Control of Texture in Al_2O_3 by Gel-casting

T. Carisey, A. Laugier-Werth & D. G. Brandon

Department of Materials Engineering, Technion, Israel Institute of Technology, Haifa 32000, Israel

(Received 19 April 1994; accepted 2 May 1994)

Abstract

Small alumina platelets were distributed in an alginate-containing alumina slip and oriented by tape-casting using a water-based doctor-blade process. The tape was gelled at the exit from the doctor-blade by a cation-exchange reaction. The tape thickness could be controlled from 0·2 to 2 mm and there appeared to be no limit to the laminate thickness which could be produced by tape lay-up and filter-pressing. The platelets were aligned parallel to the green tape to better than 10°. Several cation reactions were investigated and both their gelling behaviour and their effect on the sintering characteristics were studied. The large-grained sintered products were highly textured and showed pronounced anisotropy in their crack propagation resistance.

1 Introduction

In many engineering materials microstructural or crystallographic anisotropy (texture) can be used to inhibit crack propagation. The control of crystalline texture is a frequent objective in metal working processes but is seldom applied to conventional ceramic processing technology. Nevertheless, the production of a crystallographically and microstructurally oriented monolithic ceramic could be a useful alternative to the introduction of aligned second-phase reinforcement. Within limits, the control of crystalline texture could result in a beneficial mechanical anisotropy, avoiding the aligned two-phase microstructural geometries characteristic of a composite material, many of which have problems associated with mismatch of the chemical, thermal or elastic properties of the two phases.

Reinforcement of a ceramic matrix with semi-aligned SiC platelets has already been shown to give improved mechanical properties with pronounced mechanical anisotropy. For example,[1] the addition of 30% of SiC platelets to an Si_3N_4 matrix powder prior to hot-pressing has led to significant increases in the fracture toughness, the Weibull modulus and Young's modulus. The mechanical anisotropy was also demonstrated in indented samples, for which the extent of crack propagation in the two directions parallel and perpendicular to the direction of hot-pressing was markedly different.

The tape-casting process has been used to produce ceramic tapes, 25 to 300 μm in thickness,[2] for electronic applications, and alumina is one of the commonest tape-cast materials.[3] Particle alignment during tape-casting has also been studied[4] and it was shown that, providing the pressure gradient is neglected, the orientation of the particles depends only on their concentration and shape, while the effects of slip viscosity, trolley velocity and tape thickness on the particle alignment were minor. The flow behaviour of a ceramic slip during tape-casting has been analysed based on the principles of fluid dynamics.[5] The fluid flow process can be considered a linear combination of Poisseuille pressure flow and Couette drag, so that the velocity distribution in a slip flowing between an extended 'doctor-blade' and a moving substrate carrier is given by:

$$V_z = -\rho g H(x^2 - hx)/2\mu l + V_0 x/h$$

where ρ is the density (1750 kg/m^3), g is the gravity acceleration (9·81 m/s^2); H is the height in the container (10 mm); h is the 'blade' gap (2 mm); μ is the slip viscosity (10 Pa.s); l is the length of the 'blade' (30 mm); V_0 is the trolley velocity (200 mm/s) and V_z is the slip velocity at a distance x from the 'blade' surface.

The first term in the equation is the pressure effect component and the second is the drag effect, while the dimensions given in parentheses are appropriate for the geometry used in the present work. From this equation and with these dimensions, it is obvious that pressure flow can be

neglected and the platelets should orient in the uniform shear field of the dominant drag flow.[4] The authors have previously prepared alumina/alumina platelet composites by conventional tape-casting[6] and found that the shear forces acting during tape-casting could orient the platelets to better than 15°. However, the laminate thickness which could be prepared by subsequent tape layup was limited by the long times required for burn-out if the large amount of organic plasticizer present was not to cause bloating and delamination.

Far smaller quantities of organic additives have been reported[7] for a water-based tape-casting process which uses a cellulose ether binder. The process involved a compromise between the requirements for a high green density (a high ratio of inorganic to organic components) and a high green strength (a high ratio of binder to plasticizer). The liquid to solid (sol–gel) transformations used in green moulding can be achieved by a number of routes of which solidification of a plasticizer or solvent evaporation are two of the commonest. An acrylic polymerization reaction has been shown to give a flexible gelled slip in aqueous solution at concentrations of organic additives of only 5% with up to 60% solids loading.[8] This process has been patented under the name of *gel-casting*, although irreversible polymerization is just one gel-formation process.

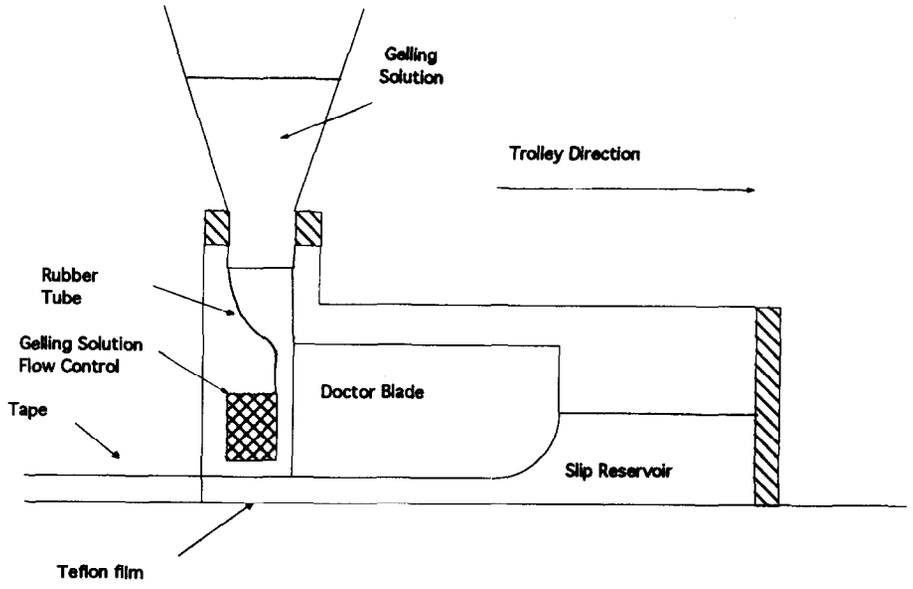
A sol–gel route has been developed for the production of a gelled thread containing aligned whiskers. An early report[9] described the production of a Ca alginate fibre containing aligned whiskers but gave no experimental details. More recently[10] it was shown that extrusion of a Na alginate-containing water-based Al_2O_3 or Si_3N_4 slip with SiC whisker additions could give good whisker alignment. Extruded thread was gelled to form a flexible 'spaghetti' on exiting an extrusion needle immersed in gelling solution. Whisker alignment was retained after filter-pressing and sintering, and the small amount of organic additives present (less than 2%) did not require any especial burn-out schedule.

The sol–gel reaction between water-soluble Na alginate and polyvalent cations yields an insoluble cation cross-linked alginate and is used in many food and pharmaceutical applications.[11] The reaction is based on ion exchange,[12] for example:

$$Na_n \text{ alginate} + n/2\ Ca^{2+} \longrightarrow n Na^{+} + Ca_{n/2} \text{ alginate} \quad (1)$$

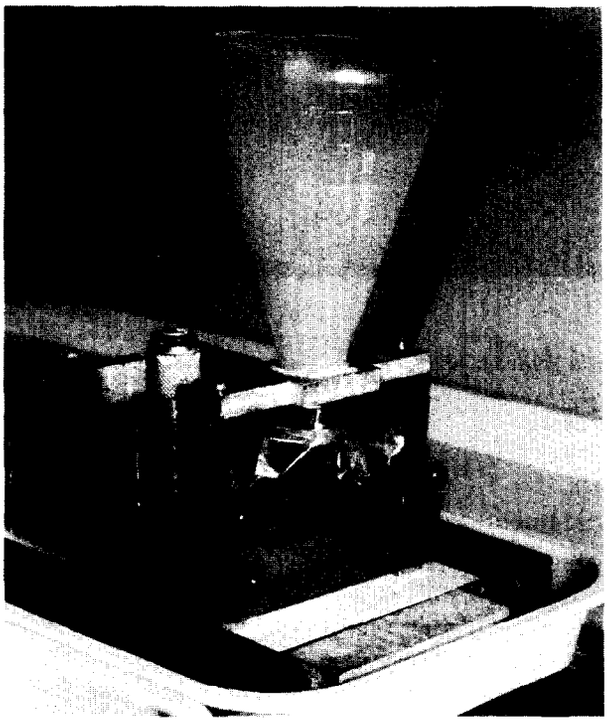
Smidsrød & Haug[13,14] showed that many divalent cations could be used to obtain the gel reaction and could be ranked according to their efficacy in precipitating the alginate. In the present application, some cation will remain as a dopant in the ceramic, so that the gelling cation should be a good sintering agent rather than a deleterious impurity.

In the present contribution a process for water-based tape-casting of a platelet-containing slip by the sol–gel route, followed by tape layup and filter-pressing to yield a green body with well-oriented platelets is reported. A number of polyvalent gelling cations have been investigated.



2 Experimental

2.1 Machine design



The tape-casting unit was based on a conventional design for the tape-caster trolley, but with an additional section for gelling (Fig. 1). The conventional sections comprise an extended doctor-blade, which controls both the thickness of the tape and the alignment of the platelets, and the slip reservoir. The new section consists of a flexible tube which is attached to the exit from the extended doctor-blade and controls the supply of the gelling solution from a reservoir. During casting the tape-caster trolley is pulled at a fixed speed up an inclined teflon-covered support plate, the inclination being necessary to drain away the gelling solution and prevent gelling of the slip beneath the doctor-blade (Fig. 2). As in conventional tape-casting, the blade gap (the tape thickness), the trolley velocity and the slip viscosity can be independently varied, together with, in the present case, the flow rate of the gelling solution.

2.2 Composite fabrication

The alumina powder used for the present study was Sumitomo AKP50 and the alumina platelets were supplied by Elf-Atochem in three different sizes: 3–7 μm, 10–15 μm and 15–25 μm. A solution of Na alginate was prepared with 4 wt% of alginic acid sodium salt. This solution was diluted with distilled water (2 : 3) and a dispersant was added (Dolapix PC85). After adding the platelets (typically 5 wt% in the final green body), the pH was adjusted to 10 by adding NH_4OH and ultrasonic agitation was used to break up any soft platelet agglomerates. The alumina powder was then incorporated and, after 18 to 20 h of ball-milling, the slip was tape-cast onto the teflon substrate. On inverting the substrate in a water bath, the cast tape detached from the teflon under its own weight and was then washed to remove excess cation. The tape was cut into squares (31 × 31 mm) which were stacked and compacted by filter-pressing before drying and sintering. The sintering programme comprised three stages: 600°C for 2 h, to burn out the small amount of organic

(a)

(b)

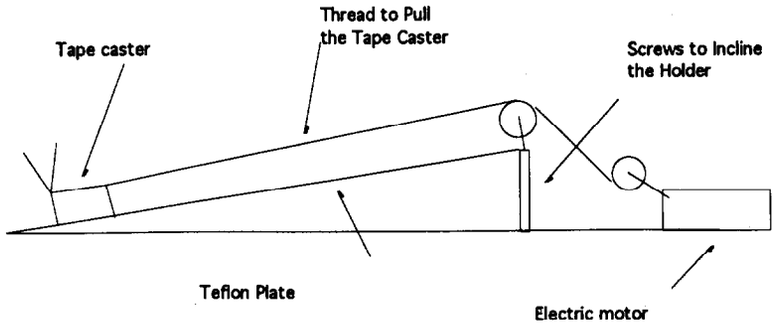


Fig. 1. (a) Schematic drawing of the gel-caster trolley, (b) photograph of the gel-caster trolley.

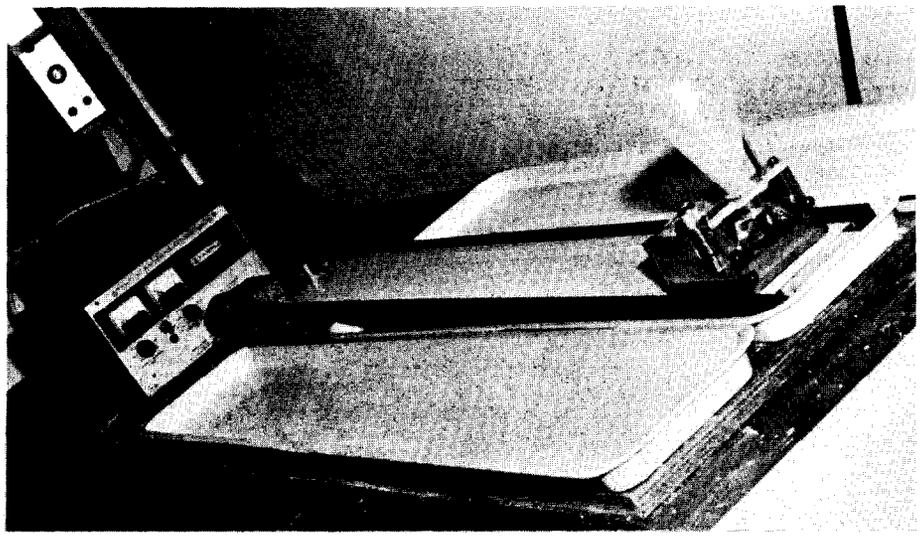
additives, 900°C for 17 h, to stabilize the interconnected pore structure, and a final sinter at 1475 to 1550°C for 3 to 15 h, to collapse the pore structure and reach the final sintered density. The heating rate was 2°C/min and the final cooling rate was 5°C/min.



The shrinkage on sintering was markedly anisotropic, with the through thickness shrinkage appreciably greater than the lateral shrinkage. Typical sample dimensions after sintering at 1500°C for 9 h were 26 × 26 mm, with a sample thickness of 3–5 mm, depending on the number and thickness of the tape layers used in the layup. Sample densities were determined by the Archimedes method, using water as the immersion medium.

2.3 Characterization

Optical and scanning electron microscopy (SEM) were used to characterize polished and thermally etched (1450°C for 30 min) sintered samples cut parallel and perpendicular to the original tape surface. Optical microscopy was used to characterize the platelet distribution in cross-sections of the dry green body which had been vacuum impregnated with epoxy resin. Crack propagation

(a)

(b)

Fig. 2. (a) General layout of the gel-caster system, (b) photograph of the gel-caster system.

was studied by Vickers indentation on polished sections of the sintered samples.

The degree of platelet alignment was determined by X-ray diffraction using the (0006) reflection (2θ = 41·65°) wth CuK_α radiation and rotating the sample about the normal to the plane defined by the incident and diffracted beams. The integrated intensity of the (0006) peak was measured as a function of the angle of tilt of the original tape surface in the diffractometer. The range of tilt angles available with the diffractometer geometry and sample size used was −10 to +15°, and peak intensity measurements were taken at 5° intervals of sample tilt.

3 Results

Figures 3 and 4 show the (0006) integrated diffracted intensities for sintered samples containing 3–7 μm and 15–25 μm platelets respectively. These 'rocking curves' were taken from both the 'top' and 'bottom' of the samples, as well as both parallel (0°) and perpendicular (90°) to the tape casting direction (where 'top' is here the surface formed by the extended doctor-blade and 'bottom' is that in contact with the teflon substrate). In all cases the samples were strongly textured parallel to the original tape surface with most diffracting grains (full-width, half-maximum of the curves) aligned within ±5°. In these samples, and as might be expected,[4] the larger platelets gave a stronger texture than the smaller platelets, but the difference was not large. The curves are symmetrical about the 0° position and there is very little difference between the top and bottom of the samples or between the texture parallel and perpendicular to the casting direction. The largest differences were for the smallest platelets, for which the texture at the interface with the teflon substrate was significantly greater parallel to the casting direction (Fig. 3). In all cases, few grains have a *c*-axis which is tilted more than 10° to the specimen surface. It should be noted that the tape thickness in the case of Fig. 4 was 2·25 mm, which was the maximum studied.

Figure 5 shows transverse sections of the green tape, dried in alcohol (to avoid cracking) and epoxy impregnated. The first two micrographs contain 5 wt% of the small (Fig. 5(a)) and large platelets (Fig. 5(b)). In both cases the platelets are seen to be uniformly aligned and distributed

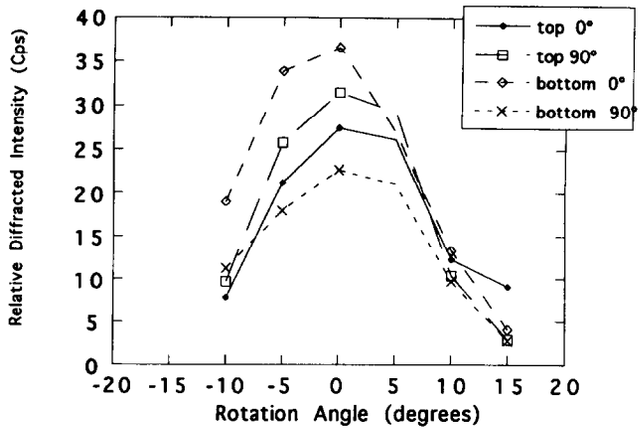


Fig. 3. Diffracted intensity versus tape surface tilt angle for a sintered sample made from 1 mm thick green tape containing 5 wt% of 3–7 μm platelets.

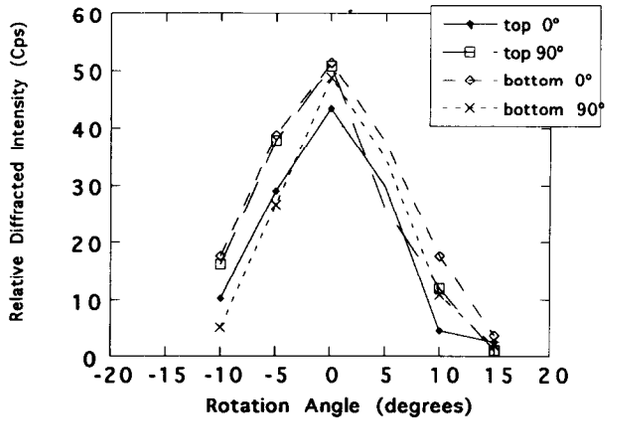
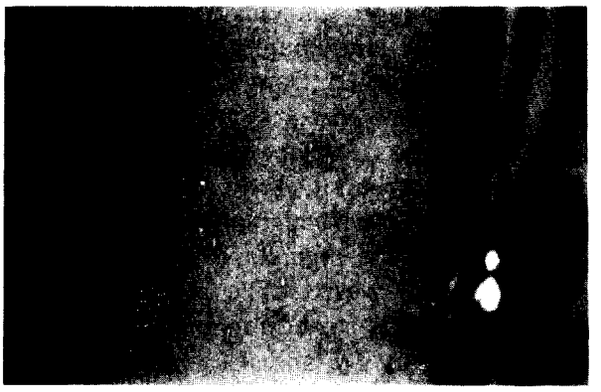
throughout the tape thickness. In Fig. 5(c) the sample contains 10 wt% of the small platelets, which again are uniformly aligned and distributed.

The maximum achievable tape thickness is determined both by the requirement to align the platelets in the shear stress field under the extended doctor-blade, and by the rate of diffusion of the ion-exchange cation through the tape as it exits from the doctor-blade. In general, good alignment for the small platelets was retained for tape thicknesses up to 2 mm, while the larger platelets were well-aligned at even larger tape thicknesses. The gelling reaction was always sufficiently fast to prevent further flow of the slip once it had exited from the doctor-blade, but the thicker tape had to be kept in contact with the gelling solution for several minutes in order to complete the gelling reaction through the full tape thickness. Typically, 10 layers of gelled tape could be stacked to produce a filter-pressed green sample 4–6 mm thick. Filter-pressing was accompanied by some loss of water and increase in green density.





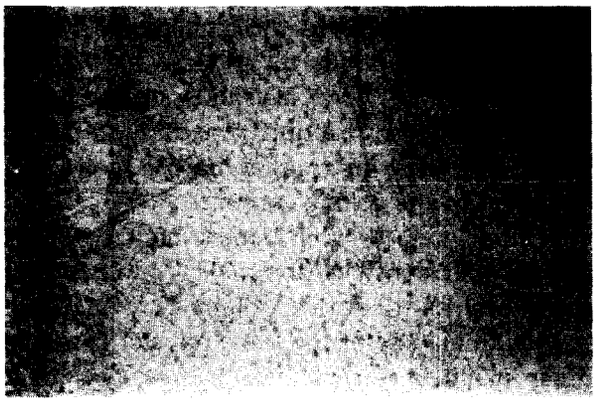


Fig. 4. Diffracted intensity versus tape surface tilt angle for a sintered sample made from 2·25 mm thick green tape containing 5 wt% of 15–25 μm platelets.

(b)

(c)

Fig. 5. Polished transverse sections of epoxy resin-impregnated green tape, showing the platelet distributions: (a) 5 wt% of 3–7 μm platelets, (b) 5 wt% of 15–25 μm platelets, (c) 10 wt% of 3–7 μm platelets.

As already noted, shrinkage on sintering was markedly anisotropic and the final sintered sample thickness was 3–5 mm.

There appeared to be no limit to the number of layers which could be bonded by filter-pressing, and no evidence for any delamination was observed either before or after sintering. Neither was there any microstructural indication of the position of the original tape surface in the polished and thermally etched cross-sections cut from the sintered product.

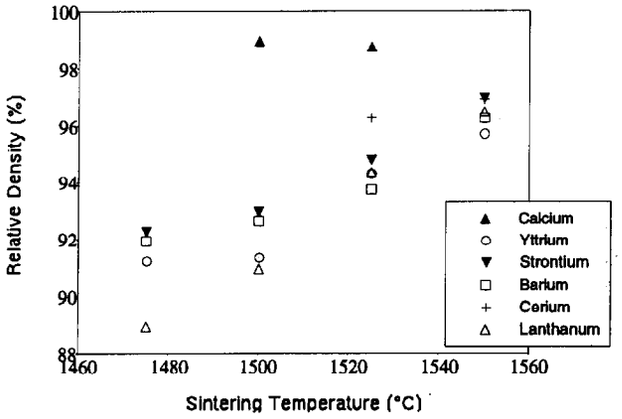
Six gelling cations were compared: 2+—Ca, Sr and Ba; 3+—Y and La; 4+—Ce. All these cations have an ionic radius of about 0·1 nm, which

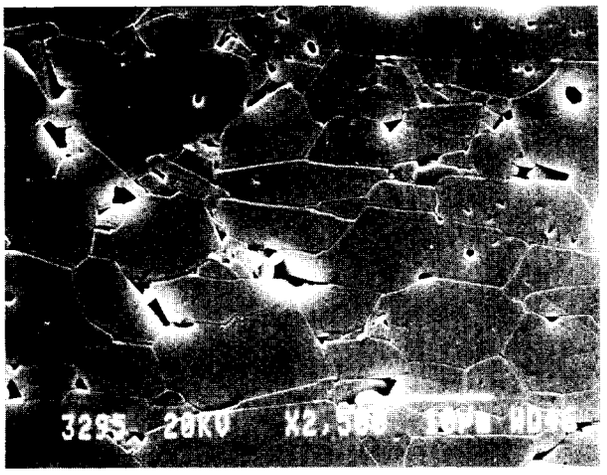
appears to be that necessary to coordinate and ionically crosslink the negatively charged polysaccharide chains.[14] The minimum concentration of alginate and the maximum volume fraction of solids which still gave a strong, flexible tape were determined approximately for Ca and found to be 1·6 wt% of alginate with 68 wt% of powder. The strengths of the gels formed using the other cations were then compared at this same slip composition, and the following rank order was observed:

$$Ba > Sr > Ca > Ce > Y > La$$

This is completely consistent with the results of Smidsrød & Haug,[13] who investigated only divalent cations. The lanthanum gelled tapes were too weak to be detached from the teflon substrate without tearing, so that a higher alginate concentration would be necessary with this cation. The yttrium and cerium gelled tapes were easily handled at the 1·6 wt% alginate level, while in the case of calcium the alginate concentration could be reduced to 1·4 wt%. The minimum alginate concentrations for strontium and barium gelled tapes were about 1·2 and 1·0 wt% respectively. Previous work has shown that the ion-exchange reaction for calcium is complete when about 20 wt% of Ca is bonded to the alginate, so 1·4 wt% of alginate corresponds to about 0·3 wt% of Ca added to the 68 wt% of solids in the slip. It follows that the gel reaction, as used in the present process, will result in an alumina product with up to 0·5 wt% of the gelling cation.

The filter-pressed green bodies made from these tapes all had densities about 47% of theoretical, significantly less than that obtained by filter-pressing an alumina slip of the same powder containing neither platelets nor alginate (57%). The highest green density was obtained for the calcium gel—50% of theoretical. The variation of sintered density with sintering temperature (9 h, in each case) is shown in Fig. 6. The rapid sintering in the presence of calcium at only 1500°C is associated with excessive grain growth. As expected, the presence of the platelets introduces local constraints which inhibit shrinkage. Nevertheless, densities exceeding 97% are readily attainable.





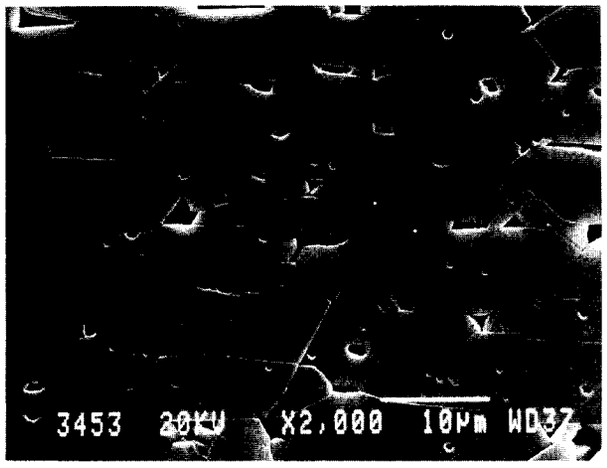


Fig. 6. Effect of sintering temperature on the relative density for different gelling cations (5 wt% of 3–7 μm platelets).

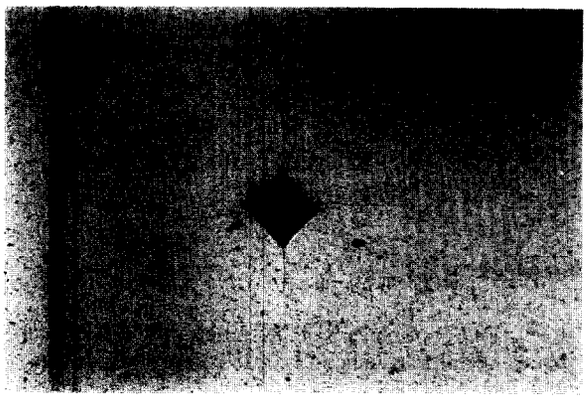

(a)

(b)

Fig. 7. SEM micrographs of thermally etched sintered samples: (a) 3–7 μm platelets at 5 wt%, (b) 10–15 μm platelets at 5 wt%.

The microstructural anisotropy of these monolithic aluminas is evident in Fig. 7. The platelets have acted as seed crystals to develop the strong (0001) crystalline texture (c-axis perpendicular to the surface) as well as significant grain-size anisotropy (flattened grains, foreshortened perpendicular to the surface). This microstructural anisotropy and texture has been found to lead to anisotropic crack propagation resistance. Figure 8 compares a 200N Vickers hardness indentation in two samples prepared by the gel-casting route. The first sample (Fig. 8(a)) contained no platelets, while the second (Fig. 8(b)) contained aligned platelets. The crack propagation resistance in the through-thickness direction is clearly superior in the platelet-containing alumina.

4 Discussion

The present results have demonstrated the practical feasibility of producing gel-cast tape preforms of alumina containing aligned seed platelets. This tape can be compacted and sintered to yield a laminated and textured product. The mechanical properties of these materials, which will be reported elsewhere, reflect the microstructural anisotropy of the product and show improved through-thickness crack propagation resistance.

The gelling cation used in the ion-exchange reaction plays a critical role, since this cation is subsequently introduced into the final ceramic product as a dopant. Calcium is known to promote grain growth and for this reason is generally considered to be deleterious. The remaining cations which have been studied are considered to be either beneficial sintering aids (Y, Ce and La), or else harmless (Sr and Ba). All these additions should lead to some second-phase formation, which is generally expected to be undesirable. The gelling response of the alginate solution should depend on the pH, so that pH control of the gelling solution, independent of the pH of the slip, offers one possibility for reducing the amount of gelling cation required for the process. The addition of an alcohol derivative could also affect the gelling response favourably and will be investigated, as will the use of other organic additives aimed at modifying either the gelling reaction, or the surface reactivity of the powder, or both.

The density of the final product is a major parameter controlling the mechanical properties. The values currently achieved (better than 97% of theoretical) are insufficient for many applications and are in part related to the comparatively low green densities of the filter-pressed layup made from the wet, gelled tape. The best way of improving the green density is probably by increasing the volume fraction of solids in the slip, which can only be done by reducing the casting velocity (for a more viscous slip) or reducing the slip viscosity. More viscous slips are difficult to handle (and may contain entrained gas bubbles), while suitable additives to reduce slip viscosity have not yet been found.

The aligned alumina platelets exercise an appreciable constraint on the shrinkage during the sintering process, and result in higher through-thickness shrinkage perpendicular to the sample surface. The relative rates of shrinkage in the transverse and radial directions change during the sintering reaction: initially the rates are approximately uniform, but the rate of transverse shrinkage then slows down while the through-thickness shrinkage continues. The sintering constraints due to the aligned platelets depend not only on the aspect ratio and volume fraction of the platelets, but also on the homogeneity and isotropy of the platelet distribution in the gelled sample. In general, the oriented platelets are not randomly distributed, but are more closely spaced in the through-thickness direction. The shrinkage anisotropy is then less than would be expected on the basis of a random, isotropic distribution of the platelets, while the aspect ratio of the final grains is appreciably less than 1.

The gel-casting process for the production of a water-based tape preform could have some interesting manufacturing potential. For example, the tape could be slit and spirally wound to form tube. Tape layups to form plate or bar products should be straightforward. Tapes of different composition (for example, alumina/zirconia slips) could be laminated to any desired thickness in any desired combination, for example to form graded structures. Tape could also be cast and fired on a substrate as a coating or enamel, and in this case control of the transverse sintering shrinkage by the aligned platelets could be used to improve the coating integrity and inhibit cracking during sintering. It should also be possible to cast onto a

rotating drum or moving band from which the tape could be stripped and collected continuously.

5 Conclusions

(1) A water-based tape of alumina containing aligned alumina platelets can be formed by gelling an alginate-containing slip in a modified design of doctor-blade tape-caster.
(2) Flexible wet tapes of 0·2–2 mm thickness can be produced in which the platelets are uniformly distributed and aligned to better than ±10°.
(3) The wet, gel-cast tape can be cut, layed up and compacted by filter-pressing into a green body with no detectable processing defects in the interface regions.
(4) The filter-pressed and dried green body can be sintered to near theoretical density to yield a strongly textured product with a high degree of microstructural anisotropy.
(5) The crystalline texture and microstructural anisotropy inhibit crack propagation in the through-thickness direction, as demonstrated by a Vickers indentation test.
(6) Several polyvalent cations are suitable gelling agents for this gelling reaction, but their effect on the microstructure and properties of the sintered product have yet to be studied.

Acknowledgements

The authors would like to acknowledge the provision of research funding for this project by Elf-Atochem, as well as the encouragement and support of Dominique Cotto and Jacques Macé of Elf-Atochem. The authors would also like to acknowledge the support of the French government for one of them (T.C.) under their VSN programme, as well as the support of École Nationale Supérieure de Mines de Paris, which enabled one of them (A.L.-W.) to contribute to this work.

Effect of Powder Granulometry and Pre-treatment on Sintering Behavior of Submicron-grained α-Alumina

Eiichi Sato* & Claude Carry‡

Laboratoire de Céramique, Ecole Polytechique Fédérale de Lausanne, MX-Ecublens, CH-1015 Lausanne, Switzerland

(Received 14 December 1993; revised version received 3 June 1994; accepted 13 June 1994)

Abstract

Two kinds of commercial, submicron-grained, non-doped α-alumina powders were cold-isostatically pressed and then sintered at a constant heating rate. Before the sintering, pre-treatments were executed at 820 or 920°C for 50 h. The effects of the pre-treatments on the densification behavior and the microstructural development are discussed.

The powders contained some nano-sized alumina particles about 10 nm in diameter as well as sub-micron-sized primary particles about 0·1 μm in diameter, which agglomerated in packs of 0·2–0·4 μm diameter. The densification rate curves showed a low temperature shoulder during sintering attributed to these nano-sized particles. After pre-treatments, the nano-particles disappeared, resulting in disappearance of the shoulder in the subsequent densification rate curves. These treatments, however, caused little change in the apparent activation energy in the intermediate stage sintering. For the weakly agglomerated powders, the bodies sintered with pre-treatments had coarser final microstructures.

1 Introduction

In order to obtain ceramics with pore-free, fine-grain structures by stress-free sintering, there is always a competition between densification and grain growth.[1] For nano-phase ceramics the competition is much more significant.[2] The main obstacles in obtaining ceramics with theoretical density have been attributed to nonuniformities in green bodies, and the particle size distribution and degree of agglomeration of the starting powder are the main origins of the nonuniformities.[3]

The packing of a powder with a bimodal particle size distribution can give a higher green density than a mono-sized powder, due to the effective interspace filling between coarse particles by fine particles.[4] In spite of the higher green density, enhanced densification in compacts prepared from powders with bimodal[5,6] or wide size distributions[7] has not been observed. This is because the shrinkage rate is primarily governed by the large grains,[8] and localized stresses developed around them prevented an enhanced densification.

A narrow size distribution, on the other hand, is thought to be important[9] because a uniform pore distribution results in sintering to high final densities.[10] It has been reported that both classification of powders[11] and controlled colloidal techniques[12] to obtain narrow-sized powders allow powder compacts to sinter more rapidly and to higher densities at lower temperatures than compacts made from conventional powders. It must be pointed out that the controlled colloidal techniques give powders not only narrow-sized but also agglomerate-free, the other factor often cited as a cause of inhomogeneities in green bodies.

Recently, Chu *et al.*[13] reported that pre-treatments of a green compact at a low temperature without densification produced a compact with a more uniform microstructure than the initial one. This kind of treatment provides an ideal stage to discuss the effect of granulometry on sintering behavior. They, however, gave neither detailed observation nor clear explanation on how the densification proceeded and the microstructure developed during the subsequent sintering. As another method of heat schedule, 'Rate-controlled sintering' (where the heating rate is decreased to avoid rapid shrinkage in the intermediate stage), has had practical success,[14] it should be fruitful to compare these two methods.

It is the purpose of the present paper to reveal the effects of powder granulometry and pretreat-

ments on sintering behavior and on microstructural development using non-doped, submicron-grained alumina powders with different particle size distributions as model materials. Adopting a constant heating rate condition allows the shrinkage behavior in the initial stage of sintering to be observed[15] and the apparent activation energy in the intermediate stage to be estimated.[16]

2 Experimental Procedure

Two kinds of commercial, submicron-grained, non-doped α-alumina powders were used: they are denoted by BO (CR15-AS1, Baikowski, France) and TA (TM-DR, Taimei Chemicals, Japan). The main impurities are Si, K, Na and Fe, for the BO powders of 57, 45, 10 and 7 mass ppm and for the TA powders of 10, 2, 2 and 8 mass ppm, respectively. Figure 1 shows the particle size distribution of the powders given by the suppliers. Both powders consist of mainly submicron-sized particles with median volume diameters of 0·2 μm (TA) and 0·4 μm (BO).

Green compacts were prepared by cold-isostatic pressing (CIP) at a pressure of 250 MPa. They were machined into cylindrical samples with 15 mm height and 10 mm diameter. Some of them were annealed in a chamber furnace in air at 820 or 920°C for 50 h; this will be referred to as a pretreatment. The treatment at 820°C caused almost no densification, and that at 920°C caused a small increase in the relative density of 0·02 for compacts of both powders.

The samples were sintered in a vertical dilatometer (DHT2050K, Setaram, France) under constant heating rate conditions at various rates from 1·0 to 10°C/min up to 1600°C under dry air atmosphere. The dimensional change was measured *in situ* using pure alumina probes with a load less than 0·02 N, which corresponds to a pressure of less than 0·25 kPa. The final density was measured by the Archimedes method. The relative density ρ and its temperature derivative $d\rho/dT$ were calculated from the final density and the continuously measured shrinkage; they are plotted as functions of temperature T. Apparent activation energies at several densities were calculated from Arrhenius plots of the densification rates at different heating rates.[16]

The morphology of the powders was observed by transmission electron microscopy (TEM). The microstructure of powder compacts at various stages of heat treatments was observed by scanning electron microscopy (SEM). Specimens with grain sizes larger than 1 μm were observed on polished and thermally etched surfaces, while those with grain sizes less than 1 μm were observed on fractured surfaces to avoid grain growth during thermal etching.

3 Results

3.1 Powder agglomeration and green bodies

Figure 2 shows the powder morphology observed by TEM. Both BO and TA powders consisted mainly of submicron-sized primary particles with diameters of 0·1 μm or less. Agglomerates of these particles had larger sizes and more irregular shapes for the BO powders than for the TA powders and this indicates that the size distribu-

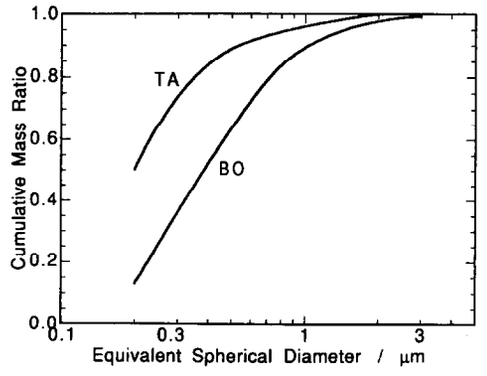

Fig. 1. Particle size distributions of BO and TA powders given by the suppliers.

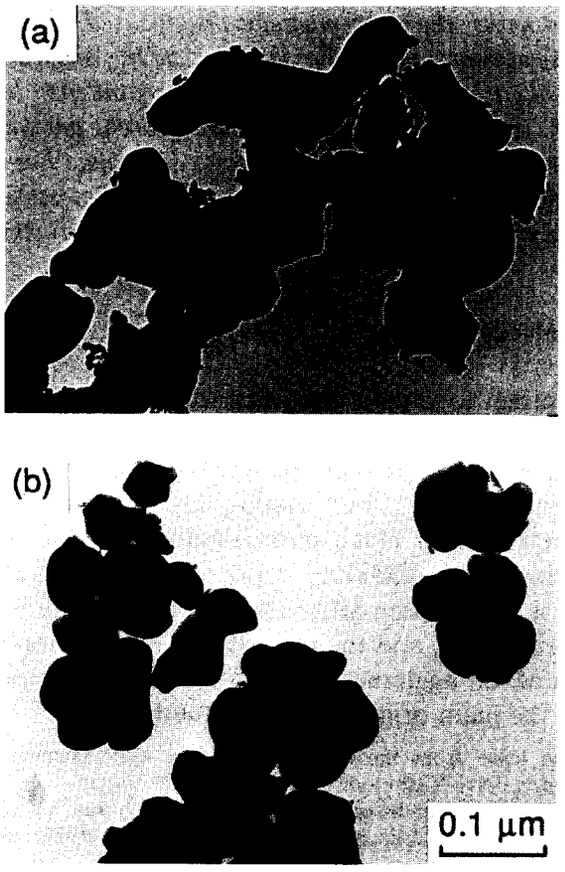

Fig. 2. Transmission electron micrographs of (a) BO and (b) TA powders.

tion shown in Fig. 1 was of agglomerates.

In addition to these primary particles, the BO powders have another kind of very fine particle with diameters of about 10 nm (they are referred to as nano-sized particles). A few nano-sized particles are also observed in the micrograph of the TA powders. These particles contained no metallic element other than aluminum based on the energy dispersion analysis of X-ray in TEM, although they were too small to determine their crystal structure. As the size is similar to the typical of γ-alumina, they might be non-transformed γ-alumina.

After CIP, the BO and TA powder compacts had relative densities of 0·481 and 0·566, respectively. This difference in green density is attributed to the difference in agglomerate size and morphology; in the BO powder compacts, the irregular shape of agglomerates made the packing more difficult.

3.2 Initial stage of sintering

General densification behavior at a constant heating rate is illustrated in Fig. 3: (a) is for the BO powders and (b) is for the TA powders. At low temperatures around 1100°C, a shoulder was observed on the densification rate curve of an as-CIPed BO powder compact (Fig. 3 (a)). The

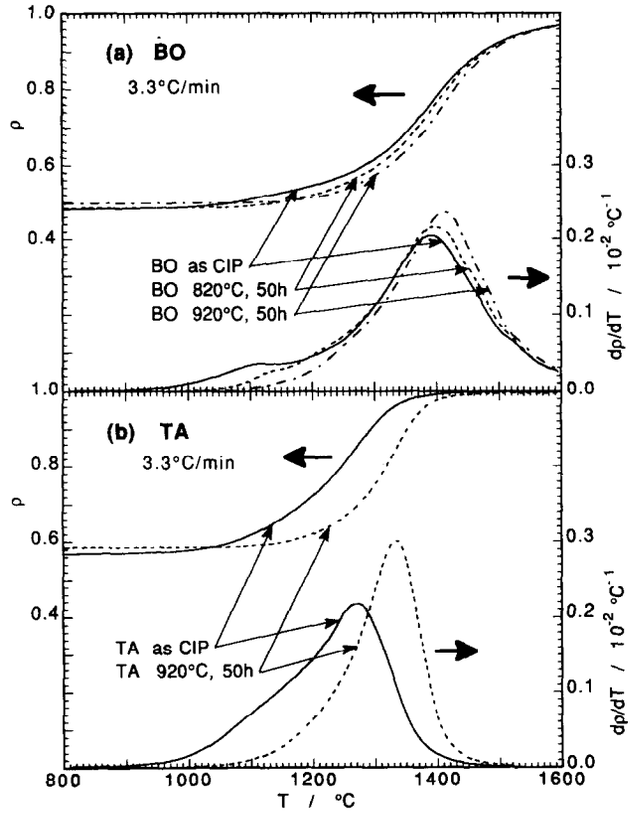

Fig. 3. Densification curves during sintering at a heating rate of 3·3°C/min for powder compacts of (a) BO and (b) RA with and without pre-treatment. The upper and lower curves in both (a) and (b) are the relative densities, ρ, and their temperature derivatives, $d\rho/dT$, respectively.

observation of such a shoulder has already been reported by the authors.[17] The shoulder became very small after the pre-treatment at 820°C for 50 h and disappeared almost completely after 50 h at 920°C. This shoulder was shifted towards lower temperatures with decreasing heating rate (not shown in Fig. 3(a)), implying a thermally activated process. For an as-CIPed TA powder compact, a much less distinct shoulder on the main peak was observed at almost the same temperature as the shoulder for the BO powder compact (Fig. 3 (b)). This shoulder also disappeared after the pre-treatment at 920°C for 50 h.

Figure 4 shows the microstructural developments during the pre-treatment and/or the initial stage sintering corresponding to the shoulder of BO powder compacts observed by SEM. The nano-sized particles observed by SEM are seen as small bright spots in the as-CIPed compact along with many large particle agglomerates of 0·1 to 0·3 μm (Fig. 4(a)). A particle network of the large agglomerates of about 0·3 μm is seen in this micrograph. After sintering up to the end of the shoulder, more than half of the nano-sized particles disappeared (Fig. 4 (b)). After the pre-treatment at 920°C for 50 h, almost all of the nano-sized particles disappeared (Fig. 4 (c)). In addition, the agglomerates of the primary particles show rather rounded morphology and seem to have a narrower size distribution. During all of these treatments the large agglomerates making up the particle network remain at a very similar size of about 0·3 μm.

Figure 5 shows the microstructural developments during the pre-treatment of the TA powder compacts. Compared to the as-CIPed TA compacts (Fig. 5(a)) the pre-treated TA compact consisted of more uniform but much larger particles (Fig. 5(b)).

In both the BO and TA powder compacts, the nano-sized particles disappear during low temperature annealing, i.e. during the shoulder in the initial stage sintering or during the pre-treatment. Their disappearance appears to be as a result of mass transport from them onto or into the submicron-sized particles which they contact. Among diffusional mechanisms considered normally, volume and grain boundary diffusions contribute to both densification and coarsening, while surface diffusion contributes only to coarsening and has the lowest values of activation energy and power index of particle size.[3] It means a process controlled by surface diffusion is more likely at lower temperatures and for finer particles. The dominant mechanism for the disappearance of the nano-sized particles could not, however, be determined clearly because the apparent activation energy

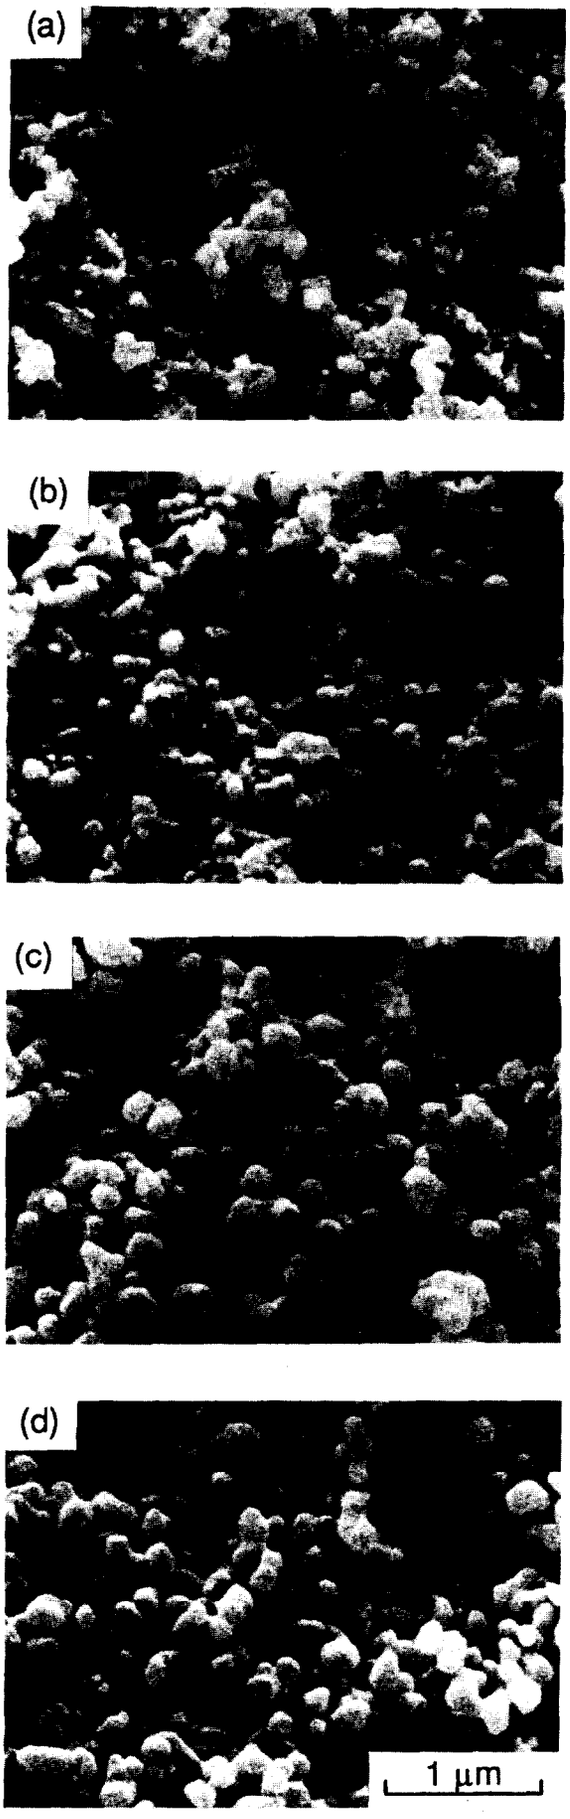

Fig. 4. Scanning electron micrographs of fracture surfaces of BO powder compacts: (a) as compacted, (b) sintered at 3·3°C/min until 1160°C, (c) pre-treated at 920°C for 50 h, and (d) sintered at 3·3°C/min until 1160°C with pre-treatment at 920°C for 50 h.

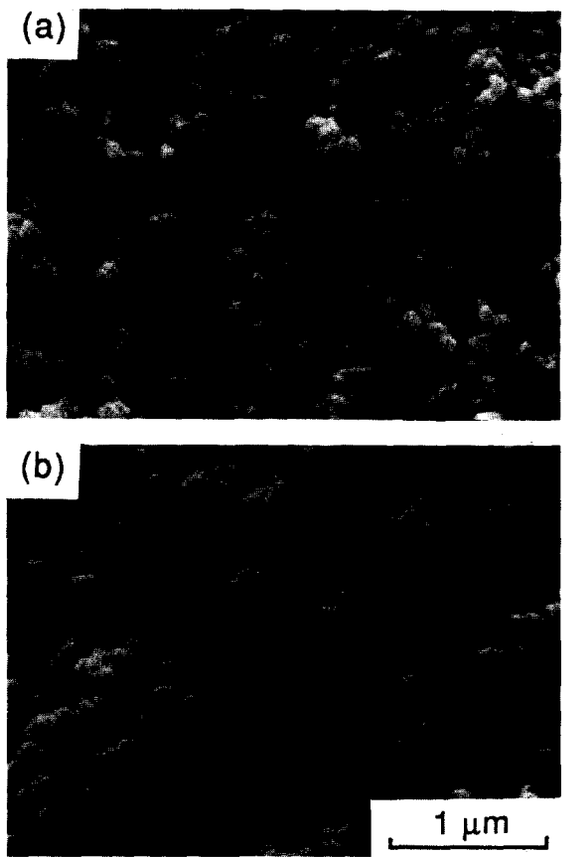

Fig. 5. Scanning electron micrographs of fracture surfaces of TA powder compacts: (a) as compacted, (b) pre-treated at 920°C for 50 h.

could not be measured, as described in the following paragraph.

Using the logarithmic plot of $T(\mathrm{d}(\Delta L/L_0)/\mathrm{d}T)$, which equals $-(T/3\rho_0)(\mathrm{d}\rho/\mathrm{d}T)$, versus $1/T$, Young & Cutler[15] obtained the apparent activation energy for the initial stage of sintering. Here $\Delta L/L_0$ is the relative change in length of the compact. Because their powder was coarser than 1 μm, there was negligible grain growth during this stage. Unfortunately, the significant grain growth of the present powder compacts does not allow a calculation of the apparent activation energy by their method.

3.3 Intermediate stage of sintering

The pre-treatment at 920°C for 50 h shifted the main densification rate peak toward higher temperatures by 60°C and raised its height by 36% in TA powder compacts (Fig. 3(b)), while it shifted the peak by only 20°C and raised the height by only 15% in BO powder compacts (Fig. 3(a)). Because the pre-treatment did not significantly coarsen the large agglomerates which made up the particle network for the as-CIPed BO powder compacts, as already mentioned, it did not cause a big change in the sintering behavior of the BO powder compacts. On the other hand, the pre-

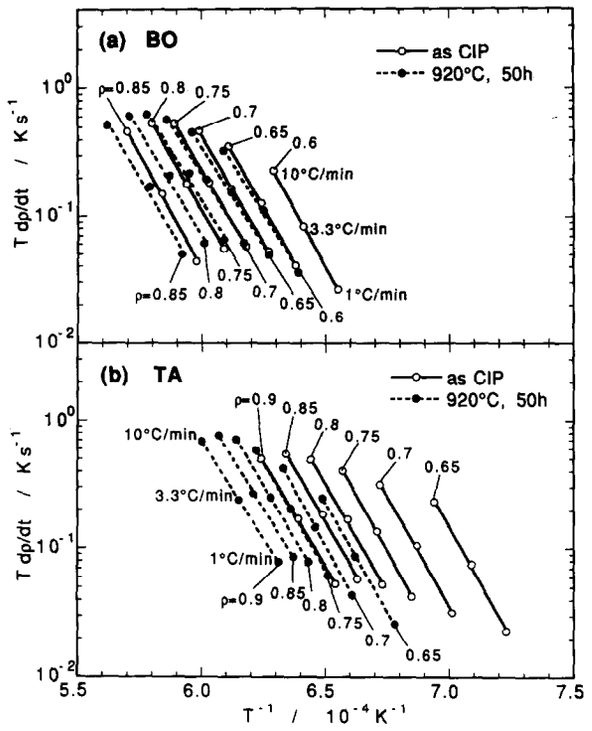

Fig. 6. Arrhenius plots of constant heating rate sintering of powder compacts (a) BO and (b) TA, with and without pre-treatment.

treatment strongly shifted the main densification peak to higher temperatures in TA powder compacts because the agglomerates coarsened very much during the treatment. The average grain size in TA powder compacts was still smaller than in BO, resulting in the lower temperature of the main densification peak.

The peaks were shifted toward lower temperatures with decreasing heating rates, as expected for a thermally activated process (not shown in Fig. 3). Figure 6 shows the Arrhenius plots of densification rates at different heating rates. In the intermediate stage of sintering, the apparent activation energies were 653 and 617 kJ/mol for the as-CIPed and pre-treated BO powder compacts, respectively, and 650, and 638 kJ/mol for those of the TA powder compacts. These values were obtained in the region of relative density from 0·65 to 0·80 for BO samples and from 0·70 to 0·85 for TA samples, where the effect of the shoulder was no longer apparent. In these regions grains did grow, but the sizes at a given density were almost identical among the compacts heated at different rates, which is indispensable for estimating the apparent activation energy. The little effect of pre-treatment on the apparent activation energy for both BO and TA powder compacts implies no change in the rate-controlling mechanism in the intermediate stage of sintering.

3.4 Final microstructure

Figure 7 shows the final microstructure of the BO materials with and without pre-treatments. The three samples shown in Fig. 7 had the same final density of 0·970 after sintering up to 1600°C at 3·3°C/min. These three had the same mean grain size of 1·9 μm; it was calculated as 1·38 times the mean intercept area on a plane section of more than 1000 grains observed in five different positions for each sample. Compared at the same sintering condition and the same density, the pre-treatment had no significant influence on the final microstructure in BO ceramics.

As already seen in Fig. 3 (b), the TA powder

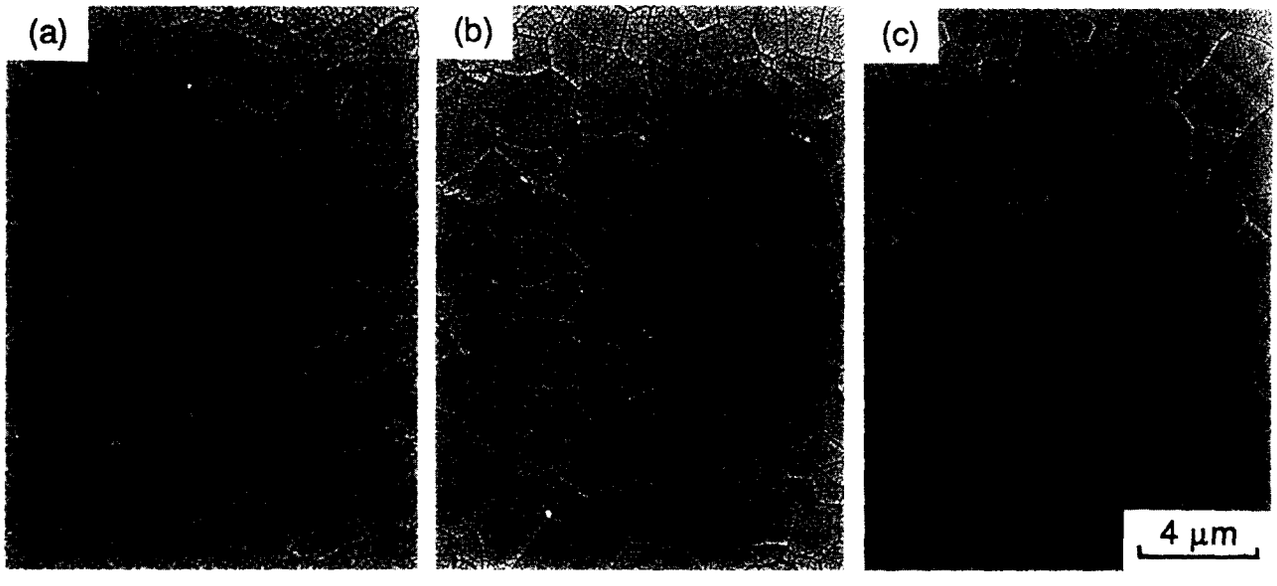

Fig. 7. Scanning electron micrographs of polished and thermally etched surfaces of BO ceramics sintered with 3·3°C/min until 1600°C: (a) without pre-treatment, (b) with pre-treatment at 820°C for 50 h, and (c) with pre-treatment at 920°C for 50 h. All of these specimens have the same final density of 0·97.

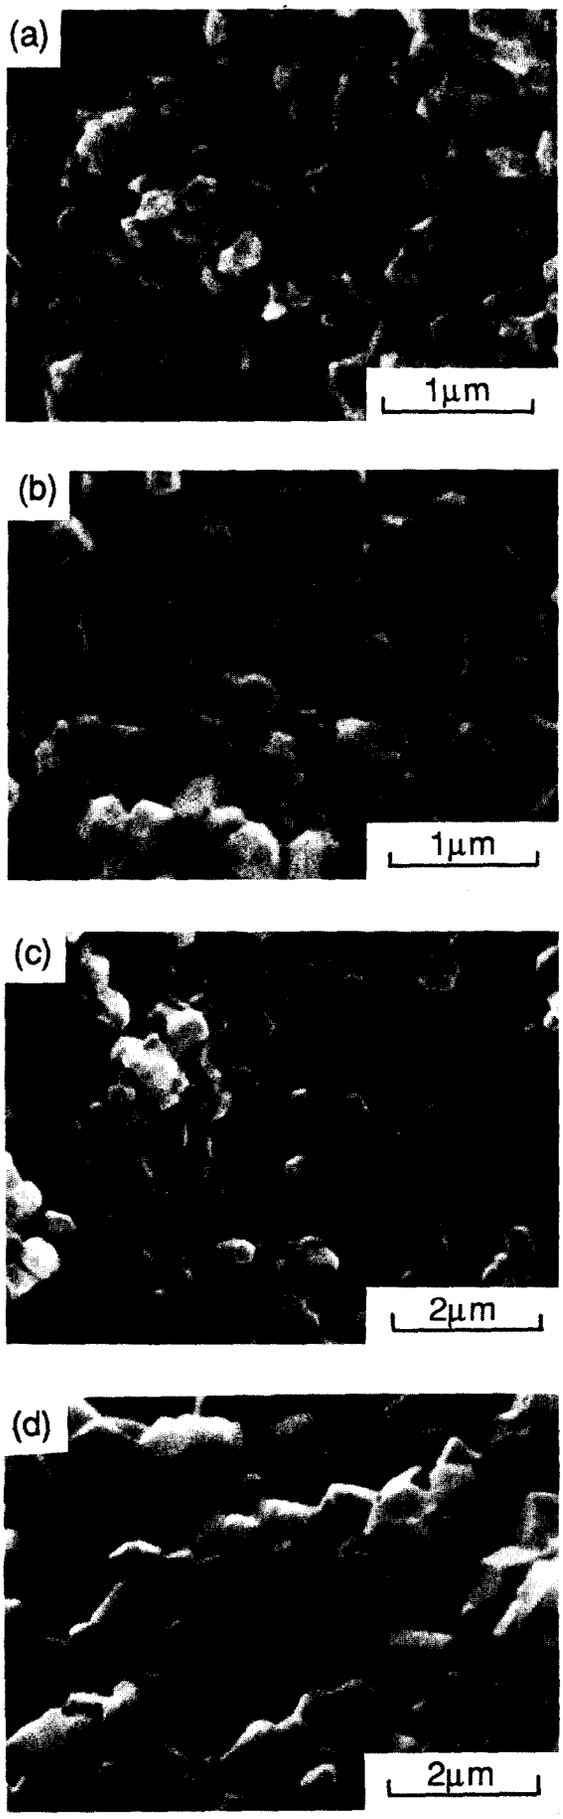

Fig. 8. Scanning electron micrographs of fracture surfaces of TA ceramics sintered at 3·3°C/min: (a) sintered up to 1290°C, (b) sintered up to 1350°C with a pre-treatment at 920°C for 50h, (c) sintered up to 1375°C, and (d) sintered up to 1430°C with the pre-treatment. Both (a) and (b) have the same final density of 0·89, and both (c) and (d) have that of 0·99.

compacts without and with pre-coarsening treatment reached the final density of 0·998 and 0·995, respectively, at about 1500°C: no more densification occurred in the sintering above this temperature. For this powder, pre-treatment decreased the highest density which a compact can achieve. The microstructures at certain densities lower than 0·995 are shown in Fig. 8, by interrupting the sintering cycle: (a) and (b) are microstructures at the density of 0·890, without and with pre-treatment, respectively, and (c) and (d) are at the density of 0·990. Here, fracture surfaces were observed because microstructures finer than 1 μm grain size easily coarsen during thermal etching. When comparing samples of the same density but different sintering temperature, the pre-treatment made the final microstructure coarser in the TA powder compacts.

4 Discussion

After pre-treatments, the nano-particles disappeared, resulting in disappearance of the initial shoulder in the densification rate curves in the subsequent sintering. For the BO powder compacts, however, the size of the large agglomerates which made up the particle network remained very similar during the pre-treatment, leading to little influence on the sintering behavior in the intermediate stage and the final microstructure. For the TA powder compacts, a coarsening of the agglomerates of the primary particles took place during the pre-treatments. The size increase influenced the sintering behavior in the intermediate stage and the final microstructure. Here we discuss these effects based on the results of TA powder compacts.

Firstly, the particle size increase in the treatment resulted in the shift of the main densification peak toward higher temperature as already mentioned. In addition to the temperature shift, the height of the main densification peak was raised by the treatment. Although the height of the densification peak has not been discussed in detail in the literature to the knowledge of the authors, it can be deduced that the narrower the size distribution, the higher the peak should be, providing all other conditions are identical. The height change in the TA powder compact data is qualitatively explained by a narrowing of the particle size distribution.

The effect of the pre-treatment, an increase in the height of the main densification rate peak, is the opposite to the policy of 'rate-controlled sintering,[14] which tries to avoid rapid shrinkage by decreasing the heating rate in the intermediate stage. Rapid shrinkage is expected to introduce

large closed pores inside the sintered body by differential densification. This explains why for TA powder compacts the sintered body with the pre-treatment could reach the final density a little lower than that achieved without the pre-treatment, and had a coarser microstructure when compared at the same density. In contrast, powders with narrow size distributions produced by colloidal techniques are not agglomerated to some extent and more regularly packed, resulting in a higher final density than powders with larger size distributions.[9,11,12]

In contrast to a coarsening effect of the pre-treatments for the final microstructure as seen for the TA powders, Chu *et al.* reported finer microstructures for conventional grade alumina and magnesia powders and high-grade alumina powders.[13] The conventional grade powder compacts revealed abnormal grain growth at the final stage (see Figs 6 and 7* of Ref. 13; Figs 7(c) and (d) must be placed in reverse order). Abnormal grain growth starts at a certain stage of annealing when some of the largest grains start to grow quickly by absorbing the surrounding grains. The more uniform the microstructure, the more strongly the onset of abnormal grain growth is retarded: this could be the microstructural fining effect found by Chu *et al.*

In the case of the high-grade powder compacts, Chu *et al.* reported that the sintered body with pre-treatment gave a finer final microstructure than without under the same sintering conditions.[13] Because the pre-treatment delays densification, an as-CIPed compact arrives at the final stage of sintering sooner (where coarsening is predominant[3]) than a pre-treated compact. For example, the TA powder compacts with and without pre-treatment showed grain sizes of 5 and 8 μm, respectively, after the sintering with 3·3°C/min up to 1600°C. This could also explain the microstructural fining effect found by Chu *et al.*

5 Conclusions

The commercial, non-doped α-alumina powders used in this study contained some nano-sized alumina particles (10 nm) as well as submicron-sized primary particles (0·1 μm), which agglomerated into diameters of 0·2–0·4 μm. The powder with many of these nano-sized particles showed a low temperature shoulder in densification rate curves of constant heating rate sintering while for the powder with fewer nano-sized particles the shoulder was less marked. The nano-sized particles disappear almost completely after a pre-treatment, resulting in the disappearance of the shoulder in the subsequent densification rate curves.

When the size of the large agglomerates which made up the particle network remained similar during the pre-treatment, the treatment had little influence on the intermediate and final stage sintering (BO powder). On the other hand when the growth of the agglomerates of the primary particles took place during the pre-treatments, the treatments shifted the main densification rate peak toward higher temperatures and raised its height (TA powder). The treatments, however, caused little change in the apparent activation energy, implying no change in the rate-controlling mechanism in the intermediate stage sintering. Because the treatments caused more rapid shrinkage in the intermediate stage, the sintered body with the treatment had coarser microstructure than the body with it when compared at the same density.

Finally, it was pointed out that pre-treatments have the possibility to retard the onset of abnormal grain growth by creating a more uniform microstructure before densification begins.

Abstract

The influence of oxygen content in the sintering atmosphere on zirconia phases in alumina–zirconia ceramics was studied. As was demonstrated, in the case of samples sintered in an atmosphere with oxygen partial pressure between $2{\cdot}80 \pm 10^{-5}$ *Pa and* $2{\cdot}80 \times 10^{-2}$ *Pa, 100% of zirconia was found to be in the cubic form. The appearance of transformable cubic zirconia is a result of oxygen vacancy concentration in zirconia. The increase of oxygen partial pressure and decrease of oxygen vacancy concentration leads to a breakdown of the cubic phase which transforms to the t- and/or m-phases. Critical values of oxygen vacancy concentration responsible for the metastability of cubic and tetragonal zirconia were estimated.*

1 Introduction

Transformation toughening in ZrO_2-containing ceramics requires the presence of metastable tetragonal (t) zirconia, so that the toughening obtainable from the stress-induced martensitic transformation to monoclinic (m) symmetry can be realized. As has been shown recently,[1–3] when this type of ceramic is sintered in oxygen-deficient conditions, transformable cubic (c) phase appears, as a result of nonstoichiometry of ZrO_2. The metastability of t- and c-ZrO_2 at low temperatures either in powder state or in compact form was proposed by different theories and hypotheses.[4–11] Unfortunately, the controlling mechanisms responsible for metastability of high-temperature phases of zirconia are still unknown.

The present work is aimed to explain the effect of oxygen content in sintering atmosphere and related oxygen vacancy concentration on c–t inversion in undoped zirconia grains dispersed in alumina matrix.

2 Experimental Methods

The starting material was a powder composition containing : 99·55 wt% Al_2O_3, 0·20 wt% MgO and 0·25 wt% Y_2O_3. Alumina powder (made by CEMAT-Skawina, Poland) was 99·99 wt% pure and the average grain size below 0·5 μm. The remaining two components were of the same purity.

The components of the composition were homogenized for 48 h in a ball mill in distilled water. Then 10 wt% zirconia—obtained from zirconyl chloride by chemical methods described earlier[12]—was added and homogenized for further 48 h. The powders were cold isostatically pressed at 140 MPa into rectangular die (41 × 65 mm). The samples were sintered at 1973 K of 90 min either in a gas furnace (air atmosphere) or in an electric furnace under eleven levels of oxygen partial pressure (p_{O_2}) in sintering atmosphere between $2{\cdot}8 \times 10^{-5}$ Pa and $1{\cdot}07 \times 10^{+4}$ Pa. The values of p_{O_2} were realized by controlled introduction (by using electronic valves) of air into the high-vacuum chamber of the furnace or earlier prepared oxygen–argon gas mixtures.

The critical stress-intensity factor, K_{Ic}, was determined after Evans[13] on notch-beam specimens of configuration described earlier[12] and an Instron TIM type testing machine. The bearing spacing was 36 mm and the rate of loading 0·1 mm min^{-1}.

The bending strength was determined by three-point bending on bars 5 × 5 × 50 mm using the same testing machine, the same rate of loading and bearing spacing. These tests were performed on 15 samples for each composition.

Table 1. Mechanical properties of alumina ceramics containing 10 wt% zirconia

Properties	*Sintering atmosphere*	
	Air	*0·133 mPa vacuum*
	Oxygen partial pressure (Pa)	
	$2{\cdot}1 \times 10^{+4}$	$2{\cdot}8 \times 10^{-5}$
Critical stress-intensity factor, K_{Ic}, MPa $m^{1/2}$	6·60 ± 0·57	8·00 ± 0·67
Bending strength, MPa	324·40 ± 58·7	397·80 ± 28·5
Grindability, mm	0·1	0·01

The measurement of grindability was carried out with a Mackensen blower using 500–630 μm SiC powder, 0·15 MPa pressure and a cell of 28 cm^3 volume. To intensify the abrasion by the grinding powder, the test was repeated three times at the same place on the samples. As a measure of grindability, the depth of the hole blown by the grinding powder in 15 samples for each composition was recorded.

The phase composition of zirconia in each of the free and fractured surfaces ceramics was determined by X-ray diffraction (Siemens diffractometer Kristalloflex 4). The measurements were carried out in the 2Θ-angle 20–160° at 293 K using monochromatized CuK_{α_1} radiation (quartz, (10$\bar{1}$1) reflection Johanson type) in steps of 1/16 deg min^{-1}. The precision of goniometer was tested using an ultrapure silicon powder standard.

The phase content was estimated using integral intensities of the strongest lines taking into account the polarization, Lorentz, structure and multiplicity factors.[14] The lattice parameters were calculated using the least-squares Cohen method.[14]

The loss of oxygen in ZrO_2 of samples sintered in atmospheres with increasing p_{O_2} was estimated by measuring the weight increasing during its reoxidation in air at 1273 K (1000 h). This allows the level of the oxygen vacancy concentration to be determined.

3 Results and Discussion

As can be seen from the data shown in Table 1, the critical stress-intensity factor, K_{Ic}, of ceramics sintered in high vacuum (0·133 mPa) is really higher than that for the air-sintered ceramics. The bending strength and Mackensen's grindability of these ceramics also differ in the same way.

Table 2. Zirconia phases in Al_2O_3–10 wt% ZrO_2 measured from free surface as a function of sintering atmosphere

Sintering atmosphere	*Phases of zirconia (%)*		
	Monoclinic	*Tetragonal*	*Cubic*
Air	16·5	83·5	—
0·133 mPa vacuum	—	—	100

Table 3. X-ray data of c-ZrO_2 in Al_2O_3–10 wt% ZrO_2 sintered in vacuum (free surface)

	2θ, degrees	I/I_0	*h*	*k*	*l*
1	30·12	100	1	1	1
2	34·96	17	2	0	0
3	50·22	32	2	2	0
4	59·74	16	3	1	1
5	62·68	2	2	2	2
6	73·94	1	4	0	0
7	81·76	2	3	3	1
8	84·40	3	4	2	0
9	94·74	1	4	2	2
10	102·68	1	3	3	3
11	125·40	1	5	3	1
12	128·64	<1	6	0	0

The observed differences can be correlated with the presence of zirconia phases in the matrix. In the case of air-sintered samples, 83·5% of zirconia is in the tetragonal form (Table 2).

X-ray analysis of samples sintered in high vacuum indicates 100% presence of the cubic form. The X-ray data of c-ZrO_2 obtained from free surface are listed in Table 3.

As can be seen from the phase diagram of the system Zr–O (Fig. 1) determined by Ruh & Garrett,[15] the presence of c-ZrO_2 at 1973 K (the tetragonal–cubic phase transformation temperature is at 2558 ± 15K) is possible under the conditions of high anion deficiency equal to $2 - x = 1{\cdot}688 - 1{\cdot}740$.

It seems that the appearance of metastable c-ZrO_2 in alumina ceramics is a result of sintering in high vacuum (under very low oxygen partial pressure) accompanied by oxygen nonstoichiometry. Furthermore, the constraint of the alumina matrix prevents the c-phase transforming during cooling from the sintering temperature to room temperature.

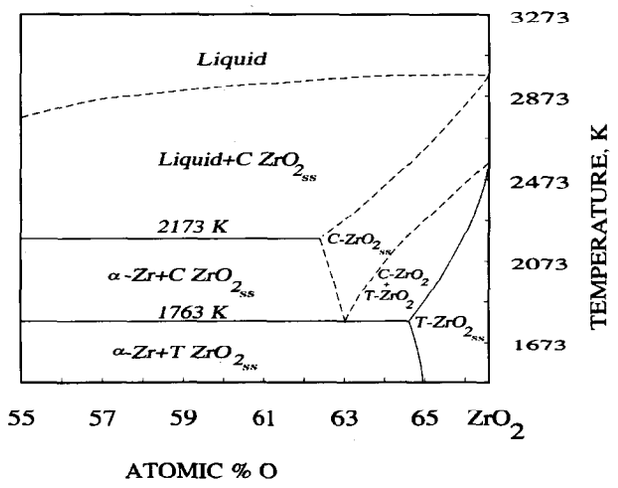

Fig. 1. Phase diagram of the Zr–O system.[15]

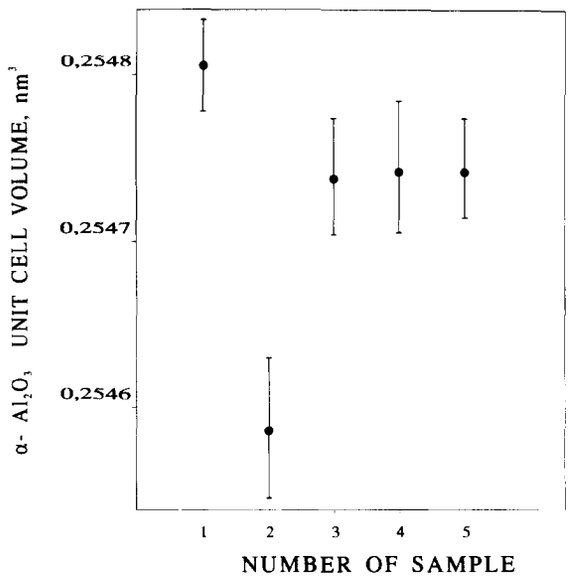

Fig. 2. Volume of α-Al_2O_3 unit cell in Al_2O_3–10 wt% ZrO_2 versus sintering and measuring conditions. The measured samples are: (1) α-Al_2O_3 matrix; (2) free surface of high vacuum-sintered alumina–zirconia ceramics; (3) free surface of air-sintered alumina–zirconia ceramics; (4) fractured surface of high vacuum-sintered alumina–zirconia ceramics; (5) fractured surface of air-sintered alumina–zirconia ceramics.

The presence of the stress field in the ceramics confirms the X-ray results for the α-Al_2O_3 unit cell volume for the alumina matrix with and without zirconia particles sintered in air and in vacuum (Fig. 2). As shown, the largest deformation of the α-Al_2O_3 unit cell is in samples where only the c-phase of ZrO_2 exists. In other samples deformations are relaxed. It should be expected that the particles of c-ZrO_2, when placed in the locally enhanced tensile stress field at the tip of an advancing crack, are freed from the constraint of the matrix and transform to the forms stable at the lower temperature range.

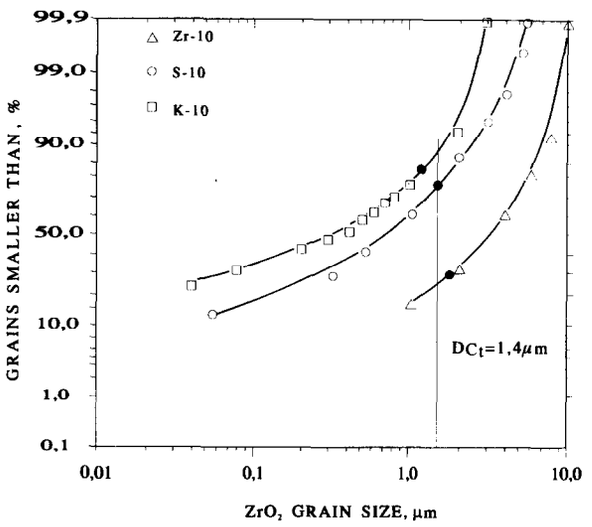

Fig. 3. Zirconia grain-size distribution of air-sintered alumina ceramics containing 10 wt% Zr-type ZrO_2, 10 wt% S-type ZrO_2 and 10 wt% K-type ZrO_2.[2] ●, Content of the finest ZrO_2 grains corresponding to the content of tetragonal form.

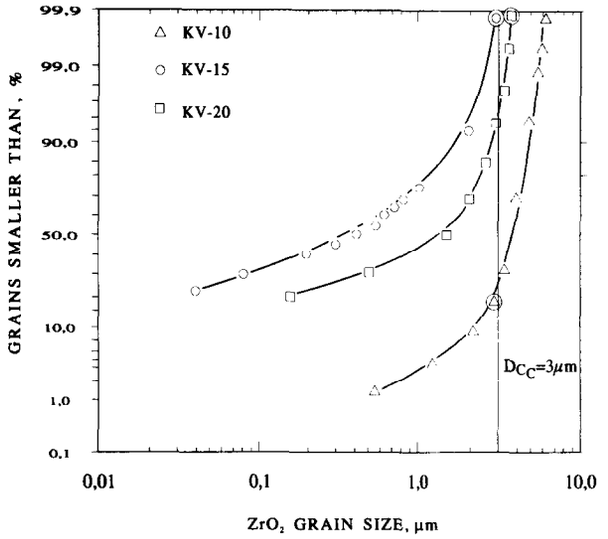

Fig. 4. Zirconia grain-size distribution of high vacuum-sintered alumina ceramics containing 10 wt%, 15 wt% and 20 wt% ZrO_2 of K-type (obtained by chemical method).[2] ○, Content of the finest ZrO_2 grains corresponding to the content of cubic form.

Tetragonal and monoclinic zirconia on fractured surfaces of vacuum-sintered ceramics show that the cubic form is the transformable phase and is responsible for enhancing the toughness of the ceramics.[3] This phase then appears to play the same role as the tetragonal form in the case of ceramics sintered in an oxidizing atmosphere.

The critical grain size of t-ZrO_2 inclusions in the case of air-sintered ceramics is d_{ct} = 1·4 μm (Fig. 3).[12] This value was estimated by comparison of ZrO_2 grain size distribution with the content of retained t-ZrO_2. A similar estimation made for samples sintered in high vacuum (Fig. 4) indicates an increase of the critical grain-size inclusion for c-ZrO_2 up to a value of d_{Cc} = 3·0 μm.[2] Obviously, the reason for the enhancement of the critical grain-size inclusion could be found in the non-stoichiometry of ZrO_2.

According to the present results, if the oxygen vacancy concentration plays a decisive role in the metastability of c-phase, it would then be possible to transform it to t- or m-phase, due to the reduction of the vacancy concentration in the ZrO_2 lattice as a result of sintering alumina–zirconia ceramics in atmospheres richer in oxygen. After Kountouros *et al.*,[11] a critical minimum and a critical maximum vacancy concentration for each ZrO_2 phase should also exist.

As can be seen from Table 4, in the p_{O_2} range between 2·80 × 10^{-5} and 2·80 × 10^{-2} Pa, the cubic form is the only phase of zirconia. However, an increase of oxygen content in the sintering atmosphere causes changes in the lattice parameters of the c-phase (see Table 5 and Fig. 5). An increase of the constant a values and the unit cell volume is observed. These results seem to be an effect of oxygen loss decrease from the zirconia structure

during sintering in less oxygen-deficient atmospheres. The decrease of the X-ray mean half breadth (Fig. 6) and lattice parameter scattering from a value of 0·000 16 to 0·000 02 (see Table 5) also indicates an improvement in the c-phase structure.

When the oxygen content in the sintering atmosphere decreases below the critical p_{O_2} value for the c-phase. t-ZrO_2 appears and coexists with c-ZrO_2 (see Table 4—$p_{O_2} = 1{\cdot}40 \times 10^{-1}$Pa).

In the case of $1{\cdot}80 \times 10^{-1}$ Pa oxygen pressure t-ZrO_2 is the only form of zirconia present, but from $1{\cdot}07 \times 10^{0}$ Pa oxygen pressure is accompanied by m-ZrO_2. It indicates that the critical minimum vacancy concentration for t-phase has been exceeded. A further increase of the oxygen content (air atmosphere) leads to an increase of m–ZrO_2 up to 16·5%.

Table 5. Lattice parameters of c-ZrO_2 as a function of oxygen content in sintering atmosphere

Oxygen partial pressure (Pa)	*Lattice constants a (nm)*	*Volume of unit cell (nm^3)*
$2{\cdot}80 \times 10^{-5}$	0·512 49 ± 0·000 16	0·134 604 ± 0·000 129
$2{\cdot}80 \times 10^{-4}$	0·512 98 ± 0·000 11	0·134 989 ± 0·000 089
$2{\cdot}80 \times 10^{-3}$	0·513 19 ± 0·000 08	0·135 155 ± 0·000 063
$2{\cdot}80 \times 10^{-2}$	0·514 63 ± 0·000 02	0·136 302 ± 0·000 017
$1{\cdot}40 \times 10^{-1}$	0·514 14 ± 0·000 32	0·135 908 ± 0·000 253

In a similar way to the cubic form, an increase of the oxygen content in the sintering atmosphere influences the lattice parameters of the t- and m-phases (Tables 6 and 7). As can be seen from Fig. 7 the tetragonality (*c/a* axial ratio) of t-ZrO_2 considerably improves. An increase of the m-phase unit volume is also observed (Table 7). Figures 8 and 9 illustrate the changes of zirconia phase composition with oxygen content in a sintering atmosphere.

The presence of the stress field in samples with c-ZrO_2 is also confirmed by XRD results of the α-Al_2O_3 unit cell volume of samples sintered in p_{O_2} atmospheres between $2{\cdot}80 \times 10^{-4}$ and $2{\cdot}80 \times 10^{-2}$ Pa (see Fig. 10). Calculated deformation of α-Al_2O_3 unit cell is equal to 0·2% (see Table 8). In other samples with t-ZrO_2 the unit cell volume becomes similar to values typical for alumina ceramics without zirconia. In this way, t-ZrO_2 seems to be a factor responsible for the relaxation of stresses caused by c-ZrO_2 in the matrix.

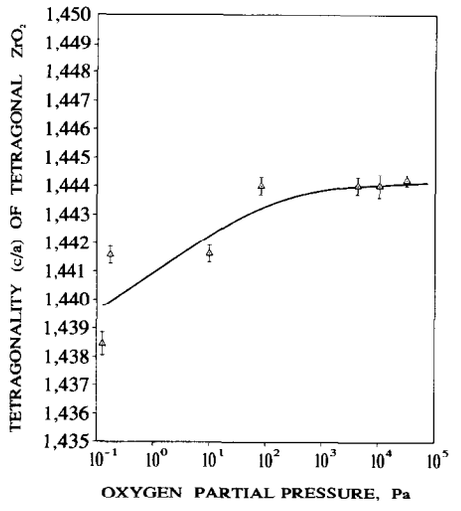

Fig. 7. Tetragonality (*c*/*a*) of t-ZrO_2 as a function of oxygen content in sintering atmosphere.

Samples sintered in p_{O_2} atmosphere equal to 1·40 $\times$ 10^{-1} Pa, where 20·6% of the tetragonal form coexists with 79·4% of the c-phase, are a good confirmation of the previously mentioned thesis.

The main conclusion concerning the influence of oxygen vacancy concentration on the meta-

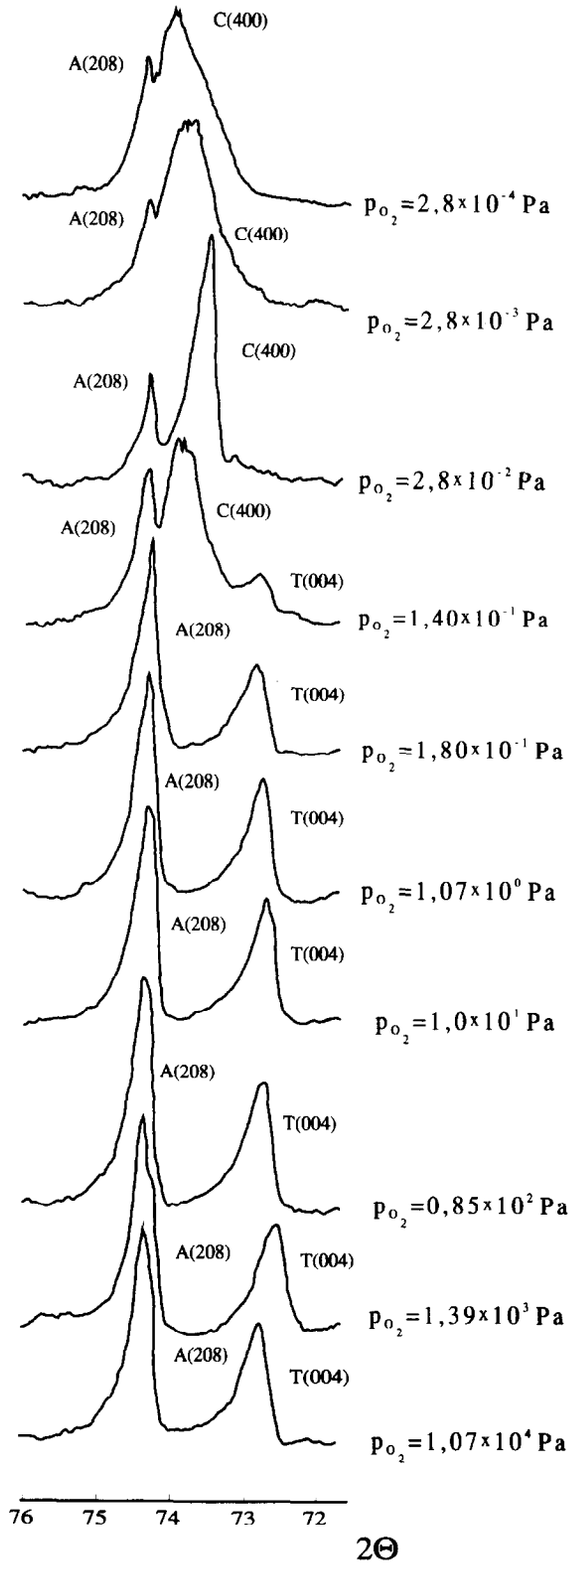

Fig. 8. Changes of XRD profiles of Al_2O_3–10 wt% ZrO_2 ceramics (2Θ = 72–76°) as a function of oxygen content in sintering atmosphere. A = α-Al_2O_3, C = cubic, T = tetragonal zirconia respectively.

stability of zirconia phases comes from thermogravimetric determinations. In this case, samples sintered in oxygen-deficient conditions were reoxidized by reheating in air at 1273 K for 1000 h and an increase of their weight was recorded. Results of oxygen vacancy concentration in zirconia are listed in Table 4.

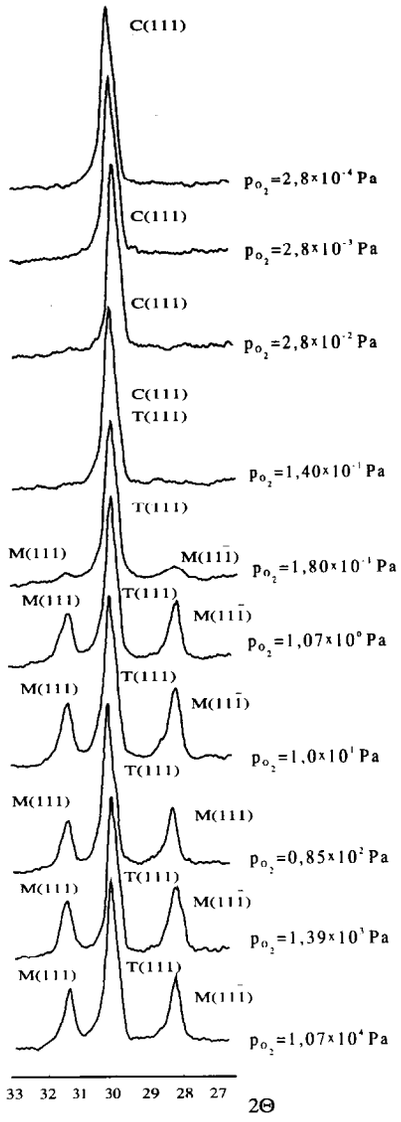

Fig. 9. Changes of XRD profiles of Al_2O_3–10 wt% ZrO_2 ceramics (2Θ = 27–33°) as a function of oxygen content in sintering atmosphere. C = Cubic, T = tetragonal and M = monoclinic zirconia respectively.

Table 8. Changes of unit cell volume and mean half breadth X-ray lines of αAl_2O_3 in Al_2O_3–10 wt% ZrO_2 as a function of oxygen content in sintering atmosphere

Oxygen partial pressure (Pa)	*Change of unit cell volume ΔV/V (%)*	*Mean half breadth (rad)*
$2{\cdot}80 \times 10^{-4}$	0·225	0·002 69
$2{\cdot}80 \times 10^{-3}$	0·182	0·002 75
$2{\cdot}80 \times 10^{-2}$	0·183	0·002 19
$1{\cdot}40 \times 10^{-1}$	0·002	0·001 35
$1{\cdot}80 \times 10^{-1}$	0·000	0·001 47
$1{\cdot}07 \times 10^{0}$	0·005	0·001 62
$1{\cdot}00 \times 10^{1}$	0·022	0·001 53
$0{\cdot}85 \times 10^{2}$	0·001	0·001 77
$1{\cdot}39 \times 10^{3}$	0·003	0·001 64

As was shown, the cubic form is the only phase of zirconia which exists in the oxygen vacancy concentration between 14·85 and 9·13%, that corresponds to a oxygen partial pressure in the sintering atmosphere in the range $2{\cdot}80 \times 10^{-5}$ Pa to $2{\cdot}80 \times 10^{-2}$ Pa. When the oxygen content increases to $1{\cdot}40 \times 10^{-1}$ Pa and the oxygen vacancy concentration decreases to a value of 5·25%, c-ZrO_2 coexists with the tetragonal form. Complete inversion to t-ZrO_2 is observed for 3·12% of oxygen vacancy content and this value seems to be a critical minimum value of oxygen vacancy concentration for this phase. Increasing the oxygen content in the sintering atmosphere the volume

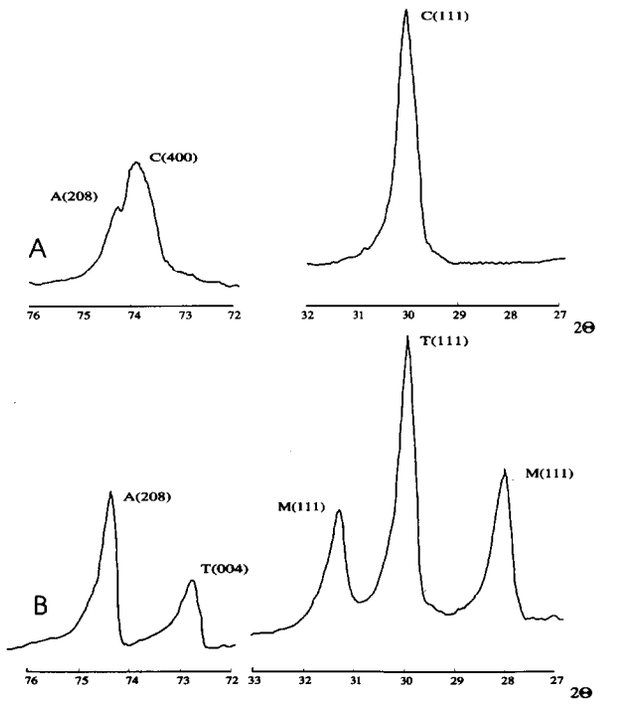

Fig. 11. Changes of zirconia phase composition as result of reoxidation heating of alumina–zirconia ceramics. A, Sample of ceramics sintered in atmosphere with oxygen partial pressure equalled $2{\cdot}80 \times 10^{-3}$ Pa; B, the same sample after reoxidation heating at 1273K for 1000 h in air. Explanation: A = α-Al_2O_3, C = cubic, T = tetragonal and M = monoclinic zirconia respectively.

of m-ZrO_2 increases also up to value of 16·5%, typical for samples sintered in oxidizing (air) atmosphere.

These results confirm the earlier thesis[11] that the oxygen vacancies in zirconia are mainly responsible for the metastability of c- and t-phases. Decreasing the oxygen vacancy concentration with an increase of the oxygen partial pressure in the sintering atmosphere below the critical minimum value leads to a breakdown of the c-phase which transforms to the t- and/or m-phase (see Fig. 11).

4 Conclusions

This study demonstrated that the oxygen content in a sintering atmosphere clearly influences the phase composition of undoped zirconia grains dispersed in alumina matrix.

In the case of ceramics sintered in atmospheres with oxygen partial pressure between $2{\cdot}80 \times 10^{-5}$ Pa and $2{\cdot}80 \times 10^{-2}$ Pa, 100% of zirconia is in the cubic form. The appearance of transformable c-ZrO_2 is a result of oxygen vacancy concentration in zirconia. The concentration of oxygen vacancy equal to 9% seems to be the critical minimum value for this phase. Decreasing the oxygen vacancy concentration, as a result of increasing the oxygen content in the sintering atmosphere, below 9%, causes an increase of the t-ZrO_2 content. The critical value of the oxygen vacancy concentration for the tetragonal form is 3%. A further increase of the oxygen content to $1{\cdot}07 \times 10^{0}$ Pa and a decrease of oxygen vacancy concentration to 0·5% lead to the appearance of m-ZrO_2.

(Received 2 February 1994; accepted 1 April 1994)

Abstract

The grain boundary resistance of 9 mol% Y_2O_3-stabilized ZrO_2 with Al_2O_3 addition was measured by the complex impedance approach. The effect of Al_2O_3 addition on the grain boundary resistance was analyzed from the aspects of microstructure and crystal defects by means of SEM, EPMA, TEM and the positron annihilation technique. The Al_2O_3 addition up to 5 mol% was found to reduce the grain boundary resistance per unit surface area of the grain boundaries and the activation energy for the grain boundary resistance. This phenomenon was explained by the scavenging of the grain boundary impurities, e.g. SiO_2, by the Al_2O_3 and the formation of the crystal grain boundary phases with very high defect concentration. By the analyses with a simplified theoretical model, the Al_2O_3 addition was considered to have no detrimental effect on the emf of the ZrO_2 oxygen sensor.

1 Introduction

In polycrystal ceramic materials, grain boundaries have a large, often controlling importance for properties. The studies on grain boundary behavior are essential for the design of ceramic materials, and the control and optimization of their performances. Thus a concept of 'grain boundary engineering' was put forward, i.e. to improve the properties of ceramics by modifying grain boundaries.[1] Now the grain boundaries of ZrO_2-based solid electrolyte have attracted much attention.

As one of the most important solid electrolytes, much research has been performed on ZrO_2. Although the research results are not totally in keeping with each other, the following points have been clarified: (1) the grain resistivity of polycrystal ZrO_2 is equivalent to that of a single crystal, and it is usually not affected by sintering temperature, atmosphere and heat treatment;[2] (2) the efforts to reduce the grain resistivity by changing composition (e.g. adding Y_2O_3, CaO, MgO, rare earth oxides, and two, three or more oxides are simultaneously added) are now nearly exhausted, the optimum stabilizer concentrations, e.g. 8–9 mol% Y_2O_3 or 13–14 mol% CaO have been generally established;[3] it is difficult to find a new stabilizer which can remarkably reduce the grain resistivity in a expectable period; (3) the property and structure of grain boundary phases are strikingly influenced by impurity, sintering temperature, atmosphere and heat treatments;[4] (4) the ZrO_2 grain boundary resistivity may be lower or higher than that of grain due to the difference of segregated elements and variation of grain boundary structure.[5,6] All these points suggest that a feasible way to further enhance the ionic conduction of ZrO_2 is to reduce the grain boundary resistivity by adding a new kind of ingredient. In order to densify ZrO_2 during sintering, certain amounts of Al_2O_3 were often added to ZrO_2.[7] After further study, it was discovered that Al_2O_3 can also reduce the resistance of ZrO_2.[8] In this paper, Al_2O_3 up to 5 mol% is added and the grain boundary resistance is studied.

2 Experimental Procedure

2.1 Preparation of specimens

The compositions of specimens are listed in Table 1. Powders used to produce the specimens were prepared from $ZrOCl_2 \cdot 8H_2O$, YCl_3 and $AlCl_3$ by

* Project supported by China Postdoctoral Science Foundation.

Table 1. Compositions of specimens

Specimen	*Composition*
0AYZ	ZrO_2–9 mol% Y_2O_3
1·5AYZ	ZrO_2–9 mol%Y_2O_3–1·5 mol% Al_2O_3
5AYZ	ZrO_2–9 mol% Y_2O_3–5 mol% Al_2O_3

a coprecipitation method, average particle sizes measured by a centrifugal particle size analyzer (type SA-CP3) are 0·45 μm, 0·40 μm and 0·48 μm respectively. The powders were subsequently pressed into pellets (22 mm in diameter by 4 mm thick) at 200 MPa, then sintered at 1600°C for 2 h. The platinum electrodes were applied to the ZrO_2 specimens by the decomposition of chloroplatinic acid at 1000°C.

2.2 Measurements and analyses

The specimens under went the following measurements and analyses. (1) Resistances were measured by the complex impedance approach in a frequency range of 20 Hz to 1 MHz with a HP4285A precision LCR meter, the grain and grain boundary resistances were separated out by the analyses of the complex plots. (2) Al distribution information inside the specimens was examined by EPMA (type JCXA-733) on the specimens polished and coated with carbon. (3) Microstructure studies were carried out with SEM (type JSM-35C) and TEM (type H-800, Philips-CM_{12}/STEM). (4) Crystal defect changes were detected by the positron annihilation technique (CANBERRA Series 35).

3 Results

3.1 Grain boundary resistance

The complex impedance approach has been used extensively in the examination and development of solid electrolytes after the initial report by Bauerle.[9] This approach can effectively probe the grain resistance as well as the resistance across grain boundaries and electrode/electrolyte interfaces.

The grain boundary resistances R_{gb} of the specimens were measured at 440°C and 500°C; the results are listed in Table 2. In order to explain further the measured results, the grain boundary resistances per unit surface area of grain boundaries R_{gbs} were calculated from[10]

$$R_{gbs} = \rho_{gb}/D = R_{gb}(S/l)/D \qquad (1)$$

where ρ_{gb} is the grain boundary resistivity, S/l is the cross-section/length ratio of the specimen and D the grain boundary density. R_{gbs} has been used before by Miyayama and coworkers to explain intrinsic and extrinsic grain boundary phenomena,[8,10] because R_{gbs} values contain no microstructural effects. The R_{gbs} values are also listed in Table 2. For the case studied in this paper, if space charges resulting from the irregularity of lattice can account for the resistance of the grain boundary surface (intrinsic effect), the R_{gbs} should be constant, i.e. independent of Al_2O_3 content. However, for the extrinsic effects (impurity dominated), when the Al_2O_3 addition increases, the concentration of Al_2O_3 per unit surface area of grain boundaries also increases, notwithstanding the change of the grain boundary density D. Therefore, the R_{gbs} should be affected by the Al_2O_3 addition; this, in fact, is the case for the specimens used in this study. The R_{gbs} of the specimen 0AYZ is much higher than those of the specimens 1.5AYZ and 5AYZ; the specimen 5AYZ has the smallest R_{gbs} value.

Activation energies for the grain boundary resistance can be calculated from the Arrhenius equation

$$R = A \exp(E/KT) \qquad (2)$$

where K and T have their usual meanings. The values are listed in Table 2. The specimen 0AYZ has the largest grain boundary resistance activation energy E_{gb}, and E_{gb} decreases with increasing Al_2O_3 content.

3.2 Positron annihilation

The measurements of positron lifetime spectra were carried out at room temperature (21 ± 1)°C by a fast–fast coincidence lifetime spectrometer with a resolution of 230ps. A ^{22}NaCl positron source was used in the measurements. A normal specimen–source–specimen sandwich arrangement was adopted. A total of 10^6 counts in each spectrum were collected. After substracting the source and background contribution, all lifetime spectra were

Specimen	τ_1 *(ps)*	τ_2 *(ps)*	τ_3 *(ps)*	I_1 *(%)*	I_2 *(%)*	I_3 *(%)*	$K(\mu s^{-1})$
0AYZ	239	269	1 802	90·5	8·2	1·3	38·3
1·5AYZ	205	353	1 685	90·5	7·6	1·5	155·4
5AYZ	204	375	1 806	92·0	6·9	1·2	153·7

analyzed with three components by the program POSITRONFIT EXTENDED. Lifetimes τ_1, τ_2 and τ_3 and their relative intensities I_1, I_2 and I_3 were obtained (listed in Table 3). The long lifetime component τ_3, whose intensity is about 1·4%, may arise from the positron annihilation in the positron source and associated foils, and/or interfaces that are unavoidable with the sandwich arrangement, so τ_3 will not be discussed. The short lifetime component τ_1 reflects the positron annihilation feature in perfect lattices, and τ_2 is the positron lifetime in crystal defects. According to the two-state trapping model,[11] the trapping rate of the defects to positron K can be derived,

$$K = I_2 \Big/ \left(\frac{1}{\tau_1} - \frac{1}{\tau_2}\right) \tag{3}$$

The K values are listed in Table 3. Because $K = \mu C$, where C is the concentration of defects and μ is the specific trapping rate which can be considered as a constant when the type or structure of the defects does not change; thus the change of K can roughly reflect the change of the defect concentration. The K value increases when Al_2O_3 is added to ZrO_2, this tendency is opposite to that of the grain boundary resistance per unit surface area of grain boundaries R_{gbs}; in other words, with increasing Al_2O_3 content, the defect concentration of the specimens increases, and consequently the R_{gbs} value decreases.

3.3 Microstructure

The solubility of Al_2O_3 in ZrO_2 grain is very low, only 0·5 mol% Al_2O_3 can be dissolved in Y_2O_3-stabilized ZrO_2 sintered at 1700°C and cooled at 220°C/h,[8] and the solubility of Al_2O_3 is about 0·1 mol% when sintered at 1300°C.[12] So it is obvious that the Al_2O_3 additions in the present work are far beyond the Al_2O_3 solubility.

Figure 1 shows the scanning electron micro-

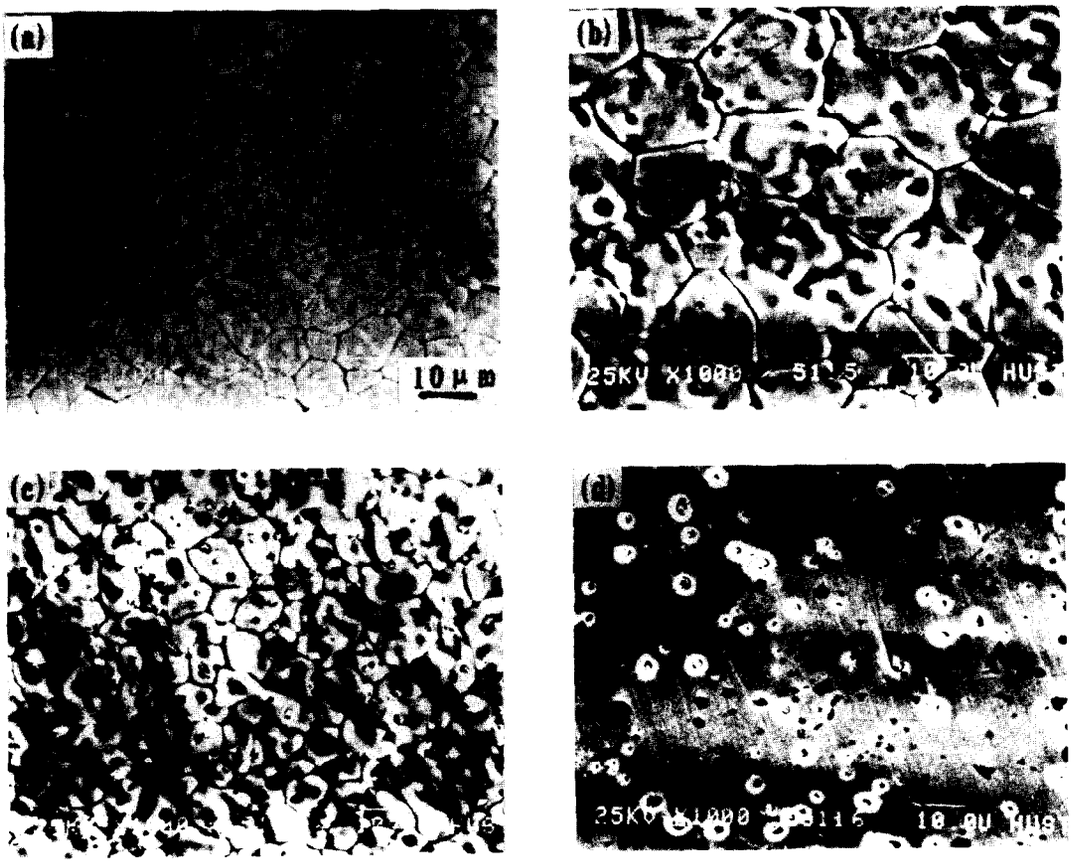

Fig. 1. Scanning electron micrographs of the surfaces of as-sintered specimens. (a) 0AYZ, (b) 1·5AYZ, (c) 5AYZ, (d) 1·5AYZ, polished surface.

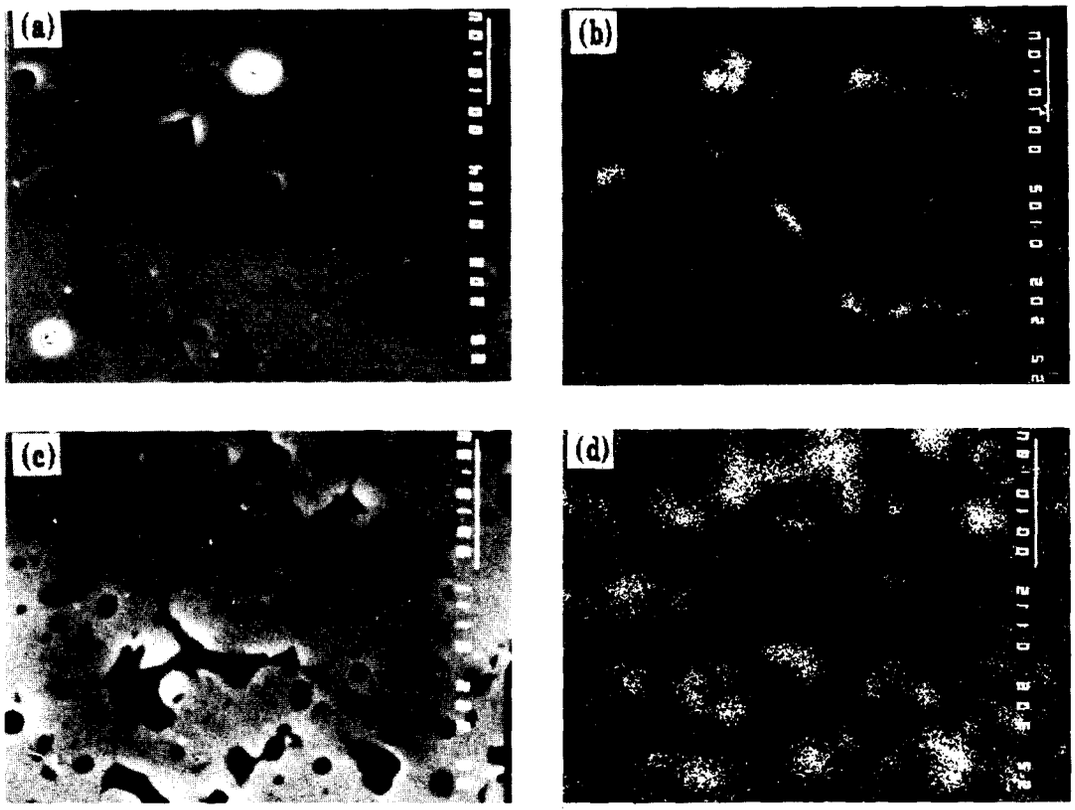

Fig. 2. EPMA photographs of the specimens with different Al_2O_3 content. (a), (b) 1·5AYZ, (c), (d) 5AYZ.

graphs of the surfaces of the as-sintered specimens 0AYZ, 1·5AYZ and 5AYZ, and the polished surface of the specimen 1·5AYZ. The specimen 0AYZ has a homogeneous mono-phase structure, while Al_2O_3 particles can be observed as bright or dark spots in the specimens 1·5AYZ and 5AYZ; the Al_2O_3 particles are situated both inter- and intragranularly. Because there are quite large differences in the elastic modulus and the thermal expansion coefficient between Al_2O_3 and ZrO_2, the intragranular Al_2O_3 particles are always accompanied by pores, which can be seen from the polished surface.

Figure 2 shows the EPMA analysis results, in which photographs (a) and (c) are scattered electron images and photographs (b) and (d) display the Al distributions. From these photographs, it can be seen that Al is mainly segregated at grain boundaries, and that the Al segregation is more serious in the specimen 5AYZ. Some small dark spots inside grains shown in the scattered electron images are Al_2O_3 particles and pores. Apparent enrichment of Si and Ca at grain boundaries was not observed.

Because of the segregation of Al_2O_3 and impurities at grain boundaries, grain boundary phases are often formed. Two types of grain boundary phases were discovered in the specimens with Al_2O_3 addition; one type is shown in Fig. 3. The small bright particle situated at the triple point of ZrO_2 grains is an Al_2O_3 particle (Fig. 3(a)), the grain boundary phases have a peculiar morphology. Figure 3(b) is the SADP of the grain boundary phases, the diffraction rings indicate that the grain boundary phases consist of large amount of crystallites. The ratio of the square radii of the diffraction rings is

$$R_1^2 : R_2^2 : R_3^2 : R_4^2 : R_5^2 : R_6^2 \approx 1 : 2 : 3 : 6 : 7 : 9 \quad (4)$$

According to the ratio and brightness distribution of the diffraction rings, these crystallites do not have crystal structure of α-Al_2O_3 or cubic ZrO_2; because of the large errors usually involved in electron diffractions, it is still difficult to determine the crystal structure of the crystallites. The composition of the grain boundary phases measured by EDAX is given in Table 4. An enrichment of Al was found and no impurities such as Si, Ca were detected. However, for the crystal grain boundary phases at different regions of the specimen, different SADP patterns are produced and different Al, Y and Zr concentrations are measured by EDAX. The phases may be con-

cluded to be a kind of Al-rich compound with a chemical formula

$$(Al_2O_3)_x(Y_2O_3)_y(ZrO_2)_z(x + y + z = 1).$$

The amount of the crystal grain boundary phases is quite large; they are distributed at grain boundaries and Al_2O_3/ZrO_2 interfaces.

Another type of grain boundary phase is shown is Fig. 4. This type of grain boundary phase is rarely found in the specimens, they are distributed at triple points (Fig. 4(a)) and Al_2O_3/ZrO_2 interfaces (Fig. 4(b)). The SADP of the grain boundary phases (Fig. 4(c)) indicates that they are amorphous, and corresponding EDAX measurement (Table 5) discovers impurities Si and Ca, besides the enrichment of Al. The grain boundaries without amorphous phases are quite clean, no impurities such as Si and Ca are presented there.

According to these analyses, it can be concluded that there are three forms of Al_2O_3 in existence in ZrO_2. They are: (1) a very small amount of Al_2O_3 is dissolved in ZrO_2 grains; (2) the surplus Al_2O_3 then forms Al_2O_3 particles, which are extensively situated intra- and intergranularly; (3) Al_2O_3 segregates at grain boundaries, and forms the crystal and the amorphous Al-rich grain boundary phases; the amorphous one contains impurities such as Si and Ca.

4 Discussions

4.1 Effect of Al_2O_3 on the grain boundary resistance of ZrO_2

Al_2O_3 can reduce the ZrO_2 grain boundary resistance. Butler & Drennan suggested that this is because that Al_2O_3 acts as a scavenger for SiO_2 located at grain boundaries.[13] There are two types of grain boundary phases in ZrO_2, the crystal and the amorphous. Table 2 shows that the ZrO_2 grain boundary resistance is controlled by the Al_2O_3 addition and that Al_2O_3 reduces the R_{gbs}. This phenomenon may be explained with two mechanisms that are related to the two types of grain boundary phases.

Mechanism I: the Al_2O_3 addition scavenges SiO_2 located at grain boundaries and results in a low grain boundary resistance. This is similar to the results of Butler & Drennan. The only difference from the experiment of Butler & Drennan is that the specimens used in this paper contain CaO as well as SiO_2. According to the $CaO–Al_2O_3–SiO_2$ phase diagram,[14] CaO, Al_2O_3 and SiO_2 with a concentration relation listed in Table 5 will react with each other according to the following equation:

$$CaO + Al_2O_3 + 2SiO_2 \rightarrow CaAl_2Si_2O_3 \quad (5)$$

The impurities CaO and SiO_2 are transported by grain boundary diffusion to the triple points with high Al_2O_3 concentration and the Al_2O_3 particle surface, and by the chemical reaction (5), the grain boundary impurities are scavenged, and as a result, E_{gb} decreases.

Mechanism II: The crystal grain boundary phases contain no CaO or SiO_2, so the mechanism I can not explain all the experimental phenomena. And besides, the positron annihilation results show that Al_2O_3 increases the crystal defect concentration in ZrO_2. The defects can be roughly divided into two main parts, the defects in grains and those in the crystal grain boundary phases. The defects in grains are determined by the dopant Y_2O_3, and the Al_2O_3 solubility in grains is very low, so the effect of Al_2O_3 on the grain defects is negligible. This means that the increased crystal defect concentration is a result of the increasing of crystal defects in the crystal grain boundary phases, and consequently the resistance of the crystal grain boundary phases is very low, so the R_{gbs} subsequently decreases. Thus a new mechanism is derived as follows: the Al_2O_3 segregated at grain boundaries forms crystal grain boundary phases with very high defect concentration, so the grain boundary resistance decreases. Aono and coworkers observed a somewhat similar phenomenon in the solid electrolyte based on $LiTi_2(PO_4)_3$[15,16] in which grain boundary conductivity increases considerably by adding Li_3BO_3 or $Li_4P_2O_7$. The reason for the conductivity enhancement was attributed to the enhancement of the lithium concentration at the grain boundaries and the formation of a new conductive phase at the grain boundaries.

It should be noted that the enhancement of the ionic conductivity of some compounds by the incorporation of fine non-conduction particles seems to be quite popular,[17,18] It was usually considered to be due to the formation of conductive, defect-rich interfaces. This explanation is not quite applicable to the phenomena observed in this study, because Fig. 1(d) shows that the intragranular Al_2O_3 particles are accompanied by pores, and no such defect-rich interfaces were found for them, only for the intergranular Al_2O_3 particles, where such defect-rich interfaces were observed. So it must be stressed that the inter- and intragranular particles have different effects on the conductivity, when there are large difference in properties between the particles and the matrix, the conductive, defect-rich interfaces can only form for the intergranular particles.

4.2 Effect of grain boundaries on the emf of the ZrO_2 oxygen sensor

As an oxygen ion conductor, ZrO_2 is popularly used in oxygen sensors. By the emf output of the oxygen sensor, the oxygen partial pressure in all kinds of atmospheres can be measured. There are lots of factors affecting the emf output, the principle ones are electrode structure, electrode/electrolyte interfaces and ZrO_2 microstructure. In a practical process of an oxygen sensor, all the above factors simultaneously bring about an influence, and it is almost impossible to differentiate the individual influences by experiments, therefore, the effect of the grain boundaries on the output of the ZrO_2 oxygen sensors is analysed with a simplified model as follows.

Figure 5 is a simplified schematic representation of an oxygen sensor containing grain boundary phases. Suppose $t_i<1$ for the grain boundary phases, because the current through the grain boundary phases is also carried by oxygen ions; apart from an increase of internal resistance, the grain boundary phases do not influence the exclusively ionic nature of the conductivity of ZrO_2. The emf of the oxygen sensor can be given by eqn (6),[19] if the

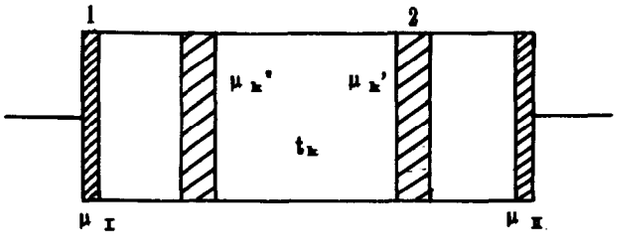

Fig. 5. Simplified schematic representation of an oxygen sensor. 1, Electrode; 2, grain boundary phases.

oxygen sensor is divided into several parts, as shown in Fig. 5. The meaning of t_k, μ_k'' and μ_k' can be seen from Fig. 5.

$$E = -\frac{1}{2ZF}\int_{\mu_I}^{\mu_{II}} t\,\mathrm{d}\mu$$

$$= -\frac{1}{2ZF}\sum t_k(\mu_k'' - \mu_k') \qquad (6)$$

When $t_k = 1$, the chemical potential of the region k can be totally transferred into the emf; when $t_k < 1$ and $\mu_k'' - \mu_k' = 0$, or $t_k = 0$ and $\mu_k'' - \mu_k' \neq 0$, the region k does not make any contribution to the emf. Under this condition, $E = E_{th}$ is held true, E_{th} being the theoretical value. When $t_k < 1$ and $\mu_k'' - \mu_k' \neq 0$, then $E < E_{th}$. When oxygen partial pressures over the electrodes are changed, during a transient situation, an appreciable oxygen potential drop may occur over the grain boundary phases, if $t_k < 1$ this yields a deviation from the E_{th} and an emf drift. Because the chemical diffusion inside ZrO_2 is very slow, the emf drift will last as long as several hours.

There are three kinds of grain boundary regions in the ZrO_2 with Al_2O_3 addition, the 'clean' grain boundaries but with Al segregation, the grain boundaries with amorphous phases and the grain boundaries with crystal phases. As Kingery has pointed out,[20] the ionic nature of ceramic oxide always leads to the formation of an electrostatic potential on grain boundaries, the sign and magnitude of the electrostatic potential depending strongly on impurity concentration. The Al segregation at the 'clean' grain boundaries certainly will change the grain boundary electrostatic potential, so the μ_k', μ_k'' values are changed, but although the nature of the 'clean' grain boundaries is unclear, $t_i = 1$ will hold true from them, thus the 'clean' grain boundaries do not have a negative effect on the emf. For the amorphous grain boundary phase, supposing $t_i = 0$ may be reasonable, and the amount of the amorphous phases is very limited, then according to this discussion the amorphous phases make no contribution to the emf. This means that the amorphous phases also do not have a negative effect on the emf. As proved by the present experiments, the crystal grain boundary phases are very conductive, and it can be seen from the Nernst–Einstein equation

$$D = \frac{\sigma KT}{CZ^2} \qquad (7)$$

where D is the charge carrier's diffusivity, C is the concentration of charge carrier, Z the charge quantity, and K and T have their usual meanings, that the oxygen ion diffusivity in the crystal grain boundary phases is very high. As long as chemical diffusivity in the grain boundary phases is very high, there will be practically no oxygen concentration drop (that is, chemical potential drop) over these phases. Therefore, for the crystal grain boundary phases $\mu_k'' - \mu_k' = 0$ might hold true, and then the phases will also possibly not have a negative effect on the emf of the oxygen sensor, notwithstanding that $t_i = 1$ or $t_i < 1$ for the crystal grain boundary phases. As the Al_2O_3 addition can scavenge the grain boundary impurities, it can be concluded that the Al_2O_3 segregation at the grain boundaries not only does not have a negative effect on the emf of the ZrO_2 oxygen sensor but also can release, even wipe out the detrimental effects of the other impurities, e.g. SiO_2.

5 Conclusion

The Al_2O_3 addition up to 5 mol% can reduce the grain boundary resistance per unit surface area of the grain boundaries and the activation energy for the grain boundary resistance of the 9 mol% Y_2O_3-stabilized ZrO_2. This is due to the scavenging of the impurities segregated at the grain boundaries, e.g. SiO_2, by Al_2O_3 and the formation of the Al-rich crystal grain boundary phases with very high defect concentration. The Al_2O_3 addition has no detrimental effect on the emf of the ZrO_2 oxygen sensor. All of this proves that the Al_2O_3-containing Y_2O_3-stabilised ZrO_2 is a kind of very good solid electrolyte and that to decrease the grain boundary resistance by adding new ingredients is a feasible way to further enhance the ionic conduction of ZrO_2. The next step that should be taken is to explore more oxides with characteristics similar to Al_2O_3.

Processing, Microstructure and Mechanical Properties of SiC Platelet-reinforced 3Y-TZP Composites

A. Selçuk, C. Leach & R. D. Rawlings

Department of Materials, Imperial College of Science, Technology and Medicine, London, SW7 2BP, UK

(Received 25 March 1994; revised version received 1 June 1994; accepted 30 June 1994)

Abstract

A study has been carried out on the processing of silicon carbide platelet-reinforced yttria-stabilised zirconia ceramics, using slip casting techniques followed by cold isostatic pressing and pressureless sintering. Optimisation of the process variables, in particular the stability and homogeneity of the composite slurry and mould configuration, enabled samples with good platelet alignment and densities >96% of theoretical to be produced routinely after pressureless sintering. The pore formation and desintering phenomena in the presence of platelets are explained in relation to the microscopy and dilatometry results. The decreases in the room-temperature fracture toughness and flexural strength with increasing platelet content are attributed to the reduction in transformation hardening and the increase in porosity.

1 Introduction

Recent studies on SiC whisker-reinforced yttria-stabilised tetragonal zirconia ceramics (Y-TZP) have shown considerable improvements in fracture toughness since the stress-induced martensitic transformation toughening in the matrix is coupled with whisker toughening, which is achieved by the combination of mechanisms, including crack pinning,[1] crack deflection,[2] crack bridging, and pull-out.[3–5] The fracture toughness of SiC whisker–3Y-TZP composite can be increased up to about 12 MPa $m^{1/2}$ at the expense of a decrease in strength to about 670 MPa.[6] Whisker reinforcement leads to improvements in strength at high temperatures where the positive modulus load transfer reduces the effective stress at the crack tip.[6] The high-temperature toughness of the composite is expected to be governed by whisker toughening mechanisms, since transformation toughening becomes less effective with increased temperature, and does not operate above a critical temperature (≈700°C for Y-TZP).

Whiskers, however, due to their geometry, are a severe health hazard when inhaled.[7] Furthermore, the formation of a whisker network in the ceramic matrix introduces constraints on the sintering, leading to a considerable reduction of sintered density.[8–10] The densification to closed porosity in these composites often requires the application of pressure and a much higher sintering temperature than that for the monolithic material. One way to overcome these problems is the use of silicon carbide platelets (SiC_p), which are thought to offer similar mechanical property improvements to those of whisker-reinforced TZPs with minimal associated health hazard and at a reduced cost. The comparable effects of SiC platelets to whiskers in improving toughness have been demonstrated in SiC platelet-reinforced alumina[11] and mullite.[12]

For SiC platelets distributed randomly in a ceramic matrix at a concentration over 10 vol.%, the geometrical arrangement of platelets has been found to inhibit densification to full density under pressureless sintering conditions.[13] Hence the overall strength is expected to be reduced by the platelets, which act as Griffith flaws. When the platelets are oriented parallel to the tensile stress axis, the defect size is effectively reduced to the thickness of the platelets and the constraints on sintering are eased, due to a better sinter shrinkage being achieved in the matrix material between the parallel planes of platelets. Thus, the reduction of strength with platelet content can be minimised by the optimisation of composite processing conditions to yield denser materials through control of the platelet orientation.

The study reported here is concerned with the slip casting, cold isostatic pressing and sintering of

SiC_p–3mol%Y-TZP composites and the resultant mechanical properties microstructural characteristics, such as preferred orientation of platelets, porosity and grain boundary and SiC/matrix interface structure. The change in strength and fracture toughness with the platelet content is related to the observed microstructural features.

2 Experimental

2.1 Materials and processing

The matrix material used for the production of SiC_p–3Y-TZP composites in this study was the commercially available tetragonal zirconia powder with 3 mol% Y_2O_3 content (TZ-3YS, Tosoh Corporation, Japan), designed for slip casting operations. TZ-3Y powder of the same composition and particle size as those of TZ-3YS powder, but with a smaller primary crystallite size (25 nm) and a larger specific surface area (15·4 m^2/g), was used for the preliminary tests on slurry preparation and slip casting operations. The properties of both powders are listed in Table 1. The silicon carbide platelets (SiC_p) were of 99·9% pure stoichiometric α-phase (Third Millennium Technologies Inc., USA, -400 mesh grade) with 10 μm average diameter and 0·5–3 μm thickness.

Figure 1 shows the processing route used for the preparation of the green structures of 3Y-TZP containing 10 and 20 vol.% SiC_p. Prior to processing in the composite, the SiC platelets were subjected to acid (0·2M HNO_3 solution) and base (0·1 5M NH_4OH solution) washes for 24 h in order to remove leachable impurities and to enhance the dispensability of platelets in water. Each wash was followed by the repeated dispersion of platelets in deionised water and filtering until the suspensions reached a constant pH. The platelets were then rinsed in ethanol, which was found to minimise agglomeration on drying and the subsequent processes in aqueous solution.

Stable composite slurries of SiC_p and 3Y-TZP powder were prepared by mixing the constituents in proportion in deionised water at pH 3 using a

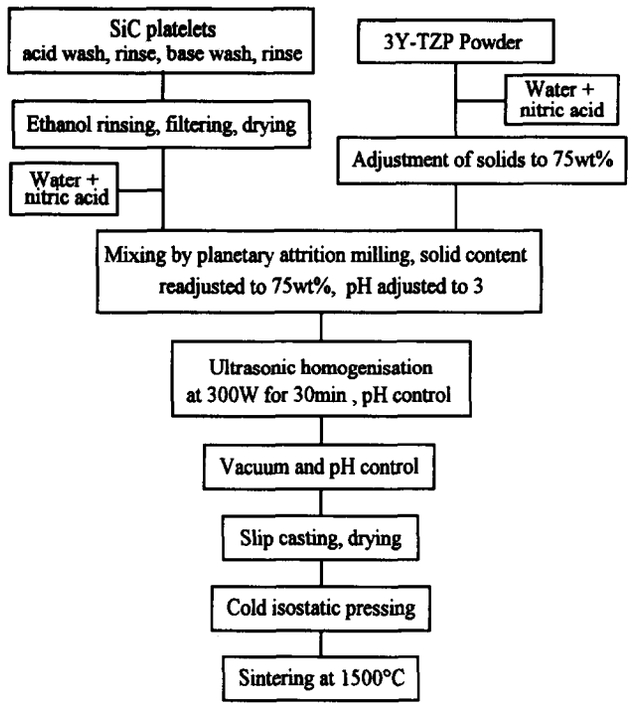

Fig. 1. Processing chart of SiC platelet–3Y-TZP ceramic composites.

planetary attrition mill with an agate container and ball. The pH was adjusted during mixing by the addition of dilute HNO_3 solution. The solid loading of the resultant slurries was always maintained at 75 wt%. Subsequent tests showed that the slurries were stable at pH 3 after planetary milling for 30 min, suggesting that sufficiently high electrostatic repulsive forces were generated to avoid flocculation. The agglomerates that were present in the as-received 3Y-TZP powder could not be broken up by the planetary milling. Ultrasonic dispersion was employed at 300W for 30 min for complete deagglomeration and homogeneous dispersion of the slurries after planetary milling. The entrapped gas in the slurry was removed under vacuum. pH 3 was maintained throughout above procedures. The final composite slurries showed very good stability and slip-casting properties.

For slip casting, samples with 0, 10 and 20 vol.% SiC platelet contents were formed into bars (48 mm × 12 mm × 10 mm) such that the SiC platelets, which orientate parallel to the mould surfaces during casting, would be parallel to the tensile stress axis of the four-point bend tests employed in the present work. Sample geometry and plaster mould configuration are shown schematically in Fig. 2. The slip-cast bars were dried at 40°C for 24 h, followed by heating at 120°C for 4 h and cold isostatic pressing at a pressure of 175 MPa. The green density was determined from the measured weight and volume of samples. Sintering behaviour of samples was

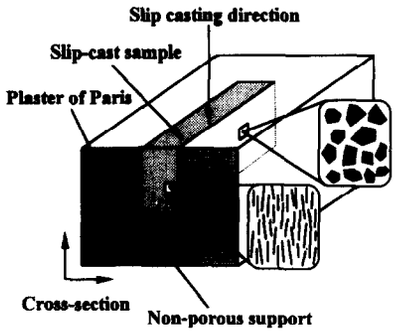

Fig. 2. Schematic configuration of a plaster mould and a sample on slip casting.

characterised by dilatometry on heating up to 1500°C at a heating rate of 4°C/min. Samples prepared for microstructural examination and mechanical testing were sintered at 1500°C for 3 h in flowing Ar atmosphere in a high-temperature graphite resistance furnace lined with impervious alumina tube to permit the control of supplied atmosphere. Heating and cooling rates of 3°C/min and 4°C/min respectively, were employed for the sintering of all samples. The sintered density and the percentage open porosity was measured by the Archimedes water-displacement technique.[14]

2.2 Specimen preparation and mechanical testing

Test pieces, containing 0, 10 and 20 vol.% SiC platelets sintered to >96% of theoretical density, were ground to produce flexural bend test specimens (38 mm × 3 mm × 3 mm) and single-edge notch beam specimens, SENB, (38 mm × 6 mm × 3 mm where $W = 2B = 6$mm) using diamond grinding wheels at 60 mm/s. For both types of specimens, the prospective tensile surfaces were kept parallel to the plane at which the platelets were aligned during slip casting so that the crack propagation direction was always perpendicular to the plane of the platelet alignment. The tensile surfaces of all flexure bars were polished through to 1 μm diamond lapping and the edges were bevelled. A straight notch, having a root radius of 80–100 μm, was introduced to each SENB specimen using a 0·15 mm thick SiC slitting disc of a sharp end profile. The relative notch depth (a/W) was in the range 0·1 to 0·12.

A four-point bend test fixture, with an inner span of 15 mm and an outer span of 20 mm, and a servo hydraulic testing machine were employed for the evaluation of fracture strength and toughness. The displacement during tests was monitored by the use of two transducers, situated at the mid-span and the outer span of each specimen. Thus, any displacement associated with the test rig was eliminated from the actual displacement of the specimen by recording the differential output from the transducers using a signal conditioning unit. At least five specimens were tested for each composition at a cross-head speed of 0·5 mm/min to determine the room-temperature strength and toughness. From the results of four-point bend tests, flexural strength, σ_b, was calculated using the equation:

$$\sigma_b = \frac{3}{BW^2}\frac{P(s-L)}{2} \tag{1}$$

where P is the applied load, s the inner span, L the outer span, B the specimen breadth and W the specimen width. The fracture toughness, K_{IC}, was determined by:

$$K_{IC} = \frac{6}{BW^2}\frac{P(s-L)}{4}Ya^{1/2} \tag{2}$$

where the geometric factor, Y, is given by:[15]

$$Y = 1{\cdot}99 - 2{\cdot}47(a/W) + 12{\cdot}97(a/W)^2 - 23{\cdot}17(a/W)^3 + 24{\cdot}8(a/W)^4 \tag{3}$$

2.3 Microstructural investigations

Phase identification after sintering was performed by X-ray diffraction using CuK_α radiation. The extent of the phase transformation from tetragonal to monoclinic structure in the matrix phase, induced by fracture toughness testing, was determined from the integrated X-ray intensity of diffraction lines, $I_{m,t}(hkl)$, of the monoclinic and tetragonal phases, using the following equations:[16]

$$X_m = \frac{I_m(111) + I_m(11\bar{1})}{I_m(111) + I_m(11\bar{1}) + I_t(111)} \tag{4}$$

where X_m is the integrated intensity ratio for monoclinic phase, which yields the volume fraction

$$V_m = \frac{PX_m}{1 + (P-1)X_m} \tag{5}$$

where $P = 1{\cdot}311$ for tetragonal–monoclinic mixtures.

The microstructures of sintered bars and the features on fracture surfaces after mechanical tests were characterised by scanning electron microscopy (SEM). The orientation distribution of platelets at different sections of slip-cast and sintered samples was determined using an optical image analysis system. For each section, at least five SEM pictures, corresponding to over 2000 platelets, were analysed.

3 Results and Discussion

3.1 Consolidation of SiC_p-reinforced zirconia structures

Slip casting followed by cold isostatic pressing is a suitable method for the production of composites where a uniform distribution and preferred orien-

tation of reinforcing agents, such as platelets, are required. High green densities, no damage to the platelets during processing, and the ease and inexpensive production of composite components are the additional advantages of the slip-casting process. However, the production of electrostatically stabilised homogeneous composite slips for the best slip casting properties depends on the simultaneous adjustment of a number of variables.

The casting characteristics are influenced primarily by the morphology, surface quality and dimensional characteristics of the starting powders. Other parameters, such as pH value, viscosity, homogeneity and solid concentration, are of particular importance to maintain the maximum colloidal stability of slurries. A commonly employed means of obtaining a well-dispersed suspension is to impart a repulsive surface charge on particles by pH adjustment. In the present case, the optimisation of the slurry variables is complicated by the presence of SiC platelets that are of different composition, size, geometry and surface quality from the matrix material. Uniform distribution and electrostatic stabilisation of both phases in the composite slurry were achieved by the acid/base surface treatment of SiC platelets, planetary mixing of the constituents in aqueous media, adjustment of solid loading, and high power ultrasonic dispersion, in sequence, accompanied by continuous pH adjustment (Fig. 1).

As observed for SiC whisker-reinforced ceramic composites,[8] the suspension stability of SiC platelets was the major factor in determining a pH that would provide codispersion of zirconia particles and platelets in dense slurries. The zeta potential, measured on dilute suspensions of platelets over a pH range of 2 to 9, showed that the moderate to high levels of surface charge necessary for the electrostatic stabilisation of the slurry occur at pH $\leq$ 3. This is in agreement with the previous electrophoresis mobility and viscosity measurements of SiC whisker suspensions.[17,18] It was further reported that the modification of whisker surface chemistry, by either surface oxidation or acid and base washing of whiskers, enhances the electrostatic stabilisation of the suspensions. Since the presence of free SiO_2 at the oxidised surfaces of SiC platelets is not desired for the zirconia matrix, the acid/base washing technique was adopted in the present processing.

Concerning the zirconia matrix phase, the recent work of Nikumbh *et al.*[19] on slip casting slurries of TZ-3YS powder has shown that the slips with $\leq$75 wt% solid content at pH $\leq$ 4 gives minimum viscosity with Newtonian flow behaviour in which the electrostatic repulsive forces at particles are large and the viscosity remains constant with the change in shear rate. They also observed that the viscosity of the slurry increases drastically when the solid loading (solid/liquid ratio) exceeds 75 wt% ($\approx$35 vol.%) ZrO_2. In the present work, the preliminary slip-casting tests on slurries of TZ-3Y and TZ-3YS powders, each containing 20 vol.% SiC platelets, revealed that stable slurries of low viscosity and with good flow behaviour can be formed at pH 3 providing solid loadings of $\leq$50 wt% for TZ-3Y powder and $\leq$75 wt% for TZ-3YS powder are used. The chemical composition and the particle size of both powders were the same and the higher solid content achieved in the slurries of TZ-3YS powder was attributed to its lower specific surface area and a higher crystallite size than those for TZ-3Y powder (Table 1). Also, slip casting times for SiC_p-TZ-3Y composite slurries to form 10 mm thick samples were as short as 1 h compared to 3 h required when TZ-3Y powder was used. Therefore, all samples for mechanical tests were prepared using TZ-3YS powder.

Although the mechanical mixing and the adjustment of pH and solid content were successful in forming stable slurries, there were always soft agglomerates of particles and platelets, inherited from the original materials. Complete deagglomeration of composite slurries were achieved using an ultrasonic probe at 300W output power for 30 min. The agitation caused by ultrasonic waves also served to increase the homogeneity of the slurry. Other workers have found similar results for the ultrasonic dispersion of SiC whisker–Al_2O_3 composites without the use of deflocculants.[8,20]

The achievement of a high green density and a strong preferred orientation of platelets was the main advantage of slip casting over other processing techniques. As shown in Fig. 3, the slip casting bar samples without SiC platelets yielded a relative green density of 55%, but this increased to 60% with increasing platelet content. The increase in green density is due to substitution of the

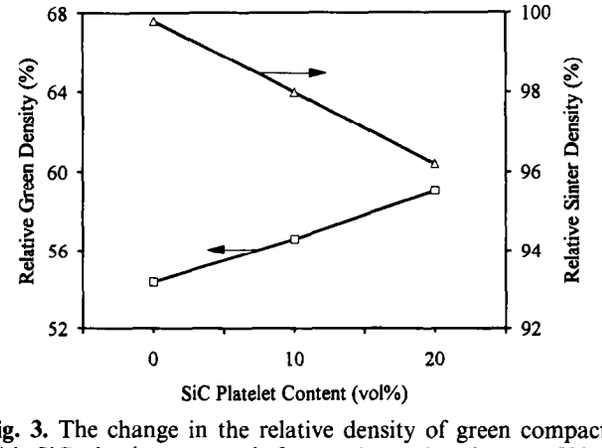

Fig. 3. The change in the relative density of green compacts with SiC platelet content before and are sintering at 1500°C for 3 h.

matrix and its porosity by fully dense SiC platelets. A further increase of the green density by around 2% was achieved by cold isostatic pressing.

3.2 Sintering characteristics

The plots of relative linear shrinkage, dL/L_o, and linear shrinkage rate, $d(dL/L_o)/dT$, as a function of temperature for a slip-cast 3Y-TZP sample and a composite containing 20 vol.% SiC_p are shown in Figs 4 (a) and (b), respectively. The dependency of the sinter shrinkage on platelet orientation was not studied in the present work and the plots for the composite sample in Fig. 4 are for data obtained in a direction perpendicular to the plane in which the basal plane of platelets are preferentially oriented. It follows that dL/L_o at a given temperature is the relative shrinkage of the matrix regions between the basal planes of platelets.

As shown in Fig. 4 (a), the shrinkage of both samples starts at around 900°C and the sintering curves are identical up to 1200°C, at which point the platelets starts inhibiting the sintering of the composite. The shrinkage of the composite up to 1200°C is referred to as the first stage sintering. This is followed by a period of negligible shrinkage until the second stage sintering commences at around 1250°C. The two stages of sintering are revealed by the presence of two successive peaks on the sintering rate plot for the composite (Fig. 4(b)) as the sintering rate approaches zero at the plateau region of the shrinkage plot and then starts increasing at ≈1250°C reaching a maximum at ≈1400°C. In contrast, the sintering rate plot for the monolithic material shows a single peak with a maximum at ≈1400°C.

Under isothermal conditions, the sintering temperature was chosen as 1500°C in order to enhance the density of the matrix, particularly in the presence of platelets. Sintering at 1500°C for 3 h yielded relative densities that depended on the SiC_p content but were >96% (Fig. 3). The relative densities obtained in the present study were superior to those of similar composites produced by other processing techniques, e.g. 91% and 94% for 20 vol.% Al_2O_3 platelet-reinforced 12Ce-TZP and 3Y-TZP composites, respectively, each pressureless sintered at 1500°C.[21] X-Ray diffraction analysis of sintered samples revealed only the presence of SiC phase and tetragonal zirconia with no detectable monoclinic phase.

As shown in Fig. 3, the sintered density reduced while the green density increased with SiC_p content. Near theoretical density (6070 kg/m^3) was easily achieved on sintering the monolithic material. However, densification in the platelet-reinforced zirconia systems depended on the flow and sintering of the matrix between platelets. An increase in platelet content resulted in partial inter-platelet bridging that hindered particle rearrangement in the matrix and thus lead to the formation of elongated crack-like pores at the platelets, as exemplified by the micrograph in Fig. 5. The number of pores increased in the regions where the platelets were

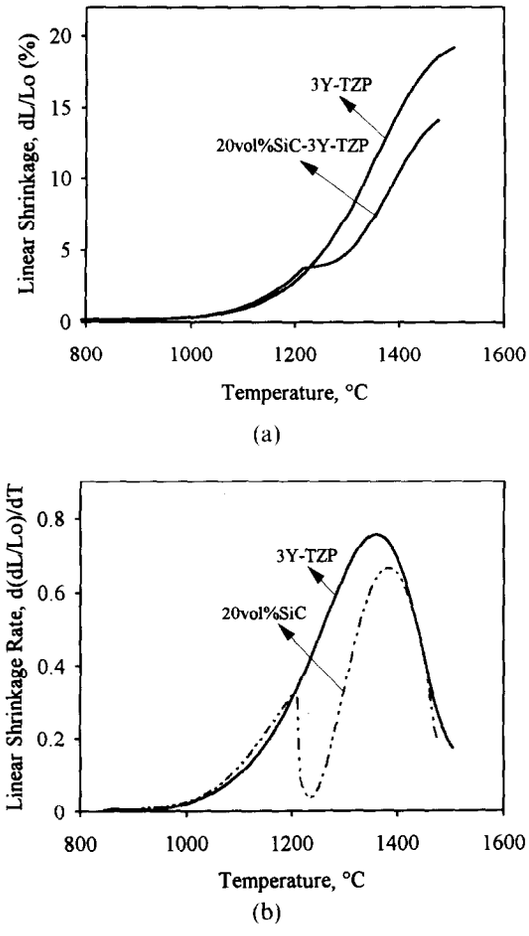

Fig. 4. (a) The relative linear shrinkage and (b) the linear shrinkage rate of 3Y-TZP and 20 vol.% SiC_p reinforced 3Y-TZP compacts on non-isothermal sintering at a heating rate of 4°C/min.

bridged or the density of platelets was relatively high. The crack-like pores are unlikely to be reduced by increasing the sintering temperature but could probably be closed by applying pressure during sintering.

Previous work on the effect of inclusions on densification[22–24] has already demonstrated that the underlying phenomenon for the interruption of sintering in the presence of rigid particles is the development of localised strains in the porous matrix. The type and magnitude of the matrix strains change with the location in the matrix, inter-platelet distance and the geometrical arrangement, volume fraction and size of platelets in the surrounding volume.[23,24] Therefore the densification of the matrix is heterogeneous. A region under localised compressive stress densifies first, producing non-deformable networks where the porosity tends towards zero.[22,23] These highly dense regions are expected to constrain the shrinkage of the adjacent porous matrix by inducing hydrostatic tensile stresses, which finally leads to desintering and the formation of local porosity. Hence the overall sintering rate is reduced with increasing ratio of the hydrostatic tensile stress to the compressive sintering stress of the matrix, σ_h/Σ_m.[25,26]

In view of these observations, it is considered that the two-stage sintering process in the 20 vol.% SiC_p–3Y-TZP composite can be explained in terms of the development of compressive and tensile stresses in the matrix. That is, the first stage of sintering in the composite sample (Fig. 4) is attributed to the free sintering of the matrix until heterogeneous densification and the compressive and tensile stresses develop in the matrix. This is evident from the sinter shrinkage plots for the monolithic and the composite samples being identical at temperatures up to 1200°C. The following reduction in the sintering rate is related to a rapid densification at locations between closely spaced SiC platelets while relatively high porosity is retained in the remaining matrix.

The onset of the increase in shrinkage at the second stage of sintering may be explained by the thermal activation at temperatures >1250°C being large enough for the growth of highly dense networks at the expense of the pore growth in the adjacent porous matrix. The porous regions under the hydrostatic tensile stresses go through desintering and the formation of crack-like voids at the SiC platelet–matrix interface. This can occur provided the hydrostatic tensile stresses are large enough to induce the break up of grain bridges linking polycrystalline clusters in porous regions.

To summarise, high sintered densities were achieved in these composites by slip casting and pressureless sintering, although the formation of some voids on sintering was unavoidable. It may be that the pressureless-sintered density can be further increased to a level, possibly close to theoretical density, by the use of SiC platelets with relatively small thickness, provided that slip-cast-

ing results in a very strong preferred orientation of platelets.

3.3 Orientation distribution of platelets after sintering

The effect of slip casting on the orientation distributions of SiC platelets was studied by determining the frequency of platelets (%), oriented with their basal planes at a given angle, θ, to the porous mould face (ABCD in Fig. 6) which is referred to as the slip-casting plane. Figures 7(a) and (b) show the plots of platelet frequency as a function of θ, taken from the sections (BCEF in Fig. 6) perpendicular to the slip-casting plane, for composite samples containing 10 and 20 vol.% SiC_p, respectively. Both plots show that θ for the majority of platelets is within $\Delta\theta = \pm 30°$. The corresponding SEM micrographs, shown in Figs 8(a) and (b), exemplify the platelet distribution and orientation presented in the frequency–angle plots; it is clear from these micrographs that there is a strong preferred orientation with the basal platelet planes, mostly in close alignment with the slip-casting plane.

(a)

(b)

Fig. 8. SEM micrographs exemplifying the platelet orientation distribution in the BCEF planes (Fig. 6) over an area near to the porous mould face in bar samples, containing (a) 10 vol.% and (b) 20 vol.% SiC platelets. Arrows are perpendicular to the porous mould face.

The platelet alignment was attributed to the flow of water towards the porous mould surface, which is believed to tilt and rotate the platelets until they reach the interface of consolidation. However, the orientation distribution of platelets, although good, was not ideal as evident from the frequency–angle plots in Figs 6(a) and (b) and the corresponding micrographs (Figs 8(a) and (b)) which show some platelets in tilted positions with their basal planes at arbitrary angles to the slip-casting plane. The misorientation of platelets may be associated with variations in their geometry; as shown in Fig. 9, some of the as-received platelets have a low aspect ratio and some are very small and irregularly shaped, resembling particulate. It was concluded that the orientation distribution of platelets is most likely to be improved by control of the SiC_p reinforcement, particularly the aspect ratio which should be large (>10), than by further optimisation of the processing conditions.

Figure 10 shows the frequency versus angle plot, obtained from averaging the data from a number of areas across the complete cross-section (ABFG in Fig. 6) of a composite bar containing 20 vol.% SiC_p. The cross-sectional orientation profile of platelets is complicated with the presence of small peaks at a tilt angle of ~25° to the slip-casting plane, superimposed on the main preferred orientation peaks. The small peaks were

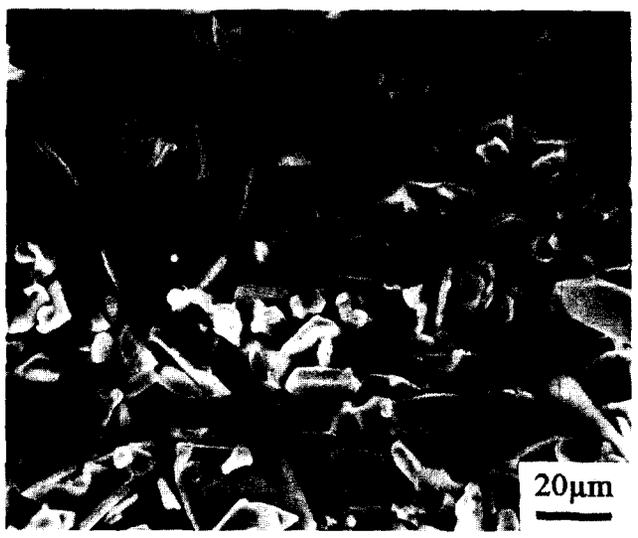

Fig. 9. SEM micrograph of as-received SiC platelets used in the production of composites.

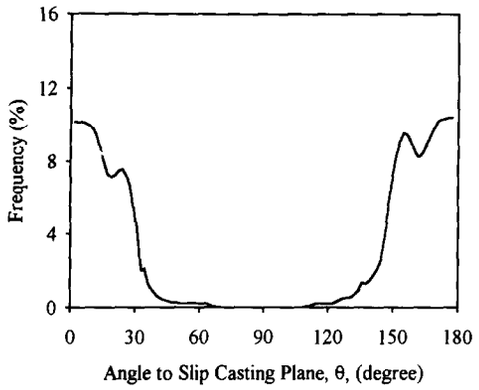

Fig. 10. The orientation distribution of SiC platelets in relation to the slip casting plane (the mould surface) observed in the ABFG planes (the cross-section in Fig. 6) of bar samples with 10 vol.% SiC platelet content.

associated with a V-shaped orientation distribution band of the platelets in the central regions of the cross-section (0·5 mm in thickness) between the porous faces of the mould (Fig. 11), whereas the rest of the cross-section has the same preferred orientation of platelets as that observed near to the porous face of the mould in section BCEF (Figs 7(b) and 8(b)).

It is known[27,28] that the capillary force of the mould, which forms the suction pressure to remove water from the slurry, becomes less effective with increasing thickness of the consolidated layer. This results in a highly reduced rate of water flow due to the pressure drop across the consolidated layer. Therefore, the central region of the cast between the faces of the mould is consolidated at a gradually reducing rate and the water flow rate is not high enough to induce a strong preferred orientation of platelets; this is partially because the SiC platelets increase the flow path of the water, as observed previously in slip casting whisker-reinforced ceramics.[10,29] Thus, the platelets are tilted under gravitational forces away from the preferred orientation, leaving them in a V-shaped configuration in central regions of the cast.

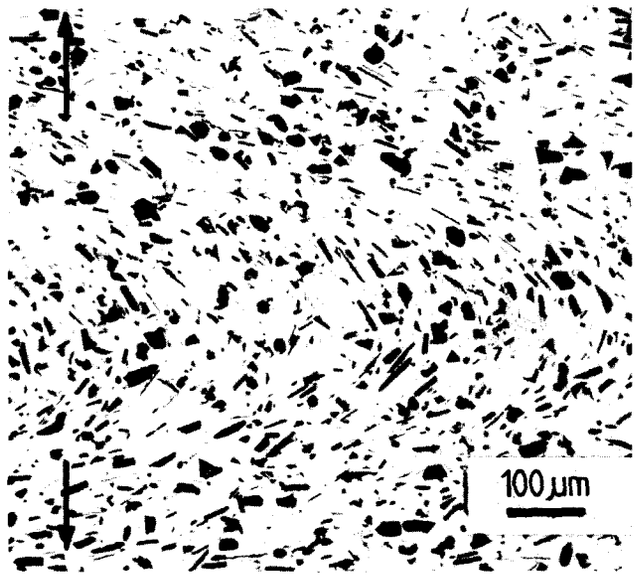

Fig. 11. SEM micrograph revealing V shaped orientation distribution of SiC platelets at the central regions of the cross-section (the ABFG plane in Fig. 6) of a composite bar, containing 20 vol.% SiC platelets. Arrows are perpendicular to the porous mould faces.

3.4 Influence of platelet content on mechanical properties

During strength and toughness testing, all composites exhibited a linear increase in stress with deflection; there was no evidence of non-linearity prior to catastrophic failure. The graphs of flexural strength and fracture toughness as a function of platelet content (Fig. 12 (a)) show that both these properties degrade with the platelet content. At 20 vol.% SiC_p content, the composite exhibits a flexure strength of 440 MPa and a fracture toughness of 6·4 MPa $m^{1/2}$. Thus the mechanical properties follow the same trend with SiC content as the sintered density (Fig. 3), which suggests that the crack-like pores, formed preferentially at some of

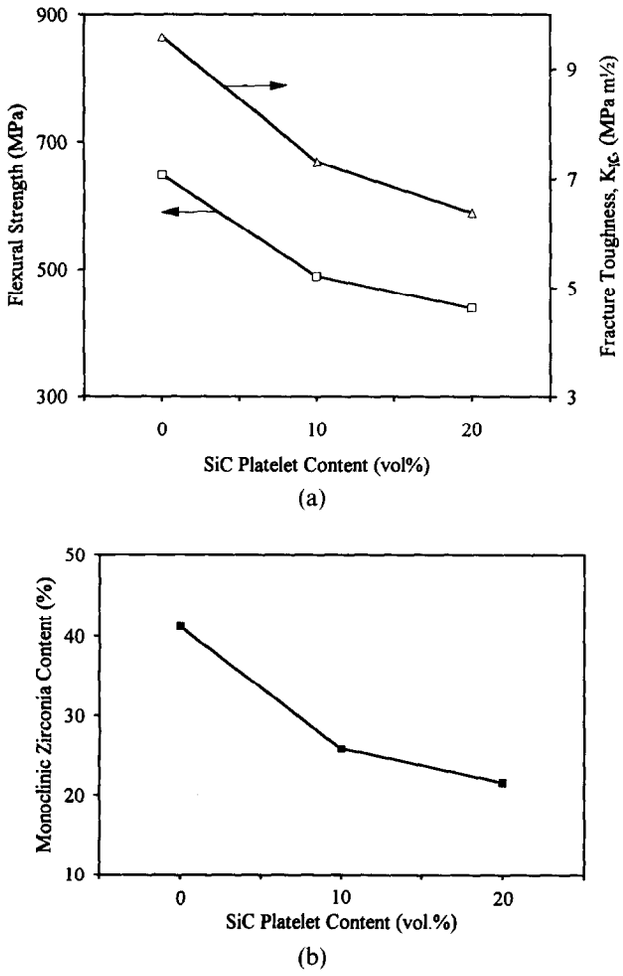

Fig. 12. (a) Flexural strength and fracture toughness of SiC_p-3Y-TZP composites as a function of volume fraction of SiC platelets and (b) the monoclinic zirconia content, determined by X-ray diffractometry at the fracture surfaces of SENB specimens, as a function of SiC platelet content.

the platelet–matrix interfaces, act as Griffith flaws on testing.

The reduced fracture toughness also suggests that the transformation-toughening mechanism in the matrix is hindered as the developing transformation zone at a crack tip is hampered by the incorporation of SiC platelets. Evidence for this type of behaviour was obtained from the determination of the monoclinic ZrO_2 content at fracture surfaces of SENB samples by X-ray diffractometry. The results plotted in Fig. 12 (b) show that the m-ZrO_2 content at fracture surfaces reduces with SiC platelet content. The decreasing fraction of transformed phase with increasing platelet content was attributed to a reduction in the transformation zone size due to platelets decreasing the stress intensity at a crack tip. Hence, the reduction in transformation toughening efficiency, together with the crack-like pores acting as flaws, lowers the strength and toughness with increasing platelet content. However, as the transformation toughening mechanism is unlikely to be significant in the monolithic material as the test temperature is raised, it is expected that the composite will exhibit relatively better, and perhaps even superior, toughness at elevated temperatures.

These explanations for the reduction in toughness with increasing SiC content requires strong interfacial bonding between the platelets and the matrix.[30] SEM observations of fracture surfaces of platelet containing specimens revealed that most of the platelets on the fracture plane had ruptured (Fig. 13 (a)), indicating that except where crack-like pores were present, the interfacial bonding was strong. As exemplified in Fig. 13 (b), the change of the crack plane from one platelet to another at the fracture surface suggests that there is some contribution of the crack deflection mechanism to toughening. Other toughening mechanisms, such as debonding and pull-out of platelets and crack bridging,[3–5] were not commonly observed due to strong interfacial bonding. Initial TEM studies of the platelet–matrix interfaces indicate the presence of amorphous films connected to sizeable pockets of glass. This will be reported in a future publication.

If the platelets are to contribute more effectively to the toughness of the composite, it is essential to eliminate porosity by applying an external pressure on sintering and to reduce the interfacial bond strength by additions of appropriate interfacial segregating species to the matrix, such as P, Si and Ti.

4 Conclusions

(1) Stable slurries of silicon carbide platelets (SiC_p) and yttria-stabilised tetragonal zirconia with good slip-casting properties have been produced with up to 75 wt% solid loading. Slurry processing at pH 3 by means of planetary milling, high-power ultrasonic dispersion and vacuum degassing resulted in a homogeneously dispersed composite slurry with minimal agglomeration.

(2) Slip casting of the composite slurries yielded relative green densities of 60%. A further increase in the green density of about 2% was achieved by cold isostatic pressing. Pressureless sintering at 1500°C for 3 h resulted in relative densities which fell with SiC_p content but were above 96%.

(3) There was a strong preferred orientation of the platelets with their basal planes parallel to the slip-casting plane, i.e. parallel to the porous mould faces, through the section of

the 48 mm × 12 mm × 10 mm bars. Overall misorientation of the platelets was attributed to variations in platelet geometry; the platelets with low aspect ratio and small size cannot be aligned to the preferred orientation by the force of water flow in the slurry. The misorientation of platelets in central regions of the cast was accounted for by the reduction in suction pressure across the consolidated cake and the gravitational forces tilting the platelets. The preferred orientation of platelets could be further enhanced by using SiC platelets with a larger aspect ratio.

(4) The room-temperature strength and toughness were found to reduce with platelet content. At 20 vol.% SiC_p content, the composite exhibited a flexure strength of 440 MPa and a fracture toughness of 6·4 MPa $m^{1/2}$. Analysis of fractography results indicated that crack deflection process may contribute to fracture toughness, but the crack-like voids, formed preferentially at the platelets, had an adversely predominant effect on both strength and toughness. The transformation toughening reduced with increasing platelet content and the toughening by debonding and pull-out of platelets could not occur due to strong interfacial bonding.

(Received 18 August 1993; revised version received 29 June 1994; accepted 1 August 1994)

Abstract

Orthorhombic zirconia codoped with 5 mol-% Nb_2O_5 and 5, 7, 10, 12 and 15 mol-% Ta_2O_5 as well as samples with 5 mol-% Ta_2O_5 and 7, 10, 12 and 15 mol-% Nb_2O_5, respectively, were made from precursors prepared by hydrolysis of the metalalkoxide solutions in 1-propanol with water. The amorphous, coprecipitated hydroxides were converted to the oxides at 900°C. The powders were characterized by the specific surface areas, the particle size distributions and by electron microscopy. The codoped zirconia powders were attributed, isostatically compacted and sintered at temperatures ranging from 1500 to 1650°C. Three-point bend-strengths, Weibull moduli, fracture toughnesses, Vickers hardnesses, densities and phase compositions were measured for the sintered specimens. Average three-point bend-strengths ranged between 85 and 257 MPa. No phase transformations occurred during fracture. Fractography showed that the fracture origins were either surface flaws or pores near the tensile surface. Depending on the composition and the sintering conditions, fracture toughnesses between 2·1 and 3·6 MPa $m^{1/2}$, Vickers hardnesses between 6·8 and 9·9 GPa and theoretical densities between 96·8 and 99·0% were observed. Increasing dopant concentrations resulted in increases in the b- *and* c-*axes and in a decrease in the* a-*axis of the orthorhombic cell.*

1 Introduction

Single doping of zirconia with either Nb_2O_5 or Ta_2O_5 above 12 mol-% of the dopant stabilized the orthorhombic phase at room temperature.[1] In a previous publication we reviewed the literature on orthorhombic zirconia and reported the preparation and mechanical properties of zirconia doped with varying concentrations of either Nb_2O_5 or Ta_2O_5. These studies are now extended to investigations on the preparation of zirconia powders codoped with Nb_2O_5 and Ta_2O_5, on the sintering conditions, the mechanical properties and the fractography of Nb_2O_5–Ta_2O_5 codoped orthorhombic zirconia ceramics, for which such data have not been reported before.

2 Experimental

2.1 Powder preparation and sintering

The preparation of the precursor materials niobium penta-l-propoxide and tantalum penta-l-propoxide from niobium pentachloride and tantalum pentachloride respectively, has been reported.[1] Zirconium-l-propoxide was commercially available (Johnson Matthey, USA). Solutions of the alkoxides of zirconium, niobium and tantalum in l-propanol were prepared in a glove-box under the exclusion of moisture to prevent decomposition. The solutions of the metal alkoxides were then sprayed into water. The precipitated hydroxides were filtered, first washed with water and then with ethanol. The powders were dried at 70°C and 670 Pa followed by a calcination at 900°C (heating rate 5 K min^{-1}). Thermogravimetric measurements showed that conversion of the hydroxides to the oxides was completed around 700°C.[1] The calcined oxides were attrition milled in portions of 30 g with 1200 g of yttria stabilized zirconia balls (2 mm diameter, 600 min^{-1}) in 160 ml of l-propanol for 4 h in an attritor lined with polyethylene. Upon filtering off the balls through a 1 mm sieve, the solvent was evaporated under vacuum. The powders were dried at 100°C at 670 Pa and then heated to 600°C to burn out the polyethylene. The powders were isostatically compressed at 800 bar into blocks of 20 mm × 15 mm × 48 mm. These blocks were presintered at 1000°C. Specimens of 5 mm × 4 mm × 40 mm were cut from the blocks and polished. These samples were then sintered at a rate of 1 K min^{-1} up to 400°C and kept there for 1 h. The temperature was then increased at

5 K min^{-1} to 1000°C and at 3 K min^{-1} to the final sintering temperature. The final sintering temperature was maintained for 2 h. The samples were cooled at 20 K min^{-1}. The powders for the analysis of the lattice parameters were heated to 1000°C at a rate of 5 K min^{-1}, then to 1400°C at 3 K min^{-1}. The cooling rate was 20 K min^{-1}.

2.2 Apparatus and procedures

BET-surface area measurements were carried out on a Quantasorb (Quantachrome, USA) and crystallite sizes were calculated from the specific surface areas from the equation: $d = 6/\rho A_s$ where d is the crystallite diameter, ρ the density and A_s the specific surface area. The particle size distribution was analysed by means of a laser particle sizer (Coulter LS 130, USA).

X-Ray diffraction spectra were measured on a Geigerflex D/max II with Ni-filtered Cu K_α radiation (Rigaku, Japan) between 25° and 80° (40 kV, 20 mA) with Si (99·999% Balzers, Liechtenstein) as internal standard. X-Ray fluorescence analysis was performed on a Geigerflex M 3064 spectrometer with a Rh anode (Rigaku, Japan) with 35 kV and 15 mA. Electron micrographs were obtained on JSM-6400 scanning microscope (Jeol, Japan). Thermogravimetric measurements were carried out on a TG-770 (Stanton Redcraft, UK). A HT 64/17 (Naber, Germany) oven with a maximum temperature of 1750°C served for sintering. Three-point bend-strength measurements were carried out on a dead weight loaded system (Tonitech, Germany).

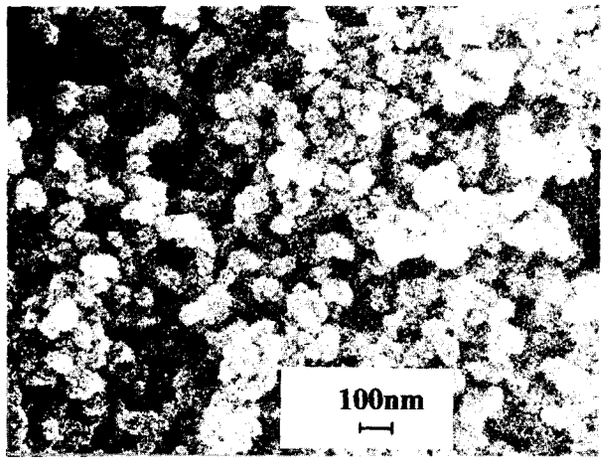

Fig. 1. SEM micrograph of zirconia powders codoped with 5 mol.% Nb_2O_5 and 10 ml.% Ta_2O_5, 50 000×.

2.3 Mechanical properties and microstructure

Three-point bend-strength tests were carried out on 4 mm × 3 mm × 40 mm samples employing a 20 mm span. The tensile surfaces of the samples were diamond-polished to a 1 μm finish and the edges chamfered prior to the bending tests. The load during the testing was increased at a rate of 12 N s^{-1}. Vickers hardnesses were measured with the load of 49 N. Fracture toughness values were obtained from the indentation fracture technique[2] with an indentation load of 49 N. The mean diagonals of the indentation sites and the indentation crack lengths were measured by optical microscopy. The fracture toughness values were calculated using the equation $K_{Ic} = 0{\cdot}0824\ P/c^{1.5}$ (K_{Ic}: in MPa $m^{1/2}$, P: indentation load in MN, c: half of the half-penny crack diameter in m). The microstructure of the samples was analysed by optical and scanning electron microscopy. Specimens were either chemically etched in 60 wt% NaOH for

2 h at 180°C or thermally etched for 2 h at 1450°C. During etching experiments we found that the Nb_2O_5–Ta_2O_5 codoped zirconia were quite corrosion resistant in both acid and basic media. Fractographic studies were carried out to learn about the fracture origins (strength degrading defects) and fracture mechanisms by means of scanning electron microscopy.

3 Results and Discussion

3.1 Powder characteristics and mechanical properties

The hydroxides obtained after hydrolysis were amorphous. The specific surface areas and the densities of the calcined, attributed powders are summarized in Table 1. The specific surface areas of the attrited Nb_2O_5–Ta_2O_5 codoped zirconia powders were very similar and ranged from 21 to 27 $m^2\ g^{-1}$. Crystallites sizes between 33 and 44 nm were calculated from the specific surface areas, in close agreement with observations made by scanning electron microscopy (Fig. 1). The particle size distribution analysis of the calcined powders showed that the prime crystallites had formed larger particles with mean diameters between 6 and 10 μm. No particles larger than 40 μm were found. Attrition milling improved the particle size distributions, yielding particles with mean diameters around 2–3 μm (Fig. 2). The largest particles observed in the attrited powders were around 20 μm.

For total concentrations of the doping oxides up to 12 mol.% an increase in the densities with increasing sintering temperatures up to 1650°C was noted. Ceramics doped with higher concentration of the doping oxides showed a slight decrease in the densities with the sintering temperatures for the temperature range studied. The temperatures for the sintering of the specimen for mechanical testing were selected according to the highest values for the densities.

[a] Ref. 4.

The mechanical properties of the sintered bodies are summarized in Table 2. The bending strengths and fracture toughnesses of the studied ceramics were rather low and showed considerable scatter. Due to the involved procedures in preparing the powders only 8 to 12 sintered specimens were available for the three-point bend-strength measurements. Table 2 therefore contains both the standard deviations and the Weibull moduli, although we realize that the number of specimens is small for reliable Weibull statistics. The maximum strength values were achieved for samples having a total dopant concentration between 15 and 17 mol.%. Maximum values from 280 to 350 MPa could be obtained for these dopant concentrations. The hardness of the samples increased with increasing Ta_2O_5-concentration in codoped samples with 5 mol.% Nb_2O_5. The fracture toughnesses varied modestly between 2·1 and 3·6 MPa $m^{1/2}$.

A comparison of the mechanical properties of the Nb_2O_5–Ta_2O_5 codoped zirconia ceramics with the Nb_2O_5 or Ta_2O_5 singly doped ceramics showed that the values for the three-point bend-strengths were higher by about 100 MPa for the codoped samples than for either the Ta_2O_5 or the Nb_2O_5 singly doped ceramic.[1] We attribute this increase in bend-strength to the improved microstructure of the codoped ceramics. The K_{Ic} values and Vickers hardness values are comparable.

The microstructures of the Nb_2O_5 and Ta_2O_5 codoped ceramics were very similar. They consisted of fine grain sized matrix with mean grain widths of 0·5–1·0 μm. The average aspect ratio was 3. The matrix formed about 70% of the material. Larger elongated grains (average width 2–2·5 μm, average aspect ratio 4) were imbedded in this matrix (Fig. 4). Pores usually ranged from 1·0 to 10·0 μm. Larger pores with pore diameters up to 150 μm were rare.

Fractographic analysis of the fracture surfaces of the samples after the bend-strength tests revealed that the main strength degrading defects were either half-penny shaped surface flaws approximately 25 μm in depth and 60 μm wide (Fig. 5) or machining damages.

Fractures occasionally also originated from

5 mol.% Nb_2O_5 5–15 mol.% Ta_2O_5	0.503 (7)	−6.460	0.99	0.509 (8)	4.278	0.95	0.526 (8)	3.127	0.88
5 mol.% Ta_2O_5 5–15 mol.% Nb_2O_5	0.503 (5)	−5.813	0.95	0.509 (8)	3.981	0.96	0.526 (6)	3.268	0.92

[a] Correlation coefficient.

volume defects, usually from large pores (100–150 μm) or pores filled with agglomerates of grains (Fig. 6). No marks around the fracture origins (mist, mirror, hackle) were identified. The fractures of the very brittle ceramics were transgranular in all cases without any reinforcing mechanisms such as crack deflection or crack bridging as shown in Fig. 3, on a crack initiated by Vickers indentations.

3.2 Lattice parameters

All codoped samples studied were composed of the orthorhombic phase (Fig. 7). Generally a slight decrease in the *a*-axis and an increase in the *b*- and *c*-axes were observed with increasing dopant concentrations (Table 3). The changes in the lattice parameters for codoped samples, with either 5 mol.% Nb_2O_5 and varying concentrations of Ta_2O_5 or with 5 mol.% Ta_2O_5, and varying concentrations of Nb_2O_5 can be presented by the following equation: $a(b,c) = a_0(b_0,c_0) + k_a(k_b,k_c)$ (X_2O_5/mol.%). X_2O_5 represents the oxide, the concentration of which has varied. The respective values for *a*, *b*, *c*, a_o, b_o, c_o, k_a, k_b and k_c together with the theoretical densities for Nb_2O_5 and Ta_2O_5 codoped zirconia—obtained from the lattice parameters—are summarized in Table 4. The Miller indices for the crystal planes of orthorhombic zirconia were assigned as published for $8ZrO_2 \cdot Nb_2O_5$.[3]

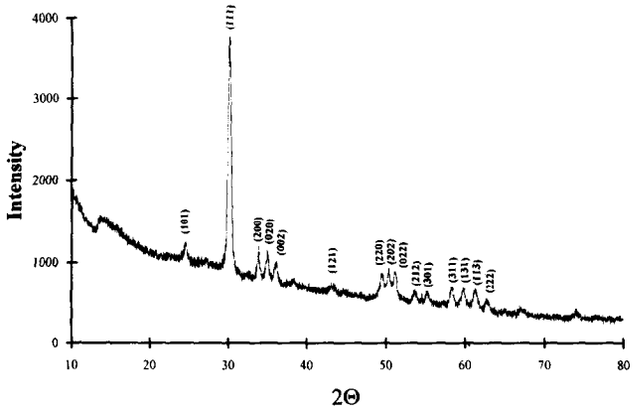

Fig. 7. X-ray diffraction of zirconia codoped with 5 mol.% Nb_2O_5 and 10 mol.% Ta_2O_5.

4 Conclusions

Zirconia ceramics codoped with Nb_2O_5–Ta_2O_5 yielded orthorhombic sintered bodies with three-point bend-strengths ranging from 140 to 260 MPa. This brittle, corrosion resistant material showed transgranular fractures originating generally from surface flaws or pores near the tensile surface. No transformation toughening, crack deflection or crack bridging occurred upon fracture. Bend-strengths for the codoped material were generally higher by 100 MPa than for Nb_2O_5 or Ta_2O_5 monodoped zirconia due to the improved microstructure in the codoped samples.

Vickers hardness values ranged between 6·8 and 9·9 GPa, relative densities between 96·8 and 99·0%, and K_{Ic}-values varied between 2·1 and 3·6 MPa $m^{1/2}$. The best values for the mechanical properties were found for a total content of doping oxides of about 15–17 mol.%.

Abstract

Ionic conductivity measurements were performed by impedance spectroscopy on ZrO_2–MgO 13·7 mol%, in the 270–700°C temperature range. The diagrams show characteristic intragrain and grain boundary semicircles. Activation energies for the intragrain conductivity and the intergrain blocking effect are 126 and 141 kJ mol^{-1}, respectively. The estimated specific conductivity is 9·8 S m^{-1} at 1000°C. The conductivity blocking effect at the grain boundaries is very similar to that of yttria-stabilized zirconia.

1 Introduction

There has been significant interest in zirconia-based ceramic materials for several applications. Some of them (SOFCs, oxygen sensors and pumps, etc.) are based on the high oxide ion conductivity of the so-called stabilized zirconias. The majority of the zirconias investigated for this property contain trivalent cations as stabilizers. They induce higher conductivities than the divalent cations.

Mg-doped zirconia solid solutions have received less attention because of an instability of the cubic phase that results in a gradual degradation of its properties. Over the last decade, it has been demonstrated that an aging treatment at 1100°C slows down the decomposition reaction and, simultaneously, improves the thermal shock resistance of partially stabilized zirconias.[1] This has prompted new investigations on this system, mostly focused on mechanical properties. So far, relatively few studies[2–6] have dealt with its electrical properties and, in most cases, the conductivities have been measured by DC techniques, with no attention given to the microstructure effects.

Muccillo[7] has examined the correlations between the phase decompositions and the electric properties of the system using impedance spectroscopy. This paper reports results on the cubic phase containing 13·7 mol% of MgO which can be regarded as a sort of reference. As in other zirconia systems, the conductivity of the ZrO_2–MgO cubic phase is predominantly ionic and oxide ions are the charge carriers. Reported conductivity values[2] at 1000°C lie between 0·82 and 4·0 S m^{-1}. The literature data[2] on the conduction activation energy present an unusually broad dispersion, ranging from 82 to 141 kJ mol^{-1}. From diffusion measurements[8] in the cubic phase, it has been found that the oxygen diffusion activation energy is 63 kJ mol^{-1}. That of the Mg–Zr interdiffusion[9] is 285 kJ mol^{-1}.

Impedance spectroscopy has been widely used for characterizing other zirconia-based materials.[3,5,10–12] It is capable of separating the specific electric response of the material, the so-called intragrain response, from that of the grain boundaries which is always characterized by an additional resistance.

2 Experimental

The starting materials were ZrO_2 (DK-2 type, Zirconia Sales) and MgO (analytical grade from Merck). The following analyses were carried out: Hf content by neutron activation, other metallic impurities by spectrographic analysis, surface area by BET, distribution of particle size by sedimentation and particle/agglomerate morphology by scanning electron microscopy.

Pellets (typically 0·95 cm in diameter and 0·16 cm high) were prepared by conventional ceramic processing involving wet mixing, pressing, sintering at 1650°C for 2 h and machining. The apparent

Table 1. Results of chemical and physical analyses performed on starting powders (S: surface area, Dp: mean particle/agglomerate size)

	Hf (%)	*Fe* (ppm)	*Si* (ppm)	*Al* (ppm)	*Surface area (S)* (m^2/g)	*Mean particle/ agglomerate size (Dp)* (μm)
ZrO_2	1·30	15	400	100	3·4	2·5
MgO	—	50	—	—	34·5	<0·2

density of the sintered specimens was determined by the hydrostatic method and their phase content by X-ray diffractometry. Microscopic examinations were done on polished and chemically etched or fractured surfaces. The Mg content was confirmed by neutron activation analysis, checking on possible MgO losses by surface evaporation.[13]

For electrical measurements, Pt and Ag electrodes were applied by painting. Silver electrodes have been found to give a much smaller interference between the material responses and the electrode characteristics, allowing a more accurate determination of the electric parameters. Impedance measurements were performed from 5 Hz to 13 MHz with a HP 4192A impedance analyzer, in the 270–700°C temperature range. Data were collected during heating and cooling cycles. The results were analyzed in the impedance mode, using a special computer program.[14]

3 Results and Discussion

The MgO content of all sintered samples was determined to be 13·7 mol%, and the diffractogram profiles only exhibited the cubic phase reflections.

Table 1 shows the results of the powder analyses. The main impurity is silicon, at a level normally found in most technical zirconia powders. The mean particle/agglomerate size (2·5 μm) obtained by sedimentation, was taken as usual as the value corresponding to 50 wt% of the particles finer than it.

The relative density of the sintered pellets was about 80%, due to a large closed porosity. Figure 1 is a typical micrograph of a fractured surface showing the extensive intragranular, intergranular and triple-point porosities. The average grain size determined from a polished and etched surface is about 18 μm.

To improve the mechanical characteristics of Mg-partially stabilized zirconias, it is common practice to sinter the material at a relatively high temperature ($T > 1800$°C) and subsequently to quench and then anneal it at a temperature slightly higher than that at which the eutectoid decomposition starts. This gives ceramics with an average grain size in the 50–100 μm range.[15] With sintering temperatures of about 1700°C, ceramics with average grain sizes of about 20 μm were obtained.[16] The present data on the fully stabilized solid solutions sintered at 1650°C agree with these last results.

A three-dimensional impedance plot obtained at 441°C is presented in Fig. 2. In the 300–600°C temperature range, all diagrams show the same features: a predominant high-frequency semicircle and a smaller low frequency semicircle (and part of the electrode response). As usual with zirconia-based solid electrolytes, the semicircle centers fall

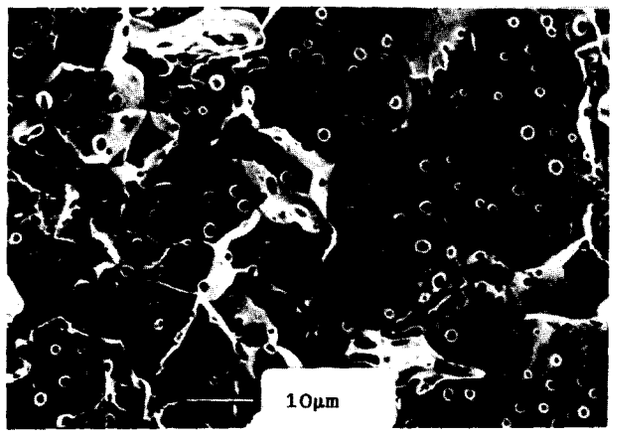

Fig. 1. Typical fracture surface of a ZrO_2–MgO 13·7 mol% sample sintered at 1650°C for 2 h.

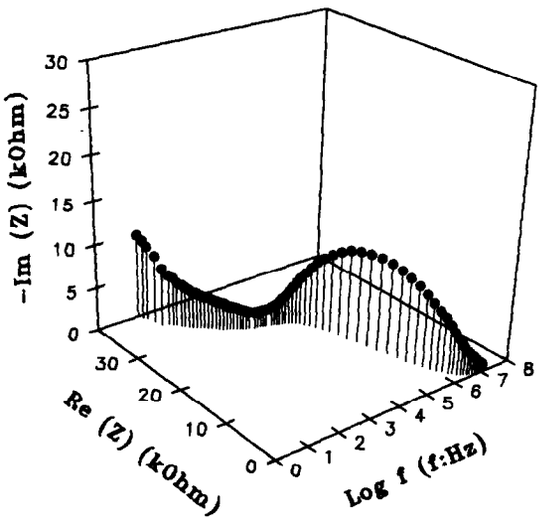

Fig. 2. Three-dimensional impedance plot recorded at 441°C (with Pt electrodes).

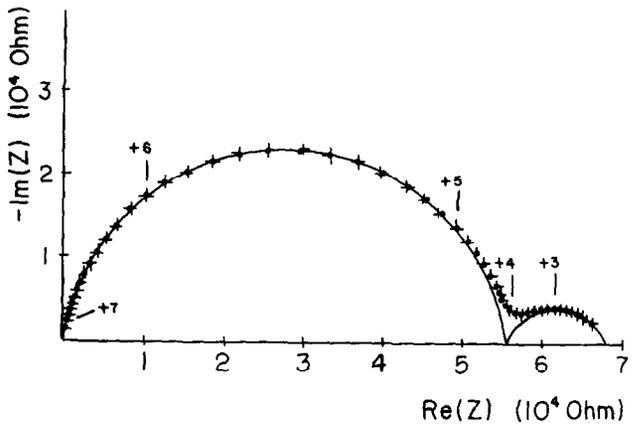

Fig. 3. Complex impedance plot recorded at 456°C (with Ag electrodes). The figures on the diagram indicate the decimal logarithms of the measuring frequencies.

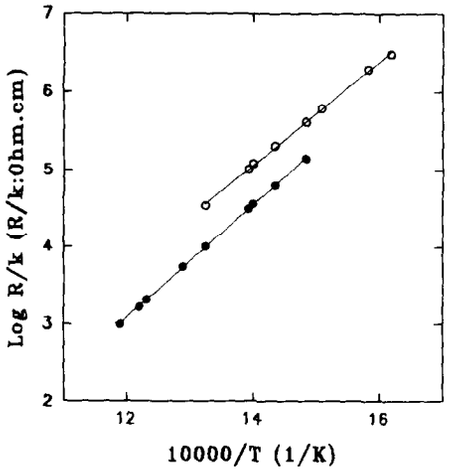

Fig. 5. Arrhenius diagram of the resistivities: (○) intragrain and (●) intergrain resistivities.

below the real axis. The off-axis angles are of the order of 12 and 18 degrees, respectively, for the high- and low-frequency semicircles. The high-frequency semicircle describes the intragrain resistance and capacitance relaxation. The low-frequency semicircle is related to conductivity blocking effects at grain boundaries. It is relatively small, because of a rather low grain boundary density (a rather high average grain size). In more conventional yttria-stabilized zirconias,[10] the relative magnitude of the grain boundary blocking effect is similar for a similar grain size. Details are given later in terms of a blocking factor.

Figure 3 presents an example of curve fitting performed on experimental data. Both intragrain and grain boundary contributions can be readily separated in this way in the temperature range 300–600°C. The data analysis was restricted to this temperature range where a reasonably good accuracy for the conductivity parameters was obtained.

Figure 4 shows the logarithms of the relaxation frequencies determined at the apex of the semi-

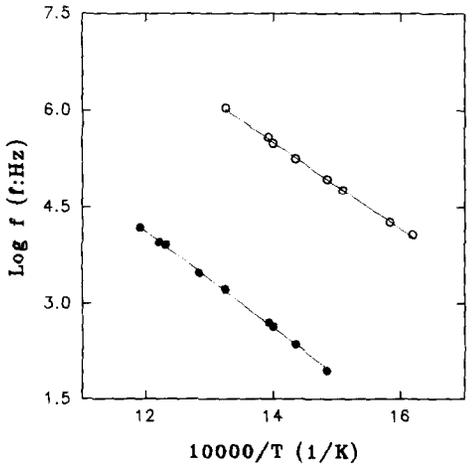

Fig. 4. Arrhenius diagram of the relaxation frequencies: (○) intragrain and (●) intergrain responses.

circles as functions of temperature. The fitted straight lines are approximately parallel. A similar observation was also made with zirconia–yttria ceramics.[11,12] At 400°C, the frequency ratio is equal to $1{\cdot}1 \times 10^{-3}$. It is very similar to the value ($0{\cdot}99 \times 10^{-3}$) quoted for an yttria-stabilized zirconia,[12] indicating similar average morphologies for the grain boundaries.

Values of the specific resistivities R/k have been determined from the intersections of the impedance arcs with the real axis, R being the resistances and k the geometrical factors of the samples. Figure 5 shows the Arrhenius plots of the intragrain and intergrain resistivities. There is no noticeable change in the slope of the intragrain resistivity in the investigated temperature range. This is in contrast with common observations on yttria-stabilized zirconias, but in agreement with results obtained by DC techniques, where no change of the Arrhenius slope has been observed, at least up to 1000°C.[6,17]

Activation energies and pre-exponential factors are given in Table 2. As is frequent in zirconia-based ionic conductors,[11] the difference between the activation energies of the intragrain and intergrain resistivities is about 15 kJ mol^{-1}. From the intragrain parameters one can estimate, by extrapolation, an intragrain conductivity of 9·8 S m^{-1} at 1000°C. At this temperature the blocking effect of charge carriers by grain boundaries is negligible, and hence intragrain and DC conductivities are the same. The conductivity value is slightly higher

Table 2. Activation energies *(E)* and pre-exponential factors *(A)* of the intragrain and intergrain resistivities

	Intragrain	*Intergrain*
E (kJ mol^{-1})	126	141
A (10^{-7} Ω m)	6·6	0·17

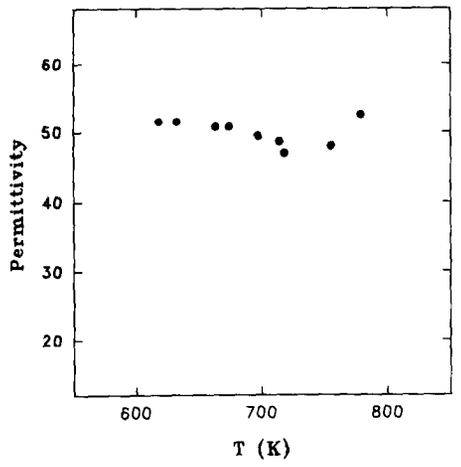

Fig. 6. Variation of the permittivity with temperature.

than reported data. This may be a consequence of different sintering conditions. It is well known that increasing the sintering temperature and sintering time greatly enhance the average grain size and modify the porosity. The grain size has no net effect on the bulk electrical characteristics, but porosity increases the intragrain resistivity.[11,18]

From the bulk semicircles a dielectric constant can also be calculated. As shown in Fig. 6, it does not vary much with temperature and is close to 50, a value similar to that (about 60) measured with yttria-stabilized zirconias under similar experimental conditions.[19]

Referring to a previous analysis by Dessemond and coworkers,[11,20] the blocking of the electric charge carriers at the grain boundaries by the blocking factor α_R can be defined by the equation:

$$\alpha_R = R_{\text{grain b.}}/(R_{\text{intrag.}} + R_{\text{grain b.}})$$

It measures the fraction of ionic carriers being blocked at grain boundaries. Over the rather narrow temperature range where it could accurately be determined, it is approximately independent of temperature (Fig. 7). Its average value is 0·24.

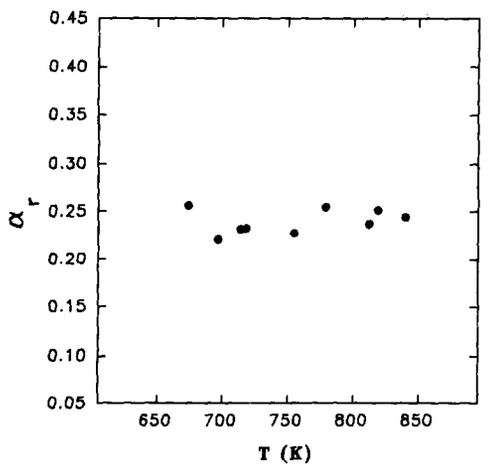

Fig. 7. Variation of the grain boundary blocking factor with temperature.

4 Conclusions

The main conclusions are:

—The impedance diagrams of fully stabilized ZrO_2–MgO ceramics prepared by solid-state synthesis present two well-resolved semicircles as for other cubic zirconia systems. The activation energies for the intragrain resistivity and the intergrain blocking effect are 126 and 141 kJ mol^{-1}, respectively.

—The estimated specific conductivity is 9·8 S m^{-1} at 1000°C.

—The specific dielectric constant and the ion-blocking parameters are very similar to the equivalent parameters of yttria-stabilized zirconias.

Synthesis and Sintering of PLZT Powder Made by Freeze/Alcohol Drying or Gelation of Citrate Solutions

M. A. Akbas & W. E. Lee

University of Sheffield, Department of Engineering Materials, Sheffield, UK

(Received 11 March 1994; revised version received 1 June 1994; accepted 14 June 1994)

Abstract

Citrate salts of PLZT 9/65/35 were prepared by drying (alcohol and/or freeze drying) and gelation of citrate solutions of PLZT. The decomposition of the citrate salts to form PLZT powder was studied by thermal analysis, X-ray diffraction, and scanning electron microscopy (SEM). It was found that the citrate salts of PLZT composition decompose in two separate stages; after decomposition, powder derived from alcohol dehydration, freeze drying and gelation have similar characteristics. Calcined powders in all cases consisted of 1 μm agglomerates with a surface area of approximately 11 m^2/g. Freeze drying and gelation are preferred over expensive alcohol dehydration. Dense pellets can be obtained from the citrate derived powder by a two stage pressureless sintering process.

1 Introduction

Lanthanum-doped lead zirconate titanate ceramics (PLZT), when fabricated as thin polished plates, have high optical transparency and exhibit excellent electro-optical characteristics.[1] As a result, many applications have been proposed in the field of electro-optics such as optical shutters, light modulators, memories and display devices.[2]

The production of high quality technical ceramics such as electro-optic PLZT components requires close control of powder characteristics such as purity, chemical homogeneity and particle-size distribution. By using chemical solution techniques for the preparation of multi-component powders, it is possible to produce fine, highly pure and homogeneous powders. The preparation of such PLZT powders via solution techniques has been demonstrated by several workers.[3–7] Another technique involves preparing multi-cation aqueous citrate solutions and co-precipitating PLZT citrate powder by alcohol dehydration of this solution.[8]

This method was first applied to the production of chemically homogeneous and fine $BaTiO_3$ powders[9] and later to the formation of PLZT and PZT powders.[8–10] In the alcohol dehydration process, droplets of a PLZT source solution are atomised into an alcohol bath to obtain PLZT citrate salt. The relative volumes of alcohol and source solution are critical; there must be at least 10 times greater volume of alcohol than solution to maintain the amount of water in the bath at a low level. The resulting powder can be filtered, and after drying, calcined to obtain PLZT.

Unfortunately, the alcohol dehydration technique is impractical because of the large volumes of expensive alcohol required which cannot be re-used without purification, and because of the susceptibility of the resulting salt to moisture absorption. Furthermore, the stoichiometry of the powder may be lost during co-precipitation. For instance, when co-precipitating titanium, 1% and 0.1% Ti remains in solution in ten-fold volumes of methyl and ethyl alcohol respectively.[9] This problem is prevented by using either freeze drying or gelation of the solution to yield the citrate salt.

The aim of the present study was to develop a technique which avoided the need for alcohol dehydration. PLZT citrate solutions were either (a) freeze dried, (b) alcohol dehydrated or (c) gelled. Freeze drying and alcohol dehydration yielded citrate powders while gelation led to a bulk citrate gel. All products were then calcined with the aim of forming PLZT powders.

The manufacture and decomposition of the citrate salts and the reaction mechanism to form PLZT powder is described. The properties and sinterability of powders obtained by freeze drying

and gelation are compared to those of a powder made by alcohol dehydration.

2 Experimental Procedure

Lead oxide (PbO, >99·9%), lanthanum oxide (La_2O_3, >99·99%), zirconium oxychloride octahydrate ($ZrOCl_2 . 8H_2O$, >99%), titanium butoxide ($Ti[O(CH_2)_3CH_3]_4$, >99%) and citric acid (Analar grade) were used as starting materials. Citrate solutions of each of the cations La^{2+}, Pb^{2+}, Zr^{4+} and Ti^{4+} were prepared by mixing their respective oxides and hydroxides with a citric acid solution and using ammonia gas to regulate the pH so as to obtain a clear solution.[9] The individual citrate solutions were then combined to obtain source solutions of PLZT 9/65/35 with excess Pb^{2+} in order to provide 10 wt% excess PbO to the composition after calcination. The Cl^- anions arising from $ZrOCl_2 . 8H_2O$ used in the preparation of zirconium citrate solutions were removed by repeating the precipitation of ammonium zirconyl citrate in large volumes of ethyl alcohol; washing the precipitate; and re-dissolving in distilled water until there was no reaction with photographic paper. This chloride-free zirconium solution was then used to produce PLZT source solution. Removal of chlorides (Cl^-) from the solution is critical to obtaining single-phase product after calcination.[11,12]

By holding the temperature at 60°C for 16–20 h, PLZT solutions were gelled under magnetic stirring. The starting pH of the solutions was around 7. However, the pH gradually decreased below 6 due to ammonia loss at the gelation temperature, and a white precipitate formed in the solution at these low pH values. The precipitate was re-dissolved by adjusting the solution pH between 8 and 8·5 with ammonia solution. This process yielded translucent or transparent bulk citrate gel.

Alcohol dehydration was carried out by spraying source solution at a rate of 15 cm^3/min (compressed-air sprayer, Aldrich Z12, 630-6) into an ethanol (99%) bath which had a volume 20 times that of the solution to be sprayed in order to maintain the water content in the bath at a low level. The pH of the bath was adjusted between 4 and 4·5 with formic acid during co-precipitation. The white PLZT citrate precipitate was centrifuged from the bath, washed with ethanol and dried at 40°C for 18 h.

PLZT citrate powder was also produced by freeze drying. The source solution was frozen by spraying the solution into liquid nitrogen. Water was then removed from the solid particles of salt and ice sublimation in a freeze dryer (Edwards, Freeze Dryer Modulyo) at −50°C and 133 Pa for 48 h.

The powder surface area was determined by using a Micromeritics Gemini 2360 unit; morphology was examined by secondary electron imaging in a scanning electron microscope (SEM, Camscan series 2). Energy dispersive spectroscopy (EDS) was performed using a LINK AN 10000 system with a Be-window detector.

Decomposition of the citrate salt was studied by DTA and TG (Du Pont thermal analyst 2000, Stanton Redcroft TG-770) at a heating rate of 10°C/min in air. To identify the intermediate phases formed, powders were quenched after being held for 4·5 h at various temperatures in air (10°C/min heating rate), and were analysed by X-ray diffraction using Cu K_α radiation (Philips diffractometer equipped with 1710 diffractometer control unit operated at 40 kV and 30 mA). Due to the 4·5 h isothermal treatment, direct comparison between thermal analysis results and those of quenched samples is not possible.

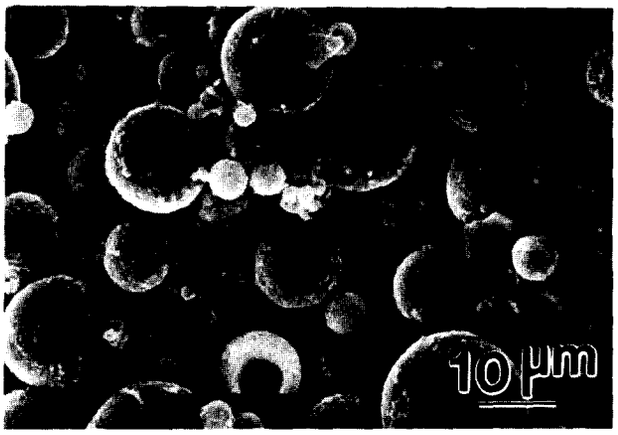
The citrate gel was calcined by heating in air at 10°C/min to 300°C for 1 h. The resulting homogeneous black powder was ground and re-heated to 500°C at 10°C/min in nitrogen and held for another hour. The nitrogen atmosphere was then diluted by passing oxygen through the furnace, and the powder was further calcined for another 4 h.

Both alcohol- and freeze-dried powders were calcined by direct heating to the calcination temperature (500°C) without any intermediate steps (as was used when calcining the gel) and the atmosphere and thermal treatment times were the same.

The resulting powders were energy milled in 2-propanol with yttria-stabilized zirconia balls in polyethylene jars for an hour. Green pellets of 10 mm in diameter and 1 to 2 mm in thickness were then produced by uniaxial pressing at 130 MPa. A two stage sintering technique was used to densify the green pellets. In this technique the pellets were placed in an upside-down platinum crucible with a tight lid. A small amount of identical PLZT powder was used to prevent reaction between the pellets and the platinum crucible. The platinum crucible was flushed with oxygen and the samples were held at 1180°C for 1 h in an oxygen atmosphere. The samples were then transferred in a closed alumina crucible (the so-called double crucible technique, one inside the other) and re-sintered at 1125°C for 13 h in air. Heating and cooling rates were 400°C/h during sintering. This two-stage sintering technique is a modified form of the improved atmospheric sintering method reported by Snow.[13]

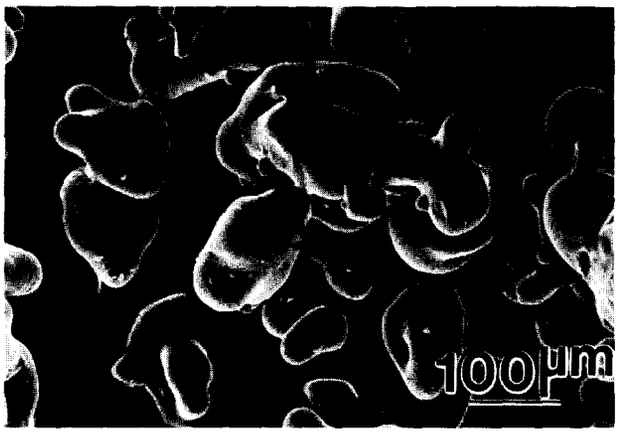
Grain size measurements were made using the linear intercept method[14] on samples thermally etched at 1050°C for 1 h in closed platinum crucibles. Optical transmission was determined by using a Perkin-Elmer 330 Spectrophotometer for wavelengths of 350 to 1050 nm on 0·2 mm thick samples polished to an optical finish with 0·25 μm diamond paste.

3 Results and Discussion



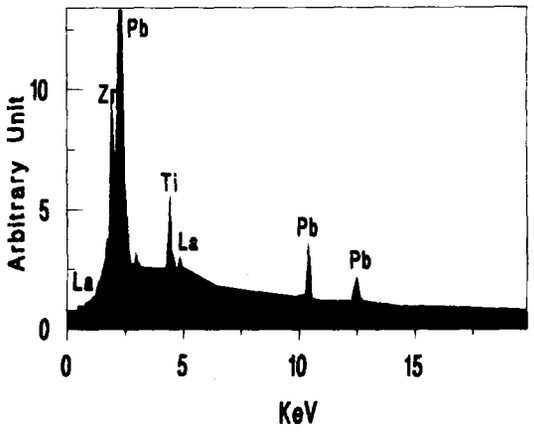
3.1 Processing and morphology of powders

3.1.1 Preparation of citrate solutions and gelation
The citrate route yielded a clear and colourless solution of each individual component of PLZT. No precipitation was observed when individual solutions were mixed together to obtain PLZT source solution of the desired composition. After gelation, the colour of the gel was cloudy white and all the solutions and gels were stable even after seven months storage in airtight plastic containers.



3.1.2 Alcohol- and freeze-dried powders
Both alcohol- and freeze-dried powders were white in colour and free flowing when fully dried. The alcohol-dried particles were spherical prior to calcination and 4–10 micron in size (Fig. 1(a)). While various particle shapes, such as globules and rods,[8,9] have been reported previously for alcohol-dried powders, spherical particles have not been obtained although this is simply achieved by control of the parameters when spraying the solution into the alcohol bath. TEM could not be used to resolve the fine structure of the powder due to rapid decomposition under the electron beam.

The freeze-dried powder consists of large 100-micron agglomerates which have the shape of deformed spheres (Fig. 1(b)). These agglomerates most likely formed due to partial melting upon freeze drying. This indicates that the freezing temperature of the solution (pH >7) is below −50°C at atmospheric pressure. The early stages of combination of the spherical particles to form agglomerates are indicated by the arrow (Fig. 1(b)).



Both the freeze- and alcohol-dried powders have surface areas below 1 m^2/g as expected from the large particle size and smooth surfaces. Although particles are susceptible to electron beam damage, many EDS analyses obtained from individual particles indicate a homogeneous distribution of elements (Fig. 1(c)).

3.2 Decomposition of PLZT citrate salts

3.2.1 Thermal analysis
TG analysis (Fig. 2) indicates that PLZT citrate salts decompose in two separate stages. Previous work by Courty *et al.*[15] recognised the existence of two types of pyrolysis for the citrate–nitrate precursors. Type I was characterised by a con-

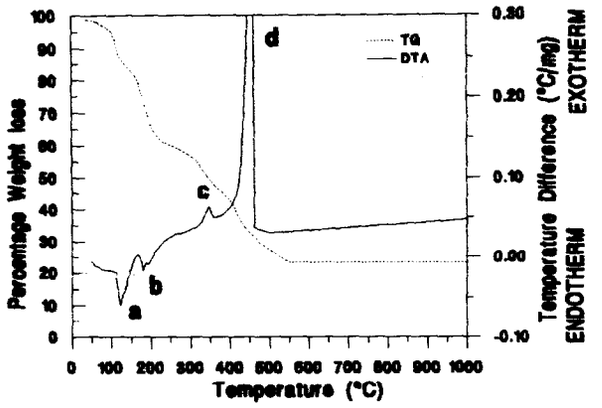

Fig. 2. DTA/TG of PLZT citrate gel. Similar curves result from alcohol-dehydrated and freeze-dried PLZT citrate salts.

tinuous and vigorous reaction which occurred with precursors containing metals with a strong catalytic activity in the oxidation process. Type I decomposition is characterised by a single-stage decomposition in TG. Type II is typified by two stages in which an intermediate decomposition step occurs as a result of the formation of a metastable semi-decomposed precursor which is thought to be a mixed citrate salt.

Citrate gel and alcohol/freeze-dried powders all showed very similar decomposition behaviour. TG and DTA (Fig. 2) indicate that the first stage of decomposition after the removal of water starts at around 120°C (endotherm a on Fig. 2), and continues until 180°C. This part of the decomposition was associated with a 20% weight loss. Samples quenched from 160°C indicated a yellow ochre intermediate phase which was amorphous (Fig. 3). Removal of ammonia and break up of some citrate chains is believed to occur at this stage.[16] The second stage of decomposition is indicated by an endothermic peak at 180°C (endotherm b on Fig. 2) and an associated loss of 25 wt% in a relatively small temperature range of 180°C to 225°C. Samples quenched from 200°C were dark brown to coffee coloured and still amorphous (Fig. 3). Most of the decomposition of the citrate chains occurs at this stage. From 225°C to 500°C, a gradual weight loss is detected due to the break up of any remaining citrate chains. Samples quenched from 300°C were black and still amorphous (Fig. 3) indicating almost complete break up of citrate chains and the presence of carbon as a decomposition product. DTA indicated an exothermic reaction at 340°C (exotherm c on Fig. 2) corresponding to the oxidation of Pb. The rate of weight loss increased after lead oxidation as indicated by TG (Fig. 2). This may imply that lead oxidation acts like a catalyst to ignite carbon oxidation. Exotherm d corresponds to vigorous oxidation of the remaining carbon. Samples quenched from 375, 505, 600, 700 and 800°C were yellow and crystalline (Fig. 3). This indicates that

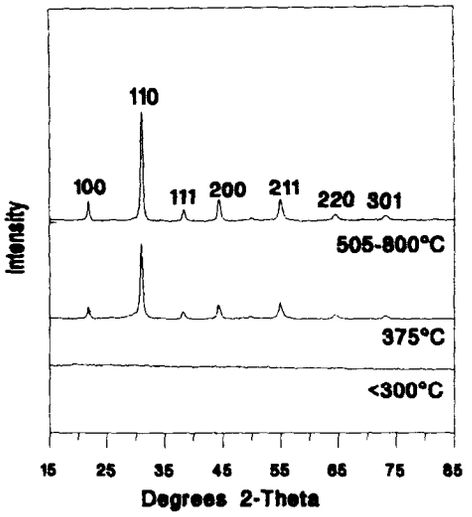

Fig. 3. X-Ray diffraction from citrate gel quenched from various temperatures after 4·5 h isothermal hold. No intermediate phases were observed during the crystallisation of PLZT.

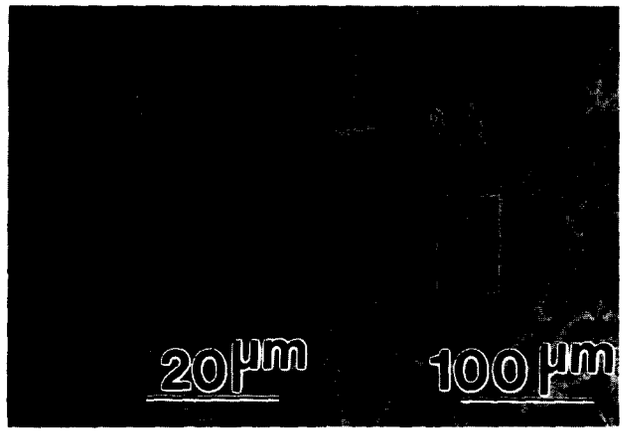

crystallisation of the powder is favoured by the heat produced by oxidation and occurred simultaneously. Although the onset temperature for this reaction was determined as 420°C by DTA, samples quenched from 375°C indicated that the reaction could start at lower temperatures if they were held isothermally for long times. No further DTA peaks were observed above 525°C and the weight remained constant from 530°C to 1000°C.

3.2.2 X-Ray diffraction, surface area and SEM analysis

Many workers have investigated the reaction mechanism of formation of PZT solid solution from oxide precursor mixtures. Although these studies reached different conclusions, invariably intermediate phase(s), such as $PbTiO_3$,[17] $PbZrO_3$,[18] and a PbO solid solution[19] were observed prior to crystallisation of PZT. Figure 3 shows a series of XRD patterns obtained from citrate gel quenched from various temperatures after 4·5 h isothermal holds. XRD was not attempted for freeze/alcohol-dried powders since thermal analysis and calcination indicated that the crystallisation mechanism was identical to that of the gel. The powder remained amorphous up to 300°C and then apparently crystallised directly to single-phase PLZT by a vigorous oxidation/ decomposition reaction after 4·5 h at a temperature of 300–375°C. Brown & Mazdiyasni,[4] Duran & Moure,[20] Thomson[5] and Yoshikawa & Tsuzuki[21] reported 600°C, 550°C (16 h), 500°C (16 h), 450°C (14 h) respectively, as the minimum temperature (and time) required to obtain crystalline PLZT phases for their chemically prepared powders. In the present work, this minimum temperature was less than 375°C (4·5 h). No intermediate phases were observed and all the diffraction peak positions and intensities match

(a)

(b)

(c)

Fig. 4. SEM micrographs of citrate gel powder quenched from (a) 160, (b) 375 and (c) 500°C after 4·5 h at temperature indicating the powder morphology at various stages of decomposition.

with those reported for PLZT.[22] With increasing temperature, the peaks get sharper and stronger indicating an increase in crystallite size and amount.

The morphology of the citrate gel powder quenched from 160°C reveals large (30 μm) platy, angular particles with smooth surfaces (Fig. 4(a)). Their smooth appearance indicates that not much citrate decomposition has occurred at this temperature. After the strong oxidation of carbon at

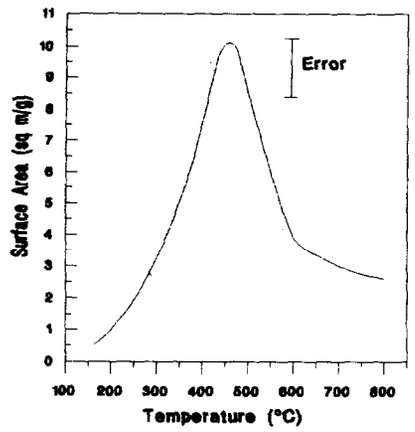

Fig. 5. Change in the surface area of powder with temperature during decomposition. Surface area was measured for powder quenched from various temperatures after 4·5 h isothermal hold of PLZT citrate gel.

375°C, the particles contain many micro-channels and pores presumably arising from decomposition of citrate chains (Fig. 4(b)). The large porous plates break up revealing many (1 μm) agglomerates after subsequent calcination at higher temperatures (Fig. 4(c)).

Figure 5 shows the variation in the surface area of the calcined gel powder with temperature. Powder surface area increases sharply with increasing temperature up to around 500°C due to the decomposition of citrate salts to porous oxide powders and the fragmentation of the larger plate-like particles (Fig. 4(a)–(c)). A maximum surface area of 10·5 m^2/g was obtained at approximately 450–500°C. Powders calcined at higher temperatures showed decreased surface area due to particle coarsening. Therefore, the optimum calcination temperature was determined to be about 500°C for citrate salts of PLZT.

3.3 Calcination and densification of resulting powder

3.3.1 Calcination of citrate salts

Mulder[9] proposed that properly dried citrate powder does not melt during calcination and hence preserves its shape. However, the morphology of the alcohol and/or freeze-dried powders (Fig. 6), calcined at 500°C in nitrogen/oxygen diluted atmosphere indicates that the spherical shape was lost during calcination. Although the alcohol/freeze-dried powder appeared fully dried and free flowing (Fig. 1(a) and (b)), it was physically observed to melt at around 90°C. The shape of the calcined alcohol/freeze dried powders and their surface areas (11 m^2/g) were similar to those obtained from gel. It was thought that the melting of alcohol/freeze-dried powders might be prevented kinetically by rapid heating of the powder above the carbon combustion temperature. Consequently, some samples were heated to 700°C in

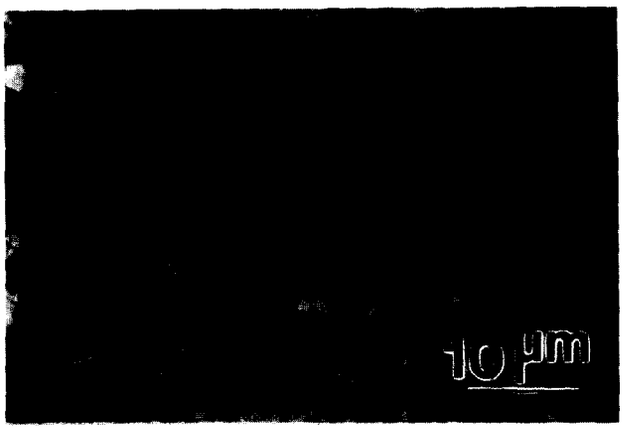

Fig. 6. SEM micrograph of calcined alcohol-dehydrated powder. A similar morphology was also observed for freeze dried powder.

less than 1 min and held for 15 min. However, the morphology of these rapidly decomposed powders was also not spherical.

3.3.2 Ceramic fabrication

After the first sintering stage, all samples were dull red, indicating the presence of excess PbO added to compensate PbO loss and to aid densification. There was no difference between the densification behaviour and final densities of the pellets prepared from alcohol/freeze dried or gel-derived powders. After the second sintering stage, pellets were pale yellow and their final densities were 97% of the theoretical density (which for this composition is 7·9 g/cm^3)[1].

Microstructures consisted of equiaxed grains (Fig. 7) with mean grain size 2·6 ± 0·2 micron. EDS analysis from various grains showed a homogeneous distribution of all elements in the microstructure. Figure 8 shows the variation of transmission percentage with wavelength. Pellets

Fig. 7. Scanning electron micrograph of thermally etched PLZT pellet made from gel-derived powder. The dense microstructure reveals equiaxed grains with mean grain size 2·6 micron. Similar densities and microstructure were observed in pellets made from powders prepared by alcohol or freeze drying.

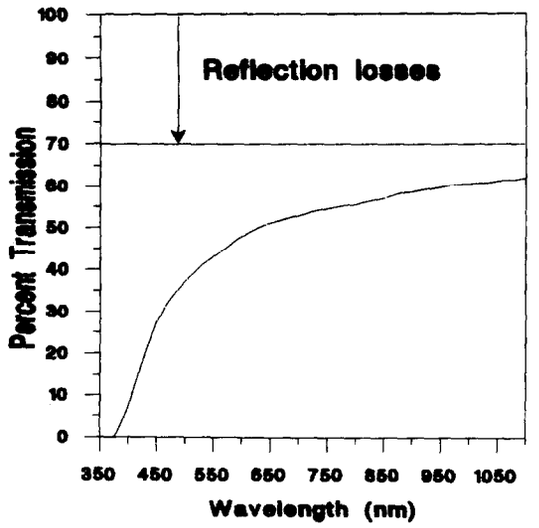

Fig. 8. Optical transmission of a 0·2 mm thick pellet. Maximum transmission was measured at 62%. This particular curve is from the gel-derived pellet with the microstructure given in Fig. 7.

prepared from precipitated or gel-derived powders had similar microstructures and the transmission reached 62% in all cases. This transmission value compares reasonably with those reported for atmosphere sintered samples.[21]

4 Conclusions

(1) PLZT composition citrate salts manufactured by freeze/alcohol drying or gelation of citrate solutions decompose in a two-step process.

(2) Crystallisation of PLZT powder is catalysed by the heat evolved on oxidation of carbon present from citrate groups, occurring at temperatures below 375°C. This is a lower temperature than comparable methods have achieved. PLZT forms directly without any intermediate phase formations.

(3) The characteristics of the PLZT powders formed in each case (alcohol/freeze-dried or gelled) are similar. Alcohol dehydrated powder, however, is expensive to produce and stoichiometry may be lost. Consequently, powders derived from citrate gel or freeze drying are preferred.

(4) Dense and fine-grained ceramics can be made from the powders and lead to high homogeneity via a two-stage sintering process.

Abstract

The crystallization of a glass powder with composition $Mg_2Al_4Si_{11}O_{30}$ to β-quartz$_{ss}$ and the transformation of β-quartz$_{ss}$ to α-cordierite were investigated by means of SEM and TEM. Crystallization of β-quartz$_{ss}$ starts at the surfaces of the glass grains. At first growth proceeds nearly isotropically, but due to mutual hindrance growth perpendicular to the surface is preferred when the β-quartz$_{ss}$ crystals impinge on each other. The transformation of β-quartz$_{ss}$ to cordierite starts at the surfaces of the β-quartz$_{ss}$ crystals. In a first stage the cordierite nuclei grow over long distances only along the grain boundaries of several β-quartz$_{ss}$ crystals. On prolonged annealing the cordierite rims grow dendritically into the cores of β-quartz$_{ss}$, maintaining the same crystallographic orientation.

1 Introduction

In recent years the fabrication and the properties of glass-ceramics based on cordierite ($Mg_2Al_4Si_5O_{18}$) have frequently been investigated due to the extraordinary combination of valuable properties of cordierite. The excellent electrical properties of cordierite such as high volume resistivity (≈ 3×10^{15} Ω cm) and low dielectric constant (≈ 5·3 at 1 MHz) make it a promising material, especially for integrated circuit devices.[1,2] Moreover, cordierite glass-ceramics have a low thermal expansion coefficient (1–2 × 10^{-6}/K),[3,4] matching approximately that of silicon, a high deformation temperature, high chemical durability and high mechanical strength.

The double-ring silicate MAS osumilite ($Mg_2Al_4Si_{11}O_{30}$) is another compound from the system $MgO–Al_2O_3–SiO_2$ with structural and physical properties similar to those of cordierite.[5] This phase is metastable but endures extended heat treatments up to 1150°C. The similar thermal expansion behaviour to cordierite makes MAS osumilite ($\alpha_{25-600°C}$: $1{\cdot}1 \times 10^{-6}$/K) also very interesting for glass-ceramic applications. MAS osumilite crystallizes from glasses of a narrow compositional range in the system $MgO–Al_2O_3–SiO_2$ with BaO or SrO additions. The crystallization of MAS osumilite from glass proceeds via a complex mechanism involving nucleation of precursor Ba- or Sr-containing osumilite phases and a high quartz solid solution (β-quartz$_{ss}$, $MgAl_2Si_xO_{4+2x}$) which subsequently is transformed into MAS osumilite.[6]

However, when a glass of MAS osumilite composition itself without any additions is heat treated, MAS osumilite never crystallizes under any conditions. The glass crystallizes only to β-quartz$_{ss}$ and, at higher temperatures, the thermodynamically stable phases cordierite and α-quartz or cristobalite.

Depending on the glass composition, the sintering additives, nucleating agents and the crystallization temperature the crystallization sequence of cordierite-type glass powders and the microstructural development differ considerably.[7–11] The devitrification process of TiO_2- and ZrO_2-containing cordierite glasses usually involves phase separation in the liquid state. At low temperatures β-quartz$_{ss}$ always appears as a metastable precursor which transforms into cordierite after prolonged heating. At higher temperatures above about 1000–1200°C no β-quartz$_{ss}$ appears and cordierite crystallizes directly from the glass.

The morphology of the initial β-quartz$_{ss}$ varies greatly. In a sintered glass-ceramic with greater MgO and lower Al_2O_3 than stoichiometric

* Present address: Laboratoire de Science des Matériaux Vitreux, Université Montpellier II, 34095 Montpellier, France.

cordierite with additions of P_2O_5 and B_2O_3 Bridge *et al.*[1] found roughly spherical crystals concentrating at the original boundaries of the glass particles. Rudolph *et al.*[12] examined a glass with a similar basic composition but without B_2O_3. They report a β-quartz$_{ss}$ skeleton forming along the original particle surfaces. In this thin β-quartz$_{ss}$ layer individual crystals could not be identified. Similar β-quartz$_{ss}$ boundary layers together with co-precipitated spherulitic ZrO_2 were observed by McCoy & Heuer[13] in a glass of similar composition containing 15 wt% ZrO_2. However, the ZrO_2 crystallites did not act as nucleation sites for the β-quartz$_{ss}$ crystals. In bulk glasses containing more SiO_2 and additions of ZrO_2, TiO_2 or CaF_2 Zdaniewski[8] observed spherulitic growth of β-quartz$_{ss}$.

Chaim & Heuer[14] studied the crystallization sequence of a glass with stoichiometric cordierite composition and an addition of 2 wt% BaO. In this glass the crystallizing β-quartz$_{ss}$ had a dendritic hexagonal morphology. BaO was rejected from the growing β-quartz$_{ss}$ and concentrated in an interdendritic amorphous phase. On the other hand, in the crystallization sequence of an MAS osumilite glass-ceramic from a similar BaO-containing glass but with higher SiO_2 content Winter *et al.*[6] found rounded and elongated non-dendritic β-quartz$_{ss}$ crystals nucleating at the original particle surfaces and growing perpendicular to the surfaces into the cores of the glass grains. BaO was rejected into an intergranular residual glass phase.

The microstructural evolution of a glass-ceramic during the transformation of β-quartz$_{ss}$ to cordierite and the mechanism of this process have been investigated by several authors. Watanabe *et al.*[15] described the variations in morphology of cordierite crystallizing both from β-quartz$_{ss}$ or directly from the glass as a function of crystallization temperature. Barry *et al.*[16] investigated the bulk crystallization of glasses of stoichiometric cordierite composition with various amounts of TiO_2 and ZrO_2. With increasing temperature these authors observed continuous exsolution of MgO and Al_2O_3 from β-quartz$_{ss}$ and formation of spinel and sapphirine. At temperatures above 1150°C the remaining SiO_2-rich β-quartz$_{ss}$ reacts with the exsolution products to form cordierite. Chaim & Heuer[14] showed that in BaO-containing compositions cordierite nucleates within the dendritic β-quartz$_{ss}$ grains or at the β-quartz$_{ss}$/glass interfaces. The morphology of cordierite also is dendritic and growth proceeds preferentially within the β-quartz$_{ss}$ grains.

The present paper presents a detailed study of the crystallization mechanism in a glass of composition $Mg_2Al_4Si_{11}O_{30}$ without any additives. The focus was mainly on the nucleation of cordierite and the transformation of the precursor phase β-quartz$_{ss}$ into cordierite. As already reported, the mechanisms of these processes are supposed to depend critically on the composition and the morphology of β-quartz$_{ss}$ and hence on the composition of the parent glass. In particular, an understanding of the present crystallization mechanism might also explain why MAS osumilite does not crystallize although the glass investigated is of MAS osumilite composition.

2 Experimental Details

The glass investigated has the composition of MAS osumilite ($Mg_2Al_4Si_{11}O_{30}$) (in wt%: 8·5 MgO; 21·6, Al_2O_3; 69·9 SiO_2). Stoichiometrically, this composition can be described as a mixture of 61·8% cordierite and 38·2% SiO_2.

A homogeneous glass was prepared from reagent grade Al_2O_3 and MgO from Merck AG (Darmstadt, Germany) and SiO_2 (Sipur, Bremthaler Quarzwerke, Usingen, Germany) by melting the constituents at 1550°C for 4 h in platinum crucibles and quenching the melt into cold water. After grinding the glass frit in an alumina ball mill to a grain size <63 μm samples for the crystallization process were cold-isostatically pressed. The 10 × 4 × 4 mm sized samples were put into a preheated furnace and crystallized isothermally at a temperature of 1150°C and various heating times.

The nucleation and crystallization sequence of the glass powder was studied by means of SEM and TEM.

For TEM preparation the crystallized samples were cut into thin sections which were ion thinned with a 5 kV argon beam. The TEM analyses were performed on a Philips CM12 microscope (Philips, Eindhoven, The Netherlands) equipped with an EDAX 9900 EDX device. Polished and HF-etched samples were studied with a Philips SEM500 scanning electron microscope.

3 Results

The first phase appearing in the crystallization sequence is β-quartz$_{ss}$ nucleating at the surfaces of the glass grains. Growth proceeds isotropically in a first stage, but due to mutual hindrance further growth proceeds preferentially perpendicular to the surface into the volume of the glass grains. Figure 1 shows a typical microstructure of an early growth stage with slightly elongated β-quartz$_{ss}$ crystals growing from the surface into the residual glass at the centre of the glass grain.

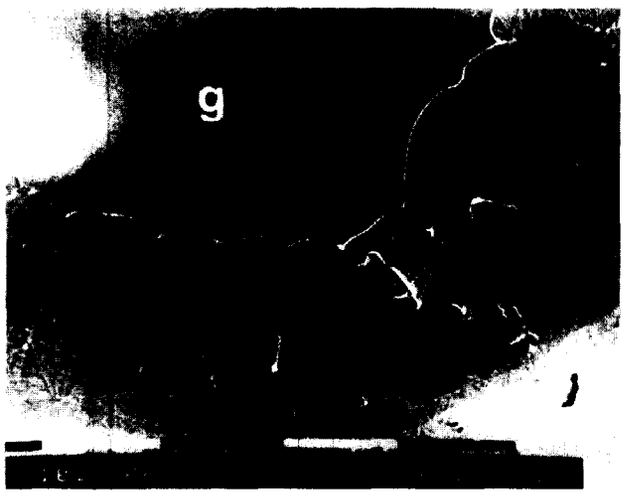

Fig. 1. SEM micrograph of several elongated β-quartz$_{ss}$ crystals growing from the surface (bottom) into the centre of a glass grain (g). Heat treatment: 1150°C, 2 min.

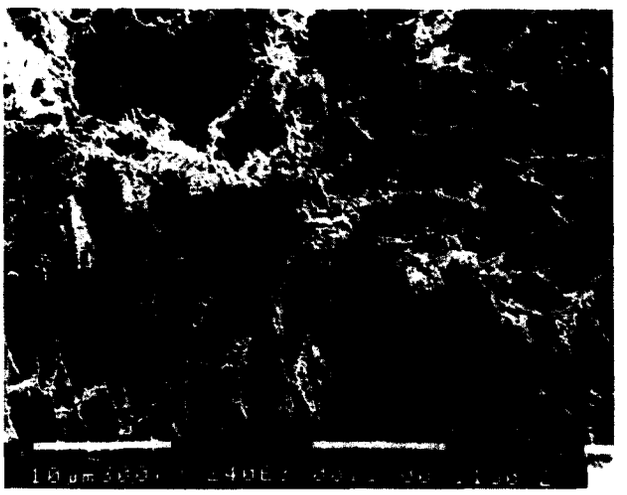

Fig. 3. SEM micrograph of the cordierite network (bright areas) around the β-quartz$_{ss}$ grains (dark areas) in the centre of a former glass grain. Heat treatment: 1150°C, 10 min.

EDX analysis confirmed that the composition of the β-quartz$_{ss}$ crystals corresponds to that of the parent glass which has the theoretical composition of the starting mixture. No residual glass phase could be found on the grain boundaries between adjacent β-quartz$_{ss}$ crystals by means of TEM (Fig. 2). EDX measurements suggest that the chemical composition is homogeneous within one β-quartz$_{ss}$ crystal and within the whole sample.

The transformation of β-quartz$_{ss}$ to α-cordierite starts at the grain boundaries of the β-quartz$_{ss}$ crystals. In a first stage the cordierite nuclei always grow along β-quartz$_{ss}$ grain boundaries. Figure 3 shows a typical cordierite network around the β-quartz$_{ss}$ crystals in the centre of a former glass grain. TEM diffraction analysis shows that this network typically consists of cordierite crystals forming rims of the same orientation over large areas and surrounding numerous β-quartz$_{ss}$ grains. Figure 4 shows an example with cordierite in an $[0\bar{2}1]$ orientation. Only a slight rotation around the $[0\bar{2}1]$ zone axis is observed during growth over about 4 μm along the grain boundaries of several adjacent β-quartz$_{ss}$ grains.

The dark field photograph of another locality of the sample shows that the cordierite rims along the β-quartz$_{ss}$ grain boundaries have a dendritic spinal-type microstructure with an interspatial amorphous phase (Fig. 5). The volume of this phase is too small for an EDX analysis but as the β-quartz$_{ss}$ crystals are much richer in SiO_2 than cordierite a second phase with a relatively high SiO_2 concentration must be formed during the β-quartz$_{ss}$ to cordierite transformation.

Starting from the β-quartz$_{ss}$ grain boundaries the cordierite rims begin to grow into adjacent β-quartz$_{ss}$ grains. Frequently, preferred growth planes of cordierite are observed. The bright and dark field photographs of Fig. 6 show a cordierite crystal with pronounced lamellar growth along (100) planes. These growth planes are preferred probably due to their high atom occupancy. It was frequently observed that starting from the same cordierite rim crystal the (100) planes grow into different β-quartz$_{ss}$ crystals without changing

Fig. 5. TEM (100) DF micrograph of the spinal morphology of the cordierite rims on the β-quartz$_{ss}$ grain boundaries. Heat treatment: 1150°C, 60 min.

Fig. 7. BF micrograph of the dendritic growth of cordierite in a highly transformed β-quartz$_{ss}$ crystal. Orientation of cordierite is [001] parallel to the electron beam. {100} faces are preferentially formed. Heat treatment: 1150°C, 60 min.

their orientation. This suggests that the transformation does not proceed along distinct directions of the β-quartz$_{ss}$ structure. Hence, it is not of a topotactic nature. The orientation of cordierite growth within a β-quartz$_{ss}$ crystal depends only on the orientation of the cordierite seed crystals.

In Fig. 7 a β-quartz$_{ss}$ grain is penetrated completely by a cordierite dendrite in a more advanced stage of the transformation process. The cordierite crystal maintains its orientation over the whole former β-quartz$_{ss}$ grain with the [001] zone axis parallel to the electron beam as can be seen from electron diffraction (SAD). This orientation shows, that preferentially hexagonal prismatic {100} planes are formed. Since the transformation of β-quartz$_{ss}$ into cordierite is not an isochemical reaction again an SiO_2-rich amorphous phase develops within the cordierite dendrites.

After about 3 h at 1150°C, the amorphous SiO_2-rich phase between the cordierite dendrites has crystallized to β-quartz. The α-quartz crystals can reach the size of a former β-quartz$_{ss}$ grain, show-

ing a dendritic morphology that is finely interlaced with the cordierite dendrites (Fig. 8).

4 Discussion

In the crystallization sequence of the studied glass MAS osumilite did not appear, although the glass is of MAS osumilite composition ($Mg_2Al_4Si_{11}O_{30}$). This is in accordance with previous results about MAS-osumilite crystallization from BaO containing glasses[5,6] and can be explained in terms of the nucleation kinetics of the crystallizing phases. For the formation of MAS osumilite pre-crystallization of a stable osumilite-type phase such as Ba osumilite ($BaMg_2Al_6Si_9O_{30}$) is necessary on which it can nucleate epitactically. Even then MAS osumilite nucleation competes with the simultaneous epitactic nucleation of cordierite on Ba osumilite. However, the nucleation rate of MAS osumilite is higher than that of cordierite in this case. In a pure MAS osumilite glass the formation of a stable osumilite-type phase is not possible. Cordierite, on the other hand, can nucleate at the interfaces between the β-quartz$_{ss}$ crystals, but although the crystal structures are similar, cordierite does not supply suitable surfaces for epitactic nucleation of MAS osumilite. One reason for this is that the cordierite surfaces are enriched in SiO_2 and hence no longer of the MAS osumilite composition.

The second interesting observation concerns the differences in the growth morphologies between β-quartz$_{ss}$ and cordierite. The nucleation of both phases is interface induced. The interfaces of the glass grains and of the β-quartz$_{ss}$ crystals, respectively, represent the nucleation sites for β-quartz$_{ss}$ and cordierite.

Metastable β-quartz$_{ss}$ nucleates first, possibly because it has a closer relation with the glass structure than α-cordierite. In a first stage the growth of β-quartz$_{ss}$ is isotropic. When neighbouring crystals impinge on each other further growth is only possible perpendicular to the surface of the glass grains into their core and the β-quartz$_{ss}$ crystals become more elongated.

On the other hand, the first nucleating cordierite crystals show a preferred growth along the β-quartz$_{ss}$ surfaces. Thus, the β-quartz$_{ss}$ crystals are characterized by an isotropic three-dimensional growth while the first nucleating cordierite crystals show only two-dimensional growth. The differences in crystal growth morphology and orientation are supposed to depend on the transformation kinetics of the glass to β-quartz$_{ss}$ and the β-quartz$_{ss}$ to cordierite transformation, respectively. The decisive difference in the crystallization of β-quartz$_{ss}$ and cordierite in the present glass lies in the different chemical compositions. The glass to β-quartz$_{ss}$ transformation proceeds isochemically, whereas the β-quartz$_{ss}$ to cordierite transformation is of an allochemical nature. Hence, the latter process is diffusion controlled. Grain boundaries generally represent a defective crystal structure of a higher energy state than the perfect crystal. Hence, crystallization and growth of cordierite along the β-quartz$_{ss}$ grain boundaries provides both a fast reduction of stored energy and effective diffusion paths. The present results show that this leads to fast two-dimensional growth. Obviously, the growth rate of cordierite along the grain boundaries is very high in comparison to the nucleation rate. During growth into the cores of the β-quartz$_{ss}$ grains the diffusion rate probably limits the growth rate of cordierite. The necessity for the cordierite crystals to pierce through a simultaneously rejected SiO_2-rich layer during growth results in the formation of a dendritic morphology.

5 Conclusion

The present results suggest that in general the nucleation and growth kinetics and the morphology of cordierite during the β-quartz$_{ss}$ to cordierite transformation depend critically on the morphology and chemical composition of the β-quartz$_{ss}$ crystals. In the present case of diffusion-controlled cordierite crystallization from β-quartz$_{ss}$ of a different chemical composition two stages can be distinguished:

(i) fast two-dimensional growth along the β-quartz$_{ss}$ grain boundaries leads to formation of a cordierite network with relatively large areas of the same crystallographic orientation.

(ii) cordierite growth proceeds dendritically into the bulk of the β-quartz$_{ss}$ grains. Quartz crystallizes within the SiO_2-rich dendritical interspaces.

Abstract

An automatic image analysis method has been used to study the microstructure evolution of polycrystalline α-SiC samples hot pressed with 0·3 wt% and 1·5 wt% Al-based additives after compression at high temperature. Microstructures have been characterized in terms of grain shape, grain size and grain orientation with respect to the macroscopic stress direction. It has been shown that grains tend to flatten perpendicularly to the external stress for the 0·3 wt% Al grade. By contrast, for the same macroscopic deformation value, grains of the 1·5 wt% Al grade do not exhibit any shape change after creep tests, suggesting that a certain amount of superplastic deformation has occurred.

1 Introduction

Among the thermomechanical ceramics, polycrystalline ceramics based on silicon carbide have been one of the primary candidate ceramic materials for use in structural applications at high temperature. Consequently many studies have been devoted to their mechanical behaviour in a wide range of stress and temperature.[1–16] However, many experiments were conducted in a temperature range not exceeding 1600–1700°C and/or with bending as the preferred mode of testing, so that overall strains of a few percent were reached.[1–7] In most cases, high-temperature creep in polycrystalline SiC has been interpreted in terms of diffusional atomic flow rather than in terms of dislocation glide even if a parallel dislocation glide mechanism can contribute to the total strain.[1–7] However, experiments conducted on SiC single crystals have shown that plastic strain was due to dislocation glide motion on the basal slip system and was controlled by a Peierls mechanism.[15,16] The same mechanism was found in CVD SiC deformed between 1400–1600°C.[10]

During the high-temperature thermomechanical treatments, a modification of the microstructure of the material can occur,depending on the experimental conditions as well as on the mechanism inducing the deformation. For example, grain shape modification is generally observed for dislocation and diffusional creep[17] but not during superplastic creep.[18] The change of the microstructure is usually investigated by means of image analysis methods. In SiC materials these methods were used in a few cases to characterize grain sizes and grain shapes before and after deformation.[11,12]

On the other hand, compressive tests of different grades of α-SiC sintered with Al-based additives were carried out by Carry & Mocellin beyond 1800°C in compression so that, in contrast to the preceding studies,[1–7] higher strain values could be reached (0·43) without cavitation.[8]

The aim of this work is to characterize by using image analysis methods the microstructural evolution of the α-SiC materials creep tested in conditions given in Ref. 8. Grain size and grain shape evolutions have been determined for the two grades containing 0·3 wt% Al and 1·5 wt% Al compressed at different stress values in a temperature range 1850–1950°C. The present study is a part of a more general microstructural investigation performed on several crept polycrystalline SiC materials taking into account creep parameters.

2 Materials and procedure

Two grades of commercial hot-pressed Al-doped α-SiC (Elektroschmelzwerk Company, Kempten,

Results of global analysis for annealed and deformed samples are given. Mean intercept length $\langle L\rangle$, eccentricity e, d_1d_2 ratios and α are displayed for several samples.
Results obtained by the classical intercept method are also given. The mean grain size $\sqrt{\bar{s}}$ and $\langle L_\parallel\rangle/\langle L_\perp\rangle$ ratios are displayed for several samples and should be compared to $\langle L\rangle$ and d_1/d_2 ratios respectively when results are displayed for the two methods.

Germany) have been crept by compression between 1850–1950°C. Aluminium levels were 0·3 wt% and 1·5 wt%. Test samples for creep experiments were obtained by diamond cutting and machining from the as-received discs (75 mm diameter by 25 mm height). Relative positions and orientations of samples inside the original discs were recorded. Indeed, structural and chemical composition variations might be expected between the core and the outer surfaces. Results of the present work have been focused on samples located in the core of the original discs. Samples for creep experiments with dimensions $a \times a \times 3a$ ($8{\cdot}7 < a < 13$ mm) were used and smaller pieces were also cut to serve as reference samples. They were heated with the piece being creep tested. Annealing and creep parameters are given in Table 1, according to the data reported in Ref. 8. Moreover, metallographic sections, which were studied by image analysis methods, were chosen in the middle part of the high-temperature deformed specimens.

3 Image Analysis Method

Automatic image analysis was used to obtain quantitative information on the microstructure of SiC samples. Metallographic sections containing the compressive and/or the hot-pressing directions were etched by the Murakami solution (NaOH + $[Fe(CN)_6]K_3$). Then optical (Olympus BH2) and SEM micrographs (Jeol JSM T330 A) were analysed by using a texture analyser Nachet Microcontrole NS1500.

For this work, two types of morphological data are necessary: the grain size and the grain anisotropy characterized by orientation and shape indices. Before measurements, the video image was thresholded to obtain a binary image (using a top hat transformation). Then binary images were filtered by morphological and geodesical opening. This is followed by a skeletonization by influence zone denoted SKIZ.[19,20] In these conditions, white pixels belong to SiC grains and black pixels to grain boundaries. After SKIZ, the grain boundary thickness was reduced to a thickness of one pixel. After this image processing two types of analyses were used. In the first case, measurements were performed on the binary image itself (global analysis). In the second case, each grain totally included in the image field was separately measured (individual analysis).

For global analysis several parameters have to be chosen. Parameters corresponding to the grain size are obtained by mean intercept measurements by unit length denoted N_L. If V_v is the volumic ratio of the additive phase, the mean grain size $\langle L\rangle$ is given by $(1 - V_v)/N_L$, or $1/N_L$ when the intergranular phase content is negligible. Since a hexagonal lattice of pixels is used in our texture analyser NS1500, the modelization of the grain anisotropy is realized by using an equivalent ellipse associated with the grains. An algorithm given by Serra[20] allows the associated ellipse to be defined by means of parameters which have been indicated in Fig. 1. The minor and the major axes of the ellipse denoted d_1 and d_2 are related to the eccentricity value e of the ellipse following the

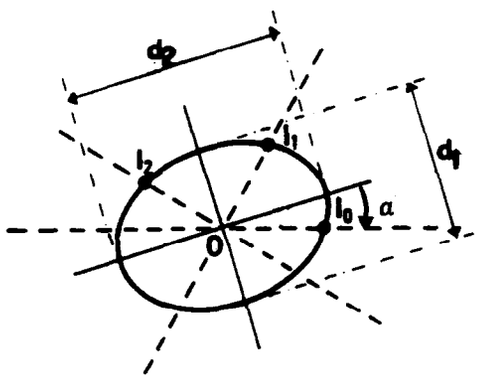

Fig. 1. Equivalent ellipse associated to the grains with its parameters.

relation:

$$e = \sqrt{1 - \frac{d_1^2}{d_2^2}} \tag{1}$$

The angle α is related to the orientation of the major axis d_2 with respect to a reference direction.

Because measurements are made in a hexagonal lattice of pixels, three intercept values N_L are determined in the three main directions (0, $\pi/3$, $2\pi/3$) (Fig. 1). Then a conic can be drawn passing through I_0, I_1 and I_2 (denoted in Fig. 1). I_0, I_1 and I_2 are expressed in a polar coordinate system. In the present case an elliptic model is always obtained.

The same type of parameters (grain size $\langle L \rangle$, eccentricity e and orientation α) have been determined by individual image analysis methods. Results are displayed either by cumulative or frequency distributions. The grain size d is given by the equivalent diameter of the surface area of each grain. The equivalent ellipse of each grain is obtained by the same algorithm as the global analysis method by using a hexagonal convex hull of each grain in order to minimize the noise of grain boundaries. By individual analysis it is possible to draw grain size and angle distributions. This information may be different from the previous one obtained by global analysis since, for example, anisotropic grains can give an isotropic texture if the grains are distributed in all directions.

This last point is illustrated in the schematic representation of Fig. 2 where anisotropic grains have been randomly orientated in Fig. 2(a). By contrast, anisotropic grains have been drawn in a preferential orientation in Fig. 2(b). In both cases (Fig. 2(a) and (b)) the individual analysis method does indicate that grains have an anisotropic shape. However, by global analysis, examples of Fig. 2(a) and (b) will be found to be isotropic and anisotropic respectively.

In parallel to this automatic method, other metallographic sections of several samples were also analysed by a classical intercept method. In this last method only average section area $\bar{s}$ and intercept values in two perpendicular directions related to the hot-pressing direction P or to the compressive stress σ are measured. Thus this method gives only two morphological parameters: the mean grain size $\sqrt{\bar{s}}$ and $\langle L_{\parallel} \rangle / \langle L_{\perp} \rangle$ ratios.

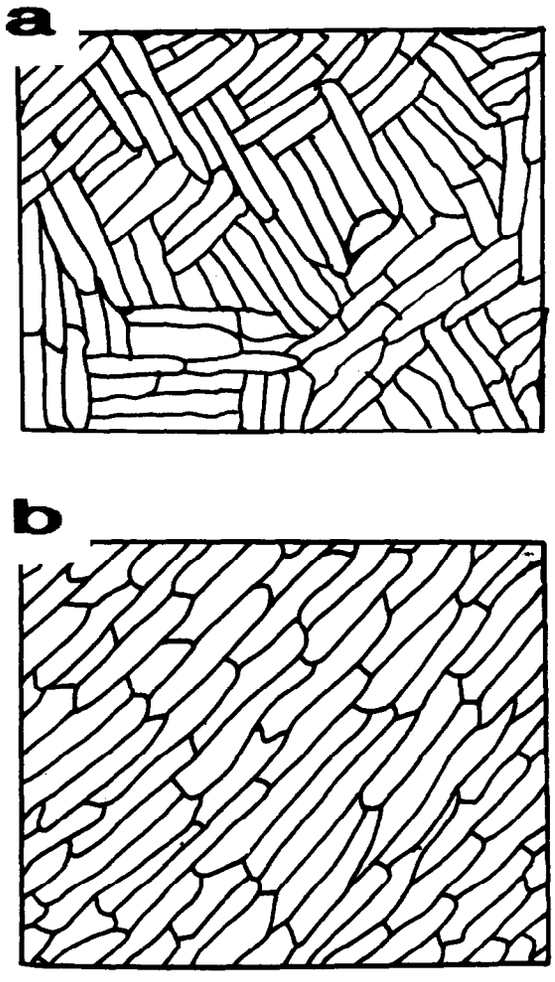

Fig. 2. Schematic representation of (a) anisotropic grains and isotropic structure; (b) anisotropic grains and anisotropic structure.

4 Results and Discussion

All specimens analysed are listed in Table 1. Two grades of SiC-Al additives samples are reported. For each grade, the as-sintered and two or three annealed samples with their deformed states have been studied. So this group is considered to be representative for the study of microstructural modifications occurring during these five creep experiments performed in a very short range of temperatures and stresses. Moreover, as shown in Table 1, results obtained from the automatic and the classical intercept methods are reported for several samples.

In Section 4.1 the main microstructural evolution is described from optical or SEM micrographs of each sample.

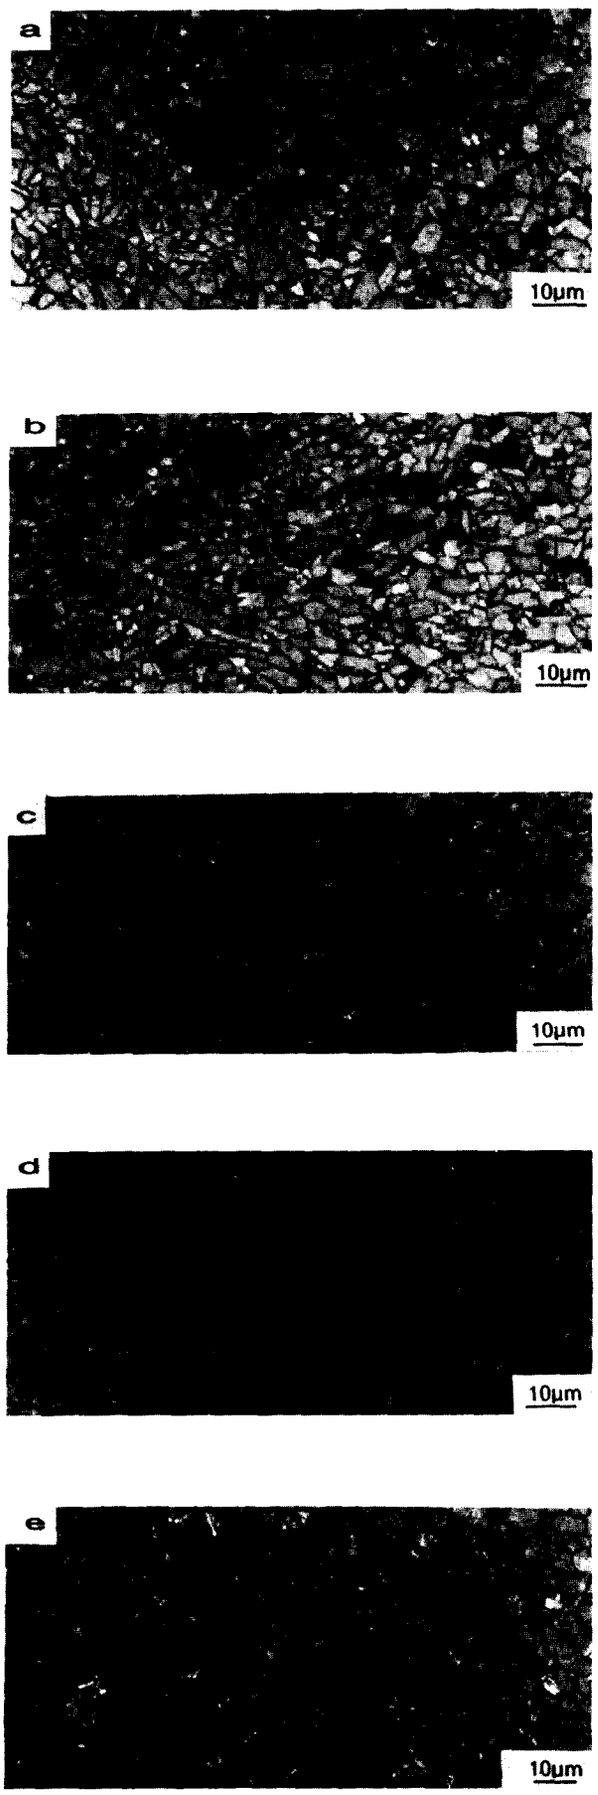

Fig. 3. Optical micrographs of the 0·3 wt% grade. (a) Sample 1 annealed at 1900°C. P is the direction of the stress acting during the sintering. (b) Sample 2 deformed with an overall strain ε_f = 0·25. The direction of the compressive stress σ is indicated. (c) Sample 3 annealed at 1950°C. (d) Sample 4 deformed with an overall strain ε_f = 0·428. (e) Same sample as in (d) but shown perpendicularly to the external stress σ.

4.1 Qualitative analyses of annealed or deformed specimens

4.1.1 Al grade (0·3 wt%)

Optical micrographs of the 0·3 wt.% Al grade are presented in Fig. 3. The two reference states (1 and 3) with their corresponding deformed specimens (2 and 4) are shown in Fig. 3(a) to (e). The hot-pressing stress direction P as well as the compressive stress direction σ have been indicated on each micrograph. Metallographic sections of deformed specimens contain the compressive stress direction σ. Moreover, a metallographic section perpendicular to σ is also given for the sample 4 (Fig. 3(e)). These optical micrographs are good enough to visualize all grain boundaries. However, in order to increase the contrast, it has been necessary to draw in dark ink all grain boundaries being acquired. The dark pockets which can be seen on these micrographs are likely to be due to the presence of the additives used during the sintering process.

In all deformed specimens, no significant grain growth could be detected by comparison with annealed samples. It appears that grains have a tendency to flatten in a direction perpendicular to the external stress σ after the compressive test (Fig. 3(b) and (d)). This is quite clear for sample 4 (Fig. 3(d)) which has the highest strain value (0·43). For the same sample the section cut perpendicularly to σ (Fig. 3(e)) shows grains with a quasi-equiaxed shape. This indicates that grains viewed in a cross-section containing σ can be probably described by an elliptic shape. Thus the large axis is located in a plane normal to σ. By contrast, no preferential orientation of the grains with respect to P is clearly visible in the reference state 3 (Fig. 3(c)). However, grains appear slightly elongated in a direction perpendicular to P (sample 1, Fig. 3(a)).

4.1.2. Al grade (1·5 wt.%)

For this grade the optical method was not suitable because the grain size is twice as small as the grain size of the 0·3 wt.% Al grade. Thus the SEM method was chosen. Micrographs of samples 5, 6 and 7 are given in Fig. 4(a)–(c). The reference state (5) is displayed in Fig. 4(a) and the two deformed samples (6 and 7) in Fig. 4(b) and (c).

Compared to the other grade (0.3 wt.%), it seems that no grain shape modification has appeared in the two deformed samples even for sample 6 which has a high strain value (0·43) and has been deformed under 88–102 MPa.

4.2 Image analysis results

Qualitative results displayed in Section 4.1 have been quantified either by global or individual image analysis.

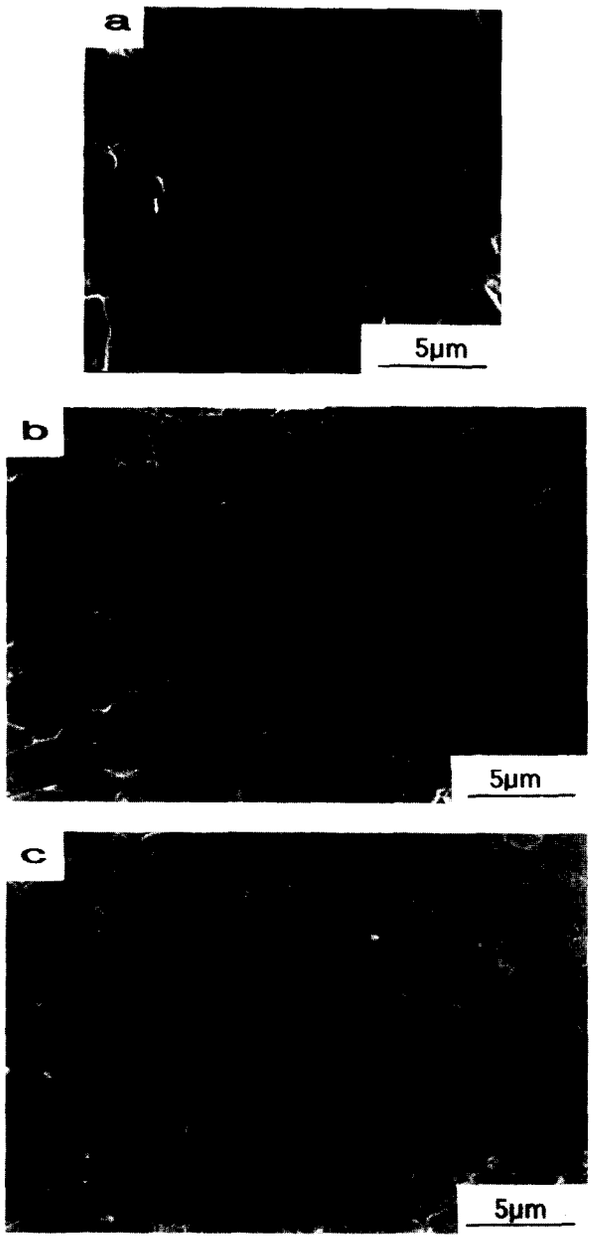

Fig. 4. SEM micrographs of the 1·5 wt% grade. (a) Sample 5 annealed at 1900°C. (b) Sample 6 deformed with an overall strain ε_f = 0·274. (c) Sample 7 deformed with an overall strain ε_f = 0·43. P and σ stress directions have been indicated on each micrograph.

4.2.1 Global analysis

Due to the two different techniques used in this work, i.e. optical and SEM, the number of analysed grains is more than 1500 for the 0·3 wt% grade and about 800 for the 1·5 wt% grade, which is enough to obtain quantitative data. Results of global and classical intercept analyses are in good agreement if $\langle L \rangle$ and d_1/d_2 ratios (global analysis) are compared with $\sqrt{s}$ and $\langle L_\parallel \rangle / \langle L_\perp \rangle$ ratios (classical intercept method) respectively (Table 1).

4.2.1.1 Al grade (0·3 wt.%). The mean grain size value is equal to ~3 μm and a very slight grain growth is observed for sample 4 (3·12 μm) compared to its reference state, sample 3 (2·58 μm).

The reference states (samples 1 and 3) are equivalent in terms of eccentricity and correspond to a quasi-equiaxed structure with d_1/d_2 ratios close to 0·9. For the two deformed specimens, d_1/d_2 ratios deduced from the eccentricity values are 0·73 (sample 2) and 0·61 (sample 4). As a comparison, a ratio d_1/d_2 equal to 0·5 corresponds to an eccentricity value of 0·86. For the reference states (samples 1 and 3) the α values do not indicate a clear preferential orientation with respect to the hot-pressing stress. By contrast, it is clearly demonstrated that, as previously suggested on the micrographs, deformed grains tend to align perpendicularly to σ (α = 1·5° (sample 4) and α = 4° (sample 2)). Consequently the minor axis of the equivalent ellipse denoted d_1 is found to be parallel to the external stress. Thus, in the following, d_1 and d_2 are denoted $d_\parallel$ and $d_\perp$ respectively.

Moreover, if grain growth is negligible, it is possible to define the grain deformation ε_g by the formula

$$\varepsilon_g = \ln (d_\parallel / d_0) \tag{2}$$

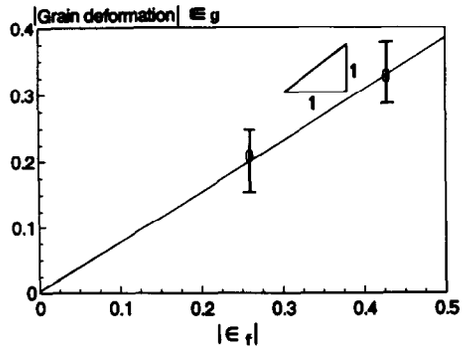
where $d_\parallel$ and d_0 are respectively the diameter parallel to the external stress and the grain diameter of the undeformed specimen.[21]

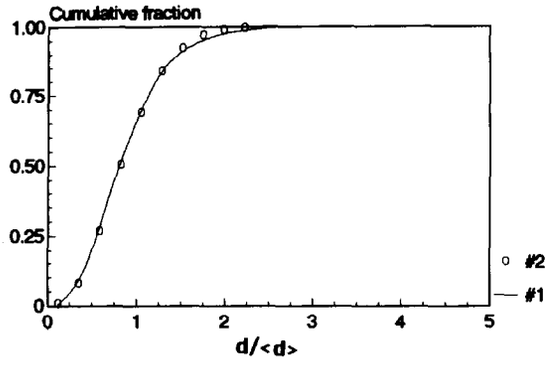
If the volume of grains remains constant before and after the grain deformation, the relation between $d_\parallel$ and $d_\perp$ and d_0 can be written $d_\parallel \cdot d_\perp^2 = d_0^3$. Then the grain deformation ε_g becomes

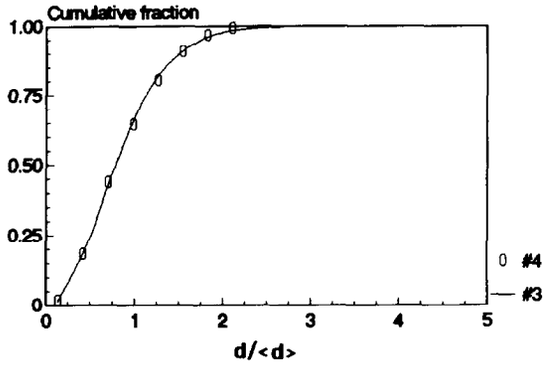
$$\varepsilon_g = 2/3 \ln (d_\parallel / d_\perp) \tag{3}$$

Grain, deformation is theoretically calculated from a quasi-equiaxed initial shape. Because grains are slightly elongated in the as-sintered state, the calculation underestimates the grain deformation.

Grain deformation ε_g and the total strain of the sample ε_f values are reported in Fig. 5 (samples 2 and 4). This curve shows that grains follow approximately the same shape change as the sample at the macroscopic level. Thus the slight grain growth observed for samples 2 and 4 (Table 1) does not affect the result shown in Fig. 5.







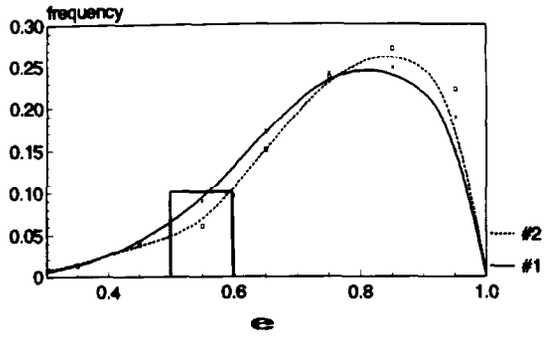


Fig. 5. Evolution of the grain deformation ε_g with the overall deformation of the sample ε_f : ε_g = 2/3 ln ($d_\parallel/d_\perp$).

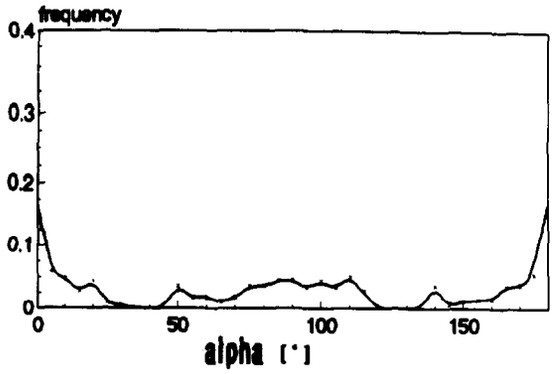
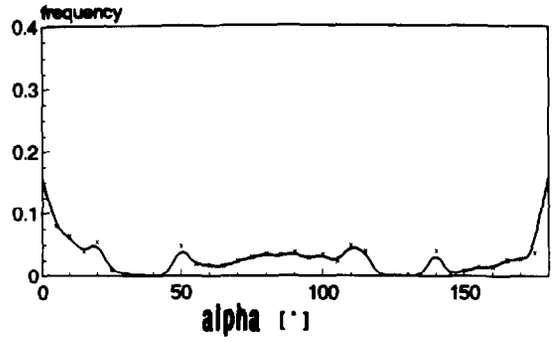
Frequency distributions of the eccentricity e (c) for samples 1 and 2 and (d) for samples 3 and 4. The value of the class used in these frequency distributions has been drawn in (c) and (d).



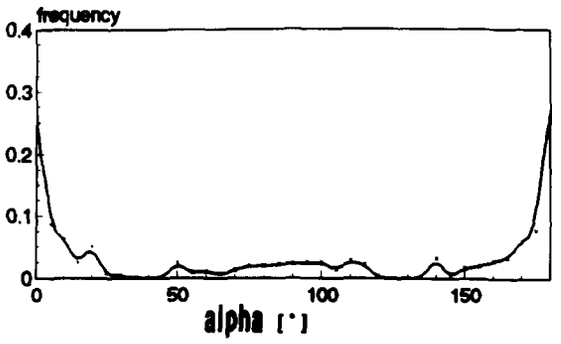
4.2.1.2 Al grade (1·5 wt%). For this grade, the grain size of annealed and deformed specimens is found to be close to 1·5 μm. The reference state (sample 5) exhibits an anisotropy of the grain shape in contrast to the preceding cases (samples 1 and 3). It can be noted that the deformed specimens, even the most deformed one (sample 7), have the same eccentricity values as the reference state (e ~ 0·7). Consequently the grain deformation cannot be correlated to the overall deformation of the sample. These results are in agreement with the α values, found to be nearly equivalent for the three samples (5, 6, 7). This indicates that no strong preferential orientation has occurred during the creep tests.

Finally the grain size $\langle L\rangle$ and d_1/d_2 ratios of the two grades in the as-sintered state have been found to be equal respectively to: $\langle L\rangle = 2$ μm, $\langle L_\parallel\rangle/\langle L_\perp\rangle = 0{\cdot}83$ (0·3% Al grade) and $\langle L\rangle = 1{\cdot}1$ μm, $\langle L_\parallel\rangle/\langle L_\perp\rangle = 0{\cdot}71$ (1·5 wt.% Al grade) (Table 1). By comparison with values concerning annealed samples (1, 3, 5, 8), it appears that a slight grain growth has occurred during the annealing treatments for the two grades.

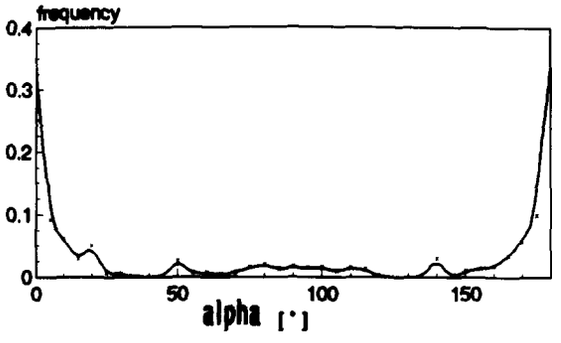


4.2.2 Individual analysis

4.2.2.1 Al grade (0·3 wt%). Results concerning the grain size and the grain shape are given in Fig. 6. Cumulative fractions of the normalized equivalent grain diameter $d/\langle d\rangle$ are given in Fig. 6(a) (samples 1 and 2) and in Fig. 6(b) (samples 3 and 4). Frequency distributions of the eccentricity e are shown in Fig. 6(c) (samples 1 and 2) and in Fig. 6(d) (samples 3 and 4). The main evolutions of these two parameters (d and e) are in agreement with the results of the global analysis. Particularly, for the two deformed samples, the eccentricity values, displayed by frequency curves, are shifted towards higher values. In fact these displacements can be evaluated by the mode values for each curve. For the most deformed specimen (sample 4, Fig. 6(d)), the mode value is found to be 0·9 compared to 0·75 in the annealed state (sample 3) which is significant, taking into account the value of the class of the distribution curve (0·1), indicated on Fig. 6(c) and (d). Therefore the slight variation of the mode found for samples 1 and 2 (0·80 to 0·85) is less significant. On the other hand, the cumulative curves of grain size distribution are close to a normal logarithmic law and seem not to be affected by thermomechanical treatments.

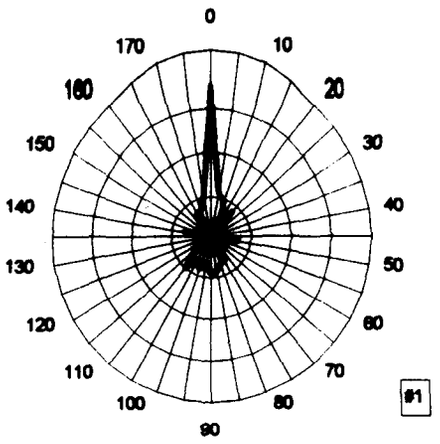


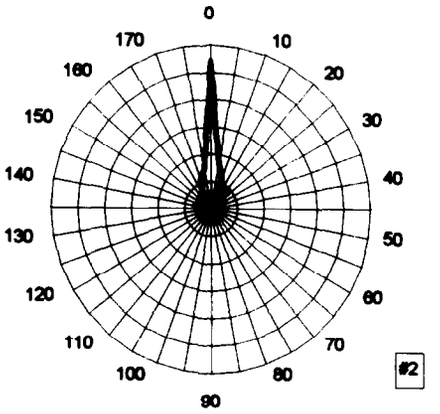
Moreover, the distribution of α values is displayed in Fig. 7 for the four samples. A difference is visible between the distribution curves of references (samples 1 and 3, Fig. 7(a) and (b)) and deformed states (samples 2 and 4, Fig. 7(c) and (d)).



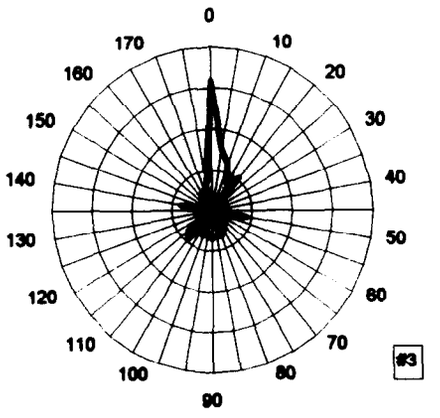
(a)

(b)





(c)



(d)

Fig. 7. Frequency distributions with respect to the angle α for the references (samples 1 and 3, (a) and (b)) and for the deformed states (samples 2 and 4, (c) and (d)).

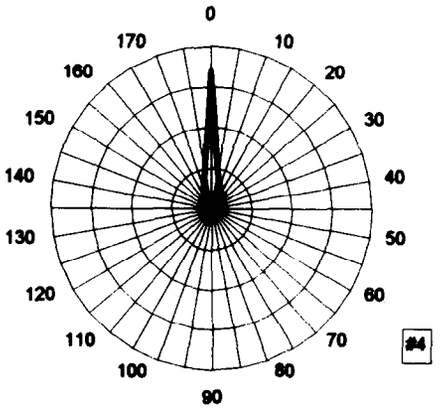


Fig. 8. Frequency distributions with respect to the angle α for the references (samples 1 and 3) and for the deformed states (samples 2 and 4) in a rose representation.

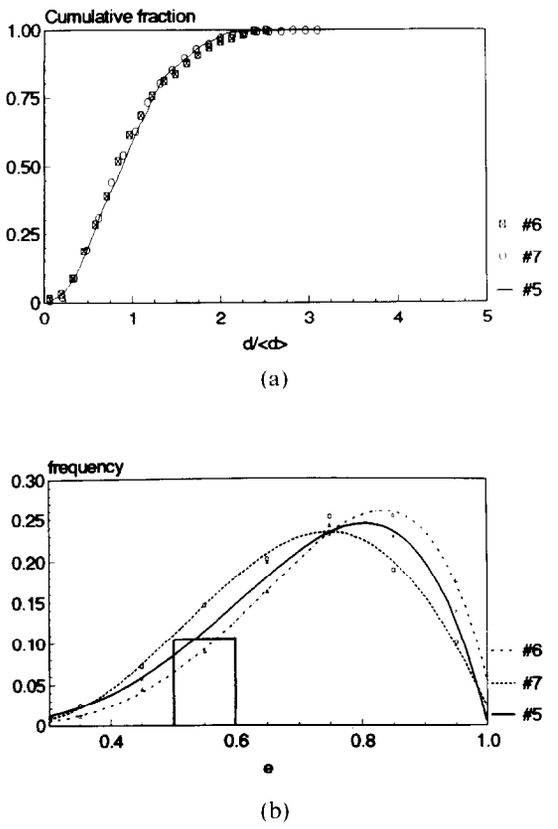

Fig. 9. Cumulative fractions with respect to the normalized equivalent grain diameter $d/\langle d\rangle$ (a) and frequency distributions with respect to the eccentricity e (b) for samples 5, 6 and 7. The value of the class has been drawn in (b).

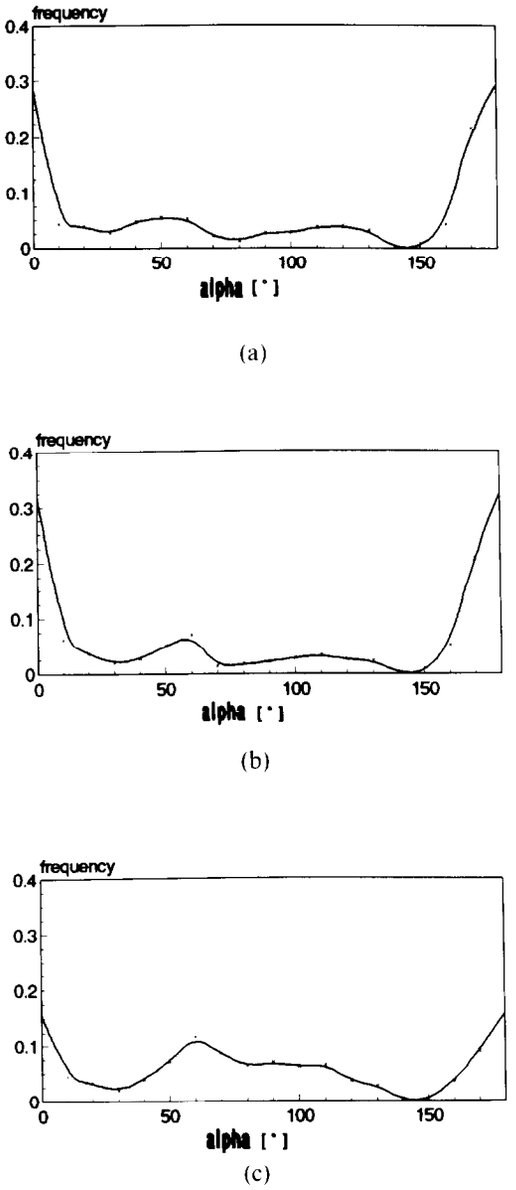

Fig. 10. Frequency distributions with respect to the angle α for samples (a) 5, (b) 6 and (c) 7.

In the curves corresponding to the two deformed states (Fig. 7(c) and (d)), it can be noticed that the number of grains for which α is close to 0° or 180° progressively increases with the deformation value, which is in agreement with the global analysis. This indicates that grains are preferentially orientated perpendicularly to the compressive stress σ.

These results are also displayed in a rose representation (Fig. 8). For the reference states (samples 1 and 3) grains are orientated in all directions. However, a maximum value of frequency is found close to 0°–180°. This indicates a slight preferential orientation of grains perpendicularly to P. This result was not clearly established by global analysis. As expected for the deformed specimens (samples 2 and 4) the majority of the grains are more preferentially orientated close to 0–180°.

4.2.2.2 Al grade (1·5 wt%). The cumulative distributions of the normalized equivalent grain diameter $d/\langle d\rangle$ (Fig. 9(a)) and the frequency curves of the eccentricity (Fig. 9(b)) (samples 6 and 7) seem not to be affected by the creep tests compared to the reference (sample 5). Taking into account the value of the class (0·1) for eccentricity, the slight shift of the modes for deformed samples is not significant compared to the reference state (Fig. 9(b)). On the other hand, if the distribution curves of α values for the three samples (5, 6 and 7, Fig. 10) are compared, sample 7 exhibits a different behaviour in terms of a decrease of the number of grains for which α is close to 0°–180°C. Consequently, grains of sample 7 (Fig. 10(c)), which is highly deformed, tend to be orientated in all directions.

The difference in distribution curves of α values for the three samples can be understood by the existence of a slight preferential orientation with respect to the stress P in the reference state (sample 5, Fig. 10(a)). Grains seem to have been reorientated with their large axes normal to the stress direction σ in sample 6 (Fig. 10(b)) while such orientated texture is not observed in sample 7 (Fig. 10(c)). These results for samples 5, 6 and 7 are also displayed in Fig. 11 in rose representations.

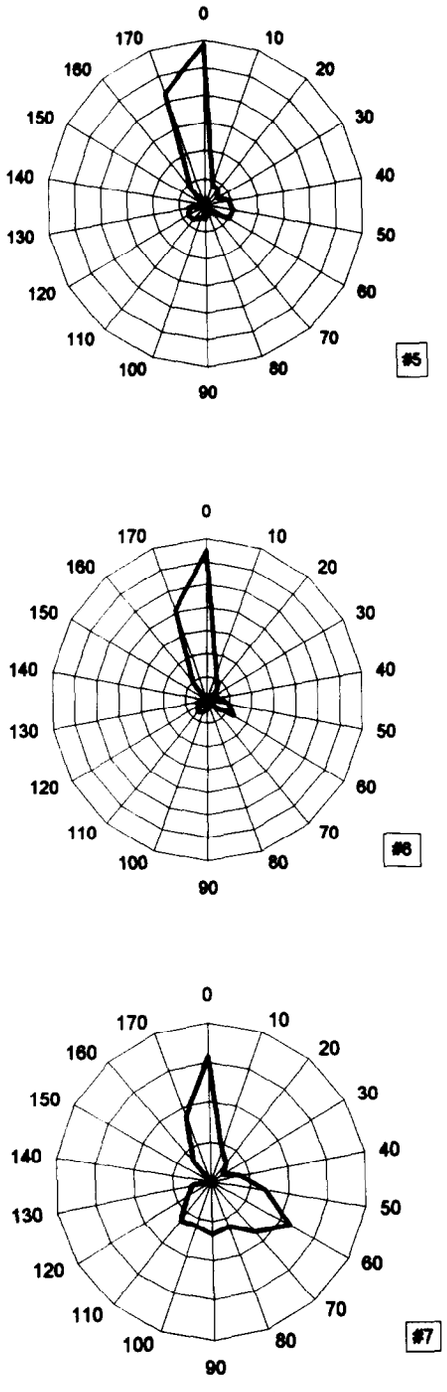

Fig. 11. Frequency distributions with respect to the angle α for samples 5, 6 and 7 in a rose representation.

5 Concluding Remarks

In this work, the microstructures of two SiC grades (0·3 and 1·5 wt% Al) have been characterized by automatic image analysis methods. Results of global and individual image analyses are in good agreement. The slight grain growth observed in annealed or deformed samples compared to the statistical scattering of the grain size does not allow a kinetic law of grain growth to be drawn in these experiments. The main results of the present work are the observation of a grain shape modification and a grain reorientation with respect to the external stresses which can be summarized as the following: grains of the deformed 0·3 wt% Al grade tend to flatten perpendicularly to the external stress. This was deduced from the eccentricity and α angle values (Table 1), showing that grains viewed in a cross-section containing σ can be described by an elliptic model. The other grade (1·5 wt%) exhibits a different microstructure evolution for a same deformation temperature range. Indeed, even for a high macroscopic deformation value, grains do not show any shape change after the creep test. Consequently, no texture formation could be found. All these results are important to understand the mechanical behaviour of these two SiC grades but further microstructural characterizations should be performed by TEM and microanalyses. Nevertheless, at this stage of the work, some hypotheses concerning the deformation mechanisms can be put forward:

(i) Al–SiC grade (0·3 wt%)
Different mechanisms could explain the fact that grain deformation follows approximately the specimen deformation as is demonstrated in this work (Fig. 3). A first mechanism is based on an important intragranular dislocation activity. SiC crystals exhibit mainly the hexagonal polytype (4H) and only one slip system (basal plane) is known to be the most activated.[13] This can induce the formation of a crystallographic texture. TEM observations[22] have effectively confirmed that grain boundaries tend to be parallel to the basal plane and normal to the stress direction. Moreover, an extended dislocation activity has also been analysed in detail in this deformed sample.[22] Consequently, an intragranular dislocation mechanism seems to be more favoured than a pure diffusion process which might also explain the grain shape change for this grade. Because no cavitation is observed, the grain boundary deformation has to be also accommodated either by an intergranular dislocation glide and/or by some diffusional matter transport via an intergranular film. Microanalyses and HREM experiments are still in progress to confirm effectively the presence of a thin intergranular film.

(ii) Al–SiC grade (1·5 wt%)
Compared to the preceding case, the mean grain size of the 1·5 wt% Al–SiC grade is now twice as small (Table 1). Because no grain shape change occurs the contribution of an intragranular dislocation activity to the overall deformation might be much lower than for the previous SiC grade. Moreover, as shown in Fig. 10, grains of the most deformed specimen (sample 7) are now dis-

tributed in all directions and have lost the slight preferential orientation observed by image analysis in the reference state (sample 5). These results suggest that an important rearrangement of grains has occurred during the deformation. All these data are in agreement with a superplastic-like behaviour for this grade as was previously suggested.[8] Because no cavitation is observed, stress accommodation could be relieved via diffusion and/or intergranular dislocation generation. Further observations in TEM should be performed to ascertain the exact mechanism.

(Received 19 November 1993; accepted 13 June 1994)

Abstract

The inhibitory role of HCl and oxygen in the chemical vapour deposition of SiC-based ceramics from the Si–C–H–Cl system, is pointed out in terms of nucleation and growth process on the basis of experimental and theoretical approaches. The addition of HCl to methyltrichlorosilane MTS–H_2 gaseous precursors (i) decreases the nucleation and growth rate, (ii) induces a transition from a diffusion to a reaction rate control of the deposition process, (iii) improves the smoothness of the films surface, (iv) results in a transition from anisotropic films with columnar microstructure and Si, C and O concentration gradients to nanocrystallized materials with quite constant Si, C and O contents. These behaviours are tentatively explained by assessments of the gas phase supersaturation and calculations of the chemisorbed layer composition. The occurrence of oxygen within the nanocrystallized films is then related to the growth inhibition effect and the presence of silicon excess shown by EELS analyses.

1 Introduction

Chemical vapour deposition (CVD) is a suitable technique to prepare silicon carbide films of high quality. Owing to its good thermal, mechanical and chemical properties, SiC is used as a ceramic matrix in fibre-reinforced ceramic–ceramic composites elaborated by chemical vapour infiltration (CVI), a technique which derives directly from CVD.[1,2]

Most of SiC-depositions involve the Si–C–H–Cl chemical system. The organometallic compound CH_3SiCl_3 (MTS) is often used as precursor partly for its ability to be decomposed at moderate temperatures (which usually favours the CVI process), and partly for economical reasons.[3–6]

A model was proposed recently to simulate and optimize the homogeneity and the rate of the infiltration in a single straight cylindrical pore.[7] This model, when applied to the CVI of SiC in the MTS–H_2 system,[8] pointed out the fundamental role of HCl in the control of the quality of the infiltration. Hydrogen chloride is successively produced by (i) the homogeneous decomposition of MTS precursor and (ii) the heterogeneous reaction of SiC deposition from carbon and silicon intermediate species.[9] The infiltration gradient along the pore is related to the HCl concentration which is found, at the pore centre, to be very similar to those of source species at the entrance.[8]

The first purpose of the present paper is to assess the influence of HCl content in the precursor gas mixture on: (i) the nucleation and growth processes and (ii) the physico-chemical nature of the deposits performed on an amorphous SiO_2 substrate. The effects resulting from a HCl excess will be discussed on the basis of supersaturation estimates and chemisorption calculations.

Under well-defined conditions, the MTS–H_2 precursor provides nanocrystalline SiC films with silicon excess and a small amount of oxygen.[10] The second purpose of this article is to correlate the silicon excess (and oxygen content) with the growth rate, through chemisorption data previously calculated.[11] Finally, a structural model will be proposed for these nanocrystalline SiC-based ceramic films, built on EELS analyses including both valence and inner-shell electron excitations.

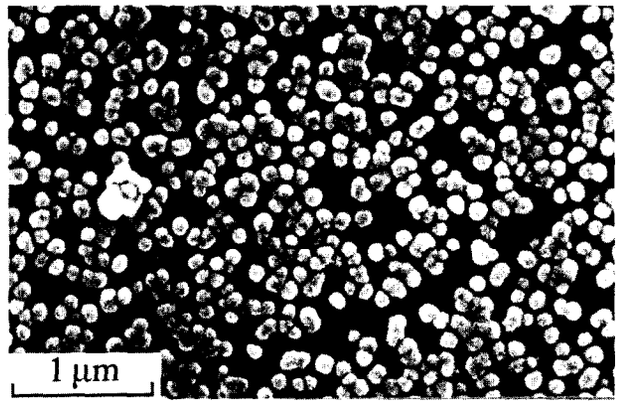
2 Experimental

The various procedures and equipments which have been used for both the nucleation/growth experiments and the physico-chemical characterization of the films, have been described in detail in Ref. 10.

The deposition experiments were performed in a vertical hot-wall CVD reactor working under reduced pressure. The initial composition of the MTS–HCl–H_2 gas precursor is given by α and δ defined as follow:

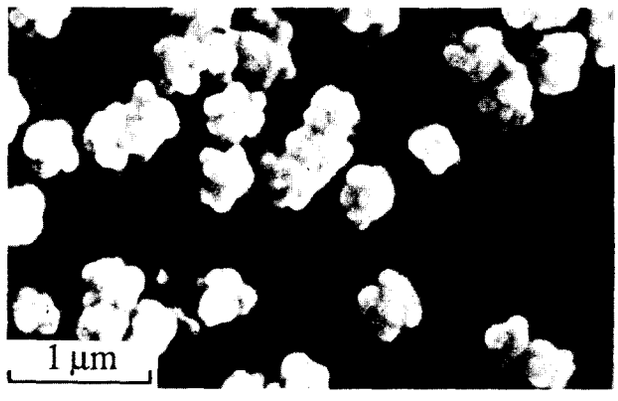
$$\alpha = \frac{P_{H_2}}{P_{MTS}} = \frac{Q_{H_2}}{Q_{MTS}} \quad (1)$$

$$\delta = \frac{P_{HCl}}{P_{MTS}} = \frac{Q_{HCl}}{Q_{MTS}} \quad (2)$$



where P_i, and Q_i are the initial partial pressures and flow rates of species i. A microbalance was used to detect the transient and steady-state stages in the deposition process and to determine the various growth rates. The substrates were amorphous silica layers obtained by oxidizing silicon wafers. To investigate the nucleation process, very short experiments were carried out, followed by (i) SEM observations of the resulting nuclei and (ii) determination of the nucleation characteristics such as the saturation nucleus density N_S, the saturation nucleus size ϕ_S and the nucleation rate I.[10]

After a first microstructural approach by SEM and X-ray diffraction, transmission electron microscopy (TEM) (bright-field and dark-field observations and selected area electron diffraction) combined with local (60 or 30 nm diameter probe sizes) electron energy loss spectroscopy analysis (EELS) were used for a description of the SiC-based films at a nanometric scale. The local chemical and structural organization of the films was investigated by using core excitations (Si-L, C-K and O-K edges) and volume plasmon characteristic signals.



3 Influence of HCl Content on the Deposition Process of SiC-based Ceramics

3.1 Nucleation process

When the initial MTS–H_2 mixture contains HCl, the initial stages of the deposition are highly modified. As shown in Fig. 1, for T = 1100°C, P = 3 kPa and α = 30, the SiO_2 surface is not totally covered by SiC-based deposit after an exposure of 2600 s to a MTS–H_2–HCl mixture (with δ = 0·5), while the saturation is almost performed after 45 s of exposure to MTS–H_2 mixture (with δ = 0). An important decrease of the nucleation rate from $2{\cdot}5 \times 10^{12}$ to 3×10^8 is readily achieved by adding 50% HCl to the MTS source, but a further increase of HCl initial concentration does not modify the nucleation rate any longer. Moreover, when δ = 0·5, nuclei are not adjacent but form aggregates from only a few sites. This result can be correlated with an inhibition effect of HCl on a SiO_2 surface.

(a)

(b)

Fig. 1. SEM pictures of nucleus density observed on SiO_2 substrates for T = 1100°C, α = 30, P = 3 kPa and (a) δ = 0 and after an exposure time of 45 s, and (b) δ = 0·5 after an exposure time of 2600 s.

3.2 Growth kinetics

When the steady state is reached, the deposition rate can be deduced from the slope of the mass–time curves. The variations of this rate as a function of HCl partial pressure (ratio varying from 0·1 to 1) are plotted in Fig. 2 for α = 10, P = 3 kPa and two temperatures (1000 and 1100°C). The growth rate is observed to decrease when δ increases above 0·2. This result confirms the inhibition effect of HCl, previously mentioned for the nucleation process.

To identify the kinetic regime of the deposition, the growth rate was studied as a function of the temperature and the total flow rate, for two initial compositions of the gas phase ((i) α = 10 and δ = 0, (ii) α = 10 and δ = 1), the total pressure being 3 kPa, the temperature ranging from 1000 to 1125°C and the total flow rate from 200 to 550 sccm (Figs 3 and 4). When δ = 0, the deposition rate does not depend significantly on the temperature (Fig. 3) and it increases continuously with the total flow rate (Fig. 4). This behaviour is typical for a kinetic

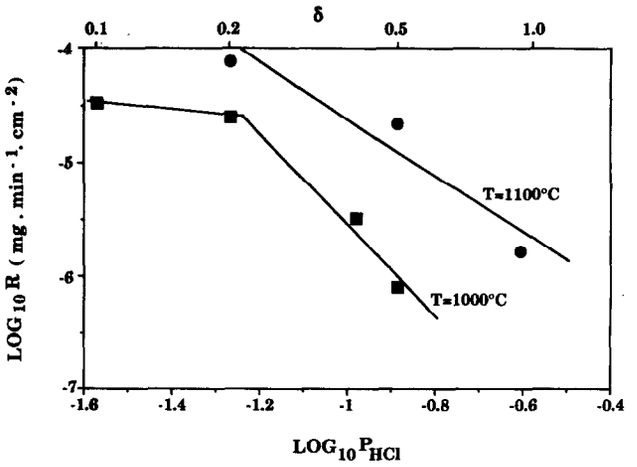


Fig. 2. Variations of the deposition rate R versus HCl partial pressure PHCl and δ ratio for α = 10, P = 3 kPa and ■, T = 1000°C; ●, T = 1100°C.

process controlled by mass transport, e.g. by diffusion through a boundary layer. When δ = 1, the growth rate decreases exponentially with the reciprocal temperature and does not depend on the total flow rate. This second behaviour, which corresponds to a kinetic control by the surface reactions, can be explained by a decrease of the heterogeneous reaction rate due to the inhibition effect of added HCl. As a consequence, the addition of HCl to the gaseous precursor results in a transition from a diffusion rate control to a reaction rate control of the deposition of SiC-based ceramics. This type of transition was already evidenced for BN deposition in the B–N–H–F system: it was induced by variations of the temperature, the total pressure and also the initial composition of the gas phase.[12,13]

3.3 Physico-chemical characteristics of the deposits

As demonstrated in a related paper, the change in the kinetic regime of SiC-based ceramic deposition has a great influence on the microstructure of the films.[10] When a diffusion-controlled kinetic process is changed to a reaction-controlled one (by

varying temperature and/or total pressure), a transition occurs from a crystallized film with columnar crystals to a nanocrystalline deposit. Thus, a detailed experimental investigation was performed in order to show whether the kinetic transition presently induced by adding HCl to the initial gas mixture results or not in similar microstructural changes.

3.3.1 Morphology and microstructure

The surface morphology of the films deposited for 1100°C, α = 10 and P = 3 kPa is influenced by the addition of HCl to the MTS–H_2 mixture (Fig. 5).

(a)

(b)

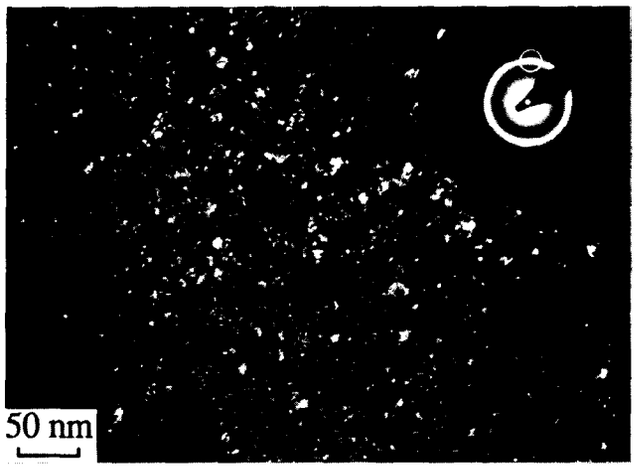
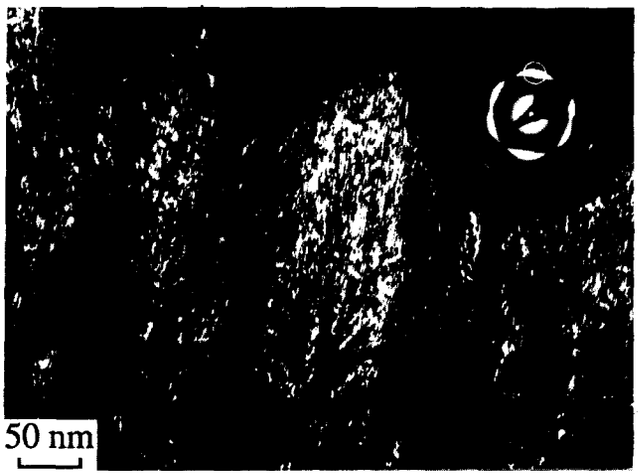
Table 1. X-Ray (CuK_α) analyses of SiC-based deposits on SiO_2 substrates for T = 1100°C, α = 10, P = 3 kPa and various δ ratios



δ	0	0·2	0·5	*References from ASTM tables*
Crystallite size (nm)	14	11	7	
I^a (111) (% a.u)	100	100	100	100
I^a (220) (% a.u)	1·5	2	8	63

[a] $I_{(111)}$ and $I_{(220)}$ represent respectively the intensities of the (111) and (220) diffraction lines.



When δ is raised from 0 to 0·5, i.e. when the kinetics become controlled by the surface reactions, the roughness of the surface is decreased, a feature which is consistent with previous results reported in Ref. 10 for SiC and Ref. 12 for BN deposition.

X-Ray diffraction analyses of the films deposited under the same T, P, α conditions for δ = 0, 0·2 and 0·5 show again the preferred growth of silicon carbide along the ⟨111⟩ crystallographic direction perpendicular to the substrate surface (Table 1). Nevertheless, the increase of HCl content in the gas phase seems to weaken this textural effect. The Scherrer formula, applied to the (111) X-ray diffraction line of the diffraction patterns without taking into account the internal stress effect, leads to crystallite apparent sizes decreasing with increasing δ values.

The nanostructure of the films prepared under the same T, P, α values and without HCl in the precursor changes when moving from the interface with the substrate to the external surface, as supported by TEM observations. Figure 6 shows dark-field images obtained by selecting with the objective aperture a part of the first electron diffraction ring (mainly SiC (111)). In the observation, close to the substrate, a nanocrystalline material is shown with isotropic grains of about 5 nm in size (Fig. 6(a)). From 500 nm away from the substrate, an anisotropy is observed, giving rise to a slightly columnar microstructure (Fig. 6(b)). Conversely, when δ = 0·5, no microstructure variation is observed through the thickness of the film (Fig. 7): the whole deposited material being nanocrystalline and rather homogeneous.

(a)

(b)

Fig. 6. Dark-field images and SAD patterns (inserts) of a SiC-based deposit on a SiO_2 substrate for T = 1100°C, α = 10 and P = 3 kPa, (a) near the substrate, (b) at 1 μm from the substrate.

3.3.2 Chemical composition

The relative concentrations of Si, C and O have been assessed by local EELS analyses which were carried out as a function of d, the distance from the substrate/deposit interface, for the samples prepared under the following conditions: T = 1100°C, α = 10, P = 3 kPa and δ = 0 or 0·5.

For the MTS–H_2 precursor (δ = 0), Si and C are present near the deposit/substrate interface in proportions respectively above and below the values corresponding to stoichiometric SiC (Fig. 8(a)). Conversely, from d = 400 nm, the silicon to

Fig. 7. Dark-field image and SAD pattern (insert) of a SiC-based deposit on a SiO_2 substrate T = 1100°C, α = 10, P = 3 kPa and δ = 0·5 at 1 μm from the substrate.

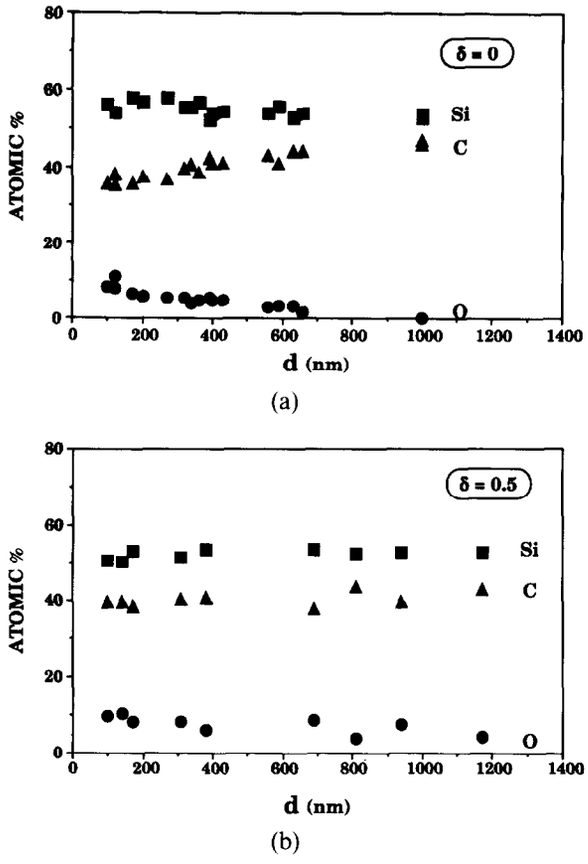


Fig. 8. Variations of Si, C and O contents with the distance d measured between the analysed area and the substrate/deposit interface, in SiC-based films obtained for T = 1100°C, α = 10, P = 3 kPa and (a) δ = 0 and (b) δ = 0·5.

carbon ratio moves towards the stoichiometric ratio. In addition a small amount of oxygen occurs in the deposit close to the substrate and decreases to zero through the thickness of the film.

Conversely, when HCl is added to the initial MTS–H_2 mixture (for δ = 0·5), the chemical composition of the film is almost constant (Fig. 8(b)), which is in accordance with the rather homogeneous nanostructure of the material. Nevertheless, a slight decrease of the oxygen content is observed from the substrate/deposit interface to the external surface of the film.

3.4 Theoretical approach: supersaturation and chemisorption

3.4.1 Assessment of gas phase supersaturation

For T = 1100°C, P = 3 kPa and α = 10, a transition from a diffusion rate control to a reaction rate control of the deposition process is induced by adding HCl to the initial MTS–H_2 mixture. Consequently, when δ is very small (δ < 0·2), the local supersaturation (which represents the departure from heterogeneous equilibrium) close to the substrate, is very low: due to the concentration gradients occurring through the boundary layer, the local gas phase composition is almost given by the heterogeneous equilibrium. Nevertheless, this low supersaturation value cannot be easily calculated under such conditions.

Conversely, when δ is increased beyond 0·2, i.e. under conditions of kinetic regime controlled by surface reactions, the gas phase becomes highly supersaturated near the substrate surface and the calculation of the supersaturation is then possible. It is based (i) on the assumption of rapid homogeneous reactions and (ii) on any heterogeneous reaction giving rise to pure SiC deposition, e.g.:

$$CH_4 + SiCl_2 \rightarrow SiC_{(S)} + H_2 + 2HCl \qquad (3)$$

As detailed in a previous study,[10] the theoretical supersaturation γ can be written as:

$$\gamma = \frac{P_{CH_4} P_{SiCl_2}}{P_{H_2} P_{HCl}^2} \cdot K_P(T) - 1 \qquad (4)$$

where $K_P(T)$ is the equilibrium constant corresponding to the reaction (3) and P_{CH_4}, P_{SiCl_2}, P_{H_2} and P_{HCl} are the partial pressures close to the solid surface calculated under the assumption of the homogeneous equilibrium. γ values were calculated for δ varying from 0·2 to 1 and for various conditions of temperature and pressure. As shown in Fig. 9, in spite of a slight decrease, calculated γ values remain very high ($\gamma > 10^4$) for the investigated range of conditions.

3.4.2 Calculation of the chemisorbed layer composition

On the basis of a previously described approach of the Langmuir chemisorption on amorphous SiO_2 or β-SiC substrates,[11] the composition of the adsorbed layer in the CVD of SiC from the Si–C–H–Cl system was calculated for various HCl contents in the precursor.

Figure 10 shows the variations of coverages θ_i on a SiO_2 surface as a function of δ ratio for the conditions used in the nucleation experiments, i.e. for T = 1100°C, P = 3 kPa and α = 30. A highly

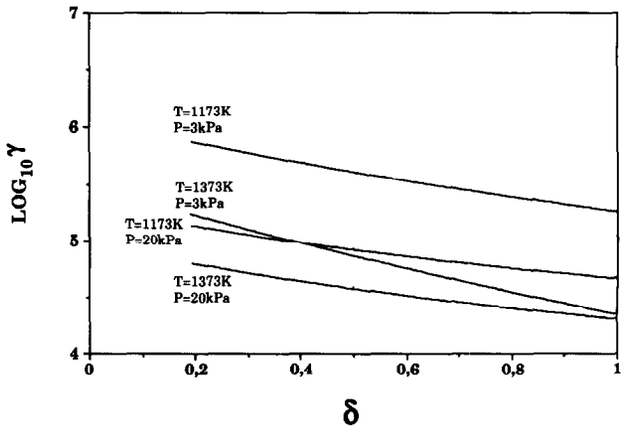

Fig. 9. Variations of the calculated supersaturation γ versus δ ratio ($[HCl]_{in}/[MTS]_{in}$) for various temperature and pressure conditions.

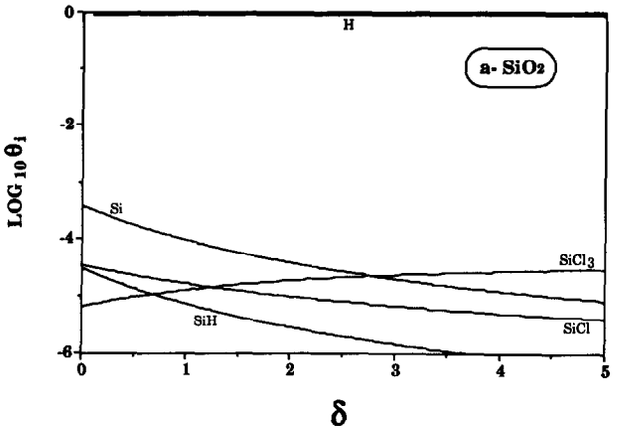

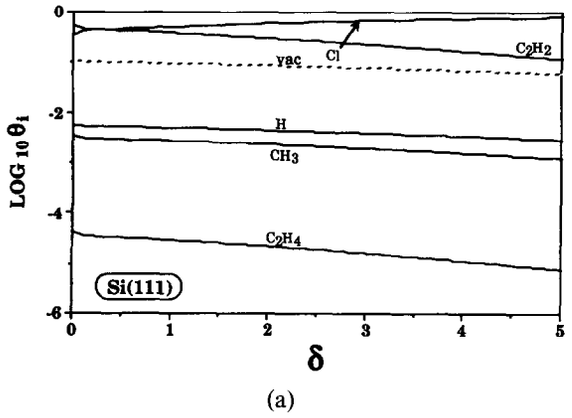

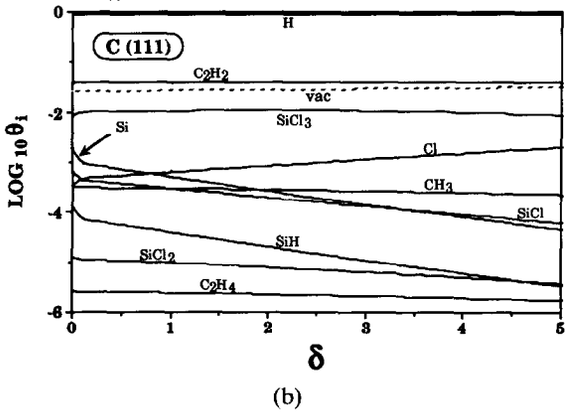

Fig. 10. Coverages of an oxygen plane of amorphous SiO_2 substrate versus δ ratio for T = 1100°C, α = 30 and P = 3 kPa.

dominant coverage is found for H radical over the whole δ range. The only source species coverages (i.e. the silicon containing species), are decreased by raising δ ratio, except for $SiCl_3$. Due to this decrease of silicon species, the addition of HCl to the gaseous precursor enhances the inhibition of the nucleation on a SiO_2 surface.

In Fig. 11, the coverages on a C(111) and a Si(111) plane of β-SiC are represented versus δ for T = 1100°C, P = 3 kPa and α = 30. For the C plane, the dominant adsorbed species are H and to a less extent C_2H_2 and $SiCl_3$ whose coverages are not influenced by δ. An increase of δ results only in the increase of Cl coverage which remains very low. For the Si plane, Cl and C_2H_2 are the main chemisorbed species. Cl coverage increases and the one of C_2H_2 decreases as δ rises. Here again, an inhibition effect of HCl, particularly on the formation of C on a Si(111) plane, is demonstrated by the chemisorption approach.

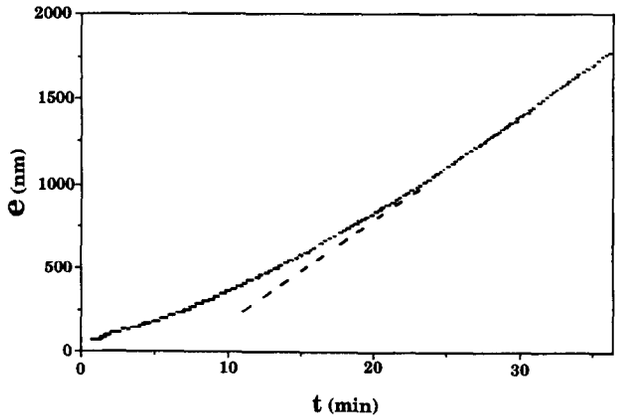
3.5 Discussion

The present experimental and theoretical approach of the SiC-based ceramic deposition permits a correlation stated in a previous study between (i) the supersaturation of the gas phase close to the deposition surface, (ii) the crystallization state and (iii) the surface morphology of the deposit to be confirmed. A high increase of the local supersaturation, presently induced by the addition of HCl to the MTS–H_2 mixture, results in a transition from a deposit with a columnar microstructure and a rough surface to a rather smooth and nanocrystallized film.

The inhibitory effect of HCl is also pointed out in the present study. The nucleation process on amorphous SiO_2 surface is particularly inhibited by HCl. This effect is partly explained by a chemisorption of source species on SiO_2 unfavoured by HCl. The selectivity of the nucleation with respect to the nature of the substrate, reported in a previous paper,[11] is highly increased by introducing HCl in the initial gaseous mixture. A continuous renucleation regime is favoured on silicon carbide rather than on SiO_2, as shown in Fig. 1.

The growth process of silicon carbide itself is highly inhibited by the HCl enrichment of the precursor, a feature which confirms the assumptions proposed in previous investigations of the deposition[14] or infiltration mechanisms for the MTS–H_2



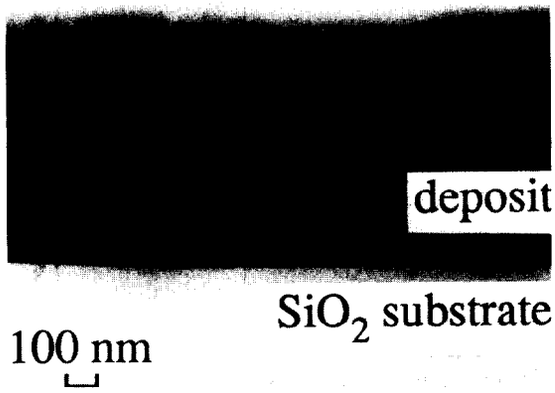


Fig. 12. Mass–time curve recorded during the deposit of a SiC-based film for T = 900°C, α = 3 and P = 3 kPa on a SiO_2 substrate.

system.[8,9] This inhibition can be explained partly by a higher coverage of Cl species on Si(111) planes of β-SiC. On the other hand, one of the main surface reaction assumed to lead to silicon formation from $SiCl_x$ intermediate, $1 \leq x \leq 3$, is probably rate-limited by the corresponding reaction:

$$SiCl_x^* + x/2\ H_2 \rightleftharpoons Si + xHCl + * \qquad (5)$$

where $SiCl_x^*$ represents the adsorbed form of $SiCl_x$ and * a free surface site. Equation (5) shows that an increase of HCl content in the gas phase can highly inhibit the growth process by favouring the reverse reaction.

4 Influence of Oxygen on the CVD Kinetic Process and Related Characteristics of SiC-based Ceramics

4.1 Growth rate

In a previous work, transient stages were reported for the mass–time curves recorded under conditions of high supersaturation, i.e. when the kinetic process is controlled by the surface reactions.[10] For T = 900°C, α = 3 and P = 3 kPa, a relatively long time (of about 25 mn) is needed to reach the steady state (Fig. 12). During the transient stage, the deposition rate is increasing continuously with time up to a value of about 5 μm h^{-1}.

4.2 Structural and chemical analysis by TEM and EELS

In order to explain this kinetic behaviour, a nano-characterization of the ceramic films prepared under the present conditions was carried out from a chemical and structural point of view. The TEM bright-field image in Fig. 13(a) shows that the deposit is nanocrystallized with an about 1·5 nm mean crystal size (Fig. 13(b)). Interreticular distances calculated from the diameter of the rings do not correspond to those of cubic β-SiC silicon carbide. This is related to a study of the relative concentrations of silicon and carbon, by using core excitation signals. These elements are present in proportions above and below the values corresponding to SiC respectively (Fig. 14). In addition, a small amount of oxygen is present in the deposit, which decreases with d to a few atomic percents. All these element concentrations change slowly but monotonically with thickness.

The corresponding valence energy loss study has been carried out. A single plasmon profile has been found for each analysed zone of the deposit, whose energy falls between the energies of Si and SiC plasmons (16·7 and 22·5 eV respectively)

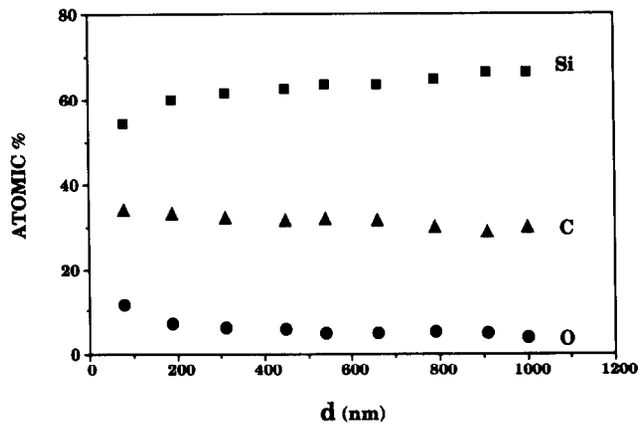

Fig. 14. Variations of Si, C and O contents with the distance d measured between the analysed area and the substrate/deposit interface, in a SiC-based film obtained at T = 900°C, α = 3, P = 3 kPa.

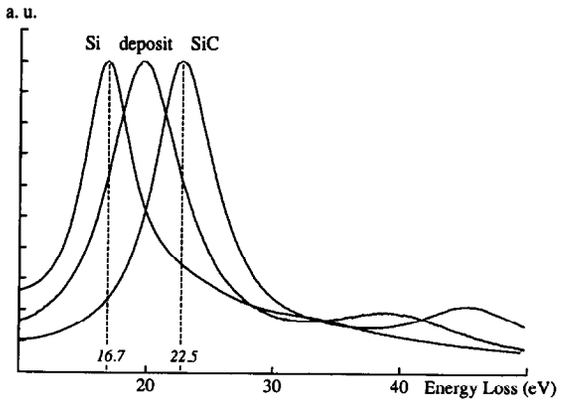

Fig. 15. Plasmon profiles of a SiC-based deposit (T = 900°C, α = 3, P = 3 kPa) and of Si and SiC reference materials.

(Fig. 15). It is also observed that this energy decreases progressively from 20·1 to 19·6 eV with d varying from 200 to 1000 nm in relation with the increase of the excess of silicon.

4.3 Discussion

The oxygen profile within the film could be correlated to the important transient stage observed in the kinetic curve: the growth rate increases when the oxygen percentage decreases and both become constant when $d > 750$ nm. This result means that oxygen might act as an inhibitor for the deposition of silicon carbide. As reported in a previous paper, the chemisorption of intermediate source species is unfavoured when the SiC substrate is replaced by an amorphous SiO_2 substrate, owing to the preferred chemisorption of the inhibitor species H (the O–H bond being very strong).[11] It has also been shown that oxygen occurs in nanocrystalline rather in columnar films.[10] The very small crystals in the former are thought to trap rather easily residual oxygen of the reactor, which results in blocking the growth sites by chemisorption of H atoms.

The above results have been used to propose a distribution of the Si, C and O elements within the deposit.[15] From thermodynamic considerations, on the one hand,[16] X-ray diffraction and Raman spectroscopy microprobe experiments, on the other hand,[9] carbon is known to be present only in silicon carbide and free silicon to be very often codeposited with silicon carbide. From the nanocrystallized structure of the deposit and the single profile of the plasmon loss which are observed, the occurrence of SiC nanocrystals including Si excess is assumed.[15]

Acknowledgements

The authors wish to thank Dr C. Bernard (LTPCM, Grenoble) for his contribution to the thermodynamic calculations, R. Fourmeaux and P. Salles (CEMES-LOE, Toulouse) for their support in electron microscopy experiments. This work has been supported by Société Européenne de Propulsion and CNRS (via a grant given to D. L.). The authors are indebted to J. Rey, C. Robin-Brosse and S. Goujard from SEP for their assistance and valuable discussions.

Computer Simulation of β'-Sialon Synthesis

Lucia F. S. Dumitrescu* & Bo Sundman

Royal Institute of Technology, Department of Materials Science and Engineering, 100 44 Stockholm, Sweden

(Received 24 January 1994; accepted 10 May 1994)

Abstract

Thermodynamic calculations in the system Si–Al–O–N were used to assess the capabilities of SiO_2 and Al_2O_3 mixtures to synthesise β'-sialon powders by reduction–nitridation. The Thermo-Calc databank, a sophisticated computer software together with assessed thermodynamic data, has been applied to calculate not just traditional phase diagrams but also various sections, isopleths, activity plots and property diagrams such as phase fraction diagrams. By controlling the temperature, the partial pressures of oxygen and nitrogen and the Si : Al ratio in the precursor mixtures the experimental work can be reduced to a minimum, based on the calculations. β'-Sialon was found to be stable only within a small region of oxygen and nitrogen partial pressures.

1 Introduction

The good mechanical and thermal properties of sialon ceramics make them useful as structural materials. To minimize the variation of the strength values, the fabrication of materials with uniform microstructure is required. When β'-sialon ceramics are formed from mixed powders such as silicon nitride, aluminum nitride and alumina,[1] the homogeneity is reduced and the microstructural control is difficult due to the complex mechanism of the preparation. The microstructure is more uniform and the densification temperature for synthesized sialon powders is 50–100°C lower when high-purity pre-prepared β'-sialon is used instead.[2] The production of nitrogen ceramics by simultaneous reduction and nitridation of oxides is of interest both because of the versatility of the process and the current availability of potential raw materials.[3]

To determine optimal values for the parameters that are necessary for the synthesis of β'-sialon powders, and thus minimize expensive and time-consuming experimental work, thermodynamic calculations have become important. Thermodynamic calculations have been used for many years to obtain information on the possible reactions in chemical and metallurgical systems.[4,5] In recent years thermodynamic software has been used not only for traditional equilibrium and phase diagram calculations but also for material development,[6] solidification simulations,[7] etc. Heterogeneous reactions make up the most significant group of interactions of interest in ceramics. In particular, those reactions involving gases and solids are of prime importance, e.g. reduction of solid oxides and chemical vapor deposition. Above 1000°C one can often use equilibrium thermodynamics together with simple kinetic estimations to understand the possible results of an experiment even if full equilibrium will not be established in the experiment. A thermodynamical description is always needed to simulate transformations as it is otherwise impossible to know the final state the system tries to reach.

Materials processes can often be described as a sequence of steps where the system is in equilibrium 'locally'. Combining extensive thermodynamic calculations in such a local equilibria simulation of a process was first done by Eriksson & Johansson[8] in the so-called SOLGAS-reactor. In a following paper a similar method will be used for the silicon nitride powder synthesis with a generic reactor module connected to Thermo-Calc.[9]

There are two requirements for the successful application of thermodynamic calculations to understand a chemical problem. One is a flexible and general software like Thermo-Calc and the other is a carefully assessed thermodynamic database for the system of interest. Such a database does not only contain data for the compounds and gases but also descriptions of the solid solution phases using sophisticated models[10] which can take into account the various types of crystalline

* On leave from MATPUR SA, Sos. Garii Catelu nr 5, Bucharest 3, Romania.

structures of the condensed phases and how the components mix on different sublattices. Databases with thermodynamical parameters describing mixtures make it possible to predict the equilibrium state of very complex systems of non-ideal phases.

In this paper a thermodynamic database for the Si–Al–O–N system[11] was used to assess the capabilities of mixtures of SiO_2 and Al_2O_3 to produce β'-sialon by reduction–nitridation. Attention was focused on important factors in the synthesis process such as the temperature, the partial pressures of oxygen and nitrogen and the Si : Al ratio in the starting oxides mixture. The calculations are a powerful tool for planning experimental work as one may eliminate a large amount of experiments that are unlikely to give useful results.

2 The SiAlON System

A system formed by four elements can always be represented by a tetrahedron. In the SiAlON system the elements form two oxides and two nitrides, and take only one valency state in these condensed compounds. The plane generated by connecting the points representing these four compounds becomes an irregular four-cornered plane. Representing such an irregular quadrangle in atom % is not very practical. Instead Gauckler & Petzow[12] suggested a representation for the silicon nitride based systems using equivalent % of one cation and one anion, which transform the irregular quadrangle into a square. The system Si_3N_4–AlN–Al_2O_3–SiO_2 represented in this way is generally called the SiAlON system in the literature.

For the SiAlON system some isothermal experimental studies are known.[13,14] Gauckler *et al.*[13] indicate the existence of an homogeneous single-phase material with an expanded lattice, isostructural with β-Si_3N_4, which was termed β'-sialon. Solubility occurs only with a constant cation : anion ratio of 3 : 4 according to an atomic formula $Si_{6-z}Al_zO_zN_{8-z}$ within a solubility range of $0 < z < 4$. Compositional variation with this ratio does not require vacancies or interstitial atoms in the β-Si_3N_4 lattice. Other important phases in the system are the Si_2N_2O solid solution (O'), the X_1 phase and the polytypes in the AlN corner.

A database for the SiAlON system has been assessed thermodynamically by Dorner *et al.*[15] and more recently by Hillert & Jonsson.[11] In such a database each phase is described by a model giving the variation of the Gibbs energy with temperature, pressure and composition. A number of model parameters must be assessed to give a good description of the experimental information. This technique has been used successfully in many metallic systems[16] and is often referred to as the 'Calphad technique'. Due to the lack of experimental information at the time when the SiAlON system was assessed some simplifications were introduced, for example only one polytype phase, 27R, is considered and it is restricted to the AlN–Al_2O_3 quasi-binary section.

Three of the phases in the SiAlON system, β'-sialon, O' and mullite have significant variations in composition and reciprocal models with ionic constituents have been selected by Hillert & Jonsson to describe this. For the β'-sialon phase the model has Si^{+4} and Al^{+3} on one sublattice with 3 sites and N^{-3} and O^{-2} on a sublattice with 4 sites, and this can be written as $(Si^{+4}, Al^{+3})_3(N^{-3}, O^{-2})_4$. Figure 1 shows the constitutional square of this reciprocal model. It has four corners and only one of these represent a real neutral compound, $(Si^{+4})_3(N^{-3})_4$, the others have a net charge and are thus unphysical. The line in Fig. 1 represents the neutral combinations of Al^{+3} and O^{-2} additions. The line goes from the Si_3N_4 corner to a composition Al_3O_3N on the opposite side.

For the O' phase the model selected by Hillert & Jonsson is a slightly modified reciprocal model. In this case there are three sublattices and the model can be written $(Si^{+4}, Al^{+3})_2(N^{-3}, O^{-2})_2(O^{-2})_1$. In the third sublattice there is only one constituent and thus the model is actually equivalent to a reciprocal one.

The mullite phase was modeled with three sublattices and the model can be written $(Al^{+3})_2$. $(Al^{+3}, Si^{+4})_1(O^{-2}, Va)_5$. As the first sublattice has only one constituent this is also a reciprocal model.

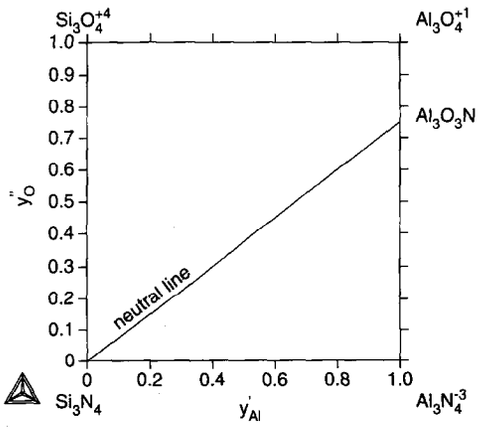

Fig. 1. The constitutional square for the β'-sialon model. The square represents a reciprocal model but only one corner is an electrically neutral compound. The axes represent the variation of Al^{+3} in sublattice 1 and O^{-2} in sublattice 2. The line drawn in the square represents the electrically neutral ratio of Al^{+3} and O^{-2} additions to Si_3N_4.

All other phases are treated as stoichiometric compounds. For X_1 the composition was selected to be $Si_{12}Al_{18}O_{39}N_8$ and $Al_9N_7O_3$ for R27.

In the development of a database it is important to be compatible with assessments of other oxide, nitride and metallic systems in order to make it possible to combine and extrapolate from different assessments. Some parameters for the spinel phase, stable at higher temperatures in the Al_2O_3 system, were thus taken from an assessment of the MgO–Al_2O_3 system by Hallstedt.[17]

Figure 2 is one example of the use of the SiAlON system assessed by Hillert & Jonsson, and shows the isothermal phase equilibrium at 1400°C without including the gas phase. Any phase or combination of phases, contained in Fig. 2, can be obtained by controlling the Si : Al ratio in the precursor and the oxygen and nitrogen partial pressures.

3 Calculated Diagrams in the SiAlON System

The database can be used to calculate any equilibrium state in the system using, for example, the Thermo-Calc software system.[18] This system uses the Gibbs energy minimization method[19] where the total free energy of the system is minimized with respect to the prescribed conditions. In Thermo-Calc a very flexible set of conditions can be used, not just the overall composition, temperature and pressure but also activities, the set of stable phases, composition of a phase, volumes, enthalpies, etc. The use of generally applicable software for thermodynamic calculations makes it possible to obtain diagrams that could not be perceived without this software. It is a useful tool for understanding how the system behaves under varying conditions and for testing the effect of different experimental techniques for controlling the system.

In this paper the calculations made to simulate the synthesis of two β'-sialon compositions, by reduction–nitridation of two silica : alumina mixture precursors with the ratio 2 : 1, composition A in Fig. 2, and 1 : 1, composition B in Fig. 2, respectively, are presented. The dotted lines into the diagram show the path of the reduction–nitridation process giving the final β'-sialon single-phase product.

Figure 3 describes the synthesis process better and shows the stable phase regions versus equivalent fraction aluminum and oxygen partial pressure in the system, at 1400°C. Reduction and nitridation of precursor mixture A shows that, as the reaction proceeds, first tridymite + mullite then tridymite + X_1, X_1 + O', β'-sialon + O' and β'-sialon are formed. For precursor mixture B first tridymite + mullite are formed as in the case of mixture A but then X_1 + mullite, X_1 + corundum, corundum + β'-sialon and β'-sialon are the phase fields through which the process progresses. The diagram was calculated at a constant activity of nitrogen equal to unity. Figure 3 emphasizes the importance of controlling the oxygen activity for the process and thus further calculations concerning that have been done.

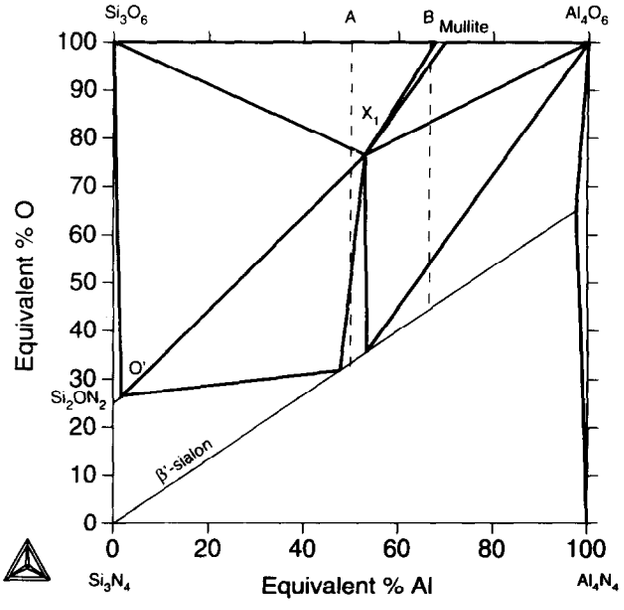

Fig. 2. Calculated isothermal section at 1400°C of the SiAlON system based on the database by Hillert & Jonsson.[11] The gas phase has been excluded. The mullite, O' and β'-sialon phases are treated with reciprocal solution models. The equivalent fraction of O and Al are used as axes. The dashed lines represent the precursor mixture A and B respectively.

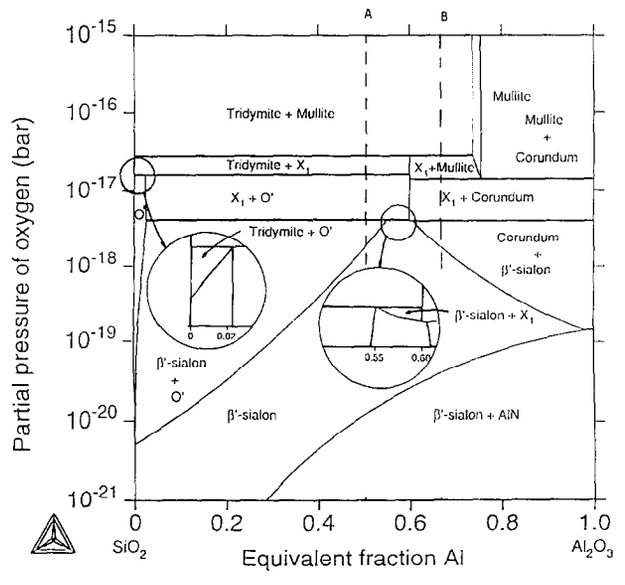

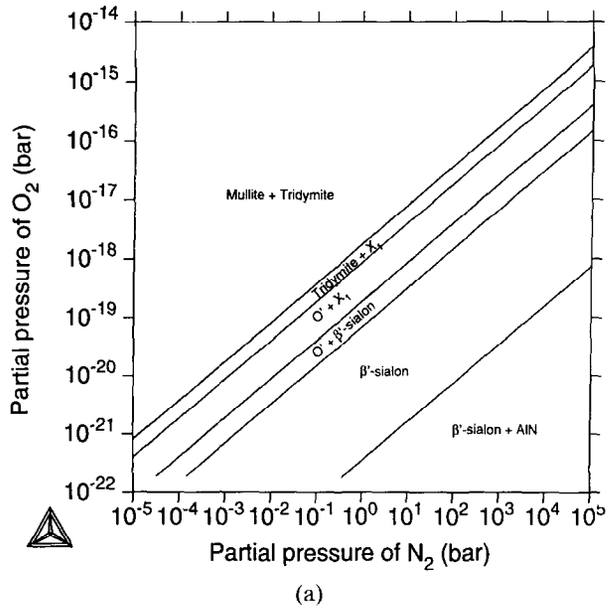

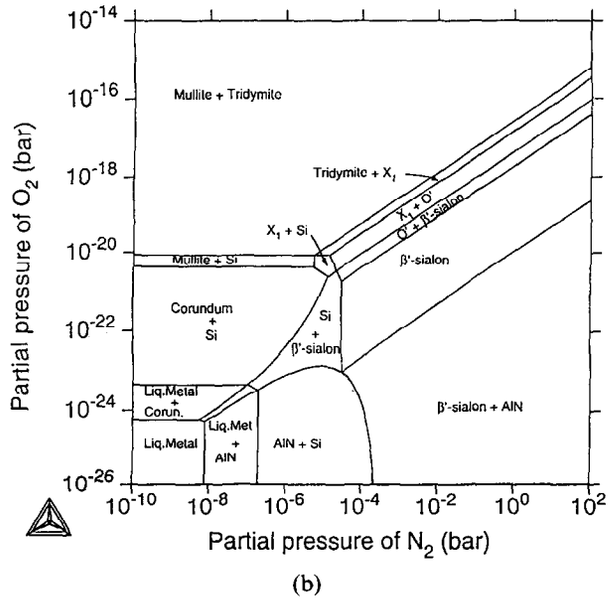

Fig. 3. The same diagram as in Fig. 2 but plotted with the variation in oxygen partial pressure instead of the equivalent % of oxygen on the vertical axis. The β'-sialon single-phase region is now an area and the three-phase regions are horizontal lines. The dashed lines represent the precursor mixture A and B respectively.

The stability regions for the phases in equilibrium at various nitrogen and oxygen partial pressures were calculated at 1250 and 1350°C for the precursor mixture A. Figure 4 shows the result. For the onset of β'-sialon formation the increase of oxygen partial pressure requires the nitrogen partial pressure to increase. This effect is more pronounced at lower temperatures. For a given nitrogen partial pressure the β'-sialon single-phase region has a width of about two orders of magnitude in oxygen partial pressure. For example at 1 bar nitrogen partial pressure Fig. 4(a) shows that the single β'-sialon region falls between 5×10^{-20} bar and 5×10^{-22} bar oxygen partial pressure. In Fig. 4(b) the phases appearing at very low oxygen and nitrogen partial pressures are shown. The left hand corner is liquid metal. Most of these phase regions are out of the experimental setup for β'-sialon synthesis.

The same tendency to displace the β'-sialon stable region toward higher nitrogen partial pressures with increasing oxygen partial pressure is also observed for precursor mixture B. Figure 5(a) and (b) show the result of calculations for this mixture at 1250 and 1350°C respectively. The difference between mixtures A and B at 1250 or 1350°C is the β'-sialon stability region which is narrower for precursor B than for A. This means that the precursor B is less suitable for preparation of β'-sialon as the oxygen partial pressure must be kept in a smaller range. Experimentally this is much more difficult.

(b)

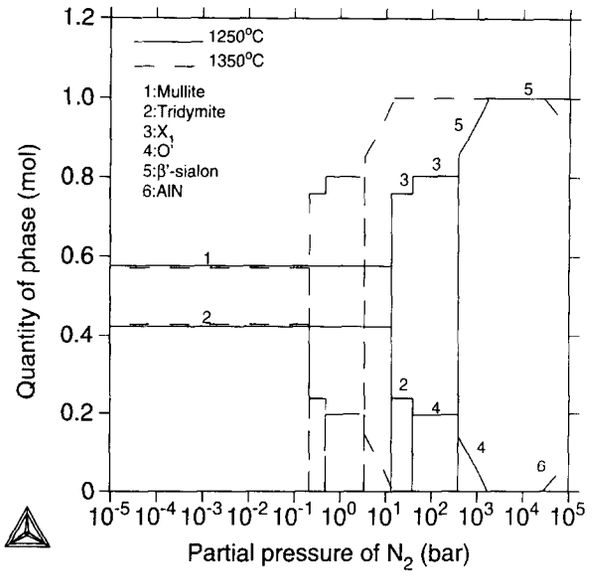

Fig. 5. The stability regions for the phases in equilibrium at various nitrogen and oxygen partial pressures. The ratio SiO_2 : Al_2O_3 is 1 : 1. (a) Calculated at 1250°C; (b) calculated at 1350°C.

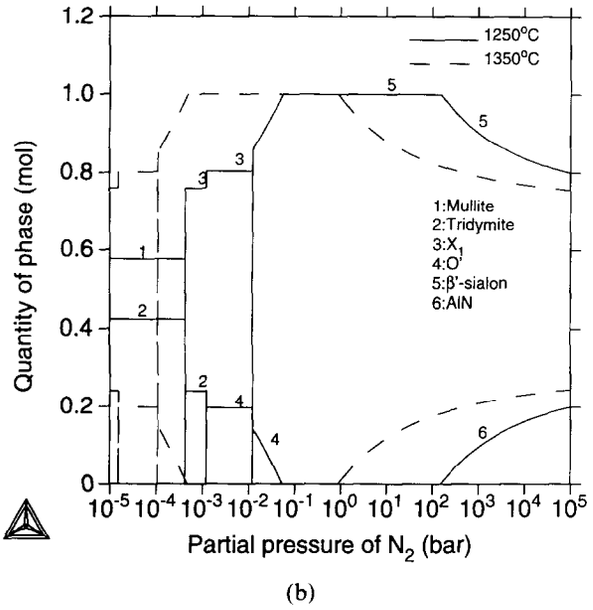
A more suggestive way to present the result of the calculations and to see the influence of temperature, partial pressures of oxygen and nitrogen on the β'-sialon synthesis is to plot the quantity of phase as a function of partial pressure of nitrogen at different fixed temperatures, partial pressures of oxygen and silica : alumina ratios.



Figures 6 and 7 show the quantity of phase for a system with one mole of components, for the precursor mixture A and B respectively, as a function of partial pressure of nitrogen. The calculations were made for a partial pressure of oxygen equal to 10^{-17} bar, Figs 6(a) and 7(a), and 10^{-20} bar, Figs 6(b) and 7(b). Each figure shows calculations at two temperatures, 1250 and 1350°C, using solid and dashed lines respectively.

The experimental facilities to obtain β'-sialon powders can provide a partial pressure of nitrogen between 1 and 5 bar. The calculated diagrams, Figs 6(a) and 7(a), show that if the partial pressure of oxygen is 10^{-17} bar, it will be impossible to produce β'-sialon.

When the partial pressure of oxygen is 10^{-20} bar the synthesis of single-phase β'-sialon is experimentally possible at the lower temperature 1250°C, for both precursor mixtures A and B, Figs 6(b) and 7(b). Experiments to synthesize β'-sialon based on these thermodynamic calculations for the precursor mixture A were presented by Teoreanu *et al.*[20]

4 Conclusions

This paper sets out the thermodynamic basis for β'-sialon powder synthesis and describes the variables which must be controlled to obtain materials of desired phase composition, chemistry and morphology.

The most important variables in the β'-sialon synthesis are partial pressures of oxygen and nitrogen, Si : Al ratio in the precursor mixture and the temperature. The β'-sialon single-phase region exists only within a small region of oxygen and nitrogen partial pressures.

Thermodynamic calculations in the SiAlON system help to screen the most effective β'-sialon synthesis conditions and give guidelines for experimental work.

Abstract

Inversion domains (IDs) are a common feature in the microstructure of AlN ceramics. It is shown by transmission electron microscopy (TEM) that the frequency of IDs can be influenced to a large extent by processing and sintering parameters. Evidence is presented that the presence of IDs has a favourable effect on thermal conductivity. This is explained by oxygen trapping at the inversion domain boundaries (IDBs). Direct proof for the oxygen enrichment at the IDBs is given by electron energy-loss spectroscopy (EELS) in combination with TEM.

1 Introduction

High thermal conductivity makes AlN ceramics (wurtzite-type crystal structure with space group $P6_3mc$) an attractive material for electronics. Slack[1] reported that thermal conductivity decreases linearly by dissolution of oxygen in the lattice of AlN single crystals. Oxygen can be incorporated into the AlN lattice by the following reaction:

$$Al_2O_3 \Rightarrow 2Al_{Al} + [\ ]_{Al} + 3O_N$$

($[\ ]_{Al}$ denotes an aluminium vacancy). Besides other defects inversion domains (IDs) have been frequently observed within the grains of AlN ceramics.[2–5] The character of the inversion domain boundaries (IDBs), showing Al–Al or N–N bonds, suggests an incorporation of oxygen. In fact, energy dispersive X-ray analysis (EDX) by Westwood & Notis indicates the presence of oxygen at the IDBs.[5]

Transmission electron microscopy (TEM) contrast analysis of different defect structures has led to a model for nucleation of IDs. In previous papers a description of inversion domain nucleation in combination with dislocations has been given.[6,7] The aim of this work was to investigate the oxygen enrichment at IDBs and their influence on thermal conductivity of the ceramic. For this purpose, it was necessary to control the formation and growth of IDs during processing. The oxygen distribution across IDBs has been measured by electron energy-loss spectroscopy (EELS). EELS in combination with TEM allows the quantitative determination of the oxygen content in AlN with a high spatial resolution. This method has been applied to AlN ceramics in earlier investigations.[8,9]

2 Experimental

Two different AlN starting powders were used. Powder A (Grade B, H. C. Starck, Berlin, Germany) has a medium particle size of 1·3–2 μm and a total oxygen content of 1·8 wt%. Powder B (Grade F, Tokuyama Soda, Tokyo, Japan) has a medium particle size of 1·2 μm and a total oxygen content of 1 wt%. Mixtures of both AlN powders and Y_2O_3 powder (H. C. Starck, Berlin, Germany) were attrition milled using Al_2O_3 balls in isopropanol. Y_2O_3 is a usual sintering aid for AlN ceramics. Attrition milling time was varied between 30 min and 8 h and Y_2O_3 addition between 0 and 4 wt%. Cold isostatically pressed cylinders were sintered in a gas-pressure sintering furnace with graphite heating elements under a pressure of 0·2 MPa N_2. End temperatures ranged between 1750°C and 2000°C and sintering times between 30 min and 4 h.

Hot gas extraction analysis (TC-436, LECO Co., St. Joseph, MI, USA) was carried out for selective determination of lattice-dissolved oxygen and oxide-bound oxygen of AlN ceramics.[10] Thermal conductivity was measured by a comparative method according to DIN 51908. In this measuring technique a cylindrical shaped sample (d = 18 mm, h = 20 mm) is placed in series with a reference cylinder between two heat reservoirs at constant temperatures (20 and 40°C). Thermal conductivity is derived by measuring the thermal gradient in the reference sample. The measuring range is 10 to 200 W/(mK) with an accuracy of ~3%.

Starting powders and sintered samples were investigated by TEM (Model Philips CM12, Eindhoven, The Netherlands, with 120 kV acceleration voltage). About 1000 grains of each sample were examined in order to determine the fraction of grains that contains dislocations or IDs. For TEM investigations grains of the uncrushed starting powders were transferred from a suspension in ethanol to a copper grid covered with a C-film after ultrasonic treatment. Electron transparent samples of the compact ceramics were prepared by argon ion milling.

The TEM is equipped with a parallel electron energy-loss spectrometer (PEELS, Model 666, Gatan, Pleasanton, CA, USA) and a double tilt specimen holder cooled with liquid nitrogen (Model 636, Gatan). Cooling of the specimen was necessary to prevent contamination effects. The EELS measurements were all recorded using the convergent beam mode in the TEM to provide a high spatial resolution. The illumination half-angle was 7 mrad, the collection half-angle was in the range of 10 to 20 mrad, the integration time was 25 ms for the low loss spectra and 100 s for the core-loss spectra, and the probe current density was approximately 3×10^6 e^-/nm^2. The EELS measurements allow the quantitative determination of the concentration ratio of nitrogen and oxygen ([N]/[O]) and of the sample thickness.[8] The complex data acquisition and processing in EELS is described in the literature.[11,12] Concentration profiles were measured by recording EEL spectra of a series of spots on a line across the IDB. The distance from the spots to the IDB was determined using the measuring function of the TEM. A series of micrographs with different exposure times was taken to estimate the electron spot size. A plot of the reciprocal exposure time versus the radius of the spot led to a Gaussian distribution with a full width half maximum (FWHM) of 15 nm in one case and 20 nm in another.

Spontaneous growth of an oxide layer at room temperature in air has to be taken into account for quantitative measurements of oxygen concentrations. In an earlier paper a method has been reported that enables the determination of the thickness of such oxide layers. The [N]/[O] ratios can then be corrected for the influence of the oxide layer.[8]

3 Results and Discussion

3.1 Occurrence of IDs during ceramic processing

Investigations of the starting powders show the presence of dislocations in both AlN powders. 90% of the grains in powder A contain dislocations, generally with a high dislocation density. The dislocations are connected to hexagonal networks in approximately 1% of the grains. By contrast, less than 1% of the grains in powder B have dislocations. While no IDs were found in starting powder A, 1% of the grains of powder B, contain IDs. Powder B was used to investigate the influence of attrition milling time on the amount of grains containing dislocations. The results are plotted in Fig. 1. Obviously, longer times of attrition milling increase the number of dislocations in the starting powder. Cold isostatic pressing of the mixed powders does not change the defect structures.

The defect structure of AlN ceramics after sintering was also investigated. IDs can be observed in ceramics made from both starting powders. They are often connected with dislocations. The amount of IDs in the sintered ceramics using powder B depends on the attrition milling time of the powder mixtures and therefore on the amount of dislocations. A higher amount of dislocations in the starting powder yields a higher number of IDs in the ceramic, as shown in Fig. 1. Powder A initially contains many grains with dislocations, therefore IDs were always observed in the sintered ceramic.

The fraction of grains containing IDs in ceramics of powders A and B after 8 h attrition milling depends on sintering temperature and Y_2O_3 content.

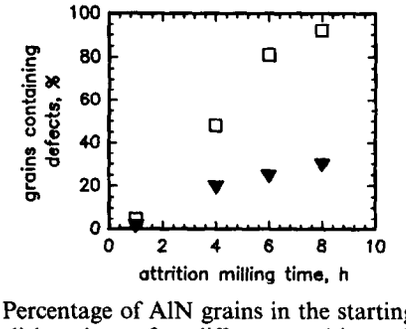

Fig. 1. □, Percentage of AlN grains in the starting powder B containing dislocations after different attrition milling times. The symbols ▼ represent the number of grains containing IDs of the sintered ceramics (1800°C).

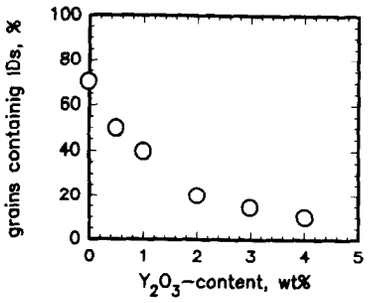

Fig. 2. Percentage of AlN grains containing IDs as a function of the Y_2O_3 content. The AlN ceramics were sintered at 1850°C for 1 h.

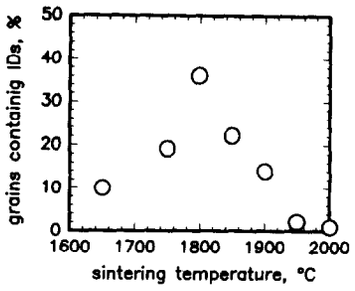

Fig. 3. Percentage of AlN grains containing IDs as a function of sintering temperature. The AlN ceramics were sintered with 2 wt% Y_2O_3 for 1 h.

Figure 2 shows the dependence of the number of IDs per 100 grains on Y_2O_3 content for a ceramic of powder A after sintering at 1850°C. As can be seen, the number of IDs decreases rapidly with an increasing Y_2O_3 content (Fig. 2). The correlation between IDs and temperature is presented in Fig. 3. A maximum of IDs is reached at 1800°C. The number of IDs drops to zero for the sintering temperature of 2000°C. Sintering time was investigated in the range between 30 and 240 min. For these sintering times no influence on the number of grains containing IDs has been found.

3.2 Thermal conductivity

Table 1 compares the oxygen content, number of IDs, and thermal conductivity of three pairs of differently sintered AlN ceramics. The difference between the two samples of each pair is that samples 1a, 2a and 3a were attrition milled for 1 h and samples 1b, 2b, and 3b, 6 h. Different dislocation densities in the powders and finally different numbers of IDs were found in each sample pair a and b (Table 1).

According to hot gas extraction analysis the powders take up oxygen during attrition milling. However, as can be seen in Table 1, milling time only increases the total oxygen concentration, not the lattice oxygen content. In the series of samples 1a to 3a and 1b to 3b thermal conductivity decreases. This is caused by an increase of the oxygen content dissolved in the AlN lattice. This in turn is a function of the Y_2O_3 content and the sintering conditions, as has been shown in several papers.[1,13]

There is no significant difference in lattice dissolved oxygen between samples a and b of each pair. However, thermal conductivity is always higher in sample a. This indicates that the presence of IDs has a favourable effect on thermal conductivity. This influence can be understood if indeed, as stated in the introduction, oxygen impurities are trapped at and dragged along with the IDBs. In this case the growth of the IDs would purify the interior of the IDs and thus increase their thermal conductivity. The IDs themselves must be supposed to be thermal conductivity barriers, but as they are very thin they probably are not very effective.[13] Oxygen segregated at the IDBs and oxygen dissolved in the AlN lattice cannot be distinguished by hot gas extraction analysis. Therefore, EELS in combination with TEM is necessary for a definite proof of the oxygen segregation at the IDBs.

The results described show the influence of IDs on thermal conductivity. Higher concentration of IDs increases the thermal conductivity. A low Y_2O_3 content is one condition to achieve a high concentration of IDs. However, a low oxygen content in the lattice resulting from high Y_2O_3 contents improve thermal conductivity. Therefore, the effect of improving thermal conductivity by IDs is contrary to the effect of high Y_2O_3 contents.

Table 1. Sintering and preparation conditions, oxygen contents, thermal conductivity and number of IDs for selected samples of powder B

3.3 Oxygen enrichment at inversion domain boundaries

Figure 4(a) shows a TEM micrograph of an ID from sample 3a of Table 1. The end of the ID, where a planar and a curved IDB run close together, is shown. The planar IDB is oriented // (0001) in the AlN crystal. Figure 4 (b) gives the oxygen concentration profile measured by EELS across these two IDBs. Significantly increased oxygen concentrations with values of ~8 at.% at the IDBs have been found.

The width of the boundaries is small compared to the electron spot size of approximately 15 nm. The distance between the two IDBs is also 15 nm. The maximum of the profile in Fig. 4(b) therefore cannot be interpreted as the real oxygen concentration at the IDB. The measured oxygen concentration profile (Fig. 4(b)) represents the true oxygen distribution convoluted with the intensity distribution of the electron spot. A convenient method to interpret this type of profile, is the calculation of theoretical profiles and comparison to the measured one. The first step is to assume an ideal rectangular oxygen distribution. The oxygen incorporation at the IDBs can be described in terms of small oxygen layers similar to those in polytypes.[14] In the following calculations Al_2O_3 layers with an oxygen concentration of 60 at.% were assumed. High-resolution TEM investigations show that the width of an IDB is approximately 0·5–1 nm. These results agree with current studies.[15] Consequently, for the profile calculations a rectangular oxygen distribution with a width of 1·6 nm (two parallel IDBs) and a height of 60 at.% was convoluted with a Gaussian function (FWHM = 15 nm, diameter of the electron spot) and drawn in Fig. 4(b) as a solid line. The model corresponds reasonably with the measured data. However, the accuracy of the method is not sufficient to derive explicit values for the true oxygen concentration at the IDB.

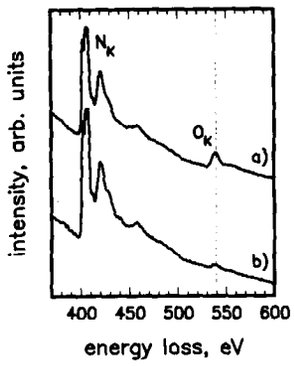

Fig. 5. EEL spectra measured (a) exactly at the IDB and (b) 35 nm beside the IDB. The EEL spectra include the characteristic N_K and O_K ionization edges.

Two typical EEL spectra are presented in Fig. 5. The range of energy loss is 370 to 600 eV including the N_K and O_K edges. The first EEL spectrum (a) was measured directly at the IDBs in Fig. 4 (x = 0). EEL spectrum (b) was recorded in a distance of 40 nm from the IDBs.

Figure 6(a) shows typical IDs of dome-like shape. A second EELS measurement (Fig. 6(b)) was obtained across one whole ID, including both the curved and planar boundary (see marks in Fig. 6(a)). The solid line in Fig. 6(b) was calcu-

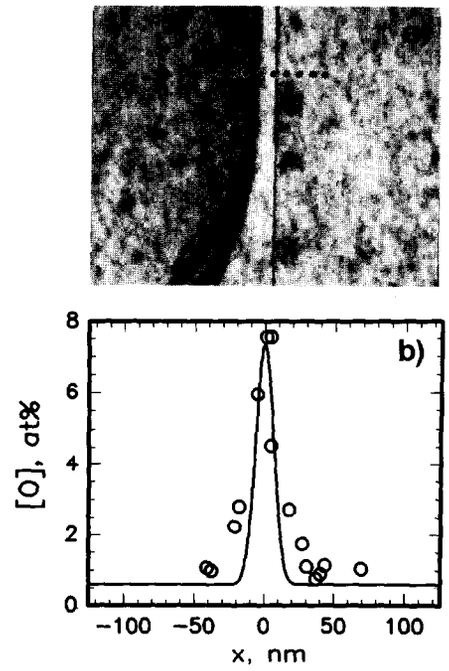

Fig. 4. (a) TEM micrograph of two IDBs. The primary beam is oriented // [$\bar{1}2\bar{1}0$]; (b) the oxygen concentration profile across the IDBs of (a) with the same scale.

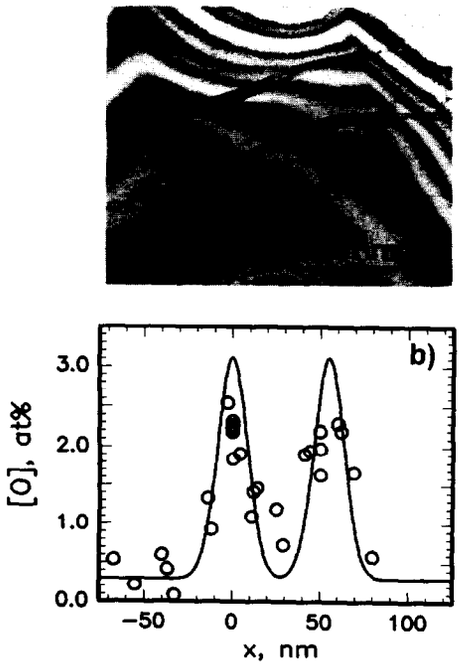

Fig. 6. (a) TEM micrograph of an AlN grain showing IDs. The primary beam is oriented // [$\bar{1}2\bar{1}0$]. (b) The oxygen concentration profile measured along the marked line.

lated using the same model as in the first example. In this case the width of each IDB amounts to 0·8 nm, the height to 60 at.% and the spatial resolution to 20 nm. The oxygen enrichment at the IDBs is again obvious.

4 Conclusions

It has been shown that the concentration of IDs in sintered AlN ceramics can be controlled by the powder processing and sintering parameters. The processing parameters chosen do not affect the total oxygen content within the AlN grains. Therefore, the influence of IDs on thermal conductivity can be evaluated directly. Evidence is presented that thermal conductivity increases with the concentration of IDs.

EELS in combination with TEM was successfully used to prove oxygen enrichment at IDBs. The improved thermal conductivity can be interpreted as an indirect result of this oxygen enrichment at the IDBs, if it is assumed that the lattice oxygen content is lowered inside the ID. This assumption has to be proved by further EELS measurements. In view of recent models[13] it seems reasonable that the positive effect on thermal conductivity resulting from the lower lattice oxygen content inside the ID overrides the negative influence of the oxygen enrichment at the narrow IDBs.

Laminar Ceramic Composites

T. Chartier, D. Merle & J. L. Besson

LMCTS, URA CNRS 320, ENSCI, 47 av. Albert Thomas, 87065 Limoges, France

(Received 18 April 1994; accepted 27 June 1994)

Abstract

The processing of laminar ceramic composites from stacking of layers obtained by tape casting is described. In the case of composites for structural applications, the reinforcement mechanisms are briefly reviewed. It is shown that both strength and toughness can be improved. The evaluation of residual stresses allows a strategy for tailoring the mechanical properties of such composites to be developed. As an example, results are given in the case of laminar composites with layers made of alumina with various zirconia contents.

1 Introduction

Designers require materials with higher and higher performances. Sometimes, materials must be corrosion resistant at elevated temperatures while retaining high mechanical properties (rupture strength and toughness). Ceramic materials, such as alumina, silicon carbide, silicon nitride or mullite seem to be potential candidates for such applications. However, these materials, like all the monolithic ceramics, are brittle, which limits their use in numerous systems.

The usual approach to improve the mechanical behaviour is to eliminate the flaws that initiate the catastrophic failure, or at least to reduce their size. Recently, new strategies have emerged that are fundamentally different from the conventional approach. These strategies involve energy dissipative mechanisms to develop 'flaw-tolerant' materials. Among them are the ceramic–ceramic composites. In the flaw tolerance approach, the microstructure is designed to promote the bridging of the cracks which leads, in the ideal case, to the strength being independent of flaw size. The process must produce a material generally with two phases, with a controlled heterogeneous microstructure. The presence of the second phase, either long fibres, whiskers or particles (zirconia, for instance) enhances the mechanical properties.

Long fibre-reinforced ceramics exhibit high mechanical and thermomechanical properties. However, the routes available to process the matrix (i.e. infiltration or impregnation across a fibre fabric) are expensive, and only parts with limited thickness can be obtained. Moreover, carbon or silicon carbide fibres, which are the most used, exhibit a limited thermal stability in oxidizing environments.

By contrast, whisker- or particle-reinforced ceramic composites can be processed following classical routes. The reinforcing phase may be dispersed quasi-isotropically in the matrix, whereas some processing techniques, such as tape casting, allow a preferential orientation of whiskers.

Special attention must be focused on laminar composites. Whereas laminar composites with organic matrix are well developed, laminar composites with ceramic matrix are relatively new. These structures provide the advantage for tailoring the properties by stacking layers of different compositions in a suitable sequence.[1–17] Then, it is possible to produce functionally gradient ceramics. Tape casting, which is extensively used for electronic ceramics, is well suited to the fabrication of ceramic sheets that can be reinforced by whiskers or particles.

In this paper, the different mechanisms that can be used to reinforce laminar composites will be briefly reviewed in the first section. Then, the next section will deal with the processing by tape casting of laminar ceramic composites. The classical laminated plate theory will be used to predict the composite behaviour in the third section and the results compared with the experimental data obtained for alumina–zirconia composites.

2 Strengthening and Toughening Mechanisms in Laminar Ceramic Composites

Laminar ceramic composites consist of alternate layers reinforced by whiskers or particles. This type of composite allows the association of two

reinforcing mechanisms: the first one, acting at the scale of the microstructure, inside the layers, due to the second phases, leading to flaw-tolerant materials; the second one, acting at a macroscopic scale, due to the interfaces between the layers. The aim is to improve both the toughness and the strength.

2.1 Reinforcement mechanisms inside the layers

2.1.1 Whiskers

The incorporation of whiskers allows load transfers from the matrix to the whiskers (crack bridging) and crack deflection. An optimum toughening is achieved by loading whiskers by internal compressive stresses. Hence, the matrix–whisker couple must be judiciously chosen with a thermal expansion coefficient mismatch and chemical compositions leading to an appropriate bonding.

Whisker reinforced composites have already been the subject of numerous studies.[1,6,18–23] Some results concerning SiC_w reinforced mullite are reported in Table 1.

2.1.2 Particles

Zirconia-toughened ceramics are the best example of particle-reinforced materials.[24–30] The most effective toughening mechanism in ZrO_2-containing ceramics is the stress-induced transformation of small ZrO_2 particles in their metastable tetragonal state. Both toughness and strength can be increased, although a compromise between these two effects must be accepted.[31] Other mechanisms, that is, crack deflection and microcracking around monoclinic particles, increase toughness but generally at the expense of strength.

The transformation of zirconia particles is also used to develop compressive surface stresses, increasing the modulus of rupture.

Some results obtained on zirconia-reinforced alumina are given in Table 2.

Table 2. Strength to failure σ_f (MPa) (four-point bend test) and toughness K_c (MPa$\sqrt{m}$) (SENB)

2.2 Reinforcement mechanisms at layer interfaces

The laminar ceramic–ceramic composites must fulfill two requirements:

—improve the toughness and the work of rupture,
—improve the modulus of rupture in bending.

The first objective is obtained using mechanisms involving crack 'clamping' stresses, crack deflection or microcracking, that operate at a macroscopic scale, thanks to the laminar structure of the material, instead of operating at a local scale (microstructure).

In the laminar structure, residual stresses develop during cooling from the sintering temperature because of the difference in thermal expansions between layers of different compositions. But, contrary to the case of monoliths, these stresses built up in the whole volume of the layers. The sign and the magnitude of these stresses may be adjusted through the compositions (ZrO_2 amount in Al_2O_3–ZrO_2 composites), but also through the layer thickness. Hence, it is possible to develop high compressive stresses in thin layers whereas the tensile stresses remain low in the associated thick layers. The propagation of the crack in mode I being impeded by the compressive stresses, propagation modes I and III can occur, leading to crack deflection at the interface and to an increase of the surface of rupture. An example is given by Chartier and coworkers[3,5] for alumina–zirconia composites.

Crack deflection at the layer interface can be favoured by a weak interlayer bond. Clegg *et al.*[10] have fabricated SiC-graphite laminar composites that, although the onset of microcracking appears at 500 MPa, exhibit an ultimate strength three times higher, an apparent toughness (calculated from the ultimate strength) of 15 MPa$\sqrt{m}$ and a work of fracture of 4625 Jm^{-2}. For comparison, the modulus of rupture, the toughness and the work of fracture of monolithic SiC were 500 MPa, 3·6 MPa$\sqrt{m}$ and 25 Jm^{-2}, respectively.

Toughness can also be enhanced by deflection

of the growing crack at a porous layer in laminar composites consisting of a sequence of dense and porous layers.[9]

Folsom *et al.*[11] have developed composites with alumina and carbon fibre-reinforced epoxy resin layers in which alumina sheets provide high strength, high stiffness and abrasion resistance, whereas the fibre-reinforced sheets provide high toughness and flaw tolerance. They suggest that composites for high-temperature applications could be designed in a similar way, replacing the epoxy resin by an inorganic glass.

The second objective is reached by choosing for the outer layers a material with a thermal expansion coefficient smaller than the inner layer one. In this configuration, the outer layers sustain compressive stresses.[2,5]

3 Processing of Alumina–Zirconia Laminar Composites

Laminar composites consisting in a regularly alternate stacking of $(2n + 1)$ layers made of alumina with various zirconia content (Al_2O_3 = A; Al_2O_3 + 5 vol.% ZrO_2 = AZ5; Al_2O_3 + 10 vol.% ZrO_2 = AZ10) were fabricated by tape casting, stacking, thermocompression, pyrolysis of organic components and sintering. The sequences were chosen to put the outer layers in a compressive state. The layer thickness was adjusted by superposing a variable number of individual identical tapes. So the AZ10/AZ5/AZ10 composite with n = 2 was fabricated by stacking five layers, each consisting in three identical tapes whereas the AZ10/AZ5/AZ10 composite with n = 10 was fabricated with 21 alternate tapes.

Tape casting is the prominent process for producing homogeneous wide and thin (25–1000 μm) ceramic sheets with controlled thicknesses and smooth surfaces.[32] Tape casting, basically, consists in depositing a suspension composed of the ceramic powder and organic components on a support, either by spreading under a blade (doctor blade process) or by coating. Typical applications are substrates of Al_2O_3 (or AlN) for thick- and thin-film circuitry and $BaTiO_3$ for multilayer capacitors, which represent the two principal markets in electronic ceramics. Tape casting is now used on a larger scale to produce thin ceramic sheets and multilayer structures of various materials for different applications. The evaporation of the solvents leads to a dried green tape with sufficient strength and flexibility to be handled and cut to the proper shape. After removal of organic components, green sheets or multilayer systems made by stacking and laminating green sheets are sintered.

3.1 Slurry formulation

The composition of the slurry and the drying stage greatly affect the microstructure and hence the properties of the green tapes (density and strength). The rheological behaviour of the slurry is an important parameter for the homogeneity and the microstructure of the green tape, and for the reproducibility of the process. Tape-casting slurries are complex, multicomponent systems, which contain ceramic powders (including sintering aids), solvents, dispersants, binders and plasticizers. The control of such a system requires the knowledge of the role of each component.

3.1.1 Powder

Powders of fine particle size are used to obtain thin films, smooth surfaces, high densities and small critical flaw size. The particle size distribution greatly influences the rheology of the slurry. The starting powders are 99·7 wt% purity, 0·5 μm grain size alumina (P172SB, Péchiney, France) and 97·5 wt% purity, 0·4 μm grain size zirconia (UPH 12, Criceram, France).

3.1.2 Solvent

The solvents ensure the dissolution of all organic components (i.e. dispersant, binders and plasticizers) to give an homogeneous slurry. Interactions between the solvent and the solid surfaces influence the further adsorption of the dispersant and of the binders, and then the stability and the rheological behaviour of the slurry. Mixtures of organic solvents, and particularly binary systems, are preferred for solubility reasons: the various organic additives have their higher solubility in different solvents. The solvent used is an azeotropic mixture of methyl ethyl ketone (MEK) and ethanol (40/60).

3.1.3 Dispersant

Dispersants are necessary to obtain a good deagglomeration and dispersion of the ceramic particles in the solvent, and to stabilize the tape-casting suspensions with a high ceramic–organic ratio. A stable dispersion of deagglomerated particles leads to a dense particle packing and to a homogeneous microstructure.

The best stabilization is given by a combination of electrostatic and steric repulsion (referred as electrosteric stabilization). The steric hindrance prevents contact between particles and the double layer, which may be due to net charge on the particle surface and/or charges associated with the adsorbed polymer, providing repulsion by a potential energy barrier at larger distances.

The dispersant used is a phosphate ester (Beycostat C213, CECA, France).

3.1.4 Binder

After evaporation of the solvent, the binders provide the strength to the green tape, to enable handling and subsequent processing steps like punching. Binders are polymeric molecules which adsorb on the particle surfaces and form organic bridges between them. The slurry should exhibit a shear thinning behaviour caused by an alignment of the binder molecules at high shear rate.

The binder used is a poly(vinyl butyral) (PVB).

3.1.5 Plasticizer

Most binders require the addition of plasticizers to improve the flexibility and workability of the green tape. Plasticizers are low molecular weight species which can reduce the glass transition temperature of the binder at room temperature or below, leading to a better plasticity. The addition of plasticizers modifies the mechanical properties of the green tape, the strain to failure increases but the strength decreases.

The plasticizer used is a mixture of poly(ethylene glycol) (PEG) and dibutyl phthalate (DBP).

The slurry must be adjusted, not only for tape casting but taking into account other processing parameters such as shaping (cutting, punching, thermocompression), pyrolysis of organic components and sintering (Table 3).

3.2 Slurry preparation

The preparation of slurries is carried out in two stages, namely (i) deagglomeration and dispersion of powders in the solvent with the aid of the dispersant, and (ii) homogenization of the slurry with binders and plasticizers. The sequence of component addition is critical. The dispersant has to be added before the binders to prevent competitive adsorption. The initial adsorption of the binder on the particle surfaces would prevent the dispersant from being subsequently adsorbed, thereby decreasing its effectiveness. Furthermore, the deagglomeration is more efficient in a low viscosity system (i.e. without binders and plasticizers) and the mechanical damage of the binder molecules is minimized by this sequence of addition. The deagglomeration is done by ultrasonic treatment. The second stage of homogenization is performed by milling for 24 h. The slurry is kept rotating at a slow speed for deairing and to prevent settling.

Table 3. Composition of a tape casting slurry

Component	*Function*	*vol.%*
Alumina + zirconia	Ceramic powder	30·6
MEK/ethanol	Solvent	57·6
Phosphate ester	Dispersant	0·8
PVB	Binder	4·6
PEG 300	Plasticizer	2·9
DBP	Plasticizer	3·5

3.3 Tape casting

Tape casting is performed with a laboratory tape-casting bench (Cerlim Equipement, Limoges, France). Slurries were tape cast onto a fixed glass plate with a moving double blade device at a constant speed of 1 m min^{-1}.

4 Evaluation of Residual Stresses in Alumina-Zirconia Laminar Composites

The determination of the distribution of the residual stresses allows the appropriate choice of the layer composition and thickness and of the stacking sequence, for an optimum reinforcement. Models have previously been developed for organic composites[33] or glass-to-metal seals.[34]

During cooling, the difference in deformation, due to the different thermal expansion coefficients of the layers, is accommodated by creep, as long as the temperature is high enough. Below a certain temperature, that will be called the 'joining' temperature, the different layers become bonded together and internal stresses appear.

For laminar composites with symmetrical stacking (odd number of layers) and with a low thickness compared with the plate size, the problem is that of an in-plane stress state with the stress normal to the surface equal to zero ($\sigma_{33} = 0$) (Fig. 1).

In the case of a solid with an isotropic, linear elastic behaviour, the mechanical strains are expressed as follow:

$$\varepsilon_{ijel} = \frac{1+\nu}{E}\sigma_{ij} - \frac{\nu}{E} Tr\tilde{\sigma}\delta_{ij} \qquad (1)$$

$$\varepsilon_{11} = \frac{1}{E}(\sigma_{11} - \nu\sigma_{22})$$

$$\varepsilon_{22} = \frac{1}{E}(\sigma_{22} - \nu\sigma_{11})$$

$$\varepsilon_{12} = \frac{1+\nu}{E}\sigma_{12}$$

$$\varepsilon_{33} = -\frac{\nu}{1-\nu}(\varepsilon_{11} + \varepsilon_{22})$$

$$\varepsilon_{13} = \varepsilon_{23} = 0$$

where $\tilde{\varepsilon}$ is the strain tensor, $\tilde{\sigma}$ the stress tensor, ν the Poisson ratio and E the Young modulus.

In a loading configuration which is symmetrical in respect to directions 1 and 2, and the axes 1 and 2 are equivalent (orthotropic system), then:

$$\sigma_{11} = \sigma_{22} \qquad (2)$$

and

$$\varepsilon_{11} = \frac{1 - \nu}{E}\sigma_{11} = \varepsilon_{22}$$

$$\varepsilon_{12} = \frac{1 + \nu}{E}\sigma_{12}$$

In each layer I, the total deformation after sintering, is the sum of an elastic component and of a thermal component. In the case of a perfectly rigid bonding between the layers, the total deformation will be the same for all the layers, then:

$$\varepsilon_{11}^I = \frac{1 - \nu_I}{E_I}\sigma_{11}^I + \alpha_I \Delta T = \text{constant} \qquad (3)$$

where ΔT is the difference in temperature between the actual temperature, T_o, and the joining temperature, T_j.

The force balance requires (in normal stresses):

$$\sum_I \sigma_{11}^I d_I = 0 \qquad (4)$$

where d_I is the thickness of the Ith layer.

That gives, for a symmetrical composite with $2n + 1$ alternate layers of type 1 and 2:

$$(n + 1)\sigma_{11}^1 d_1 + n\sigma_{11}^2 d_2 = 0 \qquad (5)$$

From eqns (3) and (5), it comes:

$$\sigma_{11}^1 = \frac{nE_1E_2d_2(\alpha_2 - \alpha_1)\Delta T}{n(1 - \nu_1)E_2d_2 + (n + 1)(1 - \nu_2)E_1d_1} \qquad (6)$$

and

$$\sigma_{11}^2 = -\frac{(n + 1)E_1E_2d_1(\alpha_2 - \alpha_1)\Delta T}{n(1 - \nu_1)E_2d_2 + (n + 1)(1 - \nu_2)E_1d_1} \qquad (7)$$

The magnitude of these stresses depends on the thermal expansion coefficient mismatch (that must be small enough to avoid delamination) and on the relative thickness of the layers.

In order to limit the sensitivity to surface flaws, the composite is tailored to develop compressive residual stresses in the outer layers. In the case of a symmetrical laminate, this is obtained by choosing the layer compositions so that the thermal expansion of the odd layers is smaller than the even ones ($\alpha_1 < \alpha_2$).

For a three layer composite ($n = 1$), the change

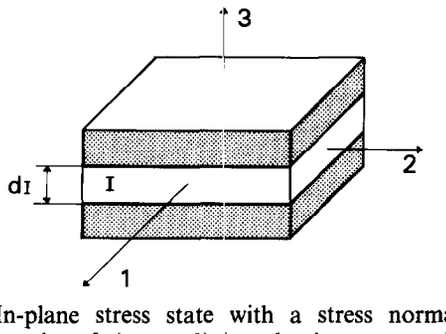

Fig. 1. In-plane stress state with a stress normal to the surface equal to 0 ($\sigma_{33} = 0$) in a laminar composite with a symmetrical stacking.

Table 4. Young modulus, Poisson ratio and thermal expansion coefficient of 'pseudo-laminar composites' consisting of 21 identical layers with a thickness of 160 μm in the green state

	E (GPa)	*ν*	*αΔT*
A/A	341	0·234	-120×10^{-4}
AZ5/AZ5	328	0·241	-125×10^{-4}
AZ10/AZ10	325	0·242	$-121{\cdot}5 \times 10^{-4}$

in compressive (σ_{11}^1) and tensile (σ_{11}^2) stresses with the thickness ratio ($x = d_2/d_1$) of the layers, taking $\nu_1 = \nu_2 = \nu$, is given by eqns (8) and (9):

$$\sigma_{11}^1(x) = \frac{E_1E_2(\alpha_2 - \alpha_1)\Delta T}{(1 - \nu)}\frac{x}{2E_1 + E_2x} \qquad (8)$$

$$\sigma_{11}^2(x) = -2\frac{\sigma_{11}^1(x)}{x} \qquad (9)$$

Figure 2 illustrates these changes for an A/AZ5 composite. The characteristics of the constitutive materials are given in Table 4.

The compressive stress increases when the d_2/d_1 ratio increases, whereas the tensile stress decreases. In the case of brittle materials, which have a high sensitivity to cracking under tensile stresses, the thickness of the layers in tension must be high enough to avoid catastrophic failure.

This result is consistent with Amateau & Messing[2] who observed a decrease in crack frequency in the inner layer (under tension) in a Al_2O_3 + y vol.% SiC_w (20/0/20) when d_2/d_1 increases from 1 to 4.

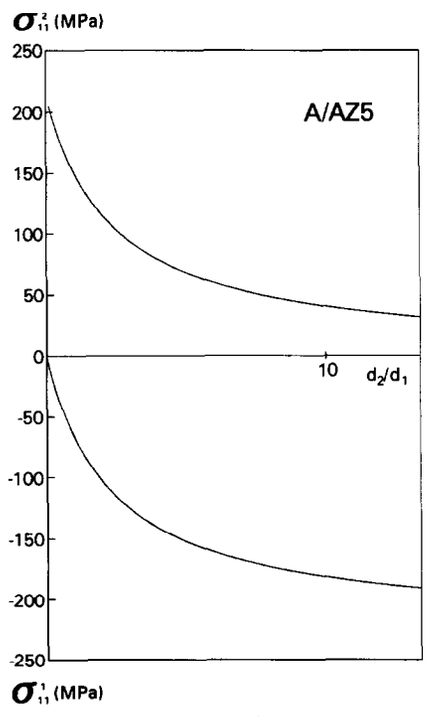

Fig. 2. Compressive stresses (σ_{11}^1) developed in alumina layers and tensile ones (σ_{11}^2) in alumina containing 5 vol.% zirconia layers versus the thickness ratio ($x = d_2/d_1$) in a A/AZ5 composite.

Table 5. Strength to failure σ_f (MPa) (three and four-point bend tests), toughness K_c (MPa$\sqrt{m}$) (SENB) and residual and calculated stresses

	K_c (MPa$\sqrt{m}$)	σ_f (three-point) (MPa)	σ_f (four-point) (MPa)	σ^1_{11} (MPa)	σ^2_{11} (MPa)	σt (calculated) (MPa)

5 Mechanical Properties of Alumina—Zirconia Laminar Composites

5.1 Characteristics of the layer materials

Young modulus and Poisson ratio of the materials were measured using a vibrating technique[35] on monoliths fabricated by stacking 21 identical layers ('pseudo-laminar composites'). The thermal expansion coefficient was measured from 20°C to 1400°C. 1400°C was taken as the joining temperature. The data are given in Table 4.

5.2 Mechanical properties

Table 5 shows the experimental results for ultimate strength in three-point and four-point bending (load normal to the layers), toughness measured by the SENB method (beam notched perpendicularly to the layer planes) together with the internal stresses and the calculated strength.

5.2.1 Flexural strength

In this sollicitation, and taking into account the fact that ceramics are more resistant in compression than in tension, the rupture is initiated in a zone in tension. It can develop either from surface flaws, or from internal defects located in the outest layer in tension.

In the first case, the rupture strength will be equal to the strength of material constituting the outer layer increased of the compressive residual stress.

In the second case, in contrast, the tensile internal stress overlaps the applied stress, leading to a strength lower than the strengths of the constitutive materials of the composite.

The experimental results in Table 5 show a good agreement with the strength calculated under the assumption of a rupture initiated from surface flaws. In fact, the processing flaws have their size limited to the thickness of the individual layer (about 135 μm after sintering) and their growth is impeded by the compressive stresses in the adjacent layers and by the deflection effects at the interfaces.

5.2.2 Toughness

The higher toughness of 'pseudo-laminar composites' AZ5/AZ5 and AZ10/AZ10 reflects the reinforcement due to the tetragonal–monoclinic transformation of zirconia particles. A slight increase of toughness is observed for A/AZ5/A composites in which the compressive stresses in the alumina layers contribute to the lowering of the stress field at the crack tip. The improvement is much higher for AZ10/AZ5/AZ10 composites in which the compressive stresses, induced by the phase transformation of the zirconia particles, are superimposed to the internal compressive stresses in the AZ10 layers, leading to a synergetic effect. Toughness increases from 4·9–5·4 to 8 MPa$\sqrt{m}$.

6 Conclusion

These results illustrate the interest of laminar ceramic–ceramic composites for structural applications. A similar concept could be used to design materials with an improved resistance to high-temperature corrosion. To achieve this goal, a corrosion-resistant material will be chosen for the outer layers and the inner layer will provide mechanical resistance.

Besides composites with layers differing by their mechanical, chemical or thermal properties, it is possible to create sequences of microstructures with different porosities or grain sizes. Hence, it could be possible to have a fluid to flaw through the composite or even to impregnate the composite with a metal (Ni, Al, etc.).

Laminar ceramic–ceramic composites afford an outstanding opportunity to create materials with functional gradients and have immense potential applications.

Shrinkage and Particle Packing during Removal of Organic Vehicle from Ceramic Injection Mouldings

Heidi M. Shaw & Mohan J. Edirisinghe

Department of Material Technology, Brunel University, Uxbridge, Middlesex, UK, UB8 3PH

(Received 21 February 1994; revised version received 3 June 1994; accepted 30 June 1994)

Abstract

Alumina suspensions, containing 50 and 57 vol.% ceramic in isotactic polypropylene and microcrystalline wax, were prepared by high shear mixing and injection moulded. The test bars produced were heated in air at 5°C h^{-1} to four different temperatures in the range 155–225°C and up to about 25 wt% of organic vehicle was removed. Shrinkage in the bars was measured after cooling to room temperature. The difference in the coefficient of thermal expansion of the suspension during heating and cooling, the changes in the crystallinity of the polypropylene and wax compared with the as-moulded state and the mobility of the ceramic particles due to removal of the organic vehicle are contributory factors to the measured shrinkage. The anticipated dimensional changes due to the first two factors have been determined experimentally and thereby the change in particle packing in the inner regions (core) of the test bars due to the mobility of the ceramic in the suspension have been calculated. Results show that in both suspensions heating to just above the softening point caused appreciable particle packing. Subsequently, particle packing decreases substantially and the reasons for this are discussed, taking into account thermal expansion of the organic vehicle, capillary migration of the microcrystalline wax, loss of organic vehicle and development of porosity. Comparison of results with previous investigations show that particle packing is affected by the rate of heating and the atmosphere used during pyrolysis. Particle packing, during pyrolysis, in the more concentrated suspension (57 vol.% ceramic) was, as expected, smaller, except at 225°C, when the core of each test bar containing this formulation showed a steep increase in weight loss. Otherwise, both formulations show similar trends in particle packing during the initial stages of the removal of organic vehicle.

1 Introduction

A commercially attractive method of producing large numbers of dimensionally accurate complex shap engineering ceramic components is plastic forming ceramic suspensions containing an organic vehicle.[1,2] However, full-scale industrial exploitation of plastic-forming methods (e.g. injection moulding, vacuum forming, blow moulding, film blowing) has not been possible, due to difficulties in removing the organic vehicle from the ceramic prior to sintering, without creating defects.

The organic vehicle can be removed by using solvents or, more frequently, by slow pyrolysis.[3] A decade ago successful use of the latter method was thought to involve mainly careful control of the rate of heating as a function of weight loss.[4] However, as plastic-forming methods were used increasingly to produce components with larger section sizes (>10 mm), it became clear that several factors determined the outcome of the crucial pyrolysis stage. These have been reviewed recently[5] and the major factors are:

(1) The rate of heating and the atmosphere in which pyrolysis is carried out.
(2) Characteristics of the organic vehicle.
(3) Characteristics of the ceramic.
(4) A balance between degradation of the organic vehicle and the outward diffusion of the resulting products.
(5) Formation of porosity.

One important phenomenon that occurs during the removal of organic vehicle by pyrolysis but has not been investigated extensively is the movement of the ceramic particles. It is known that, at the end of the organic vehicle removal stage, shrinkage and an increase in particle packing are observed.[6] Ceramic particles can be drawn towards each other under the influence of capillary forces which arise from the curvature of inter-par-

ticle surface menisci or of internal porosity formed during pyrolysis, much like in the initial stages of liquid-phase sintering.[7] However, during the initial stages of pyrolysis the liquid organic vehicle expands[8,9] and it is suggested[9] that this can result in the development of hydraulic pressures in the suspension with the ceramic particles forming a rigid network preventing further packing. Thermal expansion coefficients of ceramic suspensions can be measured in the liquid and the solid state,[10] indicating that particles are mobile and therefore the hypothesis that they form a rigid network lacks experimental evidence.

It is well known that packing of ceramic particles depends on their characteristics,[11] in particular their shape.[12] In the case of spherical powders, particle centres approach each other and porosity decreases due to the increase in packing. However, most commercial ceramic powders are non-spherical and their motion to enhance packing requires both the approach of particle centres and particle rotation. Removal of the organic vehicle from inter-particle spaces in the suspension can give rise to the former type of movement but the latter could be difficult in a suspension having high viscosity, especially during the initial stages (low temperatures) of pyrolysis. Another factor which could retard rotation of the particles is the presence of immobile layers of adsorbed organic vehicle on the ceramic surfaces.[13]

The measured shrinkage after heating to various temperatures and subsequent cooling to room temperature during pyrolysis of the organic vehicle does not fully correspond to the particle packing that has taken place. Firstly, compared to the heating cycle, the suspension contains a different amount of organic vehicle during cooling to room temperature and this can result in a difference in the coefficient of thermal expansion, causing a dimensional change that has to be taken into account. Secondly, the crystalline polymeric components in the organic vehicle, such as isotactic polypropylene and microcrystalline wax in the present work, can have different percentage crystallinities dependent on thermal history and processing[14,15] and this causes dimensional change. Therefore, the associated dimensional change due to the difference in crystallinity of the relevant constituents in the organic vehicle after heating to various temperatures during pyrolysis and subsequent cooling to room temperature has to be estimated.

Previous investigations[16,17] led to a quantitative assessment of the development of porosity (during the initial stages of pyrolysis in air) in injection-moulded test bars containing 50 and 57 vol.% alumina, suspensions made using an organic vehicle in which isotactic polypropylene and microcrystalline wax were the major and minor constituents, respectively. In the present work, identical ceramic suspensions and test bars are used and pyrolysis has been interrupted at four different temperatures to measure shrinkage after cooling to room temperature. The corresponding dimensional changes due to thermal expansion coefficient and crystallinity already discussed have been calculated from experimental results. Thereby the measured shrinkage has been corrected to calculate the vol.% shrinkage caused by the packing of ceramic particles during the initial stages of pyrolysis when up to 25 wt% organic vehicle is removed.

2 Experimental details

2.1 Production of test bars

Two formulations A and B containing 50 and 57 vol.%, respectively, of A16.SG alumina (Alcoa Manufacturing (GB) Ltd, Worcester, UK) were prepared using an organic vehicle containing isotactic polypropylene (density 905 kg m^{-3}), microcrystalline wax (density 910 kg m^{-3}) and stearic acid in the weight ratio 6:2:1. Further details of the ceramic powder and each constituent in the organic vehicle have been published earlier.[17]

Preblends of formulations A and B were prepared by tumbling the formulations in a container and then compounding in a twin screw extruder (Model TS40, Betol Machinery, Luton, Bedfordshire, UK). Compounding conditions of these formulations have been published previously.[17] The extrudate was dried and granulated, and the ceramic loading was verified by ashing samples (by heating to 600°C).

A 6GV/50 Sandretto reciprocating screw injection-moulding machine was used to produce 3 mm thick tensile test bars (Fig. 1) according to conditions reported previously.[17] The injection pressure, nozzle temperature and mould temperature used were 127MPa, 50°C and 235°C, respectively. The test bars were X-ray radiographed to verify that there were no voids or cracks present after moulding.

2.2 Pyrolysis

Test bars were pyrolysed in a muffle furnace in static air. The rate of heating was determined by trial and error experiments such that pyrolysis does not produce voids or cracks in the mouldings. The bars were heated initially from room temperature to a few degrees below the softening points of the formulations (148°C) at 50°C h^{-1} and then soaked for 24 h at this temperature. Subsequently, heating was continued at 5°C h^{-1}. Three

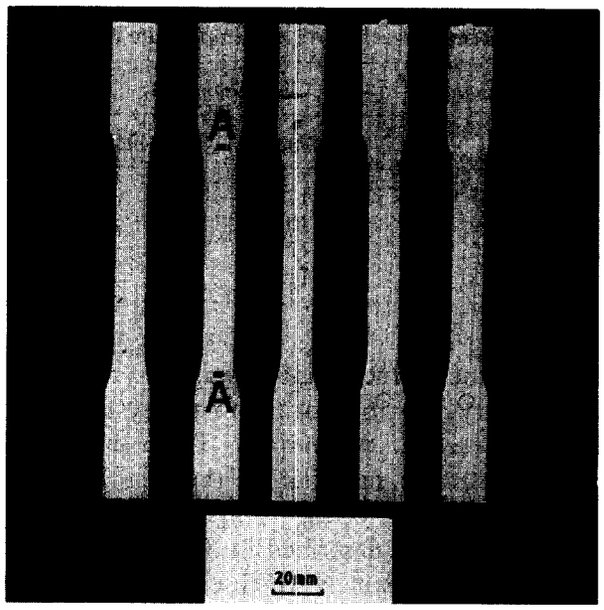

Fig. 1. Injection mouldings produced (nominal thickness 3mm). AA indicates the position and length of the test bars used for measurement of linear shrinkage.

test bars of each formulation were heated to 155, 170, 195 and 225°C (referred to as pyrolysis temperatures in the text and measured to an accuracy of ± 1°C) before cooling in the furnace to room temperature. Test bars were X-ray radiographed after pyrolysis to verify that voids and cracks were absent and subsequently were used to carry out the following experiments in triplicate.

2.3 Measured linear shrinkage

Two marks were scribed on the test bars as shown in Fig. 1 prior to pyrolysis. The distance between the two marks was measured with a travelling microscope before and after pyrolysis to the temperatures given in Section 2.2.

2.4 Loss on ignition

After pyrolysis, the test bars showed a clear contrast in colour between the core and surface regions (Fig. 2). Therefore, the material in the surface region was carefully separated from the core by scoring with a scalpel blade. The dimensions of the core were measured using Vernier callipers to calculate (separately) the vol.% of test bar that constitutes the core and the surface regions as pyrolysis progressed. Samples of both surface and core material were heated to 600°C (in triplicate) to calculate the weight loss of organic vehicle.

2.5 Dilatometry

Thermal expansion curves were obtained for 2·5 × 2·5 mm cross-section core samples (4mm thick) using a Perkin Elmer TMS1 thermomechanical analyser (TMA). Expansion was measured along the length of the test bars. A load of 3 g was used

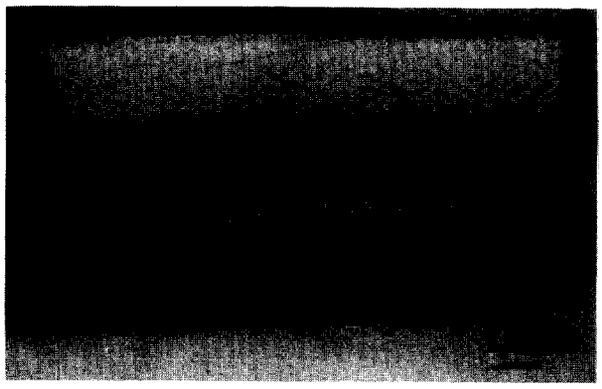

Fig. 2. Typical appearance of the cross-section of test bars after pyrolysis showing the dark surface region. Examples shown are: (a) A test bar of formulation A pyrolysed to 195°C; (b) a test bar of formulation B pyrolysed to 195°C.

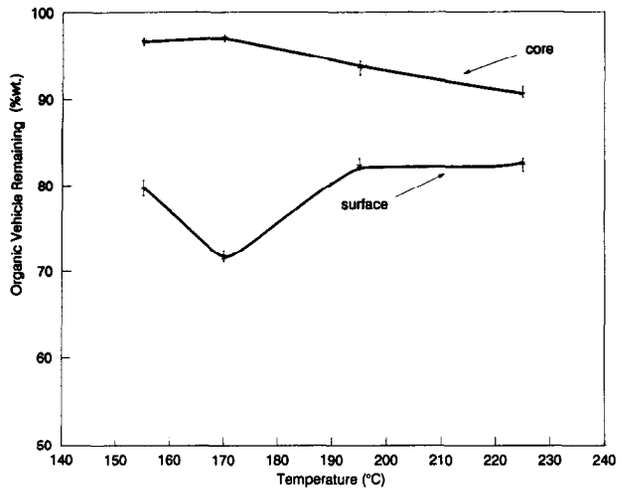
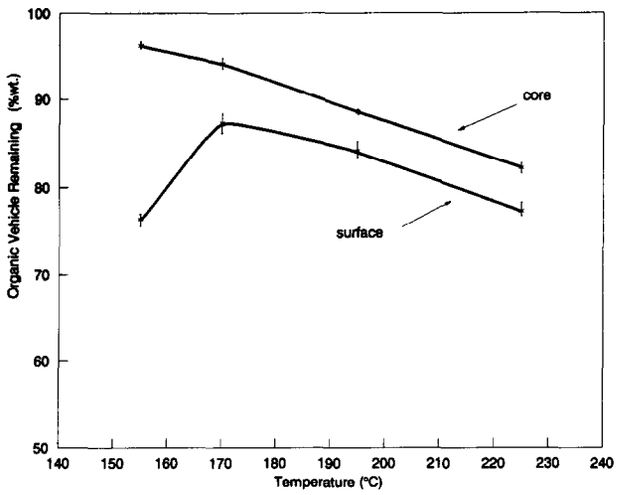
on a flat-ended silica glass rod (diameter 4 mm) during heating the samples at $8°C^{-1}$ h to 120°C. These experimental conditions have been used successfully in previous work[18] to calculate the linear thermal expansion coefficient of ceramic suspensions. The TMA was calibrated using a pure sample having a linear thermal expansion coefficient of $2·3 \times 10^{-5}$ K^{-1}.



2.6 Differential scanning calorimetry (DSC)

A Perkin-Elmer DSC2 was used to measure enthalpies of fusion of samples taken from the core of pyrolysed test bars. A scan speed of 10 K min^{-1} was used during heating the samples between room temperature and 250°C.



3 Results and discussion

3.1 Mechanisms of removal of the organic vehicle

The dark appearance of the surface of pyrolysed test bars of both formulations (Fig. 2) suggests that the organic vehicle present in these regions has been subjected to a greater level of degradation compared with the core. This is due to the presence of oxygen in the atmosphere in which pyrolysis is carried out. Oxidative degradation occurs in the surface regions while thermal degradation dominates in the core of the mouldings[19,20] and the former is known to give rise to a higher weight loss at a lower temperature.[21] Loss on ignition results of surface and core samples shown in Fig. 3 indicate an increase in the wt% of organic vehicle in the surface regions at 195 and 225°C in formulation A and at 170°C in formulation B. Therefore, enrichment of the organic vehicle in the surface regions occurred in both formulations (over a wider temperature range in formulation A which contained more organic vehicle) during the initial stages of pyrolysis. The organic vehicle in both surface and core regions of the test bars after

(b)

Fig. 3. Variation of weight of organic vehicle remaining (as a percentage of the initial weight of organic vehicle in the as-moulded test bars) with pyrolysis temperature in the surface region and the core of the mouldings of (a) formulation A; (b) formulation B. Formulations A and B contained 81·24 (±0·05) wt% (equivalent to 49·7 vol.%) and 85·17 (±0·14) wt% (equivalent to 56·7 vol.%) ceramic in the as-moulded state (from ashing at 600°C). Thus the green densities of formulations A and B are 2440 kg m^{-3} and 2655 kg m^{-3}, respectively.

pyrolysis has been analysed by gel permeation chromatography (GPC) and reported previously.[22] GPC results show that the polypropylene in the core of test bars of both formulations did not show any appreciable degradation but the intensity of the wax peak decreased. In contrast, at the surface, although the polypropylene present in the organic vehicle degraded to some extent (particularly at 225°C), the significant feature was the increase in the intensity of the wax peak. Therefore, in the context of the present investigation, the important mechanism of removal of organic vehicle from the core of the test bars of both formulations during the initial stages of pyrolysis is the capillary migration of the microcrystalline wax to the surface.

The rate of weight loss due to oxidative degradation in the surface regions was also affected by the capillary migration of the microcrystalline wax from the core to the surface. The vol.% of discoloured surface material in the test bars (presented in Table 1 using results from the experimental procedure described in Section 2.4) hardly varies in formulation A which contained more organic vehicle and showed capillary migration of microcrystalline wax over a wider temperature range, as already discussed. In contrast, there is a rapid increase in the vol.% of surface material in test bars of formulation B.

Table 1. Volume of test bar which contains discoloured surface material at each pyrolysis temperature investigated

Temperature (°C)	*Volume (%)*	
	Formulation A	*Formulation B*
155	12	6
170	10	13
195	10	19
225	11	22

3.2 Measured shrinkage

The linear shrinkages (S_L) measured (Table 2) were converted to volume shrinkages (S_v) by using the expression:

$$S_v = 3S_L - 3S_L^2 + S_L^3 \quad (1)$$

Figure 4 shows the variation of S_v with pyrolysis temperature. In order to understand further the behaviour of the suspensions during pyrolysis, S_L of the test bars was also measured at 150°C (just below the softening point of both formulations; dilatometric measurements give 151°C (formulation A) and 154°C (formulation B)) and the corresponding S_v values are also shown in Fig. 4. In both formulations S_v increases initially. This is expected as residual stresses are released on heating past the softening point and the ceramic particles have the opportunity to move towards each other as suspensions begin to lose organic vehicle. However, at 170°C both formulations show a decrease in S_v.

Bandyopadhyay & French[8] observed a similar effect during the interrupted pyrolysis of injection-

moulded test bars and spheres made using silicon nitride powder and an organic vehicle which contained microcrystalline wax and epoxy resin as the major and minor constituents, respectively. Volume expansion of the organic vehicle takes place during heating but S_L, measured at room temperature, can only show a decrease if the ceramic particles in the core of the mouldings are restrained from moving during cooling. However, S_v values can also be influenced by changes in the properties of organic vehicle during pyrolysis (see Sections 3·3 and 3·4). After off-setting the effect on S_v due to changes in the properties of the organic vehicle during pyrolysis, particle packing in the suspensions investigated is discussed in Section 3.5.

3.3 Thermal expansion

The loss of organic vehicle during pyrolysis causes the linear thermal expansion coefficient (α_L) of samples of test bars to differ from the as-moulded values during cooling and this affects the S_L values calculated. This effect can be corrected for by measuring α_L of core samples of pyrolysed test bars (Table 3) and calculating:

$$(\Delta L)_{exp} = \{(\alpha_L)_{as\text{-}moulded} - (\alpha_L)_{pyrolysed}\}\,\Delta T \quad (2)$$

where $(\Delta L)_{exp}$ is the dimensional change in the test bars due to the change in α_L and ΔT is the difference between the pyrolysis temperature and the room temperature. Since $(\alpha_L)_{as\text{-}moulded} > (\alpha_L)_{pyrolysed}$ at all the temperatures investigated (Table 3), $(\Delta L)_{exp}$ is an expansion. α_L of injection-moulded ceramic bodies shows anisotropy[23] and therefore all measurements were made along the length of the test bars, the direction in which S_L was measured. $(\Delta L)_{exp}$ values were converted to vol.%, $(\Delta V)_{exp}$, using eqn (1) and these results are also presented in Table 3. The maximum error in

Table 3. Coefficient of linear thermal expansion (α_L) of formulations A and B at each pyrolysis temperature and $(\Delta V)_{exp}$ corresponding to the average of the α_L values given

Temperature (°C)	*Formulation A*		*Formulations B*	
	$\alpha_L(MK^{-1})$	$(\Delta V)_{exp}$ *(vol.%)*	$\alpha_L(MK^{-1})$	$(\Delta V)_{exp}$ *(vol.%)*
20 (as moulded)	146, 139, 142	—	134, 147, 152	—
155	133, 110, 120	0·0114	110, 114, 93	0·0156
170	71, 73, 82	0·0303	70, 52, 74	0·0355
195	115, 114, 106	0·0160	95, 105, 107	0·0218
225	59, 51, 60	0·0526	43, 44, 46	0·0614

$(\Delta V)_{exp}$, due to the use of the average α_L values, is 36%. However, these values are of the order 10^{-2} and the actual magnitude of the error involved is extremely small. The error does not change the conclusions of this investigation. In fact, $(\Delta V)_{exp}$ has a negligible effect on particle packing, as described in Section 3.5.

3.4 Crystallinity

DSC results of each sample showed two peaks corresponding to the crystalline melting of microcrystalline wax (MCW) and isotactic polypropylene (IPP). The enthalpies of fusion of 100% crystalline MCW and IPP are 267 J g^{-1} and 165 J g^{-1}, respectively.[24] These values were compared with the measured enthalpies of fusion to calculate the percentage crystallinities of MCW and IPP in each sample (Table 4). These results show that as the test bars were cooled to room temperature, the percentage crystalinity of MCW, in particular, becomes smaller at higher pyrolysis temperatures. The vol.% shrinkage, $(\Delta V)_{crys}$, associated with the crystallinity of MCW and IPP, can be calculated separately using eqn (3):

$$(\Delta V)_{crys} = \text{specific volume change} \times \text{density of MCW (or IPP)} \times \%\ \text{crystallinity} \times \text{vol.\% of MCW (or IPP) in the organic vehicle} \quad (3)$$

The specific volume changes for MCW and IPP are 0·193 $m^3\ Mg^{-1}$ and 0·116 $m^3\ Mg^{-1}$,[24] respectively. The vol.% of MCW and IPP in the organic vehicle was estimated using the relative intensities of the gel permeation chromatograms reported previously[22] and the fact that in the as-moulded state the MCW : IPP weight ratio was 3 : 1 (as mixed proportions). Gel permeation chromatograms also show that in the pyrolysis temperature range investigated the molecular weights of MCW and IPP in the core of the test bars do not change significantly[22] and therefore their as-received densities (given in Section 2.1) were used in calculating the vol.% of the MCW and the IPP in

Table 4. Percentage crystallinity, $(\Delta V)_{crys}$ and $(\Delta V)^*_{crys}$ of formulations A and B at each pyrolysis temperature

A minus sign indicates an expansion.

the organic vehicle and $(\Delta V)_{crys}$ at each pyrolysis temperature.

The organic vehicle also contains approximately 11 wt% of stearic acid which is used as a processing aid.[25] Thermogravimetry of stearic acid shows that at 150°C (approximately the softening point of the formulations) over 50 wt% of the stearic acid is removed. In addition, taking into account processing of the ceramic suspensions in the twin-screw extruder and the injection-moulding machine (Section 2.2), it can be assumed that only a very small amount of stearic acid remains in the formulations at the pyrolysis temperatures investigated and its effect has not been taken into account in the present analysis.

$(\Delta V)_{crys}$ values and the change in $(\Delta V)_{crys}$ at each pyrolysis temperature, compared with the as-moulded samples, $(\Delta V)^*_{crys}$, are also shown in Table 4. The maximum error in $(\Delta V)_{crys}$, due to the use of the average crystallinity values, is 10% and does not change the conclusions of this investigation.

3.5 Particle packing

The measured shrinkage (Table 2) is the sum of the shrinkages caused by particle packing, expansion due to the change in the coefficient of linear thermal expansion coefficient ($(\Delta V)_{exp}$ in Table 3), and the shrinkage (or expansion) due to the change in crystallinity ($(\Delta V)^*_{crys}$ in Table 4). The shrinkage due to particle packing at each pyrolysis temperature calculated on this basis is shown in Fig. 5.

In the as-moulded state of the test bars, all inter-particle space is filled with organic vehicle.[26] Removal of organic vehicle during pyrolysis results in particles moving closer together (particle packing) or the creation of porosity. Previous work[6] has shown that once pyrolysis is complete the vol.% of ceramic in the body could increase only to V^*_{max}, where $V < V^*_{max} < V_{max}$. V is the initial vol.% of ceramic in the suspension and V_{max} is the maximum volume of ceramic that can be incorporated in the suspension and this value is deduced from viscosity data.[27] V^*_{max} is approximately equal to the measured CPVC (critical powder volume concentration) value.[28] Therefore, V^*_{max} represents a situation where the particles move closer to each other and 'lock into position', preventing any further movement.

At 155°C (just above the softening point of the suspensions), when the core of the test bars of both formulations show a 3–4 wt% loss of organic vehicle, calculated particle packing shrinkages are 3·78 vol.% and 2·03 vol.% in formulations A and B, respectively (Fig. 5). However, at 150°C (just below the softening point of the suspensions) when weight loss of organic vehicle is negligible (<1%) the core of the test bars of formulations A and B show measured shrinkages of 2·2 vol.% and 1·6 vol.% respectively (Fig. 4). Relaxation of residual stresses in the test bars caused by injection moulding occurs on heating to the softening point[29] and this can influence the bulk measured shrinkage and particle packing. The more dilute

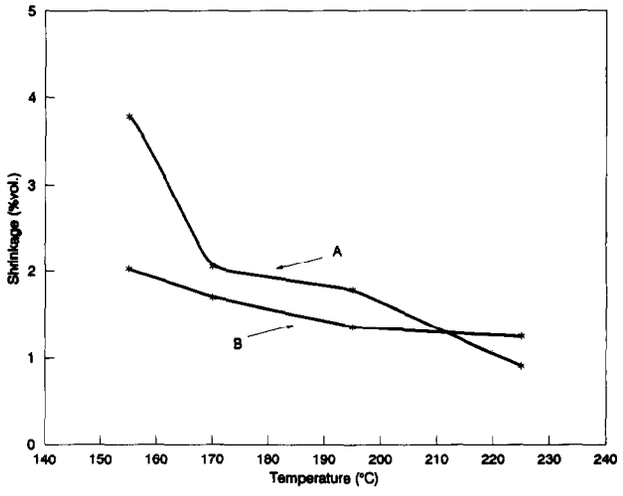

Fig. 5. Variation of shrinkage due to particle packing with pyrolysis temperature in formulations A and B.

formulation A shows a larger initial shrinkage due to particle packing. This is expected as $(V_{max}-V)$ is larger in the case of formulation A. Subsequently, at 170 and 195°C both formulations show a decrease in particle packing in the core of the test bars (Fig. 5). This shows that the volume expansion due to melting of the organic vehicle, which occurs as the temperature exceeds the softening point of the formulations, is not relaxed completely on cooling to room temperature and, in effect, particles are pulled apart. This is despite capillary migration of the MCW from the core of the test bars helping the particles to be drawn towards each other as discussed earlier (see Section 1).

This decrease in particle packing can be explained by considering the interaction between the surface region and the core of each test bar. The surface region loses a larger amount of organic vehicle (Fig. 3) and therefore will experience a greater shrinkage. Previous work[17] has shown that the surface and interconnected porosity remains virtually constant at almost 2–3 vol.% in the temperature range 155–195°C, in both formulations. V^*_{max} of formulations A and B are 51 and 58%, respectively.[6] Taking into account loss of organic vehicle from the surface region (Fig. 3) and neglecting the formation of porosity, the vol.% of ceramic in the surface increases to 54 and 61% (average for the temperature range 155–195°C), in formulations A and B, respectively. Even if the levels of porosity are accounted for completely as surface porosity, the vol.% of ceramic in the surface region is $\simeq V^*_{max}$ of each formulation. Thus, the ceramic particles in the surface region have achieved the maximum packing efficiency and are 'locked together'. This effect makes the surface regions behave like a rigid skin (which appears as a dark degraded region as shown in Fig. 2) and 'holds' the ceramic particles in the core, restraining them from further packing during cooling after being pulled apart due to the volume expansion of the organic vehicle. It can be argued that this type of restraint can lead to cracking. However, cracking was not observed in the present work. The presence of the organic vehicle (>75 wt% remaining in both formulations at 225°C) allows the suspension to behave like a plastic mass, which helps to prevent cracking.

At 225°C, this phenomenon continues to hinder particle packing in formulation A. However, in formulation B, the reduction in particle packing decreases (Fig. 5). This coincides with an increase in the development of porosity in formulation B, as discussed in previous work.[17] Figure 3 shows that in the case of formulation B, compared with formulation A, the rate of weight loss in the core of the test bars is greater and that at 225°C it has lost a higher wt% of the organic vehicle. Therefore, at this temperature, the ceramic particles in formulation B can be expected to pack to a greater extent.

This reduction in particle packing during the early stages of removal of organic vehicle was not observed in previous work.[30,31] In these instances (the same organic vehicle was used), particle packing during interrupted pyrolysis was reported as measured linear shrinkage (uncorrected) and these approached a limiting value at about 190°C. However, a variable rate of heating (much faster than the constant 5°C h^{-1} in the present work) was used to pyrolyse the test bars during the initial stages and a dark skin at the surface of the test bars was not evident. This provides additional evidence for the argument that the extent to which the surface regions form a degraded rigid skin, which seems to be related to the rate of heating during pyrolysis, is an important feature affecting the packing of the ceramic particles during the removal of the organic vehicle. It also indicates that the atmosphere in which pyrolysis takes place will affect shrinkage (and particle packing) in the artefacts. If pyrolysis was carried out in an inert atmosphere such as N_2 where oxidative degradation does not take place, a surface skin which could restrain particle packing in the core of the mouldings would not prevail and larger shrinkages will be observed, as noted by Wright *et al.*[6] Bandyopadhyay & French[8] pyrolysed mouldings in N_2 but their observation of a reduction in shrinkage during the early stages of pyrolysis, as in the present work, was most probably caused by the fact that the mouldings were packed in ceramic powders, which were used as a wicking medium, and this created a restraining effect on the surface.

4 Conclusions

The shrinkage due to the packing of ceramic particles in the core of injection-moulded test bars during the initial stages of pyrolysis in static air has been calculated by correcting measured shrinkage values for changes in the coefficient of thermal expansion and the changes in the crystallinity of the constituents of the organic vehicle. Initially, particle packing increased at a temperature just above the softening point of the formulations but it is likely that the relaxation of residual stresses caused by injection moulding would have influenced shrinkage measurements and affected particle packing. However, subsequent particle packing in the core of the test bars decreased as it was restrained by the rigid surface regions which

form due to oxidative degradation. Comparison of the results of the present work with previous investigations show that the rate of heating and the atmosphere used during pyrolysis also affect particle packing. Although shrinkage due to particle packing in the more concentrated suspension was, as expected, smaller (except at 225°C when there was a steep increase in weight loss compared to the other formulation), there were no major differences in these trends in the two formulations investigated. This indicates that the 7% difference in initial volume fraction of ceramic in the suspensions did not have a significant effect on particle packing during the initial stages of removal of the organic vehicle.

(Received 18 April 1994; revised version received 3 June 1994; accepted 30 June 1994)

Abstract

A furnace within a pressure vessel capable of withstanding 0–1 MPa and temperatures up to 600°C is described. The furnace allows the pyrolysis of injection moulded ceramics to take place at higher heating rates than is possible at atmospheric pressure without defects caused by bloating or cracking. The effectiveness of the method is described for a commercial injection-moulding composition pyrolysed in nitrogen. The various effects of gas pressure on the process are listed and the main beneficial effect is considered to be the increase in boiling point of the polymer-degradation product solution which forms the continuous phase. In the early stages of heat treatment, this allows more rapid mass transport both by diffusion and fluid flow.

1 Introduction

Many techniques drawn from polymer processing have been successfully applied to ceramic suspensions in order to facilitate the arrangement of particles into complex shapes before firing.[1] The most versatile of these is injection moulding, but they all have the disadvantage that organic matter initially filling the interstitial space must be removed before firing. This presents particular problems for thick sections made by injection moulding.

Capillary[2] and solvent[3] methods have been used for binder removal but the most popular method is pyrolysis either in an oxidative atmosphere,[4] an unreactive atmosphere[5] or in vacuo.[6] Frequently mouldings are packed in a powder bed during heat treatment and loss of molten organic vehicle is assisted by partitioning between the two powder assemblies. During pyrolysis, three weight loss processes can be identified, dependent on ambient atmosphere and molecular weight of the organic vehicle.[7] For low molecular weight material, evaporation proceeds without chain scission and the thermogravimetric characteristics are little affected by atmosphere. For high molecular weight organic vehicles, chain scission must precede evaporation and this can occur either by oxidative degradation, in which case it is likely to be affected by the diffusion of oxygen into the body,[8] or by thermal degradation, in which case it will occur uniformly throughout the body if the degradation reaction is irreversible.

Under oxidising atmospheres the former reaction predominates, although under conditions of prolonged heating, such as those needed for binder removal from thick sections, thermal degradation will proceed to some extent in all cases. Thermal degradation therefore deserves priority of attention because low molecular weight products of decomposition are formed throughout the body at a stage when interconnected porosity is absent.

A manufacturer often wishes to minimise the debinding time in order to reduce the number of stationary semi-finished products. Low-temperature furnace costs are modest and debinding times often compare favourably with raw material bulk storage times so that the debinding stage does not incur such a prohibitive debit as is sometimes claimed. The main benefit of shortening this stage accrues if the lead time for new products can be reduced. Another advantage of enhancing the debinding stage is that larger sections may be successfully treated in sensible time scales.

Several strategies are available under this objective. The organic vehicle can be selected to decompose steadily as temperature rises.[9,10] The process can be controlled by an external loop so that weight loss is a linear function of temperature.[11] The organic vehicle can be synthesised to have the combined properties needed to prevent the boiling of degradation products in solution.[12] Pressure can be applied to the decomposing system.[13] This work explores the latter intervention.

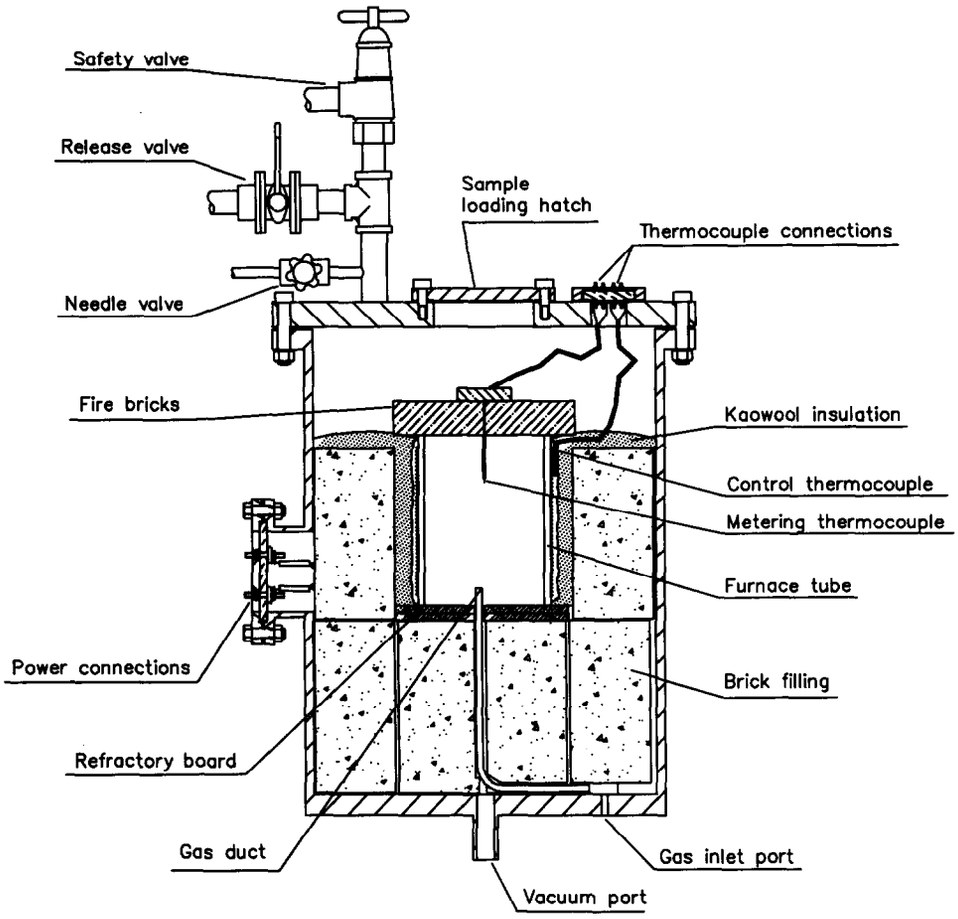

Fig. 1. Diagram of the pressure vessel and furnace.

2 Experimental Details

2.1 Furnace design

The pressure vessel was manufactured from carbon–manganese steel to the specifications of BS1500, which has recently been superseded by BS5500.[14] Its internal dimensions were 435 mm diameter × 600 mm in height. This allows a large furnace to be incorporated or alternatively a series of small furnaces. The present work was carried out with a 150 mm diameter × 200 mm furnace wound from 80/20 Ni/Cr wire on a silica glass tube. Figure 1 shows the vessel and furnace diagrammatically. The top, wall and base were water-cooled by independent circuits incorporating flow indicators. Wall temperature was monitored by three series-connected thermal switches (opening at 40°C) which latched a relay controlling electric power to the furnace. Oxygen-free nitrogen was used in all the experiments. A preset Nabic spring-operated safety valve was fitted to prevent the rated working pressure of 1·05 MPa being exceeded. Gas throughput was controlled by a needle valve venting through a flow meter into an oil indicator. Electric leadthroughs were made through 20 mm thick discs of cloth-reinforced phenol–formaldehyde resin (Tufnol, Birmingham, UK) clamped with O-ring seals. The internal and external surfaces of the vessel were treated with a two-part organic-resistant epoxy-based paint (Trimite, Uxbridge, UK). The general arrangement of the furnace vessel and its ancillary circuits are shown in Fig. 2.

A Eurotherm 818P temperature controller was used to provide linear heating rates and the controller thermocouple, mounted on the outside of the windings, was calibrated dynamically against the hot zone thermocouple at three gas pressures, 0·1, 0·6 and 1·0 MPa, and for each sample container. The procedure for filling the vessel involved evacuation to about 2·5 kPa followed by filling with oxygen-free nitrogen. A gas flow of 10^{-6} m^3 s^{-1} was maintained during experiments and the internal pipework allowed the gas to enter at the base of the furnace tube. Although the oxygen content of the nitrogen was not measured directly, the furnace was heated to 600°C with copper powder and the weight changes indicated that negligible oxidation had taken place. Significant polymer oxidation may therefore also be assumed to be absent.

2.2 Materials and mouldings

The ceramic powder was a proprietary silica (<200 μm) having a density of 2200 kgm^{-3}, used for leachable foundry cores for nickel alloy tur-

Fig. 2. The pressure vessel showing the arrangement of valving and coolant.

bine blades. The organic vehicle was a proprietory blend based on a low molecular weight polyethylene glycol diluted with waxes and a stearate as a processing aid and had a density of 1110 kgm^{-3}. Ashing showed a 22·1% weight loss indicative of a powder loading of 64 vol.%. Injection moulding of 17 mm diameter cylinders, 100 mm in length was performed at Fairey Tecramics Ltd using a Florin injection-moulding machine with a maximum barrel temperature of 60°C and a maximum injection pressure on material of 52MPa. The cylinders were contact radiographed before pyrolysis using a Hewlett Packard Faxitron camera. A Perkin Elmer TMA dilatometer with a flat-ended silica rod and a 10 g load was used to determine the dilatometric softening point of the suspension. Thermogravimetry was performed on a Perkin Elmer (Beaconsfield, Bucks, UK) model TGS2.

2.3 Pyrolysis

Three methods of sample support were used. Some samples were placed on a refractory tile with a dusting of coarse alumina (Grade LG20, Alcan Chemicals, UK). Others were fully packed in this alumina powder, either in a steel trough or a ceramic crucible. In the third series of experiments, samples were packed in coarse SiC powder (Grade C6, Besco Abrasives Ltd, Surrey, UK). Tests were done at gas pressures of 0·1, 0·6 and 1·0 MPa. After heat treatment, the samples were lightly sintered to facilitate handling, by heating to 1150°C, holding for 4 h and furnace cooling. They were then examined externally, radiographed and cut across the central lateral cross-section to establish integrity. On certain samples, measurements of the horizontal and vertical diameters were taken at the centre of the bar, to find the ovality. Positive ovality (the difference between the horizontal diameter and the vertical diameter) was taken as an indication of the degree of slumping which had occurred. Linear heating from 70°C to 500°C was used throughout, with a ramp of 60°C h^{-1} from 20°C to 70°C and from 500°C to room temperature.

3 Results and Discussion

Although it is routine practice to carry out a steady-state furnace calibration, what is required here is a dynamic calibration because the integrity of samples is assessed in terms of a critical heating rate. The hot zone temperature initially lags behind the set temperature but the hot zone rate increases as temperature rises, producing families of calibration curves such as that shown in Fig. 3.

At the low heating rates typical of thermolytic debinding at atmospheric pressure, the rates coincide over the range of temperatures of interest. The high rates of heating that are possible under overpressure conditions, however, may lead to substantial deviations. The choice of temperature at which to deduce the actual rate is fixed by the initial region of rapid thermal degradation and may be deduced from appropriate thermogravimetric curves. Since the thermogravimetric loss behaviour varies with heating rate, the problem is to decide at which temperature to convert set rate to actual rate. The procedure used here was to select the temperature at which an arbitrary 20wt% loss based on the initial weight of binder had occurred.

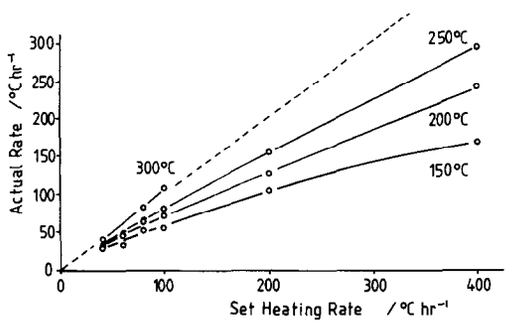

Fig. 3. An example of the dynamic calibration for heating rate at various hot zone temperatures. (0·6 MPa, setter powder LG20 alumina in stainless steel trough.) The dashed line represents set rate = actual rate.

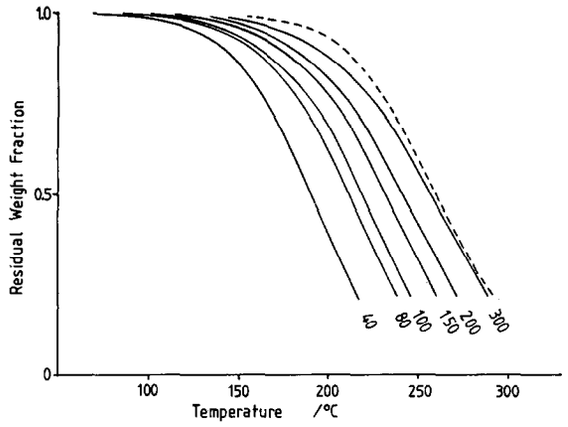

Fig. 4. Thermogravimetric curve for the organic vehicle heated in nitrogen at 300°C h^{-1} (dashed line) and calculated curves for other heating rates labelled on the curves in °Ch^{-1}.

From the thermogravimetric loss curve at a rate of 300°C h^{-1} the activation energy E and specific rate constant K_0 were obtained by the method of Wendlandt.[15] This makes the assumption that the weight loss is a first order reaction and therefore neglects the effect of evaporation of low molecular weight additives which are lost by zero order kinetics. It does not attempt to assess the loss of fluid by partitioning into the porous powder support.

The reaction is therefore treated as obeying

$$\frac{dw}{dt} = -Kw \tag{1}$$

where w is the weight fraction of binder remaining and K is the rate constant which varies with temperature as

$$K = K_0 \exp\left(\frac{-E}{RT}\right) \tag{2}$$

Once K_0 and E are known, the thermogravimetric loss curve can be constructed for any heating rate Z using

$$w = \exp\left\{-K_0 \frac{RT^2 \exp(-E/RT)}{ZE} \times \left[1 - \frac{2RT}{E} + \frac{6(RT)^2}{E^2}\right]\right\} \tag{3}$$

Figure 4 shows the experimental thermogravimetric curve at a rate of 300°C h^{-1}, together with the curve recalculated using eqn (3). This method inevitably results in some error because the activation energy plot is linear over a restricted range of temperature; in this case 212° to 276°C.

The corresponding curves for other heating rates are also shown. This is an approximate way of executing the rate calibration and the errors are most pronounced at high set rates. Both set and calculated heating rates are quoted for overpressure experiments in Tables 1—3.

The bars were radiographed to ensure that they were free from shrinkage voids or cracks caused by the injection-moulding processes which might interfere with the assessment of critical heating rate. In general the bars were free from such defects and examples of prints of radiographs are shown in Fig. 5.

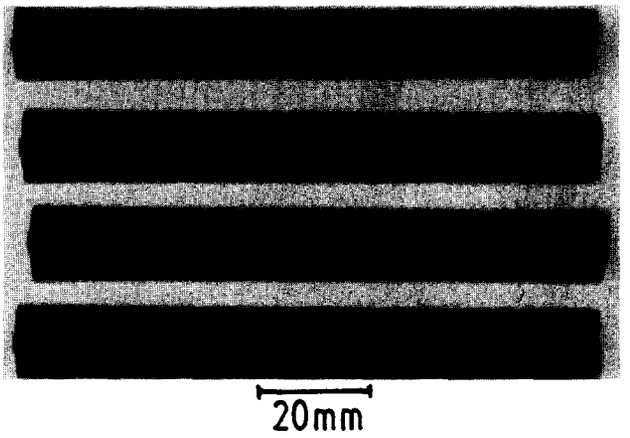

Fig. 5. Prints of radiographs of moulded bars before heat treatment.

In the first series of experiments, the samples were supported on a refractory tile with a thin layer of alumina powder. The results are summarised in Table 1. This identifies three factors influencing the quality of moulding after binder removal. The effect of heating rate is seen by comparing samples heated at set rates of 5°C h^{-1} and 15°C h^{-1}, showing that the critical heating rate at atmospheric pressure lies between these temperatures. The sample heated at a set rate of 5°C h^{-1} is shown in Fig. 6. Samples heated at a set rate of 40°C h^{-1} under 0·6 MPa pressure, although defective in cross-section, were only marginally worse than the sample heated at 15°C h^{-1} under 0·1 MPa, indicating that overpressure has a beneficial effect. Samples heated at set rates of 100 and 200°C h^{-1} showed severe deformation due to

Table. 1. Integrity of mouldings heat treated on a tile, unsupported by powder

Heating rate °Ch^{-1}		*Pressure (MPa)*	*Results*
Set	*Actual*		
5	5	0·1	No surface cracks, no visible defects in cross-section
15	13	0·1	No surface cracks, signs of slight internal cracking
20	18	0·6	Some surface cracks, signs of internal cracking
40	35	0·6	Some surface cracks, signs of internal cracking
100	83	0·6	Extensive surface cracks and parallel cracks in section, extensive slumping
200	180	0·6	Extensive surface cracks and parallel cracks in section, extensive slumping

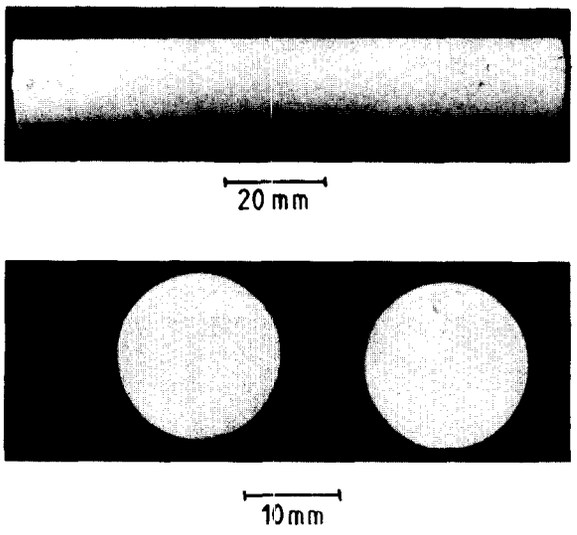

Fig. 6. Sample heated on a tile at a set rate of 5°C h^{-1} at atmospheric pressure.

slumping and the cracks in the cross-section were perpendicular to the direction of deformation. This highlights the sample support as a relevant variable; an issue that does not arise at lower heating rates (Fig. 6). It follows that the interaction of the supporting medium with the component during pyrolysis must also be assessed.

Figure 7 shows the outer appearance and cross-sections of the sample heated at 200°C h^{-1} on the refractory tile. Although the rate is well above critical for this condition, much of the damage is associated with the deformation. The extent of sagging is measured by ovality and plotted as a function of heating rate in Fig. 8 for samples resting on a shallow bed of powder (curve A) and for samples fully embedded in powder (curve B). For heating rates which could be used at atmospheric pressure, slumping does not occur. This is because the deformation of moulded ceramics is sensitive to ceramic volume loading and when sufficient

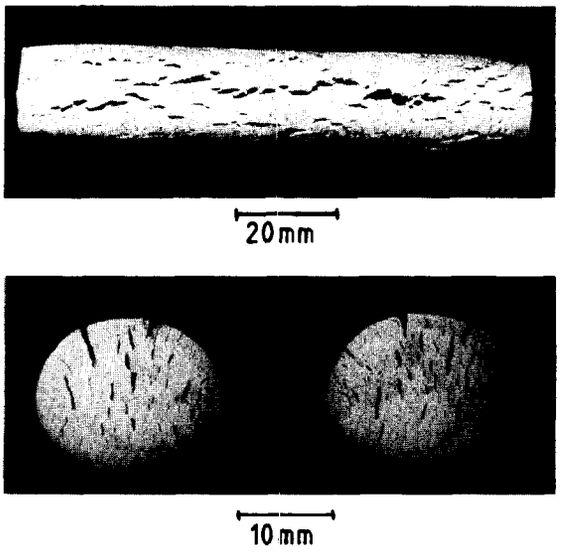

Fig. 7. Slumping caused by inadequate support during heating at a set rate of 200°C h^{-1} at 0·6 MPa.

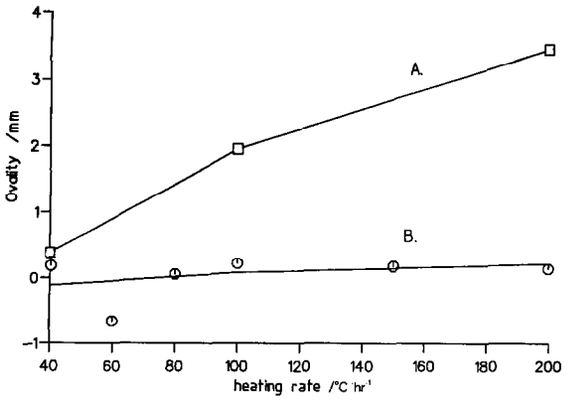

Fig. 8. The effect of sample support on deformation due to slumping. A: Samples resting on shallow powder bed. B: Samples packed inside powder bed.

binder has been displaced, the suspension acquires quasi-solid properties.[16] Under circumstances where an overpressure permits the use of higher heating rates, the thermogravimetric weight loss curve is displaced to higher temperatures.[17] The organic phase then has lower viscosity and, due to differential thermal expansion, occupies a higher volume fraction, so that flow is enhanced. Thus, when overpressure is employed, extra precautions are needed for component support.

The second series of experiments was therefore carried out with samples embedded in the alumina powder. As well as supporting the component, the powder bed may also contribute to safe debinding by capillary extraction when the organic vehicle is based on a low molecular weight system.[18,19] The amount of binder extracted in the molten state isothermally at 130°C after heating for 3 h and 19 h in the alumina powder was 21% and 69% respectively. A sample heated on an alumina tile for the same periods lost 1·4% and 6·1% respectively. Thus the alumina powder is effective in removing some of the organic vehicle by capillary extraction. However, the 19 h heat treatment considerably exceeds the time for which the binder was molten during pyrolysis under overpressure, which was typically less than 3 h at 0·6 MPa.

Figure 8 shows that shape was retained over the range of heating rates explored when a powder bed was used and this is reflected in the pattern of defects. Figure 9 shows a bar heated at a set rate of 200°C h^{-1} and 0·6 MPa, which should be compared with Fig. 7. The slumping is absent and the cracks are no longer unidirectional.

The results for samples embedded in alumina (Table 2) suggest that at 0·1 MPa the critical heating rate is not greatly increased by the presence of the powder bed. In the sample heated at a set rate of 100°C h^{-1} the effect of boiling of low molecular weight organic compounds in solution in the main polymer is clearly seen as bloating (Fig. 10). At this pressure the boiling occurs at a temperature

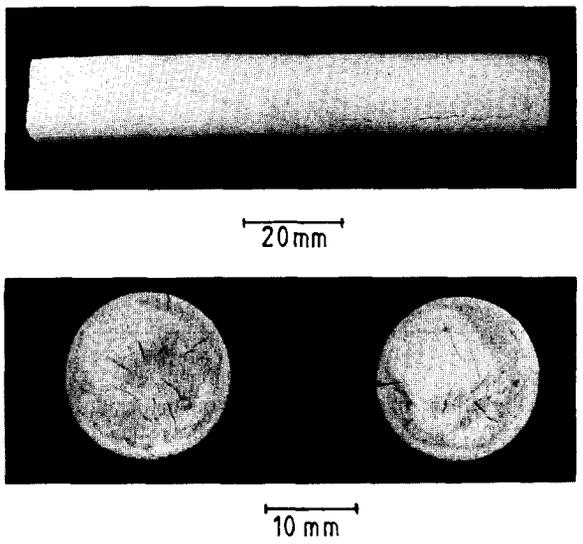

Fig. 9. Defects in a bar supported in an alumina powder bed and heated at a set rate of 200°C h^{-1} under 0·6 MPa.

where the suspension is fluid because little binder has been expelled; an effect resulting from the high heating rate. In subsequent work at higher pressures and similar heating rates the defects take the form of cracks because their initiation has been deferred to higher temperatures by the suppression of boiling and by that stage more binder has gone and the ceramic volume fraction is consequently higher.

At 0·6 MPa, the critical heating set rate is in the region 80–100°C h^{-1}. Figure 11, for example, shows the surface and sections of a bar heated at 80°C h^{-1}, which is of good quality. The use of a pressure of 1·0 MPa gave a sample free from internal defects at a set rate of 100°C h^{-1} (actual rate 63°C h^{-1}). This sample showed slight surface cracks on the top surface associated with loss of setter powder. Exposed surfaces generally presented this problem. The loss was caused by admitting nitrogen to the vessel at too high a rate. The use of 1MPa overpressure did not give an improvement over the critical rate achieved at 0·6MPa. Three reasons why the full benefit of overpressure may not be obtained in practice are discussed later.

The pressures used here do not present severe laboratory safety problems provided normal precautions are taken. The construction of the apparatus involved very modest capital expenditure.

Table 2. Integrity of moulding heat treated in an alumina powder bed

Heating rate °Ch $^{-1}$		*Pressure (MPa)*	*Results*
Set	*Actual*		
20	18	0·1	Outer surface defect-free, slight internal cracking at centre
40	30	0·1	As above
100	70	0·1	Severe surface cracking, internal bloating
15	14	0·6	Free from macro-defects
40	32	0·6	Free from macro-defects
60	44	0·6	Free from macro-defects
80	60	0·6	Free from macro-defects
100	70	0·6	Slight surface cracking, slight internal cracking
150	100	0·6	Slight cracking, internal cracks
200	130	0·6	Surface cracking, internal cracking
100	63	1·0	No internal cracks, surface cracks due to loss of powder
125	75	1·0	Surface defect-free, very slight central cracks
150	95	1·0	Surface very slightly cracked, internal cracks
200	125	1·0	Surface cracks, internal cracks

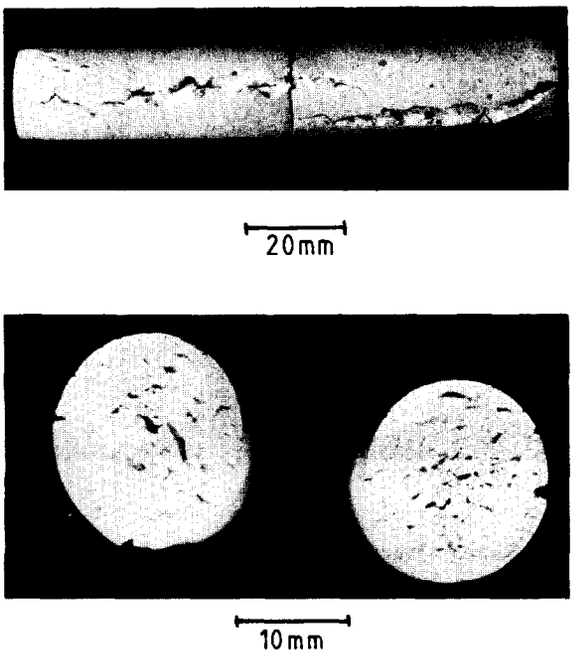

Fig. 10. Surface and sections of a bar heated at a set rate of 100°C h^{-1} under 0·1 MPa while supported in a powder bed. Defects at the centre take the form of bubbles resulting from boiling because at this heating rate the suspension retains fluidity.

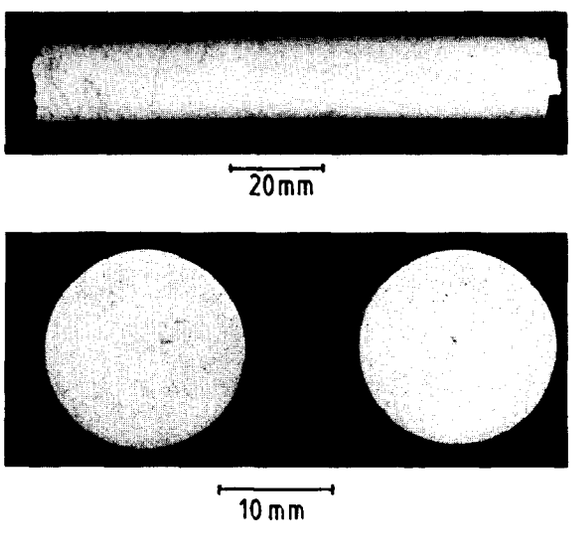

Fig. 11. Surface and sections of a bar heated at a set rate of 80°C h^{-1} under 0·6 MPa.

These factors imply that the widespread use of overpressure debinding is relatively unimpeded.

In order to understand the role of overpressure in a non-oxidising environment, one may enumerate the individual effects it may have on the system as follows:

(1) Increase in the boiling point of low molecular weight constituents of the organic vehicle and of the solution of degradation products (as solute) in molten polymer (as solvent)
(2) Decrease in diffusion coefficient of degradation product in solution caused by reduction in polymer free volume.[20]
(3) Closure of pre-existing defects when the organic vehicle is molten.
(4) Increase in vapour pressure of volatile species.
(5) Dissolution of ambient gas in the molten polymer.
(6) Increase in convective heat transfer in the furnace.
(7) Influence on gaseous diffusion of degradation products in the porous region.
(8) Changes in the distribution of degradation products.
(9) Changes in miscibility of organic liquid mixtures.

These effects are assessed individually elsewhere[21] and arguments are presented to suggest that the first contribution is overriding. Thermal degradation, which occurs throughout a moulding, liberates low molecular weight products of decomposition which dissolve in the parent polymer. When the vapour pressure over this solution at any point reaches ambience, boiling occurs. The resulting defects may take the form of round 'voids' characteristic of boiling in a liquid and examples are shown in Fig. 10 in a sample heated at 100°C h^{-1} at atmospheric pressure. If, however, some polymer has already been lost, and hence ceramic volume fraction has risen, the suspension behaves as a solid,[16] even though continuous porosity has not yet formed. Defects then take the form of a crack. When the external pressure is raised, the boiling point is elevated and the system can reach higher temperatures without defects occurring. Mass transport processes which are thermally activated are then enhanced.

The critical stage in thermolytic debinding occurs in the early stages of degradation where most pores are filled. The suppression of boiling enhances the diffusion coefficient for degradation products migrating in solution in the continuous phase both by raising the temperature and by allowing a higher diffusant concentration to prevail. In free volume theory, both effects conspire to have a pronounced influence on diffusion.[22]

Table 3. Integrity of samples heated in a coarse SiC powder bed

Heating rate °Ch^{-1}		*Pressure (MPa)*	*Results*
Set	*Actual*		
20	16	0·6	Very slight internal cracking
40	30	0·6	Outer surface defect free
150	102	0·6	Some internal cracks
200	135	0·6	Many internal cracks
400	[a]	0·6	Surface and internal cracks, no slumping.

[a] Outside the range of calibration.

Secondly, by allowing the polymer to reach a higher temperature, viscosity is reduced and capillary flow into the surrounding powder is speeded up.[19] It is beyond the scope of this work to quantify the competition between these two transport processes but an indication of their relative importance can be found by using a powder which supports the sample against slumping but has negligible ability to extract the organic vehicle by capillary flow.

This comparison is shown in the third series of experiments in which coarse silicon carbide powder was used as the setter powder. In partitioning experiments, the amount of binder based on the initial weight in the sample after 3 h and 19 h in the SiC setter powder was identical, to within 1%, to the loss experienced by companion samples heated at 130°C on a tile.

Table 3 shows the result of experiments with the silicon carbide setter. The critical heating rate at 0·6 MPa is lower than that obtained in the alumina powder, indicating that capillary extraction is a significant transport path in the alumina setter powder. At 0·6 MPa the extent of damage in samples supported in silicon carbide powder was less than that seen in samples which were unsupported or heated without overpressure for comparable heating rates.

Three reasons can be discerned for the failure to obtain the full potential benefit of overpressure. In the first place, the use of a powder bed reduces the effective surface mass transport coefficient for gaseous products leaving the body because of the static boundary layer provided by the powder. If support is mandatory, as implied by the results in Fig. 8, it will tend to provide a resistance to gaseous transport away from the surface of mouldings. A second reason is that where liquid capillary flow is a significant transport path, the capillary pressure falls with an increase in temperature due to the reduction of the surface energy of polymers with increasing temperature.[19] These factors may explain why the high values of critical

heating rate found with the alumina setter at 0·6 MPa were not further enhanced at 1 MPa.

A third reason why the full benefit of overpressure may not be achieved in practice arises from the problem of pressure transmission to the core of a moulding throughout the decomposition region. Before the open porosity stage is reached, shrinkage of the core as polymer is lost must be accompanied either by collapse of the shell or by diffusion of nitrogen to the centre. Collapse of the outer shell may be impeded if the peripheral ceramic weight fraction rises towards V_{max}, the weight fraction at which viscosity approaches infinity,[16] and this is likely to occur at an early stage and to be associated with the shrinkage due to binder removal. Pressure transmission may thus rely upon diffusion of dissolved gas in the continuous phase.

Closely related to the problem of pressure transmission is the possibility that elevated ambient pressure applied to mouldings in the molten state will cause defects to collapse. This possibility was investigated empirically for similar bars moulded with low injection pressure which contained injection-moulding voids.

Two such test bars, measuring 10 mm × 10 mm × 75 mm, were radiographed to confirm the presence of voids. They were then heated to 80°C in the pressure furnace under atmospheric pressure. The softening point of the material was determined by thermomechanical analysis to be 51°C. When that temperature had been attained, the pressure was increased as rapidly as possible to 1 MPa, and held while the samples were cooled. They were radiographed again, but showed no difference in the internal voids. It is possible that nitrogen had diffused through the material to fill the pores in the time it was being admitted to the vessel, as filling the chamber took about 90s, or that the applied pressure was insufficient to cause the necessary deformation.

Samples of the same material were heated to 130°C inside the pressure vessel and the gas pressure was raised to 1 MPa. They were then cooled to room temperature under pressure and, upon removal, promptly placed in a glass-fronted oven at 130°C. Very slight surface bloating could be detected on reheating, which did not appear on samples reheated without overpressure treatment, indicating the presence of dissolved gas in the continuous phase.

4 Conclusions

The use of modest overpressure (0–1 MPa) significantly increased the critical rate of heating of commercial injection-moulded ceramics. The main benefit is considered to result from an increase in boiling point of the binder components and their degradation products in solution. This means that higher temperatures can be reached before boiling in the continuous phase occurs. At higher temperatures, mass transport by diffusion through the continuous phase and liquid flow into a surrounding powder are both enhanced.

When the higher heating rates made possible by overpressure are used, the sample must be supported against slumping, a requirement that does not prevail at low rates of heating for the samples tested here.

(Received 15 February 1994; revised version received 24 June 1994; accepted 8 July 1994)

Abstract

The laser-induced ablation mechanism of $BaTiO_3$ ceramics has been followed by SEM and EPMA analyses. The evolution of the residual carbon content has been studied by $^{12}C(d,p)^{13}C$ nuclear technique under a 10^{-9} mbar vacuum with laser powers below and above the ablation threshold. The residual carbon remains constant for laser powers below the ablation threshold and is ejected from the crater formed and partly deposited around it when ablation occurs. Immediately after the end of laser ablation, the residual carbon diffuses from the bulk to the surface of the ceramic, leading to high C concentrations in the whole ceramic surface layer. The chemical form of carbon and its mobility in such ceramics are discussed.

1 Introduction

Residual carbon remaining in ceramic materials after the sintering step, originating from the use of organic precursors during the powder fabrication, may influence the material properties. In a previous paper,[1] the residual carbon content has been evaluated in $BaTiO_3$ ceramics. It was shown that the C content is about 50 ppm by weight in the ceramic bulk and that it increases at the surface which exhibits a concentration of several hundreds or thousands of ppm. The surface layer carbon could have two origins: an atmospheric contamination carbon adsorbed at the surface of the ceramic, and material intrinsic carbon, the concentration of which depends on the shape of ceramic pieces and the sintering temperature.

Laser ablation is becoming increasingly significant in materials processing techniques with which to obtain thin films. However, in spite of the scientific and technological importance of this process, relatively little has been published about the physical and chemical mechanisms of laser-induced desorption and ablation from these materials.[2–4] Recent works on laser ablation of $BaTiO_3$[5–11] or other perovskite oxides,[12–15] performed under partial pressure of O_2, are only interested in the production of thin films with a good stoichiometry or a preferred orientation[16] and a little has been published about bulk ceramics.

It seems appropriate to (i) study the ablation mechanism by the evolution of the microstructure by scanning electron microscopy and local analyses by electron probe microanalysis as a function of the number or the power of laser shots, (ii) follow the evolution of the residual carbon content by the $^{12}C(d,p)^{13}C$ nuclear technique after laser-induced desorption and ablation, as a function of the time under an ultra-high vacuum or in air, (iii) discuss the mobility and the chemical form of the residual carbon.

2 Experimental

2.1 Samples

$BaTiO_3$ powders were obtained by a citric resin method, described in previous papers.[17–19] The mixed citrate $BaTi(C_6H_6O_7)_3\ 6H_2O$ is prepared and then dissolved in a mixture of citric acid, ethylene glycol and water with the ratio of $BaTiO_3$ mass/solution mass (R) being 1%. This mixture was calcined at 700°C in static air and gave pure $BaTiO_3$ powders after 2 h. After an ultrasonic deagglomeration step, powders were pressed to give discoidal samples, then they were sintered in

air at 1300°C or 1400°C for 2 h with a heating rate of 300°C/h up to 600°C then 70°C/h up to 1300°C or 1400°C. Sintered discs were about 1·8 cm diameter and 1 mm thick.

2.2 Laser device

The laser ablation was performed at room temperature in an ultra-high vacuum (UHV) chamber with a pressure of about 10^{-9} mbar. Samples were mounted on a micromanipulator and placed in the UHV chamber. A YAG laser with a pulse width of 7 ns and a doubled output (532 nm) was used. Average energy levels were between 20 and 70 mJ producing powers of between 1·4 and 8·6 $\times$ 10^7 W/cm^2 on the sample. The diameter of the laser spot was between about 2 and 5 mm.

2.3 EPMA analysis

Electron probe microanalysis (EPMA) semi-quantitative measurements were performed with a Cameca instrument with a voltage of 10 kV and an intensity of 30 nA under a vacuum of 10^{-5} mbar. The detectors used were PET for Ti ($K_{\alpha 1}$ radiation) LiF for Ba ($L_{\alpha 1}$ radiation) and PC2 for C (K_α radiation). The ablated ceramics were metallized with nickel. The depth analyzed was about 0·2 μm and the surface was a few μm in diameter, thus it was possible to focus the electron incident beam on a ceramic grain. The results given have been averaged over several tens of measurements.

2.4 Raman spectroscopy

Raman spectra of the ablated ceramics were performed with a Dilor Raman microprobe using the 514·5 nm wavelength of a Ar^+ laser with a power of several hundreds of mW. The area and depth analyzed were about 1 μm.

2.5 Carbon analysis

The carbon concentration analysis was carried out by $^{12}C(d,p)^{13}C$ nuclear technique using deuterons from the Van-de-Graaff accelerator of the Centre d'Etude sur les Radiations Ionisantes (CERI). The method has been described in different articles.[20–22] The measurements were performed at 950 keV and 1420 keV deuteron energy in a UHV chamber with a vacuum of about 10^{-9} mbar. The detector was a diode with an active surface of 300 mm^2 situated 64 mm from the sample position and protected by a 20 μm thick Al foil. The detection angle θ was 150°. The beam current was 10 nA. A collimator was placed at the entry of the UHV chamber and 60 mm from the target, giving a constant deuteron beam diameter of 7 mm^2. The counting time was about 20 min per data point.

For 950 keV energy incident deuterons, the carbon content (t) is given in g/cm^2 by the formula:

$$t = \frac{dA}{\Phi} * \frac{1}{\frac{d\sigma}{d\Omega}} * \frac{1}{d\Omega} * \frac{M}{N}$$

where dA = number of detected particles = reaction peak area; Φ = number of incident particles = $Q/1{\cdot}6 \times 10^{-19}$ with Q = total incident charge measured by the integrator (C); $d\sigma/d\Omega$ = differential cross-section (cm^2/sr/nucleus); $d\Omega$ = solid angle determined by the detector and the impact point of the beam on the target (sr); M = atomic mass of the studied nucleus (g/mol); and N = Avogadro number. The differential cross-section has been taken equal to 30 mbarns according to Ref. 23. The solid angle is $7{\cdot}32 \times 10^{-2}$ sr.

Taking into account the density of the ceramics and the depth of the material analyzed (0·4 μm), it is possible to deduce the carbon content in ppm (by weight) in the surface layer.

For 1420 keV energy incident deuterons, a surface carbon content (0·4 μm depth) has been evaluated taking a cross-section of 40 mbarns, then, if it is assumed that there is no gradient of concentration as a function of the depth, the carbon content of the subsurface (between 0·4 and 4·4 μm) may be evaluated taking an average cross-section of 64 mbarns.

3 Results

The sintered ceramics had densities approaching 99% of the theoretical density (d_{th} = 6·02 g/cm^3) and SEM observations showed an average grain size of about 100 μm.

3.1 Ablation mechanism

The physical phenomena that occur when a laser beam is focused onto a material surface depend mainly on (i) the power of the laser beam, (ii) the thermal properties of the material and (iii) the absorptivity of the material at the wavelength used. According to Sankur & Cheung,[24] three power density regimes can be defined: low (<10^6 W/cm^2), intermediate (>10^6 and <10^6 W/cm^2) and high (>10^8 W/cm^2). In the low power density regime, surface melting and evaporation are under quasi-equilibrium conditions. In the high power density regime a plasma is formed. In the intermediary regime, the plasma contribution is small but dissociated species are observed in the evaporation stream. The present experimental conditions, with a laser power of about 10^7 W/cm^2, correspond to this last case

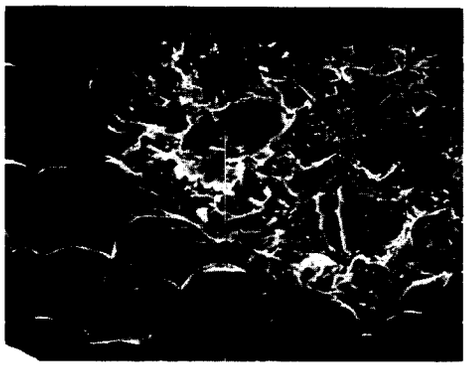

Fig. 1. SEM image of a $BaTiO_3$ ceramic damaged by 100 shots at $2{\cdot}7 \times 10^7$ W/cm^2. Grain explosion is observed without the appearance of a molten zone.

Fig. 3. SEM image of a $BaTiO_3$ ceramic damaged by 100 shots at $3{\cdot}9 \times 10^7$ W/cm^2. The first molten zones appear at triple grain boundaries and at pores, in addition to grain explosion.

The ablation phenomenon was followed by SEM by using increasing powers of the laser beam and numbers of shots.

Firstly, a series of 100 laser shots with variable powers was performed onto as-sintered ceramic surfaces. In order to avoid interactions of one series of shots with another one, a new ceramic sample was used for each series.

For a laser power of $2{\cdot}7 \times 10^7$ W/cm^2, an explosion of the grains was observed without appearance of a molten zone (Fig. 1). Thus the ablation threshold is situated at about $2{\cdot}6 \times 10^7$ W/cm^2 in these conditions. At $3{\cdot}2 \times 10^7$ W/cm^2, the same phenomenon was observed (Fig. 2) but the ceramic was ablated to 4–5 μm depth. At $3{\cdot}9 \times 10^7$ W/cm^2, the first molten zones appeared at triple grain boundaries and at pores (Fig. 3) in addition to grain explosion and an ablation depth of about 5 μm. For higher laser powers (experiments were performed at 5·1 and $7{\cdot}7 \times 10^7$ W/cm^2) only molten zones were observed with very irregular features (Fig. 4). As the laser power increases, the formation of a more and more regular crater is observed: a regular form 200–300 μm deep is obtained for laser powers of $5{\cdot}7$–$7{\cdot}1 \times 10^7$ W/cm^2. The ablation depth was roughly evaluated during SEM observations.

The influence of the number of shots at constant laser power was studied. Two values for the laser power were chosen: $2{\cdot}7$ and $5{\cdot}7 \times 10^7$ W/cm^2. A series of 500 shots at $2{\cdot}7 \times 10^7$ W/cm^2 showed, in addition to the grain explosion already mentioned for 100 shots at this laser power, a rise of grains from the surface due to the release of occluded gas (Fig. 5). Even for a number of shots greater than 500, no molten zone was observed. It seems that, below a certain laser power threshold, molten zones are never observed. Finally, for 500 shots at $5{\cdot}7 \times 10^7$ W/cm^2, the formation of a regular crater is clearly observed: Fig. 6 shows the different zones at the surface of the ceramic:

(i) The zone undamaged by the laser beam.
(ii) The circular zone around the crater, which is smooth and covered in places by more or less spherical nodules which seem to come from the crater center. Black soot-like deposits are also observed. Sometimes holes like chimneys appear that are probably due to the release of gas.
(iii) The crater bottom with a very damaged surface: the erosion seems to always originate at the pores and at the triple grain boundaries.

If the laser beam power is increased (up to $9{\cdot}3 \times$

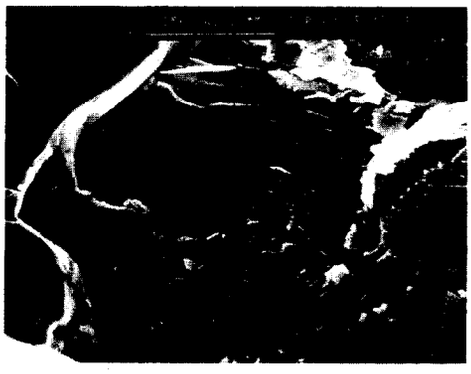

Fig. 2. SEM image of a $BaTiO_3$ ceramic damaged by 100 shots at $3{\cdot}2 \times 10^7$ W/cm^2. The ceramic is ablated to a depth of 4–5 μm.

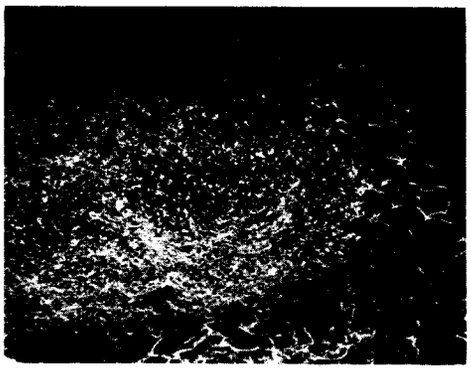

Fig. 4. SEM image of a $BaTiO_3$ ceramic damaged by 100 shots at $4{\cdot}3 \times 10^7$ W/cm^2. Very irregular molten zones are observed.

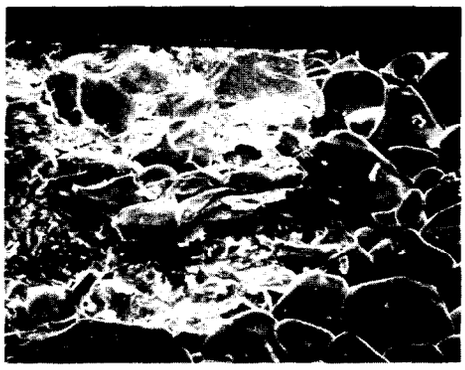

Fig. 5. SEM image of a $BaTiO_3$ ceramic damaged by 500 shots at $2{\cdot}7 \times 10^7$ W/cm^2. Grain explosion is observed as well as an upthrust of grains due to the release of occluded gas.

10^7 W/cm^2) or if the shot number is increased (up to 1500 shots) the observed phenomena are similar with the crater formed being much deeper.

3.2 Analysis of Ti and Ba compositions in ablated ceramics

Measurements of Ti and Ba contents have been performed by electron microprobe. Ceramics studied before laser treatment had a Ba/Ti ratio of $1{\cdot}03 \pm 0{\cdot}03$. The citric method used to produce the present ceramics gives, in principle, a Ba/Ti ratio equal to 1. The slightly higher value found may be explained because standards such as TiO_2 or $BaSO_4$ were not used to calibrate the measurements and because there probably exist interaction effects between Ti and Ba elements. This value is a relative value that is self-consistent and only its variation is studied.

A ceramic damaged by 500 laser shots at $5{\cdot}7 \times 10^7$ W/cm^2 was then analyzed. The crater bottom exhibits a Ba/Ti ratio of 1·25, the glossy, black circular zone around it has a ratio of 0·95 and the ejected particles a ratio of 1·08. The non-irradiated part of the ceramic exhibits a ratio of 1·03. Thus, the crater and the ejected particles are richer in Ba whereas the black circular zone is richer in Ti than the stoichiometric composition.

Measurements have also been performed by Rutherford back-scattering (RBS) technique on such a ceramic. A very slight decrease of the Ti content in the crater confirmed the electron microprobe measurements.

3.3 Analysis of the carbon content by $^{12}C(d,p)^{13}C$

Measurements performed on as-sintered ceramics at a 950 keV deuteron energy gave a carbon content of 90 ng/cm^2 in the surface layer (0·4 μm), corresponding to about 350 ppm.[1] Then, the authors tried to desorb the surface carbon by laser-beam cleaning but no change in the C content was observed until the laser power was high enough to ablate the ceramic surface.

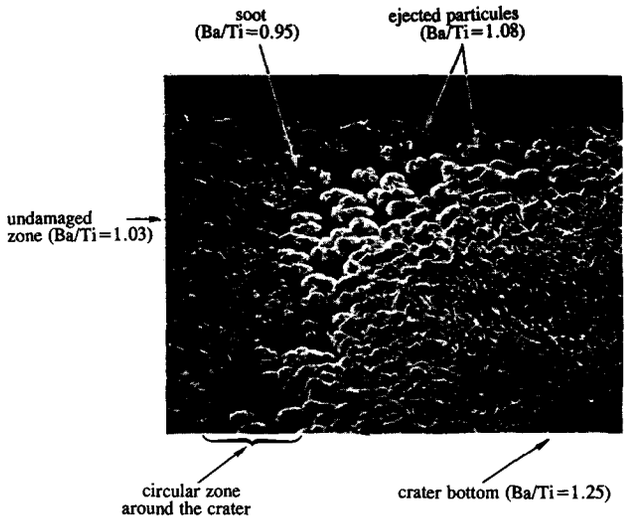

Fig. 6. SEM image of a $BaTiO_3$ ceramic damaged by 500 shots at $5{\cdot}7 \times 10^7$ W/cm^2. A regular crater is formed (200–300 μm depth) and different zones may be observed: the crater bottom, a circular zone around the crater with soot and ejected spherical particles and unperturbed surface.

Finally, ceramics damaged by 500 laser shots at $5{\cdot}7 \times 10^7$ W/cm^2 were studied. Taking into account the technical difficulties in focusing the laser and deuteron beams onto a given area, a large crater was formed by scanning the laser shots over a square of area 16 mm^2. The C content was measured in different areas of the damaged ceramics: in the crater center, around it and in unperturbed zones. The results are given in Table 1. It is observed that immediately after laser ablation, the C content is much smaller in the crater and higher in the glossy, black aureole around the crater, whereas the nonirradiated part of the ceramic exhibits a C content of about 350 ppm like the as-sintered ceramics. A measurement performed at 1420 keV energy in the crater showed also a very low carbon concentration. Thus the carbon does not migrate below the surface of the crater under the laser shots. There is, more probably, an ejection–redeposition mechanism.

The evolution of the carbon content of these ceramics left in a 10^{-9} mbar vacuum was observed, after 1·5 h, the C content had increased in all the

Table 1. Carbon content (in ppm) measured as a function of the time for areas for the ceramics with differing degrees of damage

Time	*Crater center*	*Around the crater*	*Undamaged surface*
Before laser shots[a]	350	350	350
After laser shots[a]	110	600	380
After 1·5 h[a]	180	840	560
After 72 h[a]	820	870	900
After 3 months[b]			
Surface	12000	6000	3000
Subsurface	830	100	100

[a] In UHV chamber.
[b] After an exposure to air for 3 months.

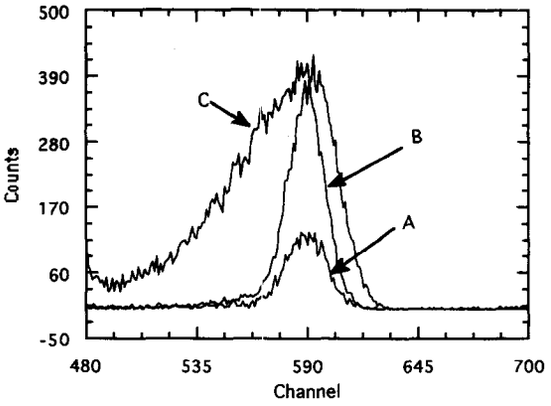

Fig. 7. The C peaks of the proton spectra of $^{12}C(d,p)^{13}C$ reaction obtained from 1420 keV incident deuteron energy: (A) far from the crater, (B) around the crater, (C) in the crater bottom. A symmetrical shape characterizes a C content much higher in the surface layer than in the bulk. The very unsymmetrical (C) peak reveals that C content is high both in the surface layer and in the bulk.

zones, particularly in the zone around the crater; after 72 h the C concentration was practically constant in the whole surface and increased by a factor close to 2·5 in comparison with the C content found in the as-sintered ceramics before laser shots. An equilibrium seemed to be established between the ceramic surface and the chamber atmosphere.

It was interesting to study the evolution of the C content with time after removing the ceramic from the UHV chamber of the apparatus. After an exposure in air for three months, $^{12}C(d,p)^{13}$ C measurements were performed in the same conditions in the UHV chamber with 950 keV energy incident deuterons. The results obtained are reported in Table 1. A strong increase of the surface carbon content was observed. The surface of the ceramic which was not damaged by the laser beam impact exhibits a C content of about 3000 ppm, whereas as-sintered ceramics of 1 mm thick generally exhibit a surface C content of about 350 ppm, a value remaining constant even after an exposure of several months in the air.[1] The surface around the crater and the crater bottom exhibit C contents of 6000 ppm and 12000 ppm respectively. These results were confirmed by EPMA analysis. In the crater bottom a large concentration of carbon was observed. $^{12}C(d,p)^{13}$ C measurements performed with 1420 keV energy incident deuterons showed that in the subsurface the C content is low (about 100 ppm) except in the crater center (830 ppm). The spectra given in Fig. 7 show the shape of the peaks: they are quasi-symmetrical for the measurements performed around the crater and further from it and very unsymmetrical for those performed in the crater center, this last profile is characteristic of a high C content both in the surface layer and in the bulk.

4 Discussion

Chan & Mazumder[2] have developed a model describing laser ablation damage. When an intense laser beam arrives at the target surface, different processes may occur. At the beginning of the laser pulse, the absorbed laser energy heats the target up to the melting point and then to the vaporization temperature. The vaporization generates a recoil pressure that pushes the vapour away from the target and expels the liquid sideways. Thus a part of the material is removed from the target both in vapor and liquid form. The absorbed laser energy should be partitioned into (i) loss into the target, (ii) latent heat of fusion and vaporization and (iii) creation of a recoil pressure to push the vapor away and expel the liquid.

In the present case, the circular zone exhibiting a glossy and black feature seems to be a consequence of the vapor ejection and lateral expulsion of the liquid. The ablation mechanism could be described as follows:

—Because of the high heating of the material, there is formation of a liquid and then vapor phases that are Ti-rich, the lightest elements being ejected first, as was observed by other workers.[14]

—The liquid phase deposited in the bottom of the crater or around it could correspond to the ultimate step before evaporation, the material not having reached a sufficient temperature to be volatilized.

—The ceramic grains which remain in the crater bottom or which have been ejected under the repeated laser shots on the surface around the crater are richer in heaviest elements, i.e. Ba in the present case.

Concerning the C content evolution after laser ablation, the same type of phenomenon is observed: the very light C element is eliminated when the ceramic is heated; thus the crater center exhibits a very low C content. One could think that C is totally evaporated when the vapor phase is formed; in fact, a relatively high C content is measured in the neighboring crater; the black color of the glossy zones could be due to the formation of carbon in a chemical form close to graphite, although this could not be confirmed by Raman microprobe. Thus carbon ejected from the crater is surely present in the vapor phase and also in the liquid phase.

The evolution of the C content with the time after laser ablation seems quite surprising. As ceramics are maintained in ultra-high vacuum conditions and the undamaged surface exhibits an increased C content, it seems more probable that

carbon comes from the bulk of the ceramic rather than from the chamber of the apparatus (although this last hypothesis could not be totally eliminated). Thus, it can be assumed that residual carbon is, in the sintered ceramic, in the form of chains; in the regions of the ceramics damaged by the laser thermal phenomenon, the C–C bonds should be broken and carbon become more mobile and diffuse to the surface of the ceramic.

After removing the ceramic from the UHV chamber and exposing it in the air for three months, the surface C content strongly increased, this phenomenon may have two origins:

(i) The observed carbon comes from the bulk of the ceramic; in this case the diffusion of carbon continues after 72 h in the UHV chamber.

(ii) The observed carbon results from the atmospheric contamination, the surface of the ceramic becoming more active under the laser bombardment. The measured C contents show in this case that this carbon is not totally desorbed when the ceramic is replaced in the UHV chamber to perform new measurements but seems quite well bonded to the ceramic.

At the present time, it is not possible to differentiate between these two points and further experiments are now in progress. In any case, the Raman microprobe spectra performed both on as-sintered and ablated ceramics showed that carbon is not present as carbonate, carbon dioxide or carbides but rather as hydrocarbon chains. XPS measurements could give more information about the chemical form of this carbon.

5 Conclusion

This work allowed the laser-induced ablation mechanism of $BaTiO_3$ ceramics to be followed and new information to be obtained about the residual carbon present in $BaTiO_3$ ceramics prepared by the citrate route. For laser powers below the ablation threshold, C is not desorbed by laser-beam cleaning, thus it seems well bounded or trapped in the material. For laser powers above the threshold ablation, C is ejected from the crater formed and deposited partly as soot around it. The laser beam–material interaction leads, after ablation, to an important diffusion of the carbon from the bulk of the ceramic to its surface. Residual carbon could be present in as-sintered ceramics in the form of hydrocarbon chains and the laser bombardment could break them and give much more mobile carbon or hydrocarbon species.

(Received 3 March 1994; revised version received 17 June 1994; accepted 30 June 1994)

Abstract

Five commercial barium titanate powders were subjected to various surface decontamination treatments: calcination at 500°C, followed by leaching either in pure water or acetate buffer solution. They were then de-agglomerated by ultrasonic treatment and finally characterised by XRD, TGA, XPS, EGA, pyrolysis/FT-IR, BET specific surface area and particle size analysis. The main contaminating elements in raw powders were carbon and sulphur, present as barium carbonate (between 0·7 and 1·2wt%) and barium sulphate (about 0·5 wt%). Barium sulphate is thermally stable up to 1400°C and is not affected by the treatments. Barium carbonate decomposes in two steps, between 500 and 900°C and 1200 and 1400°C by reaction with TiO_2 and $BaTiO_3$ to release CO_2. Carbonation is slightly reduced by calcination, but subsequent water cleaning promotes re-carbonation. Acid cleaning substantially decreases the $BaCO_3$ content, down to 0·07–0·7 wt%. The remaining quantity corresponds to the most stable form which decomposes near 1200–1400°C and is still partially present at the surface of the particles. Forming of ceramics green bodies by slip casting of aqueous suspensions stabilised by ammonium poly(acrylate) was then investigated. The dispersing solution compositions have been optimised for each powder and treatment, in order to minimise the liquid/solid ratio of the slip. In all cases, the properties of the slips and of the cast specimens have been improved by the cleaning treatments: higher solid volume fractions in the slip up to 60% for the best case and higher green densities. In particular green densities as high as 70% have been obtained which is very close to the theoretical maximum packing density of log-normally polydispersed spheres. This enhancement can be ascribed to the beneficial effect of decarbonation on the de-agglomeration of the powders.

1 Introduction

Over the past few years it has become evident that different commercial ceramic powders which are apparently identical according to supplier's data (in particular with respect to stoichiometry, granulometry, surface area and bulk composition) actually exhibit quite different behaviour during the processing steps to produce a final product. This variability is mainly related to the surface chemistry of the powders, which is very difficult to control during the elaboration process and is also very sensitive to handling (storage, contact with atmosphere). The surface of the particles can be contaminated with impurities, whose nature, amount and impact on subsequent processing is not completely understood.

Barium titanate, which is still the most widely used material in the electronic industry for capacitors[1] and positive temperature coefficient of resistivity (PTCR) devices,[2] is typically faced with these problems. Its surface is contaminated either with impurities present in the raw materials, or with carbonates,[3] which result from exposure to atmospheric CO_2 or are produced during the synthesis of the powders[4] (high-temperature solid state, wet chemical or hydrothermal). The presence of this impure surface layer can be detrimental to forming, in particular slip casting, because it alters the rheological properties of the slip,[5] either by enhancing frictional forces between surfaces of the particles, or by promoting the formation of agglomerates. The optimal solid volume fraction in the slip is consequently reduced and results in low green densities after drying. Also the sintering step is affected, with an increased porosity which eventually weakens the final properties (especially dielectric strength). Therefore, it would be interesting to be able to modify available commercial powders[6] by appropriate surface treatments in order to gain reproducibility from one powder

source to another and obtain the desired final ceramic properties.

The aim of this work presented in a series of two papers is to elucidate the exact influence of surface contamination in undoped barium titanate powders and investigate the possibility and consequences of its elimination. Therefore five commercial powders representative of different synthesis routes have been selected and subjected to various thermal and chemical treatments aimed at removing their surface carbonate. In Part I, decontamination treatments (calcination, cleaning in aqueous solution and in acid solution) are described. Investigation of the powders by X-ray diffraction (XRD), thermogravimetric analysis (TGA), X-ray photoelectron spectroscopy (XPS), evolved gas analysis (EGA), pyrolysis/infra-red spectroscopy (PY/FT-IR), specific surface area measurement and particle size distribution analysis are then reported. The effect of such treatments on casting green bodies from aqueous slips stabilised with ammonium poly(acrylate) is presented. Statistical design and analysis of experiments were used throughout this study, and results are discussed in terms of liquid limit of the slips and green densities. In Part II, the sintering behaviour of such surface modified powders will be described and correlated with relevant physical parameters of the initial powders.

2 Experimental procedure

Five commercial $BaTiO_3$ powders were used in this study: Criceram lot VPP20, TAM HPB lot 688, TAM HPB lot 745, Cabot BT10 lot 6243-24, and Rhône-Poulenc type Elmic BT 100 lot 7958. The three first powders were synthesised by the oxalate route, the fourth one by hydrothermal synthesis and the last one by suspending titania sols in barium nitrate aqueous solutions followed by drying, calcination and milling.[7] The supplier's main specifications are summarised in Table 1. Impurities such as Ca, Si, K, Cr, Fe, Sr, Na, Al are present in all powders, without exceeding 100 ppm, except Sr (<600 ppm).

Thermal treatment was intended to decompose surface barium carbonate and possible organic additives present in the raw powders. They were calcined at 500°C for 16 h in air. Since the treatment resulted in agglomeration of the powders, they were subjected to ultrasonic de-agglomeration just after calcination (see later).

Table 1. Suppliers' specifications of initial powders

Powder	*Ba/Ti*	*Specific surface area (m^2/g)*	*Median diameter by volume (μm)*
Criceram	0·99	2·5	1·3
Rhône-Poulenc	1·000	2·7	0·84
TAM 688	0·998	3·22	1·41
TAM 745	0·998	2·89	1·43
Cabot	1·007	7·87	0·4

Chemical treatment was performed on non de-agglomerated calcined powders in order to complete the surface decontamination treatment. 0·3M acetic acid–ammonium acetate buffer (pH of 4·5) was used: [CH_3COOH (50%) + CH_3COONH_4 (50%)]. 50g of each powder were put into 200 cm^3 of this cleaning solution. These amounts were determined from $BaCO_3$ content in raw powders, estimated from preliminary TGA measurements, and assuming the consumption of 20% of the acetic acid during the carbonate dissolution. The stirred suspensions (250 rpm) were maintained for 16 h at 30°C, the powders were then centrifuged, the supernatant was discarded and replaced by boiled demineralised water; washing was repeated until constant conductivity of the supernatant was obtained. The powders were then dried in a desicator in primary vacuum using $CaCl_2$ as a desiccant and finally ground lightly in an agate mortar. In order to ensure that the acid cleaning treatment has no secondary effects inherent to manipulations (suspension, drying), a control cleaning experiment with boiled demineralised water was performed under exactly the same conditions and used as a reference.

De-agglomeration of the powders in suspension by ultrasonic treatment was studied using a 2^4 factorial statistical design. The factors investigated were (A) sonication time (20–40 min), (B) volume of the suspension (125–250 cm^3), (C) solid weight fraction (20–40 wt%) and (D) nature of the solvent (either water or isopropanol). Optimal conditions were found to be 30 min ultrasonication with a 150W horn in boiled demineralised water (50 g of powder in 200 cm^3 water). After sedimentation, the supernatants were removed and the powders were dried in a 32% relative humidity desicator with $CaCl_2$.

XRD experiments were performed on a Siemens Kristalloflex 805 diffractometer with the Ni-filtered Cu K_α wavelength on 10 mg samples.

Thermogravimetric measurements were performed on a Setaram 92-16.18 thermobalance, under flowing oxygen atmosphere. For each run, approximately 200 mg of powder were accurately weighed in a platinum crucible, and the temperature was raised from ambient up to 1000°C at 10°C/min and then from 1000 to 1400°C at 5°C/min.

XPS analyses were made with a Perkin-Elmer Phi 5500 ESCA system spectrometer using the Mg K_α line (15 keV–350W). Several mg of powder

were placed for each run on an indium substrate. The signal curves were fitted using Gaussian peaks summation and Shirley baseline subtraction.[8]

Chemical analyses were carried out on a specific carbon + sulphur analyser from Leybold-Heraeus type CSA 2003. For each measurement 0·1 g of powder, mixed with melting agents (1 g Fe + 0·5 g W) to ensure complete decomposition, were placed in a crucible in an induction furnace with flowing oxygen. The evolved gases were first separated from H_2O and then analysed by infrared detectors specially calibrated for CO_2 and SO_2.

FT-IR analyses were conducted with a Mattson Instruments Inc. type Galaxy 4020 spectrophotometer coupled to a CDS1000 pyrolysis unit. Flash pyrolyses (heating rate: 5°C/ms then 20s at 700 or 1300°C) were done on 5 mg of powder for each run, with nitrogen as carrier gas. The measuring chamber was carefully purged before each run in order to avoid erroneous measurements due to the presence of residual atmospheric carbon dioxide.

Specific surface areas of powders were measured by N_2 adsorption according to the BET model with a Micromeritics type Gemini 2360 surface area analyser. 3 g of powder were used for each measurement.

Particle size distributions of powders were determined with a Horiba CAPA-700 cuvet photo centrifuge, using 10 mg of powder and an aqueous solution of poly(acrylic acid) (0·8 wt%) as dispersion liquid. Prior to measurement the suspensions were ultrasonicated (P = 300W, 7 litre bath) for 10 min. The reliability of the results was guaranteed by four repetitions of the same measurement.

Slip-cast specimens were prepared for each powder source and each treatment from aqueous $BaTiO_3$ suspensions stabilised with poly(acrylic acid)(PAA),[9] the acidity of the stabiliser being neutralised by NH_3. For each powder and treatment, the composition of the dispersion liquid has been optimised in two steps.[10] Firstly, the response of the liquid limit of the powders (LL, defined as the minimum liquid/solid ratio necessary to obtain a free flowing slurry, in cm^3/g) to variations in the PAA concentration ([PAA] = 0·3–0·5 %wt) and the neutralisation ratio ($[NH_3]$/[PAA] = 1·2–1·5) was investigated, using a 2^2 factorial statistical design; LL was experimentally measured by adding to 2 g of dry powder the dispersing solution by increments of 20 μlitre, with strong agitation between two additions, up to the liquid point. Second, LL was minimised for each powder and treatment by acting on the factor(s) found to have a significant effect. The effect of the slip composition (i.e. [PAA] around the optimum value for LL, and liquid/solid ratio in smaller or larger excess above LL) was investigated and optimised using the same statistical methodology. The liquid limit is a processing parameter directly related to the viscosity of the slip and is very sensitive to the degree of agglomeration of the powder. It is easily determined on small quantities of material and provides ready to use information for the casting process. The slips were then vibrated for 30 s at 30 Hz, ultrasonicated (P = 300W, 7 litre bath) for two min, and outgassed for 2 min under vacuum. The slips were cast in a silicon rubber mould, placed on a flat gypsum base; direct contact between the samples and the gypsum base was prevented by inserting a 0·2 μm cellulose membrane. Samples were prepared this way in the form of blocs (12·5 × 6·5 × 6·5 mm) for dilatometry measurements. The samples were withdrawn from the mould after 15 min and then left to dry for 24 h in a desicator containing $CaCl_2$ as a desiccant (32% relative humidity).

Green densities have been measured by Archimedes' method, using isopropanol as the immersion liquid, and assuming the value of 6·02 g/cm^3 for the theoretical density of $BaTiO_3$; the samples were first saturated with isopropanol under vacuum (0·15 bar).

3 Results

3.1 Powder properties

The presence of barium carbonate, which is thought to be the major contaminant at the surface of raw powders, has been investigated by *X-ray diffraction*. Only two crystalline phases were detected: tetragonal $BaTiO_3$ and orthorhombic $BaCO_3$. After acid cleaning the peaks corresponding to barium carbonate have disappeared, as shown in Fig. 1 for the Rhône-Poulenc powder.

Preliminary *thermogravimetric analyses* were performed in order to obtain quantitative data required for treatments of initial powders. Differential thermogravimetric curves of raw powders are shown in Fig. 2, and are similar for all

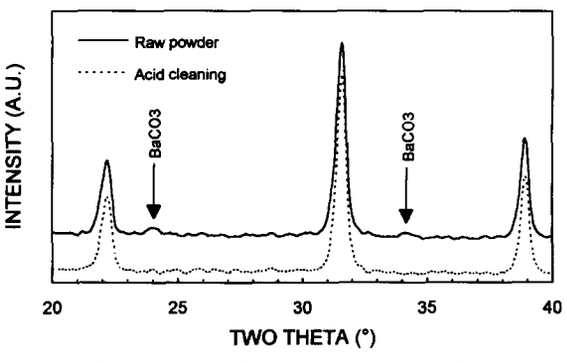

Fig. 1. XRD patterns for as-received and acid-cleaned Rhône-Poulenc powders.

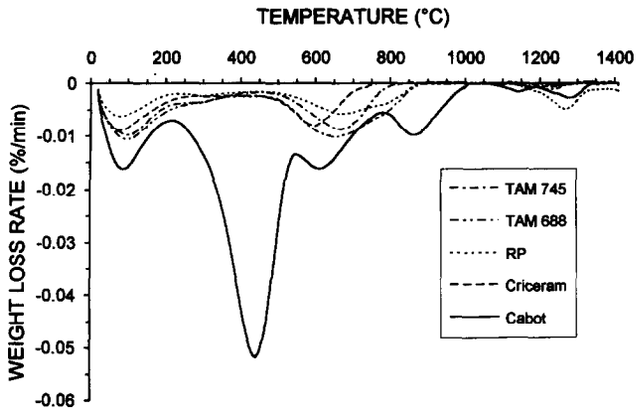

Fig. 2. DTG curves for as-received powders.

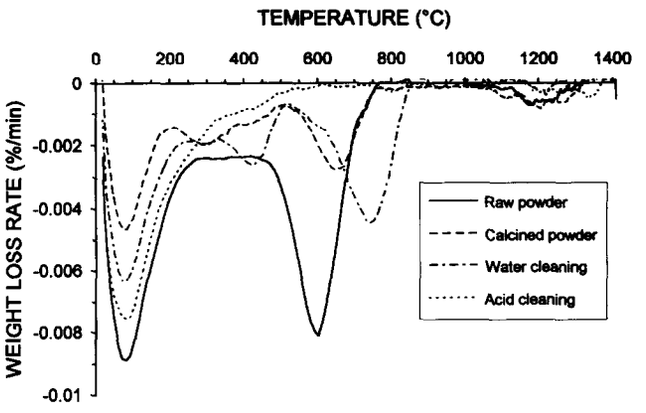

Fig. 4. DTG curves for Criceram powder.

powders: the first loss peak near 100°C results from adsorbed water removal. A second peak common to all powders between 500 and 900°C can be ascribed to the evolution of CO_2 upon $BaCO_3$ decomposition and represents 0·15–0·25% weight loss. Another diffuse peak common to all powders appears between 1200 and 1400°C: it represents only about 0·003 to 0·1 wt% and the nature of the corresponding gas release was ascertained with aid of other techniques (see later). The Cabot powder shows an extra broad peak between 200 and 600°C, due to the elimination of water incorporated in the perovskite lattice, which is typical of powders synthesised hydrothermally.[11]

The effect of the various treatments performed on the initial powders are clearly visible on DTG curves shown in Figs 3—7. In every case, calcination decreases only slightly the CO_2 losses between 500 and 900°C. Water cleaning following calcination has a negative effect with respect to $BaCO_3$ removal in that CO_2 losses increase again. Acid cleaning proves to be efficient for all powders, in that it totally eliminates the $BaCO_3$ loss peak between 500 and 900°C. The position of this peak remains unchanged after calcination and water cleaning for Cabot powder, while it is shifted to high temperatures are calcination then once again are water cleaning for the other powders. The diffuse loss peak above 1200°C is not significantly affected by the treatments, except for the Rhône-Poulenc powder, which exhibits an increase in weight loss in that temperature range after water and acid cleaning.

X-Ray photoelectron spectroscopy allowed the detection of only four elements at the surface of raw and treated powders: Ba, Ti, O and C. The ratio Ba/(Ba+Ti) calculated from the $Ba_{3d5/2}$ and Ti_{2p} transitions appears to decrease from 40 at.% for raw powders to 30 at.% after acid cleaning, meaning that Ba^{2+} ions have been dissolved and removed during this treatment. The shape of oxygen and carbon lines were not investigated in detail, because of their high sensitivity to the atmospheric contamination. The Ti_{2p} line consisted in every instance of a single narrow Gaussian peak, meaning that titanium is present only in a single chemical state, i.e. $BaTiO_3$. The $Ba_{3d5/2}$ transition could be resolved into two Gaussian components separated by 1·58 ± 0·09eV. The lower binding energy corresponds to the titanate environment, and the higher one can be ascribed to a carbonate environment.[12] After acid cleaning, this last peak is decreased by a factor of two when compared to the raw powder data, as shown in Fig. 8 for the Rhône-Poulenc powder. The fact that the peak

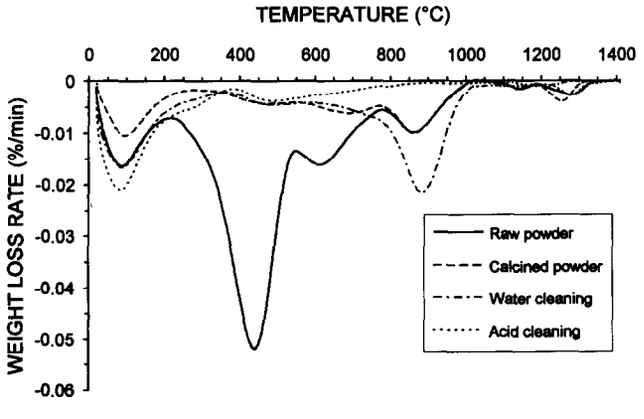

Fig. 3. DTG curves for Cabot powder.

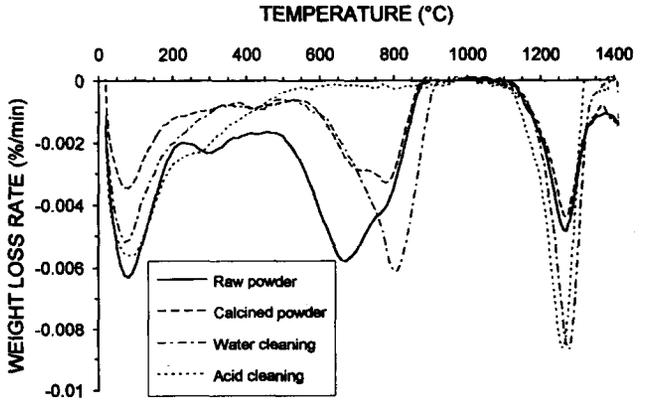

Fig. 5. DTG curves for Rhône-Poulenc powder.

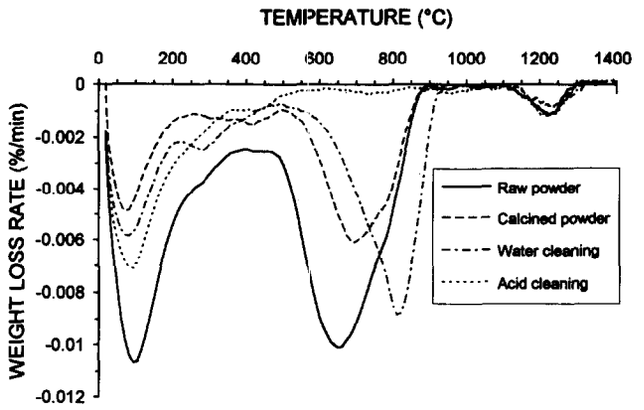

Fig. 6. DTG curves for TAM 688 powder.

has not completely disappeared after acid washing indicates that some $BaCO_3$ subsists at the surface of the particles.

Presence of elemental carbon and sulphur (which is a common contaminant in inorganic raw materials) has been investigated by *EGA* on Rhône-Poulenc calcined and acid-cleaned powders. It turns out that carbon (0·055wt%) and sulphur (0·067wt%) are both present in calcined powders, and that acid cleaning leaves the sulphur content unchanged and lowers the carbon content to 0·034wt%.

Gases released between 500 and 900°C and near 1300°C were identified on as-received powders by *FT-IR* analysis of evolving gas from a pyrolysis unit. FT-IR spectra obtained both at 600 and 1300°C on the same powder samples only reveal the presence of CO_2, as shown in Fig. 9.

Examination by *scanning electron microscopy (SEM)* of untreated, calcined water and acid-cleaned powders does not show any difference in surface roughness, nor in shape. The surface appears smooth in both cases, as shown in Fig. 10 for Rhône-Poulenc powder.

Specific areas of different powders before and after treatments are not affected by the treatments. Measured values are: 2·92 m^2/g for TAM 745 powder, 3·05 m^2/g for TAM 688 powder, 2·49 m^2/g for Rhône-Poulenc powder, 3·05 m^2/g for

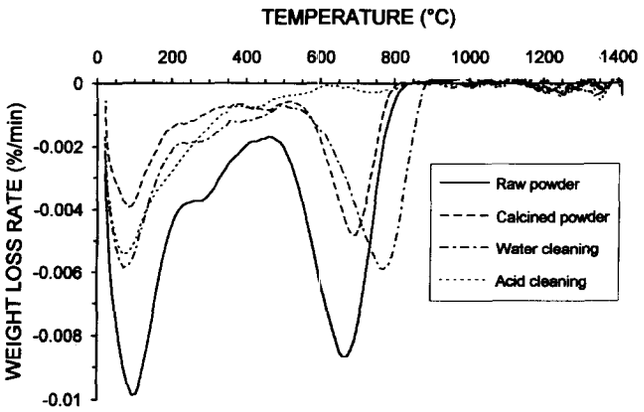

Fig. 7. DTG curves for TAM 745 powder.

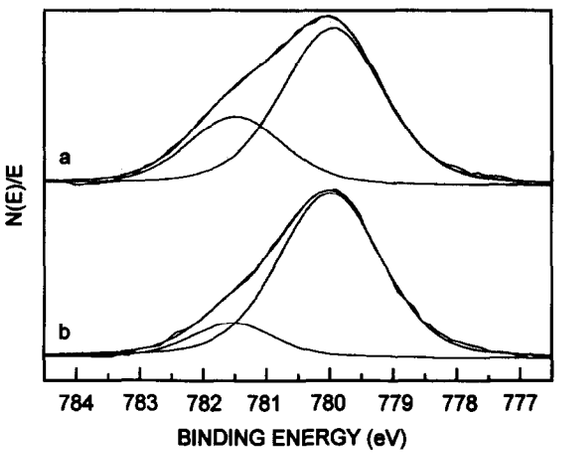

Fig. 8. $Ba_{3d5/2}$ XPS curve fit for Rhône-Poulenc powder. (a) As-received; (b) acid cleaned.

Criceram powder, and 7·79 m^2/g for Cabot powder. These values are in close agreement with the suppliers' data and confirm that the treatments have no influence on surface roughness.

Particle size distributions were determined for all powders and treatments, and are reasonably close to log-normal distributions. Calcination alone tends to slightly agglomerate the powders, which are then efficiently de-agglomerated by ultrasonication. Acid cleaning without ultrasonic de-agglomeration proved to de-agglomerate the calcined powders to the same extent as sonication alone, and subsequent ultrasonic treatment of acid-cleaned powders did not provide further improvement. Water cleaning alone did not show any significant effect. Figure 11 shows the effect of calcination–sonication and acid cleaning on Rhône-Poulenc powder particle size distribution (average of four runs): both treatments promote the removal of some agglomerates. The mean particle size remains unchanged.

3.2 Rheological properties

For all the powders, only [PAA] has been found to affect the *liquid limit* very significantly (above

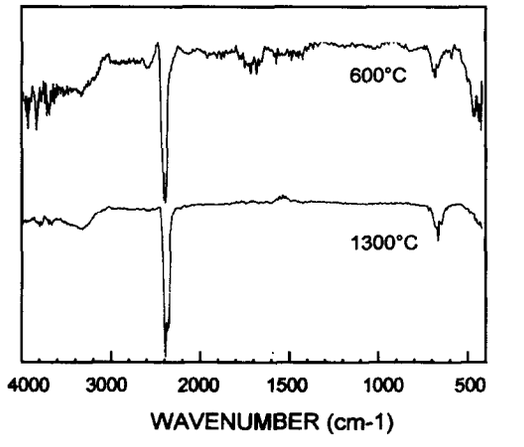

Fig. 9. Transmittance infrared spectra of gas evolved from pyrolysed Cabot raw powder at 600 and 1300°C.

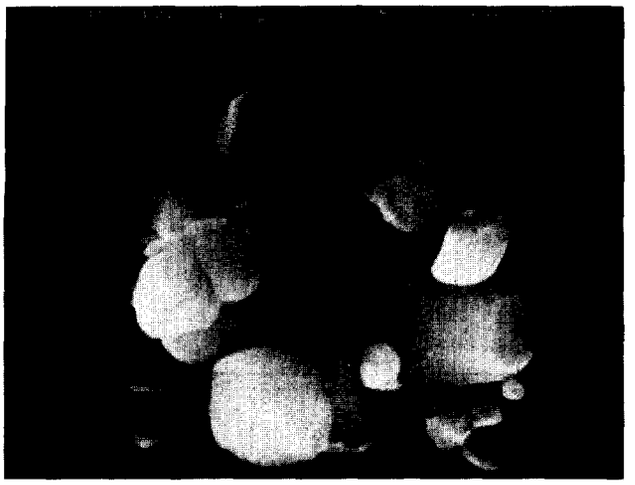

Fig. 10. SEM micrography of Rhône-Poulenc powder.

the 99·9% confidence level); within the experimental range investigated [NH_3]/[PAA] played no role, nor did it change the effect of [PAA]. The optimisation was thus conducted by varying [PAA] (0·10–1·00%wt), while keeping [NH_3]/[PAA] constant at 1·5. The effect of [PAA] on the liquid limit of raw powders is shown in Fig. 12. The lowest value for the liquid limit is reached for [PAA] = 0·6wt% for Criceram, TAM688, TAM745 and Rhône-Poulenc powders for all treatments, and between 0·8 and 1 %wt for Cabot powder depending on the treatments. The higher [PAA] level necessary for the Cabot powder is a consequence of its higher specific surface area. The corresponding optimal LL and [PAA] values are shown in Fig. 13. All the treatments have a positive effect by decreasing the liquid limit, the best improvement being for Cabot powder (−35% by acid cleaning). The best absolute value for LL is obtained for TAM 688 and Rhône-Poulenc powders after acid treatment, corresponding to a solid volume fraction in the slip higher than 60%. Acid-cleaning treatment is the most efficient in that sense except for Criceram powder, whose lowest LL is obtained on only calcined and sonicated powder. It has been observed that ultrasonic de-agglomeration of acid-cleaned powders does not improve the liquid limit.

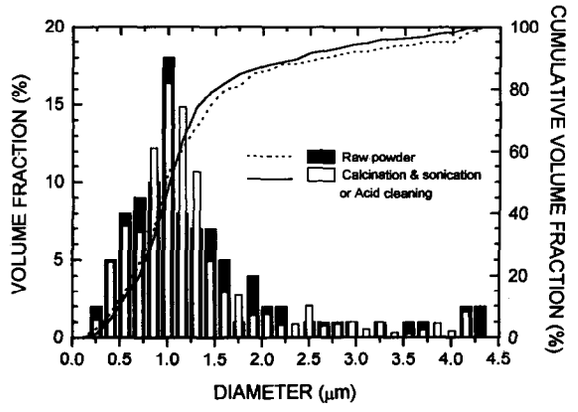

Fig. 11. Effects of treatments on particle size distribution.

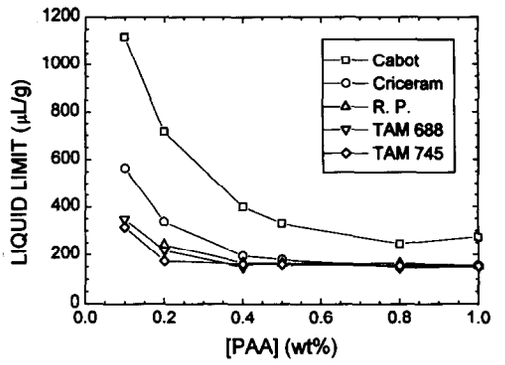

Fig. 12. [PAA] dependence of the liquid limit for raw powders ([NH_3]/[PAA] = 1·5).

3.3 Green body properties

The slip composition was then optimised in order to obtain the highest *green density*, by varying [PAA] (0·60–0·80 %wt) and the volume of dispersant added (LL + 0·025–0·050 cm^3/g). The slightly higher amount of dispersant with respect to LL is intended to compensate for evaporation during slip processing. Statistical analysis revealed a significant effect of the volume of dispersant, its lower level yielding the highest green densities for the five powders. Figure 14 shows the effect of the treatments on the green densities of cast samples, resulting from the average of four samples for each powder and treatment obtained with optimised slip compositions. Cabot raw specimens were too brittle to be manipulated and have not been considered for further studies. Large variations in relative green density can be seen with respect to the powder sources, between 57 and 70% theoretical density. Statistical analysis reveals that calcination and sonication treatment has drastically improved the green density, the most dramatic enhancement being for Rhône-Poulenc powder (+16%). However, acid or water cleaning do not significantly provide further improvement, confirming that de-agglomeration by acid cleaning is equivalent to sonication.

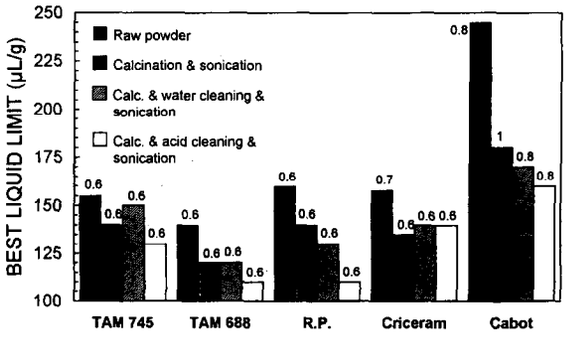

Fig. 13. Effects of treatments on the optimal liquid limit with corresponding [PAA] (in wt%).

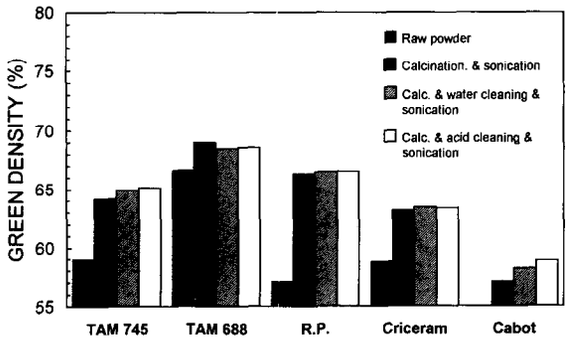

Fig. 14. Effects of treatments on green density.

4 Discussion

The major elemental contaminants in raw powders appear to be carbon and sulphur, in approximately the same weight concentration. XRD and XPS experiments show that carbon is present at the surface as barium carbonate. On the other hand, no sulphur compound was detected, neither by XRD, nor by XPS, suggesting that sulphur is distributed in the bulk of the particles, probably as $BaSO_4$, as a result of the preparation conditions of the $BaTiO_3$ powders.

FT-IR pyrolyses show that only CO_2 is released up to 1300°C; the absence of SO_2 or SO_3 release means that barium sulphate remains stable in that temperature range. The possibility of O_2 release (not detectable by infrared spectroscopy), by an exchange mechanism of oxygen between the $BaTiO_3$ lattice and the ambient atmosphere,[13] although reported for donor-doped $BaTiO_3$,[14] is not expected for undoped $BaTiO_3$ sintered in an oxidising atmosphere; TGA experiments performed in nitrogen still gave rise to similar weight losses, indicating that the origin of the gas release is not the atmosphere but the powders themselves. Therefore, weight losses observed by TGA on raw powders between 500 and 900°C, and 1200 and 1400°C, can definitely be ascribed to evolving CO_2.

Based upon this finding, three decomposition reactions for the barium carbonate contamination can be considered:[15]

$$BaCO_3 + TiO_2 \rightarrow BaTiO_3 + CO_2(g) \qquad T_d = 400{\cdot}5°C \quad (1)$$

$$BaCO_3 + BaTiO_3 \rightarrow Ba_2TiO_4 + CO_2(g) \qquad T_d = 1002°C \quad (2)$$

$$BaCO_3 \rightarrow BaO + CO_2(g) \quad T_d = 1540°C \quad (3)$$

where the decomposition temperatures T_d are computed using standard thermodynamic data[16] and assuming $p_{CO_2} = 1$ atm. Barium carbonate decomposes directly into barium oxide and carbon dioxide (reaction (3)) at a temperature higher than conventional sintering temperature for $BaTiO_3$.

Table 2. $BaCO_3$ content: Comparison of EGA and TGA estimations (Rhône-Poulenc powder)

Treatment	*Total [$BaCO_3$] (wt%) from EGA*	*Total [$BaCO_3$] (wt%) from TGA*	*Relative deviation (%)*
Calcined	0·910	0·942	3·4
Acid cleaned	0·551	0·718	23·2

The presence of $BaTiO_3$ or TiO_2 lowers its decomposition temperature; TiO_2 does not exists as a true second phase in the particles, but a compositional gradient $Ba_{1-x}TiO_{3-x}$ develops at the vicinity of the $BaCO_3/BaTiO_3$ interface. This results in a gas release in the sintering temperature range which is detrimental for obtaining high densities (see Part II).

Weight losses near 600 and 1300°C recorded on raw powders by TGA can thus be accounted for by reactions (1) and (2), respectively, the shift in temperature arising from the arbitrary value of 1 atm for p_{CO_2}. $BaCO_3$ content for all powders and treatments was then calculated from weight losses between 500 and 1400°C. Comparison with EGA measurement for Rhône-Poulenc powder showed relatively good agreement, as shown in Table 2.

For all treatments the barium sulphate content remains unchanged, due to its high decomposition temperature, low solubility and distribution in the bulk of the particles. Figure 15 shows the total barium carbonate content present for all powders and treatments, based on TGA measurements. Raw powder carbonation is not correlated with particle size; it is probably determined by a combination of synthesis conditions and ageing phenomena.

Examination of DTG curves of Figs 4, 5, 6 and 7 shows that for Criceram, Rhône-Poulenc, TAM 688 and TAM 745 powders, the calcination treatment promotes the dissociation of the most reactive part of the carbonate (low-temperature side of the 600°C loss peak), with a corresponding shift towards higher temperature of the resultant maximum loss rate. This easily decomposable carbon-

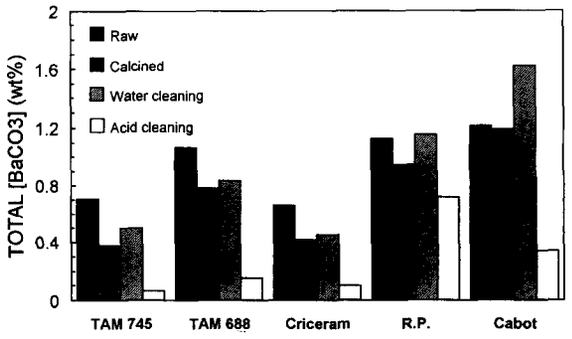

Fig. 15. Effects of treatments on total $BaCO_3$ content.

ate probably arises from atmospheric contamination. After water cleaning the 600°C loss peak is increased again, meaning that recarbonation due to CO_2 dissolved in water has occurred. This $BaCO_3$ species formed in aqueous conditions is more stable because it decomposes at a slightly higher temperature (850°C instead of 650°C). In contrast, the corresponding loss peak for Cabot powder (Fig. 3) is not affected by calcination and water-cleaning treatments, and is also centred on 850°C: The $BaCO_3$ contaminating the surface originates from the hydrothermal synthesis, resists calcination at 500°C and has the same features that those formed during water cleaning.

A substantial amount of carbonate is eliminated by acid cleaning. Recarbonation of acid washed powders does not take place because the surface is deficient in barium due to Ba^{2+} ions going into solution. TGA experiments performed six months after the treatment do not show any recarbonation.

On the other hand, $BaCO_3$ is not completely eliminated by acid cleaning (weight losses above 1100°C). Two consecutive acid cleaning treatments using the same acetate buffer (0·3M) were then performed in order to try to dissolve the remaining carbonate, but without any improvement. This suggests that barium carbonate contamination originates from different mechanisms: surface alteration, by contact with atmosphere or water, producing carbonate decomposing at low temperature (TG losses between 500 and 900°C) and easily removed by acid cleaning, and contamination during the synthesis of the powders (incomplete reactions, contaminated precursors, etc.), resulting in a more stable form of carbonate decomposing at higher temperature (TG losses between 1100 and 1400°C). This phase is still partially present at the surface after acid cleaning, as shown by XPS. Its low solubility in the cleaning solution is probably because it is more tightly bonded to the $BaTiO_3$ surface. Free carbonate grains are not likely to resist acid-cleaning treatment, but the possibility of a bulk contamination of the particles, i.e. $BaCO_3$ entrapped in $BaTiO_3$ crystals, could also be consistent with the partial removal upon acid cleaning.

The effects of the various treatments on forming can be summarised as follows: For all powders, calcination alone tends to agglomerate the powders; calcination in association with the ultrasonic de-agglomeration treatment promotes a higher green density. The same improvement results after acid cleaning of calcined powders without subsequent sonication, and a further ultrasonic treatment of acid-cleaned powders does not improve the green density, showing the efficient de-agglomerating effect of acid washing. The liquid limit of the slips is also markedly improved after calcination and sonication, and acid cleaning brings about a further improvement. Compared to calcination, water cleaning does not change significantly the green density and the liquid limit, which means that modifications by acid cleaning are definitely not due to handling artefacts (suspending, de-agglomeration and drying).

Physical characteristics of individual particles of $BaTiO_3$ such as morphology, diameter and specific surface area do not seem to be affected by the decontamination treatments. The surface carbonate distribution, either homogeneous or heterogeneous, cannot be inferred from SEM analysis, because the carbonate layer thickness is below the resolution of the apparatus. XPS analysis shows that $BaCO_3$ still subsists at the surface after acid cleaning, so that the colloidal stabilisation mechanisms involved in the slips elaboration are almost unaffected (cf. PAA content in Fig. 13). It can be concluded that the improvements of the liquid limits of the slips (i.e. decrease in viscosity) by the treatments result mainly from their de-agglomerating effects. Acid cleaning does not always improve the green density and the liquid limit to the same extent. However, a lower green density can be compensated by a larger shrinkage during drying.

The improvement due to cleaning treatments, as far as rheological and green body properties are concerned, can be interpreted according to the following scheme. In raw powders, some $BaTiO_3$ particles form soft agglomerates, $BaCO_3$ acting as a 'cement'. Calcination treatment, by its temporary decomposition of $BaCO_3$, may be sufficient to destroy these soft agglomerates. Acid cleaning is a more drastic treatment: not only does it dissolve $BaCO_3$, but it can also slightly alter the $BaTiO_3$ surface and in some instances totally dissolve the necks between partially sintered particles that form hard agglomerates (chemical de-agglomeration). The improvement of green body properties already reported can then be accounted for by a geometric argument: the surface treatments performed appear to decrease the number of agglomerates present in raw powders and consequently increase the packing efficiency by minimising bridging effects between particles. The highest green density value of 70%, obtained with calcined TAM 688 powder, is remarkably close to the theoretical maximal packing density of about 72% predicted from computer simulation[17,18] for random close packing of log-normally distributed spheres with a geometric standard deviation of 1·7, as measured for this powder.

5 Conclusions

The study presented in the first part of this series of two papers shows that commercial undoped $BaTiO_3$ powders are mainly contaminated by barium sulphate and barium carbonate. Barium sulphate is thermally stable beyond 1400°C and is unaffected by heat or washing treatments. Barium carbonate, on the other hand, thermally decomposes in two steps, near 600°C and 1300°C, to release CO_2. This carbonation originates from two sources: atmospheric or aqueous CO_2 contamination results in the formation of a surface $BaCO_3$ layer, easily decomposed, either thermally or chemically. Carbonate originating from the synthesis stage is more stable, resists acid cleaning and decomposes above 1200°C. It is thought that carbonate remaining after acid cleaning is mainly distributed at the surface of the particles, without excluding a residual bulk contamination. The decarbonating effect of the calcination or chemical treatments (acid dissolution), although not complete, proved to be substantially beneficial with respect to green body densities of ceramics samples obtained by slip casting. For all powders the liquid limits of the slips have been decreased and the green density increased, respectively as much as 35% and 16%. Advantage may be taken of the corresponding reduction of shrinkage during sintering for obtaining complex shape samples. These improvements can be seen as a consequence of the elimination of agglomerates present in raw powders, as a result of the reduction of surface barium carbonate content yielding figures very close to the theoretical optimal values of packing density. A point to note is that the range within which the processing parameters vary as a function of powder source has been substantially reduced by the treatments, which means that a better reproducibility of ceramic green samples can be achieved by controlling the surface chemistry of the raw powders.

(Received 3 March 1994; revised version received 17 June 1994; accepted 30 June 1994)

Abstract

Natural sintering and microstructure of undoped $BaTiO_3$ ceramics obtained by slip casting from five commercial powders subjected to various surface decarbonation treatments (calcination and cleaning in pure water or acetate buffer solution) were investigated. Two densification steps followed in certain instances by a desintering step were observed for as-received powders. At maximum density the microstructure is either coarse-grained or bimodal, with dense large grains between 20 and 100 μm in a fine-grained matrix (<1 μm). At the end of swelling a coarse intergranular and fine intragranular porosity is present and total conversion into large grains has occurred, their size remaining unchanged up to 1400°C. Calcination and water cleaning had no noticeable influence on sintering behaviour. Acid cleaning appeared to substantially modify the shape of dilatometric curves: shrinkage starts later, the onset of abnormal grain growth is delayed, the maximum fired densities are slightly increased, but the subsequent swelling of specimens above 1300°C is also enhanced.

It is suggested that abnormal grain growth in undoped barium titanate results from the presence of a liquid phase at grain boundaries. Due to the presence of trace impurities, it can form locally at a temperature below the eutectic temperature of 1317°C of the system BaO–TiO_2. Decontamination by acid cleaning raises the eutectic point, but also increase the amount of liquid phase above 1300°C, by lowering the Ba content at the surface of the particles. The plasticity of the material is then increased, promoting swelling due to internal CO_2 pressure, originating from the decomposition of $BaCO_3$ which still subsists after acid cleaning.

1 Introduction

Electrical properties of structural ceramics are strongly dependent on their microstructure. This is particularly true in the case of $BaTiO_3$-based capacitors, where exaggerated final porosity drastically decreases the dielectric strength and the dielectric constant.[1] The porosity evolution during sintering is often complicated by the presence of impurities and by anomalous grain growth.[2] The possibility of obtaining fully dense sintered materials is then greatly related to the impurity content in initial powders.

This is the second part of a series of two papers dealing with surface contamination effects in undoped barium titanate. It was shown in Part I[3] by chemical analyses that an important source of contamination for $BaTiO_3$ raw powders is barium carbonate, resulting from reaction of the surface with atmospheric CO_2 or formed during the synthesis of the powders, which is distributed mainly at the surface of the particles and which thermally decomposes in two steps near 700 and 1300°C to release CO_2; thermal (calcination) or chemical (cleaning in a pH 4·5 acetate buffer) treatments of different undoped barium titanate commercial powders proved to be an efficient way to reduce the surface $BaCO_3$ content. The effects of such treatments on forming green bodies by slip casting were described, the corresponding improvement in green density being ascribed to the reduction of agglomerates in the starting slips. The work presented in the present paper is focused on the sintering stage of such thermally and chemically surface decarbonated $BaTiO_3$ powders. Sintering kinetics in air were monitored by dilatometry and optical microscopy on slip-cast green bodies obtained from five commercial powders, subjected to the decontamination treatments reported in Part I.[3] Densification and grain growth processes are discussed and interpreted in terms of internal gas

release and the presence of a liquid phase correlated with the surface chemical composition of the powders.

2 Experimental Procedure

The five commercial $BaTiO_3$ powders used in this study, Criceram lot VPP20, TAM HPB lot 688, TAM HPB lot 745, Cabot BT10 lot 6243-24, and Rhône-Poulenc type Elmic BT 100 lot 7958, are described in Part I,[3] along with the de-agglomeration and decontamination treatments performed (calcination at 500°C for 16 h, acid cleaning in a 0·3M acetate buffer with pH = 4·5 for 16 h at 30°C, and demineralised water cleaning).

For each powder source and each treatment *slip-cast specimens* were prepared from aqueous $BaTiO_3$ suspensions stabilised with poly(acrylic acid)(PAA), with [PAA] ranging from 0·6 to 1 wt%. The acidity of the stabiliser was neutralised by NH_3, with $[NH_3]/[PAA] = 1·5$. The amount of dispersing liquid was between 135 and 270 μlitre/g. The methodology used is described in Part I.[3]

Non-isothermal *sintering* of the compacts was studied in dry air in a differential dilatometer Setaram DHT; the heating cycle was 10°C/min up to 800°C, 3·3°C/min up to 1400°C, and 5°C/min down to 20°C.

Fired densities were measured by Archimedes' method, using isopropanol as immersion liquid, and assuming the value of 6·02 g/cm^3 for the theoretical density of $BaTiO_3$. Intermediate fired densities were either calculated from dilatometric curves corrected for thermal expansion and calibrated with respect to measured final densities (i.e. at the end of the thermal cycle), or measured directly on specimens whose heating cycle was interrupted at some particular temperature.

Microstructures were observed with a Olympus type BHM optical microscope on polished and thermally etched samples (heating rate: 5°C/min from 20 to 1200°C then down to 20°C in air).

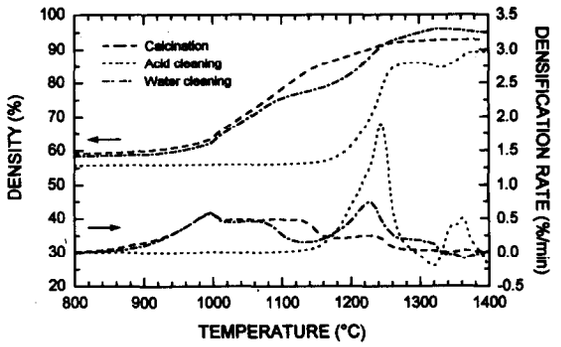

Fig. 2. Dilatometric curves for Cabot powder.

3 Results

3.1 Dilatometry

The sintering behaviour of raw powders is illustrated by dilatometric curves shown in Fig. 1. Criceram, TAM 688 and TAM 745 raw powder curves present a similar shape: shrinkage starts at 1050°C and two distinct densification peaks appear between 1240 and 1340°C. The density passes through a maximum beyond which swelling of the samples occurs, followed by a small redensification step.

The Rhône-Poulenc raw powder exhibits a quite different behaviour: shrinkage starts earlier (800°C) due to the smaller mean particle size, densification progresses continuously up to 1400°C and is not completed at this temperature. (Cabot raw powder could not be sintered because cast green bodies were too brittle).

Dilatometric curves of calcined, acid-cleaned and water-cleaned powders can be seen in Figs 2–6 along with raw powder curves for comparison. The same trend is again found for Criceram, TAM 688 and TAM 745 powders: the general shape of the densification curves is not modified, although acid cleaning slightly increases the maximum density, the corresponding temperature being slightly increased. However, the subsequent desintering step is amplified (up to 8% theoretical density for TAM 745 2nd Criceram powders) and its corresponding temperature increased. Water cleaning has no effect on calcined powders, and calcination alone only reduces the shrinkage

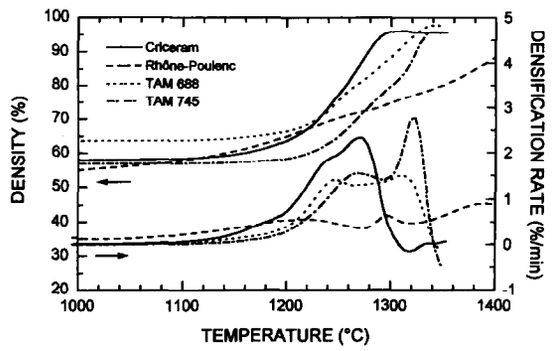

Fig. 1. Dilatometric curves for raw powders.

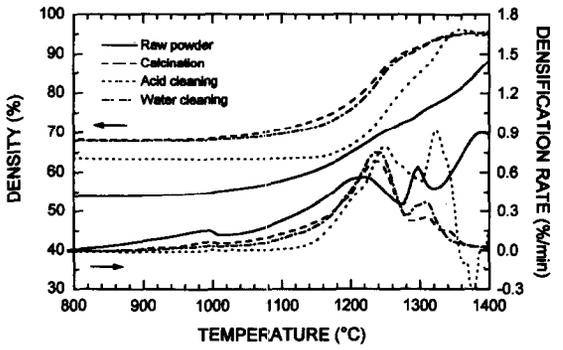

Fig. 4. Dilatometric curves for Rhône-Poulenc powder.

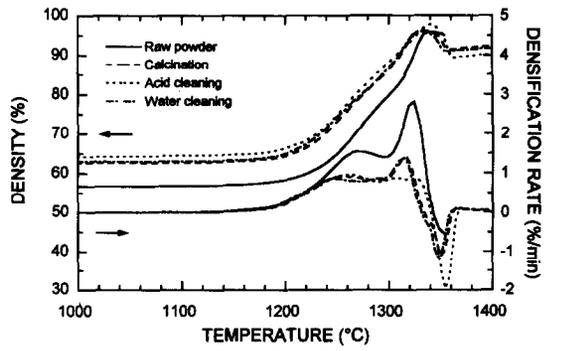

Fig. 6. Dilatometric curves for TAM 745 powder.

(because of a higher green density) to finally yield the same maximum density as raw powders. Treatments on the Rhône-Poulenc powder have drastically changed the sintering kinetics. Densification of the calcined powder is almost complete at 1400°C, maximum density has been increased and the beginning of densification is slightly delayed. Water cleaning does not affect the calcined powder, and the densification of acid cleaned powder starts later near 1100°C and then presents two peaks followed by a desintering step, as for Criceram and TAM powders. The sintering of calcined and water-cleaned Cabot powders starts at 800°C, and is continuous up to 1330°C. After acid cleaning it starts at 1100°C and a sharp densification rate peak is seen at 1240°C followed by a weak dedensification and then redensification step providing a lower density than calcined or water-cleaned powders. Figure 7 shows the maximum fired densities for all powders and treatments, which are not correlated with green densities and range between 95 and 100% except for Cabot powder. Calcination and water cleaning have no significant effect on maximum fired density, but acid cleaning slightly increases it, except for Criceram and Rhône-Poulenc powders.

3.2 Microstructures

In order to understand the mechanisms involved in the densification process the heating cycles of some specimens were interrupted at the temperature of maximum density and at the end of swelling in order to observe the corresponding microstructures. For all powders calcination and water cleaning have no noticeable effect on microstructure compared to raw powders.

At *maximum density* between 1300 and 1400°C the microstructure is bimodal for TAM 745, TAM 688 and Criceram raw powders (dense large grains of about 50–70 μm in a fine-grained matrix), while for Rhône-Poulenc raw powder it is entirely formed of large grains of about 100 μm with fine intragranular porosity. Acid cleaning decreases the proportion of large grains for the TAM and Criceram powders, and renders bimodal the microstructure of Rhône-Poulenc powder, which is now similar to that of TAM and Criceram powders. Calcined and water-cleaned Cabot powder microstructure at maximum density is formed of large grains (100 μm). Their size is reduced to 50 μm by acid cleaning, accompanied by the development of coarse inter- and intragranular porosity.

For powders presenting a dedensification step beyond the maximum density (TAM 745, TAM 688, Criceram, water and acid-cleaned Cabot and acid-cleaned Rhône-Poulenc powders) total conversion into large grains has occurred at the secondary *relative minimum density*, which is the point where the samples begin to redensify. At this point, an important porosity can be seen, both intra- and intergranular, the latter resulting from pore coalescence, and increased by acid cleaning. As the temperature goes up, some specimens slightly redensify, (TAM 745, Criceram) but grain size remains unchanged. This behaviour is

exemplified by microstructures of calcined and acid-cleaned Criceram and TAM 745 powders shown in Figs 8 and 9. The case of acid-cleaned Cabot powder is particularly interesting because it presents two consecutive desintering steps, near 1290 and then 1385°C. At the end of the heating cycle (1400°C) the microstructures are coarse-grained for all powders and treatments, with an important porosity, increased by acid cleaning. This treatment does not affect the final grain size for TAM 688, TAM 745 and Criceram powder (40 μm), but decreases it for Cabot and Rhône-Poulenc powders, from 100 to 40 μm (cf. Fig. 10).

Measured densities of specimens at the beginning of sintering, at maximum density and at the end of swelling when present are reported in Table 1, along with corresponding temperatures, for all powders and treatments.

4 Discussion

4.1 Raw powders

The apparent decrease in densification rates of treated powders compared to untreated ones is a mere consequence of the improvement of the green densities. It provides also slight but significant enhancements in the maximum fired density, except for Cabot powder, as shown in Table 1. The difference between sintering behaviour of raw powders is probably due to their particle size and specific surface contamination, resulting from both their history and their synthesis route.

Sintering of the larger particle raw powders (TAM 688, TAM 745, Criceram—d_{v50} about 1·4 μm) looks similar: during the initial stage, up to 1100°C, the compacts consolidate without densification. The first densification peak, corresponding

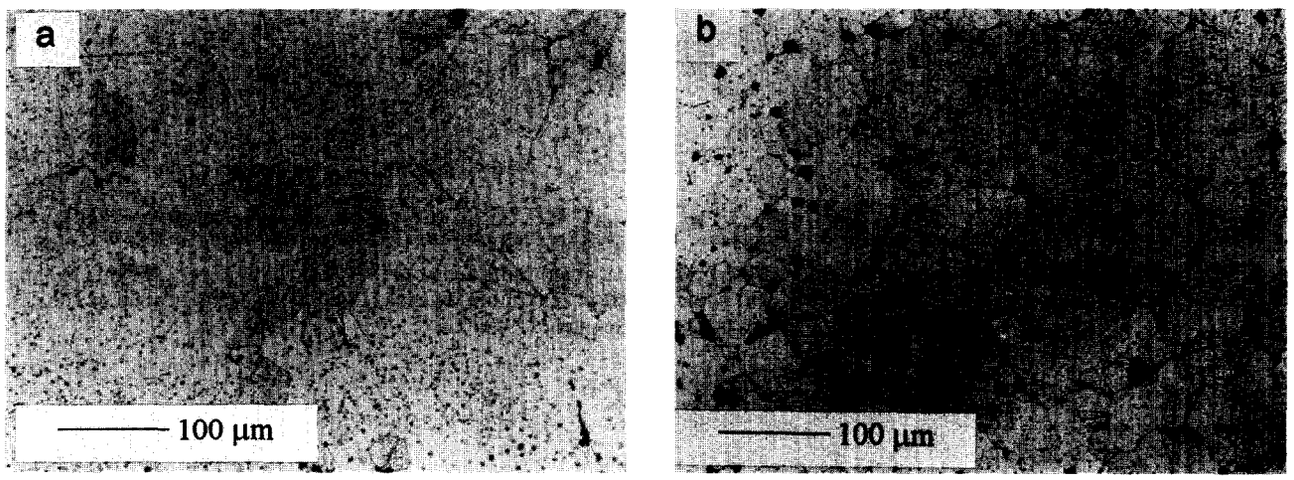

Fig. 10. Microstructure of Rhône-Poulenc samples at 1400°C: (a) Water-cleaned powder, (b) acid-cleaned powder.

to the intermediate stage, may be ascribed to normal grain growth, which progresses by bulk and boundary diffusion[4] as long as diffusion paths are not too long. At this point the most favourable mechanism to reduce surface free energy is abnormal grain growth, i.e. growth of large grains at the expense of smaller ones, which corresponds to the final stage and can account for the second densification peak. Abnormal grain growth, by reduction of the boundary areas, leads to pore coalescence. However, if this stage is too fast some pores may remain trapped inside large grains, lowering the maximum density. The temperature at which abnormal grain growth starts is correlated with the impurity content, as will be discussed later. Once total conversion into large grains has occurred, a desintering step is observed (cf. Figs 3, 5 and 6). A fine intragranular porosity is then present at the secondary minimum density which was absent at maximum density (Figs 8(a), 8(d), 9(a) and 9(d)), suggesting internal gas release. When the temperature increases, fine intragranular pores condense at the boundaries, giving rise to temporary interconnected open porosity (Figs 8(b), 8(e), 9(b) and 9(e)); at this stage evolved gas can escape from the body and further densification can occur. At 1400°C intragranular porosity has disappeared, leaving mainly intergranular porosity (Figs 8(c), 8(f), 9(c) and 9(f)).

A smaller powder such as Rhône-Poulenc (d_{v50} = 0·84 μm) is more reactive; as a result it densifies earlier, as soon as 800°C is reached (see Fig. 4). This fast shrinkage prevents the efficient removal of porosity (pore trapping), eventually yielding a low density at 1400°C. The final coarse-grained microstructure presents an homogeneously distributed intragranular porosity, which has not yet condensed at the boundaries.

4.2 Gas release

It was shown in Part I[3] by TGA and FT-IR that only CO_2 was released up to 1400°C, besides water evolution below 200°C; therefore it is suggested that CO_2 released from barium carbonate decomposition is responsible for the swelling phenomenon, because of its low solubility in $BaTiO_3$. CO_2 release in the 500–900°C range has been shown to be due to $BaCO_3$ reaction with TiO_2 to form $BaTiO_3$ (reaction (1) in Part I[3]), which does not interact with densification because porosity is still open at that temperature, so that CO_2 can escape from the compact material. The second $BaCO_3$ decomposition step near 1300°C, by reaction with $BaTiO_3$ to form Ba_2TiO_4 and CO_2 (reaction (2) in Part I[3]), undoubtedly promotes swelling at that temperature, because the porosity is then closed. The CO_2 decomposition pressure P_d for reaction (2) of Part I_3 was calculated using:

$$P_d = \exp\left(-\frac{(\Delta H^\circ - T\Delta S^\circ)}{RT}\right) \quad (1)$$

where ΔH° and ΔS° are respectively the standard enthalpy and entropy of reaction (2) of Part I[3] R the gas constant and T the absolute temperature. Thermodynamic data give ΔH° = 178 kJ/mol and ΔS°= 140·3 J/mol K at 1300°C,[5] so P_d is about 2·8 MPa; such a pressure is larger than the stress necessary to initiate plastic deformation of fine-grained $BaTiO_3$, which is 2MPa at this temperature,[6] allowing swelling and the observed bloating phenomenon. Table 2 shows measured weight losses between 1100 and 1400°C and the corresponding gas volume produced at 2 MPa and 1400°C. Based upon the lowest of these figures (0·007% weight loss between 1200 and 1400°C for TAM 745 powder) and using perfect gas law, a density decrease down to 6·2% below the maximum value can then be explained, which is consistent with the desintering magnitudes observed.

4.3 Effects of the treatments

As already mentioned, calcination and water cleaning have no noticeable effect on the sintering of TAM 688, TAM 745 and Criceram powders, while they improve the final density of Rhône-Poulenc powder, which shows the same coarse-grained porous microstructure as the untreated powder. Calcined and water-cleaned Cabot powders densify approximately the same way, which is different from the other powders. On the other hand, the sintering behaviour of all powders is substantially modified by acid cleaning, giving rise to more similar dilatograms and final microstructures. The most remarkable effect of acid cleaning is the moving from 800°C up to 1100°C of the incipient sintering temperature for the Rhône-Poulenc and Cabot powders. As mentioned before the technical data sheets indicate approximately the same level for various impurities in all powders. However, due to their smaller particle sizes, the Cabot (0·4 μm) and Rhône-Poulenc (0·84 μm) samples are likely to be decontaminated more

Table 2. Weight losses between 1100 and 1400°C (measured by TGA) and corresponding CO_2 volume produced at 2 MPa and 1300°C

Powder	*CO_2 (wt%) released between 1100 and 1400°C*	*Gas volume (%) at 2 MPa–1400°C*
TAM 745	0·007	6·2
TAM 688	0·022	17·3
Criceram	0·017	13·9
Rhône-Pulenc	0·116	52·5
Cabot	0·087	45·3

thoroughly upon acid leaching; as a consequence, one may expect that acid washing will suppress any sintering phenomena below 1100°C but surface diffusion, therefore suppressing any shrinkage below that temperature.

The delay of the onset of abnormal grain growth by acid cleaning can be explained under the assumption that this last phenomenon is triggered by the formation of a liquid phase at the boundaries, even in raw powders. Examination of Fig. 1 shows that the onset temperature of the second densification peak corresponding to abnormal grain growth may be located, for some raw powders and in particular Criceram, below the eutectic temperature of 1317°C in the BaO–TiO_2 diagram.[7] However, impurities such as Si, Al or Na are generally present in commercial undoped barium titanate: between 20 and 100 ppm according to the suppliers of the powders used in this study. Ternary diagrams of such compositions show that the eutectic point can be drastically lowered, down to 1250°C, for example, for the system $BaTiO_3$–SiO_2 or even 942°C for the system $NaSiO_3$–$BaTiO_3$.[8] Compositional fluctuation of impurities can then give rise locally to sufficiently concentrated zones to form a liquid phase at the boundaries and consequently constitute nuclei for exaggerated grain growth by a dissolution–precipitation mechanism (Ostwald ripening)[9] at temperatures far below 1317°C. Abnormal grain growth has already been reported in $BaTiO_3$ below 1322°C in the absence of a liquid phase,[10] with twinned platelike grains growing by a solid-state process. In contrast, the rounded shape of large grains found below 1317°C in the present samples strongly indicates the presence of a liquid phase. Acid cleaning, by removing such melting agent impurities from the surface of the particles, raises the eutectic point to the expected value near 1320°C for 'pure' $BaTiO_3$ and consequently retards and slows down abnormal grain growth. Dilatometric curves for TAM 688 powder (Fig. 5) reveal only a weak contamination, the position of the second densification peak and maximum density being only slightly shifted (about 10°C). Conversely, Criceram powder appears to be more contaminated (Fig. 3): the second densification peak occurs at 1270°C for raw powder and is shifted to 1301°C after acid cleaning.

Despite the fact that surface barium carbonate is greatly reduced after acid cleaning, this treatment promotes an unexpected enhancement of the desintering stage on TAM 688, TAM 745 and Criceram powders. Rhône-Poulenc and Cabot powders present a desintering stage after acid cleaning only. The same phenomenon was observed on annealing hot-pressed samples (TAM 688), compacts being obtained without organic additive (PAA): therefore it is concluded that PAA decomposition plays no role in swelling, which is only due to $BaCO_3$ decomposition. XPS, EGA and TGA investigations[3] show that barium carbonate is still found after acid cleaning; the thermogravimetric weight losses between 1200 and 1400°C after acid cleaning are the same as for the raw powders, indicating that the acid-cleaning solution used was not strong enough to dissolve the $BaCO_3$ completely. Discrete $BaCO_3$ particles are not likely to be present after acid cleaning, unless they are trapped inside $BaTiO_3$ grains. It is more probable that a layer of carbonate more strongly bonded to the surface subsists, as shown by XPS, this remaining quantity corresponding to the weight losses shown in Table 2. These weight losses, if assumed to produce CO_2, are sufficient to account for desintering amplitudes as high as those observed for TAM 745 and Criceram acid-cleaned powders (8%). The magnitude of swelling is not proportional to the residual barium carbonate content—provided it is greater than 0·03 wt%—because once the porosity opens again, CO_2 can escape freely from the material.

The *increase* in swelling after acid cleaning results from a secondary effect of this treatment. During acid cleaning some Ba^{2+} ions were dissolved from the surface of the particles, which consequently become barium deficient, as shown by XPS in Part I.[3] This means that the isocompositional line has been shifted towards the TiO_2 side: the amount of liquid phase present at grain boundaries above 1300°C is then increased. As a consequence the plasticity of the material is enhanced, hence promoting swelling upon the development of internal CO_2 pressure inside the samples.

5 Conclusions

The effect of decontamination treatments of the surface of $BaTiO_3$ powders on sintering was investigated. Calcination only improves green densities of slip-cast bodies, which then densify upon sintering in more or less the same way as raw powders. Acid cleaning has extra repercussions on the sintering stage: increases in green densities combined with a delayed abnormal grain growth improve the elimination of porosity during the first stage of sintering, yielding slightly higher maximum densities. However, swelling above 1300°C is also increased, resulting from the development of internal CO_2 pressure inside the samples at high temperature after closure of the porosity. This carbon dioxide release originates from the decomposition of residual $BaCO_3$ which still subsists after acid cleaning. It is argued that impurities com-

monly found in undoped $BaTiO_3$ can promote the formation of a liquid phase at lower temperatures, responsible for abnormal grain growth. The formation of this liquid phase, and consequently the microstructure, can be controlled by acid cleaning, by eliminating both the melting agents present as impurities, and changing the surface Ba/Ti ratio. Complete removal of surface $BaCO_3$, using more acidic cleaning solutions, could lead to fully dense specimens by suppressing gas release at high temperature, assuming no $BaCO_3$ in the bulk.

Processing of commercial $BaTiO_3$ raw powders, especially by acid cleaning, appears to be beneficial on final properties. Removal of most of the barium carbonate by this treatment and various impurities hardly quantifiable present at the surface of the particles give rise to an approximately similar sintering behaviour for all powders. A similar final microstructure less sensitive to the starting commercial powder can then be obtained, confirming the great influence of the surface chemistry of initial powders on the final properties of the ceramics made thereof.

Characterization of Submicron Alumina Dispersions with Poly(methacrylic acid) Polyelectrolyte

Wen-Cheng J. Wei, Su Jen Lu & Bu-Kon Yu

Institute of Materials Science and Engineering, National Taiwan University, Taipei, Taiwan 106

(Received 4 December 1993; revised version received 3 June 1994; accepted 30 June 1994)

Abstract

Colloidal dispersion of two submicron alumina powders (A-16SG and APA-0·2) and their mixtures were investigated in an aqueous suspension with and without dispersant (ammonium salt of poly(methacrylic acid), PMAAN). The ζ-potential and isoelectric point (iep) of the powders in aqueous solution were determined in the presence of the dispersant and electrolyte (NaCl). The adsorption of dissociated $PMAA^-$ on alumina powders was determined via the titration technique. The dispersant was observed to exert a strong influence on the surface potential, flowing behaviors and packing densities of the aluminas. The results showed that the dispersion conditions were strongly affected by factors including the solid concentration of submicron alumina particles, the pH value and the concentration of PMAAN in the suspensions, and that these three factors were cross-influencing. A reaction model at the interface of alumina—solution was developed, based on the dissociation of PMAAN and the adsorption of surface hydrocarboxyl groups on alumina surface.

1 Introduction

Fine-grained and uniform microstructures are desirable for most structural ceramic applications in producing a strong and reliable structural part. One method which accomplishes these goals involves using submicron powder[1–3] as well as processing the ceramic powder through colloidal states.[4–8] Colloidal processing has gained considerable attention during the past decade, having proven itself as being one of the effective routes in producing high-performance ceramic components.

Ceramic particles in a solution are charged and may possibly become dispersed in a repulsive manner by the forces developed at the surface of the particles. The particles can be dispersed in an aqueous solution by three mechanisms, i.e either by electrostatic, steric, or electrosteric stabilization.[9] These stabilizations are accomplished by generating common surface charges either at the surface of particles or else on the polymer chains which are adsorbed on the surface of the particle. The force, which is formed from the repulsion of similar charges and offers this stabilization, is commonly termed a Coulombic force. In addition to these forces, the adsorbed polymeric chains can also perform a spatial repulsion. Electrosteric stabilization is active if the polymer chains are absorbed on ceramic surface and the chains are charged with dissociated functional groups. It is closely related to the conformation and dissociation of polymeric chains in various acidic–basic conditions, which have been discussed extensively in consideration of the interaction with the oxide surface.[4,5,10] The electrosteric effect produces significant repulsion forces between the polymeric chains and particles. However, the ceramic particles, especially for submicron powder and in high solid-content suspensions, are easily coagulated in a poor solution unless the suspension has favorable stabilization conditions.

The rheology of a ceramic suspension is strongly influenced by the nature of the ceramic particles, the composition and chemical nature of the solvent and dispersant, as well as the solid content.[4,10,11] Two of the important parameters that can be used to describe the state of dispersion of ceramic colloids are the ζ-potential and the isoelectric point (iep) of the colloidal surface.[12] The surface potential has been extensively employed in accounting for the electrokinetics properties of ceramic suspensions.[6,7,13] The values of the potential, although somewhat controlled by the nature of the solid particles, e.g. the crystalline phase[14] and the surface impurity,[15] are most significantly controlled by the acidity of dispersing medium and the additive (or dispersant) in the medium.

Some research effort involving ceramic composites was recently undertaken which employs the colloidal process in preparing mixtures of various dissimilar ceramic and/or metallic colloids. The use of a toughening phase, e.g. zirconia particulates for toughening alumina, or the preparation of the mixture of two similar powders to tailor the size distribution of the powder mixture, or the production of nanocomposites would require understanding of the behavior of each phase, especially the fine portion of powder mixture, in colloidal states.

Many difficulties involving colloidal processing cases are encountered in powder mixtures. Phase segregation of ceramic particles in slip-casting, size segregation during sedimentation or consolidation of suspension, and flocculation of the fine particles in a mixture have a close relationship with the stability of a suspension system. Attempting to homogeneously mix two different powders is a rather difficult task.

Segregation of a heavy particle from the powder mixture or local segregation of different charged particles has been the major concern of these research efforts.[6,13] Some useful treatments are proposed as well as some promising results being provided. Velamakanni & Lange[6] reported that the requirements for colloidal particles to achieve their best packing properties were strong interparticle forces (high surface potential) and optimization of particle size distribution. Achieving strong interparticle forces is also true for stabilization of the suspensions with powders having different surface compositions and physical properties.

The principal objectives of this research involve analyzing the effects of polymeric dispersant when adsorbed on two alumina powders and identifying the critical parameters associated with the colloidal processes, as well as revealing the relationships of dispersion conditions with the purities of alumina powders. The phenomena of surface charging and adsorption of polymeric chains on alumina are cited here as accounting for the behavior of submicron alumina particles in a highly concentrated suspension system.

2 Experimental procedure

2.1 Materials

The alumina powders used in this study were A-16SG (supplied by Aluminum Co. of America, Pittsburg, PA, USA; BET surface area = 9·0 m^2g^{-1}, purity = 99·7%) and APA-0·2 (supplied by Ceralox Co., Arizona, USA; BET surface area = 34·0 m^2g^{-1}, purity = 99·97%). The properties of these powders are listed in Table 1. A-16SG and APA-0·2 powders have a different crystalline phase and average particle size (d_{50}) of 0·41 and 0·21 μm, respectively. A polyelectrolyte dispersant used in the preparation of dispersed alumina slurries was the ammonium salt of poly(methacrylic acid) (abbreviated as PMAAN) with molecular weight (Mw) ranging from 10000 to 16000. The water for dissolving dispersant was distilled, then deionized. The pH of alumina slurries was adjusted via the titrants diluted from analytical grade HCl and NaOH. Analytical grade NaCl was used as an electrolyte in a concentration of 0·01 N to adjust the ionic strength of diluted alumina suspensions which were subjected to the measurement of ζ-potential.

2.2 Sample preparation

2.2.1 Slurry preparation

The dispersant was first dissolved in the treated water. A specific amount of alumina powder was then gradually added to the solution. Some suspensions prepared for ζ-potential measurement required dilution to the concentration 0·001 mg cm^{-3} for analysis. The suspension was transferred into a polyethylene (PE) bottle which was loaded with zirconia grinding media, then agitated by a turbomixer for 1–24 h. According to the volume ratio of A-16SG to APA-0·2, powder mixtures were also prepared and designated A80, A70 and A60. For instance, A80 represents an alumina (A) mixture of eight parts of A-16SG and two parts of APA-0·2 by volume.

2.2.2 Green compact preparation

Green alumina pieces were prepared via a pressure-casting method. The alumina slurries were

contained in an air-pressurizing mold which is constituted of two plates manufactured from 316 stainless steel and a thick-wall tube of transparent polyacrylic material. Compressed air at a pressure of 10 kg cm^{-2} was supplied, along with the slurry being driven through a plastic filter paper.

2.3 Property measurement

2.3.1 Zeta (ζ)-potential measurement
Electrophoresis measurement was conducted using a Zeta-Meter 3·0+ instrument (Zetameter Inc., USA) so as to determine the ζ-potential of the alumina particles in aqueous suspension. The instrument was carefully calibrated and tested with the standard colloids offered by the manufacturer. In this study, alumina powder was dispersed in a prepared solution in a solid concentration close to 0·001 mg cm^{-3}, The pH value of the solution with a specific amount of the dispersant was adjusted via either a dissolved acidic or a basic solution, as well as NaCl electrolyte. The suspension was ultrasonicated using a NEY ultrasonicator (2Q-100) at a power level of 30 W for at least 5 min before the measurement being taken.

2.3.2 Acid titration of dispersant
Adsorption of the dispersant on alumina powders and the pH of alumina suspension with various amounts of PMAAN were determined using an auto-titration instrument (VIT90 Video Titrator, TitraLab™ Radiometer, USA). The calibration curve of PMAAN titrated with 0·1 N HCl is shown in the Appendix. The adsorption of PMAAN on alumina was then determined in the following procedure. The mixed alumina suspension was centrifuged using a Hermle Z380 centrifuger (Berthold Hormle GMBH & Co, Germany) at 6000 rpm for 60 min to obtain a clear suspension. The clear solution was next removed from the suspension container, and titrated with 0·1 N HCl standard solution. The amount of required acid to balance the dissolved PMAAN in the clear suspension was determined by the IPT (infection point titration) method, which can be referred to in the operation manual of the VIT90 Video Titrator. As a consequence, $PMAA^-$ species adsorbed on alumina could be calculated from the equivalent point of the acid measured by the previously mentioned IPT method.

2.3.3 Viscosity measurement
The measurements were conducted with two rotary viscometers (Model DV II, Brooksfield Eng. Labs Inc., USA) which have different shear-rate ranges. These instruments were calibrated with three standard viscous fluids, which have the viscosities of 93·8, 975 and 12200 cps (or mPas), respectively. Flocculation of alumina particles in a poorly dispersed slurry would influence the rheological properties of the slurry. Therefore, the measurement steps were adjusted according to previous reports;[4,5] in addition, the apparent viscosity values were taken from the average of at least two different measurements.

2.3.4 Pore size and volume measurements
Green samples were dried at 500°C for 10 min before they were tested with a mercury porosimeter (Autopore II 9220, Micromeritics Instrument Co., USA).

2.3.5 Microstructural observation
Alumina green samples were broken, coated with a thin Au film for electric conductivity, and observed using a scanning electron microscope (JSM-T100 mini SEM, JEOL Co., Japan).

3 Results and discussion

3.1 Surface potential of alumina with and without dispersant

The effect of pH on the ζ-potentials of the two alumina powders in an aqueous solution is shown in Fig. 1. The isoelectric point (iep) of A-16SG is at pH = 8·5, for APA-0·2 alumina it is at pH = 8·9. According to the literature,[11] the iep of aluminas could vary with the sources of alumina and the varieties of measurement techniques: The alumina prepared from the precipitation with incomplete hydration has a zero point of charge (zpc) (which could be considered as iep) near pH 6·9 if measured by the electrophoresis method. For the natural product, however, alumina has a zpc at pH 8·4 if measured by the same method, or 9·5 if by the streaming potential method. Rao[13] employed two different techniques in measuring the property, reporting that the iep of alumina is at pH 9.

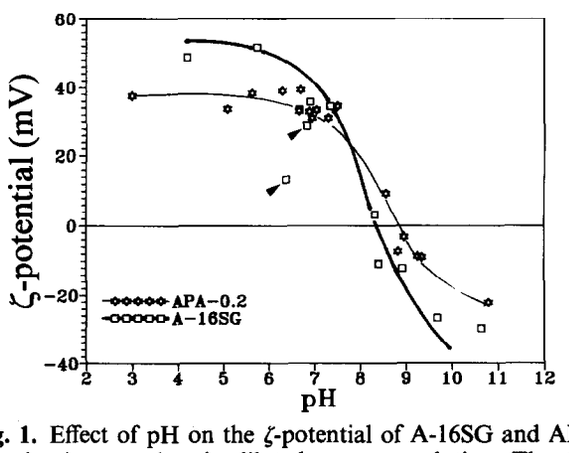

Fig. 1. Effect of pH on the ζ-potential of A-16SG and APA-0·2 alumina powders in diluted aqueous solution. The data indicated by arrows are discussed in the text.

A similar result of the iep value of the A-16SG powder, as determined by an improved measurement apparatus,[14] was reported to be at pH 8.

Kelso & Ferrazzolli[15] determined the relative acoustophoretic mobility of A-16SG alumina in water, and found a negative mobility (i.e. a negative ζ-potential on the surface) of A-16SG, as compared to a high purity alumina (XA-139SG, purity ≥99·95 wt%, supplied by Alcoa, USA) which has a positive value in deionized water (pH = 5·0). They assumed that the surface impurity Na_2O of A-16SG would possibly become ionized and for hydrated in an aqueous solution. The ζ-potential of A-16SG measured in this work was a positive value, similar to that of the high purity aluminas, XA-139SG,[14] and APA-0·2 in the present case. However, the surface potential values of A-16SG were observed in this study to be rather dependent upon the aging time of the alumina suspension. The ζ-potential values of A-16SG are relatively scattered within the range pH 5–7, and would be smaller in value if the suspension is aged more than 30 min, as shown by two data points in Fig. 1. It is due to the release of ionizable species, e.g. Na^+, Mg^{+2}, from the powder. High purity APA-0·2 powder has a consistent surface charge in an aqueous solution.

At the pH below the iep of alumina, the aqueous solution permits charge and proton transfer at the solid–solution interface, resulting in an electrically positive surface on alumina, e.g. the formation of $AlOH_2^+$. That is the reason why the alumina particles in weakly acidic water solution exhibits a positive potential. However, the observation of the pH value of freshly prepared suspensions changed from weakly acidic to neutral, or to weakly basic conditions as they aged. A similar change was reported[15] in which the pH of the water increased up to 9·6 for an alumina content in the solution of 16·7 wt%. The acidity of the suspension is dependent on the interaction of alumina in acidic suspension. However, the formation of the positive $AlOH_2^+$ species is interrupted by the presence of Na_2O and other ionizable oxide impurities. Surface Na_2O is considered here as possibly releasing Na^+ in forming a negative NaO^- so as to compensate for the positive charge ($AlOH_2^+$) on the surface of alumina. In addition, MgO, used as a grain-growth inhibitor, (as is the report indicated in by the powder supplier, Alcoa, USA), is present in A-16SG, and tends to dissolve in water to form a strongly basic solution. The contents of Na_2O and MgO are appreciable (0·08% and 0·05%, respectively) in A-16SG, but ignorable in a high purity APA-0·2 powder (Table 1). Therefore, the dissolution of Na_2O and MgO is not occurring in APA-0·2 between pH 5 to 7 in Fig. 1. The dissolved Na and Mg ions could alter the thickness of the double layer on the surface of alumina particles. As a consequence, the ζ-potential of A-16SG at the pH away from its iep is higher than that of APA-0·2 particles. The significance of surface impurities having reacted with water shows that the surface potential can be a time-dependent variable.

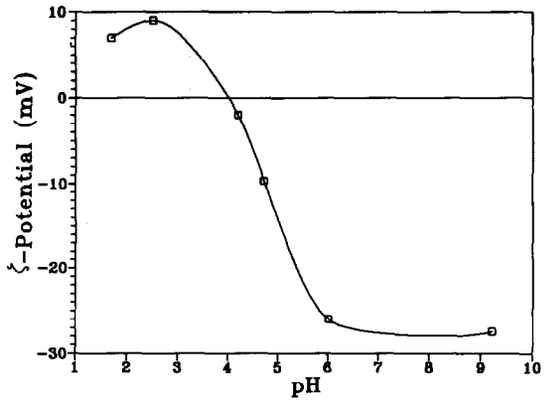

Fig. 2. Effect of pH on the ζ-potential of diluted A-16SG slurries with 0·125 wt% PMAAN (based on alumina).

Figure 2 shows the effect of pH on the ζ-potential of diluted A-16SG suspensions originally containing 30 wt% alumina and 0·125 wt% PMAAN (based on alumina). The alumina surface has reversed its electrical charging condition at pH 4·0. A similar chemical PMAA–Na salt[4] was reported as not being dissociated at the pH below 3·5, but fully dissociated at the pH values over than 8·0. If the dispersant used in this study has a similar dissociation behavior, the adsorption of dissociated $PMAA^-$ can only take place at the pH ranging from 3·5 to 8·2 (the iep of A-16SG). The surface potential of the alumina, which is positively changed, shifts to negative when the surface is covered with $PMAA^-$. As a result, the ζ-potential in the acidic conditions (pH = 3·5–8·2) is changed from a positive to a negative surface. Thus, iep of A-16SG in the presence of PMAAN is accordingly changed to pH 4·0.

A plot of the ζ-potential of A-16SG and APA-0·2 suspensions is provided in Fig. 3 which contains 0·01 N electrolyte NaCl and various amount of PMAAN. The surface potential of A-16SG alumina in diluted NaCl (0·01 N) solution is about 38 mV. However, the potential dramatically changes to negative if the amount of PMAAN is more than 0·02 wt% based on A-16SG alumina. Similarly the potential of APA-0·2 reverses as the concentration of PMAAN is greater than 0·04 wt%. That is a result of adsorption of a dispersant with an anionic-type functional group, and the amount of dispersant is surface-area dependent. The potential values, which reach a plateau, show that the adsorption on alumina becomes saturated if

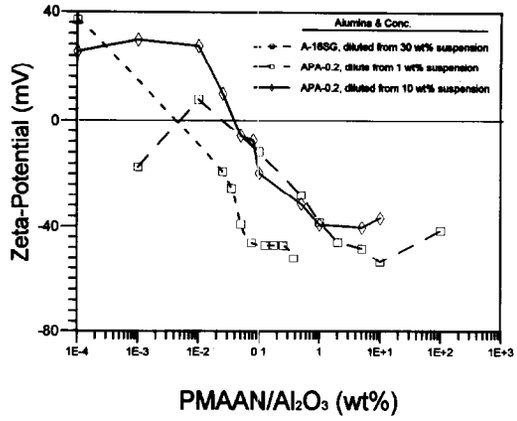

Fig. 3. Effect of PMAAN on the ζ-potential of A-16SG and APA-0·2 slurries which contain 0·01 N NaCl.

more than 0·07 wt% or 0·5 wt% PMAAN is added in the A-16SG or APA-0·2 suspensions, respectively.

The pH values of suspensions which contain various amounts of alumina are plotted in Fig. 4 against the added PMAAN. These results show that the water changes its pH value to weakly basic (pH 8·0) if PMAAN is added—even as little as 0·01 wt% (based on the solution). However, the pH becomes more basic if A-16SG powder is added at a level of more than 1·0 wt% of the deionized water. Kelso & Ferrazzolli[15] reported a similar change of the pH of pure water up to 9·6 if the addition of A-16SG alumina powder in the solution was 16·7 wt%, but up to pH 8·0 if the solution contained the same amount of high-purity alumina (XA-139SG).

First of all, the alumina surface tends to change from a neutral surface to a positively charged surface as alumina powder is steeped in deionized water. The adsorption of protons on the alumina surface causes the water to have an increasing OH^- concentration. This concentration causes the pH of the solution to be basic (pH > 7). The newly formed aluminum hydrate has an amphoteric property. The reactions of the hydrated alumina surface at various pH conditions can be expressed as follows

$$x\mathrm{H_3O^+} + [\mathrm{O{-}Al{-}}]_n(\mathrm{OH})_x \Leftrightarrow [\mathrm{O{-}Al{-}}]_n(\mathrm{OH_2^+})_x + x\mathrm{H_2O} \quad \text{at pH} \leq \text{iep} \quad (1)$$

$$[\mathrm{O{-}Al{-}}]_n(\mathrm{OH})_x + x\mathrm{OH^-} \Leftrightarrow x\mathrm{H_2O} + [\mathrm{O{-}Al{-}}]_n(\mathrm{O^-})_x \quad \text{at pH} \geq \text{iep} \quad (2)$$

However, the dissolution of PMAAN in water would interfere with the pH value of the suspension. The alumina suspension (Al_2O_3 content ≥1·0 wt% of the solution) is indicated from Fig. 4(a) to have higher pH values than the aqueous solution only with PMAAN. The difference of the pH value between the solution (with PMAAN) and alumina suspension is reducing (approaching to

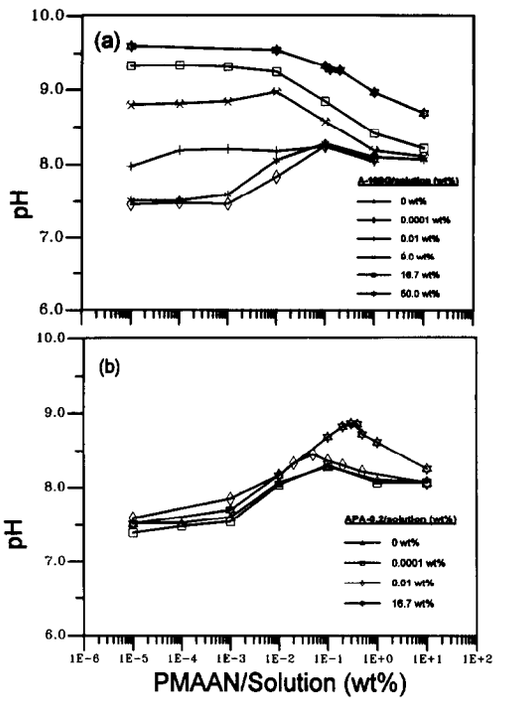

Fig. 4. Effect of PMAAN on the pH of alumina slurries for various concentrations of alumina (a) A-16SG and (b) APA-0·2.

pH 8·3) as the PMAAN concentration increases. The presence of alumina and PMAAN chemical have closely interfered with each other in aqueous solution.

Alumina is scarcely dissolved in a weakly basic solution of which the added PMAAN gives a stable pH value near 8·1. For a suspension system including a solid phase in equilibrium with the solution, the isoelectric point of the solution corresponds to the point of minimum solubility of the solid.[12] The formation of molecular $Al(OH)_3$ or AlOOH in weakly basic alumina suspension is ignorable. For the reactions of PMAAN, a combination of the dissociation of PMAAN and the adsorption of $PMAA^-$ on the alumina surface, are revealed by the pH evaluation of alumina suspensions.

The dissociation of PMAAN and the reaction with water can be expressed in the following equations:

$$\mathrm{PMAA - NH_4} \Leftrightarrow \mathrm{PMAA^- + NH_4^+} \quad (3)$$

$$\mathrm{PMAA^- + H_2O} \Leftrightarrow \mathrm{PMAA - H + OH^-} \quad (4)$$

If α is the fraction of dissociated group of PMAAN in suspension. The titration of a 33 vol.% (or 66 wt%) A-16SG suspension with 0·125 wt% PMAAN reveals that nearly 32% of $PMAA^-$ is adsorbed on the surface of APA-0·2. A high concentration (about 2/3) of the charged polymeric chains of $PMAA^-$ is available in this suspension and can be adsorbed on alumina particles, subsequently resulting in the decrease of surface potential (Fig. 3) of the alumina. However, several

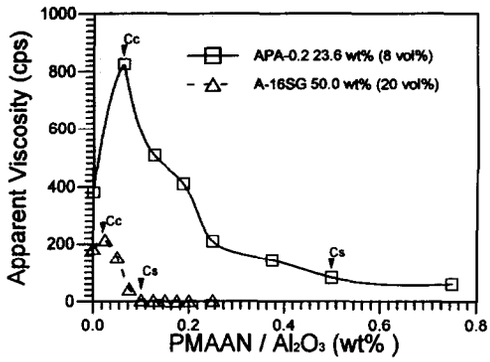

Fig. 5. Effect of PMAAN on the apparent viscosity of A-16SG and APA-0·2 slurries tested in a shear rate 18 s^{-1}.

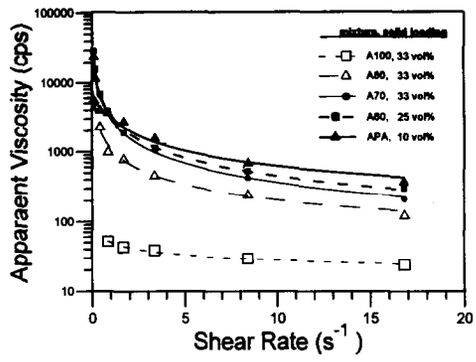

Fig. 6. Apparent viscosity of various alumina slurries with 0·5 wt% PMAAN (based on alumina) at various shear rates.

researchers[4,10] have pointed out that the conformation of $PMAA^-$ or a similar polymer, e.g. PAA^-, in weak base, influenced its adsorption phenomena near the saturation point. The stretched $PMAA^-$ prevents more $PMAA^-$ from adsorbing at the alumina particle surface. Therefore, the ζ-potential of A-16SG and APA-0·2 alumina suspensions can no longer increase their absolute values.

The adsorption of dissociated PMAAN on alumina not only alters the surface potential of alumina, but also changes the pH value of the solution if the adsorption on alumina is over the saturation point. As the concentration of PMAAN in A-16SG suspension rises over 0·01 wt%, the pH (or the acidity) of the alumina suspension changes to close to the pH of pure PMAAN with aqueous solution, but for high purity APA-0·2 it is over 0·05 wt%, as revealed in Fig. 4(a) and (b). Therefore, the pH of alumina suspension with an increase of non-adsorbed PMAAN approaches 8.1.

3.2 Slurry viscosity

The addition of dispersant $PMAA–NH_4$ can effectively reduce the viscosity of the alumina slurries if it is added into the formulation in a concentration of more than a critical amount (C_c). C_c is 0·02 wt% for A-16SG and 0·07 wt% for APA-0·2, as illustrated in Fig. 5. the electrosteric repulsion which arises from the adsorption of $PMAA^-$ polymeric chains on alumina is effective only if the added PMAAN is in an amount over C_c. This observation is consistent with the reverse of surface potential observed in Fig. 3. The interparticle forces, which are a result of surface electric potential, stabilize the colloidal particles in the concentrated suspension. Since the adsorption of the $PMAA^-$ on the alumina is near the saturation point (C_s in Fig. 5), the surface potential of A-16SG alumina is maintained at around 47 mV (Fig. 3), which is nearly the maximum potential in the suspension. A strong surface potential causes the viscosity of the A-16SG suspension to reach its lowest value. Similar behavior is found for the APA-0·2 suspension containing a lower solid content (i.e. 8 vol.%) than the A-16SG suspension.

The amount of polyelectrolyte necessary to achieve a good dispersion is surface-area dependent. The BET surface area of APA-0·2 is about four times higher than that of A-16SG powder, as indicated from Table 1. The curves provided in Fig. 5 are similar, only different in the scale of viscosity. The ratio of the critical amount (C_c) and the saturation amount (C_s) of required PMAAN implies that the specific surface area of the two powders, one of 34 $m^2\ g^{-1}$ the other of 9 $m^2\ g^{-1}$, is dominating the required amount of adsorbed $PMAA^-$.

Figure 6 illustrates the effect of PMAAN on the apparent viscosity of pure A-16SG, APA-0·2 slurries and the slurries of their mixtures, A80, A70 and A60. The rheological data in Fig. 6 were measured from the slurries with various solid concentrations. One APA-0·2 suspension can only be dispersed at the solid concentration less than 15 vol.%. All of the APA-0·2 containing slurries have a pseudo-plastic flow behavior; however, pure A-16SG slurry is nearly Newtonian. It has been demonstrated[16] by the Dougherty–Krieger equation that the rheological states are mainly affected by the solid loading (or solid/liquid ratio), particle shape and the average particle size. Interactions between the electrical double layer and/or the adsorbed polyelectrolyte have to be taken into account,[17] if the volume fraction of the particles in suspension is increased. The suspension of APA-0·2, having an average particle size two times less than that of A-16SG, was confirmed in this study as being very viscous (almost gelled) at solid concentrations over 15 vol.% if only 0·5 wt% PMAAN dispersant was used.

Rao[13] has reported that the electrophoretic mobility versus pH profiles and the position of the isoelectric point of powder mixtures are apparently governed by the powder having a large total surface area in the mixture, but not necessarily the

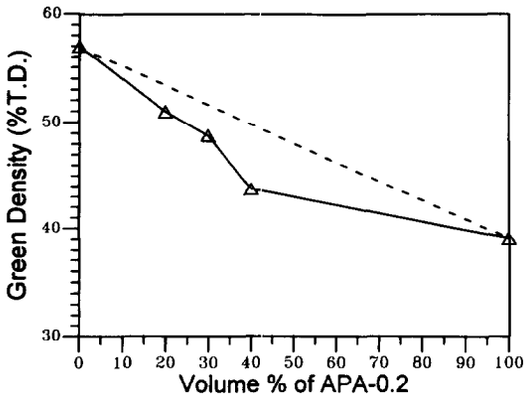

Fig. 7. Green densities of various alumina mixtures.

weight fraction. Thus, the viscosity of the mixed suspension could be controlled by the flowing behavior of fine APA-0·2 powder, as depicted in Fig. 6.

3.3 Properties of green alumina mixtures

Green densities of various alumina mixtures, which have been pressure-casted and dried, are given in Fig. 7. The green density is an index of powder packing conditions. A-16SG has a relative green density of 0·57, APA-0·2 is 0·39 only. The green pieces were prepared from the slurries with 0·125

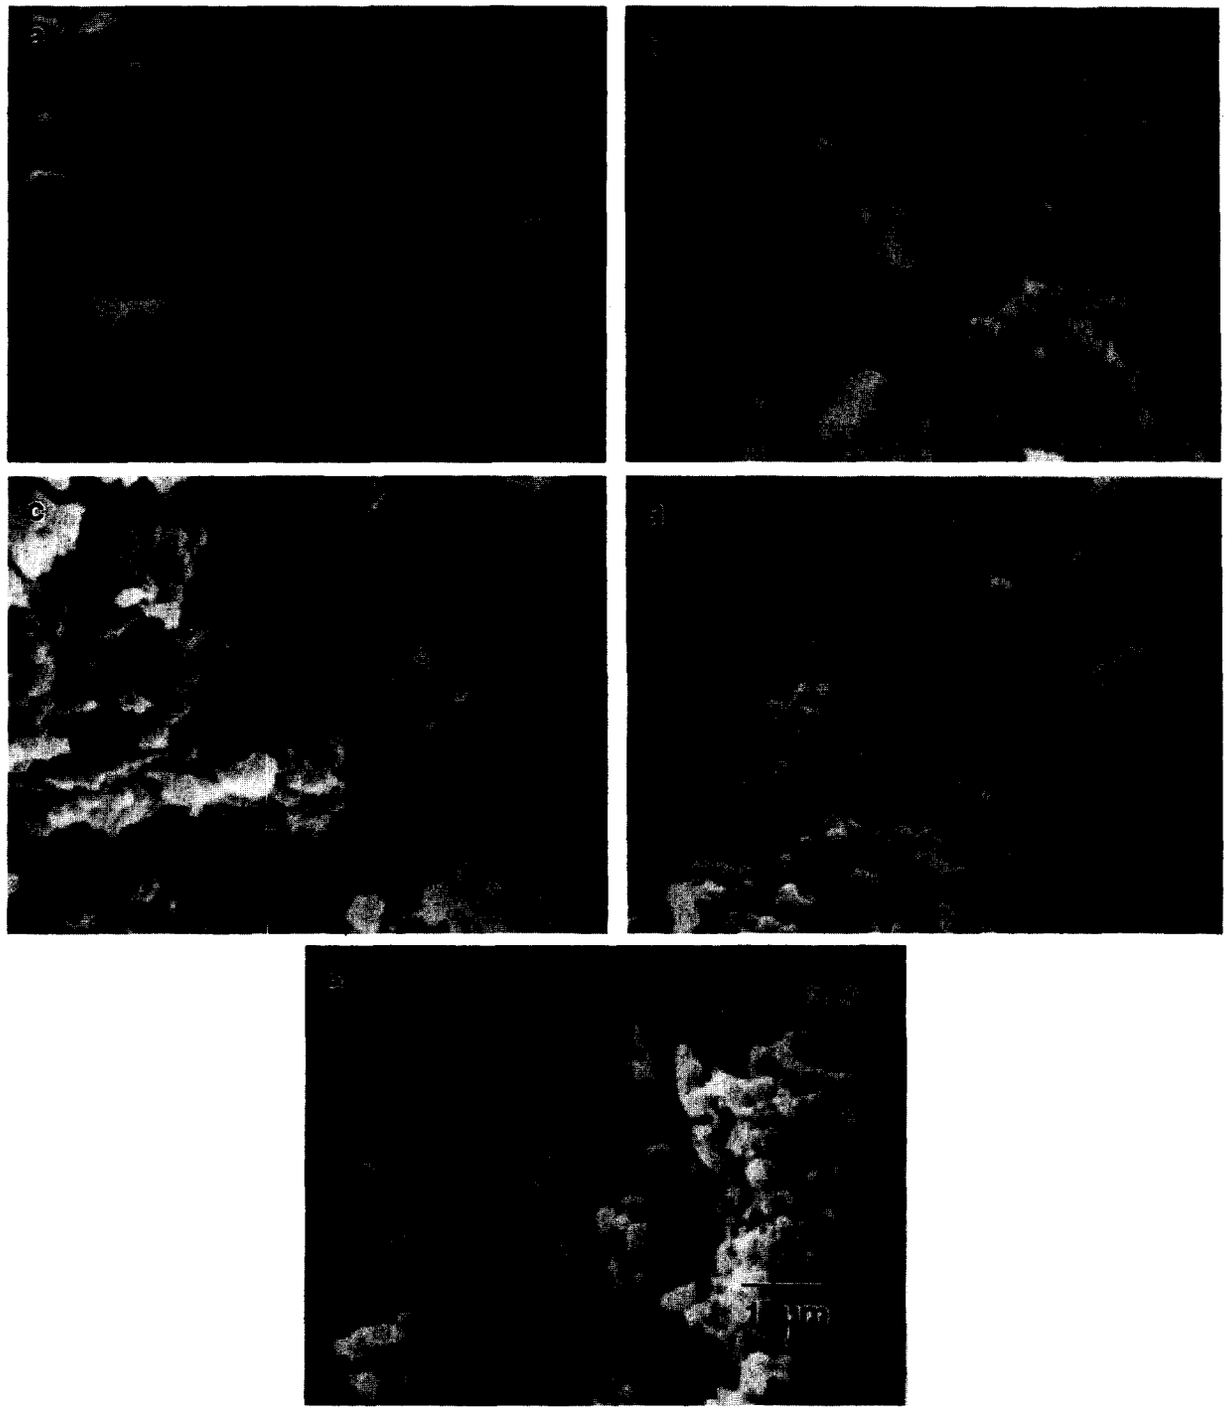

Fig. 8. SEM micrographs of the fracture surfaces of green (a) A-16SG, (b) APA-0·2, (c) A80, (d) A70 and (e) A60 powder compacts.

or 0·5 wt% PMAAN dispersant (based on alumina). The difference of green densities between two green pure materials is mainly a result of the surface forces and the dispersion conditions of powders. The slurries of the fine agglomerated APA-0·2 particles still produce the green pieces in a loose pack.

Zok *et al.*[19] developed a model of binary powder packing to illustrate the effects of large particle surface and touching of the particles on the packing density of ceramic powders. In contrast, Messing & Onoda's work[20] attempted to describe the inhomogeneity (defined by the degree of mixing) on the packing density of binary powder. Both groups pointed out that the experimental data for composite mixtures deviate from the theoretical values of ideal packing density. Particularly, packing densities of different size powder mixtures are higher than random packing densities of the mixtures. In Velamakanni & Lange's work,[6] the fine alumina, AKP-series, has a random packing density of 0·63, however the mixtures with 20 to 40% fines allow a density of 0·68 to be reached, which is far lower than the theoretical density 0·87, but those values are still larger than 0·63.

In the present case, the green densities of the mixtures (A80, A70 and A60) are even lower than those density values calculated from the volume fractions of two-ended materials, as the broken line indicates in Fig. 7. Restated, the powder mixtures have shear thickening properties. The reasons for a reduction of the packing density have been proposed by others[6] as possibly being physically a consequence of the presence of local compositional variations. In the present case, the composition variation should be treated as a packing-type structural variation in the mixtures of two alumina powders. The observation (Fig. 8(c) to (e)) of the fractured surfaces of three mixtures has confirmed that fine alumina particles (APA-0·2) are retaining some degree of agglomeration in sizes 0·6 μm or larger. The agglomerates are still retained from previous dispersion and mixing stages. Therefore, the green powder mixtures have at least two varieties of porosity. The porosity was revealed by the measurement of pore size, and the results were plotted in Fig. 9. The pore size distribution of APA-0·2 has two maxima, i.e. at 0·09 and 0·035 μm, respectively. The fine pores, which are believed to have formed between agglomerates, are one of the characteristics of partially agglomerated powder. Additionally, the pore size distributions of A80, A70 and A60 notably exhibits a fraction of pores having sizes ranging from 0·02 to 0·06 μm (Fig. 9(a)) similar to that of APA-0·2. The mixtures possess some degree of the agglomeration of pure APA-0·2 powder.

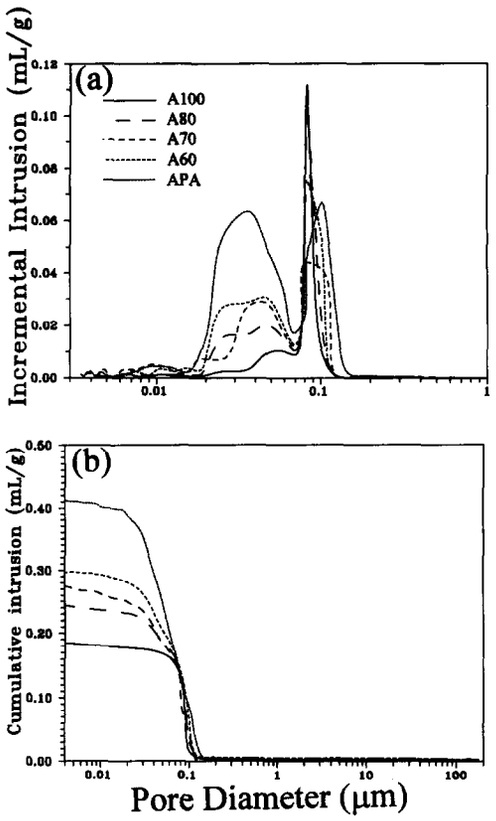

Fig. 9. (a) Pore size distribution and (b) cumulative pore volume of various alumina mixtures.

4 Conclusion

The surface potential, adsorption of dispersant, flowing behavior and green packing properties of alumina powders in additional of PMAAN dispersant were investigated in this study. The packing and mixing of ideal powder mixtures could be optimized not only from the dispersing conditions, but most importantly from the control of agglomeration—especially in fine powder. Some conclusions can be drawn, i.e.:

(1) The iep of A-16SG powder in aqueous suspension is determined to be at pH = 8·5 and that of APA-0·2 is at pH = 8·9. The iep is shifted to pH 4·0 if the anionic-type dispersant PMAAN is added to the alumina suspension;

(2) The adsorption of dispersant PMAAN changes the surface potential of A-16SG and APA-0·2 to negative values and also offers an electrosteric stabilization for alumina particles in aqueous solution;

(3) The rheological behavior of pure alumina particles in suspension is controlled by the reactions of PMAAN, the specific surface area of the powder, acidity and solid loading of the suspension. Conversely, the dissociation of PMAAN is affected by the amount of alumina powder in suspension;

(4) The flowing behavior of the alumina suspension which is the mixture of two powders is dominated by the fine powder, i.e. APA-0·2, which is still partially agglomerated in dispersed suspension; and
(5) APA-0·2 is difficult to fully disperse in an aqueous condition. Its green compacts exhibit a bimodal distribution porosity with pore sizes around 0·09 and 0·035 μm. The fine pores are retained in powder mixtures which are similar to that of pure APA-0·2.

(Received 19 April 1994; accepted 5 July 1994)

Abstract

The effect of MnO_2 as an additive on the densification behaviour and microstructural evolution of α-Al_2O_3 has been investigated over a wide sintering regime. A colloidal technique was applied for the mixing of MnO_2 in order to achieve a uniform distribution and homogeneous microstructures. Sintered density, average grain size and microstructural features were elaborated along with the microhardness and mechanical strength measurements. Manganese oxide was found to promote grain growth and an intergranular second phase formation was detected for additions over 0·5 wt% MnO_2. Excessive grain growth and draining of the second phase were observed in the samples with 3 wt% MnO_2 additions sintered above 1500°C.

1 Introduction

Additives in small amounts are deliberately and commonly used in ceramic systems to influence densification processes either by reducing sintering temperature or suppressing/promoting grain growth or enhancing mechanical and physical properties. A variety of oxides such as MgO, TiO_2, SiO_2, MnO_2, Cr_2O_3, Fe_2O_3 are some of the typical additives that have been commonly used in alumina ceramics.[1–3] As examples, it is well known that small additions of MgO to Al_2O_3 reduce the grain growth rate, while Fe_2O_3 and TiO_2 additions were found to enhance sintering along with a grain growth. On the other hand, CaO and SiO_2 additions were found to be detrimental to the densification process, although they yielded finer grain size and distribution in the microstructures.[4–7]

Very few investigations have been conducted on the influence of manganese oxide additions for the initial sintering of alumina. However, examination of the microstructural features and development during the sintering and detailed analysis in the densification regime has not been reported yet. Considering the commercial importance of structural alumina components with manganese oxide addition as thread guides, o-rings, sealants and nozzles, there is a considerable lack of information and data on these compositions.

The influence of manganese oxide addition to alumina, according to the results of those earlier studies based on shrinkage data, was shown to accelerate the sintering rate and grain growth. Similar to the effect of TiO_2, the sintering rate increases to a maximum and then levels off and starts decreasing as the Mn concentration exceeds 0·3 wt%, presumably due to the formation of a second phase. However, in these studies the formation of the second phase particles was not experimentally verified.[8–13]

It was first proposed that the addition of MnO_2 in the proportion of 0·1–1·0 wt% caused a change in diffusion mechanism from a grain boundary process to a bulk diffusion process, which was also observed for the sintering of undoped alumina samples.[9] The rate-controlling mechanism for densification by both bulk and grain boundary diffusion is oxygen ion diffusion. In the case of MnO_2 addition in the sintering of Al_2O_3, Mn occupying a cation site increases the oxygen ion vacancy concentration. A gradient in Mn concentration results in a wide region of enhanced diffusion at the grain boundaries.

Earlier studies on the Al_2O_3–MnO_2 system did not examine the grain morphologies and it was claimed that there was no evidence of grain growth observed in the composition with 0·3 wt% MnO_2 sintered at 1600°C.[11,12] However, MnO_2 is known to greatly enhance grain growth. Discontinuous grain growth and the anisotropy of the grains, especially in the large grains in Al_2O_3 with addition of MnO_2, have been reported.[10] It was

* To whom correspondence should be addressed.

also argued in the earlier reports that manganese oxide forms a spinel and also goes into solid solution in the excess Al_2O_3 which brings about grain growth of alumina.[3]

The purpose of this study was to investigate the microstructural development and densification characteristics in the Al_2O_3–MnO_2 system in an extensive sintering and composition regime using varying amounts of MnO_2 addition ranging between 0, 0·1, 0·3, 0·5, 1·0, 1·5 and 3·0 wt%. This report also discusses the measured microhardness values and strength data of the samples with respect to the microstructural features which developed at different sintering temperatures.

2 Experimental

In ceramic processing, a sufficient mixing of additives and major powders is absolutely essential to obtain high quality, homogeneous mixtures. For this reason, colloidal techniques were employed in this study to prepare homogeneous batches of Al_2O_3—MnO_2 compositions. Alcoa A 16SG alumina powder with an average particle size of 0·37 microns and specific surface area of 9 m^2/g and reagent grade $Mn(CH_3COO)_2.4H_2O$ were used as the starting materials. The acetate of manganese can easily be dissolved in water to its ions to yield a homogeneous dispersion. For the preparation of alumina suspensions with addition of 0·1, 0·3, 0·5, 1·0, 1·5, and 3·0 wt% MnO_2, manganese (2) acetate was dissolved in water and its pH adjusted to 2 with formic acid and HCl. As alumina powder is gradually added into the water–acetate solution, continuous magnetic stirring and ultrasonicating were applied to the suspension to break up the agglomerates. Colloidal suspensions with 0·1, 0·3, 0·5 and 3·0 wt% MnO_2 were oven-dried at 90–110°C for 12 h and mixed regularly to prevent sedimentation. Colloidal suspensions with 0·5, 1·0 and 1·5 wt% MnO_2 additions were freeze-dried in order to obtain soft agglomerates which form due to capillary forces between the particles during the removal of frozen solvent by sublimation. Powders dried using both oven and freeze drying were calcined at 600°C for 1 h in order to obtain insoluble oxides of the additives.

Powder compacts were prepared using the dry, uniaxial pressing technique in a steel die to make pellets nominally 2–2·5 cm in diameter and 0·3 cm in height, applying a pressing stress of 100 MPa. Freeze-dried powders were pressed into a bar shape and these samples were further isostatically cold pressed at 300 MPa. For the purpose of comparison, undoped alumina powders and pellets were also prepared using the same techniques as those applied to MnO_2-added samples. Green densities of the samples were measured dimensionally. For the compositions with 0·1, 0·3 and 0·5 wt% MnO_2 the sintering regime of 1550, 1600 and 1650°C for 1 h is selected for densification, whereas in the case of 1·0 and 1·5 wt% MnO_2 additions, the sintering temperature was selected to be 1550°C for 2 h sintering hold period. For the undoped and doped samples with 3 wt% MnO_2, sintering at temperatures ranging 1250 to 1650°C for 1 h were performed. In all cases the sintering was done under normal furnace atmospheric conditions at a heating rate of 5–10°C/min and cooled at the same rate in the furnace atmosphere.

After sintering, sample densities were determined by the water immersion technique. The microstructure of the samples were studied by scanning electron microscopy (SEM) equipped with an energy dispersive X-ray spectrometer (EDS) attachment on polished and thermally etched surfaces. Vickers microhardness values were measured with a Leitz Mini Load Hardness Tester and a Shimadzu Microhardness Tester (Type M) by applied loads E of 200, 300 and 500 g. The average of 10–20 indentations per specimen was taken. The average mechanical strength of samples was calculated using the failure loads of samples determined from a ball-on-ring test and a tensile testing apparatus (Instron, model 1115) equipped with a three-point loading system.

3 Results and discussion

Compositions, the percentage of the theoretical density attained after sintering and the average grain size values which were determined using standard line intercept technique are tabulated in Table 1. As explained before, the data and micrographs for undoped alumina samples are also presented for the purpose of comparison. The sintered densities of the samples were found to be between 98–99% of the theoretical densities with insignificant differences between the sintering temperatures of 1550–1650°C.

As can be seen in the micrographs given in Fig. 1, undoped alumina can be sintered to its full density at temperatures above 1550°C, during which a relatively homogeneous grain growth occurs and only a few pores are retained between the grains. The average grain size is increased to 3·05 microns after sintering at 1650°C for 1 h. As shown in Fig. 2, 0·1 wt% MnO_2 addition led to inhomogeneous grain growth after sintering at 1600°C for 1 h, resulting in a microstructure with localized regions of finer grains around larger sized grains. Further addition of MnO_2, 0·3–1·5 wt%, caused a drastic

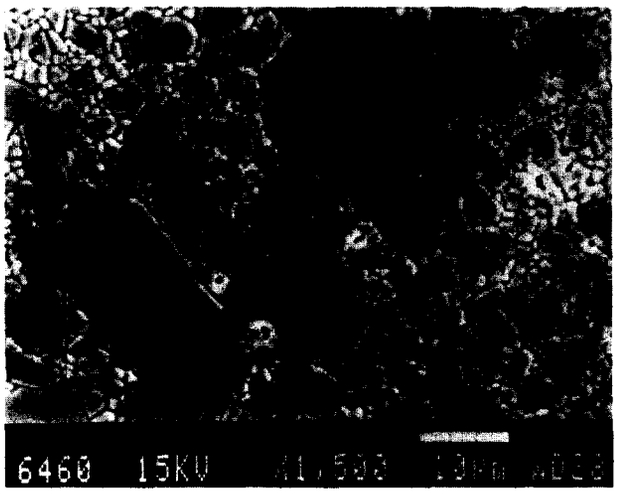

Fig. 2. SEM micrograph of 0·1 wt% manganese-doped alumina after sintering at 1600°C for 1 h.

change in the microstructures after sintering at 1550–1650°C, exhibiting exaggerated grain growth with grains as big as 25–100 microns (Figs. 3–5). A considerable amount of both inter- and intragranular pores is observed in the microstructure. At and above 0·5 wt% MnO_2 additions, less than one micron sized fine pores trapped inside the grains become more evident with sintering hold times of 2 h at 1550°C. In these micrographs (Figs. 4–6), elongated grains of up to 100 microns in length exist to yield irregular grain shapes with faceted morphologies. Furthermore, in these samples, a second phase exists as an intergranular grain boundary phase covering most of the grain boundary area, which is presumably in liquid form at the sintering temperature. It appears that this intergranular phase was distributed along the grains both as a continuous layer and in irregular forms (Fig. 7). According to the phase diagram given in Fig. 8, an eutectic composition is present in the MnO_2-rich side of the binary MnO_2–Al_2O_3 system at 1520°C. This grain boundary phase is

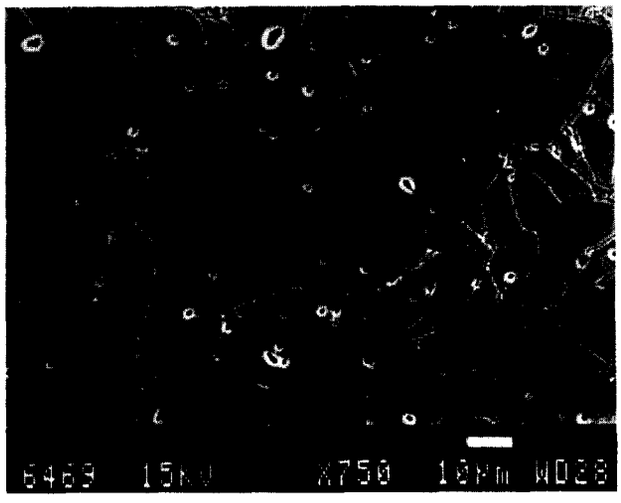

Fig. 3. SEM micrograph of 0·3 wt% manganese-doped alumina after sintering at 1600°C for 1 h.

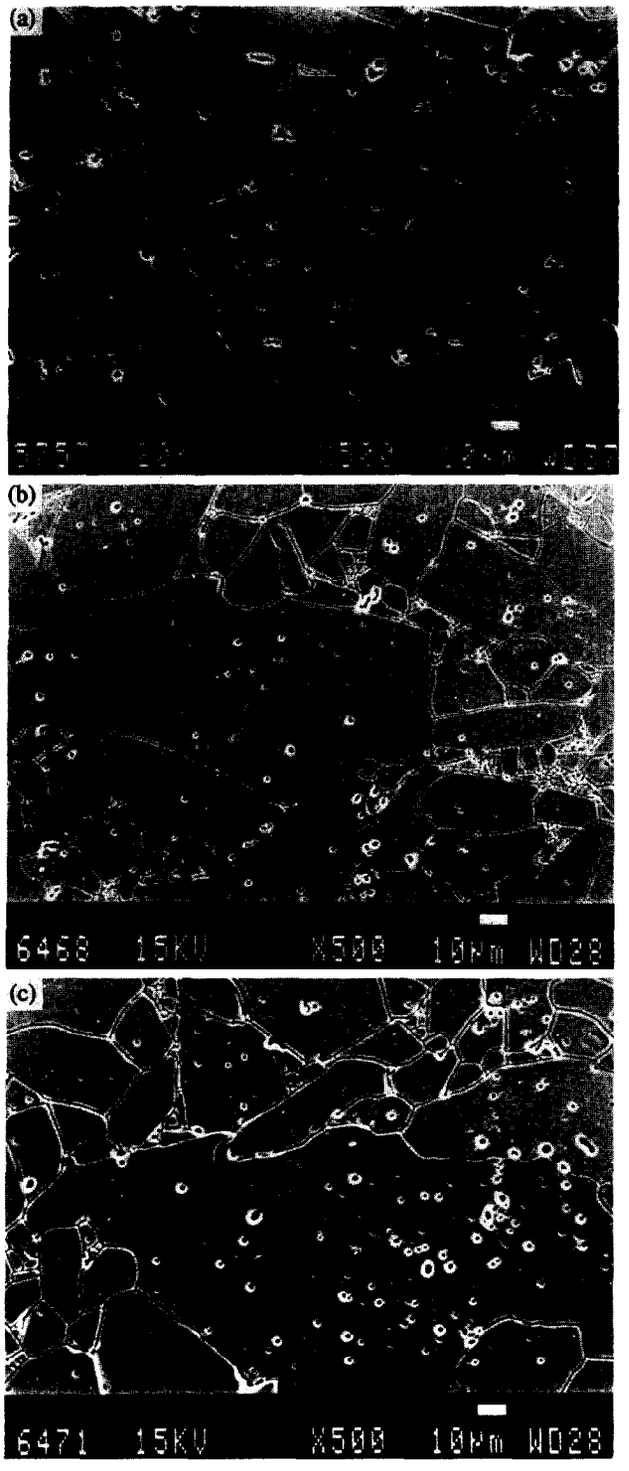

Fig. 4. SEM micrographs of 0·5 wt% manganese-doped alumina after sintering (a) at 1550°C for 2 h, (b) at 1600°C for 1 h and (c) at 1650°C for 1 h.

found to be Mn- and Ca-rich as analysed by the point analysis of energy dispersive X-ray spectroscopy (EDS) (Fig. 9).

In the earlier investigations, the shrinkage data was evaluated to show that bulk and boundary diffusion both are effective for the initial stage of sintering up to 4% shrinkage.[11,12] However, no detailed study was presented for the later stage of sintering. The micrographs shown in Figs. 2–4 for the samples with 0·1–0·5 wt% MnO_2 addition sintered at 1550–1650°C for 1 h do not indicate

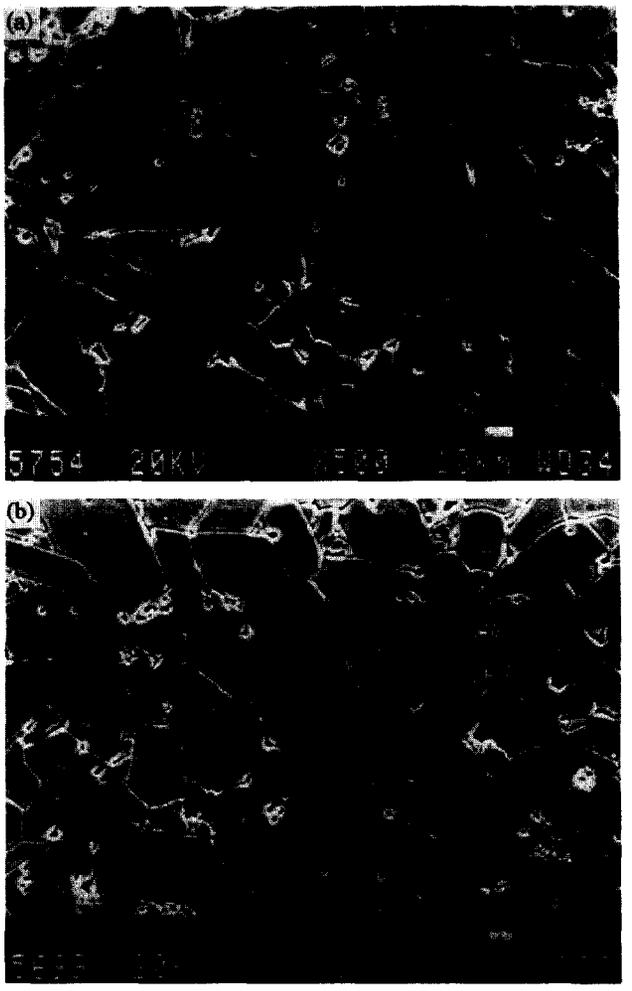

Fig. 5. SEM micrographs of manganese-doped alumina after sintering at 1550°C for 2 h; (a) 1·0 wt% and (b) 1·5 wt% manganese.

the presence of any grain boundary phase formation between the grains. Intergranular grain boundary phase was detected between the grains in those samples with 0·5–1·5 wt% MnO_2 additions sintered at 1550°C for 2 h. Based on these observations, the volume or grain boundary diffusion mechanism acts as the controlling process according to the composition and the sintering conditions during the later stages of densification.

It appears that the densification in compositions with 0·1–0·5 wt% MnO_2 additions sintered at 1550–1650°C for 1 h is enhanced via the volume diffusion process rather than the formation of an intergranular liquid phase. Manganese, like iron, displays variable valency, so that complex series of oxides and hydroxides exist. The ready valency change of manganese leads to many defect structures and non-stoichiometric compounds. Therefore, it may be suggested that different manganese cations with different valency states can substitute the Al cation sites within the crystalline structure, resulting in either vacancy formation or an extra electron. This type of phenomenon was shown to exist during sintering in the case of TiO_2 doping of alumina by activating the volume diffusion rate of

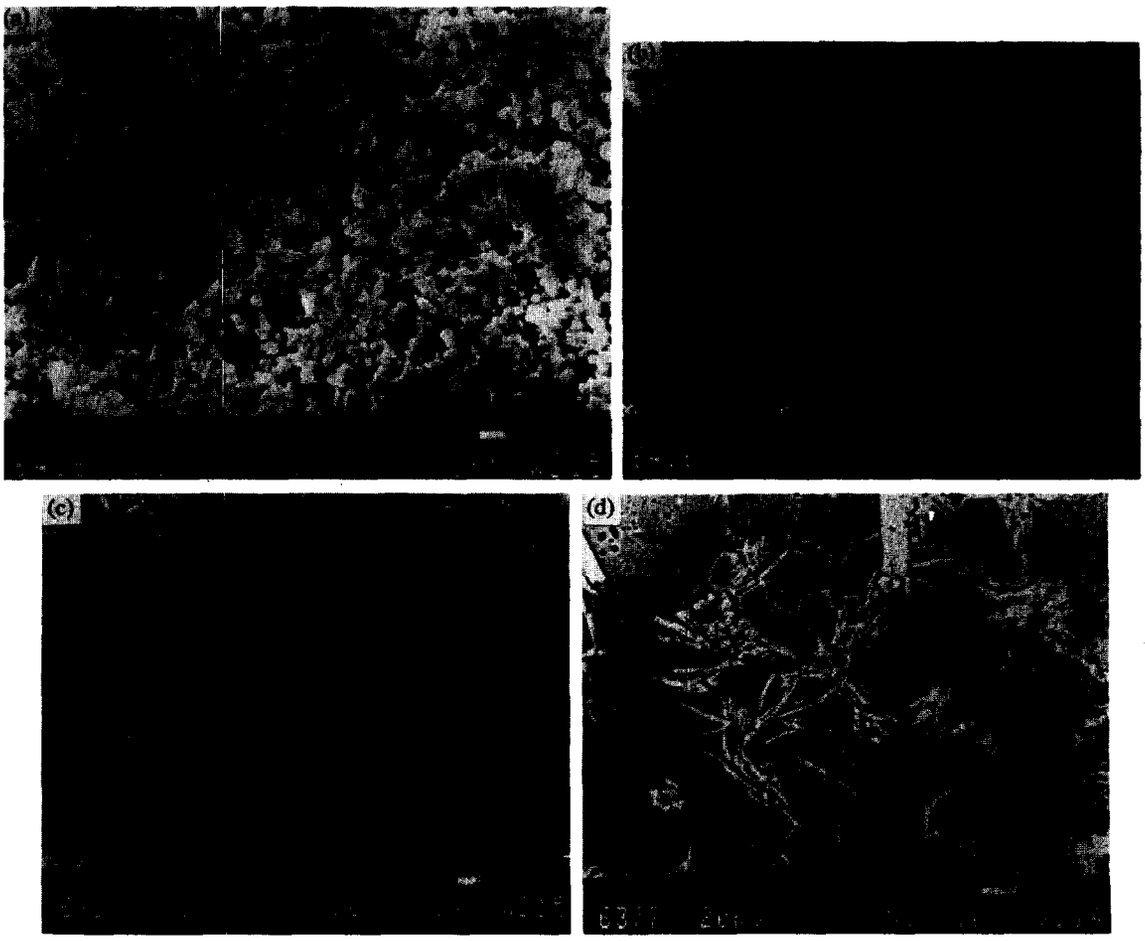

Fig. 6. SEM micrographs of 3·0% manganese-doped alumina after sintering (a) at 1250°C for 1 h, (b) at 1350°C for 1 h, (c) at 1450°C for 1 h, (d) at 1550°C for 1 h.

species[15]. The sintering rate is proportional to the vacancy concentration that forms as Ti^{+3} and Ti^{+4} enters Al_2O_3 substitutionally, and when the charge neutrality is being achieved by the presence of other divalent cations in the powder. In the earlier studies, suggested evaluation of the sintering data indicated that Mn, which substitutes Al in the alumina lattice, can be present in its Mn^{+2} and Mn^{+3} form and thus creates oxygen vacancies to increase diffusion coefficient. An energy dispersive X-ray analysis that was carried out on polished and thermally etched samples in SEM indicated that manganese was well distributed throughout the grains, and no segregation of manganese was detected at the grain boundaries (Fig. 10). Therefore, it may be elaborated that manganese cations substitute the Al sites, resulting in fast diffusion paths within the single grains during the sintering process. As a result of the faster diffusion paths formed, the process of excessive grain growth is enhanced when the amount of manganese oxide addition is between 0·1–0·5 wt% (Figs 2–4).

On the other hand, in the compositions with 1–1·5 wt% MnO_2 addition sintered at 1550°C for 2 h the presence of a secondary intergranular phase both in the form of continuous layer and irregular shapes indicates that the controlling mechanism is due to to grain boundary diffusion process (Fig. 7).

A wide range of sintering regimes, 1250–1550°C for 1 h, was studied on those samples with 3 wt% MnO_2. As shown in Fig. 6, the degree of densification can be observed in the micrographs sintered at 1250; 1350, 1450 and 1550°C for 1 h. In these samples, sintering up to 1450°C indicates a regular densification (73% to 96·2% of the theoretical density) and grain growth (0·51 to 1·34 microns) behaviour, whereas the micrographs for the samples sintered at 1550°C (Fig. 6) exhibits an abnormal and discontinious grain growth (up to 100 microns) with large number of pores trapped inside the grains. Such an abnormal and discontinious grain growth during the late stage of sintering leads to grain boundaries breaking away from the pores, resulting in excessive pore formation inside these newly formed large grains. These pores trapped inside the grains enlarge the diffusion distance to the next grain boundary to inhibit densification. Elimination of such pores is difficult. In these micrographs, the Mn-rich second phase seems to be squeezed out of the grain boundaries in needle-like shapes. Such a draining away from the grain boundaries justified the conclusion that a eutectic liquid phase formed between the grains.

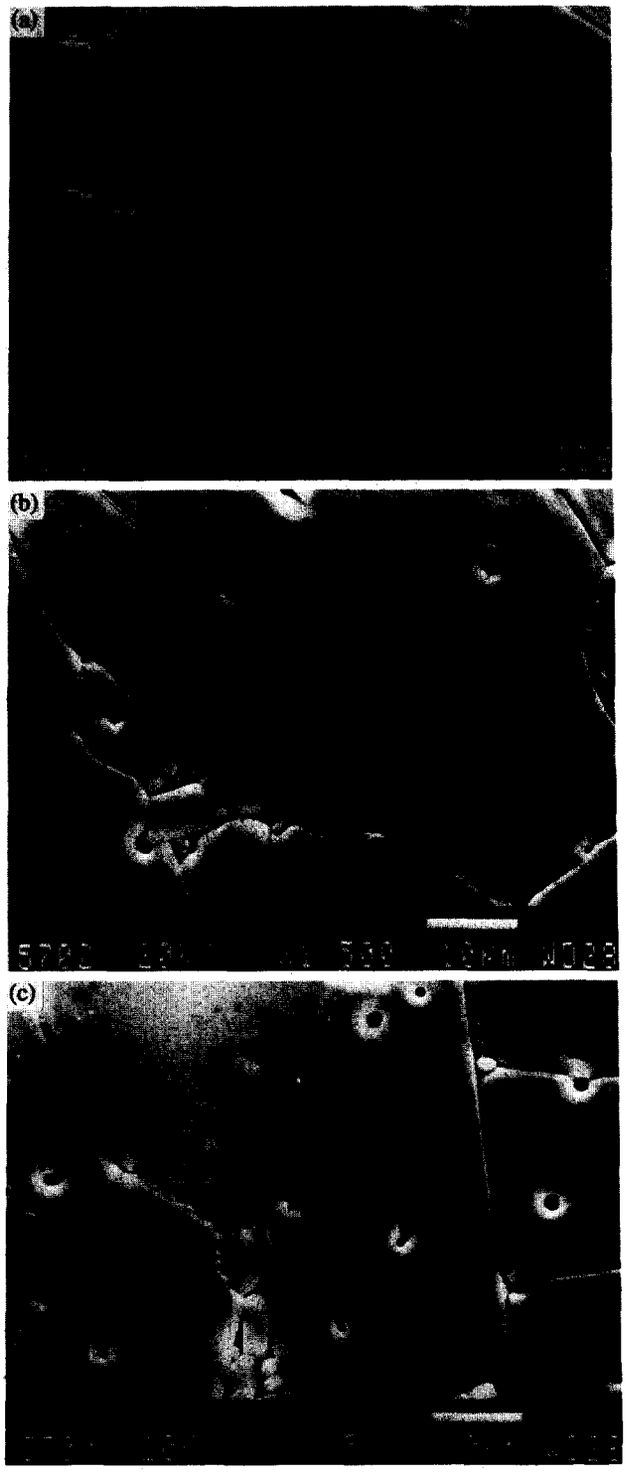

Fig. 7. Interganular second phase formation in the samples sintered at 1550°C for 2 h; (a) 0·5 wt%, (b) 1·0 wt% and (c) 1·5 wt% manganese.

Microhardness measurements and some of the strength data are presented in Table 2 as a function of sintering temperature and composition. It appears that there is an increase in microhardness values with sintering temperature and there is a slight increase with the manganese oxide additions. Microhardness measurements showed considerable variation and scatter for the compositions with 0·5 (sintered at 1550°C for 2 h, 1·0, 1·5 and 3·0 wt% MnO_2 additions, presumably due to formation of the softer second phase. It is difficult

to derive definite information regarding the strength data given in this table; even the data shows higher strength values in the case above 0·5 wt% MnO_2 addition. It seems that further cold isostatic pressing of the samples with 0·5, 1·0 and 1·5 wt% MnO_2 sintered at 1550°C for 2 h led to such an increase in strength data. However, the scatter and variation in this set of data is at considerable level and should be interpreted cautiously.

4 Conclusion

The microstructural development of Al_2O_3 with MnO_2 addition was characterized at different sintering conditions. Grain growth was promoted with manganese oxide additions and in some cases due to prolonged sintering holds, an exaggerated grain growth behaviour was observed. It appears that the densification is controlled by a grain boundary diffusion mechanism in those samples with MnO_2 additions higher than 0·5 wt%. On the other hand, the volume diffusion mechanism is suggested to be the controlling process in the case of 0·1–0·5 wt% MnO_2 addition. Microhardness values and strength data do not reveal a definite trend; however, an increase in the microhardness values with temperature and the percentage MnO_2 were evident. Strength data also shows an increase with MnO_2 addition.

(Received 3 May 1994; revised version received 24 June 1994; accepted 5 July 1994)

Abstract

The sintering behavior of mixed α'/β'-sialon ceramics, fabricated from α-Si_3N_4, AlN and Ln_2O_3 (Y_2O_3, Er_2O_3 and Yb_2O_3), was examined by high-temperature dilatometry, and the densification process was discussed through the consideration of chemical reactions to form α'- and β'-sialon and kinetical analysis of shrinkage. The formation of α'-sialon and melilite caused temporary retardation of the densification rate, while during the formation of β'-sialon the densification proceeded remarkably. The densification accompanied by precipitation of β'-sialon is ascribed to dissolution of residual α-Si_3N_4, α'-sialon with low solid solubility and melilite into a liquid, which may result in an increase of liquid volume and in a decrease of liquid viscosity. These phenomena are considered to induce the solution–precipitation process, particle disintegration process and cooperative flow process of the particle–liquid mixture, yielding to rapid shrinkage. The densification at the initial and middle stages and the reactions from α'-sialon and α-Si_3N_4 to β'-sialon accelerated in the order of Y_2O_3 > Er_2O_3 > Yb_2O_3 addition, because the liquidus temperature and viscosity of liquid formed decreased in the order of Y_2O_3 < Er_2O_3 < Yb_2O_3 addition.

1 Introduction

Two significant properties of silicon nitride (Si_3N_4) ceramics are mechanical strength and fracture toughness. Si_3N_4 ceramics with prismatic grains show high flexural strength at room temperature, but this strength degrades at temperatures higher than 1300°C due to the presence of an intergranular glassy phase containing impurities such as metals and halogens. As the viscosity of the glassy phase softens at temperatures higher than 1000°C, grain-boundary sliding occurs, accompanied by nucleation and growth of cavities in the intergranular glassy phase.[1] It is then important to reduce the amount of impurities concentrated at the grain boundaries, and to control the character and amount of grain-boundary phase in Si_3N_4 ceramics, in order to improve their high-temperature strength.

On the other hand, fracture toughness is strongly influenced by aspect ratio and volume fraction of the grown grains in the final products.[2,3] It has been reported that Si_3N_4 ceramics with microstructures consisting of elongated rod-like grains in the small grain matrix have fracture toughness as high as 8–11 $MPam^{0.5}$.[4] Such materials with duplex microstructures are called 'in-situ composites' or 'self-reinforced materials'. It is, therefore, desirable for the obtention of the Si_3N_4-based materials that both the reduction of glassy phase content at grain boundaries and the control of Si_3N_4 grain morphology are made compatible.

Si_3N_4 ceramics occur in two structural modifications, α and β. The solid solution in β-Si_3N_4, which is called β'-sialon, is formed by simultaneous equivalent substitution of aluminum and oxygen for silicon and nitrogen, and the reaction is commonly described by the following equations:

$$(4 - z)Si_3N_4 + 2zAlN + zSiO_2 \rightarrow 2Si_{6-z}Al_zO_zN_{8-z} \quad (1)$$

$$(6 - z)Si_3N_4 + zAlN + zAl_2O_3 \rightarrow 3Si_{6-z}Al_zO_zN_{8-z} \quad (2)$$

In the equations, z takes a value between 0 and 4·2.[5,6]

α'-sialon, which is the solid solution of α-phase structure, is obtained by a substitution of similar elements as for β'-sialon, with some metal cations accommodated in the two large interstices of the unit cell, thus giving a general formula of the type $Mx(Si,Al)_{12}(O,N)_{16}$, where M is Li, Mg, Ca or

lanthanide metals except La and Ce. When x is $0{\cdot}3 < x < 2{\cdot}0$, single-phase α'-sialons are fabricated. Reaction in the formation of single-phase α'-sialon is as follows:[7,8]

$$(4 - 1{\cdot}5x)Si_3N_4 + 0{\cdot}5x(Y_2O_3 + 9AlN) \rightarrow Yx Si_{12-4{\cdot}5x}Al_{4{\cdot}5x}O_{1{\cdot}5x}N_{16-1{\cdot}5x} \quad (3)$$

With x values less than 0·3, mixtures of α'-sialon and β'-sialon are obtained.[9]

Densification of these sialon ceramics proceeds in a reaction-sintering process involving the formation of a transient liquid phase, namely, during the middle and final stages of sintering the ingredients of the liquid are incorporated into the α and β structures.[9–11] In consequence, sialon ceramics have been expected to possess only a small amount of intergranular glassy phase and in recent years these materials have been reported to maintain the room-temperature strength at temperatures as high as 1300°C.[12] It has been, however, reported by several investigators that single-phase sialon ceramics show lower mechanical strength and lower fracture toughness than β-Si_3N_4 containing Y_2O_3 and Al_2O_3 additives. The reason is interpreted as that sialons consist of grains with low aspect ratio,[13] and furthermore they have weak pullout and absence of crack-branching effects due to the strong bonding between interfaces of grains.[14,15]

Recently, mixed α'/β'-sialon ceramics have received a great deal of attention, since the microstructure of these materials comprises prismatic β-grains and roundish fine α-grains, and presents a small amount of grain boundary phase.[16,17] It has also been demonstrated that they show higher mechanical strength at elevated temperatures and higher fracture toughness[16] as well as better creep properties, compared to the β-Si_3N_4 ceramics with oxide addition.[18] Furthermore, in the case of sintering of mixed α'/β'-sialon ceramics, their microstructure and their mechanical as well as thermal properties can be controlled by the phase composition, and it is possible to alter widely the quantity and type of elements that can be accommodated in a Si_3N_4 structure.[15,19] However, the densification mechanism, which links directly to control of the microstructural development and phase composition, has not been understood yet.

In this work, an attempt is made to investigate the reaction process in the formation of α'- and β'-sialons during sintering of mixed α'/β'-sialon ceramics with AlN and lanthanide oxides (Ln_2O_3) such as Y_2O_3, Er_2O_3 and Yb_2O_3. The shrinkage behavior of mixed α'/β'-sialon ceramics is studied by high-temperature dilatometry, and the densification process is also discussed in combination with chemical reactions to form sialons.

2 Experimental procedure

It is well known that powder characteristics strongly influence the sintering process of sialon as well as of Si_3N_4 ceramics. Especially, in the case of sintering of mixed α'/β'-sialon ceramics, accompanied by complicated reaction pathways, densification behavior and resultant amount of α'-sialon, as well as reaction sequence, are changed due to powder characteristics.[20] In a preliminary work, the authors have evaluated the influence of Si_3N_4 powder characteristics on the sintering behavior of mixed α'/β,-sialon ceramics, and on the sinterability and formation of α'- and β'-sialons. The results pertaining to sintering behavior are as indicated in the Appendix, and the raw powder A was used in this work. The raw powder A (Denki Kagaku Kogyo, K K, Japan) used in the present work had an oxygen content of 1·3wt%, total metallic impurities content of 350 ppm, fluorine content of 520 ppm, and a specific surface area of 11·3 $m^2\ g^{-1}$. This powder was composed of 94% α- and 6% β-Si_3N_4.

The AlN (Tokuyama Soda Co. Ltd, Japan), Y_2O_3, Er_2O_3 and Yb_2O_3 (Hokko Chemicals Industry Co. Ltd, Japan) powders were also employed as the starting materials to produce the mixed α'/β'-sialon. The starting AlN powder had an oxygen content of 1·05 wt% and a specific surface area of 3·2 $m^2\ g^{-1}$. Nominal composition of powder mixtures was 83·10 mol% for Si_3N_4, 1·69 mol% for AlN and 15·21 mol% for Ln_2O_3, and the atomic proportion in the overall composition is represented by the following formula: $Ln_{0{\cdot}15}Si_{11{\cdot}325}Al_{0{\cdot}675}O_{0{\cdot}225}N_{15{\cdot}775}$.

These powders were vibrationally mixed in toluene with deflocculant for 6 h using a Si_3N_4 pot and balls. After drying at 800°C for 1 h in nitrogen gas with 10% H_2 to remove the deflocculant, rectangular bars with dimensions of 10 × 10 × 45 mm and discs with 14 mm diameter × 8 mm height were made from the mixed powders using a homemade die, followed by cold isostatic pressing (CIP) at 490MPa for 60s. The green density of all the specimens was 1950 ± 20 kgm^{-3}.

In order to investigate the sintering phenomena, thermal shrinkage of bars was measured at temperatures from 1000 to 1850°C at a heating rate of 10°C min^{-1} under a N_2 gas pressure of 1 MPa using a high-temperature dilatometer (Rigaku Denki, HPHT-TMA, Japan).[21] From the results of preliminary work, a large amount of shrinkage was observed after thermal shrinkage measurement at 1850°C, when operated at a heating rate of 10°C min^{-1}. Therefore, the heating rate of 10°C min^{-1} was selected. Isothermal shrinkage measurements at 1500, 1550 and 1600°C were performed

to investigate the kinetic parameter on densification and to clarify the densification process. The heating rate for isothermal shrinkage measurements was 10°C min^{-1}. The reason for setting such a slow heating rate will be explained later. Detection errors of shrinkage and shrinkage rate were less than $1{\cdot}8 \times 10^{-2}$% and $3{\cdot}2 \times 10^{-3}$ %min^{-1}, respectively.

Simultaneously, specimens were prepared by firing at various temperatures followed by quenching, to observe the change in bulk density and microstructural development as well as the reaction sequence during sintering. The discs were embedded in a mixture of Si_3N_4/AlN/Ln_2O_3/BN in a graphite crucible, and fired in a graphite furnace at different temperatures starting from 1300 to 1850°C for 15 min and 4 h at a heating rate of 10°C min^{-1} under a N_2 gas pressure of 1 MPa, followed by quenching at a cooling rate of above 100°C min^{-1} until near 1000°C.

Density measurements were performed by the Archimedes method in distilled water. Relative density was obtained by comparing measured density to theoretical density. The theoretical density of mixed α'/β'-sialon was calculated from the amount and density of Si_3N_4, AlN and Ln_2O_3, and was estimated as 3221 kgm^{-3} for Y_2O_3 addition, 3288 kgm^{-3} for Er_2O_3 addition, and 3296 kgm^{-3} for Yb_2O_3 addition. Carbon and gold were evaporated onto the fractured surfaces and onto the polished surfaces, and scanning electron microscopy (SEM, JEOL, T-330AS, Japan) observation was conducted to examine the microstructure. Before the evaporation of carbon and gold, the surfaces of interest were chemically etched by immersing the specimens into molten NaOH and KOH in a silver crucible at 200°C.

The quenched samples were crushed in a tungsten carbide jar, and passed through a 200 mesh sieve. X-ray diffractometry (XRD, Rigaku Denki, RAD-B, Japan) measurements of the crushed powders were carried out using CuK_α radiation at 40kV and 100 mA to identify crystalline phase and to obtain phase composition. The α-Si_3N_4, α'-sialon, and β-Si_3N_4/β'-sialon contents in the sintered bodies were determined as follows: after XRD measurements, the X-ray peak areas of α-Si_3N_4 and α'-sialon for <102> and <201> planes, and of β-Si_3N_4/β'-sialon for <101> and <201> planes were calculated using the Lorents function, and the relative amount of these phases was obtained by comparing their peak areas. Lattice parameters were measured with Si as internal standard, and the solid solubility of AIN and oxide into a Si_3N_4 structure was determined by referring to the published data.[22,23]

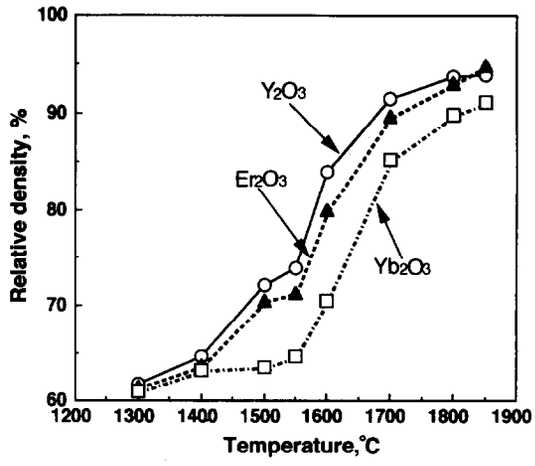

Fig. 1. Relative density of disks quenched at different temperatures for 15 min. The theoretical density of mixed α'/β'-sialon was calculated from the amount and density of Si_3N_4, AlN and Ln_2O_3, and was estimated as 3221 kgm^{-3} for Y_2O_3 addition, 3288 kgm^{-3} for Er_2O_3 addition and 3296 kgm^{-3} for Yb_2O_3 addition. After sintering at 1850°C for 4 h, bulk density of all the specimens reached theoretical values.

3 Results

3.1 Density and shrinkage

The relative densities of the discs quenched from different temperatures in the range of 1300 to 1850°C are shown in Fig. 1. For Y_2O_3 and Er_2O_3 additions, relative density increases slowly at temperatures between 1300 and 1550°C, and increases rapidly at temperatures between 1550 and 1800°C. On the other hand, the relative density of specimens obtained by Yb_2O_3 addition remains almost constant at temperatures from 1300 to 1550°C, whereas a rapid increase in the relative density was observed at temperatures higher than 1550°C. After sintering at 1850°C for 4 h, bulk density of all the specimens reached the theoretical values.

Figure 2 shows the shrinkage of rectangular bars. The shrinkage of all the compacts starts

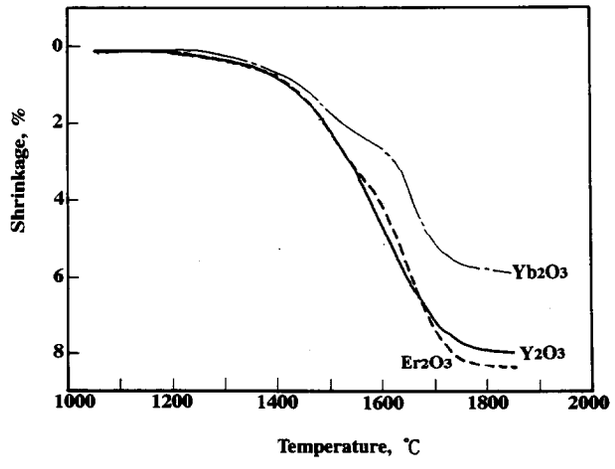

Fig. 2. Temperature dependence of shrinkage of Ln_2O_3-doped α'/β'-sialon ceramics.

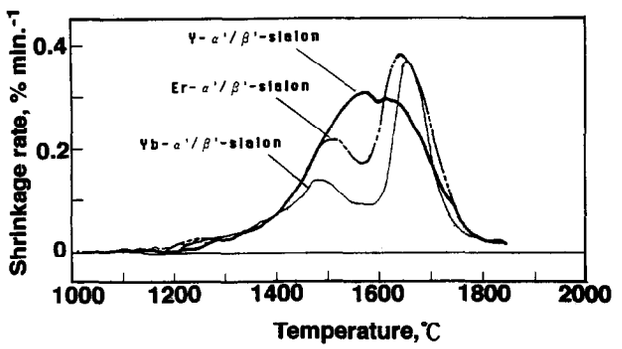

Fig. 3. Temperature dependence of shrinkage rate of Ln_2O_3-doped α'/β'-sialon.

around 1200°C, and increases with increasing the sintering temperature. The type of lanthanide oxides produces differential sintering behavior, which translates into the changes of shrinkage rate observed in the curves of Fig. 3. In the case of Y_2O_3 addition, the shrinkage rate increases gradually at temperatures higher than 1350°C, and reaches the maximum around 1570°C. Subsequently, the shrinkage rate shows a slight decrease and again an increase at temperatures between 1570 and 1620°C, decreasing rapidly at temperatures higher than 1620°C. For Er_2O_3 and Yb_2O_3 additions, the shrinkage rate shows an increase up to 1510°C for Er_2O_3 addition, and 1480°C for Yb_2O_3 addition, decreasing thereafter until reaching the vicinity of 1580°C. At temperatures over 1580°C, the shrinkage rate presents a rapid increase, showing a maximum at 1630°C for Er_2O_3 addition, and at 1650°C for Yb_2O_3 addition, decreasing thereafter with increasing sintering temperature.

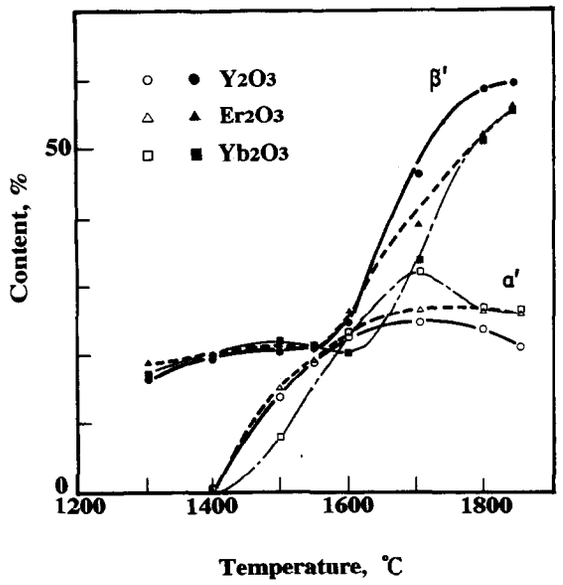

Fig. 4. Phase change during the formation of α'/β'-sialon ceramics at temperatures between 1300 and 1850°C. *J*-phase ($Ln_4Si_2O_7N_2$) and melilite ($Si_3N_4{\cdot}Ln_2O_3$) were identified as the grain boundary phase in specimens sintered at 1300–1400°C and at 1500–1700°C, respectively.

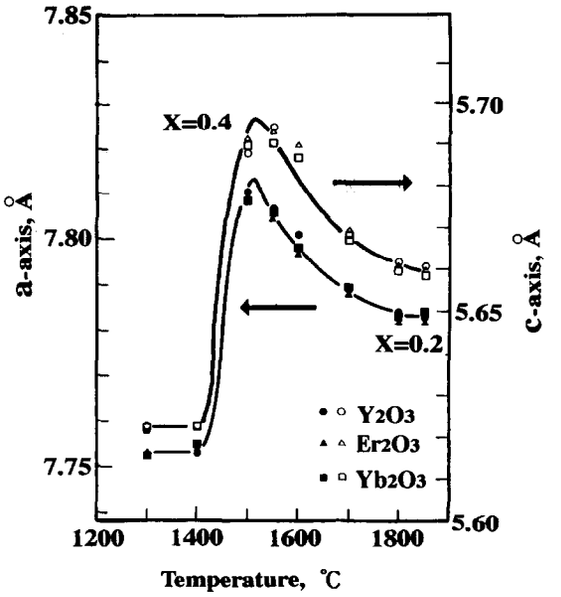

Fig. 5. Change of lattice parameters of α'-sialon. From the relationships between the x value in $Yx(Si,Al)_{12}(O,N)_{16}$ and lattice parameters,[21] the x value was 0·4 for the specimen heated at 1500°C and 0·25 for the specimen heated at 1850°C.

3.2 Phase change

Figure 4 reveals the phase change during the formation of α'- and β'-sialons at temperatures between 1300 and 1850°C. Also the variation with temperature of the lattice parameters of α'- and β'-sialons are shown in Figs 5 and 6, respectively.

α-sialon with large unit cell dimensions is initially formed at temperatures between 1400 and 1500°C, and its content increases with raising the sintering temperatures, but decreases above 1700°C . The amount of α'-sialon varies with the

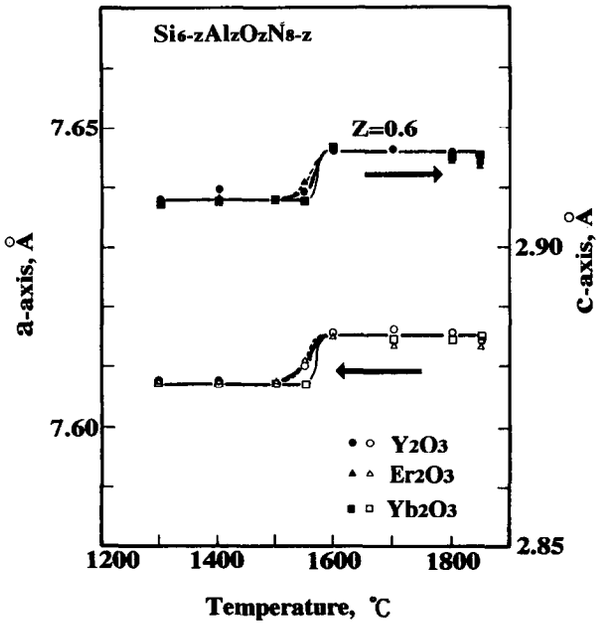

Fig. 6. Change of lattice parameters of β'-sialon. Referring to the relationships between the z value and lattice parameters,[22] the value of z in the formula, $Si_{6-z}Al_zO_zN_{8z}$, varies from 0 to 0·6 at temperatures from 1500 to 1600°C.

type of oxides. A rapid increase in the amount of α'-sialon is observed at temperatures between 1400 and 1600°C for Y_2O_3 and Er_2O_3 additions, and at temperatures between 1500 and 1700°C for Yb_2O_3 addition. Lattice parameters of α'-sialon attain a maximum at 1530°C, but thereafter decrease as the temperature is raised. The influence of the type of lanthanide oxide on the lattice parameters has not been identified in the present work. From the relationships between the x value in $Yx(Si, Al)_{12}$ $(O, N)_{16}$ and the lattice parameters,[22] the x value is 0·4 for the specimen obtained at 1500°C and 0·25 for the one at 1850°C.

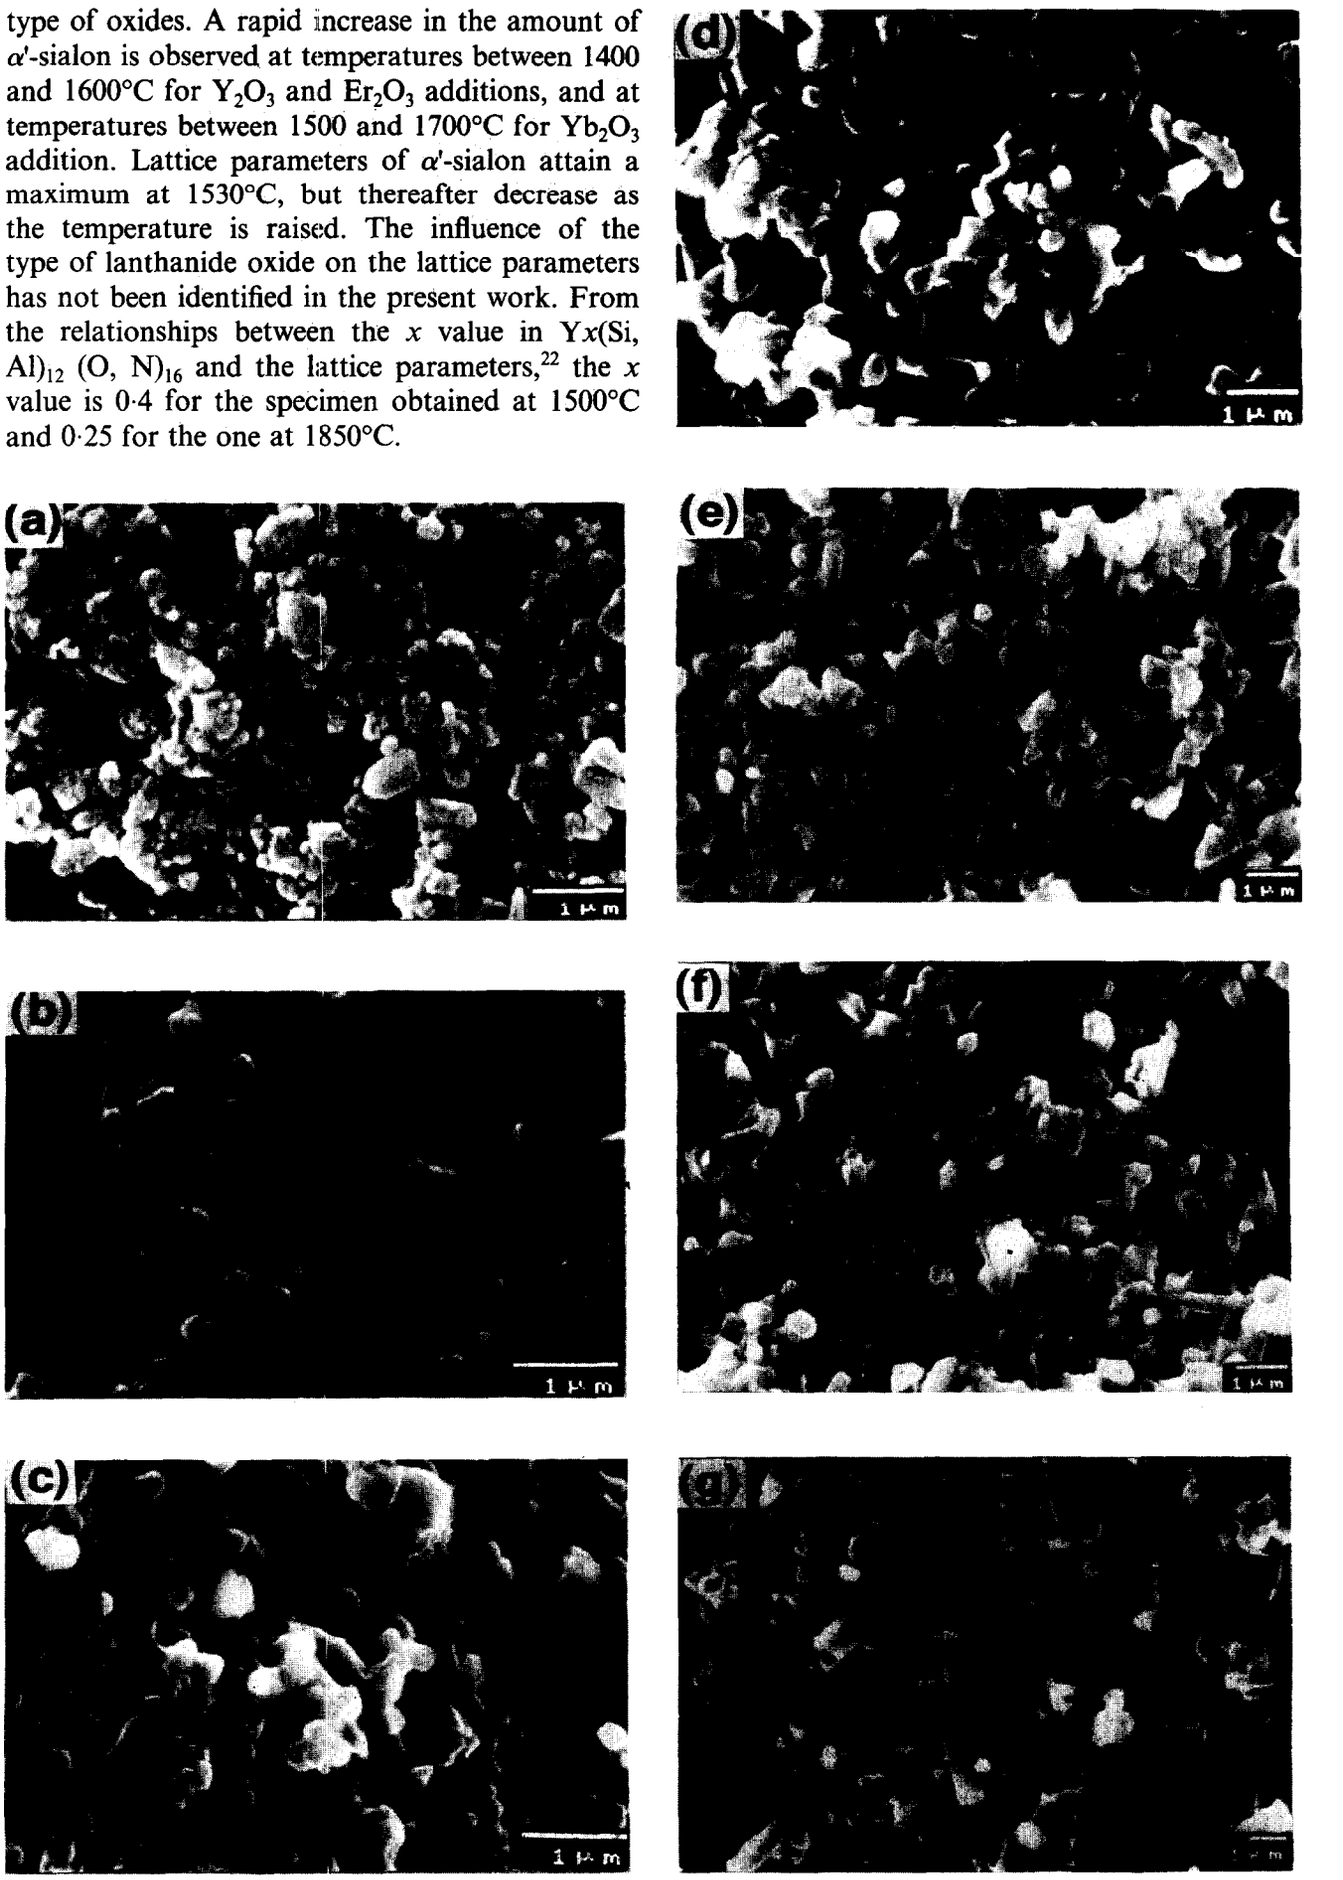

Fig. 7. Fractured surface and polished surface of a specimen with Er_2O_3 addition (a) CIPed, and quenched at (b) 1400, (c) 1500, (d) 1600, (e) 1700, (f) 1800 and (g) 1850°C for 15 min and (h) at 1850°C for 4 h. The polished surface of the specimen quenched at 1850°C for 4 h was chemically etched with molten NaOH and KOH at 200°C for 15 min.

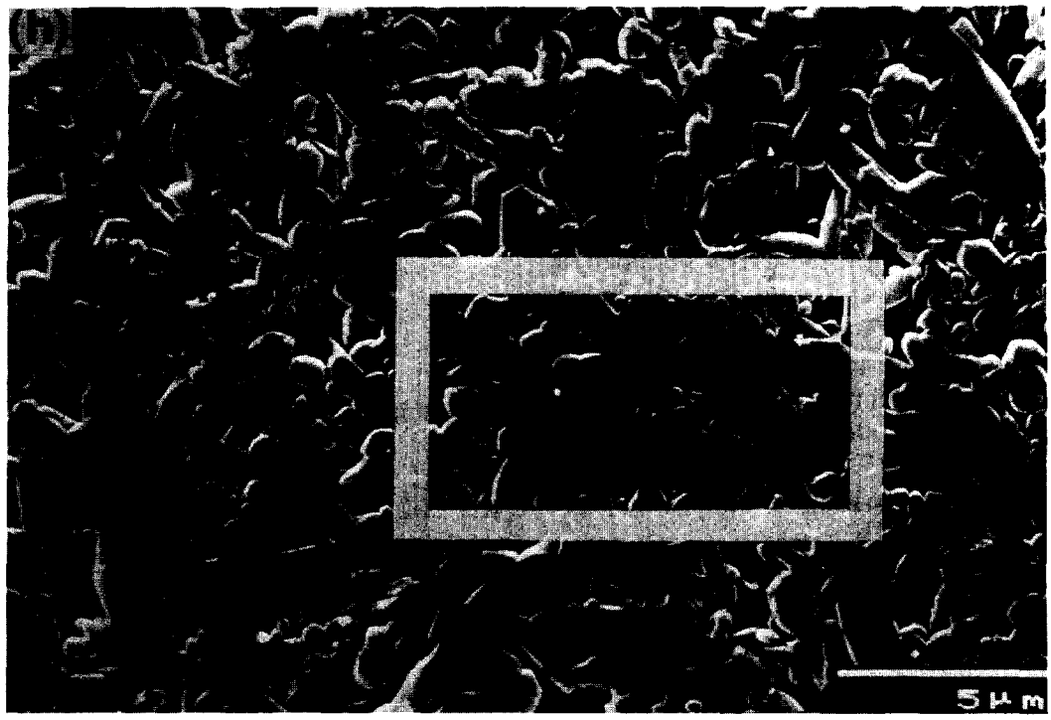

Fig. 7.—*Contd.*

A remarkable increase in the amount of β'-sialon is observed at temperatures ranging from 1600 to 1700°C for Y_2O_3 and Er_2O_3 additions, and at temperatures ranging from 1600 to 1800°C for Yb_2O_3 addition. A significant change in the lattice parameters is present at temperatures between 1500 and 1600°C, but the influence of the oxide type on lattice parameters is not detected. According to published data,[23] the value of z in the formula, $Si_{6-z}Al_zO_zN_{8-z}$, was 0·6 for the specimen sintered at temperatures higher than 1600°C.

Identification of X-ray diffraction peaks indicates, besides the formation of α'- and β'-sialons, J-phase ($Ln_4Si_2O_7N_2$) and melilite (Si_3N_4 . Ln_2O_3) in specimens quenched at temperatures between 1300 and 1400°C, and at temperatures between 1500 and 1700°C, respectively. Disappearance of X-ray diffraction peaks of raw AlN and Ln_2O_3 was recognized above 1500 and 1300°C, respectively.

3.3 Microstructure

Fractured surface of specimens with Er_2O_3 addition CIPed and sintered at temperatures between 1400 and 1850°C are shown in Fig. 7. The microstructure of CIPed specimens consists of grains with irregular shape and wide particle distribution (Fig. 7(a)). At temperatures from 1400 to 1600°C, the size and shape of particles are not well defined (Fig. 7 (b)–(d)), because the particles are covered with a material like a glassy phase. Elongated angular grains are found in specimens quenched from 1700°C (Fig. 7 (e) and (f)), and subsequent grain growth and interlocking are observed at 1850°C (Fig. 7 (g)). The microstructure of the specimens sintered at 1850°C for 4 h consists of rod-like grains with aspect ratio of around 5 : 1 and a maximum of about 8 : 1 in a small equiaxed grains matrix (Fig. 7(h)).

Figure 8 shows the fractured surface of specimens with Y_2O_3 and Yb_2O_3 addition obtained by quenching from 1400°C. In the case of Yb_2O_3 addition, roundish grains are found, but in the case of Y_2O_3 addition, identification of size and shape of particles in the fractured surface is difficult.

4 Discussion

4.1 Reaction process to form α'- and β'-sialons

From the results of the reaction sequence, change in phase composition and lattice parameters, possible reactions in the formation of α'- and β'-sialons are summarized in Table 1.

At the initial stage of liquid-phase sintering of sialon and Si_3N_4 ceramics, nitrides and oxide additives as well as impurities (oxides, metals and halogens) react to form a liquid, and subsequently, nitrogen glass and a partial crystalline phase appear at the grain boundaries. The phenomena are described by reaction (a). Here, the silica and alumina are the oxide impurities on the surface of raw Si_3N_4 and AlN particles.

α'-sialon is compatible with melilite. Furthermore, a α'-sialon with high solid solubility was observed at the initial stage. The reaction in precipitation of α'-sialon from a liquid are expressed as eqn (b). In the case of formation of α'-sialon with high solid solubility, reaction of α-Si_3N_4 with AlN and Ln_2O_3 should be considered, and eqn (c) is given. With respect to formation of α'-sialon at the initial stage, heterogeneous and homogeneous nucleation should be noted. The nucleation sites of α'-sialon formed at the initial stage were investigated by mean of TEM observation by Chatfield *et al.*[23] and Chen & Hwang.[24] Chatfield *et al.* reported that a core of unreacted α-Si_3N_4 raw material frequently remained in the α'-sialon particles, indicating that the unreacted α-Si_3N_4 raw material acts as nuclei for α'-sialon. Such a heterogeneous nucleation was also observed in sintering of β'-sialon.[23] On the other hand, the evidence of homogeneous nucleation of α'-sialon from a liquid matrix was not observed, but this event can not be discarded. The operation of heterogeneous and homogeneous nucleation of α'-sialon are thought to cause the change in solid solubility limits of the α'-sialon formed, and to greatly influence the thermal stability of α'-sialon, as will be mentioned later.

As the content of α'-sialon increases and lattice parameters decrease with raising the temperature, reaction (d) should be also considered. In the present work, it was not, however, possible to confirm the presence of α'-sialon with various solid solubilities, because the lattice parameters measured strike an average one of diverse solid solubilities.

Melilite disappeared due to precipitation of β'-sialon, and the chemical reaction in the formation of β'-sialon is expressed as eqn (e). It is also considered that precipitation of β'-sialon could proceed through reaction (f). Han *et al.*[25] investigated the phase transformation from α'-sialon to β'-sialon by liquid infiltration in the Y–Si–Al–N–O system, and they reported that during heating the glass matrix penetrated into the sintered α'-sialon specimen to induce the phase transformation of α'- into β'-sialon, and that no trace of α'-sialon existed in β'-sialon grains. Sugiyama *et al.*[26] investigated recently the thermal stability of α'-sialons with various solid solubility in mixed α'/β'-sialon. They reported that α'-sialon with a lattice parameter of the *c*-axis less than 5·65Å disappeared under heat-treatment at 1850°C for 50 h, and the amount of β'-sialon increased. On the other hand, the α'-sialon with a lattice parameter of the *c*-axis higher than 5·65Å remained after the heat-treatment, then its lattice parameters went up to nearly 5·66Å, and the amount of α'-sialon and β'-sialon decreased and increased, respectively. The former phenomena are anticipated to occur during precipitation of β'-sialon in the present work, since the increase in amount of α'-sialon is slowed by the formation of β'-sialon, and thereafter the amount of α'-sialon decreases slightly, as do, simultaneously, the lattice parameters. Consequently, reaction (f) is given.

4.2 Densification process

It is generally accepted that densification of Si_3N_4 ceramics with oxide additives and Si_3N_4 solid solu-

tions proceeds via liquid phase sintering, which consists of three stages: (I) particle rearrangement, (II) solution–precipitation and (III) coalescence of grains.[21,27] In the sintering process of sialon, several reactions to form the sialons, as described in the previous section, greatly influence the densification behavior. In the following section, the densification process of mixed α'/β'-sialon ceramics is discussed from the results of shrinkage, in connection with the reaction processes in the formation of sialons.

Shrinkage was initiated around 1200°C (Figs 1 and 2). The densification at the initial stage occurs by the rearrangement process, as the particles move to pack closer by capillary forces of the liquid.[27] It is well known that the temperature at which initial particle rearrangement occurs is related closely to the lowest eutectic temperature of oxides and impurities contained in the raw powders. Considering that SiO_2 and Al_2O_3 exist on the surface of Si_3N_4 and AlN particles, respectively, the eutectic liquid is the SiO_2–Al_2O_3–Ln_2O_3 system, whose minimum eutectic temperature is reported to be around 1450°C for Er_2O_3 addition.[28] Besides the oxide impurities, the liquidus temperature is reduced by the presence of metallic and halogen impurities. In this work, metallic impurities amounting to 350 ppm may be not high enough to reduce the liquidus temperature, but, on the other hand, a large amount of fluorine was present. In a previous work, Watari *et al.*[29] examined the effect of fluorine content (70, 440 and 670 ppm) in raw powders on the densification of Si_3N_4 ceramics with Y_2O_3 and Al_2O_3 addition by high-temperature dilatometry. They found that the temperature at which shrinkage starts decreased with increasing the fluorine content, and confirmed that shrinkage of Si_3N_4 powder with fluorine content of 670 ppm occurred at 1120°C. As the fluorine content in the raw powder used here is at the level of several hundred ppm, it must yield a reduction in the eutectic temperature.

In the case of sintering of Si_3N_4 ceramics, the influence of nitrogen ions on the liquid formation should also be considered. Hampshire & Jack[30] have pointed out that nitrogen as an additional component lowers the eutectic temperature by 100–200°C. In an experiment concerning nitrogen-glass preparation from the melting of a mixture of silica, alumina, lanthanide oxide and silicon nitride powders, the solubility of nitrogen ions in the liquid in the Si–Al–Y–O–N system is less than 15 at.%.[31] Wang *et al.*[32] have also mentioned that the solubility of nitrogen in Nd-sialon glass can reach 25 at.%, whereas in the Si–Al–Y–O–N system the highest solubility is only about 15 at.% and they also reported that the behavior of heavy rare-earth oxides is, in many aspects, similar to that of Y_2O_3. The solubility of nitrogen in a liquid is not, however, clarified in the sialon system. From the existence of impurities and nitrogen, it is, therefore, considered that reaction (a) of Table 1 occurs and that there is formation of a liquid phase around 1200°C, resulting in shrinkage due to initial particle rearrangement.

The next densification stage is due to a solution–precipitation process, which is accompanied by grain growth through the dissolution of small particles in the liquid and their reprecipitation on large particles.[27] In the fractured surface of the specimen sintered at 1400°C shown in Fig. 7 (b), the size and shape of particles are hardly distinguishable. After chemical etching for 15 min, roundish particles with a diameter of about 0·4 μm appeared, and they are different in size and shape from particles in the raw material shown in Fig. 7 (a). This microstructural change suggests that this temperature range corresponds to the solution–reprecipitation stage. Moreover, as shown in Fig. 7 (b) and (c), a large amount of glassy phase is formed, and it seems to have filled the interstice between particles. Such a phenomenon suggests that liquid flow is a significant densification mechanism at the solution–precipitation stage in sintering of Si_3N_4 ceramics.

At the solution–precipitation stage, reactions in formation of α'- and β'-sialons proceed through eqns (b), (c), (d), (e) and (f) of Table 1. The formation of α'-sialon yields reduction of the shrinkage rate at temperatures from 1510 to 1580°C for Er_2O_3 and at 1480 to 1580°C for Yb_2O_3 additions, because the ingredients in the liquid, i.e. lanthanide, aluminum and oxygen, are removed from it, causing the quantity and the viscosity of the liquid phase to decrease and to increase, respectively, interrupting then the dissolution of residual α-Si_3N_4 into the liquid. Furthermore, precipitation of melilite should be considered to hinder the densification process. As melilite formation consumes rare-earth cations, and it has a high melting point (~1900°C for yttrium-melilite[33] and >1700°C for samarium-melilite[34]), the amount of transient liquid is reduced over time. Consequently, the reduction of shrinkage rate at temperatures from 1480 to 1580°C is ascribed to formation of α'-sialon and melilite.

At temperatures higher than 1600°C, precipitation of β'-sialon and rapid increase of shrinkage rate occur concurrently, when Er_2O_3 and Yb_2O_3 were added. This increase of the shrinkage rate is associated with reactions in the formation of β'-sialon, indicated as eqns (e) and (f), which may induce the increase in liquid volume and the decrease in its viscosity, in contrast to the formation of α'-sialon, which causes the liquid volume to be

small and its viscosity high, and dissolution of residual Si_3N_4 into the liquid is difficult. As already mentioned, α'-sialon with low solid solubility is unstable thermodynamically during the sintering accompanied by formation of β'-sialon. Furthermore, disappearance of melilite occurs when β'-sialon precipitates. The acceleration of reactions (e) and (f) suggests that Ln_2O_3, which was accommodated into the α-Si_3N_4 structure or consumed by the formation of melilite, remains at the grain boundaries. In this case, it is postulated that an increase in the amount and a decrease in the viscosity of the liquid occur during precipitation of β'-sialon, and that the solution–precipitation process is, therefore, accelerated during the precipitation of β'-sialon. To date, the variations of volume and viscosity of liquid during the sintering of Si_3N_4 and sialon ceramics have not been measured in situ, and are the subject of absorbing interest when considering the liquid-phase sintering process of these materials. The authors have been considering that low-temperature specific heat and internal friction measurements can provide the information on the amount and viscosity of liquid during the heating.[35] The results concerning the character and quantity of liquid phase and grain boundary crystalline/glassy phase at various sintering temperature will be reported in the near future.

Figure 9 presents the isothermal shrinkage of compacts containing Yb_2O_3 addition with a heating rate of 10°C min^{-1}. When the heating rates of 30 and 50°C min^{-1} were used in preliminary experiments, the resultant amounts of α'-sialon and melilite formed at middle stage of sintering were small, indicating that a large amount of shrinkage took place. In this work, the heating rate was set at 10°C min^{-1} to clarify the densification process in rapid shrinkage at 1580 to 1700°C for Er_2O_3 and Yb_2O_3 additions. The kinetic parameter obtained takes values between 0·76 and 0·70, which are much larger than values predicted for the solution–precipitation process in the classical liquid-phase sintering model proposed by Kingery.[27] It is not possible here to clarify the sintering process through a mathematical analysis, and the densification can not be explained only by the solution–precipitation mechanism of the classical liquid-phase sintering model.

Since Kingery proposed a liquid-phase sintering model, a number of additional solution–precipitation mechanisms have been found, such as pore elimination due to cooperative flow of the particle–liquid mixture, Ostwald ripening with shape accommodation, and particle disintegration.[36] It is suggested that sintering of mixed α'/β'-sialon is a concurrent process involving these mechanisms. It

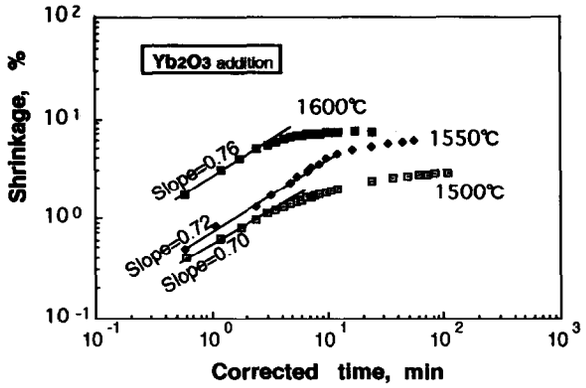

Fig. 9. Isothermal shrinkage of compacts with Yb_2O_3 addition.

is considered that the pore-elimination process due to cooperative flow of particle–liquid mixtures causes the rapid shrinkage observed at 1580 to 1700°C for Er_2O_3 and Yb_2O_3 additions and the kinetic parameters larger than any of the rate exponents predicted by Kingery' s model, since the rate of particle migration toward the interstices between particles is very fast. However, as shown in Fig. 1, the relative density at 1600°C was 80% for Er_2O_3 addition and 70% for Yb_2O_3 addition, which are much higher than a typical packing density of a monosized powder (64 vol.%). In this case, it can not be said that rapid shrinkage observed at 1580 to 1700°C for Er_2O_3 and Yb_2O_3 additions took place only by the particle migration process. It was expected from the results of Han *et al.* that in the present sintering, disintegration of α'-sialon grains occurs at temperatures higher than 1600°C, it then being easy for α'-sialon grains to migrate toward the interstice between particles, resulting in rapid shrinkage.

Besides these densification mechanisms, Ostwald ripening mechanism with shape accommodation is also anticipated to take place. In the present work, it was found that after sintering at 1850°C for 4 h, in the region containing the large grains, particles agglomerate, and large grains come into contact widely with other large ones (see Fig. 7 (h), the region surrounded with a white line). These microstructural features suggest that grain growth by Ostwald ripening occurs, grown grains contact with other ones, and subsequently the interstices between particles fill up by shape accommodation of grown grains. At the middle and final stages of sintering, this process is considered to help the densification further.

The densification process of mixed α'/β'-sialon ceramics has been discussed through the consideration of chemical reactions in formation of α'-sialon and β'-sialon and kinetical analysis of shrinkage. At the solution–precipitation stage, the formation of α'-sialon caused the retardation of densification, but during the formation of β'-

sialon, the densification proceeded rapidly. The densification at a latter stage relates to dissolution of α'-sialon formed at the early stage and of melilite into the liquid. From kinetical analysis, it was thought that dissolution of α'-sialon and melilite into the liquid and precipitation of β'-sialon induces the cooperative flow process of the particle–liquid mixture and particle disintegration process, besides the solution–precipitation process. Such an interpretation, however, may be too simplistic, and further work, such as identification of the disintegration of α'-sialon particles during heating, is necessary to understand the densification process exactly.

4.3 Effect of type of lanthanide oxide on densification and formation of sialon

The type of Ln_2O_3 added determines different sintering phenomena in mixed α'/β'-sialon ceramics and produces different amounts of α'- and β'-sialons. In Fig. 8, for Yb_2O_3 addition, the size and shape of particles can be identified, and the surface of particles is covered with a thin film of a material like a glassy-phase, which links neighboring particles. On the other hand, in the case of Y_2O_3 addition, the size and shape of particles are not well defined, because the particles seem to dissolve in the liquid. When Er_2O_3 is added, the microstructural feature (see Fig. (b)) is thought to be an intermediate microstructure between the corresponding to Yb_2O_3 and to Y_2O_3 addition. It is estimated from the microstructural features that in sintering at 1400°C for 15 min the amount and viscosity of the liquid for Y_2O_3 addition are, respectively, rather larger and lower than those for Er_2O_3 and Yb_2O_3 additions.

The resultant amounts of α'-sialon and melilite were different for each type of Ln_2O_3 addition. Recently, O'Reilly *et al.*[37] investigated the effect of diverse oxide additions on the sinterability of α'-sialon and on the resultant amounts of α'-sialon and melilite, and they summarized the correlation between the relative density and the amounts of these phases as functions of liquid volume and viscosity. Being the volume and viscosity of liquid different for diverse amounts of α'-sialon and melilite, the exact effect of the type of lanthanide oxide on densification can not be discussed. In this section, based on the reported data, the influence of the ionic radii of the lanthanide ion on the viscosity and amount of liquid is discussed without considering the effect of α'-sialon and melilite contents.

It has been reported that the eutectic temperature in the Si–O–N–M system, where M is a lanthanide, increases[38] and that the viscosity of glasses in the Si–Al–O–N–M system also increases[39] with decreasing ionic radius of the M ion. It is considered from these relations that at the initial stage of sintering, the liquidus temperature and viscosity of liquid formed decrease in the order of $Y_2O_3<Er_2O_3<Yb_2O_3$. Therefore, it is anticipated that for Y_2O_3 addition, solution–precipitation, liquid flow and cooperative flow of the particle–liquid mixture, as well as particle disintegration are accelerated, compared to Er_2O_3 and Yb_2O_3 additions.

As already mentioned, in the case of Er_2O_3 and Yb_2O_3 additions the formation of α'-sialon and melilite results in retardation of the shrinkage rate, while rapid shrinkage occurs when β'-sialon precipitates. However, as for Y_2O_3 addition, the retardation in shrinkage rate due to formation of α'-sialon and melilite was very slight. This is interpreted as dissolution of α'-sialon and melilite in the liquid and precipitation of β'-sialon occurring at an earlier stage.

5 Concluding remarks

The following conclusions can be drawn from this study:

(1) Possible reactions to form α'- and β'-sialons during the sintering of mixed α'/β' sialon ceramics were investigated from the results of reaction sequence, change in phase composition and lattice parameters. They were

$$SiO_2 + Al_2O_3 + Ln_2O_3 + Si_3N_4/AlN \rightarrow \text{Nitrogen glass} + \text{J-Phase } (Ln_4Si_2O_7N_2) \quad (a)$$

$$\text{J-Phase} + \text{Nitrogen glass} + Si_3N_4/AlN \rightarrow \alpha'\text{-Sialon}^H + \text{Melilite } (Si_3N_4 \cdot Ln_2O_3) + \text{Nitrogen glass} \quad (b)$$

$$Si_3N_4 + 9AlN \cdot Ln_2O_3 \rightarrow \alpha'\text{-Sialon}^H \quad (c)$$

$$Si_3N_4 + \alpha'\text{-Sialon}^H \rightarrow \alpha'\text{-Sialon}^L \quad (d)$$

$$Si_3N_4 + \text{Melilite} + \text{Nitrogen glass} \rightarrow \beta'\text{-Sialon} + \text{Nitrogen glass} \quad (e)$$

$$Si_3N_4 + \alpha'\text{-Sialon}^L + \text{Nitrogen glass} \rightarrow \beta'\text{-Sialon} + \text{Nitrogen glass} \quad (f)$$

where H and L indicate the α'-sialons with high and low solid solubility, respectively.

(2) As the formation of α'-sialon and melilite consumes the ingredients of the liquid, the densification is retarded over time. This phenomenon was clearly observed in sintering of mixed α'/β'-sialons containing Er_2O_3 and Yb_2O_3. On the other hand, during the formation of β'-sialon, densification was accelerated remarkably, and rapid shrinkage was observed. This is ascribed to the disso-

lution of α'-sialon with low solid solubility and melilite in the liquid and to precipitation of β'-sialon. It is, then, considered that volume and viscosity of liquid increase and decrease, respectively, resulting in acceleration of solution–precipitation, liquid flow, cooperative flow of the particle–liquid mixture, and particle disintegration.

(3) The type of lanthanide oxide strongly influences the sintering phenomena and phase composition. Densification at the initial and middle stages and reactions from α'-sialon and α-Si_3N_4 to β'-sialon accelerated in the order Y_2O_3 > Er_2O_3 > Yb_2O_3, because the liquidus temperature and viscosity of the liquid formed decrease in the order Y_2O_3 < Er_2O_3 < Yb_2O_3.

(4) The α'-sialon formed at the initial stage presented a high solid solubility in the α-structure, but thereafter lattice parameters decreased with elevating sintering temperatures. The x value in $Yx(Si, Al)_{12}(O,N)_{16}$ was 0·4 for the specimen obtained at 1500°C and 0·25 for the one at 1850°C. In the case of the β-structure, significant change in the lattice parameters were observed at temperatures between 1500 and 1600°C, and the value of z in the formula, $Si_{6-z}Al_zO_zN_{8-z}$ was 0·6 for the specimen sintered at temperatures higher than 1600°C. An influence of the type of the lanthanide oxide on lattice parameters was not apparent.

Appendix

As has been pointed out by many investigators, characteristics of raw Si_3N_4 powders such as the amount, type and distribution of impurities, grain size and particle distribution influences greatly the sintering behavior, sinterability, microstructural development and mechanical properties of sintered materials, as well as the amount and composition of the grain boundary crystalline/glassy phase. Experimental results of the shrinkage rate obtained by high-temperature dilatometry measurements provide some useful information to evaluate the relationships between the characteristics of raw Si_3N_4 powders and densification behavior. Figure A1 shows the temperature dependence of shrinkage rate of compacts, whereas the characteristics of raw Si_3N_4 powders are shown in Table A1. As can be observed, sintering behavior and sinterability are greatly influenced by the type of raw powder. The temporary retardation of shrinkage rate due to formation of α'-sialon and melilite can be seen at temperatures between 1500 and 1600°C in Fig. A1, irrespective of the characteristics of raw powders; however, the densities of specimens obtained from the powders C, D and E are very much lower than the densities of those from the powders A and B. The significant parameters affecting the densification are not clarified at present.

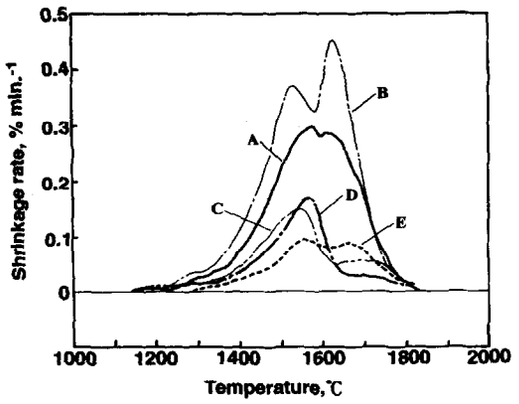

Fig. A1. Influence of powder characteristics on shrinkage rate of Si_3N_4 compacts with 1·69 mol% AlN and 15·21 mol% Y_2O_3. The characteristics of the powders used are shown in Table A1. After thermal shrinkage measurements at 1850°C for 15 min, the relative density was 85·5% for powder A, 89·2% for powder B, 63·9% for powder C, 65·2% for powder D, and 64·8% for powder E.

Table A1. Representative properties of raw Si_3N_4 powder

Abstract

A new process route for ceramic composites, associating CVI of SiC and impregnation and pyrolysis cycles with a polysilazane precursor, has been developed. The interest of this process is, firstly, a shorter time of elaboration than for CVI alone and, secondly higher mechanical properties than those resulting from a conventional use of the precursor. Composites with mechanical properties comparable to those of composites entirely obtained by CVI of SiC have been realised. The flexual strength of these materials is about 400 MPa, whereas that of composites resulting from a conventional use of the same polysilazane does not exceed 200 MPa.

1 Introduction

New materials able to operate under hostile stress–temperature–environment conditions are required for the development of high performance applications (e,.g. aeronautics).

The material used presently (e.g. SiC/C/SiC or C/SiC obtained by CVI) have high mechanical properties (e.g. flexural strength about 400–500 MPa) but their elaboration needs a very long time, and is, therefore, very expensive.[1,2] An alternative way to the CVI process is the use of organometallic precursors leading, after pyrolysis, to ceramic products. However, to date, the mechanical properties of the material obtained by this method are not able to compete with those of composites resulting from the CVI route (e.g. flexural strength lower than 200 MPa.[3–5]

The 'conventional' use of the precursor consists of a sequence of successive impregnation and pyrolysis cycles of a fabric preform with the precursor. The matrix obtained is composed of numerous ceramic blocks corresponding to the successive cycles (Fig. 1(a)). Such a structure is not as strong as the continuous one resulting from the CVI route (Fig. 1(b)). Indeed, the interfaces between the different blocks create some weak points. Moreover, when these interfaces are perpendicular to the loading direction, they lead to stress concentrations on the fibre surfaces what may cause the fracture of these fibres (Fig. 1(a)). This can explain the low mechanical properties of such composites. On the other hand, the deposition rate by CVI is very low. Therefore, the elaboration of dense composites by this process needs a very long time.

The basic idea of this study is, firstly to elaborate a high porosity composite preform by CVI of SiC on bidirectional SiC Nincalon fabrics and, secondly, to fill the porosity by successive impregnation and pyrolysis cycles with the polysilazane (Fig. 1(c)).

2 Experimental

2.1 Characteristics of Pyrofine PV Polysilazane

The precursor used is a commercial polysilazane produced by Elf Atochem: Pyrofine PV.[6] At room temperature, this product is a viscous liquid (density = 1). Its viscosity decreases with the increase of temperature up to 200°C (Table 1).

Upon heating to 300°C under introgen, the precursor becomes cross linked. the product obtained is solid unmeltable and insoluble.

Pyrolysis under a nitrogen atmosphere at a temperature between 900°C and 1400°C yields an amorphous ceramic. At 1000°C, the ceramic yield varies form 60 to 65 wt%, depending on the heating rate used during the crosslinking.[7] The typical elemental composition of the ceramic obtained is

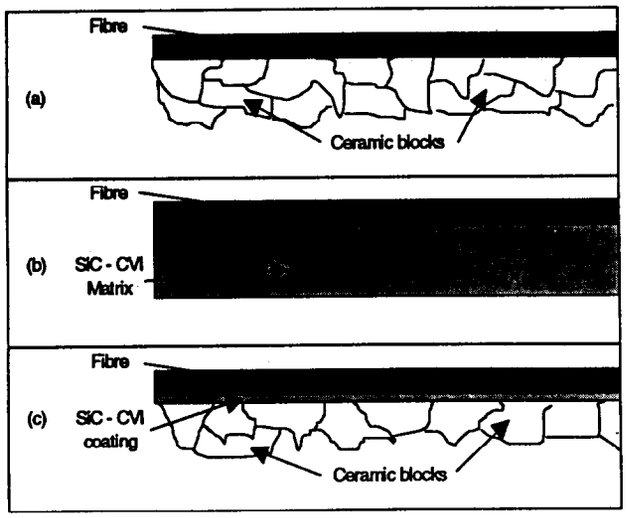

Fig. 1. Structure of the ceramics matrix obtained from (a) an organometallic precursor (b), in the case of CVI process and (c) in the present process.

given Table 2 (oxygen originates from the precursor). The density measured by He psycnometry is 2·13 g/cm^3. Thus, the volumetric yield of the transformation is about 30%.

2.2 Characteristics of the composite preforms

Starting materials are 3·0 to 3·2 mm thick plates. They are composed of eight woven layers of Nicalon NL 202 S8 fabric (from Nippon Carbon).

The fibres volume ratio is about 40 vol.%. A 0·5–1·0 μm thick graphite carbon coating of the fabric is used to limit fibres–matrix bonding and thus, to lead to the unbrittle behaviour of the materials.[8]

A 1·0–2·0 μm thick SiC coating is then realised by CVI.

The porosity determined by Archimedes' method is 36·8 ± 1% and is in agreement with the 38·6 ± 1·3% corresponding to the theoretical calculated value.

2.3 Densification process

To reduce the porosity and then to increase the mechanical properties, successive impregnation and pyrolysis cycles are realised with the polysilazane.

wt%	47·5	23·6	21·5	7·4

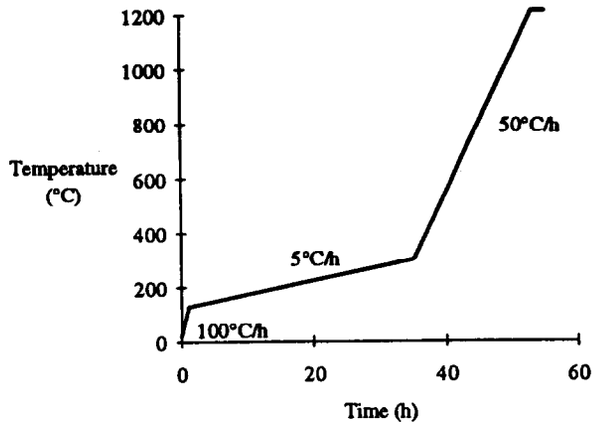

Fig. 2. Pyrolysis temperature schedule of Pyrofine PV polysilazane.

The preforms are charged into a reactor and degassed under 500 Pa at 150°C for 2 h. Thereafter, the precursor, preheated at 150°C to reduce its viscosity, is injected into the preform by means of a pressure gradient between the outside (nitrogen atmospheric pressure) and the inside of the reactor. After injection, preforms are soaked in the precursor at 150°C for 2 h under a nitrogen atmosphere before being removed and placed in the pyrolysis furnace.

Pyrolysis is operated under nitrogen according to the following temperature schedule: 100°C/h up to 130°C; 5°C/h from 130°C up to 300°C; 50°C/h from 300°C up to 1200°C + 4 h hold (Fig. 2).

A separate study has shown that pyrolysis up to 1400°C leads to the highest mechanical properties of the ceramic matrix.[7] However, the thermal resistance of Nicalon fibers limits the temperature of pyrolysis to 1200°C.

2.4 Measure of the physical and mechanical properties

The pore volumes were determined after each impregnation—pyrolysis cycle by Archimedes' method (open porosity) and from the theoretical calculation (total porosity) based on the volume ratio of the components and their absolute density.

The pore size distribution was determined by mercury porosimetry on the preform and after 1, 2 and 5 cycles.

Room-temperature flexural strengths were measured in three-point bending on a Schenck RM-T 25 kN using a support span of 50 mm and a crosshead speed of 0·5 mm/min. The average dimensions of the composite test bars are 65 × 10 × 3 mm^3.

Youngs modulus was determined from the load displacement curves.

Due to the unbrittle behaviour of the materials. The characterisation of the composite toughness requires the calculation of the resistance to crack

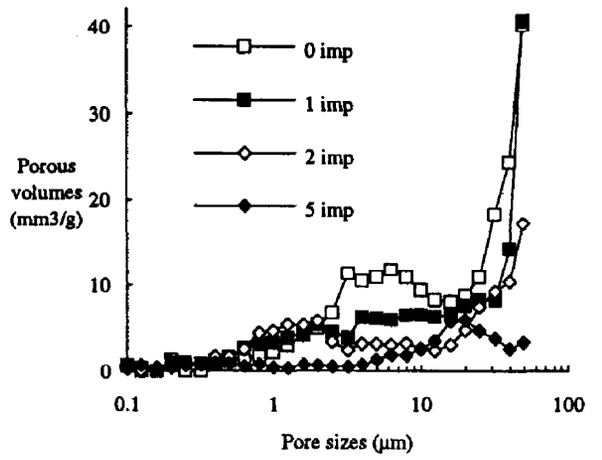

Fig. 4. Pore sizes distribution of (□) the preform and composites after (■) 1, (◇) 2 and (◆) 5 cycles.

propagation curves (*R*-curves). These curves show the stress intensity factor K versus the ratio of the crack length increase, da, to initial ligament thickness of the test bar w–a. The measures were made by the single-edge notched-beam techinque (SENB) with $a/w = 0{\cdot}5$ (a, initial crack length; w, thickness of the test bar). According to Bouquet *et al.* and R'mili,[9,10] calculations of da and K have been based on the assumption of a linear–elastic behaviour.

3 Results

3.1 Variation of the porosity with the number of cycles

Archimedes' method (open porosity) and the theoretical calculation (total porosity) lead to similar results: the porosity is essentially open.

The experimental porosity–number of cycles curve deviates for the theoretical one corresponding to a complete impregnation of the samples (Fig. 3). After five cycles, the porosity tends to an asymptotic value between 10 and 15%. The porosity being essentially open, this may be due to fine porosity which, due to the viscosity of the precursor, cannot be filled during the impregnation. However, weighing the composites after the precursor injection indicates that 96–97% of the free volume is filled.

On the other hand, after each pyrolysis, a residue of pyrolysed precursor is present at the bottom of the reactor. It is therefore concluded that the deviation between the experimental and theoretical porosity evolution curves is mainly due to the release of precursor during the early stage of pyrolysis, while its viscosity is still low (temperature range 150–200°C).

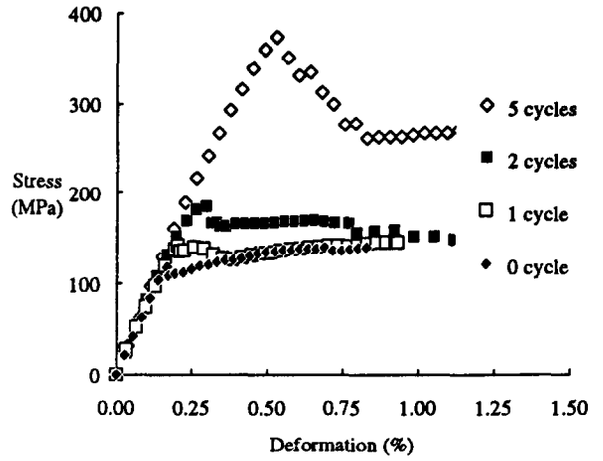

Fig. 6. Composite stress–deformation curves obtained in three-point bending.

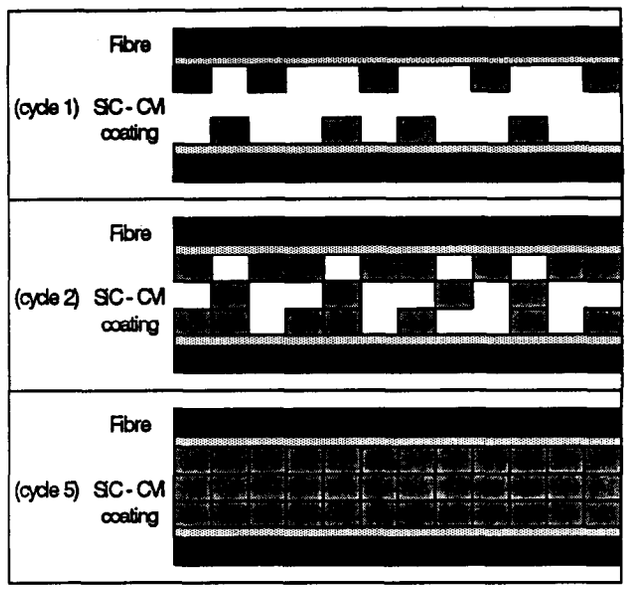

Fig. 8. Processing of the ceramic matrix during the successive impregnation and pyrolysis cycles with the polysilazane.

The pore size distribution was determined on the preform and after 1, 2 and 5 cycles. Two classes of pores are observed on the pore volume distribution graph (Fig. 4): firstly 1–10 μm radius pores corresponding to the space which separates the fibres within a same cloth; this porosity decreases readily according to the number of cycles; and secondly, pores with a radius larger than 50 μm, corresponding to the voids between two woven cloths. This porosity starts decreasing only after the second cycle. A SEM observation shows the good filling of the interfibres voids, whereas the space between cloths is only partially filled (Fig. 5(a) and (b)). This seems to confirm that the precursor could flow out of the largest process before the crosslinking.

3.2 Variation of the mechanical properties with the number of cycles

The stress–deformation curves obtained (Fig. 6) show the unbrittle behaviour of the materials. This is the result of the weak fibre–matrix interface. Samples of preform and of composites after one and two cycles fail in a shear mode by delamination between the plies. Their flexural strengths are similar, about 150 to 180 MPa, corresponding to a delamination strength of about 10 MPa.

On the other hand, the failure of the composites obtained after five cycles is perpendicular to the fabrics. The flexural strength is higher, 400 MPa, and a large amount of fibre pullout is observed on the fracture surfaces. A similar evolution of the failure mode according to the number of cycles is observed by Boisvert & Diefendorf.[3]

The Young's modulus versus porosity curves show a three-stage variation (Fig. 7).

The ceramic residues of the first cycle are too dispersed to build a continuous network (Fig. 8, 1 cycle). Their contribution to the composite elastic modulus is low. No siginficant increase is ascer-

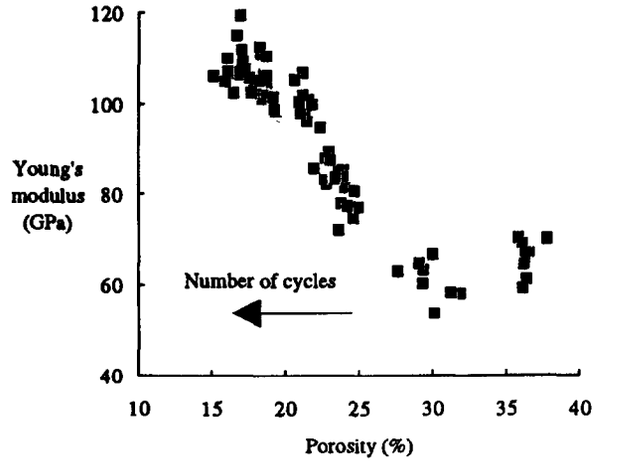

Fig. 7. Variation of the Young's modulus versus the porosity of the composites.

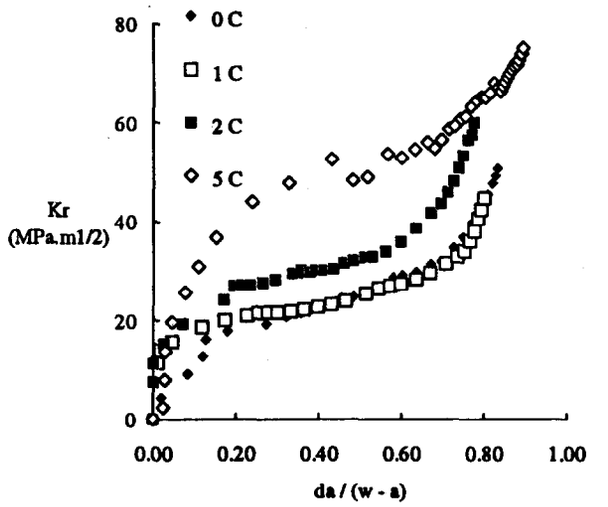

Fig. 9. R-Curves obtained on the assumption of a linear–elastic behaviour.

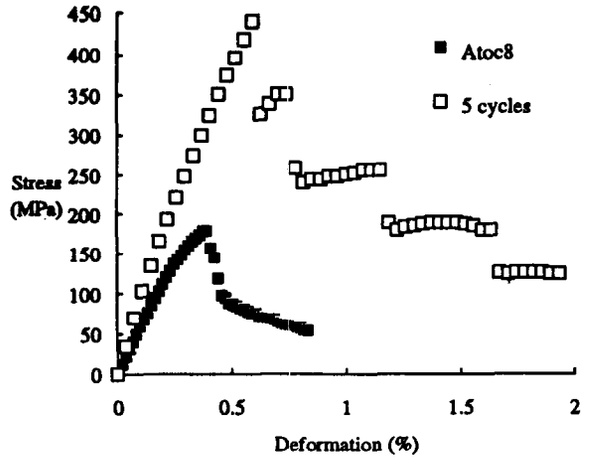

Fig. 10. Stress–deformation curves in three-point bending of composites elaborated from the new process (CVI + 5) and from the conventional one (Atoc8).

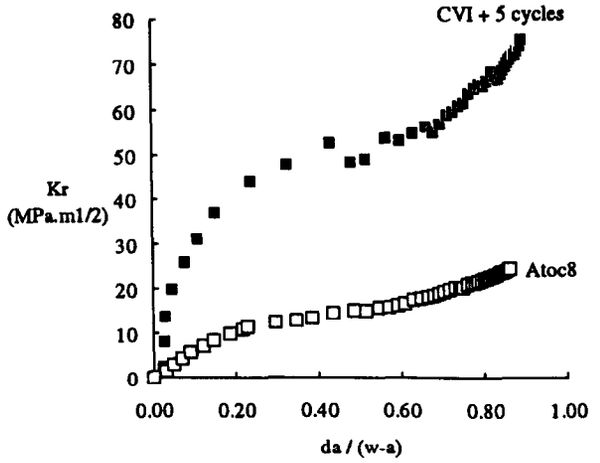

Fig. 11. *R* curves of composites elaborated from the new process (CVI+5) and from the conventional one (Atoc8).

tained. Then, the decrease in porosity from 30 to 22% leads to a large increase in the modulus. The ceramic blocks corresponding to the second and third cycles create progressively a ceramic 'framework' (Fig. 8, 2 cycles).

Thereafter, this framework is filled and strengthed (Fig. 8, 5 cycles). This corresponds to the more gradual increase in modulus when the porosity decreases below 20%, that is to say, during the fourth and fifth cycles.

As expected, the *R*-curves show that *K* increases with the crack length (Fig. 9). Indeed, in addition to the generation of new surfaces, several energy dissipative mechanisms occur during crack propagation, leading to the increase in the crack propagation resistance. The variation of these curves as a function of the number of cycles is similar to that of the flexural strength.

The curves obtained with the preforms and after one or two cycles are almost superimposed, whereas those obtained after five cycles are significantly higher. This can also be explained by the evolution of the failure mode. After the first cycles the cracks are propagated only through the matrix, the crack propagation resistance is low. On the opposite after five cycles, the crack propagation is perpendicular to the fabrics. In this case, the weak fibre matrix interface allows several energy dissipative mechanisms (e.g. fibre pull-out, interface debonding, etc.), increasing the resistance to the crack propagation.

3.3 Comparison with a conventional use of the same percursor

Another type of composite has been realised from a conventional use of the same percursor when the fibres are coated with pyrolytic carbon and placed in an injection mould. The impregnation process is similar to the one described above.

The materials have been tested in three-point bending. The values of the mechanical properties are listed in Table 3. The stress–deformation curves and the *R*-curves obtained in this case (Figs 10 and 11) are siginficantly lower than those obtained with the process CVI + precursor. The flexural strengths of the composites are lower than 200 MPa compared to 400 MPa for the first process and the elasticity modulus does not exceed 70 GPa compared to 105 GPa. Nevertheless, these results are comparable to those obtained with some other precursors used in a similar process.[3–5]

Table 3. Mechanical properties o the composites

Process route	*Ref. comp.*	*Cycle number*	*Fibre Ratio (vol.%)*	*Carbone coating (μm)*	*Porosity (%)*	*Flexural strength (sf) (MPa)*	*Young's modulus (E) (GPa)*
Conventional	Atoc6	8	49	0·50	10·4 ± 0·6	166 ± 27	81 ± 4
Conventional	Atoc7	8	49	0·25	13·6 ± 0·9	159 ± 13	62 ± 6
Conventional	Atoc7b	9	49	0·25	11·8 ± 1·1	168 ± 21	85 ± 5
Conventional	Atoc8	7	41	0·20	17·0 ± 0·7	179 ± 22	55 ± 3
New	CVI+0	0	38·5	0·5 ± 1·0	36·8 ± 1·0	156 ± 20	65 ± 10
New	CVI+1	1	38·5	0·5 ± 1·0	29·8 ± 1·1	135 ± 11	69 ± 4
New	CVI+2	2	38·5	0·5 ± 1·0	23·5 ± 1·5	185 ± 23	95 ± 6
New	CVI+5	5	38·5	0·5 ± 1·0	16·4 ± 1·3	376 ± 62	103 ± 11

4 Conclusion

This new process route leads to high mechanical property composites. Only five impregnation–pyrolysis cycles with Pyrofine PV polysilizane on the SiC/C/SiC preforms are required to increase the flexural strength form 149 to 380 MPa and the Young's modulus from 65 to 105 GPa. The toughness follows the same evolution. These results are comparable to those of composites entirely obtained by CVI and SiC and siginficantly higher than those obtained by a conventional use of the same precursor (flexural strength lower than 200 MPa). However this process is not as fast as expected. Indeed, after each cycle, the porosity decreases less than calculated from the volumetric yield of the percursor during the pyrolysis. The porosity is 15% after five cycles instead of the 7% expected. This is due to the release of the precursor from the preform during the early stage of the pyrolysis.

Abstract

Fatigue cracked and fast fractured regions in four point bend specimens prepared from 25 wt% silicon carbide whisker reinforced alumina composites were examined by Scanning Electron Microscopy. In the fatigue cracked region, the alumina matrix failed mainly in a transgranular mode and the whiskers failed mainly with a flat fracture surface but without pullout. On the other hand, in the fast fractured region, the whiskers failed predominantly by pullout and the alumina matrix failed in a mixed mode with about half in transgranular and the other half in intergranular fracture. Thus, to improve the fracture toughness of the material, the grain boundary strength of alumina and the matrix whisker interfacial bonding should be improved. To increase the resistance to fatigue, the fracture strength of the alumina grains should be improved by using finer α-alumina particles and the fatigue strength of the whisker has to be increased by improving the uniformity in distribution of β-SiC whiskers during hot pressing.

1 Introduction

Fatigue crack growth rate (FCGR)[1,2] and fracture toughness[1–3] of 25 wt% silicon carbide whisker reinforced alumina ceramic composite have been studied and reported.[1–3] Such studies are important since these materials have potential application in the production of structural components used at elevated temperatures, in high efficiency heat engines and heat recovery systems and for making cutting tools to machine special materials. When used in such applications, these ceramic components would often encounter monotonic and cyclic loading which produce crack extension. Therefore, the fractographic features of the fatigue failed samples need to be examined to identify the likely micromechanism of crack advance under monotonic and cyclic loading in this composite. Recently, Dauskardt *et al.*[4] have made an extensive fractography of fatigue failed regions in a 15 vol% SiC whisker-reinforced alumina composite. The identification of the fractographic features at the low, medium and high Stress Intensity Range (ΔK) fatigue region as well as in the fast fracture region can give us a clue to the likely mechanisms of fracture in our material.

2 Experimental Procedure

The four point bend specimens were sliced, prepared, surface finished and randomised from a 15 mm × 50 mm × 12·5 mm preformed billet of 25 wt% silicon carbide whisker reinforced alumina composite material (Fig. 1(a)). The details of fabrication of the billet are given elsewhere.[3]

The alumina powder used was of α-type.[1] The SiC whiskers had been produced by a carburization process at 1600°C where the sources of silicon and carbon were rice husk ash and rice husk hydrocarbons.[3,5]

The particle size of the alumina powder was less than 1 μm. The average whisker diameter was 0·1–0·25 μm as revealed in the LT plane of the montage of the ceramic composite investigated here (Fig. 1(b)). The length of the whiskers varied between 10 and 30 μm.[3]

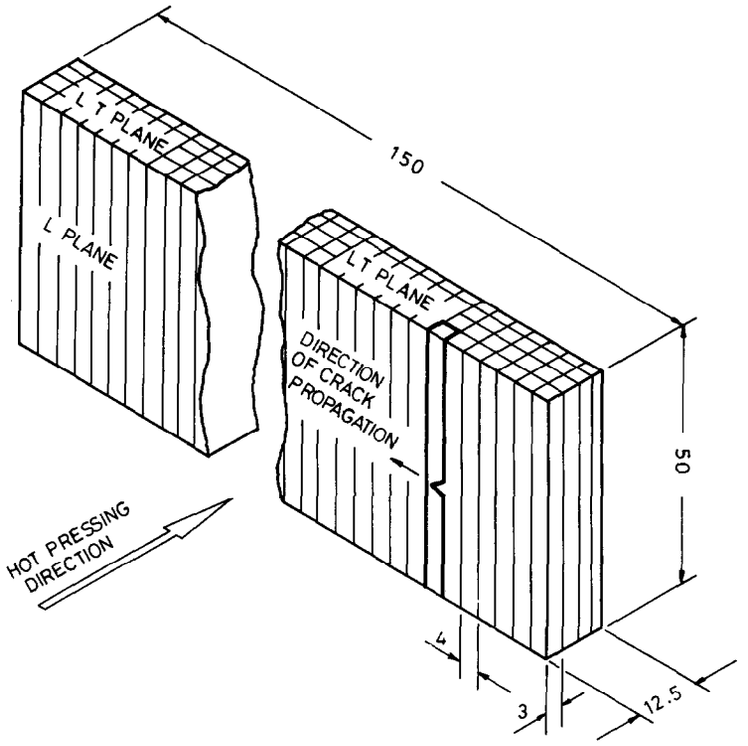

Fig. 1(a). Portion of the billet prepared from the 25 wt% silicon carbide–alumina composite. All dimensions are in mm.

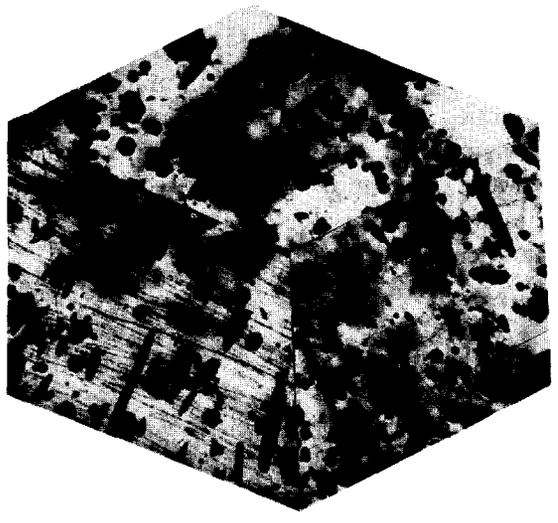

Fig. 1(b). Montage of the microstructures shows distribution of SiC_w along the three planes.

Fig. 2. Fracture surface of the composite showing the size and shape of the alumina matrix.

The SEM (Scanning Electron Microscope) examination of the fractured surface of the specimens which failed due to premature crack extension during precracking in the conventional bridge fixture,[1,3] showed that the alumina grain size after fabrication varied between 1 and 6 μm. This confirms that during hot pressing, the alumina underwent substantial grain coarsening. In areas where either whiskers were absent or there was evidence of pores (Fig. 2), the grain size was as high as 6 μm. However, in other areas, the majority of the alumina grain size was in the range of 2–4 μm.

The montage of the ceramic composite revealed the 3D-distribution pattern of the whiskers in the longitudinal (L), long transverse (LT) and short transverse (ST) planes. In the L plane, the whiskers appeared to be randomly oriented as the hot pressing direction is perpendicular to this L plane. During hot pressing, whiskers which are not normal to the L plane get further inclined thus producing the random orientation of the whiskers.[1] Since maximum material flow occurred along the LT planes during hot pressing, the whiskers tend to get oriented parallel to the L plane. In the ST plane, there was a mixture of random orientation as well as normal alignment of the whiskers.

Becher and Wei had concluded in their work[6] that whisker orientation during processing of hot pressed SiC-whisker reinforced alumina leads to anisotropy in both fracture toughness and fracture strength of the composites. In other words, their fracture strengths are limited by the nonuniformity of the distribution of the whiskers, i.e by the ability to disperse the SiC whiskers. They also found that the dispersion of the whiskers improved by using finer alumina powder and hence an increase in the fracture strength of the composite was observed. Nevertheless, they have clearly observed[6,7] that similar to our composite under investigation (Fig. 1(b)), the whiskers were preferentially aligned perpendicular to the hot pressing axis. This type of distribution of whiskers suggested that a great deal of rearrangement of whiskers and powder occurred in the initial stage of densification of the composites and/or the matrix material underwent considerable deformation or creep during hot pressing.

The dimensions of the billet and the orientation of the four point bend specimens (3 mm × 4 mm × 50 mm) in the billet is given in Fig. 1(a). The 4 mm × 50 mm faces, were normal to the hot-pressing direction so that both the direction of crack propagation (Fig. 3) and the crack plane were parallel to the LT plane (Fig. 1(a)) and normal to the hot-pressing direction.[3] The 3 mm × 50 mm faces of the specimen were parallel to the ST plane.

A Vickers indentation produced at 0·8 kN load at the centre of the 3 mm × 50 mm face of the sample acted as the crack starter on half of the four point bend specimens. On the remaining half, notches were inserted exactly at the centre of the 3 mm × 50 mm surface of the specimens with a carborundum wheel to a depth of 0·1 mm. Thereafter, the specimens were subjected to fatigue loading in a servohydraulic test machine MTS-880 (100 kN capacity) to precrack the specimen in an articulated bridge fixture,[2] till the ratio of crack length to width was 0·05 on the (4 mm × 50 mm) surface of the specimen. Precracking was conducted at a force of 4–5 kN, load ratio, R = 0·1 and frequency, f = 20 Hz. After this, the fatigue crack growth rate in the specimen was determined at increasing values of Stress Intensity Range ΔK (Fig. 4), under normal four point bend loading (see Fig. 3) until the ratio of crack length to width was about 0·45–0·5, on the 4 mm × 50 mm surface of the specimen. Thereafter, the test to determine the fatigue crack growth rate (FCGR) was terminated and the specimen was subjected to monotonic loading to determine the fracture toughness of the material[1] as per ASTM STP 410.[8] For both FCGR as well as fracture toughness (K_{IC}) tests, a 1 kN load range of the MTS-880 test machine was used. The test frequency was 1 Hz and the loading rate was 0·25 N s^{-1}. Tests were conducted in laboratory atmosphere and at ambient temperature. The fracture toughness testing produced the fast fracture. The details of fracture toughness and FCGR tests are given elsewhere.[1,2]

The fracture surfaces were coated with a thin film of gold (thickness 0·02 μm) prior to SEM (Scanning Electron Microscopic examination, in a JEOL JSM 840A microscope).

The three regions, namely low ΔK corresponding to 0·8–1·8 MPa $\sqrt{m}$; high ΔK corresponding to 2·8–3 MPa $\sqrt{m}$; and, the fast fracture region corresponding to a K_{IC} value of 5·9 MPa $\sqrt{m}$, were, at first, identified on the fracture surface at a magnification of 30 X under SEM (Fig. 5) — using the details of the crack growth rate data generated on

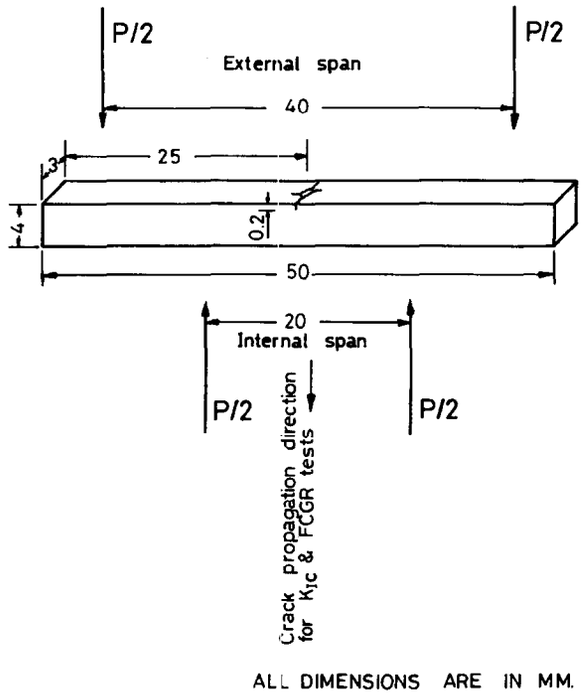

Fig. 3. Indented and precracked specimen for four point bend loading. Cracks are located at the four corners of indentation.

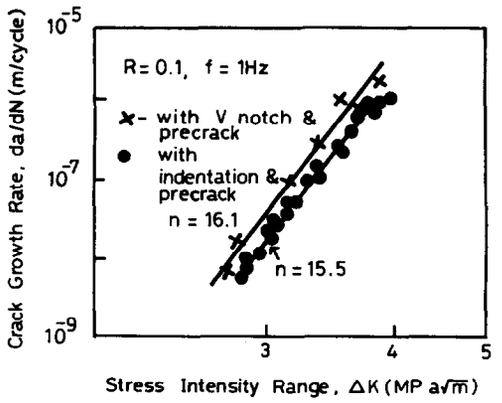

Fig. 4. Fatigue crack growth data of 25 wt% SiC reinforced Al_2O_3 composite.

Fig. 5. Entire fracture surface. Right-hand side—low ΔK region; middle—high ΔK region; left-hand side — fast fracture region (FF).

Fig. 6. At low ΔK (0·8–1·8 MPa $\sqrt{m}$) region, the majority of the whiskers failed with a square fracture without evidence of large scale pullout.

Fig. 7. At high ΔK (2·8–3 MPa $\sqrt{m}$) region the whiskers failed in a mixed mode, i.e. both with a square fracture and also by pullout.

the specimen as a guideline. The difference between the fatigue and fast fracture could, however, be discerned through observation even with the naked eye. The distinction between the low and the high ΔK fatigue regions was made from the crack length versus the number of cycles data generated during the fatigue loading of the specimen.

Each region was, at first, carefully scanned at low magnification, to identify the general and uniformly distributed features. Thereafter, it was examined at two different magnifications 4500 X and 7500 X, in order to identify the fractographic features and the mechanism of fracture in the low ΔK and the fast fracture regions.

3 Fractographic Observations

A summary of the results of the fractographic observations is reported in Table 1.

Table 1 states that, at low ΔK (0·8–1·8 MPa $\sqrt{m}$), the whiskers failed predominantly by shearing with a flat or square fracture without any visible evidence of necking; this was typical of fatigue fracture (Fig. 6). However, at high ΔK (2·8–3 MPa $\sqrt{m}$), the whisker failed in two different ways: that is about 60% of the whiskers failed with a flat fracture and the balance failed by pullout (Fig. 7). On the other hand, in the fast fracture region, the whiskers failed predominantly by pullout (Fig. 8).

Table 1. Fractographic features in the fatigue and fracture regions in a 25 wt% silicon carbide whisker reinforced alumina

Mechanism of failure		*Fatigue*		*Monotonic*
		Low ΔK 0.8–1.8 MPa√m	*High ΔK 2.8–3.0 MPa√m*	*Fracture 5.96 MPa√m*
Whisker	Pullout (%)	5	40	85

P = present; A = absent.

Table 1 also reports that the matrix alumina grains failed predominantly through transgranular fracture (Fig. 9) at low ΔK (0·8–1·8 MPa$\sqrt{m}$). In the high ΔK (2·8–3 MPa$\sqrt{m}$) region, the matrix failed in a mixed mode wherein about 45% of the alumina grains failed by intergranular and the balance by the transgranular mode, as shown in Fig. 10. During monotonic loading, the alumina grains in the fast fracture region also failed in a mixed mode with a slightly increased percentage of intergranular (~55%) and the balance by transgranular mode—as shown in Fig. 11.

It is noteworthy that in the low ΔK region, the crack had frequently branched (Fig. 12) and deflected (Fig. 13) while it propagated. River pattern

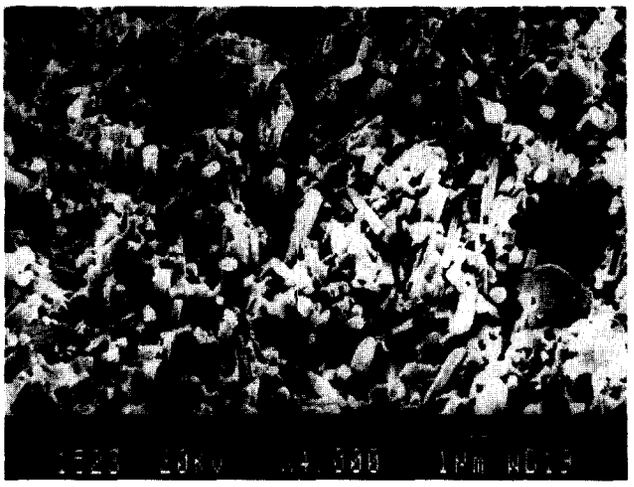

Fig. 8. In the fast fracture region (K_{IC} = 5·9 MPa$\sqrt{m}$), whiskers failed predominantly by pullout mechanism.

markings with steps (Fig.14) were also present in the cleavage facets. However, in the fast fracture region, the branching and deflection of the crack were virtually absent.

4 Discussion

Twenty-five weight percent silicon carbide whisker reinforced alumina composite is susceptible to a fatigue crack growth phenomenon[1,2] (Fig. 4), which is similar to that in the case of metallic

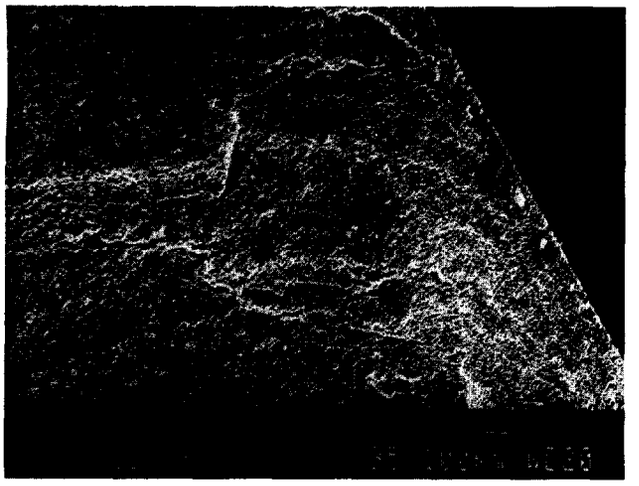

Fig. 14. River pattern marking with steps in the low ΔK region (YZ—modulation SEM image).

metals, but with a higher crack growth exponent (n = 15·5). Figure 4 shows that the FCGR data of this material fits the usual Paris equation $da/dN = A(\Delta K)^n$.

Since the manner of failure of the whiskers and the α-alumina grains were entirely different in the low ΔK fatigue and the fast fracture regions, the schemes of crack growth under these two conditions are discussed separately, to focus on their contradistinctions.

4.1 Low ΔK fatigue region

During fatigue loading at the low ΔK regions, where ΔK = 0·8–1·8 MPa $\sqrt{m}$ the alumina grains of the matrix failed mainly by transgranular cleavage with frequent crack branching and crack deflection. Also, the cleavage facets revealed river pattern and steps. At low ΔK, the K_c values and consequently the traction force ahead of the crack tip, were not adequate to promote intergranular fracture.

At low ΔK, the amount of crack extension is very low. So even though the energy dissipated per cycle is low, the number of cycles and the cumulative energy required for a given amount of crack extension is quite significant and can thus account for the higher surface area required for the various features encountered like crack branching, river pattern and steps.

At low ΔK fatigue, the whisker could fail in three different modes

- pullout,
- tensile fracture,
- fatigue.

Table 1 shows that only a few of the whiskers failed due to pullout at low ΔK fatigue. This naturally indicated that the maximum traction forces generated ahead of the crack tip during the low ΔK fatigue was not adequate to produce a pullout. Thus, it is likely that the whiskers continue to bridge the crack even after some of the surrounding alumina grains had failed by transgranular cleavage. Therefore, under these circumstances, the whisker could fail due to tensile fracture or fatigue.

One might rule out the possibility of tensile fracture if one had examined the relative values of strength and Young's modulus reported in Refs 9 and 10. The fracture strength of the whisker is about 6·5–7 times higher than that of alumina. Accordingly, the tensile fracture of the whisker was unlikely if the traction forces ahead of the crack tip were to be distributed in proportion to the relative cross sections of the whisker and alumina in the plane of the crack. Even if the whiskers were to carry the major part of the traction forces ahead of the crack tip, the high traction forces would produce failure by pullout rather than by tensile fracture, as was observed in the fast fracture region where K_{IC} values and consequently the traction forces, were high.

Since the possibility of large scale failure by pullout or tensile fracture was discounted, whiskers were most likely to fail by fatigue. At low ΔK, the whiskers which had bridged the crack after the surrounding alumina grains had failed by cleavage, would continue to experience fatigue loading, then failed with a square fracture which is typical of fatigue. The fatigue failure of the silicon carbide whisker under such circumstances, could be significantly influenced by the stacking fault such as is reported Ref. 11 in Fig. 15, since such fault could be responsible for nucleating the fatigue crack. However, this aspect needs careful study.

Since the cleavage of the α-alumina grains probably occurred before the whiskers (located mainly at the grain boundaries) had failed, it was necessary to improve the fatigue resistance of the α-alumina grains. This apart, the dislocation pile-up

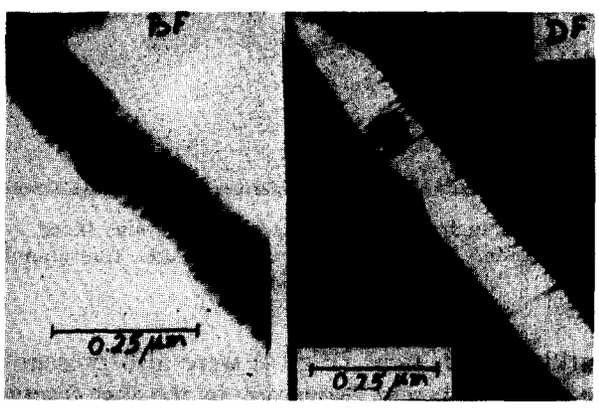

Fig. 15. TEM of β-SiC whisker showing stacking fault by dark field and bright field techniques.

model[12] would obviously indicate that the cleavage failure of α-alumina could be prevented through the refinement of alumina grains in the aggregate structure. The size of alumina grains varied between 1 and 6 μm. In this context, one should note that one could obtain higher resistance to low ΔK fatigue, if ultra-fine or nano-size alumina grains, such as that produced by the solgel technique, were to be used to fabricate this composite.

A schematic view of crack propagation mechanism is representated in Fig. 16(a). It illustrates that at low ΔK fatigue, the matrix failed predominantly by transgranular cleavage and the advancing crack frequently branched and tilted and twisted in its course of deflection. Since the whiskers were predominantly located at the grain boundaries and the crack propagation along the grain boundary at low ΔK fatigue was negligible, the possibility that the crack would encounter these whiskers as it advances would be rather low. Only a few of those whiskers which had bridged the crack with an orientation normal to the advancing crack plane, could fail by pullout. The other whiskers were likely to fail by directly experiencing fatigue loading. This could explain why

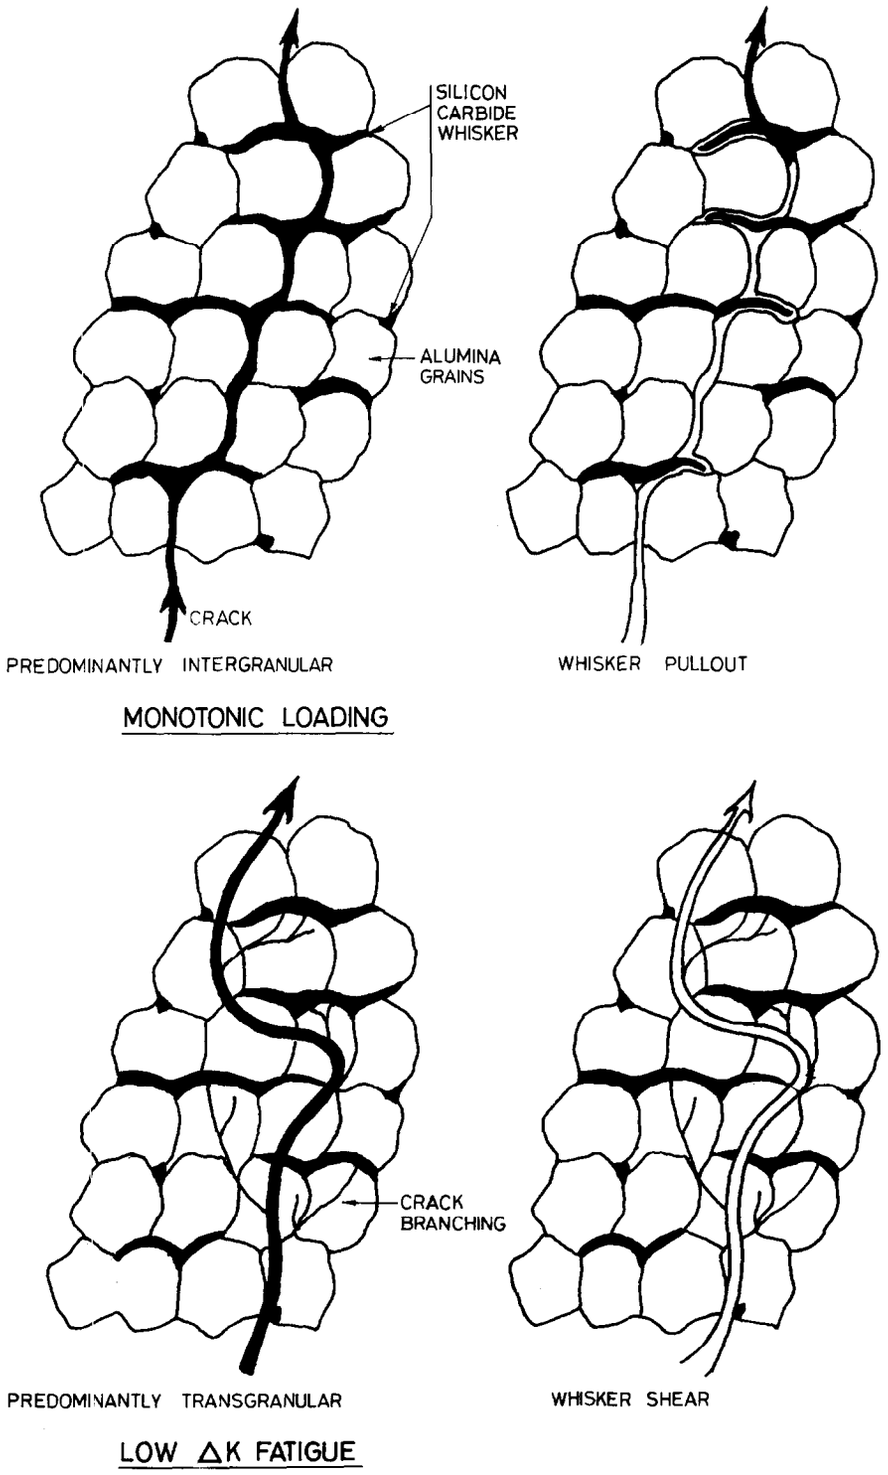

Fig. 16. Schematic of the crack propagation during monotonic and cyclic loading.

at low ΔK fatigue, the majority of the whiskers failed with a square fracture and without pullout.

4.2 Fast fracture region

During the fast fracture under monotonic loading such as during the fracture toughness testing, some of the α-alumina grains of the matrix failed by intergranular fracture; the others failed by transgranular cleavage. The value of K_{IC} during such monotonic loading was 5·9 MPa $\sqrt{m}$. At such values of K_C, the traction force generated ahead of the crack tip was adequate to produce the intergranular failure in those grains which were favourably oriented with respect to the direction of the traction force. Debonding and pullout of those whiskers at the fractured grain boundaries would therefore occur.

It is difficult to summarise from the fractographic features as to which of these, i.e. transgranular cleavage or intergranular fracture, occurred, at first, under monotonic loading.

After some of the grains had failed through the intergranular mode, the other neighbouring grains which were less favourably oriented or which were strongly anchored by the whiskers across the grain boundaries, failed through transgranular cleavage.

The pullout of the whiskers could be avoided if the whisker α-alumina interfacial strength was improved or if finer and more numerous whiskers and also finer α-alumina particles were used in fabricating the composite. Similarly, the intergranular fracture could be avoided by strengthening the boundaries.

As illustrated schematically in Fig. 16(b), the fracture due to monotonic loading showed a substantial amount of intergranular failure of the matrix and pullout of the whiskers. Crack deflection, branching and the characteristic river pattern marking with steps, were absent in this region.

The matrix failure was predominantly intergranular. Nevertheless, the whiskers were located mainly at the grain boundaries. Therefore, the probability of the advancing crack front interacting with the whiskers was extremely high. The whiskers tending to bridge the advancing crack quite frequently would therefore get debonded and pulled out—which is schematically illustrated and shown in Fig. 16(b). This justifies the fact that during the monotonic fracture, failure of whiskers by the pullout mechanism was frequently observed in the fractograph.

During fatigue loading at high ΔK, mechanism of fracture was an intermediate situation between the two extreme cases: that is between the case of monotonic fast fracture and that of the low ΔK fatigue fracture.

Since the ceramic material is often expected to survive both monotonic and fatigue loading, one could make the following general observations based on the scheme of crack growth under the two conditions as discussed above.

To prevent fracture failure of this ceramic material under monotonic loading, its microstructural features would have to be strengthened to avoid intergranular fracture of α-alumina and the pullout of the whisker. This requires that the grain boundary strength of α-alumina and the whisker—matrix interfacial strength should be increased. Similarly, to retard crack extension during low ΔK fatigue, intergranular cleavage fracture of α-alumina grains and fatigue failure resistance of the silicon carbide whiskers should be improved, possibly by using finer α-alumina powder[6,7] and by improving the uniformity of distribution of whiskers in the matrix during hot pressing.[6,7]

5 Conclusions

The micromechanism of fracture of a 25 wt% silicon carbide whisker reinforced alumina composite when loaded in fatigue was quite different from that when loaded monotonically. Consequently, the fractographic features in the two instances of loading were significantly different.

When loaded in fatigue, the alumina matrix failed in a transgranular mode and the whiskers failed by producing a flat fracture but without their pullout.

When loaded monotonically, the whiskers predominantly failed by pullout and the alumina matrix failed in a mixed mode with about 55% in intergranular and the balance in transgranular mode. Whereas the grain boundary strength of α-alumina and the whisker–matrix interfacial bonding should be increased to produce increased resistance to failure under monotonic loading. The fatigue failure resistance of the composite could be improved by improving the cleavage strength of the α-alumina grains, i.e. by using finer α-alumina particles and by increasing the fatigue strength of the whiskers by improving the uniformity in the distribution of β-SiC whiskers during hot pressing.

Determining the Fracture Toughness of Brittle Materials by Hertzian Indentation

P. D. Warren

Department of Materials, Oxford University, Parks Road, Oxford OX1 3PH, UK

(Received 21 December 1993; revised version received 14 July 1994; accepted 1 August 1994)

Abstract

The use of Hertzian indentation as a method for determining the fracture toughness of any brittle material is described. The advantage of the method described here is that the only quantity to be measured is a fracture load. Experimental determinations of K_{IC} *for soda-lime glass and high-purity alumina give results 0·71 and 3·72 MPa* $m^{1/2}$*, respectively.*

Introduction

The fracture toughness of a brittle material is one of its most important mechanical properties. Determination of this value is frequently a complicated process involving preparation of specimens with well-defined sharp cracks of known length. A recent review article[1] has presented a summary of available techniques. However, one method was conspicuous by its absence—that of Hertzian indentation. It is the purpose of this paper to suggest that this method should be looked at afresh.

Indentation techniques in general have certain advantages compared with the more conventional methods: the experimental procedure is straightforward, involving minimal specimen preparation, and the amount of material needed is small. The Vickers indentation method[2–4] is well known. However, it is not without drawbacks. There are now a very large number of theoretical models in the literature (19 are reviewed by Ponton and Rawlings[5,6]) relating the surface crack length measured after indentation to the indenter load and material parameters—Young's modulus, hardness and fracture toughness. There is still considerable debate as to the nature of the cracks observed around a Vickers indentation—the idealised 'half-penny' characteristics of the median/radial system, as opposed to Palmqvist cracking. Cook and Pharr[7] have presented a considerable amount of evidence to suggest that *radial* cracks form almost immediately on loading in a wide variety of crystalline solids. There is also debate on how to determine the type of cracking from the surface-crack length vs applied load relation. For a spirited discussion of these matters the articles by Li *et al.*[8,9] and Srinivasan and Scattergood[10] should be consulted. It should be noted, however, that Lawn[11] asserts that Palmqvist cracks '. . . retain the essential half-penny character.'

Many attempts have been made to use Hertzian indentation—where a hard sphere is pressed into the flat surface of a brittle substrate—to determine K_{IC} for brittle materials: work by Frank and Lawn—glass,[12] by Powell and Tabor—TiC,[13] by Wilshaw—glass,[14] by Nadeau—vitreous carbon,[15] by Warren—TiC, ZrC, VC and WC,[16] by Matzke *et al.*—UO_2,[17] by Matzke—ThO_2,[18] by Inoue and Matzke—ThO_2,[19] by Matzke and Warren—ThO_2,[20] by Matzke and Politis—NbC, Nb(C,N) and NbN,[21] by Matzke *et al.*—(U,Pu)C and (U,Pu)(C,N),[22] by Laugier—TiN coatings on WC–Co,[23] Al_2O_3—ZrO_2,[24] various Al_2O_3—ZrO_2 composites and Sialons,[25] various WC–Co composites[26] and finally, by Zeng *et al.*—glass, Al_2O_3 and Al_2O_3–SiC composites.[27,28]

Broadly speaking, the early work, prior to 1978, used the theory of Frank and Lawn,[12] which strictly only applies for ring-cracks initiating exactly at the edge of the contact zone. The papers by Warren and co-workers,[16–19,21,22] (and those of Laugier[23–26]) used Warren's theory,[16] which involves measuring the radius of the ring-crack seen on the surface after fracture: Matzke and Warren[20] and the recent work by Zeng *et al.*[27,28] involved the cross-sectioning of the specimens after fracture to determine the *depth* of the cone crack. The results obtained so far have been variable. Almond *et al.*[29] point out that the values obtained by Warren[16] on various metal carbides are significantly lower than conventional values; Laugier,[26] on the other hand, for various WC—Co composites, found values considerably higher. This poor

agreement may be one reason why the test is not more commonly used. This is a pity because the Hertzian indentation test has at least one considerable advantage over Vickers indentation: until fracture occurs around the indenter the deformation of the substrate is entirely elastic (unless spheres of very small radius, <1 mm, are used). This means that the complications associated with the residual stresses in the Vickers indentation technique do not exist. Furthermore, the elastic stress field is well known.[30]

The disadvantages in the method may be due to the following factors: (i) the stress gradients in the Hertzian field are very steep so that it is difficult to obtain accurate estimates for stress-intensity factors for cracks driven by Hertzian loading; (ii) the results of the analysis are extremely sensitive to the value of Poisson's ratio of the substrate, and (iii) a number of previous experimental determinations of fracture toughness have ignored the effects of elastic mismatch (and friction at the indenter–substrate interface) when the sphere and the substrate are made of elastically dissimilar materials. Much work has been done using either steel or tungsten carbide spheres on glass substrates and there is good experimental evidence[31] that the effects of this significant elastic mismatch on the observed fracture loads are *not* negligible.

Below, we summarise the main aspects of the theory of Hertzian fracture and present a method which enables the value of K_{IC} to be found for any brittle material, as long as it is indented by a sphere made of the same material. The method described here is extremely easy to use, does not require measurement of the ring-crack size and gives reliable results.

Theory

Figure 1 shows a sphere (radius R, elastic constants ν_I, E_I) pressed by a load P into a flat substrate (with elastic constants ν, E). The load is supported over a circular area whose radius, a, is given by:[32]

$$a = \left(\frac{3RP}{4E^*}\right)^{1/3} \tag{1}$$

where:

$$\frac{1}{E^*} = \frac{1-\nu^2}{E} + \frac{1-\nu_I^2}{E_I} \tag{2}$$

The peak pressure under the sphere, p_o, is given by:

$$p_o = \frac{3P}{2\pi a^2} \tag{3}$$

The stress field outside the contact zone has a tensile radial stress near to the surface which

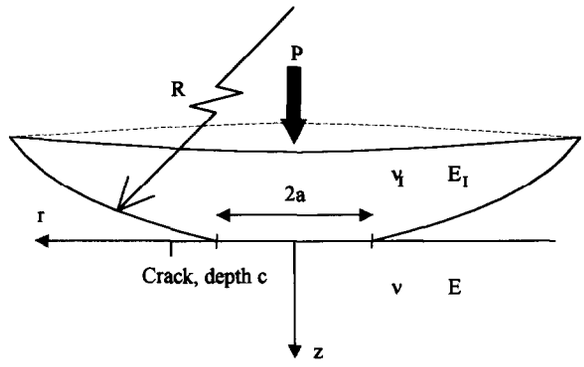

Fig. 1. The geometry of Hertzian contact.

rapidly decreases, and soon becomes compressive, with depth. Thus calculating the stress intensity factors for surface-breaking cracks is not trivial. For short cracks (i.e. those whose depth is less than $a/10$) lying perpendicular to the free surface the method of Nowell and Hills[33] (employing distributed dislocations) can be used to derive expressions for the mode I (and mode II) stress intensity factors. This approach differs from previous work[12,14,16,27,28,34] where it was assumed that the crack path initially lay along the trajectory of the minimum principal stress; here, the pre-cursor flaws are assumed to be perpendicular to the surface; this will tend to *reduce* the K_I values derived here compared to previous results. The use of the method of distributed dislocations enables the effects of the free surface to be accounted for; this will tend to *increase* the K_I values. In this method, a short plane crack of depth c, normal to the free surface, is placed close to the contact zone. The state of stress in the crack's absence is found. When the crack is inserted, unsatisfied tractions appear along the line of the crack. These may be cancelled by the application of equal and opposite tractions along the crack faces, which may be generated by installing a distribution of dislocations. (These dislocations are not real dislocations in a crystalline lattice, but a mathematical device.) The state of stress induced by one of these dislocations is known—the expressions are given explicitly in Ref. 33. By applying a distribution of dislocations, of unknown density $B_r(z)$, the requirement that the crack faces be traction-free may be ensured by writing

$$0 = \tilde{\sigma}_{ij}(z, r) + \frac{G}{\pi(\kappa+1)}\int_0^c B_r(z)K(z, r)\,dz \tag{4}$$

G is the shear modulus of the material, κ is Kolosov's constant (= $3-4\nu$ in plane strain), the coordinates r, z are as in Fig. 1; the function $K(z,r)$ is given in Ref. 33. The unknown quantity, $B_r(z)$, is defined by $B_r(z) = db_r/dz$, and $\tilde{\sigma}$ represents the state of stress induced by the contact in the crack's absence, i.e. in this case the radial

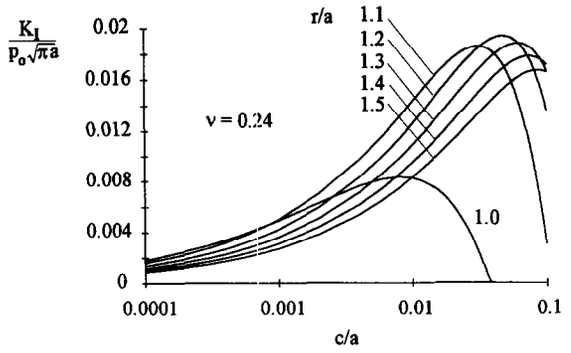

Fig. 2(a). Normalized mode I stress intensity factors as a function of normalized crack size for six normalized crack positions. Poisson's ratio = 0·24.

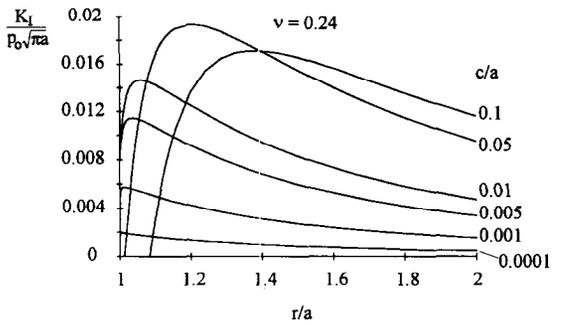

Fig. 2(b). Normalized mode I stress intensity factors as a function of normalized crack position for six normalized crack sizes. Poisson's ratio = 0·24.

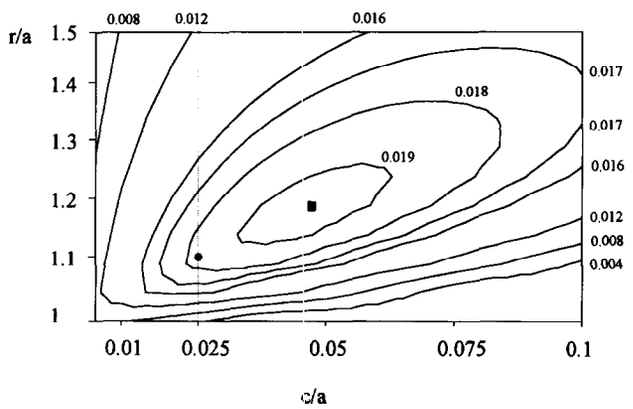

Fig. 2(c). Contours of normalized mode I stress intensity factors $K_I/(p_o\sqrt{\pi a})$ as a function of crack depth ($0{\cdot}005 < c/a < 0{\cdot}1$) and crack position ($1{\cdot}0 < r/a < 1{\cdot}5$). The filled circle shows the maximum value for $c/a = 0{\cdot}025$; at this position ($r/a \sim 1{\cdot}1$), $K_I \sim 0{\cdot}0182\, p_o\sqrt{\pi a}$. The filled square marks the position of the absolute maximum: $K_I \sim 0{\cdot}01937\, p_o\sqrt{\pi a}$ at $c/a \sim 0{\cdot}046$, $r/a \sim 1{\cdot}18$.

component of the Hertzian stress field. This integral equation is effectively represented by a set of linear algebraic equations, typically 20: the (normalized) mode I stress intensity factor can then be expressed in terms of the unknown coefficients in these linear equations. A standard computer library routine for solution of simultaneous equations is then employed. This technique is very well adapted to problems where cracks exist in a steep stress gradient. If the radial Hertzian stress (= $\tilde{\sigma}$) is expressed in terms of the peak Hertzian pressure, p_o, (eqn (3)) then the result of the calculation is a number μ which is related to the (dimensional) mode I stress intensity factor, K_I, by:

$$\mu = \frac{K_I}{p_o\sqrt{\pi c}} \quad \text{where} \quad \mu = f\left(\frac{r}{a}, \frac{c}{a}, \nu\right) \tag{5a}$$

Normalizing with respect to a (rather than c) we have:

$$\frac{K_I}{p_o\sqrt{\pi a}} = \mu\sqrt{c/a} \tag{5b}$$

The rationale for this second normalization is that the dependence of K_I on the crack size is now exclusively in the two terms on the RHS of the equation. All subsequent results presented below are in terms of this second normalization. Warren *et al.*[35] present results for the case where the sphere and the substrate are made of the same material. In this case the stress field in the substrate (and hence the values of K_I) depends on only one material parameter—Poisson's ratio of the substrate. Figures 2(a), (b) and (c) show some basic results from this analysis.

Figure 2(a) shows the normalized mode I stress intensity factor as a function of normalized crack length (c/a) for six normalized crack positions (r/a), for Poisson's ratio = 0·24. Figure 2(b) shows values for the normalized K_I as a function of r/a for six values of c/a; again $\nu = 0{\cdot}24$. Figure 2(a) shows that K_I has a maximum value as a function of c/a for each r/a; furthermore for large cracks situated close to the contact radius the implied value of K_I is negative (because the crack tip is now deep enough that it lies within the compressive region of the Hertzian radial stress). Figure 2(b) shows that for each c/a the maximum in K_I occurs for $r/a > 1$. This explains the well-known fact that ring cracks are always observed to form outside the contact zone, even though the surface radial stress has its largest value at $r/a = 1$. This point has been noted previously.[16,34,36] Figure 2(c) shows a contour plot of $K_I/(p_o\sqrt{\pi a})$ as a function of crack position and crack depth (both normalized). We note two things. For each c/a, we can mark the position of the largest normalized K_I—this is shown by the filled circle for $c/a = 0{\cdot}025$. At this position ($r/a \sim 1{\cdot}1$), $K_I \sim 0{\cdot}0182 p_o\sqrt{\pi a}$); $0{\cdot}0182/\sqrt{0{\cdot}025}$ is therefore the maximum value of μ (= μ_{max}) for this value of c/a, ($c/a = 0{\cdot}025$). μ_{max} is thus just a function of c/a and ν, $\mu_{max} = g(\frac{c}{a}, \nu)$. Secondly K_I has an absolute maximum—marked by the filled square, at $c/a \sim 0{\cdot}046$, $r/a \sim 1{\cdot}18$, $K_I \sim 0{\cdot}01937 p_o\sqrt{\pi a}$.

The above expressions are in terms of stress intensity factors; we will now re-write them in terms of loads. When K_I for one small surface flaw reaches K_{IC} (at a load $P = P_F$), it begins to grow—

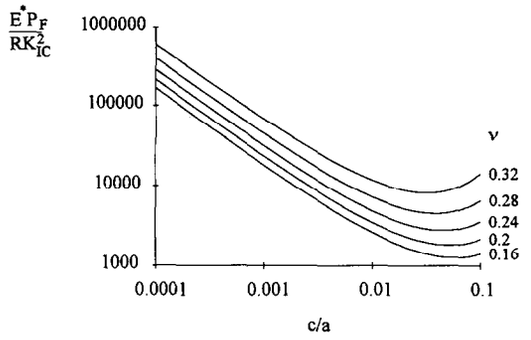

Fig. 3. Minimum normalized fracture load necessary to propagate a crack of normalized size c/a. Results for five different values of Poisson's ratio. The value of the absolute minimum for $\nu = 0{\cdot}28$ is shown.

to form either a ring crack or the well-known ring–cone system. Using eqns (1) and (3), equation (5b) becomes:

$$\frac{E^*P_F}{RK_{IC}^2} = \frac{\pi}{3\mu^2(c/a)} \tag{6}$$

We define a normalized fracture load, P_{FN}:

$$P_{FN} = \frac{E^*P_F}{RK_{IC}^2} \tag{7}$$

Assuming that the flaw distribution is dense enough so that there will always be a flaw (of size c/a) situated close to the position where the crack tip stress intensity experienced is a maximum (for this crack size) eqn (6) can be written

$$P_{FN} = \frac{\pi}{3\mu_{max}^2(c/a)} \tag{8}$$

These values of P_{FN} are therefore the minimum normalised loads necessary to propagate cracks of size c/a. Plots of P_{FN} as function of c/a (for five different values of ν) are shown in Fig. 3. For all values of Poisson's ratio there is an absolute minimum in the normalized fracture load for c/a values in the range 0·02–0·06. For a given ν, this absolute minimum in P_{FN} corresponds to the absolute maximum in $K_I/(p_o\sqrt{\pi a})$. For example, for $\nu = 0{\cdot}24$ Fig. 2(c) shows that the absolute maximum in $K_I/(p_o\sqrt{\pi a})$ is 0·01937; therefore the absolute minimum in normalized fracture load, P_{FN}^{min}, is $\pi/3/(0{\cdot}01937)^2 \sim 2790$. The values of these absolute minima and the corresponding values of c/a as a function of Poisson's ratio are shown in Fig 4 and also listed in Table 1. We emphasise that P_{FN}^{min} is a dimensionless quantity. (For all values of Poisson's ratio the absolute minimum in fracture load occurs at a relative crack position $r/a \sim 1{\cdot}20$.)

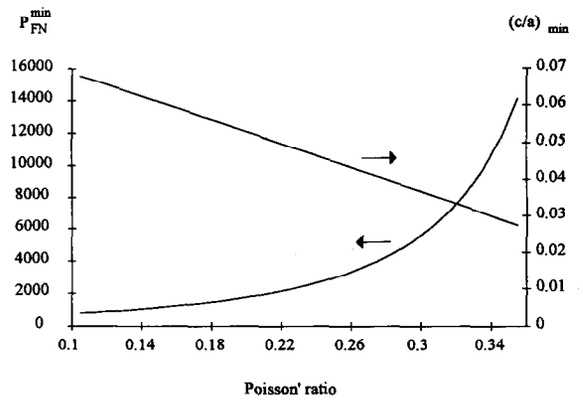

Fig. 4. Absolute minimum normalized fracture loads (P_{FN}^{min}) and the corresponding values of (c/a) as a function of Poisson's ratio.

Determination of K_{IC}

The principle of the method for determining K_{IC} is now clear. For a material with a given E^* and K_{IC} one searches for the minimum value of P_F/R. If one performs a series of Hertzian tests with a sphere of given R (25 tests should be sufficient), noting the fracture loads P_F, there exists a definite minimum load for fracture, as shown in Fig. 5. If one assumes that the crack propagated in this test (by a load P_{Fmin}) is of a size within the range where P_{FN} shows a minimum with c/a then the fracture toughness can be determined from the following equation:

$$K_{IC} = \left(\frac{E^*P_{F\,min}}{P_{FN}^{min}R}\right)^{1/2} \tag{9}$$

where the number P_{FN}^{min} can be read from Table 1 assuming that Poisson's ratio for the substrate is accurately known. Similar results, but for specific r/a values (r/a = 1·05, 1·10, 1·20) were published by Matzke *et al.*[17] Since typical Hertzian contact radii are of the order of a few hundred microns (for spheres with radii 1–5 mm), to obtain the appropriate c/a values shown in Table 1 one needs flaw sizes, $c > 10$ μm. Therefore the specimen surface should be prepared by coarse diamond polishing or abrasion with fine SiC grits. Severe grinding of the surface

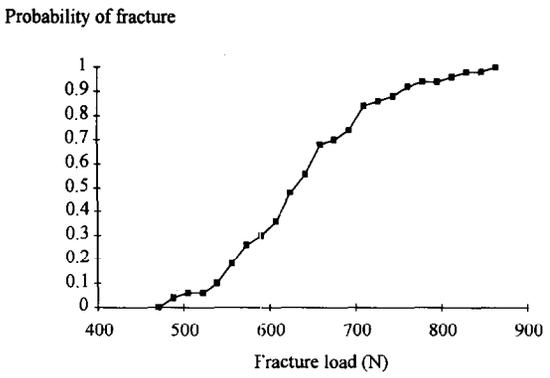

Fig. 5. Experimentally determined fracture loads, showing a minimum fracture load at P_F = 470 N. Material (substrate and sphere) — alumina; sphere radius = 2·5 mm.

may introduce flaws of suitable depth. but it is well known[37] that such treatment can introduce considerable surface residual stresses. The tests can then be repeated with spheres of different radii and the minimum value of P_{Fmin}/R found. This method requires no knowledge of the initial crack size, no measurement of the radius of the ring-crack seen on the surface after fracture, nor any measurement of the final depth of the cone-crack. It is important to note that the average fracture load found will give an overestimate of K_{IC} because not all cracks will be situated at the particular *r/a* value for which K_I, is a minimum—most cracks will be found at greater *r/a* values, since in reality the flaw density is not infinite.

It is appropriate here to discuss some of the limitations of this approach. With the sharp indentation method, part of the uncertainty in the analysis lies in the assumption of a particular crack geometry (median–radial or Palmqvist) after indentation. With the Hertzian method, the uncertainty lies in the value of the constant P_{FN}^{min}, which in turn depends on the assumed shape of the pre-cursor flaw before indentation. Warren *et al.*[35] assumed that the pre-cursor flaws were of a given depth *c*, but large in extent (with respect to the contact radius) across the surface, i.e. the sort of flaw produced by a sharp point dragged across the surface. Work is currently in progress[38] to evaluate stress intensity factors for different crack geometries, such as semi-circular or semi-elliptical flaws. The analysis presented here assumes that the sphere and the substrate are made of the same material. The method also assumes that the material does not show a substantial *T*-curve, i.e. increasing fracture resistance with crack extension. Finally, both the Vickers and the Hertzian method are affected by the presence of near-surface residual stresses. The Hertzian method may be particularly affected because the surface finish should specifically not be a fine diamond polish; the surface preparation method needs to be carefully chosen to produce 5–10 μm flaws without introducing residual stresses.

Table 2. Material properties

Material	*ν*	*E(GPa)*	P_{FN}^{min}
Glass	0·25	70	3131
Alumina	0·24	390	2790

Experimental Technique and Results

Hertzian indentation tests were performed using a modified ET500 testing machine (Engineering Systems (Nottm)*). A wide-band acoustic emission transducer was mounted in the loading train to detect the growth of a small surface flaw into the characteristic ring— or ring–cone-crack. Two different substrate materials were used—glass, and high purity (99·99%) alumina. The assumed elastic constants and the expected minimum normalised fracture load, P_{FN}^{min}, for the materials are listed in Table 2. In each case two different sphere radii were used—2·5 and 5 mm. The spheres were made of glass and alumina. The specimens had a variety of surface treatments: the alumina was either ground with 600-grit SiC slurry on a cast iron lap, or ground and then polished with 6 μm polycrystalline diamond powder; the glass was tested in the 'as received' condition, and also after grinding with 600-grit SiC. In each case about 25 tests were performed. The results are shown in Table 3 for glass and Table 4 for alumina. The average fracture loads (± one standard deviation) are also listed.

We therefore estimate the values of K_{IC} (derived from the minimum fracture loads from the SiC-abraded surfaces) to be 0·71–0·74 MPa $m^{1/2}$ for glass and 3·72–3·80 MPa $m^{1/2}$ for alumina. These values are in good agreement with those in the literature—for example Zeng *et al.*[28] found values 0·8 and 3·77 MPa $m^{1/2}$ for glass and alumina,

Table 3. Glass results

Surface treatment	*Sphere radius (mm)*	*Average fracture load (N)*	*Minimum fracture load (N)*	K_{IC} *(MPa* $m^{1/2}$*)*
As-received	2·5	290 ± 110	127	0·78
	5·0	638 ± 135	340	0·90
SiC grit	2·5	158 ± 95	105	0·71
	5·0	348 ± 107	231	0·74

Table 4. Alumina results

Surface treatment	*Sphere radius (mm)*	*Average fracture load (N)*	*Minimum fracture load (N)*	K_{IC} *(MPa* $m^{1/2}$*)*
SiC grit	2·5	739 ± 160	470	3·72
	5·0	1600 ± 280	982	3·80
Diamond	2·5	849 ± 145	540	3·99
	5·0	1751 ± 260	1273	4·33

respectively. It can be seen that in every case the average fracture load is at least 35% bigger than the minimum load, and as expected the calculated value of K_{IC} is most accurate for the most badly damaged surface indented with the smallest sphere. This is because the more damaged the surface the larger c/a because of the increase in c; the smaller the sphere the larger c/a because of the reduction in a. In either case, the more likely it is that a crack of the appropriate size will be found.

Some of the experimental limitations are now described. (1) The crack extension must be sufficiently rapid to be detected by the acoustic emission transducer.[39] In all cases here, the detection of an acoustic signal corresponded to the appearance of a circular crack seen on the surface; in a very few cases, examination of the surface after detection of a signal revealed the presence of two ring cracks, suggesting that the first fracture event was not picked up. Because the sphere and substrate were made of identical materials, it is unlikely that cracking occurred on unloading; Johnson *et al.*[31] showed that if the substrate is more compliant than the indenter then the frictional tractions at the substrate–interface, which reduce the radial tension on loading, enhance the radial tension on unloading. (2) If an acoustic emission transducer is not available then the detection of the minimum load must be done by trial and error. (3) Obviously, the substrate must crack before the sphere does, this was not found to be a problem but the fact that it may occur suggests that tough spheres with the appropriate elastic constants (to minimise the extent of elastic mismatch between the sphere and the substrate) might be used—for instance, glass–ceramic spheres to test glass, or silicon nitride spheres to test other engineering ceramics. The effects of elastic mismatch on Hertzian fracture have been analysed,[40] the use of different indenter materials can substantially affect the value of P_{FN}^{min}.

Conclusions

Use of a refined stress intensity factor formulation for surface-breaking cracks in steep stress gradients[35] has enabled accurate estimates to be made of the minimum loads necessary to propagate cracks by Hertzian indentation. At present the analysis only applies for the case where the sphere and the substrate are made of the same material. However, the analysis is comprehensive in that it can be applied to sphere–substrate systems with any value of Poisson's ratio. By measuring this minimum load (and that is the only quantity that must be measured) an accurate estimate of K_{IC} may easily be made. The only other requirement is that the surface should be coarsely polished and a sphere of relatively small radius (<5 mm) should be used.

Two further points are worthy of note. Because the only quantity that must be measured is a fracture load, it is possible that this method of determining K_{IC} can be automated. Also, the existence of an absolute minimum fracture load, for a given sphere size, suggests that the Hertzian indentation test could find use as a localized proof-test.

Mechanical Properties of C/SiC Composites as Explained from their Interfacial Features

Jean-François Després & Marc Monthioux

Laboratoire Marcel Mathieu, CNRS-UPPA, Centre Hélioparc, 2 avenue du Président Angot, F64000, Pau, France

(Received 10 March 1994; revised version received 28 June 1994; accepted 1 August 1994)

Abstract

Carbon fibre reinforced ceramic matrix composites with pyrolytic carbon interphases prepared following various conditions are compared, together with interphase-free composites. Four composite grades are thus defined, considering similarities in the ultimate tensile strength and strain values. Textural then structural investigations of the interfacial zones are performed from a centimetric to nanometric scale in an attempt to explain the specific mechanical features of the composites for each grade. Results show that the carbon interphase texture obviously controls the macroscopic behavior of the composites. Composite toughnesses are directly related to the relative strengths of the various interfaces, which depend on the covalent/Van der Waals bond ratio.

1 Introduction

Despite their high ultimate strength or elastic modulus values, monolithic ceramic materials have not been used as structural materials because of their lack of toughness. However, reinforcing them with carbon fibres, which may have both high ultimate strength and Young's modulus values, has allowed tough 2D ceramic matrix composites to be obtained,[1] making them convenient for structural uses in industrial applications.

However, composites only built with carbon fibres as reinforcement within a pure silicon carbide matrix, though reaching higher performances than the monolithic matrix, have a peculiar tensile strength/strain behavior. Considering curve 2 in Fig. 1, three different zones are seen as compared with an unreinforced bulk ceramic material (curve 1). From O to A, the composite exhibits a high elastic modulus value, which depends on the fibre/matrix volume proportions. In A, failures occur in the matrix, because of its lower ultimate strain value compared to the fibres. As failures generalize, multiple fracture of the matrix induces a high strain value, though the increase in strength remains low, resulting in the A—B plateau. In B, the multiple fracture is maximal and the slope of the curve becomes mainly influenced by the fibre modulus, assuming that, as discussed later, the fibre/matrix bonding is weak. The slope of the curve therefore increases (B—C zone). Finally, when the strain-to-failure value of the fibres is reached, fibres quickly break one after the other from C to D. D is the point of final rupture of the sample. The fact that fibres and matrix react successively instead of combining their properties does not provide a good example of the right composite. Such a behavior is specific from a two-component C/SiC composite. Fig.2 gives an example ('interphase-free' curve).

Changing the behavior becomes possible with adding a third component: the interphase (C/C/SiC composites). Fibres are therefore coated with a pyrolytic carbon interphase deposited from a chemical vapor deposition (CVD) process, prior to the densification with the silicon carbide matrix, also from a chemical vapor infiltration (CVI) process. The tensile strength/strain behavior of the resulting composites is now as shown in Fig. 2 ('Grade 3' curve for instance).

However, composites made of the same components (i.e. carbon fibres, pyrolytic carbon interphase, and SiC matrix) may have various ultimate strength and strain values, though coarsly following the same moduli (compare Grade 1, 2, and 3 curves on Fig. 2). Though useful anyway, the efficiency of the pyrocarbon interphase is therefore conditioned by factors other than the chemical nature of the components. The aim of the present paper is to determine these factors.

2 Experimental

All the composites were prepared by the Société Européenne de Propulsion (SEP), the details of

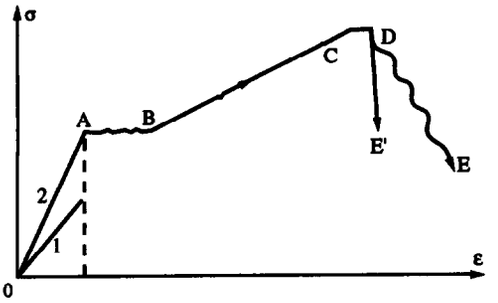

Fig. 1. Sketch of the tensile strength/strain trend for a bulk ceramic (curve 1) and a fibre-reinforced ceramic matrix composite (curve 2).

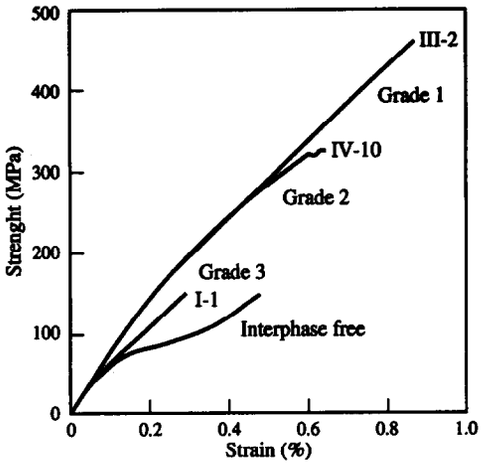

Fig. 2. Strength/strain behaviors for experimental C/C/SiC composites from the various grades and a C/SiC (interphase-free) composite.

which have to be kept confidential. They are built from about ten 2D carbon clothes (polyacrilonitrile-based fibres) which are stacked, then coated with a pyrolytic carbon interphase (from CVD) the thickness of which may vary from 80 to 800 nm, then infiltrated with a polycrystalline and pure SiC matrix (from CVI). Also, interphase-free composites were studied. Three different makes of carbon fibre have been used, including T300 from Toray (fibre A). However, no basic differences were detected in the resulting composites, though differences were observed between fibres. Discrepancies in surface topology between fibre types and the peculiar textural features of the T300 fibre (accumulation of cylindrical pores close to the surface, ring-like change in texture from isotropic to radial) were reported elsewhere from a TEM study.[2,3] As far as ultimate tensile strength, σ, and strain, ε, values coarsly evolve together (Table 1), the whole sample set (23 interphase-containing composites) is arbitrarily divided into three mechanical grades following a classification factor $F = \sigma \times \varepsilon$. Thus, composites from Grade 1 have $F > 350$, Grade 2 composites have $100 < F < 350$, and Grade 3 composites have $F < 100$. On the contrary, no relationships may be found between the grades and the interphase thickness. Tensile tests were performed by SEP according to their standard procedure (gauge length = 100 mm).

Textural and structural investigations have used a glass lens (macroscopic scale), a scanning electron microscope (SEM, micrometric scale) and a high resolution transmission electron microscope

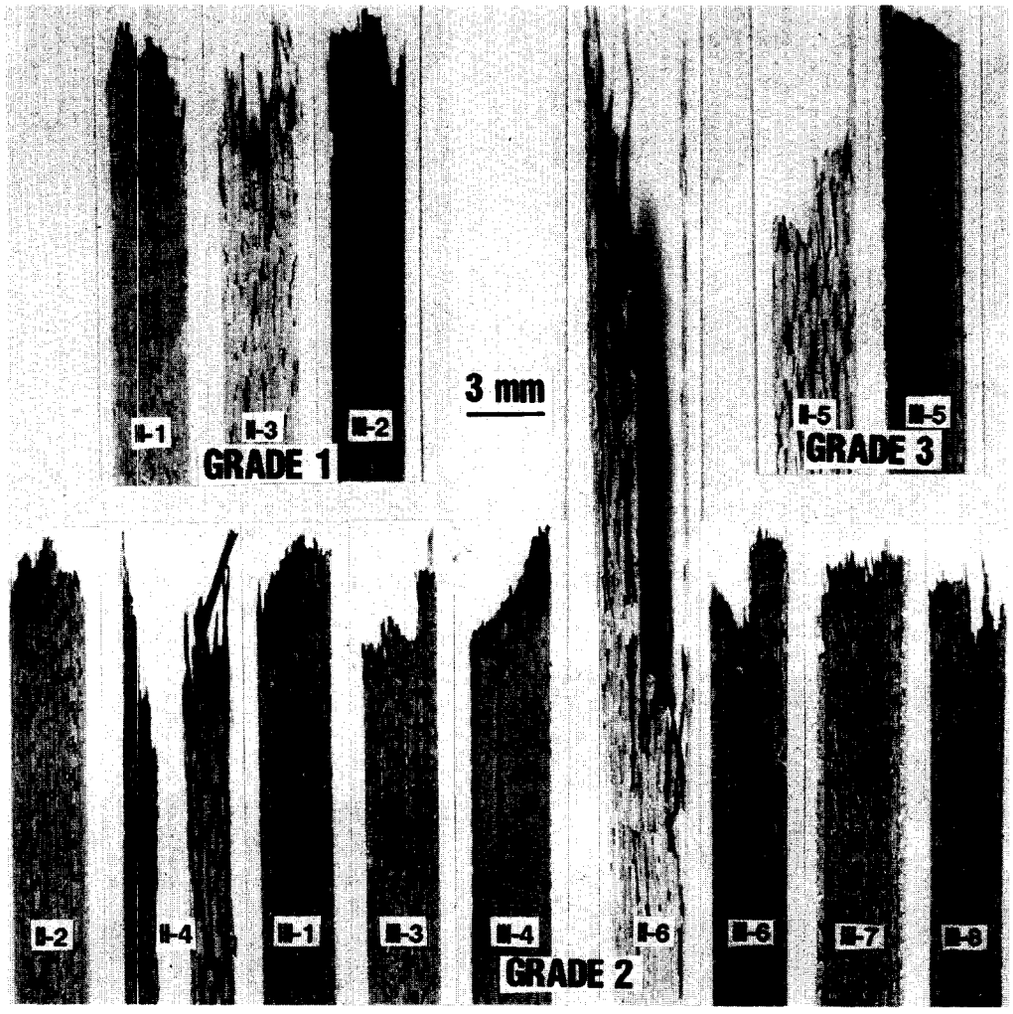

Fig. 3. Macroscopic fracture profiles of some composite samples from Grades 1, 2 and 3 (tensile test).

(TEM, nanoscopic scale). Only composite samples broken by the tensile test were examined by the glass lens and SEM (which required a Au coating to prevent charge effects). For TEM examinations, samples were taken from composites using diamond drilling performed far from the damaged zone, then prepared using a diamond saw into 3 mm disks, which were mechanically thinned (diamond powder polishing) then ion-thinned with argon ions (Gatan DUOMILL and IONTECH). TEM microscopes were Philips CM12 and Philips EM400 (120 kV). Contrasted bright field (BF), dark field (DF), lattice fringes (LF) and selected area diffraction (SAD) modes were used following conventional procedures; DF was more specifically[4] used for imaging carbon. Regarding the micrographs, DF images are mainly obtained from the 002 reflection of polyaromatic turbostratic carbon. Any graphene stack (graphene = a single polyaromatic layer) not disposed edge-on relative to the electron beam (i.e. not disposed perpendicularly to the plane of the picture) will therefore not be imaged. Because of the use of a small objective aperture, the DF images are built only with a small length of the 002 ring and therefore provide directional information. Taking two successive pictures using two orthogonal positions for the objective aperture helps any possible anisotropy to be revealed. If the two pictures appear statistically identical, (similar number and size of bright domains) the carbon material is isotropic (zone 1 in Fig. 11 for instance). If they are not, the carbon material is anisotropic (zone 2 in Fig. 11 for instance). The mean azimutal orientation is shown by the '=' sign on each picture.

Optical diffraction using a laser source has also been performed on original LF micrograph films, when lattice fringes were imaged. The diffraction patterns thus obtained act as a very local electron diffraction (scattering area is about 600 nm^2).

3 Results

3.1 Macroscopic scale

The tensile test samples were examined after mechanical testing, in order to tentatively reveal any possible correlation between the fracture profile and the mechanical behavior observed. Figure 3 illustrates the fracture profiles of the tensile test

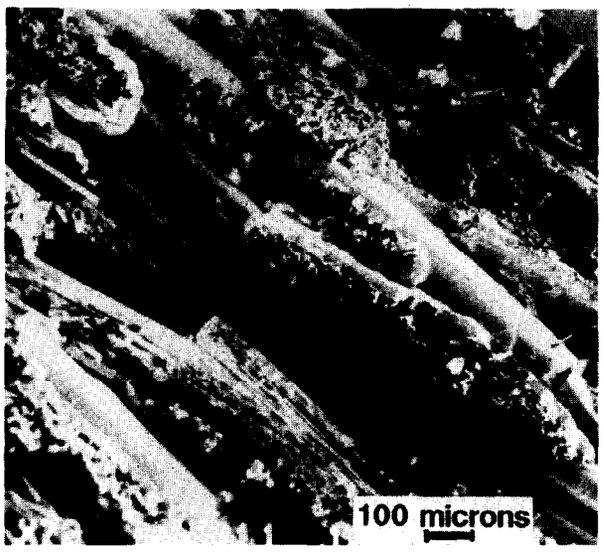

Fig. 4. Characteristic enlarged SEM view of tows within any C/C/SiC composites. Tows may often be considered as independent entities.

Fig. 5. Example of the mechanical independence of neighboring tows: one is fractured, while the transverse one is not (SEM view).

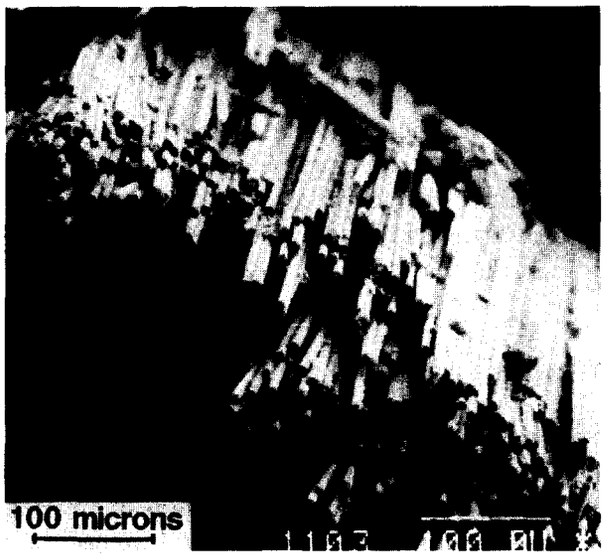

Fig. 6. Typical SEM view of the fracture surface of a tow within a Grade 1 composite.

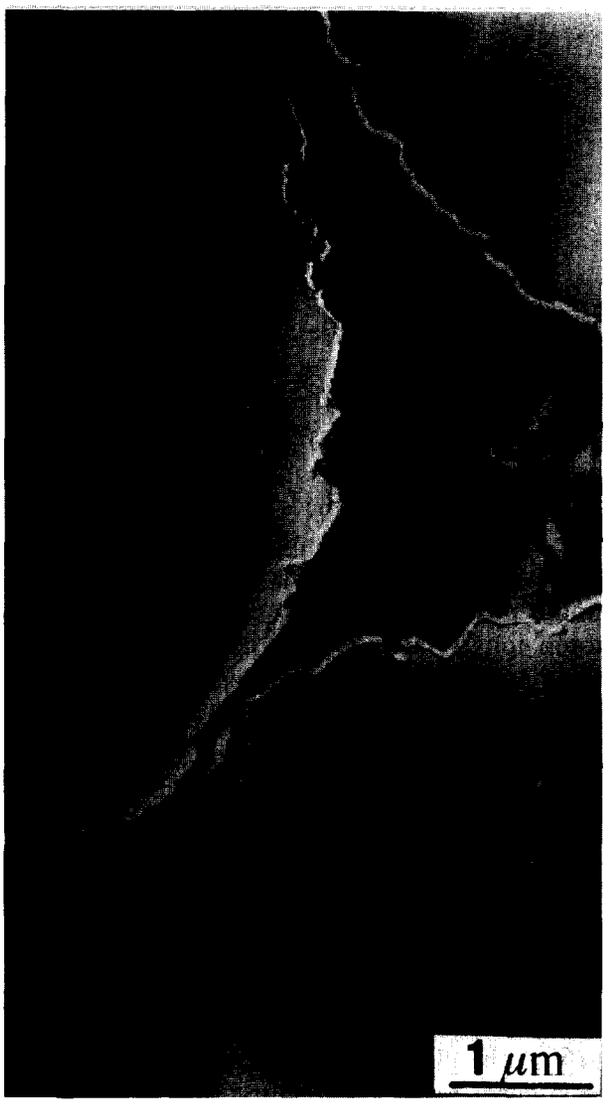

Fig. 8. Low magnification BF TEM view of a decohesion path in an interphase-free composite (C/SiC).

samples of some composites from Grades 1, 2, or 3. Obviously, a specific grade is not characterized by a specific fracture profile. For instance, samples II-5 and III-5, though both from Grade 3, exhibit very different fracture profiles. The profile amplitude is about 10 mm for the former, while only 2 mm for the latter. Likewise, samples II-6 and III-1 from Grade 2 have fracture profile amplitudes of 30 and 3 mm respectively. Therefore, no simple relationship exists between the fracture profile and the ultimate tensile strength value of the C/C/SiC composites.

3.2 Microscopic scale

A general statement is that all the C/C/SiC composites are built from an elementary entity, which is defined as a tow of pyrocarbon-coated carbon fibres, covered with a silicon carbide sheath which is more or less able to densify the tow (Fig. 4). This suggests that tows should be independent of one another regarding failure propagation, as illustrated in Fig. 5 which shows that a longitudinal entity has been damaged, while the neighboring transversal entity has not.

Starting from the statement above, simple correlations are now able to be found between the fracture profiles and the various grades, when considering the tows as 'basic mechanical units'. Indeed, any Grade 1 composite was found to mainly contain tows exhibiting fibre pull-out at the fracture surface (Fig. 6), while any Grade 3 composite was found to mainly contain tows exhibiting an almost planar fracture surface (Fig. 7). Therefore, the fracture profiles of the tows, rather than the fracture profiles of the composites, are related to the macroscopic mechanical features of the C/C/SiC composites. Obviously, this must be governed by the behavior of the pyrolytic carbon interphase within the tows.

3.3 Microscopic and nanoscopic scale

Prior to describing the pyrocarbon-containing composites, Figs 8 and 9 illustrate some specific features of the pyrocarbon-free composites. Firstly, decohesions at the fibre/matrix interface

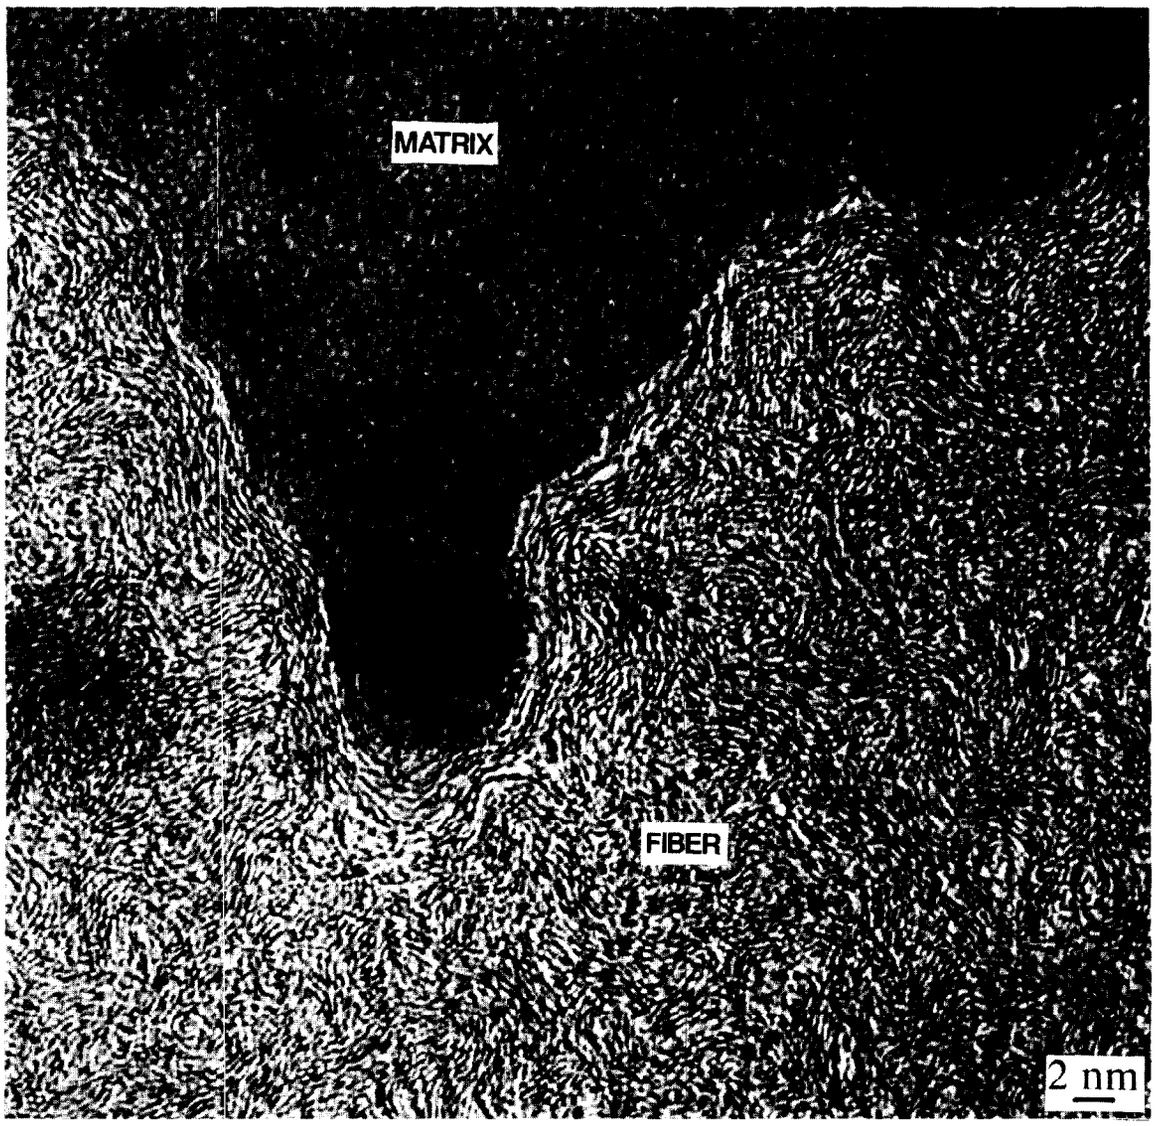

Fig. 9. LF TEM image of the fibre/matrix interface in an interphase-free composite (C/SiC).

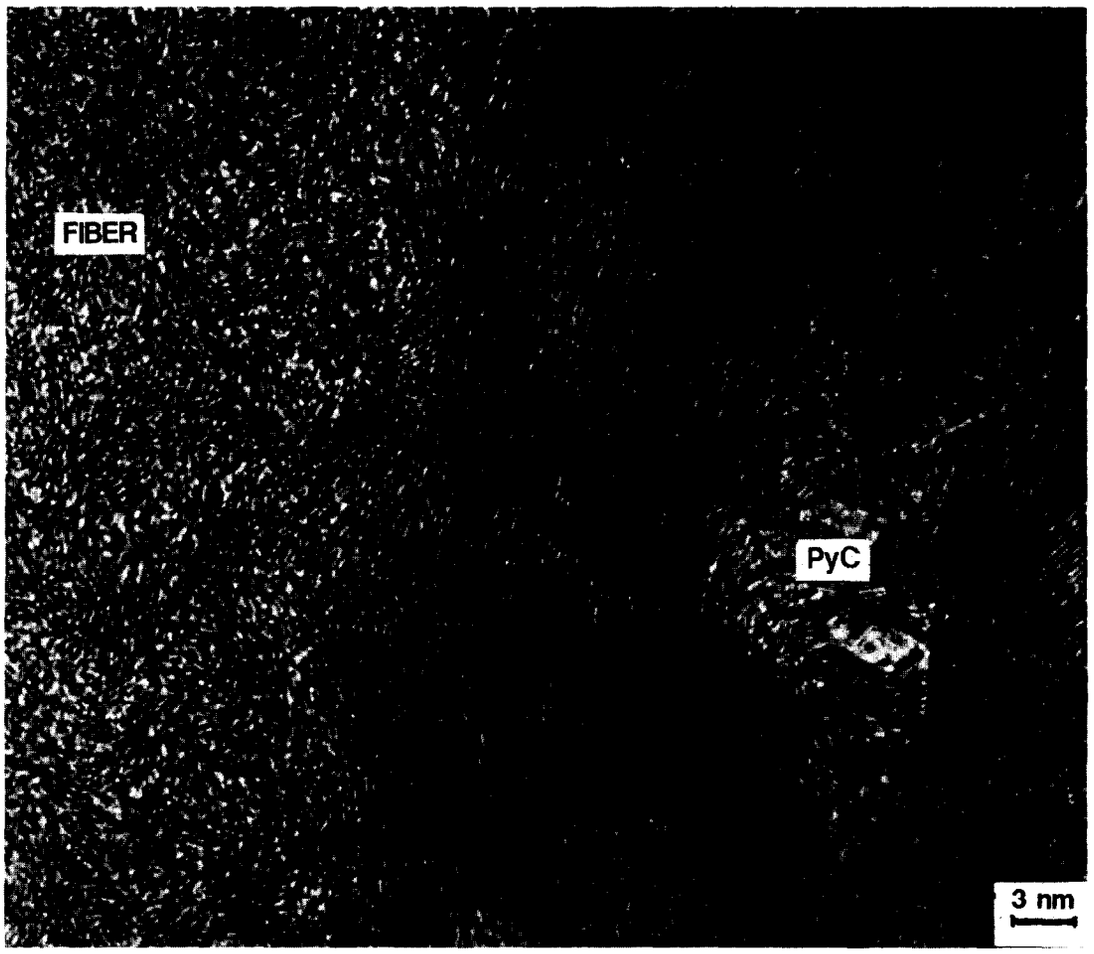

Fig. 10. LF TEM image showing how the fibre surface induces a local anisotropy of the graphene stacks at the very beginning of the pyrolytic carbon deposition.

are systematic (Fig.8), indicating that no chemical interactions occur between the carbon of the fibre and the SiC crystals. Because no pyrocarbon is covering the fibre surface, the texture of the graphene stacks at the fibre surface is clearly observable (Fig. 9). Obviously, the last 3–5 graphene layers are oriented parallel to the fibre surface (T300 fibres in that case). Such a texture does not help in promoting chemical reactions between polyaromatic carbon and SiC. Decohesions are certainly due to the difference in thermal expansion coefficients (TEC), i.e. 15–20 $\times$ 10^{-6}/K for the fibre transversally, and 4 $\times$ 10^{-6}/K for the SiC matrix, rather than to the mechanical test, and therefore are an intrinsic feature of the composites. However, because of the lack in adhesion between the fibre and the matrix, the multiple fracture of the matrix is probably not directly due to the difference in TEC but to the anisotropic stresses induced by the presence of the reinforcement during the shrinkage of the matrix when cooling. Figure 9 also illustrates the depth of the roughness of the fibre (T300) surface, which can reach about 25% of the fibre diameter for the T300, while only about 3% and 10% for fibres B and C respectively.

Investigating all the samples using TEM has allowed three interfacial pyrocarbon texture types to be described. Whatever the texture type or the grade for the C/C/SiC composites, the first ten nanometers of the pyrolytic carbon are deeply influenced by the fibre topology (Fig. 10). Graphene stacks are highly anisotropic and lie flat upon the fibre surface, despite its rather high roughness.

3.3.1 Bimorphic interphases

These are made of two parts of equal thicknesses. The pyrolytic carbon texture of the fibre-side part is identified as 'bulky oriented isotropic' (BOI-PyC), i.e. all the possible orientations are found for the graphene stacks which the pyrocarbon is made of, but a main specific orientation—parallel to the interfaces—is found (Fig. 11, zone 1). The pyrolytic carbon texture of the matrix-side part is described as 'anisotropic' (ANI-PyC), since no graphene stacks oriented perpendicularly to the main direction of orientation—again parallel to the interfaces—are found (Fig. 11, zone 2). At high magnifications (LF mode), the change in texture from zone 1 (BOI-PyC) to zone 2 (ANI-PyC) appears progressive (Fig. 12). The related optical

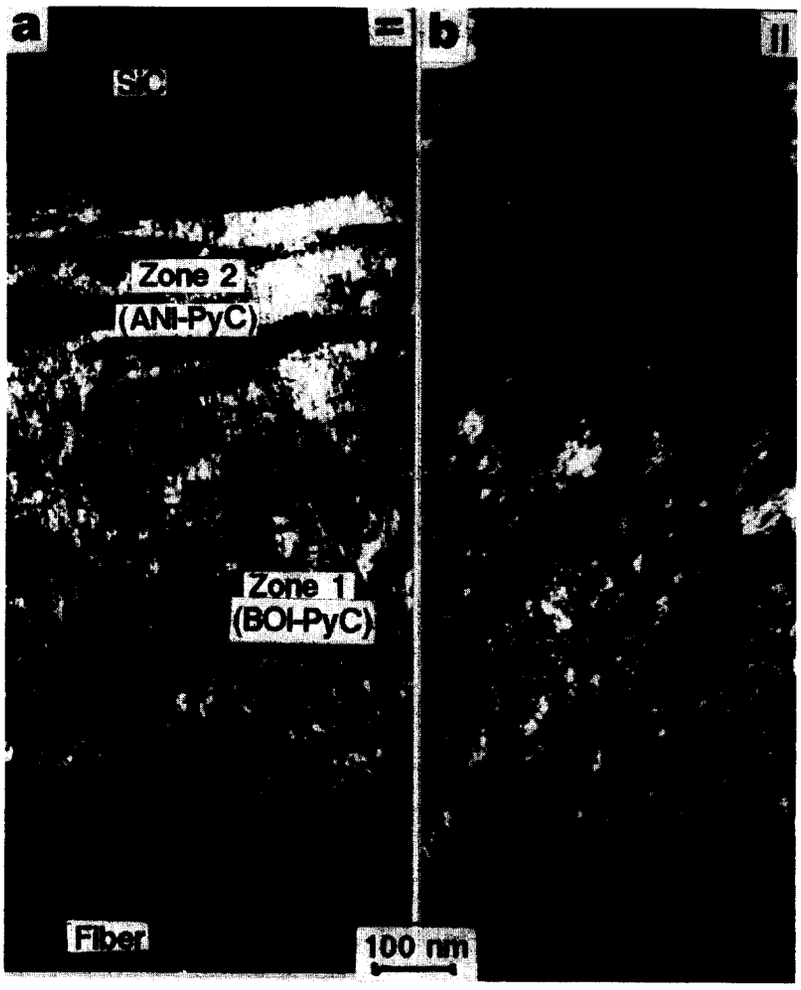

Fig. 11. C_{002} DF micrographs of a bimorphic-type interphase: two orthogonal orientations are imaged. (a) The two parts (zones 1 and 2) of the pyrocarbon interphase appear very bright. (b) Zone 1 is still lighted-on but does not appear bright, while zone 2 appears dark. Zone 1 therefore corresponds to a bulky oriented isotropic carbon (BOI-PyC) and zone 2 corresponds to an anisotropic carbon (ANI-PyC).

diffraction patterns in Fig. 12 well illustrate how the anisotropy increases from the fibre side (bottom) to the matrix side (top). The 002 ring is progressively replaced by two 002 arcs, the angular opening of which decreases as the extent of angular misorientations between graphene stacks decreases, and therefore becomes smaller. Close to the matrix (Fig. 13), the graphene stacks are very well organised, inducing a high anisotropy and a specific contrast effect as dark bands (so-called Bragg fringes) perpendicular to the direction of carbon layers.

Within the ANI-PyC texture (zone 2), slit pores are often observed, actually indicating a lenticular porosity, as far as the transverse or longitudinal views of the interphase are identical. Pore walls are made of sheets of graphene stacks locally disconnected (Fig. 14). Lateral transitions from area of high compactness to area with lenticular porosity are rather sudden, and nearly periodic (Fig. 15).

Within the bimorphic interphase type, decohesions always occur either at the pyrocarbon/matrix interface, or at the zone 1/zone 2 transition or within the ANI-PyC (Fig. 16). Obviously, the anisotropic but entangled texture is efficient in dispersing the fracture energy through a multiple fracture effect.

3.3.2 Carbon wall-ending interphases

The main part of the interphase is from the BOI-PyC type, previously described. It corresponds to the light-on part in Fig. 17(a). However, the very end part of the carbon interphase (i.e. matrix side) is made of a different texture, specifically long carbon walls preferentially oriented perpendicularly to the interfaces. They are shown in Fig. 17(b). The carbon wall zone is highly porous as seen in Fig. 18, which also illustrates the perfection of the graphene layers within the walls since they exhibit Bragg fringes, which indicate their high organisation. Important features are that the walls penetrate deeply within the SiC matrix (Figs 17(b) and 19), sometimes as far as 100 nm. The end tip of the carbon walls may exhibit an edge shape which enhances the possibility of chemical bonding with the surrounding SiC crystals (Fig. 19).

Within the carbon wall-ending interphases, decohesions are always observed at the BOI-PyC/fibre interface, or within the BOI-PyC (Fig. 20).

3.3.3 Mixed interphases

These exhibit textures combining features of both interphases. Thus, the whole pyrocarbon texture may be a mere BOI-PyC texture without being associ-

ated with any carbon-wall or ANI-PyC texture (Fig. 21, right), or may also be similar to a bimorphic type including a ANI-PyC part—but with a lower anisotropy (Fig. 21, upper left, Fig. 22). Anisotropic textures may be associated with graphene layers penetrating the SiC matrix and therefore resembling a carbon wall-ending interphase (Fig. 22).

4 Discussion

There is an exact correspondence between the three texture types of the pyrocarbon interphase described above and the three composite grades as defined in Section 2. Specifically, all the Grade 1 composites exhibit bimorphic pyrocarbon interphases. Grade 3 composites exhibit carbon wall-ending pyrocarbon interphases, and Grade 2 composites contain mixed interphases.[5] Considering the latter grade, it is worthy to note that interfacial areas may have different textures, though very close to each other (Fig. 21). On the contrary, Grades 1 and 3 are homogeneous.

Therefore, textural discrepancies in the interphases may originate from differences in deposition conditions. In addition to differences in the process, differences may also be very local, as shown by the interphase heterogeneities found in Grade 2 composites. This was rather expected, because of the 3D porous feature of the preform which is likely to induce local differences in gas flows, partial pressures, turbulences, etc. On the other hand, regarding the effect expected from a porous substrate, the interphase homogeneity of Grade 1 or 3 composites is remarkable.

4.1 Bonding strength of the various interfaces

Considering all the interface types encountered and the location of the decohesion paths in the composites (whatever the grade) allows the various interfaces to be ordered following the increasing bonding strength (Table 2). Actually, decohesions, due to either the tensile test or the preparation method for TEM examination, indicate the weak interfaces within the composites. Obviously, the weakest interface is the fibre/matrix interface in the pyrocarbon-free composite.

The ANI-PyC/matrix interface in Grade 1 composite is stronger but still weak, since no chemical bonding other than weak interactions are allowed by the planar (polyaromatic) faces of graphene

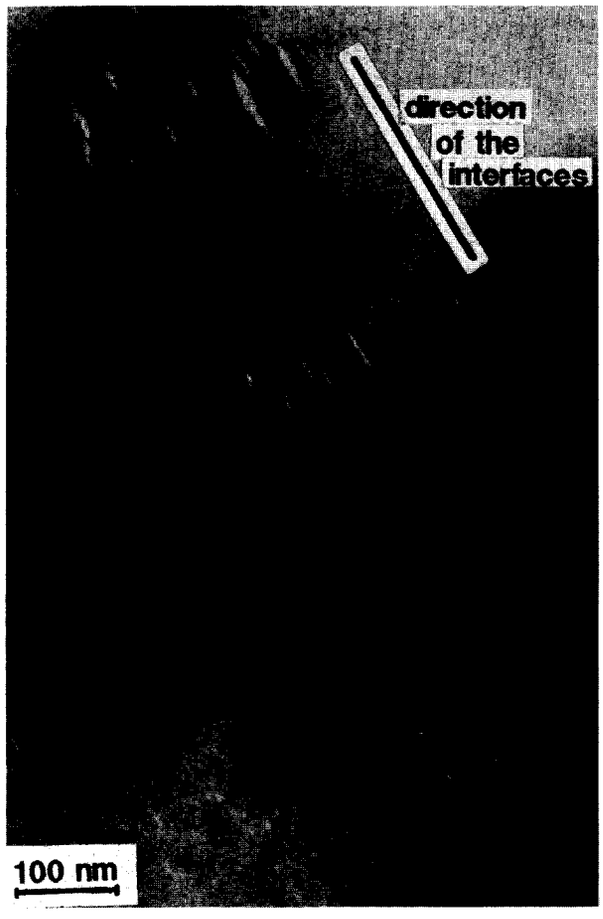

Fig. 15. BF TEM image of a carbon interphase exhibiting a nearly periodic occurrence of the lenticular porosity.

sheets. It could be wondered why the interface always exhibits a PyC/matrix contact (except when disturbed by a failure due to the mechanical test) instead of showing the same voids due to TEC differences, as in the pyrocarbon-free composite. This is probably due to a compensation effect of the pyrocarbon interphase, which is related to the presence of the lenticular porosity in the ANI-PyC part, and which will be discussed later.

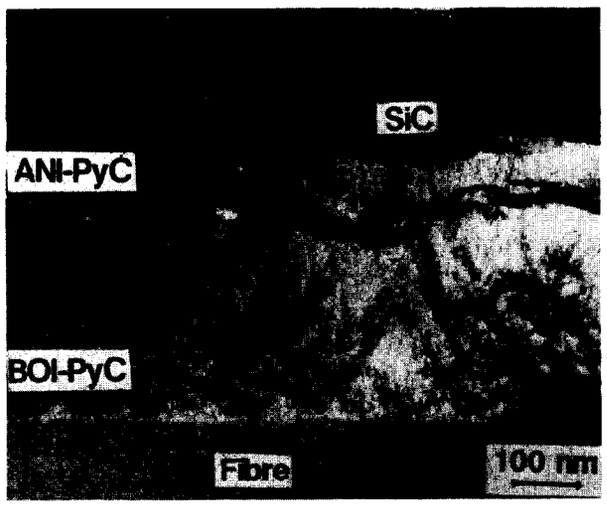

Fig. 16. Low magnification C_{002} DF image of a decohesion path within a bimorphic-type pyrocarbon interphase.

Table 2. Classification of the various interfaces in order of decreasing bonding strength

Interface	*Grade*	*Bond*
PYCX/matrix	3	σ chemical bond
Fibre/PyC	All	A majority of σ, and Van der Waals
PyC/matrix	2	Van der Waals and σ
BOI-PyC/ANI-PyC	1	Van der Waals and σ
PyC/matrix	1	Van der Waals
Fibre/matrix	Free	'Mechanical' bond

However, placing this interface type before or after the BOI-PyC/ANI-PyC interface in Table 2 is difficult since it depends on the degree of mixity.

Certainly stronger is the BOI-PyC/ANI-PyC interface in Grade 1 composites, since it allows both Van der Waals bonds—when graphene sheets are arranged face to face—and chemical (covalent) bonds—when graphene sheets are arranged edge-to-edge, or through defect sites.

The BOI-PyC/matrix interface in Grade 2 composites is stronger than the ANI-PyC/matrix interface mentioned above since it enhances the possibility of covalent bonds.

Even stronger is the fibre/BOI-PyC interface in Grade 1, 2, or 3 composites, where one failure only has been observed among about 100 interfaces investigated. Proportions of covalent bonds are higher than with the BOI-PyC/ANI-PyC interface, though also dealing with graphene/graphene interactions. It is assumed that the proportion of potential sites for covalent bonds increases as the number of defects and grain boundaries increases, with respect to the mean size of the coherent domains (i.e. the length *La* of the straight carbon layers within associated graphene stacks). Actually, it is obvious that the sizes of the coherent domains are smaller for the carbon fibre (see Fig. 9 for instance, where *La* ~2 nm) than for the pyrolytic carbon deposit (see Fig. 10 for instance, where *La* = 3–5 nm for the BOI-PyC deposit, and Fig. 13 for instance, where *La* > 10 nm for the ANI-PyC deposit). In addition, the BOI-PyC/fibre interface, because of the fibre topology, is much rougher than the ANI-PyC/BOI-PyC interface, which is not likely to promote easy delamination. Therefore, both structural and textural considerations are able to explain the difference in strength between the two graphene/graphene interfaces.

Finally, the strongest interface is the PyC/matrix interface encountered in Grade 3 composites, which is characterized by carbon walls perpendicular to the interface and deeply inserted into the matrix. This originates from the fact that the carbon walls are strongly linked on the one hand to the pyrocarbon on the other hand to the SiC

crystals by σ bonds. The high strength of the aromatic C = C bonds (the highest for solids) of the nearly perfect graphenes which the carbon walls are made of prevents any strain or shearing to occur, either perpendicular or parallel to the interface.

4.2 Mechanical behavior of the composites related to their interfacial features

Considering Table 2 explains why Grade 3 composites have the strongest fibre/matrix bonding of the sample set. Indeed, they contain the two

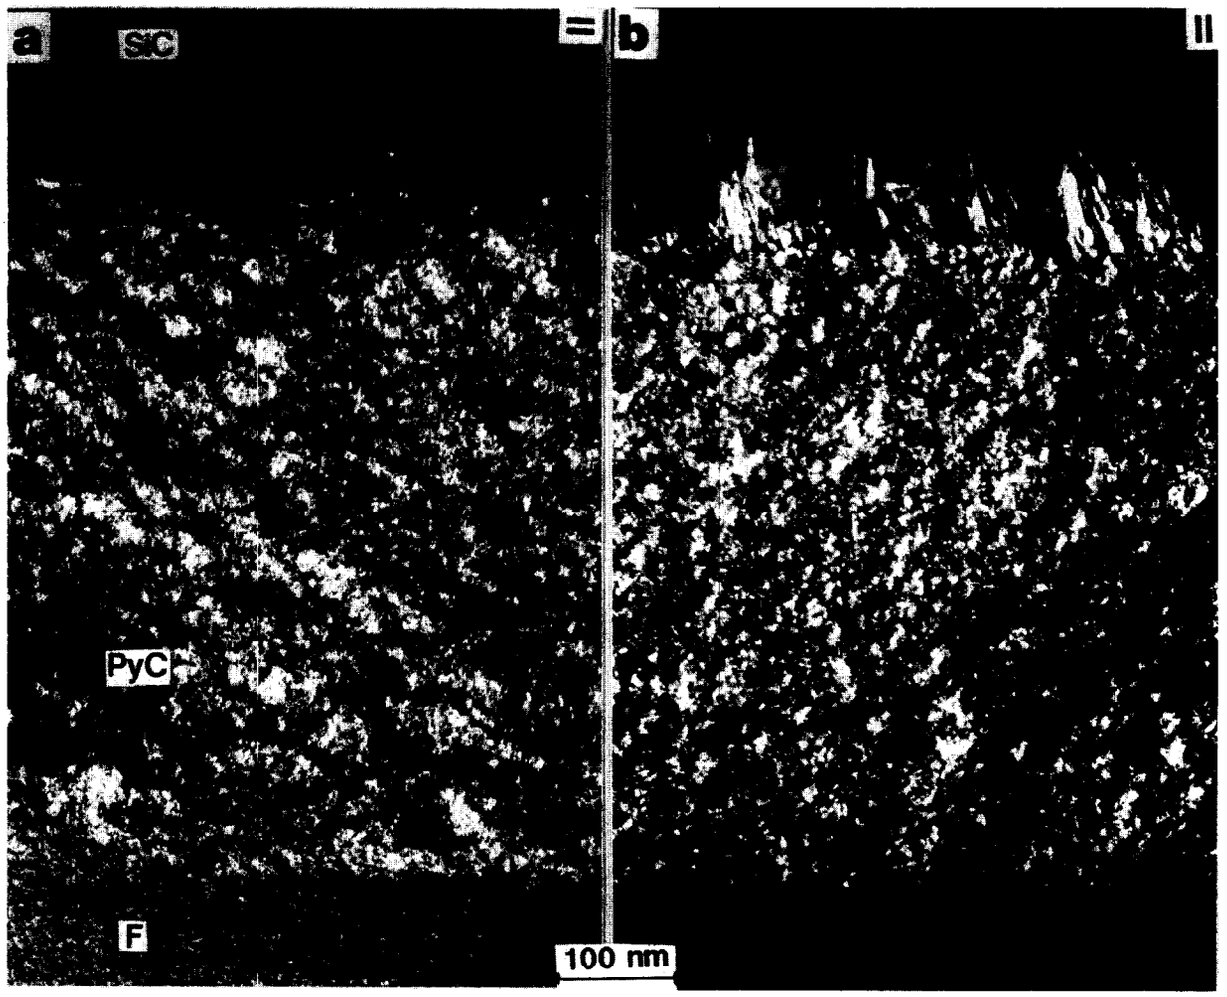

Fig. 17. Two orthogonal DF TEM images of a wall-ending type pyrocarbon interphase. Comparing (a) and (b) indicates that the whole pyrocarbon interphase is from the BOI- PyC type texture. Micrograph (b) clearly evidences the carbon walls (see text) as bright stripes oriented perpendicularly to the pyrocarbon/matrix interface.

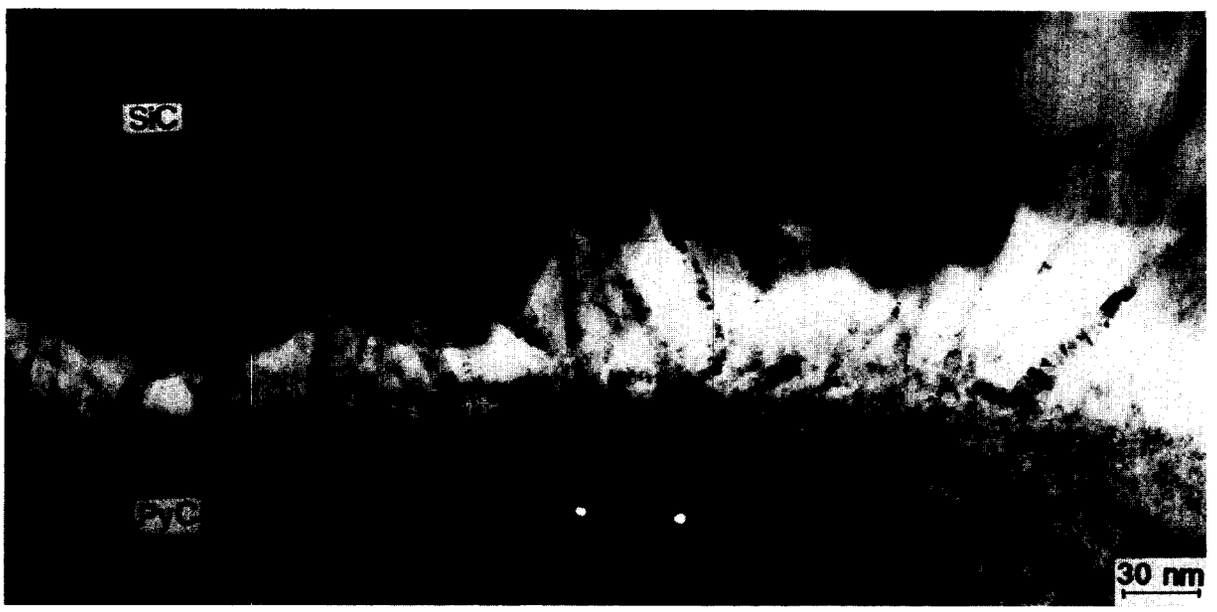

Fig. 18. BF TEM image of a carbon wall area. Note the high porosity.

strongest interfaces encountered. Therefore, a failure will progress straight from the matrix (which is the component with the lowest deformability) to the fibre through the interphase, in order to follow the strain induced by the opening of the failure edges (Fig. 23(a)). At the other extreme, Grade 1 composites have two weak interfaces, in which the

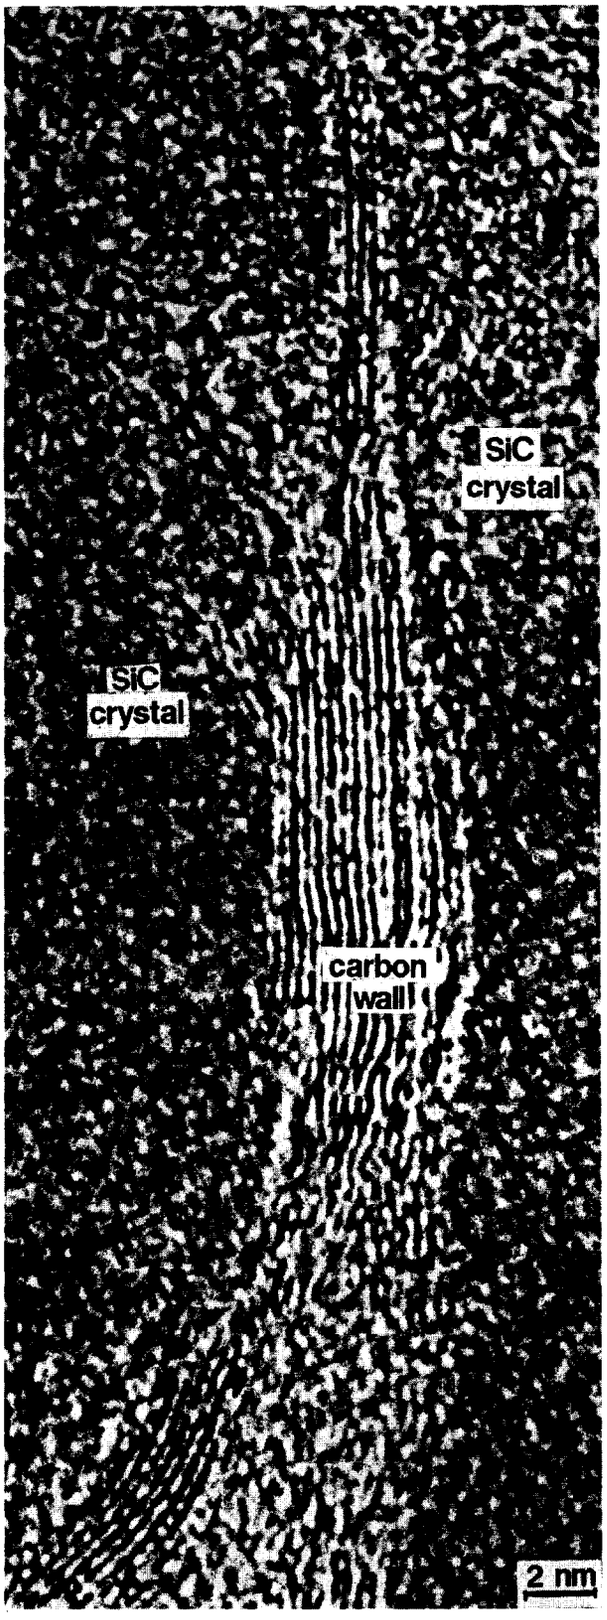

Fig. 19. LF TEM image of the end tip of a carbon wall between SiC crystals, exhibiting a peculiar edge-shape.

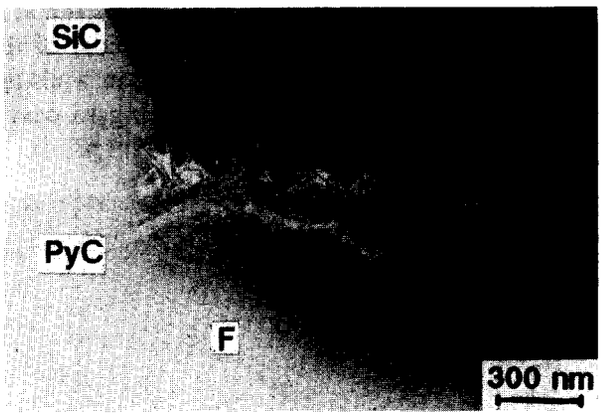

Fig. 20. Low magnification BF TEM view of a decohesion path within a carbon wall-ending type pyrocarbon interphase.

ANI-PyC part of the interphase is involved. Because the ANI-PyC is able to easily delaminate due to the anisotropic orientation of graphenes, the strain which goes with the crack propagation will not concern the fibre since it is somewhat compensated by a mode I/mode II change of the failure path (Fig. 23(b)). Successive delaminations within the ANI-PyC will help the fracture energy to disperse, and are likely to restrain the failure propagation until possibly stopping it. The fibre rupture will thus be delayed, leading to the highest ultimate strength values. Describing such an interphase as a 'fuse' is common but not appropriate, as far as the 'fuse' concept would mean that the interphase would not play any role in the mechanical behavior of the composite but once, i.e. until a critical value for the applied strength is reached

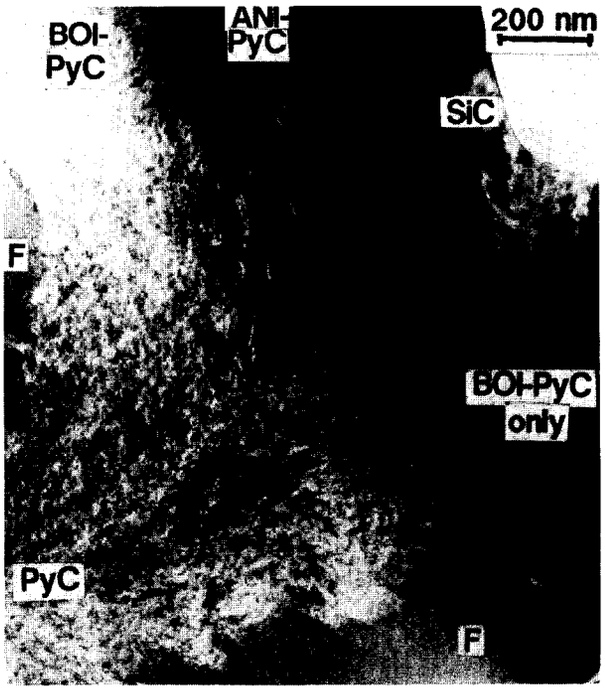

Fig. 21. BF TEM view of an example of mixed type associated interphases.

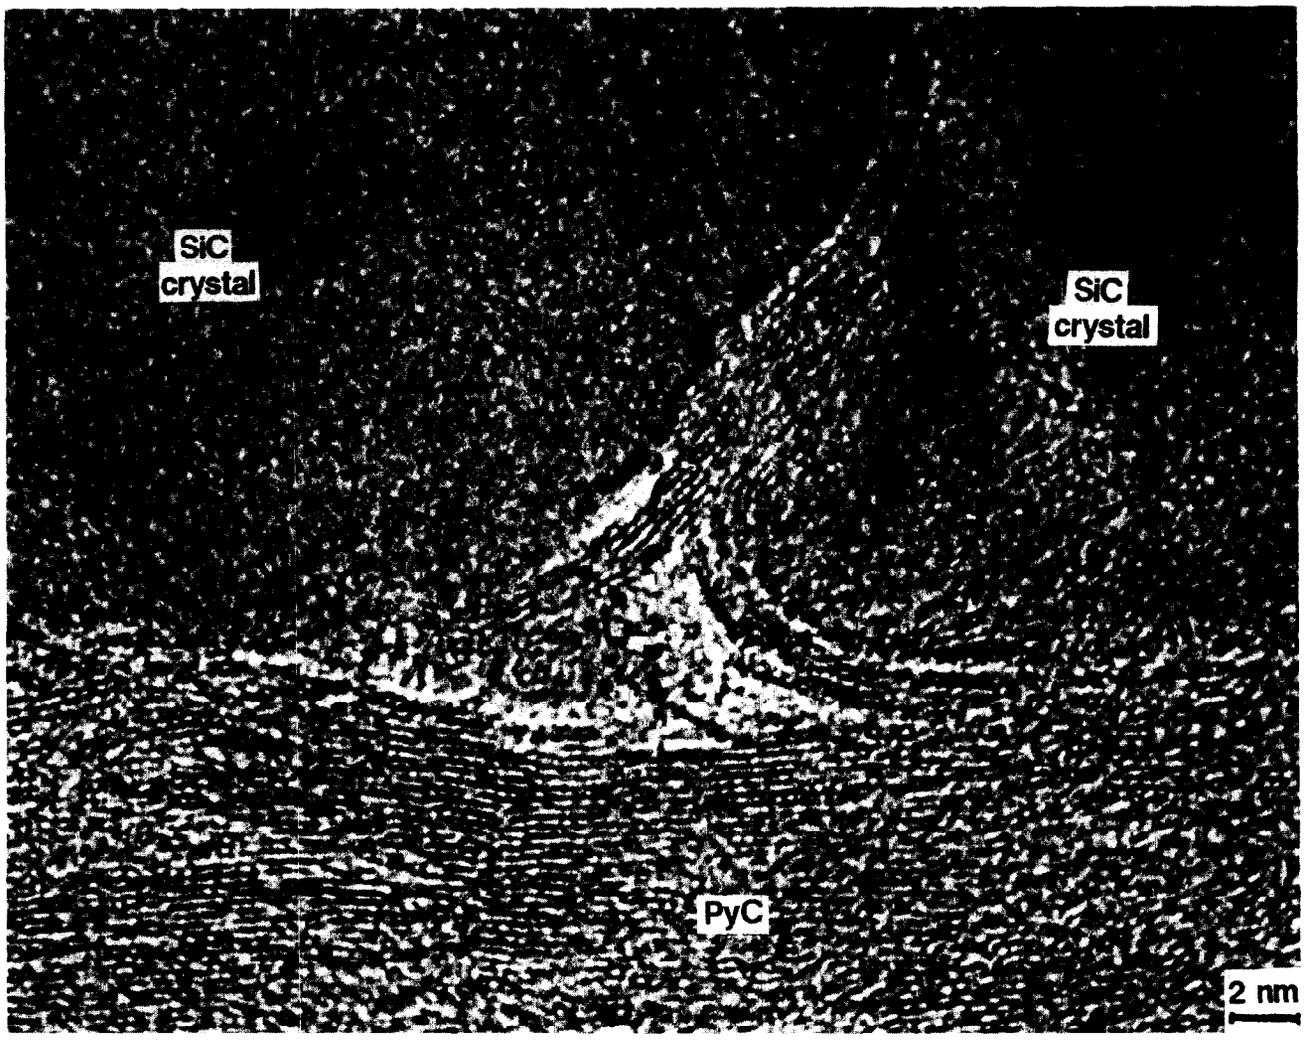

Fig. 22. LF TEM image of an example of a mixed type interphase. Note the combination of a ANI-PyC type texture with a carbon wall-ending type texture.

(corresponding to the fusing current for the electrical fuse). Obviously, the role of the interphase is not that binary, since helping in preventing the failure far before the ultimate strength is reached.

These considerations are consistent with the observations that tows exhibit mirror type fracture profiles in Grade 3 composites, while they do not exhibit planar fracture profiles in Grade 1 composites.

Due to the intermediate features of their interphases, Grade 2 composites logically behave intermediately, combining the two extreme fracture mechanisms described above in various proportions.

Finally, Table 2 indicates that the interphase-free composite has the weakest interface (PyC/fibre interface). Because differences in CET induce an interfacial void, the interface is too weak to allow the fracture energy to disperse. Even though the mode I failure propagation will again change for a mode II, the energy is fully maintained and the stress is quickly transferred to the fibre. However, the fibre will not break in front of the failure exit site within the matrix, but somewhere else along the fibre where strength is weakened by defects.

4.3 Origin of the carbon walls

Carbon walls, lying perpendicular to the interface at the pyrocarbon/matrix transition, are mainly observed in Grade 3 composites. Because they have been already observed in pyrocarbon-free SiC/SiC composites,[6–8] they have to be considered as an early step phenomenon of the SiC matrix deposition process, rather than a late step phenomenon of the pyrocarbon deposition process. They have been previously assumed to originate from the transformation of SiC crystals into C (and SiO_2, because of the presence of oxygen traces),[6] or to the decomposition into Si species and solid C of the early SiC crystals which could be abnormally unstable.[7,8] Indeed, some time is certainly required for the CVI process parameters to reach the steady-state, inducing transient and inappropriate turbulences, gas proportions, etc.[7,8] Both hypotheses are complementary, and oxygen

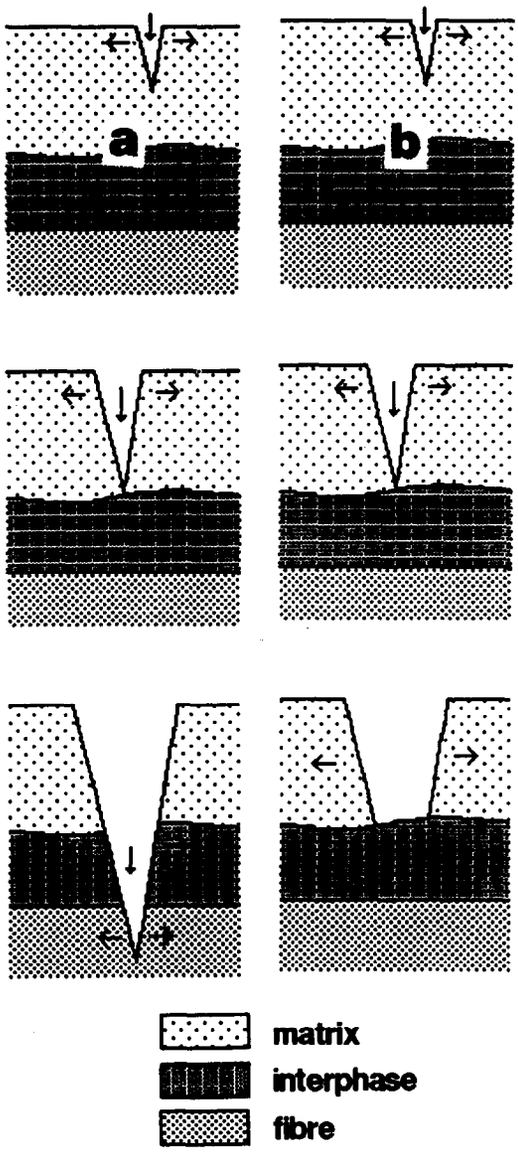

Fig. 23. Sketches of failure propagation: (a) Grade 3 composites; (b) Grade 1 composites.

traces present at the early step of the CVI process are likely to combine quickly with Si to form gaseous SiO. No silica was observed in our composites, nor those of Refs 7 and 8, but SiO_2 may be reduced to gaseous SiO as soon as gaseous hydrocarbons or hydrogen are present. Actually, such gases are used in the CVI process. Also, the presence of oxygen traces and hydrocarbons may possibly promote the direct transformations of SiC into gaseous SiO, SiH_4, SiH and solid C.[9]

4.4 Lenticular porosity

Grade 1 composites often exhibit a lenticular porosity, located within the ANI-PyC part of the bimorphic interphase. The texture suggests local decohesions between graphenes, favored by the weakness of the graphene/graphene interactions (when parallel). Such decohesions do not seem to occur spontaneously in anisotropic pyrolytic carbon films when deposited on polished alumina plates at least in the 1050–1200°C temperature range.[3,10] Therefore, we assume that they are again due to differences in TEC. Actually, the TEC for the fibre is about 20×10^{-6}/K in a transverse direction, since it is statistically isotropic. This is rather high as compared with the TEC value in the direction of the graphene sheets, which is similar to that of graphite, when considered parallel to the graphene direction (no expansion). Likewise, the TEC on the ANI-PyC part of the pyrocarbon interphase in a direction perpendicular to the graphene sheets is close to that of graphite ($28{\cdot}5 \times 10^{-6}$/K). On the opposite, the TEC for the SiC matrix is rather low (4×10^{-6}/K). Taking into account on the one hand the various TEC values above for the various phases within a Grade 1 composite, and considering on the other hand the fact that the occurrence of the lenticular porosity has appeared to be somewhat periodic, simple calculations below have allowed the lenticular porosity to be simulated (Fig. 24). The calculations mean that, while the SiC matrix does not shrink much during cooling, the fibre shrinks a lot, relatively. Because the pyrocarbon interphase is firmly bonded to the fibre, the interphase has to follow the fibre shrinkage. However, because of the low TEC along the graphene sheets, the circumference of the ANI-PyC part of the interphase all around the fibre remains unchanged. Therefore, the ANI-PyC part is led to wrinkle, that induces internal stresses strong enough to overcome the weak Van der Waals bonds between graphene and to promote decohesions (lenticular porosity).

Considering a carbon fibre 7 μm in diameter, coated with a thin pyrolytic carbon layer (thin enough for its thickness being neglected relative to the fibre diameter) partly having a ANI-PyC texture, then surrounded with a SiC matrix, both submitted to a 1000°C difference in temperature from the preparation conditions to ambient. The 'length' L_0 of the ANI-PyC around the fibre is taken equal to the circumference C_0 of the fibre and is $7 \times \pi = 22$ μm. The shrinkage of the fibre diameter during cooling is $7 \times 20 \times 10^{-6} \times 1000 = 0{\cdot}14$ μm. The circumference C imposed to the ANI-PyC by the fibre shrinkage is then $21{\cdot}56$ μm, while the real length L of the ANI-PyC remains 22 μm ($L = L_0 = C_0$). Considering a period of ~0·2 μm between the occurrence of slit pores (see Section 3 and Fig. 15), there are $21{\cdot}56/0{\cdot}2 = 107{\cdot}8$ periods around the fibre. The length x of the triangular unit of the slit pores (Fig. 24) is thus $22/(2 \times 107{\cdot}8) = 0{\cdot}102$ μm. This allows the height h of the pore to be calculated at $h \sim 20$ nm using trigonometry.

Although the calculations above are simple—even simplistic—they indicate that the porosity

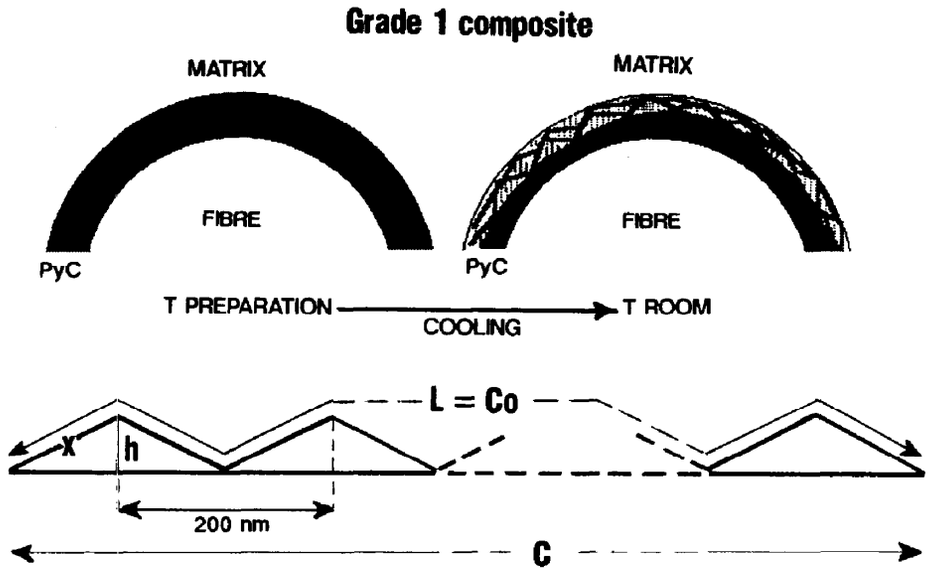

Fig. 24. Sketch of the formation mechanism of the lenticular porosity within the ANI-PyC part of the bimorphic type interphase texture, due to differences in the fibre and pyrocarbon TEC (see text).

induced by the difference in TEC is in the same range as the porosity observed. We thus believe that the lenticular porosity within Grade 1 composites is a secondary texture inherited from the cooling step rather than an intrinsic texture induced by the primary deposition step.

5 Conclusion

As previously stated for SiC/C/SiC composites, the texture of the pyrolytic carbon interphase has a major influence on the macroscopic mechanical behavior of the C/C/SiC composites. Obviously, controlling the pyrocarbon texture allows the matrix-to-fibre stress transfer to be controlled, leading to more-or-less tough composites. A common observation for tough composites is that the fibre/matrix interface has to reach a compromise: not too weak but not too strong. Whatever the texture, a pyrocarbon interphase is always efficient in dispersing the fracture energy, as compared with interphase-free C/SiC composites. Whatever the number of interfaces, the bulk behavior of the composite is mainly controlled by the weakest one. However, the efficiency is all the higher as the number of weak interfaces is high. This points out the importance of being able to order the interface strengths. For C/C/SiC composites, the interface strength may be directly related to the Van der Waals/covalent bond ratio, and increases as the ratio decreases. The 'compromise rule'—sustained by the observations—leads to the conclusion that an interface strength with a nil value is not desirable (case of the C/SiC composites), since allowing no stress transfer. In other words, some minimum strength value is necessary to get a tough composite. As compared with the interphase texture and the interface strength, other parameters such as interphase thickness or fibre topology are subordinate.

Abstract

Ni/Al_2O_3 and $Ni–Ti/Al_2O_3$ composites sintered in different atmospheres are investigated. Argon as a sintering atmosphere is found to be more beneficial to the fracture toughness of the composites than CO. Ni inclusions at 12 vol.% enhance the fracture toughness up to 36%, corresponding to a fracture energy twice that of the alumina matrix, whereas titanium alloying to Ni makes a negative contribution to the mechanical behaviour. The interfacial structures of Ni/Al_2O_3 and $Ni–Ti/Al_2O_3$ are studied by using electron microscopy. The titanium distribution at the interfaces is studied and correlated to the mechanical properties.

1 Introduction

Brittle ceramic materials can be toughened by the incorporation of ductile reinforcements. The toughening mechanism has already been investigated both theoretically and experimentally.[1–4] The plastic stretching of ductile reinforcements accounts for the predominant toughening. For effective toughening the appropriate interface bonding strength is the first requirement. If the bonding strength is too weak, cracks will propagate along the interface and plastic stretching of the ductile reinforcements will not occur. This is the usual case for many metal/ceramic composites. If the bonding strength is too strong, a rare case, the plastic stretching will be only localized to a limited zone between surfaces of propagating cracks and the toughness of the reinforcements will not be utilized adequately.[5] Therefore, in a metal reinforced ceramic composite, the fracture toughness can be enhanced by optimizing the metal/ceramic interface behaviour, which depends on both the physical properties (such as morphology, elastic modulus, thermal expansion coefficient) and the chemical characters of each material.

As a model system, Ni particle toughened Al_2O_3 has been studied.[6,7] A large increase in fracture toughness has been reported for Ni/Al_2O_3 composites compared to that of the monolithic alumina matrix. However, it seems that the potential for toughening is not fully reached because the plastic stretching of the Ni particles is limited. Cracks propagate often around the Ni particles, i.e. along the Ni/Al_2O_3 interfaces, owing to the low interface bonding strength as compared to the high yielding strength of Ni. Therefore, in order to get a well-toughened composite, the interface bonding between Ni and Al_2O_3 should be strengthened.

The common practice for interface strength adjustment is to introduce a degree of interfacial chemical reaction. In preparing composite materials, this can be achieved either by controlling the sintering atmosphere or by introducing additives. As far as the atmosphere is concerned, Ni can be oxidized to form a NiO or a $NiAl_2O_4$ spinel interlayer. As to additives, titanium is widely used as a wetting agent in brazing ceramics with alloys to achieve strong joints.[8] It has been reported that the interface energy between Ni and sapphire (or sintered Al_2O_3) decreases sharply on the addition of a small amount (about 2%) of Ti in Ni because of the segregation of Ti and the formation of Ti_2O_3 at the interface.[9] According to the concept of the work of adhesion, W_{ad}, defined as:

$$W_{ad} = \gamma_{Ni} + \gamma_{Al_2O_3} - \gamma_{Ni/Al_2O_3}$$

the interface bonding between Ni/Al_2O_3 can be improved by the presence of Ti. In the present work, pure Ni and Ni–Ti alloy toughened Al_2O_3 composites are prepared by sintering in either Ar

Table 1. Properties of the Ni(Ti)/Al_2O_3 composites

Sample	*Al_2O_3 (air)*	*1 12 vol%Ni (CO)*	*2 12 vol%Ni (Ar)*	*3 12 vol%Ni–Ti (CO)*	*4 12 vol%Ni–Ti (Ar)*

K_{1c} (MPa $m^{1/2}$)[a]	3·6	4·1	4·9	3·2	3·5

[a] Results of six measurements.

or CO atmospheres. The purpose is to investigate the influence of the atmospheres and of the titanium addition on the interface reactions and on the mechanical properties of the composites.

2 Experimental Procedures

The composites were prepared by a typical powder metallurgical route. Pure nickel powders (99·99 + %. ≤ 63 μm, Goodfellow) or Ni–Ti alloy powders (5 wt% or 6·06 at% Ti in Ni, prepared by an atomizer, sieved to under 63 μm) in the amount of 12 vol.% were mixed with fine Al_2O_3 powder (99·99% up, TM-DR, ultra pure sinterable alumina) in an attritor for 4 h with alumina balls and isopropanol as the milling media. The slurries were dried and sieved. Powder compacts with dimensions of about 13 × 21 × 57 mm were formed by cold isostatic pressing under a pressure of 625 MPa. The green compacts were sintered at 1400°C for 2 h in CO (generated by burning of carbon powder in a closed alumina crucible) and in Ar (static argon in an alumina tube furnace) respectively.

After sintering, the surfaces of the samples were carefully observed. The density was measured by the Archimedes method. Bending bars, 3 × 4 × 45 mm in size, were machined from the large sintered blocks. The mechanical testing was performed in the four-point-bending mode at a cross head speed of 0·1 mm/min. The strength was determined on the bending bars with inner/outer spans of 20/40 mm. The toughness was characterized on the subsequent half bars with inner/outer spans of 7/20 mm by the single-edge-notched-beam (SENB) method. The notch width was controlled to within 100 μm and the depth was about one fourth of the sample height, i.e. 1 mm.

The phases in the composites were examined by X-ray diffraction (XRD). The general morphology of the samples was studied with optical microscopy. The detailed structure of the interfaces was investigated by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The composition of the interfacial layers was determined by electron probe microanalysis (EPMA). Because of the uncertainties associated with analyzing oxygen content, quantitative analysis was only done on Ti, Ni and Al, using pure metals as the standards. To estimate the oxygen content, semi-quantitative (standardless) analysis was performed using energy dispersive spectroscopy (EDS) mode in SEM or TEM. Since the interfacial layers are generally very thin, analysis was always performed at places where the layers are relatively thick.

3 Results

3.1 Properties of the composites

The relative density, the fracture strength and toughness of the monolithic Al_2O_3 and of the composites are given in Table 1. All the samples were sintered nearly to their theoretical densities in the different atmospheres by normal sintering. The composites have lower fracture strength than monolithic Al_2O_3. The Ni/Al_2O_3 composites have improved fracture toughness with an increase of 14 and 36% over Al_2O_3 in the case of CO and Ar as the sintering atmospheres, respectively. Calculation from the toughness shows that the fracture energy ($\gamma = K_{1c}^2/2E$) of Al_2O_3 and of sample 2 are 16·8 J/m^2 and 32·9 J/m^2, namely a doubling of the fracture energy in the composite as compared with the pure matrix material. For the Ni–Ti/Al_2O_3 composites, a decrease in fracture toughness is found with either CO or Ar as the sintering atmosphere. These results suggest that the atmospheres have a large influence on the fracture properties of the composites, and that an Ar atmosphere is more beneficial than a CO atmosphere. The addition of Ti to Ni produces no improvement in toughening.

3.2 Microstructures and interfaces

The appearance of all the sintered composites is more or less yellow-green, but with one surface blue, which was in contact with the alumina crucible during sintering. XRD analyses reveal that the yellow-green surfaces contain NiO and the blue ones $NiAl_2O_4$ spinel. After removing the surface scales, which are thinner than 0·5 μm, the samples

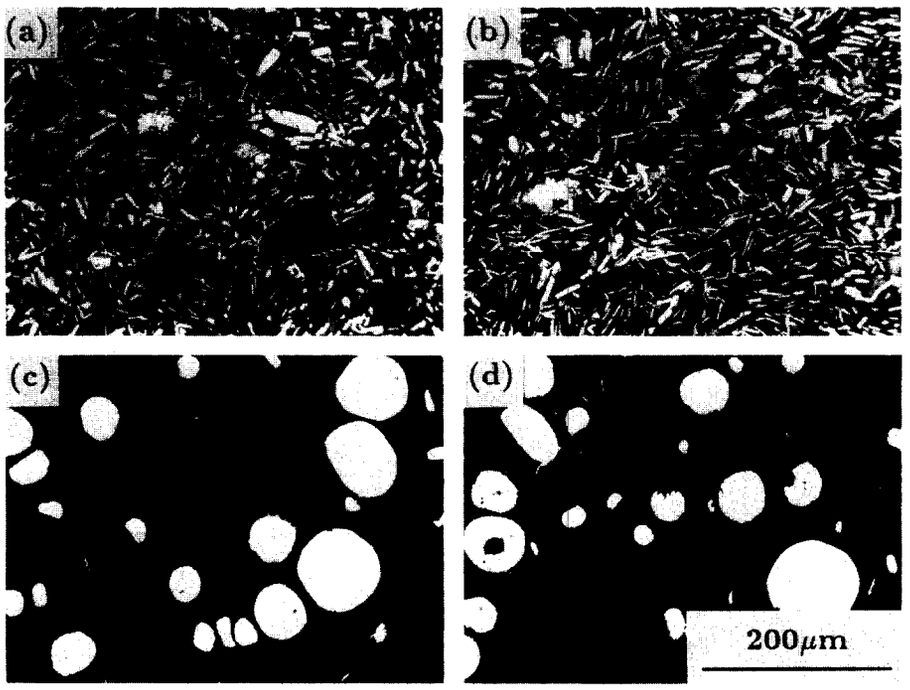

Fig. 1. Optical micrographs of the samples: (a) 1, (b) 2, (c) 3 and (d) 4.

appear dark grey for the Ni/Al_2O_3 composites and grey for the $Ni–Ti/Al_2O_3$ composites. No other phases except Ni (Ni–Ti) and Al_2O_3 can be detected by XRD. Since we are interested in the bulk properties of the composites, further analyses are based on the interiors of the materials.

Figure 1 shows the optical microstructures of the composite samples. The morphology of the Ni particles in samples 1 and 2 is very different from that of Ni–Ti particles in samples 3 and 4. The Ni particles appear to be small rods of about 20 μm long and 2–3 μm across; some particles agglomerate together. On the other hand, the Ni–Ti particles are spheres with a diameter of about 50 μm, and the particles are distributed discretely and randomly. The difference in morphology of the metal particles originates from the starting powders and from the processing. Although both powders are sieved under 63 μm, the Ni powders are originally finer and more agglomerated than the Ni–Ti powders. During attrition milling Ni particles become rod-shaped because of the plastic deformation caused by inter-particle friction, while Ni–Ti particles are very rigid and much less influenced by milling.

The regions near the interfaces between the metal particles and ceramics have been studied by SEM. In samples 1 and 2, the interface between the Ni and Al_2O_3 is sharp. In samples 3 and 4, an interfacial reaction layer between Ni–Ti and Al_2O_3 is observed. EDS analysis indicates that the interface layer is rich in Ti, as shown in Fig. 2 which is the Ti mapping in samples 3 and 4. In sample 3, Ti is mostly concentrated at the rim of each Ni–Ti particle, while in sample 4, Ti is distributed throughout the Ni–Ti particle, although it is also enriched at the particle surfaces.

To investigate the details of the structure in the

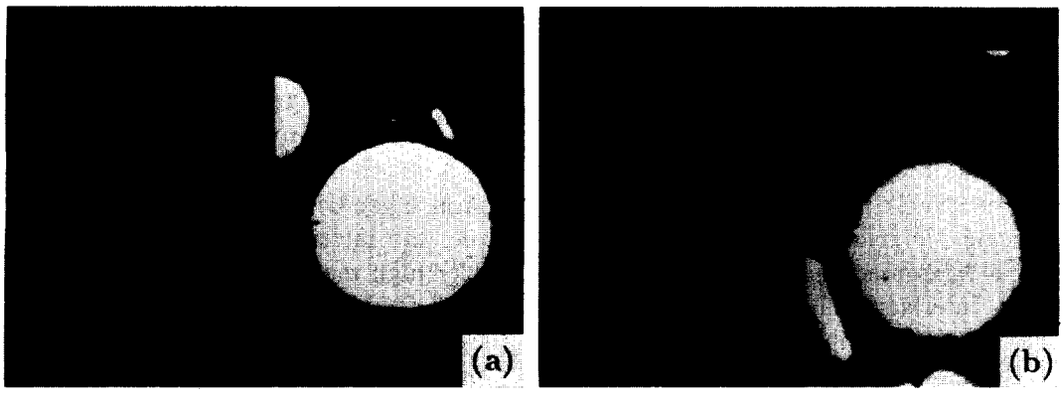

Fig. 2. Ti mapping by SEM/EDS, (a) sample 3 and (b) sample 4.

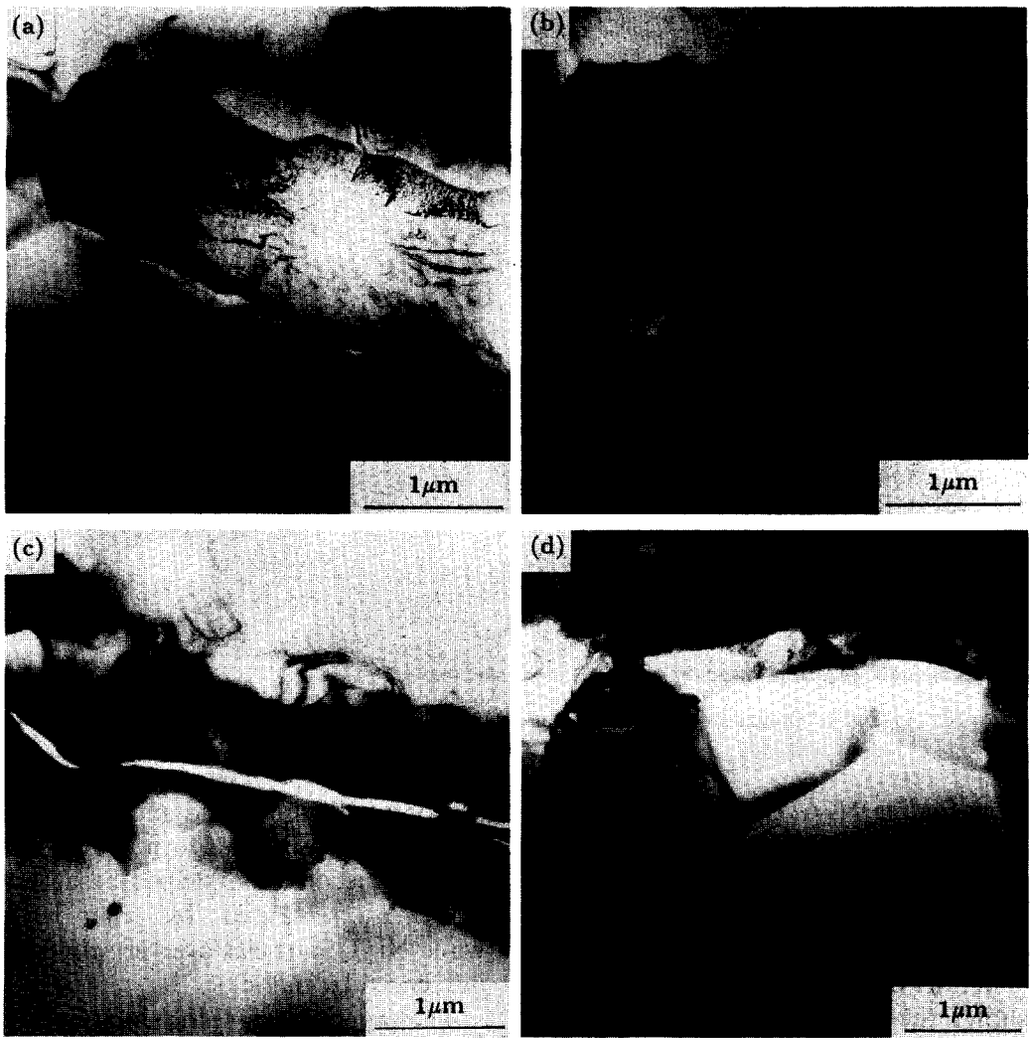

Fig. 3. TEM low magnification images which show general structures of the Ni(Ti)/Al_2O_3 interface. In (a) for sample 1 and (b) for sample 2 no interfacial layer is observed. In (c) for sample 3 and (d) for sample 4 a reaction layer can be seen.

interfacial region, TEM experiments have been carried out. Figure 3 shows the general structures around the metal particles under TEM with low magnification. In Fig. 3 (a) and (b), the bright-field images of the interfaces in samples 1 and 2, the Ni particle is surrounded by Al_2O_3 grains with an average size of about 0·6 μm, and the interface remains sharp and clear. In Fig. 3(c) and (d), an interfacial layer exists between the Ni–Ti and Al_2O_3 as also observed by SEM. On average, the layer is about 2–3 μm thick in sample 3 and about 1 μm thick in sample 4. Cracks are often observed along the interfacial regions in sample 3, within the layer as shown in Fig. 3 (c) or at the boundary between the layer and the ceramic matrix. The interfacial layer and the Ni–Ti particle are bonded very well. This indicates a relatively strong bonding between interfacial layer/metal and a relatively weak bonding between interfacial layer/ceramic. Similar interfacial behaviour is also observed by examining the details of the indentation crack path in both samples 3 and 4 under SEM.

In addition to the interfacial layer, another feature in the microstructure of the Ni–Ti/Al_2O_3 composites is the inhomogeneity of the Al_2O_3 grain size. The grains close to the interface, about 2·5 μm in sample 3 and 1·4 μm in sample 4, are much larger than the grains further away from the interface, which are, as in samples 1 and 2 (Fig. 3(a) and (b)), under 1 μm. In this study, the grain size of the monolithic Al_2O_3 is about 2·5 μm. Therefore, it can be concluded that while Ni and Ni–Ti inclusions suppress grain growth in the Al_2O_3 matrix, Ti diffusion from the Ni–Ti bulk promotes grain growth in the surrounding Al_2O_3 matrix near the interface.

To determine whether there is an interfacial reaction layer between the Ni and Al_2O_3 at a local scale, the interfaces have been analyzed by TEM under high magnification, as demonstrated in Fig. 4 (a) and (b) for a typical interface region in samples 1 and 2 respectively. Some shadowed regions along the interfaces are observed due to the projection of the interface plane which is not parallel

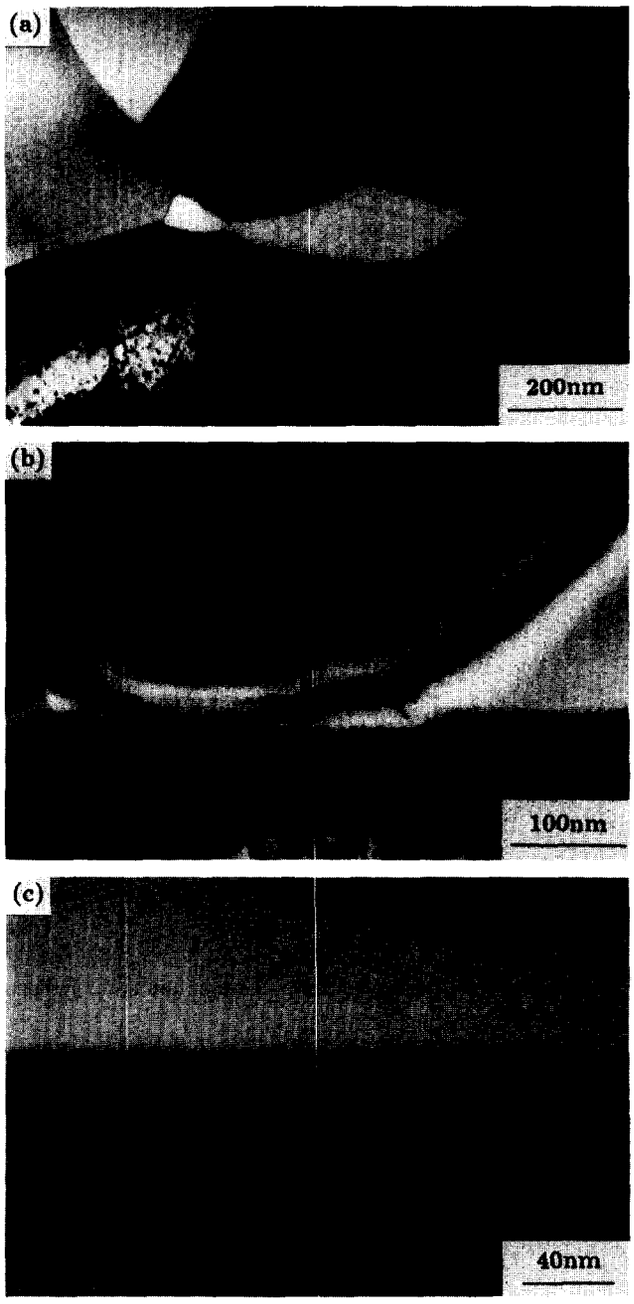

Fig. 4. High magnification TEM images of the Ni/Al_2O_3 interface, (a) sample 1, (b) sample 2; and (c) sample 1, same as (a) but at higher magnification.

to the electron beam. The interface becomes sharp and narrow when the specimen is tilted to an appropriate orientation so that the interface becomes vertical. Figure 4 (c) is a portion of the interface in sample 1 at an even higher magnification. The fringes parallel to the interface are due to the shallow interface. Apart from that there is no sign of interfacial layers or of precipitates larger than about 10 nm.

The interfacial layers in samples 3 and 4 are seen in more detail in high magnification in Fig. 5. The contrast of the interfacial layer is clearly different from that of the Ni–Ti particle and of the matrix. In Fig. 5 (a) for sample 3, some egg-shaped grains appear in the layer, and again there

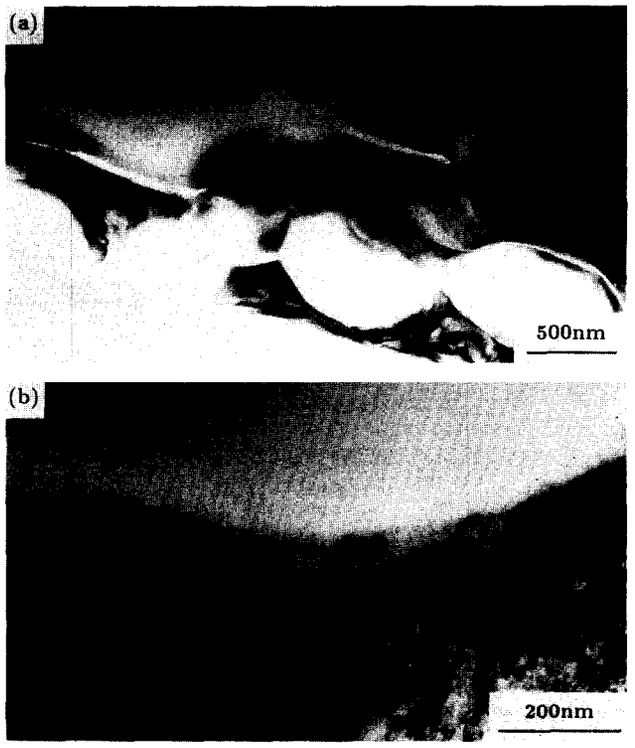

Fig. 5. High magnification TEM images of the $Ni–Ti/Al_2O_3$ interface, (a) sample 3, and (b) sample 4.

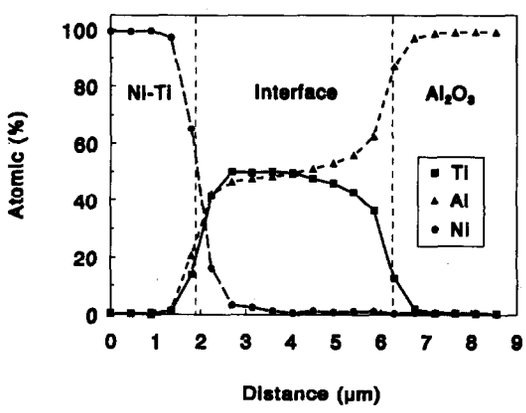
is a crack mainly along the boundary between the layer and the ceramic matrix. In Fig. 5 (b) for sample 4, the interfacial layer is thinner and less rich in structure than that in 3.

Figure 6 shows the concentration profiles of Ti, Al and Ni across an interfacial layer after a quantitative analysis by line scan from a Ni–Ti particle (left) to the Al_2O_3 matrix (right) in sample 3. In the Ni–Ti particle, Ti is almost completely depleted. In the layer, the content of Ni is very limited, and Ti is concentrated. The diffusion depth of Ti is as much as 4–5 μm into the Al_2O_3.

Semi-quantitative analysis from TEM/EDS reveals that a large amount of oxygen is present in the layers. Figure 7 (a) shows the concentration profiles after a series of analyses, and Fig. 7(b) is the corresponding TEM image with the points



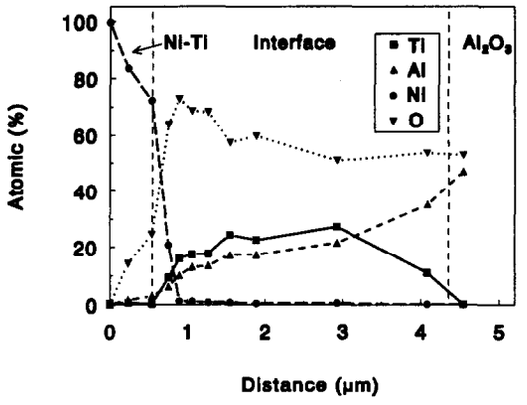


Fig. 6. Composition profile around the interface in sample 3 after a quantitative analysis by SEM/EDS with standard.

(a)

(b)

Fig. 7. (a) Composition profile in sample 3 after a semi-quantitative analysis by TEM/EDS. (b) The contamination spots indicate where the EDS analyses were taken.

where the spectra were taken indicated by the contamination spots. The high oxygen level should be treated with caution because of the nature of the semi-quantitative analysis. Some oxygen has diffused into the Ni–Ti particle to a distance of about 500 nm, associated with the diffusion of small amounts of Al. Similar to Fig. 6, Ti approaches zero in the Ni–Ti particle, but diffuses into Al_2O_3 to a distance of 4·5 μm.

The interfacial layers in sample 4 have been similarly examined. Due to the very thin thickness (only about 1 μm), the exact composition of the layer cannot be determined quantitatively. Semi-quantitative analyses by TEM/EDS indicate the presence of Ti, Al and O in the layers.

4 Analysis

4.1 Chemistry of the interface

As stated earlier, interfacial reactions play an important role in the final mechanical properties of composite materials. The probable reactions can be predicted from thermodynamic data.[10] In the Ni/Al_2O_3 system, the possible reactions are the formation of NiO or $NiAl_2O_4$ spinel. For the reaction

$$2Ni + O_2 \rightarrow 2NiO \quad (1)$$

$\Delta G = -198{\cdot}2$ kJ and the equilibrium oxygen partial pressure is 5×10^{-7} bar at 1400°C. As soon as NiO is formed, reaction with Al_2O_3 will proceed to develop $NiAl_2O_4$ spinel, because the reaction

$$NiO + Al_2O_3 \rightarrow NiAl_2O_4 \quad (2)$$

with $\Delta G = -18{\cdot}5$ kJ has a negative Gibbs energy at 1400°C.

However, direct formation of $NiAl_2O_4$ spinel between Ni and Al_2O_3 is also possible as illustrated in Ni/Al_2O_3 diffusion couples and diffusion bonding experiments.[11–13] The formation of $NiAl_2O_4$ spinel at Ni/Al_2O_3 interfaces need not proceed through a NiO intermediate, but requires a threshold activity of oxygen dissolved in Ni, which is less than the solubility limit of oxygen in Ni in equilibrium with NiO. The threshold oxygen level is 0·025 at% (250 ppm) at 1400°C from thermodynamic calculation.[13]

In the present work, the oxygen level in the CO atmosphere is estimated to be 3×10^{-17} bar in equilibrium conditions (calculated from the oxidation of C to CO at 1400°C). Comparing this value with the equilibrium oxygen partial pressure for

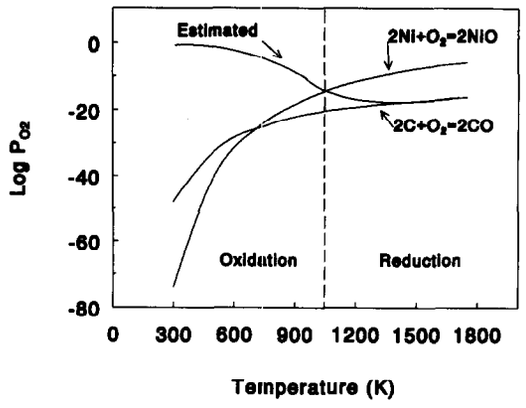

Fig. 8. Oxygen level estimated in the CO sintering atmosphere during heating.

Ni oxidation, 5×10^{-7} bar, it appears that NiO formation in the CO atmosphere is not predicted. Therefore spinel formation should not arise through a NiO precursor. On the other hand, direct spinel formation is also not predicted because the oxygen content in the Ni is very limited in the raw material (99·99 + %). In the case of Ar atmosphere, the oxygen partial pressure is expected to be 3×10^{-6} bar. Ni should then be oxidized and $NiAl_2O_3$ should be also formed subsequently. These estimations do not completely agree with the experimental observations, which show that both NiO and $NiAl_2O_4$ spinel are present on the surfaces, but not in the interiors of all the samples sintered in both atmospheres. The difference can be attributed to the real oxygen level during heating. The CO atmosphere is generated by burning C powder in a closed crucible, so that the oxygen level decreases from 0·21 bar in the initial air to as low as 3×10^{-17} bar at 1400°C under equilibrium conditions. This process is shown schematically in Fig. 8. During the initial period of heating, the oxygen level is high enough for Ni oxidation and $NiAl_2O_4$ formation. The oxide and spinel formed can be reduced again at higher temperatures when the oxygen level approaches the equilibrium one. This has been supported in our experiments by extending the holding time at 1400°C. The surface NiO and $NiAl_2O_4$ spinel layer is observed to diminish. In both atmospheres, oxygen is consumed gradually. Penetration of the oxygen into the interior of the samples is probably too limited to make Ni oxidized there. The initial oxygen enclosed in the powder compacts (green bodies) alone cannot cause prominent Ni oxidation. Provided that all the oxygen in the interior is consumed to produce NiO, a layer as thin as about 3 Å is estimated on surfaces of the Ni particles, which cannot be detected by TEM analysis. In fact, some of the oxygen may be dissolved in Ni, making the NiO layer even thinner.

In the Ni–Ti/Al_2O_3 composites, the interfacial layer contains only Ti, Al and O, and Ni is much less involved. Apparently, Ti diffuses from the interior of the Ni–Ti particles to the particle surfaces, and then the Ti at the particle surfaces reacts further with oxygen and the Al_2O_3 matrix.

From the phase diagram of the Ti–O system,[14] Ti can dissolve a large amount of oxygen and can be very easily oxidized to form a family of oxides such as TiO, Ti_2O_3, TiO_2 and so on. Considering the following reactions

$$Ti + 1/2O_2(g) \rightarrow TiO \qquad \Delta G = -382 \text{ kJ} \quad (3)$$

$$Ti + 3/4O_2(g) \rightarrow 1/2Ti_2O_3 \qquad \Delta G = -534 \text{ kJ} \quad (4)$$

$$Ti + O_2(g) \rightarrow TiO_2 \qquad \Delta G = -642 \text{ kJ} \quad (5)$$

and the activity of 6 at% Ti in Ni, estimated to be $2{\cdot}6 \times 10^{-4}$ at 1400°C,[15] the equilibrium oxygen partial pressures for the above reactions are $2{\cdot}1 \times 10^{-17}$, $3{\cdot}5 \times 10^{-18}$ and $3{\cdot}5 \times 10^{-17}$ bar, respectively. Because of the high oxygen level in both sintering atmospheres (especially high during heating in the CO atmosphere as indicated from the Ni/Al_2O_3 surface reactions), Ti can be easily oxidized. The oxide is probably in the form of TiO_2 (rutile), since experiments on the Ni–Ti powders treated in CO atmospheres similar to those of the sintering conditions show that a layer of TiO_2 (rutile) is present on the surface of each Ni–Ti particle. The titanium oxide at the Ni–Ti/Al_2O_3 interface can dissolve into the Al_2O_3 and promote Al_2O_3 grain growth.[16] The thicker reaction layer in the CO atmosphere than in the Ar atmosphere is attributed to the higher oxygen level in the former case during the heating stage. The formation of TiC is not possible from thermodynamic considerations.

4.2 Relationship between structure and properties

From the fracture surface analyses and from the indentation crack path examinations, it is found that the Ni or Ni–Ti metallic particles do not undergo substantial plastic stretching as a crack tip passes by. Cracks propagate mainly along the interface between the metal inclusions and the Al_2O_3 ceramic. The toughening mainly comes from the crack deflection instead of from the desired plastic stretching of the metal. Because crack deflection is relatively ineffective in toughening,[17] this explains the small improvement in the toughness of the composites. As to the low fracture strength of the composite compared to monolithic Al_2O_3, this is due to defects introduced by the metal inclusions (which themselves can be taken as flaws) and to the influence of the sintering atmospheres. Contamination from C due to the CO atmosphere may be responsible for the specially low strength of the composites sintered in CO. As is known, C is detrimental to the mechanical properties of alumina.[18]

For samples 1 and 2, the difference in microstructure and interface is hardly detectable. The difference in fracture toughness can be attributed to the ductility of Ni. In sample 1, the absorption of C from the atmosphere make the Ni particles more resistant to yield,[19] hence providing a lesser contribution to the toughening. For samples 3 and 4, the negative influence of the Ni–Ti inclusions on the fracture toughness is related to the weak interfacial layer and boundary between the layer and the Al_2O_3 matrix. Cracks occur at the interface resulting from the stress of thermal expansion mismatch between the large metal particles and the matrix. So the metal particles may act to some extent as pores. The weak interface debonding releases only very little energy to resist the crack propagation. Furthermore, titanium does not only modify the interface structure but also changes the yield strength of the Ni particles, which makes the plastic stretching of the metal particles even more difficult.

5 Conclusions

Ni/Al_2O_3 and $Ni–Ti/Al_2O_3$ composites have been fabricated by sintering in CO and Ar atmospheres. All the samples are well densified after sintering at 1400°C. The fracture toughness is not much improved compared with the matrix because of the very limited plastic stretching of the metal particles. Argon atmosphere is found to be beneficial to the mechanical properties relative to CO atmosphere for all the composites. In both sintering atmospheres no interfacial reaction layers are formed in the Ni/Al_2O_3 composites; in contrast there are reaction layers up to 1–3 μm in thickness in the $Ni–Ti/Al_2O_3$ composites. The reaction is due to the oxidation of Ti, and is more accelerated in CO atmosphere than in Ar. As expected, Ti diffuses from the interior of Ni–Ti alloy particles to the particle interfaces, but the weak interfacial layer and the poor bonding between the layer and the matrix result in materials which are not toughened.

Abstract

Glass to metal sealings necessitate a pre-oxidation of the metal, producing a thin superficial oxide layer. In the case of porcelain–kovar junctions a glassy interphase is necessary, which reacts and dissolves the oxide layer during the bonding thermal treatment. In the interfacial zone this leads to a good fitting of the thermal expansion coefficients of the phases present: in the alloy the superficial part is impoverished in iron and its thermal expansion coefficient is close to that of the FeO-rich glass which has dissolved the oxide layer. The resulting buffer zone limits the effect of strains appearing during cooling at the end of the bonding thermal treatment. Moreover, the FeO-rich glass penetrates the open porosity of the superficial alloy layer (due to its pre-oxidation) providing a good physical adherence of glass to kovar. At the porcelain–glass interface there is no problem because of the similarity of dilatometric behaviour of the two materials.

1 Introduction

Glass to metal sealings necessitate a preliminary oxidation treatment of the metal. The resulting oxide layer reacts subsequently with glass to make a strong junction between glass and metal. This bonding thermal treatment is achieved at temperatures near to that of glass softening, and during cooling the difference in thermal expansion between glass and metal may generate interfacial strains strong enough to break the junction. To prevent this, special alloys and glasses are used, their main characteristic being the similarity in their thermal expansion.

On the basis of this very simple theoretical approach, a technology has long been developed industrially, and many various pieces for a wide range of applications are currently produced. Nevertheless many questions remain unanswered, such as: why are the conditions (sealing time, temperature, etc.) of the alloy pre-oxidation so important, or why must the duration of the joining thermal treatment be so sharp? In spite of the industrial importance of these questions a limited number of papers is available in the literature,[1–6] and the know-how remains in the factories.

Some studies[1–4] have shown that a good junction depends on the degree of preoxidation, sealing time and temperature. It has been shown[5,6] that iron diffusion into the glass produces a modification in the thermal expansion behaviour of glasses. According to Ikeda and Samalima[5] the glass thermal expansion increases, while according to Mayer *et al.*[6] it decreases.

In order to shed some light on the mechanism of the glass to metal junction, we decided to study each step of the process, by working on the example of porcelain–kovar joining with a glass interphase. We have already our published results on the oxidation of kovar.[7] This material which is the one most used for glass junctions, is a Fe–Co–Ni alloy, but its oxidation layer is mainly composed of iron oxides. The underlying oxide is enriched in cobalt and nickel and presents an important porosity. During the reaction with glass, the oxide layer of the alloy is dissolved by the glass, and this improves its wetting quality and produces good junctions.[8]

Table 1. Measured thermal expansion coefficients, α

Material	*Kovar*	*Glass*	*Porcelain*
α ($\times 10^7$)	50	52	52

The aim of this work was to study what the effects of these treatments are on the thermal expansion of the interfacial zone in order to understand better the origins of the bonding.

2 Materials and Methods

The materials used have very similar measured thermal expansion coefficients, as shown in Table 1.

Kovar was provided by Imphy SA (ref. 08D1006), porcelain by KPCL S.A. (ref. CM10) and glass was made from a Cerdec S.A. frit.[9]

When kovar is oxidized, the composition of the alloy near the interface is very different from that of the bulk[7] and gives the approximate compositions of the metallic phase existing in the interfacial zone. From Fig. 1, it is obvious that the thermal expansion of the interfacial zone is certainly strongly perturbed by the composition modifications due to the bonding reaction as well in the alloy[7] as in the oxide and glassy phases.[9] This induces local coefficient values very different from those given in Table 1. It was impossible for us to determine directly these values on real pieces of complex morphology, and the only feasible way was to make different samples having compositions corresponding to those followed by EDX analysis across the interface in the case of a strong and vacuum-tight junction.

For the alloy, bars were prepared from metallic powders of iron, cobalt and nickel provided by Cerac Inc. mixed for 4 h in a Turbula mixer (Prolabo S.A.). Table 2 presents the main impurity contents of these powders. They were then heated in an alumina crucible at 1420°C under a flow of pure argon (L'Oxygène Liquide S.A., quality U) for 1 h in a graphite furnace. After cooling, small bars (4 × 4 × 35 mm) were cut and polished. The iron oxide–glass mixtures were made with iron monoxide (from Cerac Inc.) since it has been shown that the iron oxide scale, initially composed of Fe_3O_4 and Fe_2O_3, becomes only iron monoxide above 900°C.[9] Elemental composition is given in Table 3 and the composition of the glass frit, provided by Cerdec S.A., in Table 4.

Iron monoxide and glass powders were mixed in an agate mortar and then put in a silico-alumineous crucible previously covered with kaolin to avoid any bonding between glass and crucible. They were heated to over 900°C in accordance with the bonding thermal treatment.[9] After cooling, the pellets were cut with a diamond saw to obtain small bars for dilatometry. Great attention was paid to avoid the presence of kaolin traces, and finally the samples were carefully polished. The dimensions of the pieces were about 4 × 4 × 40 mm. Dilatometry measurements were carried out in a Netzsch 402E-3 differential dilatometer, coupled to a computer which processed the signal. Bars were heated under an argon flow to 1000°C at the rate of 2°C min^{-1} for the alloy bars and until the dilatometric softening point.

3 Results

In order to determine the composition of the alloy sample and that of the glass–FeO mixtures, we obtained the concentration profiles of the elements present in the interfacial zone after short thermal treatments.[9] Figure 2 shows that, in the interfacial zone from kovar to glass, there are four distinct domains:

- the original alloy with its nominal composition (part I);
- the Fe-impoverished alloy zone (part II) extending for about 8 μm where the alloy composition was of 42·5 wt% Fe, 21·5 wt% Co and 36 wt% Ni at 2 μm from the interface with oxide or glass;
- a narrow range (2 μm) containing both glass and iron oxide partially or entirely dissolved (part III);
- a large domain extending 30 μm in which iron diffuses into the glass.

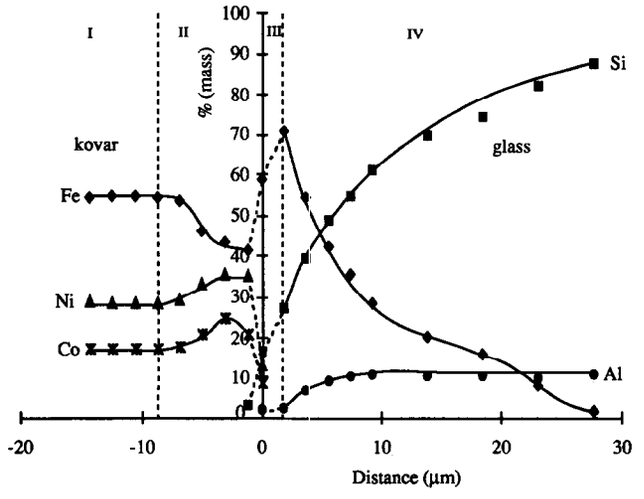

Fig. 2. Concentration profiles of the elements iron, nickel, cobalt, silicon and aluminium by EDX analysis of the kovar/glass interface after 15 min at 910°C.

Based on these observations we prepared an alloy sample with the same composition as measured near the alloy surface (Fe: 42·5 wt%; Co: 21·5 wt%; Ni: 36 wt%) and three FeO–glass mixtures with weight ratios of 20–80%, 40–60% and 60–40% respectively.

Dilatometric measurements were carried out on samples having these compositions and Fig. 3 presents their dilatometric curves between 20 and 1000°C together with those of original glass, kovar and porcelain.

One can see that the glass expansion and the softening temperature grow appreciably with increasing FeO content. The relevant values as well as the thermal expansion coefficients of kovar, prepared alloy and porcelain are given in Table 5. One can also notice, examining Fig. 3, that the increase in thermal expansion due to the glass transition becomes smaller with increasing FeO content in the glass. Concerning the prepared alloy, which contains less iron than kovar, its thermal expansion is greater than that of porcelain and of kovar.

4 Discussion

During the joining reaction, the oxide layer of the kovar reacts and is progressively dissolved into the glass.[8] As a consequence, near the interface 3 (Fig. 1)

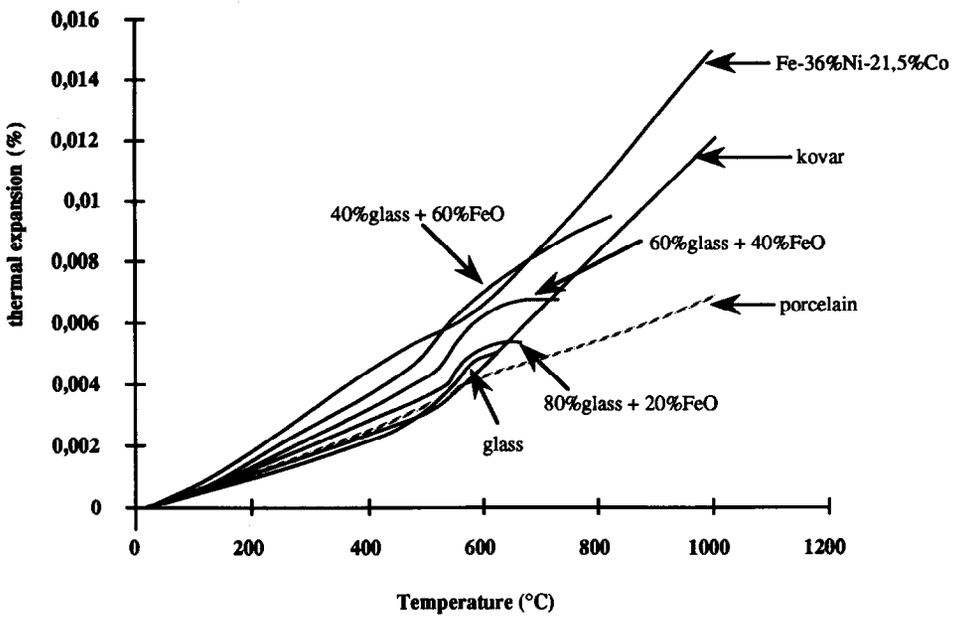

Fig. 3. Dilatometric curves of glass, prepared alloy, glass and FeO, kovar and porcelain.

the FeO content of the glassy phase increases rapidly: to a certain extent a kind of continuity may occur at this interface between the dilatometric behaviour of FeO and that of the glassy phase rich in FeO. On the dilatometric curves of Fig. 3 and considering Table 5, we actually observe that the thermal expansion of the FeO-rich glassy phases tends to approach the value[10] of pure FeO ($\alpha = 12{\cdot}2 \times 10^{-6}$ °C^{-1}), and therefore the behaviour of the glass tends towards that of a cristallized phase with the narrowing of the glass transition zone.

We have previously shown,[8] on the basis of the examination of the pseudo ternary phase diagrams of $FeO–Al_2O_3–SiO_2$[11] and $FeO–Na_2O–SiO_2$[12] (the $FeO–B_2O_3–SiO_2$ phase diagram is not available) that the effect of FeO dissolution in the glass is a lowering of the temperature of apparition of the liquid phase, the optimum being reached for FeO content of about 50 wt%, and, consequently, we have observed that FeO dissolution noticeably improves the wetting of the glassy phase. There is a double beneficial effect of the FeO dissolution in the glass which fits the dilatometric characteristics of glass and oxide layer at the interface 3 (Fig. 1) and which contributes to good wetting.

At the beginning of the dissolution process, there is a significant dilatation gap between the reaction zone and the bulk of the glass, because the diffusion area of FeO is still very restricted. For this reason this zone is very brittle and may crack when cooling. It is necessary therefore to prolong the treatment time at the joining temperature to allow the FeO dissolution gradient to attain an optimal width to avoid this problem.

In the alloy region (interface 2 of Fig. 1) the results of Fig. 3 are also very interesting. One can see that the impoverishment in iron of this zone corresponds to an increase in its thermal expansion coefficient since Table 5 shows that the Fe(42·5 wt%)–Ni(36 wt%)–Co(21·5 wt%) alloy has a thermal expansion coefficient nearly twice that of kovar and close to that[10] of FeO. Between interfaces 1 and 2 (Fig. 1) there is certainly a regular increase of the thermal expansion related to the changes of composition of the alloy in this domain. This constitutes a buffer zone which tends to fit the dilatometric behaviour of kovar and

FeO-rich glass or FeO phase. It would seem improbable that the joining can be strong if the FeO phase is present, because its porosity constitutes a low resistance zone. This result has been experimentally confirmed.[9]

In these conditions a good bonding is reached when the entire iron oxide layer has reacted with the glass. At this point the interfaces 2 and 3 meet and there is a good fitting of thermal expansion coefficients on both sides. A good fitting is also found between interfaces 1 and 2 due to the smooth change of the composition of the alloy in this zone. This condition is also fulfilled in the glassy phase through the FeO diffusion space. If the thermal treatment is too long, FeO diffusion leads to a complete homogenization of the glassy phase. In this case we have a small FeO concentration in the glass and we find again a thermal expansion coefficient similar to that of the original glass resulting once again in a dilatation gap at the interface 2/3 (Fig. 1). This result is consistent with experimental results[9] and with industrial know-how, as far as it can be ascertained.

Looking at the interface 5 (Fig. 1), there is never any dilatation problem in this region because the glass quantity is sufficient to avoid any dilatometric change when FeO is dissolved, and the values of the thermal expansion coefficients do not differ from those of Table 1.

At this point, one important question arises: if the result of this precise treatment is only to obtain a good fitting of thermal expansion coefficients in the interfacial zone, why are they necessary, since the original materials (Table 1) had already very similar dilatometric behaviour? We propose two answers: first, the glass wetting improvement as previously shown,[8] and second, the achievement of a physical adhesion through the penetration of glass into the alloy. Indeed the

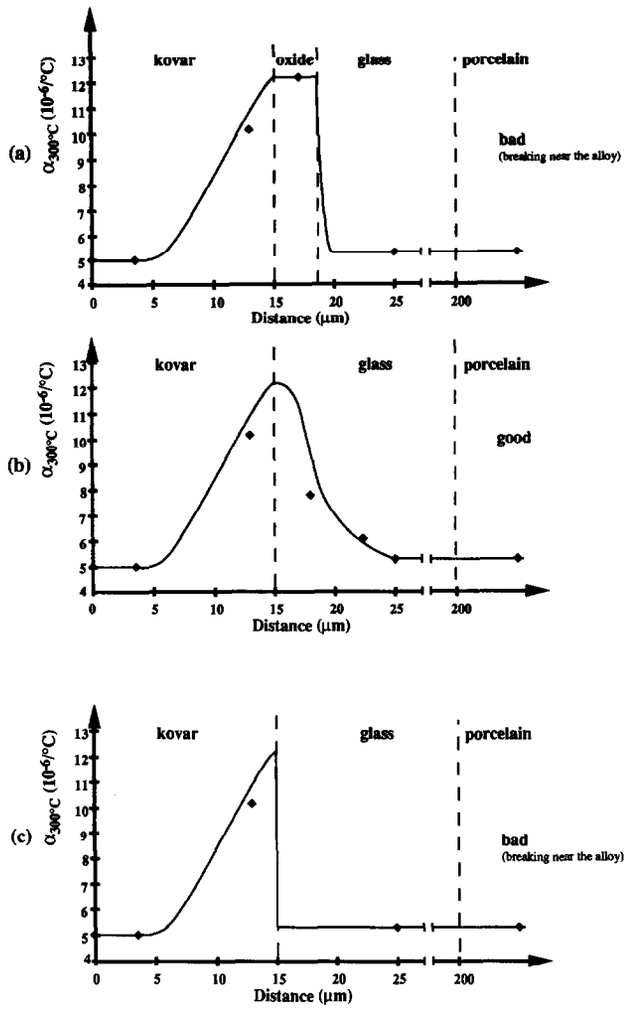

Fig. 5. Dilatometric profile of the interfacial zone: (a) oxide layer slightly dissolved; (b) oxide layer almost totally dissolved; (c) the whole oxide layer is dissolved.

pre-oxidation treatment creates some superficial open porosity in the alloy that glass invades during FeO dissolution as shown in Fig. 2. Here one may observe that there is some silicon located in the iron-impoverished alloy (part II), and otherwise it is well illustrated by the micrograph of Fig. 4 which shows the glass penetration in the open porosity of the iron-impoverished alloy. Our experiments do not allow any assertion to be made about an eventual chemical process, which is possible, but not proved.

5 Conclusion

This work sheds some light on the role of the pre-oxidation of the alloy in the glass to metal sealings. Not only does it improve the glass wetting[8] but it is also responsible for the fitting of thermal expansion coefficients in the interfacial zone. In fact the formation of the oxide layer creates an iron-impoverished zone whose thermal expansion is higher than that of underlying alloy, and the

oxide dissolution into the glass increases the thermal expansion of the glass to values approaching those of the iron-impoverished alloy. At last, the pre-oxidation creates open porosity in the alloy[7] in which FeO-rich glass penetrates during bonding treatment, so creating a strong physical adhesion.

The duration of the bonding thermal treatment is very important and its role is well summarized in Fig. 5 which presents diagrams describing the thermal expansion coefficients evolution in the interfacial zone according to the time of thermal treatment. If it is too short (Fig. 5(a)), the brittle oxide layer remains and the FeO-dissolved gradient is very strong, so that the bonding is weak. If the treatment duration corresponds to that of a complete reaction or dissolution of the FeO layer in the glass (Fig. 5(b)), it is the best case where there is a large gradient of FeO in the glass, hence a good fitting of the thermal expansion coefficients in the interfacial zone, and a sufficient penetration of the glass in the superficial porosity of the alloy. For too long times (Fig. 5(c)) homogenization of the glass leads to a significant gap of the thermal expansion coefficients at the glass to alloy interface and the bonding breaks during cooling at the end of thermal treatment.

A Thermodynamic Reassessment of the Si–Al–O–N System

Lucia Dumitrescu* & Bo Sundman

Department of Materials Science and Engineering, Royal Institute of Technology, 100 44 Stockholm, Sweden

(Received 6 June 1994; accepted 6 July 1994)

Abstract

The Si–Al–O–N system has been thermodynamically reassessed due to the new model used for liquid in the Al_2O_3–SiO_2 binary system and new experimental data in the Al_2O_3–AlN system. The β'-sialon phase is described by a new model, $(Al^{3+},Si^{4+})_3(O^{2-},N^{3-})_3(N^{3-})_1$, and a set of new parameters was found to describe better the experimental behaviour phase diagram and the β'-sialon stability in the system even at reasonably low temperatures. Phase diagrams calculated using the new assessment are presented.

1 Introduction

A thermodynamic assessment of the Al–Si–O–N system was recently presented by Hillert and Jonsson.[1] Later Hallstedt *et al.*[2] proposed changes in the model for the liquid phase in the binary subsystem Al_2O_3–SiO_2 in order to extrapolate this system into the ternary CaO–Al_2O_3–SiO_2. There is also new experimental information on the Al_2O_3–AlN system given by Willems *et al.*[3,4] This requires a revaluation of the SiO_2–Al_2O_3 and Al_2O_3–AlN systems and subsequently of the Si_3N_4–AlN–Al_2O_3-SiO_2 system. The results of this reevaluation will be presented here. A second reason for the reevaluation is that it was discovered that the parameter values presented by Hillert and Jonsson predict that the β'-sialon phase is stable in the AlN–Al_2O_3 system below a certain temperature. There is no experimental support for such a result.

2 The Al_2O_3–SiO_2 System

The amphoteric nature of Al_2O_3 causes problems when this compound is mixed with either a strong acid like SiO_2 or a strong base like CaO. Previously,[5] Al_2O_3 was treated as a basic oxide, assuming that it would easily give away its oxygen. In the ternary system Al_2O_3–CaO–SiO_2 such an assumption would give, using the ionic liquid model,[6] the following model for the liquid phase

$$(Al^{3+},Ca^{2+})_p(O^{2-},SiO_4^{4-},SiO_2)_q$$

The site ratios, p and q, are set equal to the average charge on the other sublattice in order to maintain electroneutrality:

$$p = 2y_{O^{2-}} + 4y_{SiO_4^{4-}}$$

$$q = 3y_{Al^{3+}} + 2y_{Ca^{2+}}$$

Although each binary system could be described satisfactorily with this model it was impossible to obtain a reasonable extrapolation into the ternary system. As described by Hallstedt *et al.*[2] a better extrapolation could be obtained using the neutral species $AlO_{1.5}$ which would yield the following model for the liquid phase

$$(Ca^{2+})_p(O^{2-},SiO_4^{4-},SiO_2,AlO_{1.5})_q$$

The choice of $AlO_{1.5}$ rather than Al_2O_3 may be justified by the assumption that a network of triangles of O with an Al in the middle[7] forms in the liquid. As each O is shared between two Al, the basic unit is $AlO_{1.5}$. The reason for having SiO_2 as a constituent is similar because in SiO_2, which forms tetrahedra of four O with an Si in the middle, each O is shared between two Si. For the Al_2O_3–SiO_2 system this model reduces to $(AlO_{1.5},SiO_2)$, a simple associated solution model and this system was assessed in such a way by Hillert *et al.*[8]

3 The Al_2O_3–AlN System

McCauley and Corbin[9] published a phase diagram

*On leave from Matpur SA, Sos. Garii Catelu nr. 5, Bucharest 3, Romania.

for the Al_2O_3–AlN system and they listed seven phases, AlN (with a wurtzite structure); $Al_9O_3N_7$ (with a 27R AlN polytype structure); $Al_7O_3N_5$ (with a 21R AlN polytype structure); $Al_6O_3N_4$ (with a 12H AlN polytype structure); $Al_{23}O_{27}N_5$ (with an AlON spinel structure); $Al_{22}O_{33}N_2$ (with a ϕ-spinel structure); and Al_2O_3 (with a corundum structure).

In the present work all phases, except $Al_{22}O_{33}N_2$ (ϕ-spinel structure), were taken into account. The new experimental information concerning the extention of the spinel phase in the quasibinary system Al_2O_3–AlN was also included.

The width of the homogeneity of the spinel phase varies with temperature: at 1850°C spinel is the stable phase between 66 mol% Al_2O_3 and 81 mol% Al_2O_3.[4] This region becomes smaller at lower temperatures. Below 1640°C[3] spinel is not stable.

Hillert and Jonsson[1] described the liquid phase in this quasibinary system with the model $(Al^{3+})_p(N^{3-},O^{2-})_q$. However, in line with the choice of $AlO_{1.5}$ as a species the present work will use the substitutional model ($AlO_{1.5}$,AlN).

4 The Si–Al–O–N System

The Si–Al–O–N system has four components and should be represented by a regular tetrahedron (Fig. 1). If the elements have their normal valencies (Si^{IV}, Al^{III}, O^{II}, and N^{III}) then all possible solid compounds lie on an irregular quadrilateral plane, and if the concentrations are expressed in equivalents, i.e. the corners of the tetrahedron are respectively $3Si^{12+}$, $4Al^{12+}$, 60^{12-} and $4N^{12-}$, then these solid compounds all lie on a square plane in which any point represents a combination of 12 positive and 12 negative valencies (Fig. 2). Conventionally, Si_3N_4 is placed at the bottom left-hand corner of the square diagram and distances from left to right

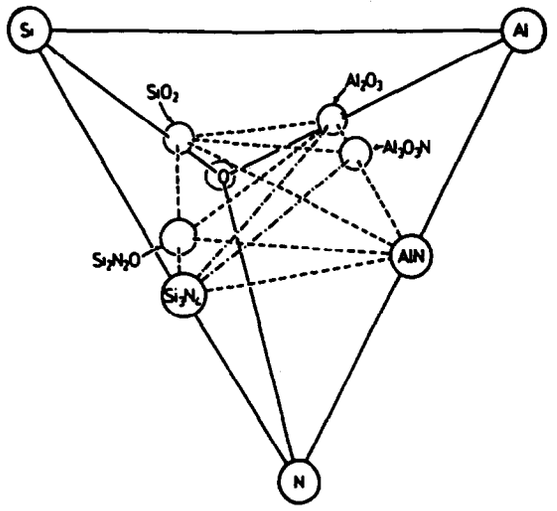

Fig. 1. The tetrahedral representation of the Si–Al–O–N system. Possible compositions are on the neutral plane indicated by the shared area.

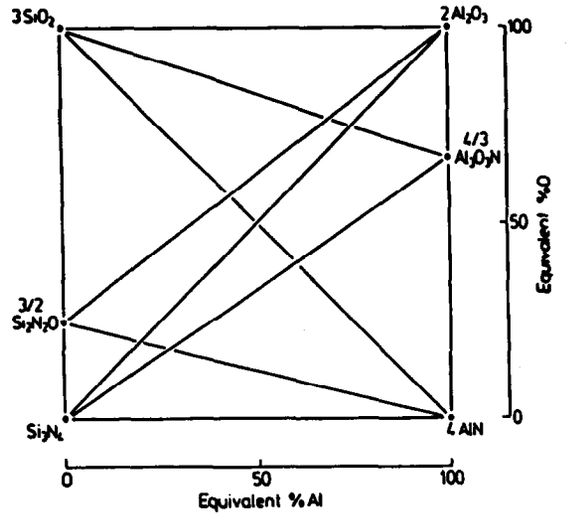

Fig. 2. The square representation of the Si–Al–O–N system using equivalent concentration.

represent replacement of silicon by its equivalent of aluminium and distances from bottom to top the replacement of nitrogen by oxygen.[10]

The experimental work on the phase relations in the quasi-ternary system Si_3N_4–AlN–Al_2O_3–SiO_2

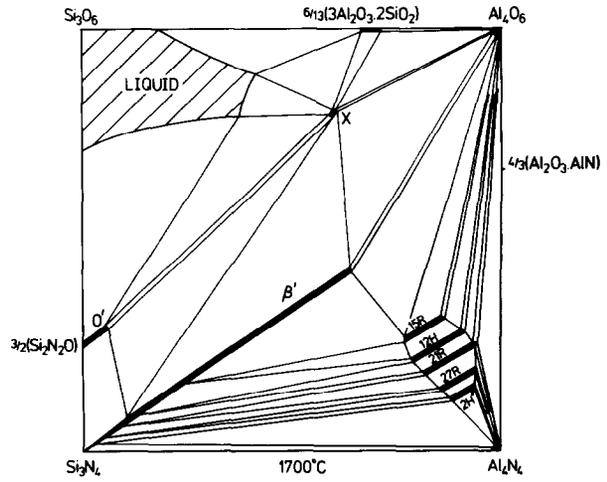

Fig. 3. The Si–Al–O–N behaviour diagram based on experimental data at 1700°C.[13]

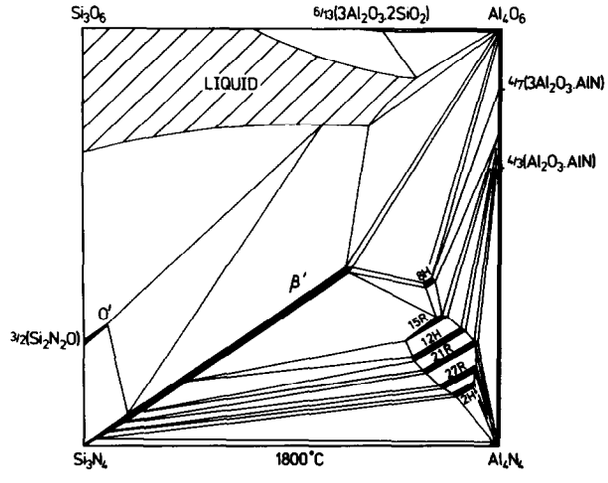

Fig. 4. The Si–Al–O–N behaviour diagram based on experimental data at 1800°C.[13]

was carried out mainly for the Si_3N_4–Al_2O_3–SiO_2 region of the diagram. The thermodynamic assessment of the SiAlON system is based on the experimental work of Naik *et al.*,[11] Bergman *et al.*[12] and on the most recent behaviour diagrams by Jack[13] for the Si_3N_4–Al_4N_4–Al_4O_6–Si_3O_6 system at 1700 and 1800°C (Figs 3 and 4). These two behaviour diagrams represent a summation of experimental observations. Jack did not claim that it is an equilibrium phase diagram in a thermodynamic sense due to the following difficulties and uncertainties of the experimental observations:

- weight losses due to evaporation, which change the overall composition;
- in the absence of liquid phase, the reaction between nitrides is very slow;
- in most experiments, the gaseous environment is ill-defined and many species are present in trace amounts (SiO(G), Si(G), Al_2O(G) etc.) and play a part depending on both thermodynamics and kinetics, and they affect the final phase assemblage.

Each phase in the system extends in a direction of constant metal:non-metal atom ratio (M:X) along which Si+N is replaced gradually by Al+O. The homogeneity ranges perpendicular to this are quite small.

The Si_3N_4 phase can dissolve a large amount of Al_2O_3 + AlN and forms β'-sialon. This phase extends essentially along the 3M:4X line with a homogeneity range described by $Si_{6-z}Al_zO_zN_{8-z}$, where z reaches a maximum of about 4 at 1700°C but decreases with decreasing temperature.

The Si_2N_2O phase can dissolve Al_2O_3 and forms O'-phase. This phase extends with a limited composition range along the 2M:3X line toward Al_2O_3.

The X-phase present in the system has a small range of homogeneity but, as in the previous assessment work by Hillert and Jonsson, it will be treated as a phase of fixed composition, $Si_{12}Al_{18}O_{39}N_8$. This composition is further supported by recent work by Anya and Hendry.[14]

Near the AlN corner of the diagram, six phases have been interpreted in terms of AlN-polytypes containing excess non-metal atoms. Their structures are directly related to their compositions M_mX_{m+1} and are described by the Ramsdell symbols 8H, 15R, 12H, 21R, 27R, and 2H.[15] In the strictest sense, polytypes are layer structures which, within very narrow limits, preserve a constant chemical composition and differ only in the way the layers are stacked together. In the sialon 'polytypes', both the composition and the unit cell dimensions show a systematic variation with structure type and the International Union of Crystallography has assigned the name 'polytypoids' to such series.[16]

For the β'-sialon phase a slightly modified model compared to that of Hillert and Jonsson will be adopted as there are two distinctly different sites for nitrogen.[17] It will be assumed that O^{2-} can enter only into one of the N^{3-} sublattices, leaving the other sublattice with one site always filled with N^{3-}. The new model would thus be

$$(Al^{3+},Si^{4+})_3(O^{2-},N^{3-})_3(N^{3-})_1$$

The maximum theoretical amount of Al to dissolve in β'-sialon would thus be Al_3O_3N.

At reasonably low temperatures the liquid phase exists mainly in the quasi-binary Al_2O_3–SiO_2 and it extends at higher temperatures considerably into the square towards the AlN corner of the diagram. It will be described with an associated solution model based on the species $SiN_{4/3}$ in addition to those already mentioned:

$$(AlN,\ AlO_{1.5},\ SiO_2,\ SiN_{4/3})$$

5 Optimization

The optimization was made using a computer program called Parrot,[18] which allows the simultaneous consideration of different types of thermodynamic and phase diagram data. First, models that depict different phases in the system were selected. A number of parameters for each phase were then optimized in order to describe the experimental information as well as possible. The program works by minimizing an error sum by varying selected model parameters. The sum of errors is calculated from the experimental information where each piece of information used is given an experimental uncertainty and also a weight according to its estimated accuracy and relative importance. In this system the available experimental information is not enough to allow the optimizing program to determine the model parameters without manual interaction.The weights were changed by trial and error and the model parameters were optimized until most of the information could be satisfactorily described. As input, selected experimental data together with known thermodynamical data for the solids and liquids were used.

The binary assessment of SiO_2–Si_3N_4 from Hillert and Jonsson[19] was accepted and together with the two new assessments of the quasibinaries, AlN–Al_2O_3 and SiO_2–Al_2O_3, a new thermodynamic assessment of the SiAlON system was attempted. There is no experimental information in the quasibinary system AlN–Si_3N_4.

The final thermodynamic description of the system, including the values of the assessed parameters, is given in Appendix 1.

The heat capacities for the crystalline phases were assumed to follow a Neuman–Kopp relation using linear combinations of the four stable compounds SiO_2, Al_2O_3, AlN and Si_3N_4.

Two interaction parameters were optimized for the liquid phase, one for the diagonal ($SiN_{4/3}$–$AlO_{1.5}$) and one for the ternary ($SiN_{4/3}$–SiO_2–$AlO_{1.5}$). Both parameters were assumed to be temperature independent.

For the β'-sialon phase two of the corner compounds were optimized, the neutral compound Al_3O_3N and for the charged compound $Al_3N_3^{4-}$. The parameter for the neutral compound was assumed to be linearly temperature dependant. In addition, the model has a reciprocal parameter, representing the simultaneous exchange of Al^{3+} with Si^{4+} and O^{2-} with N^{3-}. It was found that this parameter was necessary in order to keep the low solubility of Al_2O_3 in β'-sialon in the three-phase equilibrium liquid+O'+β'-sialon.

The solubility of Al_2O_3 in the O' phase was optimized using the fictitious corner compound $Si_2O_3^{2-}$ only. A linear temperature dependence for this parameter was required to describe the solubility for the whole temperature range. The model for the O' phase extends all the way to the composition Al_2O_3 but the parameter for this metastable compound was kept fixed to the same value as estimated by Hillert and Jonsson.

The melting temperature of the X phase was fitted to 1727°C using a single parameter representing the enthalpy of formation of X.

In the present work, the polytypes were only considered in the assessment of the AlN–Al_2O_3 system due to the very meagre information on their extension into the square diagram. They were thus treated as stoichiometric Al_2O_3–AlN phases. 21R, 27R and 12H were considered and only a single enthalpy value was fitted to describe the experimental sublimation or melting temperature. In the cases when the phases had a lower temperature limit an entropy of formation was also fitted.

6 Results

The new calculated phase diagram for the quasibinary AlN – Al_2O_3 is given in Fig. 5. Selected experimental data are included in Fig. 6 to give a comparison of the calculated diagram with the experimental data.

Figures 7–10 give a series of isothermal sections of the Si_3N_4–Al_4N_4–Al_4O_6–Si_3O_6 system. The comparison with experimental data shows good agreement. Figure 11 shows an extrapolation to higher temperature, 1900°C.

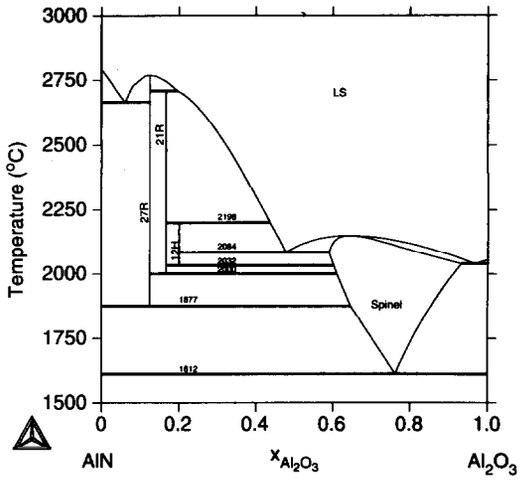

Fig. 5. The AlN–Al_2O_3 phase diagram at 1 bar, according to the present optimization, calculated without including the gas phase. The calculation includes one spinel phase and 27R, 21R, and 12H AlN-polytype phases.

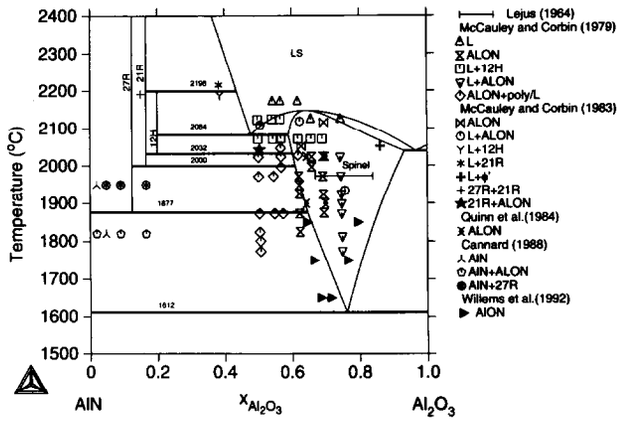

Fig. 6. Comparison of the calculated AlN–Al_2O_3 phase diagram with experimental data from several sources.

The calculated diagram at 1400°C is given in Fig. 12. Figure 13 shows an alternative presentation of this diagram using the oxygen potential as one of the axes. In this representation, the diagram is useful for determining the optimal values for the partial pressures of oxygen, an important

parameter for synthesis of different materials in the system, β'-sialon for example.

Generally there is good agreement between experimental and calculated data both for the AlN–Al_2O_3 and Si_3N_4–Al_4N_4–Al_4O_6–Si_3O_6 system.

In the AlN–Al_2O_3 diagram the spinel phase extends closer to the Al_2O_3 composition than

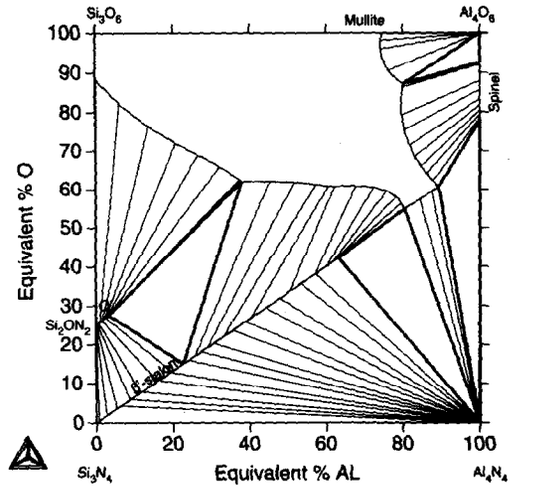

Fig. 11. Calculated section at 1900°C according to the present optimization.

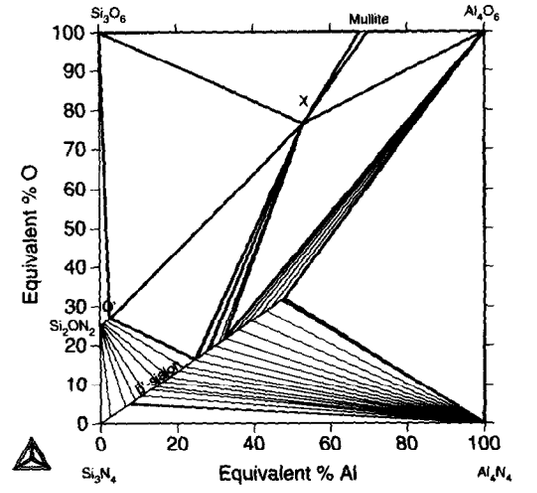

Fig. 12. Calculated section at 1400°C according to the present optimization.

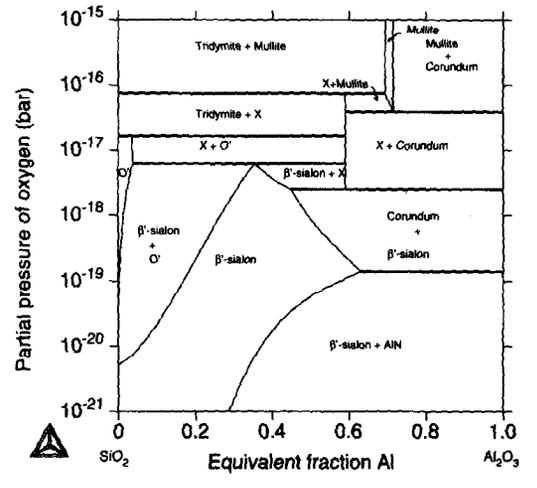

Fig. 13. The same calculation as for the diagram in Fig. 12 but using oxygen potential as an alternative presentation of the result.

experimental data can support. However, the description of the spinel phase must agree with the estimated stability of γ-alumina for pure Al_2O_3 as given by Hallstedt.[20] This restricts the possibilities to vary its composition. The experimental phase

diagram in this range has several impossible features and the current fit is acceptable until better experimental data are available. The 27R, 21R, and 12H AlN-polytypes have been considered and the assessment give a good fit of their stability temperature range. Hillert and Jonsson only considered the 27R polytype but, otherwise, the present diagram is very similar to theirs. However, it should again be emphasized that their parameter values for β'-sialon make it stable in the $AlN–Al_2O_3$ diagram, a fact which was not noticed by them. This has now been avoided by the new assessment of the β'-sialon.

Figure 14 is a reproduction of the $Si_3N_4–Al_4N_4–Al_4O_6–Si_3O_6$ system at 1750°C calculated by Hillert and Jonsson and it may be compared with Fig. 10 from the present assessment. The most striking difference is that the β'-sialon phase does not extend as close to the $AlN–Al_2O_3$ side as before. This is a result of the new model for β'-sialon and of the set of new parameters. This has also resulted in the β'-sialon corners of three-phase triangles moving closer to the Si_3N_4 corner. This has resulted in a better agreement with the experimental points for LS + β' but some of those points still fall outside the calculated two-phase field.

Another improvement can be seen in Fig. 9 where an experimental point for X+corundum falls on the calculated two-phase field. According to Hillert and Jonsson, this two-phase field only exists at considerably lower temperatures. The parameter values given by Hillert and Jonsson predict that the X phase should melt at 1721°C. This is only 1°C different from the experimental value of Naik *et al.*[11] The present assessment predicts a melting point of 1727°.

Another difference between the two assessments concerns the liquid phase field which is wider and extents deeper into the diagram according to the present assessment. This has resulted in three experimental points for O'+LS+X at 1650°C, now falling outside the calculated three-phase triangle.

It should again be emphasized that the ternary polytypes in the AlN-rich part of the diagram remain unassessed as there is no thermodynamical information available to evaluate them. Calorimetric measurements of the enthalpy of formation or the enthalpy of transformation are needed and their extension into the square diagram should be studied in more detail.

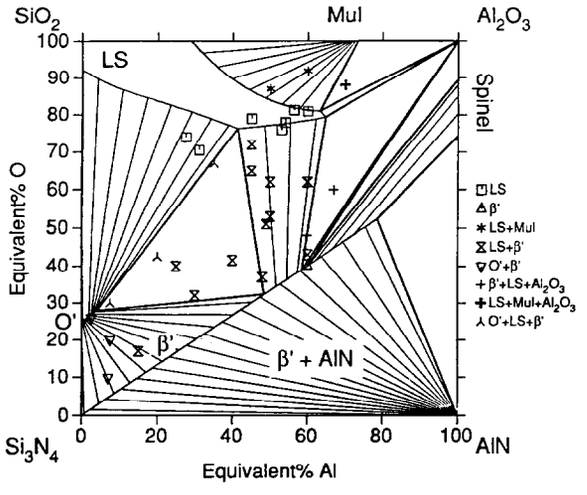

Fig. 14. Phase diagram at 1750°C calculated by Hillert and Jonsson using a different model for the liquid and β' phases.

Aluminum Magnesium Oxynitride: A New Transparent Spinel Ceramic

Arielle Granon, Patrice Goeuriot & François Thevenot

Ecole Nationale Supérieure des Mines de Saint-Etienne, 158 Cours Fauriel, 42 023 Saint-Etienne, France

(Received 13 May 1994; revised version received 27 July 1994; accepted 1 August 1994)

Abstract

A pure and dense spinel solid solution can be obtained by reaction-sintering between alumina–magnesia or aluminate of magnesium and aluminum nitride or oxynitride. The influence of post isostatic pressing on density, microstructure and transmittance (visible-IR) is studied for different starting materials. Transmittances of 65 and 80% are obtained for a 6 mm thick sample in visible and infra-red spectra, respectively.

1 Introduction

New technologies need optical materials with the best mechanical properties. Initially monocrystalline ceramics as quartz or sapphire were developed, and more recently polycrystalline ceramics like $MgAl_2O_4$[1–3] and γAlON[4–8] have been studied. Indeed these spinel solid solutions can be obtained transparent in the range 0·1–6 μm. The aluminate of magnesium is more easily sintered than γAlON (sintering temperature 1600–1700°C against 1850–1900°C for γAlON), but γAlON exhibits good mechanical properties: MOR = 500 MPa[8] instead of 400 MPa for $MgAl_2O_4$.[3]

The present paper describes the preparation of a new transparent polycrystalline oxynitride spinel phase, MgAlON (Fig. 1). A pure solid-solution containing Al–Mg–O and N could be prepared by reaction sintering between Al_2O_3–AlN–MgO or Al_2O_3–$MgAl_2O_4$–AlN. Jack[9] observed at 1800°C a large field of homogeneity of this solid-solution. Later, Weiss *et al.*[10] at 1750°C and Sun *et al.*[11] at 1600°C specified this field. Weiss *et al.*[10] remarked that the magnesium aluminate was an intermediate phase before obtaining the MgAlON phase during the Al_2O_3–AlN–MgO reaction. Laurent-Fievez[12] observed MgAlON at 1350°C and this result has been confirmed by Willems.[8] Previous papers have described the reactivity[13] and the sintering-reaction[14] of MgAlON whose main results were: (i) the control of the parasite reaction between AlN–MgO and AlN–$MgAl_2O_4$; (ii) the role of cationic vacancies of the intermediate aluminate of magnesium phase; and (iii) the morphology role of the starting materials.

2 Experiments

Six compositions (A to F) with different starting materials (Table 1) were studied: alumina (α + γ and γ crystallographic forms), magnesium oxide or aluminate of magnesium, aluminum nitride (commercial powder or obtained by nitridation of boehmite[15]), aluminum oxynitride (also obtained by nitridation of boehmite[16]) and MgAlON powder prepared in the laboratory.

Starting powders (samples A to E) were milled with highly pure alumina balls in anhydrous ethyl alcohol with phosphoric ester as dispersant agent (1·5 wt%). After drying under vacuum, the powders were sieved at 200 μm. In one case (D), polyvinyl butyral (PVB) and polyethylene glycol (PEG) were used as binder and plasticizer (1·5 wt%/dry powder). The slurry was then spray-dried.

Samples F were prepared in a different way. First, pellets with α-alumina, MgO and AlN (Starck) powders were heated at 1550°C for 6 h to perform the reaction. Then the pellets were crushed in an Aurec grinder and ball milled for 24 h with 1 wt% of MgO, 0·5 wt% PVB and 1 wt% PEG. Finally the slurry was spray-dried.

The pellets for samples A to F (about 25 × 25 × 10 mm) were obtained by isostatic pressing in plastic mold under 400 MPa; if necessary a debonding cycle was carried out to remove organic binder (samples D and F).

The reaction sintering (samples A to E), like the sintering (sample F), took place in a graphite furnace at 1675°C for 6 h in a powder bed made of 50 wt% AlN and 50 wt% MgO under a nitrogen atmosphere (0·1 MPa).

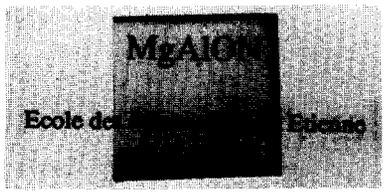

Fig. 1. MgAlON transparent piece (25 × 25 × 6 mm).

All the samples were post-hipped in the temperature range 1675–1810°C for 1 or 1·5 h under 155 MPa of nitrogen. (HIP treatments were performed by National Forge Europe (B).)

Samples were characterized by density (by the Archimede's method in water), X-ray control, microstructure analysis (SEM after thermal etching in N2 atmosphere at about 1600°C, 1 min, rate ramp: 15°C/min TEM), transmittance in visible (Perkin-Elmer Lambda 2) and infra-red (Biorad FTS40) spectra after polishing down to 1 μm diamond.

3 Results

The given compositions (Table 1) have been determined previously[13,14] to obtain pure and sintered (without open porosity) MgAlON samples at low temperature (1550°C). For each composition (A to F) the ratio between chemical elements was the same and corresponding to 21 mol% MgO, 13 mol% AlN, 66 mol% Al_2O_3.

After a treatment at 1675°C for 6 h, each sample was monophased but due to parasite reactions between AlN–MgO or AlN–$MgAl_2O_4$[13] which induce a loss of Mg and N, the spinel solid compositions differ. Each sample contained 3–3·5 wt% of nitrogen determined by complete oxidation.[13]

3.1 HIP effects on chemical composition

Monophased MgAlON samples obtained from the compositions A to F by reaction-sintering or sintering at 1675°C for 6 h, preserved the same lattice parameter after post-hipping whatever the HIP temperature was. For all the samples, lattice parameters measured after sintering were between 0·7992 and 0·8009 nm and were between 0·7994 and 0·8004 nm after HIP treatments. These values are within the accuracy of measurement (0·005 nm).

3.2 HIP effects on densification

Results are given in Table 2. As the relative accuracy of the density determination was 0·1%, HIP treatments had a significant effect at 1675°C (the same temperature as those of the sintering cycle): +3·3% for A and +0·5% for other samples (B to E). Higher HIP temperatures had no effect on the densification.

After reaction-sintering, samples A could have some very fine open porosity, not detected by measurement (in water), so HIP treatment was inefficient for these samples.

Only one HIP treatment was performed at 1810°C for 1 h, it induced an increase of densification (1·7%).

3.3 Microstructural effects of HIP treatments

Before hipping, sample microstructures could be arranged in three classes:

(i) homogeneous and fine grain size (2–3 μm) for B, C, D samples (see Fig. 2)
(ii) homogeneous and coarse grain size (about 10–15 μm) for A, E and F samples (see Fig. 3).
(iii) inhomogeneous for D with binder or D annealed above 1750°C (see Fig. 4).

A TEM observation of D with binder had shown that the fine intergranular porosity disappeared by hipping at 1675°C with a light grain growth (Fig. 5). This was also observed by SEM analysis for B and C samples up to 1810°C HIP treatment and for D up to 1765°C HIP treatment.

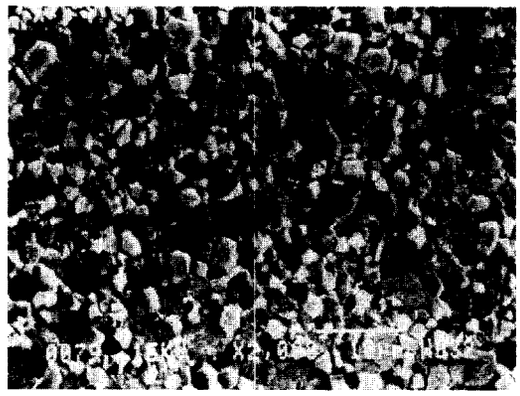

Fig. 2. Microstructures of B, C and D samples sintered at T = 1675°C, 6 h.

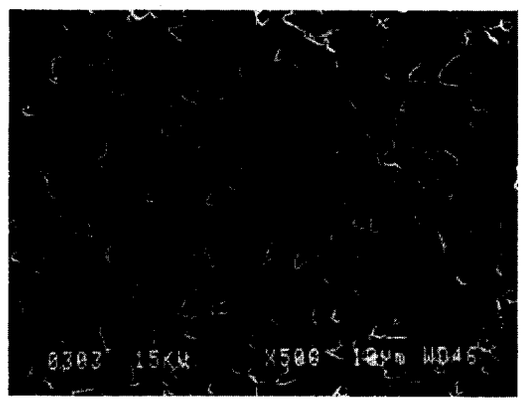

Fig. 3. Microstructure of A, F samples sintered at T = 1675°C, 6 h.

For homogeneous but coarse grain size (A,E,F samples) the grain size did not change, as shown in Fig. 6, and up to 1765°C, intergranular porosity still remained. At 1810°C, E samples presented large grains (2–300 μm) with intragranular porosity (Fig. 7) whereas F samples had a homogeneous grain size (50 μm) without porosity (Fig. 8).

When initial samples presented some heterogeneity (some large grains) as D with binder or D annealed samples, HIP treatment preserved this microstructure up to 1765°C (Fig. 9) but above this temperature the grain size became bimodal (see Fig. 10).

The post-hip treatment can be considered as an annealing treatment under pressure. To analyse the pressure effect, homogeneous samples were annealed for several hours under 0·1 MPa of N_2. Up to 1750°C a homogeneous microstructure had remained but at 1750°C the grain growth and

porosity appeared (Fig. 11). So the pressure delays the grain growth during the HIP treatment. Nevertheless this delay depends on the HIP temperature and the initial kind of microstructure. For C and D samples grain growth occurred at 1810°C HIP treatment; conversely in samples A the microstructure remained almost identical whatever the HIP treatment (between 1675 and 1810°C).

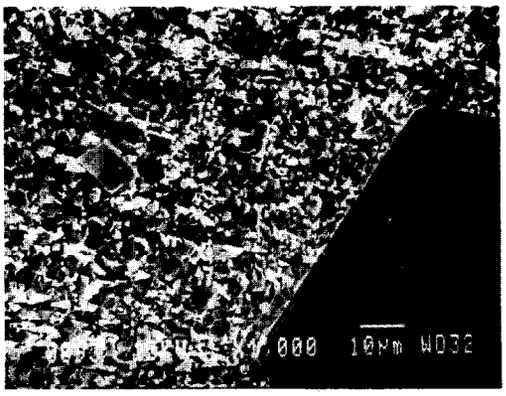

Fig. 9. Microstructure of D (with binder or annealed) after hipping up to 1765°C, 155 MPa.

Fig. 10. Microstructure of D (with binder or annealed) after hipping up to 1810°C, 155 MPa.

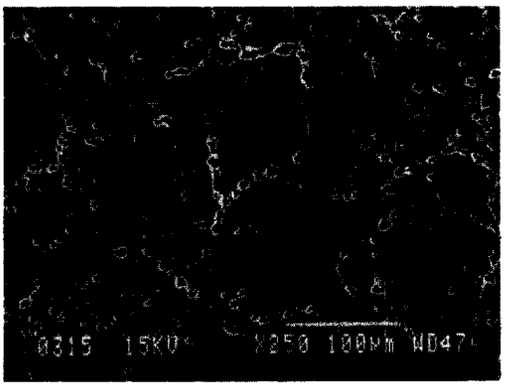

Fig. 11. Effect on grain size by annealing treatment without pressure ($T < 1750$°C).

The microstructure evolution of hipped samples was linked to the initial state of the sample and also to the HIP treatment conditions.

3.4 Optical effects of HIP treatments

Table 3 reports transmittance results (%) in visible wavelength for different HIP treatments.

Samples A and E were impervious to visible waves because of the fine intragranular porosity which has been previously observed. For B, C and D (without binder) samples, although a maximum density was reached from 1675°C, the transmit-

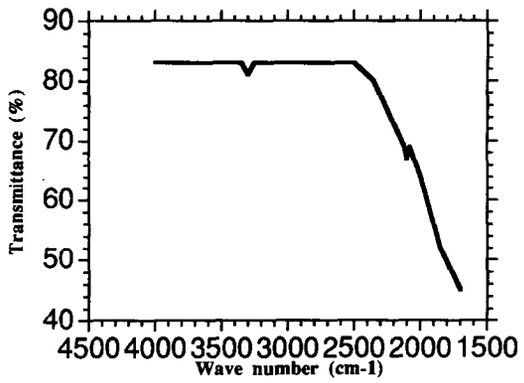

Fig. 13. Infra-red spectrum of B samples (thickness 6 mm).

tance increased above this HIP temperature (65% for B sample at 1810°C, Fig 12). For D samples the binder effect was significant on densification but when the grain size was bimodal the transmittance decreased (at 1810°C) as shown in Table 3. For F samples despite a regular grain size and no porosity, the transmittance for a thickness of about 3 mm in the visible spectrum is very poor (5%).

Unfortunately the samples were often coloured perhaps by carbon or metallic oxide pollution. Only B samples were not coloured, the nitridation could increase the purity of powders.

The I-R spectrum is shown in Fig. 13. A weak peak of OH or NH absorption can be seen. The transmittance was 80% up to 2500 cm^{-1} and the cut off appeared at 1700 cm^{-1}. This spectrum is very close to those of γAlON and $MgAl_2O_4$.

4 Conclusion

γAlON has very good mechanical properties but it is difficult to obtain it transparent with a sufficient thickness. The magnesium aluminate ($MgAl_2O_4$) is easier to sinter but its intrinsic mechanical properties are lower than those of γAlON.

It has been shown in this study that it is possible to obtain a new transparent solid solution spinel: a MgAlON spinel phase sample has been made transparent (Fig. 1) in visible (60%) and infra-red spectra (80%) for a 6 mm thickness with a very fine grain size 5–7 μm and about 3 wt% of nitrogen. The choice of the starting powders and the choice of the reaction-sintering cycle linked to a HIP temperature are the predominant parameters which allow the attainment of transparent samples with a homogeneous microstructure.

Abstract

Lanthanum dititanate ceramics have been prepared by the mixed oxide route. Up to 6 mol% Nb_2O_5 or 10 mol% excess TiO_2 was added to the starting mixes. Sintered products exhibited densities of ≥ 95% theoretical. $La_2Ti_3O_9$ was present as a second phase in all doped samples. With the addition of increasing amounts of Nb_2O_5 or TiO_2 there was formation of $La_2Ti_3O_9$ within the $La_2Ti_3O_9$ matrix, and the average grain size decreased slightly. Dielectric properties were sensitive to the presence of the second phase: relative permittivity increased from 47 to ~56 with additions; the dielectric loss tangent was independent of the amount of excess titania but increased dramatically when > 3 mol% Nb_2O_5 was added; the temperature coefficient of capacitance (TCC) decreased monotonically from +50 ppm/°C for undoped $La_2Ti_2O_7$ ceramics to —50 ppm/°C for specimens containing ~10 mol% additions. Material with zero TCC can be achieved with the addition of ~5 mol%, Nb_2O_5 or excess TiO_2.

1 Introduction

Lanthanum dititanate, ($La_2Ti_2O_7$) is an important member of the ferroelectric family, having the general formula $A_2B_2O_7$ and a layered perovskite structure. Investigations of the electrical properties of $La_2Ti_2O_7$ ceramics commenced over 30 years ago,[1,2] but more recent studies of single crystals revealed that lanthanum dititanate has a very high Curie temperature (1500°C)[3] and exhibits strong piezoelectric and electro-optic effects.[4] The room temperature structure of $La_2Ti_2O_7$ is essentially monoclinic, although two modifications have been proposed; one with symmetry $P2_1$[5,6] and one with symmetry $Pbn2_1$.[7] The structure changes to orthorhombic ($Cmc2_1$) at approximately 780°C, and at 1500°C it transforms into the paraelectric phase.[8] The layered perovskite (or perovskite - slab) structure contains slabs of four distorted TiO_6 octahedra linked by La atoms.[5] The structural anisotropy is expected to lead to anisotropy in dielectric and electrical properties.[9]

With its unusually high Curie temperature and temperature-stable dielectric properties, $La_2Ti_2O_7$ is a candidate for high temperature piezoelectric and electro-optic devices,[9] and microwave frequency components.[10]

Ceramics of $La_2Ti_2O_7$ have mainly been prepared by the classical mixed oxide route,[1,2] although Fuierer and Newnham[9] employed Evaporative Decomposition of Solutions (EDS) and molten salt synthesis routes. Takahashi and Kageyama[11] used a coprecipitation method to prepare ceramics of mixed phases of $La_2Ti_2O_7$ and $La_2Sn_2O_7$. Most studies to date have focussed on the microstructure and properties of the end member $La_2Ti_2O_7$, or solid solutions involving this compound.[11,12] The primary objectives of the present study were to assess the effect of (i) excess TiO_2, and (ii) additions of Nb_2O_5 on the behaviour of $La_2Ti_2O_7$ prepared by the mixed oxide route. Specific attention was paid to the role and effect of second phase $La_2Ti_3O_9$.

2 Experimental

Two series of samples were prepared by the standard mixed oxide route: (A) $x\mathrm{TiO_2}.(1\text{-}x)\mathrm{La_2Ti_2O_7}$ where x = 0, 0·02, 0·04, 0·06, 0·08 and 0·10; (B) $y\mathrm{Nb_2O_5}.(1\text{-}y)\mathrm{La_2Ti_2O_7}$, where y = 0, 0·005, 0·015, 0·03 and 0·06.

Hence $x = y = 0$ represents the undoped, $La_2Ti_2O_7$ reference composition.

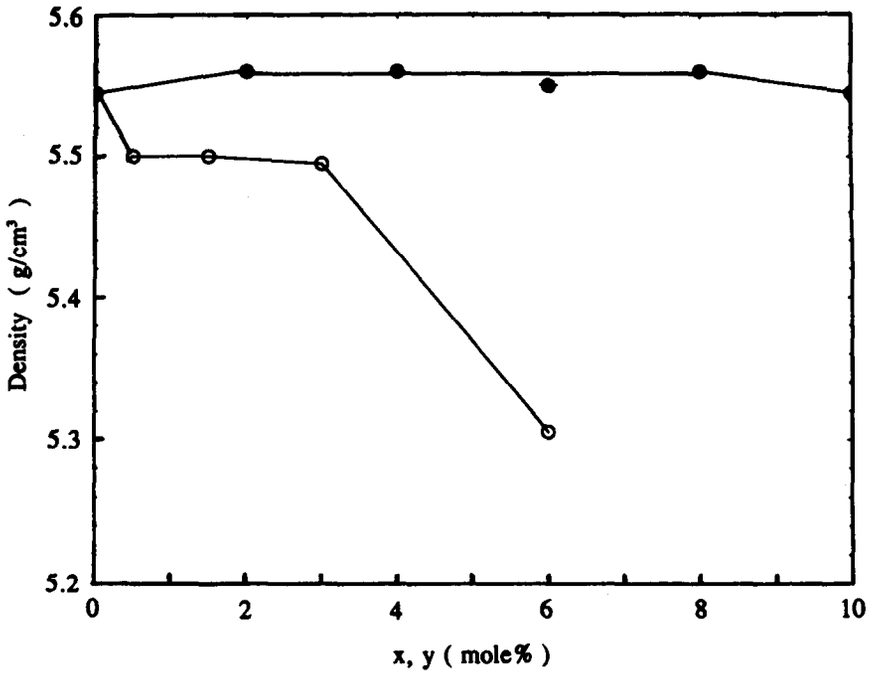

Fig. 1. Specimen densities as a function of additive content: ○ Nb_2O_5; ● TiO_2.

The starting materials were La_2O_3, TiO_2 (Fluka, purity of 99·98, and 99% respectively) and Nb_2O_5, (BDH, purity 99·5%). Prior to weighing the lanthanum oxide was dried by heating at 700°C for 4 h. Powders of La_2O_3 and TiO_2, in the molar ratio of 1 : 2, were mixed and vibration-milled in propan-2-ol with zirconia balls for 6 h. The dried mixtures were then calcined at 1100°C for 4 h. The required amounts of excess TiO_2 or Nb_2O_5 were added to batches to form compositions in the series (A) and (B). The powders were then remilled in propan-2-ol for 8 h. Pellets 16 mm in diameter and 8 mm high were pressed uniaxially at 900 kg/cm^2 without binder and then sintered at temperatures in the range 1300–1400°C for 4 h. Specimens for electrical measurements, diameter ~12·4 mm and thickness typically 1·4 mm, were cut from the sintered pellets. Specimens for microstructural studies were ground to 1200 grade SiC, polished with diamond paste down to 1/4 μm and then thermally etched at a temperature of approximately 1150°C.

X-ray diffraction analysis was carried out using Cu K_α radiation with a Philips PW1710 diffractometer and horizontal goniometer. Microstructures were studied by optical microscopy and scanning electron microscopy, Philips SEM 505 with energy

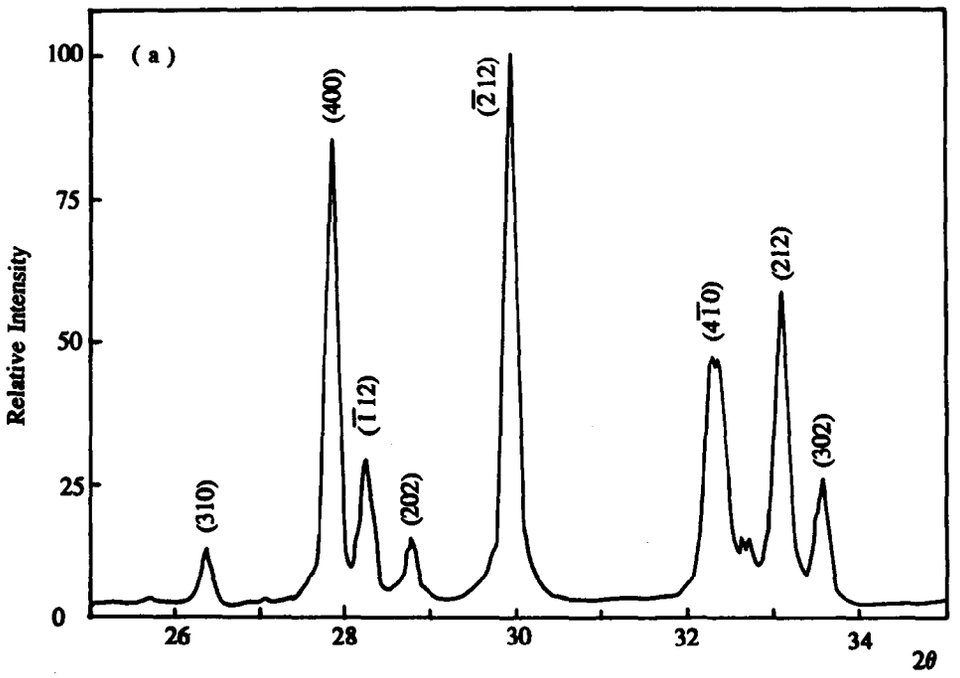

Fig. 2. X-ray diffraction spectra for ceramic specimens prepared from starting mixes $(y)Nb_2O_5.(1\text{-}y)La_2Ti_2O_7$, (a) $y = 0$; (b) $y = 0{\cdot}015$; (c) $y = 0{\cdot}06$. $LT_2 = La_2Ti_2O_7$; $LT_3 = La_2Ti_3O_9$.

dispersive X-ray analyser EDAX, model 9100. For each specimen, 5–8 grains of each type were analysed and the average composition determined. Area fractions of each phase, based upon contrast differences, were determined manually, after applying fine mesh grids to SEM micrographs for each specimen. The average grain sizes were obtained by the mean linear intercept method.

A Hewlett Packard 4284A precision LCR meter was used to determine relative permittivity (via capacitance measurements) and loss factor as a function of temperature from 15 to 120°C at frequencies up to 1 MHz. Values for the temperature coefficient of capacitance (TCC) were determined from data obtained in the range 15–85°C.

3 Results and Discussion

3.1 Specimen density

Figure 1 shows the densities for specimens of the two series as a function of composition. The theoretical density for $La_2Ti_2O_7$ is 5·782 gm cm^{-3} [13] and that of the related phase $La_2Ti_3O_9$, 5·325 gm cm^{-3}.[14] The presence of extra titania (Series A) did not have any significant effect on density. For all samples, density was approximately 96% theoretical. For the niobia-doped samples, densities were around 95% theoretical at low doping levels, but much lower in the specimens doped with 6 mol% Nb_2O_5.

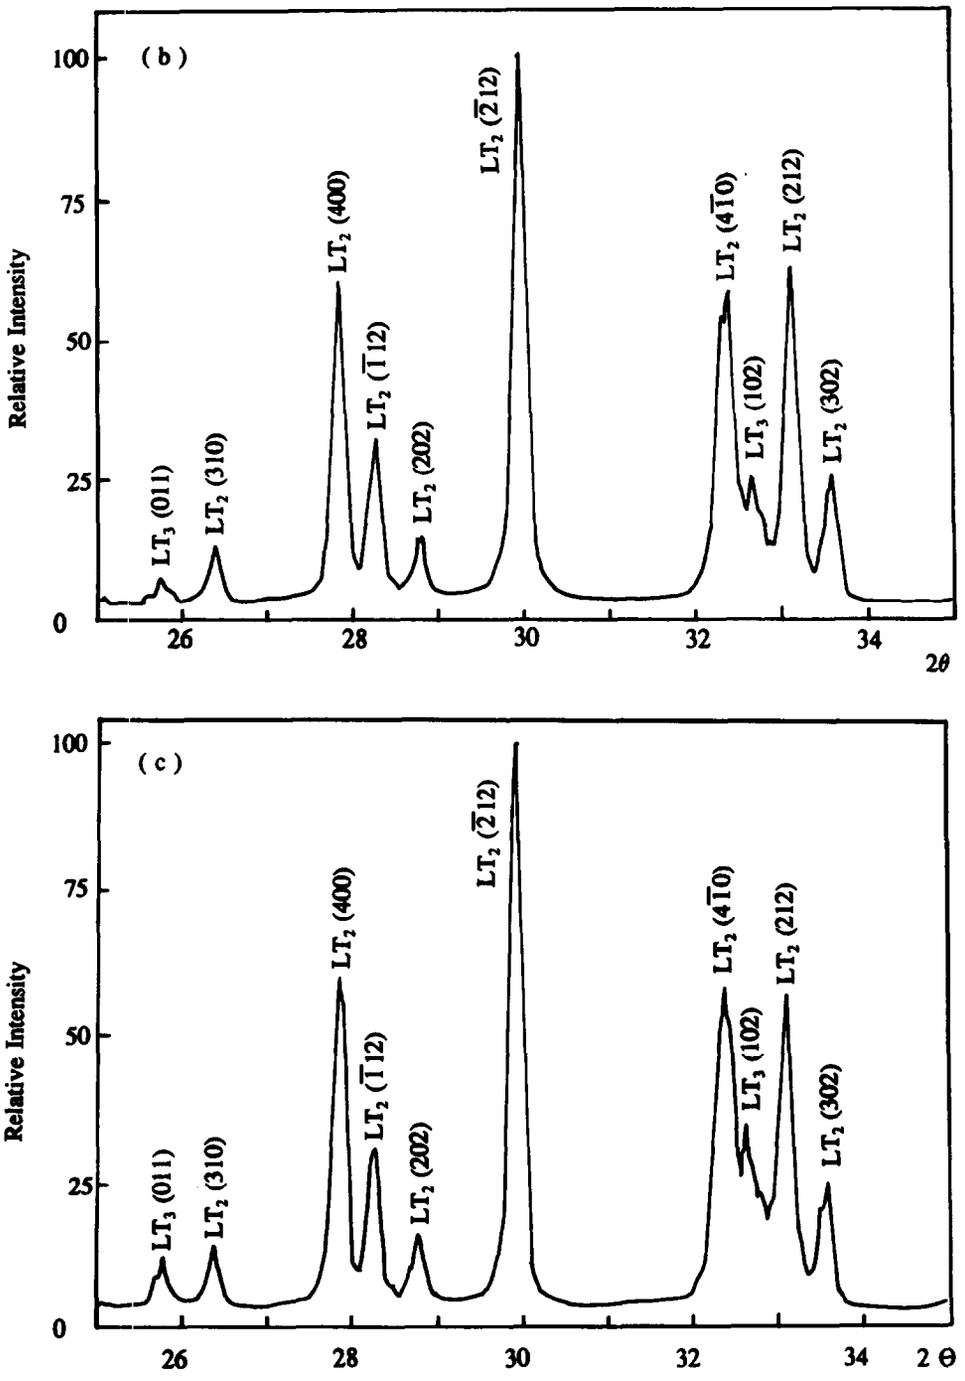

Fig. 2. — continued.

3.2 Phase analysis

Figure 2 shows parts of the X-ray diffraction spectra obtained for selected specimens. The major peaks for all the samples containing up to 6 mol% Nb_2O_5 (i.e. $y \leq 0{\cdot}06$) and up to 10 mol% excess TiO_2 (i.e. $x \leq 0{\cdot}10$) can be indexed to monoclinic $La_2Ti_2O_7$ with the space group as $P2_1$.[1] The positions and intensities of the peaks are in satisfactory agreement with published data.[13] In the X-ray diffraction spectra specimens, a number of extra reflections are present, e.g. near 25·8 and 32·7° 2θ (Figs 2(b) and (c)). None of the extra peaks could be assigned to the phase $La_4Ti_9O_{24}$, which is expected to be the nearest compound to $La_2Ti_2O_7$ on the TiO_2-excess side of $La_2Ti_2O_7$ in the phase diagram of the La_2O_3–TiO_2 system.[2] However, the positions and intensities of the extra peaks were found to represent $La_2Ti_3O_9$.[14] The peaks corresponding to the (011), (102) and (111) reflections of the $La_2Ti_3O_9$ phase grew in intensity as x and y increased. (NB: the peak for (111) occurs at 2θ angle of 40·50 which is outside the range covered by Fig. 2.)

3.3 Microstructures

Undoped $La_2Ti_2O_7$ specimens are single phase with a near homogeneous microstructure (Fig. 3). The grains, ranging in size from 10 to 30 microns, are somewhat elongated, but not to the degree reported by Fuierer[9] where the grains appeared as highly anisotropic platelets. For the specimens prepared with excess TiO_2, or Nb_2O_5 additions, a second phase is visible in SEM micrographs (e.g. Fig. 4) as clusters of grains much smaller than those of the major phase. These small grains look darker than the matrix, indicating lower average atomic number.

Quantitative EDAX analyses for the specimens prepared with excess titania gave a La:Ti ratio of approximately 50 : 50 for the large grains of the major phase (Table 1), irrespective of the level of TiO_2 added, and a La:Ti ratio of approximately 40 : 60 for the dark second phase grains (Table 2). These analyses confirm that the second phase in $La_2Ti_2O_7$ specimens prepared with excess TiO_2 is $La_2Ti_3O_9$.

For the Nb-doped materials, the elemental distribution is more complicated, because the Nb dopant atoms are incorporated into both the major and the second phases. EDAX analyses again gave a La:Ti atomic ratio of approximately

50:50 for the major phase, and approximately 40:60 for the minor phase (Tables 1 and 2). The concentrations of Nb atom in the two phases are shown as a function of the amount of dopant in Fig. 5. More niobium atoms enter the minor phase than the major phase. Since the ionic radii for Nb^{5+} and Ti^{4+} ions are very similar (0·78 and 0·745 Å respectively),[15] it is possible that Nb^{5+} ions enter the Ti^{4+} sites. The higher TiO_2 content in $La_2Ti_3O_9$ (75%) than in $La_2Ti_2O_7$ (67%), and therefore the availability for exchange with the dopant, may account for the uneven distribution of Nb between the two phases.

Kestigian and Ward[16] reported the preparation of $La_2Ti_3O_9$ in the presence of trivalent Ti^{3+} ions. Later, Marzullo and Bunting,[1] as part of a larger study concerned with TiO_2–Rare Earth Oxide compounds, reported the dielectric properties of $La_2Ti_3O_9$ produced by conventional ceramic methods. This intermediate phase was not shown in the phase diagram of the La_2O_3–TiO_2 system presented by MacChesney and Sauer.[2] Subsequently, several authors described the preparation (and some of the electric properties) of $La_2Ti_3O_9$ ceramics, e.g. prepared with a slight oxygen deficiency,[14,17] stabilized by 2+ or 1+ ions,[18–22] and prepared from coprecipitated powder.[23,24] For example, Nenasheva *et al.*[21] obtained similar results to those of MacChesney and Sauer[2] but noted that $La_2Ti_3O_9$ is unstable because there are vacancies on 1/3 of the sites in the *A* sublattice (i.e. $La_{2/3}\square_{1/3}TiO_3$, where $\square$ is a vacancy in the *A* sublattice of the perovskite structure compound $ATiO_3$); $La_2Ti_3O_9$ on its own decomposes into $La_2Ti_2O_7$ and rutile (TiO_2). Indeed, attempts by Nenasheva *et al.*[21] to synthesise $La_2Ti_3O_9$ by the mixed oxide route yielded only 80% of the desired perovskite structured phase with the remainder as $2La_2O_3.9TiO_2$. They confirmed that additions of $CaTiO_3$, $SrTiO_3$ or $PbTiO_3$ to a mixture of

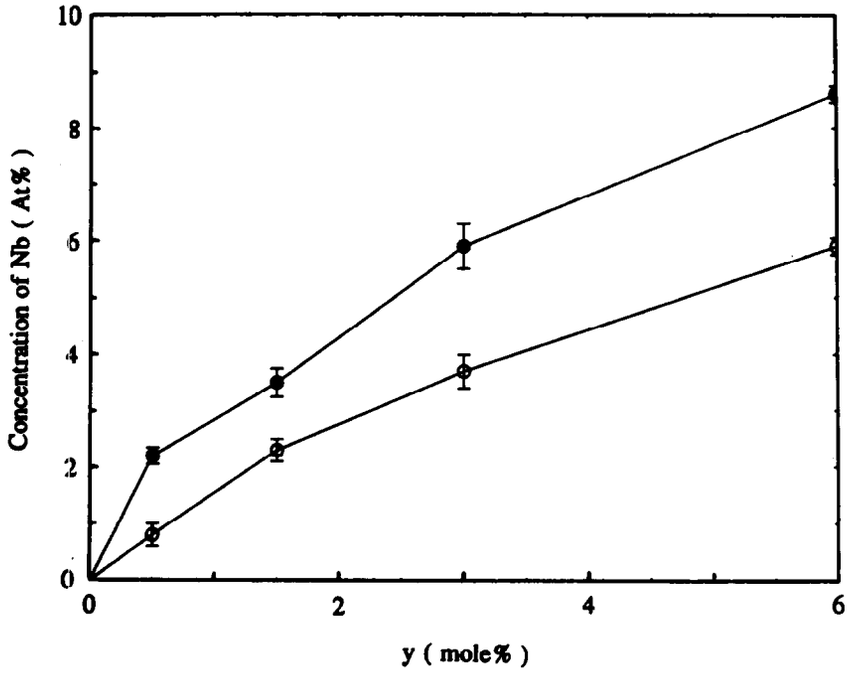

Fig. 5. Niobium (Nb) content of the major ($La_2Ti_2O_7$) phase (O) and minor ($La_2Ti_3O_9$) phase (●) of $La_2Ti_2O_7$ based-ceramics as a function of Nb_2O_5 content (y) of the starting mixture.

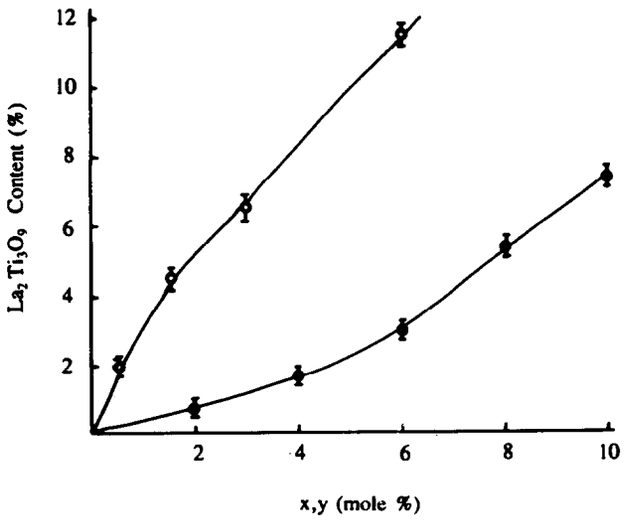

Fig. 6. Fraction of minor phase ($La_2Ti_3O_9$) in $La_2Ti_2O_7$ ceramics prepared with excess TiO_2 (●) and Nb^2O_5 (○) additions.

$La_2O_3.3TiO_2$ led to the formation of single phase perovskite-type structures ($A_{3/4}\square_{1/4}TiO_3$) although the use of lead titanate caused a tetragonal distorted structure (c/a = 1·004). In the present study, a compound of the formula $La_2Ti_3O_9$-type was formed as a second phase in ceramics in the La_2O_3-TiO_2 system prepared by means of the usual mixed oxide route when excess TiO_2 or Nb_2O_5 was present.

The formation of the phases in samples prepared with excess TiO_2 can be described by:

$$(1 - x)La_2Ti_2O_7 + xTiO_2 \rightarrow (1 - 2x)La_2Ti_2O_7 + xLa_2Ti_3O_9 \quad (1)$$

Thus in the case of specimens prepared with x mol% excess TiO_2, there should be $x/(1\text{-}x)$ mole of $La_2Ti_3O_9$ produced. For the samples doped with Nb_2O_5, the situation is more complex since the niobia enters both the primary $La_2Ti_2O_7$ and secondary $La_2Ti_3O_9$—type phases. However, if it is assumed that the Nb is located only on Ti sites, then we can envisage reactions of the form

$$(1 - y)La_2Ti_2O_7 + yNb_2O_5 \rightarrow (1 - 3y)La_2(Ti,Nb)_2O_7 + 2yLa_2(Ti,Nb)_3O_9 \quad (2)$$

Whilst accepting the approximate nature of eqns (1) and (2), it would appear that doping with niobia (eqn (2)) should generate more $La_2Ti_3O_9$ second phase than 'doping' with excess TiO_2 (eqn(1)). Figure 6, showing the $La_2Ti_3O_9$ content of the ceramics confirms that the niobia-bearing specimens contain typically 2—3 times more second phase than the samples prepared with excess titania.

The actual compositions of the products of the B series ceramics vary with doping level, but when y = 0·03 for example, typical analyses (Tables 1 and 2) indicate that the major and minor phases may be described as $La_2Ti_{1.97}Nb_{0.15}O_{7.3}$ and $La_2Ti_{2.72}Nb_{0.29}O_{9.16}$ respectively, when no allowance is made for any vacancies present.

In specimens of the Nb_2O_5-doped system, there is a tendency for the grain size to decrease as increasing amounts of dopant are employed; in addition, clusters of small grains appear, most of which are the minor phase, ($La_2Ti_3O_9$). SEM micrographs for three specimens in this series are shown in Fig. 4.

3.4 Dielectric properties

3.4.1 Relative permittivity

Figure 7 shows the relative permittivity of lanthanum dititanate ceramics as a function of added excess

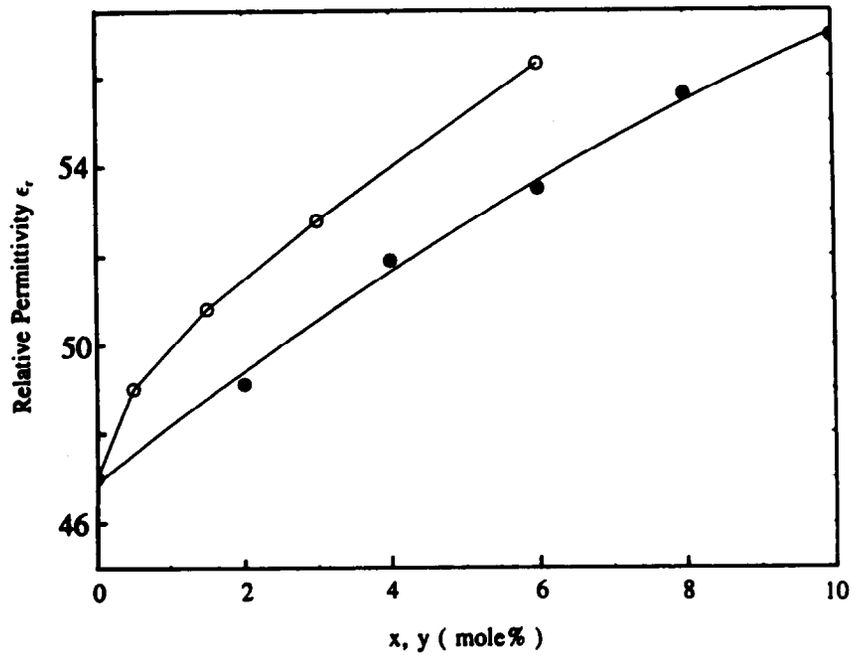

Fig. 7. Relative permittivity of $La_2Ti_2O_7$ ceramics at 1 MHz as a function of added Nb_2O_5 (○) and excess TiO_2 (●).

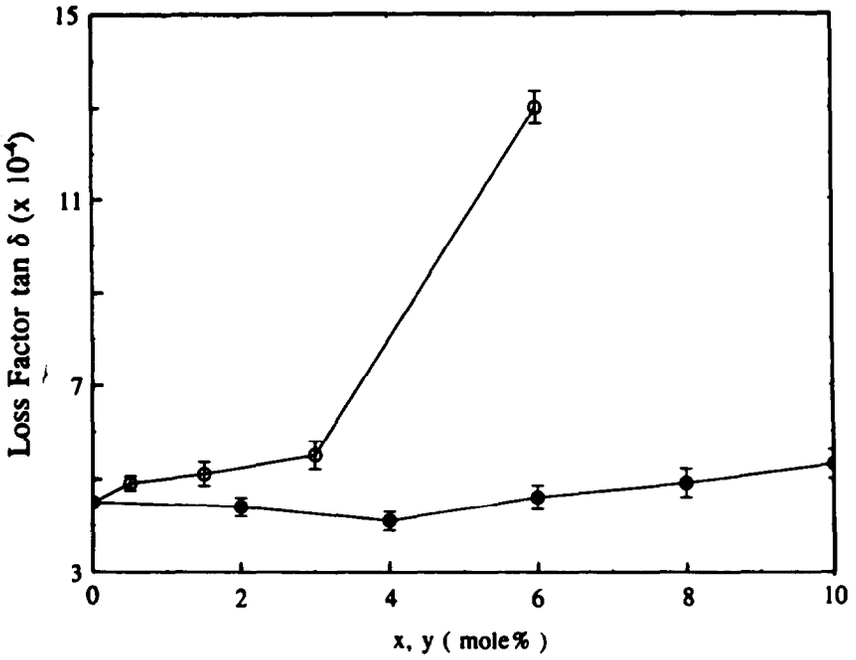

Fig. 8. Dielectric loss factor (tan δ) for $La_2Ti_2O_7$ ceramics at 1 MHz as a function of added Nb_2O_5 (○) and excess TiO_2 (●).

TiO_2 or Nb_2O_5 for the two systems. For the end-member $La_2Ti_2O_7$ the relative permittivity (at 1 MHz ~ 47) was higher than that reported by Mazullo and Bunting[1] (44) and Takahashi and Kageyama[11] (41), but close to that obtained by Fuierer and Newnham[9] for mixed oxide-prepared ceramics (48·8). The last named authors obtained marginally lower values for chemically prepared ceramics and hot forged specimens parallel to the forging direction. The increase in relative permittivity with increasing Nb_2O_5 or TiO_2 (Fig. 7) and the generation of the second phase (Fig. 6) suggests that the $La_2Ti_3O_9$ second phase has a higher relative permittivity than the primary $La_2Ti_2O_7$ phase. For the system with excess titania, extrapolation of the relationship between ε_r and composition (Fig. 7) indicates a relative permittivity of 77 for $La_2Ti_3O_9$. In spite of the long extrapolation this is clearly different from the value of 45 obtained by Marzullo and Bunting[1] (which is in fact lower than recent determinations of ε_r for the $La_2Ti_2O_7$ end member), but in excellent agreement with that reported by Nenasheva *et al.*[21] for $La_2Ti_3O_9$.

3.4.2 *Dielectric loss*

Undoped $La_2Ti_2O_7$ has a comparatively low dielectric loss with the Q value (Q ~ 1/tanδ) ranging from typically 1500 to 3500 at 100 kHz depending on the sintering and processing conditions. Winfield[12] obtained a Q value of 1250 at 1 MHz for mixed oxide prepared $La_2Ti_2O_7$ whilst Fuierer and Newnham[9] at 100 kHz obtained Q values of 900 for Evaporative Decomposition of Solution (EDS) derived material, 5300 for mixed oxide ceramics, 3500 and 4750 for molten salt synthesis products, 2600 and 2950 for hot forged samples. In general, the Q values increased with specimen density. The incorporation of excess titania does not increase the loss significantly (Fig. 8). This is predictable since, as shown in eqn (1), the addition of extra titania induces no defects which may serve as charge carriers and thereby increase conduction. However, a sharp rise in dielectric loss was observed for materials containing more than 2 mol% Nb_2O_5 (Fig. 8).

The substitution of Nb^{5+} into $La_2Ti_2O_7$ and $La_2Ti_3O_9$ requires the operation of some charge compensation mechanism to ensure charge neutrality. For the primary $La_2Ti_2O_7$ phase the situation in the undoped reference material can be described in terms of Kroger-Vink notation[25] by:

$$La_2O_3 + 2TiO_2 \rightarrow 2La_{La}^{x} + 2Ti_{Ti}^{x} + 7O_o^{x} \quad (3)$$

After doping with niobia, charge compensation could be achieved by:

(i) cation vacancies

$$5La_2O_3 + 4Nb_2O_5 \rightarrow 10La_{La}^{x} + 8Nb_{Ti}^{\bullet} + 2V_{Ti}^{''''} + 35O_o^{x} \quad (4)$$

or (ii) electronic defects

$$La_2O_3 + Nb_2O_5 \rightarrow 2La_{La}^{x} + 2Nb_{Ti}^{\bullet} + 7O_o^{x} + \tfrac{1}{2}O_2 + 2e' \quad (5)$$

Although the second phase ($La_2Ti_3O_9$) is much smaller in quantity, similar mechanisms may be envisaged for the incorporation of Nb. Starting with the undoped material:

$$La_2O_3 + 3TiO_2 \rightarrow 2La_{La}^{x} + 3Ti_{Ti}^{x} + 9O_o^{x} \quad (6)$$

After doping, charge compensation could be achieved by:

(i) cation vacancies:

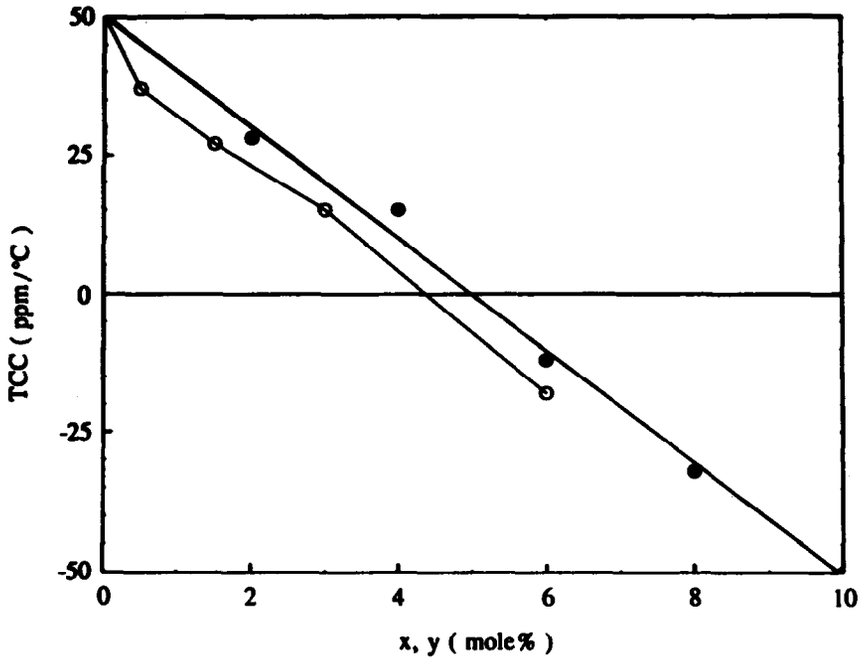

Fig. 9. Temperature coefficient of capacitance (TCC) of $La_2Ti_2O_7$-based ceramics as a function of added Nb_2O_5 (O) and excess TiO_2 (●).

$$5La_2O_3 + 6Nb_2O_5 \rightarrow 10La_{La}^{x} + 12Nb_{Ti}^{\bullet} + 3V_{Ti}'''' + 45O_o^x \quad (7)$$

or (ii) electronic defects

$$2La_2O_3 + 3Nb_2O_5 \rightarrow 4La_{La}^{x} + 6Nb_{Ti}^{\bullet} + 18O_o^x + 1\tfrac{1}{2}O_2 + 6e' \quad (8)$$

Thus, at small doping levels of Nb_2O_5, charge compensation can be achieved by cation vacancies (eqns (4) and (7)); at high doping levels there may be a transition to a compensation mechanism based on electronic defects (eqns (5) and (8)). Dielectric losses are higher in niobia-containing specimens than ceramics prepared with excess TiO_2 (Fig. 8), and losses increase rapidly above 2 mol% Nb_2O_5. It seems probable that charge compensation is by cation vacancies at the low Nb_2O_5 doping levels, but there is insufficient data to confirm whether or not there is any contribution from electronic defects at the higher doping levels.

The intrinsic losses in a material are defined by the lattice vibrational modes,[26] and these will be modified by the presence of significant numbers of defects. It is now established[27] that oxygen vacancies increase losses in $ZrTiO_4$-based dielectrics. In the lanthanum ditanate ceramics of the present study, the niobium atoms incorporated into the structure probably give rise to large numbers of cation vacancies, thereby modifying the lattice vibrational modes and increasing the dielectric losses (Fig. 8).

3.4.3 Temperature coefficient of capacitance (TCC)

It is of interest from a practical point of view to define temperature-stable ceramic compositions, particularly those which exhibit a zero value TCC. One of the standard methods to achieve this property is to prepare a solid solution from components which possess characteristics with negative and positive dependencies on temperature. Marzullo and Bunting[1] were the first to report TCC values for $La_2Ti_2O_7$ and $La_2Ti_3O_9$ of +30 and –60 ppm/°C respectively. This implies that a material with a zero TCC can be prepared if $La_2Ti_3O_9$ is introduced as a minor phase in a $La_2Ti_2O_7$ matrix. This presumption is justified by the temperature-dependence of the 'doped' materials shown in Fig. 9. With increasing Nb_2O_5 or excess titania, the TCC decreases linearly from a value of +50 ppm/°C in the undoped material to approximately –50 ppm/°C for starting compositions containing approximately 10 mol% of additions. The increasing amount of the $La_2Ti_3O_9$ phase appears to be responsible for this phenomenon.

The rate of change of TCC with additive level is greater for the niobium doped specimens than for TiO_2 excess specimens. This corresponds to the difference in the yield of the minor phases produced by equal amounts of additions. The TCC value of the sample prepared with 10 mol% excess titania is unexpectedly high in view of the previously reported value of –60 ppm/°C[1] for pure $La_2Ti_3O_9$. Due to the low level of additions, it is not possible to extrapolate the TCC data to that equivalent to the pure $La_2Ti_3O_9$ phase with any degree of reliability, but it can be anticipated that the value will be much lower than –60 ppm/°C, or even lower than the value of –170 to –200 ppm/°C

reported by Nenasheva *et al.*[21] for $La_2Ti_2O_7$–$La_4Ti_9O_{24}$ mixtures. The most interesting result, however, is that $La_2Ti_2O_7$-based compositions with zero TCC, and thus temperature stable dielectric characteristics, can be obtained by the addition of approximately 4·2 mol% Nb_2O_5 or 5 mol% excess TiO_2 to the starting mixtures. It can be seen that the presence of the second phase $La_2Ti_3O_9$ is responsible for, and therefore favourable to the improvement of the dielectric properties. However, the addition of > 3 mol% Nb_2O_5 leads to a rapid increase in dielectric losses.

4 Conclusions

(1) Good quality lanthanum dititanate ceramics have been prepared using conventional mixed oxide ceramic methods. Modification of the structure and electrical properties were achieved by the additions of up to 10 mol% Nb_2O_5 or excess titania to $La_2Ti_2O_7$.

(2) With increasing amounts of additives there was a growth of $La_2Ti_3O_9$ as a second phase within the $La_2Ti_2O_7$ matrix.

(3) Changes in the dielectric properties of the families of ceramics can be correlated with the presence of the second phase:

(a) relative permittivity increased with the additions;
(b) dielectric loss was independent of the amount of excess titania but increased dramatically when > 3 mol Nb_2O_5 was added;
(c) TCC values for the materials decreased monotonically from +50 ppm/°C for undoped-$La_2Ti_2O_7$ to approximately —50 ppm/°C for materials containing 10 mol% addition. Thus, a material with zero TCC value can easily be obtained.

Low Temperature Synthesis of Zinc Ferrite using Hydrazine Monohydrate

M. Ueda, S. Shimada & M. Inagaki

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Kita-Ku, Sapporo 060, Japan

(Received 18 May 1994; revised version received 28 July 1994; accepted 1 August 1994)

Abstract

Crystalline powder of zinc ferrite was synthesized from the mixed solution of $FeCl_2$ and $ZnCl_2$ by adding hydrazine monohydrate solution and aging near room temperature from 30 to 60°C. The temperature condition for this synthesis was the same as that using aqueous ammonia reported previously. However, it was necessary to keep the concentration of metal chlorides below 1×10^{-1} mol dm^{-3} to obtain zinc ferrite, because hydrazine complexes with metal chlorides in solutions with high concentration. Zinc ferrite was also formed starting with $FeCl_3$ solution, probably because hydrazine reduces Fe^{3+} partly to Fe^{2+}.

1 Introduction

Hydrazine (N_2H_4) is known to be complexing, strongly reducing and also a basic agent. In the first case, it behaves either as a unidentate ligand as in $BF_3N_2H_4$ or a bidentate bridging ligand as in $Zn(N_2H_4)_2Cl_2$. Its complexes with transition metal salts and lanthanide metal salts have been prepared[1,2] and characterized by infra-red absorption spectroscopy.[3–5] Thermogravimetric studies and magnetic moment measurements on the complexes with nickel salts have been carried out,[6] as has a structural analysis of $Zn(N_2H_4)_2Cl_2$ crystals.[7] As a reducing agent, hydrazine has been widely used for non-electrolytic plating (chemical plating) and for precipitation of metals from solution, e.g. fixing solution of photo films.

For the purpose of ceramic synthesis, however, only a few reports using hydrazine have been presented: hydrazine prevents the formation of ferric oxide on the synthesis of magnetite (Fe_3O_4),[8] and its complexes with metal nitrates are used as a precursor for the zinc nickel mixed ferrite.[9]

In a previous paper,[10] crystalline powder of zinc ferrite was synthesized using ammonia near room temperature. It was formed in the temperature range 30–80°C via an intermeditate phase of so-called green-rust which contains both Fe^{2+}, Fe^{3+} and possibly Zn^{2+}. For this synthesis, the use of Fe^{2+} solution was essential. Only amorphous product was formed from Fe^{3+} solution because of no formation of the green-rust phase.

The development of the synthesis of ceramics at such a low temperature is believed to be important in relation to energy conservation because most ceramic materials have been prepared at high temperatures. In the present work, the synthesis of zinc ferrite powder was attempted using hydrazine monohydrate ($N_2H_4 \cdot H_2O$). The result was compared with a previous synthesis using ammonia in order to clarify the advantages and disadvantages of the present process.

2 Experimental

The experimental procedure is shown in Fig. 1, being almost the same as the one used previously,[10] except that hydrazine was used instead of ammonia. First, aqueous solutions of metal chlorides $FeCl_2$ and $ZnCl_2$ of reagent grade were prepared separately at a concentration of 5×10^{-2} mol dm^{-3}, and then mixed with each other to give a molar ratio of iron to zinc of 2. The flask containing this reaction solution was set in a temperature controlled water bath with a shaker. Hydrazine monohydrate of reagent grade diluted to a concentration of 4 mol dm^{-3} was added to the mixed solution of metal chlorides at a temperature ranging from 0 to 80°C. After aging of the solution for air oxidation and shaking at a constant speed, the precipitates were filtered, and washed with distilled water and acetone, followed by drying at room temperature.

In order to investigate the effect of the concentrations, metal chloride solutions in the range of 5×10^{-1}–5×10^{-3} mol dm^{-3} and hydrazine monohy-

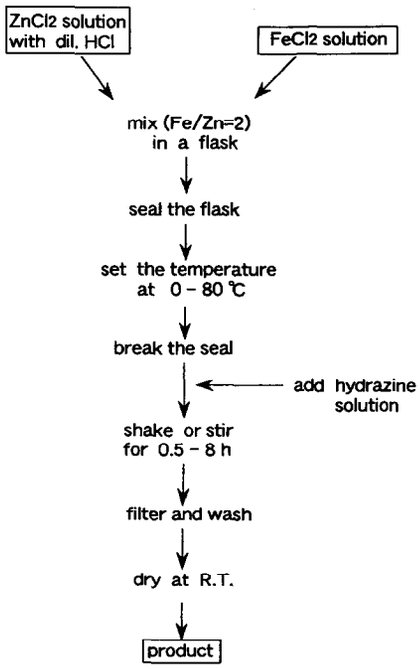

Fig. 1. Experimental procedure.

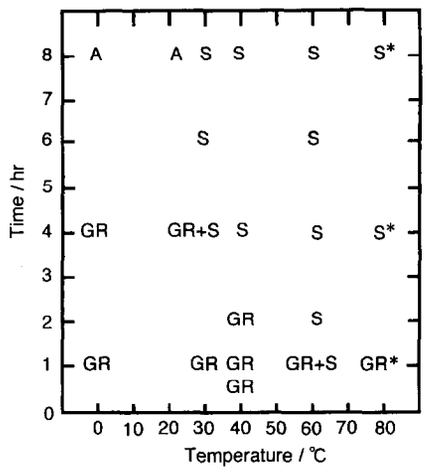

Fig. 2. Formation diagram of the phases as functions of temperature and time for aging. The symbol S stands for spinel-type $ZnFe_2O_4$, GR for green-rust and A for amorphous phase. S* and GR* indicate the coexistence of a small amount of unknown phase with S and GR, respectively. Metal chloride solutions of 5×10^{-2} mol dm^{-3} and hydrazine monohydrate solution of 4 mol dm^{-3} were used.

drate solution without dilution (20 mol dm^{-3}) were used. For the solution with high concentration, magnetic stirring was used in order to mix thick solutions.

The precipitates obtained were examined by X-ray diffraction (XRD) with Co Kα radiation, thermogravimetry coupled with differential thermal analysis (TG–DTA), infra-red spectrometry (IR) and atomic absorption spectrometry.

3 Results and Discussion

3.1 Formation of spinel phase of zinc ferrite

The phases formed in the mixed solutions of $FeCl_2$ and $ZnCl_2$ with a concentration of 5×10^{-2} mol dm^{-3} by adding hydrazine monohydrate solution with a concentration of 4 mol dm^{-3} are summarized in Fig. 2, as functions of temperature and time of aging. The resultant phases are green-rust, spinel and amorphous, as in the case where aqueous ammonia was used.[10]

At the beginning of aging, the green-rust phase is formed at all temperatures. Its XRD pattern gave broad peaks at 13·70° and 27·60° in 2θ (0·75 and 0·375 nm in d-spacing, respectively).

By further aging, the formation of zinc ferrite spinel was observed above 30°C. The line profiles of XRD patterns for the spinel phase are rather broad, as shown in Fig. 3. The crystallinity of the spinel phase was improved with increasing aging temperature. The half-maximum breadth of 311 lines for the products at 30 (Fig. 3(a)), 40 and 60°C (Fig. 3(b)) after 8 h of aging were 1·3°, 0·91° and 0·74° in 2θ, respectively. At 80°C, another phase which cannot be

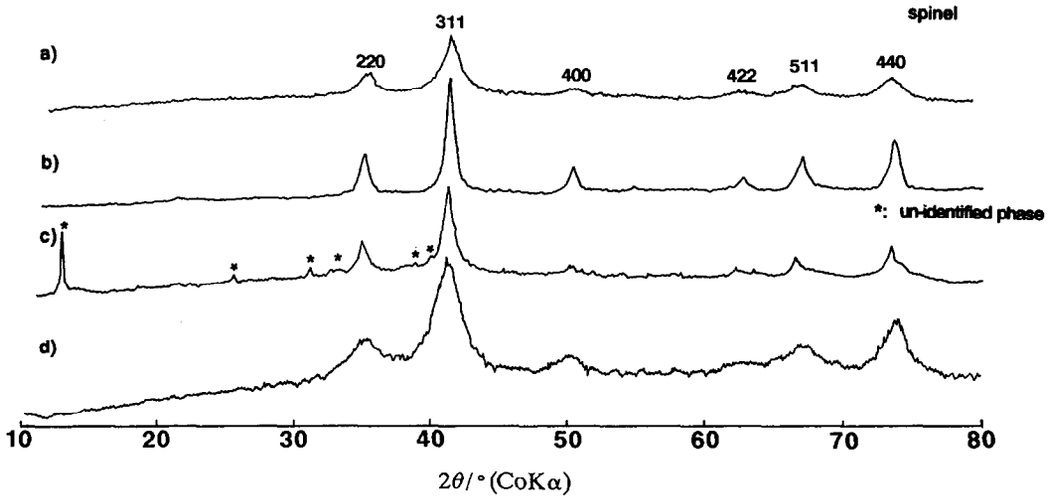

Fig. 3. X-ray powder patterns for the spinel phase synthesized from $FeCl_2$ solution at (a) 30°C, (b) 60°C, (c) 80°C and (d) that from $FeCl_3$ at 80°C.

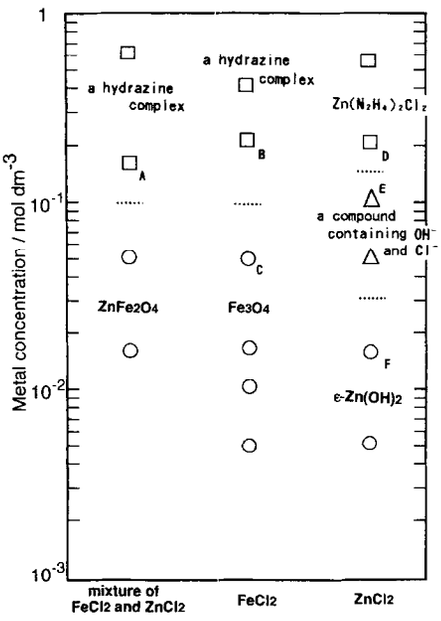

Fig. 4. The phases formed from the mixed solutions of $FeCl_2$ and $ZnCl_2$ (Fe/Zn = 2), $FeCl_2$ solutions and $ZnCl_2$ solutions with hydrazine monohydrate solution at 4 mol dm^{-3} by aging at 40°C for 4 h as a function of concentration of metal chloride solution.

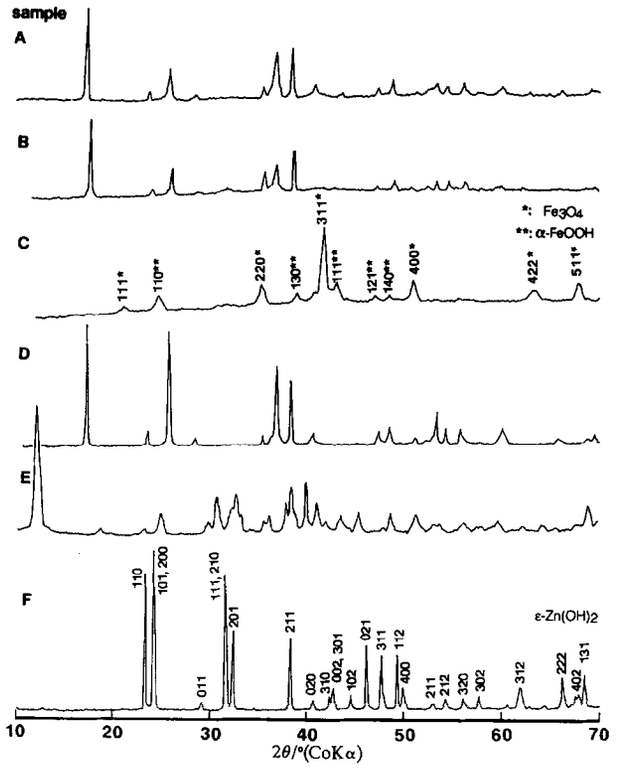

Fig. 5. X-ray powder patterns of the samples A to F of which the formation conditions are shown in Fig. 4.

identified from XRD powder patterns was formed in addition to the spinel phase (Fig. 3(c)). This seemed to be closely related to the fact that the evaporation of the reaction solution was remarkable at 80°C, suggesting that the concentration of metal ions and also anions were changed during aging, which brought considerable effect to the product phases. The relationship between the metal concentration of the solutions and products is discussed below.

The chemical analysis by atomic absorption spectrometry showed that the spinel obtained was zinc ferrite having the Fe/Zn ratio of 2·05–2·20.

Amorphous phase was formed by aging at 0°C for 8 h and it did not change to spinel phase without heating above 400°C.

3.2 Starting with $FeCl_3$

Starting with $FeCl_3$ solution, broad peaks of zinc ferrite appeared on XRD patterns by the reaction at 80°C (Fig. 3(d)). At 40°C, however, they were too broad to be detected. This result is a distinct difference from the previous one[10] where only amorphous phase was obtained by the addition of ammonia to the solution of $FeCl_3$. Using hydrazine, however, spinel phase was obtained even from $FeCl_3$ solution, probably because Fe^{2+} was produced by the strong reducing action by hydrazine.

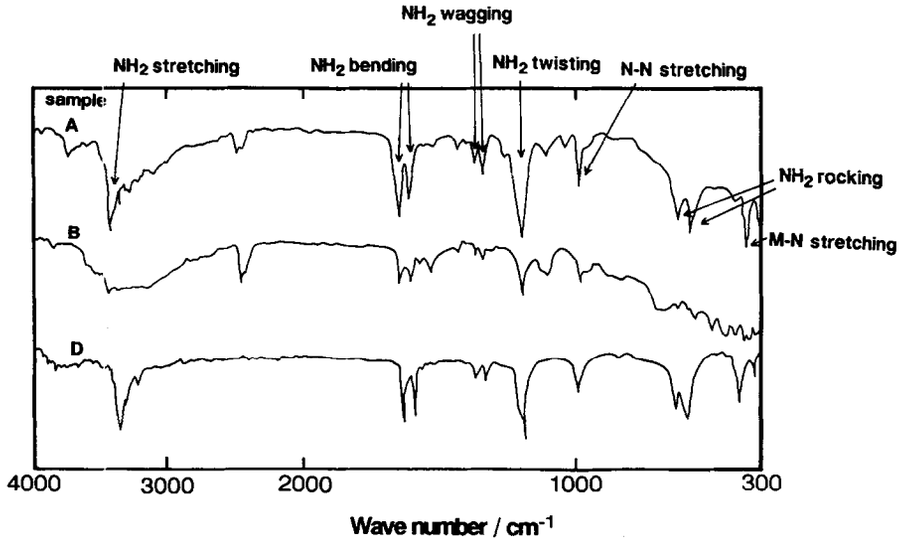

Fig. 6. IR spectra of samples A, B and D in Fig. 4.

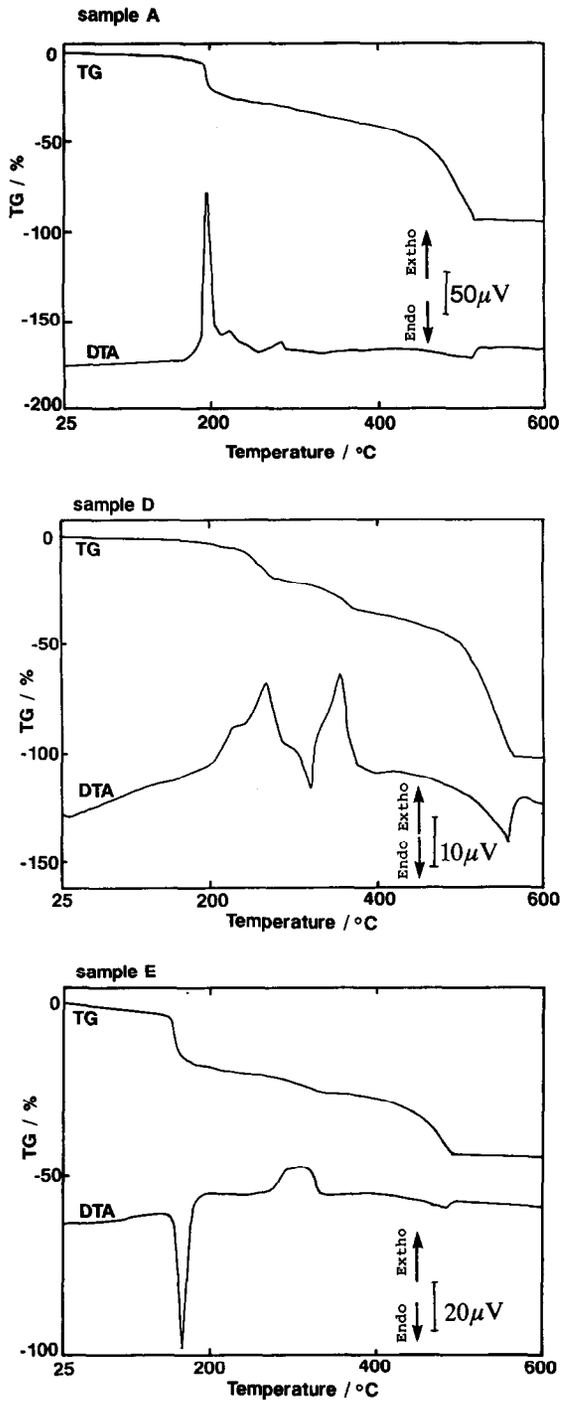

Fig. 7. TG-DTA curves for samples A, D and E in Fig. 4.

3.3 Effect of concentration

The relationship between the concentration of metal chloride solutions and the phases formed was investigated. The experimental results at 40°C after aging for 4 h are summarized as a function of metal chloride concentration in Fig. 4, by showing the concentration range for different phases which were deter mined from XRD, IR and TG–DTA studies.

It is clear that the products depend on the concentration of the starting solutions and that the borderlines are located around 1×10^{-1} mol dm^{-3} for the metal chloride solutions. Another line is present around 3×10^{-2} mol dm^{-3} for $ZnCl_2$ solution. The products shown by A to F in Fig. 4 were studied in detail in order to identify their phases.

The products formed in the solutions with low concentration are identified to be $ZnFe_2O_4$ (which has been described in Section 3.1), Fe_3O_4 (sample C) and ϵ-$Zn(OH)_2$ (sample F), respectively, from their XRD patterns (Fig. 5). The other products are not identified by XRD. Only sample D is considered to be a hydrazine complex because the d-spacings of diffraction peaks coincided with those reported for $Zn(N_2H_4)_2Cl_2$[7] though the relative intensities were different. In addition, samples A and B are also supposed to be complexes because the patterns obtained for samples A, B and D are all very similar.

For these products, IR and TG-DTA measurements were carried out and the results are shown in Figs 6 and 7, respectively.

Samples A, B and D give IR absorption peaks attributed to stretching, bending, wagging and twisting in the NH_2 group and stretching of N–N and metal–N bonds (Fig. 6), according to previous work.[6] These experimental results strongly suggest that they are the hydrazine complexes with respective metal chlorides. Characteristic sharp and strong exothermic peak, accompanying certain weight loss, observed in their TG–DTA curves also showed the existence of hydrazine in the products. TG–DTA curve of sample A is shown in Fig. 7. This exothermic peak has been considered to be due to the oxidation of liberated hydrazine to nitrogen oxides.[11] The result of sample B was very similar to that of sample A. Sample D in Fig. 7 shows slightly different behavior; the exothermic peaks are not so large and sharp. From this sample after heating above 550°C, nothing was left probably because the complexes released hydrazine to return to metal chloride which evaporated out above 500°C.

Sample E was not suggested to be a hydrazine complex, especially because of its IR spectrum which did not show any absorption peaks corresponding to the NH_2 group. On its TG–DTA curve (Fig. 7), a very strong endothermic peak, instead of an exothermic one on hydrazine complexes, is seen. This peak can be attributed to a dehydration reaction which had been observed in sample F. After heating up to 600°C, sample E gave ZnO powder, which was in contrast with sample D. As the common points among TG–DTA curves of samples D and E, a gradual weight loss above 400°C and an endothermic peak around 550°C are seen, suggesting the presence of $ZnCl_2$ component in sample E. These results suggest that the product E is the compound having both OH^- and Cl^-.

4 Concluding Remarks

Making use of a property of hydrazine as a base,

crystalline powder of zinc ferrite was obtained after aging at a temperature between 30 and 60°C though the crystallinity was rather inferior to that prepared in the same temperature range by using aqueous ammonia.[10] The concentration of starting metal chloride solutions was required to be below 1×10^{-1} mol dm^{-3} to prevent the formation of hydrazine complexes, which did not change to zinc ferrite either by aging or by heat treatment at high temperatures.

By using the strong reducing ability of hydrazine, zinc ferrite was obtained even starting with $FeCl_3$ solution, which was very advantageous compared to the use of aqueous ammonia.

Deformation and Strength of Engineering Ceramics and Single Crystals

G. A. Gogotsi & D. Yu. Ostrovoy

Institute for Problems of Strength, National Academy of Sciences of Ukraine, 2 Timiryazevskaya str., Kiev 252014, Ukraine

(Received 12 November 1993; revised version received 29 June 1994; accepted 9 August 1994)

Abstract

A comparative investigation has been performed of the laws of deformation and strength of engineering silicon nitride-, alumina, and zirconia-based ceramics, as well as zirconia crystals. The specimens were tested in four-point bending in air over a temperature range from ambient to 1400°C. The materials' mechanical behaviour was analyzed by load versus deflection diagrams (deformation diagrams). It has been found that above the brittle-to-ductile transition temperature, T_{BD}, for the ceramics studied it is possible to choose such combinations of temperature and deformation rate, which would ensure the same path of deformation diagrams, i.e. equivalent influence of those two parameters on the mechanical behaviour of ceramics is observed. The mechanism of inelastic deformation of the ceramics studied is shown to be associated with the development of two processes: viscous flow of the grain boundary phase and crack propagation to a critical size, with one of them prevailing at different load levels. In contrast to ceramics, the strength of zirconia crystals remained practically unchanged (partially-stabilized crystals) up to 1400°C or even increased (fully-stabilized crystals). For all the crystals, static elasticity moduli were independent of the number of repeated-static loading cycles at high temperatures (their values remained constant), while for ceramics a reduction was observed. Partially-stabilized zirconia crystals, as compared to other investigated materials, exhibited practically no creep up to 1400°C at loads close to limiting ones. This allows them to be considered as a promising engineering material for high-temperature application.

1 Introduction

Along with extensive investigations of engineering ceramics and their application in industry, nowadays researchers pay much attention to finding possibilities for practical application of such promising refractory materials as zirconia crystals.[1] According to some preliminary estimates[2–5] in a high-temperature loading region they can compete not only with metals but also with ceramics. One of the reasons restricting the introduction of these materials in many areas of engineering is insufficient understanding of specific features of their mechanical behaviour at high temperatures. This is associated with the fact that most studies, e.g. of zirconia crystals, are concerned with physical aspects of their deformation and fracture[6–15] and the data on their strength and fracture toughness which appear in some publications[2,4,16,17] are insufficient for the correct evaluation of their performance from the criteria used in practical engineering. This situation with both ceramics and single crystals can be explained by the use of different test methods that result in inconsistency of the results obtained. In this case, for instance, strength characteristics of such materials determined in the high-temperature region by the known standards[18] at one constant loading or deformation rate turn out to be insufficient for revealing a complete picture of their actual mechanical behaviour. This conclusion is strongly confirmed by the fact[19] known for conventional structural materials (metals, polymers), according to which appreciable changes occur in the conditions of reaching the ultimate state by them due to simultaneous temperature and loading or deformation rate variation. In this case the probability of their brittle fracture even at the temperature of viscous (plastic) flow[20] may increase. The data on this problem for ceramics[22–25] and single crystals[2,8,21] are not only limited but in most cases[21,23,25] they do not take into account such an important characteristic of the materials as their deformability. For this reason such results tell us little of possible performance of these materials under real service conditions. To eliminate this gap the present work was performed where attention was paid to the investigation of the laws of deformation and strength of zirconia crystals at different temperatures and deformation rates as compared with the

behaviour of the most widely spread types of engineering ceramics (silicon nitride, alumina, zirconia) under similar loading conditions.

2 Materials and Experimental Procedure

The materials investigated were silicon nitride-, alumina-, and zirconia-based ceramics and zirconia crystals (Table 1).

A silicon nitride-based ceramic, SN-1,[26] with an addition in the initial state of 5% Y_2O_3 and 2% Al_2O_3 was produced by hot-pressing in graphite moulds (the sintering temperature was 1750°C, pressure 50 MPa). Its main components were β-Si_3N_4 and a grain boundary phase. The latter consisted of the amorphous phase containing Si, N, Al, Y, O and yttrium oxynitrides. The SN-1 structure was a mixture of equiaxial and elongated grains of β-Si_3N_4. The average size of those grains was 3–5 μm. A silicon nitride-based ceramic, SN-2,[26] was obtained from powders: 82% Si, 2·5% Al_2O_3 and R_2O_3 (a mixture of rare-earth element oxides: 64% Nd_2O_3, 17% Pr_2O_3, 14% La_2O_3 and 1% Sm_2O_3) by the method of reaction bonding (nitriding in an atmosphere of N_2 + H_2 at 1380°C). Then it was sintered under pressure of 50 MPa at 1850°C in an atmosphere of N_2. This ceramic consisted mostly of β-Si_3N_4 and of the grain boundary phase. By varying the quantity of R_2O_3 three compositions of this ceramic were obtained: SN-2a, SN-2b and SN-2c with the content of the amorphous phase 8·5, 10·6 and 13·5%, respectively. In its structure SN-2 ceramic was close to SN-1. The cross dimension and the length of elongated grains β-Si_3N_4 of this ceramic were, on the average, 0·5 and 4 μm, respectively.

An alumina-based ceramic, A-1,[26] with an addition of MgO was produced by semi-dry pressing at a pressure of 200 MPa and sintered in air at 1600°C. Its grain size averaged between 4 μm and 5 μm.

Zirconia-based materials contained different quantities of stabilizing additive Y_2O_3. Thus Y-PSZ-3 ceramic with 3 mol% of Y_2O_3 was hot-pressed at 1750°C in an atmosphere of N_2. It contained a minute quantity of Al_2O_3. Its average grain size was less than 1 μm. Crystals[3,27] were grown by a skull melting technique using direct high-frequency heating. Their growth rate was 10 mm/h. They were then cooled down from the temperature of their crystallization at a rate of 10°C/min. The crystals contained 3(Y-PSZC-3), 10(Y-FSZC-10) and 20(Y-FSZC-20) mol% of Y_2O_3. The first of them were partially stabilized, the rest were fully stabilized. In accordance with the classification,[28] all the materials chosen for the investigation were brittle (i.e. deforming linearly-elastically at ambient temperature).

The tests in the temperature range from ambient to 1400°C were performed in air using the loading module (Fig. l) designed and manufactured for the purpose and mounted on a conventional testing machine. The test method has been evaluated elsewhere,[5,28] The test specimens were beams 3·5 × 5·0 × 50·0 mm in size cut from billets by a diamond tool and then ground along the longitudinal axis. Their sharp edges were bevelled. Crystallographic orientation of the crystal specimen longitudinal axes was defined by the Laue back-reflection X-ray technique. Prior to mechanical testing, dynamic elasticity moduli E_d were determined from measurements of the ultrasonic vibration propagation velocity along the specimen longitudinal axis.

The specimens were loaded in four-point bending under isothermal conditions with the testing machine cross-head speed, V_{ch} from 0·005 to 5·0 mm/min. As most often happens in these investi-

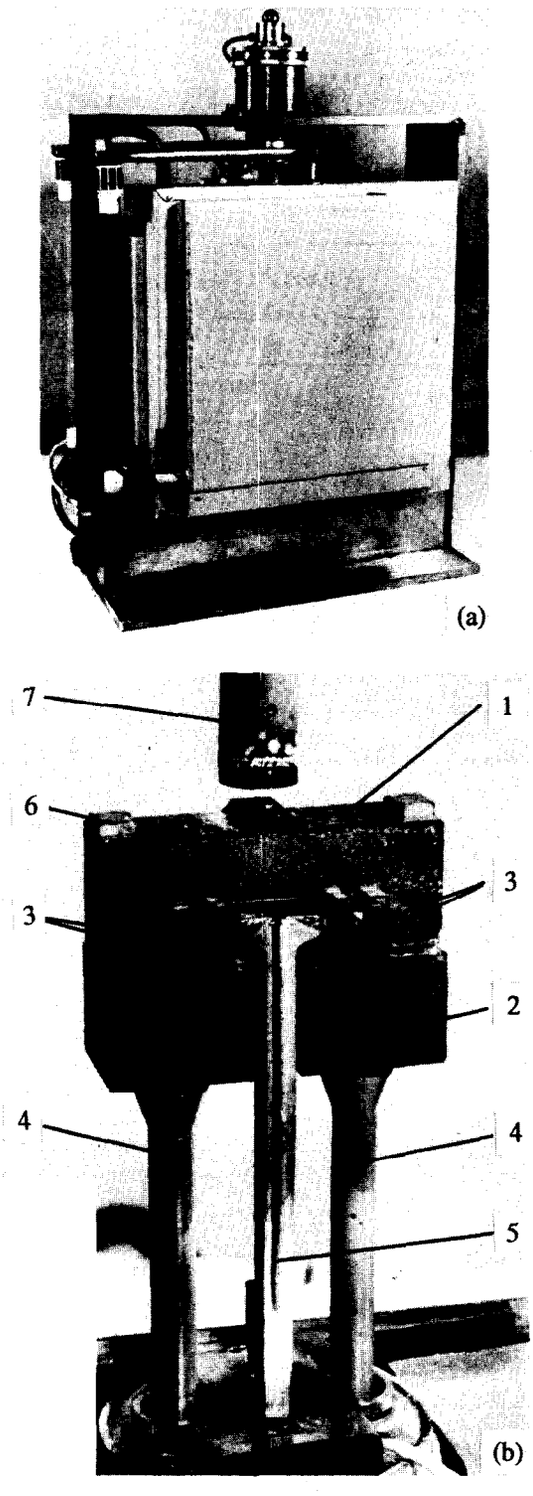

Fig. 1. General view of (a) the loading module and (b) the loading arrangement. (1) Upper prism, (2) lower prism, (3) swing roller support, (4) supporting column, (5) bending deflection measurer, (6) slide-way, (7) loading rod.

gations (Fig. 2), the cross-head speed V_{ch} equal to 0·5 mm/min was chosen as the main one. It is convenient because the time to specimen fracture in testing is less than 1 min. The distance between the inner and outer swing roller supports was 20 and 40 mm, respectively. A special feature of the experimental procedure used was recording 'applied load–specimen deflection' dependences (the deformation diagrams) using a deflection measuring

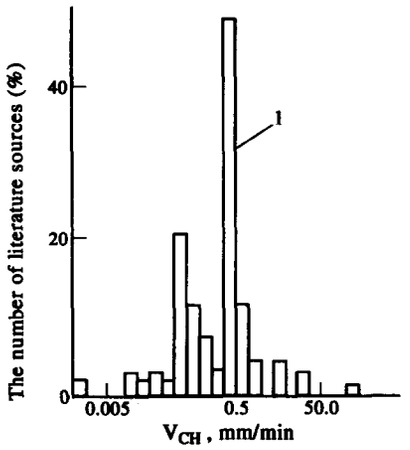

Fig. 2. Histogram of the testing machine cross-head speeds, V_{ch} (from the data from 175 literature sources): (1) the main speed.

gauge (LVDT)[29] which was hung on the specimen (5 in Fig. 1) and was in no way connected to the testing machine. In this way the influence of deformation of the loading device parts was excluded from the measurements, unlike conventional determination of specimen deflection by the testing machine cross-head displacement or by the measuring gauge connected with the testing arrangement.

Mechanical characteristics were calculated by the known relationships of applied mechanics (linear-elastic approximation), i.e. strength, for instance, was characterized by the magnitude of the modulus of rupture (MOR = $2aP/bh^2$, where P is the load, α is the length of the cantilever part of the specimen, b and h are the specimen width and height, respectively). This approach proved to be acceptable since the present work involved a comparative analysis of the mechanical behaviour of ceramics and crystals rather than precise determination of their strength characteristics. At the same time, the known Nadai formula ($\sigma = 2a/bh^2 \times (P + \delta/2 \cdot dP.d\delta)$, where σ is the mean stress in the specimen, δ is the specimen deflection) used earlier by us[3,29] and other investigators[22] turned out to be unacceptable here, since the deformation diagrams of the specimens (see below) had not only ascending but also extensive horizontal portions.

3 Results

The main investigations were performed at temperatures above some critical temperature for each of the materials at which their deformation diagrams exhibited nonlinearity, associated with the intensification of creep. At the same time, the dependence of the mechanical properties of these materials on time or strain rate was observed. The latter was defined by the cross-head speed, V_{ch}.

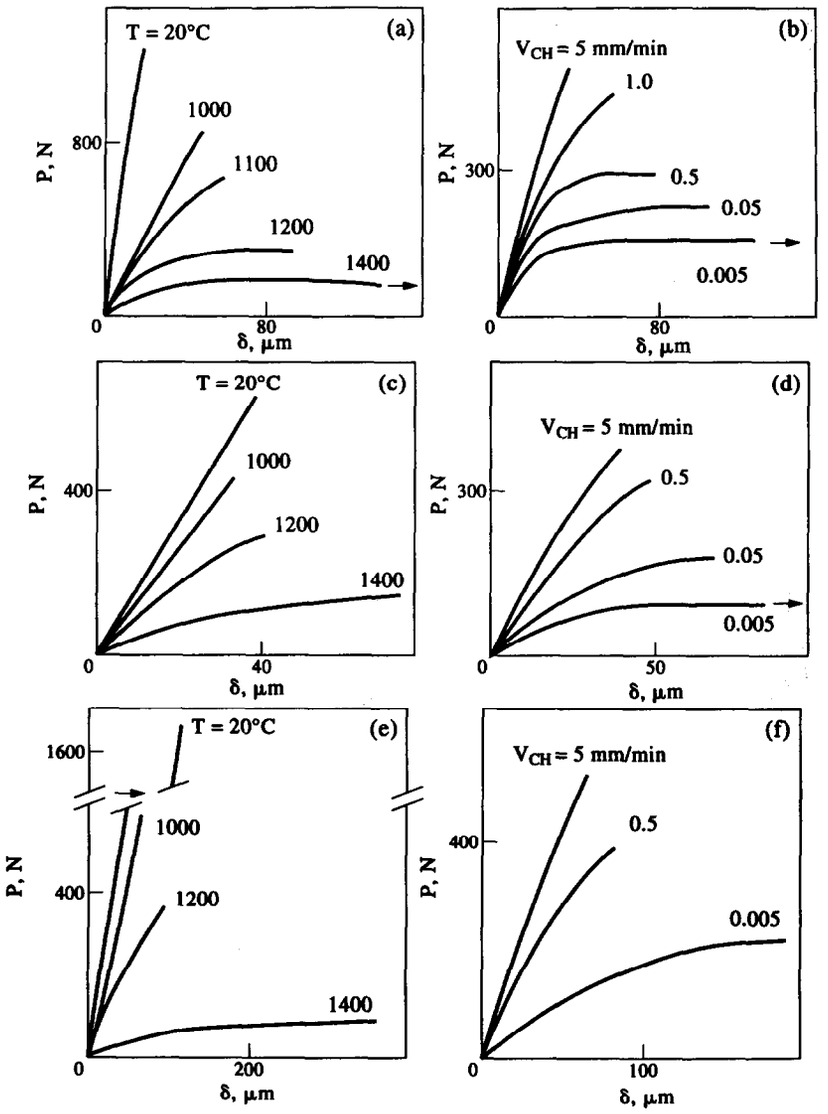

Fig. 3. The influence of the temperature, T (a,c,e) at V_{ch} = 0·5 mm/min and of the speed V_{ch} (b,d,f) at T = 1200°C on the appearance of the load (P) versus deflection (δ) diagrams: (a,b) SN-1; (c,d) A-1; (e,f) Y-PSZ-3.

This critical temperature is often called brittle-to-ductile transition temperature, T_{BD},[22,23] by analogy with the respective transition in steels. Note that the T_{BD} value is not a material constant: it depends on the strain rate, the size of the specimens, their structure, etc. In the present work, T_{BD} was determined by the deviation from linearity of the deformation diagrams for the same specimens of the materials studied, recorded while the temperature was increasing gradually and at a cross-head speed of 0·5 mm/min. For SN-1, SN-2 and A-1 ceramics the T_{BD} value was about 1100–1150°C and for Y-PSZ-3 it was about 1050°C. For zirconia crystals T_{BD} was in the range 1000–1100°C, whereas it was 500–600°C when the latter were loaded by the Vickers indenter.[30]

Check tests of ceramics at temperatures below T_{BD} revealed that, irrespective of the combination of temperature and cross-head speed, it exhibited linearly-elastic deformation and brittle fracture thus confirming the results obtained earlier.[22–24] In particular, the cross-head speed affected the strength of only alumina-based ceramics A-1. Such an influence is generally evaluated by the magnitude of the power parameter N in the equation[25] for the crack growth rate (V) in a corrosion-active environment: $V = M \cdot K_I^N$, where M is a parameter, K_I is the stress intensity factor at the crack tip. The higher the value of N, the greater the material resistance to the subcritical crack growth. The value of N was determined from the equation $\sigma_1/\sigma_2 = (V_{ch_1}/V_{ch_2})^{1/N+1}$, where σ_1 and σ_2 are fracture stresses (MOR) at speeds V_{ch_1} and V_{ch_2}, respectively, which was obtained from analytical relationships proposed elsewhere.[25] In the case for A-1 the magnitude of N was 20, whereas for the test of ceramic materials it exceeded 100. It should be noted that the above N values for ceramics remained almost unchanged up to the T_{BD} temperature, above which their reduction was observed.

The deformation diagrams obtained for ceramics at temperatures above T_{BD} revealed that irrespective of the production technology (see the test results for other similar materials[27,29]) their mechanical behaviour at increasing temperature, T, and constant V_{ch} (Fig. 3(a),(c),(e)) is similar to that at decreasing V_{ch} and constant T (Fig. 3(b),(d),(f)). In addition, at a certain combination of the temperature and speed, the ceramics exhibited (see Fig. 3) a transition from totally inelastic to linearly-elastic deformation and brittle fracture even at the temperatures of probable material creep. This was also evidenced by specific features of ceramic specimen fracture surfaces, where (e.g. material A-1) the transition from primarily intercrystalline (Fig. 4(b)) to mostly transcrystalline (Fig. 4(a)) crack propagation was observed with an increase in V_{ch}. This fact was also noted by other investigators.[31]

These data allow us to say that, at least in the temperature and V_{ch} ranges used, an equivalence of the influence of these two parameters on the resistance of ceramics to deformation took place, since different pairs of deformation conditions were selected (V_{chi}, T_i). This ensured similar paths of the deformation diagrams within the scatter band of the experimental data, as is shown, for instance, in Fig. 5 for SN-1 and Y-PSZ-3 materials. It should be noted that these equivalent conditions of deformation also result in similar features of micro- and macrofractures of specimens of the given ceramics.

An interesting feature of the ceramic behaviour also reported elsewhere[22] was the appearance of characteristic horizontal portions (Fig. 3) on the deformation diagrams at temperatures above T_{BD} and at low V_{ch} values, where the increase in the specimen deformation occurred at almost constant applied load. To find out the reasons for the appearance of such portions, as an example, a detailed investigation was carried out on SN-1 specimens only, since the behaviour of all the ceramics was similar. After testing, a lot of cracks (Fig. 6(a)) appeared on the specimen surface at the sites of action of the maximum tensile stresses σ_t. Their faces were mostly orthogonal to the direction of those stresses. On fracture surfaces there were ridged regions (Fig. 6(b)) corresponding to those cracks and their size grew with both a decrease in V_{ch} at constant temperature, and with an increase in temperature at constant V_{ch}. At sufficiently low temperature (below T_{BD}) and at high V_{ch} these regions on fracture surfaces were almost indistinguishable with a conventional optical microscope. We should note that all the observations for SN-1 materials were also true of A-1. With Y-PSZ-3 materials the size of these regions, as well as that of the cracks (Fig. 6(c)) was appreciably smaller than with other ceramics investigated under the same loading conditions (V_{chi}, T_i) (Fig. 5).

For this reason it could be expected that those cracks affected appreciably the mechanical properties at high temperatures. For SN-1 materials this influence was observed under repeated-static load-

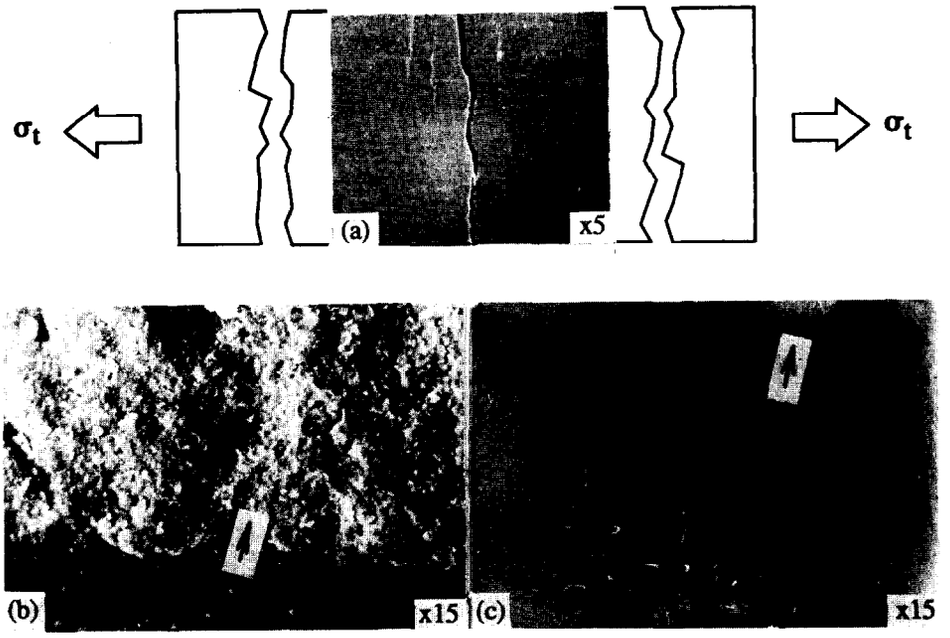

Fig. 6. Photographs of (a) tensile and (b) fracture surface of SN-1 and (c) fracture surface of Y-PSZ-3 specimens tested at T = 1200°C and V_{ch} = 0·005 mm/min. Arrows (b,c) show surface roughness.

ing (Fig. 7(a)) and in creep tests (Fig. 8(a)). Under such loading conditions the process of crack growth was strongly intensified each time when the applied load reached the magnitudes corresponding to the horizontal portions on the deformation diagrams. For this ceramic with each loading cycle the slopes (α) of the lines tangent to the diagram (Fig. 7(a)) at the origin of the coordinates decreased. The slope of the diagram is related to the elasticity modulus, E, by a simple expression $tg\alpha = Eb/2(h/a)^3 M_p/M_\delta$, where M_p and M_δ are the scales of the plot in Fig. 7(a) along the axes 'p' and 'δ', respectively. See above for other designations. The creep stage associated with such crack formation and culminating in fracture manifested itself more distinctly (Fig. 8(a)) only at loads close to the limiting ones on the deformation diagrams. At the same time, the Y-PSZ-3 material exhibited no noticeable reduction of static elasticity modulus (Fig. 7(b)) under repeated-static loading, and in creep testing no creep stage (Fig. 8(b)) characteristic of the crack propagation in SN-1 was observed due to consider-

able residual deformation of specimens which does not result in their fracture. Thus, crack propagation was probably one of the reasons for the increase in nonlinearity of the ceramics deformation diagrams, though with Y-PSZ-3 material, where the crack growth is less pronounced, such behaviour could be induced for other reasons as well.

Nonlinearity of the deformation diagrams and crack propagation could also occur in ceramics at high (above T_{BD}) temperatures as a result of softening of its grain boundary phase which has a lower melting temperature than the basic material. In order to confirm this an evaluation (Fig. 9) was made of the influence of the quantity of glass

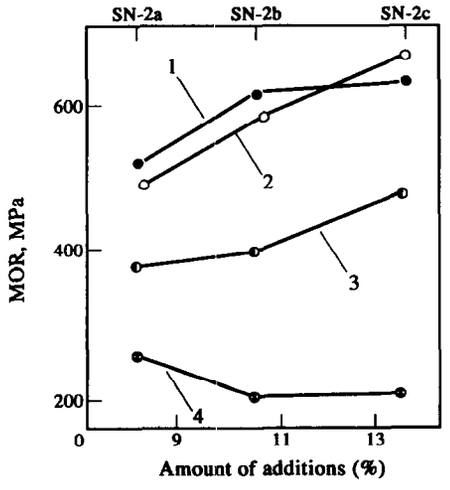

Fig. 9. The influence of the quantity of additives on the MOR (1–4) for SN-2: T = 20°C (1,2), 1200°C (3,4). V_{ch} = 0·5 (1,3) and 0·005 (2,4) mm/min.

phase upon the mechanical behaviour of the SN-2 material which is similar in its properties to SN-1 but contains different quantities of amorphous additives (composition SN-2a, S-2b and SN-2c). It was found that with such combination of the temperature and speed, which provides a near linear-elastic deformation of the SN-2 material (Fig. 10(a)), an increase in the quantity of additives resulted in the increase in its strength (1–3, in Fig. 9), while at inelastic deformation it caused a decrease in strength (4 in Fig. 9), intensification of creep (Fig. 10(b)), enhancement of the crack growth process and an increase in nonlinearity (Fig. 10(a)) of the deformation diagrams.

Zirconia crystals were studied at minimal (ambient) and maximal (1400°C) test temperatures. At ambient temperature all crystals (similarly to the ceramics studied) exhibited linear-elastic deformation (1 in Fig. 11(a) for Y-FSZC-10). At 1400°C Y-FSZC crystal exhibited an increase in strength as compared to that at ambient temperature (Table 2) at all the speeds used in the experiment (see also Refs 2 and 3).

At 1400°C, when Y-FSZC-10 crystals were tested at high V_{ch}, their deformation diagrams were linear, similar to those at ambient temperature (2 in Fig. 11(a)). At V_{ch} = 0·5 mm/min their diagrams showed horizontal portions (3 in Fig. 11(a)), at $V_{ch} \leq 0{\cdot}05$ mm/min well-pronounced upper and lower yield points were observed (4, 5 in Fig. 11(a)). Note that similar deformation behaviour at 1400°C was observed for Y-FSZC-20 crystals as

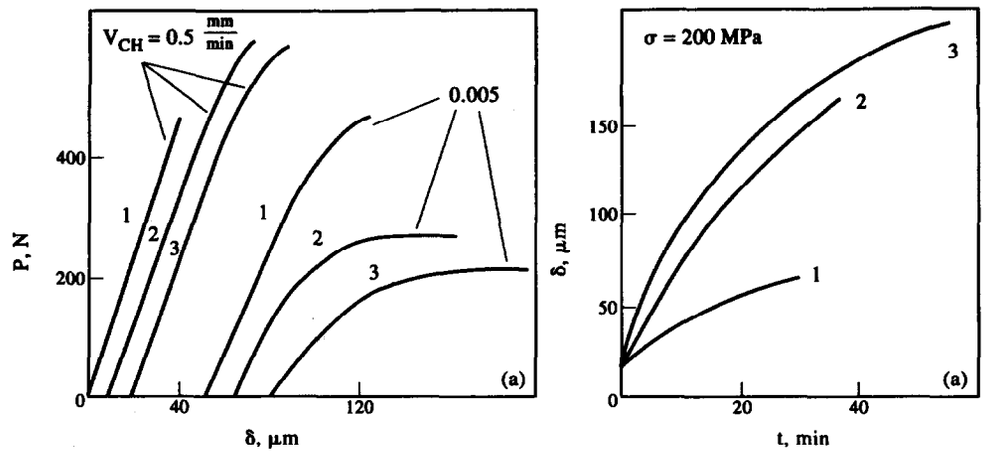

Fig. 10. The influence of the quantity of additives on (a) the load (P) versus deflection (δ) diagrams and (b) creep curves at T = 1200°C for: SN-2a (1), SN-2b (2), SN-3c (3).

well. However, the diagrams of the latter were already linear at V_{ch} = 0·5 mm/min and the ratio of the upper and lower yield points increased almost twice at V_{ch} = 0·005 mm/min as compared to those shown in Fig. 11(a). An interesting observation is that the appearance of the upper and lower yield points for all Y-FSZC crystals was preceded by characteristic maximum in strength (see 3 in Fig. 11(a)).

Y-FSZC crystal samples tested at 1400°C and at speeds equal to or above 0·5 mm/min fractured into many pieces both transverse to and along their axis (see Ref. 27 for details). In contrast, specimens tested at lower speeds (0·05 and 0·005 mm/min) were curved strongly without fracturing, the fact being also noted for similar materials.[2]

With partially stabilized Y-PSZC-3 crystals, whose strength remained practically unchanged (Table 2) up to 1400°C, there were practically no inelastic strains (Fig. 11(b)) and they appeared only at the loads close to the limiting ones irrespective of the temperature and speed regimes. In fracture the specimens of these crystals separated generally into several parts, yet no traces of residual strains were observed in them even at V_{ch} = 0·005 mm/min. We should note that ceramic specimens at all the loading regimes used fractured with only one propagating crack (Fig. 6(a)) though at high temperatures very many nuclei of other cracks could be observed next to it.

4 Discussion

The data presented above may be an indication of a noticeable difference in specific features of the mechanical behaviour of the ceramics and zirconia single crystals investigated.

A specific feature of the ceramic behaviour (as was also noted in Refs 32 and 33) is the deterioration of its strength characteristics at temperatures above T_{BD}. As has been confirmed by the results of the present investigation, this is to a great extent associated with the crack propagation in ceramics (see Fig. 6) In oxygen-free materials such defects can also originate due to oxidation.[34] The development of these defects changes appreciably the inelastic behaviour of ceramics whose specific feature is the presence of extensive horizontal portions (Fig. 3) on the deformation diagrams

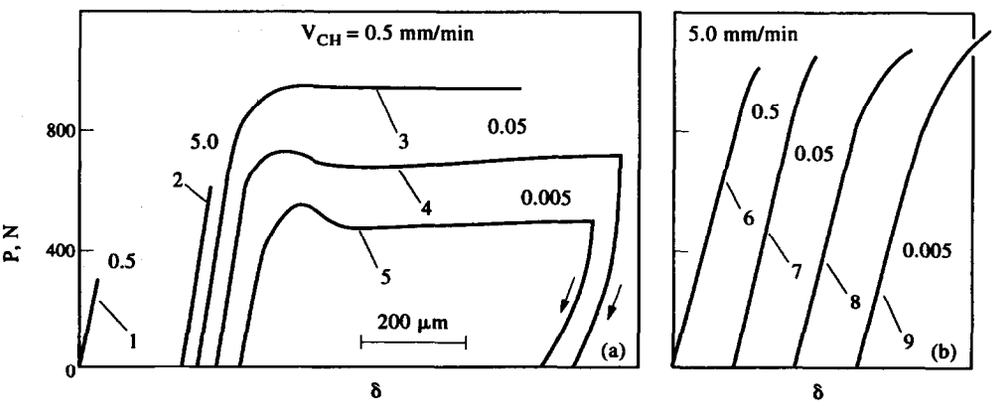

Fig. 11. Load (P) versus deflection (δ) diagrams for (a) Y-FSZC-10 and (b) Y-PSZC-3 at V_{ch} = var.: T = 20°C (1) and 1400°C (2–9). Arrows show specimen unloading.

[a]For Y-PSZC-3 crystals — ultimate stress and strain values.

recorded at a constant speed, corresponding approximately to the load (or stress) which induces a continuous increase in the strain rate at the final stage of creep (Fig. 8(a)), while, for instance in metals this effect is often associated[35] with steady-state creep stage where, as is known, the strain rate is constant.

Thus, the data obtained reveal that the general mechanism of ceramic inelastic deformation, at least for the silicon nitride- and alumina-based materials studied in this investigation, can consist of two simultaneous and competing effects: softening and viscous flow of the grain boundary phase (which has been emphasized in a number of investigations[36–38]) and the growth of cracks up to their critical size. In this case the first effect prevails at low load levels and the second becomes appreciable with the load reaching its limiting value, as can be seen in Fig. 8 from the transition, at stepwise load increase, from the stage of transient creep to that associated with cracking. If we consider zirconia-based materials, for Y-PSZ-3 ceramics the results obtained (Figs 7(b) and 8(c)) point to the existence of most likely one and the same mechanism of deformation (creep) which is not connected with noticeable upsetting of the material continuity.

For fully stabilized (cubic) zirconia crystals Y-FSZC a noticeable increase in their strength with temperature is a distinguishing feature in their behaviour compared to ceramics. One of the causes of this strength enhancement can be the annealing of specimens in the course of testing and the resulting reduction of the degree of their surface damage caused by machining. Indirect evidence for the above assumption is the fact that the ambient temperature testing of specimens annealed at 1400°C yielded the following results: the strength of specimens which were not annealed was 135 and 145 MPa and that of annealed ones 170 and 215 MPa for Y-FSZC-10 and Y-FSZC-20, respectively. A similar conclusion was also made elsewhere.[2]

An increase in the difference between the upper and lower yield points of Y-FSZC-20 crystals is probably associated with the formation of a more ordered solid solution ZrO_2–Y_2O_3[6,8] with an increase in the content of Y_2O_3 from 10 to 20%, while the appearance of two yield points in such crystals is related by some authors[6,8,11] to the involvement of additional slip systems in their deformation process. This can be evidenced by a noticeable intensification of creep in Y-FSZC crystals (Fig. 8(c)) only when the load reaches the upper yield point, whereas in ceramics it was registered at practically all load levels.

The maximum in the Y-FSZC crystal strength prior to the appearance of the upper and lower yield points has not been explained adequately in the present paper, though the effect of strength increase prior to the appearance of plasticity or creep is also known for ceramics.[23]

The deformation diagrams of Y-FSZC and Y-PSZC-3 crystals at all temperature and speed combinations used in the experiment exhibit pronounced linear portions (Fig. 11) within which the deflection disappears completely (Fig. 7(c),(d)) after removal of the applied load. With ceramics such portions on the diagrams were observed only at low temperatures (close to T_{BD} and lower) or at high speeds. It is probably owing to this fact, as well as to the absence of grain boundaries, that elastic moduli of Y-FSZC and Y-PSZC-3 crystals in contrast to ceramics were independent (Fig. 7(c),(d)) of the number of cycles of repeated loading irrespective of the limiting values of the loads reached, which correspond to the appearance of plateaus on the deformation diagrams with the former crystals and to fracture with the latter. The Y-PSZC-3 crystals under repeated loading exhibited an increase in the proportionality limit (Fig. 7(d)), though similarly for ceramics and

Y-FSZC crystals the unloading lines are indicative of their viscoelastic behaviour.

The existence in practice of equivalent ceramic deformation regimes (Fig. 5) can be probably explained by the action under such loading conditions of the same predominant deformation mechanism which is independent of the load and strain level. There was no possibility of choosing such deformation regimes for crystals, probably owing to differences in the character of their deformation (Fig. 8(e),(g)) at different loads.

As noted above, with all the ceramics and Y-FSZC crystals studied, creep intensified noticeably at the limiting loads, while with Y-PSZC-3 crystals almost complete absence of creep (Fig. 8(g)) was observed. This once again testifies to their appreciable difference from and the advantage over all other materials studied.

5 Conclusions

In the present investigation an attempt was made to obtain a general comparative picture of the mechanical behaviour of different types of ceramics and zirconia single crystals over a wide range of temperatures and deformation rates.

Specific features of the behaviour of the materials studied supplement appreciably the information about the processes which accompany their deformation and fracture and show that when making a choice among them for high temperature applications using, as most often happens in engineering practice, conventional criteria of applied mechanics, for a reliable evaluation of their load carrying capacity and, on the whole, efficiency, one should take into account their actual mechanical properties rather than idealize them using different hypotheses.

In spite of the fact that the deformation and fracture mechanisms of partially stabilized zirconia crystals have not been studied sufficiently, comparison of their mechanical properties with those of ceramics under different loading conditions reveals their higher serviceability at higher (up to 1400°C) temperatures. This makes it possible to consider them as new promising engineering materials.

Acknowledgements

This study was supported by the State Committee for Science and Technology of Ukraine. The authors are grateful to the ISF for the grant to their laboratory. The authors wish to thank Dr M. Herrmann (Fraunhofer-Einrichtung für Keramische Technologien und Sinterwerkstoffe, Germany) for cooperation in performing the test of SN-2 ceramics. Many thanks are expressed to Prof. T. Kobayashi (Toyohashi University of Technology, Japan) for supplying the Y-PSZ-3 ceramics for a joint investigation, the results of which are being prepared for publication.

Microstructure and Mechanical Properties of Textured Al_2O_3

T. Carisey, I. Levin & D. G. Brandon

Department of Materials Engineering, Technion — Israel Institute of Technology, Haifa 32000, Israel

(Received 19 April 1994; revised version received 5 July 1994; accepted 2 August 1994)

Abstract

The mechanical properties of a highly textured alumina have been studied and show a significant improvement in bend strength and Weibull modulus when compared to a randomly textured alumina of similar purity. The crystalline texture was due to growth of a small concentration of aligned and uniformly distributed alumina seed platelets into a fine-grained powder matrix during sintering. The (0001) texture of the sintered product gave a non-equiaxed, flattened grain structure, with the c*-axis of the hexagonal unit cell approximately normal to the plane of the specimen tiles. This highly textured microstructure drastically reduces the residual stresses which are associated with thermal contraction anisotropy in polycrystalline alumina, and inhibits crack propagation in the through-thickness direction. Two platelet sizes were investigated, the smaller of which gave the smaller final grain size and the better mechanical properties. At 5 wt% of platelet additions the properties were significantly more reproducible than at 10 wt% of the platelets, probably because of significant interference in packing the platelets at the higher loading.*

Introduction

The main limitation on the use of ceramics as structural materials is their brittleness. The production of a microstructurally and crystallographically oriented monolithic ceramic could be one route towards improving the strength and the resistance to crack propagation, since an oriented and textured monolithic ceramic should avoid some of the problems associated with reinforcement by a second phase; in particular, mismatch of the chemical, thermal or elastic properties of the reinforcing and matrix phases.

Previous work[1] on an alumina matrix reinforced with SiC whiskers has shown that the bend strength and the fracture toughness can be improved, although the whiskers need to be handled with care because of the health problems associated with possible ingestion. SiC platelet reinforcement is also effective, and reinforcement of a ceramic matrix with aligned SiC platelets has been shown to give mechanical anisotropy. For example,[2] the addition of 30% of SiC platelets to a Si_3N_4 matrix powder increased the fracture toughness, the Weibull modulus and Young's modulus of the hot-pressed product, while the mechanical anisotropy was demonstrated in indented samples, for which the extent of crack propagation parallel and perpendicular to the direction of hot- pressing was markedly different.

The bend strength of a zirconia matrix[3] with 5% of SiC platelet additions was reported to be slightly improved from room temperature to 600°C, while the toughness of the composite was about 50% higher than the matrix. The same matrix when reinforced with alumina platelets[4] gave a high toughness and bend strength with 10% of platelet additions from room temperature up to 800°C, and at 1400°C high strain rates resulted in 17% plastic deformation over 30 min, suggesting the onset of super plastic behaviour.

The effect of the shape of the reinforcement has been considered in other work on crack propagation[5,6] and whiskers and platelets were compared. The crack path was found to depend on the shape, size and volume fraction of the second phase particles. These were precipitated by heat treatment in a lithium-alumino-silicate glass ceramic. The fracture toughness was found to be invariant with the particle size.

The present work reports the mechanical properties of a crystallographically textured monolithic alumina produced by gel-casting of a slip containing aligned seed platelets.[7] The bend strength, Weibull modulus, fracture toughness and hardness are compared and correlated with the crystalline texture, the microstructural anisotropy and grain-size, and the state of internal stress. Vickers indentation cracking has been used to demonstrate the anisotropy of the crack propagation resistance.

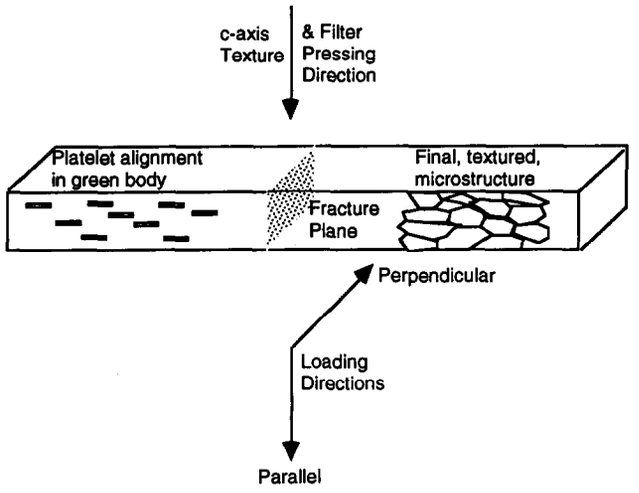

Fig. 1. Seed platelet and bend-bar geometries for textured alumina specimens.

Experimental

Composite fabrication

Highly textured monolithic alumina plate samples were prepared with the *c*-axis of the hexagonal unit cell within 10° of the normal to the plate surface. The samples were prepared by filter compaction and sintering of wet, water-based, gelled tape containing alumina seed platelets which had been aligned by a doctor-blade gel-casting process, as described previously.[7] The textured aluminas were compared with untextured (randomly oriented) samples prepared from the same powder and using the same processing route (water-based tape-casting, followed by lay-up, filter pressing and pressureless sintering), but with no seed platelet additions.

Characterization

Optical and scanning electron microscopy (SEM) were used to characterize the microstructure of polished cross-sections of the pressureless-sintered tile samples. Crack propagation was studied by varying the orientation of a Vickers indentation on polished sections cut perpendicular to the plate surface. SEM was the preferred method for evaluating the sintered microstructure, the fracture surfaces of bend specimens and the indentation crack morphology. The indentation samples were polished but unetched, while all other sintered specimen sections were polished and thermally etched at 1450°C for 30 min.

Mechanical testing

The sintered tiles were sectioned into 30 × 4 × 3 mm test bars with a 20 mm load span. The bend strength[8] was determined in 3-point bending for samples in which the tensile surface was either parallel or perpendicular to the plane defined by the original, aligned seed platelets. That is, the plane of the fracture was always the same, but the normal to the tensile surface was either parallel or perpendicular to the principal *c*-axis of the textured samples (Fig.1). The specimen span was 20 mm. About 25 samples were tested to allow for Weibull analysis of the strength data.[9,10] The fracture toughness was measured using the single edged notched beam test (SENB)[11,12] and was determined for the same fracture plane and failure directions as in the bend tests. The hardness was determined by Vickers indentation at 50 N with the loading axis either parallel or perpendicular to the normal to the original platelets (the principal *c*-axis of the textured samples), taking the average of measurements made on 10 separate indentations.

Thermal stresses

The thermal stresses present in the sintered tiles were evaluated by X-ray diffraction peak-shift measurements, as described elsewhere.[13] These measurements were taken from polished surface sections cut parallel and perpendicular to the original plane of alignment of the seed platelets. The accuracy of the measurements was limited to approximately 1 part in 10^5 by the X-ray goniometer and the positioning of the sample. The reflections used were a compromise between the requirements for reasonable signal intensity and the need to sample strains parallel and perpendicular to the *c*-axis of the textured alumina grains. The reflections chosen were 41·6 and 41·0, for which the penetration depth at 90% absorption of the incident X-ray beam is about 80 μm, much larger than the observed grain size of the samples. The average microstrain perpendicular to the sample surface for the crystallographic directions corresponding to the planes satisfying the reflecting conditions is obtained from the reflection shift with respect to a standard powder sample. For the sample section cut perpendicular to the alignment plane, the measured strains are predominantly from the textured grains, while it is the residual, randomly-oriented grains which dominates the strain measurement from the parallel section. The prediction is that thermal stresses should be absent if the material contains only ideally textured grains with the *c*-axes fully aligned, since α-Al_2O_3 has only two coefficients of thermal expansion, parallel and perpendicular to the *c*-axis, the former exceeding the latter by about 10% at all temperatures.

Results

Figures 2 (a) and (b) show the bend strengths for two seed-platelet concentrations (5 and 10 wt%)

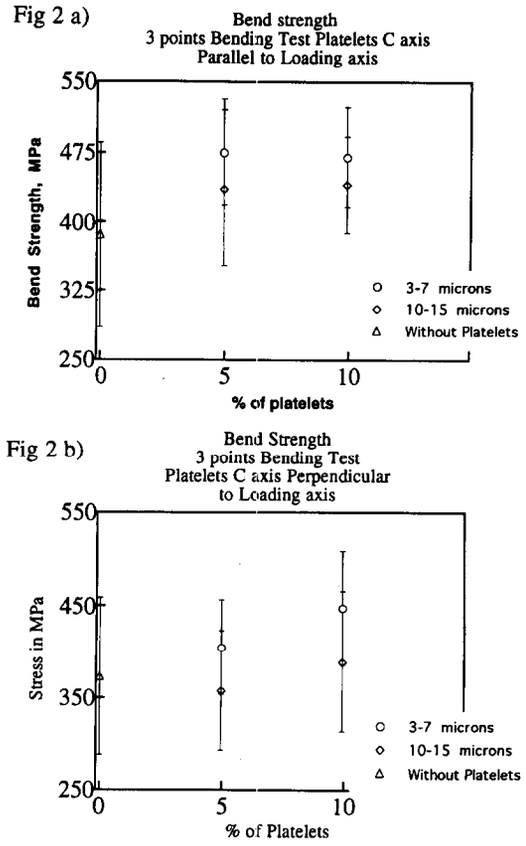

Fig. 2. Bend strength vs platelet concentration for both sizes of seed platelet additions: (a) principal *c*-axis of the textured tile parallel to the loading axis, (b) principal *c*-axis of the textured tile perpendicular to the loading axis.

and sizes (3–7 and 10–15 μm). The scatter bands shown are those calculated separately for each set of test results. In Fig. 2 (a) the tensile surface is parallel to the plane of the platelets, while in Fig. 2 (b) the plane of the tensile surface is perpendicular to the plane of the platelets. Clearly, the texture increases the bend strength when the tensile surface is parallel to the plane of the platelets, even though the grain size of the platelet-seeded and textured material is far larger than that of the unseeded alumina. The increase in bend strength after seeding with the smaller and larger platelets is 25 and 15%, respectively. In all cases the smaller seed platelets gave the smaller final grain size and were more effective than the larger ones in strengthening the product. The bend strength for crack propagation parallel to the principal *c*-axis of the texture was higher than that perpendicular to this axis. The mechanical behaviour of the specimens seeded with the larger platelets and with the tensile surface perpendicular to the original plane of the platelets was similar to that of alumina sintered without seed platelets, in spite of the much larger grain size of the seeded material, but with both sizes of seed platelets, the bend strength increased with platelet loading.

Figure 3 shows the Weibull moduli determined on 25 samples for the case of the tensile surface

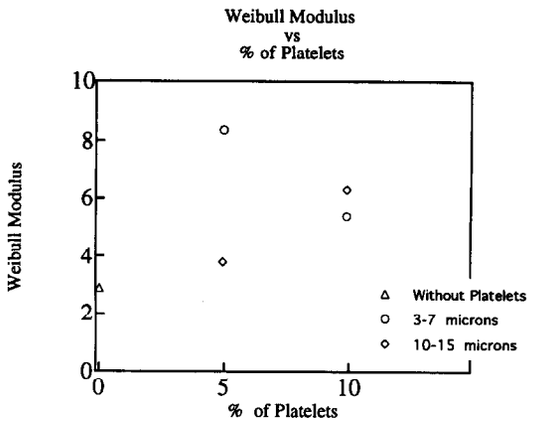

Fig. 3. Weibull modulus vs platelet concentration: principal *c*-axis of the texture parallel to the loading axis.

parallel to the original platelets. In view of the small number of samples, these values lack significance, but the small scale of the laboratory units constructed for gel-casting, tape lay-up and filter-pressing is thought to be primarily responsible for the very low value observed for the samples with no seed platelets. The improvement in Weibull modulus with the addition of seed platelets is thought to be significant. The best value of the modulus (about 8) was obtained for 5% additions of the smaller platelets. The platelet seeding appears to have improved the reliability of the sintered product, in addition to the improvement in the average mechanical strength.

The results for fracture toughness are presented in Fig.4 which again shows the two cases of the tensile surface either parallel (Fig. 4(a)) or perpendicular (Fig. 4(b)) to the platelets. The average fracture toughness calculated for the sample without platelets is questionably high for alumina, but the large standard deviation for this material puts it within the range of the other, textured samples. In Fig 4(a), the smaller seed platelets gave a better fracture toughness than the larger platelets, while in Fig. 4(b) all the values are very close together. In effect, the fracture toughness of the textured alumina is about 5 MPa $m^{-1/2}$, almost independent of the parameters examined.

Figure 5 shows the Vickers hardness results; firstly, in Fig. 5(a), as a function of the loading of the two sizes of seed platelets and, secondly, Fig. 5(b), in a comparison of the hardness measured on a cross-section of the tile (loading axis perpendicular to the principal *c*-axis of the texture) with that on the tile surface (the surface parallel to the plane of alignment of the seed platelets). The indent shape and crack propagation on the tile surface were similar for both the textured and the randomly oriented alumina. The indent shape on the cross-section will be discussed further below, but the measured hardness on this cross-section

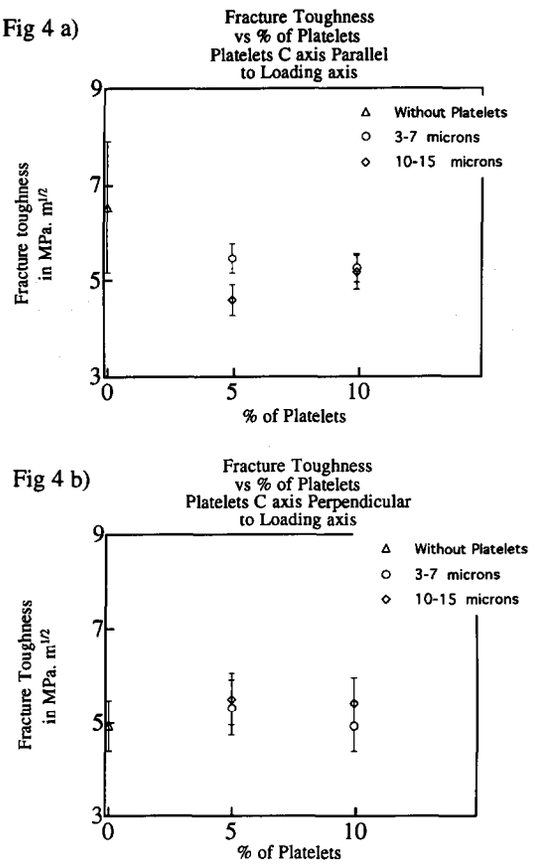

Fig. 4. Fracture toughness vs platelet concentration for both seed platelet sizes: (a) principal c-axis of the textured tile parallel to the loading axis; (b) principal c-axis of the textured tile perpendicular to the loading axis.

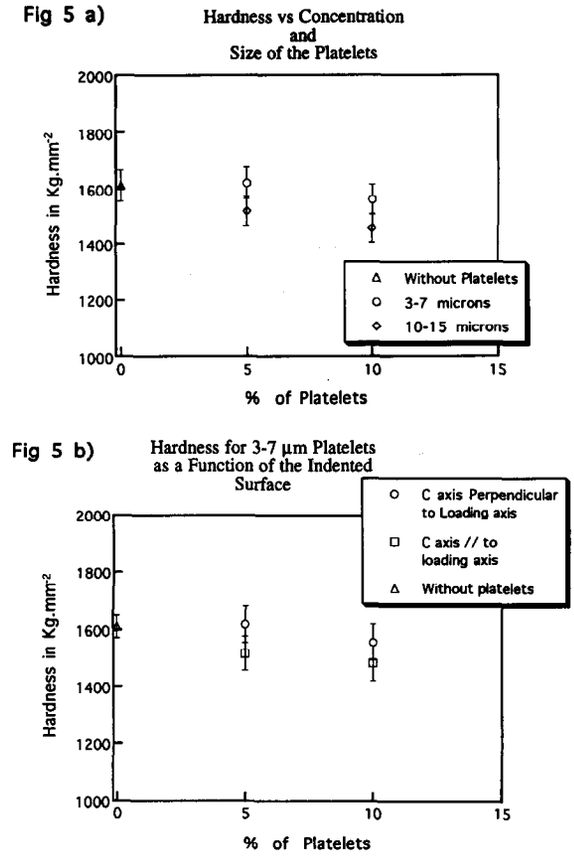

Fig. 5. Vickers hardness at 50 N vs platelet concentration: (a) for both sizes of seed platelet; (b) for two different indented surfaces: the sample cross-section and the surface parallel to plane of the original seed platelets.

was lowest for the smaller platelets (largest grain size), while the highest hardness, obtained for the sample without platelets, is associated with the small sintered grain size in the absence of the seed platelets.

The microstructure of the gel-cast alumina without platelets consisted of equiaxed grains with a grain size of about 3 μm. By contrast, the average grain size of the samples containing seed platelets was about 6 μm. The micrographs shown in Fig. 6 are taken from a tile cross-section. The non-equiaxed (oblate) grain structure is a result of the non-equiaxed distribution of the centres of gravity of the original aligned seed platelets. These have grown during sintering to consume most of the initial powder matrix. The final microstructure is highly textured and anisotropic, with a comparatively large grain size. It is the size of the original seed platelets and their volume fraction which determine the final grain size. A homogeneous distribution of the platelets[7] should give isotropic behaviour in the plane of the sample plate. In addition, grain growth has been enhanced by the presence of calcium in the green body associated with the current gel-casting process.

The mechanical anisotropy is demonstrated in Fig. 7, which shows optical micrographs of indented polished sections cut perpendicular to the tile surface. Figure 7(a) is from an indented sintered sample which contained no platelets, while Figure 7(b) shows a textured sample which contained 5 wt% of the smaller, aligned seed platelets. In the first case the cracks have the same length, while in the second case crack propagation parallel to the principal c-axis of the texture is clearly inhibited. Figure 8 shows SEM micrographs of indentation cracks, (a) propagating approximately parallel to the original direction of platelet alignment and (b) propagating approximately perpendicular to the alignment direction. In the first case, delamination has tended to generate a stepped surface, while in the second case the flattened, textured grains have inhibited crack propagation and given rise to a highly irregular crack path.

The thermal expansion coefficient α of alumina parallel to the c-axis is approximately 10% higher than that perpendicular to the c-axis, and is expected to lead to cumulative thermal strains in a random polycrystal cooled below the relaxation temperature. The total elastic mismatch at room temperature, $\Delta\alpha\Delta T$, assuming that the minimum value of ΔT is 1000°C, is about $7{\cdot}6 \times 10^{-4}$ in a random polycrystal. Assuming elastic isotropy, this will lead to a maximum c-axis compressive

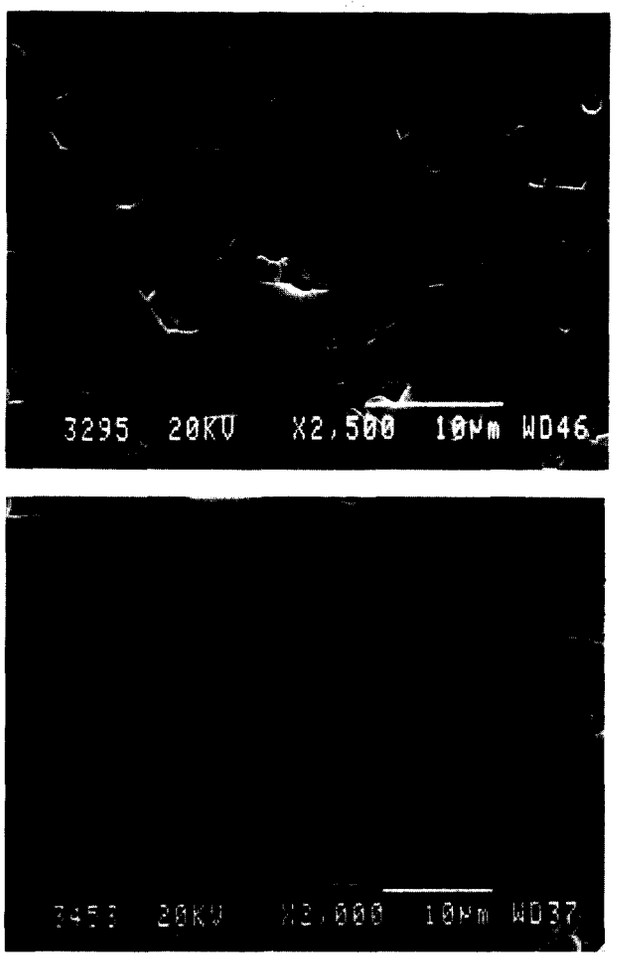

Fig. 6. SEM micrograph of thermally-etched samples: (a) sample with 5 wt% of 3–7 μm platelets; (b) sample with 5 wt% of 10–15 μm platelets.

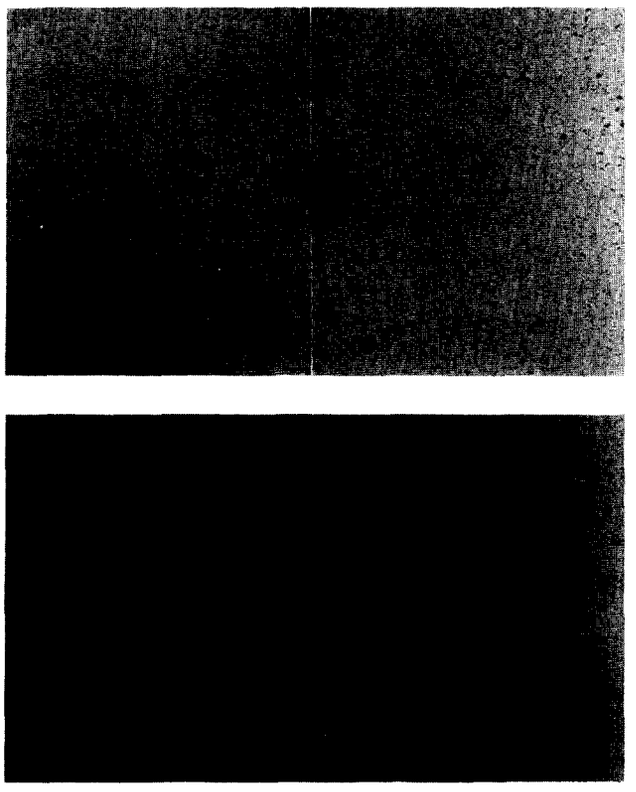

Fig. 7. Optical micrographs of Vickers indentation cracking at 200 N: (a) sample without platelets; (b) sample with 5 wt% of small platelets.

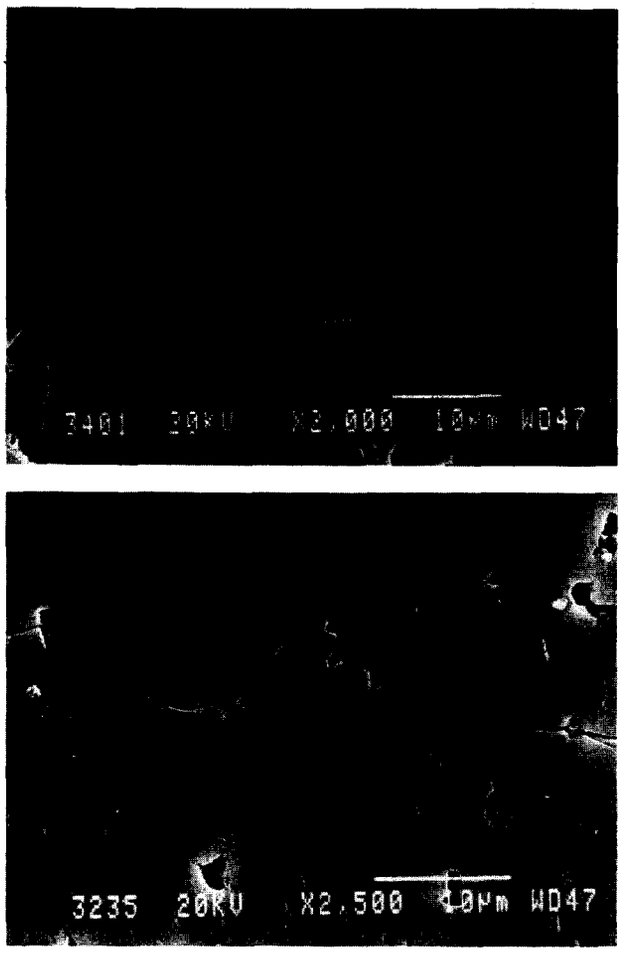

Fig. 8. SEM micrographs of Vickers indentation cracking at 200 N: (a) crack propagation parallel to the direction of original seed platelet alignment; (b) crack propagation perpendicular to the direction of original seed platelet alignment.

strain of about -5×10^{-4} and a maximum tensile strain perpendicular to the *c*-axis of about $2{\cdot}6 \times 10^{-4}$. In a *c*-axis textured alumina containing some randomly oriented material, the thermal strain in the textured material will be reduced, while that in the residual, randomly-oriented material will increase. The residual strain measurements made in the present work on a sample tile containing no seed platelets gave an average strain value for the 41·6 reflection (the only suitable high-angle, strong reflection close to the *c*-axis) of $-1{\cdot}4 \times 10^{-4}$, while that measured from the same reflection parallel and perpendicular to the *c*-axis of a strongly textured sample gave compressive strains of $-2{\cdot}4 \times 10^{-4}$ and $-0{\cdot}2 \times 10^{-4}$, respectively. The former value is associated with the strain in the small volume fraction of residual, randomly oriented grains, which are strongly constrained by the surrounding textured material, while the latter value is that associated with the dominant volume fraction of highly textured grains. The implication is that, as predicted, the textured material has a much reduced level of thermal stress.

Discussion

The present results have demonstrated a significant improvement in the mechanical properties of a textured alumina produced by gel-casting a slip containing aligned alumina seed platelets, in spite of the residual porosity and large grain size of this material. These results were obtained with high levels of calcium doping (of the order of 0·5%), due to the use of calcium as the gelling cation (the commonest cation used to promote the alginate gel reaction).

The microstructural observations on the sintered samples seeded with both sizes of alumina platelets showed that the matrix powder for the most part had been consumed during sintering to leave large, non-equiaxed, highly textured grains which had formed by the growth of the aligned seed platelets. The distribution of the seed platelets influenced both the final texture and the degree to which the grains are non-equiaxed, and the final grain size depended on both the volume fraction of the seed platelets and their initial size. The smaller platelets gave the smaller final grain size at a given loading of seed platelets and, consistent with this, the best mechanical properties. Further improvements could presumably be anticipated if the seed platelet size were to be further reduced, leading to a smaller ultimate grain size due to the greater number density of platelets at the same loading.

Calcium was selected as the gelling cation, since the calcium alginic ion-exchange reaction is well-characterized. However, calcium is known to cause abnormal grain growth which is expected to degrade the mechanical properties. Several cations have been used to gel the water-based tape used in this work[7] and satisfactory results have been achieved with alternative alumina cation dopants which are considered either beneficial (Y, Ce, La) or harmless (Sr and Ba).

The present large grain size, monolithic alumina, produced by the sintering of green bodies which contain well-aligned alumina seed platelets, is highly textured and constitutes a new class of monolithic ceramic which could have some interesting applications. These materials could be used for any wear or abrasion resistant component requiring improved crack propagation resistance normal to the surface, while the large grain size should lead to improved microstructural stability at high temperatures, and hence to improved creep resistance. The wet, gelled tape, which is produced by the gel-casting process,[7] is an intermediate product which could be wound to form tube or plastically shaped. The present results have shown that the crystalline texture reduces the thermal stresses and should also improve the thermal shock resistance, leading to potential applications as furnace tubes in electronic substrate furnaces (which are generally made only from alumina). Since only small quantities of the seed platelets are required, the increased raw material costs are minimal, while the proposed processing route is relatively uncomplicated and requires only pressureless sintering.

Conclusions

(1) A textured alumina, produced from a gel-cast slip containing aligned alumina seed platelets by tape lay-up, filter-pressing and pressureless sintering, has been found to possess good mechanical properties.
(2) Although the sintered seeded product had a far larger grain size than an equivalent, unseeded alumina, the bend strength could be enhanced by more than 20%, while the fracture toughness was unaffected.
(3) The Weibull modulus was also improved by processing with the aligned seed platelets.
(4) The Vickers hardness was only slightly reduced in the textured material, presumably due to the increased grain size.
(5) The crystalline texture and microstructural anisotropy (large, plate-like grains) inhibit crack propagation in the through-thickness direction, as demonstrated by Vickers indentation cracking.
(6) The residual thermal stresses, as determined by X-ray diffraction peak shift measurements, are significantly reduced in the textured alumina to less than one third of their value in randomly oriented alumina samples subjected to the same sintering cycle.
(7) The texture (preferred orientation) and the microstructural anisotropy (non-equiaxed grain structure) are both associated with the growth of the aligned seed platelets into the fine-grained matrix during the pressureless sintering process.

Toughening and Strengthening of Alumina with Silver Inclusions

W. B. Chou & W. H. Tuan*

Institute of Materials Science & Engineering, National Taiwan University, Taipei, Taiwan 10764

(Received 23 June 1993; received in revised form 20 June 1994; accepted 27 June 1994)

Abstract

The fracture toughness and flexural strength of Al_2O_3/Ag composites are investigated. Both the strength and toughness of alumina are enhanced as silver inclusions are added. From microstructural observation, the crack is bridged or deflected by silver inclusions. The toughness enhancement is contributed mainly by the plastic deformation of the silver inclusions. The strengthening effect is contributed both by the matrix grain refinement and by the toughness enhancement.

1 Introduction

The application of ceramics as structural components is often limited by their brittleness. A major research objective has therefore been to improve their toughness. Previous studies have demonstrated that brittle solids can be toughened by incorporating metallic inclusions into them.[1–7] Similar to the zirconia toughened ceramics (ZTC),[8] the toughness of the metal-toughened ceramics can be described as

$$K_{IC,composite} = K_{IC,matrix} + \Delta K_{IC,metal} \quad (1)$$

where $K_{IC,\ composite}$ is the toughness of the composite, $K_{IC,matrix}$ the toughness of the matrix and, $\Delta K_{IC,metal}$ the toughness increase contributed by the metallic reinforcement. The toughness enhancement for the ceramic–metal composites is believed to be contributed by the plastic deformation of metallic inclusions.[9–11]

As metallic inclusions are embedded within ceramic matrices, the metallic inclusion is constrained by the brittle and rigid matrix. The deformation behaviour of the constrained inclusion has been investigated by Ashby *et al.*[9–10] They suggested that the toughness increase, contributed by plastic deformation, $\Delta K_{IC,plastic\ deformation}$, is proportional to square root of the product of the volume fraction, F, and the inclusion size, d, as

$$\Delta K_{IC,plastic\ deformation} = C\,(F\,d)^{1/2} \quad (2)$$

where C is a constant. The constant depends on the bonding characteristics. Deve *et al.* have suggested that the toughness enhancement is increased with the increase of the ductility of metallic inclusion.[11] Among metals, silver is superior for its ductility. Furthermore, silver is chemically stable up to temperatures higher than its melting point, 960°C. Therefore, the silver containing composites can be prepared by pressureless sintering in air.[12,13]

The mechanical properties of Al_2O_3/Ag composites have been studied recently.[12,13] In these studies, the toughness is determined by the indentation technique. As we are going to show later, this technique tends to over-estimate the toughness of Al_2O_3/Ag composites. In the present study, the toughness of the Al_2O_3/Ag composites is determined by the single-edge-notched-beam (SENB) technique. Furthermore, the effect of silver inclusions on the strength of alumina is not determined in the previous studies. In this study, the strength of the Al_2O_3/Ag composites is also measured.

2 Experimental Procedures

Alumina (AKP-50, Sumitomo Chem. Co. Ltd., Japan) and various amounts of silver oxide (Ag_2O, Johnson Matthey Co., UK) were milled in ethyl alcohol for 4 h. The slurry of the powder mixtures was dried with a rotary evaporator. The dried lumps were crushed and sieved. The powder compacts were prepared by pressing uniaxially at 56 MPa. The sintering was performed in air at 1600°C or 1700°C for 1 h. The heating and cooling rates were 5°C/min. In order to determine the toughness of alumina as a function of grain size, the alumina specimens with different grain size were prepared by sintering the alumina compacts at 1400–1700°C for 1 h. These Al_2O_3 specimens

*To whom correspondence should be addressed.

were prepared with the same procedures as those for the Al_2O_3/Ag composites.

The decomposition behaviour of silver oxide was determined by a differential thermal analyzer (DTA, Netsch Co., Germany). Phase identification was performed by X-ray diffractometry (XRD). The final density was determined by the water displacement method. Before submerging the specimens in water, a wax was applied to the surface to prevent water penetration. The microstructure was observed by a scanning electron microscope (SEM) and a transmission electron microscope (TEM). Both microscopes were equipped with an energy dispersive X-ray spectrometer (EDX). Polished surfaces were prepared by grinding and polishing with diamond paste to 6 μm and subsequently with silica suspension to 0·05 μm. Since the partial pressure of liquid silver at elevated temperature is high (10 mmHg/1600°C and 23 mmHg/1700°C),[14] a silver-free surface layer is formed.[13] After removing the silver-free layer by grinding, the volume fraction of silver after sintering was recalculated by counting the point fraction on the polished surfaces. The size of silver inclusions was determined by using the linear intercept technique. The dihedral angle of the silver inclusion within alumina matrix was estimated from polished microstructures by applying a stereological counting technique.[15] The polished specimens were thermally etched at 1500°C for 1 h to reveal the grain boundaries of alumina. The size of the matrix grains was also determined by the linear intercept technique. More than 200 grains or inclusions were counted.

The sintered specimens were machined longitudinally with a 325 grit resin-bonded diamond wheel at cutting depths of 5 μm/pass. The silver-free layer was removed during the grinding procedure. The final dimensions of the samples were 3 mm × 4 mm × 36 mm. The strength of the samples was determined by the 4-point bending technique at ambient conditions. The upper and lower spans were 10 and 30 mm, respectively. The rate of loading was 0·5 mm/min. The fracture toughness was determined by the single-edge-notched-beam (SENB) technique. The notch was generated by cutting with a diamond saw. The width of the notch was around 0·5 mm. The indentation technique was also used to determine the toughness of the composites. The load applied was 50 N.

3 Results and Discussion

The DTA analysis suggests that the silver oxide starts to decompose from 410°C. The XRD patterns indicate that there is no residual silver oxide in Al_2O_3/Ag composites after sintering. The relative density of the composites is shown as a function of silver content in Fig. 1. The size of silver inclusions is shown as a function of silver content in Fig. 2. The grain size of alumina matrix is shown in Fig. 3. Typical microstructures for the composites are shown in Fig 4. The dihedral angle of the silver inclusion within the alumina matrix is 110±7·8° for the composites sintered at 1600°C and 101±5·5° for the composites sintered at

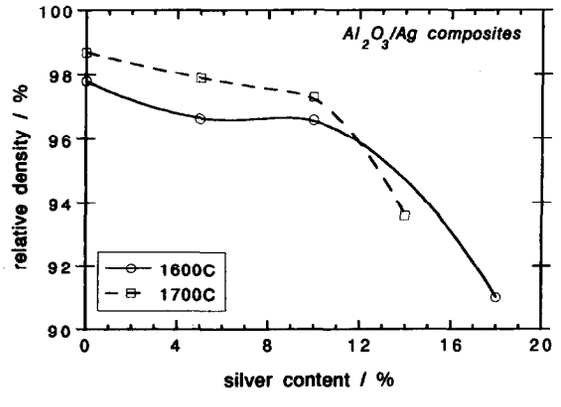

Fig. 1. The density of the composites as a function of silver content with the samples sintered at the indicated temperatures for 1 h.

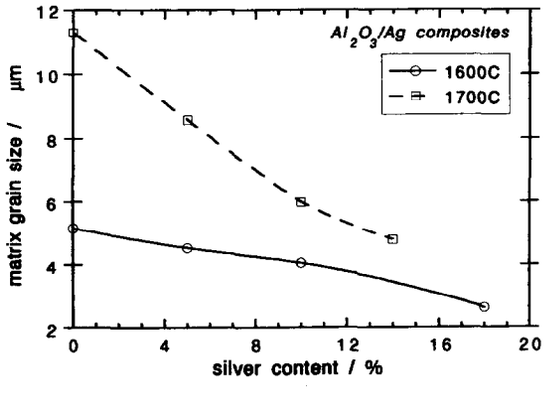

Fig. 3. The size of alumina matrix found in the composites shown in Fig 1.

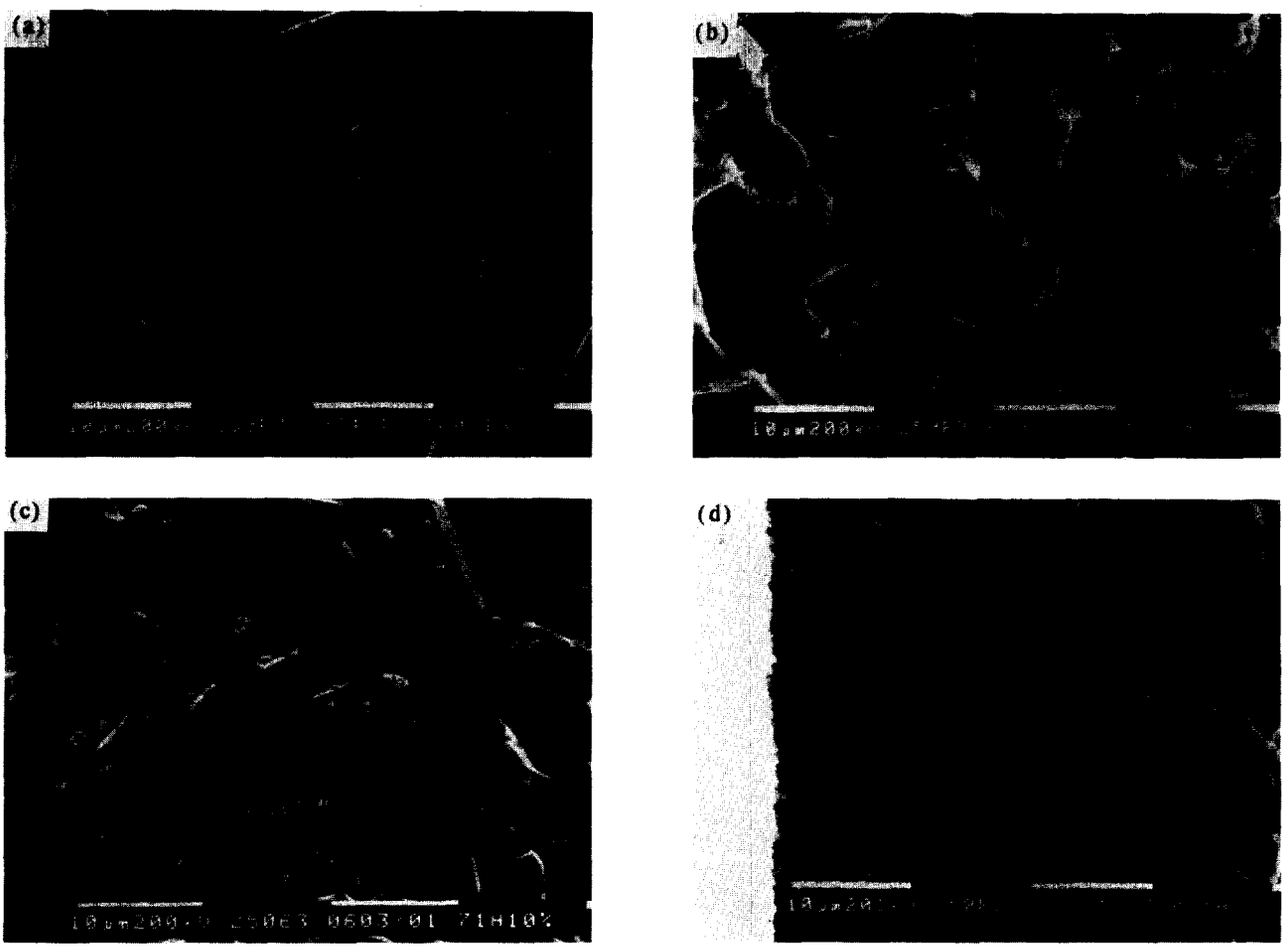

Fig. 4. Typical microstructures of Al_2O_3/Ag composites. The vol.% of silver in the composites shown is (a) 0, (b) 5, (c) 10 and (d) 14. The composites are sintered at 1700°C for 1 h.

1700°C. These values are close to the reported values determined by the sessile drop technique.[16] Since the wetting is poor, silver melt behaves as an inclusion to the alumina matrix. The densification of the alumina matrix is thus hindered. From Fig. 4, most silver inclusions are located at the grain boundaries of alumina, the grain growth of alumina matrix is slowed down due to the presence of silver inclusions.

Since the thermal expansion of silver (22/MK) is bigger than that of alumina (9/MK), thermal stress results after the cooling step. Twins can be observed within the silver inclusions, (Fig. 5). Due to the fact that the twins are lens-shaped, they are deformation twins.[17] It suggests that the silver inclusions are highly constrained due to the presence of residual stress. Occasionally, small particles can be observed near the Al_2O_3/Ag interface, (Fig. 5). The small particles analyzed by EDX are mainly composed of Cr and Fe. It may be from the contamination from the steel mold used for forming. From the TEM study, no reaction layer can be observed at the interface and no Al detected within the silver inclusions. Since the solubility of alumina in Ag is negligible, it further confirms that the silver melt can not act as an effective liquid phase to promote the densification.

The fracture toughness of the composites is shown as a function of silver content in Fig. 6. The interactions between a crack and silver inclusions are shown in Fig. 7. In the figure, the crack is bridged by, or deflected by, the silver inclusions. It suggests that the toughening mechanisms for the composites are plastic deformation and crack deflection. Both the plastic deformation[9–11] and crack deflection[18] mechanisms can contribute to the toughness enhancement. The toughness of Al_2O_3/Ag composites determined by the SENB and indentation techniques is thus higher than that of Al_2O_3 alone. However, the toughness determined by the indentation technique results in higher values. The crack opening introduced by the indentation is much smaller than the notch width produced by cutting with a diamond saw. Since the crack surfaces with a small opening are bridged by silver inclusions (Fig. 7), the propagation of the crack with a small opening is more difficult. Therefore, the toughness determined by the indentation technique is much higher than that determined by the SENB technique.

In order to determine the toughness of alumina matrix, $K_{IC,matrix}$, the toughness of the alumina

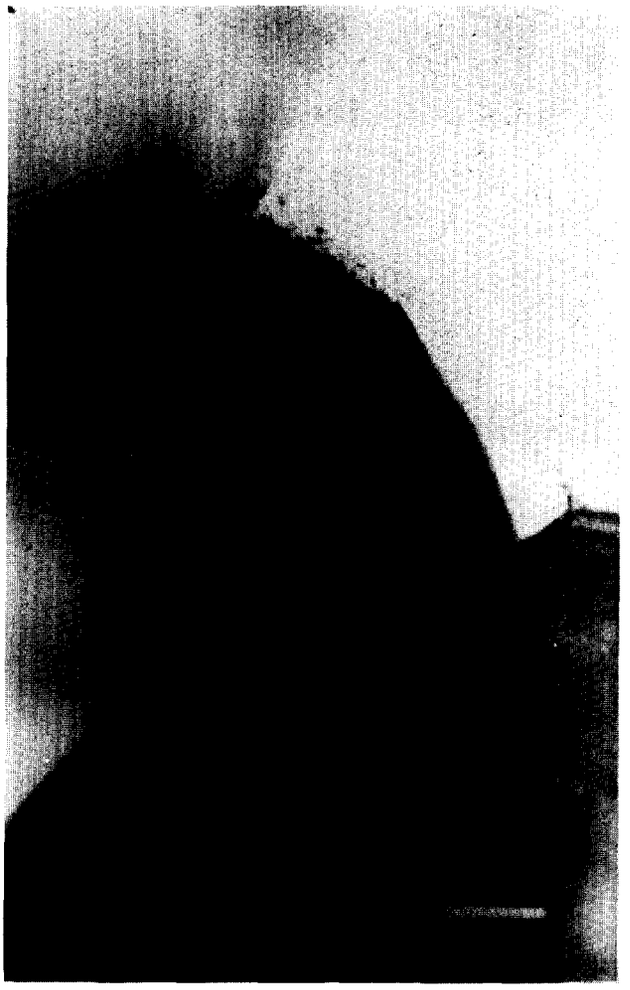

Fig. 5. A highly constrained silver inclusion found within the alumina matrix.

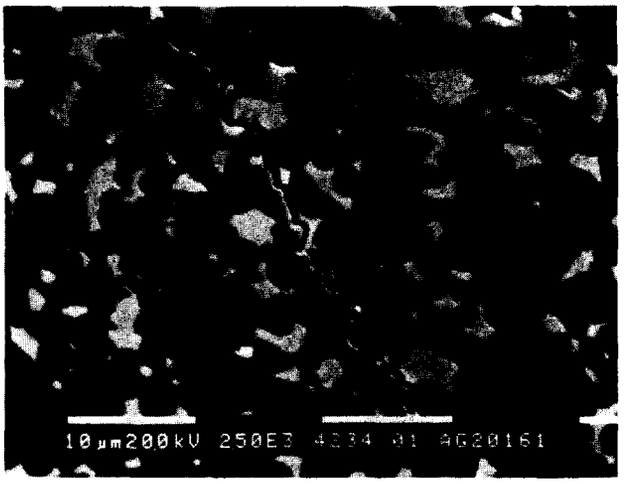

Fig. 7. The interactions between silver inclusions and a crack introduced by indentation.

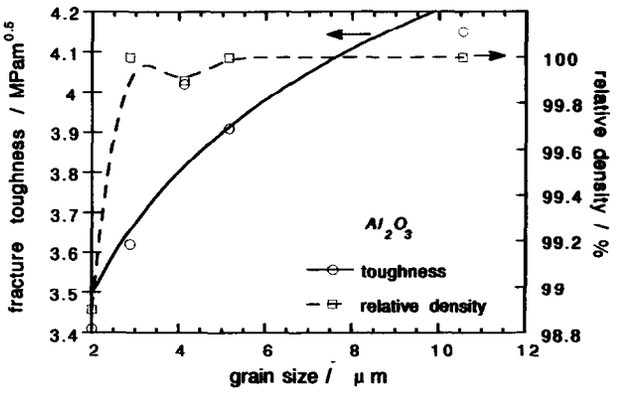

Fig. 8. The fracture toughness determined by the SENB technique and the density of Al_2O_3 specimens as a function of grain size.

specimens sintered at various temperatures is determined (Fig. 8). The toughness is determined by the SENB technique. The density of the Al_2O_3 specimens is varied from 98·9 to 99·9%; therefore, the effect of porosity on the toughness can be ignored. The toughness of alumina is increased with the increase of grain size. It is similar to the results reported by Tuan *et al.*[19] According to eqn (1), the toughness increase, $\Delta K_{IC,metal}$, contributed by the metallic inclusions which can be determined as $K_{IC,matrix}$ is known. The toughness increase of the composites is shown as a function of the square root of the product of volume fraction, F, and inclusion size, d, in Fig. 9. Since the enhancement from the deflection around spherical inclusions is limited,[18] more significance is to be given to the

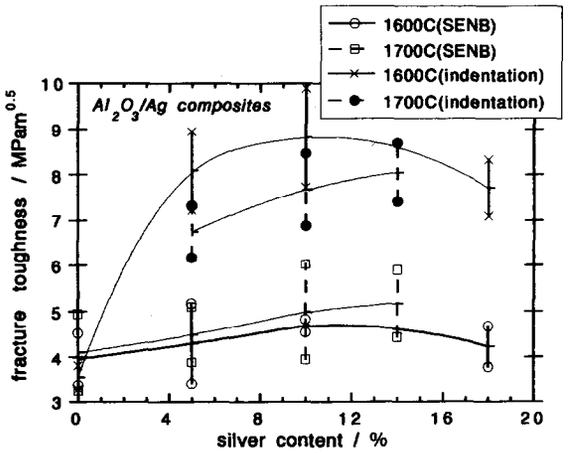

Fig. 6. The fracture toughness determined by the SENB and the indentation techniques for the composites shown in Fig. 1 as a function of silver content.

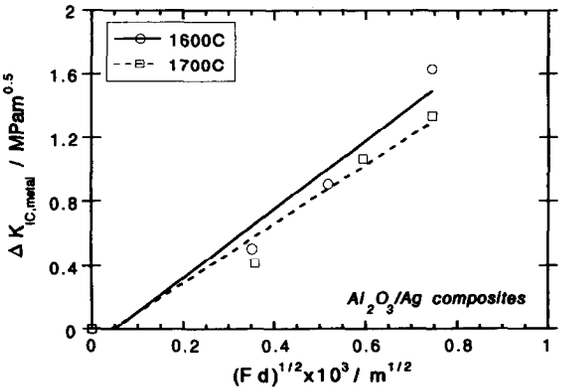

Fig. 9. The fracture toughness increase as a function of the square root of the product of volume fraction and inclusion size. The sintering temperatures are indicated.

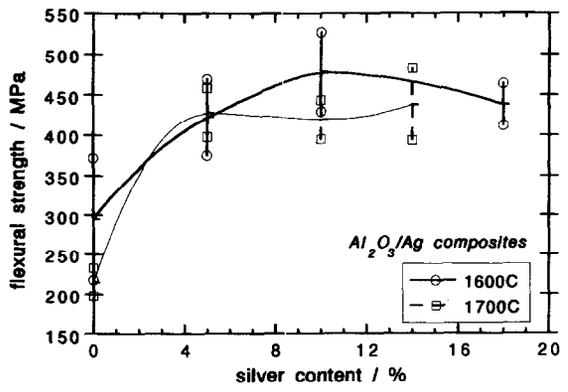

Fig. 10. The flexural strength for the composites shown in Fig. 1 as a function of silver content.

plastic deformation mechanism. This is supported by the linear relationship between the toughness increase and the square root of the product of volume fraction and inclusion size (Fig. 9).

The flexural strength of the composites is shown as a function of silver content in Fig. 10. With the enhanced toughness and the reduced grain size of alumina matrix as silver is added, the strength of alumina is improved substantially.

4 Conclusions

Dense Al_2O_3/Ag composites are prepared by pressureless sintering at 1600°C and 1700°C for 1 h. The densification behaviour, microstructure development, and mechanical properties of the composites are investigated. Even though the silver inclusions are melted during sintering, due to the fact that the wetting of silver melt on alumina is poor and the solubility of alumina in silver is limited, the presence of silver inclusions hinders the densification. The matrix alumina grains are refined due to the grain boundaries being dragged by the silver inclusions. The addition of ductile inclusions not only toughens but also strengthens the ceramic matrix. The toughening is contributed mainly by the plastic deformation of silver inclusions. Due to the increase in toughness and the refinement of matrix grain size induced by the presence of the inclusions, the strength of the alumina is also significantly increased.

Toughening of X-Sialon with Al_2O_3 Platelets

Y. Zhou, J. Vleugels, T. Laoui & O. Van der Biest

Department of Metallurgy and Materials Engineering, Katholieke Universiteit Leuven, De Croylaan 2, B-3001 Leuven, Belgium

(Received 28 January 1994; revised version received 15 July 1994; accepted 11 August 1994)

Abstract

Toughening of an X-sialon matrix with up to 53 volume percent Al_2O_3 platelets was investigated. The effect of platelet content on both matrix phase composition and mechanical properties of the composites was evaluated. The extent of cracks introduced by Vickers hardness indentations showed a reduced length with increasing platelet content, indicating an increase in fracture toughness. The toughness has been shown to increase from 1·77 MPa · $m^{1/2}$ for pure X-sialon up to 4·16 MPa · $m^{1/2}$ for the composite containing 28 volume percent platelets. For higher platelet additions, toughness increases further but the composition of the matrix shifts to β'-sialon. The E*-modulus of the composites increases with the amount of platelets. The improvement in fracture toughness was attributed to debonding, crack bridging and crack deflection.*

1 Introduction

Sialon ceramics have been investigated extensively due to their remarkable properties which make them suitable for high temperature structural applications.[1–3] They are also being considered for cutting tools; β'-sialons for instance are already being used for machining of cast irons, but they are not suitable for most steels. Our recent research has shown that at the high cutting speeds at which ceramic cutting tools need to be used to be competitive, chemical compatibility with the workpiece material may be a more important selection criterion than other material properties such as hardness.[4,5] A recent study showed that X-sialon ceramics exhibit a much better chemical compatibility with steel at high temperatures compared to β'-sialon based ceramics.[6] The high chemical wear resistance of X-sialon may indicate that cutting tools could be an interesting potential application. However, actual turning trials[7] indicated that the poor toughness of the material caused frequent chipping of the cutting edge. An indentation fracture toughness value of about 1·77 MPa $m^{1/2}$ was measured.[6] The low fracture toughness of X-sialon will thus limit the use of this ceramic in the field of cutting tools.

To overcome this common problem encountered in the application of monolithic ceramic materials, many attempts have been made to improve their fracture toughness. For instance, the incorporation of a second phase into the monolithic ceramic matrix can result in an improved fracture toughness of the composite. Toughening of ceramics has usually focused on the introduction of whiskers into the matrix phase. A recent concern regarding the reinforcing components has shown less interest in whiskers because of several unfavourable aspects, including the high price, toxicity and difficulty in achieving a uniform dispersion during processing. Platelets could be a good alternative to whiskers as a reinforcement in monolithic ceramics because the toughening mechanisms contributing to whisker composites such as crack bridging, debonding, pullout and crack deflection could also operate in platelet ceramic composites.[8,9] Furthermore, the use of platelets in ceramic composites has some advantages over whisker reinforced ceramics, including the ease of dispersion into ceramic matrix at high loading without agglomerates, safer handling and lower cost. In this study, Al_2O_3 platelets are selected to toughen X-sialon ceramic matrix. According to the Si–Al–O–N phase diagram[1] both matrix and reinforcement should be in chemical equilibrium.

A limited number of studies have been published concerning platelet reinforced ceramics. To our knowledge, toughening of X-sialon with Al_2O_3 platelets has never been reported in the literature. In a Si_3N_4–SiC platelet system, Hanninen reported that there was a dependence of fracture toughness on platelet content and direction.[10] A maximum value of 9·9 MPa · $m^{1/2}$ was obtained at 25 vol.% platelets in the plane parallel to the hot press axis and perpendicular to the platelet basal faces, whereas a toughness of 6·8 MPa · $m^{1/2}$ was obtained for the unreinforced Si_3N_4 matrix.[10] Claussen achieved a toughness of 8 MPa · $m^{1/2}$ from approximately 4·8 MPa · $m^{1/2}$ for the matrix, in RBSN with 20 vol.% SiC platelets.[9] In both cases toughness was enhanced, but strength dropped with the

addition of platelets into a Si_3N_4 matrix. Ketchion *et al.* attempted to improve the properties of a Si_3N_4 matrix by adding SiC whiskers and platelets.[11] Their results showed that there was no drastic increase in the fracture toughness, nevertheless the platelet containing composites had slightly better values than those containing whiskers. On the other hand, strength was reported to be maintained in the whisker reinforced samples, while there was a significant drop in those containing platelets. Literature on Al_2O_3–SiC platelet composites has also shown an increase in toughness and a decrease in strength with respect to the matrix. For instance, Fischer *et al.* have reported that the toughness of the Al_2O_3-SiC platelet composite increased from the base value for alumina of 4·35 to 5·68 MPa · $m^{1/2}$ for a 30 vol.% SiC platelet loaded sample, while the strength decreased from 346·1 to 198·4 MPa.[12] Becher reported fracture toughness values for SiC platelet reinforced Al_2O_3 close to those obtained with whiskers.[13] As to Al_2O_3 platelet reinforced ceramic composites, Claussen has reported, in a study on a TZP – Al_2O_3 platelet system, an increase in toughness in a low toughness TZP matrix with increasing platelet addition, but a decrease in toughness in a high toughness TZP matrix.[9] The strength dependence was reversed, i.e. the low toughness TZP matrix showed a decrease in strength with increasing platelet content.

Fig. 1. SEM micrograph of Al_2O_3 platelets.

The objective of this study is to investigate the possibility of X-sialon matrix composites reinforced with Al_2O_3-platelets in various volume fractions. Composites with Al_2O_3 platelet loading up to 53 vol.% were fabricated. Their microstructure and mechanical properties were evaluated and compared to the unreinforced X-sialon matrix material.

2 Experimental Procedure

The composition of the composites was based on $Si_{12}Al_{18}O_{39}N_8$ as a matrix material with a wide range of Al_2O_3 platelet addition. The starting materials used in this study were Si_3N_4, Al_2O_3, SiO_2 powders and Al_2O_3 platelet. Their characteristics are summarised in Table 1. The morphology of Al_2O_3 platelets is shown in Fig. 1.

The powder–platelet mixtures were processed via a wet mixing technique. The Al_2O_3 platelet and Si_3N_4, SiO_2 and Al_2O_3 powders in a desired composition were mixed with ethanol, using high density alumina cylinders as media, for about 72 h.

The resulting slurries were then heated on a sand bath for about 1–2 days in order to evaporate the alcohol. The mixture of platelet–powders obtained after drying was in the form of granulates.

A dense product was obtained by hot-pressing using graphite dies under moderate vacuum (<1 Pa). Hot-pressing schedule followed in this study is the same as the one reported in previous work,[6] e.g. hot-pressing for 1 h at a temperature of 1650°C and a pressure of 30 MPa.

The density of the hot-pressed samples was measured using the water displacement method, recording the mass in air and then immersed in water.

Phase analysis was mainly based on X-ray diffraction patterns obtained either from the hot-pressed surface as received or from a cross-sectioned surface of the specimen. Spectra were recorded using CuKα radiation from 5 to 80° 2θ

at the scan rate of 0·02°/s. Aside from XRD, electron probe micro-analysis (EPMA) was used to assist with phase identification.

The microstructure of the hot-pressed materials and crack propagation from indentation were observed with the scanning electron microscope (JEOL 733). SEM specimens were coated with gold to reduce specimen charging under the electron beam. Secondary and backscattered electron images were recorded at an accelerating voltage of 20 kV.

Vickers hardness was measured on polished samples, using a load of 10 kg. Elastic modulus was measured by the resonance frequency method with a Grindo-sonic apparatus using a test bar of approximately 25 mm long, 4 mm wide and 2·5 mm thick.

Comparative values for the fracture toughness of the different materials were obtained by the indentation method. Examination of crack morphology was made with electron micrographs on Vickers indentations for all specimens. The fracture toughness was calculated using the following equation derived by Anstis *et al.*[14]

$$K_{Ic} = 0{\cdot}016\ (E/Hv)^{1/2}\ P/c^{3/2} \qquad (1)$$

where E is the elastic modulus (Pa); H_v is the Vickers hardness (N/m^2); P is the Vickers load (N); and c is the radius of the crack length (m).

Samples for transmission electron microscope (TEM) were prepared by mechanical thinning, dimpling and then ion milling with an argon beam. Ion milled foils were coated with carbon for the examination in a JEOL 200CX microscope operating at 200 kV.

3 Results

The different grades with the amount of platelets added, are listed in Table 2.

Typical SEM micrographs of the platelet reinforced composites are shown in Figs 2 and 3. The examination of SEM micrographs revealed a dense, crack free hot-pressed body for all the composites. The pores appearing on polished surfaces could be due in part to platelet pullout during polishing. The reinforcing platelets are uniformly dispersed throughout the X-sialon matrix, without apparent cluster formation. However, the platelets are anisotropically oriented, with their basal planes preferentially aligned normal to the hot-pressing direction. This type of orientation of platelets suggests that a considerable rearrangement of platelets occurred during the liquid phase sintering of the powder mixture. The alignment of platelets was facilitated by the uni-axial load during hot pressing.

Table 2. Platelet content of the composite materials and phases identified by XRD

Sample	*Volume percent of platelets (vol. %)*	*Phase type*		
		X-sialon	*β'-sialon*	*α-Alumina*
XA0	0	X-sialon		
XA7	7·179	X-sialon		Al_2O_3
XA13	13·39	X-sialon		Al_2O_3
XA18	18·83	X-sialon		Al_2O_3
XA23	23·63	X-sialon		Al_2O_3
XA28	27·88	X-sialon		Al_2O_3
XA43	43·61	X-sialon	β'-sialon	Al_2O_3
XA53	53·71		β'-sialon	Al_2O_3

When the volume fraction of Al_2O_3 platelets increased to 53%, platelets appeared more interlocked and locally sintered together, the microstructure obtained was free of cracks and large pores as shown in Fig. 3.

The results of the X-ray diffraction (XRD) phase analysis of the hot pressed composites are summarised in Table 2. A single X-sialon phase pattern was found in sample XA0, corresponding to an Al_2O_3-platelet free X-sialon starting composition. Both X-sialon and Al_2O_3, which are the main and secondary phases, respectively, were observed in

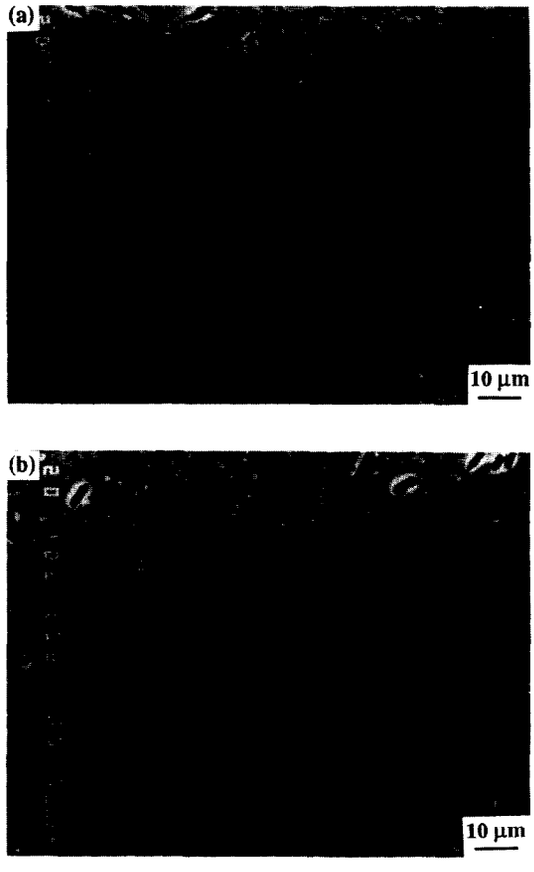

Fig. 2. SEM micrographs of the polished sections of Al_2O_3-platelet–X-sialon matrix composite containing 28 vol.% platelets. (a) Normal to the hot-pressing direction. (b) Parallel to the hot-pressing direction.

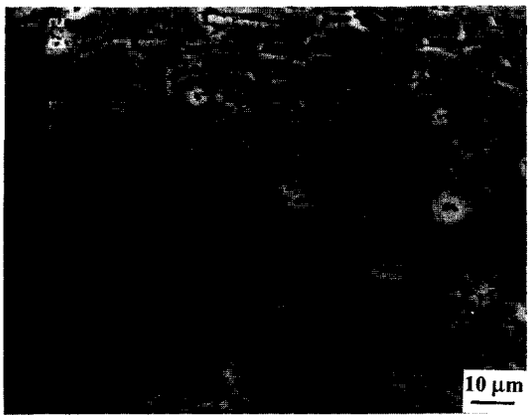

Fig. 3. SEM micrographs of the polished cross-section of sample XA53 containing 53 vol.% of the platelets.

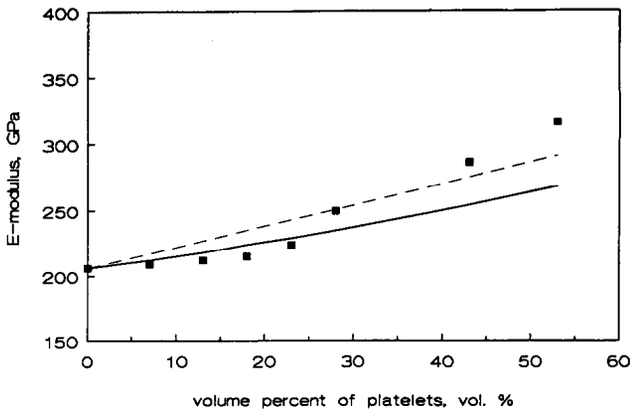

Fig. 4. E-modules vs Al_2O_3 platelet content. Calculated curves according to formula (2) and (3) are indicated.

all X-sialon composite samples with a platelet content up to 28 vol.%. If the platelet content is further increased, β'-sialon is formed in addition to X-sialon. In the composite grade XA53, containing 53 vol.% platelets, the matrix phase is β'-sialon and no X-sialon could be detected.

The measured and calculated densities of the hot-pressed sialon–Al_2O_3 platelet composites are listed in Table 3. The pure X-sialon was found to be pore-free by ceramography and was assumed to be 100% dense. The value of 3·04 g/cm^3 corresponds well with the value of 3·00 g/cm^3 reported by Zangvil *et al.*[15] The calculated density in Table 3 was estimated from nominal volume fraction of intended X-sialon matrix and reinforcing Al_2O_3 platelet, taking the constituent phase density of pure X-sialon phase as 3·04 g/cm^3 and that of Al_2O_3 as 3·93 g/cm^3.

The measured elastic modulus as a function of Al_2O_3 platelet content is shown in Fig. 4. An E-modulus of 367 GPa for a pure dense Al_2O_3 sample processed under the same experimental condition was obtained by Grindo-sonic measurement, thus slightly lower than 380 GPa given as a typical value for dense alumina.[16] The E-modulus obtained in all Al_2O_3 platelet reinforced sialon

composites has shown an increase with respect to the platelets content.

The hardness values determined for each sample from Vickers indentation are the average data of five tests. A 10 kg load was applied on a polished cross-section parallel to the hot-press axis, taking care to align the diagonals of the impression with one normal to the hot-pressing axis and the other parallel to the hot-pressing axis in order to identify if there is any anisotropy in hardness. Indentation measurements indicated essentially similar hardness levels between 1200 and 1300 kg/mm^2 for all composite samples, except for the one with 43 vol.% platelets which showed approximately an increase in hardness by 18%, compared to an unreinforced X-sialon matrix (Table 3).

Figure 5 shows three types of indentation crack patterns observed around Vickers hardness indents. The main feature of crack pattern I is chipping around indentation. The pure X-phase sample XA0 was almost exclusively matching pattern I and measurement of crack length was difficult. The brittle nature of X-sialon is evidently illustrated by crack pattern I. Crack pattern II gives clearly defined radial cracks and the crack length was easily measured. Most reinforced X-sialon composites, e.g. XA7, XA13, XA18, XA23, XA28, showed this crack pattern, indicating an improved toughness relative to X-sialon. Crack pattern III shows multiple cracking with cracks emanating from corners as well as from the sides of the indent and is accordingly unsuitable for crack size measurement. Samples XA43 and XA53 have this type of disrupted crack pattern.

Figure 6 shows the fracture toughness of the reinforced composites as a function of direction

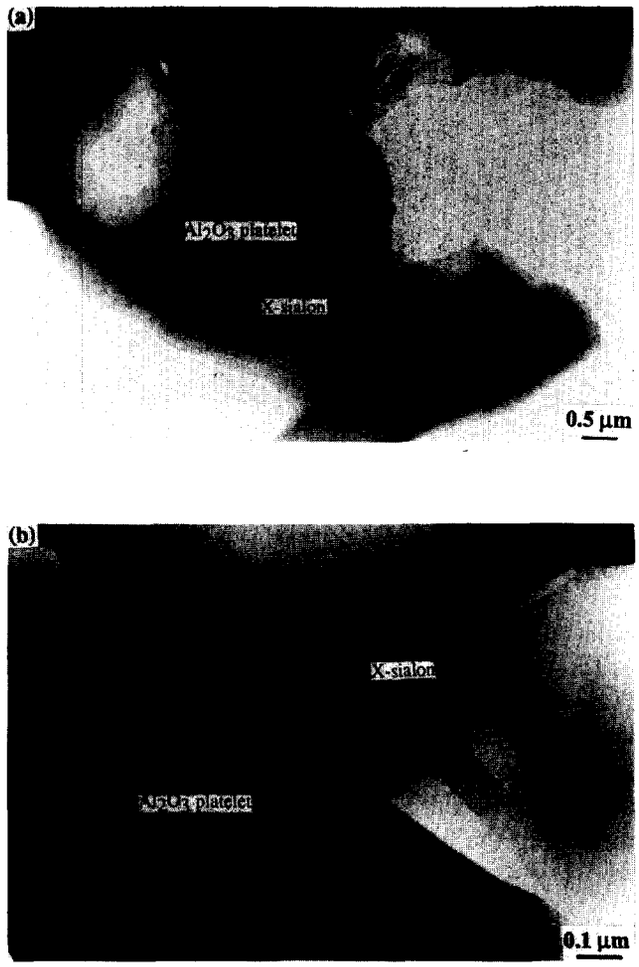

Fig. 7. TEM micrographs (a) and (b) of X-sialon matrix composite with 28 vol.% Al_2O_3 platelets showing a clean interface between X-sialon matrix and Al_2O_3 platelets.

and Al_2O_3 platelet content. There was a general increase in the fracture toughness with increasing platelet content both normal and parallel to the hot-pressing direction. However, a great deal of difference in K_{Ic} values obtained in both directions was noticeable.

For X-sialon based composites, the highest K_{Ic} value was 4·16 MPa · m$^{1/2}$ for a 28 vol.% Al_2O_3 platelet containing sample, whereas unreinforced X-sialon was only 1·77 MPa · m$^{1/2}$. When the addition of platelets exceeded 28 vol.% the value of fracture toughness could not be precisely evaluated with a Vickers indentation method due to disruption of a well defined crack propagation pattern. However, visual examination of these cracks shown in Fig. 5 reveals an apparent shortening of crack length both parallel and normal to the hot-pressing direction for higher platelet loaded sialon composites, indicating that the crack resistance is considerably enhanced. A toughness of about 7 MPa · m$^{1/2}$ could be estimated from the extent of the diagonal cracks parallel to the hot-pressing direction for a composite with nominally 53 vol.% platelets.

In TEM micrographs (Fig. 7) a clean interface between the smoothly contoured platelet and the

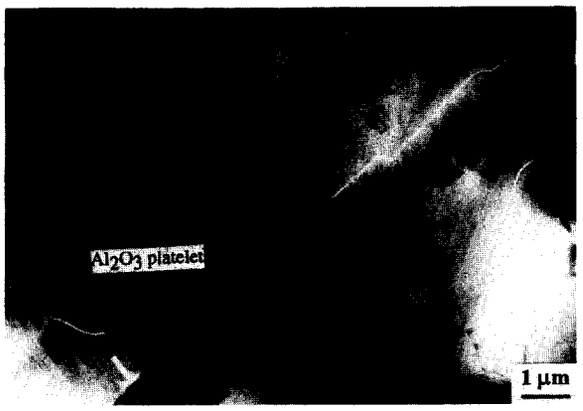

Fig. 8. TEM micrograph of X-sialon matrix composite with 28 vol.% Al_2O_3 platelets showing a crack following the X-sialon matrix–Al_2O_3 platelets interface. The arrow marks the point where the crack is deflected into the interface. Further along the interface, this crack is not always seen edge-on.

adjacent twinned X-sialon grain is observed down to the resolution at which the sample was examined. However, the existence of a very thin amorphous layer between Al_2O_3 platelets and the surrounding matrix is not excluded. As shown in Fig. 8, debonding occurs along the platelet–matrix interface indicating the weak nature of the interface.

4 Discussion

All specimens were easily fabricated to reach densities of more than 97% theoretical values by uniaxial hot-pressing. Difficulties usually experienced with processing of whisker reinforced ceramic composites such as whisker dispersion and low densities,[17] were essentially avoided. The Al_2O_3 platelets were easily dispersed into the matrix, forming highly densified X-sialon and β'-sialon composites at the hot-pressing temperature and pressure.

Analysis of densities of a series of hot-pressed products were consistent with phase analysis results as shown in Table 2. The theoretical density of Al_2O_3-platelet–X-sialon matrix composites was almost reached in samples containing up to 28 vol.% platelets, whereas the fact that measured densities of composites containing 43 and 53 vol.% platelets were higher than those predicted for the Al_2O_3-platelet–X-sialon composite can be explained by the shift from X-sialon to β'-sialon phase (density is about 3·1–3·2 g/cm^3) and the apparent growth of the platelets.

Indeed if one studies the microstructure of the composite with 53 vol.% platelets (Fig. 3) one notices that the volume fraction of platelets is much higher than the nominal value of 53 vol.%. Also the average size of the platelets appears to have increased somewhat. The composition of the

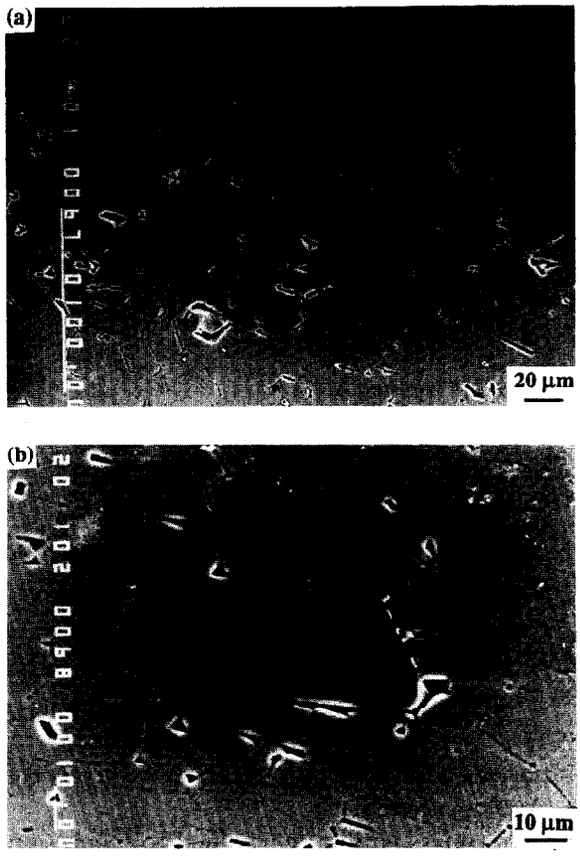

Fig. 9. SEM micrographs of the polished and etched cross section of sample with 53 vol.% Al_2O_3 platelets in Al_2O_3 matrix at two magnification; lower magnification (a) and higher magnification (b).

matrix phase of composite XA53 and pure X-sialon XA0 was compared using EPMA. An average value of 1·28 for Al–Si ratio was obtained in the pure X-sialon sample (XA0), but an average value of 0·72 was obtained in the matrix of a composite with 53 vol.% content of platelets (XA53), indicating a much lower Al content in the matrix composition. Hence it is considered that part of the Al_2O_3 powder which was intended to go to the X-sialon matrix is consumed by the growing platelets. As a consequence, the composition is shifted from the X-sialon composition towards the β'-sialon solubility region in the phase diagram.

To understand the platelet growth at high platelet volume fraction, a composite made with pure Al_2O_3 matrix containing 53 vol.% Al_2O_3 platelets was prepared under the same experimental condition as X-sialon composites. Figure 9 shows the microstructures of this sample which was polished and then etched using HF. Substantial platelet growth was clearly observed in the Al_2O_3 matrix composite with the size of the platelets increasing by a factor of about 6. The equation of the form $G^3-G_0^3 = Kt$,, where G_0 is the initial grain size, G the grain size after hot pressing, t the holding time, and K a temperature-dependent growth rate constant, has been used to

Table 4. Comparison of Al_2O_3 grain growth rate constants

estimate platelet growth rate and allow direct comparison with Al_2O_3 grain growth rate from the literature.[18–20] The average value of G is equal to $1{\cdot}5L$, where L was the average length of 10 growing platelets in SEM micrographs of the polished cross section. Table 4 shows the results of K obtained both in this study and in the literature. Two points can be noted: first, the platelet growth rate is higher in the direction perpendicular to hot-pressing than the one parallel to hot-pressing. Second, the platelet growth rate perpendicular to the hot-pressing direction is considerably higher than growth rate reported either by Bennison *et al.*[18] or Rödel *et al.*[19] for pure Al_2O_3 at 1600°C, and close to the growth rate reported by Kaysser *et al.*[20] for pure Al_2O_3 at 1800°C. This unusually fast grain growth compared with pure alumina is attributed to the high impurity content of the platelets which includes F, Si, Na and Ca. The observation that platelet growth was much slower in the composite with the same platelet content but with a nominal X-sialon composition, indicates that the presence of silicon nitride appears to slow down the growth of the platelets. It is interesting to note here that β'-sialon can suppress grain growth of alumina.[21] At the lower volume fractions of platelets (28 vol.% and below) no platelet growth was observed. The reasons for that are presumably the higher viscosity of the melt due to the lower impurity content and higher N_2 in the composite composition which may inhibit and suppress growth of Al_2O_3 platelets.

Additional evidence that impurities are responsible for platelet growth can be derived from the following experiments: no shift of matrix composition was found when X-sialon containing 43 and 53 vol.% Al_2O_3 particles (5·5 μm, low soda alumina, grade CTB 3, 99·8%, ALCOA) was processed under the same conditions as the X-sialon–platelet composites. X-sialon matrix was formed in both samples and no β'-sialon could be detected from XRD analysis. Thus the high impurity content of the platelets which includes F, Si, Na and Ca is considered as the main reason for the shift of the matrix composition from the X-sialon into the β'-sialon.

To estimate the E-modulus of Al_2O_3-platelet–X–sialon composites, the formula given by Davidge[22] was applied here, e.g.:

$$E_{\perp HP} = E_1V_1 + E_2V_2 \tag{2}$$

$$E_{\parallel HP} = E_1E_2/(E_2V_1 + E_1V_2) \tag{3}$$

where $E_{\perp HP}$ and $E_{\parallel HP}$ are the E-modulus of the composites in the direction perpendicular and parallel to hot press, corresponding to the direction parallel and normal to the platelet basal plane respectively; E_1 and E_2 represent the E-modulus of matrix phase and reinforcing phase, taking the value of 206 GPa from Grindo-sonic measurement for the pure dense X-sialon and 367 GPa for Al_2O_3; V_1 and V_2 are the nominal volume fractions of the two phases.

As Young's modulus for alumina (367 GPa) is much higher than the one for X-sialon (206 GPa), it is expected that E-modulus of Al_2O_3-platelet–X-sialon composites will increase with increasing platelet volume fraction according to formula (2) or (3). The calculated curves are also indicated in Fig. 4 for comparison with experimental data. Note that the elastic modulus was measured on bars with the long direction normal to the hot-press direction and that these bars were loaded in flexure for the measurement of resonance frequencies. One would expect that for perfect alignment of the platelets formula (2) is applicable rather than formula (3), which indeed is the case for the composite with 28 vol.% platelets, where the platelets are well aligned. At lower volume fractions the data appear to follow formula (3) better. In these composites the alignment with respect to the hot-pressing axis is not perfect. Also the presence of some residual porosity and spontaneous microcracking would need to be taken into account and could explain why the experimental values are slightly below the line for formula (3). In other particulate reinforced composites such as SiC-platelet–Si_3N_4 composite, SiC-platelet–Al_2O_3 composite and some other materials, a decrease of the E-modulus with respect to the matrix has been reported[12,23,24] and has also been attributed to the presence of pores and spontaneous microcracking. In view of the relative magnitude of the thermal expansion coefficient of the two phases ($8{\cdot}0 \times 10^{-6}$/°C for Al_2O_3[16] and $3{\cdot}7$–$4{\cdot}5 \times 10^{-6}$/°C for X-sialon[25]) spontaneous microcracking is also possible here depending on the size of the platelets. The higher values obtained for composites with 43 and 53 vol.% are due to the platelet growth and the change in matrix to β'-sialon which has a higher E-modulus of about 240 GPa.[26]

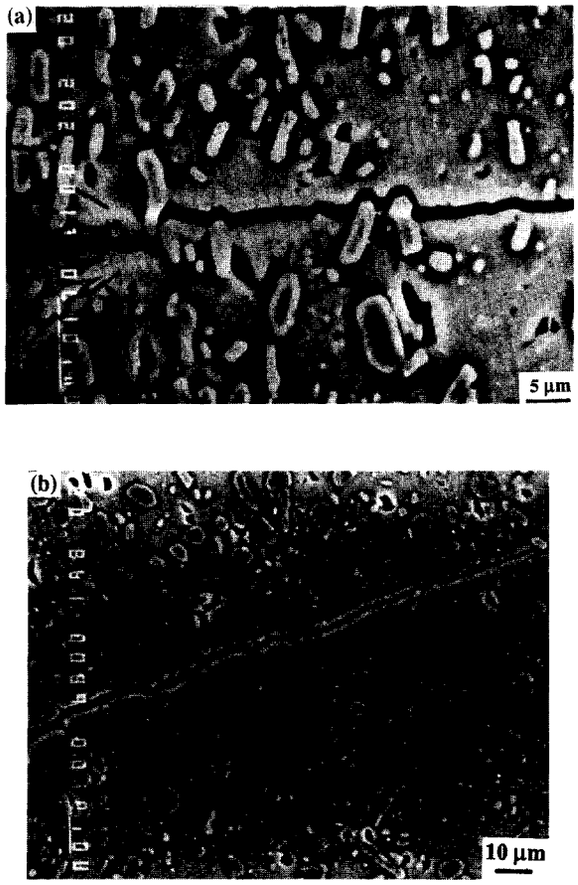

Fig. 10. SEM images of crack propagation in the composite sample with 28 vol.% Al_2O_3 platelets (XA28). (a) Plane parallel to hot-pressing direction. (b) Plane normal to hot-pressing direction.

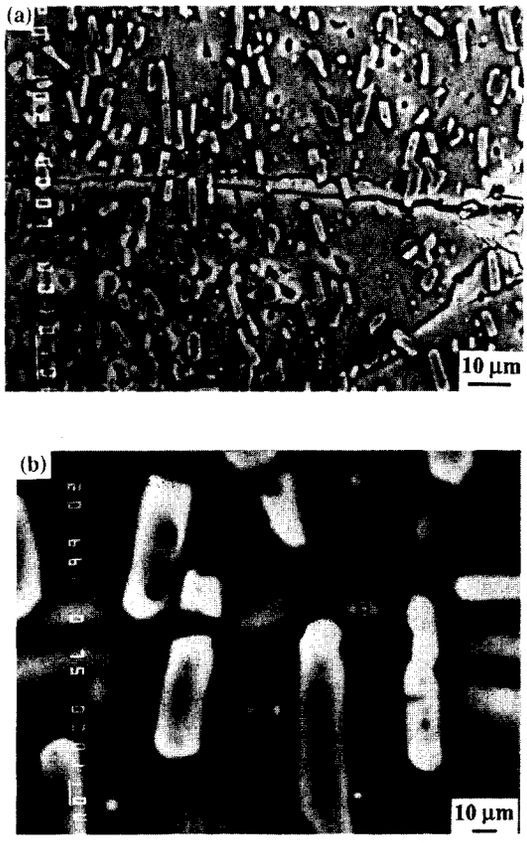

Fig. 11. SEM micrographs (a) and (b) showing crack bridging by Al_2O_3 platelets. B marks bridging sites.

The observed increase in fracture toughness for the Al_2O_3-platelet–sialon matrix composites can be attributed to a combination of crack deflection, crack debonding and crack bridging mechanisms. Figures 10 and 11 further illustrate the extent of crack–microstructure interactions. As shown in Fig. 10, cracks are frequently deflected along platelet–matrix interfaces. In Fig. 11, platelets are seen bridging across the crack wake plane, probably contributing to the greatest extent to the toughness increase over the monolithic X-sialon. A higher degree of toughening was measured when the crack plane propagated parallel to the hot-pressing direction perpendicular to Al_2O_3 platelet basal planes. The increase of fracture toughness increase normal to the hot-pressing axis was lower, because the orientation of platelets is not so favourable for crack deflection and crack bridging.

The composites displayed a much rougher fracture surface as compared to monolithic X-sialon. The fracture surface shown in Fig. 12 (a) illustrates platelet debonding and/or pullout, in contrast to the intragranular fracture exhibited by the unreinforced X-sialon as shown in Fig. 12 (b).

Thermal expansion mismatch and interfacial bonding strength between reinforcing phase and

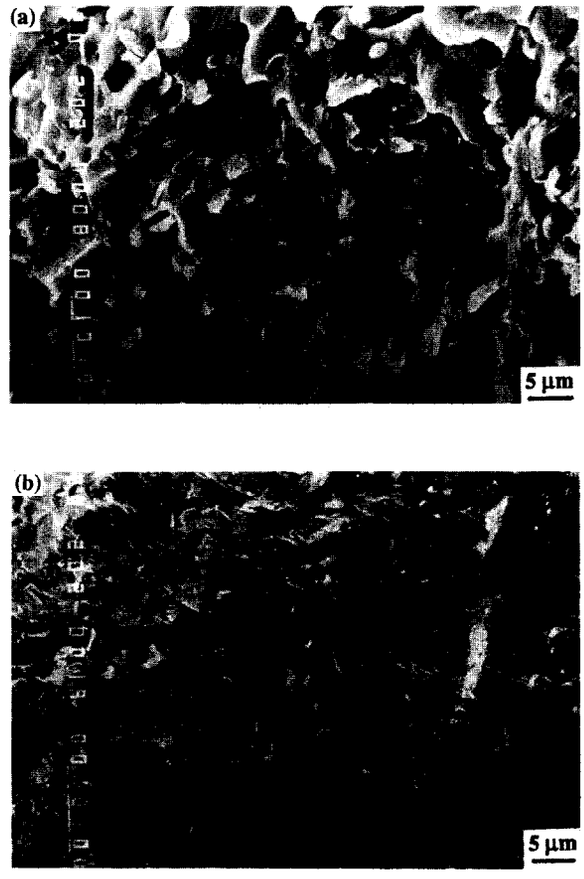

Fig. 12. SEM observation of fracture surface. (a) Al_2O_3 platelet reinforced sialon composite showing debonding. (b) Monolithic X-sialon showing intragranular fracture.

matrix are thought to be the crucial factors determining the toughening of ceramics. Since the thermal expansion coefficient of Al_2O_3 is much higher than that of X-sialon a high internal stress might be generated by this large thermal expansion mismatch in this system; circumferential compression and radial tension are created in the matrix and the platelet is in tension. In this situation cracks are deflected around the platelets. Interfacial bonding at the alumina–X-sialon interface appears to be sufficiently weak for the cracks to follow the contours of the platelets as can be seen in Fig. 8.

5 Conclusions

X-sialon phase can be toughened by Al_2O_3 platelet additions. Reinforcing Al_2O_3 platelets were not agglomerated and well distributed throughout the matrix. Due to hot-pressing, however the material shows alignment of Al_2O_3 platelets with the basal face normal to the hot-pressing direction.

The mechanical properties of hot-pressed sialon composites reinforced with Al_2O_3 platelets were investigated as a function of Al_2O_3 platelet content. The toughness has been shown to increase from 1·77 MPa · $m^{1/2}$ for pure X-sialon up to 4·16 MPa · $m^{1/2}$ for the composite containing 28 vol.% platelets. For higher platelet additions, toughness increases further but the composition of the matrix shifts to β'-sialon. A Young's modulus of 250 GPa and hardness of 1270 kg/mm^2 were achieved in the X-sialon containing 28 vol.% platelet.

SEM and TEM observations of the crack propagation behaviour, along with the fractography result revealed the evidence of debonding, crack bridging and crack deflection, all contributing to the toughening of X-sialon by Al_2O_3 platelets.

Forschungszentrum Karlsruhe, Institut für Materialforschung II, and Universität Karlsruhe, Institut für Zuverlässigkeit und Schadenskunde im Maschinenbau, D 76021 Karlsruhe, Germany

(Received 26 July 1993; revised version received 2 June 1994; accepted 28 July 1994)

Abstract

In the theoretical part of this paper a wide data base of stress intensity factors is presented for three types of tests appropriate for mixed-node investigations on ceramic materials. In the experimental part the test methods are applied to determine the failure behaviour of Al_2O_3 under mixed-mode loading. In particular, the influence of the starter crack, modelled by a narrow saw-cut and a pre-crack is illustrated.

1 Introduction

Regarding ceramic material interest is increasing in the failure behaviour under mixed-mode conditions.[1-4] The aim of the investigations is:

(1) to determine the fracture toughness data K_{Ic} K_{IIc}.
(2) to check the failure criteria by which failure under mixed-mode conditions can be predicted from the fracture toughness values K_{Ic}, K_{IIc}.

In this paper stress intensity factors will be presented for three types of tests appropriate for mixed-mode investigations. Their applications to Al_2O_3 will be demonstrated.

2 Bending Tests with Bars Containing Oblique Edge Notches

Bending specimens containing edge-cracks or narrow saw-cuts are often used in the determination of fracture toughness of ceramic materials. Whilst cracks orthogonal to the specimen surfaces are applied in K_{Ic}-determination, oblique edge-cracks are appropriate for mixed-mode fracture. Figure 1 illustrates the geometrical data of a specimen loaded in a four point bending test.

The stress intensity factors are given by

$$K_I = \sigma F_I \sqrt{\pi a}\,,\ K_{II} = \sigma F_{II} \sqrt{\pi a}\,;\ \sigma = \frac{3}{2}\frac{S_1 - S_2}{BW^2}P \quad (1)$$

where B is the specimen thickness and F_I, F_{II} are the geometric functions. A literature overview of these data is given in Ref. 5.

3 Three Point Bending with Eccentric Notch

Asymmetric bending arrangements have been studied by several authors using different methods.[6-10] In Ref. 10 the weight function method was applied. The stresses in the symmetrically supported three-point bending bar (Fig. 2) have been studied by Filon[11] who derived an analytical solution for the stress state. This solution, which take into consideration the stress magnification due to the line contacts of the rollers, is given by

$$\sigma_x = -\frac{3yPL}{2W^3} - \frac{4P}{L}\sum_{n=1}^{\infty} \frac{\sinh mW/2 - mW/2 \cosh mW/2}{mW + \sinh mW} \cos mx \cosh my$$

$$- \frac{4P}{L}\sum_{n=1}^{\infty} \frac{my \sinh mW/2}{mW + \sinh mW} \cos mx \sinh my$$

$$- \frac{4P}{L}\sum_{n=0}^{\infty} \frac{\cosh MW/2 - MW/2 \sinh MW/2}{\sinh MW - MW} \cos Mx \sinh My$$

$$- \frac{4P}{L}\sum_{n=0}^{\infty} \frac{My \cosh MW/2}{\sinh MW - MW} \cos Mx \cosh My \quad (2)$$

$$\tau = \frac{4P}{L}\sum_{n=1}^{\infty}\frac{mW/2\cosh mW/2}{mW+\sinh mW}\sin mx\sinh my$$

$$-\frac{4P}{L}\sum_{n=1}^{\infty}\frac{my\sinh mW/2}{mW+\sinh mW}\sin mx\cosh my$$

$$+\frac{4P}{L}\sum_{n=0}^{\infty}\frac{MW/2\sinh MW/2}{\sinh MW-MW}\sin Mx\cosh My$$

$$-\frac{4P}{L}\sum_{n=0}^{\infty}\frac{My\cosh MW/2}{\sinh MW-MW}\sin Mx\sinh My \quad (3)$$

with $m = 4n\pi/L$, and $M = 2(2n+1)\pi/L$

In order to determine the geometric function F_I and F_{II} defined by

$$K_I = \sigma_0 F_I\sqrt{\pi a}\,,\ K_{II} = \sigma_0 F_{II}\sqrt{\pi a}\,;\ \sigma_0 = \frac{3}{2}\frac{PL}{W^2B} \quad (4)$$

the mode-I and mode-II stress intensity factors were calculated by use of the mode-I and mode-II weight functions given in Ref. 10. The results are expressed by the normalized geometric functions $F'_I = F_I\,(1-a/W)^{3/2}$ and $F'_{II} = F_{II}\,(1-a/W)^{1/2}$, where

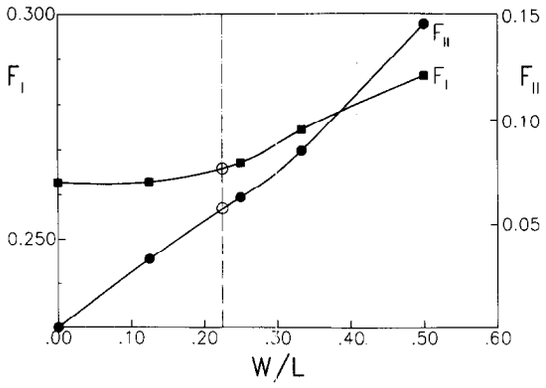

Fig. 3. Interpolations for the two geometric functions F_I and F_{II} (three-point bending with eccentric crack).

F_I, F_{II} are defined by eqn (4). Data for F'_I are entered in Table 3 and Table 4 contains values of F'_{II}.

Tables 3 and 4 allow geometric functions for a wide range of L/W ratios to be interpolated. Since additionally the values for $L/W \to \infty$ are known, namely

$$F_I\Big|_{L/W=\infty} = \left(1-2\frac{d}{L}\right) F_I\Big|_{L/W=\infty,\, d/L=0} \tag{5a}$$

$$F_{II}\Big|_{L/W=\infty} = 0 \tag{5b}$$

all L/W-values in the range $2 \le L/W < \infty$ can be evaluated. For the geometric function F_I at $d/L = 0$ the solution of Nisitani and Mori[12] may be applied.

$$F_I = 1{\cdot}122 - 1{\cdot}121\alpha + 3{\cdot}74\alpha^2 + 3{\cdot}873\alpha^3 - 19{\cdot}05\alpha^4 + 22{\cdot}55\alpha^5 \tag{5c}$$

For practical use interpolation of W/L instead of L/W is recommended as illustrated im Fig. 3 for the geometrical data (L = 20 mm, W = 4·5 mm) used in the experimental part.

4 The Asymmetric Four-point Bending Test

For the determination of the fracture toughness K_{IIc} with edge-notched (or pre-cracked) beams asymmetric bending arrangements (Fig. 4) are recommended which show a negligible mode-I contribution. Stress intensity factors have been determined for special geometrics by FE-calculations

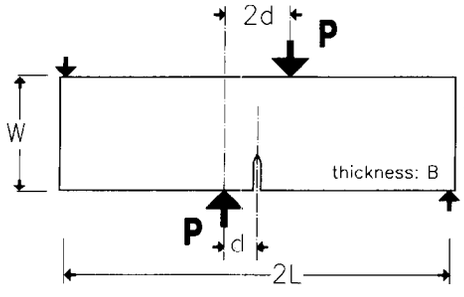

Fig. 4. Geometrical data of the asymmetrically loaded notched bending bar.

and energy considerations[9–14] and for a wide range of geometries by the weight function method.[15]

The stresses in this loading case were also computed by Filon[11] with formulae similar to eqns (2) and (3). The geometric functions F_I and F_{II} defined by

$$K_I = \frac{P}{WB}\left(1-\frac{d}{L}\right)\sqrt{\pi a}F_I,\; K_{II} = \frac{P}{WB}\left(1-\frac{d}{L}\right)\sqrt{\pi a}F_{II} \tag{6}$$

are given in Table 5 and 6.[15]

As can be seen from Table 6, the geometric function F_{II} is approximately independent of the value of d/W in the range $0{\cdot}375 \le d/W \le 0{\cdot}625$. An analytical approximation can be given by

$$F_{II} = 3{\cdot}9204\alpha - 5{\cdot}1295\alpha^2 + 14{\cdot}4566\alpha^3 - 26{\cdot}2916\alpha^4 + 17{\cdot}073\alpha^5,\; \alpha = a/W \tag{7}$$

5 Experiments

5.1 Failure diagram for edge-notched specimens

Mixed-mode fracture tests were performed with bending bars having the dimensions B = 3·5 mm, W = 4·5 mm and length >43 mm, made of two Al_2O_3–ceramics (material I: Al_2O_3+ 3% SiO_2, V37; material II: 99.1% Al_2O_3, B40; both materials from Feldmühle AG, Plochingen). The specimens were edge-notched with saw-cuts of 50 μm width. Several specimens were provided with oblique notches, angles ω = 0°, 22·5°, 30° and 40° and relative notch lengths in the range of $0{\cdot}1 < a/W < 0{\cdot}4$. In Fig. 5 the mode-I stress intensity factors at failure are plotted versus the mode-II stress intensity factors for material

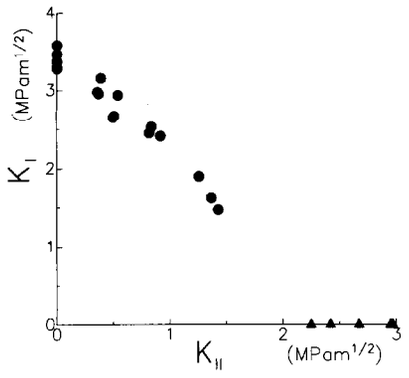

Fig. 5. K_I vs K_{II} at failure for Al_2O_3 (material I); circles: eccentric three-point bending test, triangles: asymmetric four-point bending test.

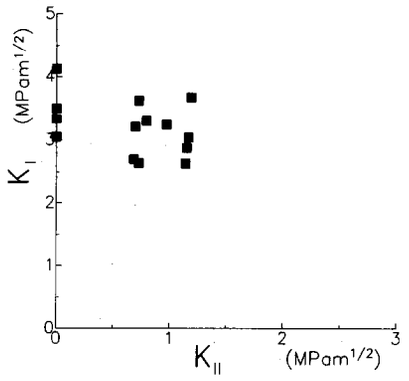

Fig. 6. K_I vs K_{II} at failure for Al_2O_3 (material II) measured with oblique edge notched specimens.

I. The circles represent fracture tests carried out in three-point bending arrangements with eccentric notch (Fig. 2), $a/W = 0{\cdot}35$–$0{\cdot}5$, $L = 20$ mm; the triangles were determined in the asymmetric four-point bending test with $a/W \simeq 0{\cdot}45$–$0{\cdot}5$, $L = 20$ mm, $d = 5$ mm. Figure 6 shows results obtained for material II. The data are obtained in tests with oblique notches. The differences in the K_I–K_{II} dependencies shown in Figs 5 and 6 seem to be caused more by the specific material properties than by the different types of measurement.

5.2 Mode-I and mode-II fracture toughness

Fracture toughness measurements were carried out in three and four-point bending tests with different starter cracks. Small saw-cuts were introduced as well as sharp pre-cracks produced with the bridging method. Some of the precracked specimens were annealed in order to remove residual stresses caused by the bridging procedure, and some pre-cracked specimens were renotched so that $\simeq$ 80–90% of the original crack was removed. The results are shown in Tables 7 and 8.

The numbers in the column heads of the tables denote the test procedure.

2 — pre-cracked ($a/W \simeq 0{\cdot}45$), four-point bending (inner roller span 20 mm, outer roller span 40 mm);

3 — pre-cracked and annealed ($a/W \simeq 0{\cdot}45$), four-point bending (inner roller span 20 mm, outer roller span 40 mm);

4 — saw-cut ($a/W \simeq 0{\cdot}33$), three-point bending (roller span 20 mm);

5 — pre-cracked ($a/W \simeq 0{\cdot}4$–$0{\cdot}35$), three-point bending (roller span 20 mm),

6 — saw-cut ($a/W = 0{\cdot}47$), asymmetric four-point bending;

7 — pre-cracked ($a/W \simeq 0{\cdot}45$–$0{\cdot}50$), asymmetric four-point bending;

8 — pre-cracked and re-notched ($a/W \simeq 0{\cdot}47$), asymmetric four-point bending.

5.3 Influence of the starter crack on the failure diagram

Mixed-mode strength tests were carried out in eccentric three-point bending with the different crack types. Figure 7 shows the results for Al_2O_3 (material I) for specimens with saw-cuts, pre-cracks and re-notched cracks. In Fig. 7 also mode-I fracture toughness data are introduced (small solid circles) which were obtained with pre-cracked specimens annealed for 5 h at 900°C in the vacuum (third column of Table 7).

6 Discussion and Conclusions

6.1 Fracture toughness of Al_2O_3

- The mode-I fracture toughness K_{Ic} of Al_2O_3 has been found to be

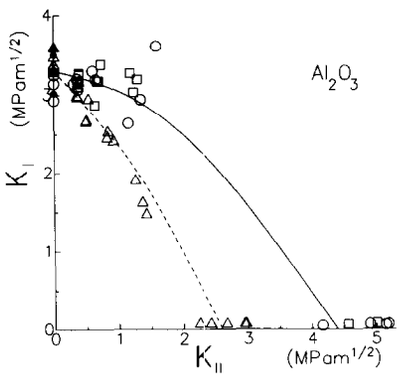

Fig. 7. K_I vs K_{II} at failure for Al_2O_3 measured in eccentric three-point bending tests and asymmetric four-point bending tests. Triangles: specimens with saw-cut, circles: pre-cracked with bridging method, squares: pre-cracked and re-notched specimens, solid circles: pre-cracked and annealed.

3·40 ± 0·13 MPa $\sqrt{m}$ for the edge-notched specimens in four-point bending;
3·32 ± 0·08 MPa $\sqrt{m}$ for the edge-notched specimens in three-point bending;
3·40 ± 0·24 MPa $\sqrt{m}$ for the specimens with an edge-precrack which has been annealed;
3·16 ± 0·14 MPa $\sqrt{m}$ for the specimens with an edge-precrack (without annealing) in three-point bending; and
2·88 ± 0·15 MPa $\sqrt{m}$ for the same specimens in four-point bending.

It is obvious that within the scatter ranges the edge-notched specimens show the same results as the pre-cracked and subsequently annealed specimens.

The precracked specimens which were not annealed show a reduced fracture toughness. One can conclude that the fracture toughness data obtained with pre-cracked specimens are reduced due to internal stresses caused by a misfit between the two crack surfaces. This effect overcompensates an expected *R*-curve effect which would yield an increase in K_{Ic} for the pre-cracked specimens.

- Under mode-II loading the pre-cracked specimens showed — in contrast to the mode-I results — significantly higher fracture toughness than the notched specimens:
  2·65 ± 0·3 MPa $\sqrt{m}$ for notched specimens;
  4·85 ± 0·3 MPa $\sqrt{m}$ for pre-cracked specimens;
  ≃4·8 MPa $\sqrt{m}$ for pre-cracked and then partially re-notched specimens.

  These results may be explained by crack surface interactions. Under mode-II loading the rough surface of the pre-crack can carry a part of the externally applied load and, therefore, the actual crack tip stress intensity factor is reduced, i.e. a crack-shielding effect occurs. Consequently, the applied load has to be increased to reach the critical crack tip stress intensity factor that is necessary for the onset of stable crack propagation followed by catastrophic failure.

From the fact that in the case of partially re-notched specimens (≃80–90% of the pre-crack were re-notched) the K_{IIc} is nearly unaffected by the re-notch procedure we conclude that the main part of mode-II crack shielding effect occurs directly in the neighbourhood of the crack tip.

- The ratio of the mode-II and mode-I fracture toughness results for the notched specimens is $K_{IIc}/K_{Ic} = 0·78$.

6.2 Conclusion

Several types of starter cracks have been used in mixed-mode fracture tests, namely

- edge-notched specimens (saw-cut of 50 μm width);
- pre-cracked specimens (bridge method);
- pre-cracked and subsequently annealed specimens;
- pre-cracked and subsequently re-notched specimens.

If a rising crack-growth resistance curve exists, the tests with specimens with a saw-cut lead to K_{Ic}-values at the onset of crack extension provided that the notch width is small enough. The results for the Al_2O_3 investigated were:

$$K_{Ic} = 3·4 \text{ MPa } \sqrt{m}\,, \quad K_{IIc} = 2·65 \text{ MPa } \sqrt{m}\,, \quad K_{IIc}/K_{Ic} = 0·78$$

As a general result of the measurements presented it is recommended to prefer edge-notched specimens for mode-I and mode-II fracture toughness measurements.

(Received 13 May 1994; accepted 20 June 1994)

Abstract

Initial oxidation behaviour of an Si_2N_2O–ZrO_2 composite material has been investigated by spectroscopic ellipsometry (SE), X-ray diffraction (XRD), and scanning electron microscopy (SEM). The material was exposed to air in the temperature range of 1000–1450°C and the oxide layer thickness was determined by SE using the Bruggeman effective medium approximation for the modelling of the oxide layer. It was shown that the oxide film on a porous Si_2N_2O–ZrO_2 material can be characterized by SE. The results provide important information about film growth in the initial stage of oxidation of this composite. The optical constants for the composite and ZrO_2 were determined.

1 Introduction

Silicon oxynitride ceramics have good oxidation, corrosion, and thermal shock resistance which makes them interesting for high temperature applications.[1] A low-cost Si_2N_2O–ZrO_2 composite, fabricated by the nitrided pressureless sintering technique (NPS) at the Swedish Ceramic Institute with $ZrSiO_4$ and Si as starting materials, according to eqn (1) was investigated.[2,3]

$$ZrSiO_4 + 3\,Si + 2\,N_2 \rightarrow 2\,Si_2N_2O + t\text{-} + m\text{-}ZrO_2 \quad (1)$$

(t tetragonal, m monoclinic)

Initial oxidation kinetics of nitride materials is expected to be important for the understanding of the entire oxidation mechanism of the material. The measurement of the oxide growth, however, is usually difficult because the oxidized layer is too thin to be detected by gravimetric methods.

To follow the initial stage of oxidation, spectroscopic ellipsometry (SE) has been anticipated to be useful for studying the growth of the oxide layer on this ceramic material. This non-contact and non-destructive optical method, has been increasingly used to study thin film materials. Several investigations on ceramic film deposited on single crystal Si wafers have been done.[4–8] However, to our knowledge, no SE measurement aiming at evaluation of the oxidation process on ceramic composite systems, such as the Si_2N_2O–ZrO_2 material, has been reported.

The advantage in use of spectroscopic ellipsometry in comparison to single wavelength ellipsometry is that by achieving a good fit of the model the probability of receiving 'true' values increases enormously.

The objective of this work has been to demonstrate that SE is a potential method to evaluate the initial oxidation kinetics, not only for monolithic ceramic materials, but also for porous ceramic composites. The kinetic data is useful for the evaluation of internal and external oxidation of the porous composite.

2 Experimental

2.1 Sample preparation

The bulk density of the as-received material was determined to be 2·55 g/cm^3 or 72·4% of the theoretical density and the open porosity of the material is 24·5%.

For the ellipsometry measurement the Si_2N_2O–ZrO_2 composite (3 × 5 × 1 mm) and ZrO_2-ceramic specimen (10 × 10 × 3 mm) were cleaned with a standardized procedure. The samples were

ground and carefully polished with diamond spray down to 0·25 μm fineness and cleaned in water, trichlorethene and acetone in an ultrasonic bath. Afterwards, the samples were cleaned in a solution of H_2O:H_2O_2:NH_3 (25%) = 5:1:1 and a solution of H_2O:H_2O_2:HCl (conc) = 6:1:1, respectively, at 80°C for 5 min and finally washed with distilled water. The samples were dried in dry nitrogen and then oxidized in an alumina tube furnace in static air at 1000, 1250 and 1450°C, respectively, and taken out periodically for the SE measurements.

2.2 Microstructural analysis

The chemical composition of the as-received and in the thermobalance oxidized material was characterized by using X-ray diffractometry (XRD, SIEMENS D5000). The micro-morphology was investigated by scanning electron microscopy (SEM, JEOL JSM-5300).

2.3 Ellipsometry

Only a brief description on SE is given here and a detailed background to ellipsometry can be found elsewhere.[9,10] The technique is based on the polarization changes that occur upon oblique reflection of polarized light. The quantity an ellipsometer measures is the so called complex reflectance ratio $\rho = \tan\psi e^{i\Delta} = R_p/R_s$, where ψ and Δ are the ellipsometric angles, and R_p and R_s are the complex reflection coefficients for light polarized parallel and perpendicular to the plane of incidence, respectively. ψ and Δ can readily be determined with a precision better than 0·01° and once ρ has been measured it can be analyzed with respect to the parameters examined. The most common parameters which are quantified by ellipsometry are film thickness and optical constants of thin films or film-free bulk materials.

In this study we have used a rotating analyser spectroscopic ellipsometer (J. A. Woollam Co.) for measuring ψ and Δ in the wavelength range 3000–8000 Å at an angle of incidence of 68°. Figure 1 shows the principle arrangement of the instrument.

Table 1. Surface phase composition at different oxidation temperatures for an Si_2N_2O–ZrO_2 material

Temperature (°C)	*Phase composition*				
	Si_2N_2O	m-ZrO_2	t-ZrO_2	$ZrSiO_4$	SiO_2
as received	s	s	m	-	-
1000	s	s	m	-	w
1300	w	w	w	m	w
1450	w	w	m	m	w
1600	w	w	w	vs	w

w-weak, m-medium, s-strong, vs-very strong

3 Results and Discussion

3.1 Elemental composition

After exposing selected samples in the thermobalance, the phase compositions were investigated by XRD. The penetration depth was calculated to be 56 μm at $2\Theta = 65°$ (which is much higher than the medium grain size), with the assumption that the material is completely converted to $ZrSiO_4$ and SiO_2. Table 1 shows the results for the exposure for 7 h at the respective temperatures.

The results obtained from XRD investigations show that the chemical reaction of the Si_2N_2O–ZrO_2 system during oxidation can be divided into two temperature areas.

(1) ≈ 1000°C

$$Si_2N_2O\text{–}ZrO_2 + 3/2\,O_2 \rightarrow 2\,SiO_2 + ZrO_2 + N_2 \quad (2)$$

At 1000°C the temperature is too low for ZrO_2 to take part in the reaction. This means that only Si_2N_2O contributes to the reaction and cristobalite (SiO_2) is formed. From other work done on this material.[11,12] it is known that at this temperature external and internal oxidation of the material takes place due to the open porosity.

(2) ≥ 1250°C

$$Si_2N_2O\text{–}ZrO_2 + 5/2\,O_2 \rightarrow ZrSiO_4 + SiO_2 + ZrO_2 + N_2 \quad (3)$$

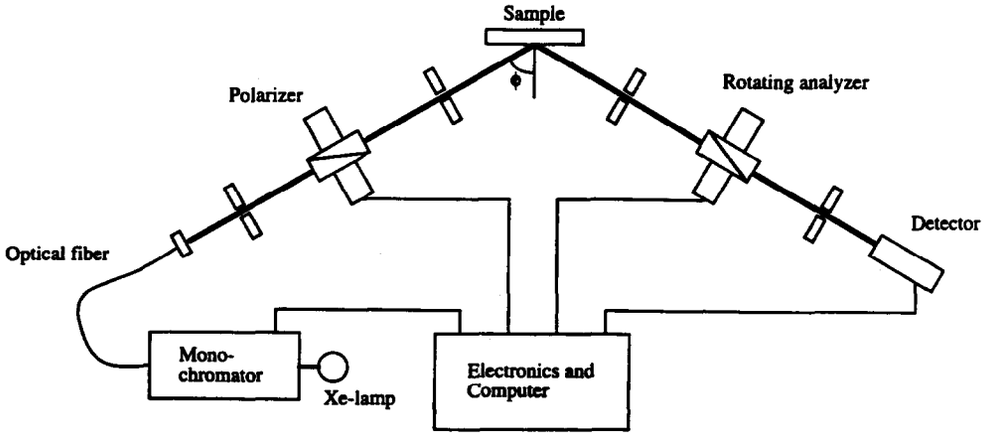

Fig. 1. Spectroscopic ellipsometer of the rotating analyzer type.

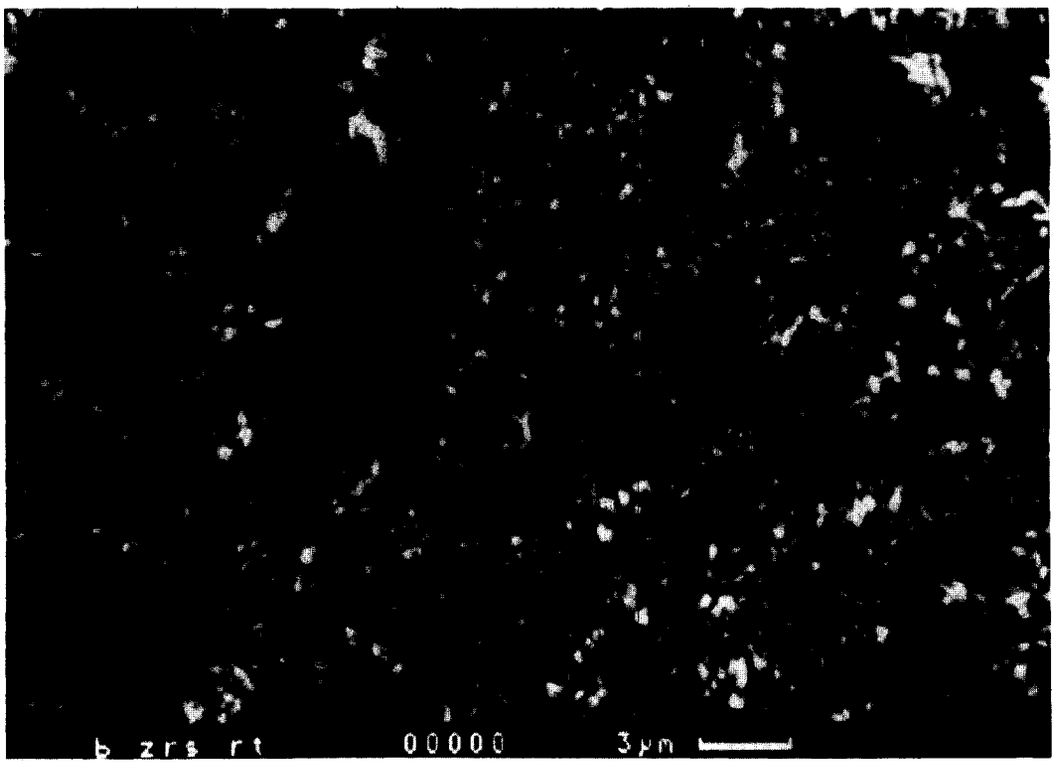

Fig. 2. Backscattered SEM image of a polished surface of an as-received Si_2N_2O–ZrO_2 material (light spots ZrO_2, dark areas Si_2N_2O and pores).

At temperatures ≥ 1250°C zircon ($ZrSiO_4$) and cristobalite are formed as the main reaction products. After initial weight gain the weight stabilizes which is thought to be caused by the formation of a dense oxide film containing $ZrSiO_4$, preventing further oxidation. The higher the temperature the less weight gain occurred.

3.2 Microstructural analysis

Figure 2 shows an SEM image of the surface of the as-received material. The porosity of the material can be clearly seen. Figure 3 shows schematic model of the as-received material, also in cross section.

3.3 Ellipsometric measurement and optical modelling

From the SEM image shown in Fig. 2 it can be seen that the surface is quite porous compared to monolithic ceramics like Si or Si_3N_4.[13] This is caused by the presence of open porosity. Because the grain size (0·5–2 µm) is larger than the selected range of wavelength of incident light, it was assumed that the surface is locally flat and the radius of curvature in a general point of the rough surface is much greater than the selected range of wavelength. The effects of surface roughness can then be neglected in the calculations.

Figure 4 shows the models of samples exposed to 1000°C, and ≤ 1250°C, respectively, which are assumed in the calculations.

At 1000°C only the thickness of the formed SiO_2 is measured. Because ZrO_2 does not react at this temperature, the index of refraction does not change and does not contribute to a change of polarization.

At all temperatures, ZrO_2 could be detected in the surface layer. Because no data for the index of refraction is available for $ZrSiO_4$ in the wavelength range needed for the modelling, the top

layer was modelled on the assumption that it was a physical mixture consisting of two distinct phases, SiO_2 and ZrO_2, and modelled with the Bruggeman effective medium approximation (EMA).[14] Accordingly, the effective (macroscopic) refractive index n of $ZrSiO_4$ can be obtained from the following equations:

$$f_{SiO_2}\frac{n_{SiO_2}^2 - n^2}{n_{SiO_2}^2 + 2n} + f_{ZrO_2}\frac{n_{ZrO_2}^2 - n^2}{n_{ZrO_2}^2 + 2n} \quad (4)$$

and

$$f_{SiO_2} + f_{ZrO_2} = 1 \quad (5)$$

where f_{SiO_2} and f_{ZrO_2} are the relative volume fractions of SiO_2 and ZrO_2 in the material. The refractive index for SiO_2 is taken from the literature,[15] while the refractive index for ZrO_2 was determined experimentally.

Samples of pure ZrO_2 and unexposed Si_2N_2O–ZrO_2 were measured with SE and their

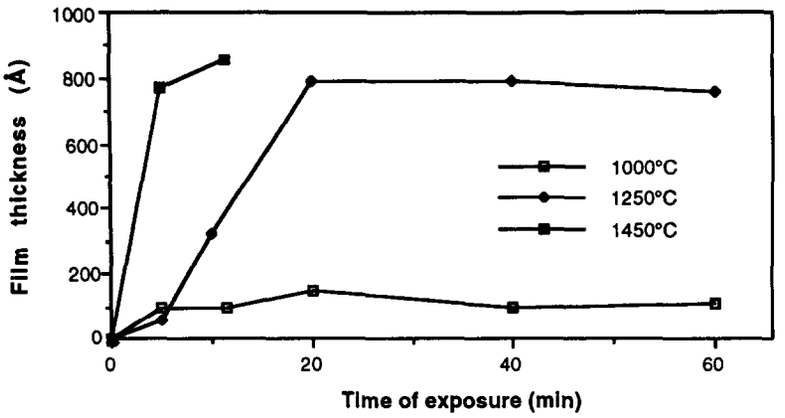

Fig. 7. Oxide film thickness as function of temperature and time of exposure for the Si_2N_2O–ZrO_2 material.

refractive indices were determined by a numeric inversion of $\rho = \tan \psi e^{i\Delta}$ in the wavelength range from 3000 to 8000 Å with results as shown in Fig. 5. Oxide thickness and film composition of Si_2N_2O–ZrO_2 samples were determined with least square regression procedures in a three-phase (Ambient-layer-substrate) model.

After oxidation of the Si_2N_2O–ZrO_2 samples, the thicknesses of the formed $ZrSiO_4/SiO_2$ surface layer were determined ellipsometrically. Figure 6 shows an example of the data fitting using the three-phase model described above. The ψ values of the model fit the experimental data closely and the Δ values show a reasonably good fit, considering the small scale given in the figure. Therefore the error of the determined thickness would be marginal, as described elsewhere.[16]

Figure 7 shows the results obtained for the external oxide scale thicknesses at different temperatures. After exposing the samples for more than 11 min at 1450°C, it was impossible to align the sample due to severe scattering of the incoming light and no results could be obtained.

The measured values of the external oxide film thickness after short exposure time are consistent with the weight gain measurements and SEM investigation.[11] At 1000°C a continuous oxidation of the pore walls occurs at a relatively low constant rate — thus the initial film thickness at the outer specimen surface does not change significantly within the time frame of 1 h. At higher temperatures (≥ 1250°C) the starting oxidation rate is much higher and thus, the thickness of the initial oxide film reaches rapidly a higher level at the outer surface. After that oxygen will diffuse into the interior and oxidize the internal pore surface. SEM observations indicate that a thicker oxide scale has been formed in the surface region of the sample.

Investigations are under way to find a quantitative correlation between the oxide film thickness values obtained through VASE and those directly observed with other methods.

4 Conclusions

(1) The refractive indices of ZrO_2 and Si_2N_2O–ZrO_2 have been determined.
(2) The film thickness of $ZrSiO_4$ formed on oxidized samples has been measured.
(3) A determination of the film thickness is possible on this rather porous ceramic material.

Abstract

The oxidation behaviour of a low-cost, porous Si_2N_2O–ZrO_2 composite material produced without the use of sintering aid was investigated in air between 1000 and 1520°C. The extent of internal oxidation was found to be dependant on the oxidation temperature. At temperatures ≤ 1300°C considerable internal oxidation of the material occurs with concommitant large weight gains. The material exhibits excellent oxidation resistance at high temperatures (>1300°C) and the higher the oxidation temperature the lower the weight gain. A very thin layer of oxide primarily consisting of $ZrSiO_4$ forms on the internal pore walls which, together with the surface oxide layer, protects the material from further oxidation. At 1300°C the stresses induced in the matrix by the volume expansion of the oxidation products cause severe cracking of the material on cooling from the annealing temperature. Following oxidation exposures at temperatures ≥1300°C the unstabilised ZrO_2 phase in the matrix is inhibited from undergoing the t–m *transformation. This is most probably due to the dissolution of nitrogen in ZrO_2 resulting in the stabilised, non-transformable* t'-ZrO_2 *phase.*

1 Introduction

The improvement in toughness hoped for by the inclusion of partially stabilised zirconia into a silicon nitride-based matrix has not been realised. This is mainly due to the additional stabilisation of zirconia by nitrogen which prevents the martensitic transformation from *t–m* ZrO_2 under mechanical stress.[1] In addition, the formation of oxidation prone zirconia oxynitride phases during material fabrication inhibits the use of these materials at intermediate temperatures (500–800°C) and the results from high-temperature oxidation studies are not promising.[2,3]

In this work a Si_2N_2O–ZrO_2 composite is examined which has been produced for high-temperature application. The material has been fabricated by the NPS technique without the use of sintering aid/stabiliser. Nitridation and subsequent reaction sintering via the reaction: $Si_3N_4 + ZrSiO_4 \rightarrow 2\ Si_2N_2O + ZrO_2$ results in a porous microstructure consisting of Si_2N_2O and unstabilised ZrO_2 and which avoids the formation of undesirable zirconium oxynitride phases. The high-temperature behaviour of porous silicon-based materials differs considerably from that of dense materials because of the inherent open porosity. Although the oxidation rate will be correlated to the net area available for reaction it has been found that the rate of oxidation appears to decrease at higher temperatures. This paper examines the oxidation behaviour of the porous composite in the temperature range 1000–1520°C.

2 Experimental

2.1 Material

A Si_2N_2O–ZrO_2 composite, fabricated without sintering aid by the NPS technique from Si and $ZrSiO_4$ was used in this work. The material was produced at the Swedish Ceramic Institute.[4,5] The as-received density was determined to be 2·55 g/cm^3 or 72·4% of TD with 24·5% open porosity. The stoichiometric composition of the sintered material was 64 wt% Si_2N_2O and 36 wt% ZrO_2.

2.2 Oxidation exposures

Specimens for oxidation were cut with a diamond saw into samples of dimensions 3 × 4 × 10 mm, polished with various grades of SiC paper and then ultrasonically cleaned in acetone and alcohol. Sample holders of Al_2O_3 were used. The samples were oxidized in an alumina tube furnace in the range 1000–1520°C in flowing dry air with 6 l/h

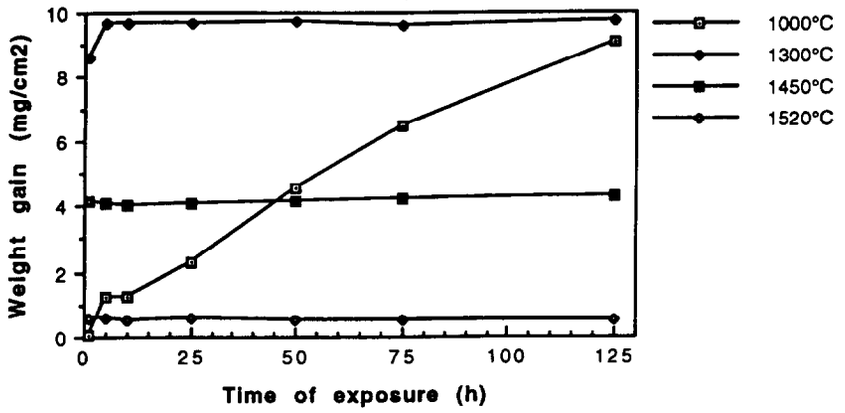

Fig. 1. Weight gain of Si_2N_2O–ZrO_2 material exposed at various oxidation temperatures.

flow rate. The samples were intermittently taken out from the furnace and weighed on an analytical balance with ±5 μg sensitivity. In so doing all the samples were rapidly cooled/reheated to the oxidation temperature. This procedure thus also reflected the effect of cycling on the stability of the oxide scale. Other samples were subjected to the same procedure for up to 250 h but when removed from the furnace were used for SEM examination and pore characteristic determinations. Additional oxidation experiments were carried out at 1450°C to examine the effect of scale removal on the weight gain. The samples were oxidized for 1 h, removed from the furnace and weighed. The oxide scale was then taken away by grinding. The samples were then exposed for another hour at the same temperature.

2.3 Microstructural analysis

Phase analysis of the as-sintered and oxidized materials was carried out by X-ray diffractometry (XRD) using a SIEMENS X-ray diffractometer (D5000). Slices of the material of dimensions *ca* 1 cm^2 were exposed in a thermobalance for 7 h at temperatures between 1000 and 1600°C. The X-ray penetration depth was calculated to be 56 μm at $2\Theta = 65°$. The microstructure of as-sintered material was characterised by analytical transmission electron microscopy (TEM/STEM/EDX) in a Jeol 2000 FX TEM/STEM instrument. The microstructure of the oxidised materials was investigated by analytical scanning electron microscopy in surface and cross-section using a CAM Scan S-4 80DV scanning electron microscope (SEM) equipped with a Link eXL EDX analysis system.

2.4 Determination of pore characteristics

All investigations have been carried out on whole unpowdered samples.

2.4.1 Determination of the surface area by nitrogen adsorption

The BET method was used to determine the internal surface area of the material. Specimens of unexposed and oxidized material were degased at 250°C in a Desorb 2300A for 100 min. The measurements were made in a Flowsorb II 2300 (Micromeritics) using N_2 as adsorbant. Around a 10% mean deviation can be expected at low surface areas (1–2 mg^2/g).

2.4.2 Determination of the density by water penetration

The bulk density was determined using Archimedes' principle. The dry weight was first measured,

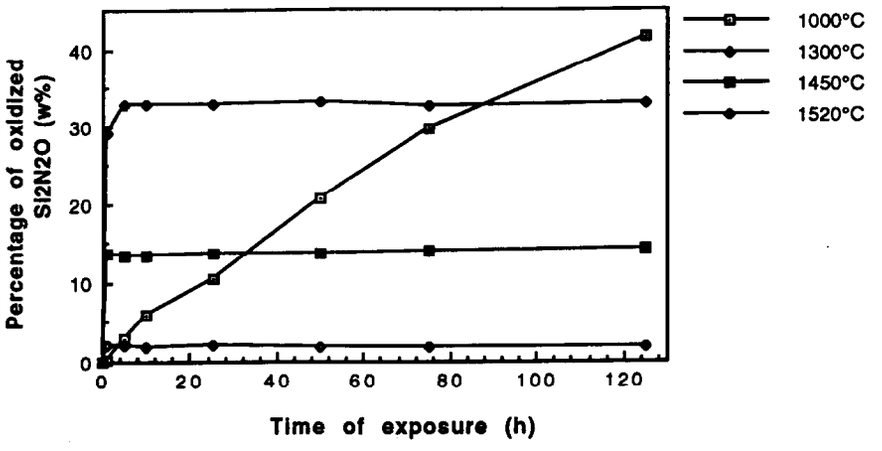

Fig. 2. The percentage of oxidized Si_2N_2O in Si_2N_2O–ZrO_2 material exposed at various oxidation temperatures.

the samples were put under vacuum (<25 mm Hg) for 30 min, then covered with distilled water (under vacuum) and left to soak for 12 h. The wet weight in air and in water was measured and the bulk density was calculated.

2.4.3 Determination of the porosity by mercury porosimetry

The open porosity and volume distribution of the porosity have been measured with the aid of mercury porosimetry using a Micromeritics Poresizer 9305 instrument. The registration of the pressure and the mercury volume intruded in the sample are related to the volume distribution of the pores.

3 Results

3.1 Weight gain versus time curves

The measured oxidation isotherms for samples cyclically oxidized at 1000, 1300, 1450 and 1520°C are shown in Fig. 1. A linear weight increase is observed for material oxidised at 1000°C. The rate of weight gain does not decrease even after long exposure times. At temperatures >1000°C the initial weight gain decreases with increasing oxidation temperature being lowest at 1520°C. At these high temperatures the isotherms show that the maximum weight gain occurs in the first 5 h of exposure after which little or no weight gain takes place.

The oxidation mass balance reaction for the composite is:

$$Si_2N_2O\text{–}ZrO_2 + 3/2O_2 \rightarrow ZrSiO_4 + SiO_2 + N_2(g) \quad (1)$$

As can be seen from eqn (1) ZrO_2 does not contribute to the mass change. Based on the weight change obtained for each measurement at a given temperature, the percentage of reacted Si_2N_2O was calculated and is shown in Fig. 2. In the case of complete oxidation the total weight gain was calculated to be 12·38 wt%. As can be seen from Fig. 1 this percentage was not reached experimentally.

Fig. 3. TEM micrograph showing the general microstructure of as-received Si_2N_2O–ZrO_2 material to consist of sub-micron size ZrO_2 grains (Z) homogeneously distributed in a matrix of sub-micron size Si_2N_2O crystals.

Table 1. Surface phase composition at different oxidation temperatures for Si_2N_2O–ZrO_2 material

Temperature (°C)	*Exposure time (h)*	*Phase composition*				
		Si_2N_2O	*m–ZrO_2*	*t(t')-ZrO_2*	*$ZrSiO_4$*	*SiO_2*
As-received	7	s	s	w	—	—
1000	7	s	s	w	w	w
1300	7	w	w	m	m	w
1450	7	w	w	m	m	w
1600	7	w	w	m	vs	w

w—weak, m—medium, s—strong, vs—very strong.

For the reoxidation experiments at 1450°C the weight increase after reoxidation was found to be approximately 10% of the original weight increase.

3.2 Microstructural analysis

3.2.1 XRD

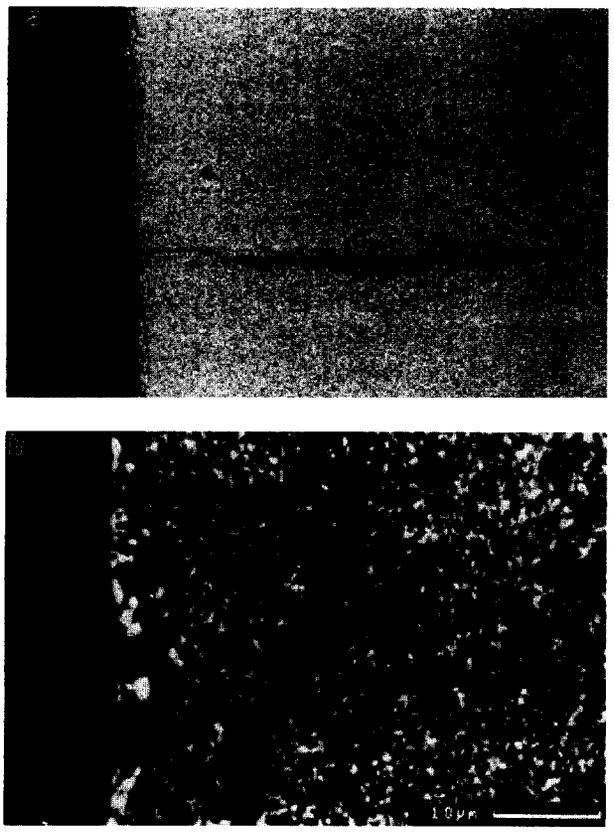
The identification of oxidation products and phase changes at the various oxidation temperatures and times is detailed in Table 1.

XRD of the surface of the oxidized materials shows an increasing volume of oxidation products, $ZrSiO_4$ and SiO_2, to be present in the scales with increasing temperature reflecting an increasing surface scale thickness. Little amorphous material could be detected. The proportion of *t*–ZrO_2 in the matrix is seen to increase following oxidation at temperatures ≥1300 with a concommitant decrease in the amount of *m*–ZrO_2 as compared with the as-sintered material.

3.2.2 TEM

As shown in Fig. 3 the general microstructure of the as-received material consists of a matrix of sub-micron Si_2N_2O grains in which sub-micron size ZrO_2 grains are homogeneously distributed. The plate-like Si_2N_2O crystals are randomly oriented and of high aspect ratio. The zirconia grains are observed to have an irregular intergranular morphology and were identified by electron diffraction to be predominantly monoclinic (Fig. 4). Small volumes of an amorphous phase surround the matrix grains. Regions of incomplete sintering, containing small (≤ 50 nm) Si_2N_2O grains in a Si rich amorphous phase were frequently observed. A more detailed description of the microstructure can be found in Ref. 6.

3.2.3 SEM



The specimens were examined in SEM in surface and cross-section using the back-scattered electron mode after 2, 10, 50, 100, 150 and 250 h exposure at each temperature. EDX analysis was carried out on cross-section specimens.

Fig. 4. TEM micrograph showing the monoclinic ZrO_2 phase (m) in as-received Si_2N_2O–ZrO_2 material: (a) bright field and (b) dark field.

(1) 1000°C

Compared with the microstructure of as-received material no unambiguous evidence or indication of external or internal oxidation could be detected in SEM. However on cutting the material for preparation for SEM it was observed visually to have 'whitened' all the way through the matrix indicating extensive internal oxidation.

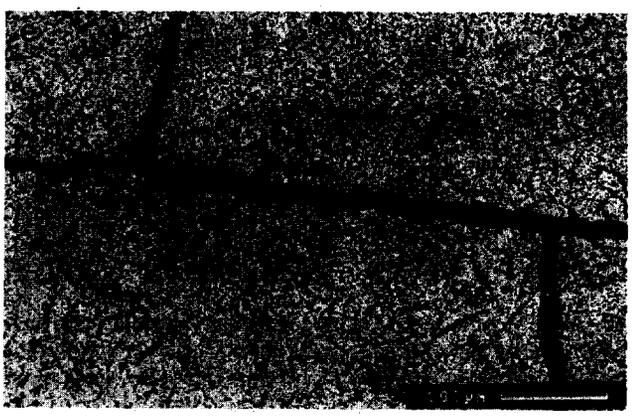


Fig. 5. SEM back-scattered images of the oxide scales of Si_2N_2O–ZrO_2 material exposed at 1300°C. (a) Cross-section showing large cracks in the matrix after 2 h oxidation. (b) Severe cracking observed in the matrix parallel with the surface after 100 h exposure. (c) Cross-section of the oxide scale after 250 h exposure showing $ZrSiO_4$ crystals (Z), crystalline SiO_2 (C) and an amorphous mixed silicate phase (A). (d) A large internal pore in the matrix showing extensive oxidation after 2 h exposure. (e) Oxide surface after 150 h oxidation showing the scale to contain large volumes of $ZrSiO_4$ crystals (Z) and a small volume of crystalline SiO_2 (C).

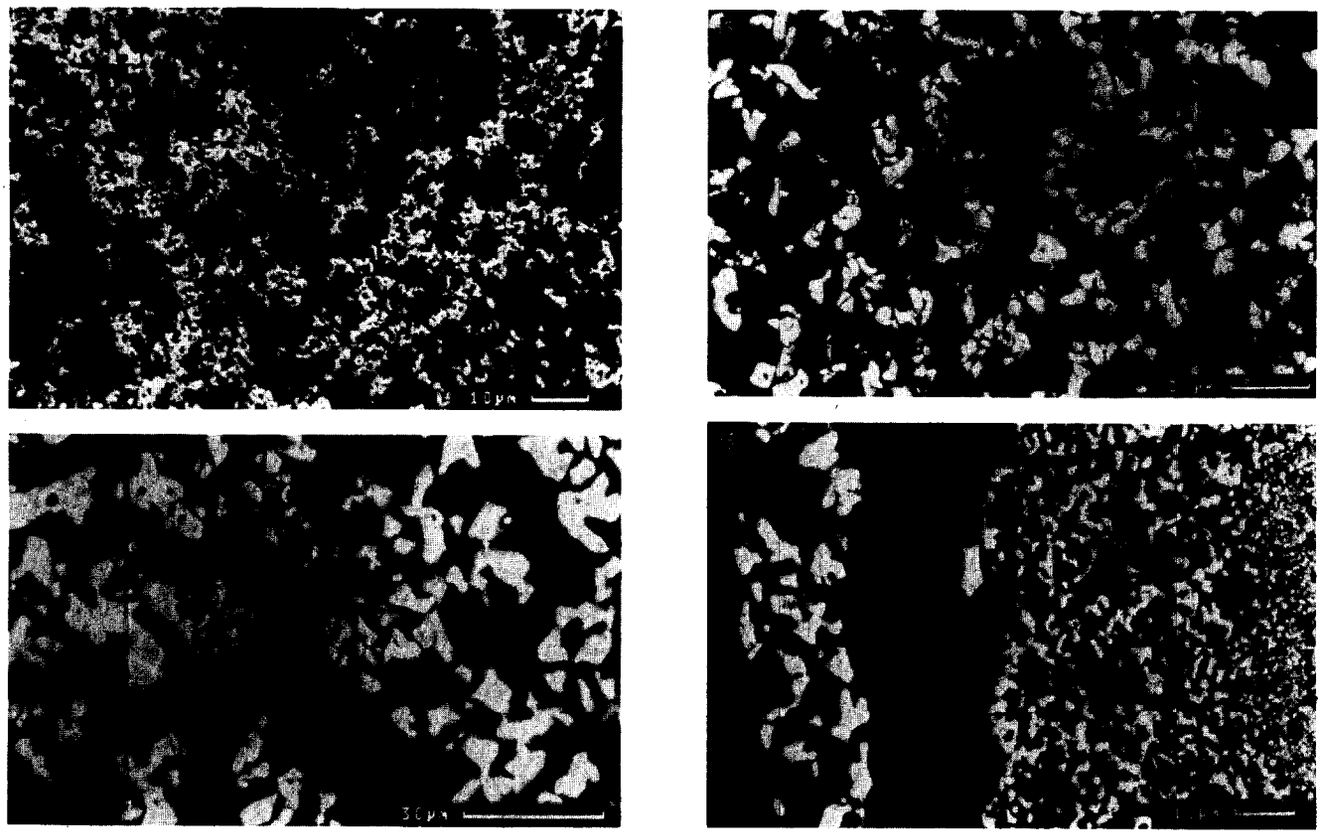

Fig. 6. Back-scattered SEM images of Si_2N_2O–ZrO_2 material exposed at 1450°C. (a) Oxide surface of material exposed for 2 h showing a rough uneven surface. (b) After 100 h extensive cracking of the surface is observed associated with the crystalline silica phase (C). (c) After 250 h the crystalline silica phase (C) assumes a long needle-like morphology. (d) In cross-section duplex scales are seen to form after 50 h exposure showing a region of extensive porosity (P) and a denser outer region with extensive cracking (O).

(2) 1300°C

As is shown in Fig. 5(a) large cracks were observed in the material following oxidation at 1300°C. The cracks frequently extended through the matrix and were of dimensions 10–30 μm in diameter. Additional severe cracking was also observed in the material parallel with and just below the surface (Fig. 5(b)). Cracking associated uniquely with the scale is observed only after longer exposures times (≥100 h). In transverse section thin discontinuous oxide scales ≤2 μm were observed for shorter exposure times. The oxide scale increased in thickness and continuity with time to reach a maximum of approximately 20 μm after 250 h exposure (Fig. 5(c)). Considerable oxidation of larger internal pores was evident in all the specimens (Fig. 5(d)).

As is shown in Fig. 5(e) the scale contained large volumes of small brightly contrasting structures, shown by EDX to contain Zr, Si and O and therefore probably crystalline $ZrSiO_4$, and small volumes of a darker contrasting phase containing Si and O, possibly cristobalite. In addition, an intermediate contrasting phase is observed which contains Si, O and small amounts Fe, Na and K and is possibly an amorphous mixed silicate. The atom number density, size and shape of the crystals increases with increasing exposure time.

(3) 1450°C

Following oxidation at 1450°C the scales have a rough, uneven topography and small cracks are observed within the scale as shown in Fig. 6(a). The cracking of the scale is more extensive after longer oxidation exposures and is observed to be associated with the crystalline silica phase (Fig. 6(b)). A continuous, thick (≤50 μm) oxide scale is observed after short exposure times. No SEM evidence of internal oxidation could be detected.

The phase content of the scales as detected by SEM consists of a large volume of crystalline $ZrSiO_4$, SiO_2 and a mixed silicate phase. After longer oxidation times the atom number density, size and morphology of the crystalline components of the scale show considerable change. The zircon crystals become larger and more particulate with increasing time at temperature as shown in Fig. 6(c). The crystalline silica phase changes in form from almost spheroidal at 100 h to long needle-like grains at 250 h. The scale structure is duplex with an outer more dense region and an inner extensively porous region (Fig. 6(d)).

(4) 1520°C.

After 2 h oxidation at this temperature considerable porosity is observed in the scales in planar section (Fig. 7(a)). With increasing time at temperature the porosity is no longer observed but

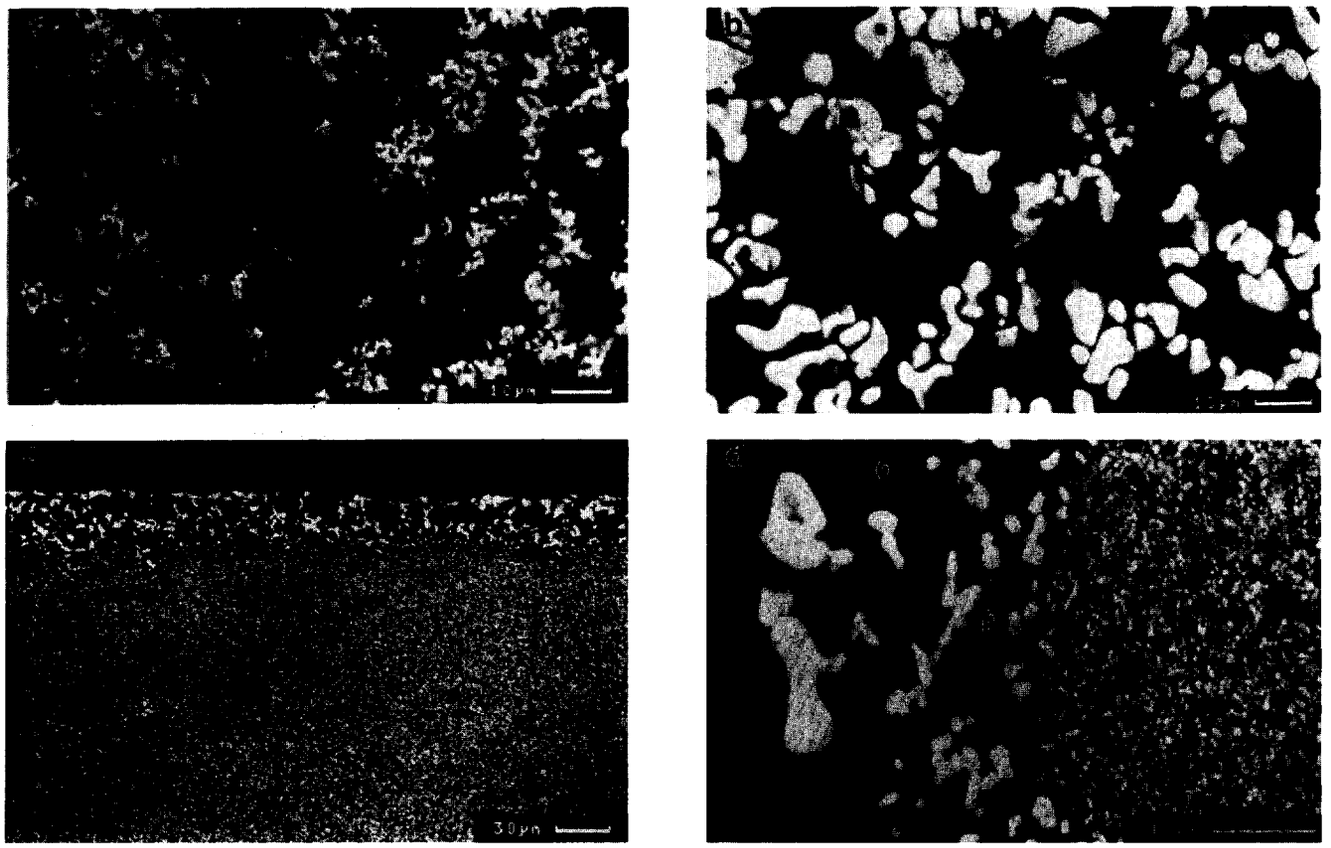

Fig. 7. SEM back-scattered images of Si_2N_2O–ZrO_2 material exposed at 1520°C. (a) Oxide surface after 2 h exposure showing considerable porosity. (b) After 150 h extensive cracking of the surface is observed associated with the crystalline silica phase. (c) Cross-section showing the oxide scale to be up to 50 μm thick after 250 h exposure. (d) Duplex scales are seen to form with a region of extensive porosity (P) and a denser outer region with extensive cracking (O) after 150 h exposure.

extensive cracking is noted associated with the crystalline silica phase (Fig. 7(b)). No evidence of matrix cracking or internal oxidation could be detected. The atom number density of the crystalline components of the scale are observed to increase with increasing time. Duplex oxide scales up to 50 μm thick are seen to develop even at short time exposures at this high temperature. The duplex scale shows extensive porosity in the lower region and extensive cracking in the outer region (Figs 7(c) and (d)).

3.3 Pore characteristics

3.3.1 Specific surface area

The specific surface area of the as-received material was 1·1 ± 0·1 m^2/g. Figure 8 shows selected specific surface area data for samples oxidized for different times at the various oxidation temperatures.

An increase in the specific surface area is observed only at 1000°C. In general the higher the temperature the less the specific surface area differs from that of the as-received material.

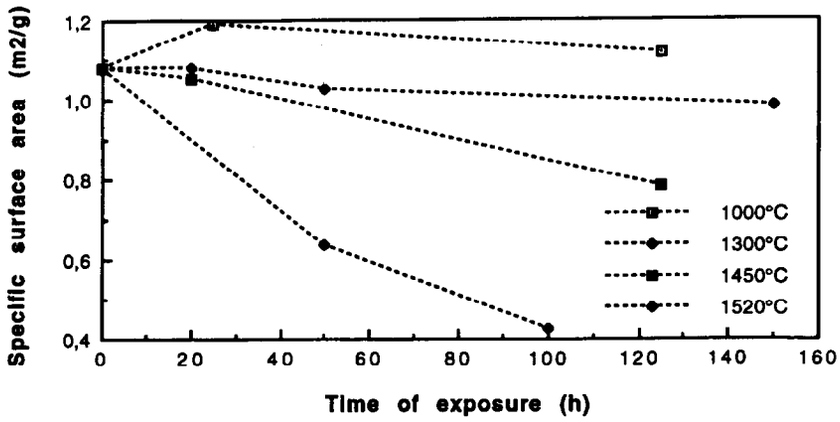

Fig. 8. Specific surface area of Si_2N_2O–ZrO_2 material exposed at various oxidation temperatures.

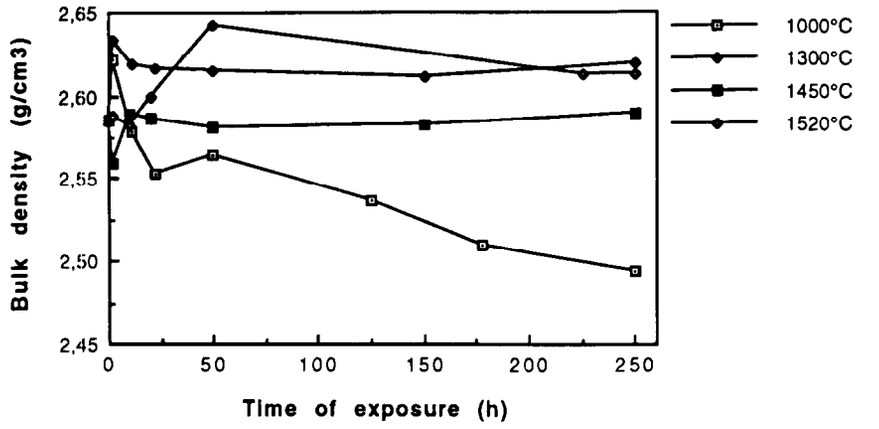

Fig. 9. Bulk density of Si_2N_2O–ZrO_2 material exposed at various oxidation temperatures.

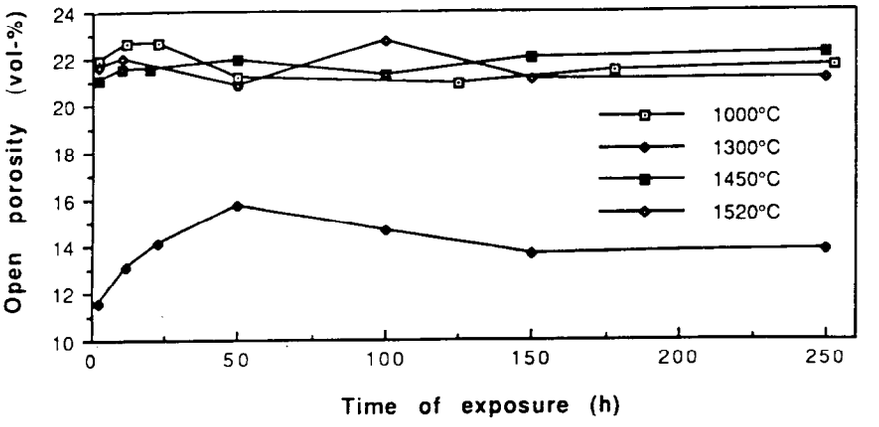

Fig. 10. Open porosity of Si_2N_2O–ZrO_2 material exposed at various oxidation temperatures.

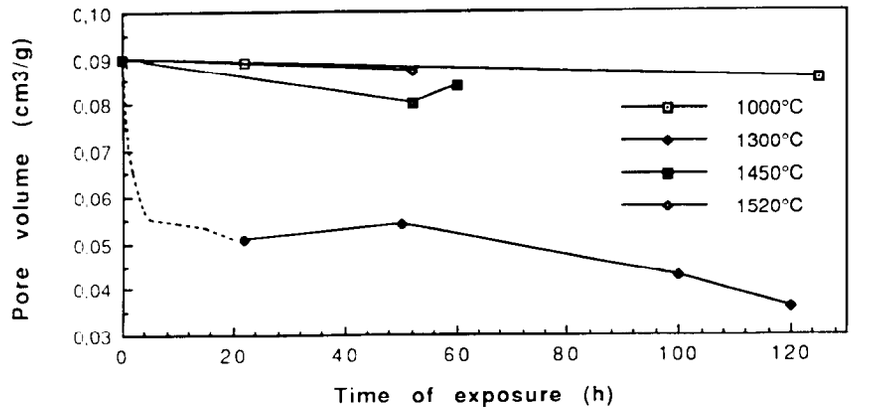

Fig. 11. Pore volume of Si_2N_2O–ZrO_2 material exposed at various oxidation temperatures.

3.3.2 Density

Figure 9 shows the results obtained for the bulk density measurements. The density of the as-received material was determined to be 2·585 g/cm^3.

A significant tendency for density to decrease with time is observed at 1000°C. At all other temperatures the density shows no significant change.

Figure 10 shows the open porosity. The open porosity of as-received material was determined to be 22·3 vol%.

The obtained results show that the open porosity only changes significantly at 1300°C showing a definite decrease.

3.3.3 Pore volume

Porosimetry measurements have been performed on as-received material as well as with oxidized specimens. Figure 11 shows the results for measurements of the pore volume. The pore volume decreases slightly on oxidation at 1000°C. At 1300°C a significant decrease in the pore volume is

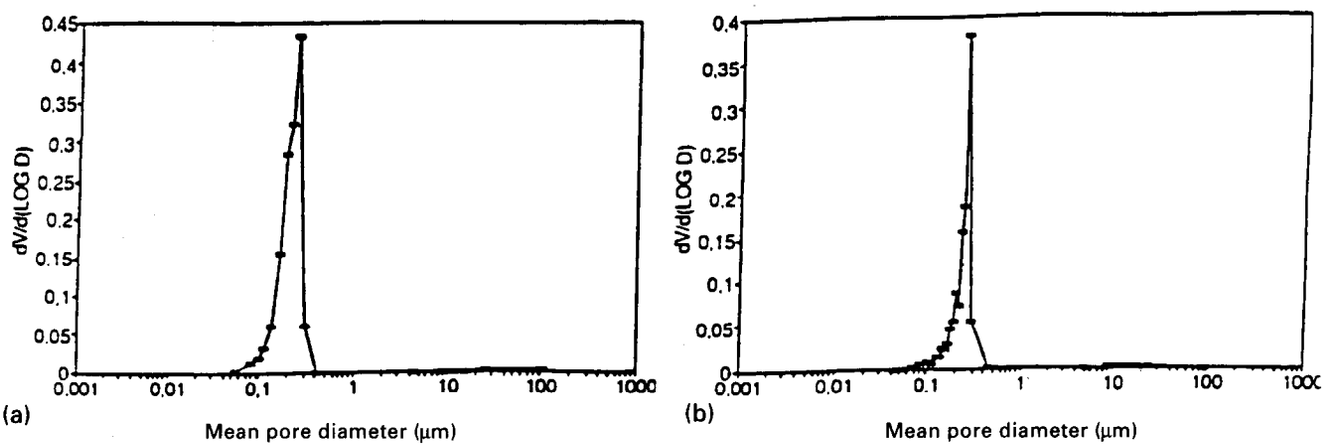

Fig. 12. Pore frequency distribution of a sample of Si_2N_2O–ZrO_2 material: (a) as-received and (b) after oxidation for 120 h at 1300°C.

observed. At higher temperatures the values do not change markedly from that of the as-received material.

Figure 12 shows the pore frequency in as-received material and in a sample exposed for 120 h at 1300°C.

The mean pore diameter is found to be around 0·2 μm. From Fig. 12 it can be seen clearly that neither the mean pore diameter nor the distribution of the pore sizes change significantly.

4 Discussion

In general the results fall into the temperature categories 1000, 1300 and >1300°C in which it is most convenient to discuss the oxidation behaviour.

(1) 1000°C

The linear weight gain curve showing a large and continuous weight increase at this temperature is not consistent with a lack of surface oxide scale formation. The calculations of the percentage of oxidized material show that approximately 40 wt% of the available matrix has reacted. This indicates that a considerable amount of internal oxidation has taken place at this temperature. SEM and XRD show that no oxidation of the ZrO_2 phase had occurred. This implies that oxidation of the Si_2N_2O phase in the pores and pore channels must account for the observed weight gain and results in a thin film of amorphous and crystalline SiO_2 throughout the specimen which could not be detected in SEM. This is reflected in the measured increase in specific surface area, decrease in pore volume and decrease in bulk density as follows:

$$\underset{2\cdot82}{\rho\ (g/cm^3)}\quad Si_2N_2O + 3/2\,O_2 \rightarrow \underset{2\cdot33}{2\,SiO_2} + N_2 \qquad (2)$$

The pores remain open as oxygen diffusion inwards is faster than the oxidation reaction which is slow at this temperature. This results in continued oxidation even after long oxidation times. This type of behaviour is similar to that observed in RBSN materials at low temperatures.

(2) 1300°C

The weight increase is observed to be highest at this temperature and to occur within the first 5 h of exposure. It was calculated that approximately 32 wt% of the Si_2N_2O had been oxidized by this time. This large initial weight increase with formation of thin (2–10 μm) oxide scales is consistent with the occurrence of both internal and external oxidation. As the XRD results show, the ZrO_2 phase is now involved in the oxidation process (eqn (1)) and zircon is formed. This is associated with a large volume increase (~8%). Cristobalite, also detected by XRD and SEM, probably forms during cooling from the oxidation temperature and its formation is also associated with a large increase in volume (~5%). SEM revealed the larger internal pores to be covered with an oxide scale containing zircon, and an Si and O containing phase. Oxidation after the first 5 h is accompanied by a significant decrease in the specific surface area, an increase in density and a decrease in pore volume implying the filling up of internal pores with oxidation products. The oxidation products are of larger volume than the original matrix material and will result in internal stresses and pore filling but will also act as a diffusion barrier to further oxidation. However, due to the volume increase significant internal stresses are built up within the material causing the severe cracking observed at this temperature and which most probably occurred on cooling from the oxidation temperature. If pore closure is responsible for the weight gain stabilisation of the samples after the first 5 h of exposure, then considering the extensive cracking that is observed in the matrix after each cycle, one would expect additional weight gain due to the oxidation of newly exposed surfaces when the samples are replaced in the furnace. However, no additional weight gain is

observed, indicating that complete pore closure does not occur.

The ZrO_2 phase, which is predominantly monoclinic in the as-received material, transforms to t–ZrO_2 at the oxidation temperature (t–m transformation ~1170°C). As it is unstabilised the t-ZrO_2 phase should transform to m-ZrO_2 on cooling. However, the XRD results show t-ZrO_2 to be the main ZrO_2 phase present in the matrix. The inhibition of the t–m transformation can arise from two sources: (i) the stresses in the matrix arising from the volume expansion during internal oxidation mechanically constrain the transformation; and (ii) a high N_2 activity during internal oxidation at these temperatures can result in the dissolution of nitrogen in ZrO_2 forming the stabilised non-transformable t'-ZrO_2 phase. It is possible that both factors contribute to stabilisation but with regard to the similar behaviour observed at higher temperatures (next section) where extensive internal oxidation does not occur, it is thought that nitrogen stabilisation is the most probable explanation and this is presently under investigation in TEM studies.[6]

(3) >1300°C

The material shows excellent oxidation resistance at high temperatures. The weight gain curves show that the higher the oxidation temperature the lower the weight gain. Calculations of the percentage of reacted Si_2N_2O indicate that only 14 and 2 wt% had oxidized at 1450 and 1520°C respectively. This weight gain occurred within the first 2 h of exposure and SEM showed it to be accompanied by the growth of thick predominantly crystalline surface oxide scales (up to 50 μm) with no evidence of internal oxidation. These oxide scales were continuous but considerable microcracking was observed associated with the formation of cristobalite on cooling. Although this implies that rapid external oxidation seals off the surface pores before internal oxidation can occur this does not seem to be the case as the specific surface does not decrease nor is any change noted in pore volume as compared to the as-received material. In addition, in the reoxidation experiments at 1450°C a weight gain of only 10% of the original weight gain (2·7%) was recorded following scale removal and reoxidation. If pore closure was entirely responsible for the low weight gains at this temperature then the weight gain upon reoxidation should be similar to the original weight gain. This indicates that pore closure may not be occurring. Instead, it is thought that the internal pores are rapidly covered with a very thin layer of oxide primarily consisting of $ZrSiO_4$ with small amounts of silica. This layer, together with the surface oxide layer, protects the material from further oxidation which should occur as a result of the surface cracks formed during the thermal cycling excursions.[6]

The XRD results show that the t-ZrO_2 is retained to room temperature as observed following oxidation at 1300°C and is presently under investigation.[6]

In general the oxidation behaviour of the porous composite is similar to that of RBSN material where the oxidation rate is also seen to decrease significantly at higher temperatures. The latter effect has been explained by Davidge who proposed a two stage oxidation process for porous ceramics, namely surface oxidation and the oxidation of the pore channel walls in the interior of the material.[7] At higher temperatures where surface oxidation is more rapid, pore closure will occur before internal oxidation is completed.[9] Although this general trend is similar for the composite as is discussed above, the results of this work indicate that pore closure may not be occurring. Instead it is thought that a very thin layer of oxide primarily consisting of $ZrSiO_4$ forms on the internal pore walls which, together with the surface oxide layer, protects the material from further oxidation. In addition, the composite consists of two highly refractory phases. Although the eutectic of the Si_2N_2O–ZrO_2–SiO_2 system is not known, the XRD results obtained for material exposed at 1600°C show no indications of amorphous material resulting from eutectic melting. This implies that the eutectic temperature lies above 1600°C. The oxidation behaviour is superior to that reported of other Si_3N_4–ZrO_2 or Si_2N_2O–ZrO_2 composites.[2,3,8] The latter have been prepared using metal oxide sintering aids/stabilisers which in general lower the eutectics of the system and decrease the viscosity and softening point of intergranular amorphous phases in the matrix with concommitant decrease in oxidation resistance.

5 Conclusions

(1) In general the trend in the oxidation behaviour of the Si_2N_2O–ZrO_2 composite is similar to that of other porous nitrogen ceramic materials where the oxidation rate is seen to decrease significantly at higher temperatures.

(2) At temperatures ≤1300°C considerable internal oxidation of the material occurs with concommitant large weight gains. At 1300°C the stresses induced in the matrix by the volume expansion of the oxidation products cause severe cracking of the material on cooling from the annealing temperature.

(3) The material exhibits excellent oxidation resistance at high temperatures (>1300°C) and the higher the oxidation temperature the lower the weight gain. Protective oxide scales form at external and internal surfaces within the first 2 h of exposure which inhibit further oxidation. It is thought that narrowing of the pore channels may take place but complete pore closure does not occur.

(4) Following oxidation exposures at temperatures ≥1300°C the unstabilised ZrO_2 phase in the matrix is inhibited from undergoing the *t–m* transformation. This is most probably due to the dissolution of nitrogen in ZrO_2 resulting in the stabilised, non-transformable *t'*-ZrO_2 phase.

Corrosion Resistance of Ceramic-coated Stainless Steel in a Br_2–O_2–Ar Atmosphere

Makoto Sasaki & Toshio Hirai

Institute for Materials Research, Tohoku University, Katahira 2-1-1, Aoba-ku, Sendai 980, Japan

(Received 13 May 1994; revised version received 15 July 1994; accepted 12 August 1994)

Abstract

Coatings of SiC/TiC compositional graded film (FGM), m-HfO_2 and c-HfO_2 films on stainless steel (SUS304) plates have been investigated as candidate materials for 'UT-3' which is an effective process of hydrogen production through thermochemical decomposition of water. Changing the source gas concentration leads to composition control in TiC–SiC composite films. Cracks in the films could not be avoided in either the TiC-coated SUS304 nor the SiC–TiC double layer-coated SUS304. However the SiC/TiC FGM-coated SUS304 had no cracks. Corrosion of the TiC and SiC–20 mol%TiC double-layer-coated SUS304 in the Br_2–O_2–Ar atmosphere was mainly caused by oxidation of the TiC film and SUS304. The SiC/TiC FGM-coated SUS304 showed superior corrosion resistance in isothermal and cyclic heating conditions.

m-HfO_2 and c-HfO_2 (7·1–44·5 mol% Y_2O_3) were attained by the changing of $Y(DPM)_3$ gas concentration. XRD measurement shows the monoclinic and cubic HfO_2. Both plate-like and columnar texture in the m-HfO_2 and c-HfO_2 films were observed. m-HfO_2, in which columnar texture, coated SUS304 showed the excellent corrosion resistance in Br_2–O_2–Ar atmosphere under heat cyclic conditions. This is thought to be due to the effects of columnar texture on the thermal stress relaxation, and of the excellent corrosion resistance of the m-HfO_2.

1 Introduction

Hydrogen gas (H_2) is expected to be used as a new energy source because conventional fuels tend to destroy the natural environment. One of the methods to produce H_2 is the thermochemical decomposition of water called 'UT-3'.[1] The 'UT-3' process causes high temperature corrosion of structural materials because highly corrosive gases such as O_2, Br_2 and HBr might be used at temperatures from 500 to 1000 K. Considering practical applications, metals should be used as structural materials. However, no metal is known to resist the corrosive conditions caused by 'UT-3'. Ceramic-coated metals are expected to be candidate structural materials. Titanium carbide (TiC) films are highly adherent to metals, and silicon carbide (SiC) is resistant to corrosion. CVD is the most suitable method for the surface modification of metals, because it allows the preparation of dense and adherent films. On the other hand, Functionally Gradient Materials (FGMs) having an excellent thermal stress relaxation property are well known as thermal barrier materials.[2–7] In the present work, single-layer TiC or SiC, double-layer SiC and TiC, and SiC/TiC FGM coatings were placed on stainless steel (SUS304) using the CVD method. On the other hand, HfO_2 has a superior thermal expansion matching to the stainless steel. Thus, m-HfO_2 and c-HfO_2(Y_2O_3) coatings were also deposited on the SUS304 using the CVD method. The corrosion behaviour of these materials in Br_2–O_2–Ar atmosphere was investigated.

2 Experimental

2.1 Preparation of TiC, SiC and SiC–TiC composite films

Stainless steel (SUS304) plates (15 mm in diameter and 2 mm in thickness) were used as substrates. Source gases $TiCl_4$, CH_3SiCl_3(MTS), CH_4 and H_2 were introduced into a hot-wall type CVD reactor. Deposition temperature (T_{dep}) and total gas pressure (P_{tot}) were fixed at 1323 K and 0·1 MPa, respectively. H_2 gas flow rate was kept at $8{\cdot}3 \times 10^{-6}m^3s^{-1}$. $TiCl_4$ gas flow rate was changed from 0 to $3{\cdot}3 \times 10^{-7}m^3s^{-1}$, MTS gas flow rate from 0 to $1{\cdot}6 \times 10^{-6}m^3s^{-1}$. The ratio of CH_4 to MTS was kept at 1·7 to fabricate the TiC-containing films. The structure of CVD films was examined by XRD (Rigaku: RAD-C), the surface and the

cross-sectional texture observed by SEM spectroscopy (Akashi:ALPHA-30). SiC and TiC content in the films were determined by EPMA measurement as substitutions for the Si (Ka) and Ti (Ka) intensity.

2.2 Preparation of SiC/TiC FGM film

On the basis of the preparation conditions of SiC–TiC composite films, SiC/TiC FGM films were fabricated on SUS304 by changing the source gas concentration ('a'=MTS/($TiCl_4$+MTS)) at T_{dep}=1323 K and P_{tot}=0·1 MPa. 'a' was changed stepwise from 0 for 4 h, 0·7 for 1 h to 1·0 for 1 h. The surface and cross-sectional texture were observed by SEM.

2.3 Preparation of m- and c-HfO_2 films

(100)Si and Stainless steel (SUS304) plates (15 mm in diameter and 2 mm in thickness) were used as substrates. Source gases $Hf(DPM)_4$, $Y(DPM)_3$, O_2 and Ar were introduced into a hot-wall type CVD reactor. Tables 1 and 2 demonstrate the CVD conditions. Deposition temperature (T_{dep}) and total gas pressure (P_{tot}) were fixed at 1073 K and 13 kPa, respectively. The structure of CVD films was examined by the XRD, the surface and the cross-sectional texture observed by the SEM. Film composition was determined by ICP and XRF measurements.

2.4 Measurement of corrosion rates

Figure 1 demonstrates the experimental set-up for the evaluation of corrosion rate. The specimens were suspended by a platinum wire in an electric furnace. Weight changes during corrosion were continuously measured using an electric balance connected to a computer (NEC:PC-9801). The electric balance was kept at 298 K in a constant temperature box. Ar gas was passed through the electric balance and introduced into the quartz tube. O_2 gas containing Br_2 was introduced from the bottom of the balance box into the quartz tube. The Br_2 reservoir was maintained at 288 K. The corrosion temperature (T_{cor}) was kept at 1173 K in isothermal experiments. In the case of cyclic heating, T_{cor} was cyclically changed from 1173 to 773 K under the same gas flow rates in isothermal corrosion experiment.

3 Results and discussion

3.1 Preparation of TiC, SiC and SiC–TiC composite films

The possibility of the CVD method to control film composition was investigated. Figure 2 shows the relationship between input gas concentration and film composition. SiC content in the film increases

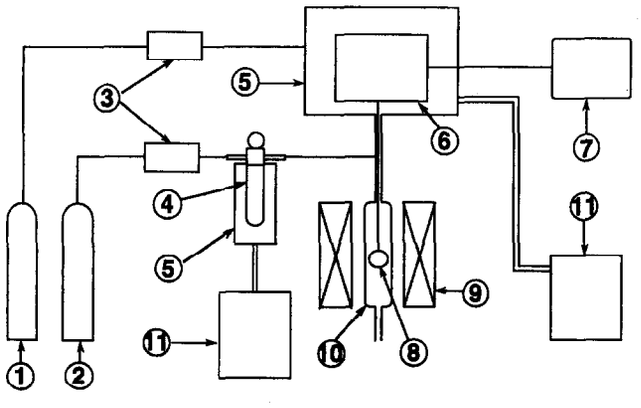

Fig. 1. Schematic diagram of corrosion rate measurement: (1) Ar gas, (2) O_2 gas, (3) mass flow meter, (4) Br_2 reservoir, (5) constant temperature bath, (6) electric balance, (7) computer, (8) specimen, (9) electric furnace, (10) quartz tube, (11) cool pump.

with increasing MTS concentration. Figure 2 also demonstrates the theoretical composition of the films calculated using JANAF data[8] under the thermodynamic equilibrium conditions based on a free energy minimisation method. Experimental compositions of the films agree well with those of the calculated values except at the *a* of 0·4. The lower value is thought to be due to the kinetics of the CVD process. These data show that SiC content in the SiC–TiC composite films can be controlled.

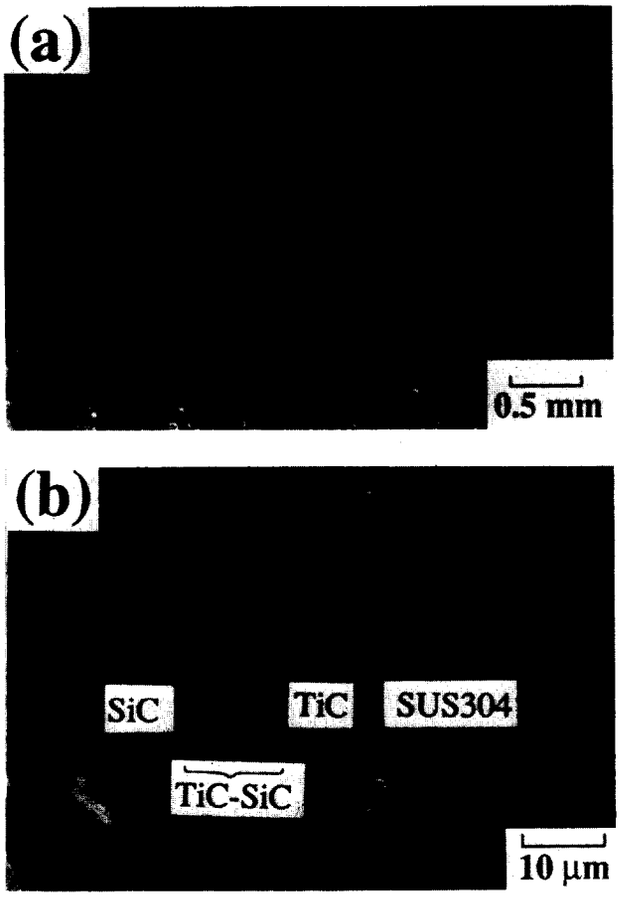

Fig. 4. SEM photographs of the SiC/TiC FGM-coated SUS304. (a) Surface of the specimen. (b) Cross-section of the specimen.

While direct coating of TiC on the SUS304 was achieved, the SiC–TiC composite film was not obtained on the SUS304 because Fe_3Si and $FeSi_2$ formed as a result of easy reaction between MTS and SUS304. This result demonstrates the impossibility of direct coating of SUS304 with SiC. Reaction protection layers such as TiC are indispensable between SiC and SUS304. An SiC coating on the TiC-coated SUS304 was attempted. Figure 3 shows the SEM photograph of the surface of the SiC/TiC double layer-coated SUS304. SiC was deposited on the TiC interlayer. Cracks were observed on the surface of the TiC-coated SUS304. Thermal expansion coefficients of TiC, SiC and SUS304 are $7{\cdot}6 \times 10^{-6}$, $4{\cdot}3 \times 10^{-6}$, $1{\cdot}73 \times 10^{-5}K^{-1}$, respectively. As shown in Fig. 4, cracking also occurred in the SiC film as a result of the mismatch between thermal expansion coefficients of SiC and SUS304. Even if the thicknesses of SiC and TiC were ranged from 2 to 20 μm, cracking could not be avoided.

3.2 Preparation of an SiC/TiC FGM film

For the purpose of residual thermal stress relaxation and the protection of crack formation, continuous change of the thermal expansion coefficients, so-called Functionally Gradient Materials (FGMs) might be useful. Figure 4 shows the SEM photographs of the surface and the cross-section of the SiC/TiC FGM-coated SUS304.

Compositional graded layer from TiC to SiC forms on the SUS304. Despite the mismatch of thermal expansion coefficients between SiC, TiC and SUS304, no cracks in the SiC/TiC FGM-coated SUS304 appear on the deposited surface, as shown in Fig. 4. The result suggests that the introduction of the compositional gradation between the SiC and TiC layers reduce the surface tensile stress of the SiC/TiC FGM-coated SUS304.

3.3 Synthesis of m-HfO_2 films

The m-HfO_2 formation was confirmed by X-ray diffraction (JCPDS card No. 34-104). The thickness increased from 0·8 to 3·2 μm with increasing T_{dep} from 873 to 1073 K, and was kept constant above 1073 K. The SEM photographs of the surface of m-HfO_2 deposited on the (100)Si substrate are shown in Fig. 5. Figure 5(a) shows a plate-like dense m-HfO_2 film deposited at a T_{dep} of 973 K and at a t_{dep} of 1·2 ks, which has cracks and detached from the substrate. On the other hand, as shown in Fig. 5(b), the film deposited at a T_{dep} of 1073 K and at a t_{dep} of 2·4 ks has a columnar texture. Figure 5(b) also shows the dense layer around the interface film-substrate with no cracks and no detachment from the substrate.

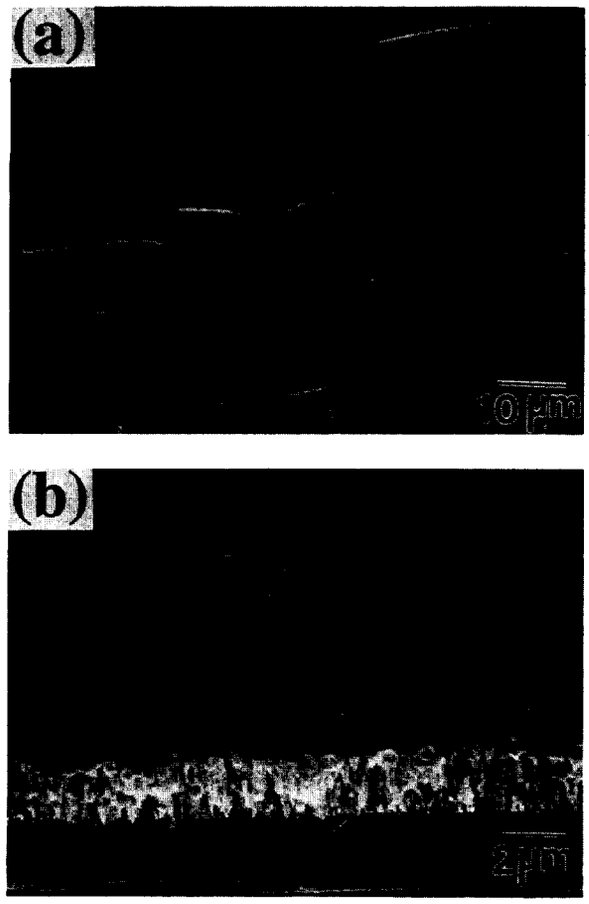

Fig. 5. SEM photographs of the plate-like (a) and columnar (b) m-HfO_2.

As shown in Fig. 5, a plate-like dense film was deposited in the T_{dep} range from 873 to 973 K. Its XRD pattern, characterised by broad peaks, demonstrated the lower degree of crystallisation. On the other hand, the film deposited in the T_{dep} range from 1023 to 1173 K has a columnar structure and showed relatively higher crystallinity.

3.4 Synthesis of c-HfO_2 films

The film deposited at a T_{dep} of 1073 K, a T_{Hf} of 453 K, a T_Y of 406 K, a t_{dep} of 2·4 ks, FA_{Ar} of 1·7 × 10^{-6} m^3s^{-1}, FR_{O_2} of 1·7 × 10^{-6} m^3s^{-1}, and at a P_{tot} of 1·3 kPa, was identified as the c-HfO_2 (JCPDS card No. 24-1406).

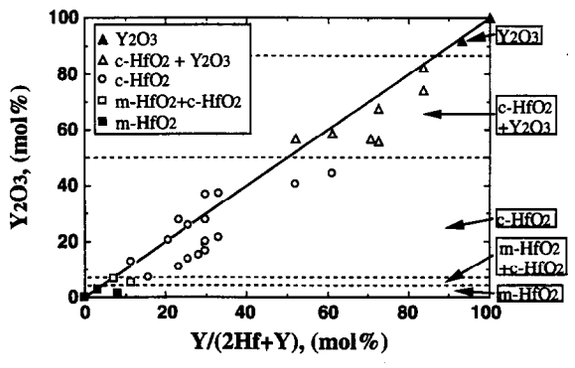

Fig. 6. Relationship between input gas concentration and film composition.

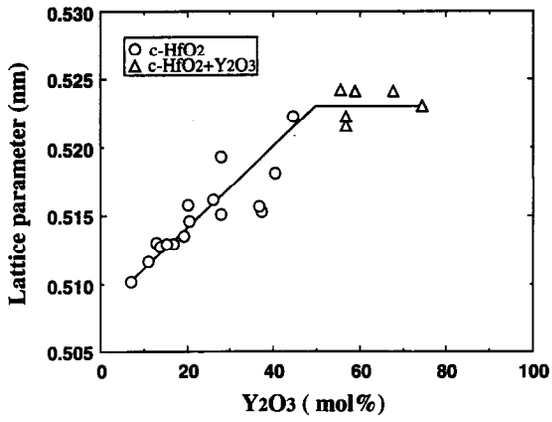

Fig. 7. Relationship between film composition and lattice parameter of c-HfO_2.

Figure 6 shows the relationship between input gas molar ratio and the Y_2O_3 content in the films. The straight line in Fig. 6 demonstrates the ideal Y_2O_3 content in the films, obtained by the following reaction:

$$x\mathrm{Hf(DPM)_4}+y\mathrm{Y(DPM)_3}+\mathrm{O_2}\rightarrow x\mathrm{HfO_2}+(y/2)\mathrm{Y_2O_3}+(\text{Volatile compounds})$$

Y_2O_3 content was determined by ICP method in which the substitution of Y content in the films. m-HfO_2+c-HfO_2) composites were deposited in the Y_2O_3 range from 5·03 to 6·52 mol%, single c-HfO_2 phase in the Y_2O_3 range from 7·1 to 44·5 mol%, c-HfO_2+Y_2O_3 composites in the Y_2O_3 range from 56·6 to 82·3 mol%.

The relationship between Y_2O_3 content and the lattice parameters measured by (400) X-ray intensity is shown in Fig. 7. The (400) peak of the substrate was used as an inner standard. The lattice parameters have a tendency to increase with increasing Y_2O_3 content.

3.5 Corrosion behaviour

(a) SiC–TiC composites and SiC/TiC FGM

Weight loss of the TiC-coated SUS304 during corrosion experiment was observed at T_{cor}=1173 K, P_{Br_2} = 4·4 kPa and P_{O_2} = 0·1 kPa. As large quantities of O_2 gas might be generated in the 'UT-3' process, corrosion experiments should be conducted at large O_2 gas concentration including Br_2 gas. Figure 8 shows the relationship between time and weight change by the corrosion at T_{cor}=1173 K, P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa (isothermal corrosive condition). All the specimens revealed weight gain in this corrosive condition. The surfaces of the TiC-coated SUS304, TiC and SiC-20 mol% TiC double-layer-coated SUS304, and SiC and TiC double-layer-coated SUS304 after the corrosion at T_{cor}=1173 K, P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa were observed by SEM. The surface of the TiC was extremely damaged by corrosion. In the case of the SiC-20 mol% TiC, the surface

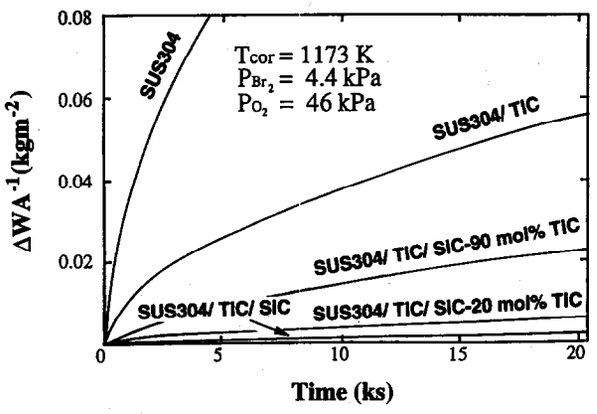

Fig. 8. Relationship between time and weight gain of the SiC–TiC composites by the corrosion at T_{cor} = 1173 K, P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa.

texture became porous and rough. This result occurs due to the difference of corrosion rate between SiC and TiC. SiC is likely to have excellent corrosion resistance. Phases formed after corrosion were investigated by using XRD. TiO_2, Fe_2O_3 and Fe_3O_4 were observed at the surface of the TiC-coated SUS304. The SUS304 substrate was oxidised by corrosive Br_2–O_2 that diffused through the cracks of the TiC film. On the other hand, only TiO_2 was formed on the TiC/SiC-20 mol% TiC double-layer-coated SUS304.

Figure 9 shows the dependence of corrosion rate on the film composition in the SiC–TiC composite system. Clearly, the addition of SiC into the TiC film improves the corrosion resistance of TiC. SiC provide high corrosion resistance, but the TiC/SiC-20 mol% TiC can not be used as the surface material in 'UT-3', because a corrosion of TiC in the composite film is indispensable. To compare the corrosion resistance of TiC/SiC-20 mol% TiC double-layer-coated SUS304 with that of the SiC/TiC FGM-coated SUS304, a corrosion experiment with different heat cycles was attempted.

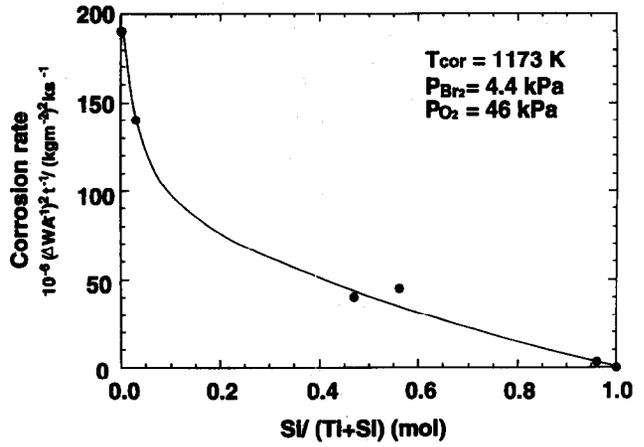

Fig. 9. Dependence of corrosion rate on the composition of SiC–TiC composite films by the corrosion at T_{cor} = 1173 K, P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa.

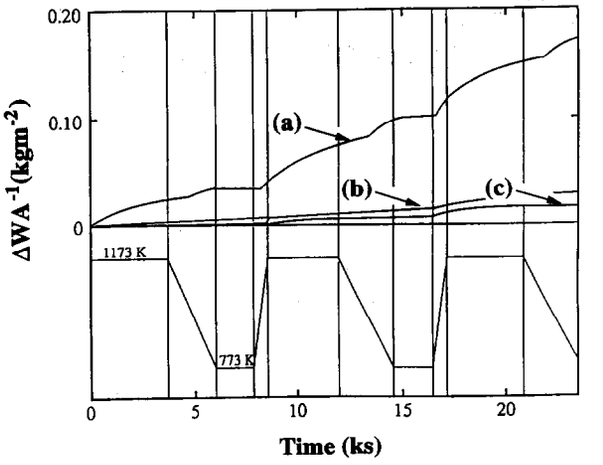

Fig. 10. Relationship between time and weight gain by the corrosion under the cyclic test between 1173 K to 773 K at P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa. (a) TiC-coated SUS304; (b) TiC/SiC–20 mol% TiC double-layer-coated SUS304; (c) SiC/TiC FGM-coated SUS304.

Figure 10 shows the relationship between time and weight gain by the corrosion under the cyclic test between 1173 and 773 K at P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa. TiC-coated SUS304 has less corrosion resistance. Both TiC/SiC-20 mol% TiC double-layer-coated SUS304, and the SiC/TiC FGM-coated SUS304 were covered with SiC on the surface.

Cracks in the film could not be avoided in the SiC/TiC double-layer-coated SUS304. However, the SiC/TiC FGM-coated SUS304 had no cracks (Figs 3 and 4). The result of corrosion experiments in the heat cyclic condition shows the capability of FGM coating to achieve thermal stress relaxation and corrosion resistance.

(b) m- and c-HfO_2 films

Figure 11 shows the weight change of the HfO_2-coated-SUS304 under the isothermal corrosion experiments at a T_{cor} of 1173 K, a P_{Br_2} of 4·4 kPa, a P_{O_2} of 46 kPa, a P_{tot} of 0·1 MPa, and at *a* t_{cor} of 21·6 ks. The specimens used for the corrosion experiments were the columnar m-HfO_2 with film thickness of 14 and 4 μm, the plate-like m-HfO_2 with thickness of 4 μm, the columnar c-HfO_2 with thickness of 14 μm, and bare SUS304. c-HfO_2-coated SUS304 was not corrosion resistant, while m-HfO_2-coated SUS304 showed a superior corrosion resistance.

XRD measurements of bare SUS304 and c-HfO_2-coated SUS304 showed that after the corrosion experiments, Fe_2O_3, Fe_3O_4 and Cr_2O_3 were formed. On the surface of the specimens after the corrosion experiments, the detachment of oxide scale from the SUS304, with a thickness of 0·19 μm could be observed. In the case of c-HfO_2-coated SUS304, the detachment of the film from

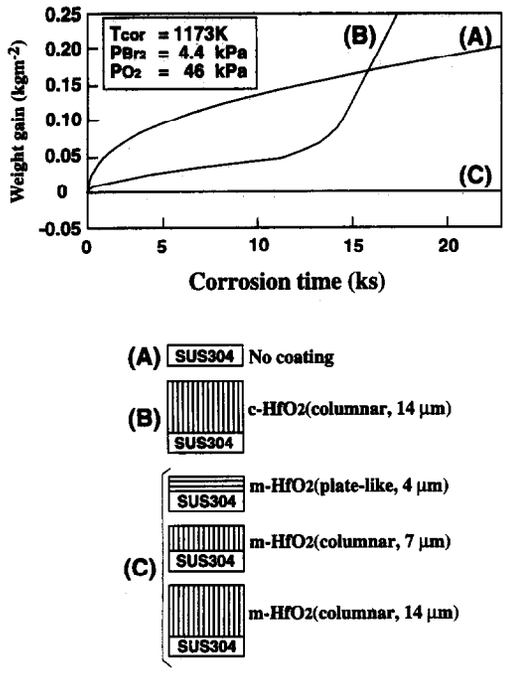

Fig. 11. Relationship between time and weight gain of m-HfO_2-coated SUS304 by the corrosion at T_{cor} = 1173 K, P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa (isothermal condition).

the SUS304 partially occurred. The corrosion and the detachment of the film might occur around the interface of c-HfO_2 film and SUS304.

The corrosion resistance of the m-HfO_2-coated SUS304, which revealed the superior corrosion resistance under isothermal conditions, was investigated by the heat-cyclic corrosive test.

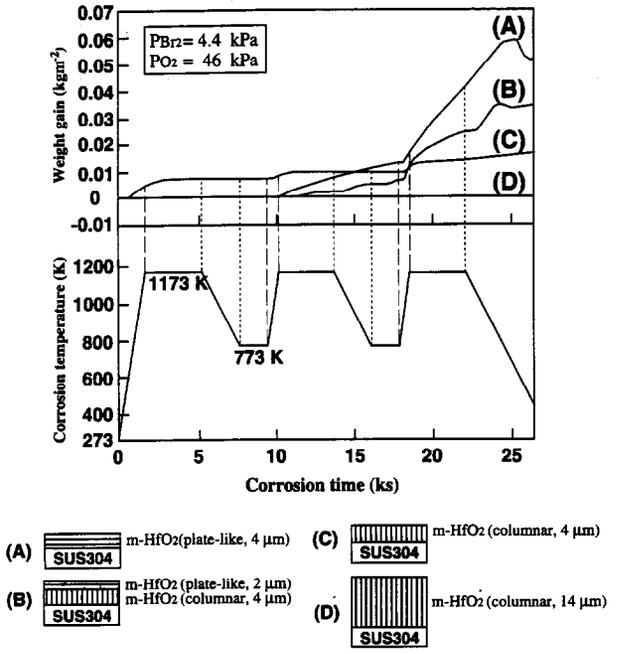

Fig. 12. Relationship between time and weight gain by the corrosion under the cyclic test between 1173 K to 773 K at P_{Br_2} = 4·4 kPa and P_{O_2} = 46 kPa. (a) m-HfO_2 (plate-like, 4 μm); (b) m-HfO_2 (columnar, 4 μm; plate-like, 2 μm); (c) m-HfO_2 (columnar, 4 μm); (d) m-HfO_2 (columnar, 14 μm).

Figure 12 shows the temperature change and the experimental results of the weight change of m-HfO_2-coated SUS304. The columnar m-HfO_2 (14 μm) coated SUS304 had superior corrosion resistance. Corrosion resistance decreased in the order: columnar m-HfO_2(4 μm), m-HfO_2 (texture changed from columnar to plate-like), plate-like m-HfO_2.

The examination of the surfaces of plate-like m-HfO_2 (4 μm in thickness) and columnar m-HfO_2 (14 μm in thickness) by SEM after the cyclic heating corrosion test, showed that the excellent corrosion resistance of the 14 μm-columnar m-HfO_2 coated SUS304, was related to the absence of cracks and detachment from the substrate. This is thought to be due to the effects of columnar texture on the thermal stress relaxation, and of the excellent corrosion resistance of the m-HfO_2.

4 Conclusions

Coatings of TiC, SiC–TiC, SiC/TiC FGM, m-HfO_2 and c-HfO_2 on stainless steel (SUS304) using CVD method were examined as possible corrosion resistant structural materials for 'UT-3.' The corrosion resistance of these materials in a Br_2–O_2–Ar corrosive atmosphere was investigated. The following results were obtained:

Changing the source gas concentration leads to composition control in the TiC–SiC composite films. The composition of TiC–SiC films prepared at a deposition temperature of 1323 K and at a total gas pressure of 0·1 MPa agreed with calculations. The SiC–20 mol% TiC composite film was prepared at a MTS/($TiCl_4$ + MTS) of 0·7. Cracks in the films after CVD could not be avoided in either the TiC-coated or the SiC, TiC double-layer-coated SUS304. However, both the TiC and SiC–20 mol% TiC double-layer-coated SUS304, and the SiC/TiC FGM-coated SUS304 had no cracks. Corrosion of the TiC and SiC–20 mol% TiC double-layer-coated SUS304 was mainly caused by oxidation of the TiC film and SUS304. SiC/TiC FGM-coated SUS304 showed superior corrosion resistance in isothermal and cyclic heating conditions.

Cracks in the m- and c-HfO_2 films after CVD could not be avoided in neither plate-like m-HfO_2 nor plate-like c-HfO_2. Columnar m-HfO_2-coated or columnar c-HfO_2-coated SUS304 had no cracks. Corrosion of the c-HfO_2-coated or plate-like-m-HfO_2-coated SUS304 was mainly caused by oxidation of the SUS304. Columnar m-HfO_2-coated SUS304 showed superior corrosion resistance in isothermal and cyclic heating conditions. This is

thought to be due to the effects of columnar texture on the thermal stress relaxation, and of the excellent corrosion resistance of the m-HfO_2.

Abstract

Sol-gel coatings on metals, as barriers against oxidation of the substrate may be obtained by the dip-coating technique. Different alkoxide solutions have been previously used to deposit coating films on various metallic substrates. Borosilicate coatings gave a good protection against the oxidation of mild steel. The preparation of these coatings has however some disadvantages, such as the required low humidity during deposition and the high cost of precursors.

In this work we studied an alternative method based on aqueous amine solutions. The borosilicate solutions prepared by amines and by alkoxides were characterized by measuring viscosity and stability. Coatings were deposited on mild steel by both methods.

Samples were treated at 550°C and the oxidation was evaluated by glancing angle X-ray diffraction. Adhesion tests and microscopic observations were performed to compare the behavior of amine- and alkoxide-derived borosilicate coating films.

1 Introduction

In recent years several works have appeared on the deposition by dip-coating of sol-gel films on metal substrates. Inorganic coating films obtained via sol-gel were used as barriers against oxidation of metal surfaces. Particularly borosilicates,[1,2] silica,[3,4] alumina,[5] aluminosilicates,[6,7] zirconia,[8,9,10] and fluorine doped zirconia[11] were used as coating films on stainless steel and mild steel.

Alkoxides were always used as precursors. In previous work[12] an alternative sol-gel technique for the synthesis of oxide materials, based on aqueous solutions of amine-containing precursors,[13–15] was used. Silica coating films were deposited on mild steel by alkoxide and water–amine solutions. The use of the amine route shows important advantages such as reproducibility of the desired chemical compositions, great choice and low cost of raw materials.

In this work borosilicate coating films on mild steel were prepared starting from alcoholic and aqueous solutions. A comparative study of their properties and protective effect against oxidation is presented.

2 Experimental

2.1 Preparation of solutions

One alkoxide and two amine-based solutions were prepared for the deposition of borosilicate coating films.

The borosilicate alkoxide solution, indicated as SiBT, was prepared using tetraethoxysilane, $Si(OC_2H_5)_4$, (TEOS) and triethylborate, $B(OCH_3)_3$, (TEOB) as precursors. The TEOS/TEOB molar ratio was 80/20. TEOS was prehydrolized in ethanol (EtOH) with H_2O (H_2O/TEOS = 5), using HNO_3 as catalyst (HNO_3/TEOS = 0·07). After refluxing for 4 h, TEOB was added and the solution was refluxed for an additional 4 h. The SiBT solution had a concentration of about 10 wt%. Methylamine–Borosilicate solutions (SiBM) were prepared as follows: solid silicic acid was mixed with an aqueous solution of methylamine (MA) (20 wt%) and the obtained mixture was stirred for 1 h in a ball-mill and for one day in a magnetic stirrer.

*To whom correspondence should be addressed.

A methylamine–borate solution was then separately prepared by dissolving boric acid (H_3BO_3) in an aqueous solution of MA. Both solutions were mixed and diluted with water to a concentration of 8 wt% oxides. SiBM solutions with different compositions were prepared to study the effect of the content of boron.

A second type of aqueous borosilicate solution (SiBQ) was obtained using quaternary ammonium cation. A silicate of the quaternary ammonium base was prepared according to the scheme proposed by Weldes,[16] replacing ethanolamine and ethylene oxide with diethylamine (DEA) and propylene oxide (PO) respectively. A solution of diethylamine silicate was prepared by dissolving solid silicic acid in an aqueous solution of diethylamine (25 wt%), stirring the solution 1 h in a ball mill and one day in a magnetic stirrer. Then PO (2 mol per mol of DEA) was added, the solution was stirred for 4 h and heated slightly to evaporate residues of PO and to increase the SiO_2 concentration up to 7 wt%. A borate solution was prepared as previously described for SiBM and added to the silicate solution. The borosilicate solution was diluted with water to a concentration of 5·8 wt% SiO_2 and 1·6 wt% B_2O_3.

2.2 Coating films preparation

Mild steel plates were used as substrates. The steel plates were cleaned ultrasonically in acetone and rinsed with ethanol before coating. Coating films were deposited by dip-coating in a humidity controlled box. The relative humidity was less than 20% for the SiBT samples and less than 40% for the others. After deposition the samples were dried at 60°C for 15 min, heated in air at a constant rate of 5°C/min up to 500°C and immediately left to cool in the off furnace. This thermal treatment will be indicated as Procedure 1.

2.3 Characterization of solutions and coatings

The viscosity as a function of time was measured for SiBT, SiBM and SiBQ, using a rotational viscometer.

The thermal evolution of gel films was observed using a multi-plate platinum holder in a thermogravimetric apparatus (TGA). Thick layers of about 100 μm were poured onto the plates and dried for 1 h at 100°C. Then the temperature was raised up to 1000°C, at a constant rate of 5°C/min.

Coating thickness was measured at different withdrawal rates on films deposited on glass slides under the same conditions as those used for coating the mild steel substrates. The influence of the substrate was assumed to be negligible. The thickness was evaluated with a profilometer, measuring the step on the coating produced with a scratch, after drying at 60°C. Samples were observed by scanning electron microscopy (SEM) after the oxidation test.

A semiquantitative evaluation of the adhesion was done by means of a scratch test, using a microindenter. Samples were moved under the indenter, at a constant rate, using different loads. The load at which delamination was observed was considered as the critical load.

2.4 Oxidation test

The resistance against oxidation was measured on samples treated in air at 500°C (Procedure 1) and on samples reheated at 5°C/min up to 550°C and maintained at this temperature for 1 h (Procedure 2). Oxidation was evaluated by Cu K_α X-ray diffraction with a glancing angle technique. The area (A) of peaks at 2θ = 35·5 (Fe_3O_4 + α-Fe_2O_3) and 2θ = 44·6 (α-Fe) was calculated using a Pseudo-Voigt representation to fit the profiles.[17]

The area ratio of the peaks at 2θ = 35·5 and 2θ = 44·6 was evaluated for coated (R_c) and uncoated (R_u) samples. The ratio R_u/R_c was taken as a measure of the oxidation degree and indicated as the protection factor (PF):

$$PF = \frac{R_u}{R_c} = \frac{\dfrac{A_u\,(Fe_3O_4 + \alpha - Fe_2O_3)}{A_u(\alpha - Fe)}}{\dfrac{A_c\,(Fe_3O_4 + \alpha - Fe_2O_3)}{A_c(\alpha - Fe)}}$$

The kinetics of oxidation at higher temperature were also measured by evaluating the weight gain by TGA, at a constant rate of 5°C/min up to 800°C.

3 Results and Discussion

Figure 1 shows the logarithm of solution viscosity η as a function of time. In the case of SiBM and SiBQ no changes in viscosity were observed even after 60 days from the preparation. For SiBT the viscosity is stable for about 10 days and then abruptly rises.

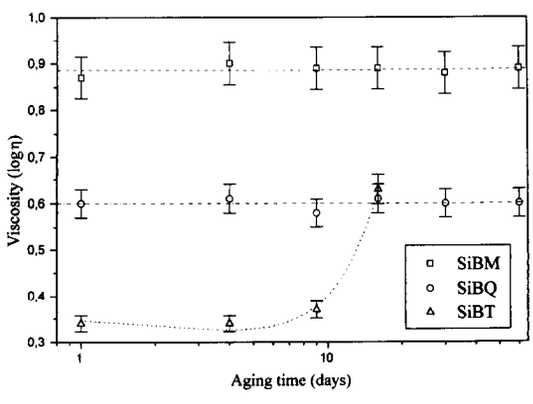

Fig. 1. Viscosity as a function of time for solutions SiBM, SiBQ and SiBT.

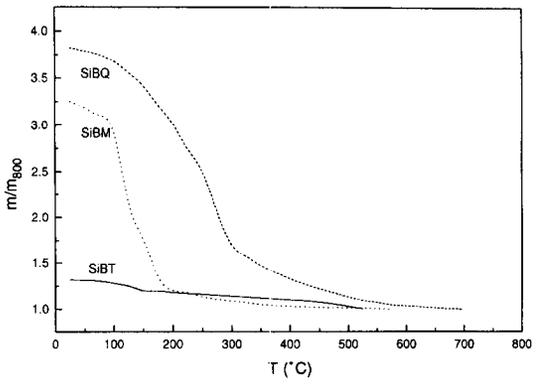

Fig. 2. TGA curves of gels obtained from solutions SiBM, SiBQ and SiBT pre-heated at 100°C for 1 h. m_{800} is referred to the mass value at 800°C.

This different behavior is ascribed to the different chemical character of alkoxide and amine solutions. SiBT, prepared from TEOS and TEOB, undergoes the sol-gel transformation by hydrolysis and condensation of alkoxides. This process continues in time giving the gelation of the solution. For alkoxide borosilicate solutions[18,19] a delaying in the gelation time proportional to the B_2O_3 content was observed and it was ascribed to the decreasing of potential condensation sites due to the trigonal coordinated boron. This can explain the stability of SiBT for about ten days, a longer time than that found with silica solutions. A much higher stability was however observed in the amine solutions, where the high pH values (11–12·5) displace the polycondensation equilibrium to low polymerized silicate and borate anions, which are stable in aqueous solutions. The viscosity of SiBM is higher than SiBQ because of the higher concentration of organic substances in the solution.

Thermogravimetric results are reported in Fig. 2. The curves relative to SiBM and SiBQ show one main effect, associated with an endothermic peak in the DTA. This effect ends at about 200°C for SiBM and 300°C for SiBQ. The weight loss is attributed to the escape of water in the case of SiBT and water

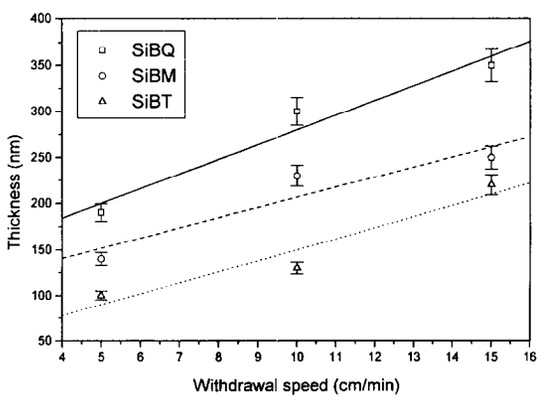

Fig. 3. Thickness as a function of withdrawal speed for coatings obtained from borosilicate solutions SiBM, SiBQ and SiBT.

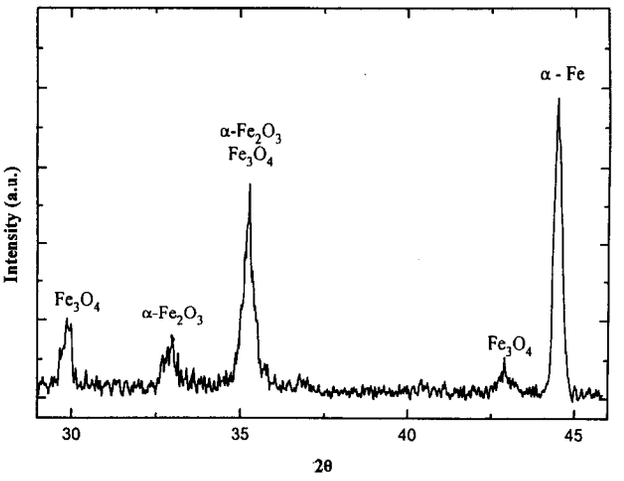

Fig. 4. Typical XRD spectra of a coated sample with partial oxidation of the substrate.

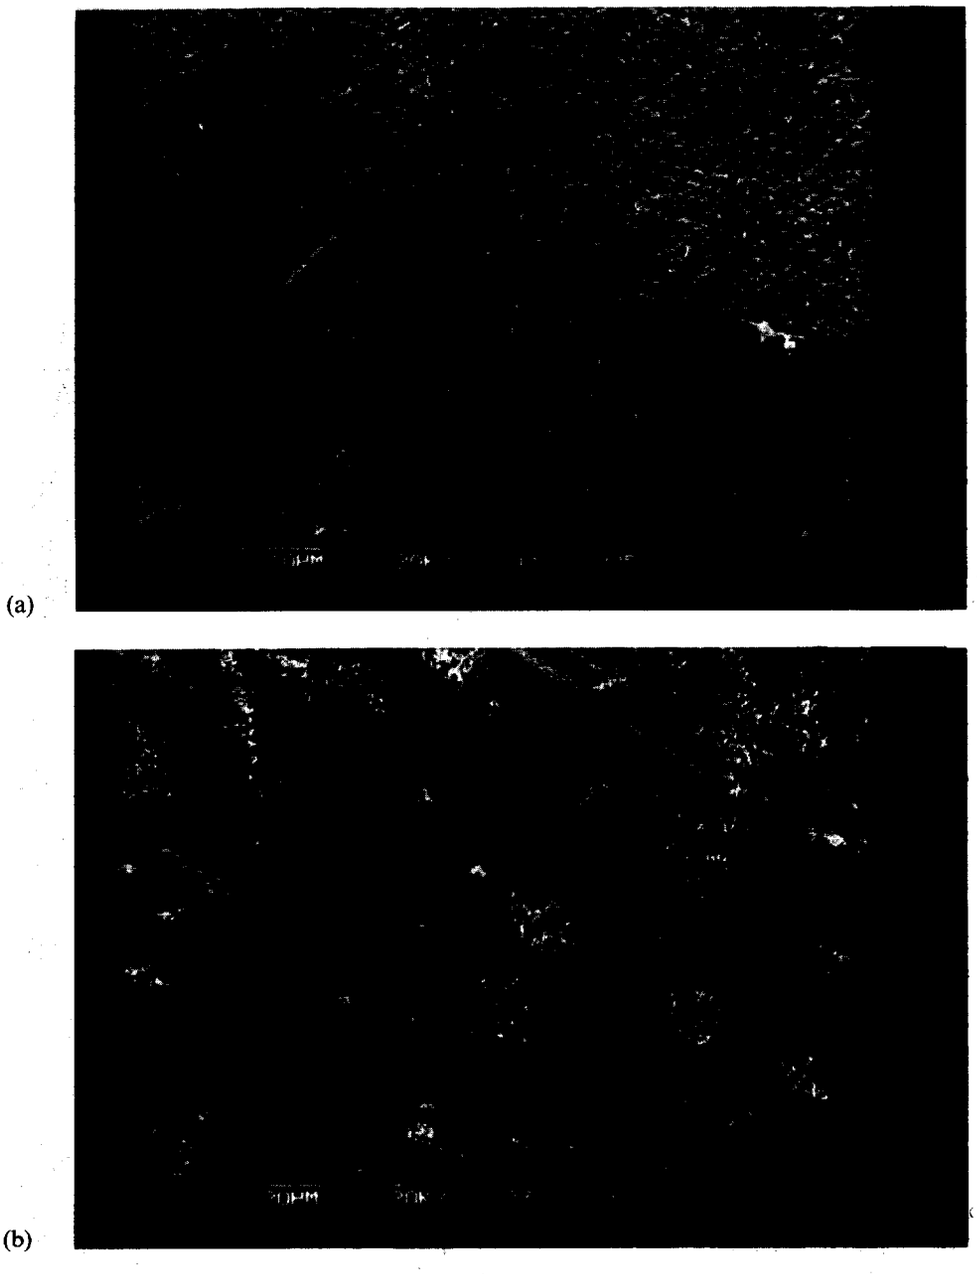
plus MA for SiBM and SiBQ. The difference in the mass loss between SiBM and SiBT may be explained by the quite strong chemical connection of MA and H_2O to the silicate network. Wet SiBT gels contain only non-bonded volatiles (ethanol and water) which are easily removed at 60°C. The mass loss over 60°C is due to the water which results from the reactions of polycondensation that continue up to higher temperatures. The SiBQ curve shows a supplementary mass loss in the range of temperature 400–600°C, accompanied by an exothermic DTA effect. This loss may be attributed to the oxidation decomposition of resin-like residuals of the quaternary ammonium silicate.

Figure 3 shows the thicknesses of the coatings deposited from solutions SiBT, SiBM and SiBQ, at three different withdrawal speeds. In the dip coating process the thickness depends on such solution properties as concentration, viscosity, density and surface tension.[20–22]

In the present case, the thickness differences are mainly due to viscosity (Fig. 1), which increases from SiBT to SiBQ.

Figure 4 shows a typical diffraction pattern obtained from X-ray glancing angle measurements on the coated samples.



Comparative XRD data, obtained in the oxidation tests are reported in Table 1. The data in the table refer to samples after firing at 550°C (Procedure 1) and to samples re-heated at 550°C for 1 h, (Procedure 2). The thickness of the coating films was tailored to obtain almost the same thickness value for SiBT, SiBM, and SiBQ. In the table the data from previous work,[12] where silica coatings were studied, are also reported. The thickness values are quite different in this case, but the data may be useful for comparison. Coatings containing boron may, in general, give higher protection, compared with SiO_2 films. As observed previously,[1] boron probably has the effect of reducing

Table 1. Comparative XRD data relative to the oxidation tests. The reported data are referred to samples after firing at 500°C (Scheme 1) and to samples re-heated at 550°C for 1 h (Procedure 2). Data referred to silica coating films on mild steel[12] are also reported for a comparison.

the intrinsic stress in the sol-gel films. As a matter of fact the critical thickness, t_c, i.e. the maximum thickness achievable free of cracks,[22] is higher. Sol-gel borosilicate coatings, prepared from fresh solutions, have a critical thickness of about 350–400 nm, while typically for silica coatings t_c is about 200–250 nm.[23] Furthermore the lower intrinsic stress may reduce the presence of microcracks in the coatings[1,3] thus increasing the protective action.

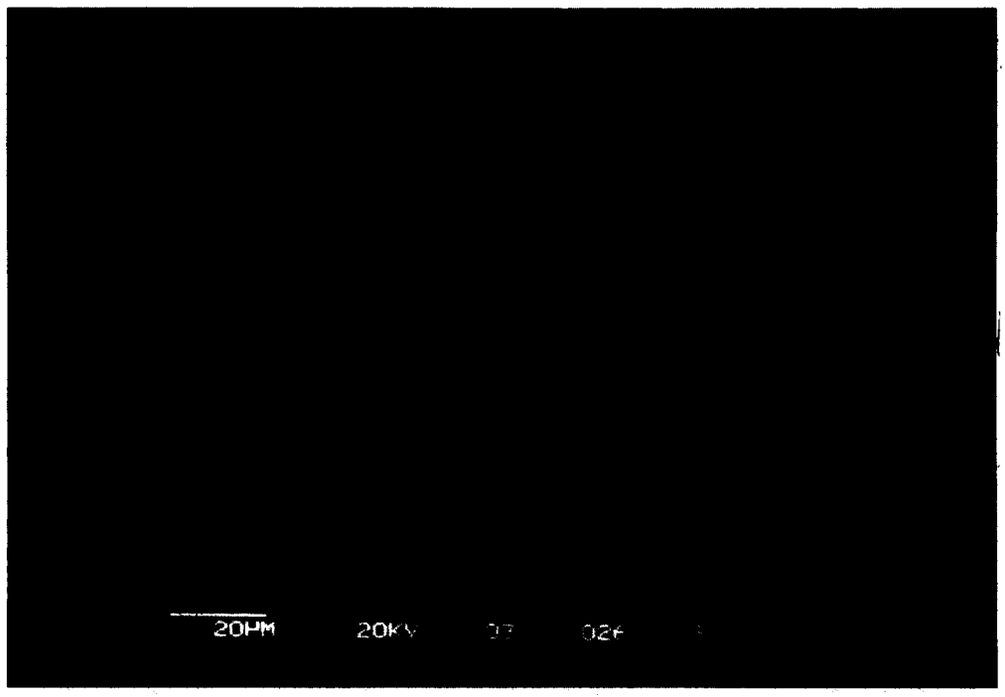

Fig. 5—*contd.*

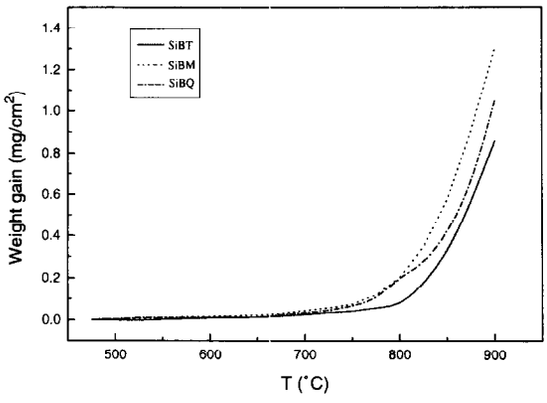

Fig. 6. Weight gain as a function of temperature for samples coated with solutions SiBT, SiBQ and SiBM.

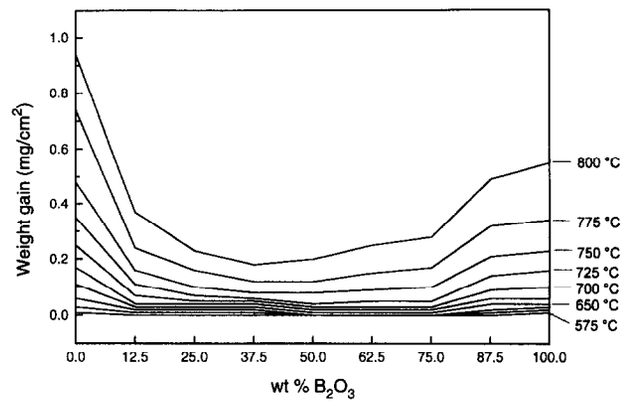

Fig. 7. Weight gain as a function of thermal treatment, for samples coated using SiBM solutions with different B_2O_3 contents.

SiBT and SiBM gave better protection against oxidation, with a quite similar PF; also SiBQ has a good protective effect, even if this is about half that of SiBM and SiBT. As the thicknesses for SiBT, SiBM and SiBQ are quite similar, the differences in the protective effect should be attributed to structural differences in the coatings.

As revealed by SEM observations, SiBT and SiBM coatings were mostly uncracked (Fig. 5(a) and (b)) differently from SiBQ (Fig. 5(c)). Also a different porosity between SiBM and SiBQ might be supposed, due to the different concentration of organic substances in the xerogels. However, due to difficulties in obtaining measures of thin film porosity, a direct proof is not available.

The kinetic results from TGA for the oxidation of samples in the high temperature region (up to 900°C) are shown in Fig. 6. Weight gain up to 750°C is negligible. At higher temperatures, the oxidation of the metallic substrate rapidly increases. In this test no significant difference between samples could be detected.

Figure 7 shows the weight gain as a function of temperature and B_2O_3 content for SiBM samples.

In Table 2, data relative to adhesion tests are reported. For every sample the adhesion was found to be good. SiBM provides the best adhesion.

Table 2. Critical load measured on samples after thermal treatment at 500°C.

Sample	$L_c(g)$
SiBQ	200
SiBT	300
SiBM	500

4 Conclusions

Borosilicate alkoxide and amine derived coatings were prepared on mild steel. Differences in the protective effect against oxidation of the metallic substrate were investigated. The anti-oxidation protective action of coatings was studied by XRD and TGA measurements up to 800°C. Amine derived films showed a protection comparable to that of coatings obtained from alkoxide solutions.

Furthermore, amine derived solutions have much higher stability, and lower costs than alkoxide ones. They are, therefore, more suitable for practical applications.

Effects of Composition Changes on the Crystallization Behaviour and Properties of SiO_2–Al_2O_3–CaO–MgO (Fe_2O_3–Na_2O–K_2O) Glass-Ceramics

V. K. Marghussian & M. H. Dayi Niaki

(Received 4 December 1993; revised manuscript received 10 June 1994; accepted 28 July 1994)

Abstract

Several glass-ceramic materials located in the SiO_2–Al_2O_3–CaO–MgO(Fe_2O_3–Na_2O–K_2O) system were formulated by using naturally occurring materials and 1 wt% chromite ore as a nucleant. The crystallization behaviour of specimens was investigated by using dilatometric, DTA and XRD techniques. It was found that the replacement of CaO by MgO has a profound effect on the crystallization behaviour of specimens and some of them show almost complete crystallization. After a two stage heat treatment, an aluminium dioxide phase was identified as the sole crystallization product in all specimens. The microstructures were investigated by SEM.

It was found that phase separation occurs prior to nucleation of dioxide and the latter phase grows into a fibrous shape. The bending strength of crystallized specimens which range from 31 to 76 MPa depends on the degree of crystallinity and on the porosity of specimens. The hardness and chemical durability values depend only on the amount of crystalline phase.

1 Introduction

Glass-ceramic materials which are produced by controlled nucleation and crystallization of glass have received considerable attention in recent years. Among various glass-ceramic materials those of the SiO_2–Al_2O_3–MgO–CaO (Na_2O,K_2O,Fe_2O_3) system are mainly produced from inexpensive natural or synthetic materials such as blast furnace slags,[1–4] basalts,[5–7] oil shales,[8] granite and tuff.[9]

In the present work, an Iranian andesite rock was used as the main constituent to produce a glass-ceramic material and the effect of compositional changes was investigated. All the chosen compositions were part of the system mentioned above.

2 Experimental Procedure

2.1 Starting materials

Local materials, namely andesite rock from the Goorid mine, Birjand (North East Iran), quartz sand from Ghezel-Ghiyeh, magnesite from Birjand, limestone from Boroojerd and chromite from Faryab were used for glass batch preparation. Six batch compositions were selected for study. The chemical compositions of the raw materials and their resultant glasses are given in Tables 1 and 2 respectively.

2.2 Melting and forming

The batch materials were ground into a fine powder, (-60 mesh for all batches, except chromite which was -200 mesh) and after mixing thoroughly were put into preheated fire clay crucibles and melted in an electric furnace at 1300°C for 3–4 h. The melts, which were homogeneous and bubble free, were then cast into stainless steel moulds. The moulds were previously preheated at 440°C which was calculated according to the Coenen procedure.[10]

The glassy specimens (14 × 2 × 1·5 cm) were then properly annealed at the 'annealing temperature' (T_g+5) for 30 min.

2.3 Heat treatment procedure

Differential thermal analysis (DTA) and dilatometric techniques were used in order to follow the changes occurring during the heating of the specimens and thus to determine the suitable nucleation and crystallization temperatures. Differential

[a] 1 wt% Chromite was added to all batches.
[b] Later omitted due to its incomplete melting.

thermal analysis was made in the range 20 – 1100° using powdered samples together with powdered alumina as an inert reference material. The rate of heating in DTA and dilatometer was 10°C/min and 5°C/min, respectively.

Each glassy sample was held at its appropriate nucleation and crystallization temperatures (as determined by DTA and dilatometric techniques) for 3 h.

The heating rate was 10°C/min up to the nucleation temperature and 1°C/min between nucleation and crystallization temperatures.

2.4 X-Ray Diffraction (XRD) and microscopic examinations

The crystallized samples resulting from any of the above mentioned heat treatment schedules were then subjected to XRD and microscopic studies, using a scanning electron microscope (SEM).

2.5 Determination of the physical and chemical properties

The bending strength, micro hardness, density, porosity and chemical durability of the crystallized samples were determined.

3 Results and Discussion

3.1 The crystallization behaviour of glasses

Table 3 shows the glass transition temperatures

Table 3. T_g and T_d values

Specimen	T_g°C	T_d°C
A	663	720
B	660	720
C	657	715
D	655	700
E	653	700

(T_g) and dilatometric softening points (T_d) for glasses A – E. A typical dilatometric curve, represented in Fig. 1 shows the exact locations of T_g and T_d. It can be concluded from Table 3 that by increasing the content of MgO at the expense of CaO, a gradual decrease in both temperatures has occurred. This can be attributed to the gradual decrease of viscosity due to the replacement of CaO by MgO.

Figure 2 gives a typical DTA curve. An endothermic peak is observed beginning at 657°C (T_g) and reaching a maximum at 715°C (T_d), which can be attributed to the glass transition.

The exothermic dip centred at about 915°C is associated with the crystallization of glass. The suitable nucleation temperature (T_n) is usually taken in the 'nucleation range', between T_g and T_d.

The T_n values were determined using 'trial and error', which consisted of holding the specimens at various temperatures within the nucleation range in a gradient furnace, followed by a second hold at 'crystallization temperature' and observing the appearance of specimens. Afterwards, it was found that T_n values determined in this way can also be located approximately at the point where a distinct slope change appeared in the endothermic 'hill' in the DTA curve (Fig. 2). This was later proved to be associated with glass in glass separation.

It is interesting to note the T_n values determined from DTA traces may be fitted into an approxi-

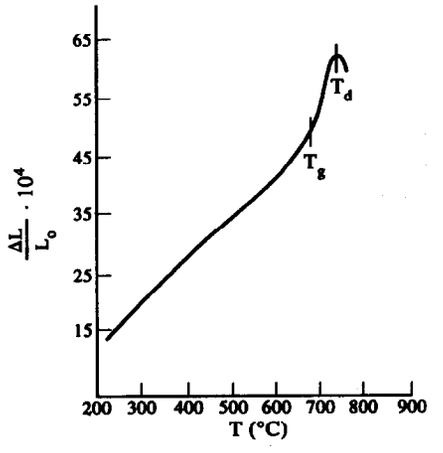

Fig. 1. Dilametric expansion curve of specimen C showing T_g and T_d values.

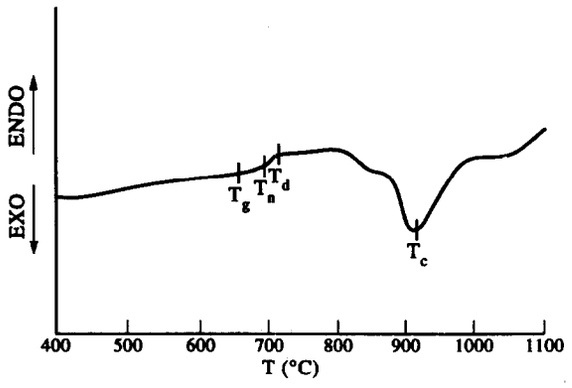

Fig. 2. DTA trace of specimen C showing, T_g, T_d, T_n and T_c values.

mate formula which relates the T_n values to the values to the glass transition and dilatometric softening points:

$$T_n = T_g + \frac{2}{3}(T_d - T_g). \quad (1)$$

Table 4 shows the nucleation and crystallization temperatures for glass samples. The gradual decrease of crystallization temperatures can also be related to the drop in viscosity caused by compositional changes.

3.2 XRD analysis

X-ray diffractometry performed on various heat treated specimens showed that an aluminium dioxide with a pattern very similar to 'Fassaite', Ca $(Mg_{0\cdot8}Al_{0\cdot2})$ $(Si_{1\cdot8}Al_{0\cdot2})O_6$ is the sole crystalline phase observed in all specimens. Regarding the compositions of glass samples, it is likely that some Fe, Na and K have also been substituted in the crystal structure (mainly for Ca). Figure 3 gives the XRD patterns for all specimens. Sample A obviously shows no sign of crystallization and exhibited only slight surface crystallization.

A quantitative X-ray analysis was performed according to the Ohlberg and Stickler method,[11] later revised by Kim *et al.*[12] Figure 4 presents the crystallization results. The amount of crystalline phase rises (Sample B to C), then drops (Sample C to D), finally rising to a very high value (95%). This behaviour can be attributed to competing

Table 4. The nucleation and crystallization temperatures

Specimen	*Nucleation temp from DTA* (T_n)°C	*Nucleation temp Calculated from Eqn. (1)* °C	*Crystallization temp.* °C
A	700	701	920
B	700	700	918
C	693	696	917
D	690	685	910
E	685	684	906

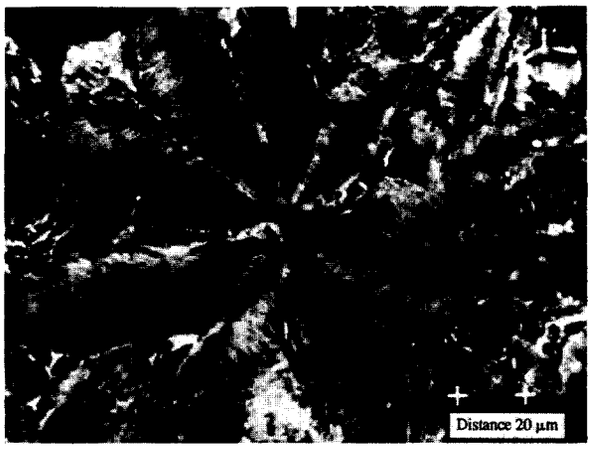

Fig. 5. SEM micrograph of specimen C showing flower-like crystalline aggregates (polished and etched in 2% HF for 5 min.)

thermodynamic and kinetic factors. As was stated previously, the viscosity decreases as a result of replacing CaO by MgO. This increases the crystallization rate. The liquidus temperature is another factor which can affect the crystallization behaviour. The rise of liquidus temperature enhances the crystallization and its drop favours the glass stability. It can be concluded therefore, that the liquidus temperature has probably increased from Specimen B to C and D to E (or if it has decreased the effect of viscosity has predominated), whereas from Specimen C to D the liquidus temperature has dropped. In addition to these factors which affect the growth process, other factors relating to nucleation, such as the effect of composition on surface tension or phase separation, may also be involved.

3.3 Microscopic examinations

Figure 5 shows the micrographs taken by SEM from polished and etched crystallized specimens. The specimens exhibit a special type of dendritic growth giving rise to flower-like crystalline collections. The microstructures of various specimens

Fig. 6. SEM micrograph of glass C after a 3 h hold at nucleation temperature showing extensive phase separation.

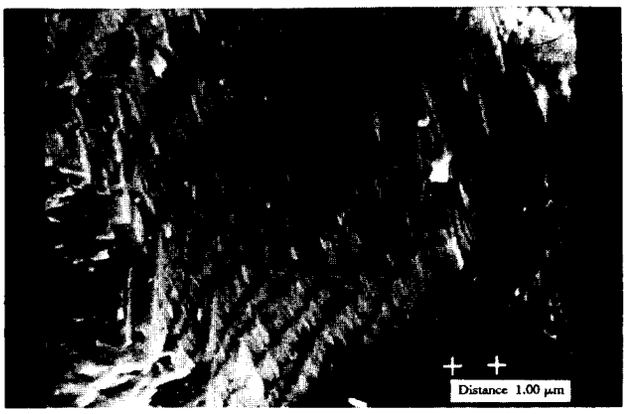

Fig. 7. SEM micrograph of glass C after crystallization showing fibrous morphology of dioxide crystals.

were also studied by SEM using fractured surfaces. Glassy samples which immediately after forming were annealed, did not show any sign of phase separation and inhomogenity up to a magnification of 300 000.

Figure 6 shows that after 3 h hold at the nucleation temperature the glassy sample has became highly phase separated. This observation is in agreement to findings of other investigators.[8,13]

According to McMillan,[13] "chromium in the Cr^{6+} state, being an ion of high field strength is likely to occupy an interstitial position and exert a marked 'ordering' effect upon its surrounding oxygen ions. Under these circumstances a chromium rich phase would separate out from the glass". A mixed spinel of formula $(Mg,Fe)(Al,Fe,Cr)_2O_4$ is then crystallized within the chromium rich phase and acts as a nucleant inducing the crystallization of dioxide.[8] It is likely that the above mentioned nucleation mechanism is also operative in the present investigation, although it was not possible to observe and identify the actual nucleating agents. Figure 7 shows the SEM micrograph of crystallized C glass.

It can be seen that the 'flower like' crystalline collections are themselves composed of 'thread like' fibrous aggregates which have grown in parallel orientation.

The fibrous aggregates consist of tiny, elongated crystals of dioxide, having about 1 μm average length and 0·1 μm average width. These crystals have grown parallel to each other in a direction which makes an angle of about 55–60° with the major axis of 'threads'.

3.4 Mechanical properties

Figure 8 gives the results of three point bending test which was carried out according to ASTM procedure C 158-84 over a span of 10 cm in bars (12 × 2 × 2 cm) cut roughly from original specimens and then ground to size. Each point represents

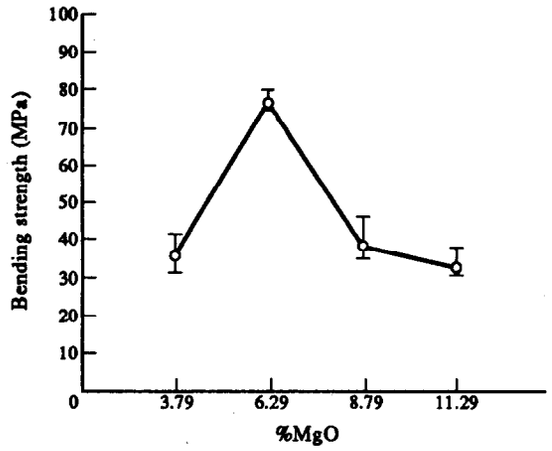

Fig. 8. Bending strength values as a function of composition (wt%). (Each point represents the average value for 10 specimens).

the average value for ten specimens.

It can be concluded that the main factor contributing to the bending strength is the amount of crystalline phase. The relatively low value for Specimen E, in spite of its very high crystallinity, can be attributed to it relatively high value of porosity (see Table 5). It seems that the porosity is mainly formed at the final stage of crystallization. At this stage, the lack of sufficient glassy phase to fill the gaps resulting from crystallization (due to a difference between densities of glassy and crystalline phases) leads to formation of some porosity. The viscous flow of glassy phase at the earlier stage of crystallization, results in pore filling and overall shrinkage of specimens without any considerable pore formation. Our calculations showed that the density of glassy specimens were in the range 2·67–2·69 Mgm^{-3} whereas the mean density of crystalline phase was 3·15 Mgm^{-3}.

From Fig. 9 which shows the knoop hardness values of various specimens, it can be concluded that with increase of crystallinity, the hardness values were also increased. (The hardness tests

E	Negligible	25·03

[a] Average values for 3 specimens.

were performed at pore-free regions of specimens under a weight of 500 g.) Each point represents the average value for three specimens.

3.5 Chemical durability

Table 6 shows the results of chemical durability of specimens after crystallization. Chemical durabilities were determined by weight loss of polished samples after immersion in 5% NaOH and 5% HCl solutions at 95°C for 24 h.

It is apparent that the resistance to acids is also a function of the crystallinity of material. Specimen E which has the highest amount of crystalline phase shows the highest resistance to acids.

4 Conclusions

Useful glass-ceramic materials can be made by using andesite rock as the primary raw material together with some lime, silica and MgO additions. Chromite ore 1 wt% is sufficient to induce glass in glass phase separation which is a precursor to nucleation in these glasses. A mixed spinel phase precipitating from a chromium rich phase after phase separation, probably acts as a nucleation agent. The replacement of CaO by MgO has a marked effect on the crystallization behaviour of glass compositions studied. There exists an optimum amount of MgO which gives rise to the highest amount of crystalline phase in a standard two stage heat treatment schedule. Although the physical and chemical properties of these glass-ceramic materials generally improve with their degree of crystallinity, the specimen with the highest amount of crystalline phase is not necessarily the strongest one. Specimen C which is almost 80%

crystalline exhibits the highest bending strength. It also possesses acceptable values for hardness and chemical durability and can be used as a suitable, inexpensive construction material.

(Received 14 April 1994; revised version received 14 July 1994; accepted 1 August 1994)

Abstract

Subsolidus phase relationships in the systems Ln–Si–Al–O–N where Ln = Nd and Sm have been determined. Forty-four compatibility tetrahedra were established in the region Ln_2O_3–Si_3N_4–AlN–Al_2O_3. Within this region, $LnAlO_3$ and M'-phase ($Ln_2Si_{3-x}Al_xO_{3+x}N_{4-x}$) are the only two important compounds which have tie lines joined to β-sialon and AlN polytypoid phases. α-Sialon coexists with the M' phase.

1 Introduction

It is well known that metal oxides are necessary for the densification of silicon nitride ceramics. During sintering, the metal oxide additives and silicon nitride (which unavoidably contains a small amount of silica as an impurity), form an eutectic melt which aids densification. The liquid composition affects the resulting microstructure and hence the properties of the final ceramics; it also determines the nature of grain-boundary crystalline phases after heat-treatment.

The importance of using rare earth oxides for the densification of silicon nitride ceramics has been recognized during recent years. Not only are they very effective for densification, either singly, or in combination with yttria, but also they can be accommodated in the α-sialon lattice, thus providing an opportunity for decreasing the transient liquid phase content after sintering, and hence reducing the amount of residual grain boundary glass. Therefore, phase relationships in Ln–Si–Al–O–N systems are of particular interest. The determination of a whole system, represents a very large amount of work and most previous studies have been restricted to the sub-systems Ln–Si–O–N,[1] Ln–Al–O–N (Ln = Ce, Pr, Nd and Sm)[2] and some planes involving α- and β-sialon.[3,4] In oxygen-rich compositions, there exist two five-component phases,[5–7] U-phase ($Ln_3Si_{3-x}Al_{3+x}O_{12+x}N_{2-x}$) and W-phase ($Ln_4Si_9Al_5O_{30}N$), which have no corresponding counterparts in the Y–Si–Al–O–N system. In the Ln_2O_3–Si_3N_4–AlN–Al_2O_3 sub-system where Ln = Sm, Nd, four compounds: Ln–melilite, $LnAlO_3$, Ln_2AlO_3N and MP ($LnAl_{12}O_{18}N$) have been identified (Fig. 1). The Ln–melilite phase extends into a five-component system, with Si and N being substituted by Al and O to form a solid solution, M', with a range of homogeneity from $x = 0$ to 1 in the formula $Ln_2Si_{3-x}Al_xO_{3+x}N_{4-x}$.[8,9] Work at Shanghai[2] on Ln–Al–O–N systems has shown that the nitrogen-containing magnetoplumbite phase of formula $LnAl_{12}O_{18}N$ is unstable in the pure oxide system.

The purpose of the present work is to complete the study of phase relationships in the region of the Ln–Si–Al–O–N systems defined by the four end-members Si_3N_4, AlN, Al_2O_3 and Ln_2O_3 (Ln = Nd,Sm). This region includes the phases α-sialon, β-sialon and AlN polytypoids, and covers the range of compositions used for the design and processing of commercial multi-phase sialon ceramics.

2 Experimental Procedure

The present paper is the result of two work programmes carried out separately at Shanghai Institute of Ceramics and the University of

All the symbols have the same meaning as in Table 1 except Ln (here Ln represents Sm).

(99·9%, Yaolung Chemical Works, China# and 99·9%, Aldrick Chemical Co. Ltd*). The oxygen contents of the nitride powders were taken into account in calculating the compositions. The starting powders were weighed out and ground in absolute alcohol# or isopropanol* using an agate pestle and mortar. The mixed powders were dried and pressed into pellets 10 mm in diameter and were then isostatically pressed under a pressure of 200 MPa. The specimens prepared at Shanghai were fired in a graphite-resistant furnace with a rather slow cooling rate (~50°C/min) whilst those at Newcastle were fired in graphite-resistant or tungsten element furnaces both of which could be cooled down to room temperature very quickly (~100°C/min). A nitrogen atmosphere was used in all cases. The specimens with the compositions near liquid phase region were prepared in Shanghai and then heat-treated in Newcastle. The heat-treatment was carried out either in a tungsten element furnace (at 1150–1450°C) or in a molybdenum element furnace (at 1550°C). All specimens were examined by X-ray diffractometry# or using a Hägg–Guinier focusing camera*. Only specimens showing less than 3% weight loss after firing were used for data analysis.

3 Results

Twenty five Nd-containing compositions and 17 Sm-containing compositions in the region bounded by Si_3N_4, AlN, Al_2O_3 and Ln_2O_3 were studied to establish compatibility relationships. The binary tie lines established were based on the results listed in Tables 1 and 2. In the region explored, the same phases were observed in both systems, but it was noted that melting temperatures were lower in the samarium system and consequently, at a given temperature, the size of the

MP = $LnAl_{12}O_{18}N$; M' = $Ln_2Si_{3-x}Al_xO_{3+x}N_{4-x}$; J = $Ln_4Si_2O_7N_2$; 15R, 12H, 21R, 27R, $2H^{\delta}$ are those on the Si-rich end of AlN polytypoids; 15R', 12H', 21R', 27R', $2H^{\delta'}$ are AlN polytypoids on the Al-rich end.

liquid-forming region is larger. Based on the much more extensive knowledge of phase relationships in the Y–Si–Al–O–N system[10–13] and other information in the literature listed above, 44 compatibility tetrahedra were established in this region for both Nd and Sm (Table 3).

As indicated in this table, tie lines exist between the compound $LnAl_{12}O_{18}N$ and all the AlN polytypoid phases as well as β_{60} (the maximum limit of the β-sialon solid solution). The compound $LnAlO_3$ was found to be compatible with β-sialon in the range $\beta_{10}(z = 0{\cdot}8)$–$\beta_{60}$, and also with the Si-rich terminal compositions of the AlN polytypoid phases. Compatibility tetrahedra are also formed between α-sialon, the Si-rich ends of the AlN polytypoid ranges (from AlN to 21R) and M'-phase. M' was also found to have tie lines with β-sialon from $\beta_0(\beta\text{-}Si_3N_4)$ to β_{10}, forming two $\alpha' + \beta'$ containing compatibility tetrahedra α'–β_0–β_{10}–M' and α'–β_{10}–21R–M'. $LnAlO_3$–AlN polytypoid and α'–β' two-phase regions are represented graphically in Figs 2–4. In the present work, α-sialon is considered as a point composition and its detailed solid solution range has not been determined.

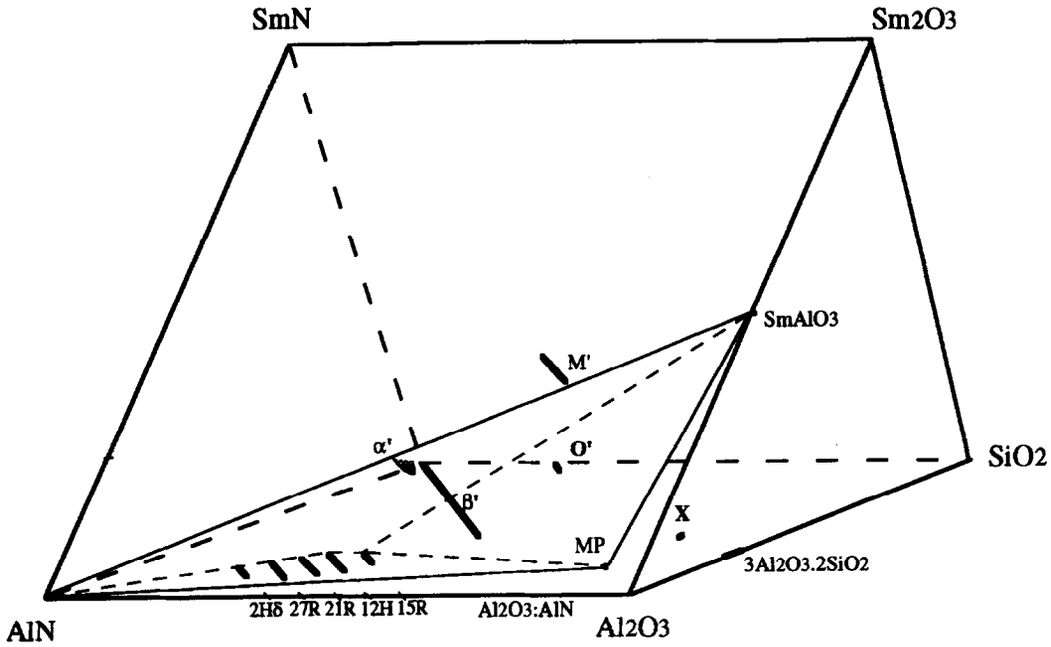

Fig. 2. Sm(Nd)AlO_3 is compatible with all polytypoid phases (Si-rich terminal), AlN and Sm(Nd)$Al_{12}O_{18}N$ (MP-compounds) forming five compatibility tetrahedra: Sm(Nd) AlO_3–15R–MP–12H; Sm(Nd)AlO_3–12H–MP–21R; Sm(Nd)AlO_3–21R–MP–27R; Sm(Nd) AlO_3–27R–MP–2Hδ and Sm(Nd)AlO_3–2Hδ–MP–AlN.

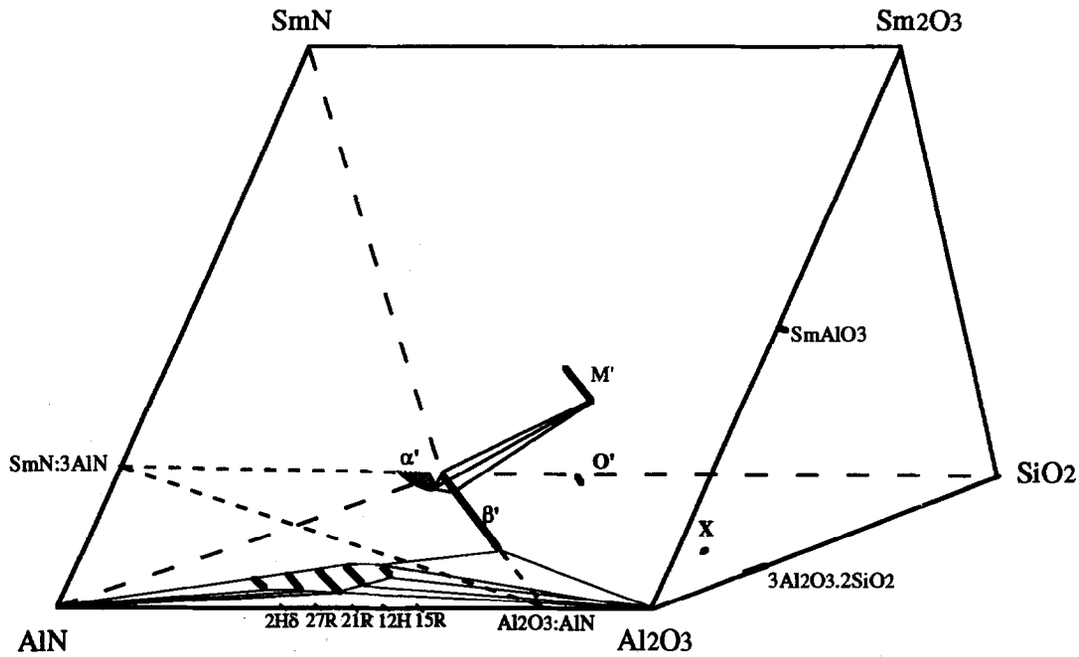

Fig. 3. M'(melilite solid solution) is compatible with β-sialon (β_0–β_{10}) and α-sialon forming α'–β'–M' compatibility tetrahedron.

4 Discussion

Previous work in the Nd-system[4] showed that at 1700°C, the liquid phase region in this system intersects the β-sialon–$NdAlO_3$ plane (Fig. 5). Moreover, $NdAlO_3$ does not appear in nitrogen-rich compositions on this plane. These observations are in contrast to the behaviour of YAG ($Y_3Al_5O_{12}$) in the β-sialon–YAG system. The appearance of 12H polytypoid phase on the β-sialon–$NdAlO_3$ plane implies that it must be in equilibrium with a liquid phase of more silica-rich composition than those on the plane. Recently, heat-treatment studies of Ln–Si–Al–O–N (Ln = La–Yb) glasses,[14] have indicated that the resulting crystalline phases vary with the composition of the glass, the atomic number (i.e. ionic radius) of the rare earth element and with the heat-treatment temperature. In the Nd- and Sm-systems, at lower temperatures (1000–1200°C), wollastonite ($LnSiO_2N$) and U-phase are the main crystalline phases formed from glasses in equilibrium with mixed α + β sialons, and with increasing temperature, $LnAlO_3$ appears. U-phase, of composition

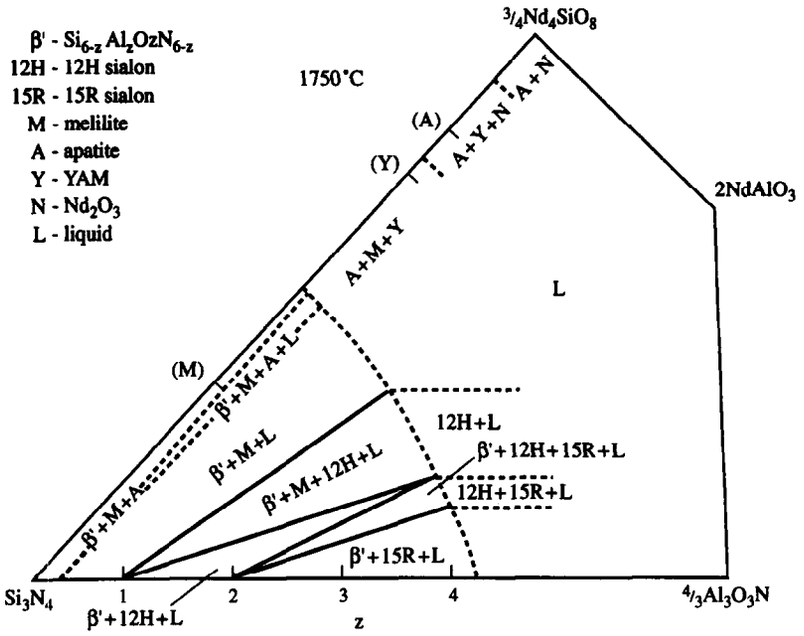

Fig. 5. Phase relationships of β'–$NdAlO_3$ plane at 1750°C.

$Ln_3Si_{3-x}Al_{3+x}O_{12+x}N_{2-x}$, where $O < x < 1$, is a crystallization product of Ln–Si–Al–O–N glasses in equilibrium with β-sialon, heated in the range 950–1400°C. The stability of this phase increases with cation size, and the melting point is around 1390°C.[6]

In the region studied, $LnAlO_3$, M'-phase and U-phase were the main phases observed after heat-treatment in the temperature range 1150–1550°C. Suitable devitrification temperatures for the formation of $LnAlO_3$ are in the range 1250–1450°C. At lower temperatures (1150–1250°C), U-phase occurred instead. In the oxygen-rich compositions explored in the present work, U-phase always occurred after heat-treatment (or even after firing in the Shanghai furnace, which has a slower cooling rate). The occurrence of U-phase in the region studied can not be considered as an equilibrium phase under subsolidus temperature conditions and is only an incompletely recrystallized form of the liquid phase. In Si_3N_4-rich compositions, M'-phase often occurs after sintering, increasing in amount after further heat-treatment at $\approx$1550°C. This is because the composition of M' is nearer to the liquid phase region and therefore M' phase dissolves into the melt during firing. The crystallization temperature for M' is about 1550°C. In establishing subsolidus phase relationships, the judgement on the correct equilibrium phases under subsolidus temperature conditions can sometimes be a difficult problem. Using phase assemblages observed at the same temperature for all conditions studied might lead to mistaken results, since different compositions may need different temperatures to fully crystallize the liquid phase.

In the present work, all starting compositions were designed to fall on supposed tie lines or into supposed compatibility triangles. For examples, in the Sm system, compositions Nos 2, 3 and 5 were on the lines between M' ($Ln_2Si_2AlO_4N_3$) and β-Si_3N_4, β-sialon ($z = 1$) and β-sialon ($z = 2$) respectively; Nos 1, 8 and 9 were on composition lines between $SmAlO_3$ and Si_3N_4, β-sialon ($z = 4$) and β-sialon ($z = 2$), respectively. If the expected phases were obtained after heat-treatment under a particular set of conditions, then equilibrium was believed to have been achieved. Based on this philosophy, compositions marked with the symbol '^' in Tables 1 and 2 were believed to have achieved equilibrium and were used to establish the subsolidus phase relationships. Composition No. 1 (Table 2) only gave M' and apatite ($Sm_{10}(SiO_4)_6N_2$) after heat treatment at 1350 and 1550°C, which indicated that the supposed tie line β-Si_3N_4–$SmAlO_3$ does not exist. In composition No.5(Table 2), the absence of M' phase implies that M' is not compatible with β_{13}. The coexistence of β-sialon with M' was found to be restricted to the range β_0–β_{10}. From the X-ray diffraction data of M' and β-sialon, it seems that Nd- and Sm-melilite ($Ln_2O_3.Si_3N_4$) has priority over β-Si_3N_4 in accommodating Al and O (thereby forming M' phase) and therefore the tie lines between melilite and β-sialon do not run parallel. The oxygen-containing α-sialon phase occurring in the present samples is believed to have a composition close to the oxygen-rich limit of the α-sialon homogeneity range in these systems; this phase is also compatible with M'.

α-sialon, 12H and 15R sometimes occurred in compositions located on the β-sialon–$LnAlO_3$ and β-sialon–M' planes, and decreased in amount or even disappeared after heat-treatment. This is partly because the liquid phase in these compositions shifts in composition with temperature, and also because some $\alpha \rightarrow \beta$ sialon transformation occurs in these samples.[15] J-phase ($Ln_4Si_2O_7N_2$) should occur in compositions along the line joining Ln_2O_3 to Si_2N_2O, but it always appears at the composition $3Ln_2O_3$:Si_3N_4, just as in the Y–Si–Al–O–N system. This could be attributed to the unavoidable existence of a silica layer on the surface of silicon nitride. In the Y–Si–Al–O–N system, J-phase forms a continuous solid solution with YAM ($Y_4Al_2O_9$). In the present work J-phase solid solution (J') was never observed. Composition Nos 11 and 12 (Table 2) were designed to produce J- and J'-phase and the X-ray data did not show visible differences in d-values between these two J-phases.

Of the 44 compatibility tetrahedra established in the present work, the following six which involve α-, β-sialon and AlN-polytypoids (which could be used as reinforcement phase for α', β' or α'-β' because of its fibre-like morphology) and the promising grain boundary phases M' and $LnAlO_3$, are the most useful for the design of multi-phase sialon ceramics. They are: α-sialon–β_0–β_{10}–M'; α-sialon–β_{10}–21R–M'; β_{25}–15R–12H–$LnAlO_3$; β_{25}–β_{10}–12H–$LnAlO_3$; β_{10}–12H–$LnAlO_3$–M' and β_{10}–12H–21R–M'.

5 Conclusions

Subsolidus phase relationships in the systems Ln_2O_3–Si_3N_4–AlN–Al_2O_3 (Ln = Nd, Sm) have been determined. Forty-four compatibility tetrahedra have been established in this region. $LnAlO_3$ coexists with β-sialon, approximately from β_{10} ($z = 0{\cdot}8$) to β_{60}($z = 4$). The liquid phase crosses the tie line between $LnAlO_3$ and β-sialon at firing temperatures (1600–1700°C) and therefore β-sialon–$LnAlO_3$ two-phase materials can only be

obtained after heat-treatment in the range 1250–1450°C. The coexistence of M' with β-sialon is restricted to the range β_0–β_{10}. α-Sialon is also compatible with M'. The compatibility tetrahedra α-sialon–β_0–β_{10}–M'; α-sialon–β_{10}–21R–M'; β_{25}–15R–12H–$LNAlO_3$; β_{25}–β_{10}–12H–$LnAlO_3$; β_{10}–12H–$LnAlO_3$–M' and β_{10}–12H–21R–M' are the most useful for the design and processing of multi-phase sialon ceramic materials.

(Received 14 March 1994; revised version received 26 June 1994; accepted 1 August 1994)

Abstract

Alumina tapes, obtained by tape-casting, were produced from different slurry compositions. The effects of organic phase concentration on the mechanical and physical properties of green and fired tapes was measured.

The amount of organic phase used did not influence the apparent density of green tapes as long as the volume of organics introduced in the slurry was lower than the pore volume of the tape. Beyond this limit, grain separation occurred, which induced a decrease in material density.

Mechanical properties of tapes, in particular the maximum strength and the rupture elongation, were strongly influenced by the organic phase concentration. Variations in these properties were dependent on the level of filling of the tape porosity by the organic phase.

1 Introduction

Tape-casting is becoming a routine process for the formation of thin ceramic sheets.[1,2] The production of ceramic tapes by this process requires the use of significant amounts of organic compounds (solvents, binders, plasticizers, and dispersing agents).

Studies carried out on tape-casting show that a large diversity of slurry compositions are used.[3] For this process of shaping ceramics, the mechanical and physical characteristics of the green tapes are very important for further processing and the final properties of the material. Indeed, after the drying stage, the tape can be either stored (roller) or made in to the desired shape and dimension (cutting, punching, etc). The ceramic tape must then have the flexibility and strength required for tape handling. On the other hand, the powder compactness inside the green tape will have an effect upon the physical properties of the fired material and in particular upon the tape density. The physical and mechanical properties for a given powder will depend upon the type and quantity of the organic phase introduced inside the suspension.

Generally, work carried out on this theme showed an increase in the mechanical strength of tapes with the rise of the binder content[4] and a tape elongation which increased with the increase of the plasticizer content to the detriment of the mechanical resistance of the material.[5,6]

However, little of the work showed the evolution of mechanical and physical properties as a function of filling level of the porous volume of tape by the organic phase. The purpose of this study was to determine the significant relationship between the physical and mechanical properties of green and sintered tapes, the concentration of organic phases used and the porous volume of tapes.

2 Experimental Study

2.1 Starting material

The raw material used for tape production was an alumina powder (Al_2O_3, CT530SG, Alcoa, USA). Its physical characteristics are shown in Table 1. This powder was a low soda grade (Na_2O = 0·08 wt%) with a nominal purity higher than 99·7% in weight of alumina.

2.2 Slurry composition

Al_2O_3 slurry dispersion was carried out in an azeotropic solvent mixture of trichloroethylene–ethanol (72/28 wt%) using a phosphate ester type (Beycostat C213 CECA, France) dispersing

Table 1. Physical characteristics of Al_2O_3 powders

Specific surface area (m^2/g)	*Mean particle diameter* (μm)	*Density* (g/cm^3)
4·2	1·3	3·98

agent.[7–9] Cohesion between powder grains was ensured with a polyvinylbutyral resin (PVB, Butvar B98 Monsanto) which was plasticized by dibutylphthalate (DBP, Aldrich Chemical). So, the production of a tape-casting suspension requires the use of numerous organic compounds. Competition can occur between the adsorption of the different compounds onto the particle surface to reduce the effectiveness of these products.[10–12] For this reason, the introduction sequence of different organic compounds inside the slurry was important. Thus, the dispersing agent was introduced in order to optimize the slurry defloculation. A first milling, within 4 h, was carried out with the powder, the solvent and the dispersing agent.

The binder and the plasticizer were then added and the suspension was mixed again after 20 h in order to obtain a good homogenization between mineral and organic compounds. These milling operations were carried out with a planetary grinding. Alumina containers and balls were used in order to minimize the pollution.

Slurries were produced with a binder content varying between 2 and 7 wt% (of Al_2O_3 concentration) and a plasticizer content varying between 0 and 300 wt% (of binder concentration). Dry matter content was fixed at 68 wt% and dispersing agent content was equal to 0·8 wt% (of Al_2O_3 concentration) for all experiments. The slurry viscosities were maintained at 1500 ± 100 mPa s using suitable solvent content.

2.3 Casting

Al_2O_3 slurries were cast on a bench by means of the doctor–blade method. The mobile carrier consisted of a polyester film, with the blade height adjusted in order to obtain tapes with a thickness of about 300 μm. Tape drying was carried out at room temperature and in the open air.

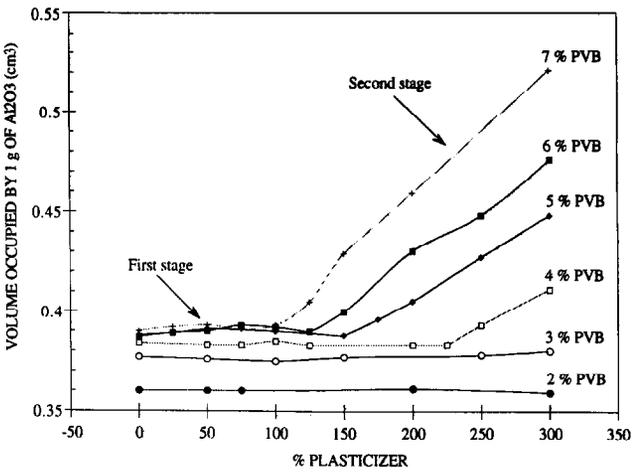

Fig. 1. Evolution of tape volume apparent as a function of plasticizer content at different binder (PVB) concentrations.

V_{lim} Maximum volume to be filled	0·109	0·125	0·133	0·138	0·140	0·141

2.4 Tape characterization

The influence of organic composition on the density of the material was studied by mercury porosimetry (Poresizer 9310 Coultronics). This instrument determines the apparent volume of 1 g of sample (powder + organic). Therefore, the powder weight inside 1 g of tape varies with the amount of organic phase used. For this reason, the accurate volume occupied by 1 g of Al_2O_3 was calculated using the porosimetry results and tape formulations.

Mechanical properties, in particular the maximum strength and the rupture elongation were

measured for different tape formulations. Measurements, performed 1 week after the slurry casting, were carried out on tapes of 300 μm thickness and dimensions corresponding with NFT51034 standard. Stress and elongation values obtained on the tape, were dependent on the loading rate.[13] For studied compositions, preliminary trials showed a stabilization of these characteristics from rates equal to or higher than 20 mm/min. Thus, the loading rate of the testing machine (Adamel Lhomargy DY30) was then fixed at 20 mm/min, for all experiments.

The rupture elongation of the tapes was measured by the cross-slide movement. Force cells used for these trials were of 10 and 100 N. Twenty specimens of each formulation were tested.

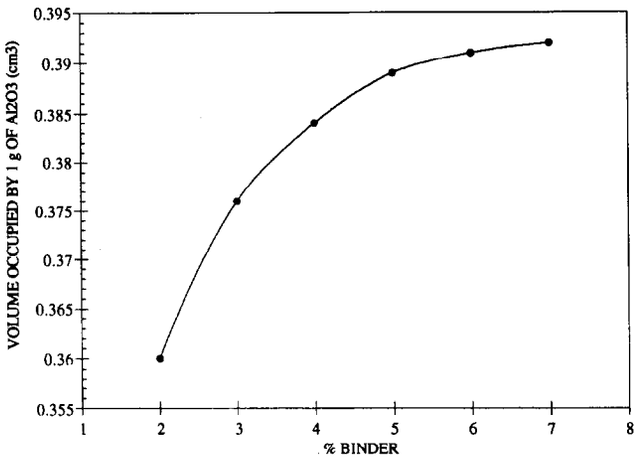

Fig. 2. Evolution of tape volume apparent for different binder contents and plasticizer contents giving an organic volume lower than porous volume of the tape (first stage).

3 Results and Discussion

3.1 Physical properties

The effect on the apparent volume of the tape (volume occupied by 1 g of Al_2O_3) as a function of increasing plasticizer content was studied on tapes fabricated with different binder contents (Fig. 1). When the binder content was equal to or higher than 4 wt% of powder content, two regions were observed as the plasticizer content was increased:

In the first stage, the volume occupied by 1 g of alumina remained constant. Organic compounds (binder, plasticizer, dispersing agent) filled the porous structure of the material without changing the distance between powder grains. In the second stage, a rearrangement of the structure occurred. The distance between the grains increased and there was a significant increase in tape volume. In this stage, the organic volume was higher than the porous volume of the tape.

For binder contents equal to 2 and 3 wt%, only the first stage is observed. The difference between the experimental volume occupied by 1 g of powder inside the tape (volume measured in the first stage, which remained constant up to a certain plasticizer concentration for the different binder contents, V_{mea}) and the theoretical volume of 1 g of Al_2O_3 (V_{th} = 0·251 cm^3) gave the limit value of organic volume (V_{lim}) beyond which structural modification of the tape occurred (Table 2)

$$V_{lim} = V_{mea} - V_{th} \quad (1)$$

Comparison between V_{lim} and V_{org} values for the different compositions (Table 3) shows that total filling of the porous structure of the tape by the organic phase would not be reached for tapes with 2 and 3 wt% of binder content, whatever plasticizer content used. However, for tapes containing 4, 5, 6 and 7 wt% of binder content, V_{org} would exceed V_{lim} for plasticizer amounts of about 250, 200, 150 and 125% respectively. These calculated values, are in agreement with the observed increases of tape volume (Fig. 1).

Whereas increasing plasticizer content did not change the volume filled by 1 g of Al_2O_3 for a given binder amount (when $V_{org} < V_{lim}$), increasing binder content induced an increase in this volume, measured in the first stage. However, for binder concentrations greater than 5% a structure stabilization occurred (Fig. 2). Two hypotheses are proposed in order to explain this behaviour:

(1) Low amounts of binder did not allow a total coating of the Al_2O_3 grain surface. Thus, powder specific surface area had a strong influence.
(2) The binder film adsorbed to the grain surfaces tended to a thickness limit.

Study of the fracture surface of green tapes, with different plasticizer concentrations corroborated the proposed model. For organic compositions lower than the filling volume limit (V_{lim}), the grain surface was 'clean'. When this limit was exceeded, a coating of the powder grain could be observed as well as the formation of granules induced by the organic phase. Micrographs shown in Fig. 3 correspond to a binder concentration of 5 wt%.

Measurements carried out on debinded tapes (1 h at 600°C) and fired tapes (1 h at 1650°C) also showed significant decrease of the tape density when the organic volume was higher than the pore volume of the tape (Fig. 4).

3.2 Mechanical properties of tapes

The maximum strength and the rupture elongation of green tapes were measured on materials introduced from different formulations (Figs 5 and 6).

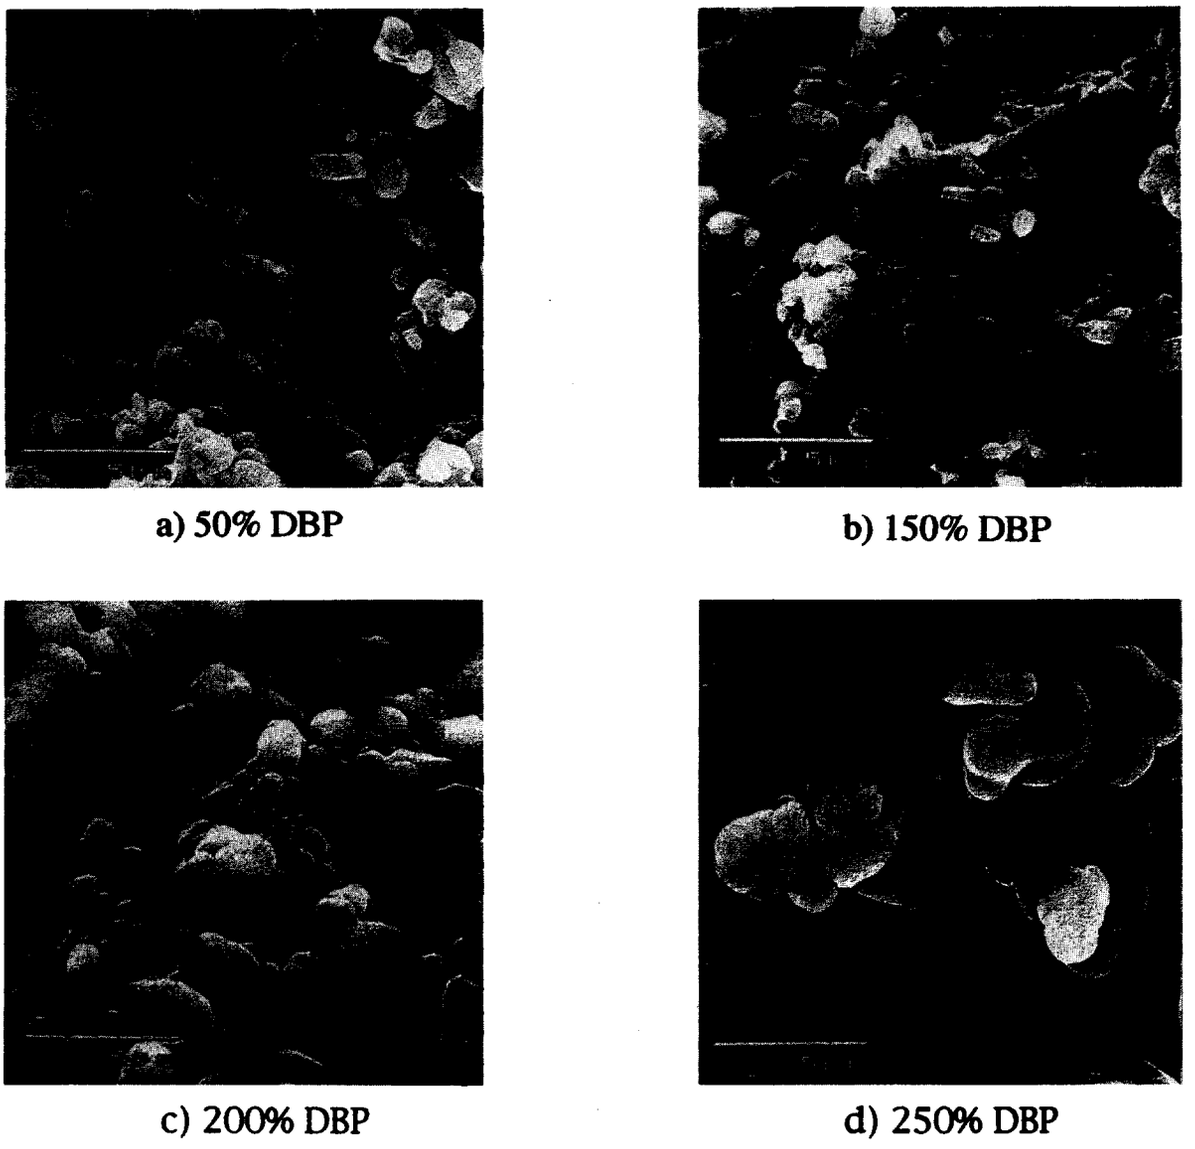

Fig. 3. Fracture surfaces of green tapes produced with 5% of binder and different plasticizer concentrations.

The effect on these properties of the plasticizer amount can be divided into several stages:

(1) In the first stage, results showed a strong decrease of the mechanical strength and a limited increase of tape elongation values. Plasticizer molecules inserted themselves inside the macromolecular network formed by the binder. This insertion destroyed locally intermolecular strength responsible for the mechanical cohesion of the compound. Chain movement is thus facilitated to the detriment of the material resistance.

(2) In the second stage, strength increased (the amplitude of which increased with binder amount). The development of this characteristic is induced by the action of two antagonistic phenomena: On the one hand, the strength decrease of the binder phase was induced by the increasing amount of plasticizer and on the other hand, the reinforcement of the mechanical strength was caused by the filling of the pores in the tape by organic compounds. This reduction in the defect number (pores) increased the mechanical strength of the tape, which occurred all the more for higher binder contents. In this stage, an increase of tape elongation values occurred.

(3) When the organic volume in the slurry was higher than the pore volume of the tape, a third stage was observed. In this stage, the mechanical strength of the tape depended only on the mechanical properties of the binding phase. The characteristics of this phase, saturated by the plasticizer agent, explained the significant decrease in the rupture strength. However, as the plasticizer content was increased, lubrication was improved and this promoted sliding between powder grains, which was manifested by a large increase of tape elongation.

The variations in rupture strength as a function of percentage binder present showed the importance of the powder particle size on the choice of slurry composition. Figure 7 shows the variation

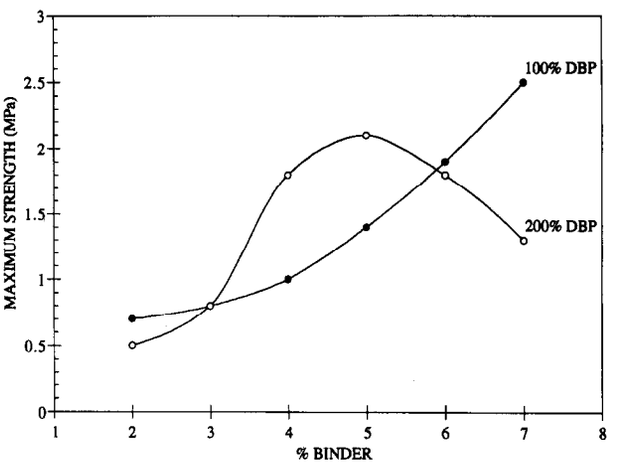

Fig. 7. Evolution of maximum strength as a function of binder content at two different plasticizer (DBP) percentages.

in this property for two DBP concentrations (100%, 200%).

Indeed, for slurry compositions in which the organic volume was lower than the pore volume of the tape, i.e. for the formulation at 100% of plasticizer whatever the content binder and the composition at 200 wt% of plasticizer up to 5% of binder (Tables 2 and 3), increasing the binder content resulted in an increase in the tape mechanical strength. However, when the organic volume was higher than the pore volume (from 5% PVB and 200% DBP) a large decrease of strength was observed, in spite of the increase in binder content.

4 Conclusions

The results of this study showed the important effect of the porous structure of the tapes on their mechanical and physical properties.

When the volume of organics used was lower than the porous volume of the tape, the material volume remained constant whatever the amount of plasticizer used (binder content fixed). On the other hand the volume increased slowly (volume measured in the first stage) when the binder concentration was increased and then tended to stabilise when a critical amount was reached. During this stage, the organic phase filled the tape porosity. When the organic volume was higher than the tape porous volume, powder grains were forced apart which induced an increase of apparent tape volume and a large decrease of fired tape density.

The tape mechanical characteristics were affected by the action of two antagonistic phenomena.

(1) The plasticization and lubrication effects caused by the plasticizer agent produced

an increase in material elongation and a decrease in network resistance.

(2) The reduction in the number of defects caused by the filling of the tape porosity by the organic phases led to an increase of the maximum strength.

The predominance of either effect determines the mechanical behaviour as a function of the amount of organic phases used.

So, for a fixed binder content, increasing of the plasticizer amount induced an increase in the mechanical resistance of the tape. However, from a certain filling level of the tape porosity by the organic phase, this behaviour was inversed and the mechanical resistance reached a maximum corresponding at an organic volume which allowed the complete filling of tape porosity. In this stage, the tape elongation increased appreciably. Beyond this maximum point a drastic reduction of the mechanical resistance appeared, induced by the weak strength of the binder phase (satured in plasticizer agent). These results showed that a judicious choice of the plasticizer concentration allow us to obtain green tapes with optimized mechanical properties, according to the desired application. Plasticizer contents corresponding to an organic volume near to the maximum filling of the tape porosity seems to give a correct compromise between mechanical strength and elongation of the tape. For applications where elongation and flexibility will predominate, significant contents of binder and plasticizer will be required. However these properties will be obtained to the detriment of mechanical resistance of the green tape and the density of sintered material.

On the other hand, increase in binder content for a fixed plasticizer amount, induced the increase of the rupture strength of the tape up to a certain amount of binder. Indeed, for binder concentrations corresponding to organic volumes higher than the porous volume, an important diminution of this characteristic appeared. When particle size distribution of the powder was optimized, the compactness of the powder can be very significant and can produce a very weak, porous volume of tape.[14–15] Thus, low binder content will be sufficient to obtain organic volumes higher than the porous volume of the tape and to induce an important decrease of the network mechanical resistance: behaviour opposed to the desired effect.

This study, carried out on interactions between porous volume and organic content for the production of ceramic tape by tape-casting must allow a better understanding of the evolution of tape properties and an optimization of slurry formulation for a given application.

Densification and Microstructure Development of Alumina/Y-TZP Composite Powder (Y-TZP-rich) Compacts

J. L. Shi & T. S. Yen

State Key Laboratory of High Performance Ceramics and Superfine Microstructure, Shanghai Institute of Ceramics, 1295 Ding-Xi Road, Shanghai 200050, People's Republic of China

(Received 25 November 1993; revised version received 1 June 1994; accepted 11 August 1994)

Abstract

Al_2O_3/Y-TZP composite powders (Y-TZP-rich) were prepared by ball milling submicron-sized alumina and coprecipitated nano-sized Y-TZP powders. The densification behavior of the composite powder compacts is studied and it is shown that the shrinkage rate is reduced at lower temperatures and the composites continue to shrink at elevated temperatures compared to single phase tetragonal Y-TZP. Compacts of the composite powders isostatically pressed at 250MPa at room temperature show duplex pore size distributions due to the presence of alumina, and it is these unusual pore size distributions, rather than the stresses arising from the differential sintering of the secondary particles that are believed to be the source of the retarded densification during constant rate heating. In spite of the retarded densification behavior, the composite powder compacts containing not higher than 30 vol.% alumina, can be sintered in 2 h to above 98% of the theoretical density at 1550°C.

1 Introduction

Alumina/Y-TZP particulate composites are of great interest because of their improved mechanical properties, such as strength, toughness and hardness.[1–5] In particular, alumina-doped Y-TZP materials show unusually high fracture strength.[5] These composites, however, show limited densification when pressureless sintered[4–6] and require hot-pressing or post-hipping to achieve density levels suitable for practical application.

Conventionally, the phase of higher content and smaller particle size is termed the matrix phase and the one of lower content and larger particle size is the secondary phase. The sintering behavior of particulate composites has been studied extensively, and it is well known that the densification of matrices (or composites) is retarded by secondary large particles (inclusions).[6–13] Numerous models have been proposed to account for this retarded densification of the matrix by the secondary phase.[14–21] The early models[14–17] proposed a hydrostatic tensile stress (back stress), believed to counter the normal sintering stress, as the main factor affecting densification. It was later proposed[18,19] that the tensile stress was too small to be the source of retarded densification; instead, the enlargement of pre-existing cracks in the compacts as a result of the tensile stress during sintering was considered to retard densification. Recently a numerical model[20,21] stated that the dense non-deformable region around high-aspect ratio reinforcements and between closely spaced reinforcements constrained the shrinkage of the adjacent, porous matrix, and thus led to the formation of large voids and cracks. These models, in spite of differences in the densification retardation mechanisms, all rely on the effect of stresses due to the presence of the secondary particles.

The retarded densification of particulate composites has also been attributed to the suppressed grain growth of the matrix grains during sintering,[22,23] because it was believed that grain growth enhanced densification.[24]

The proposed stress models are based mostly on the experimental results for composites with very large inclusions as secondary phases, i.e. with size ratios of the inclusions to matrix larger than 100.[10,11,13,21] However, many practical particulate composite systems do not use large size secondary phase particles, so as to avoid large defects in microstructure. For example, in the Al_2O_3/Y-TZP system the size ratio of the second phase to matrix is generally less than 10. For systems of inclusion size to matrix size ratios of around 10, the retarded densification may not be caused by stress alone, as the stresses brought about by the

secondary phase are somewhat limited for small secondary particle size and size ratio.

Recent reports[25,26] have shown that the back stress model[17] does not work in the ZrO_2 inclusions/ZnO matrix system. In their system, the size ratios of ZrO_2 to ZnO matrix varied from about 3 to 30. They proposed that in addition to the interaction between secondary particles and the matrix, the packing properties near the secondary particles may contribute to the retarded densification in the matrix.

In the present study on Al_2O_3/Y-TZP composites, a possible alternative factor affecting densification of composites is identified and a microstructural model based on this finding is introduced.

Fig. 1. TEM micrograph of mixed Al_2O_3/Y-TZP composite powder.

2 Experimental

Alumina powder (Sumitomo Co., AKP-50) with an average particle size of about 0·23 μm as measured by gravity sedimentation by the supplier was used. Y-TZP (3 mol% yttria stabilized tetragonal zirconia polycrystals) powder was obtained by a coprecipitation method using zirconium oxychloride and yttrium chloride as starting materials and ammonia as the precipitation medium. The copreciptation process is described briefly as follows:[27] (1) a mixed solution of zirconium oxychloride and yttria chloride with proper Y^{3+}/Zr^{4+} was prepared; (2) the mixed solution was added to an ammonia solution which resulted in coprecipitation: the pH value was kept above 9·5; (3) the coprecipitates were repeatedly washed to remove Cl^- until the Cl^- content in the filtrate became less than 10 ppm; (4) the coprecipitated cake was dispersed and dried in an oven at 110°C; (5) the powder was calcined at 750°C for 120 min. To avoid the formation of hard agglomerates, the coprecipitates of mixed hydroxide were thoroughly dispersed with a 30 min ultrasonic treatment before drying and calcination. The average primary particle size (equivalent to the crystallite size) of the 3Y-TZP powder is about 22 nm as measured by the X-ray diffraction line broadening method and/or by measuring the specific surface area by BET method (assuming a spherical shape for the particles).[28] Alumina-Y-TZP composite powders were prepared via ball milling for 4 h in a plastic jar using alumina balls as milling media. Five batches of the composite powders were prepared, containing 0, 10, 20, 30, and 40 vol.% alumina, and labelled accordingly as ZA0, ZA10, ZA20, ZA30, and ZA40 respectively. Figure 1 is a typical TEM photomicrograph of ZA30 powder after ball milling, showing a mixture of submicro-sized Al_2O_3 and nano-sized Y-TZP crystallites.

The composite powders were uniaxially dry pressed at 50 MPa, followed by cold isostatic pressing at 250 MPa, and the binder (1·5% polyvinyl alcohol) in the green compacts was burnt out by heating up to 700°C for 2 h. The pore size distributions of the pressed compacts were measured by mercury porosimetry (Model 9200, Micromeritics, USA) which detects pores in the size range 300 μm—3 nm.

The shrinkage behavior of the samples was measured with a dilatometer at a constant heating rate of 10°C/min up to 1550°C, followed by holding at this temperature for 2h. Densities of the sintered samples were measured by the Archimedes method in distilled water. The microstructure of the sintered bodies was observed with scanning electron microscopy (SEM, EPMA-8705, Shimadzu) on the ground and polished surfaces after thermal etching at 1300°C for 150 min.

3 Results

3.1 Duplex pore size distributions in the compacts

Figure 2 shows the pore size distributions of the composite powder compacts after isostatic pressing at 250 MPa. The pure Y-TZP compact exhibits pore size distribution with only one peak illustrating an agglomerate-free state in the compact.[27] Addition of alumina to the Y-TZP powders results in two peaks in the pore size distribution (a duplex distribution). The peaks at smaller pore sizes (Pore I $\leq$ 0·03 μm) are the inter-primary particle pores of the zirconia particles as the zirconia powders are much finer than the alumina powder. Those at larger size (Pore II > 0·03 μm) are the result of the presence of the alumina particles. There are two possibilities for the larger pores. They may be formed between alumina particles

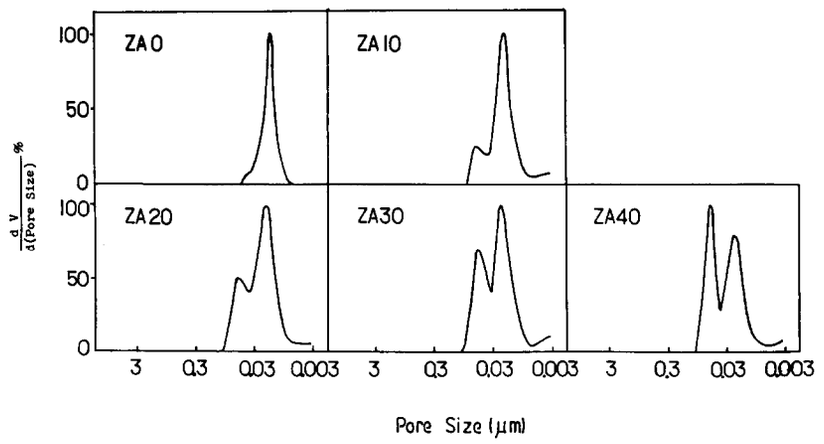

Fig. 2. Pore size distributions of the composite powder compacts at 250 MPa.

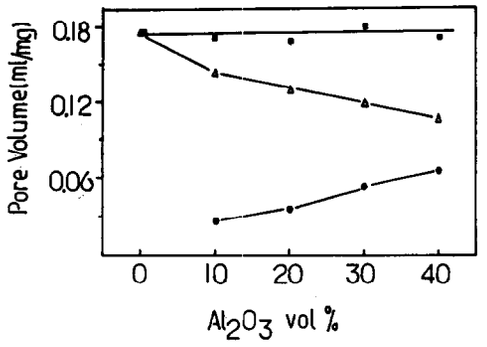

Fig. 3. Volume contents of (■) total pores, (Δ) Pore I and (●) Pore II in the composite powder compacts.

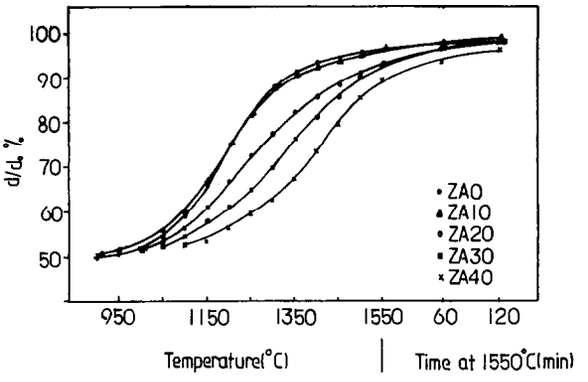

Fig. 5. Densification curves of the composites during constant rate heating of 10°C/min up to 1550°C and holding at 1550°C for 2 h.

(inter-alumina particle pores) and/or formed between alumina particles and Y-TZP matrix (inter-alumina-zirconia particle pores). The former are predicted to be present since agglomerates may also develop from the submicron-sized Al_2O_3 particles if the agglomerates are not fully dispersed especially when the alumina content is high, the latter are sure to exist because the Al_2O_3, particles or agglomerates are surrounded by nano-sized Y-TZP particles at relatively low contents.

Increasing alumina content in the composite powders leads to a volume increase of porosity (Pore II) and a decrease of porosity (Pore 1), while the total pore volume remains essentially unaffected, as shown in Fig. 3. In addition to the pore volume, the average pore sizes (Pores I and II) also increase slightly along with increasing alumina content, as shown in Fig. 4.

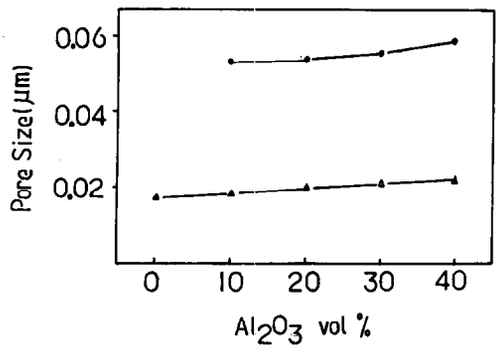

Fig. 4. Effect of alumina content on the size of (Δ) Pore I and (●) Pore II in the compacts.

3.2 Retarded densification of the composite

The densification curves in Fig. 5 show the retarded densification behavior due to the presence of alumina, especially at and beyond 20 vol.%. At the lower temperatures, the shrinkage rates decrease with the increase of alumina content. At higher temperatures and during the high temperature hold, the shrinkage rates increase with the increase of alumina content, as shown in Fig. 6 and, more clearly, in Fig. 7. Although similar final densities can be obtained for composite compacts containing not more than 30 vol.% of alumina (see Fig. 5) when sintered at 1550°C for 2h, the shrinkage rates during constant rate heating and holding depend on the alumina content in the composites.

3.3 Pore structure change during densification

During sintering, the pore volume and size change as densification proceeds. At relatively low tem-

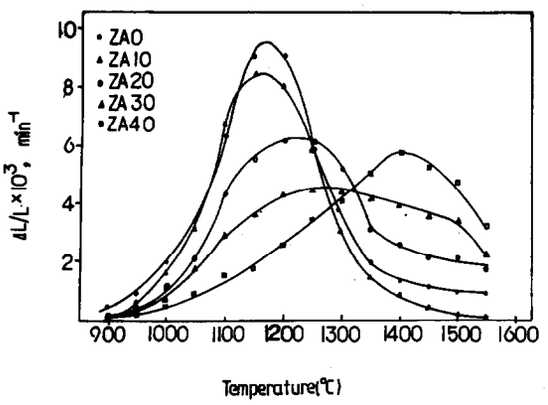

Fig. 6. Shrinkage rate versus temperature during constant rate heating for the composites.

peratures, the change is due mainly to the volume decrease and slight size increase of Pore I. This corresponds to the shrinkage of the green compacts in the early stages of sintering, especially for those with low content of alumina. Beyond 1150°C, there is only one peak (Pore II and size increased Pore I) left as shown in Fig. 8, and the volume diminution (Fig. 9) and size increase (Fig. 10) of the pores continue to relatively high temperatures, which is more evident for the materials with a higher alumina content.

3.4 Microstructure development of the composites

Figure 11 shows the photomicrographs of Al_2O_3/Y-TZP composite bodies sintered at 1550°C for 2 h. For single phase Y-TZP the microstructure is uniform and the grains are submicron-sized (0·3–0·5 μm). Addition of Al_2O_3 particles to the composites leads to a less uniform microstructure: the black particles of relatively large size are Al_2O_3 and the matrix is Y-TZP, as verified by energy dispersive spectroscopy. Both Al_2O_3 and Y-TZP matrix grains in the sintered bodies have grown compared to the powder forms: Y-TZP grains have grown as in the single phase materials by a factor of greater than 10 and the grain sizes are almost independent of the alumina content. The Al_2O_3 grain sizes became larger as the Al_2O_3 content increased, and the rate of increase depended on Al_2O_3 content. So the size ratio of alumina to Y-TZP particles becomes larger for higher Al_2O_3, content in the final sintered bodies. Even for ZA40, however, the size ratios in the final sintered bodies were less than 10, that is to say that Al_2O_3 grains grew at a slower rate than Y-TZP.

In spite of the grain size differences for different Al_2O_3 contents, the sintered bodies were dense and no pores were formed in the vicinity of the larger Al_2O_3, particles, in contrast to results of Tuan[10] and Sudre[13,21] in their particular systems.

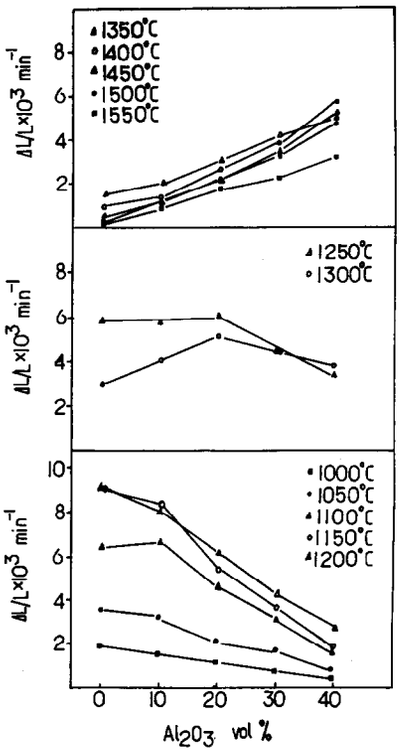

Fig. 7. Shrinkage rate versus alumina content during constant rate heating at various temperatures.

4 Discussion

4.1 Densification retardation by duplex pore size distribution

The effect of bimodal pore size distributions on the viscous sintering of single phase uniform gel compacts has been discussed by Scherer.[14] Altered sintering stress in this system results from the interaction between large and small pores. However, a gel compact with uniform composition is different from a particulate system of multiphase form

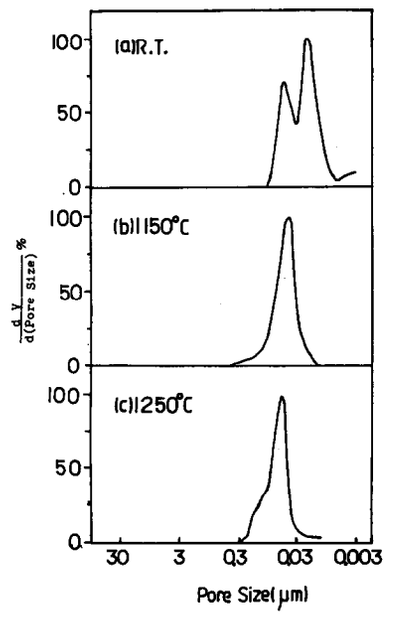

Fig. 8. Pore size distributions of 30 vol.% Al_2O_3/Y-TZP composites during constant rate heating at (a) room temperature, (b) 1150°C, (c) 1250°C.

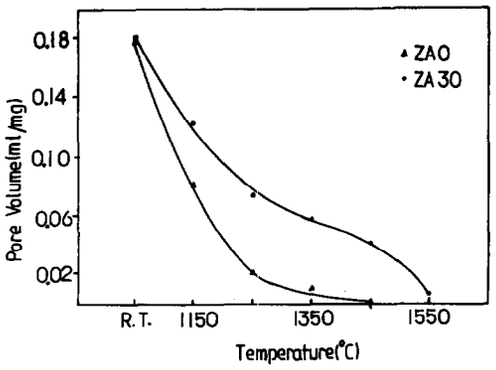

Fig. 9. Pore volume versus temperature during constant rate heating.

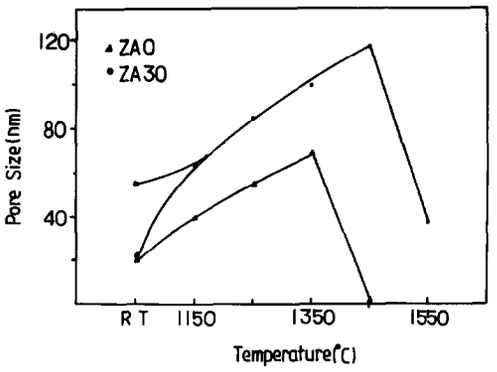

Fig. 10. Pore size versus temperature during constant rate heating.

such as has been studied in this paper. The viscous sintering mechanism of a single phased gel without phase and/or grain boundaries cannot be used to explain the solid state sintering behavior of the present multiphased particulate system.

The presence of large pores in the compacts implies that the particle packing conditions in the multiphase system have been changed. The pores of large sizes (Pore II) may be formed among large alumina particles (inter-alumina particle pores,

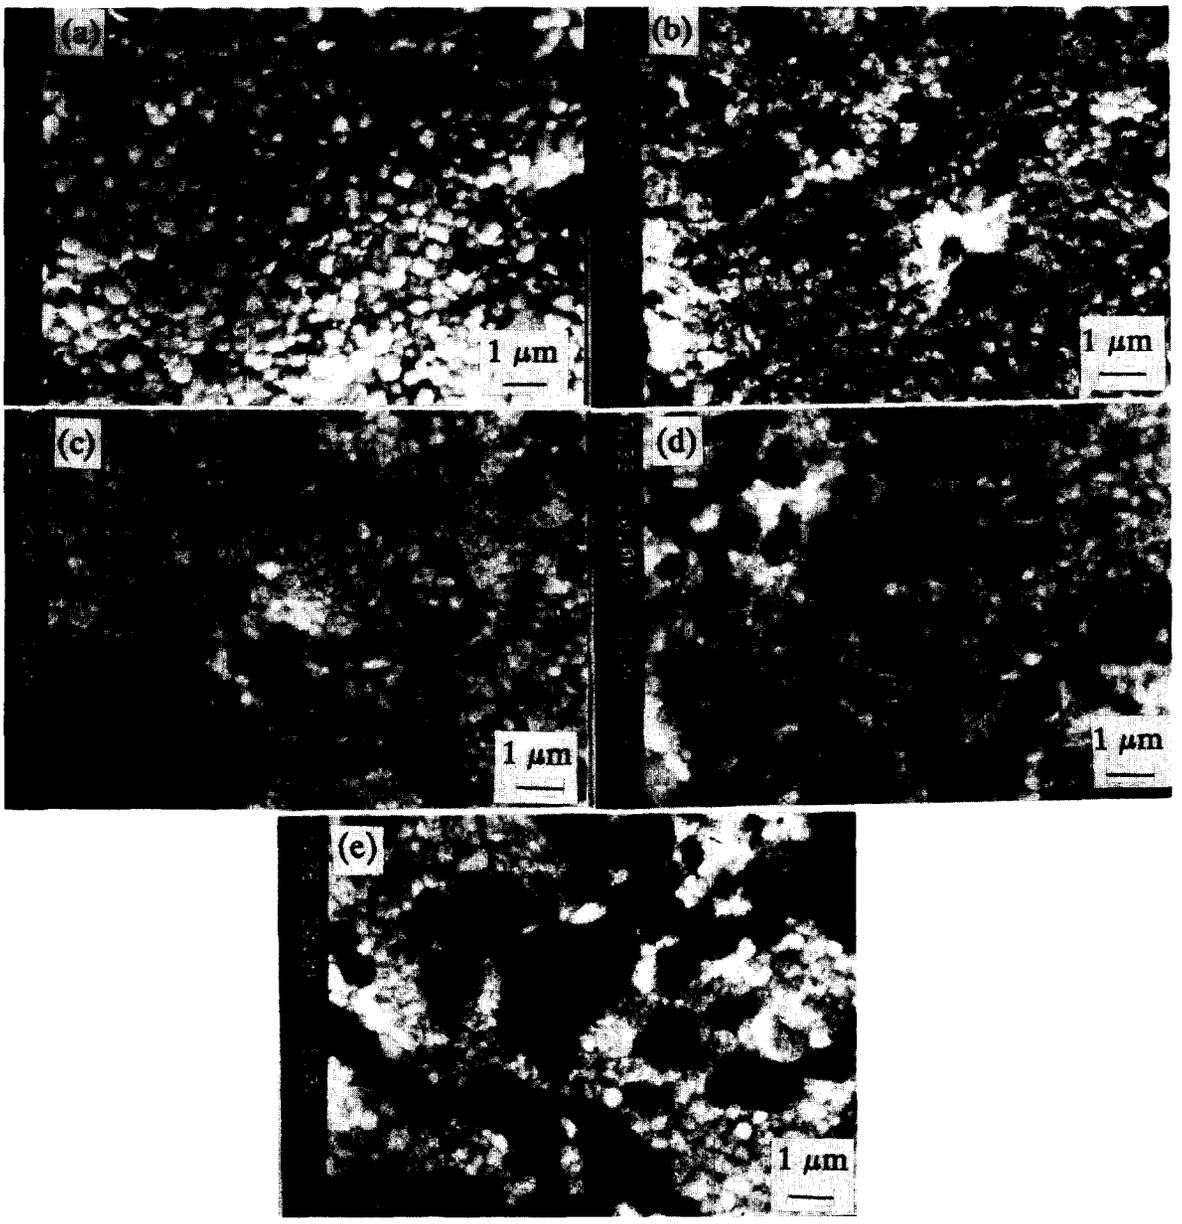

Fig. 11. SEM micrographs on polished and thermally etched surfaces of sintered composite bodies at 1550°C for 120 min, containing (a) 0, (b) 10, (c) 20, (d) 30 and (e) 40 vol.% Al_2O_3.

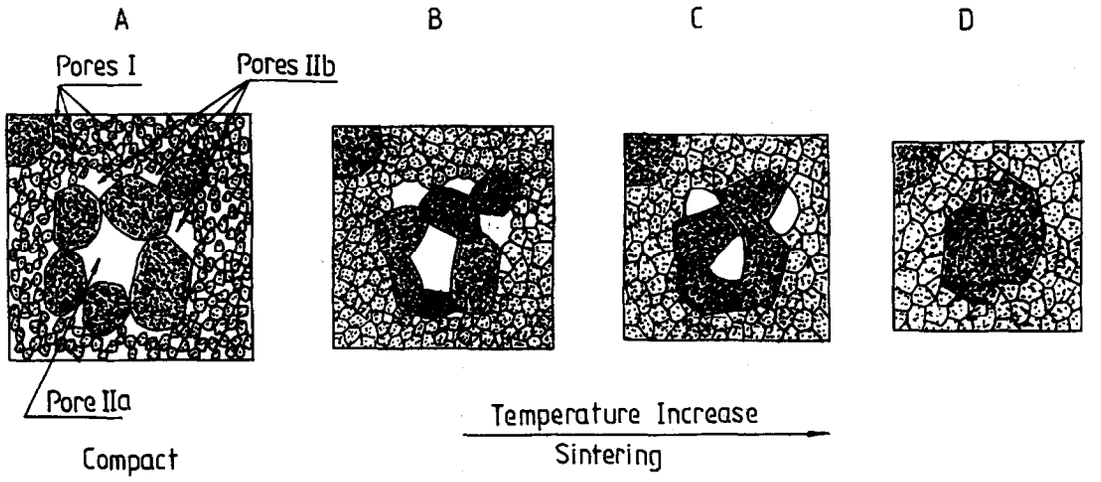

Fig. 12. Microstructure model for the removal of different kinds of pores; (A) pores in compacts; (B) removal of Pore I at relatively low temperature; (C) Pore IIa begin to shrink and Pore IIb become unstable due to the grain growth of Y-TZP as temperature increases, and (D) Pores II were eliminated at a high temperature, e.g. 1550°C.

named as Pore IIa), or between alumina particle(s) and numerous small zirconia particles (inter-alumina-zirconia particle pores, named as Pore IIb), as can be seen in Fig. 1 and shown schematically in Fig. 12(A). Pores I can be removed during sintering at relatively low temperatures, while Pores IIa will not shrink appreciably due to unfavourable kinetic conditions at low temperatures with large alumina particles surrounding the pores. Thermodynamically, Pores IIb may be stable at low sintering temperatures as such pores are coordinated by many very small zirconia particles relative to the alumina particle (Fig. 12(B)), and such pores, as analyzed by Lange,[29] will not shrink at relatively low temperatures before the zirconia particles begin to grow substantially. With the increase of temperature, when the densification process of pure Y-TZP has been completed, Pores IIa will begin to shrink and with the growth of the zirconia particles the coordination number of Pores IIb will decrease and such pores will also become unstable and start to shrink (Fig. 12(C)). So the retarded (and enhanced) densification of the composite powder compacts at relatively low (and high) temperatures, compared to single phase Y-TZP, can be understood. As temperature increases to a certain threshold, e.g. 1550°C, both Pore IIa and Pore IIb in the compacts are removed (Fig. 11, as modelled in Fig. 12(D)) and the sintered densities were rather high when the Al_2O_3 content was not higher than 30 vol.%.

However, the composite powder compact of ZA10 shows a very similar densification behavior with single phase Y-TZP. This is believed to be due to its relatively low amount of alumina. At this low content, Pores II are relatively few, and Pores IIb prevail in the compact as compared to Pores IIa. However, nano-sized zirconia grains grow readily[28] when heated above the calcination temperature of 750°C. Hence the thermodynamic requirements for the shrinkage of pores IIb can be easily satisfied at a relatively low temperature of about 1050°C (Fig. 6). As a result the densification rate of ZA10 was not affected significantly.

4.2 Effect of tensile back stress

The retarded densification of ceramic powder compacts with heterogeneities (inclusions), as a special example of composite powder compacts, has been modelled by calculating the hydrostatic tensile stress in the powder matrix.[15–17] The tensile stress is expected to oppose the sintering stress and therefore impede densification. The concept of back stress has been used[10,11] to explain the limited achievable final density of a composite compact of Al_2O_3, or Y-TZP with very large Al_2O_3 particles of 200 μm by local difference in density, grain size or chemical composition. The back stress concept was developed[20,21] for the system of large ZrO_2 particles in an Al_2O_3 matrix. The size ratio of secondary particles to matrix grains was higher than 100 and the large particles were irregularly shaped or even elongated. The stress caused by the inclusions in matrix may either be compressive or tensile. Densification and grain growth in the compressive region were promoted and formed a so-called non-deformable network. This non-deformable network constrained the shrinkage of the adjacent porous region by exerting tensile stress opposing densification. However, there are three ways where the effect of compressive and/or tensile back stress on densification may be limited in our system. First, the alumina particle size and the size ratio of alumina particles to Y-TZP matrix in the present system are much smaller as compared to those used by Tuan[10,11] and Lange;[20,21] although the stress arising from the secondary particles (or inclusions) is independent of their size,[30] nonetheless as analysed[30] and experimentally

observed by others, the defects (or cracks) are much easier to form around larger inclusions than around smaller. Secondly, the matrix of Y-TZP in this study is very porous and nano-sized, so the tensile stress that resulted from the Al_2O_3, during densification could be effectively absorbed and relaxed by microstructural modification (particle rearrangement, and plastic flow), especially at the initial and intermediate stage of sintering. Thirdly, the secondary Al_2O_3 particles are basically equiaxed and well dispersed in matrix (Fig. 11), so the so-called non-deformable network[20,21] would not form in microstructure and the densification rate in the matrix is expected to be basically the same throughout the specimen.

5 Summary

This study shows that the densification of the Y-TZP powder compacts with the addition of alumina particles (size ratio of Al_2O_3 to Y-TZP is about 10) is retarded by the presence of larger alumina particles. The alumina particles impede the shrinkage of the composites at relatively low temperature $\leq$ 1300°C) at which the single phase Y-TZP undergoes the major shrinkage, and lead to enhanced densification rate at and above 1300°C. Almost full densification is achieved at 1550°C. The retarded densification behavior of the composites are related to the duplex pore size distributions in the green compacts because of the presence of relatively large alumina particles. The presence of inhomogeneities, i.e. larger pores in the compacts for the composite powders, in addition to the smaller pores which the single phase Y-TZP contains, appears to be the main reason for the retarded densification of the composites from both the thermodynamic and kinetic point of view. Back stress effects resulting from secondary Al_2O_3 are argued to be less significant.

Fabrication of Low-Voltage ZnO Varistors by a Two-Step Process

Joo-Hwan Han, Dong-Heon Lee & Doh-Yeon Kim

Department of Inorganic Materials Engineering, College of Engineering (400), Seoul National University, Seoul 151–742, South Korea

(Received 7 June 1994; accepted 7 July 1994)

Abstract

In order to make a low-voltage ZnO varistor of uniformly large-grained microstructure, a pure ZnO powder compact was first sintered at 1500°C. The abnormal grain growth that occurred during the sintering of the ZnO resulted in a relatively uniform matrix of very large grains. Subsequent heat-treatment in contact with a Bi_2O_3 powder mixture resulted in the formation of a low-voltage ZnO varistor.

1 Introduction

Low-voltage ZnO varistors are now widely used for surge protection in integrated circuits and in automobiles.[1,2] Since the breakdown voltage (V_b) of the varistor is proportional to the number of ZnO grains in series between the electrodes,[3,4] low voltage varistors can be obtained either by decreasing the thickness of the specimen or by increasing the size of ZnO grains. The thin ZnO varistors are, however, difficult to prepare and apt to break. Note also that the energy absorption capability of the thin ZnO varistor is very poor due to its small volume.[5–8] On the other hand, low voltage ZnO varistors with grains of large size have been fabricated by using grain growth-enhancing additives,[6,9] or exceptionally large seed ZnO grains.[7,8] Consequently, its microstructure exhibits a nonuniform distribution of grain size, which causes an irregular current distribution and makes the varistor susceptible to hot spots.[10–12]

In this paper, a new processing technique for the production of a low-voltage ZnO varistor of uniformly large-grained microstructure will be described. Instead of conventional fabrication by sintering of ZnO powder which has been previously mixed with Bi_2O_3 and other oxides, the two-step process consisting of the sintering of pure ZnO alone and subsequent heat-treatment has been adopted for fabrication of the low-voltage ZnO varistor. The uniformity in grain size and low porosity of ZnO varistors obtained by this process are expected to enhance its reliability and lifetime.

2 Experimental Procedures

Commercial grade ZnO powder of 99·9% purity (Aldrich Chem. Co. Inc., Milwakee, Wis., USA) was used. Its average particle size determined by sedimentation technique was 0·5 μm. The powder was pressed to a cylindrical compact (10 mm in diameter) with a hole (3 mm in diameter) in the center, and then pressed hydrostatically at 100 MPa. The obtained compacts were sintered at 1500°C for 1 h in air to induce an extensive grain growth. In order to minimize the ZnO vaporization and consequent pore formation during sintering at such a high temperature, the specimens were put together with the same ZnO powders in a closed alumina crucible. Platinum foil was used to isolate the specimen from the surrounding powders. The sintered specimens were then ground and its thickness was controlled to be 4 mm. On the other hand, high purity Bi_2O_3 and MnO_2 powders were mixed with ZnO to give $1Bi_2O_3$–$1MnO_2$–98ZnO (in mol%). This powder mixture was then manually rubbed into the central hole of the sintered ZnO specimen. The specimen was then heat-treated at 1200°C for 1 h with Bi_2O_3 powders in a closed alumina crucible, as illustrated in Fig. 1. Preliminary experiments showed that this heat-treatment condition is most appropriate for making a varistor of the desirable I–V characteristic.

The photomicrographs of the polished section for pure ZnO, i.e. before the Bi_2O_3 atmosphere treatment were obtained after the thermal etching for 30 min at 1200°C. After the atmosphere treatment, however, etching was not needed for microstructural observation. The presence of the

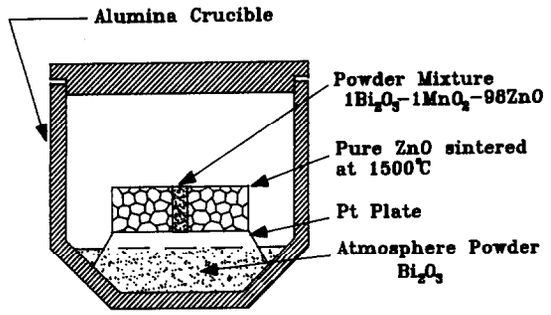

Fig. 1. Schematic illustration for heat-treatment of large-grained pure ZnO specimen in Bi_2O_3 atmosphere.

Bi-rich liquid phase at the grain boundary was observed by transmission electron microscopy. Disks of 3 mm in diameter were cut from the specimen and reduced to a thickness of ≈ 5–10 μm in the center by mechanical grinding and dimpling. A further thinning was carried out by using an ion-miller. The I–V characteristic of the specimen prepared was measured with a picoammeter (Model: 4140B pA Meter/DC voltage source, Yokogawa Hewlett Packard Co., Yokogawa, Japan). The individual specimen was ground on silicon carbide paper (No. 1200) and the electrode was made by sputtering Au on each surface of the cylindrical specimen. The voltage per unit thickness (1 mm) at a current of 1 mA/cm^2 was regarded as the breakdown voltage of the varistor specimen.[10,13,14]

3 Results and Discussion

Previous studies[15–17] on sintering of pure ZnO have shown that its densification begins at a rather low temperature such as 700°C and the full densification is achieved in a few minutes of sintering at 1200°C. On the other hand, a decrease in bulk density, which can be referred to as over-firing has been reported to occur during sintering of ZnO if the sintering temperature is too high.[18] From these works, the optimum temperature for the densification of ZnO powder compact is expected to be around 1100°C. In this investigation, however, the ZnO powder compacts were sintered at 1500°C to induce a rapid grain growth and Fig. 2 (a) and (b) show the microstructure of the specimen sintered for 0·5 and 1 h, respectively. In spite of an excessively high sintering temperature, a notable increase of porosity was not observed in this experiment. It appears likely that the atmosphere powders have minimized the ZnO evaporation from the specimen and consequent pore formation. For the specimen shown in Fig. 2 (a) and (b), most of the pores were trapped inside the grain as a result of extensive grain growth. The

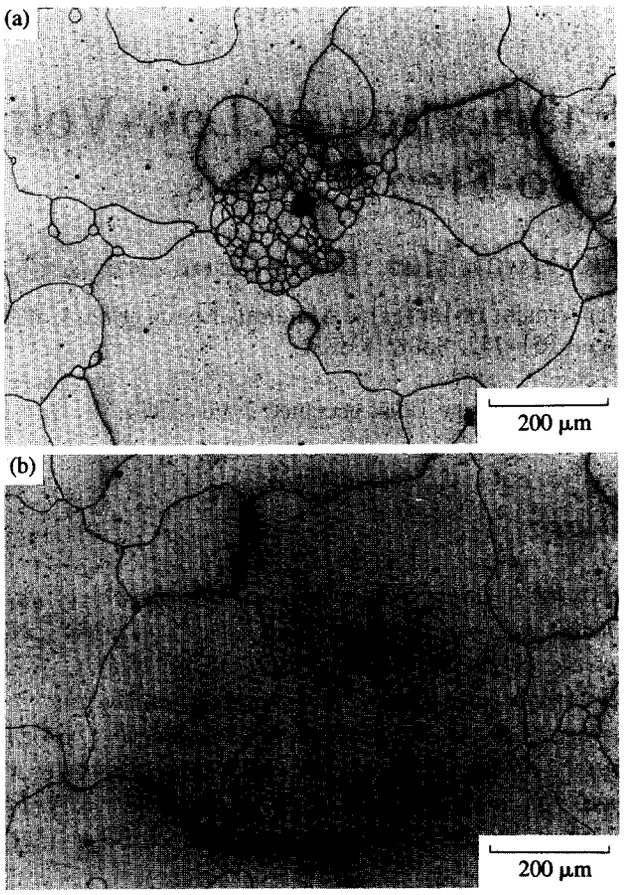

Fig. 2. Microstructures of the pure ZnO specimen sintered at 1500°C for (a) 0·5 and (b) 1 h.

porosities determined by the point counting method were 0·2 and 0·5%, respectively.

In comparison with the initial ZnO particle size (≈ 0·5 μm), the grains observed in the specimen shown in Fig. 2 are exceptionally large. Note that the specimens were made from fine powder and therefore a few particles of a size substantially larger than the average may be present, which acted as embryos for abnormal grain growth.[19,20] It has been suggested that the grains two times larger than the average may be able to start the abnormal grain growth. The assembly of small grains observed in the specimen sintered for 0·5 h (Fig. 2 (a)) may show the initial fine grained structure. Once those few abnormally growing grains reach a size where they impinge each other, the grain boundaries tend to be flat so that the driving force for migration is practically eliminated. Fig. 2 (b) is expected to exhibit such a new set of exceptionally large grains which replace completely the initial fine grained structure. For this specimen, the average grain size was determined to be ≈ 500 μm through the linear intercept method.

Inside those abnormally grown grains, the entrapped small grains were frequently observed as indicated by the arrow in Fig. 2 (b). Such grain entrapment during abnormal grain growth has

also been reported in other ceramic materials and attributed to the very rapid boundary migration.[21] It is expected, however, that the grain entrapment is related to the size and orientation of shrinking grains adjacent to the rapidly growing grains. As the shrinking grains vary in size and have random orientation, the growth rate along the advancing boundary will be uneven from point to point. The slowly shrinking grains and/or the relatively large size grains will become entrapped and be left behind to remain in an apparent metastable state. It is further expected that the grains once trapped shrink rapidly, which may explain their rare experimental observation.

The breakdown voltage of a varistor, V_b, is given by[3]

$$V_b = \nu_{gb} \frac{D}{r} \quad (1)$$

where ν_{gb} is the threshold voltage per grain boundary, which has been estimated to be around 3·6 V,[10,12,13] and D and r are the varistor thickness and average ZnO grain size, respectively. For the low-voltage ZnO varistor, such as V_b = 7 V, it has been consequently reported[22] that the thickness should be less than 100 μm, because the average grain size of ZnO grains in conventionally sintered ZnO–Bi_2O_3 is always below 50 μm. Note also that such coarse-grained ZnO–Bi_2O_3 specimens can be obtained by sintering at 1400°C for several hours during which the vaporization of Bi_2O_3 occurs.[23] The vaporization of Bi_2O_3 and concurrent increase of porosity are known[23] to be significant from 1200°C and to deteriorate the varistor characteristic.

As a consequence, the coarse-grained ZnO varistors ensuring the low V_b have been prepared either by using the grain growth enhancing additives[9,22] such as TiO_2 or by adding large ZnO seed grains.[7,8] The varistors thus prepared, however, showed a large spread of grain size and a very high porosity. The presence of a few large grains may result in the high local currents which give rise to a rapid degradation of the varistor.[10–12] In addition, the harmful effects of pores with respect to the mechanical strength are evident.

Assuming that the microstructure of the ZnO varistor is identical to that of Fig. 2 (b), several advantages may appear. First of all, the thickness of a low-voltage varistor (V_b = 7 V) becomes around 2 mm which can be manufactured and handled without great difficulty. The rather uniform distribution of grain size may provide a uniform current flow, and its low porosity enhances the strength and thermal conductivity of the varistor. The high thermal conductivity and fairly large volume may also increase the energy handling capability of the varistor.[10] However, the addition of Bi_2O_3 is known to be essential for ZnO varistors. The Bi ions segregated in the region of the grain boundary have been attributed for the nonlinear characteristics.[24] In order to make a varistor, it is therefore necessary to form a depletion layer by changing the chemistry of the grain boundaries.

Using the specimen shown in Fig. 2(b), the formation of depletion layer was carried out by the heat-treatment with Bi_2O_3 containing powder mixture. The powder mixture of $1Bi_2O_3$–$1MnO_2$–98ZnO was rubbed into the central hole of the sintered ZnO, and then it was heat-treated at 1200°C for 1 h in Bi_2O_3 atmosphere (Fig. 1). During the treatment, the Bi-rich liquid formed in the powder mixture was expected to penetrate into the grain boundaries of ZnO specimens. Note also that the Bi_2O_3 atmosphere powder in the alumina crucible may provide a high vapor pressure of Bi_2O_3.[10,14,23] In fact, Bi_2O_3 was observed to diffuse into almost all of the grain boundaries of pure ZnO specimen when it was treated at 1200°C for 1 h with a small amount of Bi_2O_3 on its surface.[25]

Figure 3 is the microstructure of the specimen obtained. The region of $1Bi_2O_3$–$1MnO_2$–98ZnO (upper part of Fig. 3) showed a typical liquid-phase sintered structure with the solid grains (white) and pores (dark) dispersed in a Bi-rich liquid matrix. Note that the powder mixture was packed by hand into the hole, which is the cause of the rather large fraction of pores. The originally pure ZnO region can be observed in the lower part of Fig. 3. Although a notable microstructural change compared to Fig. 2 (b) was not observed in this microscopic scale, the liquid was observed to present almost all the triple grain boundary junctions.

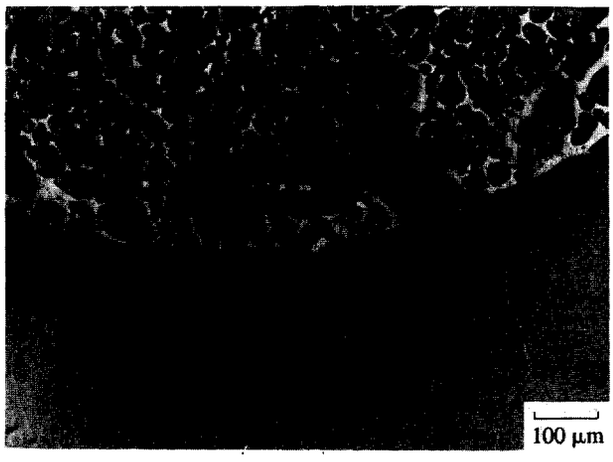

Fig. 3. Microstructure of the ZnO varistor prepared; the pure ZnO was heat-treated at 1200°C for 1 h with the powder mixture ($1Bi_2O_3$–$1MnO_2$–98ZnO in mol%).

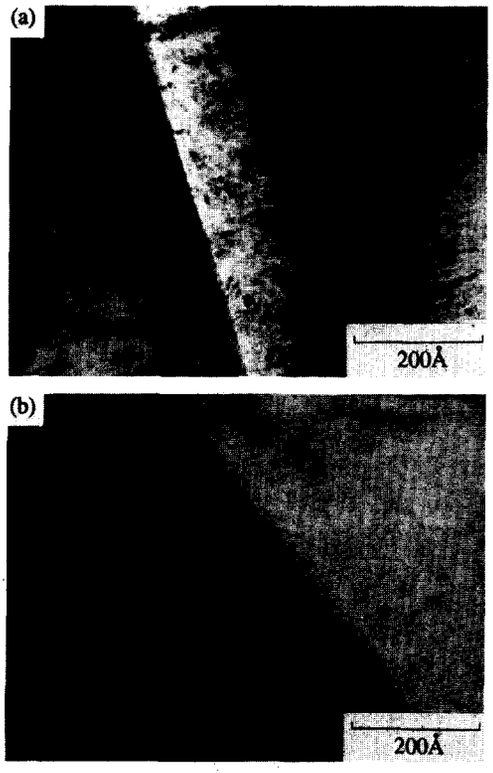

Fig. 4. TEM micrographs of the varistor prepared; (a) some boundaries show the presence of Bi-rich liquid phase and (b) the others show a typical grain boundary.

The grain boundaries and their triple junctions were examined with transmission microscopy. As shown in Fig. 4, some of the grain boundaries showed the presence of a Bi-rich liquid phase (bright region in Fig. 4 (a)), but other boundaries (Fig. 4 (b)) did not show the presence of any Bi-rich liquid phase. Approximately, 80% of the boundaries were observed to be wetted with the Bi-rich liquid and its maximum thickness was around 1 μm. The results may indicate that the grain boundary structure and its energy, which determine the liquid penetration, vary from one grain boundary to another. For ZnO varistors, in fact, three different types of boundary structure were reported,[24] a thick intergranular liquid layer (0·1 ~ 1 μm), a thin intergranular liquid layer (10 ~ 1000 Å), and the grain boundary without any liquid phase.

Figure 5 shows the I–V characteristic of the specimen obtained. The breakdown voltage at a current density of 1 mA/cm^2 is determined to be 3·6 V/mm which is much lower than that of the conventionally fabricated low-voltage varistors. Using ZnO seed grains, for instance, V_b = 6 V/mm has been reported.[7] If the threshold voltage per grain boundary is about 3·6 V, the grain size of the specimen prepared is predicted to be 1000 μm by eqn (1). Note that the current always flows through the easiest path, i.e. the path with the fewest number of grains between the electrodes.

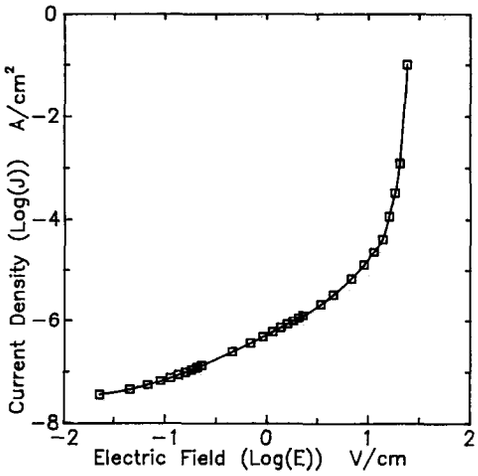

Fig. 5. I–V characteristic of the ZnO varistor prepared.

Therefore, the predicted grain size from the breakdown voltage is always larger than the microstructural average grain size. The nonlinearity coefficient of α for this specimen in the range of 10^{-3} to 10^{-1} A/cm^2 is 20. This value of α is expected to be further increased if other oxides such as CoO, Cr_2O_3, and Sb_2O_3 are incorporated in the Bi_2O_3 containing powder mixture. On the other hand, the amount of leakage current in the pre-breakdown region is acceptable. When the strength of electric field was 10 V/cm, the magnitude of leakage current was 10^{-5} A/cm^2.

4 Conclusions

Low-voltage ZnO varistors have been fabricated by a two-step process consisting of the sintering of pure ZnO and subsequent heat-treatment. The abnormal grain growth that occurred during sintering of ZnO resulted in a relatively uniform matrix of very large grains. After the subsequent treatment with Bi_2O_3 the specimens showed a typical microstructure for a ZnO varistor with a Bi-rich liquid at the triple grain boundary junctions. The breakdown voltage of the specimen obtained was 3·6 V/mm and its nonlinear coefficient α was 20.

Abstract

In ceramic materials, bridging stresses are generated in the wake of propagating cracks due to crack interactions. Such stresses can be caused by friction of sliding grains or by elastic interactions where the crack surface contact behaves like a spring. Both types of interactions are described and a model is proposed which allows us to combine the two effects.

1 Introduction

Coarse-grained Al_2O_3 shows an R–curve behaviour which is characterised by an increase in crack growth resistance with increasing crack extension. In the past it has been shown by experimental[1] and theoretical investigations[2] that the R–curve is not a unique material property. The shape of the curve depends on the geometry of the test specimens, the initial crack depth, the type of loading (tension, bending) and on the special type of crack extension (stable and subcritical crack propagation).

It was demonstrated experimentally[3–6] that this effect is caused by crack border interactions in the wake of the advancing crack. The bridging interactions were observed mainly in materials with large grains. The crack face interactions localised at single grains can transfer loads which can be modelled in a more homogeneous way by so-called bridging stresses σ_{br} which depend only on the crack opening displacement δ. The bridging stresses shield the crack tip from the external loads.

In the special case of R–curves caused by bridging effects, the relation between bridging stresses and crack opening displacement is a material property which is expected to be much less influenced by special test conditions. In the literature the bridging stresses are mostly considered to be caused by frictional effects.[7] This description is well established for coarse-grained Al_2O_3. In hot-pressed silicon nitride, bridging zones act more like elastic springs of limited extension.[8]

Recently, Dauskardt[9] found experimental evidence for a combination of frictional and elastic behaviour of bridging interactions in alumina.

It is the intention of this investigation to

- present a bridging relation for elastic bridging interactions taking into consideration a distribution for the maximum displacements at which the bridge fails and to
- describe a bridging model that exhibits the main features of load versus displacement curves as measured by Dauskardt.[9]

Therefore, in the first part of this investigation, bridging relations are described which are based on bridging interactions caused by friction and spring effects. In the second part a model is discussed which describes elastic and friction-induced response of crack surface interactions on crack opening displacements.

2 Bridging Relations

2.1 Relation for friction induced bridging stresses

For bridging stresses σ_{br} which are caused by friction effects, Mai and Lawn[7] proposed a relation

$$\sigma_{br,grain} = \begin{Bmatrix} \sigma_0(1-\delta/\delta_c)^m & \text{for } \delta/\delta_c<1 \\ 0 & \text{for } \delta/\delta_c>1 \end{Bmatrix} m = 0,1,2,... \quad (1)$$

as shown in Fig. 1(a) for $m = 1$. If we assume that the characteristic displacement for which the bridging stresses vanish is distributed like a Γ-distribution of first order[2] with a density $f(\delta_c)$

$$f(\delta_c) = \frac{1}{\delta_0}\,\frac{\delta_c}{\delta_0}\exp(-\delta_c/\delta_0) \quad (2)$$

then the macroscopically averaged bridging stresses result from

$$\sigma_{br,aver} = \int_0^\infty \sigma_{br,grain} f(\delta_c)\,d\delta_c \quad (3)$$

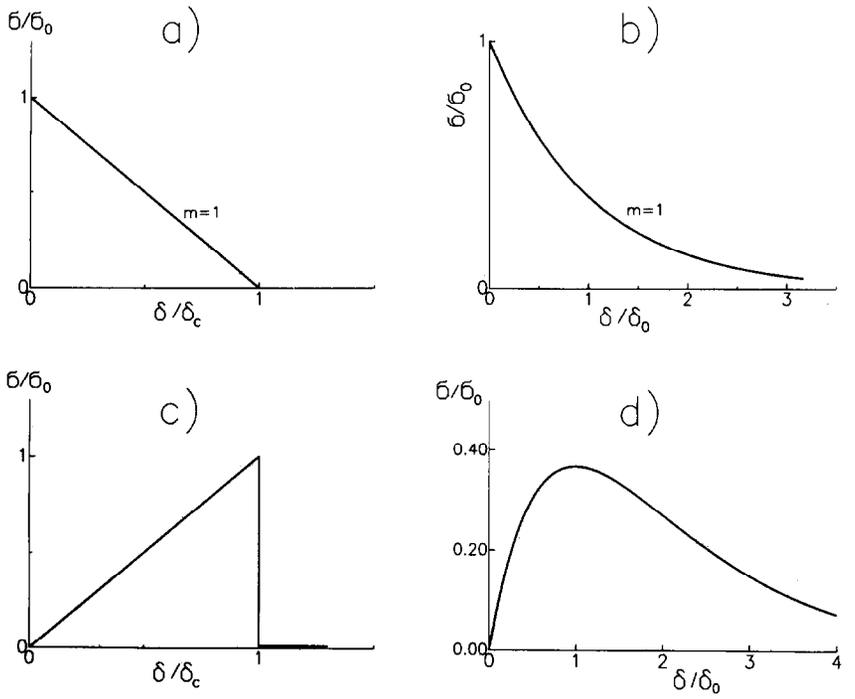

Fig. 1. Bridging stresses. (a) Local stress-displacement relation for frictional crack-surface interactions; (b) global stress-displacement relation for frictional crack-surface interactions; (c) local stress-displacement relation for a single spring; (d) global stress-displacement relation for spring-like crack-surface interactions.

For the mostly used case $m = 1$ the averaged bridging stress relation results

$$\sigma_{br,aver} = \sigma_0 \exp(-\delta/\delta_0) \tag{4}$$

as plotted in Fig. 1(b).

2.2 Bridging relations for springs with limited extensions

In case of spring-like stresses the bridging stresses in a single bridge may be expressed by

$$\sigma_{br,spring} = \left\{ \begin{array}{ll} \sigma_0 \delta/\delta_c & \text{for } \delta/\delta_c<1 \\ 0 & \text{for } \delta/\delta_c>1 \end{array} \right\} \tag{5}$$

with maximum extension δ_c and maximum stress σ_o, shown in Fig. 1(c).

Similar to the bridging effect it is assumed that the characteristic displacement δ_c for which the bridging stresses vanish is also Γ-distributed with a characteristical displacement value δ_0 characterising the 'width' of the distribution. The macroscopically averaged bridging stresses result from

$$\sigma_{br} = \int_0^\infty \sigma_{br,spring} f(\delta_c)\, d\delta_c \tag{6}$$

and one obtains by integration

$$\sigma_{br} = \sigma_0 \frac{\delta}{\delta_0} \exp(-\delta/\delta_0) \tag{7}$$

as given by Fig. 1(d). If we now assume a more narrow distribution of the values of δ_c's we can use the next higher order Γ-distribution, namely

$$f(\delta_c) = \frac{1}{\delta_0} \left(\frac{\delta_c}{\delta_0}\right)^2 \exp(-\delta_c/\delta_0) \tag{8}$$

and we obtain for the bridging-relation

$$\sigma_{br} = \sigma_0 \frac{\delta}{\delta_0} \left(1+\frac{\delta}{\delta_0}\right) \exp(-\delta/\delta_0) \tag{9}$$

For a comparison of eqns (7) and (9) see Fig. 11.

3 A Model for Frictional Bridging Stresses

In the following considerations a model is discussed that allows us to derive a relation for friction-induced bridging effects containing elastic components. As a first step the bridging effect is modelled as a two-dimensional problem for an internal crack in an infinite body, which is bridged by one single grain. In the second step a distribution of bridging grains is considered. In Fig. 2 a section

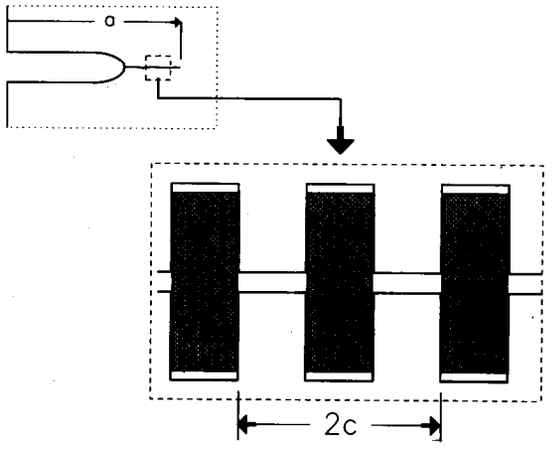

Fig. 2. Bridging model. A crack zone bridged by large grains.

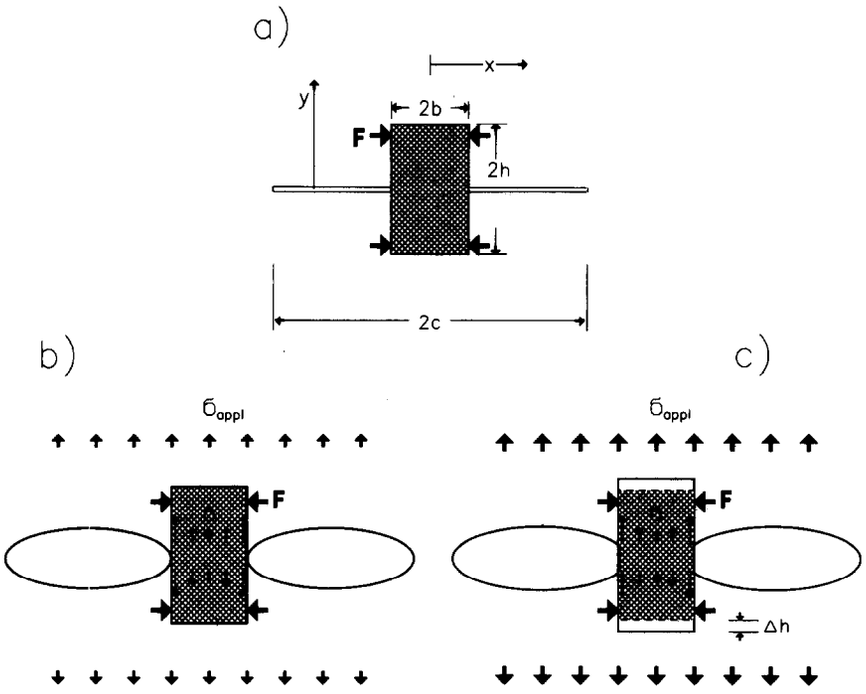

Fig. 3. Bridged crack. (a) Model of a bridged crack (unloaded). (b) Stresses and displacements for low remote loadings (schematic). (c) Stresses and displacements for high remote loadings (schematic).

of the bridged crack is shown. For the model the effect of one grain is considered and the problem can be treated as a crack of length $2c$ (twice the distance between two bridged grains). An elementary cell is shown in Fig. 3(a). Between the bridging grain and the surrounding material a residual stress acts due to mismatch of thermal expansion which creates the force F. This configuration is loaded by a remote stress $\sigma_{\text{appl.}}$ It is the aim of the following considerations to calculate the displacements at a remote location $y = y_0$ as a function of the applied stress. Figure 3(a) illustrates the geometry in the absence of externally applied stresses. For small, externally applied remote stresses σ_{appl} (Fig. 3(b)) the stresses and displacements are governed by the mixed boundary problem

$$\begin{aligned} &\delta = 0 \text{ for } |x| \le b \\ &\sigma = 0 \text{ for } |b| < |x| < |c| \end{aligned} \tag{10}$$

These conditions are valid until the load carried by the grain reaches the maximum friction force μF_0 between the bridging grain and its surroundings, i.e. for

$$2\int_0^b \sigma(x)\,\mathrm{d}x \le \mu F_0 \tag{11}$$

If the load carried by the grain exceeds μF_0, sliding between the bridging grain and the surroundings, with an amount Δh, occurs (Fig. 3(c)), the interaction force reduces to

$$F = F_0\,\frac{h - \Delta h}{h} \tag{12}$$

and the equilibrium condition of forces reads

$$2\int_0^b \sigma(x)\,\mathrm{d}x = \mu F_0 \frac{h - \Delta h}{h} \tag{13}$$

In this case, the boundary problem can be expressed by

$$\begin{aligned} &\delta = \Delta h \text{ for } |x| \le b \\ &\sigma = 0 \text{ for } |b| < |x| < |c| \end{aligned} \tag{14}$$

3.1 Calculation of displacements

Due to the symmetry of the problem with respect to $x = 0$, the computations can be restricted to positive values of x. Using the relation between stresses and displacements,[10] the mixed boundary problem can be written

$$\frac{1}{E'}\int_0^c \int_{\max(x,x')}^c h(c',x)h(c',x')\sigma(x')\mathrm{d}c'\mathrm{d}x' = \Delta h \tag{15}$$
$$\text{for } x \le b \quad \sigma = 0 \quad \text{for } b < x < c$$

The weight function for an internal crack in an infinite body under symmetrical load is[11]

$$h(x,c) = \frac{1}{\sqrt{\pi c}}\left[\left(\frac{c+x}{c-x}\right)^{1/2} + \left(\frac{c-x}{c+x}\right)^{1/2}\right] = \frac{2}{\sqrt{\pi c}}\,\frac{c}{\sqrt{c^2 - x^2}} \tag{16}$$

In the absence of a bridging interaction the crack opening displacement field is given by

$$\delta_0(x) = \frac{2\sigma_{\text{appl}}}{E'}\sqrt{c^2 - x^2} \tag{17}$$

The crack opening displacements caused by the stresses in the grain have to nullify these crack

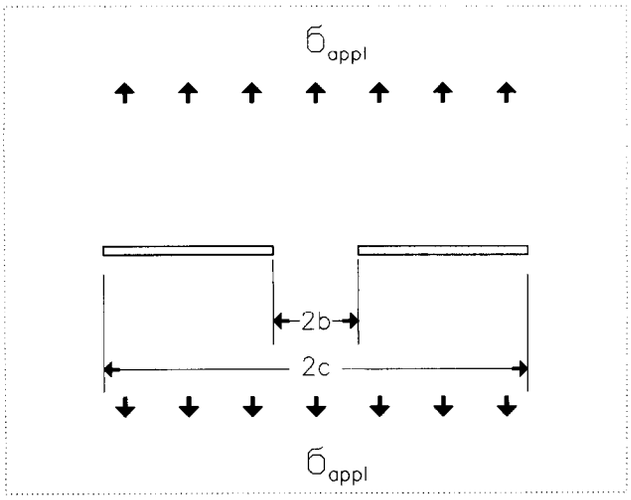

Fig. 4. Partial crack problem. Case 1: pair of collinear cracks.

opening displacements in the range $|x| \le b$. So we have to solve

$$\frac{4}{E'\pi}\int_x^c \frac{t}{\sqrt{t^2-x^2}}\left(\int_0^t \frac{\sigma(x)\,dx}{\sqrt{t^2-x^2}}\right)dt = -\frac{2}{E'}\sigma_{appl}\sqrt{c^2-x^2} + \Delta h \tag{18}$$

There are different possibilities of proceeding: (i) eqn (18) can be solved numerically; (ii) The displacement field can be superimposed by solutions existing for partial problems.

We will choose the second way here. As a first partial problem we compute the crack opening displacements for two neighbouring single cracks, Fig. 4, ensuring zero displacements within $|x| \le b$. The crack opening displacements are (see for example[11])

$$\delta_1(x) = \frac{2\,c\,\sigma_{appl}}{E'\boldsymbol{K}(k)}\,[\boldsymbol{K}(k)\,E(\varphi,k) - \boldsymbol{E}(k)\,F(\varphi,k)] \tag{19}$$

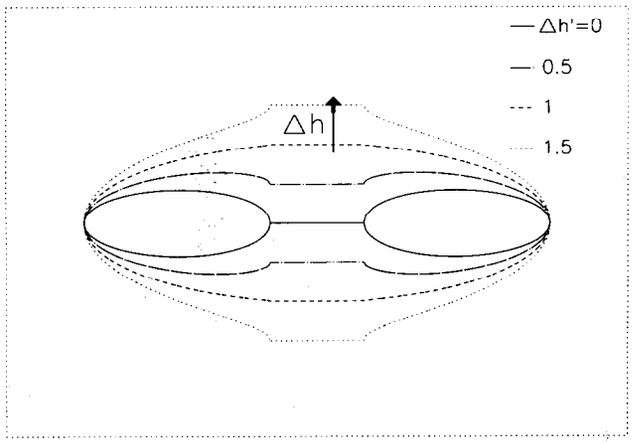

Fig. 5. Bridged crack. Displacements calculated with eqn (22), $b/c = 0{\cdot}2$ and σ_{appl} = constant, $\Delta h' = E'\Delta h/(2\sigma_{appl}c)$.

where $F(\varphi, k)$ and $E(\varphi, k)$ are the first and second elliptical integrals to the modulus k with

$$k = \sqrt{1-(b/c)^2}\quad,\ \varphi = \arcsin\sqrt{\frac{c^2-x^2}{c^2-b^2}} \tag{20}$$

and $\mathbf{K}(k)$, $\mathbf{E}(k)$ are the complete elliptical integrals. In this context, it should be mentioned that in Ref. 11 the elliptical integral $\mathbf{K}$ is missing in the denominator of eqn (19). Equation (19) represents the displacement field for $\Delta h = 0$. In order to satisfy the constant displacements $\Delta h > 0$ in $-b < x < b$, we have to add the displacement field for a parallel rigid wedge of thickness $2\Delta h$ within $-b < x < b$. In order to avoid a separation of the contact surfaces we assume the wedge to be welded with the surrounding material along the interfaces. The displacements are also given in handbooks (e.g. Ref. 11). It holds

$$\delta_2(x) = \frac{F(\varphi,k)}{\boldsymbol{K}(k)}\,\Delta h \tag{21}$$

and, finally, the total solution for the displacements is given by

$$\delta(x) = \frac{2c\,\sigma_{appl}}{E'\boldsymbol{K}(k)}\,[\boldsymbol{K}(k)\,E(\varphi,k) - \boldsymbol{E}(k)\,F(\varphi,k)] + \frac{F(\varphi,k)}{\boldsymbol{K}(k)}\,\Delta h \tag{22}$$

The crack opening displacement field resulting from eqn (22) is shown in Fig. 5.

3.2 Calculation of stresses in the bridging element

The corresponding stresses $\sigma(x)$ in the grain can be calculated numerically with eqn (18). In order to solve eqn (18), we will first calculate as a partial problem the stress distribution for a crack of length $2c$ which is opened by a parallel wedge of length $2b$ and thickness Δh (see Fig. 6). The Westergaard stress function for this problem is given in Ref. 11 as

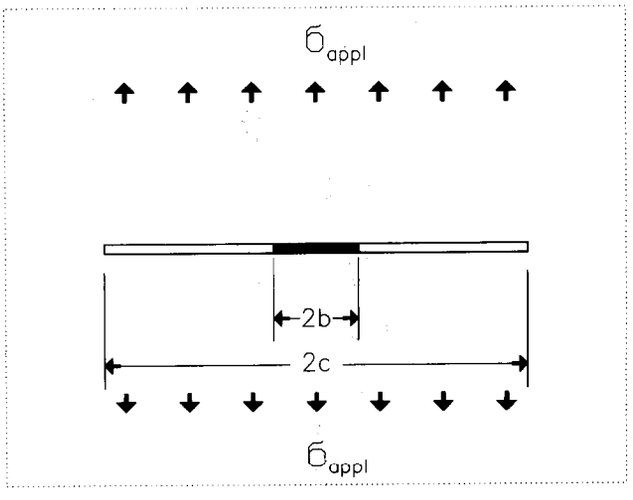

Fig. 6. Partial crack problem. Case 2: single crack opened by a wedge of constant thickness.

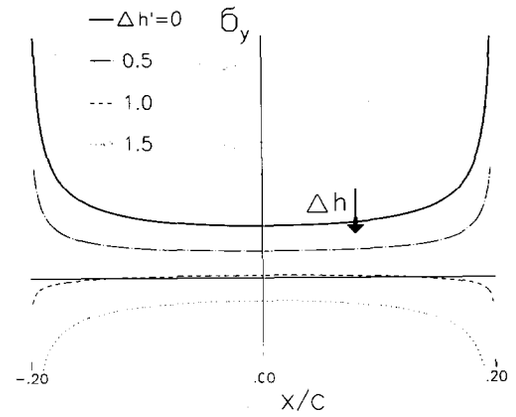

Fig. 7. Stresses in the bridging grain. Stresses calculated with eqn (18), $b/c = 0{\cdot}2$, σ_{appl} = const., $\Delta h' = E'\Delta h/(2\sigma_{appl}c)$.

$$Z(z) = \frac{E'h\,c}{2\boldsymbol{K}(k)} \frac{1}{\sqrt{z^2-c^2}\,\sqrt{z^2-b^2}}, \qquad k = \sqrt{1-(b/c)^2} \tag{23}$$

from which the normal stress σ_y results by

$$\sigma_y = \mathrm{Re}\{Z(z)\} - y\,Im\{Z'(z)\} \tag{24}$$

For $y = 0$ one obtains

$$\sigma_y = \mathrm{Re}\{Z(z)\} \rightarrow \qquad \sigma_y = \frac{E'\Delta h\,c}{2\boldsymbol{K}(k)} \frac{1}{\sqrt{c^2-x^2}\,\sqrt{b^2-x^2}} \tag{25}$$

For the pair of collinear cracks — which result for $\Delta h = 0$ — the stresses in the range $-b \le x \le b$ caused by the remote applied stress σ_{app} are (*see* Ref. 12)

$$\sigma_y = \frac{\sigma_{appl}}{\boldsymbol{K}(k)} \frac{c^2\boldsymbol{E}(k) - x^2\boldsymbol{K}(k)}{\sqrt{(c^2-x^2)(b^2-x^2)}} \tag{26}$$

Superposition of the two partial crack problems yields

$$\sigma_y = \frac{1}{\boldsymbol{K}(k)} \frac{\sigma_{appl}[c^2\boldsymbol{E}(k) - x^2\boldsymbol{K}(k)] - c\Delta hE'/2}{\sqrt{(c^2-x^2)(b^2-x^2)}} \tag{27}$$

The total force P carried by the bridging element is then

$$P = 2\int_0^b \sigma_y\,dx = 2\sigma_{appl}c[2\boldsymbol{E}(k') - \boldsymbol{K}(k')] - E'\Delta h \tag{28}$$

$$k' = \sqrt{1-k^2} = b/c \tag{29}$$

3.3 Load–displacement curve

The total volume resulting from the displacements

$$V = 4b\Delta h = 4\int_{x=b}^{x=c} \delta(x)\,dx \tag{30}$$

is a measure of the externally recorded loading-point displacements. From eqns (11) and (28) we find the applied stress at which the maximum friction force F_0 is reached

$$\sigma_{appl,0} = \frac{\mu F_0}{2c[2\boldsymbol{E}(k') - \boldsymbol{K}(k')]} \tag{31}$$

The volume at $\sigma_{appl} = \sigma_{appl,0}$ is

$$V_0 = \frac{8c\sigma_{appl,0}}{E'\boldsymbol{K}(k)} \left[\boldsymbol{K}(k)\int_b^c E(\varphi,\mathrm{k})\,dx - \boldsymbol{E}(k)\int_b^c F(\varphi,\mathrm{k})\,dx\right] \tag{32}$$

For stresses below this limit the volume is

$$V = V_0 \frac{\sigma_{appl}}{\sigma_{appl,0}} \tag{33}$$

and for higher stresses applied one obtains

$$V = V_0 \frac{\sigma_{appl}}{\sigma_{appl,0}} + 4b\Delta h + \frac{4\Delta h}{\boldsymbol{K}(k)}\int_b^c F(\varphi, k)\,dx \tag{34}$$

with Δh given as

$$\Delta h = h\,\frac{2\boldsymbol{E}(k') - \boldsymbol{K}(k')}{h' - [2\boldsymbol{E}(k') - \boldsymbol{K}(k')]}\left(\frac{\sigma_{appl}}{\sigma_{appl,0}} - 1\right) \tag{35}$$

$$h' = \frac{hE'}{2c\sigma_{appl,0}} \tag{36}$$

The volume — standing for the remote displacement at a given point — as a function of the applied remote stress is shown in Fig. 8. We can identify three regions:

1. For $\sigma_{appl} \le \sigma_{appl,0}$ the displacements are proportional to the applied load, as expressed by eqn (33).
2. At $\sigma_{appl,0}$ the applied stress overcomes the friction forces μF_0. For $\sigma_{appl,0} < \sigma_{appl} \le \sigma_{appl,max}$ the increase in displacements is steeper than in the range $\sigma_{appl} < \sigma_{appl,0}$.

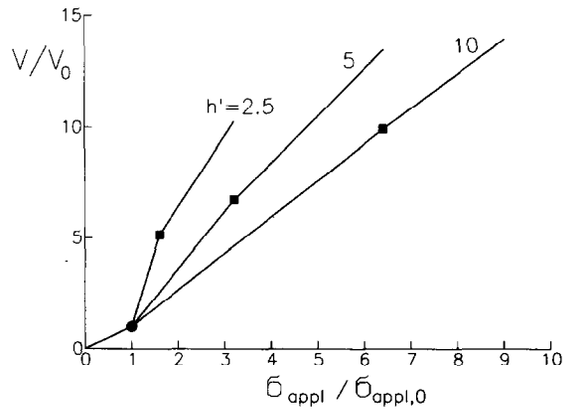

Fig. 8. Volume of the opened crack. Volume of the opened crack as a measure for the loading-point displacements, geometrical data: specimens thickness = 1 (i.e. crack opening area = crack opening volume), $b/c = 0{\cdot}2$, different values of h' as defined by eqn (36).

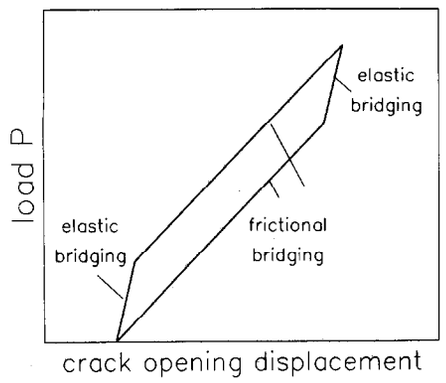

Fig. 9. COD-behaviour. Applied load, P, versus crack opening displacement curves for Al_2O_3 obtained by Dauskardt[9] (schematic).

3. At $\sigma_{appl,max}$ the bridging element is completely pulled out, equivalent to $\Delta h = h$,

$$\frac{\sigma_{appl,max}}{\sigma_{appl,0}} = \frac{h'}{2E(k') - K(k')} \tag{37}$$

and the subsequent curve follows according to

$$V = \frac{\sigma_{appl}}{\sigma_{appl,max}} = V_{appl,max} \tag{38}$$

Dauskardt[9] reports load–COD-curves which are very similar to those represented in Fig. 8. A typical P–COD-curve is schematically shown in Fig. 9 for one cycle of a cyclic test. Dauskardt calls the first steep part (corresponding to the initial flat parts of Fig. 8) 'elastic bridging' and the following phase 'frictional bridging'. Having in mind the COD-calculations made in this section, we can interpret the displacements during *elastic bridging* as the displacements occurring in the crack regions outside the actual bridging element (no elastic strain of the bridging element itself). Obviously, the displacements in Ref. 9 were not large enough ($K_I = K_{Ic}$ may be reached before) to exhibit the third part of the curve, i.e. the unbridged state.

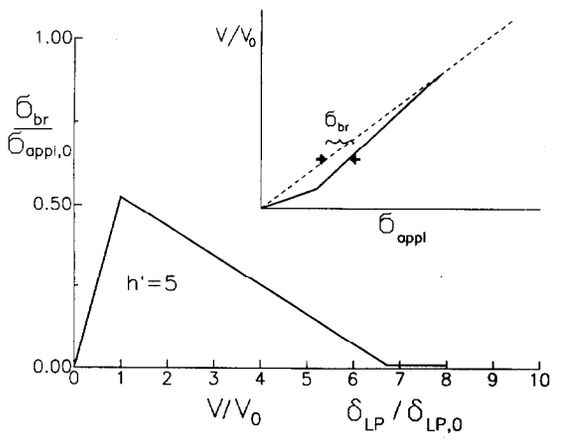

Fig. 10. Bridging stress relation. Bridging stress resulting from Fig. 8.

The bridging stresses result from the difference between the curve plotted in Fig. 8 and that curve which is obtained by prolongation of the line for $\sigma_{appl} \geq \sigma_{appl,max}$ to the origin (representing the completely unbridged state) as symbolised by the insert in Fig. 10. Considering the statistical distribution of the bridging-element lengths h, one obtains a smoother curve. If δ_{c1} is the displacement corresponding to $\sigma_{appl,0}$ and δ_c is the displacement at $\sigma_{appl,max}$, we can write the local bridging stresses as

$$\frac{\sigma}{\sigma_0} \begin{cases} \delta/\delta_{c1} & \text{for } \delta < \delta_{c1} \\ \dfrac{\delta_c - \delta}{\delta_c - \delta_{c1}} & \text{for } \delta_{c1} < \delta < \delta_c \\ 0 & \text{for } \delta < \delta_c \end{cases} \tag{39}$$

In the most general case one may consider the two typical displacements to be distributed independent of each other. But since the maximum friction force F_o characterising the onset of sliding, $\delta = \delta_{c1}$, is proportional to the length h of the bridging element and also the characteristic displacement of complete pull-out is identical to h, it is sufficient to consider the distribution of δ_c by introducing the ratio

$$\lambda = \delta_c/\delta_{c1} = \text{constant} \tag{40}$$

Replacing δ_{c1} in eqn (39) by δ_c λ and introducing this local bridging relation into eqn (3) yields for a Γ-distributed δ_c according to eqn (2) the averaged bridging relation

$$\sigma_{br} = \sigma_0 \frac{\lambda}{\lambda - 1} [\exp(-\delta/\delta_0) - \exp(-\lambda\, \delta/\delta_0)] \tag{41}$$

In Ref. 13 the authors used a Morse-like bridging relation

$$\sigma_{br} = \sigma_0 [\exp(-\delta/\delta_0) - \exp(-2\, \delta/\delta_0)] \tag{42}$$

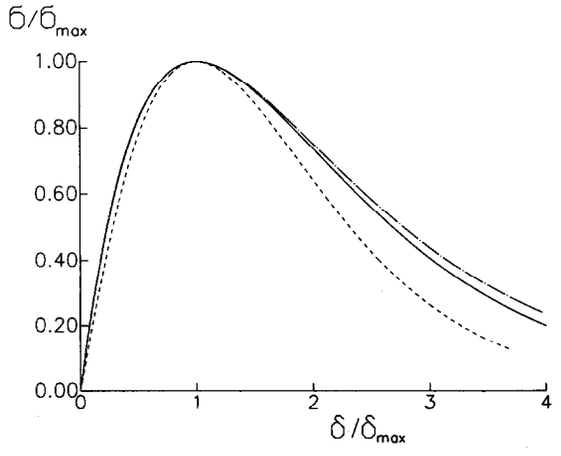

Fig. 11. Comparison of bridging stress relations. Solid curve: eqr (7), dashed curve: eqn (9), dash-dotted curve: eqn (42); δ_{max} is that displacement at which the stress reaches its maximum value.

which is a special case of eqn (41) with $\lambda = 2$. A comparison between the bridging relations described by eqns (7), (9), and (42) is given in Fig. 11.

4 Summary

Bridging stresses in ceramic materials are responsible for the R–curve behaviour. They are generated by crack surface interactions in the wake of a propagating crack and can be caused by friction of sliding grains or by elastic interactions where the crack surface contact behaves like a spring. In this paper, relations for the average bridging stresses as a function of the actual crack opening displacement are proposed and a model is discussed which allows to combine the two effects leading to 'elastic bridging' and 'frictional bridging' as observed by Dauskardt.[9]

The model yields a relation between the bridging stresses and the crack opening displacements. The three free parameters σ_0, λ and δ_0 may be determined

- by direct measurements of the bridging stresses in tensile tests,[14]
- from load–displacement curves as given by Dauskardt,[9]
- by fitting the bridging relation to measured R–curves.

Statistical Determination of Surface Flaw Distributions in Brittle Materials

P. D. Warren

Department of Materials, Oxford University, Oxford OX1 3PH, UK

(Received 19 May 1994; revised version received 24 August 1994; accepted 12 December 1994)

Abstract

A computational method is presented for determining the distribution of surface flaws in brittle materials from a series of fracture tests. The number of cracks per unit area with sizes within a range c *to* c + Δc *can be determined by the solution of a system of simultaneous linear equations. As long as the stress intensity factor for the cracks causing fracture can be calculated then results can be obtained from any loading method; the method therefore assumes that the shape of the cracks causing fracture is known. The only data inputs are the fracture loads themselves. Accurate estimates of the flaw density can only be obtained if proper consideration is given to the variation of the stress intensity factor with the angle between the crack-face normal and the tensile stress. Results are shown for computer simulations of 3-point bend testing.*

1 Introduction

The strength of ceramic materials is, unlike that of most metals, inherently variable; fracture occurs over a range of stresses as a result of a distribution of flaw sizes and positions. The most common way of describing the distribution of flaws is that due to Weibull.[1] The Weibull failure probability is defined in its simplest form as:[2]

$$F = 1 - \exp\left[-(\sigma_I/\sigma_o)^m\right] \qquad (1a)$$

where σ_I is the inert strength of the material, m is the Weibull modulus and σ_o a normalizing parameter. In the case where the stress varies with position in the surface of the body, as for instance in a three-point bend test, then the Weibull failure probability becomes:

$$F = 1 - \exp\left[-\int\left(\frac{\sigma_I}{\sigma_o}\right)^m \frac{dA}{A_o}\right] \qquad (1b)$$

σ_o and A_o are normalizing parameters. For equation (1(a)), by forming the cumulative probability of failure, a plot of $\ell n\{\ell n[1/(1-F)]\}$ against $\ell n(\sigma_I)$ should give a straight line of slope m and intercept $-m\ell n(\sigma_o)$. However, it is well known that simple Weibull statistics are not a good description of failure probabilities, particularly if multiple flaw populations are present.[3] Furthermore, this approach gives no direct information about the distribution of the flaws themselves, in terms of the number of flaws in a given size range per unit area, $n(c)\Delta c$.

Argon[4,5] proposed using the Hertzian indentation test as a way of determining surface flaw densities in glass. In this test a hard sphere is pressed against the surface of a solid until fracture occurs (the formation of a ring-crack or ring-cone crack). Argon measured *just* the fracture loads and determined $n(c)\Delta c$ by numerical inversion of Laplace transforms. Wilshaw[6] and Poloniecki and Wilshaw[7], again using Hertzian indentation, presented a different method of analysis. They were motivated by the fact that Argon, 'by analysing only the fracture forces, made the problem unnecessarily complicated'. By measuring the fracture loads *and* the radii of ring-cracks seen on the glass surface *after* fracture, the sizes of the small precursor surface flaws could be determined. For a given test and crack size, the 'searched area' could be defined: 'that area of surface within which, had there been a crack of size c, it would have caused fracture during loading up to a load P'. Thus the searched area, $A(P,c)$, is that area of surface within which $K_I > K_{IC}$ for a crack of size c during loading up to P. The flaw density is simply that number of cracks found within a given size range (c to $c+\Delta c$) divided by the total area searched for flaws of that size (c) in all the tests. This method is not restricted to Hertzian indentation, and is in principle applicable to any test method. It is thus an extremely powerful method of determining flaw densities although it suffers from the disadvantage that it is necessary to find the position from which failure started.

Matthews, McLintock and Shack[8] derived a different method for determining n(c)Δc from *just* the fracture loads measured in 3-point bend tests or Hertzian indentation tests; this method relied on the analytical inversion of an integral equation, which is possible only in limited cases. Evans and Jones[9] extended the work of Matthews *et al.* to include straight-forward tension, the expanding-ring tensile test and biaxial flexure, but again analytical inversion of the fundamental integral equation was crucial to the success of the method.

Alternatively, various analytical forms for the flaw distribution have been proposed. That due to Jayatilaka and Trustrum[10] is:

$$f(a) = \frac{c^{n-1}}{(n-2)!} a^{-n} e^{-c/a} \qquad (2a)$$

where $f(a)$ is the probability density of cracks of semi-length a; c is a scaling parameter (*not* the crack size in this case) and n is a measure of the rate at which the flaw density approaches zero. In fact, $2n\text{-}2=m$, where m is the Weibull modulus. That due to Batdorf and Crose[11] and Batdorf and Heinisch[12] is:

$$N_s(\sigma) = k\sigma^m \qquad (2b)$$

where $N_s(\sigma)$ is the surface crack density function, k is the crack density coefficient and m is the Weibull modulus. Recently, Santhanam and Shaw[13] determined flaw density distributions in ceramic tubes fractured by the crack-off process: by using a weakest-link approach (see below) combined with a flaw distribution function of the form of eqn (2a) (replacing the factorial function with the Γ function to allow for non-integral n) a best-fit of the function $f(a)$ to the fracture data was performed, leading to values for c and n.

In summary, there are three distinct approaches for determining $n(c)\Delta c$, the number of flaws per unit area in a size range Δc centred on c

(1) One can measure a fracture load *and* a fracture position (in which case the size of the crack that caused fracture can be determined); one then uses Wilshaw's[6,7] concept of 'searched area' to determine the flaw density.
(2) Alternatively, one can follow the approach of Matthews *et al.*[8] (or Evans and Jones)[9] where one measures *just* the fracture loads, and then use analytical inversion of an integral equation to determine $n(c)\Delta c$.
(3) Finally, one can follow Santhanam and Shaw's[13] approach, by assuming a functional form for n(c)Δc and obtaining the best values of the adjustable parameters in the expression for $f(a)$.

There are problems with all three approaches. For method (1), in the case of Hertzian indentation it can be extremely difficult to find the ring-cracks formed after fracture, especially on surfaces that are not highly polished. One usually has to resort to the use of chemical etches to bring out the cracks, which in the case of ceramic materials such as alumina means using molten KOH at 360°C. This is not convenient. The second problem with method (1) is that it is not possible to automate it. In principle this means that method (2) is preferable. Unfortunately, the calculations necessary to obtain $n(c)\Delta c$ require (for the analytical inversion of the integral equation) that the form of the stress-field experienced by the cracks is simple, so that the method is not of general application. For Hertzian indentation Argon,[4,5] Wilshaw[6,7] and Matthews *et al.*[8] all assumed that the only stress acting on the crack was the surface radial stress; the steep stress gradients that exist in the Hertzian field were ignored. As pointed out by Lawn,[2] the issue of stress gradients has been largely overlooked by flaw statistics analysts. Finally, in method (3) the problem lies in *assuming* a probability distribution of a particular form. While the form given above, eqn (2) is analytically straightforward, it forces the density of small cracks to be small. For many purposes, (e.g. strength of ceramics), knowledge of the density of small cracks may be irrelevant, but if one is investigating, for example, polishing processes then information about these cracks may be important. Secondly, by forcing the small-crack density to be small, one runs the risk of skewing the distribution at the large crack end.

In the method described below, these problems are overcome. The determination of $n(c)\Delta c$ is accomplished by knowledge of just the fracture loads in a series of tests; no prior assumptions are made about the form of $n(c)\Delta c$, and any loading system can be catered for, as long as K_I can be calculated. Thus the only assumption made here is one about the *shape* of the cracks causing fracture. Finally, most previous methods (with the exception of Santhanam and Shaw)[13] of estimating $n(c)\Delta c$ have ignored the effect of the variation in K_I with the angle between the crack-face normal and the tensile stress axis. It will be shown that this has a pronounced effect on the values of n(c)Δc determined.

2 Weakest-link Statistics

Following Sigl[14] and Danzer[15] we can write the cumulative probability of failure of a body during loading to a load P, $F(P)$, in terms of the *cumulative number of critical flaws* in the surface of the body, N(P):

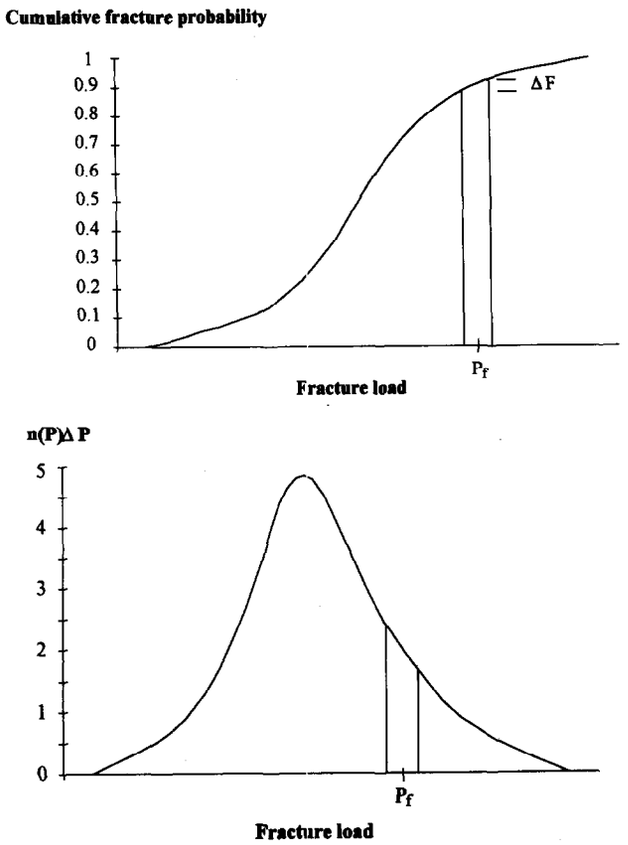

Fig. 1. Generic plots of: (a) cumulative probability of fracture $F(P)$, (b) number of fractures within a given load range $n(P)\Delta P$, both as a function of P.

$$F(P) = 1 - \exp(-N(P)) \tag{3}$$

Figure 1(a) shows a generic plot of $F(P)$, the cumulative probability of failure versus fracture load; Fig. 1(b) is the differential of this, $n(P)\Delta P$, the number of fracture loads in the range P to $P+\Delta P$. We define the number of flaws in a given size range per unit area, $n(c)\Delta c$: it is this quantity that is to be determined. Then, the number of flaws in the size range c to $c+\Delta c$ which are critical when the body is subjected to a load P is:

$$N'(c)\Delta c = A(P, c)\mathrm{n}(c)\Delta c \tag{4}$$

where, following Wilshaw,[6] $A(P, c)$ is the *area searched* for flaws of size c during loading to P i.e. that area of material within which $K_I > K_{IC}$ for flaws of size c during loading to P. It is this quantity $A(P, c)$ that can be calculated for any loading system, assuming that the crack shape is known. For a distribution of crack sizes, we finally obtain:

$$F(P) = 1 - \exp\left[-\sum_j A(P, c_j)\mathrm{n}(c_j)\Delta c\right] \tag{5}$$

A similar equation can obviously be derived for the three-dimensional case by replacing $A(P, c)$ by $V(P, c)$, the *volume* searched for flaws of size c during loading to P and by re-defining $n(c)\Delta c$ as the number of flaws in a given size range per unit volume.

Equation (5) can be re-cast in the form of a matrix equation:

$$\mathbf{b} = \mathbf{A}\mathbf{x} \tag{6}$$

$\mathbf{b}$ is a column vector with, say, m known components $b_i = -\ell\mathrm{n}[1-F(P_i)]$, $\mathbf{A}$ is an mxn matrix, whose known components are the searched areas, $A_{ij} = A(P_i, c_j)$ and $\mathbf{x}$ is a column vector with the n *unknown* components, $x_j = n(c_j)\Delta c$. $\mathbf{A}$ has $i = 1, m$ rows, corresponding to m points on the cumulative probability curve, $F(P_i)$, and $j = 1, n$ columns corresponding to those n crack sizes whose areal densities are to be determined. Strictly, m and n can be chosen arbitrarily, although as will be shown there are certain restrictions on the values that should be used in practice. We give below some examples of the utility of eqn (6).

3 Calculation of Searched Areas

In what follows we assume that the flaws controlling fracture are semi-circular surface-breaking cracks oriented normal to the tensile stress, σ. The stress intensity factor experienced by such a crack, depth c, is:

$$K_I = Y\sigma\sqrt{\pi c} \tag{7}$$

where Y is a shape factor, ~0·713.

3.1 Uniform tension

Figure 2 shows a rectangular parallelepiped pulled with a load P so that the tensile stress $\sigma = P/w^2$ where w^2 is the cross-sectional area of the block. Defining α_1 as:

$$\alpha_1 = \frac{w^2 K_{IC}}{Y\sigma\sqrt{\pi}} \tag{8a}$$

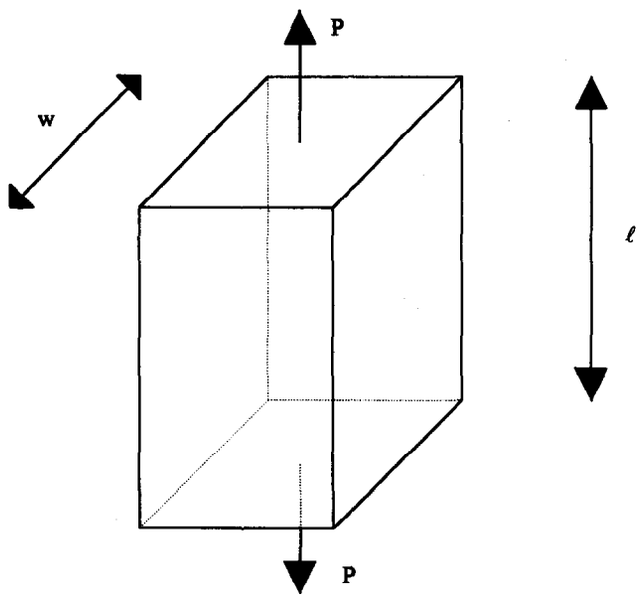

Fig. 2. Parallelepiped pulled by a uniform tension.

then, as long as $P_i \geq \alpha_1/\sqrt{c_j}$, the searched area is:

$$A(P_i, c_j) = 4w\ell \tag{8b}$$

Note that the area searched *during* loading up to P is the same as the area searched *at* a load P. It is perfectly possible to choose $m = n = 3$ (say), and also possible to choose the values of P_i and c_j such that eqn (6) takes the form:

$$\begin{pmatrix} 0 & 0 & A \\ 0 & A & A \\ A & A & A \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix} \tag{9a}$$

where the components of **b** are ranked in order of increasing load, and the components of **x** are ranked in order of increasing crack size. The solution is given by:

$$\begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} (b_3 - b_2)/A \\ (b_2 - b_1)/A \\ b_1/A \end{pmatrix} \tag{9b}$$

and it is clear that the density of the *largest* cracks, x_3, is controlled by the probability of fracture at the *lowest* load, b_1 as would be expected. Similarly, it is perfectly possible to set $m = n = 4$ and choose the values of P_4 and c_4 such that the matrix **A** has the form:

$$\begin{pmatrix} 0 & 0 & A & A \\ 0 & A & A & A \\ A & A & A & A \\ A & A & A & A \end{pmatrix} \tag{9c}$$

(This could be accomplished by choosing P_4 to be much bigger than P_3 but choosing c_4 to be only slightly larger than c_3). It is immediately clear that **A** is rank-deficient and that no unique solution for **x** exists. Surprisingly, it turns out that if $m = n$ then this is the normal situation; obviously if $m > n$, (i.e. one has more equations than unknowns) then there is never any unique solution for **x**. The method of solution of eqn (6) will be discussed in Section (5).

We now show that the matrix method of solution gives the same answers as those obtained by more conventional methods, at least in the simple case of uniform tension applied to a block. Suppose that a total of N_T fracture tests are performed and N_T fracture loads measured. From eqn (7) one can therefore derive N_T crack sizes. Let $n(P_f)\Delta P$ be the number of fracture loads in a load range ΔP, centred on P_f, this corresponds to the same number of cracks in a size range Δc, centred on c. The area searched for cracks in this size range is the product of the number of tests where the fracture load was greater than or equal to P_f (N_{crit}) with the area searched in each test (A), i.e. $N_{crit}A$. From Figs 1(a) and 1(b) we see that the fraction of tests with $P \geq P_f$ is $1\text{-}F(P_f)$. So, the total searched area is $N_{crit}A = N_T[1\text{-}F(P_f)]A$. But, also from Figs 1(a) and 1(b) the number of fracture loads that found cracks in this range is $N_T[\Delta F(P_f)]$, so that the crack density is:

$$n(c)\Delta c = \frac{\Delta F(P_f)}{[1 - F(P_f)]A} \tag{10}$$

By the matrix method, we can let $m = n$, and we can also choose the values of P and c such that A is triangular, i.e. all the upper-left components of A are 0. In this case, by analogy with eqn (9b) we see that the solution for the jth crack density is:

$$An(c_j)\Delta c = (b_{n-j+1} - b_{n-j}) = -\ell n\left[\frac{1 - F(P_{n-j+1})}{1 - F(P_{n-j})}\right] \tag{11a}$$

where P_{n-j} is the fracture load corresponding to a crack of size c_j. Letting n become large:

$$An(c)\Delta c = -\ell n\left[\frac{1 - F(P+\Delta P)}{1 - F(P)}\right] \tag{11b}$$

or, if $F(P + \Delta P) = F(P) + \Delta F(P)$, then:

$$n(c)\Delta c \approx \frac{\Delta F(P)}{[1 - F(P)]A} \tag{11c}$$

as before, eqn (10).

3.2 3-point bending

Referring to Fig. 3, we see that the tensile stress in the lower surface of the bar is given by:

$$\sigma(x) = \frac{3P(L - x)}{bh^2} \tag{12a}$$

Again, assuming that the only flaws present are semi-circular flaws oriented perpendicular to the tensile stress then the stress intensity factor for a flaw of depth c is as in eqn (7). For a load P_i and a flaw depth c_j the maximum distance that a flaw can be found from the centre of the tensile face is x_m:

$$x_m = L - \alpha_2 / (P_i\sqrt{c_j}) \quad \alpha_2 = \frac{K_{IC}bh^2}{3Y\sqrt{\pi}} \tag{12b}$$

For $P_i \geq \alpha_2/(L\sqrt{c_j})$ the area searched $A(P_i, c_j)$ is:

$$A(P_1, c_j) = \int_0^{x_m} 2b\,dx = 2b\left[L - \frac{\alpha_2}{P_i\sqrt{c_j}}\right] \tag{12c}$$

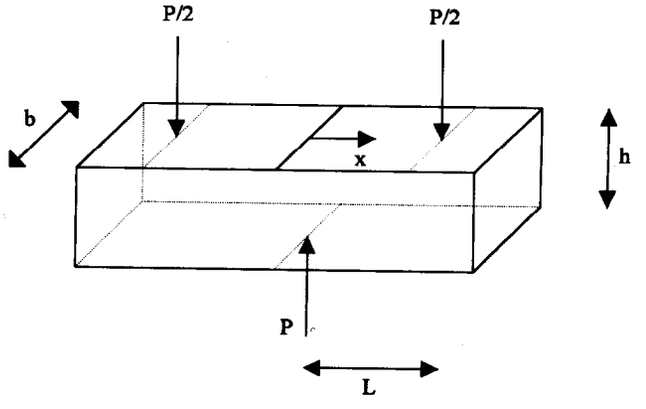

Fig. 3. Three-point bend test.

Note again that the area searched *during* loading up to P is the same as the area searched *at* a load P. In Appendix 1 we show that if eqn (6) is converted to its integral form and then combined with the expression for $A(P_i, c_j)$ from eqn (12c) one obtains the same expression for the flaw density as that originally derived by Matthews *et al.*[8]

3.3 Hertzian indentation

Finally, we consider an example where the area searched during loading to P is not the same as the area searched at a load P, the example of Hertzian indentation. If a sphere, radius R, elastic constants ν_s, E_s, is pressed with a load P into the flat surface of a substrate, elastic constants ν, E, then the two solids touch over a circular contact patch, radius a where:

$$a = \left(\frac{3RP}{4E^*}\right)^{1/3} \qquad \frac{1}{E^*} = \frac{1-\nu^2}{E} + \frac{1-\nu_s^2}{E_s} \quad (13a)$$

The stress state set up outside the contact patch *in the surface of the substrate* is one of radial tension, σ_{rr}, and hoop compression, $\sigma_{\theta\theta}$:

$$\sigma_{rr} = -\sigma_{\theta\theta} = \frac{(1-2\nu)}{2\pi}\frac{P}{r^2} \qquad r \geq a \quad (13b)$$

With K_I given by eqn (7) then for a load P_i and a flaw depth c_j the maximum distance that a flaw can be found from the centre of the indentation is r_m:

$$r_m = \left(\frac{P\sqrt{c}}{\alpha_3}\right)^{1/2} \qquad \alpha_3 = \frac{2\sqrt{\pi}K_{IC}}{Y(1-2\nu)} \quad (13c)$$

For $P_i \geq a^2\alpha_3/\sqrt{c_j}$ then the searched area *at* a load P_i is:

$$A(P_1, c_j) = \int_a^{r_m} 2\pi r dr = \pi(r_m^2 - a^2) \quad (13d)$$

However, as originally shown by Wilshaw[6] $K_I > K_{IC}$ for loads lower than P_i. The minimum load at which $K_I = K_{IC}$, for a crack size c, is P_{min}. The crack must be situated at the position of maximum tensile stress, i.e. at the corresponding contact radius, a_{min}:

$$P_{min} = \left(\frac{3R\alpha_3}{4E^*}\right)^2 \frac{\alpha_3}{c^{3/2}} \qquad a_{min} = \frac{3R\alpha_3}{4E^*c^{3/2}} \quad (13e)$$

The total area searched in loading up to P_i is therefore:

$$A(P_i, c_j) = \pi(r_m^2 - a_{min}^2) \quad (13f)$$

The variation of the maximum value of K_I with distance from the centre of the contact during loading is of importance for Section (4). At a maximum load P (and a corresponding contact radius a), for a given position $r(r \geq a)$ then the maximum K_I at that position is given by:

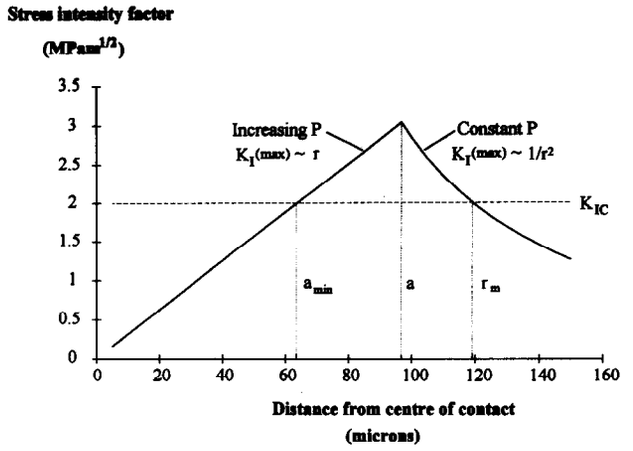

Fig. 4. Hertzian indentation: plot of maximum value of K_I as a function of distance from the centre of the contact using eqns (13g) and (13h), for the particular case $Y = 1{\cdot}12$, $\nu = 0{\cdot}24$, $E = 390$ GPa, $R = 2{\cdot}5$ mm, $K_{IC} = 2$ MPam$^{1/2}$, $P = 100$ N and $c = 3\mu$m.

$$K_I(\max) = \frac{Y(1-2\nu)}{2\pi}\frac{P}{r^2}\sqrt{\pi c} \qquad r \geq a \quad (13g)$$

However, for loads lower than P (but greater than P_{min}), the maximum K_I occurs at $r = a$. Therefore, replacing P by $4E^*r^3/3R$ in eqn (13g) we obtain:

$$K_I(\max) = \frac{Y(1-2\nu)}{2\pi}\frac{4E^*}{3R}r\sqrt{\pi c} \qquad a_{min} \leq r \leq a \quad (13h)$$

Figure 4 shows a plot of $K_I(\max)$ as a function of distance from the centre of the contact for the particular case $Y = 1{\cdot}12$, $\nu = 0{\cdot}24$, $E = 390$ GPa, $R = 2{\cdot}5$ mm, $K_{IC} = 2$ MPam$^{1/2}$, $P = 100$ N and $c = 3$ μm.

4 Angular Variation

We now consider how the expressions for $A(P_i, c_j)$ are modified if the cracks are no longer oriented perpendicular to the tensile stress, but are skewed round at an angle θ. (The cracks are still assumed to be perpendicular to the specimen surface). We now replace the elemental searched area ΔA by the *angularly-weighted* elemental searched area: $\Delta A' = \phi(\Delta A)$ where ϕ is defined as the ratio of the angular range within which $K_I = K_{IC}$ (for a given P and c), $2\phi_c$, to the angular range within which cracks can possibly be found, ϕ_0. Assuming that the angular distribution of the cracks is uniform then $\phi_0 = \pi$; this assumption will be acceptable for normal polishing and lapping procedures but may not be true if the ceramic surface has been machined in one direction only.

For Sections (4.1) and (4.2) below, eqn (7) is replaced by:

$$K_I = Y\sigma\sqrt{\pi c}\cos^2(\theta) \quad (14)$$

We make the assumption that mode I fracture still predominates, i.e. that the skewing of the

crack does not give rise to significant mode II or mode III stress intensity factors.

4.1 Uniform tension

With α_1 as in eqn (8a) we have:

$$\phi_c = \cos^{-1}\left[\left(\frac{\alpha_1}{P\sqrt{c}}\right)^{1/2}\right] \quad (15a)$$

With $P_i \geq \alpha_1/\sqrt{c_j}$ the searched area becomes:

$$A'(P_i, c_j) = \frac{8w\ell}{\pi}\cos^{-1}\left[\left(\frac{\alpha_1}{P_i\sqrt{c_j}}\right)^{1/2}\right] \quad (15b)$$

As P_i or c_j become large then $A'(P_i, c_j)$ tends to $A(P_i, c_j)$, from eqn (8b).

4.2 3-point bending

With K_I given by eqn (14), $\sigma(x)$ by eqn (12a) and x_m as in eqn (12b), we have:

$$\phi_c = \cos^{-1}\left[\left(\frac{L - x_m}{L - x}\right)^{1/2}\right] \quad (16a)$$

For $P_i \geq \alpha_2/(L\sqrt{c_j})$, the searched area $A'(P_i, c_j)$ is:

$$A'(P_1,c_j) = \int_0^{x_m}\left(\frac{2\phi_c}{\pi}\right)(2b\mathrm{d}x) = \frac{4b}{\pi}\left[L\cos^{-1}\left(\sqrt{\frac{L-x_m}{L}}\right) - \sqrt{(L-x_m)x_m}\right] \quad (16b)$$

We note that both $A'(P_i, c_j)$ and $A(P_i, c_j)$, eqn (12c), tend to $2bL$ as either P_i or c_j become large.

4.3 Hertzian indentation

If the flaws are not oriented perpendicular to the radial direction, then the compressive hoop stress must also be taken into account.

The total tensile stress acting across the crack face, oriented at θ to the radial direction is now:

$$\sigma = \sigma_{rr}\cos^2(\theta) + \sigma_{\theta\theta}\sin^2(\theta) = \frac{(1-2\nu)}{2\pi}\frac{P}{r^2}\cos(2\theta) \quad (17a)$$

With a_{min} as in eqn (13e) and r_m as in eqn (13c) we have:

$$\phi_{c1} = \frac{1}{2}\cos^{-1}\left(\frac{a_{min}}{a}\right) \qquad a_{min} \leq r \leq a \quad (17b)$$

$$\phi_{c2} = \frac{1}{2}\cos^{-1}\left(\frac{r^2}{r_m^2}\right) \qquad a \leq r \leq r_m \quad (17c)$$

The searched area up to a load P_i, $A'(P_i, c_j)$, must be calculated in two parts:

$$A'(P_1,c_j) = \int_{a_{min}}^{a}\left(\frac{2\phi_{c1}}{\pi}\right)(2\pi r\mathrm{d}r) + \int_a^{r_m}\left(\frac{2\phi_{c2}}{\pi}\right)(2\pi r\mathrm{d}r) \quad (17d)$$

$$A'(P_1,c_j) = (r_m^4 - a^4)^{1/2} - a_{min}\,a^2 - a^2_{min} \quad (17e)$$

As P_i or c_j become large, the expression for $A'(P_i, c_j)$ does *not* reduce to that for $A(P, c)$ eqn (13f), because the stress state is now different.

If the angular modifications to the searched area, eqns (15b), (16b) and (17e), are not taken into account the searched areas are over-estimated; thus the crack density required to produce a given probability of fracture, $F(P)$, is under-estimated. The calculations below show that this under-estimate can be a large factor, up to $\times 10$.

5 Method of Solution of Eqn (6)

As mentioned above, the solution of eqn (6) is apparently straightforward if one forces $m = n$ so that **A** is a square matrix. Unfortunately, standard routines for inverting matrices show that **A** is rank-deficient unless n is very small, say 3 or 4. A small value for n corresponds to representing $F(P)$ by a few points, which is obviously unsatisfactory. Therefore one chooses m to be large (say 25) and n to be smaller (say 10), in which case the system is over-determined and there is no unique solution; **A** may still be rank-deficient. Singular-value decomposition[16] of **A** may be employed to find a minimal least-squares solution for **x**. Unfortunately, in a number of cases it has been found some of the components of **x**, (i.e. the required flaw densities) are less than zero, which is physically unrealistic. The most satisfactory method has been to use a computer library 'black box' routine, Numerical Algorithms Group E02GBF, which solves over-determined linear equations subject to linear constraints on the unknowns; the routine finds **x** so as to minimise the sum of the absolute values of the residuals **Ax-b**.

6 Computer simulated 3-point bend tests

As a demonstration of the method, we describe the results from a series of computer simulations of three-point bend tests. Semi-circular cracks with randomly chosen depths, positions and orientations were generated. The stress intensity factor for each crack is given by eqn (14). When, under an increasing load, K_I at one crack reached K_{IC}, the load, crack size, position and angle were noted. The whole process was repeated a number of times (typically 100) to give average values. The average flaw spacings for flaws of size c to $c+\Delta c$, $\lambda(c)$, were inputs to the program.

$N(c)$ flaws were distributed in each size range $(c - \Delta c/2) < c < (c + \Delta c/2)$ where Δc was usually 1 μm. The minimum crack size was 1 μm, the maximum 20 μm. The flaws were positioned within a

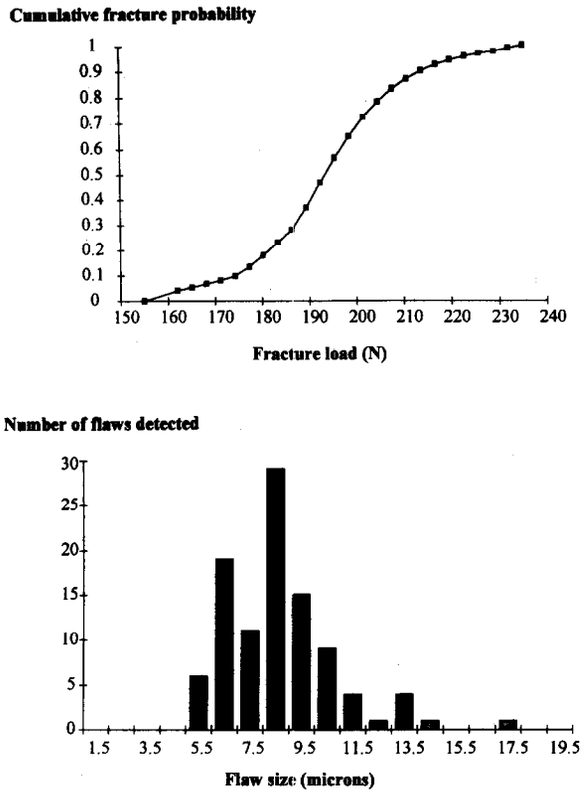

Fig. 5. Results from 100 simulated three-point bend tests: (a) cumulative fracture probability, (b) frequency plot of crack sizes found.

rectangular area, size $2bL$ (Fig. 3), with x-coordinate $-L < x < +L$. Therefore, $N(c) = 2bl/[\lambda(c)]^2$. For $\lambda(c)$ so large that $N(c) < 10$, $N(c)$ was set equal to 10, and cracks generated with x positions $-L' < x < +L'$, where $L' = 10[\lambda(c)]^2/b$.

From the results of 100 tests a cumulative probability of failure curve was constructed, usually at a probability interval of 0·04, i.e. 25 points were chosen. The vector **b** has only 24 components, $-\ln[1-F(P_i)]$; obviously the value $F(P) = 1$ is excluded. The maximum fracture load, P_{max}, sets the lower limit to the crack size, c_{min}, for which it is meaningful to calculate a density: $c_{min} = (\alpha_2/P_{max}L)^2$. The remainder of the cracks, c_j, were spaced 1 μm apart, up to $c_n = 20$ μm. With $m = 24$ values of P_i, and $n = 15$–20 values of c_j **A** and **b** were calculated and NAG E02GBF used to solve for **x**.

Figs 5(a) and 5(b) show the results from 100 simulations; the specimen dimensions were $b = 4$ mm, $h = 1{\cdot}5$ mm and $L = 10$ mm; $Y = 0{\cdot}713$, appropriate to semi-circular surface breaking flaws, and $K_{IC} = 2$ MPam$^{1/2}$. Figure 5(a) shows the cumulative probability distribution, and Fig. 5(b) shows the actual values of the crack sizes detected. (Calculating these crack sizes required knowledge of the crack position.) Figure 6 shows the areas searched for cracks of all sizes during all 100 tests; the upper curve is the searched areas calculated using eqn (12c), the lower curve those areas calculated

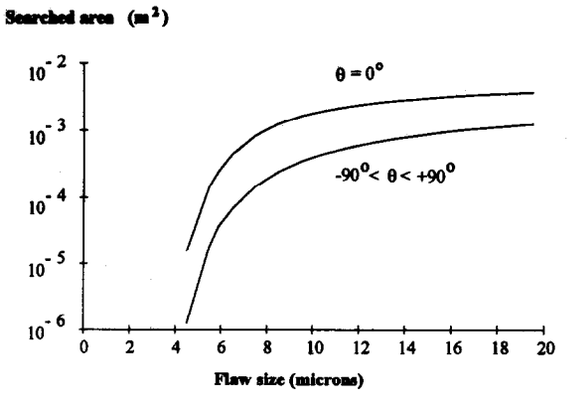

Fig. 6. Areas searched for cracks in 100 tests: upper curve assuming that all cracks are oriented normal to the applied stress; lower curve assuming cracks are randomly oriented with respect to applied stress.

from eqn (16b). The total searched area calculated ignoring the angular variation of K_I with θ is considerably larger than that calculated from eqn (16b), particularly for small crack sizes.

Figures 7(a) and 7(b) show the results of the determination of $n(c)\Delta c$, or equally $\lambda(c)$; clearly $\lambda(c) = 1/\sqrt{n(c)dc}$. Each graph shows three sets of values of $\lambda(c)$: the values input to the computer program, those calculated by Wilshaw's method,[6] and the values returned from the matrix method of calculation. Figure 7(a) shows the results with

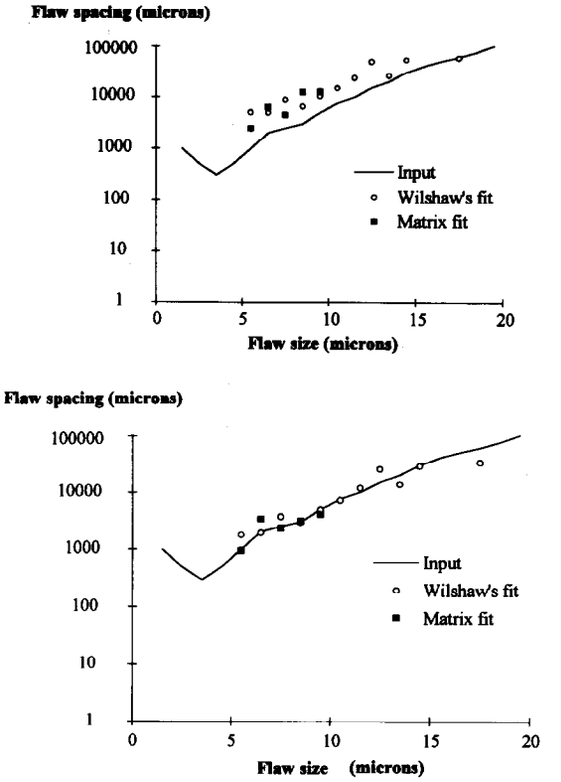

Fig. 7. Reconstruction of the input flaw distribution comparing the known input flaw density with values determined using both Wilshaw's method and the matrix method: (a) Searched areas calculated assuming that cracks are oriented normal to the applied stress. (b) Searched areas calculated assuming cracks are randomly oriented with respect to the applied stress.

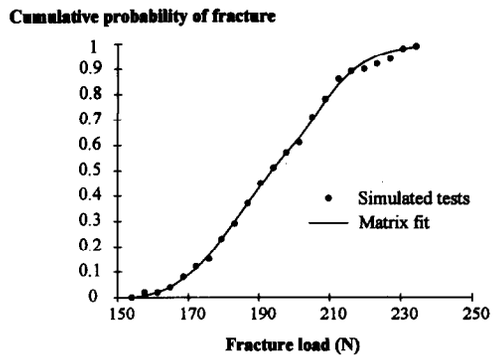

Fig. 8. Reconstruction of cumulative probability of fracture versus fracture load (Fig. 5(a)) using the flaw density distribution calculated by the matrix method.

the searched areas calculated from equation (12c), (ie. all cracks were assumed to lie normal to the tensile stress): the flaw spacings are all too high, i.e. the calculated crack densities are all too small, the discrepancy getting worse as the crack size decreases. Figure 7(b) shows the results with the searched areas calculated from equation (16b). It can be seen that both Wilshaw's method and the matrix method now give accurate estimates of the flaw spacings. Wilshaw's method gives an accurate estimate of the flaw density over almost the entire flaw size range. However, this accuracy is gained at the expense of speed; the position of the flaw actually causing fracture had to be found — to enable the flaw's size to be calculated. In the case of three-pointed bending this may not be a problem, but as mentioned above, this can be difficult in the case of Hertzian indentation. The matrix method of solution gives a reasonably accurate estimate of the flaw density, but only over a limited range of crack sizes. It appears that the best fit for the required components of **b** can be obtained by slightly over-estimating the density of small flaws (around 6–7 microns) and reducing the density of large flaws. This means that this method may not be appropriate for determining flaw densities for 'strength of ceramics' purposes where the large flaws are the ones of interest. The reason for this slight inaccuracy in the estimation of $n(c)\Delta c$ is related to the fact that the searched-area matrix **A** is frequently singular, as mentioned in Section (3(a)). The problem arises for the larger cracks. Figure 6 shows that the searched area no longer varies greatly with the size of the crack for sizes above ~12 μm. This implies that the rows of the matrix **A** may appear to be dependent and the computer routine for inverting the matrix ignores this 'unreliable' data. To compensate, the density of small flaws must be increased somewhat.

Figure 8 shows the results from taking the flaw distribution given by the matrix method, (i.e. the vector **x**) and reconstructing the cumulative probability of fracture curve: $F(P_i) = 1 - \exp(-b_i)$ with $b_i = A_{ij}x_j$. The agreement is quite remarkable.

Conclusions

Using Wilshaw's concept of 'searched area' has enabled a general method for determining the density of surface flaws in brittle materials to be derived, via the solution of a set of over-determined simultaneous equations. Weakest-link statistics are assumed, and it is also assumed that the shape of the cracks causing fracture is known, so that the stress-intensity factor for this crack under any loading situation can be evaluated. The only further inputs necessary are the fracture loads determined from a series of tests. For the three examples presented here (uniform tension, three-point bending and Hertzian indentation, ignoring the stress gradients) analytical expressions for the searched areas can be obtained, including the case where the flaws are assumed to be skewed at an angle with respect to the tensile stress. In general, this will not be possible, and numerical calculations of the searched area will be necessary. The procedure is as follows. First, for a given crack size and a given load it is necessary to calculate the minimum (r_{min}) and maximum (r_{max}) positions within which $K_I > K_{IC}$ at any stage during loading to P, bearing in mind that K_I may be greater than K_{IC} at loads less than P. Secondly, at each of a sufficiently large number of positions within this region, one must calculate the maximum value of K_I for the given crack at any load up to P, and hence determine the maximum angle, ϕ_c, through which the crack can be skewed and still maintain $K_I = K_{IC}$. Then, with the elemental area ΔA:

$$A(P_1, c_j) = \sum_{k=1}^{n} (\Delta A) \left(\frac{2\phi_c (r_k)}{\pi} \right) \qquad (18a)$$

$$r_k = \left(r_{min} + \frac{\Delta r}{2} \right) + (k-1)\Delta r \quad \Delta r = \frac{r_{max} - r_{min}}{n} \qquad (18b)$$

Work is in progress (Warren, Hills and Roberts)[17] applying this method to the determination of the surface flaw densities by Hertzian indentation taking the stress gradients of the Hertzian field into account.

We have deliberately restricted the analysis to consider only surface flaws, because our main interest is in the use of Hertzian indentation for evaluating surface damage following polishing/grinding; in Hertzian indentation the stress field is so strong at the surface that *only* surface flaws are detected. As pointed out by a referee, we recognise

that in three-point bend testing, fracture may initiate from volume flaws. In principle, it is a simple matter to repeat the analysis presented here to deal with the case where only volume flaws are present. However, further work is necessary to determine whether meaningful results can be obtained by this matrix method when *both* surface and volume flaws are present.

Appendix 1

Here we demonstrate that in the case of three-point bending, *not* taking the angular variation into account, the concept of searched areas gives the same results for the flaw density as that originally derived by Matthews *et al.*[8] The integral form of eqn (6) is:

$$\int_{c1}^{c2} A(P,c)n(c)\mathrm{d}c = -\ell\mathrm{n}[1 - F(P)] \qquad \text{(A1)}$$

$A(P,c)$ is as given in eqn (12c). The lower limit of the integral, c_1, is the smallest crack that can be detected by a load P: $c_1 = (\alpha_2/PL)^2$. The upper limit of the integral, c_2, is the largest crack that can be detected by a load P, so that by assuming K_I as given in eqn (9) there *is* no upper limit. By differentiating eqn (A1) once with respect to P we obtain:

$$\frac{2b\alpha_2}{P^2}\int_{c1}^{c2}\frac{n(c)}{\sqrt{c}}\mathrm{d}c = \frac{F'(P)}{1 - F(P)} \qquad \text{(A2)}$$

where ' denotes differentiation with respect to P. By differentiating again we obtain:

$$\frac{4b\alpha_2^2\mathrm{n}(c_1)}{P^4L} - \frac{4b\alpha_2}{P^3}\int_{c1}^{c2}\frac{n(c)}{\sqrt{c}}\mathrm{d}c = \left[\frac{F'(P)}{1-F(P)}\right]^2 + \frac{F''(P)}{1-F(P)} \qquad \text{(A3)}$$

By eliminating the integral term between eqn (A2) and (A3) we obtain:

$$n(c_1)\mathrm{d}c_1 = \frac{P^4L}{4b\alpha_2^2}\left\{\frac{2F'(P)}{P[1-F(P)]} + \left[\frac{F'(P)}{1-F(P)}\right]^2 + \frac{F''(P)}{1-F(P)}\right\}\mathrm{d}c_1 \qquad \text{(A4)}$$

where $n(c_1)$ is the number of cracks of size c_1 per unit area per unit size range. If we use the notation of Matthews *et al.*, then S_m is defined as the maximum stress corresponding to a load P and $\Phi(S_m)$ is the cumulative probability of failure. By noting that

$$P = \frac{S_m}{\beta}, \qquad \beta = \frac{3L}{bh^2} \qquad \text{(A5)}$$

$$F(P) = \Phi(S_m), \frac{\mathrm{d}F(P)}{\mathrm{d}P} = \frac{\mathrm{d}\Phi(S_m)}{\mathrm{d}(S_m/\beta)} = \beta\,\frac{\mathrm{d}\Phi(S_m)}{\mathrm{d}S_m} \qquad \text{(A6)}$$

$$\frac{\mathrm{d}^2F(P)}{\mathrm{d}P^2} = \beta^2\,\frac{\mathrm{d}^2\Phi(S_m)}{\mathrm{d}S_m^2} \qquad \text{(A7)}$$

$$c_1 = \left(\frac{\alpha_2 L}{\beta S_m}\right)^2, \qquad \mathrm{d}c_1 = \frac{-2}{S_m^3}\left(\frac{\alpha_2 L}{\beta}\right)^2\mathrm{d}S_m \qquad \text{(A8)}$$

eqn (A4) can be converted to the original result of Matthews *et al.* (their eqn 10), which is written in terms of $g(S_m)$, the number of cracks which give a strength S_m per unit area per unit strength range:

$$g(S_m)dS_m = \frac{S_m}{bL}\left\{\frac{2\Phi'(S_m)}{S_m[1-\Phi(S_m)]} + \left[\frac{\Phi'(S_m)}{1-\Phi(S_m)}\right]^2 + \frac{\Phi''(S_m)}{1-\Phi(S_m)}\right\}dS_m \quad \text{(A9)}$$

(Received 16 February 1994; revised version received 20 September 1994; accepted 12 December 1994)

Abstract

The grain size dependence of fracture strength and Weibull modulus of alumina using a high purity, commercial starting powder was investigated. In the regime of an average grain size between 1·7 and 11 μm, fracture strength increases with decreasing grain size. This behaviour could be explained quantitatively by modelling the failure-causing defect as either a spherical pore or a hemispherical surface pit with a circumferential crack proportional to the average grain size. No dependence of Weibull modulus on average grain size and hence on R–*curve behaviour could be observed. Theoretical considerations show that the closure stresses in alumina responsible for the* R–*curve behaviour are too low to affect the Weibull modulus.*

1 Introduction

The reliability of ceramics is governed by two factors; the strength and the variability of strength. In developing a material for structural applications, for example a turbo charger for heat engines, a low probability of failure can be realized either by a high Weibull modulus and a moderate characteristic strength or by a high characteristic strength and a lower Weibull modulus.[1]

An approach to increase the strength of polycrystalline ceramics is afforded by the reduction of the average grain size.[2–7] The relationship between strength and grain size has generally been described using a σ versus $G^{-1/2}$ (strength versus inverse square root of the average grain size) diagram. With large grain sizes, an increase in strength with decreasing grain size is observed. In this regime (Orowan-branch) the average grain size is larger than the flaw size due to processing defects (pores, inclusions etc), so the strength determining defect scales with the average grain radius. In the fine grain size regime (Petch-branch) the size of the processing defects is larger than the grain size. In this region only a slight increase of strength[2–6] or even a constant strength level[7] have been observed with decreasing grain size. Due to the relevance of high strength for reliability, (sufficient strength levels could only be achieved in the fine grain size regime), it is of fundamental importance to understand the grain size dependence of flexure strength. Various interpretations of the transition between the two regimes and the failure mechanism at finer grain sizes have been proposed: crack initiation through microplasticity,[2,5] the dominance of processing flaws with a microstructural dependence attributable to a monocrystal to polycrystal increase in crack resistance[3] and the variation of fracture energy with grain size.[3,4] While the early debate was based on a single value toughness for a given grain size; (the influence of a rising *R*–curve on the strength), grain size behaviour has now also been considered.[6] Then the focus remained on the low strength Orowan-branch.[6]

The second feature concerning reliability is the variability of the strength values, generally expressed by the two parameter Weibull statistics.[8] Simple theoretical models lead to the postulate of an increased Weibull modulus if *R*–curve behaviour exists.[9–12] Steinbrech *et al.*[13] demonstrated that the toughness of a coarse grained, 16 μm alumina increases from about 3 MPa $m^{1/2}$ to 6 MPa $m^{1/2}$ over a crack extension of several mm. For alumina it is well appreciated that the plateau value of the *R*–curve increases with the average grain size, due to bridging interaction.[6,13,14]

Possible complications due to residual stresses related to machining damage are considered in a second paper.[15]

In the present study we focus on the grain size dependence of flexure strength in the fine grain

size regime and present new data, as well as a simple fracture mechanical model which allows rationalization of the observed experimental findings. The general knowledge of grain size dependent R–curve behaviour in alumina is further applied to discuss the influence of the R–curve behaviour on Weibull modulus m, again under application of a simple model to account for the experimental values. Specifically, the key question may be posed as: can the decreasing strength with increasing average grain size be compensated by an enhanced Weibull modulus due to an increasing crack resistance?

2 Experimental Procedure

A commercial, ultrafine Al_2O_3 powder (Taimei Chemical Co., Ltd, TM-DAR) was used to fabricate bars (4 × 5 × 40 mm) by uniaxial pressing the as received powder at 50 MPa in a steel die followed by cold isostatical pressing at 800 MPa. Green densities of 55% of the theoretical density were attained by this procedure. The green bars were sintered at temperatures of either 1350 or 1600°C in air. The lower sintering temperature was used to produce a fine grained material and the coarse grained materials were sintered at 1600°C at different dwell times (10 min to 96 h) to alter the average grain size. The sintered densities measured by the Archimedes method using water as immersion liquid were greater than 99% TD. After preparing the surfaces by grinding and polishing the microstructure was revealed by thermal etching for 30 min at temperatures 20°C below sintering temperature for the fine grained material and 50°C for the coarse grained materials. The average grain diameter were measured using the linear intercept technique. The average grain sizes could thus be adjusted in a regime between 1·7 and 11 μm. Prior to strength testing each bar was ground to 3 × 4 mm by a rotating diamond disk.

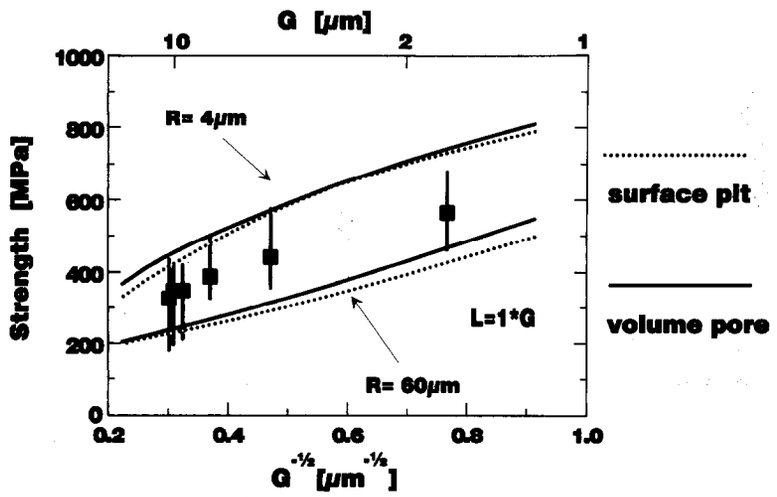

Fig. 2. Strength as function of the average grain size; solid lines represent the computed grain size dependence of strength assuming a spherical pore with an annular crack as fracture origin, dashed lines use the assumption of a hemispherical surface pit with a peripheral crack as a fracture origin.

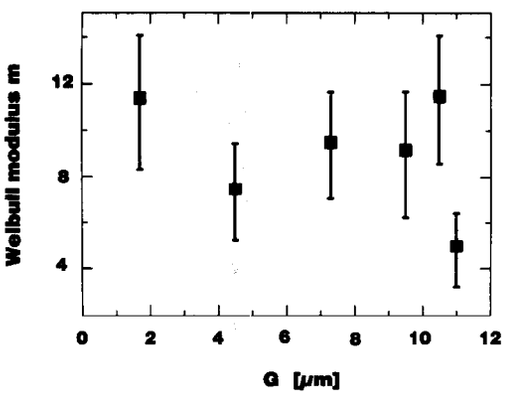

Fig. 3. Weibull modulus and 90%-confidence intervals as function of the average grain size.

The prospective tensile surfaces were finally ground with a 15 μm disk and polished by hand to a 3 μm finish. Uniaxial strength testing was carried out with a four-point bending test device, span lengths 10 and 20 mm with 20–30 bars for each batch in laboratory atmosphere of about 50% relative humidity. The loading rate was 1 mm/min.

The variability of the strength values was analysed corresponding to the 2 parameter Weibull approach, expressed by eqn 1 (with σ the fracture strength and σ_0 the Weibull scale parameter):

$$F = 1 - \exp(-(\frac{\sigma}{\sigma_0})m) \quad (1)$$

The strength values were ranked in ascending order and each strength value was associated with a fracture probability F evaluated by (with n the total number of specimens and i the i'th specimen):

$$F = \frac{i - 0{\cdot}5}{n} \quad (2)$$

The Weibull modulus, m and the 90% confidence intervals were evaluated using the maximum likelihood method.

Scanning electron microscopy was used to examine the fracture surfaces and to identify the strength determining defects.

3 Results

Figure 1 shows the strength distributions of the alumina batches with different grain size. The solid lines through the strength data are the curves representing the fit on the basis of the 2 parameter Weibull approach with the parameters m and σ_0.

Replotting the data as mean strength versus inverse square root of grain size shows the clear trend of an increasing strength with decreasing average grain size G (Fig. 2) with a rise of σ from 325 MPa at an average grain size of 11 μm to 564 MPa at G = 1·7 μm. Evaluation of the Weibull parameter m using the maximum likelihood method yields, with one exception, Weibull moduli ranging from 8 to 11 (Fig. 3). If the confidence intervals are included (Fig. 3) no dependence of m on G in the grain size region up to 11 μm could be observed. Not all the strength data correlate well with the corresponding Weibull parameter fit (Fig. 1). The small grain size materials exhibit a tendency to a low strength cut-off which may be better described by a three parameter Weibull approach, while the material with G = 11 μm might be better fitted by a bimodal strength distribution.

Most of the fracture surfaces investigated reveal volume defects in the form of large voids near the tensile surface as failure source (Fig. 4(a)–(c) see also Fig. 1). In a few cases surface flaws could be identified (Fig. 4(d) see also Fig. 1). There is no indication of a change of the defect character with grain size. Fig. 4(a)–(c) shows the fracture origins from specimens with three different grain sizes. The diameter of the defects (2R) in a batch with identical average grain size ranges from 20 to 80 μm. There is no indication for increasing defect sizes with increasing grain size.

4 Discussion

4.1 Strength as a function of grain size

Our experimental data confirm earlier experimental observations[2–6] of an increasing strength (as in our case by about 240 MPa) with decreasing grain size (in going from 11 to 1·7 μm). In the last decade this increase has been attributed to the increase of fracture toughness (or fracture energy) with grain size.[3,4] Fracture toughness, however, ought to be described by means of toughness as a function of crack length (R–curve), with the toughness at instability, as determined in a fracture test, being of particular interest. Steinbrech stated, that for strength considerations in alumina, the starting value of the R–curve — certainly more than the plateau value — is of special interest.[13,16] Therefore, most of the techniques to measure fracture toughness data are of little significance for strength issues. The starting value of the R–curve could be defined as the crack initiation toughness[13,16–18] as intrinsic,[19] or as crack tip toughness.[20] The term initiation toughness can be misleading, since it can be taken as a measure for a stress magnification before a notch or pore to initiate a crack rather than the stress intensity at the tip of an already existing crack required to define crack equilibrium. Experimental determination of the crack tip toughness is

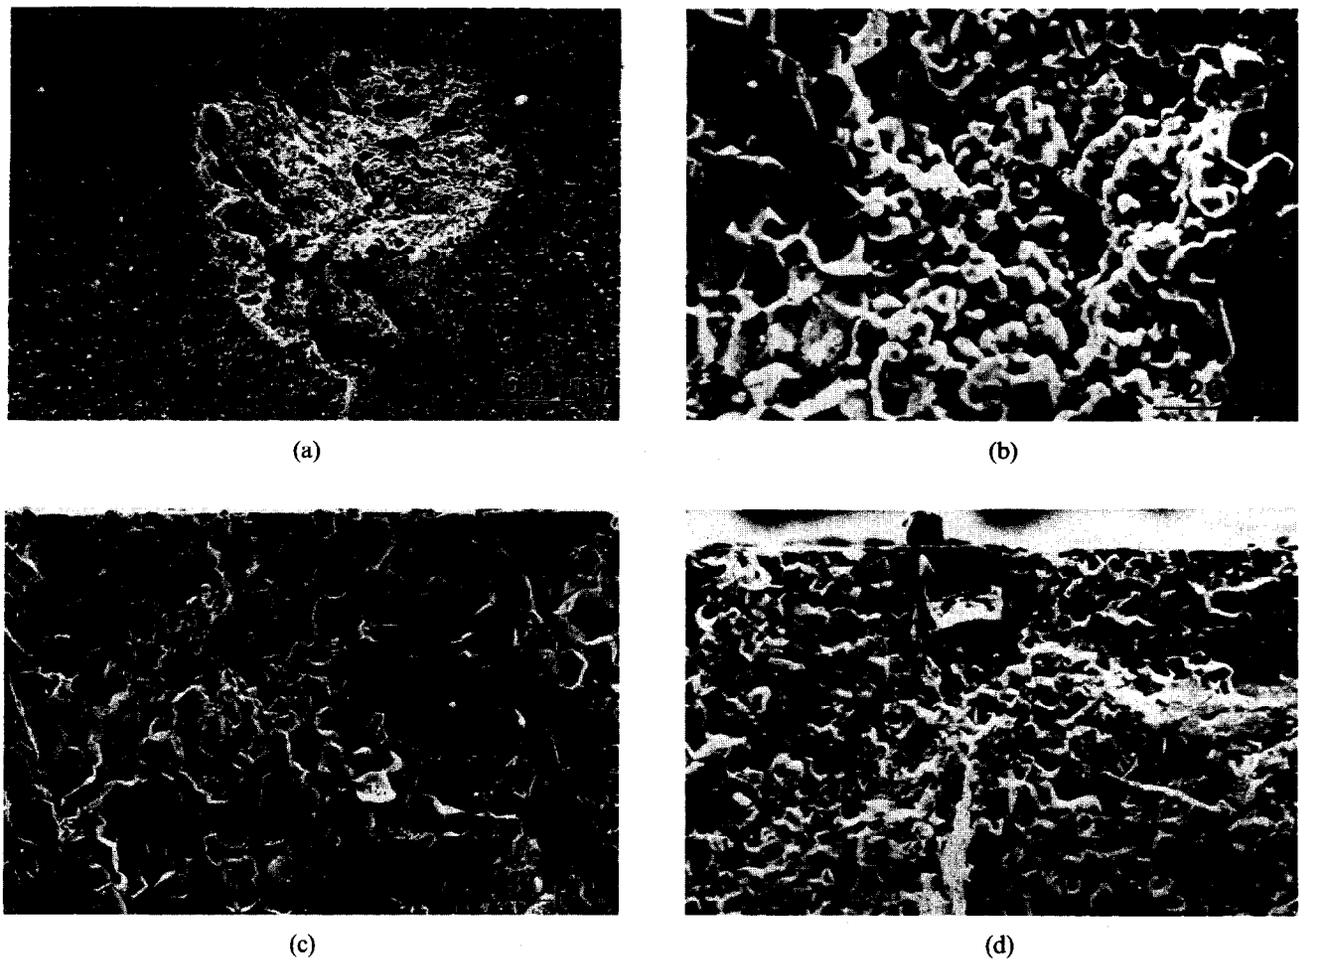

Fig. 4. Fracture surfaces of samples with different grain sizes; (a) G = 1·7 μm, σ = 461 MPa; (b) G = 11 μm, σ = 414 MPa; (c) G = 10·5 μm, σ = 340 MPa; (d) G = 11 μm, σ = 224 MPa; (a)–(c) Volume defects; (d) surface defects.

afforded by measuring the crack opening displacement (COD) near the crack tip.[20–22] This method has been applied to a hot pressed alumina of grain size 11 μm,[21] and a whisker — reinforced alumina.[22] Recently, the dependence of crack tip toughness on grain size in alumina has been investigated[20] and yielded no functional dependence, but an average crack tip toughness, K_0 = 2·3 MPa m$^{1/2}$ for all grain sizes investigated. The concept of a single valued toughness alone is therefore not sufficient to explain the observed dependence of strength on grain size.

Our alumina fractography points to pores (large voids) in the volume as major failure origin, with some occurrence of surface flaws also. Fractography also reveals that the pore size is independent of the grain size. This result can be predicted in applying the knowledge of the current sintering literature,[23] as long as no external pressure is applied and the sintering pressure is thereby only related to grain and pore curvature. In polycrystalline bodies pores should not cause fracture directly, because the stress concentration due to a pore is usually not sufficient to cause specimen fracture from the void surface. Evans and Davidge[24] as well as other authors[25,26] suggested that the pore of radius R is accompanied by a circumferential crack of length L (Fig. 5). The distance $R + L$ is taken as the initial crack length c_0, the crack length after a certain degree of stable crack growth is taken as c. Baratta,[27,28] Green[29]

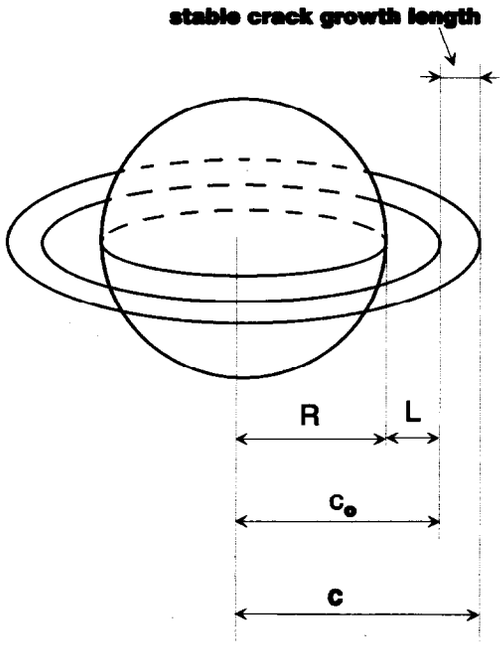

Fig. 5. Pore (void) with a circumferential crack (geometrical parameters).

and Fett[30] modelled this crack configuration and presented solutions for the normalized stress intensity factor in dependence of the ratio of L/R. On this basis it is possible to explain the grain size dependence of fracture strength assuming a pore with a circumferential crack as failure origin. For an evaluation it is assumed that the circumferential crack is proportional to the average grain size, whereas the pore sizes are constant. Equation 3 can then be used to calculate the grain size dependence of strength:

$$K_0 = \sigma \cdot \sqrt{\pi L} f(\frac{L}{R}) \quad (3)$$

The circumferential crack length is discussed in the literature to be a few grains in extent (one to three times the grain size) and perhaps vary with pore size.[3,10] In order to describe the grain size dependence of strength the exact length of the circumferential crack is of secondary nature. The basic assumptions are only that the circumferential crack length is proportional to the average grain size. Further to that, the toughness at instability is equal to the crack tip toughness, K_0. Since the stress in eqn 3 is the stress around the pore or surface pit, which in the first case is not exactly equal to the nominal flexure stress, a further small inaccuracy comes in. This is expected to be irrelevant since the volume flaws were close to the surface and thus differences in stress levels between pore location and surface were minute. To compute the grain size dependent strength for a defect modelled as a spherical pore/circumferential crack pair, we applied eqn 3 in the form given by Baratta[28] with the pore radii, R, then lying between 4 and 60 μm and the circumferential crack length $L = 1{\cdot}G$. To compare our results with possible surface defects as fracture origins, we also performed the equivalent calculation for the peripherally cracked hemispherical surface pit. For both computations, the tabulated values for $f(L/R)$ were utilized and an interpolation function used for the computations.

The solid lines in Fig. 2 show the result of the calculations for these two different pore sizes with the defect modelled as a volume flaw, while the dashed lines give the results for the hemispherical surface pit. The theoretical fits are very similar for both types of defects and in good agreement with the experimentally observed strength values, especially reflecting the decreasing strength with increasing grain size. Discrepancy between this model and the observed strength values can arise from the irregular shape of the pores in the alumina bodies. Uematsu *et al.*[26] measured the size and the size distribution of such irregularly shaped voids in hot isostatically pressed, translucent alumina. They found pore sizes up to 70–80 μm in radius, which is consistent with our calculations.

Although the assumption of a spherical pore or a hemispherical surface pit with a circumferential crack proportional to the average grain size is only an auxilliary means, it provides a plausible model to fit our experimental data. This simple model describes the grain size dependence of strength in both limiting cases, where the grain size is either larger or smaller than the initial flaw size, as well as the transition between the two.

Recently the model of a pore accompanied by a circumferential crack received further credibility by an acoustic emission investigation in alumina of various grain sizes.[31] It was found, that at a critical stress, which decreases with increasing grain size, acoustic events increased rapidly before failure. These events were located in the area where final failure occurred. One may therefore tentatively conclude, that an instability causing pore provides a stress magnification in the surrounding matrix sufficient to cause microcracking which occurs at a stress before final failure results. Physical reality may therefore be a pore with distributed microcracking at its perimeter, which is here modelled with a continuous circumferential crack. However, the actual existence of circumferential cracks around pores, be they complete or incomplete, still needs to be verified.

4.2 Weibull modulus as a function of grain size

The second feature concerning reliability is the variability of strength, normally expressed by the Weibull modulus m. The present study has shown that the Weibull modulus does not change in the grain size regime from 1·7 to 10·5 μm. The alumina of the largest grain size G = 11 μm) exhibited the smallest Weibull modulus with m = 5·8. Here the possibility of localized abnormal grain growth, which introduces a second flaw population, might already come into play. In the literature, systematic studies in the same material on the grain size dependence of the Weibull modulus are rare. Scholten *et al.*[32] for example investigated two different aluminas, a commercially available powder with an average grain size (after sintering) of 50 μm and a laboratory scale alumina with 10 μm. For the uniaxial, four-point bend test, the Weibull modulus for these two different materials was 21·6 and 6·7, respectively. In this context Scholten *et al.* denied the influence of the R–curve to explain the great difference in strength variability. For alumina, a Weibull modulus $m > 20$ has also been reported by Miyashita *et al.*[33] who demonstrated the influence of the compaction pressure on the Weibull modulus. They reported an increasing Weibull modulus with decreasing compaction

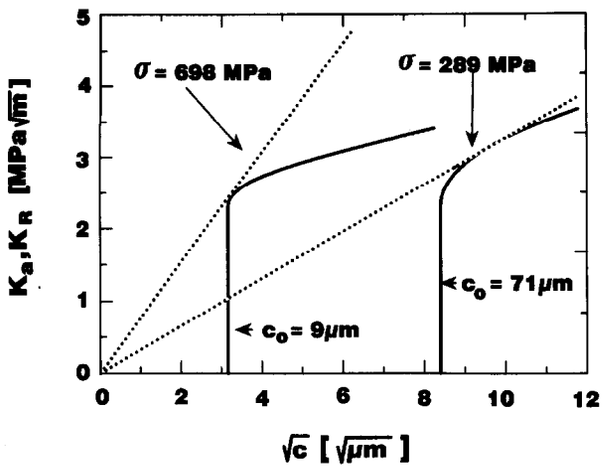

Fig. 6. *R*–curves and instability criterion for different initial flaw sizes (crack is modelled as a penny crack).

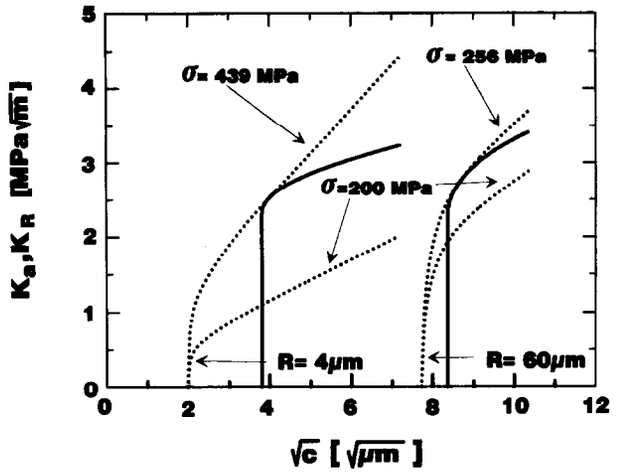

Fig. 7. *R*–curves and instability criterion for different pore sizes for the low strength material (crack configuration: pore + annular crack).

pressure, with a concurrent decrease in strength. Again, it should be emphasized that for reliability both a high strength as well as a high Weibull modulus is aspired. The Weibull moduli reported from other authors[34–36] range between 8 and 13. The important result of this study is that the disadvantage of decreasing strength with increasing grain size could not be compensated by the advantage of an increasing Weibull modulus. The higher plateau toughness of coarse grained, as compared to fine grained alumina, has no influence on the Weibull modulus. In the following section we discuss this result in greater detail.

Long crack *R*–curves of alumina ceramics have been determined by various groups.[13,16,37] In the last few years, efforts were made to measure the *R*–curves from either natural short cracks or radial indentation cracks.[14,38,39] Due to the difficulty of measuring *R*–curves of cracks originating from pores (with the notable exception of Ce–TZP composites)[40] we tried to model the *R*–curve based on the fundamental description of closure stresses. These closure stresses arise from bridging interactions and result in a bridging term R_μ which has to be added to the starting value R_0 of the *R*–curve. For our considerations we resorted to a continuum concept with smoothly varying, delocalized closure stresses (an assumption, which needs to be qualified at a later time). The total crack resistance[19] can then be expressed by eqn 4 (with $p(u)$ the crack closure stress, p as a function of half of the crack opening, u):

$$R(c) = R_0 + R_\mu = R_0 + 2\int_0^{u_b} p(u)\mathrm{d}u \qquad (4)$$

If the COD ($2u$) reaches the value $2u_b$, the closure stresses have diminished to zero and hence the *R*–curve has reached the plateau toughness.

In order to express this relationship in terms of stress intensity factors, R_0 and R_μ[19] can be transformed into K_0 and K_μ by eqns 5 and 6 (E is Young's modulus):

$$K_0 = \sqrt{R_0 \cdot E} \qquad (5)$$

$$K_\mu = \sqrt{K_0^2 + E \cdot R_\mu} - K_0 \qquad (5)$$

In the following calculation we considered the influence of closure stress on the Weibull modulus and on characteristic strength. We used two complementary approaches: Firstly, we modelled the crack as a penny-shaped crack of initial length c_0 (Fig. 6). Secondly, we applied the pore/annular crack configuration as introduced before (Fig. 7).

For mathematical simplicity we started to model the crack configuration pore with an annular crack as a penny crack. When the crack extended stably the closure stresses were only effective between c_0 and c (Fig. 5). Using the weight function of the penny crack geometry the *R*–curve ($K_R(c)$) is described by eqn 7 (where the closure stresses are taken as a function of r only):

$$K_R(c) = K_0 + \int_{c_0}^{c} p(r)\,\frac{r}{\sqrt{c^2 - r^2}}\,\mathrm{d}r \qquad (4)$$

In the very small regime of possible stable crack growth the closure stresses were taken as constant (Dugdale zone), and assumed to be equal to the peak closure stress, p_m (which occurs near the crack tip in alumina).[21]

In order to examine whether the closure stresses cause a deviation from linear behaviour in the Weibull plot we do not resort to the measured strength distributions, since some distributions deviate from exact linear behaviour due to different failure origins. For further calculations we assumed a strength distribution with the Weibull parameter m = 10 and σ_0 = 589 and 365 MPa, similar to the measured distributions with an average grain size of 1·7 and 10·5 μm, respectively,

but without any *R*–curve. Equation 8 was used to transform the strength distribution into a flaw size distribution, providing the initial crack length c_0, whereby a single valued crack tip toughness K_0 = 2·3 MPa $m^{-1/2}$ (independent of grain size) was assumed:[20]

$$K_0 = \frac{2}{\sqrt{\pi}} \cdot \sigma \cdot \sqrt{c_0} \tag{8}$$

The next step is to attach the *R*–curves to the initial crack length c_0. This is demonstrated in Fig. 6. The instability criterion, eqns 9 and 10,

$$K_a = K_R(c) \tag{9}$$

$$\frac{dK_a}{d_c} = \frac{dK_R(c)}{d_c} \tag{10}$$

was taken to calculate the crack length at instability as well as the corresponding strength. This is also shown schematically in Fig. 6.

The calculation was carried out for two peak closure stresses of p_m equal to either 40 or 120 MPa, the upper and lower bounds reported in the literature.[21,41,42] The degree of stable crack growth is found to increase with decreasing strength and increasing closure stress. The stable crack growth length and accordingly the toughness at instability increases with c_0 (Fig. 6). The computation yields a stable crack growth length of 0.5 μm for an initial crack length of 9 μm with a strength increase from 678 to 698 MPa at a K_{Ic} of 2·44 MPa $m^{1/2}$. For a specimen with a large initial flaw size, e.g. c_0 = 71 μm, σ = 243 MPa (without *R*–curve) the stable crack growth length is predicted to be 22·6 μm with instability occurring at 289 MPa at 3·15 MPa $m^{1/2}$. Therefore strength increase due to *R*–curve behaviour is more pronounced for a lower initial strength and hence an increasing

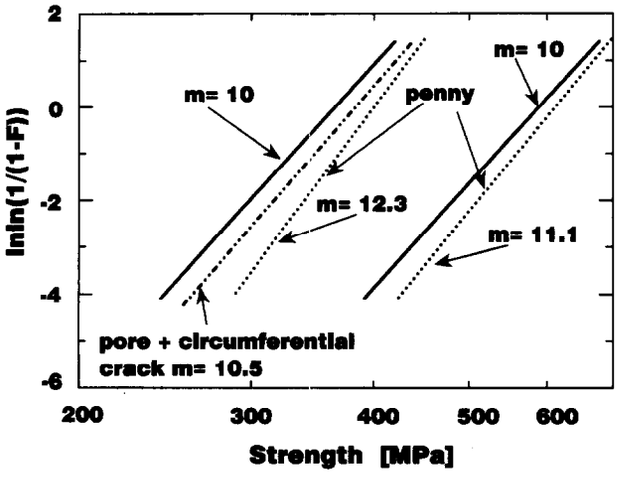

Fig. 8. Influence of constant closure stress of 120 MPa on the strength distributions of material characterized by m = 10 and σ_0 = 365 MPa and 589 MPa, respectively, assuming a penny crack geometry or a pore with an annular crack.

Weibull modulus should be the result. In Fig. 8 the influence of the closure stress of 120 MPa on Weibull modulus and characteristic strength is described. The two initial distributions are shifted to higher strength and the Weibull modulus increases from m = 10 to m = 12·3 for the low strength material and to m = 11·1 for the high strength material. Again, the effect of the closure stress is more evident at lower strength. Still, the increase of the Weibull modulus due to the closure stress of 120 MPa is relatively small. If we carry out the same calculation for a closure stress of 40 MPa the increase in σ_0 and m is negligible. For the high and the low strength material the increase of the characteristic strength is lower than 5 MPa and the Weibull modulus increases from 10 to 10·5. This calculated change would be statistically insignificant in practice for typically 20–30 test pieces. For all computations with the parameter sets used here, the closure stresses do not cause a deviation from linear behaviour in the Weibull plot.

In the calculation presented above the crack configuration was modelled as a penny crack with no bridging interactions at the initially existing crack faces. Different strength values had to be obtained by using different lengths of starting cracks, c_0. In the following section we compute the variation of strength and Weibull modulus for the crack configuration of a pore with a circumferential crack and thereby relate back to the model which could account for grain size dependent strength introduced in the earlier chapter. Again we assume strength distributions with the Weibull parameter m = 10 and σ_0 = 365 MPa (G = 10·5 μm) and σ_0 = 589 MPa (G = 1·7 μm), respectively. For the described crack configuration Barattas solution[28] (eqn (3)) for the stress intensity factor was used to evaluate the pore sizes assuming $L = G$ for the initial circumferential crack length using K_0 = 2·3 MPa $m^{1/2}$. The *R*–curves (eqn (11)) were calculated using a weight function proposed by Fett.[30] It is assumed that the *R*–curves start at $R + 1{\cdot}G$:

$$T(c) = K_0 + p_m \beta \sqrt{\frac{2}{\pi L}} \int_G^L \left(\frac{1}{\sqrt{1-\frac{r}{L}}} + 0{\cdot}6147\sqrt{1-\frac{r}{L}} + 0{\cdot}2502\sqrt{\left(1-\frac{r}{L}\right)^3} \right) dr + \frac{2p_m(1-\beta)}{\sqrt{\pi(L+R)}} \int_G^L \frac{r+R}{(L+R)^2-(r+R)^2}\, dr \tag{11}$$

with β defined by

$$\beta = \frac{1}{(1+2\cdot\frac{L}{R})^2} \tag{12}$$

The instability criterion (eqns 9 and 10) was used to calculate the degree of stable crack growth prior to failure and the corresponding strength. In Fig. 7 the R–curve and the tangency points are sketched for the low strength material for two different pore sizes. The circumferential crack length increases from $L = G = 10{\cdot}5$ μm (starting point of the R–curve) to $L = 15{\cdot}4$ μm at instability ($p_m = 120$ MPa, $R = 60$ μm) with $K_{Ic} = 2{\cdot}73$ MPa $m^{1/2}$ and an increase in strength due to crack bridging from 243 to 256 MPa. The computation for a specimen with small initial pore size ($R = 4$ μm) yields a stable crack growth regime of $1{\cdot}4$ μm and a strength increase from 420 to 439 MPa with instability occurring at 2·52 MPa $m^{1/2}$.

The influence of closure stresses of 120 MPa on the characteristic strength and the Weibull modulus of the low strength material is shown in Fig. 8. σ_0 increases from 365 to 383 MPa and the Weibull modulus from 10 to 10·5. As mentioned above the strength distribution of the high strength material remains unaffected. At a closure stress of 40 MPa the strength distributions of both materials were essentially not influenced.

In summary, the calculation for the crack configuration pore with circumferential crack yields a smaller influence of the closure stresses on the mechanical properties compared to the case when the pore is modelled as a penny crack. This trend may be appreciated if the greater stress concentration at larger pore sizes — in the pore/annular crack model — is taken into account. This results in a stronger increase of K_a with the applied stress σ at larger pore sizes. For the same externally applied stress σ (for example in Fig. 7, $\sigma = 200$ MPa) and the same annular crack length L, K_a is larger at larger pore sizes. Therefore the higher degree of stable crack growth at larger pore sizes associated with a higher crack resistance and with a stronger increase of the initial strength is compensated by a stronger increase of K_a with σ at larger pore sizes. All subleties aside, however, both models are able to reproduce the experimental findings very well and only predict small differences in the increase in Weibull modulus with incorporated R–curve.

The calculations have shown that even at relatively high closure stresses (120 MPa), only a small increase of the Weibull modulus could be achieved, which is consistent with our experimental data. Three qualifications in using our modelling approach should be considered at this point.

Firstly, in assuming a Dugdale zone, we did not specify u_b in eqn 4. Since the instability criteria was met in all computations at very low toughness values ($K_{Ic} < 3{\cdot}2$ MPa $m^{1/2}$), well below commonly reported toughness values for alumina, the plateau value of the R–curve as well as the exact position of the last active bridge are irrelevant in strength considerations of alumina ceramics. Specifically, it is evident, that the long crack toughness values measured in crack bridging materials are not pertinent for strength issues (except for very short, steep R–curves).

Secondly, the computations are strictly relevant only for a continuum with delocalized closure stresses. This condition is not met for grain bridging materials with grain sizes at the order or even larger than our calculated stable crack growth lengths. Since the distribution of bridges in the matrix is unknown, an inclusion of grain-localized stresses in the model, however, would be rather arbitrary. The current model, therefore, serves as the best possible indication for the actual occurring stable crack growth as well as the K_{Ic} values applicable for fracture testing.

Thirdly, the second model of a pore with a circumferential crack hinges critically on the very existence of microcracking around a pore. Indications for the physical reality of this model, however, have been provided recently.[31] This concept can also be understood as a strategy to design high strength materials. These may be manufactured, if microcracking around failure causing pores can be suppressed.

Our results point to the relevance of the ratio of closure stress to failure stress. In material development efforts, both material characteristics need to be appreciated. If microstructural design initially focuses on preparing a relatively weak, but flaw tolerant material, then an increase of strength will not necessarily yield a strong, flaw tolerant material, since the ratio of closure stress to fracture strength decreases. On the other hand, if the effect of closure stress on strength and strength variability is to be considered and even utilized as a measurement tool to compute the closure stresses, a low strength material ought to be employed. This approach was indeed taken by Fett and Munz,[42] who demonstrated a deviation from linear behaviour in the Weibull plot for a low strength, coarse grained alumina. This deviation is only relevant at low strength (about 200 MPa) and is attributed to the R–curve behaviour. This observation supports the result of the present investigation that the closure stresses in alumina do only affect the variability of strength at a very low strength level.

The question posed in the introduction can now be answered: for alumina ceramics a small grain size and therefore high average strength has to be favoured compared to a large grain sized alumina with low average strength, albeit long crack R–curve behaviour. This result is independent of the specific flaw type and specifically holds both

for penny shaped cracks as well as for pores with circumferential cracks. Only in applications where excessive damage may occur[6] and low strengths are tolerable, a large grain sized alumina ought to be chosen as a load bearing material.

Conclusions

(1) The strength in alumina increases with decreasing average grain size from 564 MPa at 1·7 μm to 320 MPa at 11 μm.
(2) This grain size dependence of strength can quantitatively be described by models based on either a spherical pore/circumferential crack combination or a hemispherical surface pit/peripheral crack combination.
(3) Weibull modulus m showed no dependence on grain size.
(4) A simple Dugdale zone model attached to a distribution of flaw sizes can explain the invariability of the Weibull modulus on grain size and R–curve behaviour and points to the importance of the peak closure stress, which, according to literature values appears too low to affect the Weibull modulus of alumina significantly.

Acknowledgements

The authors wish to thank Dr T. Fett for supplying his results concerning the weight function of a void with an annular crack prior to publication, Prof. R. Bordia is thanked for helpful discussions. The reviewers comments are also appreciated for being very helpful.

Abstract

Hardness and fracture toughness of cubic zirconia crystals (CZC) doped with yttria and partially stabilized zirconia crystals (PSZC) doped with yttria, terbia and ceria were studied at indentation loads of 0·1–300 N. MOR and K_{Ic} *of these materials were measured under bending conditions. A maximum hardness value of* H_K *= 21·2 GPa was obtained for CZC at a 0·1 N indentation load when a longer diagonal of the Knoop indenter being directed along <110>. Starting from a 2 N load, PSZC exhibited lateral cracks and phase transition zones. Radial cracks in Vickers indentation tests of Y–Tb–PSZC and Y–Ce–PSZC appeared above 40 N and 50 N respectively. Such cracks in Knoop indentation tests were observed above 300 N. Orientation anisotropy of lateral cracks was noticed in all crystals, radial ones were revealed only in CZC. After grinding off the specimen surfaces, lateral cracks were found to be present under the impressions. The calculations of fracture toughness* K_{Ic}^{v} *using the equation proposed by the authors gave a value corresponding to those materials determined on bending.*

1 Introduction

The fact that zirconia single crystals can be used for medical[1,2] and other cutting instruments stimulates studies on their surface fracture toughness (Fig. 1). The results obtained also appear useful[3] for understanding mechanical behaviour of the materials of such a group. In investigations, both Vickers[4,7] and Knoop indenters[5,8,9] were used. Cubic (CZC), i.e. completely stabilized[5,6,10,11] and partially stabilized crystals (PSZC)[4,9,14] doped with yttria (Y–PSZC) attracted specific interest. The crystals doped with calcia,[4] magnesia,[1,4,8] terbia[9,12] and ytterbia,[2,14] i.e. containing additives with an ionic radius smaller or larger than that of zirconia were also studied. PSZC of lower fracture toughness were tested at indentation loads which did not usually exceed 10 N[3,15] and crystals of higher fracture toughness were investigated at the same loads[1,4,11,16] that are usually for advanced ceramics. The indentation was performed on the (001),[3,5,11] (011)[3,8] or on arbitrarily oriented planes.[2,9,14,17] The comparison of data[2,11] shows no essential differences in K_{Ic} values for Y–PSZC obtained on different indentation planes. The equations used[11,18] give critical stress intensity factors K_{Ic}^{v} obtained in indentation tests which agree with K_{Ic} values determined in SENB bending. Such coincidences were not usually observed in the rest of the cases.

The Vickers indentation caused considerable anisotropy of hardness and fracture toughness for CZC[11] and certain anisotropy of fracture toughness for PSZC.[3] At room temperature, Y–PSZC exhibited[16] considerable influence of the Vickers indenter orientation on phase transition processes on the (001) plane. Similar crystals[15] also revealed phase transition zones around such impression above 200°C. It was found that at room temperature it occured only within the plastic zone of impression. The Knoop indenter caused considerable anisotropy both of hardness and of fracture processes for Y–CZC[5] and Y–PSZC.[2,8]

Y–CZC are the most extensively studied materials. The indentation behaviour of Y–PSZ (though being more interesting for structural applications) is not clear enough and there is no information available which is necessary for their positive practical application. It should be noted that all the data published on PSZC can be divided into two groups: those which was mainly obtained for stronger crystals of Ceros Corp.[3,6,15] and those obtained for tougher crystals produced in the former USSR.[1,2,9,14] The investigations of the first group pursued physical goals, the studies on the latter were aimed at the elucidation of possible practical fields of application of such crystals. In the present work we used a wider range of loads and focused our major attention on PSZC.

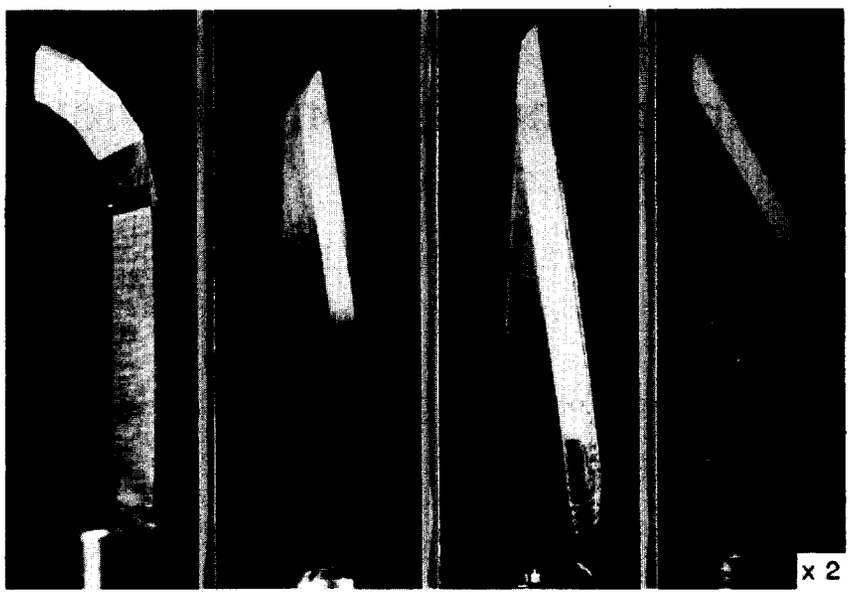

Fig. 1. Experimental samples of surgical knives with blade sharpening radii equal to 0·2–0·5 μm, made of the zirconia crystals studied. They were tested in clinics of Kiev, Moscow and Sydney (×2).

2 Materials and Methods

The crystals under study were grown by a skull melting technique[19] from zirconia powders of a purity over 99·9% (the purity of other components was higher than 99·99%). A K-1 material (Y–CZC) (Table 1) contained 10 mol% Y_2O_3,[20] a K-2 material[12] contained 3·3 mol% Y_2O_3 and less than 0·3 mol% terbia and in a K-3 material[21] ceria was added instead of terbia. After pounding the pieces of specimens in a corundum mortar, they were investigated by X-ray phase analysis. It was established that the K-1 powder consisted of a 100% zirconia cubic phase, the K-2 powder contained 30% monoclinic and 70% tetragonal phases, the K-3 material was 50% monoclinic and 50% tetragonal and cubic.

Test specimens (3·5 × 5 × 45 mm^3 bars) were cut, ground and polished with a diamond instrument. The orientation of specimens was determined by Laue back-reflection which revealed that all their surfaces coincided with the (001) planes. Thus, on mechanical tests, a fracture crack propagated in the (001) plane and tensile stresses and impression also appeared in the same plane.

MOR on four-point bending, static moduli of elasticity and critical stress intensity factors K_{1c} were determined by procedures[22] evaluated earlier in numerous tests of different advanced ceramics and single crystals. For K_{1c} measurements, the specimens were notched for a half-thickness depth and placed with their 3 mm wide surface on supports with a 20 mm span between loading rollers (for MOR measurements the loading surface was 5 mm wide).

The Knoop indentation tests at 0·1–10 N loads were performed in an MXT-70 microhardness meter (Matsuzawa, Japan). For 50–300 N loads a Ceramtest device of our production was used. The hardness was calculated by $H_k = 14{\cdot}23\ P/o^2$, where P is the load on the indenter and d is the length of a larger diagonal of the Knoop impression.

The H/E relationship determined according to the concepts of Ref. 23 was calculated by the equation:

$$H/E = \frac{0{\cdot}14 - b/d}{0{\cdot}45}$$

where b is the length of a shorter diagonal of the Knoop indenter.

The Vickers indentation at 0·1–10 N loads was tested in the same microhardness meter. For high loads, (50–300 N), a TP-2 Vickers hardness meter and Ceramtest device were used.

The values of H_V were calculated by

$$H_v = 0{\cdot}4636\ P/a^2$$

where a is the Vickers impression diagonal half-length.

To calculate critical stress intensity factors K_{1c}^V the following equations were used

$$K_{1c} = 0{\cdot}016\ (E/H)^{0{\cdot}5} P/C^{1{\cdot}5} \quad (1)^{24}$$

$$K_{1c} = 0{\cdot}018\ H\ a^{0{\cdot}5}\ (E/H)^{0{\cdot}4}/C/a - 1)^{0{\cdot}5} \quad (2)^{11}$$

Table 1. Average mechanical characteristics of crystals on fracture in the <001> direction

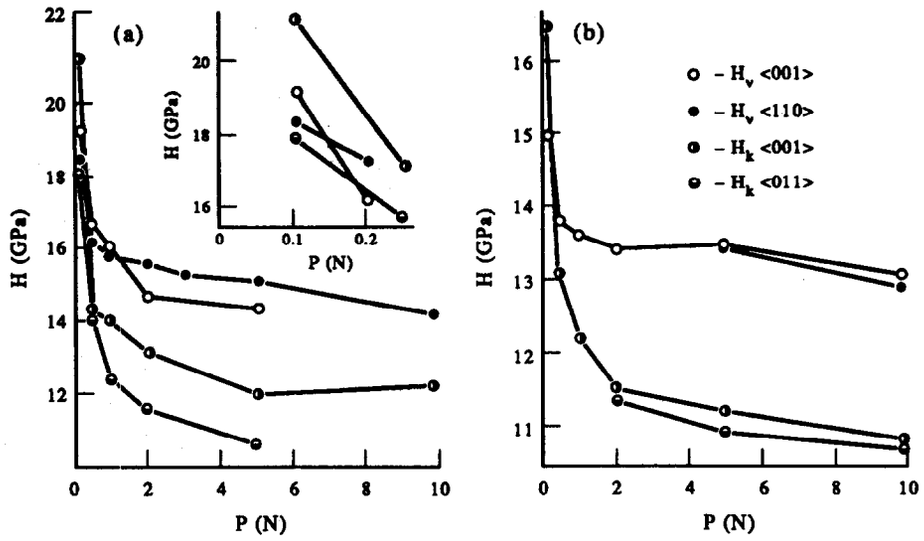

Fig. 2. Microhardness H of K-1 crystals (a) and K-3 crystals (b) as a function of indentation load and indenter orientation (crystallographic directions of the Vickers indenter diagonal (index V) and larger diagonal of the Knoop indenter (index K).

Table 2. Hardness (GPa) at a 4·9 N load

Material	*Interdenter diagonal direction*	
	<001>	*<011>*
K-1	14·4 / 12·0	15·1 / 10·7
K-2	13·6 / 11·4	13·6 / 11·1
K-3	13·6 / 11·2	13·6 / 10·9

The left hand value is the Vickers hardness, the right hand value is the Knoop hardness.

$$K_c^v = 0{\cdot}0424\ (PE/a)^{0{\cdot}5}/(C/a)^{1{\cdot}57} \qquad (3)^{25}$$

Indented specimen surfaces were studied using an NU-2E optical microscope (Carl Zeiss Jena, Germany).

3 Results

Microhardness values for K-1 cubic and K-3 partially stabilized crystals, as a function of applied loads at the orientation of indenter diagonals in the <001> and <110> directions, on the (001) plane for the loads up to 10 N, are shown in Fig. 2. (For K-2 crystals the picture was about the same.) It should be noted that partially stabilized crystals (as opposed to cubic ones) do not practically exhibit any anisotropy of microhardness on the (001) plane for both indenters (Table 2). Vickers impressions on K-1 crystals in the <001> direction of indenter diagonals were almost completely fractured at loads above 5 N; in the <001> direction this fracture occurred at loads above 10 N. (For the Knoop indenter the picture was quite the opposite.)

In Vickers indentation tests, lateral cracks appeared with the indenter diagonals in the <001> direction (Fig. 3(a)) and zones (probably pressure-induced phase transformation[16] of tetragonal phase to monoclinic symmetry) arose if they were in the <110> direction (Fig. 3(b)). In Knoop indentation tests, similar phase transition zones were revealed microscopically in phase contrast with

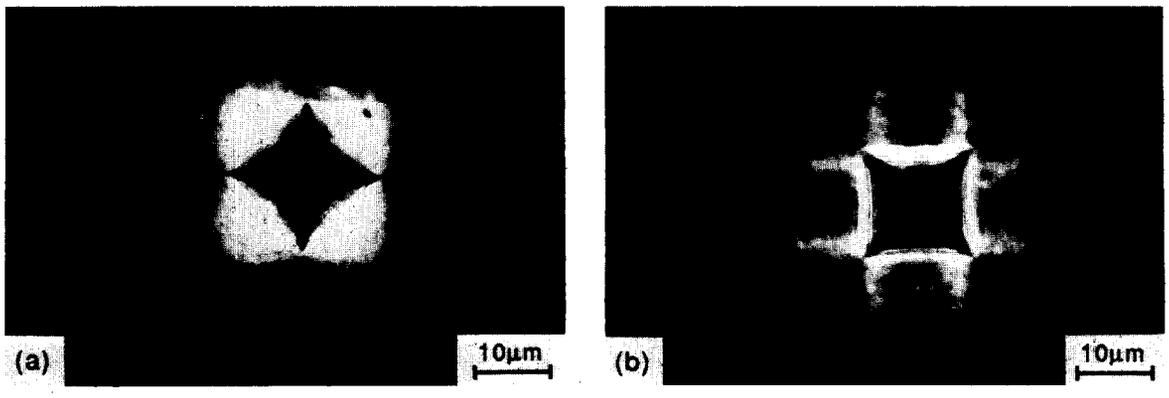

Fig. 3. Vickers impressions on the (001) plane of a K-3 crystal at a 10 N load: the diagonal coincides with the <100> direction (a) and with the <110> direction (b). Illumination: phase contrast.

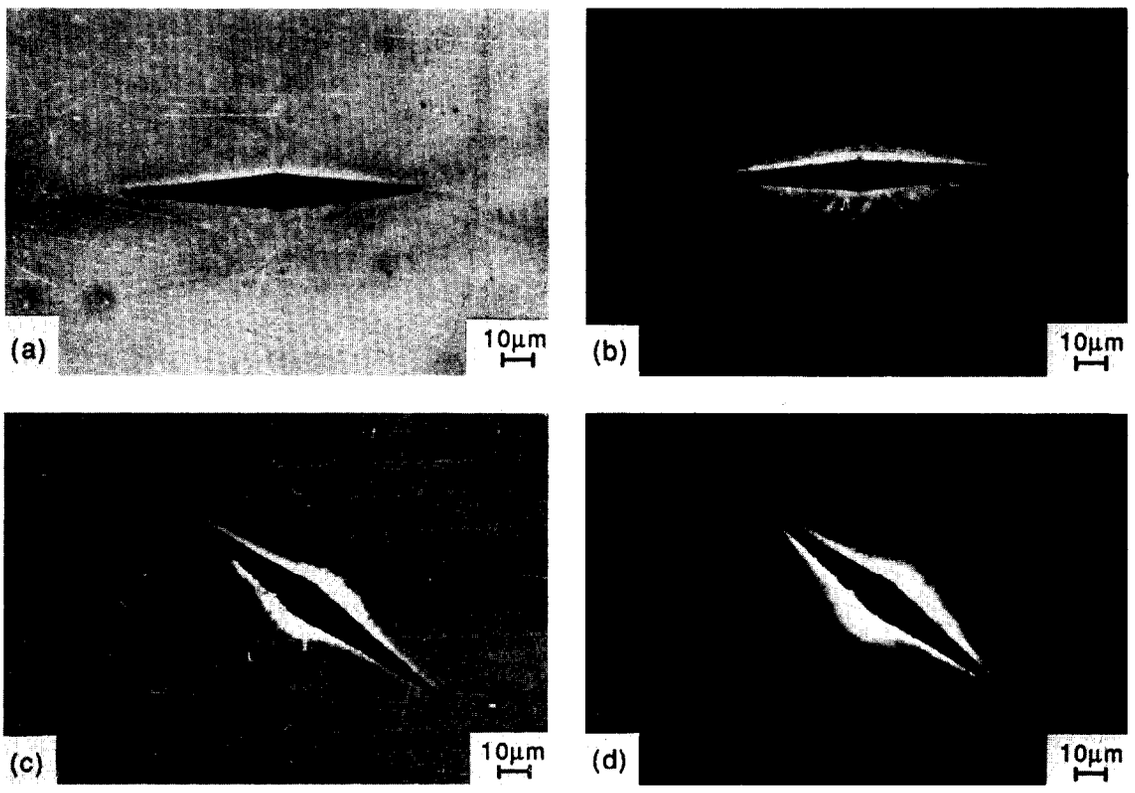

Fig. 4. Knoop impressions on the (001) plane at a 10 N load with a larger diagonal coincides with <001> (a,b) and with <110> (c,d). Illumination: reflected light (a,c), phase contrast (b,c).

the <001> direction of a larger diagonal (Fig. 4(a,b)). When this diagonal was in the <110> direction (Fig. 4(c)), lateral cracks appeared around the impression (more details in Ref. 26).

The results of studying the effect of elastic recovery of Knoop impressions are summarized in Table 3. They demonstrate that the influence of crystal anisotropy on H/E values appeared to be quite noticeable for all the cases.

For the crystals under study, the relationship (up to 10 N loads) between the Vickers impression diagonal half-length and indentation loads is described by the equations:

$$a = 5{\cdot}4\ P^{0{\cdot}52} \quad \text{for K-1}$$
$$a = 5{\cdot}83\ P^{0{\cdot}51} \quad \text{for K-2}$$
$$f = 5{\cdot}81\ P^{0{\cdot}51} \quad \text{for K-3}$$

The Knoop indenter diagonal lengths are described by the equations:

$$d = 31{\cdot}12\ P^{0{\cdot}56} \quad \text{for K-1}$$
$$d = 33{\cdot}22\ P^{0{\cdot}54} \quad \text{for K-2}$$
$$d = 33{\cdot}46\ P^{0{\cdot}55} \quad \text{for K-3}$$

Only PSZC were investigated at higher indentation loads. The results of diagonal and crack measurements and H_V and K_{1c} calculations on the (001) plane, with the <001> direction of indenter

diagonals are summarized in Table 4. These data complement our information published earlier (Table 5). The discrepancy between our data and those of other authors observed in this Table may be connected with some distinctions between the technologies of the growth of crystals and raw materials for them.

The radial cracks around Vickers impressions usually aligned with their diagonals, however, in several cases the picture was similar to that shown in Fig. 5.

The cracks around the Knoop impression were mainly lateral up to 300 N loads (Fig. 6). Only single radial cracks were noticed around some of them. The same picture existed in the tests of

Fig. 5. Vickers impression on the (001) plane of a K-3 crystal at a 200 N load (diagonals coincide with the <110> direction). Illumination: phase contrast.

crystals in Refs 2 and 9, when only at 400 N were pairs of radial cracks observed.

4 Discussion

4.1 Microhardness and hardness

From the analysis of data in Fig. 2, one can see that the maximum values of H_V and H_K we presented for K-1 cubic crystals are higher than those published[16] for the material of the same composition, but it is associated with the fact that in the present work, lower loads were used for indentation. At the same time in Ref. 5, for the <001> direction on (001), the authors obtained H_V = 17·6 GPa and H_K = 19 GPa at 0·5 N, while we obtained 16·5 GPa and 14·3 GPa, respectively. It should be noted that with higher loads this difference becomes less noticable (see Table 5). A descending curve of microhardness versus load is also characteristic of partially stabilized crystals, especially up to 10 N loads. At high loads, as follows from Table 4, it is practically a straight line. The values of H_V for other yttria-stabilized crystals also appear to be quite close.[9] It is interesting that for K-2 crystals the dependence is also about the same, with H_V measurements without strict crystallographic orientation of indentation planes (Table 5). These data point to the fact that H_V values without indication of the load at which they were obtained, should be taken into account with great care.

If the above information on the values of H_V and H_K does not contradict the data published earlier, the relationships for $(E/H)^{1/2}$ given in Table 3 are somewhat different from the results of earlier investigations of cubic crystals, e.g. Ref. 5, where the relationship between these values and the Knoop indenter orientation were not elucidated. As it should be expected, the hardness of crystals is dependent on the orientation of the Knoop indenter (Figs 2 and 6) and they are also characterized by the anisotropy of elastic moduli.[27] Thus the value of H/E determined from the Knoop impression is also orientationally dependent. It should be noted that, e.g. for K-1 crystals, d/D = 8·61 and H/E = 18·1 were obtained in the <001> indentation direction at 5 N loads and in Ref. 5 these values for the same load were 8·3 and 22·0 N respectively. Such differences can be connected with certain differences in the production technology of the crystals under study.

However we could not succeed in getting values of elastic moduli in Knoop indentation tests comparable with those presented in Table 1. There is an impression that the approach[21] to the determination of elasticity (or H/E) of crystals requires a better understanding.

4.2 Fracture

Since the present fracture studies of cubic crystals did not reveal any new results compared to those found earlier[11] and published by other authors, we considered it expedient to discuss and revise only the results for partially stabilized crystals. Single radial cracks in these crystals started appearing around the corners of the Vickers impression at the following loads:

When the Vickers indenter diagonal was parallel to <110>, single radial cracks were observed at 40 N in a K-2 material and at 50 N in a K-3 material.

Table 6

Material	*Indenter diagonal parallel to*	
	<100>	*<110>*
K-2	50	70
K-3	40	50

(Lateral cracks in the <100> direction were discussed earlier.) The difference in sizes on the turn of indenter on the (001) plane at a 100 N indentation load, can be seen in Fig. 7 (the picture was more

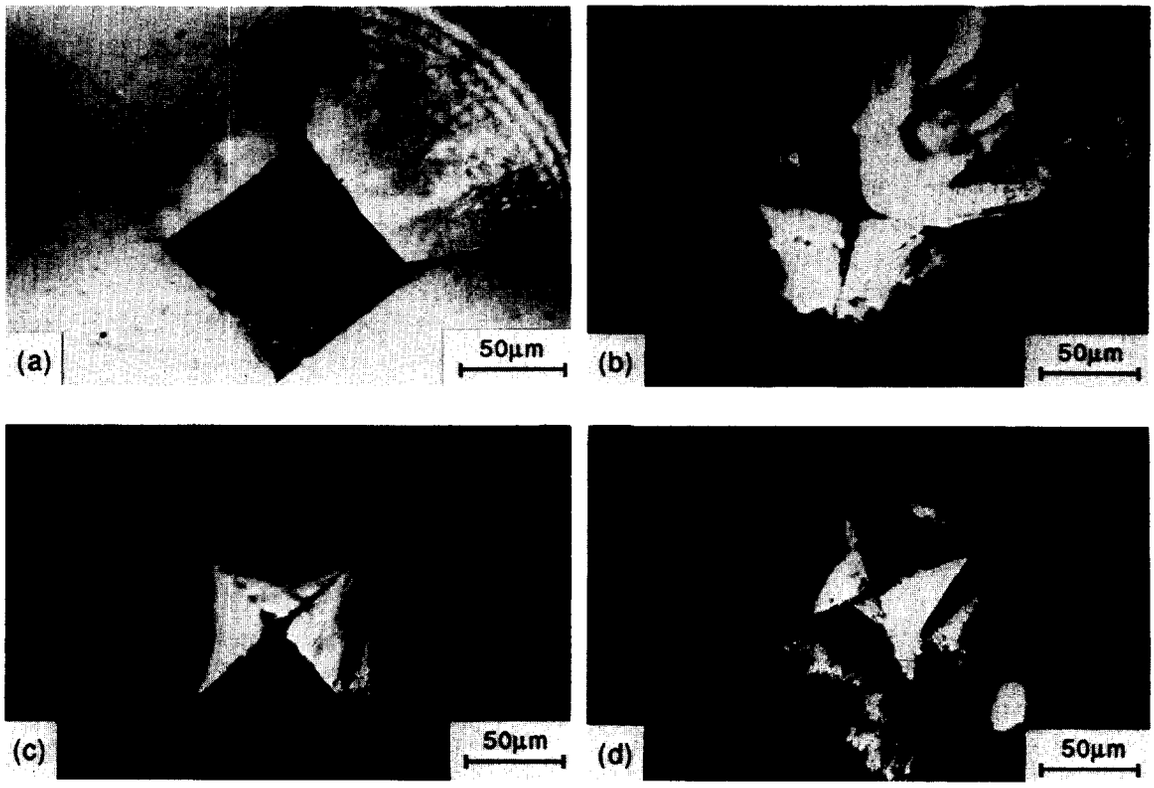

Fig. 7. Vickers impression on the (001) plane of a K-3 crystal at a 100 N load. Diagonals of the indenter correspond to the <100> direction (a,b), to the <110> direction (c) and are deflected through 30° from the <100> direction (d). Illumination: reflected light (a) and polarized light (c,d,e).

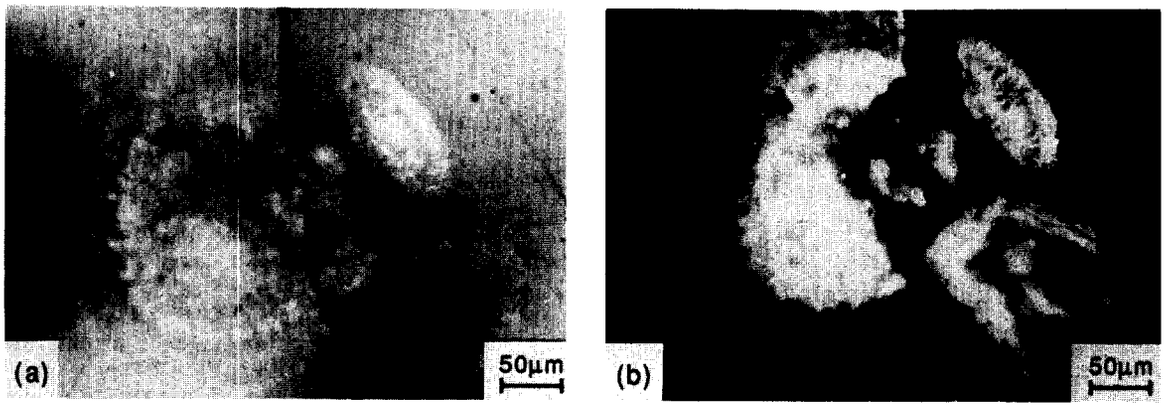

Fig. 8. Vickers impression on the (001) plane of a K-2 crystal after grinding off of its surface at a 100 N load. Illumination: reflected light (a) and polarized light (b).

or less identical for both materials). When the specimen surface is ground off in the indentation zone, lateral cracks can not only reach the surface, but also appear below the indenter impression, as is seen in Fig. 8. It should be noted that in Ref. 2 only lateral cracks reaching the surface are shown in Fig. 10. The lateral cracks in those crystals similar to those shown in Fig. 8 were not analyzed. Radial cracks usually propagating as Palmqvist cracks within the range of loads under study seemed to be branched in the subsurface layer (Fig. 9). Thus, their extent (fractured area) appeared larger than that which could be measured by optical microscope, since only one crack was revealed on the specimen surfaces under study.

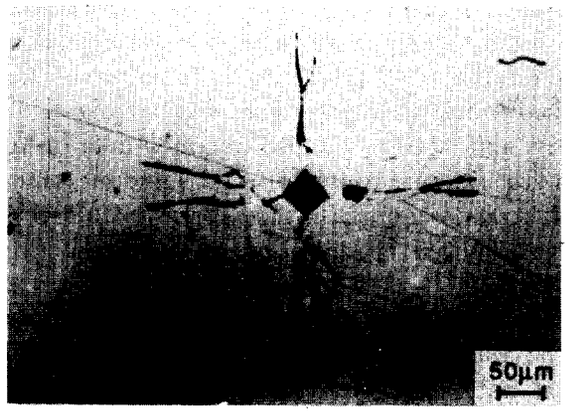

Fig. 9. Vickers impression on the (001) plane at a 200 N load with the diagonal coincides with <001> after partial grinding off of the surface. Illumination: reflected light.

This examination demonstrates that for a well-grounded judgment of the crystal capacity to resist local damages, one should take into account all the real features of their fracture on indentation.[2]

The estimates of their fracture toughness was based only on the measurement of the extent of radial cracks on the surface visible in reflected light in an optical microscope, which is usually done by investigators, (Table 4) and can probably be considered only as a first approach. However, if we take into account that any publications devoted to detailed investigations of PSZC fracture are practically non-existent, the data of the present work can be compared with the known ones only within the framework of this first approach. From Table 4 we can see that the values of K_{1c}^{v} calculated by the equation[11] are quite close to the values of K_{1c} measured on bar bending, (Table 1). If we compare the calculation results for K_{1c}^{v}[25] obtained in the case of arbitrary orientation of the indenter[2] on SC=3b surfaces with the results for Y–PSZC[11] obtained on the (100) plane with the <110> diagonal direction, (Table 4), one can see that they are very close. So we can assume that if elastic moduli of crystals are similar, the anisotropy of local fracture toughness is probably insignificant for practical purposes. The above crystals as well as the crystals in Ref. 11 exhibit higher fracture toughness than those presented, e.g. in Ref. 3 and investigated in an unannealed state. At the same time they display longer (by 20–40%) radial cracks originating on Vickers indentation than those revealed, e.g. in Ref. 9 during the studies on partially stabilised and tetragonal polycrystalline zirconia ceramics[17] doped with 3 mol.% yttria.

5 Conclusion

The investigations of cubic and partially stabilized zirconia crystals resulted in data on their hardness and fracture toughness variations during indentation on the (001) plane as a function of loads applied to the indenters, their diagonal aligned with <001> and <110>. We also obtained data on their strength, fracture toughness and static modulus of elasticity on bending (in this work we studied partially stabilized crystals doped with terbia, ceria and yttria).

It is shown that the equation proposed earlier by the authors for estimating K_{1c}^{v} from the indentation data can give values very close to those determined for K_{1c} in bending tests which cannot be achieved using other similar equations. For example it was noticed that at a 2 N load the Vickers indenter diagonals aligned with <001> lateral crack are formed and when the diagonals are aligned with <110>, phase transition zones appear. When a larger diagonal of the Knoop indenter is aligned with <001>, phase transition zones are also formed. At comparatively high (over 50 N) loads, partially stabilized crystals do not display any noticeable anisotropy of hardness or fracture toughness.

A lower fracture toughness of crystals doped with terbia as compared to those doped with ceria reveals not only lower values of K_{1c}^{v} of the former, but also as lower loads giving rise to lateral cracks in the latter. In both crystals, lateral cracks appeared under the Vickers impression. We consider that the evaluation of fracture toughness on indentation of crystals should account for all their fracture features but not only for the length of radial cracks as it is usually done.

(Received 6 May 1994; revised version received 14 October 1994; accepted 12 December 1994)

Abstract

The microstructure of a commercial silicon nitride-bonded silicon carbide ceramic composite, formed via the nitridation of silicon powder–SiC preforms, has been characterised using analytical transmission electron microscopy. It comprised coarse particles of SiC dispersed in a matrix which was a mixture of crystalline phases based on Si_2N_2O and β-Si_3N_4, and an amorphous phase. Qualitative microanalysis of amorphous matrix regions revealed the presence of significant concentrations of aluminium, silicon, calcium and oxygen, while aluminium and oxygen were also readily detectable in both of the surrounding crystalline phases. It is thus suggested that the crystalline phases in the matrix are in fact O- and β-sialons respectively. A mechanism, combining reaction bonding and solution-precipitation in a (Ca,K)–aluminosilicate liquid phase at the reaction temperature, is proposed to describe the development of the matrix microstructure.

1 Introduction

The potential for near net shape forming of Si_3N_4 ceramics via the direct nitridation of silicon compacts, together with the economic advantage inherent in the use of silicon powder compared with currently available Si_3N_4 powders, have been major factors in sustaining continued interest in the application of the reaction bonding process to these ceramics in recent years. However, the consolidated densities achieved using this approach are typically only 80% of those obtainable by hot pressing techniques and the lower density, combined with the continuous nature of the porosity typical of reaction-bonded compacts, continue to limit the applications of such materials.

One approach to overcoming these difficulties has involved the development of the nitrided pressureless sintering (NPS) technique,[1–4] which combines the nitridation process with a liquid phase sintering stage, promoted through the addition of oxide sintering aids to silicon/Si_3N_4 compacts. This technique has been shown to be capable of producing Si_3N_4-based materials with near to theoretical densities and, with improved composition control and tailoring of the final microstructure, has the potential to allow more economical production of materials exhibiting reduced shrinkage during sintering and minimal porosity.

The Si_3N_4-based materials developed in this way have potential for application as the bonding constituents in low cost composite refractory materials, typically containing a major fraction of silicon carbide aggregate.[5] Such binders offer potentially superior oxidation and alkali resistance in molten metal environments compared with alumino–silicate matrices in current usage.[6,7] There is thus ongoing interest in the characterisation of the microstructure of such materials and in elucidating the stages of microstructural evolution during the sintering cycle.

The purpose of the present paper is to report on the microstructural characterisation of a commercially produced, reaction-bonded Si_3N_4–SiC composite, containing significant oxide additions, predominantly in the form of a clay binder. This work forms part of a larger project currently being undertaken to examine, using analytical transmission electron microscopy, the microstructural development of Si_3N_4-based ceramics produced by the NPS technique.

2 Experimental Procedures

Fabrication of the composite involved the wet blending of the major components, Si powder (particle size <44 μm) and crushed SiC (70–650

[c]Present address: Defence Science and Technology Organisation, Aeronautical and Maritime Research Laboratories, P.O. Box 4331, Melbourne, Victoria, 3001, Australia.

μm, in the approximate weight ratio of 1:3, with minor additions of organic plasticising agent (Ca–lignosulphonate) and clay (≤5 wt%) to aid plasticity of the slurry prior to moulding of the composite preforms. The cast preforms were allowed upwards of 8 h for material sedimentation and water extraction before mould removal. Sintering of the preforms was carried out in an N_2 atmosphere using a slow heating cycle, with a binder–burnout stage at 400–600°C, a final sintering temperature of 1450°C and a sintering time in excess of 20 h.

Initial phase analysis of the composite was performed in a Siemens D500 powder X-ray diffractometer using Ni-filtered Cu K_α radiation. Lattice parameters of the phases were determined from the measured X-ray diffraction peaks using a least squares fitting routine within the Celsiz program,[8] with calibration performed using silicon as an internal standard.

Composite surfaces for optical and scanning electron microscopy (SEM) were prepared by initial polishing of bulk specimens on a tin lap, followed by final 1 μm diamond polishing. Polished samples were examined in a JEOL 840A scanning electron microscope operating at 20 kV. Specimens for transmission electron microscopy (TEM) were prepared by diamond cutting thin composite slices, grinding and polishing to form 120 μm thick discs, and finally ion milling these discs to electron transparency using 5 kV argon ion beams at an incident angle of 15°. The specimens were coated with a thin carbon film and examined in a Philips CM20 analytical electron microscope operated at 200 kV and equipped with an ultra-thin window Link energy dispersive X-ray spectrometer (EDXS). For comparative X-ray microanalysis, an electron probe of nominally 10 nm diameter was used routinely in the scanning transmission electron microscope (STEM) mode.

3 Experimental Results

3.1 X-ray diffraction

The X-ray diffractometer trace from the reaction-bonded composite, Fig. 1, indicates that, in addition to SiC, the major crystalline phases in the composite are silicon oxynitride (Si_2N_2O) and β-Si_3N_4, with minor fractions of α-Si_3N_4 and unreacted silicon also present. The relative fractions of Si_2N_2O and β-Si_3N_4 in the binder phase were calculated as approximately 0·6 and 0·4 respectively, employing a technique making use of the (002) Si_2N_2O and (210) β-Si_3N_4 peak intensities[9] and ignoring minor phases. Efforts to determine more accurately the phase content of the matrix and the polytypes of SiC present, using available crystallographic data and a Rietveld analysis,[10] proved difficult due to the presence of multiple phases and significant overlap of diffraction peaks. However, analysis of the SiC peaks from both the composite and the starting SiC powder indicated that the 6H structure was the dominant polymorph, with the presence of the cubic (3C) and other α-polytypes as minor constituents suggested by the asymmetry of several major peaks.

A systematic shift in the peak positions for the Si_2N_2O and β-Si_3N_4 phases to lower diffraction

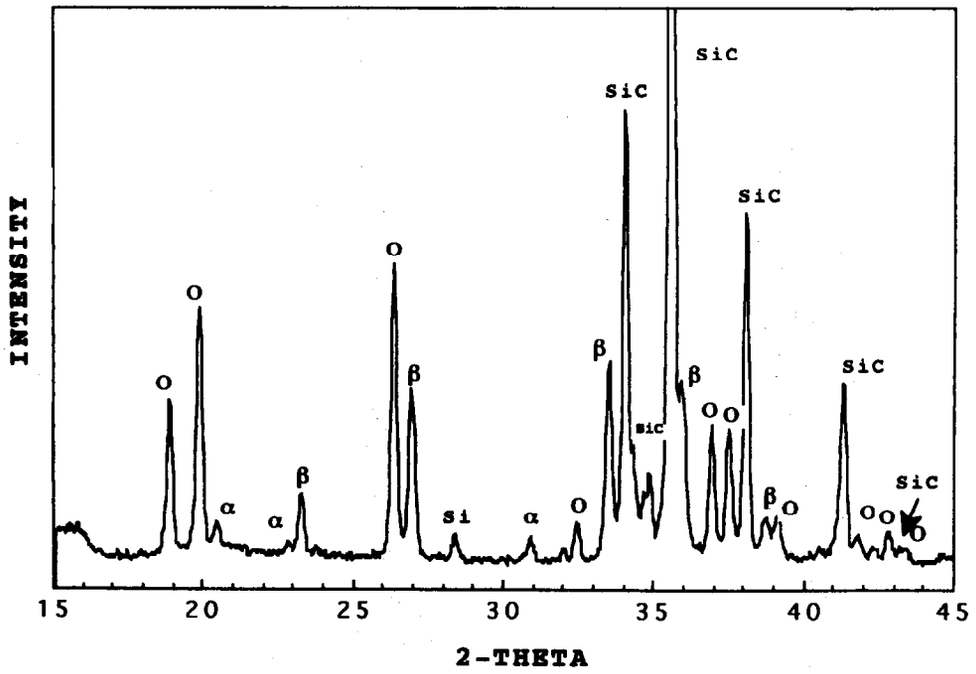

Fig. 1. X-ray diffractometer trace from as-fired material indicating the presence of SiC in a matrix that is predominantly a mixture of crystalline phases based on β-Si_3N_4 and Si_2N_2O (O).

angles (2θ) was noted, when compared with expected positions for the pure compounds. The lattice parameters of the hexagonal β-Si_3N_4 were determined to be a = 0·7617 ± 0·0004 nm and c = 0·2923 ± 0·0003 nm, while those of the orthorhombic oxynitride were measured to be a = 0·8909 ± 0·0003 nm, b = 0·5505 ± 0·0001 nm and c = 0·4861 ± 0·0001 nm. These values are systematically larger than those normally quoted for the pure compounds,[11] and are consistent with an expansion in the unit cell that might arise through Al–O bond substitution for Si–N bonds during sintering.

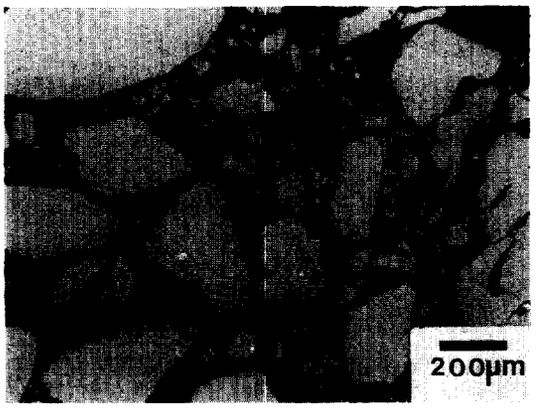
It is unlikely that the Si_2N_2O within the matrix can be attributed solely to the SiO_2 that is expected to be introduced as a surface layer on both the silicon and SiC powders. The high content of crystalline Si_2N_2O observed, and the almost exclusive appearance of β-Si_3N_4 in preference to α-Si_3N_4, suggest the presence of a liquid phase during the 1450°C reaction bonding process if proposed solution–reprecipitation mechanisms for Si_2N_2O formation are correct.[12–14] This is consistent with the presence in the original powder mixture of additional glass-forming oxides, which will promote the formation of a low melting point liquid and provide a source of oxygen for the formation of Si_2N_2O. However, the lack of a broad low-angle diffraction peak characteristic of an amorphous phase in the X-ray diffractometer trace of Fig. 1 implies that there is a low level of residual glass remaining within the composite after firing.

A few minor peaks remain unidentified in the X-ray diffractometer trace and are suspected to arise from metallic impurities introduced into the raw materials during powder processing.

3.2 Optical and scanning electron microscopy

Figure 2 is an optical micrograph typical of an unetched, polished surface of the as-fired composite, where the large silicon carbide grains in light grey contrast range in size from 20 to 450 μm and constitute approximately 75 vol.% of the composite microstructure. The microstructure of the Si_2N_2O–Si_3N_4 binder is unresolved at this scale, but it appears that it forms a near continuous, cohesive bond around the entire perimeter of the silicon carbide particles. The local dark areas within the binder represent a combination of intrinsic pores and defects introduced during polishing.

Examination in the scanning electron microscope, using backscattered electron contrast, revealed the presence of an impurity phase in light contrast at the SiC boundaries, Fig. 3, while the larger SiC grains often contained a core of slightly darker contrast. Energy dispersive X-ray spectroscopy of the two phases in light contrast (arrowed A and B respectively) indicated significant concentrations of Si, Fe and other metallic impurities, Fig. 3(b), in regions A, while in regions B, unreacted Si alone was detected. Optical and scanning electron microscopy of the raw SiC powder established the presence of the same phases intimately associated with the original SiC particles and it is thus inferred that these phases arise during the processing of the SiC. The use in the composite system of SiC produced by the reaction sintering method is the most likely source of additional metallic impurities in the microstructure, as



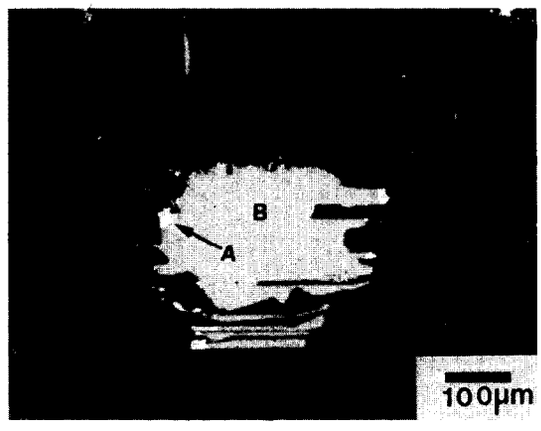


Fig. 2. Reflected light micrograph of unetched, polished surface of as-fired composite.

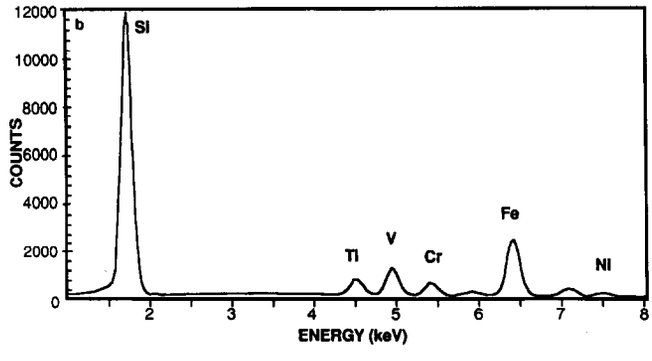

Fig. 3. (a) Backscattered electron image of as-fired composite showing impurity phase (regions A) and unreacted silicon (region B) within SiC grain, and (b) energy dispersive X-ray spectrum typical of impurity phase A.

reaction-sintered SiC is known to contain up to 10% unreacted silicon and other silicide impurities in the final product.[15]

3.3 Transmission electron microscopy

The microstructure of the binder in the composite was complex and varied significantly in grain size and morphology between thin foil specimens and even between adjacent areas within the same sample. Such variability is perhaps related to the relatively large scale of the initial SiC particles, resulting in poor mixing of the raw materials and/or segregation of components during green fabrication, which prevent the formation of a homogeneous structure. Figure 4(a) is a bright field TEM image showing a representative area of the binder microstructure, in which each of the grains in this field has been identified by electron microdiffraction to be either crystalline β-Si_3N_4 (β) or Si_2N_2O (O), while the central region is residual amorphous phase (G). Figures 4(b) and (c) show representative electron microdiffraction patterns used to identify the silicon nitride grains, indexed as (b) [0001] and (c) [$10\bar{1}0$] zone axis patterns from the hexagonal β-Si_3N_4 structure. The Si_3N_4 formed in a variety of morphologies, ranging from approximately equiaxed grains with smoothly curved surfaces and an average diameter of 350 nm, Fig. 4(a), to grains with a faceted, rod-like form. Those elongated grains, which were relatively rare, had a morphology commonly considered typical of the product of the α–β phase transformation in systems containing a liquid phase.[16–18]

In contrast to the Si_3N_4, the Si_2N_2O grains (50–500 nm) were readily distinguished by their elongated, faceted morphology[19,20] and a substructure of stacking faults parallel to the long axis, Fig. 5(a). The Si_2N_2O was also noted to have a tendency to form grains with faceted ends, with the angle of contact between grains apparently being determined by such facet angles. The form of the relationship between such contiguous crystals is at present the subject of further study. Figures 5(b) and (c) show representative electron microdiffraction patterns recorded from the Si_2N_2O grains, which may be indexed as (b) [$1\bar{1}0$] and (c) [$\bar{1}01$] zone axis patterns from the orthorhombic oxynitride structure.[21]

Non-crystalline regions observed within the binder microstructure were also identified by diffraction and diffraction contrast techniques.[22] As shown in Fig. 6, the glass had formed as discrete pockets at three and four grain junctions involving both oxynitride and β-Si_3N_4 grains, and was not readily detectable in the form of continuous intergranular films. The incidence of amorphous

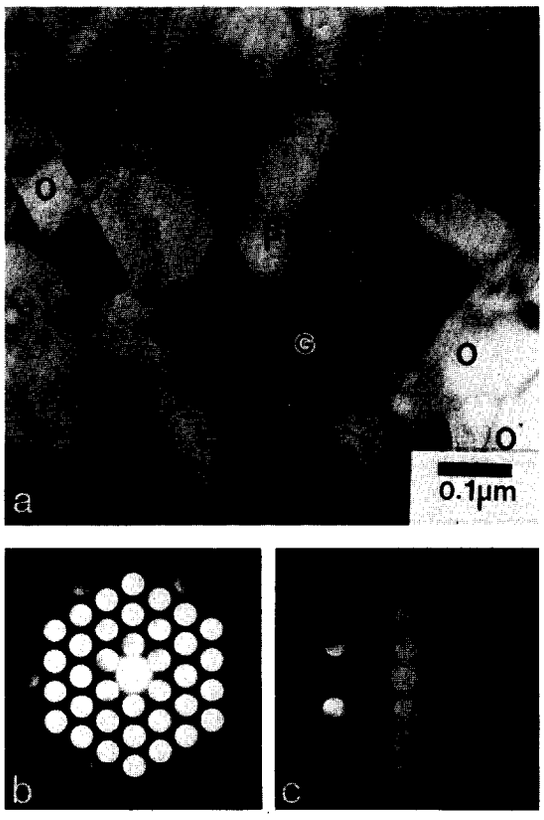

Fig. 4. (a) Transmission electron micrograph showing region of amorphous phase (G) surrounded by a mixture of crystalline phases based on β-Si_3N_4 and Si_2N_2O (O), and electron microdiffraction patterns which can be indexed unambiguously as (b) [0001], and (c) [$10\bar{1}0$] zone axis patterns from the hexagonal β-Si_3N_4 structure.

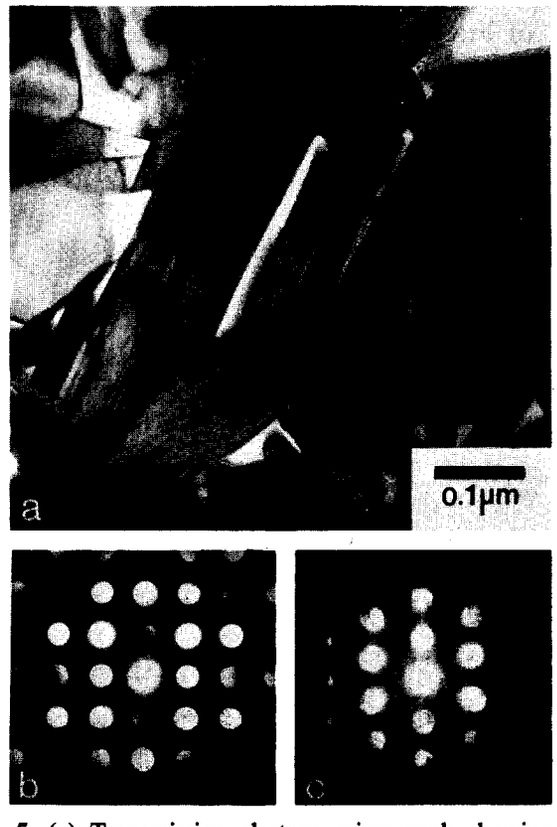

Fig. 5. (a) Transmission electron micrograph showing the morphology typical of elongated grains of the oxynitride-based phase (O), and electron microdiffraction patterns which can be indexed unambiguously as (b) [$1\bar{1}0$], and (c) [$\bar{1}01$] zone axis patterns from the orthorhombic oxynitride structure.

pockets was, however, rare, suggesting that the quantity of such phase within the microstructure was relatively small. Energy dispersive X-ray spectra, Fig. 7(a), recorded from the amorphous regions revealed significant concentrations of Si, Al, O, Ca and K; the C peak is a consequence of specimen coating and contamination. There was some evidence of the presence of nitrogen within the residual glass, but it proved difficult to detect because of the overlap of the adjacent oxygen and carbon peaks.

Microanalysis of the Si_2N_2O grains throughout the binder, Fig. 7(b), indicated the presence of significant concentrations of Al, along with Si, N, and O. It is thus suggested that the phase described thus far as an oxynitride is in fact an O-sialon ($Si_{2-x}Al_xO_{1+x}N_{2-x}$ with $x \leq 0{\cdot}2$). Similarly, significant concentrations of Al were also detected in the nitride grains in the binder, Fig. 7(c), suggesting that this phase is β-sialon ($Si_{6-z}Al_zO_zN_{8-z}$, $z < 4{\cdot}2$), formed by the limited substitution of Al^{3+} for Si^{4+}, with accompanying oxygen–nitrogen substitution for charge compensation.[23,24] The Si : Al ratio was observed to be constant, to within the limits of experimental error, in each of the two crystalline phases throughout the binder microstructure. This uniformity of composition would suggest that the liquid phase, which is the likely primary source of the Al and O, possesses a low viscosity, as would be expected for oxide liquid phases containing significant alkali-metal and alkaline earth concentrations,[25] and is uniformly distributed throughout the microstructure at the final reaction temperature of 1450°C.

Metallic inclusions were also observed occasionally at multiple grain junctions, and Fig. 8(a) shows an area containing a number of inclusions in dark contrast bounded by oxynitride grains. X-ray microanalysis, Fig. 8(b), indicated that the

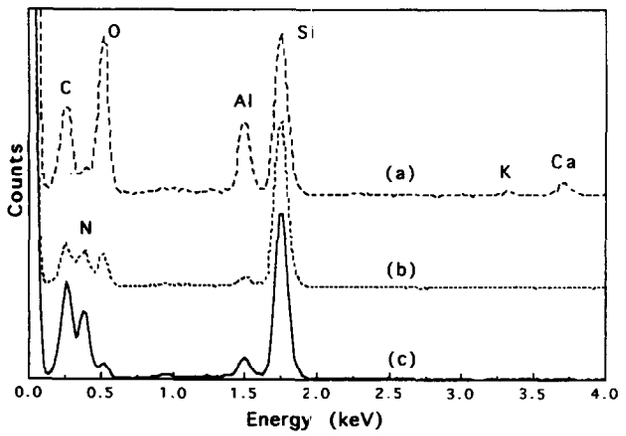

Fig. 7. Energy dispersive X-ray spectra typical of (a) amorphous phase, (b) O-sialon grains, and (c) β-sialon grains within the matrix of as-fired composite.

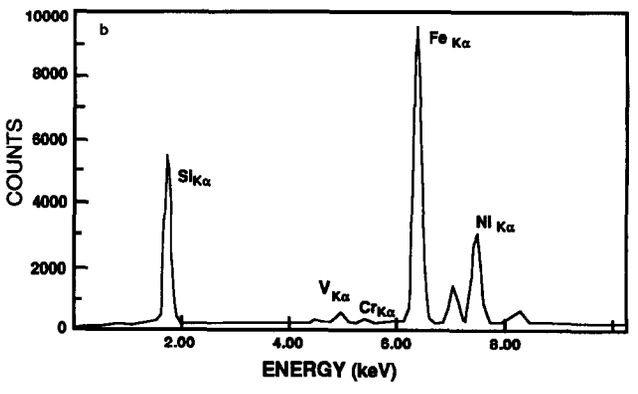

Fig. 8. (a) Transmission electron micrograph showing grains of metallic impurity phase within composite matrix, and (b) energy dispersive X-ray spectrum typical of the impurity phase.

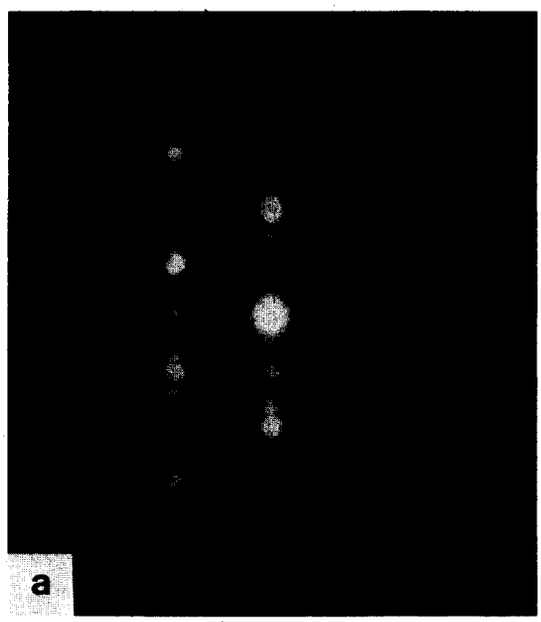
particles contained significant concentrations of Fe, Si, Cr, Ni and V, and it seems likely that such inclusions are introduced during the attrition process, perhaps as a result of the use of stainless steel milling media.



Careful examination of a number of segments of the matrix/SiC interface typically indicated that the interface was cohesively bonded along the entire boundary length. No evidence of crack formation at the interface was observed and it also proved difficult to detect any amorphous thin films between the SiC and the binder phases. More detailed investigations of the interfacial region are in progress to elucidate the interface structure and to check for the presence of the amorphous intergranular films that are often reported in silicon nitride-based ceramics.[26–30]

An interesting feature of the microstructure was the common observation of the preferred nucleation of fine, rod-like O-sialon (O') grains along the boundaries of the coarse SiC particles. Figures 9(a) and (b) show a number of O' crystals extending outwards from their preferred nucleation sites on the SiC surface, with the preferred direction of elongation corresponding to the *c*-axis of the orthorhombic O' phase. Figure 10(a) is a composite electron microdiffraction pattern containing super-

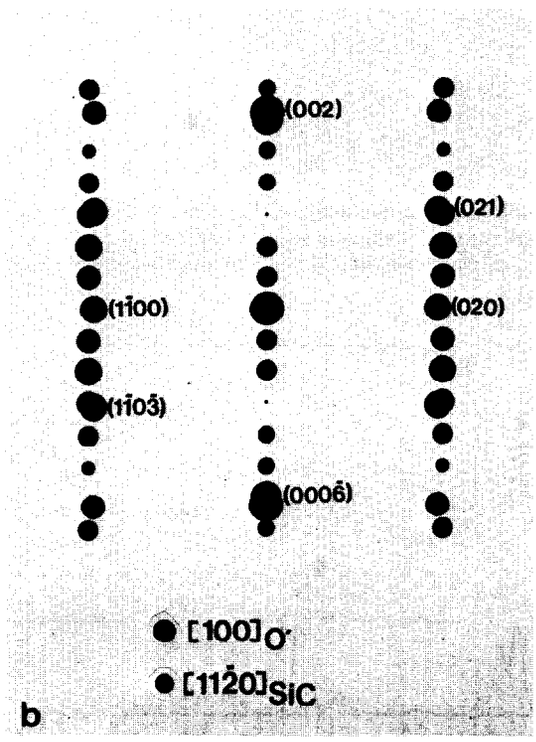

Fig. 10. (a) Composite electron microdiffraction pattern containing superimposed $[100]_{O'}$ and $[11\bar{2}0]_{SiC(6H)}$ zone axis patterns from adjoining regions of O-sialon and SiC, such as shown in Fig. 10, and (b) schematic solution to these patterns.

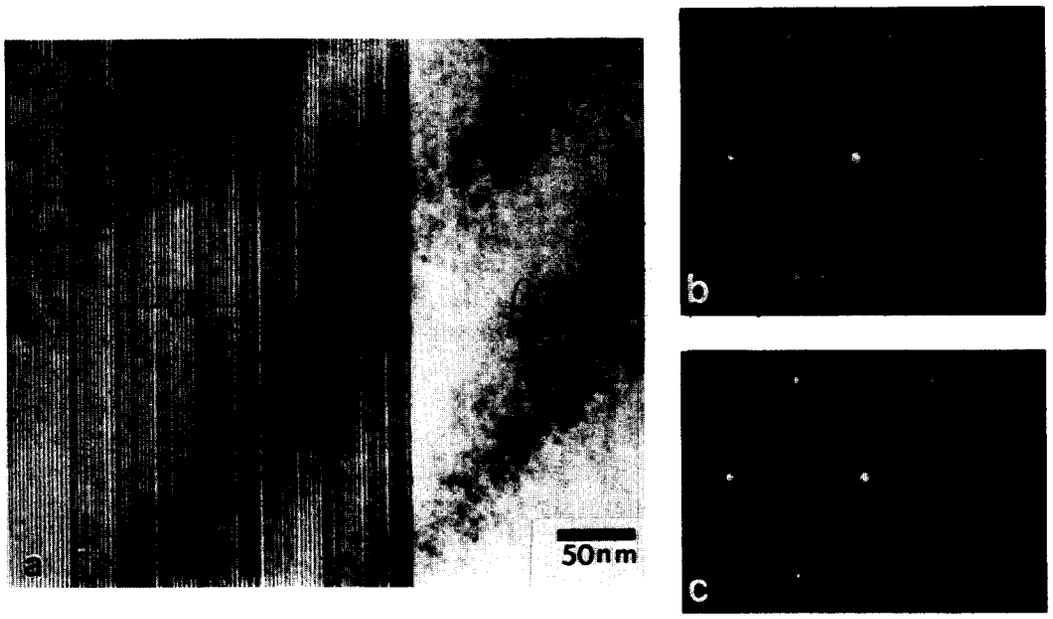

Fig. 11. (a) Transmission electron micrograph showing section of SiC grain containing regions of both the α- and β-SiC polymorphs, and corresponding (b) $[11\bar{2}0]_{SiC(6H)}$ and (c) $[110]_{SiC(\beta)}$ zone axis SAED patterns from the α and β structures respectively.

imposed zone axis patterns from adjoining regions of SiC and the O-sialon. As indicated by the schematic solution to the pattern in Fig. 10(b), the patterns imply an orientation relationship between the O' and the SiC in which:

$$(001)_{O'}// (0001)_{SiC}, \text{ and}$$

$$[100]_{O'}//[11\bar{2}0]_{SiC(6H)}.$$

Several regions in which β-sialon (β') grains were in direct contact with the SiC grains were also examined, but attempts to identify an orientation relationship[31] between the β' and the SiC have thus far been unsuccessful.

Examination of the large SiC particles using electron diffraction and lattice fringe imaging techniques[32] confirmed the existence of a variety of SiC polytypes, as suggested by the X-ray diffraction data from the composite (Fig. 1). The majority of areas examined with the electron beam parallel to a $<11\bar{2}0>$ direction exhibited lattice fringe spacings of 1·52 nm consistent with the 6H polymorph of α-SiC,[33] Fig. 11(a). However, a number of particles were observed to contain alternative α-SiC polytypes and, as illustrated in Fig. 11(a), local regions of β-SiC. The selected area electron diffraction pattern recorded from the α-SiC area in Fig. 11(a) and shown in Fig. 11(b) may be indexed for the hexagonal structure of the α-polytype. The streaking and additional low intensity reflections observed along the $\{10\bar{1}l\}$ diffraction row are characteristic of the faulted substructure of this polymorph.[33,34] In contrast, the SAED pattern in Fig. 11(c) may be indexed as the [110] zone axis pattern from β-SiC.

4 Discussion

Characterisation by analytical electron microscopy, in conjunction with X-ray diffraction, has established that the microstructure of the binder, in what is described as a Si_3N_4-bonded SiC composite, in fact comprises a mixture of crystalline phases based on Si_2N_2O and β-Si_3N_4, with a small volume fraction of residual amorphous phase rich in Si, Al, Ca, K and O. The high content of crystalline oxynitride and the almost exclusive appearance of β-Si_3N_4 (or β-sialon), both suggest the presence of a significant volume fraction of liquid phase during the 1450°C reaction bonding process, as those mechanisms proposed[12,14] for formation of Si_2N_2O invariably involve precipitation from a liquid phase, while the formation of β-sialon also commonly occurs from or in association with a liquid.[16] The residual glassy phase observed within the binder is consistent with the presence of a (Ca,K)–aluminosilicate derived liquid phase at the reaction temperature, although it is noted that the volume fraction of residual glassy phase is small in the as-fired product. These observations lead to a description of the consolidation of the composite in which the microstructure of the composite binder evolves via a modified solution–reprecipitation mechanism, such as that initially proposed for the reactive liquid–phase sintering of hot-pressed silicon nitride.[35,36]

In the case of the present Si/SiC powder composite preform, initial nitridation of the fine silicon powder during heating might be expected to lead to the formation of predominantly α-Si_3N_4 by

the vapour phase reaction of $Si_{(g)}$ or $SiO_{(g)}$ with nitrogen.[37] In the presence of Fe as a significant impurity, formation of the α phase might also arise[38] through Si vaporisation from any $FeSi_x$ liquid phase that may form. However, in studies of the reaction bonding of Si_3N_4 there are numerous reports of the formation of a product containing a significant volume fraction of β-Si_3N_4 at temperatures as low as 1330°C,[38] and it has been suggested[38] that the development of the two modifications may be determined by particular growth mechanisms. The choice of growth mechanism may be strongly influenced by the presence or otherwise of significant fractions of low melting point liquid phase generated from the natural oxide film on the original powder(s) and/or other impurity ingredients.

It is also well established that α-Si_3N_4 transforms to β-Si_3N_4 during heat treatment at temperatures in the vicinity of 1500°C,[17] and that this transformation may be facilitated by the presence of impurity elements and/or a liquid phase of appropriate composition.[16] There are thus at least two mechanisms by which the β-Si_3N_4 observed in the as-fired product may form and increase in volume fraction during the reaction cycle. It is noteworthy that two distinguishable morphologies of the β-nitride were observed within the binder; the major fraction contained rounded, equiaxed grain shapes, but there was a small fraction of grains possessing a faceted and elongated form more typical of a product forming as a precipitate from a liquid phase. These different grain shapes may constitute evidence of two different growth mechanisms contributing to the total fraction of β-Si_3N_4 in the binder.

The EDXS analyses of residual amorphous regions in the composite imply the existence at the reaction temperature of a (Ca,K)–aluminosilicate based liquid phase with a composition derived principally from the clay addition. The timing of the formation of this liquid phase in the reaction sequence may have a strong influence on phase formation within the microstructure. The formation of an extensive liquid phase early in the reaction sequence may, for example, inhibit the formation of Si_3N_4[3] by the premature closure of the pore network necessary for the access of nitrogen to the silicon, if indeed direct access of nitrogen to solid silicon is essential to continuing nitridation. This might be expected to lead to a large residual silicon content in the sintered product. However, both X-ray diffraction and direct microscopic observation indicate that only a small fraction of silicon remains within the present composite. Given that the melting point of the liquid phase is likely to be low (<1450°C) and the liquid phase is thus likely to be present from the earliest stages of the reaction bonding sequence, this suggests that the volume fraction and viscosity of the liquid phase, combined with the low green density of the compact, are such that they do not adversely affect the access of the nitrogen to the silicon.

In the initial stages of nitridation it seems likely that the product is a mix of α-Si_3N_4 formed via a gas phase reaction and β-Si_3N_4 formed perhaps by a combination of mechanisms involving the presence of the (Ca,K)–aluminosilicate liquid phase. Exposed to an increasing fraction of oxygen-rich liquid phase at the reaction temperature, the less stable α-Si_3N_4 present will dissolve to form essentially calcium sialon liquid, and be replaced by the precipitation of the Si_2N_2O-based phase. The large volume fraction of O' compared with β' in the binder is consistent with a substantial proportion of the (α-)Si_3N_4 formed by nitridation being consumed by the liquid phase, while the elongated, faceted morphology and faulted substructure of grains of this phase are characteristic of the oxynitride forming from a liquid phase.[20] It is to be expected that the relatively low solubility of nitrogen combined with a high oxygen activity in the liquid phase will favour formation of O-sialon.

The direct observation of aluminium within the Si_2N_2O-based phase, together with the measurement of lattice parameters systematically larger than the range of lattice constants reported for pure Si_2N_2O, confirm the identity of the phase as O'. The lattice parameter a of O' experiences the most significant expansion as the result of the replacement of Si^{4+} ions with Al^{3+} ions, and comparison of the present measured values with published results[39,40] suggests that the aluminium content of the O-sialon ($Si_{2-x}Al_xO_{x+1}N_{2-x}$) is such that $x \geq 0{\cdot}14$ and, according to some observations,[40] approaching the limit of aluminium solubility in the O' structure. This is consistent with the precipitation of the O' from a liquid phase in which the activity of aluminium is high, i.e. a liquid phase forming in the presence of a high Al_2O_3 concentration.

A unique feature of the present study was the common observation of elongated grains of the oxynitride-based phase extending from the surface of coarse SiC particles and sustaining a well-defined orientation relationship with the SiC. This orientation relationship is such that the long axis of the O', $[001]_{O'}$, is parallel to the c axis of the 6H SiC, and the misfit between $(002)_{O'}$ and $(0006)_{SiC(6H)}$ planes normal to the preferred growth axis is approximately 3·3%, based on lattice parameters determined at room temperature. Normal to the interface between the O' and the SiC, Fig. 10(a),

the planes $(020)_{O'}$ and $(1\bar{1}00)_{SiC}$ are approximately parallel and contain the growth axis, and differ in spacing by only approximately 2·9%. Similarly, the planes $(100)_{O'}$ and $(11\bar{2}0)_{SiC}$ are parallel across the interface and the misfit between them is approximately 3·3%. The form of these O' grains, and the relatively low lattice misfit between the O' and the SiC phases in the observed orientation relationship, imply the preferred heterogeneous nucleation of the Si_2N_2O-based grains on the SiC and their subsequent growth outward into surrounding liquid phase. That they grow into liquid phase is supported by the common observation of small glass pockets surrounding these grains in the as-fired product.

Regardless of the mechanism of formation of the β' phase, the direct observation of aluminium (and oxygen) within the various grain morphologies, together with the magnitudes of the measured lattice parameters, confirm the identification of this phase as β-sialon rather than β-Si_3N_4. There were no significant variations detectable in the aluminium concentration within the different β-sialon morphologies and across many grains of each analysed using EDXS. This suggests that the extended hold time at the final sintering temperature of 1450°C may be sufficient to allow the aluminium and oxygen concentrations within both the β' and O' to approach saturation in the solid state at this temperature. In the case of any β' formed as a solid state reaction product this would seem to imply the diffusion of aluminium and oxygen from the aluminium-rich liquid phase during or immediately following initial nitridation.

If measured values of the lattice parameters for the crystalline binder phases are compared with existing data[41,42] to determine the values of z and x for the β' ($Si_{6-z}Al_zO_zN_{8-z}$) and O' phases respectively, the results support the notion that the aluminium concentration approaches saturation within both phases during the firing treatment. The calculated values of $z = 0{\cdot}45$ and $x = 0{\cdot}14$ are equivalent to aluminium concentrations of 5·72 and 5·34 eq% respectively, indicating that, to within reasonable error limits, the aluminium content of the two phases is essentially identical.

The presence of residual glass pockets in the final microstructure results from a failure to completely exhaust the supply of liquid phase at the reaction temperature. It is noteworthy that the pockets of glass, such as shown in Fig. 4, were relatively rare and that the volume fraction of residual glass was relatively small. There would thus seem to exist, potential for largely eliminating residual glassy phase from the final microstructure through improved design of the composition of the composite and, in particular, improved control of the additions of those minor constituents which generate and stabilise the liquid phase during processing.

5 Summary

(1) The microstructure of the commercial silicon nitride-bonded silicon carbide ceramic composite, formed via the nitridation of silicon powder–SiC preforms, comprises coarse particles of SiC dispersed in a matrix or binder which is a mixture of crystalline phases based on Si_2N_2O and β-Si_3N_4 in the volume ratio of approximately 2:1, together with a small volume fraction of residual amorphous phase.

(2) The direct observation of significant concentrations of aluminium (and oxygen) within both of the crystalline phases, together with measured lattice parameters which are systematically larger than those of the pure compounds, imply that the crystalline phases within the binder are in fact O- and β-sialons respectively.

(3) The O-sialon is observed to nucleate preferentially, but not exclusively, on the 6H SiC particles with an orientation relationship with the SiC of the form:

$$(001)_{O'}// (0001)_{SiC}, \text{ and}$$
$$[100]_{O'}//[11\bar{2}0]_{SiC(6H)}.$$

(4) Direct qualitative microanalysis of amorphous matrix regions indicates the presence of significant concentrations of aluminium, silicon, calcium and oxygen. The regions are interpreted to represent the residue of a reactive, low melting point (Ca,K)–aluminosilicate liquid phase, deriving predominantly from clay binder additions to the original powder mix and present throughout the reaction sequence.

(5) It is proposed that the β-sialon within the binder is predominantly the product of a reaction-bonding sequence, perhaps facilitated by the presence of the liquid phase. The O' is suggested to arise as a result of the dissolution of α-Si_3N_4 in the oxygen-rich liquid phase, followed by precipitation of the O-sialon.

(Received 12 September 1994; revised version received 12 December 1994; accepted 10 January 1995)

Abstract

Tensile and bend strength were obtained for four compositions in the aluminum nitride–silicon carbide system: AlN, 75%AlN–25%SiC particulate, 50%AlN–50%SiC solid solution and SiC. Room temperature tensile strength, four-point bend strength, and the Weibull parameters for each of the tested materials are presented. Optical and SEM fractography were employed to identify failure initiating flaws for the fractured tensile specimens. The four-point bend strength is predicted using the Weibull tensile parameters and compared to measured values. Accuracy of the predicted results are rationalized based on observed microstructures and failure initiating flaws.

Introduction

Advanced ceramics are being increasingly utilized in a wide variety of demanding structural and electronic applications.[1] The high elastic modulus, excellent wear behavior, low density, high thermal conductivity, and outstanding high temperature strength and oxidation resistance of SiC have led to its use in wear parts, heat exchangers, fixturing for semiconductor manufacturing processes, and armor. AlN has outstanding thermal conductivity and a thermal expansion coefficient near that of silicon. These properties have made AlN the material of choice in electronic packages where heat management is a dominant design issue. However, because of its relatively modest strength and poor oxidation characteristics, except for use in armor systems, AlN receives little consideration in structural applications.

The AlN–SiC binary is somewhat unique among covalent systems in as much as a range of composites and solid solutions are possible depending on the raw materials and the processing conditions employed. If fine powders are processed significantly above 2100°C, a nearly complete range of solid solutions are possible.[2] Alternatively, if coarser materials are processed below 2000°C, where diffusion is slow, a family of two-phase particulate composites are formed.[3] While the mechanical properties of the end members, SiC[4–6] and AlN,[7–10] have been well documented, there have been only limited results reported for AlN–SiC composites and solid solution. Flexural strength data for AlN–SiC solid solutions were first reported by Ruh and Zangvil.[11] The low reported values were attributed to poor mixing. Landon and Thevenot using improved slurry preparation routes formed largely AlN–SiC solid solutions.[12] In general, the strength was higher for the SiC rich compositions. The maximum RT 3-point bend strength was reported as 1000 MPa for a hot pressed AlN–SiC material containing 25 wt% AlN. More recently, researchers at Nagoya University studied the effect of different microstructures on the mechanical properties of a single 30/70 AlN–SiC composition.[13] RT 4-point bend tests of this material demonstrated strengths and Weibull moduli increasing from 589 to 674 MPa and from 7·6 to 10·5 MPa, for the as processed solid solution and a phase separated modulated structure, respectively.[14] Mariano, *et al.*[15] have recently reported limited data on the RT 4-point bend strength of 15 and 45% SiC particulate reinforced AlN composites. They reported strengths of 477 and 347 MPa, respectively.

This work presents a detailed examination of the room temperature tensile and flexural strengths, failure statistics, and strength limiting flaws for four representative materials in the AlN–SiC system. The two end members, one solid solution alloy (50/50), and one particulate strengthened

composite (75/25) were studied. The solid solution and composite were selected based on their performance as ceramic armor materials[16] and potential for other structural applications.

Experimental Procedure

Materials

All of the specimens used in this study were machined from large billets. AlN, the AlN–SiC composite, and the AlN–SiC solid solution were prepared by hot-pressing blocks which were 38 × 104 × 20–40 mm thick in graphite dies. The three hot-pressed materials were pressed at 34·5 MPa and no sintering aids were employed. The exact processing conditions and physical characteristics of these compositions and the pressureless sintered SiC are provided in Table 1. The SiC parts were prepared using the traditional sintering aids of boron and carbon. The sintered dimensions for the SiC tiles were 112 × 112 × 16 mm. Both flexure and tensile specimens were machined out of each billet. The tensile test specimens were cylindrical rods measuring between 103 and 112 mm in length and 9–9·2 mm in diameter. B type bend bars, 3 × 4 × 40 mm, were prepared according to MIL-STD-1942A.[17]

Typical microstructures of the four ceramics studied are shown in Fig. 1. AlN and the 50/50 AlN–SiC solid solutions have uniform, fine-grained microstructures. Despite a processing temperature nearly 500°C higher than AlN, the average grain size was almost a factor of 4 smaller for the solid solution (see Table 1). The TEM micrograph, Fig. 2, of the 50/50 alloy vividly shows this fine grain size. The SiC microstructure is characteristic of other beta SiC materials having transformation induced large (50 × 2 mm) needle-like grains interspersed in a relatively fine microstructure (2 mm). From the optical micrographs, the 75/25 AlN–SiC composite appears to have fine SiC particles uniformly dispersed in an AlN matrix. However, TEM examination revealed that some dissolution of SiC into the AlN matrix grains had occurred. From EDS analysis of individual matrix grains, as much as 8% SiC was present in the AlN.[18]

Mechanical testing

Tensile tests were performed at room temperature utilizing a self-aligning hydraulic technique developed by Baratta and Driscoll[19,20] with a simplified specimen described by Hermansson, *et al.*[21] The tensile test specimens are cylindrical bars measuring between 103 and 112 mm in length and 9·0–9·2 mm in diameter. Forty mm on each end of the ceramic rod is inserted into a steel piston and adhesively bonded in place with a high strength epoxy.[22,23] The specimen–piston assembly is inserted into the pressure chamber of the hydraulic tester.* The pressure is applied and increased until the specimen is broken apart by the hydraulic pressure acting against the pistons. The pressure chamber, with specimen inserted, is shown schematically in Fig. 3. The internal pressurization of the specimen suspended between the O-ring seals minimizes bending stresses. The nominal tensile fracture stress (uncorrected for eccentricity) may be calculated by using the hydraulic pressure at failure and geometric parameters of the specimen–piston assembly.[20] A small degree of triaxiality in the hydrostatic loading of the specimen exists causing a small deviation from the uniaxial stress state, calculated to be less than 5%.[23,24] In addition, to eliminate the effects of stress intensification at the rod to piston bond transition, data from specimens that fractured within one half the radius of the specimen from the piston glue line are not used. Fractures occurring in these locations are considered invalid tests.[21]

Although this tensile method is inherently self-aligning, a small degree of eccentricity or misalignment of the tensile specimens can still occur from two sources. The specimen can be slightly curved or can be glued off-center in the pistons.

As a result, small bending moments may develop along the gage length. The procedures to correct for this error have been described,[22–25] and were applied to the data reported in this paper.

The stress is related to the hydraulic pressure and test geometry by the following expression:

$$\sigma = \sigma_{nom} + \Delta\sigma = \left(\frac{A - A_s}{A_s}\right) \times P + \Delta\sigma$$

Where: σ_{nom} is the nominal (uncorrected) fracture stress, A is the cross-sectional area of the piston, A_s is the cross sectional area of the specimen, P is the pressure at failure, and $\Delta\sigma$ is the correction for eccentricity which is equal to $\sigma_{nom} \times f$(fracture origin location, specimen eccentricity and diameter).[22–25] The maximum correction for eccentricity in this study was equal to 8·40% with an average correction being approximately 4%.

Four-point bend tests were carried out in accordance with the MIL-STD-1942A standard test.[17] B type bend bars were used, having a size of 3 × 4 × 40 mm with 40 mm outer and 20 mm inner spans as shown in Fig. 4. Tests were carried out on an Instron 4201 universal tensile testing machine.

The fracture surfaces of the tensile specimens were examined by both low magnification optical and high magnification scanning electron microscopy (SEM). SEM fractography and elemental analysis were carried out on a JEOL 840A instrument equipped with an energy dispersive analyzer. The tensile fracture surfaces were ultrasonically cleaned and coated with thin layer of Au–Pd alloy

Fig. 2. TEM of 50/50 solid solution alloy of SiC/AlN showing the sub-micron grain size, ≈ 1/2 μm.

to prevent charging in the SEM. The bend bars shattered into many fragments upon fracture. This made it difficult to do unambiguous fractographic analysis and determine the location of fracture initiation of the bend bars. Consequently, such data will not be reported.

Results and Discussion

Tensile tests

Weibull distributions for the tensile strength of all

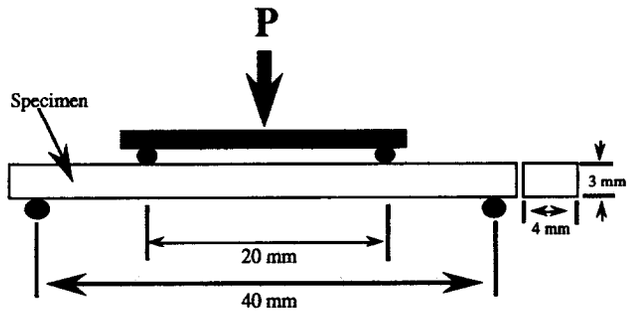

Fig. 4. Four-point bend test.

materials were plotted using the maximum likelihood estimate and are shown in Fig. 5. The characteristic tensile strength of 75%AlN–25%SiC and 50%AlN–50%SiC materials were higher than either of the base materials with values of 371 and 361 MPa, respectively. The AlN material was the weakest among the four materials with a characteristic strength of 234 MPa. The 50%AlN–50%SiC solid solution had the lowest scatter in strength with a Weibull modulus of 26·4. This may be attributed to the uniform nature of this material's microstructure. The other three materials (AlN, SiC, and 75%AlN–25%SiC) all had comparable scatter with Weibull moduli ranging between 9·1 and 12·7, as shown in Fig. 5. The summation of the effective volumes under stress for each set of materials tested is also reported in Fig. 5. 80% of the tested specimens produced valid breaks, 43 out of 53. Details on the tested specimens and the location of the fracture initiating flaws for each material are presented in Table 2.

Fractography of the tensile bars

Low magnification optical fractographs of a typical tensile specimen failure of each of the four materials are presented in Fig. 6, and higher magnification SEM's are presented in Figs 7–11. The AlN samples typically exhibit a well defined

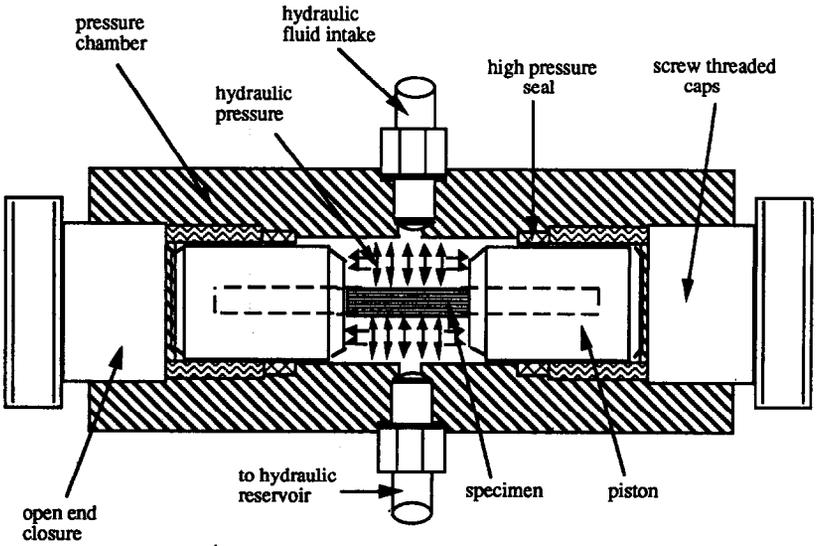

Fig. 3. Hydraulic pressure chamber with specimen–piston assembly.

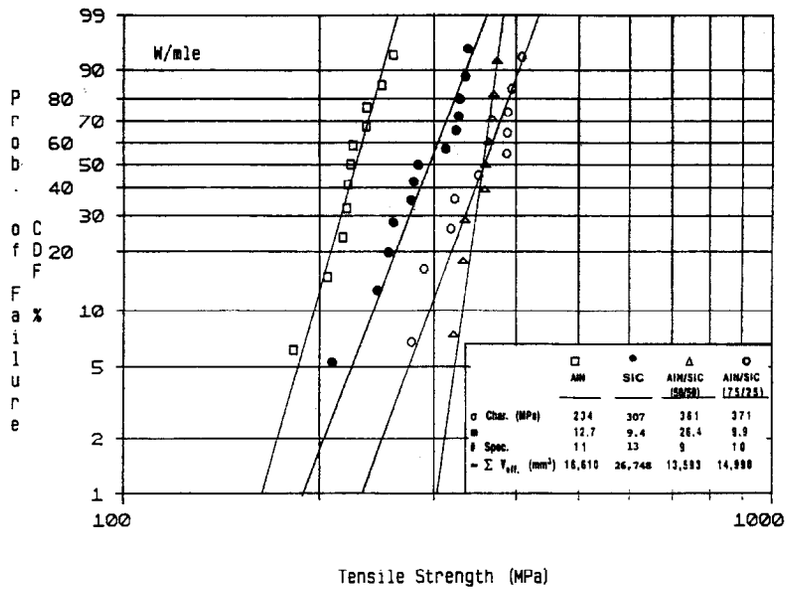

Fig. 5. Weibull strength analysis for ceramics in the AlN–SiC system (tensile tests).

origin, mirror, mist, and hackle as may be seen in Fig. 7(a). The fracture origins in AlN are typically large agglomerates surrounded by high porosity regions (Fig. 7(b)). Figure 8 presents a typical tensile fracture origin in 75%AlN–25%SiC specimens. The initiating flaw agglomerate appears to be highly porous with large grains of irregular morphology which are poorly bonded to the matrix (Fig. 8(b)). EDS results presented in Fig. 9 show a predominance of SiC in the porous region at the origin and an AlN rich region (the 'white area' in Fig. 9(a)) next to the flaw as compared to other regions of the surface. The Fe which is present at the failure origin, may play a role in this apparent segregation of SiC and AlN at the flaw. The fracture mirror in a typical 50%AlN–50%SiC failure origin appears to be smaller than in the case of AlN and 75%AlN–25%SiC (Fig. 6). The usual failure initiating flaw in the 50/50 solid solution alloy was an agglomerate composed of a mass of clustered grains with irregular morphology as shown in Fig. 10. Thus, it was sometimes difficult to locate the initiation of fracture. EDS indicated a lack of SiC at the agglomerate and the presence of pure AlN. The initiating flaw in a typical SiC specimen is also very difficult to locate. The failure initiating flaw appears to be a series of large interconnected pores adjacent to one or more large grains as may be seen in Fig. 11. A summary of the fractography of the four materials is presented in Table 3.

Prediction of bend strength from tensile data

The four-point bend strength can be predicted from the tensile Weibull parameters by applying the standard Weibull scaling factor.[26]

$$\sigma_b = \sigma_t \left(\frac{\nu_t}{\nu_b}\right)^{\frac{1}{m}} \tag{1}$$

where

σ_t = the strength of the tensile specimens
ν_t = the effective volume of the tensile specimens
ν_b = the effective volume of the flexure specimens
m = Weibull modulus of the tensile specimens

The effective volume in the tensile specimen is the product of the cross-sectional area and the length of the gage section. For four-point bend specimen, the effective volume can be calculated using the following equation:[26]

$$\nu_{\text{eff.}} = \frac{bh}{2}\left(\frac{mL_2 + L_1}{(m+1)^2}\right) \tag{2}$$

where m is the tensile Weibull modulus, and the other parameters are defined in Fig. 4.

The characteristic flexural strength of the four materials were predicted from the tensile strength data. In addition, four-point bend tests of bend bars from the same batches of the four materials used to make the tensile rods were carried out and the Weibull distribution plotted as shown in Fig. 12. The characteristic strength, Weibull modulus,

number of specimens, and the sum of the effective stressed volumes for each material are shown on the plot. The predicted and measured four-point bend strengths are compared in Table 4.

As can be seen from Table 4, the predicted flexural strength for the 75%AlN–25%SiC is in close agreement with the measured flexural strength. This is due to the fact that this material has a

Predictions based on $\sigma_{char.}$, $V_{eff.}$ and m obtained in tensile tests.

bimodal grain/phase structure and this bimodal structure gives rise to flaws that are uniformly dispersed throughout the matrix. The predicted bend strength values for the 50%AlN–50%SiC, AlN, and SiC vary by approximately 21, 18, and 11% of the measured values, respectively. This difference may be attributed to the difference in flaw populations initiating failure as compared to the 75%AlN–25%SiC material. In particular, the large AlN agglomerate which is encountered routinely in the tensile test with its large effective test volume, is likely to be only rarely encountered in bend bars. Identification of the AlN agglomerate as a common failure initiating fracture was obvious in studies of the tensile failures of AlN and 50%AlN–50%SiC, whereas, such a flaw was seen in only one of 25 bend bars. Similarly, the large grains with associated pores which are the failure origins in SiC, may be less frequently encountered in the small stressed volumes of the bend bars whereas, they are commonly encountered in the large tensile specimens. This graphically indicates the importance of obtaining fractographic analysis on tensile specimens as well as bend specimens, in order to be sure to identify all flaw populations.

Conclusions

This study has illustrated the following:

(1) Both the 75%AlN–25%SiC particulate reinforced and 50%AlN–50%SiC solid solution materials showed significantly increased strength as compared to pure AlN and SiC materials.

(2) While the nature of the failure initiating flaws varied for each of the four materials, agglomerates of AlN were common strength determining flaws in the pure AlN and 50%AlN–50%SiC solid solution. The prevalence of this flaw population was clearly evident in the tensile tests but not in the bend tests.

(3) The difference between predicted and measured flexural strength for the AlN, SiC, and 50%AlN–50%SiC materials may indicate that the flaw populations initiating failure differ. Because the tensile test interrogates a significantly larger stressed volume than does the bend test, the tensile test may well include flaw populations that are missed in conventional (10–30 specimens) bend testing. In such cases use of Weibull parameters obtained from tensile testing will tend to underpredict the fracture strength of the smaller component. Thus, the use of tensile data will yield a conservative design.

(4) Finally, the benefit of tensile tests in identifying failure initiating flaw populations was clearly demonstrated. Such information can provide useful feedback to materials' developers.

Thermal Conductivity Improvement of YAG Added AlN Ceramics in the Grain Boundary Elimination Process

Mitsuo Kasori & Fumio Ueno

Materials & Devices Research Laboratory, Research & Development Center, Toshiba Corporation, Kawasaki, Kanagawa 210, Japan

(Received 26 August 1993; revised version received 14 July 1994; accepted 10 August 1994)

Abstract

The primary cause of the thermal conductivity improvement in Y_2O_3-containing AlN ceramics caused by elimination of the grain boundary phase was investigated. $Y_3Al_5O_{12}$ (YAG)-containing AlN powder compacts were sufficiently densified by firing at 1800°C for 30 min, but had low thermal conductivity (90–110 Wm^{-1} K^{-1}). Improvement to 245 Wm^{-1} K^{-1} and elimination of the grain boundary phases was brought about by annealing in a carbo-reductive atmosphere at 1850°C for up to 100 h. During annealing, $YAlO_3$, $Y_4Al_2O_9$ and Y_2O_3 appeared as a result of the reduction–nitridation of the Al_2O_3 constituent in the YAG. Subsequently, these yttrium rich phases acted as oxygen getters for the dissolved Al_2O_3 which was originally included in the AlN grains. The Al_2O_3 continuously changed into AlN by reduction–nitridation. The cyclic oxygen removal from the AlN through the grain boundary phase composition change is seen as the primary cause for the thermal conductivity improvement.

1 Introduction

AlN ceramic is an insulator having a high thermal conductivity. Applications of AlN ceramics for high power devices and micro electronics packaging materials as heat dissipation substrates are spreading.[1] The heat carrier in AlN is the phonon. Phonon scattering may occur from impurities or lattice imperfections and decrease thermal conductivity. The most harmful impurity has been found to be oxygen. Dissolved oxygen ions in AlN occupy the nitrogen sites, and they generate Al vacancies to compensate the electric charge balance.[2] Commercially available AlN powders have around 1 wt% of oxygen as a surface layer of oxide or oxy-nitride of aluminum.[3,4] Without any oxygen getter, the oxygen in the surface layer dissolves into AlN during sintering. A full densification of AlN by pressureless sintering has been achieved by rare earth or alkaline earth additions.[5] Y_2O_3 and CaO are popular sintering aids. These sintering aids react with the aluminum oxide surface layer at a sintering temperature of around 1800°C. These reactions generate yttrium aluminate or calcium aluminate liquid phases during sintering. These liquid phases are supposed to promote liquid phase sintering of AlN. The aluminates remain in the ceramics as grain boundary phases after sintering. In this way, these sintering aids act as oxygen getters by fixing aluminum oxide as a grain boundary phase. In the case of Y_2O_3 additions, $Y_3Al_5O_{12}$ (YAG), $YAlO_3$(YAL), $Y_4Al_2O_9$ (YAM), and Y_2O_3 were found as grain boundary phases. The kinds of phases remaining depend on the ratio of the amount of oxygen in the starting AlN powder and the amount of Y_2O_3 addition.

Prolonged firing of up to 96 h in a carbo-reductive atmosphere is known to improve thermal conductivity up to around 260 Wm^{-1} K^{-1}.[6] With this kind of firing, the yttrium aluminate grain boundary phases are eliminated from the AlN ceramic. The rate of grain boundary phase elimination from the ceramic is higher when it is fired in a graphite setter than when fired in an AlN setter. A trace amount of carbon gas from the setter or from a graphite heater promotes the reduction–nitridation of the oxides in the yttrium aluminate phases at the ceramic surface. An oxide concentration gradient between the surface and the interior of the ceramics develops during firing; it relaxes by grain boundary diffusion of the oxide.[6] This kind of thermal conductivity improvement and grain boundary elimination has also been observed in other lanthanoide additions but not in alkaline earth additions.[7,8]

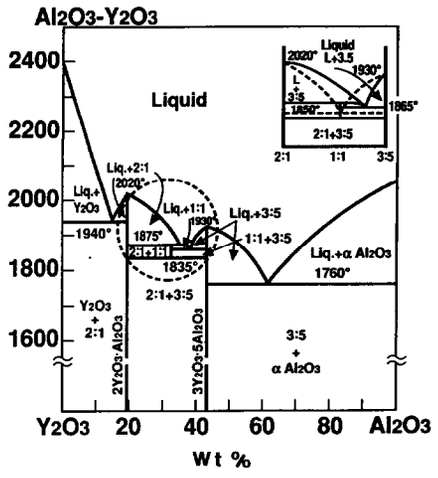

Fig. 1. Phase diagram of Al_2O_3–Y_2O_3 system.

The influence of the grain boundary phase on thermal conductivity has been considered to be slight.[9,10] This is because the grain boundary phases are located at three grain points, thus maintaining sufficient AlN–AlN contacts. AlN grain growth in the ceramics has also been observed in prolonged firing. However, the mean free path of phonons in AlN at room temperature has been estimated to be around 10–30 nm,[11] and the average grain size of AlN in the ceramics is at least around 3 μm even before the prolonged firing. Namely, the mean free path is sufficiently small for the AlN grain size and phonon scattering at the AlN–AlN grain boundaries to have a negligible influence on thermal conductivity.

The aim of this work was to clarify the primary cause of the thermal conductivity improvement in the grain boundary elimination process. The authors have considered that a further oxygen removal from the AlN grains by yttrium aluminates or yttrium oxide grain boundary phases during the grain boundary elimination process might be the primary cause. YAG was used as a sintering aid to test this hypothesis. It was considered from the Y_2O_3–Al_2O_3 phase diagram shown in Fig. 1[12] that YAG should act as a sintering aid if a YAG-containing AlN powder compact is fired at a higher temperature than the liquidus temperature of the YAG. It was also considered that the AlN ceramics densified by YAG addition should have a higher concentration of dissolved oxygen than AlN ceramics densified with Y_2O_3 addition. We can obtain AlN ceramics having a certain amount of dissolved oxygen and having YAG grain boundary phase by this method. Firings of the YAG-containing AlN ceramics in a carbo-reductive atmosphere can be expected to reveal the primary cause of the thermal conductivity improvement in the grain boundary elimination process.

2 Experimental Procedure

2.1 Ceramic preparation

Fine powders of Y_2O_3 (Shinestu Chemical, 4N) an α-Al_2O_3 (Baikowski, 4N) were mixed at a ratio of $3Y_2O_3:5Al_2O_3$. After 0·5 wt% AlF_3 fine powder (Morita Kagaku Kogyo, 3N) was added as a catalyst, the mixed powder was heated at 1500°C for 5 h in an alumina crucible in air. It was then pulverized using an Al_2O_3 mortar. The composition was identified as YAG by XRD. AlN mixed powders, (Tokuyama Soda, F-type, oxygen 0·71 wt%), containing 1, 2, 5, 10, and 20 wt% YAG were prepared. AlN mixed powders containing 1 and 3 wt% Y_2O_3 were also prepared. The mixing was carried out by a wet ball mill using butyl alcohol. After adding a 5 wt% acrylic binder (Tyukyo Oil, SERUNA-SE3000), the mixed powders were fabricated into 30 × 30 × 8 mm compacts by pressing under 50 MPa. Then, they were de-waxed by heating at up to 700°C in N_2 gas.

The mixed powder compacts were sintered at 1800°C for 30 min, in a h-BN setter under an atmospheric pressure of nitrogen using a graphite heater furnace. These ceramics were then annealed at 1850°C for 1, 3, 10, 30, and 100 h respectively, in a graphite setter under an atmospheric pressure of nitrogen in the same graphite heater furnace.

2.2 Characterization

The thermal diffusivity at 23 ± 2°C was measured by the laser-flash method (Shinku Riko, TC-3000). A ruby laser was used for the flash and InSb was used for the infrared detector. Disk samples having 10 mm diameter and around 3·5 mm thickness were coated with a thin gold layer on the surface to prevent the flash penetrating into the ceramics. A carbon black layer was applied over the gold layer to enhance the absorption of the flash energy. Corrections on thermal diffusivity regarding the flash duration time and flash inhomogeneity were carried out according to the Japanese Industrial Standard (JIS-R1611). The thermal conductivity was calculated from the thermal diffusivity, the specific heat measured by differential scanning calorimetry, and the density.

The constituents of the ceramics were identified by powder XRD after being pulverized. The *c*-axis lengths of AlN at room temperature were measured using the internal standard for Si (NIST, 640b). The yttrium contents in the ceramics were measured by the inductively coupled plasma (ICP) method.

Table 1. Comparisons of yttrium concentrations between starting powder compositions and ceramics by ICP.

		Yttrium concentration/wt%	
Additives	*(wt%)*	*Starting composition*	*Analytical result*
YAG	20	8·99	9·03
	10	4·49	3·73
	5	2·25	2·11
	1	0·45	0·44
Y_2O_3	3	2·36	2·26

3 Results

3.1 Sintering by YAG additions

The AlN mixed powder compacts fired at 1800°C–30 min were sufficiently densified without any pores. Table 1 shows the yttrium concentrations in the ceramics measured by ICP and those calculated from the starting compositions. The constituents of the ceramics besides AlN were YAG for YAG added, YAG for 1 wt% Y_2O_3 added, and YAL and YAM for 3 wt% Y_2O_3 added. Figure 2 shows the relationships between the density, the thermal conductivity and the amount of YAG or Y_2O_3 additions. The density increased linearly with the amount of additions in both cases. The thermal conductivity decreased as the amount of YAG addition increased. On the other hand, the thermal conductivity improved as the amount of Y_2O_3 addition increased.

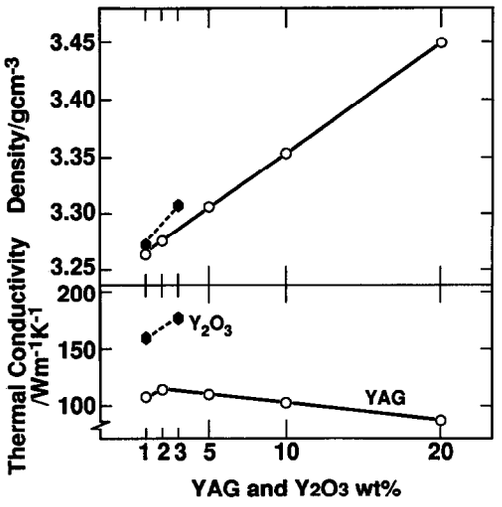

Fig. 2. Relationship between thermal conductivity and density of ceramics and amount of YAG or Y_2O_3 additions.

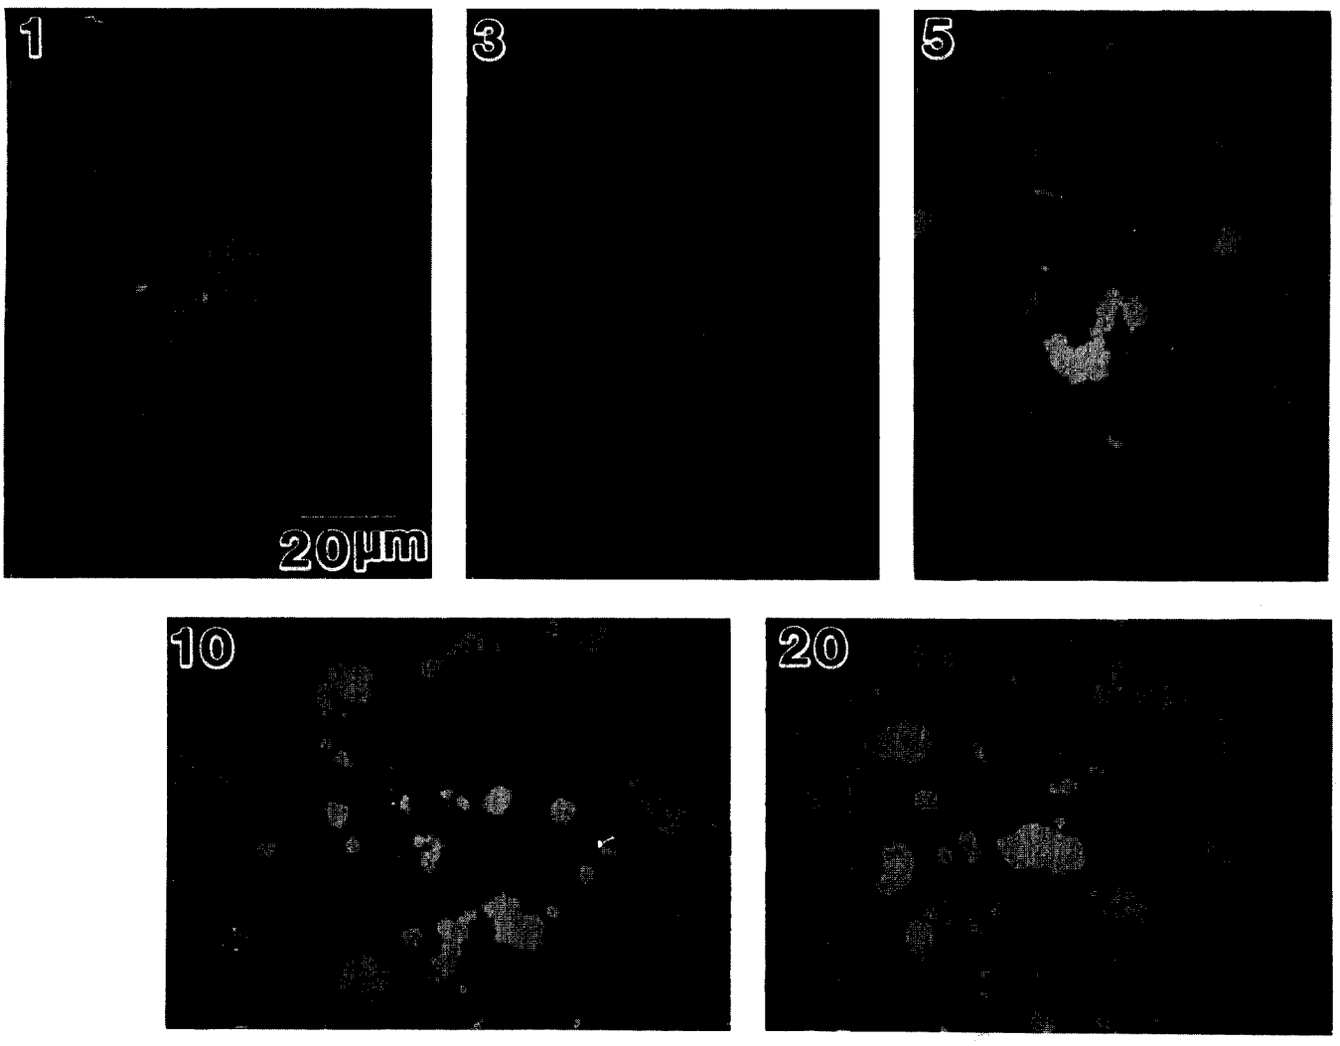

Fig. 3. SEM photographs of polished surfaces of YAG added ceramics.

Considering that the thermal conductivity of the AlN ceramics using Tokuyama Soda F-Type powder which has no additives and have at least 98% theoretical density ranged from 90 to 120 Wm^{-1} K^{-1},[6,13,14] it was considered that the YAG additions contributed to densification but not to thermal conductivity improvement. The thermal conductivity of YAG is around 13 Wm^{-1} K^{-1}.[15] Therefore, the decrease in thermal conductivity by YAG addition is considered to be the result of increase in the amount of poorly conducting phase (YAG) for a given oxygen content in the AlN.[16]

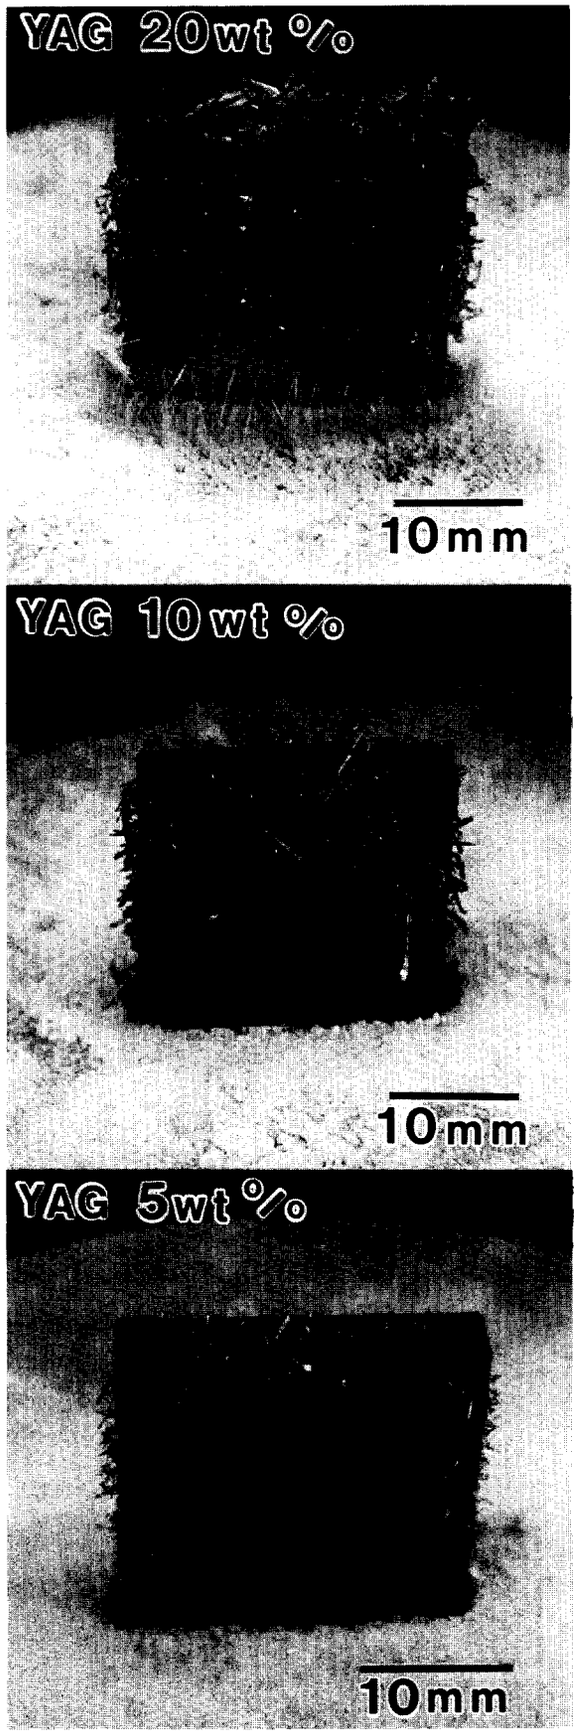

Fig. 4. Annealed appearances of ceramics after 10 h annealings.

The YAG distributions in individual ceramics are shown in Fig. 3. The photographs are SEM images of polished surfaces, and the individual numbers in the photographs represent the amount of YAG addition. The white parts can be attributed to the YAG regions. YAG was distributed as islands ranging from 1 to 20 μm in diameter in the AlN matrix except for the 3 wt% YAG added case. The ratio of $Al_2O_3/(Al_2O_3 + Y_2O_3)$ in the YAG 3 wt% addition case was 0·63, a value very close to the eutectic point composition of Y_2O_3–Al_2O_3. The amount of Al_2O_3 was calculated from YAG and the oxygen content of AlN starting powder.

3.2 Thermal conductivity improvement by annealing in the carbo-reductive atmosphere

The appearances of the as-annealed ceramics are shown in Fig. 4. The photographs show the samples of 5, 10, and 20 wt% YAG, respectively, after 10 h annealing. Needle-like AlN crystals and a black layer on the ceramic surfaces were observed in all cases. The black layer consisted of YN and AlN as determined by XRD. The needle-like AlN crystals grew larger as the YAG content became higher.

Figure 5 shows the relationship between the weight changes of the ceramic constituents besides AlN and the annealing time. The weights were calculated based on the weights of the pre-annealed ceramics, i.e. weight change (%) = (weight before annealed–weight after annealed)/(weight

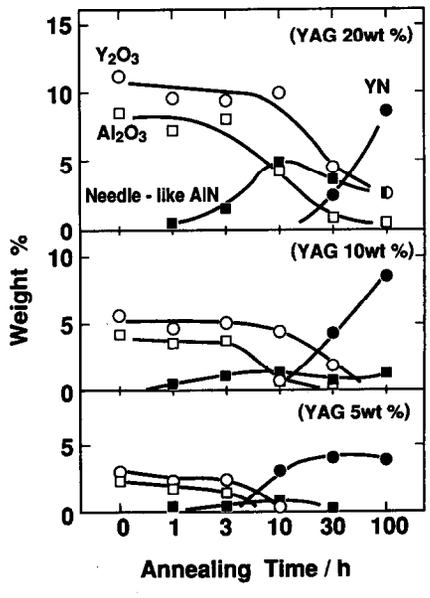

Fig. 5. Weight changes of secondary ceramic constituents during annealings.

before annealed) × 100. The weight changes of the Y_2O_3 and the Al_2O_3 constituents are commensurate with the composition changes of the yttrium aluminate grain boundary phases. The amount of the yttrium aluminate phases were measured from XRD peaks using calibration curves made in advance. Figure 6 shows the yttrium concentrations in the ceramics measured from the ICP and XRD peaks. There was little difference between them. As shown in Fig. 5, the amount of the needle-like AlN crystals increased as the Al_2O_3 constituent in the yttrium aluminate grain boundary phase decreased. The amount of YN also increased as Y_2O_3 constituent in the yttrium aluminate grain boundary phase decreased. From these results, it is considered that the Al_2O_3 constituent in the YAG changed into the needle-like AlN and the Y_2O_3 constituent changed into YN. The amount of the needle-like

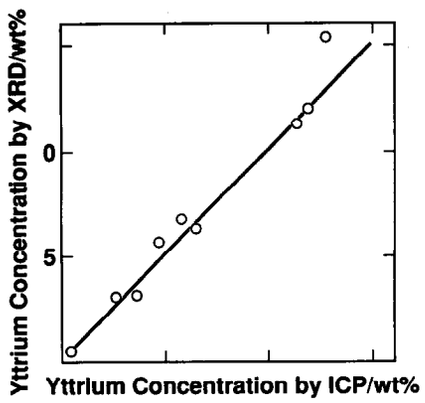

Fig. 6. Comparison of yttrium concentrations in AlN ceramics measured by ICP and XRD.

AlN crystal was maximized at 10 h and decreased over 30 h. It was considered that the enlargement of the surface area by the needle-like AlN crystal generation brought about a substantial sublima-

tion of AlN. The YN generation on the ceramic surfaces was striking for the ceramics having lesser YAG contents. The appearances of the ceramics after 3 h annealings are shown in Fig.7. The needle-like AlN crystals were taken off beforehand in these cases. The YN layer covered the whole ceramic surfaces in the case of 1 and 2 wt% YAG additions. Only the upper side of the ceramics was covered with the YN layer, in the case of 5 wt% YAG addition. There was no YN layer on the ceramic surfaces in the case of 10 and 20 wt% YAG additions. It was observed that parts near to the graphite setter tended to form YN quickly.

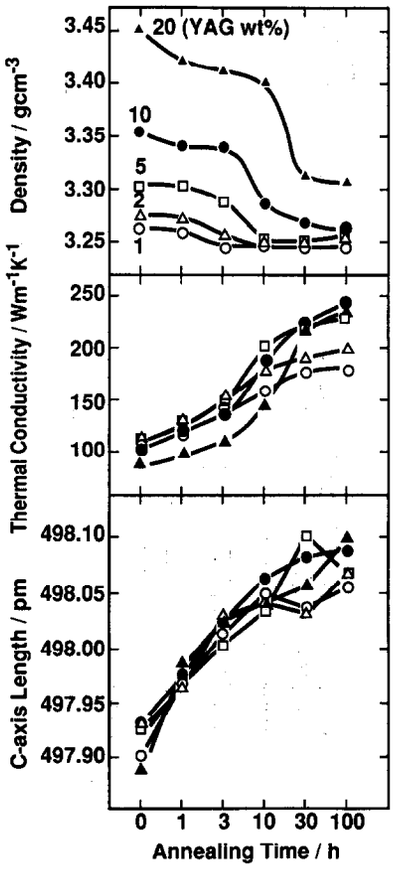

Fig. 9. Relationship between density, thermal conductivity, *c*-axis length and annealing time in different YAG additions.

It was not only the surface layer, but also the interior compositions of the ceramics that were changed during the annealing. It was expected that the grain boundary phase compositions in the vicinity of the ceramic surface were different from the interior.[17] A layer at least 0·5 mm thick was cut from the surface before pulverizing for the XRD measurements. The grain boundary compositions changed during the annealing, as shown in Fig. 8. Blanks indicate the absence of grain boundary phase examined by XRD. YAG turned into phases richer in yttrium as the annealing time was prolonged. Namely, the grain boundary phases changed in the direction of YAG→YAP→YAM→Y_2O_3. Ceramics having a lower YAG content reached the grain boundary phase free state quicker. The grain boundary phases were eliminated completely after 100 h annealing except for YAG 20 wt% addition.

The relationship of the density, the thermal conductivity and the *c*-axis length of AlN to the annealing time is shown in Fig. 9. The numbers in the figure represent the YAG content. The density converged to the theoretical density of AlN (3·26 gcm^{-3}) as the annealing time increased because of the elimination of grain boundary phases with higher densities than AlN. The smaller amount of YAG content made the density decrease earlier. The density decreased in a different manner to the YAG contents. The density decreased noticeably during 10–30 h for 20 wt%, 3–10 h for 10 and 5 wt% and 1–3 h for 2 and 1 wt% YAG. The thermal conductivity improved almost linearly in YAG 1 and 2 wt%. Thermal conductivity improvement

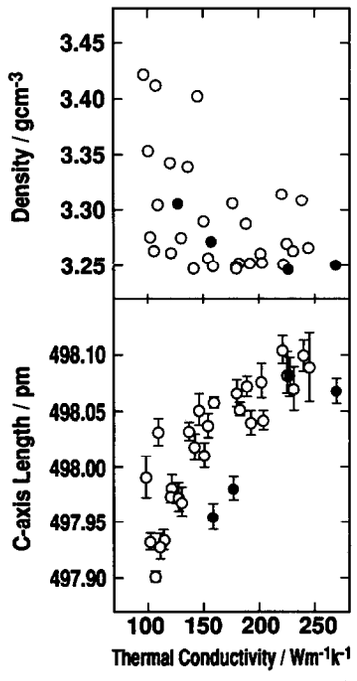

Fig. 10. Relationship between density, *c*-axis length of AlN and thermal conductivity.

occurred during 10–30 h for YAG 20 wt% and 3–10 h for YAG 10 and 5 wt%. These periods coincided with the period of decreasing density. On the other hand the *c*–axis length lengthened gradually during the annealing. Standard deviation of each of the *c*–axis lengths was within 0·10 pm. The *c*–axis lengths ranged from 497·89 to 497·93 pm before annealing and then ranged from 498·07 to 498·10 pm. The *c*–axis length of starting AlN powder was 498·05. The *c*–axis length became shorter at sintering and was then restored by annealing.

In Fig. 10 the relationship between thermal conductivity, density and the *c*–axis length for all samples in this study are shown. The open and the solid circles indicate YAG and Y_2O_3 added, respectively. Even though the density is almost the theoretical of AlN, the thermal conductivity ranged from 90 to 260 $Wm^{-1}\ K^{-1}$. The wide extent of the density range was diminished as the thermal conductivity increased. The *c*–axis length increased as thermal conductivity rose. However, it was found that, a coefficient of correlation to the thermal conductivity was different around the upper and the lower sides of 150 $Wm^{-1}\ K^{-1}$.

Thermal conductivity increased from around 100 to around 250 $Wm^{-1}\ K^{-1}$ by annealing. The *c*–axis length also increased from around 497·3 to 498·8 pm. The highest thermal conductivity within the scale of experiment was 265 $Wm^{-1}\ K^{-1}$. This was obtained by 3 wt% Y_2O_3 addition and 30 h annealing. In the case of YAG additions, the highest was 245 $Wm^{-1}\ K^{-1}$ for 10 wt% YAG after 100 h firing.

4 Discussion

Oxygen occupies nitrogen sites when it dissolves into AlN. The dissolution generates Al vacancies to preserve the electric charge balance. An increase in Al vacancy concentration decreases the *c*–axis.[18] The *c*-axis length of the starting AlN powder was 498·05 ± 0·015 pm. From the results of the *c*–axis length and the thermal conductivity changes, it was considered that the oxygen first dissolved into AlN at 1800°C–30 min sintering and was then gradually removed from the AlN grains by the annealings. Trace amounts of carbon gases are expected in the firing atmosphere. The carbon gas should stimulate the reduction–nitridation of oxides at a high temperature in a nitrogen atmosphere. Therefore, Al_2O_3 and Y_2O_3 in the yttrium aluminate were changed into AlN and YN, respectively, as in the following equations.

$$Al_2O_3 + N_2 + 3C \rightarrow 2AlN + 3CO\uparrow (-40\text{k mol}^{-1}) \quad (1)$$

$$Y_2O_3 + N_2 + 3C \rightarrow 2YN + 3CO\uparrow (80\text{k mol}^{-1}) \quad (2)$$

The YAG located at the ceramic surface reacted with the carbo-reductive atmosphere directly. Subsequently, the Al_2O_3 in the YAG located at the surface changed into AlN according to reaction (1) as a first stage. An oxide concentration gradient between the surface and the interior of the ceramics developed, and was then relaxed by the grain boundary diffusion of the oxide.[6]

The consumption of the Al_2O_3 constituent in the YAG and other yttrium aluminates formed yttrium richer phases, as in the following equations.

$$Y_3Al_5O_{12} + N_2 + 3C \rightarrow 3YAlO_3 + 2AlN + 3CO\uparrow \quad (3)$$

$$4YAlO_3 + N_2 + 3C \rightarrow Y_4Al_2O_9 + 2AlN + 3CO\uparrow \quad (4)$$

$$Y_4Al_2O_9 + N_2 + 3C \rightarrow 2Y_2O_3 + 2AlN + 3CO\uparrow \quad (5)$$

These yttrium rich phases should react with dissolved oxygen in the AlN grain as follows.

$$2Y_2O_3 + Al_2O_3 \rightarrow Y_4Al_2O_9 \quad (6)$$

$$Y_4Al_2O_9 + Al_2O_3 \rightarrow 4YAlO_3 \quad (7)$$

$$3YAlO_3 + Al_2O_3 \rightarrow Y_3Al_5O_{12} \quad (8)$$

The dissolved oxygen in the AlN grains was removed gradually and the thermal conductivity was improved by annealing. The relationship between thermal conductivity and the *c*–axis in Figs 9 and 10 is in agreement with this interpretation, as is the remarkable thermal conductivity improvement at the period of the notable density drop. The reduction–nitridation of the Al_2O_3 at the notable density drop period must be vigorous. The thermal conductivity increase after the grain boundary phase free was believed to be attributed by further oxygen removal with a small amount of yttrium compound less than several hundred ppm.

It is considered that the changes in the yttrium aluminate phase compositions during the annealings were caused by the difference between the reduction–nitridation rate of Al_2O_3 and Y_2O_3 in the YAG. In the case of eqn (2), an excess amount of carbon was in the firing atmosphere, and because the CO gas is exhausted outside the furnace, the reaction should proceed toward the right side. The reactions presented in eqns (3)–(8) should occur simultaneously. It is expected that the migration of Al_2O_3 in the yttrium aluminate should be fast, because the yttrium aluminate was expected to be a liquid at the annealing temperature.[19]

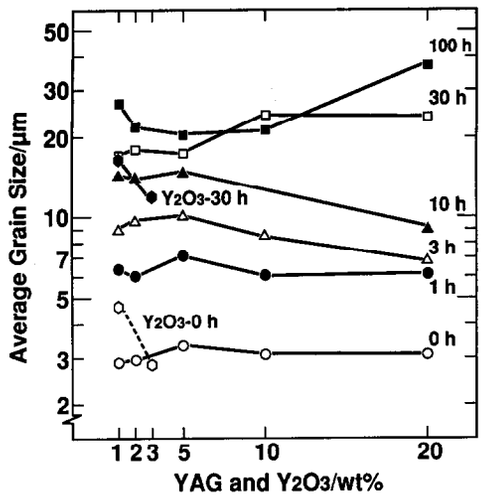

Fig. 11. Relationship between average grain size of AlN and amount of YAG or Y_2O_3 additions during annealings.

Equation (1) describes the AlN powder manufacturing method involving carbo–thermal reaction of Al_2O_3. It is interesting to ask whether oxygen removal without yttrium is possible or not. However, no thermal conductivity improvement was observed even though samples were annealed in the same way.[6,20] Figure 11 shows the grain growth of AlN during the annealings. The grains grew from around 3 μm to a range from 20 to 40 μm after 100 h annealing. One might expect the Al vacancies migrate to the grain boundaries during the grain growth. From the consideration of the mean free path of phonons in AlN, as mentioned earlier, the grain size itself is not directly related to thermal conductivity. Goto *et al.*[20] discussed that thermal conductivity has no relation to grain size ranging from 9 to 21 μm in phase free grain boundary AlN ceramics containing 500 ± 100 ppm oxygen. Watari *et al.*[21] also reported that no relationship was found between thermal conductivity and grain size from characterization of AlN ceramics that has an average grain size of between 4 and 40 μm and has 1·04–0·91 oxygen content.

It should be noted that before annealing, the thermal conductivity of 1 wt% YAG-containing ceramics was slightly lower than that of 3 wt% YAG-containing ceramic. A trace amount of oxygen removal might have occurred even for the 1800°C–30 min firing.

5 Conclusions

The thermal conductivity improvement of 260 Wm^{-1} K^{-1} grade-containing AlN ceramics can be divided into two processes. The first is fixing the original Al_2O_3 impurity in the AlN powder as a grain boundary phase. The second is the grain boundary elimination process by annealing in a carbo-reductive atmosphere. From evaluations on YAG-containing ceramics, we can obtain the conclusions listed below.

(1) The primary cause of thermal conductivity improvement in the grain boundary phase elimination process is considered to originate from a cyclic oxygen removal from the AlN grains by oxygen getters.

(2) The difference in the reduction–nitridation velocity between the Al_2O_3 and the Y_2O_3 constituents in the yttrium aluminate phases generates yttrium rich phase formation during annealing. The Al_2O_3 in the YAG changes into AlN at first. Consequently, yttrium rich phases are formed in the grain boundary phases and then they act as oxygen getters.

(3) Y_2O_3 is better for thermal conductivity than YAG. YAG has been found to be a sintering aid of AlN without any thermal conductivity improvement. The doping should be to form YAP and YAM for thermal conductivity.

On the Thermal Degradation of Lox-M Tyranno® Fibres

Constantin Vahlas[a] & Marc Monthioux

Laboratoire Marcel Mathieu, CNRS-UPPA, Centre Hélioparc, 2, avenue Angot, F-64000 Pau, France

(Received 21 April 1994; revised version received 30 September 1994; accepted 12 December 1994)

Abstract

A calculational thermodynamic investigation of the thermal degradation of the Lox-M Tyranno® fibre in inert gas flow at atmospheric pressure has been performed, based on the minimization of the Gibbs energy of the Si–C–O–Ti chemical system. The results are compared to a recent characterization of the material by Transmission Electron Microscopy (TEM) which illustrates its sequential structures and nanotextures as a function of treatment temperature. The degradation mechanisms and the corresponding temperature ranges of this and of the NL-202 Nicalon® fibre in the same conditions are compared and the observed differences are attributed to diffusion-based phenomena.

Introduction

The introduction of small amounts of titanium (less than 10 wt%) in silicon oxycarbide ceramic fibres, was first proposed in the early eighties.[1] The aim was to retard crystallization and grain growth at elevated temperatures and hence improve strength retention,[2] and also to improve compatibility for aluminum matrix composites on account of less reactivity but better wettability against molten aluminum.[3] These fibres are produced from organometallic precursors containing Si–O–Ti bonds (polytitanocarbosilane) which are typically obtained using polycarbosilane (PCS) and titanium compounds like tetra-alkoxide,[1,4] tetra-butoxide,[2] or tetra-isopropoxide.[5]

Tyranno® is the family name of a series of non-crystalline Si–Ti–C–O–H fibres fabricated by UBE Industries (Ube, Japan). Since the first publication on this material in 1984,[6] different grades have been presented. Their chemical composition varies between the following values (Ref. 7 and UBE Industries data from Tyranno® fibre, 1986 commercial brochure): Si 45–57, C 25–32, Ti 1·5–4·0, O 12–18, B ≤ 0·15, and N ≤ 0·2 wt%, together with a small amount of hydrogen as a residue of the precursor material. Low oxygen grades of this fibre have recently been commercialized. As for other similar ceramic materials, Tyranno® fibres have valuable mechanical properties up to temperature limits dependent on the operating conditions.

This paper presents a thermodynamic simulation of the behavior of the Lox-M grade of the Tyranno® fibre, under high temperature treatment at atmospheric pressure and inert gas environment. The principle and the different types of calculations as a function of the experimental situation to be simulated are discussed, together with the critical selection of the thermodynamic data for the species considered. The results of calculations are presented by means of yield diagrams, indicating the number of moles obtained at equilibrium for the condensed and the gaseous species as a function of temperature. The theoretical work is associated to a Transmission Electron Microscopy (TEM) investigation which has been presented in part in,[8] with the aim to determine the crystalline structure and nanotexture of the material in the as-received state as well as after thermogravimetric heat treatments at different temperatures, in non-oxidizing environments. This combined approach is expected to allow the stability limit of the fibre, in the investigated conditions, to be determined and to be attributed to corresponding nanotextural changes and chemical reaction mechanisms. The results are compared to the thermal behavior of the NL-202 Nicalon® fibre (Nippon Carbon), which is aimed at similar applications but contains no titanium.

Thermodynamics

The calculations are based on the minimization of the total Gibbs energy (G) of the chemical system generated from combinations of the elements

[a]Permanent address: Laboratoire de Matériaux, URA 445, ENS Chimie, 118 route de Narbonne, F-31077 Toulouse, France.

Si–C–O–Ti–Ar and they were performed by using the GEMINI2 software.[b] Twenty four condensed stoichiometric compounds and three solution phases (liquid and bcc Ti–Si and fcc Ti–C) were involved in the calculations together with twenty gaseous species.

The gas phase was assumed to be ideal. The equation adopted for the free energy of formation, as a function of temperature, T, for each stoichiometric species is:

$$\Delta G^{\circ}(T) = a_1 + a_2T + a_3T\ln T + a_4T^2 + a_5T^3 + a_6T^{-1} + a_7T^4 + a_8T^5 + a_9T^7 + a_{10}T^{-9} + a_{11}\ln T + a_{12}T^{-2} + a_{13}T^{-3} \quad (1)$$

Data were mainly drawn from the Scientific Group Thermodata Europe (SGTE) data bank[9] and from Barin's compilation.[10] Data on Si_xC_y species were drawn from Gurvich *et al.*[11]

The excess free energy of the solid solutions, G^{ex}, was described by a generalized multi-sublattice model as developed by Sundman and Agren,[12] including in particular the classical substitution and the two-sublattice models, applied to the two Ti–Si phases and to the Ti–C phase respectively. For the one sublattice (substitution) model, G^{ex} is written:

$$G^{ex} = x_{Ti}x_{Si}L_{Ti,Si}(x,T) \quad (2)$$

where x_i is the atomic fraction of the component i and $L_{Ti,Si}(x,T)$ is the binary interaction term:

$$L_{Ti,Si}(x,T) = \sum_{\nu}(x_{Ti} - x_{Si})^{\nu}L^{(\nu)}_{Ti,Si}(T) \quad (3)$$

$L^{(\nu)}_{Ti,Si}(T)$ being a binary interaction parameter of order v between Ti and Si, depending on temperature according to the relation (1). Data for these solution phases comes from Vahlas *et al.*[13] In the two sublattice model, applied to the Ti–C phase, the first and the second sublattices are considered to be filled by the carbon atoms or vacancies and by the titanium atoms respectively. In that case, G^{ex} is written:

$$G^{ex} = y_Cy_{vac}L_{C,vac:Ti}(y,T) \quad (4)$$

where y_c, y_{vac} are the atomic fractions of C and of vacancies on their sublattice ($y_c + y_{vac} = 1$) and $L_{C,vac:Ti}$ is the binary interaction parameter between carbon and vacancies within the corresponding sublattice:

$$L_{C,vac:Ti}(y,T) = \sum_{\nu=0}^{\nu}(y_C - y_{vac})^{\nu}L^{(\nu)}_{C,vac:Ti}(T) \quad (5)$$

Although Vincent *et al.*,[14] propose an eight term function for $L_{C,vac:Ti}$, (with $\nu = 4$ and $L^{(\nu)}_{C,vac:Ti} = a +$

[b]Gibbs Energy MINIminimizer (GEMINI2), available from THERMODATA, BP66, F-38402 Saint Martin d'Hères, France.

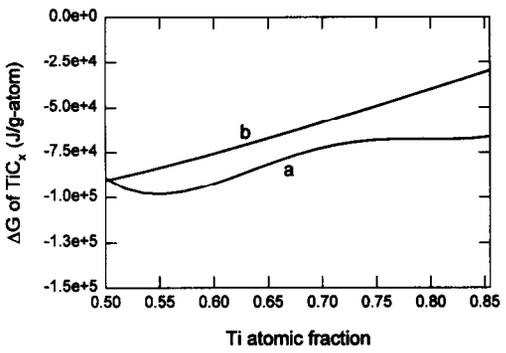

Fig. 1. Free energy of the Ti–C solid solution as a function of Ti atomic fraction for T = 800 K (527°C). (a) Vincent *et al.*[14] model; (b) present model.

bT), in these calculations we used a simpler and more realistic description where $L_{C,vac:\ Ti} = -6000$ J/g-atom. This eliminates demixing artifacts as shown for example in Fig. 1, where the free energy of TiC_x is drawn at 800 K (527°C) as a function of the Ti atomic fraction, using the models adopted in[14] (a), and in this work (b). However, a complete re-calculation of the Ti–C system with regard to available metallurgical and thermodynamic experimental data, as attempted in,[14] remains to be done.

There is no thermodynamic data available for the amorphous SiC_xO_y solid solution although there is strong evidence in the literature for the existence of this phase.[15–20] Consequently, although this phase is possibly present in the as-received material, by analogy with the NL-202 Nicalon® fibre as was shown among others in Ref. 20 it was replaced in calculations by an equivalent mixture of SiC+SiO_2+C. This assumption, the validity of which we have discussed in recent work,[21] does not allow the specific evolution of the fibre during the transition period of degradation to be simulated. However, it is expected to have little influence on the calculated degradation temperature and on the fibre and gas phase composition above it. Indeed, as is evidenced by the elemental analysis and the TEM investigation, there is no SiC_xO_y solid solution left at the end of the degradation process of the NL-202 Nicalon® fibre. By analogy with the above, no $SiTi_xC_yO_z$ solid solution was considered in the calculations.

The models for the ternary Ti_3SiC_2 and $Ti_5Si_3C_x$ compounds come from Racault *et al.*[22] Because of lack of data on the $Ti_5Si_3C_x$ solution phase, the authors considered it as a $Ti_{0.6}Si_{0.34}C_{0.05}$ stoichiometric compound.

Each phase of each chemical element considered (Si, C, O, Ti) was incorporated in the calculations as a G–H_{ser} function of temperature, equivalent to the expression (2). G–H_{ser} is the Gibbs energy relative to the enthalpy of the 'Standard Element Reference', i.e. the reference phase of the element at

298 K (20°C). The data adopted for this function come from Dinsdale's compilation.[23]

By analogy with the behavior, in the same conditions, of the NL-202 Nicalon® fibre (as experimentally illustrated in Ref. 20 and simulated in Ref. 21), the de-hydrogenation process is expected to occur in relatively early stages of the thermal treatment yielding molecular hydrogen as the main gaseous by-product. Hence, and since titanium hydrides are not very stable compared to other compounds involved in the calculations, hydrogen and hydrogen-containing species were not considered in this study. The species involved in the calculations and the source of the thermodynamic description adopted are listed in Table 1.

Various quantities of inert gas in contact with the fibre were considered in order to differentiate the chemical environments at the skin and in the core of it. This approach helps to illustrate, in the calculations, the available volume around the fibre and within the pores which may exist within the fibre as was indicated in Ref. 21. Hence, calculations were made with 1 g-atom (skin) and 10^{-4} g-atom of Ar (core) in contact with 1 g-atom of the fibre the initial elemental composition of which was experimentally determined as: Si 52·85 (33·23), C 31·64 (46·42), O 13·07 (14·37), Ti 1·85 (0·68) and H <0·30 (<5·28) wt (at)%.

In Fig. 2 the calculated results are presented for the skin environment (1 g-atom Ar/g atom) as a function of treatment temperature. The evolution of the condensed products is illustrated in Fig. 2(a). In these calculations the fibre is represented by a mixture of SiC, C and SiO_2 which remains stable up to 1500 K (1227°C). Above this temperature there is a slight decrease of the oxygen and of the free carbon content of the material. At 1600 K (1327°C) the free carbon vanishes while SiC increases significantly. At this temperature, the oxygen content reaches a plateau an order of magnitude below its initial concentration and at 1750 K (1477°C) it also vanishes. The above behavior is related to the evolution in the same operating conditions of the gaseous by-products of the heat treatment, presented in Fig. 2(b). From this figure it appears that silicon and especially carbon monoxides, SiO and CO, are the main gaseous species. Their quantities continuously increase with temperature before reaching a plateau at 1600 K (1327°C) for CO and at 1750 K (1477°C) for SiO, corresponding to the exhaustion of the free carbon and of the oxygen reserves of the fibre respectively. At and beyond 1750 K (1477°C) the quantity of CO is ten times higher than that of SiO. Other species, especially CO_2 and Si are present at high temperatures but in very low quantities. They also qualitatively follow the evolution of the free carbon and of the oxygen within the fibre. Beyond 1800 K (1527°C) their increase is delayed or stopped due to the appearance of small quantities of gaseous Si_xC_y species.

From Fig. 2(a) it appears that titanium is found in the fibre exclusively in its carbide form. An expansion on the y axis of the above diagram is presented in Fig. 3, aiming to evidence any minor evolution of TiC_x with temperature. The composition of the TiC_x phase in terms of carbon content for one g-atom of titanium is also presented in this figure. The quantity of TiC_x remains unchanged up to 1650 K (1377°C). Beyond this temperature TiC_x definitively decreases, but not in significant amounts: At 2000 K the number of moles of TiC_x, is $7{\cdot}1997 \times 10^{-3}$ to be compared to $7{\cdot}2 \times 10^{-3}$ in the as-received material. The carbon content of the TiC_x phase follows an equivalent evolution: while up to approximately 1600 K (1327°C) titanium carbide remains stoichiometric, beyond this temperature it continuously loses carbon but again in very small amounts: At 2000 K (1727°C) TiC_x is 10^{-4} g-atom understoichiometric in carbon. No gaseous Ti-containing compounds are shown in Fig. 2(b). As a matter of fact TiO and Ti

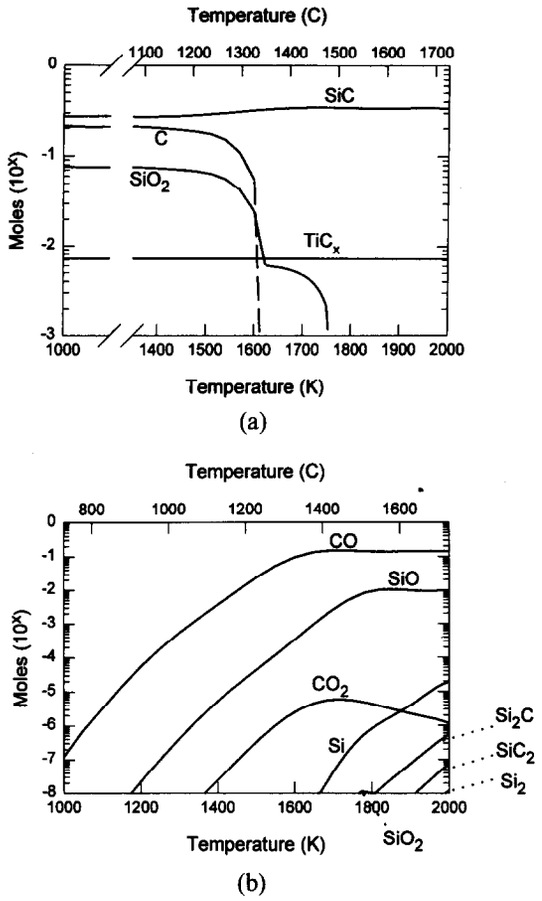

Fig. 2. Thermal evolution of one g-atom of Lox-M. Condensed (a) and gaseous (b) species in contact with one g-atom Ar as a function of treatment temperature.

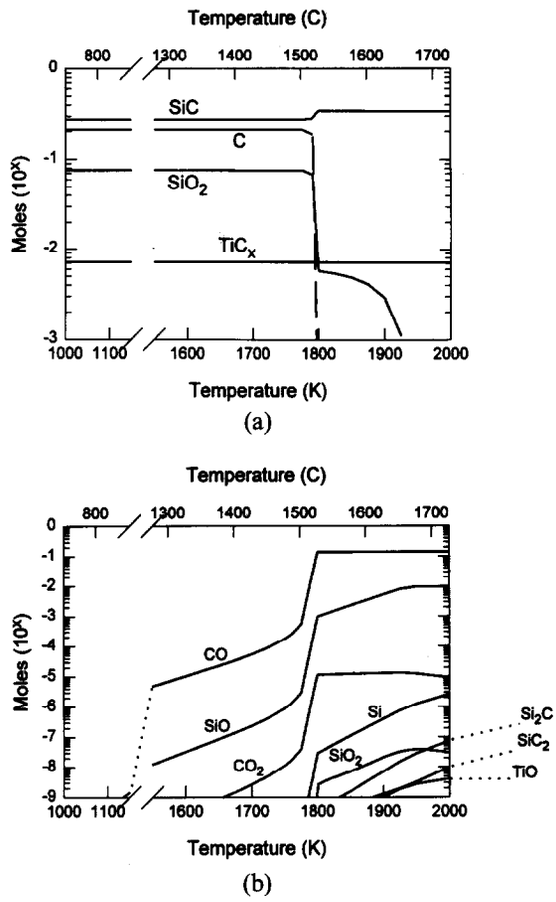

Fig. 4. Thermal evolution of one g-atom of Lox-M. Condensed (a) and gaseous (b) species in contact with 10^{-4} g-atom Ar as a function of treatment temperature.

appear above 1900 K (1627°C) in extremely low quantities ($<2 \times 10^{-9}$ g-atom) illustrating the stability of carbon and silicon oxides towards titanium compounds.

Figure 4 presents the evolution with temperature of the fibre in contact with 10^{-4} g-atom Ar (core), for the condensed species (Fig. 4(a)), and for the gaseous (Fig. 4(b)) species. The general shape of the two figures is equivalent to Figs 2(a) and 2(b) respectively with two main differences: The curves are now flatter with more sharp changes, and the degradation temperature is shifted 200 degrees higher, i.e. 1800 K (1527°C). This is also illustrated in Fig. 4(b) where the rapid increase of CO, SiO, CO_2 and Si also occurs to a higher temperature, i.e. 1800 K (1527°C).

Once again it appears that titanium is entirely linked in its carbide form (Fig 4(a)) and that it has a negligible reactivity in the gas phase (Fig. 4(b)). The quantity of TiC_x remains unchanged up to 1750 K (1477°C) and decreases above it as shown in Fig. 5. The same differences hold for the carbon content where now TiC_x becomes understoichiometric at 1650 K (1377°C). However it has to be pointed out that, as in the conditions of Fig. 3, these variations are extremely weak and, even if they show evidence of the upper stability limit of the material in the corresponding conditions, they are not representative of a significant change in the composition and, consequently in the physical properties of the fibre.

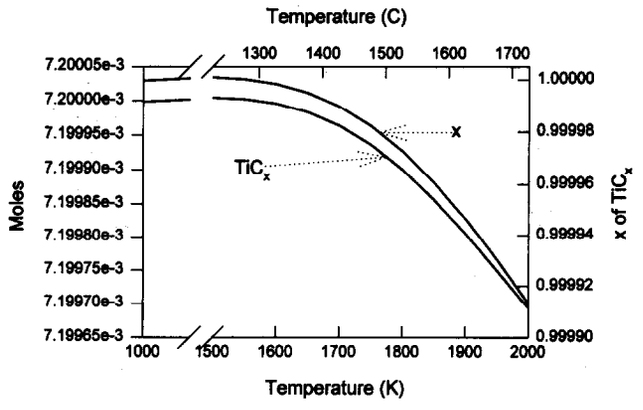

Fig. 3. Thermal evolution of one g-atom of Lox-M. Number of moles of TiC_x (left) and carbon content of TiC_x (right) in contact with one g-atom Ar as a function of treatment temperature.

Experimental

The operating procedure and the main results of the thermogravimetric analysis (TGA) and of the SEM and the TEM characterization are reported

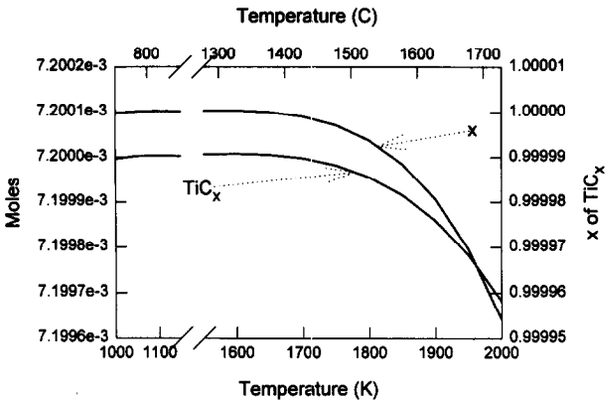

Fig. 5. Thermal evolution of one g-atom of Lox-M. Number of moles of TiC_x (left) and carbon content of TiC_x (right) in contact with 10^{-4} g-atom Ar as a function of treatment temperature.

in.[8] The operating conditions were chosen to be identical to the heat treatment conditions of the Nicalon® fibre, reported in Ref. 20.

In Fig. 6 the TG recordings for treatments at 1623, 1673 and 1773 K (1350, 1400 and 1500°C) are presented. In contrast to the 1573 K (1300°C) sample where the weight loss of the fibre had not reached a plateau at the end of the heat treatment, it appears that the duration of the treatment at each of the above temperatures was long enough to allow the material to reach a stable composition. This stabilization was produced after an almost equal weight loss for the three temperatures: 20·3, 18·3, and 21·8% respectively, to be compared to the reported weight loss of 25·6% for the NL-202 Nicalon® fibre at 2000 K (1727°C).[20]

The SEM characterization indicated that the shape and the dimensions of the 10 μm diameter fibres remain stable after the 1773 K (1500°C) treatment except for a slight increase of the surface roughness compared to the as-received material. However, TEM characterization revealed marked changes between these temperatures regarding the structure and the nanotexture of the fibre, as has been pointed out in Ref. 8 and will be next discussed.

The TEM investigation, showed that the as-received fibre has a nanometric porosity, and that it contains β-SiC nanocrystals and small free carbon units, both having a diameter less than 2 nm. Small stacks of 2–3 fringes of free carbon are shown in the C_{002} Lattice Fringe (LF) image of Fig. 7 (arrows). They are made of basic structural units, (BSUs), i.e. the elemental entities common to many other carbonaceous materials, the diameter of which was determined to be less than 1 nm.[24] Silica was not detected at the extreme surface or within the fibre.

It was not possible to characterize the inner part of samples treated at 1623 K (1350°C) since, because of the high brittleness, ultramicrotomy did not yield any entire section. The 'in-place' particles, i.e. attached to the embedding resin, correspond to the external part of the filament. However, the

investigation of the 'out-of-place' particles provides a statistical idea of the features of the whole fibre. No significant differences were found between random particles and 'in-place' particles from the outer part of the fibre suggesting that the fibre is homogeneous. The major evolution between this and the as-received samples is that carbon is now better organized since BSUs have been associated both face-to-face and edge-to-edge forming stacks of 3–6 distorted layers. This association yields distorted fringes having an average length of ~3 nm. As was shown from 1673 K (1400°C) and 1773 K (1500°C) heat treated fibres, this organization takes place around each SiC crystal, in agreement with other SiC-based material.[20,25]

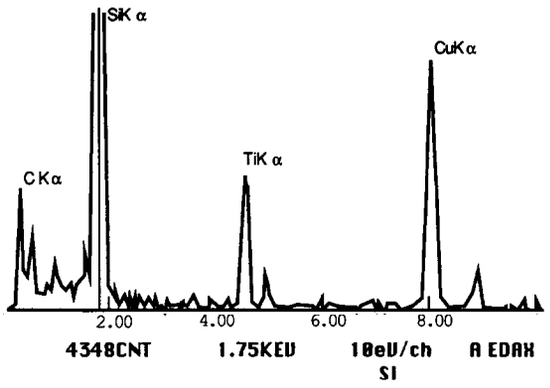

Fig. 9. EDS elemental analysis pattern for 1773 K treated Lox-M.

A C_{002} and SiC_{111} LF image of a 1673 K (1400°C) treated fibre is presented in Fig. 8.[8] At this temperature, SiC crystals have grown markedly up to 60 nm (to be compared to a maximum of 8 nm for the NL-202 fibre in identical conditions),[20] suggesting that the major degradation step has already occurred. Crystal growth is very fast as corresponding SAD patterns show polytypism marks, and free carbon seems degraded, although its aromatic layers remain oriented parallel to the crystalline faces. At 1773 K (1500°C) there is no marked evolution of the fibre except that SiC crystals become larger; their thickness is as high as 90 nm, again with a wide distribution in size.

It was not possible to evidence the titanium carbide either in Electron Diffraction pattern reflections, or in Dark Field (DF) TEM mode. While in the first case TiC reflections are too close to SiC for an unambiguous observation, in the second case TiC grains are not evidenced possibly because of their very small size or because titanium participates (at least in the original fibre) in the intergranular solid solution. The EDS elemental analysis, whose typical pattern is shown in Fig. 9 for a 1773 K (1500°C) treated fibre, did not reveal any significant difference in composition between the skin and the core of the fibre either at 1673 K (1400°C) or at 1773 K (1500°C).

Discussion

The evolution in composition of the condensed species as a function of temperature, which is evidenced in Figs 2(a) and 4(a) illustrates the capacity of the fibre to support, without major alteration, the heat treatments in the selected experimental conditions. This is valid up to a temperature which is a function of the argon dilution and which is detected in the above diagrams by an abrupt change in composition, especially by the

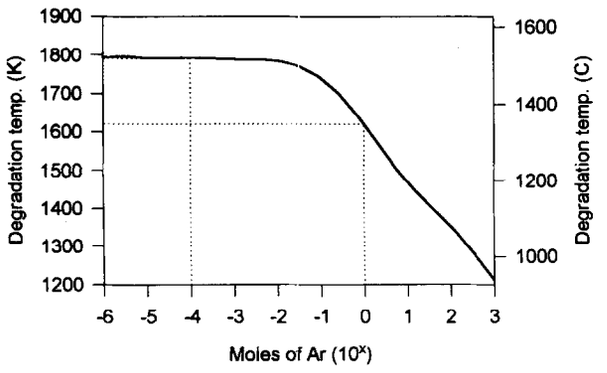

Fig. 10. Thermal evolution of Lox-M. Degradation temperature as a function of the number of moles of Ar available. Dotted lines correspond to the investigated conditions.

elimination of the free carbon, due to an endogenous oxidation mechanism leading to formation of SiC and CO. Following the results of the thermodynamic investigation, the Lox-M Tyranno® fibre is expected to change drastically in composition, morphology and hence physical properties in the range between 1600 and 1800 K (1327 and 1527°C).

The validity of these transition temperatures is studied in Fig. 10, where the degradation temperature is drawn as a function of the number of moles of Ar available in the calculations. As for the NL-202 Nicalon® fibre,[21] the degradation temperature does not depend on the dilution of the reactants up to approximately 10^{-2} g-atom Ar/g-atom. For higher dilution it decreases linearly with the logarithm of Ar quantity. From this figure it appears that, for a material containing no pores or cracks, only calculations made with 10^{-4} g-atom Ar/g-atom have a more general value and can represent the situation in the core, while calculations made with 1 g-atom Ar/g-atom qualitatively indicate that operating conditions are more severe at the external part, leading to lower values of the degradation temperature. It is worth noting that a similar behavior was evidenced by Luthra and Hee Dong[26] in carbon-fibre/oxide-matrix composites: The authors evaluated the chemical compatibility of different oxides with carbon at $T \approx 1873$ K (1600°C) and concluded that these materials are stable if they contain neither cracks nor pores allowing CO to escape.

The fact that the nanotextures of the as-received and of the 1623 K (1350°C) treated fibre are similar while at 1673 K (1400°C) degradation has already occurred, reveals the temperature interval within which degradation is initiated. In the same operating conditions NL-202 was found to be similar to the as-received material at 1523 K (1250°C), to present a skin-and-core effect at 1673 K (1400°C) and to be degraded at 1773 K (1500C).[20] No skin-and-core effect was observed during the degradation of the Lox-M. However, in view of the similarity between the two fibres concerning their precursors, their morphology and their properties, it is presumed that both present a diffusion-limited degradation mechanism. Additionally in the various ceramic materials such as Nicalon® 200 and other experimental Si–C–O and Si–C–N–O fibres investigated in the laboratory, brittleness during ultramicrotomy preparation is systematically important in the as received state and also remains elevated after low temperature treatments. This behaviour yields operating difficulties and often fragmentation. However, as soon as high temperature treatments have degraded the continuum, i.e. the cement between the SiC crystals, the diamond edge progresses among the nanometric crystals and fibres are cut considerably easier. For the investigated family of ceramic materials, this behaviour during ultramicrotomy may thus be considered as an indication of the existence of the interganular solid solution and also of the temperature domain where this solution is degraded. Lox-M behaves in a similar way: it is very brittle below 1623 K (1350°C) and much less above 1673 K (1400°C). Consequently, the degradation of the continuum and the corresponding skin-and-core effect in this fibre must occur between these two temperatures.

The thermodynamic simulation evidenced no difference between the chemical systems corresponding to Tyranno® and Nicalon® fibres. Indeed, Figs 2, 4 and 10 are identical to the corresponding figures for NL-202.[21] It can thus be deduced that degradation of the two fibres is initiated in the same temperature range. In that case, the relatively narrow temperature gap where the presumed skin-and-core effect takes place for Lox-M, compared with NL-202 (degradation of the Nicalon is initiated below 1673 K and is accomplished at 1773 K approximately), indicates that the progression of the skin-reactions to the core is faster in Tyranno®. A more rapid diffusion of the gaseous by-products may be responsible for this behavior due to a higher or more open porosity as is suggested by the lower density of Lox-M relative to NL-202: The two densities are 2·37 and 2·55 g cm^{-3} respectively and only 6% of this difference is due to the difference in composition of the fibres.

Titanium does not seem to modify the chemical behavior of Lox-M relatively to NL-202 except that it combines with an equivalent quantity of carbon. The possible existence of stoichiometric titanium carbide in the original fibre or its formation during the heat treatment is in agreement with the Si–Ti–C phase diagram, whose 1473 K

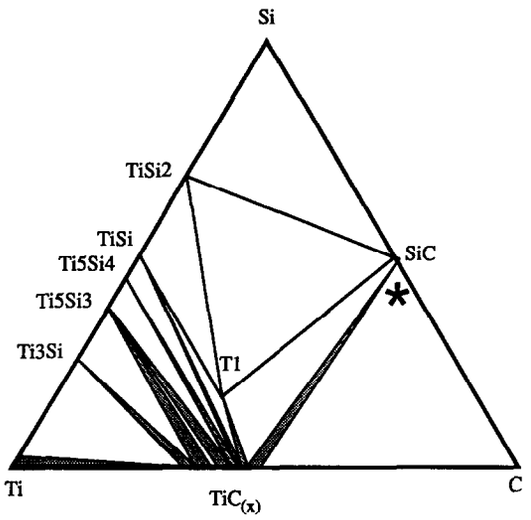

Fig. 11. Si–Ti–C phase diagram. Isothermal section at 1473 K, as calculated in Ref. 22. The initial composition of Lox-M is shown (★).

(1200°C) isothermal section is presented in Fig. 11.[22] As illustrated in this figure, the global composition point of the fibre is located at the interior of the SiC–TiC–C part of this diagram. Since this part of the isothermal section remains stable within a large temperature domain, it can be reasonably assumed that if titanium is not in solution in the original fibre, it will remain present in the form of stoichiometric TiC. The calculations showed that moderate quantities of oxygen are more likely to react with carbon and silicon rather than with titanium or titanium carbide. It is thus possible that in the investigated conditions, only a small shift of the location of the total composition of the fibre within the corresponding quaternary phase diagram takes place, relative to the Si–C–Ti ternary section. However, because of the departure of carbon from the fibre in the form of carbon monoxide but also because of the poor description of the TiC_x phase leading to uncertainties concerning the shape of the phase diagram, a shift of the global composition above the degradation temperature at the exterior of the SiC–TiC–C triangle towards silicon carbide, i.e. a very low other-than-SiC compounds' composition, cannot be excluded.

The difference between the experimentally determined upper limit of 1673 K (1400°C), and the calculated value of 1800 K (1527°C) for the degradation of the fibre, can be attributed to the fact that the concept of a material composed of silicon carbide, carbon and silica, where the core is dissociated from the skin, is not enough powerful to describe and predict more precisely its thermal behavior. However, as was discussed in Ref. 21, the comparison between the thermochemical properties of silicon carbide fibers and of silicon oxycarbide black glass with $SiC+SiO_2+C$ mixed powder, as was investigated by multiple Knudsen cell mass spectrometry in Refs 27 and 28 respectively, showed that the measured pressures of SiO and CO gaseous species above the three materials were comparable. Therefore, the SiC_xO_y solid solution can be replaced as a mixture of $SiC+SiO_2+C$ in the simulation, if the obtained results are considered exclusively in terms of the degradation temperature and of the gas phase composition above the fibre. The thermodynamic simulation is in this case helpful in order to illustrate, understand and predict the major reaction mechanisms responsible for the observed degradation. However, it has to be mentioned that other parameters may also be responsible for the observed difference between experimental results and thermodynamic predictions in similar operating conditions. One is related to the quality of the thermodynamic data adopted to describe the compounds participating in the chemical process. Although important research has already been performed on the chemical behavior of the Si–C–O[28] and of the Si–Ti–C[29] systems, more is needed to be done to improve their thermodynamic description. Other phenomena which have not been taken into account in the present work and which may also participate in the way the material is transformed during heat treatments are solid state diffusion and surface/interface kinetics. The quantification and modelization of their influence is a complex task, especially in the presence of poorly organized constituents.

Conclusions

The evolution of the Lox-M Tyranno® fibre as a function of treatment temperature in inert gas atmosphere and atmospheric pressure was thermodynamically simulated by performing thermochemical calculations in the Si–C–O–Ti chemical system, and was compared to recently performed structural and nanotextural TEM investigations.

The environments in the core and at the skin of the fibre were differentiated in the calculations by considering different inert gas dilution of the reactants. The stability limit of the material was thus calculated to be at 1800 K (1527°C) or lower. At this temperature the available carbon is exhausted and the oxygen content is highly reduced. The main reaction products are silicon carbide and carbon and silicon monoxides. The stable configuration for titanium is expected to be stoichiometric titanium carbide which exhibits a pronounced stability in terms of quantity and stoichiometry

within a large temperature domain, in agreement with the Si–Ti–C phase diagram.

From the comparison of the results of the thermodynamic study and the TEM characterization of the Lox-M Tyranno® and of the NL-202 Nicalon® fibres it appears that the chemical behavior of the Si–C–O–Ti and of the Si–C–O systems is identical in the investigated conditions and that similar mechanisms govern the thermal degradation of the materials. However, the degradation process is completed faster in the case of Lox-M, possibly because of a more rapid diffusion of the gaseous reaction by-products through the core of the fibre.

Thermal Shock Resistance of Nextel/Silica–Zirconia Ceramic-Matrix Composites Manufactured by Freeze-Gelation

A. Twitty,[b] R. S Russell-Floyd,[c] R. G. Cooke & B. Harris[a]

(Received 18 October 1993; received in revised form 24 November 1994; accepted 12 December 1994)

Abstract

Ceramic-matrix composites consisting of a silica–zirconia matrix reinforced by 25% by volume continuous Nextel alumino–silicate fibres have been manufactured by a sol–gel route incorporating freeze-gelation and subjected to thermal shock by water quenching from temperatures up to 800°C. Although it was demonstrated that the Nextel fibres exhibited significant degradation of properties during composite processing, they still had a significant reinforcing effect. The material showed a critical temperature of approximately 550°C, below which it was unaffected by water quenching. Above this level there was a 40 and 50% step reduction in modulus and strength respectively. Acoustic emission monitoring showed a significant difference in materials subject to quenching from beyond the critical temperature. There was a lower initial yet higher final AE event rate for a monotonically increasing flexural load, and a bimodal amplitude distribution. This indicated that the material responds in general terms in the manner corresponding to the well-known Hasselmann model of thermal shock of monolithic ceramics, but the presence of fibres appears to improve the thermal shock resistance by raising the predicted critical temperature somewhat.

1 Introduction

The sol–gel process offers the possibility of manufacturing a wide range of ceramic-matrix composites (CMCs) in near-net shape and size by the use of techniques familiar in the processing of polymer-based composites and without the need for such costly manufacturing procedures as are commonly required to process conventional ceramics or CMCs.[1,2] The properties of such composites are more modest than those normally required for aerospace and other high-performance applications, but there are many uses for ceramics in general engineering for which the properties available in sol–gel CMCs are adequate, provided some measure of toughness and resistance to thermal shock can be incorporated. One of the difficulties with any CMC system is that, during either manufacture or subsequent service at elevated temperature, interfacial interactions can lead to deterioration of the fibres so that the full potential strength of the system cannot be realised in practice. An advantage of the sol–gel route in this respect is that it permits lower final firing temperatures and, therefore, the possibility of restraining such adverse reactions during processing. One of the systems that we have been studying as part of a wider program on CMCs manufactured by the sol–gel route is a composite consisting of a silica-based matrix reinforced with Nextel mullite fibres. In this paper we describe a series of experiments to investigate the resistance of this material to water quenching from temperatures up to 800°C.

2 Material

The reinforcing fibre was Nextel 440, manufactured by the 3M Company, a mullite material consisting of 70 wt% alumina, 28 wt% silica and 2 wt% B_2O_3. The manufacturer gives values of 186 GPa for Young's modulus and 2·1 GPa for the tensile strength of this fibre. The matrix ceramic is a silica–zirconia compound prepared from a mixture of Syton HT50, an aqueous sol containing 50 wt% of colloidal SiO_2 and 50 wt% of water, manu-

[c]Deceased.

factured by Monsanto, and Zircosil, consisting of 61 wt% of ZrO_2, 36 wt% of SiO_2, and small quantities of Al_2O_3, HfO_2, TiO_2, and Fe_2O_3, manufactured by Cookson Minerals.

The matrix components were mixed with a high-shear disperser and the resulting sol was used in a filament-winding process to produce flat plates of unidirectional impregnated sheet. These sheets were then wet-pressed between stainless steel platens to consolidate the windings and to produce plates approximately 100 × 100 mm × 5 mm. The pressed plates were then freeze-gelled by cooling rapidly in liquid nitrogen, following which they were warmed slowly to ambient temperature to produce a porous solid that could be handled. After drying to remove the excess residual water from the sol, the plates were infiltrated three times with Syton D30 silica sol, drying between infiltrations, and then sintered at 950°C for one hour. The sintered plates were then twice re-infiltrated, following which they were cut into 10 mm wide test pieces with a water-cooled diamond saw to provide unidirectionally reinforced composite samples. The cut samples were then re-infiltrated a further three times and finally sintered again at 500°C for 90 min. Three separate batches of the composite were prepared by this procedure with identical processing conditions. Image analysis of composite cross-sections gave average values of the fibre volume fraction, V_f, of 0·26, 0·23 and 0·28, respectively for the batches identified as A, B and C. The fibre distribution was reasonably uniform the final level of matrix porosity was about 30 vol%.

3 Testing Procedures

Mechanical strength and stiffness were determined by flexural testing in three-point bending with a span-to-depth ratio of 16:1 at an Instron crosshead displacement speed of 1 mm.min^{-1}. An indication of the relative toughnesses of the samples was also obtained from the area under the flexural load–deflexion curve. And in order to establish the inherent (undamaged) stiffness of the material, dynamic stiffness values were obtained by time-of-flight and density measurements. All test results reported in this paper are the averages of at least five individual tests.

Thermal shock experiments were carried out by heating samples to different temperatures in the range 200 to 800°C, soaking for 20 min to establish thermal equilibrium, and then quenching into water at 20°C. After the samples were completely cooled, they were furnace dried at 60°C for 24 h. Five samples quenched from each temperature were then used for the determination of the mechanical properties in the quenched condition, as described above. The samples used for these experiments were all from batches A and B. For comparison purposes, a group of samples from batch C were subjected to the same thermal cycle but were slow-cooled from the upper temperature rather than quenched, and samples from batches B and C were heated rapidly from room temperature to the same maximum temperatures as used for the quenching experiments. These samples were also mechanically tested as described above.

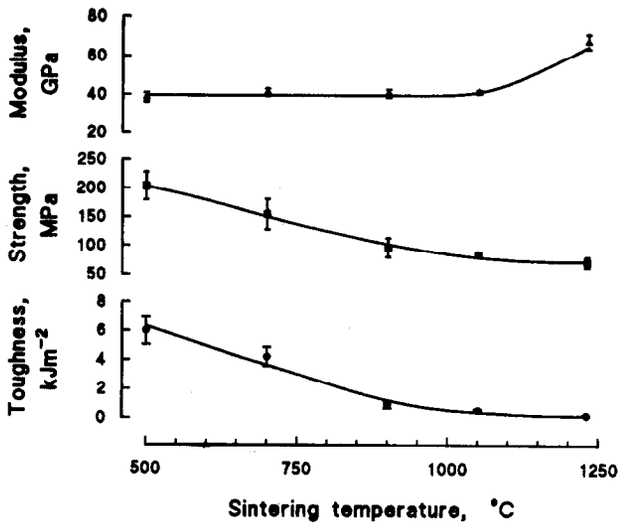

Fig. 1. The effect of raising the sintering temperature on the mechanical properties of freeze-gelled Nextel/silica–zirconia ceramic-matrix composites.

Many of the mechanical tests carried out in this work were accompanied by the monitoring of acoustic emissions. A Marandy MR1004 25-channel amplitude distribution system was used to record emissions received through a PAC U30D-174 PZT transducer and an AECL 2100/pa 60dB preamplifier. The AE data were processed by custom-written software and analysed by means of a conventional spread-sheet program.

The thermal expansion characteristics of the composite over the range 20°C to 650°C were determined in a silica tube dilatometer.

4 Experimental Results

The mechanical properties of the three batches of unidirectional composite after manufacture are given in Table 1.

It can be seen that the strengths and stiffnesses of the three batches of material (which were made by identical procedures, as described earlier) are to all intents and purposes identical, as would be expected. The dynamic stiffness is significantly higher than the flexural modulus measured from

Table 1. Mechanical properties of as-manufactured Nextel/silica–zirconia composite*

the slope of the load–deflexion curve because it effectively assesses the response of an undamaged structure, whereas the mechanical modulus is not a simple elastic property in CMCs, since it inevitably includes some effect of the loss of stiffness due to cracking during loading. It is curious to note, however, that the nominal work of fracture of batch C is almost 50% greater than that of batches A and B. There is little evidence of any kind to explain this difference, the fibre content being only marginally higher, and there being no observable difference in microstructure. The higher fracture work was clearly seen to be the result of a different fracture mode in material of batch C which exhibited a considerable amount of delamination during fracture, whereas the failures of the other two batches were by completely transverse fracture. This difference is also reflected in the higher value of the mechanical flexural modulus. The only possible difference in the processing conditions between batches might be the level of pressure applied during the wet-pressing operation to consolidate the filament-wound material prior to freeze-gelation. This pressure was not controlled, since we had not expected that it would have a significant effect on the properties of the finished composite: this could prove to have been an important processing parameter, however.

On the basis of the manufacturer's value for the fibre stiffness, 186 GPa, the measured composite (dynamic) modulus appears to reflect, almost exactly, a fibre-only contribution (i.e. ¼ of 186 ≈ 46 GPa). In a CMC, this is unlikely, even when the matrix is porous, as in the present case. Earlier work on similar systems[2] suggests that the intrinsic stiffness, E_0, of a dense sol–gel silica matrix may be of the order of 70 GPa, and for a sample with a volume fractional porosity, p, of 0·3 a reasonable value, given by the relationship:

$$E = E_0 \exp(-4p)$$

would be 21 GPa, making an expected composite stiffness of about 65 GPa, some 60% greater than the measured dynamic value. Similarly, a crude estimate of the expected composite strength, based on the manufacturer's figure for the fibre strength (in excess of 2 GPa) and ignoring any matrix contribution, gives a value of the order of 570 MPa, yet the measured strengths in Table 1 imply a fibre strength of the order of only 320 MPa. This enormous loss of strength appears to be a consequence of damage which occurs during processing. Experiments in which tows of the Nextel fibre were passed through the desizing process and then through the guide system through an empty sol bath, for example were found to have lost some 40% of their original bundle strength.[3] Tows of T300 carbon fibre similarly lost about 35% of their original strength during this part of the process. The measured bundle strength of a tow of about 2000 filaments of 11 μm diameter was 198 MPa. Assuming a Weibull modulus of the order of 10, and therefore a bundle strength of the order of 60% of the individual filament strength, a bundle strength of 198 MPa translates to a filament strength of about 330 MPa. Without any more detailed scientific basis for accounting for the difference in gauge lengths in the bundle tests (90 mm) and effective 'gauge length' *in situ* in the composite, this agreement with the measured strength in Table 1 is more than adequate.

As the sintering temperature is raised from 500°C to 950°C the strength declines by about 60%, as shown in Fig. 1, while the modulus (and also the density) increase as consolidation is enhanced. The 950°C sintering temperature was chosen for these experiments to permit the thermal shock experiments to be carried out to a maximum quenching temperature of 800°C. Microstructural evidence, such as that shown in Fig. 2, clearly indicates that significant fibre/matrix interaction does indeed occur during the sintering stage, but it appears that this is not the only

Fig. 2. Electron micrograph showing fibre/matrix interaction in a freeze-gelled Nextel/silica–zirconia ceramic-matrix composite during sintering at 500°C following infiltration.

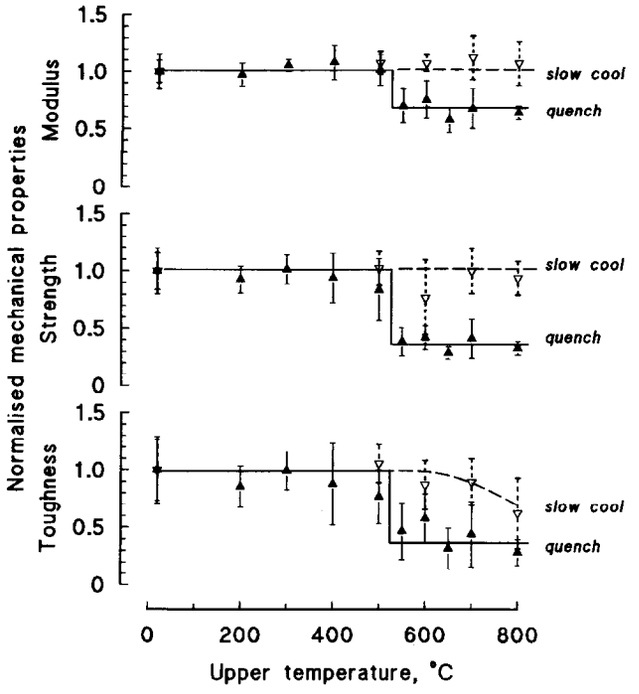

Fig. 3. The effect of slow and rapid cooling on the mechanical properties of freeze-gelled Nextel/silica–zirconia ceramic-matrix composites. The open symbols represent samples of batches A and B (pooled data) water-quenched from the stated soak temperature, while the solid symbols represent samples from batch C slow cooled from the stated temperature. Each point for batches A/B is the mean of ten individual tests, and each point for batch C is the mean of five tests: the error bars are standard deviations.

source of damage. A important secondary advantage of the freeze-gelation process is that the dried but unsintered product has considerable strength as a result of the molecular forces involved in the sol-gel transformation, a situation paralleled to some extent in the 'setting' of the tobermorite gel in cement, and this has important implications for the handling and shaping of pre-sintered products. Thus, we have found that the freeze-gelled material can be tensile tested in the unsintered state after vacuum-drying at a temperature slightly above ambient, followed by further infiltration (but no sintering) to yield a strength of only 155 ± 5 MPa, and this strength falls to 127 ± 7 MPa after sintering at only 500°C. Clearly, then, the Nextel fibre loses most of its reinforcing potential as a result of either corrosion in the sol bath, or abrasion at some stage during the consolidation process. It appears, therefore, that this fibre cannot be considered as a serious contender for use in CMCs manufactured by this process.

The axial coefficient of thermal expansion (CTE) varies strongly with temperature over the range studied, rising from about $2{\cdot}8 \times 10^{-6}(°C)^{-1}$ at ambient temperature to about $6 \times 10^{-6}(°C)^{-1}$ at about 500°C. The variation is approximately linear in temperature, being given by the relationship:

$$\alpha = 2{\cdot}69 \times 10^{-6} + 6{\cdot}44 \times 10^{-9}\, T \qquad (1)$$

The room-temperature CTE of the Nextel fibre is quoted by the manufacturer as $5 \times 10^{-6}(°C)^{-1}$. We have no measured value for the unreinforced matrix material appropriate to its condition in the sol-gel composite, but a value of about $2 \times 10^{-6}(°C)^{-1}$ would, on a crude rule-of-mixtures basis, give the observed CTE of about $2{\cdot}8 \times 10^{-6}(°C)^{-1}$ for the unidirectional composite.

4.1 Thermal shock results

The effects of water quenching on the properties of the composites of batches A and B (filled triangles) are shown in Fig 3. In view of the similarity of properties of batches A and B shown in Table 1, the data for these two batches have been pooled. The A/B data points in Fig. 3 are therefore means of ten individual tests and the error bars represent the standard deviations. Each set of results is normalised with respect to the appropriate property of the as-manufactured composite (i.e. the values given in Table 1) for ease of comparison. It can be seen that the stiffness, strength and mechanical modulus all remain unaffected by quenching until the soaking temperature exceeds 500°C. Above this all three properties fall drastically in step functions to levels that are about 50% of the original values in the case of the strength and toughness, and 60–70% of the initial values for the stiffness. In order to show that it is the thermal shock that is responsible for this sudden loss in properties, samples of batch C were subjected to the same heating and soaking procedure, but were then slow cooled in the furnace from the soak temperature. It can be seen that the strength and stiffness are unaltered by this treatment, but the toughness does change, falling more gradually beyond about 500°C to some 60 or 70% of the initial value. Table 1 shows that the original toughness of batch C was much higher than that of batches A and B, and the corresponding decline in toughness of the material of batches A and B as a result of slow cooling may well be more severe than that shown for batch C in Fig. 3.

As a further check on the role of the downquench, as opposed to other heating effects, in degrading the properties of the composite, a small group of samples was also subjected to the same temperature change by rapid heating up to the soaking temperature. These results are shown in Fig. 4, from which it is clear that the values of all three mechanical properties are substantially unchanged by either slow cooling or rapid heating from 800°C.

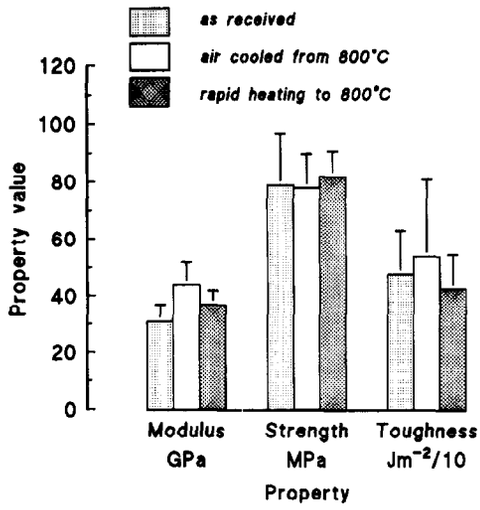

Fig. 4. Effects of slow cooling from 800°C and rapid heating to 800°C on the properties of the Nextel/silica–zirconia CMCs.

The changes in acoustic emission response from quenched and unquenched samples give some insight into the effect of the thermal shock on the damaged state of the material. Figure 5 shows the cumulative total number of AE events emitted by samples during flexural testing as a function of the soak temperature prior to quenching. The data points are the averages of five separate tests and the error bars are the standard deviations. It can be seen that in the as-manufactured state the total AE count is about 800 events, a low output for a unidirectional fibre composite material. There is little change in the total AE count for samples quenched from temperatures up to about 500°C (the slight depression between the as-manufactured level and the level at 500°C is probably not significant, given the variable character of these materials and the general nature of AE phenomena) but beyond 500°C the acoustic response increases markedly, reflecting the sudden deterioration in mechanical properties of samples quenched from above 500°C. Analysis of the amplitudes of the AE events which constitute the general pattern shown in this figure provides further information on the effects of the quench. Figure 6 shows the amplitude distribution histograms for samples loaded to fracture in bending in the as-manufactured state and after quenching from 800°C. These distributions are for the final stages of the two tests, with the samples nearing fracture, a method of AE analysis which emphasises changes in mechanisms by reducing the masking effect of the large numbers of events recorded in the early stages. The bars in the histogram therefore represent the numbers of events emitted during the last few seconds of a test which fall in the amplitude band defined by the amplitude channel number on the abscissa. The width of each amplitude bin is 2·4dB. A voltage of 10 mV at the amplitude sorter for channel 0 represents 10 μV at the transducer. The threshold in these tests was set at channel three to exclude extraneous signals, and hence the actual test threshold was 20·9 mV. In the un-quenched condition, the form of the distribution is roughly exponential, with no significant numbers of events having amplitudes above 832mV (channel 15), the normal kind of distribution found in many types of composite, including CMCs. By contrast, the distribution for the quenched sample shows three distinct features. Apart from the increase in the total event count already referred to, it is clear that there are also many events of much higher amplitude than those in the un-quenched sample, and the distribution has become bi-modal, with a peak at an amplitude of about 363mV (channel 13). This is indicative of the late onset of a different mode of damage, or the operation of an existing damage mode at much higher energy levels.

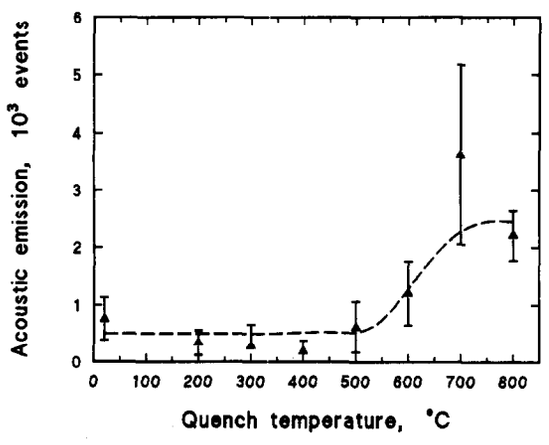

Fig. 5. Cumulative acoustic emission event count during flexural fracture tests on quenched samples of the Nextel/silica–zirconia CMCs.

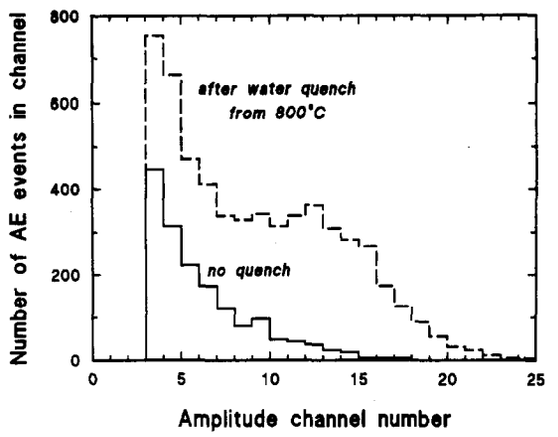

Fig. 6. Acoustic emission amplitude distributions for Nextel/silica–zirconia CMC samples tested to failure in flexure in the as-received condition and after quenching from 800°C.

5 Discussion

It is apparent from Fig. 3 that although, in the quench temperature range below 500°C, the mean strength and toughness values both begin to decline, somewhat more gently than the stiffness values, all of these reductions are still within the overall spread of experimental results and the real effect of thermal shock is more obviously manifested as a step reduction in all three properties at some quenching temperature between 500 and 550°C. Beyond this temperature all three properties remain constant, again within the scatter of the results.

The basic Kingery model[4] for an infinitely rapid quench of a ceramic body gives the maximum temperature difference, ΔT_c, which a material can withstand before the fracture stress, σ_f, is reached as

$$\Delta T_c = (R^I) = \frac{\sigma_f (1 - \nu)}{E\alpha} \quad (2)$$

Since we have no experimental results for the thermal conductivity of our composites, it is not possible to refine the model to account for finite quenching rates and finite sample geometry, but eqn 1 may be used to evaluate the results in Fig. 3, at least to a first approximation. The theoretical value of ΔT_c for a composite exhibiting the properties that would have been predicted from the basic characteristics of the matrix and fibres would have been of the order of 1200°C, assuming a mean value of α of $5{\cdot}5 \times 10^{-6}(°C)^{-1}$. As we have seen, however, the real strength of the composite is a fraction of the predicted value, and if we insert the actual experimental values from Table 1, together with a mean value of α of $4 \times 10^{-6}(°C)^{-1}$, we find that the predicted ΔT_c is about 375°C. The problem is, of course, recursive since, as we showed earlier, the actual value of α, and also its mean value over the predicted quenching range, are themselves functions of that temperature range, and these approximate values of α and ΔT_c must be obtained by successive approximations. The observation that slower cooling does not produce a change in strength implies that the second thermal shock parameter

$$R^{II} = \frac{k\sigma_f (1 - \nu)}{E\alpha} \quad (3)$$

is not significant, i.e. the conductivity, k, is not a contributor to the grading of the materials — they are susceptible only to large, rapid quenches.

It is interesting to note that a very limited number of flexural tests carried out on samples cut transverse to the fibre axis gave values of 6 GPa and 13 MPa, respectively, for the modulus and strength, and these values generate a slightly higher calculated value of ΔT_c, about 406°C, but both predicted values are 150°C or more below the clearly defined experimental value which is between 500 and 550°C.

It appears, therefore, that despite the apparently large loss in strength of the reinforcing fibres during the fabrication process, their presence remains beneficial in increasing the resistance of the material to thermal shock. We note that unreinforced freeze-gelled material has a failure strength of about 20–30 MPa and a work of fracture of 0·05–0·1 kJm^{-2}. Thus, although our experimental material is relatively weak by comparison with high-performance CMCs, it was significantly better than the unreinforced material.

The more complete Hasselmann model[5] predicts that for thermal shocks of severity less than ΔT_c the strength remains unaffected because insufficient strain energy is available to cause propagation of a number of existing flaws (which are assumed to be of a uniform size). The fibres are likely to contribute to the increase of energy required to propagate all of these flaws. When the temperature difference exceeds the critical value, the strength (and, as shown by Fig. 1, any other mechanical property associated with strength as normally defined) falls because a significant proportion of the family of pre-existing cracks has grown as a result of the thermal shock. The process of propagation of these larger cracks is stable, however, and no further drop in strength is expected with further increase in the quenching temperature interval until a second critical temperature difference, $\Delta T_c'$, is reached when the cracks present in the quenched body have become large enough to propagate in quasi-static fashion, with corresponding further decrease in strength as ΔT increases further. It can be seen from Fig. 3, however, that this higher critical temperature interval has not been reached by the time the thermal shock experiments were discontinued at 800°C, above which structural changes in the material would be expected.

The acoustic emission response of the materials in the as-manufactured and quenched states appears to be quite different. During the early stages of loading, samples quenched from above 500°C emit fewer acoustic emissions than un-quenched samples, but as failure approaches the event emission rate increases more rapidly so that, overall, quenched samples produce more events to failure. It has also been shown that a mid-range amplitude peak develops as failure approaches, indicating the possibility of the onset of a micro-failure process that is different from that which occurs normally in un-quenched material. The likelihood

is that this mechanism is the propagation of pre-existing cracks formed or extended by the thermal shock treatment. It appears, then, that cracks are propagating subcritically during thermal shock, presumably from existing defects (pores, perhaps, or reaction damage sites on fibres). During loading of quenched samples, a higher level of strain is then required to cause further propagation and stimulate AE. As failure approaches, however, the number of enlarged cracks results in more AE. The marked decline in composite strength caused by quenching suggests that the thermal shock process must also be causing further damage to the fibres, presumably as a result of the matrix cracks propagating through the fibres as a consequence of the strong interfacial bond.

6 Conclusions

(1) Ceramic-matrix composites consisting of a silica–zirconia matrix reinforced by continuous Nextel mullite fibres have been manufactured by a sol–gel route incorporating freeze-gelation and subjected to thermal shock by water quenching from temperatures up to 800°C.

(2) Nextel alumino-silicate fibres are unsuited to direct inclusion in freeze-gelled ceramic matrix composites, probably because of degradation of the fibres during the desizing and filament winding processes. The lack of appropriate low-cost ceramic reinforcing fibres and the requirement for interface control through the application of interfacial layers is nothing new in the field of CMCs.

(3) Despite 2 above, comparison of reinforced and unreinforced freeze-gelled material shows that the Nextel fibres provide significant reinforcement of the matrix and improvements in the thermal shock resistance. Nextel-fibre-reinforced silica/zirconia CMCs are essentially unaffected by water quenching from temperatures up to 550°C. Beyond this critical value there is a step reduction of strength and modulus to between 50 and 60% of virgin properties.

(4) The changes in mechanical behaviour are accompanied by significant modifications of the acoustic emission response of the materials during post-quench three-point flexural testing. A lower initial event rate during load application gives way to a much higher event rate (and more events in total) at failure. A change to a bi-modal amplitude distribution near failure gives further credence to the hypothesis that thermal shock (beyond a critical value) causes the propagation of probably pre-existing flaws to a longer but stable value. A further, and significantly higher second critical level of thermal shock is then required to cause additional propagation of the flaws and a further reduction in properties. In other words, we believe that our continuous fibre reinforced materials behave in the manner proposed by Hasselmann. We note that earlier work of a similar nature on a freeze-cast short-fibre-reinforced CMC showed that this material also obeyed the Hasselmann model.[6]

(5) Quenching from above the critical temperature results in a significant (but not catastrophic) decline in strength which is not altered by further increasing the quenching temperature. The Hasselmann quenching cracks clearly do not therefore propagate from one side of the sample to the other.

Acknowledgement

This work was carried out as part of a wider program of research on the sol–gel processing of CMC shapes with the financial support of the ACME Directorate of SERC. The authors are grateful for this support and for the encouragement of the Directorate. Sadly, Dr Richard Russell-Floyd, who was a major source of inspiration in this work, died shortly after this paper was submitted for publication.

Abstract

In this paper we report our results on the preparation and characterization of copper–cobalt manganites, $Mn_{2\cdot6-x}Co_{0\cdot4}Cu_xO_4$ ($0 \leq x \leq 1$), obtained from coprecipitated oxalate precursors. Powder and single phase ceramics have been characterized by means of X-ray diffraction (XRD) and electrical conductivity measurements. The results of both characterization techniques are indicative of the ionic distribution for the copper–cobalt manganites solid solution studied: $Mn^{2+}_{0.6-x}Co^{2+}_{0.4}Cu^{+}_{x}\,[Mn^{3+}_{2-x}\,Mn^{4+}_{x}]\,O^{2-}_{4}$; with $0 \leq x \leq 0{\cdot}6$, $Co^{2+}_{0.4}\,Cu^{+}_{0.6}\,[Cu^{2+}_{y}Mn^{3+}_{1.4-2y}\,Mn^{4+}_{0.6+y}]\,O^{2-}_{4}$; with $0{\cdot}6 < x \leq 1$ and $y = x - 0{\cdot}6$.

1 Introduction

Thermistors with Negative Temperature Coefficient of Resistance (NTC) are semiconducting thermally sensitive resistors whose primary function is to exhibit a wide change in electrical resistance with a change in body temperature. These electroceramics are often constituted of spinel structure transition metal manganites with formula: $Mn_{3-x'-x}\,Ni_{x'}\,M_x\,O_4$ ($0 \leq x+x' \leq 1{\cdot}5$; M = Ni, Co, Cu...).

The purpose of this paper is to present the study of manganites without nickel which is often present in industrial NTC thermistors.

The transition metal oxides have aroused considerable interest regarding the valency and the cationic distribution among tetrahedral and octahedral sites in the spinel structure. Many workers using different experimental techniques have sought to resolve this problem. However, the cationic distribution of manganites depends on the preparation conditions. For instance, Kulkarni *et al.*[1] have established from X-ray absorption spectroscopy that the defined compound $CoCuMnO_4$ presents a tetragonal structure with the cationic distribution: $Co^{2+}[Mn^{4+}Cu^{2+}]\,O^{2-}_4$. (the square brackets indicate octahedral sites). However, using a different route Brabers *et al.*[2] prepared a single-phase cubic spinel with the following distribution: $Cu^{+}_{0.65}Mn^{3+}_{0.35}[Cu^{2+}_{0.35}Co^{3+}_{1}Mn^{4+}_{0.65}]O^{2-}_4$. They called into question Kulkarni's preparation.

Hence, to avoid any substantial deviation from an intended composition, it seems necessary to study solid solution rather than defined compounds since one may reasonably assume that the oxidation states and the distribution of cations vary continually with the composition.

Kshirsagar *et al.*[3] studied the solid solution, $Co_xCu_{1-x}[Mn_2]O_4$, and showed that for $x < 0{\cdot}5$ the structure becomes cubic. In this solid solution the manganese is fixed which differs from the present paper in which we have studied the substitution of copper for manganese in the cobalt manganite with formula: $Mn_{2\cdot6}Co_{0\cdot4}O_4$.

Cobalt manganites $Mn_{3-x}Co_xO_4$ for $0 \leq x \leq 1$ have been previously studied.[4–7] These components have tetragonal structure and their cation distribution can be deduced from that of hausmannite as given by $Mn^{2+}\,[Mn^{3+}_2]\,O^{2-}_4$ by substituting essentially Mn with Co on tetrahedral sites implying a structural formula of type $Mn^{2+}_{1-x}Co^{2+}_x\,[Mn^{3+}_2]\,O^{2-}_4$. This structural description accounts for their tetragonal structure characterized by their stability up to very high temperatures and their practical insulating properties.

By analogy with copper manganites, we have tried to create Mn^{3+}–Mn^{4+} couples in octahedral sites which resulted in a dramatic decrease in the electrical resistivity.[8–9]

2 Experimental Procedure

2.1 Sample preparation of powders

The powders were obtained from the decomposition of oxalic precursors prepared by coprecipitation in aqueous solution from $MnCl_2$, $6H_2O$, $CoCl_2$, $6H_20$ and $CuCl_2$, $6H_2O$ and ammonium oxalate $(NH_4)_2C_2O_4$, H_2O at 25°C.

Simple thermal decompositions in air of the precipitated oxalic precursors leads to a mixture of oxides. Therefore, by analogy with the preparation of copper manganite spinels,[9] a long stage at high temperature (to increase the diffusion of the oxides), followed by a quench treatment in water (to stabilize the high temperature structure at room temperature) has been used. These heat treatments in air, with different profiles depending upon the compositions of powders prepared yield metastable single-phase oxides and are depicted in Table 1.

2.2 Sample preparation of ceramics

The earlier preparation of powder with a single-phased spinel structure was of great use in preparing ceramics with a single-phased spinel structure. To obtain well densified ceramics, the previous oxide powders were first pressed into disc form (6 mm diameter and 2 mm thickness) under 7 kbar. Then, the green discs were fired for 4 h at a temperature depending upon the amount of copper. After the sintering the samples were cooled at a rate of 120°C per hour, to the temperature used to obtain single-phased powders and were kept at this temperature for 24 h. The final cooling was a quench in water to stabilize the high temperature structure at room temperature.

It is worth noticing that the single-phased powders were difficult to sinter. Table 2 shows the evolution of densification depending on various sintering temperatures for the given composition: $Mn_{2\cdot20}Co_{0\cdot4}Cu_{0\cdot39}O_4$. It appears that for each composition, there is an optimal sintering temperature (Table 3). Moreover, for certain compositions ($x > 0\cdot5$), we report the phenomenon of exaggerated growth of manganite grains which led to grain sizes up to 500 μm. Eventually, the ceramics cracked or became extremely brittle.

Table 2. Sintering temperatures and densification for the given single-phase ceramic: $Mn_{2\cdot20}Co_{0\cdot41}Cu_{0\cdot39}O_4$

Sintering temperature (°C)	*Densification (%)*
1100	94·5
1130	98
1150	95
1170	94
1200	93

2.3 X-ray diffraction

XRD powder patterns were recorded at room temperature using an automatic diffractometer (Siemens D 501, CoKα radiation). The standard error on parameters was less than ± 0·0005 nm.

2.4 Measurement of electrical properties of ceramics

Samples for electrical measurements were prepared by depositing silver electrodes on the opposite faces of the discs formed and were subjected to thermal treatment at 850°C, so as to make good ohmic contact with the ceramics.

The d.c. resistivity was deduced by classical resistance measurements made at 25 ± 0·05°C and using the relationship $\rho = RS/l$, with R, the electrical resistance in Ohms (Ω); S the area of the specimen in cm^2 and l the thickness of the specimen in cm. Another d.c. resistance measurement was carried out at 85 ± 0·05°C so as to deduce the band gap-related constant B from the classical law of semiconductors $\rho = \rho_0\exp(B/T)$ with $B = \Delta E/2k$.

3 Results and Discussion

3.1 XRD analyses

3.1.1 Cation distribution of manganite powders

The variation of the lattice parameters of single-phased powders as a function of the copper content is reported in Table 1. Most of the solid solutions $Mn_{2\cdot6-x}Co_{0\cdot4}Cu_xO_4$ were found to be tetragonally distorted from cubic symmetry. The tetragonal distortion $c/a > 1$ decreased with copper content and disappeared for $x \geq 0\cdot79$.

The substitution of copper in the matrix $Mn^{2+}_{0.6}Co^{2+}_{0\cdot4}[Mn^{3+}_2]\ O^{2-}_4$ could be interpreted by one of the four theoretical limiting ionic configurations as follows:

(a) $Mn^{2+}_{0.6-x}Co^{2+}_{0\cdot4}\ Cu^{+}_x\ [Mn^{3+}_{2-x}\ Mn^{4+}_x]\ O^{2-}_4$;
with $0 \leq x \leq 0\cdot6$;

(b) $Mn^{2+}_{0.6-x}Co^{2+}_{0\cdot4}\ Cu^{2+}_x\ [Mn^{3+}_2]\ O^{2-}_4$;
with $0 \leq x \leq 0\cdot6$;

(c) $Mn^{2+}_{0.6}Co^{2+}_{0\cdot4}\ [Cu^{+}_xMn^{3+}_{2-3x}Mn^{4+}_{2x}]\ O^{2-}_4$;
with $0 \leq x \leq 0\cdot66$;

(d) $Mn^{2+}_{0.6}Co^{2+}_{0\cdot4}\ [Cu^{2+}_x\ Mn^{3+}_{2\ 2x}Mn^{4+}_x]\ O^{2-}_4$;
with $0 \leq x \leq 1$.

However, according to the work of Baffier and Huber,[10] the tetragonal distortion in the ferromanganite spinel structure is created by the presence of cations Mn^{3+} on the octahedral sites. Moreover, they have shown that a minimum concentration of Mn^{3+} cations in octahedral sites is necessary to raise a cooperative Jahn–Teller effect. This minimum concentration is about 50%. Thus there is a correlation between the concentration of cations Mn^{3+} in octahedral sites and the macroscopic distortion observed by X-ray diffraction.

The formulae (a), (c) and (d) might explain the decrease of tetragonal distortion as a function of copper content by diminishing the Mn^{3+} ion content in B sites, e.g. by decreasing the Jahn–Teller effect of the cations Mn^{3+} ($t^3_{2g}\ e^1_g$) localized in octahedral sites. However the components (c) and (d) cannot fit with the experimental tetragonal distortion observed for $0 \leq x < 0\cdot79$, because for $x \geq 0\cdot33$ and $x \geq 0\cdot5$ respectively, the distortion of the spinel structure should disappear while the concentration of Mn^{3+} in octahedral sites drops below the 50% critical value necessary to raise a cooperative Jahn–Teller effect. In the case of formula (b), the increased amount of copper (II) in tetrahedral sites must be responsible for a Jahn–Teller effect $c/a < 1$ and thus for the overall decrease of the distortion.

The cubic spinel structure is preserved when different kinds of cation occupy a spinel site. From this Poix[11] defined two parameters: $dCA = \Sigma i\ xi\ (CA_i - 0)$ and $dCB = \Sigma i\ xi/(CBi - 0)/2$ where dCA and dCB are the mean values of the 'oxygen–cation' distance in tetrahedral and octahedral sites respectly. The lattice parameter a of the cubic structure spinel is related to the dCA and dCB according to

$$a = 2\cdot0995\ dCA + (5\cdot8182\ dCB^2 - 1\cdot4107\ dCA^2)^{1/2}$$

Table 4. Anion–cation distance in tetrahedral and octahedral sites of cubic spinel structure[11]

Cations	*Cation–oxygen (nm)*	
	A sites	*B sites*
Mn^{2+}	·2041	·2220
Mn^{3+}	—	·2045
Mn^{4+}	—	·1843
Co^{2+}	·1967	—
Cu^{+}	·2070	·2281
Cu^{2+}	·1940	·2150

It may be seen that the theoretical lattice parameters could be calculated for various cation distributions among the two sublattices. When the phases crystallise in a tetragonally deformed spinel structure it is possible to replace a (cubic parameter) by $a' = \sqrt[3]{a^2c}$ (cubic/root of volume cell). Thus, it is possible, knowing the characteristic bond distances manganese–oxygen, cobalt–oxygen and copper–oxygen (Table 4) to calculate from the cation distributions (a), (b), (c) and (d), the theoretical decrease of the cubic parameter a (or a') as a function of the amount of copper substituted in the manganite: $Mn_{2\cdot6-x}Co_{0\cdot4}Cu_xO_4$.

The variation of the lattice parameter, a', of $Mn_{2\cdot6-x}Co_{0\cdot4}Cu_xO_4$ powders as a function of the copper content, x, calculated for the cation distributions (a), (b), (c) and (d), is compared with the experimental data (Fig. 1). It appears very clear that the hypothetical distributions (b) and (d) cannot fit with the experimental results. It is difficult to choose between the formulae (a) and (c); however the previous discussion about the cooperative Jahn–Teller effect shows that the distribution (c) involves a tetragonal–cubic transition for $x > 0\cdot33$ instead of an experimental transition observed for $x > 0\cdot66$. Thus, the most probable distribution among the four extreme hypothetical substitution processes is:

(a) $Mn^{2+}_{0.6-x}Co^{2+}_{0\cdot4}Cu^{+}_x\ [Mn^{3+}_{2-x}\ Mn^{4+}_x]\ O^{2-}_4$;
with $0 \leq x \leq 0\cdot6$.

According to this last cation distribution with $0 \leq x \leq 0\cdot6$, for $x > 0\cdot6$, the copper should substitute the manganese located in octahedral sites. Two different theoretical substitutions could appear;

(e) $Co^{2+}_{0\cdot4}Cu^{+}_{0\cdot6}\ [Cu^{+}_yMn^{3+}_{1.4-3y}Mn^{4+}_{0\cdot6+2y}]\ O^{2-}_4$;

(f) $Co^{2+}_{0\cdot4}Cu^{+}_{0\cdot6}\ [Cu^{2+}_yMn^{3+}_{1.4-2y}Mn^{4+}_{0\cdot6+y}]\ O^{2-}_4$;
with $y = x\text{-}0\cdot6$ and $0 < y < 0\cdot4$

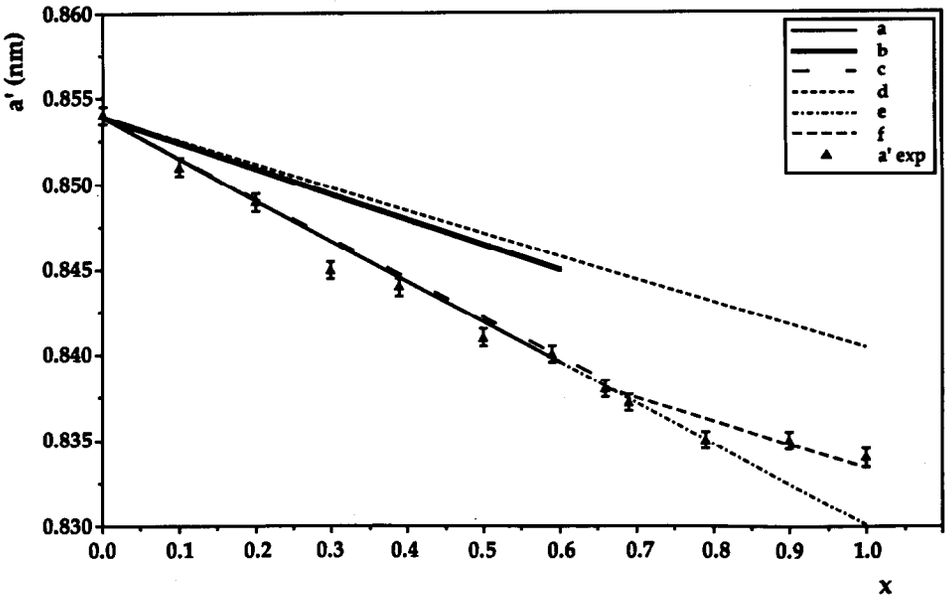

Fig. 1. Theoretical changes of the lattice parameter a' and equations to straight lines calculated for the following cationic distributions:

(a) $Mn^{2+}_{0.6-x}Co^{2+}_{0.4}Cu^{+}_{x}\,[Mn^{3+}_{2-x}Mn^{4+}_{x}]\,O^{2-}_{4}$ → a' = –0·239x + 8·539;

(b) $Mn^{2+}_{0.6-x}Co^{2+}_{0.4}Cu^{2+}_{x}\,[Mn^{3+}_{2}]\,O^{2-}_{4}$ → a' = –0·147x + 8·539;

(c) $Mn^{2+}_{0.6}Co^{2+}_{0.4}[Cu^{+}_{x}Mn^{3+}_{2-2x}Mn^{4+}_{x}]\,O^{2-}_{4}$ → a' = –0·233x + 8·539;

(d) $Mn^{2+}_{0.6-x}Co^{2+}_{0.4}[Cu^{2+}_{x}Mn^{3+}_{2-x}Mn^{4+}_{x}]\,O^{2-}_{4}$ → a' = –0·134x + 8·539;

(e) $Co^{2+}_{0.4}Cu^{+}_{04}[Cu^{+}_{y}Mn^{3+}_{1.4-3y}Mn^{4+}_{0.6+2y}]\,O^{2-}_{4}$ → a' = –0·235y + 8·536;

(f) $Co^{2+}_{0.4}Cu^{+}_{06}[Cu^{2+}_{y}Mn^{3+}_{1.4-2y}Mn^{4+}_{0.6+y}]\,O^{2-}_{4}$ → a' = –0·135y + 8·476.

– Experimental lattice parameters ī as a function of copper content x and equations to straight lines calculated for: $0 < x < 0{\cdot}6$ a' = – 0·238x + 8·534 close to equations (a) and (c); $0 < y < 0{\cdot}4$ a' = – 0·086 + 8·476 close to equation (f).

In contradiction to the formula (e) the experimental data fits well to the (f) line corresponding to the substitution of copper II to manganese in octahedral sites (Fig. 1). Thus, for $x > 0{\cdot}6$ the closer hypothetical cation distribution in these spinels is:

(f) $Co^{2+}_{0.4}Cu^{+}_{0.6}\,[Cu^{2+}_{y}Mn^{3+}_{1.4-2y}Mn^{4+}_{0.6+y}]\,O^{2-}_{4}$

3.1.2 Cation distribution of manganite ceramics

The diffraction analysis revealed the presence of pure spinel structure. The results concerning the lattice parameter values (Table 5), are very close to those observed with spinel powders (Table 1). Hence, we assume that the ionic distribution of the powder samples doesn't differ from the ceramics.

Table 5. Structure and lattice parameters of single-phase ceramics: $Mn_{2.6-x}Co_{0.4}Cu_xO_4$ (to be compared with Table 1)

3.2 Electrical properties of ceramics

The experimental data are reported in Table 6. The electrical resistivity of copper–cobalt manganite ceramics decreases with copper ion content until a minimum of resistivity for $x = 0{\cdot}79$ (Fig. 2).

The substitution of copper ions for manganese ions in insulating spinel material, $Mn_{2.6}Co_{0.4}O_4$, gives rise to a semiconductor. The resistivity of the thermistors can reach several Ω cm. The con-

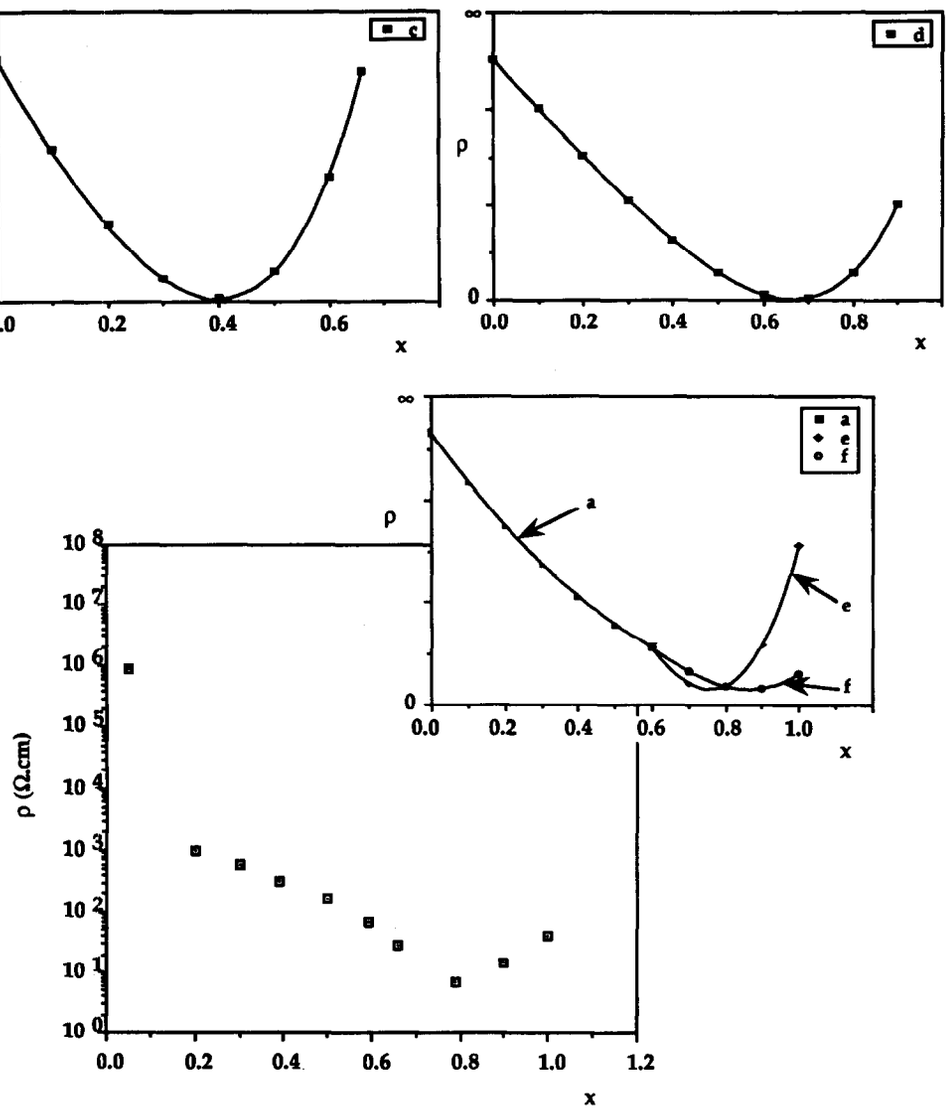

Fig. 2. ⊡ Experimental change of resistivity as a function of the copper content x. Theoretical variation of the resistivity according to the cationic distributions: (a) with $0 < x < 0{\cdot}6$ plus (e) and (f) with $0 < y < 0{\cdot}4$; distributions (c) and (d) with Cu II in octahedral sites.

ductivity of these components is dependent on the presence in the octahedral sites of Mn^{3+} and Mn^{4+}.

The electrical conductivity of a small polaron conductor can be written as[12]

$$\sigma = \frac{\sigma'_o}{T} NC(1-C) \exp\left(\frac{-E_H}{KT}\right) \text{with } \sigma'_o = \frac{N_{oct} e^2 d^2 \nu_o}{K}$$

where N_{oct} is a concentration per cm^3 of octahedral sites, d is a jump distance for the charge carrier, ν_o is the lattice vibrational frequency associated with conduction, K is Boltzmann's constant, e the electronic charge, N is a concentration per formule unit of sites which are available to the charge carriers, C is a fraction of available sites which are occupied by the charge carriers and E_H is a hopping energy.

The term NC (1-C) can be rewritten as

$$NC(1-C) = \frac{(Mn^{3+}_{oct})\,(Mn^{4+}_{oct})}{(Mn^{3+}_{oct}) + (Mn^{4+}_{oct})}$$

which represent the probability of finding Mn^{3+} - Mn^{4+} pairs in octahedral sites.

At first approximation, we take into account only the variation of the last ratio. Thus, the theoretical variation of resistivity can be plotted against copper content and compared to the experimental curve: $\rho = f(x)$. An inspection of the theoretical variations of resistivity with x calculated for the four hypothetical configurations shows an insulating character for formulae (b) (only Mn^{3+} in octahedral site) and a minimum of resistivity ($\partial(C(1-C)/\partial x=0$) with formulae (c) x = 0·4 (Fig. 2 curve *c*) and formulae (d) for x = 0·66 (Fig. 2 curve *d*). The experimental shape of the variation of resistivity (Fig. 2) with copper content does not present a minimum for x = 0·4 or x = 0·66. However, for $0{\cdot}2 \leq x \leq 0{\cdot}4$ the curve presents a slope change and hence, it should be possible that a small amount of copper be present in octahedral sites.

However, the theoretical variation of the resistivity, shown in curve *a* and *f* of Fig. 2, calculated from hypothetical configurations (a) and (f) selected from the earlier XRD study, fits the best

with the experimental data. For $0 \leq x \leq 0{\cdot}6$, the theoretical resistivity is proportional to $(2\text{-}x)x/4$ and the resistivity is expected to decrease continuously for $0 \leq x \leq 0{\cdot}6$. The minimum of resistivity should be for 0·87 ($\partial(C(1\text{-}C)/\partial y=0$) and not for 0·8 (experimental data). This slight misfit could be due to the fact that we have only taken into account the variation of density of charge carriers to calculate the theoretical variation of the resistivity; for instance the variation of the lattice volume (and hence, the hopping distance) which decreases for $0 \leq x \leq 1$ was not considered.

4 Conclusion

Precipitated oxalic have been employed to prepare oxides and ceramics with single-phased spinel structure: $Mn_{2\cdot6-x}Co_{0\cdot4}Cu_xO_4$, $0 \leq x \leq 1$. Powder XRD analysis both from powder and ceramic single-phase sample revealed the presence of a single phase having a tetragonally distorted spinel structure; the tetragonal distortion, $c/a > 1$, decreased with copper content and disappeared for $x \geq 0{\cdot}79$. The XRD powder study and the comparison of experimental curves with the calculated ones for electric resistivity measurements implemented on ceramics indicated that the cation distribution in these spinels is close, both at the powder and ceramic states, to:

$$Mn^{2+}_{0.6-x}Co^{2+}_{0\cdot4}\ Cu^{+}_{x}\ [Mn^{3+}_{2-x}\ Mn^{4+}_{x}]\ O^{2-}_{4};$$
with $0 \leq x \leq 0{\cdot}6$,

$$Co^{2+}_{0\cdot4}Cu^{+}_{0\cdot6}\ [Cu^{2+}_{y}Mn^{3+}_{1.4-2y}Mn^{4+}_{0\cdot6+y}]\ O^{2-}_{4};$$
with $0{\cdot}6 < x \leq 1$ and $y = x - 0{\cdot}6$.

This first structural approach of the solid solution gives a good base for the next step that will be the fine characterization of these components by neutron diffraction and magnetic measurements. With only one solid solution, the electrical resistivities of these thermistors cover a wide range: $>2\ 10^6\ \Omega$ cm – 10 Ω cm and might be interesting for industrial applications.

Abstract

Dry pressing is the most common industrial shaping process for ceramic pieces. Sol–gel powders are of high reactivity, but very often agglomeration–aggregation phenomena limit this advantage by inducing poor compaction behaviour. Consequently the goal of sol–gel powder research — to obtain full densification at very low sintering temperature, is not achieved. With the intention of showing the influence of sol–gel powders, specific characteristics on pressing, compaction diagrams and green body characteristics of two experimental zirconia sol–gel powders have been determined. For comparison a well-known commercial product was used as a control. These observations were correlated as densification tests and initial powder characteristics. The sol–gel powder parameters that must be adapted to dry pressing forming and the incidence of the synthesis conditions, have emerged.

1 Introduction

Dry pressing is a method extensively used for the industrial production of ceramics. It is well known that the quality of ceramic bodies is strongly influenced by the characteristics of the starting powder. A powder having good compaction behaviour gives a high-density green compact and, more importantly, a fine and homogenous porosity. This results in a high-density sintered body as already shown in many studies.[1]

The major source of the defects observed in a green body originates in the characteristics of the different constituents of the powder. The different constituents of a powder can be defined in different ways, so we will explain the definitions used in this text. The smallest unit of a powder which can be considered is the crystallite. It can be defined as a coherently diffracting region, and measured by X-ray diffraction line broadening. In a first approximation, the potential reactivity of a powder can be linked to the crystallite size (in fact a crystal can be constituted of several crystallites): this is not far away from the minimal particle size that can be individualised. In classical powder processing these particles do not appear alone, but clustered into either the aggregates or the agglomerates, depending upon the nature of the binding forces. An aggregate is an arrangement of crystallites held together by strong binding forces, e.g. chemical bands in solid bridges. A typical example is the aggregates formed during calcination of Bayer aluminas. Consequently, aggregates retain their identity under a wide variety of severe conditions, and especially under high compaction pressure.[2] The agglomerates are constituted of crystallites and/or aggregates held by weak binding forces, such as Van der Walls or electrostatic forces. Agglomerates, in contrast to aggregates, are much more easily disrupted by external forces.

All fine particle size ceramic powders contain agglomerates, because Van der Walls forces exceed gravitational ones, and very often, depending on the synthesis process, aggregates. When the powder is poured into a compaction die, one can distinguish three porosity types: interagglomerate, interaggregate and intraaggregate porosities. Irregularly shaped particles (agglomerates and/or aggregates) affect the flowability of the powder, and lead to the creation of gross interagglomerates/interaggregate porosities by promotion of arch formations. If agglomerates, or more frequently aggregates, are resistant to compaction forces, this induces packing inhomogeneities in the green

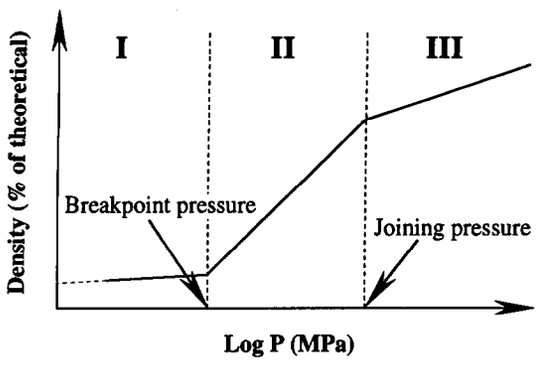

Fig. 1. Typical compaction response diagram for granulated or agglomerated powders.

body associated to important interagglomerates/ interaggregate porosities. During sintering, the denser regions formed by remaining agglomerates/ aggregates will first densify at low temperatures, then the interagglomerates/interaggregate porosities will grow, or more detrimentally, transform into cracklike defects: these porosities will require for their elimination, if it ever happens high temperatures and long sintering times.[3-4]

In classical powder metallurgy processes, the powders are granulated after deagglomeration/ aggregation treatments in order to avoid the problems mentioned earlier. An ideal granulate should be: spherical with the smallest diameter possible while enough to allow good flowability, dense and resistant to industrial manipulations, but plastically deformed under low compaction pressures to fill the intergranulate voids.

Compaction tests are useful tools for characterising the powder pressing operation. Various testing methods have been developed:[5] the most extensively reported is the compaction response diagram that relates the relative density of the compact to the logarithm of the compaction pressure. These tests are quite sensitive to the strength variations of the different particles contained in a powder, and gives good information on the compaction behaviour.[6] The typical compaction response diagram of granulated (or agglomerated) powder is given in Fig. 1. This compaction behaviour has been explained by many authors,[5,7,8] and is summarised below. The curve can be divided into three linear portions. At low pressure the density remains relatively constant which corresponds to granulate rearrangement. The limit between the two first parts defines the breakpoint pressure which is a measurement of granulate (or agglomerate) strength. The second linear portion corresponds to the rearrangements provoked during and after the crushing or deformation of the granulates. The slope remains constant up to a joining pressure where the granules (or the agglomerates) lose their separate identity. Then in the third linear part, the compact behaviour is similar to the same nongranulated (agglomerated) powder. This corresponds to the rearrangement of the crystallites (or aggregates if any). Aggregates, in the sense of the definition given here, cannot be broken under the pressure usually used for compaction tests. Indeed, for example, aggregates formed by calcination in Bayer aluminas require pressures up to 700 MPa to be broken.[8] It can be assumed that the same sequence as for agglomerates is repeated since the aggregates are fractured.

The quality of sintered bodies is also dependent on the physico-chemical characteristics of the powder: the sol–gel methods allow the synthesis of powders having high homogeneity, purity, and reactivity.[9] Sol–gel powders can exhibit crystallite clusters that can be related to granulates in the sense that their morphology and diameters are well controlled. But very often the crystallites contained in these clusters are strongly bonded.[10] This limits their compaction behaviour and does not permit them to benefit from their high reactivity. These pseudo-granules are defined as granules in this paper.

This work compares the compaction and sintering of two sol–gel powders to that of a commercial powder. It is expected that this kind of measurement will give feed-back on how to improve the synthesis process of these powders.

2 Experimental Procedure

Three powders have been studied. The control, labelled P1, is a commercial well-known powder of ZrO_2 + 3 mol% Y_2O_3 (5·8 mol% Y in ZrO_2), TOSOH TZ-3YB. P2 and P3 are ZrO_2 experimental powders. P2 contains 3·6 mol% Y_2O_3 (6·9 mol% Y in ZrO_2). This powder was prepared by a sol–gel technique using monomeric solutions of mixed inorganic salts modified by the addition of high viscosity organic polymers. The resulting viscous solution was sprayed in ammonium hydroxide to form gel particles of mixed hydroxides that were dehydrated by azeotropic distillation. After that the powder was heat-treated at 700°C for 4 h. P3 composition was synthesised with 2 mol% Y_2O_3 (3·9 mol% Y in ZrO_2) by gel coprecipitation starting from inorganic salt solutions[11] $ZrCl_4$ and YCl_3–7 H_2O. The gel obtained was first washed in water, then in ethyl alcohol. The alcohol washing was performed to avoid hard agglomeration occurrence, which derived from the hydroxy-bridges produced by the presence of water on the micelles surface. The alcoholic colloidal suspension obtained was oven-dried at 80°C. Then the resulting agglomerated powder was passed through a 40

μm sieve. This powder was heat-treated at 600°C for 30 min. This calcination temperature was chosen to ensure a development of crystalline phase without a strong decrease of specific surface area.

The powders have been characterised by means of scanning electron microscope (SEM), laser granulometry, BET adsorption method and X-ray diffraction analysis in order to determine the nature and amount of different phases and the crystallite size. The phase (monoclinic and tetragonal ZrO_2) percent composition was evaluated using the relationship presented in Ref. 12 The crystallite size was calculated with the Scherrer formula, after correcting the experimental effect by a parabolic law.[13]

The compaction tests were performed on an INSTRON mechanical testing machine, in the range 0–200 MPa with a crosshead rate of 0·5 mm/min. 2 g powder samples were poured into a cylindrical die of a 10 mm diameter, then the tap density was achieved[14] before conducting the compaction test. The density variation during pressing was deduced from the crosshead continuous displacement. Deviation due to the elastic compliance of the load cell was nullified carrying out a blank test, using the same units of measurement without powder in the die and recording its response in the same pressure range. These compaction tests allowed us to draw the relationship between density and compaction rate versus applied pressure. The tap density is approximated by measuring the density at the early stage of pressing, i.e. at sufficiently low pressure.

Hg porosimetric measurements were carried out on 0·5 g powder samples, uniaxially pressed at 100, 200, and 400 MPa, in order to follow the evolution of pore size distribution during compaction. The data were used to draw the variation of relative and cumulative pore volume as a function of pore radius.

Sintering was studied by dilatometric measurements performed on 2 g pellets obtained by 50 MPa uniaxial pressing, followed by 400 MPa isostatic pressing. Heating rate of 1°C/min and a final temperature of 1500°C were chosen. In addition, pellets were sintered, with the same pressing conditions and heating rate, up to 1350°C and 1500°C respectively, and maintained at these temperatures for 2 h. These samples were characterised by SEM observations and X-ray diffraction analysis, in order to define the nature and amount of phases, using the same protocol as for the starting powders. Hg porosimetry and He pycnometry were also conducted, in order to quantify the open and close porosity respectively, and therefore the apparent density.

Table 1. Powder characteristics

Powder	*Granulate size distribution (μm)*			*Phase composition (%)*	*Mean crystallite size (nm)*	*Specific surface area BET (m^2/g)*
	D_{50}	D_{10}	D_{90}			
P1	53·5	18	84	100% tetra	93	17
P2	34	10	52	100% tetra	9	100
P3	12·5	2·8	37·5	100% tetra	9	80

D_{50}: 50% of the distribution with equivalent diameter below D_{50}.
D_{10}: 10% of the distribution with equivalent diameter below D_{10}.
D_{90}: 90% of the distribution with equivalent diameter below D_{90}.

3 Results and Discussion

The physico-chemical characteristics of the powders are summarised in Table 1. All the powders contained spheroidal granules. But SEM observations show that the P1 powder is constituted of hollow granules characteristic of a spray-drying process. When compared to P1, the P2 and especially P3 granules are finer. It can be seen from Table 1 that the granule size distribution of P3 powder is broader than P1 and P2: the D_{50}/D_{10} and the D_{90}/D_{50} ratios are respectively 3 and 4·5 for P3 and about 1·5 and 3–3·4 for P1 and P2.

The main differences between the three powders are the crystallite size and the specific surface area: both sol–gel powders (P2 and P3) exhibit a smaller crystallite size and a higher specific surface area than the P1 powder. The values obtained are usual for sol–gel powders heat-treated at low temperature (600 and 700°C), because, under these conditions, grain coarsening is negligible.

A relative tap density of 20% is obtained for the P1 powder, while lower values, between 10 and 15%, are obtained with the sol–gel powders. It is well known that tap density is strongly dependent on particle size: with fine powders, the Van der Waals forces between particles are much higher than gravitational forces and this affects the flowability[15] (this is why granulation is required with fine powders). For zirconia it has been calculated that the particulate size limit required for these two forces to be equal is about 20 μm diameter.[16] This means that granulation is efficient for the P1 powder, because it contains a low amount of fine granules with diameter less than this limit (D_{10} value is 18 μm). But in the case of the P2 and P3 powders, the granules are too small, D_{10} values are of 10 and 2·8 μm respectively. A bad filling of the compaction dies is therefore obtained, resulting in low tap densities. These observations were made while P1 contained hollow granules which can reasonably be supposed to be the less dense. Consequently it can be assumed that low flowability due to the P2 and P3 granule sizes when compared to P1 as a predominant effect than granule densities.

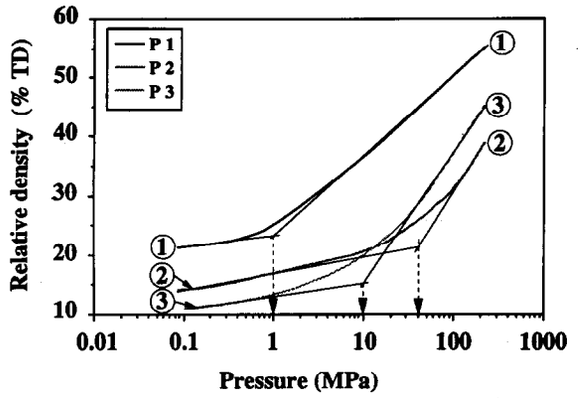

Fig. 2. Compaction response diagram of P1, P2 and P3 powders.

The relative green density (% TD) versus the applied pressure (P) curves (Fig. 2) demonstrate the better compaction behaviour of powder P1: its green density reaches about 50% TD for a pressure of 100 MPa, while 31% TD and 38% TD are reached for P2 and P3 powders. The breakpoint pressure is about 1 MPa, 40 MPa and 10 MPa for P1, P2 and P3 respectively. The compaction rate diagrams (Fig. 3) show that the compaction rate for P1 increases rapidly until 1·5 MPa, and then become stable. This plateau was also observed for the P3 powder, but only starting from 50 MPa. It was not observed for the P2 powder in the range of investigated pressures. It can be assumed that when the maximum compaction rate is obtained, the crushing or deforming of all the granulates is achieved, because they all have successively been submitted to their maximum strength by the net forces developed in the powder arrangement. So the constant compaction rate observed must correspond to reorganisation of the particles provided by the crushed or deformed granulates.

Figure 4 gives the pore size distributions of powders uniaxially pressed at 100, 200, and 400 MPa. A pressure of 100 MPa induces in the P1 sample a monomodal pore distribution of mean radius equal to 16–20 nm. This can be attributed

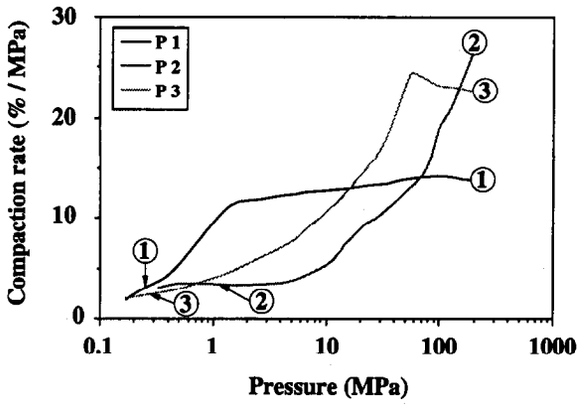

Fig. 3. Compaction rate diagram of P1, P2 and P3 powders.

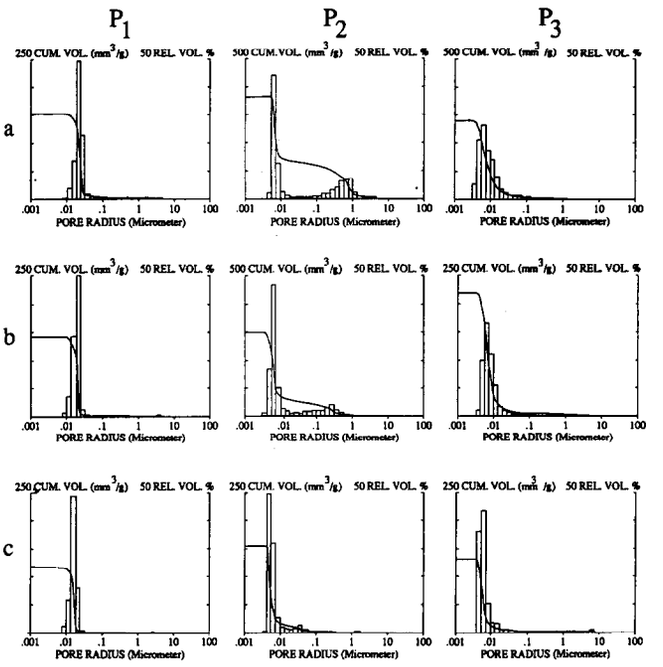

Fig. 4. Pore size distribution for P1, P2 and P3 powders pressed at: (a) 100 MPa, (b) 200 MPa and (c) 400 MPa.

to the fact that only intercrystallite pores (crystallite mean diameter of 93 nm) subsist, since reorganisation of particles due to compaction is still well progressed at this pressure. The pore distribution of the P3 sample pressed at 100 MPa is also monomodal but broader, ranging between 4 and 100 nm. This corresponds to intercrystallite pores that have still not been reduced by particle reorganisation. An increase of the pressure leads to a narrower distribution by reducing the larger intercrystallite pores that are less stable. Consequently higher pressure is required to reach the same green state as the P1 compacts. The porosity evolution of the P2 sample is more complex. At 100 MPa, it shows a bimodal distribution with the maxima at 7 and 800 nm, which correspond respectively to

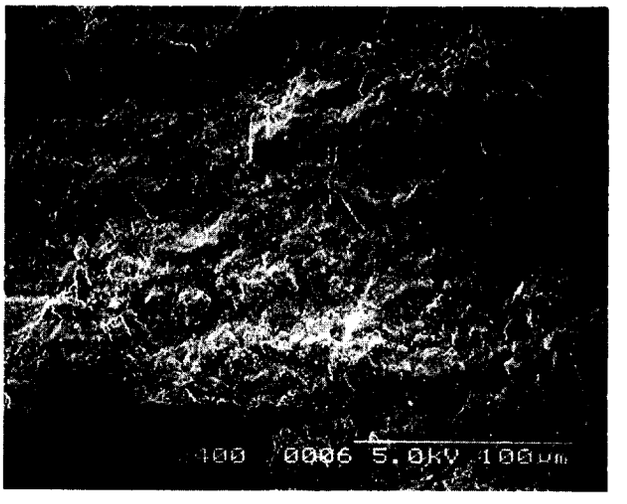

Fig. 5. Green microstructure of P1 powder pressed at 200 MPa, observed by SEM on fracture surface.

Fig. 6. Green microstructure of P3 powder pressed at 200 MPa, observed by SEM on fracture surface.

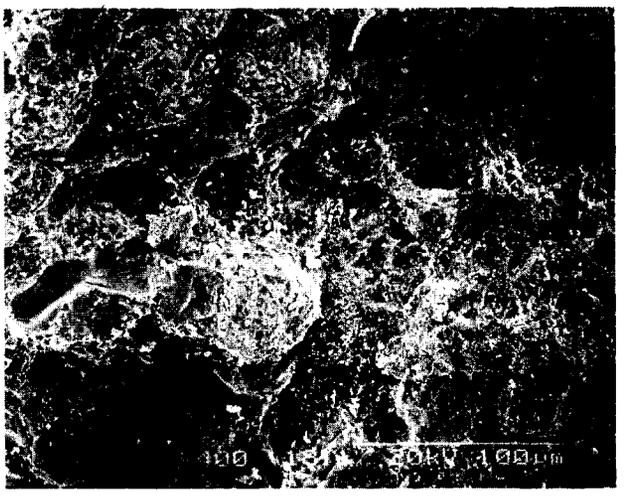

Fig. 8. Green microstructure of P2 powder pressed at 400 MPa, observed by SEM on fracture surface.

intercrystallite pores and intergranulate pores (these granulates are the starting powder granulates weakly deformed by the applied pressure). As pressure is increased, the later pore family is progressively diminished, but at 400 MPa the distribution still presents two maxima, corresponding to intercrystallite pores and intergranulate pores between the widely deformed granulates.

SEM observations substantiate the porosimetric results: at 200 MPa, in both P1 (Fig. 5) and P3 (Fig. 6) samples, the starting granulates lose their identity, although the presence of theses granulates is still well evident in the P2 sample (Fig. 7). At 400 MPa the initial granulates of the P2 powder are sufficiently deformed and the size of the largest intergranulate pores have been reduced but are still visible (Fig. 8).

Numerous relationships have been proposed to predict the tensile strength of monosized spherical particle packing.[17–21] On the basis of these relationships, it can be retained in a first approximation,

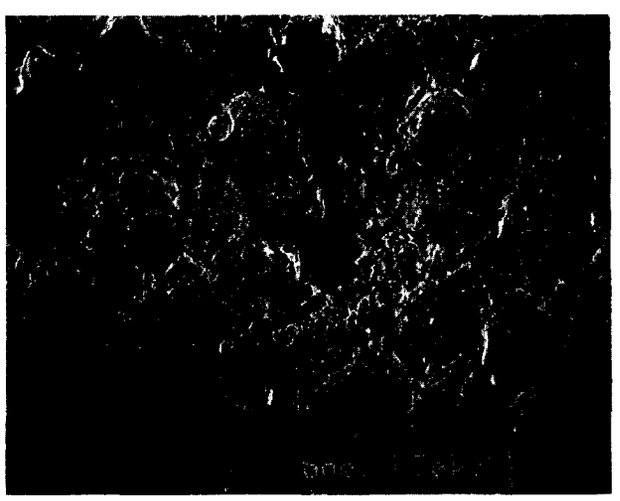

Fig. 7. Green microstructure of P2 powder pressed at 200 MPa, observed by SEM on fracture surface.

that the strength of a green body is related to the packing density, the particle diameter and the interparticle forces. It can be noticed that the JKR model,[20] elaborated on a brittle fracture base, takes also in account the defect size. Nevertheless the notion of defect in a granular material is difficult to define, especially in a granule, so this will not be taken into consideration here. Thus tensile strength is defined as the stress required to fracture a powder compact in simple tension, however these relationships remain useful to evaluate the resistance of a spherical granule under uniaxial compression.

In the case of the P1 powder, the intercrystalline binding generated during the synthesis is fully replaced by 'viscous' binding which depends on the nature of the polymer added. This permits a low breakpoint pressure and a visco-plastic behaviour, but requires some treatment of powder after synthesis.

The strength of P2 and P3 granules is only concerned with powder synthesis since no further treatment was conducted. As the crystallite sizes are the same, the two parameters that have to be considered to explain the difference in granule strength are the packing density and the nature of the intercrystallite forces. The packing density of the granules can be evaluated with consideration of the apparent density of the granules in the compacts. Galakchov[22] has proposed for slip cast green compacts, a method to obtain the apparent density of each powder unit, (aggregate, agglomerate,...), using the pore volume distribution. Indeed each peak of the pore volume distribution can be attributed to a powder unit, thus the apparent density of each unit can be calculated using the following expression:

$$\rho_{i+1} = \rho_i / 1 + \rho_i V_{i+1} \quad (1)$$

where ρ_i is the apparent density of the i^{th} order

unit, V_i is the specific volume of the pores contained in i^{th} unit in cm^3/g.

To obtain the granule density in compacted green samples, the applied pressure must be lower than the breakpoint pressure. This is, of course, to avoid any modification of intragranule porosity. With consideration of the compaction curves, compacts of P2 and P3 powders were obtained with pressures of 20 and 4 MPa respectively. Then Hg porosimetric measurements were conducted on these samples, but the intrusion pressure was limited to 280 MPa because of the fragmentation of the compacts with higher pressures. The pore volume distributions obtained at very low pressures (P < Py) shown a first peak located at large porosities. The pore volume of this peak can be connected with the intergranulate porosity. The pore channel sizes of this peak range from 0·04 to 4 μm for the P2 powder, and from 0·04 to 30 μm for the P3 powder. The first fraction of a second peak is observed, corresponding to intragranule porosities; the location of this peak is coherent with the pore distributions obtained with a compaction pressure of 100 MPa.

Two units in the powders are considered, the crystallites and the granules. Then from the previous expression, the two following expressions are used:

$$\text{apparent density of compacts: } d_o = \rho_g/1 + \rho_g V_{inter} \quad (2)$$

$$\text{first order units (granules) } \rho_g = \rho_o/1 + \rho_o V_{intra} \quad (3)$$

with V_{inter} and V_{intra} respectively the inter and intra-granules porosity. The tetragonal zirconia density (6·10 g/cm^3) was considered for the density of the crystallites ρ_0. The evaluation of the specific porosities (V_{inter} and V_{intra}) and the apparent densities of the granules and the compacts at the different compaction pressures are summarised in Table 2. In the case of low compaction pressures (P < Py), granule densities were obtained using expression (2) since V_{intra} was not measurable. From these calculations it appeared that the granule densities of the P2 and P3 powders were very close (2·168 and 2·095 g/cm^3 respectively). The granule densities are also given for high compaction pressures. Although the use of the term granule is arguable as P > Py, it can be seen from Table 2 that the reduction of intra-granule porosity with compaction pressure is more efficient in P3 granules. At P < Py, the more important inter-granule porosity of P3 compacts compares to P2, confirms that the lower tap density of P3 is due to inadequate granule sizes.

Consequently the granule strength appears to be essentially dependent on the intercrystallite forces induced during powder synthesis. Three kinds of bonds can be considered here: (i) Van der Waals, which concern all fine powders, (ii) solid bridge chemical bonds which may appear during a high temperature calcination step, because of initial sintering, and (iii) Zr–O–Zr chemicals bonds induced on drying after aqueous washing.[23] The Van der Waals bonds are weak and will lead to the formation of soft granules. On the other hand, the two others are strong. It has been extensively reported that hard granules are produced because of these bonds with direct sol–gel process. It can be assumed that solid bridge formation is avoided because of the low calcination temperatures used for powder synthesis. As a consequence of the difference in synthesis processes, we can suppose that Zr–O–Zr chemical bonds are more common in the P2 powder, and Van der Waals forces in the P3 powder.

Figure 9 displays the dilatometric results obtained from P1, P2 and P3 samples showing green densities of 55%, 47% and 49% TD, respectively. P2 and P3 samples exhibited lower starting sintering temperatures than that of sample P1 (1025°C for P1, 875°C for P2 and 950°C for P3): this is due to their smaller crystallite size and related higher reactivity. It can also be observed that the lower the green density, the higher the total shrinkage at 1500°C (18% for P1 <20% for P3 and <22·5% for P2). The high shrinkage may play a negative role in the industrial application of these powders, especially in the case of their utilisation in large and complex die designs.

A complete densification was achieved for the P1 sample at 1500°C and its microstructure was

Table 2. Specific pore volumes and apparent densities in P1 and P2 compacts obtained with different pressures

Compaction pressure (MPa)	*Intra-granules pore volume (cm^3/g)*		*Inter-granules pore volume (cm^3/g)*		*Granule apparent density (g/cm^3)*		*Compact apparent density (g/cm^3)*	
	P2	*P3*	*P2*	*P3*	*P2*	*P3*	*P2*	*P3*
$P < P_y$	—	—	0·181	0·575	2·168	2·095	1·557	0·951
100	0·230	0·257	0·135	0·020	2·540	2·377	1·891	2·267
200	0·243	0·209	0·061	0·010	2·456	2·678	1·137	2·607
400	0·142	0·123	0·014	0·008	3·270	3·481	1·131	3·381

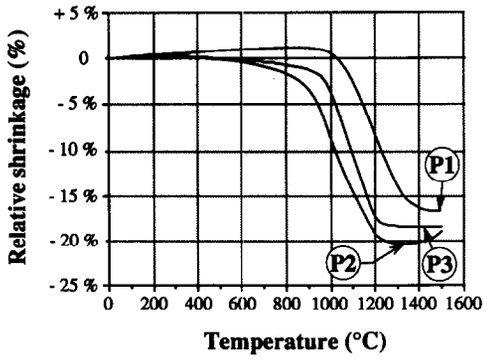

Fig. 9. Dilatometric curves of P1, P2 and P3 samples.

characterised by a uniform submicronic grain size (Fig. 10).

Above 1350°C a 'de-densification' step was observed on the dilatometric curve of the P2 sample. The same, but to a lesser extent, was also noticed on the P3 sample. This phenomenon, characterised by a more or less evident rise on the curves, may be ascribed to a secondary recrystallization, which leads to an abnormal grain growth[24-25] (Fig. 11). In addition, differential sintering phenomena are observed in the P2 sample, leading to circumferential cracks around residual granulates (Fig. 12). Then full densification is impeded by these large pore-like cracks.

So the dilatometric results can be well correlated to the green state: particle arrangements of poor quality in the green parts conducted to a shrinkage curve with a very low slope. In such a case, although the starting sintering temperature is low, the ending sintering temperature is very high because extensive grain growth must arise to allow further shrinkage, as soon as pores larger than the grains are present in the arrangement. At the extreme a total densification will not be possible since abnormal grain growth occurs before which residual porosities disappear by normal grain coarsening. Indeed during abnormal grain growth some pores will be trapped within grains before they have the opportunity to disappear and in noncubic crystalline structures a new class of pores can appear due to the fact that some grains can grow to sizes very much larger than the average particle size.

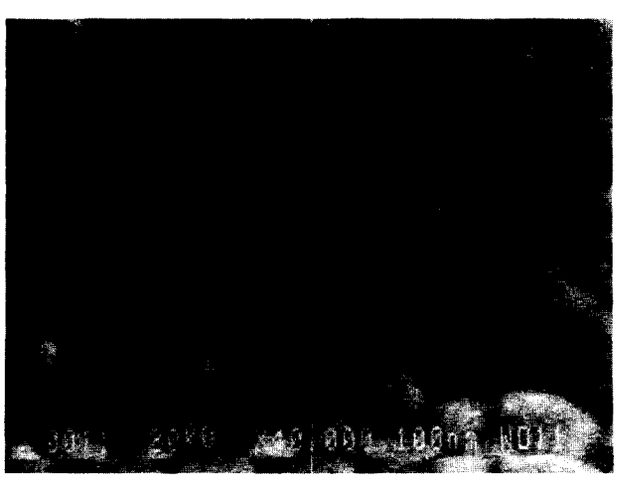

Fig. 10. Microstructure of P1 sample densified 2 h at 1500°C.

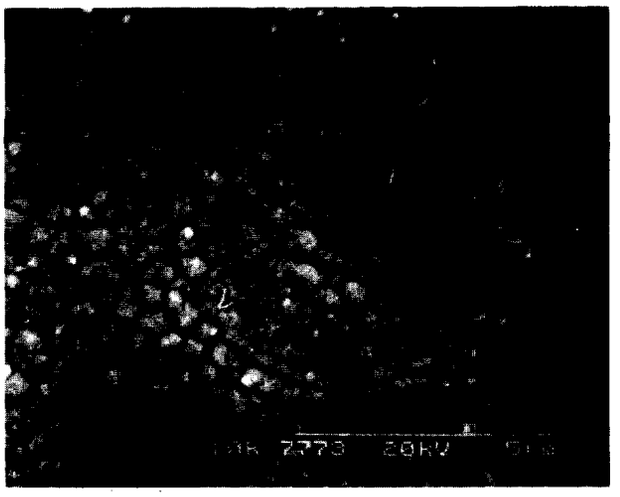

Fig. 11. Abnormal grain growth observed on P2 and P3 samples densified for 2 h at 1500°C.

To determine appropriate sintering conditions, powder pellets were heat treated at 1350°C and 1500°C. The final densities were evaluated and for each sample the relative density was determined on the ground of phase, (monoclinic and tetragonal) composition measured by X-ray diffraction analysis: Table 3 lists the results of XRD and density determinations.

Table 3. Dense material characteristics

Powder	*Sintering temperature (°C)*	*Monoclinic phase (%)*	*Apparent density (g/cm^3)*	*Density in % of theoretical*
P1	1350	0	6·05	99·1
	1500	0	6·05	99·1
P2	1350	0	5·92	97·1
	1500	0	5·35	97·7
P3	1350	42	5·85	99·8
	1500	74	5·62	98·8

Fig. 12. Circonferential cracks due to differential sintering of residual agglomerates observed on P2 densified sample.

For the P2 sample, the density values of the sintered bodies are in agreement with dilatometric curves, and confirm the 'de-densification' phenomenon observed at the higher temperatures. Up to a sintering temperature of 1350°C, no abnormal grain growth is observed in this material, and the grain size stays below 0·1 μm.

In the P3 sample, a density near the theoretical value is reached after sintering to 1350°C, although a high monoclinic zirconia content is present. At 1500°C, the monoclinic zirconia content is largely due to grain growth. This is ascribed to the low yttria content of the P3 powder (2 mol %). However, this is not the case for the P2 powder which contains 3·6 mol % of yttria. As a consequence the Y_2O_3 amount of the P3 powder is too low with respect to the microstructure to avoid the tetragonal–monoclinic transformation during cooling.

4 Conclusions

Each different synthesis process provides specific characteristics to the zirconia powder. The influence of these characteristics on application properties was studied. This allows us to evaluate the potential of sol–gel processes developed here. The significant parameters can be classified as:

— the fineness and reactivity of crystallites

— crystallite arrangement characteristics

— chemical composition

Concerning the first point, sol–gel processes usually allow a great improvement in reactivity. Consequently the starting sintering temperature is lowered.

Nevertheless crystallite size reduction is not a sufficient condition to achieve complete densification. To obtain an end sintering temperature very close to the starting sintering temperature, i.e. full densification at a low temperature, it is necessary to consider the second point and to realise parts with a green state of high quality. For fine powders it is well known that granulation is imperative. Sol–gel process offer many ways to obtain granulates. Two different methods have been tested here and can be summarised as follows:

Granulate sizes

The best results are obtained with large granules, typically 50–100 μm diameter. With minor changes to the process it will be possible to increase the granule diameters of the two sol–gel powders. Tap densities of the same order as the control powder P1 are expected.

Granulate morphology

To ensure good flowability of the powder and an easy reorganisation of the granules during compaction, a spherical geometry is needed. This condition is easily obtained with sol–gel processes. This is the case in the two methods studied here.

Granulate density

Sol–gel processes are able to produce better granules than the classic powders which are frequently spray dried: spray drying has the disadvantage of producing granulates with cavities, so that the tap density and the quality of the reorganisation during compaction are affected.

Granulate strength

The control of the granulate strength is the critical part of sol–gel processes, since industrial processes usually require compaction pressure under 100 MPa. The process used for P3 powder production allows us to produce low strength granules, by suppression of the detrimental chemical bonds Zr–O–Zr between crystallites. This results in compaction curves close to the control. But as it is not possible to use organic additives (a high temperature calcination is necessary after the granulation step), the production of sol–gel granules still encounter two major problems. Firstly, it is difficult to control the strength of the green parts, which is a major problem for industrial products. Secondly, the granule destruction arises by fragmentation instead of plastic deformation, and this is expected to be less efficient for porosity reduction. A process which solves these two problems, without any further treatment after granulation, have to be found, since this constitutes the major interest of sol–gel processes.

Chemical composition

The final point concerns the chemical composition of the powders. This point is of major importance since it has a great influence on the microstructure and phase composition of zirconia products. Sol–gel processes present the advantage of offering a better control of the chemical purity and homogeneity. For example, the stabilising agent distribution can be expected to be more homogeneous. But, as it can be seen with the P3 powder, the stabiliser amount must be optimised with respect to the final grain size.

The Packing Density of Binary Powder Mixtures

Jingmin Zheng,[a] William B. Carlson & James S. Reed

New York State College of Ceramics, Alfred University, Alfred, New York, USA

(Received 13 July 1993; received in revised form 10 June 1994; accepted 15 July 1994)

Abstract

The maximum particle packing density in a binary powder system can be predicted by the Furnas model. The packing density is lower when the size ratio of coarse particles to fine particles decreases, and is also governed by the volume fraction of coarse or fine particles. Here an empirical equation is derived which describes the packing density as a function of the initial packing efficiencies of particles, the particle size ratio, and the volume fraction variations of the system.

Introduction

The importance of particle packing in ceramic processing is generally appreciated because of its influence on the unfired mechanical properties, the shrinkage and density on sintering, and the microstructure and properties of the final ceramic product. A high maximum packing density* is directly dependent upon the particle size distribution. Many studies have demonstrated the importance of the particle size distribution to obtain dense packing.[1–14] For a two component mixture of coarse and fine particles, the ideal packing density is predicted by the Furnas model[1,3,4] (and sometimes, the Westman and Hugill model[2]), (Fig. 1). The specific packing volume is defined as the reciprocal of the packing efficiency. According to the Furnas model, the theoretical maximum packing efficiency, PE_{max}, of a mixture of coarse and fine particles is:[14]

$$PE_{max} = PE_c + (1 - PE_c)PE_f \quad (1)$$

or

$$PE_{max} = 1 - \phi_c\phi_f \quad (2)$$

where PE_c and PE_f are the packing efficiency of the coarse and fine particle fractions, respectively, and $\phi = 1 - PE$, is the interstitial pore fraction of packed particles of a single size (fine or coarse particles only). Notice that the ratio of two terms of the right side of Eqn (1) is the volume ratio of the coarse to the fine particles to achieve the maximum packing efficiency.

The packing mechanism of the Furnas model is such that smaller particles are introduced and distributed to the interstices of larger packed particles so that the porosity is reduced. The calculation of the ideal packing density is based on the assumption that the size ratio of coarse particles to fine particles is infinitely large. It has been observed in practice by many researchers that when this particle size ratio decreases, the packing efficiency of mixed powders is lower than that predicted by the Furnas model (the Westman–Hugill diagram, Fig. 1). In order to understand the reason for those packing density deviations, Messing and Onoda[15,16] developed a packing model on the notion that the Furnas model may apply locally, but the different volume fractions of coarse and fine particles through the mixture lead to reductions in the overall packing density. Zok and Lange[17] recently studied the effects of the surface of inclusions (the coarse particles) and the contacts of inclusions on the overall packing density. This theoretical analysis was on the scale of the dimension of the fine particles. However, the results from that study are not convenient for the calculation of packing density of a binary particle system with a variable volume fracion, particle size ratio, and different initial packing efficiencies.

Various empirical equations have been developed to predict the particle packing density of a binary system,[18–21] Some equations are either too complicated to apply,[18] or only consider the initial packing efficiency as a constant.[19] Most work in this research field has been reviewed recently.[22]

In this paper, an empirical equation is developed, which takes into account the particle size ratio, the volume fraction of powders, and their initial packing efficiencies. Constants in the proposed equation are adjusted to fit experimental data, which makes predicting the packing density of the mixture more accurate.

*Maximum packing density is used in a macroscopic sense; particles are assumed to be randomly arranged. The term packing density and packing efficiency are used interchangeably.

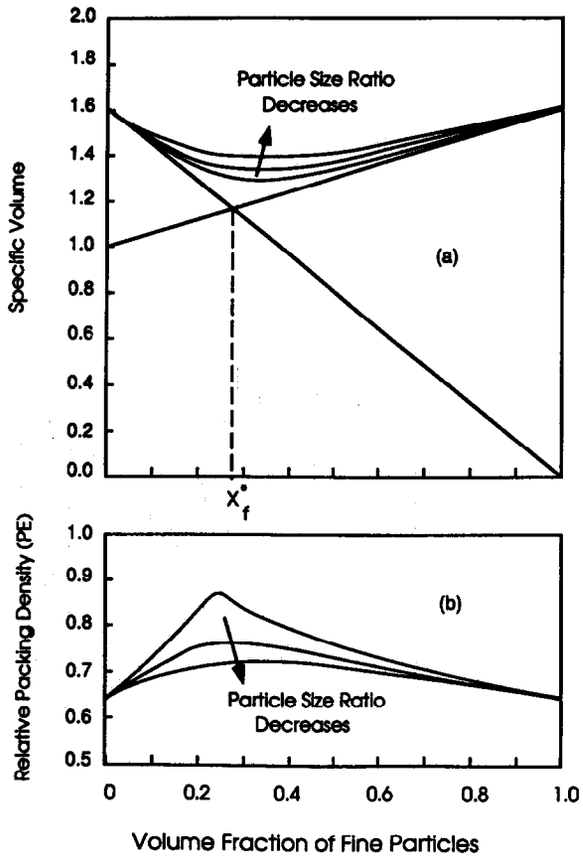

Fig. 1. The Furnas model. Theoretical variation of packing volume for the packing of smaller particles among coarser particles. (a) The Westman–Hugill plot of the Furnas model; straight lines correspond to ideal packing when the size ratio is infinite, and curved lines indicate typical behavior. (b) The Furnas model plotted as the packing density versus particle volume fraction. Figure 1(a) is preferred because the straight lines are easy to draw and their physical meaning is apparent.[15] X_f^* is the volume fraction of fine particles to achieve the maximum packing density.

Derivation of the Equation

For a coarse–fine binary particle size composite, the maximum packing density is predicted by the Furnas model (eqn (1)). The terms on the right side of eqn (1) are the volume fractions of coarse and fine particles, respectively. Starting with coarse powders and adding fine powders, the initial packing density is equal to the first term: the second term indicates the maximum possible density increase when the fine powder is added. For a real binary mixture, the maximum packing density increase should also be a function of the volume fraction and the size ratio of coarse to fine particles. Hence, we propose the following equation to calculate the packing density of a binary mixture (PE_{mix}):

$$PE_{mix} = PE_c + (1 - PE_c)PE_f F_1(X_f) F_2(R) \quad (3)$$

where F_1 is a function of the volume fraction of fine particles, X_f; F_2 is a function of the size ratio of coarse particles to fine particles, R (average particle size ratio if the pure coarse or fine particles are not exactly monosize particles). It is seen, from Fig. 1, that F_1 must be zero when $X_f = 0$ or 1, and F_1 would reach its maximum when $X_f = X_f^*$. (X_f^* is the volume fraction of the fine particles at which maximum packing density is achieved). Figure 1 also indicates that F_2 must be 0 when the size ratio is 1, and F_2 is 1 when the size ratio is infinite.

For solutions to eqn 3 the functions F_1 and F_2 must be assumed or determined.

Table 1. Volume fractions of coarse and fine particles calculated from the theoretical Furnas model

Packing efficiency	*Volume fraction*	
$PE_c = PE_f$	X_c	X_f^*
0·6	0·714	0·286
0·5	0·667	0·333
0·4	0·625	0·375

Selection of F_1

To select F_1, a realistic X_f^* value must first be determined. Table 1 lists the theoretical value of X_f^* calculated from the Furnas model with the assumption that $PE_c = PE_f$. For spherical-like monosize particles, the packing efficiency for random packing is around 0·6; and hence, from Table 1, $X_f^* \approx 0{\cdot}3$. Table 1 shows that X_f^* increases slightly with a decrease of the packing efficiency value for monosize particles. We have also observed that measured data from previous research[1,2] show that as the particle size ratio decreases, the X_f^* value tends to increase slightly. In most cases, the X_f^* is between 0·3 to 0·4.

Bearing this value in mind, F_1 is arbitrarily chosen as:

$$F_1(X_f) = |e\ X_f \ln X_f|^{C_1} \quad (4)$$

where e is the base of a natural logarithm and C_1 is a constant. F_1 versus X_f with different C_1 values are plotted in Fig. 2. It is seen from Fig. 2, that the curve of this equation meets the required criteria, i.e. it is zero when X_f equals 0 or 1, and reaches the maximum when X_f is between 0·3 to 0·4.

It is also seen from Fig. 2, that the constant C_1 affects the shapes and the curvature of the curves. The procedure to determine C_1 is to assign different C_1 values into function F_1; then substitute F_1 and F_2 into eqn (3) and use the data from eqn (3) to plot the Westman–Hugill diagram. The C_1 giving the best match to the experimental data is then selected.

After comparing C_1 values for different binary systems, it was found that by taking C_1 as a function

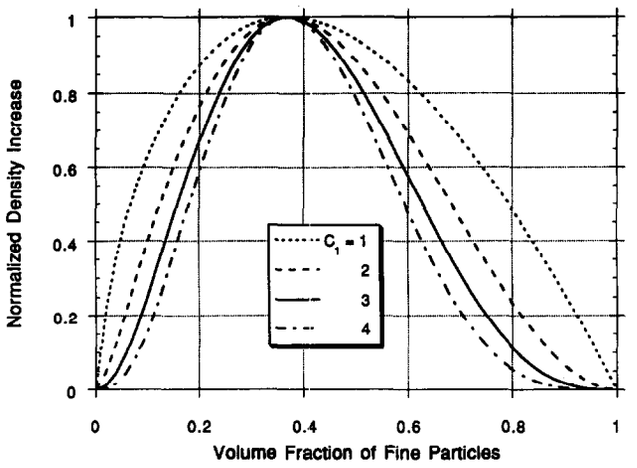

Fig. 2. Normalized packing density variation F_1 as a function of volume fraction of fine particles, X_f. F_1 is zero when X_f equals 0 or 1; F_1 is maximum when X_f is between 0·3 to 0·4. Value of the constant, C_1, alters the shape of the curves.

of PE_c, instead of a constant, a better fit was obtained. The function is:

$$C_1 = \frac{5}{4PE_c} \tag{5}$$

The fact that C_1 is a function of PE_c is actually expected because the curves in the Westman–Hugill diagram are slightly different for binary systems with different PE_c and PE_f values. The Westman–Hugill data approaches the theoretical maximum packing density, the straight lines in Fig. 1(a), when the particle size ratio is infinitely large. When the particle size ratio is small, the data is continuous. In Fig. 2, smooth curves for F_1 show that the empirical equation derived in this paper is only suitable for systems with small particle size ratios. A particle size ratio of 10 or lower is considered small. If the particle size ratio is larger than 10, the packing density of the system is more closely predicted by the theoretical model.

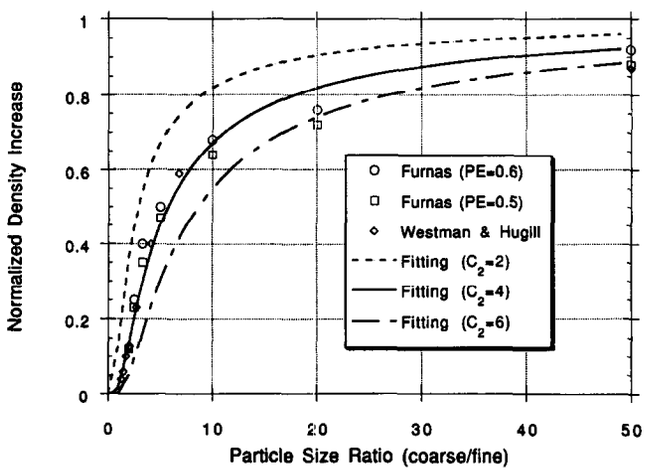

Fig. 3. Normalized packing density variation as a function of the articles size ratio for experimentally measured data and model. $C_2 = 4$ for best fit to measured data.

Selection of F_2

Function F_2 governs the increase of packing density as a function of the particle size ratio. It is seen that the maximum increase in packing density by adding fine particles to coarse, $PE_f(1 - PE_c)$, is a function of the initial packing efficiencies of coarse and fine particles. In order to compare the effects of particle size ratio on the increase in packing density, F_2 is normalized by $PE_f(1 - PE_c)$. Hence, F_2 is usually less than 1 for a real binary powder system. Figure 3 shows the normalized maximum packing density increase versus the particle size ratio of previous researchers.[1,2] According to the distribution of these data, the fitting function F_2 is proposed as:

$$F_2 = \exp\left(\frac{-C_2}{R}\right) \tag{6}$$

where C_2 is a constant. It is seen, from Fig. 3, that a smaller C_2 leads to a more rapid increase of the F_2 value when the particle size ratio increases. It is also seen that when C_2 equals 4, the curve most closely fits the measured data.

After empirically obtaining the functions of F_1 and F_2, eqn (3) is combined with eqns (4), (5) and (6), to get the full descriptive equation for calculating the packing density of a binary mixture:

$$PE_{mix} = PE_c + (1 - PE_c)PE_f[e \cdot X_f \cdot \ln X_f]^{\frac{5}{4PE_c}} \exp\left(-\frac{4}{R}\right) \tag{7}$$

The specific volume of binary mixtures calculated from eqn (7) is plotted in Figs 4 and 5. The calculations are based on the assumption that in the binary mixtures $PE_c = PE_f$, and PE_f equals 0·6 and 0·5, respectively for Figs 4 and 5. It is observed from Figs 4 and 5, that the curves

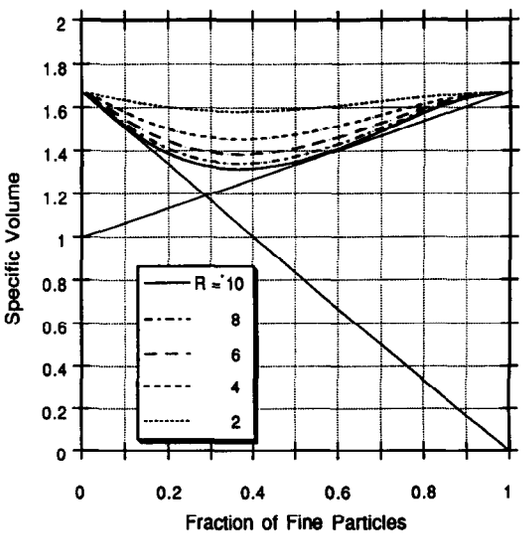

Fig. 4. Calculated specific volume versus particle size ratio using eqn (7). Initial packing efficiency $PE_c = PE_f = 0{\cdot}6$.

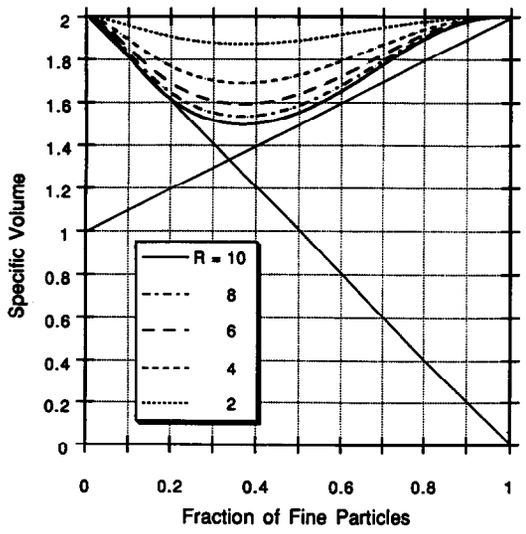

Fig. 5. Calculated specific volume versus particle size ratio using eqn (7). Initial packing efficiency $PE_c = PE_f = 0{\cdot}5$.

calculated by this empirical equation are generally similar to what is observed in practice, except that at a high volume fraction of fine particles, the calculated specific volume is slightly higher than that seen in practice. For example, if the volume fraction of fine particles is 0·8–0·9, in Fig. 5, the calculated packing density by eqn (7) could be about 2% lower than the measured one.

For a binary powder mixture $PE_c \neq PE_f$

For a binary powder system having $PE_c \neq PE_f$, eqn (7) can still be used when the volume of the coarse powders is dominant in the mixture. For a system in which the volume of fine particles is dominant, PE_f may be used as the first term in eqn (7), instead of PE_c. Figure 6 shows the experimentally measured specific volume, as well as the values calculated by eqn (7), using both PE_c or PE_f as the first term. This shows that when the volume fraction of fine particles is less than 0·3, the calculated data using PE_c fits the experimental data. When the volume fraction of fine particles is larger than 0·5, the calculated data using PE_f fits the experimental data. If the volume of fine particles is between 0·3 to 0·5, the experimental data is between the two calculated values.

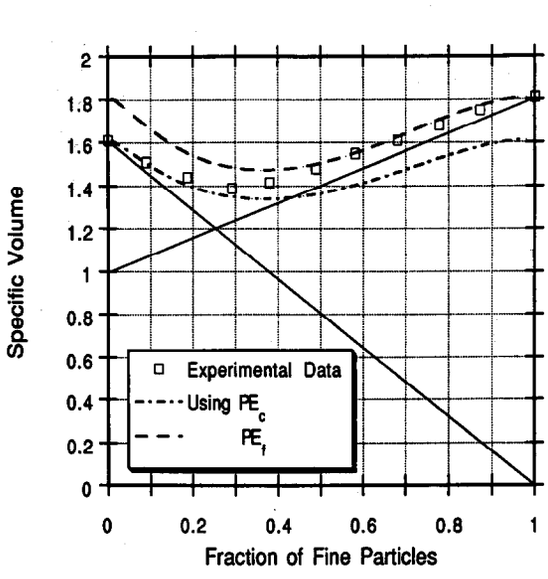

Fig. 6. Calculated specific volume versus particle size ratio using both PE_c or PE_f in the first term of eqn (7) when PE_c is not equal to PE_f.

Summary and Conclusion

The Furnas model describes the ideal particle packing behavior of a binary powder system. The packing density, however, is lower when the size ratio of coarse particles to fine particles decreases. Packing density also depends on the volume fraction of coarse or fine particles. An empirical equation (eqn (7)) was derived to estimate the packing density of a real binary system. This equation, which takes into account the particle size ratio, the compositional variations of the system, and the initial packing efficiencies of particles as variables, enables one to easily predict the packing density of a binary particle system from its particle size ratio and volume fractions of coarse and fine particles.

Review

Environmental Degradation of Zirconia Ceramics.

Simon Lawson

School of Engineering & Advanced Technology, University of Sunderland, Sunderland SR1 3SD UK

(Received 5 August 1994; revised version received 2 February 1995; accepted 7 February 1995)

Abstract

This paper critically reviews the existing published experimental evidence for ageing mechanisms in zirconia ceramics. The first part of the paper is concerned with the material and environmental variables affecting the kinetics of the transformation. The current ageing mechanisms are presented and discussed and attention is drawn to the contradictions between the theories. Finally, techniques to retard or prevent the tetragonal–monoclinic phase transformation are presented.

1 Introduction

Partially stabilized zirconia (PSZ), and in particular tetragonal zirconia polycrystalline (TZP) ceramics have excellent mechanical properties such as bending strength and fracture toughness, which are associated with the tetragonal–monoclinic phase transformation around propagating crack fronts. However, a serious limitation to their use, e.g. as cutting tools for microsurgery,[1] is the phenomenon of poor, relatively low-temperature ageing resistance first observed by Kobayashi *et al.*,[2] where surface phase transformations occur and mechanical properties rapidly deteriorate. This phenomenon is widely documented in the literature although there are conflicting views as to the likely ageing mechanism.

Zirconia ceramics stabilized with yttria, ceria, calcia or magnesia are susceptible to various environments such as humid air, water vapour and other aqueous fluids over a temperature range of 65–500°C, but in aqueous solutions the effect is more catastrophic at lower temperatures and in shorter times. It should be noted that hydrothermal corrosion over the same temperature range has been observed in silicon nitride ceramics.[3]

During ageing the degradation of properties is associated with the transformation of metastable tetragonal crystals to the stable monoclinic structure.[4] It has been shown under certain circumstances that almost total strength recovery can occur when aged specimens are annealed, thus re-transforming the monoclinic grains back to the tetragonal phase.[5] It is therefore feasible to use Y–TZPs at higher temperatures or under thermal cycling conditions above the critical ageing temperature regime.

The tetragonal–monoclinic transformation during ageing can benefit certain types of Y–TZP due to the creation of a compressive surface layer of monoclinic phase on the ceramic.[6,7] This layer can, therefore, actually improve mechanical properties, although there is a narrow range between improvement and destruction of mechanical properties, as further ageing results in property deterioration.

The experimental observations on ageing have been summarised by Yoshimura[8] as follows:

1. The degradation proceeds most rapidly at temperatures of 200–300°C and is time dependent.
2. The degradation is caused by the tetragonal–monoclinic transformation accompanied by micro- and macro-cracking.
3. The transformation progresses from the surface to the interior of the specimen.
4. Water or water vapour enhances the transformation.
5. A decrease in grain size and an increase in stabilizer content retards the transformation.

The main variables influencing the stability of the tetragonal zirconia grains are dealt with in the following section.

2 Experimental Observations

The experimental observations of hydrothermal degradation are divided into two main sections, the material variables, and the test conditions under which the zirconia ceramics are examined.

2.1 Material variables

2.1.1 Grain size

One of the principal factors in anti-degradation behaviour is the critical tetragonal grain size which is Y_2O_3 dependent. When the grain size exceeds a critical value for tetragonal phase retention, the monoclinic phase content increases with ageing, as shown in Fig. 1.[9] Tsukuma *et al.*[9] reported that grains larger than 1 μm exhibited a large amount of tetragonal–monoclinic transformation, together with a remarkable decrease in strength. On the other hand, grains of $< 0{\cdot}4$ μm showed no significant change of phase content and strength.

Below a critical tetragonal grain size, it is reported that no tetragonal–monoclinic transformation can occur. Watanabe *et al.*[4] estimated the critical grain size for tetragonal phase retention as a function of Y_2O_3 content as shown in Fig. 2. The critical grain size, D_c, increases from 0·2 to 0·6 μm as the Y_2O_3 content increases from 2 to 5 mol%. Tsubakino *et al.* however, found tetragonal grains with sizes lower than the critical grain size were also subject to ageing induced transformation.[10]

Winnubst and Burggraaf[11] found that a 3·5 mol% Y–TZP with a grain size of 0·1 μm was resistant to the ageing-induced phase transformation, although a 2 mol% Y–TZP with identical grain size was susceptible to the phase transformation. They also found yttrium enrichment at the surface which, therefore, resulted in depletion of the grain interior of yttrium. To compensate for the yttrium loss the critical grain size must be smaller than reported elsewhere for a uniform yttrium distribution. This could perhaps account for Tsubakino's results. Watanabe also found the presence of c-ZrO_2, and that the grain size and c-ZrO_2 content increases with increasing Y_2O_3 content, but the mean t-ZrO_2 grain size remained almost independent of Y_2O_3 content for a given sintering temperature.

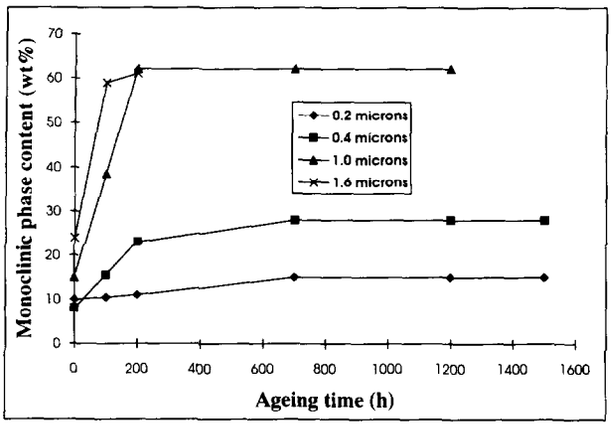

Fig. 1. Grain-size dependence of surface phase transformation on a 3Y–TZP aged at 230°C in air. (After Tsukuma *et al.*[9]).

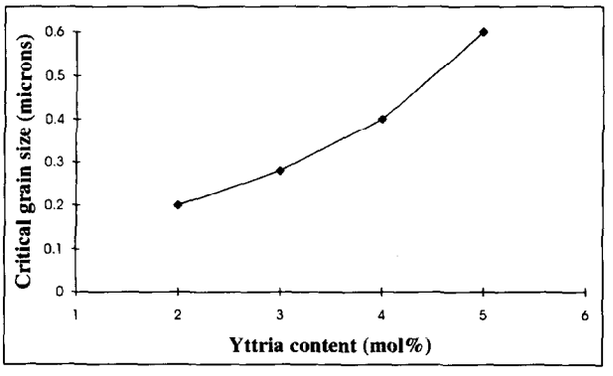

Fig. 2. Critical grain size as a function of yttria content when aged in air at 300°C for 1000 h. (After Watanabe *et al.*[4]).

There have been numerous reports on the stress-states of the tetragonal grains and grain-boundaries, and the effects of grain size and intergranular glassy phases on the residual stresses.[12–15] Schmauder and Schubert[12] used finite element analysis to determine the stress distribution in grains of different sizes. They found that for smaller grains the stresses created by thermal expansion anisotropy decrease more rapidly into the grain than for larger grains. Therefore at a fixed depth into a grain the average stress is higher for larger grains which are, therefore, less stable. Grain-shape also affects the stress levels. Spherical grains exhibit a homogeneous stress level, whereas faceted grains show singularities at the edges. Grains with rounded edges (i.e. when a glassy phase is present) have lower stresses than in perfectly sharp-edged grains. Mecartney[16] investigated the effects of glass content on the ageing resistance and found that materials with the greater glass content degraded the least. This infers that either the glassy phase reduces the residual stresses surrounding the grains, or the glassy phase protects the grain-boundaries from water attack by coating the grains.

Grain size control is normally exercised through the use of ultra fine powders and lowering the sintering temperature. The effect of calcination temperature on the powder crystallite size, the sintered grain size, and hence ageing properties has been investigated by Arai *et al.*[17] They found that of the combinations of calcination and sintering temperatures investigated, only compositions that had been calcined at the lowest temperature (800°C) survived ageing in air and water (200°C in an autoclave).

2.1.2 Stabilizer content

The level of stabilizing oxide also has a profound effect on ageing resistance. The higher the Y_2O_3 level, the more resistant to the ageing-induced tetragonal–monoclinic phase transformation are the Y–TZP ceramics,[9] and this is clearly demonstrated in Fig. 3 (the tetragonal grain sizes of all

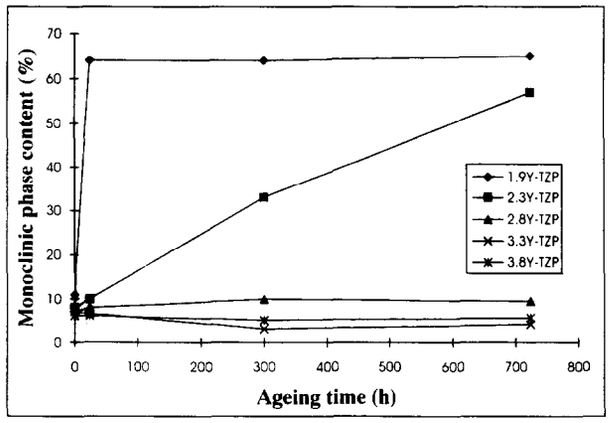

Fig. 3. Phase transformation dependence on yttria content for TZPs (grain size of ~0·4 μm) aged in air at 300°C. (After Tsukuma *et al.*[9]).

the specimens were almost the same ≈0·4 μm). The higher the Y_2O_3 content, then the larger the critical particle size for tetragonal phase retention. Watanabe *et al.*[4] found that as the Y_2O_3 content was raised from 2 to 5 mol%, then the critical particle size for tetragonal phase retention increased from 0·2 to 0·6 μm.

Sato *et al.*[18,19] showed that with increasing levels of Y_2O_3, increasing levels of *c*-ZrO_2 were formed, at the expense of the tetragonal phase. Upon ageing, the level of transformed *m*-ZrO_2 decreased with decreasing initial tetragonal content and in purely *c*-ZrO_2 (6 mol%) no monoclinic phase was detected after ageing. Therefore, they concluded that the monoclinic layer is formed from transformation of the metastable tetragonal phase and not the more stable cubic phase. Yoshimura *et al.*[20] confirmed that the monoclinic phase was a result of the tetragonal–monoclinic phase transformation, and in addition these monoclinic grains had an expanded lattice when compared to the initial lattice, whereas the cubic phase changed neither in content nor lattice parameter, therefore the transformation rate was proportional to the concentration of *t*-ZrO_2 on the surface. They also showed that the final amount of *m*-ZrO_2 decreased with increasing concentration of yttria, but the normalised transformation rate (normalised to the original tetragonal phase content) was almost constant, i.e. increasing the yttria content results in more cubic phase. Nakajima *et al.*[21] assumes that the saturated monoclinic fraction of each specimen is the transformed fraction of the metastable tetragonal phase under the test conditions. It should be borne in mind that the 'nontransformable' fraction of the tetragonal phase is actually *c*-ZrO_2 or *t'*-ZrO_2. Lawson[22,23] has shown that an increase in Y_2O_3 content (2–4 mol %) does not necessarily result in an increase in phase stability and can be detrimental to the ageing resistance of the zirconia.

It is usually thought that only Y–TZP ceramics exhibit the ageing phenomenon. However, Garvie *et al.*,[24] Swain,[25] Sato *et al.*,[26] Hecht *et al.*[27] and Drennan *et al.*[28] have shown that Mg–PSZs are also susceptible to hydrothermal degradation and exhibit the characteristic tetragonal–monoclinic phase transformation accompanied by a reduction in MOR, and Sato *et al.* observed the dissolution of Mg^{2+} ion in water above 200°C. Furthermore, Sato *et al.*[29] aged Ce–TZP in air and water vapour and found an increase in surface monoclinic content with <10 mol% CeO_2. They showed that the rate of transformation decreased with increasing CeO_2 content and smaller grain sizes, and that water vapour accelerated the transformation. The rate of change was slower than for Y–TZP, but the activation energies for transformation were almost identical. Leach and Khan[30] confirmed that <10 mol% CeO_2 exhibited the ageing-induced transformation. Tsukuma's[31] and Matsumoto's[32] results show that 12 mol% Ce–TZPs are highly resistant to the ageing-induced phase transformation. Pampuch *et al.*[33] fabricated Ca–TZP ceramics with sintered densities > 97% theoretical which were aged in air, water vapour (various temperatures) and in an autoclave (230°C). They found that samples of 4·3 mol% CaO sintered at 1300°C (grain size of 0·11 μm) were susceptible to the ageing-induced phase transformation. Samples sintered at lower temperatures were however resistant to degradation. This resistance is attributed to the smaller grain size, 0·09 μm.

Schmauder and Schubert *et al.*[12] showed that stresses caused by anisotropy of thermal expansion are Y_2O_3 dependent. By finite element analysis they showed that the higher anisotropy of the 2 mol% material resulted in higher shear stresses than 3 mol% materials. These stresses are shown schematically in Fig. 4. This figure shows that the stresses in a protruding gram decrease very rapidly

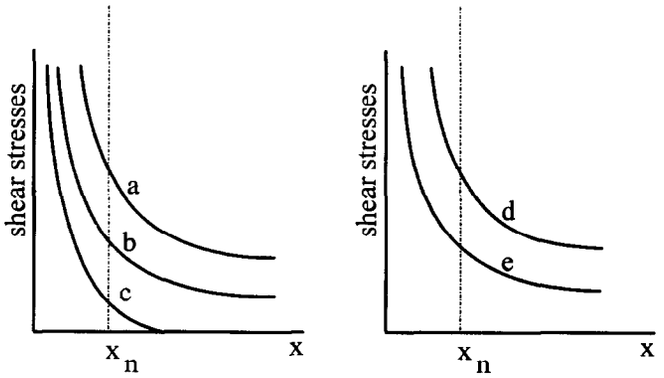

Fig. 4. Maximum shear stresses in the vicinity, *X*, of a grain corner for Y–TZPs. Curve (a) an included grain, 2 mol% Y_2O_3 (position 1 in Fig. 13); (b) an included grain, 3 mol% Y_2O_3 (position 1 in Fig. 13); (c) a protruding grain (position 4 in Fig. 13); (d) a large included grain; (e) a small included grain. (After Schmauder & Schubert[12]).

to zero, that is, these grains relax simply by changing their shape. Also, the stresses in large grains were found to be higher than those in smaller ones. The authors correlate the difference in free energy with various stresses (such as undercooling, residual and transformation stresses) and any increase in internal stresses will decrease the difference in free energy and hence reduce the activation barrier for transformation.

The Y_2O_3 content influences the free energy change of the t-ZrO_2 in two ways:

1. Undercooling is smaller for higher yttria contents,
2. Stresses due to thermal expansion anisotropy increase strongly with reduced yttria content.

Schmauder and Schubert also attach great importance to yttria distribution, and argue that inhomogeneous distribution is detrimental to the ageing resistance. They suggest the existence of a critical composition X_{cr}. For grains with a lower yttria content than X_{cr}, the stresses in the surrounding matrix will be so high as to cause micro cracking. Schubert's results suggest the critical composition X_{cr} for a 0·3 μm average grain size is between 2·2 and 2·8 mol% (4 and 5 wt%) Y_2O_3. It is obvious that the critical composition, X_{cr} will also be controlled by the average grain size of the zirconia ceramics.

The importance of the yttria distribution on stability is shown in Fig 5. The narrow grain size distribution can be achieved by low-temperature sintering. However, a narrow yttria distribution can only be reached with a homogeneous powder. Wang and Stevens[6] also state that a chemically homogeneous TZP will lead to few nucleation events and therefore less opportunity for transformation initiation. Ruhle *et al.* examined and compared commercial Y–TZP ceramics in the TEM[34] and suspected that a higher Y_2O_3 content and thinner grain-boundary layer may retard transformation. They suggest that either a stress corrosion mechanism is in operation at the specimen surface, or a surface-nucleated isothermal martensitic transformation. It is noticeable from their results that the powder which has the greatest inhomogeneous yttria distribution, is readily transformable, and is more resistant to the ageing-induced phase transformation than the other powders evaluated, and has recently been demonstrated by Lawson *et al.*[22,35] and Burger *et al.*[36]

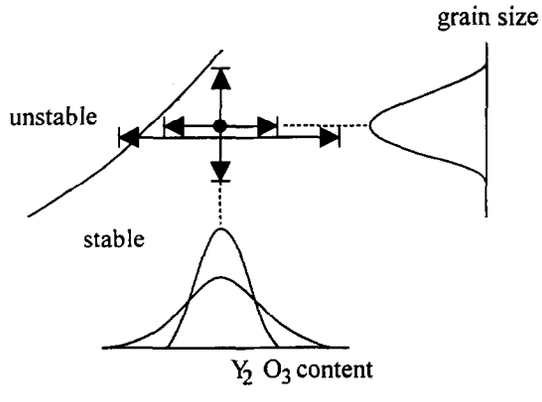

Fig. 5. Schematic of the relationships between grain size and yttria distribution, showing a stable and an unstable region. (After Schubert & Petzow[15]).

Cubic stabilized zirconia (8 mol% Y_2O_3) has been widely accepted as ageing resistant, however recent results obtained by Gibson *et al.*[37] show that such a fully cubic stabilized zirconia ceramic aged in boiling water for 24 h exhibited degradation and a phase change from the stable cubic phase to the monoclinic phase. This could possibly create problems on the use of fully stabilized zirconia in fuel cell applications.

2.1.3 Composition

The composition of the base powders is also of importance to the ageing behaviour of Y–TZP ceramics. Comparisons of commercial powders[34–36,38–41] have been made and the results show that test pieces of equivalent stabilizing oxide, behave differently under hydrothermal conditions. It is an accepted view that a homogeneous yttria distribution and small grain size distribution lead to TZPs with superior anti-degradation performance[12,42] but recent results challenge this view[35,36]

Differences in anti-degradation behaviour occur due to the technique used for incorporating yttria, i.e. co-precipitation, co-coating or milling. The purity of base materials can be of importance and Lange *et al.*[43] investigated the effects of SiO_2 impurities. They found that the intergranular glassy phase does not play a major role in the ageing process, so disproving their initial hypothesis that ageing behaviour is a result of a stress-corrosion type reaction (water vapour reacting with a glassy silicate grain-boundary phase).

Mecartney[16] investigated the effects of intergranular glassy phases on the sintering and mechanical properties of 2·5Y–TZP. She states that the 'omnipresent' glassy phase is due to contamination from two sources: SiO_2 from the powder precursor ($ZrSiO_4$) and SiO_2 and Al_2O_3 from milling media. Mecartney found that an increase in glassy phase content improved the ageing resistance. This behaviour was accounted for by a reduction in the thermal expansion mismatch stresses, and the rounding of grains, thus eliminating the stress concentrations associated with the corners of sharply faceted grains.[12]

Masaki *et al.*[44] state that high purity powders are effective transformation inhibitors. They also conclude that impurities which do not form solid solutions with ZrO_2 or additives such as TiO_2,

Fe_2O_3 and Al_2O_3 can cause strain and thermal stresses which act as transformation nucleation points along grain-boundaries. Masaki goes on to say:

> *"On the other hand these oxides [TiO_2, Fe_2O_3 and Al_2O_3] act as sintering aids, and hence different results will occur depending on their amount. This problem is important subject to be studied in the future."*

2.2 Test conditions

2.2.1 Ageing temperature

It has been found by many researchers that low temperature ageing occurs within the temperature range 65–500°C,[19] with the maximum rate at ≈250°C, and typical results are shown in Figs 6 and 7. The figures show that mechanical properties decrease[45] over the critical temperature range and are accompanied by an increase in the surface monoclinic content.[46]

The temperature limits of the ageing phenomenon are described by Sato *et al.*[47] The upper limit is due to thermodynamic constraints (stabilizer levels, grain size and thermal anisotropy), and the lower limit is due to the kinetics of the transformation. Kim and Jung[13] attribute the lower temperature limit to the onset of thermally activated dipole reorientation.

Sato *et al.*[46] found that the critical temperature below which *m*-ZrO_2 was formed decreased with decreasing sintering temperature. This may be due to the effect of the surface energy of the smaller grains; the resistance to the phase transformation increases with decreasing grain size. Kim and Jung[13] deliberately added destabilizing oxides (Ta_2O_5 and Nb_2O_5 which have little effect on the grain size) to 3Y–TZP in order to study the kinetics of ageing-induced phase transformations. They found that increasing destabilizer levels from 0 to 1·5 mol% increased the monoclinic content and raised the upper temperature limit for no transformation to occur from 250 to 500°C, the lower temperature limit being 80°C regardless of composition.

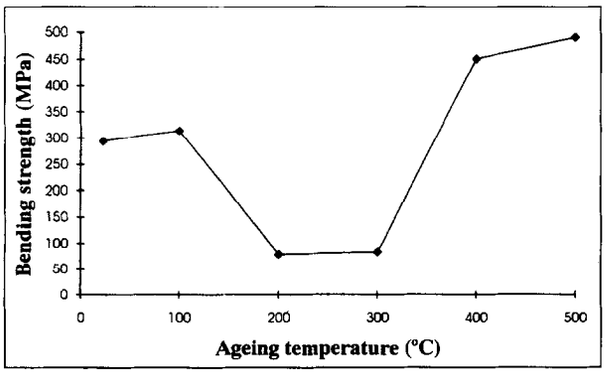

Fig. 6. Relationship between the ageing temperature and bending strength of PSZ ceramics aged in air. (After Miyazawa *et al.*[45]).

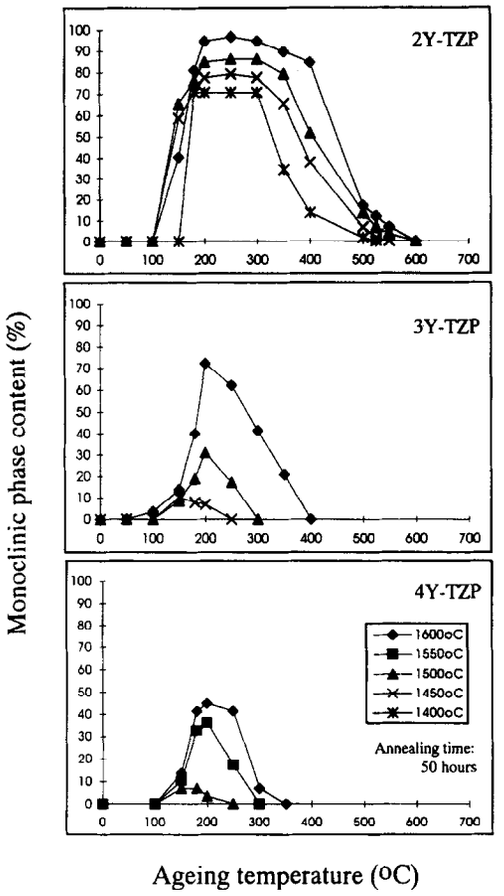

Fig. 7. Relationship between the amount of surface monoclinic phase and the ageing temperature, for a range of Y–TZPs sintered from 1400 to 1600°C and aged for 50 h in air. (After Sato & Shimada[46]).

2.2.2 Test environment

Ageing environments used to study the effects of low-temperature degradation in zirconia ceramics vary from the relatively mild, ageing in humid air (for periods in excess of 3 years[48]), to the much more aggressive autoclave conditions.[34] Generally the autoclave contains water, is heated to temperature (and corresponding pressure) and the test undertaken. The first reported autoclave results were obtained by Nakajima *et al.*[21] who aged a range of Y–PSZs in water from 100 to 180°C. At 180°C the saturation phenomenon was observed in < 5 h. They also dipped the Y–PSZ specimens into sulphuric acid, nitric acid, and caustic soda and found that the phase transformation increased with dipping time.

Sato *et al.*[47] aged specimens in air and in water vapour, and concluded that the water vapour accelerated the rate of reaction, but did not change the reaction equilibrium. The water vapour pressure was also altered and it was found that the monoclinic content increased with increasing vapour pressure. They also aged specimens under

a vacuum and they found that only a trace of monoclinic phase was formed. Sato *et al.*[19] also examined the effect of ageing in various solvents. It was concluded that aqueous solutions and non-aqueous solvents with a molecular structure containing a lone-pair electron orbital opposite a proton donor site also accelerates the tetragonal–monoclinic phase transformation.

The effect of water vapour pressure was investigated by Sato and Shimada[49,50] who found that as the vapour pressure was increased, then the rate of transformation also increased, but the saturation level remained constant. Also, ageing only occurred in water vapour and ammonia gas and not at all in vacuum or carbon dioxide atmospheres. Yoshimura *et al.*[51] investigated the effects of high pressure water (5 to 100 MPa) on the ageing behaviour, and found that transformation proceeds quicker under increasing pressure and over a greater temperature range than for lower pressures.

Perhaps the most interesting observation on the effects of ageing atmosphere was seen by Kuroda *et al.*[52] and is shown in Fig. 8. A sample was aged at 300°C in dry air for 24 h, then subsequently aged at 300°C for 72 h in a dynamic vacuum. The resultant profile (profile 4) was very similar to the one obtained for 96 h at 300°C in dry air (profile 2). Yet when they aged samples in a dynamic vacuum at 300°C they effectively saw no transformation. Therefore, once the transformation had been initiated by the water vapour, autocatalytic propagation then occurs without further chemical attack required.

There have been numerous studies on the effect of *in vitro* and *in vivo* environments on the ageing resistance of Y–TZP. Garvie *et al.*[24] aged Mg–PSZ in Ringer's solution and found that there was a slight decrease in strength and MOR. Their *in vivo* experiments showed that there had been no degradation after 6 months. Drummond found that YSZ ceramics aged in water, saline, and Ringer's solution at 37°C gave a reduction in strength with ageing time,[53] and that autoclaving in water slightly reduced the strength of Mg–PSZ.[54] Thompson and Rawlings found that ageing in Ringer's solution promoted phase transformation and MOR decrease with TZP and ZTA materials.[55]

Surprisingly, there is little data available on the effect of ageing on the wear behaviour of zirconia which is clearly of commercial significance. Preliminary results obtained at the University of Sunderland[56,57] clearly show that wear tests undertaken on aged material exhibit enhanced wear rates.

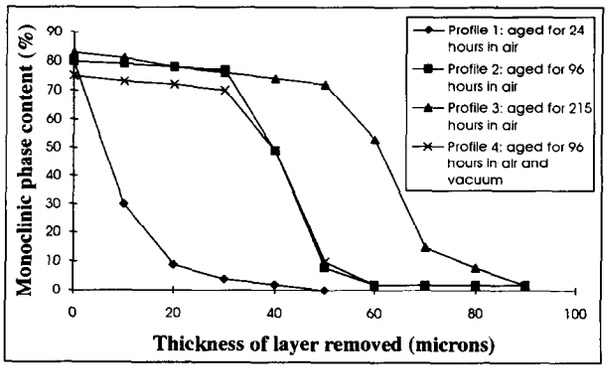

Fig. 8. Relationship between the amount of monoclinic phase and thickness of transformed layer removed for a 2Y–TZP aged in air or vacuum at 300°C. (After Kuroda *et al.*[52]).

3 Ageing mechanisms

There are many conflicting and confusing mechanisms for modelling the ageing behaviour of Y–TZP. Ageing observations have been explained using various mechanical and chemical degradation mechanisms. In the former, stress corrosion cracking of the amorphous intergranular glassy phase or of the t-ZrO_2 grains has been considered, whilst in the latter, the role of water has been suggested to form OH^- by the chemisorption at the surface of Y–TZP grains,[19] or to form $Y(OH)_3$[14,43] perhaps leading to the depletion of yttrium.[43] Part 2 of this paper will present a new ageing mechanism that accommodates all of the experimental observations.[58] The most significant ageing mechanisms are described in the following sections.

It is important, however, to firstly discuss the nature of the monoclinic layer and its kinetics. Tsukuma *et al.*[9] found that the transformation proceeds from the grain boundaries to the grain centres with time. He also suggests that the surface tetragonal grains are more unstable than those in the bulk. Therefore, thermal stability is dependent upon the surrounding grains. However, Schmauder and Schubert[12] observed that unconstrained surface grains were resistant to the ageing-induced phase transformation.

Miyazawa *et al.*[59] polished away the transformed surface layer and measured the monoclinic content with penetration depth for various samples. They found that the monoclinic content decreases with depth from the surface and that penetration depth increases with ageing time as shown in Fig. 9.

These results suggest that there is a gradual decrease in the monoclinic content with depth into the sample. However this is not the case, as the transformed layer has a fixed saturation level[21] dependent on the initial tetragonal and cubic contents of Y–TZPs. Optical microscopy clearly shows that there is a distinct transformed layer boundary with the tetragonal bulk material as shown in Fig. 10[60].

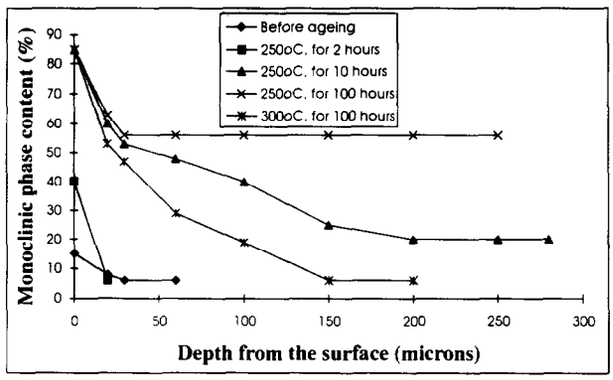

Fig. 9. Relationships between the amount of transformed monoclinic phase as a function of distance from the sample surface for a 5Y–PSZ aged in air. (After Miyazawa *et al.*[59]).

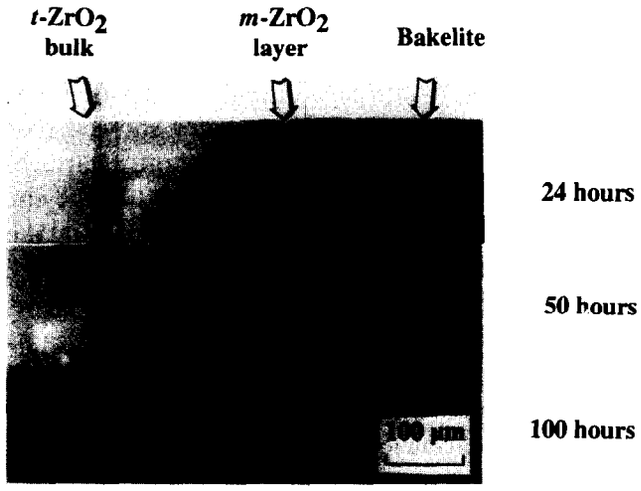

Fig. 10. Optical micrograph showing the growth of the surface monoclinic layer with ageing time for 2·5Y–TZP aged at 180°C in an autoclave containing superheated water (1MPa pressure). (After Lawson *et al.*[22]).

Tsubakino *et al.*,[10,61] Lawson[22] and Zhu *et al.*[62,63] showed that the relationship between the amount of transformation and the ageing time can be expressed by the Johnson–Mehl–Avrami equation:

$$f = 1 - e^{-bt^n} \quad (1)$$

where f is the transformation fraction, t is the time, and b and n are constants.

The value of n obtained was 0·7–1·0 irrespective of grain size or ageing environment. They also show that cracks accompanying the transformation propagate along grain-boundaries. Therefore, an increase in the cohesion of grain boundaries will probably be the most important factor in preventing the propagation of the tetragonal–monoclinic transformation from the surface to the interior.

Sintering aids that promote liquid phase formation do not enhance cohesion, but they help to prevent crack initiation. Kimura *et al.*[64] suggests the

> *"...presence of dopant in grain boundaries [acts] as a protective coating of [the] ZrO_2 grains against water (moisture) attack."*

which will therefore prevent OH^- attack on the grain surfaces.

Chen and co-workers[65–68] identified an incubation region on the kinetic plots of monoclinic content versus ageing time. The first derivative of these kinetic curves shows that generally the rate of transformation gradually increases to a maximum and then decreases. Lu and Chen extrapolated the plot of maximum rate of transformation versus grain size and deduced a critical grain size of 0·37 μm, below which degradation does not occur. Mäntylä *et al.*,[69–71] Lilley[42] and Lawson *et al.*[22,60,72] have shown that there is no incubation time and that the rate of transformation is constant, i.e. the phase transformation reaches saturation immediately and grows inwards linearly with time. Lawson *et al.* found that for 2·5Y–TZP the monoclinic transformation rate was 2–3 μm/h (0·2–0·4 μm grain size respectively) in superheated water in an autoclave at 180°C.

3.1 Corrosion mechanisms

Sato and Shimada[19] based their ageing model on the mechanism of stress corrosion in vitreous silica exposed to water.[73] The authors dismissed the dissolution of yttria or zirconia into the solutions by analysing the solvents used, and also no weight change of the aged specimen was observed. The reaction between water and Zr–O–Zr bonds at the crack tip is shown in Fig. 11. The strain which acts to stabilize the tetragonal phase[74,75] may be released on the surface (due to the reaction in Fig. 11), along with the growth of pre-existing flaws, so inducing the phase transformation.

Sato *et al.*[29] explained the reaction between water and zirconia on the basis of activation energies for transformation in Y– and Ce–ZrO_2. These studies gave similar values for both stabilizers (72·8–93·8 kJ/mol), therefore indicating that the water reacted primarily with Zr–O–Zr bonds on

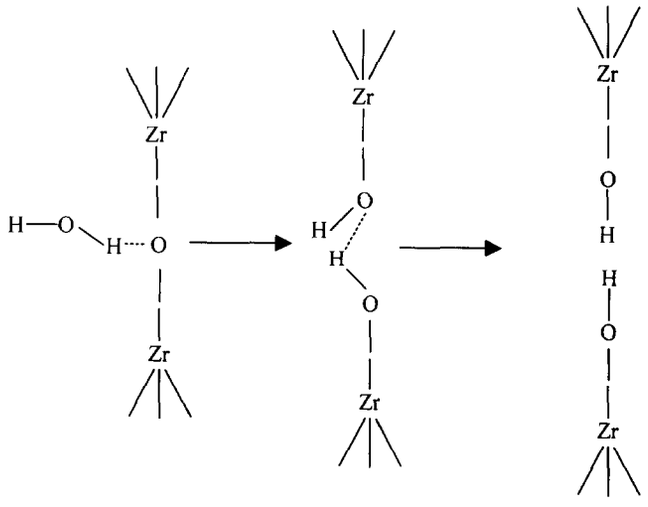

Fig. 11. Reaction scheme expected for the reaction between water and Zr–O–Zr bonds at the crack tip. (After Sato & Shimada[19]).

the surface and not the stabilizing oxide. They also expect solvent environments with a molecular structure containing a lone-pair electron orbital opposite a proton donor site to strongly affect crack growth. Investigation of various solutions[19] lead the authors to conclude that solutions which accelerate crack growth have the greatest effect on the tetragonal–monoclinic transformation.

The role of the water molecule on degradation in Y–TZPs has been investigated by Yoshimura *et al.*[20,51,76] The ageing-induced phase transformation was accompanied by an increase in the crystal lattice. The initial lattice parameters could be restored and a weight loss detected if the aged sample was annealed (400°C for 6 h in vacuum or 1300°C for 1 h in air). This reversible expansion and contraction of the monoclinic lattice seems to be caused by the inclusion and exclusion of OH^- in the lattice. The authors feel that if yttrium depletion by $Y(OH)_3$ formation or by Y^{3+} dissolution had occurred, such a reversible lattice recovery would not be observed at low temperatures and/or in a short period of time. Infrared spectroscopy clearly showed the introduction of OH^- on ageing (also confirmed by Raman spectroscopy) and its subsequent exclusion on annealing.

Yoshimura *et al.* calculate that approximately 60% of oxygen vacancies were occupied by OH^- ions, and that these OH^- ions would migrate faster than O^{2-} because of less charge and similar size. The slow diffusion of Y^{3+} to form $Y(OH)_3$ is thought unlikely by Yoshimura *et al.* and dissolution of Y^{3+} during the hydrothermal dissolution of yttria-stabilized zirconia, YSZ[76] does not occur. Based upon the arguments for anion diffusion, the OH^- ion trigger mechanism was proposed by Yoshimura *et al.*[20,51,76] is described below and shown schematically in Fig. 12.

Step 1 Chemical adsorption of H_2O at the surface.

Step 2 The formation of Zr–OH and/or Y–OH bonds at the surface, at which points stressed sites are created.

Step 3 The accumulation of strain by the migration of OH^- ions at the surface and in the lattice, to prepare nucleating defects.

Step 4 The nucleaton of monoclinic phase in the tetragonal grains: then the tetragonal–monoclinic transformation yields micro- and macro-cracking.

Further investigations[51] into the effect of high-temperature and high pressure-water showed that the activation energy remained constant regardless of temperature or pressure and seemed to be the activation energy for the diffusion of OH^- in the Y–TZP lattice, which further suggests that the degradation is controlled by OH^- diffusion. This model is based upon the accumulation of strains to exceed a critical value, i.e. the energy barrier from tetragonal–monoclinic formation. Therefore the transformation becomes barrierless, and spontaneous nucleation of monoclinic domains occurs.

The mechanism proposed by Sato *et al.*[19] also suggests the formation of Zr–OH at the surface. Sato however, assumes the formation of OH^- causes the release of strain which act to stabilize the t-ZrO_2 whereas Yoshimura *et al.* think that

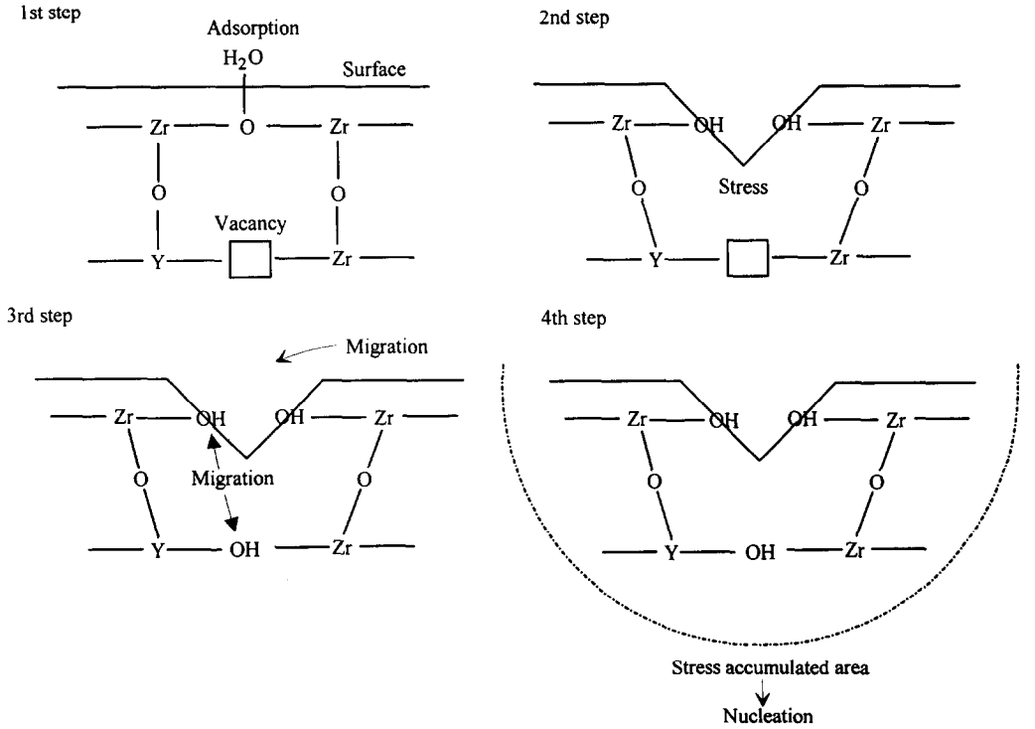

Fig. 12. Proposed degradation process of Y–TZP by the OH^- trigger mechanism. (After Yoshimura *et al.*[20]).

Zr–OH (Y–OH) creates a stressed site. Yoshimura also suggests that the mechanical stresses caused by thermal expansion mismatch as proposed by Schubert *et al.*[12,14,15] also play a role in triggering the tetragonal–monoclinic phase transformation. This mechanism is also supported by Masaki[44] who then proposes that the transformation develops along grain-boundaries causing zirconia particles to lose coherency with the matrix, therefore resulting in great loss in MOR. Masaki attributes inhibition behaviour to higher densities, therefore decreasing the number of cracks and defects for water attack.

Lepisto and Mäntylä have shown by the use of IRS and XPS,[69] that OH^- ions exist on the surface of Y–TZP, but they have also found that the OH^- ions do not extend throughout the transformed layer.[70] It is therefore considered that hydroxide formation throughout the transformed layer is not possible. However it would appear that Zr–OH formation at the specimen surface nucleates the phase transformation which then proceeds autocatalytically, without the requirement of continued hydroxyl ion involvement. Evidence for this mechanism is shown in Fig. 8[52] which shows that the transformation is nucleated in the presence of water vapour and then proceeds at the same rate under a dynamic vacuum.

3.2 Destabilization mechanism

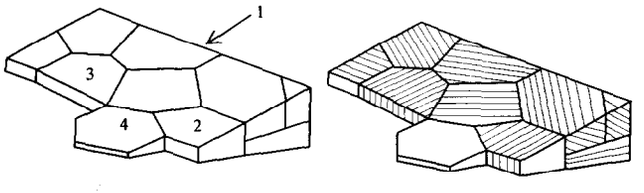
Lange *et al.*[43] initially hypothesized that the ageing phenomenon was a result of a stress–corrosion type reaction, water vapour reacting with a glassy silicate grain-boundary phase. Using specimens with and without silica additions/impurities they found that the presence of a glassy phase at the grain-boundaries had no effect on the ageing behaviour of Y–TZP, which is also supported by Mecartney.[16] Nakajima[21] examined a range of Y–TZP ceramics in the TEM and found no evidence of an intergranular glassy phase. Aged specimens exhibited twinning within grains, and cracks along the grain-boundaries. These cracks seemed to initiate from the triple points and grow along the grain-boundaries. Nakajima attributed these cracks not only to the transformation, but also to corrosion.

TEM studies by Lange *et al.* on a 6·6 mol% specimen (consisting primarily of large cubic grains) before and after ageing revealed an additional microstructural feature that was not present before ageing. Clusters of small yttrium-rich crystallites (20–50 nm) bridged gaps in the TEM foils and were frequently adjacent to the transformed m-ZrO_2 grains as well as the cubic grains. Lange *et al.* found that the crystallites were α-$Y(OH)_3$. In addition, the glassy intergranular phase remained intact and so disproved their initial hypothesis. These crystallites have not been observed by any of the other TEM studies of aged Y–TZP.

Lange *et al.* propose that the tetragonal–monoclinic phase transformation will occur when water vapour draws out an amount of yttrium from a small volume element on the surface of the grain, thus destabilizing this small volume element. As this monoclinic nucleus grows by further yttrium depletion, it will achieve a critical size whereby spontaneous growth can occur without the need for further yttrium diffusion to completely transform the tetragonal grain in which it was growing.

The volume expansion and shear strain associated with the transformation will produce a microcrack if the grain size is greater than a critical value. If the transformed grain is less than the critical size required for microcracking, then nucleation, growth, and thus transformation of subsurface grains will be limited by long-range diffusion of yttrium to the surface. If the transformed grain is larger than the critical size, then microcracks will form and open up subsurface grains to further water vapour attack. Lange comments that only short-range diffusion of the yttrium is required and that this mechanism also explains why transformation only occurs above a critical particle size. However, Tsubakino *et al.*[10] showed that grains smaller than the critical size which should be 'stable' tetragonal grains, do transform when aged under hydrothermal conditions. Yoshimura *et al.*[20] have criticized $Y(OH)_3$ crystallite formation on account of the slow diffusion of yttrium in zirconia.

Winnubst and Burggraaf[11] also favour the formation of α-$Y(OH)_3$. Water reacts with yttrium from the Y–TZP surface grains to form yttrium hydroxide. This results in an yttrium-rich surface layer (observed by AES) and an yttrium depleted region close to the enriched surface. When a critical composition and grain size are reached then the tetragonal–monoclinic transformation will be initiated. Recent work by Azzoni *et al.*[77] who have studied the degradation mechanism using electron paramagnetic resonance (EPR) clearly supports the formation of α-$Y(OH)_3$. Additionally, Kruse *et al.*[78] studied the role of water on the ageing mechanism of Y–TZP using elastic recoil detection analyser (ERDA) and found that hydrogen penetrates deep into 3Y–TZP during ageing, while no penetration was observed for an ageing resistant Y–TZP. This experimental evidence has been used by Boutz[79] as clear confirmation that Y–OH bond formation and diffusion of OH^- into the degrading material occurs. However, Hughes *et al.*[80] who also studied the role of water on the ageing of Y–TZP, concluded that hydroxides of yttrium are only observed after severe treatment and are



therefore symptomatic of the ageing process rather than initiators of the transformation.

Hernandez *et al.*[81] investigated the surfaces of aged Y–TZP using XPS and deduced that water molecules dissociate and are adsorbed at the surface. Reaction of OH^- ions with Y_2O_3 leads to formation of an oxyhydroxide, YO(OH), species. Simultaneously, tetragonal zirconia embryos form, grow and then transform when their size exceeds a critical value. Microcracking and spalling can then occur opening up new Y–TZP surfaces for continued attack.

3.3 Stress-induced transformation

The effects of internal stresses on the ageing behaviour of Y–TZP ceramics has been extensively investigated by Schubert *et al.*[12,14,15] and also more recently by Kim and Jung.[13] Schmauder and Schubert's[12] experiments were conducted on a 2 mol% Y–TZP, sintered at 1500°C for 2 h and prepared for TEM analysis. The sample was photographed in the TEM, then removed and annealed in air at 250°C for 0·5–168 h, and then remounted in the TEM with the same orientation as before.

The result was that only unconstrained, faceted grains in a protruding position (position 4), Fig. 13, were stable against environmental attack. Grains in positions 2 and 4 have the same surface area in contact with the water and should have the same surface energy. However, if the surface energy determined the stability, these grains would behave in the same way. The observation that the constrained grains behave differently than protruding ones indicates that the stress situation of the grains is the dominant factor governing grain stability. It is known that shear and tensile stresses are destabilizing, whereas compressive stresses stabilize the grains. The shear component is normally the largest and therefore nucleates, or controls, the transformation. They attribute these stresses to the anisotropy of the thermal expansion; the stresses increase with cooling.

as sintered

168 h, 250 °C, humid air

TEM experiment: unconstrained grains did not transform during degradation test.

Fig. 13. Schematic showing the effect of ageing for 168 h, at 250°C in humid air, on constrained and unconstrained grains in 2Y–TZP. (After Schmauder & Schubert[12]).

Schmauder and Schubert propose that the instability of the constrained surface grains is due to stress corrosion attack of these grains by water vapour. They favour the formation of yttrium hydroxide, not however, by diffusion of Y^{3+}, but by the self diffusion of water. The argument is based on the anion vacancies of the distorted fluorite structure coupled with the high anion mobility as a possible path for an uncharged species to diffuse into the lattice. The water molecule is smaller than the O^{2-} ion and could fit therefore into the vacancies. Migration into the lattice is dependent on substitution with an oxygen ion or a vacancy. Schubert calculated that the self diffusion coefficients for the motion of vacancies and for oxygen ions are similar to the linear diffusion coefficient of the transport mechanism for hydroxide formation. Therefore stress–corrosion attack of surface grains by water vapour results in $Y(OH)_3$ formation. The depleted area acts as a monoclinic nucleus which then grows under the influence of thermal expansion anisotropy stresses and propagates autocatalytically and is further aided by water attack via microcracks caused by the volume expansion of transforming grains.

These tensile stresses obviously increase with increasing grain size, and therefore a small grain size is required to prevent microcracking and hence transformation propagation. Schubert also attaches great importance on yttria distribution and attributes an inhomogeneous yttria distribution with reduced ageing performance. An interesting observation by Matsui *et al.*[82] on a 3Y–TZP aged sample with one face in tension and the other in compression, showed that the face in tension had nearly 100% transformation, whereas the rate of change on the other face was lower. Similar studies by Drennan *et al.*[28] on Mg–PSZ also show this behaviour.

The work of Kim and Jung[13] also mentions internal stresses caused by thermal expansion anisotropy, but in this case evidence from the literature points towards relaxation of these internal stresses by dipole rearrangement, which then create localised strains initiating the transformation. Dipole reorientation is a thermally activated process and so according to Kim's mechanism ageing-induced phase transformations would occur in dry air or vacuum. This is not experimentally observed and so this mechanism is not complete without the effect of water vapour taken into account. However, internal friction through dipole rearrangement is a plausible mechanism for aiding ageing-induced transformation initiation and propagation.

Lu *et al.*[65,67] studied the kinetics of the ageing behaviour of Y–TZP and showed that in air the

kinetic curves were sigmoidal, whereas in water they exhibited a linear logarithmic relationship. The sigmoidal kinetic relationship in air was split into three segments; an incubation time, an increase in the rate of transformation, and a reduction in transformation rate with the reaction levelling off. This premise is flawed however, as the sigmoidal shape is simply due to the monoclinic surface layer increasing in thickness until it exceeds the X-ray penetration depth.[22]

They consider that water catalyses the tetragonal–monoclinic transformation by reducing the incubation time. As the more the transformation is induced by the transformation strain, the easier it could be for water to catalyse the phase transformation when it diffuses through microcracks to the interior. Consequently the acceleration of the phase transformation is enhanced by a combination of water-vapour catalysis and subsequent autocatalytic reaction.

3.3.1 Internal friction

An initial reference to the ageing temperature regime and a similar temperature dependence of internal friction was made by Matsui *et al.*[83] Matsui referred to the work of Larsen and Adams[84] who plotted internal friction versus temperature and obtained similar results to Shimada *et al.*[85] and Weller and Schubert.[86] Matsui's results suggest that the tetragonal–monoclinic phase transformation proceeds most rapidly at ≈200°C, which coincides with the optimum internal friction temperature in Larsen's work and is suggested to be due to twin motion in *m*-ZrO_2.[85]

The temperature dependence of Young's modulus and internal friction for various engineering ceramics was studied by Shimada *et al.*[85] They found that for Y-PSZ the internal friction increased rapidly with temperature to a maximum at 200°C then decreased rapidly with temperature up to 400°C where it was a similar value to the room temperature figure. The Young's modulus decreased with decreasing temperature, but an anomolous sudden change was observed accompanied by the internal friction peak. Above 400°C the Young's modulus decreased linearly with increasing temperature up to 650°C and is shown in Fig. 14.

The internal friction, dielectric loss, and ionic conductivity of 3Y–TZP has been studied by Weller and Schuber.[86] Their results were similar to the ones shown in Fig. 14. Mechanical or dielectric loss resulting from reorientation of atomic defects by application of mechanical stress or an electric field, is proportional to the concentration of defects. The experimental results show that the activation enthalpy for mechanical and dielectric

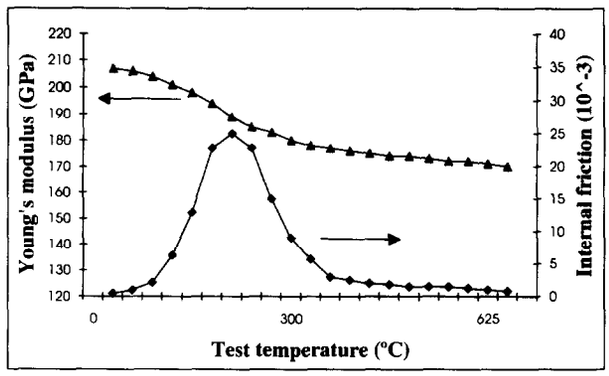


Fig. 14. Temperature dependence of Young's modulus and internal friction in 3Y–TZP. (After Shimada *et al.*[83]).

relaxation is the same (87 kJ/mol), which is similar to the activation energies calculated for ageing-induced phase transformation by Sato *et al.*[29] and Lawson.[22] They conclude that the mechanical and dielectric relaxation is caused by thermally activated reorientation of the same anisotropic defects.

Weller and Schubert propose the following atomistic model for mechanical and dielectric loss in TZP ceramics. During the formation of *c*- and *t*-ZrO_2 solid solutions, substitution of Y^{3+} for Zr^{4+} is accompanied by the introduction of oxygen-ion vacancies (for charge neutrality) in fluorite and distorted fluorite respectively. The coulomb interaction between substituted Y'_{Zr} and oxygen-ion vacancy, V''_o, produces $(Y'_{Zr}V''_o)$ complexes. This complex behaves as an anisotropic electric and elastic dipole, which reorients upon application of an electric or elastic field. It is assumed that dipoles are oriented parallel to [111] lattice direction as in *c*-ZrO_2. The reorientation is caused by oxygen vacancies jumping around the Y'_{Zr} ions for electrical and mechanical fields.

Kim and Jung[13] argue that these dipoles may reorient when residual stresses are relieved due to annealing above the lower temperature limit for ageing. This reorientation produces small localised strains along the [111] direction. When a critical value of strain is reached, the locally strained lattice becomes mechanically unstable, causing nucleation of *m*-ZrO_2. This relaxation temperature is not necessarily sensitive to additive levels or grain size.

The effect of Al_2O_3 additions to 3Y–TZP on the temperature dependence of internal friction were investigated by Ono *et al.*[87] Their results are comparable with those of Weller and Schubert for low Al_2O_3 additions. As the dopant content increased then the internal friction peak became lower and occurred at higher temperatures. They also found that the internal friction peak was accompanied by an inflection point in the Young's modulus.

They conclude that the relaxation phenomenon was concerned with the Y_2O_3 and not ZrO_2.

Nishiyama *et al.*[88] measured internal friction and modulus changes with temperature, and found similar results to those reported above. They attribute the internal friction peak to dipole relaxation (according to Weller and Schubert), to a stress-induced phase transformation, and to water initiated phase transformation (hydrothermal ageing).

3.4 Alternative mechanisms

Lepisto and Mäntylä[69] suggest that zirconia reduction and oxygen vacancy annealing was responsible for the degradation. Zirconia dissolution is initiated at grain-boundaries where the reaction proceeds deeper into the material.

$$Zr_s^{4+} + 2O_s^{2-} + 2V''_o + 4H^+ + 4e^- + 2O^{2-} \rightarrow Zr + 2H_2O$$

The dissolution at grain-boundaries relieves the internal stresses stabilizing the tetragonal structure and thus triggers the phase transformation to monoclinic symmetry.

Kuroda *et al.* suggest that the oxygen anions are responsible for the chemical attack.[52] It is proposed that thermally activated oxygen exchanges take place between the environment and the surface. Oxygen anions occupy monoclinic sites rather than the tetragonal ones, since monoclinic zirconia is thermodynamically more stable at low temperatures. As a result cations shift and therefore cause the tetragonal–monoclinic phase transformation.

Further investigations by this group on the application of an electric potential to induce the tetragonal–monoclinic phase transformation,[89] showed that the surface monoclinic content of the anode and cathode had increased. The reactions at the cathode are as follows:

$$O_2 + 4e^- \rightarrow 2O^{2-} \text{ (in the presence of oxygen)}$$
$$H_2O + 2e^- \rightarrow H_2\uparrow + O^{2-} \text{ (in the presence of water)}$$

Once the above reaction occurs only the oxygen ions can diffuse into the bulk. Oxygen ions then trigger the transformation as explained in the opening paragraph. As the tetragonal grains in the bulk are constrained by the matrix then transformation does not occur despite oxygen ion motion. They conclude that the gas–solid reaction at the surface rather than the anion diffusion through the bulk is essential for the transformation to nucleate.

4 Transformation Inhibition

The free energy change (ΔG_{t-m}) of the tetragonal–monoclinic phase transformation on cooling through the transformation temperature in absence of an applied stress field is given by:[90]

$$\Delta G_{t-m} = (G_c^m - G_c^t) + (G_{se}^m - G_{se}^t) + (G_s^m - G_s^t) \quad (2)$$

where G_c is the chemical free energy, G_{se} the (dilational) strain free energy, and G_s the surface free energy. Superscripts t and m denote tetragonal and monoclinic phases respectively.

Heuer and Lenz, and Heuer *et al.* have modified eqn (2) by taking into account bulk residual shear strains from twinning, interfacial contributions from twin boundaries and particle-matrix microcracking,[91] and an extra nucleation term[92] respectively. The influence of important parameters, however can still be assessed using eqn 2.

The metastable tetragonal phase can only exist when $\Delta G_{t-m} > 0$. The chemical free energy term is always negative, but the addition of stabilizing oxides will make this term less so. The strain free energy term is also negative, and is influenced by the matrix stress according to.[93]

$$G_{se} = 1/2\ \sigma_{ij}\epsilon_{ij}V_{mol} \quad (3)$$

where σ_{ij} is the stress tensor, ϵ_{ij} the strain tensor and V_{mol} the molar volume.

Therefore in the presence of a tensile stress the strain free energy term is negative, making the tetragonal phase less stable. When compressive stresses are present, the tetragonal phase is more stable. Without the presence of compressive stresses, or in general strain contributions, stabilization will only occur when the surface free energy term in eqn 2 is positive and larger than the sum of the first two terms.

Generally speaking, and with reference to eqn 2, the control of the tetragonal–monoclinic phase transformation can be achieved by:

1. An increase in the chemical free energy change by alloying with another stabilizing oxide, e.g. CeO_2.
2. An increase in the strain free energy change by dispersion of a second phase, e.g. Al_2O_3.
3. By increasing the surface free energy change, e.g. reduction in grain size.
4. Coating.
5. Surface microstructural engineering.

It should be noted though that an increased thermal stability by methods 1 and 2 above generally results in a decrease in mechanical properties through over-stabilization of the t-ZrO_2 phase.

4.1 Chemical free energy increase

An increase in the chemical free energy can be achieved quite simply by increasing the yttria content. However this over-stabilization of the t-ZrO_2 phase (and probable c-ZrO_2 phase formation)

leads to a sharp reduction in the mechanical properties of Y–TZP.

An alternative method of increasing the thermal stability of Y–TZP is to alloy with another stabilizing oxide. Sato and Shimada[29,49,94–96] examined the effects of various oxide additions to Y–PSZ. They found that CeO_2 was an effective additive for eliminating degradation, without any reduction in mechanical properties and actually increased the elastic modulus. The authors feel that the effect of CeO_2 may be to increase the size of the transformation zone in the vicinity of a crack front. TiO_2 did reduce the phase transformation but at a cost of increased grain size and reductions in relative density, hardness and fracture toughness. The other oxides evaluated (CaO and MgO) did decrease the surface monoclinic content, but only because of increased cubic formation, which obviously lowered the fracture toughness.

Duh and Wu[97] alloyed 1, 3 and 4 mol% Y–TZPs with 10 mol% CeO_2 and showed that the tetragonal phase could be retained in water at 300°C for up to 1 month. A similar result was obtained by Hirano and Inada[98] but they only alloyed with up to 5·5 mol% CeO_2. Further work by Duh and Wan[99] showed that 9·5 mol% CeO_2 alloyed with 1·5 mol% Y–TZP is required to inhibit ageing.

Hirano and Inada[100] found that hydrothermal stability could only be achieved by (4Y,4Ce)–TZP–25 wt% Al_2O_3 composites, although (4Y,4Ce)–TZP was resistant to ageing in air. Theunissen *et al.*[101] and Boutz *et al.*[79,102] showed improved ageing resistance with CeO_2 additions under autoclave conditions. Theunissen[103] also examined the effects of TiO_2 additions. They found that some samples aged very quickly and others showed good resistance. This variability was attributed to surface enrichment in TiO_2, for the good ageing resistant samples, that may form a TiO_2 overlayer.

4.2 Strain free energy increase

Sato *et al.*[18] added Al_2O_3 (5–10 wt%) to 3 mol% Y–TZP and found that the surface monoclinic content decreased with increasing concentration of dispersed Al_2O_3. They postulated that the Al_2O_3 grains play a major role in resisting the volume expansion of the zirconia grains accompanying the tetragonal–monoclinic phase transformation. Further investigations by Sato and Shimada[29,49,94–96] showed that Al_2O_3 additions reduced the rate of transformation but did not prevent it totally, and increased the elastic modulus. Schmauder and Schubert[12] however, argue that additions of Al_2O_3 create stresses with the bulk ceramic which are detrimental to the ageing behaviour of TZP. Masaki[44] supports this argument and includes TiO_2 and Fe_2O_3 into this category of stress raisers. However neither Schmauder nor Masaki have presented results to support their argument.

Tsukuma and Shimada[104] also found a reduction in monoclinic content with Al_2O_3 additions, and that 40 wt% Al_2O_3 almost perfectly restrained the transformation. They attributed this improvement in thermal stability of the tetragonal phase to an increase in Young's modulus of the matrix due to the Al_2O_3 additions.[105,106] Additions of Al_2O_3 or TiN to 2–6 mol% Y_2O_3–ZrO_2 have been shown to control the phase transformation and so prevent deterioration in modulus of rupture.[107]

Kim and Jung[13] show that composites of transformable and nontransformable TZPs formed in the ZrO_2–Y_2O_3–$Nb(Ta)_2O_5$ systems can act as lattice relaxation inhibitors (increase the lattice stiffness). This composite basically consists of a metastable tetragonal bulk interspersed with large stable grains. Recent research on the role of second phase additions to zirconia ceramics leading to enhanced ageing resistance has been reported for mullite, spinel and Al_2O_3,[108] MgO and Al_2O_3[109] and tungsten carbide.[48]

4.3 Surface free energy increase

The grain size of Y–TZP can be controlled by reducing the sintering (or calcination) temperature. However, unless the powders are ultra fine and highly reactive, the sintered density will not be very high. Hot-pressed or hot-isostatically pressed powders enable a small grain sized, fully dense Y–TZP to be manufactured.

A much cheaper technique is to use sintering additives to ensure a small grain size through lowering the sintering temperature. The effect of additives on the anti-degradation behaviour of Y–TZP has been investigated by Kimura *et al.*[64] and Lawson *et al.*[22,23,110] Transition metal oxide additives were used as sintering aids and resulted in densification occurring at about 1200°C. The doped 2·5 mol% Y–TZPs had a small grain size, were fully dense and were resistant to degradation in air and boiling water.[64] Similar results were also obtained by Lawson *et al.* who showed that strengths in excess of 1000 MPa could be retained after 1000 h in superheated water in an autoclave at 180°C.

Sato and Shimada[49,95] showed that reducing the grain size of the CeO_2-alloyed Y–TZP reduced the surface monoclinic content and lowered the concentration of CeO_2 required for total inhibition.

4.4 Coating

Iio *et al.*[111] coated Al_2O_3 onto the surface of Y–TZP using CVD. When this sample was aged in air at 300°C they found that the tetragonal–monoclinic phase transformation had been restrained. Any coatings however, must be fully

dense and stable against the atmosphere. Such coatings can be produced by CVD but processing is complicated and expensive. If the coating degrades or is fractured in any way, then the susceptible tetragonal grains will be open to water vapour attack.

4.5 Surface engineering

Whalen *et al.* formed a surface layer of very fine-grained tetragonal phase on Y–TZP by surface recrystallization.[112] This had the effect of resisting ageing at 200°C in air for 1000 h. Therefore large grain sized Y–TZP for maximum toughness can be protected from the ageing-induced transformation by simple postsintering treatments.

4.6 Non-transformable tetragonal zirconia (t'-ZrO_2)

The effect of t'-ZrO_2 on ageing of TZPs has been investigated by Noma *et al.*[76] and by Jue *et al.*[113] Noma found that the t'-phase was more resistant to nucleation of the ageing-induced transformation by OH^- trigger mechanism, than a more conventional t-ZrO_2. However, once the transformation had begun it proceeded at the same rate as for the t-ZrO_2 sample. Jue *et al.* showed that t'-ZrO_2 was essentially ageing resistant when it had polished surfaces. However, when surface ground, t'-ZrO_2 exhibited very slight transformation (up to 7% monoclinic content) after ageing at 275°C in air.

4.7 Density

Evidence for a density threshold for ageing was reported by Masaki[44] and is shown in Fig. 15. The solid circles and triangles show the sintered materials, the strength of which decreased greatly after ageing (the extent of the black area in each circle corresponds to the degree of strength reduction). The figure also shows lines of critical densities (thresholds) and grain sizes for the Y–TZP compositions after ageing.

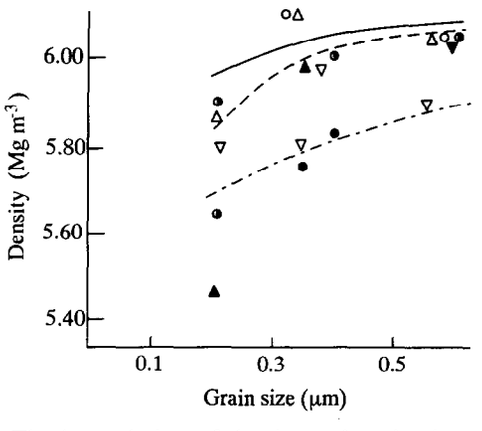

Fig. 15. The interrelation of density and grain size with the degradation of Y–TZPs aged at 200–250°C in air for 2000 h, (O, ——, 2·5 Y_2O_3; Δ, – – –, 3 Y_2O_3; ∇, –·–·–, 4 Y_2O_3. (After Masaki[44]).

According to these results if the density is greater than a critical value (Y_2O_3 dependent) then ageing will not occur. The critical density determined by Masaki will however, be an over-estimate, as his specimens were aged and then cut to the required size before the density and MOR were assessed.

4.8 Lattice spacing

An interesting aspect of Kim and Jung's work[13] is the possible existence of a critical value of d_{111}. Figure 16 shows the tetragonal zirconia (111) lattice spacing, d_{111}, and the amount of monoclinic ZrO_2 resulting from various ageing times (at 250°C). These results show that as a critical value of d_{111} is reached, then localised lattice instability occurs and transformation is initiated. Therefore, t-ZrO_2 grains whose d_{111} is larger than the critical value, transform.

Yoshimura *et al.*[20] observed a reversible expansion and contraction of the zirconia lattice with ageing and subsequent annealing, and concluded that it was caused by the inclusion and exclusion of OH^- in the lattice. Recent results obtained by Lee and Kim[114] have shown that the transformation is reversible upon annealing above 1200°C. The phase recovery was accompanied by healing of micro-cracks, but the macro-cracks remained to a large extent. Therefore the benefit of annealing severely aged zirconia in order to re-establish the tetragonal phase must be questioned.

5 Summary

The experimental evidence of hydrothermal degradation is well documented and there are compositions and conditions under which ageing will not occur. Much more work in developing ageing resistant zirconia ceramics with good mechanical properties has still to be undertaken. The current ageing models do not accommodate all of the

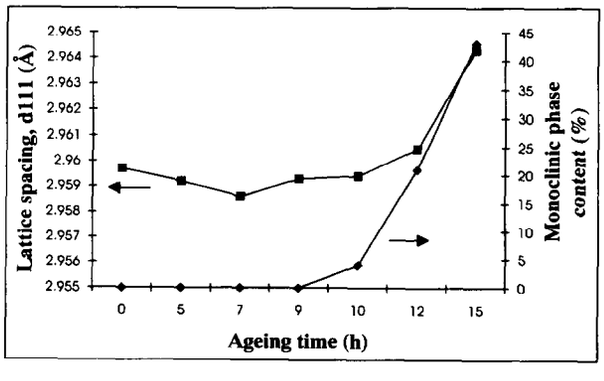

Fig. 16. Monoclinic content and lattice distance vs ageing time for a 3Y–TZP sintered at 1500°C for 5 h and aged in air at 250°C. (After Kim & Jung[13]).

experimental evidence, and there is conflict as to the nature of the attack, and whether there is accumulation or release of strain. The second paper presents a new ageing mechanism which covers all of the published experimental evidence.

Thermodynamic Assessment of the ZrO_2–$LaO_{1.5}$ System

Yong Du,* Masatomo Yashima, Toshiaki Koura, Masato Kakihana & Masahiro Yoshimura

Research Laboratory of Engineering Materials, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226, Japan

(Received 2 June 1994; revised version received 7 February 1995; accepted 14 February 1995)

Abstract

Two optimal sets of thermodynamic functions for the ZrO_2–$LaO_{1.5}$ system are obtained by coupling the CALPHAD (CALculation of PHAse Diagrams) technique, the regularity between thermodynamic properties and crystal structure parameters within the family of rare earth oxides, and the Van't Hoff equation. The phases are modelled with the substitutional solution model (liquid, cubic, tetragonal, monoclinic, and hexagonal solid solutions), as the stoichiometric compounds ($Zr_{19}La_{42}O_{101}$, $Zr_2La_2O_7$), and with the sublattice model ($Zr_2La_2O_7$). Two optimizations are performed. In the first optimization, the $Zr_2La_2O_7$ phase is treated as a stoichiometric compound, while in the second one it is described by the Wagner–Schottky model. The eutectoid reaction, high-temperature hexagonal $LaO_{1.5}$ solid solution $\rightleftharpoons$ low-temperature hexagonal $LaO_{1.5}$ solid solution + $Zr_2La_2O_7$, is predicted from the calculation. The calculated phase diagrams and thermodynamic quantities agree well with the experimental data.

1 Introduction

It is well known that accurate thermodynamic information forms the basis of the CALPHAD method.[1–4] The current use of this method consists of evaluating a small number of thermodynamic parameters required to describe binary systems and synthesizing the description of a ternary system from the properties of its corresponding binary ones. The synthetic description for the ternary system can be used to evaluate existing experimental data and design experiments most efficiently. The same is true of going from ternary systems to a quaternary one and so on.

Recently the thermodynamic modelling of zirconia-bearing systems has received considerable attention[5–10] because of the difficulties[11,12] in constructing zirconia-based phase diagrams and thermodynamic properties by means of experimental methods, and the modelling has been justified by its ability to reproduce experimental data in binary systems and to predict experimental results in ternary systems with high certainty. It is interesting to notice that the calculated ZrO_2–$YO_{1.5}$–MgO phase diagrams[9] agree reasonably with most of the experimental data later published,[13,14] and the predicted ZrO_2–CaO–MgO and ZrO_2–$YO_{1.5}$–CaO phase diagrams[15,16] are in good agreement with the experimental data available. This means that the experimental work to measure zirconia ternary phase diagrams can be reduced significantly by using the CALPHAD method. In the case of experimentally well established zirconia binary systems, such as the ZrO_2–$YO_{1.5}$ and ZrO_2–CaO systems, consistent sets of thermodynamic parameters[17,18] can be obtained by only using the CALPHAD method. For most of the technologically important zirconia binary systems, however, experimental information is uncertain, scarce or lacking. Therefore, it is of great interest to optimize and/or estimate phase diagrams and thermodynamic properties in the less well established zirconia binary systems by the combined use of the CALPHAD technique and semiempirical estimation techniques. Similar work can be found for alloy systems, such as the work due to Guillermet and Frisk[19] and Klingbeil and Schmid-Fetzer.[20]

The present work is devoted to providing an optimal set of thermodynamic functions for the ZrO_2–$LaO_{1.5}$ system by coupling the CALPHAD method and semiempirical estimation techniques. This work is part of a research project aimed at developing a thermodynamic database for the ZrO_2–$REO_{1.5}$ (RE = Rare Earth)–CeO_2 systems, which is currently being carried out in our laboratory. The database is of great importance in the production and application of zirconia-based ceramic materials.

2 Evaluation of Experimental Data

To conserve space, the cubic, tetragonal, and monoclinic structures of ZrO_2 and the low-temperature hexagonal, high-temperature hexagonal and cubic forms[21] of $LaO_{1.5}$ are denoted c-ZrO_2, t-ZrO_2, m-ZrO_2, A-$LaO_{1.5}$, H-$LaO_{1.5}$ and X-$LaO_{1.5}$, respectively. The solid solution phases based on c-ZrO_2, t-ZrO_2, m-ZrO_2, A-$LaO_{1.5}$, H-$LaO_{1.5}$ and X-$LaO_{1.5}$ are designated as C_{SS}, T_{SS}, M_{SS}, A_{SS}, H_{SS} and X_{SS}, respectively. All temperatures quoted in the present work have been converted into the international temperature scale of 1990.[22]

The liquidus for the ZrO_2–$LaO_{1.5}$ system has been measured by three groups of researchers.[23–25] The most detailed and accurate one is by Rouanet.[25] Except for one liquidus temperature at 38 mol% $LaO_{1.5}$ reported by Wartenberg and Eckhardt,[23] all of the liquidus data points published by them and Rouanet[25] are incorporated in the optimization. The qualitative liquidus data points given by Lin and Yu[24] cannot be used in the optimization.

Since Lefevre *et al.*[26] observed that the pyrochlore-type compound P ($Zr_2La_2O_7$) shows a homogeneity range, a few authors[27–30] have measured its range in a wide temperature range. However, the reported data show large scatter. All of the experimental values[26–30] were nevertheless retained in the optimization, since none of them alone can describe the homogeneity range satisfactorily. In addition to P, Rouanet[25,31] introduced another compound, C_2 (cubic-type Tl_2O_3). Qualitatively narrow range for C_2 has been reported, but definitive ranges are not given. Consequently, this compound is treated as a stoichiometric one, and its stoichiometric composition is palced at 68·8 mol % $LaO_{1.5}$, the average value of the two data points reported by Rouanet.[25,31]

Six groups of authors[24,25,30–33] contributed to the measurement of the solid state phase equilibria. Using X-ray diffraction (XRD) techniques, Brown and Duwez[32] determined the phase relations at 1623 and 2023 K, and Zheng and West[30] reported the phase relation at 1773 K. Based on XRD results, Lin and Yu[24] constructed the equilibrium diagram in the wide range of temperature and composition. All of the experimental values published by the above authors[24,30,32] are qualitative and cannot be utilized in the optimization. However, these data have been used as the checkpoints in the present assessment. By means of thermal analysis and XRD methods, Rouanet[25,31] measured the solidus curve, phase transition temperatures, and invariant equilibria. In the present optimization, all of the solid state phase equilibrium data reported by Rouanet[31] are used. Since the solidus curve is an estimated one and the reducing condition might affect temperature measurements associated with phase transitions, as pointed out by Wilder,[34] these data are attached a low weight in the optimization. Recently, Bastide *et al.*[33] measured the phase relation in the ZrO_2-rich part below about 1623 K in detail. The invariant data[33] for the reaction $T_{SS} \rightleftharpoons C_{SS} + P$ are employed in the optimization.

Using a bomb calorimeter, Korneev *et al.*[35] determined the enthalpy of formation of P at 298 K relative to the elements. This datum is included in the optimization.

3 Thermodynamic Models

3.1 Pure oxides ZrO_2 and $LaO_{1.5}$

The Gibbs free energy function ${}^0G(T) = G(T) - H^{SER}$ (lattice stability) of a pure oxide is expressed by the following equation:

$$ {}^0G(T) = A + BT + CT\ln T + DT^2 + ET^{-1} + FT^7 + GT^{-9} \quad (1) $$

in which H^{SER} is the weighted molar enthalpy of the stable element reference (SER), the pure element in its stable state at 298 K, and T the absolute temperature. For ZrO_2 and $LaO_{1.5}$, H^{SER} are $H^{SER}_{Zr} + 2H^{SER}_{O}$ and $H^{SER}_{La} + 1{\cdot}5H^{SER}_{O}$, respectively. The last two terms in Eqn (1) are used only outside the range of stability,[36] the term FT^7 for a liquid below melting point and GT^{-9} for solid phases above melting point.

As mentioned in the preceding section, $LaO_{1.5}$ has three modifications, A-$LaO_{1.5}$, H-$LaO_{1.5}$, and X-$LaO_{1.5}$. Experimental thermodynamic data are available only for A-$LaO_{1.5}$. In the present work, the lattice stability of A-$LaO_{1.5}$ is evaluated by the weighted least squares method[37] applied to the heat capacity[38–40] and enthalpy increment data.[41–43] The entropy and enthalpy of formation of $LaO_{1.5}$ at 298 K are taken from the recent compilation.[44] Based on the experimental results reported in Refs 21 and 45, the transition temperatures of A-$LaO_{1.5}$ $\rightleftharpoons$ H-$LaO_{1.5}$ and H-$LaO_{1.5}$ $\rightleftharpoons$ X-$LaO_{1.5}$ transitions and the melting temperature are placed at 2314 K, 2384 K, and 2584 K, respectively. The heat capacities of H-$LaO_{1.5}$ and liquid $LaO_{1.5}$ evaluated by Dinsdale[46] are adopted in the present work, and that of X-$LaO_{1.5}$ is assumed to be the average value of them. The H-$LaO_{1.5}$ $\rightleftharpoons$ X-$LaO_{1.5}$ transition enthalpy is estimated to be 29992 J/(mol of cation) by applying the Van't Hoff equation to the annotated ZrO_2–$LaO_{1.5}$ phase diagram.[31] Lacking further information, the A-$LaO_{1.5}$ $\rightleftharpoons$ H-$LaO_{1.5}$ transition enthalpy is assumed to be the same as that of the H-$YO_{1.5}$ $\rightleftharpoons$ C-$YO_{1.5}$ transition.[16,47] Ferro *et al.*[48] have demonstrated that within the family of the rare earth elements plus Y and Sc

constitutional properties (phase diagrams, thermodynamic properties and crystal structures) change according to a simple and systematic pattern. Regular trends of properties of trivalent rare earth oxides, such as transition temperatures[31] and enthalpy of formation of rare earth zirconates,[35] have been reported. In the present work, the enthalpy of melting of $LaO_{1.5}$ is extrapolated by plotting the experimental enthalpies of melting for $YO_{1.5}$[16,47] and $PrO_{1.5}$[44] vs the cation radii.[49] Table 1 lists the lattice stabilities employed in the present assessment.

3.2 Solution phases

Yin and Argent[8] have mentioned that the defect structures in zirconia-based systems are complicated, and for some systems, such as the ZrO_2–CaO system, the defect structure changes from anion vacancies to cation interstitials as temperature increases. Several groups of authors[6,8–10] have shown that the simple substitutional solution model used for metal systems can describe the ZrO_2-based systems satisfactorily. When this model is used to describe solution phases in ZrO_2-bearing systems, it means that clusters, such as associates and neutral species, are not introduced in thermodynamic modelling, and cations and anions were in their simplest forms, such as Zr^{+4}, La^{+3}, O^{-2}. In accordance with the substitutional solution model, the Gibbs free energy of the liquid is expressed by an equation of the form:

$$G^{L}_{m}-H^{SER} = x^{0}G^{L}_{LaO_{1.5}} + (1-x)^{0}G^{L}_{ZrO_2} + RT [x \ln x + (1-x) \ln (1-x)] + x(1-x)[a_0 + b_0T + (a_1 + b_1T)(1-2x) + \ldots] \quad (2)$$

where x is the mole fraction of $LaO_{1.5}$, and R the gas constant. The remaining solution phases are defined in a fashion similar to Eqn (2).

In view of the narrow homogeneity range for C_2, this compound is treated as a stoichiometric one, and its Gibbs free energy is expressed relative to the constituent oxides by the following equation:

$$G^{C_2}_{0.312(ZrO_2)\,0.688(LaO_{1.5})} - H^{SER} = 0.688\,{}^{0}G^{C_2}_{LaO_{1.5}} + 0.312\,{}^{0}G^{C_2}_{ZrO_2} + A + BT \quad (3)$$

In the first optimization, P is also modelled as a stoichiometric compound. For P, the enthalpy of formation at 298 K has been measured.[35] This quantity is directly expressed by A of Eqn (3), if the reference states of ZrO_2 and $LaO_{1.5}$ correspond to the states to which the measured enthalpy of formation is referred. Therefore, it is preferable to choose m-ZrO_2 and A-$LaO_{1.5}$ as the reference states in the Gibbs free energy expression of P.

In the second optimization, the homogeneity range for P is considered. If it is assumed that the cations and anions were in their simplest forms, the two sublattices $(ZO,LO)_1(LO,ZO)_1$ described by the Wagner–Schottky formalism[50] could be used to model this compound. ZO and LO are the abbreviations of ZrO_2 and $LaO_{1.5}$, respectively. According to the Wagner–Schottky formalism, the Gibbs free energy of P is given by the following expression:

$$G - H^{SER} = 0.5\,{}^{0}G^{pyro}_{ZrO_2} + 0.5\,{}^{0}G^{pyro}_{LaO_{1.5}} + RT[0.5\{Y'_{Lo} \ln Y'_{Lo} + (1-Y'_{Lo}) \ln (1-Y'_{Lo})\} + 0.5\{Y''_{Lo} \ln Y''_{Lo} + (1-Y''_{Lo}) \ln (1-Y''_{Lo})\}] + G^{*} + G_{12}n_{12} + G_{21}n_{21} \quad (4)$$

Table 1. Summary of lattice stability parameters[a]

$G^{L\text{-}LaO_{1.5}} - H^{SER}_{La} - 1.5H^{SER}_{O}$
$298 < T < 2584 = -822856.8 + 304.7303T - 59.8354T \ln T - 0.0036025T^2 + 342279.5T^{-1} - 1.7315 \times 10^{-21}T^7$
$2584 < T < 6000 = -894331.4 + 638.1947T - 100T \ln T$

$G^{X\text{-}LaO_{1.5}} - H^{SER}_{La} - 1.5H^{SER}_{O}$
$298 < T < 2584 = -915282 + 567.7316T - 90T \ln T$
$2584 < T < 6000 = -943993.1 + 657.3025T - 100T \ln T + 1.474628 \times 10^{33}T^{-9}$

$G^{H\text{-}LaO_{1.5}} - H^{SER}_{La} - 1.5H^{SER}_{O}$
$298 < T < 2584 = -921434 + 492.5469T - 80T \ln T$
$2584 < T < 6000 = -978856.5 + 671.6888T - 100\,T \ln T + 2.949257 \times 10^{33}T^{-9}$

$G^{A\text{-}LaO_{1.5}} - H^{SER}_{La} - 1.5H^{SER}_{O}$

[a]In J/(mol of cation); temperature (T) in kelvin. L is liquid, X is cubic $LaO_{1.5}$, H is high-temperature hexagonal $LaO_{1.5}$, A is low-temperature hexagonal $LaO_{1.5}$, t is tetragonal ZrO_2 and m is monoclinic ZrO_2. The stable lattice stabilities of ZrO_2 are taken from the recent evaluation by Du *et al.*[18] Lacking further information, it is assumed that the Gibbs free energy difference between L–ZrO_2 and H (A)-ZrO_2 is the same as that[6] of HfO_2.

in which ${}^0G^{pyro}_{ZrO_2}$ and ${}^0G^{pyro}_{LaO_{1.5}}$ are the Gibbs energies of ZrO_2 and $LaO_{1.5}$ in the pyrochlore structure, respectively. Y'_{LO} and Y''_{LO} are the site fractions of the species LO on the first and second sublattices, respectively. G^* is the Gibbs energy of formation of the ideal compound ($Zr_2La_2O_7$), and G_{21} and G_{12} are the Gibbs energies of formation of the fictitious compounds, ZO_1:ZO_1 and LO_1:LO_1, respectively. The colon indicates the end of first sublattice and the start of the second one. n_{ij} is the number of moles of species j on sublattice i.

4 Parameter Evaluation

For convenience, the first and second optimizations in which P is treated as a stoichiometric compound and modelled with the Wagner–Schottky formalism, are referred to as optimizations A and B, respectively. For both optimizations, the other experimental values input are the same.

The evaluation of the parameters is conducted by the program developed by Lukas *et al.*[2] For the liquid it is possible to adjust independently the coefficients a_0 and b_0 of Eqn (2), because the liquidus line has been measured accurately over the whole composition range. In the present work, it was found that the calculated liquidus lines introducing and without introducing b_0 nearly coincide. So in the final optimization, only a_0 was used. The terminal solid solutions C_{SS} and X_{SS} both are cubic[21] and are treated as the same phase in the thermodynamic modelling. The coefficients a and b of Eqn (2) for C_{SS}(X_{SS}) cannot be adjusted independently due to the less well established temperature dependence. To make the excess enthalpy of $LaO_{1.5}$-rich solid solution (X_{SS}) independent from that of ZrO_2-rich solid solution (C_{SS}), a_0 and a_1 need to be introduced. Since the experimental data associated with T_{SS}, H_{SS} and X_{SS} are limited and scatter, each of them is described by one regular parameter. In view of the low solubility of $LaO_{1.5}$ in m-ZrO_2 (0·9 mol % $LaO_{1.5}$ at 1373 K), M_{SS} was approximated as m-ZrO_2. For C_2, it is impossible to adjust A and B of Eqn (3) independently because its Gibbs energies are known only in a narrow temperature range. Since only one coefficient can be adjusted, the value of B was fixed to be 2·75 J/(mol of cation·K). When this value is converted into that corresponding to one mole atom, it is about 1 J/(mol of atom K), which is usually adopted in the assessment of metal systems.[51] In the case of P, the coefficients A and B can be adjusted in optimization A, since the enthalpy of formation and phase diagram data are available. For optimization B, the introduction of two coefficients for G^* and one coefficient for each of G_{12} and G_{21} gives a good compromise to the scatter homogeneity range. The thermodynamic parameters obtained in the present work are shown in Table 2 (optimization A) and Table 3 (optimization B).

5 Results and Discussion

In Fig. 1, the calculated heat capacity of A-$LaO_{1.5}$ is compared with the experimental values.[38–40] Except for the two data points[40] at 800 and 850 K, all of the other experimental values can be reproduced by the calculation within the estimated experimental errors. Basili *et al.*[40] gave a large uncertainty (5%) for their heat capacity data. The large uncertainty corresponds to a low weight in the weighted least squares method.[37] The comparison of the calculated enthalpy increment and the experimental points[41–43] for A-$LaO_{1.5}$ is presented in Fig. 2, which shows a very good agreement.

The estimated enthalpy of melting of $LaO_{1.5}$ is shown in Fig. 3 along with the experimental ones for $YO_{1.5}$[16,47] and $PrO_{1.5}$.[44] In Fig. 3(a), the crystal radius[49] is used, while in Fig. 3(b) the effective ionic radius[49] is utilized. As can be seen from the figures, the estimated enthalpies of melting of $LaO_{1.5}$ are nearly the same in spite of the use of a

Table 2. Optimized thermodynamic parameters for the ZrO_2–$LaO_{1.5}$ system from optimization A (P is modelled as a stoichiometric compound)[a]

Substitutional solution model (Eqn (2))

Phase	i	a_i	b_i	Phase	i	a_i	b_i

[b] Due to the lack of experimental information, the Gibbs energy differences for both ZrO_2 and $LaO_{1.5}$ in the pyrochlore structure are simply given a fixed large value (100000 J/(mol of cation)) compared to m-ZrO_2 and A-$LaO_{1.5}$.

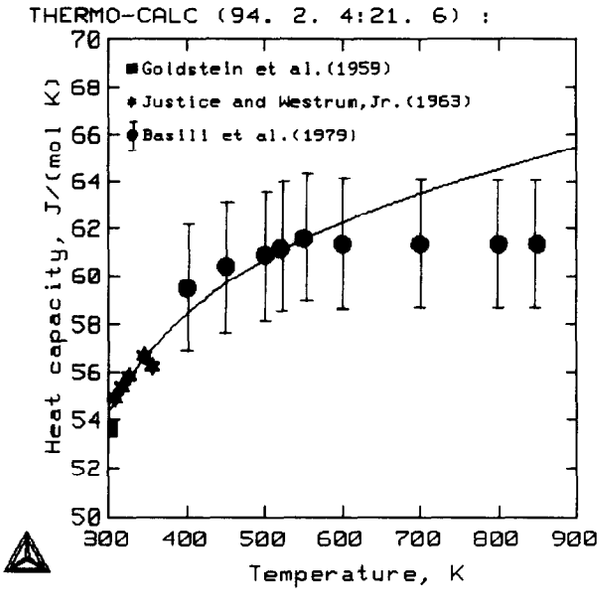

Fig. 1. Comparison of the calculated and measured[38-40] heat capacities of $LaO_{1.5}$.

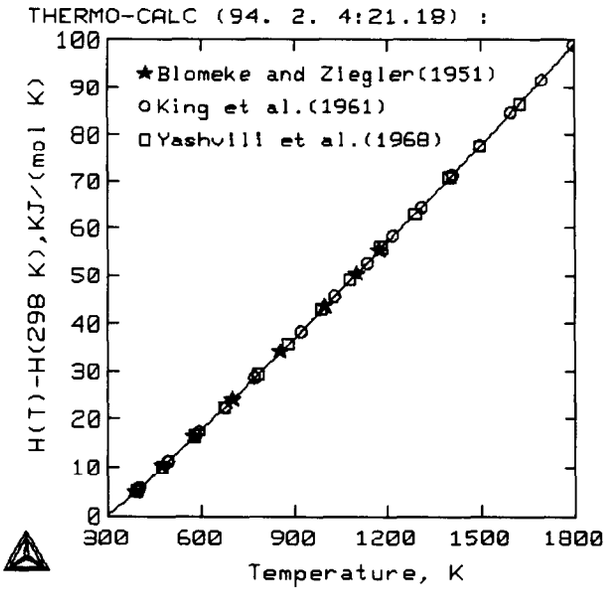

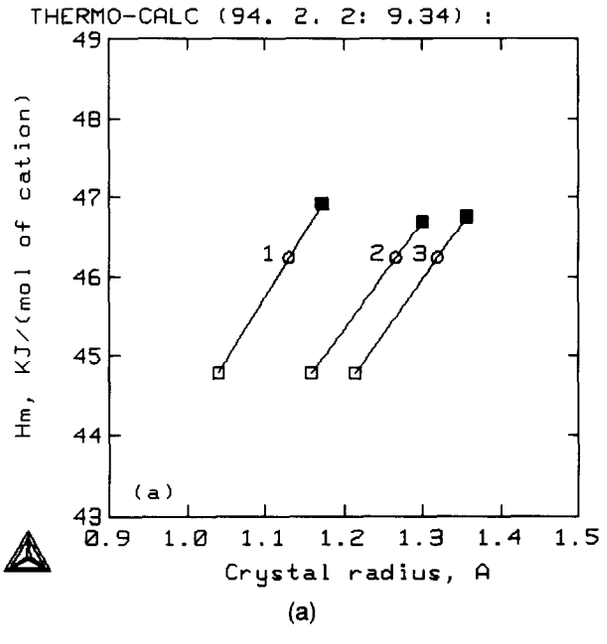

Fig. 2. Calculated enthalpy increment of $LaO_{1.5}$ with the experimental values.[41-43]

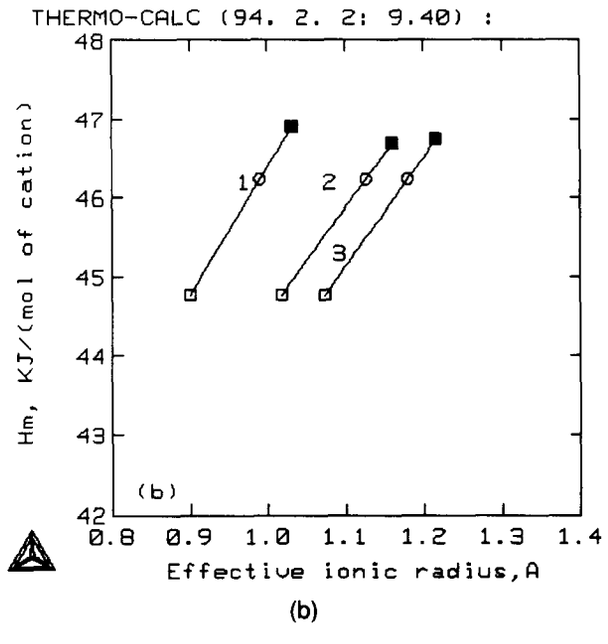

Fig. 3. Estimated enthalpy of melting of $LaO_{1.5}$ (■) along with the experimental enthalpies for $YO_{1.5}$ (□)[16,47] and $PrO_{1.5}$ (○).[44] Curves 1, 2, and 3 correspond to the coordination numbers 6, 8 and 11, respectively. (a) Enthalpy of melting is plotted vs crystal radius, and (b) enthalpy of melting is plotted vs effective ionic radius.

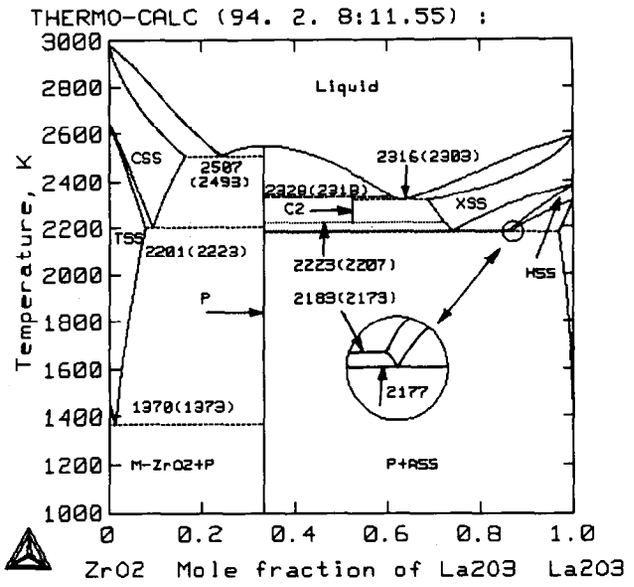

Fig. 4. Calculated ZrO_2–La_2O_3 phase diagram according to optimization A. The temperatures inside the parentheses are the experimental invariant temperatures,[31] and those outside the parentheses are the calculated ones.

different cation radius and a different coordination number. The average value (46790·7 J/(mol of cation)) of the six data points is taken to be the enthalpy of melting. The enthalpy of melting of $LaO_{1.5}$ calculated statistically from related phase diagrams, using the Van't Hoff equation, gives rise to the value of about 35000 J/(mol of cation), which is comparative with that assessed in the present work. Considering the large uncertainty (about 30%) associated with the Van't Hoff equation, the presently estimated value is preferable.

The presently calculated enthalpies of formation of P at 298 K from the elements are -1053187 J/(mol of cation) (optimization A) and -1036303 J/(mol of cation) (optimization B), which agree reasonably with the experimental one (-1020478 J/(mol of cation).[35]

The complete ZrO_2–La_2O_3 phase diagram based on optimization A is shown in Fig. 4. The eutectoid reaction, $H_{SS} \rightleftharpoons P + A_{SS}$, is a result of the calculation. No experimental information is available about this reaction. For the other invariant equilibria, the fit to the experimental data[31] is very good within the estimated errors.

In Fig. 5, the calculated ZrO_2–La_2O_3 phase diagram resulting from optimization A is compared with all of the experimental data available. Except for the homogeneity data for P, most of the other experimental data can be described by the calculation. In particular, the quantitative experimental values[23,25,31,33] are well reproduced. The calculated solidus line in ZrO_2-rich part is a little lower than the estimated one.[31] The present calculation demonstrated that the qualitative liquidus and solidus curves given by Lin and Yu[24] are probably low. Lin and Yu reported the melting temperature of $LaO_{1.5}$ to be 2533 K, which is lower by 51 K than the generally accepted one (2584 K).

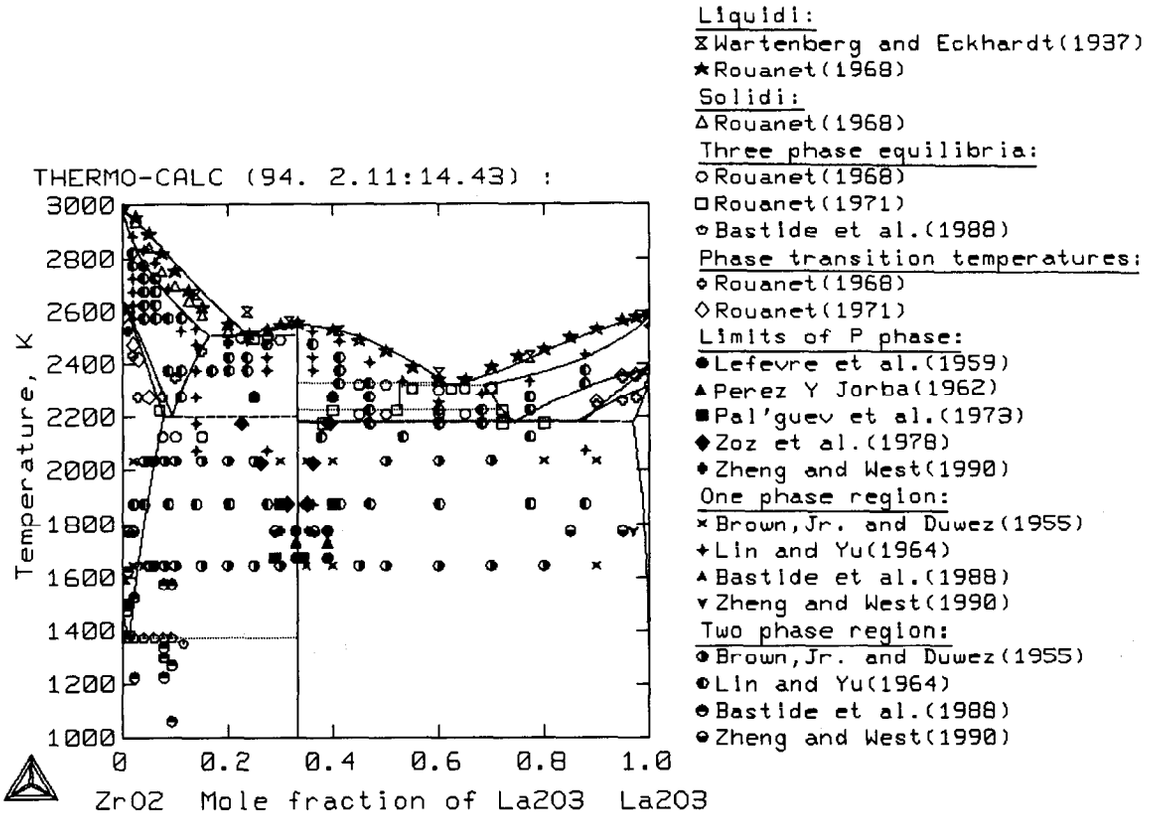

Fig. 5. Calculated ZrO_2–La_2O_3 phase diagram with the experimental phase diagram data. $Zr_2La_2O_7$ is treated as a stoichiometric compound (optimization A).

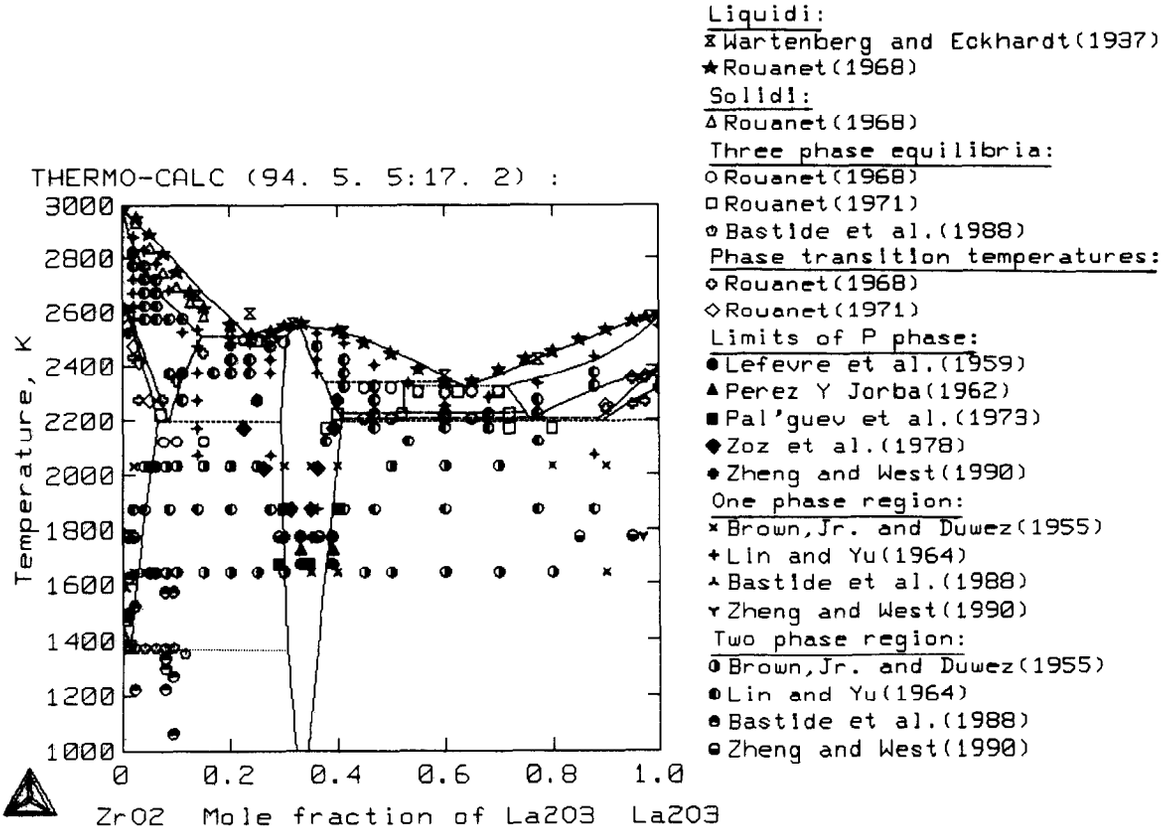

Fig. 6. Calculated ZrO_2–La_2O_3 phase diagram with the experimental phase diagram data. $Zr_2La_2O_7$ is modelled with the sublattice model (optimization B).

The computed ZrO_2–La_2O_3 phase diagram according to optimization B is presented in Fig. 6, which demonstrates an excellent fit to the quantitative experimental data[21,25,31,33] The calculated homogeneity range for P is a good compromise to the available data.[26–30] As mentioned in Section 2, the experimental data for the range of P show large scatter. The calculated limit toward La_2O_3 is located approximately at a curve between the curve reported by Lefevre *et al.*,[26] Perez Y Jorba[27] and Pal'guev *et al.*[28] and the one determined by Zoz *et al.*[29] and Zheng and West.[30] In the case of the limit toward ZrO_2, the computed limit agrees reasonably with the results from Pal'guev *et al.*,[28] Zheng and West,[30] and the datum at 1873 K published by Zoz *et al.*[29] The experimental result given by Lefevre *et al.*[26] and Perez Y Jorba[27] is higher by about 3 mol% La_2O_3 than the calculated one. In contrast, the experimental data at 2023 K and 2173 K given by Zoz *et al.*[29] are lower by about 5 mol% La_2O_3 than the computed one. Better knowledge on the homogeneity range of P is useful for further refinement of the ZrO_2–$LaO_{1.5}$ system. In the case of optimization B, it is found that the calculated solubility of ZrO_2 in $LaO_{1.5}$ is significantly lower than one quantitative datum published by Zheng and West.[30] An attempt to improve the agreement with this datum results in worse agreement with the phase transition temperatures and homogeneity range of P. In consequence, A_{SS} is approximated as A-$LaO_{1.5}$ in the final optimization. In the present work, an attempt to model P with the substitutional solution model was not successful: the calculated homogeneity range deviates significantly from the experimental data.[26–30] This implies the inapplicability of the substitutional solution model to describe P. The substitutional solution model corresponds to the random mixing of two species (ZrO_2, $LaO_{1.5}$) in one sublattice. This is not the case for $Zr_2La_2O_7$. The present work demonstrates that two sublattice model can be used to describe this compound.

The thermodynamic description of the ZrO_2–$LaO_{1.5}$ system obtained in the present work has been combined with the thermodynamic parameters for the ZrO_2–CeO_2[52] and CeO_2–$LaO_{1.5}$ systems to predict the ZrO_2–CeO_2–$LaO_{1.5}$ ternary phase diagrams, which are in reasonable agreement with the experimental data available.

6 Summary

All the phase diagram and thermodynamic data available for the ZrO_2–$LaO_{1.5}$ system have been considered in the present assessment. An attempt has been made to provide the consistent set of thermodynamic parameters describing the system

by coupling CALPHAD method and semiempirical estimation techniques. Two sets of thermodynamic functions have been obtained in the present work. The first one is for a simplified version of the ZrO_2–$LaO_{1.5}$ phase diagram in which $Zr_2La_2O_7$ is treated as a stoichiometric compound. The second one corresponds to the treatment in which $Zr_2La_2O_7$ is modelled with the sublattice model. Comprehensive comparisons with the experimental data available are made, and it is shown that the first parameter set can satisfactorily account for most of the experimental data except for the homogeneity data of $Zr_2La_2O_7$, and the second parameter set gives a good fit to all types of data for the ZrO_2–$LaO_{1.5}$ system except for one solubility datum of ZrO_2 in $LaO_{1.5}$.

Creep Properties of Single Crystal Oxides Evaluated by a Larson–Miller Procedure

Shiqiang Deng* & Richard Warren

Department of Materials Science and Production Technology, Luleå University, S-971 87 Luleå, Sweden

(Received 1 June 1994; revised version received 22 September 1994; accepted 26 January 1995)

Abstract

A collation of published results of compressive and tensile creep studies of single and binary oxide single crystals is presented. For the purposes of comparison the results were normalised by means of a Larson–Miller procedure. This method proved to be effective in providing a ranking of the oxides in terms of their creep resistance. Binary oxides with complex crystal structures exhibited the highest creep strengths; no direct correlation with the melting point could be found.

1 Introduction

Composites consisting of an oxide matrix reinforced with continuous oxide fibres are beginning to attract attention in the search for materials capable of withstanding higher temperatures than currently available materials. Thus, many oxides can provide the oxidation-resistance, high melting point and low density that are essential for high temperature aerospace applications. On the other hand, polycrystalline ceramic oxides do not exhibit adequate creep-resistance and high temperature strength. However, several studies have shown that certain single crystal oxides may be capable of providing good creep-resistance and strength; presumably because they lack grain boundaries which are a source of weakness at high temperatures.

Many isolated studies have been made of the creep behaviour of various single crystal oxides, but as far as the present authors are aware, no attempt has been made to carry out an exhaustive, systematic compilation of these. The purpose of the present work was to gather creep data from the many sources for both single and binary oxides in order to assess their relative creep resistance. A direct comparison of creep results from different sources is usually not straightforward since they have usually been obtained under different test conditions, for example, with different combinations of temperature and stress. Moreover, for oxides exhibiting large differences in creep resistance, the position of the stress–temperature regimes employed can vary significantly. To make a meaningful comparison of creep resistance in these cases, the creep data was evaluated here on the basis of a Larson–Miller normalisation procedure[1] as will be outlined in the next section.

Studies of the creep of single crystal oxides have been reported for both compressive and tensile loading and these are treated separately in this paper.

2 Larson–Miller Procedure for Creep Data Evaluation

The basis of the Larson–Miller treatment is that the creep process can be considered to be thermally activated and consequently for a given applied stress the creep rate is described by an Arrhenius-type expression of the form:

$$\dot{\epsilon}_s = A\exp(-Q/RT) \tag{1}$$

where $\dot{\epsilon}_s$ is the steady state creep rate, Q is the activation energy for the creep process, T is the absolute temperature in Kelvin, R is the gas constant and A is a constant. Equation (1) can also be written as

$$Q/R = T(\ln A - \ln \dot{\epsilon}_s) \tag{2}$$

Introducing the concept of a creep life, t_S, defined as the time taken for the steady state creep rate to yield a given arbitrary strain, ϵ_x:

$$t_s = \epsilon_x/\dot{\epsilon}_s \tag{3}$$

Equation (2) can then be written:

$$L = Q/R = T(C + \log t_s) \tag{4}$$

*Permanent address: Third Department, Central Iron and Steel Research Institute, 100081 Beijing, China.

where L is the so-called Larson–Miller parameter and C is a constant. Assuming Q to be independent of temperature, the value of L at a given stress for a given material is considered to be constant, which implies that there is a fixed relationship between T and t_S. Moreover it is generally found that L is inversely proportional to log σ, the applied stress. Thus, L values derived from creep experiments carried out at different combinations of stress and temperature can be plotted against log σ to yield a single straight line. Creep data appropriate to other combinations of stress–temperature–lifetime can then be predicted from the Larson–Miller plot by interpolation or extrapolation. For example, in the present work, the Larson–Miller plots were used to derive a 'creep strength' defined as the stress required at 1600°C to produce a strain, ϵ_x, of 10^{-5} in a time, t_S, of 10^4 s, (i.e. $\dot{\epsilon}_s = 10^{-9}$).

The derived relationship between σ, t_S and T is relatively insensitive to the value of the constant C and it is often set at a fixed value when considering a group of related materials. However, in this work, whenever sufficient experimental data was available, an individual value of C was determined for each oxide, being extracted from a plot of log t_S versus $1/T$ on the basis of a rearrangement of eqn (4):

$$\log t_s = -C + \text{constant}/T \qquad (5)$$

In the present Larson–Miller treatment of published data, values of strain rate corresponding to a steady state were sought, care being taken to avoid values corresponding to primary stages of creep. The values were taken either as reported explicitly or estimated from the published creep curves.

3 Results

Representative plots of log t_S versus $1/T$ used to derive C values are shown in Figs 1 and 2 for ThO_2 and Al_2O_3 single crystals. Several Larson–Miller plots for different oxides are presented in Figs 3–7. Derived C values and values of creep strength together with test details and source references are collected in Tables 1 and 2 for compressive and tensile loading respectively.

It was found that the log t_S versus $1/T$ plots for a given oxide and crystal orientation at different stresses yielded C values with relatively small variations as can be seen from Figs 1 and 2; in these cases average values were used. In some instances small differences in slope were observed (Fig. 2) indicating a variation in the activation energy, Q. This effect was neglected and again an average value of C was used.

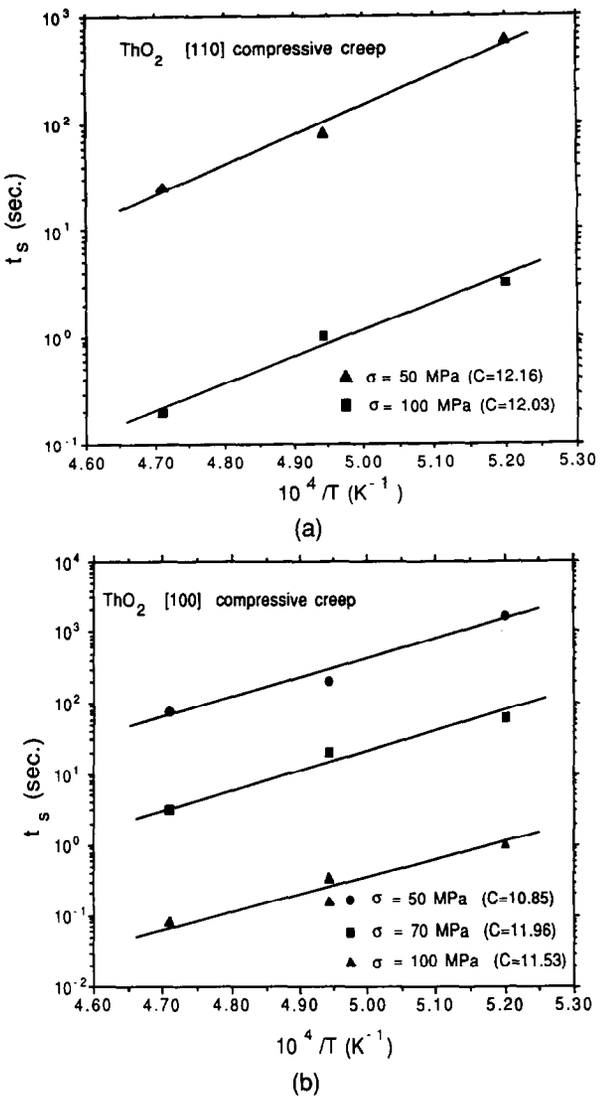

Fig. 1. Plot of log(t_s) versus ($1/T$) of ThO_2 single crystal: (a) [110]; (b) [100].

Figures 3–7 show L values derived from the stated C values using eqn (4) plotted versus the corresponding values of logarithm of applied stress. Linear regression was used to construct the

straight lines through the data. Where sufficient data is available, good correlation with the assumed linearity is observed. The constructed lines were then used to obtain the creep strength, i.e. the stress corresponding to $t_S = 10^4$s at a temperature of 1600°C. These conditions were based on a criterion for reinforcements in oxide–oxide composites proposed by Courtright.[2] As an example, for ThO_2 crystals (Fig. 3), the values of t_S and T give a Larson–Miller parameter of $L = 29968$ which gives by extrapolation creep strengths of 47 and 41 MPa for the [100] and [110] orientations respectively.

Creep data for crystals exhibiting the same C value can be displayed on plots with identical scales which permits direct comparison of the creep resistance of different crystals over the complete stress–temperature–life regime. This can be seen in Fig. 5 which demonstrates the sensitivity

of the creep of MgO to crystal orientation. Similarly, Fig. 6 reveals the sensitivity of the creep resistance of spinel to composition.

Figure 7 summarises tensile creep results for sapphire fibres; these have attracted considerable interest as potential reinforcement fibres. The figure illustrates the observed sharp decrease in creep resistance with angular deviation from *c*–axis loading but also a variation in the results from different sources. Such variation could in part be due to small variations in the axial orientation of fibres having a nominal *c*-axis orientation, reflecting the difficulty of growing the fibres with a precise orientation.

The effects revealed by the figures are also reflected in the creep strength values in Tables 1 and 2. Here it can also be seen that certain oxides such as Al_2O_3 and the binary oxides, $BeAl_2O_4$, yttrium aluminium garnet (YAG), mullite and spinel have very high creep resistance in certain crystal directions but exhibit extreme anisotropy. Others such as thoria and stabilised zirconia exhibit moderate strength with less anisotropy. Although there is small scope for direct comparison, the tensile creep results are fairly consistent with the compressive creep results, the former showing a tendency towards somewhat higher strengths. In general the results indicate that certain oxides show promise as high temperature reinforcements.

The creep mechanisms of the oxides are far from well understood and it is not the intention of this work to discuss possible explanations of the observed creep behaviour. Nevertheless, it is of interest to view the results in the light of the methodology proposed by Hillig[29] for predicting the mechanical properties of oxides at high temperature on the basis of such factors as the field strength of the cationic species, the apparent atomic volume of oxygen (V_O), the melting temperature and the crystal structure. Oxides having low values of V_O, high melting point and the most irregular and complicated crystal structure are predicted to offer the greatest strength, stiffness, creep resistance, and high temperature stability. On this basis certain oxides with complex structure, large shear moduli and large Burger's vector such as sapphire, YAG, spinel, mullite, chrysoberyl and BeO were considered to be the most promising candidates. In Table 3, several oxides are listed in the order of their melting points together with the upper and lower bound compressive creep strengths and details of their crystal structure. This confirms that the oxides with complicated structures, such as hexagonal, complex

ThO_2	Cubic (Fluorite)	3050	46	39

cubic and orthorhombic, exhibit superior creep resistance but as already noted are often very anisotropic. However, there is no obvious relationship between creep resistance and melting point. Thus, it seems that the effect of crystal structure overrides any correlation with melting point.

The extreme anisotropy of certain oxides presumably originates in an anisotropy of crystal and atomic bond structure. In this respect, a parallel can be drawn with carbon fibres in which the strong graphite basal atomic planes are oriented parallel to the fibre axis, leading to an extreme anisotropy of strength and stiffness in the fibres. In spite of their anisotropy, carbon fibres provide very successful reinforcement in composites, including carbon–carbon composites for high temperature applications.

4 Reliability of the Larson–Miller Procedure

The Larson–Miller method is a procedure that normalises creep data with respect to stress, temperature and strain rate. Its advantage over other normalisation approaches is that it permits convenient comparisons on the basis of relatively little data, only requiring the determination of two constants (the constant C and the slope of the log σ versus L plot). It may be suspected that this convenience is achieved at the expense of precision since the many variables involved in the creep processes are not accounted for individually. A more detailed description of the creep process used by Corman[3] is given by the semi-empirical power law equation:

$$\dot{\epsilon}_s = \frac{A_o D G b}{kT} (\sigma/G)^n \tag{6}$$

where A_o and n are constants, D is the appropriate diffusion coefficient, G the shear modulus, b the Burger's vector, k Boltzmann's constant, and σ is the applied stress. Putting

$$D = D_o \exp(-Q_D/RT) \tag{7}$$

where D_o is the frequency factor and Q_D the activation energy for the diffusion process, and:

$$G = G_o - (\Delta G)T \tag{8}$$

where G_o is the value of the shear modulus obtained by linear extrapolation to absolute zero, eqn (6) becomes after some rearrangement:

$$\dot{\epsilon}_s = A' \frac{G_o - (\Delta G)T}{kT} \left[\frac{\sigma}{G_o - (\Delta G)T}\right]^n \exp(-Q/RT) \tag{9}$$

where A' is a constant. For some of the oxides in Table 1, sufficient data was available for Corman to determine the values of A', Q_D and n by a regression analysis.[3] These values are listed in Table

Table 4. Comparison of the calculated results from semi-empirical equation with the results from Larson–Miller procedure

4 together with the associated values of creep strength calculated from eqn 9 with $\dot{\epsilon}_s = 10^{-9}$ s^{-1} and $T = 1873$ K, the latter being compared with the corresponding values derived using the Larson–Miller treatment. The agreement is sufficient to demonstrate that the Larson–Miller method offers a similar level of reliability.

5 Conclusions

The Larson–Miller method provides a convenient and effective means of comparing and ranking the creep resistance of oxides on the basis of results obtained under different stress and temperature conditions.

The creep of single crystals of several single and binary oxides was compared and it was found that binary oxides with complex crystal structures exhibited the highest creep strengths. However, these oxides were very anisotropic and the high strengths were found only for specific crystal orientations.

No clear correlation between the creep resistance of the oxides and their melting point could be seen.

(Received 21 July 1994; revised version received 3 September 1994; accepted 10 January 1995)

Abstract

Effect of vapor atmosphere on the formation reaction of $MSiO_3$ (M = Mg, Ca, Sr and Ba) from various precursor powders was investigated by powder X-ray diffraction. Precursors of $MgSiO_3$ and $CaSiO_3$ were prepared by the coprecipitation method by adding NH_4OH to ethanol solution dissolving a respective nitrate and tetraethyl orthosilicate (TEOS). Those of $SrSiO_3$ and $BaSiO_3$ were prepared from respective hydroxide powder and TEOS. Vapor atmosphere showed the most effective influence in the formation of $CaSiO_3$, whereas it showed the least influence in that of $MgSiO_3$ among the four kinds of $MSiO_3$ formation. The difference in effect was mainly attributed to the degree of chemical homogeneity of the precursor powder, the effect being smaller the higher the chemical homogeneity. The samples fired under a vapor atmosphere showed larger specific surface area than those under a dry atmosphere.

1 Introduction

$CaSiO_3$ (wollastonite) has been used and/or studied as a raw material of tile and pottery,[1] a filler to resin,[2] etc. Since sinterability of $CaSiO_3$, is generally not so high, fine and homogeneous powders are necessary as the raw material to prepare dense $CaSiO_3$ ceramics. A conventional synthetic method to mix and calcine raw material powders of $CaCO_3$ and SiO_2 is not appropriate to prepare fine $CaSiO_3$ powders because relatively high temperature is necessary for the formation of $CaSiO_3$ phase due to the sluggish reactivity of SiO_2 component. Several preparation methods from solution have been examined in order to prepare fine and homogeneous $CaSiO_3$ powder. We (Ref 3) reported that good $CaSiO_3$ powder could be prepared by the coprecipitation method from ethanol solution dissolving Ca nitrate and TEOS. No by-product phases were detected during the formation of $CaSiO_3$. We also clarified that fine and homogeneous $MgSiO_3$ powder could be synthesized by the same method as that of $CaSiO_3$, whereas good $SrSiO_3$[4] and $BaSiO_3$ powders could be prepared from a combination of respective hydroxide powder and TEOS.

It is well known that a vapor atmosphere has a certain effect to lower the crystallization temperature of some silicate glasses.[5,6]. Vapor is considered to react to break down Si–O–Si bonds and forms Si–OH groups, thus, weakens the glass structure. It, therefore, lowers the kinetic barrier to nucleation, and increases the mobility of atoms in the glasses.[6] Vapor atmosphere was also reported to be effective for accelerating solid state $CaSiO_3$ formation reaction.[7]

Considering these facts, formation reaction of $CaSiO_3$ and also $MSiO_3$ (M = Mg, Sr and Ba ions) were expected to be lowered by firing under a vapor atmosphere compared with firing in a normal atmosphere. In this paper, formation of $MSiO_3$ from respective precursors under a vapor and a dry air atmosphere was examined to elucidate the effect of the atmosphere on the formation of the various $MSiO_3$ phases.

2 Experimental procedures

2.1 Preparation of the starting powders

Precursor powders of $MgSiO_3$ and $CaSiO_3$ were

†To whom correspondence should be addressed.
*Nihon Cement Co., Ltd., 1-2-23, Kiyosumi, Koutou-ku, Tokyo 135, Japan

prepared using the coprecipitation method.[3] In the $MgSiO_3$ precursor powder, a starting solution was prepared by dissolving $Mg(NO_3)_2 \cdot 6H_2O$ and TEOS in ethanol. The ratio of Mg/Si in the solution was 1 and their respective concentrations were 0·2 mol/l. The same amount of 25% NH_4OH as the starting solution was added to the starting solution by stirring vigorously. The precursor powder was obtained by drying the precipitate and by calcining at 500°C for 2 h.

The precursor powder of $CaSiO_3$ was synthesized using the same method as $MgSiO_3$, using $Ca(NO_3)_2 \cdot 4H_2O$ and TEOS as the starting materials.

$SrSiO_3$ and $BaSiO_3$ precursor powders were prepared using the following method:[4] hydrate powder of $Sr(OH)_2 \cdot 8H_2O$ or $Ba(OH)_2 \cdot 8H_2O$ respectively was dispersed in ethanol, and TEOS was added to this solution. They were mixed and dried on a water bath. The hydrate powder dissolved during this process and was precipitated again by condensation of the solution. The other processes were the same as in the synthesis of the $MgSiO_3$ precursor powder.

Precursor powders of $CaSiO_3$ were also prepared using the three other methods to investigate the influence of the precursors on the formation of $CaSiO_3$ in the vapor atmosphere. They were the alkoxide coprecipitation method, the two-step precipitation method and the solid mixing method. In the first method, Ca ethoxide, $Ca(OC_2H_5)_2$ was used instead of Ca nitrate in the preparation. Ca ethoxide was synthesized by reacting Ca metal powder and ethanol by refluxing in an Ar atmosphere. Then tetramethyl orthosilicate (TMOS) was added to the solution and mixed. The following processes were the same as in the coprecipitation method. The precursor powder prepared by this method was more homogeneous than the powder prepared by the coprecipitation method. In the second method, oxalic acid was added to the starting solution proceeding to the NH_4OH addition. Oxalic acid yielded precipitation of Ca oxalate and NH_4OH yielded precipitation of amorphous silica by the hydrolysis of TEOS. Formation of α-$CaSiO_3$ instead of β-$CaSiO_3$ was the characteristic result in this precursor powder. In the third method, $CaCO_3$ powder and SiO_2 aerogel powder were mixed in ethanol by ball mill for 24 h. The mixture was then dried and calcined at 500°C for 2 h. The powder prepared by this method is less homogeneous than the other ones, i.e. β-Ca_2SiO_4 was formed as the main by-product phase by firing.

2.2 Firing experiments

The precursor powders were fired at various temperatures in a vapor and a dry air atmosphere by an electric furnace. Firing experiments in the vapor atmosphere was performed by flowing a carrier gas (air), which was bubbled in a water bath. Vapor pressure of the carrier gas was controlled at 0·47 atm by adjusting the temperature of the water bath at 80°C. Firing experiments in the dry atmosphere were performed by flowing a carrier gas excluding moisture by a $CaCl_2$ drying agent.

The samples were fired at a set temperature between 400 and 1000°C for a duration of 2 h. All the experiments were performed at the flow rate of 180 ml/min.

2.3 Characterization

After the firing experiments, crystalline phases in the samples were identified by the X-ray powder diffraction method (Rigaku, Geigerflex) using monochromated CuKα radiation. The amount of crystalline phases was estimated semi-quantitatively by comparing the X-ray diffraction intensities. The reflections used were as follows; 310 in $MgSiO_3$ (clinoenstatite), 320 in β-$CaSiO_3$, 112 in α-$CaSiO_3$, 002 in β-Ca_2SiO_4, the reflection at d = 3·08 Å in $SrSiO_3$ (metastable phase), 022 in $SrSiO_3$ (stable phase) and 111 in β-$BaSiO_3$.

Specific surface area was measured by the multipoint B.E.T. method (Carlo Elba Strumentazione, Soaptomatic Series 1800) using nitrogen gas.

3 Results and Discussion

The $MgSiO_3$ precursor powder was amorphous in the as-calcined state and crystallized at around 770°C in both atmospheres. Formation curves of $MgSiO_3$ phase under both firing atmospheres are shown in Fig. 1. The amount of $MgSiO_3$ in the two curves increased very rapidly between 770 and 800°C, and saturated above this temperature. Since the two curves almost coincided with each other, it is concluded that the vapor has no effect on the $MgSiO_3$ formation reaction.

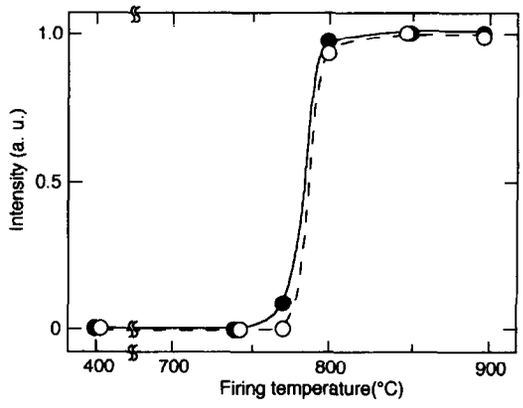

Fig. 1. Formation curves of $MgSiO_3$ by firing the precursor powder under the dry (○) and the vapor (●) atmospheres.

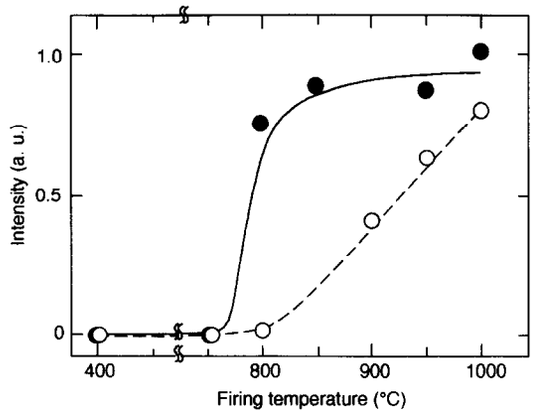

Fig. 2. Formation curves of β-$CaSiO_3$ by firing the precursor powder under the dry (○) and the vapor (●) atmospheres.

The $CaSiO_3$ precursor powder was amorphous in the as-calcined state. Fig. 2 shows the formation curves of β-$CaSiO_3$ phase after firing in the dry and the vapor atmospheres. In the dry atmosphere, crystallization occurred at 800°C and the formation amount increased gradually and linearly between 800 and 1000°C. On the other hand, β-$CaSiO_3$ started to crystallize at 750°C in the vapor atmosphere, the formation amount increased steeply up to 800°C and almost saturated over this temperature. This shows that there is a large difference in the formation of $CaSiO_3$ in the dry and the vapor atmospheres. Vapor is found to accelerate the crystallization of $CaSiO_3$ in this case.

The $SrSiO_3$ precursor powder was amorphous in the as calcined state. Crystalline $3SrO{\cdot}2SiO_2{\cdot}3H_2O$ was detected in the as-precipitated state, but it yielded an amorphous product during the calcination. Figure 3 shows the formation curves of $SrSiO_3$ phases in the two atmospheres. In these samples, the first crystalline phase appeared by firing was a metastable $SrSiO_3$ phase and it transformed to a stable $SrSiO_3$ phase by firing at higher temperature.[4] The sequence of phase changes was the same in the dry and in the vapor atmospheres but reaction temperatures were different in the two atmospheres. The reaction temperatures in the vapor atmosphere were always around 50°C lower than those in the dry atmosphere. Vapor is, therefore, fairly effective in this system.

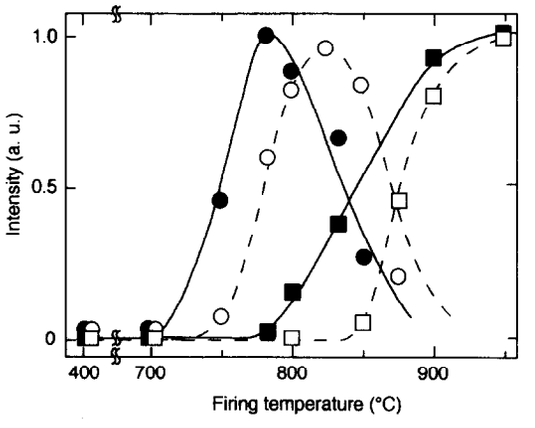

Fig. 3. Formation curves of metastable (○, ●) and stable (□, ■) $SrSiO_3$ by firing the precursor powder under the dry and the vapor atmospheres. Open and solid symbols correspond to the dry and vapor atmospheres, respectively.

In the $BaSiO_3$ samples, crystalline $BaSiO_3{\cdot}H_2O$ was formed in the as calcined state and was converted to crystalline $BaSiO_3$ during the calcination. This was the characteristic point of this sample because all the other samples were amorphous in the as calcined state. A considerable amount of $BaSiO_3$ was already formed in the samples fired at 400°C. However, crystallization to $BaSiO_3$ was not accomplished around that temperature. It means that the as-precipitated sample contains amorphous as well as $BaSiO_3{\cdot}H_2O$. Figure 4 shows the formation curves of $BaSiO_3$. The amount of $BaSiO_3$ started to increase from around 600°C and almost saturated at 800°C. Since the formation curve in the dry atmosphere differed only a little from that in the vapor atmosphere, the effect of vapor is very small in the $BaSiO_3$ samples.

In this way, the effect of vapor on the formation of crystalline $MSiO_3$ phases differed considerably largely among the samples. No significant effect was detected in the $MgSiO_3$ and $BaSiO_3$ samples whereas $MSiO_3$ crystallization was apparently accelerated in the $CaSiO_3$ and $SrSiO_3$ samples. Two different reasons were considered to yield these results. One reason can be attributed to the difference of the character of the M–O bond in the $MSiO_3$ samples. The second reason considered was the influence of the structural state of the precursor powders, i.e. the degree of homogeneity in the mixing state of the two components, and the degree of polymerization state of the silica component. Since the effect of vapor for the respective $MSiO_3$ formation showed no correlation with the order of periodic table of the alkaline earth metal ions, the second reason was considered to be

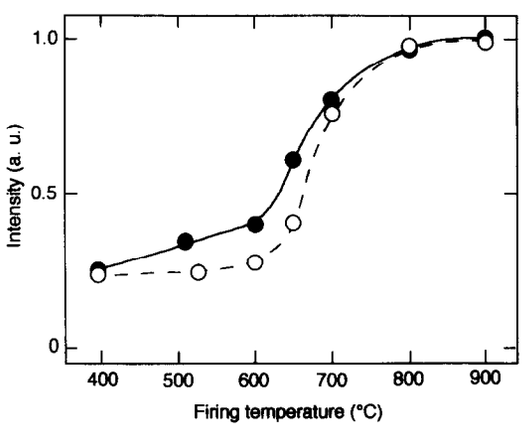

Fig. 4. Formation curves of $BaSiO_3$ by firing the precursor powder under the dry (○) and the vapor (●) atmospheres.

important. Although the precursors of $MgSiO_3$ and $CaSiO_3$ were prepared by the same method, we[8] found by an analytical transmission electron microscopy that the $MgSiO_3$ precursor powder was more homogeneous than the $CaSiO_3$ precursor powder. On the other hand, the precursors of $SrSiO_3$ and $BaSiO_3$ were prepared by the same method and crystalline phase was formed in the as-precipitated state. They were $3SrO{\cdot}2SiO_2{\cdot}3H_2O$ and $BaSiO_3{\cdot}H_2O$, respectively. Since the M/Si ratio of crystalline phase formed in the as-precipitated state was same with that of the objective crystalline phase $MSiO_3$ in the $BaSiO_3$ sample but was different in the $SrSiO_3$ sample, the $BaSiO_3$ sample was more homogeneous than the $SrSiO_3$ sample. In this way, the effect of vapor atmosphere for the crystallization was considered to change by the structural state of the as-precipitated precursor powders. Four kinds of $CaSiO_3$ precursor powders with different structural state were, therefore, prepared to examine the relationship between the effect of vapor and their degree of homogeneity. The $CaSiO_3$ formation curves in the solid mixing method, the two-step precipitation method, the coprecipitation method, and the alkoxide precipitation method are shown in Figs 5, 6, 2 and 7, respectively.

In the solid mixing method, β-Ca_2SiO_4 crystallized preceding to β-$CaSiO_3$. Such a phenomenon to form an alkaline earth metal rich phase is generally known when the formation reaction proceeds mainly by the diffusion of ions and the diffusion paths are long, because the diffusion coefficient of alkaline earth metal is larger than that of silicon. Vapor atmosphere was effective in accelerating the formation of β-$CaSiO_3$ from β-Ca_2SiO_4 and amorphous silica. Vapor is considered to attack surface Si–O–Si bonds in the amorphous silica and yields Si–OH bonds. It is very effective to cause the powder active state.

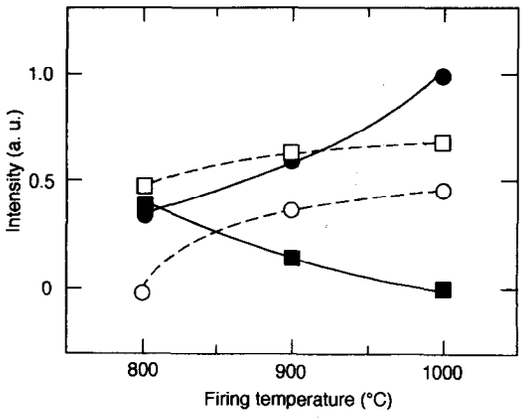

Fig. 5. Formation curves of crystalline phases by firing the solid-mixing $CaSiO_3$ precursor powder under the dry and the vapor atmospheres. Circles and squares correspond to β-$CaSiO_3$ and β-Ca_2SiO_4, and open and solid symbols correspond to the dry and the vapor atmospheres, respectively.

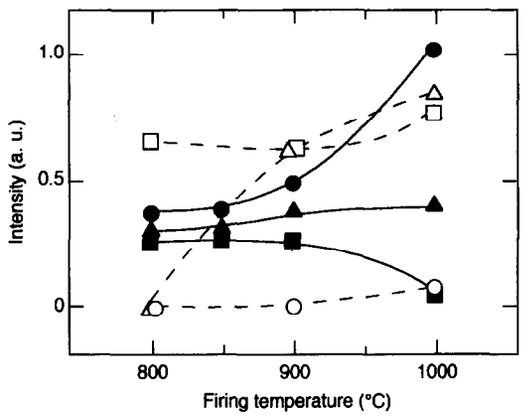

Fig. 6. Formation curves of crystalline phases by firing the two-step precipitated $CaSiO_3$ precursor powder under the dry and the vapor atmospheres. Circles, triangles and squares correspond to β-$CaSiO_3$, α-$CaSiO_3$ and β-Ca_2SiO_4, respectively. Open and solid symbols correspond to the dry and the vapor atmospheres, respectively.

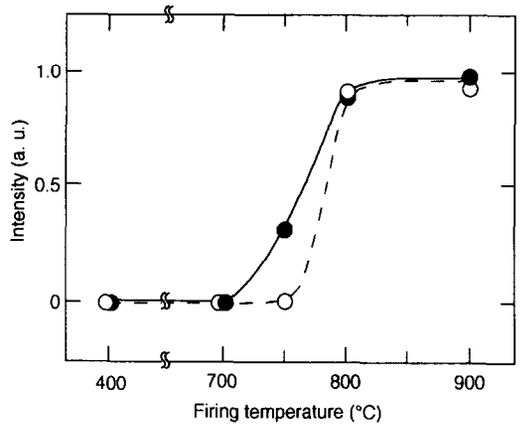

Fig. 7. Formation curves of β-$CaSiO_3$ by firing the alkoxide coprecipitated $CaSiO_3$ precursor powder under the dry (○) and the vapor (●) atmospheres.

Therefore, formation of β-$CaSiO_3$ largely accelerated under the vapor atmosphere.

Crystallization reaction in the two-step precipitation method was much more complicated and not only β-$CaSiO_3$ and β-Ca_2SiO_4 but also α-$CaSiO_3$ (pseudowollastonite) were formed simultaneously. Formation of α-$CaSiO_3$ was the characteristic point of this preparation method. It is the high-temperature phase of $CaSiO_3$ and is stable at the temperature range between 1125 and 1544°C.[9] The actual reason for the formation of this phase was not certain. Since β-Ca_2SiO_4 remained even after firing at 1000°C in the dry atmosphere, vapor was found to be very effective to accelerate the decomposition of β-Ca_2SiO_4 and formation of $CaSiO_3$ in this sample.

The results of the coprecipitation method have already been discussed. In method, only the objective crystalline phase β-$CaSiO_3$ was formed and no by-productive crystalline phase was detected. Therefore, homogeneity of the precursor powder in this method was considered to be better than

those in the solid mixing and the two-step precipitation methods. The formation reaction of β-$CaSiO_3$ was apparently accelerated under the vapor atmosphere as shown in Fig. 2. It may mean that the precursor is not homogeneous in the molecular level and is examined by the ^{29}Si NMR spectra.[10]

In the alkoxide precipitation method, β-$CaSiO_3$ crystallized at the lowest temperature among the four synthetic methods. It may mean that the precursor of this method was in the most homogeneous state. The formation curve showed only a little difference in the vapor and the dry atmospheres and the effect of vapor was the smallest among the various $CaSiO_3$ samples.

Summarizing the results of the four kinds of $CaSiO_3$ precursors, we can conclude as follows:

(1) When the mixing of CaO and SiO_2 components was particle size order, i.e. submicron to micron meter, Ca-rich by-product phase crystallized preceding to the $CaSiO_3$ phase. In this case, vapor played an important role in accelerating the formation reaction of $CaSiO_3$ by attacking Si–O–Si bonds in amorphous SiO_2. The solid mixing and two-step precipitation methods belong to this category.

(2) When the mixing of two components was partly molecular level but remained partly inhomogeneous, vapor was effective in activating the reactivity of the inhomogeneous region. The coprecipitation method may belong to this category.

(3) When the mixing was more homogeneous than the other methods and was molecular level, vapor showed little influence to $CaSiO_3$ formation because no silica-like polymerized structure remained in the precursor.

Figure 8 shows the specific surface area of $CaSiO_3$ samples prepared by the coprecipitation method and fired at various temperatures under the dry and the vapor atmospheres. The surface area fired under the vapor atmosphere was always larger than that under the dry atmosphere irrespective of the firing temperature. Ito[7] reported that the $CaSiO_3$ powder synthesized by the conventional solid reaction method was very easy to grind into fine powder when it was fired under a vapor atmosphere. This is compatible with the present results. Although the formation amount of β-$CaSiO_3$ in the sample fired at 800°C under the vapor atmosphere was almost same with that in the sample fired at 1000°C under the dry atmosphere, the surface area of the former was 5 times as large as that of the latter one. This result shows that the heat treatment under a vapor atmosphere is effective to prepare fine crystalline silicate powder at lower temperatures than that in a dry atmosphere or in a normal atmosphere.

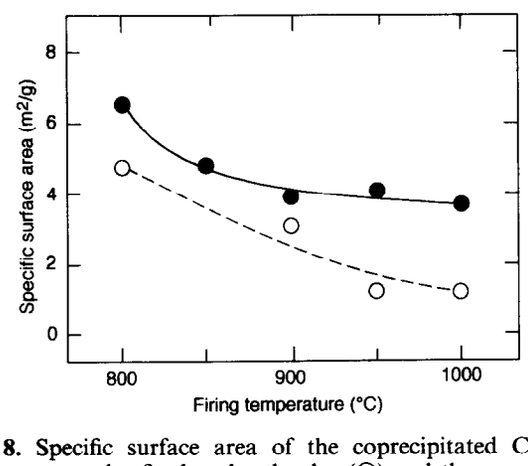

Fig. 8. Specific surface area of the coprecipitated $CaSiO_3$ precursor powder fired under the dry (○) and the vapor (●) atmospheres.

4 Summary

The effect of a vapor atmosphere on the formation of $MSiO_3$ (M = Mg, Ca, Sr and Ba) was examined using the precursor mainly prepared by the coprecipitation method. Among the four kinds of $MSiO_3$, vapor showed most effective influence in the $CaSiO_3$ sample and the least effective influence in the $MgSiO_3$ sample. The reason for these differences was mainly attributed to the chemical homogeneity of the precursor powder. It was further confirmed using the several kinds of $CaSiO_3$ precursor powders prepared by the different methods. The heat treatment of the precursor under the vapor atmosphere was effective to prepare fine crystalline powder compared with that under the dry atmosphere.

Abstract

Boron carbide, B_4C, is an attractive candidate material for reinforcement in metal matrix composites, whose application is severely hampered by its reactions with most engineering alloys at the high processing or service temperatures. The reactivity of B_4C with some of the metals, however, may be made use of to create protective coatings on its surface. In the present research, the microstructure of coatings obtained by the interaction of B_4C with Ti and Cr powders at 1000–1200°C was investigated employing X-ray diffraction, scanning electron microscopy and Auger electron spectroscopy. Coatings obtained by treating B_4C in Ti powder were found to contain Ti carbide, TiC_{1-X}, and Ti borides (TiB_2 and TiB). A relatively thin inner layer of the coating was carbide-free and contained only borides, while the major part of the coating was a mixture of TiC_{1-X} and TiB. In contrast to this, coatings formed by reaction of B_4C with Cr powder contained no carbides, and were shown to consist of Cr borides (CrB_2, CrB, Cr_5B_3 and Cr_2B) and amorphous carbon. A thick outer layer of the coating was carbon-free and consisted almost entirely of CrB. In both cases, the growth of the coatings was controlled by diffusion, the activation energy for the growth of B_4C/Ti coating being approximately 175 KJ/mol. The phase composition, layer sequence and morphology of the coatings obtained were interpreted on the basis of kinetic and thermodynamic data of the ternary systems involved. A good agreement between the experimental results and theoretical predictions was obtained.

1 Introduction

Non-oxide ceramics are important materials having a high potential for advanced structural and electronic applications, as well as reinforcements for metal matrix composites (MMCs). Boron carbide, B_4C, is especially attractive due to its very low density, high hardness and relatively low cost, at least in the particulate form. However, the use of B_4C (as well as other non-oxide ceramics) as a reinforcement for Fe-, Ni- and Co-base alloys is severely hampered by reactions that occur at the ceramic/metal matrix interface at the high processing and/or service temperatures. Although large bulk of evidence exists for the reactivity of non-oxide ceramics with metals,[1–3] the interaction between B_4C and structural Fe-, Ni- and Co-base alloys has practically not been investigated. The solid state reaction between B_4C and nickel at 880°C was reported to yield a complex product at the interface, Ni being a dominant diffusing species.[4] The formation of undesirable reaction products, as well as the dissolution of the ceramic in a metal, result in the degradation of the reinforcement and in the deterioration of the mechanical properties of the matrix and of the MMC as a whole. Since the performance of MMCs is, to a large extent, controlled by the structure and properties of ceramic/metal interfaces, it is important to prevent or, at least, to minimize the reactions at these interfaces. This may be achieved by creating diffusion barriers. The necessity of a diffusion barrier for application of B_4C as a reinforcement for MMCs was emphasized in Ref. 4. One of the possible ways of creating a diffusion barrier is by coating the ceramic prior to inserting it into a metal matrix.

It has been recently shown that non-oxide ceramics such as SiC, Si_3N_4 and B_4C, can be coated employing their interaction with powders of metals having high affinity for carbon, silicon and boron, and a new powder immersion reaction assisted coating method (PIRAC) has been proposed.[5–8] The objective of the present research is to study the microstructure of PIRAC coatings obtained by treating B_4C in Ti and Cr powders.

2 Experimental

In the present research, Cr metal powder (< 150 μm) from Merck, Ti metal powder (~ 100 μm) from Alfa Products and hot pressed boron carbide, B_4C, were used. Plates of B_4C were immersed into the metal powders and heat treated at 1273–1473 K. Heat treatments were conducted in evacuated quartz tubes (10^{-6} Torr at room temperature). After heat treatment, the reacted layers were investigated employing X-ray diffraction, XRD (Philips 1730/10), scanning electron microscopy, SEM, with energy dispersive analysis, EDS (JEOL 840), and Auger electron spectroscopy, AES (Perkin-Elmer PHI 590A).

3 Results and Discussion

3.1 Microstructure of B_4C/Ti powder interface

A representative micrograph of the coating obtained by treating B_4C in Ti powder is shown in Fig. 1. According to the XRD pattern, Fig. 2, the coating consists of a Ti boride, TiB, and the Ti carbide, TiC_{1-X}. The intensities of the TiB peaks do not match the standard intensities, indicating a pronounced (020)-preferred orientation. It should be mentioned that preferred orientation in the direction of the shortest lattice parameter (and [020]/[010] is such a direction for TiB) is often observed during the diffusion growth of compounds with orthorhombic structure.[9] The peaks of TiC_{1-X} are slightly shifted from the standard positions of the stoichiometric TiC, yielding the lattice parameter a ≈ 0·431 nm. This value corresponds to a hypostoichiometric $TiC_{0.6}$ carbide.[10]

Thin coatings obtained after short PIRAC treatments were found to be tightly bonded to the B_4C surface. On the other hand, thicker coatings (> 2–3 μm) tended to spall off the ceramic substrate and stick to the Ti powder, thus revealing the inner surface (coating/B_4C interface) of the reaction layer. A similar behavior was previously observed for PIRAC coatings obtained by treating SiC[7] and Si_3N_4[8] in Ti powder. This allowed to obtain separate AES depth profiles for both the inner, Fig. 3(a), and the outer, Fig. 3(b), layers of the B_4C/Ti coating with good depth resolution. The depth profile in Fig. 3(a) clearly shows that the inner part of the coating is carbon-free and is assumed to be TiB, since this is the only boride detected by XRD. Towards the B_4C surface, however, an increase in the boron content and a corresponding decrease in the Ti content is observed,

Fig. 3(a), suggesting the presence of a thin layer of TiB_2 (or another B-rich boride). Apparently, this layer is too thin to be detected by XRD.

Unlike the inner part of the coating, the outer part contains all the three components — Ti, boron and carbon, Fig. 3(b). It is believed that this part of the coating is a mixture of TiB and TiC_{1-X}, with the amount of TiB gradually decreasing towards the surface. The drop of carbon concentration at the surface of the coating indicates the presence of a layer of TiC_{1-X} with the composition approaching the lower homogeneity limit, i.e. $TiC_{0.5}$. The described sequence of layers in the coating obtained by treating B_4C in Ti powder is schematically shown in Fig. 4.

The results of the kinetic studies, Fig. 5, reveal that the coatings obtained by treating B_4C in Ti powder grow according to the parabolic law, suggesting the diffusion controlled process. The activation energy of growth as calculated from the slope of the Arrhenius plot, Fig. 5(b), is approximately 175 KJ/mol.

In Fig. 6, the diffusion path corresponding to the layer sequence in Fig. 4 is shown superimposed upon the isothermal section of the B–C–Ti system. This diagram has been slightly modified from the one given in[11,12] to reflect the presence of the Ti_3B_4 phase that has been discovered more recently.[13] However, since there is no experimental or theoretical evidence for the stability of this phase at temperatures as low as 1473 K, the Ti_3B_4–TiC_{1-X} tie-line is shown as a dotted line. It can be seen that the experimental results are in a good agreement with the ternary isotherm. The consideration of the diagram shows that TiB_2 is the only phase that forms a stable interface with the stoichiometric B_4C, hence the formation of a thin TiB_2 layer (or TiB_2 and Ti_3B_4 layers) on the B_4C surface. Sections of the diffusion path running along the tie lines from B_4C to TiB_2 and from TiB_2 to TiB are dashed, indicating that B_4C, TiB_2 and TiB single-phase layers are separated by flat interfaces. Similarly, sections of the diffusion path running across a three-phase field to connect a two-phase region to another single-phase region, e.g. (TiB+TiC_{1-X}) to Ti, are drawn with dashed lines, too. This is to indicate that, since no three-phase regions can be formed in course of three component diffusion,[14] the two-phase layer is directly followed (or preceded) by the single-phase layer. (The above comments on the use of dashed lines apply also to the following discussion on the B–C–Cr ternary system). The formation of the

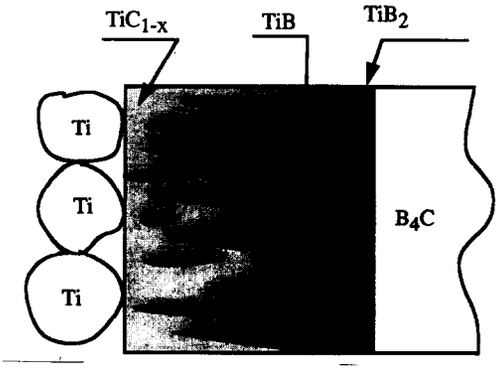

Fig. 4. Schematic of the layer sequence in the B_4C/Ti powder reaction layer obtained at 1000–1200°C.

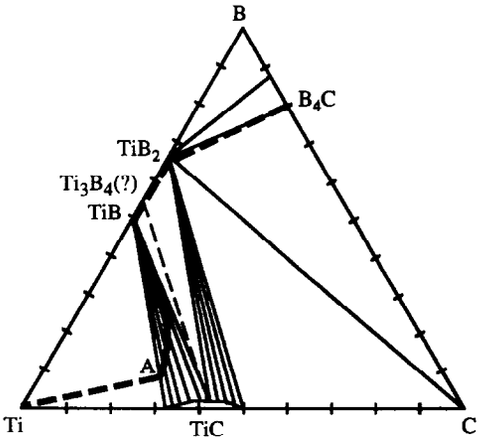

Fig. 6. Isothermal section of the B–C–Ti system at 1500°C.

hypostoichiometric $TiC_{0.6}$ is also in agreement with the diagram, since only a carbon-deficient TiC_{1-x} is in equilibrium with TiB. The same value of (1-x) = 0·6 was obtained by Barsoum *et al.*[15] as the lower limit of (1-x) for TiC_{1-x} in equilibrium with TiB_2 at 1600°C, or, conversely, as the upper limit for TiC_{1-x}in equilibrium with TiB.

In Fig. 6, the major (TiB + TiC_{1-x}) layer of the coating is represented by a section of the diffusion path that passes into a two-phase region (TiB + TiC_{1-x}) from a single phase one (TiB) at an angle to the tie lines and exits into another region. According to Kirkaldy *et al.*,[14] such a diffusion path represents a columnar or a columnar-plus-isolated-precipitate two-phase zone. This suggests that the mixed zone in the B_4C–Ti powder couple contains columnar (and, possibly, some isolated) TiB precipitates in a TiC_{1-x} matrix, the former being rooted in the parent TiB phase, as shown schematically in Fig. 4. Such a microstructure would be consistent both with the observed preferred orientation of TiB, and the columnar-like morphology of the coating cross section, Fig. 1.

The formation of the two-phase (TiB + TiC_{1-x}) layer may be explained by referring to the kinetic model for the formation of an aggregate versus layered morphology in diffusion couples, suggested by Rapp *et al.*[16] Although developed for less complicated diffusion layer sequences, the model seems to be well applicable to our B_4C/Ti powder system. If an initially planar interface between the TiB and TiC_{1-x} layers is assumed, the model predicts[16,17] that it will remain flat provided the growth of the TiB layer is limited by B diffusion through TiB. Alternatively, if the diffusion of Ti through TiC_{1-x} is the rate-limiting step, the two-phase aggregate morphology will result. In our case, the growth of TiB is, most probably, limited by Ti diffusion (the mobile B atoms usually diffuse much faster than the Ti atoms), hence the formation of the two-phase (TiB + TiC_{1-x}) layer in the coating, Fig. 4. Another comment that can be made regarding the relative diffusion rates in the B_4C/Ti couple is that, since the TiC_{1-x} carbide constitutes the major part of the foremost layer of the coating leaving behind the TiB boride, the diffusion of carbon in TiB must be more rapid than that of boron.

3.2 Microstructure of B_4C/Cr powder interface

A representative microstructure of the coating obtained by treating B_4C in Cr powder is shown in Fig. 7. In the micrograph, two morphologically different layers can be distinguished, the outer one having a pronounced 'columnar' structure. Coatings obtained after 1 – 4 h exposures at 1200°C were approximately 14 – 18 μm thick, and they

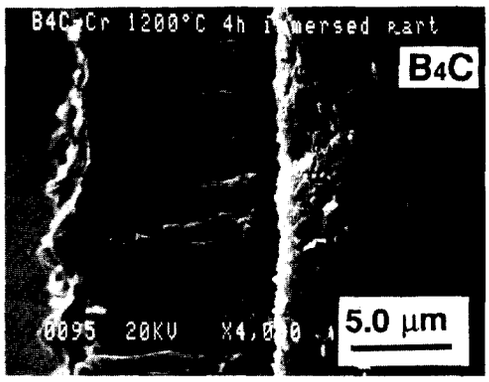

Fig. 7. A representative micrograph of the reaction layer obtained by treating B_4C in Cr powder (1200°C, 4 h), cross section.

easily split (e.g. during polishing) along the sublayer interface. A layer of carbon black was detected on both fracture surfaces. On the other hand, no splitting was observed in the thinner coatings (~7 μm) formed during 0·5 h exposure at 1100°C.

In Fig. 8(a), a typical XRD pattern of the coatings obtained at 1100–1200°C is presented. It can be seen that the coatings consist of different Cr borides: CrB as a major phase, Cr_5B_3 and Cr_2B. The pronounced (002) orientation of CrB suggests that this boride constitutes the outer layer of the

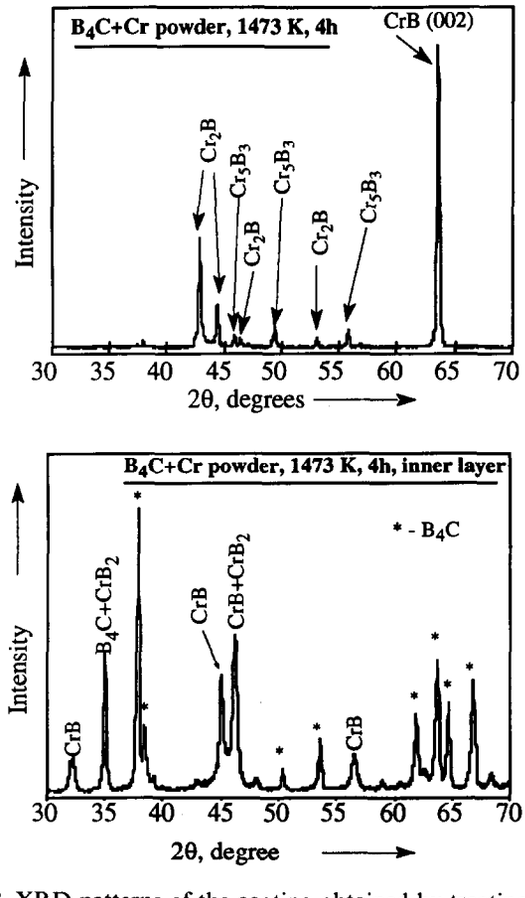

Fig. 8. XRD patterns of the coating obtained by treating B_4C in Cr powder (1200°C, 4 h): (a) the entire coating; (b) the inner layer.

coating having the 'columnar' morphology, Fig. 7. Similarly to the case of TiB, the preferred orientation is in the direction of the orthorhombic unit cell shortest parameter—[002]/[001] for the CrB lattice. The splitting of the coatings obtained at 1200°C made it possible to remove the outer layer and identify the phase composition of the inner layer more accurately. According to the XRD pattern in Fig. 8(b), the inner layer of the coatings obtained at 1200°C consists of CrB (with no preferred orientation) and CrB_2 (It should be mentioned that the XRD detection of CrB_2 is not unequivocal due to the superposition of the lines of CrB_2 and CrB or B_4C. However, the anomalously high intensity of the CrB peak at around $2\theta = 46°$ gives ground to the suggestion that the peak is, in fact, a superposition of the CrB (I/I_{max} = 80%) and CrB_2 (I/I_{max} = 100%) peaks. An alternative assumption that the high intensity of the peak is a result of a certain preferred orientation of CrB is not corroborated by other CrB peak intensities.) Since the coating obtained at 1100°C did not split, no separate XRD analysis of the inner layer phase composition was made. The XRD pattern of the coating as a whole does not indicate the presence of CrB_2 observed in the inner layer of the coating obtained at 1200°C.

The striking feature of the XRD results is the absence of Cr carbides or any other carbon-containing phases including graphite. It is clear, however, that since carbon is one of the products of B_4C decomposition, it should be present in the coating in some form. Indeed, a typical AES depth profile in Fig. 9(a) (1200°C, 4 h) shows that the inner layer of the coating contains, in addition to B and Cr, a large and constant amount of carbon. This mixed C–B–Cr layer is followed by a thin sublayer of pure carbon apparently corresponding to the 'split plane' of the coating. (It should be mentioned, that AES profiling to such a depth (~14 μm) was only made possible due to the splitting of the coating. In fact, three separate depth profiles were obtained: one from the surface of the coating, and two from each 'split surface'. The profile in Fig. 9(a) is a reconstruction based on the three above profiles.) The shape of the carbon KVV-peak in the AES spectrum, Fig. 9(b), was found to match that of the free rather than bound (carbide) carbon.[18] Since no graphite peaks were observed in the XRD pattern, the carbon in the coating is assumed to be amorphous. The profile in Fig. 9(a) clearly shows that the outer layer of the coating is carbon-free thus confirming our early assumption that this is a pure CrB layer. The increase of Cr concentration towards the surface of the coating, coupled with the XRD results, Fig. 8(a) suggests the presence of thin Cr_5B_3 and Cr_2B surface sublayers.

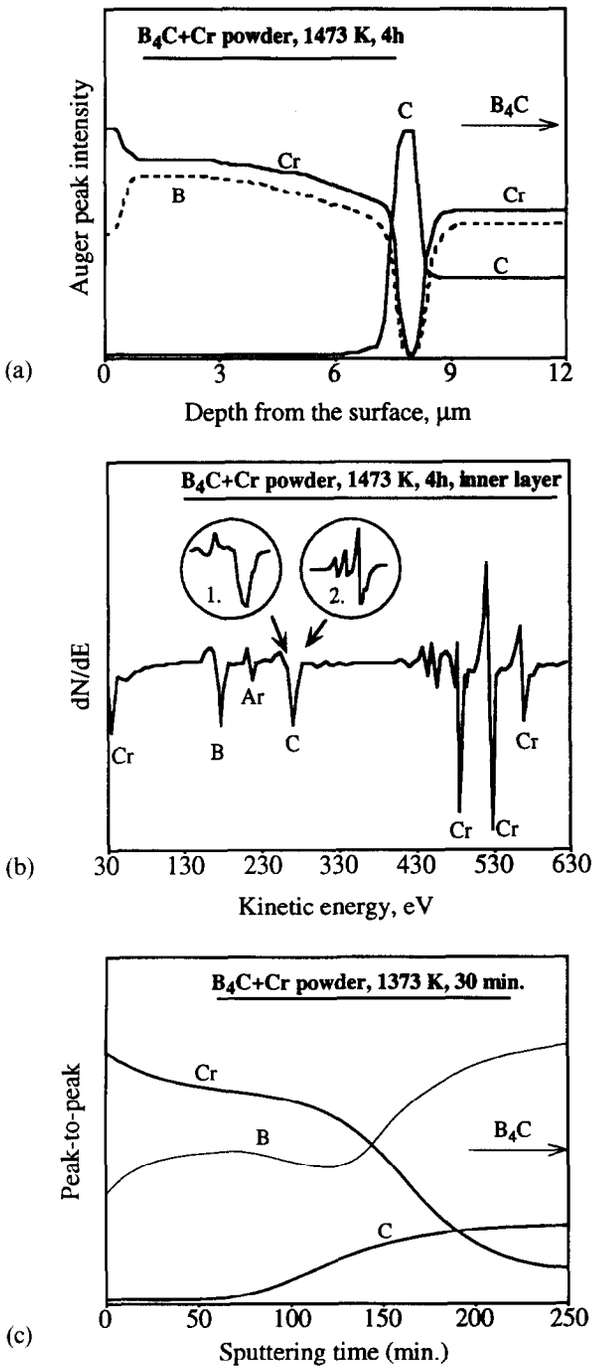

Fig. 9. AES results for the coatings obtained by treating B_4C in Cr powder: (a) 1200°C, 4 h, reconstructed depth profile, depth scale given according to SEM thickness; (b) 1200°C, 4 h, spectrum from the inner layer: 1 — KVV peak of free (unbound) carbon, 2 — KVV peak of bound (carbide) carbon; (c) 1100°C, 0·5 h, depth profile.

AES depth profile of the coating obtained at 1373 K, Fig. 9(c), being in all other respects similar to that in Fig. 9(a), does not reveal the presence of the pure carbon sublayer. This is consistent with the observation that these coatings do not split along the sublayer interface. It should be mentioned, however, that the inability to detect a thin carbon layer may also be the result of an insufficient depth resolution.

Based on the above observations, the sequences of layers in the coatings obtained by treating B_4C in Cr powder at 1100 and 1200°C were suggested

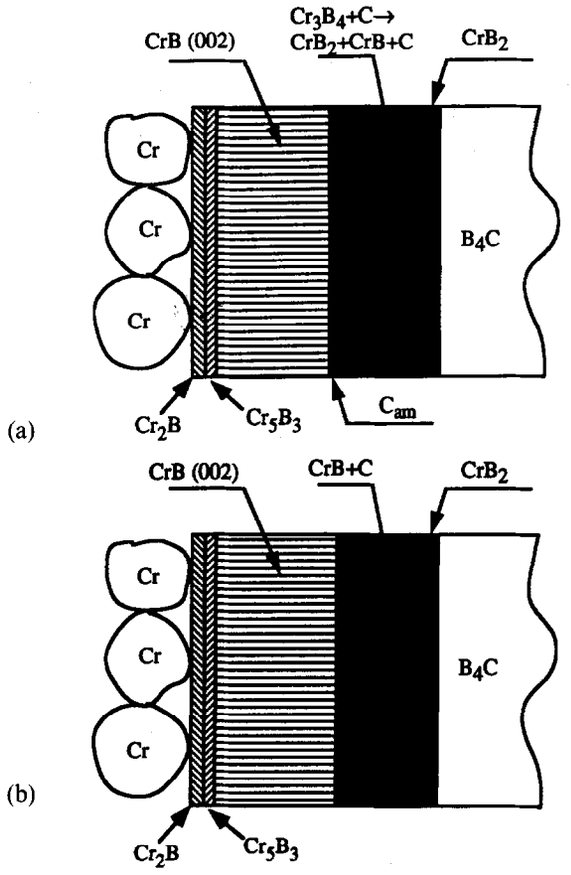

Fig. 10. Schematics of the layer sequences in the coatings obtained by treating B_4C in Cr powder at: (a) 1200°C; (b) 1100°C.

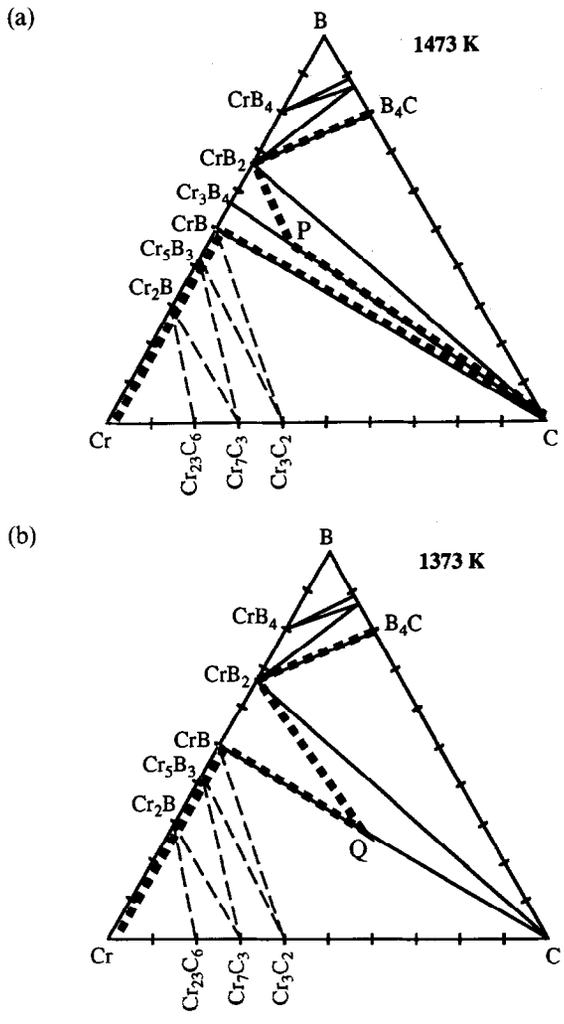

Fig. 11. Tentative isothermal sections of the B–C–Cr system at: (a) 1200°C; (b) 1100°C.

and are shown schematically in Figs. 10(a) and (b), respectively. It can be seen that for the coating obtained at 1200°C, Fig. 10(a), the inner layer containing amorphous carbon, CrB and a small amount of CrB_2, is followed by a thin sublayer of pure carbon black which is, in turn, followed by a layer of columnar (002) oriented CrB grains. Towards the surface of the coating, CrB gives way to the thin sublayers of Cr-rich borides Cr_5B_3 and Cr_2B. For the coating obtained at 1100°C, Fig. 10(b), we assume the inner layer to be a mixture of amorphous carbon and CrB only (since no indication as to the presence of CrB_2 was obtained). The outer carbon-free layer of the coating obtained at 1100°C is similar to that of the 1200°C coating; however, no intermediate sublayer of carbon black is observed in the former.

As seen from Fig. 10, the coatings obtained have rather complex microstructures. Thus, it would be very interesting to try and superimpose the diffusion paths corresponding to the observed phase sequences onto the B–C–Cr ternary diagram. (The 'diffusion path' approach is justified, since the coatings growth in the B_4C–Cr powder system was earlier reported[6] to be controlled by diffusion.) Unfortunately, no isothermal sections of either complete B–C–Cr ternary diagram, or of its B- and C-rich corners are available in the literature. In order to make the discussion of our results possible, an attempt was made to construct tentative isothermal 1100 and 1200°C sections of the B–C–Cr diagram, based on the available literature data as well as on our own experimental results. The tentative isothermal sections are shown in Fig. 11, and they are based on the following assumptions:

- B–C–Cr ternary diagram is, in general, similar to the B–C–Mo[12] and B–C–W[11,12] ternaries, since Cr, Mo and W are transition metals belonging to the same group of the periodic table;
- CrB and CrB_2 are at equilibrium with carbon at temperatures above 1350°C.[19,20] If we assume that the equilibrium pertains to the lower temperatures (down to 1100°C), there are CrB–C and CrB_2–C tie lines on the B–C–Cr ternary isotherms at both 1100 and 1200°C;
- CrB_2 is at equilibrium with B_4C up to 2100°C,[19] i.e. there is a B_4C–CrB_2 tie line on the B–C–Cr ternary isotherms at both 1100 and 1200°C;

- Cr_3B_4 is unstable at temperatures below ~1200°C, and it decomposes at 1100°C < T < 1200°C according to $Cr_3B_4 \rightarrow 2CrB + CrB_2$, similarly to the decomposition of MoB_2 into MoB and Mo_2B_5 at ~1480°C.[21] To establish this, and elemental Cr/B powder blend with the composition corresponding to Cr_3B_4 was compacted, heat treated and analyzed by XRD. The only phase found in the compact annealed at 1200°C for 4 h and rapidly cooled to the room temperature was Cr_3B_4. On the other hand, only traces of Cr_3B_4 were found in the sample slowly cooled from the same temperature, the main peaks being those of CrB and CrB_2. Similarly, the compacts annealed at 1100°C, both rapidly and slowly cooled, consisted of CrB and CrB_2 phases, only. These results suggest that Cr_3B_4 is thermodynamically stable at 1200°C, but is not stable at 1100°C. Therefore, the Cr_3B_4 boride is present in the B–C–Cr ternary isotherm at 1200°C, but it is absent at 1100°C.

Since the Cr-rich corner of the B–C–Cr ternary is very complicated and as it is not this part of the diagram that we're concerned about, its presentation in Fig. 11 is rather simplified (hence the use of dashed lines). An accurate representation of the Cr-rich corner may be found in Ref. 22.

The diffusion paths mapped onto the ternary isotherms in Fig. 11 correspond to the layer sequences shown in Fig. 10. The existence of the CrB_2 – C tie line makes the equilibrium between B_4C and CrB impossible and thus requires the presence of CrB_2 at the B_4C/coating interface. We assume, therefore, that there is a thin interfacial CrB_2 sublayer in the coatings obtained at both 1100 and 1200°C. The layer must be so thin that it could not be detected by XRD, at least for the 1100°C coating. AES depth profiling also proved ineffective in revealing this thin CrB_2 sublayer, apparently as a result of the poor depth resolution in the vicinity of the deeply buried (~7 μm for the 1100°C coating) B_4C/coating interface. (It is worth mentioning, that the detection by AES of the similar TiB_2 sublayer at the B_4C/Ti-base coating, Fig. 3(a), was only made possible due to the spalling of the coating off the ceramic substrate along the B_4C/TiB_2 interface.)

With the above considerations in mind, one can see that the diffusion path in Fig. 11(b) closely follows the layer sequence observed in the coating formed at 1100°C, Fig. 10(b). This is also the case for the coating obtained at 1200°C, with one exception, however. Namely, the diffusion path depicted in Fig. 11(a) requires the presence of a (Cr_3B_4 + carbon) two-phase layer preceding the pure carbon layer, whereas, in the real coating, the (CrB + CrB_2 + carbon) layer is observed, Fig. 10(a). It is apparent that such a three-phase layer could not be formed in our three component system during the process of diffusion growth. This discrepancy can easily be explained by the already mentioned decomposition of Cr_3B_4 at temperatures below 1200°C. We believe that a (Cr_3B_4 + carbon) layer is actually formed at the processing temperature of 1200°C, and is subsequently transformed into the experimentally observed (CrB + CrB_2 + carbon) layer on cooling to the room temperature. Since the exact compositions of the (CrB + CrB_2 + carbon) layer in the 1200°C coating and of the (CrB + carbon) layer in the 1100°C coating have not been measured, the points P and Q representing these layers on the ternary isotherms, Figs. 11(a) and (b), respectively, are given just as a reference.

The formation of the two-phase (Cr_3B_4 + carbon) layer versus the flat carbon/CrB interface in the 1200°C coating is in an agreement with the kinetic model[16] referred to in the previous section. The model predicts that, assuming initially planar interfaces and Cr diffusion as the rate-determining step (that is justified considering the much higher mobility of carbon and boron atoms), the aggregate morphology should develop at the Cr_3B_4/carbon interface yielding the two-phase (Cr_3B_4 + carbon) region, whereas the layered morphology should be preserved at the carbon/CrB interface. These are the morphologies experimentally observed in our diffusion couple, Fig. 10. On the other hand, the attempt to apply the model to the 1100°C coating morphology proved unsuccessful. A more thorough investigation of the microstructure of the coatings obtained by treating B_4C in Cr powder at 1100°C is now in progress. An interesting observation regarding the coatings in the B_4C/Cr powder system is that thick carbon-free pure boride (CrB) surface layers are formed. This suggests that, in contrast to the B_4C/Ti coatings, the diffusion of boron through the reaction products is faster than that of carbon.

4 Summary and Conclusions

It was shown that the interaction of B_4C with Ti and Cr powders at 1000–1200°C yielded complex multi-layer coatings on the ceramic substrate. Coatings obtained by treating B_4C in Ti powder were found to contain the Ti carbide, TiC_{1-X}, and Ti borides (TiB_2, TiB). A relatively thin inner layer of the coating was carbide-free and contained only borides, while the major part of the

coating was a mixture of TiC_{1-X} and TiB. In contrast to this, coatings formed by reaction of B_4C with Cr powder contained no carbides, and were shown to consist of Cr borides (CrB_2, CrB, Cr_5B_3 and Cr_2B) and amorphous carbon. A thick outer layer of the coating was carbon-free and consisted almost entirely of CrB. In both cases, the growth of the PIRAC coatings was controlled by diffusion. The activation energy for the growth of B_4C/Ti coating was found to be approximately 175 Kj/mol. The phase composition and the layer sequences in the coatings obtained were analyzed by mapping the diffusion paths onto the corresponding ternary isotherms. Since no B–C–Cr phase diagram was available in literature, tentative B–C–Cr ternary isotherms were proposed for the temperatures of 1100 and 1200°C. The layer sequence and morphology of the PIRAC coatings were interpreted also on a kinetic basis. The experimental results were found to be in a fair agreement with the kinetic and thermodynamic predictions for the ternary systems involved.

Once PIRAC has been proved useful for coating B_4C ceramic, the next question to be answered is whether the coatings obtained are feasible as protective layers at various B_4C/metal interfaces. To be effective, these coatings should act as diffusion barriers as well as be sufficiently inert with respect to the metal. In addition, thermal expansion coefficients (CTE) of B_4C, the metal and the coating should be considered. Due to the complex structure of the coatings obtained, as well as to the lack of essential data on the diffusion of metals, carbon and boron in borides and carbides and their CTE's, theoretical predictions of the coatings integrity as protective layers are hard to make. Preliminary results have shown that both the Ti- and Cr-based PIRAC coating effectively suppress the interaction of B_4C with iron at 1000–1100°C.[6] Clearly, only relatively thin reaction layers that do not spall off the B_4C surface can be considered as candidates for protective coatings. It would be especially interesting to study the effect of the pure carbon and the mixed carbon/CrB layers on the protective behavior of Cr-based PIRAC coatings on B_4C surface. Carbon coatings are now routinely used as protective layers on SiC fibers (e.g. SCS-6 Textron-AVCO SiC fibers). It should be mentioned, however, that if B_4C-particulate reinforced MMCs (e.g. for wear applications) are considered, the low strength of a pure carbon layer may have an adverse effect on the bonding integrity of B_4C particles in a metal matrix. Further investigation of the coatings' behavior in different metal matrices is required to find out whether they can act as adequate protective layers at B_4C/metal interfaces.

Abstract

The chemical system Ti–B–C–Cl–H was explored experimentally under reduced pressure (10 mbar) starting from a mixture of $TiCl_4$, BCl_3, CH_4 and H_2. The rate of growth, the composition, and the microstructure of the deposited solids were examined. The formation of titanium diboride, present in the entire explored domain, directs the chemical system. Carbon is present only in a small domain and when the concentration of $TiCl_4$ in the gas mixture is very low. Only rhombohedral boron carbide $B_{13}C_2$ and a tetragonal phase noted 'Q' with the general formula $B_{48}Ti_{2-x}C_{2-y}$ were identified, and always in the presence of TiB_2. These solids are distinguished by their very unique and varied microstructures and with the notable existence of nanometric three phase composites.

1 Introduction

The results presented, can be added to other research trying to improve certain properties of boron carbides by adding a third element to the basic boron–carbon system. A small improvement in its reactivity at a high temperature was made using silicon.[1] In this study, titanium was added to the system to evaluate its action on the mechanical properties.

In the domain of high performance ceramic materials, the Ti–B–C system is important because one can hope to obtain *a priori* the main compounds: $B_{13}C_2$, TiC and TiB_2 and their associated characteristics. The system was studied using chemical deposition starting from the gas phase under reduced pressure (LPCVD), which follows the study of the deposition, at thermodynamic equilibrium, of the solid phases starting with mixtures $TiCl_4$, BCL_3, CH_4 and H_2.[2]

It appears that the system is mainly controlled by the strong affinity between titanium and boron. The diagram in Fig. 1 shows that the concentration of $TiCl_4$ strongly influences the nature of the condensed phases and extends their domain boundaries. By contrast, the effect of the CH_4 concentration is minimal and it acts principally on the size deposition domain of the free carbon.

From these results and those of the other authors also cited in Ref. 2, it was determined that the prevailing compound in the system is TiB_2 and that combinations between the carbides of titanium and of boron, although *a priori* interesting, are not thermodynamically possible. Nevertheless, the possibility of codepositing titanium diboride and boron carbide in a narrow region exists.

2 Experimental Methods

The experiments were carried out in a CVD cold wall reactor. The substrates, heated by high frequency induction, are graphite cylinders 16 mm in diameter, and 5 mm high.

$TiCl_4$ titanium precursor, is mixed with the typical reactants used for studying the boron–carbon system (BCl_3, CH_4, and H_2). Being a liquid at ambient temperatures, its vapor is entrained by bubbling hydrogen. The considered parameters are the total pressure in the reactor (P), the temperature of the substrate (T) and the flow rate of the reactants (DX).

For practical reasons, the amount of boron trichloride (D BCl_3) was fixed. This allows one to consider the parameter $R = 100D\ CH_4/(D\ CH_4 + D\ BCl_3)$, representing the variation in the methane flow. Additionally the quantity of $TiCl_4$ participating in the reaction is controlled by the fraction of the flow rate of hydrogen carrying $TiCl_4$.

The characterization of the deposited solids depends on the following:

The identification of the species by X-ray Difraction (XRD).
The elemental analysis by Electron Microprobe (EM).
The observation of morphology of the surface by Scanning Electron Microscopy (SEM).

3 Influence of the Composition of the Gas Mixture

The initial experiments principally involved control of the concentration of the reactants in the gas phase by varying the flows of $TiCl_4$ and CH_4.

The experimental parameters were the following:

T = 1300 K, P = 10 mbar, D H_2 = 15 lh^{-1}, D BCl_3 = 1·6 lh^{-1}
0·177 < D CH_4 < 9 lh^{-1} is $10^{-2} < D\ CH_4/D_T < 0{\cdot}35$
0·01 < D $TiCl_4$ < 0·4 lh^{-1} is $4 \times 10^{-4} < D\ TiCl_4/D_T < 2{\cdot}4 \times 10^{-2}$
D_T = Total flow

3.1 Identification of the phases

An XRD analysis of the solid deposits obtained from the experiments indicated three phases: titanium diboride (TiB_2), a rhombohedral $B_{13}C_2$ solid solution and a tetragonal phase that we labeled Q, which is of the same type as the phase $B_{50}C_2$ obtained in the B–C system.[3]

The distribution of these phases and their domains are shown in the deposition diagram of Fig. 2,

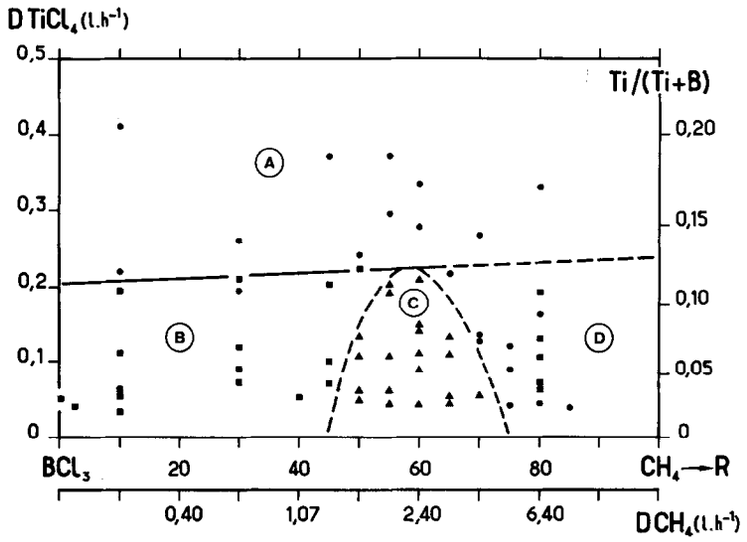

Fig. 2. Experimental deposition diagram as a function of the gas phase composition (XRD). T = 1300 K, P = 10 mbar, D BCl_3 = 1·6 lh^{-1}, D H_2 = 15 lh^{-1}. (A) TiB_2; (B) TiB_2 + Q; (C) $B_{13}C_2$ + TiB_2 + Q; (D) TiB_2 + Q.

which delineates four distinct zones: Zone A: Only TiB_2 is detected for flows of $TiCl_4$ greater than 0·2 lh^{-1} regardless of the value of *R*. For flows below 0·2 lh^{-1}, the phases $B_{13}C_2$ and Q appear. Zone B: The co-deposition of TiB_2 + phase Q is obtained for a ratio *R* less than 45. The proportion of the tetragonal phase in the mixture is more important since the two variables are lower. Zone C: The two compounds $B_{13}C_2$ and TiB_2 and the tetragonal phase Q are deposited simultaneously for values of *R* between 45 and 75. This domain becomes narrower when the flow of $TiCl_4$ is augmented. Zone D: As in Zone B, the TiB_2 and tetragonal phase coexist. Phase Q is present in a very small quantity, and is not always detected by XRD.

In agreement with the thermodynamic predictions,[2] the compound TiB_2 was synthesized in all the explored parametric domain. However, its crystallization in the depositions considered to be monophased is much better, as the gaseous mixture has a low concentration of methane and is rich in $TiCl_4$ (Fig. 3). Indeed an evolution towards the conventional conditions for the production of TiB_2, in which the ratio Ti/B in the gaseous phase is close to that in the condensed phase.

The carbonaceous phases appear jointly with TiB_2 but only for low concentrations of $TiCl_4$ in the gaseous phase. The most frequently encountered phase is the tetragonal (Q) one, probably not containing much carbon.

In fact, this phase clearly has phases very rich in boron such as $B_{50}C_2$, $Ti_{1\cdot87}B_{50}$ or $Ti_{1\cdot3\text{-}2}B_{48}C_2$ as described by Amberger and Ploog.[5–8] Figure 4 compares the RX spectra of the experimental phase Q to those of $B_{50}C_2$, $Ti_{1\cdot87}B_{50}$ or $Ti_{1\cdot86}B_{48}C_2$.

The configuration of the spectrum of the Q phase is identified with that proposed by Amberger, as much by the sequence of the peaks as by their position. The relative intensities of the peaks, by contrast, are not as reported, but the variation can be attributed to the textural effects of our material. In addition, some peaks were found which are not listed in the JCPDS data (no. 29-1356). However, a theoretical calculation of their position based on the lattice parameters determined (Table 1), allowed us to attribute these additional peaks to the tetragonal phase.

During prolonged reheating at 1670 K, this phase dissociated completely, forming $B_{13}C_2$ (the only additional phase detected), but probably also TiB_2 (already present), and boron (not detected because the amounts present are too small).

the spectra of the deposited two and three phases (Fig. 5) show that the proportion of the tetragonal phase decreases rapidly when the flow of $TiCl_4$ increases. Additionally, they show that the XRD peaks relative to the most carbonaceous phase of the system, rhombohedral boron carbide ($B_{13}C_2$), are less numerous, less intense and poorly defined.

3.2 Elemental Analysis

Sixteen of the deposited phases distributed throughout the domains of the phase diagram (Fig. 6) were analysed using an electronic microprobe on polished sections. The results of the elementary bulk (defocalization of the electronic beam on a 20 μm diameter) and local analyses on the different visualized phases are averaged from 5 to 10 measurements. The results are grouped in Table 2 and show that the deposits are of a heterogeneous composition at the level of the analysis.

The global compositions are very rich in boron and are found in only a small part of the ternary Ti–B–C diagram. Three types of composition are observed among the local analyses:

(1) The first type corresponds to TiB_2; several percent of carbon are always associated with it.

(2) The second type (92–95 atomic percent boron, 4·5 to 5·5 atomic percent titanium, and 0·5–3 atomic percent carbon) is identified with the tetragonal structure $Ti_{1·3-2}B_{48}C_2$ such that the titanium content is slightly higher and the carbon content is slightly lower as compared to the domain of the solution proposed by Amberger.[8]

(3) The third type of compound which logically corresponds to the $B_{13}C_2$ phase observed by XRD, introduces some important quantities of titanium (from 7–26 atomic percent).

This third composition could be considered as a mixture of the three phases, TiB_2, Q, and $B_{13}C_2$ identified by XRD and forming a dispersed type of material (hereafter designated 'M') for which the size of the crystals would be inferior to the resolution for the spot of analysis.

A deposition diagram was outlined from these analyses (Fig. 7). In this diagram, at the most only two of the three types of the previously defined compositions coexist. The boundary of the monophased zone of the deposition TiB_2 is shifted toward higher flows of the $TiCl_4$ (around 0·3 lh^{-1} as compared with 0·2 lh^{-1} previously). Below this value, the dispersed phase 'M' is always present, either alone or associated with the phases TiB_2 or Q.

3.3 Rate of growth of the coatings

The deposition rates are expressed in units of mass per unit time and area, where the changes in mass were determined by weighing the samples before and after applying the coating.

3.3.1 Effects of varying methane concentration of the deposition rate

Figure 8 shows that for a constant flow of $TiCl_4$, the deposition rate varies little with the methane flow for values of R between 45 and 60, following the flow of $TiCl_4$. For higher values, the deposition rate decreases. This evolution could correspond to the progressive disappearance in the deposited solids of the large crystals of TiB_2 or the Q phase for which the kinetics of growth are elevated. The rate decreases in the zones of the phase diagram where only the dispersed phase 'M' is found.

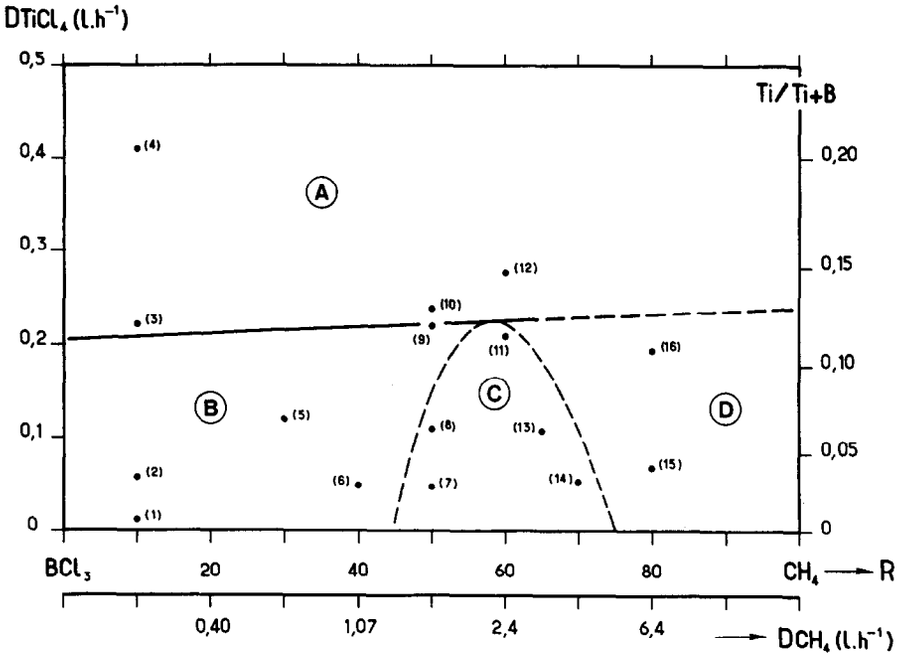

Fig. 6. Position of the analysed samples (electronic microprobe).

3.3.2 Effects of varying $TiCl_4$ concentration on the deposition rate

The influence of the $TiCl_4$ flow is clearly stronger. The rate of deposition increases rapidly with the flow of titanium tetrachloride. For example, the rate doubles when the flow increases from 0·05 to 0·2 lh^{-1}. The curve in Fig. 9(a) gathers the values obtained for values of R less than 60, which is in the domain where the concentration of CH_4 doesn't have any influence. A maximum rate is obtained for flows of $TiCl_4$ on the order of 0·2–0·25 lh^{-1}.

An analog result was established by Takahashi *et al.*[9] for the system $TiCl_4$–BCl_3–H_2 (Fig. 9(b)), giving evidence of the importance of the formation of diboride in the kinetics of the deposition.

3.4 Microstructure of the deposited layers

The crystallization of the solid phase varies strongly as a function of the composition of the gaseous mixture provoking in particular some unique surface morphologies.

3.4.1 Morphology of the surface

(a) Low flows of $TiCl_4$

If the concentration of the CH_4 is also low, the coatings are rich in the tetragonal phase. The phase $B_{50}C_2$ in the B–C system[4] is present as angular crystals of a large size (up to about 30 μm), but for which the geometry is seldom perfect (Fig. 10(a)). When the flow of methane increases, the crystallization becomes finer, and the growth becomes dendritic. Meanwhile, the concentration of angular crystals in the tetragonal phase decreases sharply and their size is clearly smaller (a few μm).

Near R = 50 (Fig. 9(b)), the surface shows some growth of the order of 10 μm and of a rounded form, characteristic of a mixture with a boron carbide base ('M') when this is the main phase present.

For greater methane flows, the growth increases (~100 μm) (Fig. 9(c), R = 65). Beyond the three phases domain (XRD), the small sub-micronic crystals are very well defined geometrically and are already formed (Fig 9(d), R = 80).

(b) Influence of the $TiCl_4$ flow

When the flow of $TiCl_4$ increases, the titanium diboride has the general tendency to form in large quantities and to become the basic material in the deposition.

In this matrix, with a low flow of methane, the crystals in the tetragonal phase are small in size (a few microns) and become more scattered as the $TiCl_4$ concentration in the gaseous mixture increases. Near R = 60 (Fig. 10(e)) the growths visible at the surface become less and less numerous, and consist of the 'M' mixture.

At high methane concentrations (R > 65) and for a $TiCl_4$ flow on the order of 0·25 lh^{-1}, the surface shows, under small magnification, aspects of an amorphous material. It is in fact comprised of the small crystals remarkably uniform and of a few μm in size (Fig. 10(f)).

3.4.2 Examination of transversal cuts

On the plates shown in Fig. 11, obtained from

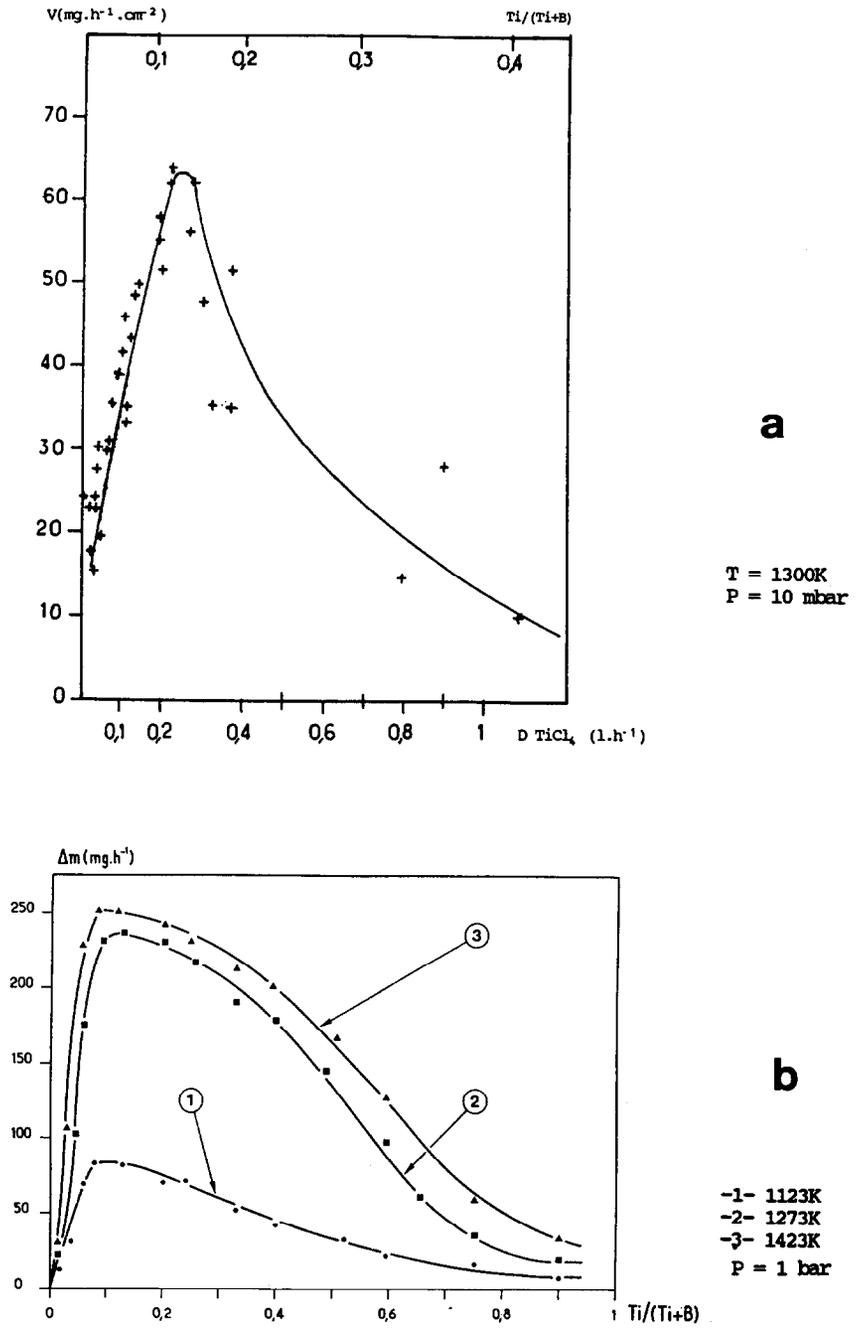

Fig. 9. Influence of the $TiCl_4$ concentration on the deposition rate $R<60$. (a) T = 1300 K, P = 10 mbar, D BCl_3 = 1·6 lh^{-1}, D H_2 = 15 lh^{-1}; (b) Influence according to Takahashi[9] (Ti–B system).

backscattering electrons, the microstructure can be seen clearly: the rich titanium (TiB_2) zones appear clearly and contrast strongly with the shadowed low titanium regions (Q and $B_{13}C_2$). The materials in the 'M' + Q domain are very dense. When the tetragonal phase is preponderant (Fig. 11(a)), the crystals grow perpendicularly to the surface. When it becomes less abundant, the orientation is uncertain (Fig. 11(b)). In the domain 'M', the crystallization is particular. The tetragonal phase is always present in a matrix formed from a mixture of boron carbide and titanium diboride (B_4C + TiB_2), either in the form of filaments without defined geometry (Fig. 11(c)) or under the form of the axis of the grain (Fig 11(d)).

The composition of the matrix is not constant. Near the interface of the substrate and deposition as well as at the center of the nucleation site, the titanium content is higher. When the size of the particles is large, this type of growth leads to the formation of large pores.

The matrix appears homogeneous with the electronic microprobe analysis. The resolution was obtained by field effect microscopy (Fig. 12(a) and 12(b)). It shows that the matrix is constituted of a dispersed mixture of nanometric crystals (about 50 nm) of a boron carbide and titanium diboride ($B_{13}C_2$ + TiB_2). The grains formed here are often found following an axis parallel to the surface with whiskers of phase Q and a cross section of about

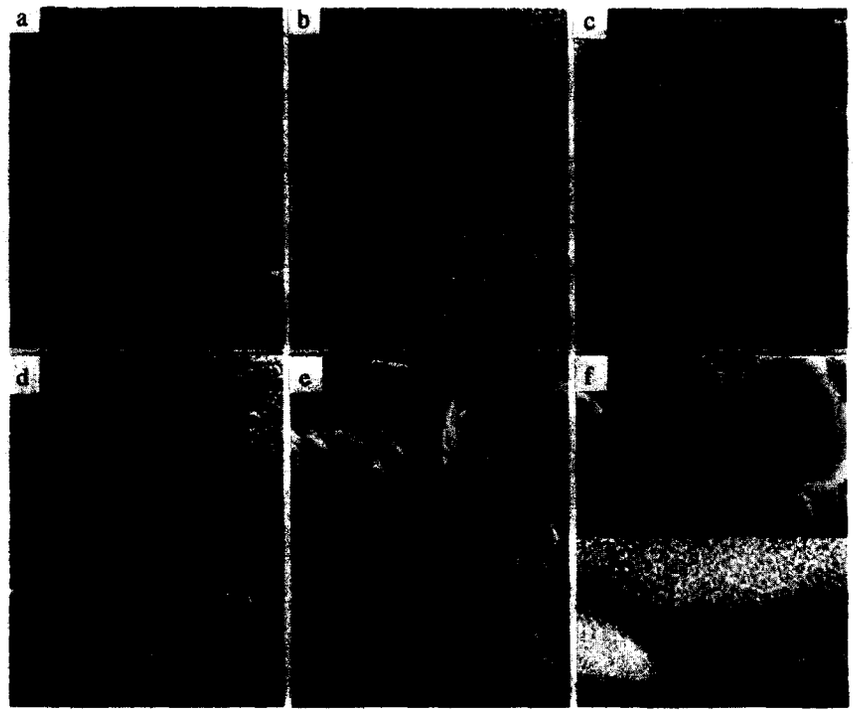

Fig. 10. Morphology of typical deposition surfaces. T = 1300 K, P = 10 mbar, D BCl_3 = 1·6 lh^{-1}, D H_2 = 15 lh^{-1}. (a) Q + 'M' (R = 10); (b) 'M' (R = 50); (c) 'M' (R = 65); (d) 'M' (R = 80); (e) TiB_2 + 'M' (R = 60); (f) TiB_2 + 'M' (R > 65).

0·5 × 0·5 μm. In the domain TiB_2 + 'M', the depositions form over a wide area and have very fine microstructure (Fig. 11(e)). The compounds evolve from 'M' to TiB_2 in forming some zones parallel to the surface. The concentration of TiB_2 is always higher near the interface. The deposits of pure TiB_2 (Fig. 11(f)) equally present a layered structure with very porous periodic layers and are characteristic of those described by Takahashi.[9] These TiB_2 coatings were obtained with weak ratios of Ti/Ti+B.

4 Influence of the Temperature

4.1 Kinetics and the nature of the phases

The results of the experiments with R = 60 and the $TiCl_4$ flow equal to 0·015 lh^{-1}, are shown in Fig. 13(a). At temperatures above 1530 K, the tetragonal phase, which is unstable at high temperatures no longer forms and a codeposit of titanium diboride and boron carbide is found. In contrast, at temperatures below 1280 K, titanium boride is the only phase identified.

The corresponding rate of deposition increases with temperature until 1500 K and then falls quickly at temperatures greater than about 1600 K. This rapid rate decrease can be attributed to the appearance of reactions in the homogenous phase. This tendency was established for the B–C system at the same ratio R.[10,11]. By contrast, the work of Besmann[12] indicates that the TiB_2 deposition rate continues to increase until 2173 K but this increase is lowered as soon as the temperature reaches 1473 K. Thus, the addition of methane essentially limits the deposition rates at high temperatures.

This effect was confirmed when the methane flow was decreased (R = 10, D $TiCl_4$ = 0·05 lh^{-1}). The deposition rate, which was higher than earlier, increased linearly with temperature (Fig. 13(b)). The tetragonal phase was observed up to our highest experimental temperature of 1580 K.

Figure 14(a) shows the deposition rate as a function of temperature for two $TiCl_4$ flow rates. In this case, the flow of BCl_3 was reduced to 0·4 lh^{-1} in order to decrease the kinetics, and R was fixed at 60. The evolution is the same as was described previously (Fig. 13(a)), but an increase in the $TiCl_4$ gas phase concentration displaces the maximum value towards lower temperatures and since the concentration of CH_4 is less, it has a smaller influence on the rate decrease. Figure 14(b) outlines the corresponding deposition diagram. The existence of the two phase region (TiB_2 + Q and TiB_2 + $B_{13}C_2$) and the three phase region (TiB_2 + B_{13} C_2 + Q) appears to be strongly dependent on temperature.

Furthermore, as was mentioned earlier, the carbon phase exist only when $TiCl_4$ concentrations are small. In this case, for flows of $TiCl_4$ > 0·1 lh^{-1}, only TiB_2, is found.

4.2 Surface morphology

The surface morphology, like the composition of the deposits, varies greatly with temperature. For

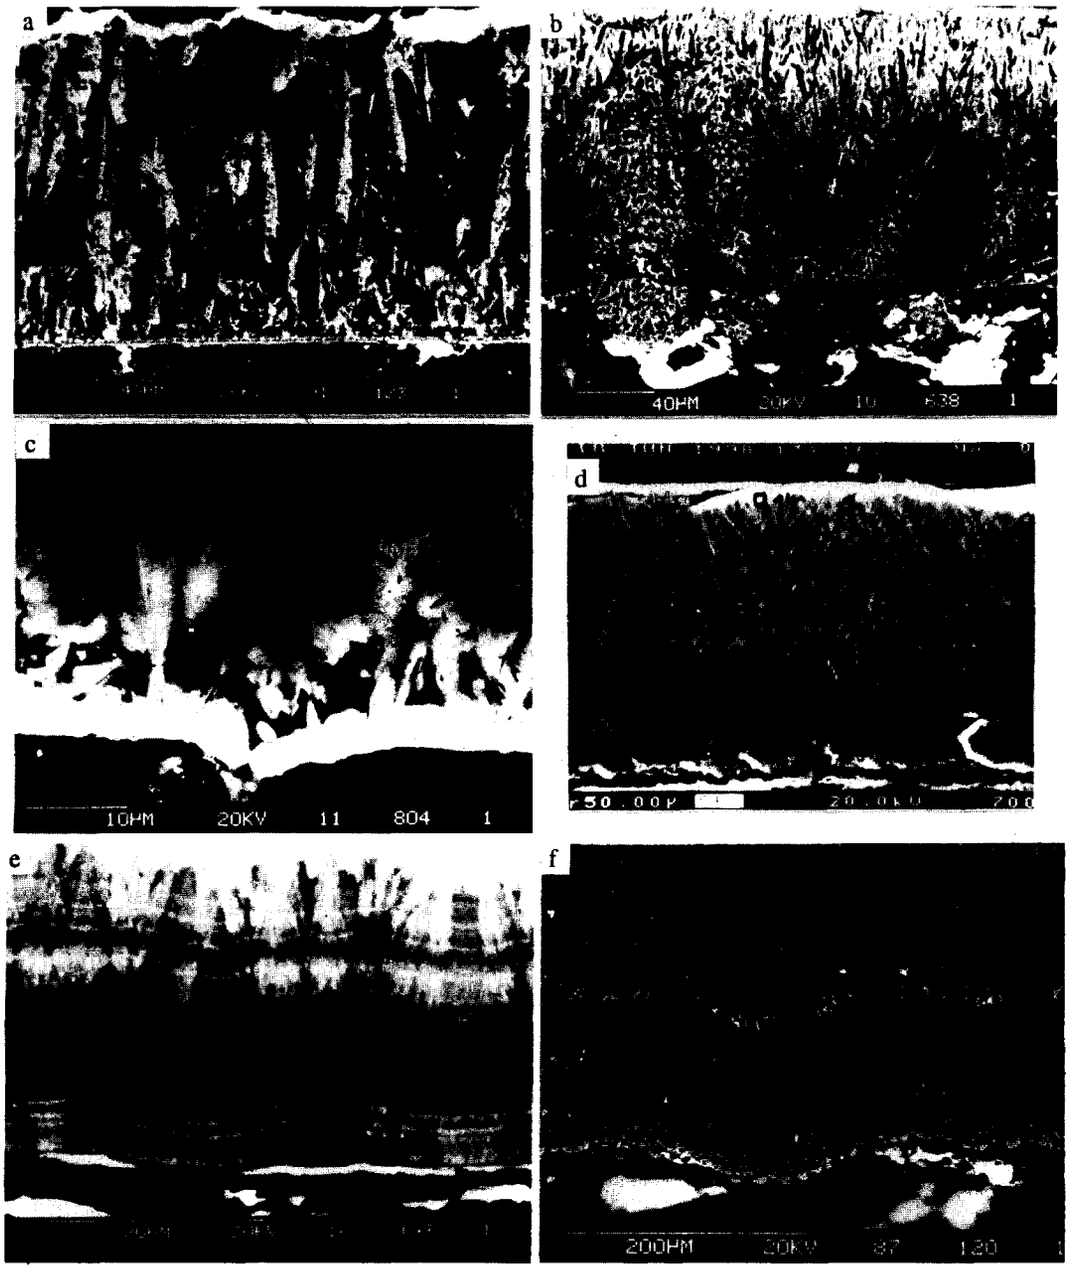

Fig. 11. Metallographic sections of typical deposits (secondary electrons). (a) and (b) 'M' + Q; (c) and (d) 'M'; (e) TiB_2 + 'M', (f) TiB_2.

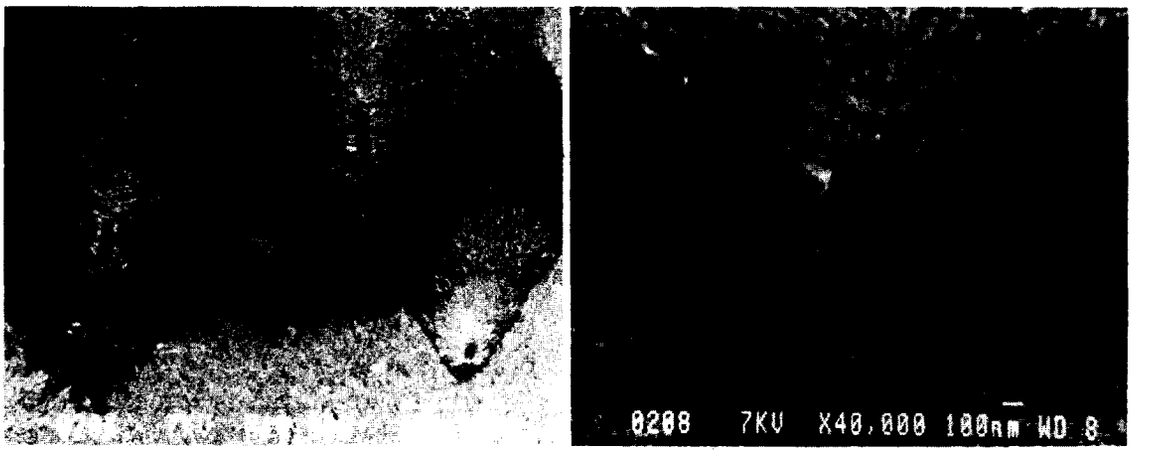

Fig. 12. Microstructural details of a type 'M' deposition (field effect microscopy). R = 65, D $TiCl_4$ = 0·108 lh^{-1}.

R = 60 and D $TiCl_4$ = 0·06 lh^{-1} and at low temperatures (only TiB_2 deposition), the surface has the characteristic partial crystallization (Fig. 15(a)). When the temperature is elevated, the tetragonal phase, which has a tendency to grow in a columnar manner, greatly influences the microstructure

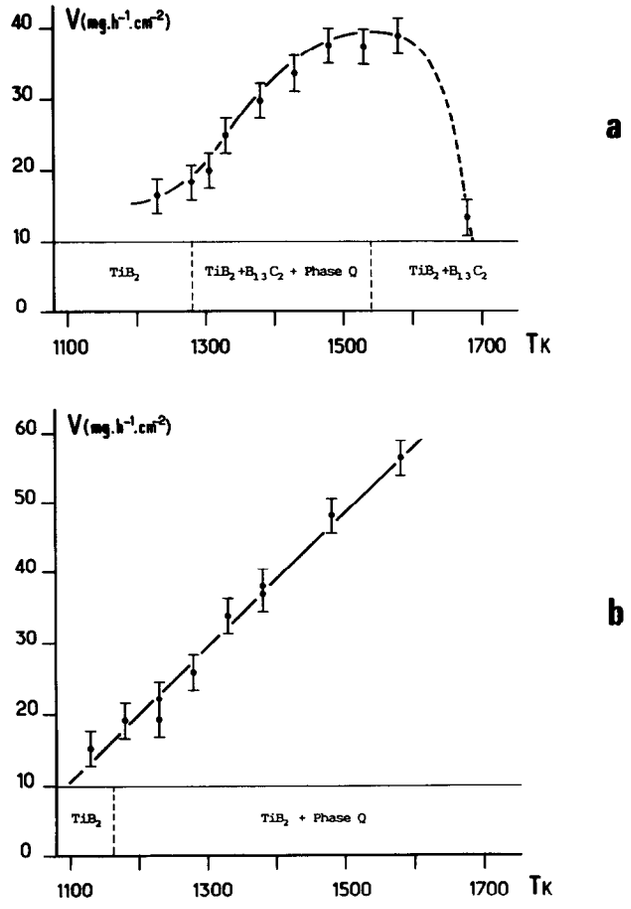

Fig. 13. Influence of the temperature on the deposited phases and on the deposition rate. P = 10 mbar, D BCl_3 = 1·6 lh^{-1}, D H_2 = 15 lh^{-1}. (a) R = 60; D $TiCl_4$ = 0·015 lh^{-1}; (b) R = 10, D $TiCl_4$ = 0·05 lh^{-1}.

of the layers. In particular, a reduction of its content is accompanied by progressive disorientation of the emerging crystals. At 1380 K for example, the surface is typical of a singular crystallization in the previously described 'M' phase (Fig. 15(b)).

Beyond 1580 K, only TiB_2 is identified. This time its crystallization is clearly evident with XRD, but it can be present under a wide variety of morphologies: fine lamellar structure at 1580 K and parallelepipedal crystals at 1685 K (Figs 15(c) and (d)).

5 Conclusions and Comments

The results of this experimental study have little in common with the thermodynamic predictions previously published.[2] The only principal in agreement is the importance of the affinity of the boron and titanium to the behavior of the chemical system. This is evident in all the cases by the omnipresence of titanium diboride in the explored regions. By contrast, the carbon vector has a weak influence experimentally, and it is only for cases with low $TiCl_4$ concentrations in the initial gas mixture that the weakly carbonated phases (Q and $B_{13}C_2$) are deposited.

According to the theoretical results, methane should be almost completely dissociated and accordingly, carbon should be the major element in coatings prepared from a gaseous starting mixture rich in methane. But, neither titanium carbide nor free carbon were ever detected.

If we compare the theoretical deposition diagrams with the experimental ones (Figs. 1 and 2), the experimental region of the $B_{13}C_2$ phase is found largely displaced towards higher values of CH_4 concentrations than in the theoretical diagram (region TiB_2 + B_4C + C) which indicates that an excess of methane (about ten times greater than the amount predicted by thermodynamics) is necessary to form $B_{13}C_2$. Similarly, the limits of the boron carbide domain are found at values less than those predicted by thermodynamics for specific amounts of $TiCl_4$ in the gas phase (Ti/Ti+B < 0·35).

Concerning yields: if one considers that titanium boride is essentially the compound formed when the maximum deposition rate is attained (Figs. 2 and 8), the ratio Ti/B is then about 1 : 6 or a third of the diboride stoichiometry. In this case, 50–60% of the $TiCl_4$ in the gas mixture reacted to form TiB_2. Thus the maximum theoretical yield of 95% as indicated by thermodynamics is not obtained. The discrepancies between the thermodynamic and experimental results can mainly predict the existence of the tetragonal phase Q which could not have been taken into account in the calculations and which also influences the microstructure of the deposited solids. This phase is a new example of the metastable phase which can be obtained far from equilibrium by CVD. It can be identified with the phases described by Amberger and Ploog[7–8] $Ti_{1\cdot87}B_{50}$ and $Ti_{2-x}B_{48}C_2$.

Nevertheless, the huge influence of titanium chloride in comparison to methane on the composition of the solid as well as the results of the local analysis (weak carbon content in the region of the 'Q' phase (Table 2)) leads one to think that, especially in the cases low in methane, the Q phase is more saturated in titanium than in carbon and could be written as $B_{48}Ti_2C_{2-y}$. The more general formulation would be $B_{48}Ti_{2-x}C_{2-y}$.

In other respects, the existence of the carbonaceous phase is also strongly influenced by the synthesis temperature. Their domain of thermal existence is in fact relatively limited (from 1150 to around 1700 K under our experimental conditions). The boundaries evolve however with different parameters. When the tetragonal phase can no longer form (at temperatures less than 1600 K in our work), a codeposit of titanium diboride and boron carbide occurs, which is an interesting *a priori* mixture from the mechanical properties

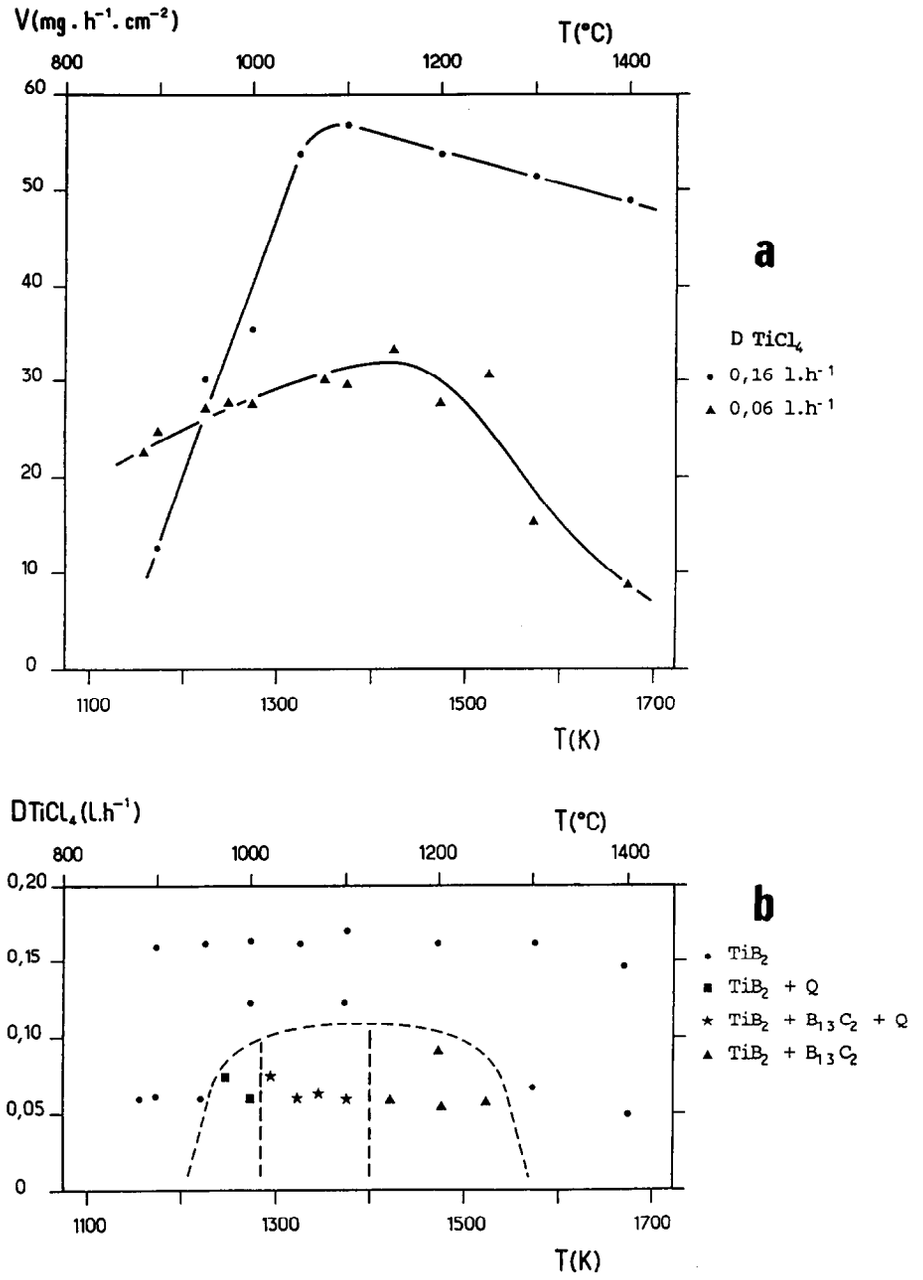

Fig. 14. Influence of temperature and of $TiCl_4$ concentration on the deposition rate (a) and on the nature of the deposited phases (b). P = 10 mbar, R = 60, D BCl_3 = 0·41 lh^{-1}.

stand-point. Since it makes $B_{50}C_2$ in the B–C–H–Cl system,[10,11] this tetragonal phase, very rich in boron, can strongly limit the deposition of non-combined boron at low temperatures. However, the phase obtained in this case differs from $B_{50}C_2$ by its large domain of existence (up to R = 80). Thus, it covers the entire deposition region of boron carbide, and the two phases TiB_2+$B_{13}C_2$ can only be isolated at higher temperatures. By contrast, the deposition domain of the rhombohedral phase is only slightly displaced or not displaced at all on the methane concentration axis as compared to the B–C–Cl–H system.

In conclusion, it can be observed that these carbonaceous phases, using a tridimensional representation of D CH_4 (R), D $TiCl_4$ and temperature, will only be present in a small zone within the large domain of TiB_2 deposition. In contrast, these phases are very interesting because of their very special and unique microstructure. The common basis of these materials is a mixture of nanometric crystals of titanium diboride and rhombohedral boron carbide which wrap the whiskers of phase Q and which also have different configurations. This composite, called 'M', can be mixed with diboride and the Q phase, which are present simultaneously in the same solid under two different crystallizations.

Abstract

The results of a thermodynamic and experimental study concerning the codeposition of three elements — silicon, boron and carbon — by a classical C.V.D. technique in a hot-wall reactor are reported. The thermodynamic approach has been described in a previous study and a first comparison was made with experiments carried out under conditions which favor the control by mass transport, at a relatively high temperature (T = 1400 K) and low mass flow rate. Experimental conditions further from equilibrium have been searched for here for depositing coatings with both good thickness and chemical composition uniformity when the process is more kinetically-controlled. The codeposits were obtained on graphite from various initial gaseous mixtures which were composed of methyltrichlorosilane (MTS), boron trichloride and hydrogen, at a total pressure of 0·395 atm, a total flow rate between 0·1 and 1·0 g/min and a temperature varying in the range 1200–1400 K. Low temperatures and high mass flow rates are shown to favour the deposition of uniform coatings but different results can be obtained as a function of the inlet gaseous composition since different kinetic limitations can arise which favor a boron or a silicon excess in the coating.

1 Introduction

In a new C.V.D. system, generally a thermodynamic study is first undertaken to predict the final composition of the system at equilibrium and to understand the influence of many parameters such as temperature, pressure and inlet gas composition. However, in a C.V.D. reactor, the thermodynamic equilibrium between the gas phase and the solid is always localized at the gas–solid interface, whereas the classic thermodynamic approach assumes that a global equilibrium is reached in a closed isothermal system between the gas phase and deposit. Near equilibrium conditions are actually reached when the chemical kinetics are intrinsically faster than the mass transfer step; generally at high temperature and low flow rate. Local equilibrium is therefore influenced by mass transport, because the material balance is changed by the element segregation transport phenomena and the well-known reactant's consumption and product's formation in downstream positions inside the reactor, especially hot-wall. Not only the influence of fluid mechanical effects has been previously shown, but also the limitations of using global equilibrium calculations to guide C.V.D. experiments. The drawbacks of chemical vapor deposition under near equilibrium conditions in a hot-wall reactor where the gas flows parallel to the surface have also been discussed.[1] As the thickness and chemical composition of the deposit were obviously not uniform, this work has now been extended to conditions which lead to a greater departure from equilibrium or supersaturation at the gas–solid interface, when the process is more kinetically-controlled.

The departure from equilibrium obtained under chemical kinetic limitations is often revealed by the deposition of certain structures differing from stable ones, for either elemental or binary deposits.[2–3] This is also manifested by the deposition of solids whose composition differs significantly from those predicted by thermodynamic calculations.[4–5] Moreover, if the departure from equilibrium or supersaturation were great, it would be easier to obtain coatings exhibiting uniformity in thickness and composition.[5–7]

As already mentioned above, the significance of the amount of supersaturation has been indicated throughout the study of elemental or binary deposits. In this work, the influence of the amount

*Present address: Société Européenne de Propulsion, Les Cinq Chemins — Le Haillan BP 37, F-33165 Saint-Médard-en-Jalles Cedex, France

of departure from equilibrium will be studied for a ternary (Si–B–C) system of deposition as follows:

— a classical comparison between the global thermodynamic predictions and the experimental compositions obtained at different temperatures or mass flow rates, keeping in mind that the material balance was changed as discussed above;

— a study of the influence of the supersaturation on thickness and composition uniformity of the deposits at either variable temperatures and constant mass flow rate, or variable mass flow rates and constant temperature.

2 Theoretical and Experimental Tools of Investigation

2.1 Thermodynamic calculations

The method used for thermodynamic calculations has been explained in another article[8] in which the choice of the solid phases, thermodynamic data and hypothesis for calculations were described in detail. To take into consideration the 'boron carbide' solid solution, the sublattice model developed by Hillert and Staffanson[9] and generalized by Sundmann and Agren[10] was used.[8]

The equilibrium yields, η, of the different gaseous and solid species were calculated. They are defined with respect to n°_{MTS} for silicon-containing species and for carbon-containing species and to $n^{\circ}_{BCl_3}$ for boron-containing species.

$$\eta = n_i\,(Si_yX_z)/n^{\circ}_{MTS},\ \eta = n_i\,(C_yX_z)/n^{\circ}_{MTS} \text{ and } \eta = n_i\,(B_yX_z)/n^{\circ}_{BCl_3}$$

where n_i represents the number of Si, C or B atoms in species i at equilibrium and n°_{MTS} and $n^{\circ}_{BCl_3}$ the initial number of CH_3SiCl_3 (MTS) and BCl_3 moles, ($\Sigma n^{\circ}_i = 1$ mole was chosen for simplicity). The equilibrium yields of the solid or gaseous species will not be represented if they remain smaller than 10^{-6} and it must be overlooked that the concentrations of H_2 and HCl are always high. One element can be incorporated in different solid phases, for example carbon in pure graphite, silicon carbide and boron carbide. From the equilibrium amount of the condensed species, the thermodynamically expected composition of the whole deposit was calculated. It will be presented by the atomic percent of each element.

2.2 Experimental techniques

2.2.1 C.V.D. device

The experimental setup was classic and has been previously described.[1] The desired flow rates of H_2, CH_3SiCl_3 (MTS) or BCl_3 were adjusted by mass flowmeters. The substrates were hung in a graphite susceptor (Fig. 1) which was heated by a high frequency generator regulated by a thermocouple fitted at the top of the susceptor. The maximum temperature fluctuations were ±3 K, but there was a constant difference of +75 K within the [1200–1400 K] range between the temperature of the substrate and that measured by the thermocouple. The gas mixture was introduced by a nozzle from the bottom to associate the natural and forced convections. The mass flow rate (F) varied in the range 0·1–1·0 g/min. Hydrogen used was of 99·995% purity by volume and boron trichloride and MTS of 99·9% purity. The substrates were fine textured polished graphite of 1·75 average density, cleaned in alcohol in an ultrasonic device and dried before weighing. Sample size was (18 × 10 × 2mm).

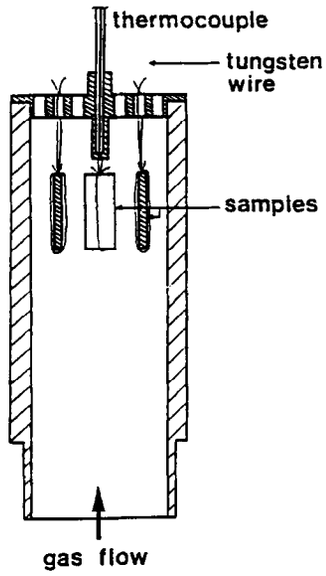

Fig. 1. Graphite susceptor and position of the samples.

2.2.2 Characterization of the deposits

The mass increase of each sample after deposition was measured with a precision balance. The thickness measurements were obtained on polished cross-sections with the help of an optical microscope. The chemical composition of the deposits was determined by the γ prompt photon spectrometry method developed at the C.E.R.I. (CNRS) laboratory in Orléans. The following nuclear reactions were used to measure the concentration of boron and silicon: $^{10}B\ (p, p', \gamma)\ ^{10}B$ and $^{28}Si\ (p, p', \gamma)\ ^{28}Si$ where γ-ray was induced by proton bombardment of ^{10}B and ^{28}Si, with a decrease of proton energy. The atomic percentage of carbon was determined by the difference. This type of measurement is valid because the carbon concentration has been verified on various samples by an independent determination by an activation technique, and because the concentration of impurities was low. The measurement did not depend on the coating density. This method is neither a function

of the crystalline state nor the type of phase, because it concerns only the atomic nuclei. The chemical compositions are given in atomic percentages and their precision, which depended on counting time, was equal to ±5% relative for the present analysis. The details of the method are given elsewhere.[11] X-ray diffraction was also used to attempt to determine the crystalline phases of the coatings.

3 Comparison Between the Thermodynamic and Experimental Studies

The experimental chemical composition was measured at the bottom of the samples, for a h = 3 mm distance from the lower end of the substrate. This position was chosen to try to minimize reactant depletion and maintain an overall material balance as close to the inlet ones as possible. Then a comparison was made between the theoretical and experimental compositions in atomic percent of each element in the coating for various deposition conditions (the coatings were generally badly crystallized and a comparison with the predicted phases cannot be done from X-ray diffraction).

First the influence of the temperature was studied at a constant mass flow rate and pressure for:

$$\alpha = \frac{[H_2]_o}{[MTS]_o} = 20 \text{ and } \beta = \frac{[MTS]_o}{[BCl_3]_o} \text{ varying from } 0{\cdot}6 \text{ to } 8.$$

where $[X]_o$ represents the initial number of X moles.

Thereafter, the same type of study was carried out with a variable mass flow rate, constant temperature and constant pressure for $\alpha = 20$ and $\beta = 1$

3.1 Influence of temperature and inlet gas composition

Figures 2–4 present, for three different temperatures, the relationship between the chemical composition of the coatings and the variation of the β value (0·6 to 8), for a fixed $\alpha = 20$; the pressure was set at 0·395 atm and the mass flow rate was equal to 0·320 g/min. The values of α and the mass flow rate were chosen following the study at $T = 1400$ K because no free carbon was obtained under these conditions.[1]

For three temperatures (T = 1400, 1300 and 1200 K), the chemical compositions predicted by thermodynamic calculations varied in the same way. When β increased, the incorporation of boron decreased, while that of carbon and silicon increased to stoichiometric SiC. For a fixed β value higher than 1, the theoretical incorporation of boron was lower when the temperature decreased, whereas that of carbon became greater when the temperature decreased.

The theoretical equilibrium yields of the solid species showed that, at 1400 K for β varying from 0·4 to 8, no free carbon was formed, whereas at 1300 K, some free carbon was expected from $\beta = 0{\cdot}4$ to $\beta = 0{\cdot}6$ and at 1200 K, free carbon was expected from $\beta = 0{\cdot}4$ to 2 (Figs 5–7).

The experimental results (Figs 2-4) were totally the reverse of the thermodynamic estimates because a decrease in the deposition temperature led to a lower incorporation of carbon and to less silicon for all the β values (except for β near 8).

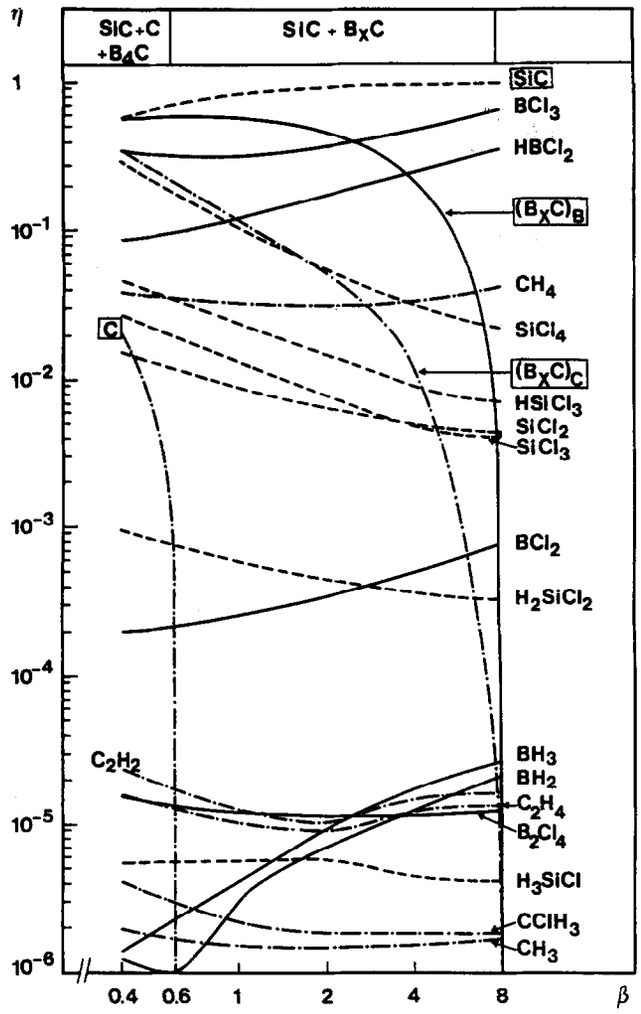

Fig. 6. Equilibrium yields η of the different gaseous and solid species at T = 1300 K, P = 0·395 atm, α = 20, β variable. —— Boron, — — — Silicon, —·— Carbon (containing species).

Simultaneously, the proportion of boron increased when the temperature decreased.

A great departure from the equilibrium predictions was brought to light when the temperature decreased, showing especially a lack of carbon deposition. This phenomenon was already reported for the deposition of boron carbide and titanium carbide where the carbon deposition kinetics from hydrocarbons often limits the process.[12–15]

This departure from equilibrium seems to increase with the deposition of the free elements as boron when $\beta \leq 2$ and silicon when $\beta > 4$.

3.2 Influence of the mass flow rate

Figures 8–10 show, for three different temperatures, the relationship between the chemical composition of the coatings and the mass flow rate when α = 20, β = 1 and P = 0·395 atm.

The compositions predicted by the global thermodynamic calculations do not depend on the mass flow rate and are shown by three straight lines in each figure. For each of the three temperatures, a departure from equilibrium was noticed. The proportion of the incorporated boron was

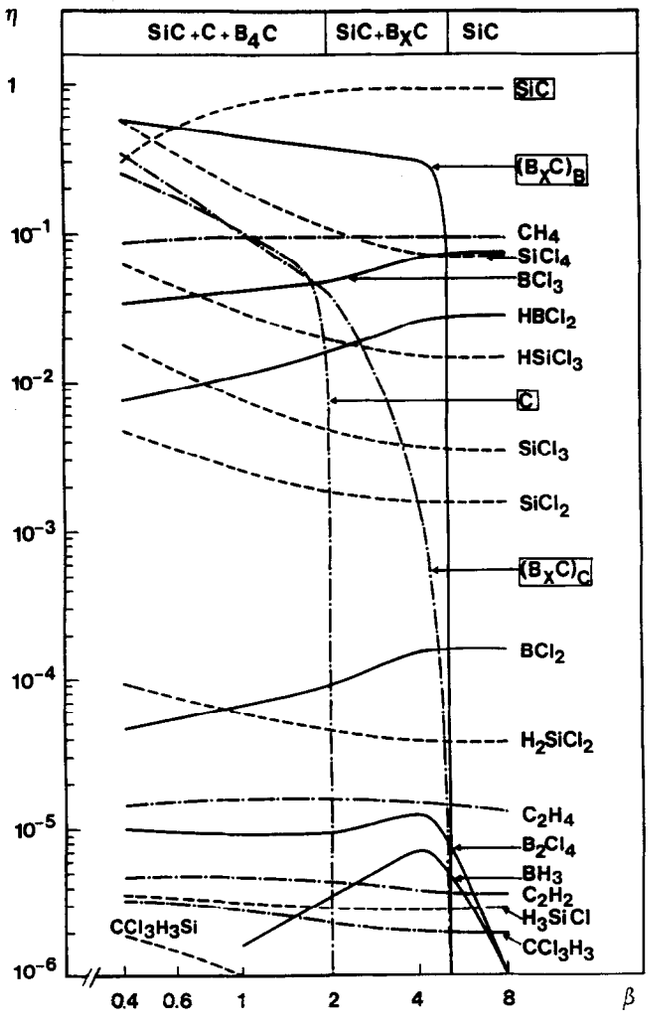

Fig. 7. Equilibrium yields η of the different gaseous and solid species at T = 1200 K, P = 0·395 atm, α = 20, β variable. —— Boron, — — — Silicon, —·— Carbon (containing species).

especially higher than expected (except at a low mass flow rate and T = 1400 K), whereas that of carbon and silicon was lower. In general, it is possible to confirm that the departure from equilibrium increases when the mass flow rate increases.

From these figures, it can be noticed, once again, that the lower the temperature was, the higher the departure from equilibrium for the specific value of β = 1. Obviously, the highest departure from equilibrium was obtained by a low temperature and high mass flow rate, as expected.

4 Thickness and Composition Uniformity as a Function of the Departure from Equilibrium

4.1 Influence of the inlet gas composition at different temperatures

The experimental conditions that were chosen for this study are the following:

P = 0·395 atm, F = 0·320 g/min, α = 20, β = 0·6-8 and T = 1200, 1300 and 1400 K.

The results are reported in Figs 11–13. The value of T = 1400 K (Fig. 11) corresponds to the

temperature at which the departure from equilibrium was lowest. The deposition rate was relatively high and increased when β increased. At the bottom of the sample (h = 3 mm), it varied from 28 μm/h when β = 0·6 to 59 μm/h for β = 8. At 1400 K, Table 1, which reports the longitudinal uniformity U_L as a function of β ($U_L = t_{15\,mm}/t_{3\,mm}$), indicates that the control of thickness was poor (t_{hmm} = thickness at the position hmm from the lower end of the sample). For a fixed α ratio value and an increase of β, the experimental conditions correspond to both a decrease of the BCl_3 proportion and an increase of the H_2 proportion in the gas phase. Then the U_L ratio decreased when β increased following an increase in the α' ratio:

$$\alpha' = \frac{[H_2]_o}{[MTS]_o + [BCl_3]_o}$$

α' expresses the relationship between the proportion of hydrogen and the chlorinated species which were to be reduced in the initial gas mixtures; the variations of α' are reported in Table 2. This inadequate control of thickness was therefore raised by the dilution, and also by a higher depletion in the reactant concentration as the deposition rate increases at the bottom of the substrates when β increases. It can be associated to a poor control of the chemical composition along each sample. Generally a decrease in the boron content along each sample, with a correspondingly smaller

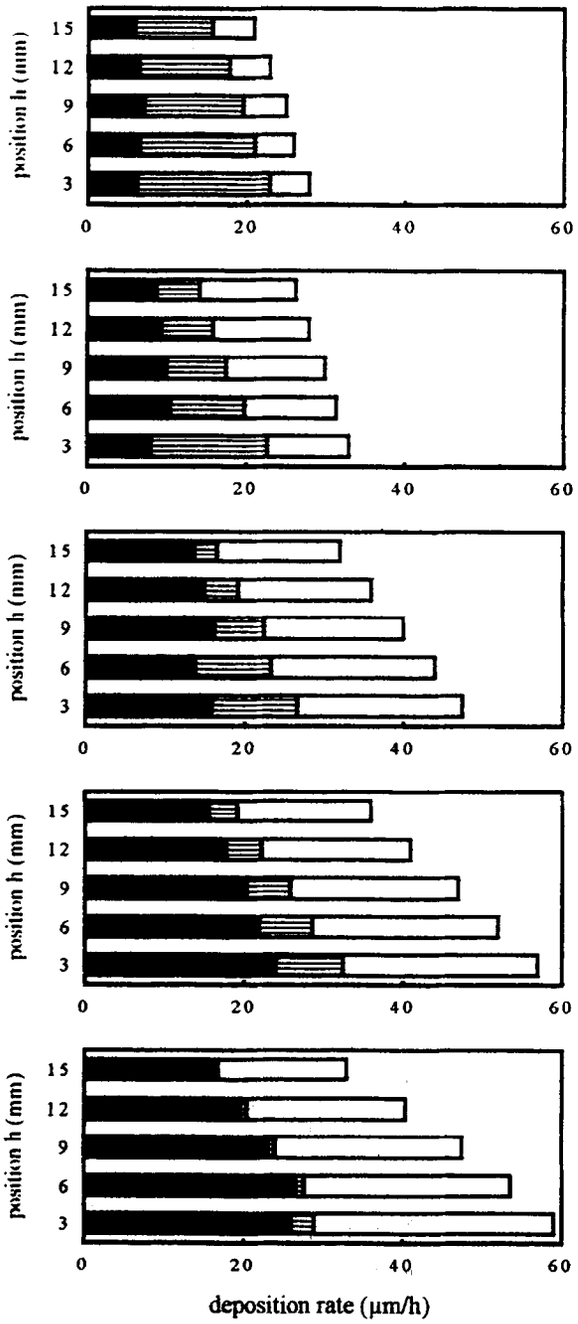

Fig. 11. Thickness and chemical composition (in at %) uniformity at T = 1400 K, P = 0·395 atm, α = 20 and F = 0·32 g/min. From top to bottom, β is equal respectively to: 0·6, 1, 2, 4 and 8. Carbon ■, Boron ▤, Silicon □.

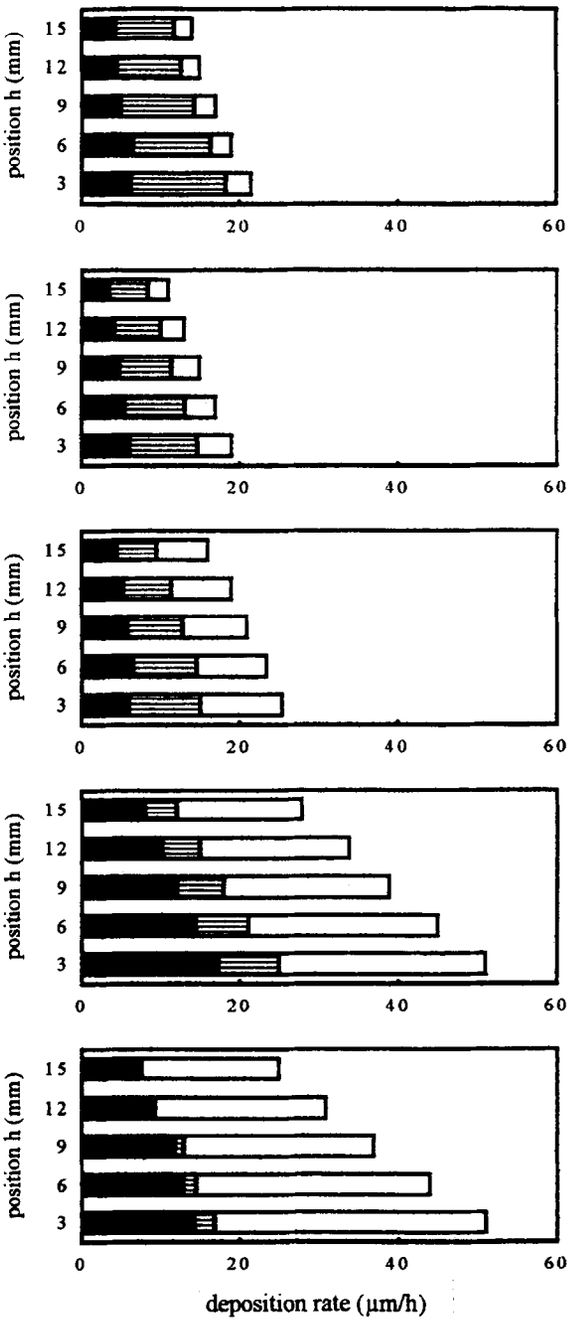

Fig. 12. Thickness and chemical composition (in at%) uniformity at T = 1300 K, P = 0·395 atm, α = 20 and F = 0·32 g/min. From top to bottom, β is equal respectively to 0·6, 1, 2, 4 and 8. Carbon ■, Boron ▤, Silicon □.

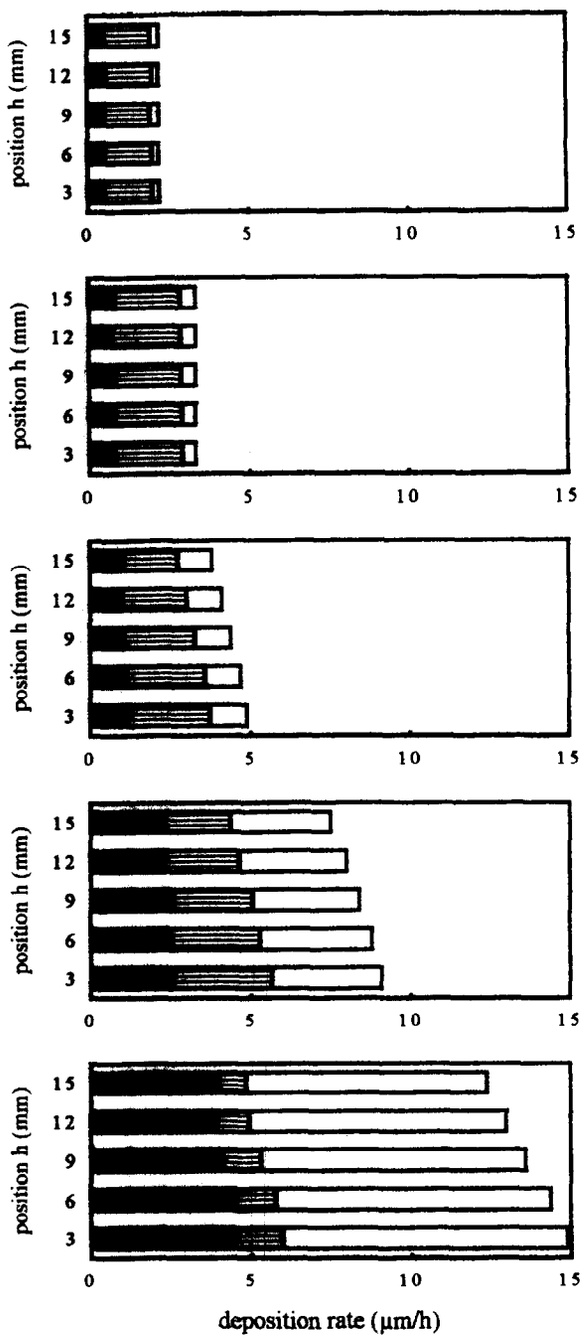

Fig. 13. Thickness and chemical composition (in at %) uniformity at T = 1200 K, P = 0·395 atm, α = 20 and F = 0·32 g/min. From top to bottom, β is equal respectively to: 0·6, 1, 2, 4 and 8. Carbon ■, Boron ▤, Silicon □.

increase in the silicon content, were observed.

At T = 1300 K (Fig. 12), the same comments can be made concerning the uniformity in thickness. The control of thickness is even poorer than at T = 1400 K (Table 1). The U_L ratio decreased, as was the case for T = 1400 K, when β increased. It corresponds to both an increase in the MTS content in the inlet gas composition and in α' (Tables 1 and 2). On the other hand, for T = 1300 K, a better control of the chemical composition was noticed especially for the lowest values of β. The deposition rate was lower than for T = 1400 K but still remained high. The values are 21·5 μm/h

Table 1. Longitudinal thickness uniformity $U_L = t_{15mm}/t_{3mm}$ as a function of ß (where t_{hmm} is the thickness at the h (mm) position from the lower end of the substrate)

	ß = 0·6	1	2	4	8
T = 1400K	U_L = 0·75	0·79	0·67	0·63	0·55
T = 1300K	U_L = 0·65	0·61	0·61	0·55	0·49
T = 1200K	U_L = 1	1	0·78	0·82	0·82

P = 0·395 atm, F = 0·320 g/min, α = 20, ß variable.

Table 2. $\alpha' = [H_2]_o/[MTS]_o + [BCl_3]_o$ values as a function of $\beta = [MTS]_o/[BCl_3]_o$; $\alpha = [H_2]_o/[MTS]_o = 20$

ß	0·6	1	2	4	8
α'	7·5	10	13·3	16	17·8

for β = 0·6, and 51 μm/h for β = 8 at the bottom of the sample, when h = 3 mm.

At T = 1200 K (Fig. 13), for β = 0·6 and 1, a good control of thickness and chemical composition was obtained (U_L = 1), the boron content was high (≈ 65%) and the carbon content remained stable (≈ 23%). Note that this good control was obtained when the deposition rate was low (≈ 2–3 μm/h). When the content of both MTS and H_2 were higher, over β = 2 in the initial gas mixture, thickness and chemical composition uniformity could not be controlled as well. Under these conditions, the deposition rate increased to 15 μm/h and the well-known influence of mass transfer and depletion of reactants arose for such a relatively high rate, when they were not compensated for by using specific reactor geometry.

4.2 Influence of the mass flow rate at different temperatures

The experimental conditions chosen for this study are the following:

$$P = 0{\cdot}395 \text{ atm}; \alpha = 20; \beta = 1; F \text{ variable};$$
$$T = 1200, 1300, 1400 \text{ K}.$$

The results have been reported in Figs 14–16. In section 3.2, it has been verified that the departure from equilibrium increased when the mass flow rate increased.

At T = 1400 K (Fig. 14), the increase in the mass flow rate from 0·1 to 1·0 g/min induced an increase in the deposition rate of the coatings from 15 to more than 70 μm/h. This mass flow rate increase induced a better control of the longitudinal uniformity in thickness U_L (Table 3), but also of the chemical composition of the coatings. This improvement in control goes along with an

Table 3. Longitudinal thickness uniformity $U_L = t_{15mm}/t_{3mm}$ as a function of F (where t_{hmm} is the thickness at the position h_{mm} from the lower end of the substrate)

	F = 0·100	0·320	0·600	0·700	0·900	1·000
T = 1400K	U_L = 0·75	0·79		1		1

T = 1200K	U_L = 0·80	1	1			

P = 0·395 atm, α = 20 , ß = 1, F variable.

increase in the boron content for when the mass flow rate increases, as well as with a decrease in the carbon and silicon content. As a result, the final composition obtained was very different from the composition at equilibrium. It is worth noting that a better control in thickness and chemical composition was obtained with a high deposition rate, which could not be reached in an industrial reactor without encountering problems of uniformity.

At T = 1300 K (Fig. 15), the increase in the mass flow rate (0·1 to 0·9 g/min) induced an improvement of the control of the thickness longitudinal uniformity U_L (Table 3) and the chemical composition of the coatings. This better control was obtained when the boron content was highest and the silicon and carbon contents lowest, in other words when the departure from equilibrium of the chemical composition was the highest. Note that an increase in the mass flow rate led, at the end, to a small decrease in the deposition rate for F = 0·9 g/min.

At T = 1200 K (Fig. 16), the increase in the mass flow rate (0·1 to 0·6 g/min) made it possible to obtain a very satisfying control of the thickness longitudinal uniformity U_L (Table 3) as well as the chemical composition of the deposits. Under these conditions, the deposition rates were much lower (2–3·3 μm/h). A good control was obtained when the composition of the coatings was very different from the expected composition at equilibrium. It can be noted that the increase in the mass flow rate led, at the end, to a small decrease in the deposition rate of the coatings as was observed at 1300 K.

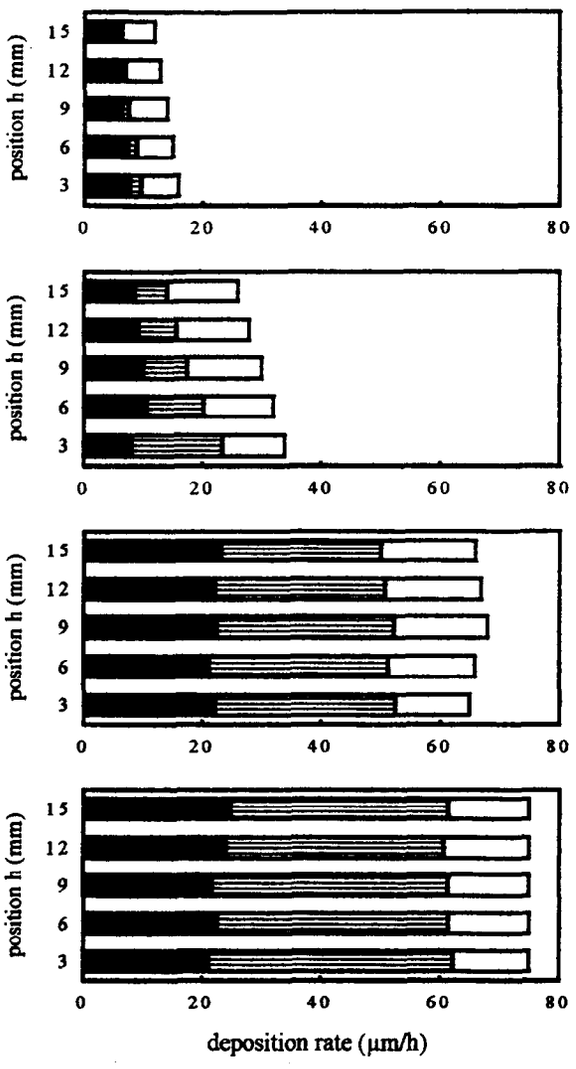

Fig. 14. Thickness and chemical composition (in at %) uniformity at T = 1400 K, P = 0·395 atm, α = 20, β = 1. From top to bottom, F is equal respectively to: 0·1, 0·32, 0·7 and 1·0 g/min Carbon ■, Boron ▤, Silicon □.

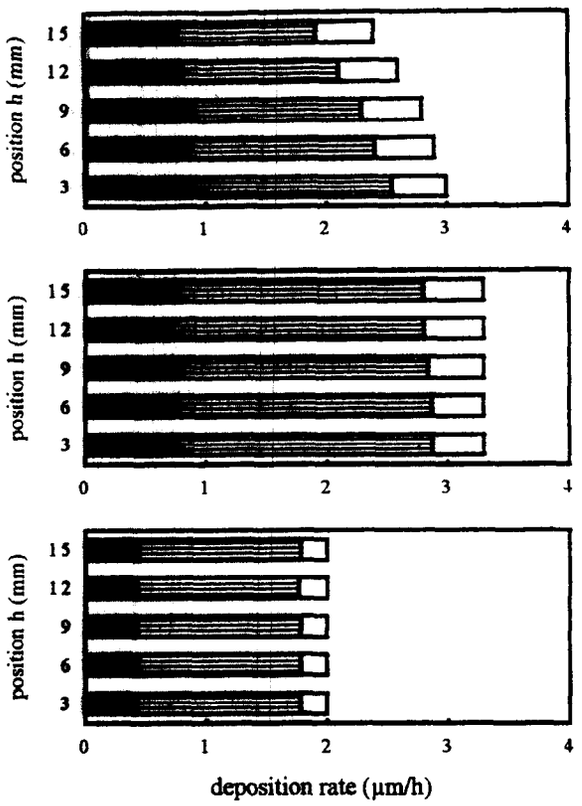

Fig. 16. Thickness and chemical composition (in at %) uniformity at T = 1200 K, P = 0·395 atm, α = 20, β = 1. From top to bottom, F is equal respectively to: 0·1, 0·32, and 0·6 g/min. Carbon ■ Boron ▤ Silicon □.

4.3 Influence of the temperature when β was fixed

When the temperature was lower, whatever the value of the mass flow rate or inlet gas composition was, the deposition rate of the coatings was lower. Moreover, the difference in the chemical composition compared with that of the equilibrium was greater because the content in the free elements (boron and/or silicon) increased.

When the temperature changed from 1400 to 1200 K, the longitudinal uniformity in thickness U_L was worse at 1300 K than at 1400 K. The best uniformity U_L was obtained for T = 1200 K (Figs 14–16).

5 Discussion

It is well-known that the departure from equilibrium at the gas–solid interface of a C.V.D. system increases when the temperature decreases and the mass flow rate increases, as a result of a deposition process which is first controlled by the mass transfer, then by a combination of mass transfer and chemical (reaction) kinetics and finally which is almost only controlled by chemical kinetics alone. When the supersaturation varies, it influences both the thickness and composition in a multicomponent system, hence their uniformity along the surface. This evolution was observed here for the codeposition of three elements (Si–B–C). It can be useful, for this particular system, to specify the relationships between this departure from equilibrium and the final results in terms of chemical composition, thickness and uniformity.

5.1 Influence of the temperature

For a given deposition mechanism, the kinetics of the surface reactions is much more influenced than mass transfer in the gas phase by a change in the deposition temperature. At lower temperatures the deposition is more controlled by the surface kinetics which is the slowest step and a uniform composition at each position on the samples is favored.

But as a function of temperature the deposition mechanism may change because some chemical reactions are favored over others, which was the case described elsewhere for the system (Si–C).[16] At a temperature higher than 1323 K, pure SiC was obtained whereas at 1273 K the coating contained a great amount of free silicon which was deposited at a higher deposition rate than the silicon carbide. A similar phenomenon seemed to occur in the case of the codeposition of the ternary (Si–B–C). When the temperature decreased from 1400 to 1200 K, the atomic percentage of boron and/or silicon increased while the atomic percentage of carbon decreased. This change in the composition may correspond to the deposition of free boron and/or free silicon at T = 1300 or 1200 K. At T = 1400 K, the deposition of a ternary Si–B–C coating with a relatively high carbon content was favored under lower supersaturation conditions.

On the other hand, the chemical kinetics control, which increases at a lower temperature with a high boron or silicon content, leads to greater uniformity of composition under this higher departure from equilibrium. This control was particularly good when T = 1200 K and β was low (0·6–1) (Fig 13). Under these conditions, the departure from equilibrium was high and the depletion in the gas phase and increase concentration of the gas products were reduced along the samples, in accordance with a lower deposition rate obtained for low β values (even at 1300 and 1400 K the results were better for low β values). This kinetic limitation at low temperature and low β values led, accordingly, to the best results for thickness uniformity as the deposition rate was reduced from about 30 μm/h at 1400 K to 3 μm/h at 1200 K when α = 20 and β = 1.

It can be therefore concluded that under a low supersaturation in CH_x species produced by a rel-

atively high α value of 20, which leads to a low carbon content in the solid, the kinetics limitation which is encountered at the lowest temperature of 1200 K depends on the β value. The process is more controlled, with the best uniformity for composition and thickness, when the β value is low. When the β value increases (for inlet concentration of MTS higher than BCl_3), the process is less kinetically controlled by the silicon incorporation in accordance with a higher silicon deposition rate (for example at 1200 K the global deposition rate varied from 2·2 μm/h for boron-rich coatings deposited at β = 0·6 to about 15 μm/h for silicon-rich coatings deposited at β = 8). However the variations of α' with β (Table 2) should not be overlooked in interpreting these chemical kinetics and final uniformity differences. These results were confirmed by the influence of the mass flow rate.

5.2 Influence of the mass flow rate.

It is clear that higher mass flow rates led to a process more controlled by the heterogeneous chemical kinetics and then to a better uniformity in thickness and chemical composition.

Even at 1400 K, a good result was obtained at the highest mass flow rate, but as pointed out previously, it can only be obtained on a small surface inside a small reactor, as the deposition rate was very high (> 70 μm/h) (Fig. 14). The results were surprisingly not improved at T = 1300 K (Fig. 15), in accordance with Fig. 9 where the coating composition does not tend to a limit with the mass flow rate. Also in Fig. 3, the variations of the carbon content appear imprecise. All these results seem to indicate a great sensitivity of the process to the experimental parameters, especially the β value, which could not have been very well controlled at the highest mass flow rates of Fig. 9. A very good control of the final composition and thickness uniformity of the coatings was obtained at T = 1200 K for a mass flow rate equal to or higher than 0·320 g/min (Fig. 16).

In general, an increase in the mass flow rate obviously leads to an increase in the deposition rate to a limit where the deposition is almost only controlled by the surface kinetic step. However for temperatures of 1300 and 1200 K, a small decrease was observed in the deposition rate for mass flow rates of 0·9 and 0·6 g/min, respectively. This phenomenon may be explained by too great a decrease in residence time of the different gaseous species inside the reactor. It can also be attributed to a possible cooling of the substrate due to an increase in the mass flow rate which would decrease the surface kinetics and thus the global deposition rate.

5.3 Influence of the total pressure

The influence of the total pressure was not studied in this work, but it is well-known that lower pressures allow the surface kinetic control of the deposition process to increase. This point is especially interesting for depositing coatings in large scale reactors. It is also important to extend the process to chemical vapor infiltration.[17] One part or the whole matrix of a composite could be composed of such material as Si–B–C which would lead to a great improvement of the oxidation resistance, especially under thermomechanical stresses.[18]

6 Conclusion

It has been shown that a high supersaturation at the gas–solid interface leads to a good uniformity of the thickness and the composition of (Si–B–C) coatings. A higher supersaturation is obviously obtained at lower temperatures and higher mass flow rates, but its amount is also a function of the α and β values, since different kinetic limitations can arise as a function of the inlet gas composition. A decrease in temperature from 1400 to 1200 K produces a change in the deposition mechanism, from near equilibrium conditions at 1400 K where the composition is a function of the element segregation transport phenomena and the reactant consumption, to conditions which deviate from equilibrium at 1200 K where the deposition of excess B or Si is favored under more kinetically controlled conditions. This change is also observed at each temperature when the mass flow rate increases. The best control of both thickness and composition is clearly obtained at the lowest deposition rate (2–3 μm/h), when boron-rich coatings are deposited at 1200 K and $\beta \leq 1$.

The ways of depositing coatings in the whole composition range can be deduced from this study and the desired deposition rate adjusted for a large-scale reactor, however very different coupled combinations of all parameters should be employed. For example, a (Si–B–near stoichiometric C content) solid would be deposited under very different conditions than for a (Si–B–low C content) coating, also as a function of the B/Si ratio in both cases.

This C.V.D. study made it possible to choose experimental conditions with high deposition rates on small substrates, even when the process control was not fully optimized, and to test the oxidation resistance of these coatings as either a (Si–B–C) monolayer or when associated with other compounds in multilayer coatings. These results are published elsewhere.[19]

Abstract

The use of commercially available and laboratory made Ni–Si–Cr brazes for wetting and bonding Si_3N_4 has been explored. The microstructure and chemistry of brazed joints has been characterized by techniques such as optical microscopy, scanning electron microscopy, electron probe micro-analysis and X-ray diffraction. Si_3N_4 was wetted well by all the braze alloys at 1150–1200°C, but the joint quality obtained was poor because of the formation of brittle phases and solid solutions.

1 Introduction

The increasing interest in the application of structural ceramics such as Si_3N_4 and SiC is due to their high-temperature strength and creep resistance, excellent wear, corrosion and thermal shock resistance. However, reliable joining technologies are needed if ceramic inserts are to be used to exploit these properties or complex components are to be made from simple ceramic bodies.

Brazing is an attractive technique for joining ceramic–ceramic and, particularly, ceramic–metal systems. However to profit from the high temperature mechanical properties of ceramics, high temperature brazes have to be employed and several studies[1–3] have suggested Ni-based alloys as suitable brazes for joining Si_3N_4 and SiC.

This paper describes an evaluation of the potential usefulness of some Ni–Cr–Si brazes for joining Si_3N_4, employing a material science approach based where possible on phase stability and thermodynamic factors.

2 Background

Brazing is a versatile and cost-effective technique for joining both similar and dissimilar material systems. However, many of the brazes used for joining metal workpieces do not wet technologically important ceramics and hence a sub-class of brazes, active metal brazes, have been developed for the joining of ceramics. The distinctive feature of these active metal brazes is that they react to change the surface chemistry and wettability of the ceramics.

Commercially available active metal brazes are generally based on the Ag–Cu–(In, Pd)–Ti and Cu–Al–Si–Ti systems and can be used for applications that do not require service temperatures higher than 400°C.[4–7] Si_3N_4 can be joined with these brazes and important applications have been found in the automobile industries. However, many of the proposed future uses of Si_3N_4 involve service temperatures in excess of 700°C. The selection of a high temperature active metal braze involves two tasks: (a) choice of a solvent and, (b), identification of a reactive component. The first task requires consideration of metallurgical and technological factors; the solvent must be sufficiently refractory and chemically inert with respect to the workpieces and the environment so that the joined structures can withstand service conditions such as high temperature oxidizing atmospheres. The development of brazes for high temperature metals such as super alloys can provide some guidance for solvent selection but the second task is often more difficult to accomplish. Identifying a suitable reactive component requires information about what type of products will be formed by the specific workpiece/braze combinations during the joining process. Equilibrium thermodynamics can provide insight about the chemistry of the products, but not about their formation kinetics or properties such as wettability or strength. Thus experimentation is almost always necessary to identify the optimum brazing materials and process conditions.

Several studies of the active metal brazing of engineering ceramics aimed to increase the service temperatures have been reported. In particular, Au–Ni–Ti and Pd–Ni–Ti alloys have been used to

join Si_3N_4 and SiC ceramics.[8] The results obtained indicate that a major problem is the enhanced chemical reaction between the ceramic and the braze.

The present work focused on the utility of Ni–Cr–Si brazes. These are based on the Ni–21%Si eutectic* which melts at 1143°C and were chosen for several reasons: their commercial availability, the expectation that the presence of Si will reduce the dissolution of the Si_3N_4,[9] the successful use of Ni–Cr alloys to diffusion bond Si_3N_4,[10,11] their potentially good high temperature mechanical properties, the ability of Cr to form bonding layers of CrN by reacting with Si_3N_4,[10] and the good oxidation resistance of Ni-Cr alloys. However, a problem to be faced when using Si as a temperature depressant for Ni brazes is the brittleness of the joints caused by the formation of silicides if the Si content exceeds about 10%.

Thermodynamic modelling can be a useful design tool in predicting the behaviour of the ceramic-braze systems and predictions for the SiC/Ni–Cr–Si braze systems are in good agreement with the experimental results.[1,2] Unfortunately Si_3N_4/Ni–Cr–Si systems are more complicated because the reaction processes are strongly influenced by the N_2 local partial pressure.[3,10,11] Furthermore, to understand the behaviour of Si_3N_4/Ni–Cr–Si systems requires a thorough knowledge of the Ni–Cr–Si–N phase diagram. This is lacking but some data, cited below, are available for the Ni–Cr–Si and Ni–Cr–N systems. Furthermore, a few (Ni–Cr–Si)/N_2 nitridation experiments were conducted as a precursor to this brazing study, as discussed later.

Some experimental data for Ni and Cr rich Ni–Cr–Si alloys have been published[12–14] and Ansara *et al.*[13] have assessed the data for Si lean alloys. The Ansara isotherms at 1027 and 1127°C are reproduced in Fig. 1. An obvious deficiency of this evaluation is that even the isotherm for 1127°C does not contain a liquid field, yet the commercial BNi-5, Ni–19Cr–18Si braze has a solidus of 1078°C. Hence, it became clear early on during this study that a more sound knowledge of this system was necessary if braze microstructures were to be interpreted, so a parallel programme[15,16] was initiated to derive a full Ni–Cr–Si diagram and reference to its results will be made in the Discussion.

The stability diagram of nitride phases in various Ni–Cr alloys at 950, 1000 and 1125°C as a function of N_2 fugacity (partial pressure) is given in Fig. 2. More details concerning the thermodynamic calculations and experimental verification of this diagram can be found elsewhere.[17] With

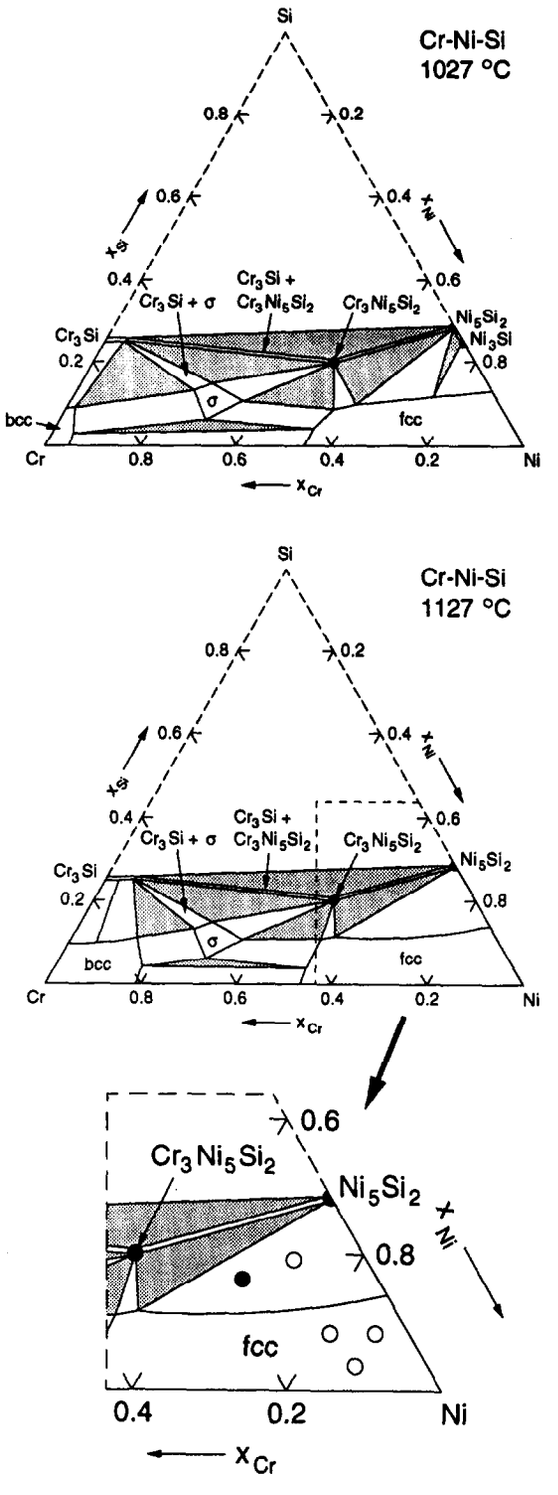

Fig. 1. Calculated partial isothermal section for the Ni–Cr–Si system at 1127°C and 1027°C (after Ref. 13). The insert displays the compositions of the braze alloys used in this study: BNi-5 is shown as a solid circle and the laboratory made alloys as hollow circles.

decreasing temperature down to 1000°C a ternary phase, π, is stable in the Ni–Cr–N system. Nitridation of Ni alloyed with at least 28%Cr produced a π phase, $Cr_{10}Ni_7N_3$[17] or $Cr_{13}Ni_7N_4$,[18] at 1000–1125°C which thermodynamic analyses demonstrated to be in equilibrium with the FCC Ni solid solution and Cr_2N at modest nitrogen activities.[19]

3 Experimental

The ceramic used in this work was a commercial hot-pressed Si_3N_4 containing 1·8% Al_2O_3 and 5·1% Y_2O_3 as sintering aids. It was obtained from Ceradyne Inc., Costa Mesa, CA, USA, as a plate from which were cut samples measuring 7 × 15 × 3 mm. The faces to be bonded were polished, using a 1 μm diamond paste, to a final average roughness (R_a) of about 0·3 μm. The braze alloys used were 90 μm thick foils of a commercial BNi-5, obtained from Wesgo Inc., Belmont, CA, USA, and 500 μm thick foils of laboratory produced alloys. Their compositions are indicated in Fig. 1 and summarised in Table 1. Table 1 also includes their liquidus temperatures, which were determined by differential thermal analysis and ranged from 1135°C for BNi-5 to 1400°C for one of the laboratory alloys.

The ceramic pieces and the braze alloy foils were ultrasonically cleaned in methanol, rinsed in water and dried using an air blast immediately before being assembled as a sandwich and placed in the brazing furnace. The brazing experiments were performed under vacuum of 6 × 10^{-4} Pa (1 Pa = 1

Table 1. Composition of the alloys used for wetting and brazing experiments

Alloy Designation	*Liquidus (°C)*	*Composition (at%)*		
		Ni	*Cr*	*Si*
BNi-5 Wesgo	1135	Bal.	18·9	18·4
N-21 Lab. Made	1150	Bal.	6	22
N-4 Lab. Made	1350	Bal.	5	10
N-5 Lab. Made	1345	Bal.	10	10
N-35 Lab. Made	1400	Bal.	10	5

$\times 10^{-5}$ bar) using temperatures of 1150 or 1200°C, times of 0·08–1 h and heating and cooling rates of 10°C/min. In accord with recommended practice for the BNi-5 alloy[20], each brazing cycle included a 1 h sub-solidus dwell at 1050°C during the cooling stage in an attempt to homogenize the seam microstructure. A slight uniaxial force of about 0·5 MPa was applied during brazing to maintain alignment of the workpieces.

Before commencing the main series of brazing experiments, the wetting behaviour of the brazes in vacuum at 1200°C was assessed. The alloy foils were placed on polished and cleaned Si_3N_4 substrates and heated at 10°C/min to 1200°C in a vacuum chamber evacuated to a pressure of less than 5×10^{-4} Pa. The samples were kept for 30 min at temperature and then cooled to room temperature at 10°C/min.

After being used in the wetting or brazing experiments, the samples were cross-sectioned, polished with diamond paste and finished with a 0·3 μm alumina slurry. The contact angles of wetting samples and the interfacial microstructures of brazed samples was characterized by optical microscopy and scanning electron microscopy. Electron probe microanalysis, (EPMA), and X-ray diffraction, (XRD), techniques were used to characterise the micro-chemistry of braze seams. The Vickers hardness of phases within the seams were derived using a 50 g load applied by Zeiss MHT-4 equipment.

Nitridation of the Ni–Cr–Si alloys under total gas pressures up to 100 bars, took place in a sintering furnace (KCE, Germany). Temperature control was carried out with an optical pyrometer within ±5°C accuracy. All experiments were carried out in pure nitrogen ($O_2 \leq 10$ ppm; $H_2O \leq 10$ ppm). After nitridation under these conditions, formation of oxides was not detected at the surface of the samples. The surface of the alloys were examined after nitriding by XRD analysis with a cylindrical texture camera using nickel-filtered Cu–Kα radiation.

4 Results and Interpretation

4.1 Wetting

The contact angles derived from the 1200°C wetting studies are presented in Fig. 3. The commercial BNi-5 braze wetted well with an angle of 10°, while the laboratory produced braze alloys wetted even better with contact angles of virtually zero.

Also included in the figure are some contact angles reported for other Ni braze alloys.[9,21,22] It can be seen that not all Ni brazes wet, the contact angle for BNi-2 (Ni–13B–8Si–7Cr–3Fe) being

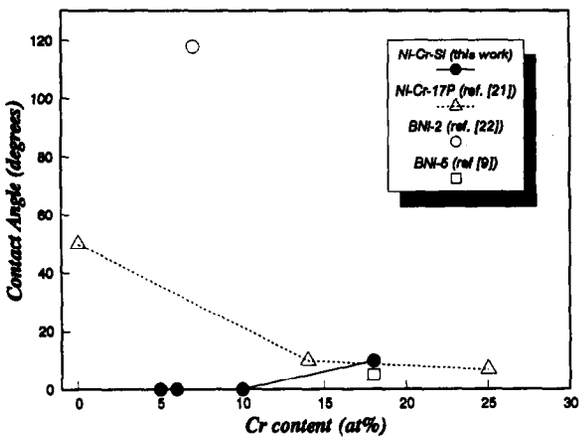

Fig. 3. Wetting behaviour of Ni–Cr–Si brazing alloys on Si_3N_4 substrates at 1200°C (filled circles). The composition of the alloys is given in Table 1. Also included are literature data for BNi-5 (open squares) Ref. 9, for Ni–17P–Cr brazes (open triangles) Ref. 21 and for BNi-2, a Ni–13B–8Si–7Cr–3Fe braze at 1150°C (open circles) Ref. 22.

120°,[22] but our observation of excellent wetting by BNi-5 confirms a literature report.[9] Using the criterion of a maximum contact angle of 30° for effective wetting of a ceramic suggested by Moorhead and Keating,[23] it can be seen that all the Ni–Cr–Si brazes used in this study are adequate but some of the other compositions are unsuitable.

4.2 BNi-5 microstructure

Comparison of the quoted Ni–19Cr–18Si composition of BNi-5 with the phase stability diagrams for both 1027 and 1127°C, Fig. 1, reveals that it lies within the solid–solid Ni_5Si_2–FCC Ni two phase field, yet very close to the boundary of the solid–solid–solid Ni_5Si_2–FCC Ni–$Cr_3Ni_5Si_2$ three phase field. It was surprising, therefore, that the microstructure of the as received BNi-5 braze, shown in Fig. 4, contained three phases. These were: (1) a matrix labelled **M** with a hardness of HV463, (2) a substantial amount of a hard irregular phase labelled **A**, and (3) a small amount of a hard angular phase labelled **B**.

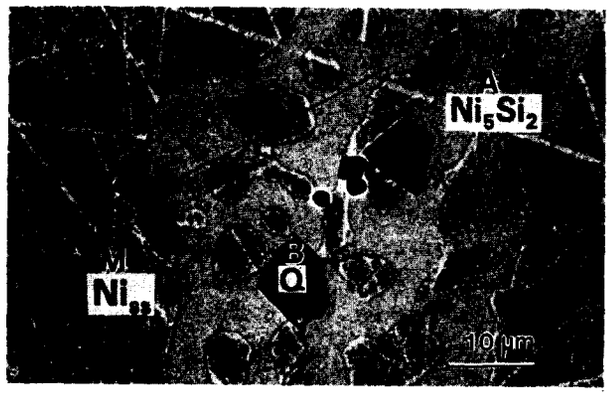

Fig. 4. Scanning electron micrographs of as-received BNi-5 microstructures.

Table 2. Phases identified in BNi-5 foils and braze seams. (Compositions are given in at%). The stoichiometry of the Q-phase was found to be $Ni_{15}Cr_{21}Si_8N_6$

Condition	*Phase M*	*Phase A*	*Phase B*
As -received foil	Ni s.s. Ni–24Cr–15Si	Ni_5Si_2 Ni–26Si–10Cr	Q-phase Ni–45Cr–15Si–3·5N
Melted foil, 1150°C, 15 min	Ni s.s. Ni–24Cr–12Si	Ni_5Si_2 Ni–27Si–7Cr	Q-phase Ni–51Cr–15Si–3·5N
Braze seam, 1150°C, 15 min	Ni s.s. Ni–24Cr–12Si	Ni_5Si_2 Ni–28Si–2·8Cr	Q-phase Cr–29·6Ni– 14·9Si–7·3N
Braze seam, 1200°C, 15 min	Ni_5Si_2 Ni–27Si–8·4Cr	Ni_2Si Ni–32Si–3·5Cr	Q-phase Cr–29Ni– 14·2Si12·2N
Braze seam, 1200°C, 30 min	Ni_5Si_2 Ni–27Si–8·2Cr	Ni_2Si Ni–32Si–4·3Cr	Q-phase Cr–28·2Ni–13·5Si–13·9N

The compositions of the phases in this and other cross-sections are summarised in Table 2. Comparison of these compositions with the Ansara diagrams shown in Fig. 1 identifies the Ni–24Cr–15Si Matrix, **M** as a Cr and Si saturated FCC Ni and the hard irregular Ni–26Si–10Cr phase **A** as a Cr enriched Ni_5Si_2. However, assigning an identity to the Ni–51Cr–15Si–3·5N composition of the angular phase **B** is difficult. The angular phase contains nitrogen and hence cannot be identified validly as any of the ternary compounds shown in the Ansara diagrams. Even if the N content is ignored, the normalised composition is not in accord with any of the phases shown in Fig. 1 but lies within the two phase field between $Cr_3Ni_5Si_2$ and the Cr_3Ni_2Si, or σ, phase. Therefore, it was decided somewhat arbitrarily for the moment, (it will be justified later on), to regard the angular phase (**B**) as a quaternary compound, Q.

The microstructure of the BNi-5 foil was little changed by subjecting it to a simulated brazing cycle by melting in an Al_2O_3 crucible and holding at 1150°C for 15 min, Table 2. The microstructure contained three phases; 53% of the Ni-based solid solution matrix phase, 40% of Ni_5Si_2 and 7% of the quaternary Q-phase. However, major changes occurred when the alloy was subjected to braze cycles in contact with Si_3N_4.

4.3 Si_3N_4/BNi-5 interactions

The good wetting behaviour of BNi-5 ensured that brazed sandwiches were formed successfully at both 1150 and 1200°C. The wetting was so good that the braze also spread over the sides of the ceramic pieces, but the structures of the joints were poor. Optical microscopy revealed that there were voids within the brazed seam and that both the seam and the ceramic–metal interfaces were cracked, presumably due to stresses caused by the mismatch between the $9·5 \times 10^{-6}$ °C^{-1} thermal expansion coefficient of the braze,[9] and the $3·3 \times 10^{-6}$ °C^{-1} of Si_3N_4.

After brazing at 1200°C (Fig. 5) it was found that the Vickers hardness of the braze matrix phase had been increased to about HV 1100 (Table 3), and that the composition of the braze seam had been changed (Table 2).

The matrix became depleted in Cr but Fig. 6 shows that extending the brazing cycle caused the

(a)

(b)

Fig. 5. Microstructure of BNi-5 joints (a) brazed at 1200°C for 15 min, (b) brazed 1200°C for 30 min.

Table 3. Hardness of the matrix phase in Ni–Cr–Si alloys before and after use in various experiments

Alloy or System	*Experiment*	*Hardness (Hv 50gr)*
BNi-5	None	463·5 ± 17·4
Si_3N_4/BNi-5	Brazing at 1200°C	1090·3 ± 40·7
Si_3N_4/N-21	Brazing at 1200°C	1109·0 ± 34·0
Si_3N_4/N-35	Wetting at 1200°C	1061·5 ± 67·8
Si_3N_4/N-4	Wetting at 1200°C	1102·3 ± 31·6

Si content of the braze seam to increase progressively as more Si rich silicides were formed. With increasing the brazing time, the Ni_5Si_2 phase identified in Fig. 4 as A was converted to Ni_2Si, Fig. 7, and became very abundant. Finally, the EPMA studies showed that quite large amounts of a complex Ni–Cr–Si–N phase was formed, the N content of which increased with the brazing temperature and time. By comparison with the microstructure of the as received filler metal this phase was identified as the quaternary Q-phase.

The large amount of Si found in the braze seam clearly demonstrates that Si_3N_4 reacts with the liquid filler metal during the brazing process. The conclusion is reinforced by the fact that decreasing the brazing time to 5 min, still caused the conversion of the matrix to a brittle silicide. Rapid reaction of the ceramic with the molten braze is reported also by Hadian and his co-workers,[9] who used the BNi-5 alloy for brazing Si_3N_4 to Mo at 1200°C. They measured a smaller increase in the Si content of the braze than it was observed in our study, but this difference may be explained by the higher partial pressure of nitrogen in their experiments (~8 Pa) compared to ours (~8 × 10^{-6} Pa), which leads to a lower chemical potential of silicon in Si_3N_4 and, therefore, to lower driving force for diffusion of silicon.

In some final experiments, the configuration of the joints was changed by the introduction of a

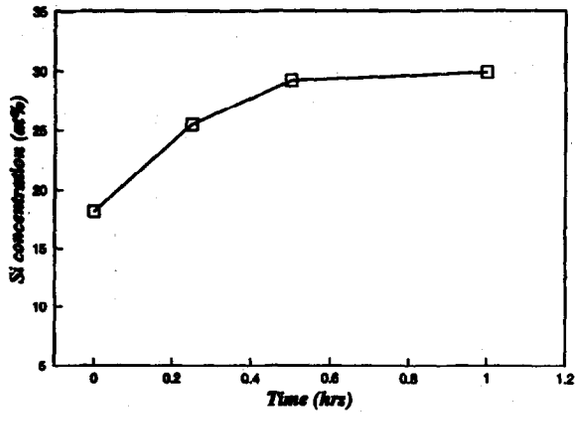

Fig. 6. Concentration of Si in the braze seam of Si_3N_4/BNi-5 joints plotted as a function of the brazing time at 1200°C. Each point is the average of 5 measurements at different 5 × 5 μm^2 locations.

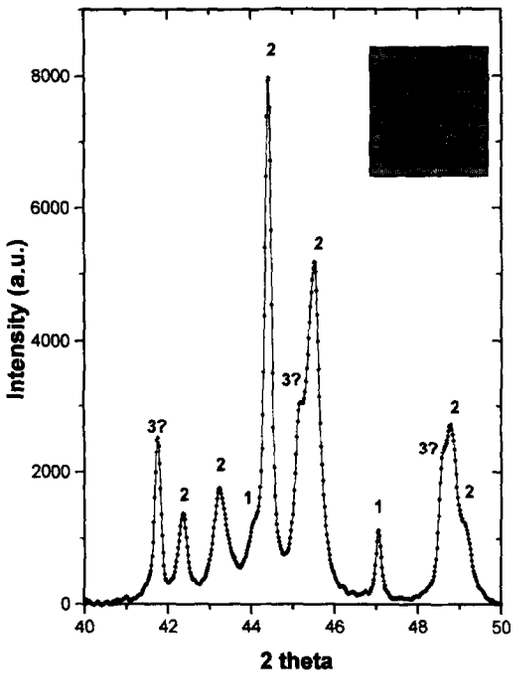

Fig. 7. X-ray diffraction spectrum of a fracture surface of a Si_3N_4/BNi-5 joint brazed at 1200°C for 30 min.

500 μm thick foil of Ni–22Cr, Fig. 8. In this case, δ-Ni_2Si was not found within the braze seam after bonding at 1200°C for 30 min. However, there was an extensive formation of the Q-phase within a matrix of Ni-based solid solution and Ni_5Si_3. In places, the Q-phase was formed as spherical particles, that suggested it had grown in the molten matrix. Another reaction product worth noting was a layer of 'CrN' at the braze–ceramic interface that was observed exclusively in the central region of the joint.

Although the brazing temperature suggested for the commercial BNi-5 alloy ranges between 1150 and 1216°C,[24] the present results demonstrate that a temperature of 1200°C is too high if it is to be used to join Si_3N_4. Hence, further brazing experiments at lower temperatures were performed. The

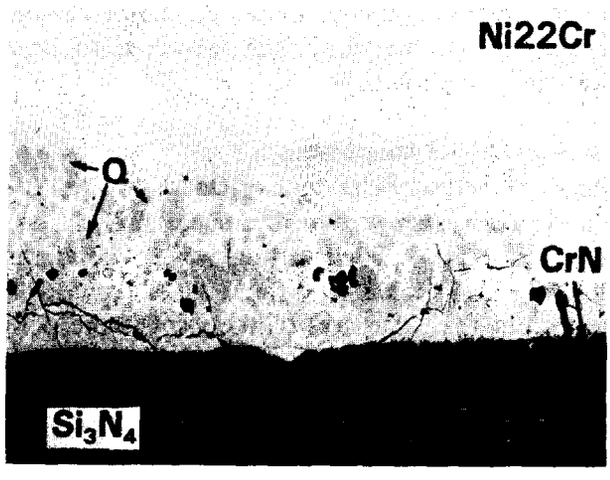

Fig. 8. Microstructure of the Si_3N_4/BNi-5/Ni–22Cr interface (1200°C, 15 min).

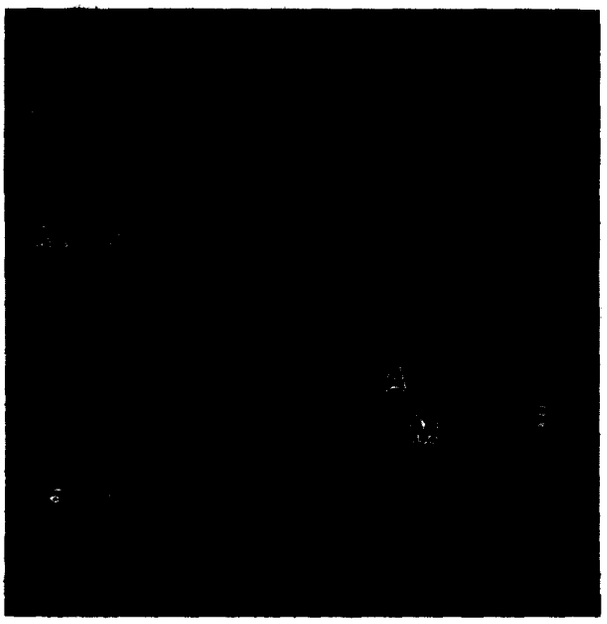

Fig. 9. Scanning electron micrographs of a Si_3N_4/BNi-5 joint brazed at 1150°C for 15 min.

microstructure of a cross-section of a Si_3N_4/BNi-5 joint brazed at 1150°C for 15 min, shown in Fig. 9, is not significantly different to that produced at 1200°C, Fig. 5. Once more, three phases are present in the brazing seam. Quantitative electron probe micro-analysis of the braze seam, summarised in Table 2, showed that the Ni solid solution matrix was still present in the seam even though large amounts of Ni_5Si_2 had been formed; the amount of Cr dissolved in the Ni_5Si_2 was decreased from 8 to about 3%, and the angular Q-phase was even more deficient in nitrogen.

4.4 Interactions of Si_3N_4 with other Ni–Cr–Si brazes

The cross-section of a Si_3N_4/N-21 alloy (Ni–6Cr–22Si) joint bonded at 1200°C for 15 min, shown in Fig. 10(a), has features similar to those observed in Si_3N_4/BNi-5 joints. Once again, the results indicate a brazing temperature of 1200°C is too high because of excessive ingress of Si. This conclusion is supported by results obtained using the other Ni–Cr–Si laboratory alloys, N-4 (Ni–5Cr–10Si), N-5 (Ni–10Cr–10Si) and N-35 (Ni–10Cr–5Si). Melting occurred even though the liquidus temperatures of the alloys are 1350–1400°C, Table 1. The melting was associated with a matrix hardness increase, as shown in Table 3, and the formation of the brittle quaternary, Q-phase.

A significantly different microstructure was produced when the laboratory alloy N-21 (Ni–6Cr–22Si) was used to braze at 1150°C for 15 min, as illustrated in Figure 10(b). In this case a reaction layer with an average thickness 2·4 ± 0·5 μm was formed at the ceramic/braze interface. A quantitative composition cannot be quoted for

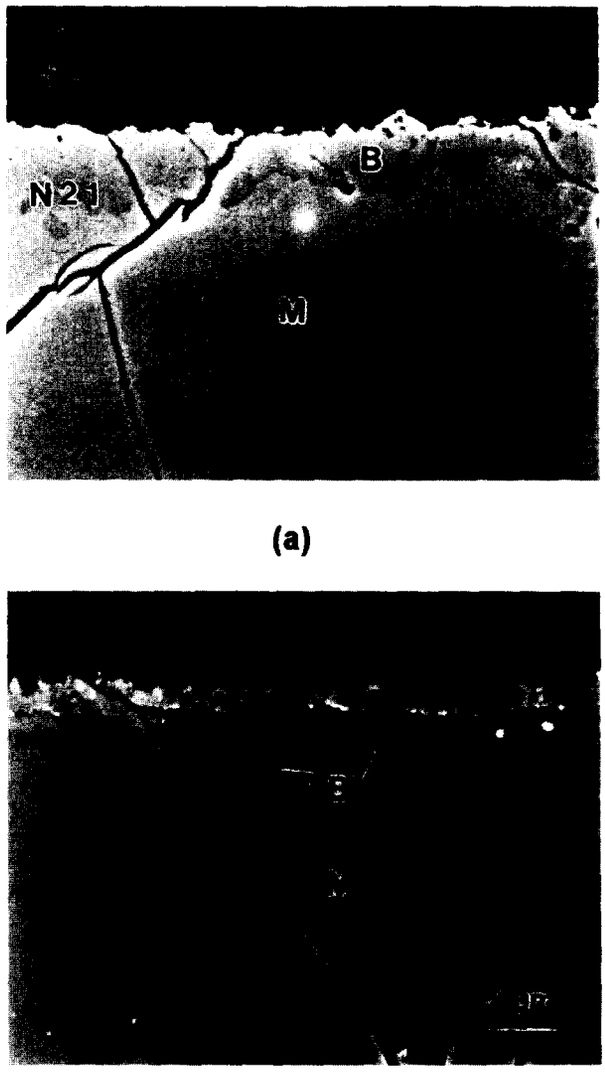

Fig. 10. Cross-sections of Si_3N_4/N-21 joints brazed at, (a) 1200°C for 15 min, (b) 1150°C for 15 min.

this reaction layer because of spatial resolution limitation of the electron probe micro-analysis technique, but from the optical appearance and morphology as well as from qualitative EDX elemental maps we may conclude that this layer is the quaternary Q-phase.

EPMA analysis of the braze seam revealed that the matrix was Ni_5Si_2 and that the angular inclusions shown in Fig. 10 had similar composition with the phases identified as Q in the other joint microstructures. Finally, cracks and voids were present in the seam, so the microstructure was unacceptable as in the case of the Si_3N_4/BNi-5 joints.

4.5 Nitridation of Ni–Cr–Si alloys

In general, as in the case of the Ni–Cr–N system, see Fig. 2, the activity of N_2 largely determines the stability of various phases in the Ni–Cr–Si–N system. Nitridation of Ni–15Cr–10Si alloy at 1125°C under 1 bar N_2 pressure or higher, produced a surface layer and internal precipitates of the

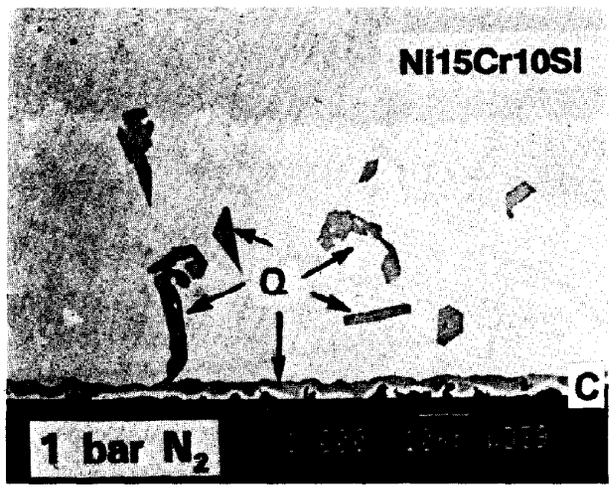

Fig. 11. The formation of the quaternary phase, Q, ($Ni_{15}Cr_{21}Si_8N_6$) after nitriding Ni–15Cr–10Si alloy at 1125°C under 1 bar of N_2 (C = Metal–gas interface).

quaternary phase Q, Fig. 11. Careful EPMA analysis of equilibrated samples pointed out to a $Ni_{15}Cr_{21}Si_8N_6$ stoichiometry for the Q-phase. Additional nitriding experiments of different Ni–Cr–Si alloys (Ni–(20–35%Cr)–(2–5% Si)) have shown that the Q-phase exists as an equilibrium phase in the quaternary Ni–Cr–Si–N system over the temperature range of 1000–1250°C.

5 Discussion

It is clear that Si_3N_4 interacts strongly with Ni–Cr–Si brazes. Thus all the brazes wetted well at 1200°C, and the behaviour of the laboratory-made brazes (N-4, N-5 and N-35) is evidence of a melting temperature depression caused by the ingress of Si from the ceramic. Vigorous workpiece/braze interactions are often associated with good wetting, and all the brazes used in this study wetted very well. The least wetting braze was the commercial BNi-5 alloy which also has the highest Cr content. However, the correlation between Cr content and wetting behaviour is unclear because, for instance, the Ni–Cr–P brazes with the highest Cr contents also formed the lowest contact angles with Si_3N_4.[21]

While braze/ceramic interactions promote wetting, the resultant microstructures are excessively brittle and none of the Ni–Cr–Si brazes used in this study can be considered satisfactory joining materials for Si_3N_4, not even the commercially developed BNi-5.

Upon brazing at 1200°C the liquid filler metal reacts with the ceramic leading to an ingress of Si and nitrogen into the braze. Since the melting point of the Q-phase is higher than 1250°C, as determined by the nitridation experiments, the interaction of the nitrogen with the liquid Ni–Cr–Si filler metal is as follows:

$$Si_3N_4 + L \rightleftarrows Q + L'$$

where L' is the remnant Cr-depleted liquid filler metal. The second eutectic isotherm in the binary Ni–Si system ($L' \rightleftarrows Ni_5Si_2 + \delta\text{-}Ni_2Si$) lies at 1215°C.[25] Chromium that is still present in the liquid may depress the temperature of this eutectic. However, the significant ingress of silicon from Si_3N_4 into the molten braze leads to the formation, inside of liquid, of precipitates of δ-Ni_2Si (or its high temperature modification θ-Ni_2Si) having a higher liquidus temperature.[26] Then, these precipitates grow through the liquid. Such a mechanism seems to be confirmed by the resultant morphology of the reaction zone after brazing at 1200°C for 15–30 minutes (Fig. 5(a), (b)).

At 1150°C the interactions between the ceramic and the braze are less severe. Still the liquid filler metal is enriched with Si and depleted from Cr. Besides the formation of the quaternary Q-phase, excess of Si within the molten filler metal result in the precipitation of Ni_5Si_2 at the brazing temperature rather than upon cooling.

In order to decide whether any other Ni–Cr–Si braze might be suitable, it is necessary to understand the reaction paths followed by the ceramic/braze systems, especially the formation of the nitride phases inside the braze seam. For instance the formation of a continuous layer of CrN at the interface is desirable[11,15] because this could impede the ingress of Si, whereas the formation of the brittle Q-phase in the seam deteriorates the joint quality. Quantitative understanding of the reaction paths cannot be achieved because of the lack of phase equilibrium data for the Cr–Ni–Si–N system but some qualitative guidance can be obtained from considering the recent Ni–Cr–Si phase diagram study in parallel with this brazing work.[15,16]

The ineffectiveness of the Si contents of the brazes in inhibiting further detrimental ingress of Si from the ceramic is further illuminated by these studies. Figure 12 displays two experimentally determined isothermal sections for 1050 and 1125°C that should be relevant to phase structures of molten and solidified brazes. Comparison of this new information with the assessments for Si lean alloys shown in Fig. 1 reveals both similarities and differences which impinge on our observations. There is agreement about the phase structure of the laboratory made alloys: N-4, (Ni–5Cr-10Si), N-5, (Ni–10Cr–10Si) and N-35, (Ni–10Cr–5Si), lie within the Ni solid solution and N-21, (Ni–6Cr–22Si), lies within the two phase field between Ni_5Si_2 and the FCC or γ-Ni solid solution.

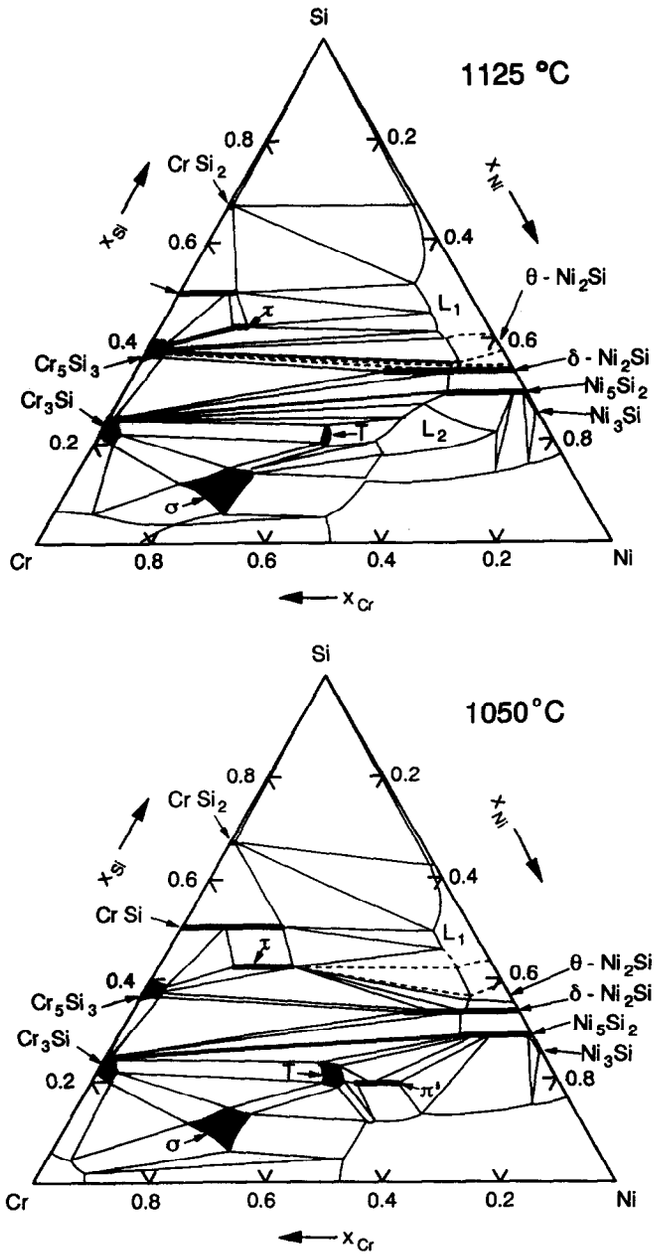

Fig. 12. Experimentally determined isothermal sections for the Ni–Cr–Si system at 1125°C and 1050°C, after Ref. 16.

Similarly, there is agreement that any σ-phase present in the as-received BNi-5 will have been a non-equilibrium or a quaternary phase.

In contrast, the isothermal sections due to Ansara *et al.*,[13] shown in Fig. 1 predict that the commercial BNi-5, Ni–18Cr–19Si, lies on the edge of a solid–solid two phase field between FCC Ni and Ni_5Si_2. This is not confirmed by the new isotherms shown in Fig. 12. In these, the BNi-5 composition lies close to the edge of the L_2 liquid field at 1125°C and presumably will lie on the actual edge of an expanded L_2 liquid field at the braze liquidus of 1135°C. Even more informatively, the new diagram for 1050°C casts light on the microstructure of the solidified braze seams produced by the equilibrium of the brazes and the dissociating ceramic. Ingress of Si will cause the Ni solid solution braze matrix to be replaced progressively by silicides and we have observed the formation of Ni_5Si_2 and Ni_2Si.

The same considerations apply to the interaction of solid Ni–Cr alloys during the diffusion bonding of Si_3N_4, but the approach to equilibrium will be much slower. The diffusion coefficient of Si in Ni–22Cr at 1200°C is $4{\cdot}9 \times 10^{-14}$ m^2s^{-1}, probably 10 000 times slower than in the molten braze because the self diffusion coefficient for molten Ni lies in the range 10^{-8}–$10^{-9}m^2s^{-1}$.[27]

A substantial displacement Cr is caused by the conversion of the Ni–24Cr–12Si matrix of the braze to Ni_5Si_2 and Ni_2Si containing only 8% of Cr. The ingress of Si from the ceramic that causes this displacement of Cr is accompanied also by a release of nitrogen and our experimental results show the displacement to result in a formation of a Cr rich nitride, $Ni_{15}Cr_{21}Si_8N_6$, which can be in equilibrium with the Ni-solid solution and Ni_5Si_2 or Ni_2Si. The presence of $Ni_{15}Cr_{21}Si_8N_6$, therefore provides proof of one logical step in the progress of a reaction path in the uncharted Ni–Cr–Si–N system created when a Ni–Cr–Si alloy is used to braze Si_3N_4.

The 1050°C isotherm in Fig. 12 shows that one or more of the Cr–35Ni–25Si (T), Cr–30Ni–10Si (σ) or Ni–30Cr–20Si (π') phases will be in equilibrium with γNi braze matrices and that the T and π' phases will be in equilibrium with Ni_5Si_2 matrices. Experimental measurements of the Cr enriched angular Q-phase in solidified BNi-5 seams with both γNi and silicide matrices yielded compositions of approximately Ni–42Cr–16Si–12N, intermediate in metal stoichiometry between that of the T and σ phases The σ-phase is not in equilibrium with the Ni_5Si_2 present in all the solidified braze seams, but there are tie lines between the T-phase and both γNi and Ni_5Si_2. Thus the designation of the angular Q-phase in BNi-5 braze seams, and possibly the reaction product layer formed by N-21, as a N modified T phase is a logical, albeit tentative, outcome of the Ni–Cr–Si phase diagram studies.

It is clear that the prospects of improving the joint characteristics by varying fabrication conditions such as time and temperature are bleak. Diffusion barriers will need to be applied to the ceramic surfaces to prevent Si and nitrogen ingress when using Ni–Cr–Si braze alloys.

6 Conclusions

Ni–Cr–Si braze alloys wet and adhere to Si_3N_4 and in some cases spreading is observed. Despite

the large range of brazing conditions explored, the joint quality obtained was very poor. Unbonded areas, cracks and voids were observed in almost all the samples.

Contact between the molten Ni–Cr–Si brazes and Si_3N_4 caused ingress of Si and nitrogen from the ceramic. In the case of the commercial BNi-5 alloy, the relatively ductile γNi matrix of the braze was converted to brittle Ni_5Si_2 or Ni_2Si. Other changes caused by the ingress of Si were the formation of a Ni–Cr–Si–N compound as inclusions or a reaction product layer.

The difficulties encountered when using the Ni–Cr–Si alloys are related to fundamental materials science effects rather than inappropriate choice of brazing conditions. None of the Ni–Cr–Si brazes can offer direct resistance to the embrittling ingress of Si and nitrogen from the ceramic.
