}, Y^{3+} and Nd^{3+} are very effective for achieving small grain sizes, the smallest grain size was obtained for the powders doped with Ca^{2+}.

The sintering behavior of CeO_2 doped with two metal cations, (i.e. double dopants) was also investigated. Figure 13 shows the sintering curves for the compacted powders doped with 3 at% Ca^{2+} + 3 at% Mg^{2+} and 2 at% Ca^{2+} + 4 at% Mg^{2+}. For comparison, the sintering curves for the powders doped with 6 at% Ca^{2+} and with 6 at% Mg^{2+} are also included in the figure. It is seen that while the

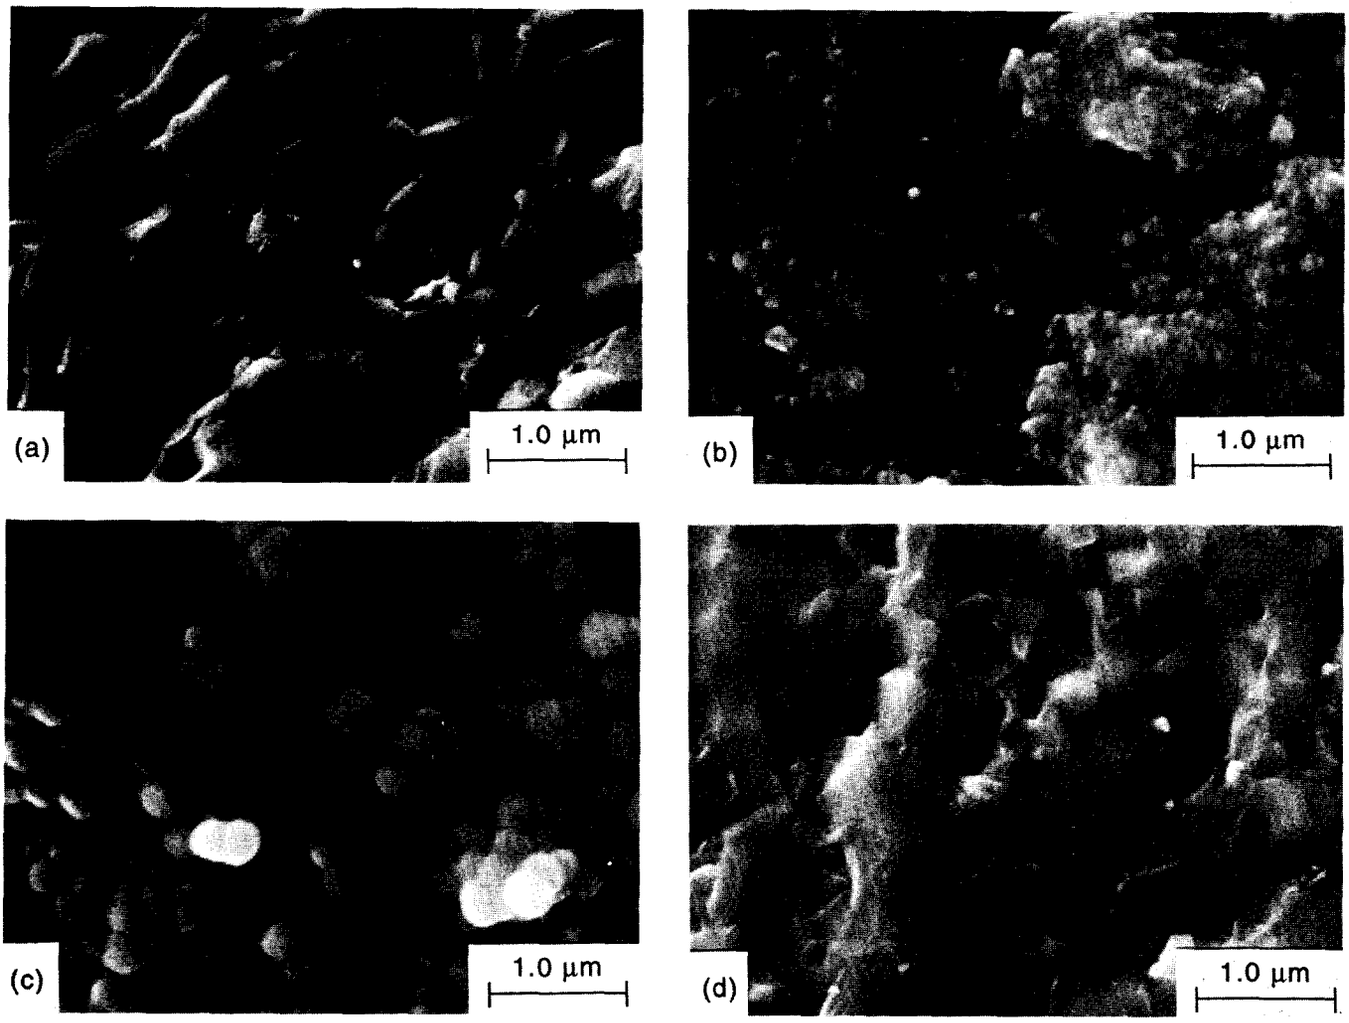

Fig. 12. SEM of the fracture surfaces of the CeO_2 powder compacts doped with 6 at% of (a) Mg^{2+}, (b) Ca^{2+}, (c) Y^{3+} and (d) Nd^{3+} after sintering at 10°C/min to 1350°C.

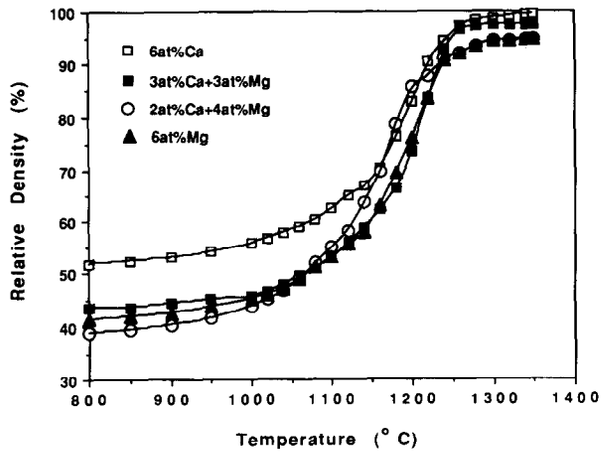

Fig. 13. Relative density versus temperature for the CeO_2 powder compacts doped with double cations, Mg^{2+} + Ca^{2+}, during sintering at 10°C/min to 1350°C. For comparison, the data for CeO_2 powder compacts doped with the single cations at the equivalent concentration are also shown.

green density of the Ca-doped powder compact is somewhat higher than those for the other samples, soon after the onset of densification the data fall within a narrow band. The data therefore indicate that for a fixed concentration of these two dopants, the elemental composition of the dopant does not have a significant effect on the sintering kinetics. The final densities of the doubly-doped samples have values which are intermediate between those for the Mg-doped and Ca-doped samples.

Figure 14 shows scanning electron micrographs of the samples containing double dopants after sintering to 1350°C. The micrograph shown in Fig. 14(a) (for the sample doped with 3 at% Ca^{2+} + 3 at% Mg^{2+}) does not represent the true fracture mode of the dense sample. The powder compact used to produce the microstructure contained a small crack (formed during the powder compaction stage). After sintering, the surface of the crack was observed in the SEM. The micrograph reveals a classical microstructure produced by solid state sintering where the flat grain boundaries have clearly developed. Figure 14(b) shows the true fracture surface of the dense sample (containing 2 at% Ca^{2+} + 4 at% Mg^{2+}). The fracture mode is predominantly transgranular. Generally, for the equivalent dopant concentration, the microstructures for the samples containing double dopants show features which are intermediate between those for the Ca-doped sample (Fig. 12(b)) and the Mg-doped sample (Fig. 12(a)).

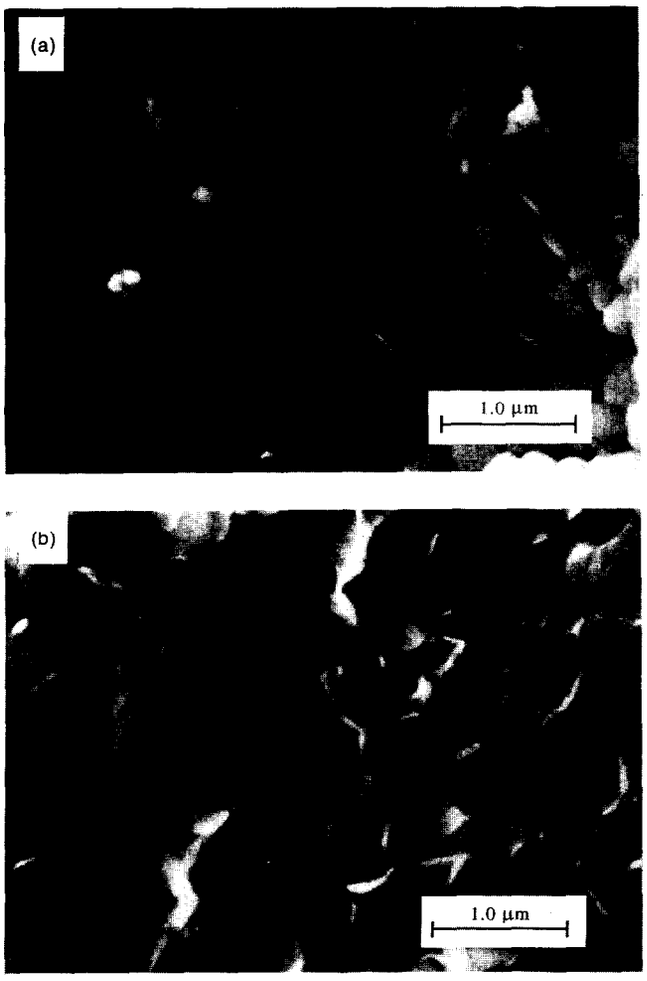

Fig. 14. SEM of the samples described in Fig. 13 containing double dopants of (a) 3at% Ca^{2+} + 3 at% Mg^{2+} and (b) 2 at% Ca^{2+} + 4 at% Mg^{2+}. Part (b) shows the fracture surface of the dense sample but (a) shows the surface of an internal flaw in the dense sample.

4 Discussion

The results indicate that the incorporation of dopants produce subtle microstructural effects in CeO_2 powders prepared by hydrothermal processing. The major processes occurring in the hydrothermal technique employed in the present work are the dissolution of an amorphous, gelatinous product and its precipitation in the form of crystalline particles. X-ray diffraction of the powders after the hydrothermal treatment revealed no evidence of free oxides of any of the dopant elements investigated (Mg, Ca, Sc, Y and Nd). Furthermore, high resolution electron microscopy of the doped powders (Figs 4 and 5) revealed that the powders were crystalline in nature. On the basis of the X-ray and electron microscopy data, the dopants may be assumed to be incorporated into the CeO_2 solid solution during the hydrothermal process.

Electron microscopy also indicates that the incorporation of dopants into the CeO_2 powders during hydrothermal synthesis influences the powder morphology and the distribution of the dopant within the powder. Powders doped with Ca^{2+} or Nd^{3+} have a relatively narrow distribution in sizes. Furthermore, EDX analysis of the Ca-doped powder indicates that the chemical composition of the individual particles is the same.

Dopants such as Mg^{2+}, Sc^{3+} and to a lesser extent Y^{3+}, lead to a bimodal distribution of particle sizes. EDX analysis of the powder doped with Y^{3+} also revealed that the dopant concentration was significantly higher in the particles with the smaller sizes. Further work is necessary in order to understand the effect of the dopants on the microstructure and microchemistry of the powders.

The sintering results indicate that the dopants investigated have a profound effect on the densification and grain growth of the compacted powders. All of the dopants lead to a shift in the sintering curve for CeO_2 to higher temperatures (Figs 10 and 11). While the mechanism of densification of CeO_2 is not clear, predictions based on Herring's scaling laws[9] indicate that grain boundary diffusion is enhanced with decreasing particle size. Compared to diffusion through the lattice, grain boundary diffusion is also expected to be more rapid at lower temperatures. For the ultrafine powders and relatively low sintering temperatures used in the present work, it seems reasonable to assume that grain boundary diffusion is the rate-controlling mechanism for densification. The shift in the sintering curves to higher temperatures indicates that the dopants reduce the rate of grain boundary diffusion. This reduction in the grain boundary diffusion, compared to undoped CeO_2, further indicates that the additive cations modify the structure of the grain boundary region.

The dopants were also found to have a dramatic effect on grain growth phenomena during sintering. Dopants can influence the structure of the grain boundary and, hence, the mobility of the grain boundary by two main processes. First, the additive may form a separate phase at the grain boundary by precipitation or by chemical reaction. The second phase can be solid or liquid at the sintering temperature. In the second process, the concentration of the additive cations may be enhanced or diminished in the grain boundary without the formation of a second phase. The term segregation will be used in a limited sense to describe the second process. For the present work, the first process appears unlikely. Detailed microstructural analysis by conventional and high resolution TEM of the sintered Ca-doped sample showed no evidence of a second phase at the grain boundaries (Fig. 15). It will be recalled (Fig. 7) that the Ca-doped samples show the most dramatic change in grain growth behavior. CeO_2 is also known to have a high solid solubility for many dopants, including those investigated in this work.[12–14] Furthermore, the presence of a liquid phase during sintering appears unlikely because of the low final sintering temperature (1350°C) used for most of the experiments in this work.

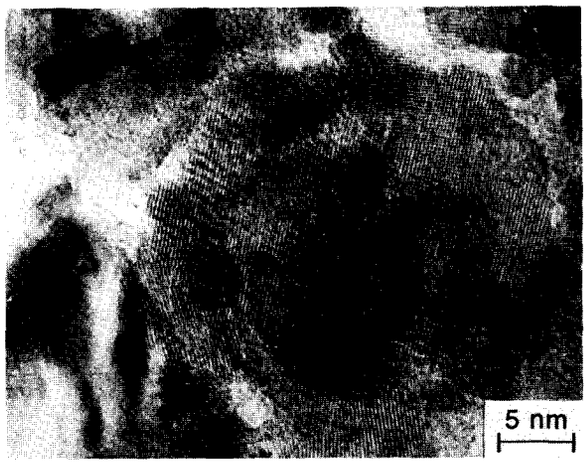

Fig. 15. HREM of a sintered sample of CeO_2 doped with 6 at% Ca^{2+}. The sample was sintered at 10°C/min to 1350°C.

The evidence described above strongly suggests that segregation of the dopants to the grain boundary (referred to as solute segregation) might be an important process by which the dopants influence the sintering and grain growth of CeO_2. The characterization of the microchemistry of the grain boundaries in the sintered samples is currently in progress. However, a number of observations pertinent to the use of solid solution additives in the sintering of ceramics can be made at this stage. One mechanism which is believed to control solute segregation to the grain boundary involves the concept of a space charge.[15–17] It has been shown recently that the effect of dopants on the grain growth of tetragonal zirconia polycrystals (TZP) can be satisfactorily rationalized in terms of the space charge concept.[18] In the space charge theory, surfaces, boundaries and dislocation cores in an ionic crystal may possess a net charge resulting from the presence of excess ions of one type. This charge is compensated by a region of space charge of the opposite sign adjacent to these lattice discontinuities. For ionic crystals doped with aliovalent cations, the magnitude and sign of the space charge are expected to be controlled by the effective charge of the solute. In the present experiments, the dopants present in the bulk of the lattice have a negative effective charge so that, in thermal equilibrium, the boundary will possess a positive charge. The dopants must then segregate to the boundary as a space charge so that the bulk of the crystal remains neutral.

For the aliovalent dopants investigated in this work we may expect, on the basis of the space charge concept, that the divalent cations (Mg^{2+} and Ca^{2+}) are more strongly segregated to the grain boundaries compared to the trivalent cations (Sc^{3+}, Y^{3+} and Nd^{3+}). However, the grain size data show that Ca^{2+}, Y^{3+} and Nd^{3+} are effective for

controlling grain growth, with Ca^{2+} being the most effective, while Mg^{2+} and Sc^{3+} are not effective. The grain size data cannot therefore be rationalized in terms of the space charge concept only.

An interaction between the moving grain boundary and the dopant cations can also originate from the strain energy caused by the mismatch in size between the dopant cations and the host cations.[19] Because of the size mismatch, there will be a difference in strain energy between a dopant cation situated at or near the grain boundary and one in the crystal lattice. For aliovalent dopants, the interaction between the strain field and the boundary must be coupled with the space charge field because of the effective charge of the dopant cations. The distribution of the dopant cations and defects within the space charge cloud can therefore be significantly affected by the strain field due to the size mismatch.

Assuming eight-fold coordination, the ionic radii of Ce^{4+}, Mg^{2+}, Ca^{2+}, Sc^{3+}, Y^{3+} and Nd^{3+} are 0·097, 0·089, 0·112, 0·087, 0·102 and 0·112 nm, respectively.[20] The cations Mg^{2+} and Sc^{3+} which have ionic radii smaller than that of host Ce^{4+} ion, (i.e. the undersize cations) are not effective for grain growth control while Ca^{2+}, Y^{3+} and Nd^{3+} with ionic radii larger than that of the Ce^{4+} ion, (i.e. the oversize cations) are effective for grain growth control. For the oversize cations, Ca^{2+} with the highest effective charge is most effective for grain growth control. It is clear that both the charge and the size mismatch of the dopant cations are important factors for grain growth control by divalent and trivalent cations.

Assuming that the segregated dopants control the grain boundary mobility by the solute drag mechanism proposed by Cahn,[21] the mobility of the grain boundary is given approximately by an equation of the form:

$$M = \frac{D}{\Delta C\, kT} \tag{3}$$

where D is the diffusivity of the dopant cation, ΔC is the excess concentration of the dopant cation in the grain boundary, k is the Boltzmann constant and T is the absolute temperature. Taking the case of the divalent dopants, the effectiveness of Ca^{2+}, compared to Mg^{2+}, for grain growth control may be due to an increased segregation to the grain boundary due to a larger size mismatch or a decrease in the diffusivity of the dopant due to its larger ionic radius or a combination of the two. The concentration of the dopants in the grain boundary is currently being investigated. However, the effectiveness of the Ca^{2+} dopant, compared to Mg^{2+}, can be rationalized in terms of its larger ionic size. For cations of nearly the same size, e.g. Ca^{2+} and Nd^{3+}, the greater effectiveness of Ca^{2+} can be rationalized in terms of its greater effective charge. Thus, based on the space charge concept and the strain mismatch, Ca^{2+} is expected to be most effective for grain size control, as is observed.

For Ca^{2+} which forms the most effective dopant for grain growth control, the data of Fig. 7 for the grain size after identical sintering conditions show that the concentration of the dopant has a significant effect on the grain size. The variation of the grain size with dopant concentration is not uniform. With increasing Ca^{2+} concentration, the grain size decreases monotonically and reaches a minimum at ≈5–6 at%, after which it increases monotonically. There is therefore an optimum Ca^{2+} concentration which is most effective for grain growth control. Grain size data for the CeO_2 doped with Y^{3+} also reveal an optimum dopant concentration for grain growth control at ≈6 at%. As outlined earlier, high resolution TEM of the sintered body doped with 6 at% Ca^{2+} did not reveal the presence of a discrete second phase at the grain boundaries. For samples containing low concentrations of dopants, (e.g. below the optimum concentration of ≈6 at%), the grain growth behavior can be rationalized in terms of the solute drag mechanism. However, the mechanism cannot be used to explain the grain growth behavior at large dopant concentrations where the grain size of the doped samples are greater than that for the undoped CeO_2 (Fig. 7).

For the same concentration of dopants (6 at%), the data indicate that the effect of double dopants (Mg^{2+} + Ca^{2+}) on the sintering and grain growth is intermediate between those of the single dopants. Under identical sintering conditions, the grain size for the sample doped with 3 at% Mg^{2+} + 3 at% Ca^{2+} is ≈0·5 μm which is approximately half-way between those for the samples doped with 6 at% Mg^{2+} and 6 at% Ca^{2+} (≈30 nm) but approximately twice that for the sample doped with 3 at% Ca^{2+} (200 nm). Both Mg^{2+} and Ca^{2+} are expected to substitute at the regular Ce^{4+} lattice sites and the nature of the charged defects produced by Mg^{2+} and Ca^{2+} substitution is therefore expected to be the same. Compensation of one type of defect by another cannot occur for the double dopants used in this study. The data for the double dopants therefore indicate that the dopants act to influence the grain boundary structure.

5 Conclusions

Divalent and trivalent dopants (Mg^{2+}, Ca^{2+}, Sc^{3+}, Y^{3+} and Nd^{3+}) produced subtle changes in the microstructure and microchemistry of ultra-fine

CeO_2 powders prepared under hydrothermal conditions. The powders doped with Mg^{2+}, Sc^{3+} and, to a lesser extent Y^{3+}, had a bimodal size distribution. EDX analysis of the Y-doped powder showed that the dopant concentration was significantly higher in the smaller particles. The undoped powder and the Ca-doped and Nd-doped powders had a fairly narrow size distribution. For the Ca-doped powder, no difference in the chemical composition of the individual particles was detected by EDX analysis.

The dopants had a dramatic effect on the sintering and grain growth behavior of the compacted powders. Compared to the undoped CeO_2, all of the dopants produced a shift in the sintering curve to higher temperature. The effect of the dopants on grain growth was dependent on both the cation charge and the cation radius. The undersize cations, Mg^{2+} and Sc^{3+} were not effective for grain growth control. Grain growth was suppressed in the samples doped with the oversize cations, Ca^{2+}, Nd^{3+} and Y^{3+}, with Ca^{2+} being the most effective for grain growth control.

At low concentrations, the influence of the dopants on the sintering and grain growth behavior can be rationalized in terms of segregation to the grain boundary by a space charge mechanism and solute drag on the grain boundary. However, this mechanism cannot explain the enhanced grain growth at large dopant concentrations where the grain size of the doped sample is significantly greater than that for the undoped CeO_2.

Abstract

Grain growth has been characterized for various zirconia alloys and cation segregations have been measured with AES and ESCA. The samples were prepared by coprecipitation, followed by compacting and sintering at 1400°C for different times. Grain growth was found to depend strongly on the dopants, e.g. on their radius and valence state. However, segregation factors of these cations did not reveal significant differences. Impurities up to 1 wt% are found to control grain growth via a grain boundary layer. Large amounts of Cr_2O_3 and SnO_2 tend to suppress grain growth effectively by the spherical shaped precipitations. The results are discussed in relation to the existing grain growth models.

Introduction

Polycrystalline tetragonal zirconia is a ceramic that combines both high strength and outstanding toughness, caused by a mechanism known as transformation toughening. One of the most important parameters for this toughening mechanism is the material's grain size. For good mechanical properties it must have a well defined value slightly smaller than a critical grain size being typically in the order of 1 μm for Y–TZP. In order to control grain growth in a ceramic body during processing, a profound knowledge of grain growth parameters is needed.

Grain growth of zirconia alloys depends very strongly on composition and is related to the phase content. The growth of cubic grains in zirconia doped with Y^{3+} is 30–250 times faster than that of tetragonal grains alloyed with the same cation.[1] Grain growth is strongly suppressed if both phases are coexistent. Furthermore it is well known, that Y^{3+} and Gd^{3+} suppress the grain growth very efficiently whereas Ce^{4+} does not. Up to now, the influence of a variety of alloying elements on the grain growth has been investigated, but there is still a strong controversy about the mechanisms involved in this process.

Two models are proposed up to now. **Model 1**: Theunissen *et al.*[2] proposed a solute drag model based on the observed enrichment of Y^{3+} at the surface of both Y–TZP and Y–FSZ. Hwang and Chen[3] confirmed this observation qualitatively and explained the segregation behavior of different dopants using a space charge concept. **Model 2**: Based on the large differences in Y_2O_3 content from grain to grain during sluggish partitioning, Lange *et al.*[4] suggested that coherency strains arise when boundaries between grains with different compositions move, suggesting one possible correlation between sluggish phase partitioning and slow grain growth. Stoto, Nauer and Carry[5] confirmed the sluggish grain growth during phase partitioning and observed an enhanced grain growth after phase segregation had occurred.

There are still some discrepancies in both of these models. **Model 1**: Hwang and Chen[3] found an enrichment factor for Y^{3+} of 1·9 whereas a much stronger enrichment factor of 4·3 has been found by Theunissen. On the other hand, Nauer and Carry found yttria segregation at grain boundaries only in combination with a 2 nm thick amorphous intergranular phase. The influence of such a glasslike layer on the segregation of dopants is said to be negligible by Hwang and Chen and not taken into consideration by Theunissen.[6,7] **Model 2**: The most significant decrease in grain growth occurs generally with concentrations up to the solubility limit. Model 2 cannot explain the strong decrease of grain growth within the homogeneity range, as there is no compositional difference between the grains. In addition, it is difficult to explain with Model 2 the observation that the grain growth of samples within the two phase field is approximately constant. This in spite of the fact, that the compositional inhomogeneities might increase with increasing dopant concentration.

*To whom correspondence should be addressed.

The aim of this study was to investigate the influence of alloying elements on the grain growth of tetragonal zirconia and based on these results to differentiate between the validity of the different models.

Experimental

Sample preparation and characterization

Doped zirconia powders were made by coprecipitating $ZrOCl_2 \cdot H_2O$ (Corustar, Frankfurt, D) and metal chlorides (Fluka AG, grade p.a.) in aqueous solutions with ammonia. The filtered hydroxides were washed chlorine free, spray dried and calcined at 700°C for 1 h. Finally these powders were attrition milled at 1500 rpm for 30 min and again spray dried. The commercial powder 6 Y–ZrO_2 (Alusuisse-Lonza Services AG, P021) has been fabricated with a similar technique, but calcined at 750°C for 8 h. For explanation: an alloy 3 7 AB–ZrO_2 has the composition 3 ct% A^{a+}, 7 ct% B^{b+} and 90 ct% Zr^{4+} (ct% = cation%). Solely the grain growth experiment at 1550°C was carried out with an other 6Y–ZrO_2 powder (Tosho, Tokio, Japan; TZ-3YB/PVA).

All powders were pressed uniaxially to cylinders (Ø15 mm, h ≈ 8 mm) without adding any binder and compressed isostatically at 250 MPa. Subsequently they were heated with 10 K/min to 1400°C and sintered for 5 min or 8, 24 or 72 h, respectively. Afterwards they were quenched in air down to room temperature.

The phases in the sintered samples were analyzed with a X-ray diffractometer (D 5000, Siemens). The diffraction patterns were collected with Cu Kα radiation (γ = 1·5405 Å) over an angular range of 10–80° 2θ. Those samples which disintegrated during cooling were ground and measured in powdered form. Measurements have been carried out on the uncracked samples before and after removing a surface layer by polishing; no change in the m : t : c phase ratio has been found between bulk and layers.

The grain size has been measured on fracture surfaces with a scanning electron microscope (SEM) and evaluated based on the mean intercept method. The results were fitted with the phenomenological equation:

$$D^n - D_o^n = kt \quad (1)$$

In this equation, grain size D depends on the starting grain size D_o, the exponential parameter n, the preexponential factor k and the time t. The exponent n depends on the microstructure.[8] Therefore, the data were evaluated for both n = 2, and n = 3. In addition, the best fitting n was determined for each material using an approximation algorithm. No significant difference could be found between these methods. In order to be able to compare the different grain growth coefficients k to each other and to published data, it has been fixed at n = 3.

Segregation measurements

Scanning electron images (SEI) and depth profiles on inter- and intracrystalline fractures at the selected areas of <0·01 μm^2 have been performed with a Perkin Elmer PHI Model 4300 SAM spectrometer operating with a primary beam energy of 3 kV and an electron beam current of 0·01 μA. Small pieces of the ceramic samples were pressed into a gold foil and heated up to 450°C by resistivity in order to enhance the electrical conductivity of the material while its thermal stability is still maintained.[9] A residual pressure lower than $9–10^{-10}$ mbar has been maintained in the analytical chamber during the measurements. The sensitivity factors of the oxides[6,7] have been used to calculate the cation's concentration with the exception of calcium,[10] where that of the oxide is unknown. The ion gun was operated with an Ar^+ ion energy of 2 keV, corresponding to an etching rate of 0·93 nm/min with an interface resolution of 2·8 nm for a 33 nm SiO_2/Si (111) standard reference which corresponds to a sputtering rate of 0·46 nm/min for a ZrO_2/Si (111) reference.

Photoelectron spectroscopy measurements have been recorded with a Perkin Elmer PHI 5400 small spot ESCA apparatus equipped with a channel plate detector and a Mg X-ray source operated at 400 W (15 kV; 26,7 mA). The pass energy of the analyzer has been set to 35·75 eV, resulting in a full width at half-maximum (FWHM) value of 1·0 eV for the Ag($3d_{5/2}$) line. The Zr($3d$) line at 182·2 eV was used as a reference to correct for sample charging.[11]

Generally, AES and XPS concentration measurements agreed only roughly with chemically determined concentrations. The estimation of errors of the measured concentrations takes only those errors into account which are due to uncertainties of data evaluation. Several factors can cause additional deviations. It was not possible to hold the incidence angle between the electron beam and different grains' surfaces constant. The deviations amount to about ±10°. Therefore, the information depth of the investigated layer varies and so does the measured cation concentration. By changing this angle, the concentration was found to alter in the order of ±3 ct%. The quantitative analysis of Y(MNN) and Ce(MNN) was difficult to perform due to a peak overlapping with Zr(MNN). If only the first half of the Y(MNN) AES-peak was taken

into consideration and this concentration was multiplied with 2, influences of the overlapping Zr(MNN)-lines could be excluded. The XPS signals were merely integrated and no deconvolution has been carried out. For such an evaluation Ce(MNN) concentrations of AES and XPS measurements showed similar results. During the enhanced exposure of the grains to the electron beam, a loss of calcium was observed. In case of Ti, Ce, Y and Zr, the sensitivity factors of the oxides have been used to calculate the cation's concentrations.[6,7] Excluding preferential sputtering,[12] the measured concentrations are compatible to the concentrations determined by chemical analysis. Since the sensitivity factor of CaO was not available, that of the metal has been taken; the absolute concentrations of the titanium is also affected. Thus, these values are not comparable with chemically determined concentrations and can be regarded just relatively to each other.

Results and Discussion

Grain growth of differently doped zirconia

Grain size of differently doped zirconia has been measured as a function of soaking time at 1400°C (Fig. 1). The grain size D increases with the soaking time t according to a law, best described by eqn (1). Undoped tetragonal ZrO_2 at 1400°C has a grain growth coefficient $k = 2{\cdot}4 \times 10^{-22}$ m^3/s. The grain growth is enhanced by doping with smaller cations whereas it becomes sluggish by doping with larger ones (Table 1). In addition, the grain growth is more effectively suppressed by large cations, if they have a lower valence state. That explains why Ce^{4+} suppresses the grain growth only weakly whereas the grain growth slows down significantly by doping with Gd^{3+} and Y^{3+}. The same relationship has been demonstrated by Hwang and Chen[2] for 12 Ce–ZrO_2 doped with ternary cations of different size and valence state. Their grain growth coefficients k are slightly larger than ours due to the smaller concentration of doping cations. However, their data depends on both the size as well as the valence of the doping cation. k factors as small as $0{\cdot}01 \times 10^{-22}$ m^3/s to $0{\cdot}02 \times 10^{-22}$ m^3/s were found for Y–TZP. This extreme grain growth suppression had not been observed in the other alloying systems.

Y–TZP has been annealed at different temperatures. The grain growth coefficients k of Y–TZP were found to be 0·02, 0·12 and $0{\cdot}49 \times 10^{-22}$ m^3/s at 1400, 1500 and 1550°C, respectively. The study was done more carefully at 1550°C up to 300 h (Fig. 2) as the mechanical properties generally are tailored at this temperature. No increased grain growth has been observed at all during and after the partitioning of an oversaturated tetragonal phase to stable (t + c) phases (a phase analysis has not been carried out, but the long annealing times at 1550°C suggest an extensive progress in phase partitioning). This is in clear contradiction to

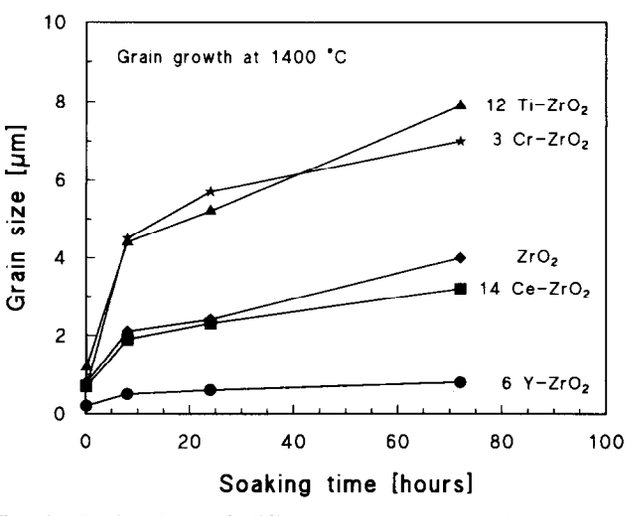

Fig. 1. Grain sizes of differently doped zirconia alloys in function of the annealing time at 1400°C.

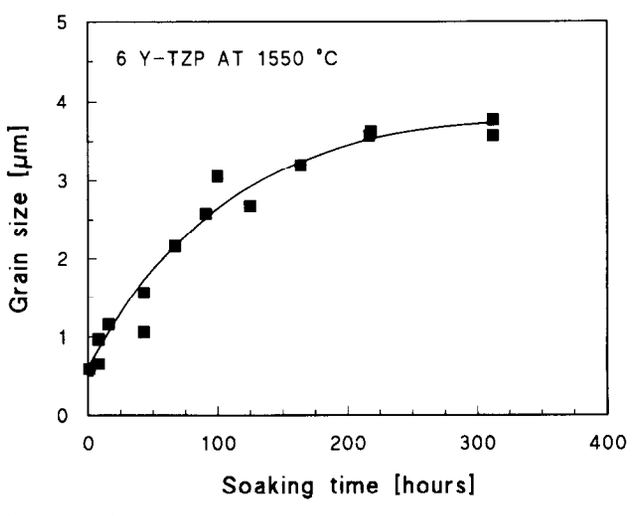

Fig. 2. Grain sizes of 6 Y–TZP as a function of the soaking time at 1550°C.

observations made by Nauer *et al.*[5] at 1400 and 1450°C up to 200 h. It is assumed that their findings are caused by another unknown growth mechanism. Our results suggest that phase partitioning has at least not a strong influence on grain growth.

Solid solutions of zirconia with 6, 10 and 12 ct% Ti^{4+} have been prepared using the described coprecipitation method. The grain growth of the annealed samples resulted in k values of 16·9, 16·7 and 16·2 10^{-22} m^3/s, respectively. This suggests that grain growth does not depend on the concentration within the investigated range. It is therefore assumed that the grain growth of zirconia doped with small cations is concentration independent above a threshold value which up to now is not known. In addition, zirconia doped with 3 ct% Cr^{3+} has a grain growth coefficient k = 12·3 10^{-22} m^3/s, which is not significantly different from that found in the samples Ti–ZrO_2. In contrast, Gd^{3+} inhibits the grain growth effectively up to a concentration of 1·5 ct%[13] (Fig. 3), which is close to the solid solubility limit of 1·1 ct%. The decrease of the grain growth in the homogeneity range is inverse proportional to the concentration as predicted by the solute drag model of Lücke.[14] In the two phase regions, the grain growth is pretty much constant. A similar behavior has been found also in other systems such as in Y–ZrO_2,[15] La–ZrO_2,[16] Ca–ZrO_2[3] and YCe–ZrO_2.[17]

The above results suggest that cations smaller than Zr^{4+} increase the grain growth, independent on both their concentration and valence. In contrast, larger cations suppress it very strongly. Grain growth coefficients decrease mainly within the homogeneity range and do not depend on the concentration in the two phase region. Our results do not give evidence for a enhanced grain growth during or after the phase partitioning process.

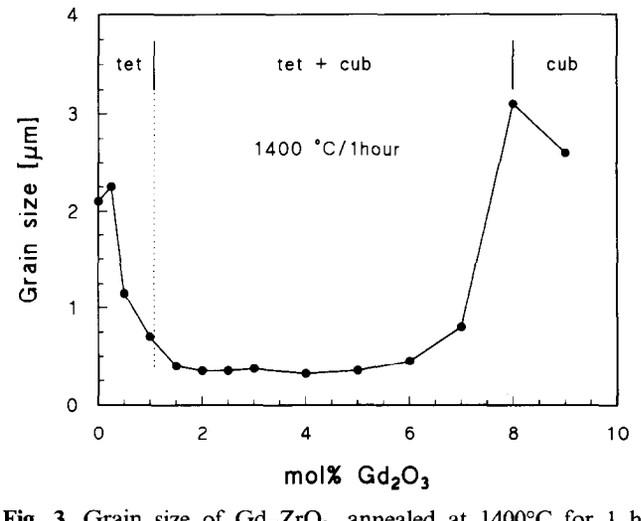

Fig. 3. Grain size of Gd–ZrO_2, annealed at 1400°C for 1 h as a function of the Gd^{3+} concentration (after Leung *et al.*)[13]

Therefore it is proposed that phase partitioning has not an essential influence on grain growth.

Segregation of dopants

Segregations of doping cations within a zirconia grain have been investigated using AES (Auger Electron Spectroscopy) and XPS (X-ray Photoelectron Spectroscopy). Surface concentrations have been ascertained on several intercrystalline broken grain facets. The observed concentrations reveal the same tendencies and are reproducible within some ct%, governed by the resolving limit of the applied method. Concentration profiles have been worked out by sputtering off layer by layer up to the grains' interior. For some samples it was possible to confirm these bulk concentrations by AES measurements on transcrystalline fracture faces. The obtained values agreed well to each other. Concentration measurements of Ca^{2+} are not compatible with values obtained from chemical analysis, as the sensitivity factor of the oxide is unknown and thus that of the metal had to be taken. Therefore, these results can be regarded just relatively to each other.

The surface and bulk concentrations were used to determine the segregation factors of the different dopants (Table 2). They are summarized briefly in the following:

Y^{3+} has a segregation factor of 2·4. The enrichment of Y-ions is observed in the uppermost layers at the surface of the grains. The surface concentration has been confirmed on several grains.

Ti^{4+}: In all binary alloys as well as in the ternary sample 7 8 CeTi–ZrO_2, the Ti^{4+} has a segregation factor of about 5. Furthermore it has been observed, that the segregation generally occurs within a broad layer, extending up to 6 nm into the grain. In a ternary alloy together with Ca^{2+}, segregation of Ti^{4+} clearly is less pronounced.

Ce^{4+} has a segregation factor of 2·2. This factor does not change significantly in ternary alloys with titanium oxide.

Ca^{2+}: The determined surface and bulk concentrations of these alloys are much too high. One explanation is, that this discrepancy is caused because the sensitivity factor of the metal is used rather than that for the oxide. We exclude that our data are collected on possible second phases, because the same values were also gathered on X-ray single phase materials. Whatever originated this error, the segregation factor of Ca^{2+} should not be affected significantly. It has been determined to about 1·5 for both the binary and ternary alloy and has been confirmed on other alloys as well.

Table 2. Concentrations of various cations at the surface (C_s) and in the bulk (C_b) and the resulting segregation factors C_s/C_b for zirconia alloys

$^+$Thickness of the segregation zone.

Segregation factors for all doping cations vary between 1 and 5·3 and seem to be relatively small for those cations which suppress grain growth and large for those which promote it. In addition, the segregation factors may not depend strongly on the dopant's concentration (Ti–ZrO_2). Furthermore, the segregation factor of Ti^{4+} is altered by alloying Ti–ZrO_2 with Ca^{2+} (6 8 CaTi–ZrO_2), but it appears not to be affected by Ce^{4+}, e.g. in the alloy 7 8 CeTi–ZrO_2. This behavior might be explained by the formation of an overcoat as mentioned by Theunissen *et al.*[6] The cations of titanium and cerium do form such an overcoat, i.e. behave in a similar way, but not that of calcium.

The segregation factors of Ce^{4+}, Ti^{4+} and Ca^{2+} in all binary and ternary alloys do not change markedly with increasing cation concentration, but the surface concentration of these cations increase if the bulk concentration is enhanced. This is consistent with the measurements of Hwang and Chen,[3] but not with those of Theunissen,[6,7] who found a constant Y^{3+} enrichment at the surface for all investigated concentrations.

Segregation factors of Ca^{2+} do not change strongly between tetragonal (at the time of soaking) and cubic grains. Similar segregation factors in these two crystal structures have also been found by Theunissen *et al.*[6,7] for yttria doped zirconia. Nevertheless, the grain growth of the tetragonal and cubic single phase microstructures are clearly different. This is surprising because the cation's segregation barrier cannot be responsible for such a large difference. One possible explanation is that lattice misfits between randomly oriented tetragonal grains inhibit grain growth. The lattice parameters of two touching grains are different and must be changed abruptly if one of that grains is growing into the other. Such lattice misfits do not exist in cubic grains and their grain growth is therefore faster.

The above results support therefore the idea that the segregation factors are similar for all cations in binary and ternary zirconia alloys. No evidence has been found for the suggestion of Hwang *et al.*,[3] that cations with a larger effective charge are more strongly attracted to the grain boundary than others. However, it is well known that cations alter diffusion significantly by their size and valence. The segregation of slowly diffusing cations thus is able to pin a grain boundary whereas the equally strong segregation of fast diffusing cations cannot do this.

Grain growth of polyphase zirconia

Second phases alter the grain growth of doped zirconia significantly. Main parameters are their mobilities, concentrations and morphologies. It is demonstrated in the following, that impurities influence the grain growth in a fundamentally different manner than second phases in amounts exceeding few mol%.

Impurities of SiO_2 and Al_2O_3 up to 1 wt% are added in various ratios to Y–TZP (Table 3(a)). The applied processing procedure is described in Ref. 18. Generally, it is found that increasing amounts of impurities lead to increased grain growth coefficients k (Fig. 4(a)). However, in the sample doped with only SiO_2, grain growth was insensitive to the amount of added SiO_2. By mixing SiO_2 and Al_2O_3 in a ratio of 1 : 1, abnormal grain growth was observed, leading to grains 10 times larger than those of the matrix. The resulting k value, evaluated merely based on the small matrix grains, does not reflect a proper grain growth mechanism and thus cannot be compared with the normal grain growth coefficients of the other samples.

Insoluble impurities have an impact on grain growth mainly by forming a grain boundary phase (Fig. 4(b)). The thickness of such grain boundaries has been measured by Impedance Spectroscopy

Table 3 (a) Grain growth coefficients k of Y–TZP with impurities of varying $SiO_2 : Al_2O_3$ ratios. (b) Grain growth coefficients k of zirconia alloys with large amounts of second phases and the characteristics

and evaluated with a 'brick layer model' described elsewhere.[19] High purity Y–TZP has no grain boundary layer (0·04 nm) and a grain growth coefficient of k = 0·12 10^{-22} m^3/s, both determined on samples annealed at 1500°C. The addition of pure SiO_2 or Al_2O_3 lead in both cases to 0·3 nm thin grain boundary layers. In spite of that similarity, these layers alter the grain growth differently, namely they suppress it by SiO_2 and enhance it by Al_2O_3 additions. This behavior is surprising as SiO_2 is thought to form a viscous layer whereas Al_2O_3 is known as unyielding. However, due to the high annealing temperature of 1500°C, the formation of $ZrSiO_4$ is plausible. Due to the small dimension of its layer, the composition could not be determined. Mixed SiO_2–Al_2O_3 impurities caused much thicker grain boundaries as well as enhanced grain growth. The thickness of the grain boundary layers increased with increasing $SiO_2 : Al_2O_3$ ratio.

The viscosity of the grain boundary layer dominates the influence on grain growth. Due to the lack of viscosity data, the latter can be estimated with the help of melting temperatures T_M. Based

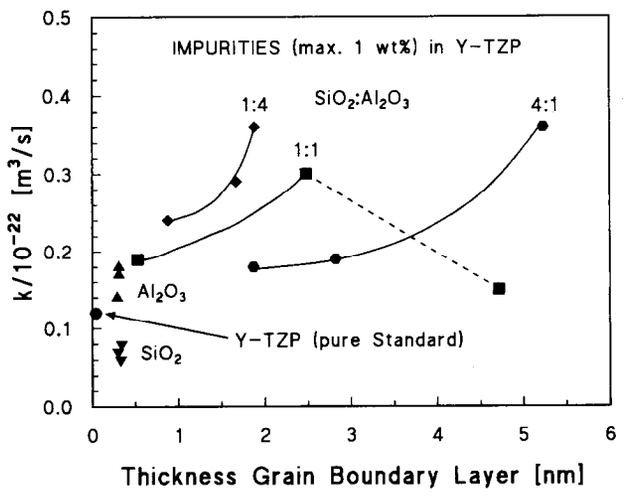

Fig. 4. (a) Grain growth coefficients k of Y–TZP containing up to 1 wt% impurities such as Al_2O_3, SiO_2 or mixtures of both as a function of the total amount of the impurities (Al_2O_3 + SiO_2). (b) Grain growth coefficients k as a function of the grain boundary layers formed.

on the ternary Y_2O_3–SiO_2–Al_2O_3 phase diagram,[18] the following relations are found: $T_{M,1:0}$ (liquidus of $ZrSiO_4$) > $T_{M,0:1}$ > $T_{M,1:4}$ > $T_{M,1:1}$ > $T_{M,4:1}$. The grain growth is enhanced in the same sequence.

If considerable amounts of a second phase are present, precipitations rather than grain boundary phases become crucial for grain growth. The grain growth coefficients k were determined for several systems containing large amounts of second phases (Table 3) and their influence could roughly be estimated. Chromium oxide in solid solution increases the grain growth but its precipitation decreases k by a factor of 200, despite the fact that chromium starts to volatilize around 1400°C. The same holds qualitatively also for tin oxide. 6 8 CaTi–ZrO_2 contained at room temperature substantial portions of monoclinic (at 1400°C tetragonal) and just few % cubic grains. Its grain growth is comparable to that of pure zirconia. The addition of 3 mol% more Ca^{2+} results in the formation of $CaZr_4O_9$. The grain growth is clearly suppressed by this second phase. Increase of the titanium oxide concentration to 7 mol% results in the formation of an additional $ZrTiO_4$ phase, i.e. the sample now contains 4 different phases. The grain growth of this sample is strongly increased, indicating a grain growth accelerating influence of $ZrTiO_4$. Bismuth additions increased the grain growth, too. This behavior must be caused by forming mobile Bi_2O_3 precipitations in triple points (as observed by SEM) and by a volatile phase. The large radius of Bi^{3+}, its valence and its low solubility[21] exclude a grain growth accelerating influence in solid solution of zirconia.

In summary, SiO_2 impurities probably in form of $ZrSiO_4$ decrease the grain growth whereas large amounts of SiO_2 increase it. In contrast, Al_2O_3 impurities enhance grain growth only slightly, whereas large amounts suppress it very efficiently. Cr_2O_3 and SnO_2 inhibit grain growth very efficiently but they evaporate at temperatures around 1400°C. These findings suggest that impurities influence grain growth over a grain boundary layer whereas larger amounts of a second phase control grain growth based on its morphology, mobility and amount.

Conclusions

Grain growth is found to be varied by the doping cations up to a factor of 10.[4] Large, low valence cations are most effective to reduce grain growth in agreement with the solute drag model whereas small ones increase it independent of their valence state and concentration. The cations' segregations are similar for all investigated alloys and do not reveal any correlation with the grain growth coefficients k. It is therefore suggested that segregations generally occur independent of the cations valence state, e.g. not with a space charge mechanism. However, the pinning of the grain boundaries is most effective in alloys doped with large cations of low valence, indicating, that the diffusion of the segregated cations is the controlling mechanism. The grain growth behavior of Y–TZP is not altered during and after phase partitioning, excluding it as a growth controlling mechanism. Impurities were found to govern grain growth by forming grain boundary layers, whereas larger amounts of a second phase controls the grain growth by mobility, morphology and amount of the precipitations. Thus, SiO_2 impurities (probably in form of $ZrSiO_4$) decrease the grain growth whereas large amounts increase it. In contrast, Al_2O_3 impurities increase grain growth, whereas considerable amounts of it suppress it very efficiently. Furthermore, grain growth could be suppressed by spherical Cr_2O_3– and SnO_2-precipitations.

Abstract

Nano-sized and well dispersed Y–TZP/alumina (Y–TZP-rich) composite powders have been prepared via a chemical method. It has been found that alumina exists metastably in the Y–TZP lattice in the composite powders at relatively low temperatures before the crystallization of α-alumina from the composites started at around 1200°C. Alumina in the composite powders impedes the crystallite growth of Y–TZP and increases the specific surface area of the composite powders. This effect is discussed and attributed to the lattice distortion of Y–TZP by alumina.

1 Introduction

Ceramic composites are of great interest to ceramists because they exhibit better performance than their individual component materials, for example, fibre and whisker-reinforced ceramics.[1,2] However, as it is well known, fibers and whiskers are expensive and sometimes toxic, and these composites are technically difficult to densify because of the impedance of the second phase to the densification of the matrix phases. Generally hot-pressing or hot isostatic-pressing techniques are used, and thus the cost of fabricating these composites are relatively high. Another kind of ceramic composite, the particle/particle composites are, however, relatively easy technically to fabricate and are thus cheap.

Zirconia (or Y–TZP, yttria stabilized tetragonal zirconia polycrystals)/alumina composite is one of the most investigated ceramic composites, from their phase stability to mechanical properties.[3–10] Zirconia is usually used as the reinforcement agent in alumina.[6–7] However, for Y–TZP matrix/alumina particles composites, the mechanical properties of the composites were also found to be significantly better than single phase Y–TZP material.[8–10] The sinterability of the composites depends on the particle properties. Defining R as the size ratio of the second phase to the matrix phase, (the matrix Y–TZP phase assumed to be easy to densify), the densification of the matrix is greatly impeded when $R \approx 100$,[11–13] which results from the inner back stress around the second particles opposite to the sintering stress; if $R \approx 10$, the back stress is believed to be smaller, and the composite can be pressurelessly sintered, but higher sintering temperatures are needed because of the bimodal pore size distributions in the composites.[14] Supposing that the R value decreases further to about 1 — the two factors affecting the densification: back stress and the duplex pore size distribution can be minimized or even cleared out, so the sinterability of the composites will not be affected significantly.

Composite powders of $R = 1$ can be prepared by chemical methods. Rejandran *et al.*[15] Exter[16] and others[17] have prepared the composite powders using the coprecipitation method resulting in very large specific areas. However, these composite powders were still difficult to fully densify via pressureless sintering. We believe that the problem is due to the agglomeration effect of the composite powders, and hardly any individual particles in the powder can be identified.

To obtain good powder properties, the composite powders were prepared using the coprecipitation method and care was taken with the coprecipitation and washing processes. In this paper, the preparation and characterization of the Y–TZP/alumina composite powders will be reported; the compaction and sintering behavior will be presented in the next paper.

2 Experimental Procedure

2.1 Powder preparation

The Y–TZP/alumina composite powders were prepared using a common coprecipitation method,

which is described as follows: (1) Preparation of the solutions of Zr^{4+}, Y^{3+} and Al^{3+} from zirconium oxychloride (chemical grade), respectively, with their concentrations determined by chemical methods. (2) Preparation of the mutual solutions with designated ratios of Zr:Y:Al. (3) Putting the solution into a 12 vol% concentrated ammonia solution and yielding the coprecipitates. The pH value of the solutions after coprecipitation was maintained at around 8–9. (4) Washing the coprecipitates with distilled water until the concentration of Cl^- in filtrates were less than 10 ppm. (5) Washing the cake further with ethanol for approximately six times until the water content in the filtrates measures less than 6 vol%. (6) Drying the coprecipitates overnight at 80°C, followed by calcination in air at different temperatures from 420 to 1350°C for 120 min. After the above steps, the composite oxide powders were obtained.

2.2 Powder characterization

The composite powders were characterized as follows:

2.2.1 Specific surface area

The specific surface area of the composite powders was measured with multi-point nitrogen adsorption BET method (Micromeritics, 220/50000/OX). The particle sizes of the composite powders were calculated by assuming the spherical shape of the powder particles.

2.2.2 Crystallite size determination

X-ray diffraction-line broadening (XRD-LB, Rigaku Denki, RAX-10) method was used for the determination of the average crystallite size of the composite powders. As a matter of fact, only the diffraction peaks of Y–TZP crystals could be obtained at less than about 1200°C, so only the crystallite sizes of Y–TZP in the composite powders were determined using its (111) diffraction peak. The half intensity breadth of the diffraction peak was calibrated by subtracting the instrumental broadening.

2.2.3 Micro-morphology observation

The crystallite size and micro-morphology of the composite powders were observed using transmission electron microscopy, (TEM, JEM-200CX, JEOL) and the composite powders were also analyzed of their components in a micro-area with energy dispersive spectroscopy (EDS) which is part of the microscope. The detailed structure of the composite crystallites were observed with a high resolution electron microscope (HREM, JEM-200CX, JEOL).

2.2.4 Phase analysis

X-ray-diffraction (Rigaku Denki, RAX-10) was used for the analysis of the phase structures. To detect the possible phases of very weak diffraction ability, very high X-ray intensity was used when the diffraction peaks of the main phase were largely out of scale.

To investigate the possible effect of alumina on the lattice distortion of Y–TZP, the (200) lattice plane distance of Y–TZP was measured using the XRD method. To prevent an instrument error, pure Y–TZP samples prepared under the same conditions as the composite powders were measured, together with other samples in every batch.

3 Results

3.1 Specific surface area as a function of alumina content

As reported by other researchers,[15,16] the specific surface area of the coprecipitated composite powders was greatly increased by the addition of alumina. This was also true for the composite powders prepared in this study, as shown in Fig. 1. Figure 2 shows the calculated particle size of

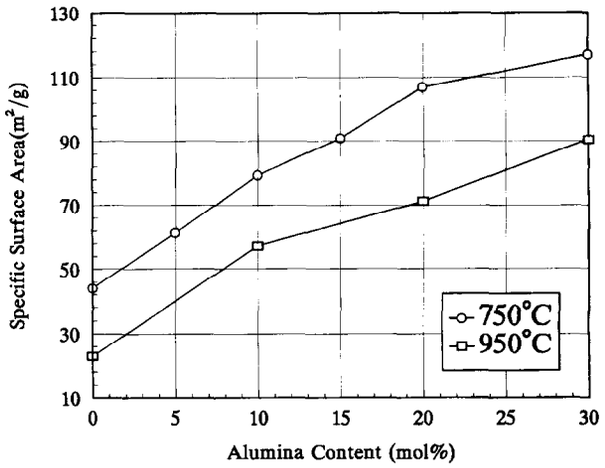

Fig. 1. Specific surface area of the composite powders as a function of alumina content, the powders were calcined at 750 and 950°C for 120 min.

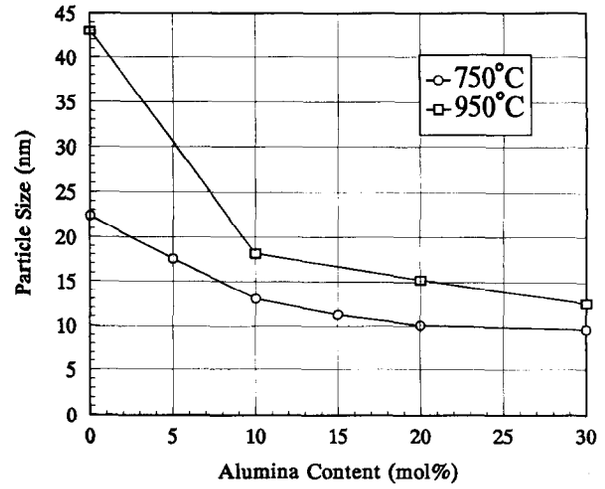

Fig. 2. Particle size calculated from the specific surface area versus alumina content.

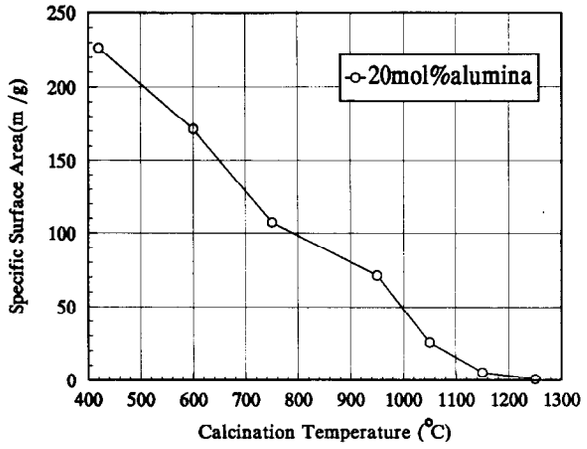

Fig. 3. Temperature dependence of the specific surface area of the Y–TZP/20 mol% alumina composite powders.

the composite powders from the specific surface area. The composite powders were very fine with extraordinarily high surface area when calcined at low temperatures such as 420 and 600°C, and decreased rapidly at elevated temperatures as illustrated in Fig. 3, which was accompanied by crystallite growth, particle coarsening and partial sintering.

3.2 Phase structure and crystallite size

The results of the XRD study for Y–TZP/20 mol% alumina composite powders (Fig. 4) shows that at less than about 1200°C, only the diffraction peaks of Y–TZP were detected but not those of alumina, even at the maximum X-ray power output of 15 kW; although γ-alumina (or other forms except for the α phase) using the same process can be detected easily under ordinary diffraction conditions.

Based on the above reason, only the crystallite sizes of Y–TZP could be determined with the

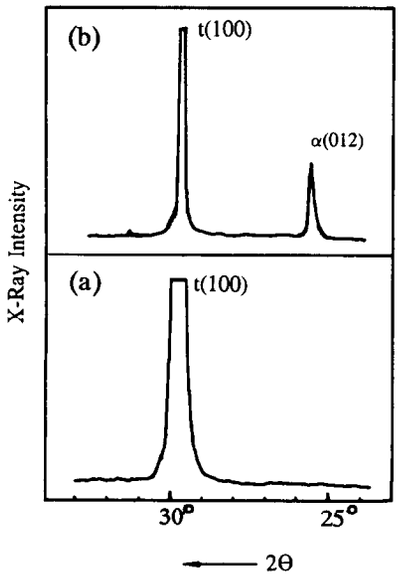

Fig. 4. XRD spectra of the Y–TZP/20 mol% alumina composite powders calcined at (a) 750°C and (b) 1250°C for 120 min.

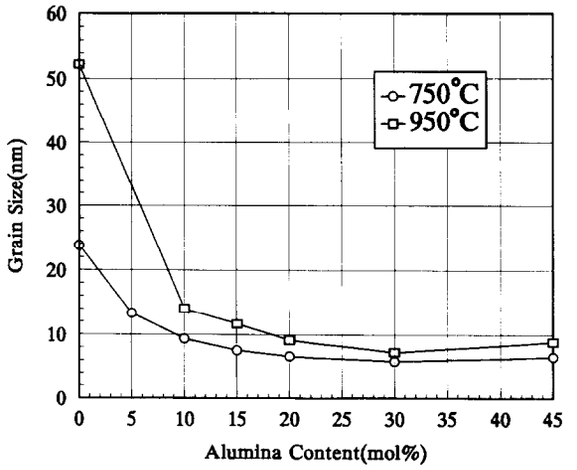

Fig. 5. Crystallite size of Y–TZP as a function of alumina content in the composite powders calcined at 750 and 950°C for 120 min.

method. The results are shown in Fig. 5 illustrating the effect of alumina on the crystallite size of Y–TZP, and such an effect was most important at relatively low alumina contents of 5 and 10 mol%.

3.3 Micromorphology of the composite powders

The effect of the addition of alumina on the crystallite size is shown in Fig. 6. The decrease of the crystallite size with increasing alumina content is apparent. Different from the powder micromorphology reported by Rajendran,[15] the particles were well dispersed and therefore could be identified separately from the micrographs, due to the careful control of the processes of the powder preparation. The temperature dependence of the particle size and morphology of Y–TZP/20 mol% alumina is illustrated in Fig. 7. At temperatures lower than 1250°C, there seems to be only one kind of particle present in the powders, which means no component separation can be observed under the conditions. At elevated temperatures of 1250°C or higher, the component contrasts can be seen in the micrographs, which means the component separation takes place. As shown in Fig. 7(f), the dark grains are Y–TZP and the lighter ones are alumina, as indicated by the EDS results in Fig. 8.

4 Discussion

4.1 Existing form of alumina in the composite powders

According to the phase diagrams, alumina and zirconia are insoluble with each other both at ambient and high temperatures. In the present study, this is true for the composite powders calcined at temperatures of around 1200°C when α-alumina crystallized out, as can be seen in Figs 4 and 7.

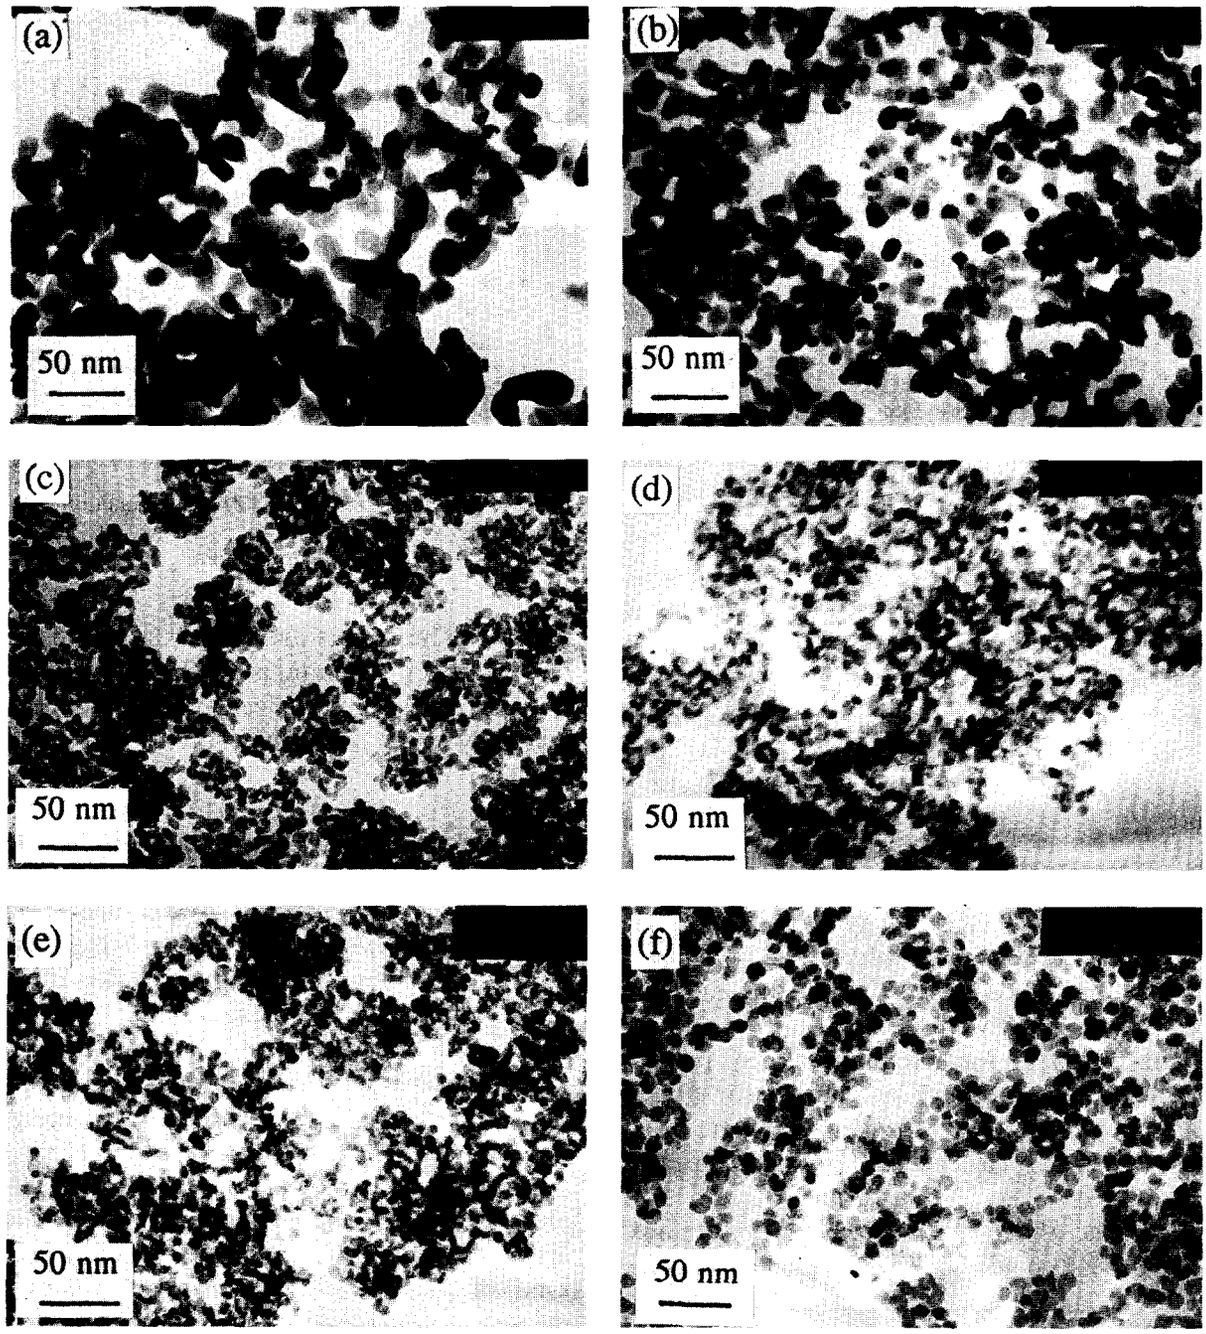

Fig. 6. TEM micrographs of the 750°C calcined composite powders containing (a) 0, (b) 5, (c) 10, (d) 20, (e) 30 and (f) 45 mol% alumina.

However, the two components (supposing yttria always dissolves in the Y–TZP lattice) were not found to exist separately from Y–TZP at lower temperatures than the crystallization point of the α phase. The detailed observation by HREM of the micromorphology of the composite powders containing 20 mol% alumina (Fig. 9) shows no alumina in the Y–TZP grains or around the grains, although alumina may be amorphous-like. However, if it existed separately from Y–TZP, there should have been a contrast between alumina and Y–TZP and between alumina and the background of carbon films which was used to support the particles. So it is believed that alumina existed in the Y–TZP lattice before the crystallization of α-alumina from the composites at around 1200°C. Direct evidence of this conclusion has been found by measuring the lattice parameters of Y–TZP, (as shown in Fig. 10), of the differences of the (200) lattice plane distances between pure Y–TZP and alumina added composite powders. Such a lattice distortion could only be attributed to the alumina existing in the Y–TZP lattice, since the lattice parameters of Y–TZP cannot be affected by alumina particles around them even in the sintered bodies.[14] Such an effect was most significant at a relatively low alumina content, which corresponded to the crystallite size decreasing effect of Y–TZP by the addition of alumina. When α-alumina crystallized out from the

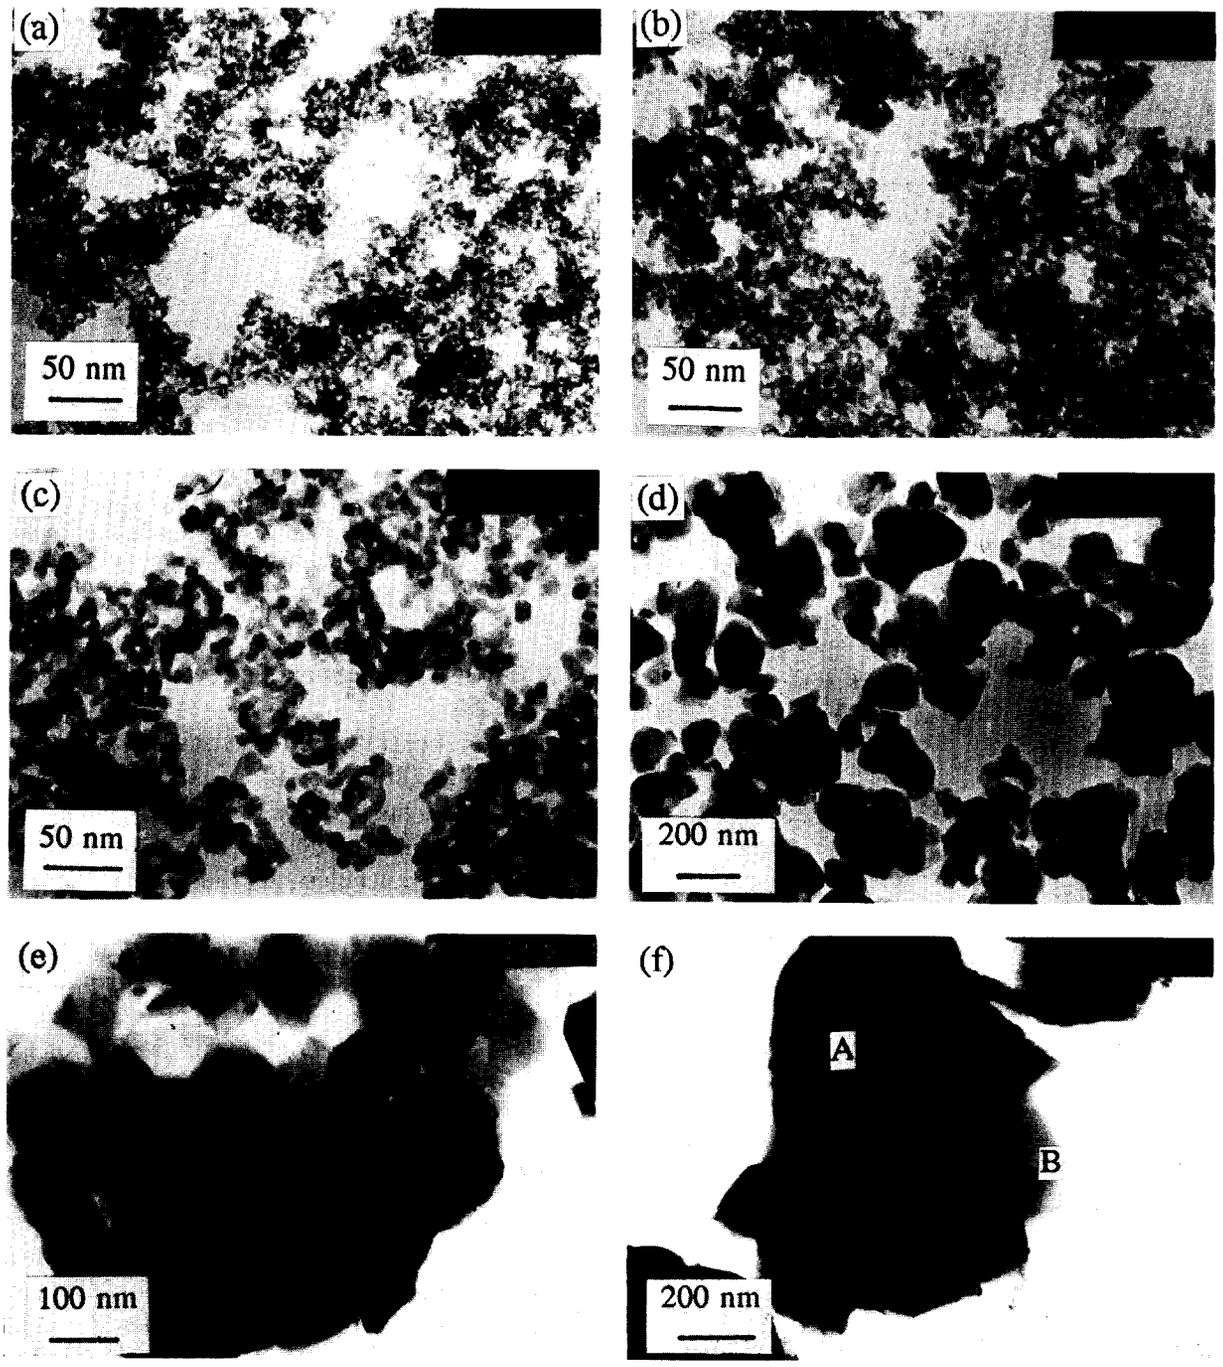

Fig. 7. TEM micrographs of the Y–TZP/20 mol% alumina composite powders calcined at (a) 420, (b) 600, (c) 950, (d) 1050, (e) 1250 and (f) 1350°C for 120 min.

composite, the difference of the lattice plane distances returned to zero, as shown in Fig. 11 for the composite powders containing 20 mol% alumina.

4.2 Crystallization process of alumina in the composite powders

Al_2O_3 presents as the γ phase (or other forms except the α phase) when decomposed from the hydroxides or other salts of aluminum at around 1200°C. These forms are amorphous-like and therefore are metastable themselves. As the phase transformation from these forms to the thermodynamically stable α phase needs a big structure rearrangement, usually a temperature range around 1200°C is required for such a transformation. For the composite powder investigated in this study, the three components were mixed homogeneously on a molecular level in their mutual solutions and such a homogeneity could be maintained in the hydroxide coprecipitates and amorphous oxides at less than about 360–400°C. Y–TZP are very easy to crystallize from its amorphous oxide at only around 400°C.[3] At this low temperature, the diffusion of alumina molecules through Y–TZP to form a separate alumina phase are difficult. This was because, firstly, the thermodynamic driving force for this process was small, as a separate alumina phase at less than 1200°C was metastable

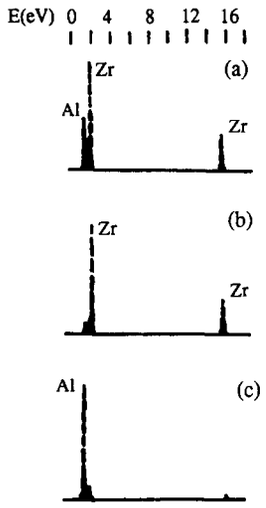

Fig. 8. EDS spectra: (a) for the sample shown in Fig. 7(c); (b) for the sample shown in Fig. 7(f) on dark area 'A' and (c) on the lighter area 'B'.

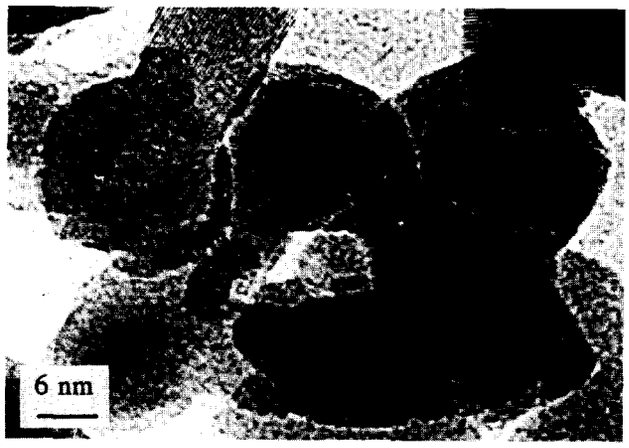

Fig. 9. HREM micrographs of Y–TZP/20 mol% alumina composite powders calcined at 950°C.

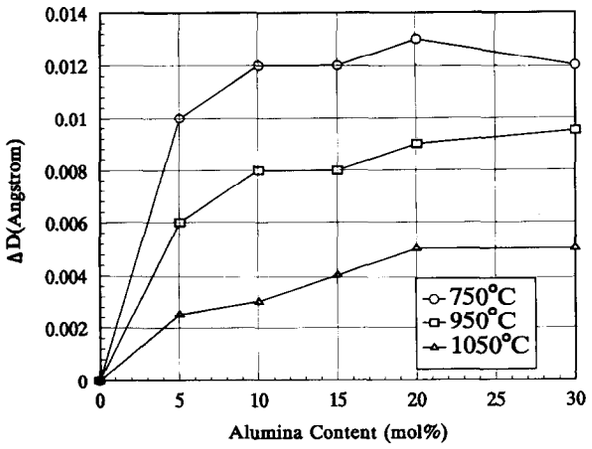

Fig. 10. Differences of the (200) lattice plane distance between pure Y–TZP and composite powders.

itself; secondly, the kinetic resistance was great because of such a low temperature and Y–TZP impedance. As temperature increases, the diffusion resistance became less and the driving force became large. At around 1200°C, thermodynamically stable α phase crystallized out and the two components became separate to one another.

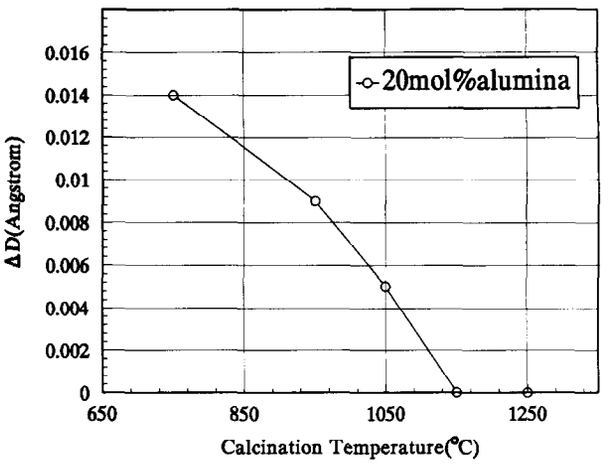

Fig. 11. Difference of the (200) lattice plane distances of Y–TZP/20 mol% alumina composite powders as a function of calcination temperature.

4.3 Influence of alumina on the crystallite growth of Y–TZP

There are possibly two reasons for the hindrance of the crystallite growth of Y–TZP by alumina: lowering the surface tension of the Y–TZP particles, or increasing the resistance for the diffusion of Y–TZP molecules. As has been argued, alumina existed homogeneously in the Y–TZP lattice before the crystallization of α-alumina from the composite powders, and the most strong effect on the crystallite growth of Y–TZP was at the relatively low alumina content of 5–10 mol%. Even so, it was still possible that some alumina components at, or near the particle surface of Y–TZP could affect the surface tension. However, this effect is believed to be limited if the homogeneous distribution of the alumina molecules in the Y–TZP lattice was true, because the amount of alumina species at the particle surface were not concentrated, which could not alter the crystallite growth behavior so much, as shown in Fig. 5. In contrast, the presence of alumina in the Y–TZP lattice caused the lattice distortion of Y–TZP, mostly at the relatively low alumina level of 5 mol%, corresponding to the dependence of crystallite size on the alumina content. The lattice distortion led by the aluminum ions would lead to the considerable additional energy fluctuations in the lattice. Such an energy fluctuation would act as the energy barrier for the diffusion of Y–TZP, so the diffusion resistance of Y–TZP species would be increased, and therefore the crystallite growth which depends on the diffusion would be impeded. So it is believed that the lattice distortion by the presence of alumina in the Y–TZP lattice is the main reason for the impedance of the crystallite growth of Y–TZP in the composite powders.

5 Conclusions

(1) Nano-sized and well dispersed Y–TZP/Al_2O_3 composite powder could be prepared by coprecipitation method with careful control of the processes.

(2) Alumina co-existed in the Y–TZP lattice at relatively low temperatures before the crystallization of the α phase from the composite powders at about 1200°C, leading to the lattice distortions of Y–TZP.

(3) The crystallite growth of Y–TZP was greatly impeded by the addition of alumina in the composite powders. The reason for this phenomenon is believed to be caused mainly by the lattice distortion led by alumina.

Processing of Nano-Y–TZP/Al_2O_3 Composites. II: Compaction and Sintering Behaviour of Nano-Y–TZP/Al_2O_3 Composite Powders

J. L. Shi, J. H. Gao, B. S. Li & T. S. Yen

Shanghai Institute of Ceramics, Chinese Academy of Sciences, 1295 Ding-Xi Road, Shanghai, 200050, P.R. China

(Received 31 August 1994; revised version received 9 March 1995; accepted 20 March 1995)

Abstract

The compaction and sintering behaviour of nano-sized and well-dispersed Y–TZP/Al_2O_3 composite powders have been investigated. It has been found that the composite powders contained no hard agglomerates, and after compaction, all soft agglomerates are fragmented. The green density of the compact was found to decrease with the increase of alumina content. The composite powder compacts containing less than 20 mol% alumina can be sintered at not higher than 1350°C to 99% of their theoretical densities. The densification behaviour of the composite powders show duplex shrinkage peak characteristics for the composites containing not less than 15 mol% alumina.

1 Introduction

Reports have shown that zirconia (or Y–TZP)/alumina composites exhibit higher performance than single phase alumina or TZP ceramics.[1–7] For the alumina matrix based composite ceramics, the main toughening and strengthening mechanisms are zirconia phase transformation and microcracking.[1–4] Another kind of composite is TZP, (mainly Y–TZP) based composite; this kind of composite also shows higher toughness and strength than single TZP ceramics. The toughening effect of the composite has been found to be increased phase transformation volume of Y–TZP by the addition of alumina particles in the Y–TZP matrix.[9]

As stated in the previous paper, the composites were more difficult to densify than the single matrix phase.[9–11] So depending on the powder properties, hot-pressing or hot-isostatic pressing techniques may be required[5–7] for the full densification. This is because the second phase usually acts as an impedance to the densification if the particles of the second phase were too large compared to the matrix phase, or if the composite powders were possibly strongly agglomerated. Pressureless sintering may also be useful if the particles of the second phase are not much larger than that of the matrix,[12] but the sintering temperature must be higher than the matrix because of the duplex pore size distribution led by the larger second phase.[13] Providing that the hard-agglomerate-free composite powders with roughly the same particle sizes between the second and matrix phases can be prepared, they could have good sinterability comparable to the matrix. In the previous paper, such a composite powder has been successfully prepared[14] and the sintering behaviour will be studied in this paper.

2 Experimental Procedure

The preparation process of the composite powders has been reported in the previous paper.[14] The powders were afterwards compacted first by uniaxial pressing at 50 MPa and followed by cold isostatic pressing at 250 MPa. The green densities of the composite powder compacts were calculated by their weights and the geometric volumes measured, and the theoretical densities were calculated according to the volume percentages of the composites. The compacts were also characterized by their pore size distributions to find if the agglomerates, (i.e. inter-agglomerate pores) were present in the compacts.

The shrinkage behaviour was recorded by a constant heating rate of 5°C/min on a linear dilatometer to 1550°C. Isothermal sintering was also conducted in a molybdenum silicide furnace at various temperatures for 120 min.

The sintered bodies were observed of their microstructure with scanning electron microscope (SEM, JCXA-733, JEOL) and transmission electron microscope (TEM, JEM-200CX, JEOL).

3 Results

3.1 The compaction behaviour

The agglomeration behaviour of the powders can be characterized by the pore size distributions of their compacts.[11-12] For agglomerate-free powder compacts, there are only one kind of pores—inter-primary particle pores could be detected in the compacts. Fig. 1 shows the pore size distribution of the compacts of the composite powders calcined at 750°C. There was only one distribution peak detected in every kind of powder compact and therefore, there was only one kind of pore present in the compacts, which were the interprimary particle pores, meaning that no agglomerates were present in the compacts. Figure 2 gives the mean pore sizes and the size ratios of the pores to the grains as a function of alumina content. The pore size decreased with the increase of alumina content when the alumina content was less than 20 mol%, corresponding to the reducing effect of alumina on the crystallite size of Y-TZP;[14] however it increased slightly when above 20 mol%. The size ratio of the pores to the crystallites increased with the addition of alumina at not higher than 30 mol%, meaning the compaction properties of the primary particles of the composite powders have changed, as proved by the measurement of the green densities of the compacts (Fig. 3).

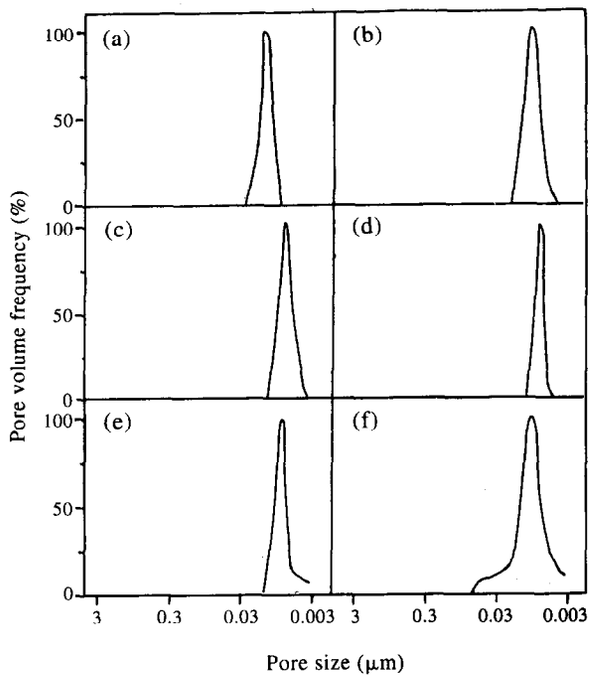

Fig. 1. Pore size distributions of the 750°C calcined composite powder compacts (250 MPa) containing (a) 0, (b) 10, (c) 15, (d) 20, (e) 30, (f) 45 mol% alumina.

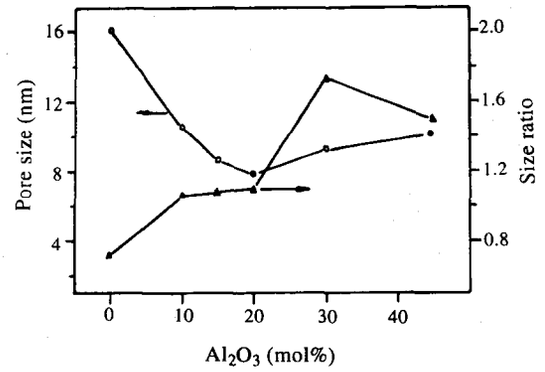

Fig. 2. Dependence of the pore size and the size ratio of pores to particles on the alumina content in the composite powder compacts (750°C calcined, 250 MPa compacted).

3.2 Densification with constant heating rate

The densification behaviour of the composite powder compacts with constant heating rate measured is shown in Fig. 4. The figure shows that the

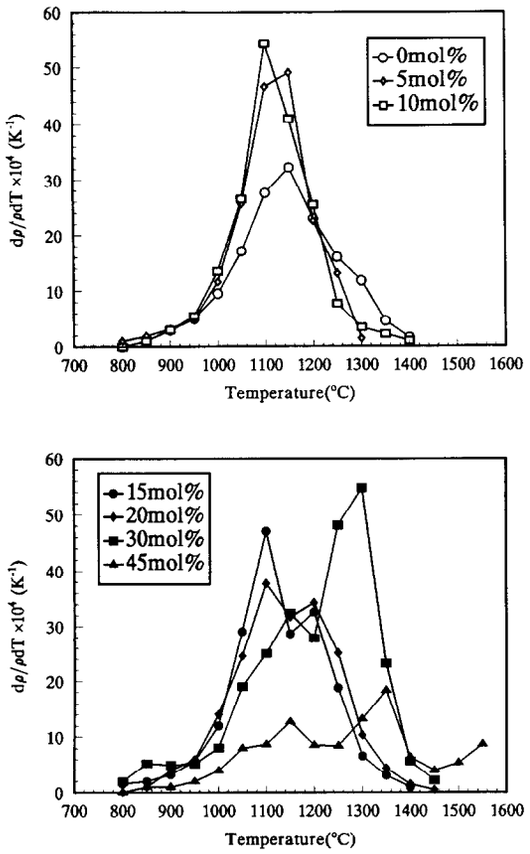

Fig. 5. Densification rate ($d\rho/\rho dT$) versus temperature profile of the composite powder compacts during sintering by a constant heating rate of 5°C/min at different alumina contents.

addition of 5–10 mol% alumina lowered the densification temperature from about 1350°C to about 1250–1300°C, but the densification process finished at higher temperatures when the composite powders contained a higher percentage of alumina. For the composite powders containing 45 mol% alumina, full densification could not be reached.

Figure 5 gives the densification rates of the composite powder compacts. The densification rates were greatly raised by the addition of 5 or 10 mol% alumina in the composites, and temperatures for the end-point of densification were lowered. Much more interestingly, when the composites contained 15 or higher mol% of alumina, there were two maximum points of the densification rates, (duplex shrinkage peaks), during heating: one at about 1050–1100°C and another at around 1200°C or higher. Despite this phenomenon, the composite powders could still be densified at about 1400–1450°C, but if the alumina content was any higher, (45 mol%), there was only a small densification effect.

3.3 Densification with isothermal sintering

Figure 6 shows the sintering densities of the composite powder compacts at different temperatures. The results show again that nearly full densification could be obtained for the composites containing 5–20 mol% alumina at sintering temperatures as low as 1250–1350°C; the sintered densities were roughly the same as or even higher than those of single phase Y-TZP in the temperature range of 1150–1350°C except for the composite containing 30 mol% alumina. At 1450°C, the sintering densities decreased for the composites containing 15 mol% or a high content of alumina.

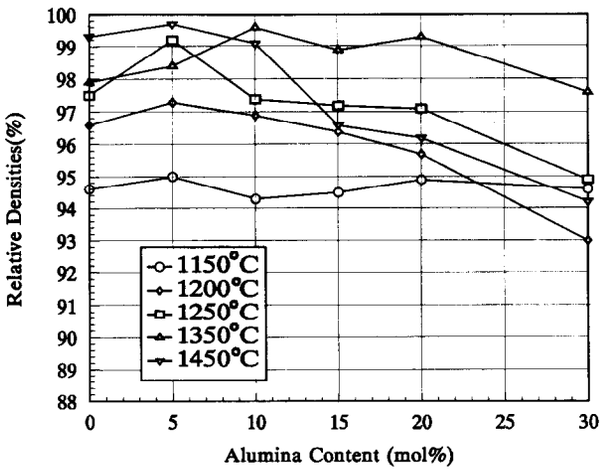

Fig. 6. Sintering densities of the composites at different sintering temperatures by isothermal sintering for 120 min.

3.4 Microstructure development

The presence of alumina does not only decrease the crystallite size in the coprecipetated composite powder, it also inhibits the grain growth in the composites, as shown in Fig. 7 and 8. The micrographs in Fig. 7 were obtained on the polished and thermally etched surface of the sample sintered at lower temperatures and no apparent contrast difference between the components could be distinguished in the micrographs. Those in Fig. 8 were the natural surfaces of the composite sintered at higher temperatures, and the contrasts between the particles can be clearly seen: the dark grains were alumina and others were Y-TZP. It is obvious from the micrographs that the microstructure is fine and homogeneous, and the grain size of the two phases of alumina and Y-TZP are almost the same.

Figure 9 shows the microstructure of a Y-TZP/45 mol% alumina composite sintered at 1350°C. The composite was not densified and the microstructure was highly porous.

Figure 10 shows the TEM microstructure of Y-TZP/20 mol% alumina composite sintered isothermally at different temperatures. In contrast to the micrographs shown in Fig. 8, in TEM micrographs, the dark grains are Y-TZP, the bright ones alumina. The grains of both Y-TZP and alumina grew with increasing sintering temperature.

4. Discussion

4.1 Particle arrangement in the compact

Although the composite powders prepared are hard agglomerate-free and could be compacted with only one kind of pores — inter-primary particle pores left in the compacts — the packing properties between the primary particles were dependent on the alumina content. The size ratios of the pores to primary particles increase with the increase of alumina content, corresponding to the decrease of the compaction densities. This phenomenon, if the agglomeration properties were not affected by the alumina addition, could be mainly attributed to the decrease of particle size when alumina was added. The dependence of the packing densities on the particle size is well known to ceramists, the poor flowability of fine powders

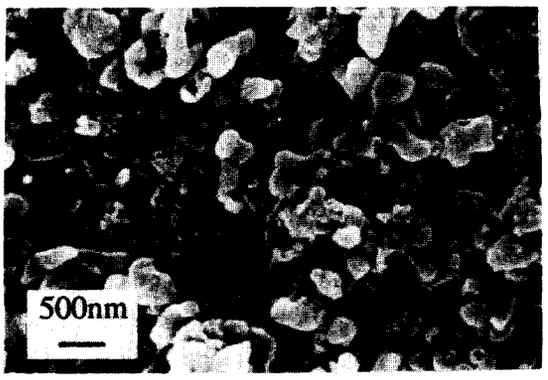

Fig. 9. Microstructure of Y-TZP/45 mol% alumina sintered at 1350°C for 120 min.

is the reason for their low packing densities. The dependence of compaction densities can be explained in a similar way. With the decrease of particle size, the contact between the particles in the unit area increases. Because of the non-deformability of the ceramic particles, the contact area for every contact is independent of particle size, so under a certain external pressure, the more contact between the particles causes lower effective internal pressure, which is the driving force for the rearrangement between particles. Thus, the compaction density would decrease with the decreasing of particle size. Higher applied pressure is needed for powders of finer particle sizes for the same density than that for powders of larger particle sizes.

4.2 Densification characteristics as influenced by alumina

The great increase of the densification rate of the composite powders at 5 and 10 mol% alumina is not fully understood. Probably it is due to the smaller grain size of the composites than the single phase Y-TZP in the compacts during sintering. Generally there is only one maximum value of the densification rate during sintering, with a constant heating rate of homogeneous powder compacts. This is true for the composites with not higher than 10 mol% alumina, the maximum temperature for this is around 1100°C. The occurence of the second maximum value occurs at around 1200°C or higher (in addition to the first maximum value), for the composite powder compacts with higher alumina content can be understood by the phase transformation of alumina in the composite powder during sintering. As this process did not take place at a calcination temperature as low as 750°C but at around 1100–1200°C.[14] When the first maximum value was reached, the crystallization of

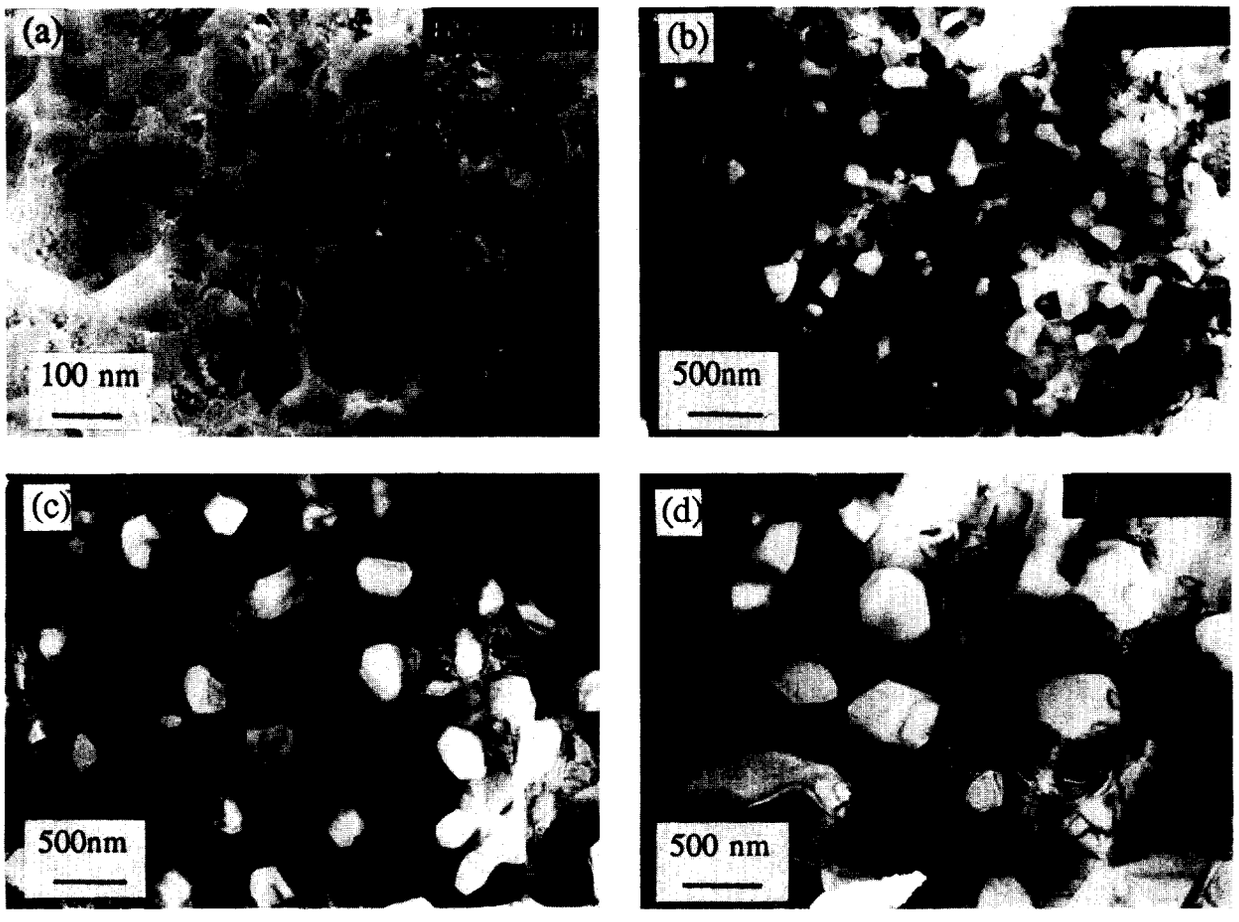

Fig. 10. TEM microstructure of the composites containing 20 mol% alumina sintered at (a) 1250, (b) 1350, (c) 1450 and (d) 1550°C for 120 min.

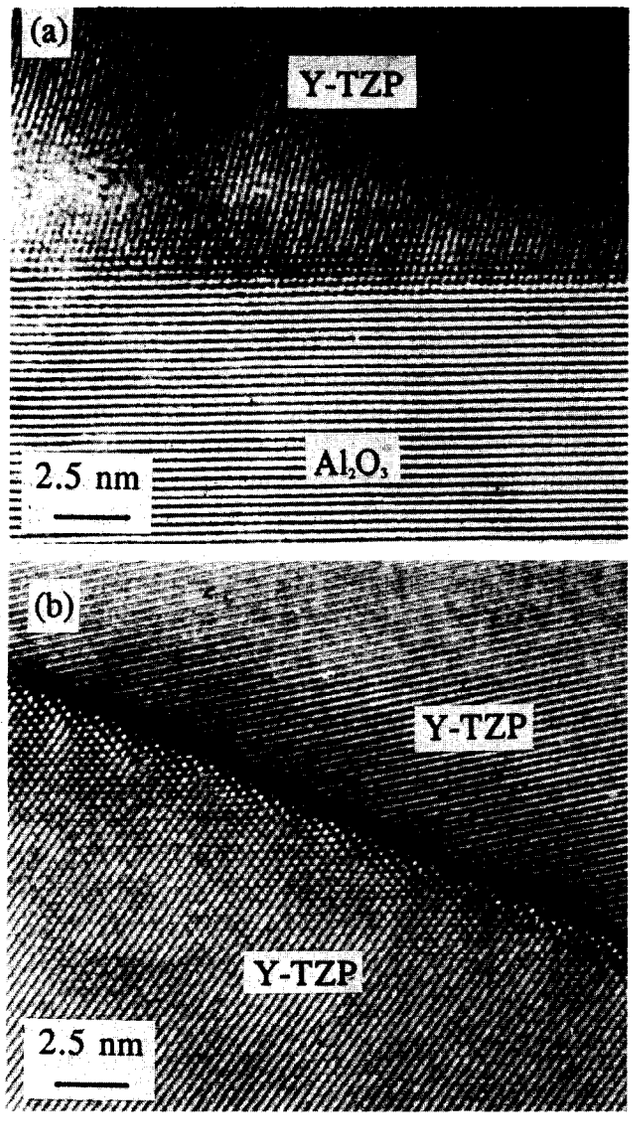

Fig. 11. Lattice images of the Y–TZP/20 mol% alumina composites sintered at 1450°C for 120 min for (a) Al_2O_3/Y–TZP interface, (b) Y–TZP/Y–TZP interface.

α-alumina from the Y–TZP matrix during sintering impeded the densification process of the composite and densification rate was lowered through the formation of the inter alumina Y–TZP pores, and/or the 'vermicular' structure between alumina particles, inhibiting matrix diffusion. As the temperature increased, the densification rate reached another maximum value through the enhancement of the diffusion ability at elevated temperatures. An alternative explanation for the second maximum densification rate may be that as the alumina content reaches 15 mol% or higher, the contacts between alumina particles increase and the alumina clusters may form, and the densification of the alumina cluster, together with the not necessarily retarded densification of Y–TZP, causes the second maximum rate. The temperatures for the second maximum were dependent on alumina content, and more alumina that is added, then the impedance effect by alumina is larger and the second maximum densification rate occurs at higher temperatures.

The composite powder compacts could be densified to near full density when alumina content is not higher than 20 mol%. 30 mol% alumina in the composite has already prevented the composite from reaching full densification; at 45 mol% of alumina, the composite compact showed only very limited densification effect, partially because of the low green density, but mainly because higher alumina content, which forms an extensive 'vermicular' structure or even a network in the body. This vermicular network leads to a large amount of inter-alumina or inter-alumina-Y–TZP pores and densification becomes greatly impeded.

4.3 The role of alumina in the development of the microstructure

The crystallization of alumina from Y–TZP grains during sintering leads to a two phase structure: alumina particles become homogeneously distributed in the Y–TZP matrix. Different from the similar composed but differently processed composites,[9–13] the particle size of the second alumina phase in this study was almost the same for those with the Y–TZP matrix (so no alumina particles could be trapped in a matrix grain or vice-versa), so the microstructure inhomogeneity was greatly suppressed. The particle size of the Y–TZP matrix was considerably affected by the presence of alumina particles at 1250°C: the matrix grain growth was inhibited by alumina. Figure 10 is the lattice image of a composite containing 20 mol% alumina. It can be seen that the interface between the two phases is very clear and no glass phase can be detected, so the inhibiting effect of grain growth by alumina is mainly from the pinning effect of the *in situ* formed second alumina phase. At a higher sintering temperature of 1550°C, the effect of grain growth inhibition of Y–TZP by alumina was not so strong as that at 1250°C.

5 Conclusions

(1) The composite powders prepared are hard, agglomerate-free and can be compacted without agglomerates left in the compacts.
(2) The composites can be densified to full densities at relatively low temperatures of 1250–1350°C for 2 h when alumina content is not higher than 20 mol%.
(3) The densification rate of the composite compacts with alumina content of 5 and 10 mol% is greatly increased because of the inhibited grain growth of the Y–TZP matrix.

Two maximum values of the densification rate (duplex shrinkage peaks) occur when alumina content is equal to or larger than 15 mol%, which is attributed to the phase transformation of alumina and/or the alumina particle clusters formed in the compacts during sintering.

(4) The homogeneous microstructure of the composite was obtained with the same grain size of the matrix Y–TZP and the second phase of alumina. The inhibiting effect of alumina on the grain growth of Y–TZP is probably led by the pinning effect.

Abstract

An attractive method for the fabrication of Al_2O_3–ZrO_2 laminar composites is described in this paper. The process consists in the centrifugation of colloidal suspensions containing alumina and zirconia particles. With this procedure, it is possible to grow thin layers with different composition and smooth interfaces. The effects of the slurry compositions, as well as aging times and centrifuging conditions on the morphology of the laminae are discussed.

Introduction

Laminar ceramic composites are attractive materials because superior mechanical performances can be achieved by tailoring the properties, geometry and interfaces of the different layers.[1–3]

In particular, brittle ceramics can be toughened by introducing weak interfaces transverse to the growing crack or by developing internal stresses.[4–6] These tensile and compressive stresses are a consequence of the different thermal contractions and determine a deviation of the propagating cracks.

From this point of view the Al_2O_3–ZrO_2 system is interesting because the thermal expansion coefficients of the oxides are quite different, therefore, it is possible, by changing the ratios between alumina and zirconia in the layers, to obtain laminar composites with high internal stresses. Furthermore Al_2O_3–ZrO_2 based ceramics are known to be high toughness materials due to the stress-induced transformation of the metastable tetragonal zirconia inclusions.

So far, ceramic laminates have been prepared through chemical methods, the doctor blade technique and the slip casting route.[6–10] In this paper an alternative methodology is presented. It consists of the centrifugation of a relatively dilute aqueous suspension, in the removal of the supernatant liquid and in the addition, on the consolidated layer, of a new suspension with a different Al_2O_3–ZrO_2 ratio. Further, centrifugation induces the consolidation of a new layer and the process is repeated until the composite has the desired number of laminae.

The advantage of this method consists of obtaining thin layers of powders free of aggregates. In fact, during suspension preparation, repulsive interactions are generated between the particles, consequently the aggregates, which are deleterious for the sinterability of the powders and for the microstructure homogeneity, are broken down. Finally, this procedure results in smooth interfaces between the laminae and therefore a sharp variation of the sign of the internal stresses. This variation causes the deviation of the propagating cracks when they cross the interfaces. Furthermore, if the outer layers are in compression, the materials are damage resistant and therefore both mechanisms give rise to better mechanical properties.

Experimental

The starting materials were commercial submicron powders of Al_2O_3 (Sumitomo AKP-20) with an average particle size of 0·5 μm and t-ZrO_2 with 3 mol.% of Y_2O_3 (ICI Advanced Ceramics) with an average particle size of 0·3 μm.

Mixtures of Al_2O_3 and ZrO_2 powders were dispersed with a blender for 20 min in distilled water (6000 r.p.m). The pH values of the suspensions were adjusted to 4·0 using HNO_3 (1 M). This pH was chosen on the basis of previous work[11] and corresponds to the minimum viscosities for both alumina and zirconia slurries.[6]

Under these conditions, the submicron oxides' particles were positively charged, electrostatic repulsive interactions were generated, the aggregates

broken down and the solid phase sedimentation inhibited.[12]

After different aging times, the solutions were ultrasonically homogenized for 15 min at 300 W in order to break down the hard aggregates.[13] The duration of this treatment was decided on the basis of a previous study.[14]

After ultrasonication the pH of several slurries were changed to 8 using NH_4OH.

Under these conditions the zeta potential of Al_2O_3 and ZrO_2 particles was close to zero and the solid phase flocculates[15,16]. In other slurries, before the ultrasonication, NH_4NO_3 was introduced to induce strong short range repulsive forces between the particles. The reasons, as well as the effects of these additions will be discussed in the next section.

Quantities of slurry sufficient to yield the desired layer thickness were placed in a teflon cylindrical container (diameter = 50 mm). The vessel was put in a centrifuge and spun at various speeds for various periods.

After centrifuging, the supernatant aqueous solution was removed and another volume of suspension, containing a solid phase with different composition, was placed in the container in order to deposit the next layer. This procedure was repeated until multilaminar symmetric composites were obtained. The sequence of the operations is shown in Fig. 1.

After water removal, the samples were kept in the container at room temperature for several hours. During this stage, a certain quantity of water evaporated and the material contracted and consolidated. The laminates were removed from the container, dried at 60°C for 24 h, cold pressed at 1000 MPa and fired at 1580°C for 3 h.

Density was measured by immersion in distilled water and the microstructure was examined on polished samples with a scanning electron microscope.

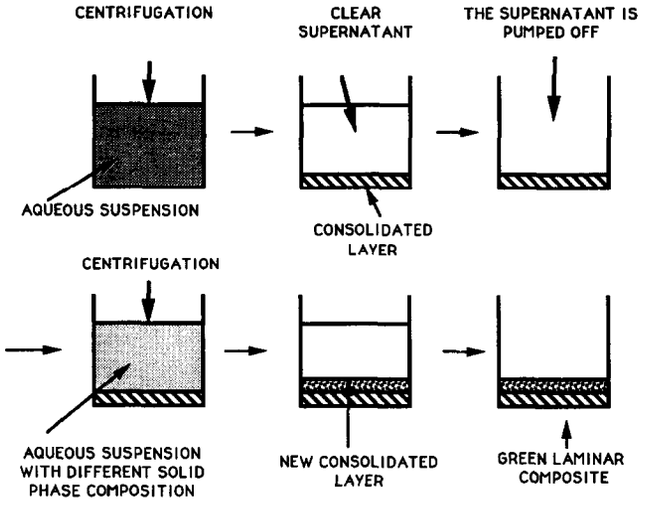

Fig. 1. Flow sheet of the procedure used for the preparation of compacts.

The suspension viscosities were measured at 25°C with a Rotowisko RV 100 viscometer. The zeta potential (ζ) was determined with a Rank Brothers Mark II equipment. For this purpose the slurries were prepared in 10^{-1} M KNO_3 solution in order to maintain a constant electrical double layer thickness.

The sedimentation rate was measured in a 100 ml graduated cylinder by observing the height of the interface between the settling suspension and its supernatant over an 8 h period.

Results and Discussion

For the the preparation of suspensions we used four powder mixtures with the following compositions:

Al_2O_3 85 vol.% – ZrO_2 15 vol%,
ZrO_2 85 vol% – Al_2O_3 15 vol.%,
Al_2O_3 65 vol.% – ZrO_2 35 vol.%,
ZrO_2 65 vol.% – Al_2O_3 35 vol.%.

The above compositions were chosen on the basis of previous experiments which showed that higher composition differences lead to the obtainment of composites containing laminae with very different thermal expansion coefficients. During the cooling, this thermal mismatch causes thermal stresses exceeding the tensile resistance of zirconia reach layers.

The influence of the chemical composition and thickness of the laminae on the composite mechanical properties is discussed elsewhere.[17]

The solid phase content of the suspensions was set to 15 vol%. This value was chosen on the basis of previous experience and on the basis of practical considerations, in fact, slurries with a high solid loading (>20 vol.%) are not able to break down the aggregates[8] and therefore homogeneous microstructures cannot be obtained.

On the other hand, high volumes of dilute suspensions are needed in order to develop layers of sufficient thickness. Therefore the considerable distance between the suspension surface and the container bottom can induce, during spinning, a concentration gradient of the oxides in the lamina.

Centrifugation conditions

The first attempts were made by centrifuging at 3000 r.p.m. for 30 min immediately after dispersion and ultrasonication pH = 4 suspensions. The results were not satisfactory because the supernatant liquid was cloudy. Longer spinning times did not cause the complete sedimentation of the solid phase. The layer thickness varied across the

diameter and reached a maximum near the walls of the container, therefore after drying and sintering the samples warped (Fig. 2) and exhibited delamination phenomena.

Furthermore, the ZrO_2 reach suspensions (85 vol.% of zirconia and 15 vol.% of alumina) exhibited on the surface a high quantity of 'bubbles'. These inhomogeneities remained also on the surfaces of the consolidated layers and were not destroyed by the deposition of other laminas (Fig. 3). Therefore, after sintering the composites exhibited irregular and porous interfaces.

Measures were taken in order to overcome the above mentioned shortcomings. An appropriate sequence in the spinning operations was studied in order to decrease the thickness differences across the samples. The best results were obtained by centrifuging the suspensions at 800 r.p.m. for 2 h and increasing the speed to 3000 r.p.m. during the last 5 min of the operation. With this procedure, the warping phenomenon was avoided.

During the centrifugation, in order to provoke complete separation of the solid phase the suspension pH was adjusted to 8 after ultrasonication. Under these conditions the zeta potential of the particles approaches zero value and the solid phase flocculates.[11]

By adopting this procedure, the supernatant liquid was clear after centrifugation, but the SEM examination of sintered samples showed the presence of large aggregates at the interfaces between the laminas, therefore no smooth interfaces were obtained using flocculated suspensions (Fig. 4). The examination of micrographs also showed a higher concentration of ZrO_2 aggregates in the bottom of layers.

These results are not in agreement with those found in another study.[18] In fact, in the paper mentioned above, homogeneous microstructures were observed in the compacts obtained with flocculated and centrifuged slurries. At present, no explanation can be given for this discrepancy.

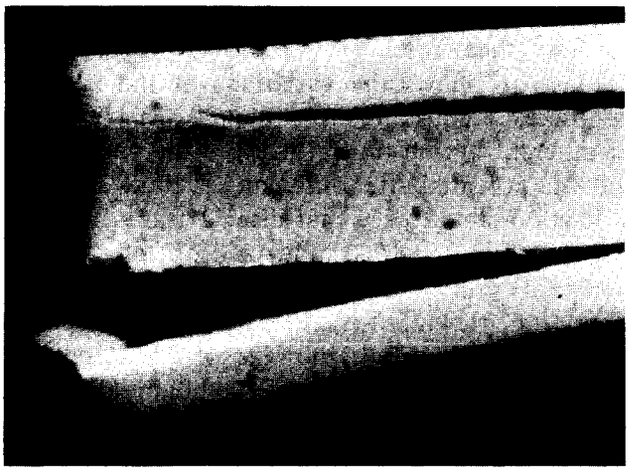

Fig. 2. Warping and delamination at the end of a sintered laminate, ZrO_2 content in the central layer 65 vol.%, in the external layers 35 vol.%. Warping and delamination are due to the different thicknesses throughout the length.

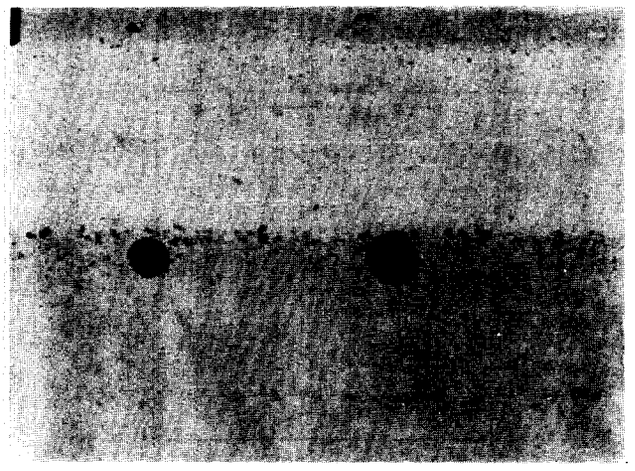

Fig. 3. Optical photomicrograph of the interface between a layer containing 15 vol.% of ZrO_2 (gray stratum) and another one containing 85 vol.% of ZrO_2. The presence of 'bubbles' is evident.

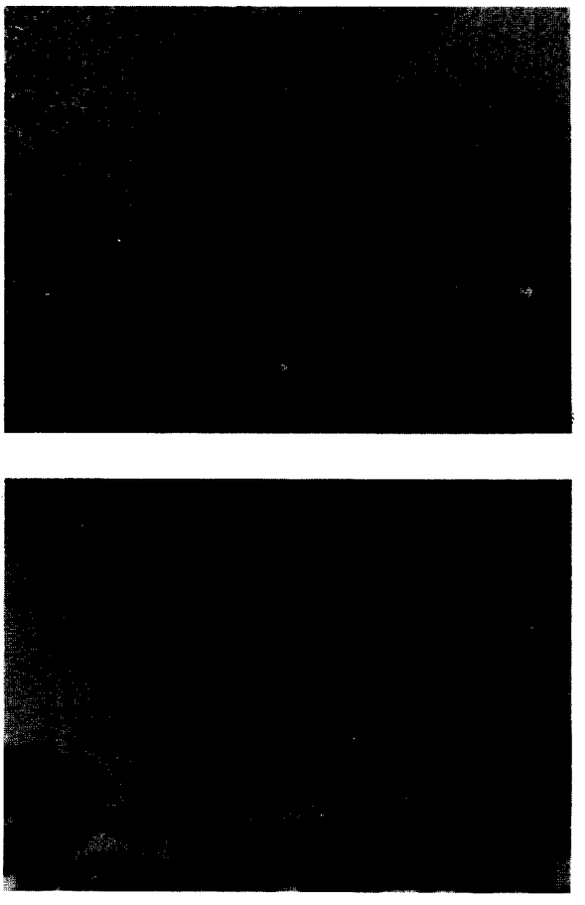

Fig. 4. SEM back-scattered micrograph of the interface between a layer containing 15 vol.% of ZrO_2 (gray stratum) and a layer containing 85 vol.% of ZrO_2 (brighter stratum). The powders were flocculated at pH = 8 before centrifugation. The presence of a large alumina aggregate is evident (darker particle).

Ageing of the suspensions

In order to eliminate the bubbles present on the surface of the zirconia reach suspensions, anti-foaming agents were used, but the best results were obtained by submitting the slurries to gentle mixing with an electric stirrer for 4 h. This treatment enabled the bubbles to deflate. After ultrasonication, the suspensions were centrifuged: smooth surfaces and an almost clear supernatant liquid were obtained. The good separation of the solid phase was surprising; therefore a short investigation was undertaken in order to explain this behavior.

For this purpose we examined the rheological behavior as a function of different ageing times of a zirconia reach suspension (ZrO_2 85 vol.%).

The results are summarized in Fig. 5 where the shear stresses measured after different rest times and at different shear rates are reported. The measurements were taken every 30 min over a period of 4 h, but in the graph, for sake of clarity, only the curves relative to 0, 90, 120, 150, 210 and 240 min of ageing times are reported. The slurry was prepared and aged using the procedures mentioned above and ultrasonicated immediately before the measurements.

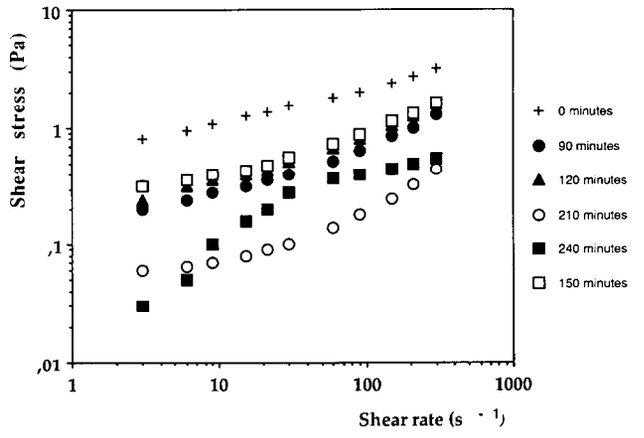

Fig. 5. Rheological behavior of aqueous suspensions aged for different times. Solid phase content = 15 vol.%, solid phase composition: ZrO_2 = 85 vol.%, Al_2O_3 = 15 vol.%, pH = 4).

The hysteresis loop method was used in order to ascertain the presence in the suspensions of a time-dependent behavior, but no thyxotropic phenomena were observed. According to the results reported by other authors for slurries of similar composition, the Herschel–Bulkley model is suitable to describe the rheological behavior of this system.[19]

$$\tau = \tau_0 + K\,\gamma^n \qquad (1)$$

Where τ is the shear stress, τ_0 is the yield value, γ the shear rate and n a constant.

However the Herschel–Bulkley equation cannot describe the behavior of suspensions aged for 4 h (see the curve in Fig. 3 indicated with full squares). Other models were used, (Casson, Bingham), in order to characterize this slurry, but the experimental and calculated data were at variance. In addition, fluctuation of the shear stress values (τ) were observed during the measurements at constant shear rate.

Figure 6 shows the variations of the apparent viscosities at constant shear rate (30 s^{-1}) as function of different ageing times. In Fig 7 the variation of the zeta potential after different rest times is shown.

It is possible to see that after 210 min, the suspensions exhibited a sudden drop of the zeta potential and a consequent viscosity increase. Therefore, the repulsive interactions between the particles are lowered, the size of the aggregates increases and the stability of the colloidal suspensions decreases. This fact can explain the obtainment of clear supernatant liquid when suspensions aged for 4 h are centrifuged. In this manner, it is also possible to explain the difficulties in characterizing the slurries aged for 4 h from the rheological point of view and the fluctuation of the τ values. Both inconveniences can be imputed to the friction of the aggregates on the walls of the measurement device.

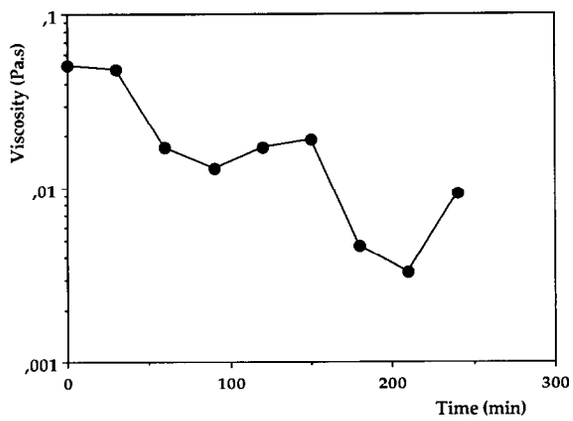

Fig. 6. Influence of the ageing times on the suspension viscosity (constant shear rate = 30 s^{-1}). The slurry composition is the same as that reported in the caption of Fig. 5.

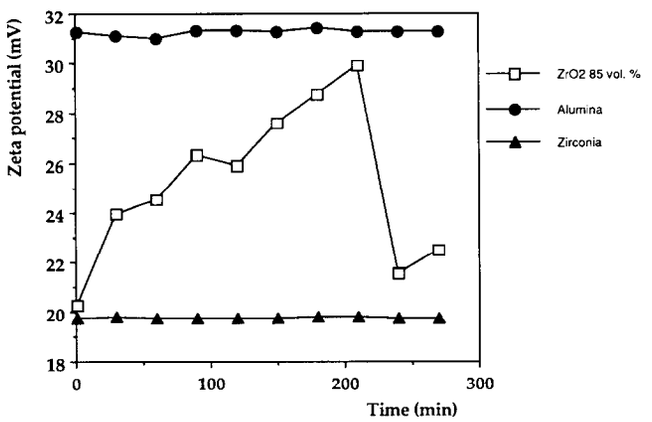

Fig. 7. Variation with the time of the zeta potential of alumina, zirconia and a mixture of 85 vol.% of ZrO_2 and 15 vol.% of Al_2O_3. Solid phase content 15 vol.%, pH = 4.

Figure 7 also shows the variations of the zeta potential of suspensions containing only zirconia and alumina powders. The preparation method and the solid phase content are the same as those used for the Al_2O_3–ZrO_2 systems. Because the zeta potentials of oxide particles remain constant during ageing, one can suppose that the variations of ζ in the suspension containing the Al_2O_3–ZrO_2 mixtures are essentially due to the interactions between the Y^{3+} ions and the surfaces or the double layers of the alumina particles. The yttrium ions in fact are released from the tetragonal stabilized zirconia in acidic conditions[20] and can decrease the stability of the slurries.

The kinetics of the interaction of Y^{3+} with the alumina are probably complicated and the observation of Figs 6 and 7 revealed the presence of several steps.

Improvement of the solid phase separation

The results obtained with flocculated and ultrasonicated suspensions aged for 4 h were encouraging and the laminae appeared homogeneous to SEM observations. These results are not in agreement with the paper of Velamakanni *et al.* [20] which showed that the centrifugation of Al_2O_3–ZrO_2 deflocculated slurries leads to a non-uniform distribution of the components; we would point out however that we did not undertake a systematic study on the distribution of the two oxides across the consolidated layers.

In Fig. 8, the microstructure of a laminar composite prepared using the procedure mentioned above is shown. The compositions of the alternating layers were 15 vol.% of ZrO_2–85 vol.% of Al_2O_3 and 15 vol.% of Al_2O_3–85 vol.% of ZrO_2 respectively.

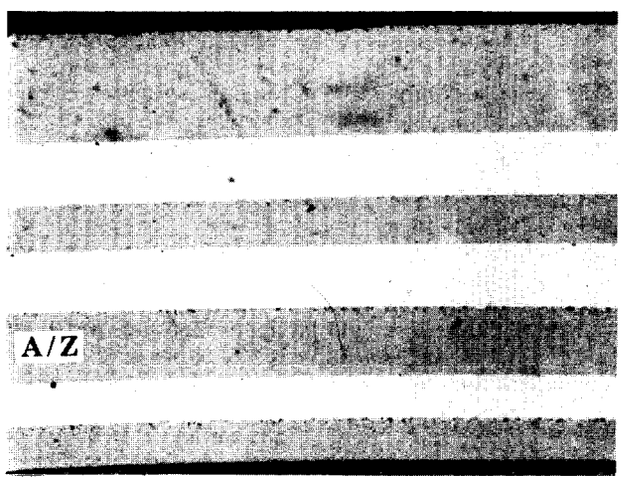

Fig. 8. Optical photomicrograph of a composite obtained by centrifugation of an aqueous suspension at pH = 4 after a gently mixing for 4 h. The slurry was ultrasonicated immediately before centrifugation. For the composition's layers, see the text.

In order to obtain a complete separation of the solid phase we added NH_4NO_3 to the suspensions. In fact the presence in the slurry of a high quantity of electrolite strongly decreases the long range electrostatic repulsive interactions and develops strong short range hydration repulsions.[20]

The salt addition provokes a viscosity increase and a destabilization of the suspension, but the permanence of a repulsive lubricating hydration layer allows the obtainment of high density bodies with well packed particles (coagulated suspensions).

The slurries were prepared using the previously discussed methods and the ammonium nitrate was added, after a certain rest time, immediately before ultrasonication. The salt concentration in the liquid phase was 1 M.

The sedimentation rate of a coagulated suspension was compared to that of a deflocculated one with the same solid phase composition (ZrO_2 85 vol.%), (Fig. 9).

Also in this case, the suspensions were aged in order to eliminate the bubbles, therefore, the evolution of the rheological behavior of the zirconia reach slurries was studied.

In order to avoid the problems related to the solid phase sedimentation, the viscosity measurements were performed immediately after the salt addition.

Again the Herschel–Bulkley model is suitable in order to describe the rheological behavior of the slurries, the only difference being that in the case of the coagulated suspensions the yield value (τ_o) is near to zero.

Good results were obtained by centrifuging the salt added slurries aged for times ranging from 1 to 4 h. Figure 10 shows the microstructures of a multilayer composite with the same composition as that of Fig. 8. Using this procedure laminae with less than 30 μm were easily obtained.

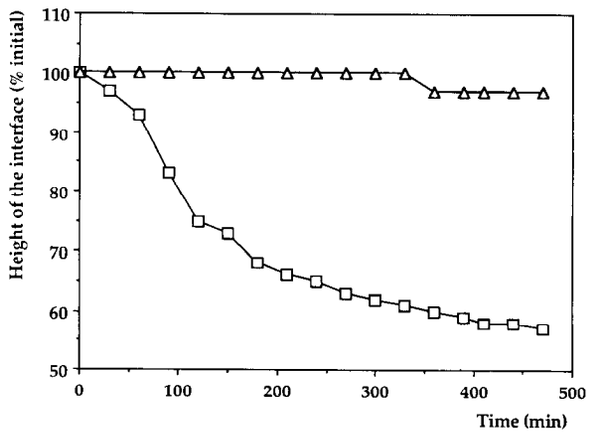

Fig. 9. Sedimentation rate of an aqueous suspension containing NH_4NO_3 1 M (squares) and without salt addition (triangles). For the slurry composition, see the text.

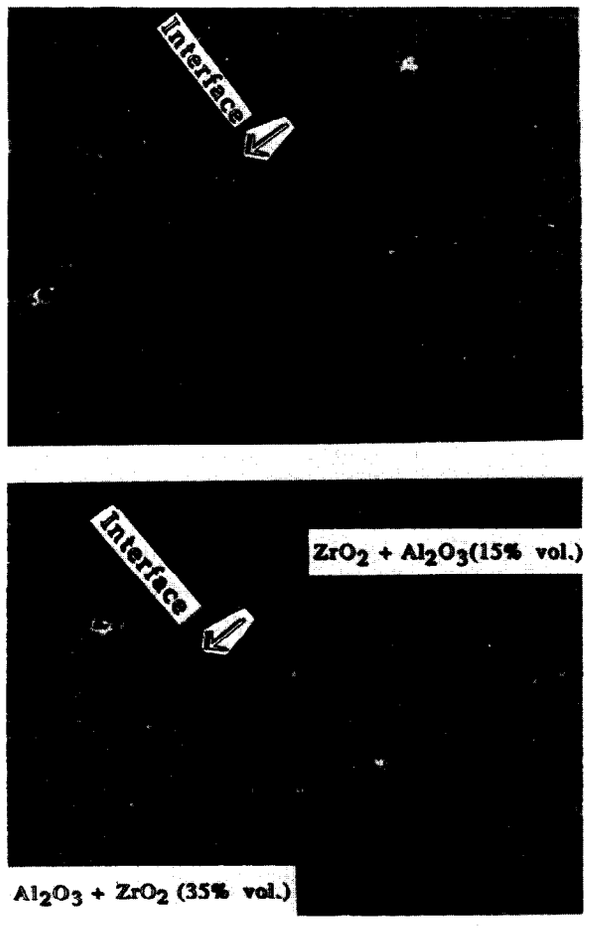

Fig. 10. SEM back-scattered micrograph of a laminar composite obtained by centrifugation of $NHNO_3$ added suspensions. The smoothness of the interface and the homogeneity of the layers are evident.

Sintering of multilayer composites

Densities of about 98–99% were reached by sintering the composites obtained from deflocculated slurries at 1580°C for 3 h (heating rate 5°C/min).

In the case of NH_4NO_3 added materials, a more complicated sintering process was needed in order to gently decompose the salt. The powder compacts were heated at 2°C/min up to 200°C and kept at this temperature for 45 min. Successively, the heating rate was increased by 5°C/min and the composites were fired for 3 h at 1580°C. With this thermal cycle, densities close to the theoretical value were obtained.

Conclusions

Zirconia and alumina based laminar composites can be fabricated by centrifuging aqueous suspensions containing the two oxide powders.

Good results were obtained using relatively dilute slurries (solid phase = 15 vol%). Strong repulsive interactions were generated by adjusting the pH at 4 with HNO_3 additions.

Centrifugation was performed in two different steps. The first one at low g and the other one, shorter, at high g. In this manner, samples with homogeneous thickness were obtained. Before centrifugation, the zirconia reach suspensions required long ageing times in order to eliminate the bubbles present in the suspensions. After 4 h, a decrease of the zeta potential of these suspensions was observed, together with a viscosity increase. The centrifugation of these aged suspensions led to an almost complete solid phase separation. This behavior at present cannot be explained. The best results were obtained with coagulated suspensions (containing NH_4NO_3 1 M) aged for several hours. With these slurries thin laminae with smooth interfaces were obtained.

Abstract

High temperature creep of two zirconia toughened alumina ceramics, fabricated by powder processing and sol–gel precursors processing, has been studied in order to determine plastic deformation mechanisms. Compressive creep tests were carried out between 1300 and 1450°C, under stresses from 10 to 150 MPa. For the sample fabricated from powders, a stress exponent of 1·4 and an activation energy of 580 kJ/mol were found below a critical stress of 40 MPa. For larger stresses, accelerated creep rates developed. In the specimens processed from precursors, values of 1·8 for the stress exponent and 540 kJ/mol for the activation energy, over the entire range of stresses have been determined. Creep parameters and microstructural evolution of the samples during the experiments have been correlated with models to establish the dominant creep mechanism.

Introduction

ZrO_2 has a very high fracture toughness and its addition to other ceramics, zirconia toughened ceramics (ZTC), has many advantages.[1] In the last eighteen years, a number of investigations of the mechanical and microstructural features of ZTCs, in particular in the system Al_2O_3–ZrO_2, also called zirconia toughened alumina, ZTA, have been performed.[2,3] The major application of ZTAs has been metal cutting tools.[4]

Available results on mechanical properties of ZTA are mainly on fracture, strength, and elasticity. All properties show a strong dependence on the volume fraction of each component, on the ratio of tetragonal and monoclinic zirconia, as well as on zirconia grain size (GS). The review by Green *et al.*,[5] summarizes most of these results.

Fracture studies[3] on ZTA, have shown an increase in K_{Ic} (up to 10 MPa.m$^{1/2}$) with increasing zirconia volume fraction, in particular for small grain sizes (< 1 μm). These authors have claimed that the total increment in fracture toughness is a combination of transformation and microcrack mechanisms of toughening. The first is only possible if t-ZrO_2 particles are present, and the second actuates if zirconia particles at the grain boundaries are transformed to monoclinic by cooling down from the sintering temperature.

In some cases, microcracking resulted in a reduction of strength which is particularly deleterious for large zirconia GS, and volume percentages.[6] To avoid flaws, some researchers have HIP-ed sintered samples,[6] and obtained improved strength, in particular for t-ZrO_2. Some improvement in flexural strength has been also reported for volume percentages of mainly t-ZrO_2 up to 10%.[3] Other authors have studied the retained strength after thermal shock.[7] A sharp decrease in this parameter occurs if samples are heated over the phase transformation temperature and then cooled down. Both room-temperature Vickers hardness, and Young's modulus decrease with increasing zirconia content, in particular, in specimens with high microcracking activity.[8]

In this study our objective is to obtain knowledge on plastic deformation mechanisms in composite systems, as well as on the microstructural effects of creep. Only a few high-temperature mechanical properties data are available. Due to such lack of data, we will compare our results with related materials, like monolithic Al_2O_3 or ZrO_2.

Experimental Techniques

(a) Material

Creep of two polycrystalline ZTA ceramics with 94·5 vol% of Al_2O_3 and 5·5 vol% of ZrO_2 has been

studied. In one case, processing was conducted by wet mixing of powder raw materials and dispersants. The alumina was in the form of α-Al_2O_3 and the zirconia powder was of high purity (99·995%), in the form of monoclinic m-ZrO_2, with a typical particle size of 0·5 μm. Densification took place after drying by uniaxial hot-pressing, at 1600°C, achieving full density. This type of material will be called pd-ZTA.

In the other materials, the processing was carried out by a sol–gel technique using an Al_2O_3 solution and a ZrO_2 precursor, which should result in a better mixing of components. After calcination, screening and drying, uniaxial hot-pressing was performed at 1600°C, obtaining fully dense samples. Throughout this paper, this material will be called pc-ZTA.

(b) Mechanical testing

Mechanical tests have been carried out under compression on 3 × 3 × 5 mm^3 samples, both at constant strain rate (CSR) of 1·7 × 10^{-5} s^{-1}, and or constant load (CL) between 10 and 150 MPa (engineering stress). Temperatures ranged from 1300 to 1450°C. All tests were performed in air.

(c) Microstructural observations

Polished surfaces of as-received and deformed samples were observed by SEM. Some were thermally etched in air at 1450°C to reveal grain morphology. Several microstructural parameters (zirconia distribution, GS, and shape) were studied by means of an image analyzer.

Other microstructural features (dislocations, cracks,...), have been studied by TEM in as-received and deformed specimens. TEM samples were prepared using standard techniques and were carbon coated before observation.

Microstructure of As-Received Samples

(a) ZTA prepared from powders

ZrO_2 grains are homogeneously distributed throughout the Al_2O_3 matrix, with a typical log–normal distribution of GS. 20% of the total volume fraction of zirconia are small particles (<0·5 μm) and are normally embedded in large alumina grains having an average GS of 4·7 ± 0·7 μm, as seen by TEM (Fig. 1). Another 60% of ZrO_2 are grains between 0·5 and 7 μm diameter, located at grain boundaries (GB) and triple point junctions. Finally, the remaining 20% of ZrO_2 are large conglomerates (>7 μm, with a maximum size of 38 μm) located between Al_2O_3 grains. These conglomerates have a lenticular shape oriented perpendicularly to the hot-pressing axis (HPA) (Fig. 2).

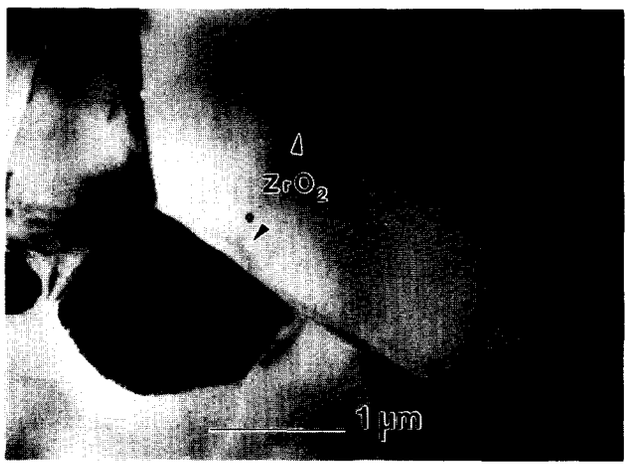

Fig. 1. TEM micrograph of pd-ZTA showing small zirconia particles.

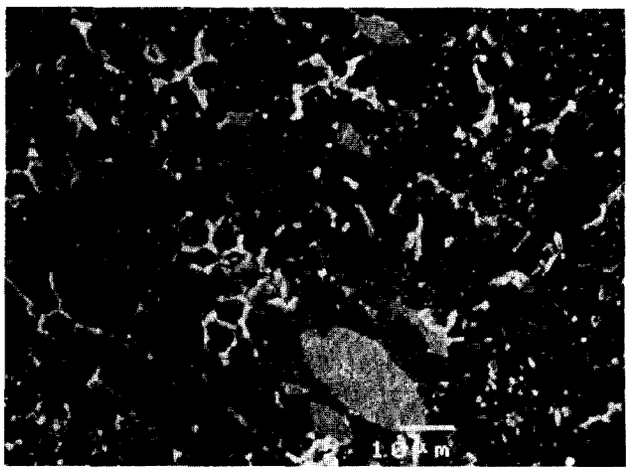

Fig. 2. SEM micrograph of polished pd-ZTA showing alumina GS and one of the lenticular agglomerates of zirconia oriented perpendicularly to the HPA axis.

Several studies have reported similar microstructures. Kibbel and Heuer,[9,10] for instance, indicated that the presence of zirconia, enhances in some cases the growth of alumina usually resulting in small-trapped ZrO_2 particles. Heuer *et al.*[11] showed that trapped grains, with GS smaller than 0·5 μm, are mostly tetragonal, and are very unlikely to transform to monoclinic in a rigid matrix like Al_2O_3,[12] while larger particles, normally placed at grain boundaries, are mainly monoclinic. When the dispersion of zirconia in matrix is not good enough, the monoclinic particles can agglomerate, and form the larger particles reported in this and other studies.[13]

The effect of the m-ZrO_2 along grain boundaries promotes poor thermal shock resistance. When heated up for sintering, etching or creep-testing, m-particles transform to tetragonal (over 1100°C for undoped zirconia). When cooled-down, they become monoclinic again, creating cracks, in particular around the large ZrO_2 particles previously mentioned.[7,8]

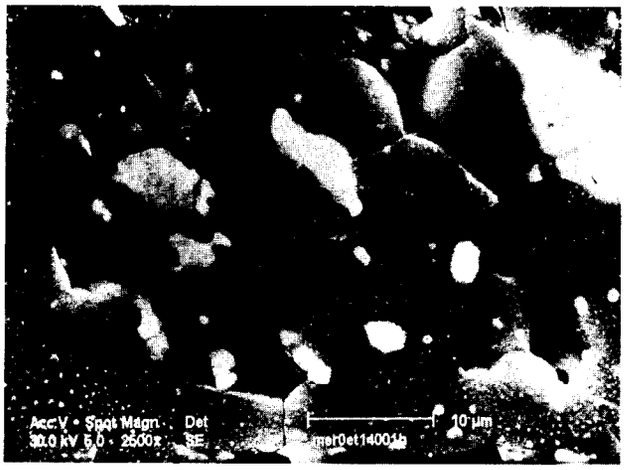

Fig. 3. SEM micrograph of polished and etched pd-ZTA showing a crack inbetween zirconia grains, and significant pull-out, due to microcracking.

In Fig. 3, a SEM micrograph taken on a polished and thermally etched surface, it is easy to observe the formation of extensive cracks between the large ZrO_2 particles. All observations confirm the activity of the martensitic transformation during etching, and, in general, during any thermal cycling over the transformation temperature.

The microstructure of the ZTA prepared by powder techniques is, therefore, 'intragranular–tetragonal/intergranular–monoclinic' as expected from all the above mentioned investigations.[1]

(b) ZTA prepared from precursors

In these samples, ZrO_2 particles are also homogeneously distributed through the matrix (Fig. 4). Nevertheless, an observed major difference compared with pd-ZTA is a much narrower log–normal distribution of zirconia grains, with 95% of the total number of particles smaller than 1 μm, mostly embedded into the Al_2O_3 grains which average a GS of $2{\cdot}6 \pm 0{\cdot}3$ μm.

When the samples were polished and etched for microstructural analysis, the features of grain pull-out, and microcracking due to thermal cycling, were not observed as in pd-samples. The absence of large monoclinic zirconia grains is responsible for this better microstructure. The ZrO_2 grains are small enough, even if they are located at grain boundaries, to keep their tetragonal structure. Therefore, we can characterize this pc-ZTA as 'intra-granular tetragonal'.[1]

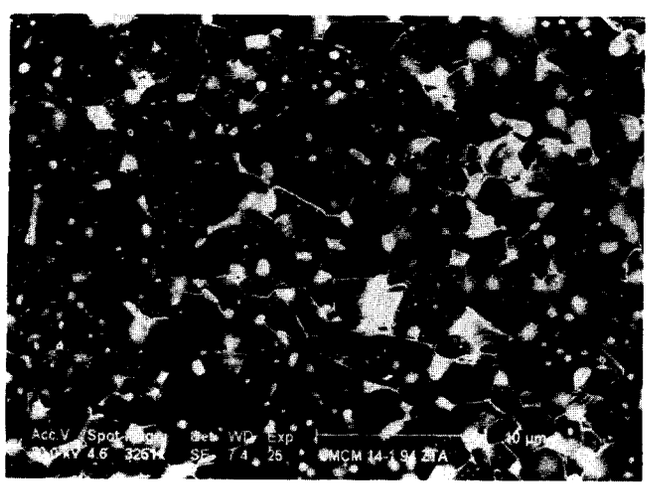

Fig. 4. SEM micrograph of pc-ZTA, showing the homogeneous GS and distribution of zirconia particles, and alumina GS.

Results

Figures 5 and 6 show results of CSR tests on pd-ZTA and pc-ZTA. At 1300 and 1350°C the samples fractured after 6–7% deformation. At the lower temperature strain/stress plots showed brittle fracture for σ = 385 MPa for pd-ZTA, and 434 MPa for pc-ZTA, while at 1350°C the samples fracture for σ = 231 MPa and 296 MPa, respectively, but exhibited plastic behavior. At 1400°C, 95 MPa was reached without fracture after 8% strain for the powder-processed samples. Some softening is detected in the final part of the plot, but without failure. Such behavior was also

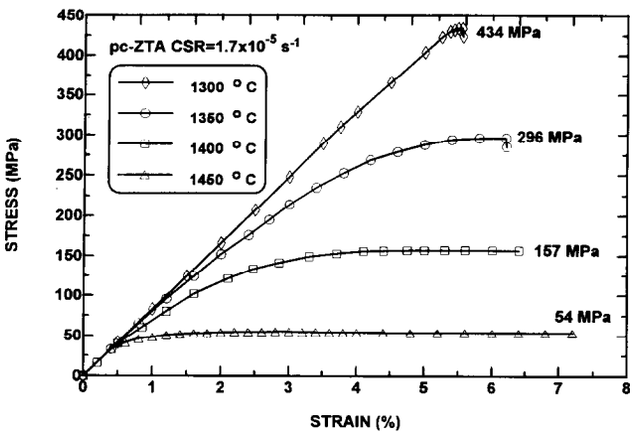

Fig. 5. Results of constant strain rate tests on pc-ZTA at different temperatures as shown.

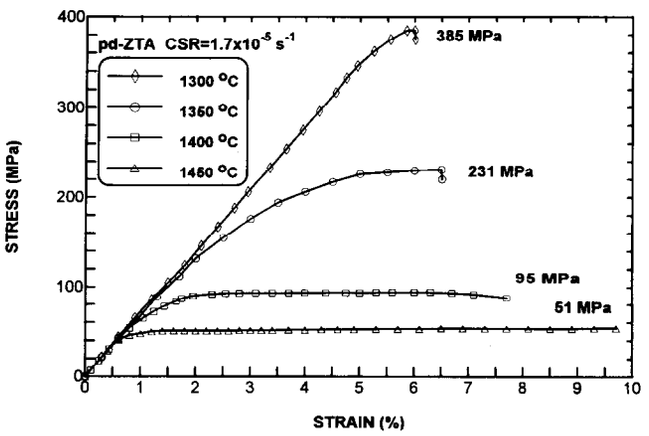

Fig. 6. Results of constant strain rate tests on pd-ZTA at different temperatures as shown.

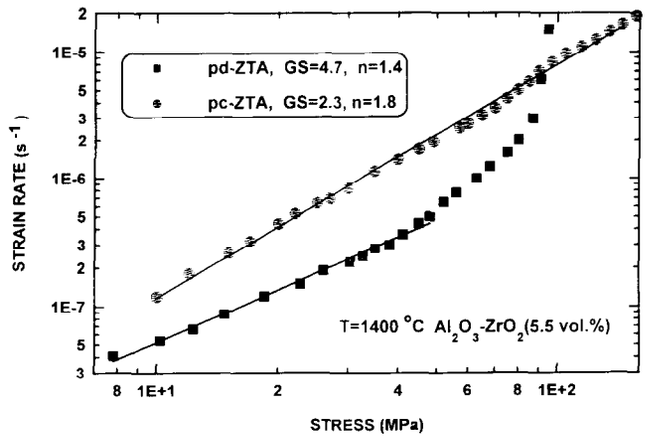

Fig. 7. Steady state strain rates reached on constant load tests versus true stresses.

observed in the tests performed on the precursor-processed samples, with a zero-work hardening stress of 157 MPa, in this case. At this last temperature, several CL tests were performed on different samples. For increasing stresses from 10 to 150 MPa, strain rates ranged between 4×10^{-8} and 2×10^{-5} s^{-1}. Steady-state strain rates are plotted in Fig. 7 versus the applied stress. The effect of temperature on creep rate, at constant load was studied between 1300 and 1450°C. An Arrhenius plot of (ln $\dot{\epsilon}$) versus (1/T) is shown in Fig. 8.

All of these results are analyzed using the phenomenological equation:

$$\dot{\epsilon} = A\sigma^n d^{-p}{}_{\exp}(-Q/RT) \qquad (1)$$

where $\dot{\epsilon}$ is the strain rate, σ is the stress, d is the grain size, A is a constant, and R and T have their usual meaning. The parameters n (stress exponent) and Q (activation energy) and p (grain size exponent) can be determined and correlated with plastic deformation mechanisms.

For the pd-ZTA material, two regimes of deformation were detected, with a change in the stress exponent from 1·4 ± 0·2 at low stresses, to variable values larger than two for higher stresses.

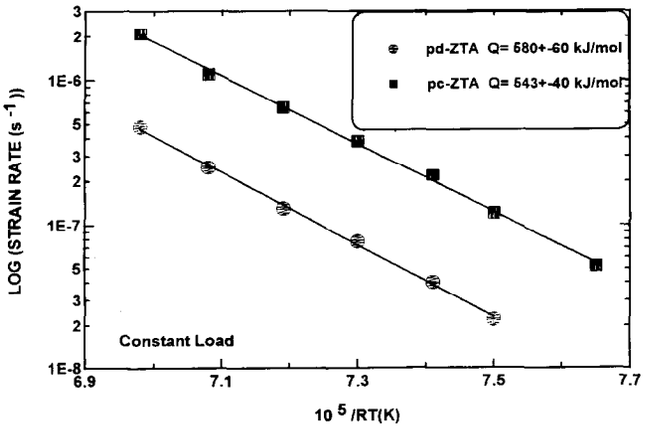

Fig. 8. Steady state strain rates reached on constant load tests versus (1/RT) in an Arrhenius plot.

The critical σ_c is above 40 MPa. On the other hand, in the range of stresses studied, a constant n = 1·8 ± 0·2 is measured for the pc-ZTA material.

We have determined the activation energy, Q, for both materials. 580 ± 60 kJ/mol is obtained for pd-ZTA, under 23 MPa ($< \sigma_c$), and 540 ± 40 kJ/mol for pc-ZTA, under 25 MPa.

However, in a complex material, like the one in this study, the meaning of these parameters in terms of creep mechanisms, is not clear without analyzing the microstructural evolution of the samples during plastic deformation. A complete discussion will follow.

Microstructural analysis was performed on samples deformed at 1400°C, from both CSR and CL tests. After the test, CSR deformed specimens showed extensive intergranular cracking. We can also see large cracks formed by coalescence of pre-existing cavities near ZrO_2 particles at grain boundaries (Fig. 9). After the CL experiments, we only observed samples deformed in the n = 1·4–1·8 regime. Some cavities were observed. However they should not control plastic deformation because it was possible to measure quasi-steady states of creep. A more detailed analysis of the role of cavitation in the creep of composite ceramics is out of the scope of this paper.

Grain size and morphology of deformed samples was studied. Neither alumina, nor zirconia grains appear to suffer major geometric changes. GS remains constant. The grains form factors, defined as

$$FF = 4\pi.(\text{area})/(\text{perimeter})^2,$$

remains around 0·8 up to 20% strain.

Discussion

For the compression rate used, with $T < 1400$°C,

Fig. 9. Cracks formed by coalescence of cavities developed at the surroundings of zirconia particles at grain boundaries during plastic deformation.

the pc-ZTA samples suffer brittle fracture at stresses typically higher than the ones measured for pd-ZTA samples. For temperatures over 1400°C both kinds of samples are plastic.

We have specifically studied plasticity at 1400°C, using a wide range of stresses. pc-ZTA specimens show a single deformation regime characterized by n = 1·8 and Q = 540 kJ/mol, while for pd-ZTA samples two regimes have been detected. In these samples, below $\sigma_c \approx 40$ MPa, approximately, the plastic deformation mechanisms is characterized by a sequence of steady states with calculated n = 1·4 and Q = 560 kJ/mol. For $\sigma > \sigma_c$ values for n and Q have little meaning. This non-steady state regime is a consequence of coalescence of cavities whose origin we have not investigated and will not be considered in the following analysis.

Absolute values of the strain-rate are between 2 and 5 times faster in pc-materials than in pd-samples, but this can be explained, in the light of eqn (1), by the difference in GS (d). If the $\dot{\epsilon}$ values are normalized for grain size differences using p = 2 or 3, the strain rates become, within the experimental scatter, equal. Figure 10 shows such a comparison for p = 2, for illustrational purposes. Also included in Fig. 10 is a comparison with results of a monolithic alumina of 3·3 μm GS, reported in a previous work.[14] Good concordance is found in the stress exponent (1·3 ± 0·1) and in the activation energy (510 ± 20 kJ/mol), and in the normalized strain rates (also included in Fig. 10). The accord might suggest that diffusion in both ZTA and Al_2O_3 is extrinsically controlled. The most important conclusion though is that no significant improvement in creep resistance in the steady-state region for either material is found.

The unchanged form factors indicate that grain boundary sliding (GBS)[15] is the dominant mechanisms of deformation since a pure diffusion mechanism requires a change of grains' shape. Additionally, large cracks can nucleate from

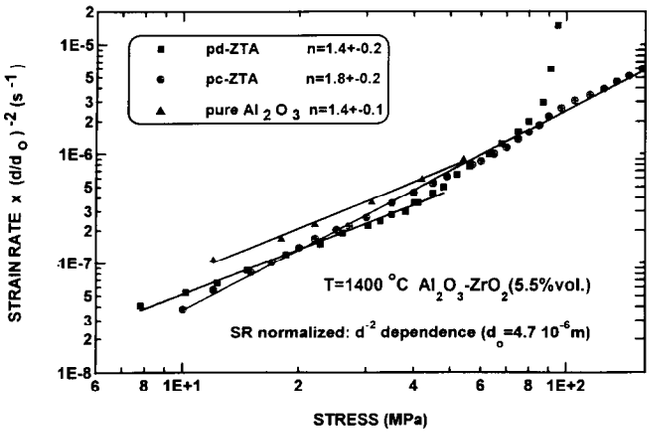

Fig. 10. Steady state strain rates normalized using p = 2, for a common grain size of 4·7 μm, for pd-ZTA, pc-ZTA and monoclinic alumina.[15]

ZrO_2-related microcracks, and will limit the utility of these materials over a certain critical strain (ϵ_c).

There are two mechanisms of diffusion accommodated GBS creep.[16] One is the mechanisms known as interface-reaction controlled (IRC) grain boundary sliding (with n = 2) and the other is transport of matter controlled (TMC) grain boundary sliding (n = 1), the first is more active in polycrystals with small grains. The creep parameter p can be either 2 or 3 in TMC creep, depending on the path of the creep controlling diffusion (p = 2 for lattice diffusion and p = 3 for grain boundary diffusion). In IRC creep the grain size exponent aries from 1 to 3. Both IRC and TMC, have been used to describe GBS in pure alumina[16,17] The parameter p in Al_2O_3 was found to be between both theoretical extremes, 2 and 3.

A range of n's from 1·1 to 2, and Q values from 410 to 568 kJ/mol has been reported in polycrystalline alumina specimens.[18] Although there is a general agreement that GBS is the dominant mechanism in Al_2O_3, there is much controversy on the meaning of the measured activation energies in terms of controlling diffusion species. Most authors claim that the higher values of Q are related to the diffusion of O^{2-} through the lattice, which is in agreement with p = 2, and has been detected in samples with large grain sizes (> 5 μm). On the other hand, the lower values of Q are claimed to result from grain boundary diffusion of Al^{3+}. A value of p = 3 is reported in these cases, usually found in samples with small grain sizes. However, comparisons are difficult because diffusion dynamics can be seriously altered by the presence of impurities,[19] and these are unknown in our samples. Our calculated creep parameters for ZTA, are consistent with the values reported for monolithic alumina. The values of n, and the microstructural observations, agree with the mechanism of unaccommodated GBS, with a mix of IRC and TMC. The largest values of n = 1·8, is found for the samples with the smallest grain size, and the lower n = 1·4 is found for samples with the largest grain size, in good agreement with predictions. The high values of Q found in this study support the control of the creep by O^{2-}, and the lattice is very likely to be the path of this transport of matter.

ZrO_2 agglomerates at grain boundaries are probably the origin of damage, and limit the strain to failure. The samples processed using the precursors technique contain less of these particles, and even though the unaccommodated GBS causes the formation of cavities, the samples remain intact with up to 40% strain. On the other hand, powder processed samples, which contains large zirconia particles, exhibit a critical stress over which the samples fail.

Baddi *et al.*[20] have studied the diffusional creep regime in a material of symmetric composition to the one in our work (zirconia matrix with alumina inclusions) and found that at low stresses IRC–GBS was dominating, while a TMC–GBS was active for the high stress range. Their microstructural analysis showed significant changes in the shape of the grains, without any cavitation. Other authors have proposed the same mechanisms (superplastic) acting in monolithic zirconia. The activation energy determined by Baddi and co-authors, also agreed with the one reported for monolithic zirconia In the material studied by Baddi *et al.*, the dominant component is then ZrO_2.

In our materials, it appears then, that the controlling component which determines the creep response is the harder phase: alumina. The role of the ZrO_2 phase is important in the brittle behavior and probably plays a role in the damage which accumulates in the plastic regime.

The better dispersion of the zirconia into the matrix in pc-TA, avoiding the formation of large intergranular monoclinic particles, results in better high-temperature mechanical response

Conclusions

It has been shown that the addition of 5·5 vol% of zirconia particles to an alumina matrix does not improve its resistance to creep. Creep takes place by grain boundary sliding and is accompanied by the formation of cavities. In the pd-samples, where large m-zirconia grains are present at grain boundaries, the linkage of the cavitation is easier because the inherent microcracking present in the samples, and results in a limited strain to failure and in a critical stress over which the formation of damage is too severe to allow measuring steady states of creep. On the other hand, for pc-samples, where a narrower GS distribution of smaller t-ZrO_2 particles has been measured, a single plastic regime of steady-states was detected. Cavities are also present in these crept samples, but the less microcracking activity promotes a better mechanical response.

We may conclude that the precursors-processed ZTA, with less microcracking, is a better candidate for high temperature applications than powder-processed ZTA, where microcracking is introduced by the presence of monoclinic zirconia grains.

Influence of Whisker Reinforcement on the Creep Behaviour of Zirconia Matrices

R. Baddi,* J. Crampon & R. Duclos

Laboratoire de Structure et Propriétés de l'Etat Solide, URA CNRS 234, Université de Lille 1, 59655 Villeneuve d'Ascq Cedex, France

(Received 23 June 1994; revised version received 10 April 1995; accepted 16 May 1995)

Abstract

Zirconia matrices reinforced with 13 vol% SiC whiskers, obtained either by hot-pressing or by extrusion, have been deformed by compressive creep. The composite behaviour is similar to that of the matrix alone and suggests identical deformation mechanisms. The creep rate was not much affected by the whiskers; in particular the creep rate was not dependent on the direction of the compression axis. By contrast, for some directions of the compression axis, a strain anisotropy appeared in the plane perpendicular to the compression axis. The influence of whisker orientation on deformation has been explored by considering the matter flows in the vicinity of whiskers and the whisker distribution.

1 Introduction

This paper deals with the high temperature creep behaviour of zirconia matrices reinforced with SiC whiskers. Its main concern is with the understanding of the interactions occurring between a creeping matrix and a hard, nondeformable phase when large strains are achieved.

In particular, in a recent study concerning the superplastic deformation of an alumina–zirconia matrix reinforced with 25 vol% SiC whiskers,[1] a strong influence of the whisker orientation on the creep rate and on the shape of strained samples was observed. For instance, samples whose compression axis (CA) was perpendicular to the hot-pressing axis (HPA) showed a strain anisotropy in the plane perpendicular to the compression axis, the two transverse strains (the one parallel to the HPA over that in the perpendicular direction) being in the ratio 2.

Such results have been rarely reported in studies concerned with the deformation of ceramic matrices reinforced with SiC whiskers either because deformation was conducted in four-point bending,[2–5] a test whose analysis is complex, or, for the few studies conducted in compression, because the orientation effect was not systematically studied.[6,7] Only Lorenz[8] and Swan *et al.*[9] investigated the influence of whisker orientation on the resultant creep rates. Lorenz studied the effect of whisker orientation for two whisker contents: 20 and 29 vol%. For the first quantity no influence of the compression axis orientation was observed, while for the second, the creep rate of specimens with the CA perpendicular to the HPA was found to be about 4 times faster than the creep rate of samples parallel to the HPA in agreement with our own results.[1] Concerning Swan *et al.*'s work, no effect of sample orientation on the creep rate was observed by these authors. These various results show the complexity of the influence of whisker orientation on the resultant deformation.

From the theoretical point of view, models accounting for enhancement of creep resistance are mainly based on stress transfers across the matrix–whisker interfaces.[10–13] At a high temperature, however, diffusion can be fast enough to partially release shear stresses on the interfaces. Moreover, models predicting an influence of the whisker orientation are seldom in agreement with experimental results.

In point of fact, the above results show that the effect of whiskers on the deformation rate cannot be reduced to a simple stress transfer effect across interfaces but that secondary effects such as whisker interaction, local plasticity or direction of matter flow, must be taken into account. It is partially with this object that this work was undertaken.

In this paper the results of creep tests on a SiC_w-reinforced zirconia composite compacted by various techniques are reported. Mechanical results and microstructure observations are first

presented. Then, the anisotropy effects are discussed, not specially for this material but more generally with reference to literature data.

2 Experimental Procedure

The material studied was a 3 mol% yttria stabilized zirconia matrix (Tosoh, Japan) reinforced with 13 vol% of both α and β SiC whiskers (Tokai Carbon, Japan). Two kinds of dense materials (ρ = 5·72 g/cm^3) were obtained at the Ecole Polytechnique Fédérale de Lausanne (Switzerland): either disks, hot-pressed at 1450 or 1550°C (to obtain various zirconia grain sizes), or cylinders extruded at 1600°C through a conical graphite die.[14] This last method partially explains why a zirconia matrix and a relatively low whisker content were used. These two techniques entail different whisker distributions. In the first case, the whiskers were almost perpendicular to the hot-pressing axis whilst in the second case, they were more or less aligned in the extrusion direction (ED).

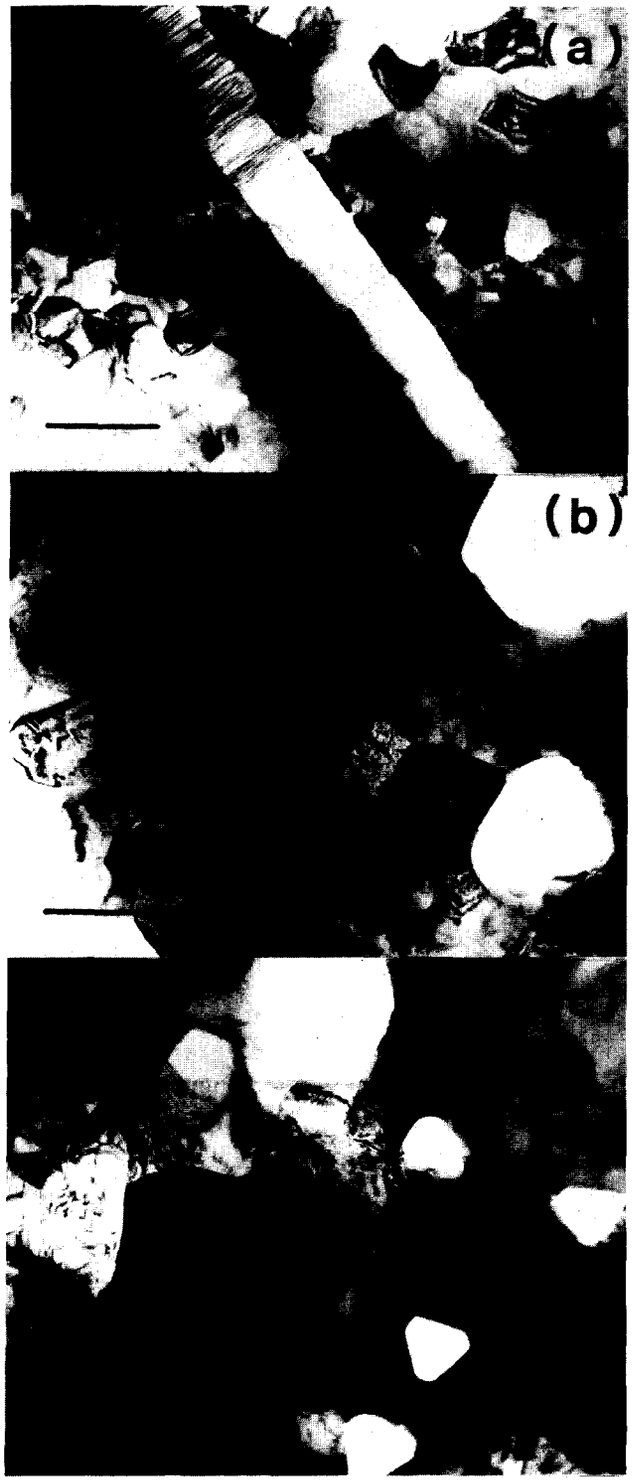

Fig. 1. Typical sample microstructures (scale bar = 0·5 μm): (a) HP at 1450°C; (b) HP at 1550°C; (c) extruded at 1600°C.

Microstructures of the three reinforced materials are shown in Fig. 1. The mean grain sizes of zirconia were respectively 0·33 and 0·54 μm in the disks hot-pressed at 1450 and 1550°C and 0·85 μm in the extruded material. The whisker diameter varied between 0·2 and 1 μm and the maximum length was 10 μm. The average aspect ratio was about 10. No glassy phase was detected by conventional transmission electron microscopy (TEM) at the matrix–whisker interfaces or in the matrix, but the presence of a thin intergranular film (~1 nm) in this kind of material is not to be excluded.

Due to the preferential whisker orientations, specimens with the compression axis either parallel or perpendicular to the hot-pressing axis or to the extrusion direction were cut, resulting in the four sample configurations of Fig. 2, called respectively P//, P⊥, E// and E⊥. These configurations correspond

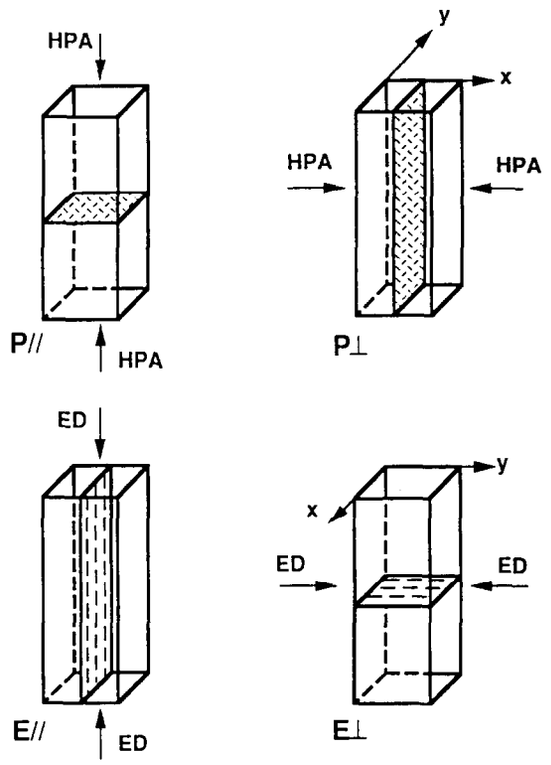

Fig. 2. Configurations of samples used in this study. P stands for hot-pressed specimen (HPA: hot-pressing axis) and E means extruded specimen (ED: extrusion direction). In each instance, the compression axis lies parallel to the long dimension of the sample.

to whiskers lying in planes perpendicular or parallel respectively to the compression axis for P samples, or to whiskers respectively parallel or perpendicular to the compression axis for E specimens. Sample size was typically $3 \times 3 \times 7$ mm^3.

Compressive creep experiments were conducted in an argon atmosphere between 1260 and 1330°C over a stress range of 20–120 MPa. Final strains varied typically between 20 and 40%. Two or even three specimens were tested for each deformation condition.

After creep tests, microstructure observations were made by TEM at 200 kV or SEM (scanning electron microscopy) at 15 kV on polished and thermal etched surfaces.

3 Experimental Results

3.1 Macroscopic behaviour

At first, to test the effect of whisker orientation on the creep rate, experiments were conducted on the two kinds of materials (hot-pressed or extruded) at several temperatures in the same stress conditions. Figure 3(a) is a plot of creep rate versus true strain for two specimens, a P// and a P⊥, deformed at 1300°C and 40 MPa. The two curves are very similar. The same inference can be drawn for E specimens as presented in Fig. 3(b) for two tests conducted at 1330°C and 30 MPa. These results do not show a significant influence of the compression axis orientation relative to the whisker direction on the creep rate. Under these conditions, the different specimen configurations can be neglected and we will assume later on, in particular in the creep rate analysis, that various specimens differed only by their grain sizes.

By contrast, in the case of P⊥ and E⊥ samples, transverse strains were whisker orientation dependent. As previously observed,[1] for these two kinds of specimens the transverse strain in the x direction in Fig. 2, the direction perpendicular to the whiskers, was systematically larger than that in the other transverse direction (y direction). The corresponding strain ratio, ϵ_x/ϵ_y, was approximately 1·5 whatever the deformation conditions. *A priori*, the insensitivity of creep rates to whisker orientation may seem to be inconsistent with the above strain anisotropy. This will be discussed later.

The experimental steady-state creep rates $\dot{\epsilon}$ were analysed according to the phenomenological relationship:

$$\dot{\epsilon} = A\,(\sigma^n/d^p)\exp(-Q/RT) \qquad (1)$$

where σ is the stress, d is the zirconia grain size, n and p are the stress and grain size exponents respectively, Q is the creep activation energy, R and T having their usual meaning. A is a constant depending on the microstructure and on the controlling rate mechanism.

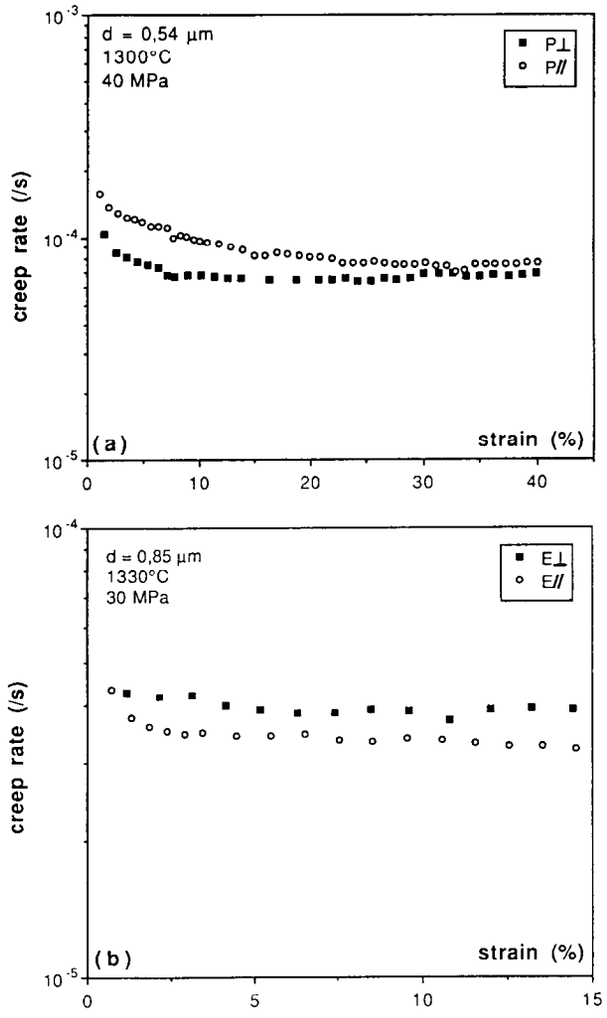

Fig. 3. Influence of whisker orientation on the creep rate: (a) case of two hot-pressed specimens deformed at 1300°C, one parallel and one perpendicular to the hot-pressing direction; (b) case of two extruded specimens deformed at 1330°C, one parallel and one perpendicular to the extrusion direction.

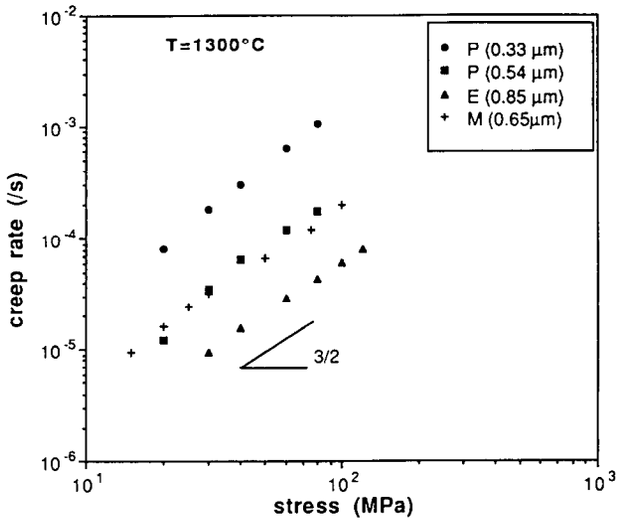

Fig. 4. Influence of stress on the creep rate at 1300°C of the three reinforced materials (P and E specimens). The curve with the open points represents the matrix behaviour (grain size = 0·65 µm).

The effect of the stress on the creep rate is presented in Fig. 4 as a log–log plot of the steady state creep rate versus stress for the three tested grain sizes. On this diagram, the experimental points concerning the zirconia matrix[15] (grain size 0·65 μm) have been added. A great similarity with the present experimental curves is observed. For the high stress range (typically higher than 40 MPa), the stress exponent has a value of 1·6. At the lowest stresses, especially for the two kinds of hot-pressed samples which have finer grain sizes than the extruded material, the stress exponent n slightly increases, as for the matrix.[15] However, the difficulties associated with conducting creep tests at very low stresses (5–10 MPa) do not allow us to investigate this stress range and to study the possibility of an increasing stress exponent in this domain or the occurrence of a threshold stress such as has been observed in creep studies of alumina–zirconia matrices reinforced with 27 vol% of SiC whiskers.[1,16,17]

From Fig. 4, the effect of the grain size on the creep rate was determined over the range 30–80 MPa (Fig. 5). The grain size exponent has a value between 3 and 4, being relatively constant throughout the entire stress range.

The temperature dependence has been analysed from temperature changes performed during tests at a constant stress of 30 MPa. The resultant activation energy does not depend on the specimen kind and ranges between 550 and 600 kJ/mol, the same activation energy as found for the matrix in the high stress regime.

3.2 Structure development

TEM and SEM examinations showed that the microstructure of crept samples was nearly identical to the microstructure of undeformed specimens. No glassy phase related to whisker oxidization

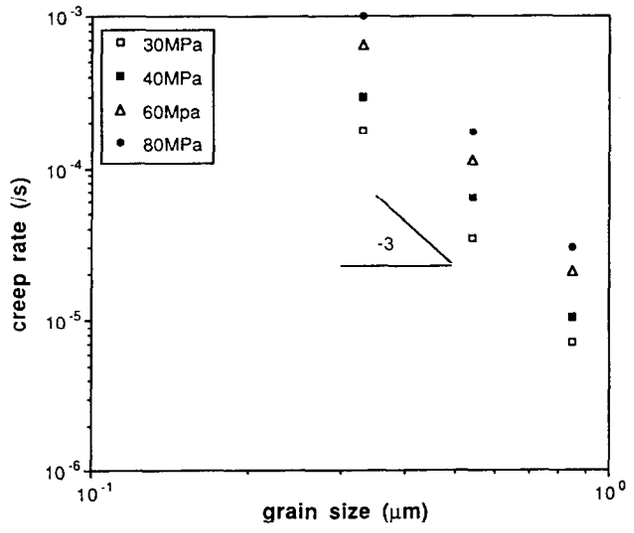

Fig. 5. Influence of grain size on the creep rate at 1300°C of reinforced materials.

Fig. 6. Microstructure inside the zirconia matrix after a strain of 40% at 1300°C for a specimen pressed at 1550°C. Scale bar = 0·5 μm.

during the deformation test, was detected at the whisker–zirconia interfaces or in the matrix by conventional TEM. SiC whiskers presented no evidence of plastic deformation such as shape change or intragranular dislocation activity. Zirconia grains which retained their initial equiaxed shape and size were generally dislocation free (Fig. 6). On the other hand, boundary dislocations were observed, especially in the extruded material. The main structure changes concerned the whisker orientation relative to the compression axis and the cavity nucleation.

During deformation of P⊥ and E// specimens, for which whiskers do not lie in planes perpendicular to the compression axis at the test onset, the angle between compression axis and mean whisker direction increased with strain. Thus, at a strain of 40%, more than 70% of the whiskers were about perpendicular to the compression axis, in good agreement with our previous results.[1] Moreover, in the case of P⊥ specimens, whiskers tended to stay in the planes perpendicular to the initial hot-pressing axis, rotation of whisker occurring more or less isotropically in the E// specimens. This means that during deformation the whisker distribution in P⊥ specimens became identical to that of E⊥ samples while E// specimens tended to be similar to P// samples.

Cavity formation was observed at every stress with an increasing tendency at high stress. The cavitational component of creep strain was determined by density measurements. According to the deformation conditions, the observed decrease in density ranged from 0·9 to 3·6% as shown in Table 1. Cavities were mainly observed at the matrix–whisker interfaces in the matrix phase (Fig. 7) but sometimes also inside the zirconia phase itself. They were generally located at triple points but could also be developed along boundaries. In this

case, porosity was preferentially oriented parallel to the stress direction. When a creep acceleration was observed, it was correlated to pore coalescence and microcrack formation (Fig. 8).

4 Discussion

4.1 Creep mechanism

As shown in Fig. 4, the stress influence on the creep rate of the three reinforced materials is nearly identical to that of the zirconia matrix. The creep rate is characterized by a stress exponent whose mean value of $n \sim 1{\cdot}6$ does not reflect a single mechanism, but rather a combination of two or more active mechanisms.

TEM examinations and density measurements showed that the contributions of intragranular dislocations and cavitation to creep strain was likely to be too weak to account for such a stress exponent. In addition, any tendency to an increase in the stress exponent should be observed at high stress and not at low stress, if cavitation and/or dislocation contributions were significant.

The activation energy, 550–600 kJ/mol, is similar to that of the matrix in the high stress range;[15] this suggests:

(1) That whiskers do not have a significant influence on the controlling mechanism of creep, in agreement with the fact that the creep behaviour was only little affected by the whiskers.

(2) That only mechanical interactions between matrix and whiskers and not chemical interactions (with consequent changes in the diffusion mechanisms and activation energy) took place during deformation.

The grain size exponent is also coherent with the value obtained in the high stress range for the matrix.

Finally, except for the A factor in eqn (1), all the thermomechanical parameters of the composites, n, p and Q, are approximately the same as for the matrix. The deformation mechanisms are therefore believed to be identical for the reinforced and unreinforced materials: grain boundary sliding and a grain rearrangement process are responsible for a large amount of deformation. If the specific nature of the accommodation mechanisms cannot be unambiguously established on the basis of the exponents and activation energy observed and owing to the lack of reliable diffusion data, some informations can be obtained from literature:

(i) a comparison of our creep rates with those expected from Nabarro–Herring diffusion creep[18] shows that ours are faster by more than two orders of magnitude suggesting in agreement with Chokshi's conclusion[19] that N–H diffusion creep should not contribute significantly to deformation of our materials;

(ii) in addition, according to several authors[20–22] the grain size of our specimens lies in the range where grain boundary diffusion should be expected.

Nevertheless, the effect of impurities and the possible presence of a thin intergranular film must not be neglected in the deformation accommodation.

With respect to the matrix behaviour,[15] whiskers behaved as an inert and non-plastic phase; their effect appears mainly: (i) in the difference of transverse strains for P⊥ and E⊥ samples and (ii) in the creep damage. For the first point, this means that the whiskers reduce the deformation in the direction parallel to the whisker axis. This point is more specially discussed in the next part. Concerning the second point, this confirms the absence of plasticity of the whiskers at the test temperatures resulting from the low diffusion coefficients and from stress levels insufficient to activate dislocation glide in the SiC phase.[23,24] Under these conditions, stress concentrations in the vicinity of the whiskers can be released only by plastic deformation in the zirconia phase. When zirconia plasticity is not efficient enough, cavity nucleation occurs.

4.2 Effect of whisker orientation on the creep rate

In contrast to our previous results,[1] the creep rates obtained in the present study were not significantly affected by the orientation of the compression axis relative to the whisker direction.

Nevertheless, in these two works, a similarity has been noted that concerns the strain anisotropy in the planes perpendicular to the compression axis in P⊥ and E⊥ specimens. (Recall that in these specimens, the whiskers were, or became during deformation, parallel lying in planes perpendicular to stress). The ratio between the two transverse strains, the strain in a direction perpendicular to the whiskers (ϵ_x in Fig. 2) over the strain in a parallel direction (ϵ_y), is dependent on the whisker content, 1·5 presently versus 2 previously.[1] This anisotropy results from a greater ease of grain rearrangement perpendicular to the whiskers, due to an easier rotation of whiskers around their own axis than around a perpendicular axis.[25] The effect of the whisker content can be understood if we consider that the influence of a given whisker on the matrix deformation decreases with the distance from the whisker. Consequently at a distance r_0 of a few grain sizes, one can assume that the whisker has no more effect on the matrix behaviour and deformation becomes again isotropic in a plane perpendicular to the compression axis. That influence occurs in a cylindrical volume of radius r_0 and length approximately equal to the whisker length, called interaction volume in what follows. In this interaction volume, the rearrangement rate in a direction parallel to the whisker axis slowed down more and more with respect to the perpendicular rate as the distance from the whisker decreases. At a low whisker content, two neighbouring interaction volumes do not overlap; as a result, the composite behaviour is little modified by the presence of the whiskers and the ratio between the two transverse strains, ϵ_x/ϵ_y, is roughly equal to one. But, as the whisker content increases, the overlapping, or interaction, between these volumes increases and the matrix deformation is more and more disturbed in the direction parallel to the whiskers relative to that in a perpendicular direction. Under these conditions, the strain anisotropy of P⊥ and E⊥ specimens must effectively increase with the whisker content.

Concerning the effect of whisker orientation on the sample strain rate, it can be partly understood by some earlier considerations.[1] The achievement of large strains results from matter flows whose direction is controlled by the applied stresses. As previously mentioned, in the vicinity of the whiskers, i.e. in the interaction volumes, the flows can be separated into two elementary flows (Fig. 9), one parallel to the whisker and the other one perpendicular, corresponding respectively to average contributions to the macroscopic strain rate R// and R⊥, with R⊥ > R// and R⊥ / R// increasing with the whisker content. According to the whisker content and distribution, the need to maintain the strain compatibility throughout the specimen imposes that the flows around a whisker are more or less coupled. This results also from the fact that the deformation in a layer perpendicular to the stress direction is dependent on deformation occurring in the layers just above and below due to the rearrangement or intercalation mechanism that increases the grain number in a cross sectional area and requires grain exchanges between neighbouring layers.

When all the whiskers are parallel, the same kinds of flow, those parallel or those perpendicular to the whiskers, occur around each whisker in the whole specimen. Consequently, the two matter flows can be treated independently and the resultant

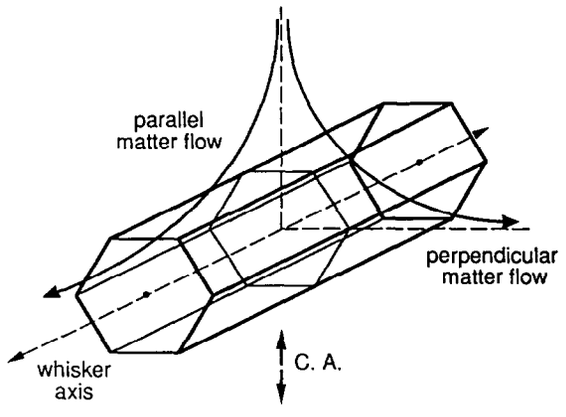

Fig. 9. Definition of parallel and perpendicular matter flows around a whisker.

strain rate should be simply the sum of R// and R⊥.

When the whisker orientations are more or less homogeneously distributed in the planes perpendicular to the compression axis, the two flows can be no more treated separately. The two extreme cases correspond to:

(i) the two flows act in parallel but the fastest one (R⊥) is slowed down by the slowest one (R//) and the resultant creep rate is estimated to twice the slowest rate. This occurs at a whisker content low;

(ii) the two flows act in series and the creep rate in them half the slowest contribution. This must correspond to high whisker contents.

Such assumptions can account, at least qualitatively, for our results at low and high whisker contents. However the above estimations assume that after hot-pressing all the whiskers laid perpendicular to the hot-pressing direction. When it is not the case, for instance when whiskers with a high aspect ratio, for which the interference threshold is reached at a relatively low content,[26] are used, the deformation of specimens with the compression axis perpendicular to the hot-pressing direction is then dependent on the whiskers out of planes perpendicular to the hot-pressing axis. Consequently in such specimens, the behaviour anisotropy related to the compression axis orientation should lessen or even disappear. The influence of whiskers on the creep rate is then strongly dependent on their orientation and morphology and cannot be simply related to their content.

5 Conclusion

The deformation of zirconia matrices reinforced with 13 vol% of SiC whiskers has shown that the creep behaviour was not strongly affected by the presence of the whiskers. The activation energy, the stress exponent and the grain size exponent were found to be similar to those of the matrix, suggesting that the same microscopic mechanisms were rate controlling. Cavity formation made a limited contribution to the deformation (a few percent for strains of 40%).

The influence of whiskers on deformation was particularly observed on the strain anisotropy of samples where the compression axis was perpendicular to the directions of hot-pressing or extrusion. The strain in a direction parallel to the whisker axis was systematically lower than that in a perpendicular direction. This observation was analysed by a greater ease of grain rearrangement when it occurs in a direction perpendicular to the whiskers. By comparison with our previous results,[1] it appeared that an increase in whisker content increased the interaction between the matrix and the whiskers and had a more pronounced effect on deformation in the direction parallel to the whiskers than in the perpendicular direction: the strain anisotropy was then dependent on the whisker content for these kinds of specimens.

The influence of specimen orientation on the creep rate has been explored by estimating the more or less high connection between the two elementary matter flows around the whiskers as a function of the whisker content.

Abstract

Microstructural changes and the related strength degradation were investigated for the Nicalon ceramic fibre heat-treated in argon and in a CO/Ar mixture (with a CO partial pressure of 40 kPa) at 1200–1400°C and for different periods of time (0·5–30 h). Detailed structural and compositional analyses were carried out using X-ray diffraction, TEM, SEM, and Auger electron spectroscopy. Strength degradation of the Nicalon fibre after heat-treatments in argon resulted from the fibre decomposition and CO gas escape which produced surface defects, grain growth and intergranular porosity. On the other hand, the strength degradation was effectively reduced for fibres heat-treated in an appropriate atmosphere of argon and CO, as long as the heat-treatment temperature was kept below 1400°C. Such conditions of heat-treatment in CO/Ar showed little effect on the grain size.

1 Introduction

Commercially available and developmental ceramic fibres are stimulating extensive research on the fabrication of ceramic and metal matrix composites for high temperature applications. To determine whether or not the composites can first be produced and then successfully used in a high temperature environment, the microstructure, microchemistry, mechanical properties, and thermal stability of the fibres are important parameters that need to be characterized. This characterization also provides information which will help to develop appropriate processes to produce fibres for high temperature use. There have been many studies of the effects of thermal exposure on the properties of polymer derived ceramic fibres, especially on Nicalon† Si–C–O fibres. It is now clear from the literature that the major factors which will influence the mechanical properties of these fibres at high temperature are microstructural instability and surface reaction. The thermodynamic calculations performed by Luthra[1] and Greil[2] indicate that the Nicalon fibre is inherently unstable at high temperatures, and other investigators[3] have proposed that the ternary amorphous SiO_xC_y phase in Nicalon would be primarily responsible for this instability. The decomposition of the silicon oxycarbide phase in the Nicalon fibre[4–6] and in other polycarbosilane based ceramics[7] results in weight loss associated with CO(g) and perhaps SiO(g) evolution and β-SiC grain growth. With or without involvement of excess carbon, this decomposition will result in the formation of gas and SiC. This means that one can anticipate the following reactions to take place in fibres at high temperature and, essentially, in any environment:

$$SiO_xC_y(a) \rightarrow n_{SiC}SiC(s) + n_{CO}\,CO(g) + n_{SiO}\,SiO(g) \quad (1)$$

or

$$SiO_xC_y(a) + C(s) \rightarrow n_{SiC}\,SiC(s) + n_{CO}\,CO(g) + n_{SiO}\,SiO(g) \quad (2)$$

and

$$SiO(g) + 2C(s) \rightarrow SiC(s) + CO(g) \quad (3)$$

According to eqns (1)–(3), the decomposition, crystallization, and gas evolution must occur simultaneously. If one of them can be suppressed, it should suppress them all, until all the SiO_xC_y species reach an equilibrium. A strong support for this assumption can be found from fibres heat-treated under various pressures. Jaskowiak *et al.*[8]

*Now with Institute of Advanced Materials, Joint Research Center, Petten, The Netherlands.

†From Nippon Carbon Co., Tokyo, Japan.

noticed that under vacuum or at normal pressure, both rapid weight loss and grain growth of Nicalon fibres start at 1200°C. A strong correlation between the grain growth and weight loss was observed. While oxidizing CVD SiC powder, Pampuch *et al.*[3,9] observed a ternary phase of Si, C, and O which was only stable for oxidation temperatures below 1200°C. It decomposed to SiO_2 and Si with the evolution of CO(g) at higher temperatures. Mah *et al.*[4] studied the decomposition of Nicalon, and the major out-gassing species was CO(g). Johnson *et al.*[5] measured the partial pressure of gases over Nicalon, and the major vaporization species were SiO(g) and CO(g). Previous investigations[10] had shown that grain growth and porosity increased with time of heat-treatment at 1300°C. Recently, the high temperature creep behavior of these fibres in argon has been characterized by a rheological model based on the viscous flow of a concentrated suspension of SiC particles in an unstable viscoelastic matrix. As a result of the decomposition of the SiO_xC_y phase, the viscosity of the fibre increased which caused the continuously decreasing creep rate and the steady-state creep impossible under such conditions.[11]

Considering the instability of Nicalon fibre leads to an important question: could the decomposition of SiO_xC_y be stopped? Two methods have proved to be effective in reducing the decomposition of SiO_xC_y: high total pressures and a carbon monoxide partial pressure. The first method was used by Jaskowiak and DiCarlo,[8] and Jaskowiak[12] with high pressure argon and nitrogen gas. However, the decomposition of the ternary phase occurred again when the high pressure argon heat-treated fibre was subsequently reheated at normal argon pressure. The second method attempted by Bibbo *et al.*[13] involves treatments of Nicalon in argon/CO mixtures with a range of CO partial pressures. A maximum effect on the strength of the fibre was found for pCO = 0·4 atm after a 30 min heat-treatment at 1300°C. However, no microstructural characterization was performed in this study. Bender *et al.*[14] have also mentioned the benefits of CO treatments (P_{CO} = 1 atm). After 3 h at 1600°C, the Nicalon fibre retained an average strength close to 1·4 GPa whereas in nitrogen at the same temperature the fibre retained less than 5% of its original strength. Bender *et al.* showed that the fibre underwent few microstructural changes in CO, i.e. limited grain growth and the beginning of the development of microporosity.

The purpose of the study was to investigate the long-term thermomechanical behavior of Nicalon fibres in a so-called chemically stable environment, i.e. by achievement of the fibre stability via suppressing SiO_xC_y decomposition and grain growth during heat-treatments in flowing CO. The results of these experiments helped to further establish the steady-state creep behavior of those fibres.[15]

2 Experimental Procedure

2.1 Material

The thermomechanical stability of Nicalon was investigated on a ceramic grade type fibre,† obtained from a polycarbosilane precursor. The Nicalon fibre contains Si, C, O as its major elements and some traces of hydrogen in it have been also reported.[16] Nicalon NLP 201 is a nanocrystalline β-SiC based-fibre. It has an average diameter of 15 μm. The fibres were received in spool form and coated with an epoxy sizing. This sizing was removed prior to the mechanical and structural characterization by washing the fibre bundle in ultrasonically agitated baths of acetone, ethyl alcohol and distilled water, successively, except for those exposed to high temperature treatments which were kept for 1 h at 550°C under vacuum prior to the temperature raise. Traces of carbon resulting from the sizing decomposition were detected by Auger analysis on the surface of the thermally desized fibres. It was verified that this method of desizing does not influence the initial strength distribution of the as-received fibres.

2.2 Heat-treatment furnaces and procedures

The custom built furnace used for the argon heat-treatments consisted of a vertical alumina tube heated by six SiC heating elements. Temperature was maintained via a controller and monitored using a Pt/Pt–10% Rh thermocouple located near the outer surface of the alumina tube and in the center of the hot zone. Fibre bundles were suspended by sewing them through a carbon cloth placed inside the cold, top part of the tube. A preliminary step consisting of vacuuming the furnace (down to $\approx 10^{-1}$ Pa) was performed at the beginning of the heat-treatment (up to 550°C). A first dwell time for at least 45 min (sometimes up to 2 h) with flowing UHP argon gas (oxygen $< 10^{-9}$ ppm) at 550°C was programmed prior to the final ramp. This was used to burn off the sizing. An in-line oxygen sensor (zirconia cell) connected to a voltmeter for a better accuracy was used to determine the oxygen level. As the temperature rose, the sensor indicated a decrease in the oxygen content. Different equipment was used for heat-treating

†Ceramic grade NLP 201.

Nicalon fibres at elevated temperatures in a very specific CO/Ar atmosphere (P_{CO} = 40 kPa). The apparatus used to heat up to 1200°C was a thermogravimetric balance consisting of a vertical fused quartz tube over which a furnace could slide. Fibre bundles were bound together by using an extra fibre bundle and were suspended in the tube by a silica hook to a platinum wire. The furnace was then raised and heat-treatment temperatures were reached within 30 min. A high temperature/atmosphere controlled tube furnace was used for heat-treating Nicalon fibres in CO at higher temperatures. Fibres were placed in a SiC boat and heated at 30°C min^{-1} in a horizontal alumina tube using Super Kanthal elements. Both furnace setups utilized mass flow controllers for the exact control of gaseous species entering the furnace tube. While the total pressure of the gases remained at one atmosphere, the partial pressures of individual gases (argon and carbon monoxide) could be adjusted through the flow-rate control of the mass flow controllers. The flow rate was adjusted to 5 standard cm^3 min^{-1}. Oxygen degassing was accomplished prior to each run by flowing argon for 30 min, and pre- and post-furnace oxygen traces were detected with an in-line zirconia cell.

2.3 Materials characterization

X-ray diffraction patterns were generated with a diffractometer* using Cu-Kα radiation. As-received and heat-treated fibres were ground into powder using an alumina mortar and pestle. Grinding was performed in acetone. The peaks in the diffraction patterns were identified using the JCPDS† files.

Auger electron analyses were performed with an AES microanalyser†† using the depth profiling mode on CO-heat-treated fibre samples mounted on indium foil. The spectra were recorded from the filament surfaces (spot size ~ 1 μm). The intensities of selected Auger electron transitions, (i.e. LVV for silicon, KLL for carbon, and KLL for oxygen) were recorded as a function of the thickness of the material which has been sputtered (established for a Ta_2O_5 standard).

Individual filament fracture surfaces after strength tests and surface degradation after heat-treatments were examined in a scanning electron microscope.[a]

TEM analyses were obtained with a 120 kV microscope.[b] The three main techniques of conventional TEM, i.e. bright field imaging (BF), dark field imaging (DF), and selected area diffraction (SAD), were used to characterize the fibre microstructure. TEM specimen preparation used two complementary techniques, i.e. ion milling to obtain longitudinal sections of the fibre core and microtomy to get cross-sections for the information concerning the fibre surface. The ion milling technique was performed using a dual ion mill,[c] whereas thin sections of fibres first embedded in a resin were cut using a diamond knife[d] and mounted on microtome.[e]

2.4 Strength tests

The room temperature strength tests on Nicalon fibres were performed on a table-top tester[f] with a small capacity Type A load cell (10, 20, 50 g full scale). Gripping of the filament was accomplished by mounting the fibre ends to paper tabs with epoxy. High temperature tests were performed in a small, custom-built furnace (Kanthal heating elements) using the same apparatus and the same cold gripping technique. All high temperature tests were begun within about 1 min after temperature stabilization because the furnace slit made the fibre loading easier. To determine fibre diameter, a portion of the test fibre was placed on a microscope slide and examined using an optical microscope.[g] All fibres were tested at the same cross-head speed of 0·5 mm/min, corresponding to a strain rate of 3·28 10^{-4} s^{-1} for the 25·4 mm gauge length for room temperature strength tests, and 5·56 10^{-5} s^{-1} for the 152·4 mm gauge length for the high temperature tests.

3 Results and Discussion

3.1 Microstructural analyses

Microstructural analyses were performed using TEM and XRD. Figure 1 represents the XRD spectra for fibres heat-treated at 1300°C at 0 and 40 kPa of CO, respectively. In the pure argon, SiC crystallization increased with time of heat-treatment, as seen in Fig. 1(a). Although image analysis using TEM dark field is not a reliable technique for ceramics containing very small grain sizes, it was just used here to evidence an increase of the

mean β-SiC grain size in Nicalon as a function of the heat-treatment time in argon. The mean grain size changed from 2·7 nm in the as-received fibre to ~10 nm after 15 h at 1300°C in argon. Figure 2 shows the grain growth and porosity resulting from this heat-treatment. It was previously mentioned that β-SiC grain growth could arise from SiO_xC_y decomposition, according to eqns (1)–(3). If one can assume that the escape of gas species, (i.e. CO or/and SiO) is faster near the fibre surface than near the center, one will assume that the same will be true for the grain growth. Thus decomposition and related grain growth will proceed further in the fibre with time of heat-treatment. On the other hand, the structural stability of Nicalon fibres was greatly enhanced when heat-treated at 1300°C with CO partial pressure of 40 kPa, as evidenced in Fig. 1(b). Figure 3, through a series of TEM micrographs of fibre cross-sections, shows evidence of carbon build-up on the Nicalon fibre. The two micrographs in Figs 3(a) and (b) indicate that carbon actually formed layers stacked parallel to the fibre surface. Figure 3(c) shows the turbostratic structure of this carbon, and the 004 reflection on the SAD pattern (inset of Fig. 3(c)) shows its orientation. The thickness of this carbon layer is about 500 nm. This carbon deposit may arise from the decomposition of CO(g) into C(s) and CO_2(g) during the cooling of the chamber at the end of the heat-treatment.

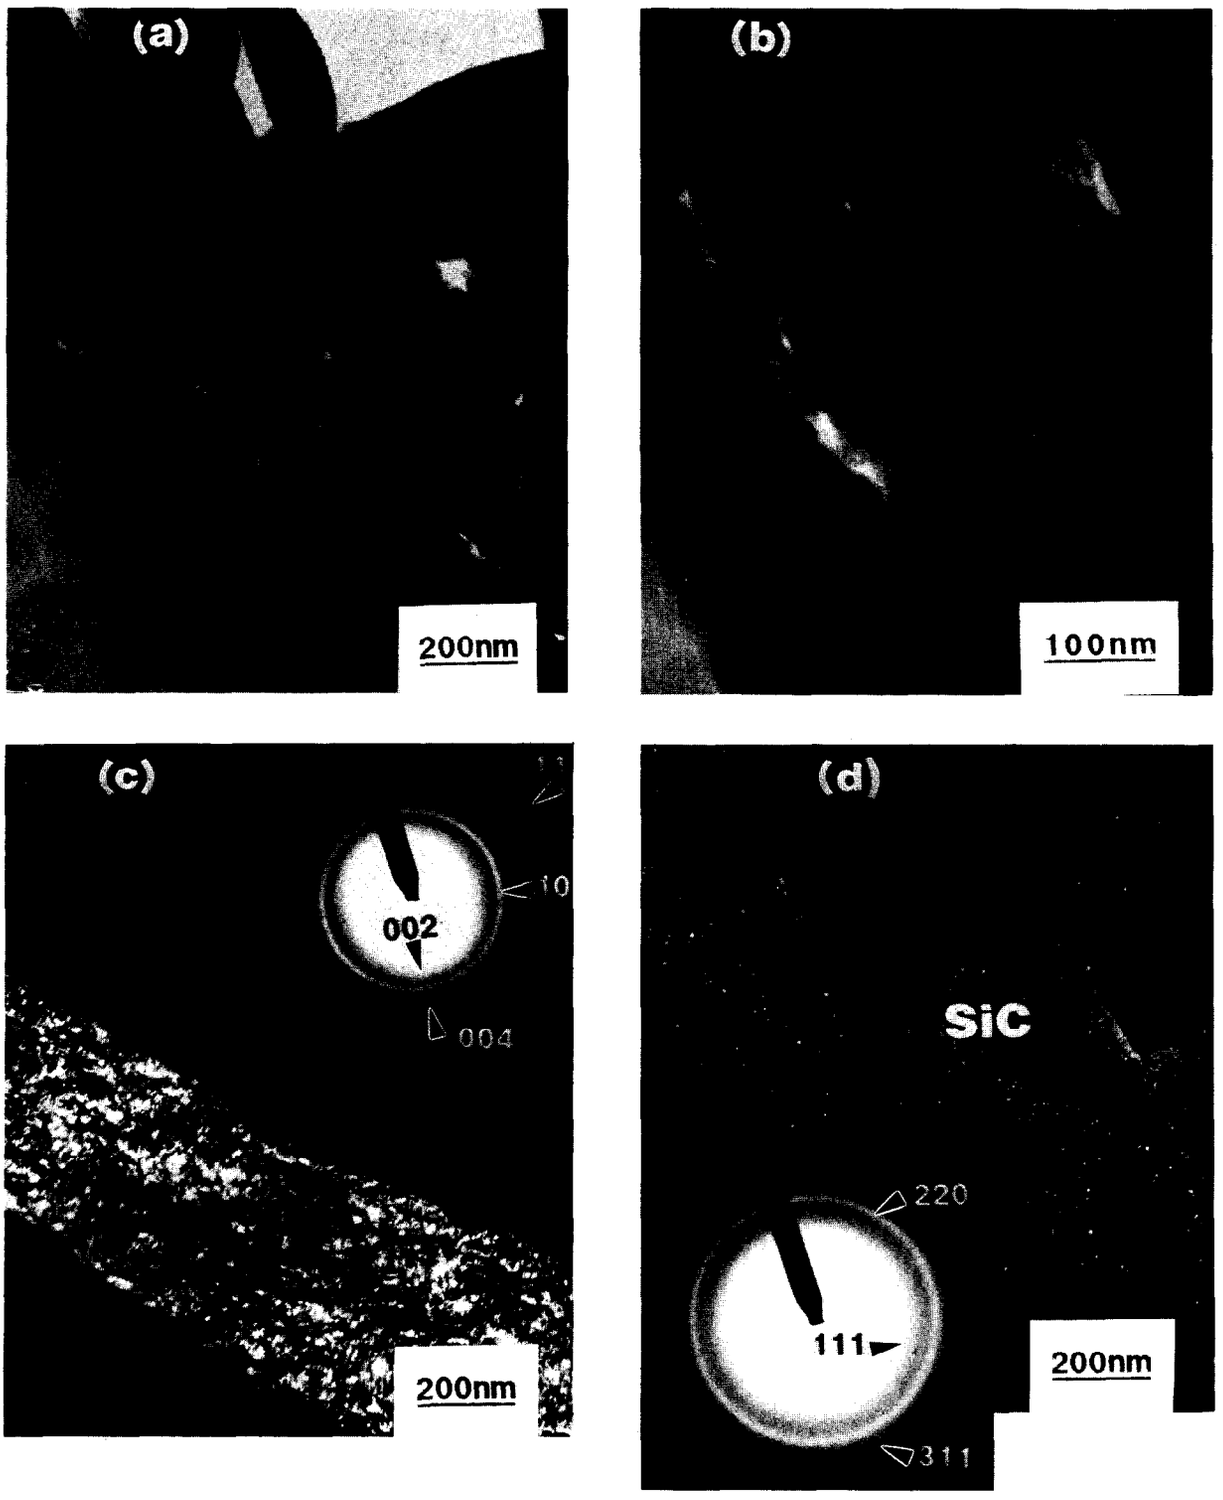

Fig. 3. TEM analysis of a CO heat-treated Nicalon fibre at 1300°C for 15 h. (a) and (b) are BF micrographs of the fibre surface, (c) and (d) are DF and SAD patterns of (c) carbon and (d) SiC.

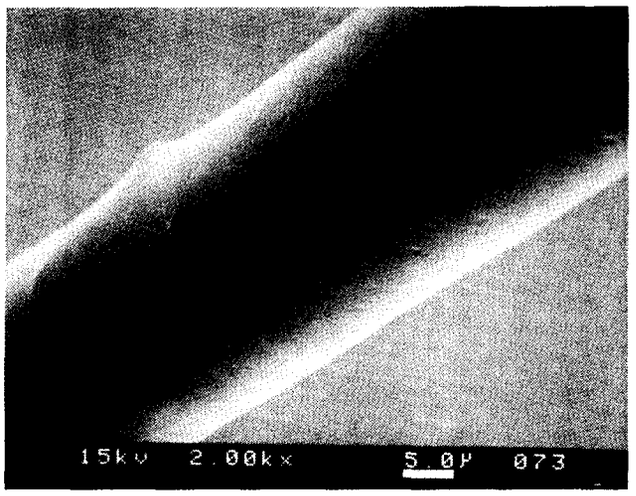
Bibbo *et al.*[13] also observed a build-up of carbon on the fibre surface in the case of a 1 h heat-treatment at 1300°C. The thickness of this carbon layer was seen to increase with the initial CO partial pressure. The SiC-111 dark field image, in Fig. 3(d), shows that little grain growth occurred after 15 h at 1300°C in 40 kPa of CO, indicating that the thermal decomposition of the fibre could be indeed minimized in 40 kPa CO. Fibres heat-treated at 1200°C behaved similarly. An example of a fibre surface is seen in Fig. 4. The previous figures, for fibres that were heat-treated at 1300°C, can be compared with Fig. 5, for fibres heat-treated at 1400°C at the same partial pressure of CO. Figure 5 indicates that, despite the presence of carbon build-up on the fibre surface (see arrows in Fig. 5(a)), an extensive crystallization of SiC occurred at higher temperatures, which showed no



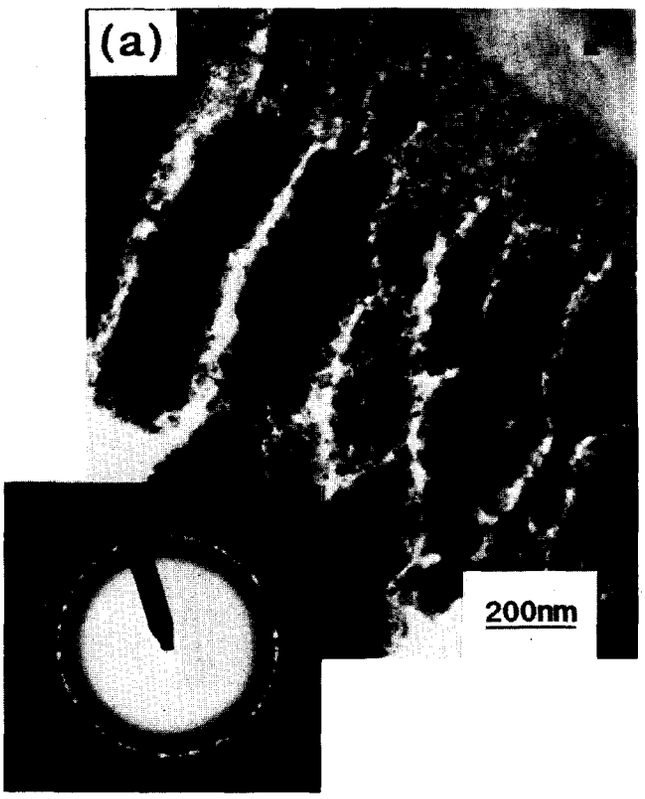


Fig. 4. SEM micrograph of a Nicalon fibre heat-treated in CO (40 kPa) at 1200°C for 0·5 h.

difference with heat-treatments in pure argon.[10] The spotty rings on the SAD pattern correspond to well developed SiC grains beneath the carbon. Some cracks are also apparent on the bright field micrograph in Fig. 5(a). It is unsure whether these cracks preexist or originate from the TEM specimen preparation. Internal pressure in the fibre is likely to build-up until the gas products resulting from fibre decomposition are released, causing a network of cracks beneath the carbon sheath. During the cutting operation by microtomy, the diamond knife can also induce damage in the degraded fibre by relieving these internal stresses. A well-developed crack network has been observed in fully decomposed fibres after prolonged heat-treatments in pure argon.[10] Because of the difference in textures (which behave differently regarding the stresses induced by the diamond knife) the cracks apparently vanish in a $\approx$ 400 nm wide region of different contrast, intermediate between the outer carbon layer and the fibre bulk. Figure 5(b) shows that the SiC grains are smaller in this transition region (indicated by double arrows) than those in the fibre bulk. This could be explained by a carbon penetration, which inhibited grain growth in the fibre surface. The microstructural changes that Nicalon underwent from 1300 to 1400°C while the partial pressure of CO was maintained at 40 kPa can be explained through thermodynamic calculations. Luthra[1] has shown that the equilibrium CO partial pressure above Si–C–O fibres at 1400°C is close to 100 kPa. Thus, it is believed that the exposure of the fibre at 1400°C to an environment containing a lower CO partial pressure than this equilibrium partial pressure will result in a more pronounced degradation of the fibre microstructure, (i.e. grain growth, porosity and gas evolution).

3.2 Scanning auger electron analyses

SAM analyses were performed on Nicalon fibres to evaluate more precisely the composition change resulting from surface reactions occurring after heat-treatment in CO/Ar. Results of surface composition for heat-treatments performed at 1300°C for 15 h, and at 1400°C for 5 h, both at the same partial pressure of 40 kPa, are shown in Fig. 6

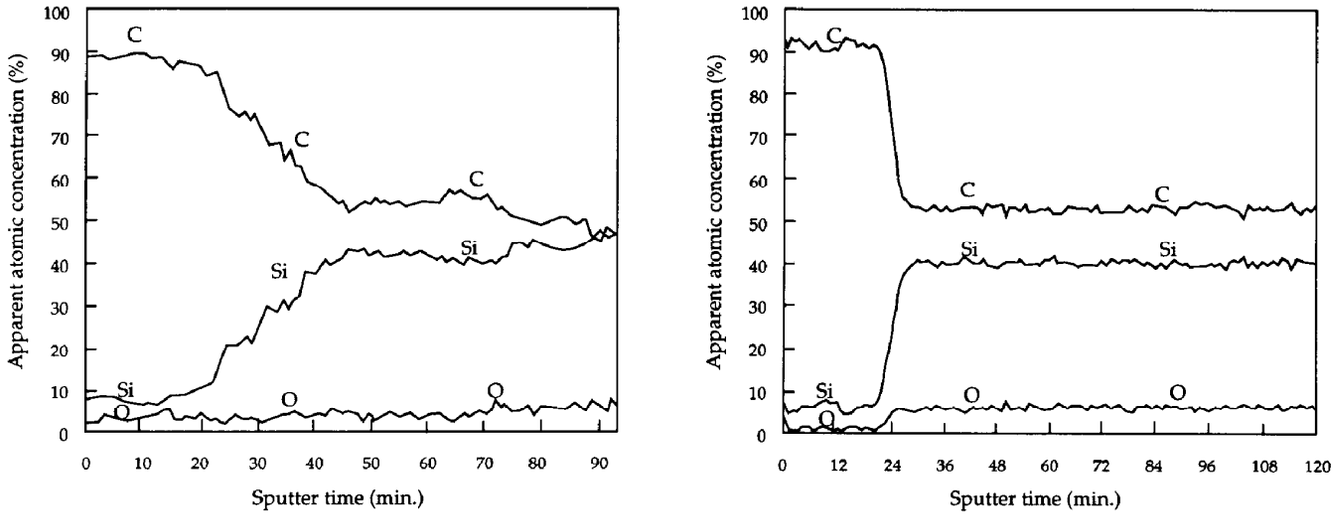

Fig. 6. AES analyses on Nicalon fibres after heat-treatment in CO and argon at CO partial pressure of 40 kPa. Fibres were heat-treated at (a) 1400°C for 5 h and (b) 1300°C for 15 h. Profiles show a carbon build-up on the surface (sputtering rate 25 nm/min; reference Ta_2O_5).

(a),(b). Both fibres developed a carbon rich layer of about 0·45 μm on their surface, according to an estimated sputtering rate of 25 nm/min (notice that this result agrees well with the TEM analysis in Fig. 3(c)). However, the sample heated at 1400°C did not show a sudden change in the composition profile compared to the other specimen. Instead, the carbon was found to decrease progressively with depth while at the same time silicon, probably as SiC, was increasing. On the other hand, the sample heated at 1300°C had a stable composition beneath the build-up of carbon. Moreover, this sub-layer composition was found to match that of the as-received fibre, i.e. 40 at% (Si), 53 at% (C), and 7 at% (O), proof that decomposition had been suppressed. After heat-treatment in the CO atmosphere at 1300°C, there was in fact only a deposition of carbon on the surface of the fibres.

3.3 Effect of heat-treatment on fibre strength

Room temperature strength tests were performed on heat-treated Nicalon fibres in CO/Ar at 0 and 40 kPa of CO. Results are reported in Table 1. In Fig. 7(a), the strength of Nicalon fibres at room temperature is plotted versus time of exposure in various environments, and follows a logarithmic decay for all heat-treatment conditions. The effect of CO partial pressure on the fibre stability is obvious. Fibres heat-treated in the CO/Ar mixture exhibit much less strength reduction compared to those heat-treated in pure argon. After a 30 h heat-treatment at 1200°C in CO, the Nicalon fibre exhibited only a 25% loss in strength, while for the

same temperature and time in argon, the loss was close to 70%. When comparing the data for a 15 h treatment at 1300°C, the losses became 22 and 76%, for CO and pure argon heat-treatments, respectively. The effect of argon and CO annealing treatments on the elastic modulus is shown in Fig. 7(b). Whereas the Young's modulus decreased from 230 to 160 GPa after 30 h at 1200°C in argon (the drop is even more drastic at 1300°C), its value never dropped below 200 GPa in CO. The observed increase after about 15 h at 1200°C and after only a few hours at 1300°C was probably due to the high stiffness of the fibre surface since a thick and oriented carbon layer ((001) carbon planes parallel to the surface) developed on the fibre surface. Figure 8 is an SEM micrograph of the fracture surface of a Nicalon fibre heat-treated at 1200°C for 0·5 h. The fibre had a rupture strength (2010 MPa) slightly above the average (1820 MPa). A notable feature observed on this figure as well as on other fracture surfaces is the evidence of debonding of the carbon layer. In some cases, fracture originated from bubbles beneath the carbon sheath perhaps because gaseous species generated by some late local decomposition

had been stopped by the carbon build-up (Fig. 9). This rare feature of the heat-treated fibres was never observed on the as-received fibres.

High temperature strength tests were performed in air on as-received Nicalon fibres as well as on those that were annealed in CO/Ar at 1200°C for 30 h. Results shown in Fig. 10 and reported in Table 2 indicate that the two sets of fibres have lost part of their strengths at high temperatures. A slightly greater strength loss is sometimes observed for the fibres previously annealed in CO/Ar, which might be related to the exposure of the defectuous surface of the fibres to oxidation after the carbon sheath was burned off.

4 Conclusions

The goal of CO treatments was to investigate the feasibility of suppressing the Nicalon fibre decomposition and more precisely to evaluate the effects of the long term and temperature variation of such annealing treatments on the thermochemical stability and the strength of the fibre. Heat-treatments at 40 kPa of CO in argon were performed in the range 1200–1400°C at times between 0·5 and 30 h. At the end of the heat-treatment, the reduction of CO from the atmosphere during the cooling of the furnace always formed a carbon-rich layer on the fibre surface. Little effect of the CO heat-treatments on the grain size was found up to 1300°C, but extensive crystallization, with ~60 nm large grains, and pronounced porosity were observed at 1400°C. An intermediate carbon-rich region with limited SiC grain growth was found beneath the carbon layer at the highest temperature. The strength degradation could be effectively reduced for Nicalon fibres heat-treated at 1200 and 1300°C in Ar/CO, with a CO partial pressure of 40 kPa. However, this gas mixture was no longer effective in preserving fibre strength when heat-treated at higher temperatures. Part of this investigation confirm the results of other authors that the presence of oxygen-rich phases inside PCS-derived fibres is responsible for the degradation of their thermo-mechanical properties. The Si–C–O fibre is inherently unstable in air and argon beyond about 1200°C but its decomposition can be delayed at higher temperatures in an atmosphere of carbon monoxide as long as the CO partial pressure is high enough. Additional studies on the fibre behavior in CO are presently being done to characterize their intrinsic creep-rupture properties.

Abstract

This paper reports the effects of different gaseous environments on the corrosion behaviour of β*-sialon materials. Six* β*-sialon materials with* z*-values of 0·2, 0·5, 1·0, 1·5, 2·0 and 3·0 were prepared by pressureless sintering. Corrosion results obtained at 1350°C in environments comprising (i) Laboratory air; (ii) Argon – 20% oxygen – 2% chlorine; (iii) hydrogen – 10% hydrogen sulphide – 2% water vapour and (iv) nitrogen – 15% carbon dioxide – 4% oxygen – 0·2% sulphur dioxide showed that for each of the four environments the* z *= 3·0 material exhibited the best corrosion resistance. The mechanism of corrosion at 1350°C in each of the four environments involves the formation of large volumes of low viscosity liquid phases. These large volumes of liquid enable the solution of* β*-sialon grains to occur and it is this process which is responsible for corrosion.*

1 Introduction

There are a wide range of fossil fuel conversion systems, eg. coal gasifiers, conventional and advanced coal-fired power generation systems and industrial incinerators where silicon nitride components may afford cycle efficiency increases due to either the employment of higher cycle temperatures or the obviation of inefficient component cooling. Whilst the excellent oxidation resistance of silicon nitride materials has been documented[1] and the effects of condensed sodium sulphate deposits assessed[2] no significant body of literature exists relating to the corrosion of such materials in gaseous environments typifying coal gasifiers, conventional/advanced power generation plant and waste incinerators. Oxychlorine and sulphur containing environments, which normally prevail in such industrial processes, can cause accelerated corrosion through the formation of volatile oxychlorides,[3,4] and SiS/SiO compounds,[5] respectively.

The corrosion of silicon based ceramics in corrosive gases at high temperatures has been investigated but it has been mainly confined either to hot pressed or hot isostatically pressed materials. The oxidation of such silicon nitride materials has been shown to be strongly dependent on the level of oxidant in the ambient gases.[6,7] When a high level of oxidant is present, a protective silicate layer is formed which separates the underlying ceramic from the environment. Oliveira *et al.*[5] defined the limits of pO_2 and pS_2 and temperature for the safe usage of hot pressed/HIPped silicon nitride by testing in gas mixtures similar to those that are likely to be encountered in coal gasifiers. An assessment of the effect of similar environments on the mechanical behaviour has also been made for hot pressed silicon nitride materials.[8] In contrast, no significant body of information is available for pressureless sintered materials.

The corrosion of silicon nitrides by gases representative of flue gases emanating from gas-, oil- or coal-fired combustion plant has not been directly studied. However, Demaison, *et al.*[9] have compared the corrosion of two similar β-sialon materials in oxygen and carbon dioxide. The results obtained by Demaison *et al.* indicate that the carbon dioxide environment encourages the development of oxide scales which are considerably more fluid than those which form during corrosion.

In studying the corrosion of materials by aggressive media it is important to understand the process by which simple oxidation takes place. The mechanism by which the oxidation of silicon-nitride based materials occurs is thus important and has been shown to depend upon temperature.[10,11] For temperatures typically in the range 1000–1150°C oxygen diffusion across a protective silica layer is rate controlling. For higher temperatures (up to 1400°C) the diffusion of sintering

additive cations and impurities from the interior of the ceramic into the surface silicon rich oxide scale is considered to be the rate controlling step. The rate controlling step in the mechanism by which silicon nitride oxidises at even higher temperatures has not been fully elucidated. In the intermediate temperature range, oxidation rates as determined from straight line relationships between the square of specific weight gain and time are observed to depend on the type and level of additives employed during sintering.[10–12] This is unfortunate since additive types and levels which facilitate pressureless sintering give rise to accelerated oxidation. One exception to this general rule is the oxidation behaviour of certain sialon materials.[12] In addition, attention has been drawn to the fact that additive rich oxide liquids, possibly containing nitrogen, are formed during the oxidation process.[9,13] Whether or not the formation of such liquids is an effect of the oxidation process or its cause has not been fully rationalised even though it is clear that the formation of such liquids and their volume is dependent on the diffusion of additive and impurity cations into the surface scales.

The research presented in this paper addresses the effect of the z-value of pressureless sintered β-sialons ($Si_{(6-z)}Al_zO_zN_{(8-z)}$) on the corrosion of these ceramics in environments typical of those arising in coal conversion and waste incineration plants.

2 Experimental Detail

The starting compositions of the materials employed in this work are given in Table 1 together with theoretical densities achieved and phase assemblages observed after firing. Weighed amounts of the relevant powders were ball milled for 24 h under isopropanol in a polypropylene container using sialon milling media. The mixtures were then homogenised for 30 min, dried and sieved to <212 μm. They were then cold isostatically pressed at 2000 atm. in a rubber mould. The cold pressed bars, typically 15 × 15 × 50 mm, were then located in a powder bed (50:50 boron nitride:silicon nitride) which was contained in an alumina crucible. The bars were then fired for 2 h at 1700°C in flowing nitrogen. The fired densities were measured by the Archimedes principle using both water and mercury as working fluids. The densities observed were compared with theoretical densities derived from the mass fractions and densities of the relevant sialon and Y–Si–Al–O–N glass phases present in the ceramic. The phase assemblages of the fired materials were determined using X-ray diffraction (XRD) and the z-value of the sialon ceramics determined using correlations and data published by Ekstrom *et al.*[14]

Following fabrication, corrosion experiments were performed in tube furnaces using specimens typically 10 × 10 × 3 mm, polished to a 1 μm finish. A heating and cooling rate of 8°C min^{-1} was employed for each experiment.

Corrosion experiments were conducted in different gaseous environments under the following conditions for all the materials chosen:

(1) Laboratory air at a temperature of 1350°C for 128 h.
(2) A chloridising environment comprising argon – 2% chlorine, 20% oxygen at a temperature of 1350°C for 100 h.
(3) A sulphidising environment comprising hydrogen – 10% hydrogen sulphide – 2% water vapour at a temperature of 1350°C for 100 h.
(4) A simulated flue gas environment comprising nitrogen – 15% carbon dioxide, 4% oxygen, 0·2% sulphur dioxide at a temperature of 1350°C for 96 h.

Corroded coupons were weighed following their removal from the relevant environment and extents of corrosion expressed as weight gain per unit area, i.e. specific weight gain. For materials exposed to the chloridising and sulphidising environments thickness loss measurements were used to assess extents of corrosion because weight losses were observed to occur in certain instances as stated below. The phase assemblage of the surface layers of the corrosion scales was determined using XRD and the surface morphology using scanning electron microscopy (SEM). Large

Table 1. Compositions (wt%), densities and phase assemblage for materials

All compositions are based on 88·9 v/o of relevant sialon–11·1 v/o Y-sialon glass of composition (in equivalent %) 28 Y; 56 Si; 16 Al; 80 O; 20 N.

(1·6 × 1·0 mm) energy dispersive X-ray analyses (EDX) of the surface layers of selected specimens were conducted in order to determine the cation (Y, Al, Si) compositions of these scales.

3 Results

3.1 Fabrication and phase assemblage

From the results presented in Table 1, it is seen that as the nominal z-value of the materials increases, greater densification occurs during firing. The data shown in Table 1 also shows that full conversion of the α-silicon nitride powder to β-sialon occurs during firing. In only one instance (z = 3·0 matrix) was a residual crystalline phase observed. This phase was yttrium aluminium garnet and it is thought that the formation of this phase contributes to the discrepancy between nominal and observed z-value. For other compositions the z-values determined from the lattice parameter shifts agree fairly well with the nominal values.

3.2 Corrosion

3.2.1 Laboratory air

The variation in weight gain as measured after 128 h at 1350°C shows that z-values in the intermediate range ($0{\cdot}5 \geq z \leq 1{\cdot}5$) are the least resistant to oxidation at 1350°C (Fig. 1). The phase assemblages as identified by XRD indicate yttrium disilicate or cristobalite as the major surface phases for the z = 0·2–1·0 materials, while for the higher z-value materials mullite is the predominant phase. Typical surface textures observed for the z = 0·2, 1·0 and 2·0 materials are shown in Fig. 2. As can be seen, both z = 0·2 and 2·0 materials show a marked level of crystallinity in terms of yttrium disilicate and needle like mullite crystals respectively. The z = 1·0 material is typified by the occurrence of needle like mullite crystals and a grey cristobalite phase located in an amorphous phase. Superposition of the large area surface analyses on the Y_2O_3–SiO_2–Al_2O_3 phase diagram[15] showed that for the z = 0·2 and 0·5 materials the compositions lay in the yttrium disilicate–silica–eutectic phase field. For the z = 1·0, 1·5, 2·0 and 3·0 the compositions lay within the mullite–silica–eutectic phase field. Indeed the surface compositions for the latter three materials lay on a line joining the eutectic and mullite.

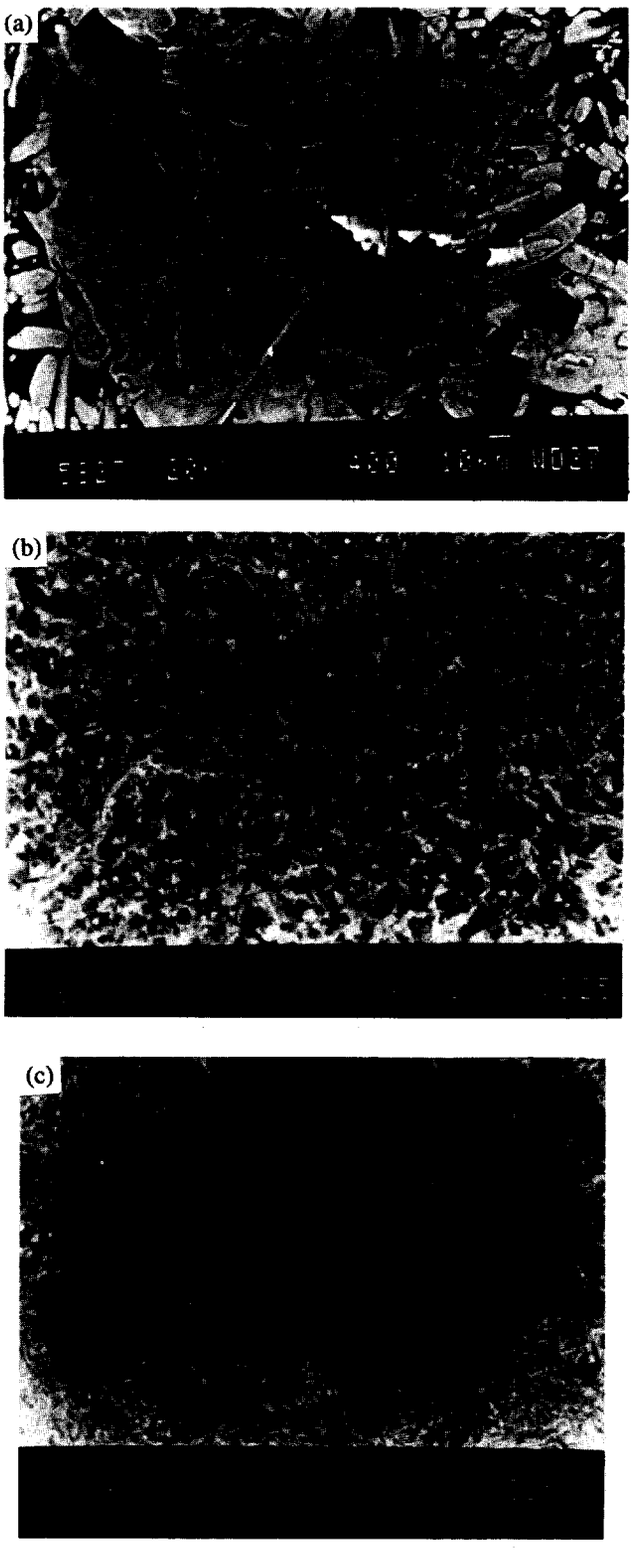

Fig. 2. Surface morphology of oxidation products formed on β-sialon materials after 128 h oxidation at 1350°C (a) z = 0·2, (b) z = 1·0 and (c) z = 2·0.

3.2.2 Chloridation environment

Figure 3 shows the weight change data for $z = 0{\cdot}2$ material following exposure to $2\%Cl_2/20\%O_2/Ar$ gas mixture at 1350°C for time periods up to 100 h. It is seen from this figure that the specific weight gain increases with time up to 50 h duration and then decreases for longer time periods. This decrease in weight gain was considered to be due to the volatilisation of corrosion products as most chloride and oxychloride reaction products are volatile at elevated temperatures.[16] Similar effects were observed in the sulphidising environments. Accordingly, it was decided that the use of specific weight change data as a measure of corrosion could be erroneous and hence thickness loss measurements were subsequently used to establish extents of corrosion after 100 h exposure. Figure 4 shows thickness loss data obtained for the β-sialons of different z values exposed to the argon – 20% oxygen – 2% chlorine environment at 1350°C. It is seen that as z-value increases the extent of corrosion after 100 h initially increases with z-value and then decreases. The most corrosion resistant material is that with a z-value of 3·0.

The morphology of the corrosion scales formed after 100 h corrosion was observed to be dependent on z-value. The scales were amorphous for materials with z-values of 0·2, 0·5, 1·0 and 1·5. For the $z = 2{\cdot}0$ material sillimanite and mullite

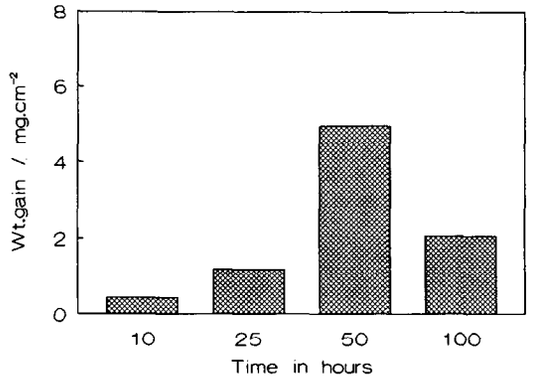

Fig. 3. Weight gain–time relationship for z = 0·2 sialon exposed to $2\%Cl_2/20\%O_2/Ar$ mixture at 1350°C.

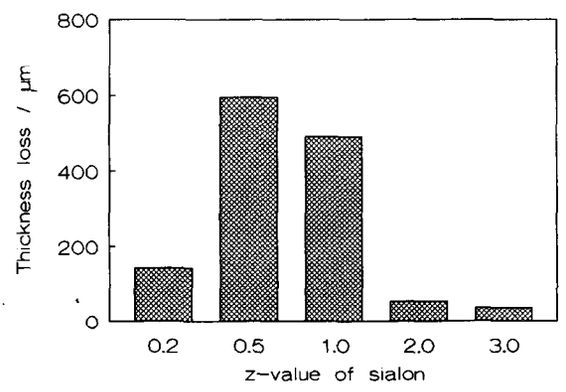

Fig. 4. Thickness loss data obtained for different sialon materials exposed to chloridising environment for 100 h at 1350°C.

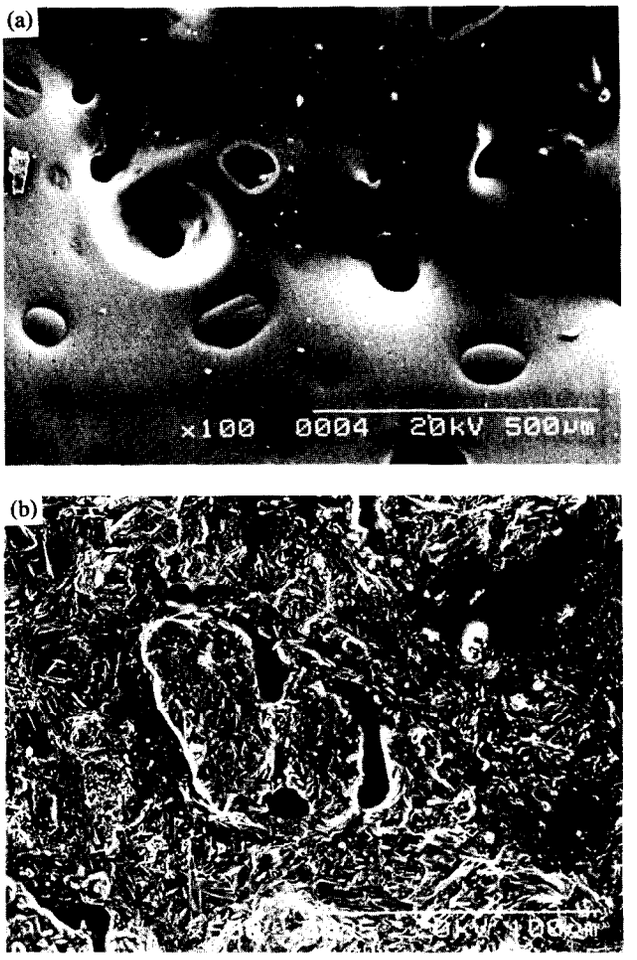

Fig. 5. Surface morphologies of the corrosion products formed following exposure to $2\%Cl_2/20\%O_2/Ar$ gas mixture at 1350°C (a) $z = 1{\cdot}0$ and (b) $z = 3{\cdot}0$.

crystals were observed in an amorphous scale and mullite crystals were observed to be present in an amorphous scale in the case of the $z = 3{\cdot}0$ material. Figure 5 shows representative surface morphologies of the corrosion products formed on the $z = 1{\cdot}0$ and 3·0 materials.

3.2.3 Sulphidising environment

The effect of z-value on corrosion thickness loss in the $H_2 - 10\%\ H_2S - 2\%H_2O$ environment is shown in Fig. 6. This figure shows that the extent of

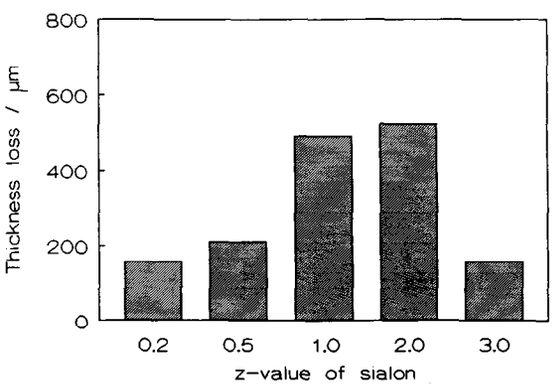

Fig. 6. Thickness loss data obtained for different sialon materials exposed to sulphidising environment for 100 h at 1350°C.

corrosion increases with increasing z-value up to 2·0 and then decreases with z = 0·2 and 3·0 materials undergoing least corrosion. The phase assemblages and surface morphologies observed for the different materials were similar to those observed for the chloridising environment.

3.2.4 Simulated flue gas environment

The form of the specific weight gain–time curve obtained for the z = 0·2 material exposed to the simulated flue gas environment at 1350°C was parabolic with rates of weight gain diminishing with time. Accordingly, it was assumed that no weight losses occurred during 96 h exposure and that weight gain data gave a true reflection of extent of corrosion. Figure 7 shows specific weight gain data as a function of z-value after exposure for 96 h at 1350°C. It is seen from this figure that as z-value increases from 0·2 to 1·0 the extents of corrosion increase. For z-values in excess of 1·0, the extent of corrosion decreases with increasing z-value.

The phase assemblages of the surface layers were observed to dependent on z-value. For the z = 0·2 material the predominant phase formed was β-yttrium disilicate which coexisted with silica and γ-yttrium disilicate. For the z = 0·5 material the predominant phase in the surface layers was silica. For the z = 1·0, 2·0 and 3·0 materials the predominant phase formed was mullite. Silica was also observed for these materials. A comparison of the amounts of liquid formed in the simulated flue gas environment with those formed during oxidation of similar materials for a similar length of time showed that the presence of carbon dioxide and sulphur dioxide in the simulated flue gas encouraged liquid formation (Fig. 8). The surface morphology of the z = 0·5 material exposed to the simulated flue gas environment for 48 h at 1350°C shown in Fig. 8 clearly demonstrates the occurrence of a large volume of liquid on the surface of the corroding sialon. The bright crystals seen in both Fig. 8 (a) and (b) are yttrium disilicate. z = 3·0 materials exhibit little liquid formation (Fig. 9) and this is consistent with the lowest corrosion rates observed (Fig. 7). Furthermore, large scale EDX analyses showed that for the low z-value materials (z = 0·2, 0·5 and 1·0) the surface layers of the corrosion scales formed in the simulated flue gas environment were richer in aluminium than

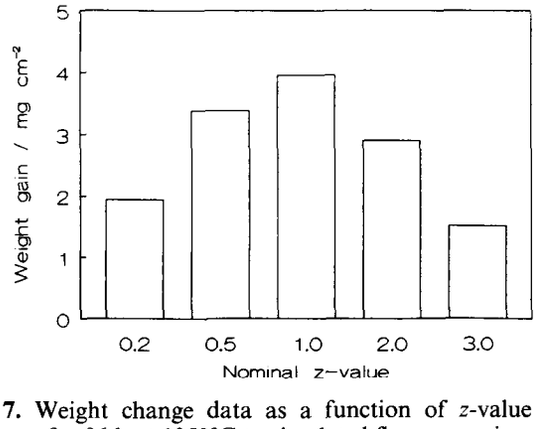

Fig. 7. Weight change data as a function of z-value after exposure for 96 h at 1350°C to simulated flue gas environment.

those formed during oxidation. It is to be noted however that the crystalline phases formed were the same in both environments.

4 Discussion of Results

4.1 Relative corrosion resistance

Of the materials tested the $z = 3{\cdot}0$ material appears to be the most resistant to oxidation/corrosion by laboratory air. This material is also without doubt the most corrosion resistant material in the other three environments used in this work. The fact that the mullite forming $z = 3{\cdot}0$ material exhibits little liquid formation during corrosion in any of the environments investigated is most probably the reason for its excellent corrosion behaviour. In general the $z = 1{\cdot}0$ material undergoes the most extensive corrosion in each of the four environments studied.

4.2 Effect of environment on corrosion scales developed

From the results presented above it is clear that liquid phases are formed on the surfaces of the materials investigated during exposure to laboratory air. In the chloridising environment, chlorine is the only reactive gas addition which can account for the accelerated oxidation and significant extent of corrosion observed. In addition, the extent of liquid phase formation is greater in the chloridising environment than the laboratory air environment; indeed the scales formed on the $z = 0{\cdot}2$, $0{\cdot}5$, $1{\cdot}0$ and $1{\cdot}5$ materials are wholly amorphous. It is to be expected that the corrosion scales formed in the chloridising environment are more fluid than those formed in laboratory air since Hetherington *et al.*[17] noted marked decreases in the viscosity of fused silica contaminated with trace amounts of chlorine. In the case of the sulphidising environment the situation is more complex since both hydrogen and sulphur vapour are present in addition to the oxygen provided as water vapour. In order to ascertain the exact effect of hydrogen sulphide on the corrosion process, additional experiments were conducted at 1350°C in a gaseous environment comprising hydrogen–2% water vapour using the $z = 0{\cdot}2$ material. The results obtained from this work demonstrated that the corrosion rate was less than that observed for the environment containing hydrogen sulphide and that the corrosion products showed some crystallinity. It may therefore be concluded that the large volumes of low viscosity liquid formed in the sulphidising environment, compared to those formed in laboratory air, arise from the synergistic effects of hydrogen and sulphur. Combining the findings of Demaison *et al.*[9] and the results obtained for the simulated flue gas environment strongly suggests that carbon dioxide and sulphur dioxide exert a similar synergistic effect on liquid volume and viscosity. This is clearly demonstrated by comparison of the micrographs shown in Figs. 8(a) and (b). As stated above, the exterior layers of the corrosion scales formed on the $z = 0{\cdot}2$ and $0{\cdot}5$ materials in the simulated flue gas environment were observed to contain more aluminium than those formed in the laboratory air environment. Since the crystalline phases formed ($Y_2Si_2O_7$ and SiO_2) do not contain this element, more liquid is expected to form in the former environment as observed above.

4.3 Corrosion mechanisms

Combining the above rationalisation of the effects of environment on the volume and fluidity of liquid corrosion products with the extents of oxidation and corrosion suffered by the different sialon materials indicates that for large volumes of a fluid corrosion product, (i.e. chloridising and sulphidising environments) extents of corrosion are significantly greater than those observed when lower volumes of liquid are formed, (i.e. simulated flue gas and oxidising environments). This correlation indicates that the role played by liquids in the oxidation and corrosion mechanisms operating at 1350°C is extremely important. Additional experiments with RBSN have shown that the $\beta/(\alpha + \beta)$ silicon nitride ratio observed in the layers beneath the cristobalite corrosion product formed in the simulated flue gas environment is greater than in the starting material. It was also observed that in addition to cristobalite a calcium containing amorphous phase was present in the surface layers of the corrosion product. In order for the α-/β-phase transformation to occur, a liquid phase must be present to facilitate the solution–precipitation reaction.[18] It would therefore appear that α-silicon nitride is dissolved by the calcium containing liquid present at 1350°C and reprecipitated as β-silicon nitride. This finding suggests that silicon nitride can be dissolved by liquid corrosion products. In order to validate the fact that the α/β transformation could occur at such a low temperature a green sample of the $z = 0{\cdot}2$ material was sintered for 96 h in flowing nitrogen at a temperature of 1350°C. The density of the material increased from 62% of theoretical to 90% and the initial β-content of 5% increased to 65% clearly demonstrating that densification and associated solution–precipitation effects could occur over long time periods at 1350°C. If α-silicon nitride can dissolve in a liquid corrosion product it seems plausible to assume that β-silicon nitride and sialons can also. However, dissolved β-silicon

nitride and β-sialons cannot be reprecipitated as α. Accordingly, if the β-silicon nitride dissolves in the corrosion scale it is likely that the resulting nitrogen saturated liquid will decompose into a liquid containing little nitrogen and the relevant crystalline silicates or silica. If this mechanism of oxidation and corrosion is accepted then the rate of corrosion should be dependent on the volume and viscosity of the liquid formed during oxidation. Greater liquid volumes will result in greater extents of silicon nitride/sialon solution and lower viscosities will enable the dissolution products to be transported away from the liquid – nitride interface more rapidly. The extensive corrosion of the various materials in the chloridising and sulphidising environments is thus easy to comprehend.

As stated in the introduction, although rates of oxidation at temperatures of the order of 1350°C are controlled by the diffusion rate of additive and impurity cations from the bulk of the ceramic into the surface scale the exact reasons for this are not fully appreciated. The above arguments relating to corrosion mechanisms enable a fuller appreciation to be put forward if it is realised that the diffusion of additive and cation impurities into the surface scale increases its liquid content and lowers the viscosity of the liquid formed. Such an argument is consistent with observations that the type and level of additive employed during densification control oxidation rate[11,12] since additive types and levels which give rise to large volumes of low viscosity liquids during densification will give rise to large quantities of low viscosity liquids in oxide scales.

In designing silicon nitride ceramics for high temperature corrosion resistant applications the selection of additive and sialon z-value are critical as the results presented show. The optimum ceramic will comprise constituents which will give rise to little liquid formation during corrosion. The observation that the mullite forming $z = 3{\cdot}0$ material exhibits less liquid formation during corrosion in any of the environments investigated and that this is consistent with the lowest corrosion rates endorses such a design criterion.

5 Conclusions

(1) In general, the most corrosion resistant material in oxidising, chloridising, sulphidising and simulated gas environments at 1350°C is a $z = 3{\cdot}0$ sialon material.

(2) The presence of gaseous impurities (sulphur vapour, chlorine, hydrogen, sulphur dioxide, carbon dioxide) in the corrosion environments employed have the effect of increasing the volumes of liquid phase formed in the corrosion scales.

(3) The occurrence of increased volumes of liquid phase results in increased corrosion rates.

(4) The mechanism by which corrosion and indeed oxidation of silicon nitride–based ceramics occurs appears to involve the solution of sialon grains by such liquids, the extent and rates of liquid formation are controlled not only by the gaseous environment but also by cation diffusion effects.

(Received 7 November 1994; revised 9 March 1995; accepted 20 March 1995)

Abstract

The oxidation behaviour of oxynitride glasses in M–Si–Al–O–N system (M = Nd, Y) has been studied in air and under various oxygen pressures. The influence of glass composition on the oxidation resistance was studied at 1075°C by varying Y/Al or Si/Al ratios and also by substituting Y by Nd and by varying the nitrogen content. The reactivities in air of the YSiAlON system is studied in the temperature range of 1000–1150°C. The oxidation resistance of YSiAlON glasses is better than for glasses containing Nd. A pressure law is determined for the YSiAlON system based upon data from oxidation at 1050 and 1075°C at oxygen pressures in the range of 15–100 kPa. The nature and morphology of oxidised samples were characterised by optical microscopy, XRD and SEM. These investigations reveal that the oxidation of the studied oxynitride glasses is governed by a reaction process where the progress of the internal interface is the limiting step.

1 Introduction

It is well established that oxidation and high temperature mechanical properties of silicon nitride ceramics are strongly dependent on the residual secondary phases. These can be glass or crystalline phases and are formed as a result of sintering additives or impurities in the material powders used in the synthesis of the ceramics. This has aroused a considerable interest in oxynitride glasses both as bulk materials and as grain boundary secondary phases in the nitride ceramics. Jack[1] was the first to report the existence of oxynitride glasses in the YSiAlON system. Additional information on the preparation and characterisation of glasses in this system has been given by Shillito *et al.*[2] and Loehman.[3,4] Subsequently, considerable investigations were carried out to determine the extent of vitreous regions in a wide range of M–Si–O–N and M–Si–Al–O–N systems[5–21] (M = either Ba, Ce, Ca, La, Li, Mg, Mn, Na, Nd or Y) including the effects of increasing nitrogen content on the properties of these glasses. The first systematic investigation of the effects of nitrogen on properties of alumino-silicate glasses was carried out by Drew *et al.*[11–13] who found that glass transition temperature, viscosity, microhardness and refractive index all increased as nitrogen was substituted for oxygen in the glass network. Another interest in oxynitride glasses is their ability to form glass-ceramics for potential thermomechanical applications. However, the mechanisms governing their transformation are still unknown. The products of glass crystallisation are also sensitive to nitrogen content and the results obtained by different authors vary.[22–26] The high temperature use of oxynitride glasses, in air, is limited by their oxidation resistance but relatively little data on their oxidation resistance are available in the literature[26–29] for a limited number of glass systems.

The present work is part of a European collaboration between four partners on the preparation and characterisation of a wide range of compositions of oxynitride glasses in various systems. This study has been undertaken to investigate the oxidation behaviour of some glasses in order to define their use under isothermal conditions and to explain the degradation mechanisms of sintered silicon nitride materials at high temperatures. In this paper some data on the influence of glass composition, heat treatment conditions and

oxygen pressure on the oxidation resistance and the morphology of glasses are reported. In contrast to CaSiAlON and MnSiAlON systems studied[27-28] the exploitation of the results was facilitated by the fact that samples preserve their geometry under oxidation. A second paper is devoted to explaining the mechanisms governing the oxidation of oxynitride glasses in the YSiAlON system.

2 Materials and Procedure

2.1 Glass preparation

The Jänecke triangular prism representation is used to represent glass composition within these M-sialon systems with concentrations of components expressed in equivalents (as shown in Fig. 1). Constant oxygen:nitrogen ratios can be represented by vertical triangular planes within the prism parallel to the oxide and nitride faces. $4N^{3-}$ are replaced by $6O^{2-}$ on moving from left to right and the distance x represents the concentration of nitrogen and the distance y represents the concentration of oxygen, in equivalents, such that $x/(x + y) = (3[N])/(2[O] + 3[N])$ where [O] and [N] are, respectively, the atomic concentration of oxygen and nitrogen within any composition. For any plane, the O : N ratio is fixed and the concentrations of the cations are calculated in equivalents in the normal way for a 3-component system. The compositions used for this study are shown in Table 1.

Glasses were prepared using the melting procedure described by Hampshire *et al.*[16] from mixtures of 99.99% pure silicon nitride powder with high purity oxides (Al_2O_3, Nd_2O_3, SiO_2 and Y_2O_3). They were mixed in isopropanol, dried, and pressed into pellets. Large batches of 40–70 g were melted in a boron nitride lined graphite crucible under 100 kPa nitrogen at 1700°C for 1 h. The glass was poured into a pre-heated graphite mould and annealed at 850–900°C for 1 h and allowed to cool slowly.

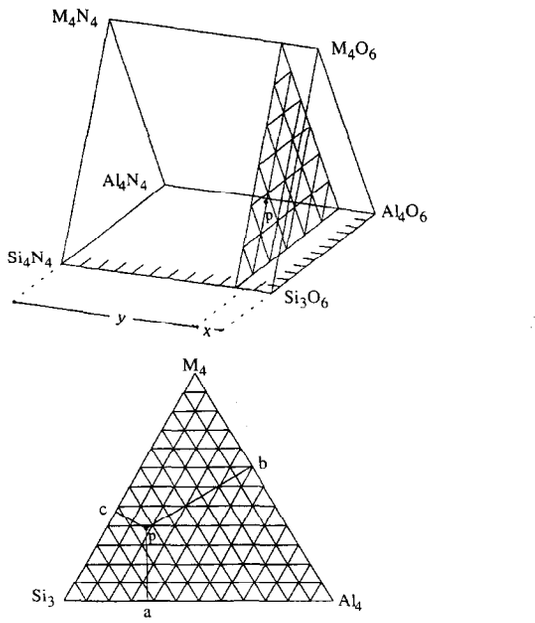

Fig. 1.. Jänecke prism representation of the M–Si–Al–O–N system.

2.2 Glass characterisation

Specimens were examined by optical microscopy (Olympus PMG3) and subjected to X-ray diffraction using a diffractometer (Philips PW1130) and a Guinier camera to confirm their amorphous nature, while chemical analysis of the nitrogen content was performed by a gas chromatographic analyser (Carlo Erba 1106). The oxidised samples were also characterised using X-ray diffraction, optical microscopy, SEM (Philips XL30) with integrated EDAX. Bulk glass densities were measured by an archimedean displacement using water as the immersion liquid, the accuracy of the measurement is ±0·05.

The nominal compositions in equivalent percent (e/o) cations/anions, glass densities and the values of nitrogen content found by analysis of the prepared glasses are detailed in Table 1.

Table 1. Glass compositions

	Composition (e.o)					*N (weight %)*		*Density*

2.3 Oxidation experiments

Cubic samples ($4 \times 4 \times 4$ mm^3) were cut from the pellets using a low-speed diamond saw and then carefully polished with diamond pastes and cleaned in an ultrasonic bath. The oxidation resistance of glasses in air and under controlled atmosphere was carried out using a thermobalance (Ugine Eyraud B60).

While the furnace was heated at a constant rate of 20°C min^{-1} to the oxidation temperature, the sample was kept in a cold zone then lowered quickly into the hot zone where it was kept only during the isothermal oxidation treatment.

3 Results

The oxidation reaction of oxynitride glasses, in the quinary systems, is very complicated due to the formation of a number of crystalline phases in the oxide layer. The nature and morphology of the oxidation products will be explained later. The crystalline phases are formed according to the following general reactions:

$$YSiAlON + aO_2 \rightarrow bY_2Si^2O^7 + cY_2SiO_5 + dAl_2O_3 + eAl_6Si_2O_{13} + \text{amorphous oxide} + N_2\nearrow$$

From weight changes it is possible to determine the fractional weight gain according to the equation:

$$\alpha = {}^{\Delta W_t}/_{\Delta W_\infty}$$

where ΔW_t is the weight gain for a given time t and ΔW_∞ is the weight gain which corresponds to a complete oxidation of the oxynitride glass. In this case ΔW_∞ corresponds to the experimental values of nitrogen content seeing that we obtain a complete oxidation when all nitrogen is substituted by oxygen in the glass network.

3.1 Influence of the glass composition

The behaviour at high temperature of oxynitride glasses is closely linked to the total composition. The nature and the concentration of each element are important parameters which influence the structure of the glass network. Oxidation resistance varies from one system to another[27–29] but the role of the different elements in the oxidation resistance of these glasses remains unknown. Considering that the structure controls the viscosity, the physical properties and the degradation of oxynitride glasses, systematic investigations were carried out to study the influence of glass composition on their oxidation resistance and to explain the contribution of each constituent. The experiments were carried out using the following series of samples:

(a) constant ratio Y/Si/Al and varying O/N ratio in order to evaluate the influence of nitrogen content;

(b) constant ratio M/Si/Al/O/N and varying the type of metallic cation;

(c) constant ratio Y/O/N and varying Si/Al to explain the role of silicon and aluminium in the network;

(d) constant ratio Si/O/N and varying Y/Al to explain the role of yttrium and aluminium as network modifiers.

The oxidised samples at 1075°C preserve their geometry. After oxidation of glasses we have seen no changes in the morphology of samples or the plasticity of the substrates.

The oxidation behaviour of oxynitride glasses is strongly dependent on the glass composition as shown in Fig. 2. The incorporation of nitrogen increases the oxidation resistance (Fig. 2(a)). As it will be shown later the oxidation starts above the glass transition temperature. When oxygen is replaced by nitrogen in silicon co-ordination tetrahedra, the increase of the degree of reticulation and the individual negative charge leads to an increase in the coulombic forces between these tetrahedra and the cations, thus enabling a higher refractoriness and compactness of the network.

The same effect is observed on the substitution of neodymium by yttrium (Fig. 2(b)). This could imply that the size of the cation alone is responsible for the behaviour changes at high temperatures; it can be explained by the fact that the strength of the bond between the metallic ion and the surrounding oxygen ions in the glass structure (M–O) where (M = Nd, Y) increases with increasing field strength of the metallic ion. It is known that the field strength varies with the reciprocal of the ionic radius which means that the Y–O bonds are stronger than Nd–O ones. As the M–O bonds are weaker than the Al–O and Si–O bonds, a more compact glass network is obtained with the stronger M–O bonds. The same results were observed by Shelby *et al.*[31] on the properties of oxide alumino-silicate glasses and by Persson *et al.*[30] while oxidising silicon nitride with Y_2O_3 and Nd_2O_3 additives.

Results for glasses that are oxidised at 1075°C for 20 h are shown in Figs 2(c) and (d). The role played by aluminium in the glass structure depends strongly on its concentration. For the low concentrations, aluminium is expected to exist in fourfold coordination with oxygen where the presence of (AlO_4) tetrahedra confers to aluminium the role of network former. As the aluminium content increases, it seems that the glass structure becomes more disordered[32–34] which could explain the decrease of the oxidation resistance. A negative effect of aluminium on the oxidation resistance of silicon nitride is also revealed by Gogotsi *et al.*[35]

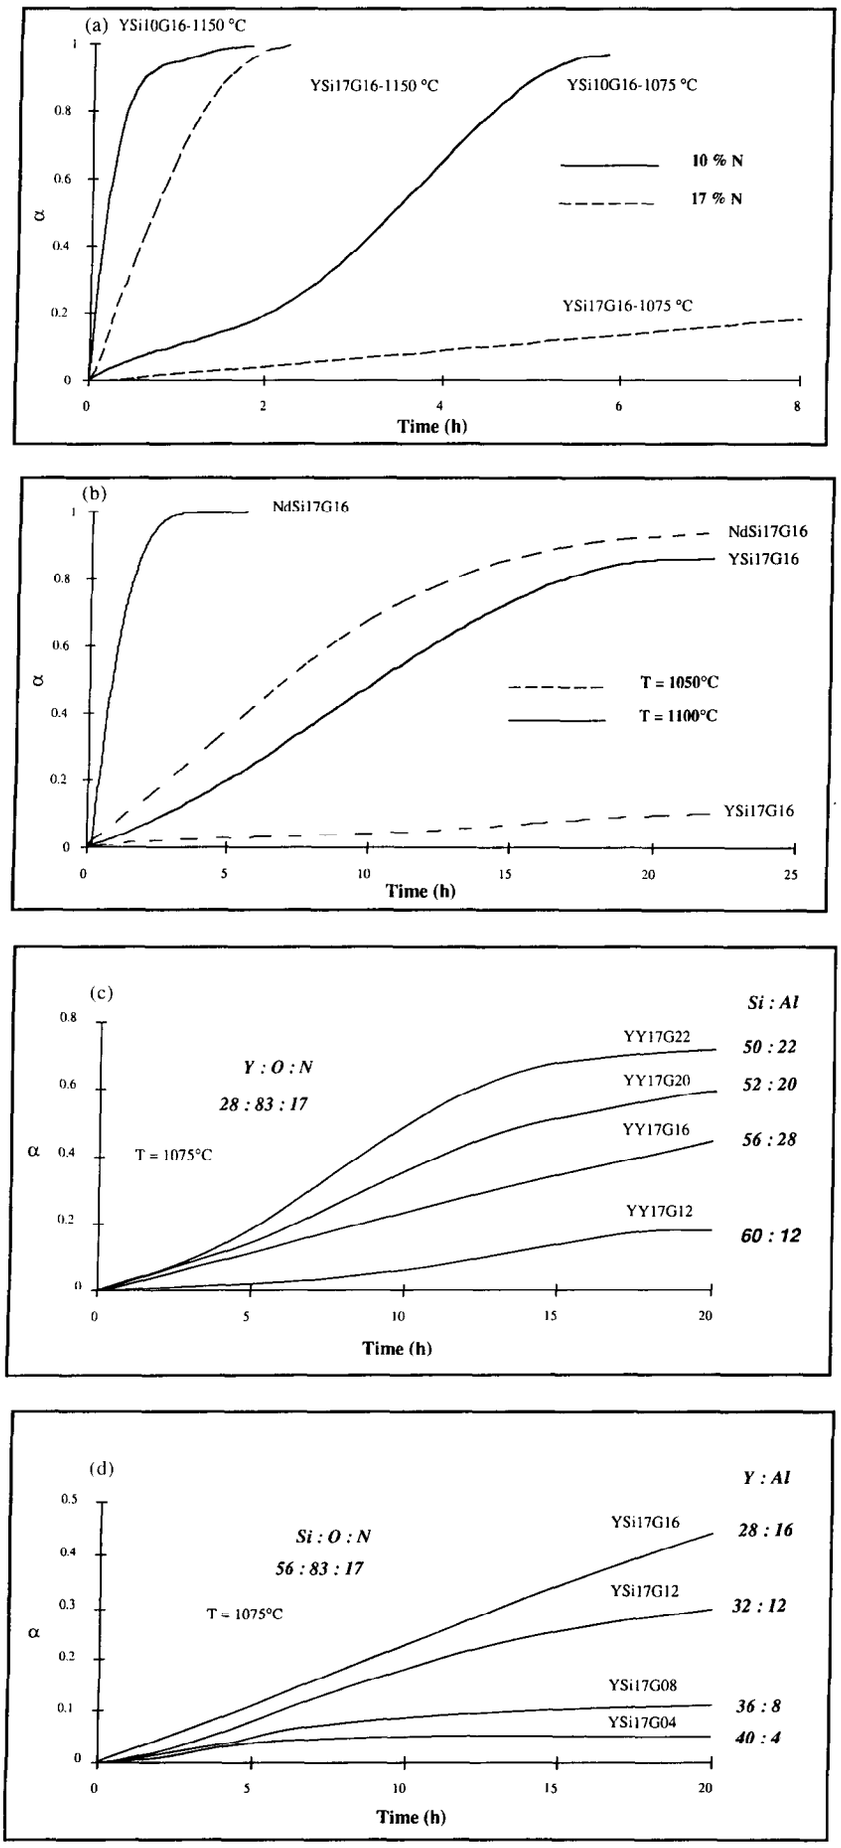

Fig. 2. Oxidation kinetics in air of oxynitride glasses: (a) with a constant ratio Y/Si/Al = 28/56/16 and various nitrogen contents; (b) with a constant ratio Si/Al/O/N=56/16/83/17 and changing rare earth element; (c) with a constant ratio Y/O/N=28/83/17 and varying Si/Al; (d) with a constant ratio Si/O/N=56/83/17 and varying Y/Al.

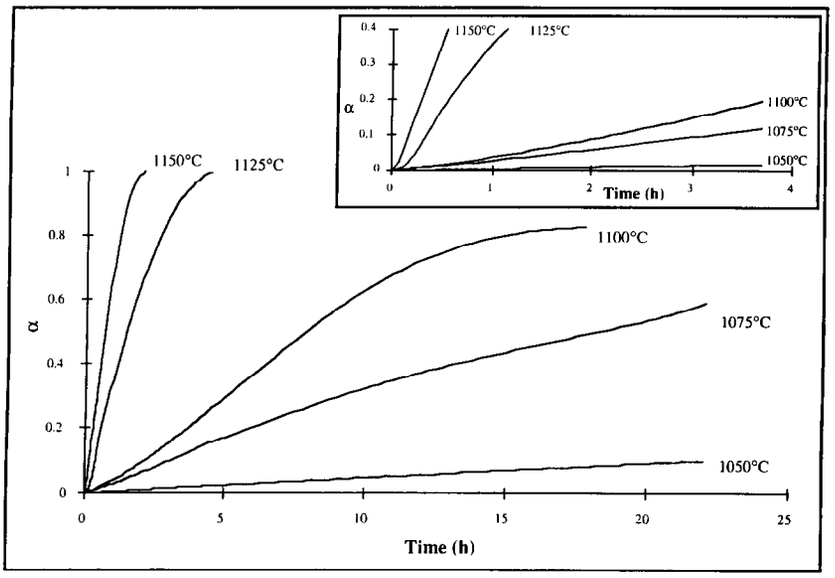

Fig. 3. Oxidation kinetics in air of YSi17G16 oxynitride glasses.

If we compare the oxidation curves of YSi17G12 and YY17G12 specimens which are characterised by a constant ratio Al/O/N and a varying Y/Si ratio, we observe that the oxidation resistance of the glasses decreases when yttrium replaces silicon. This is due to the fact that the substitution of silicon (network forming) by yttrium (network modifying) tends to make the glass structure more random. The other explanation is that, for glasses with a constant ratio Al/O/N, the increase of Y/Si ratio is followed by a slight increase in the concentration of aluminium in five-fold coordination.[33] Thus, oxynitride glasses containing more nitrogen and silicon and less aluminium are characterised by higher oxidation resistance.

3.2 Influence of the oxidation temperature

Oxidation of oxynitride glasses was investigated in air between 1000 and 1150°C for YSi17G16.

(a) Oxidation kinetics

The reactivity of YSiAlON glasses with oxygen starts around 1000°C with a weak weight gain (Fig. 3). For higher temperatures, the oxidation rate increases significantly and the oxidation is almost complete in a few hours at 1150°C. The oxidation curves of the studied glasses exhibit a sigmoïdal shape and the latent period of the reaction decreases with the increase of the oxidation temperature. For each isotherm, the oxidation rate has a maximum and the time of appearance of this maximum changes with the temperature. No initial weight loss was observed in the lower temperature range, which is not in agreement with results reported by Desmaison-Brut *et al.*[27-28] for the CaSiAlON and MnSiAlON systems.

(b) Nature and morphology of the reaction products

In order to explain the mechanisms governing the oxidation of oxynitride glasses, we have studied the nature and the morphology of the reaction products.

The oxide scale changes continuously with oxidation conditions (temperature and time). The reaction of the glasses with oxygen leads to the release of nitrogen and the formation of voids at the internal interface, which is followed by the growth of a white oxide layer.

At low temperatures, samples are covered by a thick oxide layer which increases with the oxidation time and temperature (Figs 4 and 5). The oxide layer thicknesses, measured from the micrographs (Figs 5(a), (b) and (c)) are 15, 360 and 760 μm for samples oxidised for 22 h respectively at 1000, 1050 and 1075°C. The increase of temperature favours the formation of nitrogen bubbles and the creation of porosity in the oxide scale and at the internal interface, as seen in Figs 5 (b) and (c). The presence of the bubbles leads to the formation of an irregular interface and favours the access of oxygen. The continuous changes in the morphology of oxidised samples is accompanied by the formation of a number of crystalline phases in the oxide layer. For the first oxidation temperatures, a crystalline phase transformation is observed as a function of time or temperature (Table 2). This successive change in the nature of the oxidation products indicates the non-recovering character of the formed oxide layer. The difference in mechanical properties between the oxide layer and the substrate favours the relaxation of stresses at the internal interface which leads to cracking at the edges of the samples to induce a maltese cross symmetry (Fig. 4(b)).

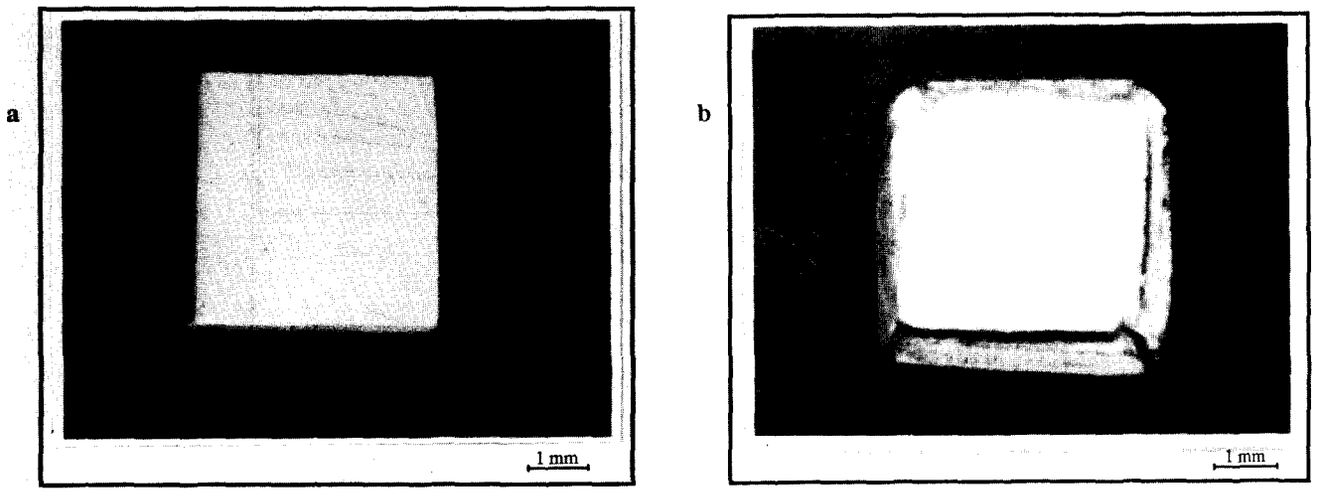

Fig. 4. Optical micrographs of oxidised glasses: (a) YSi17G16 at 1000°C (22 h); (b) YSi17G16 at 1075°C (22 h).

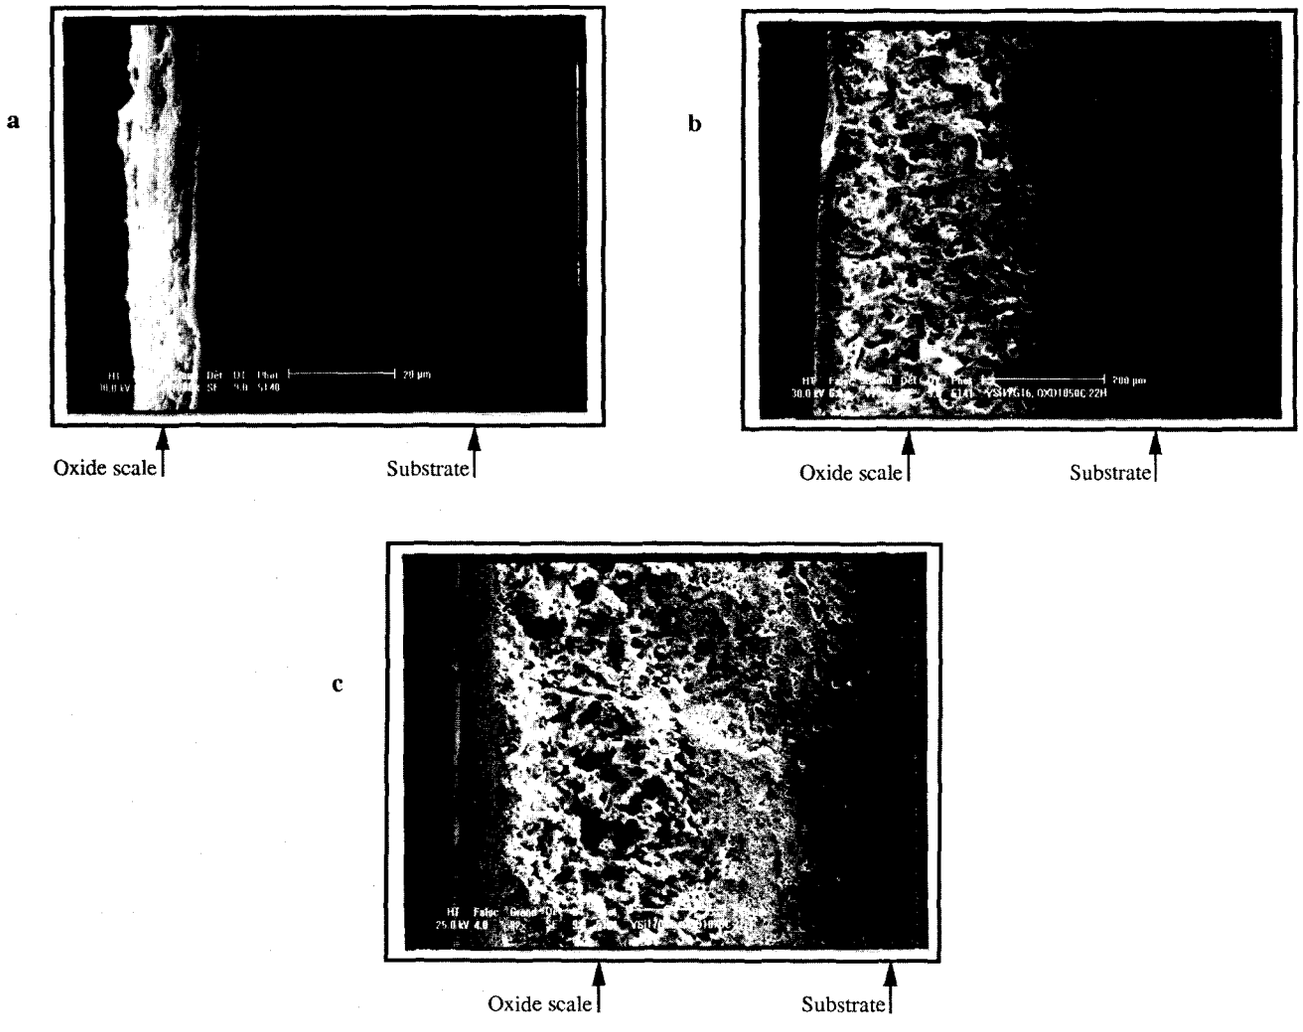

Fig. 5. Cross-section SEM photomicrographs of oxidised glasses: (a) YSi17G16 at 1000°C (22 h); (b) YSi17G16 at 1050°C (22 h); (c) YSi17G16 at 1075°C (22 h).

At high temperatures, oxidation occurs very quickly with the formation of very large bubbles and extensive porosity in the oxide layer and the substrate. The presence of this porosity in the oxide layer increases the volume of oxide scales (Fig. 6) and facilitates the rapid access of oxygen to the centre of samples.

The crystalline phases present in the oxide scales, detected by X-ray diffraction, are given in Table 2.

At 1000°C and for 22 h of heat treatment, the oxide layer contains $\alpha Y_2Si_2O_7$ and a small amount of yttriallite ($yY_2Si_2O_7$) and corundum. With the increase of oxidation time a gradual substitution of $\alpha Y_2Si_2O_7$ by yttriallite occurs. After 100 h of

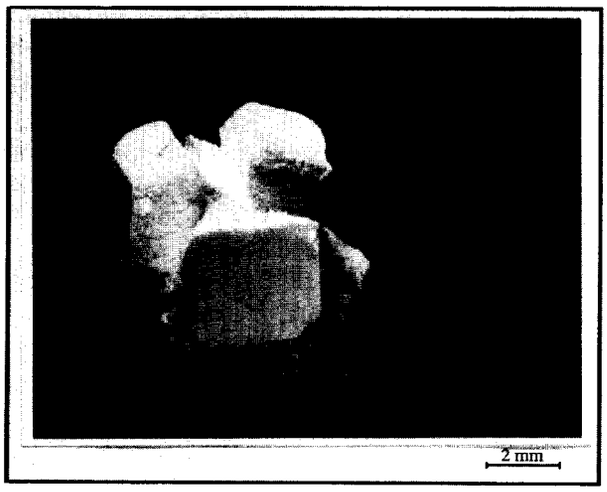

Fig. 6. Optical micrographs of YSi17G16 oxidised at 1150°C (18 h).

heat treatment the oxide layer is formed by yttrialite as the main oxide, with the presence of small quantities of mullite, corundum, cristoballite and $\alpha Y_2Si_2O_7$. The simultaneous presence of α and $yY_2Si_2O_7$ is in agreement with the crystallisation results of Hampshire *et al.*[16] and Dinger *et al.*[25] where they observe the presence of yttrium dissilicates for glasses heat treated with the same conditions. For the higher oxidation temperatures, X-ray diffraction data of oxidised samples, reveal no change in the nature of crystalline phases present in the oxide layer and confirm the absence of any transformation in the oxide layer.

A small amount of crystallisation of the substrates is detected above 1050°C ($yY_2Si_2O_7$).

(c) Kinetics modelling

For cubic samples the oxidation reaction rate is calculated up to the edge a of the cube using the following equations:

$-da/dt = 2k$

where, $a = a_0 - 2kt$

and a_0 is the initial cube edge, k is the rate constant which corresponds to the growth of the oxide layer along the time ($mm.s^{-1}$) and t the time.

α can be expressed by: $\alpha = 1 - a^3/a_0^3$)

$a = a_0 - (1 - \alpha)^{1/3}$

and we obtain the following kinetics equation:

$$F(\alpha) = 1 - (1-\alpha)^{1/3} = 2kt/a_0 \quad (1)$$

The sigmoïdal shape of the oxidation curves, the texture and the morphology of the porous oxide scale which show a direct access of oxygen to the internal interface and the growth of the maltese cross symmetry imply that the oxidation of YSi17G16 is governed by a reaction process where the progress of the internal interface is the limiting step. This assumption is confirmed by the determination of $F(\alpha).a_0/2t$ which increases from the beginning of the reaction to become constant after a few minutes or by the linearity of the transformations as a function of time as shown in Fig. 7. The

apparent activation energy calculated from the slope of the transformation curves is $E = 848 \pm 50$ kJ/mol.

3.3 Influence of the oxygen pressure

The influence of oxygen pressure on the oxidation resistance of oxynitride glasses was studied at 1075°C on YSi17G16 at oxygen pressures in the range 15–100 kPa with nitrogen added up to atmospheric pressure. Two experiments were carried out:

(1) Samples were oxidised for 8 h at different oxygen pressures since $\alpha_0 = 0$ (Fig. 8(a)).

(2) Samples were first oxidised in air for 4·5 h corresponding to $\alpha_0 = 0{\cdot}153$, after which they were put in the cold zone while the furnace was evacuated and lowered again into the hot zone when the mixture of oxygen and nitrogen had been introduced (Fig. 8(b)).

The kinetics of oxidation of YSi17G16 are affected by the oxygen pressure. The transformation as a function of time calculated using expression (1) are linear in the studied interval which permits the determination of a pressure law as:

$$k = k_0 P^n$$

where k is the oxidation rate constant ($mm.s^{-1}$), k_0 a constant, P is oxygen pressure and n is a coefficient determined from the slope of the curve $\log_{10}k$ as a function of $\log_{10}P$ (Fig. 9). For the experiments in this study $n = 0{\cdot}5 \pm 0{\cdot}05$ which is in agreement with the presence of a porous oxide layer which facilitates the access of oxygen to the internal interface.

4 Discussion

The influence of the glass composition, oxidation conditions and oxygen pressure on the oxidation resistance of oxynitride glasses have been studied. The wide range of glass compositions investigated permits us to explain the role played by each constituent on the oxidation behaviour of oxynitride glasses. As for the glass transition temperature (T_g) the incorporation of nitrogen increases the oxidation resistance of glasses. The aluminium concentration has a direct influence on the oxidation of these glasses which is due to the influence of aluminium on viscosity which decreases as aluminium content increases[36] and this results in a higher reactivity of the glass network. A high concentration of silicon is necessary to improve the oxidation resistance of oxynitride glasses, as seen

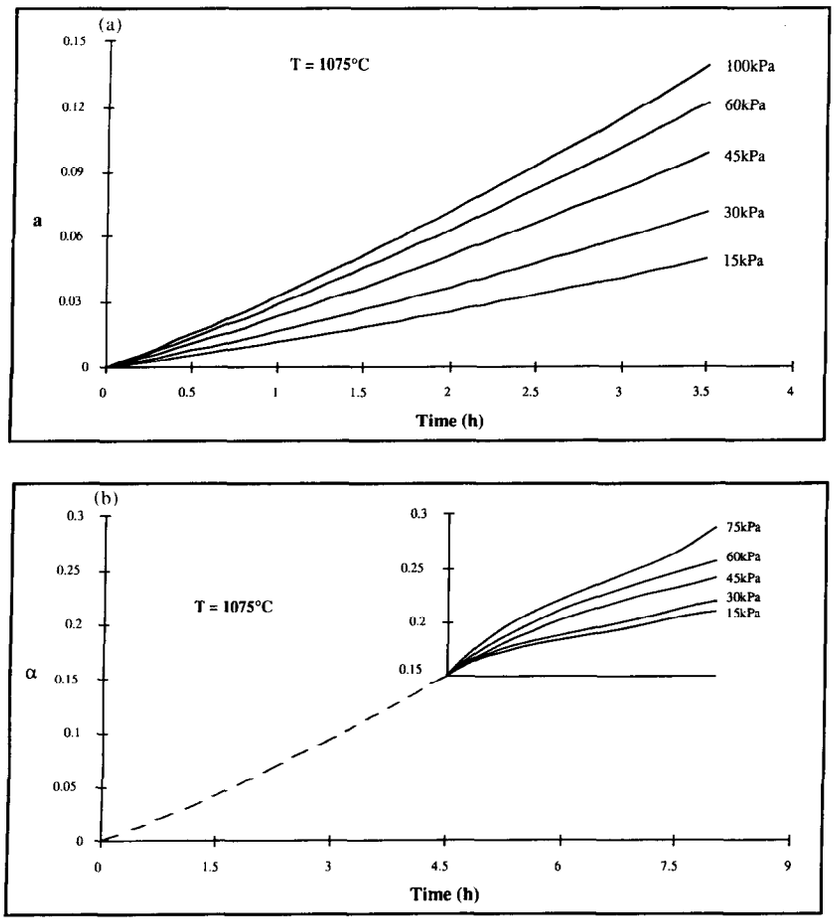

Fig. 8. Oxidation curves of YSi17G16 at different oxygen pressures: (a) $T = 1075°C$ ($\alpha_0 = 0$); (b) $T = 1075°C$ ($\alpha_0 = 0{\cdot}153$)

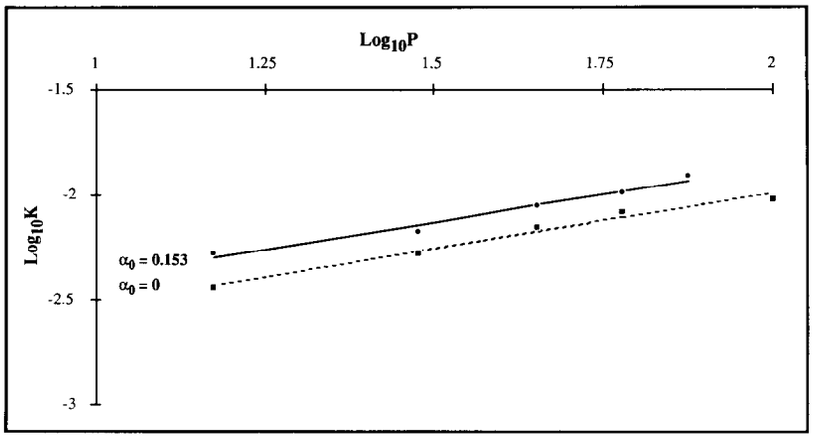

Fig. 9. $Log_{10}k$ as a function of $log_{10}P$.

also for the physical properties of yttrium alumino-silicate glasses.[37]

Temperature has a strong influence on the oxidation behaviour of the studied oxynitride glasses. At low temperatures ($T < 1075°C$), the oxidation is low and the samples preserve their cubic geometry. For higher temperatures, an extensive oxidation is produced, even during the initial stages of heat treatment, which favours the formation of a very porous and expanded product.

Study of the influence of pressure has confirmed the direct access of oxygen to the internal interface of samples.

The sigmoïdal shape of the oxidation curves of the all studied glasses suggests that oxidation is governed by a similar mechanism which is a reaction-controlled process as found for YSi17G16. The increase of temperature or time of oxidation leads to the formation of disorder in the glass structure. This disorder is followed by an increase in the average number of non-bridging oxygens per polyhedron which decreases the glass viscosity. Considering that at a fixed temperature above the glass transition temperature, the glass viscosity decreases with time, a little enhancement of the mobility of the glass constituents can be observed. The mobility of the glass constituents results in glass crystallisation under inert atmospheres and favours oxidation in the presence of oxygen. This hypothesis correlated with the formation of a non-covered oxide layer and the continuous changes in the oxidation products can be used as a basis to explain the presence of a reaction controlled process for global oxidation.

These investigations provide a guide for understanding the effects of the nature and concentrations of sintering additives in silicon nitrides on their oxidation behaviour. Yttria is preferred to neodymia and the Al_2O_3 concentration must be lower than that of Y_2O_3. The sintering of silicon nitride with a low concentration of additives allows an increase in its oxidation resistance.

5 Conclusions

The oxidation behaviour in air of oxynitride glasses is strongly dependent on the composition. The oxidation resistance increases when nitrogen content increases, when aluminium is substituted by yttrium or silicon and when yttrium replaces neodymium.

The oxynitride glasses oxidised rapidly in air at temperatures above the glass transition temperature by forming a porous oxide scale, probably due to the evolution of gaseous nitrogen during the oxidation. X-ray investigations of the oxide scale reveal the presence of different forms of yttrium silicates and mullite.

The sigmoïdal shape of the oxidation curves, the porous oxide scale which grows with the maltese cross symmetry and the linearity of the transformations as a function of time indicate the presence of a reaction process where the progress of the internal interface is the limiting step. The oxidation of oxynitride glasses is very sensitive to the oxygen partial pressure.

Thermal Properties and Devitrification Behaviour of $(2-x)CaO \cdot x/3Y_2O_3 \cdot 2SiO_2$ Glasses

A. Costantini, F. Branda & A. Buri

Dipartimento di Ingegneria dei Materiali e della Produzione, Università de Napoli 'Federico II', 80125 Napoli, Italy

(Received 23 July 1993; revised version received 7 March 1995; accepted 20 March 1995)

Abstract

The thermal properties (glass transformation, T_g, softening, T_s, and exo-peak, T_p, temperatures), and the devitrification behaviour of glasses in the system $CaO–Y_2O_3–SiO_2$ are reported. The T_g, T_p and E_c results can be explained on the basis of the increased structural rigidity when Ca^{+2} ions are substituted by Y^{+3} ions, with the formation of stronger bonds to the oxygen.

For the molar ratio of Ca/Si = 0·7 or more, wollastonite is no longer formed; at the same time a new and as yet unidentified phase appears. Surface nucleation occurs preferentially, but, in finely powdered samples, which soften and sinter before devitrifying, surface nuclei behave virtually as bulk nuclei.

Introduction

In this paper the thermal properties and the study of the devitrification behaviour of glasses of the system $CaO–Y_2O_3–SiO_2$ are reported. In particular the effect of the substitution of Y_2O_3 to CaO in a glass of composition $CaO–SiO_2$ (wollastonite) has been studied.

The devitrification process has been studied by differential thermal analysis (DTA).

CaO and SiO_2 in a molar ratio $CaO/SiO_2 \simeq 1$ are the basic components of bioactive glasses and glass-ceramics.[1,2] Otherwise it is known that the addition of yttrium oxide to silicates allows us to obtain glasses with high elastic moduli and hardness.[3] The addition of Y_2O_3 has proved to be useful in also obtaining glass-ceramics which have interesting properties. Machinable glass ceramics have been obtained in the system $CaO–Al_2O_3–Y_2O_3–SiO_2$.[4] Refractory glasses have been obtained in the system $Y_2O_3–Al_2O_3–SiO_2$.[5]

The non-isothermal devitrification of glasses in this system is interesting because, in the temperature range of efficient devitrification, powder sintering occurs. As will be shown, this has consequences on the devitrification mechanism.

Experimental

Glasses of composition expressed by the following formula

$$(2-x)CaO.(x/3)Y_2O_3.2SiO_2 \text{ where } 0 \leq x \leq 1{\cdot}0$$

were prepared by melting analytical grade reagents, Y_2O_3, $CaCO_3$ and SiO_2 in a platinum crucible in an electric furnace for 4 h, in the temperature range 1400–1600°C. The melts were quenched by plunging the bottom of the crucible into cold water.

Differential thermal analysis (DTA) was carried out by means of a Netzsch Differential Scanning Calorimeter (DSC) model 404M on about 50 mg powdered samples at various heating rates (2–20°C/min). Fine (63–90 μm) and coarse (500–315 μm) powdered samples were used. Powdered Al_2O_3 was used as reference material.

Devitrified samples were analyzed by computer-interfaced X-ray (CuKα) powder diffractometry (XRD) using a Philips Diffractometer model PW1710, with a scan speed of 1°min^{-1} and a built-in computer search program. The crystalline phases were identified by means of JCPDS cards.

Results

The DTA curves of the studied glasses, together with the derivative curve (DDTA) for one of them, are reported in Figs 1 and 2 as recorded at 10°C/min heating rate; the data are for fine, (63–90 μm), (Fig. 1) and coarse, (315–500 μm), (Fig. 2) powdered samples. When a glass is heated in a DTA apparatus a slope change appears on the recorded curve when passing through the glass transformation temperature range. The glass transformation temperature, T_g, has been taken from the derivative curve as indicated in Fig. 1.

As can be seen in many cases, the first slope change in the glass transformation range is followed by a second one at a temperature lower than the onset of the devitrification exo-peak.

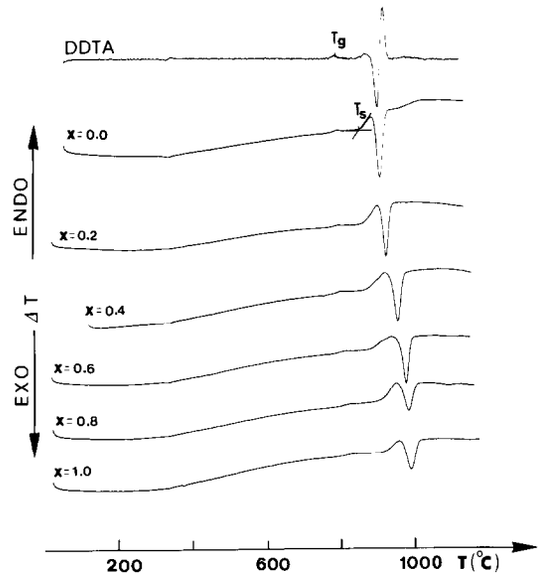

Fig. 1. DTA and DDTA curves recorded at 10°C/min heating rate on fine (63–90 μm) powdered samples.

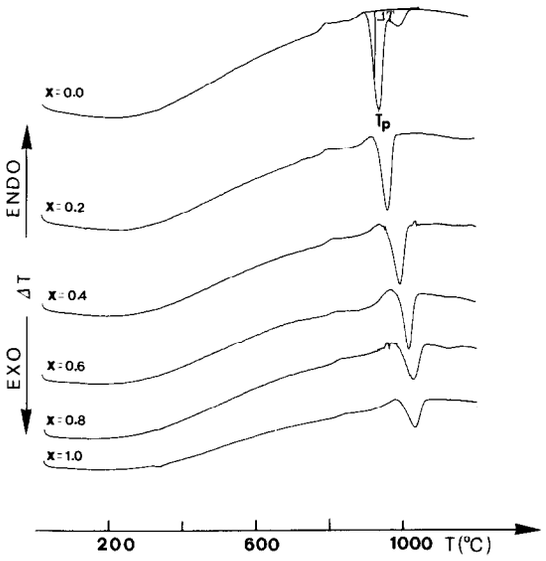

Fig. 2. DTA curves recorded at 10°C/min heating rate on coarse (315–500 μm) powdered samples.

As a matter of fact in these cases the initially powdered samples were recovered from the DTA sample holder as porous bodies. Therefore the second slope change is to be linked to the change in the thermal exchange coefficients when powders soften and sinter. The effect is much more pronounced in the case of the fine powders. The softening temperatures can be taken from the DTA curves as indicated in Fig. 1.

In Figs 3, 4 and 5 the glass transformation, T_g, softening, T_s, and DTA exo-peak, T_p, temperatures are reported as a function of composition. In Table 1 the values of the onset and peak temperatures of the devitrification exo-peaks are reported. As can be seen, all of them increase as the Y_2O_3 content is increased.

In Fig. 6 the X-ray diffraction patterns are

Composition	T_{of}(°C)	T_{pf}(°C)	T_{oc}(°C)	T_{pc}(°C)
$x = 0$	880	910	895	940
$x = 0{\cdot}2$	903	929	918	962
$x = 0{\cdot}4$	926	962	938	993
$x = 0{\cdot}6$	945	984	970	1018
$x = 0{\cdot}8$	961	991	985	1028
$x = 1{\cdot}0$	970	997	990	1034

reported relative to the pattern of a sample submitted to a DTA run which was stopped just after the exo-peak. As can be seen in the (a)–(d) patterns, the lines of wollastonite (JCPDS card

29/372) appear, but their intensity progressively reduces as the Y_2O_3 is substituted for CaO. In the (b) and (c) patterns the lines of pseudo-wollastonite, CaO.SiO_2, (JCPDS card 19/248) are also present. In the (c) pattern another, unidentified, phase appears, whose lines progressively substitute those of wollastonite phase.

In Table 2 the *d*-spacings' values and relative intensity of the lines of the unknown phase are reported.

The non-isothermal devitrification was also studied. The kinetic parameters were determined by using the following two equations:

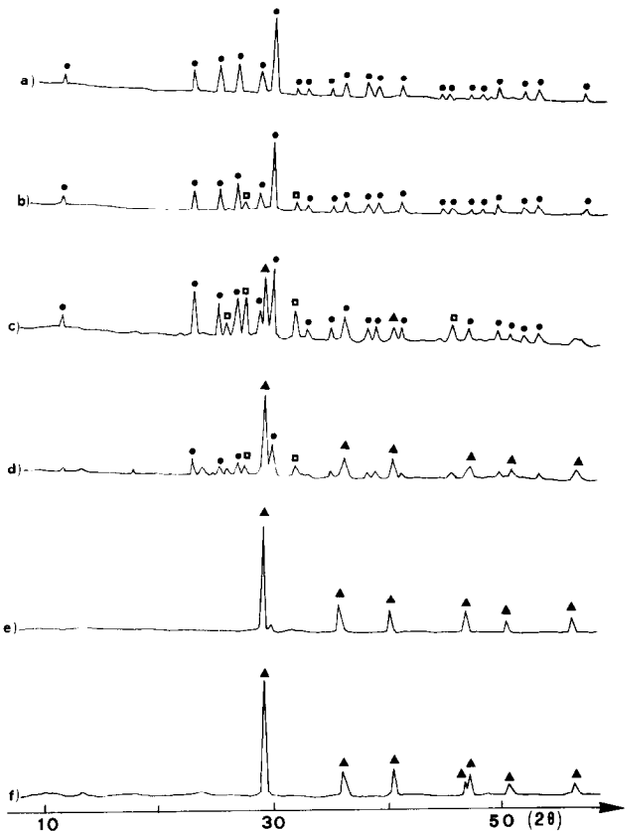

Fig. 6. X-ray diffraction patterns of samples devitrified during a DTA run: (a) $x = 0$; (b) $x = 0{\cdot}2$; (c) $x = 0{\cdot}4$; (d) $x = 0{\cdot}6$; (e) $x = 0{\cdot}8$; (f) $x = 1{\cdot}0$. (●) wollastonite (JCPDS card 29/372); (□) pseudowollastonite (JCPDS card 19/248); (▲) unknown phase.

1·920	W
1·631	WW
1·626	WW

$$\ln\beta = -E_c/RT_p + \text{const} \quad (1)$$

$$\ln \Delta T = -mE_c/RT + \text{const} \quad (2)$$

Eqns 1 and 2 can be derived from the well known following eqn:[6,7]

$$-\ln(1 - \alpha) = (AN/\beta^m)\exp(-mE_c/RT) \quad (3)$$

where α is the crystallization degree, N is the nuclei number and A is a constant, β is the heating rate, ΔT and T_p the deflection from the base line and the peak temperature taken as indicated in Fig. 2 and T is the temperature. As in inorganic glasses, the devitrification exo-peak occurs in a temperature range higher than that of efficient nucleation,[6] E_c is the crystal growth activation energy. The parameter m depends upon the mechanism and morphology of crystal growth; it ranges from $m = 1$ for 1-dimensional growth (or growth from surface nuclei) to $m = 3$ for 3-dimensional growth.[6,7]

Eqns 1 and 2 can be derived from it by supposing: (1) α at peak temperature is not dependent on the heating rate;[8] (2) ΔT is proportional to the instantaneous reaction rate:[9,10] and (3) in the initial part of the DTA crystallization peak, the change in the temperature has a much lower effect than α on the T.[11]

In Fig. 7 the plots of $\ln\beta$ versus $1/T_p$ are reported for the fine powdered samples. In Figs 8 and 9 the plots of $\ln\Delta T$ versus $1/T$ are reported for fine and coarse powdered samples taken from DTA curves recorded at 10°C/min. According to eqns 1 and 2, straight lines were obtained. Their slopes allow, therefore, to evaluate the E_c and mE_c

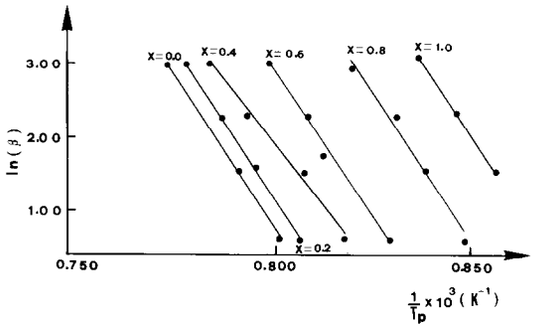

Fig. 7. Plot of $\ln\beta$ versus $1/T_p$.

values reported in Figs 10 and 11. The curve of E_c versus composition shows a minimum. As can be seen in Fig. 11, for each glass, the mE_c values appear to increase as the specific surface of the samples is increased. When comparing the values of E_c with the mE_c relative to fine powdered samples, values of $m \approx 2$ are obtained for all glasses of the studied system. In the case of coarse powdered samples values $1 \leq m \leq 2$ are always obtained.

Discussion

The increase of T_g as the Y_2O_3 is substituted to CaO can be explained by taking into account that, according to Ray,[12] the glass transformation temperature depends on the density of covalent cross-linking and the number and strength of the cross-links between the cation and oxygen atoms. It's worth remembering that CaO and Y_2O_3 are reported to be modifier oxides;[13] therefore, in the studied series, the density of covalent cross-linking doesn't change because the molar ratio O/Si is constant. When this happens, it was found that the changes of T_g when a modifier oxide is substituted for another one can be related to their coordination number and strength of bonds to oxygen atoms, linked to the field strength Z/r^2, where Z is the charge and r the radius of the cation.[13] Ca^{+2} and Y^{+3} have the same coordination number in their pure oxide structures;[13] otherwise Y^{+3} has a greater field strength (3·76 A–2 instead of 2·04 A–2) and a greater single bond strength in the pure oxide structure (210 KJ/mol instead of 130 KJ/mol.[13]) The T_g increase can therefore be ascribed to the greater strength of the cross-links between the Y^{+3} cation and oxygen atoms.

With this in mind we can also find an explanation for the increasing trend of the T_p curve.

In Fig. 10, it must be taken into account that the crystal growth activation energy, E_η, is usually equal to the viscous flow activation energy, E_η,[14] the viscosity depends upon the temperature according to the VFT equation,[15] which implies that E_η continuously decreases as the temperature increases:

$$\log\eta = A + B/(T-To)$$

where η is the viscosity, T is the temperature, A, B and To are constants whose values depend on the glass composition.

Otherwise E_η should increase as Y_2O_3 is substituted to CaO, as long as this involves the structure rigidity being increased, as discussed earlier. The trend in Fig. 10 gives an explanation for these 'temperature' and 'compositional' effects. Therefore, initially the 'temperature' effect could overwhelm the 'compositional' one, which should become dominant starting from x = 0·6. In fact, Table 1 shows that until x = 0·6, a continuous increase of T_p is observed; the maximum difference being as great as 80°C. Figure 5 shows that when x = 0·6 the slope of the T_p/x plot changes and the 'compositional' effect can became dominant.

XRD results (Fig. 6) indicate that, in the presence of Y_2O_3, starting from the molar ratio Ca/Si = 0·7 (x = 0·6), more wollastonite does not form; at the same time a new phase appears that is not reported on the JCPDS cards.

The mE_c values appear to increase as the

specific surface of the samples is increased. Usually the opposite result is obtained owing to the fact that the greater the specific surface, the greater the tendency to devitrify by growth from surface nuclei so that m is progressively reduced to the value $m = 1$. In the case of diopside glass[16] it was found that nucleation preferentially occurs at the surface of the sample, but surface nuclei formed in the glass transformation range behave as bulk nuclei in finely powdered samples that efficiently sinter before devitrifying. This hypothesis appears to be effective in explaining the devitrification behaviour of all the studied glasses. In fact in the case of coarse powdered samples that sinter badly (see Figs 1 and 2), a value $1 \leq m \leq 2$ were obtained. On the contrary, in the case of finely powdered samples that sinter well before devitrifying, higher values of the m parameter have been obtained. The value $m \approx 2$ for wollastonite agrees with the reported result that its crystals are often in the form of tablets.[17]

Conclusions

The following conclusions can be drawn from the experimental results:

(1) T_g, T_p, and E_c results suggest that the substitution of Y_2O_3 for CaO causes the structure rigidity to increase.

(2) Starting from the molar ratio Ca/Si = 0·7, more wollastonite does not form; at the same time a new phase appears that is not reported on the JCPDS cards.

(3) The homogeneous nucleation rates are very low; nevertheless surface nuclei can behave as bulk nuclei in powdered samples that sinter before devitrifying. In this case values $m \approx 2$ were found for all the studied glasses.

Constitution of Porcelain Before and After Heat-Treatment. I: Mineralogical Composition

S. P. Chaudhuri & P. Sarkar

Special Ceramics Section, Central Glass & Ceramic Research Institute, Calcutta — 700 032, India

(Received 2 February 1994; revised version received 8 July 1994; accepted 31 March 1995)

Abstract

Porcelain compositions were prepared with and without the addition of mineralizers/nucleating agents and their phase assemblages were studied before and after subjecting them to heat-treatment. Mullite, quartz and glass were detected in the compositions before heat-treatment, but cristobalite appeared as an additional phase after heat-treatment. Heat-treated compositions were comparatively rich in mullite following crystallization from the glassy phase. Nb_2O_5 was the most efficient nucleating agent among those tried.

1 Introduction

Porcelain is the vitrified product of mixtures of clay, quartz and feldspar, and chemical porcelain[1] is one such product having 60–65 wt% clay. Mullite and glass constitute the major phases[2] of porcelain which also contains some quartz,[3] cristobalite, tridymite and corundum are rarely found in it.

Although mullite is endowed with excellent mechanical, creep, thermal and chemical properties,[4] the electrical properties are not well studied. It has been shown in earlier work[5] that the electrical resistivity of porcelain decreases with increase in mullite content. The electrical resistivity of mullite depends on the $Al_2O_3 : SiO_2$ molar ratio. While mullite of composition $2Al_2O_3.SiO_2$ (2 : 1 mullite) is an electrical insulator[6] comparable to siliceous phases,[7] the $3Al_2O_3.2Sio_2$ composition, i.e. 3 : 2 mullite has poor electrical resistivity especially above 1000°C.[6] The 2 : 1 mullite has a band gap energy 7·7ev,[6] but 3 : 2 mullite has a band gap energy 1·43 ev.[8,9] Mullite crystals in porcelain have $3Al_2O_3.2SiO_2$ composition as these are derived from the solid state decomposition of the clay component and are formed by nucleation and crystallization from the feldspathic glass.

It consequently seems possible to make porcelain more conducting by increasing its mullite content. This can be accomplished by promoting reaction between the residual quartz and glass in the presence of mineralizers, e.g. Fe_2O_3 or TiO_2 by a two step reaction,[10,11] *viz.* replacement of Al^{3+} ion from glass by the cation of the mineralizer and subsequent diffusion of Al^{3+} ion into the residual silica.

The glassy phase in the porcelain body lies mainly in the Al_2O_3–SiO_2 system and is prone to crystallization[12] to mullite. This needs incorporation of suitable oxides, such as Fe_2O_3, TiO_2 or Cr_2O_3 into the glass and subsequent heat-treatment of the nucleated glass.

The glass in porcelain contains alkalis (K_2O + Na_2O) and when it is exposed to elevated temperatures, crystallization of cristobalite and tridymite phases[13] is also possible. These phases have high electrical resistivity and thereby counter balance the effect of mullite.

In the literature concerning semi-conductor and dielectric porcelain,[14] ceramic heating elements,[15,16] and glass-ceramic heating elements,[17] no mention is made of the constitution of these heating elements and its effect on electrical properties. It has, however, been observed[18] that a mullite porcelain body can be employed as a temperature indicator-cum-controller.

In the present work, chemical porcelain samples, with and without the addition of mineralizers/nucleants have been prepared and their constitution has been studied before and after subjecting them to heat-treatment. The mineralogical compositions (phase assemblages) of the porcelain samples are reported in this paper.

2 Experimental

2.1 Raw materials

The chemical analyses of the china clay, glass sand and potash feldspar are shown in Table 1. The porcelain samples were prepared from a mixture of clay (63 wt%), quartz (12 wt%) and feldspar (25 wt%).

Table 1. Chemical analyses of raw materials

Raw Material	Concentration (wt.%) of constituent oxides								
	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	K_2O	Na_2O	LOI
Clay	45·2	39·1	0·65	0·22	Trace	Trace	0·38	0·03	14·82
Quartz	99·9	—	—	—	—	—	—	—	—
Feldspar	64·43	18·05	0·30	Trace	0·89	Trace	13·55	2·22	0·30

2.2 Mineralizers/nucleating agents

The transition metal oxides, Fe_2O_3, TiO_2, Cr_2O_3, V_2O_5 and Nb_2O_5 were incorporated into the basic composition individually to the extent of 2–8 wt% and also in combinations of (V_2O_5 + TiO_2) and (V_2O_5 + Fe_2O_3). The concentrations of the oxides are given in Table 2.

2.3 Sample preparation

A good casting slip was obtained by milling a mixture of clay, quartz and feldspar. Discs of 25 mm diameter × 6 mm height were cast, dried and fired in an electric furnace at 1400°C for 1 h followed by overnight cooling.

The mineralised compositions are obtained by incorporating the oxides into the base composition during milling.

2.4 Heat-treatment

The glassy phases in the porcelain samples resembled very closely feldspathic glass and a strong exothermic peak11 characteristic of crystallization of mullite occurred in their DTA traces. This peak temperature (1150°C) was accepted as heat-treatment temperature for the 50 h duration for glass crystallization. This was carried out in an electric furnace with 10°C/min heating rate to 1150°C, held for 50 h and cooled overnight.

2.5 Identification and estimation of phases

The crystalline phases were identified and estimated by X-ray diffractometry. The quantity of glass was calculated by difference.

Table 2. Concentration (wt.%) of mineralizers/nucleating agents

Sample no.	Mineralizers/nucleating agents	Concentration (wt.%) of nucleating agents/ mineralizers
1	—	—
2	TiO_2	8
3	V_2O_5	3
4	Fe_2O_3	2·6
5	TiO_2	2·6
6	(V_2O_5 + Fe_2O_3)	V_2O_5–1·5 + Fe_2O_3–1·3
7	(V_2O_5 + TiO_2)	V_2O_5–1·5 + TiO_2–1·3
8	Cr_2O_3	2·5
9	Nb_2O_5	2

2.5.1 Crystalline phase

The identification was done in the usual manner from the peaks by running the diffractometer from 15–65° (2θ) at 2° (2θ)/min.

The quantitative analysis was done by the internal standard technique, NaF being the internal standard. Three calibration curves were drawn by scanning the zones (2θ): 37–43° for mullite, 48–58° for quartz and 20·5–23·5° and 37·5–40·5° for cristobalite and by plotting the peak-height ratios against phase concentrations. The experimental samples were similarly scanned and concentrations of phases were computed from the calibration curves.

2.5.2 Glassy phase

The SiO_2 and Al_2O_3 in porcelain occur in mullite, quartz, cristobalite and in the glass formed in combination with the other oxides. Knowing the quantities of crystalline phases, the quantity and composition of the glass can be estimated.

The feldspathic matrix glass comprised SiO_2, Al_2O_3 and K_2O to the extent of (90 ± 5) wt% in the samples before heat-treatment and (85 ± 5) wt% in the samples after heat-treatment.

3 Results

The concentrations of the crystalline and glassy phases in the samples before and after heat-treatment are compiled in Tables 3 and 4, respectively. Mullite and quartz were detected in all the samples whether heat-treated or not. Cristobalite was virtually absent in the samples before heat-treatment except the one containing Nb_2O_5. However, cristobalite appeared in all the samples after heat-treatment in sufficient quantity and mullite content also increased significantly.

The calculated chemical compositions of the glassy phases in the samples before and after heat-treatment are tabulated in Tables 5 and 6, respectively. These compositions can be represented in terms of their major constituents on the SiO_2–Al_2O_3–K_2O ternary diagram.

It was observed that the compositions of glasses of almost all the samples before heat-treatment lie

Table 3. Mineralogical compositions of porcelain samples before heat-treatment

in the ternary system within the mullite phase field but those of almost all the samples after heat-treatment are distributed within the tridymite phase and K–feldspar phase fields only.

4 Discussion

Mullite is the primary crystalline phase in the porcelain samples. The amount of clay that is present in the batch composition can provide 39·9 wt% (maximum) mullite and the maximum concentration of mullite to be available from the entire batch is 46·2 wt%. It is observed from Table 3 that the mullite content of all the samples before heat-treatment with the exception of the one with Nb_2O_5 was less than 39·9 wt%. This suggests that clay had been the only source of mullite in these samples. A small amount of mullite, about 3·1 wt%, in the Nb_2O_5 containing sample in excess of the theoretical clay-derived value originated from the glassy phase. This might be due to the highly charged Nb^{5+} cation of Nb_2O_5 which is also a more efficient nucleating agent than the other oxides used. Nb_2O_5 showed remarkable efficiency by effecting crystallization of mullite in considerable amount from the glassy phase within an hour of initial firing of the sample at 1400°C. The mullite content (43 wt%) of this sample almost reached the theoretical value. The V^{5+} ion of V_2O_5 was almost equally efficient.

The other nucleating agents also enhanced mullite formation. Higher concentration of TiO_2, however, reduced mullite content of the base compositions as also found with Cr_2O_3. TiO_2 being a fluxing agent and growth inhibitor retarded mullite formation at higher concentration but at lower concentration improved mullitization by producing a little amount of liquid phase that assisted decomposition of clay to mullite. Due to its refractory nature Cr_2O_3 failed to provide a liquid phase and thereby the mullite content of the Cr_2O_3-containing sample dropped. Small amounts of Fe_2O_3 and combinations of (Fe_2O_3 + V_2O_5) or (TiO_2 + V_2O_5) also favoured more mullite formation in these samples by generating liquid phase.

The glassy phase of the samples before heat-treatment contained 10–30 wt% Al_2O_3 (Table 5) and aluminosilicate glass of similar Al_2O_3 content could be suitably nucleated and crystallized[12] to mullite by heat-treatment. Moreover, the compositions of glass in the samples before heat-treatment exist within the mullite phase field. These criteria strongly favoured the separation of mullite from the glassy phase in these samples and this fact was supported by the results presented in Table 3 and Table 4. The mullite content of each sample in Table 4 exceeded the amount which was available from its clay component only.

The glass compositions of the samples after heat-treatment became more siliceous (Table 6) and entered the tridymite and K–feldspar zones. Good amount of cristobalite also appeared here. By virtue of their low Al_2O_3 and high K_2O content, these glassy phases almost reached mineralogically stable state but longer heat-treatment might cause microstructural changes in the samples.

5 Conclusions

(1) The glassy phase in porcelain is prone to nucleation and crystallization by incorporation of metal oxides and heat-treatment.

(2) Mullite content of porcelain can be increased by 6–7 wt%: over that is theoretically available from the clay component only.

(3) Cristobalite precipitates out along with mullite by heat-treatment.

Abstract

A series of sialon, silicon carbide (SiC) and lead zirconium titanate (PZT) ceramics joined by an electric discharge pulse-welding process have been examined to provide information on joint characteristics. Techniques used include X-ray diffraction, scanning electron microscopy and energy dispersive X-ray analysis. Results indicate that joints with variable degrees of interfacial contact, interlayer porosity and thermal stress have been produced, depending on the precise conditions used. Titanium was found to provide better wetting characteristics than aluminium when used as an interlayer material.

Introduction

Advanced ceramics have developed to become major contenders for a number of high temperature, high strength applications.[1] The versatility of these materials is becoming more and more extensive as research programmes reduce the problems of brittleness and insufficient reproducibility of properties. Currently of high interest are the family of ceramic materials based on silicon nitride, including reaction bonded, pressureless sintered and hot pressed silicon nitride with a variety of sintering aids and the sialon group of ceramics based on solid solution between silicon nitride and alumina. Silicon carbide ceramics also possess the required characteristics for many structural engineering applications and are available in the same forms as silicon nitride.[2]

As the demand for larger and more complex shaped components increases, it becomes more difficult to fabricate ceramics using a single step shaping process and economically unfavourable to machine simple blocks to complex shapes. Thus, commercial use becomes dependent upon the availability of reliable techniques for ceramic–ceramic and ceramic–metal joining.[2–3] Various techniques for chemically joining ceramics have been investigated, the most common are active metal brazing and diffusion bonding.[1–3] Both processes can be carried out with or without intermediary layers. The purpose of the intermediary layer is to absorb the effects of the mismatch in thermal expansion between the components to be joined. Other processes which may offer a potential route for ceramic bonding include ceramic adhesives and electric discharge welding.[4] Of these the former offers high temperature stability but little mechanical strength, the latter involves a high energy pulse passing through a conductive interlayer, converting it into a plasma. A ceramic–metal interaction occurs and a bond is formed. The process is exceptional for its speed, bonding typically occurring in < 60 μs, compared to many minutes for conventional brazing and diffusion bonding.

A schematic diagram of the process is shown in Fig. 1(a), and an example of a typical electric discharge pulse welded ceramic piece is shown in Fig. 1(b). A metallic foil approximately 5 μm in thickness is clamped between the ceramic specimens. No special surface condition is necessary in terms of polishing, but the surface must be clean. When the capacitor is discharged, the interlayer is vaporized and bonds to the ceramic. The process is currently under investigation at the E.O Paton Electric Welding Institute (E.O.P.E.W.I) in Kiev, Ukraine.[4]

The technique has been used principally to examine the bonding of silicon nitride based ceramics using various metallic interlayers. The properties of a good interlayer can be listed as:

(a) low electrical resistance;
(b) must wet the ceramic;
(c) must be clean and free from inclusions, porosity and gases.

Within the discharge zone the energy density is

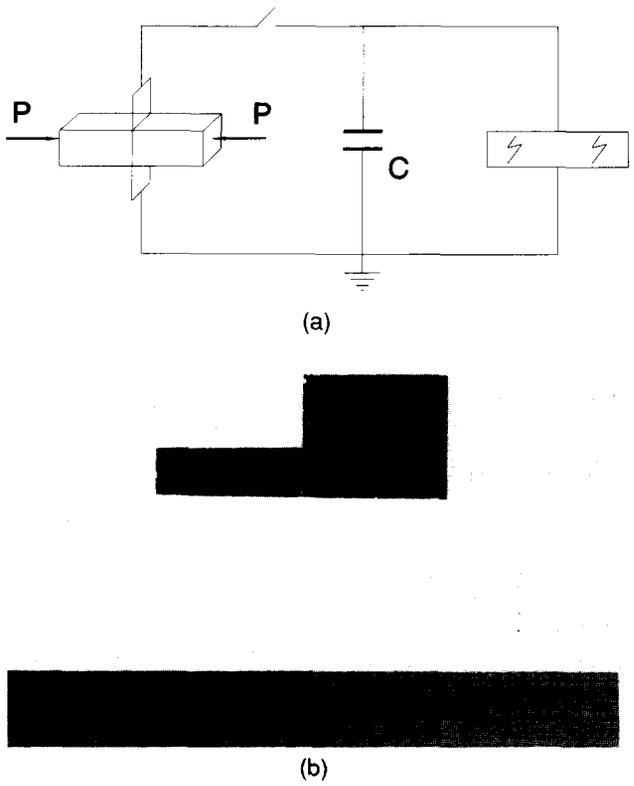

Fig. 1. (a) A schematic diagram of the electric discharge pulse welding process. P = pressure (< 20 MPa), C = capacitance (1–100 μF). Adapted from Ref. 4. (b) An example of a typical electric discharge pulse welded sialon ceramic joined using a 1·5 μm thick sputtered aluminium interlayer. Shown on a scale where each division is equal to 1 mm.

1–100 kJ/m^3, the plasma temperature approaches 10^4–10^5 K and pressures of 10^3–10^5 MPa are induced. All other conditions being equal, experiments have shown that the quality of a joint decreases with a decrease in charge energy below a minimum level. However, excess energy can result in either:

(a) fracture due to the high pressure pulse which accompanies the discharge, especially if the ceramic possesses low strength; or
(b) metallisation of the surfaces of the ceramic.

In the present study, sialon, silicon carbide and lead zirconium titanate ceramics joined by such a process, in which either an aluminium or titanium foil or sputtered interlayer was used, have been investigated.

Experimental

Ten joined ceramic–ceramic specimens were provided by the E.O.P.E.W.I. together with details corresponding to the materials involved and their respective processing parameters. This information is given in Table 1. The cross-sectional areas of all ten bonded ceramics were 5 × 5 mm and the length of each ceramic piece prior to joining was typically 6 mm.

Table 1. Composition and processing characteristics of electric discharge pulse welded specimens.

Specimen	*Material*	*Potential difference applied (V) (capacitance 12 μF, Time 40 μs)*	*Interlayer form*
1	Sialon/Al/Sialon	2100	5 μm foil
2	Sialon/Al/Sialon	2500	5 μm foil
3	Sialon/Ti/Sialon	3100	5 μm foil
4	SiC/Al/SiC	2500	5 μm foil
5	SiC/Ti/SiC	3200	5 μm foil
6	Sialon/Al/Sialon	1100	1·5 μm sputtered
7	Sialon/Al/Sialon	1500	1·5 μm sputtered
8	SiC/Al/Sic	2000	1·5 μm sputtered
9	SiC/Ti/SiC	1100	1·5 μm sputtered
10	PZT/Al/PZT	1100	5 μm foil

The specimens numbered 1–9 were sectioned perpendicular to the join, then one half mounted in a conductive resin and polished. Specimen 10, incorporated into the investigation at a later date, had previously been polished and was ready for use in the scanning electron microscope.

Three characterisation techniques were used to investigate the specimens, namely X-ray diffraction, scanning electron microscopy and energy dispersive X-ray analysis. The former was performed on both the dense, sintered samples provided and also on portions of the same samples ground into fine powder. Samples were carbon coated prior to examination on the SEM and both bulk analysis and spot analysis across the join were carried out using EDX. The latter permitted the degree of interlayer material diffusion into the bulk ceramics to be estimated. No analysis was undertaken to measure the bond strength of the joined ceramics as the number of specimens provided was too small to have any statistical merit.

Results and Discussion

X-ray diffraction analysis on both the monolithic, sintered samples and subsequently powdered material indicated that the sialon samples were composed of the X-phase ($Si_{12}Al_{18}O_{39}N_8$) as the primary phase with small amounts of (Si_3N_4)14H as a secondary phase. The primary phase present in the silicon carbide samples was (SiC)33R, however the secondary phase was too small to identify. Specimen 10 was identified as being the single phase $Pb(Z_{0.52}Ti_{0.48})O_3$. Table 2 indicates the principal impurities found in the samples.

The scanning electron microscope investigations

Table 2. Quantitative analysis of the impurities found in the samples.

carried out have indicated that all of the specimens display a degree of poor contact at the ceramic–metal interface. This suggests that the optimum conditions for joining have not been met for any of the specimens examined. However, a positive feature of the process is that at distances greater than 20 μm from the join there is no indication in any of the specimens that the process has effected the properties of the bulk ceramic.

The aluminium foil on melting appears to wet the surface of the sialon better than the silicon carbide, resulting in improved adherence. The process has produced a highly porous interlayer material, with the pressure generated at the join pushing the Al into the pores at the interface of the ceramic, hence enlarging the surface area of contact (Fig. 2). Spot analysis* across the join for both the sialon/Al/sialon and SiC/Al/SiC specimens suggests, by the sharp transition of elemental intensities shown in Figs 3 and 4, that diffusion in either direction across the interface has not occurred as would be expected for such a short joining time.

The adherence of the titanium foil interlayer at the silicon carbide interface is far superior to that at the sialon interface and for both ceramics the joint characteristics are a significant improvement on those achieved when an aluminium interlayer is used. For the SiC/Ti/SiC specimens, bonding at the ceramic–metal interface is evident from the presence of cracks running through the titanium perpendicular to the join as in Fig. 5. These cracks are thought to be caused by the differences in coefficients of thermal expansion between the two materials creating stresses at the interface on cooling. Spot analysis across the join indicates a more gradual transition of elemental intensities (Fig. 6), suggesting the existence of reaction products at the interface. For the sialon/Ti/sialon specimen, spot analysis across the join does not distinguish either way whether reaction products exist or not.

In agreement with Ref. 4, at too low a charge energy no join is formed. The limit has not been

*The spot analysis, carried out at 25 keV under a magnification of × 1000 for 100 s, can only be considered as an estimate of the element distribution. The graphs which indicate the composition variation across the join for each specimen possess errors of ±1·0 in terms of intensity. The accuracy in positioning of the spot lies within ±2 μm, which when considering the total width of the interlayer is only 5 μm, then this error is considerable.

Fig. 2. Sialon ceramic joined using a 5 μm thick aluminium foil.

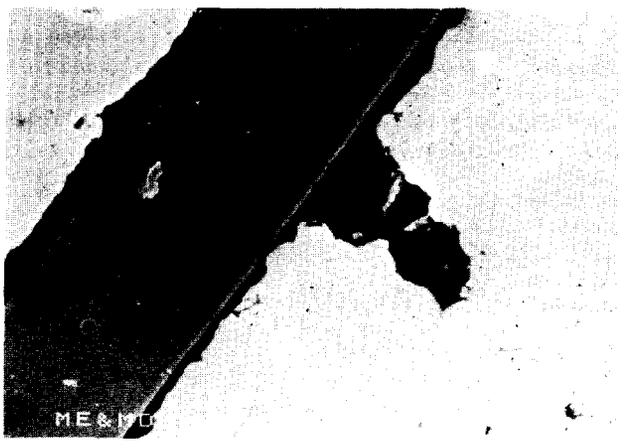

Fig. 7. Lead zirconium titanate ceramic joined using a 5 μm thick aluminium foil.

determined in the current work, however 1100 V appears to be too low for a sputtered interlayer 1·5 μm thick. The interlayer has melted but not bonded with the ceramic. Exceeding an applied voltage of 2500 V to join both sialon–sialon and SiC–SiC ceramics using an aluminium interlayer resulted in the fracture of the ceramic parallel to, and at distances of typically 10 μm from, the join. Using a titanium interlayer meant that the upper limit to the applied voltage was raised; fracture of the ceramic adjacent to the join was not observed until 3100 V was applied. At this voltage the behaviour of the ceramic is similar to that observed for aluminium at 2500 V.

The sialon and SiC ceramics have similar thermal expansion coefficients of approximately 5 MK^{-1}. Typical values for aluminium and titanium are 24 and 9 MK^{-1} respectively.[5] The variation in level of applied voltage required for damage to occur corresponds to the greater thermal expansion mismatch at the aluminium–ceramic interface compared to that at the titanium–ceramic interface. It is this mismatch which in turn results in the fracture of the ceramic. Further work is clearly required using a multilayer system, with the intention of reducing the thermal stresses developed due to the difference in materials used.

No direct comparison can be made between the two interlayer thicknesses used as the charge energy had also been varied in the samples analyzed. However the results suggest that the sputtered interlayer yields improved joins. This could be because the layer is thinner or because the sputtering process will have increased the initial ceramic–metal contact prior to joining.

The lead zirconium titanate specimen displays a similar degree of joining as the engineering ceramics (Fig. 7). The edges of the aluminium interlayer are very uniform and no evidence exists of mechanical keying by the aluminium in the pores at the ceramic interface. The electrical pulse has not weakened the ceramic adjacent to the join and thus no cracking is apparent. Spot analysis across the join (Fig. 8) shows a variation in intensity for

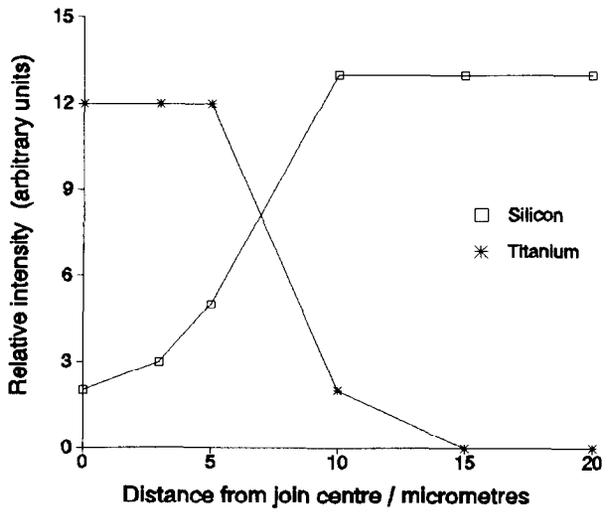

Fig. 6. Composition variation across the join for silicon carbide specimens joined using a titanium interlayer.

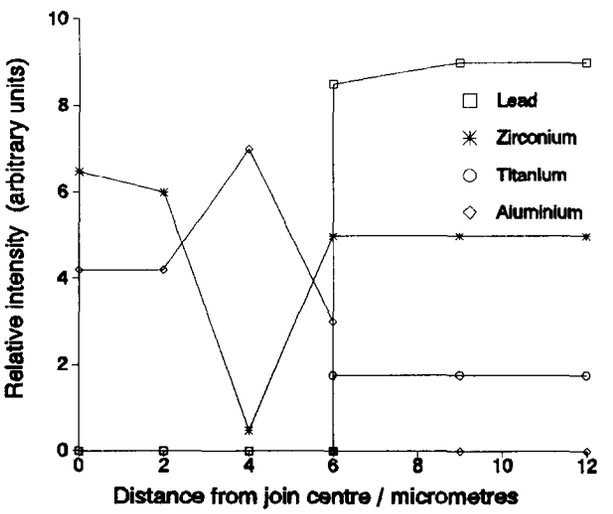

Fig. 8. Composition variation across the join for lead zirconium titanate ceramics joined using an aluminium interlayer.

the Al and Zr across the ceramic–metal interface that suggests some diffusion has occurred across the interface and reaction products exist.

Conclusions

For a ceramic–ceramic join with the aid of an active metal interlayer, then the processing parameters chosen must ensure that the metal melts, wets and chemically bonds to the surface of the ceramic interfaces. Control of the reaction zone variables such as thickness, thermal expansion coefficients and thermal stability, allows optimisation of the bond properties. Although this degree of control has not been achieved in any of the specimens provided, evidence has been found which illustrates the potential for this new processing technique.

The present study has indicated the greater wetting capabilities, and hence superior performance, of Ti-alloys over Al in electric discharge welding of sialon and silicon carbide ceramics. This agrees with the theory given in Ref. 2, in which aluminium and titanium interlayers were used in an attempt to join silicon nitride ceramics.

Limits to the range in charge energy used are: too low and bonding will not occur, too high and the ceramic fractures or metallization of the ceramic surfaces occurs. The optimum for both the foil and sputtered interlayers with the engineering ceramics studied appears to lie within the range 1·1–3·2 kV.

Since charge energy was varied simultaneously with interlayer thickness, no real indication of the effect of the latter was obtained, though the results do indicate a preference towards the use of a sputtered interlayer. A continuation in this investigation would be the introduction of a multilayer system, with the intention of reducing the thermal stresses developed due to the difference in materials used.

Abstract

The joining of the superconducting oxide, YBCO, with the piezoelectric ceramic, Pb(Zr,Ti)O_3, was studied using a thick film of YBCO. The electrical resistivity of the composite was evaluated from liquid nitrogen temperature to room temperature; the resistivity was 0·1 Ω cm at 80 K without a clear critical temperature. Furthermore, Pb(Zr, Ti)O_3 was sandwiched by YBCO electrodes to measure the piezoelectricity.

A slurry of YBCO was pasted on a sintered Pb(Zr,Ti)O_3 pellet followed by sintering for 5, 60 and 420 min at 1193 K. The YBCO film thicknesses were 5, 17 and 35 μm as determined by scanning electron microscope (SEM). An electron probe microanalyzer (EPMA) revealed diffusion of Ba into Pb(Zr,Ti)O_3. The hetero-joining was achieved, although the YBCO film was porous as investigated by SEM. A higher density film can be obtained by optimizing the sintering conditions for the composite.

1 Introduction

In considering an electrode for ceramics, the wettability of the metal for the ceramic is of importance. A glass frit is commonly employed for joining a metal to a ceramic. Sugihara *et al.* have widely studied the wettability and bondability of metal/ceramics and ceramics/ceramics for electronic ceramics in particular.[1,2]

The joining of a superconductor to a semiconductor has been theoretically studied in terms of boundary effects by P. G. De Gennes;[3] superconducting electrons migrate towards the semiconductor in the proximity effect. There have been several studies of the proximity effect in superconductors;[4] a Y–Ba–Cu–O based multilayer for optoelectronic devices was investigated on the sapphire and Al_2O_3 as as IR detector.[5] The YBCO films were hundreds of nm thick and employed for the counterelectrode and base.

On a more macroscopical scale, Srivastava *et al.* reported that $Y_1Ba_2Cu_3O_{7-x}$ (hereafter YBCO) adhered to $BaTiO_3$ and to Pb(Zr,Ti)O_3 (hereafter PZT); electrical properties of the devices were characterized.[6] Furthermore, Moya *et al.* formed YBCO composites on Ce–TZP, Y–TZP and spinel substrates.[7] The interfaces between YBCO and other ceramics are very important for devices or composites when one uses YBCO as an electrode.

The first purpose of the present work is to join YBCO thick film to piezoelectric ceramics, then to find the appropriate thickness and the best contact of the film to give satisfaction for both piezoelectricity and superconductivity. The second aim is associated with the use of YBCO electrode for a field effect transistor at the temperature even if the temperature is not below the transition.

2 Experimental

2.1 Fabrication of PZT

The PZT powder with composition of Pb ($Zr_{0.53}$, $Ti_{0.47}$)O_3 (Fuji Titanium Ind. Co. Ltd, Japan) was pressed at 180 MPa followed by sintering for 2 h at 1503 K. The sintering was carried out in an atmosphere of lead or lead oxide in the crucible. The size of the sintered pellets was 15 mm in diameter and 0·8–1·0 mm thickness. The sintered density was 95–96% of the theoretical value.

2.2 Slurry of YBCO

The YBCO powder (Seimi Chemical Co. Ltd, Japan) calcined at 873 K was milled with the solvent and ZrO_2 balls (3 mm in diameter) for 24 h. The slurry was painted on the PZT fabricated above, then sintered at 1193 K in an oxygen atmosphere (0·5 litre/min) for each sintering time; 5, 60, 420 min. The samples were cooled down to

*To whom correspondence should be addressed.

room temperature at the rate of about 1·5 K/min. The surface of the thick films was examined by X-ray diffraction analysis (XRD).

2.3 Interfaces between YBCO and PZT

The morphological analysis of the interfaces was carried out by a scanning electron microscope, and the element distributions through the interfaces were qualitatively investigated by mapping with an electron probe micro analyzer.

2.4 Electrical properties

Electrical resistivity was measured with a four-probe method from the temperature of liquid nitrogen to room temperature. YBCO-sandwiched PZT(SIS) was investigated for the frequency dependence of the composite response by impedance analyzer (YHP 4192A).

3 Results and Discussion

3.1 Interfaces of YBCO/PZT and YBCO surfaces

Figs 1(a–c) show the SEM photographs at the interfaces of the YBCO/PZT system sintered for 420, 60 and 5 min at 1193 K, respectively. The bonding of YBCO grains is seen, although there seems to be porosity in the YBCO thick film sintered for 420 min. The thickness of the film was about 17 μm. The system maintained for 60 min had a very porous structure with a film thickness of about 33 μm; the 5 min sintered system showed a denser morphology. The SEM photographs of the surfaces of the YBCO/PZT system are shown in Fig. 2 (a–c) maintained for 420, 60 and 5 min in sintering, respectively. As shown in Fig. 2(a), well-developed bonding of the YBCO occurred with porous microstructure on the 17 μm film sin-

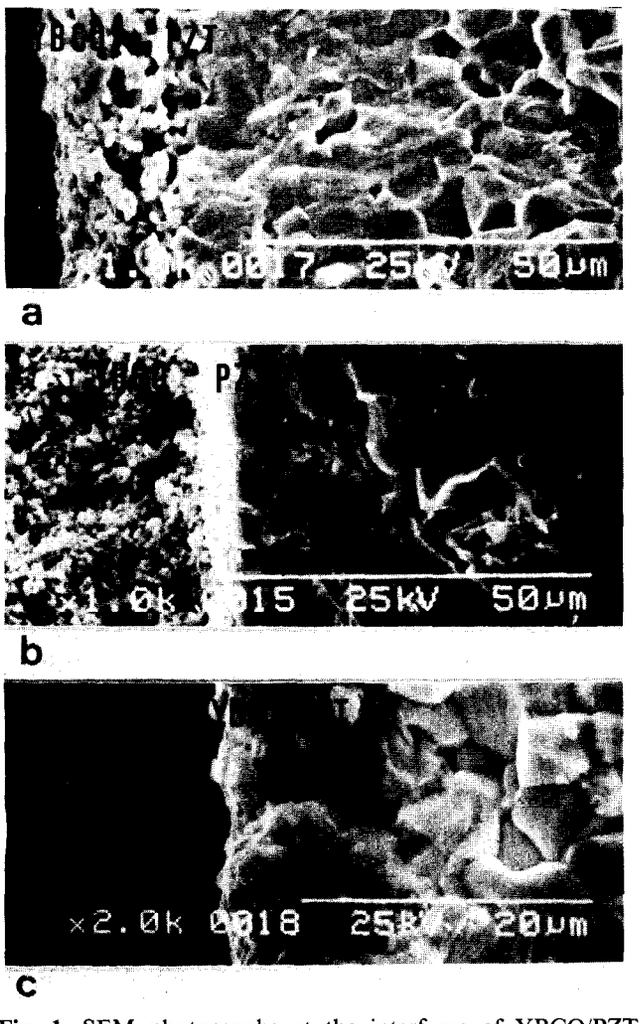

Fig. 1. SEM photographs at the interfaces of YBCO/PZT systems for each sintering time: (a) 420; (b) 60 and (c) 5 min.

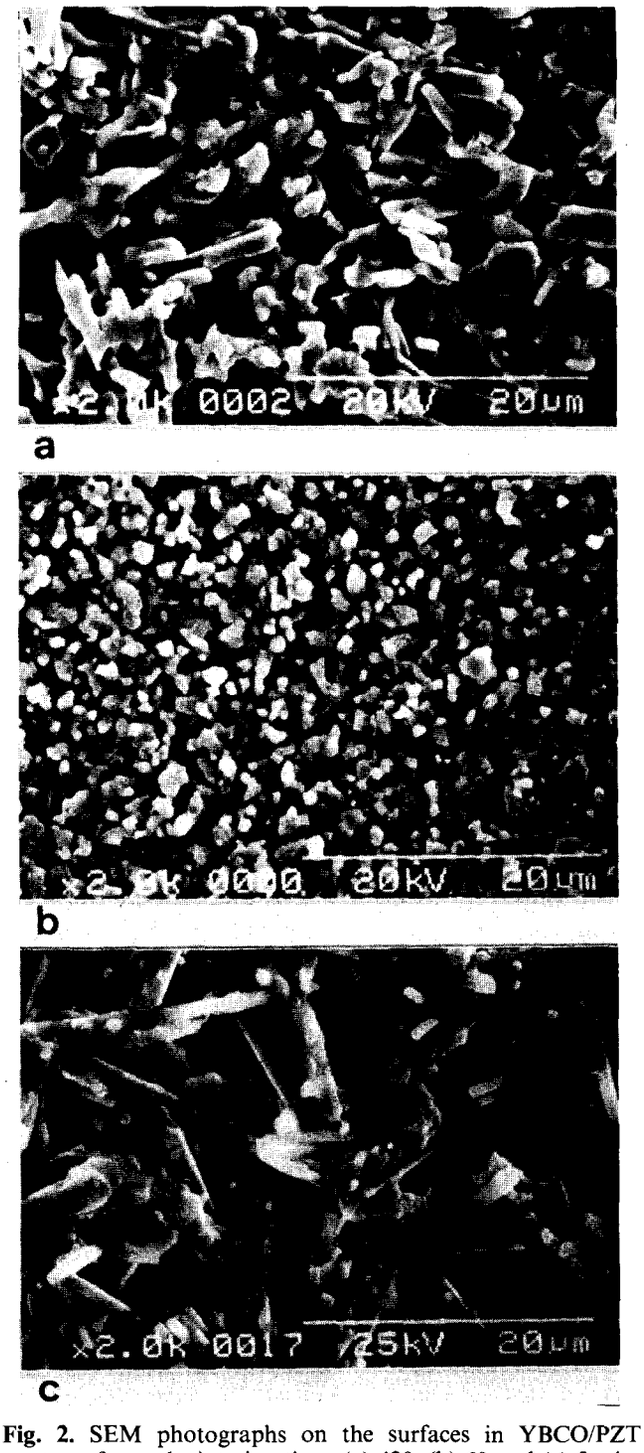

Fig. 2. SEM photographs on the surfaces in YBCO/PZT systems for each sintering time: (a) 420; (b) 60 and (c) 5 min.

tered for 420 min. The inter-particle bonding did not develop in the film which had a thickness of about 33 μm after 60 min sintering (Fig. 2(b)); this seemed to be more porous with a different microstructure from those of the 5 and the 420 min sinterings. It is not clear at this moment why the 60 min sintering shows a pronounced difference in microstructure. In the 5 min sintering, the film was thinner (5 μm) and more dense (Fig. 2(c)); the thinner film seems to be better from the viewpoint of morphology.

3.2 Diffusion of barium from YBCO to PZT

Y_2BaCuO_5 and $BaCuO_2$, as well as YBCO were found by XRD analysis in samples sintered for 420 min at 1193 K, and Y_2BaCuO_5 of green colour and non-superconducting character was detected together with YBCO peaks in the film sintered for 5 min. Figs 3(a and b) show the EPMA line analyses indicating a Ba diffusion distance of 35 and 5 μm into the PZT from the interfaces, respectively. The length of Ba diffusion is illustrated in Fig. 4.

3.3 Electrical resistivity and piezoelectric properties

The resistivities were measured at temperatures from that of liquid N_2 to 296 K. They indicated semiconductive temperature dependences. The

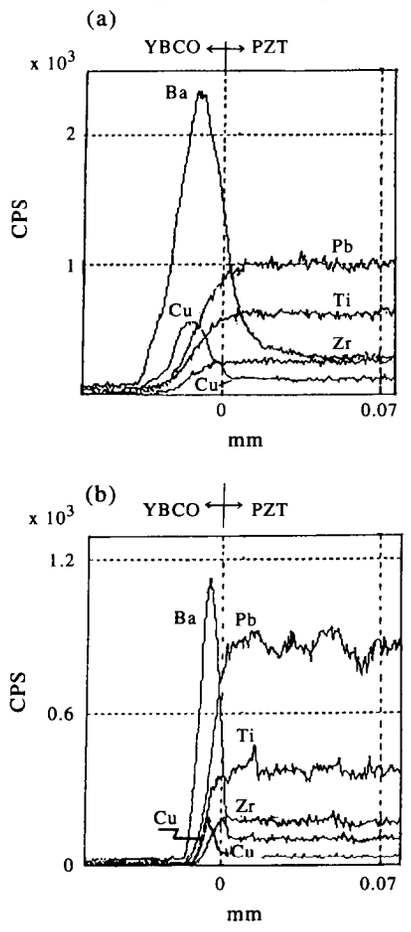

Fig. 3. EPMA line analysis at the interfaces between YBCO and PZT in each sintering time: (a) 420; (b) 60 and (c) 5 min.

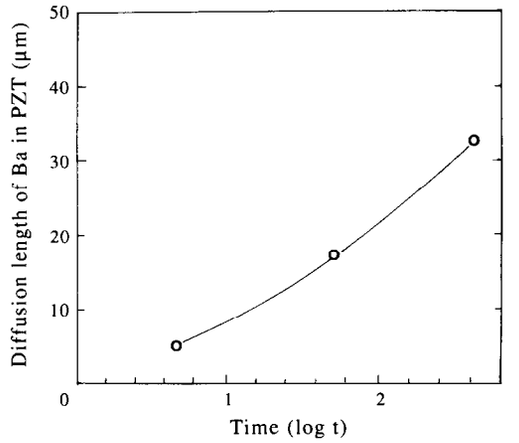

Fig. 4. Change of Ba diffusion length in PZT with sintering time at 1193 K.

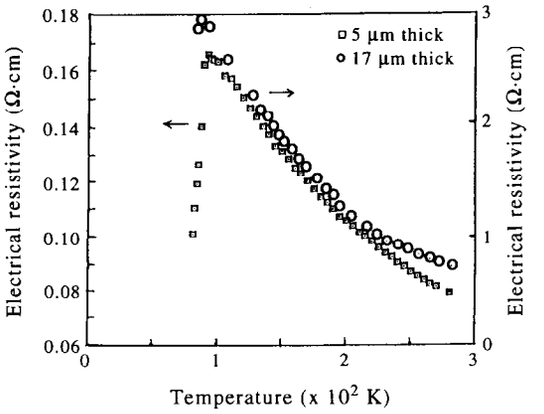

Fig. 5. Electrical resistivity changes with temperature.

critical temperature of the 5 μm YBCO film was not clear although 0·1 Ω cm was shown at a temperature of 80 K, and the resistivity at 296 K was 0·08 Ω cm. The $BaCuO_2$ produced in the 60 min sintering is a non-superconductive material. More Ba and Y were detected on the surface of the YBCO than in the bulk, due to a large amount of CO_3^{2-} ions; these elements and the ions concentrated on the surface are estimated to reduce the superconductivity.[8]

The composite piezoelectricity with electrodes of 5 μm thickness YBCO is shown in Fig. 6.

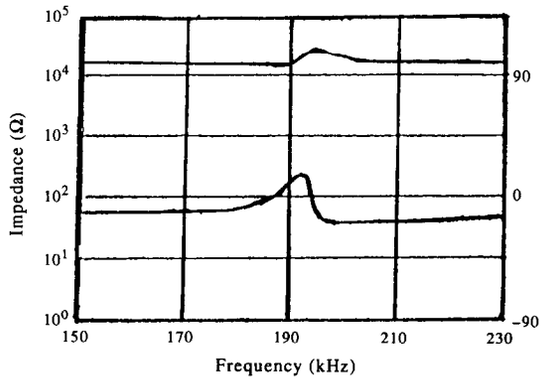

Fig. 6. Impedance analyses with frequency: (a) starting material; (b) Ba-doped PZT (electrodes were Ag).

Absorption of energy by PZT was low at a frequency around 190 kHz as indicated by impedance analysis suggesting poor piezoelectricity. The poor film density and Ba diffusion may cause the poor piezoelectricity in the YBCO/PZT/YBCO system. It is suggested that the density of the YBCO thick film is not high enough for the material to act as electrode for a device.

4 Conclusions

(1) YBCO thick films (5–33 μm) adhered onto PZT. Investigation of the interfaces revealed diffusion of Ba from YBCO to PZT; the length of the diffusion zone depended on the sintering time at 1193 K.
(2) YBCO thick film of 5 μm indicated semiconductive properties rather than superconductivity with no clear indication of a critical temperature.
(3) The thick film should be denser to function as successful electrodes for the composites consisting of superconductor/PZT/superconductor; also a film thickness of 5 μm or less can be suggested as well as a short sintering time.

Abstract

A simple shear-lag model is used to estimate the toughness of a unidirectional fibre reinfored ceramic matrix composite. In the model, which includes the residual axial stresses, the stress transfer across the fibre/matrix interface is by a constant shear stress. The estimates from the model are compared to experimental measurements for four composites and good agreement is found. The effects of distributed and localized energy uptake on fracture stability are discussed, and it is concluded that for most applications the toughness, rather than the pull-out energy absorption, should be maximized.

Nomenclature

a	fibre radius
A	cross-section area
B	specimen width
c	crack length
E	Young's modulus
f	fibre volume fraction
G	(critical) energy-release-rate
L	specimen length
l_s	sliding length
l_p	pull-out length
P	applied load
s	spacing of matrix cracks
U	toughness (energy per unit volume) of composite
v	displacement
W_{sl}	energy dissipated (per unit volume) due to frictional sliding
W_p	energy dissipated (per unit area) due to fibre pull out
γ_{WOF}	work of fracture
δ	matrix crack opening
Δ	specimen elongation
ϵ	axial strain
ϵ_u	ultimate tensile strain
Π	potential energy
σ	stress
τ_s	interfacial sliding shear stress
ϕ	strain energy density

Subscript

db	debonding
f	fibre

max	value at specimen separation
mc	matrix cracking
u	value at ultimate stress
FS	full sliding along the interface

Superscript

ACK	fully and multiply cracked matrix
ini	initiation of matrix cracks
res	residual
*	value after specimen separation
0	initial state
I–IV	stages of damage

1 Introduction

Monolithic ceramics are brittle, flaw-sensitive, and of low energy absorption capacity before and during fracture. However, a class of ceramic composites with continuous reinforcement is emerging, which has much more attractive damage and fracture behaviour. Materials in this class are *damage tolerant*, in the sense that the first mode of damage (matrix cracking) does not lead to final fracture. Instead, the strength of the materials is controlled by the strength of the reinforcement. This flaw-insensitive behaviour is a remarkable property of materials that are made of brittle constituents. As a consequence, fracture toughness is not a proper parameter to characterize such materials. Rather, the stress at the onset of multiple matrix cracking, the failure stress, and total energy uptake until failure constitute a set of property parameters.

Most theoretical works on continuous fibre reinforced ceramics focus on two topics: progression of multiple matrix cracking[1–3] and energy dissipation due to fibre pull out.[4–7] Multiple matrix cracking is of importance since it leads to non-linear constitutive behaviour that must be taken into account when these materials are used, see e.g. ref. 8. It is equally important to point out that in general there is no correlation between the 'proportional limit', i.e. the stress level at which multiple matrix cracking causes non-linearity in the stress-strain curve and the fatigue limit.[9] The energy dissipation due to pull out is important for assessment of the final fracture behaviour. A central part of all these models is the role of the interface (see ref. 10 for a recent review).

The energy uptake by distributed mechanisms (i.e. prior to localization) has not been addressed sufficiently in the previous works. Experimentally, a remarkably non-linear stress–strain response has been found for several continuous fibre-reinforced ceramics composites.[9–14] However, the details of the associated evolution of damage have been studied only recently.[15–19] On the basis of these recent findings, this paper develops a model for the energy uptake by distributed mechanisms, defined here as toughness, i.e. the total energy uptake until failure in volume-distributed mechanisms. This energy comprises both the recoverable and non-recoverable parts. It is of major importance, because this is the maximum energy that can be absorbed per unit volume without causing fracture of a component, i.e. (the component will be damaged but will retain its integrity such that it can still continue to carry loads).

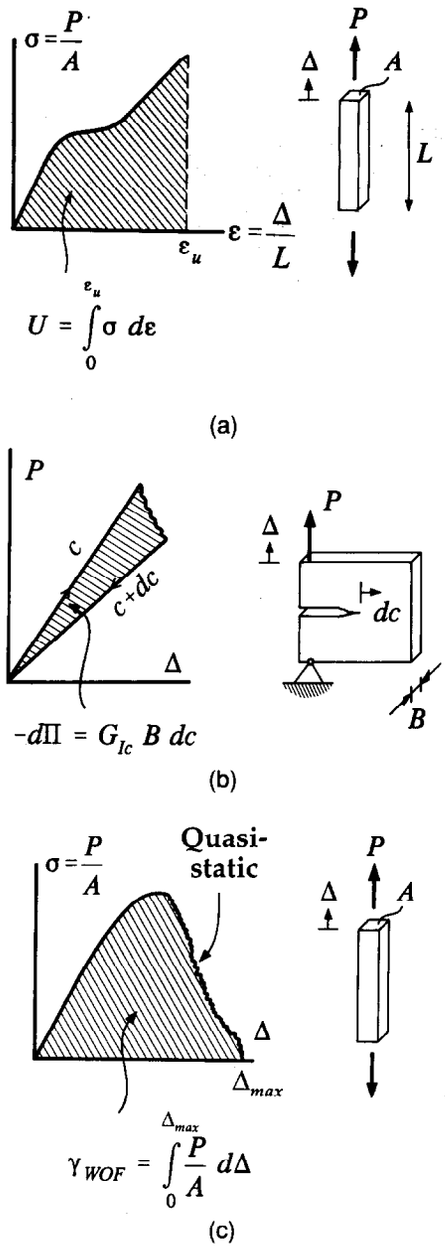

Fig. 1. Energy measures for materials: (A) the toughness, U, (B) the critical energy release rate, G, and (C) the work of fracture, γ_{WOF}.

2 Measurements of energy for material characterization

2.1 Energy quantities

Firstly, for clarity, we start off reviewing some energy concepts and quantities that are often used to characterize the fracture behaviour of materials. For simplicity the considerations are limited to the case where a specimen is loaded by a single tension force. Figure 1 illustrates three commonly used quantities: the toughness, the critical energy release rate (fracture toughness) and the work of fracture.

The toughness[20] is the ability of a material to uptake energy (per unit volume) prior to failure, i.e. the strain energy density to failure[20];

$$U = \int_0^{\epsilon_u} \sigma(\epsilon)\, \mathrm{d}\epsilon, \tag{1}$$

where σ and ϵ are stress and strain, respectively, and ϵ_u is the failure strain (onset of localization). It is the area under the stress–strain curve, and has the SI unit J/m^3.

The *energy release rate* is defined in fracture mechanics by the decrease of the potential energy per new crack area during a quasi-static crack increment[21]

$$G = -\frac{1}{B}\frac{\mathrm{d}\Pi}{\mathrm{d}c}, \tag{2}$$

where Π is the potential energy, and c and B are the length and the width of the crack, respectively. The critical value of G is equivalent to the energy absorbed per unit new crack area, during an incremental (stable) crack growth. The SI unit for G is

J/m^2. Alternatively, the critical value of G is called the fracture toughness. Sometimes in the literature the term toughness is used loosely when fracture toughness is meant. This may cause confusion. In our paper toughness is defined by (1) and fracture toughness by (2).

The *work of fracture* is defined by the total energy absorped (during a quasi-static fracture process) by the specimen per unit fracture area, i.e. the area under the load–displacement curve, per cross-sectional area (see e.g. ref. 22),

$$\gamma_{WOF} = \int_0^{\Delta_{max}} \frac{P(\Delta)}{A} \, d\Delta, \qquad (3)$$

where A is the cross-sectional area of the specimen, P is the load and Δ is the elongation. γ_{WOF} has the SI unit J/m^2.

From the definitions it follows that the quantities mentioned are suited for characterizing different phenomena. U relates the energy uptake (prior to localization) to the volume, and is the proper measure of the *fracture initiation energy*. G is a measure related to characterizing phenomena appearing with *growth of a single crack*. Work of fracture relates the *total energy absorped* (fracture energy) to the full crack area.

2.2 Distributed versus localized energy absorption of uniaxial fibre composites

When unidirectional fibre composites are loaded in the fibre direction a range of *distributed damage* mechanisms occur before final failure. The *fracture* occurs as a *localized* phenomenon, since fibre fracture and pull out only take place at a single matrix crack, namely where the specimen separates into two pieces. Throughout this paper distinction will be made between distributed energy uptake and energy absorped during localization. Distributed energy uptake should be measured by a quantity that reflects that the energy uptake is by distributed phenomena, such as the area under the stress–strain curve, U. The energy dissipation during localization also involves distributed and localized mechanisms. It is of importance to measure and calculate these contributions separately, since they do not scale in the same manner with specimen geometry, as will be elaborated later.

2.3 Choice of test method — bending or pure tension

Having recognised the importance of distinguishing between distributed and localized mechanisms, we now proceed with a discussion of test methods for measurements of the toughness. Materials having distributed damage are characterized by non-linear constitutive laws. Per definition a constitutive law is the relationship between the stress and strain states at any point in the material. For continuum mechanics to be applicable for materials experiencing distributed damage, the test volume (gage length of extensometer or strain gauge) must be much larger than any microstructural dimensions (e.g. matrix crack spacing), such that the measured volume behaviour is scale-independent, and the definitions apply. Moreover, the test *volume* must have *uniform stress and strain fields.*

In bending tests the normal stress distribution is non-uniform (going from tension on one side to compression on the other), and so is the damage evolution, as sketched in Fig. 2. The true stress–strain curve cannot be determined, since the stress and strain distributions across the specimen depth are not known (when damage takes place, the distribution of normal stress is not linear, but depends on the type of damage mechanism and degree of damage). Furthermore, at the peak load, localized fibre failure takes place at the tensile surface, multiple matrix cracking takes place in the central region of the specimen, and the compression side may still be undamaged. From the *bending load–displacement curve it is not possible to distinguish between the effects of distributed mechanisms* (matrix cracking, fibre/matrix debonding and interfacial sliding) and *localized* (fibre breakage and pull out). Furthermore, a shear stress field is present in bending tests. Thus, the damage evolution and failure may be due to shear or compressive stress components, rather than tension.[23]

It is unfortunate that bending tests have been so widely used for characterizing ceramic composites, since this has led to incorrect conclusions concerning the material behaviour. For instance, it has sometimes been suggested that the tail (the downgoing part) of the load–displacement curve (measurable in displacement controlled experiments only) represents the energy dissipation due to fibre

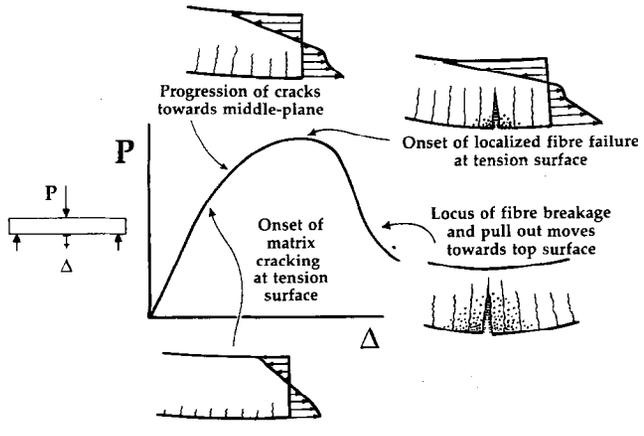

Fig. 2. A schematic illustration of various damage mechanisms operating simultaneously during a bending experiment. The damage evolution is not uniform throughout the depth of the specimen.

pull out. This is incorrect, since matrix cracking, fibre/matrix debonding, fibre sliding and fibre failure continue to take place during this part of the bending response, as the failure locus moves across the depth of the specimen towards the compression side.

Uniaxial tension experiments, on the other hand, allow an unambiguous interpretation, since the damage mechanisms initiate and develop at identifiable stress or strain levels,[15–19] and take place uniformly over the entire volume of the gage section of the specimen.

Unfortunately, tensile tests are difficult to perform, since an accurate alignment is needed to prevent bending effects.[24] Also, although tensile tests are performed with much care, it is not unusual that failure takes place at tabs,[19] so the true strength of the composite cannot always be measured. However, if there is no bending in the test section, then the relationship between stress, strain and damage mechanisms can readily be identified.

2.4 Experimental characterization of damage in uniaxial tension

Figure 3 shows an experimental stress–strain curve of a hot pressed unidirectional SiC-fibre-reinforced calcium alumino silicate (denoted CAS II from Corning Inc., NY, USA) glass–ceramic matrix composite, tested in uniaxial tension along fibres[19] at a strain rate of 4×10^{-4} min^{-1}. Throughout this paper we will refer the evolution of damage to the axial strain of the composite rather than the composite stress, since the axial stress component in the fibres resulting from the external load and the axial stress component in the matrix before matrix cracking are proportional to the axial strain of the composite. This approach also makes it easier to compare behaviour of unidirectional and cross-ply composites. For the SiC/CAS II composite shown in Fig. 3, U was measured to be 3.1 MJ/m^3, which is almost 40 times that of the pure matrix material. However, due to loading rate effects on the monotonic stress–strain behaviour,[25] the value for SiC/CAS II can vary from 1·7 MJ/m^3 (at 0·01 MPa/s) to 5·4 MJ/m^3 (500 MPa/s).

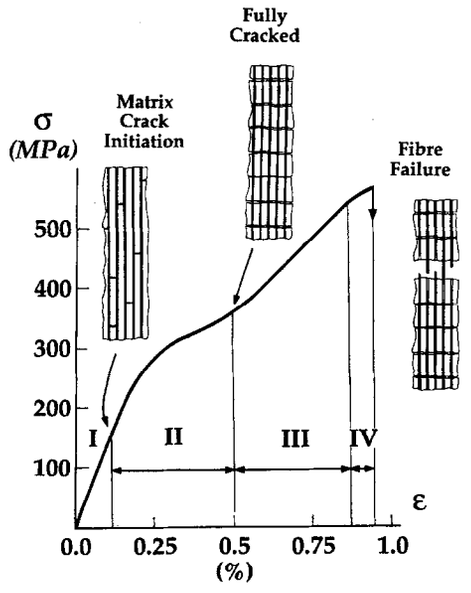

Fig. 3. The non-linear stress–strain curve of SiC/CAS II measured in uniaxial tension along fibres (strain rate of 4×10^{-4}/min). Applied stress as function of strain. The stages of damage evolution are indicated (after ref. 19).

The non-linear stress–strain curve reflects the various stages of damage (see ref. 19 for a detailed discussion). At low strain the material response is linearly elastic and reversible (Stage I). At higher strain matrix cracks initiate and evolve into fairly regularly spaced multiple matrix cracks (Stage II). This takes place over a certain strain range, rather than at a specific strain value. Fibre/matrix debonding also takes place during Stage II, and facilitates frictional sliding along the fibre/matrix interface. These damage processes cause the non-linear part of the stress–strain curve. The corresponding changes in the overall unloading modulus and Poisson's ratio in Stage II can be modelled by a continuum damage model.[8] Increasing the applied stress further leads to a second linear response (Stage III), where the stiffness is mainly due to the fibres. However, significant hysteresis appears during unloading due to effects from interfacial friction. For some specimens a small amount of distributed fibre fracture (Stage IV) may take place just prior to failure. Final failure occurs by localized fibre fracture. Recalling the preceding discussion, the area under the stress–strain curve represents the energy that the material has absorbed per unit volume of the composite up to failure. The energy quantity measured by U is the energy that has been absorbed by *distributed* mechanisms. Mechanisms operating during the *localized* fracture, such as fibre fracture and pull out do *not* contribute to this quantity.

3 Model of Energy Uptake

3.1 Basic considerations

In the following the energy uptake by distributed mechanisms of a unidirectional ceramic fibre reinforced ceramic composite is estimated, based on the damage mechanisms and scenario identified above. The tensile stress–strain curve represents the response of the material to a quasi-static loading in equilibrium with the stresses in the material, and therefore, according to the first law of thermodynamics, the work of the external force must be equal to the change of the energy in the specimen.

In many cases the stress–strain curve does not show non-linearity immediately before failure, indicating that the presence of Stage IV (distributed fibre failure) can be neglected. Thus, our analysis concerns only energy uptake in Stages I, II and III, with Stage III extended until failure. In Stage I the energy uptake per unit volume of the composite, the area under the stress–strain curve up to $\epsilon = \epsilon_{mc}^{ini}$, is denoted U^I. According to the principle of virtual work (or the first law of thermodynamics) the energy uptake U^I is equal to the increase in strain energy density in the matrix and fibres, Φ_m^I and Φ_f^I, respectively, where superscript 0 and I denote the start and end of Stage I, respectively

$$U^I = \int_0^{\epsilon_{mc}^{ini}} \sigma \, d\epsilon = \Phi_m^I + \Phi_f^I - \Phi_m^0 - \Phi_f^0. \quad (4)$$

In Stage II the external work per unit volume is, again, according to the principle of virtual work, equal to the sum of the changes in strain energy density of fibre and matrix, the fracture energy of multiple matrix cracks, fibre/matrix debonding and the energy dissipation due to interfacial frictional sliding in Stage II. Denoting superscript II for the end of Stage II ($\epsilon = \epsilon_{mc}^{ACK}$), the energy uptake in Stage II is

$$U^{II} = \int_{\epsilon_{mc}^{ini}}^{\epsilon_{mc}^{ACK}} \sigma \, d\epsilon = \Phi_m^{II} + \Phi_f^{II} - \Phi_m^I - \Phi_f^I + U_{mc} + U_{db} + W_{sl}^{II}, \quad (5)$$

where W_{sl}^{II} stands for the frictional energy dissipation per unit volume in Stage II, U_{mc} is the energy consumed due to the formation of matrix cracks and U_{db} is the debond energy per unit volume. Assuming that the deformation of fibre and matrix continues in Stage III, the energy uptake in Stage III is

$$U^{III} = \int_{\epsilon_{mc}^{ACK}}^{\epsilon_u} \sigma \, d\epsilon = \Phi_m^{III} + \Phi_f^{III} - \Phi_m^{II} - \Phi_f^{II} + W_{sl}^{III}, \quad (6)$$

where superscript III stands for the end state, when localization sets in ($\epsilon = \epsilon_u$), and W_{sl}^{III} is the frictional energy dissipation in Stage III. This gives the total energy uptake as

$$U = U^I + U^{II} + U^{III} = \Phi_m^{III} + \Phi_f^{III} - \Phi_m^0 - \Phi_f^0 + U_{mc} + U_{db} + W_{sl}, \quad (7)$$

where W_{sl} is the total energy dissipation per unit volume due to frictional sliding in Stages II and III. Note that U can be calculated from the stress and strain states in the *initial and end states*. The frictional energy dissipation can also be calculated from the strain distributions in the end state, assuming the fibre sliding to occur monotonically.

3.2 Basis of unit cell model

In this paper the strain densities and frictional sliding are calculated from a simple shear-lag model, similar to Aveston *et al.*;[1] the effect of residual stresses are added (details are given in the Appendix). The model is a simple one-dimensional analysis, i.e. only the changes in the *axial* stresses and strains are considered, and the interfacial friction shear stress τ_s is assumed to be constant throughout the experiment. This is a good assumption for the accuracy of modelling presented here, since it has been found that the effects of fibre Poisson's contraction and roughness more or less cancel out.[26,27]

Initially, i.e. in the virgin state, the composite is free from external stresses, but has axial residual stresses, σ_f^{res} and σ_m^{res} in the fibre and matrix, due to a thermal expansion mismatch between fibre and matrix. Before fibre/matrix debonding has taken place, there is no slip between fibre and matrix at the interface. During multiple matrix cracking the fibre and matrix debond during the loading, the matrix retracts and, relatively, the fibres slide along the interface monotonically (Fig. 4). It is assumed that the fibres slide symmetrically inside the matrix cylinder from both ends, such that there is sliding along the *entire* interface except at the middle of the matrix cylinder ($0<x<s/2$, Fig. 4), where sticking friction is assumed due to symmetry (the condition for full slip is given in the Appendix).

3.3 Geometrical considerations

A unit cell model is depicted in Fig. 4. The cylindrical volume cell represents a single fibre of radius, a, surrounded by a matrix cylinder. The length of the cell is s, corresponding to the matrix crack spacing, and the outer radius of the matrix cylinder is such that the fibre volume fraction is f. The cross-section area A_f of the fibre is

$$A_f = \pi a^2. \quad (8)$$

The interfacial surface area A_s is

$$A_s = 2\pi a s, \quad (9)$$

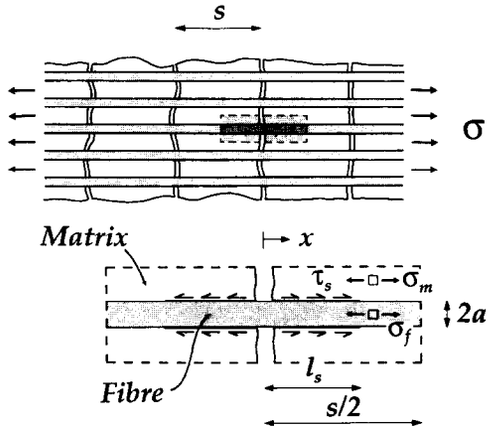

Fig. 4. The axisymmetric unit cell used in the analysis.

the cross-section area of the matrix is

$$A_m = \frac{1-f}{f}\pi a^2 \tag{10}$$

and the total volume of the cell is

$$V = \frac{\pi a^2 s}{f}. \tag{11}$$

3.4 Multiple matrix cracking

During multiple matrix cracking one crack is formed within each volume cell (Fig. 4). Thus the energy absorped per unit volume of the composite is

$$U_{mc} = \frac{G_m A_m}{V} = \frac{G_m}{s}(1-f), \tag{12}$$

where G_m is the critical energy release rate of the matrix, and eqns (10) and (11) have been used.

3.5 Fibre/matrix debonding

For each unit cell there is debonding over the surface A_s, such that the energy absorbed due to fibre/matrix debonding per unit volume of the composite is

$$U_{db} = \frac{G_{db} A_s}{V} = 2f\frac{G_{db}}{a}, \tag{13}$$

where G_{db} is the critical (mode II) energy release rate of the interface, and eqns (9) and (11) have been used. Note that an advantage of this approach is that the estimates of U_{mc} and U_{db} are independent of the load level at which matrix cracking and debonding take place.

3.6 Strain energy in matrix and fibre

The strain energy densities due to residual stresses are

$$\Phi_m^0 = \frac{A_m s}{V}\frac{1}{2}\frac{(\sigma_m^{res})^2}{E_m} = \frac{1-f}{2}\frac{(\sigma_m^{res})^2}{E_m}, \tag{14}$$

and

$$\Phi_f^0 = \frac{A_f s}{V}\frac{1}{2}\frac{(\sigma_f^{res})^2}{E_f} = \frac{(1-f)^2}{2f}\frac{(\sigma_m^{res})^2}{E_f}, \tag{15}$$

where the force balance of the residual stress components in the axial direction,

$$f\sigma_f^{res} + (1-f)\sigma_m^{res} = 0, \tag{16}$$

and eqns 8 and 11 have been used. The strain energy density in the matrix during full sliding along the fibre/matrix interface can be derived from the strain state in the matrix (Appendix), using eqns (10) and (11),

$$\Phi_m^{III} = \frac{A_m}{V/2}\int_0^{s/2}\frac{1}{2}E_m\epsilon_m^2(x)\,dx = \frac{1}{6}\frac{f^2}{1-f}\frac{s^2}{a^2}\frac{\tau_s^2}{E_m}, \tag{17}$$

where the strain is defined to be zero at the stress free state at room temperature. The factor 2 in the denominator before the integral is to account for the integration being only over half the volume of the unit cell shown in Fig. 4 (from the fibre end to the centre of the matrix block).

Likewise, the strain energy density in the fibres during full slip is (by eqns 8 and 11)

$$\Phi_f^{III} = \frac{A_f}{V/2}\int_0^{s/2}\frac{1}{2}E_f\epsilon_f^2(x)\,dx = \frac{1}{2}\frac{\sigma_u^2}{fE_f} + \frac{f}{6}\frac{s^2}{a^2}\frac{\tau_s^2}{E_f} - \frac{1}{2}\frac{\sigma_u}{E_f}\frac{s}{a}\tau_s, \tag{18}$$

where the composite strength is given by the failure strain (Appendix)

$$\sigma_u = f\epsilon_u E_f + \frac{f}{2}\frac{s}{a}\tau_s + f\sigma_f^{res}. \tag{19}$$

3.7 Interfacial frictional sliding

The energy dissipation due to frictional sliding can be assessed by considering the difference in displacement fields between the matrix and fibre at the end state (the maximum applied stress at the point of failure) and the initial state (prestressed with the residual stresses), i.e. from the difference in the displacement fields of fibre and matrix of half the volume cell,

$$W_{sl}(\sigma) = \frac{2}{V}\int_0^{s/2} |\, v_m(\sigma, x) - v_f(\sigma, x)\,|\, 2\pi a\,\tau_s\,dx, \tag{20}$$

where v_m and v_f are the displacement fields of the matrix and fibre at the applied stress σ, defined to be zero before loading (i.e. v_f and v_m are zero when the residual stresses act alone). The factor 2 in front of the integral is to account for the integration being only over the half volume of the unit cell. Using the displacement fields derived in the Appendix, the energy dissipation due to sliding is found by combining eqns (11), (19) and (20),

$$W_{sl} = \frac{f}{2}\frac{s}{a}\left(\epsilon_u + \frac{\sigma_m^{res}}{E_m}\right)\tau_s - \frac{f}{12}\frac{s^2}{a^2}\left(\frac{4f}{1-f}\frac{\tau_s^2}{E_m} + \frac{\tau_s^2}{E_f}\right). \tag{21}$$

4 Results

4.1 Available material data

Table 1 shows the available material data for four continuous fibre-reinforced ceramic composites. The values of G_{db} were taken from Marshall and Oliver,[28] who measured this property on SiC/LAS III with a single fibre push-in method. Since the interphases of most composites consist mainly of carbon,[29,30] an identical value of G_{db} was assigned for all composites. In the literature there is some variation on the values of the interfacial sliding friction for SiC/CAS II, ranging from τ_s = 5 MPa (estimated from the energy dissipation calculated by the fatigue hysteresis loop method[31]) to 15 MPa (found by a single fibre indentation method[14]). For the SiC/LAS III composite[32] Cao *et al.*[33] reported the measured composite modulus E_c to be 120 GPa and a fibre volume fraction of f = 0·5. However, using the rule of mixtures, (eqn 29), f can be calculated from E_c to be f = 0·3. For the SiC/MAS composite[34] a value of $\alpha_m = 5 \times 10^{-6}$ °C^{-1} was used in the calculation of the residual stresses.[35] However, Martin *et al.*[36] reported $\alpha_m = 3 \times 10^{-6}$ °C^{-1} for a MAS-L matrix.

4.2 Comparison of predictions to experiments

Using the material data given in Table 1 and eqns (12)–(15), (17)–(19) and (21), the individual contribution of each mechanism can be calculated, and using eqn (7) the total energy uptake, the value of U can be predicted (Table 2). The experimental results lie close to the theoretical predictions. Some deviations, however, are found, particularly for the SiC/MAS composite. For this material the predicted value is lower than the measured. However, this may be attributed to poor estimates of the residual stresses, since there appears to be some disagreement on the reported values of the thermal expansion mismatch. Neglecting the residual

Table 2. Toughness, predictions and experiments

	SiC/CAS II	*SiC/LAS III*	*SiC/MAS*	*SiC/1723*
U_{mc} (MJ/m^3)	0·10	0·04–0·05	0·22	0·26–0·28

Predicted	2·7–3·0	2·0–3·4	0·37–0·46	5·4–6·2
Experiment	3·1	2·7	0·57	5·4

Experimental data for U are from ref. 19 for SiC/CAS II, ref. 33 for SiC/LAS III, ref. 34 for SiC/MAS and from ref. 12 for SiC/1723.

stresses completely gives $U = 0{\cdot}82$ MJ/m^3, which is higher than the experimental value. Thus, it appears that the residual stresses in SiC/MAS, (Table 1), are overestimated. Therefore, it is concluded, that the agreement between prediction and experimental results is satisfactory.

It is interesting that for all the composites the strain energy in the fibres represents more than half of the total energy uptake. Therefore, the most important parameters to raise in order to maximize the toughness are the failure strain and volume fraction of the fibres (see eqns 18 and 19). The contributions from frictional sliding and distributed matrix cracking are significant, whereas the energy absorbed due to debonding is low.

5 Discussion

5.1 Localized energy absorped by fibre pull-out

The energy absorped due to fibre fracture is fG_f per unit cross-section area (assuming, reasonably, that each fibre fails only once during pull-out), where G_f is the critical energy release rate of the fibre. This product is usually very small[6] compared to the energy dissipation due to frictional sliding, and will be neglected in the following. The energy absorption due to fibre pull out can be assessed by the concept of a bridging law (see e.g. ref. 37), where the extra energy absorped due to bridging, ΔG, is given by

$$\Delta G = \int_0^{\delta_{max}} \sigma(\delta)\, d\delta, \tag{22}$$

where δ is the opening of the matrix crack and $\sigma(\delta)$ is the bridging law, i.e. the bridging stress as function of the crack opening. Although eqn 22 was originally derived for bridging in connection with a crack tip,[38] the result is also valid for our problem (in our case the crack can be considered to be infinitely long). For a fibre broken at an average distance l_p away from the matrix crack, the stress in the fibre across the matrix crack (x=0) is (Fig. 5)

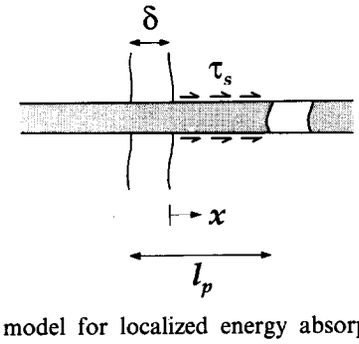

Fig. 5. The model for localized energy absorption by fibre pull-out.

$$\sigma_f(x = 0, \delta) = 2\,\frac{l_p - \delta}{a}\,\tau_s. \tag{23}$$

The bridging stress is $\sigma(\delta) = f\sigma_f(\delta)$, such that the energy absorped due to pull out, W_p, becomes (eqn 22)

$$W_p = \int_0^{l_p} 2_s \frac{l_p - \delta}{a}\,\tau_f\, d\delta = \frac{f l_p^2 \tau_s}{a}, \tag{24}$$

as also obtained elsewhere.[4,7]

Many theoretical efforts have been made to express $\sigma_f(\delta)$ and l_p by the strength variation of the fibres, described by a Weibull distribution, and the interfacial friction.[4–7] This will not be pursued here. Rather, for the purpose of comparing the magnitudes of distributed and localized energies absorped, we simply take the estimates of the mean pull out length by observations from the fracture surfaces. For the SiC/CAS II composite l_p has been reported[17,39] to be in the order of 0·2 mm, giving $W_p = 28$ kJ/m^2.

5.2 Fracture stability and total energy absorption of test specimens

Consider a specimen subjected to uniaxial tension in the fibre direction. Distributed damage (matrix cracking, fibre/matrix debonding and interfacial sliding) operates until the maximum load (the failure load) is reached. From then on the history depends on loading mode. If the test is performed under constant loading rate (load control), the specimen fractures unstably. If the experiment is controlled by the opening of the matrix crack where specimen separation occurs, fracture may take place in a quasi-static manner (solid line, Fig. 6). Although the crack opening, δ, increases monotonically, the overall elongation, Δ, decreases initially, as 'elastic' contraction takes place (due to decreasing load) in the specimen away from the localization. During this unloading the fibres away from the fracture locus contract more in the axial direction than the matrix, leading to energy dissipation by reverse interfacial sliding. In the final stages the overall elongation, Δ, may increase again, if the δ increases with a faster rate than the 'elastic' contraction. In case the experiment is conducted at constant displacement rate, a non-equilibrium load-drop will occur during localization (dashed line, Fig. 6). Depending upon the bridging law and specimen length, L, a tail may occur during separation if the maximum pull out length, $(l_p)_{max}$, is larger than the length change (contraction) due to unloading of the specimen (see Appendix), i.e. if

$$\epsilon_u - \frac{s}{2a}\frac{\tau_s}{E_f} + \frac{\sigma_f^{res}}{E_f} \le \frac{(l_p)_{max}}{L}. \tag{25}$$

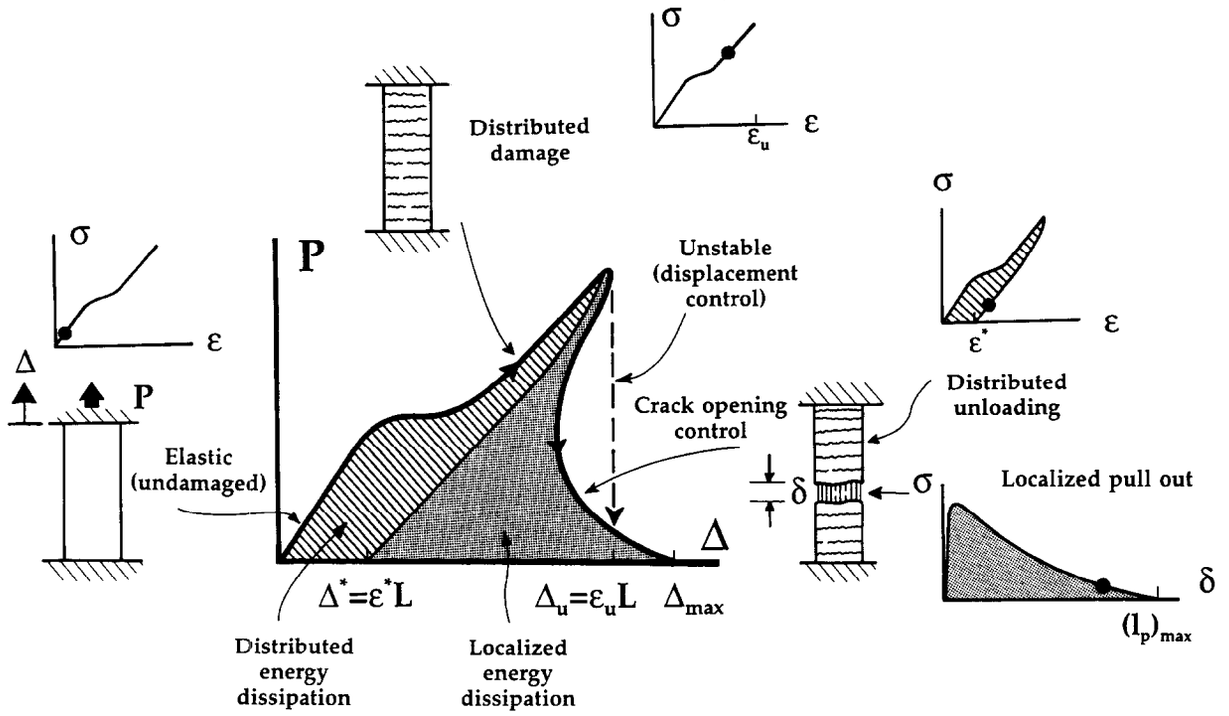

Fig. 6. Schematic illustration of overall load–displacement curve, distributed and localized energy dissipation during loading, fracture and separation of a tensile specimen. The solid line is the load–displacement curve that would occur if the experiment was conducted under crack opening (δ) control, while the dotted line indicates the unstable fracture that takes place under control of the displacement of the specimen. The deformation during loading is due to distributed phenomena, while the down-going part comprises distributed deformation ϵL and localized crack opening δ.

Thus, regarding ϵ_u and $(l_p)_{max}$ as material constants, a tail (stable fracture) will only appear if the specimen length is sufficiently short. Using the material data for SiC/CAS II and SiC/LAS III (Table 1) and $(l_p)_{max}$ = 0·4 mm for the SiC-fibres, the critical length is calculated to be $L \approx 50$ mm. The experimental results of Cao *et al.*[32] were obtained with a gauge length of 15 mm, and a small tail was measured by extensometer. The experiments of Sørensen and Talreja[19] were also conducted in displacement control, but on specimens with longer gage section (80 mm). The fracture occurred unstably (i.e. no tail), although fibre pull out occurred. These results are in agreement with eqn (25). There are examples in the literature where a tail, the down-going part of the load–displacement curve, has been termed as a tough behaviour, contrasting materials that did not show a down-going tail (unstable fracture). Such interpretation is incorrect and should not be accepted. As described above there is no correlation between U and the fracture stability, since *fracture stability is not a material property*, but depends on specimen length and loading condition. Instead, we suggest that attention should be focused on whether amaterial is damage tolerant or flaw sensitive.

As indicated in Fig. 6, the total energy dissipation (the area under the quasi-static load–displacement curve (solid line)) comprises two sources, distributed energy dissipation and localized pull out energy dissipation. During loading the energy dissipation per unit volume by distributed mechanisms is the non-recoverable part of the toughness, i.e. U_{mc}, U_{db}, and W_{sl}. During unloading the reverse sliding that takes place along the fibre/matrix interface dissipates additional energy, W_{sl}^* per unit volume (superscript* indicate unloaded state). When the composite is completely free of external forces, residual stresses exist in fibre and matrix due to interfacial friction, such that strain energy is stored in fibre and matrix. Therefore, the total energy dissipation, from initial undamaged state until the specimen is fully separated, can be calculated as the sum of distributed energy dissipation and localization

$$\int_0^{\Delta_{max}} P(\Delta)\mathrm{d}\Delta = L\,A\,W_D + A\,W_p, \tag{26}$$

where W_D is the energy absorbed per unit volume of the composite by distributed mechanisms,

$$W_D = U_{mc} + U_{db} + W_{sl} + W_{sl}^* + \Phi_m^* + \Phi_f^* - \Phi_m^0 - \Phi_f^0, \tag{27}$$

and W_p is the pull-out energy per unit area. The energy dissipation due to reverse sliding (full slip) per unit volume of the composite is

$$W_{sl}^{*} = \frac{2}{V}\int_{0}^{s/2} | (v_m - v_m^{*}) - (v_f - v_f^{*}) | 2\pi a \tau_s \, dx =$$

$$\frac{s}{2a}\frac{\sigma_u}{E_f}\tau_s - \frac{2}{3}\frac{f}{1-f}\frac{s^2}{a^2}\frac{E_c}{E_m}\frac{\tau_s^2}{E_f}, \quad (28)$$

where E_c is

$$E_c = f E_f + (1-f) E_m. \quad (29)$$

The strain energy of the fibres per unit volume of the composite is (in similar fashion to eqn (18) on noting that the applied stress is zero and the sign in front of τ_s is changed since the slip direction is reversed)

$$\Phi_f^{*} = \frac{f}{6}\frac{s^2}{a^2}\frac{\tau_s^2}{E_f} \quad (30)$$

and that of the matrix is $\Phi_m^{*} = \Phi_m^{III}$. From eqn (26) it follows that the energy dissipation by distributed mechanisms increases with an increasing specimen length, while the pull out energy dissipation does not. An important consequence of this is that the distributed energy dissipation can be raised as much as one desires simply by increasing L. Therefore, the concept of work of fracture, γ_{WOF} (eqn 3), is not applicable for this class of materials.

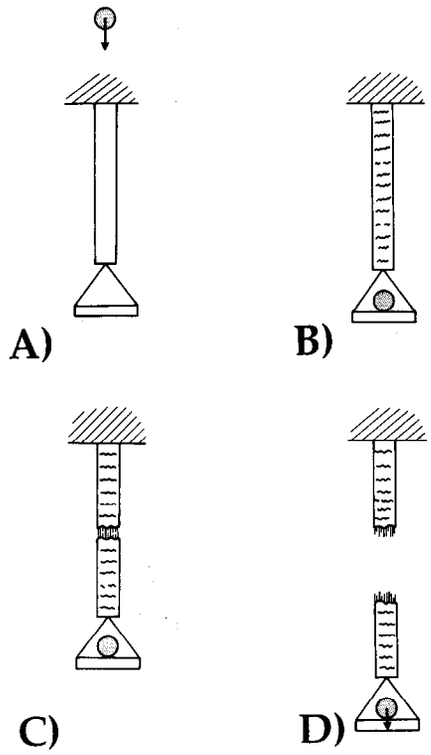

Fig. 7. (A) An impact loading at a component made of a damage tolerant ceramic matrix composite. (B) All the kinetic energy is absorbed by distributed energy uptake. (C) The kinetic energy is absorbed by distributed and localized energy mechanisms. (D) The kinetic energy is higher than what can be absorbed by distributed and localized mechanisms, so the component fractures.

5.3 Energy absorption and fracture stability of components

Now consider an *impact loading of a component* in service (Fig. 7A). This situation is different from a displacement controlled tensile test. In this case it is the actual amount of kinetic energy transferred to the specimen in the form of deformation energy that determines how the fracture behaviour will be. Consider an object hitting the composite component such that the direction of the moving object is in the fibre direction, and that during the impact the object causes uniform tension in the composite. Will the composite break, and in case it does, in which manner?

The first possibility is that the kinetic energy is lower than the total available distributed energy uptake, $U_L A$ (Fig. 7B). Then the composite will absorb the energy without fracture (it will be damaged, but it will not break). Alternatively, when the kinetic energy is higher than $U_L A$, the composite will fracture; the fibres will break, and the composite will lose strength. In this scenario, however, two possibilities exist: (1) If the kinetic energy is higher than the total fracture initiation energy but lower than the total energy dissipation (eqn 26), the component will be damaged and partly fractured (Fig. 7C); with fibres broken and partly pulled out. The composite will lose strength, because the two parts of the composite are only kept together by frictional stresses acting at the broken fibres. (2) If the impact energy is higher than the total fracture initiation energy and higher than the total energy absorped (eqn 26) (Fig. 7D), then the component will fracture unstably, since it cannot absorb the kinetic energy of the object.

Imagine that the component was a turbine blade in a jet-engine (this is a typical considered application for ceramic matrix composites). In such an application it is very important whether or not the component fractures, since a fractured blade may lead to total failure of the engine (this could be fatal for the aircraft). Now, if a turbine blade was hit by a bird or a stone having a specific amount of kinetic energy, what would happen to the component? If $U_L A$ was sufficient to absorb the energy, then the component would be *damaged*, but it would *retain its strength*. Thus, the aircraft would be able to land safely and the damaged component could be replaced. If the impact energy was so high that the component fractured, the pull out energy might stop the object, but now the component strength has decreased. The inertia forces of the rotating component could be sufficiently high that the blade could fracture completely, and the engine would

fail. It follows, that for such applications, the pull-out energy has little importance for the consequences of failure. Therefore, it can be concluded that for such applications it *is not the pull-out energy, W_p, that should be optimized, but the toughness, U.*

6 Conclusions

This paper has analyzed the energy absorption of unidirectional fibre reinforced ceramic composites. A simple model has been used to assess the energy uptake of the individual damage mechanisms. Special attention has been paid to separate energy uptake by distributed and localized mechanisms, since they scale differently with specimen dimensions. The distributed energy uptake, i.e. the toughness, has been found to be mainly due to strain energy in the fibres (this represents more than half of the energy uptake), but contributions from frictional sliding and distributed matrix cracking have also been found to be important, whereas the contribution from fibre/matrix debonding has been found to be very small. The predictions have been compared to experimental values for several composites, and a good agreement between the predictions and the measured values is found. Finally, arguments have been forwarded to conclude that in some applications the energy uptake due to the distributed mechanisms should be maximized rather than the energy for fibre pull-out, giving the most desirable material response.

Appendix

A.1 Strain fields

Before matrix cracking and interfacial debonding the composite exhibits residual stresses, e.g. due to thermal expansion mismatch. We define the strains to be zero at stress free state at room temperature. Then the strain fields in matrix and fibres due to the residual stresses are

$$\epsilon_m^{res} = \frac{\sigma_m^{res}}{E_m}, \qquad \text{(A1)}$$

and

$$\epsilon_f^{res} = \frac{\sigma_f^{res}}{E_f}. \qquad \text{(A2)}$$

When matrix cracking and fibre/matrix debonding take place frictional sliding takes place along the interface as the matrix retracts. After application of the external force the strains in the slip region are, with reference to the coordinate system in Fig. 4,

$$\epsilon_m(\sigma, x) = 2\frac{f}{1-f}\frac{x}{a}\frac{\tau_s}{E_m} \quad 0 \le x \le l_s(\sigma) \qquad \text{(A3)}$$

and

$$\epsilon_f(\sigma, x) = \frac{\sigma}{fE_f} - 2\frac{x}{a}\frac{\tau_s}{E_f} \quad 0 \le x \le l_s(\sigma). \qquad \text{(A4)}$$

In these expressions, l_s is the sliding length along the interface, measured from the matrix crack (Fig. 4). The sliding length can be found as the position x along the interface where the fibre and matrix strain changes are identical, $\epsilon_f(l_s) - \epsilon_f^{res} = \epsilon_m(l_s) - \epsilon_m^{res}$, giving

$$\frac{l_s(\sigma)}{a} = \frac{1-f}{2}\left[\frac{\sigma}{f\tau_s}\frac{E_m}{E_c} - \frac{\sigma_f^{res}}{\tau_s}\frac{E_m}{E_c} + \frac{\sigma_m^{res}}{\tau_s}\frac{E_f}{E_c}\right], \qquad \text{(A5)}$$

as also found by Pryce and Smith.[40] From eqns (A5) and (29) it follows that there is sliding along the *entire* interface ($l_s = s/2$), when the applied stress exceeds a characteristic value, σ_{FS} (subscripts indicate Full Slip)

$$\frac{\sigma_{FS}}{fE_f} = \frac{\sigma_f^{res}}{E_f} - \frac{\sigma_m^{res}}{E_m} + \frac{1}{1-f}\frac{s}{a}\frac{\tau_s}{E_f}\frac{E_c}{E_m}. \qquad \text{(A6)}$$

Above this stress level, the stress and strain states in the matrix do not change. This is a consequence of the assumption in the model that τ_s does not change. When the terms of the residual stresses are dropped in eqns (A5) and (A6), they become identical to the results in ref. 31. Inserting the strains gives the strain densities in eqns 17 and 18.

A.2 Displacement fields during loading

The displacement fields at a stress σ (after multiple matrix cracking and debonding) are, for the case of full sliding, then found by integration of the strains,

$$\int_{v_m(x)}^{v_m(x=s/2)} dv_m = \int_x^{s/2}\left[\epsilon_m(\sigma, x) - \frac{\sigma_m^{res}}{E_m}\right]dx \qquad \text{(A7)}$$

and

$$\int_{v_f(\sigma, x)}^{v_f(x=s/2)} dv_f = \int_x^{s/2}\left[\epsilon_f(\sigma, x) - \frac{\sigma_f^{res}}{E_f}\right]dx, \qquad \text{(A8)}$$

where the last terms represent the displacements due to the release of the residual stress during debonding, eqns (A1) and (A2). In eqns (A7) and (A8) $v_m(x=s/2)$ and $v_f(x=s/2)$ are the displacements at the centre of the matrix block. They are identical, since there is no sliding at the centre of the matrix block, and cancel out, when inserting into

eqn (20). Inserting eqns (A3) and (A4) into (A7) and (A8) gives

$$v_m(x) = v_m(x=s/2) - \frac{f}{1-f}\frac{\tau_s}{E_m}\left(\frac{s^2}{4a} - \frac{x^2}{a}\right) + \frac{\sigma_m^{res}}{E_m}\left(\frac{s}{2} - x\right) \quad \text{(A9)}$$

and

$$v_f(\sigma, x) = v_f(x=s/2) + \frac{\tau_s}{E_f}\left(\frac{s^2}{4a} - \frac{x^2}{a}\right) + \left(\frac{\sigma_f^{res}}{E_f} - \frac{\sigma}{fE_f}\right)\left(\frac{s}{2} - x\right). \quad \text{(A10)}$$

Inserting these displacements into eqn 20 gives the frictional energy dissipation (eqn 21).

A.3 Displacement fields during unloading

After fracture, as the specimen unloads the sliding direction changes, as the fibres contract and slide into the matrix. Then, the sign in front of τ_s changes in eqns (A3) and (A4). When the specimen is completely free of external load, the displacement fields are

$$v_m^*(\sigma = 0, x) = v_m^*(x=s/2) + \frac{f}{1-f}\frac{\tau_s}{E_m}\left(\frac{s^2}{4a} - \frac{x^2}{a}\right) + \frac{\sigma_m^{res}}{E_m}\left(\frac{s}{2} - x\right) \quad \text{(A11)}$$

and

$$v_f^*(\sigma = 0, x) = v_f^*(x=s/2) - \frac{\tau_s}{E_f}\left(\frac{s^2}{4a} - \frac{x^2}{a}\right) + \frac{\sigma_f^{res}}{E_f}\left(\frac{s}{2} - x\right). \quad \text{(A12)}$$

Inserting these displacements gives the frictional energy dissipation, W_{sl}^* (eqn 28).

A.4 Overall composite strain

The maximum composite strain during loading can be estimated by the average elongation of the unit cell, using eqn A4 (assuming full sliding),

$$\epsilon_u = \frac{2}{s}\int_0^{s/2} \epsilon_f(\sigma_u, x) - \frac{\sigma_f^{res}}{E_f}\,dx = \frac{\sigma_u}{fE_f} - \frac{s}{2a}\frac{\tau_s}{E_f} - \frac{\sigma_f^{res}}{E_f}. \quad \text{(A13)}$$

The strain offset after unloading is (full sliding)

$$\epsilon^* = \frac{s}{2a}\frac{\tau_s}{E_f} - \frac{\sigma_f^{res}}{E_f}, \quad \text{(A14)}$$

on noting that the sign of in front of τ_s is changed and σ vanishes. Subtracting these two strain values gives the strain change during unloading, i.e. the left hand side of eqn 25.

(Received 16 January 1995; revised version received 18 May 1995; accepted 19 May 1995)

Abstract

Discontinuous cracks observed in quasi-brittle materials subjected to fracture mechanics testing may be idealised by two mechanical models, i.e. an interaction model between the main crack and collinear small cracks, and a crack-wake bridging model. A study on these two models is presented in this paper and it shows that the instability of the crack system is significantly dependent on the model used. While the interaction model leads to unstable crack propagation, the crack bridging model predicts stable crack growth. It is concluded that the crack bridging model is more consistent with experimental observations on fracture in quasi-brittle materials.

Introduction

Crack-bridging due to ligament and grain pull-out has been recognized as an important toughening mechanism in quasi-brittle materials such as the non-transformable ceramics and cementitious materials, and has been successfully used to explain the non-continuous crack phenomenon observed in fracture mechanics testing of such materials.[1–13] In the idealized form, however, the bridged crack may be seen as a series of collinear cracks lying ahead of the main crack tip. As a result, two ways may be used to model or analyse the stress intensities of the crack system. One considers the interaction of the microcracks with the main crack where the singularities at each crack tip are retained and the other assumes finite stresses acting over the bridges. These are referred to as the interaction model and the bridging model, respectively. As will be shown later two completely different conclusions result from these two models.

Stress Intensity Factor Analyses

Figure 1(a) shows the interaction which consists of a semi-infinite crack along the negative x axis and a finite crack located in $a<x<b$. The stress fields in the vicinity of the main crack tip can be significantly intensified because of the presence of the finite crack. In the bridging model, Fig. 1(b), the ligament between the main crack and the finite crack is considered as a bridge and its effects on crack growth can be modelled by the actual stress distribution $\sigma_b(x)$ on the bridge.

Systematic solutions for the interaction model have been obtained by using the complex potential technique.[14–17] The stress intensity factors K_t^O, K_t^a and K_t^b at the crack tips O, a and b are normalised by the applied stress intensity factor at the main crack tip K_a^O and are given by[14,16]

$$\begin{aligned} K_t^O/K_a^O &= C/k \\ K_t^a/K_a^O &= (C-k^2)/kk' \\ K_t^b/K_a^O &= (1-C)/k' \end{aligned} \tag{1}$$

where

$$\begin{aligned} C &= E(k')/K(k') \\ k^2 &= a/b \\ k' &= (1-k^2)^{1/2} \end{aligned} \tag{2}$$

E and K denote the complete elliptic integrals of the second and first kinds, respectively. The normalised true stress intensity factors are plotted in Fig. 2 where it is found that the true stress intensity factor at the main crack tip K_t^O is always the largest. Therefore, for homogeneous brittle materials, crack growth will always start from the main crack tip, and if K_a^O is constant, the link-up of the main crack with the collinear microcrack will proceed unstably.[16]

Further study by Rubinstein[14] found that the above analysis holds also for collinear multi-

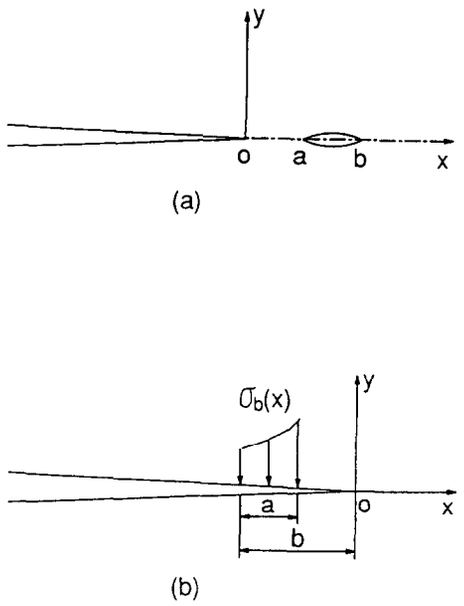

Fig. 1. Two models to study the collinear crack problem: (a) crack interaction model between a semi-infinite crack and a microcrack and (b) crack-wake bridging model.

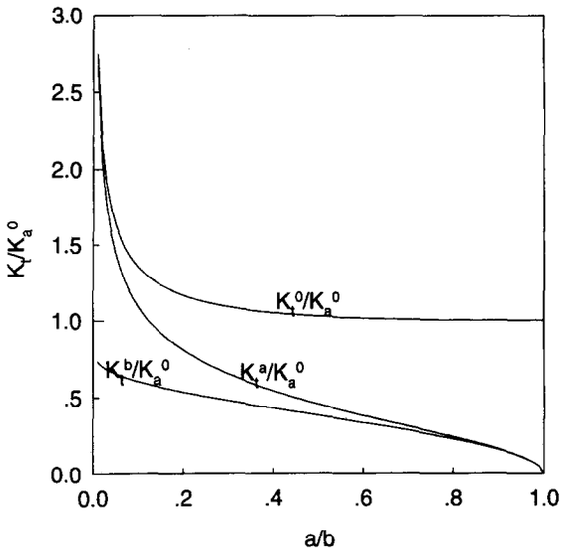

Fig. 2. True stress intensity factors normalized by the applied stress intensity factor.

microcracks. However, the stress intensity factor at the main crack tip is enlarged even further when the number of microcracks increases.

For the bridging model the ligament between the two cracks is considered as a bridge, Fig. 1(b). The true stress intensity factor K_t^O at the crack tip can be expressed as the superposition of the applied stress intensity factor K_a^O and stress intensity factor increment ΔK induced by the bridging stress on the ligament, i.e.

$$K_t^O = K_a^O + \Delta K \tag{3}$$

ΔK is usually negative and is referred to as the fracture resistance increment denoted by ΔK_R. Previous studies showed that ΔK_R due to the bridging stress $\sigma_b(x)$ can be written as[18]

$$\Delta K_R = \sqrt{\frac{2}{\pi}} \int_{b-a}^{b} \frac{\sigma_b(x)}{\sqrt{x}}\, dx \tag{4}$$

For quasi-brittle materials such as non-transformable ceramics and cements, the bridging stress $\sigma_b(x)$ usually decreases with crack face separation $w(x)$, i.e. it obeys a strain-softening law which can be approximated by[2]

$$\sigma_b(x) = \sigma_m [1 - w(x)/w_c]^n \tag{5}$$

where σ_m is the maximum bridging stress, n, softening exponent and w_c is the critical crack face separation corresponding to the saturated bridging zone length X, at which the bridging stress is zero. Further assumption that the crack faces remain straight during crack propagation leads to a simpler relationship between the bridging stress $\sigma_b(x)$ and the distance x to the crack tip, [6]

$$\sigma_b(x) = \sigma_m(1 - x/X)^n \tag{6}$$

The stress intensity factor increment due to the bridging stress can be estimated by substituting eqn (6) into eqn (4) and completing the integration. For the purposes of discussion ΔK_R for two bridging stress distributions: linear strain-softening and constant bridging stress, i.e. n = 1·0 and 0 in eqn (6), respectively are calculated. Substitute eqn (6) with n = 1·0 into eqn (4) and complete the integration, ΔK_R due to the linear strain-softening bridging stress can be obtained as

$$\Delta K_R = \sqrt{\frac{8}{\pi}}\, \sigma_m \sqrt{b}\, \{1 - k' - \frac{b}{3X}[1-(k')^3]\} \tag{7}$$

For the constant bridging stress σ_m, i.e. $n = 0$, we have

$$\Delta K_R = \sqrt{\frac{8}{\pi}}\, \sigma_m \sqrt{b}\, (1 - k') \tag{8}$$

As expected, the bridging stress reduces the stress intensity factor at the crack tip. The amount of crack shielding due to the bridging stress is related to the material parameters n and σ_m. This is different to the interacting collinear microcrack model where the stress intensity factors only depend on the dimensions of the microcracks and their spatial distribution. Corresponding to the multi-microcrack problem, the incremental resistances ΔK_R due to N ligaments with these two bridging stress functions are

$$\Delta K_R = \sqrt{\frac{8}{\pi}}\, \sigma_m \sqrt{b} \sum_{i=1}^{N} \{(\sqrt{i} - \sqrt{i - a/b} - \frac{b}{3X}[i^{3/2} - (i - a/b)^{3/2}]\} \tag{9}$$

for n = 1·0 and

$$\Delta K_R = \sqrt{\frac{8}{\pi}}\, \sigma_m \sqrt{b} \sum_{i=1}^{N} \{(\sqrt{i} - \sqrt{i - a/b})\} \tag{10}$$

for $n = 0$.

Instability of Crack System

The instability of materials containing cracks is dependent on the resistance to crack propagation. For ideally brittle materials, unstable crack propagation would proceed if the net stress intensity factor at a crack tip is equal to or above the critical stress intensity factor K_{Ic}. In the interaction model, the true stress intensity factor K_t^0 at $x = 0$ is always the largest. Therefore, the instability of the system is always preceded by unstable propagation of the main crack. This implies that the interaction situation can not be observed unless there are pre-existing microcracks ahead of the main crack. Based on eqn (1), it is also seen that the fracture resistance reduces because of the presence of the collinear microcrack.

For the bridging model with $n = 1{\cdot}0$, the fracture resistance increment ΔK_R can be expressed as

$$\Delta K_R / \sqrt{\frac{8}{\pi}}\,\sigma_m \sqrt{X} = \sqrt{\frac{b}{X}}\left\{1-k' - \frac{b}{3X}[1-(k')^3]\right\} \tag{11}$$

and for $n = 0$, one has

$$\Delta K_R / \sqrt{\frac{8}{\pi}}\,\sigma_m \sqrt{X} = \sqrt{\frac{b}{X}}(1-k') \tag{12}$$

Shown in Fig. 3 is the change of ΔK_R, due to a bridge of fixed width a with increasing distance from the crack tip. It can be seen that ΔK_R decreases as the crack advances. This indicates that the single bridging ligament can not result in stable crack propagation when subjected to steady-state loading even if it enhances the effective fracture toughness. However, if discrete bridges are developed continuously as the crack advances, an increasing ΔK_R can be obtained because the bridging stress effects from the bridges near the crack tip are much larger than those far away from it. As a result, stable crack growth can be observed when ΔK_R is larger than the crack driving stress intensity factor increment, ΔK_a.

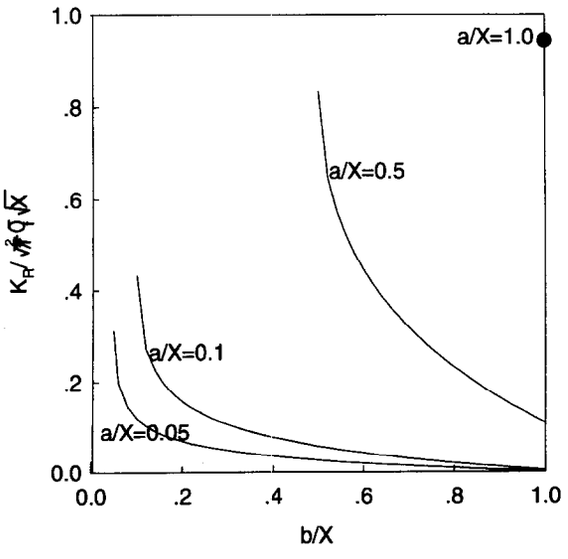

Fig. 3. Fracture resistance curves due to linear strain-softening bridging stress.

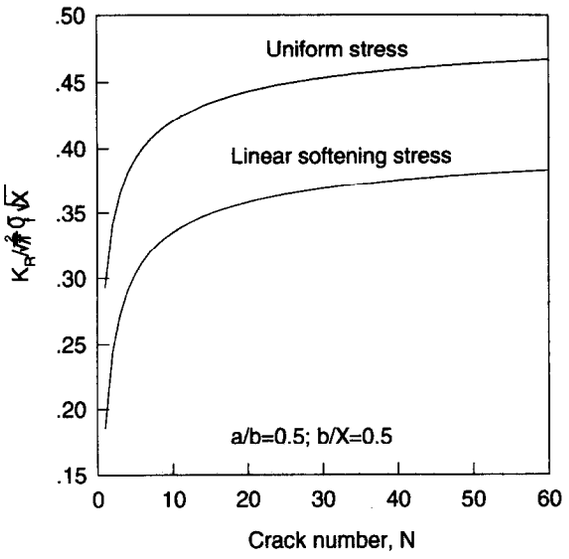

Fig. 4. Change of fracture resistance increment ΔK_R with microcrack number N.

The effect of crack number N on ΔK_R is shown in Fig. 4 where the distance between main crack tip and the most remote microcrack tip is assumed to be a constant b ($b/X = 0{\cdot}5$). For a given a/b ($0{\cdot}5$), the crack shielding effects due to bridging stresses of the ligaments increase with increasing crack number N and tend to a plateau value dependent on a/b.

Conclusions

The collinear crack problem can be simplified as two idealised mechanics models: crack interaction and crack bridging. But the two simplifications lead to two completely different conclusions. Crack propagation based on the interaction model is unstable. However, stable crack propagation can be achieved based on the crack bridging model if discrete bridges are continuously developed with the advancing crack. The increased fracture resistance from the bridging model are dependent on both geometry and material properties. Unless pre-existing microcracks are observed the collinear crack system found in the fracture of quasi-brittle materials is usually caused by crack bridging.

(Received 5 December 1994; revised version received 24 May 1995; accepted 25 May 1995)

Abstract

The sintering-aid effect of 1 vol% Ni_3Al powder addition on the nitridation of silicon at 1300–1350°C for 5–20 h and its influence on mechanical properties of the reaction sintered material have been studied. The addition of 1 vol% Ni_3Al accelerates the nitriding rate of silicon and promotes the formation of β-Si_3N_4; no free silicon phase was detected by X-ray diffraction in the 1 vol% Ni_3Al-added sample nitrided at 1350°C for 20 h. The 1 vol% Ni_3Al-added sintered material has higher relative density, higher Vickers hardness and indentation fracture toughness but lower Young's modulus and flexural strength than the contemporaneously processed reaction-bonded silicon nitride.

1 Introduction

Reaction-bonded silicon nitride (RBSN) is formed by reacting a silicon powder preform with either nitrogen or ammonia. Its outstanding characteristic is that net shape components can be prepared because no shrinkage occurs during the process, which leads to the formation of complex shapes without the expensive machining associated with sintering and hot-pressing processes. Another important advantage of reaction bonding is the absence of oxide sintering aids which degrade the high-temperature mechanical properties of sintered and hot-pressed materials.[1] In addition, combination of the advantages of the reaction-bonding process (lower shrinkage rate during sintering and lower raw material costs, compared with Si_3N_4 powder compacts) with those of hot isostatic pressing (HIP) (high density and excellent mechanical properties) has been considered,[2–4] using RBSN as starting material for HIP or sintering. The post-sintering and post-HIP of RBSN have resolved the high porosity (12–30 vol%) problem of RBSN.[5]

RBSN formation from conventional powders typically requires several days at temperature ranging up to 1420°C,[5] resulting in mainly α-Si_3N_4 phase. Our previous studies[6,7] on reaction-bonded sintering of Si_3N_4 intermetallic composite have demonstrated that the addition of Ni_3Al powder accelerates the nitridation of silicon and promotes the formation of β-Si_3N_4 phase at a low temperature such as 1250°C through the presence of some liquid phase resulting from the reaction between Ni_3Al and Si, accompanied by the formation of intermetallic compounds of the type Ni_xSi_y. Accordingly, the anomalous thermal hardening nature of Ni_3Al, i.e. the strength increases with temperature,[8] cannot be utilized. On the other hand, when the amount of Ni_3Al addition was small, e.g. 1 vol%, the nitriding rate of silicon and the resulting relative density of the Si + 1 vol% Ni_3Al sample were higher than that of the contemporaneously processed silicon compact without Ni_3Al;[7] but it was also found that there was still free silicon phase being detected in the Si + 1 vol% Ni_3Al sample nitrided at 1250°C for up to 80 h. Therefore, in this paper, a new nitriding process of the Si + 1 vol% Ni_3Al system is investigated, in which Ni_3Al is used as a sintering aid. The resulting micro-structure as well as the influence of the Ni_3Al addition on mechanical properties are reported.

2 Experimental Procedure

Commercial silicon powders were ball-milled to a particle size of < 1 μm and mixed with 1 vol% of rapidly solidified Ni_3Al particles (about 20 μm) with respect to the final Si_3N_4. These intermetallic powders, produced by vacuum gas atomization and with the composition 73·12 Ni–18·82 Al–8·06 Cr–0·019 Mo–0·10 B at% (kindly supplied by

*Present address: Dipartimento di Scienza dei Materiali e Ingegneria Chimica, Politecnico di Torino, 10129 Torino, Italy.

R. N. Wright and J. R. Knibloe[9]), have a ductile behaviour. The powder mixtures were cold-pressed using a single-action stainless steel die and formation pressure of 250 MPa, producing green compacts with a density of about 62% of the theoretical value. The reaction sintering was carried out at 1300–1350°C for 5–20 h; the nitriding gas was a mixture of purified N_2+5% H_2, at atmospheric pressure. Pure silicon compacts were nitrided under the same conditions as reference material. The samples without Ni_3Al and with 1 vol% Ni_3Al are named SN and SN/NA1, respectively. The extent of nitridation was determined by the ratio between the weight of the nitrided sample (minus the weight of Ni_3Al added) and its theoretical weight assuming that all the silicon is converted into Si_3N_4.

The nitrided phases were identified by X-ray diffraction (XRD), using Cu$K\alpha$ radiation monochromated in the diffracted beam, on the core of samples; the α/β ratio was determined by the quantitative X-ray analysis method outlined by Gazzara and Messier.[10] Microstructure was characterized by scanning electron microscopy (SEM) on polished surfaces and on samples etched using a 10% HF+15% HNO_3 solution for 14 h. Densities of samples were determined before and after nitriding by weight and volume measurements and by Archimedes' principle. Bending strength of rectangular bars (3 mm × 4 mm × 45 mm) was measured at room temperature by four-point bending using spans of 40 and 20 mm at a crosshead speed of 1 mm min^{-1}. The Vickers microhardness was measured using loads from 9·8 to 196 N. The elastic modulus was measured by dynamic mechanical analysis (DMA) at room temperature. Fracture toughness was determined by the indentation crack length technique, calculated using the formula of Anstis *et al;*[11] the induced crack length and its propagation were observed by optical microscopy and SEM. Both the fracture toughness and the hardness were measured using five indentations for each specimen.

3 Results and Discussion

3.1 Effect of Ni_3Al addition on nitridation of Si and resulting microstructure

The reaction-sintering processes applied and the resulting nitrided fraction are shown in Table 1, which indicates that the nitrided fraction of the SN/NA1 sample is much higher than that of SN sintered in the same process. These values are consistent with the results reported in our previous work,[7] which concluded that the acceleration effect of Ni_3Al addition on the nitriding rate of Si was mainly due to the presence of some liquid phase resulting from the reaction between Si and Ni_3Al, leading to the formation of low melting intermetallics of the type Ni_xSi_y. The nitrided fraction of Si in SN/NA1 has been determined by the ratio between the weight of the nitrided sample and its theoretical weight minus the weight of Ni_3Al added (both at numerator and denominator), assuming that all the silicon in the sample is completely nitrided, as listed in Table 1. It is also supposed that the weight of Ni_3Al remains the same before and after sintering.

Higher temperatures and shorter times (1300–1350°C; 5–20 h) are employed in the present study and higher nitriding rates obtained, compared with the processes (1250°C; 5–80 h) and the nitrided fraction reported in our previous work.[7] Typically, no free silicon phase is detected in SN/NA1 nitrided at 1350°C for 20 h; the X-ray diffraction patterns of SN/NA1 and, for comparison, SN nitrided under the same condition are shown in Fig. 1. The α/β ratio in reaction-sintered SN/NA1 is about 6/4. In addition, no Ni_3Al but some nickel silicides have been detected which melt at about 1000°C and are considered to be responsible for the formation of β-modification Si_3N_4. In this work, it was difficult to identify the formulae of the nickel silicides accurately, because their amount is very small. For the SN sample, the nitrided fraction increases with increasing temperature and, as shown in Fig. 1, a small amount of β-Si_3N_4 has been found in SN nitrided at 1350°C for 20 h.

As the reaction between silicon and nitrogen is exothermic, it may result in overheating of the sample and this phenomenon would be more important when the nitriding temperature applied is sufficiently high. On the other hand, the presence of a small amount of metallic impurities can also decrease the melting temperature of silicon and accelerate the formation of β-Si_3N_4.[12,13] However, a large amount of free silicon has been also detected

Table 1. Nitrided fraction of the samples obtained under different sintering processes

Sample	*Nitrided fraction (%) under following processes*			
	1300°C, 5 h	*1300°C, 15 h*	*1300°C, 5 h+ 1350°C, 5 h*	*1350°C, 20 h*
SN	77·2	79·2	82·0	89·1
SN/NA1	85·3	89·2	91·3	95·2

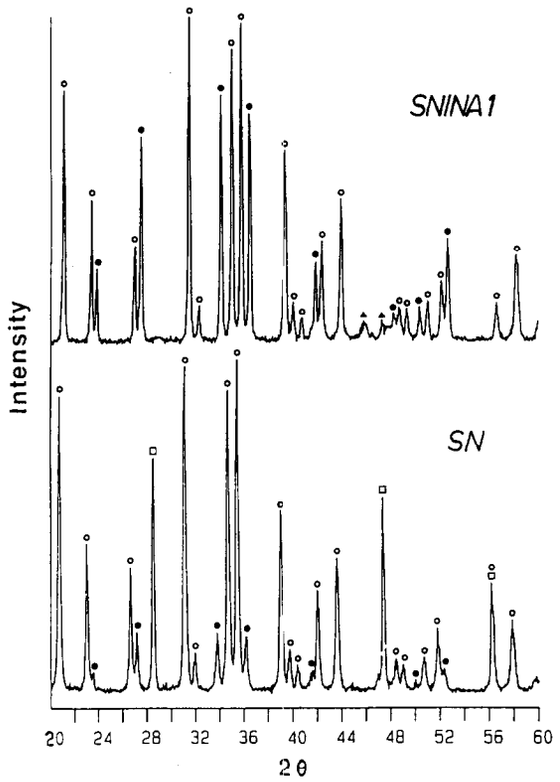

Fig. 1. X-ray diffraction patterns of the samples nitrided at 1350°C for 20 h: (○) α-Si_3N_4, (●) β-Si_3N_4, (□) Si, (▲) Ni_xSi_y.

by X-ray diffraction on the inner region of a cross-sectioned sample. This indicates that the surface is nitrided more rapidly than the bulk region for the pure silicon compact. On the contrary, no difference was found by X-ray diffraction analyses on the surface or the inner part of the SN/NA1 nitrided compact.

Figure 2 shows the morphology of SN/NA1 sintered at 1350°C for 20 h. The light particles are intermetallics, mainly nickel silicides, whose formulae have been determined on the sample containing 10 vol% Ni_3Al[6] and chiefly correspond to NiSi, $Ni_{31}Si_{12}$, Cr_3Si. It must be emphasized

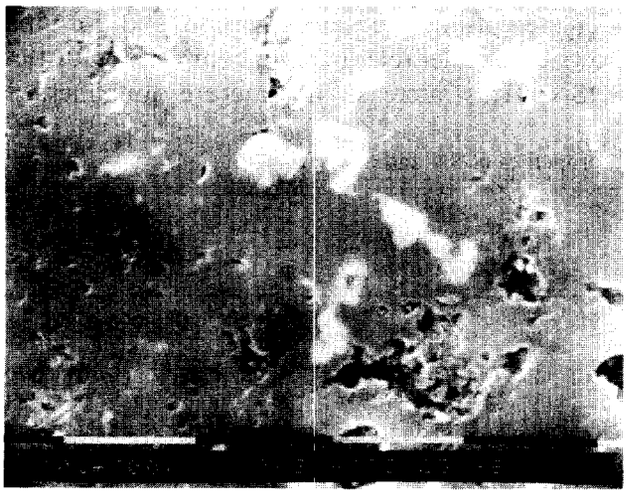

Fig. 2. SEM micrograph showing the morphology of SN/NA1 sample nitrided at 1350°C for 20 h.

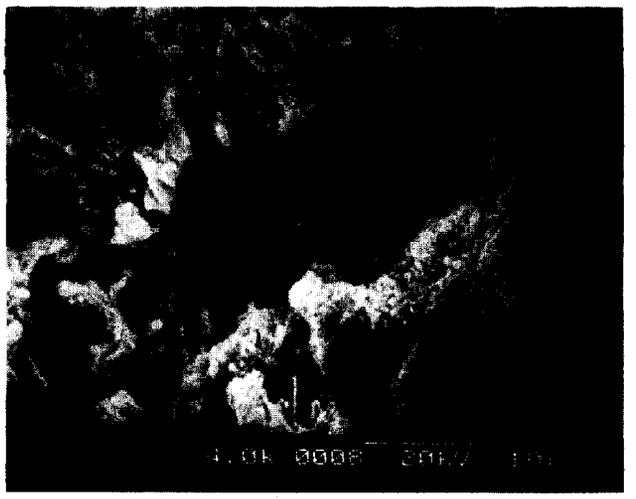

Fig. 3. SEM micrograph of an etched SN/NA1 sample, showing the cavity left by an intermetallic particle.

that more macropores (1–3 μm) were found in SN/NA1, probably owing to the reaction between Si and Ni_3Al, and this results in a less homogeneous microstructure than in SN. As indicated by X-ray diffraction analyses in Fig. 1, the microstructure of SN/NA1 consists of α-Si_3N_4, β-Si_3N_4 and traces of Ni_xSi_y intermetallics. SEM observation reveals that α-phase present in SN/NA1 contains α-grains and α-whiskers; α-grains are generally formed in zones far from intermetallic particles. On the contrary, α-whiskers and β-modification Si_3N_4 are preferably generated close to macropores and intermetallic particles because of the occurrence of some liquid phase. This is consistant with the formation mechanism of α-whisker and β-modification Si_3N_4 indicated in the literature.[5,14] Figure 3 shows a SEM micrograph of an etched SN/NA1 sample; in the cavity left by an intermetallic particle, α-whiskers and the rod-like β-Si_3N_4 are observed, as shown more clearly in Fig. 4 for α-whiskers and Fig. 5 for β-phase.

3.2 Influence of Ni_3Al addition on densification and mechanical properties of the composite

Table 2 shows the densities and mechanical properties of the SN/NA1 sample compared with two different samples of RBSN: one nitrided under the same conditions (1350°C, 20 h), the other having about the same nitrided fraction.[7]

The relative densities of SN and SN/NA1 nitrided at 1350°C for 20 h are about 80 and 90%, respectively, obtained from the ratio of the measured density and $3{\cdot}16 \times 10^3$ kg m^{-3} for SN and $3{\cdot}20 \times 10^3$ kg m^{-3} (calculated) for SN/NA1. SN/NA1 is denser than SN obtained under the same nitriding process due to the higher conversion rate of the silicon and the $\alpha \rightarrow \beta$ phase transformation of Si_3N_4,[15] although it has a less homogeneous microstructure than SN.

It should be mentioned that the values of flexural strength are not reported in Table 2 because of high scattering of the experimental data, which however show a decreasing trend of the flexural strength from SN to SN/NA1. Thus, for the mechanical properties, it can be said that the addition of 1 vol% Ni_3Al increases the Vickers hardness and the fracture toughness, but decreases the Young's modulus and the flexural strength, compared with both RBSN samples. The hardness of SN/NA1 was expected to decrease because both the Ni_3Al and Ni_xSi_y intermetallic phases are softer than silicon nitride, but the experimental results have shown a little increase, probably owing to the improvement of the relative density. As regards the decrease of the flexural strength of SN/NA1, a very significant influencing factor is the microstructure, especially the pore size. As indicated by Ziegler *et al.*[5] a homogeneous microstructure with a narrow pore-size distribution at moderate densities is better than a high-density material which contains large voids in order to achieve high-strength materials. Furthermore, the decrease in strength caused by large pores, formed during reaction bonding of the coarse-grained silicon powder, was demonstrated in the same paper. Thus, the presence of more macropores in the SN/NA1 sample results in the decrease in strength; on the other hand, it may be also responsible for the decrease of Young's modulus in SN/NA1. Even though a study on hot-pressed Si_3N_4[16] has illustrated an increase of strength with increasing amount of β-fraction and although a large amount of β-grains was found in SN/NA1, no improvement of strength was observed for this sample, perhaps owing to the inhomogeneous distribution of β-phase.

However, in contrast to reduced flexural strength, the indentation fracture toughness of SN/NA1 is higher than that of SN. Although it must be kept in mind that many formulae for the determination of K_{IC} from indentation are proposed in the literature,[17] each of them leading to different indentation toughness values,[18] the indentation crack length technique is still widely applied for toughness measurement of Si_3N_4 ceramics.[18,19] In the present work, the values of indentation fracture toughness for SN, ranging from 1·99 to 2·20 Mpa $m^{1/2}$, fall in the typical range of K_{IC} values, 1·5–2·8 MPa $m^{1/2}$, for RBSN.[5] The K_{IC} value of SN/NA1, calculated using the same method and formula, shows a considerable increase compared with that of SN. This increase in fracture toughness is

Table 2. Relative densities and mechanical properties of SN and SN/NA1

Property	*SN (1350°C, 20 h)*	*SN*[7] *(1250°C, 50 h + 1450°C, 10 h)*	*SN/NA1 (1350°C, 20 h)*

probably due to the formation of rod-like β-Si_3N_4 phase in SN/NA1 which, as reported in the literature,[19–22] shows the self-reinforcement and crack-bridging effects of the *in situ* formed β-Si_3N_4. Figures 6 and 7 show the propagation of the crack induced by the indentation in SN and SN/NA1, respectively, using a load of 196 N. It can be observed that the crack propagates smoothly in the SN sample and that it has an indented path, which causes energy consumption, around the weak intermetallic/matrix interface in SN/NA1.

4 Conclusions

The reaction-sintering processes of Si+1 vol% Ni_3Al at 1300–1350°C in purified N_2+5% H_2 atmosphere have been investigated. The addition of 1 vol% Ni_3Al accelerates the nitriding rate of silicon and increases the relative density of the resulting nitrided samples. No free silicon phase is detected by XRD in 1 vol% Ni_3Al-added samples nitrided at 1350°C for 20 h. The resulting nitrided fraction and the relative density are 95·2% and 89·80%, respectively, compared with 89·1% and 79·75% for the contemporaneously processed RBSN. The microstructure of SN/NA1 consists of α, β-Si_3N_4 with an α/β ratio of about 6/4, and a small amount of nickel silicide intermetallics; but SN/NA1 has more macropores than SN.

The Vickers hardness and the indentation fracture toughness of SN/NA1 are respectively 8·35 GPa and 2·54 MPa $m^{1/2}$, higher than those of SN owing to the higher relative density and the formation of rod-like β-modification Si_3N_4; but the Young's modulus and the flexural strength are slightly lower than in SN probably due to the presence of more macropores in SN/NA1.

(Received 20 January 1995; revised 19 May 1995; accepted 22 May 1995)

Abstract

Amorphous silicon nitride powders have been prepared in a tube reactor in the system silane–argon–ammonia in the temperature range 500–1100°C. The powders prepared at 500°C show the presence of elementary silicon. The powders prepared above 650°C are near stoichiometric in composition, isometric in morphology and the particle size distribution is in the range of 0·05–0·2 μm. The powders prepared at 1100°C are nearly monodispersive, having the particle size 0·1 μm. The influence of molar ratio of ammonia to silane shows that silicon nitride powder of near stoichiometric composition can be prepared above 11·62 and below this ratio the powders contain elementary silicon. The change in total gas flow rate shows that below 300 cm^3 min^{-1} the powders again contain elementary silicon and with further increase in flow rate the powders are near stoichiometric at 400 cm^3 min^{-1} and little hyperstoichiometric in nitrogen content at and above the flow rate of 500 cm^3 min^{-1}. Surface characterization by X-ray photoelectron spectroscopy indicates that most of the oxygen is confined on the surface and is present in the form of SiO_2.

1 Introduction

Silicon nitride based ceramics are well recognized as the material of the next generation, suitable for high temperature structural applications. Although there is a fast development in achieving superior high temperature mechanical properties, bending strength up to 950 MPa and fracture toughness 7·5 $MPa.m^{1/2}$,[1] however there are still opportunities left to improve these properties. It is commonly accepted that to prepare good quality ceramics the powder should have the following properties: low cationic impurity (< 2 wt%), low oxygen (< 2 wt%), > 95 wt% α phase content and average particle size in the range of 1 μm and close to monodispersive. Generally silicon nitride powders are prepared in four different ways: 1. nitriding of powdered silicon by nitrogen or ammonia; 2. silicon diimide, $Si(NH)_2$ decomposition; 3. carbothermal reduction and nitridation of silica; 4. gas phase reaction of silane or its halogen derivatives with nitrogen or ammonia.[2] Besides the described methods which are used in an industrial scale, there are several other synthesis methods which are under development at present, e.g. plasma synthesis, laser induced reaction etc.. The impurity contents are inherent to the method of preparation. The last mentioned method is usually applied in the deposition of thin coatings by chemical vapor deposition. Nevertheless, recently a lot of attention has been paid to prepare high quality silicon nitride powders from the gas phase reaction route.[3–8] There are three different ways in which the gas phase reactions are carried out: 1. laser induced reaction; 2. R.F. plasma synthesis;[5–8] 3. electrically heated reaction tube.[4] Each system has its own advantages and disadvantages. However, the powders prepared by the last technique are submicron and isometric. Addition of 20 wt% of this amorphous powder to the commercial powder (H. C. Stark, LC12 S) leads to the homogeneous nucleation of β-Si_3N_4, resulting in fine microstructure and improved mechanical property of sintered body.[9,10] The various gas phase systems in the deposition of thin coatings by chemical vapor deposition for application in electronics are: $SiCl_4$–NH_3, SiH_4–NH_3, $SiCl_4$–N_2–H_2, SiF_4–NH_3, SiH_2Cl_2–NH_3, $SiBr_4$–NH_3. But recently some work has been carried out to prepare ultra-fine nitride powders in the system SiH_4–N_2–NH_3[4] and SiH_4–Ar–NH_3.[3]

The main aim of the present work is to study extensively the influence of different parameters

such as temperature, ratio of NH_3 to SiH_4, flow rate of the total gas and influence of the carrier gas Ar with respect to N_2 on the particle size, morphology and the quality of the product in the system SiH_4–Ar–NH_3.

2 Experimental

Ammonia gas of technical purity (99·5%), electronic grade silane (15 wt% in argon) and argon (purity 99·5%) were used for the experiment. The details of the experimental set up of the hot wall reactor is described in an earlier publication.[4] The reactor dimensions are as follows: internal diameter = 46 mm and length = 500 mm. There was a little modification made in the sample collector to improve the collection efficiency and avoid choking of the glass frit. In the present experiments a new multiple sample collector was designed with the mechanical scrubber and rotary valve to get multiple number of samples synthesized in different conditions in one run. The schematic description of the apparatus is given in Fig. 1. The first set of experiments were carried out by varying the mole ratio of NH_3 to SiH_4 (r) in the range of 3–20 keeping the total flow of gas across the reactor at 400 cm^3 min^{-1} and temperature of reaction at 650°C. In the second set of experiments the total gas flow varied in the range of 200–600 cm^3 min^{-1} simultaneously maintaining the ratio of NH_3 to SiH_4 at 11·62 and reaction temperature at 650°C. In the third set of experiments r was constant at 11·62 and the total flow of gas increased from 400–1000 cm^3 min^{-1} by the introduction of argon stepwise and keeping the reaction temperature at 650°C. The last set of experiments were carried out in the temperature range between 500–1100°C at fixed ratio of NH_3 to SiH_4 at 11·62. In all the experiments the pressure of the reactor was kept at 110 kPa.

The properties of the powders were studied by XRD analysis, SEM, FTIR spectroscopy. The elemental analysis of silicon was done by neutron activation analysis, oxygen by LECO TC-136 and nitrogen by titrimetric method (Kjelldahl method). The surface composition of the powders were analyzed by XPS.[11]

3 Results and Discussion

In the earlier study,[4] it was revealed that in the system SiH_4–N_2–NH_3, nitrogen acts merely as a carrier gas, since in the system SiH_4–N_2 on Si_3N_4 formation was observed up to 1400°C. The molar ratio of NH_3 to SiH_4 of about 11, temperature at 650°C and total gas flow rate of 400 cm^3 min^{-1}

Table 1. Chemical composition of the products prepared at various mole ratios NH_3/SiH_4 at a constant temperature of 650°C and a flow rate of 400 cm^3 min^{-1}

r	*3*	*4*	*5·18*	*6·66*	*8·57*	*11·62*	*14·66*	*20*
N (wt%)	34·81	38·09	38·06	38·0	38·53	39·89	39·95	39·88

were suggested as the optimum conditions for the production of amorphous silicon nitride powder of near stoichiometric composition in the system SiH_4–N_2–NH_3. On the basis of these results the conditions for the present experiments were chosen.

3.1 Influence of NH_3/SiH_4 ratio, (r)

The effect of the molar ratio of ammonia to silane was studied in the range from 3–20 at a constant temperature of 650°C and total flow rate of gases at 400 cm^3 min^{-1} across the reactor. The characteristics of the products are given in Table 1.

From the nitrogen content analysis it is observed that at lower r value the nitrogen content is below the stoichiometric composition (39·96 wt% of N_2) of silicon nitride. When the r value is 11·62 and above, the products contain the stoichiometric amount of nitrogen. The trend in nitrogen content with the change in molar ratio is plotted in Fig. 2. It can be seen that for the synthesis of nearly stoichiometric silicon nitride powder a relatively excess amount of ammonia is required. Low molar ratio products are brown to light brown in colour indicating the presence of elementary silicon. As the r value is increased to 11·62 and above, the products are white and near stoichiometric in composition. However, when a high excess amount of ammonia is present, the product is a little hyperstoichiometric in nitrogen content. In the present experiments, no decrease in the nitrogen content was observed by increasing the molar ratio (r) above 11, which was distinctly observed in the previous work in the system SiH_4–N_2–NH_3.[4] The present result is in agreement with the earlier results:[3,4] that near stoichiometric silicon nitride can be prepared at a molar ratio of ammonia to silane 11. SEM studies of the powders show that powders prepared at a lower molar ratio (r), i.e. 3 and 4, are agglomerated. The particles have a tendency to agglomerate and form necks and rings.

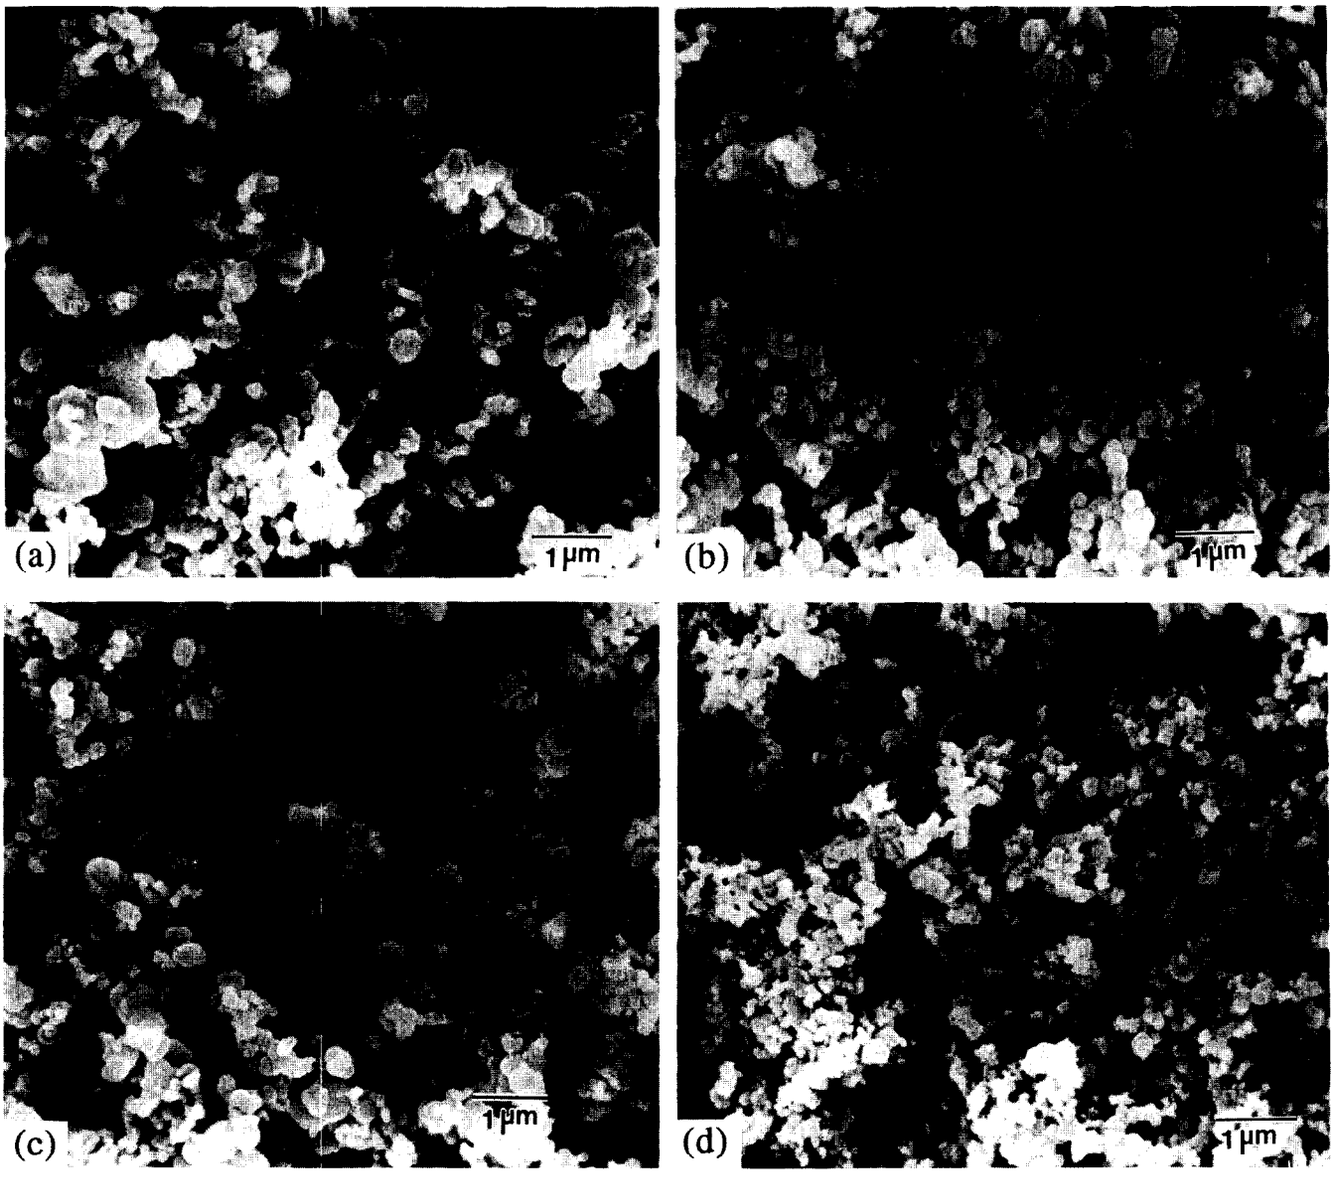

Fig. 3. SEM photographs of powders: (a) prepared at 650°C, total gas flow rate 400 cm^3 min^{-1} and ammonia/silane ratio = 11·62; (b) at 650°C, total gas flow rate 400 cm^3 min^{-1} and ammonia/silane = 20; (c) at 650°C, total gas flow rate 600 cm^3 min^{-1} and ammonia/silane ratio = 11·62; (d) at 1100°C, total gas flow rate 400 cm^3 min^{-1} and ammonia/silane ratio = 11·62.

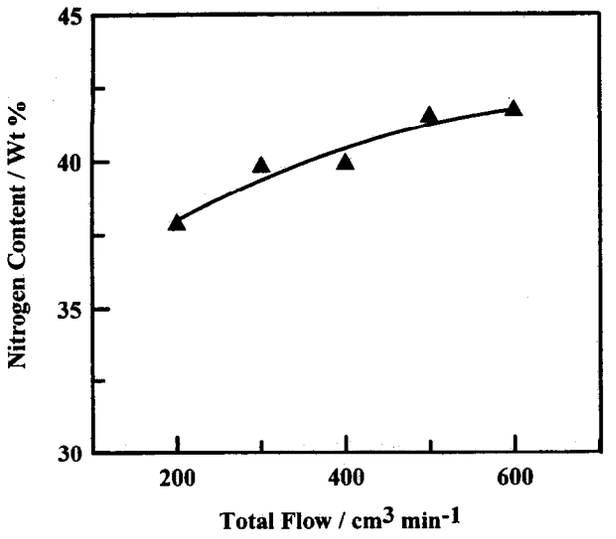

Fig. 4. The change of nitrogen content against total gas flow rate at 650°C and ammonia/silane = 11·62.

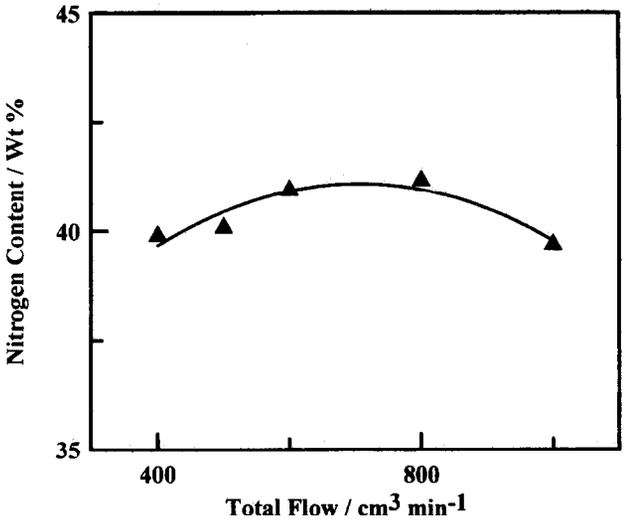

Fig. 5. The change of nitrogen content against total gas flow rate by the addition of argon to 400 cm^3 min^{-1} of the original gas mixture at 650°C and ammonia/silane ratio = 11·62.

At molar ratio of 5·18 and 6·66 the products are less agglomerated. At a further increase of molar ratio, the size of particles are in the range of 0·05–0·2 μm and practically without agglomeration. An SEM photograph of a product at molar ratio 11·62 is shown in Fig. 3(a). There is no large change in the particle size and morphology with further change in the molar ratio up to 20, which can be observed from Fig. 3(b).

Considering the stoichiometry in composition and quality of the product the powder prepared at r = 11·62, seems to be the optimum. So these synthesis conditions have been adopted as the basis for the next experiments.

3.2 Influence of total gas flow rate

In order to investigate the effect of the total flow rate of gases across the reactor, the temperature and molar ratio of ammonia to silane (r) were kept constant at 650°C and 11·62 respectively and the total flow rate, i.e. NH_3 (g) + SiH_4 (g) was varied from 200–600 cm^3 min^{-1}. The characteristics of the powders are presented in Table 2. The nitrogen content is plotted against the flow rate in Fig. 4. Increase of the flow rate above 300 cm^3 min^{-1} increased the nitrogen content gradually above the stoichiometric composition. When the total flow rate is 200 cm^3 min^{-1}, the nitrogen content is well below the stoichiometry. In this case the elementary silicon was increased and the colour of the product was light brown. This indicates that at a lower total gas flow, the rate of formation of elementary silicon is promoted. On the other hand, its recombination with ammonia leading to the formation of silicon nitride is limited at lower temperatures.

SEM observation shows, Fig. 3(c), that a finer product was obtained at a higher flow rate of 600 cm^3 min^{-1} (compare Fig. 3(a) and (c)). This fact is also confirmed by the specific surface area measurement by BET: the product prepared at 400 cm^3 min^{-1}, shown in Fig. 3(a) has a specific surface area of 12 m^2 g^{-1} whilst the product prepared at 600 cm^3 min^{-1}, shown in Fig. 3(c) has a specific area of 14 m^2 g^{-1}. The particle size distribution of this finer product is narrow and varies in the range from 0·05 to 0·2 μm.

In another series of experiments, the total gas flow rate has been increased by the addition of argon stepwise to the original total flow of gas 400 cm^3 min^{-1} of NH_3(g) + SiH_4(g) + Ar(g) to 1000 cm^3 min^{-1} keeping temperature at 650°C and the molar ratio of ammonia to silane at 11·62.

Table 2. Chemical composition of the products at various total gas flow rates and at constant molar ratio of NH_3/SiH_4 = 11.62, T = 650°C

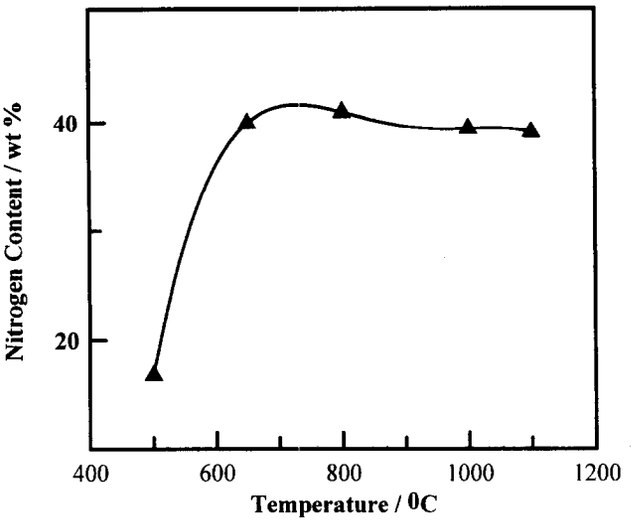

Fig. 6. The change of nitrogen content against temperature of synthesis at total gas flow rate 400 cm^3 min^{-1} and ammonia/silane = 11·62.

The chemical composition of the products are given in the Table 3, and the change of nitrogen content with respect to the total flow rate is shown in Fig. 5. From these results, it is obvious that with an increase in the flow rate there is a slight tendency to increase the nitrogen content up to 800 cm^3 min^{-1}.

3.3 Influence of temperature

For this series of experiments, the total gas flow rate was kept at 400 cm^3 min^{-1} and the mole ratio of ammonia to silane at 11·62. The chemical composition and characteristics of the products prepared in the temperature range between 500 and 1100°C are given in Table 4 and the dependence of nitrogen content on the temperature is shown in Fig. 6. From Table 4 and Fig. 6 it is clear that silicon nitride of near stoichiometric composition can be prepared at and above 650°C. At 500°C the product contains only 16·79 wt% of nitrogen and a proportionately higher amount of silicon. It seems that 650°C is the critical temperature for the formation of silicon nitride in this system. Below this temperature there is a tendency of the formation of elementary silicon. From the thermodynamic analysis (Table 5), it is obvious that the enthalpy of reaction 1 is negative, that means silicon nitride should have formed at this temperature without elementary silicon. The fact that elementary silicon is present in the product at 500°C is due to kinetic reasons. At this temperature, the decomposition rate of silane is higher than the recombination of elementary silicon to silicon nitride.

Table 5. Thermodynamic data of the different reactions

Reactions	ΔG *at 700 K* *kcal/mol*	ΔG *at 900 K* *kcal/mol*
1. 3 SiH_4 + 4 NH_3 → Si_3N_4 + 12 H_2	−212·65	−232·90
2. SiH_4 → Si + 2 H_2	−21·29	−25·97
3. 3 Si + 4 NH_3 → Si_3N_4 + 6 H_2	−148·78	−154·98

Table 6. Surface chemical composition of powders as determined by XPS (in at%)

Total gas flow rate (cm^3 min^{-1})	*Si*	*N*	*O*	*C*	*N/Si*	*O/Si*
200	28·42	24·87	38·47	8·24	0·88	1·40
300	27·44	28·69	33·13	10·74	1·05	1·20
400	28·45	26·21	38·79	6·55	0·92	1·36
500	28·39	26·60	36·48	8·52	0·94	1·28
600	28·09	24·50	39·70	7·71	0·87	1·41

The product prepared at 650°C is not agglomerated and the particles are isometric with the size from 0·05 to 0·2 μm, Fig. 3(a). On the other hand with an increase of the reaction temperature, the refinement of the product was observed. At 1100°C, superfine almost monodispersive isometric powder was prepared with the particle size ranging from 0·05 to 0·1 μm, Fig. 3(d)

The formation of finer powders at higher temperatures is most probably due to the creation of more nucleation centers. The powders are still mainly amorphous at 1100°C with partial crystallization, at about 5–10%.

4 XPS studies

According to the wide scan spectra registered for the samples prepared at 650°C r = 11·62 and with varying total gas flow rates from 200 to 600 cm^3 min^{-1}, Si, N, O and C could be detected on the surface (The characteristics of the powders are presented in Table 2). As an example the wide scan spectra of samples prepared at 400 cm^3 min^{-1} is presented in Fig. 7. The surface chemical composition and the N/Si and O/Si atomic ratios were calculated from the relevant wide scan spectra and

Table 4. Chemical composition of the products prepared at a constant molar ratio NH_3/SiH_4 of 11·62 and total gas flow rate of 400 cm^3 min^{-1} at various reaction temperatures

Temperature (°C)	*500*	*650*	*800*	*1000*	*1100*

Si (wt%)	80·50	59·39	58·58	59·49	59·30
Σ	99·5	100·71	101·31	100·26	99·56
Colour	Brown	White	White	White	Light tan

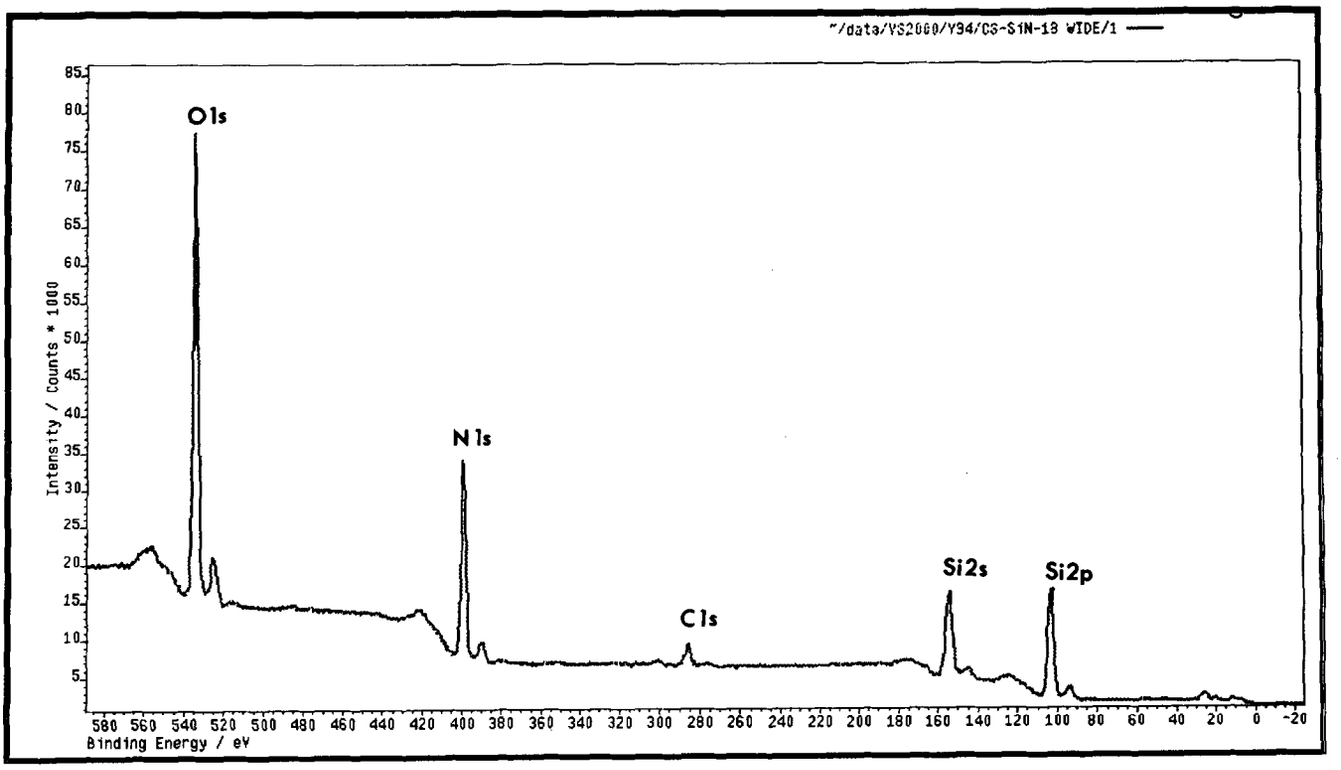

Fig. 7. Wide scan XPS spectrum of the powder prepared at 650°C, total gas flow rate 400 cm^3 min^{-1} and ammonia/silane ratio = 11·62.

summerized in Table 6. It is evident that all samples are characterized by a high surface oxygen content. In addition the tendencies in the changes of the bulk and surface compositions against the total flow rate of gases are similar (see Tables 2 and 6).

Deconvolution of the Si 2*p* peak (Fig. 8) refers to the simultaneous presence of Si–N and Si–O bonds. So most of the oxygen on the surface is present in the form of SiO_2.

5 Conclusions

Effects of the NH_3/SiH_4 molar ratio, total gas flow rate and reaction temperature on the properties of

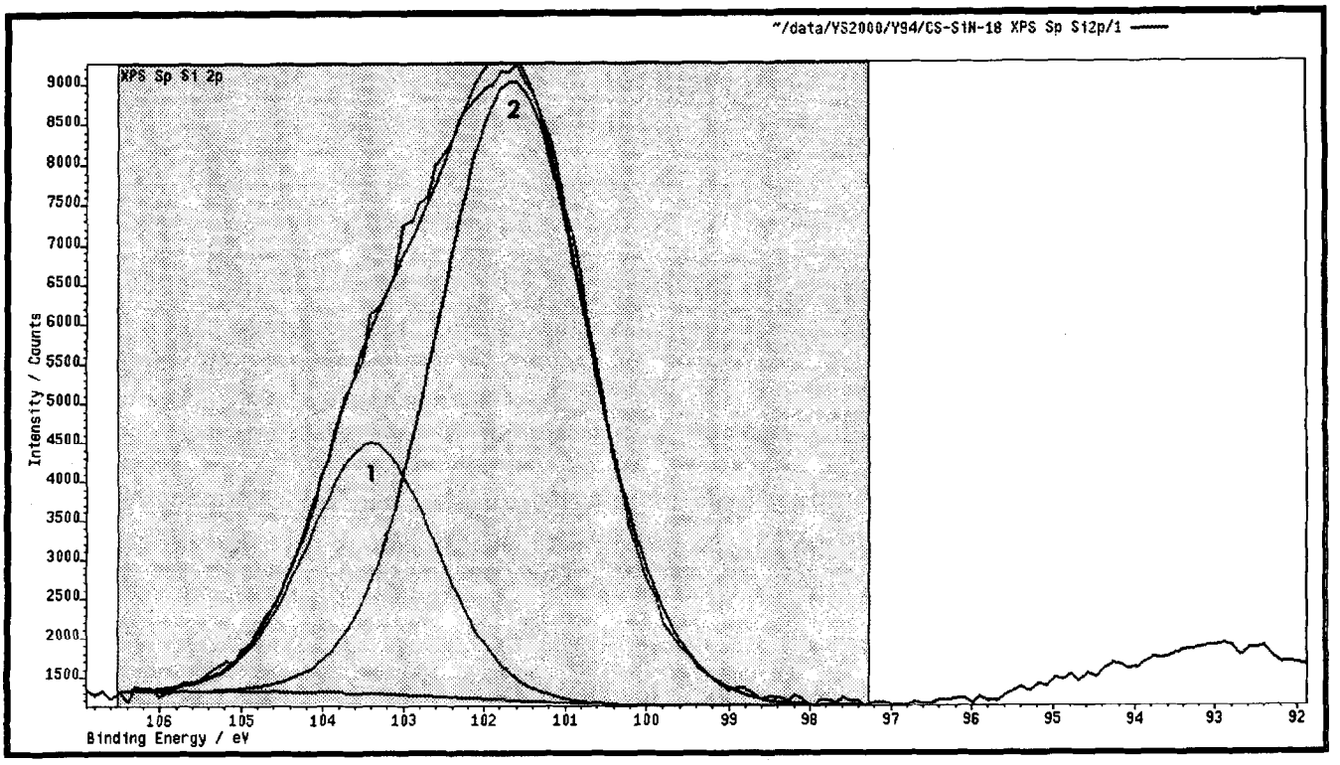

Fig. 8. Deconvolution of Si 2*p* peak; peak 1 corresponds to Si–O; peak 2 to Si–N bonds.

Si_3N_4 powders prepared in the system SiH_4–NH_3–Ar in a tube reactor have been investigated. It was found that for the formation of a stoichiometric silicon nitride powder, the NH_3/SiH_4 molar ratio should be kept at about 11. The total gas flow rate above 400 cm^3 min^{-1} creates more finer fractions of the powder without changing the morphology of the particles. However, powders of hyperstoichiometric in nitrogen content are being formed at higher flow rates. The temperature of synthesis has a substantial influence both on the nitrogen content as well as the mean particle size of the products. The optimum conditions for the preparation of nanosized, isometric, mainly amorphous silicon nitride powders in the given system are: NH_3/SiH_4 molar ratio = 11·62, total flow rate = 400 cm^3 min^{-1}, temperature 650°C.

Abstract

The surface characteristics of pure AlN powders are compared with those of so-called water stabilized powders. Both commercially available powders and stearic acid coated powders are used. By means of XPS, diffuse reflectance infrared spectroscopy and thermally programmed desorption mass spectrometry, information is obtained about the presence of surface groups. The behaviour of the different powders in aqueous suspension is compared by means of pH measurements and determination of the isoelectric points.

1 Introduction

The behaviour of powder suspensions is largely controlled by the surface chemistry of the solid. Also the sintering behaviour is influenced by the presence of physisorbed and chemisorbed surface groups. In nitride powders the surface oxygen content is also of particular importance for the sinterability. In case of AlN the oxygen content also influences the heat conductivity of the dense material. The chemical stability of AlN powders against oxidation and hydration is low and in water hydrolysis takes place. The reaction with water molecules is so fast that slip casting in aqueous suspensions is in fact not possible. For this reason some manufacturers produce AlN powders which have been treated chemically to increase the water resistance. Little is known about the surface chemistry of such AlN powders. Bowen *et al.*[1] showed the hydrolysis of uncoated AlN using diffuse reflectance infrared spectroscopy (DRIFT). A surface layer of stoichiometry close to AlOOH is formed, which gradually transforms into $Al(OH)_3$ according to the reactions:

$$AlN + 2H_2O \rightarrow AlOOH_{amorph} + NH_3 \quad (1)$$

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \quad (2)$$

$$AlOOH_{amorph} + H_2O \rightarrow Al(OH)_3 \quad (3)$$

This reaction is strongly dependent on pH and temperature.[2] Egashira *et al.*[3,4] suppressed the surface reactivity using carboxylic acid adsorption. They assume that surface hydroxyl groups play an important role during the adsorption, according to a reaction

$$\equiv Al\text{–}OH + HOOC\text{–}R \rightarrow \equiv Al\text{–}O\text{–}\underset{\underset{O}{\|}}{C}\text{–}R + H_2O$$

To obtain more insight in the surface chemistry we have used different surface characterization techniques. In this paper we present results of characterization of pure and so-called water-resistant AlN powders.

2 Experimental

Table 1 gives a survey of the specifications of the powders used. Powders C and D (A100 and A200 from Advanced Refractories Technologies, ART, Buffalo, NY, USA) and E (Toyalnite WF from Toyo Aluminium K.K., Osaka, Japan) are commercially available water-resistant powders. AlN powder A (grade C from Starck, Berlin, Germany) was tested as-received and compared with the water resistant powders. Powders B were the Starck C powders coated by us according to the procedure described by Egashira *et al.*[3] Powder B1 was coated with stearic acid by refluxing in benzene, for powder B2 cyclohexane was used as a solvent. Further details are given in Ref. 5.

The reactivity in water was measured by following the change in pH for 0·05 wt% suspensions. To obtain a stable suspension of the powders C and D 1 wt% of the deflocculant Triton X100 (a polyoxyethylene alkylether) was added to these powders.

*On leave of absence from Guanxi University, Nanning, PR China.

Table 1. Specification of AlN powders

Sample No.	*A*	*B1, B2*	*C*	*D*	*E*
Origin	Starck Germany	Powder A coated with stearic acid	ART USA	—	Toyo Aluminium, Japan
	Grade C		A100	A200	Grade WF
FSSS, μm	1·2	as A	3–4	3–4	1·94
BET, m^2/g	3·7	as A	2·5–4	2·5–4	4·30
Al wt%	64·7	as A	66·05	66·0	—
N wt%	33·5	as A	33·0	32·7	32·9
O wt%	1·7	—	1·0	1·1	1·39
Si ppm	—	—	1000–2000	1000–2000	58
Water resistance (h)	—	6–12	2·5–4	—	>72

To measure the pH_{iep} at the isoelectric point the powders were dispersed in water (again with Triton deflocculant in case of the powders C and D), containing 0·01 M KNO_3 electrolyte. The suspensions were stabilized at pH = 2·5 and titrated with 0·1 M KOH under vigourous stirring. The pH_{iep} was found from the zero crossing of the electroacoustic signal, using a Matec ESA analyser. For three powders XPS measurements were performed using a PHI Model 550 system and Al Kα radiation. On four powders diffuse reflectance infrared Fourier transform spectroscopy (DRIFT) was used. The region 4000–800 cm^{-1} was scanned with 4 cm^{-1} resolution, using 500 scans to improve the signal to noise ratio. Powders were diluted in KBr and measured against KBr as reference.

Finally we used thermally stimulated desorption (TPD) to obtain information about adsorbed species and their binding energies to the surface. Similar experiments for the characterization of Si_3N_4 powders have been published earlier.[6,7] In the TPD equipment the sample is heated under high vacuum, while the desorbed gases are monitored by a mass spectrometer. A loosely pressed powder sample of about 20 mg is placed in a sample holder in the first vacuum chamber, which is pumped by a turbomolecular pump to 10^{-7} mbar. After one night, the sample holder is transferred to the main vacuum chamber, which is pumped with an ion getter pump to a vacuum of $<5 \times 10^{-8}$ mbar. In this chamber the sample can be heated by means of an electron gun heater at a rate controlled by a PID controller. Presently the sample is surrounded by stainless steel radiation shields. This limits the maximum sample temperature to about 900°C, due to outgassing of the radiation shields. The desorbed gases are monitored by means of a quadrupole mass spectrometer (Balzers QMG511). Using the relative ionization cross sections for the different molecules, measured curves were corrected. No attempts were made to calculate ion concentrations.

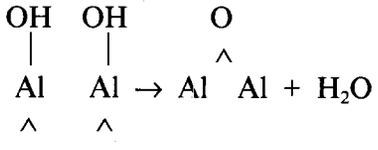
3 Experimental Results

3.1 XPS measurements

Results of the XPS measurements on pure and coated AlN powders are summarized in Table 2. The peaks at 77 and 400 eV are ascribed to Al and N respectively. The energies correspond to Al^{3+} and N^{3-}, and thus these peaks are due to bulk AlN. The carbon peaks at 288 eV are due to contamination; probably the same holds for the oxygen peak at 535 eV. Powder C shows silicon peaks at 105 and 180 eV. According to the supplier 1000–2000 ppm Si is present in these powders. Evidently this silicon is present in the surface coating. The carbon peak in this material is shifted over 0·7 eV; however, it is uncertain if this indicates the presence of organic carbon atoms. The spectra of powder E contain peaks at 199·2 and 149·2 eV

Table 2. XPS peaks for different AlN powders

Sample	*Peak centre (eV)*	*Element*
Starck Grade C (uncoated) powder A	76·7	Al
	400·0	N
	534·7	O
	287·8	C
ART A100 powder C	76·9	Al
	400·0	N
	534·7	O
	287·1	C
	105·0; 180·0	Si
Toyalnite powder E	77·4	Al
	119·02; 149·2	P (from phosphate)
	400·3	N
	535·6	O
	287·8	C



which are assigned to P in phosphate groups. The shift of the oxygen peak with 0·9 eV may also be due to the bonding in the phosphate group. The presence of phosphate is in accordance with a remark in Ref. 8.

3.2 DRIFT spectra

All powders show about 8 strong bands between 600 and 1400 cm^{-1} which can be assigned to lattice phonons of AlN.[9] A weak band at 1973 cm^{-1} in powder E agrees well with the $3TO_1$ mode found in Ref. 9. Broad IR bands at 1600 cm^{-1} and around 3400 cm^{-1} are due to weakly bonded water molecules. Powders B clearly show the CH_2 stretching bands around 2800 cm^{-1}, originating from the stearic acid coating. The spectra of the powders C and D show two extra peaks which could not be assigned unambiguously. For instance a peak at 2160 cm^{-1}, present in both C and D may be assigned to a metal–hydrogen band. Ref. 10 attributes this band on pure AlN to Al–H stretching, although the authors note that the frequency is rather high in comparison with AlH in aluminium hydrides. However, the same frequency is observed for Si–H on Si_3N_4 powders.[11] The band is not present in the uncoated powder, and since XPS shows the presence of Si on the surface of powder C this suggests that it is due to an SiH vibration. However, the absorption is also present in powder E, where no Si was found with XPS. A broad band in both powders at 3200 cm^{-1} may be due to NH,[9] while a sharper peak at 2965 cm^{-1} may indicate the presence of carbon. These assignments remain uncertain, however.

3.3 Temperature programmed desorption

TPD spectra of the different powders are shown in Figs 1–5. All powders show a high desorption peak of water at about 100°C. This is clearly physisorbed water. However, the water desorption continues up to about 600°C. By analogy with the reaction of silanol groups on silicon nitride, this may be due to the surface reaction

After coating with stearic acid (powders B) the physisorbed water peak has a much lower intensity. As could be expected, the stearic acid coated material shows many peaks due to decomposition products of the organic coating, e.g. C_6H_{11}, C_6H_7, C_6H_5, C_4H_9, C_4H_7, C_3H_7, C_3H_5, C_2H_5, and lower masses. Figure 2 shows two of these peaks, at mass 41 and 55 respectively. The hydrocarbons show a desorption maximum at about 400°C,

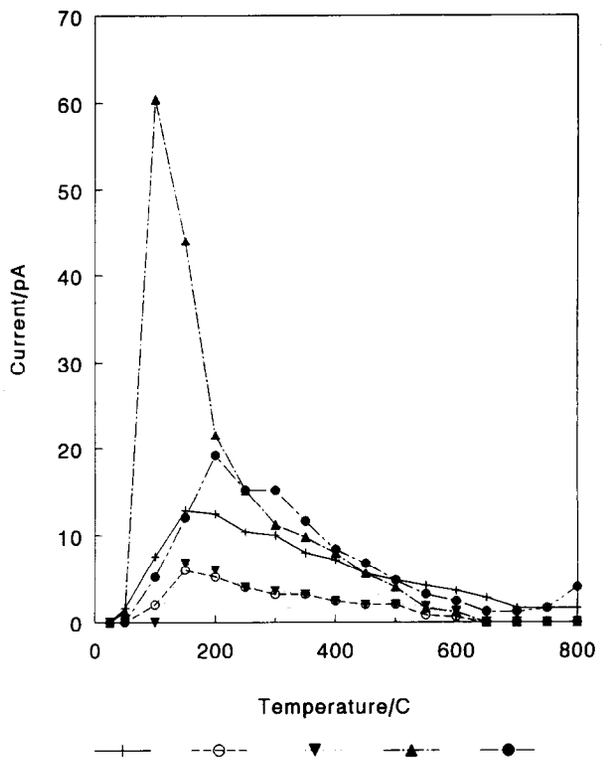


Fig. 1. TPD mass spectrum of uncoated AlN (powder A). Legends from left to right + M = 2, H_2; ○ M = 16 and ▼ M = 17 overlapping peaks NH_2, NH_3; ▲ M = 18, H_2O; ● M = 28, N_2.

indicating that the coating is chemically bonded to the AlN surface. No difference was observed between the powders coated from stearic-acid benzene or stearic-acid cyclohexane solutions.

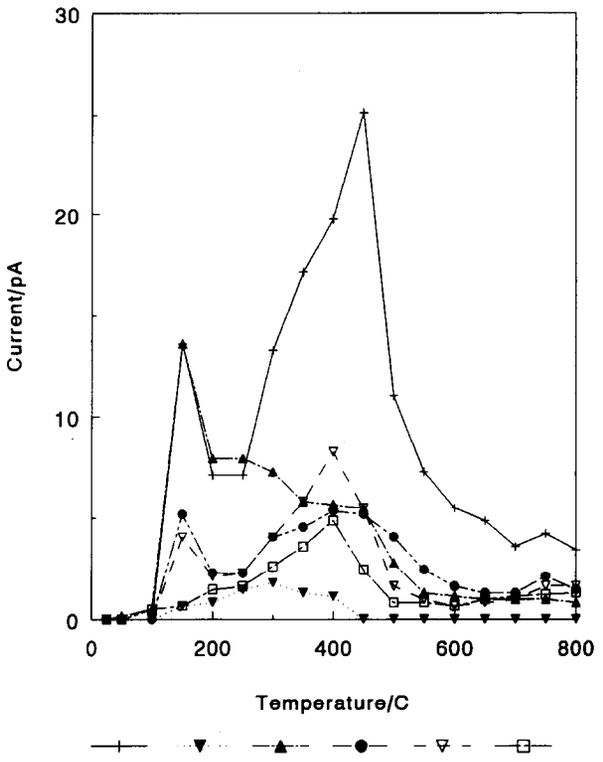

Fig. 2. TPD mass spectrum of stearic acid coated AlN (powder B). Legends from left to right + M = 2, H_2; ▼ M = 17, NH_3; ▲ M = 18, H_2O; ● M = 28, N_2; ∇ M = 41, C_3H_5; □ M = 55, C_4H_7.

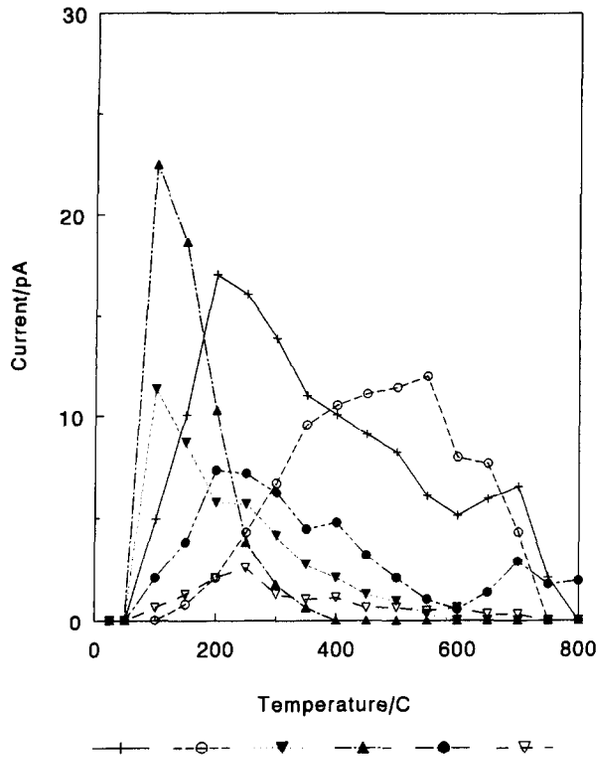

Fig. 3 TPD mass spectrum of water resistant AlN (powder C). Legends from left to right + M = 2, H_2; ○ M = 16, NH_2; ▼ M = 17, OH; ▲ M = 18, H_2O; ● M = 28, N_2; ▽ M = 41, C_3H_5.

Powder C shows a peak at mass 41, which may be due to hydrocarbon (note that in blank runs hydrocarbons have never been found, due to the clean vacuum system). The TPD spectrum of D shows a strong peak at mass 28 above 700°C, which is not observed in the other powders. This may be due to Si instead of N_2, as shown by the XPS and suggested by the DRIFT spectra, however, the fact that it is not observed with powder C contradicts this. Powders A, C, D and E all show desorption of NH_3 at about 150°C, indicating a weak bonding. As mentioned above, AlN reacts with water to form AlOOH and NH_3. Part of the ammonia formed by reaction of AlN with water vapour will remain adsorbed at the surface and may cause the low temperature desorption peak.

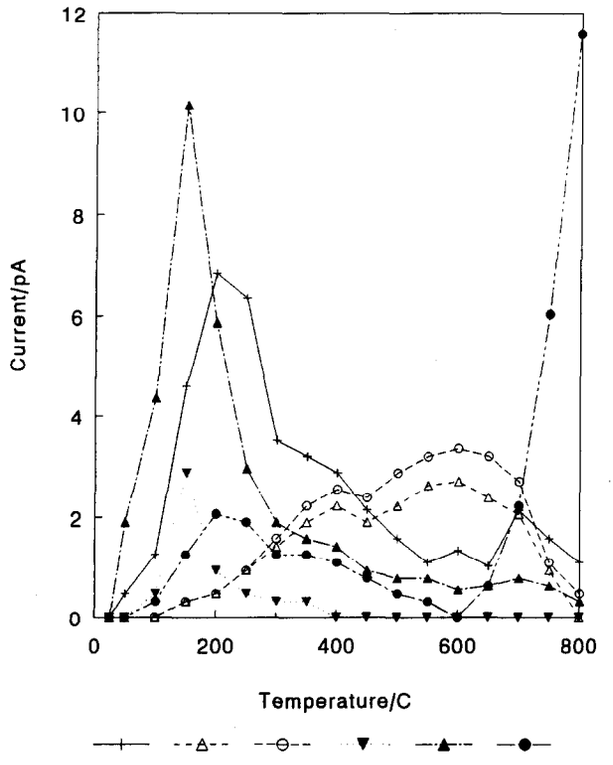

Fig. 4. TPD mass spectrum of water resistant AlN (powder D). Legends from left to right + M = 2, H_2; Δ M = 15, NH; ○ M = 16, NH_2; ▼ M = 17, OH; ▲ M = 18, H_2O; ● M = 28, N_2.

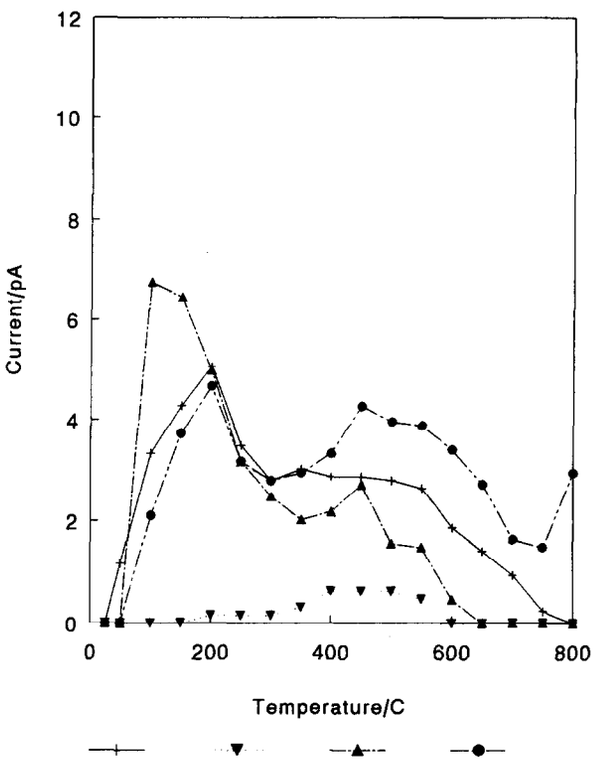

Fig. 5. TPD mass spectrum of water resistant AlN (powder E). Legends from left to right + M = 2, H_2; ▼ M = 16 and 17 overlapping peaks NH_2, NH_3; ▲ M = 18, H_2O; ● M = 28, N_2.

In all powders we find desorption of H_2 and N_2. The peaks are closely correlated and show maxima at 200 and about 400°C. A similar behaviour was found in Si_3N_4 powders.[7] In silicon nitride there is ample evidence for the presence of OH and NH surface groups.[13,14] Therefore we assume that the desorption of hydrogen and nitrogen from the AlN powders is also due to the presence of NH groups at surface sites. Powders C, D and to a lesser extent E all show a peak at about 500–600°C for mass 15 and 16. These peaks are also closely correlated and are therefore attributed to NH and NH_2. Desorption of powder E is low over the whole temperature range. No hydrocarbon peaks were detected for this powder. In view of the XPS results this may indicate a coating with phosphate without organic groups.

Milling of the uncoated AlN powder for 70 h in dry propanol gives a TPD spectrum identical with that of the untreated powder, i.e. the adsorbed species are not removed by this treatment. It also shows that AlN is quite stable in propanol, in agreement with the observation in Ref. 1.

We have also measured the TPD spectrum of uncoated Starck powder after heat treatment at 1000°C in nitrogen. Most of the H_2, N_2, and H_2O are removed, while the NH_3 and NH_2 peaks disappear almost completely.[12] A similar observation was made for silicon nitride powders.[7]

3.4 Electroacoustic measurements

The stability of the powders was measured by following the pH of aqueous suspensions at room temperature. Figure 6 shows the change in pH for 0·5 wt% suspensions of five different powders. The uncoated powder A starts to react from the very beginning. The end value for these dilute suspensions is about pH 11. As shown earlier the addition of Triton surfactant does not influence these results.[5] The figure shows that both the stearic acid coated powder B and powder E are stable for long times at room temperature. This confirms earlier results of Egashira *et al.*[3] No difference was observed between B1 and B2. Powders C and D are stable up to about 30 h, as specified by the supplier. One may suspect that the stability depends on the starting pH of the dispersions. Therefore we repeated the experiment with powder E, the most stable powder, using different initial pH values. Figure 7 shows the results. Suspensions of powder E show a decrease in stability at high pH values. For slip casting one uses much higher solid loadings. Therefore we followed the pH of 30 vol% (58 wt%) suspensions as a function of time (Fig. 8). The decomposition rate is considerably enhanced and hydrolysis of the uncoated

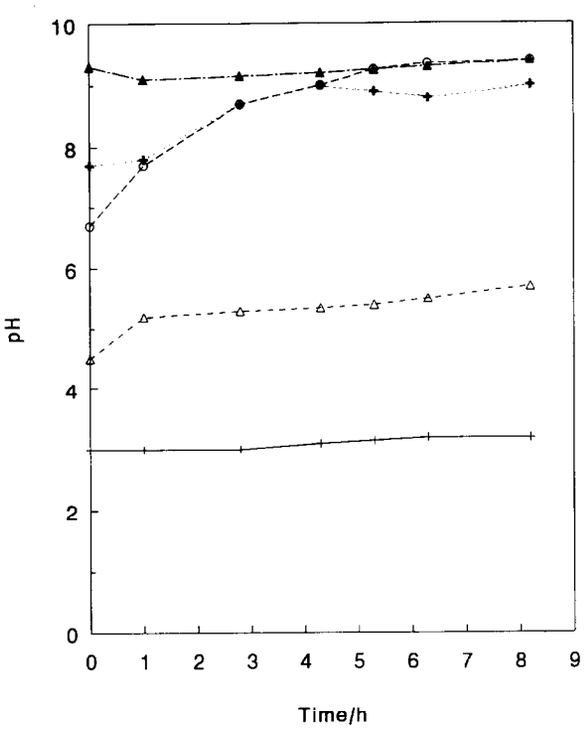

Fig. 7. Stability of powder E in water with different starting pH.

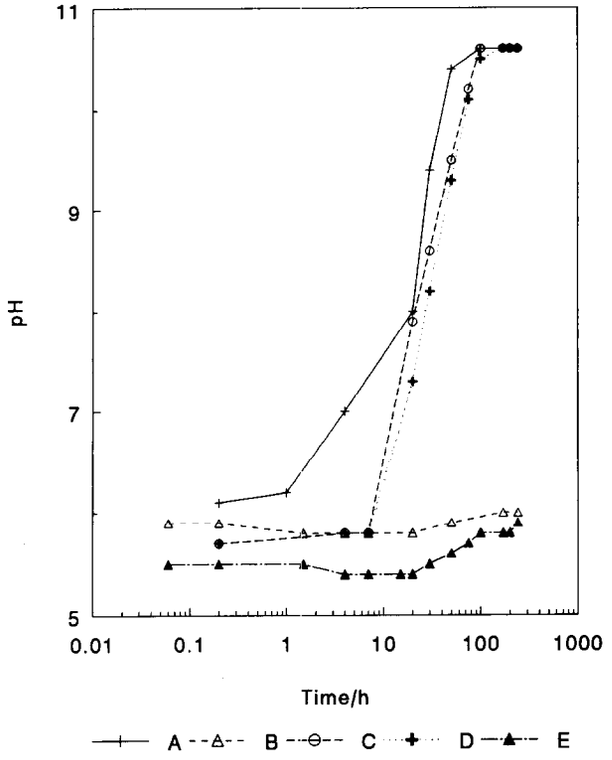

Fig. 6. Time dependence of pH of 0·05 wt% dispersions of AlN (powders A–E) in water.

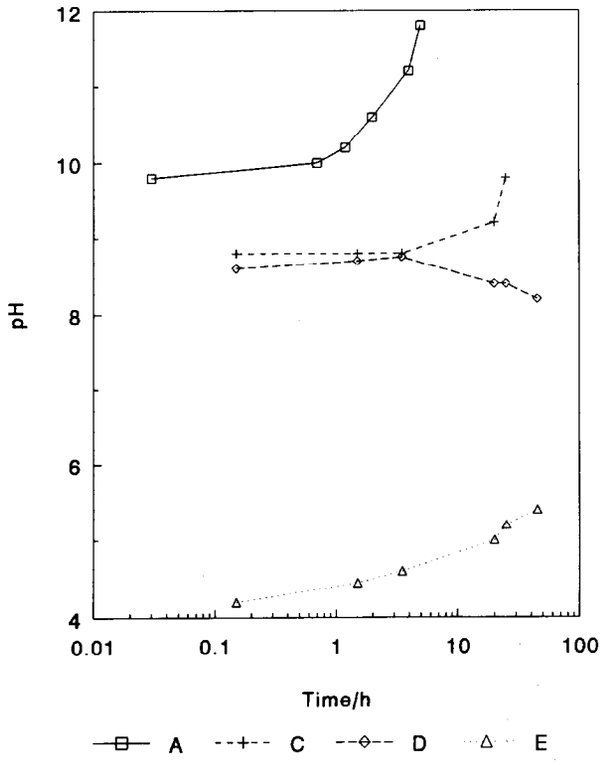

Fig. 8. Time dependence of pH of 30 vol% slips of AlN powders in water.

Table 3. Isoelectric point for suspensions with different solid contents

Sample	*Conc. wt%*	pH_{iep}
Starck Grade C	4	9·7
(powder A)	10	8·9
	25	8·8
	50	8·8
ART A100	4	8·5
(powder C)	10	8·5
	25	8·4
	50	8·1
ART A200	4	7·9
(powder D)	10	7·8
	25	7·7
	50	7·5
Toyalnite	4	6·0
(powder E)	10	6·0
	25	6·0
	50	5·8

powder is visible within 1 h. For powder B the reaction starts between 24 and 48 h. Due to the exothermal nature of the reaction the rate rapidly increases and the slip even became a solid mass. Note that although suspensions are made with water of pH = 7, the pH at the first measuring point after 2 min has changed considerably. Suspensions of powder E become acidic, powders C and D slightly basic. Results of the determination of the isoelectric point by means of ESA measurements are shown in Table 3. Measurements were performed for four different concentrations of the suspensions, *viz.* 4, 10, 25 and 50 wt% AlN in water. There is a slight tendency towards decreasing pH_{iep} values for increasing concentrations. The surface charge is positive below the isoelectric point and negative above. The pH_{iep} value of 8·9 for the uncoated powder is in close agreement with the value of 9·0 found by Seitz *et al.*[15] From a comparison with alumina these authors concluded that Al_2O_3 and AlN exhibit a similar surface. This would mean that the surface contains amphoteric AlOH groups, which may be ionized in solution according to the following reactions:

$$AlOH_2^+ \rightleftharpoons AlOH + H^+ \text{ (aq)}$$
$$K_1 = (H^+)(AlOH)/(AlOH_2^+) \quad (4)$$
$$AlOH \rightleftharpoons AlO^- + H^+ \text{ (aq)}$$
$$K_2 = (H^+)(AlO^-)/(AlOH) \quad (5)$$

The point of zero charge (pzc) is found when $(AlOH_2^+) = (AlO^-)$. From eqns 4 and 5 it follows that this is the case when $pH_{pzc} = (pK_1 + pK_2)/2$. Assuming $pH_{iep} = pH_{pzc}$ we find $pK_1 + pK_2 = 17{\cdot}8$. One also finds the ratio of basic to acid sites as a function of pH:

$$\log(AlOH_2^+)/(AlO^-) = pK_1 + pK_2 - 2pH = 17{\cdot}8 - 2\,pH \quad (6)$$

Powder E has a pH_{iep} of 6·0, which indicates the presence of acidic surface groups. This is in accordance with the observation of phosphate groups in the XPS and IR spectra. The behaviour of powder D indicates that the organosilicon coating results in a pH_{iep} of about 7·5. The pH_{iep} of powder C is in between the value of uncoated powder A and powder D, suggesting that the surface is incompletely covered. The higher water sensitivity of C compared to D points in the same direction. Both powders were poorly dispersable in water which is related to the hydrophobic coating.

4 Summary and Conclusions

The surface of coated and uncoated AlN powder has been investigated by means of XPS, DRIFT spectroscopy, TPD and electrokinetic measurements. Uncoated AlN has a surface similar to alumina with amphoteric AlOH groups. The stability of AlN in water increases in the sequence pure AlN<ART coated<stearic acid coated<Toyalnite coated. The surface of ART powder C seems to be only partially covered by a coating containing both silicon and organic carbon. Stearic acid gives a better protection, but a considerable quantity of this organic compound is present on the surface, which has to be removed before sintering. The Toyalnite powder contains phosphate groups. Due to the coatings the isoelectric point shifts from pH 9 for pure AlN via 7·5 for ART powder to 5·8 for the Toyalnite powder.

Carbothermal Synthesis of Aluminium Oxynitride (ALON) Powder: Influence of Starting Materials and Synthesis Parameters

Jie Zheng & Bertil Forslund

Department of Inorganic Chemistry, Arrhenius Laboratory, University of Stockholm, S-106 91 Stockholm, Sweden

(Received 6 February 1994; revised version received 9 May 1995; accepted 16 May 1995)

Abstract

Carbothermal synthesis of cubic aluminium oxynitride (ALON) have been performed in a graphite furnace at different temperatures (1700–1860°C) and pressures (0.1–10 MPa). The products were characterized by XRD, SEM and elemental analyses, and the overall compositions were determined by reoxidation in air. The control of excess nitridation was a crucial task in the preparation of ALON. A two-step procedure, first annealing at about 1550°C then at about 1800°C, was found to be effective to this end. CO additions to the N_2 gas stimulated ALON formation, but a pressure increase resulted in a lower nitridation rate. The particle size and morphology of ALON depended on raw material type and synthesis parameters such as temperature program, pressure, CO content in the N_2 gas, and sample compartment type. Thermodynamic calculations in the Al–O–C–N system have been performed in order to explain the experimental results.

1 Introduction

The acronym 'ALON' is used for an aluminium oxynitride, of composition $Al_{(64+x)/3}O_{(32-x)}N_x$ ($0 \leq x \leq 8$)[1] — a pseudo-binary solid solution of AlN in Al_2O_3, which may be regarded as a nitrogen-stabilized cubic γ-Al_2O_3 phase (spinel). It has interesting optical, mechanical and chemical properties, making it potentially useful as a high-performance ceramic material.

There is some controversy in the literature as to the extent of solid solubility. McCauley and Corbin[2] found the ALON field to range from about 27 to 40 mol% AlN, with fairly constant limits in the temperature range 1700 – 2000°C. They reported the lattice parameter of the cubic structure, in samples quenched from 1975°C, to vary from 7.938 Å for the most oxygen-rich composition to 7.951 Å at the other extreme. According to Lejus,[3] on the other hand, the ALON solid solution extends from about 16 to 33 mol% AlN at 1700°C, and the cell edge varies between 7.927 and 7.950 Å. In a recent study Willems *et al.*[4] established that the homogeneity range is 19–34 mol% AlN at 1850°C, becoming successively more narrow at lower temperatures, reaching zero at 1640°C.

In a comprehensive article by Corbin,[5] the physical properties of ALON are reviewed, and also various preparation methods employed since the first paper on the compound in 1959.[6] A tentative phase diagram of the AlN–Al_2O_3 system is presented, valid at 1 bar of nitrogen pressure. In total, thirteen different oxynitride phases have been reported to date. ALON is the only stable binary phase below 1900°C although other oxynitride or nitrogen stabilized alumina phases are apt to form also in this regime under specific synthesis conditions.[7,8]

Of the ALON synthesis methods tried so far, those demanding the highest temperatures (> 1500°C) are: direct reaction of an alumina + aluminium nitride powder mixture, and reduction/nitridation of alumina with carbon, aluminium metal or hydrogen in nitrogen or ammonia. Oxidation/nitridation of aluminium in air has been used at ca. 1500°C, and the gas phase reaction between aluminium chloride and ammonia is effective below 1000°C.

Carbothermal nitridation of alumina, according to:

$$\left(\frac{64+x}{3}\right)Al_2O_3 + 3xC + xN_2(g) \rightarrow 2Al_{(64+x)/3}O_{(32-x)}N_x + 3xCO(g) \quad (1)$$

is a well established preparation procedure for ALON. Several patents have been issued, some of

them describing a two-step heat-treatment process in a nitrogen atmosphere; first at 1500–1600°C, then at 1700–1800°C.[9]

The synthesis of ALON powder according to the reaction (1) might seem straightforward but control of the product stoichiometry may be a difficult task. There are several reasons for this. Firstly, at the very high preparation temperatures required, around 1800°C, evaporative losses of aluminium and aluminium suboxides from the charge are likely to be high, particularly in a dynamic atmosphere. Secondly, the reducing conditions prevailing in a graphite furnace, which is a convenient reactor type, may have a large influence on the final O/N ratio in the powder, as was early recognized.[6] Willems *et al.*[10] calculated the composition (oxygen, carbon and nitrogen activities) of the gas phase in stable coexistence with ALON, and concluded that it should be extremely difficult to prepare pure ALON in a flowing N_2 atmosphere without partial reduction or oxidation to AlN or Al_2O_3. A contributing difficulty is that we presently do not know the exact ALON formation mechanism: is it mainly a solid state reaction between aluminium nitride and alumina, or are there important reaction steps occurring *via* the gas? The relatively slow advancement of the ALON formation, even at high temperatures; and observations such as those of Ish–Shalom,[11] that the relative amount of ALON in the product mixture goes through a maximum at a certain annealing time, favour the view that ALON formation is mainly controlled by solid state diffusion. On the other hand, the high activities expected for some aluminium-bearing gas species at the reaction temperatures make it necessary to consider also gas phase reaction steps. Lefort and Billy[12] have suggested that AlN forms on the surface of the Al_2O_3 grains by nitridation of Al vapour, and that ALON subsequently forms at temperatures above ca. 1600°C as a result of solid–solid interactions at the Al_2O_3/AlN interface.

The main purpose of the present investigation of ALON synthesis, by carbothermal nitridation of alumina, was to study the effect of variation of different synthesis parameters on conversion rate, sample stoichiometry and particle morphology, and to elucidate the optimal conditions for synthesis of a monophasic ALON powder in a graphite furnace. To this end, powder mixtures of different alumina and carbon starting materials were heat-treated according to different temperature programs and annealed at 1700–1860°C in flowing nitrogen. Of particular interest was to find out if the nitrogen pressure could be a useful synthesis parameter, as previously found to be the case with Si_3N_4[13] and AlN.[14,15]

2 Experimental

2.1 Sample preparation

Raw materials were alumina and carbon black ('N330', Nordisk Philblack AB, Malmö, Sweden), having a surface area of 82 $m^2\ g^{-1}$ and a mean particle diameter = 30 nm. Alumina materials used were coarse α-Al_2O_3 ('A-591', mean particle diameter 5 μm, Fisher Scientific Co., New Jersey, USA) and fine γ-Al_2O_3 (made in-house), with a surface area of 0.6 and 138 $m^2\ g^{-1}$, respectively. The latter was a poorly crystallized decomposition product of ammonium alum. Aluminium nitride ('Grade A', Hermann C. Starck Berlin Gmbh, Goslar, Germany) was used in some comparison experiments. The nitrogen gas ('Nitrogen Plus', AGA Co., Lidingö, Sweden), specified to contain < 5 ppm O_2 and < 5 ppm H_2O, was used without further purification. An N_2 + 10% CO mixture of the same purity level and Ar ('Argon 4.8', AGA Co., Lidingö, Sweden) were used in some experiments.

Starting materials were seven mixtures of alumina and carbon black powders, denoted 'A' – 'G' (Fig. 1). Besides, 'H' was a mixture of Al_2O_3 and AlN, while 'I' was prepared from $AlCl_3 \cdot 6H_2O$ and starch by a sol–gel procedure. Their compositions, theoretical relative weight changes for full conversion and modes of preparation are given in Table 1. The water contents of the aluminas have been compensated for in these calculations.

Three charge types were used: powders, pellets and granules. Powders were obtained by drying an ethanol slurry, milled in a mortar or in a plastic bottle with SiAlON balls for 4 days. About 0.5 g of the dried, yet plastic powders was pressed into cylindrical pellets of 11 mm diameter and 4–8 mm thick, using a pressure of 840 MPa for 30 s. Granules of diameter 1.5 mm and length 1–6 mm were formed by extrusion. Residual alcohol was subsequently removed by further drying.

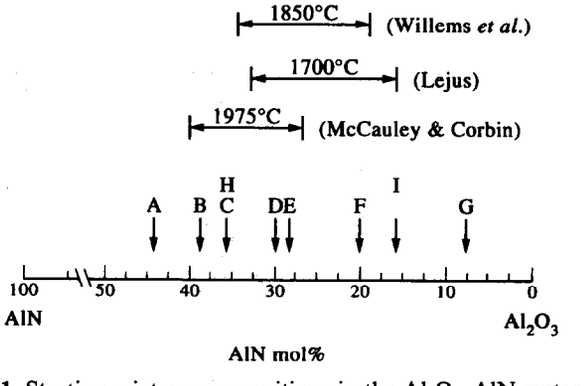

Fig 1. Starting mixture compositions in the Al_2O_3–AlN system. ALON homogeneity ranges suggested by previous authors (Refs 2, 3, and 4) are indicated.

Table 1. Compositions and theoretical relative weight changes of starting mixtures

Symbol	*Wt. ratio*	*Composition (mol% AlN)*	$(-\Delta m/m_0)_{theo.}$ (%)	*Mixing by*
A	α-Al_2O_3/C = 10·0	44·2	14·1	Ball milling
B	γ-Al_2O_3/C = 12·3	38·5	14·1	Milling in mortar
C	α-Al_2O_3/C = 13·0	35·7	11·1	Ball milling
D	γ-Al_2O_3/C = 16·0	29·9	11·3	Ball milling
E	α-Al_2O_3/C = 17·0	28·6	8·6	Ball milling
F	α-Al_2O_3/C = 25·4	20	5·9	Ball milling
G	α-Al_2O_3/C = 70·4	7·7	2·2	Milling in mortar
H	γ-Al_2O_3/AlN = 4·5	35·7	0	Milling in mortar
I	Al_2O_3/C = 33·4	15·7	8·2	Sol–gel procedure

2.2 Synthesis procedure

The carbothermal nitridations of alumina at different nitrogen pressures (0.1–10 MPa) were performed in a gas autoclave with a vertical graphite furnace, described previously.[13,14] The granules or pellets were placed in a graphite sample holder, some of them with a BN (ABB Cerama, Robertsfors, Sweden) liner. Powders were charged in alumina or molybdenum crucibles in the sample holder.

In order to eliminate air from the autoclave before nitridation, the autoclave was flushed several times with nitrogen (1 MPa) at room temperature and on heating up to 600°C. During the whole experiment the nitrogen gas was forced through the sample holder at a controlled flow rate (0–10 $l_{stp.}$ min^{-1}), and then the shortest way out *via* a reducing valve and a flowmeter.

The sample temperature was measured with a W/(W, Re) thermocouple, calibrated against the melting points of Au, Pd and Pt. The plateau temperature could be kept within ± 1 K.

Two kinds of temperature programs, controlled by a PID regulator, were used in our synthesis experiments: a 'one step reaction' with one plateau temperature and a 'two step reaction' with two plateaus. The heating rate was normally 20 K min^{-1}, the cooling rate 30 K min^{-1}. Usually the gas outlet valve was opened at 1400°C on heating and closed at 1450°C on cooling.

2.3 Characterization

The surface area of the materials was measured by an independent laboratory using the BET method. The phase compositions of the reaction products were determined by X-ray powder diffraction (XRD, Guinier-Hägg-type focusing cameras) using Cu $K\alpha_1$ radiation and Si as an internal standard. The cell dimensions of the ALON phase were calculated with the PIRUM program[16] on the basis of, at most, 11 reflexions, representing *d*-values in the range 1.1–4.6 Å. The particle size was estimated by scanning electron microscopy (SEM, JEOL JSM-820, Tokyo, Japan). A few samples were subjected to elemental (N, O, C) analyses by a commercial laboratory using a fusion-gas analysis method.

In order to determine the overall composition of a product, this was ground into powder, charged in a platinum crucible and then heat treated at 1400°C for 2 h in air. Such an oxidation procedure has been reported[7] to completely transform the sample to α-Al_2O_3, expelling all nitrogen, for example according to:

$$4Al_{23}O_{27}N_5(s) + 15O_2(g) \rightarrow 46Al_2O_3(s) + 10N_2(g) \quad (2)$$

Judging from the colour of the oxidized samples, white in all cases, the residual carbon was efficiently removed by this simple procedure. This was also confirmed by chemical analysis of some samples, showing the C content to be less than 0.2 wt%. By accurate weighing of the sample before and after oxidation, the original composition, given as the AlN molar ratio $X_{AlN} = n_{AlN}/(n_{AlN} + n_{Al_2O_3})$, could be determined with an estimated accuracy better than ± 0.01, in most cases.

3 Thermodynamic Calculations

In order to interpret some of our results, we have performed thermodynamic calculations on the system Al–O–C–N by means of the computer program 'SOLGASMIX',[17] based on the principle of free energy minimization. The system was described by 35 different gas species and 8 condensed phases (Al, C, AlN, α-Al_2O_3, γ-Al_2O_3, Al_4C_3, Al_4O_4C and ALON). All $\Delta G°_f$ data were taken from the JANAF Tables[18] except those of Al_4O_4C and ALON which are from Refs 19 and 10, respectively. In all calculations ALON was regarded as a stoichiometric phase with the composition $Al_{23}O_{27}N_5$, due to the absence of data for other compositions.

Figures 2 and 3 give the calculated partial pressures of Al(g) and $Al_2O(g)$ in equilibrium with nitrogen gas and the solid product phases after reaction between Al_2O_3 and AlN, at 2100 K and

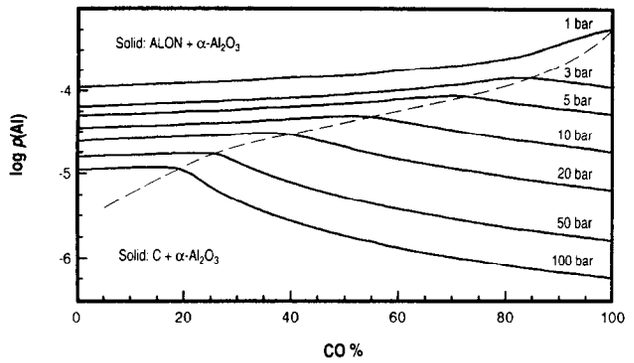

Fig. 2. Calculated equilibrium partial pressures (bar) of Al in a mixture of the products of the reaction between Al_2O_3 and AlN at 2100 K, at different pressures and CO contents in nitrogen (Al_2O_3: 9 mol, AlN: 5 mol, N_2+CO: 100 mol).

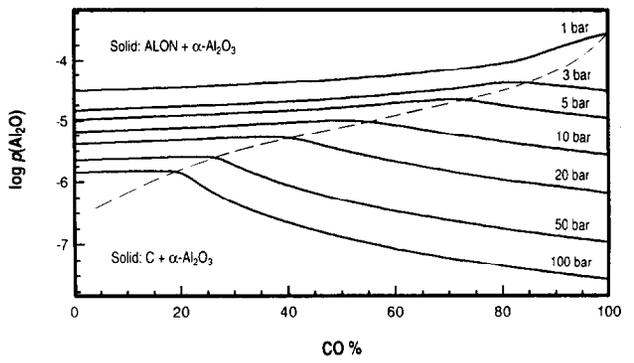

Fig. 3 Calculated equilibrium partial pressures (bar) of Al_2O in a mixture of the products of the reaction between Al_2O_3 and AlN at 2100 K, at different pressures and CO contents in nitrogen (Al_2O_3: 9 mol, AlN: 5 mol, N_2+CO: 100 mol).

different pressures and CO contents (Al_2O_3: 9 mol, AlN: 5 mol, N_2 + CO: 100 mol). The partial pressures p(Al) and $p(Al_2O)$ are not sensitive to the relative amounts of starting materials. ALON ($Al_{23}O_{27}N_5$) and α-Al_2O_3 are stable products in the field above the dashed curve. Below this line, C and α-Al_2O_3 become the product phases. In the ALON formation field, p(Al) and $p(Al_2O)$ increase slightly with CO content but decrease with increasing total pressure.

4 Results

4.1 Single step runs

A large number of synthesis experiments were carried out with the simple temperature program, the 'one step reaction', on the starting mixtures 'A'–'I', with Al_2O_3/C ratios between 10 and 70 (Fig. 1). Plateau temperatures and nitrogen pressures were in the ranges 1600–1860°C and 0.1—10 MPa. The results of only a selected number of runs are shown in Table 2. Also included are some 'two step reactions', as well as runs with recharged samples.

ALON appeared as a reaction product in all experiments at temperatures above 1700°C, although it turned out to be virtually impossible to prepare single phase ALON in a 'one step reaction'. The reason was that further nitridation of alumina easily occurred, yielding aluminium nitride even for a mixture with a high Al_2O_3/C ratio, such as 'G'.

Fine γ-Al_2O_3, for example in mixtures 'B' and 'D', was more reactive than coarse α-Al_2O_3, but also easily underwent substantial excess nitridation. Using the Al_2O_3–C precursor, made by the sol–gel method ('I') and expected to be highly reactive, ALON could actually be prepared at 1700°C in 3 h, but AlN formation occurred in spite of a starting composition at low X_{AlN}.

With coarse α-Al_2O_3 as in 'A', 1 h at 1750°C, 0.5 MPa was not sufficient for ALON formation in granules, which however was accomplished at 0.1 MPa. As is exemplified in Table 2, increasing the pressure hampered ALON formation for all compositions, but the difference in nitridation rate between high- and low-pressure runs was more marked with mixtures of fine-grained γ-Al_2O_3 (*cf.* runs No.5 and 6). Run No.3 with mixture 'B' demonstrates the rapid *onset* of the ALON formation reactions at T > 1800°C.

Heating at a rate of 5°C min^{-1}, instead of the normal 20°C min^{-1}, did not make much difference as to the synthesis result. A run with Ar as the furnace atmosphere during heating, and N_2 for the subsequent 1 h on the 1820°C plateau, yielded the same sample composition as an 'all nitrogen' comparison run. This suggests that the result is not very sensitive to the choice of heating rate (It is noteworthy though, that ALON failed to form in No.7, after very slow heating, 2°C min^{-1}, to 1800°C and then 1 h tempering). Neither did we find 'charge type', i.e. pellet, granule or loose powder, to be very important for the conversion rate with the starting materials used in this study.

The relative weight change (RWC), $-\Delta m/m_O$ (m_O is the charge weight), can be chosen as a general measure of conversion. However, RWC is not exclusively due to losses of CO following eqn (1), but also to extra reduction of the sample by the gas atmosphere and irreversible evaporative losses of Al-containing gas species, (e.g. aluminium or aluminium suboxides). It can be seen from Table 2 that the experimentally obtained RWC-values were always higher than the $(RWC)_{theo.}$, calculated for full conversion according to reaction (1), even for short time runs at low temperatures. The RWC ratio values given in parentheses were calculated from the analyzed AlN contents (X_{AlN}). They should be approximately equal to the experimental RWC ratios, if the weight decrease is exclusively due to reduction/nitridation of Al_2O_3 by the C reactant or the furnace atmosphere.

Table 2. The synthesis parameters and the results of the first series of nitridation runs

Run No.	*Mixture sample*	*T(°C) t (h)*	*p(N_2) (MPa)*	*Φ(N_2) (1 min^{-1})*	*Sample holder*	*Product phases**	*X_{AlN} (%)*	*RWC ratio (%)***	*Comment*

* O = Al_2O_3, N = AlN, O_w= weak XRD lines of alumina, N_w = weak XRD lines of aluminium nitride.
** RWC ratio = $(RWC)_{exp.}/(RWC)_{theo}$. Figures in parentheses are RWC values based on analyzed X_{AlN}.

When a graphite sample holder was used, this material reduced the sample appreciably, even without direct contact, resulting in an extra high RWC, e.g. in run No.13. In most runs, therefore, the charge was separated from the graphite sample holder by a BN liner.

Figure 4 shows that resulting RWC versus reaction time under different conditions for compositions 'A', 'C', 'E', and 'F'. It is clear that $-\Delta m/m_O$ increases with reaction time, particularly for samples charged in the graphite holder. Increasing CO concentration in the gas to 10% caused an overall decrease of RWC, but not a lower nitridation rate (see 'special tests' below) as in the carbothermal syntheses of AlN and Si_3N_4.[13,14] No obvious dependence of conversion on gas flow rate was found. Neither was this expected, as the major effect of increasing the gas flow should be to diminish the CO concentration in the sample space. The product phase assemblage was generally ALON + AlN. In mixtures 'E' and 'F', run for short times, unreacted Al_2O_3 could also be detected.

No accurate determination of the amounts of different phases in the samples was undertaken in this study. As a rough measure of the relative contents of ALON and AlN, and in order to follow the progress of reaction, the X-ray intensity ratio $I_{ALON(400)}/I_{AlN(100)}$ was used. Figure 5 shows this ratio as a function of reaction time for pelletized starting mixtures 'A' and 'F', run in graphite sample

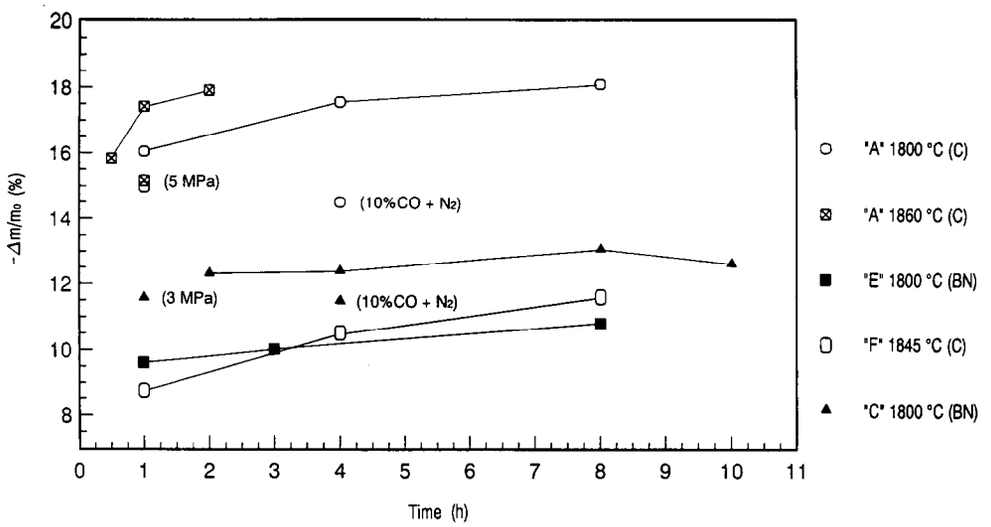

Fig. 4. RWC ($-\Delta m/m_O$) as a function of reaction time for starting mixtures A, C, E and F, run at $p(N_2)$ = 0.5 MPa, $\Phi(N_2)$ = 5 l min^{-1}, with different temperatures and sample holders (graphite or boron nitride). The furnace atmosphere and the pressure for some special runs are indicated in parentheses.

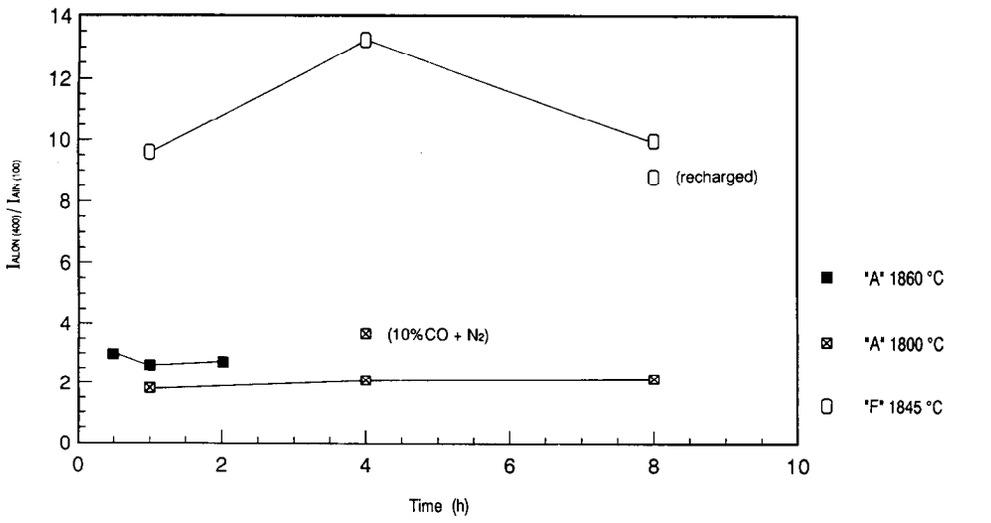

Fig. 5. The measured intensity ratio $I_{ALON(400)}/I_{AlN(100)}$ as a function of reaction time for starting mixtures A and F, run in graphite sample holders at 0.5 MPa, 51 min^{-1} and different temperatures.

holders at 0.5 MPa and different temperatures. The ratio for 'F' samples first increases with time but then decreases. Such a trend was not observed for composition 'A', possibly due to the Al_2O_3/C ratio of 'A' being much lower than that of 'F'. One sample, which had been run for 8 h, was recharged without further homogenization and the heat-treatment repeated for another 8 h, but I_{ALON}/I_{AlN} did not increase. Figure 6 shows the intensity ratio as a function of reaction time for pellets of compositions 'C' and 'E' run at 1800°C, 5 MPa, in sample holders with BN liners. For both compositions the ratio increases with time, but the rate of increase is smaller for 'C', which contains more AlN. The adverse effect on the ALON formation of an increase in pressure is evident. On the other hand, introduction of carbon monoxide into the nitrogen gas seems to slightly favour ALON formation, at the expense of AlN (Figs 5 and 6).

As stated above, none of our runs with a simple temperature programme resulted in a single-phase ALON powder. Homogenization and recharging of incompletely reacted samples and repeated heat-treatment was neither a successful means to reach this goal (compare runs No.15, and No.16 with No.14 in Table 2). Either unreacted Al_2O_3 remained, due to insufficient tempering, or AlN formed due to excessive reduction. The nitridation proceeded too far even when nitrogen was excluded during the second heat-treatment, as in runs No.10 and No.11. Nevertheless, this couple of runs, with the first annealing at only 1600°C, was an improvement upon the double run No.8 and No.9, at 1800°C. Better still was a two-step run, with a first annealing at 1600°C and a second at 1820°C without recharging, e.g. run No.12. In this case both the evaporative losses and the composition shift were smaller than in the corresponding 'single step reaction'.

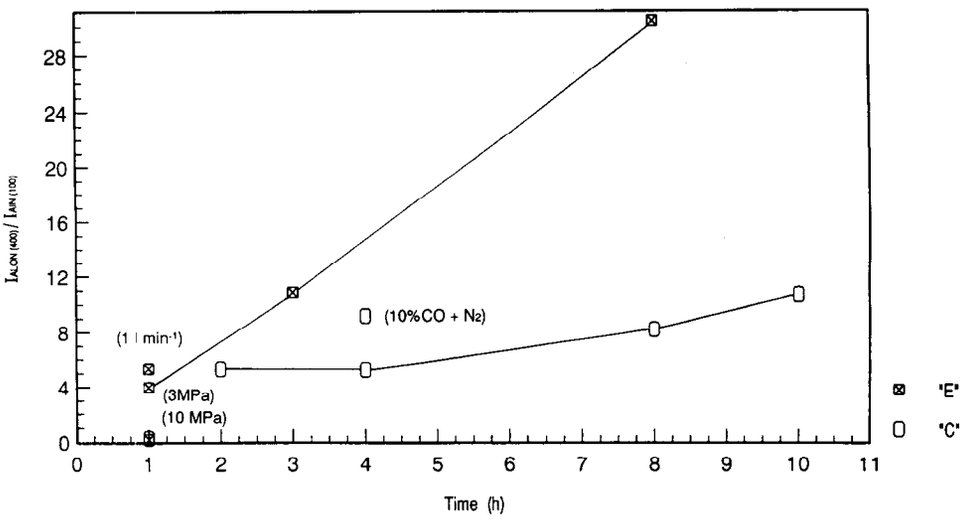

Fig. 6. The measured intensity ratio $I_{ALON(400)}/I_{AlN(100)}$ as a function of reaction time for starting mixtures C and E, run at 1800°C, 5 MPa, 5 l min^{-1} in a sample holder with BN liner. The conditions for some special runs are shown in parentheses.

4.2 Special tests

Careful control of the nitridation of Al_2O_3 thus turned out to be crucial to the carbothermal synthesis of ALON. Mainly in order to clarify the rôle of gas phase reactions in this respect, a series of special tests on pure Al_2O_3 and AlN powders were carried out. Table 3 gives the details of the experimental conditions and the results.

In all runs except No.1 and No.8, the sample was covered to prevent contamination by carbon, occasionally released from the furnace and carried away by the gas flow.

Under the experimental conditions in Nos 1–6, the Al_2O_3 charge was found to react with N_2 in the absence of C, to form substantial amounts of ALON and AlN in 4 h at 1820°C. At least qualitatively, the same results were obtained with alumina and molybdenum crucibles. Elemental analyses gave clear evidence that addition of 10% CO to the N_2 in No.6 stimulated nitridation (*cf.* No.2), while an increase in pressure had an adverse effect (No.3). Fine γ-Al_2O_3 was found to be somewhat more reactive than coarse α-Al_2O_3.

crucible resting on an Al_2O_3 powder bed, shows that with the reaction times and temperatures used in this series, AlN powder is affected by Al_2O_3, even at a distance of several mm, to form ALON. This reaction was mediated by gas species in the Ar atmosphere, as there was no direct contact between the two solids. Run No.8 is the 'blank' corresponding to No.7, proving that the Ar used was pure enough not to oxidize AlN.

4.3 Optimization of the ALON synthesis procedure

Based on the results of the first series of carbothermal nitridation, experimental attempts were made to optimize the synthesis parameters, aiming at monophasic powders of two different compositions within the ALON field. The 'two-step procedure' was chosen in a series of runs, with the temperature and nitrogen pressure varied, as well as the holding time at each temperature plateau. The mixtures 'B', 'C', 'D' and 'E' were selected as starting materials, either in pellet form or as loosely packed powders. The first two had the compositions X_{AlN} = 0.39 and 0.36; with 'B' made of fine-grained γ-Al_2O_3 and 'C' of coarse α-Al_2O_3. Mixtures 'D' with γ-Al_2O_3 and 'E' with α-Al_2O_3 had X_{AlN} = 0.30 and 0.29 (Fig. 1).

In order to prevent excessive reduction/nitridation, a BN compartment was used for the samples, which in most cases were contained in alumina crucibles. In some experiments the sample was also covered by Al_2O_3 powder or enclosed in an Mo capsule, embedded in a 'support charge' consisting of granules of the Al_2O_3 + C mixture in question. The effects on the synthesis result of changes in gas flow rate, heating rate and CO additions to the nitrogen gas were also studied in a few runs.

Some results of the optimization procedure are shown in Table 4. In many cases, samples for XRD were taken both from the surface and the bulk of the product pellet or powder bed. The overall composition (X_{AlN}) was determined by oxidation in air of the whole sample, as previously described.

Starting at the relatively low X_{AlN} = 0.30, it was possible to produce a single-phase ALON powder, both with mixtures made of fine γ-Al_2O_3 ('D') and coarse α-Al_2O_3 ('E'), and equally well with pellets and powders. Heating a 'D' pellet at 1600°C for 2 h and then at 1820°C for 40 min at atmospheric pressure in a BN environment produced a mixture of ALON + AlN and made the sample composition shift to X_{AlN} = 0.44. Limiting the first plateau holding time to one hour, though, was enough to retain the sample composition within the permissible limits (run No.1 in Table 4), demonstrating once more that the major reduction occurs already below ALON formation temperatures. Yet, this heat treatment was enough to yield pure ALON, although the top surface layer was found to contain small amounts of AlN as well. The large cell edge, 7.948 Å, calculated for this layer compared with the bulk, 7.945 Å, is consistent with the surface being more easily nitridized than the interior part of the pellet under the prevailing synthesis conditions. Monophasic ALON was also obtained (run No.2) using a lower heating rate from the first plateau to the second, but otherwise a temperature programme identical to that of run No.1. The effect of the slower heating was probably just to increase the annealing time. When using a higher pressure, 1.0 MPa (run No.3), a three-phase mixture was left, due to the decreased reactivity.

With the powder charge in run No.4, a longer reaction time was needed than with a pellet (run No.1). The overall composition became X_{AlN} = 0.40, but an excess of AlN formed in the surface parts. With Al_2O_3 powder covering the charge, the reduction/nitridation was hampered; 3.5 h heating resulted in a three-phase mixture (run No.5). In this case, the ALON cell edge was shorter in the surface layer (7.943 Å) than in the interior of the sample (7.945 Å). By the combined use of an elevated pressure (0.5 MPa), expected to reduce the nitridation rate, and a 10% CO addition to the nitrogen, a pure ALON powder was produced in run No.6 with a mean cell edge of 7.946 Å.

Optimization of the ALON synthesis based on mixture 'E' pellets typically started with runs such as No.7 and No.8, which did not yield fully reacted samples in spite of high gas flow rates and ca. 2 h tempering at 1.0 MPa. Lowering the pressure to 0.1 MPa resulted in increased nitridation (X_{AlN} = 0.41), although unreacted Al_2O_3 still remained (run No.9). To obtain pure ALON with a pellet charge slightly more than 2 h heat treatment was required at atmospheric pressure (run No.10).

If instead a powder of mixture 'E' was used, loosely packed in an alumina crucible, the reactivity decreased, as expected. In run No.11, heating

for 3 h at 0.5 MPa was insufficient to produce a monophasic powder, in spite of CO being added to the nitrogen in order to facilitate ALON formation. At 5.0 MPa, unreacted Al_2O_3 could still be found, even after 5 h heating at 1850°C (run No.12). The overall composition had shifted to $X_{AlN} = 0.41$. In this sample, as in most of the others, the surface layer was more nitridized than the interior. This difference, however, as can be judged from the calculated ALON cell edge, seems to be somewhat less pronounced for mixture 'E' than for 'D'.

At $p(N_2) = 0.16$ MPa, pure ALON powder could be prepared after 1.5 h at 1850°C (run No.13).

All our attempts hitherto to prepare pure ALON powders from the 'B' and 'C' mixtures, with starting compositions up to $X_{AlN} = 0.40$, have been unsuccessful. Excessive reduction/nitridation, leading to ALON + AlN mixtures, could not be avoided when open sample containers were used,

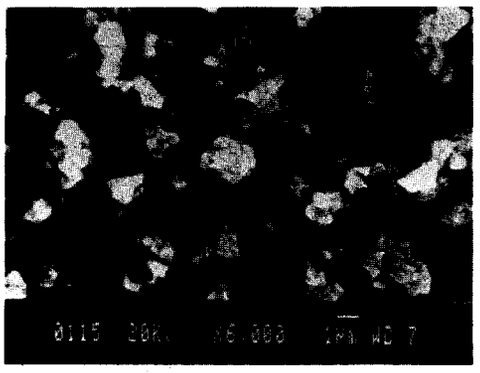

Fig. 8. SEM micrograph of the product of a two-step run with mixture E (powder) at 0.1 MPa, 0.2 l min^{-1}, 1600°C for 2 h and 1820°C for 0.67 h.

even in an Al_2O_3 and BN environment, and with moderate synthesis temperatures (1820°C)

By use of an elevated pressure (5 MPa), a 'support charge' or an Al_2O_3 cover, it was possible to partly control the compositional shift, also for several hours of heat-treatment at 1850°C, but even so, AlN and residual Al_2O_3 were found in the samples.

For a number of samples at the compositional limits ALON/AlN and ALON/Al_2O_3, the cell edge values of ALON, calculated with the PIRUM program, were found to be 7.938 ± 0.0001 Å (O-rich) and 7.951 ± 0.001 Å (N-rich). These were in fact the minimum and maximum cell parameters observed in the whole series of experiments, at 1750–1860°C and with cooling rates of ca. 30°C min^{-1}. Judging from Table 4 the ALON–AlN phase boundary seems to be close to X_{AlN} = 0.40 at ca. 1800°C, as determined by reoxidation of ALON samples in air.

The ALON diffraction lines on the XRD films always appeared sharp, even on close inspection of the peak profiles, excluding extended compositional variation over the samples. Yet, the cell parameter values presented in Table 4 were not sufficiently representative for the overall composition to allow a precise relationship between X_{AlN} and a_O to be established. A linear relationship between nitrogen content in ALON and cell parameter has previously been determined by Guillo.[20]

4.4 Powder morphology

Typical SEM photos (Figs 8–12) of ALON materials from this study reveal morphological differences

Fig. 10. between powders prepared under different conditions.

Whether coarse or fine-grained alumina powder was the starting material made a large difference. The first type persistently yielded aggregates of irregularly shaped ALON particles, with a wide size distribution (Fig. 8), irrespective of the choice of process parameters. Yet, they proved to be finer, on an average, than the α-Al_2O_3 particles of the raw material (Fig. 7).

With fine γ-Al_2O_3 in the starting mix, the temperature programme turned out to be decisive for the ALON morphology. A 'single-step' process always resulted in densely sintered particle agglomerates (Fig. 9). On the other hand, use of a 'two-step' programme apparently was a means to reduce agglomeration, and typically to produce relatively fine-grained ALON with a moderately wide size distribution. Within this class of samples some SEM-pictures reveal small morphological differences, though, and these can be related to the different sets of process parameters used.

The slightly different features of the samples seen in Figs 10(a) and (b) suggest that the grain size is somewhat better controlled in a pellet than in a powder, loosely packed in an open crucible. However, as is shown by Fig. 10(c), a fine grain size could be achieved also with a powder bed, provided it is covered by an Al_2O_3 powder layer.

Neither the pressure, between 0.1 and 1 MPa, nor the gas flow rate and heating rate from the first to the second plateau temperature were found to be important parameters for sample morphology. On the other hand, close inspection of SEM pictures such as Figs 10(d) and (e) reveals that both application of a nitrogen pressure in excess of 2 MPa and a 10% CO-addition to the reaction gas have some influence on particle morphology; the resulting ALON particles become medium-sized, possibly with a relatively narrow distribution. Besides, the grains appear more 'crystalline', with sharp edges and corners, than other ALON powders, which are typically devoid of symmetrical features.

Figure 11(a) shows the AlN + Al_2O_3 powder that results on annealing a C + Al_2O_3 mixture at the first plateau, ultimately leading to the ALON powder in Fig. 11(b). A somewhat finer powder, similar to the starting powder in Fig. 11(a), was obtained when Ar replaced N_2 at the second plateau.

It can be seen that the products (Fig. 12(a)) obtained from fine γ-Al_2O_3 and a commercial AlN raw material are non-homogeneous and that the morphology is related to that of the starting AlN powder (Fig. 12(b)).

5 Discussion

Our experimental results exemplify some difficulties, likely to be encountered in the preparation of

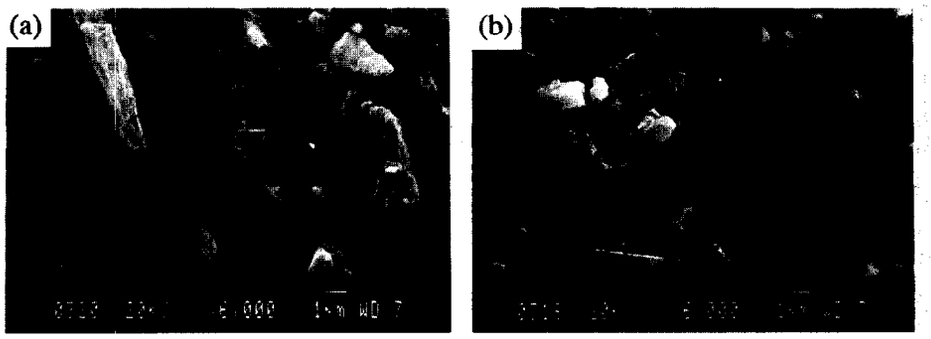

Fig. 12. SEM micrographs of (a) the product of a pellet of mixture H, run (two-step) at 1500°C for 1 h and 1820°C for 0.67 h, 0.1 MPa and 0.2 1 min^{-1}, and (b) the starting AlN material.

monophasic ALON powder by the carbothermal route. However, some possible means are also presented, to circumvent the difficulties and carry out the synthesis from mixtures of carbon and alumina powders, of ordinary grade and homogenized by simple mechanical mixing. Very fine-grained reactants do not seem to be required for a successful synthesis. Use of fine powder mixtures or a sophisticated homogenization procedure, such as sol–gel, improves reactivity but will not eliminate the problem with drifting composition inherent in the high-temperature synthesis of ALON without strictly controlled O, N, C gas phase activities.[4] A common feature of carbothermal runs in a graphite furnace is namely the tendency for continuous reduction and nitridation of the sample, beyond the point determined by the carbon content of the starting mixture. As a consequence, there will also be an extra weight loss above that expected from eqn (1), and excess AlN may form.

This problem is overcome if one starts with C + Al_2O_3 mixtures with compositions corresponding to oxygen-rich ALON, thus having some tolerance for extra reduction. Such an approach was successfully used in this study and has also been the method preferred by previous workers. However, our attempted syntheses of monophasic ALON, starting with compositions near the ALON–AlN phase boundary failed, and this was due to the inability to control the reduction strictly enough. Use of a two-step heating program, an elevated pressure, CO additions to the nitrogen gas and a 'support charge' or a cover of Al_2O_3 were measures taken to achieve compositional control of the charge. All of these were effective to some degree and will be taken advantage of in future preparative work.

From a comparison of ALON cell dimensions in different parts of the samples, we conclude that application of an Al_2O_3 cover has the extra advantage of improving the charge homogeneity. Generally, a better homogeneity was obtained with coarse α-Al_2O_3 starting material than with fine γ-Al_2O_3.

When 10% CO was added to the feed gas we noted a somewhat increased intensity ratio $I_{ALON(400)}/I_{AlN(100)}$ in the products (Figs 5 and 6). This is probably a result of hampered formation of aluminium nitride,[14] as thermodynamic calculations (Figs 2 and 3) show that the formation of AlON should not be hampered by addition of CO to the N_2 gas. The increase in nitridation rate with rising CO content, found for pure Al_2O_3 powders at 1820°C (special run No.6, Table 3), is expected from thermodynamic considerations, provided gas species such as $Al_{(g)}$ and $Al_2O_{(g)}$ are somehow involved in the nitridation process. Thermodynamic calculations show that the partial pressures of these species will increase almost 100-fold when the CO content is increased from 0 to 10% in N_2 over Al_2O_3 at 2100 K.

One reason for the lower ALON formation rate at 5 MPa than at 0.1 MPa (Fig. 6 and special run No.3, Table 3) is a slower mass transport in the gas phase at the higher pressure. Furthermore, the thermodynamic calculations show that p(Al) and $p(Al_2O_3)$ will decrease on raising the total pressure (Figs 2 and 3).

5.1 The two-step procedure

The improvement achieved with the 'two-step procedure', compared with the 'single-step runs', highlights the reaction chemistry below ALON formation temperatures.

From previous studies of carbothermal reduction and nitridation of Al_2O_3 at different temperatures and pressures[14] we know that in the ranges 0·1–5 MPa, 1400–1600°C the only solid compound formed is AlN. Because this phase will inevitably form prior to ALON on heating an Al_2O_3 + C mixture in N_2, ALON formation must somehow be connected with the AlN particles present, as these will remain also at 1800–1900°C. The Al_2O_3 particles in the reacting mixture are relatively stable, although partial pressures of species such as $Al_{(g)}$ and $Al_2O_{(g)}$ can be appreciable. This has been confirmed experimentally, e.g. by Lefort and Billy,[12] who established the presence of Al vapour over alumina at 1550°C in vacuum, by means of an emission spectrograph. They also observed a drastic decrease in p(Al) when nitrogen was introduced in the reactor to form AlN. We therefore anticipate partial dissociation of Al_2O_3 and net losses of oxygen from the sample, particularly under the reducing conditions prevailing in a graphite furnace. These losses are expected to be higher in the surface layer of a pellet, or powder charge, than in the interior.

The gaseous aluminium is probably retained to a high degree by reaction with nitrogen, and this manifested itself in the AlN whiskers, which grew radially outward from the pellets in many of our experiments (Tables 2 and 4). (They did not grow at elevated pressure, > 1 MPa, however, which probably reflects the reduced mobility of $Al_{(g)}$ and $Al_2O_{(g)}$ following an increase in total pressure). Consequently, the surface layer of the charge will be depleted of oxygen, compared with the interior, and the resulting ALON powder will contain excess AlN near the surface. Such a segregation was observed in most of our samples, particularly in runs with high-surface area γ-Al_2O_3 at low (atmospheric) pressure, high temperature, high gas

flow rate, and in a graphite sample holder. By use of a 'support charge' or an Al_2O_3 powder covering the reaction mix, this segregation could be diminished, and in some cases even an oxygen excess was left in the surface layer. Compositional variations over ALON samples, as a consequence of the gaseous environment affecting the surface parts, have been observed previously.[4]

AlN formation by the carbothermal route is not a very rapid process;[14] it is to some extent controlled by p(CO), and would demand more than 1 h for a full conversion in our set-up, even at 1600°C. While the onset of ALON formation seems to be immediate, at least 0.5 h is needed for full conversion. Dissociation of 'extra' Al_2O_3 not converted to AlN by the C reagent, proceeds concurrently and may cause considerable 'over reduction' at T > 1800°C. We therefore conclude that the benefit of a primary annealing at low temperature, ≤ 1600°C in the 'two-step procedure' is that a maximum amount of AlN with respect to the C/Al_2O_3 ratio can form at temperatures low enough to cause minimum evaporative loss of oxygen. This should be a more efficient way to prepare ALON than the 'one-step procedure', implying less excessive nitridation.

The RWC values calculated from the analyzed overall compositions (X_{AlN}) in Tables 2 and 4 are rather close to the experimentally obtained values for mixtures 'F', 'C' and 'E'. Samples of mixtures 'B' and 'D', on the other hand, gave noticeably higher experimental RWCs than expected from mere reduction/nitridation of the Al_2O_3 content. Apparently these mixtures, made up of high surface area γ-Al_2O_3, were subjected to an extra weight decrease, which may be due to an irreversible loss of Al-containing gas species, such as $Al_{(g)}$ and $Al_2O_{(g)}$. If this is the case, the difference in RWC between runs No.1 and No.4 in Table 4 shows that such losses may be minimized if an Al_2O_3 crucible is used as sample container.

Part of the excess nitridation observed in most runs could be a result of a continuous decomposition of ALON with time in the graphite furnace. A dissociation process of ALON into AlN has been suggested by previous workers.[12] As a matter of fact, the compositional variation within the ALON may be described as a substitution of oxygen for nitrogen and vice versa, and hence:[10]

$$\text{ALON} + N_2(g) \rightarrow \text{AlN} + O_2(g) \qquad (3)$$

The results of our special test series (Table 3), suggesting ALON to be the primary product phase with AlN subsequently appearing, seem to show that some decomposition mechanism is operating.

5.2 Particle size and morpholoy

The special tests (Table 3) tell us that in an AlN + Al_2O_3 powder mixture ALON may form, either by oxidation of the former or nitridation of the latter, without direct contact between particles. As the ALON particles bear no resemblance to the original Al_2O_3 particles, it is likely that the main direction of mass transport in the gas at ALON formation temperatures is from Al_2O_3 to AlN. In support of this view is the observation that ALON particles obtained in a two-step process from mixtures of C and fine γ-Al_2O_3 were relatively uniform, compared with powders made from coarse α-Al_2O_3 (Fig. 7). This was actually the size-dependence of process parameters previously found for AlN.[15] Consequently, mixtures of fine-grained γ-Al_2O_3 and a non-uniform, standard grade commercial AlN powder (Fig. 12(b)) produced non-uniform ALON powders (Fig. 12(a)).

The mechanism for the subsequent ALON forming reaction between the AlN matrix and the Al–O species, however, still remains to be elucidated. It should also be stressed that ALON easily forms by nitridation of Al_2O_3, even in the absence of AlN (Table 3). This may occur by the mechanism suggested in Ref. 12, and mentioned in the Introduction.

The small, yet noticeable morphological differences between powders prepared from mixtures with γ-Al_2O_3 (Figs 9–11) suggest that the rate of dissociation of Al_2O_3 is of some importance for the AlN particle size and thus the final ALON morphology. Rapid heating (single-step) led to a highly sintered powder (Fig. 9), while slow heating hampered ALON formation (run No.7 in Table 2). Possibly, the degree of supersaturation of Al or Al–O species in the gas, which is governed by the specific surface area and dissociation rate of Al_2O_3, is the crucial parameter. If so, the general tendency for particles in a pellet charge to be a little smaller than in a loose powder (*cf.* Figs 10(a) and (b)) can be understood, as well as the small grain size obtained, also with a powder charge, when an Al_2O_3 cover was used (Fig. 10(c)). This is supposed to minimize leakage of gas species from the sample, and thus to favour build-up of p(Al) and $p(Al_2O)$.

A relatively large AlN particle size is expected in runs at an increased pressure and a low gas flow rate (1 l min^{-1}),[15] and a similar trend was actually observed for ALON (Fig. 10(d)).

The relatively coarse powder obtained in a two-step run in an N_2 + 10% CO atmosphere (Fig. 10(e)) is probably due to a reduction of the Al_2O_3 surface area during the first annealing at 1600°C. For thermodynamic reasons,[14] the AlN formation rate is very low in 10% CO at this temperature,

but will increase on further heating to the second plateau.

6 Conclusions

- Preparation of monophasic ALON powder by carbothermal nitridation of Al_2O_3 is complicated due to the difficulties of keeping compositional control during the process. In a graphite furnace, excess nitridation is likely to occur, mediated by Al-containing gas species generated at relatively high activities at the high synthesis temperatures required > 1600°C.
- A means to prepare pure ALON powder, without excessive reduction and AlN formation, and also to obtain a reasonably narrow particle size distribution, is to perform the synthesis in two steps; first annealing for 1 or 2 h at 1600°C, and then at 1800–1850°C for another hour. Direct heating to ALON formation temperatures, ≥ 1750°C, did not yield monophasic powders with a reasonably narrow particle size distribution.
- A high pressure in the synthesis generally lowered the nitridation rate, and may therefore be used for control of sample stoichiometry, and also particle size to some degree. To this end an Al_2O_3 sample holder with Al_2O_3 covering the charge may also be used.
- Increasing the CO content in the reaction gas (up to a certain level) has an enhancing effect on ALON formation, at the expense of AlN.
- The ALON particle morphology seems to be related to the AlN (precursor) particle morphology.
- ALON formed slowly at 1850°C in the absence of carbon, by the reaction of N_2 with a pure Al_2O_3 powder. It also formed on AlN, in the presence of Al_2O_3, without direct contact, in an Ar atmosphere.
- The crystallographic unit cell edge of the ALON samples prepared in this study at about 1800°C was found to vary between 7.938 + 0.001 Å (high-O) and 7.951 ± 0.001 Å (high-N).

Abstract

A powder mixture of α-Si_3N_4, AlN and Y_2O_3 corresponding to an yttrium α-sialon composition, $Y_{0.4}Si_{10.2}Al_{1.8}O_{0.6}N_{15.4}$, was sintered both in a high temperature X-ray diffraction unit and in a regular sintering furnace. X-ray analysis was performed and it was shown that high temperature X-ray diffraction can be used to monitor the kinetics of the α-sialon phase formation during sintering at temperatures between 1450 and 1580°C as the reactions take place. A variety of yttrium-rich intermediate and secondary phases are formed during sintering; those formed in the HT-XRD unit were not the same as those formed in the regular sintering furnace, but they do not significantly influence the overall reaction sequence or the amount of α-sialon formed. Quantitative analysis of the acquired data was used to evaluate the kinetics of the α-sialon phase formation; the estimated activation energy of the initial stage α-sialon formation was 330 kJ/mol. After this initial stage of relatively rapid α-sialon formation the process became inhibited.

1 Introduction

The sialons are a group of ceramic compounds corresponding to the α and β form of silicon nitride, in which silicon and nitrogen atoms have been substituted in part by aluminium and oxygen.[1] Unlike α silicon nitride which transforms to β silicon nitride at high temperatures, α sialon can be stabilized by metal ions such as yttrium. The α sialons are characterized by good thermal shock resistance and high hardness which is retained to quite high temperatures.[2] They therefore have potential as materials for high temperature applications.

*Present address: Industrial Research Limited, Lower Hutt, New Zealand.

The present work concerns the formation of a yttrium α-sialon with the ideal composition $Y_{0.4}Si_{10.2}Al_{1.8}O_{0.6}N_{15.4}$ by reactive sintering of an appropriate mixture of silicon nitride, aluminium nitride and yttria powders. This composition is predicted to yield pure α sialon with some glassy phase upon completion of the reaction. Reactions of similar compositions have been studied earlier by means of sintering plus quenching experiments and the general sequence of reactions at temperatures between 1000 and 1750°C has been documented.[3–7] It involves the formation of an oxide liquid and then solution of Si_3N_4 and AlN into it, forming an yttrium-containing oxynitride melt from which α-sialon is precipitated. Besides α-sialon, intermediate and secondary phases like YAM ($Y_4Al_5O_9$), J-ss ($Y_4Al_{2-x}Si_xO_{9-x}N_x$), YAG ($Y_3Al_5O_{12}$) and N-melilite ($Y_2Si_3O_3N_4$) are found depending on temperatures and starting compositions. α-sialon forms at as low a temperature as 1400°C when dissolution of the two nitrides, Si_3N_4 and AlN, becomes significant.[4,6] At this temperature the amount of liquid is still low but it increases with temperature as the extent of the liquid phase field increases. However, for a given temperature the amount of available liquid decreases as the reaction to α-sialon proceeds and yttria, oxygen and aluminum are substituted into the structure.

In studies of crystallization of the intergranular glass phase in sialon ceramics it has been noted that the O/N ratio of both the bulk composition and the liquid phase as well as the temperature play a major role in determining which phases crystallize out.[8,9] The composition, quantity, and viscosity of the liquid phase has also been reported to strongly influence densification.[10] These factors might be expected to complicate the kinetics of α-sialon formation. In the present work, the sensitivity of α-sialon formation to intermediate and secondary phases, sintering conditions and controlled changes in compositions was studied.

The study of phase formation in ceramic materials is often impeded by difficulties in following the course of reactions at elevated temperatures. Generally reactions are studied by 'quenching' a series of samples at different stages of the reaction. This approach is adequate for slower reactions such as those controlled solely by solid state diffusion. If fast transformations occur during cooling, it is hard to retain a high-temperature state unless special experimental conditions are used. For example it has recently been shown that the α-sialon phase with large stabilizing ions decomposes unexpectedly rapidly upon cooling when a liquid phase is present.[11] An alternative to the quenching technique is offered by high temperature X-ray diffraction (HT-XRD). This permits study of reactions as they proceed; the uncertainty associated with quenching is avoided and the kinetics of reactions can be determined far less arduously. A potential drawback of the method is that it can only observe a thin zone of material close to the free surface of a sample which may not give a true representation of realistic bulk sintering conditions. One of the purposes of this work was to apply HT-XRD to a study of the reactions during the sintering of the α-sialon and to compare the observations with the results of conventional sintering.

2 Experimental

Powder mixtures were prepared from the starting materials, silicon nitride (H.C. Starck, Berlin, Grade LC1), aluminum nitride (H.C. Starck, Berlin, Grade A) and yttrium oxide (H.C. Starck, Berlin, Grade > 99·8% Y_2O_3) to correspond to x = 0·4 in the formula $Y_x(Si_{12-4.5x},Al_{4.5x})(O_{1.5x},N_{16-1.5x})$ for yttrium α-sialon (corresponding to 78·0 wt% silicon nitride, 14·4 wt% aluminium nitride and 7·6 wt% yttria). The oxide contents of the aluminum nitride and silicon nitride were compensated for to best approximate the above formula as discussed in a previous article by two of the authors.[12] Samples for the HT-XRD were prepared by cutting powder bodies, CIPed at 200 MPa, into thin slices with a razor, presintering them at 1350°C for 1 h in 0·11 MPa nitrogen atmosphere and then dry grinding them to a dimension of 12 × 8 × 1 mm.

HT-XRD measurements were then conducted at temperatures 1450, 1500, 1530 and 1580°C in a static atmosphere of 0·11 MPa N_2 in a specially constructed graphite furnace coated with silicon nitride. This coating was stable to a temperature of 1600°C. Furnace and HT-XRD conditions have been described earlier.[13] During a soaking time at temperature the reactions were followed by repeating a set of two scans . The first scan over a 2θ range of 28–45° at a rate of 0·04°/s was used to follow the sequence of formation of all phases and to calculate the AlN content by integrating intensities of major peaks. The second scan over a 2θ range of 42–44° and a rate of 0·01°/s was used for profile analysis of one α-Si_3N_4 peak (hkl = 301) and the corresponding peak of α-sialon. These peaks were not overlapped by peaks of other phases and could be used for quantitative estimates of the α-silicon nitride to α-sialon conversion. After the HT-XRD runs, selected samples were analysed by room temerature XRD (RT-XRD) at different depths into the sample to assess any differences between top surface and inner reactions.

Quantitative phase analysis was performed through careful calculation of the XRD peak areas. Correction for overlap of the diffraction peaks as well as the integration of the peak areas were performed by fitting of the experimental diffraction profile using a Marguardt non-linear least squares algorithm.[14] The same algorithm was also used to determine the positions of the α and α' (301) peaks and AlN (101) peak. (α and α' denote α-silicon nitride and α-sialon respectively). The highest accuracy of peak areas and positions was achieved at 1580°C, where the peak separation was largest. The amounts of aluminium nitride, silicon nitride and yttria were estimated by reference to the peaks of an unsintered sample.

The amount of α-sialon was measured in terms of the degree of conversion from α-silicon nitride to α sialon:

$$f = S\alpha'/(S\alpha'+S\alpha) \quad (1)$$

where f is the relative mass fraction α-sialon, $S\alpha'$ the area of the α-sialon (301) peak and $S\alpha$ the area of the α-Si_3N_4 (301) peak. Low amounts of α' were indicated only by an asymmetry of the α peak and therefore required careful deconvolution. It should also be noted that this estimate of the degree of conversion implies that it occurs merely as a crystallographic transformation without any change of composition or change of the total quantity of $\alpha+\alpha'$. Thus the increase in the mass of α' by incorporation of AlN and Y_2O_3 is neglected in the definition of f and consequently the fraction of α' is somewhat overestimated. However, the amounts of AlN and Y_2O_3 involved are relatively small and this approximation has relatively little effect on the values of f obtained. The small amount of β silicon nitride ($\approx$5%) in the starting powder is also disregarded in this analysis.

To verify the HT-XRD results, parallel sintering experiments were conducted in a graphite sintering

furnace with samples of the same composition. Both as-pressed samples and samples presintered as above were sintered at a temperature of 1560°C in 0·15 MPa N_2 for 3 h in a silicon nitride powder bed. All samples were analysed for phase content by XRD at room temperature. The cooling rates between the sintering temperature and 1000°C were approximately 100°C/min in the HT-XRD unit and 20°C/min in the sintering furnace.

In the HT-XRD, the investigated sintering surface is totally open to the furnace atmosphere. To assess the possible effects of this, another two sets of samples were prepared for comparison. In the first set (A) additions of 0·5–3·0 wt% silica were made to the original composition. The second set (B) was given the same nominal composition but with different raw materials. The powders used for the second set of samples had a higher oxide content than those used in the original HT-XRD study and were AlN (H.C. Starck, Berlin Grade B) and Si_3N_4 (Kemanord, Grade P95). The silica used in all the mixtures was derived from an ammonia stabilized colloidal silica, destabilized by propanol. After drying this was easily comminuted to a fine-grained silica by use of an agate spex mill. The atomic composition of the two sets of samples is shown in Table 1. To allow comparison between the two sets, the Al + Si content was adjusted to 12 in the atomic formula. The second set had a higher Si:Al ratio and this was further increased slightly by the addition of silica.

3 Results

3.1 HT-XRD analysis

The XRD diffraction pattern of the original composition presintered for 1 h at 1350°C is shown in Fig. 1. Presintering resulted in formation of yttrium-rich aluminosilicate phase(s) and no detectable α-sialon. The yttrium-rich aluminosilicate phase could be identified as $Y_{10}Al_2Si_3O_{18}N_4$ but

with small shifts in the peak positions indicating a shift from stoichiometry or the incorporation of other ions. The major peaks of this phase, however, overlap the peaks of the J–ss phase. Some additional minor diffuse peaks might belong to a J–ss type phase. Their simultaneous presence therefore cannot be excluded. Nevertheless all these phases are characterized by being yttria- and oxygen-rich and will for convenience be denoted $Y_{10}Al_2Si_3O_{18}N_4$ in this paper. The formation of $Y_{10}Al_2Si_3O_{18}N_4$ suggests either the initial formation of an oxynitride melt or a direct reaction between yttria and the oxynitride layers that can be assumed to exist on the surfaces of the Si_3N_4 and AlN powders.

Figure 2 gives an example of how the phase composition develops during sintering in the HT-XRD (at 1580°C in this case). The initial formation of α-sialon was indicated only by an asymmetric broadening of the α-Si_3N_4 peaks. Times up to 5 h were needed for a clear peak shift to occur. Only very small amounts of β-Si_3N_4 could be detected. The evolution of the phase composition with temperature (5 h sintering) as measured at room temperature after sintering in the HT-XRD is summarized in Fig. 3. The results agree well with the HT-XRD measurements as regards the

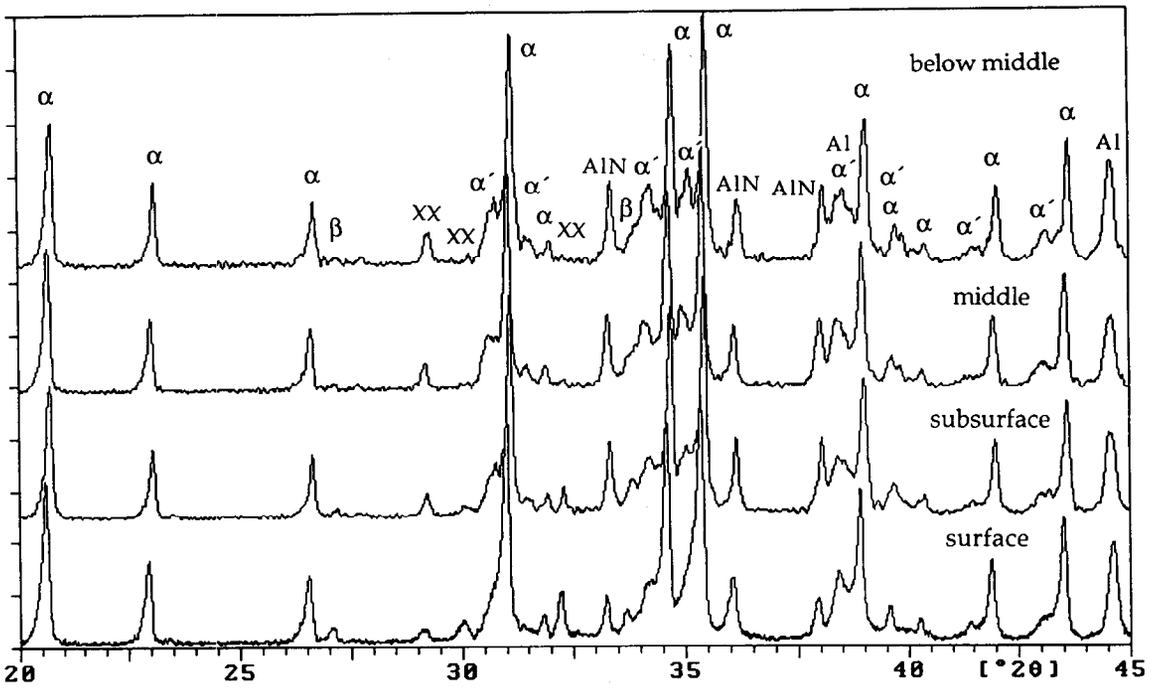

Fig. 5. RT-XRD of sample sintered at 1530°C for 5 h in the HT-XRD at different distances from the surface.

relative amounts of α and α' and with the results of other investigations of α-sialon formation.[5,6] Figures 4(a) and (b) show the increase in α-sialon and decrease of AlN with time at the different sintering temperatures. The trend in rate of formation of α-sialon corresponds well with the trend of the dissolution rate of AlN.

The amount of $Y_{10}Al_2Si_3O_{18}N_4$ was observed to decrease with both time and temperature (*cf.* Fig. 2). Instead, another phase, or possibly two phases, are formed. These are difficult to identify as they do not fit well with any single known pattern. They could however be based on a solid solution of yttrium silicates or yttrium aluminosilicates, similar to the J–ss phase or apatite.

Figure 5 shows RT diffraction patterns taken at different distances from the surface of the sample subjected to HT-XRD investigation for 5 h at 1530°C, while Table 2 shows the phase composition at corresponding distances for samples studied at different temperatures. The amounts of silicon nitride, α-sialon and $Y_{10}Al_2Si_3O_{18}N_4$ did not seem to differ significantly between the surface and the interior, except in the 1450°C sample, where the level of $Y_{10}Al_2Si_3O_{18}N_4$ is lower on the surface of the sample. The aluminum nitride content on the other hand is consistently higher in the interior. The reduced aluminum nitride content on the surface of the sample is probably due to its having a higher susceptibility to oxidation than silicon nitride. The surface of the sample showed some evidence of glassy phase after HT-XRD.

Although the differences in the amounts of α-sialon between the surface and the interior were small the nature of the α-sialon peaks was different. The peaks on the surface were broader and showed smaller separation from the α-Si_3N_4 peak than those in the interior. This was especially true for the 1530°C samples in which the peak separation in the interior was much larger than at any other temperature investigated (Table 2). This result can be compared with results reported by Walls *et al.*,[6] which showed that the cell parameters of the α-sialon are higher at the beginning of α-sialon formation than at equilibrium. They attributed this to a lower dissolution of silicon nitride than aluminum nitride in the liquid at the beginning of α-sialon formation, allowing a more highly substituted sialon to form. In this investigation the higher peak separation in the interior of the samples coincided with higher amounts of unreacted AlN than were observed at the surface. This implies that AlN does oxidize on the surface

Table 2. Relative amounts (wt fractions) of α-sialon and AlN and the α-sialon/α-Si_3N_4 peak separation at the surface and in the interior of samples sintered 5 h at different temperatures in the HT-XRD unit

Temp°C	*Position*	α'/α + α'	α'–α (2Θ) *separation*	AlN

1580	Middle	0·47	0·442	0·06

of the sample and that this influences the peak separation, while the amount α-sialon formed does not change significantly.

3.2 Conventionally sintered compositions

As explained above, samples of the same composition as those studied in HT-XRD were sintered in a powder bed in a conventional furnace. First, a comparison was made between samples pressed directly from powders and samples presintered at 1350°C with the HT-XRD samples. There was no detectable difference in the overall phase composition of the two samples.

A difference, however, was found between the surface and interior of the conventionally sintered samples. The surface consisted of α- and β-Si_3N_4 and YAG, while the interior contained α-sialon, N-melilite, unreacted α-Si_3N_4 and AlN. The samples had also gained weight slightly ($\approx$ 1%) during sintering. This implies a mass transfer from the powder bed to the sample probably caused by a higher partial pressure of oxygen or silicon monoxide in the powder bed. The reduced AlN content on the surface of HT-XRD samples suggests that a similar effect occurred in the HT-XRD unit.

Figure 6 compares the room temperature phase composition of the interior of presintered + conventionally sintered sample sintered at 1560°C with the surface compositions of presintered + HT-XRD sintered samples treated at 1530 and 1580°C. It is seen that the α-sialon content of the interior of the sample sintered at 1560°C is similar to that of the surface of the 1580°C HT-XRD sample. The intermediate phases in the HT-XRD sample were however different from those both in the surface and interior of the conventionally-sintered sample. In the 1530°C HT-XRD sample the α-Si_3N_4 to α-sialon conversion had not proceeded as far but the yttrium-rich intermediate phase(s) is the same as in the 1580°C HT-XRD sample. These experiments show that the furnace coating in the HT-XRD unit provides a reasonable atmosphere for the sample but does not interact with the sample in the same way as a powder bed.

3.3 Conventionally sintered compositions with silica additions

Since the observed decrease in AlN content on the surfaces of the HT-XRD and conventionally sintered samples might be attributed to an oxidation, it was of interest to see how an increase in oxide content of the starting compositions would influence the phase formation. The two sets of samples shown in Table 1 were sintered at 1560°C for this purpose.

Table 3 shows the room temperature phase contents of the cross sections of the different sets of samples with 0·5 to 3·0 wt% extra silica. For (A) samples, i.e. those based on the original mixture, the phase composition comprised α-sialon, melilite, β-Si_3N_4 and unreacted Si_3N_4 and AlN; with increasing silica content, the YAG phase began to develop and the fraction of melilite decreased. In the (B) samples, based on the comparison composition, the development was very similar but instead of melilite the $Y_{10}Al_2Si_3O_{18}N_4$ phase formed; moreover it disappeared faster than the melilite in the (A) samples. The amount of α-sialon was not significantly affected, except for the 3% silica addition samples in set (B).

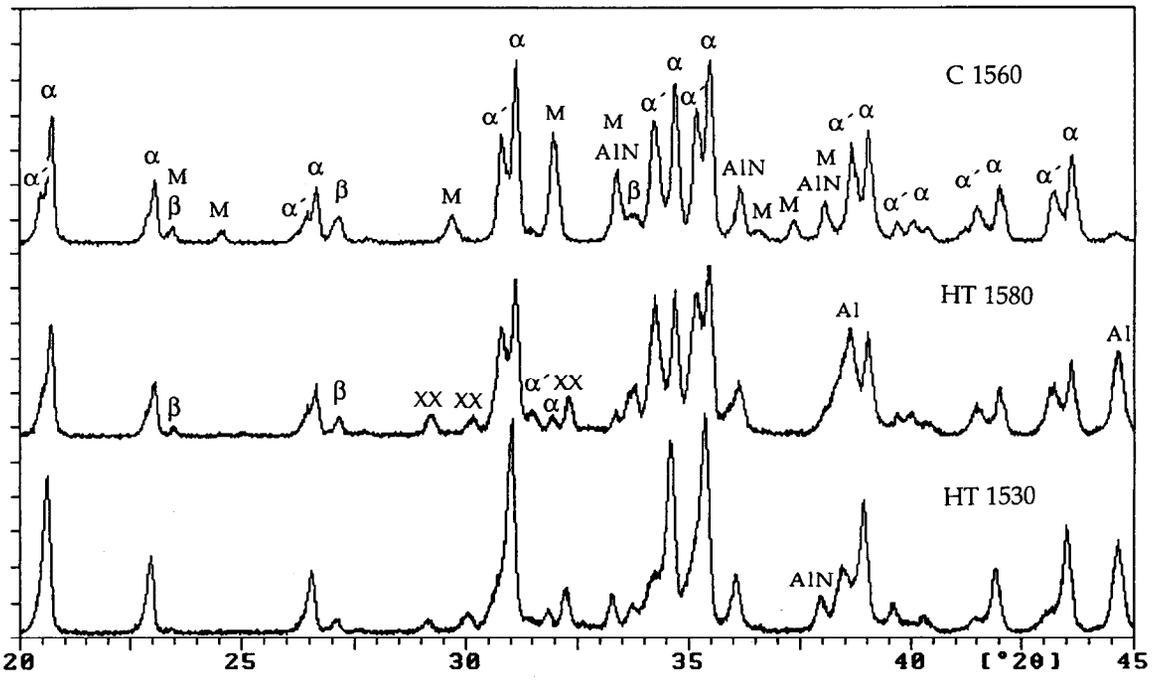

Fig. 6. RT-XRD patterns of samples presintered at 1350°C and then sintered at 1560°C in a conventional furnace (C1560), at 1530°C in the HT-XRD (HT1530) and at 1580°C in the HT-XRD (HT1580). M = $Y_2Si_3N_4O_3$.

B/3%SiO_2	α/α'/β/YAG/AlN	0·292	0·30

The most significant effect observed when slightly increasing the O/N-ratio of both series of samples, were the changes in the yttrium-rich intermediate phases that formed. Nitrogen-rich melilite in the A-series samples and $Y_{10}Al_2Si_3O_{18}N_4$ in the B-series gave way to oxygen-rich YAG as the overall oxygen content of the material increased.

3.4 Kinetics of α-sialon formation

The above sintering experiments showed that within the range of sintering conditions used here the degree of conversion to α-sialon is not very sensitive to small changes in oxygen content or to the intermediate phases formed. It is therefore possible to use the HT-XRD data to examine the kinetics of α-sialon formation under these circumstances. The isothermal plots of sialon formation in Fig. 4(a) show that the conversion rate is greatest within the first 90–120 min of the sintering, decreasing markedly at longer times. The reaction is considered to occur by dissolution and transport of the reactants in the liquid oxide phase and the formation of the α-sialon at the surfaces of α-Si_3N_4. The inhibition of the reaction could occur by a decrease in the fraction of the liquid phase, necessitating increased degree of solid state diffusion, or covering of silicon nitride surfaces. To describe the rapid early stage of the process, only the first period of 120 min was used in determining a reaction rate constant. In this stage the transformation was assumed to be described by a simple reaction law:

$$df/dt = k(1 - f)^n \qquad (2)$$

where n is the index of reaction, f the fraction of α sialon formed and k the reaction rate constant. To evaluate the results, a best-fit n-value was determined for the 1580°C data. It was then assumed that the reaction mechanism for all other temperatures was the same and consequently this n-value (3·64) was used to estimate the k values for all temperatures. The k values thus derived are 0·0023 (1450°C), 0·0045 (1500°C), 0·0061 (1530°C) and 0·0102 (1580°C). Reaction curves based on the above assumption are drawn in Fig 7(a) and indicate the extent to which the assumed kinetic description is reasonable. The temperature dependence of the reaction rate is expressed in the form of an Arrhenius diagram in Fig. 7(b) and yields an effective activation constant of 330 kJ mol^{-1} which is consistent with a liquid diffusion process.

An alternative approach to determining the activation energy, requiring no assumptions about the process kinetics, is to construct an Arrhenius plot on the basis of ln $1/t$ versus $1/T$ where t is the time required to give a fixed degree of reaction. Here a satisfactory linear relationship was achieved for t corresponding to a conversion of 10% and this confirmed the activation constant of 330 kJ mol^{-1}. This corresponded to a reaction time

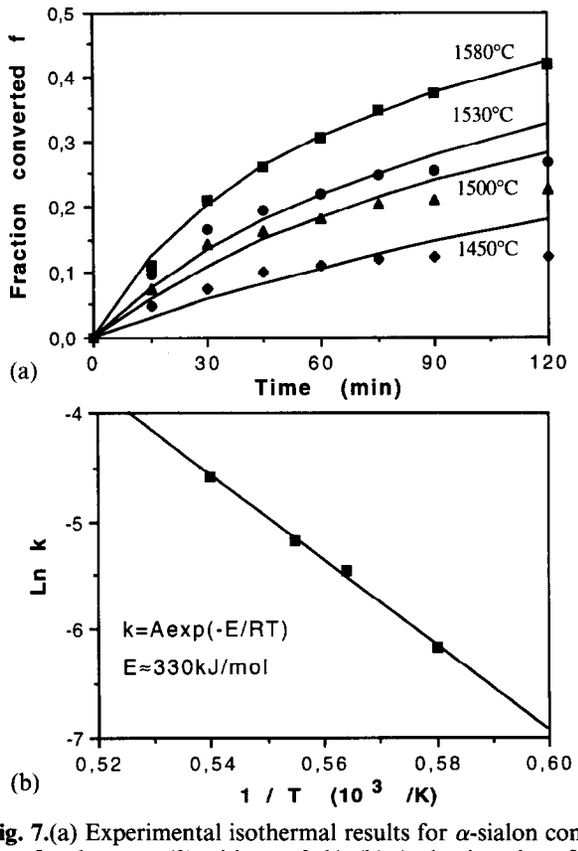

Fig. 7.(a) Experimental isothermal results for α-sialon conversion fitted to eqn (2) with n = 3·64; (b) Arrhenius plot of rate constants derived from 7(a).

of 45 min at 1450°C. Beyond this time, the results for 1450°C were no longer consistent with the linear Arrhenius plot implying an inhibiting change in reaction mechanism.

4 Discussion

As already indicated, the reaction sintering of the material studied here occurs by a complex combination of associated mechanisms occurring both in parallel and in series. After formation of an oxide liquid from surface oxides and yttria these mechanisms will include dissolution of AlN and α-Si_3N_4, transport of reactant atoms through the liquid, formation of sialon on the α-Si_3N_4 and subsequently solid state diffusion of reactants through the sialon. In addition a number of intermediate and secondary phases form depending on sintering conditions and composition. A microstructural study by Hwang *et al.*[15] has indicated that α-sialon formation occurs predominantly by heterogeneous nucleation and preferential growth on undissolved silicon nitride grains.

One of the interesting aspects of this investigation is that in the range of temperatures and conditions studied the rate and extent of α-sialon formation was relatively insensitive to small changes in oxygen content and was not influenced by the intermediate phases formed. Thus the α-sialon formation was determined mainly by the temperature and time. This is in accordance with previous findings. For example, Cao *et al.*[16] in studying the effect of extra alumina additions to an α-sialon composition concluded that, while densification was affected by the liquid phase, the early formation of α-sialon was not significantly influenced by small changes in the composition, amount or the viscosity of the liquid. The intermediate phase that formed changed from melilite to YAG with addition of alumina, but this did not influence the overall reaction sequence.

In the present work, the fact that the amount of α-sialon did not seem to change significantly with small changes in composition, while the peak separation did, suggests that the number of growing α-sialon grains was fairly constant at a given temperature but that its composition could vary. The rate of sialon formation is probably determined by the rate of dissolution and transport of silicon nitride and AlN, and therefore strongly dependent on temperature. The lower availability of AlN on the surface of the HT-XRD samples on the other hand probably only leads to a lower substitution of the α-sialon and does not affect the number and growth of grains.

β-Si_3N_4 only seem to form in very small amounts at the temperatures studied here unless major compositional changes occur, for example through a significant increase in oxygen activity, as on the surface of a sample in contact with a powder bed containing only silicon nitride and silica. It is therefore likely that the α-sialon has the lowest energy of formation at high nitrogen activities and at these relatively high temperatures. It has been suggested in the past that the α-Si_3N_4 structure is a low-temperature modification, but with yttria stabilization it readily forms.

The above observations imply that, although small compositional changes on an open surface are unavoidable, high-temperature X-ray diffraction is still an appropriate method to study the kinetics of α-sialon formation or decomposition. On the other hand, HT-XRD may not always be suitable as a means of monitoring all the products of the reactions since the intermediate and secondary phases are strongly dependent on sintering conditions. Thus, in the present study the $Y_{10}Al_2Si_3O_{18}N_4$ formed during presintering gradually disappeared during treatment in the HT-XRD while other intermediary phases formed. These were different from those formed during sintering in a powder bed in a conventional graphite furnace.

A very characteristic feature of the kinetics of sialon formation was the dramatic inhibition of growth after a certain fraction of transformation. The range of inhibition moved to higher fractions of transformation and longer times with increasing temperature suggesting that the effect may be caused by a decrease in the amount of liquid.

5 Conclusions

The reaction sintering of an yttria α-sialon from a mixture of yttria, AlN and α-Si_3N_4 has been studied at temperatures between 1450 and 1580°C. The rate of α-sialon formation was significant during an initial reaction stage but became inhibited after a limited fraction of conversion had occurred. The rate of reaction as well as the fraction of conversion and time at which inhibition set in all increased with temperature. The activation energy of the initial reaction stage was 330 kJ/mol.

A variety of intermediate and secondary phases were observed to form during sintering depending on variations in the sintering conditions such as the oxygen level of the sintering environment and small variations in the starting composition. The rates of α-sialon formation were however not affected significantly by these variations in conditions or secondary phases.

Since the rate of α-sialon formation is relatively insensitive to other sintering conditions than the

temperature, HT-XRD is considered to be a suitable technique for studying the kinetics of α-sialon formation and was applied for this purpose in this study. The technique is however considered unsuitable for the study of the formation of secondary phases since these are very sensitive to the sintering conditions.

(Received 13 February 1995; revised version received 19 May 1995; accepted 22 May 1995)

Abstract

The crystallization behaviour of a ZrO_2-containing glass and a ZrO_2-free glass in the Y_2O_3–Al_2O_3–SiO_2 system prepared at 1700°C were compared in order to study the influence of ZrO_2 on the nucleation and growth processes. Techniques used included SEM, DTA and XRD analysis. The microstructural development of the ZrO_2-containing material during crystallization was more complex than that of the ZrO_2-free material. In the crystallization treatments no phase separation prior to crystallization could be observed and no precursor crystalline phase was observed to form in the ZrO_2-containing glass. Thus the added zirconia could be considered to act as a growth modifier rather than a catalyst nucleating agent.

1 Introduction

During the sintering of Si_3N_4 materials by liquid-phase sintering an oxynitride liquid forms through reaction of oxide sintering aids (such as Y_2O_3 and Al_2O_3) with surface silica on the starting Si_3N_4 powder particles and some of the Si_3N_4. Upon cooling from the sintering temperature an intergranular glassy phase forms from the liquid. The compositions of this phase in, for example, materials with yttria and alumina as sintering aids lie within the Y_2O_3–Al_2O_3–SiO_2 system. In general, the presence of such glassy phases has a deleterious influence on the mechanical properties and oxidation behaviour of Si_3N_4 ceramics.[1–5] One approach to reducing these effects is to induce a crystallization of the amorphous phase by means of a suitable heat treatment. Experimental studies of intergranular phases to better understand their crystallization behaviour and associated property changes are difficult to perform *in situ*; for this reason it is of interest to study bulk glasses with compositions that simulate such phases.[6–10]

Nucleation catalysts are widely used in glass systems to promote crystallization. Thermal treatment at a temperature necessary for precipitation of a crystalline phase, which acts as primary nucleation centers, leads to the devitrification of the glass.[11] Another catalysis mechanism which leads to a subsequent volume crystallization and which is not yet entirely understood is phase separation leading to the formation of a fine dispersion. Phase separation can be induced by a number of oxides (such as, e.g. TiO_2 and ZrO_2).[11] Crystallization studies made by several investigators[2,12,13] have shown that ZrO_2 added to yttria–alumina–silica glasses can catalyse their crystallization.

The aim of the present work was to study the influence of ZrO_2 on crystallization of an yttria–alumina–silica glass prepared at 1700°C. The crystallization behaviour of a high Y_2O_3-content glass with and without the addition of 6 wt% zirconia was studied.

2 Experimental

The solubility limit of ZrO_2 at 1700°C in an yttrium aluminosilicate liquid with the composition of 46·9 wt% Y_2O_3, 24·3 wt% Al_2O_3 and 28·8 wt% SiO_2 was in the previous study determined as 6 wt%.[14] Therefore two glasses (A and B) with compositions x ZrO_2 + (100–x) [46·9 Y_2O_3, 24·3 Al_2O_3, 28·8 SiO_2] (where x in wt% was 0 and 6) were chosen for the present study. Both compositions were subjected to the same heat treatments as described below.

Samples were prepared from high-purity Y_2O_3, Al_2O_3, SiO_2 and unstabilized ZrO_2 powders (Rhone Poulenc, Alcoa Chemicals, Johnson Matthey Alfa Products and Sigma chemical respectively). The powders were weighed in a precision balance, mixed in polyethylene containers on a Siemens roller mill for 10 h using prophanol as mixing medium, dried and sieved. Batches of 100 g each were then mechanically compacted into molybdenum crucibles and fired in a nitrogen

*Starting materials were amorphous glasses, as evidenced by X-ray diffraction.

atmosphere (pressure of 0·17 MPa) at a temperature of 1700°C for 3 h. The heating rate up to the firing temperature was 5°C/min, the cooling rate was that given by the furnace after switching off (firing temperature to 1400°C, 20°C/min; 1400–950°C, 15°C/min and 950–500°C, 10°C/min). The furnace was a cold wall vacuum/pressure furnace with a graphite heater.

Pieces of the as-prepared glass (approximately 7 × 7 × 7 mm) were heat-treated at selected temperatures and times (see Table 1); they were placed in a Si_3N_4 powder bed in Mo crucibles and heated in a 0·17 MPa nitrogen atmosphere in the same furnace as above. The heating rate was 5°C/min and cooling was furnace cooling (see above). As-melted samples and heat-treated samples were examined by X-ray diffraction to check for crystallization and to identify crystalline phases. Powder samples of the as-melted glasses were also subjected to differential thermal analysis (DTA) at a heating rate of 10°C/min in a nitrogen atmosphere using an alumina powder reference standard. Dilatometric measurements were made on selected samples in a Netzch dilatometer 402E at a heating rate of 2°C/min. The microstructure of the samples were examined by scanning electron microscopy (SEM) using a CamScan S4-80DV instrument and attached energy dispersive spectrometer (EDS).

3 Results and Discussion

3.1 Phase identification

Crystalline phases identified by X-ray diffraction of glass cubes devitrified at temperatures between 900 and 1350°C are compiled in Table 1. These temperature limits were dictated by the measured

Table 2. Dilatometric measurements (glass transition temperatures — M_g and dilatometric softening points — M_s) and DTA measurement (the maximum of endothermic peaks indicating melting temperatures — T_L)

Sample	M_g(°C)	M_s(°C)	T_L(°C)

B	842	900	1410, 1425*

*Two melting temperatures because of the immiscibility.[14]

glass transition temperatures and melting temperatures of the glasses (Table 2). For composition A the detected phases are in general agreement with those expected from the equilibrium phase diagram.[2,6,7,15–17] namely $Y_2Si_2O_7$ and $Al_6Si_2O_{13}$, without the appearance of the Al_2O_3 phase reported in previous studies.[6,9,14] In composition B the cubic yttria stabilized ZrO_2 ($Y–ZrO_2$) phase also appeared in all the X-ray diffraction patterns of samples heat treated at temperatures >1100°C (Fig. 1). Some unidentified phases were also detected for some heat treatments. They are probably intermediate phases and are not included in Table 1.

3.2 Microstructural changes

The EDS analysis of as-prepared glasses of both compositions revealed impurities of Fe and Mo in the microstructure probably coordinating from the starting powders and from the Mo crucibles. They appeared as small (<2 μm) particles probably of iron silicides[18] and molybdenum oxides.

Fig. 2 Glass with composition A after heat treatment at 980°C for 6 h (backscatter image—500 ×).

They influenced the crystallization process during the heat treatment to some extent but it is important to emphasize that they appeared in both glass compositions and they were of a very small amount.

At 900–950°C, no observable crystallization of composition A or B occurred. At 980°C, glass A had an opaque appearance when heat-treated for 6 and 12 h; this appeared to be due to the formation of small (1–10 μm) crystals, probably of y-$Y_2Si_2O_7$ and β-$Y_2Si_2O_7$ species (Fig. 2). They occurred to approximately the same extent for both treatment times. Their crystallization appeared to be heterogeneously nucleated by the impurities in the glass.

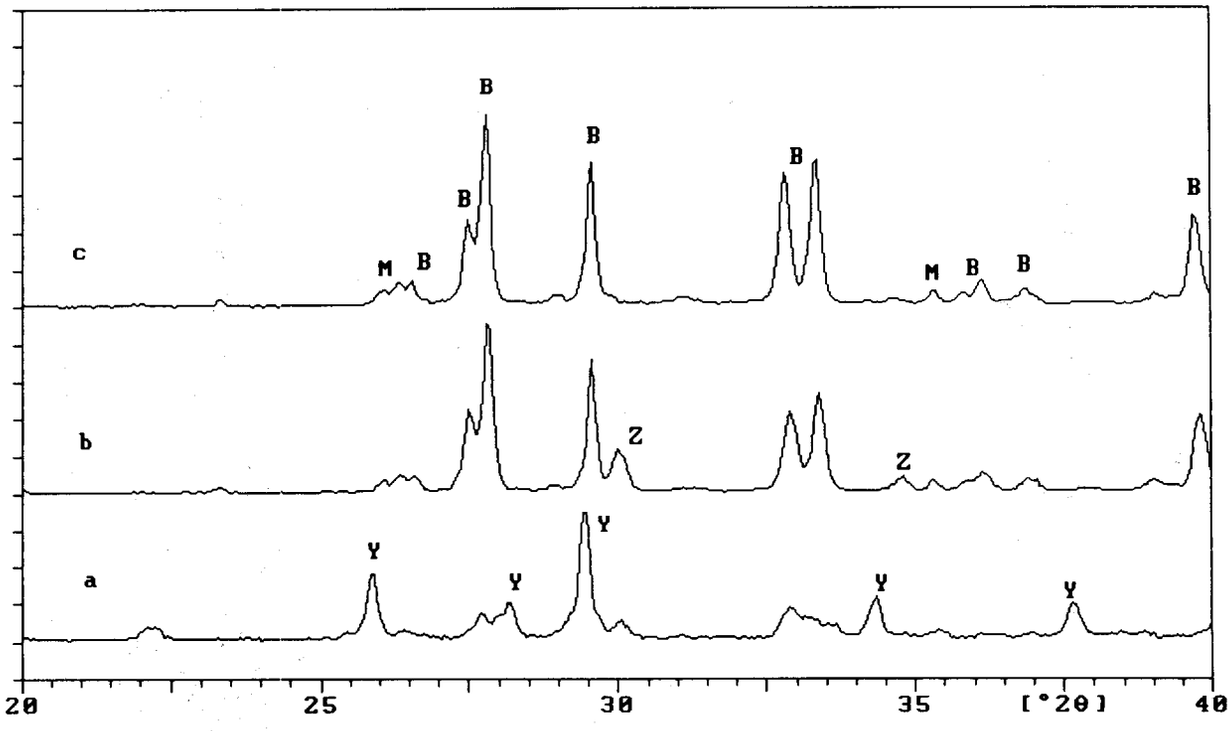

Fig. 1. X-ray diffraction patterns of the investigated glasses: (a) with 6 wt% ZrO_2 (composition B) heat treated at 1100°C for 1 h, (b) with 6 wt% ZrO_2 heat treated at 1300°C for 12 h and (c) without the addition of ZrO_2 (composition A) heat treated at 1300°C for 12 h. The symbols represent identified phases: (Y) y - $Y_2Si_2O_7$, (B) β - $Y_2Si_2O_7$, (M) mullite and (Z) cubic yttria stabilized ZrO_2. At $2\theta = 30°$ the ZrO_2 (111) peak coincides with a y - $Y_2Si_2O_7$ peak.

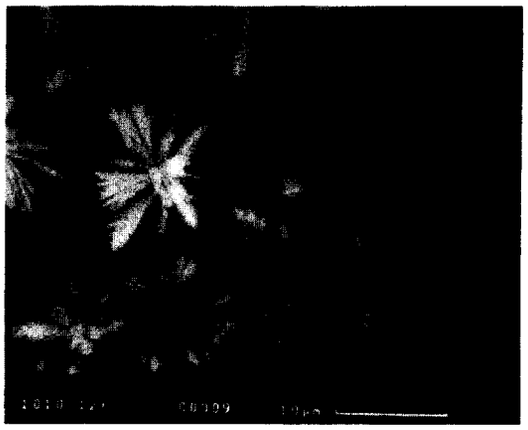

Fig. 3. Micrograph of composition A heat treated at 1010°C for 12 h with spherulitic dendrites of $Y_2Si_2O_7$ (backscatter image—2500 ×).

At 1010°C, composition A treated for 6 and 12 h exhibited an increased rate of crystallization and the occurrence of small spherulites (≈ 10–20 μm in diameter) consisting of radially growing dendrites of $Y_2Si_2O_7$ (Fig. 3). Spherulites are transient morphological forms produced during the rapid growth of crystals when the rate of growth exceeds that of diffusion and are often observed during the crystallization of highly supercooled viscous liquids. Composition B heat-treated at this temperature exhibited a similar degree of crystallization to composition A treated for 6 h at 980°C. However, in this glass the crystals were double platelike precipitates of $Y_2Si_2O_7$ in some cases with Y–ZrO_2 particles in their centers serving as nucleating catalysts (Fig. 4). These Y–ZrO_2 particles might either have been nucleated by the impurities in the glass or originated from the parent glass surviving the melting process.

At 1040°C, the crystallization rate increased for both compositions; in samples treated for 6 and 12 h the spherulites in composition A and plate crystals in composition B extended to larger dimensions (≈ 20–30 μm in diameter for spherulites and

Fig. 4. Glass B after heat treatment at 1010°C for 12 h with Y–ZrO_2 particles in centres of double platelike crystals of $Y_2Si_2O_7$ (backscatter image—2500 ×).

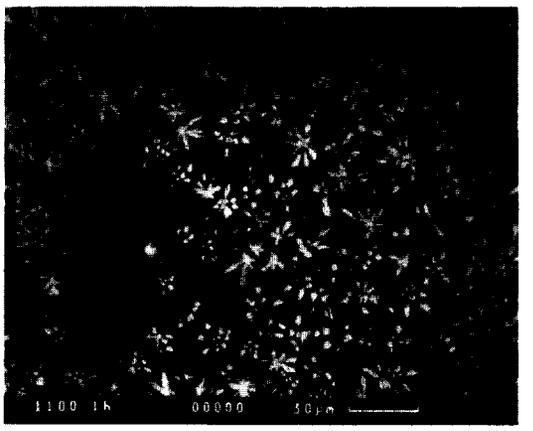

Fig. 5. Spherulites of $Y_2Si_2O_7$ in composition A after 1 h at 1100°C (backscatter image—500 ×).

20–30 μm in length for plates respectively). The microstructure of B began to be characterized by a dendritic morphology of the $Y_2Si_2O_7$. Such a morphology has been observed in the surface oxide layer of hot-pressed Si_3N_4–Y_2O_3–SiO_2 materials by Babini *et al.*[19] These authors attributed the dendrite formation to constitutional supercooling caused by a larger concentration of yttrium in the glass than in stoichiometric $Y_2Si_2O_7$. In the present case, the crystallization of y-$Y_2Si_2O_7$ requires the rejection of Al (solubility of Al in the y-$Y_2Si_2O_7$ phase decreases as a function of increasing crystallization temperature[18]), Si, O and Zr to the glass phase ahead of the glass/crystal interface. This effect would cause the constitutional supercooling resulting in dendrite formation. Glass A treated for 1 h had an opaque appearance due to a microstructure similar to those developed at 980°C after 6 and 12 h.

At 1100°C, the crystallization rate for both compositions increased dramatically with only small amounts of amorphous glassy phase retained in the microstructure (Table 1, Figs 5 and 6). The Y–ZrO_2 phase appears in the micrographs of B samples as small dendrites. In the B-glass the y-$Y_2Si_2O_7$ crystals grew to large dimensions

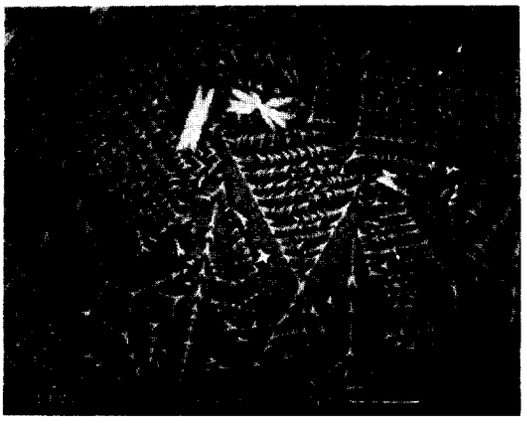

Fig. 6. Glass B after 1 h at 1100°C (backscatter image—500 ×).

Fig. 7. Crystallization of glass B at 1300°C after 12 h (backscatter image—500 ×).

presumably because they nucleated on the relatively few residual, undissolved ZrO_2 and possibly on impurity particles.

In the temperature range, 1150–1350°C (only B compositions were studied),[14] the samples were almost fully crystallized. The observations revealed different phase transformations such as crystallization of y-$Y_2Si_2O_7$, crystallization of β-$Y_2Si_2O_7$, transformation of y-$Y_2Si_2O_7$ to β-$Y_2Si_2O_7$ and crystallization of cubic yttria stabilized ZrO_2(Y–ZrO_2) occurring at different temperatures.

At 1150 and 1200°C, the microstructure of the crystallized samples was very complex with the $Y_2Si_2O_7$ occurring in the form of dendrites and fibrelike branches with an interfibrillar material which is probably amorphous.[6] At 1300°C, the y-$Y_2Si_2O_7$ phase transforms to the β-$Y_2Si_2O_7$ phase which begins to dominate the microstructure. At 1350°C, the transformation of the y-$Y_2Si_2O_7$ phase to the β-$Y_2Si_2O_7$ phase results in a β with blocky morphology to be seen growing from what were originally y-$Y_2Si_2O_7$ dendrite branches (Fig. 7). Aspects of the y $\rightarrow$ β transformation and the role of Y–ZrO_2 and its appearance in the microstructure will be discussed in the following section.

3.3 Influence of ZrO_2 on crystallization behaviour

The solubility of ZrO_2 in the investigated glass prepared at 1700°C is limited to 6 wt%.[14] As shown in Table 2 the addition of ZrO_2 leads to a decrease of the dilatometric glass transition temperature (M_g) and the dilatometric softening point (M_s) of the glass. DTA measurements on glasses with various ZrO_2 contents (0–8 wt%)[14] showed only one exothermic peak. However, this does not mean that only one crystal species is crystallizing. The broadness of the peak in ZrO_2-containing glasses indicates that ZrO_2 and other phases, mainly the $Y_2Si_2O_7$ phase, crystallize within a narrow temperature interval. The shape and lower intensity of the exothermic peak for composition B indicate a lower crystallization rate of this glass.

The crystallization of $Y_2Si_2O_7$ in composition B requires the rejection, not only of Al, Si and O but also Zr at the glass/crystal interface. The enrichment of Zr in the glass ahead of the interface would lead to a higher local viscosity of the glass near the interface than would be the case in glass A, thereby causing inhibition of the crystal growth of the $Y_2Si_2O_7$ phase. Thus, under these conditions ZrO_2 acts as a growth modifier during crystal growth.[20] The local enrichment of Zr at the glass/crystal interface might be expected to lead to the formation of ZrO_2 crystals. However, the growth of the ZrO_2 particles beyond colloidal dimensions is limited by slow diffusion of Zr in the glass at lower temperatures. In this study ZrO_2 particles growth at the glass/crystal interface was observed at higher temperatures (> 1100°C), the particles being detected by XRD and in SEM (Figs 1 and 7 and Table 1). Some of ZrO_2 remains trapped in the $Y_2Si_2O_7$ phase during cooling from the heat treatment temperature and appears as a decoration of the $Y_2Si_2O_7$ crystals in the microstructure (Fig. 8).

It has been suggested that ZrO_2 promotes liquid immiscibility because of its high cationic field strength.[21] In the present case, DTA measurements revealed two endothermic peaks in glass B around 1400°C without any mass changes occurring during the measurement.[14] They were interpreted as representing melting reactions and therefore it was concluded that the addition of ZrO_2 does enhance liquid immiscibility in this system. On the other hand, in the crystallization treatments no phase separation prior to crystallization could be observed possibly because the temperatures lay outside the appropriate range. Nevertheless, at high heat treatment temperatures (1200–1350°C) the Zr entrapped in the interfibrillar glass phase, which is rich in Al, Si and O (due to the phenomenon described above and no

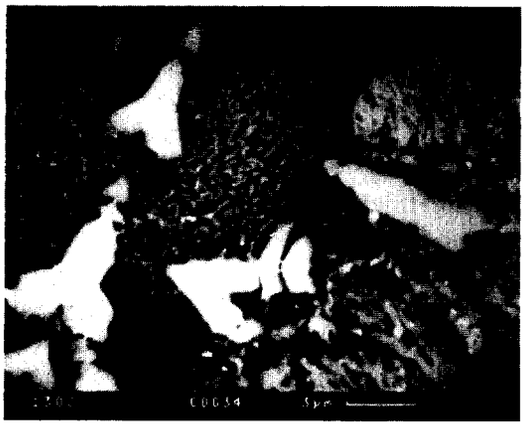

Fig. 10. Crystallization of glass B (1300°C for 1 h). Zr-rich droplets in an area that was originally y-$Y_2Si_2O_7$ fibres with the interfibrillar glass phase (backscatter image—5000 ×).

Al-containing phase having yet crystallized out) precipitated to form small Zr-rich droplets (Fig. 9). These droplets then provided nucleation sites for the β-$Y_2Si_2O_7$ and mullite crystals which then grew from the original y-$Y_2Si_2O_7$ fibres and interfibrillar glass phase (Fig. 10). Whether or not this process was initiated by phase separation[22] of the interfibrillar glass phase could not be ascertained by the available SEM analysis.

4 Conclusions

The crystallization of the ZrO_2-free glass proceeded by the formation of spherical aggregates (spherulites) consisting of radially growing dendrites. In contrast, only a small number of spherulites were observed in the ZrO_2-containing glass, the crystallization proceeding by the formation of extended dendrites rather than spherulites and being accompanied by the formation of double platelike crystals. Therefore it is believed that Zr acts as a growth modifier in this glass. As in studies of the devitrification mechanisms in $Li_2O{\cdot}Al_2O_3{\cdot}6SiO_2$ glasses[23] containing ZrO_2 as a nucleating agent, no precursor crystalline phase was observed to form in the investigated yttria–alumina–silica-glass. ZrO_2 precipitates observed in some cases, probably remaining from the glass melting, served as nucleating centers for the crystallization of the $Y_2Si_2O_7$ phase. Some of the $Y_2Si_2O_7$ crystals were probably also nucleated by impurities in the glass. The low frequency of these impurity particles and of ZrO_2 particles that survived the melting led to the formation of large $Y_2Si_2O_7$ grains. The addition of ZrO_2 might increase the rate of the y $\rightarrow$ β transformation occurring at higher temperatures compared to the ZrO_2-free glass but present results do not confirm this.

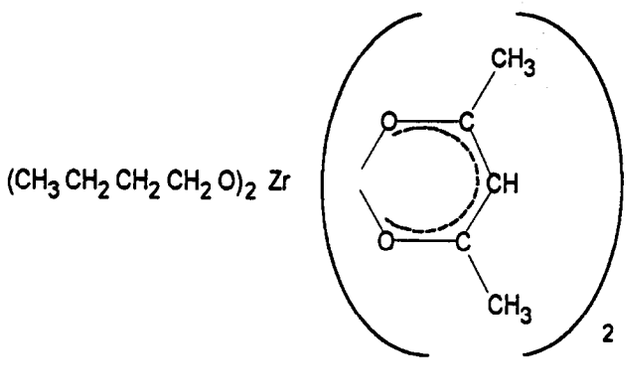
(Received 24 February 1995; revised version received 19 May 1995; accepted 22 May 1995)

Abstract

A zirconium alkoxide derivative, dibutoxybis(acetylacetonato) zirconium, was polymerized at 120°C and 300 millitorr for 3 h to form oligomers, as characterized by gel permeation chromatography and Fourier transform infra-red spectroscopy. Pyrolysis of the precursor at 675°C in flowing 5% H_2 in N_2 followed by cooling to room temperature, produced nano-scale, tetragonal ZrO_2 considerably below the tetragonal-to-monoclinic transformation temperature (approximately 1200°C). Subsequent heat treatment of the same precursor in flowing air under otherwise identical conditions produced approximately 8 vol% monoclinic ZrO_2. The possible formation of oxygen vacancies from polymer pyrolysis and their role in nucleating the metastable tetragonal phase are discussed.

1 Introduction



It has been well documented[1–4] that the pyrolysis of zirconium-based precursors produces a metastable tetragonal phase below the monoclinic–tetragonal transition temperature (approximately 1200°C) with crystallite sizes reported in the range of 5 to 460 Å.[2,3] Several investigators,[5–7] including Livage *et al.*[1] and Clearfield,[8] have speculated that the metastability of tetragonal zirconia (t-ZrO_2) is attributed to the structural similarities between the precursor phase and the tetragonal phase. In conjunction with these structural similarities, Livage *et al.*[1] and Osendi *et al.*[3] discussed the nonstoichiometry associated with the metastable tetragonal phase. By crystallizing ZrO_2 from zirconyl chloride *in vacuo*, Livage *et al.*[1] showed that a nonstoichiometric tetragonal phase predominated, whereas crystallization in air produced the monoclinic phase. From electron paramagnetic resonance studies on ZrO_2 crystallized from zirconyl chloride, Osendi *et al.*[3] concluded that tetragonal metastability results from lattice defects, specifically anionic vacancies, created upon crystallization. More recently, Igawa *et al.*[9] refined crystal structure calculations for the metastable tetragonal phase using neutron diffraction and Rietveld analysis on ZrO_2 crystallized from $Zr(O(CH_2)_3CH_3)_4$. They concluded that the crystal lattice coincided with those of doped tetragonal structures rather than pure t-ZrO_2 at 1200°C. However, in all of these cases, the origin of nonstoichiometry is unclear.

In spite of this ambiguity, these conclusions suggest that ZrO_2 crystal structure might be tailored by the choice of precursor and processing. An appealing application would be the formation of t-ZrO_2 with a preferred orientation caused by the processing of oriented, zirconium-based polymers. For such a processing strategy to be successful, the molecular configuration of the polymer must influence the final crystal structure. Establishing the existence of such a relationship relies on a full understanding of the precursor-to-ceramic transition. However, what factors influence structure on the molecular level during pyrolysis remain a critical issue not resolved in the literature. Although our intent is to control zirconia crystallization, the underlying goal is to address metallo-organic decomposition from a molecular standpoint. In this paper, we describe a mechanism by which the molecular configuration of a zirconium-based polymer might influence structural features in the pyrolysis product.

2 Experimental Procedure

Dibutoxybis(acetylacetonato) zirconium (BAZ), represented as:

*To whom correspondence should be addressed.

was obtained in a 60 wt% solution of n-butanol (97% pure 2:1 (alkoxide-to-zirconium); the remaining 3% is 1:1) from Gelest Inc., Tullytown, PA, USA. The excess n-butanol was distilled from the solution *in vacuo*, resulting in a yellow oil. Similar to the method described by Yogo,[10] the remaining BAZ was refluxed for 3 h at 120°C and 300 millitorr such that a reddish-brown gel was formed upon cooling to room temperature. To remove the retained solvent, samples were dried in flowing 5% H_2 in N_2 (300 cm^3 min^{-1}) at 200°C for 12 h, producing a fine orange powder. Samples were then fired at 675°C in a flowing gas, either H_2 in N_2 or air (300 cm^3 min^{-1}), and then allowed to cool to room temperature.

Fourier transform infra-red spectroscopy (FTIR), performed on a Nicolet 550 infra-red spectrometer, was used to identify structural features of the polymerized complex. The analysis was restricted to vibrational energies in the mid-infra-red spectrum, corresponding to a wavenumber range of 4000–400 cm^{-1}. For this study, neat samples were prepared by dispersing ground samples onto NaCl plates. Gel permeation chromatography (GPC), by Lark Enterprises, Webster, MA, USA, was used to determine the relative molecular weight and shape of the polymerized complex in solution as compared with a polystyrene standard. Styragel HR 2, 1, and 0·5 columns, employed for the analysis, were operated at 37°C using tetrahydrofuran as the mobile phase. A low molecular weight oligomer mix of polystyrene was used as a standard for calibration. Transmission electron microscopy (TEM) samples were prepared by grinding the samples with a mortar and pestle into a powder that could be applied to a graphite-coated Cu grid using acetone as the carrying medium. A JEOL 2000 FX operated at 200 kV was used to conduct bright-field imaging and selected-area diffraction (SAD) studies.

X-ray diffraction (XRD) performed on a Siemens D500 diffractometer with CuKα radiation was used to determine the phases present and the crystallite size using the Scherrer equation with respect to the {1 1 1} reflections.[11] The monoclinic volume fraction, v_m, was calculated from the linear intensity relationship

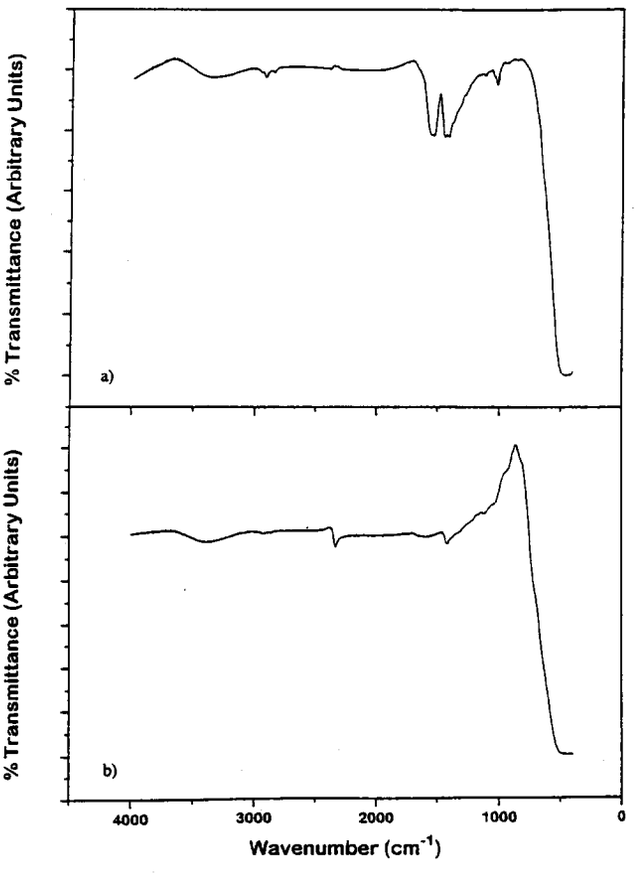
$$v_m = \frac{I_m(\bar{1}\,1\,1) + I_m(1\,1\,1)}{I_m(\bar{1}\,1\,1) + I_m(1\,1\,1) + I_t(1\,1\,1)} \quad (1)$$

where the subscripts m and t represent monoclinic and tetragonal, respectively. Although eqn (1) is consistent with literature on this topic, several investigators[12–14] have demonstrated that v_m calculated from eqn (1) can deviate from the actual v_m as much as 20% at $v_m = 0{\cdot}46$. Modifications based on structure factor calculations have been suggested,[12] unfortunately, an accurate diffraction model for metastable ZrO_2 that addresses stoichiometry and corresponding ionic position remains to be developed.

3 Results and Discussion

3.1 Molecular structure

The FTIR spectra in Fig. 1 impart information regarding the molecular structure and the precursor-to-ceramic transition of this organozirconium complex. The peak assignments were made by comparison to similar metal alkoxides[15,16] and metal bisacetylacetonate complexes.[17–19] Table 1 lists the observed frequencies and band assignments for this zirconium complex.



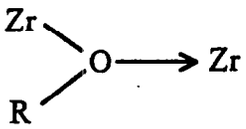


Fig. 1. Fourier transform infra-red (FTIR) spectra of (a) dried sample and (b) sample pyrolysed at 675°C.

Table 1. Observed frequencies and band assignments of *cis*-oligo[dibutoxybis(acetylacetonato) zirconium] (COBAZ) dried at 200°C; ν denotes stretching frequencies, δ denotes deformation frequencies

Observed frequencies (cm^{-1})	*Band Assignments*
3350	ν –OH
2920	ν –CH
2850	ν –CH
1550	ν C = O
1453	δ $-CH_3$
1420	δ –CH
1120	ν C – O
1025	ν Zr = O
452	ν Zr – O – Zr

The residual–OH bands in the spectra of the dried sample (Fig. 1(a)) result from possible hydrolysis of butoxy groups. The absence of bands ascribed to acetylacetonate (acac), such as Zr =O and $-CH_3$, in the spectra taken of the pyrolysed sample at 675°C in air (Fig. 1(b)) signify bidentate ligand decomposition during the pyrolysis process, leaving only the Zr–O–Zr bonds. These oxo bonds are consistent with investigations by Barraclough *et al.*[15] and Bradley *et al.*[20] which have shown that zirconium atoms, similar to other metal atoms, can be electrostatically bonded as follows:

where R represents $CH_3(CH_2)_3$ in this case.

Figure 2 shows the resulting GPC chromatograph of the precursor. The broad peak corresponds to a wide range of molecules having similar molecular weights, whereas the distinct peaks correspond to large concentrations of specific low molecular weight molecules. Preliminary GPC data indicated that the precursor molecular weight was less than the monomer

molecular weight, suggesting that the precursor was retained in the column more readily than the polystyrene standard; possibly due to apparent molecular size or packing interactions. From this observation, the molecular weight distribution was normalized to the last eluted peak, corresponding to the monomer molecular weight. Table 2 lists the molecular weight ranges assigned to the remaining peaks. Once normalized, the values of the adjacent peaks 2, 3 and 4 correspond to a dimer, trimer and tetramer, respectively.

The molecular architecture of these oligomers depends on the *cis*- or *trans*-configuration of the monomer as shown by Bradley and Holloway in an analogous system.[21,22] In their study, proton nuclear magnetic resonance (H^1 NMR) analysis of titanium bisacetylacetonate derivatives $(Ti(acac)_2(OR)_2$ where R represents Me, Et, Pr^i, Bu^t groups, etc.) demonstrated that the *cis*-isomer is favoured over the *trans*-isomer. Following this premise, the *cis*-monomers combine by alkoxy bridges, as described by Thomas,[23] forming oligomers during polymerization. The resulting oligomers, *cis*-oligo[dibutoxybis(acetylacetonato) zirconium] (COBAZ), have a host of structural isomers dependent on this *cis*-configuration and steric factors associated with the organic ligands. Two possible structures, a 'linear' and a cyclic configuration, of a tetrameric oligomer are depicted schematically in Fig. 3. For clarity, the $CH_3(CH_2)_3$ groups bonded to the oxygens that bridge the zirconiums together have been left off. Within the COBAZ backbone, each zirconium has an eight-fold coordination with oxygen; however, each zirconium in

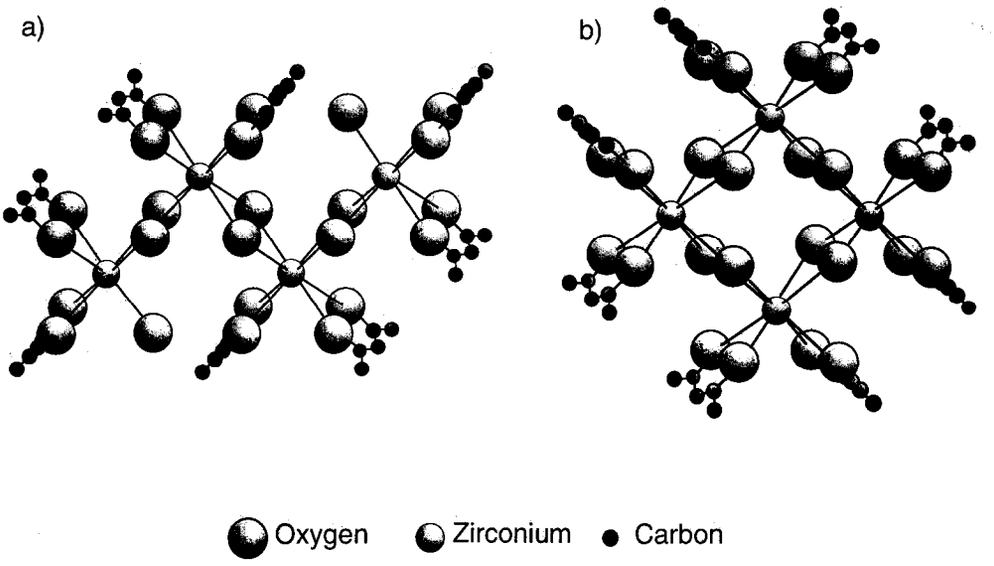

Fig. 3. Molecular structures of (a) 'linear' and (b) cyclic tetrameric *cis*-oligo[dibutoxybis(acetylacetonato) zirconium] (COBAZ). Hydrogen atoms and alkyl groups have been omitted for clarity.

the terminal positions has a seven-fold coordination due to an unshared alkoxy ligand not used in bridging, see Fig. 3(a). The acetylacetonate ligands, which hinder reaction due to steric obstruction during the polymerization process,[24] form the perimeter of the oligomer.

3.2 Pyrolysis

Although the COBAZ XRD data do not demonstrate any long-range order, brightfield imaging and SAD in TEM show (see Fig. 4) COBAZ to comprise nano-scale crystallites. Pyrolysing these COBAZ crystallites under reducing conditions of flowing 5% H_2 in N_2 produces a completely tetragonal oxide (see Fig. 5(a)), black from incomplete combustion of the organic material. The average crystallite size, approximately 110 Å, falls within such a range that line broadening masks resolution of the {200}, {220} and {113} peaks. The same sample annealed in flowing air under otherwise identical conditions shows the emergence of the (1 1 1) and ($\bar{1}$ 1 1) peaks of the monoclinic phase as can be seen in Fig. 5(b). XRD data indicate that

Fig. 4. Transmission electron micrograph (TEM) and selected-area diffraction (SAD) data of the dried precursor.

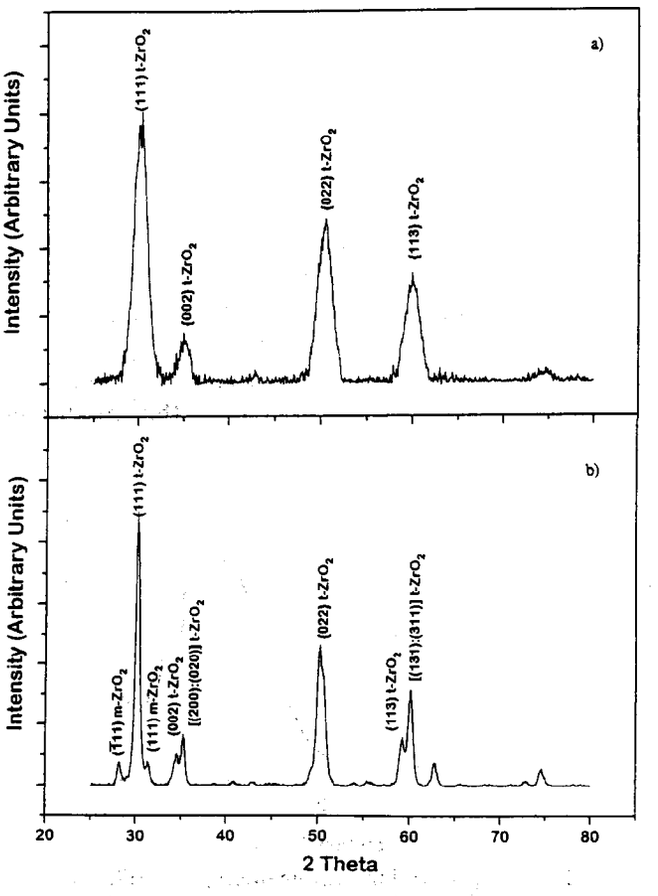

Fig. 5. X-ray diffraction (XRD) data of sample pyrolysed at 675°C in (a) flowing 5% H_2 in N_2 and (b) flowing air.

after 12 h of exposure to oxygen in air, 8 vol% of the tetragonal phase with an average crystallite size of approximately 480 Å underwent a phase transformation to m-ZrO_2 with a crystallite size of 570 Å. Furthermore, the resulting white powder was more friable after exposure to oxygen, indicative that the transformation had occurred.

Interpretation of this outcome can be related to significant structural features on the molecular level. Analogous to zirconyl chloride, COBAZ has a similar molecular structure to the t-ZrO_2 crystal lattice with the exception of the terminal positions. Upon heat treatment, the organic material decomposes, allowing the alkoxy bridges to undergo oxolation, the process by which the alkoxy bridges convert to oxygen bridges. At this point, the eight-fold coordination of zirconium within the oligomeric chain is retained, which is also true of the seven-fold coordination of the terminal zirconium. Upon pyrolysis, the terminal positions become likely sites for lattice defects, more specifically oxygen vacancies. We propose that these defects retained from the COBAZ structure are instrumental in producing the tetragonal phase during nucleation of the ZrO_2 crystallites under oxygen-deficient conditions. A similar phenomenon has been documented for other martensite systems in which point defects sustain tetragonality.[25] This inception of lattice defects based on the initial structure of the precursor may also explain the nonstoichiometry that Livage *et al.*[1] and Osendi *et al.*[3] saw in their investigations.

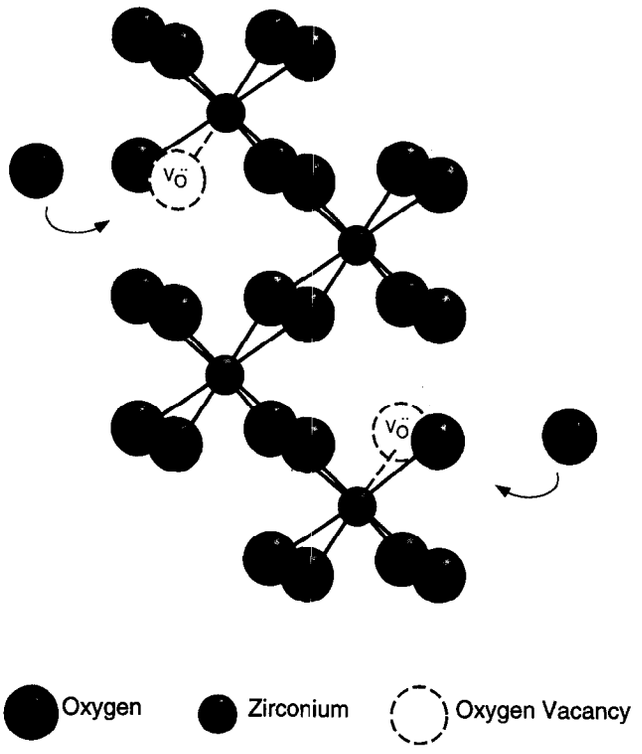

Fig. 6. Schematic of oxygen movement into oxygen vacancies that act as dopants to stabilize the tetragonal phase of zirconia during crystallization of a zirconium-based polymer. The polymer is at a point in pyrolysis in which the organic material has decomposed.

Akin to the work of Igawa *et al.*,[9] the resulting nano-crystallite, metastable t-ZrO_{2-x} should have lattice parameters similar to those of doped zirconias at room temperature. The probability of transformation to the monoclinic phase during this onset of nucleation may be relatively small due to the crystallite size.[26] Upon further heat treatment in the presence of oxygen, the anionic vacancies fill as depicted in Fig. 6. A sufficient decrease in the number of these vacancies should facilitate instability in the metastable tetragonal phase. Our results also show that crystallite coarsening and residual carbon accompany the pyrolysis. Because the metastable phenomenon also occurs in the zirconyl chloride system which is devoid of residual carbon, its actual influence is questionable; however, evidence that carbon may stabilize nonstoichiometry has been found in the literature and cannot be ignored.[27] Unfortunately, assessing the role that these factors play in nucleation, transformation and stability of metastable, tetragonal crystallites is not easily accomplished.

4 Summary

To address metallo-organic decomposition on the molecular level, we have found that the molecular configuration of the precursor, COBAZ, and the resulting oxide after pyrolysis are intimately related. We propose that zirconium, within the COBAZ backbone, has an eight-fold coordination to oxygen, similar to the t-ZrO_2 unit cell; whereas terminal zirconium has a seven-fold coordination. When pyrolysed in the absence of oxygen, COBAZ nucleates a completely t-ZrO_{2-x} bearing oxygen vacancies retained from the COBAZ structure, particularly from the terminal zirconium positions. These vacancies play an integral role in tetragonal nucleation. When t-ZrO_{2-x} is heat treated in the presence of oxygen under otherwise identical conditions, a fractional amount of monoclinic phase develops. This introduction of oxygen diminishes the number of vacancies such that tetragonal instability occurs, facilitating monoclinic growth.

Acknowledgments

Abstract

Sintered discs (1450°C) of yttria–stabilised tetragonal zirconia (3 mol% Y_2O_3) with additions of 1, 10 and 20 mol% TiO_2, were treated in distilled water in an autoclave at 170°C for times up to 144 h. X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) were used to monitor changes which occurred at the surface of the discs during autoclave treatment. The addition of TiO_2 retarded the transformation of the tetragonal (t)-phase to monoclinic (m)-phase as determined by XRD. During autoclave treatment an increase in the Ti/Zr ratio, decrease in the Y/Zr ratio and a peak in the percentage Zr^{3+} were observed using XPS. Furthermore, at long autoclave treatment times there was a surface oxygen enrichment in excess of that expected from the stoichiometry. The data have been interpreted in terms of vacancy annealing and the rate of transformation to m-ZrO_2 appears to be related to the presence of Zr^{3+}, adsorbed water and substitutional cations such as Ti^{4+} in modifying adsorption sites at the surface.

1 Introduction

Sintered and fully dense Y_2O_3–stabilized tetragonal zirconia polycrystal (Y–TZP) undergoes an unusual surface degradation at low temperatures (100–500°C) during exposure to air saturated with water vapour or autoclave treatment. The degradation is most pronounced at ~250°C and is characterized by a loss of mechanical properties[1–4] as a result of microcracking, spalling or even complete collapse of the sintered body.[5–8] The surface degradation has been shown to be due to transformation of the surface tetragonal (t) grains to monoclinic (m) phase and the microcracking results from the volume expansion associated with the transformation to the m-phase. Hence the longer the exposure time to moist environments the deeper the transformation zone and the more dire the consequences for the mechanical properties of the sintered bodies.[2,6–11]

The amount of transformation depends on grain size and yttria content of the Y–TZP.[5,11] For example, Watanabe *et al.*[3] found that the critical grain size below which no transformation occurred, increased from 0·2 to 0·6 μm as the yttria content of the Y–TZP increased from 2 to 5 mol% Y_2O_3. As the yttria content is increased the t-phase becomes more stable on a thermodynamic basis and consequently there is less transformation to the m-phase.[2,5]

Various models have been proposed to explain the low-temperature degradation of Y–TZP. Lange *et al.*[11] suggested that α-$Y(OH)_3$ formation created yttria-poor regions at grain surfaces which act as nucleation sites for the m-phase. Sato and Shimada[12] proposed that water vapour attack at pre-existing flaws resulted in crack propagation by scission of Zr–O–Zr bonds and formation of Zr–OH, releasing the strain which stabilizes the t-phase thus promoting the t→m transformation. Similarly, Yoshimura[13,14] proposed that water attack produces scission of the bridging surface oxygen groups resulting in Zr–OH or Y–OH formation thus opening up the subsurface region to further attack by H_2O and eventual crack propagation. However, in his case it was a stress corrosion cracking mechanism since the stress field at the crack tip induces the t→m transformation.

Another class of models considers the destabilization of the t-phase via annealing of the anion vacancies with a range of species, i.e. occupation

*Author to whom correspondence should be addressed.
†Present Address: Research Centre Jülich, Institute for Materials in Energy Systems, D-52425, Jülich, Germany.

of the anion vacancies with anions. Narita *et al.*[15] suggested that water reacts with anion vacancies to produce interstitial hydrogen ions and oxygen anions which occupy anion vacancies (annealing) leading to the destabilization of the t-phase. Hughes *et al.*[8] also concluded that the moisture sensitivity of Y–TZP was related to annealing of anion vacancies by O^{2-} anions. In their experiments they observed an increase in the oxygen anion/zirconium ratio during exposure to moist air at 200°C using X-ray photoelectron spectroscopy (XPS). Lepitso and Māntylā[10] also concluded that anion vacancy annealing by O^{2-}accompanied by grain boundary attack, promoted the t→m transformation. Kountouros and Petzow[16] have shown that oxygen vacancies play a decisive role in the stability of the t-phase (and c-phase) and argue that vacancy annealing by oxygen anions promotes the t→m transformation. Furthermore elastic recoil detection analysis (ERDA) spectra on TZP-samples degraded in D_2O-rich water have shown that H- and D-atoms penetrate the lattice.[17]

Much effort has been devoted to reducing or even eliminating the low-temperature degradation effect. In a number of studies the effects of different substitutional cations have been examined. For example, Sato and Shimada[18] observed that Al_2O_3 or CeO_2 additions provided some degree of control of the moisture sensitive degradation. Based on free energy considerations they concluded that the t-phase was stabilized, in the case of Al_2O_3 addition, by increasing the strain energy of the constraining matrix and for alloying with CeO_2 by increasing the chemical free energy. XPS studies by Theunissen *et al.*[19] and Duran *et al.*[20] suggested that protection of the t-phase in ternary systems containing CeO_2 and TiO_2 was imparted by surface segregation of Ce^{4+} and Ti^{4+} and formation of protective overlayers on the external surface and possibly in the grain boundary. Kountouros and Petzow[16] have noted that the activation energy for total ionic conductivity increases significantly in the presence of Ti^{4+} hence oxygen anions may become 'locked' in lattice sites due to changed bonding conditions. Under such circumstances, if there is surface enrichment of Ti^{4+} a semi-impenetrable 'vacancy-annealed barrier' may be set up protecting the interior of the grain from further vacancy annealing and consequently retarding the transformation to the m-phase.

The development of such a large variety of models to describe the one phenomenon is a consequence of the limited control over processing variables during sample preparation which significantly alter the microstructure and consequently the extent of transformation. Processing variables such as sintering times, temperatures and atmospheres can significantly alter; grain growth, average grain size, grain size distributions, yttria disproportionation, impurity phase distribution within the grain boundary network and soluble impurity distributions within grains. Furthermore, many spectroscopic studies have examined the surfaces of degraded specimens only after severe treatments rather than during transformation. For example, it is only *after* extensive autoclave or moist air treatment that either hydroxide formation has been observed using XPS[7,10,20] or significant OH^- formation has been observed using Fourier Transform Infrared (FTIR) spectroscopy.[13,15,21]

In this paper the authors have examined the effects of the addition of Ti^{4+} as a substitutional cation for Z^{4+}, on the stability of Y–TZP during autoclave treatment at 170°C. X-ray diffraction (XRD) has been used to monitor the generation of the m-phase, while XPS has been used to study chemical changes at the surface.

2 Experimental

2.1 Sample preparation

The details of preparation of the TiO_2–Y_2O_3–ZrO_2 samples has been given in detail elsewhere.[22] Briefly, powders were prepared by co-precipitation during spraying of chloride solutions of $ZrOCl_2.8H_2O$, $YCl_3.6H_2O$ and $TiCl_3$ mixed in the required stoichiometry into ammonia solution. The precipitate was then washed several times in distilled water to ensure that it was Cl^- free, distilled azeotropically to dehydrate the powder and dried at 70°C. The powder was calcined at 950°C for 3 h, wet milled in ethanol with TZP balls, dried at 70°C and pressed into 1 × 1 cm cylinders at either 200 or 630 MPa. These cylinders were sintered in air by ramping at 100–1450°C, cooled, then cut, lapped and polished to a 1 μm finish. The three compositions of interest here had 3 mol% Y_2O_3 and either 1, 10 or 20 mol% TiO_2 and are designated Z3Y1T, Z3Y10T and Z3Y20T respectively. The samples were prepared in Germany and transported to Australia for analysis.

2.2 Autoclave treatments

The discs were subsequently placed in 40 cc of distilled water in an autoclave for times up to 144 h, which represented surface saturation of m-ZrO_2, at 170°C (0·792 MPa). After each treatment time the specimens were removed, examined by XRD and XPS, then given further autoclave treatment in fresh distilled water.

2.3 X-ray diffraction (XRD)

The m-phase content was determined by XRD using the (111)m, (11$\bar{1}$)m and (111)t reflections (Cu Kα radiation). In a preliminary series of experiments the development of m-ZrO_2 in the polished surface of Z3Y10T was monitored using XRD without any XPS experiments being made on the specimens. In subsequent series of experiments both XRD and XPS measurements were made on specimens of all compositions at each autoclave treatment time. No difference was found in the amount of m-phase generated with either the XRD or the XRD followed by XPS series of experiments, therefore the XPS has no effect on the generation of m-phase.

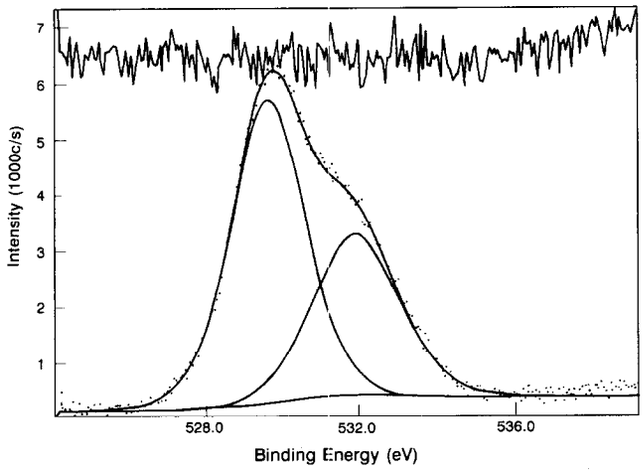

Fig. 1. Typical fit of Gauss/Lorentz product functions to an O 1*s* spectrum. Spectrum of Z3Y10T after 7 h treatment in an autoclave at 170°C. Oxygen anions contribute to the low binding energy component while adsorbed water or O_2^- contribute to the high binding energy component. Reduced χ^2 = 1·012 with 170 degrees of freedom.

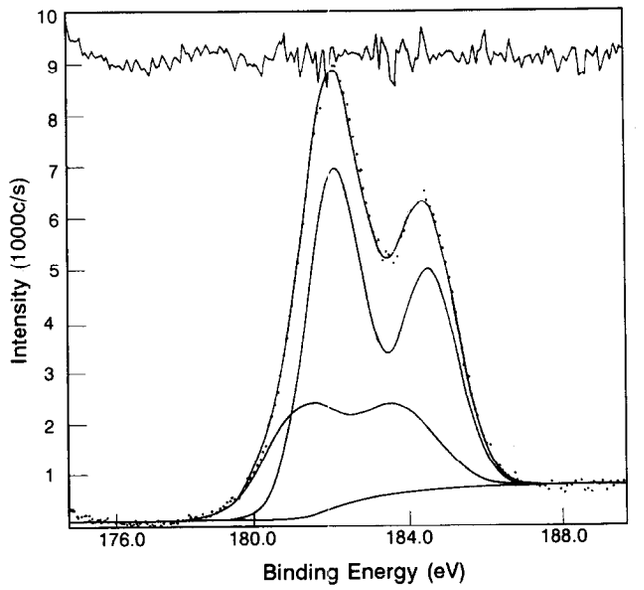

Fig. 2. Typical fit of doublets comprised of two Gauss/Lorentz product functions to a Zr 3*d* spectrum. Spectrum of Z3Y10T after 0·5 h treatment in an autoclave at 170°C. Zr^{3+} moieties contribute to the low binding energy component while Zr^{4+} cations contribute to the high binding energy component. Reduced χ^2 = 1·099 with 140 degrees of freedom.

2.4 X-ray photoelectron spectroscopy (XPS)

The experimental setup and quantification of results for XPS has been described previously.[23] Extensive analysis was made of the O 1*s* and Zr 3*d* spectra by curvefitting Gauss/Lorentz product functions. Two components, without any constraints, were fitted to each O 1*s* spectrum (Fig. 1). Two unconstrained Zr 3*d* doublets were fitted to the Zr 3*d* spectra. The Z_r^{4+} doublet had a fixed separation of 2·42 eV and relative intensity of 0·686, whereas the Zr^{3+} doublet had the same separation but the relative intensity was allowed to float and typically reached values of 0·8. The origin of this small additional intensity is not clear. A typical fit to the Zr 3*d* region is shown in Fig. 2.

3 Results

The %m-ZrO_2 generated in Z3Y1T, Z3Y10T and Z3Y20T as a function of treatment time in the autoclave at 170°C is presented in Fig. 3. It is clear that the development of the m-phase is retarded by increasing the TiO_2 content of the Y_2O_3–ZrO_2. Z3Y1T reached a saturation value of around 78%m-ZrO_2 after only 20 h treatment whereas the times to saturation with m-ZrO_2 for Z3Y10T and Z3Y20T was increased to around 70 and 144 h respectively.

It is important to note that because of the surface sensitivity of XPS, changes in the atomic ratios only reflect changes that occur in the surface grains. Hence it is worth attempting to estimate at what stage all surface grains have transformed to the m-phase. Assuming the analysis depth of XRD is approximately 7 μm[24] and the grain size and saturation value of m-phase are 1·3 μm and 78% respectively then the surface should be fully transformed between 7 and 8% m-ZrO_2, assuming transformation to a depth corresponding to half average grain size. (Recall that the surface is

polished so the surface layer is only half the average grain size in thickness.)

XPS measurements were made on the discs of Z3Y1T, Z3Y10T and Z3Y20T after each treatment time in the autoclave. It can be seen in Fig. 4 that significant changes occurred to the O 1*s* spectra as a function of autoclave treatment time as indicated by a change in the relative intensity from low to high binding energies. Curvefitting of the O 1*s* spectra revealed the presence of two components at 529·8 eV (O_I) and 532·2 eV (O_{II}). Previously four component fits were made to 3 mol%Y_2O_3–ZrO_2 after treatment in moist air at 200°C,[8,24] however, in this case no statistically significant fits could be obtained with either three or four components. The component O_I at 529·8 eV is typical of oxygen anions in lattice sites.[23,25] Adsorbed water[26] or O_2^-[27] are likely candidates for the O_{II} component at 532·2 eV. Hernandez *et al.*[7,20] attributed a high binding energy component at 532·8 eV in autoclave treated CeO_2–Y_2O_3–ZrO_2 to bound hydroxyl groups based on hydroxylation of transition metal compounds. However surface hydroxides on zirconia or yttria occur around 531 eV[28] and are unlikely to contribute to the O_{II} intensity. Likewise O_2^{2-}, which may be present on the surface, occurs at around 531·2 eV and therefore is unlikely to contribute to O_{II}.[28]

The dependence of the total oxygen to zirconium (O_{TOT}/Zr) atomic ratio as well as O_I/Zr and O_{II}/Zr on the autoclave treatment time are plotted

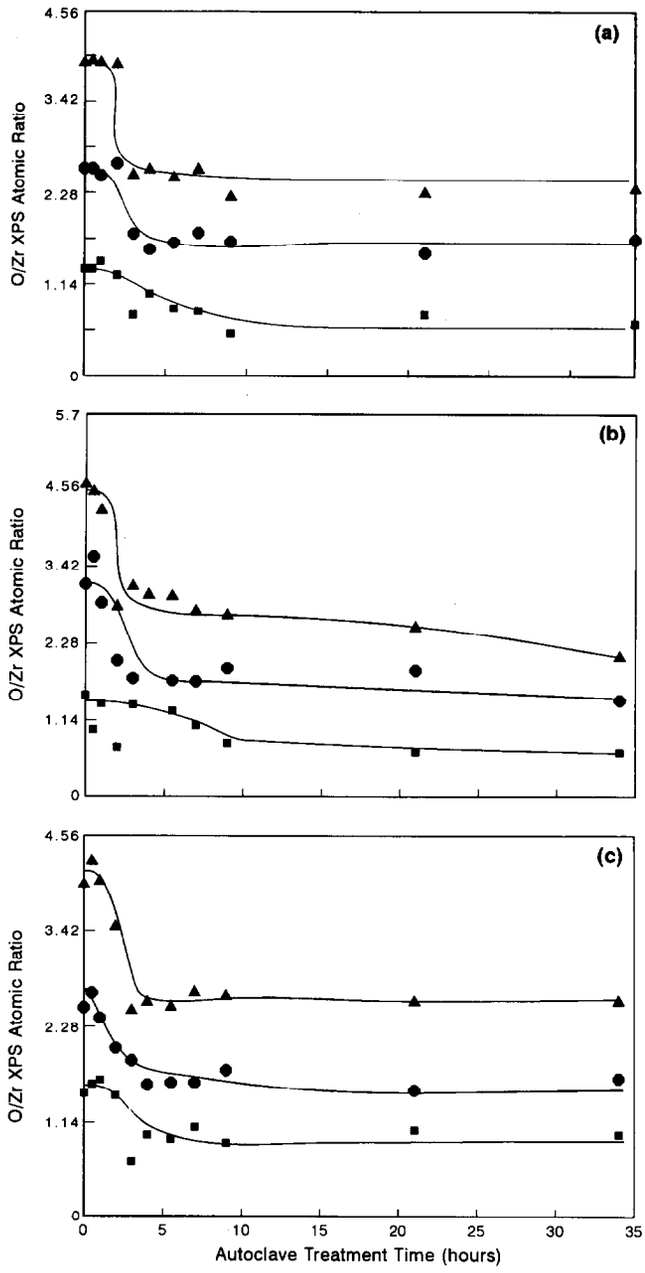

Fig. 5. (▲) O_{TOT}/Zr; (●) O_I/Zr low binding energy component due to oxygen anions and (■) O_{II}/Zr high binding energy component due to adsorbed water as a function of autoclave treatment time. (a) Z3Y1T; (b) Z3Y10T and (c) Z3Y20T.

in Figs 5(a)–(c). The O/Zr ratios displayed stepwise decreases between 1 and 2 h treatment time for Z3Y1T (Fig. 5(a)) and 2 and 3 h for Z3Y10T (Fig. 5(b)) and Z3Y20T (Fig. 5(c)) respectively. The stepwise decrease was partially obscured when the data were plotted as a function of %m-ZrO_2 suggesting that the loss of oxygen is not caused by the development of the m-phase. Indeed, the decreases occurred at much shorter times than those expected for surface saturation of the m-phase and most likely resulted from the removal of some surface carbon contamination of the specimens which may have originated during polishing and/or storage and transport. In the

presence of a carbon overlayer the high O/Zr ratios are most likely explained on the basis that the XPS is sampling a much smaller volume of the actual ceramic surface than for a material without the contaminating layer. (This was confirmed in repeat experiments on freshly polished surfaces where very little carbon was detected on the surface and the O/Zr ratio was around 1·8.) This would enhance the O/Zr signal since the external surface of the ceramic is oxygen rich. The O_{II} component displayed only a gradual decrease with increasing treatment time indicating an apparent reduction in the amount of adsorbed water. However, the $\%O_{II}$ of O_{TOT} goes through a peak as a function of autoclave treatment (Fig. 6).

Increasing autoclave treatment time also resulted in a loss of resolution in the normally well resolved Zr 3*d*5/2–3*d*3/2 spin-orbit doublet of the Zr 3*d* spectra, suggesting the presence of additional components (Fig. 7). These changes can be demonstrated, for example, by comparing the apparent loss of resolution of the Zr 3*d*5/2 and 3/2 doublet in Z3Y10T before autoclave treatment (Fig. 7(a)) with 4 and 7 h autoclave treatment at 170°C (Figs 7(b) and (c) respectively). Curve fitting of the Zr 3*d* spectra revealed two components corresponding to Zr^{4+} (182·2 ± 0·1 eV) and a second component at 181·4 ± 0·2 eV most probably due to the presence of Zr^{3+} (Fig. 2).[29,30]

Hughes *et al.*[24] have previously argued that the origin of the Zr^{3+} signal is most likely related to trapping of electrons at associated cation-vacancy pairs. Electron spin resonance (ESR) measurements indicate that associated vacancy-Zr cation moieties are efficient traps for low energy electrons.[31,32] The electron becomes trapped in the *d*-orbital resulting in a $4d^1$ configuration and Zr^{3+}. One source of low-energy electrons is the XPS experiment itself where photoelectrons undergo inelastic interactions within the solid thereby losing much of their kinetic energy. A second source of low energy electrons may arise with the exchange of O^{2-} with O_2. The broad 1/2 width of the low

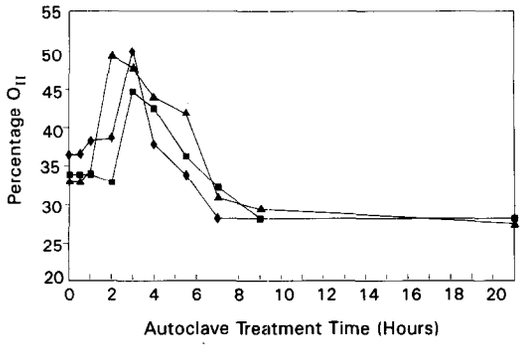

Fig. 6. Variation of $\%O_{II}$ with autoclave treatment time. (■) Z3Y1T, (▲) Z3Y10T and (♦) Z3Y20T.

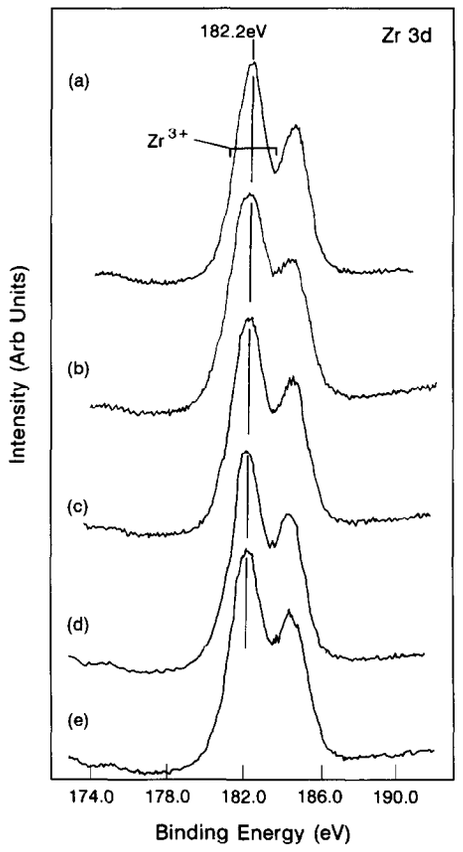

Fig. 7. Series of Zr 3*d* spectra displaying changes which occur as a result of autoclave treatment. (a) 0; (b) 4; (c) 7; (d) 9 and (e) 34 h.

binding energy Zr 3*d* component reflects a variety of Zr^{3+} configurations (Fig. 2). Regardless of their origin, these Zr^{3+} sites are important from the viewpoint of surface chemistry since ESR measurements indicate that they are co-ordinatively unsaturated but can co-ordinatively saturate through adsorption of species such as H_2O.[33,34]

The % Zr^{3+} determined from curvefitting, as a function of treatment time at 170°C is presented in Fig. 8. (As with the O/Zr ratios the $\%Zr^{3+}$ displayed no correlation with $\%m\text{-}ZrO_2$ phase content.) Although there is some scatter in the data it would seem that at short autoclave treatment

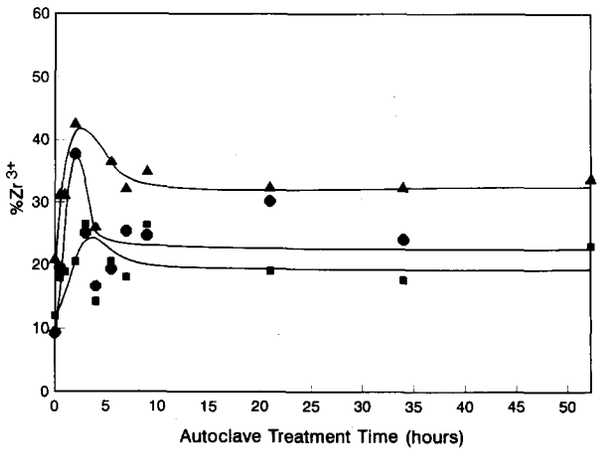

Fig. 8. % Zr^{3+} as a function of the autoclave treatment time at 170°C. (▲) Z3Y1T, (●) Z3Y10T and (■) Z3Y20T.

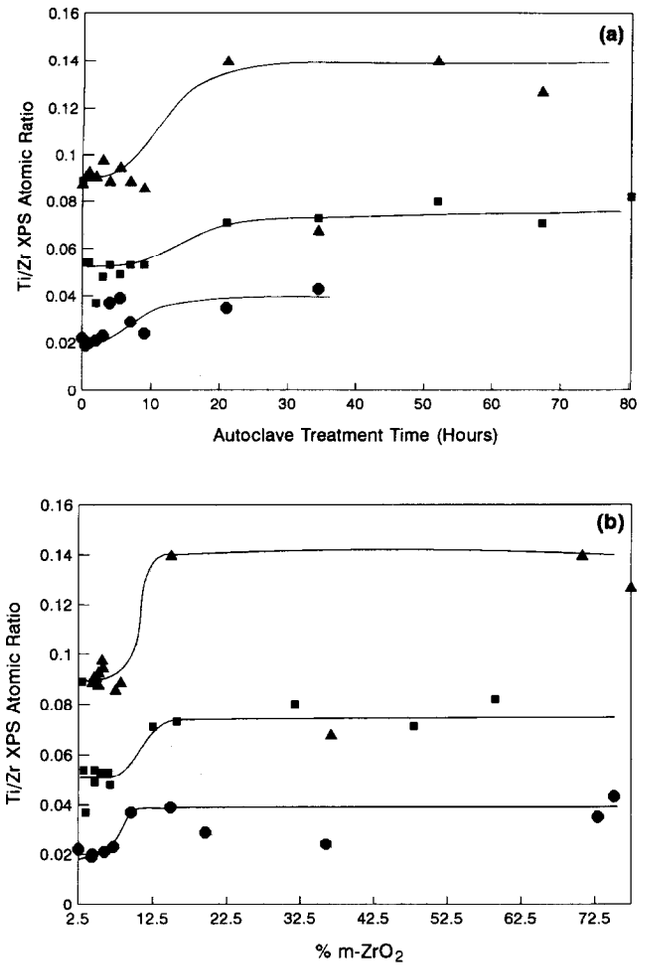

Fig. 9. Ti/Zr ratio versus (a) autoclave treatment time and (b) %m-ZrO_2. (●) Z3Y1T (■) Z3Y10T and (Δ) Z3Y20T.

times (between 2 and 4 h) there is a peak in the $\%Zr^{3+}$ but thereafter it remains constant. The peak maxima appear to be highest for Z3Y1T and Z3Y10T at around 40% Zr^{3+} but considerably less for Z3Y20T at approximately 25% Zr^{3+}.

While the O/Zr ratios and $\%Zr^{3+}$ appeared to depend primarily on the autoclave treatment time, the Ti/Zr ratios were a function of the m-phase content of the surface as clearly demonstrated in Fig. 9. The Ti/Zr ratios remained constant over the first few hours of autoclave treatment then exhibited a stepwise increase to new equilibrium values but this step was staggered in the time domain for the different compositions (Fig. 9(a)), but occurred in the single range 7–13%m-ZrO_2 for all compositions (Fig. 9(b)) which spans the region where there is complete saturation of the surface with m-phase.

The initial and final Ti/Zr atomic ratios are presented in Table 1 and compared to those expected from the stoichiometries of the different ceramics. For Z3Y1T all measured values of the Ti/Zr ratio indicate a surface enrichment of Ti^{4+}. The Ti/Zr ratio for untreated Z3Y10T indicated a small surface depletion of Ti^{4+}, which changed to enrichment after autoclave treatment. Severe surface depletion of Ti^{4+} was observed under all conditions for Z3Y20T. Z3Y10T exhibited nearly twice the level of surface Ti^{4+} compared to Z3Y20T which itself was twice the level of the Z3Y1T specimen, suggesting that there is a TiO_2 content which will give a maximum surface Ti enrichment. This is demonstrated in Fig. 10 where the Ti/Zr ratio displayed a clear maximum at 5 mol% TiO_2 for the as-sintered specimens.

all displayed either surface enrichment or ratios similar to the expected bulk values. After autoclave treatment all compositions displayed a depletion to a common value of around 0·057 ± 0·004.

4 Discussion

The most notable features of the XPS data were the decrease in the Y/Zr ratio and peaks in the $\%Zr^{3+}$ during the first 3 h treatment for all samples. Furthermore, there was an increase in the Ti/Zr ratio between 7 and 13%m-ZrO_2, a range which represents the complete transformation of surface grains to m-phase. These changes suggest that some local surface rearrangements must occur with respect to the starting compositions of the material. It would appear that these changes occur during a period where the surface is undergoing transformation to the m-phase but thereafter no further changes are observed.

The XPS data clearly deals with two different phenomena:

(i) Changes in the O/Zr ratios, particularly the $\%O_{II}$, and the % Zr^{3+}, which only depend on the autoclave treatment time and thus may herald changes in the surface chemistry which lead to the t→m phase transformation;
(ii) Changes in the Ti/Zr and possibly the Y/Zr ratios which are associated with cation redistribution as part of the m-phase transformation.

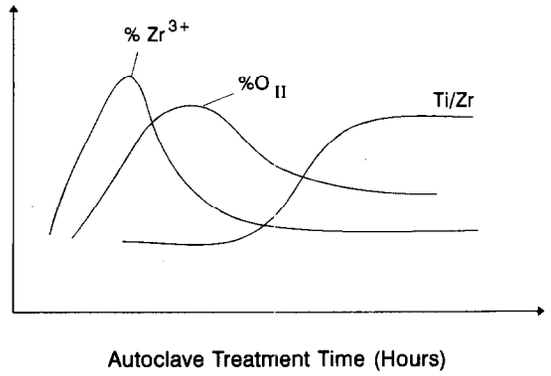

Fig. 12. Schematic representation of the temporal evolution of changes in the surface chemistry.

These changes are summarised schematically in Fig. 12.

4.1 Generation of Zr^{3+} and O_2^-

Changes in the surface chemistry appear to begin with an increase in the level of Zr^{3+} which is followed by an apparent change in the degree of occupation of surface anion sites by the O_{II} species (adsorbed water and probably superoxide). At much longer autoclave treatment times, where the surface is fully saturated with m-ZrO_2, the Ti/Zr ratios increase suggesting cation redistribution as a result of phase transformation.

In order to understand these changes this discussion will begin with the role of the Zr^{3+} sites and their influence on the O_{II} species drawing on the ESR studies of adsorbed H_2O and O_2^- on m-ZrO_2. Morterra *et al.*[33,34] have identified a number of different surface species and adsorption sites on m-ZrO_2. One of the important adsorption sites being the co-ordinatively unsaturated (cus)-Zr^{3+} centres which can co-ordinatively saturate in the presence of water without oxidizing to Zr^{4+}. Furthermore, the Zr^{3+} centres were not quenched by the presence of superoxide from which they concluded that the electron donating centres which gave rise to O_2^- at the surface, must be ESR silent. (They suggested that O_2^- was formed by donation of electrons from the conduction band.) This indicates that the Zr^{3+} centres which co-ordinatively saturate with H_2O and sites where O_2^- occur must coexist. In addition, they found that superoxide (O_2^-) formation on m-ZrO_2 is an activated process which only occurred in appreciable amounts at 150°C. In the presence of water, the activation barrier for superoxide formation was reduced and considerable quantities of superoxide were formed at room temperature.

In the work of Morterra *et al.*[33] the Zr^{3+} centres were generated by annealing in vacuum or O_2 at temperatures between 375 and 825°C. In the autoclave, the Zr^{3+} centres are most likely produced in the normal process of exchange of O^{2-} with atmospheric O_2 except that, in the autoclave environment, water molecules are also present and compete for surface sites. Consequently, it is likely that a considerable proportion of the surface Zr^{3+} sites become coordinatively saturated with water. In the presence of an increased density of adsorbed water on the surface of the ceramic much more O_2^- will be generated. Since the generation of O_2^- is the first step in the reduction of oxygen it is assumed that the presence of superoxide will lead ultimately, to much more O^{2-} than would occur on a surface largely free of adsorbed water. Some indirect evidence for the relationship between adsorbed water and the cus-Zr^{3+} sites is provided

Table 3. O_{TOT}/Zr, $\%O_I/Zr$, $\%O_{II}/Zr$ and $\%Zr^{3+}$ for Z3Y20T after 80 h autoclave treatment at 170°C versus examination time under X-ray source

Time (min)[1]	O_{TOT}/Zr	$\%O_I/Zr$	$\%O_{II}/Zr$	$\%Zr^{3+}$
0–10	2·34	61·5	38·5	26·6
30–40	2·29	65·7	34·3	24·0
60–70	2·29	70·6	29·4	21·8
90–100	2·21	71·5	28·5	19·8

[1]It takes approximately 5 min to measure each of the Zr 3*d* and O 1*s* spectra hence a 10 min window is given for each entry in the table.

by the data in Table 3. During dehydration under the X-ray source, O_{II}/Zr (adsorbed water and superoxide) decreased with a consequent loss of Zr^{3+}. In addition there was evidence to suggest that the O_{II} species may have been converted to O^{2-} since there is a 26% reduction in O_{II} but only a total reduction in O_{TOT} of 5·5%. Furthermore, there is also a 26% reduction in the $\%Zr^{3+}$ indicating that the Zr^{3+} have been oxidized up to Zr^{4+} concurrently with the decomposition of the O_{II} species to oxygen anions. As a result of O^{2-} generation there is rapid annealing of surface vacancies and likely penetration of O^{2-} into the lattice, destabilizing the t-phase and resulting in either transformation to the m-phase or the nucleation of domains of m-phase. The likelihood of m-phase nucleation domains is further improved by surface depletion of Y (Fig. 10).

4.2 Anion annealing

Evidence for anion annealing comes from the data collected at longest autoclave treatment times where all compositions have reached surface saturation with m-phase. The saturation values of O_{TOT}/Zr, O_I/Zr and O_{II}/Zr at these long treatment times are presented in Table 4 along with expected values based on the stoichiometry. Two points need to be made with respect to the table. First, the measured O_{TOT}/Zr ratios are much larger than the ratios calculated on the basis that all the anion vacancies are filled (O/Zr), suggesting the presence of oxygen rich species such as some form of molecular oxygen, perhaps superoxide (O_2^-). Furthermore, O_{TOT}/Zr is higher than the stoichiometries that take into account vacancies due to the presence of either Y^{3+} (O^{Y}_{Vac}/Zr) or Y^{3+} and Zr^{3+} ($O^{Y,Zr3+}_{Vac}/Zr$) suggesting that many of the oxygen vacancies have been filled. Second, O_I/Zr, which only accounts for the oxygen anions in the lattice, falls far short of any of the calculated stoichiometries. It is only with the contribution of O_{II}/Zr that the experimental values approach the values calculated from the stoichiometry suggesting that a significant proportion of the surface oxygen anion sites are occupied by the O_{II} species, i.e. adsorbed H_2O or O_2^-. It is difficult to distinguish adsorbed H_2O from O_2^- using XPS core levels, however, preliminary static secondary ion mass spectrometry (SIMS) spectra confirm the presence of O_2^- after autoclave treatment whereas no O_2^- was evident before treatment on freshly polished surfaces. The SIMS results indicate that superoxide must therefore partially contribute to the O_{II} species observed in XPS.

Table 4. Comparison of XPS O/Zr ratios after long treatment time with the calculated O/Zr ratios

Treatment	*Z3Y1T*	*Z3Y10T*	*Z3Y20T*
O_{TOT}/Zr*	2·36	2·65	2·65
O_I/Zr*	1·66	1·80	1·66
O_{II}/Zr*	0·684	0·857	0·964
O/Zr¶	2·14	2·37	2·68
O^{Y}_{Vac}/Zr§	2·12	2·33	2·63
$O^{Y,Zr3+}_{Vac}/Zr$†	1·82	2·03	2·33

*Average XPS atomic ratio determined after surface saturation with m-phase.

¶Calculated with known molar concentration of oxides assuming that each oxide has its full oxygen stoichiometry, e.g. for Z3Y10T there is 87 mol% ZrO_2, 6 mol% $YO_{1.5}$ and 10 mol% TiO_2 hence the O/Zr ratio is $(2 \times 87 + 2 \times 6 + 2 \times 10)/87 = 2{\cdot}37$.

§Calculated with known molar concentration of oxides assuming that each oxide has its fill oxygen stoichiometry, e.g. for Z3Y10T there is 87 mol% ZrO_2, 6 mol% $YO_{1.5}$ and 10 mol% TiO_2 hence the O/Zr ratio is $(2 \times 87 + 1{\cdot}5 \times 6 + 2 \times 10)/87 = 2.33$.

†Calculated on the basis of bulk stoichiometry but taking into account vacancies created by the presence of Y^{3+} and Zr^{3+}, e.g. for Z3Y10T $(2 \times 87 - 0{\cdot}2 \times 87 + 2 \times 10)/87 = 2{\cdot}03$ where the second term takes account of 20% Zr^{3+} in the Zr 3*d* spectra and assumes that one vacancy is associated with each Zr^{3+}.

4.3 Substitutional cations

The role of substitutional cations emerges; replacement of surface or bulk Zr^{4+} cations by Ti^{4+} or other cations will modify adsorption conditions on the surface. For example, on the rutile form of TiO_2, water adsorption has been reported up to 300°C[35] whereas on anatase water desorbs around 200°C and is dependent on the surface crystallography.[36] On m-ZrO_2 molecular water desorbs from the surface below 200°C.[37] Hence it is possible that stronger binding of chemisorbed water in the presence of Ti^{4+} may suppress the rate of formation of O^{2-}. Furthermore, it has been noted by Kountouros and Petzow[16] that the activation energy for ionic conductivity increases when TiO_2 is used as an alloying component. This suggests that oxygen may be more tightly bound in the modified neighbourhood of Ti^{4+}. Clearly, however, the surface Ti/Zr ratio has little direct bearing on the rate of transformation to the monoclinic phase since Z3Y10T had the highest surface concentration of Ti but transformed at autoclave times intermediate between those of Z3Y1T and Z3Y20T.

It should be noted that while this model is based on the XPS results of the external surface, it is likely that the same species are involved in the grain boundary network, although the mechanisms are likely to be much more complex due to the presence of impurity phases. Further, a different composition of the surface of grains due to cation segregation will lead to a significant modification of the reaction kinetics. The role of impurities is at least twofold; in modifying the defect distribution near the surface and in providing a grain boundary protective coating via the presence of the grain boundary impurity phase. Grain boundary impurity phases and grain surface composition, which vary considerably in different ceramics,[37-40] could therefore be just as critical as grain size or yttria content in determining the stability of sintered Y–TZP.

It is worthwhile considering whether there is any significant difference between moist air and autoclave treatments. It was previously reported by Hughes *et al.*[8,24] that vacancy annealing occurred during moist air treatment of Y–TZP but very little adsorbed water was present during these experiments by contrast to the significant quantities of adsorbed water during the autoclave experiments reported here. During autoclave or moist air treatment both O_2 and water vapour will be present but in different relative ratios. The different relative ratios of the two species in the gas phase as well as the higher pressure in the autoclave environment may well influence the distribution of surface adsorbed species. For example, it would appear that in an autoclave environment significantly more Zr^{3+} is generated suggesting the potential for a much higher density of adsorbed water.[24] If the formation of O_2^-, which is the first step in the reduction of O_2 to O^{2-}, is enhanced in the presence of water on m-ZrO_2[34] then it might be expected that molecular oxygen or superoxide migrates across the surface to a site adjacent to the adsorbed water.[41] Consequently, the rate of reduction of O_2 to O^{2-} will be increased if the density of adsorbed water is higher. On this basis alone, it could be expected that autoclave treatment will result in more rapid transformation to m-phase than moist air treatment.

While the route from O_2 to O^{2-} is conceptually clear, it is unclear what role the decomposition of H_2O has to play. In the case of adsorbed water it might be expected that some surface hydroxyl group are formed, however, surface OH^- was not evident in the XPS suggesting that if OH^- is formed then it must react quickly to give O^{2-} and either H_2 or interstitial H^+. Krouse *et al.*[17] have demonstrated, using ERDA, that hydrogen penetrates the lattice, and given the weight gain and desorption of H_2 from autoclave treated Y–TZP measured by Narita *et al.*[15] it seems likely that interstitial hydrogen is produced. Interstitial hydrogen ions would provide charge balance for the excess O^{2-}.

5 Conclusions

The XRD results indicate that the addition of TiO_2 to Y_2O_3–ZrO_2 as an alloying oxide retards the onset of the t→m transformation during autoclave treatment at 170°C. XPS and SIMS results further indicate that the only oxygen species on the surface of autoclave treated TiO_2–Y_2O_3–ZrO_2 are adsorbed water, superoxide and oxygen anions. XPS results indicate that treatment in an autoclave environment gives rise to the generation of Zr^{3+} sites which co-ordinatively saturate with water. The presence of adsorbed water on the surface increases the rate of formation of O_2^- which, it is assumed, leads to a much larger amount of O^{2-} than would be the case in the absence of the adsorbed water. It is thought that the excess O^{2-} anions anneal anion vacancies thus destabilising the t-phase and promoting the t→m phase transformation. The observed enrichment of Ti^{4+} occurs as a result of the t→m phase transition and does not appear to retard bulk transformation by creating a protective overlayer which retards the t→m phase transformation.

Acknowledgement

The authors would like to thank Dr M. J. Bannister and Prof. G. Petzow for useful discussions, Ms G. Roderick and Mr M. Fergus for assistance with drafting the diagrams and photography. We are also grateful to the University of Queensland for providing time on their surface analysis instrument for SIMS analysis.

Abstract

Ceramic materials have been prepared by natural sintering and hot-forging $M^{II}Bi_8Ti_7O_{27}$(M^{II} = Ca, Sr, Ba and Pb) powders synthesized using a molten salt technique. The materials are ferroelectric at room temperature and show strong dielectric anisotropy in connection with the crystal structure. In each case, a double anomaly of the dielectric permittivity was found as a function of temperature. The temperatures at which it occurs are dependent on M^{II}. The origin of this phenomenon is assumed to be closely related to a sequence of phase transitions like those already observed in other mixed Aurivillius phases.

1 Introduction

The so-called Aurivillius phases are a family of layer bismuth compounds generally formulated as $Bi_2A_{m-1}B_m O_{3m+3}$. Their crystal structure can be regarded as a regular intergrowth of $(Bi_2O_2)^{2+}$ layers and $(A_{m-1}B_mO_{3m+1})^{2-}$ perovskite-type slabs.[1,2] In these compounds, A is a mono-, di- or trivalent element allowing dodecahedral coordination, B is a transition element suited to octahedral coordination and m an integer ($1 \leq m \leq 8$) which represents the number of perovskite-like slabs intercalated between the $(Bi_2O_2)^{2+}$ layers. As they generally show ferroelectric behaviour, a number of them, e.g. $Bi_2PbNb_2O_9$ (m = 2), $Bi_4Ti_3O_{12}$ (m = 3), $BaBi_4Ti_4O_{15}$ (m = 4), have been thoroughly investigated from the point of view of both structural and electric properties.[3–7] The frequent occurrence of disordered intergrowths — corresponding to different values of m — suggested that ordered intergrowths would be obtained in suitable systems and under appropriate thermal treatment. In fact, various ordered intergrowths have been recently prepared as macroscopic pure phase.[8,9] They always correspond to a regular intergrowth of one half the unit cell of a m member structure and one half the unit cell of a m + 1 member structure, so that they have the general formula $Bi_4A_{2m-1}B_{2m+1}O_{6m+9}$, e.g. $Bi_5TiNbWO_{15}$ (intergrowth 1 + 2), $Bi_7Ti_4NbO_{21}$ (intergrowth 2 + 3) and $M^{II}Bi_8Ti_7O_{27}$ (intergrowth 3 + 4). Several papers have been devoted to the dielectric properties of $Bi_7Ti_4NbO_{21}$: the main characteristic of this ferroelectric phase is the occurrence of a double anomaly of the dielectric permittivity as a function of temperature.[9,10] An interpretation of this phenomenon was recently given from single crystal structure investigations.[11] On the contrary, there is only few literature dealing with dielectric properties of phases with 1 + 2 or 3 + 4 intergrowths.

The aim of this paper is to present the results of the investigation of the dielectric properties of $M^{II}Bi_8Ti_7O_{27}$(M^{II} = Ca, Sr, Ba and Pb) as a function of temperature and frequency and to discuss their evolution within the Aurivillius family.

2 Experimental

Polycrystalline powders were prepared by molten salt synthesis. Stoichiometric mixtures of reagent grade $M^{II}CO_3$, Bi_2O_3 and TiO_2 were thoroughly mixed with excess NaCl–KCl eutectic and ground in agate mill for 2 h. The mixtures, placed in closed platinum crucibles were heated up to 650°C for 1 h to ensure homogeneization and then soaked at 800–900°C (depending on the composition) for 1 h. After cooling, the salt was eliminated by washing with hot water until the last washing water does not react with silver nitrate and the powders finally dried at 100°C.

Ceramic samples were obtained by natural sintering of uniaxially pressed pellets at 1050–1120°C for 1–3 h in air. High oriented materials were elaborated by a hot-forging technique (920–1060°C, 4–12 MPa, 1–3 h) described elsewhere.[10]

*To whom correspondence should be addressed.

The morphology of powders and the microstructure of hot-forged ceramics were observed with a Philips XL30 scanning electron microscope. X-ray diffraction patterns were obtained with a Siemens D5000 powder diffractometer (CuKa) and the cell parameters refined by a least-squares method. Dielectric measurements were made between room temperature and 1000°C by impedance spectrometry using a HP 4194A impedance analyser. Disk-shaped samples (10 mm diameter and 1 mm thick) of naturally sintered ceramics and parallelepipedic bodies of hot-forged materials ($1 \times 1 \times 3$ mm^3) were polished and coated with platinum paste (Cerdec Pt 576402/1, 1000°C, 30 min), aged overnight at 110°C and left for at least 24 h before measurements. For hot-forged ceramics, electrodes were put on faces either parallel or perpendicular to the forging direction. D-E hysteresis loops were obtained at room temperature using a classical Sawyer–Tower device operating at 20 mHz. Piezoelectric coefficients d_{33} were determined with a Berlincourt-meter and the electromechanical coupling factors were derived from resonance–antiresonance measurements.

3 Results and Discussion

3.1 Powders

Strongly anisotropic platelet-like powders were obtained using molten salt synthesis. As shown in Fig. 1 for calcium and lead compounds, they develop large faces with areas in the range 1–10 μm^2 and thickness less than 0·1 μm. As expected, X-ray diffraction patterns confirmed that the direction perpendicular to the main faces correspond to the stacking direction of the Bi_2O_2 sheets. All the compounds are orthorhombic with lattice parameters a and b close to 0·54 nm ($\approx \sqrt{2}\, a_{perovskite}$) and c inherently long ($\approx$ 7·3 nm) due to the number of perovskite and Bi_2O_2 slabs involved in the unit cell. The evolutions of the lattice parameters are

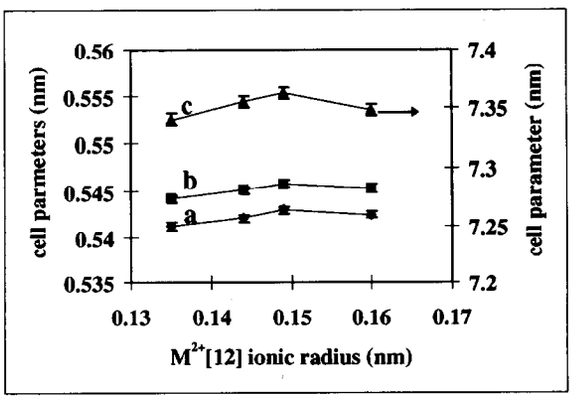

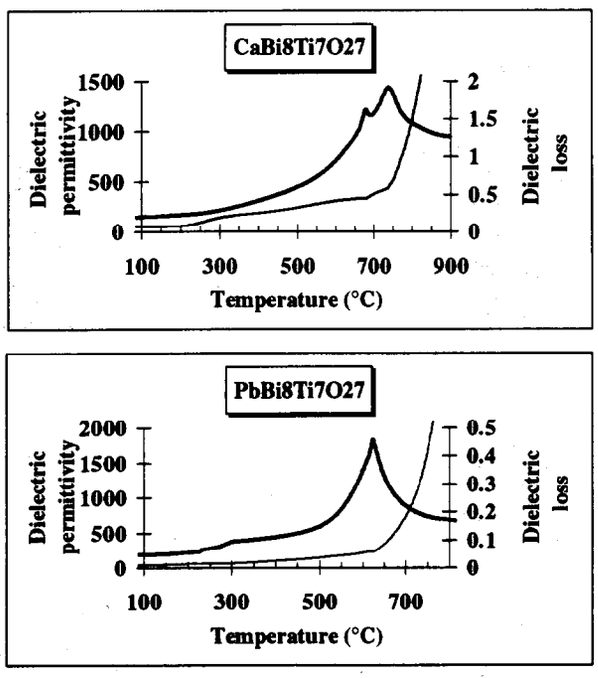

Fig. 2. Lattice parameters of $M^{II}Bi_8Ti_7O_{27}$ as a function of M^{2+} ionic radii in coordinence.[12]

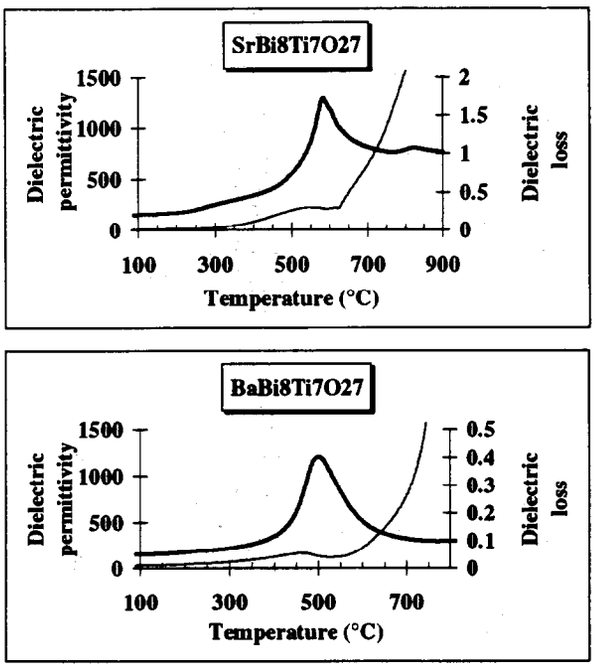

Fig. 3. Thermal variation of dielectric permittivity and loss of naturally sintered $M^{II}Bi_8Ti_7O_{27}$ ceramics at 1 MHz.

given in Fig. 2 as a function of the ionic radii in coordinence [12] of the M^{2+} cations.[12] From calcium to barium, the lattice parameters roughly increase, but the behaviour of the lead compound appears to be out of the general trend. The abnormally high values obtained for this compound would be undoubtly related to the strong polarizability of Pb^{2+} due to the $6s^2$ lone pair which is absent in the alkaline earth compounds. Such a trend was already observed in M^{II}-containing Aurivillius phases, e.g. $M^{II}Bi_2Nb_2O_9$, $M^{II}Bi_4Ti_4O_{15}$ or $(M^{II})_2Bi_4Ti_5O_{18}$.[3,4]

3.2 Naturally sintered ceramics

After natural sintering in air atmosphere, ceramic materials achieved densities lying within 92–96% of theoretical and X-ray patterns did not show any significant preferential orientation.

The thermal variations of the dielectric permittivity and dielectric loss at 1 MHz of $M^{II}Bi_8Ti_7O_{27}$ are given in Fig. 3. For M^{II} = Sr, Ba and Pb, one dielectric anomaly is observed at 580, 480 and 610°C respectively for both ϵ_r and tan δ. This behaviour was already found by Kikuchi *et al.*[9] On the contrary, the calcium compound is characterized by a double anomaly at 660 and 720°C, similar to that observed in the 'mixed phase' $Bi_7Ti_4NbO_{21}$.[9,10] For all compounds, the anomaly temperatures of ϵ_r and tan δ are frequency independent and only a slight decrease of ϵ_r as the frequency increases from 100 kHz to 5MHz is observed as shown in Fig. 4.

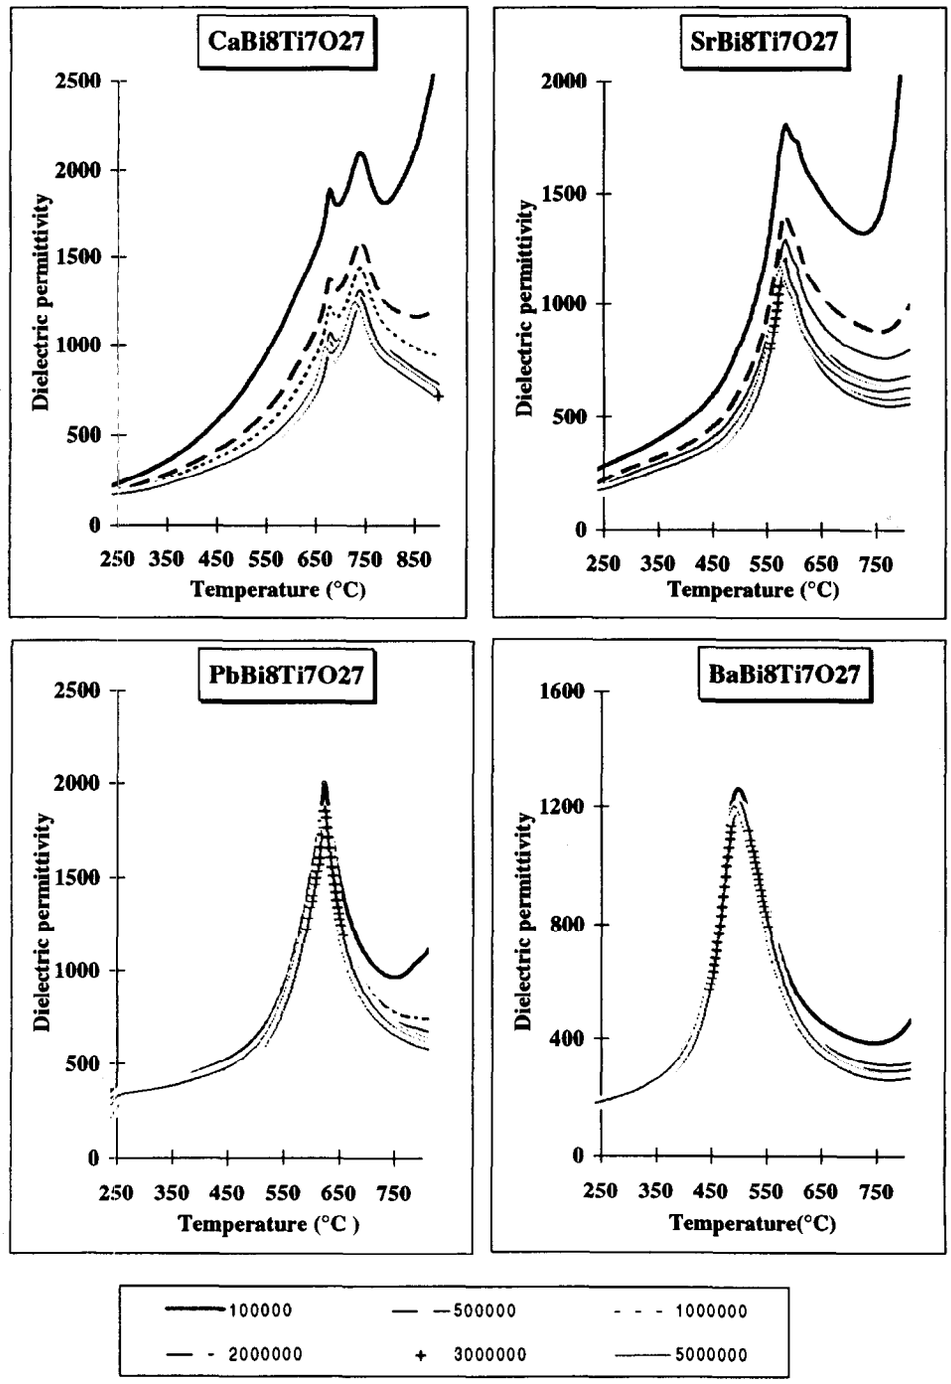

Fig. 4. Thermal variation of dielectric permittivity of naturally sintered $M^{II}Bi_8Ti_7O_{27}$ ceramics as a function of frequency.

Polarization–electric field curves confirm the ferroelectric behaviour of these compounds at room temperature. The observed loops are not fully saturated due to experimental difficulties (Fig. 5). Nevertheless they allow determination of coercive field (42–58 $kVcm^{-1}$) and remnent polarization (2·3–3·9 $\mu C\ cm^{-2}$), (Table 1). These values are slightly lower — but of the same order of magnitude — than those obtained for $Bi_7Ti_4NbO_{21}$.

Table 1 also shows the piezoelectric constants d_{33} and the planar electromechanical coupling coefficients measured on samples poled at 200°C for 10 min in silicone oil under 8 kV mm^{-1}. As for other Aurivillius phases, the obtained values are quite low, but are kept almost the same up to about 450°C.

3.3 Hot-forged ceramics

The hot-forging technique gave strongly oriented highly densified ceramics. Orientation factors — calculated using the Lotgering method — higher than 90% were currently obtained at 1050°C under 12 MPa.[13] The corresponding densities were 96–99% of theoretical. Figure 6 shows a SEM micrograph of the lead compound taken in a direction perpendicular to the forging axis. The strong anisotropy was confirmed by X-ray diffraction experiments performed along two perpendicular directions (// and ⊥ to the forging axis) and compared with the powder pattern. As expected, the ⊥ pattern shows only (001) lines which are absent in the // pattern (Fig. 7).

The thermal variations of the dielectric permittivity of hot-forged samples were measured along both // and ⊥ directions. As previously noticed for naturally sintered materials, the temperatures of

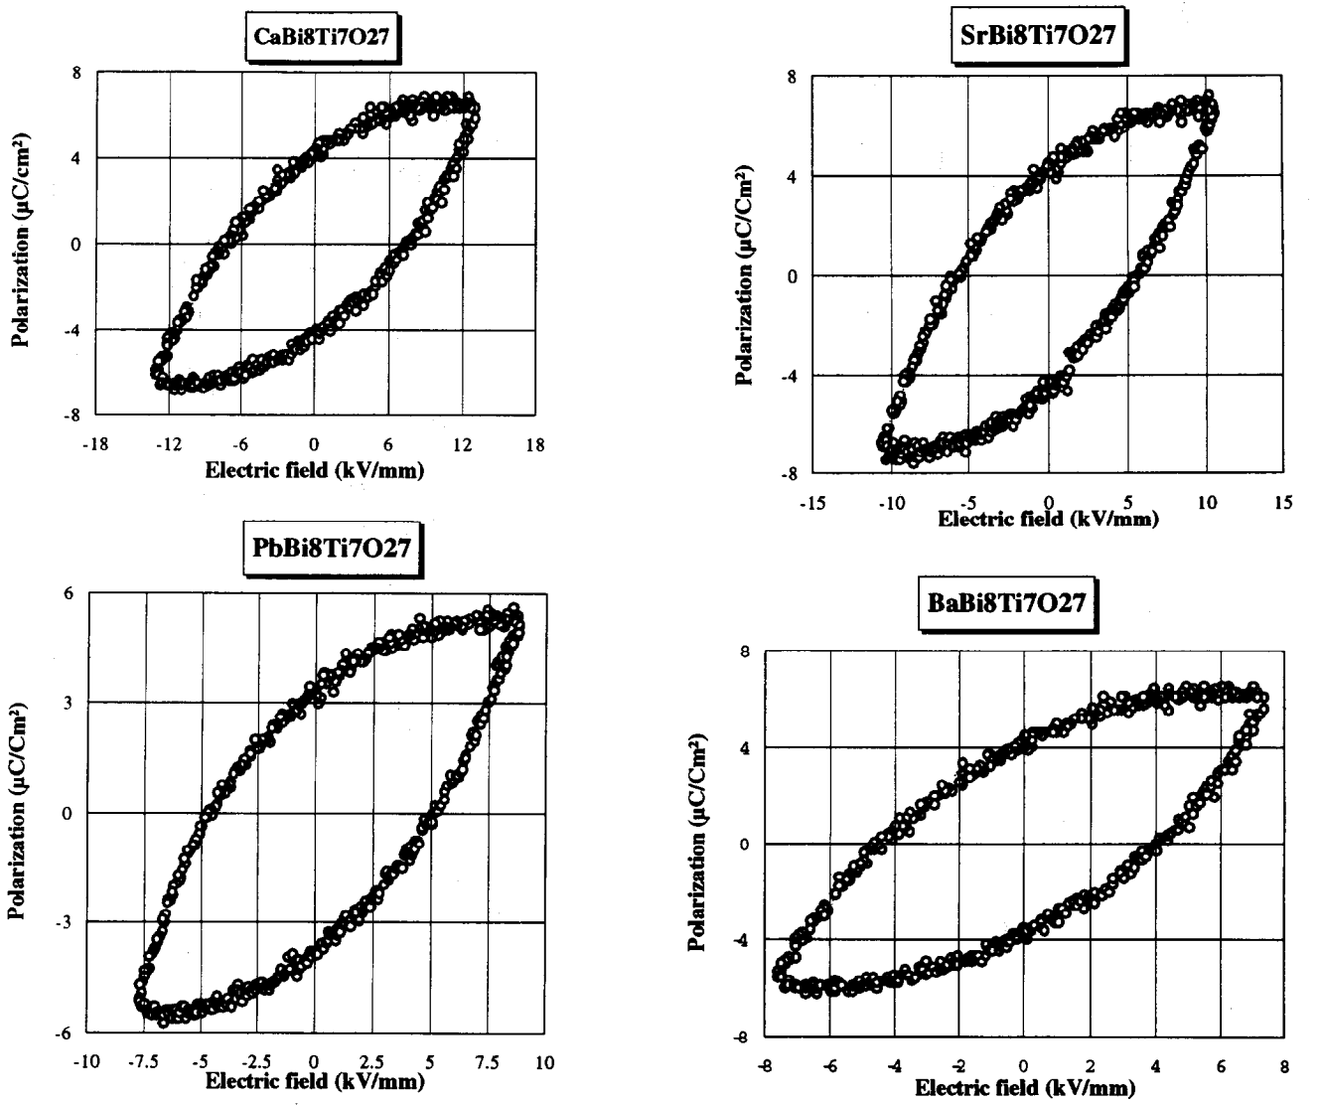

Fig. 5. Polarization-electric field loops of naturally sintered $M^{II}Bi_8Ti_7O_{27}$ ceramics.

Fig. 6. SEM micrograph of hot-forged $PbBi_8Ti_7O_{27}$ ($\perp$ to the forging direction)

the permittivity anomalies are frequency independent. From Fig. 8, which gives the results obtained at 1 MHz, two main features can be emphasized:

(i) in each case, $\epsilon_\perp$ is higher than $\epsilon_{//}$, the ratio being maximum at anomaly temperatures. Such a behaviour was already observed for other hot-forged materials, e.g. $M^{II}Bi_4Ti_4O_{15}$ and $Bi_7Ti_4NbO_{21}$, and was attributed to the strong anisotropic microstructure of the materials.[10,14] As a matter of fact, the high $\epsilon_\perp$ value was correlated to the direction of the polarization which lies, for most Aurivillius phases, in or close to the planes of the Bi_2O_2/perovskite sheets, i.e. perpendicular to the forging direction. In the same way, the slight maxima observed for $\epsilon_{//}$, would indicate the presence of a small component of the polarization along the direction parallel to the forging direction (the *c*-axis of the unit cell).[15]

(ii) in contrast with the results obtained on naturally sintered ceramics, all ϵ(T) curves show a double anomaly more or less defined according to the M^{2+} cation (for M = Pb, there is only a small hump just before the maximum). In any case, when M is an alkaline earth element, the gap between the temperatures of the anomalies decreases when the ionic radii increase.

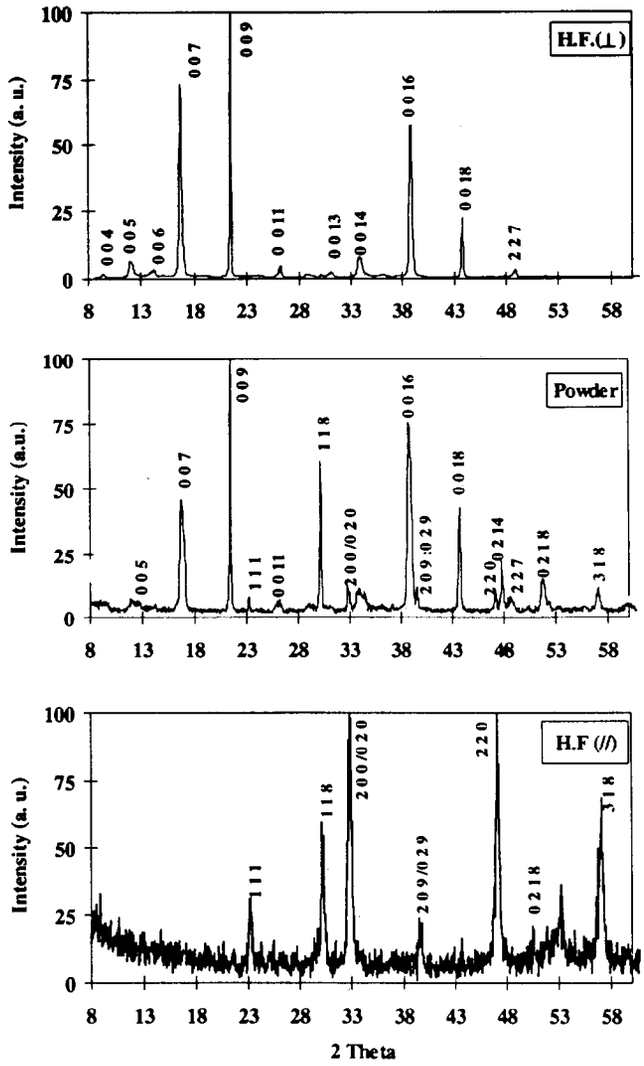

Fig. 7. X-ray diffraction patterns of hot-forged $PbBi_8Ti_7O_{27}$ ceramics.

By reference to $Bi_7Ti_4NbO_{21}$ (mixed 2–3 Aurivillius phase), one may suppose that the double anomaly would originate in a sequence of phase transitions of the following type: orthorhombic ferroelectric-(elastic) state I $\rightarrow$ orthorhombic ferroelectric-(elastic) state II $\rightarrow$ tetragonal paraelectric-(elastic) state.

The first phase transition within the orthorhombic symmetry might not occur for the lead compound because the behaviour of the lone pair Pb^{2+} cannot be strictly likened to the spherical alkaline earth cations.

4 Conclusion

Dielectric experiments on naturally sintered and highly oriented hot-forged ceramics of the so-called mixed Aurivillius family $M^{II}Bi_8Ti_7O_{27}$ have shown that all materials:

— are ferroelectric with Curie temperatures in the range 500–740°C depending on the nature of M^{II};

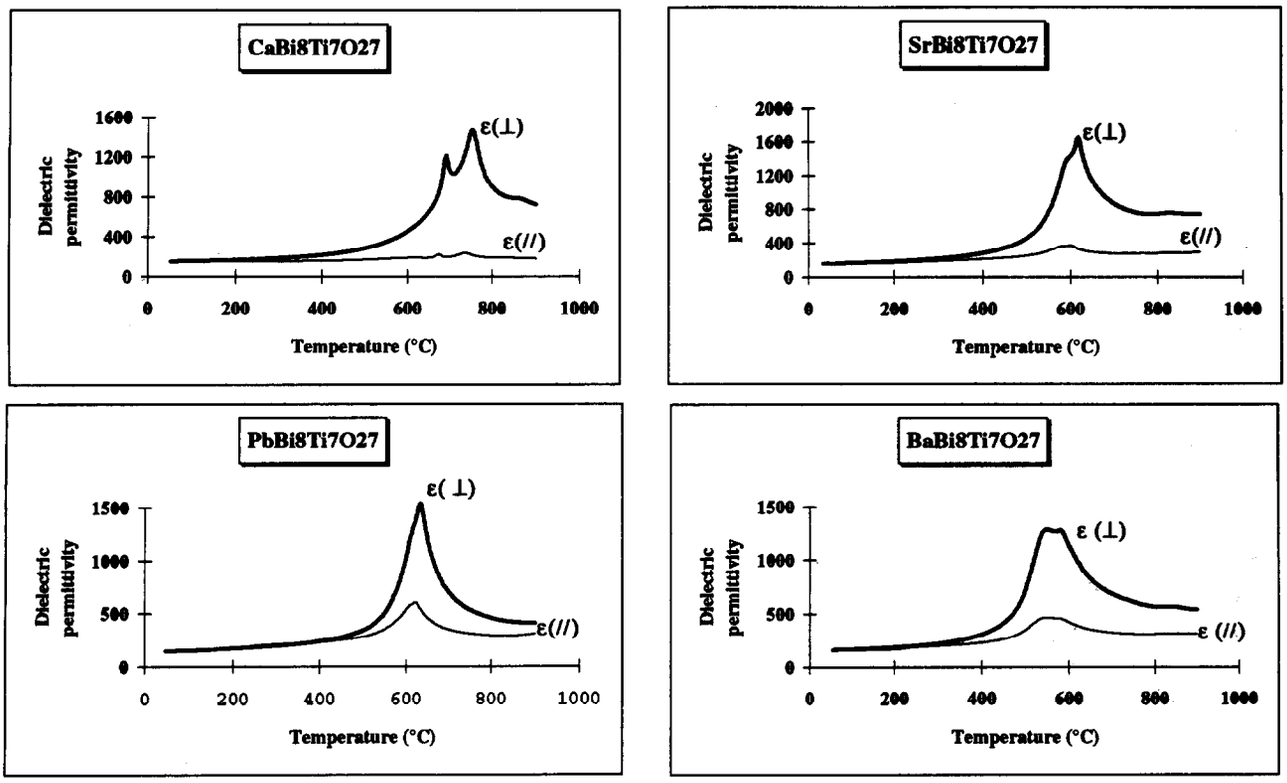

Fig. 8. Thermal variation of the dielectric permittivity of hot-forged $M^{II}Bi_8Ti_7O_{27}$ ceramics at 1 MHz (⊥ and // to the forging direction).

— present a double dielectric anomaly as a function of temperature.

The overall behaviour of the ceramics is likely to that already observed in other mixed Aurivillius phases. To confirm the assumptions about the nature of the phase transitions, further investigations (crystal structure determination, dielectric and optical microscopy measurements as a function of temperature) are now in progress on $CaBi_8Ti_7O_{27}$ single crystal.

Abstract

Single-phase iron manganite spinels, $Mn_{3-x}Fe_xO_4$ with $O \leq x \leq 1{\cdot}05$, were prepared by thermal processing of iron–manganese co-precipitated formate precursors. Powder X-ray diffraction (XRD) analysis shows a cubic–tetragonal transition for x = 1·05. *The Mössbauer spectroscopy indicates the presence of only trivalent iron ions in both sites of the spinel structure. The electrical measurements show that these iron manganites have the characteristics of negative temperature coefficient thermistors. Moreover, in these solid solutions, the resistivity* ρ *decreases with increasing of iron content* x. *Correlation of the results obtained by XRD, Mössbauer spectroscopy and electrical measurements permits one to infer the cationic distribution, given by* $Mn^{2+}_{1-y}\ Fe^{3+}_{y}\ (Fe^{3+}_{z}\ Mn^{3+}_{2-x}\ Mn^{2+}_{y})\ O^{2-}_{4}$ *with* x = y + z.

1 Introduction

Results obtained in recent years have led to much progress in the development of high performance negative temperature coefficient (NTC) thermistors[1–4] and particularly thin layer ceramics.[5] Generally, these NTC ceramics are based on Mn-spinels. Since both manganese and iron assume multiple valences in oxide structure, it is possible to elaborate spinels over a continuous range of composition from Mn_3O_4 to Fe_3O_4.[6] Thus, in determining the phase diagram of the solids present in the system $Fe_2O_3 - Mn_2O_3 - O_2$ at equilibrium in air, Wickham[7] described the chemical composition of the mixed oxides of iron and manganese which have the spinel crystal structure and proposed the formula $Fe_{3-x}Mn_xO_{4+\delta}$. The value of δ for most of the spinel compositions is very close to zero, yet relatively large for x equal to zero. Pelton *et al.*,[8] through analysis of the phase equilibrium diagram of the Fe_3O_4–Mn_3O_4 spinel system, obtained information on the thermodynamic properties and inferred the distribution of divalent and trivalent cations between the octahedral and tetrahedral sites.

Until now, many papers have been devoted to manganese ferrite $Fe_{3-x}Mn_xO_4$ with $0 \leq x \leq 1$.[9–14] But studies are rare for iron manganite (excess of manganese) and only for the defined compound Mn_2FeO_4. Thus, measurements of magnetic-moment data enabled Eschenfelder[6] to propose a cationic distribution for this compound $Mn^{2+}(Fe^{2+}Mn^{4+})O^{2-}_4$. Using the Mössbauer technique, Tanaka *et al.*[15] introduced both Fe^{3+} and Fe^{2+} ions in octahedral sites following the distributions $Fe^{3+}_{0{\cdot}09}\ Mn^{2+}_{0{\cdot}91}(Fe^{2+}_{0{\cdot}09}\ Fe^{3+}_{0{\cdot}82}\ Mn^{3+}_{1{\cdot}09})\ O^{2-}_4$. More recently, Kulkarni and Darshane,[16] by Mössbauer investigation of $FeMn_2O_4$, showed the equal distribution of Fe^{3+} ions between tetrahedral and octahedral sites and the absence of Fe^{2+} ions in the lattice. Their conductivity and thermopower measurements led them to express the cation distribution of this compound by the formula $Fe^{3+}_{0{\cdot}5}\ Mn^{2+}_{0{\cdot}5}\ (Fe^{3+}_{0{\cdot}5}\ Mn^{2+}_{0{\cdot}5}\ Mn^{3+}_{1-y}\ Mn^{2+}_{y/2}\ Mn^{4+}_{y/2})O^{2-}_4$.

The approach of Rousset *et al.*[17] is to optimize all the manufacturing and electrical parameters of NTC thermistors by a chemical process to establish correlations between composition, structure and electrical properties, so as to understand and rationalize the conventional process. In this respect, the present work reports our results on the preparation of single-phase iron manganite $Mn_{3-x}Fe_xO_4$ with $0 \leq x \leq 1{\cdot}05$. A cation distribution in the compound defined is proposed that takes account of the results obtained for the complete range of these solid solutions. This method appears to be more relevant than the one that only considers only the defined compound Mn_2FeO_4.

2 Experimental

2.1 Preparation of iron manganite powders

Co-precipitated formate precursors were obtained by the addition of water–ethanol solutions at 25°C from $MCl_2.4H_2O$ (with M = Mn, Fe) and ammonium formate. After 30 min, the precipitates were filtered and washed with water–ethanol solution. The different compositions of formate solid solutions studied, $Fe_y\ Mn_{1-y}\ (O_2CH)_2.\ 2\ H_2O$, are listed in Table 1.

After several thermal decomposition tests on formate precursors, we succeeded in obtaining the desired spinel structure phase directly: $Fe_xMn_{3-x}O_4$ (with $x = 3y$). The conditions applied were: rate of temperature increase 150°C h^{-1}, ageing for 4 h at 1000°C, and quenching in air from 1000°C to room temperature.

2.2 Preparation of ceramic samples

To prepare the ceramics, the spinel powders were mixed with an organic binder and pressed into discs under 400 MPa pressure. The resulting discs were fired at 1180°C in air, with 4 h sintering time, and then quenched in air.

The densification of the ceramics was improved by optimizing the percentage of binder. The highest densification, about 95%, was obtained for a ratio of 40 wt% of binder.

2.3 Measurements

X-ray powder diffraction (XRD) measurements were performed at room temperature using an automatic diffractometer (Siemens D501).

The ^{57}Fe Mössbauer spectra were recorded at room temperature with a spectrometer using a 25 mCi ^{57}Co source in Rh matrix. Absolute velocity calibration was carried out with an Fe foil (25 μm thick); isomer shifts (IS) are reported with reference to Fe. The spectra were computer-fitted using a general Lorentzian routine, and a nonlinear least-squares curve-fitting procedure was employed to obtain the best fit to the experimental data. We used IS and quadrupole splitting (QS) to characterize the species.

Table 1. Composition of the formate precursors $Fe_yMn_{1-y}(O_2CH)_2.2H_20$ and the corresponding iron manganites $Fe_xMn_{3-x}O_4$

y	0	0·04	0·13	0·19	0·26	0·35
x	0	0·12	0·39	0·58	0·78	1·05

To determine the electrical characteristics, the ceramic samples were electroded with silver paint and fired at 850°C. Resistivity measurements, ρ, were taken at (25 ± 0·05)°C using a Philips PM2525 multimeter. A second measurement at 85°C gave us the thermal sensitivity B.

3 Results

3.1 XRD analysis

All $Mn_{3-x}Fe_xO_4$ ($0 \leq x \leq 1{\cdot}05$) solid solutions crystallize with a spinel structure. Figure 1 and Table 2 give the overall results, the variation in the lattice parameters a and c, and the c/a ratio. For $0 \leq x \leq 0{\cdot}78$, XRD powders revealed a single tetragonally distorted cubic symmetry spinel phase. This tetragonal distortion, characterized by the ratio c/a, decrease as a function of increasing iron, x, and disappears for x equal 1·05. For $x = 1{\cdot}05$, $Mn_{1.95}Fe_{1.05}O_4$ crystallized with a cubic single phase.

The same results were observed for the ceramics, see Table 3.

3.2 Mössbauer spectroscopy

The Mössbauer spectra of all iron manganite powders have the same form; Fig. 2 shows the Mössbauer spectrum of $Mn_{2.42}Fe_{0.58}O_4$. All the

spectra exhibit two doublets with an isomer shift of between 0·3 and 0·5 mm s^{-1}, indicating the presence of two non-equivalent sites of the Fe^{3+} ion. This could be associated with the presence of Fe^{3+} ions in octahedral and tetrahedral sites. Singh *et al.*[18]

B (K)	5981	5722	5510	5468

showed that quadrupole splitting is less in octahedral sites than in tetrahedral sites. By quantitative analysis, we can calculate the percentage of Fe^{3+} ions in each site. The percentages are given in Table 4.

3.3 Electrical measurements

Electrical measurements were carried out on the ceramics. Figure 3 shows the variation in dc resistivity, ρ, as a function of iron content, *x*, while Table 5 summarizes the electrical data. The dc resistivity of the composition for $x \leq 0{\cdot}12$ was too high for measurement in our laboratory. For $x > 0{\cdot}12$, resistivity decreased until *x* is equal to 0·78, then remained constant. The substitution of ferric ion in Mn_3O_4, an insulating compound, changed the resistivity from 1 GΩ cm[19] to 2 MΩ cm. The values of thermal sensibility, *B*, also decreased with decreasing resistivity, dropping from 5980 to 5470 K for $0{\cdot}39 \leq x \leq 1{\cdot}05$.

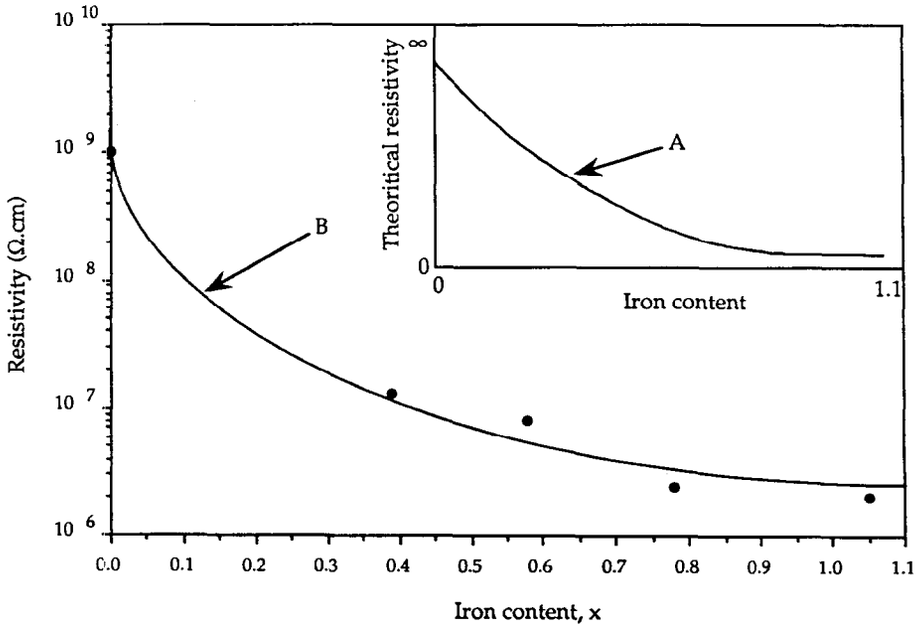

Fig. 3. Variation of resistivity as a function of iron content: (A) theoretical curve and (B) experimental curve.

4 Discussion

4.1 Valency and position of iron cations

Iron manganites were prepared by substituting iron ions for manganese ions in hausmannite Mn_3O_4, the basic crystal structure of manganites. It is now commonly accepted[20,21] that the cation distribution in Mn_3O_4 is Mn^{2+} (Mn_2^{3+}) O_4^{2-}. Thus the iron cation can occupy either the tetrahedral sites (A sites, Mn^{2+} substitution) or octahedral sites (B sites, Mn^{3+} substitution). The Mössbauer results indicate the presence of Fe^{3+} ions only (i.e. no Fe^{2+} ions) located in both octahedral and tetrahedral sites. The introduction of Fe^{3+} ions at octahedral sites does not disturb the overall electrical neutrality of the material, whereas Fe^{3+} in tetrahedral sites does. In the latter case, to preserve electrical neutrality, some Mn^{3+} at B sites change valency to Mn^{2+}. Moreover, the number of Mn^{2+} in octahedral sites is equal to the number of Fe^{3+} in tetrahedral sites. The following ionic configuration can thus be proposed for iron manganites:

$$Mn^{2+}_{1-y}\ Fe^{3+}_{y}\ (Fe^{3+}_{z}\ Mn^{3+}_{2-x}\ Mn^{2+}_{y})\ O^{2-}_{4} \text{ with } x = y + z \quad (I)$$

Using quantitative Mössbauer results, the values of the coefficients x, y and z can be calculated. For example, for $x = 0{\cdot}58$:

$$Mn^{2+}_{0{\cdot}71}Fe^{3+}_{0{\cdot}29}(Fe^{3+}_{0{\cdot}29}\ Mn^{3+}_{1{\cdot}42}\ Mn^{2+}_{0{\cdot}29})\ O^{2-}_{4}$$

The cationic distributions obtained for the other values of x are given in Table 6. Whatever the value of x (total number of iron ions) above 0·12, the number of Fe^{3+} ions in A sites is almost constant, about 0·23 – 0·29, whereas the number of Fe^{3+} ions in B sites increases with the increasing total number of iron ions.

4.2 Cubic–tetragonal transition

Most of the $Mn_{3-x}Fe_xO_4$ solid solutions were found to be tetragonally distorted from cubic symmetry. Hausmannite exhibits a tetragonal distorsion explained by the presence of Mn^{3+} ions in octahedral positions (Jahn–Teller effect). Moreover, Baffier and Huber[22] showed that a minimum concentration of Mn^{3+} ions in octahedral sites is necessary to promote a cooperative Jahn–Taller effect. The minimum is about 50%. Thus a correlation exists between the concentration of Mn^{3+} cations in B sites and the macroscopic distorsion observed by X-ray diffraction. The cationic distribution (I) could explain the decrease in tetragonal distortion as a function of iron content (x) by diminishing the Mn^{3+} ion content in B sites.

Particularly when $x = 1{\cdot}05$, the Mn^{3+} concentration in octahedral sites is below 50% and cubic symmetry appears. These results are in good agreement with the studies of Brabers[23] who pointed out the cubic–tetragonal transition in manganese ferrites $Mn_xFe_{3-x}O_4$ for $x = 1{\cdot}9$, corresponding in this work to iron manganites $Mn_{3-x}Fe_xO_4$ to $x = 1{\cdot}1$.

X-ray diffraction analysis of manganite ceramics revealed the presence of a pure spinel structure. The results concerning the lattice parameters (Table 3) are very close to those observed with spinel powders. Hence we can assume that the ionic distribution of the powder samples does not differ from that of the ceramics.

Table 6. Cationic distributions of the iron manganites $Mn_{3-x}Fe_xO_4$

x	*Cationic distributions*
0	$Mn^{2+}_1(Mn^{3+}_2)O^{2-}_4$
0·12	$Mn^{2+}_{0{\cdot}91}Fe^{3+}_{0{\cdot}09}(Fe^{3+}_{0{\cdot}03}Mn^{3+}_{1{\cdot}88}Mn^{2+}_{0{\cdot}09})O^{2-}_4$
0·39	$Mn^{2+}_{0{\cdot}77}Fe^{3+}_{0{\cdot}23}(Fe^{3+}_{0{\cdot}17}Mn^{3+}_{1{\cdot}60}Mn^{2+}_{0{\cdot}23})O^{2-}_4$
0·58	$Mn^{2+}_{0{\cdot}71}Fe^{3+}_{0{\cdot}29}(Fe^{3+}_{0{\cdot}29}Mn^{3+}_{1{\cdot}42}Mn^{2+}_{0{\cdot}29})O^{2-}_4$
0·78	$Mn^{2+}_{0{\cdot}71}Fe^{3+}_{0{\cdot}29}(Fe^{3+}_{0{\cdot}49}Mn^{3+}_{1{\cdot}22}Mn^{2+}_{0{\cdot}29})O^{2-}_4$
1·05	$Mn^{2+}_{0{\cdot}77}Fe^{3+}_{0{\cdot}23}(Fe^{3+}_{0{\cdot}82}Mn^{3+}_{0{\cdot}95}Mn^{2+}_{0{\cdot}23})O^{2-}_4$

4.3 Electrical properties of ceramics

Electrical conduction in ferrites and manganites is assumed to occur according to the 'hopping' mecanism.[24] It has been determined that hopping will occur if ions of the same element, differing in valency by one unit only, are present in crystallographically equivalent lattice sites.

According to the cationic distribution proposed for iron manganites, formulae I, both Mn^{2+} and Mn^{3+} are present in B sites so that the conditions are correct for electron hopping from Mn^{2+} to Mn^{3+}. The conductivity of the material is determined by the number of ions capable of either donating or accepting electrons in this electron transfer. Thus the electrical conductivity can be written[25]:

$$\sigma = \frac{\sigma_o}{T} NC(1-C) \exp\left(\frac{-E_H}{kT}\right) \text{ with } \sigma'_o = \frac{N_{oct} e^2 d^2 \nu_o}{k}$$

where N_{oct} is a concentration per cm^3 of octahedral sites, d is a jump distance for the charge carrier, ν_o is the lattice vibrational frequency associated with conduction, k is Boltzmann's constant, e the electronic charge, N is a concentration per formulae unit of sites which are available to the charge carriers, C is a fraction of available sites which are occupied by the charge carriers, and E_H is a hopping energy.

The term $NC(1 - C)$ can be rewritten:

$$NC(1-C) = \frac{(Mn^{3+}_{oct})(Mn^{2+}_{oct})}{[(Mn^{3+}_{oct})+(Mn^{2+}_{oct})]^2}$$

Table 7. Comparison between iron manganites and nickel manganites

	Cationic distribution	NC(*1* – C)[a]	d(Å)[b]
$Mn_{2.42}Fe_{0.58}O_4$	$Mn^{2+}_{0.71}Fe^{3+}_{0.29}(Fe^{3+}_{0.29}Mn^{3+}_{1.42}Mn^{2+}_{0.29})O^{2-}_4$	0·141	3·021
$Mn_{2.43}Ni_{0.57}O_4$	$Mn^{2+}_1(Ni^{2+}_{0.57}Mn^{3+}_{0.86}Mn^{4+}_{0.57})O^{2-}_4$	0·240	2·989

$$^{a}NC(1\text{-}C) = \begin{cases} \dfrac{(Mn^{3+}_{oct})\,(Mn^{2+}_{oct})}{[(Mn^{3+}_{oct}) + (Mn^{2+}_{oct})]^2} \\ \text{or} \\ \dfrac{(Mn^{3+}_{oct})\,(Mn^{4+}_{oct})}{[(Mn^{3+}_{oct}) + (Mn^{4+}_{oct})]^2} \end{cases}$$

^{b}d = distance of $\begin{cases} Mn^{2+} - Mn^{3+} \text{ carriers in iron manganites} \\ \text{or} \\ Mn^{3+} - Mn^{4+} \text{ carriers in nickel manganites} \end{cases}$

$$= \begin{cases} \dfrac{a\sqrt{2}}{4} \text{ for cubic phase} \\ \text{or} \\ \dfrac{a'\sqrt{2}}{4} \text{ for tetragonal phase with } a' = \sqrt[3]{a^2c} \text{ (average value)} \end{cases}$$

which represents the probability of finding Mn^{3+} Mn^{2+} pairs in octahedral sites.

As a first approximation, we shall consider only the variation in the last ratio. Thus, the theoretical variation in resistivity can be plotted against iron content and compared with the experimental curve: $\rho = f(x)$. The theoretical variation in resistivity shown in Fig. 3 curve A, calculated for hypothetical configuration I, selected from a previously Mössbauer study, fits well with the experimental data (Fig. 3 curve B). Thus for $0 < x < 0{\cdot}8$, both theoretical and experimental resistivities decrease then remain constant. Table 5 summarizes the electrical data. Note that the substitution of iron ions in hausmannite ($x = 0$) insulating material (resistivity about 10^9 Ω cm) changes the resistivity by only about 10^6 Ω cm. Compared with the substitution of the same number of nickel ions in Mn_3O_4, for example $x = 0{\cdot}57$ nickel ions, the resistivity is about 1650 Ω cm. Two parameters can influence the hopping process: the number and/or the distance of carriers. The higher resistivity in iron manganite can be explained on the one hand by a small number of carriers, 0·141 compared with 0·240 carriers in nickel manganites with approximately the same total number of substituted ions (see Table 7), and, on the other, by the distance of Mn^{2+}–Mn^{3+} carriers in iron manganites (3·021 Å), which is higher than the distance of Mn^{3+}–Mn^{4+} carriers in nickel manganites (2·989 Å).

Figure 4 shows that a plot of log resistivity against the reciprocal of absolute temperature gives a straight-line relationship between these

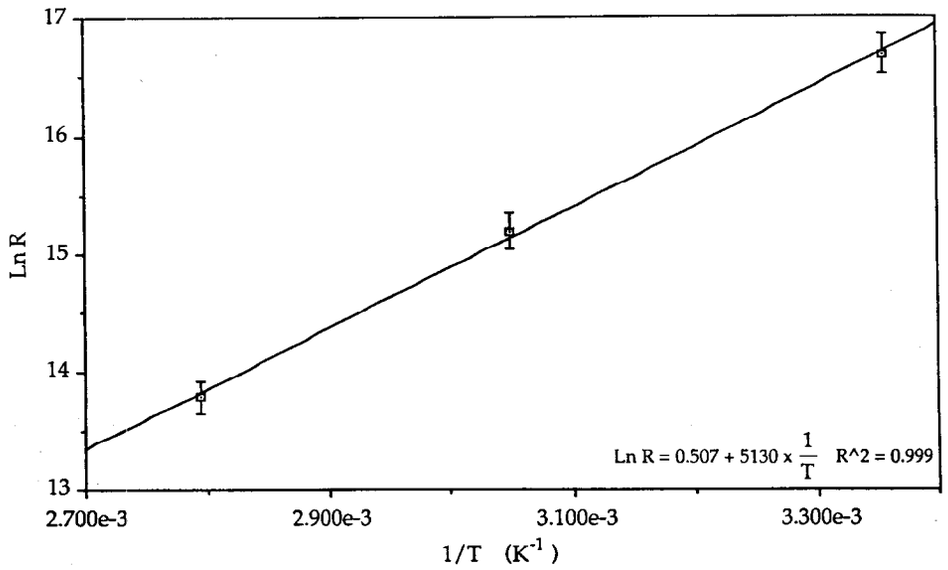

Fig. 4. Variation of ln *R* as a function of inverse of the temperature between 25 and 85°C.

parameters. This result indicates that, in spite of the high resistivity, iron manganites have thermistor characteristics. Moreover, the thermal sensibility is also very high, ranging from 5468 to 5981 K in all solid solutions.

4.4 Cationic distributions

Mössbauer studies indicate that only Fe^{3+} ions are located in both sites of the spinel structure of iron manganites $Mn_{3-x}Fe_xO_4$. Using quantitative results, a cationic distribution is proposed for all solid solutions. In these latter, the number of Mn^{3+} ions in B sites corresponds to the tetragonal distortion, observed by X-ray diffraction, and explains the cubic–tetragonal transition when $x = 1{\cdot}05$.

The electrical resistivity also correlates with the theoretical resistivity calculated by the number of charge carriers from proposed cationic distributions. These results suggest the following ionic distribution model for iron manganite solid solutions:

$$Mn^{2+}_{1-y}\ Fe^{3+}_{y}(Fe^{3+}_{z}\ Mn^{3+}_{2-x}\ Mn^{2+}_{y})\ O^{2-}_{4} \text{ with } x = y + z \quad (1)$$

Differences of opinion exist regarding the distribution and valency states of the cations on the tetrahedral and octahedral sublattices of the spinel structure of iron manganites.[6,15,16] These discrepancies may result from their preparation, since iron manganite are usually prepared by mixtures of oxides. Thus the difficulty of synthesizing single-phase compounds often limits the correlation of structure and properties.

5 Conclusions

Co-precipitated iron–manganese formate was employed to prepare single-phase iron manganite spinels, $Mn_{3-x}Fe_xO_4$ with $0 \leq x \leq 1{\cdot}05$. XRD analysis of these spinels revealed the presence of a single phase having a tetragonally distorted spinel structure for $x < 1{\cdot}05$ and a single cubic spinel phase for $x = 1{\cdot}05$. Mössbauer spectroscopy showed the presence of iron ions in both sites of the spinel structure but only with oxidation degree III. XRD results, combined with Mössbauer spectroscopy, and comparison of experimental and theoretical curves of electrical measurements indicated that the cationic distribution in these spinels approached:

$$Mn^{2+}_{1-y}\ Fe^{3+}_{y}(Fe^{3+}_{z}\ Mn^{3+}_{2-x}\ Mn^{2+}_{y})\ O^{2-}_{4} \text{ with } x = y + z$$

These electro-ceramics display high resistivity and, above all, high thermal sensibility, and should accordingly find interesting industrial applications as NTC thermistors.

Abstract

Mineral compounds $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (x = 0 and x = 0·3) have been made by co-grinding and soil–gel processes. Structural characterizations by X-ray diffraction and Raman spectroscopy indicate that alumina substitution (x = 0·3) does not modify the crystallographic structure, whatever the synthesis process: compounds crystallize in the rhombohedral system with an R-3C space group. The use of the sol–gel route makes low-temperature sintering (950°C) easier and, moreover, leads to ceramics with a high water stability. $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ compounds are fast ionic conductors: $\sigma_{25°C}$ varies from 15^{-5} to 10^{-4} S cm^{-1}, depending on the synthesis process. They have been used as ionic membranes for lithium-selective electrodes. Sensors prepared with sol–gel membranes have the best performance: the detection limit is 1·4 × 10^{-4} mol dm^{-3}. The potassium and the protonic selectivity properties are attractive for such electrodes. For sodium, they need to be improved for biomedical applications.

1 Introduction

During the last few years, numerous studies on lithium ionic conductors of NASICON-type structure have been published. Because of their significant ionic conductivity, the high reduction potential and low atomic mass of lithium, these materials were destined to be used as solid electrolytes for secondary batteries.[1–5] These ionocovalent compounds, of general formula $Li_{1+x}M'x$ (III)$_{2-x}$(IV)$(PO_4)_3$, have a particular crystallographic structure: the NASICON framework consists of a 3D network of PO_4 tetrahedra sharing corners with TiO_6 octahedra and a 3D linked interstitial space occupied by Li^+ ions.[1] These materials may have good selectivity properties as membranes for ion-selective electrodes. The possibility of similar systems has already been shown with the NASICON $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$, a sodium conductor used in sodium potentiometric sensors.[6,7]

To realize crystallized membranes for lithium electrodes, we have synthesized $Li_{1+x}M'_x$(III)M_{2-x}(IV)$(PO_4)_3$ type compounds, with M' = Al and M = Ti, by different routes. First, we have chosen the most conducting compound of this group: $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$. We have also synthesized $LiTi_2(PO_4)_3$ to compare the properties of the doped (x = 0·3) and the undoped (x = 0) ceramics. We have used two processes for their preparation: co-grinding (A) and a sol–gel (B) route. Various physico-chemical characterizations have been carried out on rough and calcined powders, and sintered materials. Afterwards, the samples were used in potentiometric sensors. The results obtained with the different methods are compared.

2 Synthesis and Structural Properties

2.1 Co-grinding synthesis (method A)

Starting materials were Li_2CO_3 (Janssen®, 99% pure), Al_2CO_3 (Baikowski®, 99·99% pure), TiO_2 (Merck®, 99% pure) and $(NH_4)_2HPO_4$ (R.P.®, 99% pure). A stoichiometric mixture was ground for ~100 h with zirconia grinding balls in ethanol. The approximate ratio was 1/3 powder, 1/3 grinding balls and 1/3 ethanol. Then, it was dried and calcined for 2 h at 900°C to decompose the precursors. Afterwards the resulting material was reground.[4] For total decomposition, we had to reheat at 900°C and regrind the product. Specific area of the obtained mixture (measured by the B.E.T. method) is 1·7 m^2 g^{-1} for dried powder. The granulometry is dispersed so that the particle sizes vary from 0·5 to 2 μm (Fig. 1(a)).

The synthesized powder was pressed into pellets at a pressure of 2500 bar (250 MPa) and sintered for 2 h at 1000°C. As seen from a micrograph of a $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ broken pellet obtained by scanning electron microscopy (SEM) (Fig. 1(b)),

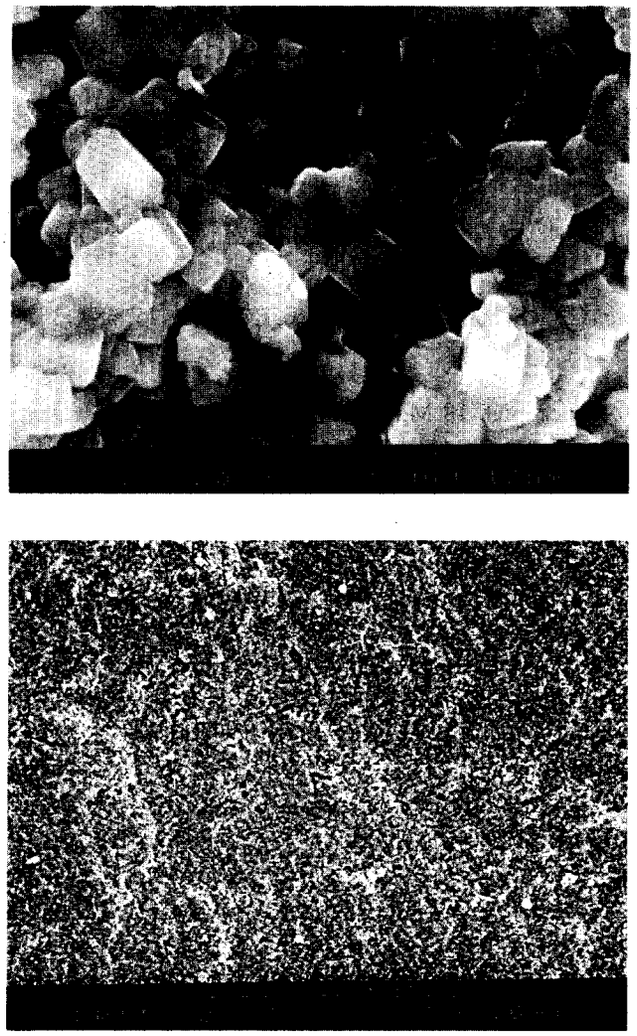

Fig. 1. Scanning electron micrographs of (a) $Li_{1\cdot3}Al_{0\cdot3}Ti_{1\cdot7}(PO_4)_3$ powder synthesized by the co-grinding process and calcined at 900°C and (b) $Li_{1\cdot3}Al_{0\cdot3}Ti_{1\cdot7}(PO_4)_3$ pellet synthesized by theco-grinding process (sintered at 1000°C).

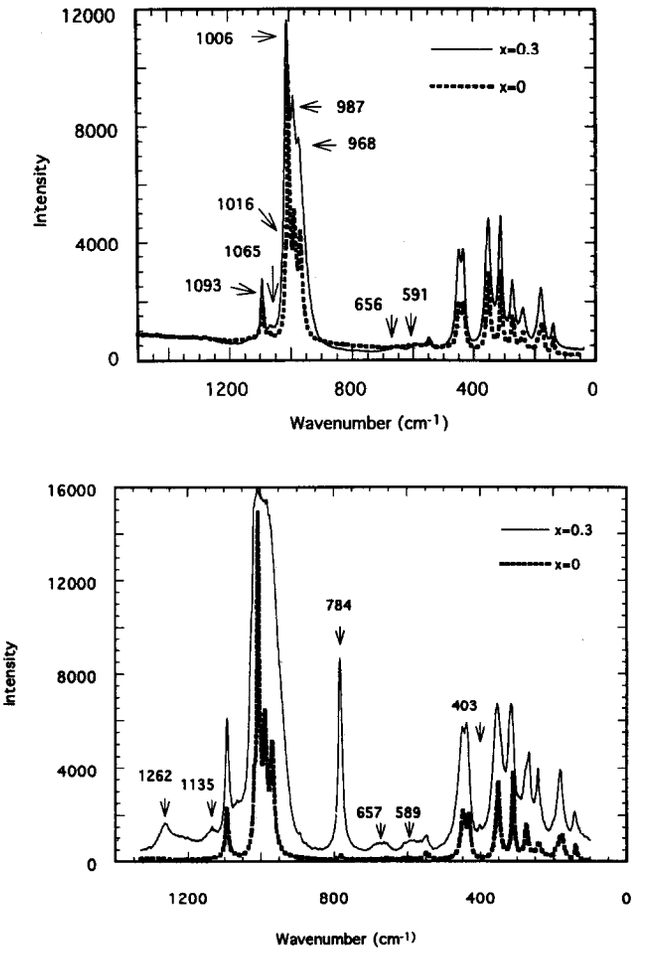

Fig. 2. Raman spectra of (a) co-ground pellet sintered at 1000°C and (b) sol–gel pellet sintered at 950°C.

the ceramic is compact with a packing density of 92%. On the other hand, the $LiTi_2(PO_4)_3$ samples are porous: packing density is about 75%. This result is in agreement with those of Aono *et al.*[4] X-ray diffraction analysis (using $K_{\alpha 1}$ Cu radiation, λ = 0·15406 nm) was conducted with a Siemens D500® $\theta/2\theta$. Doped and undoped ceramics are single-phase materials based on the $LiTi_2(PO_4)_3$ type, with a rhombohedral structure in the R-3C space group. X-ray microanalysis connected with SEM has shown heterogeneity in the composition because of the incomplete decomposition of Li_2CO_3.

To complete the structural analysis, we studied the sintered samples by Raman scattering spectroscopy. Spectra were obtained using a Dilor® *XY* multi-channel spectrometer. The excitation source was an argon-ion laser (excitation wavelength of 514·5 nm and power of 60 mW). Raman spectra of undoped $LiTi_2(PO_4)_3$ (x = 0) and doped $Li_{1\cdot3}Al_{0\cdot3}Ti_{1\cdot7}(PO_4)_3$ (x = 0·3) polycrystalline samples synthesized by co-grinding are shown in Fig. 2(a). Assignment of the different bands of the $LiTi_2(PO_4)_3$ spectra followed the works of Barj.[9,10] Table 1 compares the Raman frequencies of this material and of $NaTi_2(PO_4)_3$.[10] Concerning the co-ground compound, the vibrational frequencies of the internal modes (wavenumber > 400 cm^{-1}) of both compounds are in agreement (Table 1). The intensity inversion between ν_1 and ν_3 has been observed previously and is due to the high electrical charge of PO_4 tetrahedra.[10] For the external modes (< 400 cm^{-1}), the assignment is delicate because of the possibility of frequency coupling between the different ions. Consequently the lithium signature, which should appear at about 300 cm^{-1}, has never been identified. In this range, the correlation with $NaTi_2(PO_4)_3$ is more difficult. For the substituted compound (x = 0·3), the intensities of the unknown bands at 656 and 591 cm^{-1} increase slightly (Fig. 2(a)). This alumina doping also induces a significant modification of the relative intensities of the bands at 1006, 987 and 968 cm^{-1}, and a general enlargement of the spectrum which is due to distortion of the $(Ti/Al)O_6$ octahedra and the PO_4 tetrahedra. Doped and undoped materials are homogeneous: Raman spectra on different areas of the pellets are identical. Li_2CO_3, identified by X-ray microanalysis, did not appear in the spectra.

2.2 Sol–gel synthesis (method B)

$LiTi_2(PO_4)_3$ and $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ have already been successfully prepared by this process. Tohge *et al.*[11] used organic precursors for lithium and titanium: $LiOC_2H_5$ and $Ti(OC_4H_9)_4$. They also tested different sources of phosphorus: $PO(OC_2H_5)_3$ and H_3PO_4. It was shown that the use of $PO(OC_2H_5)_3$ leads to a heterogeneous gel and to a material containing TiO_2 after calcination. On the other hand, Ando *et al.*[12] synthesized the above ceramics from CH_3COOLi, $Ti(OC_4H_9)_4$, H_3PO_4, $AlCl_3.6H_2O$ and CH_3COONH_4. The use of CH_3COONH_4 gave a single-phase material without TiO_2 because acetate anions replace the OR groups and form a stable titanium–acetate complex.[13]

The precursors that we chose are $Ti(OC_4H_9)_4$ (Janssen®, 99% pure) and $Al(OC_4H_9)_3$ Janssen®, 97% pure), $NH_4H_2PO_4$ (Fluka®, >99% pure) and CH_3COOLi (Schuchardt®, 98% pure). We avoided the use of chloride precursors, because Cl_2 is generally difficult to eliminate during the sintering. We also tested other starting materials for Li precursors: $LiNO_3$ and LiOH. The pellets obtained were single-phase type $LiTi_2(PO_4)_3$, but the samples had very poor ionic conductivity, almost certainly because of lack of a part of the lithium due to Li_2CO_3, formation[14] and $LiNO_3$ departure during the drying stage. Consequently, we stopped using these type of precursors and chose CH_3COOLi.

The different stages of our sol–gel process are:

- a C_2H_5OH solution of $Ti(OC_4H_9)_4$ and $Al(OC_4H_9)_3$ is heated for 1 h at 70°C;
- an aqueous solution of CH_3COOLi and $NH_4H_2PO_4$ at 70°C is added to the first mixture;
- an excess of H_2O (70°C) (more than the stoichiometric amount required for hydrolysis of the alkoxides) is also used.

As soon as the solutions are mixed, a fine powder forms immediately. Strong stirring is used for 2 h at 70°C.

Then, the drying stage is conducted at low temperature. To facilitate the sublimation process, the product is frozen at –40°C with a Christ Alpha 2-4® freeze dryer. With this technique, the initial morphology of the powder is preserved, contrary to the usual hot or room temperature drying processes such as evaporation, centrifugation with acetone[15] or azeotropic distillation,[16] which can induce powder agglomeration. The specific area of this xerogel powder dried with our process is 52 $m^2\ g^{-1}$ and the particle size is about 0·25 μm diameter.

During a temperature analysis of the sol–gel pellets, very high shrinkage took place between 200 and 450°C (Fig. 3). In this range of temperature, differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) (Fig. 4) of the sol–gel compounds show exothermic peaks and considerable weight loss. All these phenomena are

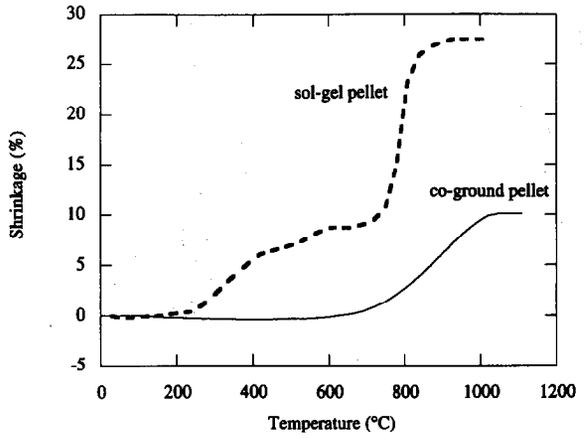

Fig. 3. Shrinkage study during the sintering of $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ synthesized by the co-grinding and sol–gel processes.

due to the combustion of organic groups. As a consequence, to facilitate sintering, it is better to burn off the organic groups. So the powder was calcined at 550°C for 4 h. It remained amorphous according to X-ray diffraction and Raman spectroscopy but the specific area decreased (35 m^2 g^{-1}) due to low temperature sintering of the gel. Nevertheless, the particles are finer than those synthesized by the co-grinding process (Fig. 5).

Sintering is much faster for the sol–gel compounds and moreover takes place at a temperature 100°C lower than that for co-ground compounds (Fig. 3). These properties are required for very high densification. They are due to the very good reactivity of the sol–gel powder, because of its homogeneity and narrow granulometry. Subsequently, doped pellets sintered at 950°C have a packing density of about 93%. At about 640°C, compounds start to crystallize as evidenced by an exothermic peak on the DSC trace (Fig. 4). Pellets sintered at 950°C for about 2 h are mono-phase $LiTi_2(PO_4)_3$.

Raman spectra of $LiTi_2(PO_4)_3$ synthesized by both processes are in agreement (Figs 2(a) and 2(b) and Table 1), except for the presence of a

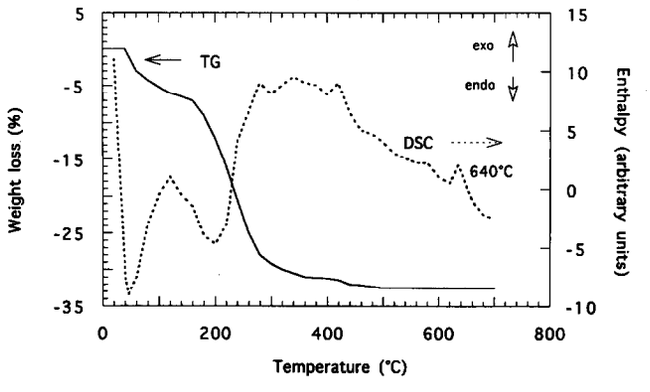

Fig. 4. Thermogravimetric and differential scanning calorimetry analysis of a doped powder synthesized by the sol–gel route.

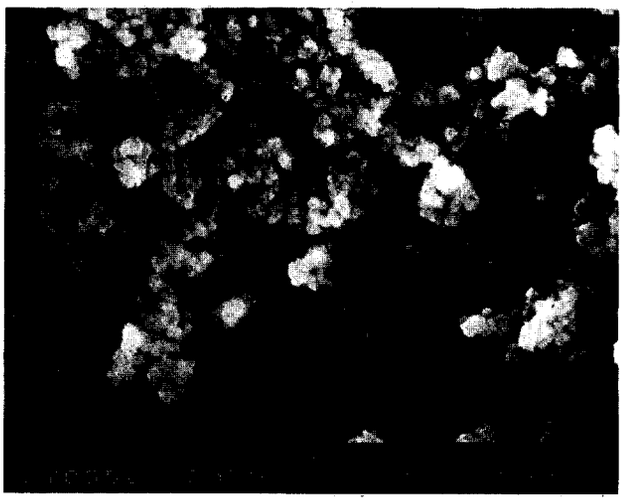

Fig. 5. Scanning electron micrograph of a $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ powder synthesized by the sol–gel process and calcined at 550°C.

very weak band at 784 cm^{-1} on the sol–gel sample spectra. The general spectrum modifications due to the substitution do not depend on the synthesis process: for x = 0·3, we notice for both compounds the relative intensity modifications of the ν_3 and ν_1 bands and a general enlargement of the spectrum. We note the presence of new bands at 1262, 1135 and 403 cm^{-1} on the sol–gel doped material (Fig. 2(b)). Analysis of different samples and powders of $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ have shown that intensity of the bands at 784 and 403 cm^{-1} is a function of the sample and of the analysis area, whereas the relative intensities of the other bands are constant. Consequently, the sol–gel samples contain a small amount of a second phase. This phase seems to be more important for the doped material and it is difficult to know its nature because it is invisible to X-ray diffraction. The complete assignments of the Raman spectra bands for $LiTi_2(PO_4)_3$ and $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ are the subject of current work.

3 Physico-chemical Properties Study

3.1 Ionic conductivity

Ionic conductivity has been measured by the AC impedance method in the range 5 to 13 MHz (impedance analyser HP 4192A®). The measurements were made in a vaccum cell between 25 and 200°C, using gold evaporation electrodes. The utilization of Au blocking electrodes allows a correct separation between the bulk and electrode impedances. An example is given in Fig. 6. The respective contributions of the grains and the grain boundaries have not been separated because their characteristic frequencies are close. As a consequence, Table 2 gives the total conductivity at

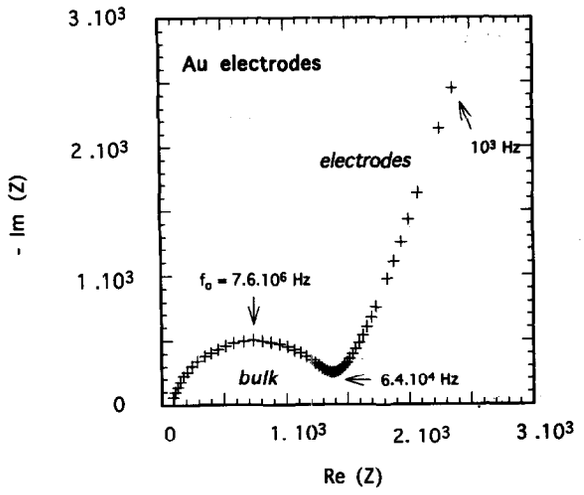

Fig. 6. Example of impedance diagram obtained at 130°C on a $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ pellet synthesized by the sol–gel process using Au electrodes.

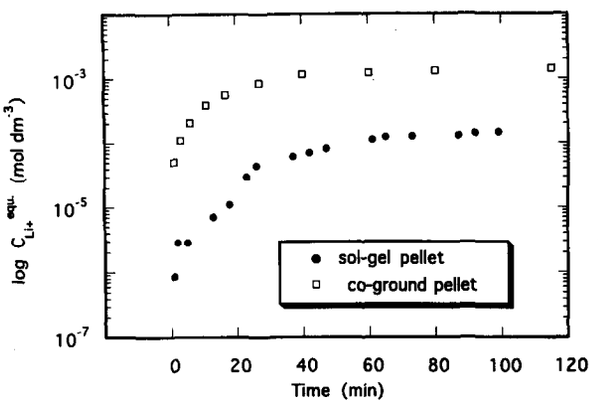

Fig. 7. Evolution of the lithium concentration in solution as a function of time for $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ sintered pellets.

25°C and the activation energy of the different sintered samples, extracted from the Arrhenius plots.

For $x = 0$, the co-ground compound (75% packing density) and the sol–gel compound (82% packing density) are poor ionic conductors. Moreover, the sol–gel material has a high activation energy. On the other hand, $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ ceramics have good electrical properties: very high lithium conductivity and low activation energy. These properties are better for the co-ground samples (95% packing density). The lithium conductivity enhancement for doped materials can be explained by the fact that conductivity depends on different factors:

- the carrier concentration — partial substitution of Ti (IV) by Al (III) has required lithium enhancement to maintain electroneutrality of the compound. This doping has been corroborated by the value of the lithium concentration in the ceramic, which was measured by the analysis laboratory of the CNRS (Vernaison, France);
- the carrier mobility — the octahedral substitution $(Ti/Al)O_6$ has led to a distortion of the structure, confirmed by Raman spectroscopy. Consequently, like in NASICON compounds, carrier diffusion is facilitated by structural transformation,[17] because of the slight decrease of the size of the conduction sites;
- the packing density of the sample — Aono *et al.*[4] have shown that the partial substitution of the Ti^{4+} site with Al^{3+} was very effective for enhancement of the conductivity, mainly because of the densification of the sintered pellets.

3.2 Stability in water

To determine the stability in water of the ceramics, we have recorded the lithium loss from the pellet to the solution. Samples were immersed in distilled water and the lithium concentration was measured every 10 min using a Varian AA1275BD® atomic absorption spectrometer (Fig. 7). Results in function of time are given in Fig. 7.

The values tend to a constant, with stability being achieved after about 40 min for the co-ground pellet and 60 min for the sol–gel pellet. The lithium concentration equilibrum value is $1{\cdot}4\ 10^{-3}$ mol dm^{-3} for the co-ground ceramic. We can think that the lithium concentration corresponds to equilibrum phenomena (solubility, ionic exchange, etc.). After about 100 h of immersion, we recorded 5% weight loss for this pellet. This very poor stability in water is due to the preferential solubility of parasite phases, invisible by X-ray diffraction. Li_2CO_3, identified by X-ray microanalysis, is certainly the origin of this solubility. On the other hand, sol–gel ceramics have a better stability: the equilibrum value is low, $1{\cdot}5 \times 10^{-4}$ mol dm^{-3}. In this case, weight loss is about 0·9%.

4 Utilization of Ceramics as Ionic Membranes in Potentiometric Sensors

The development of lithium-selective potentiometric electrodes for the determination of Li^+ activity in biological systems has already been realized, especially when using polymeric membranes.[18–23] However, the lifetime of this type of electrode is short; moreover polymers are not suitable for sterilization. Consequently, it is attractive to use ceramic membranes in potentiometric sensors for such applications. Experimentally, the specific electrode is made with the ionic ceramic, stuck at the extremity of the electrode isolant body. Inside, a silver wire covered with a silver chloride layer and immersed in lithium salt solution constitute the internal reference. Tested membranes are $Li_{1\cdot3}Al_{0\cdot3}Ti_{1\cdot7}(PO_4)_3$ synthesized by co-grinding and sol–gel processes, because of their high ionic conductivity.

The electrochemical cell is:

Ag–AgCl/Lithium salt/Ionic conductor/Analyzed solution//Saturated Calomel Electrode (SCE)

When lithium activity in the internal reference is constant, the cell potential obeys the Nernst equation:

$$E=E^0+2\cdot3RT/F \log a_{Li^+}$$

where E^0 is a constant depending on the internal (Ag–AgCl) and external (SCE) references, and consequently on temperature. R and F are the usual constants, T the absolute temperature and a_{Li^+} the lithium activity in the analysed solution. For measurements, we use generally a supported electrolyte and we have made the approximation that the ionic strength is a constant. So, as a first approximation, a_{Li^+} can be substituted for the concentration (activity coefficient is included in E^0).

4.1 Detection limit

Referring to the IUPAC recommendations, the detection limit (DL) is the crossing point of the Nernst asymptote ($2.3RT/F$ slope) and the horizontal line, corresponding to the insensitive range of the sensor. Figure 8 gives an example of a calibration curve. We used a $BaCl_2$ 10^{-1} mol dm^{-3} solution to keep constant ionic strength and also to decrease the analysed solution impedance (Ba^{2+} is not an interfering ion). Consequently, the experimental procedure for this operation is the following: the external reference electrode is equipped with an extension (double junction) containing $BaCl_2$ 10^{-1} mol dm^{-3}. The lithium salt contained in the internal reference is LiCl 10^{-1} mol dm^{-3} + $BaCl_2$ 10^{-1} mol dm^{-3}. Both electrodes are immersed in a $BaCl_2$ 10^{-1} mol dm^{-3} solution. The addition of LiCl solutions (10^{-3} to 1 mol dm^{-3} + $BaCl_2$ 10^{-1} mol dm^{-3}) and recording of the cell potential allow the calibration curve to be plotted (Fig. 8).

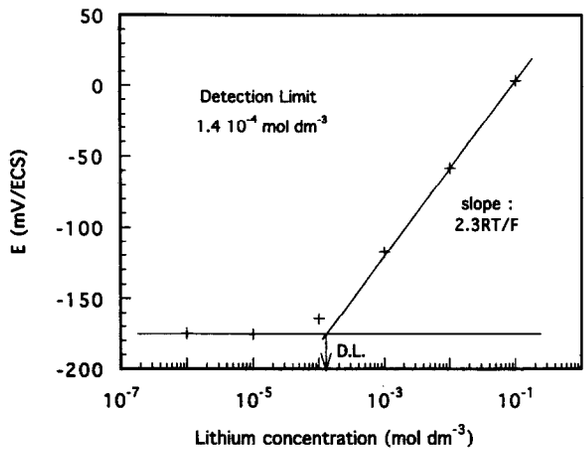

Fig. 8. Example of calibration curve and detection limit (DL) determination obtained on a Li^+ electrode using a $Li_{1\cdot3}Al_{0\cdot3}Ti_{1\cdot7}(PO_4)_3$ sol–gel membrane.

Electrodes using $Li_{1\cdot3}Al_{0\cdot3}Ti_{1\cdot7}(PO_4)_3$ membranes have a Nernst response for high lithium concentration, with a slope of $2\cdot3RT/F$ V per concentration decade. Moreover, the detection limit depends on the membrane synthesis process (Table 3): sensors using sol–gel membranes are more sensitive than those made with co-ground ones. These first type of specific electrodes are based on ionic exchanges at the membrane–solution interface. Consequently, the cell potential is a function of the ionic equilibrum at this interface. As we have seen before (stability in water), part of the lithium contained in the ceramic leaves the membrane for the solution. As a consequence, lithium concentration is more important at the interface than into the analysed solution. The detection limit of both types of sensor and the lithium solubility equilibrium value for each membrane (from Fig. 7) are compared in Table 3. The sensor sensibility is linked to the stability in water of the ceramics. Accordingly, the lithium solubility of the material is the principal limiting factor for lithium analysis with the first kind of electrodes using $Li_{1\cdot3}Al_{0\cdot3}Ti_{1\cdot7}(PO_4)_3$ ceramics. For biological appli-

Table 3. Comparison of the sensor sensibility with the concentration of Li^+ in water after about 1 h of use for co-ground and sol–gel membranes

	Co-ground membrane	*Sol–gel membrane*
Detection limit of sensors (mol dm^{-3})	$1\cdot6 \times 10^{-3}$	$1\cdot4 \times 10^{-4}$
Lithium equilibrium in water (mol dm^{-3})	$1\cdot4 \times 10^{-3}$	$1\cdot5 \times 10^{-4}$

cations, where lithium measurements in the range from 10^{-4} to 5×10^{-3} mol dm^{-3} are required,[24] sensors using co-ground membranes are not sensitive enough (DL = $1{\cdot}6 \times 10^{-3}$ mol dm^{-3}), whereas those made with sol–gel ones are usable because of their higher sensibility (DL = $1{\cdot}4 \times 10^{-4}$ mol dm^{-3}).

4.2 Ionic selectivity

The selectivity for ionic electrodes is the ability to recognize one ion amongst others. It is never perfect, because interfering ions can disturb ionic exchange at the interface. The electrode responds to the empirical Nickolskii relation:

$$E = E^{o} + 2{\cdot}3RT/z_iF \log (a_i + K_{i,j}^{pot} a_j^{zi/zj})$$

where i is the primary ion, j an interfering ion and $K_{i,j}^{pot}$ the potentiometric ion-selectivity coefficient for ion j. An example of the potentiometric ion-selectivity coefficient determination for a_{Li^+} = constant is given in Fig. 9. There are two asymptotes:

(1) $$\text{for } a_j \to 0$$
$$E^* = E^{o} + 2{\cdot}3RT/z_iF \log a_i$$

(2) $$\text{for } K_{i,j}^{pot} a_j^{zi/zj} >> a_i$$
$$E' = E^{o} + 2{\cdot}3RT/z_iF \log K_{i,j}^{pot} a_j^{zi/zj}$$

At the crossing point (Fig. 9) of both asymptotes: $K_{ij}^{pot} = a_i/(a_j^{*zi/zj})$. For the $a_j^{*zi/zj}$ value, the variation between the curve and the intersection point is 18 mV at 25°C. a_j^* is generally determined with this 18 mV variation because of the difficulty in defining the Nernst asymptote (Fig. 9).

To determine the sodium and potassium ion-selectivity coefficients, we made successive additions of a solution containing the interfering ion (LiCl 10^{-2} mol dm^{-3} + $BaCl_2$ 10^{-1} mol dm^{-3} + NaCl or KCl 10^{-1} mol dm^{-3}) in a solution of LiCl 10^{-2} mol dm^{-3} + $BaCl_2$ 10^{-1} mol dm^{-3}. To determine the protonic influence, we changed the pH of the solution by chloride acid addition. Recording and plotting of the cell potential as a function of the interfering ion lead to a_j^* determination and to $K_{i,j}^{pot}$ calculation.

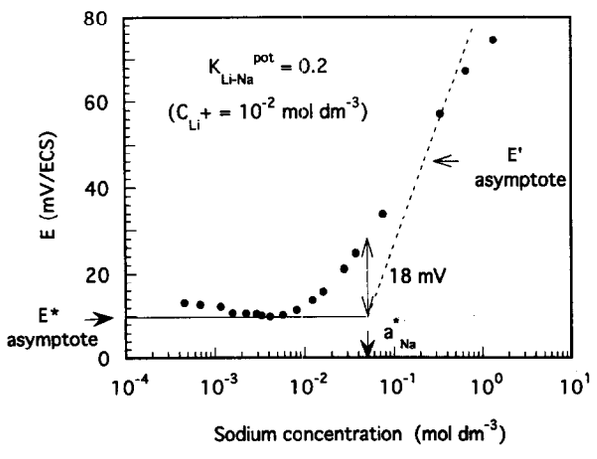

Fig. 9. Example of the determination of K_{Li-Na}^{pot} of a Li^+ electrode using a $Li_{1{\cdot}3}Al_{0{\cdot}3}Ti_{1{\cdot}7}(PO_4)_3$ co-ground membrane.

Table 4. Principal potentiometric ionic-selectivity coefficients

	Co-ground membrane	*Sol–gel membrane*
K_{Li-Na}^{pot}	0·5–1	0·2
$K_{Li\ K}^{pot}$	3×10^{-2}	5×10^{-2}
K_{Li-H}^{pot}	0·2–2	2

The synthesis process does not have a great influence on the principal potentiometric ionic-selectivity coefficients (Table 4). Both types of electrode are more selective to potassium than to sodium. This result is in agreement with Fabry and Siebert's assumption[25] that selectivity depends on the size of the interfering ion (ionic radii of Li^+, Na^+ and K^+ in 6 coordinance are 0·76, 1·02 and 1·38 Å, respectively.[8] We can explain this property by the particular structure of NASICON-type ceramics: there are two types of conduction site in the network. The way between different sites is achieved through bottlenecks, the size of which is adjustable: lattice constants depend on the stoichiometry and the composition of the material.[5] In the composition $Li_{1{\cdot}3}Al_{0{\cdot}3}Ti_{1{\cdot}7}(PO_4)_3$ the sodium mobility in the membrane is high, because the opening of the bottlenecks is sufficiently large [as a comparison, the optimal value for Na^+ diffusion is obtained for $Na_3Zr_2Si_2P_2O_{12}$ for which lattice parameters are approximately a = 9·05 Å, c = 22·9 Å (Refs. 15,16)]. As a consequence, the interface equilibrum is etablished with the contribution of the sodium contained in the analysed solution. On the other hand, the potassium is too large for the bottlenecks and then the K^+ contribution decreases greatly.

Concerning the pH effect on the sensor response, it is not due to a structural ionic exchange but arises from ionic (H^+ or OH^-) adsorption at the surface of the membrane.[26] Then, for very high protonic concentration, the electrode operates like a glass one. We note that the values of the protonic potentiometric coefficient (Table 4) are lower than those obtained with the Na^+ NASICON used in sodium-selective electrodes.[15,16,25]

5 Conclusion

The use of the sol–gel process for the synthesis of $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (x = 0·3) is fully justified. The morphology of the sol–gel powders leads to attractive sintering properties, without modification of

the structure of the sintered samples. In spite of a lower ionic conductivity than the co-ground material, the sol–gel ceramic has a better stability in water.

For aqueous analyses, ion-selective electrodes using a doped ceramic synthezised by the sol–gel process is the more attractive: the detection limit is $1{\cdot}4 \times 10^{-4}$ mol dm^{-3}. For biomedical measurements, the ion-selective electrode must be very selective for Na^+ and K^+ (low values of $K_{Li,Na}^{pot}$ and $K_{Li,K}^{pot}$) because of the important concentration of these elements in the body. Consequently, actual values of the potentiometric coefficients, especially for Na^+, are too high for lithium analysis in blood. However, the low protonic interference is very interesting for measurements in systems such as gastric juice.

Abstract

AC-conductivity measurements were performed on aluminium oxynitrides (Alons) because of their interesting defect structure. Although it became apparent that these Alons are not stable in the temperature range used, the electrical properties of the materials could be measured with impedance spectroscopy using a special procedure. The activation energy for charge transport in Alons with 67·5, 73 and 77·5 mol% Al_2O_3 at temperatures between 1173 and 1373 K was 2·78, 2·85 and 2·97 eV, respectively, while the pre-exponential factors increased with increasing number of aluminium vacancies. The conductivity shows a more-than-linear dependency on the amount of aluminium vacancies. Charge is transported via aluminium vacancies but the large amount of vacancies does not result in greatly changed mobilities: the interesting defect structure of Alon does not lead to extraordinary electrical properties.

1 Introduction

γ-Aluminium oxynitride (Alon) is a ceramic material with a spinel-type crystal structure.[1] The ideal composition for this system (Al_3O_3N) is outside the homogeneity region of Alon[2,3] and the actual Alon phase can be described with the constant anion model, in which all anion sites are occupied by oxygen or nitrogen and the cation sites are partly occupied by aluminium.[4] As about one aluminium atom is missing in each unit cell,[5] Alon is a highly defective material. Because it might be possible to have high ion mobilities in such a material and because the electrical properties of Alon were largely unknown, we decided to investigate these properties for three Alons with different compositions. During these investigations it became apparent, however, that Alon has only a limited stability, as is reported in detail elsewhere.[6] However, interesting Alon/Al_2O_3 and Alon/Al_2O_3/SiC composites can be obtained in spite of these restrictions[7,8]

The conductivity for ionic conductors is thermally activated and can be described by $\sigma = \sigma_0/T \times \exp(-\Delta H_m/kT)$, in which σ is the specific conductivity (S m^{-1}), σ_0 is a scaling constant (K S m^{-1}), T is the temperature (K), k is Boltzmann's constant, and ΔH_m is an activation enthalpy (J mol^{-1}). To determine ΔH_m, $\ln(\sigma T)$ is plotted against $1/T$ in an Arrhenius plot; the slope in this plot is equal to $\Delta H/k$, provided that the number of charge carriers is constant over the temperature range considered.[9]

2 Experimental

Details of the preparation of the Alons were reported earlier.[10] The Alons had compositions corresponding to 67·5, 73 and 77·5 mol% Al_2O_3 and will be designated 'L', 'M' and 'R', respectively, in this paper. Mechanical and optical properties of these materials were reported earlier.[11] Samples were flat discs, typically 8 mm in diameter and 0·5 to 1 mm thick. These were polished, cleaned in boiling nitric acid (60%), neutralized with ammonia, rinsed thoroughly with deionized water and dried. Platinum electrodes (diameter 5·5 mm, thickness ~3 μm) were deposited on the samples by sputtering and subsequent painting (Demetron 308 A paste). The electroded samples were annealed at 873 K for 2 h in air.

AC-measurements were performed with a set-up based on a Solartron 1174 Frequency Response Analyzer which was interfaced to a computer. The computer was also used to control a DC-driven tube furnace containing a spring-loaded alumina conductivity cell, comparable to that of Metselaar and Larsen.[12]

The partial oxygen pressure was kept low because the oxidation of Alon to Al_2O_3 is faster than the decomposition of Alon into Al_2O_3 and AlN. Experiments were done in flowing nitrogen (pressure 10^5 Pa, purity 99·999%) which was led over graphite powder at a temperature of 1273 K before it entered the measurement set-up.

For each temperature a new sample was used which was heated to the desired measuring temperature (heating rate 344 K h^{-1}) and kept there for 20 min to stabilize. For composition M, stabilization times of 6 h were also used for comparison. After this stabilization the frequency response of the material was measured in the frequency range 1 MHz–0·1 Hz, which took about 30 min, the greater part of which was spent in measuring the lower frequencies. This cycle of stabilizing and measuring was repeated two times or more (typically three impedance diagrams were taken) and the resulting impedance diagrams were extrapolated linearly to t=0, which is the time at which the sample reaches the measuring temperature for the first time. The stabilization time was chosen in such a way that the impedance–time plot for any frequency was well approximated by a straight line. Temperatures used ranged from 1123 to 1373 K. Measurements were performed with a measuring voltage of 50 mV (voltages of 100 and 200 mV gave the same results).

No Nernst potential measurements were performed because the material degrades fairly rapidly. In our equipment specimens have to be mounted at high temperature to obtain a gas–tight seal before the measurements can take place. As a result of this, the material would already change considerably before any measurement could be performed.

3 Results

A number of typical complex impedance diagrams of Alon with composition M are stacked together in Figs 1(a) and 1(b). Both diagrams show several measurements on one specimen each and the extrapolation that was made to t=0. Measurements with a stabilization time of 20 min always showed one arc only. Measurements with a stabilization time of 6 h showed results similar to Fig. 1(b) at all temperatures, although the second and third arcs were not always as clearly visible as in this figure. At t=0 the complex impedance diagram consists of one depressed arc only. As the sample is held at the measuring temperature, the intersection of the arc with the real axis shifts to higher values. At still longer holding times, a second and a third arc appear in the diagram. Table 1 lists the

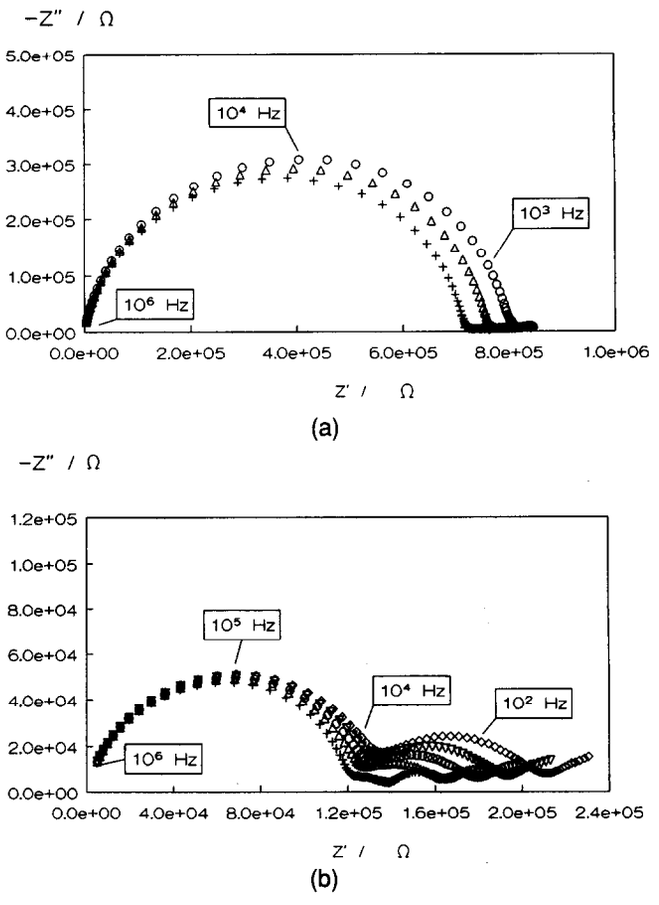

Fig. 1. Two typical sets of measurements on Alon with composition M together with extrapolations to t=0 (inner circle, +): (a) shows measurements at 1248 K with a stabilization time of 20 min); (b) measurements at 1348 K with a stabilization time of 6 h (Δ = first measurement, ○ = second measurement, ∇ = third measurement and ◇ = fourth measurement).

results of the measurements with a stabilization time of 20 min on the three types of Alon. Each entry represents the value of the real part of the complex impedance at t=0.

At temperatures above 1373 K no reliable extrapolation to t=0 could be made (degradation is too fast). Moreover, the characteristic frequency of the first arc was about 1 MHz and as this is the maximum measuring frequency, half of the arc

Table 1. Extrapolated values of the specific resistance at t=0 (the time at which the measuring temperature was reached for the first time) at various temperatures for L, M and R Alons. The stabilization time used for the measurements was 20 min.

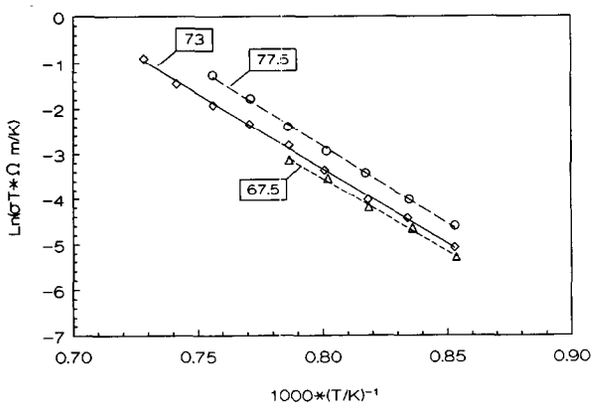

Fig. 2. Arrhenius plot for all measurements with a stabilization time of 20 min (Δ = L, ◇ = M and ○ = R).

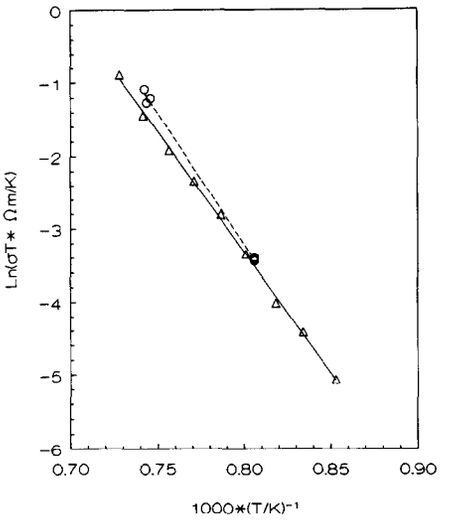

Fig. 3. Comparison between measurements on M Alon with short stabilization times (20 min, Δ) and those with long stabilization times (6 h, ○)

could not be measured. Below 1123 K, the DC-resistance of the samples was > 10 MΩ. As it is not possible to measure these impedances accurately with the set-up used, no measurements were performed in this region. At temperatures below 1173 K equilibration was too slow and reliable extrapolation was not possible.

An Arrhenius plot containing all measurements is given in Fig. 2. Activation energies of 2·78, 2·85 and 2·97 eV were obtained for L, M and R, respectively. These values were determined with a linear least-squares fit of the data. Correlation coefficients were 0·998, 0·999 and 0·999, respectively.

Table 2 lists the results of the measurements on Alon with composition M with a stabilization time of 6 h. As can be seen in Fig. 3, the measurements at 1240 K give almost the same results as the measurements with the short stabilization time and the measurements at 1340–1350 K resulted in slightly higher conductivity values than the measurements with the short stabilization time.

X-ray diffraction (XRD) on specimens before and after testing showed that the lattice parameters had decreased slightly during the experiments. Unfortunately, the uncertainty of the XRD measurement is of the same magnitude. No other phases than Alon were observed with XRD. Alons of composition L and M were still translucent after testing but specimens of composition R were afterwards slightly more opaque than before.

Table 2. Extrapolated values of the specific resistance at t=0 of M Alon at several temperatures with a stabilization time of 6 h

Temperature (K)	*Specific resistance (Ω m)*
1241	$3{\cdot}80 \times 10^4$
1241	$3{\cdot}80 \times 10^4$
1242	$3{\cdot}70 \times 10^4$
1341	$4{\cdot}5 \times 10^3$
1344	$4{\cdot}8 \times 10^3$
1347	$4{\cdot}0 \times 10^3$

If Alon specimens were kept for some days at the measuring temperature, α-Al_2O_3 was found on the outer surface of the specimens.

4 Discussion

At first, there is only one arc in the impedance diagrams, corresponding to the bulk material, while after a certain period of time one or two additional arcs appear. The bulk material decomposes because of the instability of the material at the measuring temperature. The additional arcs can, for instance, be due to accumulation of oxygen on the grain boundaries (probably the first step in the oxidation of the material) or to electrode reactions. The slight decrease of the lattice parameters also indicates an increase in the oxygen content. The opaqueness of the R specimens can be due to the formation of Al_2O_3-rich regions in the material.

The results of the experiments with long stabilization times are only different from those with short stabilization times at high temperature. At high temperature, degradation does not proceed linearly with time when the time between observation is too long and reliable extrapolation is not possible.

If the amount of intrinsic aluminium vacancies is plotted against the specific conductivity for various temperatures, Fig. 4 is obtained. As can be seen, the conductivity is higher when the amount of vacancies increases, which is an indication that the migrating species are the aluminium vacancies.

The literature data on electrical properties of Alon are limited to one publication of Kim and Richards[13] who measured the AC-conductivity of Alon with compositions corresponding to 70 and 76·3 mol% Al_2O_3 at temperatures of 1573, 1673

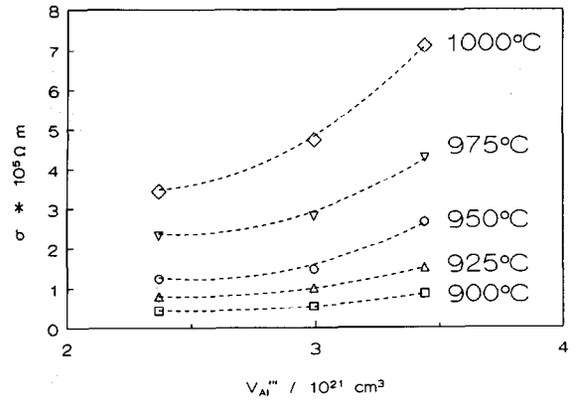

Fig. 4. Electrical conductivity of Alon as a function of concentration of aluminium vacancies at various temperatures.

and 1773 K in flowing nitrogen. They report an activation energy of 116 kJ mol^{-1}, which we were unable to reconstruct from their data. If their data are fitted with the equation for ionic conductors we obtain an activation energy of 329 kJ mol^{-1} (3·41 eV). The differences between their results and this investigation are probably due to faster degradation of the materials at the higher measuring temperatures used by Kim and Richards.

There are some data on the electrical behaviour of $MgAl_2O_4$, which has the same crystal structure as Alon. Sonder[14] showed that conduction in $MgAl_2O_4$ is almost purely ionic in character and argued that the transporting species most probably are cation vacancies. It was also shown that the conductivity between 700 and 2000 K is not greatly influenced by either ambient oxygen pressure (10^5–10^{11} Pa) or iron impurities up to 0·1%.[14,15] The activation energies ranged between 1·50 and 2·74 eV, dependent on the temperature range considered. Bates and Garnier[16] observed nearly the same range of activation energies with measurements on single crystal and polycrystalline $MgAl_2O_4$ at temperatures between 650 and 1260 K. Comparison between diffusion coefficients of magnesium, aluminium and oxygen in MgO, Al_2O_3 and $MgAl_2O_4$ show that the mobility of oxygen is several orders of magnitude lower than that of magnesium and aluminium.[17] From these literature data it can be concluded that the charge transport in $MgAl_2O_4$ takes place via cation vacancies. Because Alon has the same type of crystal structure as $MgAl_2O_4$ and nitrogen ions are even larger than oxygen ions, it seems plausible that the same situation exists in Alon. The influence of impurities on the amount of cation vacancies will also be limited in Alon because the intrinsic defect concentration is already quite high.

If we assume that aluminium vacancies are the transporting species, it is possible to calculate the diffusion coefficient of these vacancies from the Nernst–Einstein relation. If we take for instance the specific resistance of Alon with composition M at 1373 K, a diffusion coefficient of 8×10^{-15} m^2 s^{-1} can be calculated. This diffusion coefficient is of the same order of magnitude as the diffusion coefficient for Mg^{2+} in stoichiometric magnesium aluminate spinel.[17] However, the conductivity shows a more-than-linear dependency on the amount of aluminium vacancies (Fig. 3). A similar phenomenon was observed by Aggarwal and Dieckmann[18] in their investigation of non-stoichiometric cobaltous oxide, in which the mobility of the cationic defects also increased with increasing deviation from stoichiometry. They tentatively attribute this effect to a decrease in the lattice parameter and/or to changes in the type of defects, but at the moment the physics behind this phenomenon are not understood.

Let us assume for a moment that Alon is a semiconductor instead of an ionic conductor. In this case, energies of 2·64, 2·74 and 2·86 eV can be calculated for L, M and R, respectively, using $\sigma = \sigma_s \times \exp(-\Delta H_s/kT)$. The correlation factors remain unchanged. A possible mechanism could be extrinsic electron conduction due to silicon impurities (about 800 ppm) that can act as donors. If we assume complete ionization, the amount of free electrons (n) is equal to the amount of silicon atoms ($n = [Si_{Al}] = 6{\cdot}3 \times 10^{25}$ m^{-3}) which gives a mobility (b) of 3×10^{-11} m^{-2} V^{-1} s^{-1} (from $\sigma = n \times e \times b$). Although low values for the electron mobility are known to exist in small polaron semiconductors, this value is so small that it makes electron conduction improbable. Also, the activation energy of 2·8 eV is high for the activation energy of a donor. In comparison, Lee and Kröger reported a value of about 1·7 eV for the activation energy of silicon donors in Al_2O_3.[19] If we take also Fig. 4 into account we conclude that electronic conductivity can be ruled out.

5 Conclusions

AC-conductivity measurements were performed on Alons because of their interesting defect structure. Although it became apparent that Alons are not stable in the temperature range used, the electrical properties of the materials could be measured with impedance spectroscopy using a special procedure. The activation energy for charge transport at temperatures between 1173 and 1373 K was shown to be 2·78, 2·85 and 2·97 eV for compositions L, M and R respectively, while the pre-exponential factors increased with increasing number of aluminium vacancies. The conductivity shows a more-than-linear dependency on the amount of aluminium vacancies. Charge is trans-

ported via aluminium vacancies but the large amount of vacancies does not result in greatly changed mobilities: the interesting defect structure of Alon does not lead to extraordinary electrical properties.

Abstract

A sintering optimization of barium titanate ceramics from fine-grained and homogeneous reproducible powders obtained by the citric process is presented. Different sintering parameters are studied: heating rates, final temperature, dwelling times at this final temperature, and influence of the powder deagglomeration step. The sintering is followed by dilatometric measurements. The ceramics obtained by sintering at 1230 or 1300°C are free of barium carbonate, the residual carbon content being estimated at about 400 ppm in the surface layer. They exhibit a grain size close to 1 μm, a structure in which the cubic and tetragonal phases coexist, and a density of about 96% of the theoretical density. Their permittivity and loss factor are respectively about 5000 and 2·5 × 10⁻² at 25°C.

1 Introduction

Barium titanate ceramics are extensively used in the manufacture of ceramic multilayer capacitors. These applications require materials with a good density, a high dielectric constant and a low loss factor. Synthesis of materials with these properties needs fine-grained ceramics, which may be obtained from fine-grained and homogeneous reproducible powders. In a previous paper, we have presented the elaboration of such a powder from a citric resin process.[1] Here is given a sintering optimization study to obtain ceramics with good dielectric properties. The different physical and chemical characteristics of the ceramics obtained were investigated by several methods: dilatometric measurements, X-ray diffraction (XRD), scanning electron microscopy (SEM), thermogravimetric analysis (TGA), infra-red spectroscopy (IR) and nuclear analyses.

2 Experimental Procedure

$BaTiO_3$ powders were obtained from a citric resin method, described in previous papers.[1–3] The mixed citrate $BaTi(C_6H_6O_7)_3.6H_2O$ was first prepared, then dissolved in a citric acid, ethylene glycol and water mixture so that R = ($BaTiO_3$ mass)/(solution mass ratio) was 1%. This solution was calcined at 700°C in static air and $BaTiO_3$ powders were produced after 2 h. Powders elaborated by this method exhibit a Ba/Ti ratio equal to 1. After a careful deagglomeration step,[1] powders were calcined at 700°C for 4 h before being isostatically pressed at 250 MPa in the form of discs and then sintered.

X-ray diffraction patterns of crushed ceramics were obtained using a Siemens D500 diffractometer with the CuK_α wavelength at room temperature. The 400–004 diffraction lines were accurately recorded in the range $98{\cdot}5° < 2\theta < 102{\cdot}5°$ in steps of 0·01° (2θ) with a counting time of 80 s per data point.

Thermogravimetric measurements were made with a Setaram thermobalance under flowing oxygen atmosphere. Approximately 100 mg of ceramic was accurately weighted in a platinum crucible. The temperature was raised from room temperature to 1000°C at 10°C min^{-1} and then from 1000 to 1400°C at 5°C min^{-1}.

FTIR reflection spectra were recorded with a Brucker IFS 113+88 interferometer between 4000 and 400 cm^{-1} at room temperature on a sample containing 2 mg of $BaTiO_3$ dispersed in 200 mg of KBr and pressed into pellets.

The residual carbon concentration was determined by the $^{12}C(d, p)^{13}C$ nuclear technique using deuterons from the CERI's† Van de Graaff generator. The

method has been described elsewhere.[4–6] The measurements were performed at 950 keV deuteron energy in an ultra-high vacuum chamber under a vacuum of about 10^{-9} mbar obtained with a cryogenic pumping system. The disc samples were sintered ceramics of about 3 mm in thickness and 11 mm in diameter. In the experimental conditions used,[7] taking into account the differential cross-section[8] and the density of the material, the maximal penetration depth is estimated to be about 1 μm and the carbon in the surface layer (about 0·4 μm) may be determined with a precision of 10%.

The SEM images were obtained with a Cambridge stereoscan 100 microscope on the fracture surfaces of samples previously metallized with platinum. The transmission electron microscopy (TEM) images were obtained with a Philips SM20 microscope.

Final densities were evaluated by geometrical measurements and confirmed by: (i) mercury intrusion data (Micrometric 9300 apparatus); (ii) helium pycnometry data (Accupic 1330 apparatus).

Dilatometric measurements were made in a Setaram vertical dilatometer with a constant force load equivalent to 1 g. The derivative curve of shrinkage versus temperature may be calculated electronically. The measurement of the shrinkage, reported for room temperature, allows the estimation of the final density from the green compact one. The value of 6·02 g cm^{-3} was used as the theoretical density, d_{th}.

Dielectric measurements of the ceramics were carried out on an automated Hewlett-Packard impedancemeter HP 4194A. The relative dielectric constant ϵ' and loss factor tg δ were measured between 160 and 120°C at various frequencies (100 Hz, 1 kHz, 10 kHz, 100 kHz and 1 MHz) with a cooling rate of 1°C min^{-1}.

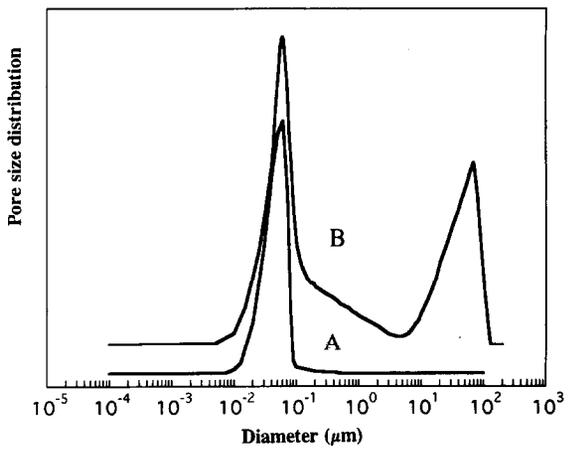

Fig. 2. Pore-size distribution for green compacts of (a) a deagglomerated powder and (b) a raw powder.

3 Results and Discussion

3.1 Raw powders

The sintering behaviour strongly depends on the green states, thus it was very important to know the powder characteristics. The latter were studied and described in detail in a previous paper.[1] Here only the microstructure of the raw deagglomerated powder is given again: it can be described by crystallites associated into 150 nm spheroid aggregates (Fig. 1).

The results obtained by mercury intrusion, for deagglomerated and non-deagglomerated powders are presented in Fig. 2. The curve obtained with a non-deagglomerated powder shows two pore-size distributions centred on 0·05 and 80 μm (Fig. 2(b)) whereas only one peak, centred on 0·05 μm, is observed on the curve obtained with a deagglomerated powder (Fig. 2(a)).

3.2 Sintering optimization

The green compacts were sintered in air at different temperatures up to 1400°C, using various heating rate conditions reported in Table 1. According to our previous studies,[2,3] it appeared that the best sintering temperature to obtain dense ceramics with fine grain size was approximately 1250°C. Thus, for this final temperature of the sintering cycle, different heating rates were

investigated. The sintering conditions, geometrical densities and grain sizes estimated from SEM observations are reported in Table 1. It can be observed that:

(i) a decrease of the heating rate between 1000 and 1250°C induces an increase of the density and grain size;

(ii) for a slow heating rate (4°C h^{-1} between 1000°C and the final temperature), an increase of the final temperature (up to 1300°C) induces an increase of the density and grain size. In this case, the higher the final temperature, the larger the grain size distribution;

(iii) for sintering steps with a final temperature of 1400°C the ceramics showed a classical bimodal grain-size distribution with large grains (100–200 μm) embedded in a fine-grained matrix. This phenomenon was evidenced by several authors[9–12] and the anomalous grain growth occured when samples were heated up to a final temperature greater than 1380°C.

It appeared that to obtain a good density and a small grain size, the final sintering temperature could be reduced to 1230°C with a slow heating rate between 1000 and 1230°C, for example 4°C h^{-1} (Table 1). The best conditions were the following: heating from 20 to 700°C at 350°C h^{-1}, then from 700 to 1000°C at 50°C h^{-1} and finally from 1000 to 1230°C at 4°C h^{-1}. These sintering conditions will be called '1230°C sintering' in the following text. The ceramics had a geometrical density greater than 96% of d_{th}, and an average grain size of 1·6 μm with 80% of the grains between 0·25 and 2·5 μm size (Fig. 3(a)). At this final temperature, the anomalous grain growth was inhibited.

With these optimized sintering conditions, the effect of the deagglomeration step was studied by sintering a green compact made with a non-deagglomerated raw powder. The resulting ceramics were not densified (61·5% of d_{th}) and showed two grain-size distributions, the first one centred on 0·3 μm and the second one on 2 μm (Fig. 3(b)). A high density (99% of d_{th}) might be obtained by sintering for 2 h at 1400°C; then the grain size was homogeneous but with grains of 100–200 μm size.

Table 1. Sintering conditions investigated around the final temperature of 1230°C. Density (in d_{th} %) and average grain size

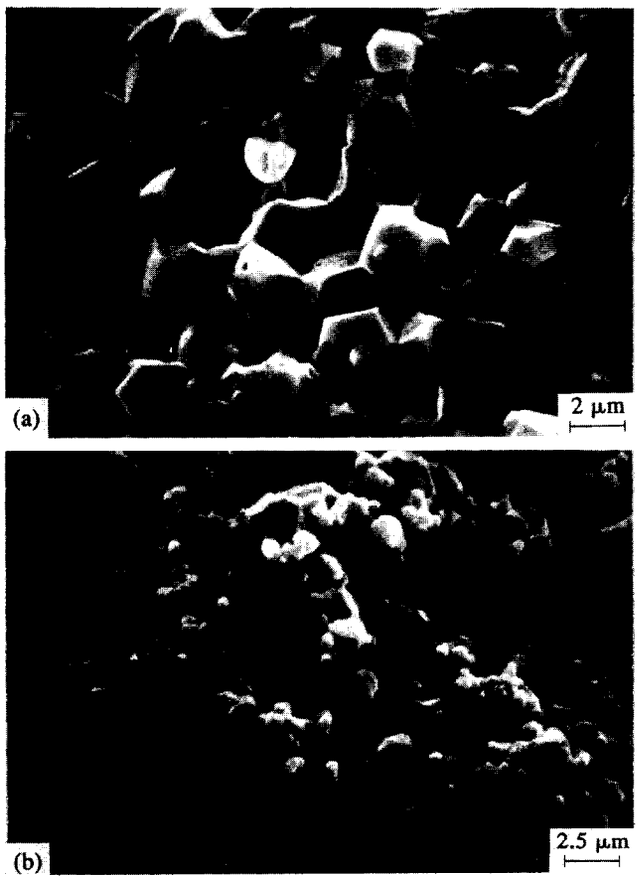

Fig. 3. Microstructure of $BaTiO_3$ ceramics sintered at 1230°C from (a) a deagglomerated powder and (b) a raw powder.

Our results are in good agreement with those of Hiesh and Fang,[12] who showed that:
(i) to obtain a high density and a uniform fine-grained microstructure, a uniform green compact with fine particles was needed;
(ii) it was possible to prepare dense ceramics from non-uniform green compacts but a higher sintering temperature should be used and the ceramics obtained exhibited a large grain size.

To minimize the sintering time it is possible to increase the final sintering temperature to 1300°C. We have followed the procedure previously described and investigated different heating rates. The results are reported in Table 2. It is important to note that an increase of the heating rate from 25 to 350°C h^{-1} between 700 and 1300°C induces a slight decrease of the density and a more sensible decrease of the grain size. This phenomenon was previously observed with the 1230°C sintering. Thus the thermal cycle chosen was the following: heating from 20 to 700°C at 350°C h^{-1} and from 700 to 1300°C at 200°C h^{-1}. The microstructure of the obtained ceramic exhibited an average fine grain size of 0·7 μm with 80% of the grains between 0·25 and 1 μm size (Fig. 4(a)). These sintering conditions will be called '1300°C sintering' in the text below.

Table 2. Sintering conditions with 1300°C final temperature. Density (in d_{th} %) and average grain size

Sintering rates	% d_{th}	*Grain size (μm)*
20–700°C at 350°C h^{-1} 700–1000°C at 50°C h^{-1} 1000–1300°C at 25°C h^{-1}	96	3·8
20–700°C at 350°C h^{-1} 700-1000°C at 50°C h^{-1} 1000–1300°C at 50°C h^{-1}	96·3	1·4

0	72·7
1	85
4	85·2
10	85·6
20	86

On the other hand, the influence of the dwelling time was investigated and the results are reported in Table 3. It appears that an increase of the dwelling time has a weak effect on the final density but modifies the grain size and the grain size distribution. The longer the dwelling time, the larger the grain size and its distribution.

The sintering of green compacts made with a non-deagglomerated raw powder in the 1300°C sintering conditions yielded a final density of about 72% of d_{th} (Fig. 4(b)). After holds at 1300°C for different dwelling times, the final density increased up to 86% of d_{th}, after 20 h (Table 4). The ceramics showed anomalous grain growth, the amount of the biggest grains depending on the dwelling time (Fig. 4(c)).

Our results show the importance of a careful deagglomeration step in the elaboration of a sinterable powder. The homogeneity of the powder allows us to obtain both a good density and a well controlled grain size in the ceramics. The double optimized synthesis processes give ceramics with a narrow grain-size distribution centred on 1·6 μm (1230°C sintering) and 0·7 μm (1300°C sintering).

3.3 Characterization of optimized ceramics

Ceramics obtained with 1230 and 1300°C sintering conditions were analysed by different techniques. The IR reflectivity spectra recorded at room temperature did not reveal any trace of barium carbonate in both cases. TGA measurements did not allow us to detect any significant weight loss. Thus, another more sensitive technique was necessary to determine the residual carbon content in these two ceramics. The $^{12}C(d, p)^{13}C$ nuclear technique was used. For ceramics respectively sintered at 1230 and 1300°C, it gave carbon contents of 95 and 130 mg cm^{-2} in the surface layer (0·4 μm). The carbon content is higher in the ceramics obtained by the 1300°C sintering. This result can be explained as follows:

(i) if the residual carbon is assumed to be located at the grain boundaries, it is more important in the finer grain size ceramic;

(ii) during the 1230°C sintering thermal cycle, the treatment time in the furnace was much longer (about 83 h) than during the 1300°C sintering (8 h). Thus the diffusion of carbon from the bulk to the surface layer and then to the atmosphere is facilited, so the detected carbon content is weaker.

The sintering behaviour of the deagglomerated powder was studied by dilatometric measurements in the conditions of pressing (250 MPa) and heating rates of both the 1230 and 1300°C optimized sintering. The obtained shrinkage curves and their derivatives versus temperature are reported in Fig. 5. The derivative curve of the shrinkage versus temperature obtained at 1230°C with a very slow heating rate between 700 and 1230°C, exhibits two minima at about 1060 and 1200°C. Previous studies[2] carried out on the same powders sintered with a constant rate of 150°C h^{-1} showed only one minimum at 1060°C on the derivative curve. Only the difference in heating rate between the two experiments can explain the appearance of a second

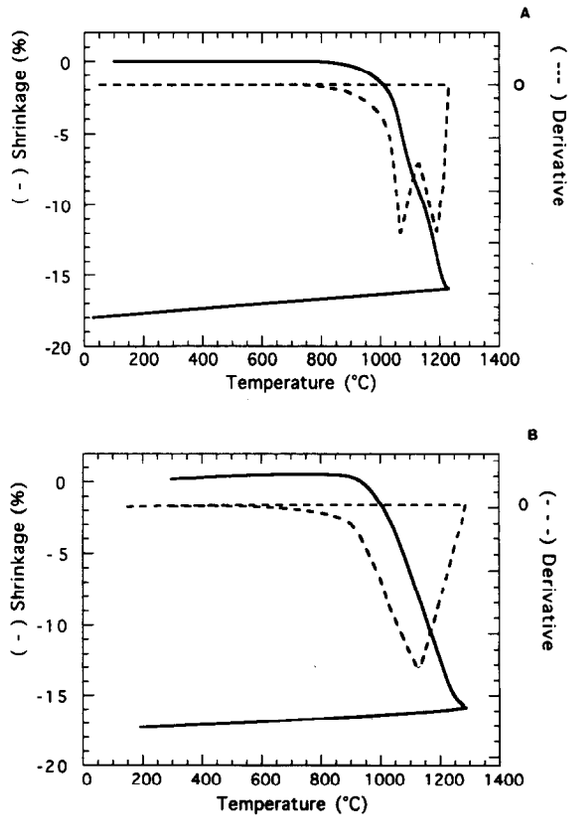

Fig. 5. Dilatometric curves obtained from $BaTiO_3$ ceramics sintered at (a) 1230°C and (b) 1300°C.

Table 5. Measurements of final densities (in %) of ceramics sintered at 1230 and 1300°C

minimum on the derivative curve in Fig. 5(a). This second minimum was observed only for very slow heating rates during the shrinkage. On the contrary, the shrinkage derivative curve obtained in the 1300°C sintering conditions exhibits only one minimum at 1130°C (Fig. 5(b)). The temperature of the minimum is shifted towards the high temperatures due to the faster heating rate (300 then 200°C h^{-1} instead of 150°C h^{-1} in Ref. 2). The shrinkage measurement reported at room temperature gives a value of the ceramic density. The final density of the two types of ceramic determined by different methods are given in Table 5. They are in very good agreement with the values deduced from shrinkage measurements. In both cases the final densities are satisfactory since they are greater than 96% of d_{th}.

X-ray diffraction patterns of the two ceramics are characteristic of a mixture of tetragonal and cubic phases. The 004–400 diffraction lines accu-

1300°C	0·76	0·7	0·15	79

rately recorded were fitted with pseudo-Voigt functions. The integrated intensities of the fitted peaks (Fig. 6) allowed us to estimate roughly the relative amounts of the two phases. Three lines were observed: for the 1300°C sintered ceramic the lines at $2\theta = 99{\cdot}64°$ and $100{\cdot}95°$ correspond respectively to the 004 and 400 reflections in the tetragonal phase and the line at $2\theta = 100{\cdot}34°$ corresponds to the 400 reflection in the cubic phase; for the 1230°C sintered ceramic the cubic component is observed at the same diffraction angle whereas the 004 and 400 tetragonal reflections are observed at slightly different angles, $2\theta = 99{\cdot}61°$ and $2\theta = 100{\cdot}98°$, respectively. The results obtained from the integrated intensities giving the fraction of the tetragonal over the cubic phases (t/c) are listed in Table 6, as are the average particle diameters deduced from SEM photogaphs and TEM observations. From results published by Niepce[13] and Takeuchi *et al.*,[14] the thickness of the cubic phase located at the surface of a tetragonal $BaTiO_3$ grain can be estimated by a simple calculation from the t/c ratio[14] using the expression:

$$\frac{t}{c} = \frac{\frac{4}{3}\pi\left(\frac{d}{2} - l\right)^3}{\frac{4}{3}\pi\left(\frac{d}{2}\right)^3 - \frac{4}{3}\pi\left(\frac{d}{2} - l\right)^3}$$

where d is the ceramic grain size and l is the thickness of the cubic layer on the grain surface.

This expression is reduced to: $t/c \approx d/6l$ since $d >> 1$.

Results are in good agreement with those of Niepce[13,15] and Arlt:[16]

(i) at room temperature the presence of coexisting cubic and tetragonal phases in one particle is confirmed;

(ii) the amount of the cubic phase increases with the decrease of the ceramic grain size. Niepce and Arlt indicated that for a ceramic with grain size below 0·7μm, the cubic phase was obtained. In our case the cubic phase was mainly obtained in the ceramic exhibiting an average grain size of 0·7 μm. In the ceramic exhibiting an average grain size of 1·6 μm, the amount of the cubic phase is lower.

Figure 7 shows the temperature dependence of the relative dielectric constant versus temperature at several frequencies for the two optimized

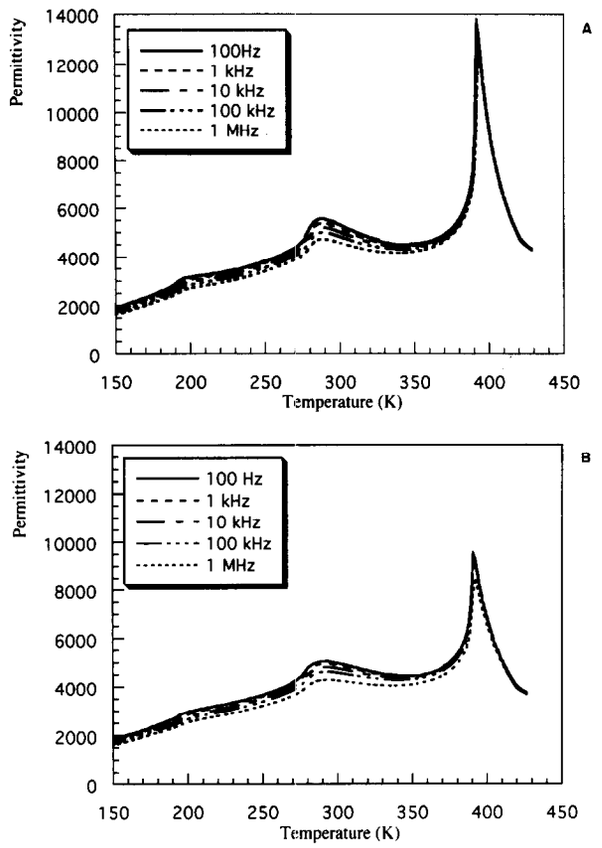

Fig. 7. Permittivity of $BaTiO_3$ ceramics sintered at (a) 1230°C and (b) 1300°C versus temperature at different measurement frequencies.

ceramics. The values of the relative dielectric constant ϵ' and loss factor tg δ at room temperature and at the ferroelectric transition, as well as the T_c temperatures, are reported in Table 7. We can observe that:

(i) the values of the permittivity obtained on the two ceramics depend on the grain size. These results confirm those of Niepce,[13] who showed that at room temperature the permittivity depends on the grain size and exhibits a maximum value for a grain size approximately equal to 0·8 μm;

(ii) the temperature of the phase transition increases with the grain size. This phenomenon was well known and described by several authors;[17–19]

(iii) the value of the permittivity at the ferroelectric transition is higher for a 1·6 μm grain size ceramic than for a 0·7 μm grain size one. This could be related to the amount of the cubic phase present in the latter ceramic which is not concerned by the ferroelectric transition.

Table 7. Dielectric characteristics of the ceramics

Grain size (μm)	*T_c(°C)*	*ϵ max*	*ϵ at 25°C*	*tg δ at 25°C*
1·6	120	13 000	5200	0·025
0·7	118	9 300	4900	0·03

4 Conclusions

The results obtained in this study may be summarized as follows.

(i) It is possible to obtain homogeneous fine-grained $BaTiO_3$ ceramics at quite low temperatures from powders elaborated by a resin citric process.

(ii) To avoid an anomalous grain growth and/or a bimodal grain-size distribution, a careful deagglomeration step of the raw powders is required.

(iii) Two sintering thermal cycles have been proposed to obtain ceramics with a density greater than 96% of d_{th} and a well-controlled grain size: a sintering cycle at 1230°C gave 1·6 μm grain size ceramics and a sintering cycle at 1300°C gave 0·7 μm grain size ceramics. In both cases a narrow grain size distribution was observed.

(iv) The ceramics obtained are free of barium carbonate, the residual carbon content has been estimated at about 400 ppm in the surface layer of the ceramics.

(v) The ceramics exhibit good dielectric characteristics in accordance with previous papers showing that, in $BaTiO_3$ ceramics, higher permittivity as well as low dielectric losses are obtained at room temperature for a grain size of about 0·8 μm.[13]

Abstract

The results of hydrothermal preparation of $BaTiO_3$ fine powders are reported. The effects of the reaction temperature, the molar ratio of Ba/Ti in the precursors, the chemical form of the precursors on the phase composition, the size and the morphology of the products are presented. The higher the temperature, the higher the basicity and the greater the molar ratio of Ba/Ti in the precursor, the easier the formation of the perovskite type $BaTiO_3$ crystallite will be. It was found that $BaTiO_3$ microcrystals(150–300 nm) could be synthesized through the hydrothermal reaction of commercial TiO_2 with $Ba(OH)_2$ aqueous solution, while the hydrothermal reaction of the newly prepared $Ti(OH)_4$ gel with the $Ba(OH)_2$ solution produced highly crystallized, well dispersed perovskite type $BaTiO_3$ crystallites with very fine (<100 nm) particles. The newly prepared $Ti(OH)_4$ gel proved to be suitable precursor for the hydrothermal preparation of $BaTiO_3$ fine powders. X-ray diffraction (XRD) of the hydrothermal $BaTiO_3$ powders reveals a simple cubic perovskite structure. Above that, the lattice constant decreased with the increase of the reaction temperature. These abnormal crystallographic features are assumed to result from lattice defects, due to OH^- incorporation in the perovskite lattice.

1 Introduction

$BaTiO_3$ is an ubiquitous electronic ceramic widely utilized in the manufacture of thermistors, multilayer capacitors (MLCs) and electro-optic devices.[1] $BaTiO_3$ powders are traditionally prepared via the calcination of $BaCO_3$ and TiO_2 or $BaTiO[C_2O_4]_2 \cdot 4H_2O$. As the temperature required is as high as 800–1100°C, the powders prepared are highly agglomerated and require extensive milling before they can be used in the various forming process. Low temperature, wet chemical routes offer an exciting possibility for the synthesis of high purity, homogeneous, ultrafine and multicomponent powders. Because of the possibility of producing highly crystallized, well dispersed and sintering active powders, the hydrothermal synthesis of ceramic powders is of great interest.

Christensen[2] and Kaneko[3] have shown that $BaTiO_3$ can be prepared from barium hydroxide solutions and oxide, esters or oxide gels of titanium, when temperatures from 380 to 500°C and pressures from 300 to 500 atm are applied. Recent work by Kutty and co-workers[4–6] demonstrates the synthesis of ultrafine $BaTiO_3$ powders at temperatures as low as 85°C and the pressures from 15 to 65 MPa. Hennings *et al.*[7] have reported the hydrothermal preparation of highly crystallized $BaTiO_3$ powders with a size of 200–300 nm from barium–titanium-acetate gel precursors.

We now report the results of the systematic study of the hydrothermal synthesis of $BaTiO_3$. The relation between the phase composition, size, morphology of the crystallites and the reaction temperature, the precursors, the molar ratio of Ba and Ti in the precursors have been found. The formation mechanism of $BaTiO_3$ under hydrothermal conditions has also been tentatively proposed.

2 Experimental Procedure

The precursors and the medium used in this study are shown in Table 1. The 160 ml reaction mixtures were charged into a Pt crucible of 200 ml capacity, which was then put into the autoclave and heated at 75–400°C for various durations. The pressure remained close to the vapour pressure curve of H_2O in this temperature range. The products were filtered and washed with dilute acetic acid to remove any excess $Ba(OH)_2$, and then washed with deionized water and alcohol and then air-dried at 120°C.

Identification of the phases was carried out by X-ray powder diffraction (XRD; Rigaku RAX-10). Transmission electron micrographs (TEM) were obtained from a JEOL JEM-2010 microscope. The extent of reaction was determined by analyzing the amount of OH^- in the residual solution.

Table 1. Precursors and solutions selected for hydrothermal synthesis of $BaTiO_3$ powders

No.	*Ba precursor*	*Ti precursor*	*Reaction medium*
1	$Ba(OH)_2 \cdot 8H_2O$	Commercial TiO_2	Aqueous solution

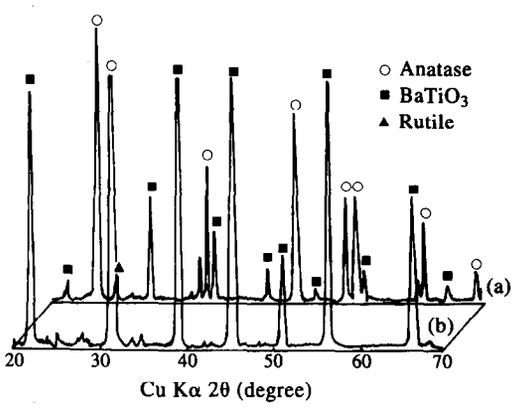

Fig. 1. XRD spectra of hydrothermal powders synthesized at (a) 75°C and (b) 400°C for 8 h using equimolar $Ba(OH)_2 \cdot 8H_2O$ and commercial TiO_2 powders.

3 Results and Discussion

3.1 The influence of temperature on the phase composition and morphology

Equimolar $Ba(OH)_2 \cdot 8H_2O$ and commercial TiO_2 powders (X-ray analysis showed that this titania consists principally of anatase with about 10–15% rutile) were hydrothermally processed at various temperatures for different durations. Figure 1(a) shows the XRD spectrum of the product of 75°C for 8 h. The $BaTiO_3$ peaks appeared besides the peaks of TiO_2, which means $BaTiO_3$ was formed. The products were nearly single phase $BaTiO_3$ when the precursors were treated at 400°C for 8 h (Fig. 1(b)). It was found by the analysis of the products synthesized at other temperatures (100, 150, 180, 200, 250 and 300°C) that the (101) peak of anatase was presented in all the products synthesized at the temperatures below 300°C.

Figure 2 illustrates the TEM morphologies of the powders prepared at different temperatures for 8 h. The morphologies of the powders were strongly dependent on the temperature. It can be easily seen from the photographs, that with an increase in temperature, the morphology of the powders changed from spheric cluster (Fig. 2(a)), to porous spheric cluster (Fig. 2(b, c)), and finally

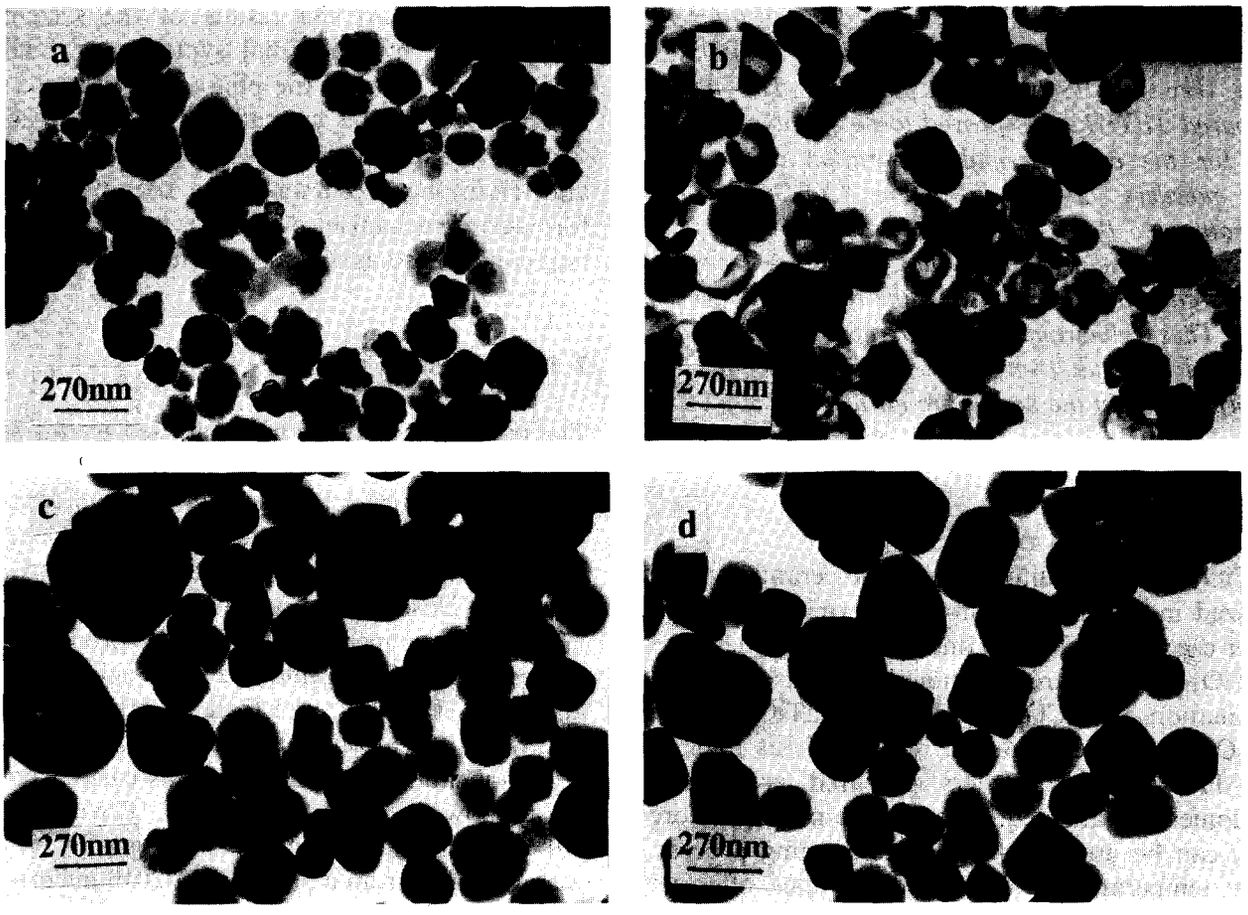

Fig. 2. TEM photographs of hydrothermal powders synthesized at (a) 75°C and (b) 400°C for 8 h using equimolar $Ba(OH)_2 \cdot 8H_2O$ and commercial TiO_2 powders.

Table 2. The relationship between reaction completeness and reaction temperature

Reaction temperature T(°C)	*Reaction completeness ρ(%)*
100	75·54
150	81·09
250	86·37
300	88·68
400	91·21

$Ba(OH)_2 \cdot 8H_2O + TiO_2$, m(Ba)/m(Ti)=1·0, 8 h.

formed well crystallized cubes or spheres (Fig. 2(d)). It can also be seen that the size of the crystallites increased slightly with the increase of reaction temperature.

The following reaction took place in the system:

$$TiO_2 + Ba(OH)_2 \rightarrow BaTiO_3(\text{crystallite}) + H_2O.$$

Since the $Ba(OH)_2 \cdot 8H_2O$ and TiO_2 used were of equal molar and there was no other OH^- source in the system, with the progress of the reaction, $BaTiO_3$ crystallites were formed and the amount of OH^- decreased. By defining

$$\rho = (1-\text{residual } OH^-/\text{initial } OH^-) \times 100\%,$$

the value of ρ can be approximately seen as the extent or the completeness of the reaction. Table 2 gives the ρ values for different temperatures. It can be clearly seen that the higher the reaction temperature, the greater the ρ value, which means the reaction took place more completely.

3.2 The relation between the lattice parameters and the reaction temperature

X-ray diffraction of hydrothermal $BaTiO_3$ revealed a simple cubic perovskite structure (Fig. 1) which is normally observed only at temperatures above the ferroelectric Curie point at 130°C or at very small crystallite size (d<0·15 μm). Above that, the lattice parameters changed with the change of reaction temperature as shown in Table 3. It can be seen from the table that the unit cell volume of the hydrothermal $BaTiO_3$ is larger than 'normal' coarse-grained $BaTiO_3$, moreover, with an increase in reaction temperature, the unit cell volume of

Table 3. The relationship between the lattice parameters of the hydrothermal $BaTiO_3$ microcrystals and the reaction temperature

Reaction temperature T(°C)	75	100	150	250	300	400
Lattice constant a (Å)	4·031	4·025	4·016	4·012	4·008	4·003
Unit cell volume Vc(Å^3)	65·50	65·21	64·77	64·58	64·38	64·14

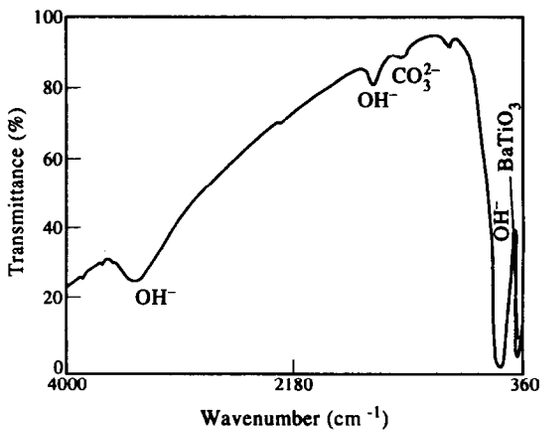

Fig. 3. IR spectrum of hydrothermal $BaTiO_3$ synthesized from $Ba(OH)_2 \cdot 8H_2O$ and TiO_2 powders.

the crystallites shrinks. When the temperature increased from 75 to 400°C, the unit cell volume shrank by about 2·08%. The unit cell volume of the crystallites prepared at 400°C for 8 h approached a value of 64 ≃ Å^3,[8] which is the typical value of 'normal' coarse-grained $BaTiO_3$ by classical calcination.

A typical IR spectrum (Fig. 3) of hydrothermal $BaTiO_3$ shows broad absorption in the region of 3200–3600 cm^{-1}, a shallow band around 1640 cm^{-1} and a strong band at 650 cm^{-1}. The 1640 cm^{-1} band (bending mode of H_2O) indicates that some H_2O is present. The strong band at 650 cm^{-1} is characteristic of the librational mode of OH^- groups and is more distinct than the OH^- stretching which is masked by the corresponding H_2O bands around 3600 cm^{-1}. A TG-DTA-MS study found that the samples gives out H and O when heated above 200°C. These phenomena suggest the OH^- is present in the lattice. Besides the $OH^\bullet$ defect, other defects may also form to meet the electroneutrality requisition. The presence of these defects suppressed the tetragonal distortion, so the crystallites can exist in cubic phase at room temperature. The defect concentration decreased when the reaction temperature increased, thus the unit cell volume of $BaTiO_3$ shrank.

3.3 The influence of Ba : Ti molar ratio in the precursors

With a fixed total amount of precursors (50 g), different Ba : Ti molar ratios of $Ba(OH)_2 \cdot 8H_2O$ and TiO_2 were hydrothermally treated at 300°C for 8 h. Figure 4 shows the XRD spectra of the products. From the figure, we can see the anatase (101) peak appeared for the lower molar ratio (1·0) (Fig. 4(a)). But the peak disappeared for the higher molar ratio (Fig. 4(b, c)). Another interesting phenomenon is that the (002) (200) and (102) (210) peaks are split for the molar ratio of

2·0, which suggests that tetragonal $BaTiO_3$ was formed in this case. Further investigations have proved this suggestion (Figs 5 and 6). The product was easily contaminated with $BaCO_3$ when a high Ba : Ti molar ratio precursor was used.

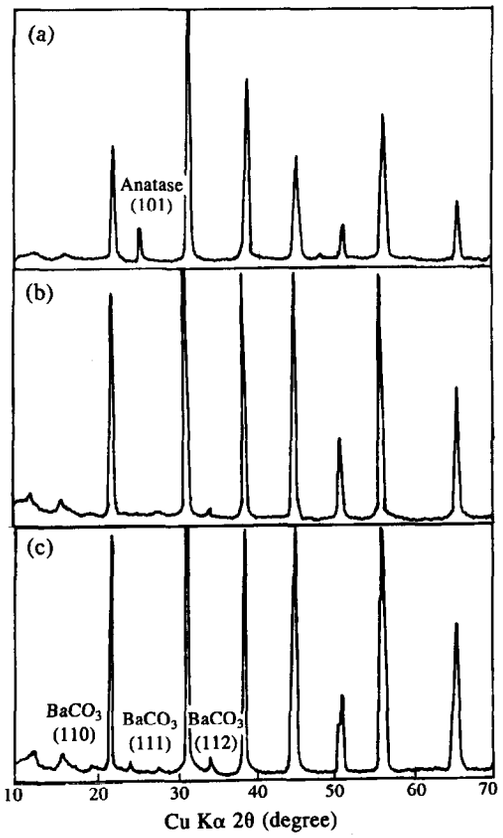

Fig. 4. XRD spectra of hydrothermal powders synthesized at 300°C for 8 h using different molar ratio of $Ba(OH)_2{\cdot}8H_2O$ and TiO_2 powders. (a) m(Ba)/m(Ti) = 1·0, (b) m(Ba)/m(Ti) = 1·5, (c) m(Ba)/m(Ti) = 2·0.

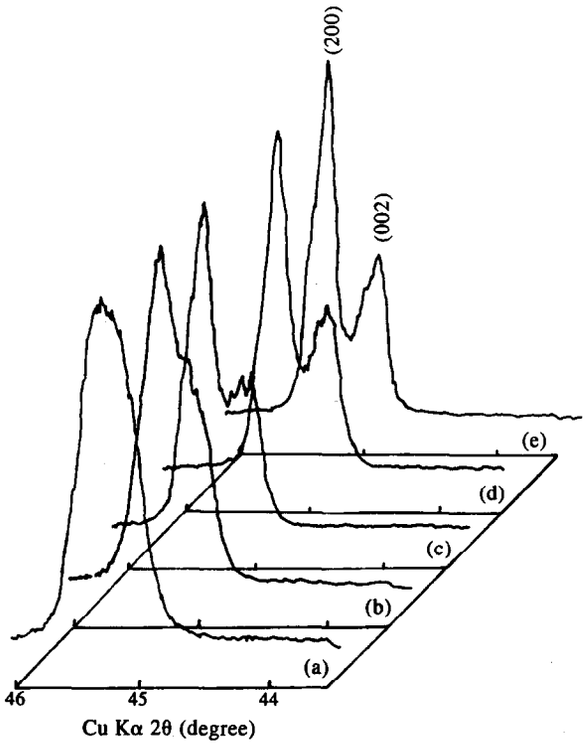

Fig. 5. X-ray diffraction traces of the (200) and (002) reflections for hydrothermal $BaTiO_3$ synthesized from different Ba/Ti molar ratio $Ba(OH)_2{\cdot}8H_2O$ and TiO_2 at room temperature. (a) 1 : 1, (b) 1·5 : 1, (c) 2·0 : 1, (d) 2·5 : 1, (e) 3·0 : 1.

3.4 The influence of the kind of precursors on the size and morphology of the crystallites

Figure 7 shows the TEM photographs of the powders prepared from different precursors. Well-crystallized $BaTiO_3$ with a size of 80–100 mn was formed (Fig. 7(a)) when precursors in $Ba(OH)_2$ aqueous solution were hydrothermally treated at 300°C for 8 h, however from the photograph some organic residual can be seen. It was found that the organic residual disappeared when some alcohol was added to the reaction solution. Figure 7(b) is the TEM photograph of the powders prepared from newly prepared $Ti(OH)_4$ gel(hydrolysis product of tetrabutyl titanate) and $Ba(OH)_2{\cdot}8H_2O$. The powders are highly crystallized, well dispersed cubic or spheric $BaTiO_3$ crystalites with a size less than 100 nm.

In summary, the kind of precursors have a strong influence on the size and the morphology of the $BaTiO_3$ synthesized.

3.5 The influences of medium

Experiments show that when $Ba(OH)_2{\cdot}8H_2O$ and TiO_2 were used as precursors, the formation of $BaTiO_3$ under hydrothermal conditions could be facilitated by using an alkaline mineralizer (e.g. NaOH). Figure 8 shows the XRD spectra of the powders synthesized at 300°C for 8 h in pure water and 1 mol/l NaOH aqueous solution. The amount of the residual TiO_2 in powders synthesized in the NaOH aqueous solution was distinctly less than in pure water, which means the reaction was more complete in the former case. The crystallinity of the $BaTiO_3$ synthesized in the NaOH aqueous solution was also higher (Fig. 9(b)).

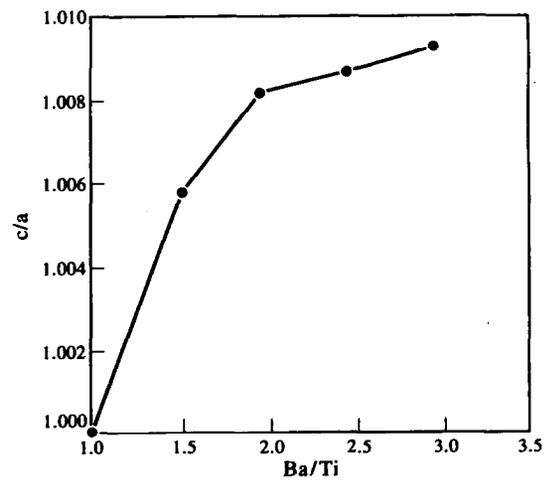

Fig. 6. The relationship between the *c/a* value of hydrothermal $BaTiO_3$ and the Ba:Ti molar ratio of $Ba(OH)_2{\cdot}8H_2O$ and TiO_2.

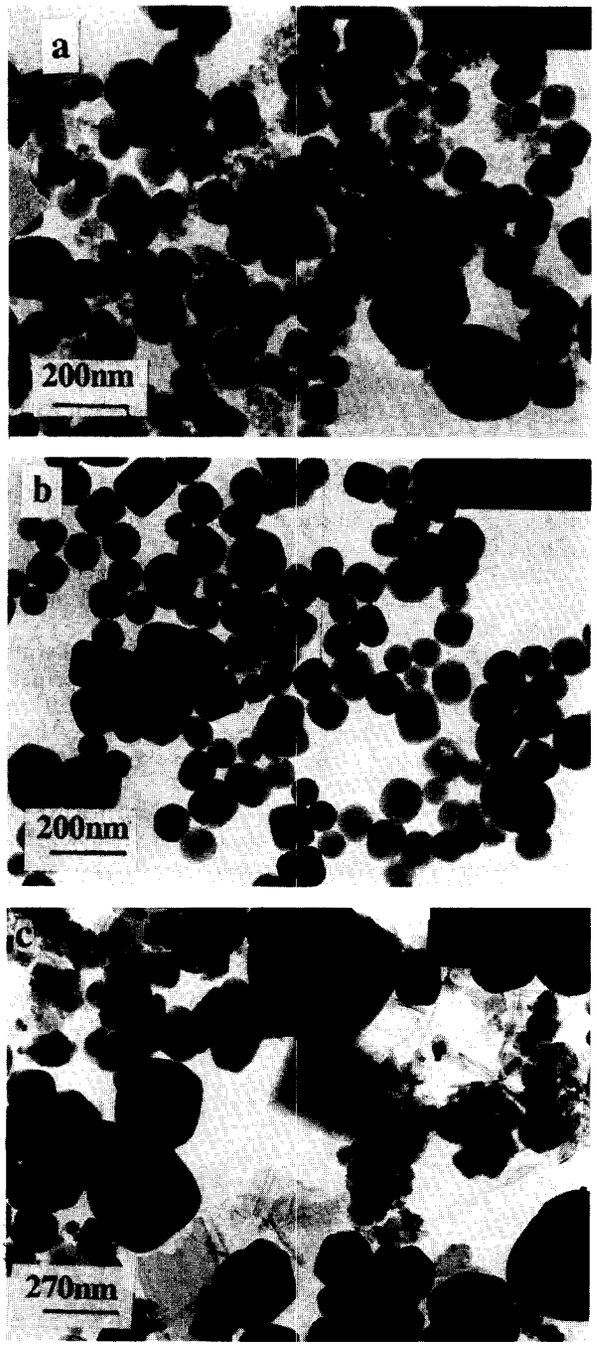

Fig. 7. TEM photographs of the powders prepared by (a) tetrabutyl titanate and $Ba(OH)_2$ aqueous solution; (b) newly prepared $Ti(OH)_4$ gel and $Ba(OH)_2$ aqueous solution; (c) commercial TiO_2 powder and $Ba(CH_3COO)_2$ in 1 mol/l NaOH aqueous solution.

The formation of ceramic powders under hydrothermal conditions is usually through a 'dissolution–crystallization' process.[9] The commercial TiO_2 powders are aggregates of particles with a primary size of 10–50 nm. When they are used as the Ti precursor, the interactions among these small particles are broken under the hydrothermal conditions. The powders are dissolved under the high temperature, high pressure and strong alkalinity of the system, and a variety of hydrated Ti–O ion groups are formed. These hydrated Ti–O ion groups are the growth units of $BaTiO_3$ crystallites. When the concentration of these growth

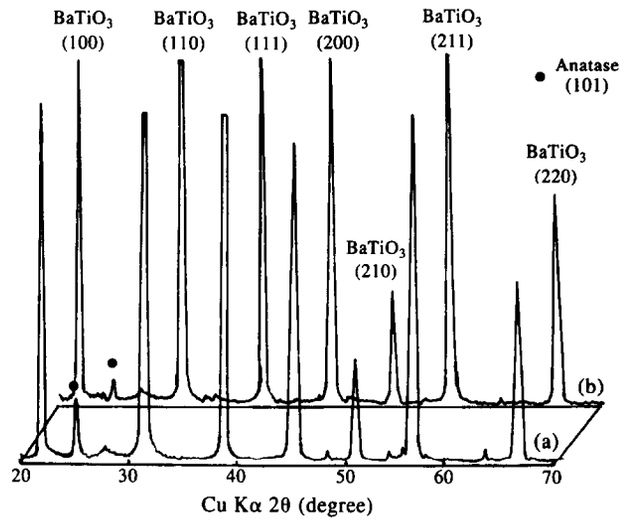

Fig. 8. XRD spectra of the powders synthesized at 300°C for 8 h in (a) pure water and (b) 1 mol/l NaOH aqueous solution.

units and Ba^{2+} reach or surpass the supersaturation for the formation of $BaTiO_3$ crystallites, the nucleation of $BaTiO_3$ begins and the crystallites grow. When freshly prepared $Ti(OH)_4$ gel is used as Ti precursor, the growth units are formed in a similar process, however, the growth units formed in these two systems are different in shape and size. Because the structure unit of TiO_2 is $Ti–O_6$ octahedron, so the growth units formed in this case are the linked $Ti(OH)_6$ octahedra units. The

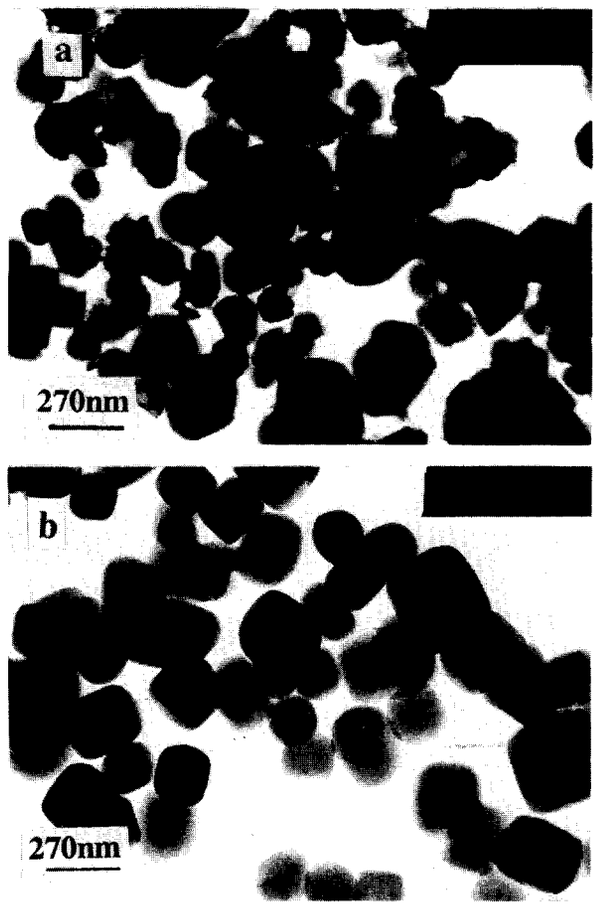

Fig. 9. TEM photographs of the powders synthesized at 300°C for 8 h in (a) pure water and (b) 1 mol/l NaOH aqueous solution.

structure similarity between these growth units and the $BaTiO_3$ crystal facilitate the nucleation and growth of the $BaTiO_3$ crystallites. On the contrary, the reticular structure of $Ti(OH)_4$ cause a slow nucleation and growth rate, so the $BaTiO_3$ produced from the reaction of the freshly prepared $Ti(OH)_4$ gel with the $Ba(OH)_2$ solution have a smaller size.

4 Conclusions

The main results of this study may be summarized as follows: (1) the higher the temperature, the higher the basicity and the greater the molar ratio of Ba/Ti in the precursor, the easier the formation of the perovskite type $BaTiO_3$ crystallite will be. (2) Hydrothermal reaction of the newly prepared $Ti(OH)_4$ gel with $Ba(OH)_2$ solution produced highly crystallized, well dispersed perovskite type $BaTiO_3$ crystallites with very fine (<100 nm) particles. The newly prepared $Ti(OH)_4$ gel turned out to be a suitable precursor for the hydrothermal preparation of $BaTiO_3$ fine powders. (3) X-ray diffraction of the hydrothermal $BaTiO_3$ powders reveals a simple cubic perovskite structure. The lattice constant (a) decreased with the increase of the reaction temperature. These abnormal crystallographic features are assumed to result from lattice defects, due to the OH^- incorporated in the perovskite lattice.

(Received 2 November 1994; revised version received 27 April 1995; accepted 31 May 1995)

Abstract

Mechanical behaviour of partially stabilized zirconia crystals (PSZC) with terbia and ceria additives was investigated under bending and indentation conditions. Test specimens were oriented along the [010] direction and along the axis of crystal growth. The PSZC bending strength (σ_b) was dependent on the crystallographic orientation of the specimens. The specimen volume subjected to stress influenced the PSZC strength. The highest mechanical characteristics were measured for ceria-doped crystals (σ_b = 1·9 GPa, K_{1c} = 11·4 MPa $m^{1/2}$, E_d = 366 GPa). The failure process was studied on the Vickers indentation, with special emphasis put on the development and propagation of lateral cracks. Anisotropy of lateral cracks in the (100) plane associated with that of the elastic moduli was revealed. At the same time anisotropy of radial cracks and hardness was not found. A new version of the equation to evaluate the fracture toughness (K_c^v) on the Vickers indentation was derived. The K_c^v values calculated by this equation correspond to those (K_{1c}) obtained by an SENB method.

1 Introduction

Considerable attention has recently been focused on partially stabilized zirconia crystals (PSZC),[1–3] some properties of which meet the requirements placed on structural materials. This rather high level of interest is probably also caused by technology[4] which allows the production of materials of high strength and fracture toughness. In published works e.g. Refs 3, 5 and 6, the authors mainly cited data on PSZC containing only yttria as a major additive (Y–PSZC). For testing, different, often contradictory procedures were used[3,7,8] with primary emphasis put on the physical nature of processes determining strength and deformation of these crystals[3,5]. It was shown[9,10] that other oxides of rare earth elements (ytterbium, cerium, etc.) present in Y–PSZC can also exert a positive influence not only on the process to make these crystals, but also on their physico mechanical characteristics. However, despite these data, certain problems associated, e.g. with the anisotropy of Y–PSZC properties still remain poorly investigated. Several results have been obtained[11,12] for the hardness of such crystals or for the development of cracks in them; however, detailed investigations of lateral cracks with the account of their crystallographic orientation have not been performed. As opposed to radial cracks, the latter can be of importance for such Y–PSZC applications as cutting elements of surgical instruments, bearing components, etc.[4,9] the production of which is accompanied with different machining, including abrasive.

The present work is therefore devoted to a complex investigation of mechanical properties of Y–PSZC containing terbia and ceria additives, with special emphasis on the development of lateral cracks in relation to other mechanical characteristics. This work continues our studies on zirconia crystals started in Refs 9 and 10.

2 Experimental Procedures

Partially stabilized zirconia single crystals with 3 mol% yttria and containing 0·3 mol% terbia (Y–Tb–PSZC) and 0·3 mol% ceria (Y–Ce–PSZC) were chosen for the investigations. These crystals, like those studied previously,[10] were prepared by direct high-frequency scull-melting technique at the Institute of General Physics, Russian Academy of Sciences.

Rectangular test specimens were cut from crystalline blocks with a diamond saw, their surfaces were ground and sharp edges rounded. The longitudinal axis of some specimens (Y–Tb–PSZC-A and Y–Ce–PSZC) was oriented by the Laue

back reflection method along the [010] direction, their mutually perpendicular surfaces corresponded to the {100} planes. The longitudinal axis of Y–Tb–PSZC-B specimens was approximately directed along the axis of crystal growth and was not strictly related to one of the characteristic directions in the cubic lattice,[13] i.e. the specimens were oriented in the same manner as for studying similar materials in Ref. 14.

Bending tests, as in Refs 4 and 9, were performed by our procedures.[15] All the specimens had the same cross-section (3·5 × 5·0 mm), the length of Y–Tb–PSZC-A specimens was about 25 mm, while the specimens of other crystals were about 45 mm long. The difference was determined by the dimensions of crystalline blocks. Therefore, the specimens were tested by three- and four-point bending. In the first case the span between supporting rollers was 20 (or 10) mm, in the second case it was 40 and 20 mm. Using different bending configurations, one could also evaluate a possible influence of the specimen volume subject to stress on the strength of the crystals under study.

In three-point bending tests the well known fact from applied mechanics was taken into account, viz. the plane stress state of the specimens occurring on such loading. Additional deflection of the specimens because of shear stresses can affect the magnitude of elastic moduli.[16] It is interesting that this fact is not usually taken into account during investigation of ceramics and single crystals. In this work we performed corrections of the experimental data obtained under three-point bending using the equation:[16]

$$E_{st} = \frac{L^3}{48J}\left[1+3\left(1+\nu\right)\left(\frac{h}{L}\right)^2\right]\frac{P}{\delta}, \qquad (1)$$

where E_{st} is the static elastic modulus on bending, P is the load, δ is the deflection, J is the moment of inertia of the cross-section, ν is Poisson's ratio, L is the span between supporting rollers and h is the height of a specimen.

Poisson's ratios (ν) were calculated from the data obtained on uniaxial compression of specimens. In this case lateral and longitudinal strain components were measured by resistance strain gauges glued to the specimen surfaces. These strain components were used to calculate known Poisson's ratio. Dynamic elastic moduli (E_d) were determined, as previously,[9,10] from longitudinal ultrasonic velocity data, v_l, measurements ($E_d=\rho v^2_l$, where ρ is the density of the material). It should be noted that here we used the concepts 'dynamic' and 'static' elastic moduli, though, as applied to crystals, one should speak rather about elastic constants for one or other crystallographic direction.[6,13] Thus, in our further discussions we confined ourselves to the above terminology which is widely used in engineering practice and can considerably simplify the analysis of the data.

The bending strength (σ_b) was calculated by applied mechanics known relations ($\sigma_b=2aP/bh^2$, where a is the length of a cantilever part of a specimen and b is the width of a specimen). As in Refs 9 and 10, a well known SENB method[17] was used to determine fracture toughness characteristics, e.g. the critical stress intensity factor (K_{1c}). The specimens were notched on their narrower surface (3·5 mm) over a half-height of their cross-section (2·5 mm) and placed with the same surface on the supporting rollers having a 20 mm span. The K_{1c} values were determined by the equation: $K_{1c} = \sigma_b c_n^{0.5} Y$, where c_n is the length of the notch and Y is the geometric factor determined from the tables.[17] The crack propagation in crystal specimens was studied by the traditional Vickers method. The data obtained were also used to evaluate the fracture toughness (K_c^V) of the crystals (see below).

3 Results

3.1 Bending strength, elasticity and fracture toughness

Major tests were performed on Y–Tb–PSZC-A specimens, the data on other crystals were used for comparison.

Strength characteristics were determined in the following way. The Y–TB–PSZC-A specimens were tested only by three-point bending, Y–Tb–PSZC-B and Y–Ce-PSZC were first tested by four-point bending, then by three-point (Table 1). The strength values (σ_b) of all studied specimens varied depending on the bending configuration. Thus, with a smaller span between supporting rollers, σ_b for the Y–Tb–PSZC-B and Y–Ce–PSZC specimens tends to increase (Table 1). The σ_b values of the Y–Tb–PSZC-A specimens were somewhat lower under such loading conditions. Maximum σ_b values (for several specimens, e.g. Y–Ce–PSZC they reached 1·9 GPa) corresponded to the highest values of elastic moduli (Table 2) for the [010] direction.

It is interesting to note that the differences were also observed in the nature of fracture surfaces for all specimens after bending tests. The Y–Tb–PSZC-A and Y–Ce–PSZC specimens exhibited traces of secondary cracking on their fracture surfaces visible even to the naked eye (Fig. 1(a)), while the fracture surface of Y–Tb–PSZC-B was smoother, displaying smaller flake-like cleavage. All the specimens (see also Ref. 9) are characterized by a step-wise propagation of the main crack

front (Fig.1(b)). Fracture sources were concentrated in the surface layer on the side of a tensile zone, however we did not succeed in establishing their type because of the complex structure of fracture surfaces.

Bending tests of SENB specimens enabled K_{1c} values to be calculated, they were 9·96, 7·0 and 11·43 MPa $m^{1/2}$ on average for Y–TB–PSZC-A, Y–Tb–PSZC-B and Y–Ce–PSZC, respectively. In the first and third cases notch directions were coincident with [001].

3.2 Vickers indentation tests

3.2.1 Indentation surfaces

Both groups of Y–TB–PSZC specimens were indented in the loading range of 0·1–200 N, since a further increase of loads resulted in less satisfactory impressions. The Y–Ce–PSZC specimens were also tested at higher loads (up to 300 N), since this problem arose to a less extent. The Vickers indenter was successively rotated through 360°C relative to the longitudinal axis of the specimen in a chosen plane only for Y–Tb–PSZC-A specimens, in the case of other crystals it was rotated only through 90°.

For all crystals, hardness values (H_v) determined from the impression half-diagonal[18] did not practically depend on the indentation direction in the planes under investigation (Fig. 2). In this case an increase in loading up to 70 N resulted in a certain decrease of H_v, e.g. for Y–Tb–PSZC-A from 14·3 GPa at 0·2 N to 12·5 GPa at 70 N. Starting from this load, H_v remained practically constant (this problem was detailed in Ref. 10).

In the process of indentation the cracks of different types were formed, viz. radial (Palmqvist)[10,19] and lateral,[10,20] or both. The presence of radial cracks is confirmed by the fact that partial grinding-off of the impressions resulted in the separation of such cracks from each corner of the impression (see also Refs 9 and 10). The extent of radial cracking was evaluated by an average length [$\bar{l} = \frac{1}{4}(l_1 + l_2 + l_3 + l_4$] of these cracks measured from each corner of the impression (Fig. 3). A relative size of lateral cracks was characterized by the parameter $L(\bar{R}) = \frac{\overline{ON} - \overline{OM}}{\overline{OM}} \approx \frac{\bar{R}}{0{\cdot}707a} - 1$ (Fig. 3), where $\overline{ON} = \bar{R}$ is the average distance from the impression center to the most distant part of the

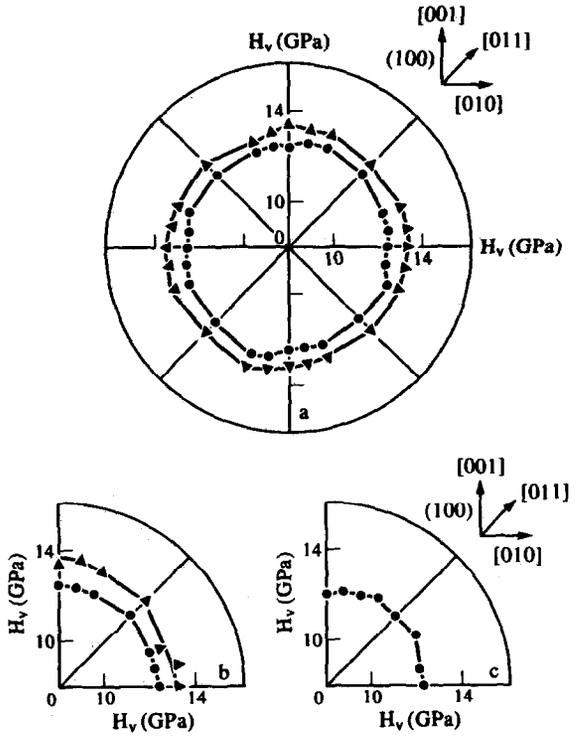

Fig. 2. Hardness (H_v) versus an angle of indenter rotation for: (a) Y–Tb–PSZC-A, (b) Y–Tb–PSZC-B, (c) Y–Ce–PSZC. Loads: 50 N (▲) and 100 N (●).

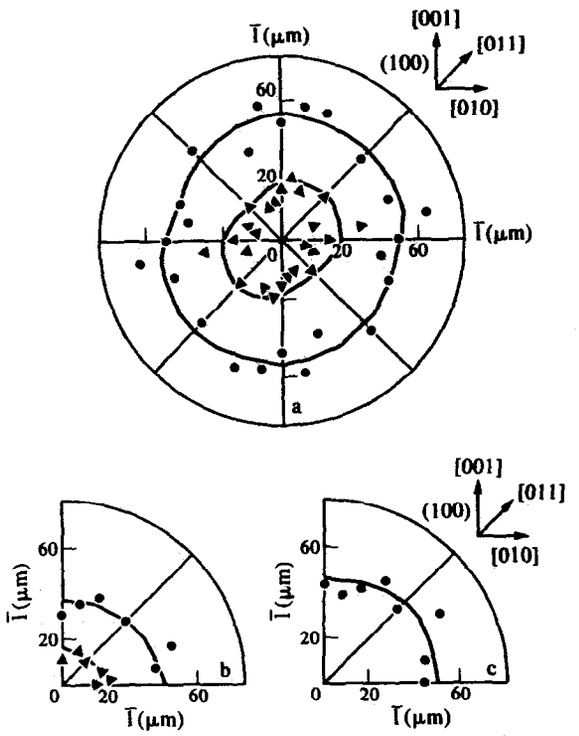

Fig. 4. Average length of radial cracks ($\bar{l}$) versus an angle of indenter rotation for (a) Y–Tb–PSZC-A, (b) Y–Tb–PSZC-B and (c) Y–Ce–PSZC. Loads: 50 N (▲) and 100 N (●).

front of the lateral crack calculated from each side of the impression, OM is the half-length of the impression side ($OM = a \sin 45°$) and a is the half-diagonal of the impression.

The experiments have demonstrated that the value of $\bar{l}$ for all crystals varies slightly depending on the indentation direction (Fig. 4). This may be investigated by drawing regression curves through a series of experimental points (Fig. 4). It was necessary to use this approach since experimental points had a relatively wide scatter in different directions. At the same time the extent of lateral cracking L ($\bar{R}$) differed considerably for the planes under consideration. Thus, when the indenter is turned in the (100) plane (Y–Tb–PSZC-A and Y–Ce–PSZC specimens), L ($\bar{R}$) varied from a certain maximum value ([010] direction) at a given load to a minimum one ([011] direction) and so on. If we average the data obtained (as in Fig. 4), they can graphically be represented as four-fold symmetry (Fig. 5(a),(c)). In this case $L(\bar{R})$ for Y–Ce–PSZC were lower (Fig. 5(c)) than those for Y–Tb–PSZC-A (Fig. 5(a)) at the same loads. For Y–Tb–PSZC-B

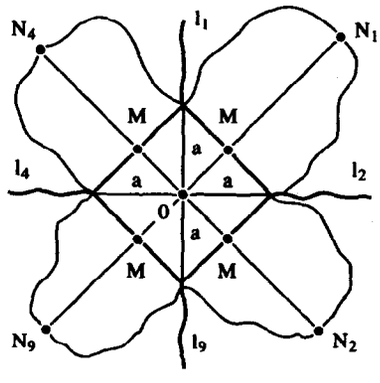

Fig. 3. Schematic representation of cracks formed around the Vickers impression (explanations in the text).

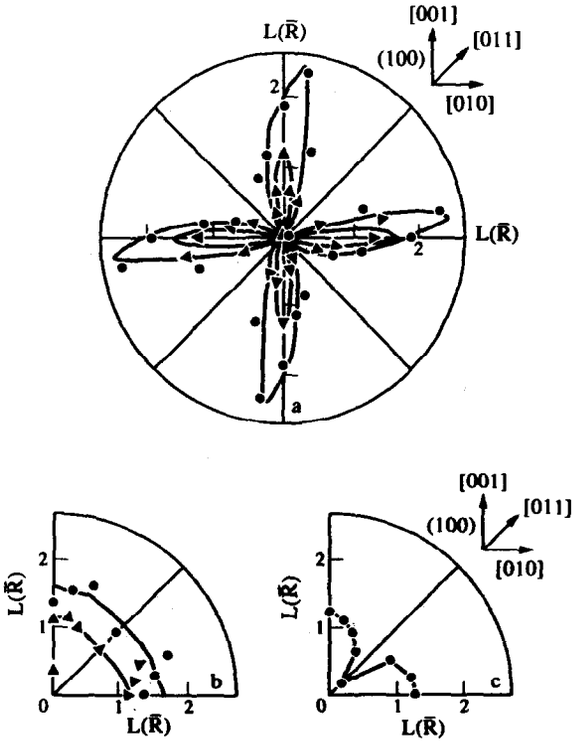

Fig. 5. Relative length of lateral cracks $L(\bar{R})$ versus an angle of indenter rotation for (a) Y–Tb–PSZC-A, (b) Y–Tb–PSZC-B and (c) Y–Ce–PSZC. Loads: 50 N (▲) and 100 N (●).

specimens $L(\bar{R})$ did not depend on the indentation direction, and its absolute values were somewhat different for different specimen surfaces (one of them is shown in Fig. 5(b)).

3.2.2 Fracture toughness

On the basis of earlier investigations,[9,21] we made the next step in terms of evaluating the fracture toughness of zirconia crystals from the length of radial cracks. For this purpose we used experimental values of a and $\bar{l}$ at various loads to plot calibration curves for each crystal[19] as a relation between normalized fracture toughness and normalized length of radial cracks. All these curves were approximated using an equation of the following type[22]

$$\frac{K_c^v \phi}{H_v a^{0.5}} \left(\frac{H_v}{E\phi}\right)^{0.4} = M \left(\frac{c}{a}\right)^{-N} . \quad (2)$$

In this equation the left side is the normalized fracture toughness, ϕ is the constraint factor ($\phi \approx 3$), H_v is the load-independent hardness and E is the static or dynamic elastic modulus. The right side contains the normalized length of radial cracks [$\frac{c}{a} = \frac{l+a}{a}$] and the coefficients ($M$ and N) are determined experimentally. In this case $c = l+a$ was taken as the length of radial cracks instead of ι (Fig. 4) which is often used in practice.[10,18,21] The value of K_c^v, as in Ref. 18, was set equal to K_{1c} and H_v = 12·5 GPa was chosen as its average value for all crystals in a load-independent regime. Major parameters of calibration curves in Fig. 6 being a log–log plot determined by the least-squares method are summarized in Table 3. The values of K_c^v calculated from these data, e.g. for Y–Tb–PSZC-A (Fig. 8), did not differ significantly from those obtained by the SENB method. Such calculations should also account for possible variations of elastic modulus (E) in different crystallographic directions.

We established that at least for Y–Tb–PSZC-A,

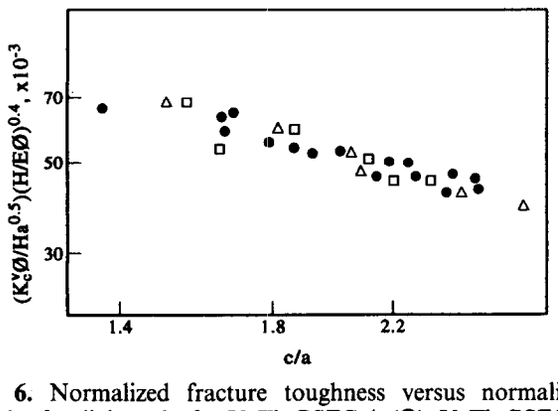

Fig. 6. Normalized fracture toughness versus normalized length of radial cracks for Y–Tb–PSZC-A (●), Y–Tb–PSZC–B (Δ) and Y–Ce–PSZC (□).

Table 3. M and N coefficients in eqn (2)

Material	*Coefficient*		*Correlation coefficient*
	M	*N*	
Y–Tb–PSZC-A	0·092	0·80	0·96
Y–Tb–PSZC-B	0·099	0·92	0·99
Y–Ce–PSZC	0·097	0·90	0·89

different E values, all other coefficients in the left side of eqn. (2) being constant, contributed only to M changes. At the same time the relations between a and c, e.g. in the [010] and [011] directions, were practically identical (equal values of N) despite a different extent of lateral cracking. The M and E values are inversely proportional, as a result we have practically coincident K_c^v values for a number of M and E values. Therefore, in our case the calculations were restricted to the M values (Table 3) corresponding to the E values obtained in the present work.

4 Discussion

The results obtained show that relatively high strength values correspond at least to the [010] direction in the (100) plane. This was already recognised.[9] By and large one may say that for such crystals, high strength values σ_b correspond to higher elastic moduli (Tables 1 and 2).

It should be noted that, for polished Y–PSZC specimens which contained only Y_2O_3, a σ_b of 2 GPa was found[2]. Among the crystals under investigation only some Y–Ce–PSZC specimens exhibited similar values of σ_b (~1.9 GPa), and the state of the specimen surface (ground or polished) for all crystals did not exert a noticeable influence on the magnitude of σ_b. This indicates that the strength of such crystals is probably determined

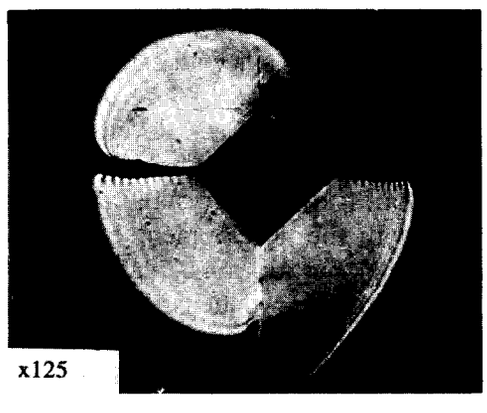

Fig. 7. Lateral and radial cracks around the impression on the Y–Ce–PSZC-A specimen surface corresponding (100) plane at a 150 N loading (the diagonals of the impression coincide with [010] and [001] directions).

rather by structural features in the bulk of the material rather than the surface effects. A reduction of σ_b for Y–Tb–PSZC-A specimens (Table 1) on three-point bending (10 mm span) could also be associated with the latter. Although for the specimens of other crystals a growth of σ_b was observed under the same loading conditions, which does not contradict Weibull's theory of strength.[23] Lower σ_b values for Y–Tb–PSZC-A specimens were not explained convincingly enough. However, such regularity is confirmed by testing of these specimens under different conditions.

Y–Tb–PSZC-A and Y–Ce–PSZC specimens exhibited the highest elastic moduli (Table 2). They are quite close to the literature data[6] for specimens of these crystals having similar orientation. The elastic moduli Y–Tb–PSZC-B specimens were much lower (Table 2). As was expected,[16] the static elastic moduli, E_{st}, determined for Y–Tb–PSZC-A specimens on their three-point bending, as in Ref. 9, were lower than the dynamic moduli E_d (Table 2). It is interesting that the uniaxial compression of these specimens in the [010] direction resulted in an elastic modulus of 370 GPa which slightly differed from E_d. The calculated Poisson's ratio (ν) was 0·17. It does not contradict[24] the values of ν for ceramics and related crystals which are usually in the range of 0·13–0·32. As a rule, materials with high elastic moduli exhibit lower ν. The value of E_{st} corrected by eqn. (1) was 334 GPa. For the specimens of other crystals this procedure was not necessary, since they were tested on four-point bending. A certain discrepancy between E_d and E_{st} for Y–Tb–PSZC-B obtained under the same loading conditions is probably associated with the fact that the specimen surfaces correspond to different crystallographic planes.

It should be noted that elastic moduli for Y–Tb–PSZC were measured on specimens cut from different crystalline blocks. However, they point to a considerable anisotropy of elastic properties of such crystals since all crystals were grown under similar conditions.

From the analysis of crack development around the impressions, it can be concluded that lateral cracks appearing in the crystals are not directly connected with the development of radial cracks. It is confirmed by additional data obtained, e.g. for Y–Tb–PSZC-A specimens. For them, depending on the indentation direction in the (100) plane, different sequence of crack types was observed. Thus, for the impressions where the diagonal is parallel to [010], a threshold value of the load (P_r) when first radial cracks appeared from the corners of the impression was 20 N. For the [011] direction P_r is equal to 15 N. Lateral cracks around the impressions when their diagonals were oriented along [010] were observed at a load (P_L) of 2 N, i.e. long before the radial ones appeared. The same was observed for Y–PSZC.[21] In the [011] direction the picture was quite opposite: radial cracks preceded the lateral ones. The latter were observed only at P_L=40–50 N. The Y–Ce–PSZC specimens in the [010] direction exhibited P_r=50 N and P_L=10 N. We could not establish certain specific P_r and P_L for Y–Tb–PSZC-B specimens since their surfaces displayed quite different fracture patterns. It should be noted that in Ref. 10 most equal values of P_L but higher values of P_r were observed for similar crystals in the same planes. This is probably caused by the fact that the tests in Ref. 10 were performed at loads of 50 N or higher as well as by the fact that, in the two cases, optical microscopes with different resolution levels were used.

For Y–Tb–PSZC-A and Y–Ce–PSZC the chipping around the impressions with the diagonals oriented along the [010] direction occurred starting from 70 and 200 N, respectively. This phenomenon is due to the uplift on the front of lateral cracks. These chips were observed in the [011] direction, e.g. for Y–Tb–PSZC-A already at 100 N or higher, whilst for Y–Tb–PSZC-B this value was not established because of a considerable scatter of experimental data for arbitrarily chosen directions.

Thus, the results show that in many cases radial cracks in these crystals play the role of a barrier for the propagation of the front of lateral cracks to an adjacent sector of the impression (Fig. 7), this was also observed for ceramics.[20] Radial cracks do not influence the distance of the front of lateral cracks from the center of an impression (ON in Fig. 3) for various loads and directions which also points to the absence of relationship between these types of cracks. For comparison, fully stabilized zirconia crystals (FSZC) exhibited[25] longer radial cracks in [110] as compared to [100] in the (100) plane. It was considered to be associated with the influence of lateral cracks. The latter were of minimum sizes in the [110] direction. Such influence is sometimes explained[20] by the redistribution of strain energy in favour of radial cracks due to a smaller extent of lateral cracking. As was shown above, we did not observe any noticeable anisotropy of radial cracking (Fig. 4) and, as a result, of the fracture toughness (see also [10]). Even when we increased the number of impressions up to 15, e.g. on the (100) surface of Y–Tb–PSZC-A specimens, 100 N loads give l values of 60 μm for [010] ($L(\bar{R})$=2) and of 72 μm for [011] ($L(\bar{R})$=0·19) which is within the scatter of

experimental data. It also applies to the hardness of such crystals (earlier noticed for Y–PSZC[12]), while FSZC displayed[26] its strong anisotropy in the (100) plane. The graphic representation of this anisotropy resembles the variation of elastic moduli[6] and $L(\bar{R})$ (in our case) (Fig. 5) in the same crystallographic planes. One may say that for Y–Tb–PSZC-A and Y–Ce–PSZC the anisotropy of lateral cracks is proportional to that of the elastic moduli: the higher $E_{st}(E_d)$, the higher $L(\bar{R})$. It is interesting that the same relationship was established[27] for several cubic ionic crystals but only between the anisotropy of elastic modulus and that of hardness.

We should also emphasize particular behaviour of crystals on indentation as the formation of 'irregular' radial cracks around some impressions (see also Refs 10,14), these cracks propagate from the sides of the impression or at an angle from its corners. Such cracks are the most characteristic of the impressions, the diagonals of which are oriented along [011]. We did not take them into account when the fracture toughness of crystals was evaluated.

To calculate fracture toughness (K_c^v) from the length of radial cracks, quite a number of semiempirical relations have been proposed,[18,19,22] based on the models of half-penny or Palmqvist cracks. The application of several well known and widely used equations[18]

$$K_c^v = 0{\cdot}028\, H_v a^{0.5} \left(\frac{E}{H_v}\right)^{0.5} \left(\frac{c}{a}\right)^{-1.5}, \tag{3}$$

$$K_c^v = 0{\cdot}142\, \frac{H_v a^{0.5}}{\phi} \left(\frac{E\phi}{H_v}\right)^{0.4} \left(\frac{c}{a}\right)^{-1.56} \tag{4}$$

and

$$K_c^v = 0{\cdot}035\, \frac{H_v a^{0.5}}{\phi} \left(\frac{E\phi}{H_v}\right)^{0.4} \left(\frac{c}{a} - 1\right)^{-0.5}. \tag{5}$$

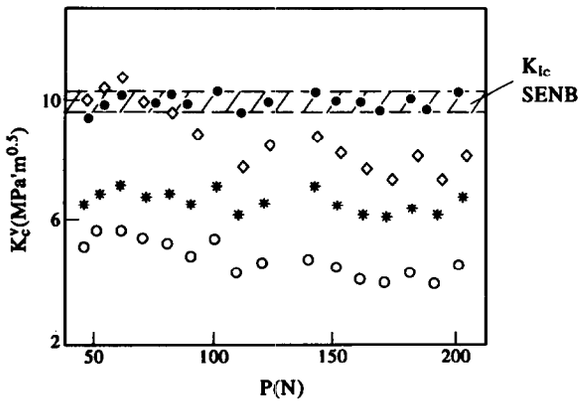

Fig. 8. Fracture toughness (K_c^v) versus the indentation load (P) for Y–Tb–PSZC-A determined by eqn (2) (●), eqn (3) (○), eqn (4) (◇) and eqn (5) (∗).

To evaluate fracture toughness, e.g. of Y–Tb–PSZC-A crystals, resulted (Fig. 8, see also Ref. 10) in K_c^v values which are lower than those obtained by a conventional (SENB) method. It can point to the differences in propagation of radial cracks in ceramics (eqns (3)–(5) were proposed for the latter) and in the crystals under study. Therefore, numerical coefficients from Table 3 substituted in eqn (2) which is similar to eqns (3)–(5) in its structure are more suitable for practical calculations of K_c^v. These coefficients characterize a real behaviour of such crystals on indentation. The equation derived in Ref. 21 which was used[10] to evaluate K_c^v of similar crystals contained coefficients somewhat different in their magnitude. Therefore, it should probably be considered as a foregoing approximation of the problem to be solved. The fact that calibration curves (Fig. 6, Table 3) are spaced so closely is most likely to be random in nature. A relative position of these curves can be different for the specimens of other crystals taking into account possible anisotropy of their mechanical characteristics.

5 Conclusions

The complex investigation of zirconia crystals stabilized with yttria and containing terbia and ceria additives gave additional information about the mechanical behaviour of these materials. It further elucidated the poorly studied field of lateral cracking of crystals on Vickers indentation. This information is also of great interest for the application of crystals as a material for surgical instruments,[9] since this lateral cracking resembles fracture features observed on the surface of scalpels during their sharpening. It gives the impression that the performance of these crystals at room temperature applications can be inferior to that of similar ceramics. It is associated with noticeable local failure when in contact with a sharp concentrator (some grains of abrasive powder, etc.). This behaviour of the crystals was not specially treated by earlier investigators.

In addition, the data obtained in the present work could be useful for the development of more perfect crystals possessing more uniform structure (data on fractographic investigations were published previously[9,10]). The results (including the equation for determining K_c^v) suggest that we should concentrate on the development of the most acceptable approaches for evaluating the fracture toughness of crystals. This problem should be given as much attention as that paid to advanced technical ceramics (see, e.g., Ref. 28).

Acknowledgements

The work was performed within the programme 'New Zirconia-Based Materials and Components' financed by the State Committee of Science and Technology of Ukraine. This research was made possible in part by Grant No. UBV000 from the International Science Foundation.

(Received 5 August 1994; revised version received 13 March 1995; accepted 31 May 1995)

Abstract

Investigations were carried out on four tetragonal zirconia polycrystalline (TZP) ceramics of differing grain size containing 9 mol% CeO_2. Precision flexural tests on these materials were conducted to determine the elastic modulus, the non-linear deflection and the associated acoustic emission during such testing. The deformation was characterized in terms of the number and size of the transformation bands that developed during the non-linear response. The finest grained material initially exhibited permanent set without the presence of such bands, whereas all the coarser grained materials showed a linear relationship between the summation of the band widths and the residual deflection. The acoustic emission and plastic strain behaviour are discussed in terms of the number and size of the stress induced phase transformation bands.

1 Introduction

The development of tough ductile ceramics has been the long cherished dream of many materials engineers. Recently this situation has to some extent been realised with the development of Ce–tetragonal zirconia polycrystalline (TZP) materials which behave almost like mild-steel as shown initially by Tsukuma and Shimada[1] and subsequently verified by numerous authors.[2–6] The main emphasis of such papers has been to rationalize the basis of the non-linear response and the development of bands where the tetragonal grains had transformed to monoclinic zirconia without any associated cracking.

Ce–TZP materials are somewhat unique amongst the zirconia phase transformable materials in that the tetragonal (t) to monoclinic (m) transformation exhibits burst or autocatalytic behaviour. Previous studies by Reyes-Morel and Chen,[4] and Becher and Swain[7] have investigated this behaviour and shown that a strong grain size effect exists and influences the burst temperature M_B for the t → m transformation. The latter authors have also provided a simple thermodynamic explanation of this size effect, relating it to a critical nuclei size and degree of undercooling or applied stress to initiate the transformation.

In this paper a more critical appraisal is given of the force–displacement response of the Ce–TZP materials tested in four point flexure. In particular the non-linear response is characterised in terms of the acoustic emission that develops and the size and number of the transformation bands. In a previous paper the authors[8] also investigated acoustic emission activity during the flexure testing of Mg–PSZ ceramics. However, that study did not enable an unambiguous interpretation of the acoustic emission (AE) data, that is, whether it was generated by stress induced phase-transformation or microcracking of the coarse grained microstructure of that material.

2 Materials

The investigations were carried out on Ce–TZP ceramics containing 9 mol% CeO_2. These materials were sintered at temperatures from 1400 to 1550°C in air for 1 h and their fabrication has been described by Grathwohl and Liu.[2] The designation, sintering temperature, mean grain size and relative density are listed in Table 1.

Specimens in the form of rectangular bars 2 × 2·8 × 48 mm were cut from a large sintered plate and polished on two adjacent sides prior to flexure testing. Four point bending tests were conducted on a precision rig described elsewhere[9] with inner and outer supports of 20 and 40 mm at a crosshead speed of 0·5 mm/min. The specimen deflection and accumulated acoustic emission counts were measured during the test using the same procedure as described in Ref. 8.

Table 1. Designation and properties of investigated ceramics

Designation	*Temperature of sintering (°C)*	*Mean grain size (μm)*	*Relative density (%)*
Ce–TZP-I	1400	1·14	94
Ce–TZP-II	1450	1·62	97
Ce–TZP-III	1500	2·22	98
Ce–TZP-IV	1550	3·00	97

3 Results and Discussion

3.1 Force–displacement curves

3.1.1 Monotonic loading

Typical force–displacement (P–δ) curves and associated acoustic emission counts (P–N_Σ) of the four ceramics are shown in Fig. 1(a–d), and the results are summarized in Table 2. The brittleness measure has been discussed in detail elsewhere by Gogotsi[9] and is the ratio of the elastic to the total energy under the force–displacement curve at the onset of fracture. It is clear from the data in Table 2 that the materials differ insignificantly in terms of their density, elastic modulus and ultrasonic velocity. The force–displacement curves are similar to those reported by Grathwohl and Liu[2] in that there is initially a linear response from which the 'static' estimate of the elastic modulus was calculated.

Beyond the linear response region of the P–δ curves the materials exhibit inelastic behaviour that may be approximated by a straight line whose slope decreases with increasing grain size of the Ce–TZP material as shown schematically in Fig. 2(a). The critical load at the onset of inelastic behaviour P_{el} and for failure P_m for each of the ceramics is shown in Fig. 2(b). The maximum deflection δ_m and residual deflection δ_r (maximum deflection less elastic recovery) are shown in Fig. 2(c). The residual or plastic deflection, δ_r, is almost independent of the grain size of the material.

The materials exhibit significant differences in the form of the inelastic portion of the P–δ deformation. The Ce–TZP-1 material exhibits a very smooth curve with the onset of nonlinear behaviour only being determined by the almost imperceptible change in slope. This behaviour is similar to that observed with Mg–PSZ (TS grade) material. Whereas the materials CE–TZP-II to Ce–TZP-IV are characterized by very jerky behaviour with the magnitudes of the intermittent

load drops increasing with material grain size. These peculiarities of the P–δ response during monotonic loading appeared as part of the continuous load–deflection curves, and alternated with sharp load drops accompanied by an increase in deflection. It should also be noted that similar drops in load (but developing more slowly) were also occasionally observed for periods of up to a few minutes after the testing machine-crosshead had been stopped at maximum load. Thus although a time factor of loading can not be ruled out, nevertheless the shape of the P–δ curves did not essentially differ at crosshead speeds of 0·5 and 0·005 mm/min. Unfortunately, the limited number of samples did not enable this time dependent effect to be investigated in detail.

The nature of the load drops during continuous load–deformation curves should not be associated with the nucleation and growth of cracks in the specimen. Crack initiation or growth would lead to a change of the specimen compliance, $c = \tan^{-1}\alpha_1$ (Fig. 1(b, c or d)), by the value $\Delta c = \tan^{-1}\alpha_1 - \tan^{-1}\alpha_2$. Such a change in compliance should be related to a decrease in load ΔP_i by the relationship

$$\frac{\Delta c_i}{c_o} \simeq \frac{\Delta P_i}{P}.$$

This expression is also valid for the total change of specimen compliance Δc_i, which should be related to the sum of the successive load drops by the total value $\Sigma \Delta P_i$, i.e.

$$\frac{\Delta c_i}{c} \simeq \frac{\Sigma \Delta P_i}{P}.$$

The right-hand part of the above expression for samples Ce–TZP-III and -IV reaches 10–20%, such a change of compliance would have been readily measured on the reloading portion of the monotonic load–deflection curve after a few such load drops. However, the slope of these curves within the limit of experimental error (2–3%) showed undetectable change throughout the course of loading. In addition, the anticipated crack depth associated with such a load drop would have been readily visible, and in the range 0·6–1·0 mm.

Analysis of the acoustic emission data is of particular interest. This data which must be considered as only comparative because of the difficulty of attachment of the AE detector to such a small bar. It is for this reason that the total AE count to fracture was characterized by considerable scatter from specimen to specimen, which did not allow for example one to relate N_Σ values to

the grain size of the ceramics. However, the results consistently showed that for sample II, III and IV the onset of AE counts corresponds to the onset of nonlinearity of the P–δ curve, whereas for the Ce–TZP-I material the AE began only after considerable non-linearity. Also, one can clearly observe a correlation between AE outbursts and load drops (in Fig. 1(b–d) such correlations are connected by means of dashed horizontal lines). In contrast to this, very few AE events were detected during the continuous portions of the load–deflection curve.

3.1.2 Cyclic loading tests

To provide a more detailed understanding of the above deformation, sequential load–unloading cycles were performed on samples with polished tensile and adjacent side face. These materials were loaded to increasing maximum force and between each cycle the tensile and side surfaces were visually inspected. Such a testing procedure enabled us to quantify the surface deformation bands on the tensile surface that formed perpendicular to the longitudinal axis and their extension on the side surface. Typical P–δ curves and associated AE, P–N_Σ curves are shown in Figs 3–6 (a and b) for all the Ce–TZP materials. The location

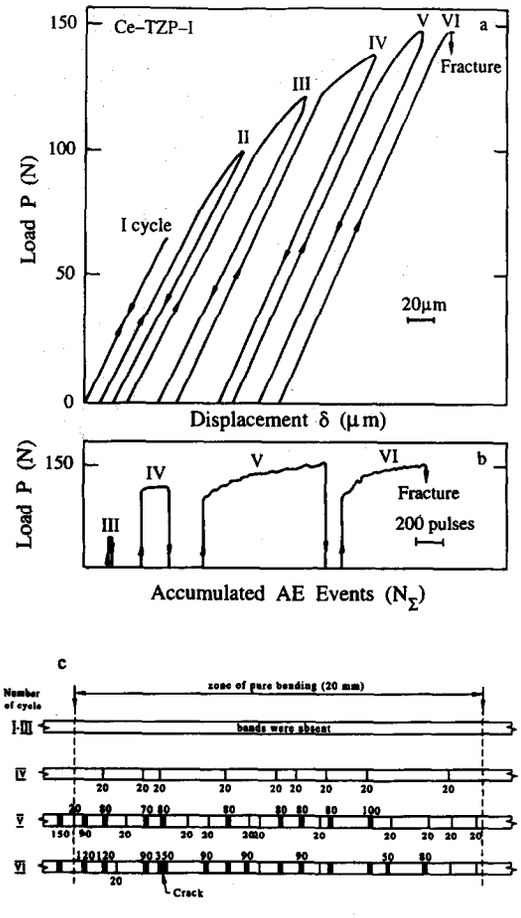

Fig. 3. (a) Cyclic load–displacement data; (b) accumulated AE events; and (c) location and width (in μm) of transformation bands in Ce–TZP-I.

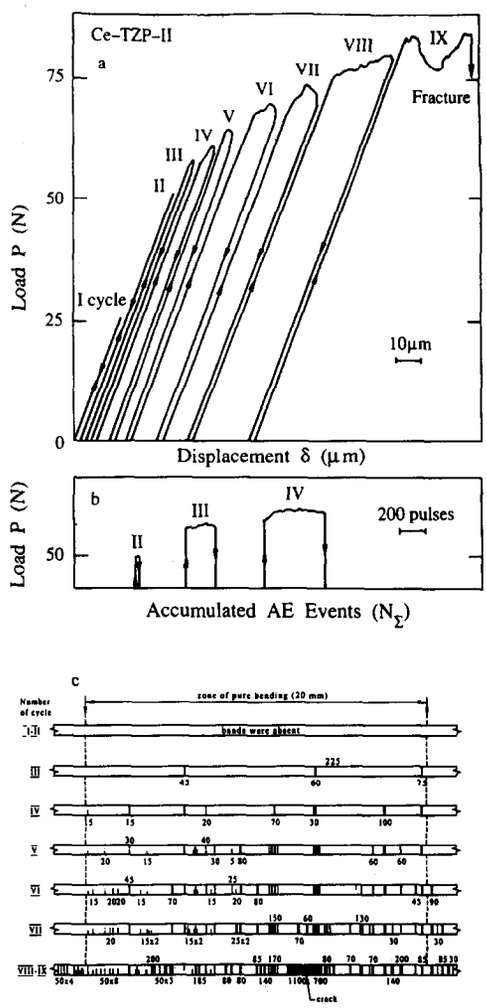

Fig. 4. (a) Cyclic load–displacement data; (b) accumulated AE events; and (c) location and width of transformation bands in Ce–TZP-II.

and size of the transformation bands on the tensile surface are shown in Figs 3–6(c) again for all the Ce–TZP materials. Representative micrographs of the transformation bands on the tensile and side surfaces for samples Ce–TZP-I to -III are shown in Fig. 7. In some instances the transformation band associated with the fracture surface is also visible in the micrograph. Previous examples of this type of deformation for Ce–TZP materials was first shown by Hannink and Swain[3] and reproduced by other authors.[2,4,6]

The present observations enable the following critical aspects of these transformation bands to be made:

(i) Deformation bands appear to initiate randomly and increase in number with increasing strain. They appear to be uniformly distributed within the region of constant stress of the four point flexure specimen. The bands are present only above a critical load (or stress) that for specimens Ce–TZP-II to -IV corresponds to the onset of permanent set or 'plastic' deformation, whereas for material Ce–TZP-I the initial stages of permanent set are not associated with band formation.

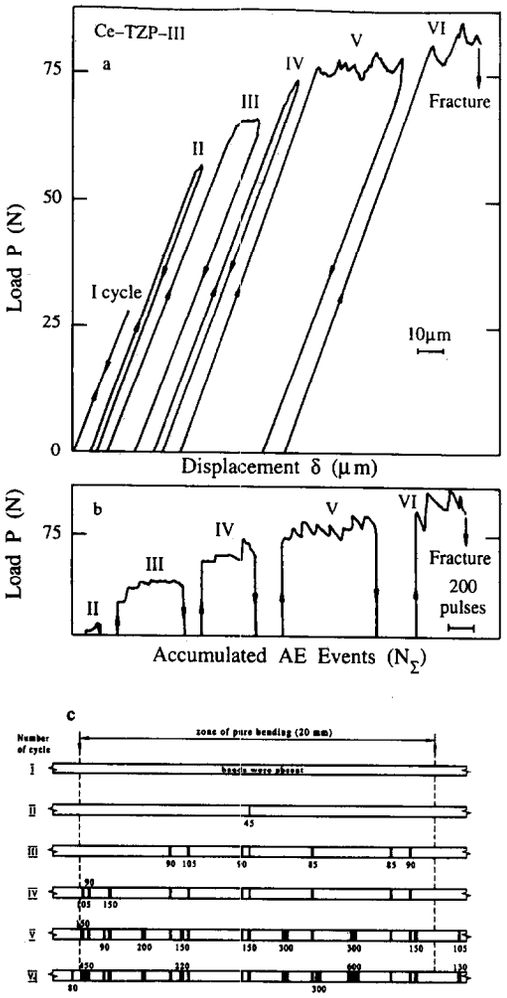

Fig. 5. (a) Cyclic load–displacement data; (b) accumulated AE events; and (c) location and width of transformation bands in Ce–TZP-III.

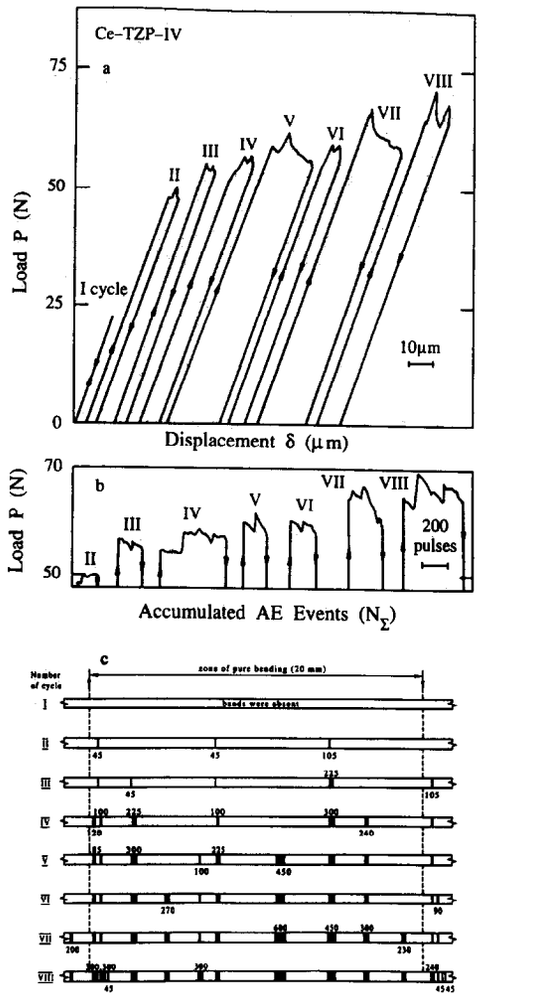

Fig. 6. (a) Cyclic load–displacement data; (b) accumulated AE events; and (c) location and width of transformation bands in Ce–TZP-IV.

(ii) With increasing loading cycles beyond the elastic limit new bands appear and those which were initiated during a previous cycle either increase in width discretely or remain unchanged up to fracture.

(iii) For each cycle the slope of the P–δ curve remains constant upon loading and unloading although the proportionality limit increases with each subsequent cycle. Upon loading to the proportional limit for each cycle no change in the number and size of the transformation bands or AE events is observed.

(iv) The observation of the first AE event coincided with the formation of the first transformation band for all of the Ce–TZP specimens. However, for sample Ce–TZP-I the first detectable AE event occurred after the onset of considerable 'plastic' strain.

(v) For specimens Ce–TZP-III and -IV, that exhibited more pronounced load drops during either monotonic or cyclic loading, a direct relationship between the number of load drops, AE event bursts and number of transformation bands was observed.

(vi) Fracture of the various specimens occurred almost in the centre of one of the widest pre-existing bands and never occurred at a new location.

A more detailed analysis of the deformation bands and their width at the moment of specimen fracture and a histogram plot of the transformation band widths is shown in Fig. 8. This figure reveals major distinctions between the various samples. In particular, the width of the transformation bands increases with specimen grain size. Thus, for example, whilst for the Ce–TZP-I specimen only narrow bands of width $\Delta_i \sim 20$ μm are formed, they are often grouped together in packets of three or four bands, or more at the fracture location. In contrast for specimens Ce–TZP-II to -IV the bands become increasingly thicker and fewer in number. The total number of transformation bands $n_{tr} = \epsilon n_{\Delta}$, observed on the tensile surface of the fractured specimen is also given on the histogram plots.

Analysis of the total width of the bands versus the number of bands formed during the loading

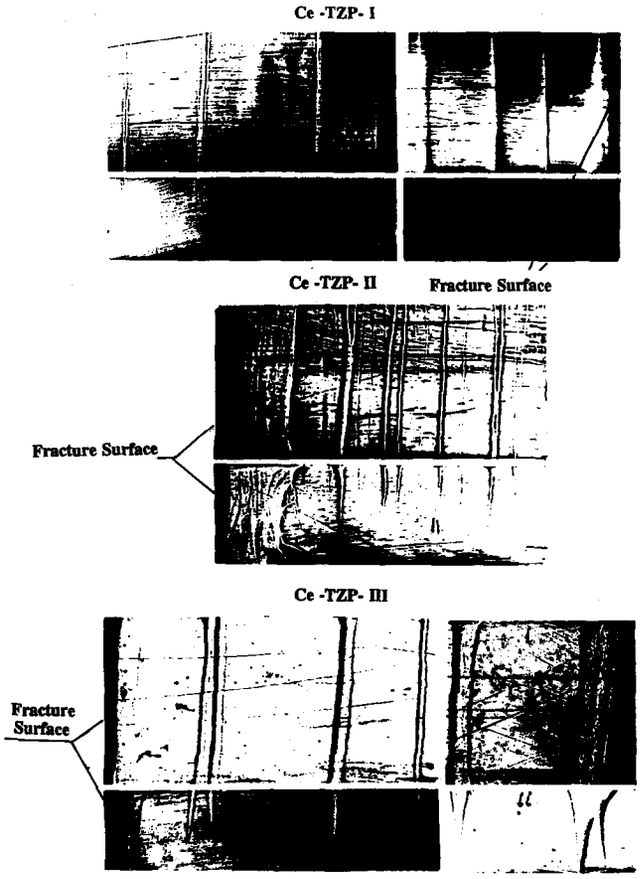

Fig. 7. Typical optical micrographs of the tensile and side faces of various Ce–TZP materials, illustrating the transformation banding.

cycles shows a nonlinear trend and increasing slope with increasing grain size as shown in Fig. 9. This behaviour is most pronounced for samples Ce–TZP-III and -IV, and appears to be related to the magnitude of the load drops with increasing strain during flexure. It is as though the easier initiation sites for transformation band nucleation become exhausted leading to overload conditions

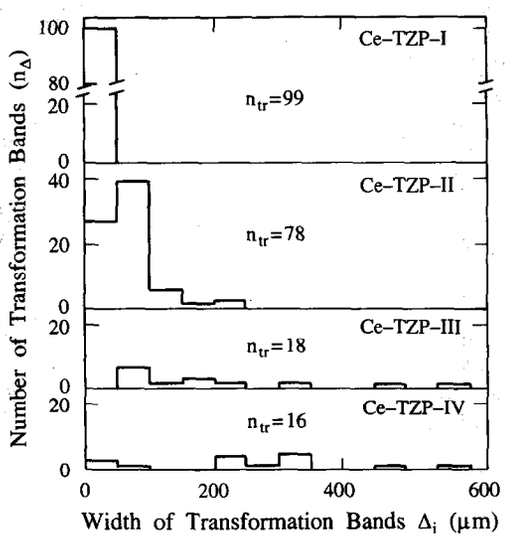

Fig. 8. Histograms of the number (n_Δ) and width (Δ_i) of the transformation bands developed on the tensile surface of the Ce–TZP materials.

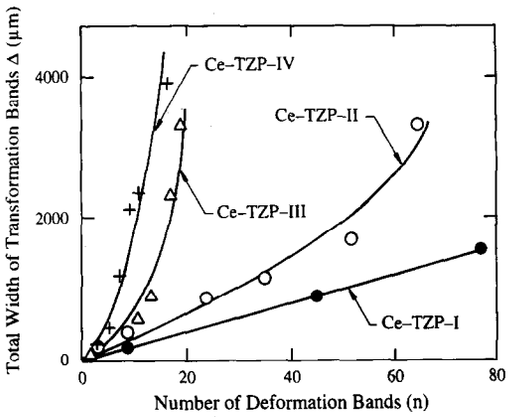

Fig. 9. Relationship between the total transformation band widths Δ versus the number of bands.

for the more difficult sites. This overload instability initiation condition leads to the formation of wider bands.

A more linear relationship may be established between the residual 'plastic' displacement δ_r and the sum of the widths of the transformation bands during each cycle as shown in Fig. 10. The obvious exception to the near universal curve is Ce–TZP-I, which in contrast to that shown in Fig. 9 is very nonlinear. For samples Ce–TZP-II to -IV a linear relationship of the form ($\delta_r = k_i \Delta$) fits the data very well, with the constant k_i tabulated for these materials in Table 3. It is not clear why sample Ce–TZP-I does not show such a linear dependence although it may be due to the presence of some fine scale microcracking as well as transformation that accounts for the significant plastic strain measured. However, one might have expected such microcracking to be associated with a reduction of specimen compliance with each loading cycle. Alternatively, some transformation reversibility upon unloading may occur, but this would be anticipated to have produced some non-linearity during the unloading phase. Perhaps with this sample some ferro-elastic tetragonal grain reorientation

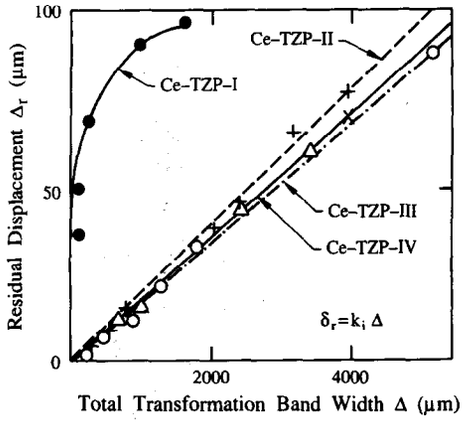

Fig. 10. Relationship between the residual displacement δ_r and the sum of the transformation band widths Δ.

Table 3.

Ceramics	k_1	k_2
Ce–TZP-I	—	25
Ce–TZP-II	0·0193	71
Ce–TZP-III	0·0177	117
Ce–TZP-IV	0·0169	126

as proposed by Virkar and Matsumoto[11] may be occurring during loading which is irreversible upon unloading. If this is the case then it suggests that the fine grained Ce–TZP material initially responds above a critical tensile stress to re-orientation of some tetragonal grains. Upon further loading these or perhaps other sites undergo transformation to monoclinic zirconia. Both of these processes (re-orientation and phase transformation) are associated with residual deformation. The absence of AE events during the initial phase of non-linear response of the Ce–TZP-I material (Fig. 1(a)) is also supportive of this interpretation.

It would be anticipated that because of the observed relationship between δ_r and the sum of the deformation bands Δ, a similar correlation should exist with the inelastic strain ϵ_r of the flexure specimen. For this purpose consider the point Δ = 4000 μm and δ_r = 70 μm (marked as a cross in Fig. 10), which may be thought of as the averaged value for specimens -II to -IV. Then using the simple relationship between strain, ϵ, to the flexure of a beam of height h and inner span length L (20 mm) namely

$$\epsilon = \frac{4h}{L^2}\,\delta\,,$$

this simple hypothesis may be confirmed. Upon substituting for h and δ_r(2·8 mm and 70 μm, respectively), $\epsilon_r = 1{\cdot}7 \times 10^{-3}$. Whereas taking into account that during the phase transformation of tetragonal to monoclinic zirconium oxide there is a volume dilation, ΔV ~4%, which is a linear strain of only ~1/3 (ΔV), that is 1·3%. Therefore, the anticipated 'plastic' strain associated with the total transformation band width is ~4000 μm × $1{\cdot}3 \times 10^{-2} \simeq 52$ μm and, therefore, its value is

$$\epsilon_i^{\Delta} \simeq \frac{\Delta l}{l} = \frac{52 \times 10^{-6}}{20 \times 10^{-3}} = 2{\cdot}6 \times 10^{-3}.$$

The difference between the predicted ϵ_i^{Δ} and measured strain ϵ_r may be accounted for if not all the tetragonal grains within the band are transformed to monoclinic. The present calculation suggests that less than 65% is transformed which is in reasonable agreement with micro-Raman measurements of the phase content of similar transformation bands in a 12 mol% Ce–TZP material by Becher and Swain.[7]

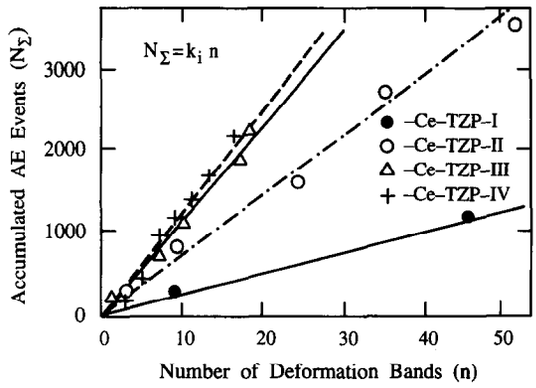

Fig. 11. Correlation between the total AE event count and the number of transformation bands.

Another interesting aspect of the present observations is the comparison of the number of AE pulses N_Σ obtained for a given number of loading cycles with the number of transformation bands, n (Fig. 11). This figure shows an excellent linear relationship for all the Ce–TZP materials with the slope increasing from sample I to IV. That is, this data may be represented by the simple expression $N_\Sigma = k_2 n$ where k_2 is given in Table 3 for all samples. Considering that AE events are associated with the appearance of deformation bands, one may assume that individual AE events are the result of burst like nucleation of such a band.

It is tempting to try to interrelate the observed strain hardening, increasing width of the bands, and the increasing magnitude of the load drops and AE events during the present experiments. Unlike metallic materials the strain hardening does not appear to be related to dislocation (or band) interaction or pile-up processes. Rather it is as though there is a distribution of defects within the materials that provide stress concentration sites from which the transformation bands are nucleated. Thus within the uniform tensile stress zone the initiation load or stress generates a critical tensile strain energy density at the largest defect site (flaw, pore or inclusion). When this local energy density exceeds a critical value it is released as a transformation band which lowers the total strain energy of the beam. As there is likely to be a distribution of such defect sizes within the beam the load must be increased to initiate a transformation band from the next most potent defect site upon the exhaustion of the previous largest defect. However, the increased total strain energy of the beam has the potential to form a wider band of transformation in the otherwise near homogeneous material. This process will continue until a pre-existing or newly initiated band results in the specimen fracture. A more detailed discussion of the fracture of this material is given in the accompanying paper.[12]

4 Conclusions

The present observations have shown the influence of grain size on the deformation behaviour of these 9 mol% Ce–TZP materials. It has been established, as previously shown by Becher and Swain,[7] that the onset of plastic deformation or ease of stress induced phase transformation is grain size dependent.

This study has established a relationship between the grain size and the width of the transformed bands generated on the tensile surface. It has also been shown that for the coarser grained Ce–TZP-II to -IV materials there is a linear relationship between the sum of the width of the transformation bands and the residual plastic strain ϵ_t. A simple analysis of this situation indicated that the accumulated strain was less than anticipated assuming all the tetragonal grains within the band transformed to monoclinic zirconia. The results could be rationalized if only 65% of the grains transformed which is in good agreement with Raman microprobe measurements of such bands by Becher and Swain.[7] It is suggested that a ferro-elastic grain re-orientation may be responsible for the observance of non-linear behaviour of the fine grained Ce–TZP-I material in the absence of transformation bands. Acoustic emission data showed a linear relationship between the number of bands and total AE events.

Acknowledgements

The authors wish to thank Dr T. S. Liu and Dr Grathwohl for the provision of the samples used in these tests. Collaboration was made possible by a grant from the Australian Department of Industry, Technology and Regional Development under the Bilateral Science Program.

(Received 27 January 1995; revised version received 31 May 1995; accepted 31 May 1995)

Abstract

The wear resistance of stabilized zirconias was investigated on both a pin-on-disk machine and a Dangoumeau apparatus under dry and lubricated (water) conditions. Under the experimental conditions (80 N load and 12 mm/s speed) the wear mechanism can be described as initial plastic deformation and then grain pull-out. The role of the third-body in the interface of friction has been demonstrated with asymmetric couples where one of the antagonists is made of alumina. If for pure friction it is not easy to differentiate the magnesia partially stabilized zirconias (MgPSZ) from the yttria tetragonal zirconia polycrystal (YTZP), after shock tests we can conclude that the YTZP have a better wear behaviour than the MgPSZ, especially in the case of attrition applications.

1 Introduction

Recently, considerable attention has been applied to stabilized zirconia ceramics, because of their special mechanical, chemical and thermal properties. For the application of high capacity attrition mills for fine grinding and homogeneization millings, beads with a large surface and high energy input are required. High density, good sinterability and improved fracture toughness make stabilized zirconias very attractive as wear-resistant materials. However, their potential applications are still limited by the lack of reliable data concerning the wear behaviour and mechanism. Although a number of studies have been carried out to investigate the wear characteristics in a variety of conditions, most of them deal with metal/ceramic contacts and ceramic/ceramic friction is not well known as yet.

Scott[1] studied the wear behaviour of MgPSZ and suggested that their particular wear resistance depended on the amount of transformable phase in the sample. Aronov[2] also observed a range of temperature where the wear of MgPSZ decreased by three orders of magnitude. He proposed a phenomenological model to explain this wear by phase transformation due to frictional heating. Fisher *et al.*[3] examined the wear behaviour of tough and brittle zirconias in different environments. They concluded that water has a deleterious effect on wear resistance. Stachowiak *et al.*[4] found similar wear for both MgPSZ and YTZP in a pin-on-flat test despite their significant difference in grain size. The delamination and plastic deformation were considered as the main wear mechanisms. For Chen *et al.*[5] rapid wear of MgPSZ and YTZP was found in a special range of sliding speed, wear resistance of MgPSZ, however, remained better than that of YTZP. Lee *et al.*[6] carried out an extensive study on YTZP zirconias by setting wear maps. They identified wear transitions depending on the environment. In mild-wear regimes plastic deformation and microcutting are dominant. Thermal-shock-induced brittle fracture is the predominant mechanism causing severe wear in the high-speed regimes. Probable moisture-induced destabilization of YTZP is evident specifically under water-lubricated conditions.

Considering the results above, the wear behaviour of zirconia ceramics seems to be very sensitive to the structure of the material, and to the test parameters, such as temperature, environment and sliding speed as underlined by Liang *et al.*[7]

2 Experimental

2.1 Wear apparatus

The first wear tests were conducted on a pin-on-disk tribometer described in Fig. 1. The linear speed was 12 mm/s and the load applied by a dead-weight system of 8 kg, i.e. about 80 N. Wear is measured with a rugosimeter which gives the profile of the track on the disk. With width W, depth D and length L of the track it is possible to calculate the removed volume V:

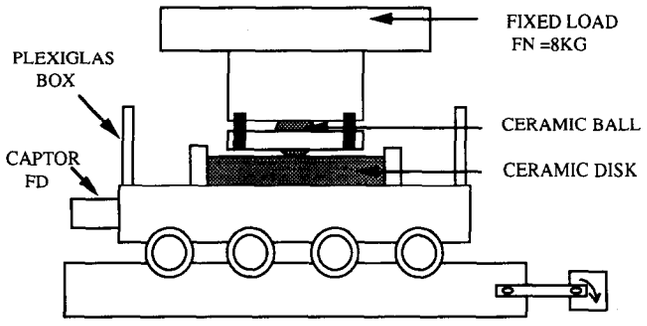

Fig. 1. Schematic representation of the pin-on-disk tribometer.

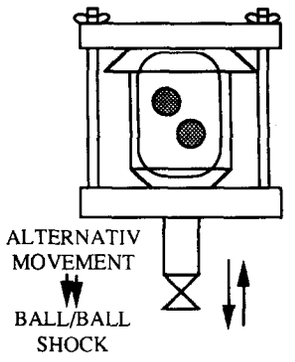

Fig. 2. Schematic representation of the Dangoumeau machine.

$$V = L\,(R^2 \arccos(\frac{R-D}{R}) - W\frac{R-D}{2}),$$

$$\text{where } R = \frac{D^2 + \frac{W^2}{4}}{2D}. \qquad (1)$$

For balls the wear volume is obtained from the scar diameter, knowing the radius of the ball:

$$V = \Pi\frac{R^3}{3}(2 - 2\cos\beta - \sin^2\beta\cos\beta),$$

$$\text{where } \beta = \arcsin(\frac{D}{2R}). \qquad (2)$$

A captor can measure the longitudinal force F_D, this leads to the coefficient of friction μ which is the ratio between the normal force F_N and the longitudinal force F_D.

Bearing in mind the attrition application we have chosen the Dangoumeau test which allows, by an oscillating movement, shock between two balls closed in a closed jar. This can be made both in air or in water, see Fig. 2.

2.2 Materials

The zirconias used for the investigations were of two kinds: either partially stabilized with magnesia (MgPSZ) or totally stabilized with yttria (YTZP) or a mixture of yttria and ceria (YCeTZP, YC). We have also studied alumina as a reference and a composite structure containing 80 wt% of YTZP and 20 wt% of Al_2O_3 (ATZ).

PSZ samples were sintered at 1700°C for 2 h then heat-treated at 1425°C to make the tetragonal phase precipitate in the cubic matrix. The average cubic grain size was about 30–50 μm, the tetragonal precipitates being submicronic. With long soaking times at 1425°C, these grew above the critical size[8] of ≈ 0·3 μm and become monoclinic on cooling. TZP ceramics were sintered between 1350 and 1500°C for 2 h and were constituted by grains of less than 1 μm. Phase contents were determined by X-ray diffraction analysis (XRDA).[9]

The surface roughness, R_a, of the disks was about 0·002 μm after polishing, the balls were as-sintered. Other properties of the materials are listed in Table 1.

3 Results

3.1 Wear results

Wear results of symmetric couples (ball and disk of the same ceramic) are given in Figs 3 and 4. In order to be clear we have only plotted data

concerning some of the materials. No typical behaviour can be determined for MgPSZ or YTZP. The wear volume (for disks), or the scar volume (for balls), can remain quasi-constant, reach a steady-state value or increase with the friction time. A PSZ disk may react like a TZP one, whilst the wear of two TZP disks may be totally different. In fact we can only classify the ceramics according to the severity of wear, depending on the antagonist (ball or disk) and on the environment; no absolute classification is feasible. Concerning balls, however, the PSZ ceramics are less resistant than the TZP ones. We also note that the YTZP5 was the least worn TZP ceramic, both for disks and for balls and that the ATZ composite has one of the best wear behaviours.

The presence of water reduces the wear of PSZ ceramics, whereas in most cases it increases the wear of TZP ceramics as predicted by the literature[3,6] because of the destabilization of the tetragonal phase which transforms into the monoclinic one. When the tetragonal phase is very stable (YTZP3 and YTZP6) no transformation is possible and water has again a favourable effect on wear resistance (Fig. 5).

The addition of alumina in the ATZ composite leads to a better resistance (Figs 3 and 4), because of the increase in hardness. In all configurations the wear of this composite is one of the lowest. Alumina disks are just polished during friction, whereas alumina balls reacts like TZP balls.

To really compare our materials, we studied asymmetric couples where either the disk or the ball is in alumina. The wear volumes are given in Figs 6 and 7. The wear of balls rubbed against an

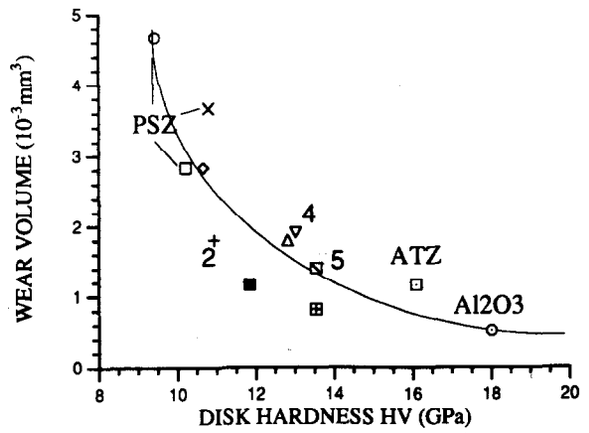

Fig. 7. Wear of Al_2O_3 ball on disk (water).

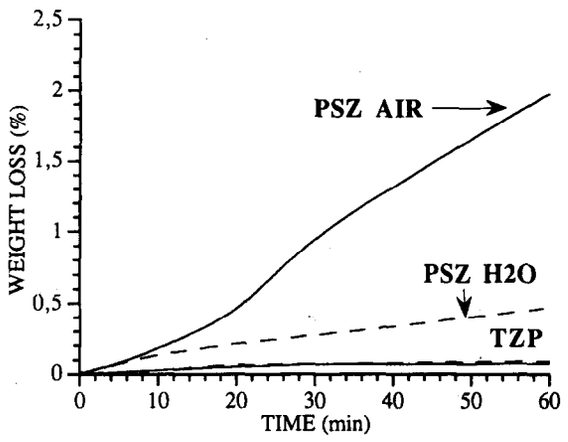

Fig. 8. Weight losses after Dangoumeau shock tests.

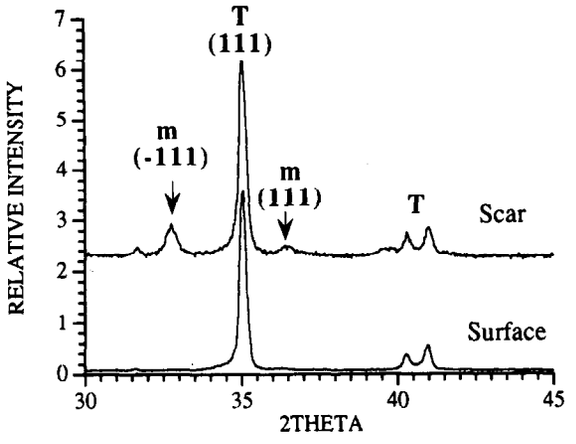

Fig. 9. Wear-induced surface transformation on a YTZP2 disk.

alumina plate had a tendency to decrease with increasing hardness, even when the wear of TZP seems to be independent of the material (except for YTZP1 and YTZP6 — see horizontal line in Fig. 6). The same tendency was observed for the wear of disks by an alumina ball: the harder the plate, the less worn. This was still true for the alumina ball which was worn more on smooth disks than on hard ones (Fig. 7). These results were valid both in air and in water.

After tests in the Dangoumeau[10] jar, the PSZ balls were strongly worn, especially in air where TZP are less sensitive. Water significantly reduces the wear of PSZ ceramics, whereas it has only a slight influence on TZP (Fig. 8). The ATZ balls were extremely spoilt and the alumina one totally destroyed (under the same experimental conditions).

3.2 Worn surface analysis

In order to understand the wear mechanisms of pins and disks, the worn surfaces were analysed both by a secondary electron microscope (SEM) with an EDAX attachment and by XRDA. A phase transformation can occur on the surface of the more transformable disks which reduces the wear rate (Fig. 9); wear debris are transformed into the monoclinic phase. When the surface of disks is too stable (no possible transformation) the disks are more worn because they are less able to absorb energy.

On the PSZ plate no real variation in the monoclinic content was observed. This can be explained by the reversal monoclinic → tetragonal transformation which takes place at the frictional interface. The tetragonal → monoclinic martensitic transformation occurs on cooling on the transformed monoclinic grains which results in a macroscopic steady-state.[11]

Wear of pins leads to the formation on the surface of a dense third body layer (Fig. 10) which consists of a mixture of the two antagonists (Fig. 11). After sliding on an alumina plate the presence of alumina on the surface of the TZP ball is obvious.

Different wear profiles are obtained after shock tests depending on the nature of the materials (Fig. 12). Grain pull-out is observed on TZP balls, transgranular fracture on PSZ balls (Fig. 12(a, b)) and macrochipping on ATZ balls with shearing of the alumina grains (Fig 12(c, d)).

4 Discussion

No significant difference between MgPSZ and YTZP can be observed after symmetric tests without shock, either in air or in water. The wear mechanism depends on the geometrical shape and not on the material. Wear of disks begins with

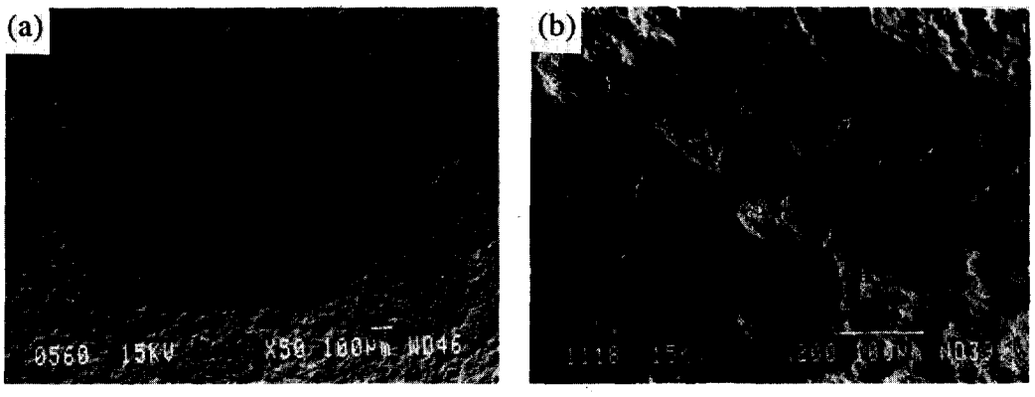

Fig. 10. Wear scar on a zirconia ball: (a) erosion of a YTZP2 ball; (b) dense layer on a YTZP4 ball.

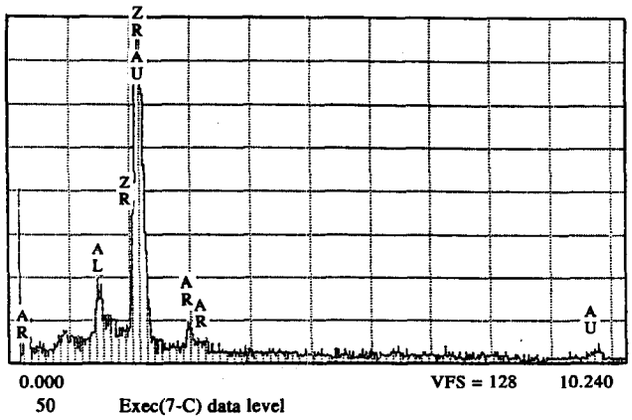

Fig. 11. Surface analysis of a YTZP2 ball rubbed on Al_2O_3. Presence of alumina on the ball.

plastic deformation or polishing of the surface, then above a typical critical strain value intergranular fracture occurs first along circular paths resulting from mechanical stresses (Fig. 13).

The properties of the materials (i.e. hardness, toughness, grain size, porosity, etc.) may influence the first steps in the wear process but then the adherence of the third body becomes the predominant factor. The constant load of 8 kg also has an influence, depending on the materials it can induce too high stress and cause severe wear.

Wear of balls starts with filing of the surface spheres and then wear is inversely proportional to the ability of debris to adhere to the surface and to form a dense protective layer. If debris cannot stick to the surface, extensive wear takes place. So the more easily the layer is formed, the less worn the pin. When these tests are conducted in water the PSZ properties are improved, those of the TZP are generally reduced (Fig. 5).

However, at this stage no real distinction can be seen between the different classes, even though the alumina–zirconia composite is in general less damaged. Friction tests with asymmetric couples clearly show the influence of material properties on wear: the soft PSZ ceramics are more worn and harder TZP ceramics are less worn against alumina, except the YTZP1 and YTZP6 balls which are less resistant.

Wear of an alumina ball on a disk confirms the important role of wear debris defined before as the third body in the interface. When sliding, the alumina ball creates abrasive debris which in turn can wear the alumina ball.

With shock tests (Dangoumeau) the TZP ceramics shows a better wear resistance than the PSZ, despite equivalent toughnesses. These tests also reveal the inadequacy of the ATZ ceramic because of the presence of brittle alumina. The analysis of the worn ball confirms that fracture occurs on alumina grains by pull-out or shearing.

Nevertheless, we can note that, for identical hardnesses and toughnesses, tribological properties can be very different. So we have to find other explanations: one may be the third body part because its adhesion to the surface is essential,

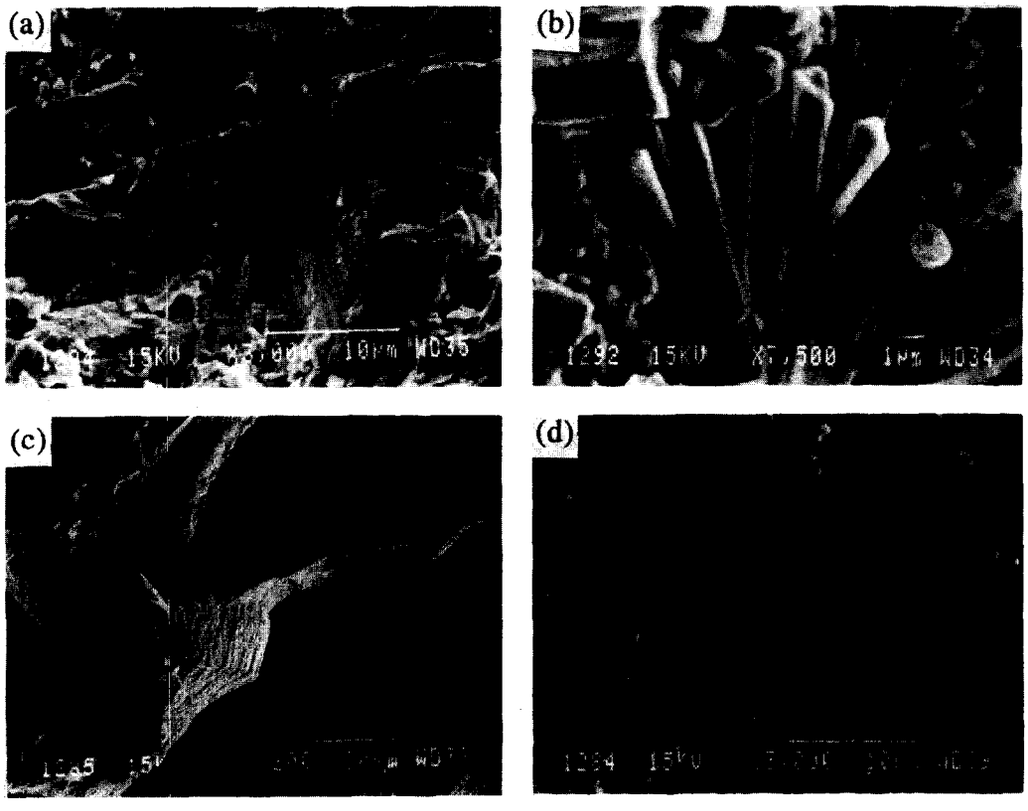

Fig. 12. Surface of worn balls after shock tests: (a, b) transgranular fracture for MgPSZ; (c, d) extensive macrochipping, shearing of Al_2O_3 grains for ATZ.

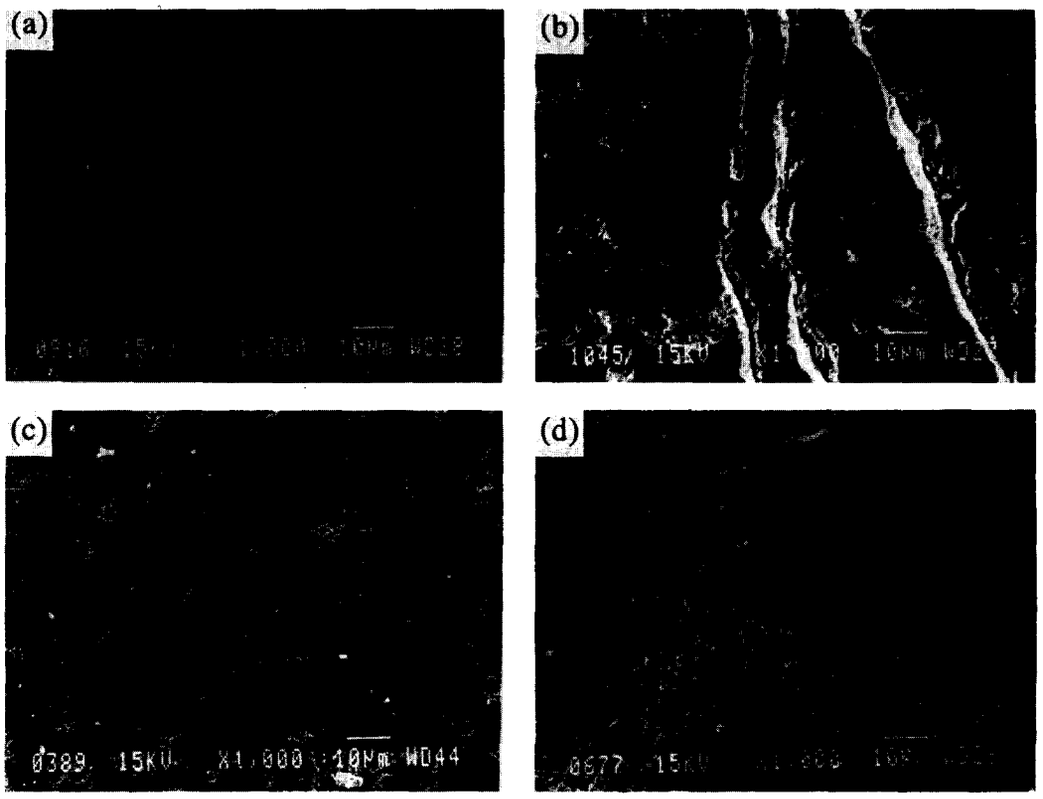

Fig. 13. Surface of worn disks after pin-on-disk tests (symmetric YTZP couple) Wear mechanism: (a) plastic deformation with micro-fracture and polishing; (b) circular fracture; (c) intergranular fracture with grain pullout; (d) failure.

however results may differ for equivalent compositions (TZP) so other properties interfere: the study of the influence of materials dielectrical properties (susceptibility) on wear is in hand. Thus electrostatic phenomena can affect:[12–14]

- — the first steps of wear (stored polarization energy relaxation which induces cracks)
- — the energetic balance of the martensitic transformation T → M
- — the charge effects (triboelectrification) in the contact area which depend on the presence of water and modify the electrostatical adherence of the third body.

5 Conclusions

With continuous friction without shock (pin-on-disk) wear of disks occurs first by plastic deformation then by microfracture, the third body debris control the final wear steps. Wear of balls depends on the ability of the dense protective third body surface layer to form. The more stable the layer, the less worn the ball. Generally speaking MgPSZ and YTZP are equivalent when tested symmetrically on a pin-on-disk tribometer. Although water has an effect on their wear behaviour, it reduces the wear of PSZ, whereas it has only a slight influence on the TZP tested. When rubbed against alumina the TZP are less worn than the PSZ. Introduction of alumina in zirconia ceramics leads to a strengthening and reduces sliding wear. TZP have a better wear resistance to shock tests than the PSZ. The addition of alumina results in the failure of the material. These results cannot be explained by the intrinsic mechanical properties of the materials. So we have to consider other parameters such as dielectrical phenomena like polarization energy, contact charges which can modify fracture of ceramics or third body adhesion.

Abstract

Spherical shaped spray-dried admixtures of chemical pure and very fine α-Al_2O_3 and quartz powders with mullite composition (72 wt% Al_2O_3, 28 wt% SiO_2) were used as starting materials. The spray-dried powders (10–100 μm) were melted in a nitrogen plasma flame and subsequently quenched in water thus producing spherical, hollow, and porous particles (≤100 μm). The as-quenched spherules consist of mullite glass, some residual α-Al_2O_3 and quartz, and a very low amount of newly formed mullite. Double quenching of the material increases the glass content to >90 wt.%. ^{27}Al and ^{29}Si MAS NMR studies show that the rapidly quenched mullite glass is composed of a network of (SiO)-tetrahedra and (AlO)-octahedra, -pentahedra, and -tetrahedra. The frequency distribution of (AlO)-structural units is similar to those in metakaolinite, type I (polymer) mullite precursors, and in other melt-quenched aluminium-silicate glasses suggesting strong structural similarities of these phases. This has been supported by the exothermic mullite crystallization process taking place at ≈ 980°C in all cases.

Introduction

Due to its excellent thermal shock and creep resistance, its high temperature strength and chemical stability mullite has become increasingly important as a structural high temperature material.[1,2] Various preparation methods have been investigated for mullite synthesis. The most important techniques are:

- mullite formation by reaction sintering of oxides or silicates,
- crystallization of mullite from melts,
- mullite formation from chemical precursors.

Conventional fabrication methods using powders or reaction sintering routes require high sintering temperatures (1600–1800°C) in order to produce dense ceramics. Ceramics with suitable densities can be achieved at much lower temperatures if chemical produced precursors are used as starting materials. An alternative method to process mullite ceramics at relatively low temperatures is densification of viscous glass particles with mullite composition and subsequent mullite crystallization.[3] However, preparation of glasses with mullite composition is difficult, since its glass forming ability is low, and extreme cooling rates are required to suppress crystallization during the quenching of the melt. This paper presents a possible glass formation route using ultra-rapid quenching of aluminium silicate liquids produced by melting the starting powder materials in a plasma flame. It also provides data on the structural constitution of Al_2O_3-rich aluminium silicate glasses.

Experimental

Starting material

An aqueous slip, corresponding to stoichiometric 3/2-mullite ($3Al_2O_3{\cdot}2SiO_2$) was prepared from chemically very pure α-Al_2O_3 (A16SG, ALCOA, USA) and quartz powders (SIPUR A1, Bremthaler Quarzitwerk, Germany). Mean grain size of the starting material as determined by laser diffraction was 0·68 μm for the alumina powder and 1·92 μm for the silica powder. The raw materials were admixed in water under conditions assuring high stability of the suspensions which was verified by zeta potential measurements (pH 10, dry matter content of 30%). Mixing took place in a vibration mill (Sweco) for 16 h using alumina balls. After milling the chemical composition of the raw materials was checked again. If there was enrichment in Al_2O_3 due to wear of α-Al_2O_3 milling balls the composition was adjusted to 3/2-mullite composition.

The slurry was spray-dried with a centrifugal rotating disc atomiser in an Anhydro Lab 1 spray dryer. By spray drying spherical agglomerates ranging from ≈ 10 to 100 μm in diameter were formed.

Plasma quenching experiments

The dried agglomerates were sprayed into a 24 kW DC plasma torch using nitrogen both as plasma and powder carrier gas (Fig. 1). The powder was introduced into the nozzle under a 70° angle. When leaving the plasma, the particles were quenched in water. Care was taken that the water surface was as close as possible to the plasma flame. A second batch of powders was prepared by sieving the already once quenched powder and quenching the fraction below 40 μm a second time. This double quenched material was used for subsequent structural investigations.

Characterization of plasma-quenched mullite glasses

The chemical composition of the starting material and of the quenched powders were determined by X-ray fluorescence analysis (ARL 8410). Differential thermal analyses (DTA) were performed with a computer-controlled Netzsch STA 409 apparatus (sensitivity: DTA: 50 mV) in air. About 80 mg of the samples and of the reference material (fired kaolinite), respectively, were heated up in Pt crucibles, with a constant heating rate of 10 K/min.

The contents of crystalline phases were determined by X-ray diffraction (Siemens D 5000 XRD equipment) comparing the diffraction line intensities of the quenched samples with those of a α-Al_2O_3 reference material.[4] Quenched powders were analyzed by optical microscopy, scanning-electron microscopy (SEM, Model 525 M, Philips) and transmission electron microscopy (Model 430 TEM, Philips, with LaB_6-filament, 300 kV accelerating voltage and a TRACOR system for energy dispersive X-ray spectroscopy (EDX)). Sample preparation for transmission electron microscopy was difficult, due to the small sizes and spherical, porous shapes of the quenched powder particles. However, by embedding the powders in epoxy and subsequent grinding and ion beam thinning electron transparent areas of a few microns were achieved.

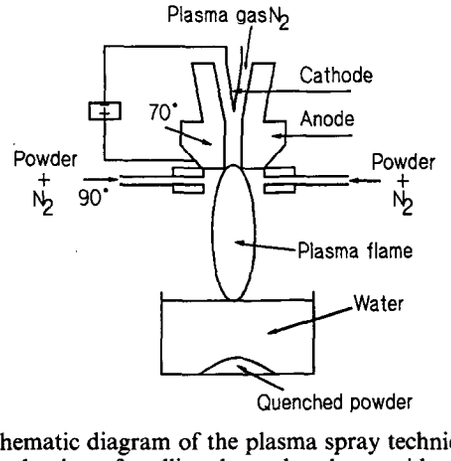

Fig. 1. Schematic diagram of the plasma spray technique used for the production of mullite glasses by ultra rapid quenching the melt droplets.

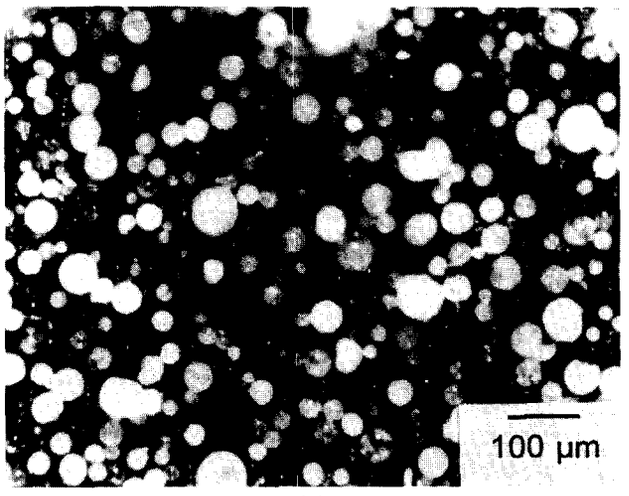
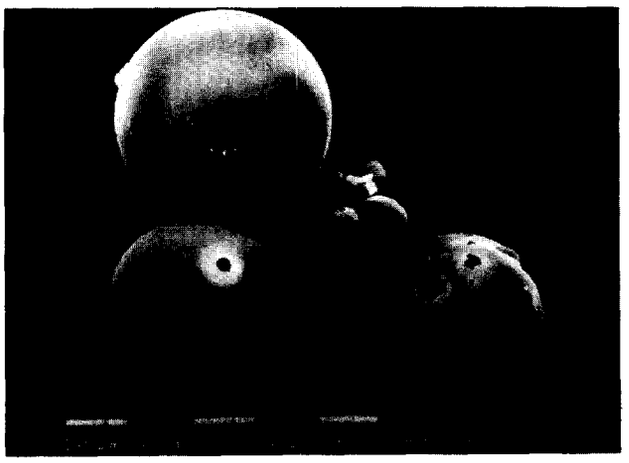


Nuclear magnetic resonance spectroscopy was performed in a Unity 500 spectrometer at 11.7T, using a Doty Scientific Magic Angle Spinning probe at a spinning speed of 10 kHz. For ^{29}Si 798 transients were accumulated with a delay of 100 s between 90° pulses. T_1 was found to be 52 + 9 s. Chemical shifts are referenced with respect to external tetramethylsilane. For ^{27}Al a 1 s delay between $\pi/12$ pulses was used and shifts referenced relative to a 0·1M aqueous aluminium sulfate solution.

Results and Discussion



The spray-dried powders used for the plasma quenching experiments consisted of spherules composed of an admixture of very small quartz and α-Al_2O_3-crystallites. The powder particles exhibit spherical shapes ranging between about 10 and 100 μm. After plasma melting and subsequent rapid quenching the batch consists of hollow and porous spherules (Fig. 2(a) and (b)) with a similar size distribution as the starting spray-dried powder. The formation of hollow and porous spherules is attributed to the fact that gas molecules incorporated in the starting spray-dried spherules rapidly expand in the plasma flame.

The smaller grain fraction (≤20 μm) of the plasma sprayed and subsequently ultra-rapidly quenched materials consists of an optically transparent glass, whereas the coarser particles (≥20 μm) frequently are non-transparent due to light scattering on crystalline phases. By means of TEM and XRD α-Al_2O_3, quartz (Figs 3 and 4), and mullite were detected. Obviously the former are relictic starting compounds, whereas mullite crystallized from the melt in regions of relative low quenching rates. The correlation between size and crystalline phase content of the quenched powders has been proved unambiguously by quantitative XRD.

In order to achieve a high degree of glass formation ultra-rapidly plasma-quenched materials with a particle size below 40 μm was plasma-sprayed again under the same experimental conditions as in the first quenching run. After double plasma quenching the amount of residual quartz

(a)

(b)

and α-Al_2O_3 is reduced considerably with respect to the powder quenched only once (crystalline phase content $\approx$10 wt%). On the other hand the amount of newly formed mullite slightly increases

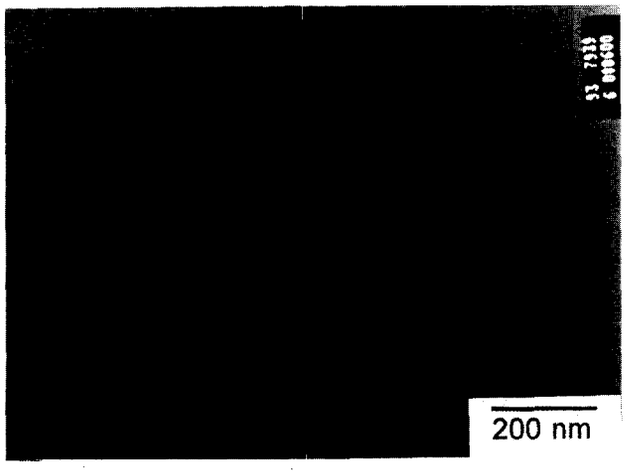

Fig. 3. Transmission electron (TEM) micrograph of ultra-rapidly quenched mullite glasses, showing a residual α-Al_2O_3 crystal embedded in a glassy matrix.

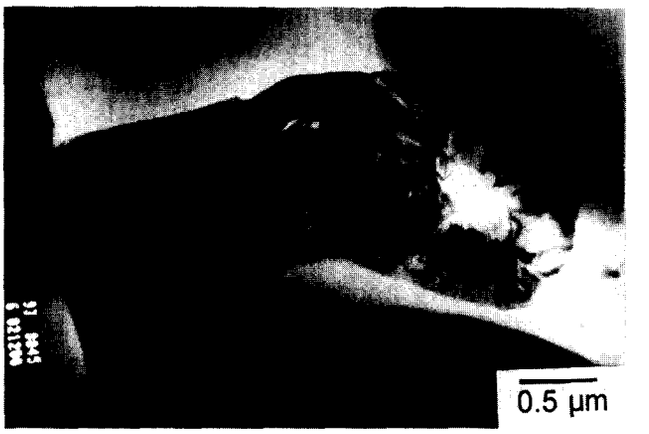

Fig. 4. Transmission electron micrograph of ultra-rapidly quenched mullite glass showing a large residual quartz crystal embedded in a glassy matrix.

in double quenched materials probably due to the crystallization of liquid phase on already existing mullite nuclei produced by the first quenching procedure.

The composition of the glass phase produced by plasma quenching as determined by EDX-analyses generally lies near 63 mol % Al_2O_3 and 37 mol % SiO_2 corresponding to a composition in between that of 3/2-mullite (60 mol % Al_2O_3) and of 2/1-mullite (66 mol % Al_2O_3). However, glass areas richer in SiO_2 are also detected. They are interpreted as to be due to unsufficient homogenization of the melt droplets during the short dwell time in the plasma flame. The fact that the bulk Al_2O_3 content of the plasma quenched powder is slightly higher than that of the starting material (74·5 wt% Al_2O_3 instead of 72 wt%) is attributed to a minor silica vaporization in the hot plasma flame.[5]

^{27}Al NMR spectra display broad signals near 2, 33, and 60 ppm and a sharp peak of higher intensity near 14 ppm (Fig. 5(a)). The broad 2, 33, and 60 ppm peaks are very similar to these described in some mullite precursors and in Al_2O_3-rich glasses in the system SiO_2–Al_2O_3.[6] They are assigned to octahedrally, pentahedrally, and tetra-

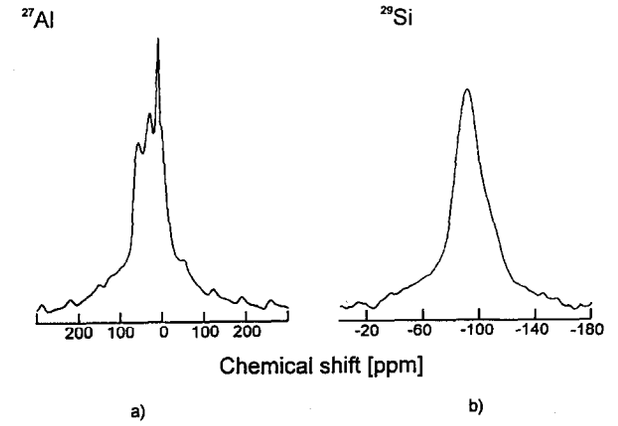

Fig. 5. Nuclear magnetic resonance (NMR) spectra of ultra-rapidly quenched mullite glass. (a) ^{27}Al; (b) ^{29}Si.

hedrally aluminium sites in the Al_2O_3-rich plasma-quenched glass, while the sharp and intense 14 ppm peak is due to the presence of α-Al_2O_3 (e.g. ref. 6). The broadness of ^{27}Al NMR-peaks associated with the glass phase show that the (Al O)-polyhedra may be distorted giving broadening by electric fields gradients or they may have a number of different environments. Though it is difficult to give quantitative approach of the relative abundance of the (Al O)-polyhedra in the glass, a predominance of (Al O)-pentahedra with respect to (Al O) octahedra and tetrahedra can be taken into account.

The ^{29}Si spectrum (Fig. 5(b)) shows a peak at –89·8 ppm and an upfield shoulder. The spectrum can be deconvoluted to show a peak at –89·3 ppm with 70% of the intensity and one at –104·8 with 23% of the intensity; the remaining 7% is a peak at –47·9 ppm. A slightly improved fit is found by fitting to four broad peaks with positions and intensities: –52·6 ppm (11%); –85·2 ppm (19%); –91·6 ppm (48%); –106·0 (22%). Thus about 22% of the Si occurs in a peak near –106 ppm with a width of 2300 Hz. This position is consistent with amorphous SiO_2 and the width indicates a variety of environments as often found in glasses, perhaps with contributions at more positive shifts from incorporation of Al. The main peak near –89 ppm is close to that in mullite itself. According to the studies of Engelhardt and Michel[7] and Mägi *et al.*[8] this is likely to arise from Si with a fully condensed oxygen network and perhaps surrounded by four Al cations; which fits well with the Al_2O_3-rich composition of the glassy phase. Again, the width of this peak (1900 Hz) indicates a variety of environments as often found in glassy materials. The peak near ≈50 ppm interestingly appears in the chemical shift region expected for silicon nitride or sialon which might form by high temperature reactions in the nitrogen plasma flame.

According to the ^{29}Si and ^{27}Al NMR studies the structural short-range-order of the (Si O)-tetrahedra, and of (Al O)-octahedra, -pentahedra and tetrahedra is very similar to these of metakaolinite, type I (polymer) mullite precursors and of melt quenched Al_2O_3-rich glasses of the system Al_2O_3–SiO_2 (see e.g. Schneider *et al.*[9]). The structural similarity of these materials also becomes evident by their crystallization behaviour. Differential thermal analysis (DTA) measurements carried out on corresponding powders all exhibit sharp and strong exotherms near 980°C which is associated with mullite crystallization in each case (Fig. 6). In a previous study on the constitution on non-crystalline mullite precursors it was suggested that the driving force of the 980°C reaction process is the dissappearence of (Al O)-pentahedra

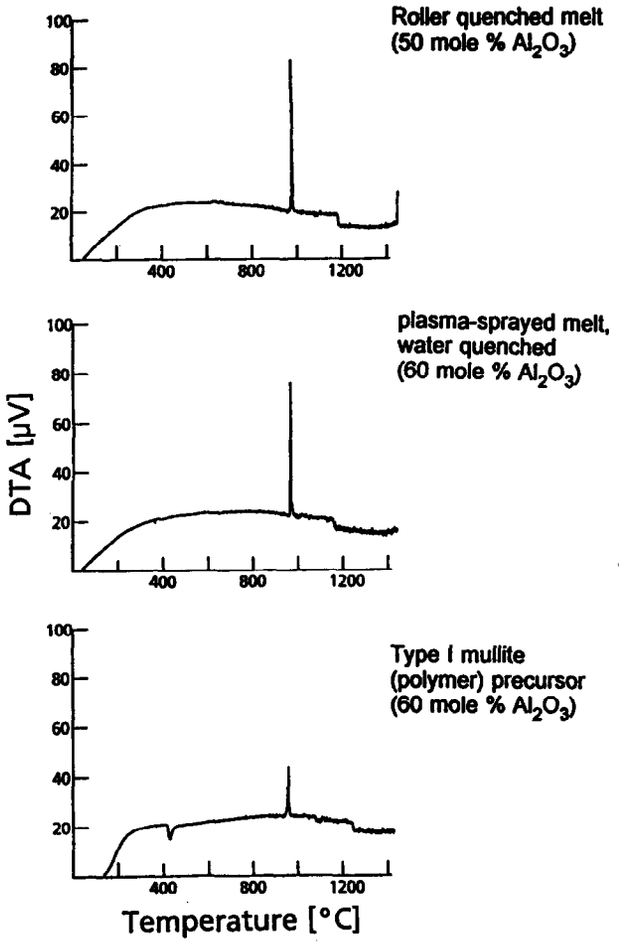

Fig. 6. Differential thermal analysis (DTA) curver of ultra-rapidly quenched mullite glass in comparison to type I (polymer) mullite precursor and roller-quenched aluminium silicate glasses.

due to its sudden instability in this temperature range and subsequent crystallization either of mullite or γ-Al_2O_3.[9]

It is an important result of the present study that mullite-type melt glasses can be produced under the extreme conditions of plasma spraying and subsequent water quenching, in spite of the extremely low viscosity of the melts.[10] However, glass formation is strongly influenced by particle size, which limits melting rate as well as quenching rate. Since the particles are melted in the plasma flame by propagation of a melting front from the outside to the inside of the particles[11] coarser grains cannot be completely melted in the plasma due to the low thermal conductivity (a few W/mK) of the material and the short dwell time in the plasma flame (about 1 ms[12]). On the other hand it is known from experiments of Gani and McPherson[3] that mullite formation by quenching melt droplets into water can be suppressed only if particle size remains below 19 μm. The size limit of glassy particles of ≈20 μm determined in our study agrees well with the observation of Gani and McPherson.

Abstract

Three different approaches have been investigated to synthesize alumina–chromium composites by displacement reactions between aluminium and chromia. The reactions have been performed either by pure mechanosynthesis or pure thermal ignition or also by a combined mechanical and thermal activation process. Differential thermal analysis, dilatometry and high temperature X-ray diffraction have been used to show the various reaction mechanisms and chemical transformations. High-energy milling of the powder modifies the reactivity of the system. A partial pre-milling treatment not only reduces the reaction temperature but can also induce a different reaction path. It has been shown that an appropriate mechanical–thermal treatment leads to the synthesis of an alumina–chromia composite by a pure solid-state process: intermediate reaction stages exhibit little if any liquid phases.

1 Introduction

Solid-state displacement reactions proceed generally by diffusional transformations whereby two or more reactants form new product phases.[1] Such reactions are of considerable interest for producing ceramic/ceramic or metal/ceramic composites *in situ* with novel microstructures and possibly improved properties.[1–6] Depending upon the thermodynamic and kinetic parameters of the reacting system, several types of product morphology can be obtained: from interwoven to more or less connected and dispersed microstructures.[7] The control of such morphologies during synthesis is a critical aspect of these processes. Their detailed mechanisms and kinetics have been investigated in several typical cases and found to be strongly related to the diffusion paths and rates of individual species within the corresponding multicomponent system.[8–9]

In a conventional, thermally activated system, the diffusion processes are strongly related to temperature and the microstructure then depends on the thermal schedule. Nevertheless, for the case of some thermite reactions or self-propagating high temperature synthesis reactions (SHS), the prediction and control of the product morphology are less straightforward. In this type of reaction, involving for example the reduction of metallic oxides with aluminium to yield alumina and metals, a large quantity of heat is released,[10] which may be sufficient to heat some of the phases present above their melting points, thus making the control of microstructure difficult. Fine interwoven or dispersed homogeneous microstructures, favourable *a priori* for reaching high composite strength and toughness for example, require that displacement reactions be effected in carefully optimized conditions.

To this aim, a mechanical initiation of the reaction, referred to as 'mechanosynthesis', has been proposed as an alternative to the more classical thermal initiation. This mechanical process consists of repeated welding, fracturing and rewelding of powder particles in a high-energy ball charge. Reactive powder surfaces are brought into intimate contact and chemical reactions may take place gradually by short-range interdiffusion across welded interfaces. Then, after an appropriate milling time, the powders consist of finely divided, nanometre-sized crystallites with a high defect density and interface content. The exchange reaction occurs during this room temperature process. Sometimes the heat released during the reaction may initiate an unstable combustion effect which leads to a partial melting of the product and/or a phase separation as previously described, but in such a case a chemically inert substance[11] or a less reactive milling[10] can be used to keep the process under control. Although mechanosynthesis appears a simple and promising technique to

*To whom correspondence should be addressed.

yield homogeneous composite powders with nano-type characteristics, the benefits due to the displacement reaction approach may not be fully achieved as subsequent firing, necessary for consolidation into solid pieces, usually brings about coarsening and perhaps side reactions. Moreover, contamination from the milling environment is difficult to avoid.

To gain better understanding of the specific features, mechanisms and kinetics of reaction as influenced by thermal and mechanical activations respectively, the present experimental programme was devised so that sound comparisons could be made between either approach. It is conceivable that the results of such an investigation may subsequently find practical applications in composites processing via an optimized sequence of partial milling in order to bring the degree of reaction advancement to some appropriate level, followed by more conventional thermal activation up to completion. Three sets of experiments were consequently performed with a simple model system. The first one, consisting of pure thermal activation, was carried out with a blend of chromia and aluminium powders. The second, consisting of pure mechanical activation, was conducted by high-energy milling up to completion of the reaction. Finally, a combined mechanical and thermal activation was performed by short milling times followed by thermal treatment. These short milling times do not exceed the incubation time for the reaction when performed by grinding at room temperature.

2 Experimental Procedures

The starting high purity (>99·9%) powder materials were metallic aluminium and chromium oxide (Cr_2O_3). Average particle sizes of both these powders were in the micrometre range: 1·3 and 0·5 μm, respectively. The as-received atomized aluminium powders were oxidized on their surface and their typical alumina content was 0·5–1 wt%.[12]

Powder blends of aluminium and chromia were prepared in proportions corresponding to the reaction scheme:

$$Cr_2O_3 + 2Al \rightarrow Al_2O_3 + 2Cr \qquad (1)$$

Milling was carried out in a planetary ball-mill (Fritsch Pulverisette 7) under argon atmosphere. Grinding utensils (seven balls of 15 mm diameter and vials) were either hardened chromium steel or tungsten carbide.

Thermal differential analyses were performed with a Setaram HTC-1800K equipment under argon flux. Heating rate was 10 K min^{-1} and alumina was used as reference. Dilatometry experiments used an Adamel-Lhomargy DI 24 dilatometer under argon flux from 20 to 1500°C at a rate of 10 K min^{-1}. Samples (5 × 5 × 15 mm) were obtained by cold pressing the powders.

The resulting products were characterized at room temperature by X-ray diffraction (XRD) using CoK_α radiation. The mean crystallite size was estimated from the full-width at half-maximum of X-ray peaks.[13]

In addition, high temperature X-ray diffraction (HT-XRD) was used to follow directly the progress of reaction in samples pre-milled for different times with hardened steel tools. The XRD unit was a Philips powder diffractometer with a vertical goniometer PW 1050/25, graphite monochromator PW 1752/00, proportional counter for reflected beam PW 1711/10 and PW 1730/10 generator. The XRD was controlled by a PW 1710 diffractometer control system. The raw data were collected, processed and analysed with APD 1700 software supplied by Philips. The high temperature unit is based on an Anton-PAAR HTK-10 high temperature chamber. This standard equipment was re-engineered to increase the maximum working temperature to 2300 K. In designing the high temperature attachment, much attention was paid to the heating element. The platinum strip which is used as heater in the standard HTK-10 equipment was replaced by a graphite furnace.[14] The generator settings were 50 kV and 30 mA with a Cu-target tube. The temperature of the samples was measured with a Pt–13% Rh/Pt thermocouple. The runs were conducted with a quasi-constant heating rate of 7°C min^{-1} in a static helium atmosphere of 0·11 MPa. All scans were performed over a 2Θ range of 20–60°.

3 Results and Discussion

3.1 Thermal displacement reaction

Uncompacted $2Al/Cr_2O_3$ powder mixtures were heated to 1500°C in argon. These mixtures reacted, the chromium oxide being reduced by aluminium. The corresponding DTA is shown in Fig. 1. The endothermic melting of aluminium is quite apparent at 660°C, and the aluminothermic reaction is seen to initiate at 800°C and be completed at about 1200°C. The XRD analyses confirmed that the reaction products consisted of α-Al_2O_3 and chromium metal. HT-XRD revealed an amorphous liquid phase around 650°C, corresponding to the melting of aluminium (Fig. 2). No other intermediate transient phases were detected. Chromia is reduced in the simple direct but progressive way according to the following reaction as expected:

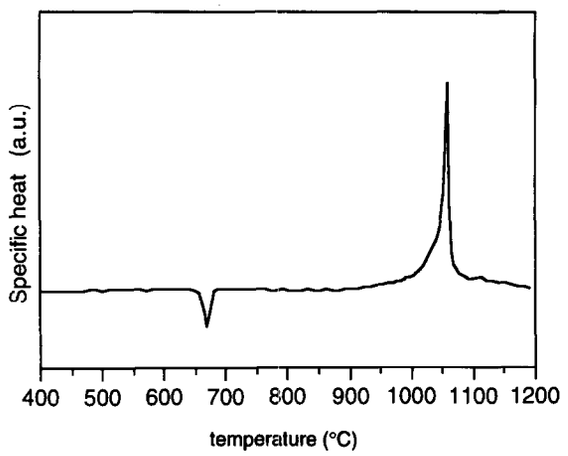

Fig. 1. DTA of 2Al + Cr_2O_3 powders (dT/dt = 10 K min^{-1}).

$$Cr_2O_3 + 2Al_{(liq)} \rightarrow \alpha\text{-}Al_2O_3 + 2Cr \quad (1)$$

Dilatometry experiments confirmed the melting of aluminium and showed a sudden expansion of the sample (Fig. 3). The slight shrinkage observed just before aluminium melting can be explained by particle rearrangements favoured by the increasing ductility of the Al phase. The slope discontinuity at 850°C has not yet been unambiguously rationalized. It does not result from the overall molar volume change which is negative for reaction (1). Neither can it be ascribed to an effective thermal expansion coefficient which would be higher after

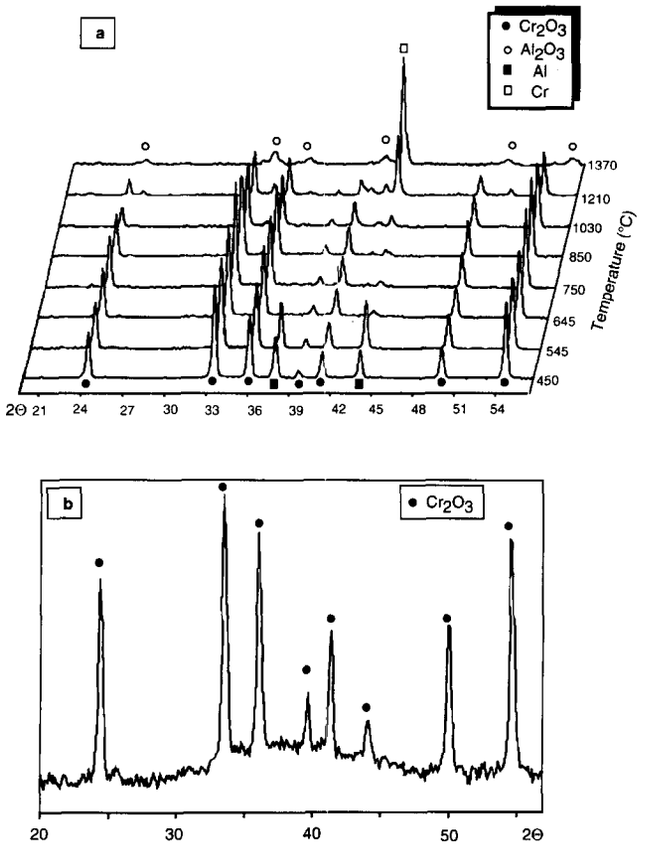

Fig. 2. HT-XRD patterns of 2Al + Cr_2O_3 powders: (a) as a function of temperature; (b) T = 650°C.

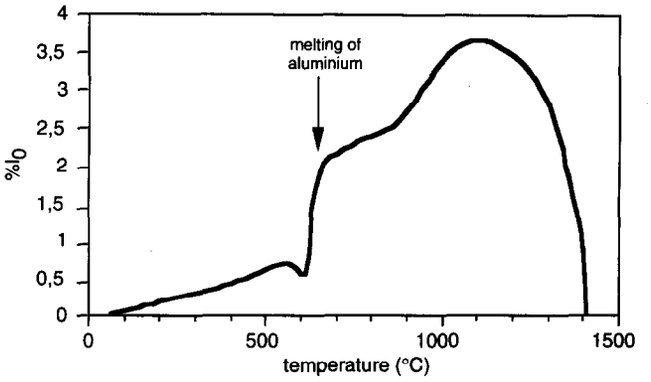

Fig. 3. Dilatometry of 2Al + Cr_2O_3 powders (dT/dt = 10 K min^{-1}).

the system has reacted than before, because re-heating the same sample after cool-down yields a different and smaller slope than upon this first heat-up. Bloating due to some gas evolution can also be ruled out since thermogravimetric experiments showed that, if anything, the sample mass tended to increase very slightly (presumably due to oxidation by residual oxygen present in the system). It may nonetheless be worth pointing out that 850°C coincides with the temperature at which Al_2O_3 characteristic lines are first detected on the HT-XRD patterns.

3.2 Mechanosynthesis

The synthesis of nanocomposite powders of alumina–Cr has been investigated by reactive milling with either hardened steel or tungsten carbide tools. In the former case, only a partial reaction was obtained. Even milling for 48 h was not enough to reach a complete transformation of the initial mixtures. In the latter case, the reaction starts suddenly after ~15 min incubation milling time (Fig. 4), then the reaction needs 1 h to be completed. Beyond that time, the XRD patterns show peaks of α-alumina and chromium, neither chromia nor aluminium could be detected by XRD.

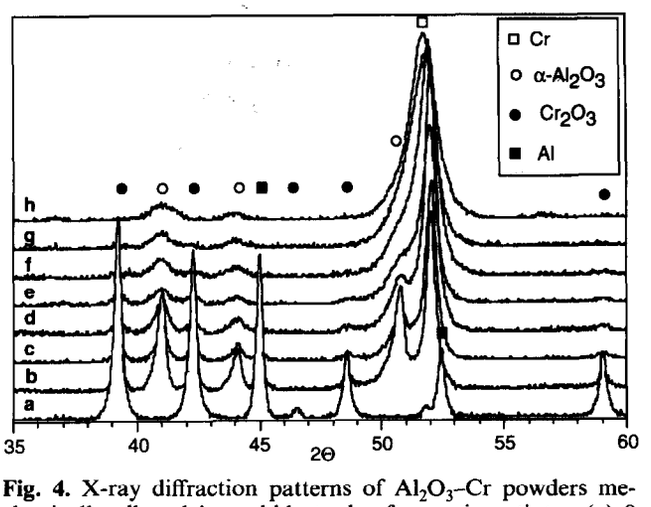

Fig. 4. X-ray diffraction patterns of Al_2O_3–Cr powders mechanically alloyed in carbide tools after various times: (a) 8 min; (b) 15 min; (c) 23 min; (d) 30 min; (e) 45 min; (f) 60 min, (g) 90 min; (h) 180 min.

After 1 h, nanometre-sized crystallites are produced from micrometre-sized powders (Fig. 5). And after a milling time of 3 h, for example, the mean crystallite size lies around 10 nm for both Al_2O_3 and Cr. The corresponding particles show homogeneous sub-micrometre microstructure of α-Al_2O_3 and chromium (Fig. 5).

No major changes were detected by differential thermal analysis on the powders milled for 3 h except for a large variation of the baseline up to 800°C. The diffraction patterns of samples before thermal treatment are identical to those of the original milled powders, except for the line width. Such variation of the DTA baseline and X-ray peak profiles with decreasing width reflect crystallite growth. Significant crystallite growth occurred only after reaching 900°C.[15]

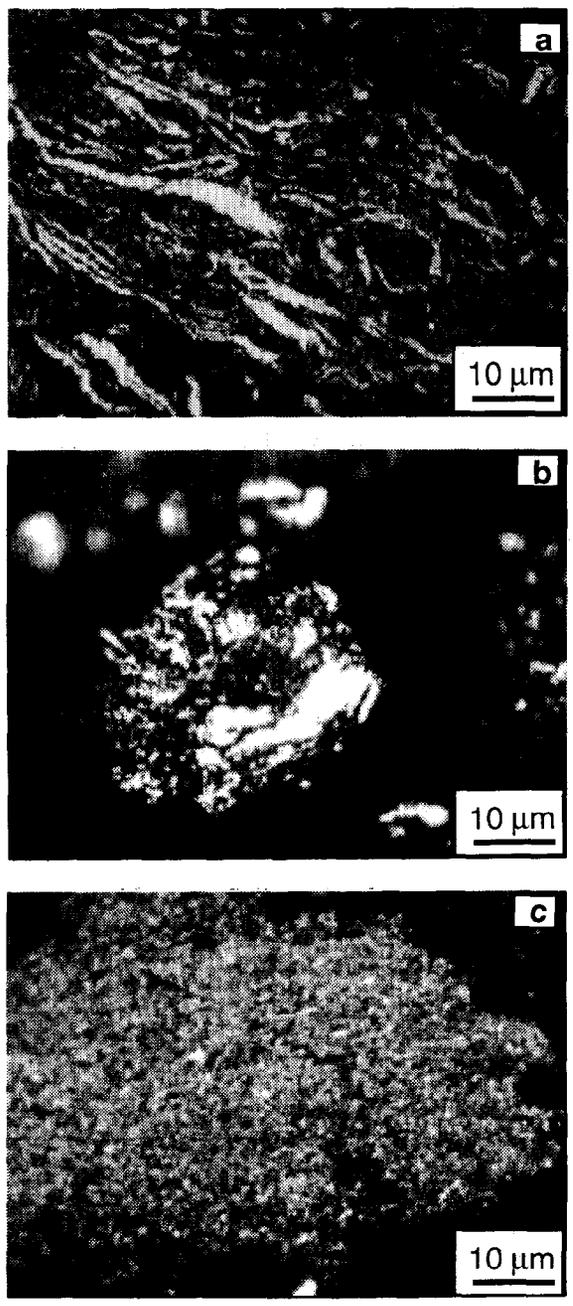

Fig. 5. Optical micrographs of Al_2O_3–Cr powders prepared by mechanosynthesis 2Al + Cr_2O_3 powders after various milling times: (a) 20 min; (b) 60 min; (c) 180 min. Light phase: chromium, dark phase: alumina.

3.3 Combined mechanical–thermal synthesis

The above experiments have shown the existence of an 'incubation time' during mechanosynthesis. A certain level of mixing, particle refinement and accumulation of lattice defects are thought to be needed for ignition, and then the combustion reaction may be completed rather quickly. The pre-ignition time depends on the experimental conditions and the start of the reaction is a direct consequence of the so enhanced chemical reactivity.[16]

To gain a better understanding of the effect of short milling on the subsequent course of events, two-stage experiments were carried out. The powders were mechanically alloyed with steel utensils using different grinding times within the incubation period, and the resulting powders then were thermally treated. The choice of steel grinding tools was made so that the kinetics of mechanosynthesis be slower and the incubation time longer than with the carbide utensils.[10] The reduction was studied by DTA (Fig. 6), dilatometry (Fig. 7) and high temperature X-ray diffraction (Fig. 8).

For the powders milled for 5 min, these different experiments revealed no large differences compared with the unmilled powders, i.e. the melting of aluminium and the occurrence of the displacement reaction were still observed in the range 650–750°C and 800–1200°C, respectively. Thus the first 5 min can be viewed as a time of mixing and of homogeneization at the particle size scale. No significant energy due to grinding is present in the

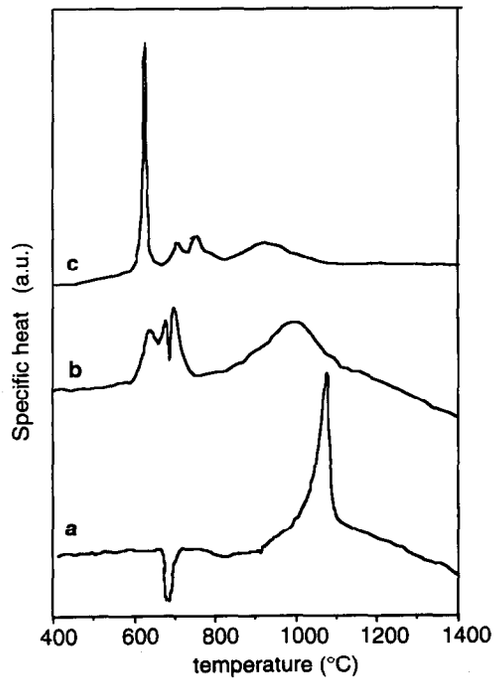

Fig. 6. DTA of milled 2Al + Cr_2O_3 powders (dT/dt = 10 K min^{-1}) after (a) 5 min, (b) 15 min and (c) 30 min.

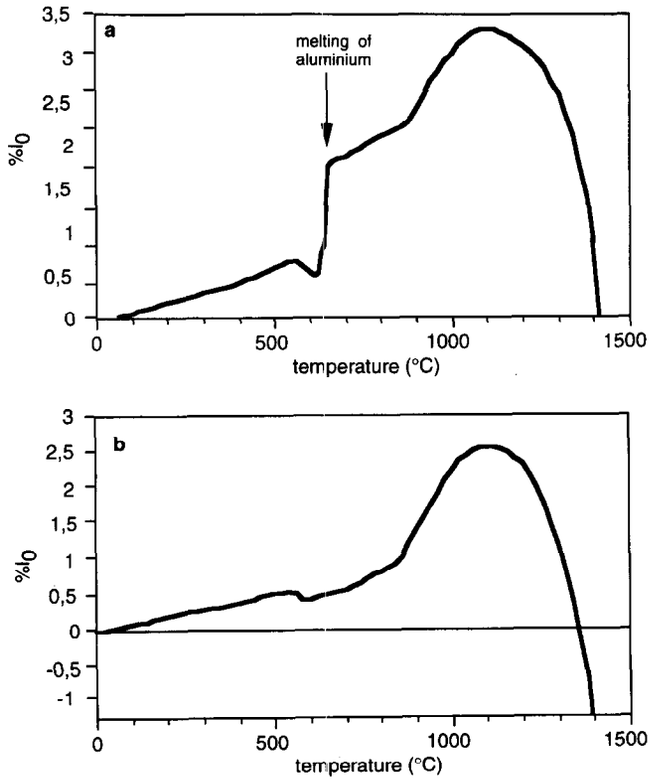

Fig. 7. Dilatometry of 2Al + Cr_2O_3 powders mechanically alloyed for (a) 15 min and (b) 30 min (dT/dt=10 K min $^{-1}$).

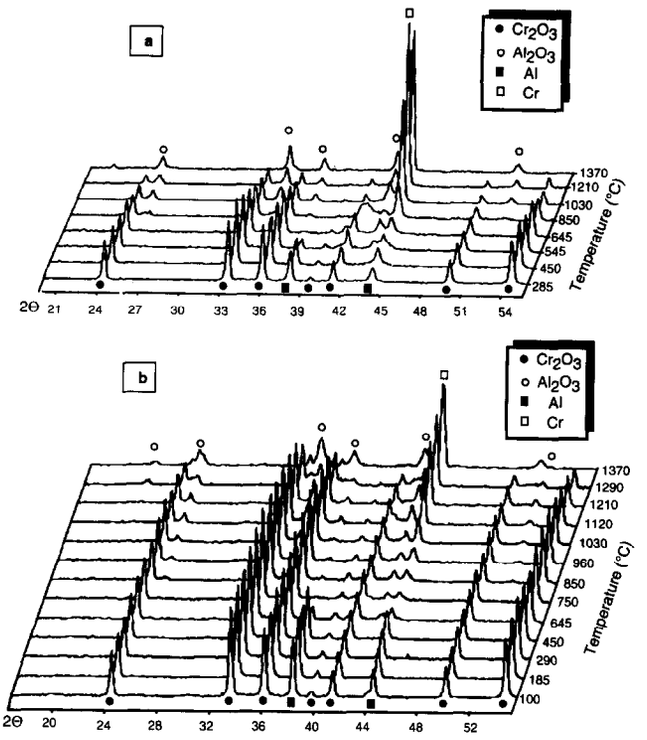

Fig. 8. HT-XRD patterns of 2Al + Cr_2O_3 powders mechanically alloyed for (a) 15 min and (b) 30 min.

crystallite, except possibly for a small amount of extra surface energy arising from a small reduction of average particle sizes.

For longer milling times (15 and 30 min), the experiments showed drastic differences. Concerning the melting of aluminium, we observed near 660°C a progressive decrease both of the endotherm in the DTA curves and of the expansion effect in the dilatometry curves. With the 30 min milled powders it was not possible to detect any aluminium melting. Parallel to this phenomenon, the large exotherms in the DTA curves due to the displacement reaction were modified. New exotherms appeared in the range 550–700°C, while the large exotherm centred near 1100°C progressively decreased in intensity with milling time and was shifted to lower temperatures. For the 30 min milled powders, only a weak thermal effect was observed between 800 and 1000°C, but a large exotherm was observed at 620°C. On the other hand, except for the modification of the aluminium melting, the dilatometry recordings were similar to those obtained with the unmilled thermally reacting system (Fig. 3).

The HT-XRD patterns help clarify the reaction path. First of all an amorphous liquid phase is observed around 650°C with the powders milled for short times. But this phase could not be observed for the 30 min powders. For this milling time, a solid-state reaction was obtained without any intermediate liquid phase.

For the 5 min milled powders, the (110)Cr peak was observed above 850°C and the converted fraction of chromia strongly increased above 1000°C. For the 30 min milled powders, however, a small amount of metallic chromium was detected at room temperature and the converted fraction of chromia was seen to increase above 600°C. The 15 min sample appeared to exhibit an intermediate behaviour and two steps may be identified. A first formation of chromium is observed in the range 650–800°C and a second formation appears above 1000°C. The temperature intervals of both chromium formation steps appear to correspond to exotherms observed on the DTA curves. Each exotherm, either between 600 and 650°C or 850 and 1200°C, thus corresponds to the heat released by the reduction of chromia by aluminium. It is interesting to note the presence of an intermediate second low temperature exotherm (650–750°C). This one is thought to be related to the transient formation of Al_7Cr and/or Al_6Cr compounds[17] observed by HT-XRD on the 15 and 30 min samples. The X-ray peaks were too few and too weak to allow for their compositions to be more precisely established but it is thought that formation of these phases is due to the reaction between the already formed chromium and the not yet reacted aluminium.

In summary, the present experiments revealed two different chemical reaction paths: a classical 'non-milled reaction' path (near 1000°C) between Cr_2O_3 and liquid aluminium, and a modified 'milled reaction' path (near 600°C) which is a pure solid-state reaction.

4 Conclusions

The present experiments show that, depending on activation mode and milling time, a displacement reaction path can be modified by an appropriate choice of experimental conditions. The onset of a reaction is essentially determined by its activation energy, i.e. the difference in energy between the activated and the initial states. Repeated milling enhances the reactivity of powder particles via the development of large amounts of interfaces and defects. During an 'incubation period', chemical characteristics are modified and energy is being stored in the powders, thereby reducing the activation barrier compared with that of the classical reaction route. If the thermal treatment provides an energy to overcome the activation barrier, due to the modification of the reaction path, the reaction may initiate at lower temperature and could result in different final microstructures.

Some monitoring of this residual activation barrier is then possible by the way of choosing the grinding conditions. Then, by appropriate choices of the chemical status of the reactants and the operating conditions (grinding and heating), the systems are allowed a greater freedom in selecting reaction paths than with temperature as the only activation parameter. The ability to control the size and morphology of the composite particles, while not demonstrated here, gives thermal–mechanical displacement reaction processing important advantages over other routes of synthesis. By avoiding the formation of liquid phase, such oriented reaction paths could bring novel solutions to the development of a whole range of composite microstructures.

(Received 10 March 1995; revised version received 12 May 1995; accepted 31 May 1995)

Abstract

The incorporation of Al into nitrogen (N-)melilite phases has recently been reported [Cheng and Thompson, J. Am. Ceram. Soc., *77, 143–48 (1994)]. This occurrence allows simultaneous substitution of Al and O through replacement of Al–O for Si–N bonds and therefore, may offer potential improvement to the oxidation resistance properties of original N-melilite, which in the past was a problem that deterred the utilization of N-melilite as a grain boundary phase for Si_3N_4-based ceramics. In this work, the techniques of X-ray diffraction, scanning electron microscopy with quantitative energy dispersive X-ray spectroscopy and solid state ^{27}Al and ^{29}Si nuclear magnetic resonance spectroscopy with magic angle spinning have been used to study the solubility of Al in the structure of neodymium and samarium N-melilite phases.*

1 Introduction

N-melilites have the general formula $R_2Si_3O_3N_4$ (where R = yttrium or rare earth metals) and occur as an intermediate phase during the sintering of some Si_3N_4-based ceramics.[1] N-melilite has a tetragonal structure that is built up of an infinite linkage of corner-sharing $Si(O,N)_4$ units in tetrahedral sheets perpendicular to the [001] direction. Sandwiched between these sheets are Y^{3+} or rare earth Ln^{3+} ions which hold the silicon oxynitride layers together.[2] With a high nitrogen content of 67 eq%, N-melilite is very refractory; a melting point of ~1900°C has been quoted for yttrium N-melilite.[3] This feature alone makes N-melilite attractive as a grain boundary phase in Si_3N_4-based ceramics since the grain boundary phases control the high temperature performance of the materials, and grain boundary phases with superior thermal and chemical stability at elevated temperatures are highly sought after in Si_3N_4 materials research. Moreover, N-melilite is located in the phase compatibility regions of α and α–β SiAlONs, which in theory, can produce a good microstructure of SiAlONs with melilite as the only other secondary phase. These two characteristics of N-melilite combine to make it a potentially suitable grain boundary phase for Si_3N_4-based engineering ceramics. However, research in N-melilite has been slow coming primarily due to the poor reputation it has acquired during the early years of Si_3N_4 development. When yttria (Y_2O_3) was used in the 1970's as a sintering additive for Si_3N_4, a large number of silicon oxynitride phases emerged and N-melilite was one of them.[2] However, it was soon discovered that Si_3N_4 materials containing N-melilite had poor oxidation resistance with N-melilite oxidising rapidly at ~1000°C to form cristobalite and β-$Y_2Si_2O_7$.[3] The associated volume expansion of ~30% from the oxidation products caused extensive cracking of the ceramic component and presence of N-melilite has since been deemed undesirable.

Recent studies[4,5] have observed a significant solubility of Al in N-melilite phases resulting in a solid solution of the general formula, $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ designated as M'_{ss}. In M'_{ss} phases, Si–N bonds are progressively being replaced by Al–O bonds as the Al solubility in the structure increases and this increase in oxygen content may provide a possible solution to the oxidation problem described above. M'_{ss} is gaining interest as a refractory grain boundary phase for SiAlON ceramics[6] with particular interest in the extent of Al solubility in M'_{ss} phases which will lead to a better understanding of their structure and properties and hence, the usefulness of these materials.

2 Experimental

Eight neodymium samples with the designed composition of $Nd_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ (x = 0·0, 0·2, 0·6, 0·8, 1·0, 1·2, 1·4 and 2·0) along with two samarium

samples of composition $Sm_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ (x = 0·2 and 1·0) were prepared from the starting powders of Si_3N_4 (Starck Berlin LC10), AlN (Starck Berlin Grade C), Al_2O_3 (Unilab) and Nd_2O_3 (CERAC), or Sm_2O_3 (Fluka) as appropriate. The surface oxide in both 'Si_3N_4' and 'AlN' was compensated using the calculated formulae of $Si_{2.823}N_{3.645}O_{0.177}$ for 'Si_3N_4' and $Al_{1.014}N_{0.985}O_{0.043}$ for 'AlN', which allow 4·0 wt% of SiO_2 for the Si_3N_4 powders and 3·5 wt% Al_2O_3 for the AlN powders. The pelletised powder mixes weighing approximately 3 g were placed into a BN-coated graphite crucible and sintered in an induction heating furnace with flowing nitrogen gas at 1700°C for 1 h. Weight loss of the samples after firing was less than 3 wt%.

The density of the sintered samples was determined by water immersion technique based on Archimedes Principle and all samples were boiled in water for 1 h prior to measurement. The crystalline phases were determined from powder X-ray diffraction (XRD) using a Rigaku Geigerflex diffractometer. Unit cell dimensions of the phases were calculated from the measured XRD peaks using a least square method[7] after calibration with Si as an internal standard. The actual Al content in the M'_{ss} phases was determined from quantitative EDXS using a ZAF correction method[8] with Y_2O_3 and elemental Al and Si as standards. The data was collected using a Jeol JSM-840 microscope operating at 10 kV and probe current of 1 nA with the final result being the mean of 10 experimental points. Micrographs of the phases were also taken with the Jeol JSM-840 operating in backscattered mode. MAS-NMR analysis was performed on a Varian VXR-600 spectrometer operating at 156·32 MHz for ^{27}Al and Bruker MSL-400 spectrometer operating at 79·47 MHz for ^{29}Si. The powdered samples were packed into conventional zirconia spinners and were spun at 12 and 4·5 kHz for ^{27}Al and ^{29}Si, respectively. ^{29}Si spectra were accumulated using 1·5 μs (tip angle ~30°) pulses with 15 s recycle delays while the corresponding conditions for ^{27}Al were 0·65 μs (15°) pulses and a 1–2 s recycle delay. ^{27}Al spectra were referenced against an external secondary standard of $Y_3Al_5O_{12}$ (AlO_6 = 0·7 ppm with respect to $[Al(H_2O)_6]^{3+}$). ^{29}Si MAS-NMR spectra were referenced to tetramethylsilane (TMS) at 0 ppm.

3 Results and Discussion

3.1 Weight loss and density

Compositions, weight loss and density of the neodymium samples after sintering at 1700°C for 1 h are shown in Table 1. There appears to be a trend whereby reduction in weight loss is accompanied by Al addition. The Al-free sample, N0 has a weight loss (ΔW) of 2·7% and this is reduced to 0·6% in the highest Al-containing sample, N20. All samples have a weight loss of < 3·0% which may in part be responsible for the relatively single-phase melilite samples obtained here since low weight loss is indicative of minimal changes to the starting composition during sintering. Density increases substantially with increasing Al addition, from 3·267 g/cm^3 in sample N0 to 4·618 g/cm^3 in sample N20. With increasing Al addition, the formation of a liquid phase which may possess a lower viscosity than the Al-free melilite composition is promoted, facilitating densification. The relatively high density of samples N14 and N20 may in part be due to the large amount of $NdAlO_3$ found in those samples since $NdAlO_3$ has a higher density than N-melilite.

3.2 Crystalline phases

The crystalline phases of the sintered samples as detected by X-ray diffraction (XRD) are shown in Table 1. Most of the samples except those with a high Al content produce almost single phase melilite with only trace amounts of apatite ($Nd_{10}(SiO_4)_6N_2$) and wollastonite ($NdSiO_2N$).

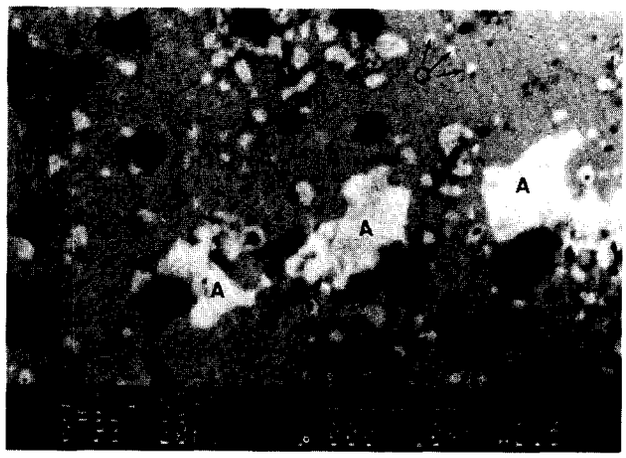

Table 1. Weight loss, density and crystalline phases of the sintered $Nd_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ samples

M = N-melilite ($Nd_2Si_3O_3N_4$); M'_{ss} = Al-containing N-melilite ($Nd_2Si_{3-x}Al_xO_{3+x}N_{4-x}$); A = apatite ($Nd_{10}(SiO_4)_6N_2$); W = wollastonite ($NdSiO_2N$).
X-Ray intensities: s = strong, m = medium, w = weak, v = very.

Neodymium N-melilite is detected in the Al-free sample N0, but from sample N2 onwards, the d-spacings for melilite phases continuously increase with Al addition indicating the formation of neodymium M'_{ss}. Similar to samarium and yttrium M'_{ss} phases,[4,5] the neodymium analogues do not display a different XRD pattern from that of Al-free N-melilite, implying a random solid solution with Al which does not alter the original melilite crystal structure. Apatite is observed in small amounts in all the sintered products and since there has been very little change in its lattice spacing, very limited Al, if any, is incorporated into the apatite structure.[9] Wollastonite is also detected in some of the samples. Neodymium wollastonite forms at a relatively low temperature and is unstable at high temperatures, melting at approximately 1700°C.[9] Slasor *et al.*[9] reported that wollastonite formation was dependent on firing schedule and with fast cooling, wollastonite did not appear. The wollastonite present here could have been retained during firing at 1700°C or it may have precipitated during the cooling process. Similar to apatite, neodymium wollastonite also exhibits limited Al solubility.[9] $NdAlO_3$, which is detected from sample N6 onwards forms readily and its concentration increases systematically with increasing Al content. In the Al-rich samples, N14 and N20, $NdAlO_3$ becomes the principal phase although M'_{ss} is still clearly present. A further increase in Al_2O_3 could only make $NdAlO_3$ so dominant that a reliable analysis for M'_{ss} phase become impossible. J-phase or the solid solution, J'_{ss} which was reported in the yttrium[5] and samarium[4] melilite-containing systems is not detected in any of the neodymium compositions produced in this work although neodymium J-phase is known to exist.[9]

Figure 1 shows the backscattered scanning electron microscopy (SEM), micrograph of sample N14 and quantitative energy dispersive X-ray spectroscopy (EDXS) spectra of the phases detected. SEM microstructural observation is in good agreement with phases identified by XRD. The EDXS spectrum of M'_{ss} clearly shows a substantial concentration of Al in this phase while for apatite, the Al peak is almost absent, indicative of negligible Al solubility. While atomic number contrast could not be distinguished between apatite and $NdAlO_3$ (both phases have a high neodymium concentration), EDXS is able to reveal that the smaller and relatively well-dispersed white regions are $NdAlO_3$ while apatite is significantly larger (Fig. 1).

matrix = M'_{ss} A = apatite O = $NdAlO_3$

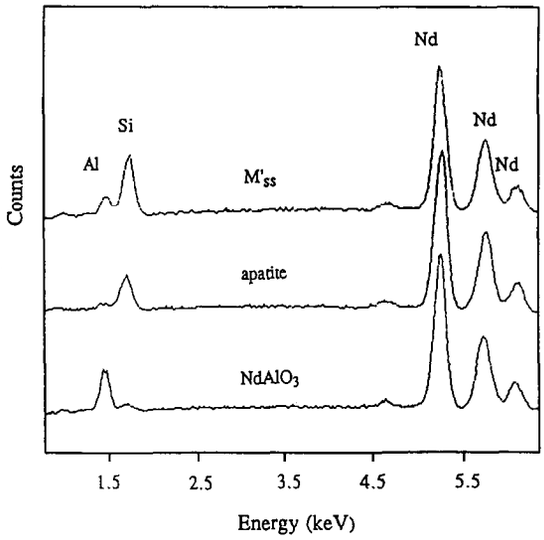

Fig. 1. Back-scattered SEM micrograph and EDXS spectra of sample N14.

3.3 Solubility of Al in neodymium M'_{ss}

Figure 2 shows the variation in the unit cell dimensions of neodymium M'_s as a function of starting x value in the designed composition, $Nd_2Si_{3-x}Al_xO_{3+x}N_{4-x}$. The starting x value ranging from 0·0 to 2·0 exhibits a relatively large expansion in both a and c lattices of the tetragonal M'_{ss} structure from x = 0·0 to about 1·0. Further increase in Al content beyond x = 1·0 produces a relatively smaller expansion rate indicating that the Al solubility of neodymium M'_{ss} is approaching saturation. A plot of cell dimension changes as a function of the measured amount of Al in the M'_{ss} phases as determined from quantitative EDXS is shown in Fig. 3 where, within the solubility limit the a and c lattices increase linearly with increasing Al according to the following equations:

$$a(\text{Å}) = 7{\cdot}719 + 0{\cdot}054x \quad (1)$$

$$c(\text{Å}) = 5{\cdot}032 + 0{\cdot}036x. \quad (2)$$

The above equations show a very similar lattice expansion to that exhibited by samarium M'_{ss}

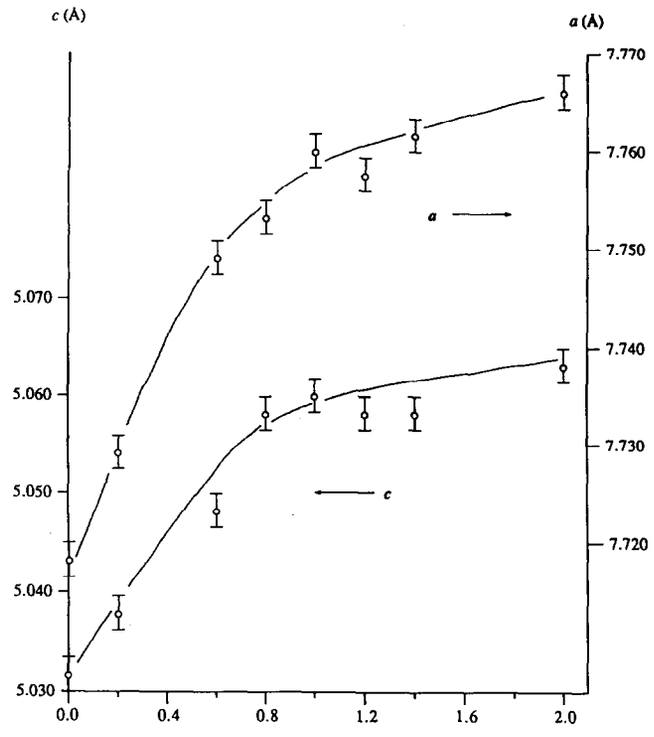

Fig. 2. Variation in the cell dimensions of neodymium M'_{ss} with starting x value.

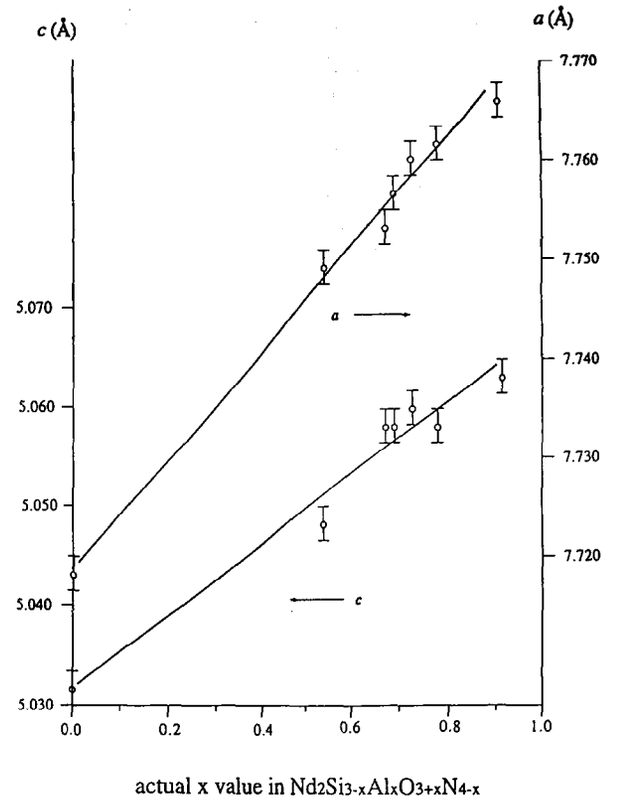

Fig. 3. Variation in the cell dimensions of neodymium M'_{ss} with actual x value determined from EDXS.

phases[4]. While both a and c lattices increase with Al addition, the calculated c/a ratio remains almost constant at 0·652 as shown in Table 2 indicating a random, uniform distribution of Al atoms within the M'_{ss} tetrahedral layers. Table 2 also provides a comparison between the designed x value and the actual Al concentration in M'_{ss} as determined by EDXS. Initially, most of the Al from the powder mixture is incorporated into M'_{ss} but as the composition further increased, discrepancy between the starting x and the actual x becomes larger. The maximum Al content obtained in neodymium M'_{ss} is $x = 0{\cdot}91$, implying that approximately one Si atom is replaced by an Al, therefore, giving a terminal composition of $Nd_2Si_{2\cdot0}Al_{1\cdot0}O_{4\cdot0}N_{3\cdot0}$.

The cell dimension measurements and EDXS analysis have clearly shown that neodymium M'_{ss} has a maximum Al solubility limit which is similar to that of samarium M'_{ss} phases[4] but higher than that of yttrium M'_{ss}.[5] It appears that the varying levels of Al substitution of different M'_{ss} phases may be related to the size of the interlayer cations. Table 3 is a compilation of experimental data on the formation of melilite phases in different systems with respect to the ionic radius of the cations. It is seen from Table 3 that there is a certain size criterion for N-melilite formation and in systems where the cation size is between ~0·9 and ~1·0 Å, N-melilite forms readily. If the cation radius is too big such as La^{3+} (1·016 Å) or too small as for Yb^{3+} (0·858 Å), N-melilite is not observed in those systems.

While the results shown in Table 3 are not conclusive, there seems to be a correlation between cation size and the maximum Al solubility limit where systems of relatively smaller cation sizes exhibit a significantly lower Al accommodation ability. Previous studies[4,5] have suggested that $x = 1{\cdot}0$ is the maximum Al solubility that can be accommodated by M'_{ss} phases without structural changes and it is seen from Table 3 that this limit has been achieved in the neodymium and samarium systems. Dy^{3+} and Y^{3+} which have ionic radii of 0·908 and 0·893 Å, respectively, have correspondingly lower Al solubility limits of $x = 0{\cdot}7$ and 0·6.

Table 2. Cell dimension calculations and EDXS measurements of the neodymium M'_{ss} samples

Figure 4 is a schematic representation of the structure of yttrium melilite projection on (100). With non-bridging anions taking up position on the apex of the tetrahedra, each silicon oxynitride layer of the N-melilite structure possesses an overall negative charge that has to be balanced by the cations (e.g. Y^{3+}). These cations separate the silicon oxynitride layers by a finite distance. In systems with small cation sizes such as yttrium or dysprosium, the negatively charged layers are allowed to come relatively closer together and possibly create a repulsive force which may destabilise the melilite structure. A structurally unstable M'_{ss} phase may result in a low Al accommodation capability. The exact mechanism involved in this process is currently unknown but the size of the interlayer cations appears to play an important role in determining the level of Al substitution in M'_{ss} phases.

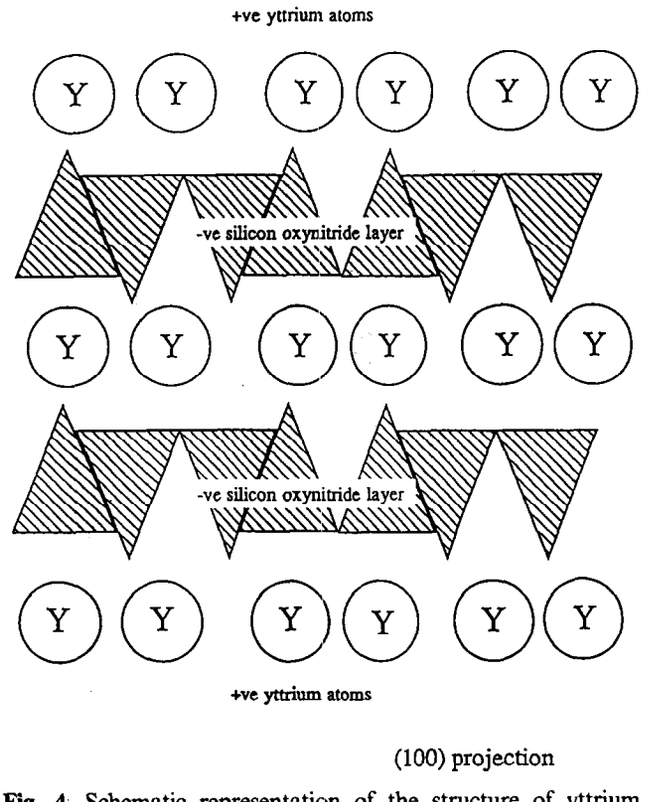

Fig. 4. Schematic representation of the structure of yttrium N-melilite showing the separation of the negatively charged silicon oxynitride layers by Y^{3+} cations.

3.4 ^{27}Al and ^{29}Si MAS-NMR data

Solid state ^{27}Al and ^{29}Si magic angle spinning NMR (MAS-NMR) were used to probe the Al and Si structural coordination in M'_{ss}. Paramagnetic ions possess unpaired electrons which produce large fluctuating magnetic field in the neighbourhood of the ions. The NMR signals from nearby nuclei can experience severe broadening, that for lanthanide stannates was found to be proportional to the square of the magnetic moment.[16] The unpaired electron can also produce a significant shift through the electron spin density being transferred onto the nucleus and is termed the Fermi contact shift. The magnitude of these effects depends on the relative orientation of the nuclei in the structure. This means that compared to diamagnetic analogues the NMR spectra may be much broader and show unconventional shift. Neodymium has a moderately large magnetic moment and contact shift[14] and it proved difficult to obtain NMR spectra from neodymium N-melilites. These effects are much smaller for samarium and NMR spectra could be obtained for samarium analogues. The two samarium samples prepared under identical conditions as those of the neodymium samples contain crystalline phases as shown in Table 4.

^{27}Al MAS-NMR spectra of the samarium samples, S2 ($x = 0{\cdot}2$) and S10 ($x = 1{\cdot}0$) are shown in Fig. 5(a) and (b), respectively. In Fig. 5(a) two resonances are observed, a sharp peak at 110 ppm and a much broader one centred at 55 ppm. From the literature, the 110 ppm resonance is attributed to AlN_4 coordination units.[15] However, it is unlikely that the substitution of Al–O for Si–N bonds in the melilite phase could lead to all Al in the AlN_4 coordination because this will cause charge imbalance in the solid solution. In addition, if some of the Al atoms are coordinated as AlN_4, there would have to be two distinct $Si_2(O,N)_7$ coordination in the M'_{ss} structure[15] but the present ^{29}Si NMR results could not strongly support this postulation (Fig. 6). The small area under the 110 ppm resonance is indicative of a very minor phase

Table 4. Weight loss, density and crystalline phases of the sintered $Sm_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ samples

Sample	*Formula*	*x-value*	*ΔW(%)*	*D(g/cm³)*	*Crystalline phases as determined by XRD*

and previous studies[17] have attributed this peak to unreacted AlN which was beyond XRD detection. The other Al site in this sample is AlO_4 as represented by the resonance at 55 ppm. The much larger area under this peak suggests that it represents a structural unit of significant proportion. Since there are no Al-containing phases in sample S2 other than M'_{ss} according to XRD, this resonance must arise from the Al environment in the M'_{ss} structure. There are few signs of any paramagnetic broadening or shifting of these resonances which must be a result, at least for the N-melilite, of the orientation of the samarium and aluminium in the structure. The spectrum of S10 in Fig. 5(b) shows a principal resonance at 10 ppm which is attributed to AlO_6 units in $SmAlO_3$.[5] The strong intensity of this resonance corresponds to the XRD results which shows a significant amount of $SmAlO_3$ present in the sample. The ^{27}Al resonance from $SmAlO_3$ shows no noticeable shift from the position expected for AlO_6 units in such a structure, but there is an extensive envelope of broad sidebands which demonstrate the influence of the samarium ion. This indicates that the contact shift is small but the broadening effect marked. The peak at approximately 100 ppm is mainly the result of a spinning sideband which probably overlaps with a small amount of AlN_4 contribution. Similar to the low Al containing sample S2, sample S10 shows a clear peak at 55 ppm corresponding to AlO_4 coordination from M'_{ss}. A major difference between samarium and yttrium ^{27}Al spectra[16] is the absence of a well-defined 30 ppm resonance in the samarium samples. This confirms the correct assignment of the 30 ppm peak in the yttrium samples to the Al-containing J-phase (J'_{ss}) since samarium J'_{ss} does not form in the samples produced here hence, no corresponding 30 ppm or equivalent peaks are observed.

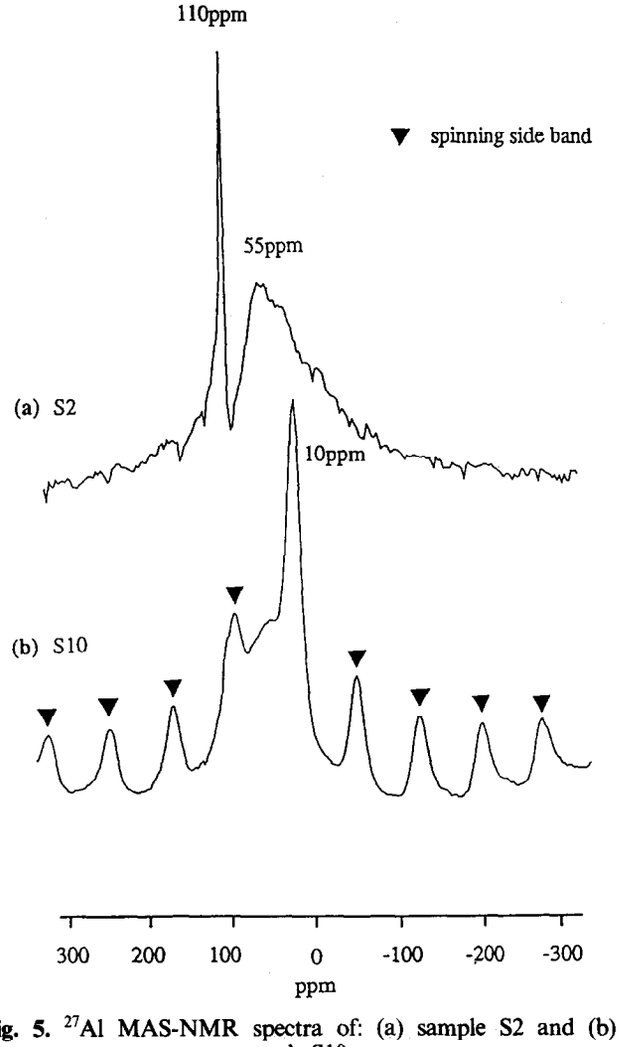

Fig. 5. ^{27}Al MAS-NMR spectra of: (a) sample S2 and (b) sample S10.

The ^{29}Si spectra of S2 and S10, shown in Figures 6(a) and (b) are very similar with both spectra producing a single resonance at approximately –35 ppm. The rest of the peaks in the two spectra are attributed to spinning sidebands and it appears that the Si environments in both low and high Al-containing samples are identical. Unlike yttrium silicon oxynitride compounds which have been extensively studied and a catalogue of ^{29}Si resonance positions defined,[18] phases in the samarium silicon oxynitride system have not been investigated by NMR and there is no reference to associate the ^{29}Si chemical shift values to particular Si environments. Apart from the 'normal' isotropic chemical shift, the resonance at –35 ppm also has an additional contact shift, further complicating peak assignment.[19] Obviously the fields produced by the Sm ion at the Al and Si sites in the M'_{ss} structure are slightly different. While the type of Si coordination which gives rise to the –35 ppm resonance is uncertain since this is not simply the chemical shift, the spectra provides unequivo-

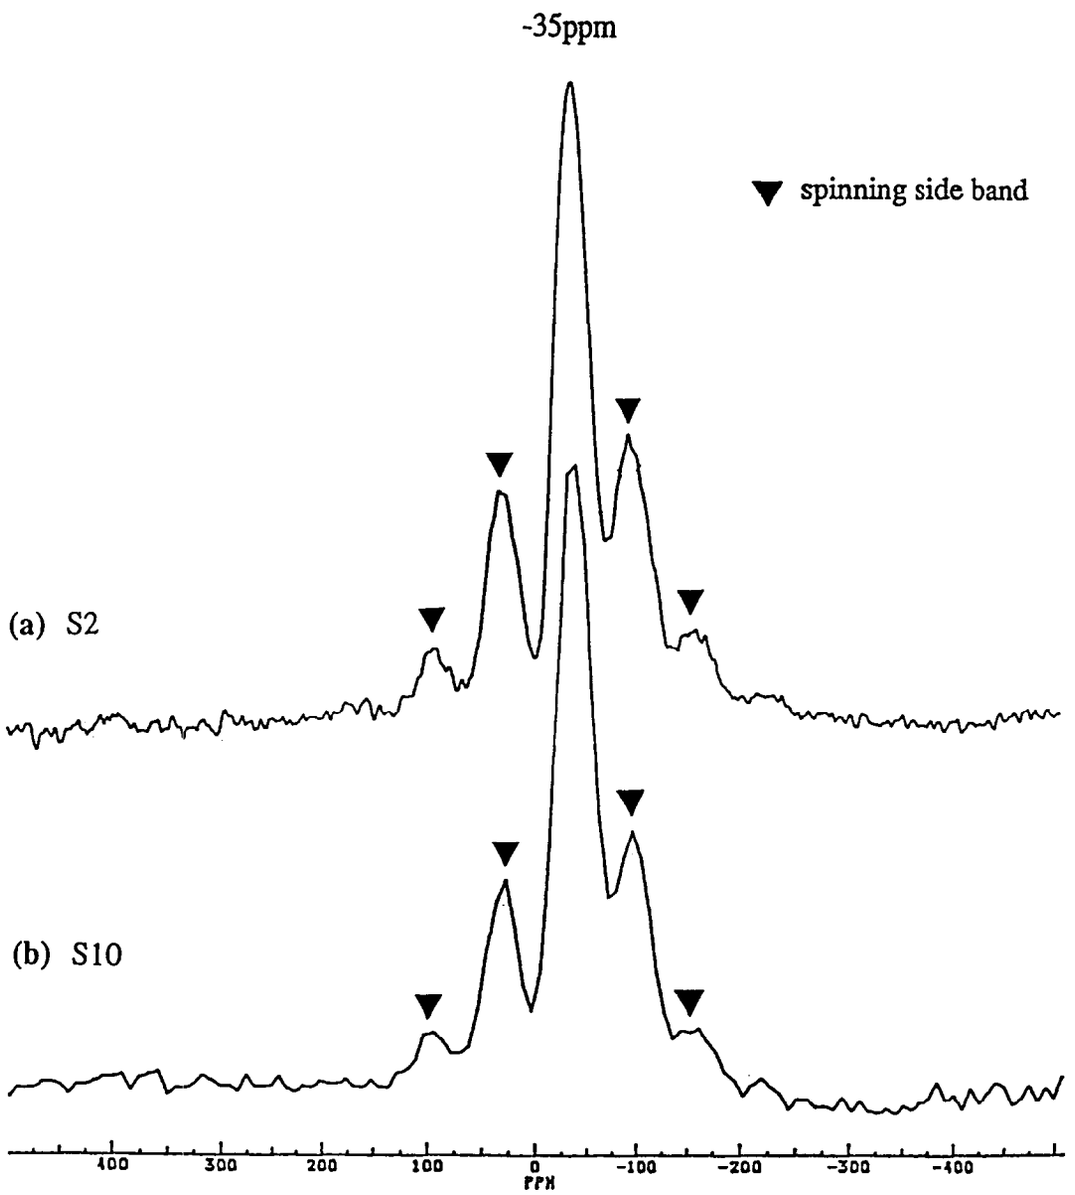

Fig. 6. ^{29}Si MAS-NMR spectra of: (a) sample S2 and (b) sample S10.

cal evidence that there is only one Si site in samarium M'_{ss} phases and by comparison with results from the yttrium system[16,18] the Si coordination in samarium M'_{ss} is more than likely to be SiO_2N_2.

From the ^{27}Al and ^{29}Si MAS-NMR data obtained, the predominant coordination's of Al and Si in samarium M'_{ss} are interpreted as AlO_4 and SiO_2N_2, respectively, and there is no evidence of transformation from one type of coordination to another with increasing Al solubility. The atomic arrangement of rare earth M'_{ss} is, therefore, similar to that proposed for yttrium M'_{ss}[16] where Al occupies the corner and centre positions of the M'_{ss} unit cell as shown in Fig. 7. From this model of atomic arrangement, the maximum number of Al atoms per unit cell will have to be two. This translates to an x value of 1·0 since two M'_{ss} chemical formulae of $R_2Si_{3-x}Al_xO_{3+x}N_{4-x}$ make up one unit cell, suggesting a terminal composition of $R_2Si_2AlO_4N_3$. This is in good agreement with the EDXS results described above where the maximum Al solubility for neodymium M'_{ss} approaches $x = 1{\cdot}0$.

4 Conclusions

There is a significant solubility of Al in neodymium M'_{ss} phases. A maximum of one Si can be replaced by Al giving the terminal composition of $Nd_2Si_2AlO_4N_3$. Cell dimension measurements and EDXS analysis have shown that neodymium M'_{ss} has a maximum Al solubility limit $x = 1$ in the formulae $Nd_2Si_{3-x}Al_xO_{3+x}N_{4-x}$, which is similar to that of samarium M'_{ss} phases but higher than that of yttrium M'_{ss}. This discrepancy is thought to be related to the size of the interlayer cations in the M'_{ss} structure. Structural investigation by MAS-NMR has suggested that samarium M'_{ss} phases consist predominantly of AlO_4 and SiO_2N_2 coordination units, regardless of the extent of Al solubility.

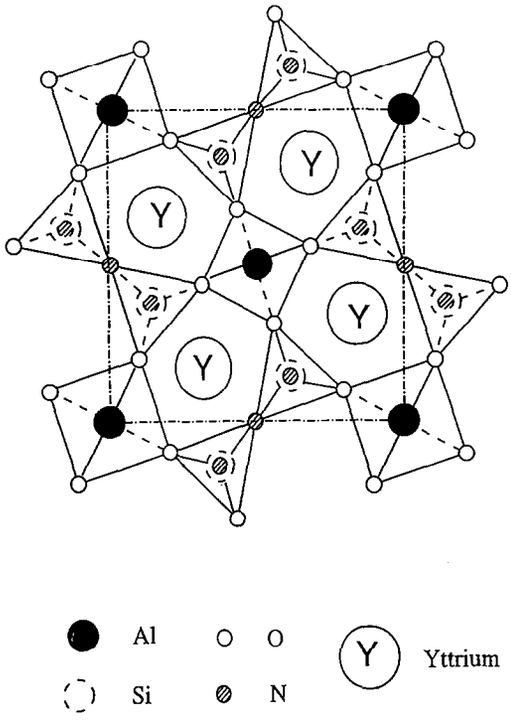

Fig. 7. Proposed atomic arrangement of yttrium M'_{ss} at the possible maximum Al solubility based on NMR results, after Ref. 18.

Phase Transformations in Sm (α+β)-SiAlON Ceramics during Post-sintering Heat Treatments

Rupeng Zhao & Yi-Bing Cheng*

Department of Materials Engineering, Monash University, Melbourne 3168, Australia

(Received 14 February 1995; revised version received 19 May 1995; accepted 22 May 1995)

Abstract

Phase transformations in Sm (α + β)-SiAlON ceramics during post-sintering heat treatments at 1300 and 1450°C were investigated using XRD, SEM, TEM and EDS techniques. The transformation from α to β SiAlON, (i.e. α' to β') phases was observed at both temperatures. However, other phase transformations occur simultaneously at grain boundaries of the materials and also involve the β' phase, namely, Glass $\rightarrow$ $SmAlO_3$ + β' and $SmAlO_3$ + $\beta' \rightarrow M'$. Their effects on the amount of β' in the materials must therefore be considered in the study of the α' to β' transformation. It is thought that the increase in the β':(α' + β') ratio during a heat treatment process depends not only on the rate of the α' to β' transformation, but also on the amount and composition of the intergranular phases.

1 Introduction

Post-sintering heat treatment is a technique commonly used in manufacturing SiAlON ceramics. The main objective of the post-sintering heat treatment includes the crystallisation of the glassy grain boundary phase in the materials to improve the materials' performance at elevated temperatures. This is usually achieved via a conventional glass-ceramic process during which the glass devitrifies at a temperature above its T_g point but without being 'melted'.[1,2] There has been much work in understanding of the grain boundary crystallisation, but very little attention has been paid to the effects of the post-sintering heat treatment on the stability of SiAlON phases until very recently. Mandal *et al.*[3] found that some α-SiAlON (α') phases could transform to β-SiAlON (β') during the process. It was observed that the transformation from α' to β' readily occurred in some rare earth α' + β' composite materials when heat-treated between 1000 and 1600°C and the extent of the transformation was more pronounced with increasing temperatures.[3] α' and β' have different mechanical properties,[4] therefore, these findings have opened a new possibility of tailoring the microstructures and properties of SiAlON ceramics in a way that was previously not expected.

α' and β' are two different crystallographic modifications of SiAlON structures.[5] Although both phases are basically built up of corner-sharing (Si,Al)(O, N)$_4$ tetrahedra, there is a distinct difference in the atomic arrangement between the two phases.[6] The bonds in SiAlON structures are strongly covalent and the atoms have a very low self-diffusivity even at 1800°C; these features bear the virtual responsibility of a relatively poor densification behaviour of Si_3N_4-based materials. The transformation between the α' and β' phases has a reconstructive nature which involves the breaking of chemical bonds and substantial atomic diffusion, and hence requires significant amounts of thermal energy. The transformation from α-Si_3N_4 to β-Si_3N_4 did not occur without the presence of a liquid phase in which α-Si_3N_4 grains could dissolve above ~ 1400°C.[7] All these facts naturally raise some questions on the mechanism of α' to β' phase transformations, particularly those taking place at temperatures below the eutectic of the system. The present paper provides some evidence of the α' to β' phase transformation in a Sm α' + β' ceramic composite at both below and above the eutectic temperatures, and further reveals additional phase transformations that could involve the β' phase during post-sintering heat treatments.

2 Experimental Details

Samples were prepared from Si_3N_4 (Starck, Berlin, LC10), AlN (Starck, Berlin, Grade B), Al_2O_3 (Alcoa, A17) and Sm_2O_3 (RE Acton, Rare Earth Products, 99.9%) powders with a starting composition

The white regions are intergranular glass, the grey grains are α' and the dark grains either β' or 21R. The EDS spectra of: (a) α'; (b) β'; (c) 21R and (d) grain boundary glass correspond to the regions marked on the micrograph.

of $Sm_{0.379}Si_{9.548}Al_{2.381}O_{1.668}N_{14.403}$. The pelleted green body of the designed composition was initially sintered at 1820°C for 4 h in an industrial furnace. The slow cooling rate of the furnace produced a SiAlON material with wollastonite as the grain boundary phase. Further sintering was carried out in a laboratory carbon resistance furnace at 1800°C for 30 min and the specimen was then cooled in the furnace. Due to a much faster cooling rate, the final material contains mainly α', a small amount of β' and 21R phases with an amorphous phase at grain boundaries.

The samples that contained glassy grain boundaries were subsequently heat-treated at 1300 and 1450°C respectively for various periods. The heat treatments were carried out in flowing nitrogen in an alumina tube furnace with heating and cooling rates of 3°C/min. After heat treatments, the surfaces of the samples were removed by grinding on SiC paper and the bulk of the material was exposed for

crystalline phase and microstructural examinations.

Scanning electron microscopy (SEM) observations and energy-dispersive X-ray spectroscopy analysis (EDS) were carried out using a JEOL 840A instrument. A JAVA image analyser was used to analyse the backscattered SEM electron images. A Philip CM20 TEM instrument fitted with an ultrathin-window EDS detector was used for microstructural observations and compositional analyses. Specimens for TEM were mechanically ground, dimpled to thickness of ~20 μm, and then ion-milled to electron transparency. All specimens were carbon coated before SEM and TEM observations to avoid surface charging.

Phase characterisation was performed with X-ray diffraction (XRD) using a Rigaku X-ray diffractometer. The relative amounts of α' and β' phases, i.e. the β':(α' + β') weight ratio, were calculated using the calibration curves developed by Liddell[8] with the intensities of the (210) peaks of both the α' and β' phases.

$$\beta'(\text{wt}\%) = K/[I_\alpha(210)/I_\beta(210) + K] \times 100\% \quad (1)$$

where K is a constant, equal to 0·702.

The amounts of crystalline grain boundary phases (namely, $SmAlO_3$ and the Al-containing N–melilite, M'[9]) after heat treatments were estimated by comparing appropriate XRD peak intensities of these phases with that of the 21R phase which remained unchanged throughout the heat treatment process. The specific result calculated from this way may possess a certain error, but the trends, i.e. the relative changes in the amount of $SmAlO_3$ and M' phases versus the heat treatment time and temperature, should be indicative. This is true for the β':(α' + β') ratio as well.

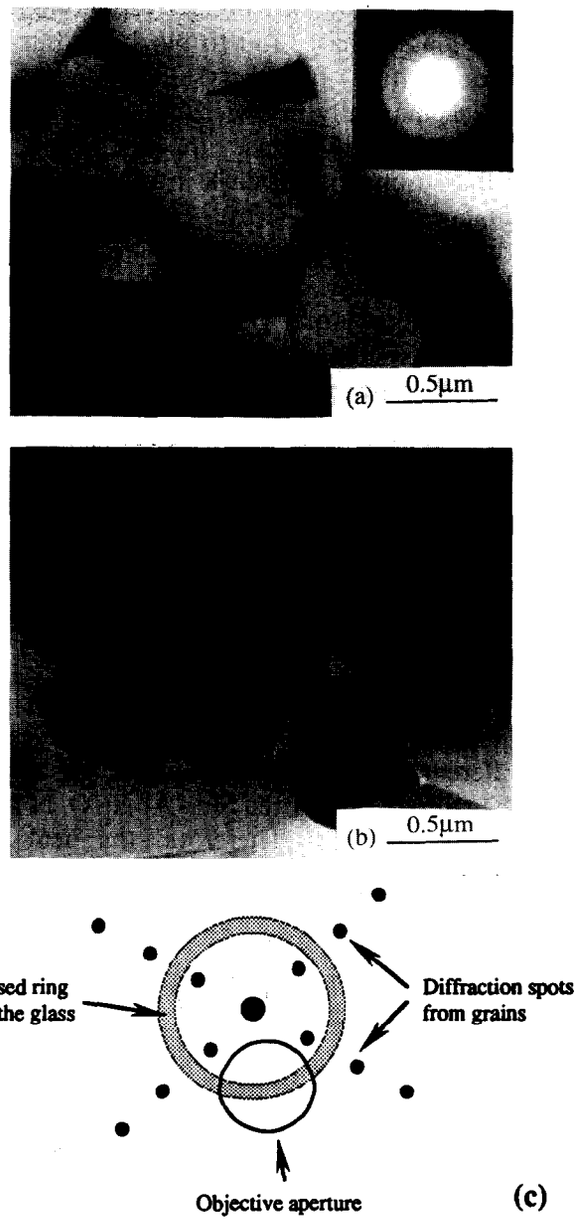

Fig. 2. TEM: (a) bright field and (b) diffused dark field images from the as-sintered specimen. (c) Schematic illustration of the objective aperture position for diffused dark field imaging. The glassy nature of the grain boundary phase is indicated by the electron diffraction rings (inset in (a)).

3 Results

3.1 The as-sintered materials

XRD analyses showed that the crystalline phases in the as-sintered sample consisted of mainly α' and β' phases, with a small amount of 21R polytypoid phase. The β':(α' + β') ratio was about 11%. Figure 1 shows a typical SEM backscattered image of the as-sintered material. Since the backscattered electron intensity depends mainly on the mean atomic number, the differences in the amounts of samarium presented in the α', β' and grain boundary phases make them easily identified. The white grain boundary regions are the intergranular glassy phase containing large amounts of samarium. The equiaxed grey regions are α' grains with a small amount of samarium, and the dark regions are β' or 21R phases with no samarium. This has been supported by the EDS analytical results (Fig. 1). The β' and 21R phases can be differentiated by EDS analyses or by their morphology. The needle-like grains with high aspect ratios are usually the 21R phase while the slightly elongated ones with low aspect ratios are β'. Image analyses indicate that the as-sintered sample contained around 75% α' and 10% intergranular glassy phase, with the rest being β' and 21R.

Figure 2 shows typical bright field and diffused dark field TEM images of the as-sintered sample. In the bright field image, the intergranular phase is darker because of its high samarium content. Diffused dark field images are obtained by using the objective aperture of the microscope to select

a part of the diffraction ring corresponding to the expected glassy phase, and to block all diffraction spots originating from crystalline grains,[10] as shown schematically in Fig. 2(c). As a result, the intergranular glassy phase appears bright while crystalline grains are all dark in the diffused dark field image (see Fig. 2(b)). Electron diffraction confirmed that the intergranular phase was amorphous, as indicated by the ring pattern (Fig. 2(a)). The intergranular glass comprises all five elements in the system, although its composition may vary slightly from pockets to pockets (Fig. 3). To a first order approximation (using calculated parameters and neglecting absorption effect), the estimated composition of the glass is around Sm:Si:Al = 0·7:1·0:0·8 and N:O = 1:2·3 (in atomic ratio). Therefore, the Si, O and N contents in the glass are significant.

3.2 Heat treatment at 1300°C

Post-sintering heat treatment was conducted at both 1300 and 1450°C respectively to investigate the different phase transformation behaviour. The eutectic temperature of the Sm– Al–Si–O–N system is about 1350°C.[11,12] Therefore, the heat treatments at 1300 and 1450°C represents the thermal processes below and above the eutectic temperature of the system respectively.

Samarium aluminate ($SmAlO_3$) was observed as the only devitrification product of the intergranular glass in the sample heat-treated at 1300°C. XRD results of the samples after heat treatments at this temperature for various periods are presented in Fig. 4. Both the β':(α' + β') ratio and the amount of $SmAlO_3$ increased with the duration of the heat treatment. The increases in $SmAlO_3$ and the β':(α' + β') ratio can be divided into two distinct stages according to the rate of the phase transformations. There is a rapid increase in both

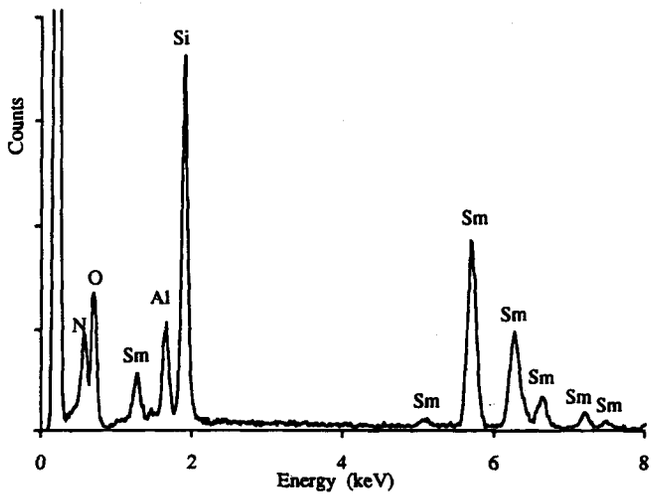

Fig. 3. EDS spectrum from the intergranular glassy phase in the material showing that it contains significant amounts of Si and N.

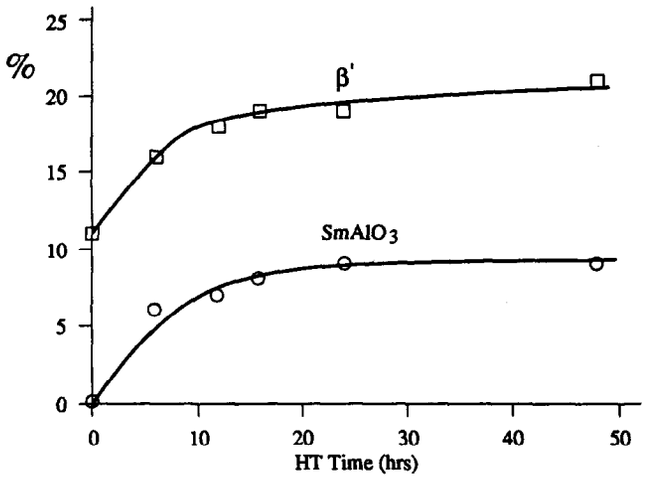

Fig. 4. The β':(α' + β') ratio and the relative $SmAlO_3$ fraction of the samples heat-treated at 1300°C as a function of heat treatment time.

$SmAlO_3$ and β' phases in the initial heat treatment stage ($0 < t < 6$ h). Further heat treatment up to 48 h resulted in only a slight increase in these two phases. The initial rapid increase in $SmAlO_3$ indicates that the intergranular glassy phase devitrifies very rapidly at the temperature, and grain boundary

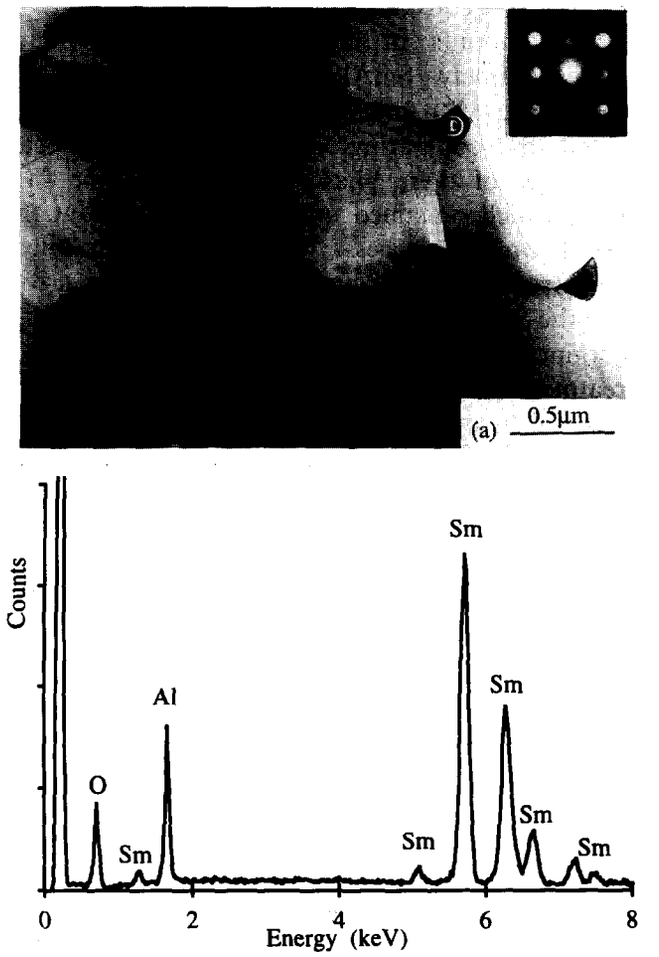

Fig. 5. (a) Typical TEM bright field image of the sample heat-treated at 1300°C for 24 h. The dark crystals at the grain boundaries are $SmAlO_3$ with an orthorhombic structure, as confirmed by electron diffraction from the crystal marked 'D' (inset) and by EDS analysis (b). The diffraction pattern is [001] zone for $SmAlO_3$.

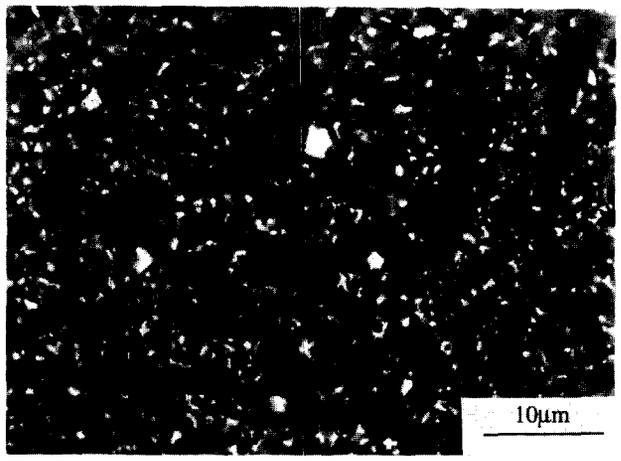

Fig. 6. SEM backscattered image of the sample after heat treatment at 1300°C for 24 h showing homogeneous distribution of $SmAlO_3$ crystals (the white phase).

devitrification may have been completed in a few hours. It is interesting to notice that the increase in the β':(α' + β') ratio follows a similar pattern as that of $SmAlO_3$.

TEM observations revealed that the glass phase in all multiple junctions of the as-received samples was fully crystallised after the heat treatment at 1300°C for 24 h. A typical bright field image is shown in Fig. 5(a). EDS analysis (Fig. 5(b)) and electron diffraction (Fig. 5(a)) confirmed $SmAlO_3$ as the intergranular crystalline phase. SEM observations on all samples heat-treated at 1300°C showed that apart from a few agglomerates of about 2 μm in size, the $SmAlO_3$ grains in general were homogeneously distributed, as shown in Fig. 6, indicating that there was no significant grain boundary migration during the heat treatment at this temperature.

3.3 Heat treatment at 1450°C

Figure 7 summarises the XRD results of the samples after heat treatments at 1450°C for various times. It can be seen from the figure that the β':(α' + β') ratio increases with the duration of the heat treatment. Such an increase in the β' phase can be partially explained in terms of the α' to β' transformation.[3] However, it has been noted that the rate of the increase in β' contents varies significantly with the heat treatment time; as a result, three distinct stages are recognised. In the first few hours, the β':(α' + β') ratio increases rapidly, more than 10% in 4 h. In the second stage (4 h < t < 16 h), the amount of β' remains almost unchanged. With further time, however, the β' phase increases again in the third stage (t > 16 h), but at a lower rate than that in the initial stage. Such a discrete nature of the change in the β':(α' + β') ratio during an isothermal process cannot be simply explained by the α' to β' transformation alone, and other mechanism(s) may also be involved.

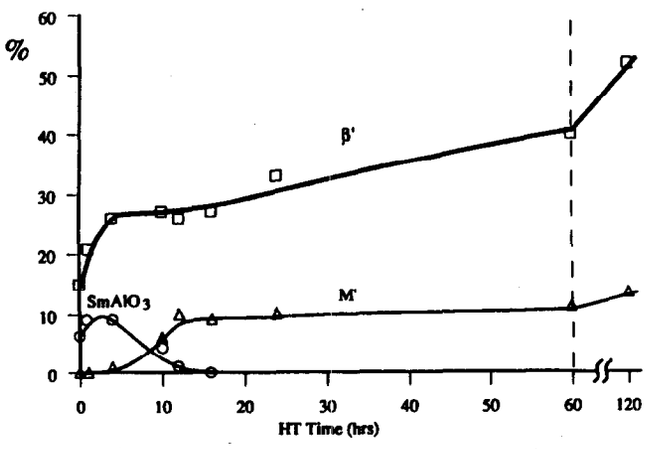

Fig. 7. The β':(α' + β') ratio, $SmAlO_3$ and M' fractions in the samples heat-treated at 1450°C as a function of heat treatment time. The result marked at zero hour in the figure was obtained by heating up the sample to 1450°C and then immediately cooling down to room temperature.

Both $SmAlO_3$ and M' were observed after heat treatment at 1450°C, but their relative contents varied with time. Figure 7 shows the weight fractions of the $SmAlO_3$ and M' phases in the samples. $SmAlO_3$ was observed in the initial stage of the heat treatment at 1450°C prior to the appearance of M'. The amount of $SmAlO_3$ reached a maximum after about 4 h then started to decrease, and completely disappeared after 12 h. The initial heat treatment at 1450°C did not produce any M' phase, but it appeared simultaneously with $SmAlO_3$ after 4 h, and then became the only grain boundary phase at the expense of $SmAlO_3$ in the samples heat-treated for longer than 12 h. There are two interesting correlations among the different phase changes at 1450°C: (i) the initial rapid increase in the β':(α' + β') ratio is associated with the rapid formation of $SmAlO_3$, similar to that observed at 1300°C, suggesting the formation of β' is associated with the devitrification of the intergranular glassy phase; and (ii) the plateau in the curve of the β':(α' + β') ratio is correlated with the decomposition of $SmAlO_3$ and the formation of M'.

Microstructures of the samples heat-treated at 1450°C were studied by SEM. Figures 8(a–c) show three typical SEM backscattered images of the samples heat-treated for 4, 12 and 24 h, respectively. EDS confirmed that the white grain boundary phase in Fig. 8(a) was $SmAlO_3$, while those in Figs 8(b) and (c) were M'. It can be seen from Fig. 8(a) that, as for heat treatment at 1300°C (Fig. 6), most $SmAlO_3$ grains are fine in morphology and are homogeneously distributed at grain boundaries despite a few large agglomerates of around 2 μm. There is virtually little difference in the microstructures of the grain boundary phase between samples heat-treated at 1300°C for 24 h and that at

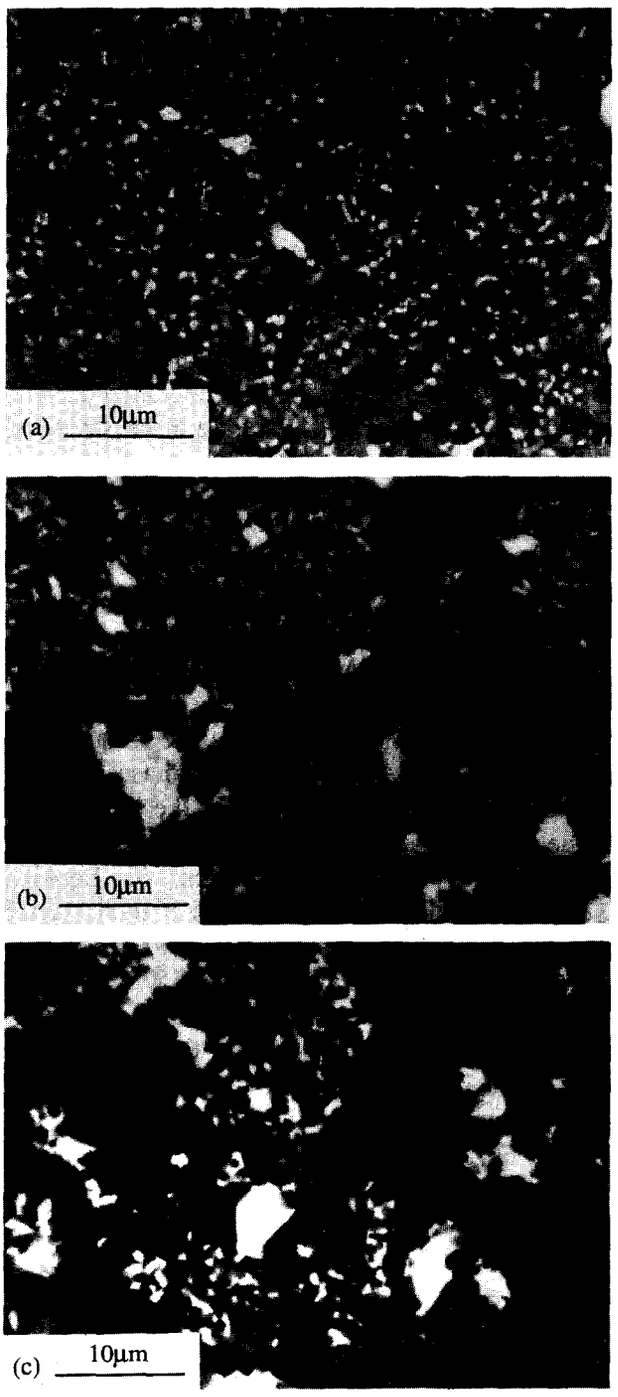

Fig. 8. SEM backscattered images of samples heat-treated at 1450°C for (a) 4 h, (b) 12 h and (c) 24 h. The grain boundary phase (white regions) was $SmAlO_3$ in (a), and the M' phase in both (b) and (c).

1450°C for 4 h, indicating that no significant grain boundary migration occurred when $SmAlO_3$ was formed. As a contrast, the distribution of M' grains is agglomerative and inhomogeneous (Figs 8(b) and (c)), suggesting that considerable intergranular migration has taken place. The grain boundary M' phase forms only above the eutectic temperature,[9] involving a liquid phase which promotes the grain boundary migration. TEM observations on samples heat-treated at 1450°C for 24 h failed to identify any residual amorphous phase (Figs 9 and 10), therefore the liquid phase that

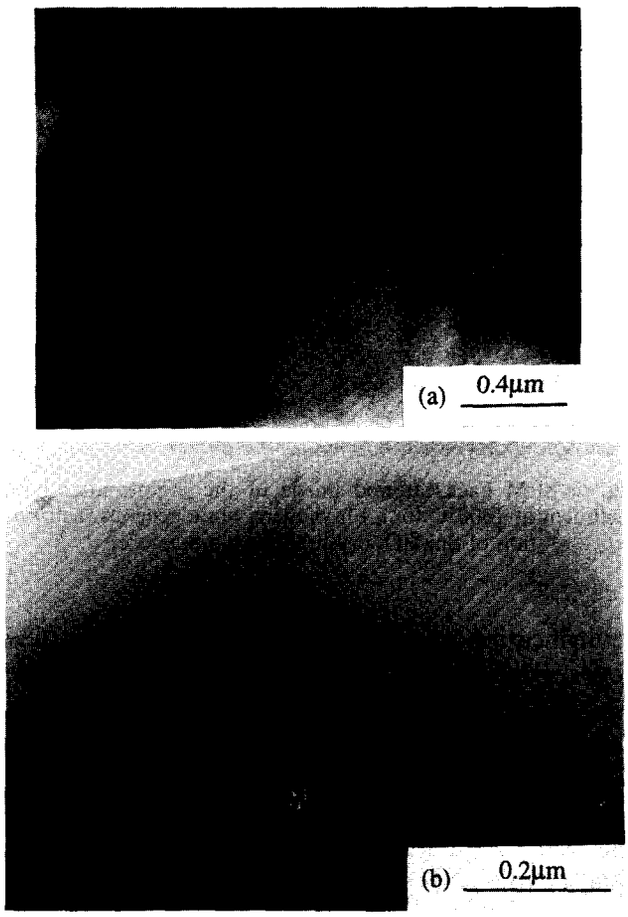

Fig. 9. Typical TEM bright field images of the sample heat-treated at 1450°C for 24 h. Note that little residual glass can be found at grain boundaries. The dark grain in (b) is the M' phase and other grains are either α' or β'.

exists at grain boundaries during the heat treatment must be of a transient nature.

4 Discussion

4.1 β-SiAlON formation during post-sintering heat treatments

The present results have shown that different

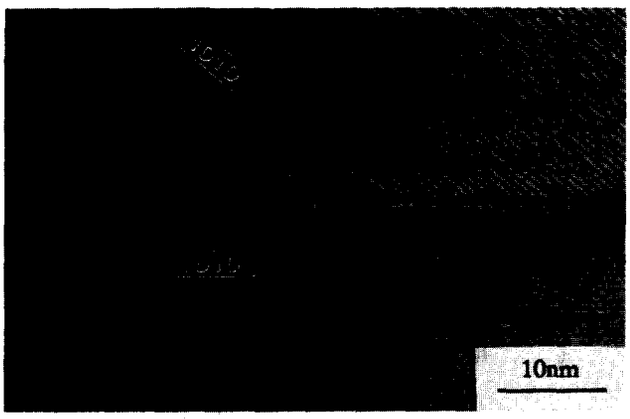

Fig. 10. High resolution lattice fringe image of the boundary between two α' grains in the sample heat-treated at 1450°C for 24 h. Fringes can be followed up to the boundary from either side, indicating the lack of a glass thin film.

phase transformations can take place during post-sintering heat treatments. The increase in the β' concentration after the heat treatments is significant and this provides some evidence for a phase transformation from α' to β' at the heat treatment temperatures. However, due to the simultaneous devitrification of the grain boundary glass and the formation of $SmAlO_3$ and M', other mechanisms may also contribute to the increase in β'.

Although the exact composition of the grain boundary glass is yet to be determined, preliminary EDS analyses indicate that the glassy phase contains all the five elements (Sm–Si–Al–O–N) with significant contents of both Si and N. When $SmAlO_3$ is formed by devitrification, it has consumed most samarium, aluminium and oxygen in the glass, leaving a phase rich in Si and N. However, extensive TEM analyses cannot detect any glassy phase in the samples after devitrification and this leads to a postulation that the residual Si and N in the glass have also formed a crystalline phase in an amount comparable with that of $SmAlO_3$. Considering there is no new unidentified phase from XRD analyses, the anticipated Si and N rich phase formed from the glass must be either α' and/or β'. It is known that Si and N in a glassy phase can partition in the existing SiAlON grains during grain boundary crystallisation.[1] Moreover, the observation of α' to β' transformations in the rare earth SiAlON systems between 1000 and 1500°C[3] indicates a lower free energy for the β' phase than that for the α' phase. Therefore it is thought that the precipitation of β' from the glassy phase is thermodynamically preferred at the present heat-treatment temperatures.

On account of the simultaneous rapid increase in both the β' and $SmAlO_3$ phases in the initial stage of the heat treatment at both 1300 and 1450°C, it is plausible to propose the following phase transformation:

$$\text{Glass} \rightarrow SmAlO_3 + \beta' \qquad (2)$$

Therefore the initial rapid increase in the β':($\alpha' + \beta'$) ratio during the heat treatments is attributed to a combined effect of two different mechanisms, namely, the α' to β' transformation and glass devitrification. The activation energy for the glass devitrification should be much lower than that for the α' to β' transformation at these temperatures, and hence the glass devitrification may make the major contribution to the increase in the β' content at the initial stage of heat treatment processes. The increase in the β':($\alpha' + \beta'$) ratio will therefore depend not only on the heat treatment conditions, but also on the amount and composition of the grain boundary glassy phase in the materials. Significant differences in the extent of the α' to β' phase transformation could occur in samples of the same SiAlON system if the amount and composition of the glassy phase are different.

Table 1. The β': ($\alpha' + \beta'$) ratio of two groups of samples after heat treatment at 1450°C

HT time (h) at 1450°C	*Group I (no glass) (%)*	*Group II (with glass) (%)*
Before HT	19	11
4	27	26
24	34	33

Note: The Group I samples were heat-treated at 1300°C for 24 h and contained $SmAlO_3$ as a grain boundary phase prior to the heat treatment at 1450°C, whereas the Group II samples were as-sintered with a glassy grain boundary phase before the heat treatment.

The proposed mechanism of the transformation, eqn (2), is further supported by another set of experiments in which two groups of samples are compared. Both groups were originally from the same bulk specimen and heat-treated at 1450°C for 4 and 24 h respectively. Prior to this heat treatment, the Group I samples were preheat-treated at 1300°C for 24 h, hence containing $SmAlO_3$ and very little glass, while the Group II samples had no pre-heat treatment and contained a glassy phase at grain boundaries. Table 1 shows the results after the heat treatment at 1450°C. Although the same amount of β' was found in both groups after heat treatments for 4 and 24 h, there appeared a significant difference in the rate of β' increase during the initial 4 h; the sample with a glassy phase (Group II) had a much higher yield of β' compared to the one that contained $SmAlO_3$ prior to the heat treatment (Group I). It is apparent that crystallisation of the intergranular glassy phase has made a significant contribution to the higher increase in the β':($\alpha' + \beta'$) ratio in Group II samples and so this is in agreement with the proposed transformation of eqn (3).

4.2 β-SiAlON consumption during phase transformations

Cheng and Thompson[13] found that the M' phase was the only stable intergranular crystalline phase above 1400°C in the Sm ($\alpha + \beta$)-SiAlON system. Although $SmAlO_3$ was observed in the initial stage of the heat treatment at 1450°C, possibly formed during the slow heating and cooling, it became unstable and formed a eutectic liquid through a reaction with other phases in the system upon further 1450°C heat-treatment. The experimental results indicate that the decomposition of $SmAlO_3$ results in the precipitation of the M'($Sm_3Si_2AlO_4N_3$) phase at the SiAlON grain-boundaries. However, the significant compositional

difference between these two phases implies that the phase transformation must involve an additional Si and N rich phase to complement the Sm–Al–O composition of the grain boundaries. The coincidence between the M' formation and the plateau in the curve of the β':(α' + β') ratio of Fig. 7 suggests that $SmAlO_3$ may have reacted with the β' phase to form a transient liquid necessary for the M' phase precipitation:

$$SmAlO_3 + \beta' \rightarrow \text{liquid} \rightarrow M' \qquad (3)$$

The existence of this transient liquid is supported by the observation that considerable grain boundary migration occurs when the M' phase forms (Fig. 8). The consumption of β' in the above reaction may be compensated by the simultaneous α' to β' transformation. As a result, a balance is maintained and the overall β' content in the sample remains unchanged as shown in Fig. 7. Once reaction (3) is complete, a further steady increase in β' is anticipated.

At 1450°C for 120 h, the relative β' content in the sample was 54%, a significant increase compared to the sample heat-treated for 24 h. This result strongly suggests the transformation from α' to β' during the extended heat treatment. The slight increase in the amount of the M' phase may accommodate the Sm released from the transformed α' structure.

5 Conclusions

Three different phase transformations may occur simultaneously during the post-sintering heat treatment of (α + β)-SiAlON ceramics: (i) grain boundary glass devitrification; (ii) phase transformations among different crystalline grain boundary phases; and (iii) the α' to β' phase transformation. Significant differences in the β':(α' + β') ratio of Sm (α + β)-SiAlON ceramics are observed when the samples are heat-treated at below and above the eutectic temperature of the system. Although there is a transformation between the α' and β' phases during the heat treatments at both the temperatures, other phase transformation mechanisms may also occur and affect the amount of β'.

Devitrification of the intergranular glassy phase can lead to the formation of β' via the transformation

$$\text{Glass} \rightarrow SmAlO_3 + \beta'$$

The amount and composition of the grain boundary glass could have significant effects on the change of the β' phase during the heat treatment. The stabilities of different crystalline intergranular phases may change with temperature, resulting in phase transformations that involve β' phases. In Sm (α + β)-SiAlON materials, the following transformation will take place if the heat treatment is above the eutectic temperature:

$$SmAlO_3 + \beta' \rightarrow \text{liquid} \rightarrow M'$$

These phase transformations may also occur in other rare earth (Ln) (α + β)-SiAlON composites during post-sintering heat-treatments, where the aluminate could be either $LnAlO_3$ or a YAG-type phase. The effects of these transformations on the β':(α' + β') ratio can be significant and have to be taken into account in any studies of the α' to β' phase transformation.

Effect of Acid Treatment on the Formation of SiC Whiskers from Raw Rice Husks

Raghavarapu Venkata Krishnarao & Yashwanta Ramachandra Mahajan

Defence Metallurgical Research Laboratory, Kanchanbagh, Hyderabad–500258, India

(Received 30 January 1995; revised version received 19 May 1995; accepted 22 May 1995)

Abstract

Raw rice husks have been treated by boiling for 1 h in 5 N hydrochloric acid. The washed and dried acid-treated raw rice husks (TRRH) and untreated raw rice husks (RRH) were directly pyrolysed (without precoking) in argon atmosphere at different temperatures between 1050 and 1600°C. Silica obtained from TRRH has a lower level of impurities than that obtained from RRH. Acid treatment has been found to decrease the degree of crystallization of silica and carbon in rice husks. The whisker formation has been decreased in TRRH. As the carbon loss due to the formation of CO was high, the SiC content in the pyrolysed TRRH was higher than that in pyrolysed RRH.

1 Introduction

Silicon carbide (SiC) whiskers, useful in reinforcing light metal alloys and ceramics, are produced by thermal decomposition of rice husks (RHs). Lee and Cutler[1] performed the pioneering work on the formation of SiC from RHs. Later several reports appeared in the literature.[2–16]

A rice husk can be regarded as consisting of SiO_2 embedded in a matrix whose approximate average composition is 51 wt% carbon, 7 wt% hydrogen and 42 wt% oxygen.[6] Rice husks produce a high ash content, varying from 13 to 29 wt% depending on the variety, climate and geographical location. The ash is largely composed of silica (87–97%) with small amounts of alkalis and trace elements.[17] When RHs are converted, these impurities will enter into SiC. In this investigation the raw RHs were treated with hydrochloric acid to decrease the level of impurities. The acid-treated RHs (TRRH) and untreated raw RHs (RRH) were directly pyrolysed without precoking and the formation of SiC was studied.

2 Experimental Procedure

Dry raw RHs, which had been sieved to eliminate residual rice and clay particles, were used in this work. They contain 81·52 wt% of organic material and 18·48 wt% of ash (silica). The RRH were fed into 5 N hydrochloric acid and boiled for 1 h. The treated RHs were thoroughly washed with water and dried in an oven at 90°C. The acid-treated RHs (TRRH) were found to contain 74·64 wt% organic material and 25·36 wt% silica. The silica obtained by burning of organic material from RRH and TRRH was analysed by a Varian model AA-5 atomic absorption spectroscope (AAS).

A 15g sample of RHs was taken in a 2·5 mm thick walled cylindrical graphite container closed with a graphite lid. An ASTRO high temperature furnace, model 1000-3060-FP20 equipped with a Honeywell small target radiation pyrometer, model 939A3 was used for pyrolysis experiments. The RRH and TRRH were subjected to pyrolysis at different temperatures from 1050 to 1600°C for 1 h in an inert atmosphere of Ar at atmospheric pressure. Heating rate employed was $\approx$ 40°C min^{-1}. Argon flow was maintained at 0·1 1 min^{-1}.

The product of pyrolysis was analysed by X-ray diffraction (XRD), scanning electron microscopy (SEM) and chemical analysis. A Philips X-ray diffractometer, model PW1840 with Cu *K* radiation through Ni filter, was used. A scanning electron microscope from International Scientific Instruments, model ISI-100A, was used to study the morphology of SiC. The excess carbon content in the pyrolysed RH was determined by burning at 700°C for 3 h. The unreacted SiO_2 content was estimated by treating the carbon-eliminated sample with HF.

3 Results

SEM micrographs of the outer epidermis of RRH and TRRH are shown in Fig. 1. The part of the

RHs leached out due to acid treatment can be seen in Fig. 1(b). The XRD pattern of TRRH was not much different from that of RRH (Fig. 2(a)).

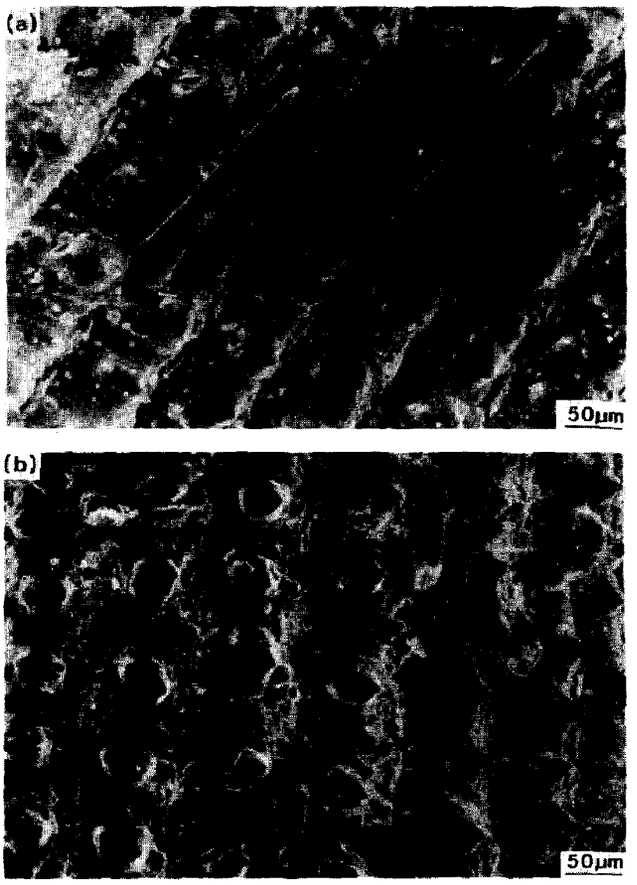

Fig. 1. SEM micrographs of outer epidermis of (a) RRH and (b) TRRH.

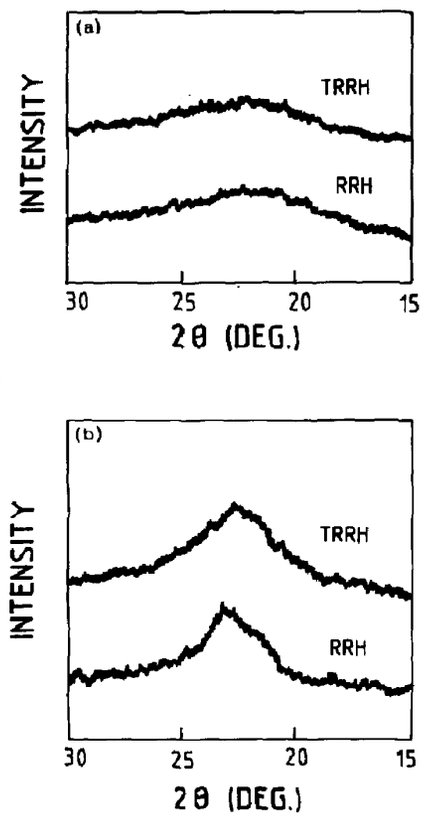

Fig. 2. XRD patterns of (a) RRH and TRRH, (b) silica from RHs.

Similarly, the XRD pattern of silica obtained from TRRH did not show any difference from

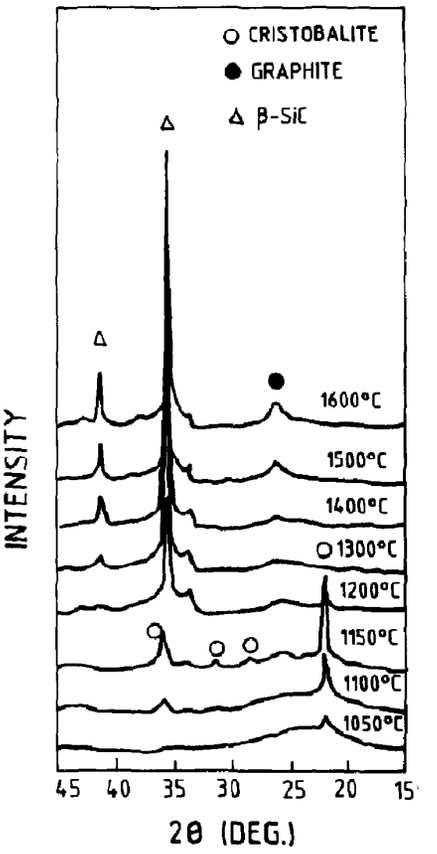

Fig. 3. XRD patterns of pyrolysed RRH samples.

that of silica obtained from RRH (Fig. 2(b)). The silica from TRRH appeared bright white. An AAS analysis revealed that the level of impurities in RH silica decreased considerably after acid treatment (Table 1).

Table 1. Impurity analysis (in wt%) of RH silica

Element	*Silica from*	
	RRH	*TRRH*
Al	0·50	0·25
Fe	0·60	0·30
Ca	0·44	0·33
Mg	0·41	0·13
Mn	0·069	0·0054
K	1·51	0·054
Na	0·064	0·063

The XRD patterns of pyrolysed RRH samples are shown in Fig. 3. The crystallization of amorphous silica to form cristobalite was the dominant process up to 1150°C. All the peaks of SiC appeared at and above 1300°C. At higher temperatures (1500 and 1600°C), the degree of graphitization of amorphous carbon was rapid. From Fig. 4 it is clear that the degree of crystallization of silica and carbon is negligible in TRRH samples.

Through SEM, the formation of considerable quantities of SiC whiskers has been observed in RRH samples pyrolysed up to 1400°C (Fig. 5). As the temperature of pyrolysis increased, thick and short whiskers formed (Fig. 5(b)). At higher temperatures, the whiskers formed at lower temperatures were converted into particulates

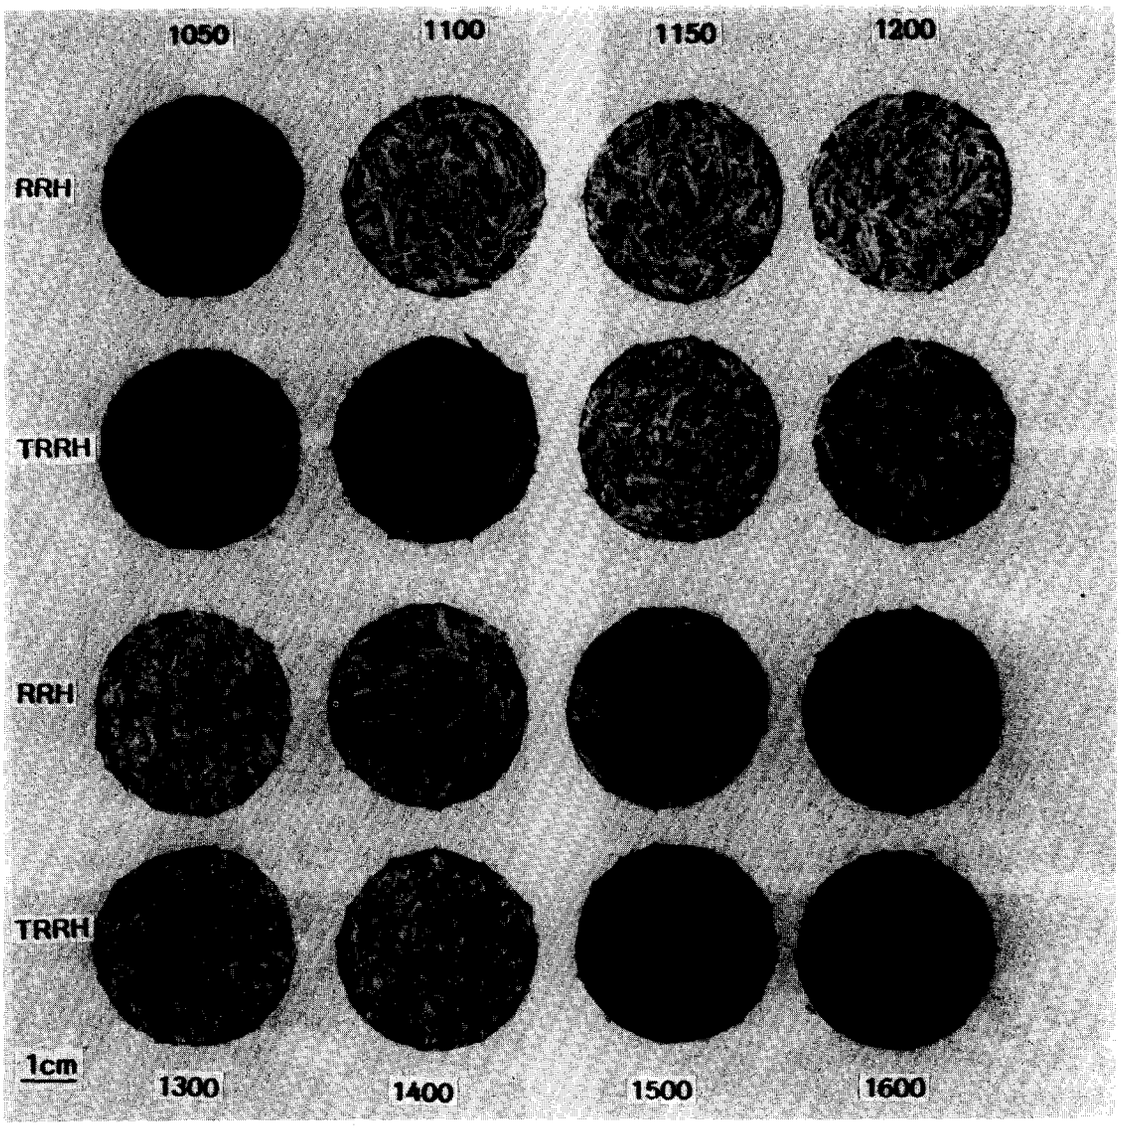

Fig. 7. Optical photograph of rice husks pyrolysed at different temperatures.

(Fig. 5(c)). Similarly in TRRH samples with increase in pyrolysis temperatures, formation of particulates has been observed (Fig. 6). However, the formation of SiC whiskers in TRRH samples was found to be lower than that in RRH samples. After identifying whiskers through SEM, the relative whitish appearance of pyrolysed RHs can be compared for a rough estimation of the percentage of SiC whiskers formed.[11] The appearance of RHs after pyrolysis is shown in Fig. 7. From this optical micrograph one can observe that the whitish deposition on TRRH at any pyrolysis temperature is lower than that on RRH.

The weight % of excess carbon, unreacted SiO_2, and the total SiC in the pyrolysed RHs is shown plotted in Fig. 8. The excess carbon content is very low in TRRH. The unreacted silica was slightly higher in TRRH up to 1150°C. The SiC content in TRRH is slightly low up to 1150°C and much higher above 1200°C. After acid treatment of RHs, as the part of organic matter was leached out, the silica content in TRRH has increased from 18·48 to 25·36%. Assuming that all the SiO_2 in the RHs becomes converted to SiC according to reaction $SiO_2 + 3C + C_{(excess)} \rightarrow SiC + 2CO + C_{(excess)}$, the theoretical values of SiC content and excess carbon in the product of pyrolysis can be calculated.[13] The theoretical values of SiC content in the converted RRH and TRRH are 14·88 and 22·14 wt%, respectively.

Similarly, the theoretical values of excess carbon are 81·52 wt% for RRH, and 77·86 wt% for TRRH. During the carbothermal reduction of silica to form SiC, the carbon loss as CO is generally higher than the theoretical value.[13] From Fig. 8 it is clear that the carbon loss as CO in TRRH is much higher than that in RRH.

4 Discussion

During pyrolysis of RHs at higher temperatures, four processes, i.e. graphitization of carbon, crystallization of amorphous silica, formation of SiC

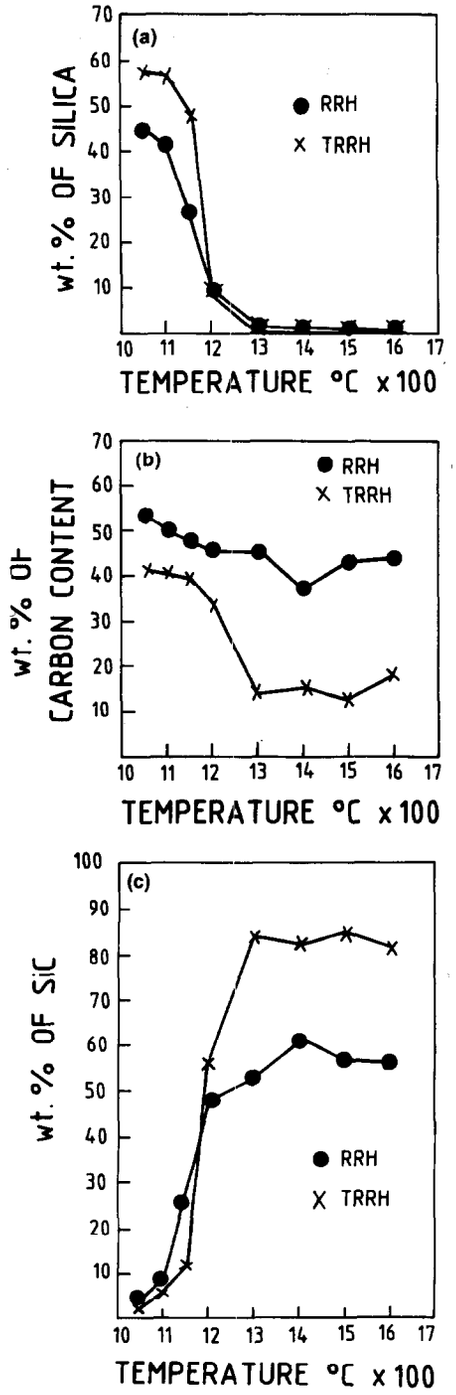

Fig. 8. Plots of (a) residual carbon, (b) unreacted silica and (c) SiC content, all versus pyrolysis temperature.

particles and formation of whiskers, are simultaneously advancing.[11] When RRHs are treated with acid, the cellulose which forms the main body of raw RHs is reduced and the carbohydrate is blackened due to the removal of oxygen. The proteins in the RHs are decomposed into amino acids, and the cellulose of large molecular weight is leached out as smaller molecular weight compounds.[18] The impurities in the RH are substantially removed (Table 1). This results in higher purity of RHs with a porous structure. Potassium (K) in the RH causes surface melting and accelerates the crystallization of amorphous silica to form cristobalite.[19] Due to the porous structure and low level of impurities like K, the crystallization of silica and carbon in TRRH was negligible (Fig. 4).

It is well known that SiC forms at relatively low temperature because of the intimate contact available for carbon and silica in RHs. The reaction between silica and carbon to form SiC can be represented as

$$SiO_2 + C \rightarrow SiO + CO \quad (1)$$

$$SiO + 2C \rightarrow SiC + CO \quad (2)$$

$$SiO_2 + 3C \rightarrow SiC + 2CO \quad (3)$$

Since the TRRH is porous, the intimacy between silica and carbon is disturbed. The quantity of SiC formed in TRRH up to 1150°C was slightly low (Fig. 8). When SiO_2 and carbon are gradually consumed by reaction (1), they no longer remain in contact. Then CO produced by reaction (1) reacts with SiO_2 to form SiO and CO_2 (reaction (4)). The CO_2 then reacts with carbon to form CO (reaction (5)).

$$CO + SiO_2 \rightarrow SiO + CO_2 \quad (4)$$

$$CO_2 + C \rightarrow 2CO \quad (5)$$

Because of porous structure and low degree of crystallization, carbon in TRRH can form a larger quantity of CO. This is evident from the very low quantity of residual carbon in TRRH (Fig. 8). The SiO formed by reaction (1) or (4) can be adsorbed by carbon and form isometric SiC particles. The carbon in TRRH could adsorb a larger quantity of SiO than the carbon in RRH. As the quantity of SiO that could be evolved from TRRH is low, the possibility of whisker formation is low (Fig. 7).

At higher temperatures, due to the rapid deposition of SiO and the high rate of formation of SiC, the whiskers formed at lower temperatures are converted into particulates through a process of coagulative recrystallization. Formation of particulates through coagulative recrystallization of SiC whiskers is observed in both RRH and TRRH (Figs 5 and 6).

The results from this investigation clearly show that under similar conditions of pyrolysis the formation of SiC whiskers is low in TRRH.

5 Conclusions

(i) Relatively pure and bright white silica is formed from acid-treated raw rice husks.
(ii) The degree of crystallization of silica and carbon in pyrolysed TRRH is decreased.
(iii) The formation of SiC whiskers in TRRH is lower than in RRH.

(iv) At pyrolysis temperatures higher than 1300°C the formation of SiC particulates is the dominant process.
(v) Residual carbon content in TRRH is lower than that in RRH.

Abstract

In this paper a critical examination of the diagrams of different silicate systems is presented: LAS, MAS YAS, MLAS and YMAS (A: alumina; L: lithia; M: magnesia; S: silica; Y: yttria). These systems have been developed to fabricate ceramic matrix composites based on a glass ceramic matrix, because of their low thermal expansion coefficient and good mechanical properties up to 1000°C. The observations and microanalyses, by transmission electron microscopy, of different batches of MLAS and YMAS confirm the complexity of the systems investigated.

Introduction

The new class of materials known as ceramic matrix composites (CMCs) is concerned with a ceramic matrix reinforced either by ceramic fibers, whiskers or particles. But the matrix could be (i) a monolithic ceramic — such as SiC, Al_2O_3, Si_3N_4... — or (ii) a glass ceramic. The first ones are prepared for CMC materials from the ceramic routes, that is to say sintering or chemical vapour infiltration (CVI) processes, and the second ones result from the glass route which is easier and needs a lower process temperature. Nevertheless the domain of applications of glass ceramic matrices is lower than for ceramic matrices — the 1000°C domain —, but is of interest for specific applications in parts for motor aerospace and aircraft engines due to their strength and low densities (~2·5).

The scope of this paper is to present and to comment upon the complexity of several glass ceramic matrices which occur due to the crystallographic characteristics of many silicate phases which can arise in a very narrow domain of temperatures and, moreover, which can also lead to allotropic transformations and/or ionic substitutions in the same temperature domain.

Due to the fact that the lithium aluminum silicate (LAS) system has crystalline phases with a very low thermal expansion coefficient, and because these phases can appear in a very controlled way, this system is one that is investigated most to fabricate CMCs. But we shall see that such a system is in fact extremely complex. To fabricate CMCs with SiC Nicalon fibers and a glass ceramic matrix, several requirements are necessary: the glass ceramic must be chemically compatible with the SiC fibers (or alumina fibers) in order to avoid a resultant fibers degradation. Moreover the matrix and fibers must have an elastic modulus different enough and a thermal expansion coefficient low enough to have a reinforced material which is not damaged during the process. Finally such materials have to involve a correct pull-out process to exhibit a good mechanical strength. The LAS system is the most suitable but there are other systems which also seem promising, but with some advantages and disadvantages:[1] CAS, MAS, YAS,... for ternary systems, or BMAS, MLAS, YMAS,... for quartenary systems. Among these different systems, we shall discuss the LAS, MAS, YAS, MLAS and YMAS systems.

The LAS, MAS and MLAS Systems

The Li_2O–Al_2O_3–SiO_2 system gives a wide range of compositions with the thermal expansion coefficient ranging from 0 to about 120 $10^{-7}°C^{-1}$.[2] These materials have a very good thermal shock resistance and consequently they are used either for cooker panels, saucepans, or for specific optical devices for space applications such as blanks for laser gyroscopes or for X-ray telescopes.[3] But this thermal expansion coefficient is considerably affected by the existence of some crystalline phases: for example, if the alumina content is low, the materials present a higher thermal expansion coefficient, while if its content is high, the result is a material with a zero thermal expansion value.

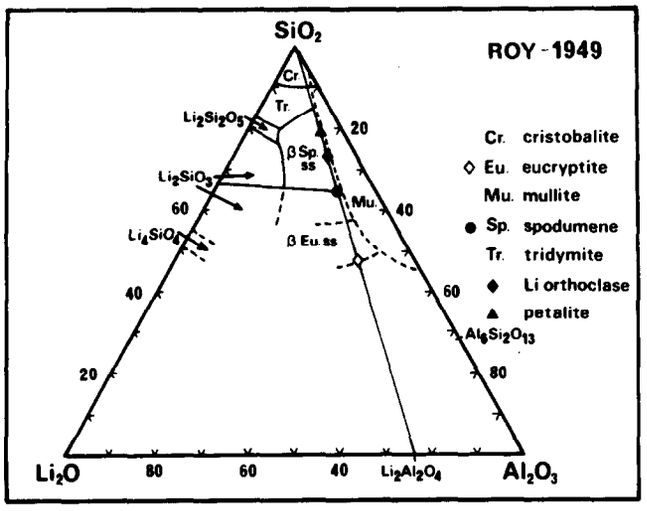

Fig. 1. Ternary diagram of phase equilibria of the Li_2O–Al_2O_3–SiO_2 system (LAS)[4]

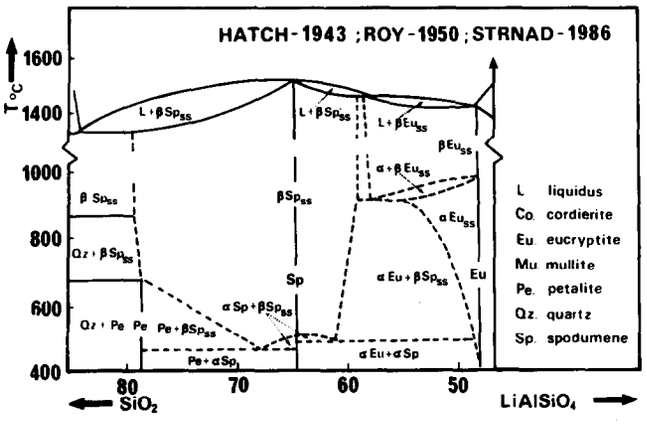

Fig. 2. Pseudo binary diagram of phase equilibria of the eucryptite–silica (Li_2O–Al_2O_3–$2SiO_2$–SiO_2) system.[4,5,7]

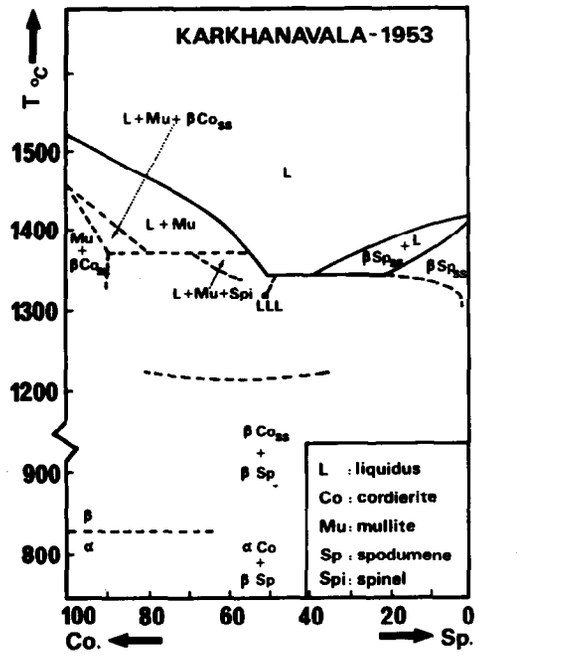

Fig. 3. Pseudo binary diagram of phase equilibria of the cordierite–spodumene (Co–Sp) ($2MgO$–$2Al_2O_3$–$5SiO_2$–Li_2O–Al_2O_3–$4SiO_2$) system (LLL: low limit of liquidus) after using the new nomenclature for α and β cordierite.[8]

There are no recent phase diagrams concerning the Li_2O–Al_2O_3–SiO_2 ternary system. The diagram proposed by Roy and Osborn in 1949[4] and by Roy *et al.* in 1950[5] is still used (Fig. 1). In this diagram we can see the presence of many different silicate phases such as β eucryptite, lithium orthoclase, mullite, petalite, β spodumene and tridymite.

Also useful are the pseudo binary diagrams eucryptite–silica which has also been reported by Hatch,[6] Roy *et. al.*[5] and slightly modified by Strnad in 1986 [7] (Fig. 2), and the pseudo binary diagram, cordierite–spodumene, proposed by Karkhanavala and Hummel,[8] (Fig. 3). For the latter diagram, we have used the new nomenclature for α cordierite (pseudo-hexagonal orthorhombic or low cordierite) and β cordierite (hexagonal or high cordierite).[9] Table 1 shows the crystallographic characteristics of some silicate phases which could appear in different M–M'–Si–O systems.[10]

From these three diagrams, the information from the works of Roy *et. al.*[4,5] and Karkhanavala and Hummel[8] concerning the eucryptite, spodumene, petalite and cordierite phases, and the eucryptite–silica and cordierite–spodumene pseudo binary systems, one can say:

Eucryptite: Li_2O–Al_2O_3–$2SiO_2$

— α eucryptite inverts into the high temperature form, β eucryptite, at 972 ±10°C during an incongruent melting;
— α eucryptite is rhombohedric, with the aluminum atoms in 6 coordination;
— it has been shown by Winkler[11] and also by Roy *et. al.*[5] that the structure of the β eucryptite is the same as that of the high temperature quartz, where the aluminum atoms are in the $A10_4$-tetrahedra.

Spodumene: Li_2O–Al_2O_3–$4SiO_2$

— the spodumene corresponds to the one found in the nature and to the high temperature form called β spodumene;
— the α form inverts in the β high temperature form at a maximum temperature of 500°C;
— it is a monoclinic pyroxene, with a tetragonal type structure.

Petalite: Li_2O–Al_2O_3–$8SiO_2$

— petalite is decomposed congruently to a β spodumene solid solution at 680± 10°C.

Cordierite: $2MgO$–$2Al_2O_3$–$5SiO_2$

— cordierite can appear in three crystallographic forms:[9]

(i) two low temperature forms, the stable low temperature α cordierite, which inverts reversibly to the high temperature β form at

830°C under hydrothermal conditions, and the metastable μ cordierite which is produced by the glass crystallization in air at about 850°C;

(ii) one high temperature form which can be produced by heating the material or by crystallizing the glass at temperatures between 1000 and 1400°C; at 1460°C the material is decomposed into mullite and liquid, with a complete melting at 1530°C.

Eucryptite–silica

— from these diagrams and the authors' comments,[5] there exists the possibility that a complete series of solid solutions occur between β eucryptite and β spodumene at high temperature;

— crystals of α spodumene are formed in the 375–500°C range;

— spodumene is stable only until 500± 15°C;

— petalite is found to invert completely to β spodumene at about 700°C.

Cordierite–spodumene

— the pseudo binary system cordierite–spodumene[8] is also of interest;

— it shows that α cordierite, α cordierite solid solution, β cordierite, β spodumene, β spodumene solid solution (which is partially metastable) are identified phases, but with also the presence of corundum, mullite and spinel;

— the spinel phase could probably be a solid solution of Li and Mg spinels.

The MAS ($MgO–Al_2O_3–SiO_2$) system was originally investigated by several authors, Rankin and Merwin in 1918, modified by Bowen and Greig in 1924 and Greig in 1927 and was reported by Prokopowicz and Hummel in 1956.[12] Some details have been more recently reported by Osborn and Muan,[13] Jouenne[14] and Partridge *et. al.*[2] (Fig. 4). There is little information regarding the MLAS

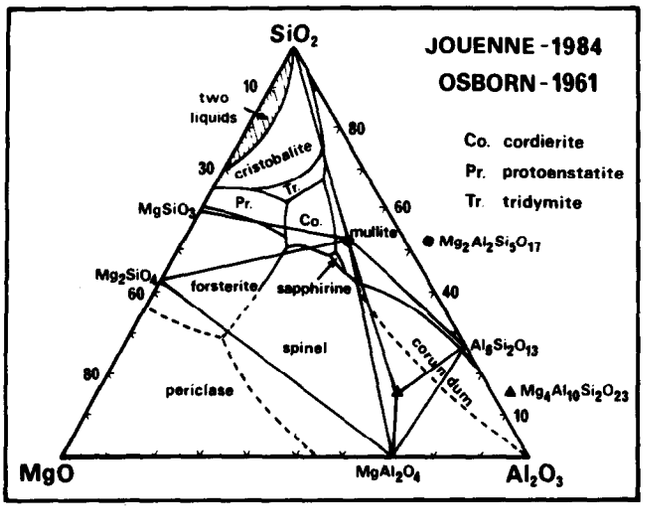

Fig. 4. Ternary diagram of phase equilibria of the $MgO–Al_2O_3–SiO_2$ system (MAS).[13]

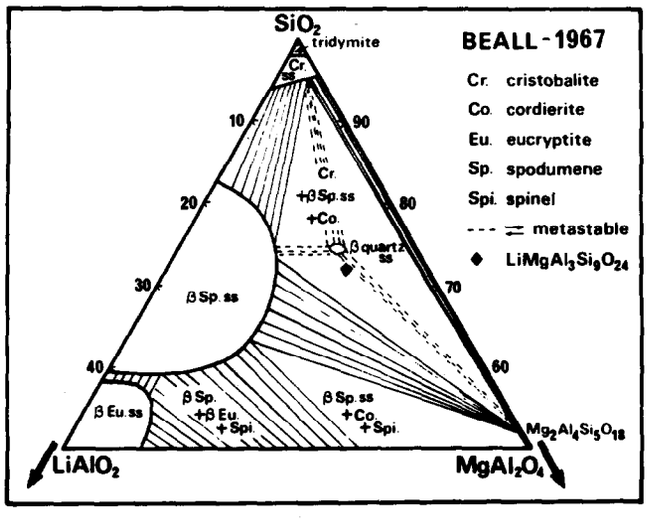

Fig. 5. Isothermal section at 1230°C for the pseudo ternary diagram of the $SiO_2–LiAlO_2–MgAl_2O_4$ system (MLAS).[15]

($MgO–Li_2O–Al_2O_3–SiO_2$) system,[12,15,16] (Fig. 5). It is based on cordierite ($2MgO–2Al_2O_3–5SiO_2$) and protoenstatite (or clinoenstatite (another allotropic form) according to different authors) ($MgO–SiO_2$), with other crystal phases: cristobalite (SiO_2), forsterite ($2MgO–SiO_2$), mullite ($3Al_2O_3–2SiO_2$) and spinel ($MgO–Al_2O_3$), and with the nucleating agents for cordierite based materials: TiO_2 or a combination of $TiO_2–ZrO_2$. As for LAS, it was found by Barry *et. al.*[17] that following the formation of the nucleating phase (a magnesium aluminosilicate structurally similar to the petalite), a number of intermediate phases appears prior to the development of the cordierite at about 1150–1250°C.

At high temperatures the relationships between spodumene and cordierite are very complex and involve also corundum, mullite and spinel, while at low temperatures, there exists a complete series of metastable solid solutions between μ cordierite and β spodumene.

In Ref. 18 details on the preparation of MLAS glass ceramic materials from a glass powder are given either by a traditional route (melting, nucleation and crystallization) or by simultaneous sintering and crystallization. The last method is largely cost-saving as it reduces the time at the fabrication temperature due to the difference in the viscosity. The interest of such a system (MLAS) is the ability to adjust the properties such as the thermal expansion coefficient, softening temperature, viscosity or the dielectric constant according to the chemical composition. Moreover it has been proved that the addition of MgO to $Li_2O–Al_2O_3–SiO_2$ glasses modifies the nonbridging oxygen, and consequently affects the bond strength, with a direct consequence on the glass transition temperature (T_g) of the MLAS.[19]

In the two pseudo ternary systems LAS and MAS, there exists equivalent crystallographic phases where cations can be located in a position of insertion. So it could be possible to combine the low values of the thermal expansion coefficient of LAS with the excellent mechanical properties of MAS. From the pseudo binary diagram,[8] there is effectively a large domain where there are both β spodumene solid solution and β cordierite. Moreover due to the similar sizes of Li^+ (0·68 Å) and Mg^{2+} (0·78 Å) there is a possible substitution which reinforces the glass ceramic phase.[15,20] Recently it has been shown that, in the presence of boron, there is also a substitution of boron for aluminum in the β eucryptite structure.[21]

The YAS and YMAS Systems

Systems based on Y_2O_3 are interesting because of

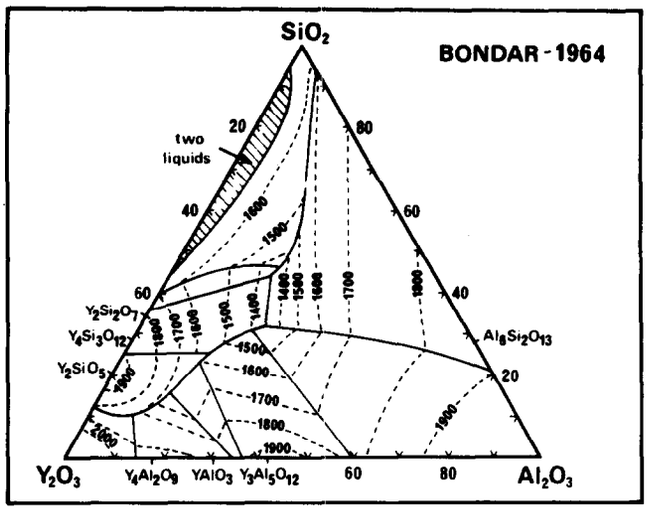

Fig. 6. Isothermal sections for the ternary diagram of the Y_2O_3–Al_2O_3–SiO_2 system (YAS).[24]

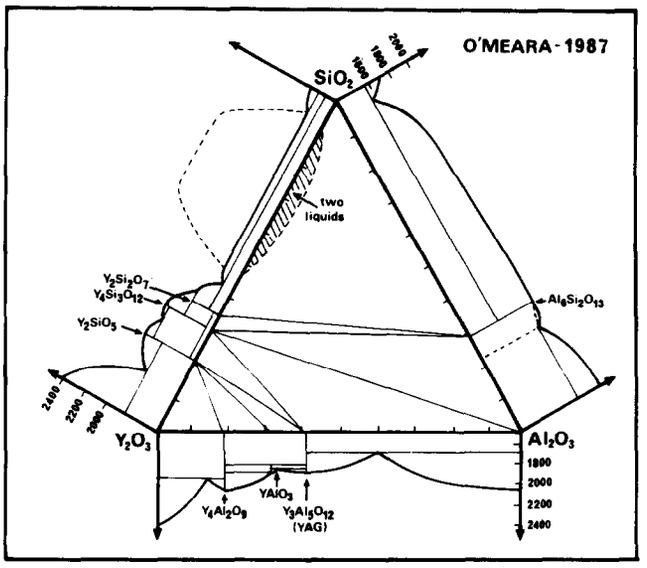

Fig. 7. Ternary and binary diagrams of phase equilibria of the Y_2O_3–Al_2O_3–SiO_2 system (YAS).[22]

its refractory nature and its oxidation resistance. Although the Y_2O_3–Al_2O_3–SiO_2 (YAS) system is extremely important for the understanding of sialons and β Si_3N_4 based ceramics containing Al_2O_3 and Y_2O_3 as sintering additives,[22] there is little information on this phase diagram. One can also note that this system was also investigated to develop YAS glass microspheres for radiotherapeutic applications (the ^{90}Y isotope being activated *in situ* by neutron bombardement, while Al, Si and O are not affected).[23]

Bondar and Galakov proposed a ternary diagram in 1964,[24] (Fig. 6), which was reinvestigated more recently by O'Meara *et al.* in 1987,[22] (Fig. 7). The crystalline identified phases are mainly yttrium disilicate (Y_2O_3–$2SiO_2$) under the two forms α and β (α being the main crystalline product), YAG ($3Y_2O_3$,$5Al_2O_3$) and mullite ($3Al_2O_3$,$2SiO_2$). However, Y_2O_3, Al_2O_3, and some other phases are unidentifiable using classical X-ray tables.

The YAS system has been investigated, more recently.[23] Ten glasses were fabricated at $T<1800$°C, each one corresponding to a specific composition. Among them only one gave a partially crystallized material. These authors were able to give some information and comments on the ternary diagram. As for the LAS system, the thermal expansion coefficient varies significantly with increasing the Y_2O_3 content, while it decreases as SiO_2 is added.[1] One of these compositions was also investigated later by other authors.[1] Their attention was focused on the fact that for the four polymorphic transformations of the $Y_2Si_2O_7$ phase, three different temperatures are reported for each transformation according to three different authors, (Table 2).[25–27] Moreover they found that the triclinic α form inverts in the β monoclinic form at 1285°C. In order to obtain good mechanical behaviour they proposed to sinter these materials above 1300°C to induce β $Y_2Si_2O_7$, otherwise brittle fracture behaviour will occur, which is an undesirable effect for CMC applications[1] as there is a change in the atomic volume associated with the allotropic transformations.[28]

Due to the fact that the distribution of the

$Y_2Si_2O_7$ particles in these glasses is sufficiently uniform and dilute, Arita *et al.*[29] have recently investigated the nucleation and crystallization of different glass compositions in the system Y_2O_3–Al_2O_3–SiO_2. They found that it is very sensitive to the initial composition of the glass, that Al_2O_3 enhances the sinterability of such a system, and that some specific heat treatment allows us to crystallize all or part of the amorphous phase: that may result in improving their mechanical behaviour and particularly their creep resistance, and will be useful to know for further investigations.

There is no published quaternary diagram on the YMAS system. To our knowledge the only information on the two ternary MAS and YAS systems comes from Refs 30 and 31. Regarding the process and the relationships between the process and crystallographic phases appearing, one can make the following points.

In these materials there are mainly α $Y_2Si_2O_7$, cordierite ($2MgO$–$2Al_2O_3$–$5SiO_2$), and some spinel crystals. Up to 1200°C, the cordierite and α yttrium silicate ratios evolve very slightly, while for a temperature greater than 1230°C, the ratio of α $Y_2Si_2O_7$ decreases significantly while the β $Y_2Si_2O_7$ phase appears; this also corresponds to a decrease in the density (4·30 → 4·03).[25] If there is the presence of yttria, then the low temperature cordierite crystallizes. If the sintering temperature is well chosen (> 1200°C) and the heating rate fast enough to have a short treatment period at $T > 1200$°C to avoid the crystallization of the β $Y_2Si_2O_7$ phase, then the densification is complete within few minutes. So such materials must be fabricated in compromised conditions: at a temperature not too high, but high enough to have a good microstructure and a density not too far from the theorical one. As it has been shown in Ref. 1, in the case of the SiC–YAS composites, the rupture of SiC_f–YMAS also becomes less catastrophic with some pull-out if the temperature process is higher than 1250°C.

Materials and Techniques

Materials investigated in this paper were experimental CMCs with glass ceramic matrices reinforced with Nicalon NLM 202 SiC fibers (Nippon Carbon, Japan). Two types were studied.

SiC_f–MLAS composites were CMCs developed by Aérospatiale (Etablissement de Bordeaux France). The matrix was produced by a chemical sol–gel route. After drying the slurry of a $0{\cdot}5MgO$–$0{\cdot}5Li_2O_3$–$Al_2O_3 4SiO_2$ initial composition which impregnated SiC bundles, tapes are formed, stacked and then densified in a hot press under pressure, in the 1200–1300°C domain.[16,32] Two temperatures were used, T_1) and T_2 ($T_2 > T_1$). The phase crystallization is in fact obtained in controlling the pressing temperature (T_1 or T_2) as well as the cooling rates. The stability of the matrix depends upon the crystalline nature of the matrix phases. In the presence of the β eucryptite solid solution, the stability is limited to 1050°C in the MLAS system (and only to 950°C in the LAS system), (see for example Figs 1 and 5). Above this temperature there is the β eucryptite → β spodumene transformation which modifies the thermomechanical equilibria as the thermal expansion coefficients α are different. Then the new composite possesses new properties (α, σ_r, ...)[32] As-received materials were plates 120 × 100 × 3 mm^3 with either a 1D texture or a $(0–90°)_{ns}$ cross–ply texture, with n = 2 or 3 and *s* meaning for symmetry (Fig. 8(a)).

SiC_r–YMAS composites were fabricated by ONERA (Etablissement de Palaiseau, France) either by a chemical route from organometallic salts and a colloidal sol, or by a glassy route from oxide melting. The initial chemical compositions were always a mixture of oxides: Y_2O_3–MgO–Al_2O_3–SiO_2. Two composites were particularly investigated: Composite A for which the binder burnout is realized in a specific furnace at 700°C under air, while for Composite B it occurs during the hot pressing cycle at 500°C under vacuum.

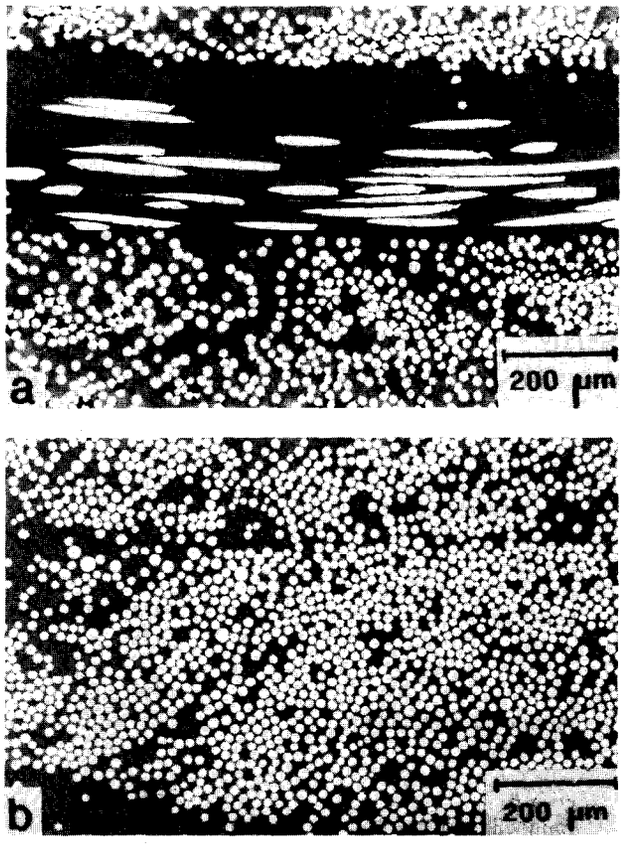

Fig. 8. Optical micrographs of the 2D SiC_f–MLAS (a) and of the 1D SiC_f–YLAS (b) composites.

Composite A is pressed under 10 MPa from 1000°C until 1300°C for 1 hr and then ceramised at 1200°C. Composite B, preloaded under 2 MPa from 500°C, is heated under vacuum until 500°C and pressed under 10 MPa when the maximum temperature, is reached (about 1300°C), and then ceramised at about 1200°C as for Composite A, the vacuum being maintained only until 700°C. Composites A are densified to 98% of the theoretical density and composites B up to the theoretical density. As-received materials were plates 100 × 100 × 3·5 mm^3 with a 1D texture (Fig. 8(b)).

All the specimens were cut with great care and very slowly using diamond wheels: either plates for rupture and creep experiments, or small samples inserted into cylinders of 3 or 2·7 mm in diameter and then cut. These last specimens were mechanically ground up to 50–100 μm, a dimpler was used to thin them up to about 10 μm and finally ion milled under argon (6 kV) at liquid nitrogen temperature (Gatan Duo Mill, Pleasanton, USA).

Microstructural investigations were performed: (i) by X-ray analysis; (ii) by transmission electron microscopy with a Jeol 200 CX and with a Topcon EM 002B: these two TEM operating at 200 kV, were equipped with a Kevex EDS microanalyser and were used to perform TEM, HREM and microanalysis studies; (iii) by scanning electron microsocopy with a Jeol 840 GLS with a Tracor 5200 EDS system, and a Zeiss DSM 60 with a Kevex system and (iv) by an electronprobe analyzer Jeol 6300 F.

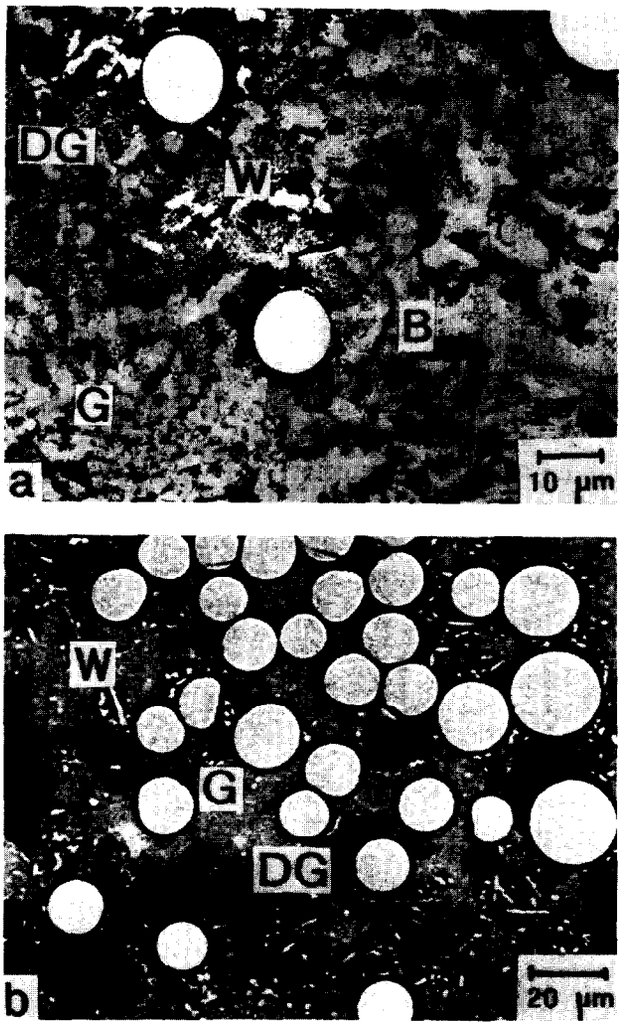

Fig. 9. Scanning electron micrographs of the MLAS matrices of the 1D (a) and 2D (b) composites (W = white: mullite, G = grey: cordierite, DG = dark grey: spodumene, B = black: carbon).

Results

Because of their very fine microstructure the composites have been investigated by scanning and transmission electron microscopies with microanalysis. The identification of the different present phases was confirmed regularly by X-ray analysis, EDS spectra and from the diffraction patterns.

SiC_f–MLAS

Although the 1D and 2D SiC_f–MLAS composites were elaborated in similar conditions, the as-received materials themselves differ, by several points. From observations and images of the MLAS matrix by scanning electron microscopy, it appears for the 2D materials white (W), grey (G) and dark grey (DG) areas, while for the 1D materials in addition there are black zones (B), (Figs 9(a) and (b)). All these phases seem to be not uniformally distributed inside the matrix.

The white phase was analyzed as mullite ($Al_6Si_2O_{13}$) as it coincides to crystals, generally elongated (Fig.10) and richer in aluminum than in silicon, with the correct ratio. The mullite crystals appear square section like. They are spread throughout the matrix with no particular orientation. The mullite needle shape is not so clearly observed in the 1D composite compared to the 2D ones. Moreover, the amount of mullite crystals is greater in the 2D than in the 1D materials. TEM

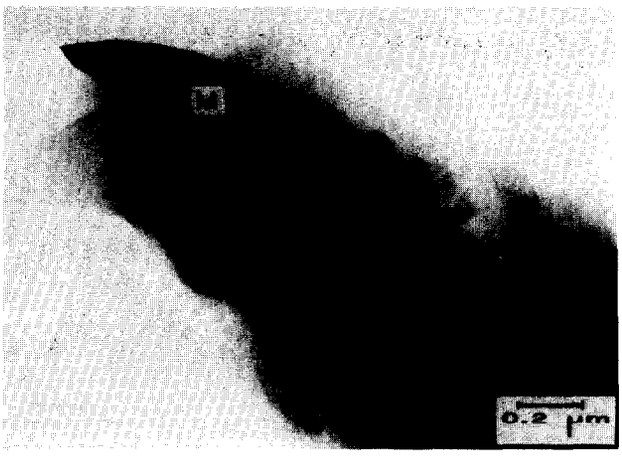

Fig. 10. TEM micrograph showing a mullite (M) needle in Bragg's conditions.

observations realised on the 1D composites show that these needles are sometimes surrounded by large crystals identified as β spodumene.

The dark-grey phase corresponds to the main phase only in the 1D materials: these areas are richer in silicon than in aluminum. Inside this phase the presence of magnesium is also detected. The presence of Mg is always detected whatever the phase is analyzed: mullite was even containing very few percent of Mg. By considering the Si/Al ratio and the diffraction patterns, the dark-grey phase was identified as β spodumene ($LiAlSi_2O_6$) or to a solid solution of β spodumene whose lithium cannot be detected, and where the magnesium ratio is not always the same in the whole specimen. The 1D composite investigated in TEM confirms that the main phase is β spodumene with quite large grains (Fig. 11). In the 2D materials, β spodumene zones appear only as inclusions dispersed in the grey phase.

These inclusions, recognised as β spodumene, have also been observed in 2D as-received SiC_f–MLAS composites, having a size greater than 100 nm.[33] The grey phase corresponding to the main phase in the 2D materials is the one richest in magnesium. Although the amount of magnesium is always lower than the theoretical value predicted from β cordierite formula ($Mg_2Al_4Si_5O_{18}$) this phase has been recognised as β cordierite or as a solid solution of β cordierite. These results of cordierite in the 2D material need further complementary investigations. In the 1D material β cordierite crystals have never been observed alone but always near to β spodumene crystals (Fig. 12).

Finally in the 1D materials one also observes black zones corresponding to areas with a very high concentration of carbon. This probably comes from the decomposition of organic compounds used during the fabrication of these composites as no carbon is used to coat the silicon fibers during the process route. Observations in TEM agree with this presence of carbon. Figure 13 shows carbon patches inside a β spodumene grain.

With regard to the fiber/matrix interface one observes several phases and turbostratic carbon layers. Close to the fiber side, EDS analysis gives

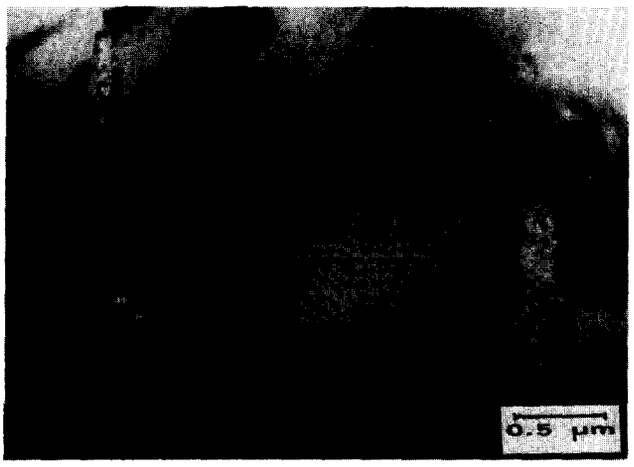

Fig. 11. Large grain of β spodumene observed in the 1D SiC_f–MLAS composite.

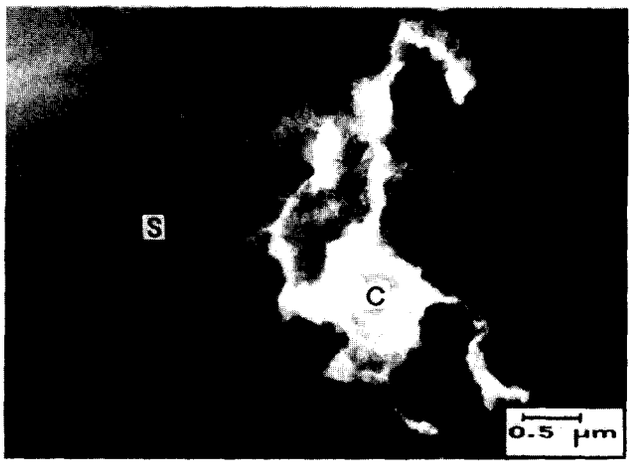

Fig. 13. Presence in the 1D composite of large carbon patches (C) inside spodumene grain (S).

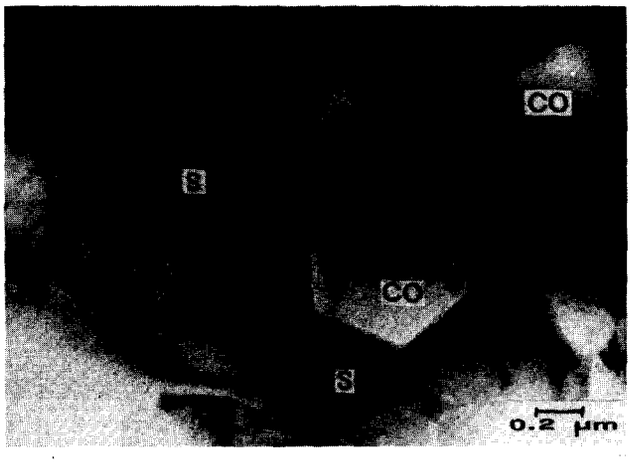

Fig. 12. Close mixture of β cordierite (CO) and β spodumene (S) grains in the 1D composite.

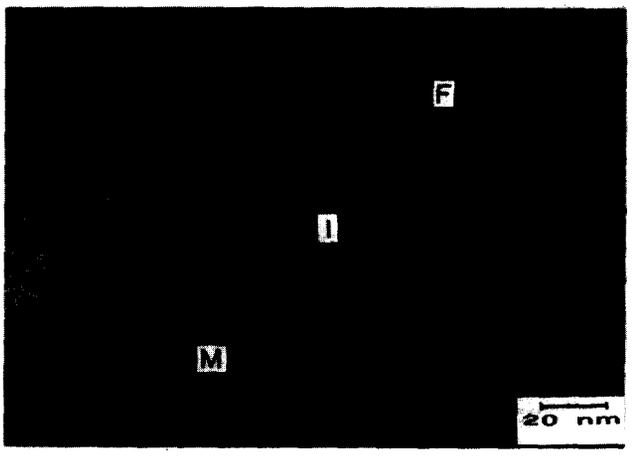

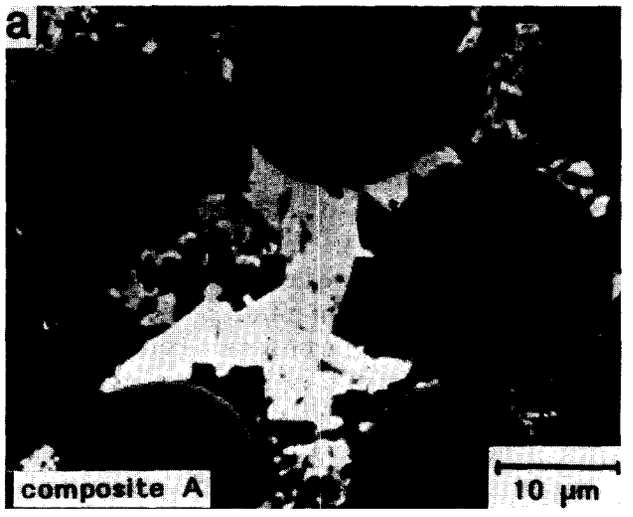

Fig. 14. Interface (I) between SiC fiber (F) and MLAS matrix (M) exhibiting mainly turbostratic carbon.

more silicon and oxygen and at the matrix side there is also a quite extended area along which the matrix appears to have reacted,[34] (Fig. 14). In these materials the interphase areas have a thickness which can vary from 10 to 100 nm.

SiC_f–YMAS

Figures 15(a) and (b) present the scanning electron micrographs of each composite. The phase containing yttrium appears in white. Large grains of that phase are present in Composite A. After microanalysis they have been identified as an yttrium silicate compound.[35] Due to the probe size (2 μm^3) it has not been possible to identify the small white grains as yttrium silicate. The black areas (Fig. 15(b)) show a phase rich in aluminum, magnesium and silicon elements, without the presence of yttrium. Composite B presents a more homogeneous microstructure without the presence of large grains. Globally the microstructure of these two types of composite is too fine to be analyzed at that scale because of the classical probe size used. Observations of Composite A reveals the existence of two main phases appearing in black and white. The dark crystals are distributed in a complex network and are elongated with a dendritic shape. Most of the yttrium phase is located in these zones (Fig. 16). The yttrium silicate has been identified as the high temperature form. The white areas generally correspond to more homogeneous zones. They are formed with cordierite crystals (the high cordierite) with a hexagonal symmetry (Fig 16).

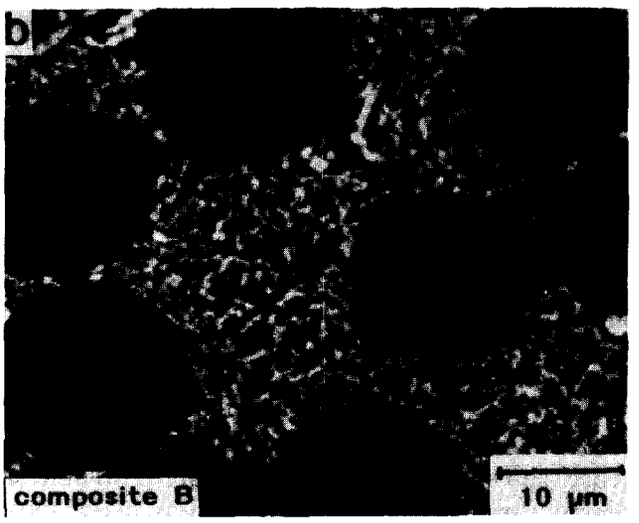

Fig. 15. SEM micrographs of the SiC_f–YMAS composite prepared by the sol–gel route (a) and by the glassy route (b).

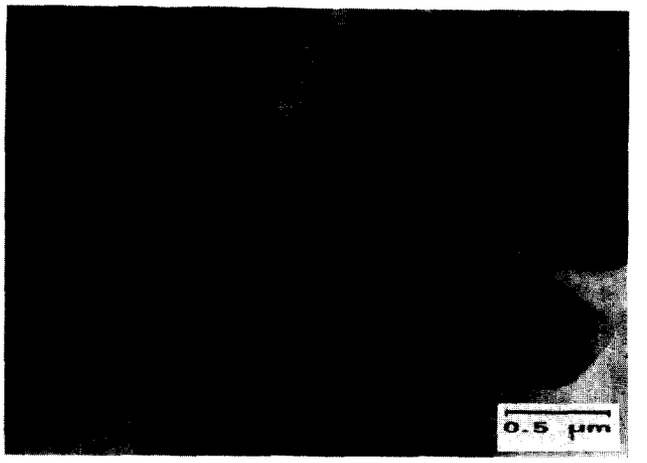

Fig. 16. Matrix formed by a network of yttrium silicate crystals with dendritic shape (dark) inside cordierite phase (clear), in Composite A.

For Composite A, some areas with a totally different microstructure also appear. An example is shown in Fig. 17. In that case, elongated and square shaped crystals are present in a phase which corresponds to a mixture of cordierite and yttrium silicate. These crystals were identified as mullite ($Al_6Si_2O_{13}$). Moreover some spinel crystals ($MgAl_2O_4$) are often observed within the cordierite or in the grain boundaries (Fig. 18)

Composite B exhibits the main microstructural features as Composite A. However, mullite crystals are rarely observed and the matrix appears finer and more homogeneous. In addition it has been observed that the cordierite crystals contain

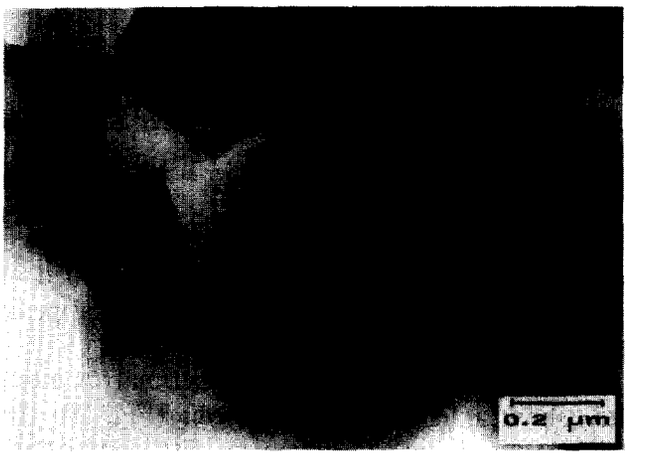

Fig. 17. Example of mullite crystal inside a mixture of yttrium silicate and cordierite in Composite A.

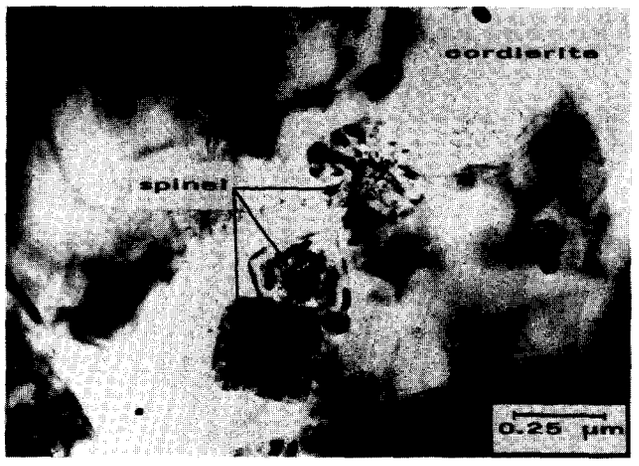

Fig. 18. Spinel crystals inside cordierite grain in Composite A.

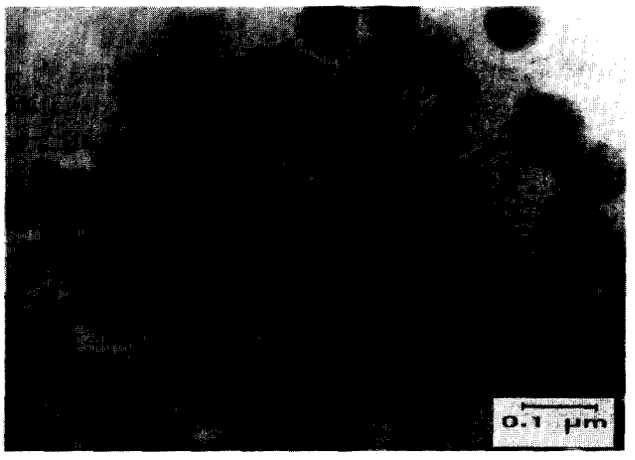

Fig. 19. Zirconia crystals inside cordierite phase in Composite B.

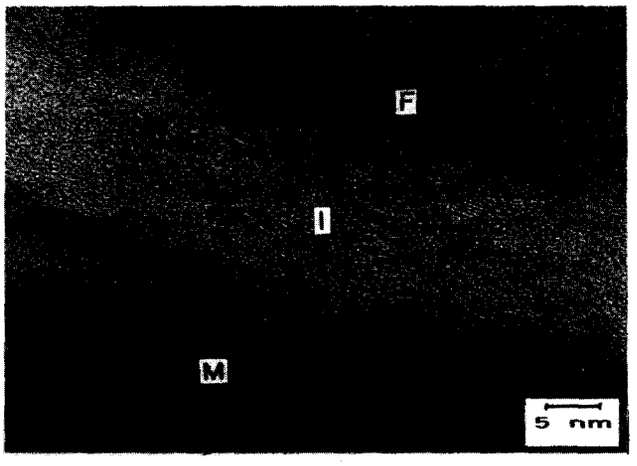

Fig. 20. HREM micrograph of the fiber/matrix interface, in Composite B.

some small inclusions (~20–100 nm) identified as zirconia (Fig. 19). At this scale, the matrix appears totally crystallized.

HREM observations at the fiber/matrix interface show a light contrasted layer (Fig. 20). Its thickness is about 20–30 nm in both composites. The nanostructure of the interface is similar to that one observed by Monthioux[36] in another type of glass ceramic composite (SiC_f–MLAS), with a layer of turbostratic carbon The sharp interface observed in the matrix side of the carbon layer and the diffuse interface observed on the Nicalon SiC fiber. support the concept of a carbon layer growing in the fiber.

Discussion

SiC_f–MLAS

The glass composite we had for the MLAS matrix — $0{\cdot}5MgO–0{\cdot}5Li_2O–1Al_2O_3–4SiO_2$ — is supposed to give as the first major phase, β eucryptite solid solution. As an immiscibility dome between SiO_2 and $Li_2O–Al_2O_3$ exists, one can have either a glass with the expected composition or a glass which can be richer or poorer in SiO_2 than expected. This leads to a β eucryptite solid solution in the LAS system whose composition can be quite far from the theoretical formula $Li_2O–Al_2O_3–2SiO_2$.[37]

The β eucryptite phase is subjected to microcracking and therefore has poor mechanical properties.[16] It is why one seeks to invert β eucryptite into β spodumene in this system. This transformation is possible whenever a glass composition has at least $3{\cdot}5SiO_2$ for $1MgO$ and $1Li_2O$[38] By heating the previous solid solution at 1050°C the transformation takes place and a β spodumene solid solution appears. This phase is suitable for thermomechanical applications generally because no microcracking appears. Moreover, it has recently been shown that this phase can be corroded easily by boiling sulfuric acid or by molten sodium nitrate.[39]

The precursor phase can have a composition in quite a large range, so it is not surprising that for the β spodumene a solid solution with different ratios of elements can crystallize.

At higher temperatures the MAS system (Fig. 4) considers the formation of β cordierite which also has no stable composition, particularly in magnesium. But substitution between Li^+ and Mg^{2+} are quite easy as they have a close ionic radii (Li^+:0·68 Å; Mg^{2+}:0·78 Å).

The presence of mullite crystals is evident in both the LAS and MAS systems (Figs 1 and 4) as they contain its existence domain.

The noticeable differences between the 1D and 2D materials in terms of majority phases is perhaps shown in the pseudo binary diagram cordierite–spodumene (Fig. 3).[8] To our knowledge this is the only one which makes a junction between the LAS and the MAS systems. Its existence shows that liquid phases are available at temperatures in the ternary diagrams taken separately. According to this diagram and depending upon the predominant phase in a cordierite–

spodumene mixture two different situations can arise. On one hand if we have more cordierite than spodu- mene a heat treatment will lead to even more cordierite and then to mullite. On the other hand a mixture richer in spodumene will give even more spodumene and less cordierite.

The association of cordierite and mullite was also predicted in Refs 13 and 14. It was noticed that in the MAS diagram the cordierite is able to melt incongruently by giving mullite at a temperature between 1355 and 1465°C.

In conclusion, the 1D SiC_f–MLAS matrix seems to belong to a system which has at the beginning more β spodumene than β cordierite, whilst for the 2D matrix it is the opposite. The materials evolution during creep tests confirm this assumption, as the 1D was evolving towards the β cordierite disparition to the benefit of β spodumene.[10] Concerning the 2D materials, no evolution between spodumene and cordierite has been reported as yet, but great enhancement of mullite crystals has been evident.

SiC_f–YMAS

Whatever the YMAS composites (A or B) one considers that the matrix contains two major and two minor phases, that is to say cordierite and yttrium silicate for the major and spinel and mullite for the minor. Besides this, zircone inclusions have been found in composite B. This can be easily explained by the oxide used in order to enhance the crystallization in the glassy route.

Microstructural observations and analyses on these materials have shown that yttrium silicate is the only compound which contains yttrium. This is in good agreement with previous investigations.[30,40] So it can be supposed that all the Y_2O_3 reacts with SiO_2 to form the $Y_2Si_2O_7$ phase.

Diffraction patterns allows us to identify the β form of that oxide. Because of the temperature of fabrication, it is in good agreement with the literature despite the fact that many temperatures are given for the same allotropic transformation according to different authors (cf. Table 2).

As yttrine is only in the $Y_2Si_2O_7$ silicate form, one can consider that alumina and magnesia react together to give binary or ternary compounds by reaction with silica as well. This leads us to consider the MAS system.

Moreover if one considers the amount of remaining silica, alumina and magnesia, it corresponds to a composition close to the sapphirine, which is present in the MAS ternary diagram. Unfortunately this phase has not been detected, but its existence domain is very small (Fig. 4). On that diagram one also notes that this phase is surrounded by three large domains corresponding to the three other phases identified in our composites, i.e. cordierite, mullite and spinel.

The cordierite is the second major phase with the yttrium silicate. It has been previously shown[13,14] that its formation by sintering begins at 1200°C. From the MAS diagram (Fig. 4) it appears as the phase existing at the lowest temperature domain. That is the reason why that phase appears as the most important at that fabrication temperature.

Very few mullite crystals appear in the YMAS matrix as silica reacts first to form cordierite rather than mullite because of its lower temperature of sintering (1200°C): that is in good agreement with the process temperature. As for the excess in magnesia, it reacts with alumina to form spinel above 1000°C.

Conclusion

The development of glass ceramic matrices is important in the field of ceramic matrix composites (CMCs) due to their very low thermal expansion coefficient and their good mechanical strength. So it requires a good knowledge of the corresponding pseudo–binary, ternary and quaternary diagrams. From their accurate analysis one can note many important difficulties: (i) different silicate phases can appear in very close domains; (ii) many allotropic transformations exist; (iii) different atom substitutions can arise and (iv) several crystallographic parameters of different silicate phases have the same value. These different points emphasize the complexity of knowing with accuracy which phases are present in the materials. Anyway, during long term applications, these silicate phases can evolve.

The management (control) of the stability of the glass ceramic matrices in these multicomponent systems is an essential step to consider applications for long durations, such as for motors, hypersonic structures, etc.... Moreover, for glass ceramic systems with aluminum or lithium reinforced by silicon carbide fibers, such as LAS, MAS, YAS, MLAS or YMAS systems, the diffusion of aluminum or lithium in the SiC fibers is an important factor to consider: it can act on the crystalline phases of the matrix due to change in composition and can make the fibers even more brittle. Moreover a matrix with lithium or lithium components can evaporate during the process.[41]

These different points have been illustrated by investigations in scanning and transmission electron microscopies with microanalysis, of the MLAS ($MgO–Li_2O–Al_2O_3–SiO_2$) and YMAS ($Y_2O_3–MgO–Al_2O_3–SiO_2$) systems.

It appears that the matrices in the 1D and 2D SiC_f–MLAS composites are slightly different, although the composition of the started gel and the process were the same. This simple fact shows the difficulty in obtaining any point reproductible matrices with exactly the same phases and distributions.

This is due to the multitude of possibilities deduced from the thermodynamic diagrams. In fact the detectable phases in the two composites are identical but their size distribution is not. The 1D matrix shows the following phase distribution: β spodumene > β cordierite >> ϵ mullite, while in the 2D it is β cordierite >> β spodumene > mullite. Consequently when the SiC_f–MLAS composites are submitted to creep test, the matrix which is not totally crystallized, will be subjected to chemical and morphological evolution. As the as-received matrices are not exactly equivalent, different ways of phase evolution will have to be considered. But depending on which scale we are working, these phenomena will be considered as crucial or as minor: for example, if one has to compare the damage due to a crack running from one ply to another with regard to a phase transformation.

The main phases in YMAS matrices were β $Y_2Si_2O_7$ and β cordierite, the secondary ones being mullite and spinel. It is maintained by a very complex network acting like a spider's web where minor and major phases are sometimes overlapping. One other advantage of this system is that no substitution can occur between magnesium and yttrium.

In the two YMAS and MLAS matrices one expects a more stable YMAS type matrix because this one is totally crystallized.

Acknowledgements

This work has been performed: (i) in the frame of the Groupement Scientifique GS 4C 'Comportements thermomécaniques des composites céramique–céramique à fibre' supported by CNES, CNRS, DRET, MRE and Aerospatiale, SEP and SNECMA companies, and (ii) under DRET contract no. 92/1221 A.

Contents of Volume 15

Number 1

1 Control of Texture in Al_2O_3 by Gel-casting
T. CARISEY, A. LAUGIER-WERTH & D. G. BRANDON (Israel)

9 Effect of Powder Granulometry and Pre-treatment on Sintering Behavior of Submicron-grained α-Alumina
E. SATO & C. CARRY (Switzerland)

17 Influence of Oxygen Partial Pressure on the Metastability of Undoped Zirconia Dispersed in Alumina Matrix
H. TOMASZEWSKI & K. GODWOD (Poland)

25 Grain Boundary Ionic Conduction in Zirconia-based Solid Electrolyte with Alumina Addition
X. GUO, C.-Q. TANG & R.-Z. YUAN (China)

33 Processing, Microstructure and Mechanical Properties of SiC Platelet-reinforced 3Y-TZP Composites
A. SELÇUK, C. LEACH & R. D. RAWLINGS (UK)

45 Nb_2O_5 and Ta_2O_5 Codoped Zirconia
G. GRITZNER, C. PUCHNER (Austria) & J. DUSZA (Slovakia)

51 Ionic Conductivity of Fully Stabilized ZrO_2:MgO and Blocking Effects
E. N. S. MUCCILLO (Brazil) & M. KLEITZ (France)

57 Synthesis and Sintering of PLZT Powder Made by Freeze/Alcohol Drying or Gelation of Citrate Solutions
M. A. AKBAS & W. E. LEE (UK)

65 TEM Investigation of Cordierite Crystallization from a Glass Powder with Composition $Mg_2Al_4Si_{11}O_{30}$
W. WINTER, A. BERGER, G. MÜLLER & W. PANNHORST (Germany)

71 Morphological Characterization of Hot-pressed α-SiC with Al-based Additives Deformed by Compression at High Temperature
M. L. DUVAL-RIVIERE, M. COSTER, L. CHERMANT, J. VICENS & C. CARRY (France)

81 Chlorine and Oxygen Inhibition Effects in the Deposition of SiC-based Ceramics from the Si–C–H–Cl System
D. LESPIAUX, F. LANGLAIS, R. NASLAIN, S. SCHAMM & J. SEVELY (France)

89 Computer Simulation of β'-Sialon Synthesis
L. F. S. DUMITRESCU & B. SUNDMAN (Sweden)

95 Oxygen Enrichment at Inversion Domain Boundaries in Aluminium Nitride—Influence on Thermal Conductivity
G. GORZAWSKI, M. STERNITZKE, W. F. MÜLLER, A. BERGER & G. MÜLLER (Germany)

Number 2

101 Laminar Ceramic Composites
T. CHARTIER, D. MERLE & J. L. BESSON (France)

109 Shrinkage and Particle Packing during Removal of Organic Vehicle from Ceramic Injection Mouldings
HEIDI M. SHAW & MOHAN J. EDIRISINGHE (UK)

117 The Use of Overpressure in Thermolytic Debinding of Moulded Ceramic Bodies
P. D. HAMMOND & J. R. G. EVANS (UK)

127 Laser Ablation of Barium Titanate Ceramics Prepared by the Citric Route: The Evolution of Residual Carbon Content
C. MIOT, C. PROUST, E. HUSSON, G. BLONDIAUX & J. P. COUTURES (France)

135 Surface Decontamination Treatments of Undoped $BaTiO_3$—Part I: Powder and Green Body Properties
CLAUDE HÉRARD, ANNELISE FAIVRE & JACQUES LEMAÎTRE (Switzerland)

145 Surface Decontamination Treatments of Undoped $BaTiO_3$—Part II: Influence on Sintering
CLAUDE HÉRARD, ANNELISE FAIVRE & JACQUES LEMAÎTRE (Switzerland)

155 Characterization of Submicron Alumina Dispersions with Poly(methacrylic acid) Polyelectrolyte
WEN-CHENG J. WEI, SU JEN LU & BU-KON YU (Taiwan)

165 The Densification and Microstructural Development of Al_2O_3 with Manganese Oxide Addition
H. ERKALFA, Z. MISIRLI, M. DEMIRCI, Ç. TOY & T. BAYKARA (Turkey)

173 Reaction Process and Densification Process of Mixed α'/β'-Sialon Ceramics
KOJI WATARI, MASAKI YASUOKA, MARIA CECILIA VALECILLOS & SHUZO KANZAKI (Japan)

185 Association of the CVI Process and of the Use of Polysilazane Precursor for the Elaboration of Ceramic Matrix Composites Reinforced by Continuous Fibres
M. F. GONON (Ireland), G. FANTOZZI, M. MURAT & J. P. DISSON (France)

Number 3

191 Fractography of Fatigued and Fractured Regions in a Silicon Carbide Whisker Reinforced Alumina Composite
A. K. RAY, S. K. DAS, P. K. ROY & S. BANERJEE (India)

201 Determining the Fracture Toughness of Brittle Materials by Hertzian Indentation
P. D. WARREN (UK)

209 Mechanical Properties of C/SiC Composites as Explained from their Interfacial Features
J.-F. DESPRÉS & M. MONTHIOUX (France)

225 Properties and Interface Structures of Ni and Ni–Ti Alloy Toughened Al_2O_3 Ceramic Composites
X. ZHANG, (The Netherlands), G. LU, M. J. HOFFMANN (Germany) &
R. METSELAAR (The Netherlands)

233 Thermal Expansion and Adhesion of Ceramic to Metal Sealings: Case of Porcelain–Kovar Junctions
A. ZANCHETTA, P. LEFORT & E. GABBAY (France)

239 A Thermodynamic Reassessment of the Si–Al–O–N System
L. DUMITRESCU & B. SUNDMAN (Sweden)

249 Aluminum Magnesium Oxynitride: A New Transparent Spinel Ceramic
A. GRANON, P. GOEURIOT & F. THEVENOT (France)

255 The Effect of $La_2Ti_3O_9$ Second Phase on the Microstructure and Dielectric Properties of $La_2Ti_2O_7$ Ceramics
Y. J. ZHONG, F. AZOUGH & R. FREER (UK)

265 Low Temperature Synthesis of Zinc Ferrite using Hydrazine Monohydrate
M. UEDA, S. SHIMADA & M. INAGAKI (Japan)

Number 4

271 Deformation and Strength of Engineering Ceramics and Single Crystals
G. A. GOGOTSI & D. YU. OSTROVOY (Ukraine)

283 Microstructure and Mechanical Properties of Textured Al_2O_3
T. CARISEY, I. LEVIN & D. G. BRANDON (Israel)

291 Toughening and Strengthening of Alumina with Silver Inclusions
W. B. CHOU & W. H. TUAN (Taiwan)

297 Toughening of X-Sialon with Al_2O_3 Platelets
Y. ZHOU, J. VLEUGELS, T. LAOUI & O. VAN DER BIEST (Belgium)

307 Fracture Tests for Ceramics under Mode-I, Mode-II and Mixed-Mode Loading
T. FETT, G. GERTEISEN, S. HAHNENBERGER, G. MARTIN & D. MUNZ (Germany)

313 Determination of Oxide Thickness on an Si_2N_2O–ZrO_2 Composite by Spectroscopic Ellipsometry
M. HEIM, H. ARWIN, J. CHEN & R. POMPE (Sweden)

319 The Oxidation Behaviour of a Porous Si_2N_2O–ZrO_2 Composite Material
COLETTE O'MEARA, MAIKEN HEIM & ROBERT POMPE (Sweden)

329 Corrosion Resistance of Ceramic-coated Stainless Steel in a Br_2–O_2–Ar Atmosphere
MAKOTO SASAKI & TOSHIO HIRAI (Japan)

337 Borosilicate Coatings on Mild Steel Prepared from Aqueous Amine Solutions: A Comparison with the Alkoxide Routes
N. MALIAVSKI, E. TCHEKOUNOVA (Russia), P. INNOCENZI, D. FESTA, M. GUGLIELMI & L. MANCINELLI DEGLI ESPOSTI (Italy)

343 Effects of Composition Changes on the Crystallization Behaviour and Properties of SiO_2–Al_2O_3–CaO–MgO (Fe_2O_3–Na_2O–K_2O) Glass-Ceramics
V. K. MARGHUSSIAN & M. H. DAYI NIAKI (Iran)

349 Subsolidus Phase Relationships in the Systems Ln_2O_3–Si_3N_4–AlN–Al_2O_3 (Ln = Nd, Sm)
W. Y. SUN, D. S. YAN, L. GAO (China), H. MANDAL, K. LIDDELL & D. P. THOMPSON (UK)

357 Tape-casting: Relationship Between Organic Constituents and the Physical and Mechanical Properties of Tapes
M. DESCAMPS, G. RINGUET, D. LEGER & B. THIERRY (France)

363 Densification and Microstructure Development of Alumina/Y-TZP Composite Powder (Y-TZP-rich) Compacts
J. L. SHI & T. S. YEN (China)

371 Fabrication of Low-Voltage ZnO Varistors by a Two-Step Process
JOO-HWAN HAN, DONG-HEON LEE & DOH-YEON KIM (South Korea)

Number 5

377 Bridging Stress Relations for Ceramic Materials
T. FETT & D. MUNZ (Germany)

385 Statistical Determination of Surface Flaw Distributions in Brittle Materials
P. D. WARREN (UK)

395 Reliability of Alumina Ceramics: Effect of Grain Size
J. SEIDEL, N. CLAUSSEN & J. RÖDEL (Germany)

405 Vickers and Knoop Indentation Behaviour of Cubic and Partially Stabilized Zirconia Crystals
G. A. GOGOTSI, S. N. DUB, E. E. LOMONOVA & B. I. OZERSKY (Ukraine)

415 The Development of Microstructure in Silicon Nitride-Bonded Silicon Carbide
D. P. EDWARDS, B. C. MUDDLE, Y.-B. CHENG & R. H. J. HANNINK (Australia)

425 Room Temperature Tensile and Flexural Strength of Ceramics in AlN–SiC System
H. A. TOUTANJI (Puerto Rico), D. FRIEL, T. EL-KORCHI, R. N. KATZ, G. WECHSLER & W. RAFANIELLO (USA)

435 Thermal Conductivity Improvement of YAG Added AlN Ceramics in the Grain Boundary Elimination Process
M. KASORI & F. UENO (Japan)

445 On the Thermal Degradation of Lox-M Tyranno® Fibres
C. VAHLAS & M. MONTHIOUX (France)

455 Thermal Shock Resistance on Nextel/Silica–Zirconia Ceramic-Matrix Composites Manufactured by Freeze-Gelation
A. TWITTY, R. S. RUSSELL-FLOYD, R. G. COOKE & B. HARRIS (UK)

463 The Preparation, Characterization and Electrical Properties of Electroceramics made of Copper–Cobalt Manganite Spinel: $Mn_{2\cdot6-x}Co_{0\cdot4}Cu_xO_4 0 \leq x \leq 1$
R. LEGROS, R. METZ & A. ROUSSET (France)

469 Compaction and Sintering Behaviour of Sol–Gel Powders
Y. JORAND, M. TAHA, J. M. MISSIAEN (France) & L. MONTANARO (Italy)

479 The Packing Density of Binary Powder Mixtures
J. ZHENG, W. B. CARLSON & J. S. REED (USA)

Number 6

Review

485 Environmental Degradation of Zirconia Ceramics
S. LAWSON (UK)

503 Thermodynamic Assessment of the ZrO_2–$LaO_{1\cdot5}$ System
Y. DU, M. YASHIMA, T. KOURA, M. KAKIHANA & M. YOSHIMURA (Japan)

513 Creep Properties of Single Crystal Oxides Evaluated by a Larson–Miller Procedure
S. DENG & R. WARREN (Sweden)

521 Effect of Vapor Atmosphere on the Formation Reaction of $MSiO_3$ (M = Mg, Ca, Sr and Ba)

185 Recent Progress in the Fabrication of Ceramic Negative Temperature Coefficient Thermistors
A. ROUSSET, R. LEGROS & A. LAGRANGE (France)

197 Failure Behaviour of Al_2O_3 with Glassy Phase at High Temperatures
T. FETT, M. MIßBACH & D. MUNZ (Germany)

211 Sintering of Wet-Milled Centrifugal Cast Alumina
P. HIDBER, F. BAADER, T. GRAULE & L. J. GAUCKLER (Switzerland)

221 Processing of Aluminium Nitride Powder by the Tape-Casting Process
M. DESCAMPS, G. MOREAU, M. MASCART & B. THIERRY (France)

229 Aluminium Nitride Ceramics with High Thermal Conductivity from Gas-Phase Synthesized Powders
P. GREIL, M. KULIG, D. HOTZA, H. LANGE & R. TISCHTAU (Germany)

239 Improvement of Oxidation Behaviour of Dense Silicon Nitride by Surface Modification
C. TAUT, M. HERRMANN, G. GROßE, P. THIELE (Germany) & Y. GOGOTSI (Japan)

247 Sintering, Hardness and Indentation Fracture Toughness (K_{IC}) of Mullite and its Composite with 15 wt% X-Phase Sialon
C. C. ANYA & A. HENDRY (UK)

257 Surface Scaling in SiC-Whisker–Alumina under Flowing Hydrogen at 1300–1500°C
WANG DEQING & H. F. LOPEZ (USA)

265 Characterization of Agglomerate Strength of Coprecipitated Superfine Zirconia Powders
J. L. SHI, Z. X. LIN, W. J. QIAN & T. S. YEN (China)

275 Thermal Stability of Cordierite Catalyst Supports Contaminated by Fe_2O_3, ZnO and V_2O_5
P. SCARDI, N. SARTORI, A. GIACHELLO, P. P. DEMAESTRI & F. BRANDA (Italy)

Number 4

283 Editorial

285 Synthesis and Characterization of Nanocomposite Si/C/N Powders by Laser Spray Pyrolysis of Hexamethyldisilazane
N. HERLIN, M. LUCE, E. MUSSET & M. CAUCHETIER (France)

293 Neutron Diffraction Study of the Amorphous Phase Structure in Silicon Carbonitride Ceramics Obtained by Pyrolysis of a Polyvinylsilazane
J. DIXMIER, R. BELLISSENT, D. BAHLOUL & P. GOURSAT (France)

299 Microstructure and Mechanical Behaviour of Self-Reinforced Si_3N_4 and Si_3N_4–SiC Whisker Composites
F. ROSSIGNOL, P. GOURSAT, J. L. BESSON & P. LESPADE (France)

313 Influence of Oxidation in SO_2–Air Mixtures on the Room-Temperature Strength of Silicon Nitride
J.-B. VEYRET, R. J. FORDHAM (The Netherlands) & M. BILLY (France)

323 Study of the Interaction between Liquid Aluminum and Silicon Nitride
L. MOURADOFF, A. LACHAU-DURAND, J. DESMAISON, J. C. LABBE, O. GRISOT & R. REZAKHANLOU (France)

329 Compatibility between Molybdenum and Aluminium Nitride
P. LEFORT & R. QUERIAUD (France)

335 Effect of Oxygen Content on the Corrosion of AlN Powder in Diluted Acid Solution
F. BARBA, P. ORTEGA, J. BERMUDO, M. I. OSENDI & J. S. MOYA (Spain)

339 An In-situ Study of the Oxidation of AlN Layers Elaborated by LPCVD Using X-Ray Diffraction
C. LABATUT, D. KHARCHI, B. ASPAR, F. SIBIEUDE & B. ARMAS (France)

345 Transmission Electron Microscopy Studies of AlN Deposits
D. DORIGNAC, A. MAZEL, Y. KIHN, J. SEVELY, B. ASPAR, B. ARMAS, C. COMBESCURE (France)

355 High Temperature Compressive Tests of Aluminium Nitride: Mechanical Properties and Microstructure
I. MASSON, J. P. FEIEREISEN, J. P. MICHEL, A. GEORGE, A. MOCELLIN & P. BLUMENFELD (France)

365 Reactivity in the Al_2O_3–AlN–MgO System. The MgAlON Spinel Phase
A. GRANON, P. GOEURIOT, F. THEVENOT, J. GUYADER, P. L'HARIDON & Y. LAURENT (France)

371 Nanometric Boron Nitride Powders: Laser Synthesis, Characterization and FT-IR Surface Study
M. I. BARATON, L. BOULANGER, M. CAUCHETIER (France), V. LORENZELLI (Italy), M. LUCE, T. MERLE, P. QUINTARD & Y. H. ZHOU (France)

379 Mechanical Properties and Oxidation Behaviour of HIPed Hafnium Nitride Ceramics
M. DESMAISON-BRUT, J. MONTINTIN, F. VALIN & M. BONCOEUR (France)

Number 5

387 V_2O_5, Nb_2O_5 and Ta_2O_5 Doped Zirconia Ceramics
G. GRITZNER & C. PUCHNER (Austria)

395 Subeutectoid Precipitate Growth Activation Energies in Mg-PSZ
C. S. MONTROSS (Australia)

403 Preparations and Characterisations of Ceramics Based on Cesium Titanate
V. PERES, P. FABRY, F. GENET & P. DEHAUDT (France)

411 Reaction Sintering of Aluminium Titanate: I — Effect of MgO Addition
V. BUSCAGLIA, P. NANNI, G. BATTILANA, G. ALIPRANDI (Italy) & C. CARRY (Switzerland)

419 Reaction Sintering of Aluminium Titanate: II — Effect of Different Alumina Powders
V. BUSCAGLIA, P. NANNI, G. BATTILANA, G. ALIPRANDI (Italy) & C. CARRY (Switzerland)

427 High Temperature Fracture of a SiC Whisker-Reinforced Alumina in Air and Vacuum
T. HANSON, A. H. SWAN & R. WARREN (Sweden)

437 Sintering Behaviour of Tape-Cast CMAS Glass–Ceramic Reinforced with Alumina Chopped Fibers
C. LEONELLI, T. MANFREDINI, G. C. PELLACANI & D. S. BLUNDO (Italy)

441 Constitution of the γ-Alumina Phase in Chemically Produced Mullite Precursors
H. SCHNEIDER, D. VOLL, B. SARUHAN, M. SCHMÜCKER, T. SCHALLER & A. SEBALD (Germany)

449 The Determination of the Crystallite Size in Alumina with Submicron-sized Crystallites
F. K. VAN DIJEN (Germany), K. KAMPFER & H. HOFMANN (Switzerland)

453 Stresses Near the Free Edge of the Interface in Ceramic-to-Metal Joints
D. MUNZ & Y. Y. YANG (Germany)

461 Preparation of R–α′–β′-Sialons (R = Sm, Gd, Dy, Y and Yb) by Pressureless Sintering
H. WANG, W.-Y. SUN, H.-R. ZHUANG & T.-S. YEN (China)

467 The Oxidation Kinetics of β-Sialon Ceramics
J. PERSSON & M. NYGREN (Sweden)

Number 6

485 Tape Casting of Zirconia for Ion Conducting Membranes: A Study of Dispersants
H. RAEDER, C. SIMON (Norway), T. CHARTIER (France) & H. L. TOFTEGAARD (Denmark)

493 Single-Target Sputter Deposition and Post-Processing of Perovskite Lead Titanate Thin Films
D. REMIENS, J. F. TIRLET, B. JABER, H. JOIRE, B. THIERRY & C. MORIAMEZ (France)

501 Significance of Specimen Size for the K_R-Curve Behavior of Quasi-Brittle Materials
E. H. LUTZ (Germany), M. V. SWAIN & P. S. COOK (Australia)

509 Comparison of Evaluation Procedures for the Subcritical Crack Growth Parameter n
H. PETERLIK (Austria)

521 Characterization of Glass–Ceramic Corrosion and Durability
S. N. SALAMA & S. M. SALMAN (Egypt)

529 Development, Characterization and Oxidation Behaviour of Si_3N_4–Al_2O_3 Ceramics
J. VLEUGELS & O. VAN DER BIEST (Belgium)

545 Sintering of Magnesium Oxide Obtained from Sea Water
N. PETRIC, B. PETRIC, V. MARTINAC, N. BOGDANIĆ, M. MIROŠEVIĆ-ANZULOVIĆ & M. LABOR (Croatia)

551 β-Sialon Ceramics with TiN Particle Inclusions
T. EKSTRÖM & P.-O. OLSSON (Sweden)

561 Influence of Matrix and Interface on the Mechanical Properties of Unidirectional Carbon/Carbon Composites
P. W. M. PETERS, G. LÜDENBACH, R. PLEGER & R. WEIß (Germany)

571 Contributor Index

573 Contents of Volume 13

Contents of Volume 14

Number 1

1 HREM and AEM Studies of Yb_2O_3-Fluxed Silicon Nitride Ceramics with and without CaO Addition
H.-J. KLEEBE, J. BRULEY & M. RÜHLE (Germany)

13 Preparation and Grain Boundary Devitrification of Samarium α-Sialon Ceramics
Y.-B. CHENG (Australia) & D. P. THOMPSON (UK)

23 Low-Shrinkage Refractories by an Infiltration Technique
N. LEQUEUX, P. LAROSE, P. BOCH & N. BURKARTH (France)

29 Fabrication of Yttria/Niobium Laminar Composites by Plasma Spraying
M. BONCOEUR & G. SCHNEDECKER (France)

37 The Interactions between Silver and Zirconia Inclusions and their Effects on the Toughening Behaviour of $Al_2O_3/(Ag + ZrO_2)$ Composites
W. H. TUAN & W. R. CHEN (China)

45 Effect of SrO on Densification and Mechanical Properties of Reaction-Sintered Mullite–Zirconia
S. KINIKOĞLU & M. MARSOĞLU (Turkey)

53 System Si–Al–Mg–O: Thermodynamic Aspects of its Influence on the Oxidation Resistance of Silicon Carbide at High Temperature
A. DERRE, M. DUCARROIR & M. ALLIBERT (France)

61 Characterization of $MgSiO_3$, $CaMgSi_2O_6$ and $CaSiO_3$ Precursor Powders by ^{29}Si MAS NMR
S. HAYASHI, K. OKADA & N. OTSUKA (Japan)

67 X-Ray Absorption Spectroscopy Study of the Local Structure and the Chemical State of Yttrium in Polycrystalline α-Alumina
M. K. LOUDJANI & R. CORTÈS (France)

77 Phase Transformations and Control of Habit in Lyothermal Synthesis of α-Al_2O_3
A. KAISER, D. SPORN & H. BERTAGNOLLI (Germany)

85 Low-Temperature Aqueous Preparation of Barium Metatitanate Powders
P. NANNI, M. LEONI, V. BUSCAGLIA & G. ALIPRANDI (Italy)

91 Damage Investigations in Unidirectional SiC-MAS.L Composite Materials under Quasi-Static Tensile Loading
M. DRISSI-HABTI, T. DESPIERRES, J. FOUBERT & M. GOMINA (France)

Number 2

97 Reaction Bonding of Aluminum Oxide (RBAO) Composites: Processing, Reaction Mechanisms and Properties
N. CLAUSSEN, S. WU & D. HOLZ (Germany)

111 In-situ Scanning Acoustic Microscopy of Crack Bridging in Alumina
T. J. MARROW, G. A. D. BRIGGS & S. G. ROBERTS (UK)

117 Preparation of an Alumina Aerogel with SiC Whisker Inclusion
Y. MIZUSHIMA & M. HORI (Japan)

123 Synthesis of Yttrium Aluminum Garnet Precursor Powders by Homogeneous Precipitation
D. J. SORDELET, M. AKINC, M. L. PANCHULA, Y. HAN (USA) & M. H. HAN (Korea)

131 Influence of Formation pH and Grinding of Precursors on Compaction and Sintering Behaviours of 3 mol% Y_2O_3–ZrO_2
A. SAMDI, B. DURAND (France), A. DAOUDI (Morocco), F. CHASSAGNEUX, J. P. DELOUME, M. TAHA, J. PALETTO & G. FANTOZZI (France)

143 Prediction of Overall Shape of Sintered Alumina Compacts
N. ÖZKAN & B. J. BRISCOE (UK)

153 R-Curve Behaviour in Ceramic Composites Produced by Directed Metal Oxidation
J. RÖDEL, M. SINDEL, M. DRANSMANN, R. W. STEINBRECH & N. CLAUSSEN (Germany)

163 Liquid Phase Sintering, Electrical Conductivity, and Chemical Stability of Lanthanum Chromite Doped with Calcium and Nickel
G. M. CHRISTIE, P. H. MIDDLETON & B. C. H. STEELE (UK)

177 Oxidation Effects on the Mechanical Properties of 2D Woven C/SiC Composites
F. LAMOUROUX & G. CAMUS (France)

Number 3

189 Synthesis of Monodispersed Silica Powders I. Particle Properties and Reaction Kinetics
H. GIESCHE (USA)

205 Synthesis of Monodispersed Silica Powders II. Controlled Growth Reaction and Continuous Production Process
H. GIESCHE (USA)

215 Residual Carbon Detection in Barium Titanate Ceramics by Nuclear Reaction Technique
C. PROUST, E. HUSSON, G. BLONDIAUX & J. P. COUTURES (France)

221 Influence of High Pressures and Temperatures on the Behaviour of Bismuth-Based Superconductors
T. A. PRIKHNA, V. S. MELNIKOV, V. V. KOVYLYAEV, V. E. MOSHCHIL, S. N. DUB, A. P. SHAPOVALOV, P. A. NAGORNY, P. P. GORBIK & V. F. SOLOVYOV (Ukraine)

227 Grain Boundary Modifications of Manganese Ferrites
J. H. BOY & G. P. WIRTZ (USA)

237 Interactions in the Sol–Gel Processing of Alumina–Zirconia Composites
V. SRDIĆ & L. RADONJIĆ (Yugoslavia)

245 Chemical Vapour Infiltration of TiB_2 and TiN in Porous Al_2O_3
J. P. DEKKER, P. J. VAN DER PUT, H. J. VERINGA & J. SCHOONMAN (The Netherlands)

257 Thermal Fatigue Resistance of CVD SiC/C Functionally Gradient Material
M. SASAKI & T. HIRAI (Japan)

261 Yttrium Oxynitride Glasses: Properties and Potential for Crystallisation to Glass-Ceramics
S. HAMPSHIRE, E. NESTOR, R. FLYNN (Ireland), J.-L. BESSON, T. ROUXEL, H. LEMERCIER, P. GOURSAT, M. SEBAI (France), D. P. THOMPSON & K. LIDDELL (UK)

275 Release of Foreign Matter During Sintering of Aluminium Nitride and Silicon Nitride
T. REETZ (Germany), H. W. GÄGGELER & D. T. JOST (Switzerland)

Number 4

281 Editorial

283 Texture Formation in Al_2O_3 Substrates
A. BÖCKER, H. J. BUNGE, J. HUBER & W. KRAHN (Germany)

295 Preparation and Characterization of Mullite–Zirconia Composites from Various Starting Materials
T. KOYAMA, S. HAYASHI, A. YASUMORI & K. OKADA (Japan)

303 Processing and Mechanical Properties of a Silicon Carbide Platelet/Alumina Matrix Composite
Y.-S. CHOU & D. J. GREEN (USA)

313 Thermal Behavior of Polymer-Derived Ceramics. IV. Si–C–N–O Fibers from an Oxygen-Cured Polycarbosilazane
O. DELVERDIER, M. MONTHIOUX, D. MOCAER & R. PAILLER (France)

327 A New Approach for Slow Crack Growth Measurement
C. OLAGNON, J. CHEVALIER, F. SUDREAU & G. FANTOZZI (France)

337 Solute Effect on Grain Growth in Ceria Ceramics
D. D. UPADHYAYA, R. BHAT, S. RAMANATHAN, S. K. ROY (India), H. SCHUBERT & G. PETZOW (Germany)

343 Pressureless Sintering and Phase Relationship of Samarium α-Sialons
Y.-B. CHENG (Australia) & D. P. THOMPSON (UK)

351 The Effect of B_2O_3 Addition on the Direct Sintering of Barium Hexaferrite
O. T. ÖZKAN, H. ERKALFA & A. YILDIRIM (Turkey)

359 Factors Affecting the Sintering and the Electrical Properties of Sr-Doped $LaCrO_3$
P. H. DUVIGNEAUD, P. PILATE & F. CAMBIER (Belgium)

369 Thermopower and Electrical Conductivity of Single Crystal and Polycrystalline CoO
G. BORCHARDT (Germany), K. KOWALSKI (France), J. NOWOTNY (Australia), M. REKAS & W. WEPPNER (Germany)

377 Glass Formation in the System Y_2O_3–Al_2O_3–SiO_2 Under Conditions of Laser Melting
R. HARRYSSON & P. VOMACKA (Sweden)

Number 5

383 Progress in the Fabrication of Si_3N_4 Turbine Rotors by Pressure Slip Casting
O. LYCKFELDT, E. LIDÉN, M. PERSSON, R. CARLSSON & P. APELL (Sweden)

397 The Design of a Circulating Fluid Bed Reactor for the Carbothermal Synthesis of Silicon Nitride
F. K. VAN DIJEN (Germany)

403 A Surface Study on Adsorption of Lignosulphonate on Mixed Si_3N_4–Y_2O_3 Powder Dispersions
H. FAGERHOLM, L.-S. JOHANSSON & J. B. ROSENHOLM (Finland)

411 Nitridation of SiC for the Production of SiC–Si_3N_4 Nanocomposites
E. GOMEZ, T. GÓMEZ-ACEBO, J. ECHEBERRÍA, I. ITURRIZA & F. CASTRO (Spain)

419 Fine SiC Inclusions and Grain Boundary Phases in Pressureless Sintered SiAlON
W.-C. J. WEI (Taiwan) & J. W. HALLORAN (USA)

427 Structure and Properties of Interlayers in Polymer-Derived C/SiC Composites
R. OSTERTAG, T. HAUG, J. WOLTERSDORF, E. PIPPEL, A. HÄHNEL & R. SCHNEIDER (Germany)

441 Thermal and Elastic Properties of Alumina–Silicon Carbide Whisker Composites
L. FABBRI, E. SCAFÈ & G. DINELLI (Italy)

447 The Brittle/Ductile Transition in Cubic Stabilised Zirconia
T. J. MARROW, S. G. ROBERTS & A. K. PEARCE-HIGGINS (UK)

455 The Effect of Boria and Titania Addition on the Crystallization and Sintering Behavior of Li_2O–Al_2O_3–$4SiO_2$ Glass
Y.-M. SUNG, S. A. DUNN & J. A. KOUTSKY (USA)

463 Temperature-Stable Dielectric Materials in the System $BaTiO_3$–Nb_2O_5–Co_3O_4
D. F. K. HENNINGS & B. S. SCHREINEMACHER (Germany)

473 An Initial Stage Model for the Sintering of Constrained Polycrystalline Thin Films
D. R. CARROLL & M. N. RAHAMAN (USA)

Number 6

481 On the Mechanism of Delamination Fracture of $BaTiO_3$-based PTC Thermistors
C. DEWITTE, R. ELST & F. DELANNAY (Belgium)

493 An Evaluation of Ce–Pr Oxides and Ce–Pr–Nb Oxides Mixed Conductors for Cathodes of Solid Oxide Fuel Cells: Structure, Thermal Expansion and Electrical Conductivity
M. NAUER (UK), CH. FTIKOS (Greece) & B. C. H. STEELE (UK)

501 Electrical Conductivity and Thermal Expansion of Bi_2O_3 Doped with Pr
CH. FTIKOS (Greece) & B. C. H. STEELE (UK)

505 Crystallite Growth Characteristics in Superfine Zirconia Powders and Compacts
J. L. SHI & T. S. YEN (China)

511 Mullite Formation by Reaction Sintering of Quartz and α-Al_2O_3—A TEM Study
M. SCHMÜCKER, W. ALBERS & H. SCHNEIDER (Germany)

517 Glass–Ceramic from Fly Ash with Added MgO and TiO_2
R. CIOFFI, P. PERNICE, A. ARONNE, M. CATAURO & G. QUATTRONI (Italy)

523 Mechanical Behaviour and Reliability of Sintered Clinker Portland
J. M. TORRALBA, L. E. G. CAMBRONERO & J. M. RUIZ-PRIETO (Spain)

529 Uniaxial Tensile and Creep Behaviour of an Alumina Fibre-Reinforced Ceramic Matrix Composite: I. Experimental Study
F. LAMOUROUX, M. STEEN & J. L. VALLÉS (The Netherlands)

539 Uniaxial Tensile and Creep Behaviour of an Alumina Fibre-Reinforced Ceramic Matrix Composite: II. Modelling of Tertiary Creep
F. LAMOUROUX, J. L. VALLÉS & M. STEEN (The Netherlands)

549 Liquid-Phase Hot-Pressing and WC-Particle Reinforcement of SiC–Si Composites
B. R. ZHANG (China), F. MARINO & M. FERRARIS (Italy)

557 Calculations of Chemical Equilibria in the Mo–B–N System
E. BENKO & A. WYCZESANY (Poland)
