appears to be immaterial at the 20% level; however, at the 5% fat level, unsaturated fat (corn oil) induced more colon tumors than did saturated fat (lard) (13). Pence and Buddingh (18) reported that DMH-induced colon tumors were increased in male F344 rats fed a high-fat diet as compared with those fed a low-fat diet. A recent study by Sakaguchi *et al.* (19) demonstrated a significantly higher incidence of colon tumors in rats fed 5% linoleic acid diet than in those fed 4.7% stearic acid plus 0.3 linoleic acid diet.

Investigations also were carried out to test the effect of diets comprising 20% and 5% beef fat on colon carcinogenesis by a variety of carcinogens which differ in metabolic activation, namely DMH, MAM acetate, DMAB, or MNU (14,20). In these studies, semipurified diets containing high and low levels of fat were fed to animals before, during and after carcinogen treatment to study the specific effects on the initiation and promotion stages of colon carcinogens. Combined results of these two studies (14,20) indicate that, irrespective of the nature of the carcinogens, animals fed the diet containing a high amount of beef fat had a greater incidence of colon tumors than did rats fed a low beef-fat diet.

There are studies, however, which did not show an enhancing effect of dietary fat in colon carcinogenesis (21,22). Results from the laboratory of Nauss (21,22) indicated that 20% beef fat or corn oil had no colon tumor enhancing effect. Animals fed a diet which promoted optimal growth had a significant increase in colon tumor incidence, but not in frequency or size. This effect was not observed using a second diet, which resulted in slower growth.

TYPE AND AMOUNT OF DIETARY FAT DURING INITIATION AND POSTINITIATION PHASES

The pioneering study of Bull *et al.* (23) indicated that ingestion of a high amount of beef fat increased the intestinal tumor incidence in rats when fed after AOM treatment, but not during or before the carcinogen administration, suggesting that excess dietary beef fat acts during the postinitiation phase of colon carcinogenesis. We investigated the effect of various levels of polyunsaturated (corn oil) and saturated (lard) fats fed during the initiation or postinitiation phases of colon carcinogenesis (24). When the animals were fed the diets containing 23.5% corn oil during the stage of initiation, there was no increase in the incidence of colon tumors as compared with that of animals on a 5% corn oil diet. When the 23.5% corn oil diet was fed during the postinitiation stage of carcinogenesis, there was a significant increase in colon tumor incidence compared with that of animals fed the 5% corn oil diet. These results suggest that the effect of a high corn oil diet in colon carcinogenesis is observed mainly during the postinitiation stage, rather than during the initiation stage of carcinogenesis. On the other hand, animals fed the 23.5% lard diet during the initiation or postinitiation phase had a higher colon tumor incidence as compared to those fed 5% lard diet, suggesting the importance of type of dietary fat during the initiation and postinitiation stages of colon carcinogenesis.

The effect of high-fat diets containing coconut, olive, safflower and corn oil fed during the postinitiation phase of colon carcinogenesis also was investigated in rats (25). As expected, the animals fed the high corn oil and safflower oil (23.5%) diets had a higher incidence of AOM-induced colon carcinogenesis than did those fed the diets low in their respective fats (5%). In contrast, high-fat diets containing coconut oil or olive oil had no colon tumor enhancing effect.

In another study, we investigated the effect of various levels of *trans* fat on AOM-induced colon carcinogenesis in female F344 rats (26). The experimental high-fat diets containing 23.5% corn oil, 5.88% *trans* fat + 5.88% corn oil + 11.76 oleinate (low *trans* fat), 11.76% *trans* fat + 5.88% oleinate (intermediate *trans* fat), and 5.88% corn oil + 17.64% *trans* fat (high *trans* fat) were fed during the postinitiation phase of colon carcinogenesis. The results indicate that the high-fat diets with increasing levels of *trans* fat had no significant effect on colon tumor incidence. Animals fed the high-fat diets containing various levels of *trans* fat have a lower colon tumor incidence as well as multiplicity of adenocarcinomas compared to those fed the diet containing high corn oil (23.5).

The lack of colon tumor promoting effect of high dietary olive oil, coconut oil and *trans* fat in contrast to that of high dietary corn oil, safflower oil, beef fat and lard suggests that the fatty acid composition of a dietary fat is one of the determining factors in colon carcinogenesis. The stage of carcinogenesis at which the effect of dietary fat is exerted appears to be mostly during the promotional phase of carcinogenesis, rather than during the initiation phase.

ω3 FATTY ACIDS (FISH OIL) AND COLON CANCER

The high levels of highly polyunsaturated ω3 fatty acids such as eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) present in marine oils make them unique dietary fats. Most common animal and vegetable fats are virtually devoid of these fatty acids, except for perilla oil which contains high levels of α-linoleic acid, an ω3 fatty acid (18:3n-3). Most commonly consumed vegetable oils in the United States, such as corn oil and safflower oil, contain high levels of polyunsaturated fatty acids of ω6 type, *e.g.*, linoleic acid (18:2n-6) (Table 1).

Interest in the potentially beneficial effect of marine lipids originated by a reportedly lower incidence of thrombotic and immunologically-mediated diseases in Greenland Eskimos when compared with mainland Danish population (27). A low prevalence of cardiovascular disease has been observed in Eskimos, who eat a mostly fish diet, a high source of ω3 fatty acids (27,28). The Greenland Eskimo diet was found to contain more protein and less carbohydrates than average Danish foods and an almost equal amount of fat (27). It is also well known that Japanese people have a dietary habit of eating fish as a main source of protein and that incidence of thrombotic cardiovascular disease in Japan is lower than that in western countries. A recent epidemiologic study by Hirai *et al.* (10) on the intake of fish and the mortality rate of ischemic heart disease and cardiovascular disease indicates a lower mortality rate in the fishing area of Japan, where the intake of fish was about 260 g/day, than in the farming area of Japan, where the fish intake was about 90 g/day.

Interest in marine oils also emerged from the findings that cancer incidence rates are generally low in Eskimos

of Alaska and Greenland as compared to North Americans and other western population groups who consume diets containing high amounts of fat (9,29–31). In Greenland and Iceland, a rise in the incidence of breast cancer followed a period when the dietary habits became westernized, changing from a typical fish diet to one containing decreased amounts of ω3 fatty acids (29). A recent report on prostatic cancer in Japan indicated that, among other factors, the risk for the development of prostate cancer was higher in individuals whose diets contained little or no seafood (32). These studies resulted in an interest in the role of fish oil in health and disease.

Studies conducted in our laboratory on the relationship of dietary fish oil and colon cancer revealed that fish oil protects against chemically-induced colon carcinogenesis (33,34). In the first study, we tested the effect of diets containing 5% corn oil, 23.5% corn oil, 3% menhaden oil + 1% corn oil or 22.5% menhaden oil + 1% corn oil fed during postinitiation phase on AOM-induced colon carcinogenesis in male F344 rats (33). The results indicated that the colon tumor incidence (% animals with tumors) and multiplicity (number of tumors/animal) were significantly lower in animals fed low and high menhaden oil diets than in animals fed the high corn oil diet, suggesting that high intake of dietary fish oil had no colon tumor promoting effect (Table 2).

Although high dietary fish oil inhibited colon carcinogenesis in the above study (33), large amounts of fish oil may induce a variety of pathophysiological conditions and harmful side effects. Therefore, another study was conducted to investigate the efficacy of varying amounts of menhaden oil and corn oil on colon carcinogenesis to determine the optimum dietary levels at which the combination of two sources of fat elicits maximum inhibition when fed during the postinitiation phase of carcinogenesis (34). In this study, in addition to 5% corn oil (5% CO) and 1% corn oil + 4% menhaden oil (1% CO + 4% MO) diets, high-fat diets containing 23.5% corn oil (23.5% CO), 17.6% corn oil + 5.9% menhaden oil (17.6% CO + 5.9% MO), 11.8% corn oil + 11.8% menhaden oil (11.8% CO + 11.8% MO) or 5.9% corn oil + 17.6% menhaden oil (5.9% CO + 17.6% MO) were tested (Table 3). Feeding of high-fat diets containing 17.6% CO + 5.9% MO, 11.8% CO + 11.8% MO or 5.9% CO + 17.6% MO significantly inhibited the incidence of colon tumors as compared to 23.5% CO.

The fatty acid composition of the microsomal fraction of colonic mucosa and tumors was also measured in the animals fed the experimental diets. This study demonstrated that feeding increasing levels of menhaden oil altered the incorporation of fatty acids into the microsomes of colonic mucosal cells and tumors (Tables 4 and 5). The monounsaturated and saturated fatty acids in colonic mucosa were unaffected by feeding various levels of corn oil and menhaden oil, whereas the polyunsaturated

fatty acids were modified by dietary corn oil and menhaden oil (Table 4). Compared to microsomes prepared from rats fed the 23.5% CO diets, microsomes from the animals fed the menhaden oil diets were enriched with ω3 fatty acids. The increasing levels of menhaden oil in the diet significantly increased the ω3 fatty acids, namely EPA, docosapentaenoic acid (DPA) and DHA, and decreased the ω6 fatty acids such as linoleic and arachidonic acid (AA). Significant differences also were observed in the polyunsaturated fatty acid composition of microsomal lipids of colonic tumors among the animals fed the various levels of corn oil and menhaden oil (Table 5). Increasing levels of menhaden oil in the high-fat diets decreased the linoleic acid, linolenic and AA, but increased EPA, DPA and DHA. There was also a significant increase in monounsaturated fatty acids, namely palmitoleic acid and oleic acid, with increasing levels of menhaden oil in the high-fat diets.

The phenomenon of initiation-promotion as stages of carcinogenesis developed for skin has been observed in a variety of different organs. Since many carcinogens require metabolic activation in liver and other organs, including colon, to exert their carcinogenic effects, and enzyme systems that metabolize carcinogens have been shown to be influenced by dietary fats, it is likely that different types of fat may have an effect during the initiation stage in colon cancer. Studies conducted in our laboratory demonstrated that F344 rats fed the high-fat diet containing lard during the initiation or postinitiation phase enhanced the development of colon adenocarcinomas, whereas feeding of the high corn oil diet had an enhancing effect only during the postinitiation stage of colon carcinogenesis (24). These results suggest that the effect of dietary fat during the initiation phase of colon carcinogenesis depends on the types of fat and their fatty acid composition.

We have designed a study to investigate the modulating effect of high fish oil diet rich in ω3 fatty acids when fed during the initiation phase of colon carcinogenesis (35). In this study, five-week-old male F344 rats were divided into seven groups (39 rats/group) and fed the semipurified diets containing 5% corn oil (LCO), 23.5% corn oil (HCO) or 18.5% menhaden oil plus 5% corn oil (HFO). At seven weeks of age, all animals except the vehicle (normal saline)-treated groups were given two weekly *s.c.* injections of AOM at a dose rate of 15 mg/kg body weight, once weekly. Three days after the second injection of AOM, groups of animals fed LCO, LCO, HCO, HCO, HCO, HFO or HFO diets were transferred to LCO, HCO, LCO, HCO, HFO, HCO or HFO, respectively, and continued on these diets until termination of the experiment (Table 6). All animals were necropsied 42 weeks after carcinogen treatment. As expected, the HCO diet fed during the postinitiation period significantly increased the AOM-induced incidence and multiplicity of colon tumors, whereas the HCO diet fed during the initiation phase of carcinogenesis had no effect (Table 6). Colon tumor incidence and multiplicity were significantly reduced in groups fed the HFO diet either at initiation and/or postinitiation phases of carcinogenesis as compared to those fed the HCO diet (Table 6).

A recent study demonstrated a protective effect of menhaden oil on DMH-induced colon carcinogenesis in mice (36). In addition to menhaden oil, the modulating effect of EPA and perilla oil rich in α-linolenic acid (18:3n-3)

in colon carcinogenesis has been studied in laboratory animal models. Minoura *et al.* (37) compared the AOM-induced colon tumor promoting or inhibitory effect of dietary EPA and linoleic acid in male Donryu rats. Animals fed the EPA diet (4.7% EPA + 0.3% linoleic acid) had a significantly lower colon tumor incidence as compared to those fed the 5% linoleic acid diet. In addition, the EPA diet suppressed the excessive production of prostaglandin (PG) E_2, whereas linoleic acid diet caused a marked increase in the tumor content of PGE_2. In another study, Hirosa *et al.* (38) demonstrated that the dietary perilla oil significantly inhibited AOM-induced colon carcinogenesis and DMBA-induced mammary carcinogenesis in female Sprague-Dawley rats. In the other organs examined, the incidence of kidney nephroblastomas was lower in animals fed the perilla oil diet.

POSSIBLE MECHANISMS OF DIETARY FAT IN COLON CANCER

Various mechanisms have been proposed to explain the promoting effect of a high corn oil diet. These mechanisms include high-fat-induced alterations of tumor-promoting secondary bile acid (deoxycholic acid and lithocholic acid) content of the gut and of cell proliferation as indicated by an increase in colonic mucosal ornithine decarboxylase (ODC) activity (9). Dietary fat increases the concentration of colonic secondary bile acids, as well as modifies the activity of gut microflora which, in turn, enhances the formation of tumor promoting compounds in the colon (12). These secondary bile acids have been shown to act as tumor promoters in the colon (12). Takano *et al.* (39) demonstrated that the induction of colonic epithelial ODC activity by bile acids may play a role in these mechanisms. Increased levels of ODC and of polyamines have been found in tissues undergoing rapid growth and differentiation and in tumor promotion. Our studies (12) and those of Rozhin *et al.* (40) indicate that high dietary corn oil or beef fat increases colonic ODC levels. In addition, there is evidence that activation of protein kinase C by bile acids in colonic epithelium may represent a critical intracellular event in the process by which bile acids provoke a proliferative response (41). Bile acids induce release of arachidonate from colon and the conversion of arachidonic acid to PG (41). With regard to the lack of tumor-promoting

effect of high dietary fish oil fed during the postinitiation phase in comparison to high dietary corn oil (Table 6), several mechanisms, including eicosanoid metabolism, have been proposed. In our study, high corn oil and fish oil diets and a low corn oil diet contained, respectively, about 13.2, 3.5 and 2.8% linoleic acid, a precursor for PG synthesis. EPA and DHA present in fish oil have been shown to inhibit oxidative metabolism of AA by the cyclooxygenase pathway that is involved in PG synthesis (42,43). EPA is also a competitive inhibitor of the lipoxygenase pathway. Recent studies have demonstrated that certain PG synthesis inhibitors such as indomethacin and piroxicam inhibit colon carcinogenesis (44-46). It is therefore possible that the lack of colon tumor promoting effect of a high fish oil diet in comparison to a high corn oil diet might be due to alterations in PG synthesis.

The difference in colon carcinogenesis between the high dietary fish oil as compared to high corn oil when fed during the initiation phase (Table 6) may be related to the action of $\omega 3$ fatty acids on the metabolic activation and detoxification of AOM. The metabolic activation of AOM to a reactive species capable of alkylating DNA occurs in two steps: (i) the hydroxylation of AOM to MAM; and (ii) the oxidation of MAM to the highly unstable methylazoxyformamide (MAF) (47,48). Whereas hydroxylation of AOM to MAM was found to occur in the rat liver (47), the oxidation of MAM to MAF is affected by microsomes from rat liver and colon (48), as well as by alcohol dehydrogenase from the cytosol of both these organs (49). It is likely that $\omega 3$ fatty acids might increase the rate of detoxification of AOM, which could result in decreased delivery of MAM to the colon *via* the bloodstream, thereby reducing AOM-induced colon carcinogenesis during the initiation phase.

In summary, the results thus far generated in laboratory animal models indicate that the colon tumor promoting effect of high dietary fat depends on the type of fat and its fatty acid composition. High-fat diets containing corn oil, safflower oil, beef tallow and lard have been shown to enhance colon tumorigenesis, whereas the high-fat diets containing olive oil, *trans* fat and fish oil have no such enhancing effect. Potential mechanisms for these varied effects have not been completely identified. Future research is indicated for the identification of the mechanism of dietary fat-mediated colon carcinogenesis at the molecular level.

[Received March 8, 1991, and in revised form August 7, 1991; Revision accepted July 19, 1992]

Humans, Lipids and Evolution[1]

S. Boyd Eaton*
Department of Radiology, West Paces Ferry Hospital and Emory University School of Medicine, and Department of Anthropology, Emory University, Atlanta, Georgia 30327

The genetically ordered physiology of contemporary humans was selected over eons of evolutionary experience for a nutritional pattern affording much less fat, particularly less saturated fat. Current dietary recommendations do not accord exactly with those generated by an understanding of prior hominoid/hominid evolution. Similarly, widely advocated standards for serum cholesterol values fail to match those observed in recently studied hunter-gatherers, whose experience represents the closest living approximation of "natural" human lipid metabolism. The evolutionary paradigm suggests that fats should comprise 20-25% of total energy intake, that the ratio of polyunsaturated to saturated fat should exceed 1.0, and that total serum cholesterol levels should be below 150 mg/dL (~4 mM/L).
Lipids 27, 814-820 (1992).

The current human gene pool appears to be of ancient origin. Mammalian oncogenes are functionally homologous to those of yeast and house flies (1,2); humans and chimpanzees are only 1.6% different, genetically, even though our ancestral lines diverged at least five million years ago (3); and dental analysis suggests that Africans, Asians and Europeans are more like their ancestors of 15,000 years ago than they are like each other (4). Such considerations make it likely that the collective human genome has changed only minimally since anatomically modern *H. sapiens* became widespread, approximately 40,000 years ago.

One of the most important influences affecting genetic selection and adaptation is the interaction between a species and its food supply. For nearly all our line's existence, evolutionary forces maintained an appropriate relationship between our ancestors' metabolism and their diet. However, since the Agricultural Revolution of 10,000 years ago and, particularly, following the Industrial Revolution of the late eighteenth century, genetic evolution has been quite unable to keep pace with changes in human living conditions, including our altered nutritional patterns.

The diets of late Stone Age humans must have varied greatly with latitude and season; certainly there was no one "paleolithic diet" just as there is no one "American diet." However, as the average dietary intake of people in industrialized Western nations can be described and statistically characterized, so can that of our preagricultural ancestors. Their earlier experience has continuing relevance because the Late Paleolithic, from about 35,000 to 15,000 years ago, may be considered the latest time period during which the collective human gene pool functioned within the nutritional parameters for which it had been originally selected. It is quite likely that our physiology today is designed for a Stone Age diet.

Diets in current affluent nations deviate in many important respects from those of preagricultural societies: differences in our intake of sodium, fiber, protein, calcium, refined carbohydrate, vitamins and alcohol variously affect our growth, reproduction and health. Changes in dietary fat patterns, with their resultant impact on lipid metabolism and endocrine function, are perhaps most important of all.

HUMAN FOOD SOURCES

Animal Foods

Wild game. The meat which formed a major part of human diets for the past million years was predominantly wild game. Neither fowl nor fish became common dietary constituents until about 20,000 years ago (5), so the main nutritional adaptation over this period was to red meat.

It was during the transition from *Homo habilis* to *H. erectus,* an evolutionary stage which occurred in Africa approximately 1.7 million years ago, that meat consumption assumed increased importance. *H. erectus* remained largely confined to the African continent until about one million years ago when migration into the tropical, subtropical and even the warmer temperate regions of Asia and southern Europe began. The geographical origin of anatomically modern humans, *H. sapiens,* is currently debated, but both archeological remains and studies of mitochondrial DNA are beginning to indicate that the earliest truly modern humans evolved between 200,000 and 100,000 years ago, probably in Africa.

Accordingly, the ancestors of today's humans consumed African game animals as a substantial part of their diet for over 1.5 million years. The nutritional composition of free-living African mammals is, on average, reasonably similar to that of wild game from other continents (Table 1) but, because animals in tropical regions seldom hibernate and have less need for thermal insulation, there is less seasonal variation in their fat content than in animals in the colder portions of temperate zones (7).

Commercial meat. For over a century, one of the major goals of "scientific" animal husbandry was to increase the carcass fat content of animals raised for consumption. The economic importance of carcass fat content is evident in the official grading system—those animals with the highest proportion of fat to lean are labeled "prime" and command the highest prices; those with the least fat are graded "utility" and are not used for human consumption. In the past few years meat producers have begun to reverse this trend, but the most recent U.S. Department of Agriculture figures reveal the extent to which the past century's efforts succeeded and how nutritionally different the animals we consume are from those available to our pre-industrial ancestors (Table 2).

Although some of the fat in commercial meat carcasses is intramuscular (the marbling which makes meat tender), most is "separable," lying between muscles and as

independent deposits elsewhere in the carcass. Neither component is as prominent in African game. Ledger (6) agrees, writing "In (African) game animals . . . high yields of lean . . . result from higher lean constants (carcass muscular tissue as a percentage of live weight) . . . there was no evidence these animals compensated the low carcass fat by increased deposits of internal fat (pericardial, omental, and mesenteric). The low intramuscular fat (marbling) in game animals was consistent with their low total fat content . . . the roundness of form so often

referred to in the description of condition of tropical game animals as 'fat' is a misnomer." The actual amount of fat ingested by individuals eating meat from Western supermarkets depends to an important degree on how much or how little of the separable fat is cleaned from the muscle tissue before consumption. This was a factor of relatively little significance for our African ancestors and, to a lesser extent, for all people prior to the twentieth century.

Recent breeding and feeding practices presumably account for the reduced proportion of polyunsaturated fat in commercial meat. The structural fats of mammals, those found in cellular and intracellular membranous structures, are preferentially polyunsaturated, whereas depot or storage fat is predominantly saturated, possibly reflecting in part ergonomic considerations as more energy can be stored at a lower weight. The fat of wild game is roughly three times as polyunsaturated as that of commercial meat, reflecting the increased depot or storage fat which accumulates in domestic meat animals. In addition, game has more ω3 fatty acid (about 3% of total fat) than does commercial meat (about 0.4% of total fat in beef) (14).

Vegetable Foods

Millennia of agricultural practice have altered the fruits and vegetables most commonly consumed in Western nations. On average, the wild plant foods utilized by foragers provide more calcium (31), fiber (32), vitamin C (33) and vitamin E (Shostak, M., 1989, unpublished data) than do their cultivated counterparts. There have been changes in protein as well: for example, wild einkorn wheat has a greater protein content (22.8% crude protein) than does modern bread wheat (34), but most of today's raw fruits and vegetables still provide almost insignificantly small amounts of fat. Wild beans and nuts were probably the major sources of vegetable fat for our ancestors. Some cultures (*e.g.*, the Miwoks of California and the !Kung of Botswana) made nuts their major dietary staples, and most preagricultural peoples utilized them seasonally.

More important than the intrinsic fat content of individual plant items, which has changed relatively little over time, are the cultivation, storage, transportation and distribution capabilities of twentieth-century Western nations. Avocados (88% energy from fat), indigenous to North America, were inaccessible for all except Native Americans until the past few hundred years. Olives (90% energy from fat) and soybeans (47% energy from fat) are foods which had regional and seasonal importance for our ancestors but which are now consumed worldwide and year-round. They have assumed dietary significance for Mediterraneans and East Asians, respectively, which would have been impossible 10,000 years ago. Coconuts (92% energy from fat), one of the few plant foods whose lipids are overwhelmingly saturated, are now available everywhere, not just in Southeast Asia and the Pacific.

Paleontologically "New" Foods

Americans think of bread and milk as quintessentially "natural" foods. This is understandable, as nutritionists have designated cereal grains and dairy products as two of the four "essential" food groups. However, from the standpoint of genetically determined human biology, these foods are Johnny-come-latelies. No humans regularly consumed cereals until about 15,000 years ago, and the use of dairy products, apart from mother's milk, began later still.

Cereal grains. The potentially edible vegetation in tropical forests is almost exclusively dicotyledonous—fruits, shoots, buds, leaves, roots, etc.—so for 30 million years the prehuman primates in our ancestral line became genetically adapted to vegetable foods from this category. Existing great apes still focus on plant foods of this nature, so the present dependence of many human populations on monocotyledonous plants, especially cereal grains, is a notable departure from mainline primate experience, both in the past and currently (35).

Unprocessed cereal grains are poorly digested by the human gut; they must first be milled. Grindstones together with crude mortars and pestles designed for this purpose first appear in the archeological record during the final phase of the Late Paleolithic, perhaps 15,000 years ago in the Near East. Consequently, paleontologists infer that cereals constituted an insignificant dietary constituent for humans prior to that time (36).

Cereal grains present some intrinsic nutritional problems for humans (*e.g.*, their proportions of soluble and insoluble fiber, their calcium/phosphorus ratio, their limited calcium content, their phytate, etc.) (31,32), but although they do provide more fat than do most dicotyledonous plant foods, their lipid content seems relatively innocuous. Furthermore, traditional foods made from cereal grains, *i.e.*, breads, gruel, porridge, tortillas, etc., pose few, if any, lipid-related health problems for humans. However, many cereal-based bakery items popular in today's affluent nations represent significant sources of fat (Table 3).

Dairy products. Since they had no domesticated animals, Stone Age people had no dairy products whatsoever after they were weaned (typically around age three). The fat in mother's milk is valuable, if not essential, for normal postnatal development (*e.g.*, myelination), but for older children and adults dairy foods help increase dietary fat intake above the levels common for preagricultural humans. They do so when consumed as primary foods (*e.g.*, yogurt, ice cream) and also as complements (*e.g.*, toast and butter, cereal and cream) (Table 4). Furthermore, dairy fats are highly saturated, typically 55–65%, a proportion greater, on average, than that of any other commonly consumed food category except for tropical oils.

Food Processing and Preparation

The technology extant in industrialized nations has permitted profound distortion of the intrinsic nutritional properties of foods in several categories. Seed oils were

not directly available until relatively recently, but now safflower, sunflower, rapeseed, corn and peanut oils form a significant part of many people's daily caloric intake. Stone Agers may have occasionally consumed some of the kernels and seeds from which such oils are obtained, but where the original foods provided fiber, protein and micronutrients, for practical purposes the processed oils provide only lipid. Except for those of tropical origin, most current vegetable oils are predominantly poly- or monounsaturated in composition. However, hydrogenation converts many of the unsaturated fatty acids to their saturated counterparts and, in addition, alters others to *trans* forms, where increasing evidence suggests they function more like saturated fats (38).

Our current propensity for frying foods gratuitously increases their fat content (Table 5). Humans have cooked their food for at least several hundred thousand years, and possibly for over a million (40), but while roasting, steaming and baking were all commonly employed techniques, frying was not. The necessary utensils were unknown and there was no ready source of fat for the purpose, at least in tropical climates where animals neither hibernate nor require insulation from excessive cold.

DIETARY COMPOSITION: PAST AND PRESENT

Late paleolithic humans. In 1985, the late Stone Age diet (of perhaps 20,000 years ago) was estimated to derive about 21% of its food energy from fat, and its polyunsaturated/saturated fatty acid ratio (P/S) was calculated to be about 1.41 (41). These estimates were derived from nutritional analyses of 21 wild game species and 44 uncultivated plant foods. The values for animals and plants were averaged separately and employed in a simple model which assumed a 35:65 animal/plant subsistence ratio (42) and a daily energy intake of 3000 kcal. (Other assumptions can easily be accommodated by this model.)

$$A(C^aX) + B(C^pX), \text{ assumed caloric intake} \quad [1]$$

Where A is mean energy content of animal food (kcal/g); B, mean energy content of plant food (kcal/g); C^a, proportion of animal food in diet; C^p, proportion of plant food in diet; X, total weight (g) of food necessary to provide an assumed caloric intake.

New information has become available since 1985, the data base now includes 41 species of game and 153 types of wild plant foods. For the animals, simple averaging was again employed; however, for vegetable resources a weighted average based on forager plant exploitation in eastern and southern Africa (43) was utilized. The resulting mean nutritional values for game and wild plant foods are given in Table 6. When substituted in the original model, they produce estimates of average paleolithic nutrition reasonably similar to those presented in 1985 (Table 7).

The increased fraction of daily energy derived from fat (24.7 *vs.* 21%) resulted chiefly from an increased number of seeds (16/153 *vs.* 1/44) in the expanded data base; the proportions of beans and nuts, and other relatively high-fat vegetal items, have remained fairly constant. As noted earlier, paleoanthropologists currently believe that substantial seed use by hunters and gatherers was uncommon until the very late Paleolithic Era (around 15,000 years ago), when a broad-based subsistence pattern became necessary (36,44). Accordingly, the updated projections for average wild plant fat content and for the total

[b]Saturated fat equaled approximately 6% of total energy intake.

contribution of fat to daily energy intake are probably overestimates for humans living prior to the last phase of the Paleolithic Era.

Complete fatty acid distribution patterns have been published for 17 wild game species (10,24,25). These, together with previously published estimates for fatty acid distributions in wild plant foods (41), suggest that the P/S ratio for late paleolithic diets was approximately 1.45 (the 1985 estimate was 1.41) (Table 8). The cholesterol concentration of meat from 14 wild animals averages 65.9 mg per 100 g portion, so paleolithic humans consuming 723 g of game each day would have had an average intake of 482 mg.

Current Americans. Recent estimates cited by the Committee on Diet and Health of the National Research Council (45) suggest that in the early 1980s Americans obtained 36–40% of their dietary energy from fat[2] (a range slightly below that of countries in northern and western Europe, ref. 46) and that saturated fats made up 38.5% of total fat intake. The P/S ratio was thought to be about 0.47. Cholesterol intake is estimated to have remained stable at approximately 480 mg/d between 1979 and 1985.

The Committee on Diet and Health, as do other expert groups in the United States, Canada and Europe, currently recommends that dietary fat be reduced to 30% or less of total energy intake, that saturated fatty acids supply less than 10% of total energy, that P/S should be approximately 1.0, and that dietary cholesterol average less than 300 mg per day. These authoritative recommendations can be compared with the estimated paleolithic nutritional pattern (Table 9). Of the differences, the most noteworthy probably involves dietary cholesterol intake. This discrepancy has potentially important economic implications; it will be comparatively easy for meat producers to reduce the fat content of animals raised for consumption, but decreasing tissue cholesterol concentration would be difficult (47).

TABLE 9

Paleolithic, Current and Currently Recommended Dietary Lipid Intake

	Paleolithic	Current	Recommended
Fat, % total energy	20–25	36–40	<30
Saturated fatty acids, % total energy	~6	15	<10
P/S ratio	~1.4	<0.5	~1.0
Cholesterol, mg/d	480	480	<300

[2]There is suggestive, although not conclusive, evidence that American fat consumption has been gradually declining over the past two decades (45).

SERUM CHOLESTEROL LEVELS

Americans, foragers and nonhuman primates. Just as generally accepted recommendations for lipid intake differ from estimated paleolithic human experience, norms for serum cholesterol concentration deviate from the observed levels in recently studied hunter-gatherer populations. The National Cholesterol Education Project (48) designates serum cholesterol levels below 200 mg/dL (5.18 mM/L) as "desirable." However, for five hunter-gatherer groups studied in this century, mean serum cholesterol concentration was 123.2 ± 7.2 mg/dL (33) (3.19 ± 0.19 mM/L). Furthermore, a larger series of pre-industrial populations, *e.g.*, 20 societies including foragers, rudimentary horticulturists, simple agriculturists and pastoralists exhibited an almost equally low mean level: males 131.8 ± 4.4 and females 135.2 ± 4.7 mg/dL (3.42 ± 0.11 and 3.50 ± 0.12 mM/L). Only three groups had mean values exceeding 150 mg/dL (3.89 mM/L), and none averaged as much as 175 mg/dL (4.53 mM/L) (49).

Free-living nonhuman primates have low serum cholesterol levels. For four species (Rhesus, Macaca and squirrel monkeys together with baboons), the average was 108.5 ± 11.9 mg/dL (2.81 ± 0.31 mM/L), and the highest mean value for any species was 135 mg/dL (3.50 mM/L) (50–53). The overlapping ranges of serum cholesterol values in foragers and nonhuman primates suggests that general primate physiology is designed to accommodate cholesterol levels of this magnitude, not those commonly found in modern Americans.

Serum cholesterol and coronary heart disease. American experience has shown that many individuals whose serum cholesterol levels are below 200 mg/dL nevertheless develop coronary heart disease, which is often sufficient to produce myocardial infarction. On the other hand, members of pre-industrial societies rarely show clinical manifestations of coronary atherosclerosis, and little or no significant coronary disease has been found when autopsy studies have been performed (49). Although many factors undoubtedly contribute to their reduced susceptibility, their low serum cholesterol levels are probably a major protective influence.

The understandably limited, near anecdotal evidence concerning coronary heart disease among hunter-gatherer populations has recently been supplemented by epidemiological studies among rural Chinese whose serum cholesterol levels are similar to those of foragers, *e.g.*, 126.6 ± 15.1 mg/dL (3.28 ± 0.39 mM/L) (54) and among whom mortality from coronary heart disease is less than one-tenth that in the United States.

Meat and serum cholesterol levels. Third World populations, like the rural Chinese, manifest "low" serum cholesterol levels although their diets include very little fat (15% of total energy intake) and relatively little protein (10% of total energy intake) (54). Saturated fatty acids comprise about 25% of total fat intake (4% of total energy intake) (55). It is perhaps significant that the cholesterol intake of rural Chinese (whose serum cholesterol levels are lower and who have less coronary atherosclerosis) exceeds that of urban Chinese (340 mg/d *vs.* less than 300 mg/d) (55).

Recently studied hunter-gatherers, who serve as "best approximation" surrogates for late Stone Age humans, achieve similarly "low" serum cholesterol concentrations although their subsistence is quite different. In some respects their lipid parameters are reasonably similar—dietary fat intake is 20–25% total energy and saturated fats contribute only about 6% of total energy intake. However, cholesterol intake, at 480 mg/d, is 50% greater and they consume approximately three times the protein, *i.e.*, 30% or more of total daily energy intake. Furthermore, most of this protein is of animal origin, about 70%.

The red meat commonly available to Western consumers includes considerable fat, and its consumption has been consistently correlated with elevated serum cholesterol levels. In contrast, the wild game available to recent hunter-gatherers, as to all preagricultural humans, was very lean. Current research has shown that such meat has little, if any, tendency to increase blood cholesterol levels, even when protein makes up a high proportion (24–30%) of total energy intake (56–58).

Simple agriculturists, like the rural Chinese, have probably consumed low-fat, low-animal protein diets for thousands of years, and it is appealing, therefore, to consider this nutritional pattern the human norm, especially since populations who eat in this way have little atherosclerosis and relatively few fat-related cancers (*e.g.*, breast, prostate, colon). However, even though a 5,000-year experience is impressive, it pales beside the 1,500,000-year period during which humans existed as hunters and gatherers consuming a low-fat but high-animal protein diet.

Propositions. These considerations logically imply a series of proposals for research, product development and, ultimately, nutritional and health guidelines: (i) The goal for dietary fat intake should be 20–25% of total energy intake, not 30%. (ii) The proportion of saturated fat needs to be decreased below 10% of energy intake. The P/S ratio should exceed 1.0, not as a result of increased polyunsaturated fat intake, but by marked reduction of saturated fat intake together with substitution of poly- and monounsaturated fat for saturated whenever possible. (iii) Cholesterol intake is a less significant dietary consideration and can moderately exceed 300 mg/d unless serum cholesterol levels remain undesirably high. (iv) The "desirable" level for serum cholesterol concentration is below 150 rather than below 200 mg/dL. Values below 150 mg/dL (~4 mM/L) are desirable, those between 150–200 (4–5 mM/L) are borderline, and those over 200 mg/dL (~5 mM/L) are dangerous. (v) The meat industry needs to devise economically viable methods of producing products whose nutritional properties duplicate those of wild game. (vi) Products based on milk and cereal grains need to be manipulated so that the beneficial properties of the raw materials are emphasized and their undesirable qualities, including their lipid content, are minimized.

The American food industry has made enormous contributions to human health by providing an ample, varied, safe and inexpensive food supply. It is now grappling with the interaction between diet and chronic illnesses. As the industry addresses this issue, it would do well to keep in mind our remote ancestors' likely subsistence pattern. Heart attack and breast cancer are commonly considered "diseases of civilization" because of their rarity among peoples whose eating habits maintain the essentials of our original human pattern. Their nutritional experience may well constitute a continuing paradigm for humans today.

ARTICLE

Dietary Fat and Breast Cancer Risk: The Feasibility of a Clinical Trial of Breast Cancer Prevention[1]

N.F. Boyd*, M. Cousins, G. Lockwood and **D. Tritchler**
Division of Epidemiology and Statistics, Ontario Cancer Institute, Toronto, Ontario M4X 1K9, Canada

Animal experimental evidence and human ecological data suggest that dietary fat intake is related to breast cancer risk. Epidemiological studies within countries have given inconsistent results but are limited by the restricted range of dietary intake found in Western populations and by error in the measurement of fat consumption. Experimental evidence, derived from controlled clinical trials in which the range of fat intake is increased beyond that seen in most Western populations, is capable of overcoming this limitation of observational epidemiology, and would provide the strongest evidence available concerning the relationship of dietary fat intake to breast cancer risk. Further, such trials are the only means likely to answer the question of whether breast cancer risk in high-risk subjects can be modified by changing dietary fat intake. We describe here several aspects of the feasibility of an experimental approach to this problem, including the identification of subjects at increased risk for breast cancer, and the demonstration that such subjects will enter a clinical trial of dietary fat reduction and comply with a low-fat diet. It is shown that subjects can be recruited and retained in such trials, that satisfactory dietary compliance can be achieved over at least 24 mon and that the subjects selected are at demonstrably increased risk of breast cancer. This finding indicates that it is feasible to test the dietary fat-breast cancer hypothesis experimentally by means of a clinical trial.
Lipids 27, 821-826 (1992).

Breast cancer is the commonest cancer in women in most of the developed world. It is the commonest cause of death from cancer among women at all ages and the commonest cause of death from any cause in women aged less than 50 (1). Mortality from breast cancer has not changed over a substantial period of time, despite intensive research in methods of treatment, and the best prospects for reducing mortality from this disease at present lie in screening and prevention.

There is considerable evidence that breast cancer is, in principle, preventable (2). This evidence comes from the sevenfold variation in incidence of the disease seen internationally, from increasing breast cancer incidence in migrants from low-risk to high-risk countries, who eventually acquire the risk of their adoptive country, and from the increase in the incidence of the disease that has been observed in several formerly low-risk countries. The identity of the factors responsible for the influence of environment on breast cancer incidence is at present unknown, but evidence from animal experiment and human epidemiological data suggests that diet, and in particular dietary fat, may play a key role. This paper briefly discusses the evidence that dietary fat intake may be related to breast cancer risk and describes the rationale, methods and early results of a clinical trial designed to test experimentally the dietary fat breast cancer hypothesis.

Evidence that fat intake is related to breast cancer risk. Dietary fat intake influences breast cancer risk in animals (see refs. 3-5 for recent reviews). In animals, increasing intake of dietary fat increases tumor incidence, increases the number of tumors that develop per animal and decreases the latent interval before the appearance of tumors. When given with a carcinogen, dietary fat acts as a tumor promoter and appears to have an effect on tumorigenesis that is independent of caloric intake.

Human ecological studies comparing breast cancer incidence or mortality with dietary fat consumption within countries show a more than fivefold variation in breast cancer rates between countries which is strongly correlated (r = 0.8-0.9) with international variation in estimated dietary fat intake. Countries with the highest estimated fat intake in general also have the highest breast cancer rates, and countries with the lowest fat intake the lowest rates. Prentice *et al.* (6) have examined international breast cancer rates and estimates of fat consumption using regression analysis. Dietary fat intake explained more of the international variation in breast cancer (58%) than did total calories (14%) or any other dietary constituent considered and the effect of fat remained highly significant after controlling for differences in intake of total calories between countries. Dietary fat remained significantly associated with breast cancer rates after controlling for Gross National Product, height, weight and age at menarche (6). These analyses therefore showed a remarkably consistent effect of dietary fat intake in explaining international differences in the frequency of breast cancer.

Rationale for a clinical trial. Observational cohort and case control studies, however, have given much less consistent results (see refs. 7-12 for recent reviews). The largest of these is the Nurses Health Study (13) which showed no association between dietary fat intake and breast cancer risk in more than 100,000 nurses in the United States followed for 6 yr. However, it is now recognized that the intake of dietary fat in "western" countries is remarkably homogeneous (6,9,10). Given the narrow range of dietary fat intake observed in the Nurses Health Study and the error known to be associated with the method used to measure fat consumption in that study, it is unlikely that the study would have found an association between fat intake and breast cancer risk, even if

[1]Based on a paper presented at the Symposium on Lipids in Cancer held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

Abbreviations: BCDDP, Breast Cancer Detection and Demonstration Projects; CI, confidence interval; HDL-C, high-density lipoprotein cholesterol; LDL, low-density lipoprotein.

international variation in breast cancer rates is entirely due to differences in fat intake. Prentice *et al.* (6) calculated that the Nurses Health Study had only 24% power to detect the 15% gradient in breast cancer risk across the observed gradient in fat intake that would be expected from international ecological data. A recent reanalysis of twelve case control studies from several countries by Howe *et al.* (14) showed, in contrast to the Nurses Health Study, a strong evidence of an association between dietary fat intake and breast cancer risk, strongest in postmenopausal women. Observational epidemiological studies, which are the conventional approach taken to examine potential etiological associations, are severely constrained in their ability to answer questions about the relationship of dietary fat intake to breast cancer risk in humans.

Experimental evidence, derived from controlled clinical trials in which the range of fat intake is increased beyond that seen in most Western populations, is capable of overcoming this limitation of observational epidemiology, and would provide the strongest evidence available concerning the relationship of dietary fat intake to breast cancer risk. Further, such trials are the only means likely to answer the question of whether breast cancer risk in high-risk subjects can be modified by changing dietary fat intake.

We describe here several aspects of the feasibility of an experimental approach to this problem, including the identification of subjects at increased risk for breast cancer and the demonstration that such subjects will enter a clinical trial of dietary fat reduction and comply with a low-fat diet.

METHODS

Selection of subjects. Subjects were recruited from the Breast Diagnostic Clinics at Women's College Hospital, Mount Sinai Hospital, St. Michael's Hospital and the Toronto Western Hospital between 1982 and 1990. Subjects were eligible for the trial if they were aged at least 30 yr and had been examined by mammography within 3 mon of entry and found to have at least 50% of the breast volume occupied by the radiological changes of dysplasia. Subjects were excluded if they were pregnant or breast feeding, if they were taking a medically prescribed diet for any reason, or if they had a previous history of breast cancer. Potentially eligible subjects were identified first from lists prepared in the Departments of Radiology at collaborating hospitals where mammograms were classified according to the extent of mammographic dysplasia, and were then contacted by letter from their referring surgeon. The letter described the study in outline, was accompanied by a brochure giving the background and procedures involved in the study and indicated that one of the study personnel would telephone the subject within a few days. The purpose of the telephone call was to answer any questions concerning the study, to identify those subjects interested in entering the study and to arrange an appointment for them with a study dietician.

Preliminary assessment. After an appointment with a dietician had been arranged, subjects were enrolled in the study in two phases using different procedures. These phases involved the same events but differed in the sequence in which they occurred and in the time required for their completion. In Phase I, used initially, dieticians explained and discussed the study with subjects and sought signed consent. Subjects who provided consent were then allocated randomly to control or intervention groups. For subjects in the intervention group, dietary counselling and the preparation of an individual dietary prescription then began (see below) and the subject was seen monthly for the following 12 mon.

In Phase II, the procedure for entry adopted subsequently, the dietician at the first visit explained the study as before but then taught the subject to keep food records, using scales and household measures to record quantitatively all food consumed during a specified 3 d including one weekend day. At a second appointment, these records were reviewed and for subjects who had completed records of satisfactory quality, consent was then sought and randomization carried out. The quality of the food records was assessed subjectively by inspecting them for the completeness and the amount of quantitative detail required for their subsequent coding and nutrient analysis. All dieticians working in the trial had been certified by the Nutrition Coordinating Center and were familiar with the procedures of coding and analysis. Dietary counselling and the preparation of an individual diet prescription then proceeded as before. For subjects who failed to keep satisfactory records, further instruction was given and record keeping repeated. Consent for entry to the study was only sought after records of adequate quality had been kept.

Randomization and dietary intervention. For dietary intervention studies, subjects were randomly allocated to either a control group who were taught the principles of a healthy diet using Canada's Food Guide but who were not counselled to change the fat content of their diet or to an intervention group who were taught how to reduce their dietary fat intake to an average target level of 15% of calories. This was done by preparing an individualized dietary prescription, based on a detailed assessment of subject's eating habits at entry to the study. In this prescription, fat was substituted by the isocaloric exchange of complex carbohydrate. Subjects were encouraged to introduce these dietary principles into their diet as soon as possible and to adopt the new diet fully within 4 wk. In addition, we provided several dietary aids that included dietetic scales, a food guide containing the subject's individualized meal pattern, daily food allowance and additional information such as exchange lists for fat, cereals, fruit and vegetables, an extensive shopper's guide, suggestions for eating away from home and approximately 200 low-fat, high carbohydrate recipes.

For follow up during the trials and for assessment and promotion of compliance, subjects in the intervention group were seen once every month for 12 mon, and those in the control group once every 4 mon for 12 mon. At each visit, both groups provided a record of foods eaten on three randomly selected days and a 1-d dietary recall. Nutrient intake as indicated by these sources was initially calculated manually and compared with the diet prescription to assess compliance, to provide the subjects with feedback and to serve as the basis for discussion about difficulties or about further changes that might be made. Particular attention was paid at follow-up visits to the maintenance of caloric intake and preservation of initial weight. Food records were subsequently analyzed by the Nutrition Coordinating Center, Minneapolis, MN, and the results of these analyses are shown in the present paper.

RESULTS

Characteristics of subjects. In Phase I of the study, 227 subjects were randomized, after providing consent but before being taught to keep food records. Their characteristics have been described elsewhere (15). Subjects in the control and intervention groups were similar with respect to demographic features and risk factors for breast cancer. The mean age of subjects was 44 yr and 75% were premenopausal at entry. Approximately 20% of subjects had a first-degree relative with breast cancer, 39% of the intervention group and 40% of controls were nulliparous and the mean age at first live birth of those who were parous was 25 yr. The characteristics of subjects entering Phase II, which is still in progress, are shown in Table 1. The mean age, the proportion who are premenopausal and the high prevalence of first-degree relatives with breast cancer are similar to Phase I. Intervention and control groups again resemble each other with respect to risk factors for breast cancer.

Recruitment and retention of subjects. In Phase I, following randomization, of 115 subjects allocated to the control group, 99 (86%) remained in the study at the end of 12 mon compared to 80 (71%) of the 112 subjects allocated to the intervention group. Statistical comparison of the proportion of subjects remaining in the control and intervention groups showed that they differed significantly ($P = 0.011$). Of a total of 32 dropouts from the intervention group, 19 (59%) occurred within 60 d of randomization. Of 16 dropouts from the control group, 11 (69%) occurred within 60 d of randomization. Many of those who dropped out did so at randomization and never returned for further appointments and so provided no nutrient data.

In Phase II, a total of 25 (9%) subjects dropped out, 14 from the intervention group and 11 controls. Approximately 90% of both the intervention and control groups showed no significant differences ($P = 0.31$). The probability of subjects in the intervention groups in Phases I and II of the study remaining did differ significantly ($P = 0.0001$). The probability of controls remaining in the study for 12 mon was not significantly different in Phases I and II ($P = 0.13$).

Nutrient intake. The intake of dietary fat as assessed by the nutrient analysis of food records at baseline, 4, 8, and 12 mon after randomization in Phase I has been reported elsewhere (15,16). Results to date for Phase II are shown in Table 2. The intake of dietary fat in the control group, in terms of the proportion of calories derived from fat, remained stable over the 24 mon of observation. Four months after randomization, the dietary fat intake of the intervention group fell from a mean of 33% of calories at baseline to a mean of 22%. From 4 mon to 24 mon after randomization, approximately 60% of the intervention group had an intake of dietary fat that fell within 5% of the target of 15% of calories, and approximately 80% had an intake within 10% of this target. Protein intake was unchanged and the mean percentage of calories from carbohydrate rose from 43% to 56%. The reduction in total fat intake in the intervention group was due to a reduction in both saturated and polyunsaturated fat, and the ratio of these sources of fat did not change over the course of 24 mon. No change in dietary fat intake was seen in the control group. Intake of dietary cholesterol also fell in the intervention group. The increase in carbohydrate consumption after randomization shown in Table 2 was attributable to increased intake of starch and other complex carbohydrates without any significant increase in sucrose consumption. No change in carbohydrate intake was seen in the control group.

Statistical comparison of fat and carbohydrate intake between intervention and control groups after randomization was highly significant ($P < 0.0001$) at all intervals after randomization. The changes in dietary fat consumption indicated in the food records were supported by a quantitative relationship between nutrient intake and changes in serum cholesterol (see below).

Association of nutrient intake and serum cholesterol. Duplicates of all food consumed during one 24-h period were collected from 57 volunteer subjects, 29 from the intervention group and 28 from the control group, at either 6 or 12 mon after randomization, and foods homogenized and chemically analyzed. Chemical analysis of fat showed that the intervention group consumed an average of 27 g per day (18% of calories) and that the control group consumed an average of 47 g per day (31% of calories) (16).

Further, the nutrient intake recorded in the food records was supported by a quantitative relationship between changes in intake and changes in serum cholesterol. Serum cholesterol in women in the intervention group fell an average of 8% at 4 mon, 6% at 8 mon and 4% at 12 mon. Predicted changes in serum cholesterol were calculated by the formulas of Keys and Hegsted. Observed changes were not significantly different from the changes predicted for subjects with initial serum cholesterol values in the upper tertile of the population in whom serum cholesterol fell 14% at 4 mon, 12% at 8 mon and 10% at 12 mon. Observed changes were also not significantly different from those predicted for subjects with baseline values in the middle tertile but were significantly less than predicted for those with initial values in the lower tertile in whom values rose 3% at 12 mon. Regression analysis now showed that the prediction of change in serum cholesterol for a given change in diet can be substantially improved by a model that includes initial serum cholesterol value and

TABLE 1

Distribution of Selected Characteristics in Subjects in Intervention and Control Groups (present study)

Characteristics	Intervention	Control
Number of subjects	249	248
Mean age in years	44	45
Marital status (%)		
Never married	22	19
Divorced	9	9
Married	63	68
Separated	4	3
Widowed	2	2
Mean weight in kg	61	62
Mean height in cm	163	163
Mean age at menarche	13	13
Parity (% parous)	61	60
Mean age at first live birth (years)	25	26
First-degree relative with breast cancer (%)	21	19
Menopausal status (%):		
Premenopausal	79	77
Postmenopausal	21	23

change in total fat intake ($R^2 = 0.41$) than by the Keys or Hegsted formulas ($R^2 = 0.04$), which do not include initial serum cholesterol value. Details of the relationship between changes in nutrients and serum cholesterol have been given elsewhere (17).

Cancer risk. Seventeen invasive cancers have been found to date, 5.2 times the number expected (95% confidence interval [CI] 2.9–8.4) based upon age-specific person years of follow-up for the Ontario population. This increase in risk persists after exclusion of cancers found within 12 mon of randomization (risk = 5.2 times population risk; 95% CI = 2.8–8.9). We can therefore be confident that the risk observed in this trial population is substantially greater than the risk in the general population and that a group at high risk for breast cancer is being selected.

Sample size required for a breast cancer prevention trial. The sample size for a trial is based upon the expectation that cancer incidence will be reduced by 35% in the intervention group. As is discussed below, the planned duration of this trial is 10 yr which will comprise 2 yr of patient entry and 8 yr of follow-up. The sample size will be sufficient to provide an 81% probability of detecting an effect of this size.

Estimation of cancer incidence in the control group. We have estimated the cancer incidence of the control group from data reported from the Breast Cancer Detection and Demonstration Projects (BCDDP) (18). The report of Brisson *et al.* (18) describes the breast cancer incidence over 9 yr of observation in women with "dense or glandular" breast parenchyma at entry (an appearance of the breast parenchyma that corresponds approximately to the appearance of extensive dysplasia that will be used to select subjects for the present trial). This report shows that there is an elevation of breast cancer risk in women with dense breast parenchyma at entry, relative to women without dense breasts, that persists for at least 9 yr. The incidence of breast cancer according to age at entry is shown in Table 3. Age-specific cancer risks were applied

TABLE 3

Distribution of Subjects According to Age and Expected Annual Cancer Incidence in Proposed Clinical Trial

Age at entry	CI[a]	Annual rate	Proportion[b]
35–49[c]	16.04	2.01	0.77
50–54	25.55	3.19	0.143
55–59	26.45	3.31	0.067
60–65	54.78	6.85	0.022

[a] CI, cumulative incidence of breast cancer per 1,000 over years 2 to 9. The data are taken from Table 1 of reference 20 supplemented by information kindly supplied by Dr. Brisson. These rates have been used to calculate an average annual incidence (3rd column) from which 10 yr incidence has been estimated.

[b] This column shows the proportion of subjects according to age group in our present trial.

[c] The distribution of subjects aged 35–49 in 5-yr age groups within the range 35–49 years is similar in the BCDDP and in our present population. In both populations approximately equal proportions of subjects are within each of these 5-yr age groups. In our population 0.28, 0.26, and 0.23 of all subjects are respectively in the 5-yr age groups 35–39, 40–44, 45–49. In the BCDDP 0.14, 0.17, and 0.18 of all subjects were in these 5-yr age groups. We have therefore treated the age group 35–49 as a single category for the purposes of risk calculations.

to a population with the age distribution observed in the 600 subjects enrolled in our trials to date to derive an expected breast cancer incidence in the absence of the intervention.

Estimation of the effect of the intervention. The risk reduction has been assumed to be linear and to decline from 1.0 at the start of the trial to a final relative risk of 0.30 at the end of 10 yr. This estimate of the effect of the intervention is derived from estimates of the effect of dietary fat on breast cancer risk from international epidemiological data and from the threefold or greater changes in risk that have been observed in migrants (6). Because of the age of the population, competing causes of death should be negligible and have been ignored in the calculations.

Sample size required. Using an adaptation of the procedure described by Self *et al.* (19), taking into account the age distribution of the subjects already enrolled and assuming a linear decline in risk, we calculate that 8,500 subjects recruited over 2 yr and followed for 8 yr will give an 80% probability of detecting a relative risk of 0.3 at the end of 10 yr. Because we expect a drop-out rate of approximately 4% in the first year after entry and 1% per year thereafter, we need to recruit a total of 9,500 subjects to ensure that 8,400 will remain in the study at the end of 10 yr. We expect 105 cancers in the control group and 68 in the intervention group for a reduction in breast cancer incidence of 35%. (Drop-outs will also be followed for the development of cancer but are not included in these calculations.)

The risk of breast cancer in the control group may, however, be higher than estimated. Quantitative methods of classifying breast dysplasia, and standardized readers will be used rather than the qualitative methods of classification used in the BCDDP. Quantitative methods of classifying breast densities have, in general, identified groups of subjects with higher risks of breast cancer than have qualitative methods (20–22), and while 5% of subjects in BCDDP with dense breasts had first degree relatives with breast cancer (23), 20% of subjects recruited to date have at least one first-degree relative with breast cancer. Further, the observed cancer risk in subjects enrolled to date is approximately double that estimated from BCDDP data, even after the exclusion of cancers diagnosed within 12 mon of entry.

Influence of recruitment from breast screening centers on trial power. The Ontario Provincial Breast Screening program plans to examine with mammography all women in the population over age 50. Recruitment to the trial from screening centers will change the age distribution of the trial population from that used above to calculate sample size to one with a higher mean age. We have examined the potential effect of this change on the power of the trial by recalculating age-specific incidence rates for breast cancer using the age distribution expected in the screening program. We would expect 184 cancers in the control group. A trial of this size and age distribution could detect with 80% power a 27% reduction in the incidence of breast cancer over a period of 10 yr, when we would expect 136 cancers in the intervention group. A 27% reduction in breast cancer incidence would be associated with a final relative risk of 0.44, considerably more conservative than the final relative risk of 0.3 on which calculations of sample size were originally based. The inclusion of subjects recruited from breast screening centers will therefore increase the ability of the trial to detect an effect of dietary fat reduction on breast cancer incidence.

DISCUSSION

Animal and human ecological data suggest that dietary fat may play a major role in the aetiology of breast cancer. Human epidemiological evidence is, however, inconsistent, and because of the homogeneity of dietary fat intake in most populations combined with the substantial error associated with measurement of fat intake in most epidemiological studies, but this does not exclude a strong association between fat consumption and disease risk. Evidence now exists indicating that the experimental study of the influence of dietary fat reduction on breast cancer incidence is feasible in a randomized controlled trial. Feasibility has been shown for the recruitment and retention of subjects, for dietary compliance and for the observed cancer risk of the subjects selected. Further, the sample size required for such a trial is attainable in Canada by a multicenter trial. Such a trial would provide the strongest evidence available concerning the relationship of dietary fat intake to breast cancer risk and is the only means to determine whether high-risk subjects can reduce their risk by a modification in diet.

Several unanswered questions remain, however. These include the feasibility of maintaining the dietary intervention past the present period of observation of 24 mon and the uncertainty as to whether the control group will not change their diets and come to resemble more closely the intervention group. A substantial reduction in the difference in fat intake between intervention and control groups would of course greatly reduce the ability of a trial to detect any influence of dietary change on breast cancer incidence. A longer period of observation will be required before these questions can be answered with certainty. However, we have to date not observed any tendency for compliance in the intervention group to diminish over time, and follow up data (not shown here) from subjects enrolled in Phase I for 1 yr shows persistence of dietary modification after the cessation of dietary counselling. It appears therefore that a sustained period of dietary change may give rise to long lasting changes in eating patterns. Similarly no evidence has been detected to date of dietary fat reduction among control subjects.

The randomized trial described here thus provides opportunities to examine a number of potential mechanisms for the postulated effect of dietary fat on breast cancer risk. These include the effects of diet on plasma lipids, other products of fat metabolism and plasma sex hormones.

Plasma lipids have been extensively studied in the context of ischaemic heart disease, and there is now also evidence that lipids, particularly high density lipoprotein cholesterol (HDL-C) may be related to breast cancer risk (24–26). In short term human experimental studies, it has been shown that reduction in dietary fat intake of the magnitude proposed here is followed by a fall in plasma levels of HDL-C (27–30). These studies and preliminary data from previous work of our own (16) show that in women low-fat high-carbohydrate diets, including the current diet recommended by the American Heart

Association, reduce plasma HDL-C by approximately 8%. Total serum cholesterol and low-density lipoprotein cholesterol fall by about the same amount. All studies to date have been of short duration, our own to 12 mon being the longest. Because HDL is a strong predictor of risk of ischaemic heart disease in women, there is a need to document the longer term effects of dietary fat reduction on all blood lipids and lipoproteins (31).

Reduced-fat diets have been shown to lower serum estradiol in postmenopausal women with breast cancer (32), premenopausal women with cystic disease (33) and healthy postmenopausal women (34). Plasma estradiol levels have also been found to be lower in premenopausal vegetarians than in omnivores (35). All of these studies have been of short duration, usually a few weeks, and to our knowledge the longer term effects of dietary fat reduction on plasma hormone levels have never been studied despite the widespread belief that both estradiol and dietary fat may be relevant to carcinogenesis in the breast.

The trial thus provides a setting in which answers to these and other biological questions relevant to both cancer and heart disease can be addressed and the relationship of these and other potential intermediaries of disease risk can be examined in relation to the relevant disease outcomes.

ARTICLE

Utilization of Extracellular Lipids by HT29/219 Cancer Cells in Culture

S. Pazouki[a], J.D. Baty[a,*], H.M. Wallace[b] and C.S. Coleman[b]

[a]Department of Biochemical Medicine, Ninewells Hospital and Medical School, Dundee DD1 9SY, Scotland and [b]Clinical Pharmacology Unit, Departments of Medicine and Therapeutics and Pharmacology, University of Aberdeen, Foresterhill, Aberdeen AB9 2ZD, United Kingdom

Uptake and incorporation of long-chain fatty acids were studied in a human colorectal cancer cell line (HT29/219) grown in culture medium supplemented with either fetal calf serum (FCS) or horse serum (HS). The cells were grown for 120 h with no change of medium; the two major cellular lipid classes, the phospholipids and the triacylglycerols, were analyzed at regular time-points. We observed significant changes in the concentration of most fatty acids throughout culture, and differences in their composition when different sera were used to supplement the medium. Minimal levels of free fatty acids were found in the cells, indicating a very small "free fatty acid pool". A major difference between the cells grown in media supplemented with different sera was the changes observed in concentrations of cellular polyunsaturated fatty acids during growth. In cells grown with FCS (in which 20:4n-6 is present), the levels of this acid in the phospholipid and triacylglycerol fractions declined rapidly during cell growth, suggesting further metabolism. In cells grown in medium supplemented with HS, 18:2n-6 was the major polyunsaturated acid present. There was clear evidence that this acid accumulated in the cellular triacylglycerol and phospholipid fractions. Furthermore, its concentration did not decline during growth in culture, suggesting minimal conversion to other polyunsaturated n-6 acids. Our results suggest that fatty acids from additional sources in the medium, for example triacylglycerols and phospholipids associated with the lipoproteins, are taken up by the cells. There is also indication of cellular fatty acid synthesis, particularly of monounsaturated and saturated acids during the culture period. HT29/219 cells were shown to take up and incorporate radioactivity when trace amounts of [1-^{14}C]-labeled arachidonic, linoleic or oleic acids were added to the culture medium. Most (80%) of the label was detected in cellular phospholipids and triacylglycerols, although the specific activities of these various fatty acids were different in the two lipid fractions.

Lipids 27, 827–834 (1992).

To compare data from different laboratories studying lipid metabolism in cultured cells, growth conditions must be kept as constant as possible. It has been shown that the serum supplement is important in studies on the lipid metabolism of cultured cells, as it is the most prevalent source of lipids in culture media. One of the major lipid fractions in serum, if not the main fraction, taken up by cultured cells, are free fatty acids (1–4). Cells grown in media supplemented with different sera (which contain different types and concentrations of free fatty acids) are thus subjected to different lipid environments. Investigations involving modification of cellular lipids, in particular the phospholipids in the membrane, have shown that the cell membrane's normal barrier function, as well as the responsiveness of the integral proteins, are affected when cellular fatty acid levels and compositions are changed (5,6).

The present study was designed to investigate the effect on cellular fatty acid levels when a cancer cell line was grown in media supplemented with different sera. Two serum supplements containing different concentrations of fatty acids were used. We have analyzed the fatty acid composition of the different lipid classes in a human colorectal carcinoma line grown in fetal calf serum (FCS)- supplemented and horse serum (HS)-supplemented media. FCS and HS, which are the two most commonly used serum supplements in cell culture studies, were first analyzed to obtain detailed information about their fatty acid composition.

Although in the routine culture of the cells used in this study, the medium is changed and/or the cells are passaged once every 48 h, for the purposes of this work no medium change was carried out during the period of culture (120 h). The reason for this approach was that we were particularly interested in studying fatty acid uptake and turnover in the cells during the rapid logarithmic phase of growth. From preliminary studies using HT29/219 cells grown in fetal calf serum-supplemented medium, 120 h was shown to be a satisfactory time period as cells were found to grow most rapidly between 48 and 96 h.

MATERIALS AND METHODS

Materials. HT29/219, a human colorectal carcinoma cell line, was obtained from the European Animal Cell Culture Collection (Porton Down, Salisbury, U.K.). Dulbecco's modification of Eagle's essential medium (DMEM) was purchased from Flow Laboratories Ltd. (Rickmansworth, U.K.). FCS, HS, trypsin, penicillin and streptomycin were from Gibco-BRL Ltd. (Irvine, Scotland). Ethylenediaminetetraacetic acid (EDTA) was supplied by BDH Ltd. (Glasgow, U.K.). Brain heart infusion (BHI) and Sabouraud liquid medium (SAB) were from Oxoid (Basingstoke, U.K.). Fatty acid standards were obtained from Sigma Chemical Co. Ltd. (Poole, U.K.), and [1-^{14}C]-labeled acids were from Amersham International (Aylesbury, U.K.). All solvents used were of high-performance liquid chromatography (HPLC) grade and supplied by BDH Ltd.

Cells and culture conditions. Stock cultures of cells were maintained in 75-cm^3 flasks containing 30 mL of DMEM supplemented with 10% fetal calf serum, penicillin (50 IU/mL) and streptomycin (50 μg/mL) at 37°C in a humid-

ified atmosphere of 5% CO_2/95% air. This medium will be referred to as DFC10. To study the effect of horse serum on cellular lipid metabolism, the cells were subcultured in DMEM supplemented with 10% HS for a minimum of five passages prior to the setting up of the experiments. This medium will be referred to as DH10. Cultures were periodically monitored for bacterial and fungal contamination using BHI and SAB, respectively. Viability was assessed by Trypan blue exclusion and was determined to be >93% for all experiments.

Cells grown routinely (either in DFC10 or DH10) were harvested *via* trypsinization. The detached cells were washed with and then suspended in the medium to be used for their growth. Cells were seeded at a density of 1.9×10^4 cells/cm^2 in 9-cm diameter petri dishes and grown in 10 mL of either DFC10 or DH10 for up to 120 h. After incubation for specific time periods (4, 24, 48, 72, 96 and 120 h) at 37°C, plates were removed from the incubator and the medium removed and kept at −20°C for lipid analysis. In our study, the 4-h time-point was regarded as representing the initial state of the cells. No analyses were carried out at the true start of the experiments (0 h) because the HT29/219 cell line is an anchorage-dependent cell line. As the cells had not attached to the plates until at least 4 h after plating, studying their growth and metabolism at any time before 4 h was not a true starting point for comparison with other time-points.

The attached cells were washed twice with approximately 1 mL of ice-cold phosphate buffered saline (PBS) solution and harvested by scraping with a rubber policeman. After centrifugation, the cell pellets were stored at −20°C until further analysis (see below).

Lipid extraction and analysis. The cell pellets were resuspended in 1 mL of PBS and disrupted by three freeze-thaw cycles followed by sonication using an ultrasonicator. An aliquot of the cell suspension was removed for protein analysis by a turbidimetric method (7). This method correlated well with the more traditional Lowry method (8) of protein determination and was preferred to the Lowry method due to the reported unspecificity of the latter (9). Total lipids were extracted from the remainder of the cell suspension according to the procedure of Folch *et al.* (10) using chloroform/methanol (2:1, vol/vol) containing 0.01% butylated hydroxytoluene (BHT) as antioxidant. The lipids were fractionated into phospholipids, cholesterol, triacylglycerols and free fatty acids by thin-layer chromatography (TLC) on 0.25-mm Silica Gel 60 precoated plates (Merck, Darmstadt, Germany) using hexane/diethyl ether/acetic acid (70:30:1, vol/vol/vol) as the developing solvent. Dichlorofluorescein (0.1%) in 95% methanol was used to spray the plates, and the bands were visualized under ultraviolet light. The phospholipid, triacylglycerol and free fatty acid bands were scraped off and the lipids eluted with chloroform/methanol (2:1, vol/vol) containing 0.01% BHT. At this stage of the analysis, heptadecanoic acid methyl ester (5 μg/mL of cell suspension for early time-points and 50 μg/mL for later time-points) was added to each extract as an internal standard (11). Phospholipids and triacylglycerols were transesterified using sodium methoxide-methanol (12), and free fatty acids were methylated using diazomethane (13). The fatty acid methyl esters (FAME) were dissolved in dry heptane and analyzed on a Hewlett-Packard benchtop gas chromatography/mass spectrometry (GC/MS) system (Winnesh, U.K.) equipped with a 30-m DB-WAX column with an internal diameter of 0.25 mm and 0.25 μm film thickness (J&W Scientific, purchased from Jones chromatography Ltd., Mid Glamorgan, U.K.). Details of the operating conditions and quantitative analysis of the FAME are published elsewhere (14).

The recovery of triacylglycerols and free fatty acids throughout the workup was found to be 95% ± 9% and 84% ± 14%, respectively. For phospholipids the recovery was lower (42% ± 4%). However, all data presented have been corrected for these losses.

Free fatty acids were extracted from an aliquot of the culture medium at each time-point, as well as at the start of the experiments, using chloroform/heptane/methanol (28:21:1, vol/vol/vol) containing 0.01% BHT (15). Heptadecanoic acid methyl ester (5 μg/mL of culture medium) was used as an internal standard, and the dried extract was methylated using diazomethane (see above). The recovery of free fatty acids in this procedure was found to be 92% ± 7%. The results presented have been corrected accordingly.

Incubation of cells with radiolabeled fatty acids. In order to investigate the uptake and incorporation of free fatty acids into cellular lipids, [1-^{14}C]arachidonic, [1-^{14}C] linoleic or [1-^{14}C]oleic acid (15 nCi/mL) were added in ethanol to the cell suspension at the time of plating. The final concentration of [1-^{14}C]-labeled acid and ethanol were 75 nM (equivalent to 150 nCi/plate) and 0.05% per plate, respectively. Cells were incubated as above, harvested at each time-point, lysed, and the lipids extracted and fractionated as outlined above. The separated lipids were then scraped off the TLC plates for counting of radioactivity. A portion of the growth medium was also removed at each time-point for measurement of radioactivity remaining in the medium.

Statistical methods. For experiments where three or more replicates were available, means, standard deviations and coefficients of variation were calculated in the usual way. The 95% confidence limits also were determined using the appropriate t values from the t-distribution table. Statistical significance was tested by the Mann-Whitney U-test.

RESULTS

HT29/219 cells were found to grow in medium supplemented with either FCS or HS. The growth rate of the cells, measured as the change in the amount of protein with time, was, however, found to be higher in DFC10-grown cells after 48 h (Fig. 1). Fatty acid analysis of the two serum supplements revealed significant differences in both the concentrations of individual lipids and the types of fatty acids present. Table 1 shows the concentration of fatty acids present in the phospholipid, triacylglycerol and free fatty acid fractions of each serum. Other fatty acids (for example 20:0, 22:0, 22:4n-6 and 22:5n-3) were not detectable in either the sera or the cellular lipids. The phospholipids, triacylglycerols and free fatty acids were found to account for 78% of the total fatty acids present in the sera. Horse serum contained an approximately sixfold higher concentration of total fatty acids as compared to FCS. However, FCS contained slightly higher concentrations of *cis*-vaccenic acid,

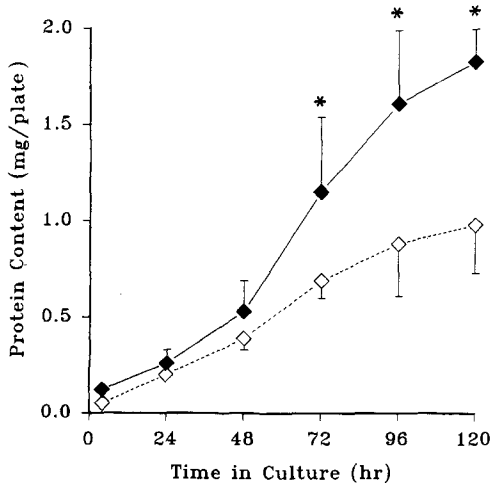

FIG. 1. Growth curves for HT29/219 cells grown in medium supplemented with fetal calf (◆) or horse (◇) serum (FCS or HS). Results shown represent the mean and 95% confidence limits of five replicates (FCS data) or three replicates (24–96 h HS data), or half the range for two replicates (4 h and 120 h HS data). In some cases the 95% confidence limits lie within the area covered by the symbols. *, Significant difference between DFC10- and DH10-grown cells, $P < 0.05$ (Mann-Whitney U-test).

[a]PL, phospholipid; TG, triacylglycerol; FFA, free fatty acid; FCS, fetal calf serum; HS, horse serum. 18:1 *c9*, Oleic acid; 18:1 *c11*, *cis*-vaccenic acid; 18:2, linoleic acid; 18:3, α-linolenic acid; 20:3, 8,11,14-eicosatrienoic acid; 20:4, arachidonic acid; 20:5, 5,8,11,14,17-eicosapentaenoic acid; 22:6, docosahexaenoic acid. Results are the mean of two replicates.

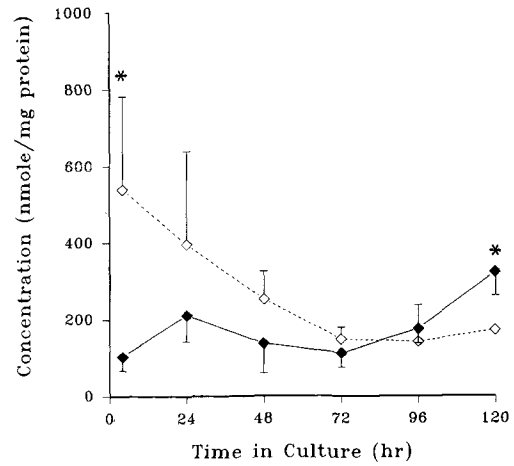

FIG. 3. Total fatty acid concentration in the triacylglycerol fraction of HT29/219 cells grown in medium supplemented with fetal calf (◆) or horse (◇) serum (FCS or HS). Results shown represent the mean and 95% confidence limits of five replicates (FCS data) or three replicates (24–96 h HS data), or half the range for two replicates (4 h and 120 h HS data). In some cases the 95% confidence limits lie within the area covered by the symbols. *, Significant difference between DFC10- and DH10-grown cells, $P < 0.05$ (Mann-Whitney U-test).

and the long-chain polyunsaturated acids 20:4n-6, 20:3n-6 and 22:6n-3. HS, on the other hand, contained considerably more of the essential fatty acids linoleic and α-linolenic, which were present in FCS at very low concentrations.

The sum of total fatty acids present in the cellular phospholipid fraction during growth in culture is shown in Figure 2. The corresponding data for the triacylglycerol fatty acids is shown in Figure 3. It was found that the fatty acid content of cellular phospholipids rose gradually with time in culture for both DFC10- and DH10-grown cells. The concentration of fatty acids in the triacylglycerol fraction of cells grown in DH10 was high at 4–24 h, after which time the levels dropped. In cells grown in DFC10, the fatty acid concentration of triacylglycerols rose in the first 24 h of growth, but then declined between 48 and 72 h.

Tables 2 and 3 show the fatty acid profiles of cellular phospholipids and triacylglycerols throughout growth in DFC10 and DH10, respectively. Levels of polyunsaturated

acids were increased in the lipids of DH10-grown cells as compared to DFC10-grown cells. This increase was mainly due to significantly higher levels of linoleic and α-linolenic acids being incorporated into lipids of DH10-grown cells. These two acids accounted for approximately 40% of total fatty acids in the phospholipids and 20% of total fatty acids in the triacylglycerols of DH10-grown cells throughout culture, whereas they were either absent (or present at low levels) in DFC10-grown cells (Tables 2 and 3). The latter, however, contained increased amounts of C_{20} acids as well as 22:6n-3, as compared to DH10 grown cells. Levels of these acids were at their maximum 24 h after growth and decreased afterwards. In cells grown with either serum supplement, the proportion of monounsaturated acids increased during culture (Tables 2 and 3).

For both media analyzed, the concentration of all free fatty acids fell to <10% of their initial values over 24–48 h. This was confirmed using ^{14}C-labeled 18:1n-9, 18:2n-6 and 20:4n-6 added to DFC10 medium at the start of the experiment. After 48 h in culture, only 10% of the original radioactivity was detected in the medium. Within the cells, 90% of the radioactivity taken up from the medium was found to be associated with the phospholipids and triacylglycerols, the former containing most of the label. The results are presented here as the specific activity of label in each lipid fraction (*i.e.*, the amount of label incorporated per unit mass of total fatty acids in each lipid fraction) (Fig. 4). This gives an indication of incorporation relative to cellular concentration of the different lipids. No difference was observed in the incorporation of [1-^{14}C]linoleic acid into the phospholipids and triacylglycerols (Fig. 4b). Incorporation of label into both lipid classes was most rapid in the first 24 h, reaching a maximum at 24–48 h and falling thereafter. When the HT29/219 cells were incubated with [1-^{14}C]arachidonic acid, the amount of label incorporated per unit mass of lipid was lower for the triacylglycerol fraction as compared to the phospholipid fraction (Fig. 4a). However, more [1-^{14}C]oleic acid was incorporated into the triacylglycerol fraction compared to the phospholipids (Fig. 4c). When these experiments were repeated at a later time, the same trend was observed for the incorporation of the acids, confirming the results reported here.

DISCUSSION

The fatty acid compositions determined for total extracted lipids from the two sera closely resemble those reported by other investigators (1,16–19). However, some differences were observed for a number of acids. The percentage composition of stearic acid found in FCS in this study was twice that found by other investigators, whereas the percentage composition of palmitoleic acid was 2–3-fold lower. The percentage composition of α-linolenic acid in HS varied from 1.5% in one study (1) to 10.2% in the present work. These discrepancies may be due to differences in fatty acid concentrations of different batches of serum as observed by Stoll and Spector (16). However, no significant differences were found in this study for the different batches of sera used.

The gradual rise in the fatty acid content of the phospholipid fraction of both DFC10- and DH10-grown cells with time in culture indicates a higher rate of phospholipid synthesis relative to protein synthesis within the cells or, alternatively, a higher degee of protein catabolism. Measurement of cellular DNA may provide useful information regarding the most likely explanation. In contrast, the level of total acids in the triacylglycerol fraction of the cells followed a different pattern which depended on the serum supplement used. The results indicate a greater initial incorporation of fatty acyl moieties into the cellular triacylglycerol fraction when cells were grown with HS. This is probably due to stimulation of triacylglycerol synthesis by higher concentrations of fatty acids in this serum (20). We have not considered the role of the free fatty acids within the cells, because levels of this lipid class were very low (<5% of total cellular fatty acids for DFC10-grown cells and <10% for DH10-grown cells) in every experiment, suggesting a high esterification rate.

The phospholipid fraction of cells grown with FCS was particularly high in monounsaturated acids and low in polyunsaturated ones, whereas the reverse was true in cells grown with HS. These alterations in the fatty acyl composition of cellular phospholipids as a result of changing the serum supplement confirm the reports on MDCK and 3T3 cells (16). Such alterations are expected to influence the cell membrane. For example, Simon *et al.* (21) have shown that increased unsaturation of the phospho-

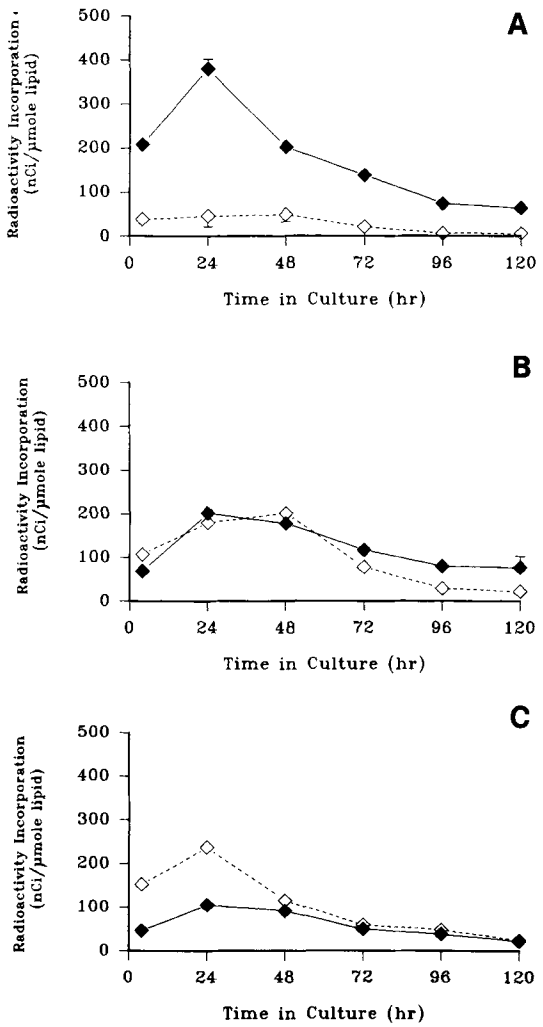

FIG. 4. Specific activity of incorporated (a) [1-^{14}C]arachidonic acid; (b), [1-^{14}C]linoleic acid; and (c) [1-^{14}C]oleic acid in the phospholipids (◆) and triacylglycerols (◇) of HT29/219 cells during growth in medium supplemented with 10% fetal calf serum and 15 nCi/mL of radiolabeled fatty acid. Results shown in (a) and (b) represent the mean and half the range of duplicate calculations (in most cases the range lies within the area covered by the symbols). The results shown (c) were calculated from a single measurement. Each point was derived by dividing radioactivity measurements (nCi/mg protein) by the means of cellular total phospholipid or triacylglycerol concentrations (nmoles/mg protein) shown in Figures 2 and 3.

lipid fatty acyl chains leads to an increase in the fluidity of the membrane. The role of membrane fluidity in relation to cell membrane functions such as carrier-mediated transport, activity of membrane-bound enzymes, binding properties of cellular receptors and phagocytosis has been well-documented (22). As a result, it may not be acceptable to compare biochemical studies carried out on cells grown in different serum-supplemented media. This is particularly important with a view to recent attempts to encourage the use of "cheaper" horse and adult bovine serum supplements instead of the most common, but costly FCS (23). Furthermore, care must be taken when comparing *in vitro* and *in vivo* systems with regard to lipid metabolism. An illustration of this can be found in the findings of Isseroff *et al.* (19) and Madison *et al.* (24). Both groups showed that murine keratinocytes grown in culture supplemented with FCS have much less linoleic acid than uncultured fresh cells due to the lower levels of this fatty acid in FCS as compared to mouse serum. They suggest that this finding may be partly responsible for the incomplete differentiation pattern of these cells *in vitro*.

Radioactivity taken up from the medium was found to be associated with the cellular phospholipids and triacylglycerols, the former containing most of the label. Results showing the specific activity of the label in each lipid fraction suggest some selectivity in the incorporation of [1-^{14}C]oleic acid into the triacylglycerols, no specificity for incorporation of [1-^{14}C]linoleic acid into the two lipid classes, and a higher selectivity for incorporation of [1-^{14}C]arachidonic acid into the phospholipid fraction. As the same amount of label was removed from the medium when cells were incubated with any of the labeled acids, there does not seem to be any selectivity in the uptake of the different acids. Rather, selectivity is more likely to be involved in (i) their transport within the cells; (ii) their activation by coenzyme A; or (iii) their final incorporation into the different lipids. As the total amount of label detected in the cellular lipids was very similar for the three acids, (i) and (ii) seem less likely to be appropriate in these cells. Therefore, the most probable point of selectivity appears to be in the activity of the acyltransferase enzymes involved in glycerolipid synthesis. Our results have shown that more polyunsaturated acids are channelled into phospholipid production and less into triacylglycerol synthesis.

Athough the phospholipid fatty acyl composition of the cells reflected the free fatty acid composition of the added serum, some major differences were observed (Tables 1, 2 and 3). The fatty acids found to be less affected by the medium free fatty acid composition were stearic acid, linoleic acid and α-linolenic acid. It was found that the cells accumulated linoleic acid so that the medium contained lower proportions of this as the free acid as compared to the cells. Conversely, the cells incorporated less α-linolenic acid than the quantity present in the medium free fatty acid fraction. A similar finding of lower 18:3n-3 incorporation compared to 18:2n-6 has been reported in skin fibroblasts and in cells of neuronal origin (1). Clouet *et al.* (25) have reported that α-linolenic acid is oxidized by rat liver mitochondria at a greater rate than linoleic acid. One pathway of 18:3n-3 metabolism is its repeated desaturation and elongation to yield 20:4n-3 and 22:5n-3. Although our results showed some evidence for this conversion (see below), the rate of this conversion did not exceed that of 20:4n-6 synthesis from 18:2n-6.

The differences observed in composition of the abovementioned fatty acids may be due to different rates of incorporation and/or mobilization of these acids. However, when we consider the fatty acid composition of total lipids in the sera, it is observed that the cellular profiles reflect this more closely than the free fatty acid composition of sera. This is indicative of uptake of lipids other than free fatty acids by the cells and is discussed in more detail below.

In cells grown with either serum supplement, the acylation of all C_{20} polyunsaturated fatty acids and 22:6n-3 into cellular phospholipids and triacylglycerols increased in the first 24 h, probably as a result of rapid uptake from the medium. The majority of the polyunsaturated fatty

acids were incorporated into the phospholipids. After 24 h these acids were mobilized from cellular lipids, possibly for utilization in other cellular functions, such as production of prostaglandins and leukotrienes. Due to the important function of these acids in cellular metabolism, this finding is an important factor to consider for timing of biochemical studies in cultured cells.

Linoleic acid was progressively acylated into the phospholipids for up to 48–72 h, after which time levels remained relatively constant. It would therefore seem that the cells were continuously taking up more of this acid from the medium throughout the culture period. Analysis of medium free fatty acids showed that practically all of the free linoleic acid was removed from the medium by 24–48 h. Our results thus indicate that linoleic acid from other lipid sources in the medium was taken up by the cells. These other sources are triacylglycerols, phospholipids and cholesteryl esters, mostly contained in lipoproteins. Evidence for this is provided by the quantitative analysis of fatty acids in medium and cellular lipids. The concentration of 18:2n-6 in the free fatty acid fraction of DH10 was 50 nmoles/plate at the start of the 120-h culture period. At 4 h the amount of this acid present as cellular phospholipid and triacylglycerol (no free fatty acid) was approximately 10 nmole/plate. This rose to 410 nmoles as the cells multiplied in culture. Therefore, the cells took up 400 nmole of linoleic acid during the 4–120 h culture period. Analysis of horse serum lipids revealed that there was approximately 850 nmole/plate of linoleic acid available in the phospholipid fraction of the medium at the start of the culture in addition to the 50 nmole already mentioned as the free acid (Table 1). In other words, 80% of the total linoleic acid present in HS was in the phospholipids and only 5% was present as the free acid. Despite this abundant supply of linoleic acid in the phospholipid fraction of the medium, we were unable to detect any free linoleic acid in the medium after 48 h. Therefore, the cells must have been taking up either intact lipids, as previously reported for a number of mammalian cells (1), or if prior hydrolysis of these lipids did occur in the medium, as has been suggested for human diploid cells (3), then uptake of the released fatty acids was very rapid. Furthermore, labeled fatty acid experiments revealed that no significant efflux of the label into the medium occurred after the take up phase was complete. Further studies using radiolabeled phospholipids and triacylglycerols are necessary to confirm these findings.

When similar comparisons of cellular and medium fatty acid concentrations are carried out for other fatty acids, it is found that for a number of acids, even when total fatty acids in the medium are taken into consideration, there is not sufficient levels in the medium to account for the levels accumulated in the cells during the culture period. This indicates that these acids are being actively synthesized within the cells. The calculated data for all fatty acids analyzed are presented in Table 4. In our analysis of the data, a higher concentration of fatty acids incorporated into the cells compared to that available in the medium indicates synthesis. Therefore, a positive value in Table 4 indicates that there is enough fatty acids in the medium to account for all the phospholipid and triacylglycerol fatty acids measured in the cells. Similarly, a negative value indicates that there is not enough fatty acid in the medium to account for all cellular fatty acids, and therefore the cell is actively synthesizing fatty acids.

Table 4 provides evidence that cells grown with FCS synthesize almost all the fatty acids by the end of the culture period. There is substantial synthesis of the monounsaturated acids as early as 48 h after plating, thus indicating a high Δ9 desaturase activity. The only acids for which no evidence of cellular biosynthesis was found were, as expected, the essential acids 18:2n-6 and 18:3n-3, as well as 20:3n-6. The synthesis of the polyunsaturated acids, 20:4n-6, 20:5n-3 and 22:6n-3, indicates the presence, although minimal, of Δ5 and Δ4 desaturase, as well as elongase enzymes in the HT29/219 cells. Although elongases have been found in most cells in culture (1), the desaturases have been shown to be absent from a number of cell lines (26,27), the Δ4 desaturase having been found in only a few cases (1).

When cells were grown with HS, the only acids for which synthesis was established were palmitoleic, myristic and, to a lesser extent, *cis*-vaccenic acids (Table 4). Little, if any, of the large amount of cellular linoleic and α-linolenic acids were converted to the long-chain polyunsaturated acids analyzed. This is probably due to a low activity of the Δ6, Δ5 and Δ4 desaturase enzymes, plus the fact that a large load of linoleic and α-linolenic acids taken up from the medium compete with relatively small amounts of longer chain polyunsaturated acids that may be formed for incorporation into cellular lipids. Similar results were reported by Spector's group (1) studying human 1603 skin fibroblasts grown in medium supplemented with linoleic acid.

Although due to variation in extraction procedures, the absolute magnitude of the values presented in Table 4 may not be significant, the trends should be considered as important. The positive or negative sign of the values are also significant in that they indicate whether or not cellular fatty acid biosynthesis may have taken place during culture. However, it must be noted that although a negative value indicates synthesis, a positive sign does not exclude it. Although the results of the mass balance studies need to be verified by pulse-chase experiments using radioactive precursors such as [1-^{14}C]glucose or [1-^{14}C]acetate, they cannot be rationalized by any process other than *de novo* fatty acid synthesis. The concentration of fatty acids in the serum used to supplement the growth medium influenced the rate of biosynthesis and the time period after which synthesis was shown to occur.

Cellular protein measurements show that although the cells used in this study grow in medium supplemented with either fetal calf or horse sera, the type of serum used influences the rate of growth of the cells. A number of reports in the literature have shown a direct effect of some unsaturated acids on cellular growth (1,18,28,29). The present finding that cellular growth rates were similar for the first 48 h with either serum supplement suggests that there were sufficient fatty acids in both systems for growth and that the increased growth observed with FCS after 48 h was probably due to serum factors other than the lipid component. However, since 48 h is often the timepoint at which a medium change is performed in the routine culture of these cells, this particular observation may not be significant in routine work.

TABLE 4

Difference Between HT29/219 Cellular Fatty Acid Levels During Culture and the Levels Present in the Total Lipids of the Medium at the Start of the Experiment[a]

[Received May 8, 1992; Revision accepted August 13, 1992]

Effects of Aging on the Content, Composition and Synthesis of Sphingomyelin in the Central Nervous System

Norma M. Giusto*, Marta E. Roque and **Monica G. Ilincheta de Boschero**
Instituto de Investigaciones Bioquímicas de Bahía Blanca, Universidad Nacional del Sur y Consejo Nacional de Investigaciones Científicas y Técnicas, 8000- Bahia Blanca, Argentina

Sphingomyelin (SPH) content and composition in different regions of the brain were analyzed in 2.5, 21.5 and 26.5-month-old rats. SPH content increased in the cerebral hemispheres, cerebellum and medulla oblongata plus pons as age increased. The highest SPH content was observed in 26.5-month-old rats, with values increasing by 1.74, 2.75 and 0.88-fold, respectively, over 2.5-month-old rats. The SPH fatty acid composition of brains from aged rats was markedly different from that of adult rats. Between 2.5 and 26.5 months of age the monoenoic/saturated fatty acid ratio increased from 0.22, 0.30 and 0.54 to 0.54, 0.68 and 1.03 in cerebral hemispheres, cerebellum and medulla oblongata plus pons, respectively. The percentage and content of fatty acids longer than 22 carbon atoms esterified to SPH increased with age from 18, 26 and 44 to 48, 52 and 62 mole % in cerebral hemispheres, cerebellum and medulla oblongata plus pons in 26.5-month-old rats. In subcortical white matter from aged rats, monoenoic 22–26 carbon atom fatty acids increased more than the saturated ones in 21.5-month-old rats relative to 2.5-month-old rats. *In vitro* synthesis of SPH from [^{3}H]choline and [^{3}H]palmitic acid in cerebral cortex and cerebellum showed no significant differences between adult rats and those 21.5 months of age. In cerebellum and in cerebral cortex, [^{14}C] serine incorporation increased in aged rats. The results suggest that aging induces increases in both SPH content and in the monoenoic/saturated fatty acid ratio. These increases are quantitatively different in all brain regions analyzed.
***Lipids* 27, 835–839 (1992)**

The molecular basis of aging in nervous tissue is still largely unknown. Cell membrane composition alters during the aging process with subsequent alterations in membrane biophysical properties. Polyunsaturated acyl groups of glycerophospholipids have been shown to decrease in the brain and retina of rodents (1–3). Many membrane-bound enzymes and transport systems are affected by alterations in the properties of the lipid bilayer (4,5). The synthesis of sphyingomyelin (SPH), one of the phospholipids of mammalian cell membranes (6–8), occurs by the transfer of the phosphocholine group from phosphatidylcholine to ceramide (9). Inserted into biological membranes, sphingomyelin generally increases membrane viscosity (9). SPH is also thought to have a high affinity for cholesterol (10–12). In rodents, aging is associated with a progressive increase in brain weight, cholesterol content, cholesterol to phospholipid molar ratio and myelin content (13).

Abbreviations: CC, cerebral cortex; CNS, central nervous system; FA, fatty acids; GLC, gas-liquid chromatography; M/S, monoenoic-to-saturated FA ratio; MUFA, monounsaturated fatty acids; PC, phosphatidylcholine; SFA, saturated fatty acids; SPH, sphingomyelin; SWM, subcortical white matter; TLC, thin-layer chromatography; TPL, total phospholipid; UV, ultraviolet.

In the present work the effect of aging on sphingomyelin content and composition in different regions of the brain was examined. The synthesis of this sphingolipid from [^{3}H]palmitic acid, [^{3}H]choline and [^{14}C]serine also was studied. The level of SPH in the brain increased with age, and the fatty acid composition of SPH was dramatically affected by age.

MATERIALS AND METHODS

[^{14}C(U)]L-Serine (specific activity, 168 mCi/mmol), [*methyl*-^{3}H]choline chloride (specific activity, 69.5 Ci/mmol), palmitic acid [9,10-^{3}H(N)] (specific activity, 15.2 Ci/mmol) and Omnifluor were purchased from New England Nuclear (Boston, MA). All other reagents were of analytical grade. Wistar-strain rats were kept under controlled environmental conditions and were fed a standard pellet diet. The cerebral hemispheres, cerebellum and medulla oblongata plus pons were obtained from a group of rats 2–3 (2.5) or 26–27 (26.5) months old. From a second group of rats, aged 2–3 (2.5) or 21–22 (21.5) months, the cerebral cortex and subcortical white matter were removed in addition to the above-mentioned regions. Rats were killed by decapitation.

For metabolic studies, the cerebral cortex and cerebellum of 3 and 21.5-month-old rats were used. The tissues were minced to obtain about 1 mm^3 fragments and transferred to conical tubes containing minimum essential medium (Gibco Lab, Grand Island, NY) supplemented with 2.2 g/L of $NaHCO_3$, 5% fetal calf serum (Sigma Chemical Co., St. Louis, MO) and L-glutamine, at a final concentration of 2 mM (10 mL of medium per cortex or cerebellum). The tissue fragments were aspirated and expelled 10 times using a 1-mm diameter Pasteur pipette according to Alperin *et al.* (14). After sedimentation, particles were resuspended in Krebs-Ringer bicarbonate buffer (pH 7.4). Samples (about 100 μg of protein/sample) were incubated for 15, 30 and 90 min at 37°C in the same medium using 5 μCi of [^{14}C]serine or [^{3}H]choline or 20 μCi of [^{3}H]palmitic acid in a final volume of 0.2 mL.

In all cases lipids were extracted from tissue as described by Folch *et al.* (15). Unlabeled DL-serine (1%) or choline (1%) (or choline [1%]) were added to the upper phases to wash lipid extracts labeled with [^{14}C]serine or [^{3}H] choline, respectively. Phospholipids were isolated by two-dimensional thin-layer chromatography (TLC) (16) and located by exposure to iodine vapors. The fractions were scraped off and transferred to tubes for measurement of lipid phosphorus (16) or to vials containing 0.4 mL water and 10 mL of 0.5% Omnifluor in toluene/triton X-100 (4:1, vol/vol) to measure radioactivity by liquid scintillation counting.

Sphingomyelin was isolated by two-dimensional TLC to determine the fatty acid composition. The plates were sprayed with 2′7′-dichlorofluorescein, and the spots were located under ultraviolet (UV) light. Methyl esters were prepared (17) and analyzed by gas-liquid chromatography (GLC). Two glass columns (2 m × 2 mm i.d.) packed with

[a]The amounts of SPH and TPL [nmol/mg protein] are presented as mean values ± SD.
[b]SD from TPL/SPH ratio were calculated according to Johnson and Kotz (19).
[c]Numbers in parentheses refer to the numbers of samples. Each sample corresponding to 21.5 or 26.5-month-old rats consisted of two or three cerebrum, cerebellum and medulla oblongata plus pons, respectively.
[d]The numbers in parentheses refer to the percentage composition of SPH with respect to total phospholipid.
[e,f]Data are compared to adult rats using the Student's *t*-test ([e]$P < 0.001$; [f]$P < 0.025$).

15% OV-275 on 80–120 Chromosorb WAW (Varian, Sunnyvale, CA) were connected to two flame ionization detectors operated in the dual-differential mode. A linear (5°C/min) temperature program, starting at 160°C and ending at 220°C, was used. The oven temperature was held constant at 220°C for 20 min to permit the analysis of very long-chain fatty acids. The injector and detector temperatures were 220 and 230°C, respectively. Protein content was determined by the method of Lowry *et al.* (18). Statistical analysis was performed using Student's *t*-test, with the values representing the mean ± standard deviation (SD) of the total number of samples indicated in each legend. In the case of the ratios, the SD was calculated according to the *ad-hoc* statistical treatment of Johnson and Kotz (19):

$$SD = \bar{x}_1/\bar{x}_2 \times [(SD_1)^2/n_1 \times (\bar{x}_1)^2] + [(SD_2)^2/n_2 \times (\bar{x}_2)^2]$$

RESULTS AND DISCUSSION

Total phospholipid (TPL) and SPH contents were measured in different brain regions of adult (2.5 mo) and aged (21.5 and 26.5 mo) rats. TPL content in adult rats was higher in medulla oblongata plus pons than in cerebral hemispheres and cerebellum (Table 1). Sphingomyelin represented about 5% of the total phospholipid in the different brain regions studied. When compared to the SPH concentration in adult rats, the SPH concentration (expressed as the amount of lipid phosphorus per mg of tissue protein) in 26.5-month-old rats increased by a factor of 2.7, 3.7 and 1.9, respectively, in cerebral hemispheres, cerebellum and medulla oblongata plus pons. However, the SPH content increased only slightly in 21.5-month-old rats, showing that the most dramatic changes occur between 21.5 and 26.5 months of age. The percentage distribution of SPH with respect to total phospholipid content also increased with age reaching the highest value in medulla oblongata plus pons. The ratio of total phospholipid to sphingomyelin content diminished with age, from 24.3, 20.8 and 19.4 to 8.8, 5.8 and 9.9 in cerebral hemispheres, cerebellum and medulla oblongata plus pons, respectively. Total phospholipid content was not affected by aging, which is in agrement with results from previous studies (20,21).

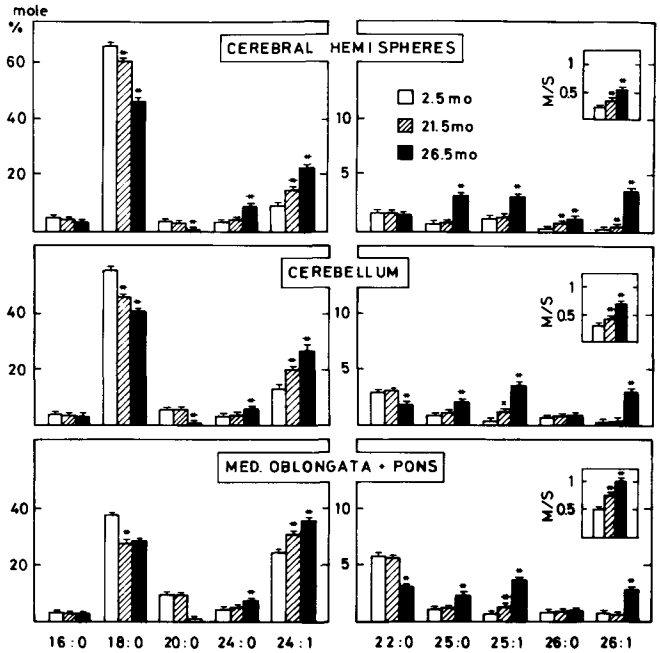

FIG. 1. Fatty acid composition of sphingomyelin in different regions of the central nervous system from adult and aged rats. Results are presented as means ± SD from a number of samples, as indicated in Table 1. Data are compared to controls by using the Student's *t*-test. +, $P < 0.025$; *, $P < 0.001$; M/S, monoenoic-to-saturated FA ratio.

Figure 1 shows the SPH acyl group composition in dif-

ferent regions of the central nervous system. SPH contains mainly saturated and monounsaturated fatty acids. Stearic acid (18:0) was the major saturated SPH fatty acid and accounted for 38 to 66% of the total in all regions analyzed. Other quantitatively important saturated fatty acids were palmitic (16:0), arachidic (20:0), lignoceric (24:0) and behenic (22:0) acids (Fig. 1). The major very long-chain unsaturated fatty acid was nervoneate (24:1), which was more concentrated in medulla oblongata plus pons. The degree of unsaturation followed the order: cerebral hemispheres < cerebellum < medulla oblongata plus pons (Fig. 1, inset).

Aging produced a pronounced change in the fatty acid composition of SPH. The mole percentage distribution of stearic acid decreased at 26.5 months of age to 69, 74 and 78% of the adult rat values for cerebral hemispheres, cerebellum and medulla oblongata plus pons, respectively. By comparison, nervoneate increased with age, and showed the highest change of all monounsaturated fatty acids in rats aged 26.5 months (155, 105 and 145% over the adult rat values in the same regions, respectively). The total percentage of saturated fatty acids diminished and that of monounsaturated fatty acid increased; thus aging affected the ratio of monoenoic to saturated acyl groups, which increased in brain regions of older rats in the following order: cerebral hemispheres < cerebellum < medulla oblongata plus pons (Fig. 1, inset).

The content and composition of SPH were analyzed in the cerebral cortex and subcortical white matter of 2.5- and 21.5-month-old rats to determine whether the changes observed in whole cerebral hemispheres were due to variations produced in either region. Figure 2 shows that the most significant changes were observed in subcortical white matter. The content of SPH in 21.5-month-old rats increased about 27% in this region; however, no changes were observed in cerebral cortex of rats from the same age group. Total phospholipid content was not affected by aging in any region. Figure 2 also shows that the fatty acid composition of these two regions in aged rats is different from that in adult rats. The acyl groups of SPH from subcortical white matter showed more changes in their fatty acid composition than did those of the cerebral cortex. In addition, the ratio of monoenoic to saturated fatty acids increased in 21.5-month-old rats with respect to adult animals, as was observed in rats aged 26.5 months (Fig. 1, inset).

These findings suggest either that a different turnover of the molecular species of this sphingolipid takes place and/or that Δ9 desaturase may be stimulated by aging. In agreement with our observations, earlier studies have found that the acyl groups of ethanolamineglycerophospholipid in myelin from the older mice, rhesus monkeys and humans have higher proportions of monoenes (mainly 18:1 and 20:1) than those found in adult rats (22–24).

In Table 2 the contents of both saturated and monoenoic fatty acids of SPH from adult and aged rats are presented. Fatty acids with carbon chain lengths of 22 or more carbon atoms also are shown. Monounsaturated fatty acids amounted to approximately 17–32% of the total fatty acids in adult rats and increased by 5.4, 5.04 and 2.76 times in cerebellum, cerebral hemispheres and medulla oblongata plus pons, respectively, at 26.5 months. Significant changes also were observed in medulla oblongata plus pons at 21.5 months of age. Greater changes were observed in SPH content of subcortical white matter than in that of the cerebral cortex at this age (Table 2).

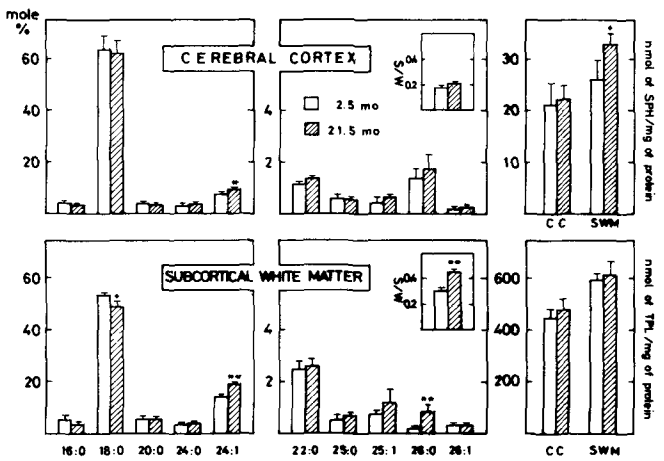

FIG. 2. Content and fatty acid composition of sphingomyelin in cerebral cortex (CC) and subcortical white matter (SWM) from adult and aged rats. Results are presented as mean values ± SD from 5–4 samples analyzed separately from control (2.5 mo) and aged (21.5 mo) rats, respectively. Each sample corresponding to 2.5- and 21.5-month-old rats was prepared with CC or SWM from two rats. Data are compared to controls using the Student's *t*-test. +, $P < 0.05$; *, $P < 0.025$; **, $P < 0.001$; M/S, monoenoic-to-saturated FA ratio.

In adult rats, the proportion of fatty acids with carbon chain lengths of 22 or more carbon atoms ranged from 18.2 to 44.6% of the total fatty acids in the brain regions studied. When the chain lengths were analyzed in cerebral cortex and subcortical white matter, the latter showed longer acyl chains than the former (Table 2).

As the age of the rats increased, the chain length of fatty acids increased. The content of acyl groups with carbon chain lengths of 22 or more carbon atoms increased 1.3-, 1.6- and 1.5-fold in 21.5-month-old rats with respect to adult rats in cerebral hemispheres, cerebellum and medulla oblongata plus pons, respectively. At 26.5 months, the content of these acyl groups increased 7.2-, 7.1- and 2.6-fold, respectively, with respect to adult animals in the regions studied.

The sum of fatty acids longer than 26 carbon atoms (C_{27} and C_{28}) represented less than 1 mole % of the total in 2.5- and 21.5-month-old rats, except in cerebral hemispheres and cerebellum, where these fatty acids increased to 1.25 and 2.08 mole %, respectively, in rats at 26.5 months.

The chain length of some fatty acids of glycolipids was shown to increase with age (25). Long-chain fatty acids with carbon chain lengths greater than 22 also have been shown to increase in patients suffering from inherited abnormalities (26) in which a deficiency in the β-oxidation of saturated and monounsaturated very long-chain fatty acids, a reaction now thought to be located exclusively in peroxisomes, takes place (27,28). Phosphatidylethanolamines and ethanolamine plasmalogens have been shown to have a lower turnover in brains of 24-month-old mice than in those of 5-month-old mice, with the half-life of the latter phospholipid being more affected than that of the former (29,30). Current evidence suggests that the respective enzymes of ether lipid metabolism are located in peroxisomes (31).

[a]The amounts of fatty acids from sphingomyelin are given in nmol/mg protein. Results are presented as mean values ± SD from a number of animals as indicated in Table 1 and Figure 2. SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; FA, fatty acids.
[b,c,d]Data are compared to adult rats using the Student's *t*-test ([b]$P < 0.05$; [c]$P < 0.005$; [d]$P < 0.025$).

Sphingomyelin synthesis was studied in minced cerebral grey matter and cerebellum of 3- and 21.5-month-old animals as a function of incubation time. [^{3}H]Choline was actively incorporated into lipids of cortical grey matter fragments from adults and aged rats. The precursor was mainly incorporated into phosphatidylcholine (PC) and, to a minor extent, into lysophosphatidylcholine and SPH. Figure 3 shows that the SPH of aged rats incorporated [^{3}H]choline to the same extent as the SPH of adult rats. However, the SPH/PC ratio was increased by 73 and 93% at 60 and 90 min of incubation, respectively, in cerebral cortex of 21.5-month-old rats as compared to that of 3-month-old rats, showing that [^{3}H]choline incorporation into PC was inhibited by aging.

Cerebral cortex and cerebellum were incubated with [^{14}C]serine to label the sphingoid base backbone. The precursor was mainly incorporated into phosphatidylserine, followed by phosphatidylethanolamine and SPH. Figure 3 shows that the pattern of serine incorporation into SPH of aged cerebral cortex was quite similar to that of adult tissue. However, the level of incorporation into SPH of cerebellum from aged rats was twice that of adult values at 60 and 90 min of incubation.

The labeling of SPH by [^{3}H]palmitic acid was similar in cerebral grey matter and cerebellum from aged rats to that in adult animals. These data are in accordance with previous findings on the effect of aging on glycerolipid synthesis of rat retina, used as a model for the central nervous system (3,32).

Our data show that *in vitro* incorporation of different

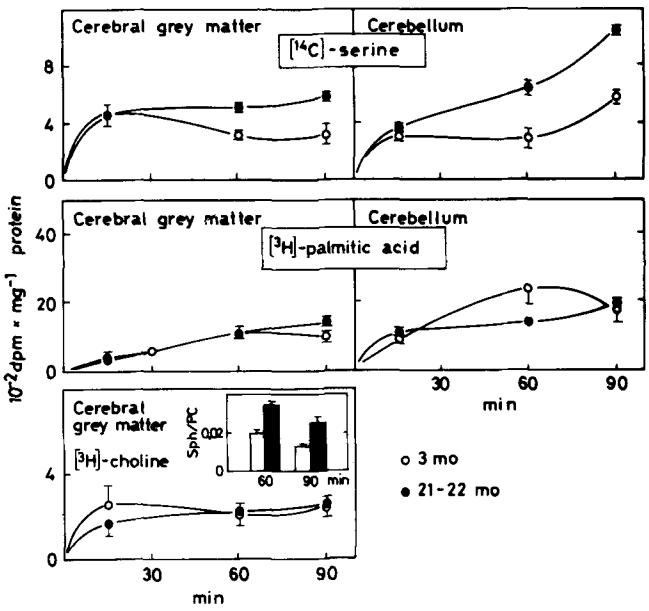

FIG. 3. Incorporation of different precursors into sphingomyelin in cerebral grey matter and cerebellum from adult (○) and aged (●) rats. Samples from cerebral grey matter and cerebellum of 3 and 21.5-month-old rats were prepared as described in Materials and Methods. Samples were incubated in Krebs-Ringer bicarbonate buffer (pH 7.4) for 15, 30 and 90 min at 37°C using 5 μCi of [^{14}C]serine or [^{3}H]choline or 20 μCi of [^{3}H]palmitic acid in a final volume of 0.2 mL. Results for each time are presented as mean value ± SD from four individual samples. Each sample was prepared with cerebral grey matter or cerebellum from two rats.

precursors, used to label the sphingoid backbone, was not affected by aging. This finding is quite surprising since RNA and lipid synthesis and turnover generally decrease with age in the central and peripheral nervous system (1,33). However, in agreement with our findings, no differences in cholineglycerophospholipid biosynthesis were observed in glial-enriched cell fractions from the brain of aged rats (34) and in aged rat retina (3,32).

In summary, our results demonstrate that [^{3}H]palmitic acid and [^{3}H]choline are incorporated *in vitro* into SPH of the central nervous system of aged rats to the same extent as they are incorporated into the SPH of adult rats; however, the labeling of SPH by [^{14}C]serine from cerebellum of aged rats was higher than in adult rats. In addition, an increase in the content of fatty acids with a carbon chain length of 22 or more carbon atoms and in the content of monoenoic fatty acids in SPH were observed. These results suggest that an altered metabolic turnover of different molecular species of SPH may be taking place and/or that the Δ9 desaturation system may be stimulated by aging.

ACKNOWLEDGMENTS

This research was supported by the Consejo Nacional de Investigaciones Cientificas y Técnicas (CONICET) Argentina. We are grateful to Celia Carucci for technical assistance and Phyllis Johnson-Barrantes for her help in correcting the manuscript. N.M. Giusto is a career member of the CONICET.

METHOD

Determination of β-Carotene in Plasma, Blood Cells and Buccal Mucosa by Electrochemical Detection

Takuji Murata[a], Hiroshi Tamai[a,*], Takao Morinobu[a], Mitsuhiro Manago[a], Akira Takenaka[b], Hiroyuki Takenaka[c] and Makoto Mino[a]

[a]Department of Pediatrics, Osaka Medical College, Takatsuki, Osaka, [b]Department of Obstetrics and Gynecology, Shiga University of Medical Science, Ohtsu, Shiga and [c]Nikken Sohonsha Co. Ltd., Gifu, Japan

The β-carotene concentrations in plasma, blood cells and buccal mucosal cells were determined by high-performance liquid chromatography with electrochemical detection. This method was 1,000 times more sensitive than the conventional spectrophotometric method. Polymorphonuclear cells and red blood cells had lower β-carotene levels than the other cells. After oral administration of 580 mg/day of all-*trans* β-carotene to human male volunteers for a week, the β-carotene concentrations in all cell types increased at least several times above the original levels. ***Lipids 27,*** **840–843 (1992).**

The risk of developing cancer has been reported to be inversely correlated with the dietary intake of β-carotene (1–3), which is the major precursor of vitamin A among carotenoids. β-Carotene in part converts to vitamin A in the intestinal mucosa (4,5), while most of it is absorbed and remains in the circulation. There have been some reports (6–8) on the transport of β-carotene after ingestion in humans. Although β-carotene is known to be as efficient a singlet oxygen quencher as is lycopene (9,10), to our knowledge there have been few reports (11–13) on the physiological effects of β-carotene in association with antioxidants. Also, few reports have appeared on the β-carotene levels in body cells (14–16), which are quite low for being measured by conventional methods. Several recent studies have demonstrated the advantages of high-performance liquid chromatography (HPLC), coupled with electrochemical detection (ECD), for the determination of tocopherols (17,18), ascorbic acid (19) and thiols (20). In the present study, we were able to determine very low levels of β-carotene in biological samples by using HPLC coupled with ECD. Furthermore, changes in β-carotene levels were investigated after administration of a high-dose of oral β-carotene to adult humans.

MATERIALS AND METHODS

Sample preparation. Three healthy male volunteers (age 25 to 38) were enrolled in this study and given 580 mg of all-*trans* β-carotene/day for one week. All-*trans* β-carotene was a gift from Nippon Roche Ltd. (Tokyo, Japan). None of the volunteers took any other vitamin supplements or medication during the study. The β-carotene levels in red blood cells (RBC), plasma, platelets, mononuclear cells (MN), polymorphonuclear cells (PMN) and buccal mucosal cells (BMC) were analyzed before and at the end of β-carotene administration. Heparinized blood was collected after an overnight fast. RBC, plasma and platelets were obtained by the method reported previously (18). MN and PMN were separated by density-gradient centrifugation using "monopoly resolving medium®" (ICN Biomedicals, Asse-Relegem, Belgium) (21). The cells were then washed three times with normal saline before being used for the β-carotene analysis.

BMC were collected by gently scraping off the buccal mucosa with a spatula (18). The scraped-off cells were suspended in normal saline, washed three times with normal saline and resuspended in distilled water. The suspension was vortexed and then sonicated at 20 KHz for 30 s. Aliquots of the suspension were taken separately for the β-carotene and protein assays (22).

The protocol of the study was approved by the Ethics Committee of the hospital and was performed after informed consent was obtained from each of the subjects.

Analysis of β-carotene. One mL of ethanol containing 0.15% butylated hydroxytoluene (BHT) was added to 0.4 mL of plasma or cell suspension, followed by vigorous shaking in a nitrogen atmosphere. Five mL of *n*-hexane was added to this mixture, which was then centrifuged at 3,000 rpm for 10 min; then 4 mL of the hexane layer was evaporated under a stream of nitrogen. The residue was dissolved in 50 μL of ethanol, and a 20-μL aliquot was injected into the HPLC column. For the separation, an Irika Σ 871 HPLC instrument (Irika Co. Ltd., Kyoto, Japan) with a Vydac reverse phase C_{18} column (250 × 4.6 mm; Vydac, Hesperia, CA) was used; the detector was an Irika Σ 875 amperometric detector. The standard eluent was methanol/acetonitrile (95:5, vol/vol), which included 50 mM $NaClO_4$, and the flow rate was 1 mL/min. Authentic β-carotene was obtained from Nippon Roche K.K. (Tokyo, Japan) and dissolved in ethanol for use as standard. The purity of the standard was checked by HPLC; at least 98% of the detectable carotenoid was eluted as a single fraction. The concentration of the authentic β-carotene standard was determined with a Hitachi U-2000 spectrophotometer (Hitachi Co. Ltd., Tokyo, Japan) using a molecular coefficient $E^{\%}_{cm} = 2620$ at 453 nm in ethanol.

RESULTS AND DISCUSSION

Method of β-carotene determination. ECD is possible only for substances supporting an electrolytic reaction within an applied voltage range. A typical chromatogram of an extract of plasma obtained from a volunteer without β-carotene supplementation is shown in Figure 1 (top). The eluent was methanol/acetonitrile (95:5, vol/vol) with 50 mM $NaClO_4$. The arrow shows the putative β-carotene peak with a retention time identical to that of an authentic β-carotene standard. The voltamogram of plasma β-carotene was consistent with that of the standard β-carotene, as shown in Figure 2; both were oxidized at 0.6 V. When the eluent was changed, the presumed β-carotene peak moved in accordance with the mobility of the stan-

Abbreviations: BHT, butylated hydroxytoluene; BMC, buccal mucosal cell; ECD, electrochemical detection; HPLC, high-performance liquid chromatography; MN, mononuclear cell; PMN, polymorphonuclear cell; RBC, red blood cell.

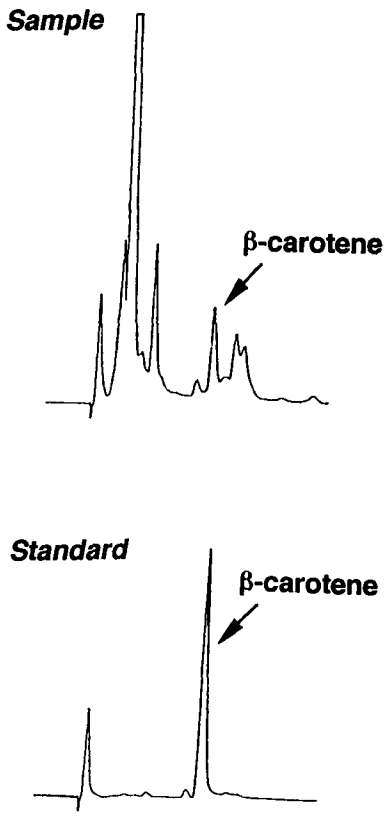

FIG. 1. Typical chromatograms of plasma and standard β-carotene. The arrows point at the β-carotene peaks. The β-carotene peaks were symmetrical and well separated from other peaks.

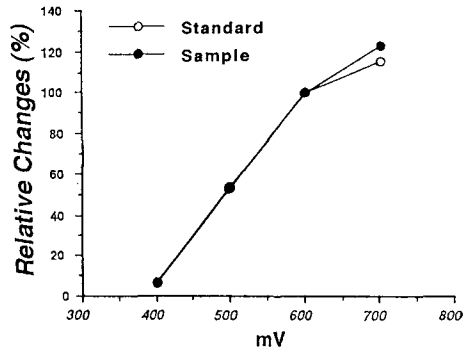

FIG. 2. Voltamograms of sample and standard β-carotene. The voltamogram curve of standard β-carotene was consistent with that of plasma; both were oxidized at 0.6 V. The X-axis shows the relative changes in current against those at 0.6 V.

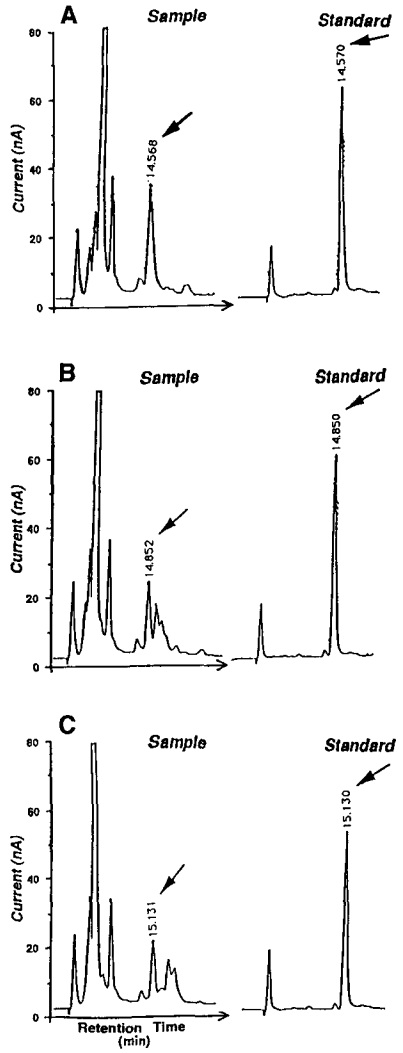

FIG. 3. Effects of eluent composition on the mobility of β-carotene in high-performance liquid chromatography. Panel A shows a chromatogram of plasma when the eluent was composed of methanol/acetonitrile (80:20, vol/vol) with 50 mM $NaClO_4$. The presumed β-carotene peak was not separated from other peaks. With an increase in the methanol concentration of the eluent (B; 90:10, C; 95:5), the surrounding peaks moved and the β-carotene peak appeared as a single symmetrical peak. The peak also moved in accordance to the mobility of the standard β-carotene.

dard β-carotene (Fig. 3). Based on this, the putative β-carotene peak was established as being due to β-carotene.

The concentration and peak area correlated in linear manner throughout the β-carotene concentration range from 0 to 100 ng. The detection limit for β-carotene (a peak area greater than 10 times the background) was 15 pg, making this assay 1,000 times more sensitive than previous methods based on spectrophotometric detection (Fig. 4). The sensitivity was sufficient to determine β-carotene levels in various biological samples.

Five replicate samples from pooled plasma were analyzed. The mean concentration was 0.195 μg/mL, and the intra-batch coefficient of variation was 3.6%, as shown in Table 1. When the recovery test was done for this assay, a satisfactory 95.3% recovery was measured as shown in Table 2.

Determination of cellular β-carotene levels. We measured the concentrations of β-carotene in plasma, blood cells and BMC from volunteers which did not receive a supplement of β-carotene. Typical chromatograms are shown in Figures 1 and 5. Although the β-carotene levels of these samples were very low, our assay was sensitive enough to detect them. When conventional detection was used for the red blood cell (14) and leukocyte (15) assays, β-carotene could be detected, but it could not be quantified.

The β-carotene concentrations in the cells and in plasma from the three male volunteers are shown in Table 3. After oral administration of 580 mg of β-carotene/day for one

METHOD

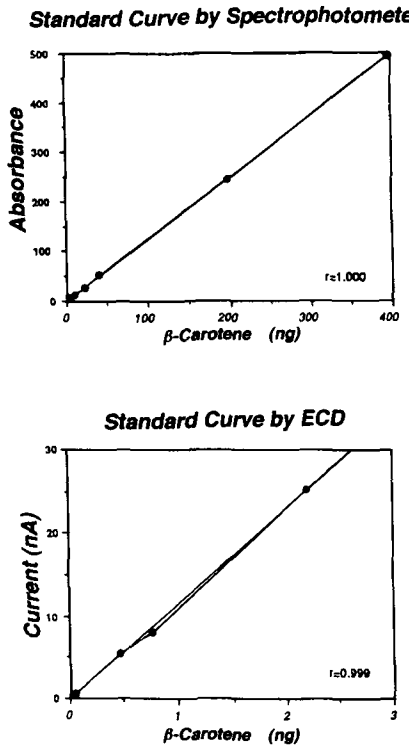

FIG. 4. Calibration curves for standard β-carotene by electrochemical detection (ECD) and spectrophotometric detection. The limit of detection by the spectrophotometric method was 15 ng of β-carotene, and that for ECD was 15 pg.

week, the β-carotene concentrations in plasma, platelet, BMC, MN, PMN and RBC increased to 35-, 6-, 8-, 4-, 3- and 7-fold, respectively. The difference in incremental changes in β-carotene levels are likely to depend on variations in lifespan, turnover and lipid content of the cells. Further studies are needed to determine the factors that influence the incremental changes in β-carotene levels in biological samples.

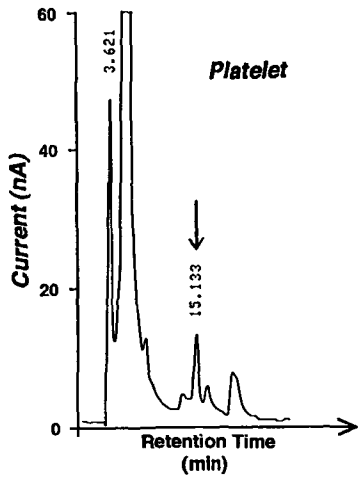

FIG. 5. Typical chromatogram of a platelet sample. The arrow points at the β-carotene peak. β-Carotene also was detected in red blood cells, mononuclear cells and buccal mucosa.

COMMUNICATION

Gender and Dietary Fat Affect α-Tocopherol Status in F344/N Rats

Haw-Wen Chen, Laura R. Cook and **Suzanne Hendrich***
Department of Food Science and Human Nutrition, Iowa State University, Ames, Iowa 50011

For four weeks, groups of eight male and eight female F344/N rats were fed diets containing 15.5, 20, 30 or 40% of energy (en%) as fat. The fat was composed of corn oil and beef tallow with 9 en% from linoleate in all diets. Females had greater mean hepatic α-tocopherol levels, whereas males had greater plasma α-tocopherol and cholesterol concentrations. In males, the plasma ratio of α-tocopherol/cholesterol was significantly greater than in females ($P < 0.05$). Plasma α-tocopherol increased with increasing en% fat ($r = 0.51$, $P < 0.001$) in both sexes, but dietary fat did not alter hepatic α-tocopherol levels. These results suggest that plasma α-tocopherol may serve as a biomarker of total dietary fat intake and that in F344/N rats gender differences affect α-tocopherol and cholesterol status.
Lipids 27, 844-846 (1992).

Oxidative stress may underlie tumor promotion since many tumor-promoting agents, such as phenobarbital and 12-*O*-tetradecanoyl phorbol acetate stimulate oxidative stress (1-3). Antioxidants suppress growth of preneoplastic cells (4) and inhibit promotion-associated cellular transduction (5) but may, like α-tocopherol, be depleted during oxidative stress (6).

Increased or altered dietary fat concentrations promote cancer development, which may be due to increased oxidative stress (7,8). Total dietary fat, by stimulating elongation, desaturation and deposition of fatty acids, can influence the tissue content of oxidizable lipids. Because α-tocopherol functions as an antioxidant *in vivo*, increased dietary fat may stimulate α-tocopherol depletion and result in increased oxidative stress and cancer susceptibility.

In two model systems, female rats have been reported to be more susceptible to the promotion of hepatocarcinogenesis than males (9,10). The mechanism underlying the greater susceptibility of the female to the promotion of hepatocarcinogenesis is unknown but may be related to susceptibility to oxidative stress. Therefore, gender differences in response to dietary fat may be an important determinant of cancer development. This study was designed to determine to what extent gender and fat calories alter an animal's susceptibility to oxidative stress, as reflected in hepatic and plasma α-tocopherol status.

MATERIALS AND METHODS

Animals and diets. Thirty-two male and thirty-two female F344/N rats were purchased from Harlan Sprague-Dawley (Indianapolis, IN) at eight weeks of age. They were housed in a room maintained at 22°C and approximately 50% humidity. Four diets were fed which contained 15.5, 20, 30 or 50 en% (percentage of energy) fat (Table 1). Each diet provided 9% of energy (en%) as linoleate and was prepared from corn oil and beef tallow. Diets were designed to provide equal amounts of amino acids, vitamins and minerals per calorie and 4.0-4.6 cal/g diet. After four weeks, rats were anesthetized with diethyl ether and blood was obtained from the jugular vein. Animals were killed by ether inhalation and 0.5 g minced liver was homogenized from each rat in 5 mL of 50 mM potassium phosphate buffer adjusted to pH 7.4. Tissue and plasma samples were frozen on dry ice and stored at −80°C for later analysis.

α-Tocopherol and cholesterol analyses. α-Tocopherol content was determined in both plasma and liver by the method of Catignani and Bieri (11). All samples were processed in a room illuminated with yellow light. Samples were mixed with internal standard (α-tocopheryl acetate in ethanol) and extracted two times with hexane. A portion of the hexane extract was evaporated under nitrogen and the residue redissolved in methanol. A portion of the methanol solution was injected into a high-pressure liquid chromatography (HPLC) system which consisted of a Beckman pump (Model 110A, Palo Alto, CA) with solvent injector (Rheodyne, Cotati, CA), a Hitachi ultraviolet (UV)/visible spectrophotometer (Model 110-10, Tokyo, Japan) set at 290 nm, Beckman recorder (Model 155-00) and a Hewlett-Packard integrator (Model 3390A, Avondale, PA). Reversed-phase HPLC was carried out on a Waters "Resolve" 5 μm C-18 column (Milford, PA) equipped with an Upchurch guard column (Oak Harbor, WA). The mobile phase was 100% methanol and the flow rate was 2.0 mL/min. Plasma cholesterol concentrations were

Abbreviations: en%, percentage of energy; HDL, high density lipoproteins; HPLC, high-pressure liquid chromatography; LDL, low density lipoproteins; UV, ultraviolet.

measured by an enzymatic method (12) (Kit No. 352, Sigma Chemical Co., St. Louis, MO).

Statistical analysis. Each sample analysis was performed in duplicate. Statistical analysis was done with the Pearson Correlation Coefficient procedure of the Statistical Analysis System, version 5.16 (SAS, Cary, NC). Student's *t*-tests were used to determine the least significant difference between means. Two-way analysis of variance was used to determine the interaction between en% fat and sex.

RESULTS AND DISCUSSION

Plasma α-tocopherol concentrations were significantly greater in males than in females, whereas hepatic α-tocopherol concentrations were significantly greater in females than in males (Table 2). Plasma α-tocopherol and hepatic α-tocopherol were negatively correlated ($r = -0.30$, $P < 0.01$). Plasma total cholesterol concentrations were not affected by diet but were significantly elevated in males as compared with females ($P < 0.05$), as was the plasma ratio of mg α-tocopherol to g cholesterol.

Few previous studies have assessed the effects of gender on α-tocopherol status. In a recent cross-sectional study in adolescents which examined fat-soluble vitamin status, males with certain indices of maturation demonstrated higher plasma α-tocopherol concentrations than females. However, this effect disappeared after adjustment for plasma cholesterol concentrations (13). In gray seals, lactating females were found to have significantly lower concentrations of vitamin E than males, whereas no differences in serum vitamin E were found in juveniles of the species (14). In humans, the main carriers of α-tocopherol are the low density lipoproteins (LDL) and high density lipoproteins (HDL), and more α-tocopherol has been found in LDL than HDL in males, with the opposite distribution in females (15). Therefore, male hepatic α-tocopherol may be diminished and plasma levels enhanced by lipoprotein export (especially LDL), because males of a species generally have greater plasma LDL levels than females (16). Our study suggests that under carefully controlled feeding regimens, gender differences do exist in F344/N rats that may affect α-tocopherol transport and storage.

The correlation between increasing dietary fat and increasing plasma α-tocopherol ($r = 0.51$, $P < 0.0001$) and the significant increase in plasma α-tocopherol when 40 en% fat was fed compared with 20 en% fat suggest that increasing dietary fat stimulated α-tocopherol transport.

TABLE 2

Effect of Gender on α-Tocopherol and Cholesterol Status[a]

Sex[b]	Plasma α-tocopherol (μg/mL)	Plasma total cholesterol (mg/mL)	Plasma α-tocopherol/ cholesterol (mg/g)	Hepatic α-tocopherol (μg/g)
M	8.7 ± 1.4[d]	72.8 ± 8.1[d]	12.2 ± 1.4[d]	37.8 ± 7.8[c]
F	6.1 ± 1.4[c]	54.6 ± 4.9[c]	11.2 ± 2.2[c]	51.0 ± 8.3[d]

[a]Values are means ± standard deviations. Groups that do not share the same letter are significantly different from one another, $P < 0.05$.

[b]n = 32 for either males or females.

TABLE 3

Effect of Fat Intake on α-Tocopherol and Cholesterol Status[a,b]

Diet (en% fat)	Plasma α-tocopherol (μg/mL)	Plasma total cholesterol (mg/mL)	Plasma α-tocopherol/ cholesterol (mg/g)	Hepatic α-tocopherol (μg/g)
15.5	7.2 ± 2.0[d,c]	66.5 ± 12.2	10.7 ± 1.8[c]	42.9 ± 10.5
20	7.0 ± 1.9[c]	66.2 ± 12.2	11.2 ± 1.8[c]	44.5 ± 10.9
30	7.9 ± 2.3[d,c]	62.3 ± 12.0	12.5 ± 2.3[d]	46.7 ± 10.6
40	8.1 ± 1.4[d]	62.6 ± 9.1	12.6 ± 0.9[d]	43.6 ± 10.3

[a]Values are means ± standard deviations. Groups that do not share the same letter are significantly different from one another, $P < 0.05$.

[b]n = 16 for each dietary group.

It is possible that greater fat intake stimulated absorption of fat-soluble vitamins (17). However, plasma α-tocopherol concentrations did not reflect liver α-tocopherol status (Table 3). Petersson *et al.* (18) also showed that increased plasma α-tocopherol concentrations were not associated with increased hepatic α-tocopherol content. Perhaps greater en% fat diets increased hepatic export of α-tocopherol as increasing dietary fat, especially saturated fat, increases plasma LDL (19).

Plasma α-tocopherol concentration may be a useful biomarker of human dietary fat intake and an important tool in monitoring compliance with modified fat diets. Plasma α-tocopherol levels are increased when 10% lard is fed, compared with 10% corn oil, and both oils are stripped of vitamin E (20). Human subjects given α-tocopherol supplements had greater plasma α-tocopherol levels when fed a high fat (43 en%) diet than when fed a low fat (25 en%) diet (21). Five out of eight adult males fed a diet containing beef fat for 5 d after 7 mon of corn oil feeding showed increased plasma tocopherol levels (22).

Differences, such as those observed in α-tocopherol status due to gender and dietary fat content, may be mediated by mechanisms which involve α-tocopherol absorption and transport and are related to lipoprotein composition. Carnivorous species, in general, have greater plasma α-tocopherol than herbivorous species (23), and the influence of dietary fat source (animal *vs.* plant) and fatty acid composition on plasma α-tocopherol status is an important point for further study.

SYMPOSIUM

Milk Lipids

A Symposium held at the AOCS Annual Meeting, Baltimore, MD, April 1990

Opening Remarks

Research on milk lipids, which languished in the seventies, has had a renaissance in the eighties. Most of the recent interest in this field has been focussed on the lipids of human milk. In fact, there have been more papers published on human milk lipids during the past ten years than on milk lipids of bovine origin. More recently, researchers have also analyzed the milk of various mammals with the implicit goal that animal models applicable to the human situation would be found.

The metabolism of $\omega 6$ and $\omega 3$ fatty acids, primarily in human milk, has become a fertile area of research, and many intriguing questions remain to be answered. Also, as various non-nutritive roles of lipids in human milk are being recognized, *e.g.*, the inhibition of enterotoxins by gangliosides, these functions of milk deserve further study. It is also astonishing that only a few fatty acid analyses of bovine milk lipids have been done since gas-liquid chromatography capillary columns have been available. Most fluid dairy products consumed in the United States today are homogenized by processes which totally alter the membrane surrounding the fat globule which, in turn, can be expected to alter digestion. Yet, there are no data addressing these questions. Clearly, additional research efforts and support are needed to carry out further investigations.

I hope that the papers presented in this symposium will stimulate advanced research on milk lipids and generate the funding required to support these urgently needed efforts.

REVIEW

Human Milk in Disease: Lipid Composition[1]

Margit Hamosh[a,*] and **Joel Bitman**[b]

[a]Division of Developmental Biology and Nutrition, Department of Pediatrics, Georgetown University Medical Center, Washington, D.C. 20007 and [b]Milk Secretion and Mastitis Laboratory, U.S. Department of Agriculture, Beltsville, Maryland 20705

Differences in the lipid composition of human milk have been described in maternal diseases known to affect fat metabolism. Diseases such as diabetes, cystic fibrosis, hypobetalipoproteinemia and Type I hyperlipoproteinemia affect the quantity and quality of human milk fat. Increased fatty acid chain elongation and changes in desaturation (especially Δ6 desaturase), as well as changes in lipid class composition, have been shown in diabetes and cystic fibrosis, whereas compensatory increases in medium-chain fatty acids have been described in hypobetalipoproteinemia and Type I hyperlipoproteinemia. It is important to realize that these observations were made either on single women or on very small groups of women. In infant diseases, such as breast milk jaundice and ectopic eczema, changes in polyunsaturated fatty acids in maternal milk have been described.

Lipids 27, 848–857 (1992).

Human milk is the recommended food for the newborn infant (1,2). The increase in breastfeeding in America (3) has paralleled our growing understanding of the composition of human milk (4,5) and of its specific function in the newborn (5–7). As a result of the increasing knowledge of the beneficial effects of human milk for the newborn infant, women with chronic metabolic diseases now elect to breastfeed their children. However, although information is available on changes of milk composition as a result of some diseases, such as mastitis (8,9), little is known about the effects of metabolic diseases on human milk. In this report we are reviewing information about milk lipid composition in disease.

Lipids are essential for infant growth not only because they provide more than 50% of the energy requirements and are vehicles for fat soluble vitamins, but also because they are needed for brain development, are precursors of prostaglandins and hormones, and are essential constituents of all cell membranes. Lipids are the most variable component of milk, their amounts changing as a function of length of lactation (*i.e.*, lower concentrations in colostrum than in mature milk), as well as changing within the day (diurnal) and within each individual feed (low in fore and high in hind milk) (10). Furthermore, milk fat composition is markedly affected by maternal nutrition (10) as well as by length of gestation (10,11), parity (12) and other modulating factors. In established lactation, however, the amount of fat secreted into milk is independent of nutritional intake and is constant for individual women. It was therefore of interest to assess whether maternal diseases known to affect lipid metabolism might also affect the content and composition of the fat secreted into milk. To date there are not many studies that have investigated this topic. Thus, most of the data are derived from studies of single patients or of small numbers of women suffering from the same disease. The studies that we summarize here are of either maternal diseases, such as diabetes, cystic fibrosis, hypobetalipoproteinemia, type I hyperlipoproteinemia; or diseases of the infant, such as atopic eczema or breast milk jaundice.

Composition and origin of milk fat. The fat in milk is contained within membrane-enclosed milk fat globules. The core of the globules consists of triglycerides (98–99% of total milk fat), whereas the globule membrane is composed mainly of phospholipids, cholesterol and proteins. The triglycerides are composed chiefly of long-chain fatty acids (up to 90% of fatty acids in mature human milk) derived from the circulation. These long-chain fatty acids reach the mammary epithelial cells after their release from lipoprotein-triglyceride at the capillary endothelium by the enzyme lipoprotein lipase (13–15). Short- and medium-chain fatty acids (C_8–C_{16}) in human milk are synthesized by the fatty acid synthetase thioesterase II Complex (13,16). Phospholipids are synthesized *de novo* within the mammary gland, whereas cholesterol originates from *de novo* synthesis and from the circulation. The large body of literature on the topic of human milk lipids has been reviewed recently (10). The amount and fatty acid composition of milk fat are the final product of the processes of fat digestion, absorption, transport in the circulation, release from adipose tissue storage and, finally, uptake into the lactating mammary gland for long-chain fatty acids, as well as *de novo* biosynthesis for medium-chain fatty acids. Therefore, diseases that affect any of these processes might also affect the fat of human milk.

Diabetes

Diabetes affects many aspects of lipid metabolism. Amount and composition of milk lipids have been studied by several investigators at early lactation only (17) and up to three months of lactation (18–20). The total amount of milk fat is within the normal range in diabetic woman (Table 1). There are conflicting data on the concentration of medium-chain fatty acid (C_{10}-C_{14}) in the milk of diabetic women. Significantly lower than normal levels of medium-chain fatty acids were reported in the milk of one diabetic woman studied at the onset of lactation (17) and in the milk of three diabetic women studied during the first three months of lactation (19) (Table 2). However, when the number of subjects studied was increased from 3 to 21, significantly higher medium-

chain fatty acid levels were found in the milk of the diabetic women at 14–84 d of lactation, as compared to that of healthy women. Jackson *et al.* (20) however, showed that in this latter study there were no differences between diabetic and control women in milk medium-chain fatty acid concentrations at 7 d *postpartum* (9.46 and 8.85% in the milk of 23 diabetic and 20 control women, respectively). The significant difference between higher medium-chain fatty acids of diabetic as compared to control milk was eliminated when gestational age was used as a covariate for both mothers of full term (>37 wk) and all subjects. Gestational age differences in the diabetic (37.6 wk) and control (39.6 wk) groups may account for the group differences. Medium-chain fatty acid concentrations were reported to be higher in the milk of women who deliver prematurely (11).

The cholesterol content of milk has been studied at the onset of lactation in one diabetic woman (17), and during the first three months of lactation in seven diabetic women (21). Cholesterol concentrations were lower at the onset as well as during established lactation in milk secreted by diabetic women when compared to appropriate control groups (Table 3). Detailed analyses of lipid classes and of fatty acid composition are only available to date on the milk from one diabetic woman studied at the onset of lactation. The main difference in lipid class composition (Table 4), in addition to lower milk cholesterol, was the much higher concentration of free fatty acids (FFA) [normally less than 0.5% (22)] that increased to 23% of total lipid on days 4–7 *postpartum*. The high FFA concentration is not due to a technical artifact since there was no relationship between milk FFA concentration and sampling, handling or storage of the milk specimens (17). The possibility that the high FFA level is due to hydrolysis of milk triglyceride by the lipoprotein lipase of milk was investigated. However, the data show no correlation between lipoprotein lipase activity level and FFA concentrations (17). It seems, therefore, that there might be impaired esterification in the mammary gland in diabetes. These observations on a single subject during a period of only four days after initiation of lactation will have to be confirmed in a large group studied throughout lactation. Com-

parison of the fatty acid composition of the milk from one diabetic woman with that of 12 healthy controls shows several marked differences. The technique of Holman and Johnson (23) in which the ratio of the value in the disease as compared to that in the control is used as an index of normalcy was applied to the evaluation of differences in milk fatty acid pattern between diabetes and control. The data presented in Table 5 show, in addition to lower levels of medium-chain fatty acids described above (Table 2), higher concentration of long-chain unsaturated (oleic and linoleic) and polyunsaturated (18:2n-6, 18:3n-3, 22:5n-6, 22:5n-3), as well as 21:0 fatty acids in the milk of the diabetic subject, as compared to the healthy controls. Although our knowledge on the changes in milk fat composition in diabetes should await more comprehensive studies in a greater number of subjects, the studies described above suggest that (i) total milk fat is within the range of healthy women; (ii) medium-chain fatty acid synthesis may be impaired (at least at early stages of lactation), whether this might be due to lower dietary carbohydrate intake or to differences of mammary gland metabolism secondary to imbalance of insulin secretion remains to be evaluated; (iii) increased chain elongation comparable to that described for serum phospholipid fatty acids of diabetic patients (23); and (iv) lower levels of milk cholesterol. Since cholesterol is a component of the milk fat globule membrane, the latter suggests possible physical changes in globule size, *e.g.*, greater diameter to permit packaging of more core triglyceride per unit membrane. Whether this might affect the stability of milk fat globules and fat digestion by the infant (24) requires further study.

Cystic Fibrosis

Cystic fibrosis is a genetic disease with highest incidence (1 in 2000) in Caucasians. Patients with cystic fibrosis with (25–28) and without (29) pancreatic insufficiency have changes in blood and tissue fatty acid composition that are consistent with essential fatty acid deficiency (23,30,31). Lower plasma and tissue levels of linoleic acid (18:2n-6) have been attributed to fat malabsorption or dietary deficiency (32–37). Decreased caloric intake and increased caloric needs in cystic fibrosis patients could lead to oxidation of linoleic acid to meet immediate energy needs and, thus, decrease the amount of linoleic acid available for arachidonic acid and prostaglandin (33) synthesis. Differences in plasma and tissue levels of linoleic acid as related to pancreatic function (lower levels in pancreatic insufficient patients) have been described (37). Altered hepatic function (36) or an enzymatic defect in fatty acid desaturation (27,28,38) also have been suggested as possible reasons for the fatty acid changes in cystic fibrosis.

We have studied the lipid composition of milk of six women with cystic fibrosis who delivered full term infants and decided to breastfeed (39). An earlier study of one woman indicated very low milk fat content (1.3 g/dL), suggesting that in cystic fibrosis, breastfeeding might not be able to meet the needs for normal infant growth (40). Be-

cause of changes in fatty acid profiles of plasma and tissues in cystic fibrosis, we have examined lipid distribution within neutral lipid and phospholipid classes, as well as the fatty acid composition of the total lipids of milk. The data are presented in Tables 6–9 and Figure 1. Total milk fat, although slightly lower than normal, was within the range compatible with normal infant development (Table 6). Indeed, all six mothers breastfed their infants for 3 to 13 wk and infant weight gains were normal. No major changes in neutral lipids were evident, triglycerides amounting to approximately 98% of total fat. Differences were, however, evident in phospholipid classes—milk of the cystic fibrosis patients contained similar amounts of sphingomyelin, phosphatidylcholine and phosphatidylethanolamine (about 25% each) as compared to higher concentrations of sphingomyelin and lower concentrations of phosphatidylethanolamine in healthy human milk (Table 7). These changes might affect the milk fat globule membrane. Cholesterol levels and distribution between the free and esterified forms were similar to those in normal milk (Table 8). Fatty acid composition of total fat indicated lower levels of the essential fatty acid linoleic acid 18:2n-6, as well as of its elongation and desaturation product arachidonic acid 20:4n-6 (Table 9). Other polyunsaturated fatty acids were elevated in cystic fibrosis (Table 9). The concentrations of 16:2, 18:3 and of several long-chain polyunsaturated fatty acids were about twice those in healthy milk. Normalcy ratios (cystic fibrosis to healthy) showed that 16:2/17:0, 18:3n-3, 20:2n-6, 22:4n-6, 22:5n-6 and 22:5n-3 were all elevated in cystic fibrosis milk. The data indicate that while the enzymes responsible for Δ6 desaturation and for chain elongation were elevated, Δ4, Δ5 and Δ9 desaturation were within normal ranges (Fig. 1). The fatty acid pattern of the milk of cystic fibrosis patients showed a number of abnormalities consistent with essential fatty acid deficiency. Given the important role that linoleic acid and its metabolites have in maintaining structure (membranes) and function (prostaglandin synthesis) of cells, it may be important to supplement breastfeeding women who have cystic fibrosis with this essential fatty acid in order to provide adequate nutrition for their infants. Given the precarious nutritional status of cystic fibrosis patients and the additional caloric demand of milk production (41), it is advisable to closely monitor the nutritional status of lactating cystic fibrosis patients. This is necessary for both maternal and infant health.

Type I Hyperlipoproteinemia

Type I hyperlipoproteinemia (also known as Type I hyperlipidemia) (42) is characterized by the postprandial accumulation of chylomicrons in the circulation. This is a rare disease characterized by the absence of lipoprotein lipase activity. Since this enzyme regulates the tissue uptake of lipoprotein triglyceride, chylomicrons and very low density lipoprotein (VLDL), the carriers of plasma triglyceride accumulate in the circulation postprandially. The disorder can be primary (*i.e.*, absence of lipoprotein lipase) or secondary to (i) the absence of apoprotein C-II, the specific cofactor of lipoprotein lipase (43); or (ii) the presence of a lipoprotein lipase inhibitor (44). Two women with this disorder of lipoprotein metabolism have been studied during lactation (45–47). Table 10 provides data on the triglyceride fatty acid composition of the patients' milk taken at 3, 9 and 10 d *postpartum*. The milk fatty acid profile is compared to that of the mother's plasma and to the milk of a healthy control subject. Total milk triglycerides were much lower in the patient's milk than in control milk [1.5 and 0.9 g/dL at day 9 and 10, respectively, as compared to the normal value of 3.5–4.5 g/dL (10,11)]. The proportion of long-chain fatty acids in the patients' milk was much lower than that in healthy milk, suggesting that the absence of lipoprotein lipase activity also was evident in the lactating mammary gland. This conclusion is supported by the marked difference in long-chain fatty acids > 18:1 (*i.e.*, 18:1–20:4) between the patient's plasma and milk, levels being much higher in the circulation than in milk. It seems therefore, that long-chain fatty acids were not efficiently incorporated from circulating lipoprotein triglyceride into the lactating mammary gland, a process that is dependent upon lipoprotein lipase activity (14,15). Indeed, administration of heparin, which releases lipoprotein lipase from the endothelium into the circulation, failed to release measurable amounts of enzyme in this patient (45). Furthermore, the patient remained hypertriglyceridemic during lactation, indicating that circulating triglycerides were not taken up by the mammary gland for milk fat synthesis. To compensate for the low long-chain fatty acid levels, mammary gland synthesis of medium-chain fatty acids ($<C_{14}$) was markedly increased (Table 10). Structural analysis of the lipids showed that, as in healthy milk (10), the medium-chain fatty acids were present at the *sn*-3 position of the triglyceride molecule and were essentially absent in milk phosphatidylcholine.

[a]Data given as moles %; nd, not detectable. From Steiner *et al.* (45).

The composition of the patient's milk was closer to normal during the colostral phase (at day 3 *postpartum*), *i.e.*, higher amount of long-chain and proportionally lower level of medium-chain fatty acids. This raises the question whether in early lactation [a period when intercellular rather than transcellular transport from the blood into milk is evident in the mammary gland (7)] circulating lipoprotein triglycerides could enter the mammary gland by a lipoprotein lipase-independent mechanism. Low total fat, but normal levels of long-chain fatty acids are present in *prepartum* mammary secretion (48), a period when, contrary to *postpartum* milk, lipoprotein lipase activity cannot be detected in this secretion (49). Although the authors did not comment on other abnormalities of the milk of their patient (45), three other deviations from normal milk (50,51) were apparent—total cholesterol, phospholipid and FFA levels were all elevated. Whether these are due to milk collection, handling and analysis techniques or are associated specifically with Type I hyperlipidemia is not known. The milk of the second patient studied (47) had similar changes in fatty acid composition as the patient whose milk fatty acid analysis is presented in Table 10.

[a]Fatty acid composition of breast milk from a patient with homozygous hypobetalipoproteinemia and normolipidemic lactating women. Data are expressed as mean ± SEM. From Wang and Illingworth (54).

Hypobetalipoproteinemia

In this rare disorder of lipid metabolism, apoprotein B is absent (52). As a consequence, chylomicron and VLDL, the major vehicles for the transport of triglyceride in the circulation, are absent from the plasma of these patients. Since chylomicron and VLDL-triglyceride are the main source of milk triglyceride fatty acids, one would expect a lower milk fat content, as well as a much lower concentration of long-chain fatty acids in the milk of these patients. One such patient studied first in the early 1980s (53) was followed after the delivery of her second child, when her milk fat composition was examined (54). The data presented in Table 11 show a milk fatty acid profile similar to Type I hyperlipidemia (Table 10) which is characterized by markedly lower levels of long-chain fatty acids and proportionally higher levels of medium-chain fatty acids (*i.e.*, 12:0–16:0). However, contrary to type I hyperlipidemia, there was also a shift in plasma fatty acid composition toward shorter chain components. Because patients with hypo- or abetalipoproteinemia are unable to synthesize chylomicrons or VLDL, their plasma triglyceride levels are consistently very low (about 10 mg/dL). The essential fatty acid deficiency was more pronounced in the milk of the hypobetalipoproteinemia patient (Table 11). Because of the important role of long-chain polyunsaturated fatty acids for brain development, prostaglandin synthesis and infant growth, breastfed infants of these patients might have to be supplemented with these fatty acids. While total milk fat content was lower than normal (Table 11, and refs. 10 and 11), milk protein content during the first six months of lactation was higher. It is interesting that milk lipoprotein lipase activity was higher in hypobetalipoproteinemia than in the milk of healthy women (54). This might represent a compensatory increase in enzyme activity in the lactating mammary gland with the aim to maximize the uptake of circulating long-chain triglyceride fatty acids.

Thus, two disorders of lipid metabolism that are char-

acterized either by the absence of the enzyme that regulates tissue uptake of circulating lipoprotein triglyceride or by the absence of triglyceride-rich lipoproteins from the circulation result in similar changes in milk fat amount and composition.

Atopic Eczema

A relationship between atopic eczema and abnormal serum essential fatty acids was first reported by Hansen in 1937 (55). Diets rich in polyunsaturated fatty acids were subsequently found to ameliorate the condition (56). More recent studies show that higher concentrations of linoleic acid are found in plasma phospholipids (57–59), leukocyte membrane lipids (60) and adipose tissue (61 cited in ref. 64) and proportionally lower levels of γ-linoleic and arachidonic acids in these subjects as compared to healthy individuals. Furthermore, these fatty acid abnormalities are present in umbilical cord sera, suggesting that they may have a role in the pathogenesis of atopic disease (62). These changes are consistent with lower than normal activity of Δ6 desaturase and a defect in the conversion of dietary linoleic acid to its long-chain polyunsaturated metabolites (63). Clinical improvement is achieved following treatment with evening primrose oil which is rich in linoleic acid. Recent studies show that the same abnormality in Δ6 desaturase activity is evident in the fatty acid composition of the milk of mothers of children with atopic eczema (64). The recent study of Wright and Bolton of Zimbabwean women (64) (Table 12) shows that whereas linoleic and α-linolenic acid levels were significantly higher in milk of mothers of atopic children, their metabolites, γ-linolenic, dihomo-γ-linolenic and arachidonic acids were all lower than in the milk of control women (64).

The difference in the essential fatty acids and their metabolites in the milk of mothers of healthy children as compared to those of children with atopic eczema suggests that the milk of the mothers of atopic children might not be able to alleviate the infants' symptoms. Indeed, milk of healthy women might delay the onset of symptoms in atopic infants (64). These findings explain the controversy about the role of breast feeding in the prevention or treatment at atopic eczema (65).

Breast Milk Jaundice

Within the first 3–4 d of life and later (within the 2nd and 3rd wk after birth), episodes of hyperbilirubinemia in the newborn have been associated with breastfeeding. Whereas the early postnatal jaundice is considered physiologic (66–68), the later onset of jaundice in breastfed infants is generally described as breast milk jaundice (66,69). High levels of free (unconjugated) bilirubin in these infants have led to the search for factors in milk that inhibit the conjugation of bilirubin. Initial studies suggested that the inhibitor might be an unusual steroid metabolite of progesterone, pregnane-3(α),20(β)-diol, that was shown to competitively inhibit the activity of hepatic glucuronyltransferase *in vitro* (70–72). However, later studies have failed to confirm this observation (73).

The high unconjugated bilirubin in infants with breast milk jaundice has led to the search for inhibitors of glucuronyltransferase in the abnormal milks. The finding that FFA inhibit the enzyme *in vitro* (74,75) resulted in studies that have quantitated the amount of FFA in jaundice-causing milks as compared with healthy milks (74–77). Furthermore, because FFA might be produced during the action of milk lipases (78–79) on the triglycerides of milk (11), several studies have examined this topic.

Although high activity of milk lipoprotein lipase (80), bile salt stimulated lipase (81,82) or "nonstimulated" lipase (83) could be associated with breast milk jaundice, this link has not been found (84–87). Furthermore, FFA levels also were found to be similar in healthy and in jaundice-causing milk (84,88,89). The association between FFA and increased unconjugated bilirubin level (either because of inhibition of the conjugation or because of increased absorption of bilirubin from the intestine) has led to studies of the amount and composition of the fat in jaundice-causing milk. Reports of significantly higher fat concentration in jaundice-causing than in healthy milk (90) have not been confirmed (Bitman, J., Hamosh, M., Gartner, L.M., and Wood, D.L., unpublished observations). Indeed, in the former study, fat was quantitated by the creamatocrit technique, a method that often overestimates milk fat, whereas in the latter study milk fat was quantitated by wide bore gas chromatography. However, while finding similar levels of total fat, Bitman and coworkers found differences in the concentration of specific fatty acids.

The fatty acid composition of the milk (7 specimens from 3 mothers of healthy infants and 10 specimens from 3 mothers of jaundiced infants) is presented in Tables 13 and 14. Differences in most fatty acids were small and the gross composition was similar in milks from the two groups for the major fatty acids, 10:0, 12:0, 14:0, 16:0, 16:1, 18:0, 18:1, 18:2, 18:3n-3, which comprise over 90% of milk fat. This can be seen readily in the normalcy ratios which compare the value for the diseased population to the comparable normal value. Normalcy ratios for these major fatty acids were close to 1.0, indicating little alteration in these fatty acids. However, although the gross composition of the major fatty acids was similar, a number of alterations were observed in the polyunsaturated fatty acids (PUFA) (Table 13 and 14) suggestive of metabolic aberrations. A 2% decrease in total PUFA was observed which was compensated for by an increase in monoenoic fatty acids (Table 14). Although the content of linoleic acid was only reduced by about 10%, there was a much greater decrease in the n-6 fatty acids derived from linoleate (Table 14). Thus, arachidonic acid, 20:4n-6, the principal PUFA metabolite, was only 62% of the normal amount (Table 13).

Desaturation and elongation reactions are involved in the step-wise metabolism of linoleic acid to fatty acids of 20-carbon atoms and longer. The normalcy ratios for desaturase enzymes indicated that Δ5 desaturase activity was reduced and conversely, Δ6 desaturation products were increased (Table 14). The products of elongation also were greatly reduced.

Recently, Uhari *et al.* (91) studied the role of fatty acids in neonatal jaundice. Immediately after delivery, a change was instituted in the diet of a group of mothers being fed the ordinary hospital diet, with a polyunsaturated diet [polyunsaturated to saturated ratio (P/S) = 1.5]. Although the breast milk readily reflected these dietary differences and showed high 18:2 levels, there were no differences in the incidence of neonatal jaundice in the infants of the two groups of mothers. Nine of the 145 newborn infants (6.2%) of mothers on the low P/S diet had jaundice as compared to 12 out of 187 (6.4%) of newborn infants of mothers on the high P/S diet. These dietary changes and changes in the breast milk compositions also were reflected in changes in the blood fatty acid patterns of the newborns ingesting these very dissimilar milks. Uhari *et al.* (91) concluded that the changes in the composition of the serum fatty acids had no effect on neontal jaundice.

In the present study, changes in patterns of the fatty acids in the milk from mothers of infants with jaundice were consistent with changes in polyunsaturated fatty acid metbolism. Similar changes in PUFA metabolism have been associated with a number of disease states characteristic of essential fatty acid deficiency (23,30,31).

The studies described in this review show that maternal

[a]Authors' unpublished data; normalcy ratio = value in disease/value in control.

diseases result in changes in fatty acid composition and/or changes in lipid class composition of milk. However, in spite of these changes, the amount and composition of milk fat is compatible with normal infant development. Detailed dietary information was not provided in many of these studies; therefore, the possible effect of diet on the fatty acid composition of milk could not be assessed.

More studies are needed to assess the effect of maternal diseases that affect lipid metabolism on the composition of milk fat. Studies also are needed to evaluate whether such changes have long or short term effects on infant development.

ACKNOWLEDGMENTS

The expert help of Vivian F. Carter in the preparation of the manuscript is greatly appreciated. The authors' (MH) studies are supported by NIH Grants HD 10823 and HD 20833 and by grants from Wyeth-Ayerst and Mead Johnson.

[Received January 31, 1991, and in revised form May 20, 1991; Revision accepted September 12, 1992]

The Absorption of Fish Oils and Concentrates[1]

R.G. Ackman*
Canadian Institute of Fisheries Technology, Technical University of Nova Scotia, Halifax, Nova Scotia, B3J 2X4, Canada

Both preventive and curative therapies have created a considerable demand for eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids. The most common sources for ω3 fatty acids are fish oil. The concentrations of EPA and DHA in commercial oils, after modest enrichment, reach about 300 mg/g; alternative technologies can produce reasonably priced fish oils containing 400 or even 500 mg/g of ω3 acids. When the acids are liberated from the glycerides, concentrates of ethyl esters or free acids with 65 to 70% total ω3 fatty acids (at least 50% EPA + DHA) are readily prepared. Difficulties have arisen because most clinical trials have used fish oils of unspecified composition, and some trials are now based on either ethyl esters or free acids. There are at least three different, but not mutually exclusive, absorption routes in humans, namely the preduodenal route, the lymphatic route *via* chylomicrons, and the route *via* the portal vein to the liver. This makes it difficult to compare results. The difficulty in obtaining dose-related clinical data may in part be due to the form in which the ω3 acids are offered and due in part to the natural presence of these fatty acids in the body. The nontriglyceride forms, especially the free acids, have been advocated for standardization of trials to facilitate interlaboratory comparisons.
Lipids 27, 858-862 (1992).

The epidemiology of the health benefits of ω3 fatty acids in Greenland Eskimos (1-5) has been the source of much discussion. Excluding difficulties in diagnosis and *post mortem* evaluations (5), the effect of dietary ω3 fatty acids could be attributed to an extremely high intake of long-chain ω3 fatty acids and to a possible role of ω3 docosapentaenoic acid (DPA).

It is well to remember that the studies on Greenland Eskimos were started nearly a decade before the first publication (6) on the potential role of ω3 fatty acids appeared in 1979. At the same time, a survey of Alaskan Eskimo consumption of fats and fatty acids was the subject of a U.S. doctoral thesis in 1973 and provided a comparable data base (7). Table 1 provides the proportions of the three important long-chain fatty acids in fats of several marine mammals from Alaska, the Arctic and the Atlantic coast of Canada. Other evidence has been published on fats of northern food sources (7,9,11), but fish fats basically have relatively low levels of DPA (12) compared to fats of seals and whales.

DPA and marine mammal fats. The function of DPA in marine mammal fat has been obscure, and it is not known to be linked to an eicosanoid in the same way as is eicosapentaenoic acid (EPA). In fact it seems rational to propose that

TABLE 1

Proportions (wt/wt% of total fatty acids) of Three Long-Chain ω3 Fatty Acids in Blubber Fats of Alaskan Marine Mammals, and of Atlantic Harbor Seal, Ringed Seal and Finwhale

Marine mammals	Fatty acid[a]			
	EPA	DPA	DHA	Reference
Walrus (Pacific) *(Odobenus rosmarus)*	7.63	5.99	5.83	(7)
Bearded seal (Pacific) *(Erignathus barbatus)*	8.59	5.99	6.73	(7)
Pacific harbor seal *(Phoca vitulina richardi)*	8.67	4.92	8.33	(7)
Pacific bowhead whale *(Balaena mysticetus)*	8.52	3.23	5.22	(7)
Atlantic harbor seal *(Phoca vitulina)*	4.35	3.95	8.09	(8)
Atlantic finwhale *(Balaenoptera physalus)*	3.72	2.28	6.23	(10)
Ringed seal *(Phoca hispida)*	9.8	5.9	10.0	(9)

[a]EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid, DPA, docosapentaenoic acid.

in most fatty tissue the Δ4,5 desaturase postulated to convert DPA to docosahexaenoic acid (DHA) is relatively inactive. Brain and neural tissues are clearly exceptions, but in humans relatively little work has been done on EPA-DPA-DHA proportions in whole body studies (13) as compared to that on the blood platelet phospholipids (14) which may, however, not be representative. Instead it has become increasingly apparent that DPA is a temporary storage site for surplus EPA. The hypothesis that DHA has no specific role in movine mammal fats could also account for the accumulation of DPA in the seal fats (Table 1). In the fish eaten by seals, the DPA level is usually only 2-5% of combined EPA and DHA (12).

Triglycerides. Long-chain ω3 fatty acids, especially DHA, are reputedly located in the *sn*-3 position of marine mammal triglycerides, as distinct from the fish oils where DHA is found mainly in the *sn*-2 position, (15-18). H. Brockerhoff (cited in ref. 16) published much of the data and theory on this difference.

The fats in the foods eaten by humans have been dealt with by various authors (19,20). The major fat types are triglycerides, followed in nutritional importance by phospholipid or other "polar" lipid and finally by free fatty acids. Ethyl esters will also be included here.

In small populations consuming a high level of marine fats, pros and cons exist as to the benefits of a high ω3 fatty acid intake (21-23). In other groups (24,25), it is difficult to demonstrate health benefits of eating fish (26) on a par with those of the Kromhout study (27). The latter study was supported by retrospective examination of fish consumption in other diet-health studies (28,29). In the recent spectacular extension of survival in patients advised to eat more fatty fish three times a week (30), the most interesting result was that the benefits became apparent in just over three months. In the study by Burr *et al.* (30), fish oil cap-

Abbreviations: DHA, 4,7,10,13,16,19-docosahexaenoic acid, 22:6ω3; DPA, 7,10,13,16,19-docosapentaenoic acid, 22:5ω3; EPA, 5,8,11,14,17-eicosapentaenoic acid, 20:5ω3; FFA, free fatty acid(s); HDL, high density lipoprotein; MG, monoglyceride(s); PUFA, polyunsaturated fatty acid(s); TG, triglyceride(s).

sules were provided as an alternative for those patients not wishing to consume large quantities of fish.

Even fish oil studies of short duration can be relevant. For example, Boyce and Fordyce (31) fed cod liver oil for 14 d as either a bolus of oil while fasting or with lunch. The subjects then had a washout period of 14 d and then reversed the consumption pattern. The ratio of high density lipoprotein (HDL) cholesterol to total cholesterol changed according to the time of consumption. A favorable result, an increase in HDL levels, followed from taking capsules with meals.

Free acids in the diet are totally absorbed, and fatty acids of triglycerides are usually absorbed to the extent of 90% or more (32,33). The distribution of long-chain ω3 fatty acids on the glycerol moiety differs between fish and seals or other marine mammals (15), including seal milks (34) but is of course limited to a total of about 30 mole% for all ω3 fatty acids in all natural triglyceride (17). Thus U.S. menhaden oil (see Table 2) might have (in wt%) 9.4% DHA, 2.1% DPA, 14.8% EPA and 3.3% 18:4n-3 (35). By comparison the ubiquitous MaxEPA (Seven Seas Health Care, Hull, U.K.) has a nominal label composition (wt %) of 18% EPA and 12% DHA which, in parallel with other "oils," may not be the actually correct figure in some samples (36). In one product, a "reesterified" ω3 polyunsaturated fatty acid (PUFA)-enriched triglyceride (37–39), the concentrations were: EPA 34%; DPA 3.5%; DHA 19.0% (wt/wt% basis). However the distribution of fatty acids on glycerol in such highly enriched triglyceride oils may not follow that expected for natural fish oils. It is widely accepted based on the work of Brockerhoff and others (cited in 16–18) that in fish oils EPA should be primarily in the 2-position, and DHA should be distributed according to a formula: *sn*-1, 0.28x; *sn*-2, 2.06x; *sn*-3, 0.66x, where x = the mole% total of DHA. Table 2 shows a recent analysis of an encapsulated product in which more EPA is found in positions 1 and 3 than in position 2, and the DHA is higher in position 3 than in position 2. For comparison menhaden oil data are included to confirm that DHA should be located primarily in the 2-position. EPA is less specific in distribution. A recent investigation on the hydrolysis of menhaden oil (40) showed that pancreatic lipase would hydrolyze fatty acids of the outer (1 and 3) positions of triglycerides at different rates related to ethylenic bond positions nearest the carboxyl group, but independently of chain length and number of double bonds (Table 3). The fatty acids liberated from glycerol may follow different distribution routes in the body (Fig. 1) and are not necessarily reassembled with the 2-monoglyceride in chylomicrons.

Ethyl esters and free acids. An increasing number of biomedical papers have reported the use of ethyl esters (42–48). These can offer a high concentration of ω3 fatty acids based on urea complexing (35), or urea complexing combined with supercritical CO_2 (49) or chromatographic techniques (50). The hydrolysis of ethyl esters by pancreatic lipase *in vitro* is 10–50 times slower than that of triglycerides (40). This is not the same as *in vivo* hydrolysis by this lipase in the intestinal lumen (41). The possibility of hydrolysis in the intestinal wall after absorption, as shown in Figure 1, is suggested by the preferential incorporation of EPA, administered as ethyl esters, into plasma phospholipids (51). There is a basic difference in the effects of EPA, as acids or esters, on arachidonic acid in human plasma (52).

The normal human diet does not contain much fatty acid in free form. There is, however, considerable lipolytic activity present in humans which affects esters prior to the important intestinal lipolytic activity; lipase is the major enzyme found in human gastric juice (53,54). In piglet stomachs, fish oil was broken down to the extent of 50% to diglyceride and free fatty acids (55). Iverson (56) has shown that there is rapid gastric hydrolysis of seal milk triglycerides in the stomach of nursing grey seal pups, and Puppione *et al.* (34) have suggested more studies on this form of fat absorption and transport. In humans, a feedback mechanism may limit hydrolysis (57), but local absorption of EPA or DHA is still possible. One reference to a beneficial effect of fish oil in the stomach (58) may be pertinent.

There are numerous problems created by the various forms of administration possible for the long-chain ω3 fatty acids in humans. The enriched triglycerides may have abnormal fatty acid distributions on the glycerol backbone and this information is rarely provided. Presumably enzymes are used to add an enriched fatty acid mixture to glycerol (59). Usually the total for EPA and DHA is indicative of one or more such fatty acids per molecule, but as Figure 1 indicates, whether these go to the liver or are circulated as chylomicron triglycerides is an open question. That ethyl esters are fully absorbed is now known (60). It is reported that 6 g of ethyl ester per day is totally absorbed (Horrobin,

TABLE 2

Mole Percent Distribution of Selected Fatty Acids on Glycerol of Efamol Fish Oil[a,b] and of Menhaden Oil[c]

Glycerol position	Fatty acid			
	18:4ω3	20:5ω3	22:5ω3	22:6ω3
Efamol total	4.0	18.0	2.2	10.8

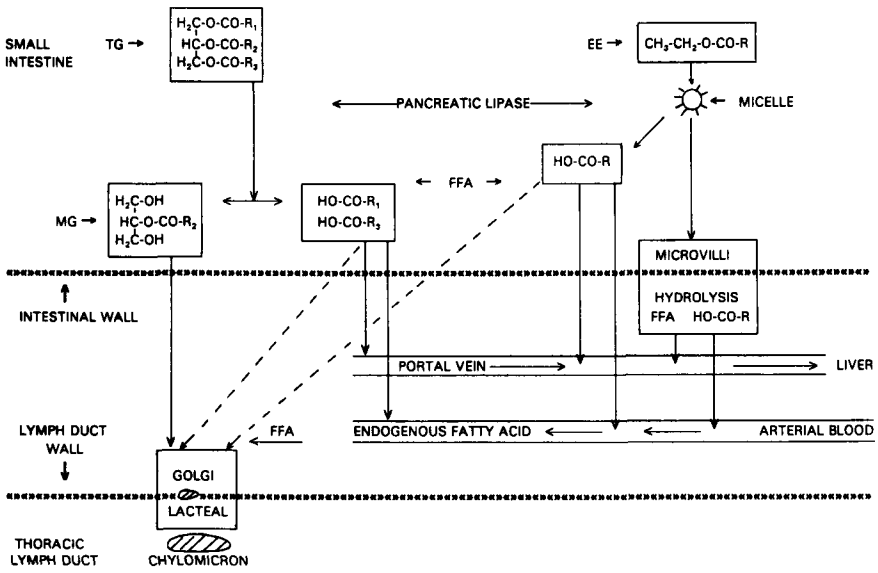

FIG. 1. Some possible origins for fatty acids found in chylomicrons, with special reference to hydrolysis of ethyl esters. The action of pancreatic lipase on ethyl esters *in vivo* and *in vitro* is described elsewhere in detail (40,41).

private communication), and as much as 15 g/day has been administered. Another report on blood pressure suggests that 3 g/day is effective but 6 g/day does not double the clinical effect (45). No ethyl esters have been reported in the blood lipids of humans given highly purified EPA in that form (61), so it is evidently totally hydrolyzed during digestion. Since 60–70% (by weight) concentrates of EPA plus DPA plus DHA are readily prepared, the 6 g/day yields about 4 g/day of the ω3 fatty acids, which, depending on the symptoms, could be a therapeutic dosage (45,62–64). As little as 300 mg/day could be a "preventive" (in cardiovascular terms) dosage (64). Ethyl esters, which are already established encapsulated products in the health supplement market, could in most cases be free from cholesterol and saturated acids (Fig. 2). The possibility of comparing different clinical studies on a dose basis is also clear. This is, at present, often virtually impossible with triglycerides for the reasons given above, but the nonlinear absorption of ethyl esters creates another problem.

Free acids have been reputed to irritate the stomach. This may refer in practice to shorter chain fatty acids, for example butyric acid from rancid butter. Historically, very thorough mastication of foods was practiced at various times, usually with beneficial results (65). Lingual gastric lipase could have been effective, in such cases, in providing all types of free acids for gastric absorption (66). Another report refers to avoiding esophageal irritation through the use of free acids in capsules (33). Since most encapsulated ω3 products are taken with food, there does not seem then to be a serious objection to their use in free acid form beyond some eructation (48). Co-absorption with other fats is well established, and if gastric absorption is rapid, it may explain why the plasma triglyceride input from free acid sometimes follows the triglyceride rise (67) or precedes it (33). Gastric lipases actually produce free acids *in vitro* (54,57), a further indication that free acids are probably well accepted as reported elsewhere (48).

Ethyl esters of ω3 fatty acids could be used for encapsulated supplements or enteral products, but triglycerides are traditional for parenteral nutrition. A new challenge is then to consider whether highly concentrated free acids could be administered in this way, perhaps as salts (68) or absorbed on albumin, or even simply dissolved in the triglycerides already in these products (69). The point is that relative to the total fat only 1 or 2% of long-chain ω3 fatty

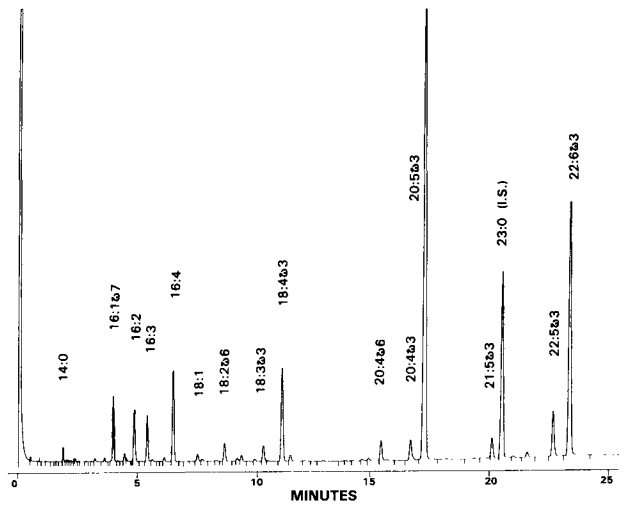

FIG. 2. Gas-liquid chromatographic analysis of a retail fish oil concentrate sold in ethyl ester form, with added ethyl 23:0 internal standard for quantitation. A bonded polyglycol Omegawax-320 flexible fused silica column (Supelco Inc., Bellefonte, PA) (30 × 0.32 mm i.d.) was operated in a Perkin-Elmer model 8420 gas chromatograph (GC, Norwalk, CT). GC oven temperature: 195° for 8 min, program at 3°/min to 240°, hold at 240°.

acids (EPA, DPA, DHA) needs to be supplied if it is in the form of a 60–70% free fatty acid concentrate. Like the ethyl esters, free acid concentrates can be obtained free of saturated acids, cholesterol, etc. Whether the free acids so administered are in any way toxic or are more immediately beneficial compared to triglycerides are some of the questtions to be answered.

Fish. Fatty fish eaten in moderation (30,70), or as a steady diet (71,72), show no obvious side effects. However, fish can be expensive and is not always a popular food in many population groups (73). It is surely important to provide access to fish oil fatty acids for those who do not or cannot eat fish, despite numerous warnings of risks (74), most of which are somewhat hypothetical compared to the real risks and side effects often associated with potent synthetic drugs. In contrast, the long-chain ω3 fatty acids, whether from fish or fish oil concentrates of any type, are purely natural dietary components and part of a system of checks and balances normal in the human body (75,76).

For example fish oil administration to achieve triglyceride reduction (77) may be accompanied by an increase in plasma glucose, which can be offset by increased administration of vitamin E (78). The latest considered opinions of experts (79,80) are that we are still grappling with various aspects of functions of ω3 fatty acids in what are instances of adult-onset degenerative diseases, a rather different problem from that of treating acute disease states. Peculiarly, our understanding of nutritional aspects of longer-chain ω3 fatty acids for early human development is not much further advanced at the other end of our life spans (81,82).

ARTICLE

Effect of Fish Oil on the Fatty Acid Composition of Human Milk and Maternal and Infant Erythrocytes[1]

Robin A. Henderson[2], Robert G. Jensen*, Carol J. Lammi-Keefe, Ann M. Ferris and Kenneth R. Dardick[3]
Department of Nutritional Sciences, The University of Connecticut, Storrs, Connecticut 06269-4017

To examine the effect of fish oil supplementation on the fatty acid (FA) composition of human milk and maternal and infant erythrocytes, five lactating women were supplemented with 6 g of fish oil daily for 21 d. Usual maternal diets contained 1,147 mg of total n-3 FA, with 120 mg from very long-chain (>C_{18}) n-3 FA. Supplementation increased dietary levels to 3,092 mg of total n-3 FA and 2,006 mg of very long-chain n-3 FA. Milk samples were collected daily, prior to fish oil ingestion, and at 4-h intervals on days 1, 7, 14 and 21. Milk n-3 FA content increased within 8 h and reached steady state levels within one week. The n-6 fatty acid content decreased. Erythrocyte eicosapentaenoic acid content increased from 0.24% to 1.4% ($P < 0.01$) in mothers and from 0.11% to 0.70% ($P < 0.05$) in infants. Docosapentaenoic acid increased from 1.4% to 2.2% ($P < 0.05$) in mothers and from 0.30% to 0.78% ($P < 0.01$) in infants. There was no significant change in docosahexaenoic acid or n-6 fatty acid content. Maternal platelet aggregation responses were variable. No differences in milk or plasma tocopherol levels were noted.
Lipids 27, 863-869 (1992).

Animals are unable to synthesize n-6 and n-3 fatty acids and are dependent on dietary sources. Linoleic (18:2n-6) and linolenic (18:3n-3) acids can be converted into their respective families of very long-chain polyunsaturated fatty acids (VLC-PUFA). However, because both fatty acid classes are elongated and desaturated *via* the same enzyme system, the presence of high levels of 18:2n-6 relative to 18:3n-3 may limit the formation of n-3 VLC-PUFA (1,2). The acids of interest derived from 18:3n-3 are eicosapentaenoic (EPA, 20:5n-3), docosapentaenoic (DPA, 22:5n-3) and docosahexaenoic (DHA, 22:6n-3) acids.

Supplementation with 18:3n-3 has been shown to be less effective than fish oil for increasing tissue n-3 VLC-PUFA content (3), and preferential incorporation of dietary VLC-PUFA over their precursors into rat liver and brain has been demonstrated (4). These findings raise the possibility that preformed n-3 VLC-PUFA from the diet are an important source of n-3 VLC-PUFA for tissues.

There is increasing evidence that the n-3 VLC-PUFA have an important role in the structure and function of biological membranes, particularly in brain and retinal tissues. In animals, retinal depletion of DHA has been shown to result in altered electroretinogram response (5-7) and decreased visual acuity (8). Decreased learning ability of rats fed 18:3n-3 deficient diets has been demonstrated, corresponding with the brain DHA depletion (9,10). Visual and neurologic changes attributed to n-3 PUFA deficiency have been reported (11,12) in humans, but it is difficult to separate n-3 PUFA deficiency from other nutrient deficiencies in these studies.

Ascertaining the effect of diet on the fatty acid composition of brain and retinal tissues in humans must be accomplished using indirect markers such as erythrocytes and plasma. Based upon studies in rats and piglets which show that neural and erythrocyte tissues have similar relative effects from dietary modification of n-3 PUFA (13,14), it is likely that human erythrocytes are appropriate indicators of brain n-3 VLC-PUFA composition.

In addition to the potential role of DHA in tissue membranes, the n-3 VLC-PUFA EPA is a precursor for eicosanoids, which are potent metabolic effectors associated with inflammation and platelet aggregation (15,16).

The potential importance of the n-3 VLC-PUFA during perinatal growth and development has stimulated research into the effects of infant feeding practices on the fatty acid composition of infant tissues. Human milk contains small amounts of n-3 VLC-PUFA in addition to 18:3n-3, whereas commercial infant formulas contain only 18:3n-3. Differences between the plasma and erythrocyte fatty acid profiles of breast-fed and formula-fed infants have been observed (17-20). Fish oil supplementation of formula fed to preterm infants resulted in erythrocyte phospholipid DHA levels more similar to those of infants fed human milk (21). The requirement for n-3 VLC-PUFA for optimal infant health and development has not been determined, although recommendations have been made (22).

Maternal dietary fatty acid composition affects the fatty acid composition of breast milk with the PUFA content responding markedly (23-26). The n-3 VLC-PUFA content of human milk can be increased above the levels observed in women consuming a Western omnivorian diet. Inuit women consume high levels of dietary n-3 VLC-PUFA and had significantly higher levels of EPA and DHA in their milk compared to Vancouver controls (27). Harris *et al.* (28) supplemented the usual intake of breast-feeding mothers with fish oil, and dose dependent increases in the n-3 PUFA content of the milk were observed. The effect of high levels of n-3 fatty acids in human milk on infant tissues has not been determined.

A potential side effect of increased consumption of fish and fish oil is that it may increase the need for vitamin E.

Abbreviations: ADP, adenosine phosphate; ANOVA, analysis of variance; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acid(s); GLC, gas-liquid chromatography; HPLC, high-pressure liquid chromatography; P/S, polyunsaturated/saturated ratio; RDA, recommended daily allowance; VLC-PUFA, very long-chain polyunsaturated fatty acid(s) (longer than C_{18}).

In animals, fish oil supplementation has been shown to induce tissue vitamin E deficiency, even with excess dietary supply (29). Hartog *et al.* (30) found no adverse effects of fish oil supplementation on tissues at about twice the vitamin E dosage reported above. Vitamin E supplementation led to decreased susceptibility to *in vitro* peroxidation in tissues from rats fed diets supplemented with menhaden oil (31). It is not known whether humans are susceptible to disturbances in vitamin E metabolism due to increased n-3 PUFA consumption. However, in populations ingesting high levels of n-3 fatty acids, vitamin E deficiency is usually not seen (32).

The goal of the present research was to provide data on the changes in the fatty acid composition of breast milk and maternal and infant erythrocytes during maternal fish oil supplementation at a level equivalent to consuming a 4-oz portion of salmon daily. In addition, maternal dietary intake, milk and plasma vitamin E levels and maternal platelet aggregation response were measured. This information may help determine the optimum intake of n-3 fatty acids during infancy and maternal dietary requirements during lactation.

MATERIALS AND METHODS

Study design and data collection. Five lactating women and their infants were recruited for the study. All subjects signed an informed consent form, and the study had human subjects' approval from The University of Connecticut.

The supplementation period was 21 d, between 2 and 5 wk *postpartum.* None of the subjects were consuming any medications which might alter platelet aggregation. Infants received breast milk as their sole source of nutrient intake from birth and throughout the study. Mothers and infants were weighed weekly.

Mothers supplemented their usual diets with six 1-g capsules of Bio-EFA (PGE Technology, Cambridge, MA) daily. Capsules were consumed once daily at approximately the same time each day. Each capsule contained 180 mg EPA and 120 mg DHA, confirmed by gas-liquid chromatography (GLC), and 1 mg of vitamin E. This provided 1,080 mg EPA, 720 mg DHA and six mg of vitamin E per day.

Dietary intake was evaluated by collecting food records for six days (33,34), which were divided into three randomly assigned 48-h periods during the study. At least one weekend day was included. Forms with instructions to record all food and drink consumed and a 2-dimensional visual aid for estimating portion sizes of food and beverages were provided (cited in 35). Overall nutrient composition (Massachusetts Nutrient Data Bank, University of Massachusetts, Amherst, MA), α-tocopherol content (36), and the fatty acid composition of the diets were calculated (37).

Milk samples were collected immediately prior to ingestion of fish oil capsules each day. On days 1 (baseline), 7, 14 and 21, samples were also collected at 4, 8, 12 and 16 h postsupplementation. All samples were collected using an Egnell electric breast pump (Egnell Inc., Cary, IL). Mothers did not use any creams or oils on their breasts during the study. The pump was held to one breast until completely emptied, and an aliquot was taken for analysis. Samples were placed in the home freezer and stored for a maximum of 3 d, transported on dry ice, then stored at −70°C until analysis.

Blood was collected by a physician on days 1 and 21. Maternal blood was sampled by brachial arm venipuncture, and infant blood by heel prick.

Sample analysis. Total lipid was extracted from human milk using a modified Folch procedure (38). Total lipid weight was determined gravimetrically. Lipids were converted to methyl esters for analysis by GLC (39). Fatty acid methyl esters were dissolved in heptane to achieve a concentration of approximately 35 g/L for GLC analysis.

GLC analysis was performed on a Varian Vista 6000 gas chromatograph (Varian Associates, Sunnyvale, CA) using a Supelcowax 10 fused silica capillary column (30 m × 0.34 mm (Supelco Inc., Bellefonte, PA). Temperature programming was as follows: 180°C for 20 min, then increased 5°C/min to the final temperature of 200°C, and held for 20 min.

Quantification was based on relative peak areas as determined by a Hewlett-Packard 3390A integrator (Hewlett-Packard Co., Avondale, PA). Peak identification was made based on relative retention times of two external standard mixtures, PUFA1 and PUFA2 (Supelco).

Blood for the analysis of erythrocyte fatty acid composition was collected and prepared according to the method of Rose and Oklander (40), and fatty acids were methylated for GLC analysis as described above.

Blood for the measurement of platelet aggregation was collected separately into citrated vacutainer tubes. Platelet-rich plasma was obtained by centrifugation at 120 × *g* for 10 min. Platelet-poor plasma was obtained by centrifuging the remaining blood at 1,500 × *g* for 15 min. Platelet-rich and platelet-poor plasmas were prepared within one hour, and aggregation response was measured within 6 h of sample collection. Platelet aggregation response to 1, 2 and 4 μM concentrations of adenosine diphosphate (ADP) was measured in platelet-rich plasma using a Chronolog-Lumi Aggregometer (Chronolog, Philadelphia, PA).

Milk lipid for tocopherol analysis was extracted by the modified Folch prcoedure described above and dissolved in hexane for high-performance liquid chromatography (HPLC). Plasma lipids were extracted by the method of Driscoll *et al.* (41). Lipid weight was determined gravimetrically. Instrumentation for HPLC analysis and methods for quantification of vitamin E in both milk and plasma samples were as described by Lammi-Keefe (42).

Statistical analysis. Erythrocyte fatty acid composition, tocopherol levels in milk and plasma and platelet aggregation response were analyzed by a paired T-test (43). Components in milk samples taken at 4-h intervals during the day were analyzed by repeated measures analysis of variance (ANOVA) (44).

To determine if there was a plateauing, after an initial rise in the n-3 PUFA content of baseline milk samples, a two-step procedure in SAS was used (45). First, a spline model was fitted through the data to characterize the shape of the curve and to determine the approximate location of the knot, the point at which no further increase was observed. For data to the right of the knot, the hypothesis that there was no trend in the data was tested using repeated measures univariate ANOVA. The significance of the linear, quadratic and cubic components of the orthagonal polynomial contrasts generated by the SAS statement summary were analyzed.

RESULTS

Five mother-infant pairs participated in the study. All subjects who volunteered completed the study, and no deleterious side effects were reported. Infants were full term, between 37–42 wk gestation, and gained weight normally (mean 35 g per day) during the study. Maternal weight for all subjects remained constant within 1 kg.

Maternal diet analysis. Nutrient composition was analyzed for each of the 6 d of food record data collected, and an average intake calculated. The average intake of α-tocopherol for subjects during this study was 1.9 mg (range 0.8–5.1 mg). Subjects consumed an average of 34% of their calories as fat with a polyunsaturated to saturated fat (P/S) ratio of 0.4 and 376 mg cholesterol per day.

Average daily intake of n-3 fatty acids, the n-6/n-3 ratio and the change in dietary fatty acid composition when fish oil was supplemented are shown in Table 1. The study population consumed an average of 1,148 mg of dietary n-3 PUFA with 121 mg from the n-3 VLC-PUFA. Fish oil supplementation tripled dietary intake of n-3 PUFA to an average of 3,093 mg. Over 15 times more n-3 VLC-PUFA, 2,007 mg, was consumed. Total n-6/n-3 PUFA ratio decreased from 9 to 3.

Daily measurement of the fatty acid composition of human milk. The content of individual fatty acids in human milk before and after the study period is presented in Table 2. No significant changes in 18:2n-6 or 18:3n-3 were noted. Increases were: total n-3 VLC-PUFA 162%, EPA 525%, DPA 143% and DHA 89%. Total n-6 VLC-PUFA levels decreased 30%, and the ratio of n-6/n-3 VLC-PUFA decreased 275%. The ratio of total n-6/n-3 fatty acids decreased 45%. The P/S ratio of the milk was similar to that of the maternal diet and was not affected by the supplement.

Mean total milk lipid levels (±SD) for the 5 subjects were 2.74 ± 1.06 g/dL on day 1, and 2.10 ± 0.83 g/dL on day 21, not significantly different.

Analysis of the daily changes in fatty acid composition during the study are presented in Figure 1. There was a significant linear increase ($P = 0.001$) in total saturated fatty acid content and a quadratic decrease in total monounsaturated fatty acid content ($P = 0.02$) during the study (data not shown). The LC n-3 PUFA in human milk were best fit to a cubic-constant spline model. The equation for this model is as follows:

$$\text{Wt\%} = \text{BO} + \text{B1Z} + \text{B2U} + \text{E} \qquad [1]$$

where $z = [(\text{Day-6}) - (\text{Day-6})_+]$, $U = [(\text{Day-6})^2 - (\text{day-6})_+^2]$, $w = [(\text{Day-6})^3 - (\text{Day-6})_+^3]$.

Figure 1a–d shows the plot of EPA, DPA and DHA, and total n-3 VLC-PUFA contents using this model. For EPA, the knot was estimated to be at day 6.2, with correlation coefficient (r/2) of 0.38, and parameter estimates B/O = 0.4424, B/1 = 0.1357, B/2 = 0.0578 and B/3 = 0.0090. For DPA, the knot was estimated to be at day 6.6, with r/2 of 0.43 and parameter estimates B/O = 0.3463, B/1 = 0.3463, B/1 = 0.0711, B/2 = 0.0208 and B/3 = 0.0078. For DHA, the knot was estimated to be at day 6.3, with r/2 of 0.22, and parameter estimates B/O = 0.6604, B/1 = 0.1974, B/2 = 0.0851 and B/3 = 0.0115. For total n-3 VLC-PUFA (EPA + DPA + DHA) content, the knot was estimated to be at day 6.3, with r/2 of 0.35, and parameter estimates B/O = 1.446, B/1 = 0.4450, B/2 = 0.1858 and B/3 = 0.0263. Univariate analysis supported the hypothesis that there was no significant change to the right of the knot.

Figure 1E is the plot of total n-6 VLC-PUFA (20:2 + 20:3 + 20:4 + 22:4) content during the study. The decline in n-6 fatty acid content was best depicted using a cubic-linear spline model because levels continued to decrease significantly to the right of the knot ($P = 0.004$). Nonlinear estimation of the knot was day 6.5, with r/2 of 0.30. The equation for the cubic-linear model is:

$$\text{wt\%} = \text{B/O} + \text{B/1 (Day L)} + \text{B/2U} + \text{b/3W} + \text{E} \qquad [2]$$

n-3/n-3 VLC-PUFA ratio	3.60 ± 1.10	0.96 ± 0.30[b]

[a]Values are daily mean wt% ± SD (n = 5). P/S, polyunsaturated/saturated ratio. VLC-PUFA, very long-chain-polyunsaturated fatty acids.

[b]Values are significantly different by nonlinear regression analysis.

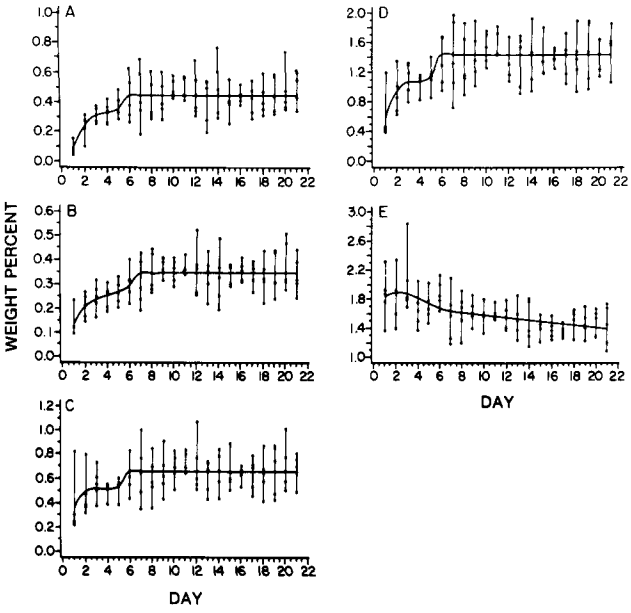

FIG. 1. Fatty acids in human milk during fish oil supplementation, plot of spline fit over raw data. A. Eicosapentaenoic acid (EPA), cubic-constant spline, assumed knot 6; B. Docosapentaenoic acid (DPA), cubic-constant spline, assumed knot 7; C. Docosahexaenoic acid (DHA), cubic-constant spline, assumed knot 6; D. Total n-3 very long-chain polyunsaturated fatty acid (VLC-PUFA), cubic-constant spline, assumed knot 6; E. Total n-6 VLC-PUFA, cubic-linear spline, assumed knot 7.

where Day L = (day-7), U = $[(\text{Day } 7)^2 - (\text{day-}7)_+^2]$, w = $[(\text{Day-}7)^3 - (\text{Day-}7)_+^3]$. Parameter estimates for this model are B/O = 1.635, B/1 = 0.0179, B/2 = 0.0260 and B/3 = 0.0039.

n-3 PUFA composition of milk sampled at four-hour intervals. Figure 2 represents the change in total n-3 LC-PUFA content of milk measured at 4-h intervals on days 1, 7, 14 and 21. Time 0 is the baseline level prior to taking the fish oil capsules for that day. Samples were then taken at 4, 8, 12 and 16 h postsupplementation. On day 1, LC n-3 PUFA content of the milk was significantly increased ($P = 0.0001$) by 8 h postsupplementation, and peak increases were observed at 12 h. The increase in milk LC n-3 PUFA resulting from fish oil ingestion continued on days 7 ($P = 0.02$), 14 ($P = 0.007$) and 21 ($P = 0.001$).

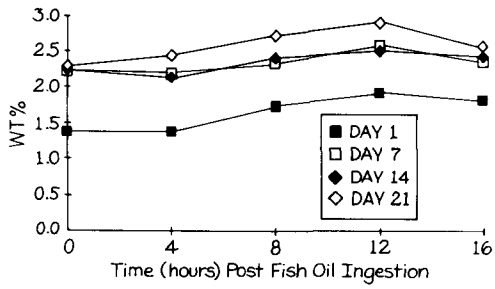

FIG. 2. Total n-3 polyunsaturated fatty acids (PUFA) content of human milk measured at four-hour intervals postsupplementation. Curves represent mean values (n = 5).

Erythrocyte fatty acid composition. The change in fatty acid composition of maternal erythrocytes is shown in Table 3. Significant increases were observed for EPA (583%) and DPA (150%) and for total n-3 PUFA (148%) contents. The n-6/n-3 fatty acid ratio was significantly decreased (77%) after fish oil supplementation. Although there was a trend toward increased DHA content (124%), this was not statistically significant. No significant changes were observed for the other fatty acids analyzed.

Infant erythrocyte fatty acid composition is shown in Table 4. Supplementation resulted in significantly increased EPA (636%) and DPA (260%) content, decreased n-6/n-3 fatty acid ratio (78%), and no change in DHA content (136%), similar to maternal changes.

Maternal platelet aggregation. Maternal platelet aggregation was measured in response to 1, 2 and 4 μM concentrations of ADP. Similar results were obtained at all ADP concentrations. Although there was no significant difference between mean measurements, some changes in response to fish oil supplementation were noted. Mean total aggregation response (%) to 4 μM ADP was 85 ± 12 on day 0, and 78 ± 3 on day 21. Total aggregation decreased 21% in subject 1, 7% in subject 2, 12% in subject 4, 5% in subject 5, and increased 10% in subject 3. Mean time to reach 50% aggregation was 24 ± 5 s on day 0 and 33 ± 12 s on day 21. Time to reach 50% aggregation doubled after supplementation in subjects 1 and 2, while subjects 3–5 showed little or no change.

Tocopherol content of human milk and plasma. No significant differences were observed in the tocopherol content of human milk or plasma from mothers or infants measured before and after the supplementation period. Mean α- and γ-tocopherol contents of milk and plasma are listed in Table 5.

DISCUSSION

This study assessed the changes in human milk and maternal and infant erythrocytes in response to daily fish oil supplementation.

Analysis of human milk during fish oil supplementation. Fatty acids with chain lengths greater than C_{16} are derived from the diet and mobilized from adipose tissue stores. Because maternal weight remained stable during the study, it is assumed that the majority of milk fatty acids were derived from dietary sources (46).

In milk sampled at 4-h intervals on day 1, the n-3 VLC-PUFA content increased within 8 h after ingestion of the supplement. Peak levels occurred by 12 h and began to decline by 16 h. These results are in agreement with the findings of Hachey *et al.* (47) that peak fatty acid enrichment of breast milk occurred 8 to 10 h after consuming a labeled triglyceride meal.

Evidence indicates that the fatty acid composition of human milk does not exhibit diurnal variation (48–50). In the present study, samples taken at 4-h intervals had a significant rise in n-3 VLC-PUFA levels at 8 and 12 h postsupplementation on all days tested (see Fig. 2). It is not clear whether this within-day variation would persist if an equivalent level of n-3 VLC-PUFA was consumed in the form of a fish meal, or what effect smaller doses throughout the day would have on this variation. This observation is important to consider when planning a supplementation trial or comparing results between studies. Consistency in timing of sample collection is necessary for appropriate assessment and analysis of results.

Only one study has previously examined the change in fatty acid composition of human milk during fish oil supplementation. Harris *et al.* (28) supplemented 6 lactating women with 5 g of fish oil per day for 28 d. Samples were taken at only three time points, on days 0, 14 and 28. The authors also studied the effect of higher intakes for shorter time periods, again collecting only baseline, mid, and endpoint milk samples. Dose response-related increases were noted.

In the present study, daily milk samples were collected in order to formulate a model to characterize the change in fatty acid composition over the course of the supplementation period. The n-3 VLC-PUFA content increased most rapidly during the first and second day of supplementation, with smaller daily increases occurring between days 2 and 7. The n-3 VLC-PUFA content remained constant after day 7, at which point daily intake of the supplement served to maintain milk levels. There was a reciprocal decline in the n-6 VLC-PUFA content of the milk as n-3 fatty acid levels increased. Apparently, the synthesis and/or transport of n-6 VLC-PUFA were decreased by increased n-3 VLC-PUFA intake.

There was a decline in monounsaturated fatty acids and a significant increase in saturated fatty acids during the study period. These fatty acids did not exhibit response curves or knot estimates similar to those of the n-6 or n-3 fatty acids. Thus, it is not clear whether these changes were related to the supplementation trial or due to other factors, such as the stage of lactation. There is some evidence that 14:0 is increased, and 18:1 is decreased as lactation progresses (51), although Clark *et al.* (38) found that the fatty acid composition of mature milk remains constant between 2 and 16 wk *postpartum.*

Data from various studies indicate that human milk usually contains 0.03–0.2% EPA, trace–0.5% DPA and

TABLE 5

Tocopherol Status Before and After Fish Oil Supplement[a]

	α-Tocopherol		γ-Tocopherol	
Sample	Day 0	Day 21	Day 0	Day 21
Human milk (μg/L)	1779 ± 804	1592 ± 522	886 ± 290	1032 ± 439
Maternal plasma (μg/mL)	1.50 ± 0.6	1.49 ± 1.1	3.75 ± 1.1	3.48 ± 1.0
Infant plasma (μg/mL)	1.71 ± 1.9	4.17 ± 3.0	1.72 ± 0.3	2.06 ± 0.7

[a]Values are mean ± standard deviation (SD) (n = 5).

0.1-0.6% DHA (17,19,20,52). The present study is the first to calculate the dietary intake of n-3 VLC-PUFA. Our data show that mean breast milk composition from women consuming about 1 g of total n-3 PUFA, with 120 mg from n-3 VLC-PUFA, was 0.08% EPA, 0.14% DPA and 0.37% DHA.

A comparison of the n-3 fatty acid composition of human milk from women supplemented with fish oil (29) to milk from Inuit women naturally consuming increased levels of n-3 VLC-PUFA (28) indicates that supplementation with over 10 g of fish oil is necessary to produce n-3 VLC-PUFA levels comparable to those found in Inuit breast milk. Recommendations to increase fish consumption to this level are impractical in our society, and the optimal level for health benefits and infant development may not need to be this high. Studies regarding the effect of maternal dietary changes on infant tissue fatty acid composition are crucial to determine dietary requirements for lactating women as well as for making appropriate recommendations regarding the composition of infant formulas.

Erythrocyte fatty acid composition. This study was the first to examine the change in fatty acid composition in response to maternal fish oil supplementation. It is interesting to note the large increase in EPA, the doubling of DPA, with no significant change in DHA content (Tables 3 and 4). There was no change in the n-6 fatty acid composition. These findings are in agreement with studies in adults, where fish or fish oil consumption resulted in a much greater increase in EPA than DHA in erythrocyte phospholipids, while 18:2n-6 and 20:4n-6 did not change or decreased only slightly (32).

The high level of DHA found in brain and retinal phospholipids is thought to be important to the physical properties of membranes in these tissues. The membrane content of DHA is tenaciously maintained in the face of deficiency (5). Subjects in this study consumed only 33% more EPA than DHA and a small amount (22 mg) of DPA per day (Table 1). The lack of increase in DHA content, with correspondingly large increases in EPA and DPA, suggests that retroconversion of DHA to EPA and DPA may be occurring. This phenomenon has been demonstrated in platelet phospholipids (53) and is suggesetive of a regulatory mechanism which controls the level of DHA in cell membranes.

Increased tissue content of EPA is thought to be an important modulator of eicosanoid metabolism with potential cardiovascular benefits. The level required to confer such benefits without adverse effect remains uncertain.

Maternal platelet aggregation response. This is the first study to examine platelet aggregation in lactating women. Total aggregation response was similar to the mean of 78 ± 11% observed by Roper *et al.* (54) in 51 females. Some changes in platelet responsiveness were noted, although mean differences were not statistically significant. Decreased aggregation response was expected based on previous studies using similar dosages of fish oil for 3-4 wk (55,56), although Boberg *et al.* (57) also found no significant difference in ADP-induced platelet aggregation response after fish oil supplementation. The clinical relevance of the changes observed in this study remains to be determined.

Tocopherol content of diets, milk and plasma. Although dietary vitamin E was found to be below the recommended daily allowance (RDA) of 12 mg during lactation, only the α-tocopherol content of foods was calculated for this study, thus there was an underestimate of dietary tocopherol intake. As the tocopherol content of foods and daily intakes are widely variable and the available databases are incomplete with regard to the tocopherol content of foods, it is difficult to truly assess the adequacy of vitamin E intake in this study. Others have also found dietary intake to be below the RDA for vitamin E (58,59), although subjects maintained adequate plasma levels of vitamin E (59).

The tocopherol content of the milk sampled in this study was within the range observed by others (60-62). Maternal plasma α-tocopherol levels were lower than levels observed by others (63,64). This may be a manifestation of the low dietary intake noted in this study. Alternately, data regarding plasma tocopherol status during lactation are lacking, and levels may be different from nonlactating women. Infant plasma tocopherol was also somewhat lower than the 6.89 μg/mL observed in 4-15 d-old infants (65), despite comparable milk levels.

As no changes in tocoperhol levels were noted, this suggests that vitamin E deficiency is not induced by fish oil supplementation. However, fish oil supplementation provided mothers with an additional 6 mg of vitamin E per day, and the significance of this contribution to dietary intake was not determined. Knapp *et al.* (66) also found no change in serum α-tocopherol during fish oil supplementation.

Conclusion. Maternal fish oil supplementation increased the n-3 VLC-PUFA and decreased the n-6 VLC-PUFA contents of human milk. One week was required to reach steady state levels. Increases in milk n-3 VLC-PUFA were observed within 8-h postsupplementation, and a diurnal variation existed throughout the study. Maternal and infant erythrocyte fatty acid compositions were similarly affected with significant increases in EPA and DPA but no change in DHA or n-6 PUFA contents. No differences in mean tocopherol values or maternal platelet aggregation responses were noted.

Long-chain n-3 polyunsaturated fatty acids (n-3 PUFA) of marine oils are important dietary components for both infants and adults, and are incorporated into milks following maternal dietary intake. However, little is known about the hydrolysis of these PUFA from milk triglycerides (TG) by lipases in suckling young. Seals, like humans, possess gastric lipase; however, the milk lipids of seals and sea lions are almost devoid of the readily hydrolyzable medium-chain fatty acids, and are characterized by a large percentage (10–30%) of n-3 PUFA. Gastric hydrolysis of milk lipids was studied *in vivo* in suckling pups of three species (the California sea lion, the harp seal and the hooded seal) in order to elucidate the actions and specificity of gastric lipases on milk TG in relation to fatty acid composition and TG structure. Regardless of milk fat content (31–61% fat) or extent of gastric hydrolysis (10–56%), the same fatty acids were preferentially released in all three species, as determined by their relative enrichment in the free fatty acid (FFA) fraction. In addition to 16:1 and 18:0, these were the PUFA of 18 carbons and longer, except for 22:6n-3. Levels of 20:5n-3 were most notably enriched in FFA, at up to five times that found in the TG. Although 22:6n-3 was apparently also released from the TG (reduced in the diglyceride), it was also notably reduced in FFA. Positional analysis of milk TG based on the products of Grignard hydrolysis revealed that these PUFA, including 22:6n-3, were preferentially esterified at the α-position of the TG, and that the fatty acids not released during gastric hydrolysis were located at the *sn*-2 position. The extreme reduction of 22:6n-3 and enrichment of 20:5n-3 in FFA is discussed. Results from this study are consistent with reports that gastric lipase acts stereospecifically to release fatty acids at the α-positions (*sn*-3, *sn*-1). We conclude that the n-3 PUFA in milk are efficiently hydrolyzed by gastric lipase and that this has important implications for digestion of milks enriched in PUFA by neonates in general.
***Lipids* 27, 870–878 (1992).**

Long-chain n-3 polyunsaturated fatty acids (n-3 PUFA), characteristic of marine oils, have become a major focus of research due to their potent antiatherogenic (1,2), antineoplastic, and antiinflammatory (3) effects. Recent evidence suggests their intake to be important from an early age for these reasons (*i.e.*, eicosanoid synthesis), as well as for normal neonatal brain and nervous development and cell membrane structure (4–7). Long-chain n-3 PUFA are readily incorporated into milks of various species following maternal dietary intake (8,9). However, information on the hydrolysis and absorption of these n-3 PUFA in milks by suckling young is limited.

Milk lipid is composed primarily of triglyceride (TG; 97–99%) and, in order to be absorbed in the intestine, must be hydrolyzed to free fatty acid (FFA) and monoglyceride (MG). Although lipids are essential to the neonate for both normal growth and metabolism, in species that have been studied (*e.g.*, human, rat, dog), intestinal function is immature, resulting in reduced levels of pancreatic lipase and bile salts (10–12), both of which are required for the intestinal digestion of fat. Additionally, it is reported that pancreatic lipase, which is specific for the α-positions (*sn*-1 and *sn*-3) of TG, does not hydrolyze TG ester bonds containing long-chain n-3 PUFA (13,14). In fish oils, n-3 PUFA are esterified primarily at the *sn*-2 position of the TG and thus can be readily absorbed as *sn*-2 MG upon pancreatic lipase action (15–18). However, the n-3 PUFA in depot fats of mammals are located primarily at the *sn*-3 and secondarily at the *sn*-1 positions (18–21), and thus whale oil TG have been found to be resistant to pancreatic lipase (22).

Thus, in view of these relative inadequacies, fat absorption in newborns may depend upon compensatory or alternative mechanisms of hydrolysis by means of preduodenal lipases. In particular, initial intragastric lipolysis by lingual and gastric lipases may be especially important for the digestion of milk fat, which is packaged as globules and is otherwise resistant to pancreatic lipase (23,24). However, studies of lipolysis by gastric and lingual lipases have been based largely on *in vitro* studies using a single component fatty acid in artificial lipid emulsions and have stressed their preferential release of medium-chain fatty acids (MCFA). While milks of some species contain notable proportions of MCFA, milk lipids of humans and most carnivores are composed mostly of long-chain fatty acids (25–27). Milk lipids of seals and sea lions furnish 85–95% of the total caloric intake of neonates and are characterized primarily by long-chain and unsaturated fatty acids, including a very large percentage (10–30%) of n-3 PUFA derived from their marine diets (28,29). Suckling pups consume phenomenal quantities of lipid daily at 600 g to 5 kg (30,31), or up to 10- to 20-fold higher on a body weight basis than neonates of the human or dog. Rapid blubber deposition suggests rapid and efficient absorption of milk lipid (28,32,33), but the mechanisms of hydrolysis and digestion are unknown. Gastric lipase is present in seal pups (34); however, milks are virtually devoid of the readily hydrolyzable MCFA. These species thus provide an excellent opportunity to elucidate the actions of gastric lipases on milk TG in relation to fatty acid composition and TG structure.

[1]Based on a paper presented at the Symposium on Milk Lipids held at the AOCS Annual Meeting, Baltimore, MD, April 1990; part of this work is from the doctoral dissertation by S.J.I., University of Maryland, 1988.

In this study we examined milk lipid hydrolysis by gastric lipase in suckling neonates of the harp seal *(Phoca groenlandica),* the hooded seal *(Cystophora cristata)* and the California sea lion *(Zalophus californianus).* Our objectives were to characterize the location of the n-3 PUFA in seal milk TG by positional analysis using Grignard hydrolysis (35) and to measure *in vivo* hydrolysis during intragastric digestion. We used data on the milk TG structure and comparison of the proportions and compositions of hydrolysis products, produced during both gastric lipase hydrolysis and Grignard hydrolysis, to elucidate the actions and stereospecificity of gastric lipase and the digestibility of n-3 PUFA in milk.

MATERIALS AND METHODS

Sample collection. Samples were collected from mothers and pups of harp seals and hooded seals on the pack ice off the southeast coast of Labrador, Canada, and from California sea lions on San Nicolas Island, Channel Islands, California. Milk was manually expressed from chemically immobilized females following administration of oxytocin. Prior to analysis, milk samples were stored frozen at −20°C (sea lion) or frozen in chloroform/methanol (2:1, vol/vol) containing 0.01% butylated hydroxytoluene (BHT) (harp and hooded seals) from the time of collection.

Pups were physically restrained and stomach contents (ingested milk) were evacuated by intubation with a 3/8 inch veterinary stomach tube, opportunistically in harp (n = 15) and hooded seals (n = 17), or at timed intervals following observed suckling in sea lions (n = 20). At the time of collection, all samples were placed in chloroform/methanol (2:1, vol/vol) with BHT and stored frozen at −20°C until analysis. Characterization of gastric hydrolysis (analysis of milk TG and hydrolysis products) was investigated in five mothers and pups of each species.

Neutral lipid class analysis and separation. All solvents used were HPLC (high-performance liquid chromatography) grade or analyzed reagent grade and all containers and equipment were composed of glass or teflon and pre-washed with solvent prior to use. Samples were extracted using a modification (25,28) of the method of Folch *et al.* (36).

Proportions of neutral lipid classes were determined in milk and gastric samples by thin-layer chromatography (TLC) and quantitative densitometry. Plates used for TLC were commercial 20 × 20 cm, precoated (Si250-PA) channeled glass plates (Baker Chemical Co., Phillipsburg, NJ) with a preadsorbent spotting area. Plates were predeveloped in 100% diethyl ether in order to remove the organic binder which typically runs at the solvent front, and were activated at 120°C for 20 min before spotting. A two-stage development process was employed using chloroform/methanol/ethanol/acetic acid (98:2:1:0.1, by vol) (partial plate development to 17 cm) followed by hexane/diethyl ether/acetic acid (94:6:0.2, vol/vol/vol) (37). Plates were charred in a temperature-programmed oven after dipping in 10% cupric sulfate in 8% phosphoric acid (38). Quantitative spectrodensitometry was performed using a Shimadzu CS-910 Dual-Wavelength TLC scanner (Shimadzu Scientific Instruments, Inc., Columbia, MD) using a linear scanning mode (39). Peak areas were automatically integrated and lipid concentrations were calculated from standard curves fitted by least squares regression from a range of standards run each day of analysis.

Individual neutral lipid classes (TG, α,α- and α,β-diglyceride (DG), α- and β-MG and FFA) were separated for subsequent fatty acid analysis as follows. Aliquots of the initial chloroform extract containing approximately 40 mg lipid were spotted on predeveloped activated (1 h at 100°C) preparative TLC plates. Plates were 20 × 20 cm glass, coated with silica gel G-60 (E. Merck, Elmsford, NY) at 0.5 mm thickness. A standard lane was spotted on each plate with a mixture of neutral lipid standards. Plates were developed in the same 2-solvent system described above. Lipid classes were visualized and marked under UV light after spraying lightly with 0.2% 2′,7′-dichlorofluoresceine in absolute ethanol (w/v). Silica gel areas containing the different classes were carefully scraped onto aluminum foil using a teflon spatula and transferred into separate glass tubes for subsequent transesterification.

Positional analysis. After initial comparison of results obtained from methods outlined by Brockerhoff (40) and Christie (41), the following procedure was used to hydrolyze TG to α,α-DG, α,β-DG, α-MG and β-MG. Anhydrous diethyl ether (5 mL) was added to approximately 50 mg of mammary milk TG and the sample was set in an ice bath. To this was added 0.5 mL of ethyl magnesium bromide (Grignard reagent) (3.12 M in diethyl ether, Alfa Chemicals, Morton-Thiokol Inc., Davers, ME). The mixture was then agitated for 4 min, after which 0.2 mL glacial acetic acid and 1 mL H_2O were added to stop the reaction, followed by 1 mL aqueous potassium bicarbonate (2%). The tube was shaken, centrifuged, and the lower layer (H_2O) pipetted out. The remaining ether layer was washed an additional three times with H_2O, removing as much H_2O as possible at each wash. Anhydrous sodium sulfate was then added to dry the ether extract. Hydrolysis products were separated by TLC on silica gel (G-60) impregnated with 5% (w/w) boric acid and developed in chloroform/acetone (96:4, vol/vol) (42). Fractions were visualized and isolated as described above for subsequent transesterification.

Preparation of fatty acid methyl esters. Transesterification and subsequent extraction of methyl esters were performed in the presence of the silica after initial verification that the presence or absence of silica did not alter fatty acid patterns. To each sample was added 1.5 mL of methylene chloride with 0.01% BHT and 3.0 mL Hilditch reagent (0.5N H_2SO_4 in methanol); the sample was flushed with nitrogen and stored in a glass tube with teflon-lined cap in the dark at room temperature for 72 h. This method resulted in similar recoveries of methyl esters as were obtained using methanolic HCl at high temperatures, and was considered preferable due to the elimination of the risks of oven heating effects on PUFA, as well as the absence of artifact production. Alkali isomerizarion is reported with basic reagents (41).

Following transesterification, methyl esters were extracted into hexane. Hexane extracts were then concentrated to about 0.25 mL under nitrogen at 30°C, applied to thin-layer plates and purified by preparative TLC using a solvent system of light petroleum ether (30–60°C boiling point)/diethyl ether (95:5, vol/vol) (43). Methyl esters were visualized and collected from the silica gel by eluting with five column volumes of methylene chloride in a glass column plugged with glass wool. The sample was then concentrated under nitrogen, and isooctane was added at approximately 25 mg lipid/mL isooctane.

Gas-liquid chromatography. Fatty acid analyses were performed by temperature-programmed gas-liquid chromatography (GLC) on a Hewlett-Packard (Avondale, PA) Model 5880 Gas Chromatograph (GC) fitted with a Monarch series flexible glass capillary column (25 m × 0.25 mm i.d.) according to the methods of Sampugna *et al.* (43). The column was coated with SP-2340 (Quadrex Corp., New Haven, CT) at 25 μ film thickness. The carrier gas was helium and the make up gas was nitrogen. The GC was equipped with a flame ionization detector (temperature 275°C). The temperature of the injection port was maintained at 250°C. Following sample injection, the temperature of the column was held at 153°C for 2.0 min, then programmed to increase to 174°C at the rate of 2.25°C per min, then to increase to 200°C at the rate of 2.5°C per min and held there until the end of the run. The entire run time was approximately 24 min.

Identifications of fatty acid methyl ester peaks were based on retention times of known standard mixtures run daily and also after isolation of fatty acid classes in selected samples from each species using silver nitrate ("argentation") chromatography (28). Methods for silver nitrate chromatography essentially followed recommendations by Christie (41), except that a mobile phase of hexane/diethyl ether (90:10, vol/vol) was used to separate methyl esters containing zero to two double bonds, hexane/diethyl ether (40:60, vol/vol) to separate three to six double bonds and, finally, petroleum ether/diethyl ether/acetic acid (90:8:2, vol/vol/vol) to separate zero to six double bonds for comparison. Peak areas were measured with an electronic integrator and normalized by individual response factors obtained from available standards. Sample injection volume was usually 0.3 μL, or about 7.5 μg lipid. Fatty acids are designated by shorthand nomenclature of chain length:number of double bonds with (n-x) denoting the position (x) of the last double bond relative to the terminal methyl end.

Calculations and statistical analyses. The relative weight contribution (*i.e.*, molecular weight) of individual fatty acid methyl esters differs greatly according to chain length and degree of unsaturation. Therefore, in the comparison of hydrolysis products to that of TG and in the positional analyses, fatty acid composition was expressed on a mol % basis rather than wt %, unless otherwise indicated. The average molecular weight used in calculations for each component (TG, DG, MG and FFA) was based on their actual fatty acid compositions as determined from GLC analysis. The extent of hydrolysis in gastric samples was defined as the disappearance of TG (or increase in sum of hydrolysis products) from that originally present in milk.

Although 40–50 fatty acids (including isomers) were routinely observed in samples, fatty acid profiles were summarized according to the 14 major representative fatty acids of marine oils and seal lipids (28,44). Because all isomers of a given monounsaturated component behaved identically in this study, isomers were combined and expressed as a single value.

The mol % composition of the *sn*-2 position of milk TG was calculated from Grignard hydrolysis data as:

$$[sn\text{-}2] = 4\ [\alpha,\beta\text{-DG}] - 3\ [\text{TG}] \qquad [1]$$

(*e.g.*, refs. 40,41). For each fatty acid, the percent of the total amount present in milk which was located at the *sn*-2 position was then:

$$\%\ @\ sn\text{-}2 = \frac{[sn\text{-}2]}{3\ [\text{TG}]} \times 100 \qquad [2]$$

The average composition of the α-positions (*sn*-1, *sn*-3) was calculated as:

$$[sn\text{-}1,\ sn\text{-}3] = \frac{3\ [\text{TG}] - [sn\text{-}2]}{2} \qquad [3]$$

Calculations were performed using values obtained for α,β-DG rather than for α,α-DG since the latter tend to be more highly contaminated by acyl migration of α,β-DG components (40).

Data are presented as mean ±SEM. Unless otherwise indicated, all percentage values are mol %. Statistical analyses were performed using Statview 512+ (Brain-Power Inc., Calabasas, CA) for the Macintosh.

RESULTS

Neutral lipid class composition and evidence of gastric hydrolysis. Milk TG composition and extent of gastric lipolysis were determined for each species (Table 1). Milk lipids of harp and hooded seals, stored in solvents from the time of collection, were composed of greater than 99% TG, with very minor amounts of FFA (0.0–0.1%), DG

TABLE 1

Gastric Hydrolysis of Milk Lipid in Seal Neonates[a]

	Milk fat (wt %)	TG in milk (mol %)	n	Gastric hydrolysis (mol %)		
				Average[b]	Maximum	n
Sea lion	31.7[c]	98.4 ± 0.06	(4)	9.3 ± 1.33	25%	(20)
Harp seal	51.8[d]	99.6 ± 0.05	(5)	10.1 ± 2.65	37%	(15)
Hooded seal	61.0[e]	99.4 ± 0.95	(5)	23.0 ± 3.24	56%	(17)

[a] Average values are means ± SEM. TG, triglycerides.

[b] Average values taken from mid-sampling point in sea lions (28) and from all animals sampled in harp and hooded seals.

[c] From ref. 31.

[d] From ref. 30.

[e] From ref. 45.

(0.2–0.5%) and cholesterol (0.1–0.2%). Sea lion milks (n = 4 samples which had not undergone thawing and refreezing), although stored frozen for six years without solvents prior to analysis, showed similarly high levels of TG (98.4%). Although amounts of other components were sightly higher (0.2% FFA, 0.8% DG and 0.1% MG), evidence of hydrolysis during storage was minimal. Cholesterol ester was not detected in any sample.

The comparison of neutral lipid class composition of gastric samples from pups revealed that substantial amounts of hydrolysis occurred in all species (Table 1). The average level of hydrolysis was at least twofold higher in the hooded seal than in the harp seal and sea lion and corresponded to the higher levels of total milk fat. Milk TG levels were found to drop as low as 43.6%, 62.8% and 75.0% in the hooded seal, harp seal and sea lion, respectively. In all cases, the primary products of hydrolysis were α,β-DG (0.2–20.0%) and FFA (0.0–31.2%). Small amounts of MG (0.0–4.4%) and only trace amounts of α,α-DG (0.0–1.1% in harp and hooded seals only) were occasionally present.

Positional analysis. Positional analysis by Grignard hydrolysis of milk TG of all three species revealed distinct differences in the distributions of saturated (SFA), monounsaturated (MUFA) and polyunsaturated fatty acids (PUFA) as groups (Fig. 1). SFA tended to be very enriched at the *sn*-2 position of the milk TG, which contained essentially 70–90% of all SFA occurring in milks (see equation 2). By contrast, MUFA and PUFA were reduced at the *sn*-2 (Fig. 1), indicating their tendency to be esterified to the α-position. In all three species, 13–27% of the MUFA in milk were at the *sn*-2 position, while only 2–11% of all PUFA were at *sn*-2.

Grignard hydrolysis data also provided information on the composition of individual fatty acids at the *sn*-2 position in comparison to that of the intact milk TG (Fig. 2). Specifically, the major fatty acids enriched at the middle position in seal milk TG were the shorter-chain saturates 14:0 and 16:0. The other principal SFA, 18:0, was enriched at *sn*-2 in the hooded seal but reduced at *sn*-2 in the harp seal and sea lion (not illustrated); however, it was less than 2% of total fatty acids and therefore absolute differences were not large. The other major fatty acid which was always enriched at *sn*-2 was 16:1.

The MUFA 18:1 was reduced at *sn*-2 in comparison to the intact TG, but absolute levels at *sn*-2 were still high; thus 16:1 and 18:1 contributed to most of the measurable MUFA at *sn*-2 (Fig. 1). The other MUFA, 20:1 and 22:1, as well as all major PUFA, were virtually absent from the *sn*-2 position (Fig. 2), indicating that all were located at the α-position of the TG. Of the 14 major marine oil fatty acids, the PUFA 18:2n-6, 18:3n-3, 18:4n-3 and 20:4n-6 were variably reduced (or enriched) at *sn*-2, but are not illustrated in Figure 2 as these were generally less than 1.5% of total fatty acids and, therefore, absolute amounts and differences were very small. All three species exhibited the same patterns.

Fatty acid composition of milk TG and gastric hydrolysis products. Five mother/pup pairs were chosen for this part of the study to account for the variability in fatty acid compositions found among individual milks. Because some of the gastric samples from pups of each species had very low levels of hydrolysis, it was not always possible to obtain individual lipid classes (FFA, DG, MG) in sufficient quantity for fatty acid analysis of each class. Hence n differed from five in these cases, since composition of milk TG could only be compared to the FFA, DG and MG produced from the same milks after gastric digestion.

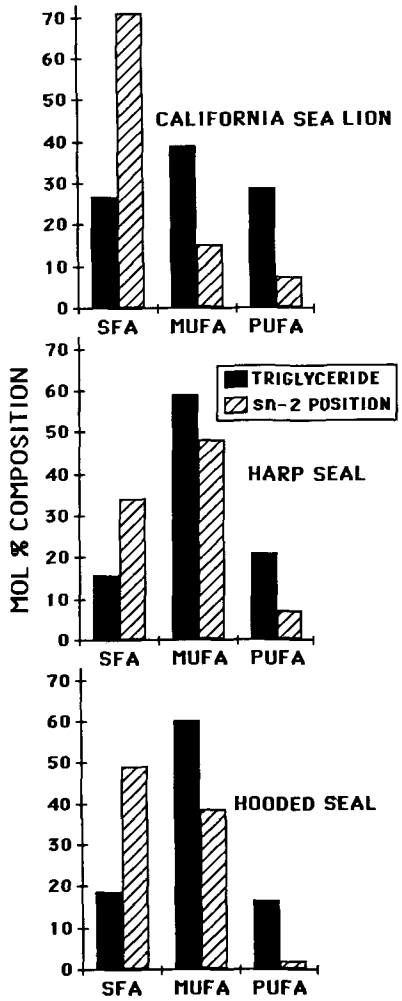

FIG. 1. Positional distribution of saturated (SFA), monounsaturated (MUFA) and polyunsaturated fatty acids (PUFA) in the triglyceride and at the *sn*-2 position in milk of three seal species as determined from Grignard hydrolysis. Mol % composition of fatty acid groups at *sn*-2 position was calculated as: [*sn*-2] = 4 [α,β-DG] − 3 [TG].

Analyses of the fatty acid composition of milk TG and the FFA released during gastric hydrolysis revealed highly significant differences between all components in each species ($P < 0.01$, paired-t, Fig. 3). The FFA were significantly reduced in the SFA 14:0 and 16:0, as well as in the MUFA 18:1, 20:1 and 22:1. In fact, the fatty acids preferentially released during gastric digestion, other than 18:0 and 16:1, were the long-chain PUFA, as determined by their significant enrichment in FFA. The n-3 PUFA 20:5n-3 was extraordinarily enriched, at up to five times the level in the TG. The single exception was 22:6n-3, which was surprisingly greatly reduced in FFA of all species (Fig. 3), at levels as low as one-sixth of that found in TG.

In examination of the composition of the other gastric hydrolysis products, as expected, the specific fatty acids

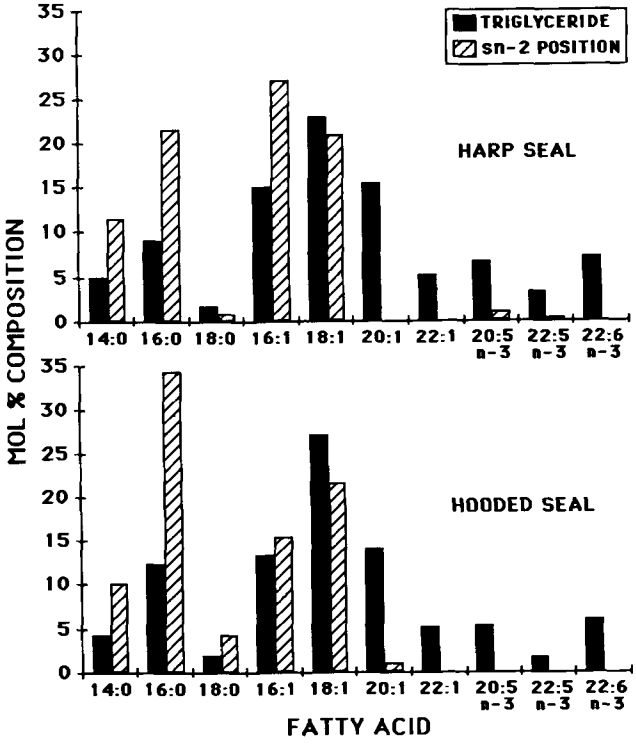

FIG. 2. Fatty acid composition of the triglyceride and at the *sn*-2 position in seal milk as determined from Grignard hydrolysis. Mol % composition of individual fatty acids at *sn*-2 position was calculated as: [*sn*-2] = 4 [α,β-DG] − 3 [TG]. Of the 14 major marine oil fatty acids, the PUFA 18:2n-6, 18:3n-3, 18:4n-3 and 20:4n-6 are not illustrated as these were usually less than 1% of total fatty acids. Data for the sea lion are not presented but exhibited the same patterns.

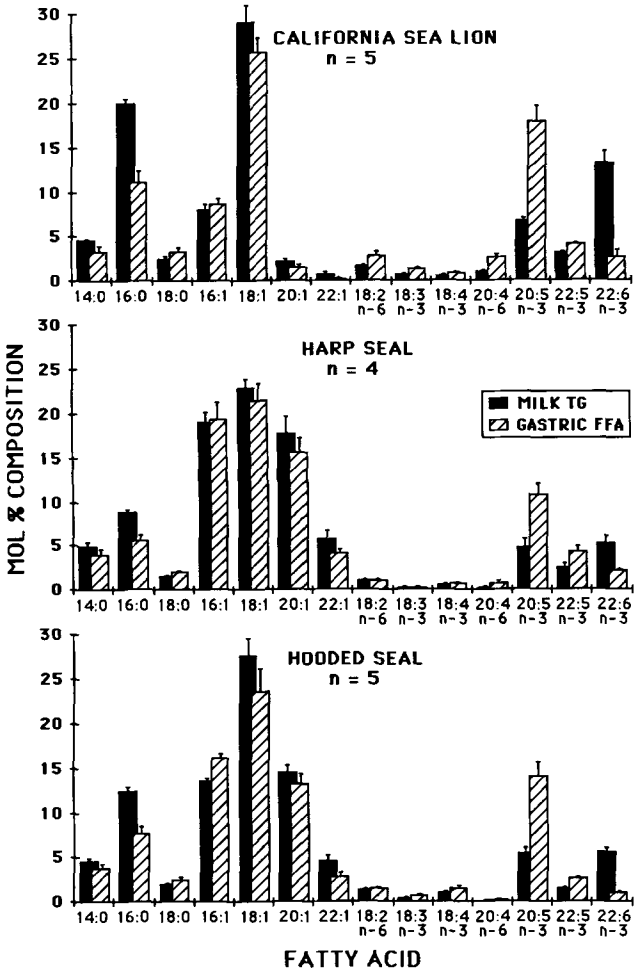

FIG. 3. Fatty acid composition of maternal milk TG and the FFA subsequently released during intragastric hydrolysis in pups of three seal species. Bars are mean mol % composition and vertical lines are + 1 SEM. Differences in fatty acid composition between TG and gastric FFA were in the same direction for all species and were significant for all fatty acids ($P < 0.01$, n=14, paired-t).

which were reduced in FFA were found enriched in the DG compared to the TG. Likewise, those fatty acids found at enriched levels in FFA were found at reduced levels in DG. In other words, the fatty acids which were preferentially released from the TG consequently left the DG reduced (*e.g.*, 20:5n-3 and 22:5n-3, Fig. 4). However, once again the single exception was 22:6n-3, which was reduced in DG (indicating its release from the TG), but also greatly reduced in the FFA (Fig. 4). In spite of differences in absolute levels of hydrolysis and fatty acid compositions, the exact same patterns occurred in all three species.

The levels of individual fatty acids in the MG obtained from gastric hydrolysis accentuated the trends found in the DG in that the fatty acids enriched in DG as compared to TG were further enriched in MG and those reduced in DG were further reduced in MG. The MG obtained in gastric samples was almost exclusively *sn*-2 MG, whereas Grignard hydrolysis produced both *sn*-2-MG and α-MG, which were difficult to separate on preparative thin-layer plates and also likely to be cross-contaminated by acyl migration. Thus the gastric MG were considered to be truly representative of the *sn*-2 position. Hence, these data were compared to both the estimated *sn*-2 position, as determined from Grignard hydrolysis, as well as to the average composition of the α-position of the milk TG (Fig. 5). In fact, in all species, the fatty acid composition of the MG obtained following gastric hydrolysis *in vivo* was remarkably similar to the estimated *sn*-2 composition calculated from the positional analysis using Grignard α,β-DG. Conversely, the α-position was in marked contrast to both estimates of the 2-position; in comparison, the α-position was particularly reduced in 14:0, 16:0 and 16:1 and highly enriched in the MUFA, 20:1 and 22:1, and the n-3 PUFA (Fig. 5).

DISCUSSION

Milk lipid is the principal source of energy for suckling neonates of most mammalian species. Even in human milk at about 4% fat, it provides greater than 50% of total calories. More significantly, it is the sole source of essential and n-3 PUFA for the rapidly developing suckling neonate. Recent studies have shown that when maternal dietary intakes of long-chain PUFA are elevated, milk lipids become readily enriched in these fatty acids (8,9,46). However, the actual absorption and utilization of these fatty acids by the neonate depends upon initial hydrolysis.

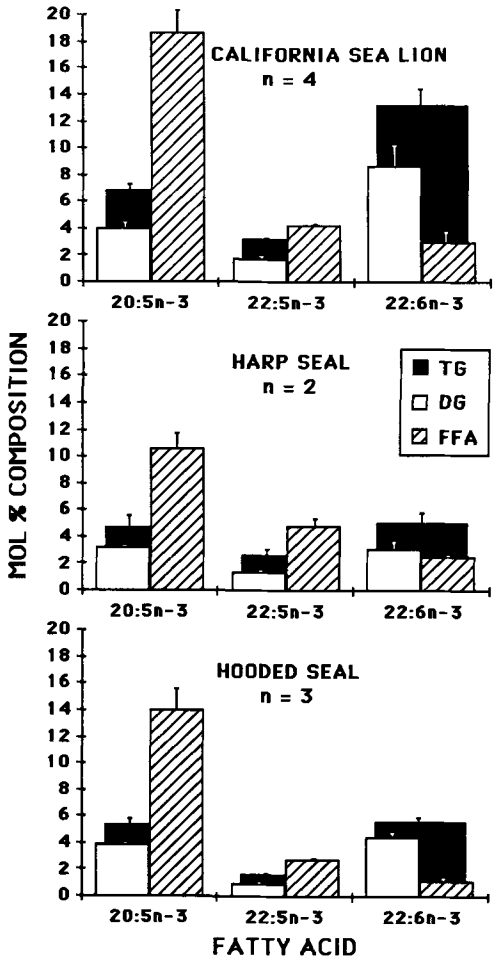

FIG. 4. Composition of the long-chain n-3 PUFA in maternal milk TG and in the hydrolysis products (DG and FFA) released during intragastric hydrolysis in pups of three seal species. Bars are mean mol % composition and vertical lines are +1 SEM.

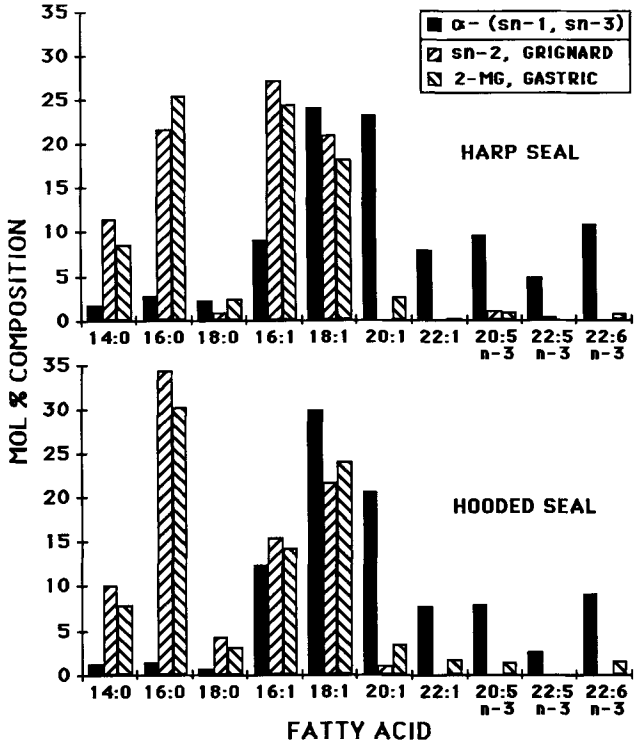

FIG. 5. The average fatty acid composition of the α-positions (*sn*-1, *sn*-3) (from positional analysis), in comparison to the estimated ("Grignard") *sn*-2 position (from positional analysis) and the *sn*-2 MG obtained following intragastric hydrolysis. Average mol % composition of the α-positions was calculated as: [*sn*-1, *sn*-3] = (3 [TG] − [*sn*-2])/2. Mol % composition of the *sn*-2 position (Grignard) was calculated as: [*sn*-2] = 4 [α,β-DG] − 3 [TG]. Data for the sea lion are not presented but exhibited the same patterns.

The importance of initial gastric digestion of dietary lipid by lingual and/or gastric lipases, especially in the neonate, has become increasingly evident (47). However, most information on hydrolysis has been limited to artificial homogeneous TG containing fatty acids of chain-length and degree of unsaturation of 18:1 or lower. Neonates of the three species of seals used in this study are similar to humans, some carnivores and the rabbit (48–52), in that they possess gastric lipase as the primary preduodenal lipase acting in the stomach (28,34). The study of gastric hydrolysis of lipid-rich seal milks (Table 1), which contain high proportions of long-chain PUFA, may provide a better understanding of the digestion of the n-3 PUFA in milks in general and of the stereospecificity of gastric lipases.

Lipases typically exhibit specificity for substrate, position and/or fatty acid. Gastric and lingual lipases, which are analogous in both structure and function (53–57), are reported to exhibit considerable stereospecificity for the α-position of the TG and to hydrolyze the *sn*-3 position twice as fast as the *sn*-1 position (23,58–61). In this study, the primary products of hydrolysis were α,β-DG and FFA in all three seal species. The occurrence of α,β-DG as virtually the sole DG product and the predominance of DG rather than MG as gastric hydrolysis products is consistent with the stereospecificity of gastric lipase. The occurrence of trace amounts of α,α-DG was probably due to small amounts of acyl migration. The *sn*-2 position did not appear to be hydrolyzed.

Thus, stereospecific analysis of TG and hydrolysis products provides some clues about the mechanisms of gastric digestion. Although pancreatic lipase hydrolysis is often used for positional analyses, it is not appropriate for TG which contain long-chain PUFA in the primary positions since pancreatic lipase is specific for the α-position, but does not hydrolyze long-chain PUFA, such as 20:5n-3, 22:5n-3 and 22:6n-3 (13,14,41). In contrast, Grignard reagent (ethyl magnesium bromide) releases the fatty acids (as tertiary alcohols) from all three positions of TG, generating intermediate products, which include α,β- and α,α-DG. In this study, Grignard hydrolysis tended to produce some breakdown products within classes which were recorded as unidentified peaks during GLC analysis and excluded from calculations. The cleanest products were the α,β-DG. Because α,β-DG produced during chemical hydrolysis also tend to be free of acyl migration (41), these were used for calculations of the 2-position.

Previous studies have shown that the positional distribution of specific fatty acids in milk TG tend to be very similar across a wide range of mammalian species (7,40,

62,63); however, the distribution of long-chain and n-3 PUFA in milks has rarely been studied. The positional data obtained in this study are comparable to those found in other marine mammal species (Table 2). In all species, the *sn*-2 position of milk TG contained about 70–100% of the 14:0 and 16:0 present in milk (Table 2 and Fig. 2), a finding characteristic of the milks of many mammalian species, including human, pig and dog (7,62,63). This distribution is consistent with the observed action of gastric lipase in seal neonates. Preferential hydrolysis of the α-position by gastric lipase would explain the paucity of 14:0 and 16:0 in FFA (Fig. 3) and the relative accumulation of these fatty acids in DG. Similar accumulations of 14:0 and 16:0 have been reported in rat milk DG and MG following gastric hydrolysis (66).

In all mammalian species previously investigated, 18:0 has been found selectively esterified at the *sn*-1 position with roughly 9–11% occurring at the *sn*-2 (62,63). Similar proportions of 18:0 have been found at the *sn*-2 in most seal and whale milks (Table 2), thus the slight enrichment of 18:0 in gastric FFA in this study (Fig. 3) may have been due to accumulation from hydrolysis of both *sn*-1 and *sn*-3. However, the hooded seal is exceptional in that selective esterification (74%) appears to occur at *sn*-2 (Table 2), suggesting that some aspects of milk TG structure may actually differ among species, as has previously been indicated in selected species (63).

In marine mammals, as in virtually all other species studied (62,63), 16:1 tends to be evenly distributed at all positions of the milk TG, whereas 18:1 tends to be more enriched at the α-positions. As expected, 16:1 and 18:1 are readily hydrolyzed during gastric lipase action. In the Weddell seal, 16:1 is more prevalent at *sn*-3 than at *sn*-1, whereas the reverse is true for 18:1 (63), which may account for the slight enrichment and reduction in FFA of 16:1 and 18:1, respectively, as compared to milk TG in this study (Fig. 3). MUFA 20:1 and 22:1, which are found at unusually high levels in some marine oils and milks (*e.g.*, Fig. 3), were virtually absent from the *sn*-2 position of milks of all marine species studied (Fig. 2 and Table 2) and thus primarily at the α-position (Fig. 5). In human milk, 20:1 has been reported to be preferentially located at *sn*-1 (7); locations of 20:1 and 22:1 have not been reported for the milks of other species. Reasonably high levels of release during gastric hydrolysis, yet at slightly reduced levels in FFA compared to TG (Fig. 3), suggest their tendency also to be esterified to the *sn*-1 position in seal milk.

While the *sn*-2 position of pinniped milk TG was found to contain variable and sometimes relatively high proportions of the minor PUFA 18:2n-6, 18:3n-3, 18:4n-3 and 20:4n-6 (Table 2), these fatty acids usually accounted for less than 1% of fatty acids. Data from other species indicate variable distribution of 18:2n-6 and 18:3n-3, but the majority of both tend to be found at the *sn*-3 position (63). The most important long-chain n-3 PUFA of seal milk, comprising up to 26% of all fatty acids (28), are 20:5n-3, 22:5n-3 and 22:6n-3. These fatty acids were found to be essentially absent from the *sn*-2 position in all species (Fig. 2 and Table 2) and are most likely located primarily at the *sn*-3 position (40,63). The slightly higher levels of these PUFA reported at the *sn*-2 position in the milks of the fur seal, elephant seal and fin whale (64,65) may have resulted from the use of pancreatic lipase rather than Grignard hydrolysis for positional analysis. Thus, the fatty acids most preferentially released from the milk TG during gastric digestion (other than 16:1 and 18:0) were the PUFA of chain-length 18 carbons or longer (Fig. 3), which is consistent with their location in the milk TG (*e.g.*, Fig. 5) and the specificity of gastric lipase for the *sn*-3 position. These findings were supported by the relative depletion of the long-chain PUFA in the DG fraction (Fig. 4). Preferential release during intragastric hydrolysis has also been reported in puppies for the major PUFA of dog milk, 18:2n-6, 18:3n-3 and 20:4n-6 (47).

The single PUFA which did not fit this pattern was 22:6n-3. While the extraordinary enrichment of 20:5n-3 in FFA during gastric hydrolysis was surprising (Figs. 3 and 4), the extreme reduction of 22:6n-3 in FFA was even more surprising since it is likely that 22:6n-3 also occurs

TABLE 2

Comparison of Percentage Distribution of Fatty Acids at the *sn*-2 Position in Milk TG of Various Marine Mammals[a]

[a] Percent of each fatty acid present in milk which is located at the *sn*-2 position of the triglyceride (TG) as determined from positional analyses; dashes indicate values not reported or analyzed. % @ *sn*-2 = [*sn*-2]/3[TG] × 100. CA, California.

[b] Total weight % present in milk TG of these species (ref. 28, this study).

[c] From this study.

[d] Calculated from ref. 64.

[e] Calculated from ref. 63. All PUFA > 18:3 reported as a single value.

[f] Calculated from ref. 65.

primarily at the *sn*-3 position (this study, refs. 40 and 63). Additionally, like 20:5n-3 and 22:5n-3, proportions of 22:6n-3 were found to be depleted in the gastric DG obtained from all three species, suggesting that it also had been released from the TG (Fig. 4). In all samples, 22:6n-3 was stable in all fractions (total, TG, DG, FFA) and was readily and reproducibly collected from preparative plates, transesterified and measured. The lower levels of 22:6n-3 found in both the DG fraction (as expected) and FFA fraction were considered to be accurate measurements; no evidence of loss through autooxidation or overlap in various fractions was found, despite numerous efforts to elucidate such occurrences. The DG and FFA data, in addition to the residual TG available, also demonstrated no evidence of intermolecular specificity by lipases (*i.e,* preferential hydrolysis of TG species). Thus the extreme reduction of 22:6n-3 in FFA, in conjunction with the enrichment of 20:5n-3 in FFA at levels much higher than expected, suggests some kind of metabolic loss, conversion or preferential absorption. The retroconversion of 22:6n-3 to 20:5n-3 has previously been reported (67–69), although how this process could possibly occur during digestive metabolism and whether this could account for the observed discrepancies is unclear. Given that most hydrolyzed lipids are believed to remain with the parent milk fat globule until its disruption in the intestine (23,24), preferential absorption of a single and very long-chain fatty acid, such as 22:6n-3, seems unlikely. Clearly, these patterns require further investigation.

The rapidly accumulating information on the effects of n-3 PUFA in marine oils confirms the notion that these are important dietary components for both infants and adults (4–7). Nevertheless, this stands in contrast to the relatively limited knowledge about the digestion of n-3 PUFA, particularly from milk TG. In this study, high intakes of total milk fat and PUFA were coupled with high levels of gastric lipolysis in pups. Despite apparent individual and species variation in the extent of hydrolysis, the same fatty acids, primarily the long-chain and n-3 PUFA, were preferentially released in pups of all three species. This is explained by their unique location in the milk TG at the α- and probably mostly at the *sn*-3 position and by the corresponding specificity of gastric lipase. Reports of preferential hydrolysis of short- and medium-chain fatty acids in milk (*e.g.*, ref. 66) may be partly attributable to the fact that these fatty acids, at least in the human and the rat, are also preferentially esterified at the *sn*-3 position in milk (70,71).

We conclude that the n-3 PUFA in milk are efficiently hydrolyzed by gastric lipase and that this has important implications for the digestion of milks enriched in PUFA by neonates in general. Given the general similarity in milk TG structure among species and the fact that many mammalian species, including the human, possess lingual and/or gastric lipases, hydrolysis of milk fat enriched in the important long-chain n-3 PUFA may be primarily dependent upon the actions of these lipases prior to reaching the intestine. Furthermore, while pancreatic lipase may not be able to continue hydrolysis of these fatty acids in the α-positions, bile salt-stimulated lipase, present in the milk of species such as seals, humans and a number of other primates and carnivores studied, non-specifically hydrolyzes TG and partial glycerides in the intestine (72–74), and may account for further PUFA release.

ACKNOWLEDGMENTS

We are very grateful to Dr. W. D. Bowen of the Department of Fisheries and Oceans, Canada, for organizing the expedition to the pack ice, for assistance in the collection of harp and hooded seal samples and for valuable comments on an earlier version of the manuscript. We thank members of the U.S. Navy at the Pacific Missile Test Center, Pt. Mugu, CA, for permission to conduct research on San Nicolas Island and for logistical support during field studies. We thank Dr. D. J. Boness for assistance in sample collection during both field studies and for general research support. We also thank Dr. J. Bitman and especially D. L. Wood of the USDA Milk Secretion and Mastitis Laboratory, Beltsville, MD, for their time, advice and use of their laboratory facilities to conduct TLC work. This study was supported by research grants (to S.J.I. and O.T.O.) from the Friends of the National Zoo and the Office of Fellowships and Grants of the Smithsonian Institution, Washington, D.C., and by the Department of Fisheries and Oceans, Canada.

n-3 Fatty Acid Requirements of the Newborn[1]

Sheila M. Innis*
Department of Paediatrics, The University of British Columbia, Vancouver, British Columbia, Canada V5Z 4H4

Whether docosahexaenoic acid (22:6n-3) is an essential nutrient for term or preterm infants, or if not, the quantity of dietary linolenic acid (18:3n-3) needed to support sufficient synthesis of 22:6n-3 for assimilation in the central nervous system is unknown. Infants fed formulas have lower plasma and red blood cell (RBC) levels of 22:6n-3 than breast fed infants. No relationship between the intake of 18:3n-3 in formula (0.8 or 4.5% of fatty acids, 18:2n-6/18:3n-3 ratio 35:1 or 7:1, respectively) and the infant's RBC 22:6n-3 was found. Premature infants (<33 wk gestation) also showed a decrease in RBC 22:6n-3 during feeding with formula containing 18:3n-3 as the only n-3 fatty acid. However, a marked decrease in plasma and RBC 22:6n-3 occurred between premature birth and the start of full enteral feeding at 1-2 wk of age. This was not reversed by breast milk or formula feeding. Piglets, which are appropriate for studies of infant lipid metabolism, had decreased brain synaptic plasma membrane, retina and liver 22:6n-3 and increased 22:5n-6 when fed formula with 0.8% fatty acids (0.3% of kcal) as 18:3n-3. Formula with 4.0% fatty acids (1.7% of kcal) as 18:3n-3 resulted in similar accretion of 22:6n-3 in the organs compared to milk fed animals. The studies suggest the dietary requirement for 18:3n-3 in term animals in energy balance exceeds 0.3% diet kcal. Studies in the premature infants suggest 18:3n-3 may be oxidized rather than desaturated to 22:6n-3 if energy requirements are not met, and that due to early lipid restriction and later rapid growth, premature infants may have higher dietary n-3 requirements than term infants.
***Lipids 27,* 879-885 (1992).**

The two fatty acids accepted as essential dietary nutrients for humans are linoleic acid (18:2n-6) and linolenic acid (18:3n-3) (1). Once obtained from the diet, 18:2n-6 and 18:3n-3 may undergo sequential desaturation and elongation to a series of longer chain polyunsaturated fatty acids (LCP) with 20 or 22 carbon atoms and 3 to 6 double bonds. Of these, arachidonic acid (20:4n-6) and docosahexaenoic acid (22:6n-3) are of particular interest because they are found in very high concentrations in membrane structural lipids of the central nervous system (CNS), especially the excitable membranes such as those of the synaptic terminals and visual elements of the retina (2,3).

Synthesis of 20:4n-6 depends on sequential desaturation with alternate elongation of 18:2n-6 by Δ6 and Δ5 desaturases. The synthesis of 22:6n-3 from 18:3n-3 involves similar Δ6 and Δ5 desaturation and elongation, to 22:5n-3, then additional elongation and desaturation, possibly by Δ6 desaturase, and β-oxidation (4). Substrate competition between 18:2n-6 and 18:3n-3 for the Δ6 desaturase may influence the synthesis of 20:4n-6 and 22:6n-3; however, clear preference of the enzyme for 18:3n-3 over 18:2n-6 is known (5-7). The desaturase enzymes are also sensitive to inhibition by the LCP products of either the n-6 or n-3 fatty acid pathway (5,8,9). Consequently, the quantity and balance of 18:2n-6 and 18:3n-3 in infant diets, as well as the addition of n-3 LCP without 20:4n-6, has important implications for the synthesis of 20:4n-6 and 22:6n-3 in developing tissues (1). In addition to the diet 18:2n-6 and 18:3n-3 supply, the fatty acid desaturase enzyme mass and activity, and utilization of fatty acids for energy, can also be expected to influence the rate of LCP formation from 18:2n-6 and 18:3n-3.

It has been known for many years that dietary deficiency of 18:2n-6 and/or 18:3n-3 during development may have long-term consequences with regard to CNS function (10-18). The characteristic fatty acid compositional changes which occur in brain and other organs during essential fatty acid deficiency (deficiency of both 18:2n-6 and 18:3n-3) are an increase in 20:3n-9/20:4n-6 (triene/tetraene) ratio, but maintenance of the normal 20:4n-6/22:6n-3 ratio (1). Dietary deficiency of only 18:3n-3 results in decreased tissue lipid 22:6n-3, as well as increased 20:4n-6/22:6n-3, but not 20:3n-9. Levels of 22:5n-6 seem to be increased in CNS tissues of animals fed diets deficient in both 18:2n-6 and 18:3n-3 or diets deficient in only 18:3n-3 (1). Abnormalities in visual function assessed by electroretinograph (ERG) and direct measures of visual performance (11,15,16) and altered learning (11,17,18) have been found in animals fed diets containing less than about 0.015% kcal 18:3n-3. The functional deficit is presumably related to the accompanying reduction in CNS 22:6n-3. Evidence of reduced visual acuity also has been described in premature infants with low circulating lipid levels of 22:6n-3 (19,20). The functional roles of the normally high levels of 20:4n-6 in the CNS (3), beyond the role as precursor for synthesis of eicosanoids (21), are not well understood.

Large amounts of 20:4n-6, 22:4n-6 and 22:6n-3 are deposited in the CNS during the rapid phase of brain growth (22-25) known as the brain growth spurt (26). In human this commences around the beginning of the third trimester of gestation and continues through the first 18 mon after birth (26). The n-6 and n-3 LCP in fetal and infant tissues are probably derived, at least in part, by placental transfer before birth and from the milk fat after birth. These preformed n-6 and n-3 LCP are undoubtedly taken up and incorporated into developing organ structural lipids (1). The extent to which the developing fetus or newborn depends on a preformed source of 20:4n-6 and 22:6n-3, however, or the amounts of 18:2n-6 and 18:3n-3 needed to achieve adequate synthesis of 20:4n-6 and 22:6n-3 to support optimal composition and function in the developing CNS lipids, is not yet clear.

Our laboratory has combined clinical studies of plasma and red blood cell (RBC) phospholipid fatty acids in term and in preterm infants (1,27-30), with detailed tissue compositional studies of piglets fed similar defined formulas or natural milk (31-36). The parallel studies in the piglet

Abbreviations: CNS, central nervous system; ERG, electroetinograph; LCP, long-chain polyunsaturated fatty acids of carbon chain ≥ 20 and containing > 2 double bonds; LDL, low density lipoprotein; PC, choline phospholipids; PE, ethanolamine phospholipids; RBC, red blood cell(s); UI, unsaturation index.

have addressed concerns over specificity and sensitivity of plasma and RBC fatty acids, which are influenced by the composition of the fat absorbed from the diet (1), as measures of the n-6 and n-3 LCP composition in developing organs of formula or natural, milk-fed animals. The studies with piglets have included comparison of the efficacy of dietary 18:3n-3 as compared to 22:6n-3 as a source of 22:6n-3 for developing hepatic and CNS structural lipids (31–33). Similarities in physiology and metabolism, brain lipid and natural milk lipid composition (34–36), and in the timing of the brain growth spurt in relation to birth between the piglet and human (26) combine to make the piglet useful for study of fatty acid requirements as they pertain to the human infant. Results of studies on the effect of premature birth and intravenous nutrition (1,27), and formula or breast milk feeding on the plasma and RBC n-3 fatty acids of preterm (1,27,28) and term (1,29,30) infants are discussed in the present paper. Data on the accretion of n-6 and n-3 LCP in CNS membranes, liver and circulating lipids of piglets fed formulas varying in quantity and balance of 18:2n-6 and 18:3n-3, or with marine oils (31–36) are reviewed with regard to interpretation of the effect of milk and formula feeding on the circulating lipids of infants. All of the methods and results discussed from studies with piglets have been published (see references cited).

MATERIALS AND METHODS

Studies of term gestation infants fed breast milk or formulas varying in 18:3n-3. Term gestation infants were fed formulas containing (in % fatty acids) about 32% 18:2n-6 and 4.5% 18:3n-3 (18:2n-6 to 18:3n-3 ratio about 7:1), or 28% 18:2n-6 and 0.8% 18:3n-3 (18:2n-6 to 18:3n-3 ratio about 35:1), or were breast fed from <3 days to 8 wk after birth (n = 16 infants per group). Blood samples were taken by venipuncture at 3 d, and 4 and 8 wk of age, and the plasma and RBC separated. Plasma phospholipids were separated from other lipid classes, and RBC choline phospholipid (PC) and ethanolamine phospholipid (PE) were separated by thin-layer chromatography. The fatty acid composition of each fraction was analyzed by capillary column chromatography. Plasma cholesterol concentration was determined enzymatically. All of the methods have been published in detail (31–36).

Studies of premature infants fed formula or breast milk. The effect of feeding a preterm formula containing (in % fatty acids) about 20% 18:2n-6 and 2% 18:3n-3 or the mother's expressed breast milk on the fatty acid composition of plasma phospholipid and RBC PC and PE of very premature infants was studied using a longitudinal, repeated measures design (28). The expressed breast milk, based on analyses of the milk fed to infants, had (mean wt% fatty acids ± SEM) 11.1 ± 0.8% 18:2n-6, 0.9 ± 0.2% 18:3n-3, 0.8 ± 0.1% 20:4n-6 and 0.5 ± 0.1% 22:6n-3 with about 1.1% total n-6 LCP and 0.9% total n-3 LCP. The infants were of appropriate weight for gestational age, growing well and had an enteral intake of ≥120 kcal/kg/d with no intravenous nutrient support at the start of the study. Blood samples were obtained by venipuncture at enrollment into the study and again 28 d later. Plasma phospholipid, RBC PC and PE fatty acids, and the plasma cholesterol concentration were determined. Characteristics of the infants, including postnatal age, intravenous nutrition from birth to full enteral feeding, and growth during the study have been published (28).

Importance of gestational age at birth and subsequent parenteral nutrition on circulating lipid n-3 fatty acids. Cord blood was collected from fetuses or infants delivered at 20–41 wk post conception (n = 55) to allow study of the potential changes in the plasma and RBC n-6 and n-3 fatty acids with increasing gestational age. Blood was collected from the clamped cord within 5 min of delivery.

Changes in the plasma phospholipid and RBC PC and PE fatty acid composition of premature infants, less than 33 wk gestation and of appropriate weight for gestational age, were studied longitudinally from birth through parenteral nutrition support until full enteral feeding was attained. Intravenous and enteral nutrition was at the discretion of the attending physicians and not altered in any way because of this study. At 72 h post-conception, infants had received parenteral dextrose and amino acids, but no intravenous lipid, with or without enteral feeds with formula (containing in fatty acids, 20% 18:2n-6, 2% 18:3n-3). Analysis of the plasma phospholipid fatty acids from these infants was used to study the effect of 72 h dietary deficiency of n-6 and n-3 fatty acids (23).

Ethical approval for all studies involving infants and cord blood was obtained from the University of British Columbia, British Columbia Childrens' Hospital and Grace Hospital's Clinical Screening Committees for Research and Other Studies Involving Human Subjects (Vancouver, Canada). Written informed consent from a parent was obtained in all cases.

RESULTS

Studies of term gestation infants fed breast milk or formulas varying in 18:3n-3. The fatty acid composition of the plasma phospholipid and RBC PC and PE of the term gestation infants fed the formulas varying in 18:3n-3 content or breast fed has been reported (1,29). For the present purpose, the plasma phospholipid and RBC PE levels (wt% total fatty acids) of 20:4n-6, 22:4n-6, 22:5n-6, 22:6n-3 and unsaturation index (UI) at 3 d, 4 and 8 wk of age are summarized in Figures 1 and 2. Although several consistent and marked differences were found in the plasma phospholipid and RBC PE, as well as in PC, n-6 and n-3 fatty acids levels between the breast and formula fed infants, no differences were found in these fatty acids between infants fed the formula with 0.8% 18:3n-3 and those fed the formula with 4.5% 18:3n-3. The plasma phospholipid % 18:2n-6 were significantly higher in three-day-old infants fed formula than in the breast fed infants (Fig. 1). This difference persisted throughout the 8-wk feeding study. The plasma phospholipid % 20:4n-6 and 22:6n-3 and the (UI) were significantly lower in the formula compared to breast fed infants at both 4 and 8 wk of age.

The RBC PE is distinctly different from plasma phospholipid and is known to contain much lower levels of 18:2n-6 and higher levels of 20:4n-6, 22:4n-6 and 22:6n-3. The CNS also has a very low content of 18:2n-6, usually 1–2% fatty acids, and large amounts of 20:4n-6, 22:4n-6 and 22:6n-3 (3). The effects of milk and formula fats on the fatty acid composition of RBC PE are of interest, because it resembles CNS lipids more closely than RBC PC or plasma lipids, and because it is readily accessible in clinical studies with infants. As found in plasma

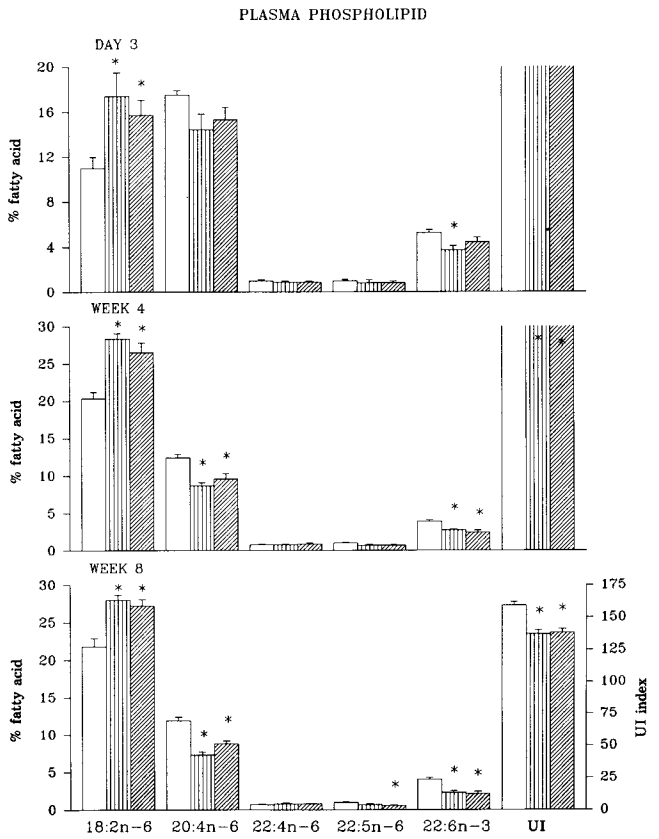

FIG. 1. Major n-6 and n-3 fatty acids (wt% total) and unsaturation index (UI) in plasma phospholipids of term gestation infants who were breast fed or fed formula differing in 18:3n-3 from <3 d to 8 wk of age. Values given are means ± SEM for breast fed infants (open bars) and infants fed the formula containing (in fatty acids) 27% 18:2n-6, 4.5% 18:3n-3 (vertical hatch), or 30% 18:2n-6, 0.8% 18:3n-3 (diagonal hatch). Significant differences ($P < 0.05$) between infants fed formula as compared to breast milk are indicated by an asterisk. There were no significant differences as a result of the type of formula fed. The UI index was calculated as the sum of the wt% fatty acid × number double bonds as in ref. 36.

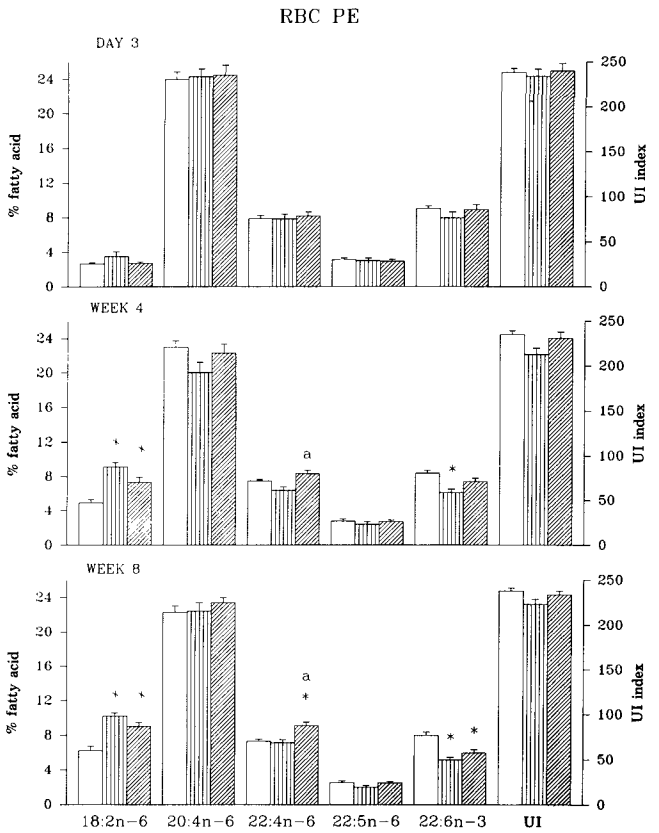

FIG. 2. Major n-6 and n-3 fatty acids (wt% total) and unsaturation index (UI) in red blood cell (RBC) ethanolamine phospholipids (PE) of term gestation infants who were breast fed or fed formula differing in 18:3n-3 from <3 d to 8 wk of age. Values given are means ± SEM for breast fed infants (open bars), and infants fed the formula containing (in fatty acids) 27% 18:2n-6, 4.5% 18:3n-3 (vertical hatch), or 30% 18:2n-6, 0.8% 18:3n-3 (diagonal hatch). Significant differences ($P < 0.05$) between infants fed formula as compared to breast milk are indicated by an asterisk, and infants fed the formula with 0.8% 18:3n-3 compared to those fed the formula with 4.5% 18:3n-3 are indicated by the letter a. The UI index was calculated as the sum of the wt% fatty acid × number double bonds as in ref. 36.

phospholipid, the RBC PE % 18:2n-6 was significantly higher and 20:4n-6 was significantly lower in infants fed the formulas as compared to breast milk for 8 wk (Fig. 2). There were no differences in RBC PE % 22:6n-3 in infants fed formula with 0.8 compared to 4.5% fatty acids as 18:3n-3. The RBC PE % 20:4n-6, and all other C_{22} n-6 and n-3 fatty acids, and the UI also were similar between the breast and formula fed infants with the single exception that the % 22:4n-6 was significantly higher in eight-week-old infants fed the formula with 0.8% 18:3n-3 than in the breast fed infants.

The plasma cholesterol and triglyceride concentrations were significantly higher after 4 wk ($P < 0.01$) and 8 wk ($P < 0.001$) in the breast fed compared to formula fed infants. There were no significant differences in the plasma cholesterol and triglyceride concentration between the two groups of formula fed infants. Results for the plasma cholesterol concentrations at 8 wk of age were (mean ± SEM) 2.93 ± 0.2, 2.91 ± 0.15 and 4.98 ± 0.36 mmol for infants fed the formula with 4.5% 18:3n-3, the formula with 0.8% 18:3n-3 or breast fed, respectively. The triglyceride concentrations in the same three groups at 8 wk of age were (mean ± SEM) 1.70 ± 0.21, 1.41 ± 0.09 and 2.53 ± 0.19 mmol, respectively.

Studies of premature infants fed formula or breast milk. Infants who were fed their mother's expressed breast milk (n = 9) or formula (n = 16) were 12.4 ± 1.4 or 13.9 ± 2.1 days old, respectively, when full enteral feeds of at least 120 kcal/kg/day were attained. The plasma cholesterol decreased significantly, from 3.41 ± 0.29 to 2.58 ± 0.28 mmol and from 4.55 ± 0.44 to 3.05 ± 0.28 mmol over the following 28 d of feeding with the mother's expressed breast milk or formula, respectively. The plasma cholesterol concentration in the infants fed formula and infants fed breast milk were not significantly different at either time point. The concentration of cholesterol in cord blood was 2.46 ± 0.13 mmol for infants of similar prematurity (24) and 1.63 ± 0.21 mmol for term gestation infants (Innis, S.M., and Hamilton, J.J., unpublished data).

No significant differences were found in the % n-6 and n-3 LCP composition of the RBC PE, PC or plasma phospholipid between infants fed expressed breast milk

and infants fed the formula with 20% 18:2n-6, 2% 18:3n-3 for 28 d (25). Repeated measures of longitudinal analysis of variance, however, showed a significant decrease in the RBC PE % 22:6n-3 during the feeding study in infants fed the formula, but not in those fed breast milk (Fig. 3).

Effect of gestational age at birth and subsequent parenteral nutrition on circulating lipid n-3 fatty acids. The % 22:6n-3 in RBC PC, PE and plasma phospholipid was lower in premature infants at the start of full enteral feeding, and after 4 wk feeding with expressed breast milk or formula, than found in newborn or 4-wk-old term gestation infants fed breast milk (37). It seemed important, therefore, to determine whether this was due to premature birth or had occurred during the initial two weeks of parenteral nutrition prior to establishing full volume enteral feeding. Regression analysis of the RBC PC and PE % 22:6n-3 from preterm and term infant cord blood against gestational age showed either no change or a positive correlation with increasing gestation from 20 to 41 wk (1; Fig. 3). Levels of 22:6n-3 decreased, however, from birth to the start of full enteral feeding. Subsequent feeding with either breast milk or formula did not restore the RBC PE 22:6n-3 to the levels of about 8-9% fatty acids found at birth and in cord blood of newborn infants of equivalent post-conceptional age (Fig. 3).

Premature infants (26–34 wk gestation) maintained for the first 72 h after birth with parenteral dextrose and amino acid solutions and no exogenous lipid had higher % and mg/dL 18:1 and 20:3n-9 in their plasma phospholipid than found in cord blood or in plasma phospholipid of similar 72-h-old premature infants given formula (Fig. 4; ref. 27). The elevation of 18:1 and 20:3n-9 provides biochemical evidence of rapidly developing essential fatty acid deficiency. The mg/dL 20:4n-6, 22:4n-6, 22:5n-6, 22:5n-3 and 22:6n-3 in plasma phospholipids also increased significantly in infants deprived of lipid for the first 72 h after birth. It is reasonable to assume that this increase in plasma LCP was due to mobilization of tissue fatty acids, and secretion as hepatic lipoprotein phospholipid. The exogenous energy supply in all the infants at this time was less than the maintenance requirements for premature infants in a thermoneutral environment, usually assumed to be at least 50–60 kcal/kg/day (38).

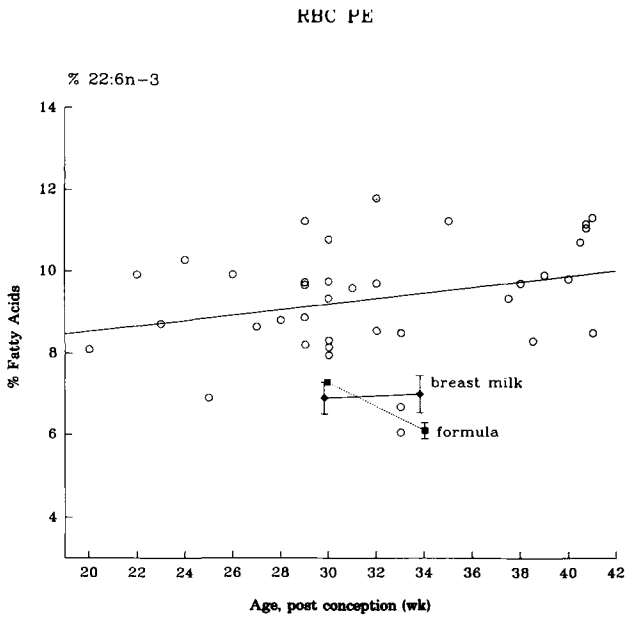

FIG. 3. Content of 22:6n-3 (% total fatty acids) in the red blood cell ethanolamine phospholipids (RBC PE) of cord blood and of premature infants fed breast milk or formula. The premature infants were fed their own mother's expressed breast milk or formula (with 2% fatty acids as 18:3n-3) for four weeks, following birth at 29.4 ± 0.4 and 28.2 ± 0.6 weeks postconception, respectively. The % 22:6n-3 in the RBC PE decreased in infants fed the formula ($P < 0.05$), but was not significantly different from infants fed expressed breast milk at any time in the study.

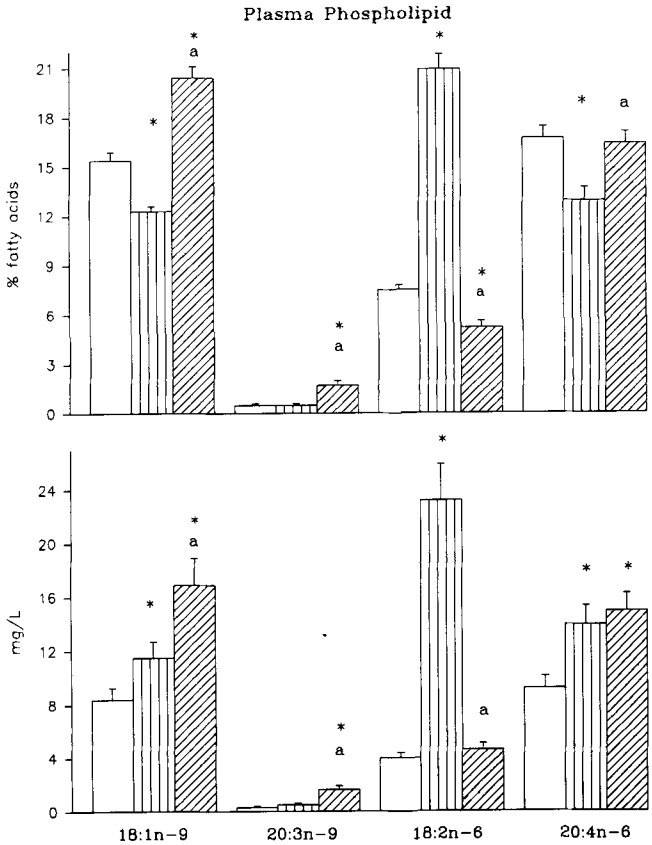

FIG. 4. Plasma phospholipid n-9 and n-6 fatty acids (% total and mg/dL) of premature infants at birth, and at 3 d of age. Values given are means ± SEM for cord blood (n = 22, gestation 29.5 ± 2.3 wk, open bars) and 72-h-old infants who received intravenous dextrose and amino acids with enteral feeds of formula (140–297 mL/kg total, vertical hatch); (n = 12, gestation 31.8 ± 1.4 wk) or no enteral feeds (n = 15, gestation 28.1 ± 2.0 wk). Significant differences ($P < 0.05$) between the 72-h-old infants and the cord blood are indicated by an asterisk, and between the infants who received no lipid compared to those fed formula are indicated by the letter a.

DISCUSSION

The results of analyses presented here showing lower % 22:6n-3 in plasma and RBC phospholipids of term gestation infants fed formulas containing blends of vegetable oils with no n-6 or n-3 LCP, rather than breast milk, are similar to the results of others (1,39). Premature infants fed formulas, but not those fed expressed breast milk, also show a significant decline in their RBC PE % 22:6n-3

(Fig. 3). The difference in the levels of 22:6n-3 between the premature infants fed formula and those fed breast milk, however, did not reach statistical significance in this 28-d study. Similar levels of 22:6n-3 in RBC lipids of preterm infants fed formula containing 2.7% total fatty acids as 18:3n-3 and preterm infants fed breast milk from less than 11 d to 25–36 d of age have been found by others (20). Studies using a longer feeding period of 47 d, however, found significantly lower RBC PE % 22:6n-3 in premature infants fed formulas with 0.6–0.9% 18:3n-3 rather than breast milk (36).

It seems clear from clinical studies with term and preterm infants fed formulas that either: (i) dietary 18:3n-3 is not desaturated to 22:6n-3; or (ii) 18:3n-3 is desaturated to 22:6n-3 but the 22:6n-3 formed in the organs is not secreted into plasma in amounts related to the diet 18:3n-3 supply, or to equal the levels circulating when 22:6n-3 is absorbed from breast milk lipid. Failure to achieve adequate desaturation of 18:3n-3 could be explained by an inadequate dietary supply of 18:3n-3, competitive inhibition of 18:3n-3 desaturation by the high 18:2n-6 in the formulas, or limited capacity for desaturation-elongation of 18:3n-3 to its LCP products.

Substrate competition between 18:2n-6 and 18:3n-3 for Δ6 desaturation *in vitro* and *in vivo* in animals fed diets limiting in 18:3n-3 or with very high 18:2n-6 is well known (5–7). The similar circulating lipid levels of 22:6n-3 in term gestation infants fed formulas containing 27–30% 18:2n-6 with 0.8 or 4.5% fatty acids as 18:3n-3 (Figs. 1 and 2) suggest that ratios of 18:2n-6 to 18:3n-3 over the range of 7:1 to 35:1 were not a determinant of the circulating lipid 22:6n-3 in the infants fed formula in these studies.

Relatively little attention has been given to the marked differences in n-6 fatty acids between infants fed breast milk and infants fed formula. The significantly higher levels of 18:2n-6 in the plasma phospholipids of term and preterm infants fed formula as compared to those fed breast milk (28,29,39,40) may reasonably be related to the higher levels of 18:2n-6 in many formulas than in typical breast milks (41). The reason for the lower 20:4n-6 in association with higher 18:2n-6 in the plasma phospholipids of the infants fed formulas, however, is not known. The results suggest inability of, or interference with, desaturation of 18:2n-6. This could be due to low Δ6 and/or Δ5 desaturase activity in newborn infants, or possible substrate inhibition of desaturation (1) by the relatively high (about 12–15% kcal) 18:2n-6 in the formulas. Either explanation could provide a common reason for the accompanying decrease in plasma and RBC phospholipid levels of 22:6n-3. The RBC PE % 20:4n-6 is much higher than that found in plasma phospholipids. Despite this, the decreased plasma phospholipid 20:4n-6 associated with formula feeding (Fig. 1) was not associated with reduced levels of 20:4n-6 in the RBC PE (Fig. 2). This, together with the decrease in plasma phospholipid 20:4n-6 with increasing age in all infants, irrespective of feeding group, suggests that factors other than desaturase enzyme activity may be important to the metabolism of plasma n-6 fatty acids.

As has been reported by others (42), the plasma cholesterol concentration was significantly lower in term gestation infants fed formula than in breast fed infants. Infant formulas usually supply about 4 mg cholesterol/dL, whereas analyses of mature human breast milk typically report cholesterol concentrations of 20–50 mg/dL (41). The esterification of plasma-free cholesterol by lecithin:cholesterol acyltransferase involves transfer of 18:2n-6 from the *sn*-2 position of plasma PC to free cholesterol (43). It seems reasonable to question whether or not the lower dietary cholesterol intake and plasma cholesterol concentration in formula fed infants results in slower turnover of plasma phospholipid 18:2n-6 than in breast fed infants. The higher plasma cholesterol concentration in preterm than term infants, and the decline in plasma cholesterol in preterm, compared to increase in term infants, over the first month of full enteral feeding (44) provides evidence of marked differences in plasma cholesterol and lipoprotein metabolism. Whether or not this has implications for the metabolism of lipoprotein phospholipid 18:2n-6, or other n-6 or n-3 fatty acids, has yet to be considered.

An increase in tissue lipid n-6 fatty acids, particularly 22:5n-6, is a characteristic feature of nonhuman primates, rodents and piglets fed diets deficient in 18:3n-3 (1,10, 15–18,31–36). The lack of a consistent increase in plasma and RBC PC or PE 22:5n-6 in the term gestation infants fed the formulas with 0.8 or 4.5% fatty acids as 18:3n-3 (Figs. 1 and 2), or in preterm infants fed breast milks or formulas (28) could be interpreted as evidence that there was no overt biochemical deficiency of n-3 fatty acids in the infant tissues. The ability to respond to n-3 fatty acid deficiency with an increase in 22:5n-6, however, is dependent on desaturation of 18:2n-6 in liver, and subsequent secretion of the n-6 LCP products into plasma as lipoprotein phospholipid. Thus, until optimal activities of the desaturase enzymes in infant tissues are assured, and it is known that 22:5n-6 is incorporated into secreted lipoprotein phospholipid, findings of "low" C_{22} n-6 LCP in the circulating lipids of infants should not be considered as evidence of adequate tissue levels of 22:6n-3.

Studies in nonhuman primates and rodents have shown biochemical and functional deficiency of 22:6n-3 as a result of feeding diets with less than 0.02% kcal 18:3n-3 (1,10, 15,16). The control diets in the latter studies provided >0.3% kcal 18:3n-3 (usually from soybean oil), but no LCP. Biochemical deficiency, based on increased 22:5n-6 and decreased 22:6n-3 in brain, its synaptic plasma membranes, retina and liver has been shown in piglets fed exclusively from birth with formula containing 0.8% fatty acids (0.35% kcal) as 18:3n-3 rather than sow milk (34–36). Liver and CNS levels of 22:6n-3 were similar or higher in piglets fed formula with 4% fatty acids (1.7% of kcal) as 18:3n-3 to that in piglets fed sow milk (31). The increase in 22:5n-6 in developing rodents, piglets and nonhuman primates fed diets limiting in 18:3n-3, and the accumulation of large amounts of 22:6n-3 when generous amounts of 18:3n-3, but no LCP, are fed (10,15–18,31–36) provides clear evidence of adequate desaturase activity in these term newborns. The results from studies on the CNS synaptic plasma membranes and retina PE, which usually contain very high levels of 22:6n-3, show that when using the amounts and ratios of 22:5n-6 and 22:6n-3 in these tissues as criteria of dietary n-3 fatty acid adequacy, the dietary requirement for n-3 fatty acids in the exclusively formula-fed term gestation piglet is between 0.35 and 1.7% of diet kcal.

Small amounts of fish oil, to provide up to 1% fatty acids (0.5% kcal) in formula as n-3 LCP (2 to 6 g menhaden oil/L formula), also have been shown to be effective in

supporting similar levels of 22:6n-3 in CNS lipids of piglets to levels found in naturally suckled piglets (31-33). The quantitative superiority of dietary 20:5n-3 and 22:6n-3, compared to 18:3n-3, as a source of 22:6n-3 for developing membrane tissues is clear. This may be explained by the known differences in affinities for 18:3n-3 and 22:6n-3 of the acyltransferases involved in structural lipid synthesis and turnover, and predominant mitochondrial oxidation of 18:3n-3, but not 22:6n-3 (1). Piglets fed formulas with 20:5n-3 and 22:6n-3 (from marine oil), in contrast to piglets fed 18:3n-3 (from soy or canola oils), showed a significant reduction of 20:4n-6 in liver and plasma phospholipids (32,33). Evidence is available to suggest this may be explained by inhibition of 18:2n-6 desaturation, as well as competition between 20:5n-3 and 20:4n-6 for acylation (1). Although natural milks contain 22:6n-3, levels of 20:5n-3 are normally very low, and 20:4n-6 is always present (41). Although marine oils with 20:5n-3 and 22:6n-3 appear to provide an efficacious dietary source of 22:6n-3 for the developing CNS (31-33), the studies with piglets suggest that they should not be added to infant diets unless a source of 20:4n-6 also is included.

The specificity of measures of plasma and RBC 22:6n-3 in infants fed diets which do (breast milks, marine oils) and do not (vegetable oil formulas) contribute n-3 LCP to the circulating lipid pool, as an index of adequate 22:6n-3 in developing organs, remains an important question. Numerous studies have shown that fish oil supplements increase plasma and RBC 20:5n-3 and 22:6n-3 (1). Levels of 22:6n-3 were also higher in the breast milk and in the RBC lipids of breast fed infants whose mothers followed omnivorous rather than vegetarian diets (45). Studies with the piglet support others in demonstrating that dietary n-3 fatty acid deficiency leading to tissue 22:6n-3 deficiency is accompanied by low plasma and RBC 22:6n-3 (1). The results of studies with these animals, however, also show that diet-related differences in neither plasma nor RBC 20:4n-6 or 22:6n-3 necessarily predict differences in brain or retina in animals fed diets adequate in 18:3n-3 or containing n-3 LCP.

The decrease in n-6 and n-3 LCP in premature infants between birth and the start of breast milk or formula feeding has been recognized (1,37,40). Whether or not the postnatal decrease during parenteral nutrition is due to oxidation of 18:2n-6 and 18:3n-3 for support of vital metabolic functions during periods of inadequate energy intake (1), delay in administration of 18:2n-6 and 18:3n-3 (27), inappropriate content or balance of 18:2n-6 and 18:3n-3 in parenteral lipid emulsions (46,47), or immature desaturase activities in the infant born before term is unclear. It is clear, however, that infants who receive no intravenous lipid, formula or breast milk during the first days after birth (27) will mobilize tissue n-6 and n-3 fatty acids, probably to meet the energy needs of obligatory metabolic and physiological functions. Whether or not this results in subsequent higher n-3 fatty acid requirements may be worth consideration, particularly since the results of studies here have found that neither expressed breast milk nor formulas lacking 22:6n-3 were able to restore circulating 22:6n-3 levels of 2-6-wk-old premature infants to levels found at birth or in cord blood of infants of equivalent post-conceptional age (1).

Results of clinical studies have been presented and show that levels of 22:6n-3 in the plasma and RBC phospholipids of infants change after birth to reflect the differences in the amount of 22:6n-3 in the milk or formula diet. Thus, levels of 22:6n-3 decrease in infants fed formulas, in which the only n-3 fatty acid is 18:3n-3, but remain relatively constant in infants fed breast milk containing 22:6n-3. The decrease in 22:6n-3 of formula fed infants occurs in the order of plasma phospholipid, followed by RBC PC and then the RBC PE, reflecting exchange of the RBC fatty acids with the plasma and the constraints to full equilibration imposed by the specificity of the RBC acyltransferase reactions. Studies in term gestation piglets fed during the usual suckling period with similar formulas to those used in clinical studies have shown adequate fatty acid desaturation-elongation of 18:2n-6 and 18:3n-3 in organs, which cannot be reliably predicted from analysis of circulating lipid fatty acids. The dietary n-3 fatty acid requirement in the piglet for normal assimilation of 22:6n-3 in the brain and retina is >0.3% and <1.7% diet kcal as 18:3n-3. Requirements for n-3 fatty acid can also be met in this species with about 0.3% diet kcal as 20:5n-3 and 22:6n-3, emphasizing the higher biological activity of dietary C_{20} and C_{22} n-3 fatty acids as compared to 18:3n-3.

Results of studies in the preterm infant suggest that dietary 18:3n-3 may be oxidized for energy, and thus not an efficacious precursor for synthesis of 22:6n-3. Reasons for this may include possible low desaturase enzyme activity, early negative energy balance, delayed intravenous lipid administration, subsequent rapid growth and the possible need to restore depleted tissue 22:6n-3 pools. The available information suggests that the n-3 requirements of preterm infants may be higher than for term infants, and may not be adequately met by dietary 18:3n-3.

Essentiality of Dietary ω3 Fatty Acids for Premature Infants: Plasma and Red Blood Cell Fatty Acid Composition[1]

Dennis R. Hoffman and **Ricardo Uauy***
The University of Texas Southwestern Medical Center, Department of Pediatrics and The Human Nutrition Center, Dallas, Texas 75235-9063

Pre-term infants, that are not breast-fed, are deprived of vital intrauterine fat accretion during late pregnancy and must rely on formula to obtain fatty acids essential for normal development, particularly of the visual system. Preterm infants (30 wk postconception) receiving human milk were compared to infants given one of the following formulae: Formula A was a commercial preterm formula with predominantly 18:2ω6 (24.2%) and low (0.5%) 18:3ω3; Formula B was based on soy oil and contained similar 18:2ω6 levels (20%) and high 18:3ω3 (2.7%); Formula C was also a soy oil-based formula (20% 18:2, 1.4% 18:3) but was supplemented with marine oil to provide ω3 long-chain polyunsaturated fatty acids (LCP) at a level (docosahexaenoic acid, DHA, 0.35%) equivalent to human milk. At entry (10 days of age), the fatty acid composition of plasma and red blood cell (RBC) membrane lipids of the formula groups were identical. By 36 wk postconception, the DHA content in lipids of group A was significantly reduced compared to that in the human milk and marine oil formula groups. Omega-3 LCP results were further amplified by 57 wk with compensatory increases in 22:5ω6 in both plasma and RBC lipids. Provision of 2.7% α-linolenic acid in formula group B was sufficient to maintain 22:6ω3 levels equivalent to those in human milk-fed infants at 36 wk but not at 57 wk. Effects on the production of thiobarbituric acid reactive substances and fragility of RBC attributable to the marine oil supplementation were negligible. The results support the essentiality of ω3 fatty acids for preterm infants to obtain fatty acid profiles comparable to infants receiving human milk. Formula for preterm infants should be supplemented with ω3 fatty acids including LCP.
Lipids 27, 886–895 (1992).

Since animals lack the desaturating enzymes (1,2) necessary to form the ω6 and ω3 series of fatty acids (FA), they must rely on plant sources to obtain the parent essential fatty acids (EFA). Animal tissues are capable of further elongating and desaturating the parent EFA, linoleic acid (18:2ω6) and α-linolenic acid (18:3ω3), generating a family of long-chain polyunsaturated fatty acids (LCP) of each respective series. Alternatively, dietary LCP may be provided to infants directly from sources such as breast milk, marine oils or egg phospholipids.

The functional and structural roles of specific long-chain fatty acids are being increasingly recognized. Synthesis of eicosapentaenoic acid (EPA, 20:5ω3) from α-linolenic acid in animals provides a precursor for series-3 prostaglandins which may suppress some effects of the series-2 prostaglandins originating from ω6 FA by limiting their production. Although the actions of EPA may be beneficial in pathological conditions, concern persists as to the safety of limiting the action of arachidonate-derived eicosanoids in infants. Docosahexaenoic acid (DHA, 22:6ω3) may provide a structural micro-environment in the membrane that influences important membrane functions such as ion or solute transport, receptor activity or enzyme action (3,4). The enrichment of DHA in retina and neural tissues (5,6) may reflect a unique and critical role for this ω3 LCP in visual function. Although the essentiality of ω6 FA in the diet has long been recognized, only recently have studies focused on the more subtle biochemical and functional effects of dietary ω3 FA deficiency. The highly unsaturated nature of DHA may be responsible for the observed effects of ω3 FA deficiency on the function of developing brain and retina (3,7). Wheeler *et al.* (8) demonstrated dramatic enhancement of both a- and b-waves of electroretinograms from rats fed dietary supplements of ω3 FA compared to fat-free diets or supplementation with only ω6 FA. Neuringer *et al.* (9) reported visual acuity impairments of up to 50% in newborn rhesus monkeys receiving safflower-based diets deficient in ω3 FA pre- and postnatally compared to controls given a soybean oil-based diet. These primates have depressed levels of DHA in plasma phospholipids at birth and nearly undetectable amounts at 12 wk of age (10). These visual and neural derangements may also occur in human infants; however, evidence of FA status in the brain presently must rely on the direct correlations of brain and red blood cell (RBC) lipid FA distribution found in rat and primate studies (9,11).

During fetal growth in the human, accretion of C_{18}-EFA is not linear but is approximately 400 mg of ω6 and 50 mg of ω3 EFA per kg of body weight deposited daily during the last trimester of gestation (12) and continues postnatally in brain tissue (13). However, a preterm infant born at less than 34 wk will be deprived of this critical period of intrauterine lipid accretion and thus, is dependent on diet to fulfill its EFA requirements. Although formula supplementation with ω6 and ω3 EFA (*i.e.*, 18:2ω6 and 18:3ω3) may be beneficial (14), evidence for a limited FA desaturase activity (15) indicates that LCP such as arachidonic acid (16) and DHA (17,18) may also be required by the low-birth-weight infant.

Preterm infants fed their own mother's milk receive a typical intake of 140 mg ω3 FA/kg/d including 45 mg ω3 LCP/kg/d (19), thus meeting the requirements for neural tissue and whole body EFA accretion. Preterm infants given commercial formula receive less α-linolenic acid and elevated linoleic acid compared to breast-fed infants. This relative excess of 18:2ω6 may limit the formation of ω3

Abbreviations: ANOVA, analysis of variance, DHA, docosahexaenoic acid (22:6ω3); EFA, essential fatty acid(s); EPA, eicosapentaenoic acid (20:5ω3); FA, fatty acid(s); HM, human milk; LCP, long-chain polyunsaturated fatty acid(s); MCT, medium-chain triglycerides; RBC, red blood cell(s); TBARS, thiobarbituric acid reactive substances.

LCP in cell membranes (20–22) and blood lipids (11,17,18) because the Δ6 desaturase shared by both series of FA is subject to substrate inhibition (1). Typical premature infant formulas available up to 1987 (when the study commenced) had a low content of α-linolenic acid and no ω3 LCP. Thus, we considered the preterm infant at risk for ω3 LCP deficiency because biosynthesis is limited and formula diet supply was insufficient to meet the needs of the developing visual and neural systems (23).

The purpose of the present study was to evaluate the potential effects of ω3 FA deficiency in very-low-birthweight human infants by studying functional and biochemical indicators of ω3 FA status. The FA composition of plasma and RBC lipids of human milk-fed infants and three formula-fed groups receiving different EFA and LCP supplementation are reported herein. A secondary objective included the evaluation of RBC membrane peroxidation and resistance to hemolysis in the four diet groups. Interim visual function results for the infants under study have been recently published (18).

MATERIALS AND METHODS

Subjects. Ninety-five newborns with body weights of 1000–1500 g, who received enteral feedings but were free of major neonatal morbidity by day 10 of life, were eligible for the study. Twelve infants receiving breast milk served as controls for the study. The human milk (HM) fed group (supplemented with Enfamil Fortifier, Mead-Johnson, Evansville, IN) received ⩾75% of their intake as HM up to 36 wk postconceptional age (usual discharge age); if mothers were unable to fully provide HM for a brief period (<48 h), formula C (see below) was used to supplement their feeding. The remaining 83 infants were randomly assigned to three formula groups varying in EFA. Experimental formula feedings began at day 10 of life and continued until 57 wk postconceptional age (*i.e.*, equivalent to 4 mon postterm). Further description of inclusion and exclusion criteria related to the study cohorts have been previously described (18).

Diets. Formula A corresponds to the fat composition of Enfamil Premature (Mead-Johnson Bristol-Myers Co., 1987 formulation) based on a medium-chain triglyceride (MCT)/coconut/corn oil mix and was low in all ω3 FA. Formula B, based on MCT/coconut/soy oil, was adequate in 18:2ω6, enriched in 18:3ω3 but contained no ω3 LCP. Formula C, based on MCT/coconut/soy oil, was enriched with ω3 LCP by addition of marine oil (winterized, deodorized, stabilized menhaden oil provided by Zapata-Haynie Co., Reedville, VA) and was thus comparable in content of ω3 LCP to preterm human milk. After 36 wk, respective full-term formulae of similar EFA composition were given. The diet formulations were specially prepared for this study by Mead Johnson Nutritional Division; the FA compositions are presented in Table 1. The macronutrient composition of formulas A, B and C consisted of protein, 2.4 g/dL; carbohydrate, 8.9 g/dL; and fat, 4.1 g/dL with varying proportions of ω3 FA but similar ω6 FA content. The vitamin and mineral content of the preterm and full-term milk formula met the recommendations of the American Academy of Pediatrics for low-birth-weight neonates and full-term infants, respectively (24). The tocopherol content was at least 2 mg per g unsaturated FA to ensure stability of the LCP in the formula for about 24 mon. FA peroxidation analysis confirmed that this objective was attained.

Fatty acid analysis. The composition of FA in total plasma and total RBC membrane lipids was measured to assess the effect of dietary EFA on biological function and to ensure compliance. FA composition of RBC membrane lipids are correlated with changes in FA of other membranes including brain and retina and have been

[b]Formula A was based on medium-chain triglycerides (MCT)/coconut/corn oil blend, Formula B was based on MCT/coconut/soy oil blend, and Formula C was based on MCT/coconut/soy/marine oil blend. Average of triplicate determinations.

[c]LCP, long-chain polyunsaturated fatty acid(s).

related to functional effects (9,11). In addition, these lipid patterns serve as biochemical indicators of specific dietary FA supply.

Blood samples were obtained by venipuncture from a small arm vein at entry (approximately 32 wk postconception, 10 days postnatally), at 35 to 37 wk (usual discharge age) and at 57 wk postconception. Plasma and RBC were separated by centrifugation (3,000 × *g* for 10 min). RBC were washed twice with saline, and an aliquot was lysed with water prior to lipid extraction using methanol/chloroform as described by Bligh and Dyer (25). Plasma lipids were similarly extracted.

Lipid samples were analyzed immediately or stored briefly under N_2 in solvent containing butylated hydroxytoluene (0.02%) as antioxidant at −20°C until transmethylation. FA of lipids were converted to methyl esters by transesterification under N_2 with 14% boron trifluoride in methanol at 100°C for 10 min (26). FA methyl esters were stored in antioxidant-containing solvent and under N_2 at −20°C until chromatography. FA methyl esters in methylene chloride were separated and quantified using a capillary column gas chromatograph fitted with a flame-ionization detector. Analyses were done on a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) equipped with a 0.25 mm i.d., 30-m capillary column filled with SP-2330 stationary phase (Supelco, Bellefonte, PA). Helium at a flow of 1 mL/min was used as carrier gas; the split ratio was 9:1. The oven temperature was kept at 150°C for 5 min, then raised 4°/min to 220°C, stabilized at 220°C for 8 min, then raised again at 15°/min to 240°C, and finally stabilized at 240°C for 8 min. Peaks were identified by comparison with individual purified standards and standard FA methyl ester mixtures (GLC 68, PUFA2, Rapeseed oil) obtained from either NuChek Prep (Elysian, MN) or Supelco. The relative concentration of individual FA was expressed as percent of total FA equal to or greater than six carbons for diets and greater than 14 carbons for plasma and RBC membrane samples. In most instances, FA percentages of total below 0.2% have been excluded from tabulation. The FA analyses of formulae were performed by Mead-Johnson Laboratories and confirmed in our laboratory using methodologies based on procedures of the Association of Official Analytical Chemists (27). Briefly, lipids were extracted using ethanol/diethyl ether/petroleum hydrocarbon. Methyl esters were prepared as above under N_2 and extracted twice with 0.5 mL methylene chloride essentially according to MacGee and Allen (28). Recovery of short-chain FA in formulas was monitored by addition of 9:0 and 19:0 FA as internal standards (500 ng each), and evaporation steps were avoided after formation of methyl esters.

Integrated data from each gas chromatogram were filed and stored on an IBM AT computer. A customized software package was developed to allow for semi-automated identification of FA methyl esters, and accurate peak identification was verified by an experienced technician. The coded data were sorted and compiled into Lotus files for further inspection and statistical analysis.

Determination of thiobarbituric acid reactive substances (TBARS). Lipid peroxidation products (TBARS) from RBC exposed to H_2O_2 were quantitated by the method described by Cynamon *et al.* (29). TBARS were measured with and without sodium azide in the incubation mixture. Azide inhibits antioxidant enzymes (*e.g.*, catalase); thus a maximal release of TBARS is obtained. The percentage of the native TBARS concentration in RBC (− azide) divided by the maximal TBARS released (+ azide) gives a value that is normalized for individual biological variation. A high percentage value suggests a high capacity for intrinsic lipid peroxidation in the RBC membrane as has been demonstrated in vitamin E deficiency (29). Briefly, washed RBC are incubated with 0.75% H_2O_2 (+ azide, maximal TBARS) or 3% H_2O_2(− azide) for 1 h at 37°C. The reaction is terminated with 0.1 M arsenite in 2.8% trichloroacetic acid, color developed with 1% thiobarbituric acid/50 mM NaOH, and absorbancy measured at 535 nm. TBARS were quantitated by comparison to a tetraethoxypropane standard curve. Limited amounts of sample obtainable from the infants restricted the number of TBARS determinations. The "n" for the HM, Formula A, B and C groups was 7, 9, 9 and 8, respectively.

RBC fragility. The susceptibility of RBC from HM- and formula-fed infants to H_2O_2-induced hemolysis was determined according to the method described by Gordon *et al.* (30). Washed RBC were incubated at 37°C for 3 h with saline, water, and 2.4%, 8% or 10% H_2O_2. After centrifugation, released hemoglobin was measured spectrophotometrically at 540 nm. H_2O_2 values minus saline control values were divided by maximal hemoglobin release values (after H_2O_2 incubation) to give a percent of total hemolysis induced at different peroxide concentrations. The number of subjects studied was limited by the available amounts of blood.

Data analysis. Descriptive statistics were computed for all dependent variables in the analysis. Analysis of variance (ANOVA) was used to analyze the effects of the four diet groups at each of three times. Significant main effects were analyzed *post-hoc* using Newman-Keuls multiple comparison procedure with an α at 0.05. The sample size of 15 for each of the formula groups allowed us to detect a difference of 0.7 standard deviation (SD) between mean FA relative content with an α of 0.05 and a β of 0.8.

RESULTS

Characteristics of study groups. Twelve HM-fed infants and 83 formula-fed infants were entered into the study. No significant differences in birth weight, length, head circumference, gestational age or sex distribution were noted. Table 2 summarizes the main characteristics of the infants on entry and their growth throughout the study. The HM-fed infants were, however, slower in reaching 1800 g relative to the three formula-fed groups (ANOVA, $P < 0.07$). Growth, based on body weight, length and head circumference was essentially identical for the 4 groups upon completion of a 5 to 6 mon feeding regimen (57 wk postconception). Small losses (n = 3) in cohort population between entry and 36 wk (discharge from nursery) were due to illnesses which interfered with feeding regimens. One subject developed necrotizing enterocolitis, one had patent *ductus arteriosus* requiring surgery and another had feeding intolerance with feeding suspended for more than 24 h. However, there was a significant attrition of subjects during the 4–5 mon out-patient follow-up despite monthly appointments and direct involvement of the research nurse in promoting their return through repeated

TABLE 2

Characteristics of Study Subjects

Variable	Human milk	Formula A	Formula B	Formula C	ANOVA F	ANOVA P

[a]The number of measurements (n) for each group was: Human milk, n = 12; Formula A, n = 25; B, n = 28; C, n = 30; F, follow-up; P, preterm; ANOVA, analysis of variance.

[b]Mean ± SD.

[c]Significantly different from formula groups using *post-hoc* Newman Keuls, $P < 0.05$.

[d]The number of measurements (n) for each group was: Human milk, n = 9; Formula A, n = 16; B, n = 18; C, n = 16.

phone calls. More than one-third of the patients did not complete the out-patient follow-up phase of the study.

Fatty acid analysis. Upon entry (10 d postnatally), the FA profiles for the total plasma and RBC lipids of the four cohorts were similar as shown in Tables 3 and 4. A notable exception was the elevated monounsaturated FA, primarily 18:1ω9, present in the plasma lipids of the HM-fed infants due to the higher concentration of oleic acid in HM received by these infants before the onset of the study. Similarly, the higher concentration of linoleic acid (18:2ω6) received by formula-fed infants prior to the study was reflected in their plasma lipids compared to that of the HM-group. In contrast, only slight differences were found for the 18:1 and 18:2 contents in the RBC lipids of the HM-group compared to formula-fed infants. A significant elevation in the content of a typical marker for EFA deficiency, 20:3ω9, was found in RBC lipids of the three formula-fed groups compared to HM-fed infants. Clinical EFA deficiency was not a consideration in these infants as the triene/tetraene ratio (20:3ω9/20:4ω6) was well below threshold values (31,32). Even upon entry to the study, selective effects of the ω3 FA in the HM-fed group compared to the formula-fed groups were evident as a slight elevation of DHA in the plasma lipid fraction. Other FA of the ω3 series were slightly reduced in the HM-group (Table 3) including an unexplained decrease in 20:5ω3 content, although all values were within published ranges (14,16,17). No differences between the four cohorts were observed in the FA profiles (except 20:3ω9) of total RBC lipids at entry (Table 4).

At an average of 36 wk post-conception, after 4 to 6 wk on study diets, major differences were found in the ω3 FA of both plasma and RBC lipids (Tables 5 and 6). Monounsaturated FA were elevated and 18:2ω6 was reduced in the plasma lipids of the HM-fed group compared to the formula groups, similar to that found at entry. The EFA deficiency marker, 20:3ω9, also remained significantly elevated in the RBC lipids of the three formula groups. The ω6 FA, 20:2 and 22:5, were significantly elevated in the plasma lipids of low ω3 FA group receiving Formula A. Slight enrichment of the other ω6 FA was evident in both plasma and RBC lipids of infants fed Formulas A and B. The order of mean values in ω3 FA concentrations in plasma and RBC lipids was generally: Formula C = HM > Formula B > Formula A. An important enrichment was observed in the DHA content of the plasma and RBC lipids of the infants receiving the diets containing ω3 LCP, HM and Formula C. Of additional interest were alterations in the end product/precursor ratios for both ω6 and ω3 FA desaturation pathways at this time point. Since the 18:2ω6, 18:3ω3 and 22:6ω3 contents vary in the four diets, a true comparison of metabolic conversion is confounded; however, similar 20:4ω6/18:2ω6 ratios for all diets in both plasma and RBC lipids suggests that metabolism of the ω6 series was unaffected by diet FA composition. In contrast, the ω3 FA conversion ratio (22:6ω3/18:3ω3) was significantly reduced in plasma and RBC lipids of infants fed Formula B compared to HM and Formulas A and C. However, interpretation of this ratio is complicated by the high proportion of 18:3ω3 in this formula.

Results of FA analysis from infants at 57 wk postconceptional age, receiving diets for 5–6 mon, presented very little difference in the monounsaturated FA of either plasma or RBC lipids (Tables 7 and 8). Despite the fact that all formulas contained a greater percentage of saturated FA (62–67%) than in HM (45%), both plasma and RBC lipids from HM-fed infants were enriched in saturates compared to formula groups, particularly the corn oil-based Formula A group. Of additional interest, the plasma and RBC lipid FA distributions of the HM- and Formula C-fed groups were remarkably similar, yet the ω6 EFA (18:2ω6) compositions of these two diets varied markedly, 12.7% *vs.* 20.4%.

In Formula A and B groups, the 18:2ω6, 22:5ω6 and 22:4ω6 content in plasma and RBC fractions were comparable but differed from that of the two groups receiving ω3 LCP (Formula C and HM). Studies of ω3 FA dietary enrichment in rats specifically implicate an inhibition of Δ6 desaturase as leading to a reduction of ω6 LCP in serum lipids (33). These observations are confirmed in long-term human infant studies (34). The ω3 FA composition of plasma and RBC lipids were lowest in the Formula A-fed group, intermediate in Formula B infants and essentially equivalent for the HM and marine oil (Formula C) groups as found at 36 wk. Similarly, a reduction in the ω3 product/precursor ratio (22:6ω3/18:3ω3) was found for

[b]Sum of [number of double bonds for each fatty acid (FA) × % of each FA].

Formula B infants. Group differences in 20:3ω9 were no longer significantly different by 57 wk postconception.

The ratio of end-products of the ω3 (DHA) and ω6 (DPA) FA desaturation (namely, 22:6ω3/22:5ω6, DHA to DPA) have been compared for each dietary regimen as a measure of the dietary ω3 FA sufficiency (Fig. 1). This ratio of sufficiency after 36 wk was significantly elevated in RBC total lipids of infants receiving the HM and marine oil diets (Formula C) relative to infants receiving the two formulas lacking in ω3 LCP (A and B). At 57 wk, the sufficiency ratios in HM- and Formula C-fed infants were nearly identical and both were significantly elevated above that of the corn (A) and soy (B) oil formulas. At 36 wk, the infants receiving α-linolenic acid-rich Formula (B) were able to maintain their 22:6ω3 at a level equivalent to the HM and marine oil (C) groups (Tables 5 and 6); however, the balance of ω3 to ω6 LCP was reduced. By 57 wk, the infants receiving 2.7% α-linolenic acid (Formula B) were unable to synthesize sufficient 22:6ω3 and a compensatory elevation in 22:5ω6 was evident from the ratio. The 22:6ω3/22:5ω6 ratio in total plasma lipids paralleled that of the RBC lipids at 36 and 57 wk.

Lipid peroxidation and RBC fragility. The lipid peroxide products, TBARS, were measured in the RBC of the four study groups (Table 9). The native TBARS concentration was measured in RBC after 3% H_2O_2 treatment. Maximal release of TBARS from RBC was determined after treatment with 0.75% H_2O_2 and azide, to block antioxidant enzymes. Native TBARS concentrations (− azide) in the HM- and formula-fed groups were essentially identical whereas the total TBARS concentrations (+ azide) generated by the LCP-enriched groups (HM and Formula C) were not significantly greater than in infants receiving formulas A and B lacking ω3 LCP. The trend to higher values may reflect the greater unsaturation in these formula groups. The lower percentage of maximal TBARS release in the LCP-enriched groups may reflect a lower potential for lipid peroxidation in the RBC membranes due to higher antioxidant contents of these diets. In a *post-hoc* analysis combining the two ω3 LCP supplemented groups (Formula C and HM) as compared to the combined Formulas A and B groups, the difference becomes significant, $P < 0.05$.

No significant (ANOVA, $P < 0.05$) differences in the fragility of the RBC membranes was found between diet groups when RBC were treated with 2.5% or 8–10% H_2O_2. The mean ± SE percent hemolysis observed with 2.5% H_2O_2 for groups receiving Formula A (n = 6), B (n = 8) and C (n = 6) were 5.5 ± 0.9, 11.3 ± 2.2, and 8.1 ± 2.5%, respectively. The percentages of hemolysis when RBC were treated with 8 to 10% H_2O_2 were 9.1 ± 2.2, 11.5 ± 4.2 and 14.9 ± 2.2%, respectively for the three formula groups.

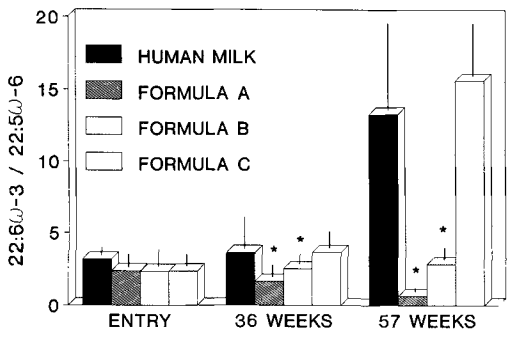

FIG. 1. Ratio of end products of ω3 and ω6 fatty acid (FA) metabolism (22:6ω3/22:5ω6) in red blood cells (RBC) total lipids. The 22:6ω3/22:5ω6 ratios are given for entry of infants into study (10 d postnatal age), 36 wk postconceptional age (~5 wk on study diets), and 57 wk postconceptional age (~6 mon on diets). See Materials and Methods for formula description. *Values are significantly different from other values by analysis of variance, $P < 0.001$. Bars and posts are means ± SD.

DISCUSSION

This study confirms previous observations that dietary EFA composition affects the relative content of ω3 and ω6 LCP in plasma and RBC lipids in infants (16,35,36) and supports an essential role for ω3 FA for premature infants. The corn-oil based formula (Formula A) is associated with important compositional changes of plasma and RBC lipids within a few weeks of study. The decreased content of DHA and elevation of 22:5ω6 suggest that ω3 deficiency exists in this group. The effects become more pronounced at 57 wk. The soy oil-based formula (Formula B) provides sufficient α-linolenic acid; however, infants fed this formula had a lower DHA content in plasma and RBC at 57 wk than those given HM or Formula C. These results suggest that despite the enhanced provision of substrate for Δ6 desaturation and a low ω6 FA/ω3 FA ratio in formula, provision of pre-formed ω3 LCP in the infants' formula diet is necessary to achieve a lipid profile comparable to that in HM. The supplementation of the soy oil formula with marine oils provides the ω3 LCP to obtain a FA profile in plasma and RBC lipids

TABLE 9

Thiobarbituric Acid Reactive Substances in Red Blood Cells (RBC) of Infants on Study Diets at 57 Wk Postconception[a]

[a]HM, human milk. TBARS, thiobarbituric acid reactive substance. Abbreviations as in Table 3.

close to that in the human milk-fed group. Although the marine oil-enriched formula contains an EPA content in excess of DHA, this relationship is not reflected *in vivo* in plasma or RBC lipids. This excess of ω3 FA in Formula C appears to decrease the arachidonic acid content of RBC membranes after several months of feeding but not after 4–5 wk.

The functional implications of these findings are not the subject of this report, but it is relevant to indicate that the FA compositions of plasma and RBC in these infants are significantly correlated with measures of retinal function and visual acuity maturation as we have previously reported (18,37,38). The small nonsignificant effects on indices of lipid peroxidation and RBC fragility indicate that this level of marine oil supplementation is not associated with major adverse effects on RBC membranes.

The purpose of this study was to evaluate the potential alternatives for supplementing preterm infant formulas with sources of ω3 FA. The comparison of the soy and soy/marine oil blends was included since there are questions as to the capacity of low-birth-weight infants to elongate and desaturate α-linolenic acid. A recent study of low-birth-weight infants (14) suggests that α-linolenic acid is sufficient to achieve an adequate DHA content in plasma and RBC phospholipids. Our data confirm this finding at 36 wk postconception; however, by 57 wk, α-linolenic acid is insufficient to maintain DHA levels in plasma and RBC lipids comparable to those found in infants fed ω3 LCP. The use of marine oils as a source of ω3 LCP in infant formula has been debated for some time. Previous studies have evaluated the use of marine oil supplements (17) and egg phospholipids (16) as sources of ω3 LCP over several weeks of feeding. This current study evaluated the inclusion of marine oil ω3 LCP into formula for a prolonged period of time and documented the possibility of maintaining DHA levels postnatally. In addition, significant associations between low DHA levels and delays in both retinal electrophysiologic and visual acuity development (18,37,38) were found when infants are provided formula lacking ω3 LCP. The possibility of accumulation of EPA has been raised by some investigators yet our data confirm studies (39) in the ω3 deficient chick indicating that there is active conversion of EPA to DHA and the modest accumulation of EPA in plasma and tissue lipids that we observed is without significant adverse effects. Our results suggest that EPA is metabolized to DHA since the ratio of EPA to DHA in Formula C was 2 to 1 in comparison to that in the infant's RBC lipids of 1 to 3.2. This conclusion is further supported by ω3 and ω6 FA product/precursor ratios for the Δ4 desaturase (*i.e.*, 22:6ω3/22:5ω3 and 22:5ω6/22:4ω6). The ratios for desaturation of the ω3 and ω6 series of FA were similar for the HM- and marine oil-fed infants (1.78 and 0.18 for HM *vs.* 2.04 and 0.20 for Formula C, respectively) and agree with the results of Koletzko *et al.* (16).

Interpretation of product/precursor ratios as indices of desaturase activity is complicated by inclusion of either product or precursor FA in the study diets. However, careful evaluation of these indicators of desaturase activity would suggest that sufficient LCP can be produced by an active Δ4 desaturase, but production of its precursor by Δ6 desaturation may be the limiting factor. A similar conclusion was reached by Koletzko *et al.* (16). This restriction is readily avoided by a supply of LCP in the infants' diet.

The decrease in arachidonic acid in RBC of the marine oil group compared to the corn and soy oil groups observed at the 57 wk follow-up (Table 8) is of interest since Carlson *et al.* (34) have reported that low arachidonic acid levels may be associated with poor growth in formula-fed preterm infants. Although the RBC arachidonic acid content at 57 wk postconceptional age was reduced in the marine oil group, no differences among the three randomized groups in weight, length and head size were noted. The adverse effects on growth may not become evident unless prolonged supplementation is employed as in the study of Carlson and colleagues (34) where infants were fed marine-oil containing formula for 9 mon. The long-term safety of using marine oil in formulae and the optimal duration of ω3 LCP supplementation should be addressed by future studies. The potential need for arachidonic acid supplementation of formulas that have soy oil or marine oil sources added is supported by our data and is in accordance with the known competition of both series of EFA as substrates for the desaturases (1). If human milk is considered as the model for EFA supply in early life, both ω3 and ω6 LCP should be provided by the formula. Formulas used to feed premature infants should reflect the newly acquired knowledge on the EFA needs of this group of infants at known risk for improper development.

ACKNOWLEDGMENTS

This work was supported in part by National Institute of Child Health and Development Grant HD 22380, United Cerebral Palsy Research Foundation UCP R 375-87 and GCRC Pediatric Subunit USPHS M01-RR0063. The authors thank the Mead-Johnson Nutritional Division for providing the infant formulas used in this study. We extend our appreciation to Joy Burns, Helen Price and Vickey Thomas for expert technical assistance, to Dawn Waidelich, R.N. and Mary Nickell, R.N. for exhaustive nursing support, and to Mary Blanchett for careful typing of this manuscript.

Thirty-four premature infants who were appropriate for gestational age and weighing less than 1500 g at birth were fed "preemie" SMA-24 formula, "preemie" SMA-24 formula manufactured to contain C_{20} and C_{22} ω6 and ω3 fatty acids (LCPE-SMA), or expressed milk (EBM). Blood samples were drawn from a small arm vein during the first week of life and after 28 days of feeding. The fatty acid content of plasma phospholipids was determined. Infants fed SMA-24 had a high content of 18:2ω6 in plasma phospholipids. Feeding LCPE-SMA normalized plasma phospholipid levels of C_{20} and C_{22} ω6 and ω3 fatty acids to be similar to levels of C_{20} and C_{22} ω6 and ω3 fatty acids found in infants fed EBM, and significantly higher than characteristic levels for infants fed SMA-24. Feeding LCPE-SMA or EBM results in a balanced incorporation of C_{20} and C_{22} ω6 and ω3 fatty acids into phospholipids derived from the liver or perhaps the small intestine. ***Lipids 27*, 896-900 (1992).**

Metabolism of long-chain polyunsaturated fatty acids derived from 18:2ω6 and 18:3ω3 by chain elongation-desaturation is essential for synthesis of complex structural lipids, leukotrienes, thromboxanes and prostaglandins. These essential fatty acids are required for normal function in developing tissues and appropriate maturation of a wide variety of physiological processes. During development, fetal accretion of long-chain metabolites of ω6 and ω3 fatty acids may result from maternal or placental synthesis and transfer or, alternatively, from the metabolism of 18:2ω6 and 18:3ω3 to longer chain homologues by the fetus (1). After birth the infant must synthesize or be fed the very long-chain polyunsaturated fatty acids of C_{20} and C_{22} type derived from 18:2ω6 and 18:3ω3. Limitation of this metabolic capability would be most critical to very low birth weight infants due to very low fatty acid reserves.

Metabolism of ω6 and ω3 fatty acids utilizes the same enzyme system and is competitive. When levels of dietary ω3 and ω6 C_{18} fatty acids are altered, the levels of metabolites of these precursor fatty acids change in specific brain membranes, influencing membrane lipid dependent functions (2-5). A diet balanced in very long-chain ω3 and ω6 fatty acids may increase brain membrane ω3 fatty acid content when 20:5ω3 is fed, while decreasing membrane fatty acid content of the ω6 series of competing fatty acids. As 20:4ω6 is quantitatively and qualitatively important to brain phospholipid (6), significant reduction in brain levels of 20:4ω6 may be less than optimal.

TABLE 1

Long-Chain Polyunsaturated Fatty Acids Required for a Physiological Intake Similar in Composition to Human Milk and That Provided by Modified SMA

Fatty acids	Range	Breast milk[a]	Modified SMA
C_{20} and C_{22} ω6	0.13 to 5.6%	1.0 ± 0.2	0.81
C_{20} and C_{22} ω3	0.013 to 3.3%	0.7 ± 0.2	0.7
Ratio of C_{20} and C_{22} ω6 to ω3		1.4 ± 2.0	1.14
18:2ω6		12 ± 4.3	14.1
18:3ω3		0.9 ± 0.4	1.6

[a]Ref. 6.

Human milk is generally believed to provide an optimal balance of fatty acids, particularly of essential fatty acids (6-8). During fetal development, C_{20} and C_{22} ω6 and ω3 fatty acids are utilized in the synthesis of new tissue membranes (6,8,9). Research has emphasized the need to provide these essential membrane components by maintaining the proper balance of 18:2ω6 to 18:3ω3, and by addition of C_{20} and C_{22} fatty acids of either ω6 or ω3 type to infant formula (6,8-12). With one exception (12), previous studies have supplemented low birth weight infant formulas with only C_{20} and C_{22} ω3 fatty acids derived from fish oils (11,13,14). When low birth weight infants have been fed formulas supplemented with C_{20} and C_{22} ω3 fatty acids, these fatty acids are apparently incorporated into red blood cell membrane lipids (11,13) and are probably incorporated into brain and other tissues, but the degree to which these fatty acids alter neutral membranes when fed in the diet as compared to controls is not known (15).

Infant formulas presently marketed do not contain longer chain polyunsaturated homologues of 18:2ω6 or 18:3ω3. We have suggested that these longer chain homologues should only be incorporated into low birth weight infant formulas in a manner and composition reflecting the consistent overall fatty acid balance found in the fatty acid mixture present in human milk (8,9; Table 1). Supplementation of feeds with only very long-chain ω3 fatty acids, although easily achieved, may not be desirable because it would reduce synthesis, metabolism and incorporation of 20:4ω6 into membrane phospholipids. Testing of balanced fat mixtures containing both ω6 and ω3 very long-chain polyunsaturated fatty acids is thus cogent, given the lack of information on neonatal ability to chain elongate and desaturate essential fatty acids. The present paper reports the effect of feeding low birth weight infants a triglyceride mixture providing a balanced fatty acid profile with a C_{20} and C_{22} ω6 and ω3 fatty acid content characteristic of human milk.

MATERIALS AND METHODS

All procedures concerning use of human subjects in this study were approved by the Human Experimentation

Review Committee of the University of Alberta Hospitals (Canada).

Study population and feeding design. Thirty-four premature infants who were appropriate for gestational age and weighing less than 1500 g at birth were selected from admissions to the Neonatal Intensive Care Unit of the University of Alberta Hospitals. Informed written parental consent was obtained for all infants. Infants were divided, based on maternal preference, into human milk or formula groups. Infants were allocated into the formula groupings of with or without added ω6 and ω3 long-chain polyunsaturated fatty acids on a randomized basis. All infants were considered healthy upon enrollment. Infants included were those receiving oral nasogastric feedings within the first day of life and who were medically stable, without major respiratory or metabolic illness or severe congenital malformations. Gestational age was confirmed by Dubowitz score (16) and, in most cases, by early ultrasound dating.

Infants studied (Table 2) attained full feeds of 150 mL/kg/day by day 5 *postpartum*. Seven male and five female infants received their own mothers' milk up to 180–200 mL/kg/day (Group 1). Preterm expressed mothers' milk (EBM) was prepared in the hospital or at home, frozen, and delivered to the neonatal unit within 24 h. Five male and five female infants were fed "preemie" SMA-24 formula (SMA-24, Group 3), and six male and six female infants received "preemie" SMA-24 formula manufactured to contain C_{22} and C_{22} ω6 and ω3 fatty acids (LCPE-SMA, Group 2; Table 2). Infants receiving formula were fed apparent rates of energy intake approximately similar to those for infants fed human milk. All infants were strictly maintained on their particular feeding protocol. Introduction of any other source of fat intake resulted in loss of that infant from the study. Infants requiring transfusions were excluded from the study. Infants received vitamin (Tri-visol) and mineral supplements given routinely in the neonatal intensive care unit. Supportive therapy was provided as required in the form of aminophylline, phototherapy and, in some cases, oxygen. Infants were nursed predominantly on their sides and in an elevated position, in temperature controlled incubators at thermoneutral temperature with 60% humidity.

SMA-24 (Wyeth-Ayerst Laboratories, Radnor, PA) was chosen because it provides a fatty acid profile similar to that of human milk. A second formulation (Wyeth-Ayerst) of similar overall composition was prepared to contain an appropriate level of C_{20} and C_{33} ω6 and ω3 fatty acids (Table 3). This formulation was made by incorporating a fish oil triglyceride preparation containing C_{20} and $C_{22}2$ ω6 and ω3 fatty acids into the fat blend. The balance between C_{20} and C_{22} ω6 to C_{20} and C_{22} ω3 fatty acids was approximately 1.14 (see Tables 1 and 3).

[a]As in footnotes [c] and [d] of Table 2.

Crown-heel length and occipitofrontal head circumference were measured on entry to the study and weekly. Body weight measurement was also made on entry, and daily weight was recorded for the first five weeks. All anthropometric measurements were made by one research nurse with an assistant.

A blood sample (1.0 mL) was obtained from each infant during the first week of life and after four weeks of feeding. Blood samples obtained from a small arm vein were immediately placed in ice, then centrifuged to separate plasma from blood cells. Both plasma and red blood cells were stored at −70°C under nitrogen until analysis.

Lipid analysis. Lipids were extracted from erythrocytes (17) and plasma (18), and antioxidant (1–2 μg of 2-ethoxyquin) was added to each sample. Internal standards (15:0, 17:0 and 19:0 as phosphatidylcholine, triglyceride and cholesteryl ester) were added to quantitate fatty acid content of each lipid class. Phospholipids were separated and detected under UV light with appropriate standards (19). Individual lipids were scraped from plates and quantitatively analyzed for fatty acid content.

Phospholipid fatty acid methyl esters were prepared using 14% (wt/vol) BF_3/methanol reagent (20). Fatty acid methyl esters were separated and quantitated by automated gas-liquid chromatography (GLC; Vista 6000 GLC and Vista 654 data system; Varian Instruments, Georgetown, Ontario, Canada). Chromatography was performed

using a fused silica BP20 capillary column (25 m × 0.25 mm i.d.; Varian; ref. 5). The analytical conditions used separate all *cis* saturated-, mono-, di- and polyunsaturated fatty acids from C_8 to C_{24} carbons long.

Statistical analysis. Statistical analyses included a preliminary one-way analysis of variance followed by multiple regression analysis, and analysis of variance to assess effect of feeding and postnatal age. Differences were determined using a multiple range comparison (21).

RESULTS AND DISCUSSION

In North America, marketed infant formulas do not contain the longer polyunsaturated homologues of 18:2ω6 and 18:3ω3. Balanced inclusion of these longer chain homologues (Table 1) in formula fat blends has proven problematic as sources of oil high in C_{20} and C_{22} ω3 fatty acids contain little or no 20:4ω6 or other C_{20} and C_{22} ω6 fatty acids. Thus, dietary studies have emphasized addition of fish oil, MAXEPA (11,14). Most marine oil sources can be ruled out because they are too high in ω3 fatty acids. Fresh water cat fish, however, is a source of high quality oil that contains a close to optimal balance of very long-chain polyenoic essential fatty acids after triglyceride purification. When combined with appropriate levels of other triglyceride components of SMA-24, an appropriate fatty acid balance was achieved (modified-SMA; Table 3). This modified SMA formula contained approximately one-third to one-half the 20:4ω6 level typical of human milk, significant levels of other C_{20} and C_{22} ω6 fatty acids, an approximately equal balance between 20:4ω6 and 20:5ω3, and an overall ratio of C_{20} and C_{22} ω6 fatty acids to C_{20} and C_{22} ω3 fatty acids of approximately 1.14 (Tables 1 and 3).

The present study was not designed to specifically measure growth in body constituents. No apparent differences were observed in birth weight, length, head circumference or gestational age between EBM and formula fed infants (Table 2). Phototherapy, sodium bicarbonate or antibiotic therapy, and oxygen requirements were similar for the three feeding groups. Clinical laboratory studies, such as acid base status, plasma and urine electrolytes, and total plasma proteins and calcium remained within normal limits. The initial sample of blood was drawn on approximately day 5 of life (Table 4), when body weight, length and head circumference were similar among the three groups of infants (Table 4). The final blood sample was drawn after four further weeks of feeding and during the fifth week of life (Table 4). By the fifth week, formula fed infants exhibited greater rates of growth in body weight than infants fed EBM (Table 4). Linear growth was not apparently different between infants fed SMA-24 and LCPE-SMA.

As expected, fatty acid analyses of red blood cell phospholipids during the first and fifth week of life indicated few differences between dietary treatment and age in fatty acid composition (data not shown). We found it difficult to conclude how the fatty acid composition of the red blood cell membrane phospholipids reflects diet and the infant's overall essential fatty acid status during this period of life.

Although the 18:2ω6 content of SMA-24 is similar to that found in human milk, a higher content of 18:2ω6 was found in plasma phospholipids of infants fed SMA-24 than in plasma phospholipids of milk-fed infants (Table 5). When the fatty acid profile of SMA was modified by incorporation of long-chain polyenoic essential fatty acids, the high level of 18:2ω6 in plasma phospholipid fraction normalized to a level similar to that found in infants fed human milk. By the fifth week of life, plasma phospholipid levels of C_{20} and C_{22} ω6 and ω3 fatty acids in infants fed LCPE-SMA were identical to those levels found in infants fed EBM, which are significantly higher than levels characteristic of infants fed SMA-24. Feeding EBM and LCPE-SMA with a balance in C_{20} and C_{22} ω6 and ω3 fatty acids resulted in similar incorporation of these fatty acids into phospholipids derived from liver or perhaps from the small intestine.

Feeding formula with a balance in long-chain polyenoic essential fatty acid similar to that of human milk (LCPE-SMA) can result in synthesis of major plasma lipid fractions with similar fatty acid content to that observed for infants fed human milk. Based on the plasma phospholipid content of C_{22} and C_{22} ω6 and ω3 fatty acids, it is apparent that the small intestine and liver of infants fed EBM or LCPE-SMA produce lipids of fundamentally different composition as compared to those of infants fed SMA-24. Whether or not tissues, such as developing brain and retina, utilize essential fatty acid constituents derived from the plasma compartment and the liver for structural membrane synthesis in a manner that also reflects similar, clearly diet-induced differences in fatty acid composition remains to be determined. Animal studies indicate that dietary intake, which produces physiological change in membrane structure and function in the intestinal mucosa and liver (22,23), also results in differences in membrane composition and transitions in functions in other tissues, including specific brain

membranes (for reviews, see refs. 2, 3, 22). Moreover, dietary fat composition has clear effects on intestinal desaturase activity (24). Whether or not such differences in function can be demonstrated for infants and are beneficial remains to be determined.

Several parameters need to be evaluated to fully evaluate if the premature infant requires nutritional support with C_{20} and C_{22} ω6 and ω3 fatty acids. First, it is clear from presently available data that feeding *vs.* not feeding very long-chain polyenoic essential fatty acids results in differences in the composition of a variety of fatty acid pools potentially available for uptake by tissues. Recent research in our laboratory indicates that the enterocyte in the brush border has desaturase activity (23) that responds by adaptation to physiological state and short-term change in diet fat intake (24). Secondly, the role of enterocyte Δ6, Δ5 and Δ4 desaturase activity in the infant's small bowel in meeting the infant's requirements for C_{20} and C_{22} ω6 and ω3 fatty acids must be examined. It is conceivable that although neural tissues may not synthesize the required C_{20} and C_{22} homologues of 18:2ω6 and 18:2ω3, the enterocyte may at some stage of life have sufficient capability to supply required chain elongated desaturated essential fatty acids. Based on differences in C_{20} and C_{22} ω6 content of plasma phospholipids between milk and formula fed infants, this stage must occur after five weeks of life. Third, definition of fatty acid pools and their dynamic turnover for uptake into neural and excitable tissues should be determined to enable provision of enrichment of C_{20} and C_{22} ω6 and ω3 constituents into the most appropriate pool for uptake. The relationship between functional tests and structural membrane composition is likely to remain tenuous as it is impossible to biopsy critical tissues. This relationship will need to be more closely established before meaningful functional assessments can be associated with differences in nutritional intake. Moreover, animal studies, while helpful, can never provide the final answer to the requirements of the preterm infant. Finally, this assessment largely ignores the potential impact of diet fat composition on the process of myelin formation in brain. Clearly, before the optimum fat composition of infant formulas can be defined, it will be necessary to determine how the level and balance between ω6 and ω3 fatty acids alters incorporation of saturated and monounsaturated fatty acids into myelin. Feeding infants LCPE-SMA results in an overall balance between C_{20} and C_{22} ω6 to ω3 fatty acids more similar to that characteristic of infants fed human milk, as illustrated by lowering 18:2ω6 and raising 20:4ω3 and 22:6ω3 content of the plasma phospholipids.

Very low birth weight (VLBW) infants (748–1390 g, n = 65) were randomly assigned to receive control or marine oil-supplemented formula when they achieved intakes >454 kJ (110 kcal)/kg/d of a formula designed for VLBW infants. Study formulas with or without marine oil were provided until 79 wk of postconceptional age (PCA), first in a formula designed for preterm infants followed by a formula designed for term infants. Infants were studied at regular intervals through 92 wk PCA. Weight, length, and head circumference were determined by standardized prodedures and normalized to the National Center for Health Statistics figures for growth of infants born at term of the same age and gender. Mean normalized weight, weight-to-length, and head circumference were greatest at 48 wk and decreased thereafter. The decline in normalized weight was greater in infants fed the marine oil-supplemented formula. Beginning at 40 wk, marine oil-supplemented infants compared to controls had significantly poorer Z-scores for weight, length and head circumference. In addition, birth order (negatively) and maternal height (positively) influenced weight and length achievement in infancy as shown previously in infants born at term.
Lipids 27, 901-907 (1992).

The purpose of this study was to compare growth in preterm infants who were randomly assigned to receive either commercially available formulas or experimental formulas (also prepared commercially) which included a low level of marine oil. The marine oil was added experimentally to test the hypothesis that membrane phospholipid docosahexaenoic acid (DHA, 22:6n-3) could be maintained in a physiological range (1,2) and the development of visual acuity enhanced (3) compared to controls. The experimental formulas provided 0.2% of total fatty acids as DHA, the amount reported in milk of American women delivering prematurely (1,4). The marine oil added to the experimental formulas also provided 0.3% of total fatty acids as eicosapentaenoic acid (EPA, 20:5n-3). This EPA concentration is higher than generally found in human milk (1,4) without regular fish (5) or fish oil (6) consumption. Together, DHA and EPA provided 0.5% of total fatty acids (approximately 0.25% of dietary energy) in the experimental formulas.

Two studies in rodents had shown that marine oil reduced weight gain during periods of rapid growth and development (7,8). In both of these studies, marine oil provided a much greater proportion of total energy than in the present infant study. On the other hand, the rodent studies were of only 2 to 3 wk duration whereas preterm infants were fed the marine oil-supplemented formula for many months. Consequently, we monitored growth in these infants to assure that growth was not adversely affected by the low levels of marine oil included in the experimental formulas. The results of this study show that low levels of marine oil supplementation reduced growth in very low birth weight (VLBW) preterm infants compared to controls beginning approximately 8 wk after feeding.

METHODS

Selection of patients. Infants selected for this study were admitted to the Newborn Center at the University of Tennessee, Memphis, TN. Although infants weighed between 748 and 1390 g at birth, they had no risk factors for poor growth other than prematurity, *i.e.,* they were not severely growth retarded *in utero* (weight less than the 5th percentile for their gestational age), and did not require long-term mechanical ventilation or gastrointestinal surgery after birth. Other exclusion criteria (intraventricular/periventricular hemorrhage > grade 2, retinopathy of prematurity > stage 2, history of maternal cocaine use) were designed to eliminate risk factors for cognitive and visual development. Infants developing problems after enrollment were replaced with another infant assigned to the same formula.

Study design. The study was designed to test the effects of marine oil-supplementation on biochemistry, visual acuity, cognition and growth in the first year of life. This paper deals with the effects on growth. Infants were eligible for enrollment when they had reached intakes of a nutrient enriched formula designed for preterm infants >454 kJ (110 kcal)/kg/d. Parental consent was obtained according to an Institutional Review Board-approved protocol, and infants were randomized to receive either the standard or the marine oil-supplemented formula. Infants were assigned a postconceptional age (PCA) in weeks by averaging the obstetric assessments of age (dates and ultrasound). If there was a discrepancy of >2 wk between these and the pediatric assessment of PCA based on physical and neurological maturity (9), all assessments were averaged.

Infants were considered study completers if they remained in the study through 57 wk PCA. A total of 79 patients were enrolled, ten to replace infants who did not complete the study through 57 wk for a variety of reasons. Four additional infants were excluded for receiving enteral nutrition other than study formulas through 57 wk. The profile of the 65 infants who completed the study is shown in Table 1. All 65 infants remained in the study through 68 wk. At 79 wk, 31 control and supplemented infants returned for followup. At 92 wk, 28 infants in each group returned for followup.

From enrollment until discharge (1800 g) infants were fed a preterm formula with or without marine oil supplementation. From discharge until 79 wk, infants received a formula designed for term infants with or without marine oil supplementation according to their original assignment. The fatty acid composition of control and experimental preterm and term formulas is shown in Table 2. Formula A and A-T were commercially available; Formula B and B-T were experimental.

Infants were studied at the following ages adjusted for early delivery: term (38 ± 2 wk PCA, mean ± SD), 2 mon (48 ± 2 wk), 4 mon (57 ± 2 wk), 6.5 mon (68 ± 2 wk), 9 mon (79 ± 2 wk) and 12 mon (93 ± 2 wk). Nutrition counseling at each visit emphasized methods for assuring that infants were fed as much formula as desired without overfeeding or underfeeding. A history of dietary intake was obtained. All except one infant consumed at least 0.72 L of formula per day through 79 wk PCA.

Reported mean energy intakes from formula (kcal/day; kcal/kg/d) were not affected by dietary assignment or gender at 48 and 57 wk PCA. At 68 wk PCA, infants consuming the marine oil-supplemented formula had significantly higher energy intakes from formula (kcal/day; kcal/kg/d) compared to infants fed standard formula (Table 3).

Measurement of growth. Infants were weighed undressed on a calibrated infant balance. Length was determined in the supine position to the nearest 0.1 cm by two individuals using an infant measuring board (Jim's Instrument Manufacturing, Inc., Coralville, IA). Head circumference was measured at the largest occipitofrontal circumference with a non-stretchable paper tape. Individual size determinations were made at each age and group data expressed as mean ± SD for a given PCA with the exception of 40 wk PCA which was interpolated from sizes at the 38 and 48 wk measurements. The growth of individual preterm infants was also normalized to that of term infants of the same gender and precise age (10) using data from the National Center for Health Statistics (Hyattsville, MD) (11) to generate percentiles for norms. The growth index generated was an approximate Z-score which indicated the SD from the fiftieth percentile (+ or −).

Statistical methods. The effects of formula on normalized first year growth were evaluated by a repeated measures analysis of variance (ANOVA) for the effects of time and marine oil supplementation (Fig. 1). A similar analysis was done for each diet-gender group to compare absolute measures of size, but this data should be interpreted with caution since the numbers of infants in each diet-gender group are not adequate to eliminate a Type II error. Preplanned comparisons between least-squares means were made using Fisher's Least Significant Difference (12). Stepwise multiple linear regression was used to determine the independent factors which affect normalized growth at each age. In addition to marine oil-supplementation (shown here to affect growth), maternal height and birth order (shown previously to affect growth in term infants, 13) were included. All statistical analyses used software from SAS Institute Inc. (Cary, NC) (14) and the mainframe computer at University of Tennessee.

RESULTS

Population of infants studied. Thirty-four control and 31 marine oil-supplemented infants completed the study. The groups were statistically similar with regard to all descriptors (Table 1) and were not at risk for poor growth. Infants with chronic lung disease (bronchopulmonary dysplasia, BPD) are known to have poorer growth (15–17). Although three of the final 65 infants were diagnosed with BPD, all of these infants were weaned from oxygen before discharge and had growth indistinguishable from their dietary group. Intrauterine growth retarded infants are also known to have poorer growth achievement in the first year of life (18). Most of the infants who completed the study (= 60) were appropriately grown (>10th percentile for gestational age), and the remaining five infants were mildly growth retarded at birth (*i.e.,* between the 5th and 10th percentile.

Weight achievement. At enrollment, all diet-gender groups had the same absolute weight (1.3 ± 0.13 to 0.18 kg, mean ± SD) (Table 4). Likewise, at the term visit (38 ± 2 wk PCA), diet-gender differences were not seen: male control 2.25 ± 0.21 kg; male marine oil-supplemented, 2.44 ± 0.41 kg; female control, 2.42 ± 0.34 kg; female marine oil-supplemented, 2.28 ± 0.20 kg (mean ± SD). However, by 40 wk, and continuing throughout infancy, infants supplemented with marine oil had lower normalized weight than those fed standard formula by Fisher's Least Squares Difference (Fig. 1A). The Z-scores depicted in Figure 1A are the most valid measure of comparison as they are adjusted for gender differences, making the number of infants per group large enough to avoid Type II errors. In addition, the Z-score is calculated for the precise age of each infant at the time of growth assessment. Although absolute and normalized weight by age, diet and gender are included in Table 4 as a basis for comparison with the data of others, they do not meet these criteria and a null hypothesis is not necessarily correct.

Length achievement. Normalized lengths were significantly lower in marine oil-supplemented infants compared to controls by 40 wk PCA ($P < 0.05$) and remained lower ($P < 0.01$) for the remainder of infancy (Fig. 1B). As with weight, the only truly valid comparison between formulas is seen in Figure 1B. The mean absolute and normalized values for length by formula, time and gender are shown in Table 5 for comparison with the data of others. Infants returning for their term visit (38 ± 2 wk PCA) were 44.1 ± 1.3, 45.6 ± 1.8, 45.4 ± 1.8 and 44.5 ± 1.0 cm long (mean ± SD; male control, male marine, female control and female marine, respectively).

TABLE 3

Mean Reported Energy Intake from Formula of Infants Fed Standard (control) and Marine Oil-Supplemented Formula at 48, 57 and 68 Wk Postconceptional Age

		48 Wk		57 Wk		68 Wk	
Formula	Gender	kcal	kcal/kg/d	kcal	kcal/kg/d	kcal	kcal/kg/d
Control	male	718	150	759	112	627	80
	female	599	129	649	108	650	90
Marine	male	599	126	712	113	764	104
	female	592	138	692	127	712	108
ANOVA[a]	formula	n.s.[b]	n.s.	n.s.	n.s.	$P < 0.04$	$P < 0.01$
	gender	n.s.	n.s.	n.s.	n.s.	n.s.	n.s.

[a]Analysis of variance. [b]Not significant ($P > 0.05$).

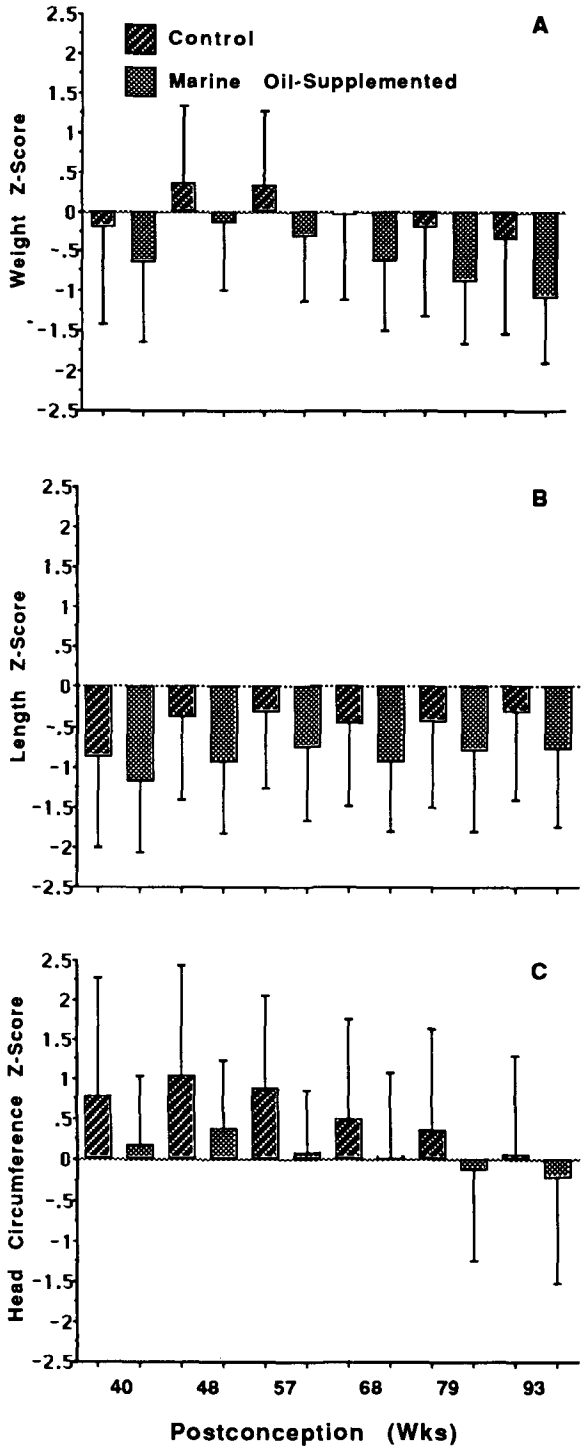

FIG. 1. Normalized growth of control and marine oil-supplemented infants at regular intervals from 40 to 93 wk postconception (mean ± SD). Individual comparisons were made between formulas using Fisher's Least Squares Difference (12). Control infants fed commercially available formulas were larger than marine oil-supplemented infants at all ages beginning at 40 wk ($P < 0.01$). The only exceptions were length at 40 wk and head circumference at 93 wk which were significant at $P < 0.05$. Analysis of variance of Z-score by formula and time: A. Weight: Formula, $P < 0.04$; time, $P < 0.001$; formula by time, n.s.; B. Length: Formula, $P < 0.08$; time, $P < 0.001$; formula by time, n.s.; C. Head circumference: Formula, $P < 0.056$; time, $P < 0.001$; formula by time, n.s.

Weight-to-length ratio. Independent of formula, the normalized weight-to-length ratio decreased significantly over time ($P < 0.0001$, Table 6). Marine oil supplementation did not affect weight-to-length ratios by ANOVA, but individual means for marine oil-supplemented infants at 79 and 93 wk PCA were lower than in the controls ($P < 0.01$). These data are not shown.

Head circumference. Head circumference Z-scores were significantly influenced by time and marine oil supplementation. Z-scores declined over time and were significantly lower in infants fed the experimental formulas compared to the standard formulas at all ages (Fig. 1C). Head circumference was the only measurement in which gender differences were seen after data were normalized to the size of term infants of the same age and gender: males had a normalized head circumference smaller than that of females at 68, 79 and 93 wk PCA (ANOVA by gender and formula, $P < 0.01$). Absolute and normalized values for head circumference by formula, time and gender are given in Table 7. As with absolute measurements of weight and length, these values are presented primarily for purposes of comparison with the data of others.

Factors affecting growth achievement. Marine oil supplementation negatively affected first year growth in these preterm infants. Previously, maternal height and birth order have been shown to affect first year growth of term infants (13). The effects of these independent variables (maternal height, birth order and marine oil supplementation) on first year growth were studied by stepwise multiple regression. Length was positively associated with maternal height, but negatively associated with marine oil supplementation; weight was negatively associated with both birth order and marine oil supplementation (Table 8).

DISCUSSION

Studies of VLBW infants cared for in neonatal intensive care centers in the late 1980s have repeatedly shown that growth in the first year of life, even when corrected for prematurity, is not equivalent to that of infants born at term. Karniski *et al.* (18) demonstrated that growth of appropriate-for-gestational age (AGA) VLBW infants appeared to be catching-up to that of infants born at term when expressed by chronological age, but not when normalized for age and gender. Georgieff *et al.* (19) also showed that VLBW infants (mean birth weight 1143 g) did not reach term-equivalent growth by 92 wk PCA, and an eight-site collaborative study of <1250 g birthweight infants concluded that normalized growth did not catch up by the 12-mon examination (20).

Infants enrolled in our study were a select group of VLBW infants without prolonged ventilator requirements or other serious illness which would limit energy intake or growth, and without evidence of chronic illness after discharge. Their parents received counseling about appropriate feeding at regular intervals during their first year at home to insure that intakes of formula were voluntary and unlimited. Growth achievement in these infants was excellent compared to published data of first year growth, *i.e.*, despite their very low birth weight (mean 1074 g), they achieved weights, lengths and head circumferences in the first year of life equivalent to much larger male and female infants (mean birth weight 1690 g)

in an eight-center survey (20). Nevertheless, infants supplemented with marine oil compared to controls had significantly lower Z-scores for weight and length by 40 wk PCA; these lower Z-scores continued throughout the first year of life. The lower normalized growth in marine oil-supplemented infants was not related to lower energy intakes compared to controls (Table 3).

Infants fed both standard and marine oil-supplemented formulas achieved weights closest to standards for infants born at term when they were 48 and 57 wk PCA. After this age, their normalized weights fell consistently to the end of infancy as has been reported by others (18,19). The decline in weight in late infancy was greater in marine oil-supplemented infants compared to those infants fed standard formulas, and appeared to be responsible for the significantly lower weight-to-length ratio seen in the supplemented compared to the control infants at 79 and 93 wk PCA.

The mechanisms by which growth of VLBW infants falls progressively farther behind that of term infants in the last half of infancy is not known. This pattern of growth is more consistent with a response to some extrinsic factor, *e.g.*, the quality and quantity of nutritional intake, than with failure to recover from the insults of the neonatal intensive care period. The mechanism by which such low levels of marine oil supplementation might influence growth in preterm infants is also not known. Marine oil has been reported to slow weight gain in rodents during periods of rapid growth (7,8). Although these rodent studies were of only two to three weeks duration, they provided more dietary energy from EPA and DHA than the 0.25% of energy fed to preterm infants in this study. We recently reported a positive correlation between arachidonic acid status and growth in VLBW infants fed standard formulas (21). Since marine oil supplementation decreased the concentration of plasma arachidonic acid further (2), it is tempting to speculate that a common mechanism related to arachidonic acid status is involved in both the decline in normalized growth of preterm infants in the last half of infancy (18,19) and the greater decline in normalized growth in infants randomized here to receive marine oil-supplemented formula compared to standard formula.

Human Mammary Gland Function at the Onset of Lactation: Medium-Chain Fatty Acid Synthesis[1]

M.L. Spear[a,*], J. Bitman[b], M. Hamosh[c], D.L. Wood[b], D. Gavula[a] and P. Hamosh[c]

[a]Division of Neonatology, Medical Center of Delaware, Newark, Delaware 19718 and Jefferson Medical College, Philadelphia, Pennsylvania 19107, [b]Milk Secretion and Mastitis Laboratory, USDA-ARS, Beltsville, Maryland 20704 and [c]Departments of Pediatrics, Physiology and Biophysics, Georgetown University Medical Center, Washington, D.C. 20007

The onset of medium-chain fatty acid synthesis in the human mammary gland was investigated. Colostrum and serum were collected from 31 healthy women and the fatty acid composition of total lipid was analyzed by gas-liquid chromatography. Although colostrum/serum ratios for most fatty acids range from 0.7–2.4, very low levels of 10:0 and 12:0 were present in serum lipids as compared to much higher concentrations of these fatty acids in colostrum lipids (colostrum/serum ratio 16.23 and 17.11 for 10:0 and 12:0, respectively). We have previously found that medium-chain fatty acid levels are very low in *prepartum* mammary secretions (6–10 wk before term delivery) but are higher and similar in colostrum of women who deliver preterm (3–14 wk) or at full term. The data indicate that parturition, irrespective of length of pregnancy, is the trigger for medium-chain fatty acid synthesis in the human mammary gland.

Lipids 27, 908–911 (1992).

Milk fat is important for the newborn infant as a major source of energy and as a source of specific fatty acids that are essential for normal growth and development (1). Long-chain polyunsaturated fatty acids are essential for brain development (2), myelination (3) and retinal function (4) and medium-chain fatty acids are important as an easily absorbable energy source (5). Medium-chain fatty acids can be absorbed directly through the gastric mucosa (6–8) and are transported from the intestine to the liver, where they are rapidly metabolized to ketone bodies (9). This provides a distinct advantage to the newborn. The preferential incorporation of ketone bodies into brain and lung lipids in the neonatal period (10) suggests that medium-chain fatty acids also might be important as substrates for organ growth and not only as energy source. This is consistent with reports that although these fatty acids contribute little to lipogenesis (11), they can be stored in the adipose tissue of orally fed infants (12).

Animal studies have shown that medium-chain fatty acids are synthesized within the mammary gland (13–15), contrary to the majority of long-chain fatty acids that are provided to the mammary gland through lipoprotein lipase mediated uptake from circulating lipoprotein triglyceride (16). In this study we have investigated the onset of medium-chain fatty acid synthesis in the human mammary gland.

MATERIALS AND METHODS

The subjects of this study were 31 healthy mothers of full term infants. All women gave informed consent for this study which was approved by the Institutional Review Board of the Medical Center of Delaware. The women were studied during the first two days after the delivery of healthy infants. Maternal blood specimens were taken simultaneously with the collection of colostrum. Colostrum was collected at mid-feed, as described previously (17). Serum and colostrum specimens were stored at −70°C until analysis. Lipids were extracted with chloroform/methanol (2:1, vol/vol) and the fatty acid methyl esters were prepared and quantitated by wide bore capillary gas-liquid chromatography as previously described in detail (18).

RESULTS

Data on the subject population are given in Table 1. The 31 healthy women studied consumed balanced diets resulting in a weight gain during pregnancy that is in accordance with the recent recommendation of the National Academy of Science (19). Eighty percent of the women studied were multipara, a majority of them having breastfed previously.

Analysis of the fatty acid composition of colostrum shows that most fatty acids are present at concentrations similar to those previously reported (18) (Table 2). Comparison of the composition of colostrum and serum shows similar concentrations for most long-chain fatty acids, resulting in a milk/serum ratio of 0.74 to 2.45. Exceptions were medium-chain fatty acids, present at much higher concentrations in colostrum than in serum (milk/serum fatty acid ratio as high as 17.11) and a few long-chain unsaturated fatty acids such as 20:1, 20:4n-3 and 22:5n-3 (milk/serum ratio 6.01, 2.90 and 3.87, respectively). Assuming that a ratio close to 1.0 indicates uptake of the fatty acid from the circulation after its release from chylomicrons or from very low density lipoproteins by lipoprotein lipase, at the capillary endothelium of the lactating mammary gland, a milk/serum ratio greater than 2.0 would indicate synthesis within the mammary gland. The

[a]Data are from 31 healthy women who delivered full term infants. The characteristics of the women studied are given in Table 1. There were no statistically significant differences in colostrum fatty acid composition as function of weight gain during pregnancy or parity, except that myristic acid (14:0) concentration was significantly higher in primipara than in multipara (6.60 ± 0.38 *vs.* 5.19 ± 0.46% $P < 0.05$).

[b]Percent of total fatty acids.

lowest colostrum/serum ratio was for arachidonic (20:4n-6) and docosahexaenoic (22:6n-3) acids, at 0.18 each. There was no difference in colostrum fatty acid composition as a function of weight gain during pregnancy or parity, except that myristic acid concentration was higher in milk lipids of primipara ($P < 0.05$).

DISCUSSION

The data presented indicate that the human mammary gland is able to synthesize *de novo* medium-chain fatty acids as well as to elongate and desaturate some long-chain fatty acids shortly after parturition. We have reported earlier that *prepartum* mammary secretions, collected between 1 and 70 days before full term delivery, contain lower amounts of fat than colostrum and mature milk (1.15 and 1.28 g/dL at an average of 42 and 9 d before delivery, respectively) and have a markedly different lipid composition than *postpartum* secretions (17). The data presented in Table 3 show that *prepartum* secretions contain considerably lower concentrations of 10, 12 and 14 than *postpartum* colostrum or mature milk (Tables 2 and 3). As *prepartum* secretions collected at an average of 42 or 70 d before term delivery correspond to secretions collected at 6–10 wk *prepartum*, we also have compared the medium-chain fatty acid composition of total lipids in these secretions with those in the colostrum secreted by women who delivered at similar periods of prematurity. As can be seen from the data presented in Table 3 (18), there was no difference in the medium-chain fatty acid level between the colostrum of women who delivered prematurely and colostrum of women who delivered after a full term pregnancy (Tables 2 and 3). Thus, parturition, irrespective of length of pregnancy, seems to be the trigger for the increase in *de novo* fatty acid synthesis within the mammary gland. It is also possible that milk removal, whether by the newborn's suckling or by milk expression, after full term or premature delivery, respectively, is an important factor in the increase of lipogenesis within the human mammary gland. Animal studies have shown that a marked increase in lipogenic enzymes acetyl-CoA carboxylase, ATP citratelyase and fatty acid synthetase occurs immediately after parturition and that milk removal is essential for this increase (20). Whether the presence of long-chain fatty acyl-CoA, which is a potent inhibitor of the two former enzymes in the mammary gland (21,22), or other factors (23) might contribute to the lower concentration of medium-chain fatty acids in *prepartum*

TABLE 3

Medium-Chain Fatty Acids in Human Mammary *Prepartum* Secretion, in Colostrum and in Milk Secreted After Premature or Full Term Delivery

Specimen	*n*	Fatty acid %		
		10:0	12:0	14:0
Prepartum secretion[a]	10	0.10 ± 0	1.7 ± 0.4	4.9 ± 0.6
Postpartum colostrum[b]				
Premature delivery				
26-30 wk	15	0.26 ± 0.14	3.09 ± 0.59	5.52 ± 0.68
31-37 wk	23	0.31 ± 0.10	3.14 ± 0.43	5.87 ± 0.50
Full term delivery	6	0.27 ± 0.22	3.10 ± 0.91	6.81 ± 1.06
Mature milk[c]				
Prepartum delivery				
26-30 wk	15	1.37 ± 0.17	7.47 ± 0.72	8.41 ± 0.83
31-37 wk	23	1.27 ± 0.18	6.55 ± 0.77	7.55 ± 0.89
Full term delivery	6	0.97 ± 0.28	4.46 ± 1.17	5.68 ± 1.36

[a]*Prepartum* secretion collected from women 1-70 d before full term delivery, from Bitman *et al.* (17).

[b]Data for colostrum and milk fatty acid composition after preterm and full term delivery, from Bitman *et al.* (18).

[c]Mature milk collected at 6 wk lactation, from Bitman *et al.* (18).

secretions is not known. The absence of lipoprotein lipase from *prepartum* secretions (17) suggests low activity in the mammary gland before term delivery, as previously shown in the rat (24). This would indicate that the long-chain fatty acids present in these secretions might originate mainly from the albumin-bound free fatty acids in the circulation. The absence of tight junctions between mammary epithelial cells before parturition would facilitate this transfer of fatty acids into the mammary gland.

Synthesis of medium-chain fatty acids is specific to the mammary gland, because only this tissue contains a specific enzyme, thioesterase II, which terminates chain elongation at 6-14 carbon atoms (25,26). In all other tissues, lipogenesis results in long-chain fatty acids associated with the enzyme thioesterase I, which terminates chain elongation at or above 16 carbon atoms (27). We could therefore use the milk/serum fatty acid ratio to assess the origin of milk fatty acids. Indeed, the serum concentration of fatty acids shorter than C_{14} was extremely low. Concentrations were, however, considerably higher in colostrum, resulting in very high milk/serum fatty acid ratios for 10:0 and 12:0, at 16.23 and 17.11, respectively.

Fatty acid synthetase has been characterized (28,29) in a permanent human mammary epithelial cell line, SkBr 3 (30), and the production of medium-chain fatty acids in *in vitro* studies has been reported (31). The onset of fatty acid synthetase and thioesterase II activity in the human mammary gland is, however, unknown. Because human lactating mammary gland cannot be studied for ethical reasons, one depends on indirect observations such as those described in this study. Based on these studies, which include colostrum (Table 3; refs. 18,32), milk (18) and serum as well as *prepartum* mammary secretion (17), one can conclude that in the human, as in other species, parturition, irrespective of length of pregnancy, is the trigger for the synthesis of medium-chain fatty acids. Whether this is dependent upon hormonal changes associated with delivery and onset of lactation or with removal of milk from the mammary gland (by suckling or pumping), or a combination of both, remains to be determined. As in other species (7), the rate of synthesis of medium-chain fatty acids increases with length of lactation (Table 3; refs. 18,33,34).

Lactation Curves and Effect of Pup Removal on Milk Fat of C57Bl/6J Mice Fed Different Diet Fats[1]

Beverly B. Teter, Joseph Sampugna* and **Mark Keeney**
Department of Chemistry and Biochemistry, University of Maryland, College Park, Maryland 20742

Groups of C57Bl/6J mice, fed either a *cis* (C-Diet) or *trans* diet (T-Diet) were milked without preconditioning at 6, 8, 10 and 12 days *postpartum*. On day 10, groups of mice were also milked 4, 6 and 18 h after separation of the pups. Except for the 18-h separation, all T-Diet fed animals produced milk of lower fat content than did the C-Diet animals ($P < 0.001$) throughout the lactation period measured. In the C-Diet mice, the 6-h separation period resulted in a decrease ($P \leq 0.03$) in fat, but the diet-depressed milk fat of T-Diet animals was not decreased further until the 18-h separation period. Milk volume increased as lactation progressed and was greatly increased as a result of preconditioning ($P \leq 0.001$), even at 4 h of separation when fat was not reduced, and was always greater for T-Diet animals. Within diet groups, fatty acid composition was similar throughout the lactation period studied and was not affected by preconditioning, except in the 18-h separation period, when *de novo* fatty acids were significantly reduced ($P \leq 0.05$). The data are consistent with the hypothesis that preconditioning results in lowered milk fat values and that preconditioning techniques can explain discrepancies in literature values for murine milk fat.
***Lipids* 27, 912-916 (1992).**

Separation of pups from dams (preconditioning) is frequently used to increase milk volume collected from laboratory rodents (1-5). Since previous work (6), in which dams and pups were not separated prior to milking, resulted in higher milk fat values than reported for mice (7-11), it was hypothesized that the lower literature values were due to preconditioning. Thus, the major objective of the present study was to determine whether preconditioning affects the percentage of milk fat obtained from lactating mice. This paper also contains data on a partial lactation curve in the presence of suckling pups and the fatty acid composition of milk from mice fed diets with or without *trans* fatty acids.

MATERIALS AND METHODS

Diets. Upon arrival, female mice were randomly assigned to one of two diets, which were fed *ad libitum* throughout the study. The two diets were essentially identical, except for the presence or absence of *trans* fatty acids (see Tables 1 and 2). As can be seen in Table 2, nearly 50% of the 18:1 in the fat of the *trans* diet (T-Diet) consisted of *trans* isomers, whereas all of the 18:1 consisted of *cis* fatty acids in the *cis* diet (C-Diet). The T-Diet also contained less than 2% of dienes that contained one or two *trans* double bonds.

Animals. The C56Bl/6J mice used in this study were purchased as weanlings from The Jackson Laboratory (Bar Harbor, ME). Animals were maintained under conditions conforming to the National Institute of Health guidelines (12). Mice were kept in plastic shoebox cages in a facility maintained at 23°C and 50% RH on a 12-h light cycle. Water and diet were provided *ad libitum*. At about 35 d of age, females were harem mated, with 1 male randomly assigned to each group of 4 females. After 1 wk, males were removed, each female was housed in a separate cage and births were noted daily at about noon. At day 4 *postpartum*, litter size (3-8 pups) was adjusted to 5 or 6 pups within the same diet group. Dams were allowed two days to acclimate, and milk was collected as previously described (6) on days 6, 8, 10 and 12 *postpartum*.

Lactation curve data (day 6, 8, 10 and 12) were collected from females remaining with their pups until the time of milking (1300–1500 h). After milking, they were returned to their cages and individual pup weights were obtained. Animals used in the preconditioning studies were milked after being separated from their pups for 4, 6 or 18 h. For the 4 and 6 h preconditioning data, females were separated from their pups at day 10 in the morning, at which time individual pup weights were obtained. The separated dams were milked at about 1500 h prior to reuniting them with their pups. For the 18-h separation values, pups were individually weighed and then killed at about 1700 h on day 10. The dams were milked in the early afternoon of the next day (day 11), about 18 h after separation from their pups.

A total of 25 females on the C-Diet and 20 females on the T-Diet were used in these studies. For the lactation curve studies, all mice were used for 6- and 8-day points, but 22 C-Diet and 17 T-Diet dams were used for the 12-day points. At 10 d *postpartum* the lactating females were separated into four groups. One group of 10 females on the C-Diet and 5 on the T-Diet were milked without preconditioning the dams, and the data were used in the lactation studies as well as in the preconditioning studies. A second set of dams (4 on the C-Diet and 6 on the T-Diet) were milked at 4 h after the pups were removed; a third set (5 on the C-Diet and 6 on the T-Diet) were milked 6 h after preconditioning, and the last set of 6 females, half on the C-Diet and half on the T-Diet, were milked 18 h after they were separated from their pups at day 10 *postpartum.*

Milk fat and volume measurements. The standardized creamatocrit technique for determining milk fat percentage has been described previously (6). Milk fat for fatty acid analysis was obtained by a dry column method (6,13). Milk volumes were estimated after calibrating ten of the capillary tubes (VWR, Scientific, Chicago, IL; microhematocrit) employed in the creamatocrit procedure. The capillary tubes were pre-weighed, filled about 2/3 full with distilled water, weighed again, and then sealed with a plug of Critoseal. Based on the weight and column height of the water and assuming a density of 1.0 for water, the tube volumes (average ± SD) were calculated to be 0.934 ± 0.0005 μL/mm.

Fatty acid analyses. Milk fat and dietary fats were converted to fatty acid methyl esters (FAME) using anhydrous methanolic HCl and methylene chloride as a cosolvent. After purification by thin-layer chromatography, the FAME were separated on a 25 m × 0.25 mm fused silica column coated with SP-2340 (Quadrex Corp., New Haven, CT). Procedures employed to esterify the lipids and to separate, identify and quantify the FAME have been described (14).

RESULTS AND DISCUSSION

Throughout these studies, average body weight and weight gain were similar for pups of dams fed either diet. At day 10 the C-Diet pups weighed 4.4 ± 0.4 g (mean ± SEM) and the T-Diet pups weighed 4.6 ± 0.2 g. There was no evidence that milking the dams every other day affected the health of the dams or pups or altered the milk values obtained. However, if the dams were disturbed at day 1 or 2 *postpartum*, they tended to kill the pups. By day 4 it was possible to augment or cull litters without severe losses. The addition of pups was accomplished by gently dusting the new pup with bedding from the foster mother and placing the pup under the natural pups in the cage. By day 6, it was possible to collect sufficient sample from most animals nursing 5–6 pups; however, milk volumes prior to day 6 *postpartum* were generally insufficient for analysis.

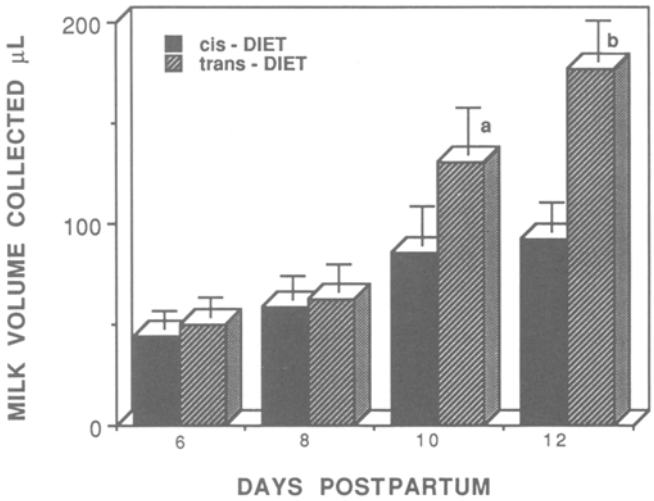

FIG. 1. Volume of milk collected as lactation progresses in C57Bl/6J mice fed the *cis* or *trans* Diet. Means and SEM are shown. For days 6, 8, 10 and 12 the number of observations for the *cis* Diet were 3, 8, 7 and 6 and for the *trans* Diet 5, 4, 5 and 5, respectively. The "a" and "b" indicate volumes significantly greater than the *cis* Diet values (*t*-test $P \leq 0.03$).

Lactation curve. Data for the lactation curve studies are shown in Figures 1 and 2. The milk volume collected (Fig. 1) increased during lactation. This was expected since growing pups require more milk. However, animals on the T-Diet always gave the larger nominal volume of milk with statistically significant differences ($P < 0.01$) at 10 and 12 days *postpartum.* At the same time, although the fat values were constant within a diet group, the dams fed the T-Diet always gave milk with fat percent values that were significantly lower ($P < 0.01$) than dams fed the C-Diet (Fig. 2).

The differences observed in the fat values were expected and confirm our previous work (6) regarding a depression of milk fat in lactating mice fed diets containing partially hydrogenated fat. In contrast, the differences in milk volume produced by dams on the two diets were not expected, but there is little doubt that they are a reflection of the differences in fat. Given the difference in fat concentration and the lack of detectable differences for either protein or lactose concentration (15), a given volume of the *trans* milk would have less calories than an equal volume of the *cis* milk. Yet, despite the lower calorie T-Diet milk, there were no significant differences in weight and growth rate of pups in the two diet groups. Thus it appears that a greater volume of the low-fat milk was required by pups in the T-Diet group to meet their caloric and nutrient needs.

Throughout these studies the volume measurements were more variable than the fat measurements. The large variability in volume may be due to the fact that pups

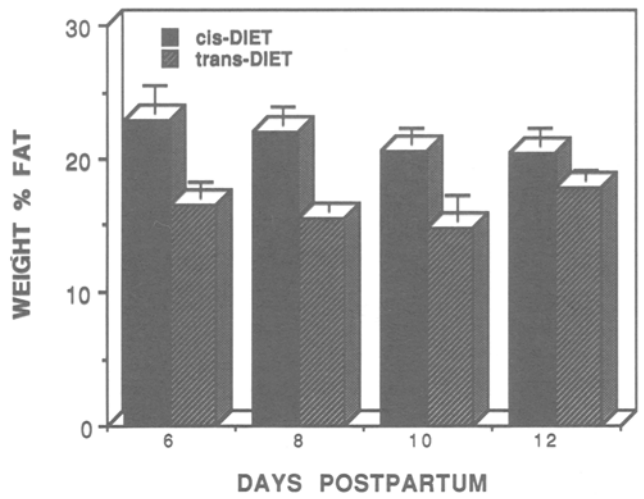

FIG. 2. Percentage milk fat from C57Bl/6J mice fed the *cis* Diet or *trans* Diet. Means and SEM are shown. All *cis* Diet values are significantly ($P \leq 0.001$) greater than all *trans* Diet values. See Figure 1 for number of observations.

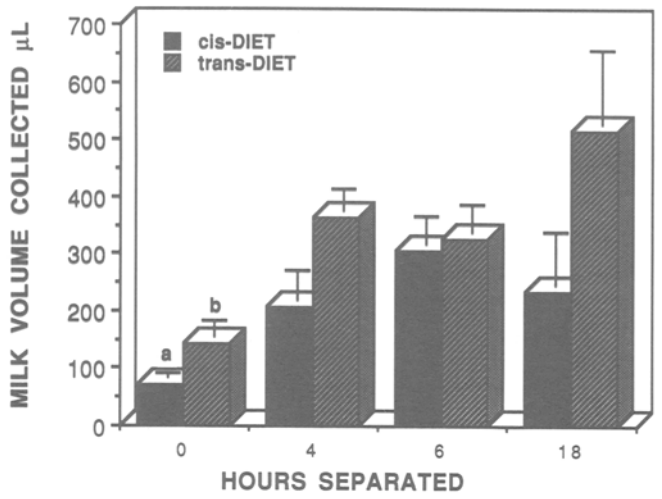

FIG. 3. Volume of milk collected from C57Bl/6J mice after separation of dams from pups. Means and SEM are shown. Sample numbers for 0, 4, 6 and 18 h are 7, 5, 5 and 3, for *cis* Diet and 5, 6, 6 and 3 for *trans* Diet, respectively. The "a" and "b" indicate significantly smaller volumes than when separated (*t*-test $P \leq 0.001$).

remained with the dams and that the time from the last nursing was not controlled. The smaller variability in the fat values was probably a reflection of the consistency of fat values obtained for "fore" and "hind" milk, as discussed previously (6).

Pup removal study. The pup removal study was conducted to test whether preconditioning practices might be responsible for discrepancies in murine milk fat values reported in the literature (6). Pups were separated on day 10 *postpartum* as lactation was clearly well established, milk volumes were greater than at earlier time points and it was likely that pups could consume milk solely at that stage of lactation. Also, 10-day-old pups were able to survive short separation times with no apparent ill effects.

As can be seen in Figure 3, milk volume was increased ($P \leq 0.001$) when pups were separated for 4 h or longer. However, preconditioning periods greater than 4 h did not yield statistically significant greater volumes of milk. Within each diet group, the fat values for these milks (Fig. 4) were not different after 4 h of preconditioning, but 6 h of preconditioning resulted in a statistically significant decrease ($P < 0.03$) in fat percent of milk from dams fed the C-Diet, and decreased fat values ($P < 0.01$) were observed for dams fed either diet after 18-h of preconditioning. It should be noted (Fig. 4) that except at the 18 h preconditioning period, fat values for dams fed the T-Diet were consistently lower ($P \leq 0.01$) than for those fed the C-Diet.

As expected, preconditioning increased milk volume, but it adversely affected the proportion of fat. The decrease in fat in the C-Diet group was a result of separation, since reuniting dams and pups resulted in normal values when checked on day 12 (data not shown). These data support the work of others who have reported that preconditioning beyond 6 h is unphysiological (11) and affects lipogenesis as well as milk secretion (16). These data also are consistent with the hypothesis that preconditioning techniques are responsible for discrepancies in milk fat values in the literature (6).

Although milk fat was decreased in C-Diet animals as a result of preconditioning at 6 h, the T-Diet animals did not respond until 18 h of separation. This difference in response may be related to the fact that T-Diet animals were already in a fat depressed state (6) (Fig. 2 and 4). It is possible that certain enzyme activities (which are sensitive to suckling) were partially depressed in animals fed the T-Diet and moderate preconditioning periods did not depress them further. It is likely that by 18 h of preconditioning, glandular involution had progressed to the point that milk synthesis was seriously impaired. Thus at this stage both diet groups gave milks with lower fat values.

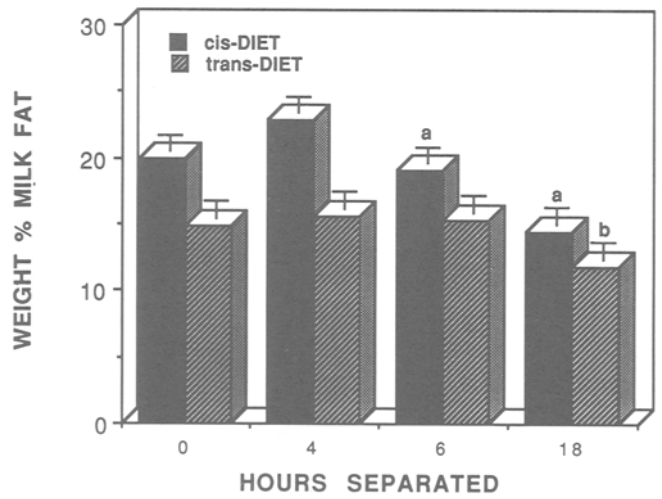

FIG. 4. Percentage of milk fat from C57Bl/6J mice separated from their pups prior to milking. Means and SEM are shown. See Figure 3 for sample sizes. The "a" and "b" signify values different from 0 h of that diet (*t*-test $P \leq 0.03$). Except for the 18 h values the *trans* Diet values are significantly less than *cis*-Diet values ($P < 0.01$).

Fatty acid composition of murine milk fat. Fatty acid compositions of milk fat were monitored throughout the lactation and preconditioning studies. A summary of data for milks obtained at 10-d lactation is given in Table

TABLE 3

Fatty Acid Composition of Milks at Day 10 of Lactation[a]

Major fatty acids[c]	Fatty acid methyl ester wt%[b] C-Diet[d]	T-Diet[d]
≤16:0	21 ± 3	23 ± 3
16:0	24 ± 3	19 ± 1
18:0	2 ± 0.2	2 ± 0.1
16:1*c*	4 ± 0.7	4 ± 0.8
18:1*t*	ND	8 ± 0.6
18:1*c*	40 ± 5	28 ± 8
18:2n-6	8 ± 1.5	11 ± 2.0
18:2*i*	ND	0.7 ± .2
20:4	0.8 ± 0.3	1.4 ± 0.6
Summary of 18 carbon fatty acids		
18:0	2	2
18:1*c*+*t*	40	36
18:2n-6+*i*	8	12
Total 18 carbon	50	50

[a]Pups remained with dams until milking.
[b]Means ± SD. n, 12 C-Diet, 5 T-Diet.
[c]Fatty acid carbon number:double bonds; *c*, *cis* isomers; *t*, *trans* isomers; *i*, isomers, both *cis* and *trans* of 18:2n-6.
[d]Diets are defined in Tables 1 and 2. Diets differ in the composition of 18:1 and 18:2 isomers. In the T-Diet about half of the 18:1 is *trans* geometrical isomers. ND, not detected.

3. Fatty acid composition within a diet group was similar throughout the lactation study. The milk fatty acid composition reflected the dams' diet in that milk from both diet groups contained 18:2n-6 and the T-Diet samples contained *cis* and *trans* isomers derived from the partially hydrogenated fat in the diet.

Data for groups of fatty acids in preconditioned milks are given in Figure 5 as percent of the total FAME. There were no differences in fatty acid compositions within a diet group until 18 h of preconditioning, when the *de novo* group of fatty acids (<16 carbons) were dramatically decreased and the proportion of 18 carbon acids, derived from diet and adipose stores (17), were increased. However, when the decrease in total fat also was taken into account, the *de novo* group was severely decreased and the other fatty acid groups were slightly decreased or present at nearly the same level as was found at the 0-h point (data not shown).

These alterations in fatty acid composition coupled to the lack of an increase in total fat suggest that dramatic changes have occurred in the mammary gland at 18 h of preconditioning. The changes in fatty acid composition are consistent with those observed by Hurley *et al.* (18) in dairy cows during early involution and are similar to those of Grigor *et al.* (19), who reported decreased percentages of 12:0 and 14:0 and increased 18:0 in milk from glands of rat dams suckling two pups as compared to those suckling 10 pups. The dramatic alterations in milk fat after the 18-h preconditioning period in the present studies are probably due to physiological changes associated with mammary gland involution.

In summary, the studies suggest that extensive preconditioning prior to milking can yield inaccurate and potentially misleading data. Since there was no significant increase in the volume of milk obtained when dams were preconditioned beyond 4 h, we recommend that the preconditioning period, if employed, not exceed 4 h.

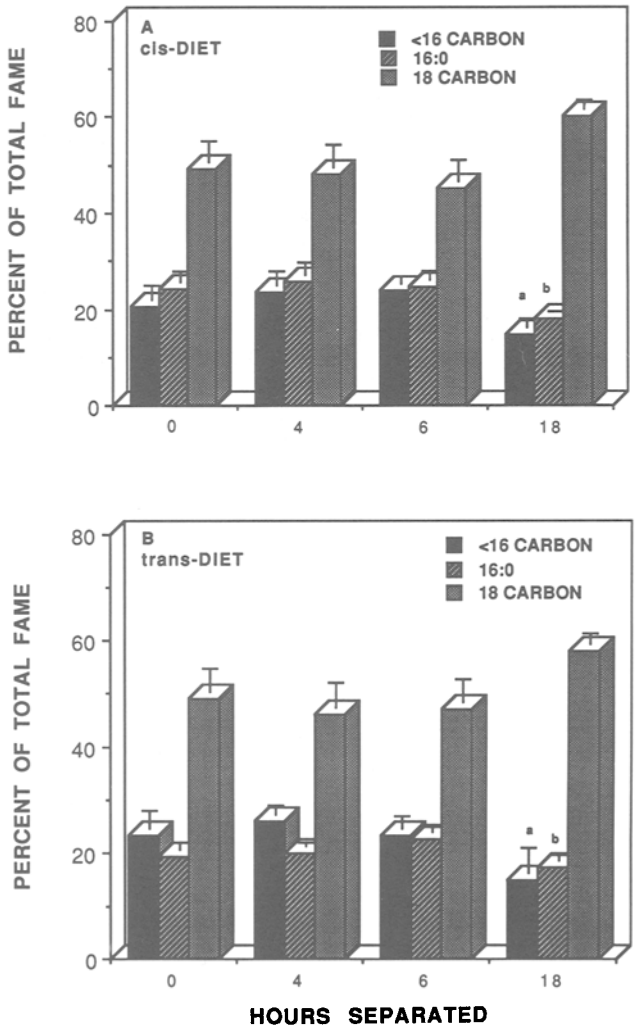

FIG. 5. Selected fatty acids in milk of C57Bl/6J mice after pups are separated from dams. Means and SEM are shown for the *cis*-Diet groups (A) and the *trans* Diet groups (B). Sample sizes for 0, 4, 6 and 18 h are 12, 5, 5 and 3 for *cis* Diet and 5, 5, 6 and 3 for *trans* Diet, respectively. The "a" and "b" indicate significantly lower values ($P \leq 0.05$) than at earlier times.

Bile Salt Stimulated Lipase: Comparative Studies in Ferret Milk and Lactating Mammary Gland[1]

Lorie A. Ellis[2] and **Margit Hamosh***
Division of Developmental Biology and Nutrition, Department of Pediatrics, Georgetown University Medical Center, Washington, D.C. 20007

Bile salt stimulated lipase (BSSL) activity is 10–20 times higher in ferret milk than in human milk. We have used the ferret to study BSSL activity in lactating mammary gland and in mammary cells isolated by hyaluronidase-collagenase treatment followed by Ficoll gradient centrifugation. Furthermore, we have compared the characteristics of BSSL in the tissue preparations (homogenate or cells) to BSSL of ferret milk and to BSSL purified from ferret and human milk. The characteristics of BSSL in ferret mammary gland preparations and milk were similar to those of human milk BSSL—absolute requirement of primary bile salts, pH optimum of 7.5–9.0, stability at pH 3–9 and inhibition by eserine (physostigmine) and by serum. Purified ferret milk BSSL had a lower molecular weight (90kD) than did human milk BSSL (125 kD). There was an 86% homology of the *N*-terminal amino acid sequence between BSSL of ferret and of human milk. The marked similarity in characteristics between BSSL in ferret and human milk and the high activity of BSSL in ferret milk (520 U/mL colostrum and 250 U/mL mature milk) indicate that this species is an ideal animal model for the study of the synthesis and secretion of this digestive lipase which constitutes a significant portion (1–2%) of total milk protein.
Lipids 27, 917–922 (1992).

The presence and functional significance of bioactive components in human milk have been elucidated (1–3) only recently. Although enzyme activities of human milk have been demonstrated by *in vitro* studies (1), *in vivo* studies of the mechanisms of synthesis and secretion of these milk components have not been possible.

Bile salt stimulated lipase (BSSL), an enzyme previously found in the milk of humans (4,5), high primates (6), and carnivores such as the dog and cat (7), represents a significant proportion of total milk protein (1–2%) (8,9) and is probably the most abundant of the enzyme components in milk. BSSL is functionally similar and immunologically homologous to pancreatic carboxyl esterase (10). Because pancreatic lipase activity is low in the infant during the first months of life (11), it has been suggested that BSSL serves a compensatory role in fat digestion in the infant (5,12–15). Although several studies have assessed the possible compensatory role of this enzyme in the digestion of fat in the newborn (12–15), only one study has addressed localization of the enzyme in the lactating mammary gland (16).

In the present study, we have used a new animal model (the ferret) to quantitate and to compare the characteristics of the activity of BSSL in milk, in mammary gland and in cells isolated from the lactating mammary gland to those of the enzyme purified from ferret milk, as well as to known characteristics of BSSL activity of human milk.

MATERIALS AND METHODS

Two primiparous ferret jills, species *Mustela putoris furo* (Marshall Farms, North Rose, NY) were obtained in late pregnancy. The animals were housed separately in 18 × 10-inch stainless steel cages containing a four-inch bed of cedar shavings (17). Both jills received Purina Ferret Chow (Ralston Purina, St. Louis, MO) and water *ad libitum*. Kits were born at term on day 43 of gestation.

Milk collection. Milk was collected from each jill on days 3 (colostrum), 7, 10 and 15 of lactation. The jills were lightly sedated with acepromazine (TechAmerica Group Inc., Elwood, KS) and 2–5 units of oxytocin (pitocin, Parke Davis Division of Warner Lambert Co., Morris Plains, NJ) were injected intramuscularly to initiate milk let-down. Milk was manually expressed from each teat, collected by capillary action into a pasteur pipette and immediately transferred to a collection tube held on ice. Milk specimens were frozen at −70°C within 45 min from initiation of collection.

Mammary biopsy/tissue collection. Samples of mammary tissue were taken from each jill on day 10 (by sterile surgery) and on day 14 (sacrifice). Three hours prior to surgery, kits were separated from jills and placed in an incubator (70% humidity; 32°C). Milk was fully expressed from each teat prior to surgery. Ferrets were sedated with telezol (Fort Dodge Labs, Fort Dodge, IA) (14 mg/kg) delivered intramuscularly. The entire lobe of the left anterior mammary gland was removed through a half-moon incision and immediately placed on ice. Subsamples of the gland were rinsed in saline and frozen at −70°C, or used for cell dissociation. On day 14 *postpartum*, jills were sacrificed by an overdose of pentobarbital and exsanguination by cardiac puncture. Mammary tissue in the right inguinal area was perfused through the right femoral artery with 30 mL cold saline. The gland was removed and subsampled for frozen storage at −70°C. The left inguinal and right anterior glands were then removed, rinsed in saline and either frozen at −70°C or used for cell dissociation.

Mammary cell isolation. A mammary cell suspension enriched in secretory epithelial cells was prepared as previously described (18). Briefly, 0.25 to 10 g of mammary tissue were minced and subjected to enzymatic digestion with hyaluronidase and collagenase (100 U/mL and 150 U/mL, respectively; Worthington, Freehold, NJ) during 25–30 min incubation at 37°C with constant infusion of O_2/CO_2 (95:5%). The isolated cells were counted under light microscopy using a Neubauer homocytometer and

[1]Presented in part at the Annual Meeting of the Federation of American Societies for Experimental Biology (FASEB), Washington, D.C., and published in abstract form [FASEB J. 4, A 913, (1990)].

crystal violet staining. When approximately 1×10^6 cells per mL of suspension were present, the digestion process was stopped by addition of trypsin inhibitor (Sigma Chemical Co., St. Louis, MO) and slow cooling on ice. The suspension was filtered and subjected to a series of three washings and sedimentations on a 30% discontinuous Ficoll gradient (18). The cell band was collected and diluted to approximately 1×10^6 cells/mL before freezing. DNA from both tissues and cells was extracted by the method of Schneider (19) and quantitated by the method of Burton (20). Protein content of milk and purified enzyme was determined by the method of Lowry *et al.* (21).

Purification of BSSL. BSSL was purifed from ferret milk using a small-scale version of the method developed by Blackberg and Hernell (18). Molecular weight was determined by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) on both 11–23% gradient (22) and 7.5% total acrylamide concentrations according to the methods of Laemmli (23). *N*-Terminal amino acid sequence was determined using an Applied Biosystems (Foster City, CA) Gas Phase Protein Sequencer (Model 470A) and a Waters Associates (Milford, MA) HPLC (high-performance liquid chromatography) System.

Assay of BSSL. Activity of BSSL was measured using glycerol tri[9,10-(n)^{3}H]oleate as substrate (24). The triglyceride was emulsified at 4°C with a Branson Model 200 Sonifier (Branson Sonic Power, Danbury, CT) for two 2-min intervals at setting 3, 50% of time pulsed. The standard assay system contained 1.6 mM triolein, 60 mM Tris-HCl buffer pH 8.5, 150 mM NaCl, 12 mM sodium taurocholate, 2.8% bovine serum albumin and dilute enzyme in a total volume of 200 μL. After incubation at 37°C for 15 min, the reaction was stopped by the addition of a mixture of chloroform/methanol/heptane (1.25:1.41:1, vol/vol/vol). The [^{3}H]oleic acid released was separated by liquid-liquid partition (25) and quantitated by liquid scintillation spectrometry with automatic external standardization as previously described (7). One unit of lipase activity is the release of 1 μmol of fatty acid per min. A milk sample of known BSSL activity was included in each assay to verify accuracy and reproducibility of the assay.

RESULTS

Concentration of BSSL in ferret milk during lactation. The activity of BSSL in ferret colostrum and milk collected on days 3, 7, 10 and 15 of lactation is shown in Figure 1. Additional samples of ferret milk (Marshall Farms) at various points throughout lactation were tested for comparison and are included in Figure 1. Marked differences were evident between the activity of BSSL in colostrum produced by each jill (310–634 units mL). However, beyond day 7 of lactation, activity of BSSL remained relatively constant in a range of 250 units/mL among different jills.

Purification of BSSL. Data for the purification of BSSL from ferret milk are presented in Table 1. There were differences in the partition of BSSL into whey and casein fractions between ferret milk and human milk. Initial purification of BSSL from human milk in this laboratory has resulted in 80–90% of total BSSL activity remaining in the whey fraction. Furthermore, loss of enzyme protein was appreciable only after acidification and incubation at 40°C for removal of casein. However, only 51% of the

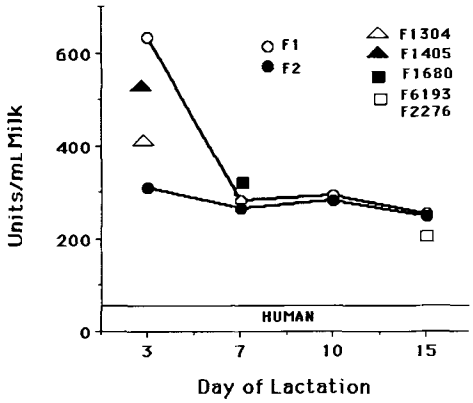

FIG. 1. Bile salt stimulated lipase (BSSL) activity in ferret colostrum and milk. Longitudinal data are presented for two ferrets. Additional data are provided for individual specimens of ferret colostrum and milk. Average activity of BSSL in human milk during the first two weeks of lactation is given for comparison.

BSSL in ferret milk was associated with the whey fraction. Centrifugation (10,000 × *g* for 1 h) alone resulted in significant precipitation of BSSL protein (17%) from ferret milk, whereas acidification and incubation at 40°C resulted in additional loss of enzyme in the precipitating fraction. The remaining (16%) BSSL activity not accounted for is most likely associated with the lipid fraction as this amount was lost after the defatting stage.

BSSL purified in this laboratory (26), as well as by others (8,9), has been shown to represent 1–2% of total milk protein. Data from the purification of BSSL in ferret milk indicate that the enzyme represents 8% and 3% of total protein in colostrum and in milk collected at day 18 of lactation, respectively. The molecular weight of BSSL in ferret milk as determined by SDS-PAGE is 90,000 Daltons. The molecular weight of the BSSL in ferret milk is identical to the molecular weight of BSSL in the milk of the cat (27), a close relative of the ferret, but is somewhat smaller than the human form [determined in this and other laboratories to be 125,000 Daltons (8,28,29) (Fig. 2)].

The *N*-terminal amino acid sequence determined for BSSL purified from ferret milk is shown in Table 2. The amino acid sequence of BSSL in the milk of the ferret shows 86% homology to the known amino sequence of human BSSL (9). There were differences between ferret and human BSSL at amino acids 2, 11 and 18 (Ser, Gly and His, respectively). In all cases these amino acids substituted for lysine residues in the BSSL of human milk.

Enzyme kinetics. Kinetics of BSSL purified from ferret milk and those of BSSL in whole ferret milk are presented in Figure 3. The substrate concentration curves for BSSL in ferret and in human milk are shown in Figure 4. While BSSL purified from ferret milk showed a hyperbolic response to increasing substrate concentration, the response of human milk BSSL was sigmoidal with a lag phase at substrate concentrations below 0.8 mM and inhibition at substrate concentrations greater than 3.2 mM. The apparent Km of BSSL in ferret milk was 1.67 mM. The apparent Km of human milk BSSL was close to that of the ferret enzyme, ranging between 1.6–1.7 mM.

Characterization of BSSL in ferret milk, in mammary tissue and in mammary cells and comparison to BSSL

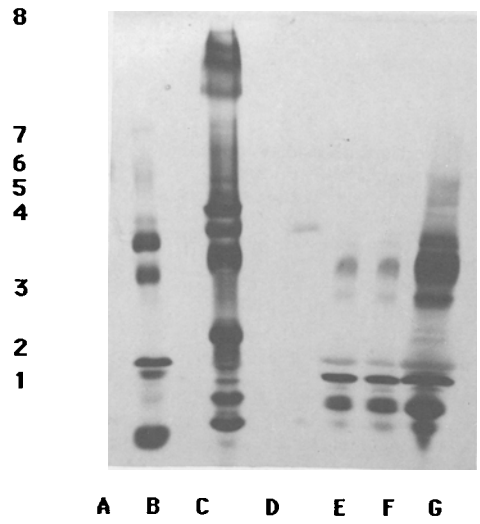

FIG. 2. Sodium dodecyl sulfate polyacylamide gel electrophoresis of purified ferret and human milk bile salt stimulated lipase (BSSL). Lanes: A, BSSL purified from ferret milk; B, BSSL purified from human milk; C, human milk, skim milk fraction; D, standards for molecular weight; E, BSSL purifed from ferret milk; F, ferret milk casein pellet, second centrifugation; G, ferret milk casein pellet, first centrifugation; H, ferret milk, skim milk fraction. Standards for molecular weight (kD), lane D: 1, lysozyme (14.4 kD); 2, trypsin inhibitor (22 kD); 3, carbonic anhydrase (31 kD); 4, ovalbumin (45 kD); 5, serum albumin (66 kD); 6, phosphorylase B (97 kD); 7, β-galactosidase (116 kD); 8, myosin (200 kD).

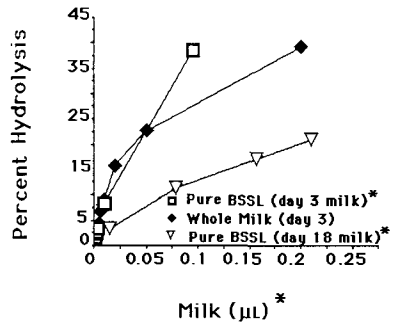

FIG. 3. Bile salt stimulated lipase (BSSL) enzyme concentration curve. Comparison of activity of pure ferret milk BSSL (expressed in equivalent milk volume based on purification data, Table 1) with BSSL activity in whole milk.

purified from ferret milk. The effect of bile salts on the activity of BSSL purified from ferret milk, in whole ferret milk, mammary tissue and mammary cells (0–30 mM taurocholate or glycocholate) is shown in Figure 5. Maximal enzyme activity for whole milk and for purified BSSL was achieved at taurocholate concentrations of 12–15 mM, whereas BSSL in mammary tissue and mammary cells was maximally activated at 10 mM taurocholate. In terms of absolute values, at 10 mM taurocholate, BSSL activity in the mammary tissue was 6.2-fold greater than cellular BSSL. Inhibition of BSSL activity in mammary tissue and mammary cells occurred at concentrations greater than 12 mM taurocholate, with 51–57.5% inhibition of maximum activity at 30 mM taurocholate. Likewise, purified BSSL and BSSL in whole milk showed inhibition in activity at taurocholate concentrations greater than 20 mM; however, at 30 mM taurocholate inhibition was somewhat less (34.2 and 46%, respectively) than that of the enzyme in mammary tissue and mammary cells.

BSSL activity in whole milk, in purified enzyme, in mammary tissue and in mammary cells was maximal in the presence of 10 mM glycocholate but declined in activity at glycocholate concentrations greater than 10 mM.

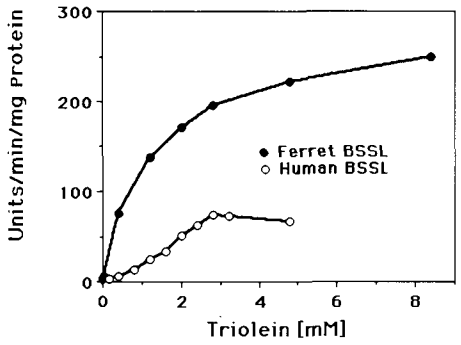

FIG. 4. Substrate concentration curve for bile salt stimulated lipase in ferret milk and in human milk.

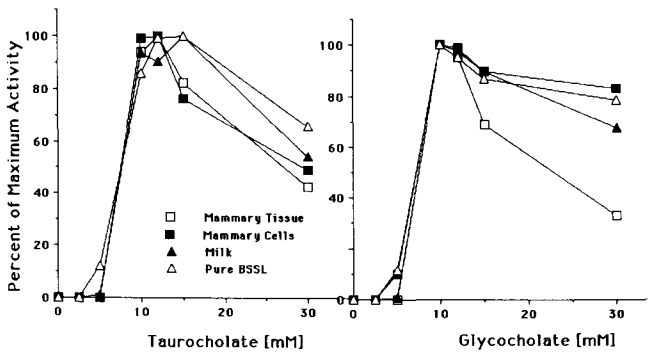

FIG. 5. Effect of bile salts, glycocholate and taurocholate, on bile salt stimulated lipase activity of ferret mammary tissue, mammary cells, milk and the purified enzyme. No enzyme activity was detected in the presence of secondary bile salts.

BSSL activity in mammary tissue was most affected with 67% inhibition at 30 mM glycocholate as compared to 17-32% inhibition of purified, whole milk and cellular BSSL. The response of BSSL was greater to glycocholate than to taurocholate at all bile salt concentrations: enzyme activity in cells, tissue and whole milk was 120-170% greater in the presence of glycocholate as compared to taurocholate; purified BSSL was 300-415% more active with glycocholate than with taurocholate. Secondary bile salts did not elicit BSSL activity in milk, mammary tissue or cells. In human milk, BSSL activity was slightly higher with glycocholate than taurocholate in the range of 10-15 mM, and no activity was detected in the presence of secondary bile salts.

Effect of pH. The effect of pH on the activity of BSSL in milk, purified enzyme, mammary tissue and mammary cells is shown in Figure 6. Maximal activity of purified BSSL and BSSL in whole milk was achieved at pH 8.0, and mammary tissue and mammary cells reached optimum activity at pH 8.5. At pH 7.5-9.0, greater than 75% of BSSL was present in whole milk, purified enzyme and mammary cells. No activity was detected in mammary tissue homogenate below pH 8.0 or above pH 9.0.

Stability of BSSL as function of pH. Dilute samples of purified BSSL, ferret milk, mammary tissue and mammary cells were incubated at 37°C for up to 60 min at pH 1.5-9.5. Samples were assayed after 0, 30 and 60 min of pre-incubation at optimal conditions (pH 8.5, 12 mM taurocholate) to determine the stability of enzyme activity. Stability of BSSL to 60 min pre-incubation is shown in Figure 7. Greater than 75% of BSSL was present in whole milk after 60 min of preincubation at pH 4.0-9.0. BSSL purified from ferret milk retained 75% of control activity when pre-incubated for 60 min at pH 8.5, but only 25-30% of initial activity was measurable after pre-incubation at pH above or below optimum. In comparison to purified BSSL and whole milk BSSL, the BSSL activity in mammary tissues and mammary cells was more stable at extremes of pH. As compared to initial activity, mammary cells showed enhanced activity after 60-min pre-incubation at pH 3.0.

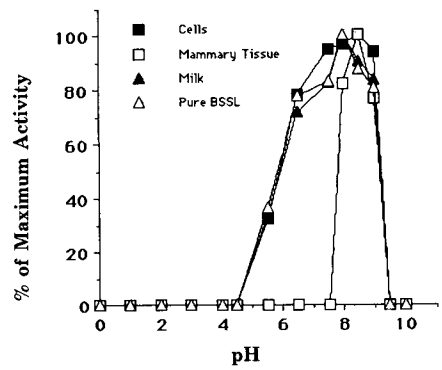

FIG. 6. The effect of pH on bile salt stimulated lipase (BSSL) activity. Comparison of the activity of purified ferret milk enzyme with that of BSSL in ferret mammary tissue, mammary cells and ferret milk. The standard assay system was adjusted to the various pH values using buffers at a final assay concentration of 60 mM. Buffers used were: pH 2.4-3.6 glycine-HCl; pH 3.6-6.0 Na acetate; pH 6.0-7.5 Na phosphate; pH 7.5-8.5 Tris-HCl; and pH 8.5-9.5 glycine-NaOH.

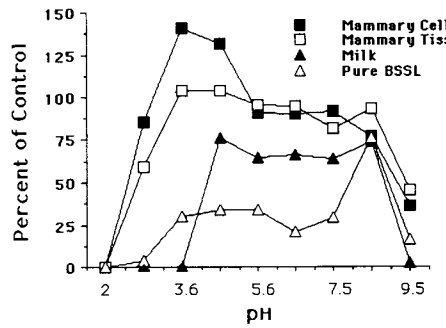

FIG. 7. Stability of bile salt stimulated lipase (BSSL) as a function of pH. Mammary tissue, mammary cells, milk and purified enzyme were incubated in 0.05 M buffer (see legend to Fig. 6) for 60 min at a pH range of 2.0-9.5, followed by incubation in the standard assay system (pH 8.5) for quantitation of BSSL activity. Note: the X axis is not drawn to scale.

Inhibition of BSSL activity by eserine hemisulfate and serum. Both eserine (physostigmine) and serum are potent inhibitors of milk BSSL (24). Activity of BSSL in milk, mammary tissue and mammary cells was measured in the presence of 0.1 to 10 mM eserine hemisulfate (Fig. 8). In all cases, less than 10% of maximum activity remained when 2 mM eserine was included in the assay.

Activity of non-perfused mammary tissue homogenate was compared to activities of purified BSSL, ferret milk and serum-free mammary cells in the presence of 0.5-5% heat-inactivated serum (vol/vol) (Fig. 9). At concentrations

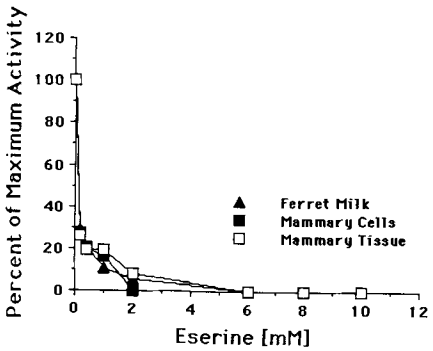

FIG. 8. Effect of eserine (physostigmine) on bile salt stimulated lipase activity in ferret milk, mammary cells and mammary tissue.

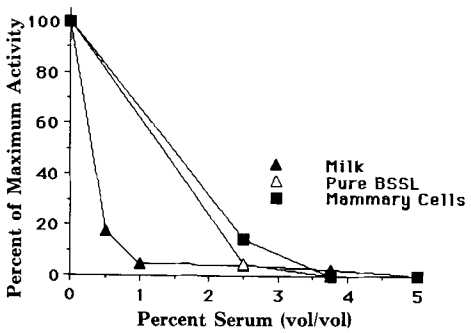

FIG. 9. Effect of serum on bile salt stimulated lipase activity in ferret milk, mammary cells and mammary tissue.

of 0.5% serum, less than 20% of maximum activity was measured in whole milk, and complete inhibition was reached with 4% serum. The nature of the BSSL inhibitor in serum is not known. Recent studies have established that the serum inhibition of acid and neutral cholesteryl ester hydrolases is due to serum apoprotein A-I (30). Whether milk BSSL, an enzyme identical to pancreatic carboxylester hydrolase (10,31), is likewise inhibited by apoprotein A-I remains to be established. It is of interest that while BSSL activity is inhibited by serum, a lipolytic activity stimulated by taurocholate was measured in the serum of the ferret (275 nmol/min/mL serum). This serum lipase did not contribute to mammary homogenate lipolytic activity at the concentration of tissue assayed (0.01 mg).

DISCUSSION

This study describes the strong similarities in both structural and functional characteristics of BSSL produced by the ferret and by the human. Ferret milk contains 10–20 times higher BSSL activity than human milk. This difference does not appear to be a result of higher quantities of BSSL protein in mature ferret milk (after day 7 of lactation) but is more likely due to the greater Vmax (160% of human) and higher turnover number (5800 sec^{-1}) of BSSL in ferret milk as compared to human BSSL. The data demonstrate the presence of BSSL in the mammary gland and in the mammary cells of the lactating ferret. Although this study does not delineate the site of synthesis for BSSL, the data suggest that the enzyme is synthesized in the mammary gland. Although a bile-salt activated lipase is present in the serum of the lactating ferret (probably pancreatic lipase or carboxylester hydrolase), it is unlikely that this is the source of BSSL in milk as there is a greater than 1000-fold difference in milk BSSL activity as compared to serum bile salt stimulated lipolytic activity. Comparison of the activity of BSSL in mammary tissue homogenate to activity of cellular BSSL shows a 3–5-fold greater activity of BSSL in tissue homogenate (expressed per μg DNA). This observation may indicate that synthesis of BSSL is specific to a particular cell type or that enzyme activity might be lost during the cell isolation procedure. A cell preparation enriched in epithelial cells was used in this study. However, the BSSL in mammary cells also may be in a bound form either at the cellular or subcellular membrane or may somehow be modified once transported from the cell. The time dependent increase of BSSL activity in mammary cells at low pH may represent the lysis of Golgi vesicles transporting protein from the cell or release of BSSL from a membrane-bound receptor.

The physiological mechanisms of lactation are poorly understood, particularly with respect to specialized bioactive components in milk. BSSL is a particularly unique component of milk since it possesses no known function in milk nor in the lactating mammary gland. Comparison of species with and without BSSL shows a strong evolutionary link in species secreting BSSL. Milk of ruminants, rodents and omnivorous mammals has no BSSL activity (32,33), whereas BSSL is secreted in milk produced by carnivores (7,33). Further study of this protein is necessary to elucidate the reasons for species differences. Human milk also contains large quantities of amylase (34,35) which, likewise, has no known function in milk or in the lactating mammary gland. Study of genetic similarities in mammary and pancreatic cells may provide evidence of an evolutionary expression of DNA coding for these enzymes as the mammalian species evolved.

While the evolution of lactation and the origin of bioactive components in human milk are still unknown, the functional significance of BSSL to the neonate cannot be ignored. Once ingested by the infant, BSSL is active in the digestion of milk lipid in the intestine. Because pancreatic function of the human infant is not fully developed in early life, this bioactive component is important for the neonate, especially the premature (36). Wang *et al.* (27) reported a greater rate of growth in kitten fed milk replacer supplemented with purified human BSSL. Similarly, addition of human milk to low-birth-weight infant formulas resulted in a lower excretion of fat by very premature infants as compared to infants fed formula alone (37). Furthermore, fat absorption is lower in preterm infants fed pasteurized as compared to fresh human milk (38).

Use of the ferret as an animal model will allow detailed investigation of the mechanisms of BSSL synthesis in the mammary gland and secretion into milk throughout lactation. Furthermore, animal studies will enable the investigation of the regulation of *prepartum* synthesis and secretion of BSSL. Preliminary studies indicate that BSSL is present in human *prepartum* mammary secretions as early as three months before full term delivery (39). In addition, the use of the ferret will allow study of the *in vivo* role of BSSL in fat digestion in the newborn's

intestine and its impact on normal growth and development.

Neutral Glycolipids of Human and Bovine Milk[1]

David S. Newburg* and **Prasoon Chaturvedi**
Biochemistry, Shriver Center for Mental Retardation, Waltham, Massachusetts 02254

The neutral glycolipids of milk, a small fraction of the total lipids, are of potential biological importance. The simultaneous quantitation of the simple (less than five sugars) glycosphingolipids of human milk samples was achieved by high-pressure liquid chromatography. The samples, representing various stages of lactation, parity of the nursing child, and age of the mother, contained similar glycolipid patterns, but with varying individual glycolipid concentrations. The cerebrosides are major glycosphingolipids of human milk: the non-hydroxylated fatty acid (NFA)-containing species are present at 1.8 μM, and the hydroxylated and/or short-chain fatty acid-containing species (HFA) are present at 1.7 μM; NFA lactosylceramide is present at 931 nM. The cerebrosides appear to be primarily galactosylceramides (galactocerebrosides); glucosylceramides (glucocerebrosides) are a minor component. Globotriaosylceramide (Gb_3) is found at 50 nM and 73 nM for the NFA and HFA species, respectively, while globoside (Gb_4) is found at 45 nM and 46 nM for the NFA and HFA species. Bovine milk glycosphingolipids differ from those of human milk, with bovine milk containing mainly NFA glucosylceramide (8 μM) and NFA lactosylceramide (17 μM); bovine milk contains little Gb_3 or Gb_4.
Lipids 27, 923–927 (1992).

Many reports now indicate that breast-fed infants may have a lower incidence of morbidity and mortality than artificially-fed infants, not only in less developed nations with high endemic levels of pediatric disease (1), but also in more developed countries (2,3). Although many factors could contribute to this phenomenon, non-immunoglobulin protective factors found in human milk are receiving increasing recognition as contributors to human protection. For example, the milk ganglioside GM_1 binds to cholera toxin and labile toxin of *Escherichia coli* (4), and to a related toxin produced by *Campylobacter jejuni* (5).

Many other glycolipids are able to bind to pathogens. The simple (less than five sugars) neutral glycolipids of the globo-series which are a common feature of most mammalian membranes are shown in Figure 1. Gb_3 (globotriaosylceramide), with its terminal galactose α1-4 galactose, is known to bind to Shiga toxin I (6) and to Shiga-like toxin types 1 and 2 (7,8), as well as to the P pili of uropathogenic *E. coli* (9). Gb_4 (globoside), whose galactose α1-4 galactose moiety is found in the internal sequences of the molecule, binds to P pili (10) and to the type 2 variant of Shiga-like toxin (11). Thus, the presence of such lipids in milk would be consistent with the general hypothesis that human milk contains non-immunoglobulin compounds capable of competing with infantile host cell receptors for binding to pathogens, thereby conferring protection to the nursing infant.

Glycolipids have been investigated in ruminant and human milk: over half of the glycolipids of caprine milk and 70% of the glycolipids of bovine milk are associated with the milk fat globule membrane (MFGM). Bovine MFGM contains glucocerebroside and lactosylceramide as its major constituents; both of these glycolipids contain mainly non-hydroxy fatty acids (NFA), and lactosylceramide is present at slightly higher concentrations than cerebroside (12). Human MFGM also contains cerebroside and lactosylceramide as its major constituents. However, it contains four times the total glycolipids as bovine MFGM, galactocerebroside accounts for 88% of the total monohexosylceramide, 20% of the fatty acid residues are hydroxylated fatty acids (HFA), and lactosylceramide is present in much lower concentrations than the cerebrosides (13) (see structures in Fig. 1). The molecular species of cerebrosides found in the bovine MFGM differed from those found in the skim milk; MFGM cerebrosides contained primarily long-chain fatty acids, while those in the skim milk contained fatty acids primarily of 18 carbons and shorter.

To our knowledge, the degree of individual variation in milk glycolipid levels has not been determined. This is of particular interest because of the potential for these milk

glycolipids to alter binding of enteric pathogens in the infant.

The present study had two purposes: The first was to compare the glycolipid profiles of whole human and whole bovine milk, with particular interest in Gb_3 and Gb_4 levels. The second was to measure the degree to which the concentrations of these glycolipids vary among human milk samples obtained from a diverse population of healthy lactating mothers and how they vary among commercially available bovine milk samples.

EXPERIMENTAL PROCEDURES

Milk samples. For qualitative analysis of bovine milk, a cow in the Boston area was milked, and, within 30 s, aliquotted directly into methanol to produce a sample that was subjected to no further storage or processing prior to glycolipid analysis. For quantitative analysis, five samples of pooled bovine milk from different processing plants were obtained commercially, and duplicate aliquots of each sample were analyzed on the day of purchase. Human milk samples were obtained from the Central Massachusetts Regional Milk Bank, Worcester. Thirty random samples were pooled for a representative human milk glycolipid profile to be compared with the bovine profile. Sixteen individual samples were selected to represent a wide range of maternal age (mean, 29 yr; SD, 5 yr; range, 20–37 yr), ethnicity, parity of the child (primiparous, 5; secondiparous, 7; tertiparous, 2; quadriparous, 2), and stage of lactation (1–17 mon).

Duplicate aliquots of each sample were utilized to quantitate the concentrations of the individual glycolipids in human milk, and to determine the degree to which they vary among individuals. Human samples were frozen immediately after pumping, stored for a period of up to ten days at −20°C, and transported and stored at −80°C until analysis.

Glycolipid extraction. Duplicate aliquots of 3 mL of well mixed milk samples were placed into 15-mL screw-capped glass culture tubes. Methanol (4 mL) and chloroform (8 mL) were added sequentially with vigorous mixing to establish the Folch lipid distribution (14). After centrifugation, the upper phase was removed, and the lower phase was rinsed with 2 mL of chloroform/methanol/water (3:48:47, vol/vol/vol; theoretical upper phase), filtered through glass wool, and dried and the residue was dissolved in 200 μL of chloroform and applied to a 125-mg silicic acid column (15). The column was washed with 3 mL of chloroform, and the lower phase glycolipid fraction was eluted from the column with 4 mL of acetone/methanol (9:1, vol/vol). The dried glycolipid fraction was subjected to mild alkaline hydrolysis for one hour at ambient temperature with 1 mL 0.6M NaOH in methanol and 1 mL of chloroform to hydrolyze glycerol-derived fatty acid esters. After 1 h, the reaction was stopped with 1.5 mL 0.4M HCl_{aq} and Folch distribution established with the addition of 1 mL methanol and 3 mL chloroform; the upper phase, containing salts and hydrolysis products, was discarded; the lower phase was washed twice with theoretical upper phase, and the glycolipid fraction was dried and lyophilized.

Perbenzoylation. A fresh solution of 10% benzoyl chloride in dry pyridine (0.5 mL) was added to each glycolipid sample; after 16 h at 37°C, the sample was dried under nitrogen (16). Hexane (3 mL) and 80% $methanol_{aq}$ saturated with Na_2CO_3 (2 mL) were added, mixed vigorously for 1 to 2 min, and the lower phase was discarded. The upper phase (hexane) was rinsed five times by vigorous mixing with fresh lower phase, three times with 80% methanol, and then dried under nitrogen to yield the dry perbenzoylated glycolipids.

High-pressure liquid chromatography (HPLC). Perbenzoylated glycolipids were dissolved in CCl_4 and separated on a 50-cm × 2.1-mm column of Zipax uncoated silica (Rockland Technologies, Newport, DE; obtained through Mac-Mod Analytical, Chadds Ford, PA), using a 16-min linear gradient from 1% to 20% dioxane in hexane at 2 mL/min (17). Absorption at 229 nm was monitored on a Macintosh SE computer running Dynamax software (Rainin, Woburn, MA). Peaks were identified by co-elution with authentic commercial standards (Matreya, Pleasant Gap, PA), as well as co-elution with our own standards whose identities were previously determined by chemical and mass spectrometric methods. The identity of Gb_3 was further confirmed by its binding to pure Shiga toxin I (gift of Thomas G. Cleary, Houston, TX). Quantitation was derived from the area under the peaks. Glycolipid recovery from the original samples was 70 ± 10% by this method, and values given have been corrected for losses.

Statistics. The square of Pearson's product-moment correlation coefficient r^2 was calculated (18) for each glycolipid across duplicate analyses of milk samples from 16 different mothers to determine the proportion of the variance common to both sets of duplicate data, which we used to differentiate the biological variation (variance in common) from that inherent to our analytical method (random variance).

RESULTS

The glycolipid pattern of the unprocessed milk sample obtained from an individual cow was similar to that from commercially obtained bovine milk, which is pooled and processed; however, the individual sample contained low but measurable levels of Gb_3, while Gb_3 was rarely detected in any commercial bovine milk samples in our laboratory. The individual bovine sample was used in Figure 2 to compare the neutral glycosphingolipid HPLC profile of an individual human milk sample (upper panel) with that of an equivalent bovine milk sample (lower panel). The major constituents of whole bovine milk are glucocerebroside and lactosylceramide (see Fig. 1 for structures) of the non-hydroxylated fatty acid-containing species. In contrast, the principal constituents of whole human milk are the galactocerebrosides containing both NFA and HFA, and, to a lesser extent, NFA lactosylceramide. The shoulder on the leading edge of the NFA galactocerebroside peak was found to be NFA glucocerebroside by a separate analysis. Small but appreciable quantities of NFA and HFA Gb_3 and NFA and HFA Gb_4 are found in human milk; whereas this bovine milk sample contains less Gb_3 and no Gb_4. The compilation of five independent analyses of pooled bovine milk is shown in Table 1.

It is striking that the dominant glycolipid of bovine milk is NFA lactosylceramide, which, at a concentration of 17 μM, represents 64% of the neutral glycosphingolipid fraction. NFA glucocerebroside, at 8 μM, represents another 29% of this fraction, and HFA cerebrosides, at

[b]NFA, non-hydroxylated (normal) fatty acids.

1.3 μM, accounts for approximately 5%. HFA lactosylceramide and NFA phytoglucosylceramide are found in small amounts. Neither Gb_3 nor globoside was detected in these commercial samples. Note the lower relative standard errors for these analyses, possibly reflecting the highly pooled nature of these samples.

The glycolipids of sixteen individual samples of human milk, representing a wide range of maternal age, stage of lactation, and parity, were measured in duplicate, and the results are shown in Table 2. In this set of analyses, the HFA lactosylceramide was more fully resolved than in the chromatograms shown in Figure 2; its peak, immediately following NFA lactosylceramide, was baseline resolved, allowing unequivocal quantitation. In a separate chromatographic analysis (not shown), the NFA glucocerebroside and NFA galactocerebroside peaks were baseline resolved, and the glucocerebroside, which occurs as a shoulder of the galactocerebroside in Figure 2 and included in the total

[b]NFA, non-hydroxylated (normal) fatty acids.

[c]HFA, hydroxylated fatty acids.

NFA cerebroside value of Table 2, was found to comprise 21% of the NFA cerebrosides. The HFA cerebrosides (glucocerebroside and galactocerebroside) always coelute in this chromatographic system. The total cerebroside peaks (NFA glucocerebroside, NFA galactocerebroside, and HFA cerebrosides) represent 75% of the lower phase neutral glycolipids of human milk. Lactosylceramide accounts for over 20% of the total. Thus, Gb_3 and Gb_4 represent a minor but consistent component of human milk. For most of the glycolipids of human milk, the NFA and HFA species are present in approximately equal proportions, except for lactosylceramide, of which 90% is the NFA species.

When the concentration of each type of human milk glycolipid was expressed as a percentage of the total glycolipids, the standard error of the mean represented by each species was approximately 10% of the mean, with the exception of the major constituents, the cerebrosides, for which the standard error was less than 4% of the mean. When expressed as absolute glycolipid concentrations in milk, the measured error was approximately 15% of the mean in most cases, except for the cerebrosides, which displayed an error of approximately 10% of the mean. The Pearson product moment correlation ($r = 0.7$) indicates that approximately half ($r^2 = 0.5$) of this variation is attributable to aspects of the analytical method, and approximately half is attributable to biological differences in the glycolipid content of the milks of individual donors.

DISCUSSION

The differences in the HPLC profiles of the neutral glycosphingolipids of whole human and of whole bovine milk are striking (Tables 1 and 2). The dominant species of bovine milk are NFA lactosylceramide and its precursor, NFA glucosylceramide. In human milk, NFA cerebrosides and HFA cerebrosides predominate; NFA lactosylceramide is the other major component. These findings are consistent with previous reports on the major glycolipids found in milk and in milk components. For example, ceramide monohexoside and ceramide dihexoside were identified in bovine milk (19). These glycolipids were isolated from bovine milk fat globules (20), and glucose was found to be the only carbohydrate in the ceramide monohexoside, thus identifying it as glucocerebroside, and

ceramide dihexoside contained both glucose and galactose, consistent with the lactosylceramide structure. The major fatty acids identified from these compounds were 16:0, 22:0 and 23:0, consistent with our finding mainly NFA glucocerebroside and NFA lactosylceramide. The glycolipids from MFGM were compared with those from skim milk for both bovine and caprine milks (12). For both of these milks, the glycolipids were of the NFA type, the milk fat globule membrane contained over half of the total glycolipids of milk, and their glycolipids contained longer chain fatty acids than those from the skim milk. This is consistent with the glycolipid patterns we found in whole bovine milk.

In a comparison of the glycolipids of human and bovine milk fat globule membrane, 88% of the monohexoslycerамide in human milk fat globule membrane was galactocerebroside, and only 12% was glucocerebroside, in contrast to bovine monohexosylceramide, which was all glucocerebroside (13). In whole human milk we found that glucocerebroside was approximately 21% of the NFA monohexosylceramide. The content of cerebrosides was reported to be approximately equal to that of lactosylceramide in bovine MFGM, whereas in human MFGM there is much more cerebroside than lactosylceramide; our results from whole milks are consistent with these findings. Also, the bovine MFGM glycolipids were reported to contain only NFA species, whereas human MFGM galactocerebroside contained 20% HFA.

Human MFGM was reported to be much higher in total glycolipids than that of bovine; however, our data from whole milks (Tables 1 and 2) indicate that the total neutral glycosphingolipid of whole bovine milk is greater than 27 μM, while the concentration in whole human milk is approximately 5 μM. We chose to compare the glycolipids of whole milk rather than of purified milk components to avoid potentially confounding effects such as differential yields of similar compartments from the milks of different species.

The data reported herein are consistent with the above reports, taking into account that glycolipids of the MFGM differ from those found in the fluid phase, and that the MFGM glycolipids represent only one component of the total glycolipids found in whole milk.

During the analysis of bovine and caprine milk polar lipids by thin-layer chromatography, the sporadic presence of a faint band corresponding to trihexoside ceramide has been reported (21). Our data confirm that Gb_3 is present infrequently, and only in very low amounts, in bovine milk samples. To our knowledge, ours is the first report to define this material as Gb_3, and to demonstrate the presence of Gb_3 and Gb_4 in human milk. These glycolipids were found in all of the human samples tested, although the amount in milk was relatively low (approximately 1% for the NFA and HFA species of each glycolipid), and somewhat variable.

Although the Gb_3 and Gb_4 levels were low relative to the mono- and dihexosides, they have the potential to be highly significant biologically. Both of these glycolipids contain the galactose α1-4 galactose structure that acts as the receptor for adhesins of pathogenic *E. coli,* and as the receptor for toxins.

The variation in measured glycolipid levels of bovine milk was quite low, consistent with the virtual elimination of individual variation due to the extremely highly pooled nature of commercial milk. In contrast, the variation in measured glycolipid levels of human milk was statistically attributed half to error in the measurement technique and half to biological variation. The lower variation seen when the data was expressed as the percent of total glycolipids, compared with the data expressed as absolute amounts per volume of milk, suggests that much of the error of the analytical method occurs during lipid extraction, isolation, and/or the absolute injection, which would affect absolute quantitation more than the relative ratios of glycolipids. The presence of significant variation among different mothers suggests biological variation in the glycolipid content of human milk, which could be related to the blood group types of the mothers, in which genetic differences in glycolipid metabolism could result in biological variation in milk glycolipids. Supporting this concept is the report that individuals of different P blood group types have different globo-series glycolipid patterns in erythrocytes, including Gb_4, Gb_3, and lactosylceramide (see structures, Fig. 1) (22). Thus, the relationship between blood group types, milk glycolipid patterns, and incidence of specific disease in infants should be the subject of further studies.

ACKNOWLEDGMENTS

We wish to thank Dr. Robert H. McCluer for his encouragement and advice in these studies. The technical assistance of Leslie Finck Ledsham, Edward Ullman and Jesse Lerman is gratefully acknowledged; we also thank Miriam Erikson, Director of the Central Massachusetts Human Milk Bank, Worcester, MA, for providing the human milk samples. This study was supported in part by grant HD13021 from the National Institute of Child Health and Human Development and contract #100220023SC from the Massachusetts Department of Mental Retardation.

Oxidative Interactions of Cholesterol in the Milk Fat Globule Membrane[1]

S.K. Kim and W.W. Nawar*
Department of Food Science, University of Massachusetts, Amherst, Massachusetts 01003

The effects of oxidative interactions between cholesterol and milk fat globule membrane (MFGM) components, *i.e.*, nonlipid fraction, total lipid, nonpolar lipid and polar lipid, on cholesterol oxidation were studied in the presence and absence of water. In the dry state, cholesterol natively present in MFGM appeared to be protected at 135°C. The nonpolar lipid and nonlipid fraction contributed to the protective effect of MFGM. Added cholesterol accelerated the oxidation of membrane lipid fractions. At 75°C, pure cholesterol and membrane lipid fractions did not show significant interaction. However, cholesterol and other lipids in MFGM were less stable than when these were heated separately. When cholesterol and membrane lipids were mixed in an aqueous medium at 75°C, each accelerated the oxidation of the other. The MFGM exhibited a high protective effect on cholesterol oxidation in an aqueous environment. The nonlipid fraction protected cholesterol against oxidation, whereas the lipid fraction was destructive. In the absence of water, the net balance between these two opposing factors was destructive. The presence of water reversed the balance in favor of protection.
Lipids 27, 928-932 (1992).

Bovine milk contains approximately 3-5% fat in the form of globules and these are surrounded by a thin membrane (1). This milk fat globule membrane (MFGM) consists of proteins, glycoproteins, triacylglycerols, cholesterol, enzymes and other minor components. The unsaturated lipids in the membrane were reported to play a role in initiating the oxidation of milk fat (2). Chemical and microscopical data (3-7) indicate that the MFGM originates from the plasma membrane of the secretory cells. Therefore, MFGM can be defined as a modified plasma membrane. Oxidation of membrane lipids would naturally be expected to cause alterations in membrane function which eventually lead to disturbance in cell physiology.

The objective of this work was to investigate the influence of the interaction among the membrane components on their oxidative stability using MFGM as a model membrane system.

EXPERIMENTAL PROCEDURES

Materials. Cholesterol and silicic acid were purchased from Sigma Chemical Co. (St. Louis, MO). Cholesterol used in this study contained less than 0.9% of contaminants, including 7-ketocholesterol, 7β-hydroxycholesterol, 5,6-epoxides and cholest-3,5-dien-7-one. Cholesterol oxide standards and silylating agents were obtained from Steraloid Inc. (Wilton, NH) and Pierce Chemical Co. (Rockford, IL), respectively. Solvents were high-performance liquid chromatography (HPLC) grade from various sources.

Preparation, fractionation and characterization of MFGM. Raw milk was obtained from the University of Massachusetts farm and pasteurized at 63°C for 30 min. Cream was separated by centrifugation, then washed twice with 3 vol of Tris-HCl buffer (10 mM, pH 7.5 containing 0.25 M of sucrose and 1.0 mM of $MgCl_2$) and once with 1 vol of 50 mM Tris-HCl buffer (pH 7.5) (4). The washed cream was resuspended in 50 mM Tris-HCl buffer, and the cream structure was destroyed by freezing and thawing to liberate MFGM from the cream structure (8). Butter was separated from the MFGM suspension by centrifugation at $2,500 \times g$ for 20 min. The butter was washed with 1 vol of distilled water to recover the residual MFGM, and the water part was combined with the MFGM suspension (9). The membrane suspension was centrifuged at $100,000 \times g$ for 1 h to obtain the membrane (10). The pellets were dispersed in distilled water and quickly recentrifuged to remove the buffer salts from the membrane fraction. The membrane was then freeze-dried and stored at −40°C.

The freeze-dried MFGM was washed 3 times with 5 vol of $CHCl_3$/MeOH (2:1, vol/vol) and centrifuged at $5,000 \times g$ for 30 min to obtain the nonlipid fraction (NL) of MFGM, which was dried and stored at −40°C. Solvent in the extract was removed on a rotary evaporator to obtain crude MFGM lipid. The crude lipid was purified (11) and fractionated into polar and nonpolar fractions by silicic acid column chromatography. Chloroform and methanol were used to elute the nonpolar lipids (NPL) and the polar lipids (PL), respectively (12).

PL and NPL fractions were separated into their components by thin-layer chromatography (TLC) (silica gel G, 0.25 mm thickness). The solvent system used for NPL was petroleum hydrocarbon/diethyl ether/acetic acid (90:10:1, vol/vol/vol) (12), and that used for PL was $CHCl_3$/MeOH/water/18.4% aqueous NH_3 (130:70:8:0.5, vol/vol/vol/vol).

TLC fractions were visualized by heating the plates at 120°C for 25 min after spraying with a potassium dichromate/sulfuric acid solution. The lipid classes were quantitated with a TLC densitometer.

Sample treatment. Solutions of cholesterol and membrane lipid in chloroform (1 mg each) were placed in vials, and the solvent was evaporated on a rotary evaporator to make a thin film on the bottom of each vial. For the dry samples, the vials were placed in an oven at 135°C for 40 h or at 75°C for 40 d. For the aqueous samples, 1 mL of 10 mM Tris buffer was added to each vial and incubated at 75°C for 6 d. The lipids in the reaction tubes were extracted with 3.5 mL of chloroform/methanol (2:1, vol/vol) and divided into two parts, one for cholesterol analysis and the other for fatty acid analysis.

Cholesterol analysis. Cholesterol and its oxides were separated from the heated mixtures of cholesterol and membrane lipids by silicic acid column chromatography. The NPL, mainly triacylglycerols, were eluted with hexane/diethyl ether (95:5, vol/vol), followed by cholesterol and its oxidation products with 100% diethyl ether. Phospholipids remained on the column. The ether fraction was

[1]Based on a paper presented at the Symposium on Milk Lipids held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

Abbreviations: BSTFA, *N,O-bis*-(trimethylsilyl)trifluoroacetamide; HPLC, high-performance liquid chromatography; MFGM, milk fat globule membrane; NL, nonlipid fraction; NPL, nonpolar lipids; PL, polar lipids; TL, total lipids; TLC, thin-layer chromatography; TMCS, trimethylchlorosilane.

collected and silylated with *N,O-bis*-(trimethylsilyl)trifluoroacetamide (BSTFA) and 1% trimethylchlorosilane (TMCS) at 80°C for 1 h. The trimethylsilyl ethers were separated on a Varian 3700 GC (Varian Associates, Palo Alto, CA) equipped with an Ultra-1 capillary column (50 m, 0.2 mm i.d. and 0.33 μm film thickness, Hewlett-Packard, Avondale, PA) with temperature programming from 100°C to 300°C at the rate of 10°C/min. 5α-Androstan-3β-ol-17-one acetate was used as an internal standard for the analysis of cholesterol and its oxides.

Fatty acid analysis. Oxidation of triacylglycerols and free fatty acids was traced according to the loss of their fatty acyl chains. Fatty acid analysis was done by methylating the whole lipid portion directly without using silicic acid column chromatography. The lipid samples containing 1–2 mg of lipid were saponified with 0.5 mL of 2N methanolic KOH solution at 65°C for 25 min, then methylated with 0.5 mL of 14% BF_3/methanol solution at 65°C. After 25 min reaction, residual methylating agent was deactivated by adding 0.5 mL of water. The fatty acid methyl esters were extracted with hexane and analyzed by gas chromatography on a Supelcowax-10 capillary column (30 m, 0.32 mm i.d. and 0.25 μm film thickness, Supelco Inc., Bellefonte, PA). Triheptadecanoin was used as an internal standard. The graphs in this report represent the averages of triplicate analyses.

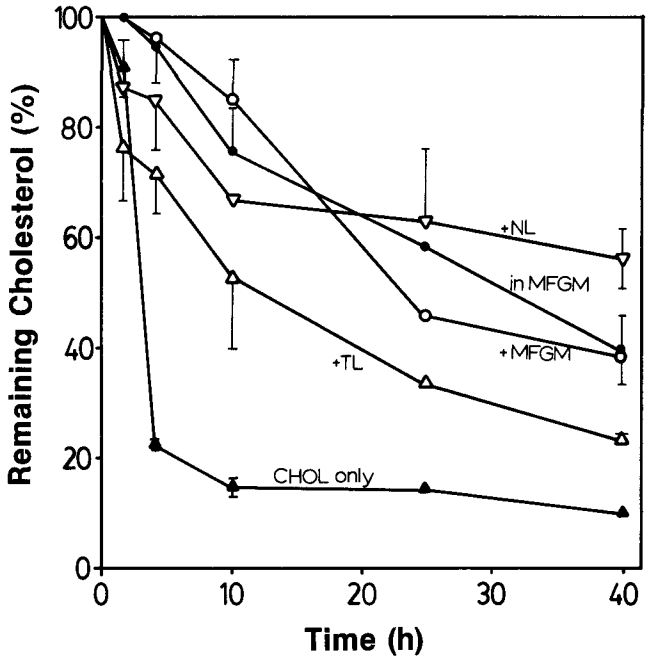

FIG. 1. Effect of membrane components on cholesterol oxidation in the dry state at 135°C. MFGM, milk fat globule membrane; NL, nonlipids; TL, total lipids; CHOL, cholesterol.

RESULTS

Composition of milk fat globule membrane. The water content of the dried MFGM was 7.6% (w/w). The MFGM solids, 92.4%, consisted of 59.7% total lipids (TL) and 32.7% NL. Spectrophotometric analysis of the protein in MFGM using bovine serum albumin as a standard showed a total protein content of 32.0% (w/w), indicating that 98% of the nonlipid fraction was protein. TL were fractionated into NPL and PL on a silicic acid column. The NPL were eluted first with chloroform followed by PL with methanol. The NPL and PL in the dried MFGM accounted for 46.6% and 13.1%, respectively.

The NPL contained mainly triacylglycerols (42.5%), diacylglycerols (32.0%) and free fatty acids (6.3%). The PL contained 17.5% phospholipids (29.7% sphingomyelin, 24.8% phosphatidylcholine, 17.4% phosphatidylethanolamine, 13.3% phosphatidylinositol and 14.8% others) and 82.5% of unidentified compounds, probably glycerides. The lipid fractions (TL, NPL and PL) did not show significant differences in their fatty acid profiles (38.6–41.4% palmitate, 10.3–17.8% stearate, 12.6–15.5% oleate, etc.).

Effect of MFGM and its components on cholesterol oxidation in the dry state. At 135°C, cholesterol in the MFGM appears to be protected against oxidation when compared to pure cholesterol (Fig. 1). The TL fraction inhibited cholesterol destruction. The NL fraction of MFGM was more protective than the TL fraction. When the whole MFGM (containing 32.7% NL and 59.7% TL) was added to pure cholesterol, no changes in cholesterol amount were observed until 5 h heating at 135°C, when it started to decrease. Finally, the remaining cholesterol reached a level in between those produced by NL and TL (Fig. 1). The added MFGM showed a net protective effect on cholesterol oxidation.

When the PL fraction of MFGM was added to cholesterol at 135°C, it did not influence the stability of cholesterol (Fig. 2). The NPL protected cholesterol against oxidation. The effect of TL (containing 21.9% PL and 78.1% NPL) on cholesterol oxidation was in between the effects of its two components, *i.e.*, polar and nonpolar.

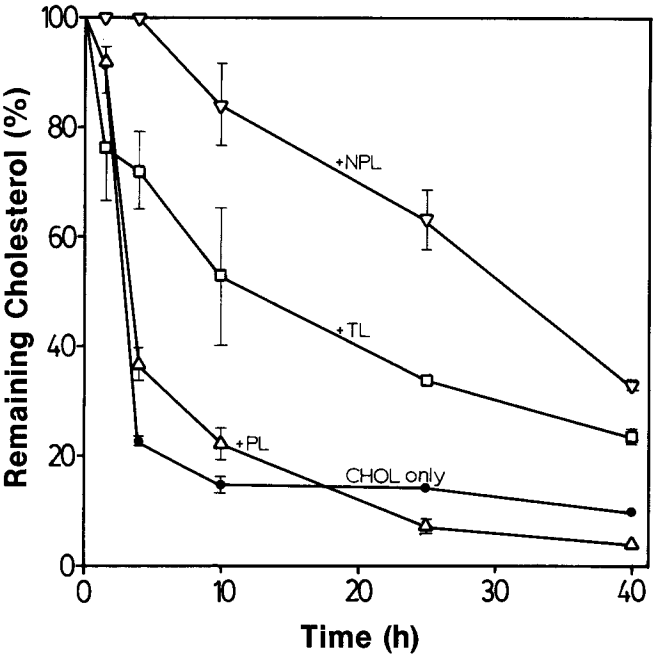

FIG. 2. Effect of membrane lipid fractions on cholesterol oxidation in the dry state at 135°C. TL, total lipids; NPL, nonpolar lipids; PL, polar lipids; CHOL, cholesterol.

At 75°C, cholesterol in MFGM was much less stable than pure cholesterol (Fig. 3). Solid cholesterol is very

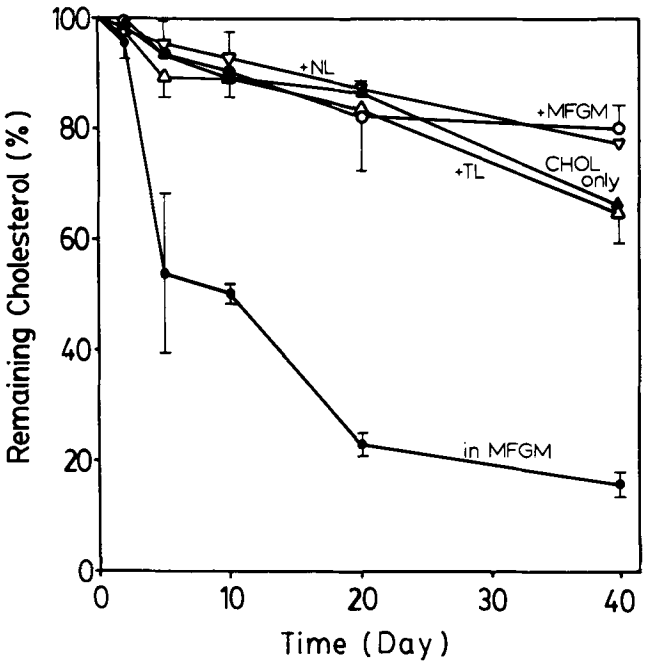

FIG. 3. Effect of membrane components on cholesterol oxidation in the dry state at 75°C. MFGM, milk fat globule membrane; NL, nonlipids; TL, total lipids; CHOL, cholesterol.

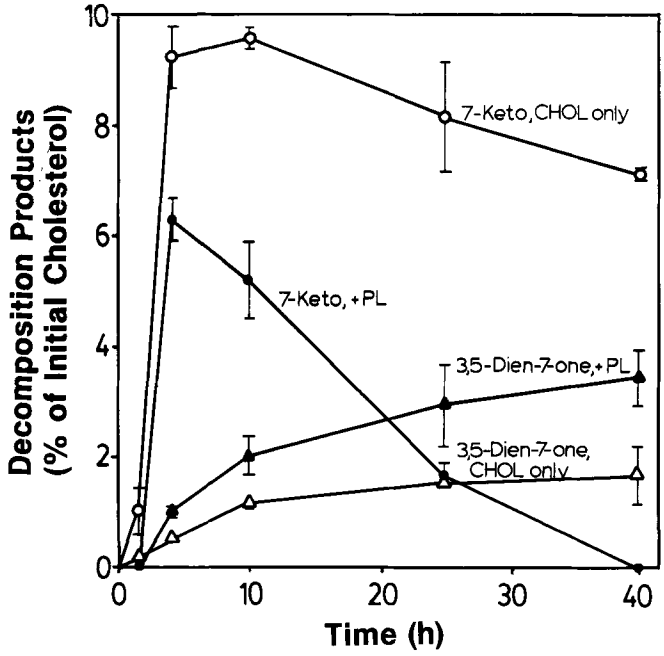

FIG. 4. Effect of membrane polar lipids (PL) on the production of 7-ketocholesterol (7-Keto) and cholesta-3,5-dien-7-one (3,5-Dien-7-one) in the dry state at 135°C.

stable at low temperature. Molecular orientation or the surrounding components in MFGM may have accelerated cholesterol oxidation. Addition of MFGM, TL or NL did not show a significant effect on cholesterol oxidation at 75°C. Only a slight protective effect of added NL and MFGM was observed after 40 d of heating (Fig. 3). The lack of an effect of added MFGM and its components on cholesterol oxidation at 75°C may be due to the lack of interaction between cholesterol and these components. When the solvent was evaporated during sample preparation, cholesterol was crystallized and separated from the other components added. Therefore, at 75°C the opportunity for interaction was minimized, whereas at 135°C, the cholesterol crystals were melted and well mixed. The difference in cholesterol stability between the mixtures and dry MFGM at 75°C appears to reflect the effectiveness of the natural mixing in MFGM.

In the presence of MFGM and its components, cholesterol produced very low levels of oxides, although substrate cholesterol was decreased during heating. Only when the PL fraction was added did cholesterol produce relatively large amounts of 7-ketocholesterol and cholesta-3,5-dien-7-one (Fig. 4). Since the PL fraction of MFGM contains phosphatidylcholine and sphingomyelin as the main components, the oxide profile produced was similar to that of phosphatidylcholine and sphingomyelin, *i.e.*, formation of 7-ketocholesterol at the beginning of heating followed by its conversion to cholesta-3,5-dien-7-one.

Effect of MFGM and its components on cholesterol oxidation in aqueous system. As demonstrated in Figure 5, MFGM cholesterol was very stable during six days of incubation in buffer at 75°C. Sonication of the MFGM to destroy or reorganize its native structure did not affect the stability of cholesterol in the membrane. When MFGM was added to pure cholesterol, it exhibited a

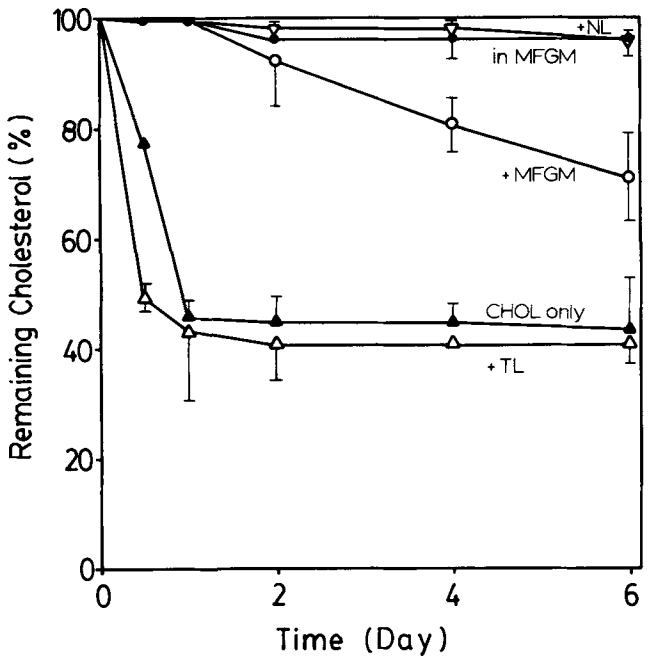

FIG. 5. Effect of membrane components on cholesterol oxidation in dispersion at 75°C, pH 7.4. MFGM, milk fat globule membrane; NL, nonlipids; TL, total lipids; CHOL, cholesterol.

protective effect. In contrast to the dry state, in aqueous dispersion the lipid portion of MFGM (TL, NPL and PL) accelerated cholesterol oxidation at the beginning of incubation, *i.e.*, the first 12 h of heating. The stability of cholesterol in the presence of NPL or PL was similar to that in the presence of TL (Fig. 5). The NL fraction

appears to be the most protective among the MFGM components tested.

In the presence of whole membrane materials or NL fraction of MFGM, cholesterol did not produce appreciable amounts of cholesterol oxides. However, in the presence of the lipid portion (TL, NPL or PL) of MFGM, approximately the same level of total oxides was produced as that observed in the pure cholesterol control. Higher amounts of epoxides and 7-hydroxycholesterols also were observed when the MFGM lipid was added. The lipid fraction favored 7-hydroxylation but did not have a significant effect on the β- to α-form ratios of 7-hydroxycholesterols and epoxides.

Effect of added cholesterol on the oxidation of membrane lipid. The saturated fatty acids exhibited higher stability than the unsaturated ones in dry MFGM heated at 135°C, and in MFGM, TL, PL and NPL heated at 75°C in the presence of water. However, saturated short chains in the lipid fractions (TL, PL and NPL) of MFGM showed low stability when heated at 135°C in the dry state. Figure 6 shows that the short chain fatty acids were less stable than the longer chains, both saturated and unsaturated. An explanation for the more rapid disappearance of the short chains cannot be provided at this time.

When cholesterol was added to MFGM or its lipid fractions at 135°C, it accelerated the destruction of the C_{18} chains, *i.e.,* stearate, oleate and linolenate, of membrane lipid, but the short chain fatty acids became more stable. The destructive effect of cholesterol on the oxidation of C_{18} chains was much greater when it was added to membrane PL (Fig. 7).

In contrast to the behavior at 135°C, addition of cholesterol to MFGM did not affect the stability of membrane lipids at 75°C. As discussed earlier, at 75°C in the dry state, cholesterol and added components did not appear to interact.

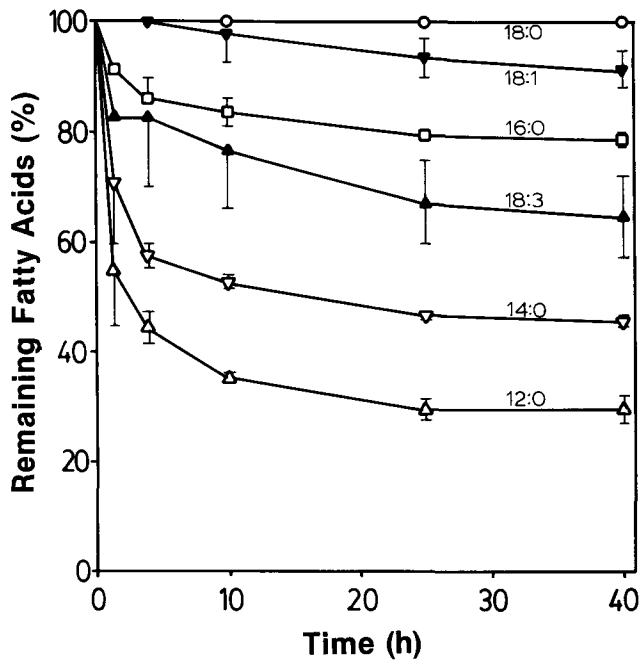

FIG. 6. Stability of fatty acyl chains in membrane total lipid fraction during heating in the dry state at 135°C.

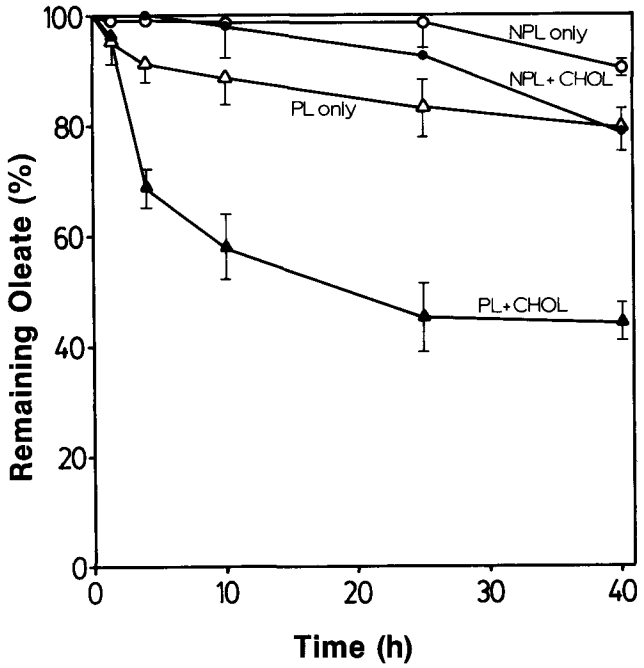

FIG. 7. Effect of cholesterol on the oxidation of oleate in membrane lipids at 135°C. NPL, nonpolar lipids; PL, polar lipids; CHOL, cholesterol.

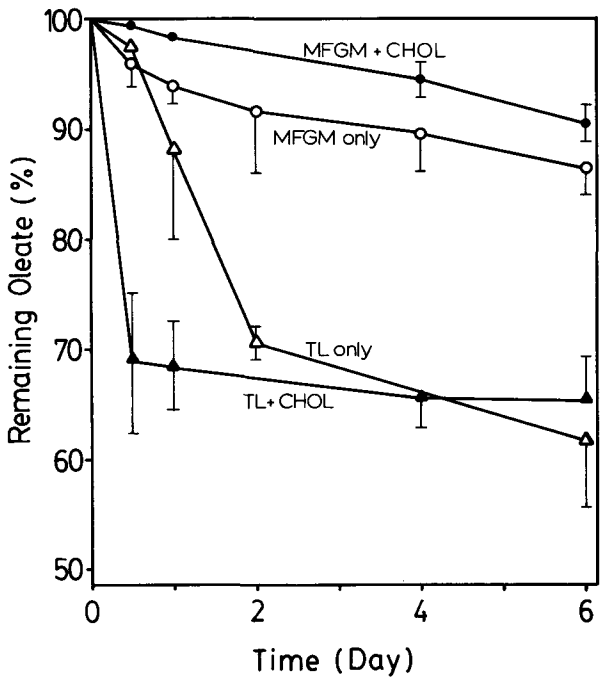

FIG. 8. Effect of cholesterol on the oxidation of oleate in membrane lipids in dispersion at 75°C, pH 7.4. MFGM, milk fat globule membrane; TL, total lipids; CHOL, cholesterol.

The lipids in MFGM were very stable in aqueous dispersions when compared to each of its lipid fractions incubated alone (Fig. 8). Stability of PL and NPL in the absence or presence of cholesterol also showed similar patterns to those of TL. When cholesterol and whole MFGM

were mixed in aqueous dispersion, they protected each other from oxidation. However, when cholesterol was mixed with the MFGM lipid portion, they accelerated each other's oxidation at the beginning of incubation and then reached a plateau (Figs. 5 and 8).

DISCUSSION

The MFGM consists of various components, such as proteins, triacylglycerols, phospholipids and other compounds, including monoacylglycerols, diacylglycerols and free fatty acids.

In the dry state at 135°C, the effects of added membrane components on cholesterol oxidation and the oxidation of cholesterol natively present in MFGM showed consistent results, *i.e.,* MFGM and its components protected cholesterol from oxidation, and cholesterol accelerated the oxidation of membrane lipids. However, because of poor interaction between cholesterol and added MFGM components at 75°C, only cholesterol in MFGM showed a significant difference from the cholesterol control. Cholesterol natively present in MFGM is well surrounded by other membrane components. The interactions between cholesterol and neighboring molecules, and perhaps their physical arrangement, appears to have accelerated cholesterol oxidation. When the heating temperature was increased from 75 to 135°C, the stability of pure cholesterol changed drastically whereas in MFGM, the interaction between cholesterol and neighboring molecules counteracted the temperature effect on the stability of cholesterol. Consequently, the neighboring components in MFGM which are destructive at 75°C showed apparent protection at 135°C.

When incubated alone, cholesterol oxidized faster in aqueous dispersion than in the dry state at the same temperature (Figs. 3 and 5). However, cholesterol natively present in MFGM exhibited high stability in aqueous dispersion. The lipid portion of MFGM (TL, NPL, PL) accelerated cholesterol oxidation at the beginning of incubation, then did not show a significant effect on further cholesterol oxidation in the aqueous system.

Added cholesterol accelerated the oxidation of MFGM lipid fractions (TL, NPL, PL) in both dry and aqueous systems, and it also promoted oxidation of the lipids in whole MFGM in the dry state. However, in the aqueous system, added cholesterol protected the lipids in MFGM against oxidation. Cholesterol tended to accelerate the oxidation of the other lipids in the membrane. However, in the presence of water, the NL fraction of MFGM appeared to provide a condition where both cholesterol and the other lipid components protected each other (Table 1).

The MFGM exhibited a high protective effect on cholesterol oxidation in an aqueous environment. Its NL fraction protects cholesterol from oxidation, while the lipid fraction was destructive in the early stages of cholesterol oxidation. In the absence of water, the net balance between these two opposing factors was destructive. The presence of water tipped the balance in favor of protection.

The results of this study suggest that both biochemical and physico-chemical factors are important in protecting the membrane against destruction.

High-Performance Liquid Chromatography of Human Milk Triacylglycerols and Gas Chromatography of Component Fatty Acids[1]

Karen D. Dotson[a], John P. Jerrell[b], Mary Frances Picciano[c] and Edward G. Perkins[a,b,*]
[a]Division of Nutritional Sciences and [b]Department of Food Sciences, University of Illinois, Urbana-Champaign, Illinois 61801 and [c]Department of Nutrition, Pennsylvania State University, University Park, Pennsylvania 16802

Human milk triacylglycerols were separated by high-performance liquid chromatography. A 5-μ Supelcosil LC-18 column (Supelco, Inc., Bellefonte, PA) was used with acetone/acetonitrile (64:36, vol/vol) as mobile phase. Triacylglycerols were tentatively identified based on theoretical carbon number and relative retention time. Despite changes resulting from dietary fat variation, the major component triacylglycerols were those composed of palmitic, oleic and linoleic acids. Triacylglycerols with palmitic, stearic and oleic acids were present as minor components. Fatty acids were quantified by gas chromatography relative to an internal standard. Ratios of n-6/n-3 fatty acids were found to be higher than previously reported. *Lipids 27*, **933-939 (1992).**

The lipids contained in human milk are derived from maternal depot fat stores, endogenous synthesis in the mammary gland and dietary sources. Several studies have demonstrated the relationship between maternal dietary intake and milk fatty acid composition and have shown a dietary effect on both mobilization of fats from body stores and endogenous synthesis. Insull *et al.* (1) were the first to show that human milk lipids are affected by maternal diet: when on a high fat diet, the women studied produced milk high in triacylglycerols of long-chain fatty acids, reflecting the fatty acid composition of the dietary fats and low endogenous fatty acid synthesis; when on a low fat, calorie-restricted diet, the milk predominated in triacylglycerols of long-chain fatty acids derived from body fat sores; upon ingesting a very low fat diet, the milk showed a marked increase in medium-chain fatty acids indicating increased endogenous synthesis. In agreement with the principles proposed by Insull *et al.* (1), studies on Gambian women (2), Egyptian women (3) and American vegetarian women (4) have shown that milk fat content mirrors maternal dietary fat intake.

While the component fatty acids of human milk are well documented (4-7), only a few studies have investigated the triacylglycerol composition of human milk (8,9). Because triacylglycerols represent approximately 98% of the lipids of human milk (7), the availability of a method for their analysis would facilitate a greater understanding of the direct effect of maternal diet on milk fat composition and structure. To this end, we have developed a procedure for the separation and identification of triacylglycerols by high-performance liquid chromatography (HPLC).

HPLC of naturally occurring lipids has been extensively used, and the sequence of triacylglycerol elution in the present system has been established (10). Using this method, triacylglycerols were identified by their equivalent carbon numbers (ECN), which takes into account the carbon numbers and number of double bonds of the various acyl groups. Identification of triacylglycerols was further verified by calculating retention times relative to triolein and by comparing these retention times with those of known standard triacylglycerols, as well as by further analysis of component peaks (10).

The fatty acids composing human milk triacylglycerols were quantified by gas chromatography relative to an internal standard. The content of long-chain polyunsaturated fatty acids (LC PUFA; C_{18} and greater) in milk could thus be accurately quantified. The very low concentrations of LC PUFA in human milk should not be taken as an indication of their unimportance in infant nutrition (11-14). Carlson *et al.* (11) observed that premature infants fed human milk containing docosahexaenoic acid (DHA, 22:6n-3) had significantly higher concentrations of DHA in red blood cell (RBC) membrane phospholipids than infants fed milk formulas lacking DHA. Using nonhuman primates, Neuringer *et al.* (13) have presented evidence implicating the n-3 fatty acids, particularly DHA, in critical neural and retinal development in the neonate. DHA appears to be preferentially incorporated into brain and retinal phospholipids (15), and the high level of LC PUFA in these phospholipids seems to contribute to the characteristic membrane fluidity observed in these tissues (16-18); it also appears essential to their proper functioning (19). The data by Anderson *et al.* (12) suggest that DHA is the optimal n-3 fatty acid for brain and retinal development; yet current infant formulas do not provide this long-chain fatty acid nor its precursor, eicosapentaenoic acid (EPA, 20:5n-3).

EXPERIMENTAL PROCEDURES

Materials. The instrument used for triacylglycerol analyses consisted of a Waters 501 chromatographic pump (Waters, Inc., Milton, MA), a Rheodyne loop injector (20 μL, Rheodyne Model 7120, Berkeley, CA), and a Waters Model 410 differential refractometer detector; a Hewlett-Packard (Palto Alto, CA) Model 3390A electronic integrator was used to record separations and retention times. Triacylglycerols were separated on a 25 cm × 4.6 mm i.d. column packed with Supelcosil LC-18 (5 micron particle size, Supelco, Inc., Bellefonte, PA).

A Hewlett-Packard Model 5890 gas chromatograph

Abbreviations: AA, arachidonic acid (20:4n-6); CN, carbon number; CV, coefficient of variation; D, decanoic acid (10:0); DHA, docosahexaenoic acid (22:6n-3); ECN, equivalent carbon number; EPA, eicosapentaenoic acid (20:5n-3); FA, fatty acid(s); FAME, fatty acid methyl ester(s); GC, gas chromatography; HPLC, high-performance liquid chromatography; L, lauric acid (12:0); LC PUFA, long-chain polyunsaturated fatty acid(s); Ln, linolenic acid (18:3n-3); Lo, linoleic acid (18:2n-6); M, myristic acid (14:0); O, oleic acid (18:1n-9); P, palmitic acid (16:0); Po, palmitoleic acid (16:1n-7); TAG, triacylglycerol; S, stearic acid (18:0); RBC, red blood cell(s); TCN, theoretical carbon number; TLC, thin-layer chromatography.

equipped with a Supelcowax 10 column (30 m × 0.25 mm i.d.) (Supelco, Inc.) of film thickness 0.25 microns was used for fatty acid analyses. The column conditions were: temperature, 180°C; injector 250°C; detector 270°C; linear velocity, 44.6 cm/s. Sample size for injection was approximately 2 μL containing 0.0094–0.0099 μg ester. Separations and retention times were recorded on a Hewlett-Packard Model 3392A electronic integrator.

Reagents and standards. A mixture of HPLC grade acetone/acetonitrile (64:36, vol/vol) was used as mobile phase for HPLC analysis. Triacylglycerol standards were purchased from Nu-Chek-Prep, Inc. (Elysian, MN).

n-Octacosane was purchased from K and K Laboratories, Inc. (Plainview, NY) for use as an internal standard in fatty acid analysis. Standard PUFA methyl esters were obtained from Nu-Chek Prep, Inc.

Sample collection and preparation. Human milk was collected at 4, 6 and 8 wk *postpartum* (± 3 days) by electric pump expression of the entire contents of one breast from healthy women residing in Champaign-Urbana, IL. All samples were collected between 8 a.m. and 11 a.m., placed on ice, and transferred to the laboratory for immediate extraction.

The fat portion of a 20-mL aliquot of a milk sample was separated by centrifugation at 10,000 × *g* for 20 min at 0°C, using a Beckman Model J2-21 centrifuge (Beckman Instruments, Fullerton, CA). The lipid layer was suspended in *ca.* 100 mL of chloroform/methanol (2:1, vol/vol) for 5 min and gravity-filtered; the extract was then concentrated to approximately 2 mL with a rotary evaporator and further evaporated to dryness under N_2. The triacylglycerols were subsequently extracted with 3 mL hexane. Solid-phase extraction chromatography of the extracted lipid on silicic acid was accomplished using 6 mL Supelclean LC-Si SPE tubes (Supelco, Inc.). Subsequent elution with chloroform yielded the triacylglycerol fraction and elution with chloroform/methanol the polar fraction, following the method of Juaneda and Rocquelin (19). Purity of the triacylglycerol fraction was verified by thin-layer chromatography (TLC) on silica gel (20), and was found to be >98% triacylglycerol. Samples in chloroform were stored for a short time at −20°C in glass vials with Teflon-lined caps. Triacylglycerol solutions were prepared for HPLC by dissolving a known quantity of the triacylglycerol fraction in the mobile phase at a concentration of 10 mg/mL.

Fatty acid methyl esters (FAME) were prepared from aliquots of the triacylglycerol fractions using the AOCS Official Method Ce 2-66 (21). To measure absolute fatty acid content, octacosane was added as an internal standard because it did not coelute with any of the fatty acids. Standard FAME mixtures were cochromatographed to verify sample retention times and identify the methyl esters. The weight of each fatty acid was calculated from the equation:

$$\text{wt of FA} = \frac{\text{(peak area of FA)}}{\text{(peak area of standard)}} \times \text{(wt of standard added)} \quad [1]$$

Triacylglycerol identification[2]. The separation of the triacylglycerols in our studies was found to follow that predicted by El-Hamdy and Perkins (10). Elution progresses from the component with the lowest ECN to the highest and within an ECN from the highest degree of unsaturation to the lowest (Fig. 1). Triacylglycerol identification was based on a scheme outlined by El-Hamdy and Perkins (10): critical pairs are structures with an equivalent carbon number, defined as:

$$\text{ECN} = \text{CN} - 2n \quad [2]$$

where CN = actual carbon number; n = number of double bonds per molecule.

Triacylglycerols elute in a pattern dependent on solvent

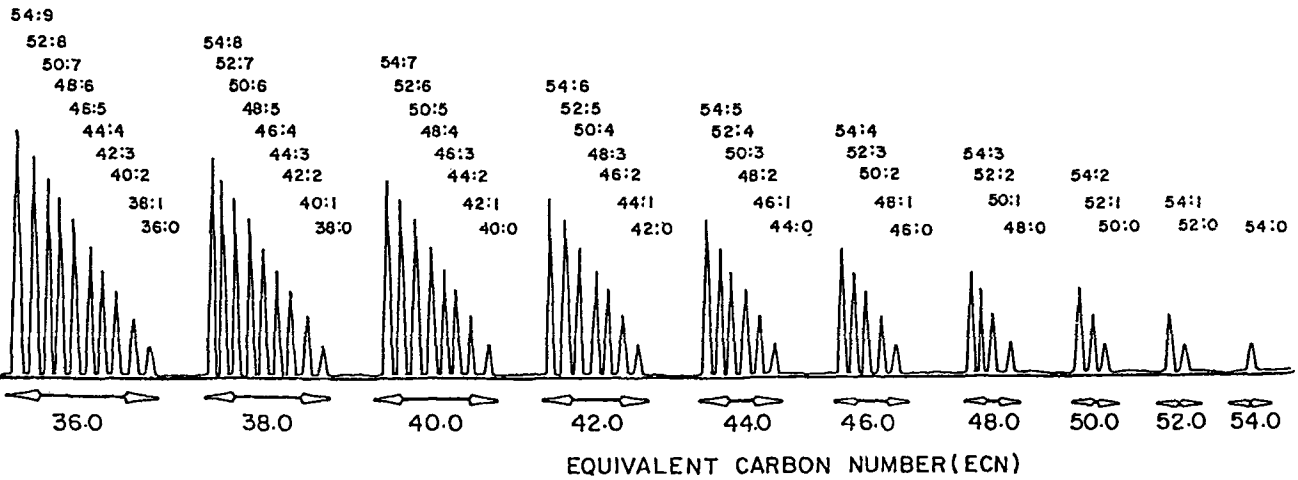

FIG. 1. Elution of triacylglycerols. Theoretical separation pattern by high-performance liquid chromatography (40).

[2]Triacylglycerol abbreviations used (*e.g.* PLO) are intended to define composition rather than positional fatty acid distribution; *i.e.*, a peak identified as PLO may be composed of the triacylglycerolisomers PLO, POL, LOP, LPO, OLP and OPL.

[a]Triacylglycerol components as defined in footnote 2.

[b]Equivalent carbon number (ECN) is defined as ECN = CN − 2n where CN equals the actual carbon number and n equals the number of double bonds per molecule.

[c]Theoretical carbon number (TCN) is defined as: TCN = ECN − (Σ_1^3 U_i), where TCN = theoretical carbon number; ECN = equivalent carbon number; U_i = a factor determined experimentally for several fatty acids and found to be: 0.6 for oleoyl, 0.7 for linoleoyl, 0.2 for elaidoyl groups, and 0.0 for saturated acyl groups; (Σ_1^3 U_i) = the total U_i of component fatty acids present in a particular triacylglycerol (11).

composition and resolution of the column. Critical pairs may co-elute because of their close ECN values, if the column resolution is less than adequate. Among components of identical ECN, triacylglycerols containing more saturated acyl groups will tend to elute more slowly because of their higher affinity with the column packing (10). Conversely, the triacylglycerols with more unsaturated acyl groups will elute more rapidly because of decreased affinity with the stationary phase. Thus their order of elution may be accurately predicted (10).

Furthermore, the theoretical carbon numbers of all possible triacylglycerols within an essential carbon number group may be used to predict the order of elution of critical pairs of triacylglycerols (Table 1). The theoretical carbon number can be calculated by the following formula:

$$TCN = ECN - (\Sigma_1^3 U_i) \quad [3]$$

where TCN = theoretical carbon number; ECN = equivalent carbon number; U_i = a factor determined experimentally for several fatty acids and found to be: 0.6 for oleoyl, 0.7 for linoleoyl, 0.2 for elaidoyl groups, and 0.0 for saturated acyl groups; Σ_1^3 U_i = the total U_i of component fatty acids present in a particular triacylglycerol (10). Differences between TCN values indicate the possibility of separating the triacylglycerols. Some triacylglyerols, however, will have identical TCN values and cannot be separated in this system. For example, the TCN of OMM = 43.37 and the TCN of OPL = 43.37, therefore OMM

and OPL cannot be distinguished by this method, although identification may be accomplished by examining fatty acid composition of the factions.

Additionally, peaks were identified by retention time relative to triolein. To calculate relative retention times, triolein was added to mixtures for which the triacylglycerol components are known (*e.g.*, corn oil, olive oil, beef tallow) and to standard mixtures of triacylglycerols.

RESULTS AND DISCUSSION

Triacylglycerols. The separation of human milk triacylglycerols is illustrated in Figure 2. The chromatographic patterns varied slightly between subjects and with the stage of lactation; however, relative retention times were consistent among all milk samples. If a peak could not be positively identified because of co-elution with other triacylglycerols of identical TCN, the fatty acid composition of the sample was examined. Thus, if a peak could be identified as LLM, MMD, PLD or SDD (all of TCN = 38.00), and the fatty acid data revealed only trace amounts of decanoic acid, the fraction could be reliably identified as LLM. In all cases of multiple assignment choices, the triacylglycerol most closely reflecting the sample fatty acid composition was assigned to the peak.

Human milk was shown by this method to contain more than twenty-seven triacylglycerol structures, of which six, LPP, PPO, LoLoP, SSL, LSO and LoPL, accounted for 55% of the total; the remaining triacylglycerols contributed less than 5% each. The average triacylglycerol composition of human milk is shown in Table 2, representing milk samples from ten women collected at three time periods each. The data are also expressed as average percent by stage of lactation. Considerable variation existed among women, reflecting the sensitivity of milk fat to dietary fat intake. Although some variation was seen between time periods, no significant variation ($P > 0.05$) in triacylglycerol content was noted at various stages of lactation at 4, 6 and 8 wk. The data for the six most predominant triacylglycerols are shown in Figure 3 as average percentages at 4, 6 and 8 wk.

A more complex elution pattern was obtained when two columns were fixed in series (Fig. 4). Although greater resolution was obtained, more than 90 min was required to effect a separation. The increased resolution resulted in separation within critical pairs, creating shoulders on the elution peaks. This made identification and quantification considerably more difficult. Therefore the data obtained on a single column, as shown in Figure 2, were used to assess the composition of the major triacylglycerols.

Fatty acids. Palmitic, stearic, oleic and linoleic acids were the most abundant, constituting approximately 76% of the total fatty acids. Fatty acid composition was observed to differ among subjects and between time periods, but the differences were not statistically significant. Fatty acid data are compiled in Table 3.

Unlike fat from sources such as cow's milk-based formulas, the fat of human milk is very efficiently adsorbed by both the term and the preterm neonate; this is due in part to the structure of the human milk triacylglycerols (22). The distribution of fatty acids within the triacylglycerols of human milk is not random, as certain fatty acids are preferentially esterified at the *sn*-2 position (23). When

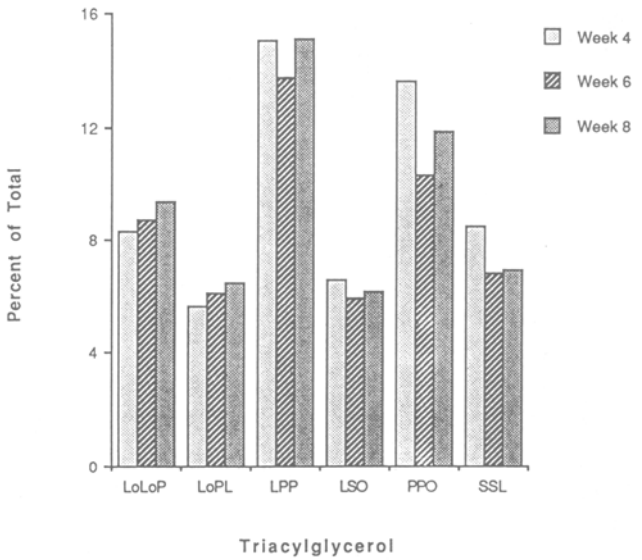

FIG. 3. Distribution of major triacylglycerols identified in human milk. Each bar represents mean of 10 samples. No significant differences were observed between time periods. Triacylglycerol components as defined in footnote 2.

Freeman *et al.* (24) hydrolyzed total human milk triacylglycerols with pancreatic lipase, they observed that 74 mol% of the palmitic acid was esterified at the *sn*-2 position. Breckenridge *et al.* (8) also observed that most of the palmitic acid was in the *sn*-2 position of the triacylglycerol moiety. After hydrolysis of the 1- and 3-position by specific lipases (such as lingual and pancreatic lipases), much of the remaining 2-palmitoylglycerol may be absorbed by the neonate. Alternatively, when palmitic acid is esterified in the *sn*-1 or *sn*-3 position, as it is in cow's milk, and subsequently released upon hydrolysis as free fatty acid, it would become susceptible to precipitation by calcium and thus excreted, resulting in the loss to the neonate of both energy and calcium (25). Oleic acid, typically the most abundant fatty acid found in milk of women on Western diets (4–7), is also present in human milk triacylglycerols in a characteristic pattern. Kuksis and co-workers (8,9) separated the saturated and unsaturated triacylglycerols and examined the fatty acid composition of the classes thus separated. They observed that 52.6% of oleic acid in the sample was present as triacylglycerols containing two oleic acids. In other naturally occurring lipids, the more unsaturated fatty acid component is usually esterified in the 2-position of the glycerol moiety (26). Based on fatty acid data from human milk, one would expect to find increased linoleic and oleic acid concentrations in the 2-position and greater concentrations of saturated fatty acids in the 1- and 3-position. That such distribution is not predominant further emphasizes the distinct differences of human milk triacylglycerols from other triacylglycerols in nature.

As with adults, the fatty acid composition of infants' depot fat reflects the dietary fat intake (22). This was demonstrated by Widdowson *et al.* (27) in comparing the fat stores of English and Dutch infants. English infants, ingesting cow's milk formula, had approximately 3% linoleic acid in their subcutaneous fat; Dutch infants had approximately 35% linoleic acid in their fat stores as a result of the substitution of maize oil, high in linoleic acid, for the fat of cow's milk-based formulas. Gairdner (28) also noted that depot fat of breast milk-fed infants differed from that of formula-fed infants and reflected the fat composition of the diet.

Of particular importance to the neural and retinal development of the neonate is the presence in human milk of essential fatty acids and certain long-chain polyunsaturated fatty acids. Experiments in nonhuman primates have shown that n-3 fatty acids are necessary for normal

visual development (13,29,30). DHA appears to be of singular importance in both retinal and neural function. Human milk is the only infant food currently available which contains DHA (31); it also contains the important LC PUFA arachidonic acid (AA, 20:4n-6) and EPA. A physiological significance to the infant of DHA has not been demonstrated in humans. However, some recent studies (32-35) have shown an effect of differing n-3 fatty acid compositions in formula fed to premature infants; lowered erythrocyte DHA levels have been correlated with changes in electroretinogram, visual acuity and a test of infant memory. A specific requirement for DHA has not been demonstrated. Sinclair (36) showed that preformed dietary DHA was incorporated into the developing brain at ten times the rate of DHA formed from dietary linolenic acid by the infant, suggesting that the presence of DHA in human milk may confer a developmental advantage on breast-fed infants.

Although it is recognized that n-3 fatty acids are essential components of the diet, the Food and Nutrition Board of the National Research Council (37) has not established a neonatal requirement for n-3 fatty acids. Neuringer *et al.* (14) have suggested that the ratio of n-6/n-3 fatty acids present in human milk be used as a basis for dietary recommendations for normal neonatal development. This ratio appears to vary greatly among women and time periods, again reflecting the sensitivity of human milk fat to maternal dietary fat intake. The ratio reported for human milk is 4:1 to 10:1 (38,39). We have found a somewhat higher ratio in the milk of our subjects, all on self-selected Western diets; n-6/n-3 ratio averaged 12:1 and ranged from 2:1 to 22:1. Milk from our subjects contained approximately 18% of total fatty acids as n-6 fatty acids, in agreement with other data (4,6) from women on Western diets. We observed an average DHA concentration of 0.16 ± 0.01 weight %; Finley *et al.* (4) observed 0.23 ± 0.14% of DHA in milk of California women, while Bitman *et al.* (6) found a lower average of 0.06 ± 0.004% DHA in milk of Maryland women. The developmental significance of these levels of DHA in milk remains to be shown in human infants.

Using high-performance liquid chromatography and gas chromatography for dual analysis of the same samples, we were able to obtain quantitative measurement of triacylglycerols and fatty acids, including the n-3 and n-6 LC PUFA. We observed that the predominant triacylglycerols consisted of lauric, palmitic, stearic, oleic and linoleic acids. Four of the fatty acids, palmitic, stearic, oleic and linoleic acids, composed the major portion of the total fatty acids. Much variation in triacylglycerol and fatty acid composition was seen among subjects and time periods, reflecting dietary effects on milk lipid composition. Our data suggest that infants breast-fed by women on self-selected diets receive preformed LC PUFA from breast milk; however further analysis is necessary to understand the positional incorporation of these LC PUFA into milk triacylglycerols. The present method of triacylglycerol analysis is advantageous as a technique of sample analysis. Minor components may be concentrated from the sample for further analysis by collecting the triacylglycerol fractions as they elute from the column.

COMMUNICATION

Fatty Acid Composition of Black Bear (*Ursus americanus*) Milk During and After the Period of Winter Dormancy[1]

Sara J. Iverson[a,b,*] and **Olav T. Oftedal**[b]

[a]Canadian Institute of Fisheries Technology, Technical University of Nova Scotia, Halifax, Nova Scotia, B3J 2X4 Canada and [b]National Zoological Park, Smithsonian Institution, Washington, D.C. 20008

Black bears give birth and lactate during the 2-3-mon fast of winter dormancy. Thereafter the female emerges from the den with her cubs and begins to feed. We investigated fatty acid patterns of milk from native Pennsylvania black bears during the period of winter dormancy, as well as after den emergence. Throughout winter dormancy, milk fatty acid composition remained relatively constant. The principal fatty acids at all times were 14:0, 16:0, 16:1, 18:0, 18:1, 18:2n-6, 18:3n-3 and 20:4n-6. After den emergence, large changes occurred in almost all the fatty acids, particularly in 18:2n-6 and 18:3n-3. Large variability among the active free-ranging animals likely reflected differences in diet. In a carnivore, with apparently limited *de novo* synthesis of fatty acids, milk fatty acid composition may be affected by factors such as transition from reliance on stored lipids to feeding, and by temporal changes in dietary intake.
***Lipids 27,* 940-943 (1992).**

The pattern of fatty acids in milk lipids varies considerably among mammalian species. Triglycerides (TG) account for 97-99% of milk lipid in the species that have been studied (1-3). However, among different species TG are composed to varying degrees of fatty acids originating from *de novo* synthesis within the mammary gland and/or from circulating fatty acids (4,5). The extent to which milk fatty acids reflect dietary or body storage lipids will depend on the extent of *de novo* synthesis. Other factors which may affect milk fatty acid composition include lactation stage and, in humans, gestation length (1,5-7).

Carnivores are believed to secrete milk lipids that result primarily from the uptake of circulating fatty acids and thus largely reflect dietary lipids. This is in contrast to ruminants, which secrete milk lipids high in short-chain fatty acids (4:0-6:0) of *de novo* origin, and some monogastrics (*e.g.*, rabbit, rat, mouse, elephant, and primates, including human), which secrete milk lipids high in medium-chain fatty acids (8:0-12:0) of *de novo* origin (4,5,8,9). The longer-chain fatty acids (≥ 16:0) may originate from either *de novo* synthesis or from uptake by the mammary gland. Although it is generally believed that the long-chain fatty acids are derived primarily from circulating blood lipids, the mammary gland of at least one species, the guinea pig, synthesizes primarily 16:0, as well as 18:0 and 18:1 (5,10,11). Unfortunately, fatty acid synthetase of the mammary gland has been studied in relatively few species, none of which are carnivores (5,12). Degree of plasma lipid uptake by the mammary gland also has been studied in only a few species, primarily in ruminants (9,12,13), and patterns may change with starvation (13).

Bears (family Ursidae) are of particular interest because they enter a period of winter dormancy, during which females give birth to and begin nursing their cubs (14). In the black bear *(Ursus americanus),* the first 2-3 mon of milk secretion occur while the female is fasting and mobilizing body lipid stores. Subsequently, the lactating female emerges from the den with her cubs and begins to feed on an omnivorous diet during the next months of lactation (15,16). Thus we would expect that milk fatty acids would reflect the composition of stored lipid in the denned-up period and dietary lipids thereafter. Although a number of studies on fatty acid composition of bear milks (17-20) have been undertaken, they have not been sufficiently detailed or comprehensive to permit an assessment of the effect of either winter dormancy or subsequent feeding on fatty acid composition.

The relationship of milk lipid composition to lactation stage is largely unknown for most free-ranging mammals. Prior reports on milk fatty acid composition for nondomestic species have usually been based upon analysis of only one or a few samples; information on lactation stage is often omitted, and it is sometimes unclear whether samples were taken from captive or wild individuals (*e.g.*, 18,21-23). In the present study we examined the fatty acid patterns of milk obtained from wild black bears at various stages of winter dormancy, as well as after den emergence. Our aims were to investigate i) whether changes occur in milk fatty acid composition during the prolonged fast in the den and ii) the extent to which milk fatty acid composition changes upon the transition from fasting to feeding.

MATERIALS AND METHODS

Milk samples were collected from a native population of black bears in the Poconos Mountains in eastern Pennsylvania. In Pennsylvania, as in other populations, females begin denning in late November and early December, about the same time that delayed implantation of the fertilized egg occurs (14-16). The average birth date is mid-January, and the female remains in the den with her cubs until late March or early April (15). Samples from the denned-up period were obtained from nine lactating females inhabiting natural or artificial dens in January [0-1 days *postpartum* (PP)], February (3-4 wk PP) and March (7-9 wk PP) 1984, corresponding to early (n=3), mid (n=3) and late (n=3) winter dormancy, respectively. Post-dormant samples (n=4) were collected from additional

[1]Based on a paper presented at the Symposium on Milk Lipids held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

Abbreviations: ANOVA, analysis of variance; EFA, essential fatty acid; GC, gas chromatograph; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; PP, *postpartum*; PUFA, polyunsaturated fatty acid; TG, triglyceride.

free-ranging females from June to October (5–9 mon PP) of the same year. Females were immobilized with a mixture of ketamine HCl and xylazine delivered with a pole syringe (denned-up bears) or a dart (free-ranging bears). Milk was expressed manually following intramuscular injection of oxytocin. Milk samples were stored frozen at −20°C until analysis.

Total milk fat was determined gravimetrically using the standard Roese-Gottlieb procedure for milks (24). All solvents used for fatty acid analysis were high-performance liquid chromatography (HPLC) grade and all containers were composed of glass or teflon. Aliquots were extracted into chloroform using a modification (25) of the method of Folch *et al.* (26). Fatty acid methyl esters were prepared using the Hilditch reagent (0.5 N H_2SO_4 in methanol) (3) and extracted into isooctane for analysis. Methyl esters were separated by temperature-programmed gas-liquid chromatography (GLC) on a J&W DB-23 glass capillary column (30 m × 0.25 mm i.d.) (J&W, Folsom, CA) on a Shimadzu model GC-14A gas chromatograph (Shimadzu Scientific Instruments, Columbia, MD). Carrier gas was helium. Starting column temperature was 153°C and temperature was increased stepwise to 220°C over a 30 min period. Peak identities were determined from known standards, and peak areas were quantified and normalized by automatic integration using a Shimadzu C-R4A Cromatopac. Fatty acids are herein designated by shorthand nomenclature of chain length:number of double bonds, where n-x denotes the position of the last double bond relative to the terminal methyl end. Data were tested by one-way analysis of variance (ANOVA) and subsequent Fisher PLSD multiple mean comparison tests or by two-tailed *t*-tests using a statistical package (Statview 512+, Brain Power Inc., Calabasas, CA) for the Macintosh. Data are presented as mean wt % ± SEM unless otherwise indicated.

RESULTS AND DISCUSSION

During the period of winter dormancy, fat content of the milk of eastern Pennsylvania black bears increases significantly as lactation progresses (27). In the present study, milk fat content was similar to that of the larger population, averaging 13.2 ± 2.75%, 22.8 ± 2.81% and 22.2 ± 3.09% at early, mid and late winter dormancy, respectively. However, despite the doubling of total fat content, milk fatty acid composition remained relatively constant throughout the period of dormancy (Fig. 1). The principal fatty acids of bear milk were 14:0, 16:0, 16:1n-9, 16:1n-7, 18:0, 18:1n-9, 18:1n-7, 18:2n-6, 18:3n-3 and 20:4n-6. During the winter dormancy, there was generally very little variability in levels of individual fatty acids among lactating females and little change occurred over time, except in levels of 16:0, 16:1n-9 and 20:4n-6, which decreased significantly after 1 day PP (ANOVA, Fig. 1). At all three stages, 16:0, 16:1, 18:0 and 18:1 accounted for about 85% of fatty acids. The major polyunsaturated (PUFA) and essential fatty acid (EFA) was 18:2n-6; the other principal PUFA were the EFA 18:3n-3 and 20:4n-6, although absolute levels were relatively low (Fig. 1). A number of minor fatty acids were also present at trace or very small amounts (≤ 0.6%) throughout lactation (Table 1).

Following the several months of lactation during winter dormancy, the female black bear emerges from the den

FIG. 1. Fatty acid composition of black bear milk over the period of winter dormancy. Early, 0–1 d *postpartum* (PP); mid, 3–4 wk PP; and late, 7–9 wk PP. Bars are means and vertical lines are 1 SEM. Means with different superscripts were significantly different (analysis of variance), *$P < 0.05$, **$P < 0.01$ and ***$P < 0.001$.

TABLE 1

Fatty Acid Composition of Black Bear Milk During and After the Period of Winter Dormancy[a]

Fatty acid	wt% Den (n=9)	wt% Post dormancy (n=4)
14:0	2.0 ± 0.16	3.2 ± 0.36[c]
16:0	28.9 ± 1.16	23.5 ± 1.74[b]
16:1n-9	0.8 ± 0.16	0.3 ± 0.04[e]
16:1n-7	6.9 ± 0.46	3.0 ± 0.38[d]
18:0	2.9 ± 0.21	5.8 ± 0.44[d]
18:1n-9	40.7 ± 1.42	37.2 ± 3.24[e]
18:1n-7	3.9 ± 0.17	1.6 ± 0.03[d]
18:2n-6	7.4 ± 0.74	15.7 ± 3.61[c]
18:3n-3	0.5 ± 0.06	5.1 ± 3.34[b]
20:4n-6	1.6 ± 0.34	0.3 ± 0.04[b]

[a] Values are means ± SEM. Minor components included 12:0 (0–0.1%), 14:1n-5 (0.2–0.3%), 17:0 (0.1–0.4%), 17:1 (0.3–0.6%), 18:1 (other isomers) (0.1–0.6%), 20:1 (0.4–0.5%), 22:1 (0.2–0.6%), 20:5n-3 (0–0.3%), 22:5n-3 (0–0.2%) and 22:6n-3 (0–0.2%). Data were tested by two-tailed *t*-test.

with her cubs and begins to roam in search of food (14,15). During this time, milk fat content was somewhat higher than it was earlier in lactation, averaging 28.0 ± 3.50%. Although there was little change or variability in milk fatty acid patterns over the period of winter dormancy, large changes occurred following emergence from the den (Table 1). Significant differences were found between the denned-up period and the active post-dormant period for every major fatty acid except 16:1n-9 and 18:1n-9. Levels of 14:0, 18:0 and 18:2n-6 approximately doubled after emergence, while levels of 16:1n-7, 18:1n-7 and 20:4n-6 were less than half those of the denned-up period. Most notable were the extremely high levels and considerable variability in the EFA 18:2n-6 and 18:3n-3 (Table 1). The levels of 18:2n-6, which averaged 7.4% during winter dormancy, were found to be as high as 21.6% after den

emergence. The levels of 18:3n-3 were even more remarkable. This fatty acid ranged between 0.2 and 0.8% during the denned-up period but was found to be as high as 15.0% during the active free-ranging period, with great variability among individual females. EFA intake may be particularly important to a bear cub because cubs are extremely small and altricial at birth [at <0.3% of maternal weight (14,15)], even for a carnivore (28). EFA appear to be adequately supplied in bear milk, with 18:2n-6 at about 6-13% of total calories over lactation, which is far in excess of human infant requirements (29,30).

In the present study, we found no evidence for *de novo* synthesis of short- or medium-chain fatty acids in the black bear; 12:0 was found in only trace amounts at a few stages (Table 1). Jenness *et al.* (31) came to the same conclusion with respect to a variety of bear milks, even though some reports from polar bears (17,19) and Yeso brown bears (20) indicate significant amounts of short-chain fatty acids. It is not clear whether the latter data may have been artifacts, as short-chain fatty acids are usually considered unique to ruminant milks (5). Whether the longer-chain fatty acids in bear milk derive from serum through uptake by the mammary gland or from *de novo* synthesis is not known. However, the long-chain n-6 and n-3 PUFA are all of dietary origin and, hence, must come from uptake.

During winter dormancy, milk lipids are secreted over an extended period of fasting. One might expect fatty acid composition to vary over this period due to changing rates of *de novo* synthesis, selective mobilization of depot fatty acids, or depletion of depot stores (*e.g.*, ref. 25), but the observed changes in fatty acid patterns were relatively minor (Fig. 1). Unfortunately, we were not able to compare milk fatty acid patterns to those of depot stores in these individuals. As such comparisons would need to be made in samples taken from the same animal (*e.g.*, ref. 25), data from other sources would not be appropriate.

The large changes that occurred after emergence (Table 1) presumably reflect dietary intake. Black bears feed primarily on a variety of fruits, nuts, acorns and succulent vegetation, as well as scavanged meat, human garbage, corn from farmed fields and, at least in Pennsylvania, handouts provided by human well-wishers (14-16). Hence the diets of individual bears may be highly variable. This may explain the high variability seen in the fatty acid patterns after emergence (Table 1). The high levels of 18:2n-6 and 18:3n-3 found in some plant materials, such as fruits, nuts, corn and leafy vegetation (*e.g.*, ref. 32), could account for the extraordinary levels found in some of the post-dormant milks. Lactating fur seals and sea lions that begin feeding after an initial fast also show substantial changes in milk fatty acid patterns with the onset of feeding (25,33). Significant increases in 18:2n-6 and 18:3n-3 have been observed in human milk lipids when subjects switch to vegetarian or corn oil-based diets (30). Although data is very limited, longer-chain PUFA have been reported in milks of the polar and grizzly bear (19). The diets of these animals are probably high in PUFA due to intake of fish and/or seal oils (*e.g.*, ref. 25).

Unfortunately, comparison of our data to those for other bears and other carnivores is difficult, given the limited nature of previous reports, as well as apparent misidentification of fatty acid peaks and/or failure to separate components with similar retention times. Species other than carnivores for which such very high levels of 18:3n-3 have been reported include the horse [n=1, (ref. 23)], koala [n=1, (ref. 23)] and red and mantled howler monkeys (wild, n=12, Iverson, S.J., and Oftedal, O.T., unpublished data), species which feed solely on vegetation.

Clearly, lactation stage and composition of the maternal diet are extremely important to the interpretation of milk fatty acid data in bears, and probably in other carnivores as well. In characterizing the fatty acid composition of any species, it is important to assay fatty acid composition on an adequate number of samples representing different lactation stages and, where known, maternal diet should be described. Results from this study also suggest that detailed data on milk fatty acid composition for free-ranging carnivores may allow inferences about the nature of their diet and thus may be useful in understanding both mammary gland physiology and the foraging ecology of a species, as has recently been demonstrated for several seal species (25,33).

ACKNOWLEDGMENTS

We are especially indebted to G. Alt of the Pennsylvania Game Commission, who made this study of black bear milk possible. He and his assistants provided logistical support, conducted all immobilizations and assisted in milk collection. M. Jakubasz of the National Zoo's Nutrition Lab, also assisted in sample collection and preparation. We are grateful to Drs. M. and P. Hamosh, Departments of Pediatrics and Physiology and Biophysics, Georgetown University Medical Center, Washington, D.C., for use of their GC in fatty acid analyses. We thank Dr. W. D. Bowen for valuable comments on the manuscript. Research on the black bear was supported in part by a grant from the Scholarly Studies Program of the Smithsonian Institution.

ARTICLE

The Existence of a Soluble Plasmalogenase in Guinea Pig Tissues

Christopher R. McMaster, Can-Qun Lu and Patrick C. Choy*
Department of Biochemistry and Molecular Biology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada, R3E 0W3

The distribution of plasmalogenase for the hydrolysis of 1-alkenyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (plasmenylethanolamine) in the subcellular fractions of guinea pig tissues was examined. Plasmalogenase activity was found in high abundance in the cytosolic fractions of the brain and the heart. Assessment of microsomal marker enzyme activities in the cytosolic fraction revealed that plasmalogenase activity in the cytosol was not due to microsomal contaminations. The characteristics of the cytosolic plasmalogenase were very similar to the microsomal enzyme with respect to the pH profile of the reaction, the presence of divalent cations and K_m values for plasmenylethanolamine. However, the cytosolic enzyme was slightly less stable at 55°C than the microsomal enzyme. Cytosolic enzyme activity was eluted as a broad peak in Sepharose 6B chromatography with an average molecular weight of 250,000. Our results demonstrate that most of brain plasmalogenase activity is soluble which makes the brain cytosol an excellent source to initiate the purification of this enzyme.
Lipids 27, 945-949 (1992).

Phospholipids containing an *O*-alkenyl group at the C-1 position (plasmalogens) are abundant in many mammalian tissues (1). The most widely distributed plasmalogens are the 1-alkenyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (plasmenylethanolamine) species (1). Despite their ubiquitous distribution, only limited information is available on the metabolism or function of these phospholipids (2). The high concentrations of plasmenylethanolamines in electrically active tissues such as the brain and the heart imply that they may be involved in ion transport across membranes (3). Plasmalogens may also serve as reservoirs for prostaglandin precursors due to the large proportion of arachidonic acid at the C-2 position (4-6). Recently, a 1-alkenyl-2-acetyl-*sn*-glycero-3-phosphoethanolamine analogue of platelet activating factor has been identified in human neutrophils (7). The importance of plasmalogens to protect cell membranes from oxidative stress with the 1-alkenyl bond functioning as an oxygen radical scavenger has also been postulated (8).

The 1-alkenyl bond of plasmenylethanolamine can be hydrolyzed by two separate catabolic pathways. In the mammalian brain and heart, a microsomal plasmalogenase has been identified that cleaves plasmenylethanolamine to lysophosphatidylethanolamine and a fatty aldehyde (9,10). An alternate route for the cleavage of the vinyl ether bond of plasmenylethanolamine involves the action of a putative phospholipase A_2 followed by a lysoplasmalogenase. A lysoplasmalogenase activity has been characterized in both liver (11) and brain (12) microsomes. In view of the irreversible damage to both cerebral and cardiac tissues by oxidative stresses during and after ischemia (13) and the protective role plasmalogens play in this process (8), the identification and characterization of plasmalogenase activities in these tissues is highly desirable. In this study, the distribution of plasmalogenase activity in the subcellular fractions of the guinea pig tissues was investigated. Surprisingly, plasmalogenase activity was found in high abundance in the cytosolic fraction from guinea pig brain and heart. The characteristics of the cytosolic enzyme activity were studied and compared to the activity found in the microsomal fraction.

Abbreviations: AU, absorbance unit; CDPethanolamine, cytidine diphosphoethanolamine; EDTA, ethylenediaminetetraacetic acid; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. Aldehyde dehydrogenase, NAD^+, glutathione (reduced form), NADPH, cytochrome c (reduced form), iodine, potassium iodide, butylated hydroxytoluene, Triton QS-15, polyoxyethylene sorbitan monolaurate (Tween 20), and CDPethanolamine (cytidine diphosphoethanolamine) were purchased from Sigma Chemical Company (Toronto, Ontario, Canada). Thin-layer chromatography (TLC) plates (Sil-G25) were obtained from Fisher Scientific (Ottawa, Ontario, Canada). Silicic acid (BIO-SIL A) for column chromatography was a product of Bio-Rad Laboratories (Mississauga, Ontario, Canada). BDH Limited (Poole, England) provided the 2% dimethyldichlorosilane in 1,1,1-trichloroethane solution. Phospholipid standards were purchased from Serdary Research Laboratories (London, Ontario, Canada). Sepharose 6B for column chromatography was a product of Pharmacia LKB Biotechnology (Uppsala, Sweden). CDP[1,2-^{14}C]ethanolamine was a product of ICN Biomedicals (Costa Mesa, CA). All other chemicals were of the highest grade available and were acquired from the Canlab division of Baxter Diagnostics Corporation (Mississauga, Ontario, Canada). Guinea pigs weighing 275 ± 25 g were used throughout the study.

Preparation of plasmalogens for enzyme assays. Plasmalogens were prepared as previously described (10). Briefly, lipids were extracted from porcine hearts by the method of Folch *et al.* (14) in the presence of 0.5% butylated hydroxytoluene (wt/vol). The volume was reduced *in vacuo* and the lipid sample was dissolved in chloroform and applied to a silicic acid column. The individual phospholipids were eluted from the column with increasing amounts of methanol in chloroform (15). Fractions from the column were analyzed by TLC with a solvent containing $CHCl_3/CH_3OH/CH_3COOH/H_2O$ (70:30:2:4, by vol). The fractions containing diradylglycerophosphoethanolamine were pooled. Phoshatidylethanolamine in the pooled diradylglycerophosphoethanolamine fraction was destroyed by the preferential hydrolysis of the ester bonds of phosphatidylethanolamine by mild alkaline hydrolysis with 0.35 M NaOH in 96% methanol as described by Renkonen (16). Lysoplasmenylethanolamine was prepared by hydrolyzing the diradylglycerophosphoethanolamine fraction in 0.35 M NaOH in 96% methanol for 45 min. The plasmenylethanolamine and lysoplasmenylethanolamine obtained after alkaline hydrolysis were repurified by

silicic acid column chromatography. The purity of the plasmalogen fractions was assessed by determining the ratio of the vinyl ether content and the total phosphorus content in the samples. Only preparations with purity greater than 96% were used for enzyme assays.

Preparation of subcellular fractions from guinea pig tissues. Guinea pig tissues were removed and placed on ice. The tissue was homogenized in 0.25 M sucrose/10 mM Tris-HCl (pH 7.4) with two 20 s bursts of a Polytron probe (PT-30) (Brinkmann Instruments; Rexdale, Ontario, Canada) at a speed setting of six. Alternatively, the brain tissues was homogenized in a Potter-Elvehjem homogenizer equipped with a teflon pestle. The tissue homogenates were centrifuged at 10,000 × *g* for 20 min and the supernatant was centrifuged again at 100,000 × *g* for 60 min. The supernatant obtained from the last centrifugation was removed with a Pasteur pipette and designated as the cytosolic fraction. The precipitate containing the microsomal pellet was dispersed in the homogenizing buffer with a Dounce homogenizer equipped with a type A pestle.

Plasmalogenase assay. All glassware including test tubes were treated with a 2% dimethyldichlorosilane in 1,1,1-trichloroethane solution to minimize the adherence of lipids to glass containers. Plasmalogenase activity was monitored by the disappearance of the substrate (9,10). Purified plasmenylethanolamine (2 μmol) was suspended in 1 mL of 10 mM Tris-HCl (pH 7.4) containing 0.05% Tween 20. The mixture was sonicated in a water bath until translucent. The reaction mixture (1.5 mL) contained 300 nmol dispersed plasmalogen, 50 mM Tris-HCl (pH 7.4) and an enzyme preparation containing 0.75–1.0 mg of protein. The reaction was initiated by the addition of the enzyme, and the mixture was incubated at 37°C for 15 min. Control tubes contained either no enzyme or enzyme that had been incubated at 100°C for 5 min. At 0 and 15 min of incubation, 600 μL was removed from the reaction mixture and placed into a tube containing 1.5 mL $CHCl_3$/CH_3OH (2:1, vol/vol). Water and chloroform were added to cause phase separation. The upper phase was removed, and an aliquot of the lower phase was assayed for vinyl ether content spectrophotometrically at 355 nm. Plasmalogenase activity was calculated from the difference in vinyl ether content between the 0 and 15 min time points. Total enzyme activity was calculated from the product of the specific activity of the enzyme and the total protein content in the subcellular fraction.

The determination of marker enzyme activities. The degree of microsomal contamination in the cytosolic fraction was determined by the activities of known microsomal marker enzymes in the cytosol. NADPH-cytochrome c reductase (17), phosphoethanolaminetransferase activities (18) and 5′-nucleotidase activities (19) were used as microsomal markers.

Analytical procedures. Lipid phosphorus was assayed by the method of Bartlett (20). Plasmalogen (vinyl ether) content in the sample was assessed by the method of Gottfried and Rapport (21) based on iodine determination. The correction factor for alkylacyl compounds was not used for the calculation of vinyl ether content. Protein was determined by the method of Lowry *et al.* (22). All results are expressed as the mean ± standard deviation of at least three separate experiments except where otherwise indicated. The points on all figures have standard deviations of less than 15% of the mean.

RESULTS AND DISCUSSION

Plasmalogenase assays. The disappearance of plasmenylethanolamine was monitored by the loss of the vinyl ether bond. A typical assay resulted in the disappearance of 10–20 nmol of the vinyl ether bond of plasmenylethanolamine over the 15 min incubation period. This change in vinyl ether content resulted in an increase in absorbance of 0.040–0.080 A.U. at 355 nm (Fig. 1) which could be easily detected by a modern spectrophotometer. Enzyme activity was linear with protein concentration between 0.5–3.0 mg of protein from guinea pig brain cytosol or microsomes.

Subcellular localization of plasmalogenase activity. The distribution of plasmalogenase activities in the subcellular fractions of guinea pig brain, heart and liver was investigated. The enzyme activity was assessed by the disappearance of the substrate during the reaction. A small amount of plasmalogenase activity was found in the mitochondrial fraction of the brain and heart (data not shown); however, most of the enzyme activity (>90%) was located in the microsomal and cytosolic fractions. As depicted in Table 1, 83% of the total brain enzyme activity was found in the cytosolic fraction, whereas 68% of the total heart enzyme was located in the cytosol. A similar distribution of plasmalogenase activity was also observed in the subcellular fractions of the rat brain and heart (data not shown). The distribution of enzyme activity between the cytosol and microsomes was not affected by the mode of tissue homogenization. Plasmalogenase activity in the liver had a similar subcellular distribution, but the activity was very low.

In order to determine if the hydrolysis of the vinyl ether group of the plasmenylethanolamine by guinea pig brain cytosol was due to the direct acton of the plasmalogenase or the combined action of phospholipase A_2/lysoplasmalogenase, the reaction mixture was analyzed for the disappearance of plasmenylethanolamine as well as the formation of the radylglycerophosphoethanolamine. The reaction mixture contained 300 nmol of plasmenylethanolamine, and the assay for plasmalogenase activity was carried out as described in the preceding section. The reaction was terminated by the addition of 3 mL of $CHCl_3$/CH_3OH (2:1, vol/vol), and the lipids in the lower phase

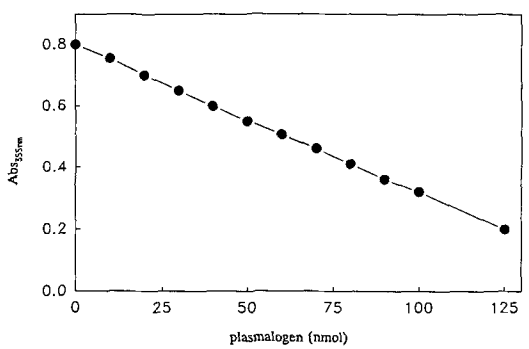

FIG. 1. The relationship of plasmenylethanolamine content *vs.* absorbance by the determination of the vinyl ether group. Each point is the mean of four separate experiments. An identical curve was obtained when lysoplasmenylethanolamine was used as the vinyl ether source.

TABLE 1

Plasmalogenase Activities in the Subcellular Fractions of Guinea Pig Tissues[a]

Tissue	Specific activity: Plasmenylethanolamine disappearance (nmol/h/mg protein)	Total activity[b]: Distribution (%)
Brain		
Cytosol[c]	89.8 ± 7.3	83%
Microsomes[c]	66.1 ± 3.6	17%
Cytosol[d]	84.2 ± 7.9	78%
Microsomes[d]	77.8 ± 13.1	22%
Heart		
Cytosol	47.6 ± 5.8	68%
Microsomes	57.0 ± 8.1	32%
Liver		
Cytosol	6.5 ± 2.5	75%
Microsomes	5.1 ± 1.5	25%

[a] Plasmalogenase activities were determined by substrate disappearance as described in Materials and Methods. Each value represents the mean ± standard deviation of at least four different experiments.

[b] Total activity was calculated from the specific activity of the enzyme and the amount of protein in each subcellular fractions.

[c] Prepared by homogenization with a Polytron generator equipped with a PT-30 probe.

[d] Prepared by homogenization with a Potter-Elvehjem homogenizer equipped with a teflon pestle.

were separated by TLC with a solvent containing $CHCl_3$/CH_3OH/CH_3COOH/H_2O (70:30:2:4, by vol). At the 0 min time point (control), no radylglycerophosphoethanolamine fraction was detected after TLC separation. After 15 min of incubation, 22 ± 3 nmol of plasmenylethanolamine was hydrolyzed with the formation of 14 ± 2 nmol of radylglycerophosphoethanolamine. Analysis of the vinyl ether content in the radylglycerophosphoethanolamine fracton revealed that there was no detectable vinyl ether group in this fraction. Our results indicate that the majority of the plasmenylethanolamine was hydrolyzed by plasmalogenase and not by a phospholipase A_2/lysoplasmalogenase system.

To further confirm the above results, time courses for the hydrolysis of plasmenylethanolamine and lysoplasmenylethanolamine in guinea pig brain cytosol were determined (Fig. 2). The hydrolysis of plasmenylethanolamine was linear up to 30 min. However, the brain cytosol had very limited ability to hydrolyze lysoplasmenylethanolamine. The results obtained in this study support the notion that the hydrolysis of plasmenylethanolamine resulted from the direct action of plasmalogenase in the brain cytosol.

It could be argued that the plasmalogenase activity in the brain and heart cytosol might arise from the contamination of microsomal particles. Hence, the microsomal marker enzyme activities in the cytosolic fractions were assessed (Table 2). The result shows that the contamination of the cytosolic fraction by microsomal enzyme markers did not exceed 12% in any of the cases. Hence, the plasmalogenase activities in the cytosolic fraction of the brain and heart could not arise solely from microsomal contamination.

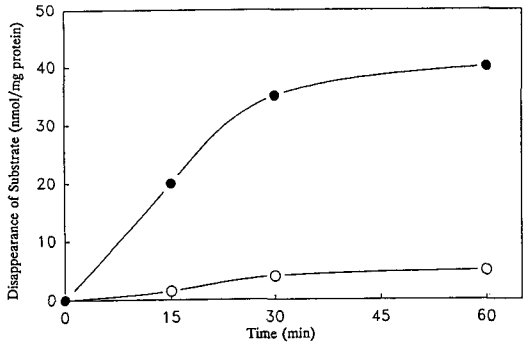

FIG. 2. Time course for the hydrolysis of plasmenylethanolamine and lysoplasmenylethanolamine in guinea pig brain cytosol. Enzyme activities (1.25 mg cytosolic protein) were assayed at 37°C in the presence of 300 nmol plasmenylethanolamine (●) or lysoplasmenylethanolamine (○) by measuring substrate disappearance as described in Materials and Methods. Each point represents the mean of three separate experiments.

TABLE 2

The Distribution of Microsomal Marker Enzyme Activities in the Microsomal and Cytosolic Fractions of Guinea Pig Brain and Heart

Enzyme		Percentage distribution[a]: Brain	Heart
NADPH-cytochrome c reductase	Cytosol	12	—
	Microsomes	88	—
5′-Nucleotidase	Cytosol	—	2
	Microsomes	—	98
Phosphoethanolamine transferase	Cytosol	6	N.D.[b]
	Microsomes	94	100

[a] Each value is the average of three separate experiments.

[b] N.D., not detectable.

Characterization of plasmalogenase activities. In view of the abundance of soluble plasmalogenase in the brain, its cytosol was employed for further characterization of the enzyme activity. The effect of substrate concentrations on plasmalogenase activity was investigated (Fig. 3). From the double reciprocal plot of enzyme activity *vs.* plasmenylethanolamine concentrations, the K_m of the enzyme for plasmenylethanolamine was estimated to be 154 μM. The K_m of plasmenylethanolamine for the cytosolic enzyme is comparable to the microsomal enzyme (105 μM) and also the enzyme obtained from an acetone extract of the bovine brain (285 μM) (9). Similar to the microsomal enzyme (data not shown), the cytosolic enzyme from the brain was also inhibited by 1 mM ethylenediaminetetraacetic acid (EDTA) and 1 mM Mn^{2+}. However, the presence of 1 mM Ca^{2+} or Mg^{2+} had very little effect on either enzyme activity (Table 3) (10). Taken together, our results show that plasmalogenase activity in the cytosol may require a minimum level of metalic cation(s) for full activity. The pH profiles of the brain cytosolic and microsomal plasmalogenase activities were determined (Fig. 4). Both enzymes displayed similar pH profiles with optima at pH 7.5. When the enzymes from

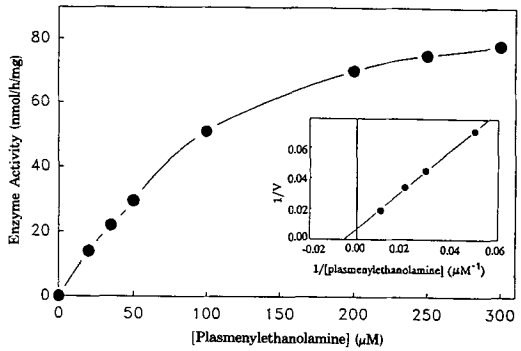

FIG. 3. Effect of substrate concentrations on guinea pig brain cytosolic plasmalogenase activity. Plasmenylethanolamine (2 μmol) was suspended in 1 mL of 10 mM Tris-HCl/0.05% Tween 20 by sonication and appropriate aliquots of the suspension were added to the enzyme assays. Each assay contained 1.25 mg of cytosolic protein and the reaction was carried out at 37°C for 15 min as described in Materials and Methods. Inset is the Lineweaver-Burke plot of the same data. Each point represents the mean of three separate determinations.

TABLE 3

Effects of EDTA and Cations on Cytosolic Plasmalogenase Activity of Guinea Pig Brain[a]

Cation (1 mM)	Enzyme activity (% control)
Control	100
Ca^{2+}	85
Mg^{2+}	100
Mn^{2+}	N.D.[b]
EDTA	N.D.[b]

[a] Plasmalogenase activities were assayed by the substrate disappearance method as described in Materials and Methods, in the absence (control) or presence of 1 mM of various cations or ethylenediaminetetraacetic acid (EDTA). Each value is the average of three separate experiments.

[b] N.D., not detectable.

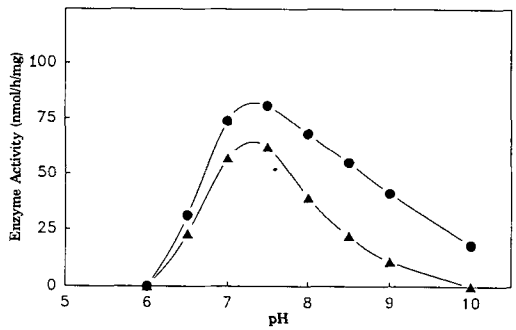

FIG. 4. The pH profile of guinea pig brain cytosolic and microsomal plasmalogenase activities. Enzyme activities in the cytosolic (●) and microsomal (▲) fractions were assayed by substrate disappearance as described in Materials and Methods section. Each assay contained 1.25 mg cytosolic protein or 0.8 mg microsomal protein and the reactions were incubated at 37°C for 15 min. Tris-succinate buffer was used from pH 6–7, and Tris-HCl was used from pH 7–10. No significant difference was detected in enzyme activity at pH 7 when either buffer was utilized. Each point represents the mean of four separate experiments.

the microsomal and cytosolic fractions were incubated at 50°C and 55°C (Fig. 5), the microsomal enzyme was more stable than the cytosolic form.

Gel filtration chromatography of guinea pig brain cytosol. Gel filtration chromatography was employed to confirm the true solubility of the brain cytosolic plasmalogenase. The brain cytosol (2 mL) was applied to a Sepharose 6B column (3 × 48 cm) equilibrated with 0.1 M Tris-HCl (pH 7.5). Subsequent to sample application, the column was washed with the same buffer, and fractions of 1.2 mL were collected and assayed for enzyme activity (Fig. 6). Plasmalogenase activity was eluted as a broad peak away from the void volume of the column. The fraction with the highest enzyme activity had an apparent molecular weight of 250,000. The broad and asymmetrical

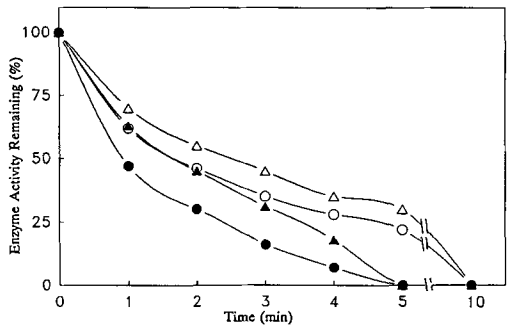

FIG. 5. Effect of heat treatment on plasmalogenase activities in the cytosol and microsomes of the guinea pig brain. Aliquots of brain cytosol (○, ●) and microsomes (△,▲) were incubated at 50°C (open symbols) or 55°C (closed symbols) for 0–5 min. Each aliquot contained 1.25 mg cytosolic protein or 0.8 mg microsomal protein. Subsequent to incubation, enzyme activities in the aliquots were determined by the disappearance of substrate as outlined in Materials and Methods. Each point is the mean of three separate experiments.

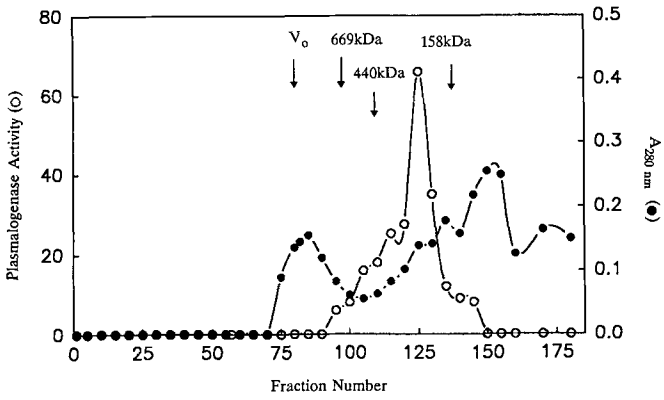

FIG. 6. Sepharose 6B chromatography of plasmalogenase activity in guinea pig brain cytosol. Guinea pig brain cytosol (2 mL) containing 16 mg of protein was applied to a Sepharose 6B column (3.0 × 48 cm) equilibrated with 100 mM Tris-HCl (pH 7.5). Subsequent to sample application, the column was washed with the same buffer and 1.2 mL fractions were collected. An aliquot (0.8 mL) of the fraction was used for enzyme activity determination and the activity is expressed as nmol/h/mL. The total yield of plasmalogenase activity after column chromatography was 41 ± 5% of the enzyme activity applied to the column. The void volume of the column is indicated by V_o. Thyroglobulin (669 kDa), ferritin (440 kDa) and aldolase (158 kDa) were used for column calibration.

peak of enzyme activity implies that the enzyme was eluted as multimeric proteins or in aggregation with other cytosolic proteins. An alternate explanation is that the enzyme might still be associated with some lipid molecules present in the cytosol. The fact that none of the enzyme activity was eluted near the void volume of the column suggests that it was not complexed with microsomal or large liposomal particles.

In a previous study, the existence of a metabolite in the rat brain cytosol for the elimination of the vinyl ether bond of plasmenylethanolamine was reported (23). The material was thermostable at 100°C, had a low molecular weight and was found to be a non-protein entity which was later identified as ascorbic acid (24). Hence, our study is the first identification of a truly soluble plasmalogenase from mammalian sources. In the last two decades, the existence of plasmalogenase activity in the brain has been a matter of debate. Plasmalogenase activity was identified in the microsomes of rat brain (9), in neuronal perikarya, astroglia, and oligodendroglia from bovine brain (25), and from the brains of rats and monkeys (26). Using another approach, it was shown that the rat brain had no ability to catabolize radiolabeled plasmalogens, but low levels of lysoplasmalogenase activity were detected in brain (12). Our results support the existence of considerable amounts of plasmalogenase activity in the brain and also the presence of low levels of lysoplasmalogenase activity. At present, the reason for the discrepancy in the identification of plasmalogenase activity is not entirely clear. One explanation is that the activity of the plasmalogenase is highly dependent on the source of the plasmalogen and the method of suspension in the buffer. The assay procedure in this study had been optimized to provide a high plasmalogenase activity.

The similarity in characteristics between the cytosolic and microsomal enzyme makes it plausible to speculate that both enzymes may originate from the same protein. However, the ability to obtain the same distribution of enzyme activity between the two compartments by different methods of homogenization confirms that the cytosolic enzyme was not mechanically detached from the microsomes during tissue homogenization. The identification of a truly soluble plasmalogenase makes the guinea pig brain cytosol an ideal source of the enzyme for its subsequent purification. At present, the physiological significance of the distribution of the enzyme in two subcellular compartments remains undefined.

Adipose Hormone-Sensitive Lipase Preferentially Releases Polyunsaturated Fatty Acids from Triglycerides

Victor C. Gavino* and **Grace R. Gavino**
Department of Nutrition, Université de Montréal, Montréal, Québec Canada H3C 3J7

Rat adipose hormone-sensitive lipase-mediated release of fatty acids from triglycerides was studied in three model systems: i) cultured preadipocytes containing polyunsaturated fatty acid-enriched triglyceride; ii) perfused epididymal fat pads; and iii) *in vitro* incubations of crude preparations of hormone-sensitive lipase with synthetic triglyceride-analogues as substrates. We found that cultured preadipocytes challenged with 10 μM norepinephrine tended to release more ω6 and ω3 polyunsaturated fatty acids than saturated fatty acids. Fat pads perfused with 10 μM norepinephrine preferentially released arachidonate and α-linolenate but tended to retain oleate and linoleate. Finally, crude preparations of hormone-sensitive lipase released from the triglyceride-analogue substrates α-linolenate twice as fast as oleate. We conclude that rat adipose hormone-sensitive lipase preferentially releases polyunsaturated fatty acids from triglycerides. We suggest that this may be a mechanism by which these fatty acids are kept from being trapped in fat depots and maintained in the circulation.
Lipids 27, 950–954 (1992).

The control of the flux of polyunsaturated fatty acids (PUFA) in adipose tissue is not completely understood. While it is true that adipose fatty acid profiles correlate with dietary lipid composition (1), the ratio of PUFA to saturated fatty acids as well as the ratio of ω3 to ω6 PUFA in adipose tissue is consistently lower than that in the diet (2–7). Furthermore, adipose tissue contains a higher proportion of saturated fatty acids over PUFA relative to other tissues and organs in the body (2,3,8–14). The tendency to store saturated fatty acids rather than PUFA ensures that PUFA precursors of eicosanoids are not trapped within adipose tissue.

We have investigated the ability of hormone-sensitive lipase (HSL) to release PUFA from triglycerides (TG) as a factor in maintaining a low relative content of PUFA in adipose tissue. We have approached this problem using three models: cultured rat perirenal preadipocytes, perfused epididymal fat pads, and a pH 5.2 precipitate preparation of adipose hormone-sensitive lipase.

EXPERIMENTAL PROCEDURES

Cell culture and fatty acid release. We have previously established the culture conditions necessary to enrich differentiating cultured preadipocytes with PUFA (15). Briefly, the culture medium of differentiating preadipocytes undergoing TG-loading was supplemented with 50μM fatty acid (NuChek Prep, Elysian, MN) complexed to CPSR-1 serum replacer (Sigma, St. Louis, MO). Fat-loading of the cells was monitored by gas-chromatographic quantification of intracellular TG (15) and by the accumulation of visually-apparent intracellular lipid droplets in cultures stained with osmium tetroxide (16). TG-loaded cells were rinsed twice with M199E (Sigma) containing 10 mM glucose, penicillin (100 U/mL), streptomycin (0.1 mg/mL) and 2% (wt/vol) fatty acid-free bovine serum albumin (Sigma) to ensure complete removal of treatment fatty acids and insulin. The rinsed cells were incubated in the same medium used to rinse the cells, plus 10 μM norepinephrine (Boehringer, Montréal, Québec Canada) for 24 h. The medium was changed once at 6 h during this 24-h incubation with norepinephrine. Intracellular TG before and after treatment with norepinephrine was analyzed by gas chromatography as described previously (15). The relative content of PUFA of the cells is expressed as the ratio of total PUFA, ω6 PUFA or ω3 PUFA to total saturated fatty acids, symbolized as P/S, P(ω6)/S and P(ω3)/S, respectively.

Epididymal fat pad perfusion. The technique for surgery, cannulation and perfusion of the epididymal fat pad was described by Ho and Meng (17) and followed without modification. The isolated fat pad was perfused in open circuit at 37°C with oxygenated Krebs-Ringer buffer containing 10 mM glucose and 4% (wt/vol) fatty acid-free bovine serum albumin at 50 μL/min × g tissue. After an initial 30-min perfusion period, 10 μM norepinephrine was added to the influent. The effluent during the norepinephrine infusion was collected and its non-esterified fatty acid (NEFA) profile analyzed by gas chromatography and compared with the TG-fatty acid profile of the fat pad.

Synthesis of [^{3}H]oleoyl-[^{14}C]linolenoyl-2-O-(9-octadecenyl)glycerol as substrate for HSL. Ten μmol each of [^{3}H]oleic acid and [^{14}C]α-linolenic acid (specific activities of 4μCi/μmol) were mixed and converted to acyl chlorides using oxalyl chloride as described previously (18). To the fatty acyl chlorides was added 1.5 mL of toluene containing 6 μmol 2-*O*-(9-octadecenyl)glycerol (Serdary Research Laboratories, London, Ontario, Canada) and 50 μM 4-pyrrolidinopyridine (Sigma). The mixture was stirred overnight at 50°C (19), and the product was extracted with diethyl ether/hexane (1:1, vol/vol). The organic layer containing the reaction products was washed with 2 M HCl followed by water. The washed organic layer was evaporated to dryness, and the residue purified by thin-layer chromatography (TLC) using hexane/diethyl ether/acetic acid (80:20:1, vol/vol/vol) as developing solvent. The band corresponding to diacyl-2-*O*-alkylglycerol was further fractionated by argentation TLC to separate the desired product, *rac*[^{3}H]oleoyl-[^{14}C]linolenoyl-2-*O*-(9-octadecenyl)-glycerol, from the dioleoyl and dilinolenoyl derivatives of 2-*O*-(9-octadecenyl)glycerol. The $AgNO_3$/TLC plates were prepared by dipping pre-coated Whatman LK6D silica gel plates (Chromatographic Specialties, Brockville, Ontario, Canada) into a 4% (wt/vol) $AgNO_3$/15% (vol/vol) NH_3/1% (vol/vol) methanol solution and activating them at 200°C for 2 h. Samples were applied and the $AgNO_3$ plates were developed twice in diethyl ether/benzene (2:8, vol/vol).

Abbreviations: HSL, hormone-sensitive lipase; NEFA, non-esterified fatty acids; PUFA, polyunsaturated fatty acids; TG, triglycerides; TLC, thin-layer chromatography.

Fractions were visualized with 1% dichlorofluorescein, and the band corresponding to 5 double bonds was scraped and eluted as described (20,21). The purified product was analyzed by gas chromatography using triheptadecanoylglycerol as internal standard, and sodium methoxide as the transmethylating agent. The fatty acid methyl esters obtained were separated from the parent 2-*O*-(9-octadecenyl)glycerol by TLC prior to injection into the gas chromatograph. The final product was 99% pure and contained equimolar quantities of esterified oleic and α-linolenic acids. The overall yield was 5–10%.

Preparation and assay of crude HSL. Sprague-Dawley male rats (200–225 g, Charles River, St. Constant, Québec Canada) were starved overnight and sacrificed by decapitation. Epididymal and perirenal fat pads were immediately excised and processed as described previously (22) up to the "pH 5.2 precipitate fraction" containing the HSL activity. The activity of protein kinase-activated HSL was determined using glycerol-dispersed solutions of substrates (23). The release of NEFA was measured by direct extraction (24) or by TLC (25).

RESULTS

We have previously shown that cultured differentiating perirenal preadipocytes when undergoing fat-loading also accumulate significant proportions of PUFA in TG when the lipid-poor culture medium is enriched with PUFA (15). Using this technique, we prepared TG-loaded control, oleate-, linoleate-, α-linolenate-, arachidonate- and docosahexaenoate-enriched perirenal preadipocytes. These cells released NEFA and lost intracellular TG when the insulin and serum supplement in the culture medium were replaced with 10 μM norepinephrine and 4% fatty acid-free bovine serum albumin (Fig. 1). After a 24-h treatment with norepinephrine, the fat-loaded cells lost an average of 1680 nmol/9.6 cm^2 flask of TG-esterified fatty acid ($P < 0.001$, two-way analysis of variance, pooled SEM = 330 μmol, n = 36). The decrements in intracellular TG expressed as μmol fatty acid/9.6 cm^2 flask and in percentage of the initial TG (given in parenthesis) for each group were: control, 2300 (70%); oleate-enriched, 1100 (40%); linoleate-enriched, 2700 (66%); α-linolenate-enriched, 600 (27%); arachidonate-enriched, 1600 (53%); and docosahexanoate-enriched, 1500 (70%). The cells lost an average of 54% ± 10 intracellular TG. Norepinephrine did not affect the total phospholipid content of the cells (data not shown).

The norepinephrine-induced hydrolysis of TG shows a significant degree of specificity for PUFA (Fig. 2A). After the 24-h incubation with norepinephrine, the P/S ratios of intracellular TG dropped by an average of 33% (28 to 44%) in preadipocytes enriched with linoleate, α-linolenate, arachidonate and docosahexaenoate. Norepinephrine had no effect on the P/S ratios in oleate-enriched cells. The apparent drop in the P/S ratio in the linoleate group was not statistically significant. Calculation of the proportion of ω6 PUFA relative to saturated fatty acids in preadipocyte intracellular TG (Fig. 2B) showed an average drop of 33% (26 to 42%) in the P(ω6)/S ratio as a result of norepinephrine treatment. Similarly, the proportion of ω3 PUFA in preadipocyte TG (Fig. 2C) also dropped by 30% and 36% for α-linolenate- and docosahexaenoate-enriched cells,

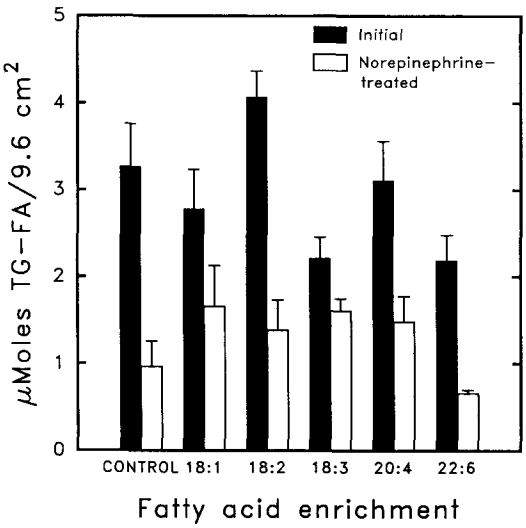

FIG. 1. Norepinephrine-induced loss of intracellular triglycerides (TG) from cultured perirenal preadipocytes. TG of differentiating cells were enriched with the indicated fatty acids, after which the cells were treated with 10 μM norepinephrine for 24 h. Intracellular TG was measured and compared with that of non-treated cells. Values represent the mean ± SEM of three experiments.

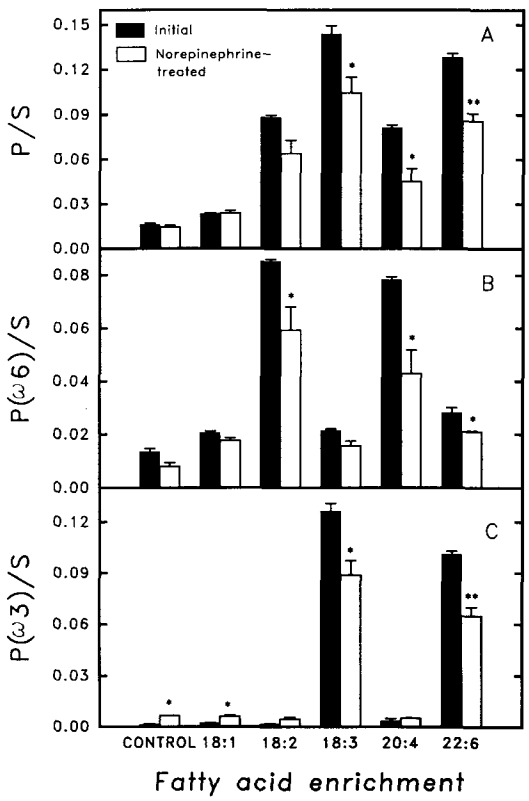

FIG. 2. Preferential release of polyunsaturated fatty acids (PUFA) from pre-adipocytes. Triglycerides (TG) of cells were enriched with the indicated fatty acids; then the cells were treated with 10 μM norepinephrine. The fatty acid composition of intracellular TG was determined and compared with that of non-treated cells. The results, mean ± SEM of three experiments, are expressed as: A) P/S ratios; B) ω6 PUFA to S (P(ω6)/S) ratios; and C) ω3 PUFA to S (P(ω3)/S) ratios. Statistical significance is indicated by a "*," $P < 0.05$, or by "," $P < 0.01$ (two-tailed Student's *t*-test).**

respectively. However, there was a statistically significant 2.4-fold and 2.1-fold enrichment in ω3 PUFA of TG in control and oleate-enriched cells, respectively (Fig. 2C). This suggests conservation of ω3 PUFA in cells with a very low content (<1%) of ω3 PUFA.

The data show that the drop in the overall P/S ratio is accounted for by the preferential release of both ω6 and ω3 PUFA from preadipocyte TG. The preferential retention of oleate in intracellular TG (Fig. 3) upon norepinephrine-stimulation of TG hydrolysis indicates that the preferential release of PUFA cannot be adequately explained by the "last-in first-out" hypothesis for fatty acids widely accepted for adipose tissue (26–28). Results from 6-h treatment of cells with norepinephrine gave similar trends, with an average release of 10% of intracellular TG-esterified fatty acid (results not shown).

The results from the epididymal fat pad perfusion (Fig. 4) support the hypothesis that adipose preferentially releases PUFA over saturated fatty acids. Norepinephrine increased the rate of release of glycerol into the effluent from a basal rate of 0.3 μmol/h to 1.1 μmol/h (single experiment), indicating stimulation of TG hydrolysis in the perfused fat pad. The data shown in Figure 4 represent ratios between the relative percent of selected fatty acids exiting with the effluent from the fat pad, and the relative percent of the corresponding fatty acid in the fat pad after the perfusion experiment. Except for palmitate, the effluent/tissue fatty acid ratios were significantly different from unity ($P < 0.05$, two-tailed Student's t-test). Values greater than unity represent preferential release of the fatty acid. Figure 4 shows that there is a 3-fold greater concentration of arachidonate in the effluent than in the TG of the perfused fat pad indicating that this fatty acid is preferentially released. Consistent with the preadipocyte data, the fat pads tend to preferentially release α-linolenate and to preferentially retain oleate. In contrast to the preadipocyte data, the perfused fat pads tend to retain linoleate. It is unlikely that PUFA enrichment of the effluent was the result of phospholipase C activation by α_1-receptor activity. Brooks *et al.* (29) had shown that

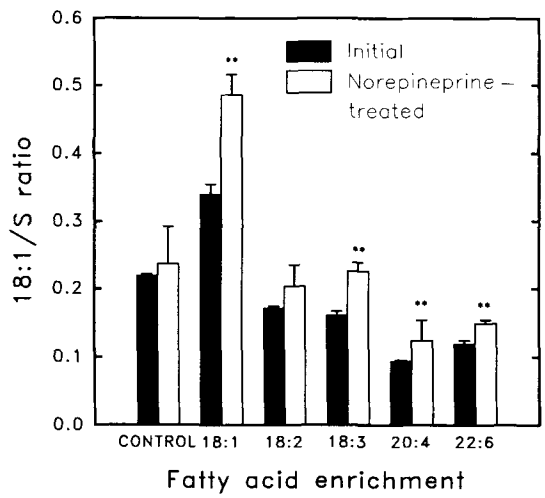

FIG. 3. Preferential retention of 18:1 in pre-adipocyte triglycerides (TG). Cells were treated and intracellular TG analyzed as in Figures 1 and 2. The results, mean ± SEM of three experiments, are expressed as 18:1/S ratios. Statistical significance is indicated by "," $P < 0.01$ (two-tailed Student's t-test).**

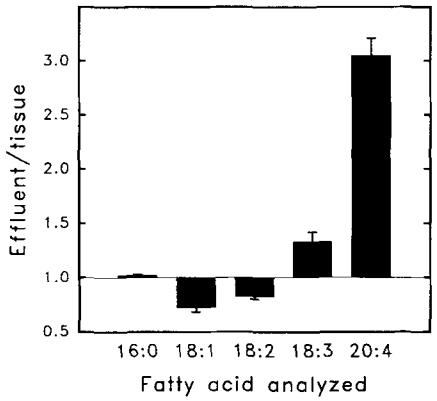

FIG. 4. Preferential release of 18:3 and 20:4 from norepinephrine-stimulated, perfused epididymal fat pads. The fat pads were perfused for one hour at 37°C with Krebs-Ringer bicarbonate buffer with 10 mM glucose, 4% fatty acid-free bovine serum albumin and 10 μM norepinephrine. The fatty acid composition of the effluent nonesterified fatty acids and of fat pad TG were analyzed. The results, expressed as mean ± SEM of three perfusions, are given as the ratios of the relative proportions of the indicated fatty acids.

norepinephrine-induced fatty acid release by adipocytes obtained from rat epididymal fat pads is due to β-receptor activity. Furthermore, phospholipase C acts primarily on phosphoinositides (30), an extremely small pool relative to intracellular TG in adipocytes.

The crude preparations of epididymal and perirenal HSL, the "pH 5.2 precipitate" (22), hydrolyzed tri[^{3}H]-oleoylglycerol at a rate of 4.8 ± 0.2 and 3.3 ± 0.1 nmol/mg × min (n = 3), respectively. Although this is comparable to the rates for HSL reported in the literature (31), our results are overestimates because the pH 5.2 preparation (22) contains 2-monoacylglycerol lipases. The use of the TG analog 1,3-diacyl-2-*O*-alkylglycerol as substrate circumvents this difficulty since HSL hydrolyzes both the 1- and 3-acyl moieties of the substrate but the contaminating monoacylglycerol lipases cannot hydrolyze the remaining 2-(9-octadecenyl)glycerol (32,33). The HSL preparation from epididymal and perirenal tissue hydrolyzed *rac*[^{3}H]oleoyl-[^{14}C]linolenoyl-2-*O*-(9-octadecenyl)glycerol at rates of 1.29 ± 0.01 and 1.8 ± 0.1 nmol/mg × min (n = 3), respectively. Figure 5 shows the proportions of radiolabeled oleate and α-linolenate released from the TG analog substrate. The molar ratio α-linolenate/oleate in the substrate was 1.06 ± 0.01 (n = 4). The enzyme reaction hydrolyzed 3–6% of the total esterified fatty acid during the 30-min incubation period. The epididymal preparation released 35% and the perirenal preparation released 67% more α-linolenate than oleate. The α-linolenate/oleate ratio in the remaining TG analog substrate (Fig. 5) did not change perceptibly because the total amount of fatty acid released was small compared to the total esterified fatty acid present in the reaction mixture.

DISCUSSION

We have used three different and mutually independent models, namely, intact perfused tissue, isolated cultured cells and semi-purified enzyme, representing increasing degrees of organizational complexity. The results from each model show that HSL-mediated TG hydrolysis

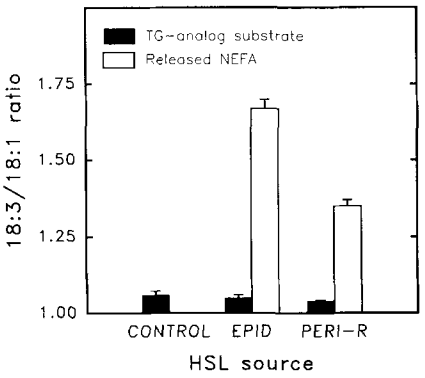

FIG. 5. Preferential hydrolysis of 18:3 by "pH 5.2-precipitate" preparations of hormone-sensitive lipase. The enzyme preparations from peri-renal or epididymal fat pads catalyzed the hydrolysis of the synthetic triglyceride (TG)-analogue substrate *rac*-[^{3}H]oleoyl-[^{14}C]linolenoyl-2-*O*-(9-octadecenyl)glycerol. The ratios of 18:3 and 18:1 in released NEFA were compared with the corresponding ratios in remaining esterified fatty acid. The results represent mean ± SEM of three experiments.

preferentially releases PUFA, regardless of the experimental conditions used. The data indicate that the relase of PUFA is "preferential" and not stringent as it would be in the classic sense of enzyme specificity. Rather, the heterogeneity of TG molecules in adipose gives rise to a situation where the enzyme HSL is confronted with multiple analogous but kinetically different substrates. The results are therefore best explained by postulating that the configuration of TG with PUFA at either the *sn*-1 or *sn*-3 of the glycerol backbone gives it a "kinetic advantage" over the more saturated TG species. Such preference based on degree of unsaturation of the fatty acid moiety has been observed for other lipid enzymes (34,35).

It must be noted that the release of NEFA from adipose is the result of the concerted action of HSL and the re-esterification pathway (36,37). The latter may also be a factor in the preferential release of PUFA, if it re-esterifies saturated fatty acids more than PUFA back into adipose TG. However, others have shown that the extent of release of NEFA from adipose is primarily a function of the availability of fatty acid-poor serum albumin perfusing through the tissue (38–40). Hence, the re-esterification pathway becomes less important when enough carrier is available to trap the released NEFA and keep it away from the adipocyte. We have not fully resolved this point in our experiments, but the use of 2 to 4% fatty acid-free albumin in our experiments should favor the release more than the re-esterification of NEFA in both the pre-adipocyte model and the perfused fat pad model. In contrast, the HSL preparation model is not affected by the re-esterification of NEFA, primarily because of the absence of free CoA in the HSL assay mixture. The results from the latter model reinforce the hypothesis that preferential release of PUFA from the perfused fat pad and from the cultured cells is due at least in part to the preference of HSL for PUFA. It may be argued from the data that adipose HSL does not exhibit dramatic preference for PUFA, and therefore may be of little consequence. While this may be true for the acute short-term experiments described in this report, the *in vivo* situation involves a continuous and multiple-pass perfusion of the fat depots. Thus, preferential release of PUFA observed in an acute experiment represents a high rate of PUFA loss from adipose relative to saturated fatty acids, when considered in the physiological context. It is interesting to note that PUFA-containing chylomicron TG exhibits resistance to hydrolysis by lipoprotein lipase (41). Thus, HSL and lipoprotein lipase act in an opposite but complementary fashion to prevent PUFA from being trapped in fat depots.

The HSL-mediated preferential release of PUFA from adipose TG raises an interesting possibility concerning the control of the positioning of fatty acids on the TG glycerol backbone. It is generally accepted that the 2-acyl moiety of TG tends to be unsaturated while the 1- and 3-acyl moieties tend to be saturated (42,43). This phenomenon has not yet been adequately explained apart from the necessary postulate that the lysophospholipid acyltransferase be specific for PUFA. Thus, the product phosphatidic acid which can either be further processed to TG or to phospholipid, would already contain an unsaturated fatty acid esterified to *sn*-2 of glycerol. However, Christie and Vernon (42) reported that the positional distributions of fatty acids on the glycerol backbone of rat adipose TG is not controlled solely by fatty acid availability nor by acyltransferase specificity. In the extreme case where the esterification of different fatty acids on the glycerol backbone is entirely at random, the preferential hydrolysis of PUFA from the *sn*-1 or *sn*-3 positions by HSL would eventually result in significant accumulation of TG species with PUFA at *sn*-2 of the glycerol backbone. If this alternative mechanism was generally true, then HSL from pig adipose which contains a high proportion of palmitate esterified at the *sn*-2 of the TG-glycerol backbone (42) should preferentially release saturated fatty acids instead of PUFA. We will verify this in future experiments.

In conclusion, we have shown that rat adipose HSL preferentially releases PUFA from TG. This may be an important mechanism in the control of adipose fatty acid composition and the maintenance of a low PUFA content relative to other organs and tissues in the body. This may also be a mechanism by which essential PUFA are kept from being trapped in fat depots and thus maintained in the circulation.

Production of the Criegee Ozonide During the Ozonation of 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine Liposomes

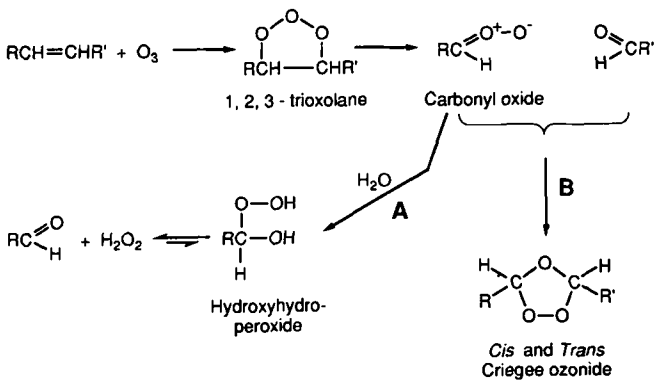
Giuseppe L. Squadrito, Rao M. Uppu, Rafael Cueto and **William A. Pryor***
Biodynamics Institute, Louisiana State University, Baton Rouge, Louisiana 70803-1800

It is likely that Criegee ozonides are formed in small amounts in the lungs of animals breathing ozone-containing air. This makes these compounds potential candidates to act as secondary toxins which relay the toxic effects of ozone deeper into lung tissue than ozone itself could penetrate. Therefore, we have determined the yields of Criegee ozonides from unsaturated lipids in liposomal systems as a model of the types of yields of Criegee ozonides that might be expected both in the lung lining fluid layer and in biological membranes. Ozonation of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine liposomes produced both *cis*- and *trans*-Criegee ozonides. These ozonides have been isolated by solid phase extraction and high-performance liquid chromatography of the ozonized lipid, and the products have been identified by two-dimensional ^1H nuclear magnetic resonance. The combined yield of the *cis*- and *trans*-Criegee ozonides is 10.7 ± 2.8% (avg. ± SD, n = 7) with small unilamellar liposomes and 10.6 ± 2.7% (n = 3) with large multilamellar liposomes. We had previously reported (*Chem. Res. Toxicol. 5*, 505–511, 1992) that ozonation of methyl oleate in sodium dodecylsulfate micelles also produces an 11% yield of the Criegee ozonides. Thus, ozonation in a variety of models gives about 11% of the Criegee ozonide, suggesting that these products also would be formed in small but significant amounts in the lungs of animals breathing polluted air. Further research on the pharmacokinetics and possible toxicity of the Criegee ozonides of fatty acids is suggested.
***Lipids* 27, 955–958 (1992).**

Primary targets for ozone, a highly reactive oxidant present in polluted air, are thought to include the unsaturated fatty acids in the lipids of the lung lining fluid layer and in biological membranes (1–5). Little is known, however, about the mechanisms of ozone toxicity and especially about those steps involved in transmitting the toxicity to distant tissues that ozone itself cannot reach (5).

The ozonation of unsaturated fatty acids gives a 1,2,3-trioxolane, which rapidly decomposes to give a carbonyl oxide and an aldehyde (Scheme 1). In nonparticipating organic solvents, these two species recombine to give the Criegee ozonide (6,7) (Scheme 1, path B). If water is present, the carbonyl oxide can react to give hydroxyhydroperoxides and, ultimately, hydrogen peroxide and a second mole of a carbonyl compound (8–10) (Scheme 1, path A).

The Criegee ozonide, which is relatively stable, must be placed on the list of compounds that could relay the toxic effects of ozone to distal sites. Thus, it is important to determine the yields of Criegee ozonides in systems that model the lung lining fluid layer and cellular membranes, sites where the ozonation of unsaturated fatty acids might occur



SCHEME 1

in vivo. Although Criegee ozonide formation might be inferred from the vast literature available in ozonation in nonparticipating organic solvents (11,12), the yields of Criegee ozonides have not been determined in liposomal systems. We give yields of the ozonides from the ozonation of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) in two types of liposomes.

MATERIALS AND METHODS

Chemicals were obtained from the following sources: POPC (Avanti Polar Lipids, Alabasater, AL); choline chloride and sodium phosphate dibasic heptahydrate (Mallinckrodt, Paris, KY); diethylenetriaminepentaacetic acid (DTPA) (Sigma, St. Louis, MO); potassium indigotrisulfonate (Aldrich, Milwaukee, WI); potassium iodide (EM Science, Gibbstown, NJ); and high-performance liquid chromatography (HPLC) grade water and potassium phosphate monobasic (J.T. Baker, Phillipsburg, NJ). Supelclean LC-18 solid phase extraction tubes (3 mL capacity) were purchased from Supelco (Bellefonte, PA).

Generation of ozone. Ozone was generated by passing dried air or oxygen at a constant flow through a Welsbach (Philadelphia, PA) Model T-23 at a fixed voltage (90 V), or an OREC (Phoenix, AZ) O3V-O Series, ozonator producing a silent electric discharge at a fixed amperage (2 amps). Ozone production was estimated iodometrically (13) or by an indigo bleaching method (14).

CAUTION: Due to the possibility of explosion, all ozonation mixtures should be handled with gloves behind a safety shield.

Synthesis of POPC ozonides. A solution of 132 μmoles of POPC in 10 mL of chloroform was dried in a rotary evaporator at 40°C. The dry lipid was dissolved in 100 mL of anhydrous methylene chloride, chilled to −78°C in a dry ice/acetone mixture, and then treated with a stream of ozone (4 μmol/min) in air (60 mL/min) for 30 min. The contents were then brought to room temperature, any unreacted ozone was expelled by a stream of nitrogen, the solvent was evaporated under vacuum, and the residue dissolved in about 3 mL of methanol.

The *cis*- and the *trans*-POPC ozonides in the above sam-

Abbreviations: DTPA, diethylenetriaminepentaacetic acid; HPLC, high-performance liquid chromatography; NMR, nuclear magnetic resonance; PB, phosphate buffer; POPC, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine, SDS, sodium dodecylsulfate.

ple were purified by HPLC according to the method of Lai *et al.* (15) with minor modifications. Aliquots (100 μL each) were chromatographed on a Hypersil ODS (200 × 4.6 mm) column using a mobile phase that consisted of 0.05 M choline chloride in methanol/water (95:5, vol/vol) at a flow of 1.5 mL/min. A Perkin-Elmer (Norwalk, CT) series 410 liquid chromatograph pump equipped with a Perkin-Elmer LC-95 UV/Vis detector was used. The absorbance of the eluent was monitored at 212 nm.

Preparation of liposomes. Small unilamellar liposomes were prepared using the standard sonication method described previously (16,17). Briefly, solutions of 100 mg each of POPC in chloroform (10 mg/mL) were dried in a rotary evaporator at 40°C in a 125-mL pear-shaped flask, giving a thin film of lipid at the bottom half of the flask. A solution of 0.1 M sodium/potassium phosphate buffer (PB, pH 7.4) containing 0.2 mM DTPA was then added to give a final lipid concentration of 2 mM. The lipid film was peeled off and dispersed into the solution by rotating the flask slowly in a L&R sonication bath (Kearny, NJ) Transister/Ultrasonic (T-14 B), yielding large multilamellar liposomes. To prepare small unilamellar liposomes, the milky suspension of large multilamellar liposomes was transferred to a separate beaker and sonicated 3 × 2 min (at intervals of 10 min each) at 0-4°C using a Branson (Danbury, CT) 450 sonifier at full power and 50% duty cycle. The resulting suspension of small unilamellar liposomes was diluted 4-fold with 0.10 M PB, pH 7.4 and allowed to stand at room temperature for 30-60 min before use.

Ozonation of liposomes. Aqueous solutions of ozone were prepared by bubbling a stream of about 1% ozone in oxygen into water that was previously acidified with H_2SO_4 to a pH of 1.95-2.00 (16). The concentration of ozone in solution was estimated after bubbling for 5-10 min by allowing a 1-mL aliquot to react with 1 mL of 0.5 mM indigo trisulfonate in 0.02 M phosphoric acid. The amount of dye bleaching was determined by measuring the decrease in absorbance at 600 nm (ε = 20,000 M^{-1} cm^{-1}) (14). The concentration of ozone in solutions prepared as above ranged between 0.21 and 0.24 mM. Equal volumes (50-100 mL) of ozone solution and liposomal suspension were mixed with stirring and allowed to stand at room temperature for 5 min before further analysis, giving a final pH of about 7.2.

The extent of ozonation of phospholipid in the liposomal suspensions was determined by HPLC with a 20-μL aliquot using a Hewlett-Packard (Avondale, PA) microbore column (200 × 2.1 mm) and a mobile phase consisting of 0.03 M choline chloride in methanol/water (97:3, vol/vol) at a flow of 0.5 mL/min. The eluent was monitored at 205 nm.

Solid phase extraction of ozonized POPC from liposomal ozonation. Supelclean LC-18 3 mL capacity columns were conditioned first with 2 mL of methanol and then with 2 mL of 0.05 M phosphate buffer (prepared by diluting 0.1 M PB, pH 7.4 with H_2SO_4, pH 1.95-2.00). Samples of ozonized liposomes (50-200 mL) were loaded onto the column at a flow of 1.5-2 mL/min. The column was then washed with 3 × 2 mL each of 0.05 M PB and water. The trapped lipids were desorbed with 3 × 2 mL of methanol and the solvent evaporated under a stream of nitrogen.

Purification of POPC ozonides from liposomal ozonations. Phospholipid ozonides in the eluents were purified by HPLC as described above. The fractions with retention times identical to those of synthetic POPC ozonides were collected from several runs. The pooled fractions were evaporated under a stream of nitrogen, the moist residue was resuspended in about 100 mL of water, and subjected to solid phase extraction using a Supelclean LC-18 column. The ozonides were desorbed with 3 × 2 mL of methanol, the solvent evaporated under a stream of nitrogen, and then the ozonides freeze-dried to remove any residual water.

Quantitation of the yield of POPC ozonides in liposomal ozonations. The yield of POPC ozonides in the liposomal reaction was calculated by estimating the phosphorus content of the HPLC fractions corresponding to the unreacted POPC and the POPC ozonides. The fractions were evaporated to dryness under a stream of nitrogen at 60-70°C, and the amount of phosphorus in the residue was estimated according to the method of Ames (18). The relative yields of *cis*- and *trans*-ozonides were calculated by integrating the area under the curves in the HPLC chromatograms of the crude, solid phase extracted POPC ozonation mixtures.

^1H nuclear magnetic resonance (NMR) experiments. Spectra were recorded on a Bruker AM 400 spectrometer (Bruker Spectrospin, Billerica, MA) operating at 400.13 MHz using $CDCl_3$ as solvent. The 2D ^1H-^1H correlation spectroscopy (COSY) spectra were measured at 25°C employing the COSY.AU microprogram of the Bruker software. The spectra were obtained with a digital resolution of 5.425 Hz after zero filling. Zero filling (one) was done in the F1 dimension of a 512 × 512 matrix, the data were 2D transformed, and the magnitude spectra multiplied by a sine window in each dimension and symmetrized along the diagonal.

RESULTS

The solid phase extraction protocol described here allows for a rapid extraction of ozonized lipids from dilute aqueous microemulsions. The ^1H NMR COSY spectra of the *cis*- and *trans*-POPC ozonides obtained by ozonation of POPC in methylene chloride are presented in Figure 1. The resonance assignments are based on the connectivities provided by the proton scalar coupling constants. The *cis*- and *trans*-POPC ozonides show very similar ^1H nuclear magnetic resonance (NMR) spectra except for the resonances at 5.18 and 5.14 ppm that correspond to their respective 1,24-trioxolane ring protons (15,19,20). Other resonances are listed below using the following notation for the H-atoms: H_m-n: where m denotes the moiety within the POPC molecule and can be g (glyceroyl), p (palmitoyl), o (oleoyl), or c (choline), and n denotes the C-atom number to which the H-atom is bonded. The numbering systems used are the standard numbering system for the fatty acid chains and the numbering system of *sn*-glycero-3-phosphocholine for the glycerol moiety. In the case of choline, the numbering starts next to the phosphoryl moiety. POPC ozonides ^1H NMR ($CDCl_3$) δ 5.23 ppm (*m*, 1H, H_g-2); 4.41 ppm (*dd*, 1H, H_g-1); 4.33 ppm (*m*, 2H, H_c-1); 4.12 ppm (*dd*, 1H, H_g-1′); 3.96 ppm (*m*,2H, H_g-3); 3.81 ppm (*m*, 2H, H_c-2); 3.37 ppm (*s*, 9H, H_c-Me); 2.27 ppm (*m*,4H, H_p-2,H_o-2); 1.66 ppm (*m*, 4H, H_o-8,H_o-11); 1.57 ppm (*m*, 4H, H_p-3,H_o-3); 1.40 ppm (*m*, 4H, H_o-7, H_o-12); 1.33-1.17 ppm (*m*, 40H, H_p-4 to H_p-15,H_o-4 to H_o-6,H_o-13 to H_o-17); 0.87 ppm (*t*, 6H, H_p-16,H_o-18). The

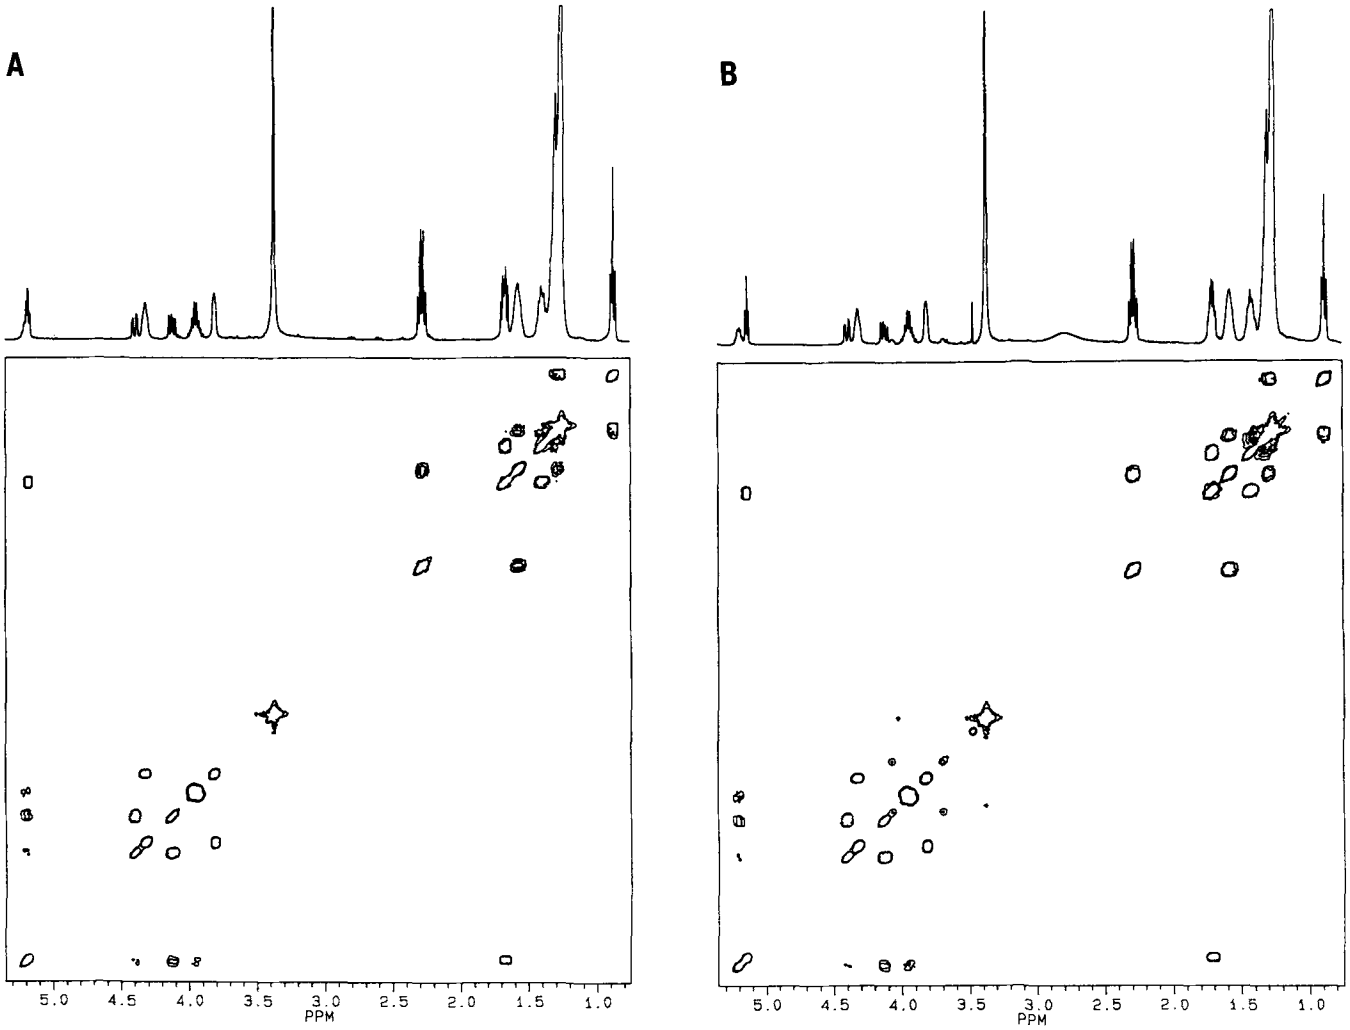

FIG. 1. ^1H-^1H correlation spectroscopy 2D nuclear magnetic resonance spectra of (A) *cis*- and (B) *trans* 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine Criegee ozonides.

POPC ozonides formed by ozonation of POPC liposomes were identified by comparing their ^1H NMR spectra to those of standard samples prepared by ozonating POPC in dry methylene chloride, reaction conditions that we have found to afford high yields of ozonides. A comparison of the ^1H NMR characteristic resonances of the 1,2,4-trioxolane moiety of *cis/trans* mixtures of POPC ozonides obtained by ozonation of POPC liposomes or methylene chloride solutions is shown in Figure 2, confirming that they are indeed the same products (formed in a slightly different *cis/trans* ratio).

DISCUSSION

The average yield of the sum of both the *cis*- and *trans*-POPC ozonides from the ozonation of POPC small unilamellar liposomes is 10.7 ± 2.8% (avg. ± SD, n = 7) and for large multilamellar liposomes is 10.6 ± 2.7% (n = 3). Ozonation conversions were carried to 28–49% in order to obtain sufficient samples for HPLC detection and NMR analysis (Table 1).[1] The POPC ozonides are formed in approximately identical *cis/trans* ratios in the two types of liposomes: 0.86 ± 0.12 (n = 7) and 1.02 ± 0.08 (n = 3) in small unilamellar and large multilamellar liposomes, respectively. This suggests that both the ozonides yield and their *cis/trans* ratios are independent of the type of liposomal preparation.

We have recently reported that Criegee ozonides are formed in about 11% yield when methyl oleate is ozonized in aqueous sodium dodecylsulfate (SDS) micelles (21), a system in which water can penetrate more deeply into the lipid microphase than in the liposomal lipid bilayers reported here. Thus, approximately 10% of the fatty acid is converted to the Criegee ozonide in all three of these model systems: SDS micelles, large multilamellar, liposomes, and small unilamellar liposomes. Since these systems differ in their degree of hydration (22,23) but afford very similar yields of Criegee ozonides, it seems reasonable to extrapolate a similar yield of Criegee ozonides in the lining fluid layer and/or cellular membranes in the lungs of animals exposed to ozone.

Cortesi and Privett (24) found that methyl linoleate ozonides injected into the tail vein were lethal to rats at 0.07 nnol/100 g body weight. Although these workers report that damage occurs primarily in the lung of the in-

[1] At these conversions, it is possible that the liposomal structure is altered by the presence of broken and oxygenated fatty acid chains.

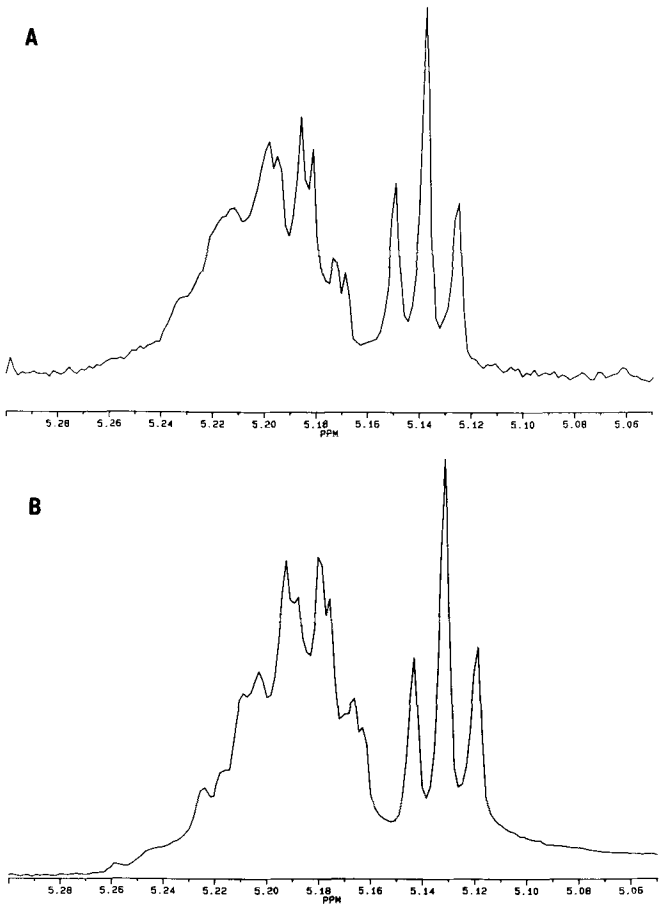

FIG. 2. Comparison of the ^1H nuclear magnetic resonance characteristic resonances of the 1,2,4-trioxolane moiety of *cis/trans* mixtures of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) ozonides obtained by ozonation of (A) POPC liposomes or (B) methylene chloride solutions.

TABLE 1

Formation of Criegee Ozonides from the Ozonation of POPC Liposomes[a]

% POPC ozonized	% Yield of ozonides	*cis/trans* Ratio
39[b]	9.4	0.98
41[b]	8.9	0.63
36[b]	16.0	0.91
37[b]	12.8	1.00
43[b]	8.4	0.81
38[b]	9.1	0.84
43[b]	10.0	0.87
28[c]	13.7	1.11
37[c]	9.2	0.98
49[c]	8.8	0.97

[a]Values presented are means of analyses carried out in either duplicates or triplicates. The variation among replicates was less than 5% in all cases. POPC, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine.

[c]Large multilamellar liposomes.

jected rats, this does not appear to be the optimum approach to model the situation that would exist in the lung when ozone-containing air is breathed. In that situation, the Criegee ozonide would be formed *in situ* in the lung lining fluids and/or bilayers. It is known that the Criegee ozonide can initiate lipid peroxidation, although at slow rates (19). Thus, the Criegee ozonide is of some interest as a potential secondary toxin from ozone exposures, underlining the need for more detailed investigations of the formation and toxicity of ozonides *in vivo*.

The hydrolytic stability of Criegee ozonides in carbon tetrachloride and in SDS micelles at physiological pH is quite good, with lifetimes in the order of several days (19, 21); however little is known about the half-life, metabolism and clearance times for Criegee ozonides in biological systems. Clearly, some data on the pharmacokinetics of the Criegee ozonide is needed, and we have initiated a program to obtain the relevant data. Additionally, because Criegee ozonides are expected to be formed only in reactions with ozone, these compounds might serve as useful biological marker molecules for ozone toxicity.

Kinetics of Photoperoxidation of Arachidonic Acid: Molecular Mechanisms and Effects of Antioxidants

Jean-Pierre Iliou*, David Jourd'heuil, Frédéric Robin, Bernard Serkiz, Pascale Guivarc'h, Jean-Paul Volland and **Jean-Paul Vilaine**
Institut de Recherches Servier, 92150 Suresnes, France

The kinetics of photoperoxidation of [1-^{14}C]arachidonic acid (20:4n-6) at 1.32 mM was studied either with the unsaturated fatty acid alone or in the presence of 10 μM of antioxidants and/or inhibitors of eicosanoid metabolism. The photosensitizer used was *meso*-tetraphenylporphine. The time-course of the reactions was followed by ultraviolet spectral analysis, thiobarbituric acid reactivity and high-performance liquid chromatographic analysis of aliquots sampled every 15 min during the 4 h of irradiation. The kinetics of photoperoxidation of 20:4n-6 can be divided into three main successive steps: (i) monohydroperoxidation, characterized by the appearance of conjugated diene patterns and monohydroperoxidized 20:4n-6; (ii) secondary oxidation characterized by polyoxygenated products such as dihydroperoxidized 20:4n-6 possessing conjugated triene patterns; and (iii) the disappearance of conjugated patterns and the oxidative cleavage of the products of the two first steps into aldehydic molecules reacting with thiobarbituric acid. During the first 90 min of irradiation, the mechanism of monohydroperoxidation (step one) is purely or predominantly type II photoperoxidation involving only singlet oxygen. This step was inhibited by β-carotene and by BW755C (3-amino-1-[3-trifluoromethylphenyl]2-pyrazoline). In contrast, the reactions involved in the second and third steps were predominantly type I photoperoxidation involving radical mechanisms. These latter steps were inhibited by β-carotene, BW755C, vitamin E and probucol. Indomethacin and 5,8,11,14-eicosatetraynoic acid did not alter 20:4n-6 photoperoxidation. This *in vitro* model of lipid photoperoxidation allows the screening of antioxidants in accordance with their singlet oxygen quenching and/or free radical scavenging properties.
***Lipids* 27, 959–967 (1992).**

Nonenzymatic peroxidation of unsaturated membrane lipids has been induced using photochemical processes in numerous *in vitro* and *in vivo* studies of basic and/or pharmacological relevance (1-6). Lipid photoperoxidation is of obvious significance as a model for the study of diseases involving photoreactive processes, such as porphyrias or cataracts (7–9). However, the relevance of photochemical processes to the study of "dark" oxidative stress, such as that generated during cardiac or cerebral ischemia-reperfusion injury remains less certain. Indeed, the photoperoxidation of unsaturated lipids involves both nonradical peroxidation by singlet oxygen (type II photoperoxidation) and radical peroxidation by free radicals derived from a photosensitizer (type I photoperoxidation) (10,11). The nature of the photosensitizer is one of the factors which determines the relative balance between these two mechanisms (12). The participation of singlet oxygen in "dark", nonenzymatic peroxidation of lipids has been suggested by numerous authors (13–15). However, there is no clear proof that "dark" generation of singlet oxygen occurs *in vivo*.

We wished to compare the pharmacological sensitivity of nonenzymatic lipid peroxidation occurring *via* free radical processes and nonradical processes involving singlet oxygen. In this report, we describe experiments in which the kinetics of photoperoxidation of the polyunsaturated lipid arachidonic acid (20:4n-6) was studied with the unsaturated fatty acid alone, or in the presence of one of the six drugs described hereafter. Each drug tested displays a unique activity profile as an antioxidant and/or as an inhibitor of eicosanoid metabolism. Vitamin E (VitE) is the main physiological antioxidant (9). Probucol (PROB; 2,2-*bis*[3,5-di-*t*-butyl-4-hydroxyphenylthio]propane) is a free radical scavenger used for the inhibition of the oxidation of low density lipoproteins probably involved in atherosclerosis (16,17). β-Carotene (βCAR) is physiologically relevant both as a free radical scavenger and as a singlet oxygen quencher (18,19). BW755C (3-amino-1-[3-trifluoromethylphenyl]2-pyrazoline) is a dual inhibitor of cyclooxygenase and lipoxygenase acting *via* a free radical mechanism of inhibition of these enzymes (20). BW755C protects the heart against oxidative stress associated with ischemia-reperfusion injury (21–23). ETYA (5,8,11,14-eicosatetraynoic acid) is an analogue of 20:4n-6 and a competitive inhibitor of both cyclooxygenase and lipoxygenase (24). Indomethacin (INDO) is an inhibitor of cyclooxygenase (24).

MATERIALS AND METHODS

Materials. Unlabelled 20:4n-6 and eicosapentaenoic acid (20:5n-3), βCAR, INDO, *meso*-tetraphenylporphine (mTPP), soybean lipoxygenase and VitE were obtained from Sigma Chemical Co. (St. Louis, MO). ETYA was from Fluka (Buchs, Switzerland). The nonlabelled eicosanoids employed as standards were purchased from Cayman Chemicals (Denver, CO). [1-^{14}C]20:4n-6 (specific activity 2.2 GBq/mmol) and [1-^{14}C]20:5n-3 (specific activity 1.9 GBq/mmol) were obtained from Amersham (Cardiff, U.K.) as toluene solutions containing no antioxidant. BW755C and PROB were from Wellcome (London, U.K.) and Merrell Dow (Cincinnati, OH), respectively. All organic solvents and alcohols used were high-performance liquid chromatography (HPLC) grade (Farmitalia Carlo Erba,

Abbreviations: AU, absorbance unit; BHT, butylated hydroxytoluene; βCAR, β-carotene; CP-HPLC, chiral-phase high-performance liquid chromatography; DiHETEs, dihydroxyeicosatetraenoic acids; DiHpETEs, dihydroperoxyeicosatetraenoic acids; ETYA, 5,8,11,14-eicosatetraynoic acid; 15(*S*)-HEPE, 15(*S*)-hydroxyeicosapentaenoic acid; HETEs, hydroxyeicosatetraenoic acids; 15(*S*)-HpEPE, 15(*S*)-hydroperoxyeicosapentaenoic acid; HpETEs, hydroperoxyeicosatetraenoic acids; INDO, indomethacin; MDA, malondialdehyde; mTPP, *meso*-tetraphenylporphine; NP-HPLC, normal-phase high-performance liquid chromatography; PROB, probucol; RP-HPLC, reverse-phase high-performance liquid chromatography; TBARS, thiobarbituric acid-reactive substances; TFA, trifluoroacetic acid; UV, ultraviolet; VitE, vitamin E.

Milano, Italy). All others chemicals were analytical grade and were obtained from Merck (Darmstadt, Germany). All chemicals were used as received, with the exception of 20:4n-6 and 20:5n-3 which were purified as described below.

Purification of 20:5n-3 and labelled 20:4n-6. Isotopic dilution of [1-^{14}C]20:4n-6 (12.4 KBq/μmol) was accomplished by mixing 2.05 MBq of labelled 20:4n-6 (2.2 GBq/mmol) with 1645 μmol (50 mg) of nonlabelled 20:4n-6. Because of the great sensitivity of 20:4n-6 to spontaneous autoxidation in the presence of air, the dilution of [1-^{14}C]-20:4n-6 (12.4 KBq·μmol^{-1}) was purified less than 5 d prior to experiments to eliminate autoxidation products. Briefly, 50 mg of labelled 20:4n-6 were passed through a column packed with 1 g of silicic acid Silicar CC-4 (Mallinckrodt, Paris, KY) using hexane/diethyl ether (92:8, vol/vol) as mobile phase. Only the first 35 mL of eluate were collected. After rotary evaporation at 20°C, a methanolic solution of purified 20:4n-6 was prepared. The purity of 20:4n-6 was confirmed by ultraviolet (UV) spectroscopy and reverse-phase high-performance liquid chromatography (RP-HPLC) in combination with radioactive detection as described below. The concentration of the methanolic solution of 20:4n-6 was measured spectrophotometrically using an experimentally determined molar extinction coefficient of 17130 absorbance unit (AU)·cm^{-1}·M^{-1} at 204 nm. Eicosapentaenoic acid was purified as for 20:4n-6 using a molar extinction coefficient of 21400 AU·cm^{-1}·M^{-1} at 204 nm. The purified solutions of 20:5n-3 and labelled 20:4n-6 were stored at −85°C.

Preparation of [1-^{14}C]15(S)-hydroxyeicosapentaenoic acid. The isotopic dilution of [1-^{14}C]20:5n-3 (11.2 KBq/μmol) was prepared by adding 370 KBq of [1-^{14}C]-20:5n-3 (1.9 GBq/mmol) to 10 mg of purified 20:5n-3. [1-^{14}C]15(*S*)-hydroperoxyeicosapentaenoic acid (15(*S*)-HpEPE) was synthetized by incubating 10 mg of isotopically diluted [1-^{14}C]20:5n-3 as sodium salt with 7 mg of soybean lipoxygenase for 10 min at 25°C in 250 mL of *tris*(hydroxymethyl)aminoethane/HCl buffer (50 mM, pH 9). After acidification, 15(*S*)-HpEPE was extracted with diethyl ether. [1-^{14}C]15(*S*)-hydroxyeicosapentaenoic acid ([1-^{14}C]15(*S*)-HEPE) was obtained by reduction of the dried diethyl ether extract resolubilized in 50 mL of methanol with 15 mg of $NaBH_4$ for 120 min at 0°C. After drying and addition of acidified water, [1-^{14}C]15(*S*)-HEPE was extracted with diethyl ether. [1-^{14}C]15(*S*)-HEPE was purified from the diethyl ether acidic extract by isocratic normal-phase HPLC (NP-HPLC) using a 350 mm × 7.5 mm Nucleosil 120-10 column (Macherey-Nagel, Düren, Germany). The column was eluted at a constant flow of 6 mL/min (Waters 590 pump, Millipore, Milford, MA) with a mobile phase consisting of *n*-heptane/ethanol/acetic acid (995:4:1,vol/vol/vol). The effluent was monitored with a UV detector (Waters 481, Millipore) at 235 nm. The retention time of [1-^{14}C]15(*S*)-HEPE was 26 min. [1-^{14}C]15(*S*)-HEPE was collected at the outlet of the UV detector. [1-^{14}C]15(*S*)-HEPE was identified by comparison of its retention time with that of nonradioactive commercial 15(*S*)-HEPE and was quantified by UV analysis using 23000 AU·cm^{-1}·M^{-1} as molar extinction coefficient at 235 nm. [1-^{14}C]15(*S*)-HEPE was stored at −85°C in methanol.

Photoperoxidation procedure. The reactions were performed at 25°C in the apparatus illustrated in Figure 1.

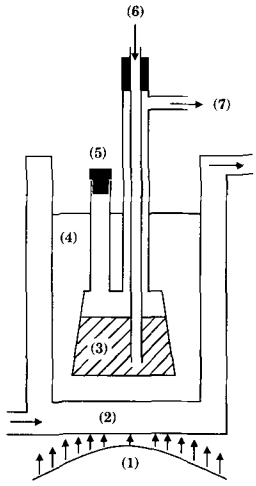

FIG. 1. Apparatus for the photoperoxidation experiments. The reaction vessel and the cooling jacket were constructed from glass. (1): 120 W tungsten lamp operated at 24 V; (2): cooling jacket with circulating water at 25°C; (3): reaction vessel containing irradiated and oxygen-bubbled sample; (4): yellow filter-solution K_2CrO_4 (0.1M); (5): sampling tube; (6) and (7): inlet and outlet for O_2 stream at 10 mL/min.

In a typical experiment, 10 mg of labelled and purified 20:4n-6 and 300 μg of mTPP in a final volume of 25 mL in CCl_4 were irradiated in the reaction vessel. The appropriate amount of test drugs was added in 250 μL of ethanol at 0 min or at 135 min of irradiation. The final concentrations were 1.32 mM of 20:4n-6, 17 μM of mTPP and 10 μM of drugs to be tested. The molar ratio of tested drug/oxidizable substrate (20:4n-6) was 0.0076. For the analytical procedures, an aliquot of 500 μL of reaction solution was removed and placed on ice every 15 min during 240 min of irradiation.

UV analysis. A portion of the peroxidized aliquot was treated to obtain 1 mL of methanolic solution at 55 μM equivalent initial concentration of 20:4n-6. UV spectra were obtained using a scanning spectrophotometer (Uvikon 860, Kontron, Zürich, Switzerland). The methanolic solutions were scanned from 190 nm to 320 nm with methanol as background. The conjugated diene and conjugated triene patterns present absorbance maxima between 234-237 nm and at 268 nm, respectively. These specific absorbances were studied because the majority of monohydroperoxides and dihydroperoxides derived from polyunsaturated fatty acids possesses conjugated diene and conjugated triene patterns, respectively (25). The specific absorbances were characterized by analysis of the second derivative of spectra (26,27). The UV spectral results were expressed as mAU/μM equivalent initial concentration of 20:4n-6 at 235 nm and 268 nm as a function of irradiation time.

RP-HPLC analysis. RP-HPLC of peroxidized products was done on a 150 mm × 7.4 mm Nucleosil 120-3 C18 column (Macherey-Nagel). The column was eluted at a constant flow of 1 mL/min for a run duration of 55 min, with two successive isocratic steps: the first 40 min with ethanol/water/sulfuric acid (630:370:0.5, vol/vol/vol) and the last 15 min with ethanol/sulfuric acid (1000:0.5, vol/vol). The effluents were successively monitored in line with a

photodiode array detector (Waters 990, Millipore) between 190 nm and 300 nm and with an HPLC radioactivity detector (Berthold, model LB507A, Wildbad, Germany) using solid scintillation with an yttrium glass cell. The injected samples were prepared from a photoperoxidized aliquot of 400 nmoles of equivalent initial 20:4n-6. This aliquot had been previously stabilized by reduction with 1-2 mg of $NaBH_4$ in methanolic solution for 120 min at 0°C. After rotary evaporation at 20°C, the dry sample was dissolved in 500 μL of an ethanol/water/acetic acid (50:50:20, vol/vol/vol) mixture and filtered through a nylon membrane. The sample volume injected was 250 μL. The results were expressed for each class of peroxidative product as the area under the corresponding peaks as a percentage of the total area of all peaks of radioactivity as a function of irradiation time.

Separation of optical isomers of isolated positional isomers of hydroxyeicosatetraenoic acids (HETEs). The stereochemical analysis of each HETE required prior purification of the positional isomers of HETEs by NP-HPLC. NP-HPLC of HETEs was performed with a 250 mm × 4.6 mm Nucleosil 120-3 column (Macherey-Nagel). The column was eluted at a constant flow of 1 mL/min for a 75 min run. The first 10 min and the last 30 min were isocratic steps with *n*-heptane/2-propanol/trifluoroacetic acid (TFA) (995:5:0.1, vol/vol/vol) and *n*-heptane/2-propanol/TFA (985:15:0.1, vol/vol/vol) as mobile phases, respectively. From 10 min to 45 min, the mobile phase consisted of a linear gradient between the two solvent mixtures described above. The detection mode was identical to that used for RP-HPLC. Ten mg of [^{14}C]-20:4n-6 photoperoxidized during 60 min were reduced with 15 mg of $NaBH_4$ in 50 mL of methanol for 120 min at 0°C before rotary evaporation. The dry samples were washed with 1 M HCl. The reduced products of photoperoxidation were extracted from the acidic solution with diethyl ether. After rotary evaporation, the dry samples were dissolved in 250 μL of injection mixture consisting of *n*-heptane/2-propanol (995:5, vol/vol). Chiral-phase HPLC (CP-HPLC) was performed on a 250 mm × 4.6 mm Chiralpak AD 10 μm column (Daicel, Düsseldorf, Germany) as stationnary phase and with *n*-heptane/2-propanol/TFA (980:20:0.02, vol/vol/vol) as mobile phase at a constant flow of 1 mL/min. The samples were injected in 100 μL of mobile phase; the detection mode was identical to that used for the NP-HPLC procedure.

Thiobarbituric acid-reactive substances (TBARS). The determination of TBARS formation during control photoperoxidation in absence of test drugs was based on procedure as described (28). TBARS were evaluated directly from 500 μL of photoperoxidized samples after acidic aqueous extraction from the CCl_4 phase with 1.5 mL of 0.5 M HCl. The extraction was performed without evaporation steps because it became evident that during rotary evaporation volatile aldehydes can be lost. Butylated hydroxytoluene (BHT) was added to the reaction solution before incubation at 95°C. The addition of BHT inhibits the thermocleavage of lipid hydroperoxydes to aldehydic products. Photoperoxidized aliquots of 400 nmoles of equivalent initial 20:4n-6 were used for TBARS determination. Malondialdehyde (MDA) was employed as calibration standard. TBARS formation was expressed in nmoles MDA/μmole equivalent initial amount of 20:4n-6 as a function of irradiation time.

RESULTS

Characterization of conjugated dienes and trienes. Photoperoxidation of 20:4n-6 during the first 150 min led to rapid, time-dependent formation of conjugated patterns (Fig. 2). The maxima of absorbance spectra of photoperoxidized 20:4n-6 corresponded to the maxima of absorbance spectra of authentic enzymatically-generated standards of conjugated dienes 5(*S*)-hydroxyeicosatetraenoic acid (5(*S*)-HETE) and conjugated trienes 5(*S*),12(*S*)-dihydroxyeicosatetraenoic acid (5(*S*),12(*S*)-DiHETE). These results were confirmed by analysis of the second derivative of the spectra (26,27).

Chromatographic characterization of peroxidized products of 20:4n-6. Figure 3 shows a representative RP-HPLC analysis of labelled 20:4n-6 which was photoperoxidized for 135 min. The distribution of the total radioactivity was 4.1% for residual 20:4n-6 with an elution time of 50 min, 34.4% for intermediate monohydroperoxidized products (hydroperoxyeicosatetraenoic acids, HpETEs) that eluted between 29 and 43 min and 61.5% for polar terminal products. This last group included all the peaks that eluted between 5 and 28 min. In this group, numerous peaks (not formally identified) exhibited conjugated diene and triene patterns. This group included the products of secondary peroxidation such as endoperoxides, cyclic peroxides and dihydroperoxyeicosatetraenoic acids (DiHpETEs) and the aldehydic products of final cleavages of mono and dihydroperoxidized 20:4n-6. $NaBH_4$ reduction of endoperoxides generated dihydroxylated compounds. The

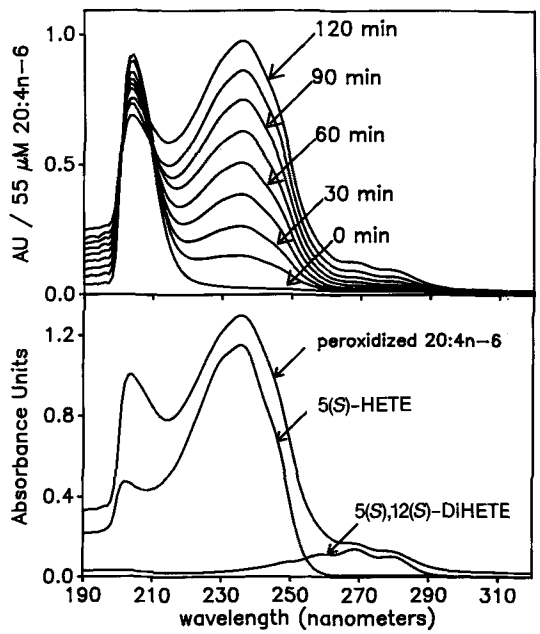

FIG. 2. Appearance and characterization of conjugated patterns during photoperoxidation of 20:4n-6. Upper panel: ultraviolet (UV) spectra of the successive production of conjugated dienes and trienes during the first 120 min of irradiation, one measurement every 15 min. Lower panel: comparison of the UV spectrum of 20:4n-6 photoperoxidized for 120 min with the UV spectra of 5(*S*)-hydroxyeicosatetraenoic acid (HETE) and 5(*S*),12(*S*)-dihydroxyeicosatetraenoic acid (DiHETE). The two molecules possess conjugated diene and conjugated triene patterns, respectively.

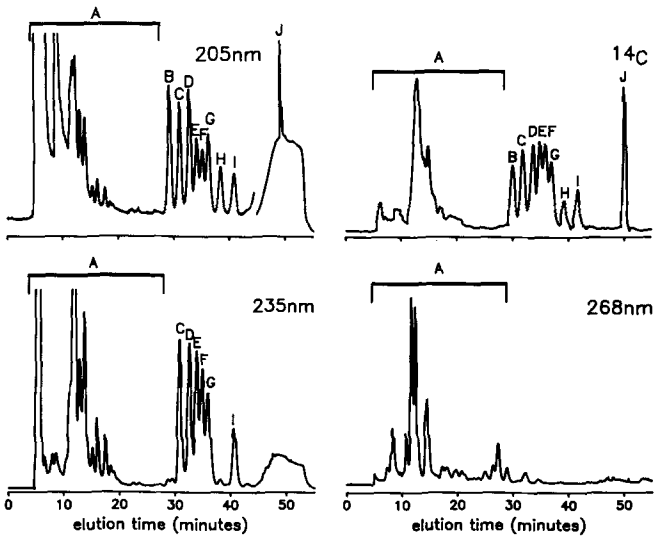

FIG. 3. Reverse-phase high-performance liquid chromatography of [1-^{14}C]20:4n-6 photoperoxidized for 135 min. For the same run, ultraviolet (UV) (205 nm, 235 nm and 268 nm) and radioactive detections were used. The sample was stabilized by reduction with $NaBH_4$. Peaks A: group of terminal products of peroxidation in which were pooled reduced products of secondary oxidation such as dihydroperoxyeicosatetraenoic acid and aldehydic products of the oxidative cleavage of hydroperoxidized 20:4n-6. Peaks B–I represent the reduced hydroperoxyeicosatetraenoic acids as hydroxyeicosatetraenoic acids (HETEs). Peak B: 14-HETE. Peak C: 15-HETE. Peak D: 11-HETE. Peak E: 12-HETE. Peak F: 8-HETE. Peak G: 9-HETE. Peak H: 6-HETE. Peak I: 5-HETE. 14-HETE (peak B) and 6-HETE (peak H) do not possess conjugated diene patterns and do not absorb at 235 nm. Peak J: residual 20:4n-6.

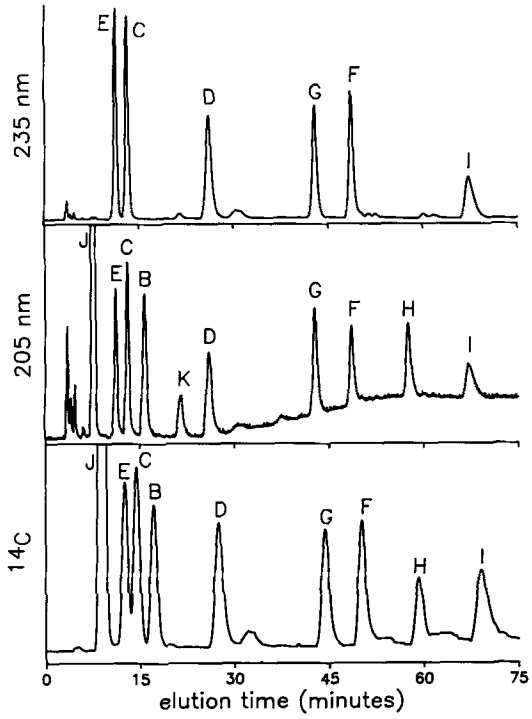

FIG. 4. Normal-phase high-performance liquid chromatography of [1-^{14}C]20:4n-6 photoperoxidized for 60 min. Ultraviolet (205 nm and 235 nm) and radioactive ^{14}C detections were successively used for each run. The sample was stabilized by reduction with $NaBH_4$. The identification of the peaks (B–I) is identical to that used in Figure 3. Peak K: oxidized *meso*-tetraphenylporphine (mTPP).

aldehydic nature of the products generated by cleavage of peroxidized 20:4n-6 was confirmed by the appearance of TBARS. TBARS generation is not a valid index for a dynamic evaluation of the cascade of reactions involved in *in vivo* lipid peroxidation, but it is a relevant index for the global quantification of carbonyl molecules in an *in vitro* model containing no cellular contaminants (carbohydrates and nucleic acids) as described here. The production of HpETEs preceded the appearance of the peaks of the terminal products.

In autoxidation experiments (radical mechanism), only six conjugated positional isomers of HpETEs have been obtained: 15-HpETE, 12-HpETE, 11-HpETE, 9-HpETE, 8-HpETE, 5-HpETE (29,30). In contrast, eight positional isomers of HpETEs have been formed in photoxidation experiments: the six conjugated HpETEs as those obtained in the case of autoxidation and two supplementary nonconjugated products, 14-HpETE and 6-HpETE (Fig. 3). The formation of these two nonconjugated isomers is characteristic of the initiation of peroxidation of 20:4n-6 by singlet oxygen *via* a nonradical mechanism, *i.e.* ene addition (31–33). The positional isomers of HpETEs (measured as HETEs after stabilizing reduction) were identified by comparison of their elution times and of their UV spectra (performed on line with photodiode array detector) with those of standards. The six conjugated HETEs standards were from commercial sources, while 14-HETE and 6-HETE were previously identified using an NP-HPLC procedure illustrated in Figure 4 in agreement with Chacon *et al.* (33). The relative distribution of radioactivity between the eight positional isomers of HpETEs after 90 min of irradiation were 15.5% for 15-HETE, 13.4% for 14-HETE, 12.9% for 12-HETE, 14.2% for 11-HETE, 11.5% for 9-HETE, 14.3% for 8-HETE, 7.9% for 6-HETE and 10.3% for 5-HETE, respectively. These results were similar to those of Chacon *et al.* (33) using methylene blue or haematoporphyrin as photosensitizer. Figure 5 shows four examples of a separation of optical isomers of isolated HETEs produced by photoperoxidation in comparison with the corresponding *S*-isomers. Production of HETEs by photoperoxidation yielded racemic mixtures of *R*- and *S*-isomers.

Time-course of nonenzymatic peroxidation of 20:4n-6. The successive appearance and disappearance of conjugated patterns were indicative of the formation of mono- and dihydroperoxidized compounds followed by their oxidative cleavages to final aldehydic products that do not contain conjugated patterns (Fig. 6). The TBARS generation was strictly linked with the phase of disappearance of conjugated patterns. The absorbance maxima of conjugated dienes and trienes were observed after 150 min and 165 min of irradiation, respectively. The transition from the formation of conjugated patterns to the disappearance of these structures occurred after 165 min of irradiation. At this time, the irradiated solution became opaque, indicating the formation of polar molecules as aldehydic products that are insoluble in CCl_4. The lag period of 60 min before the appearance of conjugated trienes contrasted with the direct formation of conjugated dienes in the early minutes of irradiation and underlined the successive transformation of monohydroperoxidized products to dihydroperoxidized products as described (31).

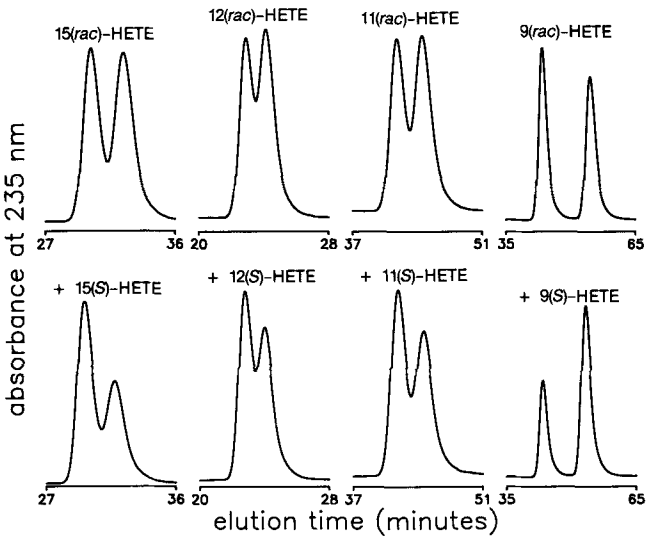

FIG. 5. Chiral-phase high-performance liquid chromatography (CP-HPLC) of separated positional hydroxyeicosatetraenoic acid (HETE) isomers produced by photoperoxidation. Top row: CP-HPLC of four HETEs produced by photoperoxidation. Bottom row: CP-HPLC of these four HETEs produced by photoperoxidation mixed with the corresponding optical *S*-isomers.

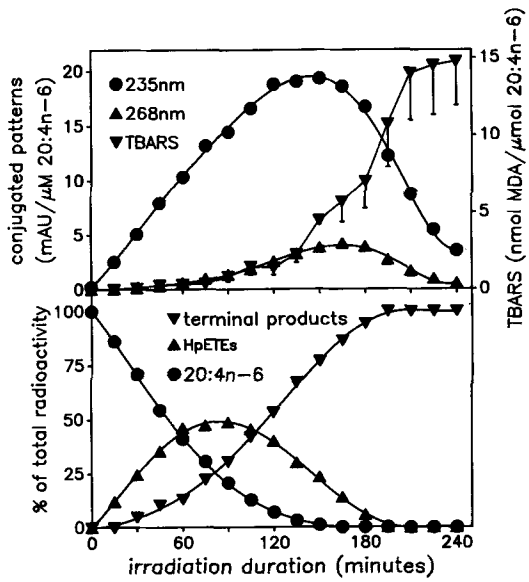

FIG. 6. Time-course of the production of conjugated patterns, thiobarbituric acid-reactive substances (TBARS) and the evolution of classes of peroxidation products during photoperoxidation of [1^{-14}C]20:4n-6 at 1.32 mM. Upper panel: conjugated diene and conjugated triene patterns are expressed as milli absorbance unit (mAU) at 235 nm/μM 20:4n-6 and mAU at 268 nm/μM 20:4n-6, respectively, as a function of irradiation time. The data were obtained from ultraviolet (UV) spectra as described in Figure 2. TBARS are expressed as nmoles of malondialdehyde (MDA) produced by μmole of initial 20:4n-6 as a function of irradiation time. Lower panel: from reverse-phase high-performance liquid chromatography analysis as described in Figure 3, the distribution of total ^{14}C between terminal products of peroxidation (products of secondary oxidation and aldehydic products of the oxidative cleavage of hydroperoxides), hydroperoxyeicosatetraenoic acids (HpETEs) and 20:4n-6 are expressed as a function of irradiation time. The results for the conjugated patterns and the distribution of total ^{14}C were expressed as the mean of eleven experiments; the standard deviations were less than 3% of the mean. For TBARS, the results are expressed as the mean ± SD for four experiments.

The chromatographic results shown in Figure 6 illustrated that: (i) 20:4n-6 is completely peroxidized after 150 min of irradiation; (ii) HpETEs are the early transitional peroxidized compounds formed with a maximum accumulation of 48.7% of total radioactivity after 90 min of irradiation; and (iii) HpETEs are totally transformed to terminal products after 195 min of irradiation; these terminal products, including secondary oxidation products as dihydroperoxides and final aldehydic compounds, accounted for 100% of total radioactivity.

In preliminary experiments, [1^{-14}C]15(*S*)-HEPE was used as an internal standard for RP-HPLC analysis. There was no change in total radioactivity of each aliquot sampled during the 240 min of irradiation (data not shown). This indicated that there was no formation of volatile terminal compounds possessing labelled carbon from the carboxylic function of 20:4n-6 during the 240 min of irradiation.

The initial lag period in the formation of TBARS is identical to that obtained for the formation of conjugated trienes (Fig. 6). TBARS, like the terminal products identified chromatographically, exhibited a plateau beginning after 195 min of irradiation. However, a difference of 60 min was observed between the irradiation times necessary for these two indices of final peroxidation to reach 50% of their maximal values. The formation of chromatographically-identified terminal products preceded TBARS formation.

Effect of Vitamin E. The addition of VitE (10 μM) at the beginning of the irradiation period modified neither the rate of formation of HpETEs and conjugated dienes, nor the time of irradiation necessary to obtain maximal values (Fig. 7). In contrast, VitE added at 0 min decreased the rate of formation of conjugated triene patterns by 43.4% and the rate of disappearance of HpETEs by 55.4%. VitE added at 0 min inhibited totally the phase of decrease of conjugated patterns. Under these conditions, VitE inhibited the later steps of cleavage of mono- and dihydroperoxidized products to terminal aldehydic compounds. To test directly the effects of the antioxidants on the oxidative cleavage of monohydroperoxidized products, drugs were added after 135 min of irradiation. When VitE was added after 135 min of irradiation, the rate of disappearance of HpETEs was diminished by 61.1% and as described above, VitE totally abolished the phase of decrease of conjugated patterns (data not shown).

Effect of Probucol. The addition of PROB (10 μM; data not shown) at the beginning of the irradiation period modified the indices of peroxidation in the same way as VitE. PROB added at 0 min decreased the rate of formation of conjugated triene patterns and the rate of disappearance of HpETEs by 36.7% and 46.1%, respectively.

Effect of BW755C. The addition of BW755C (10 μM) at the beginning of the 240 min irradiation period decreased the formation of HpETEs and conjugated dienes and trienes by 53.5%, 53.4% and 61.2%, respectively (Fig. 8), and the step of disappearance of mono- and dihydroperoxidized products was not observed. The addition of BW755C (10 μM) after 135 min of irradiation decreased the rate of disappearance of HpETEs by 81%, and conjugated dienes

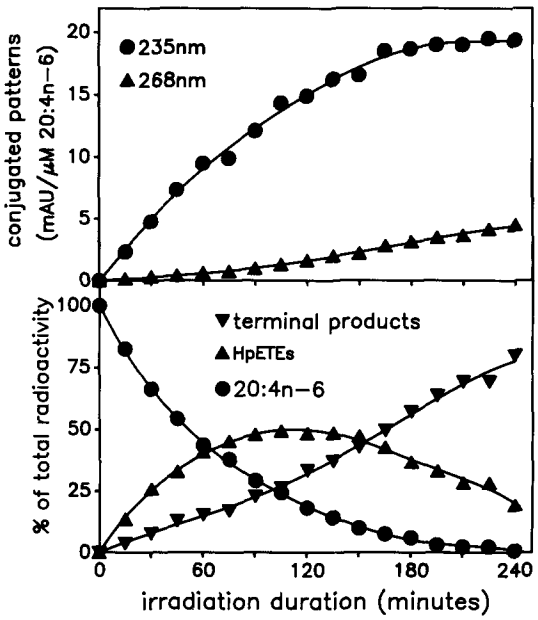

FIG. 7. Effect of Vitamin E (VitE) (10 μM; added at 0 min of irradiation) on the time-course of production of conjugated patterns and evolution of classes of peroxidation products during photoperoxidation of [1^{-14}C]20:4n-6 at 1.32 mM. The molar ratio of tested drug (VitE)/oxidizable substrate (20:4n-6) was 0.0076. The results are expressed as a function of the duration of irradiation for ultraviolet spectral analysis (upper panel) and reverse-phase high-performance liquid chromatography analysis (lower panel) as described in Figure 6. The results represent the mean of three experiments.

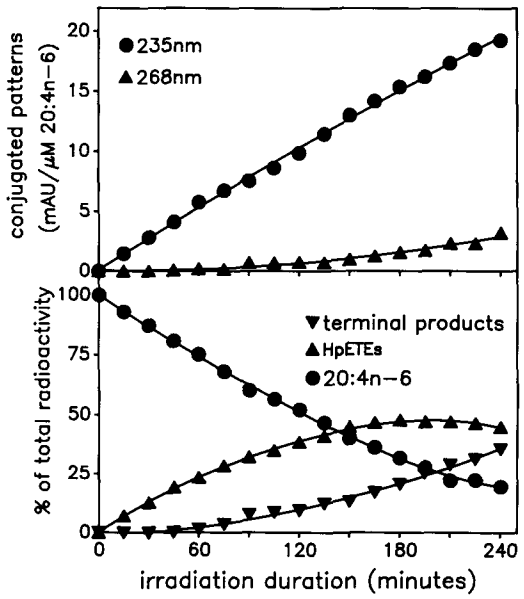

FIG. 8. Effects of BW755C (10 μM; added at 0 min of irradiation) on the time-course of the production of conjugated patterns and the evolution of classes of peroxidation products during photoperoxidation of [1^{-14}C] 20:4n-6 at 1.32 mM. The results are expressed as described in Figure 7.

and trienes were stabilized at maximal levels (data not shown). BW755C was thus able to inhibit both the generation of mono- and dihydroperoxidized products and the subsequent oxidative cleavage of these products.

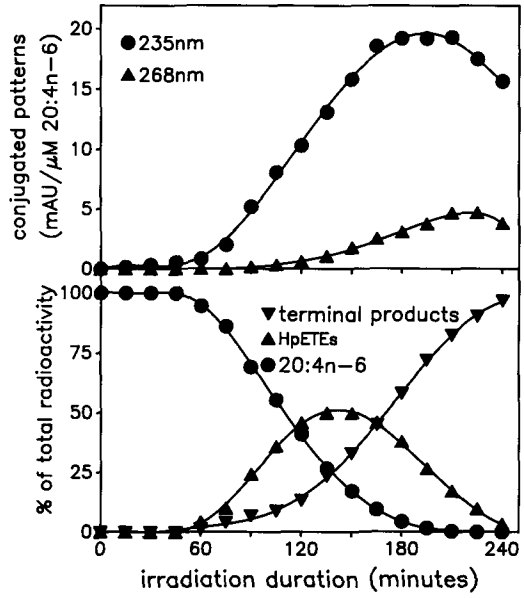

FIG. 9. Effects of beta-carotene (10 μM; added at 0 min of irradiation) on the time-course of the production of conjugated patterns and the evolution of classes of peroxidation products during photoperoxidation of [1^{-14}C] 20:4n-6 at 1.32 mM. The results are expressed as described in Figure 7.

Effect of β-carotene. The addition of βCAR (10 μM) at the beginning of the irradiation period produced a lag period of 60 min prior to the formation of HpETEs and conjugated dienes and trienes (Fig. 9). At the end of this lag period, characterized by the disappearance of the orange color of βCAR, the peroxidation reactions began at rates equal to those observed under control conditions.

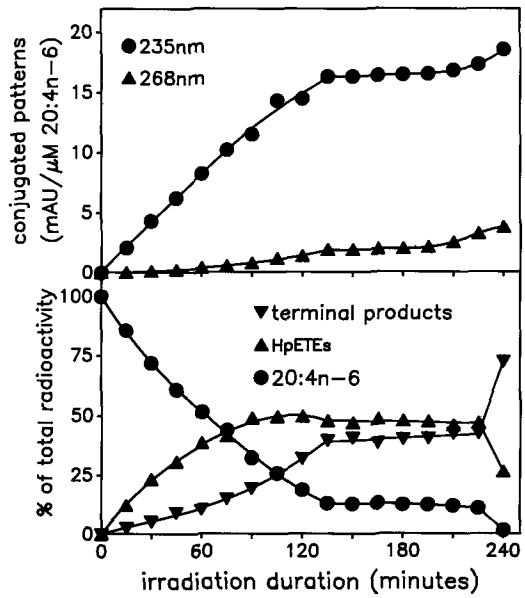

FIG. 10. Effects of beta-carotene (10 μM; added at 135 min of irradiation) on the time-course of the production of conjugated patterns and the evolution of classes of peroxidation products during photoperoxidation of [1^{-14}C]20:4n-6 at 1.32 mM. The results are expressed as described in Figure 7.

The addition of βCAR (10 μM) after 135 min of irradiation stabilized the different parameters at the values observed at 135 min for a period of 90 min (Fig. 10). After 225 min of irradiation, the different reactions began at rates equal to those observed under control conditions. As described above, the resumption of the reactions was associated with the disappearance of the orange carotenoid dye. If in the absence of βCAR, the irradiation was interrupted at 135 min of irradiation and resumed 90 min later, the kinetics of the different indices of peroxidation were similar to those observed with βCAR addition at 135 min (data not shown). These results indicated that βCAR protected the lipids from photoperoxidation by acting as a preferential substrate. Once all the βCAR was consumed by reaction with the oxygen reactive species, the generation of mono- and dihydroperoxydized products from 20:4n-6 and their subsequent cleavage resumed.

Effects of ETYA and INDO. The addition of ETYA (10 μM) or INDO (10 μM) at the beginning of the irradiation period did not affect the various reaction parameters under control conditions (data not shown).

DISCUSSION

Nonenzymatic peroxidation of lipids results in a complex cascade of reactions (32,34–36). The *in vitro* model of lipid photoperoxidation described here illustrates this complexity. The kinetics of photoperoxidation of 20:4n-6 can be divided into three main steps: (i) monohydroperoxidation characterized by formation of HpETEs; these molecules can possess conjugated diene patterns; (ii) secondary oxidation characterized by formation of polyoxygenated products, including endoperoxides and DiHpETEs; the latter molecules can possess conjugated triene patterns; (iii) oxidative cleavage of the products of the two first steps into aldehydic molecules; these terminal molecules do not possess conjugated patterns and do react with thiobarbituric acid (TBA). The experimental results underline the intermediate appearance of monohydroperoxides and conjugated patterns during the cascade of reactions involved in lipid peroxidation. As early as in 1967, Esterbauer and Schauenstein (37) observed the transient formation of conjugated dienes during the oxidation of a methyl linoleate emulsion in water. In 1970, Tam and McCay (38) showed the transient formation of lipid peroxides during a kinetic study of radical peroxidation of liver microsomes. Terao and Matsushita (31), in a model of photoperoxidation of 20:4n-6 with methylene blue as photosensitizer, showed the early steps of the formation of HpETEs to be followed by secondary oxidation product formation such as DiHpETEs after a lag period of 4 h. These authors, as well as Chacon *et al.* (33), demonstrated the formation of eight positional isomers of HpETEs including the two nonconjugated isomers characteristic of peroxidation by singlet oxygen *via* ene addition. The observation of racemic mixtures of optical isomers of the isolated positional isomers of photoperoxidized HETEs is in agreement with Kuhn *et al.* (39) and is representative of nonenzymatic lipid peroxidation. The significant production of nonconjugated 14-HpETE and 6-HpETE in comparison with diene conjugated HpETEs produced at 90 min of irradiation indicates that during the first 90 min of irradiation the mechanism of monohydroperoxidation is purely or predominantly type II photoperoxidation (10,11,31,33,40). The lack of an effect of VitE in comparison with the total inhibition induced by βCAR during the first 60 min of irradiation confirms that nonradical peroxidation occurred during this period. The results emphasize the low singlet oxygen quencher effect of VitE in comparison with the important effect of βCAR. This is consistent with previous reports (18,41) which indicated that βCAR exhibits a physical quenching rate constant with singlet oxygen which is 50-fold greater than that of VitE. *In vivo*, the significant difference between the singlet oxygen quencher effects of βCAR and VitE may be compensated for by the plasma concentration. In plasma of healthy human population, Riemersma *et al.* (42) showed that the VitE concentration is more than 44-fold higher than the βCAR concentration. The lack of an effect of the free radical scavenger PROB also argues for the occurrence of nonradical monohydroperoxidation during the first 90 min of irradiation. The lack of TBARS production during this period confirms the predominance of a type II mechanism during the first 90 min (10,11).

In contrast, the reactions involved in the steps of secondary oxidation and cleavage of hydroperoxidized 20:4n-6 were predominantly type I photoperoxidation with radical mechanisms. Indeed, VitE and PROB inhibit both the production of conjugated trienes and the disappearance of conjugated dienes. Both molecules decrease the rate of disappearance of HpETEs after 90 min of irradiation. The significant production of TBARS after 120 min, indicative of the free radical cleavage of hydroperoxides, supports the argument of a significant involvement of type I photoperoxidation during this period (10,11). The involvment of singlet oxygen in secondary oxidation remains low under these experimental conditions because VitE and PROB did not inhibit the monohydroperoxidation of 20:4n-6 by singlet oxygen. Type 1 photoperoxidation, but no autoxidation, is predominantly involved in the fragmentation of peroxidized 20:4n-6 because when the irradiation is interrupted after the first 135 min of reaction, there is total inhibition of the oxidative cleavage of peroxidized 20:4n-6. The formation of conjugated dienes persists 60 min after the beginning of the disappearance of HpETEs, indicating that secondary oxidation products formed from HpETEs as endoperoxides and dihydroperoxides can enter into a peroxidation process yielding numerous molecules possessing conjugated diene patterns; these molecules could lead to a secondary generation of conjugated aldehydes (43).

Only the predominant oxidative reactions involved in the successive steps of 20:4n-6 photoperoxidation can be analyzed. The antioxidants used to screen oxidative mechanisms are not absolutely specific in their action. VitE, the main physiological free radical scavenger, is a low quencher of singlet oxygen, and βCAR, a powerful quencher of singlet oxygen, can act under certain conditions as a free radical scavenger (9,18,19).

VitE does not act as an inhibitor of the initiation step of autoxidation but scavenges chain-propagating radicals and inhibits the secondary oxidation and oxidative cleavage of monoperoxidized compounds (44–46). The reaction products of VitE with peroxyl radicals of methyl linoleate formed by autoxidation have recently been isolated and characterized (47).

The inhibitory effect of BW755C on each index of peroxidation after addition at 0 min or at 135 min of

irradiation demonstrates that in addition to its established free radical scavenging properties, this molecule can possess singlet oxygen quenching and/or scavenging effects. Janero *et al.* (48,49) demonstrated that BW755C is ten times more potent than VitE in protecting cardiac lipids against oxidative stress.

The lack of effects of ETYA on photoperoxidation of 20:4n-6 is representative of its mechanism of inhibition of eicosanoid metabolism. ETYA, a structural analogue of 20:4n-6, competitively inhibits both cyclooxygenase and lipoxygenase (24). Indeed, ETYA inhibits the release of prostacyclin but not the production of TBARS by cultured smooth muscle cells in response to the addition of 20:4n-6 (50). In the presence of VitE, the opposite result is obtained. The lack of a protective effect of INDO on photoperoxidation of 20:4n-6 is consistent with the lack of an antioxidant effect of this molecule against peroxidative damage of myocardial phospholipids (49). ETYA and INDO were used here as negative controls for a complete description of the limits and the selectivity of the model of 20:4n-6 photoperoxidation.

In our *in vitro* experiments, repeated sampling of the reaction mixtures permitted the detection of transient formation and subsequent degradation of monohydroperoxidized lipids and conjugated patterns. These observations point at "kinetic restrictions" which should be considered in the interpretation of *in vivo* studies of lipid peroxidation in which monohydroperoxidized lipids are measured by HPLC as the sole index and at a single time point (51–53). The coupling of the measurement of monohydroperoxidized lipids with the quantitative analysis of aldehydic products would be a valid index of the dynamics of the cascade of reactions involved in lipid peroxidation (54,55).

The case of BW755C, an inhibitor of both nonradical and radical peroxidation, underlines the limitations of the use of a photochemical process in ischemia-reperfusion studies. Indeed, for this type of oxidative injury, the involvement of "dark" generation of singlet oxygen has not been formally demonstrated.

Antioxidants are promising therapeutic agents for numerous diseases involving oxidative stress (56,57). The combination of singlet oxygen quenching and free radical scavenging properties could be avantageous for specific diseases in which singlet oxygen intervention is involved. The *in vitro* model of lipid photoperoxidation described here provides a simple and reproducible method for the preliminary screening of scavengers of reactive oxygen species of therapeutic interest.

Eicosapentaenoic Acid at Hypotriglyceridemic Dose Enhances the Hepatic Antioxidant Defense in Mice

Abraham Demoz*, Nina Willumsen and **Rolf Kristian Berge**
Laboratory of Clinical Biochemistry, University of Bergen, Haukeland Sykehus, 5021 Bergen, Norway

The effect of oral administration of purified (95%) eicosapentaenoic acid on serum lipids, hepatic peroxisomal enzymes, antioxidant enzymes and lipid peroxidation was compared with that of palmitic acid fed mice and corresponding controls. After 10 d, a dose of 1000 mg eicosapentaenoic acid per day/kg body weight lowered serum triglycerides by 45%, while no significant change in serum cholesterol level was noted in comparison to palmitic acid fed mice and controls. Hepatic acyl-CoA oxidase and catalase activities increased by 50% and 30%, respectively, in the eicosapentaenoic acid fed group. In addition, the hepatic reduced glutathione content and the activities of glutathione transferase, glutathione peroxidase and glutathione reductase, increased significantly during eicosapentaenoic acid treatment. The levels of hepatic lipid peroxides were lower after eicosapentaenoic acid feeding, while no significant change was noted in the palmitic acid fed mice when compared to the controls. Taken together, the present data demonstrate for the first time that at hypolipidemic doses eicosapentaenoic acid feeding i) enhances the hepatic antioxidant defense, and ii) does not cause a significant differential induction of the two peroxisomal enzymes, acyl-CoA oxidase and catalase, as was noted after administration of hypolipidemic peroxisome proliferating compounds, such as clofibrate in rodents.
Lipids 27, 968-971 (1992).

Excess of lipids in the blood is considered to accelerate the development of arteriosclerosis and is a risk factor in myocardial infarction. Accordingly, reduction of high blood lipid levels by diet or by drugs is used as a preventive measure in people at risk (1,2).

Hypolipidemic drugs such as clofibrate, benzafibrate and nafenopin are effective in lowering serum lipids in various dyslipidemic disorders in human subjects (1,2) and experimental animals (3). However, at hypolipidemic doses, these compounds markedly induce peroxisome proliferation in rodents (3-5). This can lead to an increase in hydrogen peroxide generation due to the concomitant increase in peroxisomal β-oxidation which is an undesirable effect of the compounds as it may create cellular oxidative stress. In addition, these drugs have been shown to compromise the activities of the glutathione requiring detoxification enzymes, such as glutathione transferase and glutathione peroxidase (3). It is, therefore, likely that the combined effect of these changes on the metabolism of hydrogen peroxide may directly or indirectly induce membrane lipid peroxidation and oxidative damage to DNA (4,5). Ultimately, such changes are thought to be the cause for the increased incidence of hepatic neoplasia in rodents treated with hypolipidemic peroxisome proliferator compounds (6-8). For this reason there is a need to look for new hypolipidemic compounds with minimal effects on the peroxisomal H_2O_2 metabolizing enzymes and other antioxidant defenses in the liver.

Recently, there has been a growing interest in the hypolipidemic effect of the polyunsaturated fatty acids of fish oil origin and especially eicosapentaenoic acid (EPA, 20:5) (9-11). Furthermore, these fatty acids have been shown to inhibit the growth of colonic tumors in experimental animals (12) and are implicated to exert an inhibitory effect on tumor growth (13). In view of these findings, there is little or no work done on the effect of EPA on peroxisomal H_2O_2 metabolism and other cellular antioxidant defense mechanisms.

Based on these facts, it was of particular interest to investigate the effects of administering purified (95%) EPA on the activities of acyl-CoA oxidase and catalase, the two peroxisomal enzymes involved in the production and decomposition of H_2O_2, the levels of glutathione, and the glutathione requiring detoxification enzymes in mouse liver. The impact of these changes on hepatic lipid peroxidation will be discussed.

MATERIALS AND METHODS

Chemicals. Ethyl EPA (95% purity) was obtained from Norsk Hydro AS, Research Centre (Porsgrunn, Norway). Palmitic acid and glutathione reductase were purchased from Sigma Chemical Co. (St. Louis, MO). The other chemicals used were of analytical grade and were obtained from common commercial sources.

Animals and treatments. Male OF1 mice were purchased from IFFA Credo (Lyon, France). Two-week-old mice weighing 25-30 g were housed in groups of five in metal wire cages in a room maintained at a constant temperature of 20 ± 3°C. The animals were acclimated for one week under these conditions at 12-h light-dark cycles before the start of the experiment.

Stock suspensions (20% wt/vol) of EPA and palmitic acid (16:0) were prepared in 0.5% sodium carboxymethyl cellulose (CMC). α-Tocopherol (0.5% wt/vol) was added to the stock suspensions to minimize autooxidation. The fatty acids were administered to the mice by gastric intubation in a volume of 0.125-0.150 mL (1000 mg/kg body weight) once a day for 10 d. The first group received EPA, while the second group was fed 16:0 in an attempt to minimize the discrepancy in caloric intake with the first group; the third group was given an equal volume of the vehicle (CMC) used to suspend the fatty acids and are designated controls. While the animals were administered the selected compounds, they were fed a commercial pelleted diet and had free access to food and water.

On the 11th day, overnight fasted mice were lightly anesthetized and cardiac puncture was performed to obtain blood samples in heparinized tubes. The livers were removed immediately, weighed and then chilled on ice.

*To whom correspondence should be addressed.

Abbreviations: CMC, sodium carboxymethyl cellulose; EDTA, ethylenediaminetetraacetic acid; EPA, eicosapentaenoic acid (20:5n-3); GSH, reduced glutathione; HEPES, *N*-[2-hydroxyethyl]piperazine *N'*-[2-ethanesulfonic acid]; HPLC, high-performance liquid chromatography; TBARS, thiobarbituric acid reactive substances.

Plasma was prepared from the whole blood samples by centrifugation at 1000 × *g* for 10 min.

Preparation of tissue homogenates. The livers from individual mice were homogenized in ice-cold sucrose medium, containing 0.25 sucrose in 10mM *N*-[2-hydroxyethyl]piperazine *N'*-[2-ethanesulfonic acid] (HEPES) buffer and 1mM ethylenediaminetetraacetic acid (EDTA), pH 7.4, using a Potter-Elvehjem homogenizer at 720 rev/min and two strokes of a loosely fitting Teflon pestle. The resulting total homogenates were then centrifuged at 600 × *g* for 10 min and the postnuclear fraction was used for the enzyme assays. Liver homogenate (10%) in 1.15% KCl and in 5% sulfosalicylic acid were prepared for the determination of lipid peroxidation and glutathione, respectively. All procedures were performed at 0–4°C. The various liver fractions were stored at −80°C until analyzed.

Enzyme assays and other analytical methods. The activity of peroxisomal acyl-CoA oxidase was measured as previously described by Small *et al.* (14). Catalase activity was determined by spectrophotometry at 240 nm by the method of Lück (15). The activity of glutathione peroxidase was measured as described by Flohé and Günzler (16) with *t*-butyl hydroperoxide as substrate. Glutathione transferase activity was measured according the method of Habig *et al.* (17) using 1-chloro-2,4-dinitrobenzene as a substrate, while the activity of glutathione reductase was measured by the method of Eklöw *et al.* (18). The levels of glutathione were quantitated by reverse-phase high-performance liquid chromatography (HPLC) and fluorescence detection as described by Svardal *et al.* (19). Briefly, 10% liver homogenate in 5% sulfosalicylic acid was centrifuged at 600 × *g* for 5 min, and the resultant supernatant was derivatized with the fluorescent reagent monobromobimane. The glutathione-bimane adduct was then separated and quantitated by HPLC and fluorometry. Lipid peroxidation was measured by using the thiobarbituric acid assay described by Ohkawa *et al.* (20).

Protein was assayed with the Bio-Rad protein assay kit (Bio-Rad, Richmond, CA).

Lipid analyses were carried out using the monotest cholesterol enzymatic kit (Boehringer, Mannheim, Germany) and the Biopak triglyceride kit (Biotrol, Paris, France).

Statistical analysis and presentation of results. Data are presented as means ± SD. Five animals were used in each group. One-way analysis of variance was used to determine significant differences among the different groups. Where appropriate, the Fisher's Least Square Difference was used to determine the significance of differences between the means at the 95% confidence level.

RESULTS AND DISCUSSION

One of our recent studies had shown that EPA at a dose of 1000 mg/kg body weight/day lowers serum triglycerides in rats by about 40%. This effect was reached by the 10th day with no further decline in serum triglycerides after 15 d of treatment (N. Willumsen, J. Skorve, S. Hexeberg and R.K. Berge, manuscript submitted for publication). Based on these findings, similar doses of EPA and 16:0 were administered to mice for 10 d in the present study.

All mice treated with EPA and 16:0 gained weight at the same rate as did controls (data not shown). The amount of food consumed was similar in the different treatment groups indicating that the fatty acids administered had minimal effect on appetite at the doses given.

In comparison to the controls, significant changes were noted in liver weight, liver/body weight ratio and the hepatic protein concentration per gram liver in EPA treated mice (Table 1). As shown in Figure 1, EPA feeding caused a decrease in serum triglycerides by 45%, while there was no such reduction in the 16:0 fed mice as compared to the controls. This is in agreement with the previously documented hypotriglyceridemic effect of EPA in rats (21). In addition, the serum cholesterol level was little affected by either EPA or 16:0 feeding (Fig. 2). As illustrated in Table 2, EPA treatment caused an increase in the hepatic peroxisomal acyl-CoA oxidase by 50% as

Glutathione reductase (μmol/min/g liver)	15.1 ± 2.1	12.3 ± 2.6	19.4 ± 3.4[b]

[a]All values are means ± SD of five animals.

[b]Statistically significant different means from both the controls and 16:0 fed mice at 95% confidence level.

compared to 16:0 fed mice and corresponding controls. This is in marked contrast to the 5- to 20-fold induction of the enzyme activity seen after administration of hypolipidemic doses of clofibrate in rodents (8,22). As peroxisomal oxidation of fatty acid generates H_2O_2, induction of acyl-CoA oxidase, the first key enzyme in the chain, is likely to be accompanied by increased production of H_2O_2. Furthermore, the activity of catalase, the main peroxisomal enzyme that degrades H_2O_2, was shown not to be induced proportionally after clofibrate treatment (8). It seems reasonable that the greater the difference in the extent of induction between acyl-CoA oxidase and catalase the more the imbalance would be in cellular H_2O_2 metabolism. Increased generation of H_2O_2 is detrimental to cellular function and DNA and is thought to be the underlying mechanism of the induction of hepatic neoplasia in rodents treated with peroxisome proliferating compounds (8,23). However, as illustrated in Table 2, the activity of catalase was increased by 30% in the EPA treated group when compared to the controls. Thus, the ratio of induction of acyl-CoA oxidase to catalase was about 1.2 in mice treated with EPA. This is far less than the ratio of about 5 shown with clofibrate treatment (8).

Along with the imbalance in peroxisomal H_2O_2 metabolizing enzyme activities, the levels of hepatic glutathione requiring detoxification enzymes are compromised by hypolipidemic drugs (3). In contrast to these findings, our present study shows that the treatment of mice with EPA enhances the activities of glutathione peroxidase, glutathione transferase and glutathione reductase by 27–30% when compared to both the 16:0 fed mice and the control group (Table 2). Furthermore, the level of reduced glutathione was noted to increase in the EPA fed group (Table 3). It is well known that glutathione peroxidase scavenges H_2O_2 and lipid peroxides (24). Hence, an increase in the activity of the enzyme may cause the modulation of H_2O_2 and of lipid peroxide metabolic processes in the liver. Unlike the hypolipidemic compounds of the clofibrate type, EPA feeding enhances the antioxidant defense in the liver of mice thereby increasing the capacity of the liver to challenge the damages inflicted by reactive oxygen species and other xenobiotic toxic metabolites.

TABLE 3

Changes in Hepatic Reduced Glutathione (GSH) and Lipid Peroxide Levels Measured as Thiobarbituric Acid Reactive Substance (TBARS) in Mice Treated with Eicosapentaenoic Acid (EPA) and Palmitic Acid (16:0) After Treatment for Ten Days[a]

Treatment group	GSH (μmol/g liver)	TBARS (nmol/g liver)
Control	5.4 ± 0.8	26.5 ± 1.5
16:0	5.7 ± 0.9	26.9 ± 1.4
EPA	8.7 ± 0.8[b]	20.5 ± 1.6[b]

[a]All values shown are means ± SD for five animals.

[b]Statistically significant different means from both the controls and 16:0 fed mice at 95% confidence level.

Reddy *et al.* (12) demonstrated that the incidence of colonic cancer is lower in rodents fed ω3 than ω6 fatty acids. Furthermore, EPA has been shown to have anticachexia and antitumor growth effects in rodents (13). Based on the present data, whether these effects can be attributed to enhanced antioxidant status by EPA has to be considered. The mechanism by which EPA enhances the antioxidant defense in the liver needs to be further investigated. Preliminary studies seem to suggest that EPA feeding diminishes the protein catabolic rate rather than the induction of their *de novo* synthesis (13).

The administration of EPA could lead to a corresponding increase in polyunsaturation of membrane lipids and thus could render cell membranes to be more susceptible for attack by reactive oxygen species. Contrary to this expectation membrane, lipid peroxidation as measured by thiobarbituric acid reactive substances (TBARS) assay was lower in the EPA than in the 16:0 fed mice and controls (Table 3). Although measurement of lipid peroxidation by this method is crude and controversial, the above finding suggests that both the increase in glutathione content and the activities of the glutathione requiring enzymes after EPA feeding (Table 3) may have protected membrane lipids against peroxidation. Increased glutathione reductase activity (Table 2) and effective reconversion of oxidized glutathione to its reduced form is one possible mechanism by which EPA enhances the reduced glutathione content.

In conclusion, the present data show for the first time that at hypotriglyceridemic doses of EPA the ratio of induction of acyl-CoA oxidase to catalase, the two main peroxisomal enzymes involved in the metabolism of hydrogen peroxide, is far less than the ratio of induction noted after the administration of clofibrate (8). Furthermore, EPA feeding enhances the levels of hepatic glutathione and its associated enzymes and thus improves the hepatic antioxidant defense in mice and thereby decreases membrane lipid peroxidation.

ACKNOWLEDGMENTS

The authors are grateful to Mr. Svein Krüger for excellent technical assistance. The work was supported by research grants from Norsk Hydro and The Norwegian Council for Scientific and Industrial Research. We are also thankful for the contribution from the Richard With Jonsen & Hustru Fannys Fund.

Zinc Deficiency in the Rat Alters the Lipid Composition of the Erythrocyte Membrane Triton Shell

Eric R. Driscoll and **William J. Bettger***
Department of Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada N1G 2W1

The effect of dietary zinc deficiency on the lipid composition of the erythrocyte membrane Triton shell was determined. Weanling male Wistar rats were fed an egg white-based diet containing <1.0 mg Zn/kg diet *ad libitum*. Control rats were either pair-fed or *ad libitum*-fed the basal diet supplemented with 100 mg Zn/kg diet. A Zn refed group was fed the −Zn diet until day 18 and then pair-fed the +Zn diet until day 21. Dietary Zn deficiency caused an increased cholesterol/phospholipid ratio in Triton shells compared to those from pair-fed controls. Zn deficiency caused a decreased double bond index of fatty acids in phosphatidylinositol (PI) and phosphatidylcholine (PC); there was a decreased proportion of 18:2n-6 and 22:4n-6 in PC and 20:4n-6 in PI as compared to that found in pair-fed controls. All glycerophospholipids that were retained in the shell had a lower double bond index and increased content of 16:0 and/or 18:0 relative to the phospholipid in the intact membrane.
Lipids 27, 972-977 (1992).

The erythrocyte membrane from zinc-deficient rats has been used as a model system to test whether there is a physiological role of zinc in the structure and function of membranes (1-3). An alteration in the composition and/or the organization of the lipid domains of the membrane may be precipitated by dietary Zn deficiency. Erythrocytes from Zn-deficient rats are more susceptible to hemolysis induced by the anionic detergents sodium dodecyl sulfate and sodium dodecyl *n*-sarcosine, compared to those from pair-fed, Zn-adequate controls (4). Melittin, a protein which inserts itself into lipid bilayers and disrupts the permeability barrier of membranes (5,6), has increased hemolytic activity in erythrocyte membranes from Zn-deficient rats (4); on the other hand, dimethylsulfoxide, a solvent which perturbs the organization of lipid bilayers (7,8), has decreased hemolytic activity (4). The fat content (9) and fat type (10) of the diet have been shown to modify the increased osmotic fragility of erythrocytes from Zn-deficient rats, and Zn deficiency has been shown to exacerbate the effect of vitamin E deficiency on the peroxidative fragility of erythrocyte membranes (11).

Recent studies have suggested that dietary Zn deficiency does not have a dramatic effect on the fatty acid composition of the major phospholipids of erythrocyte membranes compared to those from pair-fed controls (12, 13). However, diminished levels of phosphatidylserine (PS), a phospholipid located on the inner surface of the mammalian erythrocyte membrane, suggests an altered asymmetry of erythrocyte membrane lipids in Zn deficiency (13). Mammalian erythrocyte membranes exhibit lipid asymmetry in terms of inner surface *vs.* outer surface steady-state distribution of individual phospholipids (14, 15) and in terms of lipid association with integral (16,17) and peripheral (18,19) membrane proteins. The lipid composition of asymmetric zones in the erythrocyte membranes has been probed by at least three methods—treatment of the outer membrane surface with phospholipases (20,21); release of protein and lipid containing microvesicles from the membrane (22,3); and selective solubilization of some lipids and proteins from the membrane (24-26). The present experiments were performed to examine the effect of dietary Zn deficiency on the lipid composition of the erythrocyte membrane Triton shell, *i.e.,* the lipids that remain associated with the membrane skeletal proteins in the presence of detergent.

*To whom correspondence should be addressed.

Abbreviations: aGPE, alkenylacyl glycerophosphoethanolamine; Chol, cholesterol; DBI, double bond index; dGPE, diacyl glycerophosphoethanolamine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SPH, sphingomyelin; −Zn, zinc-deficient rats; +ZnAL, zinc-adequate *ad libitum*-fed rats; +ZnPF, zinc-adequate pair-fed rats; −ZnRF, zinc-refed rats.

MATERIALS AND METHODS

Male weanling Wistar rats (45-58 g) were divided into zinc-deficient (−Zn), zinc-refed (−ZnRF), zinc-adequate, pair-fed (+ZnPF) and zinc-adequate *ad libitum* (+ZnAL) treatment groups and were fed the appropriate diet for three weeks. The basal diet (−Zn) contained <1 ppm Zn and was based on egg white, glucose and corn oil (27). Control diets (+ZnAL, +ZnPF) were supplemented to contain 100 μg Zn as $ZnCO_3$/g diet. The −ZnRF group was fed the basal diet *ad libitum* for 18 d and then pair-fed the Zn supplemented diet on days 19 to 21. Feed was removed from all rats 12 h prior to sacrifice. After light anesthesia with diethyl ether, the rats were killed by decapitation and trunk blood was collected in heparinized tubes. Plasma Zn concentration was determined by atomic absorption spectrophotometry (27).

Preparation of the erythrocyte membrane Triton shell. Erythrocyte ghosts were prepared according to the method described by Avery and Bettger (28). Triton shells were prepared according to the method of Yu *et al.* (24). One mL of packed ghosts was aliquoted to a 10-mL polycarbonate centrifuge tube and 7 mL of 1% (vol/vol) Triton X-100, 100 μM phenylmethysulfonylfluoride, 1 μM leupeptin and 1 μM pepstatin, in 5.0 mM sodium phosphate, pH 8.0 at 4°C, was added. The white ghost pellet immediately dispersed and the solution clarified. This solution was incubated on ice for 30 min without further agitation and then centrifuged at 4°C for 30 min at 28,000 × *g*. Careful removal of the supernatant fluid left a clear, Triton shell pellet (approximately 200-300 μL) which was frozen at −20°C until analyzed.

Biochemical analyses. Frozen pellets of Triton shells were thawed and then resuspended in 500 μL of 5 mM sodium phosphate, pH 8.0. To eliminate clumping, the shell suspension was sonicated at 60 mW power for 10 s on a 30% duty cycle on a Branson (Danbury, CT) model 300 sonicator. The resulting clear, apparently homogeneous solution was then assayed for protein, total cholesterol, phospholipid phosphorus and the fatty acid composition of individual phospholipid classes as previously

described for the analysis of erythrocyte ghosts (13). Freshly prepared Triton shells were analyzed for protein and glycoproteins by the method of Fairbanks *et al.* (29).

Statistics. Data were analyzed by a general linear modelling procedure followed by Tukey's studentized range test and a least square means analysis comparing −Zn to −ZnRF and +ZnPF groups. All data were examined to determine whether they represented a normally distributed population by calculation of the Shapiro-Wilk statistic on the residuals. Data were transformed prior to analysis, if necessary, to obtain a normal distribution (30).

RESULTS

At the end of the experiment the rats had the following weight gains (g/3 wk): −Zn 4.3 ± 0.7, −ZnRF 13.3 ± 1.4, +ZnPF 23.4 ± 1.7 and +ZnAL 130.3 ± 2.2; and plasma Zn concentrations (mg/L): −Zn 0.35 ± 0.03, −ZnRF 1.30 ± 0.05, +ZnPF 1.30 ± 0.06 and +ZnAL 1.64 ± 0.07. There were no mortalities associated with any of the dietary treatments.

Erythrocyte membrane Triton shells from −Zn rats had significantly less phospholipid per mg protein than those from +ZnAL rats and had a higher cholesterol/phospholipid ratio than both +ZnPF and +ZnAL rats. Cholesterol/mg protein, the phosphatidylcholine (PC)/sphingomyelin (SPH) molar ratio, and the unsaturation index of phospholipid fatty acids were not affected significantly by the dietary treatment (Table 1). Similarly, the mole percentage of phospholipids in the shell was not affected significantly by dietary treatment (Table 2). The protein composition of rat erythrocyte membrane Triton shells was virtually identical to that illustrated by Kunimoto *et al.* (32); in the Triton shells, most of the Band 3 had been removed and there was no remaining periodic acid-Schiff reagent-staining glycoprotein. There was no effect of dietary Zn deficiency on the protein composition of the shell as measured by densitometry of the stained gels (data not shown).

The Triton shell PC from −Zn rats contained significantly more saturated and less mono- and polyunsaturated fatty acids than +ZnPF controls. The feed restriction associated with dietary Zn deficiency resulted in less 20:4n-6, 22:4n-6 and 22:5n-6, and in more 18:2n-6 than found in +ZnAL rats (Table 3). In response to decreased

TABLE 2

Effect of Dietary Zn Deficiency on the Mass (mol%) of Phospholipids in the Erythrocyte Membrane Triton Shell

[g] Double bond index.

food intake, SPH contained more saturated and less mono- and polyunsaturated fatty acids than +ZnAL controls, leading to a decreased double bond index (DBI) (Table 4).

The fatty acid composition of alkenylacyl glycerophosphoethanolamine (aGPE) and diacyl glycerophosphoethanolamine (dGPE) is shown in Tables 5 and 6. In aGPE, dietary Zn deficiency resulted in lower 22:4 and 22:5n-6 as compared to the +ZnPF group. Reduced food intake resulted in lower 22:5n-3 and 22:6n-3 compared to +ZnAL controls. In dGPE, Zn deficiency caused a significant elevation in 16:0 and a reduction in 22:5n-6 compared to +ZnPF controls.

In erythrocyte Triton shell PC, feed restriction was associated with decreased 22:5n-6 and increased 22:5n-3 (Table 7). In phosphatidylinositol (PI), Zn deficiency caused increased 16:0 and decreased 20:4n-6 compared to the +ZnPF group. It also resulted in a decreased DBI (Table 8).

DISCUSSION

The Triton shell referred to in this paper is the erythrocyte membrane Triton shell as originally defined by Yu *et al.* (24), and subsequently described by several researchers in various biochemical and ultrastructural studies (23,25,33–39). Triton shells can be derived from intact red cells or from isolated erythrocyte membranes under a variety of conditions (25). The exact lipid and protein composition of the human erythrocyte Triton shell is thought to vary with pH, temperature, detergent concentration, time of extraction, ionic strength and the composition and structural arrangement of the proteins and lipids in the membrane (18,24,25,40). It has been stated succinctly by Niggli and Berger (18) that "co-isolation of components with the Triton X-100 insoluble cytoskeleton is at best an indication, but never a conclusive proof, for a specific interaction of proteins or lipids with the cytoskeleton. . . ." However, in the original report by Yu *et al.* (24), free ^{32}P-labelled phospholipid mixtures, when incubated with the Triton shells, did not show significant exchange with shell phospholipids, nor were they deposited on the shell

structure. This suggests that the lipids of the shell are tightly associated with specific membrane proteins.

The lipid composition of the rat erythrocyte membrane Triton shell has not been described previously. The Triton shells used in the present study represent, for the most part, the same samples used for our previously reported (13) analysis of the effect of Zn deficiency on the lipid composition of the intact membrane. Samples were analyzed in parallel; this permitted us to make comparisons of shell lipid composition to intact membrane composition with considerable confidence. The phospholipid composition of the rat erythrocyte membrane Triton shell, when compared to the composition of the erythrocyte ghost (13), suggests that phospholipids are retained according to the following order: SPH >>> PC >> PI > dGPE > PS = aGPE. This is similar to the results of Yu *et al.* (24) for the human erythrocyte Triton shell which retains in the order: SPH > PC > phosphatidylethanolamine (PE) > PS. However, the final phospholipid profile is significantly different for the rat and human erythrocyte membrane Triton shell. The human shell has approximately 54–70% SPH, 20–25% PC and 10–17% PE. In contrast, the Triton shell from rat erythrocytes has more PC than SPH and less than 6% PE; a phenomenon which may partially reflect the differences in the ratio amounts of PC, SPH and PE in the membrane of the two species. The cholesterol/phospholipid ratio is elevated in the rat erythrocyte Triton shell by approximately 70% as compared to the intact ghost, whereas the data of Yu *et al.* (24) suggest that the cholesterol/phospholipid ratio is relatively constant between ghosts and shell in the human erythrocyte. The calculated cholesterol/SPH ratio remains relatively constant in the ghosts and shell in the rat. Assuming a 90% recovery of SPH, the minimum mass loss that can account for the change in SPH fatty acid composition in the shell *vs.* the intact membrane (13), the following recoveries can be estimated: protein 43%, cholesterol 51% and phospholipid 31%. Individual phospholipid recoveries can be estimated to be: PC 35%, SPH 90%, aGPE 5.8%, dGPE 9.2%, PS 5.1% and PI 11.8%. Kunimoto *et al.* (32), who prepared rat erythrocyte membrane Triton shells under conditions of high ionic strength, reported a 22% recovery of phospholipid and a similar phospholipid composition in the Triton shells.

Our studies with the rat erythrocyte Triton shell suggest that phospholipids are retained in Triton shells according to the head group, but also according to their fatty acid composition. For all phospholipids except SPH, the phospholipids retained in the shell have a lower DBI than those found in the intact membrane in our previous report (13); there is a substantial enrichment of 16:0 in PC and 16:0 and 18:0 in PS, aGPE, dGPE and PI retained in the Triton shell. Interestingly, PS, PI, aDPE and gDPE retain a higher proportion of 22:4n-6 compared to 20:4n-6 and 22:6n-3 when comparing ghost *vs.* shell phospholipid fatty acid composition (13). In contrast, the SPH retained in the shell is diminished in 16:0 and 18:0 fatty acids and enriched 22- and 24-carbon saturated and unsaturated fatty acids (13). The speculation of Sheetz (25) that SPH is retained because of its high proportion of saturated fatty acids could not be confirmed for the rat erythrocyte Triton shell where SPH containing long-chain fatty acids are preferentially retained relative to SPH containing 16:0 and 18:0. The structure of the sphingosine base that is part of retained SPH molcules may be a factor in its retention in the shell, as no other phospholipid associated with the shell is enriched in long-chain fatty acids (41). The composition of the lipids of the Triton shell, specifically cholesterol/PC, PC/SPH, unsaturation index and the DBI of individual phospholipid classes, suggests that the lipid domains are much less "fluid" than those of the intact

membrane. A similar phenomenon may occur in the Triton shells of stimulated and unstimulated rabbit and/or human platelets; there have been reports of enhanced recovery of palmitate-containing phospholipids relative to arachidonate-containing phospholipids in platelet Triton shells (42-44).

The effect of dietary Zn deficiency and the associated drop of voluntary food intake on the composition of the erythrocyte membrane Triton shell generally reflects the differences in the lipid composition found in the intact membrane (13), with some notable exceptions. Decreased feed intake causes a significant decrease in shell-associated phospholipid, as it does in intact membranes (13). The cholesterol/phospholipid ratio is only elevated in the shells of Zn-deficient rats; in intact membranes, all feed restricted groups have significantly elevated cholesterol/phospholipid ratios. Although there are no significant dietary effects on the profile of shell-associated phospholipids, it would appear that −Zn rats have shells that are depleted of PS, aGPE and dGPE (on a protein basis) compared to *ad libitum*-fed and, possibly, pair-fed controls. A similar trend exists in the intact erythrocyte membranes of −Zn and +ZnAL rats (13). In terms of fatty acid composition, the feed restriction associated with dietary Zn deficiency decreases the 22:4n-6 and 22:5n-6 in PC, aGPE, dGPE and PS and 24:2n-6 in SPH, and increases the n-3 polyunsaturated fatty acids in PS, aGPE and dGPE as it does in intact erythrocyte membranes (13). Similarly, the elevation in 18:2n-6 and the depression of 20:4n-6 in the shell-associated PC is an effect of feed restriction which stems from altered composition of the intact membrane (13). The biochemical and/or physiological basis for the carryover of diet-induced changes in the fatty acid composition of individual phospholipids into the phospholipids of the Triton shell is unknown.

There are two alterations attributable to dietary Zn deficiency (not to feed restriction) that are unique to shell-associated lipids and may be of some physiological significance. First, there is an elevated cholesterol/phospholipid ratio associated with the Triton shell of zinc-deficient rats. The effect appears to be attributable to decreased PS, aGPE, dGPE and, to a lesser extent, PC (Tables 1 and 2). The loss of these particular phospholipids may suggest a decreased binding affinity of these inner membrane bilayer-associated proteins for membrane proteins. Inner membrane surface PS and PE are bound, under some conditions, with specific cytoskeletal proteins such as spectrin (45,46) and protein 4.1 (47-49). The second change associated with zinc deficiency is a decrease in the 20:4n-6 concentration in PI in erythrocyte Triton shells. This may suggest that there is an alteration in the role of PI and, possibly, polyphosphoinositides in the membrane. Recent data suggests that arachidonoyl-containing PI and polyphosphoinositides may have a special role in the sensitivity of membranes to anesthetics (50), and polyphosphoinositides are thought to be critical for erythrocyte membrane integrity (51,52). Whether the decrease in shell-associated arachidonoyl-containing PI is a factor in the altered sensitivity to certain hemolysins (4), and/or is a factor in the reduced levels of arachidonoyl-containing polyphosphoinositides in erythrocyte membranes from zinc-deficient rats (53) warrants further investigation.

Familial Dysautonomia (FD) is an autosomal recessive disease of unknown etiology, occurring primarily in Ashkenazi Jews. Patients are neurologically impaired, with deficits primarily in autonomic and sensory functions. The biochemical and genetic defects have remained elusive, precluding carrier detection and prenatal diagnosis. High-performance liquid chromatography data indicated up to a threefold increase in the neutral glycosphingolipid globotriaosylceramide in Dysautonomic fibroblasts and lymphoblasts. Total ganglioside values, measured by colorimetric, fluorometric or specific sodium borohydride incorporation, were decreased. Affected fibroblasts exhibited a range of pleomorphic phenotypes, such that the usual swirl-like confluent growth pattern of normal fibroblasts was distorted to varying degrees, suggesting abnormalities in the FD plasma membrane, possibly affecting cell-cell contacts. The glycosphingolipid increase could not be accounted for on the basis of markedly decreased α-galactosidase activity, as in Fabry's disease, where patients also display decreased autonomic function.
Lipids 27, 978–983 (1992).

Familial Dysautonomia (FD) is an autosomal recessive genetic disease of unknown etiology, involving deficits in autonomic, central and sensory functions (1). It is generally found within the Ashkenazi Jewish population, with an incidence of 1/3700 (2). Some clinical features include vasomotor instability, absence of fungiform papillae on the tongue, scoliosis, pulmonary complications, poor suckling, gastrointestinal problems, neurological impairments such as ataxia, absent or diminished deep tendon reflexes, impaired taste and temperature perception, reduced or absent overflow tears, peripheral nerve abnormalities, and a markedly reduced response to intradermal histamine (3). A defect in catecholamine metabolism was originally proposed, based on often decreased serum levels of dopamine-β-decarboxylase (4) and elevated urinary ratios of homovanillic acid to vanillylmandelic acid (dopamine and epinephrine metabolites, respectively) (5). The nerve growth factor receptor system, implicated for many years, has been shown by molecular biological techniques to be normal (6,7). Wrathall (8) demonstrated that the ability of fibroblasts to stimulate the outgrowth of neurites from newborn mouse sensory neurons is reduced when using FD cells or conditioned media derived therefrom. Complexing of all the nerve growth factor with antibody did not diminish the effect, implicating other unidentified factors.

Based on these observations and on the dramatic effects of exogenous gangliosides on neurite outgrowth (9–11), we began to examine glycosphingolipids (GSL) in FD. It is well known that glycoproteins and GSL cell surface components play major roles in cell differentiation, reception, recognition, myelination, synaptogenesis and neuronal transmission (12–14). Our goal was to quantitate the amount of the four major neutral GSL, namely GL_1 (glucocerebroside, GlcCer); GL_2 [lactosylceramide, Gal(β1-4)GlcCer]; GL_3 [globotriaosylceramide, Gal(α1-4)Gal(β1-4)GlcCer] and GL_4 [globotetraosylceramide, GalNac(β1-4)Gal(α1-4)gal(β1-4)GlcCer], and the total gangliosides in FD *vs.* those in normal fibroblasts, and to correlate any differences with microscopic changes associated with abnormal membrane GSL composition.

MATERIALS AND METHODS

Karyotyping. A single male proband and his father were used for chromosomal studies in the chromosome laboratory at the Hospital for Sick Children in Toronto. Chromosomes were prepared after the colcemid arrest of mitotic phytohemagglutinin-stimulated lymphocytes using G banding and high resolution banding procedures.

Micrography. Growth of FD and normal fibroblast cell lines was monitored by phase contrast microscopy; when confluent, cultures were photographed on T-MAX 100 (Kodak) film.

Tissue culture. Six FD fibroblast lines and one FD lymphoblast line from the NIGMS Human Genetic Mutant Cell Repository (Camden, NJ) were used: GM 00850A male; GM 02341 male; GM 02342 male; GM 02343 female; GM 04638 female; GM 04663 female; and GM 05041 male. Lymphoblasts from one local male patient (HSC 3654) were used as well. Two each of normal fibroblast and lymphoblast lines were obtained from the Hopsital for Sick Children cell bank. Fibroblasts were grown in α-MEM (Eagle's modified with Earle's salts, ref. 15) containing penicillin and streptomycin (Penicillin-Streptomycin, lyophilized, 10000 U/mL Penicillin G, 10000 μg/mL Streptomycin sulfate, Gibco, Toronto, ON, rehydrated to 20 mL, and used at a concentration of 1% in the growth medium), using 10% fetal calf serum. RPMI 1640 medium, containing 15% serum, and penicillin and streptomycin, was used for growing lymphoblasts. When serum-free medium was desirable, 1% HL-1 Supplement (Fisher, Toronto, Ontario, Canada) containing penicillin and streptomycin was added to maintain cell growth.

Neuritogenesis. Control and FD cells were grown to confluency in 24-well plates and seeded with human NUB-6C4A3 clone neuroblastoma cells. The induction of

neurites with 10^{-6} M retinoic acid in NUB-6C4A3 cultures and characterization of this cell line have been reported (16).

Ganglioside extraction. Cells (1 mL of saline added to fresh or frozen pellet per T75 flask) were extracted with 10 vol of chloroform/methanol (1:2, vol/vol) with stirring for 1 h; then chloroform was added to change the chloroform/methanol ratio to 2:1 (vol/vol) and the extraction was continued for 30 min (17). KCl, 0.9%, in an amount equal to 1/5 of the total extraction volume was added (18) and after centrifugation the lower phase was washed with chloroform/methanol/0.9% KCl (3:48:47, vol/vol/vol). The combined upper phases were applied to a Sep-Pak C18 cartridge (Waters, Millipore Corp., Milford, MA) (17) pre-equilibrated in the same solvent, the cartridges were washed with 25 mL of water, and the gangliosides were eluted with 20 mL of methanol. Gangliosides were concentrated by rotoevaporation, taken up in a minimum volume of chloroform/methanol (1:1, vol/vol), sonicated, and run on high-performance thin-layer chromatography (HPTLC) plates (Merck, Darmstadt, Germany) using chloroform/methanol/0.25% $CaCl_2$ (75:67.5:15, by vol). Each T75 flask of cells contained approximately 1 μg of sialic acid, or 4 μg of ganglioside. The HPTLC bands were difficult to see with a resorcinol spray (0.2 g resorcinol, 80 mL concentrated HCl, 0.1 mL of 0.1 M $CuSO_4$ in 100 mL total volume) since the 1-μg amount was associated with 3 to 10 bands (see below for AUF sensitivity). Gangliosides extracted from cells in several T75 flasks (where the equivalent amount of protein was 1 to 3 mg) were spotted per lane for detection. Ganglioside standards were obtained as follows: GM_3 and GT_{1b} were purchased from Sigma (Windsor, Ontario, Canada). GM_2 was purified in our laboratory from Tay-Sachs brain by Dr. Anton Novak. GM_1, GD_{1a} and GD_{1b} were generously donated by Dr. John Callahan (Hospital for Sick Children, Toronto, Ontario, Canada). The ganglioside nomenclature used in this paper is that described by Ledeen and Yu (19).

Neutral GSL determination. The neutral GSL (GL_1, GL_2, GL_3, and GL_4) are present in the lower phases of lipid extracts prepared as described above. The lower phases obtained from extracts of cells from 2 to 4 T75 flasks were dried under nitrogen, taken up in 1 mL of chloroform, and applied to 80 mg columns of silica gel, previously equilibrated with chloroform. The columns were washed with 2 mL of chloroform, and the neutral GSL eluted with 4 mL acetone/methanol (4:1, vol/vol) (20). The GSL were benzoylated and analyzed by high-performance liquid chromatography (HPLC), using monogalactosyldiglyceride as an internal standard, according to our standard procedure (21,22). In some cases, the underivatized GSL were dried and spotted directly onto thin-layer chromatography (TLC) plates (Sil G25, Macherey Nagel, Düren, Germany). Standard GSL were obtained as follows: GL_1 was purified in our laboratory from Gaucher spleen by Mrs. M. A. Skomorowski; GL_2 and GL_3 were purified in our laboratory as described previously (21); GL_4 was purchased from Matreya (Pleasant Gap, PA). The internal monogalactosyldiglyceride standard used in HPLC (21,22) was from Supelco (Oakville, ON).

Extraction of gangliosides and neutral GSL from media. Fifty mL of medium was centrifuged twice at 15,000 × *g* for 30 min to eliminate any extraneous cells, and then freeze-dried. Water (5 mL) was added, and gangliosides or GSL was extracted as above.

Quantitation of total cellular gangliosides. Two methods were used for this purpose. The colorimetric procedure is based on the reaction of sialic acid bound to ganglioside with resorcinol (19). Fibroblasts of one T75 flask contained approximately 1 μg of sialic acid corresponding to a reproducible AUF at 580 nm of 0.015 at 1 μg per mL. The fluorometric procedure depends on reaction with 3,5-diaminobenzoic acid (23). One μg of sialic acid reads 30 at maximum sensitivity on the Perkin-Elmer 650-40 fluorometer (Norwalk, CT).

Tritiation of gangliosides. Gangliosides were specifically labelled with NaB^3H_4 after periodate treatment (24).

Tritiation of GL_3. GL_3 was labelled by Dr. John Callahan according to the galactose oxidase procedure (25).

Loading cells with GL_3. Normal and FD fibroblasts were seeded onto P35 plates (Falcon 3001, Becton Dickinson and Co., Lincoln Park, NJ) and grown to confluency. [^{3}H]GL_3, 3.4×10^5 cpm, and 0.5 nmoles of cold carrier, were sonicated in 1 mL of α-MEM, without fetal calf serum (FCS), with penicillin and streptomycin added. The radioactive GL_3 medium was used to overlay the cells in place of the normal growth medium. After 24 h, the radioactive medium was replaced with normal medium containing 10% FCS. After another 24 h, fresh medium was reapplied. Ninety-six hours later, the amount of radioactive galactose liberated into the medium was measured. The percent hydrolysis was expressed as the radioactive galactose released into the medium divided by the sum of the radioactivity both in the released galactose and in the [^{3}H]GL_3 remaining in the cells (26). In other experiments, the [^{3}H]GL_3 was added to medium containing 10% FCS, and the percentage hydrolysis measured after 6 d with no media changes (26).

Debenzoylation and α-galactosidase digestion of GL_3. The benzoylated GL_3 fraction from the GSL standard mixture, from control cells, and the putative benzoylated GL_3 fraction from FD cells were collected as they emerged from the HPLC column. The fractions were debenzoylated by mild alkaline hydrolysis (27) after removing hexane/isopropanol with a stream of nitrogen. For this purpose, the dried benzoylated GSL was dissolved in 1 mL 0.6 N methanolic NaOH, plus 1 mL chloroform, and incubated at room temperature for 1 h. After addition of 1.7 mL of water and 3.4 mL of chloroform, the phases were mixed, and the lower phases were washed with methanol/water (1:1, vol/vol), and dried under nitrogen. One-half of the standard and of the FD debenzoylated GL_3 were digested to GL_2 using α-galactosidase (28) as follows: 500 μg of taurodeoxycholate was added to the dried GSL, and the mixture resuspended in 0.5 mL of 50 mM sodium citrate buffer, pH 4.5, containing 20 mM ethylenediaminetetraacetic acid (EDTA) and 1% bovine serum albumin (BSA). One unit of α-galactosidase (Sigma Chemical Co., St. Louis, MO) was added, and incubations were carried out overnight at 37°C. GL_2 and the remaining undigested GL_3 were extracted as above.

Enzyme studies. Cells were sonicated for ten seconds in phosphate-buffered saline, and assays for lysosomal hydrolases were performed for β-glucosidase, β-galactosidase, α-galactosidase, β-hexosaminidase, and α-neuraminidase using 4-methylumbelliferyl substrates (29), and natural substrates for β-galactocerebrosidase (30) and GM_1-β-galactosidase (31). Lignoceroyl acid oxidation, as a measure of peroxisomal integrity, was also determined (32).

RESULTS AND DISCUSSION

FD fibroblasts exhibited a normal karyotype. When grown on tissue culture plastic, FD fibroblasts attained confluency at a rate similar to that attained by normal fibroblasts but exhibited a range of pleomorphic phenotypes. The usual swirl-like confluent growth pattern of normal fibroblasts (Fig. 1A) was distorted to varying degrees in FD fibroblasts (Figs. 1B to D). FD fibroblasts ranged in phenotypes from the ones resembling the normal fibroblasts to enlarged, flattened cells overlapping in a random manner. This observation suggested possible aberrations in FD cell-cell interactions which could be clues to changes in plasma membrane cell surface components, *e.g.*, GSL.

The neuritogenic effects of cells and conditioned media on neuroblastoma cells were tested before we began the biochemical studies. As described in Materials and Methods, FD and control cells were grown to confluency and seeded with human NUB-6 C4A3 clone neuroblastoma cells. The cultures were induced with 10^{-6} M retinoic acid, required to induce neurite formation (21). No difference in the degree of neurite formation or in the proliferation of the neuroblastoma cells seeded on FD or control cells was found, nor was there any difference in these parameters when neuroblastoma cells were overlayed with conditioned medium from FD or control fibroblasts. These findings did not support the observations reported by Wrathall (8) according to which FD conditioned medium or FD cells inhibited the outgrowth of neurites from newborn mouse sensory neurons. Possibly mouse-human cocultures behave differently or perhaps our model which requires retinoic acid for the induction of neurites may not involve GSL at the site of interaction between retinoic acid and the cell membrane. Since human neuroblastomas represent a wide spectrum of peripheral nervous system types, other cell lines may have to be surveyed using this assay to develop a human bioassay model for inhibition which could be used to isolate the inhibitory factor(s).

HPLC determination of the four major neutral GSL (Table 1) revealed a significant increase in GL_3 in FD fibroblasts and lymphoblasts. Nervous tissue is generally not available for such studies. However there was a considerable range in values. The fibroblast FD values for GL_3 ranged from 1.98 to 24.31 nmoles/mg cell protein; the control fibroblast values ranged from 0.85 to 7.41 nmoles/mg cell protein. Cell lines with the greatest degrees

[a] Familial Dysautonomia (FD) cell lines were grown, and GSL and gangliosides extracted and quantitated as described in the Materials and Methods.

[b] Elevated over control; $0.005 < P < 0.01$.

[c] Decreased below control; $0.025 < P < 0.05$.

[d] Decreased below control; $0.05 < P < 0.10$.

of histological distortion (Figs. 1C and 1D) had higher levels of GL_3 than the line which was close to normal (Fig. 1B). GL_3 levels ranged from 0.83 to 3.18 and 0.17 to 0.83 nmoles/mg cell protein for FD and normal lymphoblasts, respectively. Data on Fabry cell GSL are included for comparison (22).

Since GSL were quantitated by HPLC, the increase in the GL_3 peak may have represented an increase in a GSL other than GL_3, sharing the same retention time, such as GA_2 (asialoGM_2). GM_2 was hydrolyzed to yield GA_2 (33), which was examined on TLC alone and mixed with GSL extracted from cells. GA_2 can be separated from GL_3 on TLC and was not observed in the FD or control cells (Fig. 2). The peak emerging in HPLC as benzoylated "GL_3" from the FD cells, benzoylated GL_3 from control cells, and benzoylated standard GL_3 were collected, debenzoylated (27), digested with α-galactosidase (28) and examined by TLC. The R_f values of the three bands were identical. Benzoyl groups remain on the -NH- of the ceramide portion of the dewbenzoylated GL_3, making it a poor substrate for α-galactosidase, causing it to migrate slightly more slowly than underivatized GL_3. All three lipids were converted to GL_2 to the same limited extent, suggesting that they contained a terminal α-galactosyl linkage (Fig. 3). One hundred percent of underivatized GL_3 was converted to GL_2 (results not shown).

Gangliosides were quantitated by both colorimetric and fluorometric assays (see Materials and Methods). Fibroblast studies were carried out on cells from one to four T75 flasks in an attempt to obtain consistent results. The fluorescent method for measuring gangliosides was found tedious, time-consuming (2 d) and not significantly more sensitive as compared to the resorcinol method which took much less time to complete (one hour). Contrary to the literature, the fluorescent method did not become linear until a ganglioside lower limit of 0.5 μg/mL, close to the resorcinol sensitivity. There was an average 40% significant decrease in the ganglioside content of FD cells, from 5.59 to 3.66, and from 1.52 to 0.90 nmoles/mg in fibroblasts and lymphoblasts, respectively (Table 1). The amount of ganglioside was also quantitated by measuring the specific incorporation of NaB^3H_4 into cellular ganglioside fractions following periodate treatment (see Materials and Methods). This incorporation was 50% diminished, at $0.025 < P < 0.05$ and $0.01 < P < 0.025$ for fibroblasts and lymphoblasts, respectively.

The major ganglioside component of fibroblasts was GD_3, followed by GM_3 and a ganglioside which was neither GM_2 nor GM_1, but with a mobility intermediate between the two. Fibroblasts do not have the UDP-galNAc transferase enzyme necessary to synthesize GM_2 from GM_3 (34). The ganglioside in this area might have been NeuAc(α2-3)Gal(β1-4)GlcNAc(β1-3)Gal(β1-4)GlcCer (MG-3, or MG-4) which occurs in serum (35). We have designated this ganglioside as '$GM_{2\text{-}1}$,' until exact identification can be made.

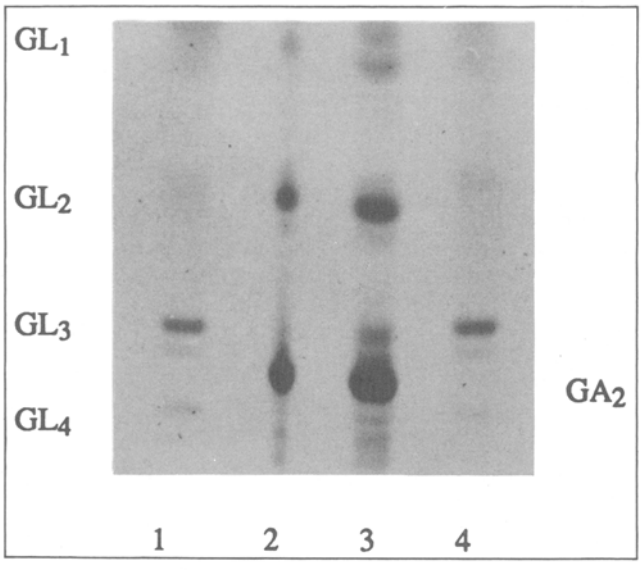

FIG. 2. Investigation of fibroblasts for the presence or absence of asialoGM_1GalNAc(β1-4)Gal(β1-4)GlcCer (GA_2). Fibroblast neutral glycosphingolipids (GSL) fractions and GA_2 were analyzed by thin-layer chromatography (TLC) as described in the Materials and Methods. Lanes 1, 2, 3, and 4 represent neutral GSL extracted from Familial Dysautonomia (FD) cells, a GA_2 preparation, FD cell GSL extracts with added GA_2, and GSL extracted from control cells, respectively. The GSL spotted per lane were not normalized to represent an equivalent amount of total cell protein. The positions of the standards are indicated at the side.

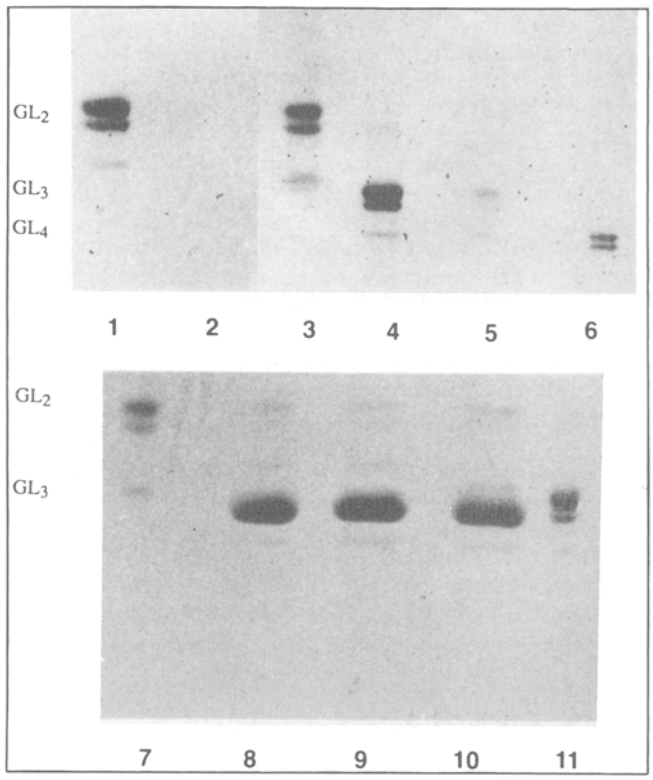

FIG. 3. High-performance thin-layer chromatography (HPTLC) analysis of benzoylated and debenzoylated globotriaosylceramide, Gal(α1-4)Gal(β1-4)GlcCer ("GL_3") from Familial Dysautonomia (FD) and control cells. Lanes 1 to 11 represent, in order, standard lactosylceramide, Gal(β1-4)GlcCer (GL_2), benzoylated FD "GL_3" at the starting line, standard GL_2, standard GL_3, debenzoylated FD "GL_3," standard globotetraosylceramide, GalNac(β1-4)Gal(α1-4)-gal(β1-4)GlcCer (GL_4), standard GL_2, debenzoylated FD cell "GL_3" after reaction with α-galactosidase, debenzoylated control cell GL_3 after reactin with α-galactosidase, debenzoylated standard GL_3 after reaction with α-galactosidase, standard GL_3.

The major ganglioside of lymphoblasts was GM_3. Cells possessed minute quantities of ganglioside in the 'GM_{2-1}' and the GD_3 regions. FD cell ganglioside composition did not differ from that of normal cells.

The ganglioside compositions of conditioned media from FD and control fibroblasts were also similar. Examination of fresh medium containing 10% FCS (as used for growing cells) revealed a complement of gangliosides much the same as conditioned media from FD and control cells, and somewhat similar to human plasma, the major component being GM_3, followed by GD_3, MG-3 and -4 (35) (see above), GM_2, and occasionally GD_{1a}, GD_{1b}, and GT_{1b} (35,36). Thus an HPTLC resorcinol study of gangliosides is non-informative in media containing FCS.

The conent of GSL in conditioned FD or normal media (HPLC), expressed per mL medium (0.28, 0.12, 0.37, and 0.07 nmoles for GL_1 to GL_4, respectively) or per mg cell protein (5.62, 1.43, 14.47, and 2.70 nmoles for GL_1 to GL_4, respectively), did not reveal any major changes. However, published data on the neutral GSL content of FCS revealed that the amount of GSL in medium containing 10% FCS was within range of the levels we found (0.08, 0.05, 0.04, and 0.01 nmoles/mL for GL_1 to GL_4, respectively) (37). Thus neutral GSL, as well as gangliosides, could not be determined meaningfully in the presence of FCS. Lipoprotein-deficient serum (38) still contained GSL (HPTLC results not shown). Accordingly, confluent cells were incubated in roller bottles in serum-free α-MEM medium containing 1% HL-1 Supplement (see Materials and Methods). Only secreted glycolipids, previously masked by the serum GSL, were present.

The total neutral GSL in all conditioned media from FD and control cells remained similar (0.03, 0.02, 0.01 and 0.01 nmoles/mL or 0.48, 0.46, 0.66 and 0.20 nmoles/mg cell protein for GSL GL_1 to GL_4, respectively). When ganglioside fractions were studied on HPTLC, often no resorcinol positive bands were visible, nor was it possible to quantitate the gangliosides using resorcinol *in vitro* as the HL-1-containing medium always interfered. Therefore, the extracts were labelled with NaB^3H_4 which can specifically label only gangliosides (see Materials and Methods), and the incorporation of radioactivity into the samples was measured. Ganglioside fractions from FD cells incorporated three to five times the radioactivity of those fractions from normal cells, suggesting an increase in gangliosides released into the medium in FD.

Since an elevation in GL_3 implies aberrant enzyme activity(s), some lysosomal enzymes were assayed. Our data indicated normal activities for the following lysosomal hydrolases: β-glucosidase, β-hexosaminidase, β-galactocerebrosidase, α-neuraminidase, α-galactosidase (using artificial 4-methylumbelliferyl substrates), and both GM_1 β-galactosidase and β-galactosidase (using natural substrates). Peroxisomal function, assayed as lignoceroyl acid oxidation, appeared intact.

The α-galactosidase enzyme activity, assayed with the natural or artificial substrate, would appear normal even when activator deficienct (29), as the detergent used performs the function of an activator. Therefore FD, Fabry, and control and cells were preloaded with radioactive GL_3, 0.5 nmoles and 340,000 cpm per mL, for one day in serum-free medium to avoid dilution of the GL_3 with unknown amounts of cold GL_3 present in the serum. The extent to which radioactive GL_3 was taken up by the various cell types did not differ, as noted by Kobayashi *et al.* (26) in their study of Fabry's disease. After one day, the radioactive medium was replaced with regular medium, and the percent of the loaded GL_3 hydrolyzed by the cells was measured (see Materials and Methods) on a *per diem* basis, over a period of one to four days. There was a tendency for the percent hydrolysis (7.8, 1.0 and 8.8 for FD, Fabry and control, respectively) and the rate of appearance of radioactive galactose in the medium (72, 9 and 90 pmoles/mg/day for FD, Fabry and control cells, respectively) to be lower in FD cells (averaging data from all the lines listed in the Materials and Methods) than in an average of four control cell lines. These studies were complicated by the fact that FCS itself has α-galactosidase activity, which would degrade any GL_3 released intact from the cells. In parallel studies mirroring those of Kobayashi *et al.* (26), cells were incubated with radioactive GL_3 in medium containing 10% FCS for a period of up to 6 d, and the same parameters determined. Since the serum activity itself accounted for from 25 to 50% of the liberated radioactive galactose, the experiments could not be interpreted when looking for small changes.

These results allude to an alteration in the synthesis and/or degradation of certain GSL and/or gangliosides in FD. We are currently investigating biosynthetic and degradative pathways for neutral GSL and gangliosides in FD, including hydrolases and transferases to see how they relate to this problem. Since GSL contribute to the organization and function of the plasma membrane, a change in GSL composition might affect the organization of other integral and associated glycoproteins, some of which are involved in promoting cell-cell and cell-substratum interactions and adhesions. Our studies were done on fibroblasts and lymphoblasts as nervous tissue is not available for study. The pertinence of similar neuronal membrane component changes to nervous tissue differentiation, reception, synaptogenesis and function is inestimable, and may be involved in the etiology of FD.

In Fabry's disease, denoted by α-galactosidase deficiency and storage of GL_3, there have been many reported indications of impaired autonomic function, such as impaired pupillary response to pilocarpine, altered gastrointestinal function, dimished tear and saliva formation, loss of the cutaneous flare response to scratch and histamine, absence of thermal fingertip corrugations, and preferential loss of myelinated and unmyelinated nerve fibers. This dysfunction is generally attributed to storage of GL_3 in dorsal root and peripheral autonomic ganglia (39–41). The impairments resemble those found in FD (1–3). An overabundance of GL_3 in plasma membranes may be equivalent to 'storage' in other organellar locations and contribute to these impairments in autonomic function. Whereas Fabry's disease is an X-linked disorder distinct from FD, the associated autonomic dysfunction and the biochemical correlation is intriguing.

ACKNOWLEDGMENTS

We are grateful to Elizabeth Bienkowski for carrying out fluorometric assays to measure ganglioside concentrations. The research was funded by the Familial Dysautonomia Foundation of Canada.

[Received August 11, 1992; Revision accepted October 9, 1992]

Lipid Composition of Subcellular Membranes from Larvae and Prepupae of *Drosophila melanogaster*

Helen E. Jones[a], John L. Harwood[a], Ivor D. Bowen[b] and Gareth Griffiths[a,*]
[a]Department of Biochemistry and [b]School of Pure and Applied Biology, University of Wales College of Cardiff, Cardiff CF1 1XL, United Kingdom

Subcellular membranes were analyzed for their lipid composition and protein content at two developmental points representing the third instar wandering larvae and prepupal stages of *Drosophila*. At both stages, phosphatidylethanolamine (PE) and phosphatidylcholine (PC) were the major constituents with phosphatidylinositol (PI), phosphatidylserine (PS), diphosphatidylglycerol (DPG) and phosphatidic acid (PA) being relatively minor components. In total homogenates and in the nuclear-enriched fraction there was no significant difference in the phospholipid composition of the wandering larvae and prepupae. In mitochondria only a significant increase in the minor component PS was observed in the prepupae. In lysosomal membranes on the other hand, the relative abundance of the major components PE and PC increased in the prepupae although the molar ratios of the two lipids remained almost constant. The fatty acid composition of the phospholipids remained virtually unchanged in all of the fractions examined, including the lysosomes, and there was no evidence of lipid peroxidation. With regard to cellular degeneration and the involvement of lysosomes, we conclude that mechanisms other than gross modification of the lipid and/or lipid/protein ratio of their membranes are involved in the liberation of the acid phosphatase contents.
Lipids 27, 984-987 (1992).

In recent years extensive lipid analyses have been reported on a wide variety of insect classes (1). The majority of these reports have concentrated on the analysis of whole organisms and a few on more specific organs, such as the fat body and haemolymph (2). To date, only a limited amount of work on the lipid composition of subcellular fractions has been undertaken. The *Diptera* to which *Drosophila* belongs are known to contain relatively high levels of phosphatidylethanolamine (PE) (3); this to some extent is unusual in as much as phosphatidylcholine (PC) is generally regarded to be the major phospholipid component in most insects (2) and other animals (4), as well as in plants (5). In the current study we analyzed the subcellular lipid composition of *Drosophila melanogaster* at two stages in the life cycle, namely the third instar wandering larvae and the prepupae. Between these two developmental stages, extensive breakdown of the larval tissues is initiated, and the role of lysosomes and their acid phosphatase compliment has been well documented in the cellular disintegration process (6,7). Lipid peroxidation of the lysosomal membranes due to the action of free radicals on the polyunsaturated acyl constituents may damage the membrane and make it more leaky to the acid phosphatase (8,9). Here we report on the lipid composition of several membranes, including the lysosomes, and draw conclusions on the possible role of lipid peroxidation in the mechanism of lysosomal rupture.

Abbreviations: DAG, diacylglycerol; DPG, diphosphatidylglycerol; EDTA, ethylenediaminetetraacetic acid; GLC, gas-liquid chromatography; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; RSA, relative specific activity; TAG, triacylglycerol; TLC, thin-layer chromatography; UFA, unesterified fatty acids.

MATERIALS AND METHODS

Insects. Stock wild type *Drosophila melanogaster* were reared in sterilized glass bottles containing a standard ready-mix *Drosophila* medium (purchased from Philip Harris Biological, Weston-super-Mare, U.K.). A yeast pellet was placed on the food surface to aid fermentation. The cultures were maintained at 23 ± 1°C with a light-dark cycle of 12 h. Physical criteria were used to stage the organism (10). Some 8 h before pupariation begins the third instar larva stops feeding and crawls out of the medium, this is known as the wandering larval stage. Pupariation begins with the formation of the white prepupa with its everted spiracles and the cessation of movement. These stages are very distinct and can be readily categorized.

Subcellular fractionation. The isolation of individual organs for subcellular analyses is impractical because of size and, in addition in the prepupal stage, there is extensive tissue degeneration. For these reasons, whole wandering larvae and prepupae (between 70-100 individuals, equivalent to 90-130 mg fresh weight) were used and were hand homogenized using a Potter-Elvehjelm homogenizer in 30 vols (wt/vol) of Tris-HCl (20 mM, pH 7.0), sucrose (0.25 M), ethylenediaminetetraacetic acid (EDTA, 1 mM) and protease inhibitors (1 mg/L leupeptin, 10 mg/L pepstatin and 80 mg/L phenylmethylsulfonylfluoride), on ice. The homogenate was filtered through 4 layers of miracloth (Calbiochem, La Jolla, CA) centrifuged for 10 min at 1,000 × *g*, and the resultant pellet (nuclear enriched fraction) was washed and recentrifuged. The combined supernatants were then centrifuged for 10 min at 10,000 × *g* yielding a mitochondrial fraction which was washed and repelleted as above. An 18,000 × *g* pellet was then obtained from the remaining supernatants and was regarded as the lysosomally-enriched pellet. The post 18,000 × *g* supernatant was also retained for enzyme assays.

Enzyme assays. All assays were performed at 25°C and were completed within 3-4 h following subcellular fractionation. Succinate dehydrogenase was assayed using *p*-iodonitrotetrazolium violet (11) and acid phosphatase using *p*-nitrophenyl phosphate (12) with the addition of L-homoarginine (1 mM) to the incubation medium to inhibit alkaline phosphatase. The glucose 6-phosphatase assays were performed essentially as described (13). The peroxisomal marker enzyme, catalase, is generally unstable and was, therefore, always assayed first by monitoring hydrogen peroxide degradation at 240 nm (14).

Lipid extraction. Lipid samples of homogenates and subcellular fractions in buffer (0.1 M phosphate, pH 7.2; 1 mL) were extracted by adding 0.15 M acetic acid (1 mL)

and chloroform/methanol (1:2, vol/vol; 7.5 mL) followed by gentle mixing. After 2 min, chloroform (2.25 mL) and water (2.25 mL) were added and rapid phase separation was achieved by low-speed centrifugation yielding a lower chloroform layer containing the complex and neutral lipids (modified from Bligh and Dyer, ref. 15). The chloroform phase was reduced to dryness under nitrogen and the residue dissolved in a small volume of chloroform. The polar and neutral lipids were purified by thin-layer chromatography (TLC) on pre-coated silica gel plates (Silica Gel 60; Merck, Darmstadt, Germany) with chloroform/methanol/acetic acid/water (170:30:20:7, by vol) and hexane/diethyl ether/acetic acid (70:30:1, vol/vol/vol), respectively. In the polar solvent system, the phosphatidic acid and the diphosphatidylglycerol (DPG) co-migrate. Lipids were located on the TLC plates by lightly staining with iodine vapor and then removed from the plates for transmethylation and fatty acid analysis. Fatty acid methyl esters were prepared in dry methanol containing 2.5% sulfuric acid and were quantified by gas-liquid chromatography (GLC) on an EGGS-X (15% on 100/120 mesh, Chromosorb W-AW, Supelco Inc., Bellefonte, PA) column at 180°C using heptadecanoic acid as the internal standard. Co-chromatography with authentic methyl ester standards (Sigma Chemical Co., Poole, Dorset, U.K.) was used to identify the sample components. Protein determinations were made using the dye binding method outlined in the Biorad assay kit (Bulletin 1069; Biorad, Hemel Hempstead, U.K.).

RESULTS

Subcellular fractionation. Homogenates of wandering larvae and prepupae were subcellularly fractionated by differential centrifugation to yield nuclear (1,000 × *g*), mitochondrial (10,000 × *g*) and lysosomal (18,000 × *g*) enriched fractions. The post 18,000 × *g* supernatant was also collected and assayed. The relative specific activities and yields of a number of marker enzymes were assessed in the different fractions; the results are presented in Table 1.

The bulk of the cellular protein at both stages of development resided in the post 18,000 × *g* supernatant (71–74%); 13–20% was present in the nuclear fraction, 7–11% in the mitochondria, and 4–5% in the lysosomes. The relative specific activity (RSA) of acid phosphatase, as expected, was highest in the lysosomal fractions while that of succinate dehydrogenase was highest in the mitochondria. Contamination of the lysosomes with mitochondria was low although significant levels of acid phosphatase were detected in the mitochondrial fraction. This probably reflects lysosomal heterogeneity (16) in addition to the presence of free acid phosphatase (see ref. 7). The highest yield of both catalase (peroxisomal marker) and glucose 6-phosphatase (endoplasmic reticulum marker) was in the post 18,000 × *g* supernatant; although variations in the RSA in the different fractions were observed, both enzyme activities were low in the lysosomes. Thus, the lysosomes obtained at both stages of development were relatively enriched in the characteristic marker, acid phosphatase and were generally low in contamination from other membrane fractions.

Phospholipid composition of subcellular membranes. The phospholipid composition of the total homogenate extract and of the various subcellular fractions obtained from it are given in Figure 1 (a–d). The major membrane phospholipid in all fractions and at both stages of development was phosphatidylethanolamine (PE). It generally constituted between 50–60% of the total phospholipids with the exception of the lysosomal membranes where it was somewhat lower with values between 35–50%. In the homogenate (Fig. 1a), the next most abundant phospholipid was PC which represented 20–25% of the total, with phosphatidylinositol (PI), phosphatidylserine (PS) and DPG/phosphatidic acid (PA) making up the rest. In the homogenate and nuclear fractions, no significant differences were found in any of the phospholipid compositions between the wandering larvae and prepupae. Similarly, in mitochondria only a significant increase in the relative proportion of the minor component, PS, was observed in the prepupae. In the lysosomes, a wider range of variability in the phospholipid compositions was observed even within a single stage of development compared with that seen in other fractions. The relative abundance of PE (and to a lesser extent, PC) in the membrane

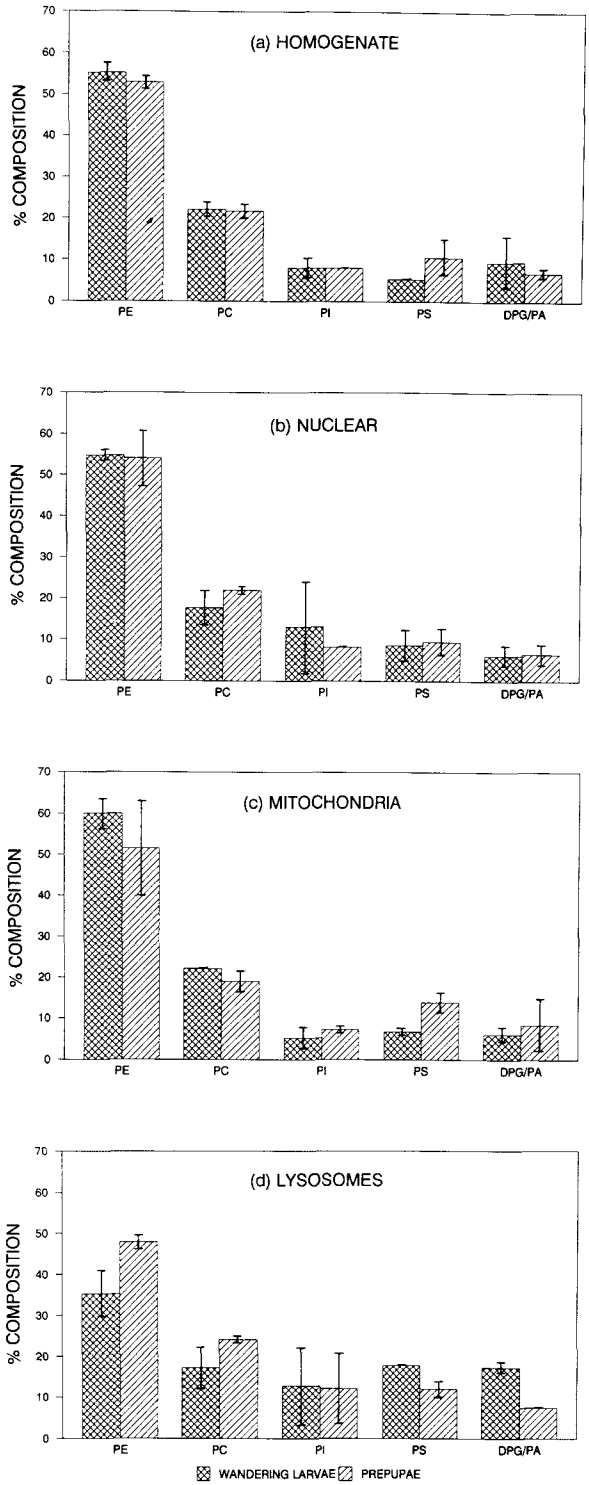

FIG. 1. Phospholipid composition of homogenates and subcellular fractions from wandering larvae and prepupae. Cross-hatched bars, wandering larvae; diagonal bars, prepupae; SEM (n = 3).

increased during the transition to the prepupal stage while that of PS and DPG/PA decreased. On the other hand, the molar ratio of the two major phospholipids, PE and PC, was similar during both stages of development in the lysosomes (2.0 ± 0.1) as well as in the homogenate (2.5 ± 0.1) and mitochondria (2.7 ± 0.1). In the nuclear fraction, however, the ratio was higher in wandering larvae (3.1 ± 0.2) than in prepupae (2.5 ± 0.1). Similarly the protein/phospholipid ratio of the membranes changed little during development. In the mitochondria and lysosomes, the ratios were 2.0 ± 0.1 and 2.4 ± 0.1, respectively. The highest ratios were observed in the nuclear fraction, being in the range of 5.6 ± 0.2.

Fatty acid composition of phospholipids and neutral lipids. The fatty acid composition of the phospholipids in the homogenate and in the lysosomes derived from it was almost identical; for this reason the data for the lysosomes alone are presented in Table 2. Generally, at both stages of development the major acyl constituents were palmitate (16:0), oleate (18:1) and linoleate (18:2) although palmitoleate (16:1) was particularly abundant in PC. PE contained higher levels of 18:1 than 18:2 whereas the reverse was true for PC, PI and DPG/PA. Fatty acids of chain lengths shorter than sixteen carbons, as well as stearate (18:0), gamma-linolenate (γ18:3) and alpha-linolenate (α-18:3) were relatively minor components in most phospholipids except PI where substantial levels of α18:3 were observed. Again, acyl constituents of chainlengths greater than eighteen carbons were generally low in abundance with the exception of DPG/PA lipids where these constituted major components. Based on GLC retention times, the major component of this fraction was tentatively identified as a twenty-carbon unsaturated fatty acid which eluted ahead of arachidonate (20:4). No significant differences between the acyl composition of the phospholipids at the two stages could be found (n = 6 determinations).

The major component of the lysosomal neutral lipids was storage triacylglycerols (TAG, 90%) with diacylglycerol (DAG) and unesterified fatty acids (UFA) and sterols making up the bulk of the remainder. The relative abundance of each of these neutral lipid classes was almost constant at both stages, indicating little degradation of TAG. In both stages of development, typical values for the ratio of phospholipid/neutral lipid were, for homogenate 0.12 ± 0.02, for the nuclear fraction 0.26 ± 0.02, for mitochondria 0.82 ± 0.04, and for lysosomes 0.35 ± 0.05. The acyl composition of the neutral fraction was markedly different from that of the phospholipids and was particularly rich in 14:0 (22.4 ± 1.4%), 16:0 (20.9 ± 0.5%), 16:1 (23.1 ± 1.1%) and 18:1 (19.0 ± 0.2%) with minor proportions of 18:2 (6.8 ± 0.5%), 18:0 (0.7 ± 0.2%), α18:3 (1.3 ± 0.2%) and acyl groups of chainlength greater than eighteen carbon (4.9 ± 1.6%; n = 8, ±SD). Again, there was no significant difference between the acyl composition of the neutral fraction at either stage of development.

DISCUSSION

The major membrane phospholipid in all subcellular fractions of larvae and prepupae of *Drosophila melanogaster* is PE, and high levels of this constituent are generally characteristic of the *Diptera* as a whole (3). From the wandering larvae to the formation of the prepupa, there was little change in the phospholipid composition of the subcellular fractions. The reported ratios, by weight, of phospholipids to protein were in the range commonly encountered for lysosomal membranes (17) and changed little during the transition from the third instar larvae to prepupae. The presence of extensive amounts of neutral

[a]Values are average of six analyses. N.D. = not detected. PE, phosphatidylethanolamine; PC, phosphatidylcholine; PI, phosphatidylinositol; PS, phosphatidylserine; DPG/PA, diphosphatidylglycerol/phosphatidic acid.

[b]Tentatively identified as a C_{20} unsaturated fatty acid.

lipids in all fractions (predominantly TAG) almost certainly results from the disruption of the fat bodies in the larvae and the subsequent non-specific binding of these lipids to the subcellular membranes.

In the lysosomes, the relative increase in PE (which in pure form exists in hexagonal phase type II) is offset by the relative increase in PC (a bilayer forming lipid). In this regard, it is the ratio of such lipids which is important in maintaining membrane stability in terms of bilayer structure (18). If lipid peroxidation had played a major role in disrupting lysosomal membrane integrity, then one would have predicted significant decreases in the relative levels of the eighteen carbon polyunsaturated acyl constituents of the membranes in prepupae. The observation that the levels of 18:3 and 18:2 (the constituents most prone to peroxidation) remained almost unchanged in the major lipid components argues against this possibility. Recent evidence (19) indicates that phospholipase A_2 preferentially hydrolyzes peroxidized fatty acid esters in phospholipid membranes as part of a general repair mechanism. Whether such mechanisms operate in *Drosophila* tissue was not investigated in the current study. However, the relatively low levels of PA and the virtual absence of lysophospholipids indicated that little or no phospholipase D and A activities damaged the lysosomes during cell fractionation as has been reported for other preparations (17).

The constancy, therefore, of the membrane parameters investigated at these two developmental points leads us to conclude that mechanisms other than lipid peroxidation or changes in lipid composition are responsible for the disruption of these organellar membranes which are associated with cell degradation.

[Received August 5, 1991, and in final form October 7, 1992; Revision accepted October 7, 1992]

Free Fatty Acids Inducing Mouse Lethal Toxicity in Lipid Extracts of *Engraulis japonica*, the Japanese Anchovy

Junko Sajiki* and **Katsuhiro Takahashi**
The Public Health Laboratory of Chiba Prefecture, 666-2 Nitona-cho, Chuo-ku, Chiba City 260, Japan

Mouse lethal toxicity was detected in the ether extract of *Engraulis japonica* (anchovy). The mouse toxicity of extracts was more potent from viscera than from other organs. Okadaic acid ($C_{44}H_{68}O_{13}$) and dinophysistoxin ($C_{45}H_{70}O_{13}$), lipophilic toxins derived from phytoplankton, which are usually considered to be the diarrhetic shellfish toxins, were not detected in the ether extract of ancovy. There occurred, however, two prominent peaks in high-performance liquid chromatography, which were identified as free eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The mouse toxicity observed correlated with the intensity of these two peaks. Toxicity was reduced considerably by pretreatment with Na_2CO_3. By quantitating EPA toxicity, it was concluded that the toxicity was not due to EPA only but also to DHA. The results indicate that substances in Japanese anchovy associated with mouse lethal toxicity include free polyunsaturated fatty acids, mainly EPA and DHA.
***Lipids* 27, 988-992 (1992).**

Bivalves purchased locally in Japanese fishing villages sometimes contain a toxin acquired from marine plankton (1,2), which causes diarrhea in humans. The main active components of this lipophilic diarrhetic toxin have been shown to be okadaic acid (OA) (3) and dinophysistoxins (DTX) (4-6). Since these toxins also have mouse-lethal activity, the presence of the toxin in bivalves has traditionally been monitored by the mouse toxicity test.

While studying the toxicity of bivalves in this laboratory, the presence of a mouse-lethal toxin which was different from the diarrhetic toxins was noted (7). Takagi *et al.* (8,9) reported that major lipophilic toxic substances in the digestive gland of poisonous scallop were polyunsaturated acids. In testing the hemolytic activity to mice of the ether extract of toxic bivalves in our laboratory, the extract was found to change oxyhemoglobin to methemoglobin. Authentic OA at one mouse toxicity unit was, however, found to lack such activity toward oxyhemoglobin. Through further study (10), a group of polyunsaturated fatty acids (PUFA), including eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), became suspect as major active agents of the mouse lethal toxins which differ from OA and DTX.

We now report a study on these novel diarrhetic toxins associated with the lipophilic fraction of fish and on their chemical structure.

Abbreviations: AA, arachidonic acid; ADAM, 9-anthryl diazomethane; DHA, docosahexaenoic acid; DTX, dinophysistoxins; EPA, eicosapentaenoic acid; HPLC, high-performance liquid chromatography; LA, linoleic acid; LNA, linolenic acid; MU, mouse unit; OA, okadaic acid ($C_{44}H_{68}O_{13}$); PBS, phosphate buffered saline; PUFA, polyunsaturated fatty acids; SDA, stearidonic acid; TLC, thin-layer chromatography; UV, ultraviolet.

MATERIALS AND METHODS

Fresh and dried fish were collected from local markets. Fish used in the experiment were *Trachurus japonicus* (Japanese mackerel), *Sebastolobus macrochir* (Kichiji rockfish), *Loligo loligo bleckeri* (squid), *Katsuwonus pelamis* (Arctic bonito), *Cololabis saira* (mackerel pike) and *Engraulis japonica* (Japanese anchovy). In the present study, all tissues in the abdominal cavity, including the mesentery, were used as viscera. Male mice (Funabashi Farm Co. Ltd., Chiba, Japan) weighing 18-20 g were used for the toxicity tests.

Superspecial grades of methanol, *n*-hexane and acetonitrile (Wako Pure Chemical Ind. Ltd., Tokyo, Japan) were used for high-performance liquid chromatography (HPLC). Other chemicals used were of special grades. ADAM (9-anthryl diazomethane) was purchased from the Funakoshi Pharmacy Co. Ltd. (Tokyo, Japan). Linoleic acid (18:2, LA), linolenic acid (18:3, LNA), stearidonic acid (18:4, SDA), arachidonic acid (20:4, AA), EPA (20:5) and DHA (22:6) used as reference materials were from Sigma Chemical Co. (St. Louis, MO) and were of 99% or better purity. Authentic OA and dinophysistoxin-1 (35-methylokadaic acid, DTX_1) purified from cultured cells of the dinoflagellate, *Prorocentrum lima*, and mussels, *Mytilus edulis*, respectively, were provided by Professor Yasumoto of Tohoku University (Sendai, Japan).

DL-α-tocopherol (Wako) was used as antioxidant in an experiment aimed at avoiding PUFA autoxidation. EPA of 92% purity containing 0.2% DL-α-tocopherol, provided by Dr. Hamazaki of Toyama Medical and Pharmaceutical University, Toyama, Japan, was also used in a mouse toxicity tests.

Silica gel plates ($60F_{254}$, 20 cm × 20 cm and 20 cm × 5 cm, 0.5 mm thickness, E. Merck, Darmstadt, Germany) were heated for 2 h at 110°C for activation and kept in a desiccator until use.

The HPLC instrument and the fluorescence detector used for the assay of OA and DTX_1 were a Jasco FLC-A20 (Nihonbunko Ind. Ltd., Tokyo, Japan) and a Jasco 820FP, respectively. Recorders used were the Pantos U-228 (Nippondensi Co. Ltd., Tokyo, Japan) and the Shimadzu C-R3A (Shimadzu Co. Ltd., Kyoto, Japan).

For treatment with ADAM before HPLC, ordinary Seppak silica cartridges (Waters Associates, Milford, MA) were utilized. The HPLC and the ultraviolet (UV) spectrophotometric detector for the determination of EPA and DHA in anchovy were the Shimadzu LC-6A and SPD-6A, respectively; a Shimadzu C-R6A was used as recorder.

Extraction of lipophilic toxin from various fish. Lipophilic toxin was extracted according to the method previously described for the preparation of shellfish lipophilic toxin (4). One-hundred grams of various fish (80 g for viscera) were homogenized in 300 mL of acetone. After filtration, the extraction was repeated twice with 400 mL acetone. After three extractions, the acetone was combined and evaporated, and the residue was further extracted with 200 mL of diethyl ether.

Crude lipid. A crucible, in which the ether extract corresponding to one gram wet weight of fish was placed, was dried at 120°C for 1 h and was left to cool to room temperature in a desiccator for 30 min. The difference in weight was considered the weight of crude lipid.

Mouse bioassay. The test solution for the mouse bioassay was prepared from the crude lipid so as to represent 4 g of fish in 1 mL phosphate buffered saline (PBS, pH 7.4) containing 1% Tween 60.

Based on the definition (11) that one mouse unit (MU) was the amount of toxin injected intraperitoneally (i.p.) to kill a mouse weighing 20 g within 24 h, the toxicities of test solutions from fish were measured. In the present paper, samples showing less toxicity than 0.25 MU/g were coded as not detectable (ND).

Determination of OA and DTX_1 in various fish. The assay to determine OA and DTX_1 was performed according to the method of Lee *et al.* (12). Ether extracts from 5 g of fish were dissolved in 5 mL of methanol and mixed vigorously; 100 μL of the methanol solution was evaporated under N_2, and 0.1 mL of 0.1% ADAM in methanol was added. After esterification by standing in the dark at room temperature for 1 h, the ADAM reaction mixture was placed on a Sep-pak cartridge. The column was washed with 5 mL of *n*-hexane/chloroform (1:1, vol/vol) and eluted with 5 mL of pure chloroform. Finally, a fraction of ADAM-esterified OA and DTX_1 was obtained with 5 mL of chloroform/methanol (95:5, vol/vol). After removing the solvent under N_2, the residue was dissolved in 0.1 mL of methanol, of which 20 μL was submitted to HPLC. The HPLC assay conditions were as follows: Column, ODS (4.6 mm i.d. × 250 mm, Jasco Fine-pak Sil C_{18}, Nihonbunko); mobile phase, acetonitrile/methanol/water (8:1:1, vol/vol/vol); flow rate 1.1 mL/min; assay wavelengths, Ex = 365 nm, Em = 412 nm. Peak areas were calculated by integration with the C-R3A recorder. HPLC peaks were identified by comparison of retention times with those of authentic standards in two different solvent systems, namely acetonitrile/methanol/water (8:1:1, vol/vol/vol), and methanol/water (95:5, vol/vol).

Fractionation of lipids from the ether extract of anchovy viscera by thin-layer chromatography (TLC). Ether extracts containing 0.16 g of lipids from anchovy viscera (0.5 MU/g toxicity), with α-tocopherol added (0.5%) to minimize oxidation throughout the extraction procedure, were applied onto four silica gel plates (20 cm × 20 cm), and the plates were developed with petroleum ether/diethyl ether/acetic acid (74:15:1, vol/vol/vol) as described by Ozawa *et al.* (13). Lipids were thus fractionated into five zones as shown in Figure 1. Fraction (Fr.) 1 consisted mainly of phospholipids (at origin); Fr.2 contained two bands (R_f 0.06 and 0.13); Fr.3 contained mainly free fatty acids (R_f 0.26); Fr.4 contained mainly triglycerides (R_f 0.43); and Fr.5 consisted of two bands of esters (R_f 0.73 and 0.80) including cholesteryl esters. The bands were extracted as follows. The fractions between phospholipids and free fatty acids were extracted three times with 30 mL of methanol. Other lipids such as triglyceride and cholesteryl ester were extracted three times with 30 mL of diethyl ether. After evaporating the solvents under N_2, test samples for the mouse bioassay were prepared by adding 3.0 mL of PBS to each lipid fraction dissolved in 0.2 mL of methanol.

Concentrations of free EPA and DHA in anchovy viscera. The total concentrations of free EPA and DHA were determined by HPLC following a modification of the method by Ozawa *et al.* (14). Ether extracts of anchovy viscera were prepared at a concentration of 9.4 mg wet weight of viscera/mL in methanol, and 10 μL of the sample was submitted to HPLC. The concentrations of EPA and DHA in the samples were determined from calibration curves. The HPLC assay conditions were as follows: Column, ODS (4.6 mm i.d. × 250 mm, Shim-pack CLC ODS(M), Shimadzu); mobile phase, acetonitrile/methanol/water/phosphoric acid (53:20:17:0.1, by vol); flow rate, 1.2 mL/min; assay wavelength, 195 nm. The identity of the EPA and DHA peaks in HPLC was confirmed by capillary gas chromatography.

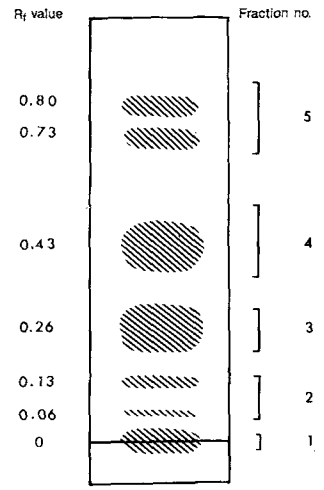

FIG. 1. Thin-layer chromatogram of the ether extracted lipids (0.5% α-tocopherol added) from anchovy viscera corresponding to 0.5 MU/g toxicity. Solvent: petroleum ether/diethyl ether/acetic acid (74:15:1, vol/vol/vol).

Mouse lethal toxicity of EPA of 92% purity. To examine whether the EPA concentrations found in anchovy would be lethal to mice, standard EPA (92% pure) containing 0.2% α-tocopherol was tested for mouse toxicity. A stock solution of 0.5 g of EPA dissolved in 2 mL of methanol was prepared, and was serially diluted with PBS containing 1% Tween 60 (pH 7.4) to give concentrations of 25, 12.5, 6.3 and 3.2 mg per 0.2 mL. Each sample (0.2 mL) was injected i.p. into each of four mice. The solvent, 0.2 mL of 50% methanol, showed no mouse toxicity upon i.p. injection.

RESULTS

The mouse toxicity of the crude lipids extracted from the fish examined is shown in Table 1. Phospholipids were present at relatively low levels because acetone was used for lipid extraction. Extracts of the fresh fish, *i.e. Trachurus japonicus, Sebastolobus macrochir* and *Loligo loligo bleckeri,* had lipid contents in the range of 1.4–5.6%, and pH values between 3.5–4.1. Extracts from muscles and viscera of *Katsuwonus pelamis* gave 1.1 and 1.5% lipid, and pH values of 3.5 and 3.6, respectively. Fresh viscera of *Cololabis saira* contained 33.3% lipid. Fresh muscle and viscera of *Engraulis japonica* had lipid contents in the range 1.1–5.6% and pH values between 3.1 and 4.5. The lipid percentages and pH values were 3.3 and 3.0 for dry whole anchovy, and 7.5 and 3.1 for dry viscera,

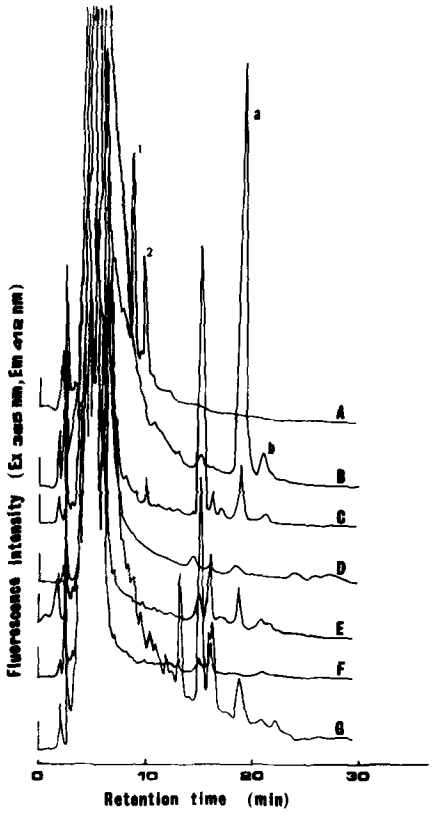

FIG. 2. High-performance liquid chromatography (HPLC) tracing of 9-anthrylmethyl esters of okadaic acid, dinophysistoxin-1, and of extracts from various fish. Fractions eluted with chloroform/methanol (95:5 vol/vol) corresponded to 20 mg fish homogenate when submitted HPLC. A, 15.3 ng okadaic acid (peak 1) and 13.3 ng dinophysistoxin-1 (peak 2); B, *Engraulis japonica*, viscera; C, *Sebastolobus macrochir*, whole; D, *Cololabis saira*, viscera; E, *Trachurus japonicus*, whole; F, *Loligo loligo bleckeri*, whole; G, *Katsuwonus pelamis*, viscera. Peaks a and b were identified as eicosapentaenoic acid and docosahexaenoic acid, respectively, based on HPLC analysis and comparison with authentic standards. Assay conditions: Column, ODS (4.6 mm i.d. × 25 cm); solvent, acetonitrile/methanol/water (8:1:1, vol/vol/vol); flow rate, 1.1 mL/min; wavelength, Ex = 365 nm, Em = 412 nm.

respectively (Table 1). Mouse toxicity was observed only in anchovy, *Engraulis japonica*, especially in the viscera and in the dried product. No mouse toxicity was detected in the other fish. Mice injected with 1 mL of test solution extracted from anchovy with 1 MU/g toxicity died within 1–3 h; those injected with ether extract possessing a toxicity of less than 0.5 MU/g died between 10 and 24 h after injection. Symptoms were immobilization and crouching down, but not diarrhea.

To see whether oxidation of lipid (*i.e.*, PUFA) throughout the pretreatment phase would affect mouse toxicity, α-tocopherol (0.5%) was added to a parallel sample of fresh anchovy, showing 0.5 MU/g, before extraction with acetone. No change was apparent in mouse lethal toxicity by the addition of α-tocopherol.

Crude lipid contents were high in *Trachurus japonicus*, *Sebastolobus macrochir* and *Cololabis saira*, which showed no mouse toxicity. In anchovy, samples with high lipid content did not always show high mouse toxicity, and samples containing less lipid often showed a higher toxicity. Almost all ether extracts from the fish showed acid pH (3.0–4.5).

Since OA and DTX_1, which have been identified as acidic toxins in bivalves, presumably originate from phytoplankton, detection of these acidic agents was attempted from anchovy, which is basically a plankton feeder (15), with zooplankton typically making up 70% and phytoplankton making up 30% of the diet. OA and DTX_1 were not detected by HPLC in any of the fish examined (Fig. 2).

An unknown substance (marked a in Fig. 2) was eluted at a retention time of 18.6 min from ether extracts of anchovy viscera. A small amount of this substance was also observed in other fish but not in the squid *Loligo loligo bleckeri*. Also detected was another unknown substance at a retention time of 14.9 min which occurred at the same level in *Katsuwonus pelamis* viscera and in *Sebastolobus macrochir*.

The concentrations of the substance a in viscera from three samples of Japanese anchovy were 4.8, 5.7 and 10.1 times higher than those in the respective whole bodies. The amounts of substance a as represented by the peak areas and the mouse toxicities of the respective six samples of anchovy viscera are listed in Table 2. The mouse toxicities appear to correlate quite well with the amounts of substance a present. Changes upon treatment with Na_2CO_3 to remove acidic substances are shown in Table 3. Remarkable decreases in the amounts of substance a detected by HPLC and in mouse toxicities were observed while total lipids decreased much less (Table 3).

Because substance a reacted with ADAM, and based on its polarity in HPLC, the substance was considered likely to be a free fatty acid. By comparison with authentic free fatty acid standards, using two different HPLC solvent systems, the substances with retention times of 18.6 min (a) and 21 min (b) (Fig. 2) were identified as EPA

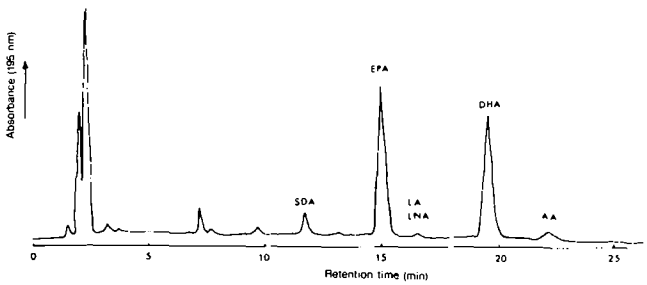

FIG. 3. High-performance liquid chromatography (HPLC) tracing of methanol-soluble substances in an ether extract from anchovy viscera corresponding to 1.0 MU/g of mouse toxicity. A fraction corresponding to 94 μg anchovy viscera was submitted to HPLC. LA, linoleic acid; LNA, linolenic acid; SDA, stearidonic acid; AA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid. Assay conditions: Column, ODS (0.46 × 25 cm); solvent, acetonitrile/methanol/water/phosphoric acid (53:20:17:0.1, by vol); flow rate, 1.2 mL/min; wavelength, 195 nm.

and DHA, respectively. A spectrum of the ether extract of anchovy viscera analyzed by HPLC with a UV detector is shown in Figure 3. It is apparent that EPA and DHA in their free fatty acid form were the main components detected in the anchovy viscera lipid extract.

To examine the accuracy of the present method for the detection of EPA, 1 mg of EPA was added to 1 mL of the ether extract from anchovy viscera containing 0.25% EPA, and the mixture was assayed. The recoveries for

[a]As wet weight of anchovy viscera. [b]Not detectable.

EPA in duplicate experiments were 101 and 103%. Reproducibility for the same sample in six experiments was within 2.4%. To confirm with which lipid class mouse lethal toxicity was associated, 1 mL of each of the samples of the five lipid classes isolated by TLC (Fig. 1) was injected i.p. into two mice. The mice injected with the free fatty acids (Fr.3) were dead within 24 h; all others survived.

The free EPA and DHA concentrations in the ether extracts of four anchovy viscera, whose mouse lethal toxicities were 1.0, 0.25, 0.25 and ND, are shown in Table 4. DHA levels were only slightly lower than those of EPA. The mouse lethal toxicities, however, correlated better with the EPA concentrations. This was tested with authentic EPA (92% pure). Upon injection with 25 mg, 12.5 mg, 6.3 mg and 3.2 mg of authentic EPA into four mice each, 4, 4, 1 and 0 mice, respectively, died within 24 h. Thus 12.5 mg of EPA was considered to correspond to approximately 1 MU.

DISCUSSION

It had previously been reported that lipid fractions from bivalves can be toxic to mice and can change oxyhemoglobin to methemoglobin when added to blood *in vitro* (7). In the present study, the presence of a similarly toxic substance was examined in several species of fish. Remarkably, the toxicity was detected only in ether extracts from anchovy viscera, although this material contained lower lipid concentrations than did other fish, such as *Cololabis saira, Trachurus japonicus* and *Sebastolobus macrochir.* The result suggested that the substance associated with mouse toxicity was specific for the anchovy.

Because mouse toxicity was reduced by treatment with Na_2CO_3, the toxic substance was presumed to be acidic. Because mouse toxicity correlated with the amount of ADAM-reacted EPA measured (Table 2), and EPA was notably decreased by treatment with Na_2CO_3 (Table 3), EPA appeared to be the cause of mouse lethal toxicity. As shown in Table 3, the reduction of EPA after Na_2CO_3 treatment as determined by HPLC was 91.3%, while that of total lipid was only 12.0%. This is consistent with the observation that free fatty acid levels in sardines are quite low (1.9–3.2%) (16).

The fact that more ADAM-reacted EPA was detected in anchovy than in other fish, in spite of the ancovy having a low lipid content, suggested the presence of more EPA in free acid form. Takagi *et al.* (8,9) had previously reported that free unsaturated fatty acids, including EPA,

were more toxic than the corresponding methyl esters. The amount of EPA corresponding to 1 MU, calculated from toxicity tests on extracts from anchovy viscera, was 7.25 mg (Table 4) when EPA alone was considered toxic. Based on use of authentic EPA, 1 MU was about 12.5 mg. These data are close to those reported by Takagi *et al.* (8), who correlated 1 MU with 6–12 mg. These authors also reported (8,9) that LNA and AA had mouse lethal toxicity equal to EPA, and LA and DHA were nearly half as toxic as EPA.

Enzymic oxidation of fish lipids *in vivo* is known to promote the formation of undesirable volatile carbonyl compounds (17). Cyclooxygenase (18) and lipoxygenase (19,20) were recently discovered in the gill and skin of teleost fish, such as trout and turbot. In the barnacle, *Elminius modestus,* 8-hydroxyeicosapentaenoic acid (8-HEPE), an oxidative metabolite of EPA, was identified as a highly active hatching factor (21). However, toxicity was absent in our Fr.2 separated by TLC (Fig. 1), which would contain the fatty acid oxidation products. Although enzymic oxidative metabolites, including eicosanoids, should not be ignored as substances inducing mouse lethal toxicity, PUFA appear to be the major cause of mouse lethal toxicity in the present study.

The reason why toxicity was higher in dry fish than in the fresh fish can probably be attributed to the fact that PUFA were liberated enzymatically from the more complex lipids of viscera *post mortem.* Free EPA and DHA in anchovy actually increased with the time elapsed after death (data not presented).

Mouse assays have been widely used in place of chemical assays for detecting the agents that cause human diarrhea, *i.e.* OA and DTX from bivalves. From the present study we can conclude that the presence of free EPA, DHA and similar PUFA can appreciably confound the mouse assay.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Prof. T. Yasumoto of the Tohoku University for providing okadaic acid and dinophysistoxin-1, to Dr. T. Hamazaki of the Toyama Medical and Pharmaceutical University for supplying EPA and to Prof. H. Tanaka, the director of this institution, for his helpful suggestions and criticisms.

Palmitic Acid Enhances Cholesterol Gallstone Incidence in Sasco Hamsters Fed Cholesterol Enriched Diets

Nariman Ayyad, Bertram I. Cohen, Erwin H. Mosbach* and **Shigeo Miki**
Departments of Surgery, Beth Israel Medical Center and the Mount Sinai School of Medicine of the City University of New York, New York, New York 10003

In an established hamster model of cholesterol cholelithiasis, a semipurified lithogenic diet containing 4% butterfat and 0.3% cholesterol leads to the production of cholesterol gallstones in only 50–60% of animals after a 6-wk feeding period. The purpose of this study was to investigate whether gallstone incidence could be increased while feeding a nutritionally adequate diet of moderate cholesterol content. The semipurified lithogenic diet was modified as follows: (i) substitution of 1.2% palmitic acid for 4% butterfat, and (ii) varying the amount of dietary cholesterol from 0.0 to 0.3% with either butterfat or palmitic acid as the lipid component of the diet. Substitution of palmitic acid for butterfat produced a significantly higher incidence of cholesterol gallstones (94% *vs.* 53%). Palmitic acid also raised the incidence of gallstones when added to the 0.1% and 0.2% cholesterol diets as compared to butterfat: 0% *vs.* 44% and 50% *vs.* 81%, respectively. Gallstone incidence increased from 0% to nearly 100% when the cholesterol content of the palmitic acid diets was raised from 0.0% to 0.3%, indicating a dose response effect with respect to dietary cholesterol. Hamsters fed cholesterol-free diets did not form gallstones. Increased dietary cholesterol led to increased liver weight associated with a significant increase in liver cholesterol concentration. However, the palmitic acid groups had significantly lower liver cholesterol values than the corresponding butterfat groups. Serum and biliary cholesterol concentrations increased with increasing dietary cholesterol intake, but there were no differences between the butterfat and palmitic acid groups. The cholesterol saturation index increased from 0.56 to 1.32 in the butterfat groups and from 0.56 to 1.30 in the palmitic acid groups upon raising the dietary cholesterol from 0.0 to 0.3%. Biliary total bile acid concentration did not vary significantly within all groups; however, the addition of cholesterol produced an increase in the ratio of chenodeoxycholic acid to cholic acid. It is concluded that in Sasco hamsters the saturated fatty acid, palmitic acid, when substituted for butterfat in a nutritionally adequate lithogenic diet, is capable of increasing gallstone incidence to almost 100% during a 6-wk feeding period.
Lipids 27, 993–998 (1992).

Many animal models of cholesterol cholelithiasis have been described in the literature (1–17). The hamster has been used extensively because its bile composition has many similarities to that of humans. Although several hamster models have been described, none was entirely satisfactory. For example, Dam and Christensen (13–15) used a fat-free, nutritionally inadequate diet that inhibited normal growth and resulted in premature deaths. Some "strains" of hamster tend to form pigment rather than cholesterol gallstones, and in other "strains" the incidence of gallstones can be very low (12,17–19). The diet of Pearlman *et al.* (16) required dietary cholesterol and ethinyl estradiol, and, for unexplained reasons, the model lost its reproducibility as noted in several laboratories.

Recently, we developed a hamster model of cholesterol cholelithiasis using a nutritionally adequate diet of moderate cholesterol content (12). We employed a semipurified diet (SPD) containing 0.3% cholesterol leading to the production of pure cholesterol gallstones with an incidence of 50–60%. The male golden Syrian hamster from Sasco Inc. (Omaha, NE) was chosen since this "strain" gave a satisfactory and a reproducible incidence of cholesterol gallstones (12). The hamsters exhibited normal weight gain and were healthy throughout the 6-wk experimental period. However, the proportion of animals developing cholesterol gallstones never approached 100% with this diet. In the present manuscript, we investigated ways of raising gallstone incidence while feeding a nutritionally adequate diet.

The semipurified diet (SPD) contained 4% butterfat, which has a very high proportion of saturated fatty acids varying in chain length from C_4 to C_{18}. We previously showed that butterfat was an important dietary ingredient for gallstone formation in our model (20). Palmitic and oleic acids are major fatty acids in butterfat (21). Substitution of olive oil (71% oleic acid) for butterfat prevented stone formation completely even in the presence of 0.3% dietary cholesterol (22). However, substitution of palm oil (45% palmitic acid) for butterfat enhanced cholesterol gallstones (84%, Cohen, B.I., and Mosbach, E.H., unpublished data). Therefore, we hypothesized that removal of the monounsaturated acid would further enhance gall-stone formation. We therefore modified the SPD by substituting palmitic acid for butterfat and studied the effect of this diet on gallstone formation. In addition, we also carried out a dose response experiment to examine the effect of varying the dietary cholesterol from 0.0 to 0.3% with either butterfat or palmitic acid as the lipid component of the diet.

The data suggest that palmitic acid plays an important role in cholesterol gallstone formation in the male golden Syrian hamster from Sasco, since substitution of palmitic acid for butterfat produced a higher incidence of cholesterol gallstones (94% *vs.* 53%). There was a dose response effect with respect to dietary cholesterol: gallstone incidence increased from 0 to nearly 100% when the cholesterol content of the palmitic acid diet was raised from 0.0 to 0.3%.

MATERIALS AND METHODS

Animals. Male golden hamsters *(Mesocricetus auratus)*, weighing 53–68 g, were purchased from Sasco Inc. The animals were maintained with Purina rodent chow and water *ad libitum* for a 1-wk quarantine period prior to the start of the experimental diets. The animals were divided

Abbreviations: alloCA, allocholic acid; CA, cholic acid; CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; FT-IR, Fourier Transform Infrared; HDCA, hyodeoxycholic acid; LCA, lithocholic acid; MDCA, murideoxycholic acid; PAD, palmitic acid diet; SPD, semipurified diet.

into 8 groups and fed the following diets (purchased from Dyets Inc., Bethlehem, PA): group 1, SPD containing 43.7% corn starch, 20% casein, 14.6% dyetrose (soluble starch), 10% fiber (cellulose), 5% salt mix (modified U.S.P. XIV salt mix, no. 200951), 4% butterfat, 2% corn oil, 0.5% vitamin mix (no. 300000), 0.2% choline chloride, 0% cholesterol; group 2, SPD with 0.1% cholesterol; group 3, SPD with 0.2% cholesterol; group 4, SPD with 0.3% cholesterol; group 5, palmitic acid diet (PAD), 0% cholesterol, equivalent to SPD with 1.2% palmitic acid substituted for 4% butterfat; group 6, PAD with 0.1% cholesterol; group 7, PAD with 0.2% cholesterol; group 8, PAD with 0.3% cholesterol. The hamsters were fed the experimental diets for 6 wk. The food intake was monitored; water was supplied *ad libitum*. At the end of the 6-wk feeding period, the hamsters were fasted for 24 h and anesthetized with 20 mg of ketamine hydrochloride (Aveco Co., Inc., Fort Dodge, IA). Blood was withdrawn by cardiac puncture for the determination of serum cholesterol. The gallbladder was examined for gallstones. Bile was removed with a 50 μL Hamilton Syringe and examined under a polarizing light microscope (Olympus MCHAP microscope, Olympus Corp., Lake Success, NY) for the presence of liquid crystals or cholesterol crystals. The remaining bile was immediately aliquoted for the determination of biliary lipids. The liver was excised, weighed, and a portion was taken for cholesterol analysis.

Analytical procedures. Biliary bile acids were determined as the methyl ester acetates using an SPB-5 15 m capillary column (Supelco, Bellefonte, PA) attached to a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA); 3α,7α-dihydroxy-12-keto-5β-cholanoic acid was used as an internal standard (9). Biliary phospholipids were determined by an enzymatic-colorimetric procedure using the Wako phospholipid B kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan). Cholesterol concentrations of bile, serum and liver were analyzed by gas-liquid chromatography of the trimethylsilyl ether derivative, using 5α-cholestane as an internal standard (23). Gallstones were analyzed by Fourier Transform Infrared (FT-IR) spectroscopy on a Perkin-Elmer model 1710 spectrometer (Norwalk, CT) attached to a model 7500 laboratory computer for data storage and analysis.

Calculations and statistics. The cholesterol saturation index of bile was determined using published methods (24,25). The data were reported as the mean ± SD. Differences of gallstone incidence between the various groups were determined using chi-square analysis (26,27). Other differences among groups were calculated using one-way analysis of variance followed by Student's *t*-test (26,27).

RESULTS

All hamsters were fed the experimental diets for 6 wk. In all 8 groups, there were no significant differences in food intakes, which ranged from 9 to 12 g/d. The animals remained healthy and gained similar weights throughout the experiment; cholesterol feeding led to increased liver weights (Table 1).

The incidence of gallstones and biliary cholesterol crystals was determined at sacrifice (Table 2). The hamsters fed the cholesterol-free SPD (group 1) formed neither gallstones nor cholesterol crystals. The addition of 0.1% cholesterol to the SPD (group 2) also failed to elicit the production of gallstones. Formation of cholesterol gallstones (50%) and crystals (50%) occurred with the addition of 0.2% cholesterol to the SPD (group 3). The highest and usual dose of cholesterol (0.3%) added to the SPD (group 4) did not significantly increase the incidence of gallstones (53%) and crystals (65%) from that in group 3. Substitution of palmitic acid for 4% butterfat in the SPD without cholesterol (PAD, group 5) failed to induce gallstones. However, the addition of 0.1% cholesterol to PAD (group 6) increased the formation of gallstones (44%) and crystals (62%) from the corresponding SPD with butterfat (group 2). Increasing dietary cholesterol to 0.2% (group 7) caused the formation of gallstones (81%) and crystals (94%) to increase still further. The highest dose of cholesterol (0.3%) added to the PAD (group 8) further increased gallstones (94%) and crystals (100%). FT-IR analysis found the gallstones to consist mainly of cholesterol (<90%); palmitic acid was not a constituent of the gallstones. In all cases, the palmitic acid diets plus cholesterol resulted in significantly more stones and crystals than the corresponding SPD butterfat diets (groups 6–8 *vs.* groups 2–4, respectively).

TABLE 1

Hamster Data: Body Weight, Food Intake and Liver Weight[a]

Group	Diet	Number of animals	Initial weight (g)	Final weight (g)	Food intake (g/d)	Liver weight (g)
1	Semipurified diet (SPD)	14	57 ± 3	94 ± 7	10 ± 1	3.8 ± 0.4[b]
2	SPD + 0.1% cholesterol	16	60 ± 3	101 ± 10	10 ± 1	5.5 ± 0.8
3	SPD + 0.2% cholesterol	16	60 ± 2	109 ± 7	11 ± 0	6.5 ± 1.0
4	SPD + 0.3% cholesterol	17	60 ± 4	102 ± 10	11 ± 1	6.2 ± 0.6
5	Palmitic acid diet (PAD)	10	53 ± 4	88 ± 16	9 ± 1	3.9 ± 0.5[c]
6	PAD + 0.1% cholesterol	16	59 ± 3	95 ± 15	10 ± 1	5.3 ± 1.1
7	PAD + 0.2% cholesterol	16	59 ± 3	100 ± 8	11 ± 0	5.5 ± 0.5
8	PAD + 0.3% cholesterol	16	61 ± 4	100 ± 7	12 ± 1	6.0 ± 0.6

Table 3 summarizes the cholesterol levels in liver, serum and bile. There was a significant increase in liver cholesterol concentration as the dietary cholesterol in the SPD and PAD groups was raised from 0.0 to 0.3%. The PAD groups (5-8) had much lower liver cholesterol concentrations, which ranged from 2.82 to 40.13 mg/g, compared to the corresponding SPD groups (1-4), which ranged from 8.22 to 96.57 mg/g. The serum cholesterol level increased from 197 to 333 mg/dL on the SPD with 0.0 to 0.2% cholesterol (groups 1-3) but did not increase further with 0.3% cholesterol (group 4) (344 mg/dL). In the PAD groups (5-8), the serum cholesterol increased from 137 to 399 mg/dL as dietary cholesterol was raised from 0.0 to 0.3%. Biliary cholesterol also increased as the cholesterol concentration in the diet was raised from 0.0 to 0.3%; however, there were no significant differences between the SPD (2.30-5.46 mg/mL) and the PAD (1.86-5.58 mg/mL) groups.

Biliary lipids and cholesterol saturation indices are summarized in Table 4. As expected, the molar percentage of biliary cholesterol increased as a function of dietary cholesterol content in each group. The mole percent phospholipids did not significantly change as cholesterol was carried from 0.0 to 0.2% in the SPD (groups 1-3) but significantly increased to 20.6% with the 0.3% cholesterol diet (group 4). In the PAD groups, the percent phospholipids increased with 0.2 and 0.3% dietary cholesterol (groups 7 and 8) to 17.7 and 20.9%, respectively, compared to the 0.0 and 0.1% (groups 5 and 6) which both had 14.4%. There were no major differences between the SPD and PAD groups. Molar percent of bile acids decreased when dietary cholesterol increased from 0.0 to 0.3% in the SPD and PAD groups, ranging from 80.8 to 71.2% and 82.8 to 70.5%, respectively. With the addition of cholesterol to the diet, the cholesterol saturation index

TABLE 4

Effect of Diet on Biliary Lipids[a]

Group	Diet	Mole % biliary lipid			Total lipid (g/dL)	Cholesterol saturation index
		Cholesterol	Phospholipid	Bile acid

increased from 0.56 to 1.32 in the SPD groups and from 0.56 to 1.30 in the PAD groups.

Table 5 summarizes the biliary bile acid composition in the gallbladder. The total bile acid concentration did not vary significantly within the 8 groups and averaged 44.5–62.3 mg/mL. The addition of cholesterol produced an increase in the proportion of chenodeoxycholic acid (CDCA) and a corresponding decrease in cholic acid (CA), as was previously observed (12). The gradual increase in CDCA as cholesterol was raised from 0.0 to 0.3% ranged from 23.0 to 42.4% in the SPD and from 23.3 to 38.2% in the PAD.

DISCUSSION

The aim of this study was twofold: (i) to study how the substitution of palmitic acid for butterfat in the diet affects gallstone incidence, and (ii) to examine the dose response of the model to increasing cholesterol intake. Palmitic acid (1.2%) was substituted for 4% butterfat in the SPD to maintain a similar level of palmitic acid in both the SPD and PAD diets. Butterfat contains palmitic acid as a major saturated fatty acid, about 27% of total fatty acids (21).

We determined that both cholesterol and butterfat were essential additions to our SPD hamster diet to achieve the induction of gallstones (20). Butterfat (4%) without cholesterol (group 1) in the diet does not induce gallstones. In addition, no stones were formed with 0.1% cholesterol; however, the incidence was 50% using 0.2% dietary cholesterol. The highest dose of cholesterol (0.3% did not significantly increase stone incidence further. Our hamster model clearly shows a dose response to choelsterol in the induction of the cholelithiasis.

Raising dietary cholesterol from 0.0 to 0.3% increases the proportion of cholesterol relative to bile acids and lecithin in bile which would favor the formation of lithogenic bile (28-31). Since cholesterol is insoluble in bile, an aqueous medium, it is solubilized in mixed micelles composed of bile acids and lecithin (32-34). In addition, excess cholesterol may be carried in the bile in the form of cholesterol-lecithin vesicles. Unlike the micelles, these vesicles may be unstable, and cholesterol is more likely to precipitate when the bile has a high level of such vesicles (35-37).

Gallstone formation increased upon substituting free palmitic acid for butterfat; presumably, the cholesterol solubilizing capacity of bile was reduced. The dietary saturated free fatty acid, palmitic acid, has a definite enhancing effect on gallstone formation. This effect is not ascribed to the presence of free fatty acid *per se* since our unpublished results have shown that the substitution of palm oil (containing 45% palmitic acid) for butterfat (containing 27% palmitic acid) also enhances gallstone incidence. Therefore, the addition of this saturated fatty acid in any form, either free or as triglyceride, seems to enhance gallstone formation. This is also suggested by our results showing that 0.1% cholesterol in the palmitic acid diet produced a gallstone incidence of 44% while the corresponding SPD (butterfat diet) gave a 0% incidence. The 0.2% and 0.3% cholesterol diets containing palmitic acid also produced a higher stone incidence than the corresponding butterfat groups (81% and 94% *vs.* 50% and 53%). These studies suggest that cholesterol gallstone induction results from increased secretion of cholesterol into the bile which can be stimulated in two ways, by increasing the intake of dietary palmitic acid, or reducing the proportion of mono- and diunsaturated fatty acids. It may well be that the oleic acid component of butterfat contributed to the reduced gallstone incidence with butterfat as opposed to palmitic acid. In studies carried out in our laboratory, the substitution of olive oil, which contains 13% palmitic acid and 71% oleic acid, for butterfat, yielded 0% stone incidence with our 0.3% cholesterol diet (22). Apparently, the types of fatty acids in the diet are important in lithogenesis. In our model, saturated fatty acids enhance gallstones incidence, while the unsaturated fatty acids seem to protect against gallstone formation.

As dietary cholesterol was increased from 0.0 to 0.3% in the SPD and PAD, the liver cholesterol levels became significantly elevated. Liver cholesterol ranged from 2.82 to 40.13 mg/g in the PAD groups and from 8.22 to 96.57 mg/g in the SPD groups. The palmitic acid partially reduced the accumulation of cholesterol in the liver. Studies have shown that dietary cholesterol is esterified and stored in the liver cells as relatively inert cholesteryl esters (38). It has further been shown that the cholesteryl esters in the liver increase with increases in the dose of cholesterol (39). Storage of cholesterol in the liver as the ester has been shown to be reduced by certain fats in the diet (40). The ω6 unsaturated fatty acids seem to be the preferred substrates in cholesterol esterification (41). Saturated fatty acids have been shown to be poor substrates for the esterification reaction (42). Since palmitic acid is a saturated fatty acid, this may explain why liver cholesterol levels were lower with PAD than with the butterfat diets, which contain many fatty acids, saturated as well as unsaturated. As a second alternative, the liver cholesterol levels suggest that palmitic acid promotes cholesterol absorption to a lesser extent than butterfat.

In summary, the present data demonstrate that dietary palmitic acid and cholesterol affect gallstone incidence. Specifically, when palmitic acid was substituted for butterfat, there was an increase in cholesterol cholelithiasis. Therefore, a lithogenic diet containing palmitic acid and cholesterol is a potent alternative to feeding a butterfat-cholesterol diet. In the hamster model, the palmitic acid-cholesterol diet is capable of raising gallstone incidence to almost 100% during a 6-wk feeding period. The mechanism of the enhancement of cholesterol cholelithiasis by dietary palmitic acid requires elucidation.

The effect and possible interactive influence of different dietary amounts of wheat bran, fat and calcium on the fecal excretion, concentration and composition of bile acids was studied in Fischer-344 rats. The fecal bile acids were analyzed using gas-liquid chromatography. Dietary wheat bran increased both total bile acid excretion and fecal weight without changes in fecal bile acid concentration. The proportion of fecal hyodeoxycholic acid decreased with increasing dietary fiber, whereas that of lithocholic and deoxycholic acids increased significantly with fiber intake. The percent content of fecal chenodeoxycholic acid did not change. Increasing dietary fat led to an increase in bile acid excretion without changes in either fecal weight or bile acid concentration. In contrast, the level of dietary calcium did not affect the total excretion of bile acids. However, since calcium increased the fecal weight, it consequently diluted bile acids and decreased their fecal concentration. Dietary fat and calcium had no influence on fecal bile acid composition. There were no interactive effects of wheat bran, fat and calcium on fecal bile acids. The finding in this study that dietary fiber, fat and calcium induce significant changes in fecal bile acids may be of relevance to the potential of bile acids to promote carcinogenesis.
Lipids 27, 999-1004 (1992).

Bile acids have been shown to express cancer-promoting properties which are modified by dietary factors (1-18). In particular, fiber, fat and calcium have received increased attention for their ability to induce changes in the metabolism of bile acids which affect their potential for promoting the development of experimental colon cancer (6-18). Whereas both dietary fiber and calcium can suppress the experimental induction of colon cancer by carcinogens (10,12,14-16,18), increased ingestion of fat has the opposite effect (7,13,19).

The potential changes in bile acid metabolism, which are considered to be relevant to the promotion of colon cancer, consist of increases in the fecal excretion and concentration of bile acids as well as their modification by bacteria. Most authors have reported that diets high in any type of fiber lead to both an increase in the total excretion and a suppression in the bacterial degradation of bile acids (6,9,11, 15,20-23), but the effect on fecal bile acid concentration appears to be less certain (11,23-26). Several studies in human subjects indicate that fecal concentrations of bile acids decrease after the ingestion of a diet high in either wheat bran or a mixtue of dietary fibers (24,25). In other human studies that involved diets high in oat bran and citrus pectin, respectively, no decreases in fecal bile acid concentrations were observed (20,22).

On the other hand, a high fat intake has been reported to result in an increased fecal excretion and concentration of bile acids (7,14). Although it is known that calcium binds to bile acids (27,28), little information is available regarding the effect of dietary calcium on fecal bile acids. There also appear to be no systematic studies of the combined or interactive effects of fiber, fat and calcium on bile acids. The aim of the study reported in the present paper, therefore, was to determine the individual effects of different levels of wheat bran, fat and calcium, and the influence of their possible interactions on the fecal excretion, concentration and composition of bile acids.

MATERIALS AND METHODS

Study design and animal groups. Male albino Fisher-344 rats (F344/NHsdBR, Hilltop Lab Animals, Inc., Scottsdale, PA), weighing approximately 190 to 225 g, were used to measure the effects of 36 different experimental diets. The latter were characterized, in a factorial study ($4 \times 3 \times 3$), by the combinations of different concentrations, by weight, of wheat bran (0, 2.5, 10 and 20%), fat (1, 5, 10%), and calcium (0.18, 0.52 and 1.04%). The dietary fat, 1/3 of it saturated, 1/3 monounsaturated and 1/3 polyunsaturated, consisted of 44.2% lard, 46.2% corn oil and 9.6% hydrogenated coconut oil. Calcium carbonate served as the source of calcium in the diets. Two standard additional diets, Purina Rat Chow 5001 and AIN-76A (Purina, St. Louis, MO) served as controls. The calcium content of the Purina Rat Chow is 1%, and that of the AIN-76A diet is 0.52%. The rats were kept for 28 d on these diets. Each of the 38 study groups consisted of 10 animals.

Preparation of diets and collection of fecal samples. The above described combinations of wheat bran, fat and calcium were mixed into a basal diet. There were no other sources of fiber, fat and calcium. The only cholesterol within the diet was derived from the fat mixture. The basal diet had the following composition (g/kg): casein, 198; DL-methionine, 2; choline bitartrate, 2; sucrose, 369 to 269; dextrose, 369 to 269; a vitamin mixture, 10; and a salt mixture, 35. The salt mixture provided the phosphorus to the diets and did not vary. The diets followed the standard guidelines established for experimental animals (29). The diets were produced and pelleted by Dyets Inc. (Bethlehem, PA). The designated composition of the experimental diets was independently verified by analyses which were performed by two other laboratories.

Following a one-week quarantine, the rats were housed in groups of two, under standard conditions of 23°C with a 12-h dark-light cycle, in the core animal facility of The George Washington University Medical Center, Washington, D.C. The animal care was provided according to HHS/NIH guidelines. The respective diets were fed along with water *ad libitum* for 28 d. To ensure an accurate assessment of animal intake, any food that was spilled or uneaten was measured and the weight was subtracted from the total weight of food ration. Three days before the

Abbreviation: GLM, group least square means.

completion of the diet treatment, the animals were transferred, in groups of two, into metabolic cages which contained a funneled tray for accurate collection of feces, without contamination by urine or food. All feces were collected for 72 h, weighed and then stored in polypropylene test tubes at −80°C overnight. Following lyophilization and mechanical homogenization, the fecal material was reweighed in order to determine the wet/dry ratio. The feces from each paired group were pooled and immediately stored at −20°C until analyzed for fat and bile acid content.

Fecal bile acid analysis. The fecal bile acids were qualitatively and quantitatively analyzed using gas-liquid chromatography, essentially as previously described by this laboratory and others (30-33). In brief, aliquots of fecal material, with nordeoxycholic acid added as an internal standard, were refluxed with absolute ethanol for 30 min, cooled and then decanted through filter paper and collected. This process was repeated using chloroform/methanol (1:1, vol/vol). In order to separate the bile acids from the neutral sterols, the filtrate with the extracted bile acids was evaporated, then redissolved in 15 mL of 0.01 N HCl, and percolated through a prewashed Lipidex column (Lipidex 1000, Packard Instrument Corporation, Downers Grove, IL). The column was then washed with 20 mL of distilled water. The bile acids were eluted with 20 mL of 68% methanol. After elution from the column, the bile acids were subjected to alkaline hydrolysis. The deconjugated bile acids were extracted with dichloromethane, and the bile acid methyl ester acetates were formed as previously described (31-33). The recovery of bile acids in the extraction and deconjugation procedures was evaluated with the use of ^{14}C-labelled bile acids. The recovery was 64 ± 2.66 (M ± SEM) % for lithocholic acid, 79 ± 0.44% for cholic acid and 62 ± 3.77% for chenodeoxycholic acid. The derivatized bile acids were analyzed on a Packard Gas Chromatograph (Packard Instrument Corporation) using a 6-ft coiled column with a cyanosilicone stationary phase (3% AN-600 on Gas Chrom Q; Analabs, Camden, CT).

Fecal fat analysis. The fecal fat content was determined by the method of van de Kamer *et al.* (34).

Fecal calcium analysis. Fecal calcium was assayed by atomic absorption spectroscopy (Varian Techtron AA-5, Palo Alto, CA) using commercially prepared standards (Fisher Scientific, Silver Spring, MD) (35,36). A 0.5% $LaCl_3$ standard was included in all calcium analyses to correct for phosphate interference.

Statistical analysis. The effects of fiber, fat and calcium and their interactions were evaluated by three-way analysis of variance, using the group least square means (GLM) procedure in the SAS statistical computer package (37). GLM were then compared using the conservative Bonferroni adjustment for multiple comparisons (38). Pearson correlations were also computed between selected pairs of variables. The criterion for statistical significance was set at $\alpha = 0.01$.

RESULTS

The overall results of the measurements of body weight and fecal weights and bile acids, as well as fecal fat and calcium content derived from rats in the combined dietary groups are presented in Table 1. The correlations between

[a]Fecal bile acid concentration per fecal dry weight.
[b]See Table 2, footnote *a*.

the fecal bile acids, and fecal weight, fat, and calcium, respectively, are presented in Table 2 and Table 3. The effect of varying concentration of dietary fiber, fat and calcium upon rat body weight, fecal weight, bile acid concentrations, percent composition of the individual bile acids, as well as total and individual fecal bile acid excretion was analyzed.

Body weight. The average weight gain, which was very similar in the different groups, was approximately 65 g. There was no significant difference in the amount of diet consumed between the different experimental groups. Neither the fiber nor the calcium content of the diet had any appreciable influence on weight gain. However, there was a small, but statistically significant increase in body weight with increasing dietary fat. There was a significant increase ($P < 0.001$) in animal weight in the 10% dietary fat group (Table 1).

Dietary fiber. Fecal wet weight (Fig. 1) as well as fecal dry weight increased significantly with increasing dietary fiber ($P < 0.001$). The total fecal excretion of bile acids increased significantly with increasing dietary fiber (Fig. 2). It increased from a mean value of 5.48 in the 0% fiber group to that of 23.66 mmol/24 h in the animals which received 20% fiber ($P < 0.001$) (Table 1). This significant increase of fecal bile acid excretion with increasing dietary fiber content was seen with lithocholic, chenodeoxycholic, deoxycholic and hyodeoxycholic acids, which constituted the major fecal bile acids (Fig. 3, Table 4). Total bile acid excretion showed significant positive correlations with fecal wet weight ($P < 0.01$), fecal fat content ($P < 0.001$) and fecal calcium excretion ($P < 0.005$), in the 10% fiber group, as well as a negative correlation ($P < 0.005$) with fecal calcium content in the 0% fiber group (Table 2 and Table 3).

The fecal bile acid concentrations, based on both wet and dry fecal weight, were not affected by increasing dietary fiber. With the exception of the 0% fiber group, there was no correlation between fecal bile acid concentration per fecal dry weight or fecal wet weight, and fecal wet weight, dry weight, fat and calcium. In the 0% fiber group, the bile acid concentration showed a significant negative correlation ($P < 0.001$) with fecal dry weight and calcium ($P < 0.001$).

The dietary wheat bran-associated changes in fecal acid composition are shown in Table 4. The proportion of hyodeoxycholic acid decreased significantly ($r = -0.7999$, $P < 0.001$) from a mean value of 50.34% in the 0% fiber group to that of 39.09% on 20% fiber. In contrast, lithocholic and deoxycholic acids increased significantly ($r = 0.7871$, $P < .001$ and $r = 0.7580$, $P < .001$, respectively) with fiber intake. The respective values in the 0% and 20% fiber groups were 1.91 and 15.34% for lithocholic acid and 15.74 and 28.59% for deoxycholic acid. The percent content of fecal chenodeoxycholic acid did not change. Cholic, α-muricholic and β-muricholic acids, which were not present in all animals, did not show significant changes in response to the different diets (Table 4).

Dietary fat. Total bile acid excretion increased signifi-

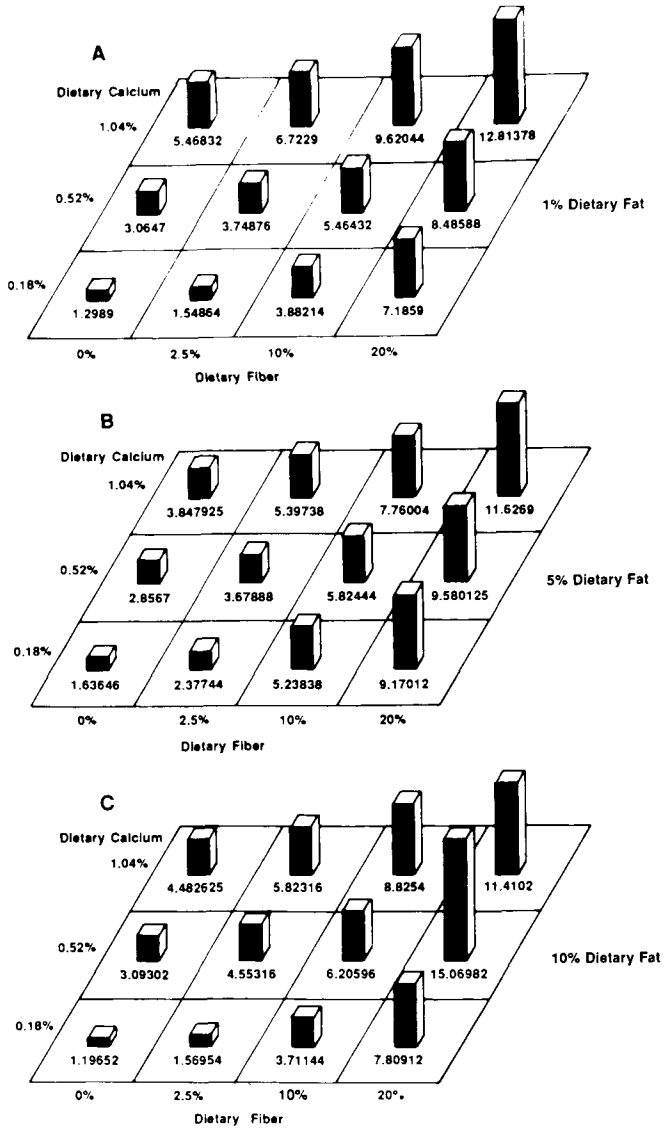

FIG. 1. Effects of dietary fiber, fat and calcium on fecal wet weight (g/24 h). The bars represent the effects of increasing dietary fiber and calcium on fecal wet weight in relation to dietary fat content. Panel A, 1% fat diet; panel B, 5% fat diet; panel C, 10% fat diet.

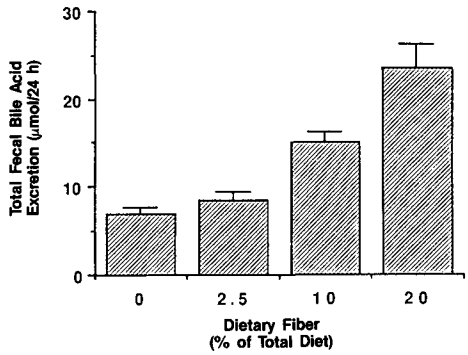

FIG. 2. The effect of increasing dietary fiber content on the total fecal excretion of bile acids.

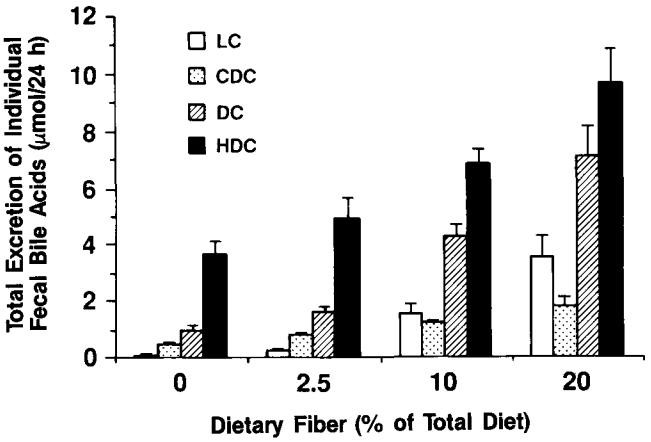

FIG. 3. Effect of dietary fiber on the excretion of the major fecal bile acids. LC, lithocholic; CDC, chenodeoxycholic; DC, deoxycholic; HDC, hyodeoxycholic.

cantly from 12.37 umol/24 h in the 1% fat group to 15.19 μmol/24 h in the animals which received a 10% fat diet ($P < 0.05$) (Table 1). Fecal fat showed significant increases with increasing dietary fat content (Table 1). The fecal wet and dry weights as well as fecal bile acid concentrations and composition were not affected by dietary fat.

Fecal bile acid excretion showed a significant positive correlation with fecal wet weight ($r = 0.452$, $P < .005$ for the 5% fat group and $r = 0.656$, $P < .001$ for the 10% fat group) (Table 2). Significant positive correlations existed also between bile acid excretion and fecal fat in all three dietary fat groups (Table 2). There was a significant negative correlation ($r = -0.357$, $P < .005$) between the fecal bile acid concentration per fecal dry weight and fecal calcium excretion in the 5% dietary fat group (Table 3).

Dietary calcium. Fecal weight (wet) increased significantly ($P < 0.001$) with increasing dietary intake of calcium, *i.e.* from 23.70 μmol/g in the 0.18% calcium group to 11.67 μmol/g in the rats which received a 1.04% calcium diet (Table 1, Fig 4). The total excretion (Table 1) and percent composition of fecal bile acids did not change with dietary calcium.

Correlations in combined dietary groups. Total fecal bile acid excretion (Table 2 and Table 3) correlated significantly with fecal wet weight ($r = 0.4536$, $P < 0.001$) and with fecal fat ($r = 0.3555$, $P < 0.001$).

Total fecal bile acid concentrations showed a significant negative correlation with fecal calcium when the data from all dietary groups were combined ($r = 0.2835$, $P < .001$). Cholic, α-muricholic and β-muricholic acids were not present in all animals and did not show significant changes in response to the different diets (Table 4).

Additive effects of diets. The only additive effect of any combination of the diets was observed with fiber and calcium in relation to increasing fecal wet and dry weight.

DISCUSSION

In agreement with work by others, this study shows that a diet high in wheat bran is associated with significant increases in fecal bile acid excretion (6,9,11,15,20–23). The

TABLE 4

Percent Composition of Fecal Bile Acids in Relation to Fiber Content of Diet (M ± SEM)

Bile acid	Dietary fiber content (%)			
	0	2.5	10	20
Lithocholic	1.91 ± 0.33	4.38 ± 1.55	7.77 ± 1.23	15.34 ± 1.91
Deoxycholic	15.74 ± 1.37	20.64 ± 1.69	26.69 ± 1.17	28.59 ± 1.76
Chenodeoxycholic	7.71 ± 0.80	8.66 ± 0.54	7.83 ± 0.33	8.08 ± 1.39
Hyodeoxycholic	50.34 ± 3.34	53.80 ± 2.85	47.15 ± 1.66	39.09 ± 2.92
Cholic	2.94 ± 0.89	2.07 ± 0.32	3.33 ± 0.82	2.10 ± 0.56
α-Muricholic	17.44 ± 9.25	9.34 ± 2.08	7.35 ± 1.56	5.09 ± 2.66

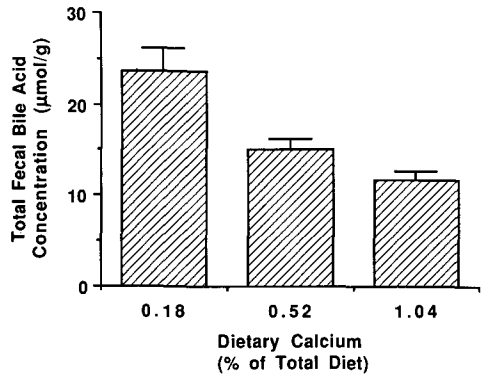

FIG. 4. Fecal bile acid concentration per dry fecal weight in relation to increasing dietary intake of calcium.

main mechanism of the increased bile acid excretion appears to be bile acid binding to fiber (39–42). In comparison to dietary fiber, dietary fat exerted a smaller, but significant influence on fecal bile acid excretion. The effect of fat on fecal bile acids appears to depend upon the type of fat in the diet (43,44). For example, the feeding of a high fat corn oil-based diet has been reported to be associated with an increased bile acid excretion, whereas *trans* fat in the diet had no significant effect (44). In contrast to dietary fiber and fat, calcium exerted no significant effect on bile acid excretion.

In contrast to our study, van de Meer *et al.* (45) found that supplemental dietary calcium increased the fecal bile acid excretion in healthy men. The authors speculated this to be due to the binding of calcium to intraluminal bile acids. The difference between our data and those by van der Meer *et al.* (45) seems to indicate that the rat model may not completely correlate with humans as far as calcium-bile acid interactions in the intestine are concerned.

Although fecal bile acid concentrations were not affected by either the fiber or fat content of the diet, they decreased significantly with increasing dietary calcium. The absence of an effect of wheat bran on fecal bile acid concentration appears to be in disagreement with reports by other investigators (45–47). However, although all these authors observed decreased bile acid concentrations, there were considerable variations in the total fecal bile acid excretion measurements. The increases in fecal bile acid concentration were associated with either a rise (46) or no change (45,47) in bile acid excretion. It appears, therefore, that the differences among the studies are mainly attributable to the varying degrees of dilution induced by dietary fiber. In the present study, both dietary fiber and calcium exerted a dilutional effect, as indicated by their close correlation with fecal wet as well as dry weight.

The absence, in this study, of a correlation between fecal bile acid concentrations and the amount of fat in the diet is in contrast to the results of most other authors who found that fecal bile acid concentrations increased with increasing dietary fat (7,19). The lack of a correlation in this study appears to be due to the finding that dietary fat had only a moderate effect on total fecal bile acid excretion and that there was no correlation between dietary fat and fecal weight. In addition, these findings may have been affected by the fact that in some of the other studies the dietary fat was considerably higher than in the present experiments (≥20% *vs.* ≤10%).

The decrease in fecal bile acid concentration, which we observed in response to increased dietary calcium, was the result of dilution, since fecal weight increased with dietary calcium without changes in total fecal bile acid excretion. Although calcium has been shown to bind to both free and micellar bile salts, it is not known whether this reaction influences the intestinal absorption of bile salts and calcium (28,48).

The fecal bile acid composition in this study was comparable to that reported by other authors (19,30,36,45,49). Similar to these reports, hyodeoxycholic and deoxycholic acids formed the major constituents of rat fecal bile acids. Among the minor bile acids, ω-muricholic acid has been observed by others to be present in rat feces (30,36,45). After completion of the present study, we reanalyzed eighteen fecal samples of different dietary fiber groups using an ω-muricholic acid standard recently made available to us through the courtesy of Dr. A.F. Hofmann, University of California, San Diego. Independent of the fiber content of the diet, less than 5% of the fecal bile acids consisted of ω-muricholic acid (data not presented). This observation was consistent with that of other investigators (30,36,45).

The finding that dietary fiber decreased the proportion of fecal bile acids consisting of hyodeoxycholic acid, but caused no significant change in the percent content of chenodeoxycholic acid, agrees with similar observations by others (8). However, in contrast to what others observed, the percentages of fecal lithocholic and deoxycholic acids increased with dietary fiber (8,16). The reason for the dietary fiber-related increase in intestinal bacterial 7-de-hydroxylation of bile acids is not clear. However, this

shift to secondary bile acids with increased cancer-promoting potential may not raise the cancer risk if the bile acids are not solubilized in the colon. Preliminary studies in our laboratory indicate that feeding of wheat bran to rats leads to a marked fall in both colonic pH and aqueous bile acid concentrations (51,52). The latter conditions may, therefore, reflect a decrease in the ability of bile acids to promote carcinogenesis in the colon, in spite of an overall increase in the proportion of lithocholic and deoxycholic acids in the feces.

In summary, the study shows that, in the rat, dietary wheat bran leads to increases in both total bile acid excretion and fecal weight, without changes in fecal bile acid concentration. The dietary fat increased the total fecal excretion but not the concentration of bile acids. In contrast, calcium feeding does not affect the total excretion of bile acids. However, since calcium causes an increase in fecal weight, it dilutes bile acids with a consequent decrease in their fecal concentration.

Studies are now in progress in our laboratories to determine the effect of the different diets on the solubility and watery concentrations of bile acids in the cecum. Such measurements, in conjunction with those obtained in the present study, should provide a possible explanation of the mechanisms by which dietary fiber and calcium may reduce the promotion of carcinogenesis by bile acids.

The plasma kinetics of a preparation of dilinoleoyl phosphatidylcholine (DLPC) specifically labeled with ^3H in the choline moiety and with ^{14}C in the 2-fatty acid (FA) were evaluated in six healthy volunteers after oral administration. Retention of both isotopes in plasma exceeded expectations, with a half-life in the elimination phase of 172.2 h for ^3H and 69.7 h for ^{14}C. Up to 60 d after administration, there were still significant levels of radioactivity present in plasma. The relative stability of the [^{14}C]FA label was demonstrated by the retention for more than 12 h of an isotope ratio close to that of the compound administered. The ^{14}C label of DLPC remained in position-2, as assessed by cleavage of plasma phospholipids with phospholipase A_2. The [^3H]choline label showed an early incorporation into high density lipoproteins and subsequently into low density lipoproteins (LDL); conversely, the ^{14}C radioactivity was rapidly incorporated into triacylglycerols that were mainly associated with very low density lipoproteins. Radioactivity measurements revealed that both isotopes remained the longest time in LDL. In red blood cell (RBC) lipids, [^3H]choline radioactivity accumulated over time, with a plateau after 48 h, whereas FA radioactivity accumulated more rapidly and was followed by a progressive decay. Analysis of the isotope ratio in these cells suggested an early incorporation of lyso products followed by rapid transfer of FA from plasma. The RBC maintained considerable radioactivity for a prolonged time, thus acting as a possible reservoir for the DLPC administered. Our study showed that dilinoleoyl PC remained in plasma longer than predicted based on earlier studies, and that after absorption the FA label was found in position 2.

***Lipids* 27, 1005–1012 (1992).**

Administration of phosphatidylcholine (PC) is still being proposed in the therapeutic management of arterial disease (1,2) and nervous degenerative disease (3). Recent data have underlined the fact that PC liposomes may improve clearance of atherogenic lipoproteins, even in the absence of high affinity lipoprotein receptors in the liver (4,5). The still uncertain therapeutic role of exogenous PC in humans is partly due to a lack of studies that have examined in detail the metabolic fate of PC in humans. The few studies published have mostly used dilinoleoyl phosphatidylcholine (DLPC), labeled either in the choline or in the acyl moieties, or both (6–8). A general conclusion from these studies has been that PC is more than 90% absorbed from the intestine and that, while the choline moiety is retained in circulating PC, fatty acids (FA) are rapidly cleared (8). Animal experiments have suggested that PC may be hydrolyzed in the intestinal mucosa and then partly resynthesized (9,10). The remaining FA and glycerophosphate can then be utilized in triacylglycerol (TG) synthesis (10).

Studies on the distribution of orally administered PC in humans have shown a preferential association of PC with high-density lipoproteins (HDL) rather than with atherogenic lipoprotein particles (8). Inconsistent data, however, are on hand on the plasma elimination kinetics for the FA and choline moieties, with half-lives reported ranging from 32 h to 6 d (6–8). Earlier studies have generally not taken into account the possibility of a net transfer of phospholipids from lipoprotein particles to cells, which occurs *in vivo* (11), particularly in the lipid phase of cell membranes.

Kinetic studies of PC selectively labeled in the 2-position, where the fatty acid can be specifically cleaved by phospholipase A_2 (12), allow a more detailed evaluation of the enzymatic steps involved in the metabolism of the acyl moiety (13). This type of substrate was used in the present investigation, where the kinetics, distribution in plasma lipid and lipoprotein, as well as incorporation into red blood cells (RBC) of dilinoleoyl PC, labeled both in the choline and the 2-FA moieties, were evaluated in healthy volunteers. An additional objective of the study was to determine the metabolic stability of the PC molecule in plasma over nine long time periods after oral administration.

MATERIALS AND METHODS

Labeled PC. Doubly labeled dilinoleoyl PC (DLPC) was prepared by separately synthesizing 1-linoleoyl-2-[1-^{14}C]-linoleoyl-*sn*-glycero-3-phosphocholine ([^{14}C]DLPC) and 1,2-dilinoleoyl-*sn*-glycero-3-phospho-[*methyl*-^3H]choline ([^3H]DLPC) (14). The latter was prepared as follows: Linoleic acid, 5.34 mL (17.3 mmol), was first added to a solution of 1,1'-carbonyldiimidazole (17.3 mmol in 10 mL of dry $CHCl_3$) at room temperature, followed by warming for 1 h at 40°C. A solution of glycero-3-phospho-[*methyl*-^3H]choline (4.332 mmol, 3,387 μCi), prepared from 1,2-dipalmitoyl-*sn*-glycero-3-phospho-[*methyl*-^3H]choline (Amersham, Buckinghamshire, UK) by hydrolysis (14), and 2.631 mg (17.3 mmol) of 1.8-diazobicyclo[5.4.0.]undec-7-ene in 12 mL of dry $CHCl_3$ were added, and the resulting reaction mixture was kept at 40°C for 40 h. The mixture was then treated with 10 mL of methanol and stirred for 2 h at 40°C. Subsequently the mixture was cooled

to 0°C, and 10 mL of 20% HCl plus 10 mL of saturated aqueous NaCl was added. The organic layer was removed, and the aqueous layer was re-extracted with $CHCl_3$ (3 × 15 mL) and diethyl ether (2 × 10 mL). The organic extracts were dried over Na_2SO_4, filtered, and the solvent was evaporated under reduced pressure. The crude product was purified by repeated flash chromatography (15) (CH_2Cl_2/MeOH, 1:1, vol/vol), giving 1050 mg (1.343 mmol, 1050 μCi) of 1,2-dilinoleoyl-*sn*-glycero-3-phospho-[*methyl*-^{3}H]choline in 31% yield.

In order to prepare DLPC labeled in the 2-position with [1-^{14}C]linoleic acid, a solution of [1-^{14}C]linoleic acid (1.058 mmol, 413 μCi) in 1.1 mL of dry $CHCl_3$ was added to a solution of 1.1′-carbonyldiimidazole (1.058 mmol) in 1.1 mL of dry $CHCl_3$. The mixture was warmed for 1 h at 40°C. Then solutions of 1-linoleoyl-*sn*-glycero-3-phosphocholine (LPC; 0.529 mmol), which was prepared by phospholipase A_2 hydrolysis of 1,2-dilinoleoyl-*sn*-glycero-3-phosphocholine (kindly supplied by Nattermann GmbH, Cologne, Germany), and of 1.8-diazabicyclo[5.4.0]undec-7-ene (1.058 mmol), both in 1.1 mL of $CHCl_3$ were added. After stirring for 30 h at 40°C, the crude product was purified by repeated flash chromatography (CH_2Cl_2/MeOH, 1:1, vol/vol) (15), resulting in 302 mg (0.386 mmol, 302 μCi) of 1-linoleoyl-2-[1-^{14}C]linoleoyl-*sn*-glycero-3-phosphocholine ([^{14}C]DLPC) in 73% yield.

The final, doubly labeled product was obtained by dissolving in 50 mL of $CHCl_3$, 780 mg (780 μCi) of [^{3}H]DLPC, 260 mg (260 μCi) of [^{14}C]DLPC, and 5440 mg of unlabeled 1,2-dilinoleoyl phosphatidylcholine (DLPC, Nattermann). After solvent evaporation, 6480 mg of doubly labeled product (^{3}H: 0.1120 μCi/mg; ^{14}C: 0.0401 μCi/mg) was obtained and divided into 24 capsules, each containing 250 mg of lipid, with specific activities of 94 μCi/mmole and 31 μCi/mmole for ^{3}H and ^{14}C, respectively.

Experimental design. Six healthy subjects volunteered for the study (3 males and 3 females; age range, 24–44 yr) (Table 1). The subjects were fully informed of the modalities and goals of the study and signed a written consent form. None of the volunteers was undergoing treatment with drugs or was on a diet affecting plasma lipids or intermediary metabolism. Women were not on oral contraceptives. All subjects were found to have normal liver, kidney and bone marrow function. On day 0, after overnight fasting, each subject took three capsules of the labeled PC preparation, containing a total of 90 μCi of [^{3}H]DLPC and 30 μCi of [^{14}C]DLPC. Immediately after taking the capsules, each volunteer consumed a small breakfast consisting of whole milk, 200 mL; dry cookies, 50 g; and sugar, 10 g (calculated composition: 11.9% protein, 30.8% fat, 57.3% carbohydrates; 329.7 Kcal; 22.2% saturated FA; 8.2% monounsaturated FA; traces of polyunsaturated FA; cholesterol, 50.4 mg). Blood samples were drawn at time 0, and at 1, 2, 4, 6, 8, 12, 24, 36, 48, 72, 96 and 120 h after DLPC administration. Samples drawn at the beginning of the day (24,48, 72, 96 and 120 h) were from fasting subjects. The design of this protocol was based on a previous study by Zierenberg and Grundy (8). Since analysis of the data revealed that the radioactivity was present in the circulation far longer than predicted, a further sample was collected from all subjects 60 d after administration (see below).

Urine was collected in a beaker, in the presence of sodium azide, at 0–2, 2–4, 4–8, 8–12, 12–24, 24–48, 48–72, 73–96, 96–120 h post-dose, and stored at −25°C until radioactivity was determined. Fecal excretion of radioactivity was also monitored by collecting daily fecal samples from all subjects. The samples were pooled in 5-d pools and later extracted for measuring radioactivity.

Analytical procedures for plasma and RBC. A minimum sample of 10 mL of blood was drawn [in Na_2 ethylenediaminetetraacetic acid (EDTA), 1 mg/mL] each interval in order to monitor plasma radioactivity (both ^{3}H and ^{14}C). In addition, at 2, 6, 12, 24, 48 and 120 h, an additional 20 mL of blood were drawn. These samples were subjected to a complete lipoprotein fractionation [very low density lipoprotein (VLDL), low density lipoprotein (LDL) and HDL] by standard density ultracentrifugation (16). In all samples, the cholesterol content was measured using a standard enzymatic method (17). Radioactivity distribution in plasma lipids (triglycerides, cholesteryl esters, phospholipids) was determined after thin-layer chromatography (TLC) of the lipid extract (see below). In order to monitor the stability of the choline and linoleoyl residues in PC, the specific activity of choline lipids and of lipid classes labeled in the acyl moieties was evaluated. At each interval, RBC were separated from the blood samples using ACD (citric acid, 71 mM; Na citrate, 85 mM; dextrose, 3 mM) as anticoagulant. After removal of platelet-rich plasma (PRP) by low-speed centrifugation, RBC were obtained after three cycles of centrifugation at higher speed (800 × g for 15 min, three times). Pellets were washed in ACD, and membranes were obtained by a final osmotic shock, followed by further washing and recentrifugation in distilled water.

Lipid extraction. Lipids in 1-mL aliquots of plasma and in lipoprotein fractions were extracted by stepwise addition of water, methanol and chloroform (2, 8, and 16 mL, respectively). This was followed by phase separation and

collection of the organic layer. No radioactivity was detected in the aqueous layer. Lipids were extracted from RBC membrane pellets with solvents containing butylhydroxytoluene (BHT) (5 μg/mL) as antioxidant (18).

Chromatographic techniques. Cholesteryl esters (CD), TG and phospholipids (PL) in plasma lipid extracts were separated by TLC using hexane/diethyl ether/acetic acid (80:20:1, vol/vol/vol) as developing solvent. Separation of major plasma phospholipid classes was achieved by one-dimensional TLC using chloroform/methanol/aqueous ammonia (65:35:5, vol/vol/vol). Separation of RBC membrane lipids into individual phospholipid classes was accomplished by two-dimensional TLC (19). Authentic reference compounds (Supelco, Bellefonte, PA) were used for the identification of the products separated by TLC; chromatographic fractions were detected by exposure to iodine vapors.

Radioactivity determination. The amounts of ^{3}H and ^{14}C in aliquots of lipid extracts were assessed after evaporation of solvent in the presence of scintillation fluids using a Kontron scintillation counter with automatic quenching correction. The radioactivity in individual lipid classes separated by TLC was measured after scraping the respective silica fractions off the plates into counting vials. Counting efficiencies were corrected by submitting the labeled, original DLPC to the same chromatographic procedures. Aliquots of at least 1–2 mg of lipids were used for chromatographic separations and radioactivity counting. Final values are expressed as dpm/mg total lipid.

Pharmacokinetic analyses. These were done according to a two-pool model previously suggested by Wagener (6) and by means of a computerized procedure (20).

Localization of the ^{14}C label in DLPC. The position of the ^{14}C label in the compound administered and in the lipids extracted from plasma was verified by phospholipase A_2 (EC 3.1.1.4 from Naja naja naja venom, Sigma, St. Louis, MO) degradation according to Deems and Dennis (12). Briefly, the respective phospholipid fraction was subjected to enzymatic treatment, and the products were extracted and chromatographed by TLC. The LPC formed contained only ^{3}H; no ^{14}C radioactivity was found in the product indicating that the ^{14}C label was incorporated only in position-2 both of the original compound and the PC isolated from plasma. Tritium-labeled choline was detected in both the LPC and PC fractions.

RESULTS

In this study, as in a previous one (8) with a similar protocol, intestinal absorption of doubly labeled dilinoleoylphosphatidylcholine was found to be nearly complete as judged by measuring the area under the curve (AUC) of radioactivity in plasma over time (Table 2).

Absorption of the FA moiety was more rapid (Fig. 1), without reaching a plateau, while choline radioactivity rose steadily in the first 24 h after administration. The major kinetic parameters of the two isotopes are given in Table 2. Plasma half-lives ($t_{1/2}$) of the distribution (α) and elimination (β) phases, as calculated according to a two-pool model (6,8), indicate a more rapid distribution and elimination of the ^{14}C isotope, the volumes of distribution at steady-state (Vd_{ss}) being nearly identical for ^{3}H and ^{14}C. Calculation of absorption as: AUC = Dose/Clearance (Cl) yielded, for both isotopes, values

TABLE 2

Major Plasma Kinetic Parameters After Oral Administration of Doubly Labeled Dilinoleoyl Phosphatidylcholine to Healthy Volunteers (n = 6; X ± SEM)[a]

	^{3}H	^{14}C
Dose (dpm)	198 × 10^6	66 × 10^6
AUC (dpm/mL/h)	2,435,445 ± 79,719	323,664 ± 24,423
$t_{1/2}$ α (h)	21.17 ± 2.45	12.48 ± 2.70
$t_{1/2}$ β (h)	172.20 ± 8.01	69.65 ± 10.35
VD_{ss} (L)	20.33 ± 0.93	18.67 ± 1.21
T Cl (mL/h)	82.18 ± 2.69	210.98 ± 15.53

[a]AUC, area under the plasma concentration curves over time; $t_{1/2}$, half-life in the α and β phases; Vd_{ss}, volume of distribution at steady-state in liters (L); T Cl, total clearance. Absorption can be calculated from AUC = dose/Cl.

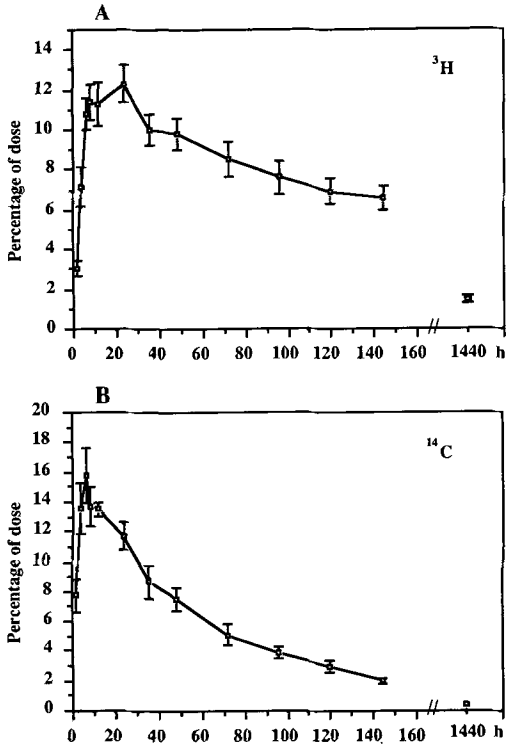

FIG. 1. Levels of ^{14}C and ^{3}H label in plasma after oral administration of doubly labeled dilinoleoyl phosphatidylcholine. Values are expressed as percentages of the administered dose. Means ± SEM, n = 6.

exceeding 95%. After 120 h from administration, *i.e.* at the projected end of the kinetic study, about 50% of the ^{3}H concentration at peak time was still present in plasma. For this reason, the volunteers were re-examined 60 d later (at 1440 h), when a low level of ^{14}C radioactivity (0.43 ± 0.1% of the dose) was still detected as well as a somewhat higher amount of ^{3}H (1.52 ± 0.1% of the dose). Insignificant amounts of radioactivity (≤5% for both isotopes) were found in urine and feces after 120 h.

The ratio of the two isotopes ($^{3}H/^{14}C$) in plasma (Fig. 2), at the earliest time periods (2–7 h after DLPC

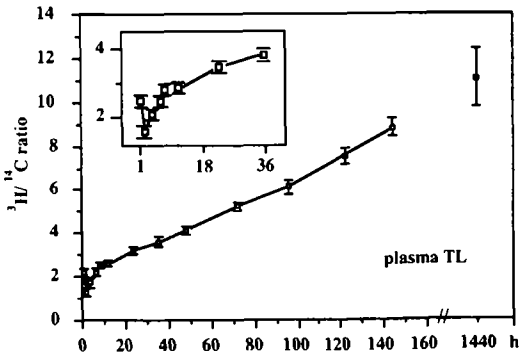

FIG. 2. $^3H/^{14}C$ ratios for total lipids in plasma. Means ± SEM, n = 6.

intake) fell below 3, *i.e.* below the isotope ratio originally present in the compound administered. The data indicate that the lyso compound and/or free glycerophosphocholine are absorbed or distributed at a different rate than are the fatty acids. PC isolated from plasma retained a $^3H/^{14}C$ ratio comparable to that of the compound administered up to 40 h after administration.

The ^{14}C isotope was retained in position-2 of the DLPC isolated from plasma at the different time intervals; in fact, no ^{14}C radioactivity was found in LPC after selective cleavage with phospholipase A_2 (PLA_2); also no ^3H label was detected in glycerophosphate (data not shown) (Table 3). These data, however, do not rule out the possibilities that (i) the fatty acid in position-2 was hydrolyzed and then reesterified in the same position, and (ii) that position-1 may at the end have contained fatty acids other than linoleic acid.

Distribution of labels in lipids and lipoprotein. The fate of the choline and FA moieties was somewhat different in terms of the distribution of the isotopes among the lipoprotein fractions (Fig. 3). Incorporation of ^3H radioactivity (Fig. 3, panels A-C) into VLDL was somewhat delayed and did not correlate with the incorporation of radioactivity into other lipoproteins. The FA radioactivity appeared, instead, almost immediately in VLDL, later in LDL and, particularly, HDL (panels D-F). The incorporation of both isotopes into LDL was progressive, reaching a maximum at 120 h, whereas the time courses of ^3H and ^{14}C radioactivity in HDL followed the same pattern as it did in plasma. The patterns of $^3H/^{14}C$ isotope ratios in the different lipoproteins over time (not shown) indicated that [^3H]choline was retained longer than the FA label. The VLDL $^3H/^{14}C$ ratio rose in fact constantly, from a value of about 0.2 to a value of 9 at 120 h, indicating that the progressive loss of ^{14}C label over time gave rise to particles relatively enriched in ^3H. A similar pattern was observed in HDL, with a rise of the ratio up to a value of about 6.5, whereas in LDL the ratios of the choline and FA radioactivities did not differ appreciably for the entire period under investigation from the $^3H/^{14}C$ ratio in the DLPC administered.

The distribution of the ^3H label among lipoprotein fractions (Fig. 4, panel A) changed over time: from a value of 47% in HDL, 35% in LDL, and 18% in VLDL and chylomicrons at the earliest time period up to about 60% in HDL, with a concomitant decline to 8% in VLDL at 16 h, and then remaining constant at around 10% thereafter. Analyses of the incorporation of [^3H]choline into individual lipid classes of plasma revealed that, as expected, [^3H]choline incorporation did not occur into lipid classes (*e.g.*, triglycerides, cholesteryl esters) other than phospholipids with incorporation of label into PC ranging from 73% at 4 h to 65% at 120 h (not shown) with respect to that in total PL (Table 4).

The percentage distribution of the ^{14}C label in lipoproteins (Fig. 4, panel B) showed a marked early incorporation into VLDL, followed by a rapid decline, consistent with the rapid catabolism of these lipoproteins (19). The isotope was readily incorporated into HDL and progressively into LDL. This metabolic behavior was confirmed by measuring the percentage distribution of the ^{14}C isotope into the different lipid classes of the three major lipoproteins (Fig. 5). Whereas the radioactivity in VLDL was found mainly in TG, [^{14}C]PC were the major labeled components of HDL and LDL. In both, PL radioactivity tended to decline slowly, with a progressive rise of CE labeling, particularly in LDL.

The $^3H/^{14}C$ ratios in plasma total PL and PC (Fig. 6) rose progressively, from an initial value of around 3 up to values of 30 and 40, respectively, which are far higher than those observed in total plasma lipids (Fig. 2). The faster increase of this ratio in total PL, as compared to that in PC, is due to the presence of LPC (containing only ^3H) in the former.

In RBC, a progressive accumulation of ^3H radioactivity in total lipids (TL) occurred over time, with a plateau

after 48 h (Fig. 7, panel A). Values are expressed as dpm/mg of total lipids, corresponding to about 2.2×10^9 cells, as determined after the extraction of lipids from a known number of cells. The accumulation of ^{3}H in PC (panel B), measured as dpm in the fraction per mg of total RBC lipids, followed up to 48 h a trend similar to that in TL and in PL (not shown). A significant incorporation, progressively increasing with time up to 120 h, was detected in LPC (panel C).

The accumulation of the ^{14}C label in RBC total lipids (Fig. 7, panel D) was far more rapid, with a peak at 12 h, followed by a progressive decline, similar to that observed for ^{14}C in whole plasma. Incorporation of ^{14}C label in PC (not shown) followed a pattern which was superimposable over that of FA in total lipids. Accumulation of both isotopes in RBC occurred mainly in PL with a pattern very similar to that observed in total lipids (data not shown). Both isotopes essentially plateaued after 48 h, while radioactivity was still detectable 60 d after administration. The observed initial ^{3}H/^{14}C ratio in RBC lipids, that was far higher (about 3.7) than in plasma lipids (about 1.3) (Fig. 2) and in the administered DLPC, suggests an early incorporation of lyso products into RBC membranes.

DISCUSSION

The fate of orally administered PC has previously been investigated in experimental animals (9,10,21,22) and in humans (6–8). Only a small portion of PC is taken up as intact molecule and up to 50% of the LPC formed is re-esterified after absorption (8). The final water-soluble products, including *sn*-glycero-3-phosphocholine, glycerophosphate, glycerol and LPC can be absorbed *via* the portal route (10); LPC can also be reacylated in the mucosal cells by acyltransferases (22).

All information available on the fate of PC in humans, in particular of dilinoleoyl PC, has been derived from orally administered, randomly labeled PC species with FA label being associated with both the 1 and 2 positions (6–8). The labeled FA can readily be cleaved by various lipase-type activities at the absorption site or in the circulation (23). Fatty acids cleaved from position-2 are utilized for cholesterol esterification by way of lecithin-cholesterol acyltransferase (LCAT) (24), as well as for TG synthesis (10). Dilution with unlabeled linoleic acid is likely to occur at the 2 position, when the LPC produced is reacylated. However, no quantitative data are available to estimate the rate of this replacement. In previous investigations,

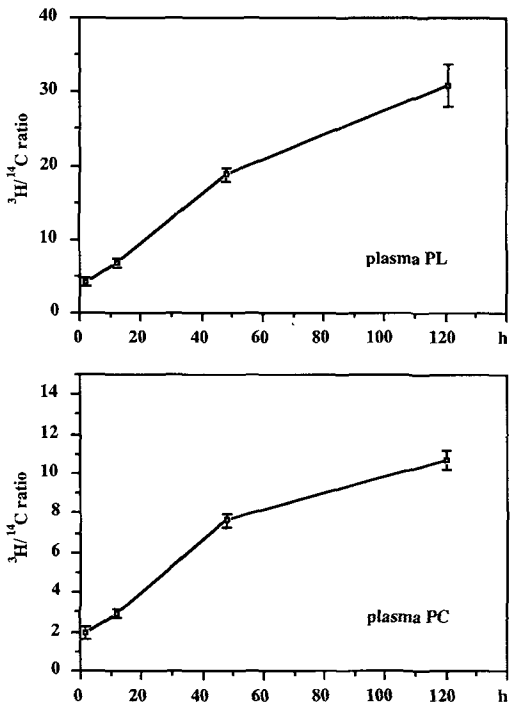

FIG. 6. $^3H/^{14}C$ ratios for plasma phospholipids (PL) and phosphatidylcholine (PC). Means ± SEM.

the extent and site of fatty acid hydrolysis/re-esterification could not be defined. Changes in $^3H/^{14}C$ ratio in blood following administration of DLPC labeled in both the 1 and 2 acyl moieties could result from FA loss from either position. After an oral dose of such a substrate, the $^3H/^{14}C$ ratios rose for several hours (8). Animal experiments, by contrast, strongly suggest that hydrolysis at the 2 position occurs preferentially in the intestinal lumen, due to the selective activity of pancreatic phospholipase A_2 (10,21,25).

In the present study, it was observed that the radioactivity in plasma maintained for many hours a $^3H/^{14}C$ ratio close to that of the product administered, an indication that the labeled FA remained in position-2 far longer than has been described for the 1 and 2 positions combined in previous studies (6–8). We did not determine, however, whether linoleate was retained in the 1 position.

The stability of the molecule was particularly evident in LDL. The exclusive association of FA radioactivity with the 2 position, as determined by selective hydrolysis with PLA_2, does not exclude the removal of the labeled FA; it indicates, however, that the ^{14}C label upon hydrolysis was not reintroduced into the 1 position. The data are therefore consistent with either a lack of hydrolysis in position-2 during intestinal absorption, contrary to what was found in animal experiments (10,21,22,25), or with hydrolysis followed by re-incorporation of the isotope-labeled FA into the same position. In view of the very low endogenous pool of free linoleic acid in the intestinal mucosal cells (26), recycling of the exogenous labeled FA cannot be excluded. In the present study, however, some incorporation of [^{14}C]FA released from PC into TG did occur as clearly shown by the relatively high proportion of total ^{14}C radioactivity in VLDL-TG. Recently, Ikeda *et al.* (27) suggested that more than 80% of PC, recovered from the intestinal lymph of rats after oral administration of the product labeled in the choline moiety, was still intact.

Since an earlier study using PC labeled in the 1 and 2 FA moieties found a relatively rapid decline of FA associated radioactivity both in plasma and in RBC (8), our experiment was originally set up for 144 h only. Surprisingly, ^3H and ^{14}C radioactivity was retained in plasma lipids far longer than predicted, and an appreciable

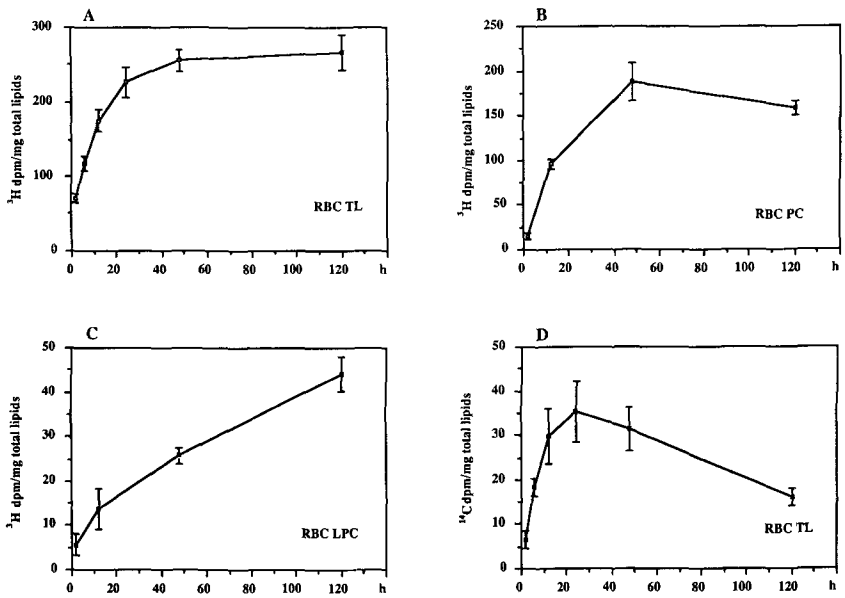

FIG. 7. ^3H and ^{14}C incorporation into total lipids of red blood cells (RBC), expressed as dpm/mg of total lipids (TL) over time. means ± SEM.

amount of labeling was found even 60 d after administration.

The fate of absorbed PC can be related to the incorporation into selected lipoproteins, followed by catabolism in plasma (28), or to transfer/exchange processes mediated in plasma by the lipid transfer protein-I and II (LTP-I and II) systems (29). The rapid incorporation of ^{14}C into VLDL-TG suggests an early partial degradation of PC. HDL ^{14}C-labeled PL showed a slow disappearance, with a concomitant rise in [^{14}C]CE, resulting from cholesterol esterification *via* LCAT; transfer of HDL cholesterol to LDL would then be accomplished by LTP-I (30).

The ^{14}C distribution pattern in the different lipid classes of the three major lipoproteins (Fig. 5) supports the hypothesis of a transfer of surface PL from small chylomicrons to HDL, which show the highest relative [^{14}C]PL radioactivity. The behavior of the isotopes in LDL and HDL does not seem to bear a close relationship with that of VLDL associated radioactivity. In LDL, both ^{14}C and ^{3}H decline slowly, with a stable $^{3}H/^{14}C$ ratio, very close to that of the compound administered, thus supporting the hypothesis by Williams *et al.* (5) that PC may constitute a relatively stable portion of these lipoproteins. About 50% of the total ^{3}H radioactivity at 120 h was associated with the LDL fraction and, in this fraction, the $^{3}H/^{14}C$ ratio was the same as in the original PC. Calculations of the relative specific activity of PC in LDL *vs.* that of the PC administered indicate that exogenous PC constituted about 1.5% of LDL-PC at the peak plasma concentration, after a single oral dose of 750 mg.

Finally, radioactivity was progressively incorporated into RBC lipids, with choline radioactivity still plateauing 120 h after administration. The $^{3}H/^{14}C$ ratios in RBC rose at a much slower rate than in plasma lipids for the first 40 h, thus suggesting minimal FA hydrolysis.

Taken together, the observations support the conclusion that dilinoleoyl PC is retained in plasma unchanged for a substantial period of time. However, some hydrolysis gives rise to the transfer of LPC to RBC membranes, while most of the intact molecule tends to become associated with LDL. At the earliest time points, a portion of ^{14}C radioactivity was also present in VLDL-TG. The observed long-lasting association of PC with LDL is of interest because of the well-known role of LDL in cellular cholesterol homeostasis and in the receptor mediated delivery of polyunsaturated fatty acids to cells (31), findings which tend to support the early hypothesis by Friedman *et al.* (32) that PC is not just a short-lived circulating molecule.

ACKNOWLEDGMENTS

We thank Giuseppe Conte (Nattermann GmbH) for providing DLPC and for his encouragement and support. This study was supported in part by the Consiglio Nazionale delle Ricerche of Italy.

Reduction in Triacylglycerol Levels by Fish Oil Correlates with Free Fatty Acid Levels in *ad libitum* Fed Rats

David A. Otto*, Janet K. Baltzell[1] and Joseph T. Wooten
Department of Research, The Baptist Medical Centers, Birmingham, Alabama 35211

Rats were fed (for 2 or 6 wk) purified diets containing lard (LD) or menhaden oil (MO) at two levels of dietary fat, *i.e.*, at 11.5 and 20.8% of energy in the low fat (LF) and the medium fat (MF) diets, respectively. Following the diet period, rats were sacrificed after either an overnight fast or after uninterrupted *ad libitum* feeding. The studies were designed to investigate the dependence of our previously reported effects of MO, *i.e.* the reduction of plasma free fatty acid (FFA) levels and accumulation of hepatic triacylglycerols, on the dietary fat concentration and the nutritional state of the animal at the time of sacrifice. Reductions in plasma triacylglycerol and cholesterol levels in MO-fed relative to LD-fed rats were observed under all conditions. FFA levels were consistently reduced by MO-feeding at both dietary fat concentrations, but only when blood was sampled from *ad libitum* fed rats. Under these conditions there was a significant positive relationship between plasma FFA and triacylglycerol concentrations. Reduction in plasma FFA levels may be an additional mechanism associated with the triacylglycerol-lowering effect of fish oil (FO). The LF and MF MO diets caused a rise in plasma glucose levels with no significant change in insulin concentration, indicating that the reduction of FFA by MO was not related to changes in insulin concentration or insulin sensitivity. The MO diets had no effect on skeletal muscle or epididymal adipose tissue lipoprotein lipase activity, demonstrating that catabolism of triacylglycerol-rich lipoproteins contributes little, if any, to the MO-dependent reductions of plasma triacylglycerol and FFA. The previously reported accumulation of hepatic triacylglycerols after high fat (HF; 30% of energy) MO-feeding was not observed with the LF or MF MO diets, suggesting that the apparent direct inhibition of triacylglycerol secretion by FO imposes a rate-limitation only when feeding HF diets.
***Lipids* 27, 1013–1017 (1992).**

In earlier studies (1,2) we observed significant but inconsistent reductions in plasma free fatty acid (FFA) levels in fish oil (FO)-fed, overnight fasted rats. An effect on plasma FFA by FO was also observed by Singer *et al.* (3), who reported that dietary ω3 polyunsaturated fatty acid (n-3 fatty acids) supplementation in hyperlipidemic patients resulted in a marked decrease in FFA during a standard glucose tolerance test that was associated with a decline in serum triacylglycerol levels. The authors (3) suggested that the decrease in FFA indicated reduced lipolysis and that it might contribute to the triacylglycerol-lowering effect of n-3 fatty acids. We and others also demonstrated a decrease in adipose tissue mass in FO-fed rats (2,4,5) that was accompanied by a decrease in adipocyte volume without a decrease in fat cell number (4,5). Additionally, we found that this decrease in adipose tissue mass was positively correlated with the FO-mediated changes in plasma FFA (2), suggesting a causal relationship. Since a reduction of plasma FFA may reflect an important mechanism involved in FO-mediated effects, we investigated why this effect of FO has not been routinely observed in the numerous studies conducted with dietary FO. Specifically, we considered whether observing a reduction in plasma FFA levels was dependent upon the concentration of dietary n-3 fatty acids or the nutritional state (overnight fasted *vs. ad libitum* fed rats) of the animals at the time of sacrifice. We also investigated the relationship between plasma FFA and the lowering of plasma triacylglycerol levels by FO. A preliminary account of this work has been presented (6).

MATERIALS AND METHODS

Experimental design and diets. Male Sprague-Dawley rats (225–250 g; VAF/Plus, Charles River Laboratories, Inc., Raleigh, NC) were housed in suspended transparent polycarbonate cages with stainless steel wire bottoms in an animal facility maintained at 22 ± 1°C, 70% humidity and with a 12-h light/dark cycle. Rats were acclimated to the surroundings and fed a standard AIN-76A purified diet (7) (Table 1, low fat diet with corn oil as the fat source; Research Diets, Inc., New Brunswick, NJ) for 1 wk. Animals had free access to deionized water.

Following the acclimation period, rats were matched for weight and assigned to respective groups (6 rats/group), based on the diet, the length of feeding, and the nutritional state of the animal at sacrifice. Rats were assigned to one of four diet groups. These included low fat (LF; 11.5% of energy) and medium fat (MF; 20.8% of energy) diets, prepared with either lard (LD) or menhaden oil (MO; vacuum stripped MO provided by the National Institutes of Health, Bethesda, MD) as the major fat source (Tables 1 and 2). All diets contained a minimum of 4% of energy from corn oil (CO) to prevent essential fatty acid deficiency. Thus, LD and MO provided 7.5 and 16.8% of energy in the LF and MF diets, respectively. The purified diets were based on the AIN-76A diet (7) and contained identical ingredients except for the source of fat. In the MF diets, the additional fat energy was balanced by an isocaloric reduction in carbohydrate (sucrose/corn starch, 2:1, w/w). Therefore, the nutrient (protein, vitamins and minerals)/energy (g/kJ) ratios were the same in all diets. As in our previous studies (1,2), the diets were also balanced for cholesterol (8.96 mg/1000 kJ) and β-sitosterol (76.8 mg/1000 kJ) relative to the energy content of the diets, and for the antioxidant content (α- and γ-tocopherols, and *tert*-butylhydroquinone; 1.5, 1.2 and 0.2 mg/g fat) relative to the amount of fat in the diets. The importance of including antioxidants in the diets is emphasized by a recent report by Haglund *et al.* (8) indicating that an FO diet rich in vitamin E (1.5 IU/g fat) had a greater triacylglycerol-lowering effect than one with only 0.3 IU/g. Our diets

Choline bitartrate	2.0	0.0	2.1	0.0

[a]Diets were based on the AIN-76A diet. Medium fat diets were prepared by isocaloric substitution of fat for carbohydrate; thus the nutrient (protein, vitamins and minerals)/kJ ratios were unchanged from the low fat diet. The energy contents of the respective diets were 16.4 and 17.3 kJ/g for the low and medium fat diets.

[b]All diets contained a minimum of 4% of energy from corn oil to prevent essential fatty acid deficiency. The remaining fat energy was supplied by either lard or menhaden oil. Thus, lard and menhaden oil provided 7.5 and 16.8% of energy in the low and medium fat diets, respectively. Menhaden oil was provided by the Fish Oil Test Materials Program of the National Institutes of Health.

[c]Salt mix (in g/kg of mixture) calcium phosphate, dibasic, 500; magnesium oxide, 24; potassium citrate, monohydrate, 220; potassium sulfate, 52; sodium chloride, 74; chromium potassium sulfate, 0.55; cupric carbonate, 0.3; potassium iodate, 0.01; ferric citrate, 6.0; manganous carbonate, 3.5; sodium selenite, 0.01; zinc carbonate, 1.6; sucrose, 118.03.

contained approximately 1.4 IU of vitamin E/g fat along with *tert*-butylhydroquinone. The MO diets were prepared in our laboratory by addition of MO to a basal diet as previously described (1,9). All other diets were custom-prepared by a commercial vendor (Research Diets, Inc.). Diet cups were placed in the cages such that the diets were not exposed to direct light. All diets were replaced every third or fourth day (9).

Rats were fed one of the four diets for 2 wk (12 rats/diet group) or 6 wk (6 rats/diet group). At the end of the feeding period, half of the animals from each group were sacrificed in the morning after uninterrupted *ad libitum* feeding. The other half were sacrificed after an overnight fast. The data from 6 wk fed rats are presented in the text only when relevant to the discussion.

Plasma and tissue collection. At the time of sacrifice, rats were anesthetized with pentobarbital (5 mg/100 g body wt). Blood was drawn from the abdominal aorta into a syringe containing 0.25 mL of 0.2 M ethylene diaminetetraacetic acid, pH 7.4, and plasma was collected by centrifugation at 500 × *g* (4°C) for 20 min. Immediately after drawing blood, livers were rapidly removed, weighed and freeze-clamped with aluminum tongs precooled in liquid nitrogen (10). The thin layer of frozen liver tissue was later ground into a fine powder under liquid nitrogen. Soleus muscles and epididymal fat pads were collected, weighed and immediately frozen by dropping into liquid nitrogen. All samples were stored at −80°C until assayed.

Analytical procedures. Plasma triacylglycerol, cholesterol and glucose were measured using Baker kits with the Encore Chemistry System centrifugal analyzer (Baker Instruments Corp., Allentown, PA). The assay for FFA (Amano International Enzyme kit reagents, Troy, VA) was adapted for use on the Encore chemistry System (1). Plasma insulin was determined by radioimmunoassay using a commercial kit (Ciba Corning Diagnostics Corp., Medfield, MA).

Liver triacylglycerol was extracted and assayed as previously reported (1). Soleus muscle and epididymal adipose tissue lipoprotein lipase (LPL) activities were measured as described earlier (2).

Statistical analysis. Statistical differences between LD and MO diet groups were determined by the Student's *t*-test. Correlation between measured parameters was determined by least squares regression analysis. All statistical analyses were performed utilizing the SYSTAT statistical software package (SYSTAT, Inc., Evanston, IL).

RESULTS AND DISCUSSION

Plasma triacylglycerol, cholesterol and free fatty acids. The reduction in plasma triacylglycerol and cholesterol levels in MO-fed relative to LD-fed rats was observed consistently under all conditions of dietary fat concentration and nutritional state (Table 3). In this study we considered whether the normal rise in plasma FFA that occurs with fasting might sometimes mask effects of FO on FFA, and thus, explain the inconsistencies of our previous observations with overnight fasted rats (1). After 2 wk of feeding, a significant decrease in plasma FFA was observed in the MO- *vs.* LD-*ad libitum* fed rats at both fat concentrations. In contrast, after an overnight fast, FFA were reduced

TABLE 3

Plasma Metabolites from *ad libitum* Fed and Overnight Fasted Rats[a]

Nutritional state	Diets: Fat concentration	Diets: Fat source	Triacylglycerols (mM)	Cholesterol (mM)	Free fatty acids (μM)	Glucose (mM)	Insulin (μU/mL)
ad libitum Fed	Low fat	LD	3.35 ± 0.11	2.40 ± 0.18	316 ± 35	8.9 ± 0.4	70 ± 8
		MO	1.25 ± 0.20[b]	1.86 ± 0.13[b]	207 ± 21[b]	10.4 ± 0.3[b]	65 ± 6

		MO	1.74 ± 0.07[b]	1.47 ± 0.16[b]	168 ± 16[b]	9.9 ± 0.2[b]	75 ± 8
Overnight fasted	Low fat	LD	1.90 ± 0.21	1.78 ± 0.13	418 ± 41	8.1 ± 0.2	66 ± 6
		MO	0.69 ± 0.06[b]	1.60 ± 0.16	410 ± 36	8.7 ± 0.6	47 ± 8
	Medium fat	LD	1.44 ± 0.12	1.99 ± 0.18	499 ± 52	5.9 ± 0.3	56 ± 4
		MO	0.78 ± 0.06[b]	1.29 ± 0.08[b]	343 ± 18[b]	8.2 ± 0.7[b]	44 ± 3

[a]Rats were fed the respective diets for 2 wk before sacrifice. Values are the mean ± SE (n = 6). Abbreviations: MO, menhaden oil; LD, lard.
[b]Significant difference between MO- and LD-fed animals, $P < 0.05$.

only in the MF MO group. After 6 wk this effect was again significant in *ad libitum* fed rats (with LF diets, 429 ± 54 *vs.* 186 ± 23 μM FFA; and with MF diets, 338 ± 92 *vs.* 176 ± 21 in LD-fed and MO-fed rats, respectively) but not seen at all in the overnight fasted rats (with LF diets, 406 ± 13 *vs.* 410 ± 38; and with MF diets, 463 ± 45 *vs.* 413 ± 53 in LD-fed and MO-fed rats, respectively). In our earlier study (1) we made similar observations with high fat (HF) diets (30% of energy; identical to diets described in Table 1 with an isocaloric substitution of fat for carbohydrate). After uninterrupted *ad libitum* feeding of HF CO, LD and MO diets for 2 wk, FFA were significantly reduced in the MO-fed rats relative to the CO- and LD-fed rats (435 ± 34, 448 ± 68 and 201 ± 43 μM in CO-, LD- and MO-fed rats, respectively; $P < 0.05$; data from *ad libitum* fed rats were not previously reported). However, like the LF- and MF-fed rats after an overnight fast, there were no differences between the three HF diet groups (351 ± 28, 392 ± 102 and 377 ± 83 μM in CO-, LD- and MO-fed rats, respectively). Thus, the data clearly demonstrate that blood must be sampled in the fed state in order to consistently observe the effects of dietary FO on plasma FFA.

There was a highly significant correlation between plasma triacylglycerol and FFA levels in *ad libitum* fed rats (Fig. 1; data from Table 3). We also observed this with *ad libitum* fed rats receiving HF diets [r = 0.74, $P < 0.006$, n = 12; from the experiment of (1), but data not previously shown]. These data strongly suggest that along with other mechanisms, the lowering of plasma FFA levels by FO-feeding may contribute significantly to the decrease in plasma triacylglycerols by decreasing the supply of substrate for hepatic triacylglycerol synthesis. This is consistent with the recent report of Singer *et al.* (3) and focuses attention to possible effects of dietary FO on adipose tissue lipolysis, as has been observed by Parrish *et al.* (5).

Plasma insulin and glucose. We previously reported that feeding HF MO diets followed by an overnight fast resulted in a reduction in plasma insulin levels with an accompanying reduction or no change in plasma glucose levels (1,2). This is consistent with an improvement in peripheral insulin sensitivity. In the present experiment with the LF and MF MO diets, insulin levels were only

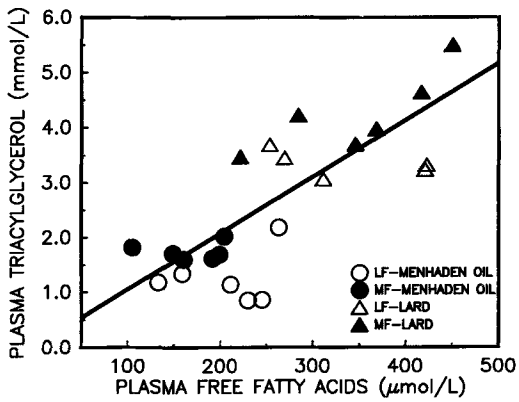

FIG. 1. Correlation between plasma free fatty acids and plasma triacylglycerols from *ad libitum* fed rats [data from Table 3; for all data, r = 0.71, $P < 0.001$, n = 23; for low fat (LF) diets, r = 0.68, $P = 0.022$, n = 11; and for medium fat (MF) diets, r = 0.92, $P < 0.001$, n = 12].

slightly lowered or unchanged relative to those in LD-fed rats (Table 3; approaching significance only in overnight fasted rats adapted to the LF or MF MO diets, $P = 0.074$ and 0.059, respectively). Under these conditions, plasma glucose was generally elevated (Table 3). The rise in glucose may have been in response to the slight reductions in plasma insulin levels, but it is also possible that insulin sensitivity (peripheral or hepatic) actually worsened with LF and MF MO-feeding. The data clearly show that the lower plasma FFA levels seen with MO-feeding at all concentrations cannot be explained by either an increase in insulin concentration or improved insulin sensitivity at the site of the adipose tissue.

LPL and adipose tissue mass. Unlike our earlier study (2) in which we observed a significant elevation of soleus muscle LPL in HF MO-fed rats, feeding LF and MF MO diets had no effect on soleus muscle or epididymal adipose tissue LPL activities from rats sacrificed in either the fed or overnight fasted state (data not shown). Since these diets did cause significant reductions in plasma triacylglycerol and FFA levels (Table 3), it is unlikely that regulation of these enzyme activities contributes significantly

TABLE 4

Liver Weight and Triacylglycerol from *ad libitum* Fed and Overnight Fasted Rats[a]

Nutritional state	Diets: Fat concentration	Diets: Fat source	Liver weight: (g)	Liver weight: /Body weight (× 100)	Liver triacylglycerols (μmol•liver^{-1})
ad libitum Fed	Low fat	LD	16.8 ± 0.7	4.3 ± 0.1	429 ± 61
		MO	16.4 ± 0.5	4.2 ± 0.1	259 ± 37[b]
	Medium fat	LD	17.9 ± 0.3	4.4 ± 0.1	673 ± 111
		MO	18.4 ± 0.4	4.6 ± 0.1[b]	411 ± 51[b]
Overnight fasted	Low fat	LD	13.0 ± 0.7	3.4 ± 0.1	250 ± 35
		MO	13.1 ± 0.8	3.4 ± 0.2	254 ± 37
	Medium fat	LD	11.3 ± 0.6	2.9 ± 0.1	342 ± 67
		MO	13.3 ± 0.4[b]	3.4 ± 0.1[b]	270 ± 33

[a]Rats were fed the respective diets for 2 wk before sacrifice. Values are the mean ± SE (n = 6). MO, menhaden oil; LD, lard.
[b]Significant difference between MO- and LD-fed animals, $P < 0.05$.

to either of these effects of FO, at least at the FO concentrations used in this study. Although not statistically significant, there was a tendency for the LF and MF MO-fed rats (both *ad libitum* fed and overnight fasted) to have reduced epididymal adipose tissue wt/body wt ratios (not shown) as observed previously by us (2; with HF diets) and others (4,5). In our earlier study we demonstrated that this reduction in adipose tissue mass was positively correlated with the FO-dependent decrease in FFA levels. It is, thus, reasonable to propose that the reduction in FFA is linked to the decrease in adipose tissue mass. Parrish *et al.* (5) reported that the decrease in adipose tissue mass was accompanied by a decrease in lipoprotein binding and basal lipolysis in epididymal adipocytes, and an increase in hormone-stimulated lipolysis in both epididymal and perirenal adipocytes. These effects together with the hypotriglyceridemic effect of FO could explain the decrease in adipose tissue mass and the related decrease in plasma FFA.

Liver weight and triacylglycerol levels. In our earlier study (1), we observed that feeding HF MO diets caused significant hepatomegaly that was due entirely to hypertrophy. The current study demonstrates that this effect of FO, which is reflected in an increase in the liver wt/body wt ratio was also observed in the MF, but not the LF diet groups regardless of the nutritional state of the rats at sacrifice (Table 4). We (1) and others (11) have suggested that the hepatomegaly is related to peroxisomal proliferation induced by FO-feeding.

We also reported earlier (1) that there was an elevation in liver triacylglycerols caused by HF MO-feeding concomitant with the lowering of plasma triacylglycerol levels, suggesting a primary inhibition of hepatic triacylglycerol secretion by MO, independent of triacylglycerol synthesis. Our suggestion is supported by the recent *in vitro* experiment by Lang and Davis (12) indicating that eicosapentaenoic acid and docosahexaenoic acid decreased the secretion of both triacylglycerols and apo B by cultured rat hepatocytes independent of their synthesis, but only at the highest concentration tested (1 mM fatty acid/0.13 mM albumin). Consistent with this, we did not see an accumulation of liver triacylglycerols after feeding rats LF or MF diets (Table 4). In fact, there was a significant reduction in liver triacylglycerol levels in MO-fed rats (Table 4; *ad libitum* fed only) under these dietary conditions, resulting in a highly significant relationship between the plasma and liver triacylglycerol concentrations (data from Tables 3 and 4; r = 0.71, $P < 0.001$, n = 24). Thus, our data suggest that very low density lipoprotein secretion *per se* may be rate-limiting, but only with HF diets when the supply of exogenous FFA may exceed the capacity of the liver to dispose of them. With the MF and LF diets, the rate of hepatic triacylglycerol synthesis appears to limit secretion.

Conclusion. The present study offers an explanation for the apparent variable response of plasma FFA to feeding dietary FO. Our data indicate that this is due to the nutritional state of the animal at the time of blood sampling. The FO-induced reduction of plasma FFA was consistently observed in *ad libitum* fed animals at all fat levels (LF, MF and HF), resulting in a strong positive relationship between plasma FFA and triacylglycerols. This strongly suggests that lowered plasma FFA levels by FO-feeding may play a significant role in the triacylglycerol-lowering effects by limiting the availability of substrate for hepatic triacylglycerol synthesis. We have shown that the reduction in FFA levels by MO-feeding was not related to changes in the insulin concentration or insulin sensitivity. The previously observed effect of the HF MO diet on skeletal muscle LPL was not seen with the LF or MF diets, suggesting that catabolism of triacylglycerol-rich lipoproteins contributes little, if any, to the FO-dependent reductions of plasma triacylglycerols or FFA. The current study indicates that the apparent direct inhibition of triacylglycerol secretion by FO (1) imposes a rate-limitation only when feeding HF diets. At the lower fat concentrations, hepatic triacylglycerol synthesis appears to limit secretion.

Borage or Primrose Oil Added to Standardized Diets Are Equivalent Sources for γ-Linolenic Acid in Rats

D. Raederstorff* and **U. Moser**
F. Hoffmann-La Roche Ltd., Department of Vitamin and Nutrition Research, CH-4002 Basel, Switzerland

The aim of this study was to evaluate the effect of different doses and sources of dietary γ-linolenic acid (GLA) on the tissue phospholipid fatty acid composition. Rats fed four different levels of GLA (2.3, 4.6, 6.4 and 16.2 g of GLA/kg diet) in the form of either borage oil or evening primrose oil during 6 wk were compared with animals fed corn oil. The levels of dihomo-γ-linolenic acid (DHLA) and GLA showed a significant dose-related increase in liver, erythrocyte and aorta phospholipids. Moreover, the arachidonic acid/DHLA ratios in tissues decreased with increasing intake of dietary GLA. There was no significant difference in tissue GLA and DHLA levels within groups given equal amounts of dietary GLA either as borage oil or evening primrose oil. The amount of dietary GLA administered did not significantly influence prostaglandin E_2 production in stimulated aortic rings and thromboxane B_2 levels in serum; however, an increase in prostaglandin E_1 derived from DHLA was observed in the supernatants of stimulated aorta.
Lipids 27, 1018–1023 (1992).

γ-Linolenic acid (GLA), an essential fatty acid (EFA) of the n-6 series, is synthesized from dietary linoleic acid (LA) by Δ6 desaturation, which is rate-limiting, and then is rapidly elongated to dihomo-γ-linolenic acid (DHLA) (1). A breakdown in this regulation has been associated with various disease states, including diabetes, atopic eczema, premenstrual syndrome, and coronary heart disease (2–10). In fact, several clinical studies have demonstrated improvement in patients with atopic eczema after administration of GLA-rich oil (11–15). DHLA is the precursor of prostaglandin E_1 (PGE_1), which has potent vasodilatory, anti-aggregatory and anti-inflammatory properties (16–21). In addition, DHLA can be metabolized to 15-hydroxy-eicosatrienoic acid, a potent inhibitor of lipoxygenase (22–24). DHLA also competes with arachidonic acid (AA) in various oxidative processes catalyzed by lipoxygenases and cyclooxygenases and thus can ameliorate the potential deleterious effect of elevated proinflammatory AA metabolites. GLA and DHLA may therefore be useful to correct for abnormalities in EFA metabolism and/or imbalanced eicosanoid formation (2). Seeds of borage, evening primrose and black currant plants contain relatively large amounts of GLA. Several studies have shown that the application of GLA-rich oils results in the accumulation of GLA and its metabolite DHLA in tissue phospholipids (25–35). In previous studies, GLA-containing oils have been compared by feeding equal amounts of fat but different amounts of GLA (36,37). In one study, the amount of GLA was kept constant in all groups, but the total amount of fat varied between 1.6% of the diet (BO) to 4.5% of the diet (EPO); however, with GLA-containing oils being the only fat source, this led to considerable variations in linoleic acid levels in the diet (38).

The aim of the present study was to investigate the effect of the dose and source of GLA on the fatty acid composition of liver, erythrocytes and aorta and on prostanoid formation in stimulated aorta in animals fed equal amounts of fat and GLA.

MATERIALS AND METHODS

Animal treatment. Male albino SPF rats, weighing about 200 g and maintained on a standard pelleted diet, were randomly divided into seven groups. The rats were fed a fat-free diet, SODI2007, obtained from Klibamühle (Kaiseraugst, Switzerland) containing one of the following dietary lipids: (i) 7% (wt/wt) corn oil (CO); (ii) 7% borage oil providing 16.2 g of GLA/kg diet; (iii) 7% evening primrose oil (6.4 g of GLA/kg diet); (iv) 2% BO plus 5% CO (4.6 g of GLA/kg diet); (v) 5% EPO plus 2% CO (4.6 g of GLA/kg diet); (vi) 1% BO plus 6% CO (2.3 g of GLA/kg diet); (vii) 2.5% EPO plus 4.5% CO (2.3 g of GLA/kg diet). The fatty acid compositions of the dietary oils are shown in Table 1. The experimental diets were freshly prepared every two weeks and stored in tightly sealed plastic bags at −20°C. The rats were allowed free access to water and diet, and they were maintained on a 12-h light-dark cycle. Food intake was measured daily. After 6 wk, 1 mL of blood was taken by retroorbital puncture. Blood samples were allowed to clot by incubating at 37°C for 30 min, and serum was obtained to measure the production of thromboxane B_2 (TXB_2). The animals were sacrificed by withdrawing blood from the abdominal aorta under halothane anesthesia. Blood was collected into tubes containing heparin as an anticoagulant. The

Abbreviations: AA, arachidonic acid, 20:4n-6; BO, borage oil; CO, corn oil; DHA, docosahexaenoic acid, 22:6n-3; DHLA, dihomo-γ-linolenic acid, 20:3n-6; DPA, docosapentaenoic acid, 22:5n-3; EFA, essential fatty acid; EPO, evening primrose oil; GLA, γ-linolenic acid, 18:3n-6; HBSS, Hank's balanced salt solution; LA, linoleic acid, 18:2n-6; PGE_2, prostaglandin E_2; PGE_1, prostaglandin E_1; PUFA, polyunsaturated fatty acid(s); TXB_2, thromboxane B_2.

thoracic aorta was rapidly excised, cleared of the adhering tissues and rinsed in Hank's balanced salt solution (HBSS) to remove the blood. The aorta was then cut into rings, incubated and stimulated in 1 mL of HBSS containing 10 μM ionophore A23187 (Sigma Chemical Co., St. Louis, MO) for 5 min at 37°C, in duplicate for each animal. After centrifugation, the supernatants were removed and stored at −70°C until analyzed for prostaglandin E_2 (PGE_2) and PGE_1. The segments were blotted dry and weighed. The remaining material was stored at −70°C for fatty acid analysis. The liver was excised, quickly frozen in liquid N_2, and stored at −70°C until analyzed.

Lipid extraction and analysis. The organs were powdered in liquid nitrogen and the tissues were extracted by the method of Bligh and Dyer (39). Phospholipids were separated from total lipids by solid phase extraction with silica Bond Elut (500 mg) columns (Analytichem International, Harbor City, CA) according to the method of Hamilton and Comai (40). The fatty acids of total phospholipids were transesterified and analyzed by capillary gas chromatography on an OV-1 column as previously described (41). A standard mixture of fatty acid methyl esters was used to establish the response factors for the components identified. The fatty acids were quantified using heptadecanoic acid as internal standard. After correction for the various response factors, the amount of each fatty acid was calculated as mole percentage of the identified fatty acid peaks, which represent more than 98% of the integrated area (41).

Prostanoid analysis. Thromboxane B_2 (TXB_2) was measured using an [^{3}H]TXB_2 radioimmunoassay kit (NEK-007, New England Nuclear, Boston, MA). Serum was diluted about five hundred times with 50 mM phosphate buffer at pH 7.3, containing 0.1% gelatin. The results were expressed as ng/mL serum. PGE_2 and PGE_1 *ex vivo* synthesis was determined in the supernatants of stimulated aorta by radioimmunoassay (42). PGE_2 produced during the incubation of the thoracic aorta was analyzed using an [^{125}I]PGE_2 radioimmunoassay kit (NEK-020, New England Nuclear). The cross reactivity of the antiserum was 100% for PGE_2, 3.7% for PGE_1 and less than 0.4% for other prostaglandins. PGE_1 was measured with an antibody obtained from Pasteur Diagnostica (Marnes La-Coquette, France). Tritiated PGE_1 (NET 344, 60 Ci/mmol) was obtained from New England Nuclear, unlabeled PGE_1 from Medipro (Teufen, Switzerland). The cross-reactivity of the PGE_1 antibody was 15% against PGE_2 and less than 0.2% against other prostaglandins. The data obtained were corrected for the 15% cross reactivity of the antibody with PGE_2. The results were expressed as pg/mg aorta tissue. The measurements were in the linear portion of the standard curve.

Statistical analysis. All data are expressed as means ± SEM for animals in each diet group, with n being the number of rats. Statistical significance of mean differences between dietary groups was established by one-way analysis of variance. If significant differences were found, the Tukey's range test for multiple comparison was used to compare each group with the others. *P* values of less than 0.05 were considered significant. In order to evaluate a possible difference between the two oils, the data were analyzed by a univariate two-way analysis of variance by means of the program GLM procedure of SAS (43). For this purpose, the animals of the control group had been randomly assigned to the two treatment groups, BO and EPO. The effect of the two factors "oil" (BO resp. EPO) and "diet" (five levels of GLA) were tested for several variables. If the factor "oil" and the interaction "diet*oil" were not significant, both oils can be considered as equal for the variable analyzed when they provide the same amount of GLA.

RESULTS AND DISCUSSION

Animal characteristics. The growth of rats was similar in all dietary groups during the 6-wk feeding period. The mean food intake for the 6-wk period of the seven dietary regimes was 20.2 ± 0.2 g/d/rat. Dietary treatment had no significant effect on body weight and food consumption.

Tissue fatty acid changes. The fatty acid profiles of liver, erythrocyte and aorta phospholipids from rats fed various diets are presented in Tables 2–4. The levels of saturated fatty acids in tissue phospholipids were similar in all groups in spite of variations in the dietary saturated fatty acids. Moderate alterations were observed in the monounsaturated fatty acids. Oleic acid was slightly decreased in the groups fed EPO compared to the 7% CO diet. This was due to the lower content of 18:1n-9 in EPO (Table 1). Irrespective of any fat supplement, the total amount of polyunsaturated fatty acids (PUFA) was only modestly altered. However, the animals fed diets containing BO or EPO showed an increase in the proportion of the major PUFA of the n-6 series and a decrease in those of the n-3 series (22:5, 22:6) according to the n-3 content of the diets. In general, the fatty acid profiles of the phospholipids reflected the fatty acid content of the oils ingested by the various groups. Thus, LA levels were highest in tissues from EPO and CO fed groups and lowest in those from the BO groups reflecting the differences in the LA content of the oils (Table 1). Animals fed either BO or EPO converted GLA into DHLA, which were both incorporated in erythrocyte, liver and aorta phospholipids. The use of corn oil as dietary fat allowed us to study the effect of equal amounts of dietary GLA fed either as BO or EPO while keeping the total amount of fat constant and to compare the effect of both sources of GLA with a high supply of LA as it is usually the case in human diets, which contain up to 14 g LA/day (44). The data demonstrate that an equal amount of dietary GLA fed as BO or EPO produced a similar and selective increase in tissue DHLA levels (Tables 2–4). Furthermore, a linear dose response in the increase of DHLA and GLA was observed in liver and erythrocyte phospholipids with both BO and EPO. This is in good agreement with results obtained in human studies (30,45). Ziboh and Fletcher (45), *e.g.*, showed a dose-related increase of the DHLA content in human neutrophils of volunteers after supplementation with dietary BO. In recent years it has been debated whether the position of the fatty acids within the triacylglycerols, as found by Lawson and Hughes (46), plays a role in the absorption of GLA and other PUFA (47). In our experiment the two sources of GLA, BO or EPO, behaved identically in regard to the absorption and metabolism of GLA. The percentage of AA in erythrocyte phospholipids varied between 23.7% and 25.1% (not significant) independently of the diet, whereas in the liver a slight but significant increase from 29.9% (7% CO) to 32.6% (7% BO)

was observed (Table 2). EPO had no effect on the AA level. In the aorta, there was a similar increase from 24.4% (7% CO) to 26.3% (7% BO), but in contrast to the liver there was no dose relationship between the AA level and BO content in the diet. Although the DHLA levels are only about 1 to 6% of AA levels, the increase in DHLA in the three tissues tested followed the GLA content in the diet. The highest values were always obtained with 7% BO. The AA/DHLA ratio of phospholipids was reduced with both BO and EPO diets independently of the source of GLA (Tables 2–4). Due to the low n-3 fatty acid content of those diets, EPA was almost not detectable in the tissues analyzed. When rats were fed diets containing EPO or BO, the proportion of 22:6n-3 was decreased and that of 22:5n-6 and 22:4n-6 increased as reported previously (25). Those changes were mainly due to a shift in the dietary n-3/n-6 ratio and thus confirmed the well known competition between n-6 and n-3 fatty acids for desaturases and

[a]Values expressed as mole percent of total fatty acids are means ±SEM (n = 6–8). Values within a line without a common superscript are significantly different ($P < 0.05$). Rows without any superscripts contain values that are not significantly different.

[b]CO, corn oil; BO, borage oil; EPO, evening primrose oil. The amount of fat added to the basal diet is given in weight percent of the diet.

acyltransferases (48). The interactions between n-3 PUFA and GLA-containing oils have been reported previously (31–35), showing that a combination of fish oil and GLA-containing oil is needed to achieve the highest 20:3n-6/AA ratios in tissue phospholipids.

An overall effect of the factors "oil" (EPO and BO) and "diet" (five levels of GLA) on the n-3 or n-6 fatty acids was tested by means of multivariate analysis of variance where the vectors of the dependent variables were either 18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6, 22:4n-6 and 22:5n-6 for the n-6 series or 18:3n-3, 22:5n-3 and 22:6n-3 for the n-3 series. The factor "oil" had no significant effect for the n-6 fatty acids in all tissue tested (liver $P = 0.078$, aorta $P = 0.374$, erythrocytes $P = 0.053$), whereas for the n-3 fatty acids the differences were significant in liver and aorta (liver $P = 0.007$, aorta $P = 0.008$, erythrocytes $P = 0.252$). The factor "diet" was significant in all cases. The interactions between the two factors and particular fatty acids have been calculated by two-way analysis of variance (Table 5). In liver, the factor "oil" had a significant effect on total n-3 fatty acids which can be explained by the difference in DHA levels. The factor "diet" was significant for all fatty acids. An interaction "diet*oil" was observed regarding AA and docosapentaenoic acid (DPA). In aorta, a similar pattern was found as in the liver. The n-3 fatty acids depend on the factor "oil" due to DPA and DHA, and all fatty acids except 22:5n-6 were dependent on the factor "diet." An interaction "diet*oil" was also seen regarding AA. The erythrocytes behaved differently: the factor "oil" had a significant effect on the n-6 fatty acids due to the 22:4n-6 but not on the n-3 series. The factor "diet" had a significant effect on all fatty acids except on total n-6 fatty acids, 20:4n-6, 22:5n-6 and on the ratio AA/DHLA. Here, an interaction "diet*oil" was seen with regard to 18:2n-6 and 22:4n-6. In all cases, LA, GLA and DHLA were only dependent on the factor "diet" but not on the factor "oil," and there were no interactions with the exception of LA in erythrocytes. This means that the contents of GLA and DHLA in phospholipids depend only on the GLA content in the diet and not on the type of oil supplemented. An interference with dietary LA, as it could be expected from the different LA content in BO and EPO, has been avoided by feeding a diet already rich in LA. However, the total amount of n-3 fatty acids in the diet was very low, therefore the significant differences of n-3 fatty acids in the phospholipids can be explained by the slightly higher content of 18:3n-3 in BO.

Prostanoid levels. PGE_2 levels in stimulated aorta and TXB_2 levels in serum were not significantly influenced by dietary GLA-rich oils. PGE_1 levels were increased in stimulated aorta in all the groups fed GLA compared to the corn oil diet (Table 6). Two-way analysis of variance indicated a significant increase of PGE_1 by dietary GLA ($P = 0.006$), whereas neither the factor "oil" nor the interaction between the two factors had a significant influence on PGE_1 levels (Table 6). Previously, an increased production of PGE_1 was observed in epidermis, aorta and platelets after supplementing with GLA (23,49–52). Moreover, Ziboh and co-workers (22–24) observed a significant increase in 15-hydroxyeicosatrienoic acid content in the epidermis of BO fed animals. 15-Hydroxyeicosatrienoic acid is a potent inhibitor of 5- and 12-lipoxygenases (24). Due to the beneficial effects attributed to PGE_1, an increased production may be of relevance in atherosclerosis and inflammation (2,16–24). Recently, Ziboh and Fletcher (45) showed that the conversion of AA to leukotriene B_4, a potent pro-inflammatory metabolite, was inhibited by dietary BO in human polymorphonuclear neutrophils of healthy volunteers.

[a]Two-way analysis of variance for the following factors. Oil; two levels: borage and evening primrose oil. Diet; five levels: 0.0, 2.3, 4.6, 6.4 and 16.2 g of GLA/kg diet. Diet*Oil; interactions between diet and oil.

Results of this and other studies, therefore, show that the levels of GLA and DHLA in tissue phospholipids can be significantly increased by feeding either BO or EPO, resulting in lower AA/DHLA ratios in phospholipids (22,24,33,35,37,45). Moreover, when equal amounts of GLA were fed, either as BO or as EPO (group 4, 5 and 6, 7), no significant differences were observed in the tissue GLA or DHLA levels. The data suggest a dose-related effect between the amount of dietary GLA ingested and the levels of GLA, DHLA and AA/DHLA ratios measured in the tissues. Finally, the selective increase of the levels of DHLA, with either BO or EPO, produced a small increase in the *ex vivo* production of PGE_1 in the aorta.

[Received April 20, 1992, and in final revised form October 12, 1992; Revision accepted October 15, 1992]

Nonessential Fatty Acids in Formula Fat Blends Influence Essential Fatty Acid Metabolism and Composition in Plasma and Organ Lipid Classes in Piglets

Katharine M. Wall[a], Deborah Diersen-Schade[b] and Sheila M. Innis[a,*]
[a]Department of Paediatrics, University of British Columbia, Vancouver, British Columbia V5Z 4H4, Canada and [b]Mead Johnson Research Center, Evansville, Indiana 47721-0001

The n-6 and n-3 fatty acid status of developing organs is the cumulative result of the diet lipid composition and many complex events of lipid metabolism. Little information is available, however, on the potential effects of the saturated fatty acid chain length (8:0–16:0) or oleic acid (18:1) content of the diet on the subsequent metabolism of the essential fatty acids 18:2n-6 and 18:3n-3 and their elongated/desaturated products. The effects of feeding piglets formulas with fat blends containing either coconut oil (12:0 + 14:0) or medium chain triglycerides (MCT, 8:0 + 10:0) but similar levels of 18:1, 18:2n-6 and 18:3n-3, or MCT with high or low 18:1 but constant 18:2n-6 and 18:3n-3 on the fatty acid composition of plasma, liver and kidney triglycerides, phospholipids and cholesteryl esters, and of brain total lipid, were studied. Diet-induced changes in the fatty acid composition of lipid classes were generally similar for plasma, liver and kidney. Dietary 18:1 content was reflected in tissue lipids and was inversely associated with levels of 18:2n-6. Lower percentage of 18:2n-6, however, was not associated with lower levels of its elongated/desaturated product 20:4n-6 but was associated with higher levels of 22:6n-3. Feeding coconut oil *vs.* MCT resulted in lower 18:1 levels in all lipids, and higher percentages of 20:4n-6 in tissue phospholipid. Increasing the dietary n-6/n-3 ratio from 5 to 8 significantly increased tissue percentage of 18:2n-6 and decreased phospholipid 22:6n-3. In contrast to plasma, liver and kidney, brain lipid fatty acid composition was not influenced by the formula saturated fatty acid chain length, content of 18:1, or n-6/n-3 ratio. In summary, the studies show that the dietary requirement for n-6 and n-3 fatty acids may be influenced by the nonessential saturated and monounsaturated fatty acids fed concurrently.
Lipids 27, 1024–1031 (1992).

Formulas presently available for infant nutrition commonly use blends of vegetable oils, sometimes with the addition of oleo oils, as their source of fat. Although almost all formulas provide the essential fatty acids linoleic (18:2n-6) and linolenic (18:3n-3), levels of oleic acid (18:1) and the chain length of the saturated fatty acids may differ widely. Infant formulas often use coconut or medium chain triglyceride (MCT) oils as a preferred source of saturated fat, usually for term and preterm formulas, respectively. The medium chain fatty acids (MCFA) in MCT oils are more soluble in water than long chain fatty acids (LCFA, C > 14), thus facilitating fat absorption when intraluminal hydrolysis or micelle formation is compromised (1,2). The absorption of triglycerides containing LCFA, by contrast, requires intraluminal hydrolysis of the triglycerides to free fatty acids and monoglycerides, and micelle formation for absorption (1). Monoglycerides and LCFA are reassembled into triglycerides in the enterocyte and secreted into the lymph as components of chylomicrons, thus initially by-passing the liver. In contrast, MCFA are predominantly transported directly to the liver *via* the portal vein (1,2). In the liver, MCFA cross the mitochondrial membrane independent of carnitine (3), and provide a readily available source of fatty acids for oxidation (4,5). In addition, since MCFA are not good substrates for fatty-acid binding protein (6), they are not readily activated to fatty acyl-CoA for incorporation into hepatic lipid pools (4,5,7). It is not known whether these differences in metabolic handling of dietary MCFA and LCFA influence the fate of the accompanying dietary essential fatty acids, specifically their shunting either to oxidation or to acylation into triglyceride (TG), phospholipid (PL) or cholesteryl ester (CE).

Desaturation of 18:1n-9, 18:2n-6 and 18:3n-3 is subject to competitive inhibition, with preferential desaturation occurring in the relative order of n-3 > n-6 > n-9 fatty acids (8). Human milk fat typically contains about 3% (w/w of total fatty acids) 16:1 and about 30–40% 18:1, whereas infant formula fat blends vary widely with 10–40% 18:1 and no appreciable 16:1. Human milk fat also contains small amounts (<1%) of the long chain polyunsaturated fatty acids (LCP) 20:4n-6 and 22:6n-3. The importance of these n-6 and n-3 LCP for normal tissue development and function is being increasingly recognized (9,10). It is well documented that formula feeding, compared with human milk feeding, results in lower plasma and red blood cell (RBC) PL levels of the elongated/desaturated derivatives of 18:2n-6 and 18:3n-3, namely 20:4n-6 and 22:6n-3 (11–14). The possible effect of the monounsaturated fatty acid content of the formula on n-6 and n-3 fatty acid metabolism, however, has received little attention.

The two-fold objective of the present study was to examine the effect on specific tissues of diets containing (i) MCT or coconut oil with 8:0 + 10:0 (MCFA) or 12:0 + 14:0 (intermediate chain fatty acids, ICFA), respectively, as the predominant source of saturated fatty acids, and with similar levels of 18:1, 18:2n-6 and 18:3n-3 and (ii) MCT oil with low and high levels of 18:1, and similar quantities of 18:2n-6 and 18:3n-3. The fatty acid composition of piglet plasma, liver and kidney PL, TG and CE, and brain total lipid were analyzed.

Abbreviations: ANOVA, analysis of variance; CE, cholesteryl ester; EDTA, tetrasodium ethylenediaminetetraacetic acid; FA, fatty acid; ICFA, intermediate chain fatty acids; LCFA, long chain fatty acids (C > 14); LCP, long chain polyunsaturated fatty acids (C_{20} and C_{22} with ≥2 double bonds); MCFA, medium chain fatty acids; MCT, medium chain triglyceride; PL, phospholipid; RBC, red blood cell; TG, triglyceride; TRIS, *tris*(hydroxymethyl)methylamine; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Animals and diets. Male Yorkshire piglets, delivered at 116–118 d of gestation, were obtained from Jansen Farm (Abbotsford, British Columbia, Canada) and Peter Hill Holdings (Langley, British Columbia, Canada). Six piglets, each born to a different sow, were kept at the farm and suckled by their natural mothers for 18 d. These piglets provided a reference group for formula fed animals. An additional 24 piglets were taken from their mothers immediately after birth, and were housed in the animal care quarters at the University of British Columbia (Shaughnessy Site). Six piglets were randomly assigned to each of four dietary groups, and no group had more than one piglet born to the same sow. The piglets were bottle-fed every 3–4 h for 18 d from birth, and porcine serum immunoglobulins were added to the liquid diets for the first 72 h after birth to provide passive immunity (15).

The liquid piglet diets were manufactured by Mead Johnson (Evansville, IN), and were based on commercial infant formula modified to meet the nutrient requirements of growing piglets (16). The formula fat blends are given in Table 1 and are designated diets A, B, C and D. The comparisons discussed in this paper will focus on the percentage of dietary 18:1 and the chain length of the predominant saturated fatty acid. Formulas A and B contained 37% MCFA + 11% 18:1 and 18% MCFA + 36% 18:1, respectively, with similar amounts of 18:2n-6 and 18:3n-3. Formulas C and D compared MCT *vs.* coconut oil in the fat blend, and contained similar amounts of 18:1, 18:2n-6 and 18:3n-3.

The studies were approved by the Animal Care Committee at the University of British Columbia, and conformed with Canadian Council on Animal Care guidelines for the care and use of animals for research.

Sample collection and analysis. After an overnight fast of 10–12 h, the piglets were anaesthetized with ketamine/rompun (37.5/3.75 mg/kg, respectively) by intramuscular injection. Blood was withdrawn by cardiac puncture into ethylenediaminetetraacetic acid (EDTA)-rinsed syringes and the animals sacrificed by intracardiac injection of 10 mL 1M KCl. Plasma was separated by centrifugation and the liver, kidney and brain were rapidly excised and weighed. The entire liver and brain were quickly homogenized in ice-cold sucrose buffer [225 mM sucrose, 25 mM tris(hydroxymethyl)methylamine (TRIS), 10 mM glutathione, 500 mg/mL leupeptin and 2 μg/mL aprotinen]. Kidneys were prepared by removing the capsule and fibrous cortex, and the organs were then frozen in liquid nitrogen and stored at −80°C until further processing.

Kidneys were homogenized in saline, and aliquots of liver, kidney and brain homogenate were removed for determination of protein concentration (17) and for lipid analysis. Plasma and organ lipids were extracted according to Folch *et al.* (18), aliquots dried under nitrogen, reconstituted in isopropyl alcohol and total cholesterol, triglycerides (Diagnostic Chemicals Inc., North Vancouver, British Columbia, Canada) and free cholesterol (Boehringer Mannheim, Laval, Quebec, Canada) determined with enzymatic reagents. Phospholipid, triglyceride and cholesteryl esters from plasma, liver and kidney lipid extracts were separated by thin-layer chromatography on Silica Gel 60 plates (0.5 mm; E. Merck, Darmstadt, Germany) using petroleum hydrocarbon (b.p. 30–60°C)/diethyl ether/glacial acetic acid (85:15:3, vol/vol/vol) as the solvent system. Lipid classes were recovered from the silica gel by extraction with chloroform/methanol (1:1, vol/vol), heptadecanoic acid (Sigma Chemical Co., St. Louis, MO) was added as internal standard for fatty acid analysis, and the samples were dried under nitrogen. Phospholipid fatty acid methyl esters were prepared in 1 mL methanol/conc. HCl (5:1, vol/vol) at 100°C for 5 min, and triglyceride and cholesteryl ester fatty acid methyl esters in 1 mL of 14% boron trifluoride in methanol, at 100°C for 45 min. Fatty acid methyl esters were recovered in pentane, dried under nitrogen, and resuspended in hexane for separation by gas-liquid chromatography (Varian 3400 Gas Chromatograph, Georgetown, Ontario, Canada, with an Rtx 2330 capillary column, 30 m × 0.25 mm i.d., Restek Corporation, Bellefonte, PA) and quantification using a Varian Star Integrator data system. Identification of fatty acids was based on the retention times of authentic standards (Sigma Chemical Company; Supelco Inc., Bellefonte, PA; Nu-Chek-Prep Inc., Elysian, MN). The fatty acid composition of the piglet diets was analyzed similarly, following preparation of methyl esters by the method of Lepage and Roy (19).

Statistical analysis. Comparisons were made between the formula diets A, B, C and D and between formula and sow-fed controls using analysis of variance (ANOVA) and Fisher's least square difference tests (Number Cruncher Statistical System, Version 5.1, Kaysville, UT). Differences were considered significant at the equivalent of $P < 0.05$, after correction with the Bonferroni factor for the number of comparisons made. Values given are means ± SE for the number of animals indicated.

TABLE 1

Composition of Dietary Fat Blends[a]

	Diet			
	A	B	C	D
Oils (% w/w of total)				
Medium chain triglyceride	40	20	31	
Soy	40	40		
Coconut	20	10		34.7
High-oleic safflower		30	26.1	23.1
Canola			33.3	33.3
Safflower			9.6	8.8
Fatty acids (% w/w of total)				
8:0 + 10:0	37	18	30	5
20:0 + 14:0	13	6	0.7	26
16:0 + 18:0	11	12	7	10
18:1	11	36	41	39
18:2n-6	24.0	25.6	16.2	15.6
18:3n-3	2.9	3.2	3.4	3.2
n-6/n-3 ratio	8.3	8.0	4.8	4.9

[a]The macronutrient content of the formulas was similar to that of sow milk and provided 58 g/L protein, 67 g/L fat and 60 g/L carbohydrate with a total caloric density of 1075 kcal/L.

RESULTS

Body weights were not significantly different among the groups of 18- d-old piglets fed the formulas (mean value for all formula groups, 4136 + 314 g, n = 24) but were

significantly lower than sow-fed piglets (5085 ± 176, n = 6; $P < 0.05$). Liver and kidney weights were not significantly different between any of the groups.

Quantitation of plasma TG, total cholesterol and free cholesterol revealed no significant differences among the groups of formula-fed piglets; total cholesterol and free cholesterol levels, however, were significantly lower in the formula-fed than in the sow-fed animals (mean value for all formula groups, 79 ± 5 and 23 ± 2 mg/dL respectively, and for sow-fed, 174 ± 7 and 50 ± 5 mg/dL, respectively). No significant differences in the concentration of TG, PL, total cholesterol or free cholesterol (mg/g protein) were found in the liver, kidney or brain among any of the formula-fed groups or between formula-fed and sow-fed animals.

The design of the experiments allows for comparisons between formulas with similar levels of 18:2n-6 and 18:3n-3 but in which the percentage of 18:1 was increased threefold at the expense of MCFA (group A *vs.* B) and between formulas with similar 18:1, 18:2n-6 and 18:3n-3 but with MCFA or ICFA as the predominant source of saturated fatty acids (group C *vs.* D). The effect of differences in n-6/n-3 ratio (reflecting the ratio of 18:2n-6 to 18:3n-3, which are known to compete with each other for desaturation and acylation) can also be addressed by comparing diets A and B, in which the n-6/n-3 ratio was approximately 8, with diets C and D which had n-6/n-3 ratios of approximatey 5 (Table 1). Analyses from piglets fed sow milk were done concurrently and are included for reference. The sow milk contained (% w/w of total fatty acids) 0.18% 8:0 + 10:0, 3.80% 12:0 + 14:0, 34.90% 16:0 + 18:0, 37.54% 18:1, 11.08% 18:2n-6, 1.10% 18:3n-3, 1.05% LCPn-6 and 0.44% LCPn-3, with an n-6/n-3 ratio of 7.9.

Comparisons between formula-fed and sow-fed piglets. Results of analyses of piglets suckled by their natural mothers, or fed formula are included in Tables 2–5 and Figures 1–3. Comparisons between formula-fed and sow-fed piglets are considered in brief, with subsequent more detailed discussion given to differences between the formula groups.

Several consistent differences in plasma and tissue lipid composition are evident between sow-fed and formula-fed piglets. The plasma TG, PL and CE percentage of 16:0 was lower and percentage of 18:2n-6 higher in all the formula than sow-fed piglets (Fig. 1). Plasma PL percentage of 20:4n-6 was also lower in all the formula groups compared to the sow-fed group. In addition, piglets fed diets with n-6/n-3 ratios of about 8 (A and B), had lower plasma PL percentage of 22:6n-3 than sow-fed controls, but piglets fed diets with n-6/n-3 ratios of about 5 (C and D) had similar plasma PL percentage of 22:6n-3 to the sow-fed group (Fig. 1). Differences in the fatty acid composition of plasma and kidney lipids were similar between formula-fed and sow-fed animals, but patterns were not always similar in the liver. Thus, in contrast to plasma, the liver CE percentage of 16:0 of formula-fed piglets was not different from the sow-fed group, neither was the liver CE percentage of 18:2n-6 altered by feeding diets C or D. Also unlike the plasma, the liver PL levels of 18:2n-6 in piglets fed diet D, 20:4n-6 in piglets fed diets A or D, and 22:6n-3 in all the formula groups were not different from the sow-fed group. Levels of 18:3n-3 were consistently higher in all lipid fractions of the plasma, liver and kidney for formula *vs.* sow-fed animals, and for a given diet treatment the percentage of 18:3n-3 was higher in the PL and CE than TG fraction. This can be seen from the difference in

[a]Values are means ± SE for five (sow-fed) or six (formula) animals per group. Values within groups A, B, C and D without a common superscript (a or b) are significantly different from other formula groups; x, significantly different from the sow-fed group ($P < 0.05$, corrected with Bonferroni factor). The abbreviations Σ Saturated FA, Monounsaturated FA, n-6, n-3, LCPn-6 and LCPn-3 are as listed in Table 2.

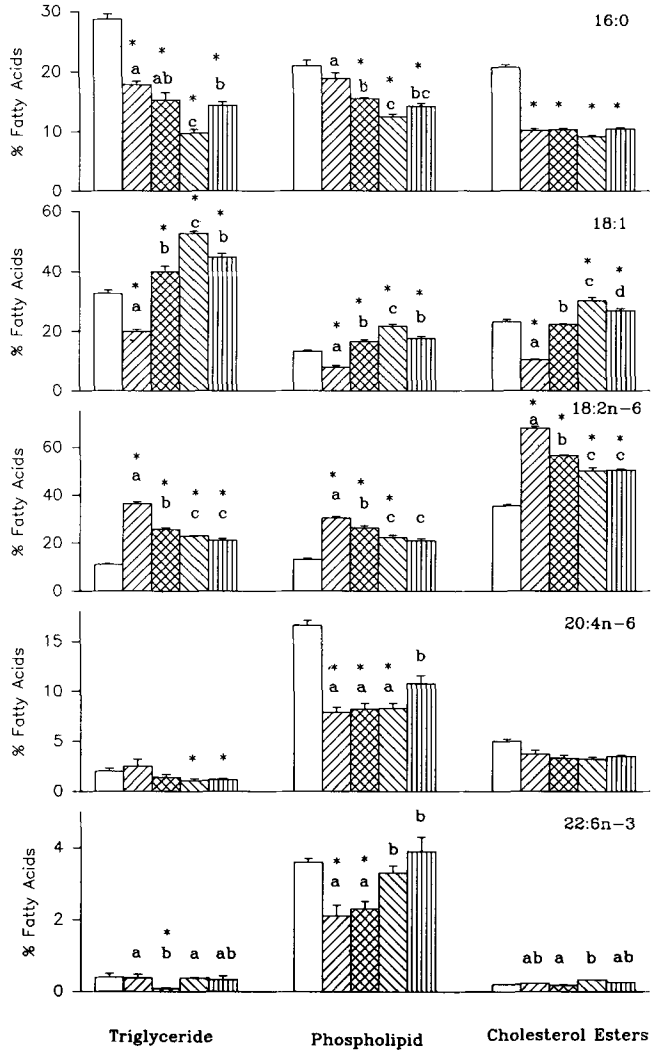

FIG. 1. The effect of formula fat composition, or sow milk feeding on the percent composition of 16:0, 18:1, 18:2n-6, 20:4n-6 and 22:6n-3 in plasma triglyceride, phospholipid and cholesterol ester fractions. Values are means ± SE for five (sow-fed) or six (formula groups) animals per group. Formula groups without a common superscript are significantly different from each other, or with the superscript *, are significantly different from the sow-fed group ($P < 0.05$, corrected with the Bonferroni factor). Groups (as defined in the text) are identified as: sow-fed (open bars), formula A (right-hatched bars), formula B (cross-hatched bars), formula C (left-hatched bars) and formula D (vertical line bars).

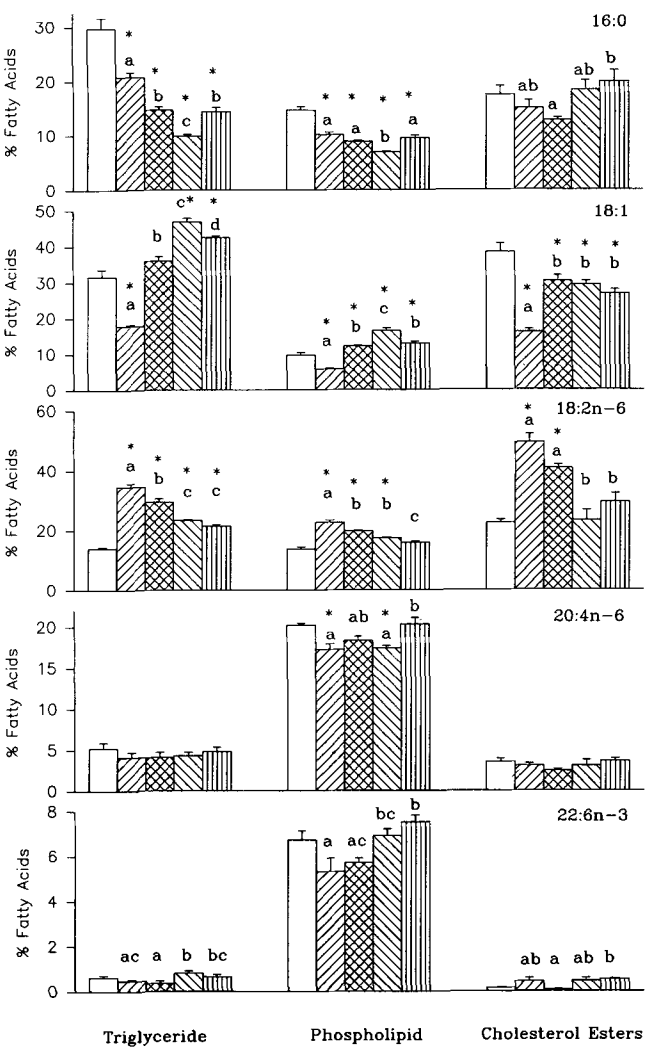

FIG. 2. The effect of formula fat composition or sow milk feeding on the percentage of 16:0, 18:1, 18:2n-6, 20:4n-6 and 22:6n-3 in liver triglyceride, phospholipid and cholesterol ester fractions. Values are means ± SE for five (sow-fed) or six (formula groups) animals per group. Formula groups without a common superscript are significantly different from each other, or with the superscript *, are significantly different from the sow-fed group ($P < 0.05$, corrected with the Bonferroni factor). Groups (as defined in the text) are identified as: sow-fed (open bars), formula A (right-hatched bars), formula B (cross-hatched bars), formula C (left-hatched bars) and formula D (vertical line bars).

Σ n-3-Σ LCPn-3 in the results in Tables 2-4. No significant differences in brain total lipid were found between formula and sow-fed animals, with the exception of lower Σ monounsaturated and higher Σ n-6 fatty acids in piglets fed formula A (Table 5).

Plasma lipids. The increase in dietary 18:1 at the expense of MCFA in formula B compared to A resulted in significantly higher levels of 18:1 and lower percentage of 18:2n-6 in the piglet plasma TG, PL and CE, even though the formulas had similar amounts of 18:2n-6 (Fig. 1). The percentage of 20:4n-6 in plasma TG, PL and CE, and the percentage of 22:6n-3 in PL and CE, however, were similar in piglets fed these two formulas. In contrast, the TG percentage of 22:6n-3 was lower in piglets fed formula B than formula A (Fig. 1). These changes are reflected in the sum (Σ) of the percentage of monounsaturated, n-6 and n-3 fatty acid values in Table 2. The significantly lower Σ saturated fatty acids in plasma PL of piglets fed formula B compared to A (Table 2) was predominantly due to the lower percentage of 16:0 (Fig. 1).

Piglets fed formula D had lower levels of 18:1 in plasma TG, PL and CE but higher levels of 20:4n-6 in PL than piglets fed formula C, containing similar amounts of 18:1, 18:2n-6 and 18:3n-3 but with MCFA rather than ICFA (Fig. 1). The Σ saturated fatty acids (Table 2) in all the lipid classes and the percentage of 16:0 in TG (Fig. 1) were also higher in piglets fed formula D *vs.* formula C.

Formulas B and D had similar amounts of 18:1 and 18:3n-3, but 25.6 and 15.6% 18:2n-6 with n-6/n-3 ratios of 8.0 and 4.9, respectively. Piglets fed formula D, with the

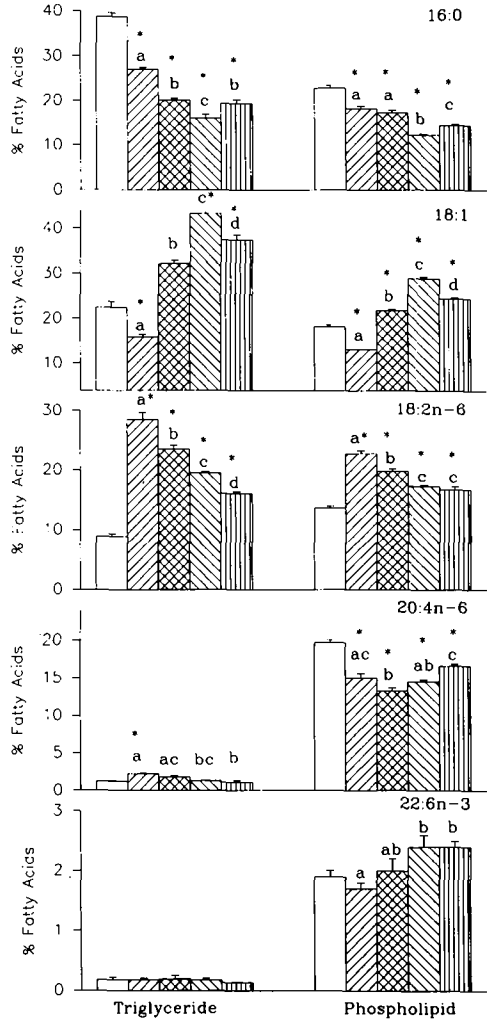

FIG. 3. The effect of formula fat composition or sow milk feeding on the percentage of 16:0, 18:1, 18:2n-6, 20:4n-6 and 22:6n-3 in kidney triglyceride and phospholipid fractions. Values are means ± SE for five (sow-fed) or six (formula groups) animals per group. Formula groups without a common superscript are significantly different from each other, or with the superscript *, are significantly different from the sow-fed group ($P < 0.05$, corrected with the Bonferroni factor). Groups (as defined in the text) are identified as: sow-fed (open bars), formula A (right-hatched bars), formula B (cross-hatched bars), formula C (left-hatched bars) and formula D (vertical line bars).

lower 18:2n-6 and n-6/n-3 ratio, had lower levels of 18:2n-6 in the plasma TG, PL and CE and higher 20:4n-6 and 22:6n-3 in PL than piglets fed formula B (Fig. 1).

Liver lipids. Analysis of the fatty acid composition of liver from piglets fed formula A containing 11% 18:1 showed significantly lower levels of 18:1 in the TG, PL and CE but higher 18:2n-6 and Σ saturated fatty acids in TG and PL than in piglets fed formula B containing 36% 18:1 (Fig. 2 and Table 3). No significant differences were found in the % 20:4n-6, 22:6n-3 (Fig. 2) or n-6 or n-3 LCP (Table 3) between these two groups. Feeding formula with saturated fatty acids as ICFA (formula D) rather than MCFA (formula C), with similar levels of 18:1, 18:2n-6 and 18:3n-3, resulted in significantly lower percentage of 18:1 and 18:2n-6 in PL and 18:1 in TG. Levels of 16:0 and 20:4n-6 in PL, and 16:0 in TG, however, were higher (Fig. 2). Although the fatty acid composition of the liver CE was similar between piglets fed formulas C and D (Table 3 and Fig. 2), the higher n-6/n-3 ratio of 8.0 in formula B compared to 4.9 in formula D was associated with significantly higher levels of 18:2n-6 and lower 22:6n-3 (Fig. 2) and total saturated fatty acids (Table 3), in liver CE.

Kidney lipids. Cholesteryl ester levels were low in the kidney, and were not analyzed in the present study. The higher dietary intake of 18:1 in piglets fed formula B compared to A was associated with significantly higher levels of 18:1 in kidney TG and PL, lower percentage of 16:0 and 18:2n-6 in TG (Fig. 3) and lower Σ saturated fatty acids (Table 4), percentage of 18:2n-6 and percentage of 20:4n-6 (Fig. 3) in PL.

Feeding formula D containing ICFA compared to formula C containing MCFA resulted in significantly higher levels of 16:0 and 20:4n-6 and lower levels of 18:1 in kidney PL. Levels of 16:0 were higher and 18:1 and 18:2n-6 lower in TG despite the similar quantities of 18:1, 18:2n-6 and 18:3n-3 in these two diets (Fig. 3).

The kidney lipids of piglets fed formula B containing 36% 18:1 and with an n-6/n-3 ratio of 8.0 had significantly more 18:2n-6 and less 18:1 in TG and PL, and more 16:0 and less 20:4n-6 in PL (Fig. 3) than piglets fed formula D with 39% 18:1 and an n-6/n-3 ratio of 4.9.

Brain lipids. There were no significant differences in the fatty acid composition of brain total lipid (primarily phospholipid) between piglets fed formulas A and B containing 11 and 36% 18:1, or formulas C and D containing MCFA and ICFA, respectively (Table 5). These findings are in contrast to analyses of plasma, liver and kidney, in which (i) the monoenoic fatty acid content of the diet (11% in formula A and 36–41% in formulas B–D) and (ii) the lower 18:2n-6 content of formulas A and B *vs.* C and D, were reflected in TG, PL and CE fatty acids. Similarly, feeding diets B and D with n-6/n-3 ratios of 8.0 and 4.9 did not influence brain fatty acid composition (Table 5).

DISCUSSION

Results from these studies comparing four groups of formula fed and a group of sow-fed piglets show that (i) substitution of monoenoic fatty acids for MCFA, while maintaining diet 18:2n-6 and 18:3n-3 levels, influences the metabolism of 18:2n-6 by altering the content of 18:2n-6, and the ratio of 18:2n-6 to its desaturation product 20:4n-6, in plasma and organ lipid classes, (ii) the dietary source of saturated fatty acid—either MCFA from MCT oil or ICFA from coconut oil—when fed with similar levels of 18:1, 18:2n-6 and 18:3n-3, selectively alters the percentage of 18:1, 18:2n-6 and 20:4n-6 in plasma, liver and kidney TG, PL and CE, (iii) the chain length of dietary saturated fatty acids (MCFA *vs.* ICFA) is an important determinant of tissue 20:4n-6 levels, (iv) dietary percentage of 18:2n-6, and/or n-6/n-3 ratio may influence plasma and organ PL 22:6n-3, (v) manipulation of saturated and monounsaturated fatty acids in formula fat blends can change the plasma and tissue levels of essential fatty acids and their LCP products, and (vi) in contrast to plasma, liver and kidney lipids, brain total lipid fatty acid composition was not influenced by dietary 18:1 content, MCFA *vs.* ICFA or n-6/n-3 ratio with the formulas used in the present studies.

The competition for chain elongation and desaturation among oleic (18:1), linoleic (18:2n-6) and linolenic (18:3n-3) acids (8) and specificity for incorporation of fatty acids into different lipid classes (20–23) are well known. The complexity of fatty acid metabolism and the limitations in experimental design imposed by available oil sources, however, often make it difficult to interpret the effect of a specific dietary fatty acid on the tissue fatty acid response. Little information is currently available on the effect of dietary 18:1 on the incorporation of other dietary fatty acids into tissue lipids. In agreement with previous studies (24,25), the diets containing high levels of 18:1 led to an increase in plasma and tissue percentage of 18:1, and a concomitant decrease in percentage of saturated fatty acids. Results from several studies suggest that 18:1 may have unique or different effects on fatty acid metabolism when compared with saturated or polyunsaturated fatty acids. For example, stimulation of Δ5 desaturase activity following triolein administration (26), avid incorporation of 18:1 into liver TG, and higher rates of secretion of 18:1 than 18:2n-6 or 18:3n-3 in liver very low density lipoprotein (VLDL) (21,27,28) have all been shown. Dietary oleic acid may also result in higher liver cholesterol levels than polyunsaturated fatty acids such as 18:2n-6 (29). It is reasonable to assume, therefore, that the diet 18:1 content may influence or determine, at least in part, the metabolism of other dietary fat components.

The present studies in which piglets were fed diets with constant levels of 18:2n-6 but different levels of 18:1 (and MCFA) show that increased tissue levels of 18:1 are accompanied by decreased 18:2n-6 in the plasma, liver and kidney TG, PL and CE. This effect does not appear to be related to the formula content of MCFA, as no correlation between dietary MCT content and tissue 18:2n-6 was found among groups A, B and C containing 20–40% (w/w of diet fat) MCT oil. Recent studies from this laboratory (30) reported that the dietary intake of 18:3n-3 from formula influenced the amount of 18:1 in piglet plasma and liver PL, but that the effect also was influenced by the 18:2n-6 content of the formula. In the latter studies, the formula 18:2n-6 was adjusted by changing the 18:1 content. The results of the present studies, in which the 18:3n-3 content of the formula fat blends was held constant (Table 1), suggest the interaction of diet 18:1 and 18:2n-6 is the predominant determinant of plasma and tissue levels of these fatty acids.

Differences in plasma, liver and kidney PL 18:2n-6, but not 20:4n-6, were found among piglets fed formulas providing similar amounts of 18:2n-6. The increased 18:1 and decreased 18:2n-6 in the PL of piglets fed diet B, containing 36% 18:1, compared to diet A, containing 11% 18:1, could possibly be explained by competitive replacement of 18:1 for 18:2n-6 in pathways of acylation. High levels of 18:1 in a formula containing ICFA (D; 39% 18:1) compared to MCFA (B and C; 36–41% 18:1) also resulted in lower tissue PL and/or TG 18:2n-6. This suggests that the acylation, and potentially also the oxidation, of 18:1 and 18:2n-6 are influenced by the diet saturated fatty acid chain length.

The maintenance of plasma and tissue PL 20:4n-6, despite the significant differences in PL 18:2n-6, among piglets fed formula varying in saturated and monounsaturated fatty acid content is noteable. These results provide evidence that tissue PL levels of 20:4n-6 are tightly regulated and not necessarily influenced by dietary intakes of 18:2n-6 which are well in excess of minimum requirements. In this regard, a specific arachidonyl-CoA synthetase has been identified (31). It is suggested that the diet fatty acid composition influences the metabolism of the dietary 18:2n-6, primarily by changing the proportion of 18:2n-6 directly acylated into tissue lipid, or potentially the amount oxidized, rather than by altering the amount entering the microsomal desaturation-elongation pathway. It is possible, however, that recycling of 20:4n-6 during turnover reactions could maintain tissue 20:4n-6 levels.

Increased tissue levels of 22:6n-3 following feeding with diets high in 18:1 have been reported by Periago *et al.* (25). The studies reported here provide further evidence that the diet 18:1 content may influence the desaturation-elongation of 18:3n-3 to 22:6n-3 (Figs. 1–3). The difference in plasma and tissue PL percentage of 22:6n-3 (group C = D > A = B), despite similar dietary intake of 18:3n-3, could possibly be explained by the lower intake of 18:2n-6 and lower n-6/n-3 ratio of formulas C and D, thus reducing the competition between 18:2n-6 and 18:3n-3 for desaturation. Data published by Lee *et al.* (32), however, do not support an effect on tissue lipid levels of 20:4n-6 and 22:6n-3 due to changes in the n-6/n-3 ratio within the range used in the piglet formulas.

The present studies compared the effects on tissue fatty acids of feeding MCT containing primarily fatty acids of chain length 8:0 and 10:0, and coconut oil containing primarily fatty acids of chain length 12:0 and 14:0 in similar amounts to that used in infant formulas. The physical and biochemical properties of 12:0 and 14:0 are intermediate between fatty acids of chain length >14:0 and ≤10:0. However, 12:0, unlike 8:0 or 10:0, is accepted as substrate by *sn*-glycero-3-phosphate and 1-acyl-*sn*-glycero-3-phosphate acyltransferases and is secreted from liver in VLDL TG (28). Deposition of 12:0 in adipose tissue TG at rates comparable to that expected for dietary LCFA has also been reported (33,34). In contrast, 8:0 and 10:0 do not appear to be used as substrate for phospholipid synthesis (7,35) and are incorporated only slowly into hepatic TG *via* 1,2-diacyl-*sn*-glycerol acyltransferase (35). The saturated fatty acids of coconut oil and MCT oils, therefore, can be expected to be handled differently. In addition, oxidative flux of MCFA far exceeds that of longer chain fatty acids (36), such that lesser amounts of these fatty acids are available for incorporation into lipids. Differences in route of absorption, direct transport of MCFA as unesterified fatty acids *via* the portal vein *vs.* transport of longer chain fatty acids (C > 14) in chylomicron TG *via* the lymph, may also be expected to alter processes such as intestinal apoprotein expression (37–39), the composition and size of the chlyomicron (37) and subsequent processing, including the activity of hepatic and lipoprotein lipase on chylomicron and VLDL TG (40,41). Dietary MCFA therefore, by nature of its rapid and almost complete oxidation, and specific metabolism, may be expected to also influence the oxidation, acylation and further metabolism, such as elongation/desaturation, of concurrently fed fatty acids. For example, despite similar levels of 18:1 in the fat blends of formulas C and D, animals fed formula C with MCFA had consistently higher levels of 18:1 in TG, PL and CE than animals fed formula D with ICFA. This could be explained by higher endogenous 18:1 synthesis, including Δ9 desaturase activity, in piglets fed

MCFA. Alternatively, preferential oxidation of 8:0 and 10:0 from MCT could spare longer chain dietary fatty acids, including 18:1, from oxidation for energy. The latter hypothesis is compatible with the higher levels of 18:2n-6 found in the tissues of piglets fed formulas containing MCFA compared to ICFA.

Clinical studies on fatty acid nutrition often include measures of the fatty acid composition of plasma and RBC PL (10–14). The present studies indicate that while these measures generally reflect liver and kidney lipids, they are not an accurate reflection of brain lipid, which appears to maintain a very stable fatty acid profile over a wide range of dietary fatty acid intakes. It seems that much more information is needed regarding the effects of various dietary fatty acids on the processes involved in tissue structural lipid formation before the dietary fatty acid composition required for optimal development and function of different organs can be defined.

CONCLUSION

The results of these studies demonstrate interaction between dietary nonessential saturated and monounsaturated fatty acids and metabolism of n-6 and n-3 fatty acids. This is relevant for future development of infant formulas, especially those for very premature infants with concomitant complications of immaturity, particularly those related to fat digestion and absorption. A major emphasis in recent years has been on the potential need for a dietary supply of carbon chain 20 and 22 n-6 and n-3 fatty acids (9,10,12,13), particularly 20:4n-6 and 22:6n-3. Our data indicate that the saturated and monounsaturated fatty acids supplied in the diet with 18:2n-6 and 18:3n-3 can affect the metabolic handling of the n-6 and n-3 fatty acids.

ACKNOWLEDGMENTS

The technical assistance of L. Nicol and R. Dyer and assistance in care of the animals from the Staff of the Animal Unit are gratefully acknowledged. Administering 17β-estradiol (E_2) to juvenile trout results in plasma hyperlipidemia and hyperlipoproteinemia associated with significant increases in the concentrations of triglycerides (TG), free cholesterol, phospholipids, free fatty acids and proteins, both postprandial and during starvation. TG undergo the greatest increase (9 times control level 96 h after feeding). The concentration differences between E_2-treated and control trout increase during starvation, primarily by progressive decreases in the concentrations of various lipids in controls. E_2-induced hypertriglyceridemia is mainly caused by an increase in the concentration of very low density lipoproteins (VLDL) during both the postprandial period (6 times control level at 24 h) and during starvation (15 times control level at 96 h); hyperlipoproteinemia lasts up to at least 7 d after the last feeding. E_2 treatment does not change the concentration of high density lipoproteins, but does increase plasma concentrations of a very high density lipoprotein, vitellogenin (VTG). In E_2-treated VLDL, cholesteryl esters are depleted while proteins are enriched. During the postprandial phase, the apolipoprotein (apo) profile of VLDL (d < 1.015 g/mL) is comparable in E_2-treated and control trout. Starvation of E_2-treated trout is accompanied by an enrichment in apo B_{240}, A-I and A-II. The secretion levels of TG and VLDL-TG, as determined *in vivo* by injecting Triton WR-1339 to starving animals, are significantly higher in E_2-treated trout than in controls. In trout, as in chicks, E_2 administration significantly increases the concentration and hepatic secretion of plasma VLDL independent of the nutritional status and the appearance of VTG in the plasma. This suggests the existence of similar mechanisms for the regulation of lipoprotein metabolism by estrogens in oviparous vertebrates.
Lipids 27, 1032–1041 (1992).

Sex steroids modify the risk of atherosclerosis by regulating the levels of plasma lipoproteins (1–3). Natural or induced changes in estrogen concentrations in various species have been shown to affect the production and catabolism of lipoproteins. The mechanisms involved in the action of estrogens on lipoprotein metabolism appear to be largely dose dependent (4,5).

Pharmacological doses of estrogens in mammals stimulate the number of low density lipoprotein (LDL) receptors in rat (6,7) and rabbit liver (8) and in the HepG2 human hepatocarcinoma cell line (9). In humans, estrogens reduce hepatic triglyceride lipase activity (10–12) and increase the concentrations of plasma high density lipoproteins (HDL) (10–13) and very low density lipoproteins (VLDL) (11,14). In humans, estrogens also stimulate apolipoprotein synthesis by HepG2 cells (15,16). Plasma concentration and hepatic secretion of VLDL have been shown to increase in rats after treatment with ethinyl estradiol (17–19).

Vitellogenesis is characterized by the accumulation of large reserves of yolk by growing oocytes. Yolk proteins and lipids are derived from plasma precursors, primarily lipoproteins (20). Vitellogenesis in birds results essentially from oocyte uptake of two classes of different density lipoproteins, VLDL and vitellogenin (VTG), a very high density lipoprotein. Hepatic synthesis of these two macromolecular complexes is stimulated dramatically by estrogens during sexual maturation of females or during estrogen treatment of males or immature females (21,22). The molecular mechanisms of the regulation of lipoprotein and apolipoprotein syntheses have been studied in birds, especially in chicks (4,22,23). Estrogen-induced hyperlipidemia in this species is characterized by a pronounced increase in VLDL levels, a smaller increase in LDL levels and a decrease in HDL levels (24–26). VLDL possess only two major apolipoproteins (apo), apo B and apo VLDL-II; the latter is synthesized by the liver under the strict control of estrogens (22). The presence of apo VLDL-II results in a considerable decrease of VLDL sensitivity toward lipoprotein lipase (LPL) (27,28). These VLDL are then incorporated in growing oocytes by an apo B-specific surface receptor (29) which is identical to the VTG receptor (30).

VTG has been detected in the blood of a large number of fish species during their normal reproduction cycle or in response to estrogen stimulation (31). Its hepatic synthesis can be induced by 17β-estradiol (E_2) (32) and is correlated with the circulating levels of this hormone during vitellogenesis (33,34).

No data exist on the possible role of estrogens in the metabolic regulation of other lipoprotein classes in fish. The aim of this work was to investigate the combined effects of nutritional status and brief E_2 treatment in juvenile trout on the qualitative and quantitative changes in the different lipoprotein classes of the plasma. In particular, we have shown that in trout, as in chicks and rats, E_2 administration causes a significant increase in the concentration and secretion of plasma VLDL, independent of nutritional status.

MATERIALS AND METHODS

Plasma. Juvenile rainbow trout, *Oncorhynchus mykiss* (formerly *Salmo gairdneri*) were raised at constant temperature (13 ± 0.5°C) and nourished *ad libitum* three times a week with granules (Aqualim, Nersac, France) containing 8% lipids. The trout were anesthetized with ethylenglycol monophenyl ether (0.3 mL/L). Blood was removed over ethylenediaminetetraacetic acid (EDTA) disodium salt and NaN_3 (3 and 0.15 mg/mL blood) dissolved in 0.15 M NaCl, final pH 7.4, by cardiac punc-

Abbreviations: Apo, apolipoprotein; BSA, bovine serum albumin; BW, body weight; CE, cholesteryl esters; E_2, 17β-estradiol; EDTA, ethylenediaminetetraacetic acids; FC, free cholesterol; FFA, free fatty acids; HDL, high density lipoproteins; IDL, intermediate density lipoproteins; LDL, low density lipoproteins; LW, liver weight; LPL, lipoprotein lipase; LSI, liver somatic index; PL, phospholipids; SDS, sodium dodecylsulfate; TC, total cholesterol; TG, triglycerides; TGSR, triglyceride secretion rates; VLDL, very low density lipoproteins; VTG, vitellogenin.

ture with a fine catheter (diameter 0.58 mm) and kept at 4°C throughout the procedure. Plasma was obtained by centrifugation (3000 × *g*, 10 min).

17β-Estradiol and fasting treatments. A graphic representation of our study design is shown in Figure 1. Animals were anesthetized and injected intraperitoneally with E_2 (7 mg/kg body wt) on days 0, 4, and 8; the injection volume was 1 μL/g body wt. E_2 was first dissolved in anhydrous ethanol and then in cottonseed oil (1:4, vol/vol). Controls were injected with ethanol and cottonseed oil without E_2. This treatment was selected to produce a rapid elevation in E_2 and VTG plasma levels, to the same range found during exogenous vitellogenesis in females (33–37). During the treatment there was no mortality, and the trout were still feeding.

Two-year-old juvenile trout of both sexes, weighing 278 ± 61 g (± SD, n = 26) from controls and the E_2-treated group were starved for 3 d and then fed *ad libitum* on day 10 of the treatment. The effects of starvation with or without estrogen treatment on plasma lipoprotein profiles were evaluated with serial blood samples taken until 7 d after the last meal. The blood volumes collected were lower than 2% of the whole body blood volume. Quantitative and chemical analysis of plasma lipids, proteins and lipoproteins in the two groups were performed with blood samples taken in series at 24, 96 and 154 h after feeding. The blood volumes punctured were lower than 10% of the total whole body blood volume. Alimentary assimilation is slower in fish than in mammals (31).

At the conclusion of the experiments (day 17, see Fig. 1) fasted fish were anesthetized and killed. Body (BW) and liver weights (LW) were determined to calculate the liver somatic index [LSI = (LW/BW) × 100].

Lipoprotein fractionation and analysis. A density gradient ultracentrifugation procedure previously described (38) was used with modifications for the fractionation of whole plasma lipoprotein classes and proteins. Discontinuous six-step density gradients were prepared with NaBr solutions, containing 0.05% EDTA (pH 7.4). Successive densities were (from top to bottom of tube): 1.006 g/mL (1.1 mL); 1.019 g/mL (2.5 mL); 1.063 g/mL (3.5 mL); 1.210 g/mL (2.5 mL); 1.310 g/mL (plasma at 1.310 g/mL, 0.55 or 0.01 mL, adjusted to this density with solid NaBr, and completed with a 1.310 g/mL NaBr solution to give a final volume of 1 mL); and 1.386 g/mL (0.8 mL). Six percent of the plasma volume is assumed to consist of macromolecules, and the remaining 94% is equivalent to a salt solution of density 1.015 g/mL. Instead of the adjusted plasma sample, control gradients were prepared using a NaBr solution of density 1.015 g/mL adjusted to 1.310 g/mL with solid NaBr. The gradients were then placed in a Beckman (Palo Alto, CA) SW 41-Ti swinging bucket rotor (average radius 110.2 mm) and centrifuged at 180,000 × *g* for 24 h at 10°C in a Beckman L8-70 ultracentrifuge, without braking at the end of the run.

The centrifuge tube containing the separated lipoproteins was punctured at the bottom and connected to the fractionation system filled with a 1.386 g/mL NaBr solution. The lipoprotein profile was recorded by continuously monitoring absorbance at 280 nm with a UV monitor (LKB 2238 Uvicord SII, LKB, Bromma, Sweden) as the lipoproteins were pumped from the centrifuge tube (collection speed 0.6 mL/min, chart speed 10 mm/min). One arbitrary unit of absorbance was taken as the optical

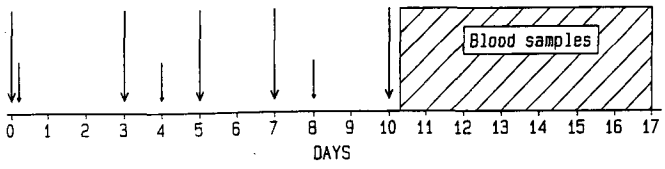

FIG. 1. Graphic representation of the study design. The small arrows indicate when 17β-estradiol or vehicle alone was intraperitoneally injected. The large arrows indicate when trout were nourished. The shaded area represents the period of blood sampling.

density of a 1 mg/mL solution of bovine serum albumin (BSA; Cohn fraction V, Sigma Chemical Co., St. Louis, MO). At the end of the fractionation, distilled water was carefully deposited onto the upper layer of the tube until VLDL was completely eluted. Fractions were collected with a fraction collector. Quantitative lipoprotein profiles were determined based on total lipoprotein concentration and the volume of the combined tube fractions (60 fractions, mean volume 300 μL). For each fraction, the lipoprotein concentration was calculated as follows: total lipoproteins = cholesteryl esters (CE) + free cholesterol (FC) + triglycerides (TG) + phospholipids (PL) + proteins. Density regions used were VLDL (VLDL + chylomicrons at + 24 h after feeding), d < 1.015 g/mL; LDL (intermediate density lipoproteins (IDL) + LDL), 1.015 < d < 1.085 g/mL; HDL, 1.085 < d 1.210 g/mL; VTG, (presence of VTG only for estrogen-treated fish), 1.210 < d < 1.310 g/mL; proteins, d > 1.310 g/mL. The concentrations were expressed as mg/dL plasma after correction for dilution introduced by the anticoagulant. The recovery after the entire procedure was 86.03 ± 4.32% for CE, 92.94 ± 2.93% for FC, 95.58 ± 3.24% for TG, 84.57 ± 3.09% for PL, and 88.73 ± 2.19% for proteins (n = 14).

The apolipoprotein compositions of the major classes of trout lipoproteins have recently been described (31,38, 39). Apolipoproteins were electrophoresed under reducing conditions in sodium dodecylsulfate (SDS)/glycerol/polyacrylamide slab gels using a linear gradient of 3.5–15% polyacrylamide and 8–12% glycerol (39). The relative molecular mass (Mr) values of trout apolipoproteins were determined as previously described (39) by comparison with simultaneously run proteins of known Mr (MW-SDS-70L and MW-SDS-200 molecular weight marker kits from Sigma Chemical Co.). Gels were subsequently fixed and stained using a highly sensitive Coomassie Blue G-250 procedure (40).

The size distribution of VLDL isolated 96 h after feeding was monitored by electron microscopy (80 kV) after dual staining of the particles (41). VLDL were diluted first with saline EDTA, mixed with 1:1 (vol/vol) 4% OsO_4, and fixed for 2 min. The fixed and positively stained particles were then negatively stained with 1% neutral phosphotungstic acid in the presence of 0.1% sucrose on a Formvar/carbon grid (Balzers, Selles S/Cher, France).

Chemical analysis. The lipid compositions of the lipoprotein fractions and of plasma were estimated using commercially available enzymatic kits from Boehringer-Mannheim (Meylan, France) for FC, total cholesterol (TC) and free fatty acids (FFA), and from Wako-Unipath (Dardilly, France) for PL and TG. The assays were performed as described elsewhere (42,43). Protein concentrations were determined by a modified Lowry assay (44) using BSA

as standard. The amount of CE was calculated using the formula CE = 1.7 × (TC−FC), using 288 as the average molecular weight of the trout plasma fatty acids (45). The amount of total lipids (TL) in plasma were calculated from the expression TL = CE + FC + PL + TG + FFA (46). Concentrations in plasma were expressed as mg/100 mL plasma after correction for the dilution introduced by the anticoagulant.

Ultrastructural study. The tissues were fixed for 1 h at 4°C in osmium tetroxide (OsO_4) buffered with sodium cacodylate (0.15 M, pH 7.3) and embedded in Epon 812. The lipids were preferentially contrasted by the OTO method (47). Thin sections of tissue were collected on gold grids and successively placed on 1% aqueous solution of thiocarbohydrazide (1 h at 50°C) and on 2% aqueous solution of osmium tetroxide (1 h at 50°C).

VLDL triglyceride secretion. To evaluate the effect of E_2 on TG and VLDL-TG secretion rates, trout were injected with Triton WR-1339 (Tyloxapol, Sigma Chemical Co.), a nonionic detergent which has been used widely as an indicator of VLDL secretion *in vivo* (25, 48–51). Eleven-month-old juvenile trout of both sexes, weighing 63.61 ± 10.3 g (±SD, n = 23) from controls and the E_2-treated group were starved for 96 h before Triton injection. Preliminary experiments indicated that adequate inhibition of TG removal occurs at 70 mg/100 g body wt or above. Animals were anesthetized, and Triton WR-1339 (25 g/dL in 0.9% NaCl, 70 mg/100 g body wt) was injected intracardialy at day 14 of the estrogen or control treatment (injection volume, 145 μL). For each trout, blood samples were taken intracardialy at 15 min (arbitrary zero time) and 3 h or 6 h after the Triton injection. The mean of TG secretion rates (TGSR) for each group, E_2-treated or control animals, was determined by the equation TGSR = 1/2 (TG1/T1 + TG2/T2) × PV (49). TG1 and TG2 are means augmentations of plasma TG concentrations (mg/dL) 3 and 6 h after Triton injection, and T1 and T2 are times between zero time and time of sampling after Triton injection. PV is the estimated whole body plasma volume (3.25 mL/100 g body wt) (52,53).

VLDL were isolated by micro-ultracentrifugation in an air-driven ultracentrifuge (Airfuge, Beckman, Palo Alto, CA) (54,55) from plasma of the same trout obtained 15 min (zero time) and 3 h after Triton injection. One hundred μL plasma was transferred to a centrifuge tube, layered gently with 75 μL of NaBr solution (d = 1.015 g/mL), and centrifuged at 100,000 rpm (30 psi) for 3 h in a fixed angle rotor (A-100/30). The air was refrigerated at 4°C using an air drying and cooling system (56). Thirty μL of top VLDL fraction was cut with a tube slicer specifically designed for the small tubes. TG values were determined in control and E_2-treated trout to evaluate the difference in VLDL output *in vivo* after Triton WR-1339 injection. Pure VLDL, not contaminated by other lipoprotein classes or plasma proteins, were isolated by this procedure (57). However, the volume collected here was too low for a complete recovery of the VLDL fraction (54,55).

Statistical methods. Data are presented as means ± SEM and were tested for statistical significance by analysis of variance followed by an evaluation employing Scheffe's multiple range test. LSI comparison was made by Student's *t*-test. Statistical evaluations of the results were performed using the Statistical Analysis System (SAS) (58). The *P* value chosen for statistical significance was 0.05.

RESULTS

Concentration of plasma lipid fractions and proteins. The effects of starvation on the concentration of different plasma lipids and proteins, with or without E_2 treatment, are shown in Table 1. Plasma samples were obtained from juvenile control or treated trout 24, 96 and 154 h after the last feeding.

E_2 treatment increased the concentrations of plasma lipids and proteins except CE, regardless of the time after feeding, with the levels of TG increasing the most. Plasma TG levels at 96 h were nine times higher in E_2-treated animals than in controls (874 mg/dL *vs.* 96 mg/dL). The other parameters assayed, FC, PL, FFA and protein, also increased in treated *vs.* control trout, reaching maxima at 154 h. Starvation in controls was accompanied by a significant decrease in the plasma concentrations of all lipids, except FC (total lipids = 1212 mg/dL at 24 h *vs.* 734 mg/dL at 154 h). In E_2-treated animals rendered hyperlipidemic and hyperproteinemic, only the plasma concentrations of CE and TG decreased during starvation (significant at $P < 0.05$ for TG), while those of PL and proteins increased significantly (PL = 802 mg/dL at 24 h *vs.* 1034 mg/dL at 154 h; proteins = 8019 mg/dL at 24 h *vs.* 11,879 mg/dL at 154 h). During fasting, triglyceridemia

[c]$P < 0.01$.
[d]$P < 0.001$.

in control trout dropped faster than in E_2-treated trout, but both were decreasing, thus amplifying the difference.

The increase in total plasma cholesterol in E_2-treated trout was not reflected in a concomitant increase in the plasma CE concentration. This indicates that the percentage of esterified cholesterol was lower in these animals and that the increase in cholesterolemia was due only to an increase in free cholesterol. The percentage of esterified cholesterol decreased even during starvation, from 63% in controls to only 30% after 154 h of starvation in E_2-treated animals.

Effects of starvation and 17β-estradiol on lipoprotein profile. The observed changes in plasma concentrations of the different lipids and proteins after feeding and E_2 administration revealed changes in plasma lipoprotein concentrations. A complete lipoprotein profile was obtained by fractionating 10 μL of plasma by density gradient ultracentrifugation. The lipoprotein profile was recorded by continuously monitoring absorbance at 280 nm as lipoproteins were pumped from the centrifuge tube. The different classes of lipoproteins were clearly identifiable (Fig. 2) and have been previously characterized (see ref. 38). Successive blood samples from the same animal, E_2-treated or control, illustrated the changes at different times after feeding.

The peak in alimentary absorption in controls was reflected in a substantial increase in the concentration of the TG-rich lipoproteins, VLDL and chylomicrons (d < 1.015 g/mL), reaching a maximum 16 h after feeding. At the time of the absorption peak and under standardized alimentary conditions, postprandial plasma triglyceridemia and the plasma concentration of the TG-rich lipo-

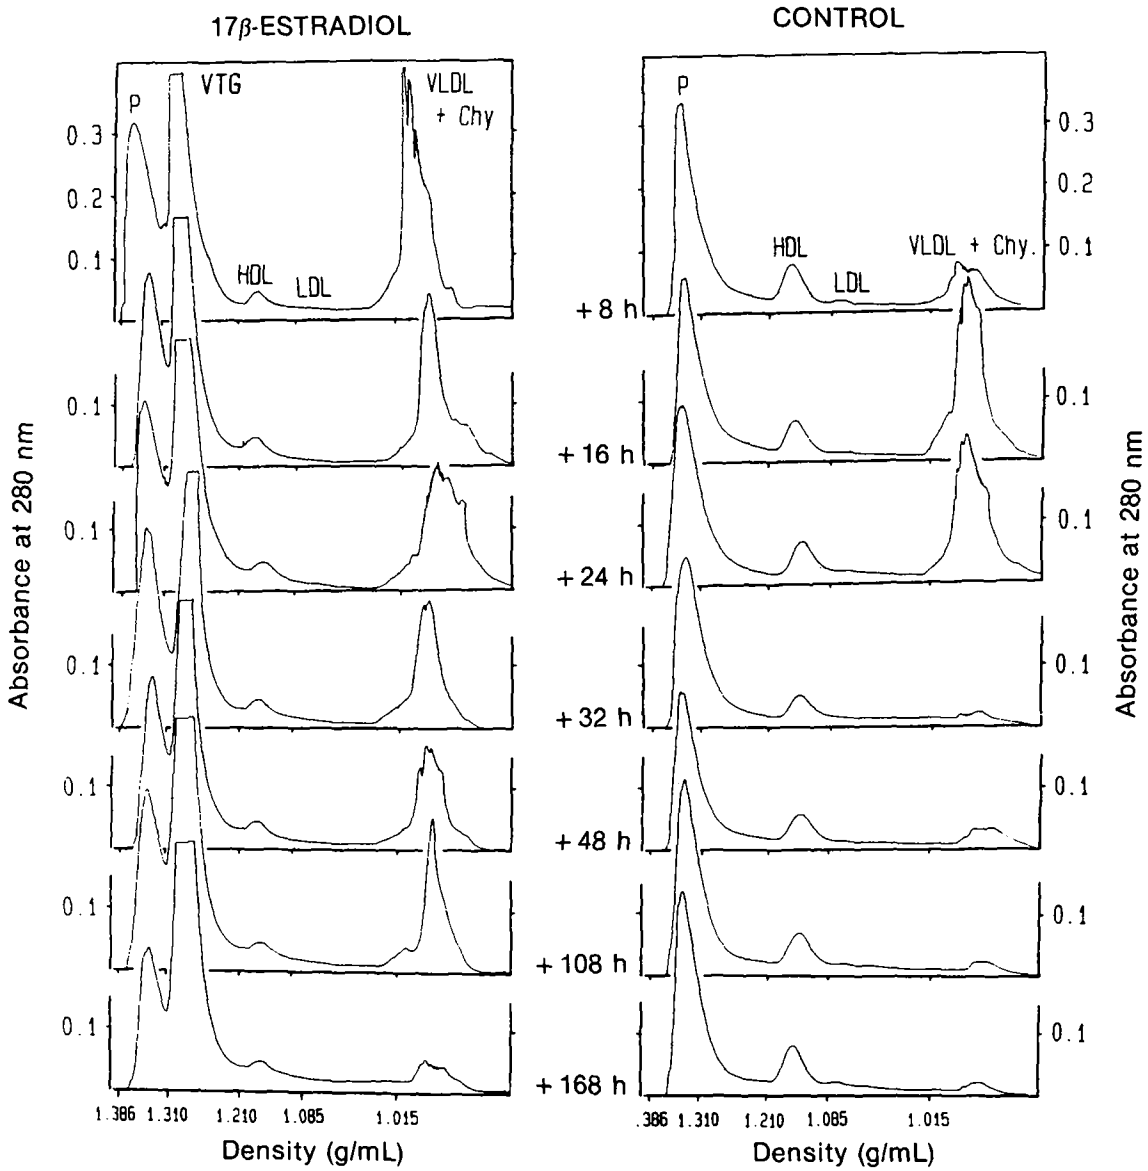

FIG. 2. Effects of starvation and 17β-estradiol on plasma lipoprotein profile in juvenile trout. Ultracentrifugal single-spin absorbance profiles of 10 μL of plasma were obtained at different hours after feeding. The two trout were selected for comparable postprandial triglyceridemia, 1126 mg/dL for the estrogen-treated trout *vs.* 1007 mg/dL for the control trout, 16 h after feeding. HDL, high density lipoproteins; LDL, low density lipoproteins; VLDL + Chy., very low density lipoproteins + chylomicrons; VTG, vitellogenin.

proteins, VLDL and chylomicrons, depended on the quantity of food ingested during the meal (data not shown). To eliminate variations arising from nutritional variables, an E_2-treated trout and a control trout having comparable postprandial triglyceride levels and quantities of lipoproteins of $d < 1.015$ g/mL at the absorption peak were compared (Fig. 2) (TG 1126 *vs.* 1007 mg/dL at 16 h and 1108 *vs.* 957 mg/dL at 24 h; the lipoproteins were quantitated by integrating peak areas).

The administration of E_2 caused a very high concentration of VTG ($1.21 < d < 1.31$ g/mL) in the plasma. The concentrations of VLDL-chylomicrons and VLDL were much higher in E_2-treated trout than in controls. At 32 h, the quantity of circulating VLDL had returned to normal levels in controls (TG = 185 mg/dL), and it remained very high in E_2-treated trout (TG = 999 mg/dL), and lasted up to at least seven days of starvation (TG = 566 mg/dL in E_2-treated *vs.* 156 mg/dL in controls on day 7). The plasma concentration of VLDL-chylomicrons in E_2-treated trout was higher at 8 h than at the time when alimentary absorption peaked (16 and 24 h). The animals had been starved for 72 h (days 7 to 10) before the last feeding (see Fig. 1); therefore the peak at 8 h for the last feeding also represented the VLDL peak at 80 h (72 h + 8 h) for the penultimate feeding. The magnitudes of the VLDL peaks at 48 h and 108 h in Figure 2 clearly indicate that the peak at 8 h resulted from the addition of VLDL from the two feedings.

Concentrations and compositions of plasma lipoproteins. The quantitative changes in the different classes of lipoproteins in both groups of trout are listed in Table 2. Plasma hypertriglyceridemia induced by E_2 was due primarily to a significant increase in the concentration of VLDL, whether at the alimentary absorption peak (VLDL-chylo.: 6 × control level at 24 h) or in starving animals (VLDL: 15 × control level at 96 h). LDL (IDL + LDL), most of which are derived from lipolysis of VLDL, also were present in higher concentrations in E_2-treated animals than in controls, especially during starvation. Thus, 96 h after feeding, the mean concentration of LDL in treated animals was twice that in the controls (492 *vs.* 222 mg/dL), but the difference was not significant. E_2 treatment did not significantly change the concentrations of HDL and plasma proteins in the pellet ($d > 1.31$ g/mL). E_2 induced hepatic synthesis of VTG, a phospholipid-rich lipoprotein (18% lipids, of which 2/3 are phospholipids) which is the major protein in the plasma of E_2-treated trout. Due to the high density and the high concentration of VTG, it was not possible to satisfactorily separate VTG from the plasma proteins in the pellet (see Figs. 2 and 3). The values in Table 2 for juvenile control trout show the protein concentration in the density zone of 1.21 to 1.31 g/mL and do not imply the existence of VTG.

During starvation, the concentration of VLDL decreased in both control and E_2-treated trout, while LDL decreased in the controls (Table 2). The HDL concentration was not significantly changed in either controls or treated animals. The VTG concentration, however, increased significantly (twofold increase between 24 and 154 h), explaining the previously mentioned increase in plasma PL and proteins during starvation in E_2-treated trout (Table 1). The lipoprotein profiles presented in Figure 3 were typical of the mean concentrations induced (Table 2) after E_2 administration and/or starvation; they illustrate the increase in VLDL concentrations after E_2 administration (3492 *vs.* 973 mg/dL at 24 h, 1861 *vs.* 95 mg/dL at 96 h, 1046 mg/dL at 154 h). The progressive increase in VTG concentration during starvation also is well illustrated (3874 mg/dL at 24 h, 4772 mg/dL at 96 h and 8168 mg/dL at 154 h).

The percentages of lipid and protein in VLDL ($d < 1.015$ g/mL) of controls were different at 24 h and 96 h (TG/CE, 50:10, for core lipids and FC/PL/proteins, 5:23:12 for surface components at 24 h; *vs.* 45:14 and 6:23:12 at 96 h; in weight ratios). At 96 h, the core lipids were depleted in TG and enriched in CE. By contrast, the compositions of E_2-treated VLDL were identical at 24 h and 96 h (TG/CE, 49:6 for core lipids and FC/PL/proteins, 6:20:19, for surface components). However, the compositions of VLDL of E_2-treated trout and control trout were different. CE was depleted in E_2-treated VLDL, especially at 96 h, whereas protein was enriched. The increase in total plasma cholesterol in E_2-treated trout was not reflected in a concomitant increase in plasma CE concentration (Table 1). This was consistent with the high concentration of VLDL depleted in CE in E_2-treated trout.

A comparison of the VLDL apolipoprotein profiles of

TABLE 2

Effects of 17β-Estradiol Administration and Fasting on Plasma Lipoprotein Concentrations in Juvenile Trout (mg/dL plasma)[a]

Time after feeding		Bottom proteins (P)	Vitellogenin (VTG)	High density lipoproteins (HDL)	Low density lipoproteins (LDL)	Very low density lipoproteins (VLDL)

[a]Values are means ± SEM. Sample numbers are given in parentheses. A density gradient ultracentrifugation procedure was used for the fractionation of whole plasma lipoproteins and proteins. The concentrations were calculated as follows: total lipoproteins = cholesteryl esters + free cholesterol + triglycerides + phospholipids + proteins. Density regions used were VLDL (VLDL + chylomicrons at + 24 h after feeding), $d < 1.015$ g/mL; LDL (LDL + IDL), $1.015 < d < 1.085$ g/mL; HDL, $1.085 < d < 1.210$ g/mL; VTG (presence of VTG only for estrogen-treated fish), $1.210 < d < 1.310$ g/mL; P (bottom proteins), $d > 1.310$ g/mL. At each time point after feeding, the significances of the differences between control and treated trout were tested using analysis of variance and Scheffe's multiple range test.

[b]$P < 0.05$.

[c]$P < 0.001$.

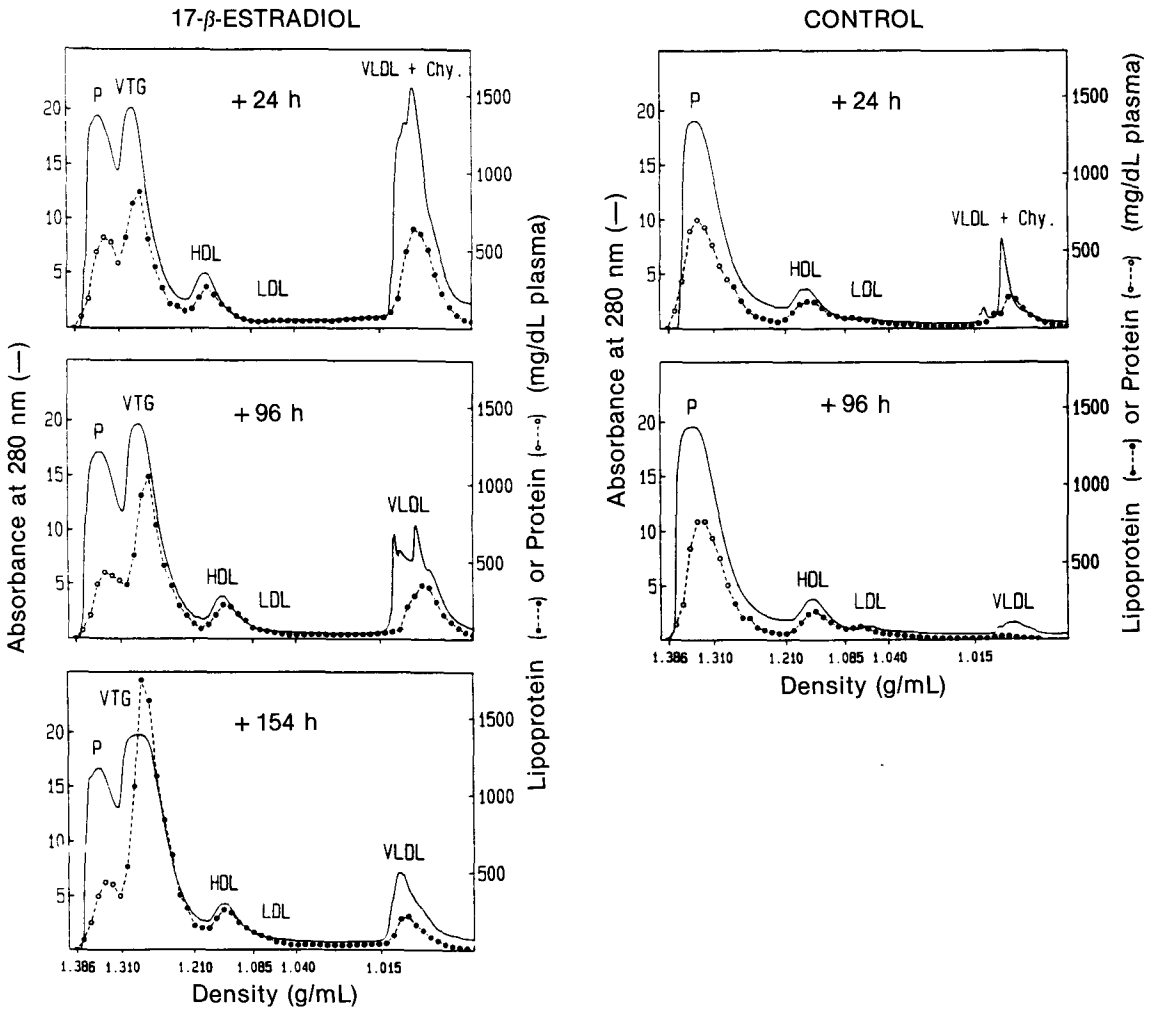

FIG. 3. Density gradient ultracentrifugal lipoprotein quantitative profiles of a 17β-estradiol (E_2)-treated or a control juvenile trout obtained at different times after feeding. The lipoprotein profiles presented were typical of the mean concentrations induced (Table 2) after E_2 administration and/or starvation. Absorbance at 280 nm (——), lipoprotein (when lipids were present in the fraction) (●—●—●), or protein (O—O—O) profiles. The lipoprotein concentration was calculated from the expression: total lipoproteins = cholesteryl esters + free cholesterol + triglycerides + phospholipids + proteins. The concentrations are expressed in mg/dL plasma. Abbreviations as in Figure 2.

control and E_2-treated trout did not show any new apolipoproteins in the E_2-treated animals (Fig. 4). At 24 h, the electrophoretic profiles were similar, but marked changes in the distribution of apolipoproteins were observed at 154 h. In control trout, prolonged starvation resulted in the total disappearance of Mr 240,000 apolipoprotein (apo B_{240}) which persisted in VLDL of E_2-treated trout. In these VLDL there was also a depletion of Mr 76,000 and 66,000 apolipoproteins at 154 h and an enrichment in species of Mr 25,000 (apo A-I) and Mr 13,000 (apo A-II).

The plasma concentration of VLDL in estrogenized trout was very high 96 h after feeding (Fig. 3). Electron microscopy of these VLDL (Fig. 5B) indicated that their size was homogeneous and that their mean diameter was lower than at the peak of alimentary absorption (24 nm *vs.* 20–50 nm) (31,38).

Ultrastructural study. The ultrastructural analysis of liver cells from estrogenized trout 96 h after feeding showed active synthesis of small VLDL, with a diameter similar to that observed in plasma (Fig. 5A and 5B). The cavities of the endoplasmic reticulum contained particles the size of VLDL which accumulated on the Golgi complex formation face. The extremities of the Golgi complexes formed secretion grains which released lipoproteins into intercellular space. The same feature was observed for control trout; however, at the end of the experiment, the LSI of E_2-treated and control animals were significantly different ($P < 0.001$): 4.01 ± 0.25% (n = 8) *vs.* 1.35 ± 0.11% (n = 9) and indicated hepatomegaly in the treated animals.

Triglyceride and VLDL-triglyceride output in vivo. The levels of plasma TG secreted by E_2-treated and control trout were determined *in vivo* after 96 h of starvation, after injecting Triton WR-1339.

Mean TG increases were 45.2 ± 14.6 mg/dL (n = 7) in E_2-treated animals *vs.* 15.1 ± 2.8 mg/dL (n = 8) in controls 3 h after injecting Triton, and 78.5 ± 34 mg/dL

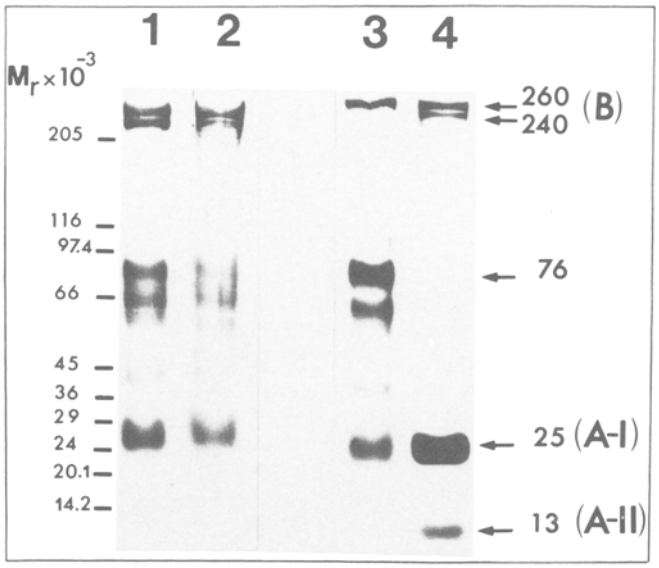

FIG. 4. Electrophoretic patterns in sodium dodecylsulfate/glycerol/polyacrylamide gradient gel of very low density lipoprotein (VLDL)-apolipoproteins from control and 17β-estradiol-treated trout (75 μg of proteins for lanes 1 and 2, 50 μg of proteins for lanes 3 and 4). 1, control VLDL 24 h after feeding; 2, 17β-estradiol-treated VLDL 24 h after feeding; 3, control VLDL 154 h after feeding; 4, 17β-estradiol-treated VLDL 154 h after feeding. Mr × 10^{-3}, reference markers relative molecular weight × 10^{-3}; (B), apo B; (A-I) apo A-I; (A-II), apo A-II (see references 31, 38 and 39 for details about trout apolipoproteins).

(n = 8) *vs.* 17.1 ± 3.2 mg/dL (n = 8) 6 h after injecting Triton. Based on these values the mean TGSR could be calculated as: 0.086 mg/h in controls and 0.308 mg/h in treated animals (control × 3.5) for a mean body of 63 g. The LSI values at the end of the experiment were significantly different ($P < 0.001$): 2.786 ± 0.23% (n = 11) in treated animals *vs.* 1.40 ± 0.06% (n = 11) in controls.

The difference in VLDL output, during starvation, between E_2-treated and control trout was determined by reproducibly isolating a part of plasma VLDL by microultracentrifugation 3 h after injecting Triton. Pure VLDL, not contaminated by other lipoprotein classes, were isolated. However, the volume collected was too small to completely recover the VLDL fraction. Under these conditions, the mean increases in VLDL-TG concentrations were significantly different: 17.1 ± 7.8 mg/dL (n = 5) in treated animals *vs.* 1.2 ± 0.4 mg/dL (n = 6) in controls.

DISCUSSION

Fish are poikilothermic vertebrates which preferentially utilize lipids rather than carbohydrates as energy source (59,60). Ovarian growth and reproduction activity are reflected by a clearcut increase in energy demand (61). There are two sources for this energy, one exogenous and of alimentary origin, the other endogenous, from lipid storage tissues (muscle, liver and possibly perivisceral adipose tissue) which are characterized by a succession of phases of deposition and mobilization of lipid reserves. Exogenous vitellogenesis, *i.e.*, endocytosis of the yolk precursors by oocytes, is shown by, among other things, elevated plasma concentrations of E_2 and testosterone, hypertrophy of the liver and the ovaries, and profound changes in lipid metabolism. These are reflected in qualitative and quantitative changes in the different classes of plasma lipoproteins.

Trout exhibit seasonal variations, which still are poorly defined, in the levels of the different classes of plasma lipoproteins other than VTG, and which are related to the annual reproductive cycle (31,62-64). In particular, the VLDL concentration increases during exogenous vitellogenesis (62,64). Studies on the effects of sex steroids on plasma lipids unrelated to VTG have been few in fish (65,66). No data exist on the possible role of sex hormones in the metabolic regulation of various classes of plasma lipoproteins other than VTG.

The injection of E_2 into juvenile trout enabled us to obtain LSI and VTG concentrations comparable to those in adult trout in exogenous vitellogenesis (31,67). Our results show that in addition to inducing VTG synthesis, E_2 led to a considerable increase in the concentration and secretion of VLDL in plasma. As in chicks (68) and rats (18), the increased concentration of VLDL appears to be due to stimulated hepatic secretion of VLDL. These effects on VLDL are apparently common to all vertebrates (11,14,17,19), particularly oviparous (24-26,68). Induced hypertriglyceridemia in trout arises primarily from the increased concentration of the triglyceride-rich VLDL and, to a lesser extent, LDL, whereas VTG in this species contains only 4% TG (69). In fish, as in mammals, most LDL are derived from the sequential lipolysis of VLDL to IDL and then LDL (38,70), which would explain the slightly increased concentration of LDL in E_2-treated trout.

Hyperlipidemia and hyperproteinemia induced by E_2 in trout are at least partially due to increased secretion of lipoproteins, which persists after several days of starvation, consistent with recent observations in chicks (71). The increased levels of FFA under the effect of estrogens, which are especially pronounced during starvation in trout (as shown here), but also in chicks (71,72) and lizards (73), suggest that estrogens also may cause the mobilization of fatty acids in reserve tissues (71,73-75).

Alimentary assimilation is slower in fish than in mammals (31). The appearance of TG-rich lipoproteins in plasma, characteristic of the postprandial absorption peak, thus occurs later in trout than in humans. After the postprandial phase, progressive decreases in VLDL and LDL concentrations were observed, while HDL levels stayed the same, in agreement with other observations in trout during starvation (76). The very high concentrations of VLDL in E_2-treated animals also were associated with a slow and gradual decrease in VLDL concentrations during starvation, indicating that plasma clearance is effective and/or hepatic secretion is reduced. The progressive increase in VTG concentration during starvation may be due to VTG accumulation in plasma of juvenile trout, in the absence of ovarian uptake.

In chicks, the VLDL present in plasma during E_2 treatment are very different from the VLDL of controls, especially in size, electrophoretic migration and apolipoprotein composition (77). The VLDL of E_2-treated chicks are composed of at least two different lipoprotein classes with different particle sizes and apolipoprotein compositions. Small VLDL were predominant in E_2-treated chicks (24,77).

In fish, as in other vertebrates, the peak of alimentary absorption results in a mixture of TG-rich lipoproteins of

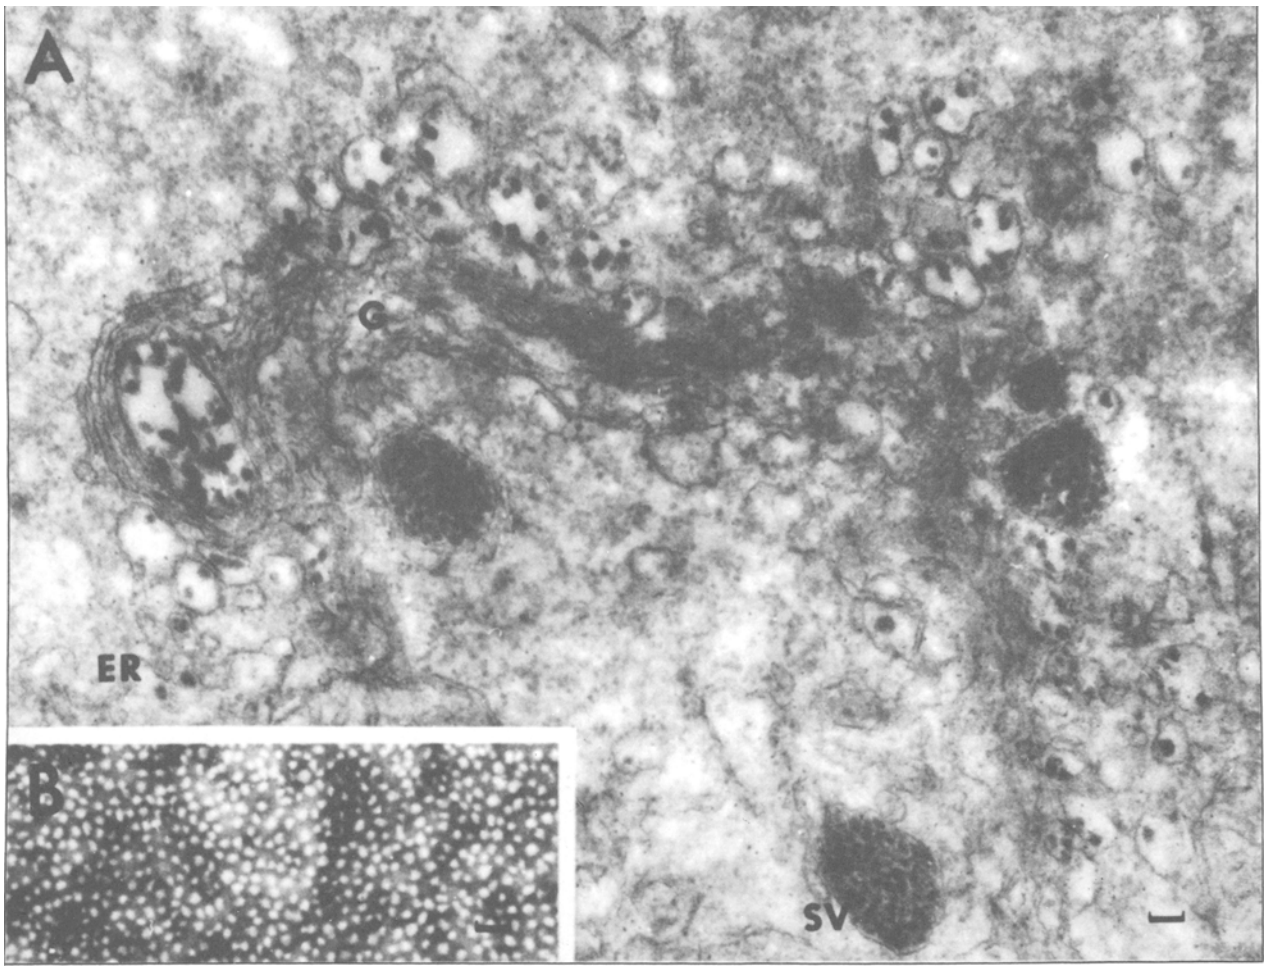

FIG. 5. Liver cell ultrastructure (A) and plasma VLDL (B) of juvenile estrogenized trout in the course of fasting (96 h after feeding). (A), ultrastructural analysis was carried out on sections in which lipids were contrasted by the OTO method. Very low density lipoproteins appeared as black particles in endoplasmic reticulum (ER), Golgi complex (G), and secretory vesicles (SV). (B), lipoproteins were isolated by density gradient ultracentrifugation (d < 1.015 g/mL), positively stained with OsO_4, and then negatively stained with phosphotungstate. Scale bar = 100 nm.

intestinal (78,79) and hepatic origin (79) in the plasma. Fasting results in a progressive disappearance of TG-rich intestinal lipoproteins (78). In E_2-treated animals, there is a high concentration of small VLDL in the plasma, similar to those synthesized by the liver, and being enriched in certain apolipoproteins. These results suggest that treatment with E_2 may change the apolipoprotein distribution of endogenous hepatic VLDL.

The increased rate of secretion of TG or VLDL-TG after injecting Triton WR-1339 in fasting animals, between control and estrogenized trout, may be partially due to the increase in the LSI. This index, increased by a factor of two or three in estrogenized trout, indicates hepatomegaly in these animals. Hepatomegaly is coupled with active synthesis of VLDL by liver cells and may be responsible for the very high concentration of plasma VLDL in estrogenized fish. The increase in net secretion of hepatic VLDL does not exclude the possibility of a simultaneous decrease in the activities of plasma lipases or in the production of VLDL particles, which are less sensitive to the action of LPL. Aside from the modified CE and protein contents of the entire VLDL pool and an enrichment of the fraction in certain apolipoproteins during starvation, we were unable to show qualitative differences in the apolipoprotein composition of VLDL between E_2-treated and control trout (38,39). In chicks, the presence of apo VLDL-II in VLDL after E_2 treatment is reflected in a decrease in their sensitivity to LPL (27,28) and by slower catabolism of the particles in the plasma of males (77). In laying hens, this decreased sensitivity toward LPL enables these VLDL to be incorporated in growing oocytes (80), mediated by an apo B-specific surface receptor (29) which is identical to the VTG receptor (30). Even though no direct proof exists, the strategy appears to be different in trout. In addition to taking up VTG (81) by a specific surface receptor (82), the ovary may be able to take up lipid components by lipolysis of circulating lipoproteins. This is suggested by the considerable increase in LPL and salt-resistant lipase activities in the ovary during exogenous vitellogenesis (63). LPL in this species is greatly activated by VLDL and, to a lesser extent, by HDL (83).

In conclusion, estrogen-induced hyperlipidemia in the juvenile trout results in major changes in lipoprotein profiles. Estrogen-induced changes in the profiles can occur spontaneously in females during the reproductive cycle. The increased concentration of VLDL and the appearance

of VTG after administering E_2 are similar to those observed in chicks and suggest the existence of similar mechanisms for the regulation of lipoprotein metabolism by estrogens in oviparous vertebrates.

ACKNOWLEDGMENTS

The authors thank Marie-France Sire for kindly performing electron microscopic analyses. They also thank Patrick Gasqui (Laboratoire de Biométrie, INRA, Jouy en Josas, France) for valued support and advice regarding statistical analysis with the SAS program.

METHOD

A Method for Determination of the Absolute Stereochemistry of α,β-Epoxy Alcohols Derived from Fatty Acid Hydroperoxides

Mats Hamberg*
Department of Physiological Chemistry, Karolinska Institutet, S-104 01 Stockholm, Sweden

A method for the determination of the absolute configuration of the alcohol group of fatty acid α,β-epoxy alcohols was developed. The method consists of: (i) deoxygenation of the saturated epoxy alcohol to an allylic alcohol by treatment with triphenylphosphine selenide and trifluoroacetic acid; (ii) oxidative ozonolysis of the (−)-menthoxycarbonyl derivative of the allylic alcohol; and (iii) steric analysis of the resulting 2-hydroxy acid (methyl ester, (−)-menthoxycarbonyl derivative) by gas-liquid chromatography using appropriate reference compounds. The result obtained, coupled with knowledge of the relative configuration of the epoxy alcohol *(erythro/threo)* and of the geometrical configuration of the epoxide group *(cis/trans)*, permitted assignment of the absolute configuration of all three asymmetric carbons of the α,β-epoxy alcohol. The method was applied to the determination of the absolute stereochemistry of two hepoxilins recently isolated from the red alga *Murrayella periclados*. *Lipids 27,* 1042-1046 (1992).

A variety of regio- and stereoisomeric fatty acid epoxy alcohols are formed from unsaturated fatty acid hydroperoxides. Epoxy alcohols of types **I** and/or **II** (Fig. 1) have been obtained in studies where hydroperoxides have been exposed to heat (1), Fe^{2+} (2), hemoglobin (3), hematin (4), soybean lipoxygenase (5), acid (6) and rat lung homogenate (7). Formation of these types of epoxy alcohols involves homolytic or heterolytic cleavage of the O–O bond of the parent hydroperoxide, followed by attack by the proximal hydroperoxide oxygen at the α-unsaturation to produce the epoxide function. The epoxyallylic radical or carbocation is subsequently attacked by either dioxygen, the distal hydroperoxide oxygen or solvent, to provide a non-allylic α,β-epoxy alcohol (type **I**) or an allylic γ,δ-epoxy alcohol (type **II**) (8). Epoxy alcohols of types **III** and **IV** have been obtained by enzymic reactions, *i.e.,* following incubation of hydroperoxides with a fatty acid hydroperoxide isomerase from the fungus *Saprolegnia parasitica* (9) and with a hydroperoxide-dependent epoxygenase from *Vicia faba* (10,11). In addition, epoxy alcohols of type **III** are produced from hydroperoxides by intermolecular epoxidation catalyzed by vanadium oxyacetylacetonate (12).

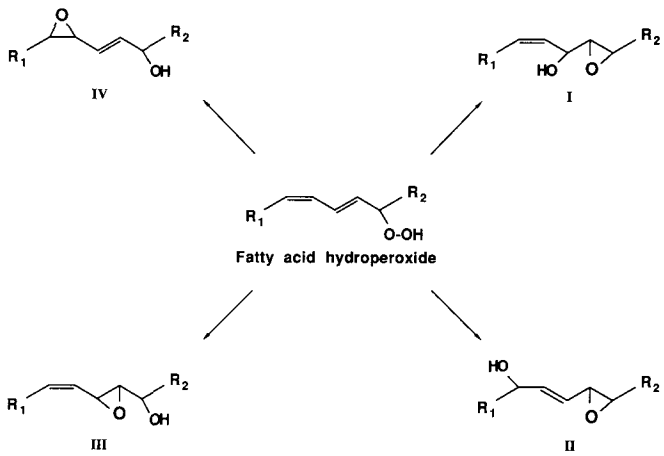

FIG. 1. Rearrangement of fatty acid hydroperoxides into epoxy alcohols.

The configuration of the allylic alcohol group of γ,δ-epoxy alcohols (types **II** and **IV** in Fig. 1) has been determined by cleavage of the double bond followed by steric analysis of the resulting 2-hydroxy acid (see *e.g.,* refs. 9 and 13). In addition, these epoxy alcohols, as well as epoxy alcohols of type **III**, are easily hydrolyzed to derivatives containing a 1,2,5-trihydroxy-3*E*-pentene structure. Methodology for determination of the absolute stereochemistry of such trihydroxy fatty acids has been developed (14) and can be utilized for assignment of the stereochemistry of the parent allylic epoxy alcohol. On the other hand, in the case of epoxy alcohols of type **I**, neither chemical degradation nor acid-catalyzed hydrolysis into trihydroxy derivatives has been useful for determining the absolute configuration. The present paper describes a simple method to establish the absolute configuration of the allylic hydroxyl group of this type of epoxy alcohols. The method, in combination with existing chemical and physical methods for determining relative configuration, allows assignment of the absolute stereochemistry of epoxy alcohols of type **I**.

MATERIALS AND METHODS

Linoleic acid was purchased from Nu-Chek Prep (Elysian, MN), and [1-^{14}C]linoleic acid was obtained from Amersham Laboratories (Amersham, U.K.). [1-^{14}C]-Labeled 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid (13*S*-[1-^{14}C]HPOD; specific radioactivity, 2.1 kBq/μmol; enantiomeric composition, 13*S*/13*R*, 98:2) was obtained by incubation of [1-^{14}C]linoleic acid with soybean lipoxygenase (1). Triphenylphosphine selenide was purchased from Fluka (Buchs, Switzerland), and human hemoglobin was obtained from Sigma Chemical Co. (St. Louis, MO).

Methyl erythro-*11-hydroxy*-trans-*12,13-epoxy-9Z-octadecenoate.* The methyl esters of the *erythro* and *threo* isomers of the α,β-epoxy alcohol 11-hydroxy-12,13-epoxy-9-octadecenoic acid were prepared by modification of a procedure described earlier (3). Thus, 13(*S*)-[1-^{14}C]HPOD (32 mg) was added to a solution of 2 g of hemoglobin in 20 mL of potassium phosphate buffer, pH 7.4, and the mixture was shaken at 37°C for 10 min. In order to remove

the γ,δ-epoxy alcohol 9*R,S*-hydroxy-12,13-epoxy-10-octadecenoic acid (3), which interfered with the isolation of the more polar of the two α,β-epoxy alcohols, the reaction mixture was acidified to pH 2 and kept at this pH at 23°C for 3 min. The mixture was extracted with two volumes of diethyl ether, and the combined ether phases were washed until neutral. The residue obtained following evaporation of the solvent was esterified by treatment with diazomethane and subjected to preparative thin-layer chromatography (TLC). Five main products appeared, *i.e.*, methyl 13-oxo-9,11-octadecadienoate (14%, $R_f = 0.74$), the methyl ester of 13*S*-hydroxy-9*Z*,11*E*-octadecadienoic acid (13*S*-HOD, 32%, $R_f = 0.55$), methyl *erythro*-11-hydroxy-12,13-epoxy-9-octadecenoate (7%, $R_f = 0.40$), material (10%, $R_f = 0.35$) mainly due to methyl *threo*-11-hydroxy-12,13-epoxy-9-octadecenoate, as well as polar material (26%, $R_f = 0$–0.02) mainly due to stereoisomers of methyl 9,10,13- and 9,12,13-trihydroxyoctadecenoates formed from 9*R,S*-hydroxy-12,13-epoxy-10-octadecenoic acid in the acid treatment step.

Analysis of the trimethylsilyl (Me_3Si) derivative of methyl *erythro*-11-hydroxy-12,13-epoxy-9-octadecenoate by gas chromatography/mass spectrometry (GC/MS) showed a C value (15) of 20.62. The mass spectrum showed a prominent ion at *m/e* 285 (Me_3SiO^+=CH-CH=CH-$(CH_2)_7$-$COOCH_3$; 100%) as well as ions at *m/e* 398 (M, 0.5), 383 [M − 15 (loss of $\cdot CH_3$), 1], and 327 [M − 71 (loss of $\cdot C_5H_{11}$), 3]. That the relative configuration at C-11/C-12 was *erythro* followed from previous work which had shown that $LiAlH_4$ reduction of the saturated epoxy alcohol resulted in the formation of similar amounts of a 11,13-dihydroxy-1-octadecanol and *erythro*-11,12-dihydroxy-1-octadecanol (3). Infrared spectrometric analysis of methyl *erythro*-11-hydroxy-12,13-epoxy-9-octadecenoate showed bands at *inter alia* 3620–3350 cm^{-1} (hydroxyl), 1730 cm^{-1} (ester carbonyl) and 890 cm^{-1} (*trans*-epoxide). No absorption band appeared in the region 950–1000 cm^{-1}, thus showing that the configuration of the Δ9 double bond remained *Z*. These experiments confirmed and extended the previous structural work (3) and showed that the epoxy alcohol was identical with methyl *erythro*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate.

Methyl threo-*11-hydroxy*-trans-*12,13-epoxy-9Z-octadecenoate.* 13*S*-[1-^{14}C]HPOD was treated with hemoglobin as described above, and the esterified product was subjected to TLC. Material present in the band at $R_f = 0.35$ was previously found to be due to *ca.* 80% methyl *threo*-11-hydroxy-12,13-epoxy-9-octadecenoate and 20% of an *erythro* isomer, probably methyl *erythro*-11-hydroxy-*cis*-12,13-epoxy-9-octadecenoate (3). The material was subjected to reversed-phase high-performance liquid chromatography (HPLC) affording pure methyl *threo*-11-hydroxy-12,13-epoxy-9-octadecenoate (effluent volume, 23.4–26.1 mL). The C value of the Me_3Si derivative of methyl *threo*-11-hydroxy-12,13-epoxy-9-octadecenoate was 20.64, and the mass spectrum was similar to that recorded on the Me_3Si derivative of the corresponding *erythro* isomer. Steric analysis of 11,12-dihydroxy-1-octadecanol obtained following reduction of the saturated epoxy alcohol with $LiAlH_4$ (3) confirmed the *threo* relationship at C-11/C-12. The infrared spectrum of the epoxy alcohol showed bands at 3620–3350 cm^{-1} (hydroxyl), 1730 cm^{-1} (ester carbonyl) and 890 cm^{-1} (*trans*-epoxide), but no band in the region 950–1000 cm^{-1}. These data demonstrated that the epoxy alcohol was identical to methyl *threo*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate.

Hepoxilins B_3 and B_4. Hepoxilins B_3 and B_4, isolated from the red alga *Murrayella periclados* (*cf.* ref. 16), were kindly supplied by Drs. M. W. Bernart and W. H. Gerwick, College of Pharmacy, Oregon State University, Corvallis, OR. The Fourier-transform infrared (FTIR) and nuclear magnetic resonance (NMR) spectra recorded on the methyl esters demonstrated that the configurations at C-10/C-11 of the samples of hepoxilins B_3 and B_4 were *erythro* and *threo*, respectively, and that the configuration of the 11,12-epoxide group of both hepoxilins was *trans*.

Dimethyl 2S-hydroxydodecane-1,12-dioate. Dimethyl 2*S*-hydroxydodecane-1,12-dioate was prepared by anodic coupling of ethyl 2*S*-acetoxy-3-carboxypropionate (ref. 17; 5 mmol) and methyl hydrogen sebacate (15 mmol) in methanol (20 mL) containing sodium methoxide (0.8 mmol). A current of 0.4 A was passed through the solution for 2 h. Subsequently, the volume of the solution was adjusted to 60 mL by addition of methanol, and the product was transesterified by treatment with sodium methoxide (0.5 M). After 15 min at 23°C, water and hydrochloric acid were added and the solution extracted twice with diethyl ether. The isolated material was subjected to silicic acid column chromatography. Elution with diethyl ether/hexane (1:3, vol/vol) yielded dimethyl 2*S*-hydroxydodecane-1,12-dioate (0.5 g; yield, 36%), which was crystallized from hexane at −30°C. The identity of the material was confirmed by mass spectrometric analysis of the Me_3Si derivative. Prominent ions were observed at *m/e* 331 (M − 15, 2%), 315 [M − 31 (loss of $\cdot OCH_3$), 6], 303(14), 287 [Me_3SiO^+=CH-$(CH_2)_9$-$COOCH_3$, 100], 271(29), and 183 [OHC-$(CH_2)_9$-C≡O^+, 14]. The optical purity of the material was better than 99% as judged by gas-liquid chromatography (GLC) analysis of the (−)-menthoxycarbonyl (MC) derivative (*cf.* ref. 18).

Dimethyl 2R,S-hydroxydodecane-1,12-dioate. Dimethyl 2*S*-hydroxydodecane-1,12-dioate (16 mg) was oxidized with CrO_3 (6 mg) in 97.5% acetic acid (2.4 mL) at 37°C for 30 min. The ketodiester was isolated by preparative TLC (solvent system: ethyl acetate/hexane, 15:85, vol/vol; $R_f = 0.42$). The mass spectrum showed prominent ions at *m/e* 272 (M, 0.5%), 241 (M − 31, 14), 213 [M − 59 (loss of $\cdot COOCH_3$), 100], 181 [M − (59 + 32), 7], 153(28), and 135(33). An aliquot of the dimethyl 2-ketododecane-1,12-dioate was treated with $NaBH_4$ in methanol. GLC analysis of the MC derivative of the resulting dimethyl 2*R,S*-hydroxydodecane-1,12-dioate showed two peaks (areas, 1:1) due to the MC derivatives of the *S* and *R* hydroxydodecanedioates. In accordance with previous results (18,19), the first eluting diastereomer was the MC derivative of dimethyl 2*S*-hydroxydodecanedioate.

Catalytic hydrogenation. The unsaturated compound (0.1–2 mg) was stirred with 20 mg of palladium on calcium carbonate (E. Merck, Darmstadt, Germany) in 3 mL of ethyl acetate under hydrogen gas for 1 h. Use of this catalyst rather than the more active platinum or palladium on carbon catalysts considerably reduced the extent of hydrogenolysis of allylic alcohol groups.

Deoxygenation. The epoxy alcohol (0.1–2 mg) was dissolved in methylene chloride (1 mL) containing trifluoroacetic acid (3.5 mg), and triphenylphosphine selenide (31 mg) was added (20). After 15 h at 23°C the mixture was added to diethyl ether (50 mL) and the solution was

washed with water and taken to dryness. The residue was subjected to TLC.

Steric analysis. The allylic alcohol (0.05–1 mg) was derivatized by treatment with toluene (50 μL), pyridine (10 μL) and a toluene solution (50 μL) of (−)-menthoxycarbonyl chloride (Aldrich-Chemie, Steinheim, Germany; 1 μmol/μL) at 23°C for 30 min (14). The MC derivatives were purified by TLC (solvent system; ethyl acetate/hexane, 7:93, vol/vol) and subjected to oxidative ozonolysis as described (18). Material obtained following ozonolysis was esterified by treatment with diazomethane and subsequently analyzed by GLC. MC derivatives of synthetic 2*S*- and 2*R*,*S*-hydroxy-alkanoates/alkanedioates were used as references.

Chromatographic and instrumental methods. TLC was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck and, unless otherwise indicated, a solvent system composed of ethyl acetate/hexane (25:75, vol/vol). Material was located by spraying with 2′,7′-dichlorofluorescein and viewing under ultraviolet (UV) light. Radioactivity on TLC plates was determined with a Berthold Dünnschichtscanner II (Wildbad, Germany) interfaced with a Macintosh SE/30 PC. Silicic acid chromatography was carried out with glass columns packed with silicic acid (Mallinckrodt, Paris, KY; 100 mesh, activated at 120°C). The columns were eluted under pressure with increasing concentration of diethyl ether in hexane. Reversed-phase HPLC was performed using a column of Nucleosil 5 C_{18} (250 × 4 mm) purchased from Machery-Nagel (Düren, Germany) and acetonitrile/water (6:4, vol/vol) at a flow rate of 1.5 mL/min. The absorbancy of the effluent at 210 nm was monitored. GLC was performed with a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm). Helium at a flow rate of 25 cm/s was used as the carrier gas. GC/MS was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. Infrared spectra were recorded with a Perkin-Elmer (Überlingen, Germany) model 257 infrared spectrophotometer. Radioactivity was determined with a Packard (Downers Grove, IL) Tri-Carb model 4450 liquid scintillation counter.

RESULTS AND DISCUSSION

The present method for the determination of the stereochemistry of α,β-epoxy alcohols was based on deoxygenation of the epoxide function followed by steric analysis of the resulting allylic alcohol. Deoxygenation was carried out by treatment with triphenylphosphine selenide and trifluoroacetic acid in methylene chloride (Fig. 2). This method for deoxygenation of epoxides was originally described by Clive and Denyer (20) and was found to work satisfactorily with epoxy alcohols in the present study. As expected (20), the reaction proceeded stereospecifically to produce *E*-allylic alcohols from the *trans*-epoxides used in the present work. The yields of allylic alcohols were limited to 30–50%, mainly because of further reaction to produce the corresponding trifluoroacetates. Determination of the absolute configuration of the allylic alcohol was achieved following derivatization into the MC derivative, oxidative ozonolysis and GLC analysis of the resulting 2-hydroxy acid (methyl ester, MC derivative). The method

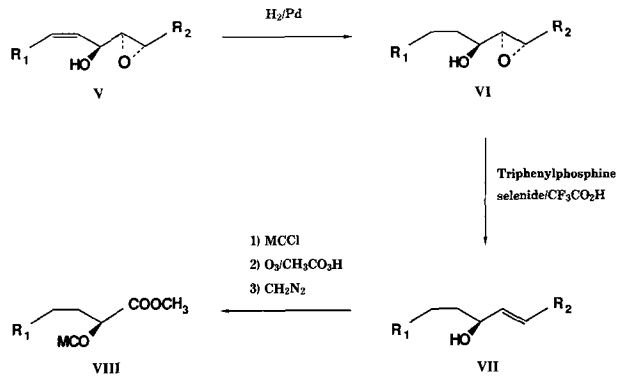

FIG. 2. Reactions used for steric analysis of α,β-epoxy alcohols as applied to methyl *erythro*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate. V, methyl 11*S*-hydroxy-12*S*,13*S*-epoxy-9*Z*-octadecenoate; VI, methyl 11*S*-hydroxy-12*S*,13*S*-epoxyoctadecanoate; VII, methyl 11*S*-hydroxy-12*E*-octadecenoate; VIII, (−)-menthoxycarbonyl derivative of dimethyl 2*S*-hydroxydodecane-1,12-dioate. R_1, $(CH_2)_7$-$COOCH_3$; R_2, $(CH_2)_4$-CH_3. "MCCl," (−)-menthoxycarbonyl chloride.

was used to confirm the absolute stereochemistry of methyl *erythro*- and *threo*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoates obtained from linoleic acid 13*S*-hydroperoxide in the presence of hemoglobin. In addition, the method was applied to establish the absolute stereochemistry of *erythro*-hepoxilin B_3 and *threo*-hepoxilin B_4 that had been recently isolated as natural products from the red alga *Murrayella periclados*.

Absolute stereochemistry of methyl erythro-*11-hydroxy-trans-12,13-epoxy-9Z-octadecenoate.* A sample of methyl *erythro*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate (1 mg; V in Fig. 2) was hydrogenated and an aliquot of the product was converted into the Me_3Si derivative and analyzed by GC/MS. The C value recorded was 21.08 and the mass spectrum showed a prominent ion at *m/e* 287 [Me_3SiO^+=CH-$(CH_2)_9$-$COOCH_3$, 64%], as well as weaker ions at *m/e* 385 (M − 15, 11), 301(8), and 215 [M − 185 (loss of ·$(CH_2)_9$-$COOCH_3$), 12]. The hydrogenated epoxy alcohol (**VI**, Fig. 2) was treated with triphenylphosphine selenide and trifluoroacetic acid and the product was subjected to TLC. Two major compounds appeared, *i.e.*, methyl 11-hydroxy-12-octadecenoate (R_f = 0.51, 41%) and a nonpolar by-product (R_f = 0.83, 29%), tentatively identified as the trifluoroacetate of methyl 11-hydroxy-12-octadecenoate. The C value of the Me_3Si derivative of the methyl 11-hydroxy-12-octadecenoate was 19.77, and the mass spectrum showed a prominent ion at *m/e* 199 (Me_3SiO^+=CH-CH=CH-C_5H_{11}, 100%), as well as weaker ions at 384 (M, 1), 369 (M − 15, 2), 337 [M − (15 + 32), 5] and 313 (M − 71, 3). The infrared spectrum of the allylic alcohol showed an absorption band at 970 cm^{-1}, demonstrating that the double bond had the *E* configuration. Oxidative ozonolysis performed on the MC derivative (see below) localized the double bond to the Δ12 position. Thus, the allylic alcohol formed by deoxygenation of the hydrogenated derivative of methyl *erythro*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate was identical to methyl 11-hydroxy-12*E*-octadecenoate (**VII**, Fig. 2).

Figure 3 (C and D) shows a gas chromatographic analysis of the esterified product obtained following oxidative ozonolysis of the MC derivative of the methyl

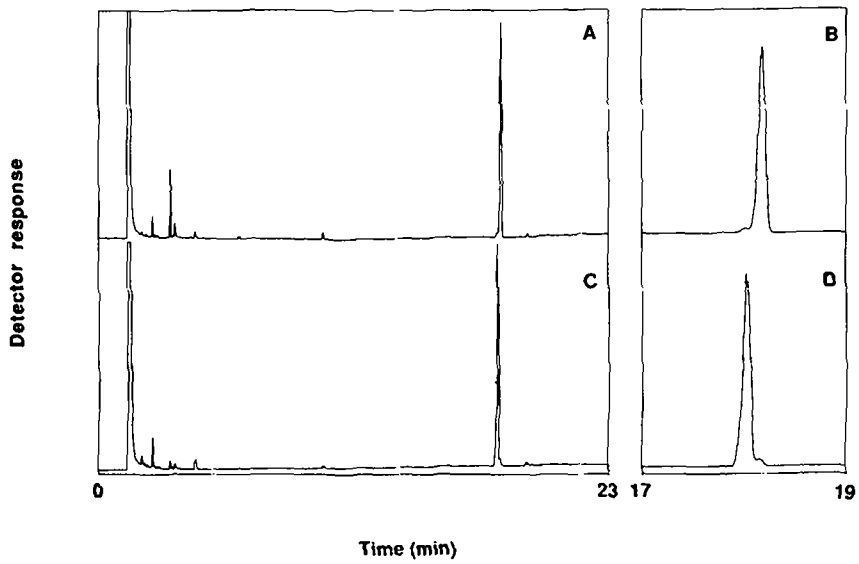

FIG. 3. Gas-liquid chromatographic analysis of the (−)-menthoxycarbonyl derivatives of dimethyl 2-hydroxydodecane-1,12-dioates obtained from methyl *threo*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate (A,B) and from methyl *erythro*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate (C,D). Conditions: methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm); carrier gas, helium; flow rate, 25 cm/s; injection port temperature, 260°C; column temperature, 230°C raised to 276°C at 2°C/min.

11-hydroxy-12-octadecenoate. The main peak was due to the MC derivative of dimethyl 2*S*-hydroxydodecane-1,12-dioate (**VIII**, Fig. 2; 3% or less of the derivative of the *R* isomer), demonstrating that the absolute configuration of C-11 of the parent epoxy alcohol was *S*. This configuration coupled with the relative stereochemistry of C-11/C-12 *(erythro)* and the configuration of the 12,13-epoxide group *(trans)* further showed that the absolute stereochemistry of the epoxy alcohol was methyl 11*S*-hydroxy-12*S*,13*S*-epoxy-9*Z*-octadecenoate. The *S* configuration established for C-13 was in agrement with the mode of formation of the epoxy alcohol from 13*S*-HPOD, *i.e.*, by a reaction in which the absolute configuration of C-13 was not affected (8).

Absolute stereochemistry of methyl threo-*11-hydroxy-trans-12,13-epoxy-9Z-octadecenoate.* Catalytic hydrogenation of methyl *threo*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate (1 mg) yielded the corresponding saturated epoxy alcohol. An aliquot was analyzed as the Me_3Si derivative by GC/MS. The C value was 20.96 and the mass spectrum was similar to that of the corresponding derivative of hydrogenated methyl *erythro*-11-hydroxy-*trans*-12,13-epoxy-9*Z*-octadecenoate. Treatment of the hydrogenated *threo* epoxy alcohol with triphenylphosphine selenide and trifluoroacetic acid afforded methyl 11-hydroxy-12*E*-octadecenoate. The C value of the Me_3Si derivative of this compound was 19.77 and the mass spectrum was identical to that of the Me_3Si derivative of methyl 11-hydroxy-12-octadecenoate obtained from the *erythro* epoxy alcohol (see above). The infrared spectrum showed an absorption band at 970 cm^{-1}, confirming that the Δ12 double bond had the *E* configuration. Gas chromatographic analysis of the esterified product obtained following oxidative ozonolysis performed on the MC derivative of the allylic alcohol is shown in Figure 3 (A and B). A main peak due to the MC derivative of dimethyl 2*R*-hydroxydodecane-1,12-dioate appeared (3% or less of the derivative of the *S* isomer), demonstrating that the absolute configuration at C-11 of the epoxy alcohol degraded was *R*. This result, coupled with the relative stereochemistry of the epoxy alcohol, showed that its absolute stereochemistry was 11*R*-hydroxy-12*S*,13*S*-epoxy-9*Z*-octadecenoate.

Absolute stereochemistry of erythro-*hepoxilin* B_3. A sample of the methyl ester of *erythro*-hepoxilin B_3 (0.3 mg) was hydrogenated to afford methyl *erythro*-10-hydroxy-*trans*-11,12-epoxyeicosanoate. The mass spectrum of the Me_3Si derivative showed prominent ions at *m/e* 413 (M − 15, 15%), 381 [M − 47 (loss of $\cdot CH_3$ plus CH_3OH), 1], 287(13), 273 (Me_3SiO^+=CH-$(CH_2)_8$-$COOCH_3$, 100), 257 [M − 171 (loss of $\cdot(CH_2)_8$-$COOCH_3$), 26], and 169 (OHC-$(CH_2)_8$-C≡O^+, 25). Deoxygenation by treatment with triphenylphosphine selenide and trifluoroacetic acid afforded methyl 10-hydroxy-11-eicosenoate as judged by analysis of the Me_3Si derivative by GC/MS. Prominent ions in the mass spectrum were present at *m/e* 397 (M − 15, 2), 365 [M − (15 + 32), 3], 322 [M − 90 (loss of Me_3SiOH) 1], 299 [M − 113 (loss of $\cdot C_8H_{17}$), 6], and 241 (Me_3SiO^+=CH-CH=CH-C_8H_{17}, 100). The MC derivative of this hydroxyester was subjected to oxidative ozonolysis. The esterified product contained a major MC derivative, *i.e.*, that of dimethyl 2*S*-hydroxyundecane-1,11-dioate (Fig. 4, A and B; 3% or less of the derivative of the *R* isomer), demonstrating that C-10 of the parent hepoxilin B_3 had the *S* configuration. Because of the *erythro* relationship between C-10/C-11 and the fact that the 11,12-epoxide group had the *trans* configuration, it followed that the absolute stereochemistry of the hepoxilin B_3 degraded was 10*S*-hydroxy-11*S*,12*S*-epoxy-5*Z*,8*Z*,14*Z*-eicosatrienoic acid. This hepoxilin was isolated together with *inter alia* 12*S*-hydroxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid (16). It seems probable that the compound was formed by a rearrangement analogous to that occurring in the formation of the above-mentioned *erythro*- and

METHOD

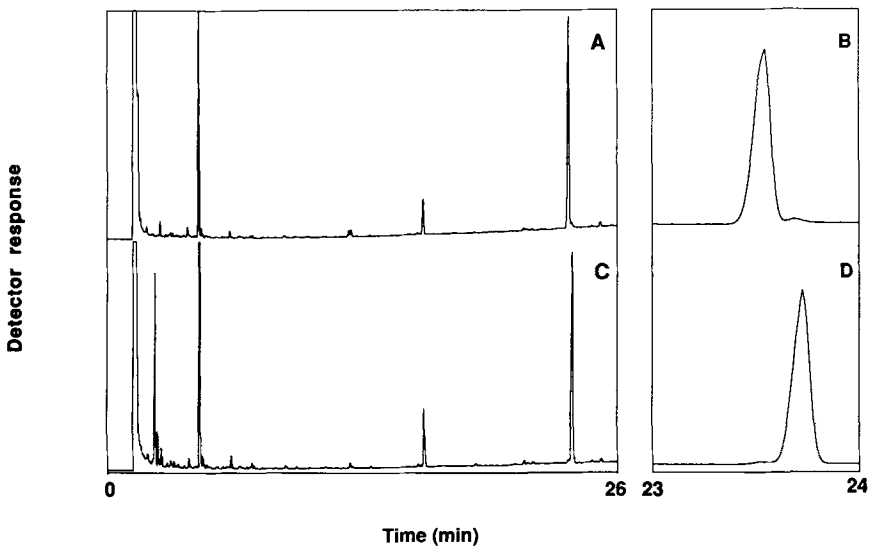

FIG. 4. Gas-liquid chromatographic analysis of the (−)-menthoxycarbonyl derivatives of dimethyl 2-hydroxyundecane-1,11-dioates obtained from the methyl ester of *erythro*-hepoxilin B_3 (A,B) and from the methyl ester of *threo*-hepoxilin B_4 (C,D). Conditions were the same as those given in Figure 3, except for the column temperature, which was programmed from 210°C to 262°C at 2°C/min.

threo-hydroxy-epoxy-octadecenoates from 13*S*-HPOD, *i.e.*, from 12*S*-hydroperoxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid by a process that did not affect the absolute configuration of C-12.

Absolute stereochemistry of threo-*hepoxilin* B_4. Catalytic hydrogenation of the methyl ester of *threo*-hepoxilin B_4 (0.2 mg) yielded methyl *threo*-10-hydroxy-*trans*-11,12-epoxyeicosanoate. Deoxygenation afforded methyl 10-hydroxy-11-eicosenoate, the MC derivative of which was subjected to oxidative ozonolysis. GLC analysis of the esterified product showed the presence of a major MC derivative, *i.e.*, the MC derivative of dimethyl 2*R*-hydroxyundecane-1,11-dioate (Fig. 4, C and D; 2% or less of the derivative of the *S* isomer). Thus, the parent hepoxilin B_4 had the *R* configuration at C-10 and, as deduced from the stereochemistry at C-10/C-11 and of the epoxide group, the absolute stereochemistry 10*R*-hydroxy-11*S*,12*S*-epoxy-5*Z*,8*Z*,14*Z*,17*Z*-eicosatetraenoic acid.

Conclusion. The present method for determination of the absolute stereochemistry of epoxy alcohols of type **I** (Fig. 1) is useful for steric analysis of, *inter alia*, hepoxilins of the B series from various sources. Hepoxilins B_3 and B_4 are formed from arachidonic and 5,8,11,14,17-eicosapentaenoic acids, respectively, *via* 12-hydroperoxide intermediates (7,21,22). Hepoxilin B_3 exerts biological effects in several systems, notably an insulin release-promoting effect in the rat (23). In addition, the method will be suitable for determination of the absolute stereochemistry of new *cis*-epoxy alcohols recently isolated following incubation of fatty acid hydroperoxides with flaxseed allene oxide synthase (24).

Headspace Gas Chromatography to Determine Human Low Density Lipoprotein Oxidation

E.N. Frankel[a,*], J. Bruce German[a] and Paul A. Davis[b]
[a]Department of Food Science and Technology and [b]Department of Internal Medicine, Division of Clinical Nutrition and Metabolism, University of California, Davis, California 95616

We previously described a rapid headspace gas chromatographic method for the determination of hexanal, an important decomposition product of n-6 polyunsaturated fatty acid (PUFA) peroxidation in rat liver samples and human red blood cell membranes. This method was applied to the measurement of Cu^{2+} catalyzed-oxidation of freshly prepared human low density lipoproteins (LDL) from 10 healthy adult volunteers. A twofold variation in oxidative susceptibility was found by this assay for hexanal and other volatiles. Hexanal values correlated significantly ($P < 0.05$) with total polyunsaturated fatty acid (PUFA), 18:2 and n-6 PUFA contents of LDL; but poorly with 20:4 and with vitamin E. Therefore, in addition to α-tocopherol, other endogenous antioxidants and factors may contribute to LDL's resistance to oxidation. This simple, rapid and sensitive method for oxidative susceptibility provides a useful component in the analysis of the prooxidant/antioxidant status of biological samples. The method is used routinely in our laboratories to determine specific peroxidation products of n-6 and n-3 PUFA.
Lipids 27, **1047–1051 (1992).**

Modification of low density lipoproteins (LDL) by oxidation of its polyunsaturated fatty acid (PUFA) components appears to play a major role in atherosclerosis (1). Oxidative modification of LDL is promoted by arterial endothelial cells, smooth muscle cells and macrophages. Aldehyde decomposition products are formed by *in vitro* oxidation of LDL catalyzed by iron or copper ions (2–5). However, the *in vivo* origin of these metal catalysts has not been identified. The aldehydes produced by metal-catalyzed PUFA peroxidation are cytotoxic and may react with and derivatize the amino acid residues of the apoprotein B to generate modified LDL.

Cholesterol oxides and oxysterols formed in oxidized LDL appear to injure endothelial cells, promote build-up of plaques, are atherogenic and mutagenic, and inhibit cholesterol metabolism (6). Hydroperoxy and hydroxy fatty acid derivatives accounted for about 70% of the products formed from linoleate during *in vitro* oxidation of LDL in the presence of $CuSO_4$ (7). However, considerable variation was observed in the oxidative susceptibility of different LDL samples. LDL particles were suggested to contain some unidentified factor conferring susceptibility or resistance to oxidation (8).

The results of *in vitro* and *in vivo* studies to assess the effects of oxidation and antioxidation processes in LDL are difficult to interpret because inherently imprecise methodology has been used to measure lipid oxidation and the oxidative susceptibility of LDL to oxidation.

Abbreviations: EDTA, ethylenediaminetetraacetic acid; GC, gas chromatography; HPLC, high-performance liquid chromatography; LDL, low density lipoprotein; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reacting substances; ultraviolet, UV.

Measurements of the susceptibility of LDL toward oxidative stress have been based on determinations of thiobarbituric acid-reacting substances (TBARS) (3,8–16), conjugated dienes (3,12–14,17,18), fluorescent products (3,13) and peroxide value (13,19–21). These methods are, however, complex assays that lack specificity and measure a great variety of compounds. Chemically more specific measurements also have been used to measure oxidative modification of LDL, including specific aldehydes by high-performance liquid chromatography (HPLC) (3,13) and products of cholesterol oxidation by gas chromatography (GC) (8), but these methods are too tedious for routine analyses of oxidative susceptibility. The loss of 18:2 and 20:4 has also been used to measure LDL oxidation (3,7), but this method is not sufficiently sensitive to follow early stages of oxidation. Other changes measured in modified LDL include electrophoretic mobility (8,13,15), degradation by macrophage and endothelial cells (9–11,13,15,20, 22), and cytotoxicity (16).

We recently described a rapid headspace gas chromatographic method for the determination of hexanal, an important volatile PUFA decomposition product, as an indicator of n-6 PUFA peroxidation in rat liver samples (23). By this method, no work-up is necessary, and clean samples of hexanal can be taken from the headspace above a biological specimen. This method was used to study the effects of dietary lipids and vitamin E on *in vitro* and *in vivo* lipid peroxidation in rat liver and kidney (24) and in tissues from rats induced by iron (25). This method was further improved for the determination of specific volatile peroxidation products of n-6 PUFA (pentane and hexanal) and n-3 PUFA (propanol), and applied to a study of the susceptibility of human red blood cell membranes to lipid peroxidation (26).

Although much work has been published on the biological properties of oxidized human LDL, the data on the oxidative susceptibility of different LDL samples are sparse. This paper describes the application of headspace GC to measure Cu^{2+}-catalyzed oxidation of freshly prepared human LDL. This simple, rapid and sensitive method may provide a useful complement to the measure of the prooxidant/antioxidant status of biological samples.

MATERIALS AND METHODS

Materials. Hexanal and propanol used as standards for the headspace GC analyses were purified by chromatography through a Waters Sep-Pak silica cartridge (Waters Associates, Milford, MA) (23). Copper sulfate (10 mM $CuSO_4$, Fisher Scientific, Fairlawn, NJ) solutions used as oxidant were prepared fresh daily.

Human LDL. Blood was collected after overnight fasting by venipuncture in ethylenediaminetetraacetic acid (EDTA) from normolipidemic healthy adult volunteers and centrifuged at 1500 × *g* at 4°C to prepare plasma. Plasma LDL was prepared by sequential density ultracentrifugation (27) in the presence of 0.01% EDTA. Prior to the

oxidation experiments, LDL was exhaustively dialyzed with deoxygenated phosphate-buffered (10 mM, pH 7.4) saline (100 mM) for 24 h. The final concentration of each LDL sample was diluted with phosphate-buffered saline (10 mM) to the same protein concentration (1 mg/mL LDL). One portion was stored at −5°C for later lipid extraction and GC analyses of fatty acid composition (28,29), and vitamin E analyses (30). Oxidative susceptibility was determined immediately by headspace GC.

Oxidative susceptibility by headspace capillary GC. The oxidative susceptibility of LDL was measured by headspace capillary GC (23,26) to detect low levels of aldehyde products and to distinguish between oxidation of n-6 (hexanal and pentane) and n-3 (propanal) PUFA at various oxidation levels. Volatiles were determined by capillary gas chromatograph with a headspace sampler (Perkin-Elmer Sigma 3B gas chromatograph with an H-6 headspace sampler, Norwalk, CT), a capillary DB-1701 column (30 m × 0.32 mm, 1 μm thickness, J&W, Folsom, CA) heated isothermally at 80°C. The GC conditions were the same as those used previously to measure hexanal in red blood cell membranes (26): capillary column, DB-1701; oven temperature, 80°C; injector, 180°C; detector, 200°C. Volatile compounds derived from the oxidation of LDL were identified by comparison of retention times with those of authentic reference compounds. Analyses were standardized daily with solutions of 10 μM hexanal.

Duplicate samples of 0.25 mL LDL in phosphate-buffered saline and standard solutions of hexanal were measured into special headspace 6-mL bottles sealed with silicone rubber teflon caps with a crimper and incubated in a water bath shaker for 1, 2, 4 and 24 h at 37°C in the presence of various levels of Cu^{2+} (2, 4, and 8 μM $CuSO_4$). After incubation, the bottles were inserted into the headspace sampler heated at 40°C, pressurized with carrier gas for 30 s, and an aliquot of gas phase (headspace) was injected directly into the gas chromatograph through the stationary injection needle.

Lipid analyses. Total lipids were extracted by the method of Burton *et al.* (29) using mixtures of ethanol and hexane in the presence of sodium dodecylsulfate (29). An aliquot of the lipid extract was methylated with acetyl chloride in methanol/benzene (4:1, vol/vol) (31) in the presence of triheptadecanoin added as internal standard. Fatty acid analyses of extracted lipids (28) were carried out by GC (Hewlett Packard, Avondale, PA, model 5890, equipped with a flame ionization detector) with a polar DB-23 capillary column (50% cyanopropylphenyl, J&W, 30 m × 0.25 mm) and identified by comparison with authentic standards (NuChek Prep, Elysian, MN).

Other determinations. The protein content of LDL samples was estimated by the method of Bradford (32). Vitamin E was determined by HPLC (30).

RESULTS

Volatile lipid oxidation products were measured by the headspace GC method directly on LDL samples without extraction. The addition of Cu^{2+} at different concentrations was very effective in catalyzing lipid peroxidation in human LDL as measured by the headspace GC method. A typical gas chromatogram of human LDL oxidized with 4 μM $CuSO_4$ is shown in Figure 1. Four main components were identified by comparison of retention times

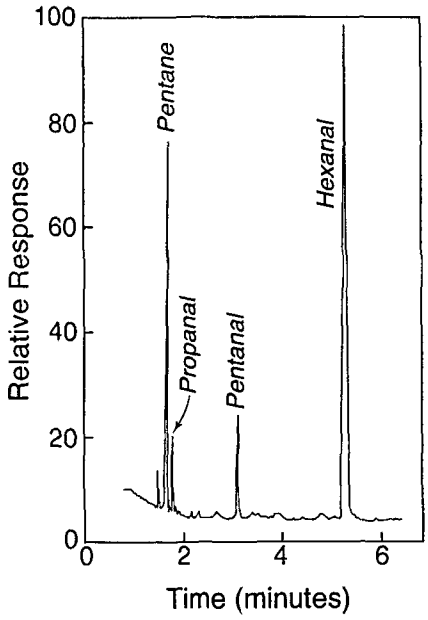

FIG. 1. Capillary gas chromatography of a 0.25-mL sample of human low density lipoprotein (LDL) (containing 1.0 mg protein/mL LDL) in 10 mM phosphate-buffered saline after incubation for 4 h at 37°C in the presence of 4 μM $CuSO_4$.

with those of authentic reference compounds, namely pentane, propanal, pentanal and hexanal. Pentane and hexanal are derived from oxidation of n-6 PUFA, and propanal from oxidation of n-3 PUFA (33). Pentanal is presumed to come from hexanal by formaldehyde formation in the presence of Cu^{2+} (33).

Table 1 shows the distribution of 4 volatiles in 10 different LDL samples oxidized with 2, 4 and 8 μM Cu^{2+} for different time periods at 37°C. Hexanal is the main volatile, followed by pentanal, pentane and propanal. Significant levels of volatiles were determined after incubation with 4 and 8 μM Cu^{2+} for 2 or 4 h. A wide range of volatiles were formed from the different LDL samples assayed. With 2 μM Cu^{2+}, 2.6 times more hexanal was produced after 4 h by LDL-F than LDL-D. With 4 and 8 μM Cu^{2+}, hexanal formation varied from 113 (LDL-B) to 371 nmol/mg (LDL-A) after 4 h. These results indicate that LDL from different individuals have a wide variation in oxidative susceptibility as measured by the headspace GC method.

Figure 2 shows time plots of hexanal formation obtained with 4 samples of LDL oxidized in the presence of 8 μM $CuSO_4$. These plots show a lag phase of about 1 h, followed by rapid production of hexanal, then slowing down between 4 and 24 h. The Cu^{2+}-catalyzed oxidation of LDL can thus be conveniently monitored by headspace GC of hexanal, which is the main decomposition product of hydroperoxides of n-6 PUFA.

Hexanal formation follows kinetics similar to those reported by Esterbauer *et al.* (17) for conjugated diene formation after a variable lag phase in LDL oxidized with 1.66 μM Cu^{2+}. Esterbauer *et al.* (17) used the duration of the lag phase as a measure of oxidative susceptibility of different LDL samples, and considered the lag phase to reflect the antioxidant status of the samples. By using the headspace GC method, more variation in hexanal

[a]Determined by headspace capillary gas chromatography directly on 0.25 mL LDL (1 mg protein/mL LDL; see Materials and Methods). Average SD of duplicate analyses is 5.2%.

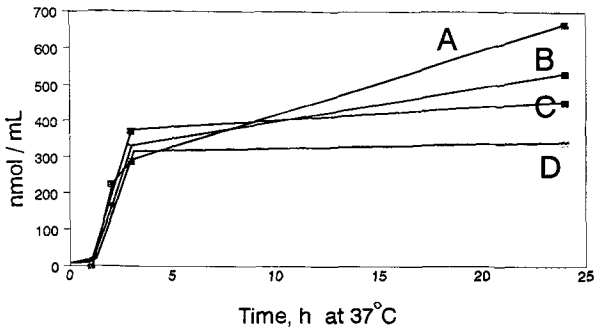

FIG. 2. Kinetics of hexanal formation in four different samples (A, B, C, D) of human low density lipoprotein oxidized for 24 h in the presence of 8 μM $CuSO_4$ (see Table 1 for data on other volatile oxidation products).

formation was observed after 2 and 4 h incubation with Cu^{2+}. Therefore, hexanal values reflect variation in n-6 PUFA content of LDL, as well as variation in the rate by which they decompose.

Variation in oxidative susceptibility was studied by determining the effect of Cu^{2+}-catalyzed oxidation on samples of freshly prepared human LDL from 10 healthy adult volunteers. The headspace GC assay for hexanal as a direct measure of LDL oxidative susceptibility was compared with the fatty acid composition and vitamin E contents of the corresponding lipid extracts (Table 2). Hexanal values correlated significantly ($P < 0.05$) with total PUFA, 18:2 and n-6 PUFA contents of LDL of eight subjects. There was no correlation, however, between hexanal formation and tocopherol contents and 20:4 in these LDL samples. These results indicate that dietary PUFA may be

one of the most important factors affecting the *in vitro* oxidative susceptibility of human LDL.

DISCUSSION

Oxidation of LDL and other lipoproteins in circulating blood has been implicated in the etiology of coronary heart diseases (1,13). Esterbauer *et al.* (3,13) discussed the impact that aldehydes produced by hydroperoxide decomposition have in the modification of LDL recognized by the scavenger receptor. Although the free aldehydes measured as dinitrophenylhydrazones after separation by thin-layer chromatography (TLC) and HPLC were minor products, they concluded that most of the aldehydes reacted with apo B and lipids to produce fluorescent materials.

Recent reports showed that the fatty acid composition of LDL is influenced by diets rich in oleic acid (12,14) and by supplementation of fish oil n-3 PUFA (34,35). Oleate-rich LDL particles from rabbits (12) and from humans (14) fed diets rich in oleic acid were highly resistant to oxidative modification based on formation of TBARS, conjugated dienes and cell induced oxidation by incubation with endothelial cells. However, since oxidation of oleic acid does not produce TBARS (36) and conjugated dienes (37), these assays would not be appropriate to test oxidative susceptibility of oleate-rich LDL.

Oxidative modification of LDL from smokers fed fish oil resulted in significantly higher TBARS, compared to baseline values, than in nonsmokers (34). In another study (35) the susceptibility to Cu^{2+}-catalyzed peroxidation as measured by TBARS was similar in LDL from human groups on fish oil and corn oil diets. Therefore, our results agree with those of Jessup *et al.* (20), who reported no correlation between the rate of peroxidation and tocopherol contents in LDL of five subjects. In another study, Esterbauer *et al.* (13,18) found no correlation between the oxidation resistance (as measured by the lag phase in Cu^{2+}-induced LDL oxidation) and the α-tocopherol content of human LDL. Clearly vitamin E content of LDL is not the sole determinant and not necessarily predictive of the oxidative susceptibility of LDL. Therefore, in addition to the *in vivo* antioxidant activity of α-tocopherol, other endogenous antioxidants or inhibitors may contribute to the resistance of LDL to oxidation. Our results are also consistent with previous observations that LDL from individuals have varying and characteristic susceptibilities to oxidative modification, as measured by electrophoretic mobility, TBARS and oxysterol formation (8), and by the lag phase of conjugated diene formation (13,18).

Studies of dietary, genetic and pathological modification of LDL need to be undertaken and will require sensitive, chemically distinctive and practical methods. However, much of the methodology used to investigate LDL oxidation yields results that are difficult to interpret. The conjugated diene method of Esterbauer *et al.* (17), and several variations of the thiobarbituric acid (TBA) test have been used most commonly to determine oxidation in LDL. The validity of these methods have been questioned by Halliwell and Gutteridge (38). Although diene conjugation is a useful method to measure oxidation in pure lipids, it cannot be used directly on biological samples, especially human body fluids that contain substantial amounts of ultraviolet (UV)-absorbing material. The rapid UV conjugated diene method developed by Esterbauer *et al.* (17) has been used extensively to make continuous measurements of LDL oxidation and to determine duration of the lag phase as a sensitive

method for oxidative susceptibility. However, a recent study from the same group (21) compared conjugated diene with peroxide content by an iodometric assay in oxidized pig LDL. They found ratios of peroxides to conjugated dienes varying from 2.33 to 2.79 in oxidized LDL subfractions, and concluded that non-UV absorbing peroxides are formed besides conjugated hydroperoxides.

The validity of the TBA determination as an index of lipid peroxidation in biological samples has been a matter of considerable debate for some time. The determination of TBARS inherently lacks specificity and is flawed by analytical artifacts because it is affected by the same factors as lipid peroxidation (39). Factors reported to affect the color formation in the TBA reaction include heating temperature and time, pH, and the presence of metal-ion catalysts and of antioxidants (40). Because the TBA method is open to interference by many substances, including compounds that do not derive from lipid peroxidation, careful corrections are necessary through use of appropriate blanks (41). With its lack of specificity, the TBA test is not recommended for human biological materials (38,42).

The headspace GC method, used in this study to determine hexanal, provides a useful tool to measure the effect of Cu^{2+}-catalyzed oxidation on samples of freshly prepared human LDL. Because this method measures specific volatile aldehydes, it not only provides information on the degree of hydroperoxide decomposition but can distinguish between products of n-6 PUFA (pentane, hexanal) and n-3 PUFA (propanal) oxidation. The method can thus complement the conjugated diene absorbance method, which measures the effect of antioxidants on initial hydroperoxide formation. The method is sensitive and is used routinely in our laboratories to determine specific peroxidation products of n-6 and n-3 PUFA, and the prooxidant/antioxidant status of biological samples. Because the headspace technique is simple and rapid, we are now able to analyze biological samples with a throughput of 48 determinations per day. This feature of our assay is essential in analyzing replicate fresh samples and in minimizing storage that would affect results of oxidative susceptibility. More research is needed to elucidate factors that influence the balance between antioxidant and prooxidant factors that affect the susceptibility of LDL to oxidation.

ACKNOWLEDGMENTS

We would like to acknowledge the excellent technical assistance provided by Kimberly Vruwink and Janet Alexander. This research was supported by funds provided by the Cigarette and Tobacco Surtax Fund through the Tobacco Related Diseases Program of the University of California, grant number RT606; and by the California Cancer Research Coordination Committee.

Fluorescence Assay of Glucosylceramide Glucosidase Using NBD-Cerebroside

Akira Abe[a,b], **James A. Shayman**[a] and **Norman S. Radin**[a,b,*]
[a]Department of Internal Medicine, University of Michigan Medical Center and [b]Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan 48109-0676

A sensitive fluorometric assay for glucocerebroside β-glucosidase [Dinur, T., Grabowski, G.A., Desnick, R.J., and Gatt, S. (1984) *Anal. Biochem. 136*, 223–234] has been reexamined. It was found that the lipids containing the NBD moiety (12-[*N*-methyl-*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)] used for standardization of the assay are light-sensitive and that the yield of fluorescent light is very sensitive to the composition of the solvent used in the fluorometric measurement. Some protection against fading could be obtained by adding a free-radical trapping agent, SlowFade. The fading of the free NBD-acid, when used for standardization, could be prevented by adding ethanol to the solvent, but this reduced the fluorescence yield. It is recommended that some of the fluorescent substrate be enzymatically hydrolyzed completely to NBD-ceramide, which can be utilized as the standard without the need to add ethanol. A warning about enzyme reaction rate stability with time is given, with a suggestion for ensuring constancy of activity.
Lipids 27, 1052–1054 (1992).

A simple, sensitive and useful method for the assay of glucosylceramide β-glucosidase (EC 2.3.2.45) has been described (1,2), in which a fluorescent analog of glucosylceramide (NBD-GlcCer) is used as the substrate and the fluorescent enzyme product (NBD-ceramide) is separated from the substrate by liquid/liquid partitioning. While other useful methods are also available, this one has the advantages of simplicity, commercial availability of the substrate and elimination of the need for radioactivity. However, there is a problem in converting the fluorescence readings to molar amounts, since the substrate is not soluble in the solvent used for reading. The authors (2) suggest that a standard solution of NBD-ceramide or NBD-dodecanoic acid be used instead.

Two solvent partitioning steps are used to isolate the product of enzyme action. The first involves the incubation mixture (0.45 mL of water), 0.45 mL of isopropyl alcohol, and 1.5 mL of heptane. NBD-ceramide enters the upper phase, together with a little of the substrate; the latter is removed by transferring most of the upper phase, possibly 1.4 mL, and partitioning it against 0.35 mL of water. The first upper phase (called "theoretical upper phase", TUP) differs in composition from the second, final upper phase (FUP).

The earlier authors (2) calculated the amount of enzymatically-formed ceramide by measuring the fluorescence of a known amount of NBD-ceramide or NBD-acid in the first upper phase, although FUP is the solvent actually used in the fluorometric measurement. The statement is made that the two compounds yield the same molar fluorescence values.

No comment was offered about the possible bleaching by light of the NBD compounds during handling and reading, although fluorescent compounds are notorious for fading under some conditions.

In our utilization of the NBD method, we found some discrepancies that led us to investigate the method in more detail. This note describes changes in the procedure that improve the reliability of the method.

MATERIALS AND METHODS

NBD-GlcCer, NBD-dodecanoic acid, mixed ceramides (Type III) from brain sphingomyelin, and Na taurocholate were from Sigma Chemical Co. (St. Louis, MO). SlowFade was from Molecular Probes, Eugene, OR (gift of Elizabeth Marcus). GlcCer was prepared from a Gaucher spleen (3).

Homogenized Madin-Darby canine kidney cells were used as the glucosidase source. The substrate emulsion in Triton X-100 + Na taurocholate and the incubation mixture were prepared as described (2), and the resultant fluorescent ceramide was assayed as described in a 1-mL cuvet in a Perkin-Elmer (Norwalk, CT) Luminescence Spectrometer LS-5B, with excitation at 460 nm and emission at 515 nm. A relatively large batch of NBD-ceramide was prepared by scaling up the standard incubation and partitioning procedures, using a 20-h incubation at 37°C to hydrolyze all of the substrate.

By similar scaling up, TUP was prepared with water, isopropyl alcohol and heptane (15:15:50, vol/vol/vol) in a separatory funnel. FUP was prepared from the upper layer.

RESULTS

Portions of 2 μM NBD-acid in FUP were stored under fluorescent laboratory light for 10, 40 and 70 min, yielding readings of 90, 70 and 57 units, respectively. Similar instability was found also with more dilute solutions. Thus it was evident that the acid was unstable in light after final partitioning. When NBD-acid was stored under the same conditions in absolute ethanol-FUP solutions, all the solutions were stable to light even with as little as 10% ethanol. The wavelengths of maximal excitation and emission in 100% ethanol were shifted to 475 and 535 nm, and there was a small loss of fluorescence yield (74 units for 2 μM acid).

Further study with 190 nM NBD-acid in test tubes stored 15 to 120 min in FUP or FUP/EtOH (90:10 vol/vol) showed that the readings with FUP could be brought up to the FUP/EtOH readings by adding the EtOH just before the readings were made. For example, NBD-acid stored in the dark for 15 min in FUP yielded 19 units, stored in FUP/EtOH they yielded 56 units and the addition of EtOH to FUP solutions yielded 55 units. Under these conditions, it appears that the NBD-acid solution, if used as a standard, should contain ethanol.

Abbreviations: FUP, final upper phase; GlcCer, glucosylceramide; NBD-acid, 12-[*N*-methyl-*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)]aminododecanoic acid; NBD-GlcCer, the cerebroside made by acylating glucosylsphingosine with NBD-acid; TUP, theoretical upper phase.

METHOD

The fluorometric readings, with 462/523 nm settings in the fluorometer and NBD-acid in FUP/EtOH (90:10), were proportional to concentration between 25 and 400 nM, with the extrapolated line passing through the origin. At the 400 nM level, omitting the ethanol yielded a reading 78% lower.

Study of 100 nM NBD-ceramide in FUP or FUP/EtOH showed a somewhat different relationship. The ceramide in FUP, read at 515 nm, yielded 96.5, 101.5 and 103.5 fluorescence units after 15, 60 and 120 min of exposure to ambient fluorescent light, respectively. However, in FUP/EtOH (90:10, vol/vol), read at 523 nm, ceramide yielded much lower values: 38.1, 39.8 and 40.0 units for the same time periods. Thus, while ethanol stabilized the readings over time here too, it quenched the fluorescence from ceramide. Both solvents yielded readings that were proportional to ceramide concentration between 50 and 250 nM.

SlowFade, a proprietary free-radical scavenger solution, was tested to see if it exerted a stabilizing action. The reagent was included in the aqueous phase, using 5.6% of the total water, and the first upper phase was then prepared by adding heptane and isopropyl alcohol. FUP was prepared from this TUP and a 1-mL portion of each solution was added to 190 pmol of NBD-ceramide or acid. The readings, made after 30 min storage in ambient light (Table 1), showed, first, that there was a great difference in fluorescence when the two upper phases were compared, especially with NBD-ceramide. Second, the two fluorescent compounds responded differently to the two solvents. Third, SlowFade was only slightly useful in the case of ceramide (11% more fluorescence). Inclusion of SlowFade in the incubation system interfered with glucosidase activity.

The difference between the two fluorescent compounds with regard to the effect of the second partitioning step (decreased fluorescence with the acid *vs.* increased fluorescence with ceramide) is probably due to dimerization of the acid in the less polar FUP, and consequent self-quenching.

A point which does not seem to have been considered before is the possibility that the fluorescent yields might be affected by the detergents in the enzyme incubation solutions. We prepared TUP and FUP using an equeous system similar to the enzyme medium (Triton X-100 and Na taurocholate in phosphate-citrate buffer), as well as plain water. Results similar to those in Table 1 were obtained, and the detergents were found to make no significant difference in the readings with NBD-ceramide or NBD-acid. In this experiment, a slight amount of self-quenching was found with 250 nM ceramide and much more with the acid (*i.e.*, the reading with 250 nM NBD-acid in FUP was only 2.3 times the reading with 50 nM acid).

Another question needing study was the possibility that the presence of ceramide in the incubation system (due to enzyme action) affects the partition constant of the still-unhydrolyzed GlcCer. A test with the standard assay mixture (2), containing NBD-GlcCer and nonfluorescent GlcCer, was compared with the same mixture containing also 5 μg of ceramide. The readings obtained in the resultant FUP were very low and similar in the two samples. Evidently the two lipids do not form an extractable complex under these conditions.

TABLE 1

Effect of an Anti-Fade Reagent on the Fluorescence of NBD Lipids in the Upper Phases Obtained by the Two Partitioning Steps in NBD-Ceramide Isolation[a]

	Fluorescence intensity at 515 nm			
	NBD-ceramide		NBD-dodecanoic acid	
Solvent SlowFade present	No	Yes	No	Yes
First upper phase	88	100	75	75
Final upper phase	203	225	45	42

[a]The values shown are the means of duplicates.

DISCUSSION

In view of the difficulty of making an accurate comparison between free NBD-acid and NBD-ceramide molar light yields, and the incomplete constancy of the fluorescence/concentration ratio of the acid, it is preferable to use the ceramide as the standard. Because of the high cost of the ceramide, and since only a small amount of NBD-ceramide is needed to standardize each set of assays, it is much more economical to make it enzymatically from the substrate. β-Glucosidase, in the form of crude lysosomes, is readily prepared from any tissue by differential centrifugation. We incubated NBD-GlcCer at 37°C overnight in the standard incubation medium (2) and then isolated the product by partitioning in the usual way between heptane, isopropyl alcohol, and water. It is not necessary to purify the NBD-ceramide further since the background fluorescence from the reagents and enzyme is negligible. A thin-layer chromatogram of the material in the FUP, with a silica gel plate and chloroform/HOAc (90:10, vol/vol), examined under ultraviolet light, showed virtually complete conversion of the substrate, with just a trace of free NBD-acid. The concentrations of stock substrate and product solutions were determined by measuring at $\lambda = 475$ nm, rather than at 485.

In summary, our recommended changes in the procedure are (i) to make and use NBD-ceramide as the molar standard rather than NBD-acid, (ii) to standardize the assay with NBD-ceramide in FUP, not in TUP, and (iii) to handle the samples in reduced light as much as possible. Moreover, the sensitivity of the fluorescence yield to solvent composition emphasizes the need to do the partitioning and upper phase transfer with maximal reproducibility, preferably with a suction transfer device.

A weakness in the published method (2) is that the reaction rate, using human granulocyte extracts, was not constant over time. The initial rate was relatively high, then it slowed down and became constant after the first 30 min. This makes it difficult to calculate K_m and V_{max} values accurately. While it might be satisfactory to use short incubation times, when the linearity problem is not so severe, this weakens the sensitivity of the assay, since much higher readings can be obtained at the cost only of some patience. Another approach, also unsatisfactory, is to double the number of assay tubes and measure the amount of ceramide formed at the 30-min point and at a somewhat later point.

Perhaps an explanation for the changing velocities lies in a report that the human spleen contains two different GlcCer glucosidases (4). Later study (5) showed that one

form could be converted into the other, so it is posssible that the conversion occurs during incubation and that the final equilibrium mixture of enzymes is less active than its initial mixture. An early study in the laboratory of the senior author (NSR) yielded a very similar biphasic velocity activity curve with β-glucosidase from human placenta; preincubation with taurocholate eliminated the first velocity phase (6). Thus systems showing a biphasic time course should be tested with a preincubation protocol.

A study of the literature discloses several papers that give K_m and V_{max} values for this enzyme but very few of these make the claim that the reaction velocity was constant. Using Madin-Darby canine kidney cells, we found the rate was constant over time at all time points studied (5 to 60 min) with a K_m of 0.20 mM. Similar constancy was reported for porcine epidermis (7), mouse kidney (8), and purified enzyme from ox brain (9). Glucosidase from human tissues was said to yield constant activities in the case of placenta (10) and, for at least 60 min, with spleen membranes (11), and for 6 h with skin fibroblasts (12). At present, we can only urge investigators measuring β-glucosidase to check their velocity constancy.

COMMUNICATION

Heterogeneity of Molecular Weight and Apolipoproteins in Low Density Lipoproteins of Healthy Human Males[1]

Talwinder S. Kahlon[a,*], Virgie G. Shore[b] and Frank T. Lindgren[c]
[a]Western Regional Research Center, USDA-ARS, Albany, California 94710, [b]Lawrence Livermore National Laboratory, Livermore, California 94550 and [c]Donner Laboratory, University of California, Berkeley, California 94720

The molecular weights of five low density lipoprotein (LDL) subfractions from four normal healthy males were determined by analytic ultracentrifuge sedimentation equilibria. Protein content of each subfraction was determined by elemental CHN analysis, and weights of apoprotein peptides were calculated. Molecular weights in subfractions of increasing density were 2.92 ± 0.26, 2.94 ± 0.12, 2.68 ± 0.09, 2.68 ± 0.28 and 2.23 ± 0.22 million Da, and protein weight percentages were 21.05, 21.04, 22.05, 23.10 and 29.10, in subfractions 1, 2, 3, 4 and 5, respectively. Total mean apoprotein weights for respective subfractions were 614 ± 53, 621 ± 45, 588 ± 9, 637 ± 83 and 645 ± 62 KDa. In addition to a single apoprotein B-100 (apo B-100) peptide with a mean carbohydrate content of 7.1% and a molecular weight of 550 KDa per LDL particle, there may be one or more apoprotein E peptides of 34 KDa and/or apoprotein C-III of 9 KDa. In addition, subfractions 4 and 5 may contain 3–7% apolipoprotein (a). There is considerable heterogeneity among LDL subfractions as well as within the same fraction from different individuals. This heterogeneity may relate to differences in origin, metabolism and/or atherogenicity as a result of their content of apoproteins other than apo B-100.
Lipids 27, 1055–1057 (1992).

Apolipoprotein B-100 (apo B-100) is the major apolipoprotein of very low density lipoproteins (VLDL), intermediate density lipoproteins (IDL), and low density lipoproteins (LDL). This apo B-100 is synthesized primarily in the liver and plays a pivotal role in lipoprotein metabolism as the LDL ligand that interacts with the LDL receptor and initiates receptor-mediated endocytosis and LDL catabolism. Chen *et al.* (1), Knott *et al.* (2), Yang *et al.* (3) and Law *et al.* (4) determined the complete 4536 amino acid sequence of the apo B-100 peptide, calculating a molecular weight of apo B-100 of 512,723 to 514,000 Da. La Belle and Krauss (5) found that 7.1% carbohydrate is associated with LDL apolipoproteins. While LDL contains predominantly apo-B, Campos and McConathy (6), Lee and Alaupovic (7) and Chapman *et al.* (8) observed the presence of apoprotein E and apoprotein C-III in the LDL density range.

The present study was undertaken to determine the accurate molecular weight of five LDL subfractions (1.0267–1.0492 g/mL) and the total mass of the apolipoproteins of these subfractions.

[1]Presented in part at the 78th AOCS Annual Meeting held in New Orleans, LA, May 1987; received best presentation award.

Abbreviations: apo B-100, apo LP, apolipoprotein; apolipoprotein B-100; EDTA, ethylenediaminetetraacetic acid dipotassium salt; IDL, intermediate density lipoproteins; LDL, low density lipoproteins; VLDL, very low density lipoproteins.

MATERIALS AND METHODS

Four healthy normolipoproteinemic male subjects were selected for this study. Subjects were fasted overnight. Blood was drawn into evacuated tubes containing ethylenediaminetetraacetic acid dipotassium salt (EDTA), 130 mg/100 mL, and centrifuged at 1300 × *g* for 20 min at 4°C to obtain plasma. The antimicrobial agent garamycin (7.5 mg/100 mL) and the protease inhibitor ε-amino caproic acid (130 mg/100 mL) were added. The plasma density was adjusted to 1.019 g/mL by mixing 4 mL plasma with 2 mL of a NaBr solution of density 1.0426 g/mL containing 0.196 moles of NaCl and 10 mg/100 mL EDTA. The resulting 6-mL solution(s) were centrifuged at 17°C in a 40.3 Beckman (Palo Alto, CA) rotor at 40,000 rpm for 18 h. The top 1 mL VLDL-IDL fraction was removed, and the second 1 mL was taken as background. The subnatant 4 mL was adjusted to 1.0670 g/mL by adding 2 mL of a NaBr solution, 1.1566 g/mL, containing 0.196 moles NaCl and 10 mg/100 mL EDTA. Again these tubes were similarly centrifuged for 24 h, and the top 1-mL fraction containing total LDL was recovered (9). Five LDL subfractions with densities 1.0267, 1.0306, 1.0358, 1.0422 and 1.0492 g/mL, respectively, were isolated by density gradient preparative ultracentrifugation (Model L8, Beckman) using a Beckman SW 45 Ti rotor (10). LDL subfractions were dialyzed overnight at 4°C against NaCl, 1.0063 g/mL, pH 7.2–7.4. Meniscus depletion equilibrium fringes were obtained after 72 h at 6704 to 9442 rpm in a Beckman Model E ultracentrifuge using a Rayleigh interference optical system for sedimentation equilibrium measurements (11). Air in the samples was displaced by N_2 in all the procedures in order to minimize oxidation. Apoprotein mass was determined in delipidated subfractions by CHN analysis. Procedures of the determination of partial specific volumes and CHN mass analysis have been described previously (12). The partial specific volume ($\bar{v}$), mL/g, of LDL subfractions was determined according to the equation given by Schachman (13):

$$\bar{v} = 1/\varrho_o - 1/x\{(\varrho-\varrho_o)/\varrho_o\} \quad [1]$$

where ϱ_o = solvent density (g/mL); ϱ = lipoprotein solution density (g/mL); x = mass concentration of LDL solution (g/mL).

Each lipoprotein subfraction together with an aliquot of its corresponding equilibrium gradient background salt solution was dialyzed (3×, 24 h each) in a 250-mL cylinder at 4°C against 1.0063 g/mL NaCl solution (10 mg/dL EDTA, pH 7.2–7.4). The CO_2 present in the dialysate was displaced by bubbling N_2 through it before use. Solvent and solution densities were measured to ± 0.000001 g/mL using an Anton-Paar DMA-60 sixth place density meter (Anton-Paar, Richmond, VA). The temperature of the density measuring cell was stabilized at 20 ± 0.001°C. The reference standards used for the density calibrations were dry air (corrected for barometric pressure) and purest

deionized water (boiled for 10 min to remove dissolved CO_2 and cooled to 20°C). The mass (g/mL) of each LDL solution was determined to ± 0.5% using a modified CHN analyzer (Model 185, Hewlett-Packard, Palo Alto, CA). Elemental CHN determinations were carried out in triplicate, sedimentation equilibrium runs in duplicate. Considering all experimental uncertainties a molecular weight of 2.68 million Da can be determined with an error of ± 40 KDa (± 1.5%). This amounts to an 8-12 KDa error in the molecular weight of the apolipoprotein depending upon the protein content of a particular subfraction. In reality, the errors may be considerably smaller.

RESULTS AND DISCUSSION

The molecular weights of five LDL subfractions from four healthy male subjects, as determined by sedimentation equilibrium analysis, ranged from 1.70 to 3.61 million Da (Table 1). The mean molecular weights for subfractions 1, 2, 3, 4 and 5 were 2.92 ± 0.26, 2.94 ± 0.12, 2.68 ± 0.09, 2.68 ± 0.28 and 2.23 ± 0.22 million Da, respectively. The mean protein content expressed as wt% of LDL was 21.05, 21.04, 22.05, 23.10 and 29.10 for subfractions 1, 2, 3, 4 and 5, respectively (Table 2). Calculated mean molecular weights of apoprotein for LDL subfractions 1, 2, 3, 4 and 5 were 614 ± 53, 621 ± 45, 588 ± 9, 637 ± 83 and 645 ± 62 KDa, respectively (Table 3).

The mean molecular weights of the five LDL subfractions analyzed in this study (Table 1) tended to decrease with increasing density and decreasing flotation rate of the subfractions. We previously reported that molecular weights of LDL subfractions did not consistently decrease with increasing density (14). The different result is probably due to the small number of subjects involved in these studies. In the current study the molecular weights of the LDL subfractions of individual subjects did not consistently decrease with increasing density. There was a different subfraction in each of the four subjects showing the highest molecular weight. In general, protein as weight percent of LDL increased as the density of LDL subfractions increased (Table 2). The total apolipoprotein contents of subfractions 1 and 2 were similar, but increased by 38% from fraction 2 to fraction 5.

The total apoprotein associated with various LDL subfractions had molecular weights ranging from 475 to 841 KDa (Table 3). Since a single molecule of apolipoprotein B-100 with a peptide weight of 514 KDa (1-4) is associated with each LDL particle (15), the two subfractions 6622 No. 1 and 7222 No. 2 with peptide weights of 502 and 475 KDa, respectively, appear to contain only apoprotein B-100. The low molecular weight suggests either that the apo-B in these fractions is not glycosylated or, alternatively, that these fractions may contain truncated apo B-100. Truncated forms of apo B such as apo B-37, apo B-40, apo B-54.8 and apo B-90 have been reported (16-18).

Since certain fractions contain more apoprotein than could be contributed by apo-B, it is possible that LDL can contain additional apoproteins. Since a single molecule of apo B-100 weighs 550 KDa including its carbohydrate component, a mean of 12, 13, 7, 16 and 17 wt% of subfractions 1, 2, 3, 4 and 5, respectively, may be comprised of other apoproteins. These other apoproteins could consist of apo E with a molecular weight of 34 KDa and/or apo C-III of 9 KDa (8). Since we did not determine the

apo C-III or apo E content of these subfractions, we can only speculate on the relative amounts of apo E and/or apo C-III in these LDL subfractions. Lee and Alaupovic (7) reported apoprotein C-III and apo E ratios of 3.67, 1.91 and 3.09 for their subfractions designated 2, 3 and 4, respectively, which appear to correspond quite closely to fractions 1, 3 and 5 in this study. Only our fraction 1 with a possible apo C-III to apo E ratio of 3.0 may be considered close to the molar ratio of 3.09 reported for their subfraction 4 (7). Chapman *et al.* (8) reported one apo E per 60 LDL particles; however, from our data it is possible to have no apo E per LDL to three apo E per LDL molecule. Fractions 4 and 5 may also contain 3–7% as apolipoprotein (a) as previously suggested (8,19).

The current study demonstrates that there is considerable heterogeneity in molecular weight and apoprotein content among LDL subfractions as well as among the same subfraction from different individuals. The data strongly suggest that in addition to one apo B per LDL molecule there are variable amounts of smaller apoproteins, probably apo E and apo C-III. Subfractions of LDL may have different origins, metabolism and/or atherogenicity based on their content of apoproteins other than apo B-100.

Recent research was shown that oxygen-derived free radicals are involved in the pathogenesis of various diseases, including ischemia-reperfusion injury. We have also reported that oxygen-derived free radicals and lipid peroxidation may play an important role in gastric mucosal injury induced by ischemia-reperfusion. The hypoxanthine-xanthine oxidase system and neutrophils are considered important sources of oxygen-derived free radicals in this process. In recent years, it also has been shown that serum platelet-activating factor (PAF) levels increased during ischemia-reperfusion, and that induction of superoxide generation by neutrophils is one of the important biological effects of PAF. In the present study, we examined the effect of CV-6209, a specific PAF receptor antagonist, on gastric mucosal injury induced by ischemia-reperfusion, to shed some light on the possible involvement of PAF in such lesions. CV-6209 significantly attenuated the gastric mucosal injury induced by ischemia-reperfusion, and inhibited both an increase of thiobarbituric acid reactive substances and a decrease of α-tocopherol in gastric mucosa after ischemia-reperfusion. However, CV-6209 had no effect on gastric mucosal blood flow during ischemia-reperfusion. These results suggest that endogenous PAF may play an important role in gastric mucosal injury induced by ischemia-reperfusion, and that CV-6209 exerts its beneficial effect mainly by inhibiting neutrophil superoxide production induced by PAF.
Lipids 27, 1058–1060 (1992).

Platelet-activating factor (PAF) is an endogenous phospholipid that is produced by a variety of activated cells including neutrophils, basophils, macrophages, monocytes and endothelial cells (1–3). PAF exerts a wide spectrum of biological effects, such as stimulation of platelets and leukocytes, hypotension and bronchoconstriction, as well as an increase in vascular permeability (4). Considerable attention has recently been focused on PAF's potent ulcerogenic activity. PAF appears to be a mediator of endotoxin-induced gastrointestinal damage (5) and of gastric mucosal lesions induced by water-immersion and constriction (6). However, the precise mechanisms of PAF's ulcerogenic activity remain unknown. Oxygen-derived free radicals have been implicated in mediating tissue damage observed after ischemia in various organs (7). It also is known that PAF is synthesized by various cells under hypoxia (8) and that neutrophils and macrophages stimulated by PAF produce oxygen-derived free radicals (9). In the present study, we examined the effect of CV-6209, a PAF antagonist, on gastric mucosal injury induced by ischemia-reperfusion in rats. The experiments were intended to shed some light on the possible involvement of endogenous PAF in such lesions.

MATERIALS AND METHODS

Male Sprague-Dawley (SD) rats weighing 200 g were obtained from Keari Co., Ltd. (Osaka, Japan). Acute gastric mucosal injury was induced by using the technique previously described (10). After an 18-h fast, a laparotomy was performed on SD rats under pentobarbital anesthesia (25 mg/kg) and the celiac artery was blocked with a clamp for 30 min, followed by 30-min reperfusion upon release of the clamp. The extent of gastric mucosal lesions was carefully examined macroscopically and microscopically, and expressed in terms of the total area of the erosions (10). Thiobarbituric acid (TBA) reactive substances, as an index of lipid peroxidation, in serum and gastric mucosa were measured by the method previously reported (11,12), and serum α-tocopherol and gastric mucosal α-tocopherol were measured by the method of Abe *et al.* (13). α-Tocopherol is an excellent antioxidant which reacts with free radicals and terminates free radical-mediated chain reactions (14); hence, it is often used as an index of free radical involvement in the lesion. The PAF antagonist, CV-6209, which is 2-[*N*-acetyl-*N*-(2-methoxy-3-octadecylcarbamoyloxypropoxycarbonyl)aminomethyl]-1-ethylpyridinium chloride (Takeda Chemical Industry, Osaka, Japan) was dissolved in saline with 0.25% bovine serum albumin (BSA; Sigma Chemical Co., St. Louis, MO) added, and was given to rats intravenously 10 min before clamping. Because CV-6209 is a surfactant, the solution was injected over a 5-min period to avoid hemolysis (15). The control group was treated with BSA-supplemented saline only. The microcirculatory blood flow in the gastric mucosa was measured using a laser Doppler flowmeter (16) (ALF 2100, Advance Co., Ltd., Tokyo, Japan).

Data are expressed as the mean ± SE of seven rats. Comparisons between groups were by the Dunnet test. With all statistical analysis, a probability (*P* value) of <5% was considered significant.

RESULTS

Clamping the celiac artery decreased the gastric mucosal blood flow to about 10% of that measured before the clamping. Just after the removal of the clamp, the blood flow in the gastric mucosa recovered completely. The decrease of blood flow during ischemia was not affected by treatment with CV-6209 at a dose of 10 mg/kg (Fig. 1).

Multiple erosions and bleeding were revealed in the gastric mucosa after 30 min of reperfusion following 30 min of ischemia. The total area of erosions induced by

TABLE 1

Effects of CV-6209 on Total Area of Gastric Mucosal Lesions and Thiobarbituric Acid (TBA) Reactive Substances After 30 min of Reperfusion Following 30 min of Ischemia[a]

Treatment	Total area of erosions (mm^2)	TBA reactive substances (nmol/g wet wt)
Normal	0	38.6 ± 3.0
BSA-added saline (control)	38.2 ± 5.1	62.9 ± 6.8
CV-6209 (0.1 mg/kg)	27.3 ± 4.8	55.3 ± 4.3
CV-6209 (1 mg/kg)	16.7 ± 5.2[b]	42.9 ± 3.9[b]
CV-6209 (10 mg/kg)	14.6 ± 4.2[b]	44.8 ± 3.6[b]

[a] Each value indicates the mean ± SEM of seven rats. BSA, bovine serum albumin.

[b] $P < 0.05$ when compared with the control group without administration of CV-6209. CV-6209 was injected intravenously 10 min before clamping.

ischemia-reperfusion was significantly decreased by treatment with CV-6209 at doses of 1 and 10 mg/kg (Table 1).

TBA reactive substances in the gastric mucosa significantly increased 30 min after reperfusion. This increase of TBA reactive substances was significantly inhibited by treatment with CV-6209 at doses of 1 and 10 mg/kg (Table 1). Serum TBA reactive substances in the control group and in groups treated with CV-6209 did not show any significant changes after ischemia-reperfusion when compared with a healthy group that had undergone sham operations (data not shown).

α-Tocopherol in the gastric mucosa significantly decreased after 30 min of reperfusion. This decrease was inhibited by treatment with CV-6209 at a dose of 10 mg/kg (Table 2). The serum α-tocopherol/total cholesterol ratio of the control group and of the groups treated with CV-6209 showed no significant changes after ischemia-reperfusion when compared with the healthy control group (Table 2).

TABLE 2

Effect of CV-6209 on Serum and Gastric Mucosal α-Tocopherol After 30 min Reperfusion Following 30 min Ischemia

Treatment	α-Tocopherol	
	Serum α-toc/cholesterol ratio[a] ($\times 10^{-3}$)	Gastric mucosa (ng/mg protein)
Normal	9.1 ± 0.8	13.7 ± 2.3[b]
BSA-added saline (control)	7.9 ± 0.6	9.8 ± 2.8
CV-6209 (0.1 mg/kg)	7.8 ± 1.1	10.1 ± 3.0
CV6209 (1 mg/kg)	9.0 ± 1.2	11.6 ± 2.4
CV-6209 (10 mg/kg)	8.6 ± 0.9	12.1 ± 1.8[b]

[a] Serum α-tocopherol (α-toc)/total cholesterol ratio was examined in order to eliminate the influence of serum lipids. Each value indicates the mean ± SEM of seven rats. BSA, bovine serum albumin.

[b] $P < 0.05$ when compared with the control group without administration of CV-6209. CV-6209 was injected intravenously 10 min before clamping.

DISCUSSION

The possibility that oxidative stress due to excess formation of oxygen-derived free radicals is closely involved in various disease states (17–19) has been the focus of much attention. However, it has been extremely difficult to establish a direct cause-and-effect relationship between oxygen-derived free radical formation and the actual lesions that develop. Thus, the mechanism of injury still remains unclear. However, an increasing number of reports (20,21) suggests that free radicals play an important role in ischemia-reperfusion injury based on inhibition experiments involving superoxide dismutase (SOD) and catalase. We also reported (10) that oxygen-derived free radicals and lipid peroxidation may play a role in the formation of gastric mucosal injury induced by ischemia-reperfusion, because this type of injury was significantly attenuated by SOD, catalase and other free radical scavengers. We also suggested that xanthine oxidase may be a major source of oxygen-derived free radicals in this model, because allopurinol, a competitive inhibitor of xanthine oxidase, significantly ameliorated gastric mucosal injury (22). Neutrophils also are being considered as an important source of oxygen-derived free radicals (23).

In the present study we showed that CV-6209 significantly attenuated gastric mucosal injury induced by ischemia-reperfusion and that it inhibited both an increase of TBA reactive substances, an index of lipid peroxidation, and a decrease of α-tocopherol in the gastric mucosa after ischemia-reperfusion. These results suggest the involvement of endogenous PAF in gastric mucosal injury induced by ischemia-reperfusion, because CV-6209 has been shown to act as a specific PAF receptor antagonist to compete for the PAF receptor with PAF, and to block various biological effects of PAF, with little effect on the enzymes of the arachidonic acid cascade, or on α-adrenergic receptors, on Ca channels, and so on (15). Thus, it appears that in our system the CV-6209 blocked ulcerogenic effects of endogenous PAF, which resulted in a decrease in gastric mucosal lesions. CV-6209 had no

effect on gastric mucosal blood flow during ischemia-reperfusion.

On the other hand, Yoshida (24) reported that exogenous PAF administered to rats induced acute gastric mucosal lesions, and that such lesions were attenuated by the treatment with radical scavengers or with anti-neutrophil antibody. Other authors (9,25) have reported that PAF induced superoxide generation by neutrophils in a dose-dependent manner, and that preincubation with a small amount of PAF (5×10^{-9} M) enhanced neutrophil superoxide release induced by various stimuli. We have reported (26) that CV-6209 inhibited both superoxide production by neutrophils and PAF priming *in vitro*. Considering all these reports, it appears that CV-6209 attenuated the gastric mucosal lesions mainly due to inhibition of superoxide production by neutrophils stimulated by endogenous PAF. Increased PAF levels in blood during ischemia-reperfusion have been demonstrated by others (27,28); however, we did not verify the endogenous PAF level in the present model. Such measurements would be highly informative and should be researched in the future.
