ARTICLE

Nonmembrane Associated Dolichol in Rat Liver

P. Löw[a], E. Peterson[a], C. Edlund[b], U. Brunk[c] and E.L. Appelkvist[b,*]

[a]Department of Biochemistry, University of Stockholm, S-106 91 Stockholm, Sweden, [b]Division of Basic Research in Dementia, Clinical Research Center at Huddinge Hospital, Karolinska Institutet, S-141 86 Huddinge, Sweden and [c]Department of Pathology, University Hospital, S-581 85 Linköping, Sweden

The distribution of dolichol in rat liver was studied. Upon high-speed centrifugation, 9% of the total tissue dolichol was recovered in the supernatant. Dolichol was enclosed in vesicles and in lipidic particles which were isolated by gel filtration and density gradient centrifugation. The particles had a diameter of 20 nm and contained dolichol, ubiquinone, cholesterol, phospholipid and some protein. Similar particles were recovered upon incubation of isolated hepatocytes with liposomes containing dolichol. From the lysosomal lumen, lipid particles containing dolichol, ubiquinone, cholesterol and phospholipid, but no protein, were isolated. The diameter of the particles was 20–40 nm with a molecular weight of 130 kDa. Puromycin treatment inhibited protein synthesis, but did not affect dolichol transfer from the endoplasmic reticulum to lysosomes, suggesting that the transfer is not mediated by newly synthesized apoprotein. The results indicate that a sizeable portion of the total cellular dolichol is present in cytoplasm and in lysosomal lumen. Furthermore, dolichol probably participates in the translocation process.

Lipids 27, 1-9 (1992).

Ubiquinone and dolichol appear to be located in the central hydrophobic core of membranes (1,2), whereas cholesterol is known to be asymmetrically distributed between the phospholipid fatty acyl groups in the transverse plane of the bilayer (3). The major lipids in the cell are phospholipids, and the types and amounts of phospholipids present can vary somewhat under extreme pathological conditions (4). By comparison, induction of the endoplasmic reticulum or peroxisomes with xenobiotics can increase dolichol concentrations manyfold. This finding raises the possibility that not all dolichol in organelles is membrane associated (5). In addition, biosynthesis of dolichol occurs largely in the endoplasmic reticulum, which necessitates extensive transport to various other organelles (6). Dolichol is also found in the high-speed supernatant fraction, which may imply that dolichol utilizes transport systems involving carrier proteins; such transport processes have been extensively studied for phospholipids (7).

The functions of dolichol in the cell are presently not well understood. Dolichyl-P, which participates in the biosynthesis of glycoproteins (8), is usually present in a small amount and appears to be synthesized by a separate pathway (9,10). In addition to membrane-associated functions, such as regulation of membrane stability, fluidity and permeability, dolichol may be involved in metabolic processes which are not necessarily associated with membranes.

In the present study we have investigated the intracellular distribution of dolichol. The main objective was to find out whether dolichol is mainly associated with membranes or is also found in the cytosol and lumen of some organelles. The functional importance of observed intracellular dolichol distribution was assessed.

MATERIALS AND METHODS

Animals. Male Sprague-Dawley rats weighing 180-200 g were used. In experiments where puromycin (15 mg/100 g body weight) was injected intraperitoneally, the rats weighed 60 g. In the *in vivo* experiments, 0.5 mCi (*RS*)-[5-^{3}H]mevalonolactone (24 Ci/mmol, New England Nuclear, Boston, MA) or 60 μCi [^{14}C]leucine (57 mCi/mmol, Amersham International, Buckinghamshire, England) dissolved in 0.9% NaCl was injected into the portal vein under Mebumal anaesthesia.

Fractionation. For the preparation of microsomal, mitochondrial/lysosomal and supernatant fractions, rat livers were homogenized in 0.25 M sucrose in a glass-Teflon homogenizer with 4 strokes at 440 rpm. The homogenate (20%, w/v) was centrifuged at 310 × *g* for 10 min to remove debris and nuclei, and the mitochondrial fraction was subsequently obtained by centrifuging the resulting supernatant at 3,800 × *g* for 20 min. The pellet thus obtained was washed twice by recentrifugation in 0.25 M sucrose, and thereafter repelleted at 3,800 × *g* for 20 min. This fraction also contained lysosomes and was designated the mitochondrial/lysosomal fraction. The supernatant obtained after centrifugation at 10,000 × *g* for 20 min was recentrifuged in a 50 Ti rotor (Beckman, Palo Alto, CA) at 105,000 × *g* for 1 hr. The resulting microsomal pellet was suspended in 0.25 M sucrose. The high-speed supernatant fractions were prepared by recentrifugation of the postmicrosomal supernatant at 150,000 × *g* for 3 hr in 7-mL centrifuge tubes. The upper 1.5 mL, designated the top-layer supernatant, was removed with a Pasteur pipette. The rest of the supernatant, with the exception of the lower 1 mL (4.5 mL), was analyzed and designated as the middle-layer supernatant.

Lysosomes were isolated on a Metrizamide gradient as described earlier (11). In order to separate membranes and luminal contents, the lysosomes were suspended in distilled water and subjected four times to freeze-thawing, followed by sonication, twice for 1 min, with the fine tip of a Branson sonicator (model S-125) at a setting of 0.5 A. The membranes were subsequently separated by centrifugation at 105,000 × *g* for 2 hr.

To determine crosscontamination in isolated fractions, the various organelles were prepared and analyzed for marker enzymes. The degrees of contamination (1-8%) were similar to those described in detail earlier (12).

Isolation and labeling of hepatocytes. The rat livers were perfused through the portal vein with Hanks' buffer con-

Abbreviations: EGTA, ethylene-*bis*(oxyethylenenitrilo)tetraacetic acid; HPLC, high-performance liquid chromatography; SDS, sodium dodecyl sulfate.

taining 0.5 mM EGTA and 2% albumin, followed by Hanks' buffer containing 0.12% collagenase (Type V, Boehringer Mannheim) and 2 mM $CaCl_2$. The solutions were gassed with 93.5% O_2 and 6.5% CO_2 (carbogen gas) and heated to 37°C prior to use. The perfused livers were shaken in Krebs-Henseleit buffer to disperse the hepatocytes. The cell suspensions were washed once with the same buffer. Cell viability was estimated by incubation with 0.04% trypan blue, and by counting the cells which excluded the dye using a Burker chamber.

Isolated hepatocytes (200×10^6 cells) in 40 mL Krebs-Henseleit buffer were incubated for 60 min at 37°C under a "carbogen" atmosphere with liposomes containing [^{3}H]dolichol-19. The liposomes were prepared by mixing 20 mg egg lecithin (Lipid Products, South Nutfield, England) in chloroform/methanol (2:1, v/v) with 50 nmoles [^{3}H]dolichol-19 (specific activity 5.5×10^6 dpm/nmol) labeled according to Keenan and Kruczek (13). After evaporation of the solvent, 4.5 mL of 0.9% NaCl was added and the suspension was pulse-sonicated for 50 min in an ice-bath under a nitrogen atmosphere. The liposomes containing [^{3}H]dolichol were incubated with hepatocytes at 37°C. The hepatocytes were subsequently sedimented by centrifugation at $50 \times g$ for 5 min and washed five times with 20 mL of 0.9% NaCl. The cells were finally suspended in 20 mL of 0.25 M sucrose. For subfractionation, hepatocytes were sonicated for 30 sec in order to disrupt the plasma membranes, and then subfractionated as described earlier (14).

Gel filtration. In order to isolate the dolichol-containing components in the middle-layer supernatant, 5 mL of this supernatant was subjected to gel filtration on a 1.5×70 cm Bio-Gel A-1.5 m column (Bio Rad, Richmond, CA), 200–400 mesh. The column was eluted with 50 mM Tris-HCl, pH 7.8, at a flow rate of 0.2 mL/min, 2-mL fractions were collected.

Gel filtration on Sephacryl S-200 superfine (Pharmacia, Uppsala, Sweden) was used to estimate the molecular weight of the dolichol-rich vesicles recovered from the lysosomal lumen. The size of the column was 1.6×90 cm, and the elution buffer was 100 mM Tris-HCl, pH 7.0, containing 300 mM NaCl. The flow rate was 0.1 mL/min.

Gradient centrifugation. The peak in the void volume (10 mL) from the Bio-Gel column was mixed with 3.4 g KBr and placed on the bottom of a centrifuge tube. This mixture was overlayed with 28 mL of 0.9% NaCl and centrifuged in a VTi-50 vertical rotor at $203,000 \times g$ for 3 hr. Fractions of 1.3 mL were then collected from the tube.

Flotation of lysosomal contents was carried out in a vertical VTi-65 rotor by mixing 3 mg of the content protein with solid KBr and water to adjust the density to 1.3 g/mL. The fraction was overlayed with 1.1 mL 0.9% NaCl and centrifuged at $203,000 \times g$ for 5 hr. The tubes were punctured at the bottom and 10 fractions collected. The last fraction was designated the uppermost fraction. A number of lysosomal enzyme activities were assayed in the lysosomal fractions, and all of these activities were absent in the uppermost fraction.

Lipid analysis. Dolichol and cholesterol were assayed by HPLC, as described earlier (15). The lipid extract was subjected to alkaline hydrolysis and applied to a C18 Sep-Pak column (Waters, Milford, MA). Cholesterol was collected in the methanol phase and dolichol was subsequently eluted with hexane. HPLC was performed using a Hewlett-Packard (Palo Alto, CA) Hypersil ODS (C18) 3μ column. For analysis of dolichol, a linear gradient from the initial methanol/2-propanol/water (60:40:5, v/v/v) in pump system A to methanol/2-propanol/hexane (60:40:20, v/v/v) in pump system B was employed. The flow rate was 2 mL/min and the program time was 25 min. The absorbance was recorded at 210 nm.

For analysis of cholesterol, a linear gradient from the initial (A) methanol/water (9:1, v/v) to (B) methanol/2-propanol (8:2, v/v) was used. The flow rate was 2 mL/min and the program time 25 min; the eluate was monitored at 210 nm. Dolichol (C23) and ergosterol were added as internal standards prior to alkaline hydrolysis.

Ubiquinone is partially degraded by alkaline hydrolysis and therefore the extraction was done with chloroform/methanol/water (1:1:0.3, v/v/v) as described earlier (16). In HPLC the same linear gradient was used as for the analysis of cholesterol. Elution was monitored at 275 nm. Ubiquinone-6 was added as internal standard before extraction. Phospholipids were measured as described earlier (17).

Sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis. Aliquots of fractions were dialyzed against distilled water and concentrated by lyophilization. Electrophoresis was then performed in 1.5-mm vertical slab gels with 10–15% polyacrylamide, according to Laemmli (18).

Electron microscopy. The samples were fixed in 3% glutaraldehyde in 0.2 M sodium cacodylate-HCl with 0.25 M sucrose, pH 7.2, at 4°C overnight. Following postfixation in 1% osmium tetroxide in 0.15 M sodium cacodylate-HCl, pH 7.2, for 90 min at 20°C, the samples were dehydrated and embedded in epoxy resin.

For negative staining a drop of the specimen was placed on the copper grid covered by a thin film of Formvar, which was stabilized with a 40 Å coating of carbon. After 15 min at 20°C, the fluid was absorbed with filter paper and one drop of 2% uranyl acetate was added.

Immunoprecipitation. For the isolation of plasma proteins, microsomes were solubilized with sodium deoxycholate at a final concentration of 0.5% and mixed with protein-A-Sepharose CL-4B (Pharmacia). After centrifugation, aliquots of the supernatant were mixed with excess antibody against rat albumin, fibrinogen and transferrin. After 1 hr at room temperature, incubation was continued at 4°C overnight. The samples were chromatographed on a protein-A-Sepharose column.

Protein precipitation. Protein content was measured according to Lowry *et al.* (19) using bovine serum albumin as standard.

RESULTS

Isolation and metabolism of dolichol. After centrifugation at high g force of the postmicrosomal supernatant, a white, milky top-layer was obtained. This "top-layer" was removed while the remainder of the supernatant was designated as "middle-layer". Most of the dolichol and dolichyl ester was recovered in the top-layer (Table 1). Approximately 20% of the total free dolichol was present in the middle-layer, and only a minor portion was present in esterified form.

Upon injection of [^{3}H]mevalonate into the portal vein of rats, the initial rate of incorporation of label into

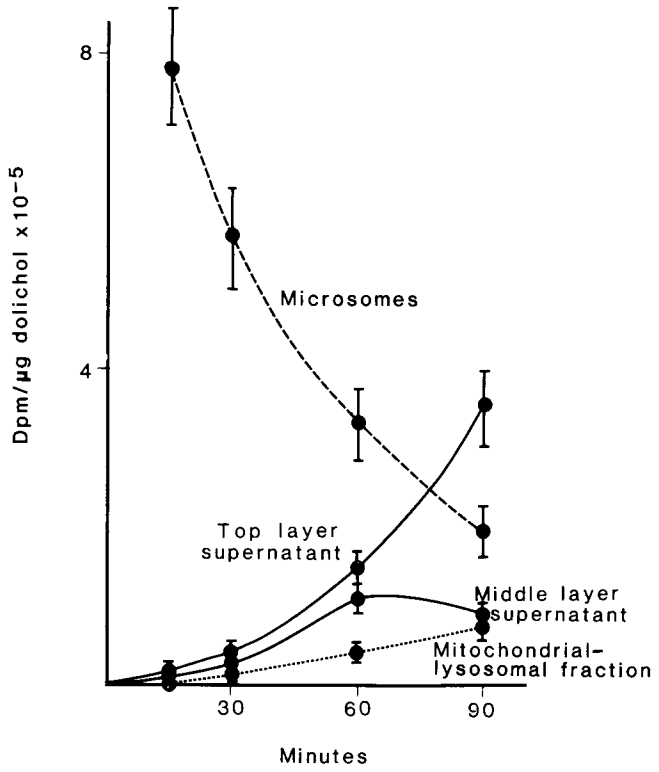

FIG. 1. Incorporation of radioactivity into dolichol of various hepatic subcellular fractions after injection of [^{3}H]mevalonate into the portal vein of rats. At indicated times, the livers were removed for subcellular fractionation and for the isolation of dolichol as described in Materials and Methods.

isolated microsomes was high and then decreased rapidly, presumably due to transport of newly synthesized lipid to other cellular compartments, catabolism, and/or production of other metabolites (Fig. 1). During the first 10 min after injection, no labeled dolichol was detected in the cytosol, but later on labeling in both the middle- and the top-layer increased. In the middle-layer maximal incorporation was attained at 60 min after injection, whereas in the top-layer the specific radioactivity in dolichol continued to increase for at least 90 min. Labeling of dolichol in the mitochondrial/lysosomal fraction was low initially, but subsequently increased slowly.

Size distribution of particles containing dolichol. Millipore filtration was routinely used to estimate the size

[b]The numbers denote the percent of the original dolichol recovered in the filtrate. The values are the means ± SE of three experiments.

of particles in both layers of the high-speed supernatant fraction (Table 2). When the top-layer was passed through filters with decreasing pore size and the amounts of dolichol in the different filtrates were measured, we found that at a pore size of 0.8 μm only 23% of the dolichol appeared in the filtrate. By comparison, as much as half the dolichol was recovered in the filtrate of the middle-layer, even with a pore size of 0.025 μm.

These filtration experiments demonstrated that the dolichol in the top-layer is associated with structures larger than microsomal vesicles. Electron microscopy revealed the existence of membrane-bound vesicles of various sizes, most ranging from 1.5–2.5 μm (Fig. 2). Most of the vesicles contained material that was stained heavily with osmium and apparently was lipid. Since this fraction contained both membranous and nonmembranous materials, it was not further characterized.

Properties of the middle-layer dolichol in the high-speed supernatant fraction. The dolichol present in the middle-layer in nonmembrane-bound form was isolated and further characterized. When the layer was subjected to gel filtration on a Bio Gel column, most of the dolichol-containing fraction was excluded (Fig. 3A). The excluded material was then subjected to centrifugation on a KBr gradient (Fig. 3B), and we found that most dolichol-containing material equilibrated at a density of approximately 1.05 g/mL. The fraction isolated by gradient centrifugation (Table 3) contained mostly phospholipid, some cholesterol (about 20%) and dolichol at about 0.2% of the total lipid content.

SDS-PAGE analysis indicated substantial enrichment of proteins from the middle-layer upon chromatography on Bio Gel and further enrichment on the KBr gradient (Fig. 4). In the fraction isolated by gradient centrifugation, the five major protein bands had molecular weights of approximately 30, 65, 150, 250 and 300 kDa.

The fraction isolated by gradient centrifugation was also characterized by electron microscopy using negative staining (Fig. 5). Particles with a diameter of about 20 nm were visible and apparently were of the lipoprotein type.

In vitro *lipid transfer.* Previous experiments had demonstrated that isolated hepatocytes take up liposomal vesicles that contain dolichol (20). The uptake apparently does not involve the LDL (low density lipoprotein) receptor or endocytotic vesicles. When the hepatocytes were subfractionated in the same manner as hepatic

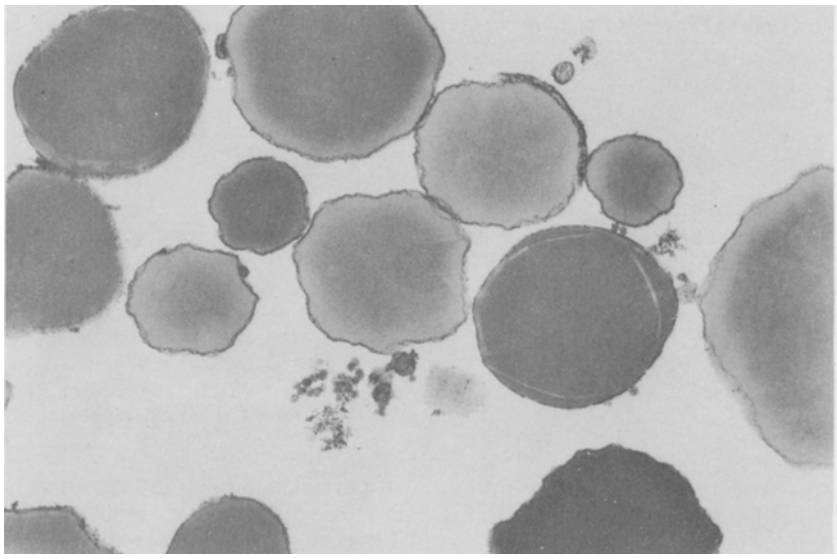

FIG. 2. Electron micrograph of the vesicles in the top-layer supernatant. Lipid-filled vesicles with a diameter of 1.5–2.5 μm are seen. Magnification × 25,600.

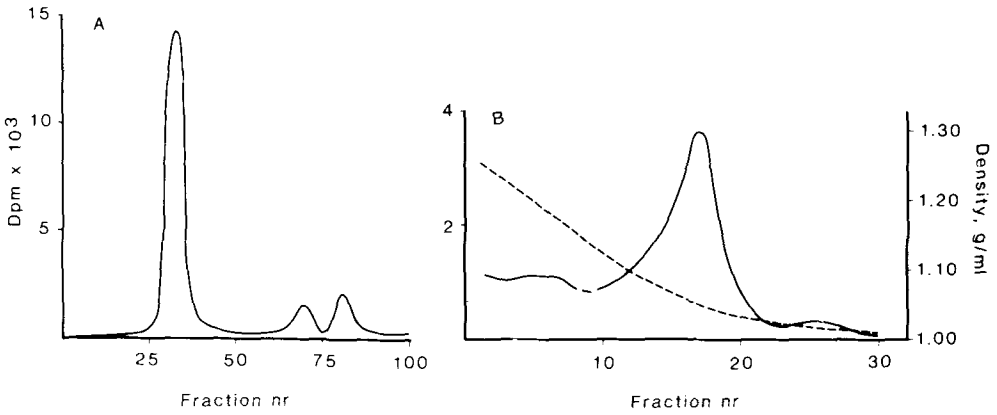

FIG. 3. Purification of the dolichol-containing fraction from the middle-layer supernatant. A. The middle-layer supernatant was prepared 60 min after the injection of [^{3}H]mevalonate, 5 mL was placed onto a Bio-Gel A-1.5 m column (1.5 × 70 cm), and fractions (2 mL) were eluted with 50 mM Tris-HCl, pH 7.8, at a flow rate of 0.2 mL/min. Dolichol was isolated from the eluted fractions by HPLC and analyzed for radioactivity. B. The dolichol-rich fraction of the void volume after gel filtration was subjected to centrifugation on a KBr gradient. After centrifugation, the contents of the centrifuge tubes were divided into 1.3 mL fractions and analyzed for density. Dolichol was isolated and its radioactivity determined.

tissue, a continuously increasing level of radioactivity was associated both with the middle- and the top-layers (Fig. 6). In this way it was possible to obtain dolichol-containing cytoplasmic structures with a high level of radioactive labeling.

The middle-layer first was subjected to gel filtration followed by gradient centrifugation in order to purify the dolichol-rich fraction. This purified fraction was then used in lipid transfer studies. Increasing amounts of the purified fraction resulted in a linear increase in transfer of labeled dolichol into the mitochondrial/lysosomal fraction (Fig. 7A). An excess of cytoplasmic [^{3}H]dolichol in the incubation medium resulted in a time-dependent dolichol transfer to both the mitochondria and the microsomes (Fig. 7B and 7C).

Lysosomal content. Lysosomes contain 20 times more dolichol (4.5 μg/mg protein) than do microsomes. Upon sonication or osmotic treatment, 90% of the lysosomal dolichol was solubilized without solubilizing the lysosomal membrane. The dolichol removed from the lumen of lysosomes was mixed with KBr and centrifuged in a self-generating gradient using a vertical rotor. The top fraction, with a density of less than 1.20 g/mL, was examined further using negative staining electron microscopy.

TABLE 3

Lipid Composition of the Dolichol Containing Fraction Purified from the Middle-Layer Supernatant by Gel Filtration and Density Gradient

Lipid	Amount (μg)[a]
Phospholipid	52.3 ± 5.9
Dolichol	0.18 ± 0.03
Cholesterol	13.8 ± 1.5
Ubiquinone	0.27 ± 0.04

[a]The values represent the lipid contents in the fraction obtained from 1 g liver. The values are the means ± SE of six experiments.

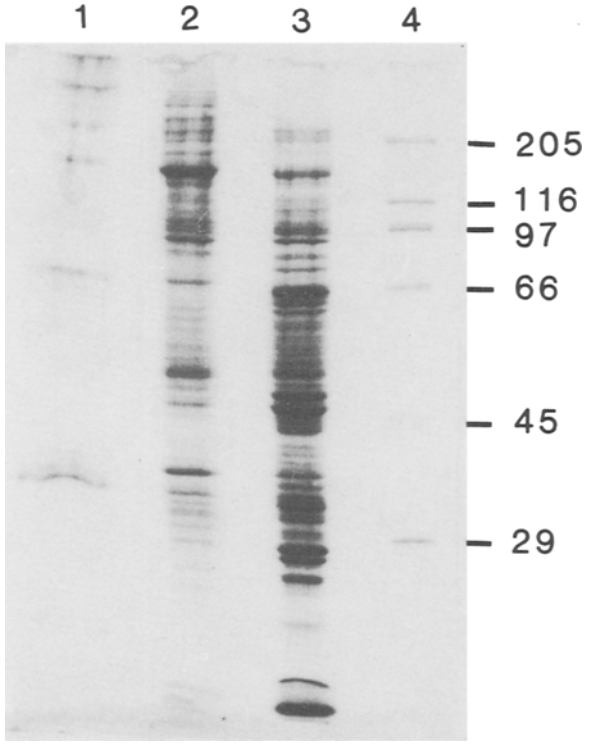

FIG. 4. SDS-polyacrylamide gel electrophoresis of the proteins in the dolichol-containing fraction after Bio-Gel chromatography and density gradient centrifugation (lane 1), dolichol-containing fraction after Bio-Gel chromatography only (lane 2) and middle-layer supernatant (lane 3). Molecular weight standards consisted of myosin (205 kDa), β-galactosidase (116 kDa), phosphorylase B (97 kDa), bovine serum albumin (66 kDa), ovalbumin (45 kDa), and carbonic anhydrase (29 kDa) (lane 4).

FIG. 5. Negatively stained preparation of the purified dolichol-containing particles. The diameter of the particles is 20 nm. Magnification × 240,000.

Round particles with a diameter of 20–40 nm and homogenous, non-staining inner contents were seen (Fig. 8). In contrast to many types of negatively stained lipoprotein particles, no grooves containing contrast solution were found.

The fraction of lysosomal contents obtained by flotation consisted mainly of lipid (Table 4). The total lysosomal contents contained phospholipid, cholesterol, dolichol and ubiquinone. About half the total phospholipid placed on the gradient was recovered in the uppermost fraction, while almost all the cholesterol, dolichol and ubiquinone of the lysosomal contents flotated upon centrifugation in this system. No protein was detectable by chemical assay, and virtually no protein bands appeared when the uppermost fraction was analyzed by SDS-gel electrophoresis (not shown).

The content of the uppermost fraction was analyzed on a Sephacryl S-200 superfine column and lipid was measured in the eluted fractions. Dolichol eluted exclusively at an apparent molecular weight of about 130 kDa. The other lipids of the uppermost fraction also appeared at this location.

Puromycin treatment. Dolichol is present in the lumen of lysosomes in nonmembrane-associated form. One explanation for this may be that the lipid synthesized in the endoplasmic reticulum is transported *via* the luminal pathway to the lysosomes through the Golgi system. The transport may or may not involve carrier proteins.

Puromycin is known to inhibit protein synthesis both *in vivo* and *in vitro* by terminating polypeptide elongation

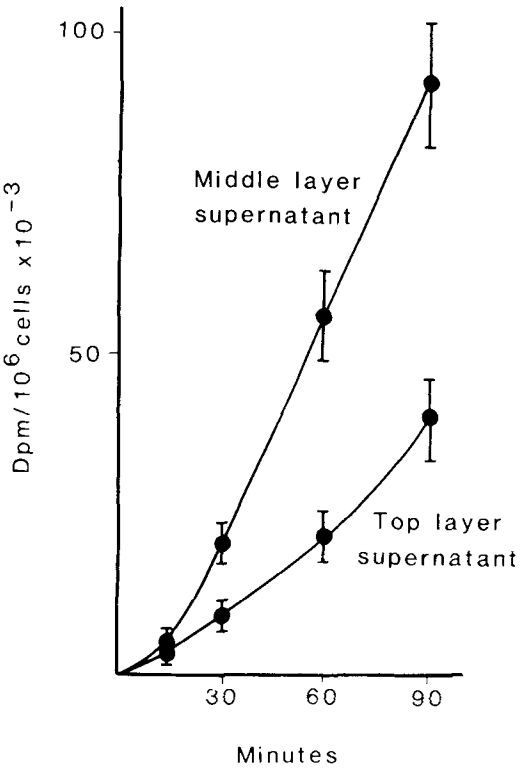

FIG. 6. Recovery of liposomal [^{3}H]dolichol-19 in the supernatant fractions of hepatocytes. Liposomes containing [^{3}H]dolichol-19 were incubated with hepatocytes. At indicated times the reaction was stopped by adding 0.9% NaCl and the hepatocytes were sedimented by centrifugation. The washing procedure was repeated five times. High-speed supernatant fractions were prepared from these hepatocytes, and dolichol was isolated and radioactivity counted.

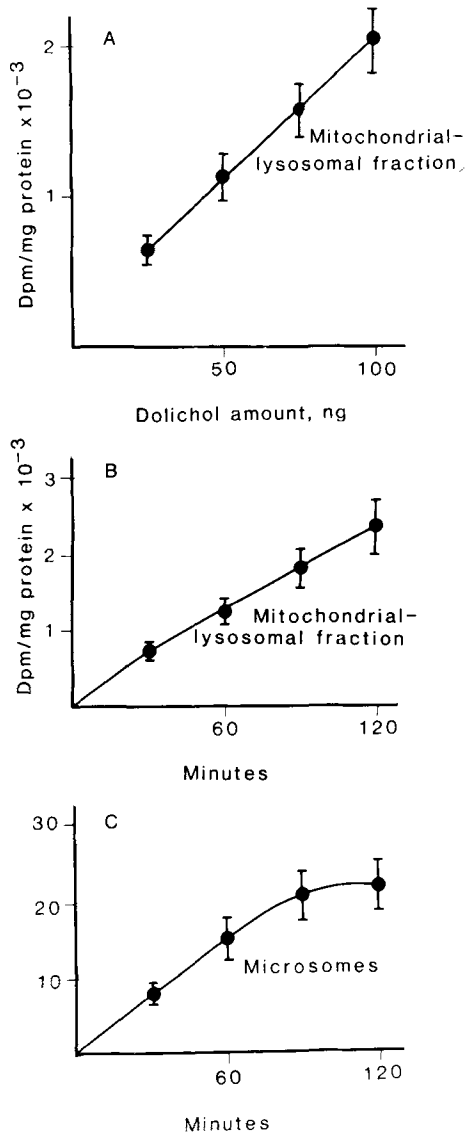

FIG. 7. Transfer of dolichol from purified vesicles to mitochondrial/lysosomal and microsomal fractions. The middle-layer supernatant fraction from hepatocytes labeled with liposomal [^{3}H]dolichol-19 was purified using gel filtration and density gradient centrifugation. The purified fractions were incubated with isolated mitochondria/lysosomes and microsomes. A. Fractions containing 25–100 ng dolichol were incubated for 60 min at 37°C with 12.5 mg mitochondrial/lysosomal protein in the presence of 50 mM Tris-HCl, pH 7.5. B. Fractions containing 50 ng dolichol were incubated for various times at 37°C with 12.5 mg mitochondrial/lysosomal protein. C. As in B, except that the incubation mixture contained 12.5 mg microsomal protein.

at the ribosomal level. Such treatment is useful in the study of export proteins, because most have short half-lives in the endoplasmic membrane system. Under the same conditions, most metabolic processes mediated by complex enzyme systems are unaffected by puromycin, because the majority of the constitutive enzymes have half-lives in the range of days (21).

The effectiveness of the inhibition of protein synthesis by puromycin under our conditions was tested by analyzing [^{14}C]leucine incorporation into newly synthesized plasma proteins (Table 5). Using immunoprecipitation and isolation on protein-A-Sepharose, highly labeled, newly synthesized albumin, fibrinogen and transferrin were separated from the solubilized microsomal fraction. Treatments of rats with puromycin 2 hr prior to removal of the liver resulted in complete inhibition of the biosynthesis of all three of these plasma proteins. Thus, the puromycin treatment completely inhibited protein synthesis associated with the endoplasmic reticulum.

Microsomal dolichol exhibits a high initial level of labeling when [^{3}H]mevalonate is used as precursor *in vivo*, because dolichol is synthesized in the endoplasmic reticulum (Fig. 9). The rapid decay of this radioactivity indicates that the transport to other locations may occur. Simultaneously, the lysosomal pool of dolichol shows increasing labeling, which may indicate that at least a portion of the newly synthesized dolichol is transported to the lysosomes.

Puromycin treatment moderately inhibited the labeling of microsomal dolichol by [^{3}H]mevalonate. In spite of this inhibition, however, the time-course of the decrease in microsomal radioactivity was very similar to that of the control. Puromycin treatment caused only a slight inhibition in the labeling of lysosomal dolichol. The specific radioactivity in both control and treated lysosomes in-

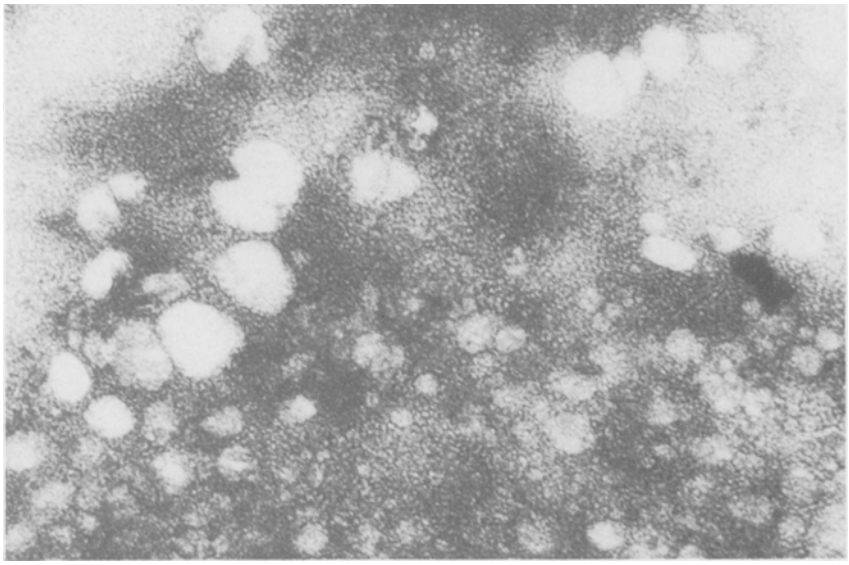

FIG. 8. Electron micrograph of the uppermost fraction obtained by flotation. The lysosomal content was flotated on a KBr gradient and the uppermost fraction examined by negative staining. The size of the lipidic particles is approximately 20–40 nm. Magnification × 160,000.

	Albumin	Fibrinogen	Transferrin[b]
	(Dpm/mg protein)[c]		
Control	4400 ± 422	738 ± 103	1830 ± 238
Puromycin treated	71 ± 7	19 ± 3	72 ± 11

[a]Rats were treated with puromycin (15 mg/100 g body weight) 2 hr before injection of 60 μCi [^{14}C]leucine into the portal vein.

[b]Precipitation with antibody is described in Materials and Methods.

[c]The values are the means ± SE of six experiments.

creased continuously with time. The above experiments demonstrate that puromycin abolishes synthesis of luminal export proteins, but does not hinder the transport of dolichol from its site of synthesis to lysosomes.

DISCUSSION

Most cellular lipids are present in membrane-bound form. Upon subcellular fractionation it has also become apparent that all organelles isolated from rat liver contain dolichol (22). Based on model membrane studies, it has been suggested that dolichol is typically located in the hydrophobic core of the phospholipid bilayers (1,23). This, of course, limits the amount of dolichol which membranes can accommodate. By comparison, the amount of dolichol in subcellular organelles varies greatly, *i.e.*, lysosomes contain 30 times more dolichol than do microsomes. For example, the human pituitary gland contains 7 mg dolichol/g wet weight, which is more than the total content of phospholipid (6 mg/g) (24). It would appear unlikely that all dolichol in this tissue would be membrane associated.

In the present study we found that dolichol can be recovered both in the high-speed supernatant fraction and from the lysosomal lumen (9% and 31% of the total liver dolichol, respectively), which raises questions concerning the physical association of this lipid at these locations. In the supernatant fraction dolichol is concentrated in the fatty layer, as well as in particles of the middle-layer. Electron microscopy revealed that the supernatant dolichol is enclosed in vesicles. Whether this is a storage form, as has been described for secretory proteins (25), or serves a mode of lipid translocation from the site of synthesis to the final site of product use (26) remains to be investigated. Lipid vesicles can be produced by endocytotic processes, a mode that is utilized for uptake of low density lipoproteins (27). However, such a mode is less likely for the formation of dolichol-containing vesicles, because of the labeling patterns observed in the *in vivo* experiments.

Dolichol in the supernatant is also associated with particles 20 nm in size. This particle contains various lipids and proteins, and one or several of these proteins may serve a carrier function in dolichol transport. It cannot be ruled out that the large size of these dolichol particles is the result of secondary aggregation of subunits that could occur during the isolation procedure. However, these particles exhibit chromatographic properties, densities, and compositions, which makes these particles clearly distinct. A transport function of these particles is indicated by the observed labeling patterns, as an increase in radioactivity in these particles occurs when labeling in the microsomes is lost.

When hepatocytes were incubated with dolichol-containing liposomes, dolichol appeared preferentially in the cytoplasm, and the properties of these particles were similar to those that were recovered from rat liver after mevalonate labeling *in vivo*. The close similarity of the middle-layer particles in the *in vitro* and *in vivo* experiments was demonstrated by assessing density, particle size, electron microscopic appearance, and composition. However, *in vivo* labeling occurred at a higher rate in the top-layer vesicles than in the middle-layer supernatant. These differences are likely to reflect the different processes that are involved. One is the transfer of liposomal, labeled dolichol and the other is the *de novo* dolichol synthesis. Dolichol in the cytoplasmic form was transferred to mitochondria and microsomes upon *in vitro* incubation. It appears possible that dolichol is transferred from the site of synthesis *via* the cytoplasm to its final site of cellular use. This type of transport would be reminiscent of that described for phospholipids, the latter being *de novo* synthesized in the endoplasmic reticulum and distributed then through the cytoplasm to various intracellular membranes. Cytoplasmic transport of dolichol is consistent with the model developed by van Dessel *et al.* (28) based on binding studies.

Most dolichol in lysosomes is present in nonmembranous form, together with other lipids and without association to proteins. Labeling studies had previously established that after synthesis in the ER, dolichol is transported to the lysosomes (29). There are several routes for this transport process to occur. One possibility is transport in the ER lumen to the Golgi system, followed by translocation to the newly synthesized primary lysosomes, a route resembling the pathway described for lysosomal enzymes (30). Puromycin treatment inhibited protein synthesis completely without inhibiting dolichol transport, indicating lack of involvement of a luminal carrier protein. This type of lipid transport is not unexpected, because there is evidence that lipoproteins are first assembled in the Golgi system (31). Since primary lysosomes are the product of "exocytosis" of Golgi membranes, a transfer of dolichol in membrane-bound form is also possible. However, the predominantly free occurrence of this lipid in the lysosomal lumen argues against this type of transfer. The transfer of dolichol between ER and lysosomes could also involve a cytoplasmic route, because the particles in the middle-layer exhibited an intermediate labeling pattern.

Several explanations are possible for the presence of free dolichol in the lysosomal lumen. Consistent with their major function, lysosomes may be involved in the modification or breakdown of dolichol. Accumulation in the lumen could also be a step towards a storage process, which could be of a temporary nature. Not unlike cholesterol, newly synthesized dolichol also may be translocated to the bile (32). Some of the dolichol in the lysosomes may originate from the blood by endocytosis. However, this can only account for a minor portion of the total lysosomal dolichol. Finally, one cannot exclude the possibility that there are several dolichol pools in the cell of which the lysosomal pool represents a separate entity.

The extensive transport of dolichol within the cell appears to necessitate the presence of a nonmembranous form at various locations. The lipid is transported to the blood and also to the bile (33,34). In peroxisomes, local synthesis of dolichol is known to occur, and a rapid decay after *in vivo* labeling indicates that rapid transport from this pool takes place (35). In analogy to the enzymes catalyzing its biosynthesis, dolichol may be located in the lumen of the peroxisomes, as it is in lysosomes. The large amount of dolichol in endocrine human tissues suggests nonmembranous storage at this site.

Luminal transport processes may not only take place for dolichol, but also for its breakdown products. Dolichol metabolites have been suggested to be present in bile and at other locations (34). It is possible that these metabolites are simply breakdown products. Alternatively, however, they may represent active substances, including various hormones modulating function. The high turnover of dolichol in the liver, together with the lack of specific and identified end-products, would point in this direction.

Compartmental Study of Rat Renal Phospholipid Metabolism

Norma Sterin-Speziale*, Veronica L. Kahane, Clara Patricia Setton, Maria del Carmen Fernandez and Emir H. Speziale

Departamento de Química Biológica, Química Biológica Patologica, Facultad de Farmacia y Bioquimica, Universidad de Buenos Aires, 1113 Buenos Aires, Argentina

Phospholipid content and metabolism were studied in rat renal papillary, medullary and cortical slices. The highest concentration of phospholipids was found in cortex and the lowest in papilla samples (ratio cortex/medulla, 1.3; cortex/papilla, 3.7). The profile of the various phospholipids was different depending on the zone. The most important difference was the relative concentrations of sphingomyelin (Cer*P*Cho) and phosphatidylinositol (PtdIns) with ratios for PtdIns/Cer*P*Cho of 5.0, 3.3 and 2.5 in papilla, medulla, and cortex, respectively. In the three zones, PtdIns showed the highest specific activity for [2-^{14}C]glycerol and [1-^{14}C]arachidonic acid incorporation. By contrast, a higher amount of [1-^{14}C]palmitic acid was incorporated into phosphatidylcholine than into any other phospholipid. The various radioactive precursors were only poorly incorporated into phosphatidylethanolamine. No radioactivity was associated with phosphatidylserine. The papilla possesses the most active phospholipid metabolism of all the pathways studied.
Lipids 27, 10-14 (1992).

The kidney can be divided into three zones, the papilla, the medulla and the cortex, each having different functions. The zones are composed of various segments of nephron. The cellular composition of nephron has been established by the Renal Commission of the Union of Physiological Sciences (1).

The involvement of lipids in cell membrane structure and function has been well accepted (2). In the kidney, phospholipids comprise more than half of the total lipid pool (3,4).

There is substantial evidence that specific phospholipids can modulate enzyme activities (5,6). The relative distribution and composition of phospholipids in different cellular membranes also influence membrane fluidity (7,8); therefore, phospholipids would be expected to be involved in the regulation of kidney function.

The purpose of our study was to determine whether there are differences in phospholipid metabolism in the three zones of rat kidney. Specifically, we examined endogenous phospholipid contents and profiles, phospholipid *de novo* synthesis, and phospholipid fatty acid turnover in rat renal papilla, medulla and cortex.

MATERIALS AND METHODS

[1-^{14}C]Arachidonic acid (spec. act., 52.8 mCi/mmol), [2-^{14}C]glycerol (spec. act., 14.1 mCi/mmol) and [1-^{14}C]-palmitic acid (spec. act., 53.0 mCi/mmol) were obtained from New England Nuclear (Boston, MA). Silica Gel G plates (0.25 mm thick) and Fiske-Subbarow reagent were purchased from Sigma Chemical Co. (St. Louis, MO). X-Ray film for autoradiography was obtained from Eastman Kodak Co. (Rochester, NY).

Preparation of tissue slices. After decapitation of male Wistar rats (250-280 g), both kidneys were removed and maintained in ice-cold Krebs solution. Each kidney was cut in half through the pelvis along its longitudinal axis, and the papilla (inner medulla), medulla (outer medulla) and cortex were isolated by scissor and scalpel dissection. The renal papilla, medulla and cortex were sliced (*ca.* 0.5 mm thick) using a Stadie-Riggs microtome. The tissue slices were collected in Krebs Ringer bicarbonate buffer containing 5.5 mM glucose. The medium was gassed with 95% O_2/5% CO_2.

Incorporation of radioactive precursors. For each experiment, 5 mg of tissue slices were collected in 0.5 mL of Krebs Ringer bicarbonate buffer containing 5.5 mM glucose. The medium was gassed with 95% O_2/5% CO_2.

Samples were incubated at 37°C with 0.12 μCi of [1-^{14}C]arachidonic acid, 0.12 μCi of [1-^{14}C]glycerol, or 0.12 μCi of [1-^{14}C]palmitic acid in a metabolic shaking bath under an atmosphere of 95% O_2/5% CO_2 for different periods of time. Time course experiments were performed, but the results in the Figures correspond to the time of the steady-state equilibrium (60 min for arachidonic and palmitic acid, 90 min for glycerol).

Extraction and separation of lipids. Incubations were stopped on ice, and samples were washed three times by centrifugation in an ice-cold incubation medium. After the addition of four parts of chloroform/methanol (1:2, v/v) (9), samples were homogenized in glass tubes with a Teflon pestle at 3000-5000 rpm. Phases were separated by adding one part of chloroform and one part of water (10).

The lower chloroform phase was removed. The inorganic phase was washed twice with chloroform, and the organic phases were pooled and dried under a stream of nitrogen at 25°C. This extraction procedure ensures 80-85% recovery of lipids. The extracts were redissolved in chloroform and applied onto precoated thin-layer plates (0.25 mm thick). Lipids were separated by one-dimensional, two-solvent system thin-layer chromatography. The first solvent system used was a mixture of chloroform/methanol/acetic acid/water (40:10:10:1, by vol). The plates were dried and developed to a level 0.6 cm below the first solvent front in a solvent system consisting of chloroform/methanol/acetic acid/water (120:46:19:3, by vol). The R_f values in this system were 0.20, 0.30, 0.47, 0.55 and 0.70 for sphingomyelin (Cer*P*Cho), phosphatidylcholine (PtdCho), phosphatidylinositol (PtdIns), phosphatidylserine (PtdSer) and phosphatidylethanolamine (PtdEtn), respectively; the free fatty acids migrated in the solvent front (11). Lipid fractions were detected with I_2 vapor or by autoradiography. Zones of the thin-layer chromatographic plates corresponding to the various phospholipid fractions were

Abbreviations: AA, arachidonic acid; C, cortex; Cer*P*Cho, sphingomyelin; Gro, glycerol; M, medulla; P, papilla; PL, phospholipid; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine.

scraped off and added to 6.0 mL of toluene/omnifluor (0.4%). Phospholipids were quantified in a liquid scintillation counter. Counting efficiency for ^{14}C was 75%.

Endogenous phospholipid determination. For the quantitation of the phospholipids, specific areas of the plates were scraped off and digested with 70% perchloric acid in the presence of ammonium molybdate (0.5%). The resulting inorganic phosphate was assayed with Fiske-Subbarow reagent (12). Recovery of added PtdCho before extraction was 85%.

All results were compared by Student's *t*-test, differences were considered statistically significant when p values were less than 0.05.

RESULTS

Phospholipid content of rat renal papilla, medulla and cortex. Different amounts of endogenous PL were found in the three zones of the kidney (Table 1). The total phospholipid content (expressed as nmol/mg tissue wet weight) was 5.6, 15.8 and 20.7 in papilla, medulla and cortex, respectively. No changes in these values were observed after a 90 min incubation at 37°C. The profiles of the various phospholipids were different depending on the zone studied. In the papilla (P), PtdCho and PtdEtn represented 46.4% and 26.5%, respectively, of total PL. The percentages of PtdIns and PtdSer were both 8.8, while sphingomyelin constituted 9.1%. In the medulla (M), the percentages of the different PL classes were: PtdCho, 37.8; PtdEtn, 39.4; PtdSer, 7.4; PtdIns, 3.9; and Cer*P*Cho, 12.2. In the cortex, PtdCho represented 41.4%; PtdEtn, 32.5%; PtdSer, 5.8%; PtdIns, 3.6%; and Cer*P*Cho, 16.5%.

Incorporation of [2-^{14}C]glycerol in papillary, medullary and cortical phospholipids. The incorporation of [2-^{14}C]-glycerol ([2-^{14}C]Gro) into the kidney phospholipids after 90 min of incubation is shown in Figure 1. The insertions in the Figures show specific activities as cpm/nmol PL. In each zone studied, the highest incorporation (cpm/mg tissue wet weight) was found in PtdCho, followed by PtdIns, and the lowest value was observed in PtdEtn. No radioactivity was associated with PtdSer.

When the results are expressed as specific activity (cpm/nmol PL), PtdIns showed the highest incorporation. The ratio of PtdIns/PtdCho increased gradually from papilla to cortex (1.6, 4.5 and 9.3 for P, M and C, respectively).

The radioactivity incorporated into PtdEtn was lower than that incorporated into PtdIns in the three zones and, when the results are expressed as specific activities, the differences are exacerbated. No radioactivity had been found in PtdSer, indicating that this phospholipid must

TABLE 1

Phospholipid Content of Rat Renal Papillary, Medullary and Cortical Slices[a]

PL	Papilla	Medulla	Cortex
PtdCho	2.60 ± 0.32	5.96 ± 0.67[b]	8.58 ± 1.00[b]
PtdEtn	1.49 ± 0.21	6.24 ± 0.94[b]	6.73 ± 0.95[b]
PtdSer	0.49 ± 0.10	1.18 ± 0.09[b]	1.19 ± 0.10[b]
PtdIns	0.49 ± 0.09	0.62 ± 0.11	0.75 ± 0.09[b]
Cer*P*Cho	0.50 ± 0.07	1.78 ± 0.19[b]	3.42 ± 0.45[b]
Phospholipid content after 90 min incubation (37°C)			
PtdCho	2.63 ± 0.29	5.66 ± 0.71[b]	8.43 ± 1.10[b]
PtdEtn	1.39 ± 0.26	6.11 ± 1.00[b]	6.75 ± 0.98[b]
PtdSer	0.51 ± 0.09	1.15 ± 0.10[b]	1.21 ± 0.11[b]

Cer*P*Cho	0.48 ± 0.08	1.79 ± 0.18[b]	3.40 ± 0.50[b]

[a]Tissue slices were homogenized and lipids were extracted and separated by thin-layer chromatography. Results are means ± SE; for each value n = 5. Data are expressed in nmol/mg of tissue wet weight.

[b]Significantly different ($p<0.05$) from that of papilla.

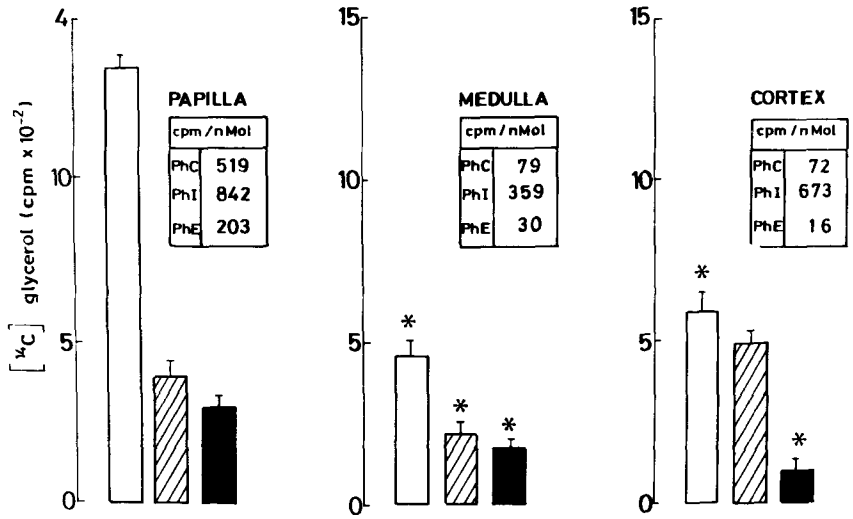

FIG. 1. Incorporation of [2-^{14}C]glycerol into phospholipids of rat renal papilla, medulla and cortex. Tissue slices were incubated for 90 min at 37°C in the presence of 0.12 μCi of [2-^{14}C]Gro. Phospholipids were extracted and separated as described in Materials and Methods. Each bar represents the means ± SE of five experiments (cpm/mg tissue wet weight). PtdCho, white bar; PtdIns, hatched bar; and PtdEtn, black bar. *, Significantly different ($p<0.05$) from the same phospholipid in papilla.

come from an exchange process, possibly derived from plasma phospholipids.

Incorporation of [^{14}C]fatty acids into rat renal papillary, medullary and cortical phospholipids. [1-^{14}C]-Palmitic acid ([1-^{14}C]16:0) can be incorporated into PL by *de novo* synthesis or by the deacylation-reacylation cycle. This saturated fatty acid was incorporated into position 1 of glycerol. By contrast, arachidonic acid (AA) is an essential polyunsaturated fatty acid that is incorporated into PL only during phospholipid remodelling that occurs *via* deacylation-reacylation.

Figure 2 shows the incorporation of [1-^{14}C]16:0 at 60 min of incubation. Most of the radioactivity was incorporated into PtdCho in the three zones. In papilla and medulla, almost ten times more radioactivity was found in PtdCho than in PtdEtn. In cortex, the amount of radioactivity in PtdEtn was 1/5 that of PtdCho.

[1-^{14}C]16:0 Acyl incorporation into PtdIns was very low and showed the lowest levels of radioactivity. In terms of specific activity, PtdCho seemed to be the most active phospholipid, followed by PtdIns and then by PtdEtn. No radioactivity was associated with PtdSer.

The pattern of [1-^{14}C]AA incorporation (Fig. 3) was different from that of the saturated fatty acid.

Although more radioactivity was found in phosphatidylcholine than in PtdIns and PtdEtn, when the results are expressed as specific activity the value obtained for PtdCho was two (papilla) to three times (medulla and cortex) lower than that for PtdIns. [1-^{14}C]AA radioactivity associated with phosphatidylethanolamine was similar to that obtained in phosphatidylinositol in medulla and cortex, but the specific activities were ten (medulla) or more (cortex) times lower. In papilla, the incorporation of radioactive arachidonic acid into phosphatidylethanolamine was 1/2 that of phosphatidylinositol.

DISCUSSION

Table 1 shows that papillary, medullary and cortical phospholipids differ both in concentration and in distribution profiles. Papilla is the tissue that possesses the highest phosphatidylinositol and the lowest sphingomyelin levels. These two Pl are particularly important because of their functional implications. Thus, it has been reported that Cer*P*Cho inhibits both PtdCho breakdown brought about by the deacylating phospholipase A_2 (13) and the non-stimulated activity of phosphatidylinositol phosphodiesterase (14). For these reasons, it has been proposed that the enhanced content of Cer*P*Cho in the membrane bilayer tones down the action of cellular phospholipases (13). Phosphatidylinositol has been proposed as a link between hormone receptors and cellular response (15). In the kidney, PtdIns breakdown is brought about by a specific phosphodiesterase which precedes the arachidonic acid mobilization produced by bradykinin stimulation (16).

The relative amount of Cer*P*Cho and PtdIns in the membrane bilayer may regulate some aspects of its phospholipid metabolism as is discussed below.

The two main pathways in kidney phospholipid metabolism are *de novo* synthesis (17) and the deacylation-reacylation cycle (18). [2-^{14}C]Gro enters the phospholipid molecule only by *de novo* synthesis (19). Therefore, our results (Fig. 1) suggest that most *de novo* synthesis of active phospholipids occurs in the papilla. However, the activity of the glycerol kinase (the first enzyme in glycerol metabolism) is over ten times lower in papilla than in medulla and cortex (20,21). One possible explanation for this is that cortex and medulla are very efficient in using the glycerol phosphate formed to produce glucose and lactate, respectively. By contrast, glycerol does not serve as precursor of glucose or lactate in papilla because the

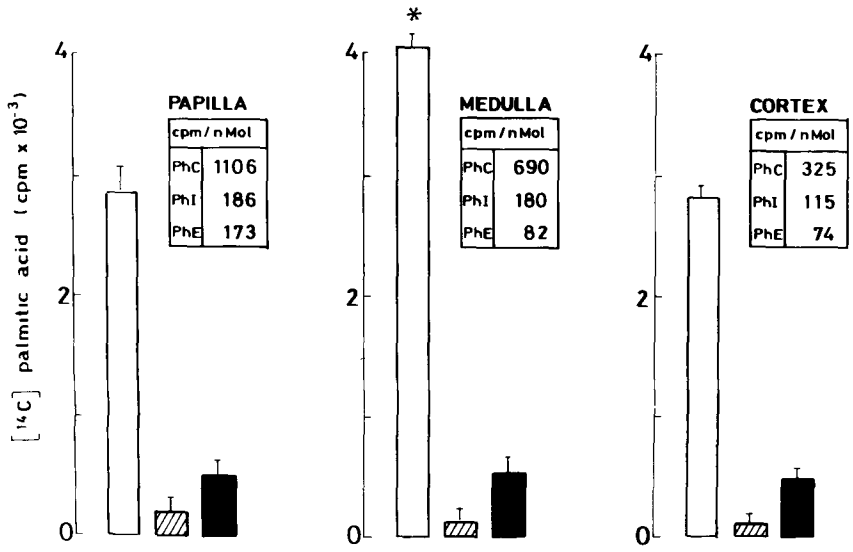

FIG. 2. Incorporation of [1-^{14}C]palmitic acid into phospholipids of rat renal papilla, medulla and cortex. Tissue slices were incubated for 60 min at 37°C in the presence of 0.12 μCi of [2-^{14}C]16:0. Phospholipids were extracted and separated as described in Materials and Methods. Each bar represents the means ± SE of five experiments (cpm/mg tissue wet weight). PtdCho, white bar; PtdIns, hatched bar; and PtdEtn, black bar. *, Significantly different ($p<0.05$) from the same phospholipid in papilla.

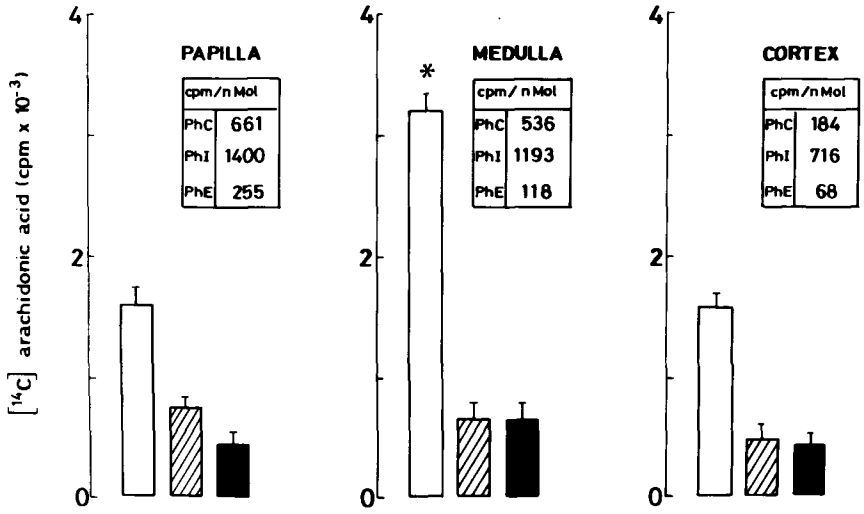

FIG. 3. Incorporation of [1-^{14}C]arachidonic acid into phospholipids of rat renal papilla, medulla and cortex. Tissue slices were incubated for 60 min at 37°C in the presence of 0.12 μCi of [1-^{14}C]AA. Phospholipids were extracted and separated as described in Materials and Methods. Each bar represents the means ± SE of five experiments (cpm/mg tissue wet weight). PtdCho, white bar; PtdIns, hatched bar; and PtdEtn, black bar. *, Significantly different ($p<0.05$) from the same phospholipid in papilla.

gluconeogenic enzymes and the pyruvate kinase necessary to form glucose and lactate, respectively, are not present (21). In consequence, glycerol phosphate may be more available for phospholipid biosynthesis. Results from our experiments with [1-^{14}C]palmitic and [1-^{14}C]arachidonic acid (Figs. 2 and 3) suggest that the incorporation profile for the two fatty acids is different. While phosphatidylcholine is the most active phospholipid for palmitic acid incorporation, phosphatidylinositol shows the highest specific activity for arachidonic acid in the three zones. The highest value described in the insertions in Figure 3 for all phospholipids correspond to papilla. Incorporation of arachidonic acid occurs by deacylation-reacylation. The first step in the cycle is the release of the fatty acid in position two (deacylation) by an endogenous phospholipase A_2. The efficient incorporation of arachidonic acid may, in part, be due to the low level of papillary sphingomyelin, which enhances lipase cleavage and, as a consequence, provides more substrate for the incorporation of fatty acid (reacylation).

The incubation time used in experiments with radioactive precursors corresponds to the steady-state period of the most metabolically active pools and does not include the total phospholipid pool. Still these results are relevant because this active pool may be easy to modify and may be the substrate for the changes induced by endogenous hormones and neurotransmitters that regulate cellular function.

The results clearly indicate that the zones of the kidney differ in phospholipid properties. The papilla, where the terminal segment of the nephron is located, is involved in the final adjustments of urine volume and composition. It is the zone where less endogenous phospholipid is present, but it is also where its turnover is more active. Phosphatidylinositol is the most active phospholipid in the three zones studied except for its ability to incorporate palmitic acid.

Evidence has been presented that many of the cells' physiological activities are strongly influenced by membrane phospholipid composition. The observation that induction of changes in lipid composition can impair membrane function is evidence of this interrelationship (22).

In conclusion, we found that non-stimulated cells with different phospholipid compositions also differ in some aspects of phospholipid metabolism. We suggest that such differences in lipid profile are responsible, at least in part, for the metabolic dissimilarities.

Lipids of Selected Molds Grown for Production of n-3 and n-6 Polyunsaturated Fatty Acids

Andrew Kendrick and **Colin Ratledge***
Department of Applied Biology, University of Hull, Hull, HU6 7RX, United Kingdom

The lipid classes and component fatty acids of seven fungi were examined. Three marine fungi, *Thraustochytrium aureum, Thraustochytrium roseum* and *Schizochytrium aggregatum* (grown at 30, 25 and 25°C, respectively), produced less than 10% lipid but contained docosahexaenoic acid (DHA) up to 30% and eicosapentaenoic acid (EPA) up to 11% of the total fatty acids. *Mortierella alpina-peyron* produced 38% oil containing solely n-6 polyunsaturated fatty acids (PUFA) with arachidonic acid (AA) at 11% of the total fatty acids. *Conidiobolus nanodes* and *Entomorphthora exitalis* produced 25% oil and contained both n-3 and n-6 PUFA, with AA at 16% and 18%, respectively. *Saprolegnia parasitica* produced 10% oil and contained AA and EPA, respectively, at 19% and 18%. The triacylglycerol fraction always represented the major component at between 44% and 68% of the total lipid. Each fungus, except *T. aureum*, had the greatest degree of fatty acid unsaturation in the phospholipid fraction. The triacylglycerol fraction of *T. aureum* was the most unsaturated with DHA representing 29% (w/w) of all fatty acids present. The presence of the enzyme ATP:citrate lyase correlated with the ability of molds to accumulate more than 10% (w/w) lipid when the fungi were grown in nitrogen-limiting media. In those molds that failed to accumulate more than 10% lipid, the enzyme was absent.
***Lipids 27,* 15–20 (1992).**

In recent years, nutritional studies have shown the potential benefits of including long-chain polyunsaturated fatty acids (PUFA) in the diet. Evening primrose oil, which contains about 8% (w/w) gamma-linolenic acid (18:3n-6) has long been recommended for the treatment of a wide variety of ailments (1). Other recent work has concentrated on PUFA of the n-3 series, mainly eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) which may be beneficial in the prevention of coronary heart disease (2).

Certain fungi, referred to as oleaginous species, have the ability to accumulate up to 85% (w/w) lipid as a storage compound of the biomass (3). This accumulation is triggered by exhaustion of a growth nutrient, other than carbon, thus preventing cell proliferation but still allowing conversion of substrate into lipid (3). Such oleaginous fungi, which produce PUFA of both n-6 and n-3 species, could provide an economically viable source of PUFA providing that most of the PUFA occur in the triacylglycerol fraction of lipids which would then be extractable as a plant-like oil rather than a complex array of lipid classes.

*To whom correspondence should be addressed.

Abbreviations: AA, arachidonic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FAME, fatty acid methyl esters; GLC, gas-liquid chromatography; PUFA, polyunsaturated fatty acids; TAG, triacylglycerols; TLC, thin-layer chromatography; UV, ultraviolet.

The organisms used in this study were carefully selected as being potentially useful for the production of PUFA, though it was not known whether these organisms were oleaginous. The marine fungi, *Thraustochytrium aureum, Thraustochytrium roseum* and *Schizochytrium aggregatum*, were examined because of their low natural growth temperature which should lead to a high PUFA content of the cellular lipids (4) as had been reported (5). No report has appeared to indicate how much lipid can be maximally accumulated by these species. *Saprolegnia parasitica* was examined as it has been reported to produce up to 10% (w/w) of total fatty acids as arachidonic acid and 20% (w/w) as eicosapentaenoic acid (6) in its extracted lipids.

Although a number of species of *Mortierella* have been recently examined by Japanese groups for PUFA formation (7–9), these species have all belonged to the sub-genus, *Mortierella mortierella*, with no attention being given to any representative of the other sub-genus, *Mortierella micromucor*. Accordingly, we have included in our study a representative of the latter group, *Mortierella alpina-peyron*, to see whether it is similar to members of the other sub-genus in the potential formation of arachidonic and eicosapentaenoic acids.

Fatty acids of the *Conidiobolus* and *Entomorphthora* were originally examined by Tyrrell (10–12) with the view to using this data as an aid for fungal classification. Both classes of fungi were reported to contain PUFA and were hence included in this study but their potential as oleaginous species has not before been fully explored.

MATERIALS AND METHODS

Micro-organisms and growth. The fungal strains examined were *Conidiobolus nanodes* (IMI 92299), *Thraustochytrium aureum* (ATCC 34304), *T. roseum* (ATCC 28210), *Schizochytrium aggregatum* (ATCC 28209), *Saprolegnia parasitica* (ATCC 22284), *Entomorphthora exitalis* (NRRL 3742) and *Mortierella alpina-peyron* (CBS 696.70). Fungi were cultivated using vegetative inocula in vortex-aerated, 1-L bottles with 800 mL semi-defined medium which contained (g/L) glucose, 30; ammonium tartrate, 3.3; KH_2PO_4, 7.0; Na_2HPO_4, 2; $MgSO_4 \cdot 7H_2O$, 1.5; yeast extract, 1.5; $CaCl_2 \cdot 2H_2O$, 0.1; $FeCl_3 \cdot 6H_2O$, 0.008; $ZnSO_4 \cdot 7H_2O$, 0.001; $CuSO_4 \cdot 5H_2O$, 0.0001; $Co(NO_3)_2 \cdot 6H_2O$, 0.0001; $MnSO_4 \cdot 5H_2O$, 0.001; with pH adjusted to 5.5. The marine fungi *T. aureum, T. roseum* and *Schizo. aggregatum* were grown in the same medium supplemented with 27 g NaCl/L and $MgSO_4 \cdot 7H_2O$ increased to 7 g/L. *T. aureum, C. nanodes,* and *E. exitalis* were grown at 30°C; *M. alpina-peyron* was grown at 28°C; *T. roseum* and *Schizo. aggregatum* at 25°C, and *Sapro. parasitica* at 24°C.

Lipid content determination. The lipid content of the fungi was determined after 72-hr growth. The mycelial fungi and non-mycelial fungi were harvested by vacuum filtration and by centrifugation (10,000 × *g* for 10 min at 4°C). Harvested fungi were washed once with distilled

water (100 mL), frozen to −20°C and then freeze-dried for 18 hr. The mycelia were ground into a fine powder and lipids were extracted into 100 mL chloroform/methanol (2:1, v/v) for 15 hr at room temperature (13). The lipid extract was washed with distilled water (3 × 20 mL) and dried over anhydrous $MgSO_4$; the solvent was removed by evaporation.

Fractionation of extracted lipid. A known weight of extracted lipid (approx. 100 mg) was dissolved in chloroform (1 mL) and fractionated by using a column (25 × 100 mm) of silicic acid (activated by heating at 110°C overnight) (14). Successive applications of 1,1,1-trichloroethane (100 mL), acetone (100 mL) and methanol (50 mL) produced fractions containing neutral lipids (triacylglycerols), sphingolipids plus glycolipids, and polar lipids (phospholipids), respectively. The weight of each fraction was determined. Recoveries were usually between 85 and 90% (w/w).

Hydrogenation of lipid extract. Lipid (100 mg) from *T. aureum* was dissolved in chloroform/methanol (1:1, v/v), mixed with 0.25 g 5% (w/w) Pd/charcoal catalyst (BDH, Poole, Dorset, United Kingdom) vigorously stirred in an atmosphere of hydrogen at atmospheric pressure for 2 hr. The catalyst was then removed by filtration through Celite filter aid (BDH). Excess solvent was removed by rotary evaporation, and the sample was treated as before.

Thin-layer chromatography of lipid fractions eluted from sililic acid column. Lipid fractions were separated by thin-layer chromatography (TLC) using Silica Gel G plates (0.25 mm thick) developed with petroleum ether (b.p. 60–80°C)/diethyl ether/acetic acid (85:15:1, v/v/v). Plates were exposed to iodine vapor to reveal the neutral lipids, or were sprayed with 2′,7′-dichlorofluorescein (0.2% w/v in ethanol) and viewed under ultraviolet (UV) light for the polar lipid fraction, or were sprayed with α-naphthol or Dragendorff reagent for the sphingolipid plus glycolipid fraction. Identifications were made by reference to authentic standards.

Detection of glycolipids using α-naphthol (15). Following development and drying of the chromatogram, the TLC plate was sprayed with α-naphthol solution (0.5% w/v in methanol/water, 1:1 v/v). After drying, the plate was sprayed lightly with sulfuric acid (95% v/v) and heated at 120°C for 5 min after which time glycolipids turned blue.

Detection of choline-containing lipids using the Dragendorff reagent (16). Four parts of solution 1 (2.7% bismuth nitrate in 20%, v/v, acetic acid) were mixed with 1 part of solution 2 (40% w/v potassium iodide), and the resulting solution was diluted with 14 parts of water. The developed and dried chromatogram was sprayed with the Dragendorff reagent and choline containing lipids stained orange/red.

Further fractionation of phospholipid fraction obtained from E. exitalis *and* C. nanodes *(14).* Phospholipids were analyzed by TLC on Silica Gel G plates (0.25 mm thick) developed with chloroform/methanol/acetic acid/water (65:43:3:1, by vol), visualized with 2′7′-dichlorofluorescein, and viewed under UV light.

Fatty acid analysis. Fractionated lipid extracts were transesterified with sodium methoxide (17), and the fatty acid methyl esters (FAME) were analyzed by gas-liquid chromatography using a 2 m × 4 mm column packed with diethyleneglycol succinate (10% w/w on Celite); nitrogen was used as the carrier gas (35 mL/min). FAME were identified by reference to authentic standards and a graph of chain length against retention time (for each degree of unsaturation).

Preparation of cell-free extracts. Cultures were grown for 72 hr and harvested. The mycelia were resuspended in extraction buffer which contained 30 mM Tris/HCl pH 7.8, 2 mM dithiothreitol, 2 mM benzamidine/HCl, 1 mM EDTA, and 20% (v/v) glycerol. Cells were disrupted by two passages through a French pressure cell. The supernatant solution was centrifuged at 48000 × *g* for 20 min and then filtered through Whatman no. 1 paper to remove lipid material. The filtrate was re-centrifuged (100,000 × *g* for 1 hr) and again refiltered to remove final traces of lipid. This filtrate was termed "the cell-free extract." The concentration of the protein in the cell-free extract was determined by the method of Bradford (18).

ATP:citrate lyase (E.C. 4.1.3.8) assay (19). The following were added to a 1 mL cuvette (containing up to 0.42 mL cell-free extract) to produce the final concentrations indicated: 10 mM Tris/HCl pH 8.2; 10 mM $MgCl_2$; 20 mM potassium citrate; 0.3 mg CoA/mL; 10 mM dithiothreitol; 0.125 mg NADH/mL; 500 units malic dehydrogenase/mL. The reaction was initiated by adding 10 mM ATP. The mixture was incubated at 20°C and the reaction was followed at 340 nm.

RESULTS AND DISCUSSION

Growth and lipid accumulation of fungi. Two of the marine fungi, *T. roseum* and *Schizo. aggregatum,* grew only sparingly in the glucose/ammonium tartrate medium. The cells exhibited a non-mycelial, yeast-like morphology. Their respective biomasses were 1.2 and 1.4 g dry weight/L and they produced very little lipid (0.5% and 1.7% w/w, respectively). Attempts to improve these results by including Bacto-peptone, malt extract or glutamate, or by varying the salinity of the growth medium, did not increase the amounts of lipid formed. The reason for the very low amount of lipid accumulated by the fungi *T. roseum* and *Schizo. aggregatum* is not known but may well be connected with the poor growth of the organisms.

By contrast, the third marine fungus, *T. aureum,* grew (to 4 g dry weight/L) readily in the same basal medium (see Materials and Methods) used for the other two marine organisms. The fungus grew as a pink/purple non-mycelial, yeast-like culture but never exceeded a content of 10% (w/w) lipid.

All other fungi grew readily as dispersed mycelial cultures. The growth yields and lipid contents are given in Table 1.

The efficiency of lipid extraction was tested by refluxing the extracted mycelial residues of *C. nanodes* and *E. exitalis* with chloroform/methanol (2:1, v/v) for 1 hr. The results showed that the initial chloroform/methanol treatment extracted 94% (w/w) of total cellular lipids.

Fractionation and analysis of fungal lipid extracts. The extracted lipids were fractionated as detailed in Materials and Methods. Analysis of each fraction by TLC showed that the neutral lipid fraction (eluted with 1,1,1-trichloroethane) contained predominantly triacylglycerols and small amounts (less than 10%) of diacylglycerols and monoacylglycerols. Triacylglycerols (TAG) represented 68 to 44% (w/w) of total extracted lipid from both oleaginous and non-oleaginous fungi. These results are also summarized in Table 1.

TABLE 1

Growth and Lipid Accumulation by Fungi[a]

Fungus	Biomass (g dry weight/L)	Lipid content (%, w/w)	Percentage of each lipid fraction present (%,w/w)		
			N	S + G	P

M. alpina-peyron	3.2	37.7	52.6	18.4	28.9

[a]Abbreviations used: N, neutral lipids; S + G, sphingolipids plus glycolipids; P, phospholipids.

The polar lipid fractions (eluted with methanol) from each organism contained only phospholipids. More detailed analysis of the fraction from the lipid extract of *C. nanodes* showed phosphatidylcholine, phosphatidylinositol and phosphatidylethanolamine to be present in approximately equal proportions. Phosphatidylcholine accounted for approx. 80% of the total phospholipids in *E. exitalis*.

TLC of the sphingolipid plus glycolipid fraction obtained from *E. exitalis* and *C. nanodes* revealed, respectively, the presence of four and five components which were not identified further beyond establishing that two or three were sphingolipids and two contained a sugar moiety.

Fatty acid analysis of lipid extracts. The seven fungi examined produced an exceptionally large number of fatty acids, many of which contained two or more double bonds (*i.e.*, are classified as PUFA). These results are summarized in Tables 2–4. However, although a large number of fatty acids were found in every lipid fraction, one PUFA (two in the case of *Sapro. parasitica*) predominated in each fungal lipid.

C. nanodes and *E. exitalis* produced both n-3 and n-6 PUFA but the n-6 PUFA were in greater abundance. The

predominating n-6 PUFA produced was arachidonic acid (20:4n-6), which in the phospholipids of these fungi represented 15% and 18%, respectively, of the fatty acids in this lipid class.

The marine fungus *T. aureum* produced only n-3 PUFA and docosahexanenoic acid (DHA) represented 30% of total fatty acids in TAG.

M. alpina-peyron produced n-6 PUFA only. Similar to the lipid from *C. nanodes* and *E. exitalis,* this lipid contained arachidonic acid (AA) as the principal PUFA; AA represented 11% (w/w) of the fatty acyl groups in the phospholipids.

The two classes of PUFA discussed above are derived from the two isomers of linolenic acid. The alpha isomer (18:3n-3) is the fatty acid from which the n-3 PUFA are directly synthesized. The gamma isomer (18:3n-6) is similarly the parent fatty acid of the n-6 PUFA series. The relative proportion of the two classes of PUFA present in each fungus is reflected in the ratios of the isomers of linolenic acid.

The exception to the above pattern of PUFA is *Saprolegnia parasitica* which contained only one n-3 PUFA eicosapentaenoic acid, though many n-6 PUFA were present as well. These included gamma-linolenic acid, dihomogamma-linolenic acid and arachidonic acid. This finding of only one n-3 PUFA amidst many n-6 PUFA supports the proposal of Gellerman and Schlenk (6) who demonstrated the conversion of AA into eicosapentaenoic acid (EPA) *via* a Δ17 desaturase in *Saprolegnia parasitica.* As yet, this is the only known point of conversion between the two classes of a PUFA, and occurred in *M. alpina* when grown at low temperatures (7). Interestingly *Sapro. parasitica* was the only fungus examined here that metabolized arachidonic acid further by elongation to 22:4n-6.

In all the fungi examined, except *T. aureum,* the phospholipid fraction contained the greatest proportion of PUFA. This was true for both classes of PUFA. Phospholipids are highly specialized membrane components which regulate membrane fluidity in response to high salinities, temperature variations, etc. In turn, this allows the range of complex membrane functions to continue. The high degree of unsaturation of the fatty acyl groups in the phospholipids may be a structural necessity of their function as membrane components. The desaturases in micro-organisms and all cells so far examined have been membrane-bound (20–22), and strong evidence suggests that fatty acids are desaturated when attached to phospholipids rather than as the thiol ester of CoA (20). Once the necessary desaturation has occurred, acyl transferase reactions then facilitate distribution of the newly synthesized PUFA to other cellular lipids.

A high concentration of PUFA within the polar lipid fraction was also evident in the marine fungus *T. aureum.* DHA made up 17% (w/w) of total fatty acids and 30% of TAG. The high concentration of DHA in TAG of this organism may make it a potentially useful source for DHA production. However changes in growth medium and growth conditions have, so far, failed to increase either the amount of total lipid produced or the content of DHA (Kendrick, A., unpublished work).

The long-chain PUFA, 24:2 and 26:2, found in the marine fungi were tentatively identified from their initial retention times in gas-liquid chromatography (GLC) and also those of the saturated fatty acids (24:0 and 26:0) obtained by hydrogenation of the lipids extracted from *T. aureum.* (The number of double bonds in the original fatty acids was calculated from a graph of chain length against log retention time.) No work as to the location of the double bonds within these molecules has been undertaken. The metabolic role of 24:2 and 26:2 is unclear though the occurrence of 24:2 in all three of the marine fungi examined here might suggest a role in halotolerance. No other C_{24} or C_{26} fatty acids were present in the marine fungi.

TABLE 5

Correlation of Lipid Accumulation in Molds with ATP:Citrate Lyase Activity

Fungus	Lipid content % (w/w)	ATP:citrate lyase activity (nmol/min/mg protein)
T. aureum	10.0 ± 1.9	0
T. roseum	0.5 ± 0.1	0
Schizo. aggregatum	1.7 ± 0.2	0
Sapro. parasitica	10.1 ± 0.8	0
C. nanodes	25.7 ± 0.5	19
E. exitalis	24.6 ± 0.5	11
M. alpina-peyron	37.7 ± 2.3	18

ATP:citrate lyase activity of fungi. Activity of the enzyme ATP:citrate lyase was detected in cell-free extracts prepared from the fungi *E. exitalis, C. nanodes* and *M. alpina-peyron* (Table 5). These three fungi can be termed oleaginous because they accumulated over 20% lipid (25%, 26% and 38% w/w lipid, respectively). No activity of the enzyme was found in any of the marine fungi or *Sapro. parasitica* (Table 5), a non-oleaginous species.

ATP:citrate lyase is associated with lipid accumulation in oleaginous yeasts (23). The present results concur with the hypothesis that when this activity is absent, lipid accumulation is likely to be low. The maximum lipid content attained by a fungus lacking this enzyme was 10% (w/w). Thus, fungi with ATP:citrate lyase activity should, theoretically, be metabolically capable of accumulating substantial amounts of lipid.

M. alpina-peyron, the organism which accumulated the greatest amount of cellular lipid (38% w/w), produced the smallest proportion of PUFA. Conversely, organisms which produced the largest amount of C_{20} and C_{22} PUFA, *Sapro. parasitica* and *T. aureum,* respectively, only accumulated low amounts of lipid and, by the absence of the enzyme ATP:citrate lyase, would appear constitutionally unable to achieve lipid accumulation beyond these amounts.

Any organism chosen for the commercial production of a given PUFA would ideally be both oleaginous and produce a triacylglycerol oil rich in the desired fatty acid. None of the fungi examined, however, fit these criteria. Prospects of increasing the oil contents (and thus the TAG content) of a mold must be confined to those with a propensity for oil accumulation as indicated by the presence of ATP:citrate lyase, the key enzyme for lipid accumulation (23).

[Received April 10, 1991, and in revised form September 5, 1991; Revision accepted September 30, 1991]

Note added in proof. After submission of this paper, L5986, two related publications (Bajpai, P., Bajpai, P.K. and Ward, O.P. (1991) *Appl. Microbiol. Biotechnol. 35,* 706-710; Bajpai, P.K., Bajpai, P., and Ward, O.P. (1991) *J. Am. Oil Chem. Soc. 68,* 509-514) have appeared reporting the production of docosahexaenoic acid (DHA) by *Thraustochytrium aureum* ATCC 34304 grown under different regimens. Maximum lipid contents of 20% (w/w) of biomass were recorded, with DHA in total lipid amounting to up to 50% of total fatty acids. Although these data represent slight improvements on the results reported here, the fungus continued to grow slowly reaching only 5 g of biomass/L after 144 hr. Thus our conclusions (see last paragraph) still hold good.

Linoleoyl-Enriched Triacylglycerol Species Increase in Maternal Liver During Late Pregnancy in the Rat

Zhen-Yu Chen, Jilin Yang, Chantale R. Menard and **Stephen C. Cunnane***
Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada M5S 1A8

In view of the previously reported changes in the fatty acid composition of maternal liver triacylglycerols in late pregnancy, changes in the composition of maternal liver triacylglycerol species were assessed in rats fed a semi-purified diet during pregnancy. Between day 18 and day 21 of pregnancy, total maternal liver triacylglycerols increased by 50%. Triacylglycerol species with a total acyl carbon number (C) of 50 or 60 (C50, C60) remained unchanged while C48 and C52–C58 were relatively increased. The individual triacylglycerol species containing one, two or three linoleoyl moieties were incompletely recovered using a polar high temperature gas-liquid chromatography (GLC) column. Nevertheless, at day 21 compared to day 18, the linoleoyl-containing species were relatively increased by 62–463%, while tripalmitin was decreased by 38%. Our data suggest that despite an adequate intake of linoleic acid (25 g/kg in the diet), maternal hepatic triacylglycerol content of linoleic acid decreased during mid-pregnancy but increased significantly toward term possibly in preparation for the transfer of linoleic acid to the neonate during lactation.
Lipids 27, 21-24 (1992).

Pregnancy involves significant metabolic adaptations by the mother to the developing conceptus. These metabolic adaptations include transfer from the mother of polyenoic acids especially arachidonic (20:4n-6) and docosahexaenoic (22:6n-3) acids essential for the structure and function of cellular membranes in the developing fetus (1,2). Many studies have addressed the importance of the changes in long-chain fatty acid composition and metabolism that occur during fetal and neonatal development with respect to neonatal brain and somatic development (3–8). However, it is still unknown where within the maternal organism the essential fatty acids (EFA) used by the developing fetus and neonate do originate. Also unknown are the relative contributions of maternal EFA pools, *e.g.*, phospholipids, triacylglycerols (TG) or free fatty acids, to the EFA acquired by the fetus.

There is evidence that the maternal hepatic triacylglycerol pool may be quantitatively important in supplying EFA to the developing fetus (8). Since linoleic acid (18:2n-6) has several important functions, including as energy substrate (9), main dietary precursor of 20:4n-6, and as structural component of membranes, we have extended our initial study of EFA changes during pregnancy (8) by examining the changes in composition of maternal liver TG species late in pregnancy when the fetus is developing rapidly. We hypothesized that, as previously shown in fasted rats (10), identification of the TG class(es) (monolinoleoyl, dilinoleoyl, trilinoleoyl glycerols) may provide insight into the functional role of 18:2n-6, whether structural or as an energy substrate, during late pregnancy.

MATERIALS AND METHODS

Second parity pregnant rats (Sprague-Dawley) were obtained from Charles River (St. Constant, Quebec, Canada) at the earliest day of pregnancy possible (day 8). To provide known and constant fatty acid intake, they were given a semi-purified diet and deionized distilled water from day 8 until day 18 or term (day 21). The period between day 18 and day 21 was studied because it is when most of the changes in 18:2n-6 occur in maternal hepatic TG and also because it is when most fetal growth occurs in the rat. This period is therefore of greatest interest with respect to possible changes in maternal liver TG species. Animals killed on day 8 and did not consume the diet fed during pregnancy; hence, data for day 8 serve only as a reference. The semi-purified diet was prepared according to American Institute of Nutrition standards (components from Teklad Test Diets, Madison, WI) and contained (g/kg): 605, corn starch; 200, casein; 100, cellulose; 50, soybean oil (51% linoleic acid, 18:2n-6, and 7% linolenic acid, 18:3n-3); 35, Teklad modified AIN-76 mineral mix; and 10, AIN-76 vitamin mix.

All sovents used for lipid analysis were glass-redistilled prior to use. Maternal livers were removed and washed in saline and, prior to lipid analysis, 500 mg aliquots were kept in chloroform containing 0.02% butylated hydroxytoluene (BHT) (Sigma, St. Louis, MO) at −20°C. The total lipids were extracted from liver samples using chloroform/methanol (2:1, v/v) containing a final concentration of 0.02% BHT. To quantitate the individual TG species, 1,2-distearoyl-3-palmitoyl-glycerol (SSP) (Sigma), which was found to be naturally undetectable, was added to an aliquot of each sample as an internal standard (10). Total liver TG was isolated by thin-layer chromatography (TLC) with the solvent system of hexane/diethyl ether/acetic acid (80:20:1, v/v/v). The TG band was recovered and eluted from the silica with 60 mL of hexane/diethyl ether (90:10, v/v). The TG species were analyzed using a Varian 3700 gas-liquid chromatograph (GLC) (Palo Alto, CA) equipped

Abbreviations for triacylglycerol species are as follows: LLL, trilinoleoyl glycerol; MLO, myristoyl linoleoyl oleoyl glycerol; MPO, myristoyl palmitoyl oleoyl glycerol; MSP, myristoyl stearoyl palmitoyl glycerol; OLL, dilinoleoyl oleoyl glycerol; OLO, dioleoyl linoleoyl glycerol; OOO, trioleoyl glycerol; PLL, dilinoleoyl palmitoyl glycerol; PLO, palmitoyl linoleoyl oleoyl glycerol; PLP, dipalmitoyl linoleoyl glycerol; PLPo, palmitoyl linoleoyl palmitoleoyl glycerol; POO, dioleoyl palmitoyl glycerol; PoOO, dioleoyl palmitoleoyl glycerol; POP, dipalmitoyl oleoyl glycerol; POPo, palmitoyl oleoyl palmitoleoyl glycerol; POS, palmitoyl oleoyl stearoyl glycerol; PPP, tripalmitoyl glycerol; PPoPo, dipalmitoleoyl palmitoyl glycerol; PPPo, dipalmitoyl palmitoleoyl glycerol; PSL, palmitoyl stearoyl linoleoyl glycerol; PSP, dipalmitoyl stearoyl glycerol; PSPo, palmitoyl palmitoleoyl stearoyl glycerol; SLL, dilinoleoyl stearoyl glycerol; SLO, stearoyl linoleoyl oleoyl glycerol, SOO, dioleoyl stearoyl glycerol; SSL, distearoyl linoleoyl glycerol; SSP; distearoyl palmitoyl glycerol. (The sequence of letters used does not imply a specific positional order.)

with a TG column (25 m × 0.25 mm) coated with 65% phenylmethyl silicone film (Quadrex, New Haven, CT). The operating temperature was increased at 2°C/min from 320–355°C. A movable cold on-column injector (J & W Scientific, Folsom, CA) was used to permit injection of the sample at room temperature followed by rapid vaporization of the entire sample at the initial oven temperature (320°C), thus avoiding sample discrimination between TG species of different molecular weights (10,11). Peak areas were integrated using a Hewlett-Packard 3390A integrator (Palo Alto, CA), and total TG were quantitated based on the amount of standard added. The data for C52 and C54 TG species is not corrected for partial recovery of these species (see Results).

An aliquot of the total TG was hydrogenated at 70°C in a small conical vial. The TG sample was dissolved in 300 μL of hexane and transferred to the hydrogenation vial followed by addition of 1 mg of 5% rhodium on alumina powder (Aldrich Chemical Co., Milwaukee, WI) as a catalyst. The TG sample was bubbled with hydrogen gas for 5 min. Hexane (200 μL/min) was added to compensate for loss of solvent by evaporation. After hydrogenation was complete (verified by GLC of fatty acid methyl esters; ref. 10), the hexane layer was saved for separation of TG species according to total carbon number as described above.

An aliquot of the total lipid extract was used to analyze the fatty acid composition of liver TG. After TLC separation, the TG band was recovered and the fatty acids were converted to the corresponding methyl esters using 14% boron trifluoride in methanol (Sigma). Fatty acid methyl esters were analyzed by GLC using a capillary column (Durabond 225, 30 m × 25 mm, i.d.) coated with 25 μm cyanopropylphenyl (J & W Scientific) in a Hewlett-Packard 5890A GLC (Palo Alto) with automated sample delivery and injection (Hewlett-Packard 7671A) and peak integration (Hewlett-Packard 3393 integrator). The column temperature was programmed from 150°C to 220°C in three stages with each run complete within 30 min (8).

All data are expressed as the mean ± SD. Statistical comparison of data for day 18 and 21 was by Student's t-test.

RESULTS

Data are shown for day 8 (start of study), 18 and 21 of pregnancy. Emphasis is on the changes during days 18 to 21 when dietary fatty acid composition was constant. Liver weight increased 11% between days 18 and 21 (ns). During the same period, total liver TG increased by 53% (mg/g) or 69% (mg/liver; both $p<0.01$, Fig. 1).

Total non-EFA and total n-6 EFA in the maternal TG pool quantitatively increased while total n-3 EFA remained unchanged at day 21 compared to day 18. Palmitic (16:0), oleic (18:1n-9), linoleic (18:2n-6), eicosatrienoic (20:3n-6) and eicosapentaenoic (20:5n-3) acids increased quantitatively from day 18 to 21, while other fatty acids did not change (Table 1).

Individual TG species were identified by reference to standards, from the known fatty acid composition of the sample, and by reference to previous work (12,13). With the column used, resolution of TG species is on the basis of their total acyl carbon number (C) and total number of double bonds. Thus, overlapping of TG species with the same molecular weight and degree of unsaturation will occur; for example, dioleoyl palmitoyl glycerol and palmitoyl stearoyl linoleoyl glycerol overlap. As has been previously reported, liver TG with C >52 showed recoveries of less than 100% (10,12). This is consistent with the improved recovery of C > 54 after hydrogenation; however, information on individual species is thus lost (Fig. 2). Some individual TG species were identified; they are named by combining the first letter of the three fatty acid moieties, but not necessarily in specific positional order. These fractions may also include other species with the same total number of acyl carbons and double bands.

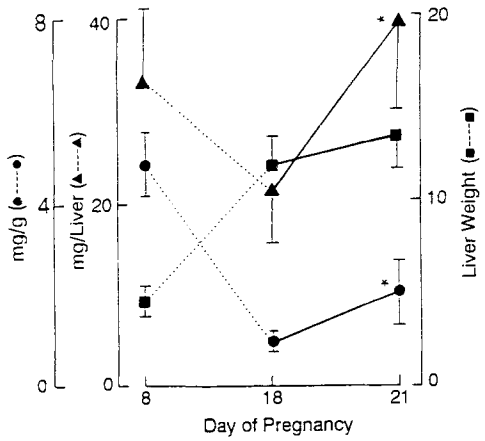

FIG. 1. Changes in rat liver weight (g, ■) and liver triacylglycerol content (mg/g, ●; mg/liver, ▲) from day 8 to day 21 of pregnancy (n = 6/group; mean ± SD). *p<0.01 in contrast to day 18.

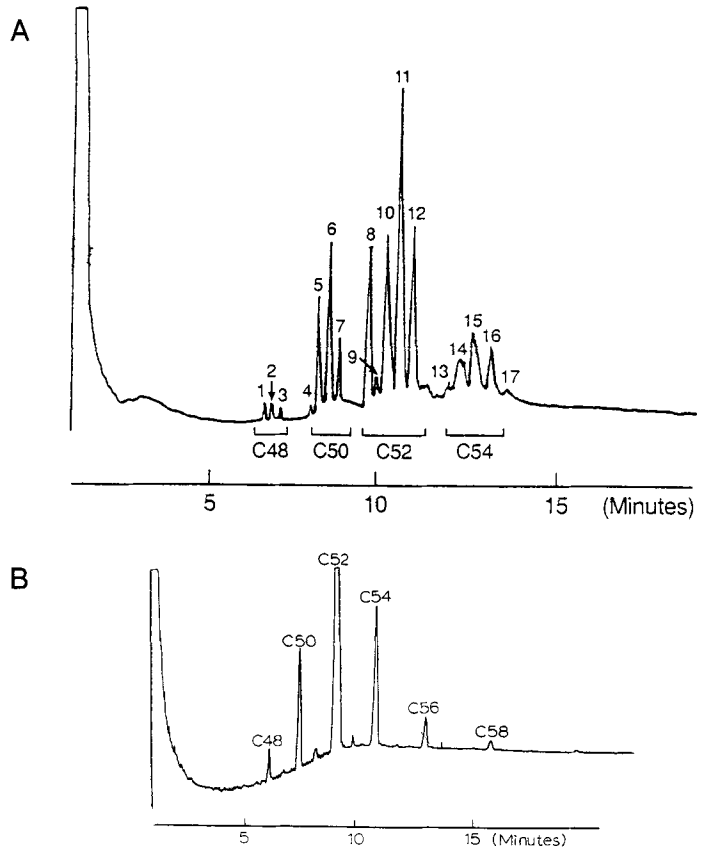

FIG. 2. A: Gas-liquid chromatogram of rat liver triacylglycerol species at day 21 of pregnancy. Column: fused silica capillary (25 m × 0.25 mm, i.d.) coated with 65% phenylmethyl silicone. Temperature: 320°C–355°C at 2°C/min. Carrier gas: Hydrogen (15 psi). Peak identification (including alternate species in brackets): 1, PPP (MSP); 2, PPPo (MPO); 3, PPoPo; 4, PSP; 5, POP (PSPo); 6, PLP (POPo); 7, PLPo (MLO); 8, SSP, internal standard; 9, POS; 10, POO (PSL); 11, PLO (PoOO); 12, PLL; 13, SOO (SSL); 14, SLO (OOO); 15, OLO (SLL); 16, OLL; 17, LLL; where P, palmitic acid; Po, palmitoleic acid; S, stearic acid; O, oleic acid; and L, linoleic acid. B: Gas-liquid chromatogram of hydrogenated rat liver triacylglycerol species (C, total acyl carbon number) from day 21 of pregnancy.

Between days 18 and 21, total C48 decreased, and C52–C58 increased, while C50 and C60 remained unchanged, relative to what was observed on day 18. Amounts of TG species >C52 are not corrected for recoveries, and are therefore only compared across time, not across TG species. 18:2n-6 represented more than 30% of total fatty acids in maternal liver TG and increased by 66% between days 18 and 21 ($p<0.01$). Consistent with the increase in 18:2n-6 in liver TG between day 18 and day 21, monolinoleoyl TG species increased: C50:3 (mainly PLPo), +47%; C52:3 (mainly PLO), +58%; C54:4 (mainly OLO), +67%, while C50:2 (mainly PLP) was unchanged. Dilinoleoyl species were also increased: C52:4 (mainly PLL), +155%, and C54:5 (mainly OLL), +96%. Trilinolein (C54:6) increased 429% from day 18 to 21. The other TG species did not change significantly except for tripalmitoyl glycerol, which decreased by 38% between day 18 and day 21 (Table 2, $p<0.05$).

Although data of day 8 and day 18 are not strictly comparable, total maternal liver TG at day 18 was significantly lower than at day 8 (mg/g or mg/liver; Fig. 1) with a proportional decrease over this period in n-6 and n-3 EFA, and a proportional increase in non-EFA; this is in agreement with our previous data (8). Based on the analyses of the hydrogenated TG species on day 18 compared to day 8, C48–C50 were significantly increased while C52-C60 were decreased (Table 2). Between days 8 and 18–21, when the rats were consuming twice as much linoleic acid/g diet as before day 8, TG species with one, two or three linoleoyl moieties were significantly decreased in maternal liver (μg/g).

DISCUSSION

Our data indicate that in the rat late in pregnancy (day 18 to 21-term), the composition of long-chain fatty acids and TG species in the total maternal liver TG pool is significantly altered, probably reflecting changing fatty acid requirements of the developing fetus or anticipation of lactation. The net changes reflect significant quantitative increases in non-EFA and n-6 EFA with no overall change in n-3 EFA. With the provision that recoveries are incomplete at >C52 and such species can only be compared across time, our data provide preliminary evidence that most of the quantitative increase in long-chain fatty acids in maternal liver TG was related to changes in 18:2n-6. Thus, although 16:0 and 18:1n-9 in maternal liver TG were increased 160 and 310 μg/g, respectively, between

day 18 and 21 of pregnancy, most of this increase could be accounted for by changes in the 16:0 and 18:1n-9 content of TG species also containing 18:2n-6 with no significant change or a decrease occurring in non-linoleoyl TG species (Table 2). Thus, 18:2n-6 appears to play a role in maternal liver TG of facilitating the accumulation of both 16:0 and 18:1n-9 during late pregnancy.

Total n-3 and n-6 EFA (μg/g) in the maternal hepatic TG pool increased markedly late in pregnancy and/or early in lactation with the highest values being observed at day 3 of lactation (4,8). These changes in maternal liver TG composition occur simultaneously with a dramatic increase in (4–10 fold) total n-3 and n-6 EFA in neonatal carcass or liver TG pools (14). Thus, the increase in the total linoleic acid-enriched TG pool in maternal liver seems to be an adaptation, or a reservoir, protecting against low maternal intake of linoleic acid during late pregnancy and early lactation.

Alteration in Mouse Splenic Phospholipid Fatty Acid Composition and Lymphoid Cell Populations by Dietary Fat

Shu-Cai Huang and **Kevin L. Fritsche***
Department of Animal Sciences, University of Missouri-Columbia, Columbia, Missouri 65211

The fatty acid composition of diacyl- and alkylacyl-glycerophosphocholine (PC), phosphatidylinositol (PI), phosphatidylserine (PS), alkenylacyl-glycerophosphoethanolamine (aPE), and diacyl- and alkylacyl-glycerophosphoethanolamine (dPE) was assessed in isolated splenocytes from C3H/Hen mice fed one of four purified isocaloric diets for six weeks. Diets contained 20% by weight of either a high-linoleate sunflower oil (Hi 18:2), a high-oleate sunflower oil (Hi 18:1), a mixture of 17% menhaden fish oil and 3% high-linoleate sunflower oil (Hi n-3), or a mixture of 17% coconut oil and 3% high-linoleate sunflower oil (Hi SFA). Spleen weight and immune cell yield were significantly higher ($P < 0.05$) in mice fed the Hi 18:1 or the Hi n-3 diets compared with those fed the Hi 18:2 and Hi SFA diets. Distinctive patterns of fatty acids were observed for each phospholipid in response to dietary fatty acids. Dietary fat significantly affected ($P < 0.05$) total polyunsaturated fatty acids (PUFA) in PC and dPE, total saturated fatty acids (SFA) in PC, total monounsaturated fatty acids (MUFA), and n-3 PUFA in all phospholipid classes examined. In mice fed the Hi n-3 diet, n-3 PUFA were significantly elevated, whereas n-6 PUFA decreased in all of the phospholipids. In these mice, eicosapentaenoic acid (EPA) was the predominant n-3 PUFA in PC and PI, whereas docosahexaenoic acid (DHA) was the major n-3 PUFA in aPE and PS. Interestingly, the ratios of n-3/n-6 PUFA in the phospholipids from these mice were 3.2, 2.4, 1.8, 0.8 and 0.8 for aPE, PS, dPE, PC and PI, respectively. These data suggest a preferential incorporation of n-3 PUFA into aPE, PS and dPE over PC and PI.
Lipids 27, 25-32 (1992).

Phospholipids are the major structural components of cellular membranes and are involved in a range of biological responses including signal transduction and second messenger generation. It has been shown that the fatty acid composition of phospholipids can influence cell membrane fluidity, membrane-associated receptor and enzyme activities, as well as lipid mediator biosynthesis (1-7). Feeding animals diets which differ in fatty acid composition have been shown to influence cell membrane properties and biosynthesis of lipid mediators, such as eicosanoids and platelet-activating factor (7-10).

The spleen is a major site of immune response to blood-borne antigens, and it has been shown that dietary fat can significantly influence spleen immune cell function, such as antibody production and proliferation (11-14). Previously, Lokesh *et al.* (15) examined the fatty acid composition of the major phospholipid classes from whole spleen homogenates from mice fed diets containing either menhaden fish oil or coconut oil. Little is known about the effect that dietary fat source has on the fatty acid composition of spleen leukocyte phospholipid classes and subclasses, although such data have been reported for several other immune tissues and cells, including peritoneal macrophages and peripheral blood neutrophils (16-18).

The objective of the present study was to determine the effect of feeding various fat sources on the fatty acid composition of diacyl- and alkylacyl-glycerophosphocholine (PC), phosphatidylinositol (PI), phosphatidylserine (PS), alkenylacyl-glycerophosphoethanolamine (aPE), and diacyl- and alkylacyl-glycerophosphoethanolamine (dPE) of murine spleen leukocyte membranes. The fats tested in this study were menhaden fish oil, which is rich in n-3 polyunsaturated fatty acids (PUFA), a high-linoleate sunflower oil, a high-oleate sunflower oil, and coconut oil, which is rich in saturated fatty acids. Thus a wide range of fatty acid compositions are represented in these diets. All diets contained adequate linoleic acid to prevent essential fatty acid deficiency.

MATERIALS AND METHODS

Animals and diets. Weanling female C3H/Hen mice (Office of Laboratory Animal Medicine, University of Missouri, Columbia, MO) were used throughout this study. Mice were housed in hanging wire stainless steel cages (2-3 mice per cage) in a room where temperature and humidity were kept constant (*i.e.,* 21-24°C and 50-60%, respectively); a diurnal light cycle of 12 hr was maintained. Upon arrival, mice were randomly allotted to one of the following four purified diets that contained 20% by weight of either: i) a high-linoleate sunflower oil (Hi 18:2); ii) a high-oleate sunflower oil (Hi 18:1); iii) a mixture of 17% menhaden fish oil and 3% high-linoleate sunflower oil (Hi n-3); and iv) a mixture of 17% coconut oil and 3% high-linoleate sunflower oil (Hi SFA). The addition of 3% high-linoleate sunflower oil to Hi n-3 and Hi SFA was to ensure meeting the requirement for essential fatty acids (Table 1). The purified diets were isocaloric and formulated according to AIN guidelines (19). The composition of the purified diets was as follows (g/100 g): casein, 20; DL-methionine, 0.3; corn starch, 20; dextrose, 29.3; fiber, 5; mineral mix (AIN-76), 4; vitamin mix (AIN-76), 1.2; choline bitartrate, 0.2; oil, 20. The fatty acid composition of the diets is shown in Table 1. Animals were given

22:6n-3	nd	nd	10.2	nd
SFA (C_8-C_{18})	12.8	8.3	24.8	77.7
MUFA	17.0	77.1	20.9	8.9
Total n-3	1.3	1.6	29.2	tr
Total n-6	68.1	12.0	13.9	13.1
Total PUFA	69.4	13.6	43.1	13.1

[a] Hi 18:2 contained 20% linoleic sunflower oil (Beatrice/Hunt-Wesson, Inc., Fullerton, CA); Hi 18:1 contained 20% oleic sunflower oil (SVO Enterprises, Painesville, OH); Hi n-3 contained 17% menhaden fish oil (Zapata Haynie, Reedville, VA) plus 3% linoleic sunflower oil; Hi SFA contained 17% coconut oil (Karlshamns USA Inc., Harrison, NJ) plus 3% linoleic sunflower oil. All data are expressed as percentage (%) by weight.

[b] Fatty acids are denoted by the number of carbons; the number of double bonds, followed by the position of the first double bond relative to the terminal methyl group ("n-"). SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; tr, trace (<0.2%); and nd, not detectable.

fresh diet every day, with any remaining diet being discarded, and were provided with tap water *ad libitum*. Autoxidation of diets was prevented by adding 0.02% *t*-butyl hydroquinone (Eastman Kodak Co., Rochester, NY) to the oils upon receipt. Diets were made up every two weeks. Peroxide values of extracted diet lipids were periodically checked and never exceeded 50 meq/kg.

Preparation of spleen cells. After six weeks of feeding mice the experimental diets, mice were anesthetized by intramuscular injection of 0.15 mL Ketaset (Aveco Co., Inc., Fort Dodge, IA) containing 8 mg/mL of Rompun (Mobay Co., Animal Health Division, Shawnee, KS). Spleens were removed, weighed and dispersed in 10 mL of RPMI 1640 medium by passage through a 80-mesh stainless steel screen. A single cell suspension was obtained by allowing tissue clumps to settle out at room temperature for 10 min. Cells were then sedimented by centrifugation (300 × *g*) at 20°C for 5 min. Erythrocytes were lysed with 1% NH_4Cl. After the sedimentation of lysed-cell debris for 3 min at room temperature, the cell suspension was centrifuged (300 × *g*) at 20°C for 5 min. The obtained leukocytes were washed twice and resuspended in RPMI 1640 and were enumerated using a Coulter Counter (Model ZIP, Coulter Electrics Inc., Hiaheah, FL). A small portion of cells was subjected to cytospin for 5 min at 800 rpm on a Shandon Cytospin (Boyce Scientific Inc., St. Louis, MO), and were stained with Hema-Tek Stain Pak using an Hema-Tek Slide Stainer (Ames Company, Division of Miles Laboratories, Elkhart, IN). Differential counts of spleen cells were done using a light microscope. The remaining cells were washed once with PBS and resuspended in 1 mL of 10 mM EDTA and stored at −20°C until analyzed for phospholipid fatty acid composition.

Phospholipid separation and fatty acid analysis. Total cell lipids were extracted as described by Sun (20). Briefly, to one volume of spleen leukocyte suspension, four volumes of chloroform/methanol (2:1, v/v) were added. The tubes were thoroughly mixed by vortexing, then centrifuged at 500 × *g* for 10 min at 10°C. The lower organic phase was removed and transferred to another test tube. The aqueous phase was subjected to a second extraction with 2 volumes of chloroform/methanol/12 N HCl (4:1:0.013, by vol). The acidic organic phase was transferred to another tube and neutralized with 1 drop of 16 N NH_4OH before combining with the first organic extract. It has been shown that by using this procedure, a complete extraction of both neutral and acidic phospholipids can be attained (20). The combined extract was filtered through anhydrous Na_2SO_4 and taken to dryness under N_2. Lipids were resuspended in chloroform/methanol (2:1, v/v) and applied to the left lower corner of high-performance thin-layer chromatography (HPTLC) silica gel 60 plates (E. Merck, Darmstadt, Germany) and developed in a solvent system containing chloroform/methanol/acetone/NH_4OH (35:20:5:5, by vol) for 30 min. After developing the plates, the solvent was removed by blowing a light stream of air over the plates for 10–15 min. The plates were then exposed to HCl fumes for 3 min to hydrolyze the plasmalogenic PE fraction to give lysoPE and aldehyde. After drying in an air stream for 10–15 min, the plates were turned 90° and placed in the second solvent system consisting of chloroform/methanol/acetone/acetic acid/0.1 M ammonium acetate (35:15:13.8:1.55:2.5, by vol) and developed for another 30 min. The TLC plates were then dried and sprayed with 2′,7′-dichlorofluorescein (0.1% in methanol). The lipid fractions were made visible under a UV lamp and scraped into 30-mL screw-capped tubes and closed with Teflon-lined caps. An appropriate amount of 17:0 fatty acid methyl ester was added as an internal standard. Fatty acid transmethylation was carried out by incubating with 1 mL of 0.5M NaOH per tube for 10 min, followed by 2 mL chloroform for another 10 min. Fatty acid methyl esters (FAME) were then extracted by adding 0.75 mL H_2O. The lower phases were then filtered through sodium sulfate, and FAME were analyzed using a Hewlett-Packard 5890 gas chromatograph (GC) (Hewlett-Packard, Norwalk, CT) equipped with a 30-m × 0.25-mm inside diameter fused silica capillary column (Supelco, Bellefonte, PA). Helium was used as carrier gas at a flow rate of 1 mL/min. Oven temperature was held at 190°C for 10 min, then increased at 3°C/min to 230°C, where it was maintained for 11.67 min. FAME were identified by comparing their relative retention times with those of the commercial standards PUFA-1 and PUFA-2 (Supelco).

Since fatty acyl groups of aPE are derived exclusively from the *sn*-2 position, whereas the fatty acyl groups of PC, PI, PS and dPE represent both *sn*-1 and *sn*-2 positions, the molar amounts of total FAME from aPE were

divided by one, while those from PC, PI, PS and dPE were divided by two for relative phospholipid class and subclass composition analysis as described by others (15). The data were expressed as mol% of total phospholipids or total FAME identified.

Statistical analysis. The data were subjected to one-way analysis of variance to test for the effect of the dietary fat source. When significant differences occurred ($P < 0.05$), Fisher's least significant difference was used for comparison of treatment means. Data analyses were processed on a Macintosh II computer using version 1.03 of StatView II (Abacus Concepts, Inc., Berkeley, CA).

RESULTS

Body weight, spleen weight and splenic cellularity. Feeding mice the experimental diets for six weeks resulted in an average body weight gain of 19.2 g. As shown in Table 2, there was no effect of dietary fat source on body weight gain. However, dietary fat source did have a significant influence on spleen weight, as well as the number of spleen leukocytes recovered ($P < 0.01$). Spleens from mice fed the Hi 18:1 and Hi n-3 diets were heavier and had more leukocytes than those from mice fed the Hi 18:2 and Hi SFA diets. There was no diet effect on the percentage of lymphocytes, macrophages, and polymorphonuclear leukocytes (PMN) found in the spleen. However, the total number of both lymphocyte and macrophages per spleen were significantly influenced by dietary fat source. Mice fed the Hi 18:1 and Hi n-3 diets had significantly more lymphocytes and macrophages than mice fed the Hi 18:2 and Hi SFA diets ($P < 0.05$).

Phospholipid composition of murine spleen leukocytes. The two-dimensional TLC procedure allowed for a separation of PI from PS, and plasmalogens from their respective diacyl phospholipids, but was unable to separate the alkylacyl phospholipid species from diacyl species (20). Therefore, PC contained both diacyl- and alkylacyl-glycerophosphocholine and dPE contained both diacyl- and alkylacyl-glycerophosphoethanolamine. Figure 1 shows the relative composition as mol% of leukocyte phospholipids examined. As shown in the Figure, the dietary fat source did not alter the phospholipid composition of murine splenic leukocytes. PC was the most abundant phospholipid in the cell membrane and it accounted for about 60% of the total phospholipids examined, followed by dPE, which was about 20% of total phospholipids. PI, PS and aPE each accounted for only about 6–8% of total phospholipids tested.

Fatty acid composition of murine leukocyte diacyl- and alkylacyl-glycerophosphocholine (PC). Table 3 shows the fatty acid composition of PC from murine splenic leukocytes. SFA, MUFA and n-3 PUFA, as well as linoleic acid (18:2n-6) in PC, were reflective of dietary fatty acids. In mice fed the Hi n-3 diet, an elevation of n-3 PUFA, predominantly eicosapentaenoic acid (EPA, 20:5n-3) and, to a lesser extent, docosahexaenoic acid (DHA, 22:6n-3) and docosapentaenoic acid (DPA, 22:5n-3), were observed in leukocyte PC. A small but significant increase of AA was observed in mice fed the Hi SFA diet as compared to mice fed the Hi 18:2 and Hi 18:1 diets. Total n-6 PUFA were significantly altered by dietary fat source (Hi 18:2 > Hi SFA > Hi 18:1 > Hi n-3, $P < 0.05$). Total PUFA in PC were also significantly affected by dietary fat source

TABLE 2

Effect of Dietary Fat on Spleen Weight and Spleen Cell Populations of Mice[a]

Parameters	Diet			
	Hi 18:2	Hi 18:1	Hi n-3	Hi SFA
Initial body weight (g)	12.2 ± 0.4	12.4 ± 0.3	12.2 ± 0.4	12.2 ± 0.4
Final body weight (g)	30.9 ± 0.5	32.5 ± 0.7	31.3 ± 0.7	31.2 ± 0.6

[a] Three separate experiments (N=9 per treatment) were conducted with three-week-old female C3H/Hen mice. Mice were fed the experimental diets for six weeks and spleens were obtained for separating leukocytes as described in the Methods section. Cell types were characterized by differential count from cytospin staining. Values represent mean and standard error of mean (SEM); values within each row which do not share a common letter (e,f) are statistically different at $P < 0.05$.

[b] Cell numbers ($\times 10^7$).

[c] PMN, polymorphonuclear leukocytes.

[d] Other cells were those cells that were neither lymphocytes, macrophages, nor PMN.

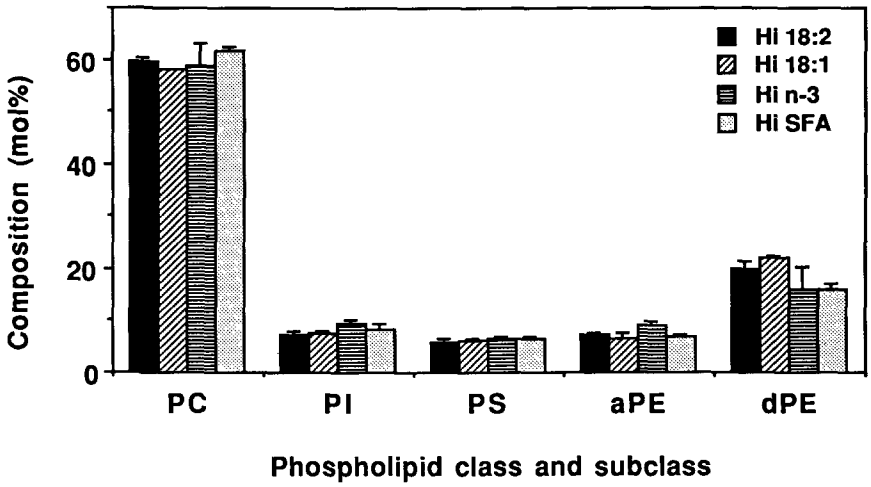

FIG. 1. Phospholipid composition of murine spleen leukocytes. Results represent mean ± SEM (n=3). Values are not significantly different (P > 0.05).

$^{a-e}$All values are expressed as means (mol%) and pooled SEM. Means with different letter within the same fatty acid group are significantly different at P < 0.05; n=3 per treatment.

(P < 0.05), with mice fed the Hi 18:2 diet having the highest, and mice fed the Hi 18:1 diet having the lowest total PUFA.

Fatty acid composition of murine spleen leukocyte phosphatidylinositol (PI). Table 4 shows the fatty acid composition of PI from murine splenic leukocytes. Unlike PC, dietary fat source did not significantly affect percentage of SFA in membrane PI. In mice fed the Hi 18:1 diet, MUFA in PI were the highest as compared to other dietary fat sources. Linoleic acid level in PI of mice fed the Hi 18:2 diet was the highest compared to other diets. However, this level was only one fourth of that in PC. Feeding diets high in SFA and MUFA did not alter AA nor total PUFA level in PI when compared to high linoleate feeding. However, feeding the Hi n-3 diet reduced AA by almost 50% with a concomitant increase in EPA, which was the major n-3 PUFA in PI. Unlike in PC, total PUFA in PI were not affected by dietary fat source.

TABLE 4

Effect of Dietary Fat on Fatty Acid Content of Murine Spleen Leukocyte Phosphatidylinositol (PI)

Fatty acids	Diet (mol %)

Fatty acid composition of murine spleen leukocyte phosphatidylserine (PS). Table 5 shows the fatty acid composition of PS from murine splenic leukocytes. Unlike PC, but similar to PI, leukocyte PS contained similar amounts of SFA for all the four dietary treatments. Similar to PI, stearic acid (18:0) was the predominant fatty acid present in spleen leukocyte PS and accounted for over 55% of the total fatty acids present. The amount of oleic acid (18:1) in PS from mice fed Hi 18:1 diet was similar in magnitude as that observed for PC and PI. Hi n-3 feeding caused an elevation of EPA, DPA and DHA with a concomitant reduction in AA and other longer chain n-6 PUFA. Unlike PC and PI, where EPA was the major n-3 PUFA, PS contained predominantly DHA as the major n-3 PUFA. Consumption of a diet rich in SFA and MUFA did not alter AA nor total n-6 PUFA levels in PS when compared to a diet rich in linoleate (Hi 18:2). Total PUFA levels in PS were not affected by dietary fat source.

Fatty acid composition of splenic leukocyte alkenylacyl-glycerophosphoethanolamine (aPE). Table 6 shows the fatty acid composition of aPE from murine splenic leukocytes. Splenocyte aPE contained less SFA and much higher amounts of PUFA as compared to the other phospholipids examined. Dietary fat source did not influence SFA level in aPE. The effect of dietary fat on MUFA in splenocyte aPE were similar to those observed in other phospholipids with total MUFA being the highest in mice fed the Hi 18:1 diet. Hi n-3 feeding caused an elevation of EPA, DPA and DHA with a concomitant reduction in AA and other longer chain of n-6 PUFA. Similar to PS, aPE contained predominantly DHA as the major n-3 PUFA. In addition, consumption of a diet rich in SFA and MUFA did not alter AA nor total n-6 PUFA levels in aPE when compared to a diet rich in linoleate (Hi 18:2). Total PUFA levels in aPE were not affected by dietary fat source.

Fatty acid composition of diacyl- and alkylacyl-glycerophosphoethanolamine (dPE) of murine splenic leukocytes. Table 7 shows the fatty acid composition of dPE from murine splenic leukocytes. Dietary fat source significantly affected the percentage of palmitic acid (16:0) and stearic acid (18:0) in dPE. However, there was no diet effect on total SFA. The pattern of MUFA in leukocyte dPE were similar as in other phospholipids with MUFA being the highest in mice fed the Hi 18:1 diet. Hi n-3 feeding caused an elevation of EPA, DPA and DHA with a concomitant reduction in AA and other longer chain of n-6 PUFA. Unlike other phospholipids, dPE contained both DHA and EPA as the predominant n-3 PUFA (12.4% *vs.* 10.0% for DHA and EPA, respectively, $P < 0.05$). The effect of fat source on AA and total n-6 PUFA in dPE was very similar to that noted in PC. A small but statistical significant increase of AA was also observed in mice fed the Hi SFA diet as compared to mice fed the Hi 18:2 or Hi 18:1 diets. Total n-6 PUFA were significantly altered ($P < 0.05$) by dietary fat source (Hi 18:2 > Hi SFA > Hi 18:1 > Hi n-3). Total PUFA in dPE were also significantly affected by dietary fat source ($P < 0.05$) with mice fed Hi 18:2 diet having the highest and mice fed Hi 18:1 having the lowest total PUFA.

The n-3/n-6 PUFA ratio of murine splenic leukocyte phospholipids. Figure 2 shows the effect of dietary fat on phospholipid n-3 PUFA/n-6 PUFA ratio. As shown in the Figure, the n-3/n-6 ratio in every phospholipid examined was significantly higher ($P < 0.0001$) in mice fed Hi n-3 diet than mice fed other diets. Interestingly, the n-3/n-6 ratio in mice fed Hi n-3 diet was significantly different among the five phospholipids (aPE > PS > dPE > PI and PC, $P < 0.05$).

DISCUSSION

In the present investigation, we have demonstrated that the source of dietary fat provided to mice produces marked changes in the fatty acid composition of their splenic leukocyte membrane phospholipids. Furthermore, these data show that the effects were unique for each phospholipid. Similar results have been observed by others (15,17, 18,21-23) who studied the effect of dietary fat source on fatty acid composition of whole spleen or splenocyte phosphatidylcholine and phosphatidylethanolamine in rats or mice. These data indicate that there is a marked difference in fatty acid composition between these two classes of phospholipids in the spleen of mice or rats fed diets containing different fats. We have shown that the differences in fatty acid composition induced by dietary fats were observed not only between classes, but also between subclasses of phospholipids. Others have observed

[a-c]All values are expressed as means (mol%) and pooled SEM. Means with different letter within the same fatty acid group are significantly different at $P < 0.05$; n=3 per treatment.

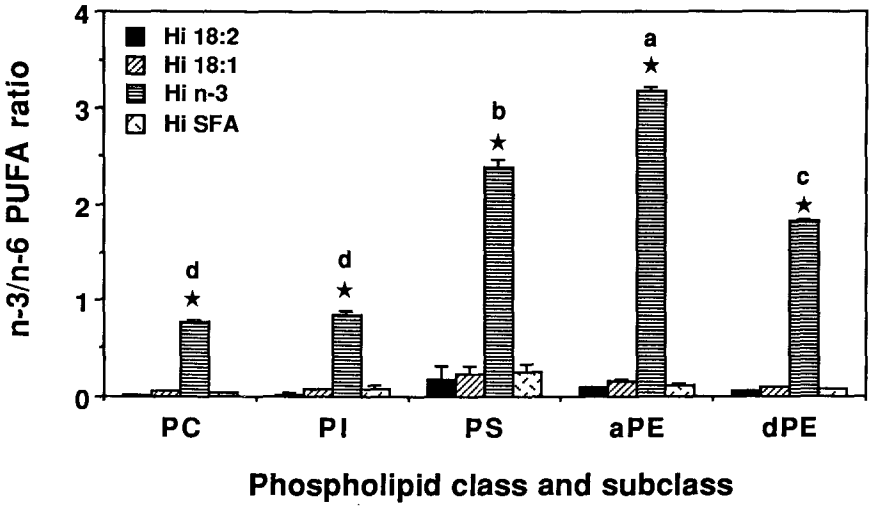

FIG. 2. Ratio of n-3 PUFA/n-6 PUFA of phospholipids. Results represent mean ± SEM (n=3). Values bearing an asterisk are significantly different from other dietary treatments in the same phospholipid. Values with the same or no superscripts are not significantly different ($P > 0.05$) between phospholipids from mice fed Hi n-3 diet.

similar results in murine macrophages (18), and rat neutrophils (16). However, it is clear from this study that the distinctive effect of each dietary fat on the fatty acid profile of certain phospholipids cannot be entirely predicted from dietary fatty acid composition. A similar phenomenon with the total phospholipids of rat splenocytes has been observed by Cleland and co-workers (24). It is not clear why incorporation of arachidonic acid in these phospholipids is resistant to dietary SFA, MUFA and linoleate feeding, but susceptible to n-3 PUFA feeding. Similar results have been observed using an *in vitro* cell culture system (25). These data suggest that incorporation of AA is a saturable process, which appears to compete with n-3 PUFA.

Dietary consumption of fish oil (Hi n-3) profoundly altered fatty acid composition of leukocyte phospholipids when compared to other fat sources. We observed that the sum of AA and EPA in each phospholipid from mice fed n-3 PUFA diet was always lower than the AA level from mice fed other diets (Tables 3-7). This finding is in accord

with the results of others (15,16,18). Interestingly, Hi n-3 feeding caused preferential incorporation of certain n-3 PUFA into specific phospholipid subclasses. We observed that DHA was the predominant n-3 PUFA in aPE and PS, whereas EPA was the predominant n-3 PUFA in PC and PI. The preferential location of DHA in PE and PS relative to other n-3 PUFA has been observed in retinal rods of other animals (26) and in rat liver (27). In addition, preferential incorporation of certain n-3 PUFA into specific phospholipid subclasses has been observed in human platelets (28), but not in murine macrophages (18) or rat neutrophils (16). This indicates that such preferential incorporation may be organ or cell type specific. It is not clear at present what the underlying mechanism involved in such a preferential incorporation process would be.

The ratio of n-3 PUFA/n-6 PUFA in mice fed the Hi n-3 diet were quite different between phospholipid classes and subclasses (Fig. 2). The highest ratio of n-3 PUFA/n-6 PUFA coincided with those phospholipids which had DHA as the predominant n-3 PUFA. This may indicate that either *in situ* formation through elongation and/or desaturation or preferential acylation of DHA is more active in aPE and PS than in PC and PI.

In the present study, we observed that dietary fat source did not alter the percentage of spleen lymphocytes, macrophages as well as polymorphonuclear leukocytes (Table 2). This suggests that our lipid analysis was done on a similar cell population across diet groups. However, we consistently observed that dietary fat source significantly influenced spleen weight, and the number of leukocytes, lymphocytes and macrophages recovered from those spleens. The enlargement of the spleen and the increase in spleen cell yield due to fish oil feeding has been observed previously (29). At present, it is not known why both Hi 18:1 and Hi n-3 feeding caused splenic hyperplasia. We believe that the effect of dietary fat on spleen weight and number of lymphocytes and macrophages may be related to leukocyte membrane phospholipid fatty acid composition. For instance, both the Hi 18:2 group and Hi SFA group were more alike in their phospholipid fatty acid profile and they both had similar spleen weight and number of lymphocytes and macrophages. The incorporation of MUFA and n-3 PUFA into cellular membrane phospholipids may cause a change in membrane integrity, membrane associated enzyme and receptor activities, lipid mediator biosynthesis and the production of cytokines. This may directly or indirectly influence the immune cell proliferation and/or migration (30).

We observed that source of dietary fat did not influence the overall phospholipid composition of spleen leukocytes. Our data are in agreement with the results reported by Careaga-Houck and Sprecher (16), who showed that corn oil and fish oil feeding had no effect on rat neutrophil phospholipid content. Similarly, Chapkin and Coble (31) have demonstrated that dietary fat source did not alter phospholipid class or subclass levels in murine kidneys. However, Chapkin and Carmichael (18) have shown that dietary fat can affect PE subclass levels in rat peritoneal macrophages. Such an effect may be organ or cell type specific.

In conclusion, the present study has shown that dietary fat source can have a profound effect on the fatty acid composition of murine leukocyte membrane phospholipids, and that such effects were unique for each phospholipid class or subclass. Hi n-3 feeding can result in preferential incorporation of n-3 PUFA, particularly DHA into aPE, PS and, to a lesser extent, dPE. Source of dietary fat can also influence spleen weight and cellularity, and such effects may be correlated to the fatty acid composition of phospholipids.

ACKNOWLEDGMENTS

We are grateful to Zapata Haynie Inc. (Reedville, VA) for supplying the menhaden oil and SVO Enterprises (Painesville, OH) for supplying the high-oleate sunflower oil used in this study. We thank Nancy Ann Cassity for technical assistance in preparation and staining of spleen cells, and Dr. Grace Y. Sun for technical advise on phospholipid separation. Financial support for this research was provided by the Food for the 21st Century Program and the University of Missouri Agriculture Experiment Station.

Effect of Human Mammary MX-1 Tumor on Plasma Free Fatty Acids in Fasted and Fasted-Refed Nude Mice

Chu Lin, Edward W. Blank, Roberto L. Ceriani and **Nome Baker***
John Muir Cancer and Aging Research Institute, Walnut Creek, California 94596

We hypothesized that tumor-bearing (TB) nude mice, because they are reported to have no detectable, circulating tumor necrosis factor (TNF)/cachectin, would regulate their plasma free fatty acid (FFA) levels normally when fasted and refed. We compared levels of individual plasma FFA in response to fasting (24 hr) and to refeeding (for 20 hr after fasting) a fat-free, 65% sucrose diet in control, nude mice and in mice bearing 1.3 ± 0.4 g MX-1 tumors. Total plasma FFA levels were typically high in 24-hr fasted mice [mean concentrations in μM ± SE (n); controls 515 ± 63 (6); TB, 625 ± 63 (6)]. FFA levels were reduced by 65% in each group in response to refeeding. Each major plasma FFA species fell in response to refeeding, except arachidonate, which did not change significantly (fasted *vs.* fasted-refed concentrations) in either controls or TB mice. In refed mice, the molar FFA ratio of oleate to linoleate rose; however, that of oleate to arachidonate fell markedly. TB nude mice had normal appetites. We conclude that all species of FFA were mobilized from adipose tissue in a normal manner in TB nude mice; therefore, regulation of adipose triacylglycerol fatty acid mobilization (as plasma FFA) by dietary sugar is probably not affected by MX-1 tumor growth in these mice. Our findings are consistent with the hypothesis that nude mice may be unable to secrete TNF/cachectin in response to tumor growth, but they do not establish whether or not endogenous, circulating TNF/cachectin increases FFA mobilization in any TB animal.
Lipids 27, 33–37 (1992).

Immunodeficient mice, such as nude BALB/c mice, are commonly used as experimental models to study factors that regulate growth of human cancers and to evaluate the effects of anti-cancer therapies against human cancers *in vivo*. Mice with defective immune systems are also potentially useful for studying the effects of cancer-derived and host-derived cytokines upon both the cancer and the host. Effects of tumor necrosis factor (TNF)/cachectin, produced by Chinese hamster ovarian (CHO) tumors transfected with the mouse TNF/cachectin gene, have been reported in nude mice (1). However, to our knowledge, the cachectic effects of human carcinomas on adipose tissue or on the regulation of plasma free fatty acid (FFA) mobilization by diet in nude mice have not been studied. Such studies would seem to be of considerable interest because nude mice bearing large CHO tumor burdens apparently do not have detectable levels of circulating TNF/cachectin (1), nor do they increase circulating TNF/cachectin levels in response to bacterial vaccines and other agents as do normal mice, despite being able to increase production of macrophages (2). This abnormality in TNF production may be attributable to the total or partial absence of T-cells which are required in order for certain agents to activate macrophages so that they can respond to substances that induce TNF/cachectin production and/or secretion by the macrophages (2,3).

Cancer cachexia, and loss of body fat in particular, may be due to the effects of cytokines such as TNF/cachectin acting on appetite centers (1) or on adipose tissue to increase triacylglycerol fatty acid (FA) mobilization (4–7) and/or to prevent deposition of very low density lipoprotein (VLDL) and chylomicron triacylglycerol fatty acids (TGFA) by inhibition of lipoprotein lipase synthesis (8–10). According to these hypotheses, one would not expect to observe cancer cachexia and increased mobilization of plasma free fatty acids (FFA) in nude mice bearing human carcinomas in the absence of significant levels of circulating TNF/cachectin.

In the present study we have examined total and individual plasma FFA concentrations following both fasting and refeeding, as indices of plasma FFA mobilization and regulation, in nude mice bearing MX-1 mammary carcinomas and in their non-tumor-bearing controls. We have also studied the effects of MX-1 tumor growth on food intake and, in a separate study on adiposity (unpublished data). Our studies are consistent with, but do not prove, the hypothesis that in the absence of detectable circulating TNF/cachectin (1) both appetite and the dietary regulation of fat metabolism in adipose tissue are unaffected by tumor growth, at least in nude mice bearing MX-1 mammary carcinomas.

METHODS

Mice. Female BALB/c (nu/nu), 7–8-weeks-old, were obtained from Simonson (Gilroy, CA). They were housed (four mice/cage) in autoclaved cages with filter tops and bedding in a temperature-controlled room with a 12-hr light (daytime) and a 12-hr dark cycle. The average weights (± SE) of the control and TB mice on the day of the experiment were as follows: fasted controls, 20.4 ± 0.22; fasted-refed controls, 22.4 ± 0.65; fasted TB (MX-1), 20.6 ± 0.23; and fasted-refed TB, 22.8 ± 1.0 g.

Tumor. The estrogen receptor-negative transplantable human breast carcinoma, MX-1, derived from a primary breast tumor, was obtained originally from the EG & G Mason Research Institute (Worchester, MA) and transplanted serially in nude mice since 1983. Under sterile conditions, the least necrotic pieces of a well-developed MX-1 tumor from a donor mouse was minced with a scalpel in

Abbreviations: BHT, 3,5-di-*t*-butyl-4-hydroxytoluene; CHO, Chinese hamster ovarian; DME, Dulbecco's modified Eagle's (medium); EDTA, ethylenediaminetetraacetic acid; FA, fatty acids; FAME, fatty acid methyl esters; FFA, free fatty acids (unesterified fatty acids); GLC, gas-liquid chromatography; TB, tumor-bearing; TGFA, triacylglycerol fatty acids; TLC, thin-layer chromatography; TNF/cachectin, tumor necrosis factor; VLDL, very low density lipoprotein.

a minimal volume of Dulbecco's modified Eagle's (DME) cell culture medium, passed through a syringe without a needle and then through a syringe with a 16-gauge needle attached. Recipient nude mice were then injected subcutaneously, proximal to the right no. 4 mammary gland, with the MX-1 tumor suspended as a gel in DME cell culture medium. The volume of tumor gel suspension injected was 50 μL delivered through a 16-gauge needle attached to a 1-mL syringe. After each experiment, tumors were either excised and their sizes estimated based upon direct wet weight measurements or upon the tumor volumes measured *in situ* and assuming a density of 1.0 (a minimal estimate). Tumor volumes (V) were calculated from caliper measurements of 3 perpendicular dimensions; thus, V = (length × width × depth)/2. The mean tumor weight (± SE) of 12 mice was 1.27 ± 0.37 g, 5–7 weeks after tumor inoculation.

Diet. The mice were fed Purina laboratory chow (5058) *ad libitum* until they were fasted for 24 hr. Those that were refed for 20 hr following the fasting period were given fat-free pellets that contained, by weight, 64.8% sucrose, 24.0% vitamin-free casein, 3.75% salt mixture (AIN #76), 2.2% vitamin fortification mixture (ICN Nutritional Biochemicals, Cleveland, OH), 0.3% methionine, 5.0% cellulose, and 0.01% BHT (3,5-di-*t*-butyl-4-hydroxytoluene). Estimates of individual daily food intakes during the 72-hr period before fasting, and when the mice were still eating Purina laboratory chow, were based upon the average food consumed by 32 control mice and by 32 TB mice. It was from each of these populations that 24 mice were chosen (randomly, in the case of controls, and selected to obtain the most homogenous tumor sizes, for the TB group). Daily food intake per mouse was calculated using a factor of 12 (four mice/cage × three-day intake). The average food consumed during the 20-hr refeeding period (65% sucrose, fat-free diet) was based on the average food eaten by 12 control mice and by 12 TB mice. Food intakes are given in the Results section.

Experimental protocol. Twelve chow-fed animals (six control and six bearing MX-1 tumors) were fasted for 24 hr and then refed the special fat-free diet for 20 hr. The mice were sacrificed between 10 a.m. and 12 noon along with another 12 animals (six controls and six TB mice) fasted for 24 hr. Retroorbital blood or blood following decapitation, both under diethyl ether anesthesia (30 seconds before killing), was collected in tubes containing solid ethylenediaminetetraacetic acid (EDTA). The stomach contents in all fed mice were examined and found to be between 3/4 full and full.

Plasma FFA analysis. The standard reference, "Method I", of Lin *et al.* (11) was used without modification. Briefly, this method consisted of extracting total lipids (12) from 0.1 mL of plasma to which 5 μg of heptadecanoic acid had been added as internal standard, thin-layer chromatographic (TLC) separation of the FFA fraction, scraping of the FFA zone, methylation of FFA with a diazomethane ethereal solution added to the TLC scrapings, quantitative transfer into hexane of the fatty acid methyl esters (FAME), concentration, and gas-liquid chromatographic (GLC) separation of FAME using a 5 μL aliquot of the hexane solution; the instrumentation and GLC conditions were exactly as described previously (11). Similar results were obtained when FFA, separated by TLC, were methylated by either diazomethane (13) or acetyl chloride (14).

RESULTS

Food intake of MX-1 and control nude mice during the 20-hr refeeding period. Since cancer growth often induces anorexia in rodents, and anorexia influences FFA mobilization, it was important to monitor the food intake carefully both before the fasting period was begun and again during the 20-hr refeeding period. The average daily intakes of Purina laboratory chow in the period preceding the fasting period were as follows: controls, 3.5 ± 0.064 g/mouse; TB, 3.3 ± 0.073 g/mouse (mean ± SE; n = 8 cages/group of either 32 control or 32 TB mice). The difference was not statistically significant. Both groups of animals also ate nearly identical quantities of food (65% sucrose, fat-free diet) during the 20-hr refeeding period, as follows: controls, 4.2 ± 0.32 g/mouse; TB, 4.4 ± 0.21 g/mouse (mean ± SE; n = 3 cages/group of either 12 control or 12 TB mice).

Effect of fasting and refeeding on plasma FFA levels of control nude mice with and without MX-1 tumors. As shown in Table 1 the levels of plasma FFA as measured by GLC were slightly higher in TB mice than in controls, but the differences were minor and statistically insignificant. Plasma FFA levels fell in response to refeeding a high-sucrose, fat-free diet by 63% in the nude controls (from 515 to 190 μM) and, to a similar extent, 65% in the MX-1-bearing nude mice (from 625 to 220 μM). Therefore, this human mammary carcinoma had no apparent effect on this insulin-dependent regulatory process, *i.e.*, on suppression of hormone-sensitive lipase and augmentation of FFA reesterification in adipose tissue, the net effect of which is usually reflected in the plasma FFA levels (15–17).

All of the major individual C_{16} and C_{18} FFA, which constitute the bulk of the component FFA showed highly significant decreases upon refeeding, and the changes in each were essentially the same in TB and in control mice (Fig. 1). The greatest percentage changes were found for 18:2 and 18:1 (decreases of about 83% and 74%, respectively), followed by 16:1 and 16:0 (decreases of 65% and 55%, respectively). The change in 18:0 levels, about 35%, was less than that of the others, with the exception of 20:4, which was unique in that its plasma FFA concentration showed no change in response to refeeding.

The relationships of the plasma FFA oleate and FFA arachidonate concentrations to the mean concentrations

TABLE 1

Effect of Fasting (24 hr) and Fasting Followed by Refeeding a Fat-Free 65% Sucrose Diet for 20 hr on Plasma FFA Levels of MX-1 Tumor-Bearing and Control Nude Mice[a]

Mice	Plasma FFA concentration [x ± SE (n)]	Decrease (%)
Controls		
Fasted	515 ± 63 (6)	—
Fasted-refed	190 ± 17 (6)	63
MX-1 Tumor-bearing		
Fasted	625 ± 63 (6)	—
Fasted-refed	220 ± 9.6 (6)	65

[a]Units (μmol/L) based on the six major GLC peaks in relation to a 17:0 FAME standard. As an approximation, FFA mol. wt. was assumed to be 270 for each individual FFA. Statistical evaluation: Fasted *vs.* fasted-refed, $p \leq 0.001$, both controls and TB groups.

of each of the other FFA moieties, in the fasted and fasted-refed states for both control and TB mice, are summarized in Figure 2. First, oleic acid (18:1) is shown as the reference FFA (Fig. 2, upper), selected because it was the most highly concentrated individual FFA in the fasted state in both the control and the TB mice (Fig. 1). The ratio of 18:1 to every other FFA was greater than 1 and greater in the fasted state than in the fasted-refed state in every case except 18:1/18:2. In the fasted state, the relative approximate molar ratios of 18:1 to each of the other FFA moieties were similar to those in the fasted-refed state; however, there were some noticeable differences. First, the ratio of 18:1 to 18:2 rose from 2 to 3 in fasted-refed mice, the only instance in which the ratio did not fall upon refeeding. For example, the ratio of 18:1 to 18:0 fell from 3 to 1. Second, the ratio of 18:1 to 20:4 showed a striking difference between the two nutritional states in both TB and control mice. The ratio averaged 19 (controls) and 13 (TB) in the fasted state and fell to about 4 in both groups when they were refed. Note that these are the ratios of the mean values and not the means of the individual ratios, which were highly variable, especially with respect to levels of 20:4. The difference in this ratio between control and TB mice in the fasted state (*i.e.*, 19 *vs.* 13) was not significant.

The second relationship explored was the mean molar ratio of arachidonate (20:4) to each major FFA (Fig. 2). Arachidonate was chosen here as the reference FFA because, along with linoleate, it is thought to be of special significance with respect to the regulation of tumor growth (18,19), and it is the one plasma FFA whose concentration remained unchanged after refeeding. As shown in the bottom half of Figure 2 the ratios of 20:4 to each of the other FFA increased upon refeeding, with the most striking increases occurring in relation to 18:2 (ratio rising from 0.1 to 0.75) and to 16:1 (ratio rising from 0.5 to 1.5, average). Note that 20:4 is less concentrated than all other plasma FFA (ratio <1.0), except 16:1, and is only more concentrated than 16:1 in the fasted-refed state.

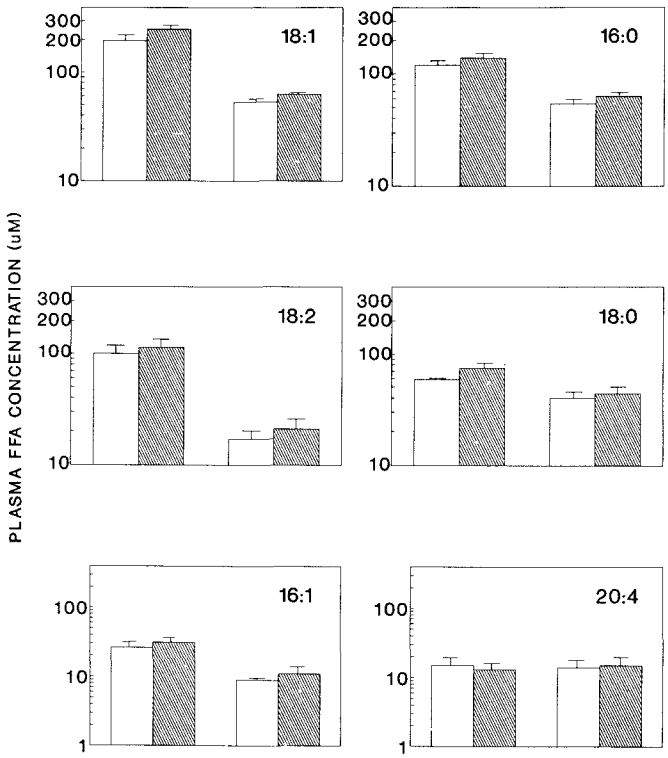

FIG. 1. Effect of fasting and fasting-refeeding on the mean concentrations of individual plasma FFA in control nude mice and in MX-1 tumor-bearing mice. The Figure illustrates that the average response to refeeding of each individual FFA is the same in the TB as well as in the control groups and that each of the major individual FFA species is significantly affected by refeeding, with the notable exception of arachidonate (20:4). Each bar represents the mean values (vertical bar, ± SE) of six mice for each of four groups: two bars on the left of each frame are mean values for the mice that were fasted for 24 hr; the two bars on the right of each frame are mean values for the 24-hr fasted, 20-hr refed mice. Open bars, control nude mice; hatched bars, TB mice. Note the use of a logarithmic scale for plasma FFA concentrations and the different scale range for 16:1 and 20:4 compared to the other four FFA. Statistical analysis, fasted *vs.* refed, for each FFA species (except 20:4, n.s.) in both control and TB groups was $p \leq 0.001$, except for the following, each of which was statistically significant at $p \leq 0.01$—18:0 (both controls and TB) and 16:1 (TB).

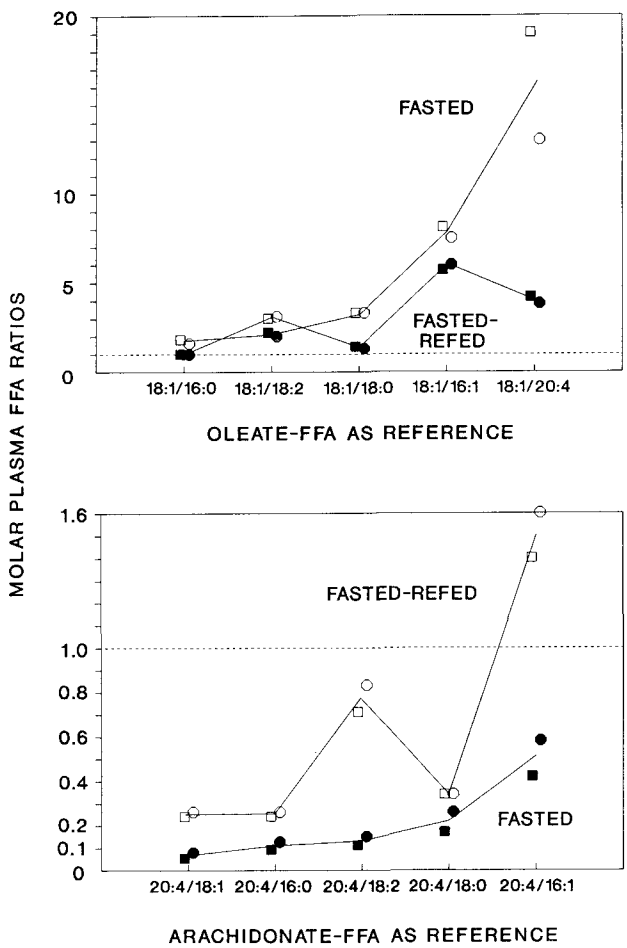

FIG. 2. Relative molar ratios of individual plasma FFA in fasted and fasted-refed nude control and MX-1 tumor-bearing mice. In the upper Figure, the mean molar ratios are shown for oleate (18:1), the most abundant FFA in the fasted state, to each of the other five major FFA species. In the lower Figure, the mean molar ratios of the concentration of arachidonate (20:4) in relation the other five major FFA are shown. A reference line (at 1.0), corresponding to an equimolar ratio, is indicated in each Figure. The patterns for control and tumor-bearing mice were nearly identical. Symbols: controls, fasted (○), refed (●); TB, fasted (□), and refed (■).

DISCUSSION

Although immunodeficient, nude mice are widely used to study such important aspects of human carcinoma growth as its detection, prevention and treatment, little information is available regarding fat metabolism in these mice. Such studies are highly relevant because of the growth-promoting effects of certain dietary fats, the possibility that linoleate and arachidonate transport to tumors may be rate-limiting for tumor-growth, and the frequent association of increased mobilization of adipose tissue fat stores and of hypertriglyceridemia with cancer in both rodent models and human subjects. Nude mice are also of potentially special significance because they lack T-cells, which control the production of TNF/cachectin by macrophages (2,3). Since this cytokine has been implicated in cancer cachexia and in abnormalities of fat metabolism in TB mice, we have hypothesized that, in the assumed absence of TNF/cachectin, fat metabolism will be unaltered in nude mice bearing a human mammary carcinoma (MX-1).

In the present study, the first of several designed to provide information relevant to this hypothesis, we found that nude mice bearing MX-1 human mammary carcinomas did not have elevated levels of any plasma FFA in either the fasted or fed state. Therefore, it is unlikely that tumor growth increases FFA mobilization in these mice. Furthermore, since plasma FFA levels are determined by insulin-dependent processes, *i.e.*, hormone-sensitive lipase activity and FFA reesterification in adipose tissue (15–17) in relation to plasma FFA utilization rates, no tumor-associated insulin resistance or deficiency was apparent in our TB mice.

Although several authors have suggested that FFA mobilization is increased in TB rodents (*e.g.*, refs. 4–6), mice bearing Ehrlich ascites tumors respond normally to fasting and refeeding by raising and lowering plasma FFA levels and production rates (17), and briefly fasted lymphoma-bearing mice produce FFA at a somewhat slower than normal rate (20,21). At night (simulated), palmitate is mobilized and oxidized at an increased rate in lymphoma-bearing mice (21); however, later studies have shown that this abnormality results from anorexia rather than from defective regulatory mechanisms (Kannan, R., Gan-Elepano, M., and Baker, N., unpublished observations). Our nude mice with MX-1 tumors were not anorexic at the tumor burden studied; therefore, elevated plasma FFA mobilization rates secondary to decreased caloric intake would not be anticipated.

Elevated nocturnal mobilization of plasma FFA in anorexic lymphoma-bearing mice (21) is associated with marked loss of body fat. We have found that the mean inguinal fat pad weights of MX-1 TB mice and their nude controls do not differ significantly (Baker, N., Lin, C., Ceriani, R.L., Blank, E.W., Chengson, R.J., and Corten, C.E., unpublished observations). Apparently, the MX-1 tumor, at the present tumor burden, does not cause a net loss of body fat, a finding consistent with the normal FFA levels and responses to fasting and feeding.

We assume that nude mice bearing human mammary MX-1 tumors, like those bearing CHO tumors (1), cannot produce detectable levels of circulating TNF/cachectin because they lack T cells (2,3). This may account for their normal appetites, their apparent ability to conserve body fat, and their normal regulation of FFA mobilization from adipose TGFA. However, it is still conjectural as to whether or not endogenously generated TNF/cachectin plays any significant role with respect to FFA mobilization in TB mice or in cancer patients (22). Even the hypothesis that the lipoprotein lipase activity of adipose tissue from human cancer subjects is inhibited by TNF/cachectin has been questioned recently (23).

Defective regulation of FFA mobilization and oxidation after ingestion of multiple, small glucose test meals has been reported in humans with cancer (24). When mice are given multiple small glucose-rich test meals, each successive test meal greatly increases the efficiency with which the glucose in the next test meal is cleared from the circulation, provided that there is protein and/or other (non-fat) additives included in the complete diet (25). Whether human subjects with cancer can regulate fatty acid mobilization in a normal fashion after eating regular meals remains to be determined.

Finally, we call attention to the unique behavior of arachidonate in response to fasting and refeeding, in both control and TB mice. Apparently there is a special homeostatic mechanism that maintains the plasma FFA level of this important substrate for the cyclooxygenase and lipoxygenase pathways at a constant level under conditions in which all of the other major FFA are undergoing significant and typically large changes in concentration. Additional experiments are needed to confirm this observation in other strains of mice, as well as in other species, and to determine both the regulatory processes involved and the potential physiological significance of the phenomenon. It is generally considered that membrane phospholipids and diglycerides provide the substrate for the cyclooxygenase and lipoxygenase pathways in tissues. It would seem important to determine the extent to which plasma FFA arachidonate complexed to albumin, serves as a precursor for these pathways in various host tissues, especially in platelets, endothelial cells, and cells of the immune system, as well as in the tumor cells themselves, in each of the dietary states studied here.

Comparative Uptake of α- and γ-Tocopherol by Human Endothelial Cells

Khai Tran and **Alvin C. Chan***
Department of Biochemistry, University of Ottawa, Ottawa, Ontario, Canada K1H 8M5

The intake of γ-tocopherol by North Americans is generally higher than that of α-tocopherol. However, the levels of α-tocopherol in human blood have consistently been shown to be higher than those of γ-tocopherol suggesting differential cellular retention of the two tocopherol forms. We sought to resolve this question by studying tocopherol metabolism by human endothelial cells in culture. The time- and dose-dependent uptake of γ-tocopherol by endothelial cells was similar to that of α-tocopherol. To determine the comparative uptake between α- and γ-tocopherol, we adopted two approaches in which cells were enriched with either increasing concentrations of an equimolar mixture of α- and γ-tocopherol; or cells were enriched with a fixed concentration of tocopherols in which the α to γ ratio was varied. Our results indicated that there was a preferential uptake of γ-tocopherol by the cells. When cells were enriched with either α- or γ-tocopherol and the disappearance of individual tocopherols was monitored over time, γ-tocopherol exhibited a faster rate of disappearance. The faster turnover of γ-tocopherol can explain the discrepancy between high intake and low retention of γ-tocopherol in man.
***Lipids* 27, 38–41 (1992).**

γ-Tocopherol represents a significant portion of total tocopherol in the North American diet. Depending on the type of dietary fat used, the daily intake of γ-tocopherol can easily be twice that of the biologically more active α-form (1,2). Despite this disproportionally higher intake of γ-tocopherol, analyses by different laboratories of human plasma and blood cells consistently revealed a high alpha to gamma ratio ranging from 3.4 to 6.5 (3–5). This may suggest that the turnover rates of the two tocopherols are different and that the retention of γ-tocopherol is lower than that of the α-form.

In vivo, the tocopherols are transported by lipoproteins and the amounts present in the circulation are dependent upon a complex interplay of various physiological factors including dietary intake, absorption, peripheral clearance, hepatic secretion, and clearance of lipoprotein remnants (6–8). The biological activity of γ-tocopherol is generally thought to be lower than that of α-tocopherol, and depending on the type of bioassays used to assess bioactivity, γ-tocopherol usually possesses only 10–20% of the activity of the α-form (9,10). However, when assessed *in vitro*, γ-tocopherol has been shown to be a better antioxidant than the α-form (11,12). Thus, the biological activities of the tocopherols do not correlate well with their apparent antioxidant property.

We have recently developed a method to disperse *RRR*-α-tocopherol in culture medium, and we have used this approach to study the uptake and disappearance of α-tocopherol by endothelial cells isolated from human umbilical cord veins (13). The incorporation of α-tocopherol by these cells allows complete control of cellular tocopherol levels. This endothelial cell model thus permitted us to study the effects of tocopherol on various biochemical processes in these cells (14,15). The present paper describes the uptake and disappearance of γ-tocopherol as well as the comparative uptake of γ- and α-tocopherol by human endothelial cells.

MATERIALS AND METHODS

Materials. Medium 199 with Hank's salt and L-glutamine, heat-inactivated fetal bovine serum, sodium penicillin G (10,000 units/mL), streptomycin sulfate (10,000 μg/mL), fungizone, trypsin-EDTA, and culture flasks and dishes were purchased from Gibco (Burlington, Ontario, Canada). *All-rac*-α-tocopheryl acetate, HEPES, *i.e.* 4-(2-hydroxyethyl-1-piperazine-ethanesulfonic acid, collagenase type IV, gentamycin sulfate, and heparin (180 units/mg) were from Sigma (St. Louis, MO). Endothelial cell growth supplement was from Collaborative Research (Bedford, MA). γ-Tocopherol was a generous gift from Eisai Co. Ltd. (Tokyo, Japan). High-performance liquid chromatography (HPLC) grade solvents were from BDH Chemicals Inc. (Toronto, Ontario, Canada).

Endothelial cell cultures. Endothelial cells isolated from human umbilical veins were cultured in medium 199 as previously described (13). Medium 199, pH 7.4, was supplemented with heat-inactivated fetal bovine serum (10%), endothelial cell growth supplement (30 μg/mL), heparin (90 μg/mL), HEPES (25 mM), gentamicin sulfate (40 μg/mL), penicillin (100 units/mL), streptomycin sulfate (100 μg/mL) and fungizone (amphotericin B 2.5 μg/mL). Cells were subcultured after confluent monolayers were detached with trypsin-ethylenediaminetetraacetic acid disodium dihydrate (EDTA) (0.05%) and divided at a 1:2 split ratio. Cells from passages 1–3 were used in all experiments.

Enrichment of γ-tocopherol in culture medium. γ-Tocopherol was enriched in the culture medium in the same manner as we previously enriched α-tocopherol (13–15). Briefly, γ-tocopherol dissolved in dimethyl sulfoxide (DMSO) was added to heat-inactivated fetal calf serum (10% of medium volume). The tocopherol and the serum mixture were vortexed vigorously and incubated in the dark at 37°C for 15 min. Medium 199 and other culture reagents were then added, and the culture medium was incubated at 37°C for another 15 min, before the medium was added to the endothelial cells. The control medium contained the same amount of DMSO which did not exceed 0.1% of total culture medium.

Abbreviations: BSA, bovine serum albumin; EDTA, ethylenediaminetetraacetic acid disodium dihydrate; HEPES, 4-(2-hydroxyethyl)-1-piperazine-ethanesulfonic acid; HPLC, high-performance liquid chromatography; UV, ultraviolet.

Lipid extraction and determination of tocopherol and cell numbers. The cells were harvested by trypsinization and were washed twice with HEPES buffered saline (HBS) containing 0.1% essential fatty acid-free bovine serum albumin. The cells were resuspended in HBS and an aliquot was taken for cell counting with a hemocytometer. Total cellular lipids were extracted by the method of Bligh and Dyer (16), in the presence of *all-rac*-α-tocopheryl acetate as internal standard. Cellular tocopherols were separated by reversed phase HPLC using ultraviolet (UV) detection (280 nm). The mobile phase contained methanol/water/trifluoroacetic acid (99:1:0.1, v/v/v). The flow rate through a Bondpak C-18 column was adjusted to 1.5 mL/min. The tocopherols were quantitated by peak/height ratio relative to the internal standard (tocopheryl acetate) as described (13). Tocopherol values were expressed in nmol/10^6 cells.

RESULTS

To define the time course of γ-tocopherol incorporation, confluent endothelial cell monolayers were incubated with 23 μM γ-tocopherol for various time periods. The monolayers were then rinsed with buffer containing bovine serum albumin (BSA) to remove non-specifically bound γ-tocopherol from the cell surface, and cellular tocopherol was measured after total lipid extraction. Figure 1 shows that the uptake of cellular γ-tocopherol increased proportionally with incubation time and that after 8 hr maximum incorporation of γ-tocopherol was attained. The dose dependence of γ-tocopherol incorporation was followed by incubating confluent monolayers in medium enriched with increasing concentrations of γ-tocopherol (12–92 μM). After 4 hr, uptake of γ-tocopherol by endothelial cells was directly proportional to the amount of γ-tocopherol supplemented to the medium (Fig. 2). This time- and dose-dependence of γ-tocopherol uptake is strikingly similar to that previously observed for α-tocopherol (13).

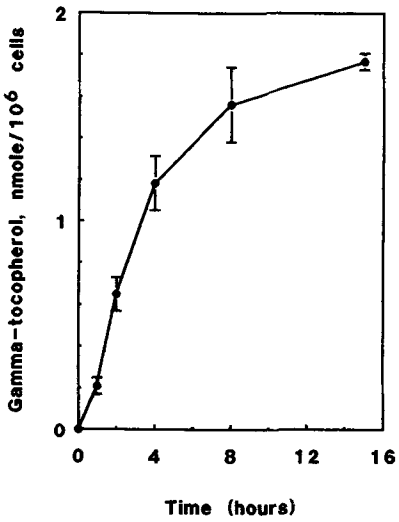

FIG. 1. Time course of γ-tocopherol incorporation by human endothelial cells. Confluent monolayers were incubated with 23 μM of γ-tocopherol; at indicated time points, cells were harvested and total lipids were extracted. Tocopherol was immediately determined by HPLC as described in Materials and Methods. Values are means ± SD of three dishes.

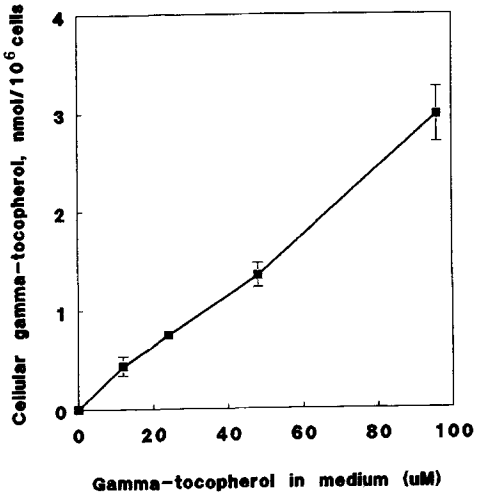

FIG. 2. Dose-dependent uptake of γ-tocopherol by human endothelial cells. Confluent monolayers were incubated with indicated γ-tocopherol concentrations for 4 hr at which time cells were harvested and total lipids were extracted. Tocopherol was determined by HPLC as described in Materials and Methods. Values are means ± SD of three dishes. Absence of deviation bars in data point denotes bars are within points.

To compare cellular uptake of α- and γ-tocopherol, we adopted two approaches in which cells were either enriched at increasing concentrations of an equimolar mixture of α- and γ-tocopherol, or the cells were enriched at a given total tocopherol concentration (46 μM) with the α to γ ratio being varied from 0.14 to 5.0. Figure 3 shows that after 4 hr of incubation with medium containing an equimolar mixture of α- and γ-tocopherol, net cellular uptake of γ-tocopherol was consistently higher than that of α-tocopherol at all concentrations tested. These data indicated that when α- and γ-tocopherol were present at equimolar concentration in the culture medium, there was a preferential uptake of γ-tocopherol. To follow up on this observation, cells were incubated for 4 hr with a 46 μM

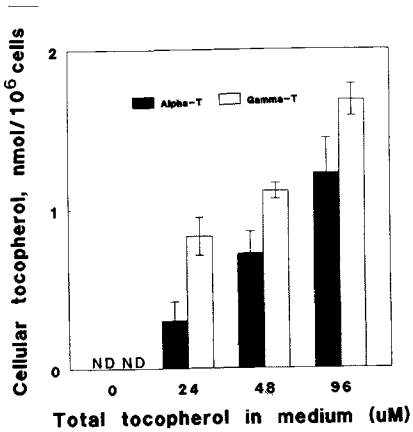

FIG. 3. Competitive uptake of α- and γ-tocopherols by human endothelial cells. Confluent monolayers were incubated with equimolar amounts of α- and γ-tocopherol. Total concentrations of α- plus γ-tocopherols are indicated on the x-axis. After 4 hr, cellular tocopherols were determined as described in Materials and Methods. Values are means ± SD of 3 dishes; N.D., not detectable.

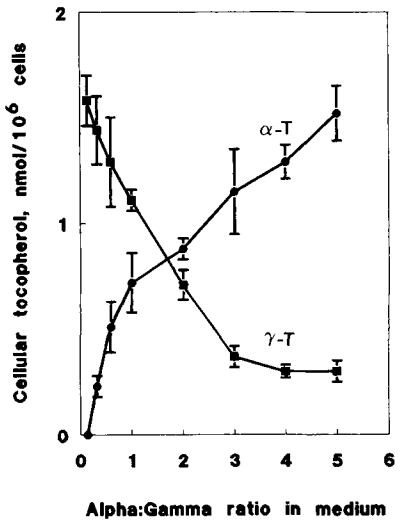

FIG. 4. Competitive uptake of α- and γ-tocopherols by human endothelial cells. Confluent monolayers were incubated for 4 hr with mixtures of α- and γ-tocopherols at the indicated α/γ ratios. Total concentration of α- and γ-tocopherol in the mixture was 46 μM. Cellular lipids were extracted and tocopherols were determined as described in Materials and Methods. Values are means ± SD of three dishes.

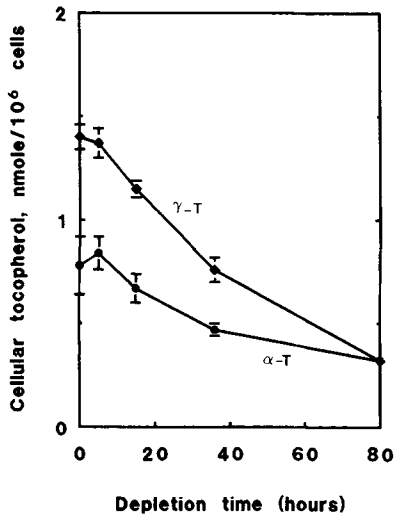

FIG. 5. Disappearance of α- and γ-tocopherol from human endothelial cells. Confluent monolayers were incubated with 23 μM of either α- or γ-tocopherol for 4 hr, after which the tocopherol-enriched media were removed. The cells were rinsed with buffer containing 0.25% BSA and reincubated with fresh culture medium without added tocopherol. At indicated time points, cells were harvested, total lipids were extracted, and tocopherol was determined as described in Materials and Methods. Values are means ± SD of three dishes.

mixture of α- and γ-tocopherol in which the ratio of α/γ was varied from 0.14 to 5.0, and incorporation of α- and γ-tocopherol into cells was measured. Figure 4 shows that the two tocopherols generally displaced each other as the α/γ ratio in the medium was varied. When the α/γ ratio was equal to 1, cellular uptake of γ-tocopherol was higher than that of α-tocopherol, and at an α/γ ratio of 2, the cells retained virtually the same amount of α- and γ-tocopherol. Thus, the preferential uptake of γ-tocopherol is clearly evident.

TABLE 1

Half-Life of α- and γ-Tocopherol Retained in Cultured Human Endothelial Cells[a]

Half-life (hr)	
α-Tocopherol[b]	γ-Tocopherol
65 ± 9	52.5 ± 5

[a] Endothelial monolayers were incubated with 23.2 μM of either α- or γ-tocopherol for 4 hr at which time the tocopherol-enriched medium was removed and replaced with fresh medium without tocopherol. Cellular tocopherol was monitored over time as described in Figure 5. The half-life was calculated from linear extrapolation of the plots as previously described (13) and values were means ± SD for 3 separate experiments.

[b] Cells were incubated with 20% fetal calf serum. The amount of tocopherol incorporated was not different at 10 or 20% fetal calf serum. Results from ref. (13).

To compare the individual rates of uptake and disappearance of α- and γ-tocopherol, cells were incubated with either α- or γ-tocopherol (23 μM) for 4 hr, and the disappearance of individual tocopherols was monitored after the culture medium had been replaced with fresh medium that was not tocopherol-supplemented. Figure 5 shows that when equal concentrations of the two tocopherols were incubated, cellular uptake of γ-tocopherol was higher than that of α-tocopherol. However, the rate of γ-tocopherol disappearance from the cells was more rapid. After 80 hr of depletion, cellular retention of the two tocopherols was similar. When the half-lives of α- and γ-tocopherol were calculated from the linear extrapolations of the disappearance curves, γ-tocopherol showed a faster rate of disappearance than did α-tocopherol. Table 1 summarizes the cumulative half-lives of α- and γ-tocopherol from several experiments. The average half-life of γ-tocopherol was 12.5 hr less than that of α-tocopherol, indicating that although the uptake of γ-tocopherol was rapid, the rate of its disappearance from the cells was also faster than that of α-tocopherol.

DISCUSSION

In a previous study, we reported the development of a human endothelial cell culture system suitable for the study of α-tocopherol uptake and disappearance (13). The usefulness of this system is enhanced by the very low amount of tocopherol present in endothelial cells isolated from human umbilical cord vein and because tocopherol becomes virtually undetectable after 2-3 cell passages. This permits studies over a wide range of tocopherol concentrations upon solubilization of the tocopherol in the culture medium aided by DMSO (13).

We sought to define the competition between α- and γ-tocopherol by using this human cell model. Figures 1 and 2 show that the uptake of γ-tocopherol as function of time and dose closely resembles that of the α-form as previously described (13). However, when examined by itself, or in different combinations with α-tocopherol, the rates of γ-tocopherol uptake (Fig. 3-4) and disappearance (Fig. 5 and Table 1) are more rapid than those of the α-form.

The mechanisms underlying the faster uptake and disappearance of γ-tocopherol are not clear at present. The

absence of a 5-methyl group on the chromanol ring of γ-tocopherol (7,8-dimethyl tocol) may render it more soluble than α-tocopherol (5,7,8-trimethyl tocol) in an aqueous medium. Conversely, the presence of a 5-methyl group in α-tocopherol may facilitate incorporation of the α-form into the membrane bilayer.

In a human study, Traber and Kayden (17) have recently demonstrated that although γ-tocopherol was absorbed as well as α-tocopherol, the plasma level of γ-tocopherol declined sharply during the post-absorptive state, indicating a faster tissue clearance of γ-tocopherol. The preferential uptake of γ-tocopherol observed in the present study may be relevant to this observation. The more rapid loss of γ-tocopherol which we observed on our present human cell model is therefore consistent with retention studies described for rat (18) and man (17). The faster turnover of γ-tocopherol may help in explaining the imbalance between high intake but low tissue retention of γ-tocopherol in humans on a typical North American diet (1–5).

ACKNOWLEDGMENTS

This work was supported by the Medical Research Council of Canada. We thank the Nursing Team of the Ottawa Civic Hospital for providing fresh umbilical cords and Joanne Barlow for typing the manuscript. *RRR*-α-tocopherol was generously donated by C. Megremis of Henkel Corporation, La Grange, IL, and *RRR*-γ-tocopherol was provided by Dr. Y. Kayamoto of Eisai Company, Tokyo, Japan.

Glutathione and Antioxidants Protect Microsomes Against Lipid Peroxidation and Enzyme Inactivation

Miao-Lin Hu and **Al L. Tappel***
Department of Food Science and Technology, University of California, Davis, California 95616

The study investigated the relationship between lipid peroxidation and enzyme inactivation in rat hepatic microsomes and whether prior inactivation of aldehyde dehydrogenase (ALDH) exacerbated inactivation of other enzymes. In microsomes incubated with 2.5 μM iron as ferric sulfate and 50 μM ascorbate, ALDH, glucose-6-phosphatase (G6Pase) and cytochrome P450 (Cyt-P450) levels decreased rapidly and concurrently with increased levels of thiobarbituric acid-reactive substances. Microsomal glutathione *S*-transferase and nicotinamide adenine dinucleotide phosphate-cytochrome *c* reductase were little affected during 1 hr of incubation. Addition of reduced glutathione partially protected and *N,N'*-diphenyl-*p*-phenylenediamine and butylated hydroxytoluene completely protected microsomes against inactivation of ALDH, G6Pase and Cyt-P450, as well as lipid peroxidation induced by iron and ascorbate. ALDH was more susceptible than G6Pase to inactivation by iron and ascorbate, and was thus an excellent marker for oxidative stress. Inhibition of ALDH by cyanamide injection of rats exacerbated the inactivation of G6Pase in microsomes incubated with 0.1 mM, but not 25 μM 4-hydroxynonenal (4-HN). 4-HN did not stimulate lipid peroxidation. Thus, 4-HN may play a minor role in microsomal enzyme inactivation. In contrast, lipid peroxyl radicals play an important role in microsomal enzyme inactivation, as evidenced by the prevention of both lipid peroxidation and enzyme inactivation by chain-breaking antioxidants.
Lipids 27, 42-45 (1992).

One result of oxidative stress is damage to membrane lipids, a process known as lipid peroxidation. Much less studied is the damage to proteins by oxidants. Possible results of protein damage include cross-linking, scission and chemical changes in individual amino acids (1). Recent studies indicate that oxidatively-damaged proteins undergo rapid proteolytic degradation, a process that has been proposed as part of the cellular secondary antioxidant defenses (2).

During oxidative stress, various reactive species, including oxygen radicals and lipid hydroperoxides, and secondary products such as aldehydes are produced. An unresolved question is whether damage to biological molecules other than membrane lipids results mainly from attack by oxygen radicals or by lipid peroxidation products (3-5). The site-specific nature of radicals and the very low steady-state concentration of hydroperoxides in living cells imply that oxygen radicals and hydroperoxides may not play a dominant role in oxidative damage (3). 4-Hydroxyalkenals such as 4-hydroxy-2,3-*trans*-nonenal (4-HN) react readily with sulfhydryl (SH) groups and are highly cytotoxic (4,6,7). Because of its relatively high concentration, diffusibility and known toxicity, 4-HN has been hypothesized as a long-sought second messenger of oxidative damage (3,4,6). However, this hypothesis has been disputed (5).

4-HN was recently suggested to impair the glutathione dependent vitamin E radical reductase, thereby stimulating microsomal lipid peroxidation (8). As aldehyde dehydrogenases (ALDH) are the major aldehyde-removing enzymes in liver (9,10), inhibition of ALDH may accentuate cytotoxic effects of reactive aldehydes generated during oxidative stress. Indeed, ALDH have been suggested as protective enzymes (11-13). In the present study we investigated the relationship between membrane peroxidation and enzyme inactivation in microsomes and tested the hypothesis that tissues devoid of ALDH activity are more susceptible to *in vitro* lipid peroxidation and to inactivation of other sensitive enzymes.

MATERIALS AND METHODS

Preparation of microsomes. Liver from rats (350-400 g) fed a standard diet were homogenized in 0.9% NaCl (20%, w/v) and centrifuged at 12,000 × *g* for 10 min at 4°C. The postmitochondrial supernatant was centrifuged at 100,000 × *g* for 60 min at 4°C. The pellet was washed in saline and centrifuged at 100,000 × *g* for 50 min at 4°C. The washed microsomal pellet was suspended in 1 mL of saline/g liver by three 20-second bursts of sonication in ice. Sonication with care to suspend the microsomal pellet is more satisfactory than homogenization and use of a detergent, as homogenization often results in some loss of samples, while use of detergent can lead to denaturation of enzymes. The average protein content as measured using the Bio-Rad method was approximately 12 mg/mL of microsomal suspension.

Incubation of microsomes with iron and ascorbate. A portion (0.5 mL) of hepatic microsomes was transferred to a serum vial that contained 3.5 mL of 0.15 M KCl/0.01 M Tris buffer (pH 7.4) such that the average protein content was approximately 1.50 mg/mL. The microsomes were incubated at 37°C with or without 1.0 mM GSH and either 0.36 mM butylated hydroxytoluene (BHT) dissolved in ethanol or 20 μM *N,N'*-diphenyl-*p*-phenylenediamine (DPPD) dissolved in dimethyl sulfoxide. The concentrations of ethanol (0.2%) and dimethyl sulfoxide (0.1%) used did not affect lipid peroxidation. The reaction was initiated by adding ascorbic acid and ferric sulfate to final concentrations of 50 and 2.5 μM, respectively. The reaction was terminated by adding EDTA and BHT to final concentrations of 1.0 and 0.45 mM, respectively. The mixture was used immediately for lipid peroxidation measurement.

*To whom correspondence should be addressed at the Department of Food Science and Technology, 109 Food Science and Technology Building, University of California, Davis, CA 95616.

Abbreviations: Aa, ascorbic acid; ALDH, aldehyde dehydrogenase(s); BHT, butylated hydroxytoluene; Cyt-*c*-Rx, cytochrome *c* reductase; Cyt-P450, cytochrome P450; DPPD, *N,N'*-diphenyl-*p*-phenylenediamine; EDTA, disodium ethylenedinitrilotetraacetate; GSH, reduced glutathione; G6Pase, glucose-6-phosphatase; GSH *S*-Tr, glutathione *S*-transferase; 4-HN, 4-hydroxynonenal; TBARS, thiobarbituric acid-reactive substances.

For enzyme measurement, the mixture was stored in ice for up to three days, during which there were no appreciable changes (± 5%) in lipid peroxidation and enzyme activities.

Injection of cyanamide and incubation of microsomes with 4-HN. Rats (250–300 g) fed a standard diet were injected *i.p.* with cyanamide (2.5 mg/0.1 mL/100 g body wt) or an equivalent volume of saline 30 min before they were killed. 4-HN (kindly provided by Dr. H. Esterbauer) was dried under nitrogen and dissolved in deionized water. Hepatic microsomes (approximately 12 mg protein/mL) from control or cyanamide-injected rats were prepared as described above. An aliquot (0.5 mL) of hepatic microsomes was added to 3.5 mL of the KCl/Tris buffer containing 0.25 mM NAD^+ in a serum vial. Incubation was carried out at 37°C for 1 hr with or without 4-HN. Reaction was slowed by storing the microsomes in ice and by adding BHT (final concentration, 0.45 mM).

Measurement of lipid peroxidation and enzyme activities. Thiobarbituric acid-reactive substance (TBARS) in microsomes were measured as described previously (14,15). Other measurements included ALDH (12), glucose-6-phosphatase (G6Pase) (16), NADPH cytochrome *c* reductase (Cyt-*c*-Rx) (17), cytochrome P450 (Cyt-P450) (18) and microsomal GSH *S*-transferase (GSH S-Tr) (19).

Statistical analysis. Data were subjected to either Student's *t*-test or analysis of variance, and mean values were compared using Duncan's Multiple Range test with an SAS program (SAS Institute, Cary, NC); $p < 0.05$ was considered significant.

RESULTS

Effect of GSH, BHT, and DPPD on lipid peroxidation and enzyme activities in microsomes incubated with iron and ascorbate. The time-course study showed that iron and ascorbate rapidly and strongly induced TBARS and decreased Cyt-P450 and the activity of ALDH and G6Pase (Fig. 1). However, iron and ascorbate only slightly decreased Cyt-*c*-Rx activity (Fig. 1) and did not affect microsomal GSH S-Tr activity (Table 1).

Inclusion of 1.0 mM GSH effectively decreased TBARS induced by iron and ascorbate (Fig. 1). GSH prevented the inactivation of ALDH and G6Pase and the loss of Cyt-P450 by 75, 49 and 40%, respectively, at the end of 1 hr incubation. GSH also slightly decreased the loss of Cyt-*c*-Rx activity. An increase of GSH to 2 mM did not result in further changes in TBARS and enzyme activities.

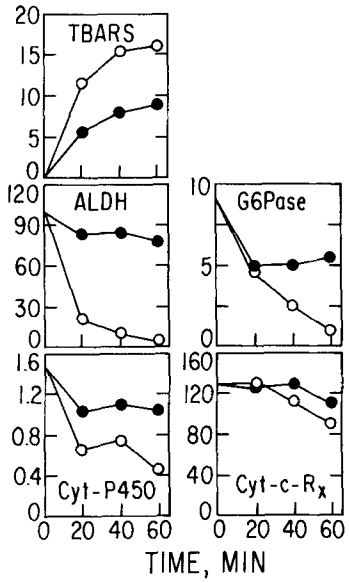

FIG. 1. Lipid peroxidation and enzyme activities in rat liver microsomes incubated with 2.5 μM ferric sulfate and 50 μM ascorbic acid at 37°C. ○, Control; and ●, 1.0 mM GSH added. Each data point is the mean of 2–4 replications of liver pooled from 3 rats. Units are (in min^{-1} mg $protein^{-1}$); TBARS, nmol; Cyt-P450, nmol; ALDH, nmol NAD^+ reduced; and Cyt-c-Rx, nmol cytochrome *c* reduced. G6Pase is μM Pi/20 min/mg protein.

Inclusion of 0.36 mM BHT or 20 μM DPPD completely inhibited lipid peroxidation induced by iron and ascorbate (Table 1). These two nonthiol antioxidants also prevented iron and ascorbate-induced loss of Cyt-P450 and of ALDH and G6Pase activities.

Effect of cyanamide injection on microsomes incubated with 4-HN. The microsomal preparations exhibited detectable activity for oxidation of 4-HN. With 0.1 mM 4-HN as substrate the activity was 10.7 ± 0.7 nmol NADH

TABLE 1

Effect of Butylated Hydroxytoluene and *N,N'*-Diphenyl-phenylenediamine on TBARS and Enzyme Activities in Hepatic Microsomes Incubated with Iron and Ascorbic Acid[a]

	Control	Fe + Aa	Fe + Aa + BHT	Fe + Aa + DPPD
ALDH	83.9 ± 3.3[b,a]	10.1 ± 2.5[b]	81.4 ± 6.2[a]	78.7 ± 1.7[a]
TBARS	0.61 ± 0.06[a]	14.0 ± 1.05[b]	0.52 ± 0.03[a]	0.45 ± 0.04[a]
Cyt-P450	1.16 ± 0.15[a]	0.60 ± 0.06[b]	1.25 ± 0.12[a]	1.28 ± 0.14[a]

[a]Microsomes (1.5 mg protein/mL) prepared from rats injected *i.p.* with 2.5 mg cyanamide/100 g body wt/0.1 mL saline or an equivalent volume of saline were incubated with 0.1 mM 4-HN for 1 hr at 37°C.

[b]Units of measurements and statistical analysis are the same as those in Table 1, except that ALDH was analyzed using Student's *t*-test (N = 3 rats).

[c]nd, Not detected.

reduced/mg protein, which was 20% of that using 1.0 mM hexanal as substrate (53.8 nmol NADH reduced/mg protein). The activity was lost in microsomes incubated with iron and ascorbate for 1 hr. 4-HN at 0.1 mM did not significantly increase TBARS in microsomes from cyanamide-treated rats as compared to those from controls (Table 2). The Cyt-P450 and the activities of Cyt-*c*-Rx and GSH *S*-Tr were slightly, but not significantly, decreased in microsomes from cyanamide treated rats. The 4-HN-induced loss of G6Pase activity in microsomes from cyanamide-treated rats was twice that in control rats. When 4-HN was added at 25 μM to the microsomes, none of the above differences was observed (data not shown).

DISCUSSION

The present studies investigated the relationship between enzyme inactivation and membrane lipid peroxidation in rat hepatic microsomes. We have studied both lipid peroxidation and enzyme inactivation induced by iron and ascorbate, as well as by 4-HN. We studied several enzymes located at different membrane sites and examined the effect of antioxidants; others had previously either examined only a single enzyme (11,20) or did not use antioxidants (21). In our studies, particular emphasis was placed on G6Pase and ALDH. G6Pase has long been known as an integral structural membrane protein (22) and also for its susceptibility to lipid peroxidation (5,22). By contrast, the sensitivity to lipid peroxidation of microsomal ALDH was discovered only recently (11,23).

In microsomes incubated with ferric sulfate and ascorbate, there was a marked increase in TBARS and a decrease in G6Pase activity. Cyt-*c*-Rx was not significantly affected by iron and ascorbate. These findings are in agreement with those of Itoh *et al.* (21). The study further showed that iron and ascorbate strongly decreased ALDH activity and Cyt-P450, but not GSH *S*-Tr, in hepatic microsomes. The time-course study showed that changes in these enzymes were concurrent with the progression of lipid peroxidation. ALDH was previously shown to be inactivated rapidly by carbon tetrachloride in hepatocytes (11), and in liver of rats injected with diethylmaleate alone and diethylmaleate followed by bromotrichloromethane (23). The present study demonstrated that ALDH was a more sensitive marker of microsomal lipid peroxidation induced by iron and ascorbate than was G6Pase.

The susceptibility of enzymes to iron and ascorbate inactivation appeared to depend upon the location of the enzyme in the microsomes. For instance, G6Pase is tightly associated with, and deeply embedded into, the hydrophobic core of the microsomal membrane (22), while Cyt-*c*-Rx (21) and GSH *S*-Tr (24) are located closer to the cytosolic surface of the microsomal membrane. Like G6Pase, the microsomal ALDH is tightly bound to the membrane and cannot be solubilized by sonication or extensive washing (9,10). Inactivation of G6Pase and ALDH thus indicates that the microsomal membrane was extensively disrupted during incubation with iron and ascorbate. Interestingly, the nonthiol antixoidants BHT and DPPD inhibited lipid peroxidation and protected enzymes against inactivation by iron and ascorbate. Similarly, dietary vitamin E protects hepatic Cyt-P450 peroxidase against *in vivo* lipid peroxidation induced by methyl ethyl ketone peroxide (25). Although the microsomal enzyme inactivation occurred rapidly and concurrently with lipid peroxidation, our data do not conclusively demonstrate that the former was caused by the latter.

SH enzymes are known to be susceptible to oxidative damage (1). While microsomal GSH *S*-Tr (24) and Cyt-*c*-Rx (17) do not depend upon SH groups for activity, the SH groups essential for activities of G6Pase (21,26), ALDH (27) and Cyt-P450 (28) may be modified readily by reactive substances produced in microsomes by iron and ascorbate. This is suggested by the observation that addition of GSH to microsomes not only decreased TBARS but also protected these enzymes against inactivation by iron and ascorbate. The activity of hepatic ALDH is highly correlated with the level of hepatic GSH in the rat (23).

In the present study we also investigated whether prior inactivation of ALDH by cyanamide accentuated inactivation of enzyme in microsomes incubated with 4-HN. Mitchell and Petersen (12,13) have reported a single ALDH isozyme in rat liver microsomes, and the purified ALDH does not metabolize 4-HN. However, we found that microsomal preparations had low, but clearly detectable,

ALDH activity using 4-HN as substrate (20% the activity using hexanal). This activity was not due to contamination from cytoplasmic isozyme since our microsomes were thoroughly washed and the activity was measured under greatly diluted condition (to 0.10 mg protein/mL of assay mixture). 4-HN added at 0.1 mM strongly inactivated G6Pase without enhancing lipid peroxidation in microsomes devoid of ALDH activity as a result of injection of rats with cyanamide. The inactivation was greatly decreased in microsomes containing active ALDH and its cofactor, NAD^+. However, there was no inactivation of G6Pase when 4-HN was added to microsomes at 25 μM (equivalent to 17 nmol/mg protein), a concentration that is 5- and 85-fold greater than that produced in rat liver microsomes incubated with carbon tetrachloride and ADP-Fe, respectively (6). Thus, our data suggest that inactivation of G6Pase by 4-HN *in vivo* is questionable, although Benedetti *et al.* (29) have attributed the inactivation of the enzyme in microsomes to long-chain aldehydes produced from lipid peroxidation. Since TBARS were not increased in microsomes incubated with 4-HN, the inactivation of enzymes by 4-HN was not attributed to stimulation of lipid peroxidation. Because 4-hydroxyalkenals, such as 4-HN, require no prior activation by the mixed function oxidase system (28), 4-HN may inactivate enzymes through its well-established reactivity with the SH groups of the enzymes. However, the following reasons show that 4-HN does not act as a major second cytotoxic messenger of lipid peroxidation: i) G6Pase was only inactivated by a rather high concentration of 4-HN; ii) the high reactivity of 4-HN with GSH, which is of the order of 10 mM in liver, renders 4-HN unlikely to damage cellular components that are remote from microsomes (10); and iii) the presence of ALDH in mitochondria, microsomes and cytosol (9,10) provide stringent protection of liver against toxic aldehydes. G6Pase may not be the most sensitive target of 4-HN toxicity. Eckl and Esterbauer (6) have recently shown that 4-HN is genotoxic at submicromolar concentrations to rat hepatocytes. It also cannot be excluded that the concentration of 4-HN in the microsomal membrane microenvironment may be locally high enough to cause enzyme inactivation.

In summary, iron and ascorbate induced microsomal enzyme inactivation and membrane lipid peroxidation, both of which were inhibited by antioxidants. Enzymes tightly bound to microsomal membrane, particularly the SH enzymes, were most susceptible to oxidative damage, and ALDH was an outstanding example. Inactivation of ALDH by cyanamide injection of rats showed that 4-HN and other aldehydic products of lipid peroxidation exacerbated inactivation of certain liver enzymes. However, 4-HN appears unlikely to play a significant role in enzyme inactivation because it inactivated G6Pase only at very high concentrations and it did not stimulate lipid peroxidation. By contrast, lipid peroxyl radicals may play a dominant role in microsomal enzyme inactivation induced by iron and ascorbate. This was evidenced by the protection of microsomes by chain-breaking antioxidants.

Nitric Oxide, an Inhibitor of Lipid Oxidation by Lipoxygenase, Cyclooxygenase and Hemoglobin

Joseph Kanner*, Stela Harel and **Rina Granit**
Department of Food Science, Agricultural Research Organization, The Volcani Center, Bet Dagan 50250, Israel

The present study demonstrated that nitric oxide, which is an important mammalian metabolite, can inhibit oxidation by lipoxygenase, cyclooxygenase and hemoglobin. The inhibition is manifested as a lag-phase that is reversible. The inhibitory effect of nitric oxide on lipoxygenase and cyclooxygenase seems to derive from i) the capability of •NO to reduce the ferric enzyme to the ferrous form, which is inactive; ii) competition for the iron site available for exogenous ligands; and iii) the radical scavenging ability of the nitroxide radical. Nitric oxide may act as a modulator of the arachidonic acid cascade and in the generation of oxygen-active species.
Lipids 27, 46-49 (1992).

Mammalian cells can synthesize nitric oxide (•NO) (1). Nitric oxide is synthesized from L-arginine by vascular endothelial cells (2), macrophages (3), the adrenal gland (4), and brain cytosol (5). The main function of •NO seems to be to stimulate the soluble guanylate cyclase to elevate cyclic guanidine monophosphate (cGMP) (6). The system activates a variety of biological functions which include endothelium-dependent relaxation, cytotoxicity of phagocytic cells and cell-to-cell communication in the central nervous system (7,8). Nitric oxide plays an important role in the cardiovascular system, not only by controlling the vascular tone but also by inhibiting platelet aggregation and platelet adhesion (9,10). •NO is thought to activate soluble guanylate cyclase through interaction with the iron of the enzyme's heme (11). In the same way •NO interacts with hemoglobin (12,13), the FeS cluster of nitrogenase (14), and FeS center proteins in *Clostridium botulinum* (15).

Inhibition of platelet aggregation by •NO is also thought to occur through stimulation of guanylate cyclase (7). Platelet aggregation is known to be affected by cyclooxygenase, which activates the arachidonic acid cascade and the production of thromboxane A_2 (TXA_2) (16). Lipoxygenase, which is present in platelets, leukocytes and many other cells, is another enzyme which affects the arachidonic acid cascade and converts arachidonic acid to leukotrienes. Leukotrienes are potent eicosanoids which, *inter alia*, cause smooth muscle contraction, bronchoconstriction, increased vascular permeability, and edema (17).

Reduced iron (Fe^{2+}), complexed by anions and especially by protoporphyrin to form heme, has a high binding affinity for, and reactivity with, •NO. The •NO reacts with the Fe^{2+} ion of heme or other complexes to yield the paramagnetic •NO/Fe complex species (13,18). Most recently, we found that nitric oxide adducts with ferrous complexes affect the Fenton reaction and prevent hydroxylation of benzoate to monohydroxy compounds (19).

Lipoxygenase and cyclooxygenase are enzymes which contain iron at the active site of the molecule (20,21). Nitric oxide, by interacting with iron at the active site, may inactivate these enzymes. The aim of this study was to demonstrate that nitric oxide acts as an inhibitor of lipid oxidation by lipoxygenase, cyclooxygenase and hemeproteins, such as hemoglobin.

MATERIALS AND METHODS

Ascorbic acid, all-*trans*-β-carotene, linoleic acid, Tween-20, diethylenetriaminepentaacetic acid (DETA), hemoglobin (bovine), and soybean lipoxygenase type I were purchased from Sigma Chemical Co. (St. Louis, MO). Sodium nitrite was obtained from BDH Ltd. (Poole, U.K.).

Nitric oxide was prepared according to the method of Bunton *et al.* (22). Ascorbic acid (0.1 M) in acetate buffer, pH 4.5, was reacted with sodium nitrite (0.2 M) under a stream of N_2. Nitric oxide generated by this reaction was transferred by the N_2 stream at a rate of 6 mL/min (corresponding to 480 nmole/min •NO) through a tube which contained the lipoxygenase, microsomal cyclooxygenase or hemoglobin in phosphate buffer, pH 7.3, for 2 min for lipoxygenase and cyclooxygenase, and for 5 min for hemoglobin, followed by a 2-min stream of only N_2. The same procedure of •NO flushing was applied to distilled water and phosphate buffer alone. Nitric oxide was quantified by a difference-spectrometric method which is based on the rapid conversion of oxyhemoglobin to metmyoglobin by •NO (23).

Bovine seminal vesicles were obtained fresh from a slaughter house. Seminal vesicle microsomes were prepared as described previously (24). Briefly, fresh seminal vesicles (250 g) taken from bovines were homogenized with a polytron in 0.25 sucrose/5 mM Tris buffer, pH 7.4, at 4°C. After removing the nuclei erythrocytes, mitochondria and cells by centrifugation, the microsomal fraction was obtained by centrifugation at 105,000 × *g* for 60 min. The sedimented microsomes were resuspended in fresh sucrose/buffer and recentrifuged. The final pellet was used for our experiments. The microsomal pellet could be kept for several weeks at −20°C without any considerable loss of activity. Microsomal cyclooxygenase activity was determined by the β-carotene bleaching assay.

β-Carotene/linoleate oxidizing activity was assayed colorimetrically (25). The technique consists of following the decrease in absorbance at 460 nm in the cuvette of a double-beam recording spectrophotometer. The test sample contained 1.5 mL of buffered carotene linoleate mixture at pH 7.3, 0.1-0.4 mL active fractions, and distilled water to a final volume of 2.0 mL. Concentrations in the initial reaction mixture were as follows: β-carotene, 14 μM;

Abbreviations: cGMP, cyclic guanidine monophosphate; Cyclo, cyclooxygenase; DETA, diethylenetriaminepentaacetic acid; Hb, hemoglobin; LPO, lipoxygenase; •NO, nitric oxide; •NO-Cyclo, nitric oxide cyclooxygenase; •NO-Hb, nitric oxide hemoglobin; •NO-LPO, nitric oxide lipoxygenase; TXA_2, thromboxane A_2.

linoleate, 2 mM; Tween-20, 0.05%; phosphate buffer, pH 7.3, 0.1 M; DETA, 0.5 mM. The blank sample contained all the reagents except β-carotene.

The assay of linoleate diene conjugation was carried out by the method described by Ben-Aziz *et al.* (26). The reaction mixture contained linoleic acid (400 μM), Tween-20 (0.05%) and DETA (0.5 mM) in 0.1 M phosphate buffer at pH 7.3. For microsomal cyclooxygenase, the assay was done after extraction of the lipid fraction and solubilization in cyclohexane. Both assay methods employed a DB Varian recording spectrophotometer (Varian Associates, Palo Alto, CA). Protein was determined by a modified Lowry method (27).

RESULTS AND DISCUSSION

Cyclooxygenase generates prostanoids *via* the stereospecific introduction of oxygen into arachidonic acid, and lipoxygenase synthesizes the oxygenated fatty acids, which are the precursors of leukotrienes. Both enzymes also could oxidize other free fatty acids containing a *cis,cis*-1,4-pentadiene structure, such as linoleic acid (28), or cooxidize β-carotene in the presence of linoleate.

Nitric oxide inhibits lipoxygenase and microsomal cyclooxygenase cooxidation of β-carotene in the presence of linoleate. The inhibition was demonstrated by an activity lag phase of almost 2 and 3.8 min, respectively (Fig. 1). The inhibitory effect of •NO on lipoxygenase activity was also demonstrated by following the accumulation of conjugated dienes during linoleate oxidation (Fig. 2). The formation of the native enzyme is essentially reversible if the •NO-Fe enzymes are treated by evacuation or N_2 flushing for 30 min (Table 1).

Deoxyhemoglobin reacts with nitric oxide to form the •NO-hemoglobin complex. The same compound is obtained when methemoglobin is reacted with nitric oxide (Fig. 3), consistent with earlier results by us and others (28). Hemoglobin partially simulated the oxidative activities of cyclooxygenase, a known hemeprotein. Hemeproteins in the presence of trace hydroperoxides are known to catalyze polyunsaturated fatty acid oxidation (29). Hemoglobin oxidizes linoleate, during which reaction β-carotene cooxidizes and conjugated dienes are formed. However, •NO-hemoglobin lost this activity (Fig. 4). •NO-hemoglobin, like lipoxygenase and cyclooxygenase, was reactivated by 30-min gassing of the complex (results not shown).

We have already shown that nitric oxide prevents the prooxidative effects of myoglobin or Fe^{2+}-cysteine toward lipid peroxidation in model systems (30,31). •NO-myoglobin and •NO-Fe^{2+}-cysteine, by themselves, act as

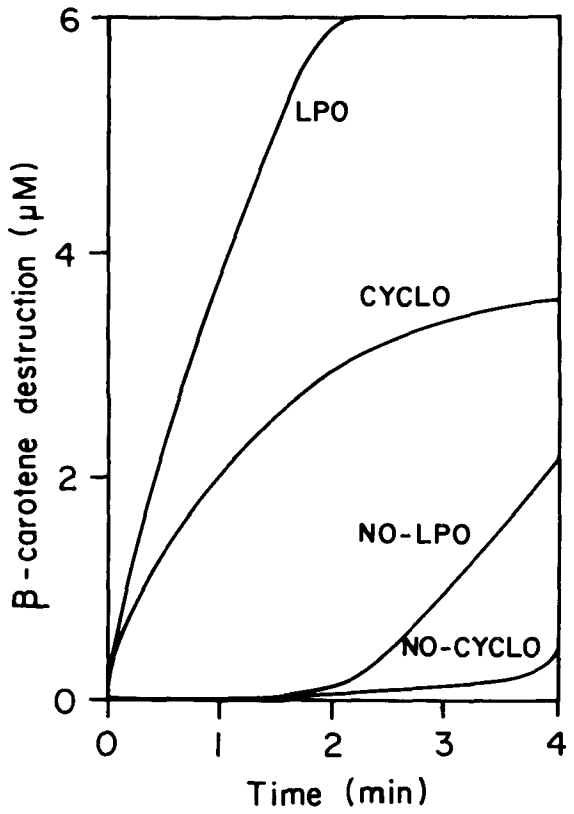

FIG. 1. Coupled oxidation of β-carotene/linoleate by lipoxygenase (LPO) (80 U/mL) and microsomal cyclooxygenase (Cyclo) (320 μg protein/mL) before and after treatment (2 min) with nitric oxide (480 nmole/min, followed by 2 min of N_2 flushing).

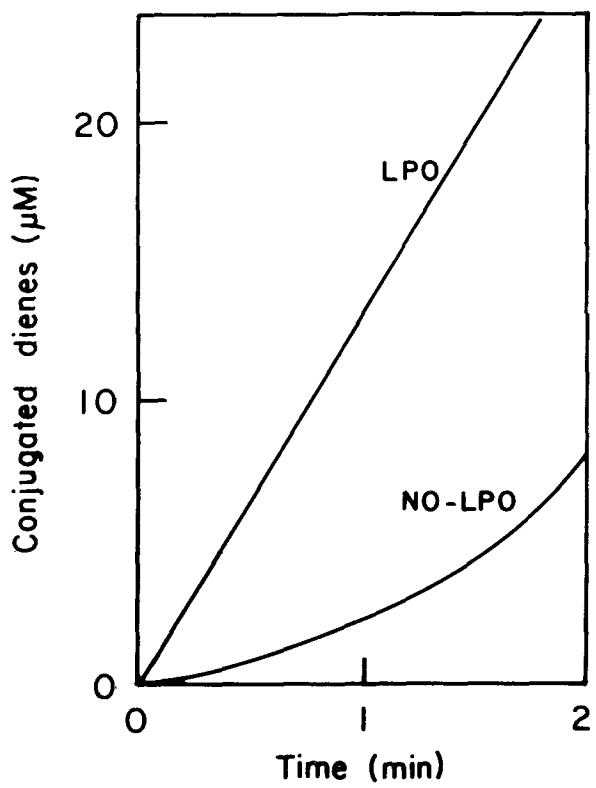

FIG. 2. Linoleate peroxidation determined by accumulation of conjugated dienes, as affected by lipoxygenase (80 U/mL) before and after treatment with nitric oxide (•NO flushing, see Fig. 1).

antioxidants. The mechanism we proposed for the antioxidative effect of the nitric oxide compounds was based on the rapid reaction of the nitroxide radical with free radicals involved in lipid peroxidation (32). Recently, Nilsson *et al.* (33) also demonstrated that nitroxide spin labels act as inhibitors of lipid peroxidation.

ESR spectra of •NO-hemoglobin were reported some

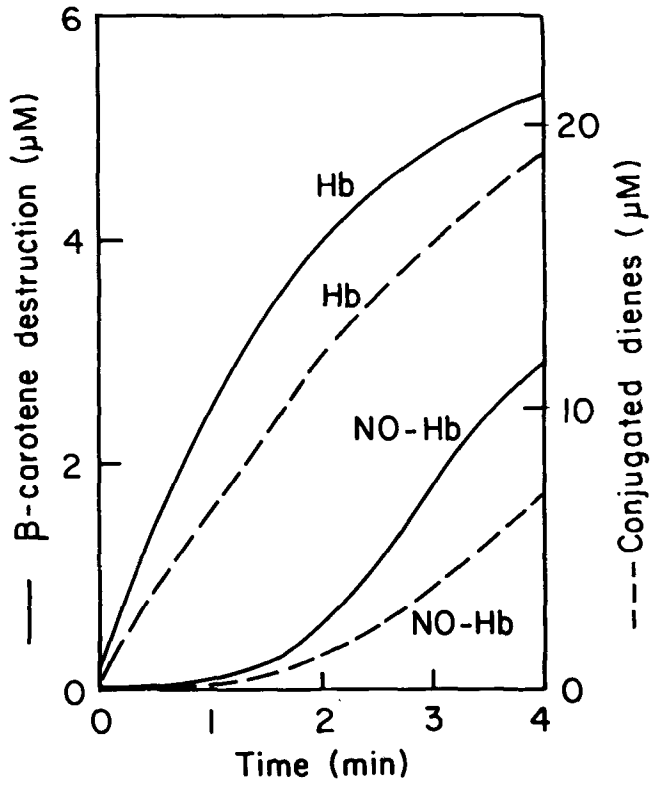

FIG. 4. Coupled oxidation of β-carotene/linoleate and linoleate peroxidation determined by accumulation of conjugated dienes as affected by hemoglobin (Hb) (2.2 μg/mL) before and after (5 min) treatment with nitric oxide (480 nmole/min, followed by 2 min of N_2 flushing).

time ago (12,13). Cyclooxygenase probably also forms a •NO-heme adduct. Lipoxygenase, which is a non-heme protein, contains iron in the active center; the ESR spectrum of •NO-lipoxygenase has been described (34,35).

The binding of linoleic acid to lipoxygenase is competitive with that of •NO at pH 9, but not at pH 7, suggesting that the affinity of ferrous lipoxygenase to •NO at pH 7 is high. In lipoxygenase there seems to be only one coordination site available at the ferrous ion for exogenous ligands (35). It is also important to note that the affinity between •NO and iron-heme is very high (36). An iron-heme without the proximal base reacts with •NO at a rate constant of 3×10^8 M^{-1} S^{-1} (37). These results suggest that the rate constant of •NO with iron-heme and non-heme compounds, especially with more open iron complexes, reaches a diffusion controlled limit.

The inhibitory effect of nitric oxide toward lipoxygenase and cyclooxygenase may stem not only from the radical scavenger ability of the nitroxide radical, but also from the capability of •NO to reduce the ferric-active enzyme to the ferrous-inactive form. The reducing capability of •NO was demonstrated with methemoglobin forming the •NO-ferrous hemoglobin. The ferrous forms of lipoxygenase and cyclooxygenase are inactive (28,38) and need to be activated to the ferric form by traces of hydroperoxides or hydrogen peroxide. The availability of a free coordination site is a stringent requirement for coordinative binding of H_2O_2 or hydroperoxides to ferrous or ferric heme proteins (39). •NO liganded to the coordination site

of iron in lipoxygenase or to the six coordination sites of iron cyclooxygenase may prevent the hydroperoxides or H_2O_2 from being bonded in a coordinating manner to the ferrous enzymes. However, it does not prevent the interaction of iron valence electrons from tg and t2g orbitals with H_2O_2 or hydroperoxide valence orbitals (28,39). These changes by •NO may decrease the activation rate of the enzymes from the ferrous to the ferric form by hydroperoxides, and explain the lag phase in •NO-enzyme activities, as shown in our study. We must consider that basal synthesis of •NO *in vivo* is continuous upon stimulation and therefore may afford extended inhibition as long as the stimulatory effect persists.

We conclude that, in addition to its stimulatory effect on soluble guanylate cyclase, nitric oxide seems to affect oxidative reactions by: i) modulating enzymes containing transition metals; ii) chelating "free" iron ions in a form which prevents or reduces the catalytic effects of the metal; and iii) scavenging free radicals. Generally, these reactions of nitric oxide may serve to protect cells from the cytotoxicity of active oxygen species, but •NO may also act as a cytotoxic compound (40,41). Since •NO has a very short life span, its overall effect seems to be dependent upon its site of biosynthesis, its concentration and the simultaneous presence of compounds containing transition metals.

Formation of Formaldehyde and Malonaldehyde by Photooxidation of Squalene

H.C.H. Yeo and **T. Shibamoto***
Department of Environmental Toxicology, University of California, Davis, California 95616

Formaldehyde and malonaldehyde were identified upon exposure of squalene to ultraviolet (UV) irradiation at 300 nm. Formaldehyde was derivatized by reaction with cysteamine to form thiazolidine; malonaldehyde was derivatized by reaction with *N*-methylhydrazine to produce *N*-methylpyrazole. The derivatives were subsequently analyzed with a gas chromatograph equipped with a fused silica capillary column and a nitrogen/phosphorus detector. The levels of formaldehyde and malonaldehyde produced increased with irradiation time. The amount of formaldehyde produced reached a maximum of 3.40 nmol/mg squalene after 7 hr irradiation; the maximum amount of malonaldehyde generated, 0.92 nmol/mg, was found after 5 hr of irradiation. Prior to this study, formaldehyde had not been reported as a photoproduct of squalene. Acetaldehyde and acetone were also detected in the irradiated squalene, which may be formed *via* a 6-methyl-5-hepten-2-one intermediate. 6-Methyl-5-hepten-2-one can also undergo breakdown to form malonaldehyde.
***Lipids* 27, 50–53 (1992).**

Lipid peroxidation, which has been linked with carcinogenicity, mutagenicity, aging, and cytotoxicity, involves production of aldehydes from lipids (1–3). Among the aldehydes formed, malonaldehyde (MA) has received the most attention. Studies have shown, for example, that mice developed carcinomas of internal organs when MA was applied to their shaved backs (4). Other studies have found MA to be mutagenic (5).

Numerous studies on the formation of aldehydes, including formaldehyde, acetaldehyde, acrolein, MA, and 4-hydroxynonenal, from fatty acids have been reported (6,7). The recent development of a highly sensitive gas chromatographic method has made the measurement of these reactive aldehydes possible (8,9).

Excessive exposure of human skin to ultraviolet (UV) radiation causes peroxidation of skin lipids (10,11). Therefore, squalene, a major lipid component of skin, may generate carbonyl compounds by reaction with UV light. Previous studies have demonstrated that a correlation exists between the amount of lipid peroxides formed and the total amount of squalene exposed to UV irradiation (12,13).

In the present study, squalene was exposed to 300 nm UV light, to stimulate exposure to sunlight, and the levels of HCHO and MA were determined by gas chromatography. In addition, the mechanisms by which HCHO and MA are formed in lipid systems were examined.

Abbreviations: GC/MS, gas chromatography/mass spectrometry; MA, malonaldehyde; 6-MHO, 6-methyl-5-hepten-2-one; NPD, nitrogen/phosphorus detector; SDS, sodium dodecyl sulfate.

MATERIALS AND METHODS

Materials. Squalene and 6-methyl-5-hepten-2-one (6-MHO) were purchased from Sigma Chemical Co. (St. Louis, MO). Cysteamine HCl, thiazolidine, sodium dodecyl sulfate (SDS), 2-methylpyrazine, and tributylamine were obtained from Aldrich Chemical Co. (Milwaukee, WI). *N*-Methylhydrazine was purchased from Fluka Chemical Co. (Ronkonkoma, NY). Dichloromethane and chloroform (reagent grade) were obtained from J.T. Baker Chemical Co. (Phillipsburg, NJ).

Standards of 2-alkylthiazolidines were synthesized according to a method published earlier (14). The purity of the standards determined by gas chromatography varied between 99.1 and 99.9%. *N*-Methylpyrazole was synthesized by a method previously reported (9) and was 99.5% pure. Stock solutions of the internal standards were prepared by adding 100 mg of tributylamine to 100 mL of chloroform, and 15 mg of 2-methylpyrazine to 100 mL dichloromethane.

Photoirradiation of squalene. Pyrex tubes each containing 172 mg of squalene, 10 mL of deionized water, and 4 mL of 5% SDS were irradiated for various time periods in a Rayonet RPR-100 Chamber Reactor. Eight lamps (300 nm wavelength) were fitted in the reactor. Several pyrex tubes containing the above mixtures were wrapped with aluminum foil and stored in a freezer to serve as controls. The irradiated and the not irradiated sample were then divided each into two equal portions for derivatization.

Photoirradiation of 6-MHO. Pyrex tubes each containing 85.5 mg of 6-MHO, 10 mL of deionized water, and 4 mL of 5% SDS were treated following the same procedure as for squalene, except that the samples were irradiated for 5 hr only.

Derivatization of formaldehyde. Cysteamine (0.6 mmol) was added to a portion of the above solutions, and the pH was adjusted to 8.5 with 1N NaOH. The mixture was stirred at 25°C for 1 hr and then extracted with approximately 12 mL of chloroform using a liquid-liquid extractor for 5 hr. The extract was then brought to a final volume of 10 mL, and 400 μL of tributylamine stock solution was added as internal standard for gas chromatography (GC).

Derivatization of malonaldehyde. N-Methylhydrazine (40 μL) was placed into the second portion of the above solutions, and the mixture was stirred for 1 hr at 25°C. The derivatives were then extracted with approximately 12 mL of dichloromethane for 3 hr using a liquid-liquid continuous extractor. Saturated NaCl was added to the aqueous layer before extraction to prevent emulsion formation. The extract was then adjusted to a final volume of 10 mL, and 150 μL of the stock solution of 2-methylpyrazine was added as an internal standard.

Instrumental analysis. A Hewlett-Packard (HP) Model 5890A gas chromatograph (Palo Alto, CA) equipped with a nitrogen/phosphorus detector (NPD) and a 30 m × 0.25 mm i.d. × 0.25 μm film thickness bonded phase DB-1 fused silica capillary column (J & W Scientific, Folsom, CA)

was used for the quantitation of the thiazolidine derivative of HCHO. The GC peak areas were integrated by a Spectra-Physics Chromjet Integrator (San Jose, CA). Oven temperature was held at 80°C for 2 min and then programmed to 200°C at 8°C/min. Injector and detector temperatures were 250°C and 300°C, respectively. Linear velocity of helium carrier gas was 25.5 cm/sec at a split ratio of 55:1.

An HP 5880 GC equipped with an NPD and a 30 m × 0.25 mm i.d. × 0.25 μm film thickness bonded phase DBWAX fused silica capillary column (J & W Scientific) was used for the analysis of the *N*-methylpyrazole derivative of MA. The GC peak areas were integrated by an HP 3390A integrator. The oven temperature was held at 35°C for 2 min and then programmed to 190°C at 4°C/min. Injector and detector temperatures were 250°C and 300°C, respectively. Linear velocity of helium carrier gas was 35.5 cm/sec at a split ratio of 30:1.

An HP model 5890 GC interfaced to a VG Trio II mass spectrometer with a VG 11-250 computer data system was used for mass spectrometric identification of the GC components. The ionization voltage was 70 eV, and the ion source temperature was 150°C. The column and oven conditions for gas chromatography/mass spectrometry were as described for the GC/NPD analysis.

RESULTS AND DISCUSSION

Figure 1 shows a typical gas chromatogram of the thiazolidine derivatives obtained from squalene after ultraviolet (UV) exposure. In addition to HCHO, other monocarbonyl compounds, such as acetaldehyde and acetone, were detected as 2-methylthiazolidine (peak 4) and 2,2-dimethylthiazolidine (peak 5), respectively. The two peaks after peak 8 are SDS breakdown products.

The *N*-methylhydrazine derivative of MA was detected as *N*-methylpyrazole. *N*-Methylhydrazine reacts with α,β-unsaturated aldehydes such as acrolein to form *N*-methylpyrazoline. Acrolein, however, was not detected in this study.

The levels of HCHO and MA formed after various irradiation times are presented in Figure 2. The levels of these aldehydes were increased by UV irradiation. The maximum amount of HCHO was formed after 7 hr of irradiation and was four times the control level. The maximum amount of MA formed was ten times the control level and occurred after 5 hr of irradiation. The results obtained for MA were consistent with those reported previously (15).

In the present study, formaldehyde was detected as a peroxidative product of squalene. Formaldehyde has previously been reported to crosslink with DNA and nucleoproteins (16–18), possibly leading to carcinogenicity. In addition, formaldehyde has been implicated as an animal and human carcinogen (19–22) and has been shown to cause dermatitis in rats (23).

Other volatile aldehydes observed are shown in Table 1. After 7 hr of irradiation, acetaldehyde was the major aldehyde formed, followed by HCHO, acetone, and MA. In the control sample, HCHO and acetone were formed in relatively low amounts (less than 1.3 nmol/mg squalene) while acetaldehyde was produced in relatively high amounts (1.70 nmol/mg squalene). The formation of acetone as a product of lipid peroxidation *in vivo* has been reported (24). Studies have also associated the accumulation of acetone with diabetes mellitus (25). The precursor of acetone in these studies, however, is still unclear.

The presence of 6-MHO was observed only in the irradiated squalene samples, suggesting that 6-MHO is a possible intermediate in the formation of the low-molecular-weight volatile carbonyl compounds from squalene. The amount detected was approximately 120

Volatile Peroxidation Products Recovered from 6-Methyl-5-hepten-2-one (6-MHO) After 5 hr of UV-Irradiation

	6-MHO (nmol/mg)[a]	
Compound	Dark	Irradiated
Formaldehyde	<1.30	4.14
Acetaldehyde	1.84	4.22
Acetone	<1.30	3.95
Malonaldehyde	0.65	1.28

[a]Values are means of two replicates.

μg after 6 hr of UV irradiation. The proposed mechanism for the formation of 6-MHO from squalene is shown in Figure 3. The formation of 6-MHO results from the abstraction of a proton from the C-8 carbon of squalene. This is followed by the generation of a 6-hydroperoxide intermediate, which undergoes cleavage between the C-6 and C-7 carbon-carbon bond.

Samples with 6-MHO were irradiated by UV for 5 hr to examine the formation of volatile carbonyl compounds from 6-MHO. The results are shown in Table 2. Among the carbonyl compounds quantitated, acetaldehyde had the highest level in the control samples. The amounts of HCHO, acetaldehyde, and acetone produced in irradiated samples were significantly higher than those of MA. Similar to samples from irradiated squalene, acrolein was also not detected in the irradiated 6-MHO samples. The observation further indicates that 6-MHO is a possible intermediate of volatile carbonyls.

In our study, MA was formed from a compound with only one double bond. Earlier studies proposed the formation of MA *via* a cyclic peroxide (26). Later, MA was proposed to form through a bicyclic endoperoxide intermediate (27). This widely accepted mechanism requires at least three methylene-interrupted double bonds for the formation of MA. However, our results with 6-MHO imply that compounds with one double bond could also produce MA. There may be an alternative route involving compounds with less than three double bonds, as is the case with 6-MHO. Studies on the formation of MA from precursors with one double bond have been reported (6,28). Other studies have demonstrated the formation of malonaldehyde from unsaturated carbonyl compounds (29).

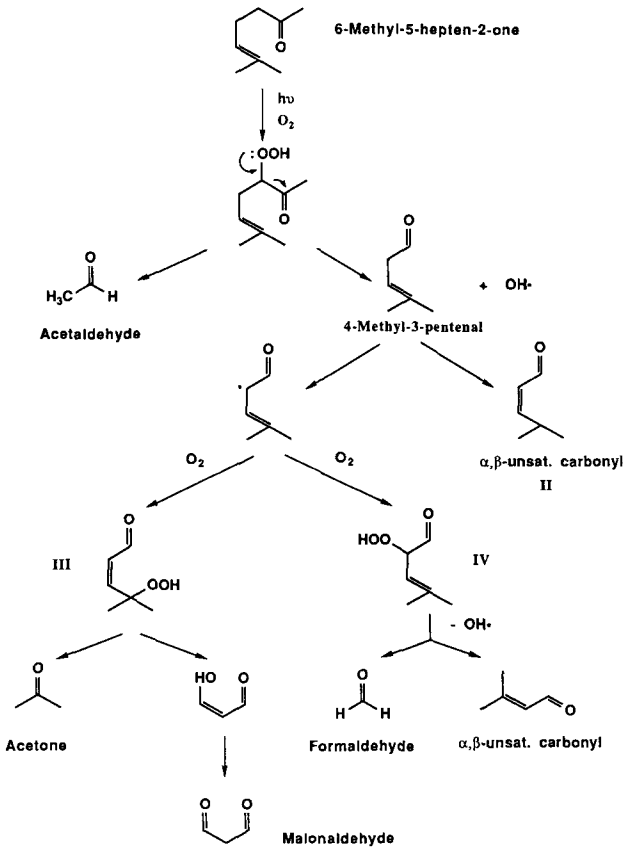

FIG. 4. Proposed formation of volatile carbonyls from 6-methyl-5-hepten-2-one upon UV irradiation.

The proposed mechanism of formation of the various carbonyl compounds identified in this study is shown in Figure 4. The formation of acetaldehyde involves the initial abstraction of a proton from 6-MHO. The resulting hydroperoxide may then undergo decomposition to form acetaldehyde and 4-methyl-3-pentenal intermediate **I**. 4-Methyl-3-pentenal was not detected as it may have undergone further reaction to form HCHO, MA, and acetone, or it may have isomerized to **II**, an α,β-unsaturated aldehyde. Similarly, abstraction of a proton may occur on 4-methyl-3-pentenal to form either 4-hydroperoxide **III** or 2-hydroperoxide **IV** intermediates. Subsequently, intermediate **III** undergoes chain-scission type reactions to form acetone and malonaldehyde (30); and intermediate **IV** would form HCHO.

Although squalene is one of the major components of the skin, composing 5% of the skin surface lipids (31), few reports have appeared on the mechanisms by which reactive aldehyde may form upon lipid peroxidation. Some

studies have demonstrated that squalene is the major source of lipid peroxide in the skin surface (10,11). Further studies will be necessary to establish the relationship between lipid peroxidation and the formation of toxic aldehydes that can cause skin damage.

Acute Toxicity of *trans*-5-Hydroxy-2-nonenal in Fisher 344 Rats

Akiyoshi Nishikawa, Rama Sodum and **Fung-Lung Chung***
Division of Chemical Carcinogenesis, American Health Foundation, Valhalla, New York 10595

The potential toxicity of *trans*-4-hydroxy-2-nonenal (HNE), a product formed *in vivo* during lipid peroxidation, which is also present in foods, was investigated in Fisher 344 rats. Five groups of five male rats each were given by gavage 1000, 300, 100, 30 or 10 mg/kg body weight HNE dissolved in 0.5 mL corn oil. The sixth group, the control, received corn oil alone. Two rats died 6 and 8 hr after being treated with 1000 mg/kg HNE. These two rats showed extensive acute tubular necrosis of the kidney, but had very little liver damage. Diffuse liver cell necrosis was observed in a dose dependent manner in all the rats killed 14 days after treatment, whereas renal change was mild. Interestingly, body weight of the lowest dosage group was significantly higher than that of the control group at termination of the experiment. The results of this study show that HNE has almost the same toxicity as other enals, such as *trans*-2-heptenal, and that kidney and liver are the main organs affected by toxicity of HNE. Although animals may have efficient defense systems, such as glutathione, to detoxify low to moderate dosages of HNE, at high doses of HNE this defense system is overwhelmed, resulting in serious renal and hepatic damage.
Lipids 27, 54-58 (1992).

Some lipid peroxidation products generated by oxygen radicals cause various types of cell injury (1,2). Benedetti *et al.* (2) have suggested that *trans*-4-hydroxy-2-nonenal (HNE) is a major diffusible toxic product of lipid peroxidation; such enals are believed to act as secondary toxic messengers for free radicals (2-6). *In vitro* studies have shown that HNE can damage functional proteins and DNA, cause cell lysis and disturb cellular reproduction (6-10). In addition to its generation during lipid peroxidation, small amounts of HNE are found in various foods and oils (11,12). Some analogous enals of HNE, such as *trans*-2-heptenal, *trans,trans*-2,4-hexadienal and *trans*-4-hydroxy-2-hexenal, which are also present in foods, have been shown to be toxic (13,14). The median lethal dose (LD_{50}) of HNE given intraperitoneally to mice has been estimated to be 68 mg/kg of body weight (15), but the potential toxic effects of oral administration of this enal are not clear. In the present study, the lethal dose of HNE was determined in male Fisher 344 rats. The results of detailed histopathological examination of the major organs are discussed.

MATERIALS AND METHODS

HNE was synthesized according to the method described by Esterbauer *et al.* (16). The purity was greater than 99% as indicated by thin-layer chromatography, high-performance liquid chromatography, and nuclear magnetic resonance spectroscopy. Thirty, seven-week-old male F344 rats were purchased from Charles River Breeding Laboratories (Kingston, NY). Rats were separated into 6 groups and housed 2-3 per cage in polycarbonate cages with hardwood bedding under standard conditions (20 ± 2°C; 50 ± 10% relative humidity; 12 hr/12-hr light/dark cycle). Before the experiments, animals were fed NIH-07 diet and given tap water for six days. After overnight starvation, each group (consisting of five rats) was given a different treatment. The control group was given 0.5 mL corn oil only. The other five groups were given by gavage 1,000, 300, 100, 30 or 10 mg/kg body weight of HNE dissolved in 0.5 mL corn oil. After the treatment, rats were kept on NIH-07 diet and tap water *ad libitum,* and body weights were measured every three or four days. Animals were sacrificed and a complete autopsy was performed 14 days after gavage. All the main organs were weighed. Most of the organs were collected and fixed in 10% neutral-buffered formalin for routine histological processing and light microscopic evaluation of sections stained with haematoxylin and eosin. The extent of necrosis in the liver and kidney was interpreted according to the criteria described by Mitchell *et al.* (17) and Mizutani *et al.* (18), respectively. The statistical significance was evaluated by Student's *t*-test.

RESULTS

Two rats given 1,000 mg/kg body weight of HNE died six and eight hours after the treatment, respectively. The other animals remained alive until the termination of the experiment. Thus, the LD_{40} of HNE given orally in Fisher rats was estimated as 1,000 mg/kg, although the number of animal used in this study is low. The body

Summary of Histopathology of the Liver and Kidney

	Hepatic necrosis[a]					Renal necrosis[b]				
HNE treatment	0	1+	2+	3+	4+	0	1+	2+	3+	4+
1,000 mg/kg	0	2[c]	2	1	0	0	3	0	0	2[c]
300 mg/kg	0	0	5	0	0	0	5	0	0	0
100 mg/kg	0	2	3	0	0	0	5	0	0	0
30 mg/kg	3	2	0	0	0	1	4	0	0	0
10 mg/kg	5	0	0	0	0	5	0	0	0	0
Control	5	0	0	0	0	5	0	0	0	0

[a,b]The extent of hepatic necrosis and renal tubular necrosis was scored according to the criteria described by Mitchell *et al.* (17) and Mizutani *et al.* (18), respectively. [c]Rats found dead.

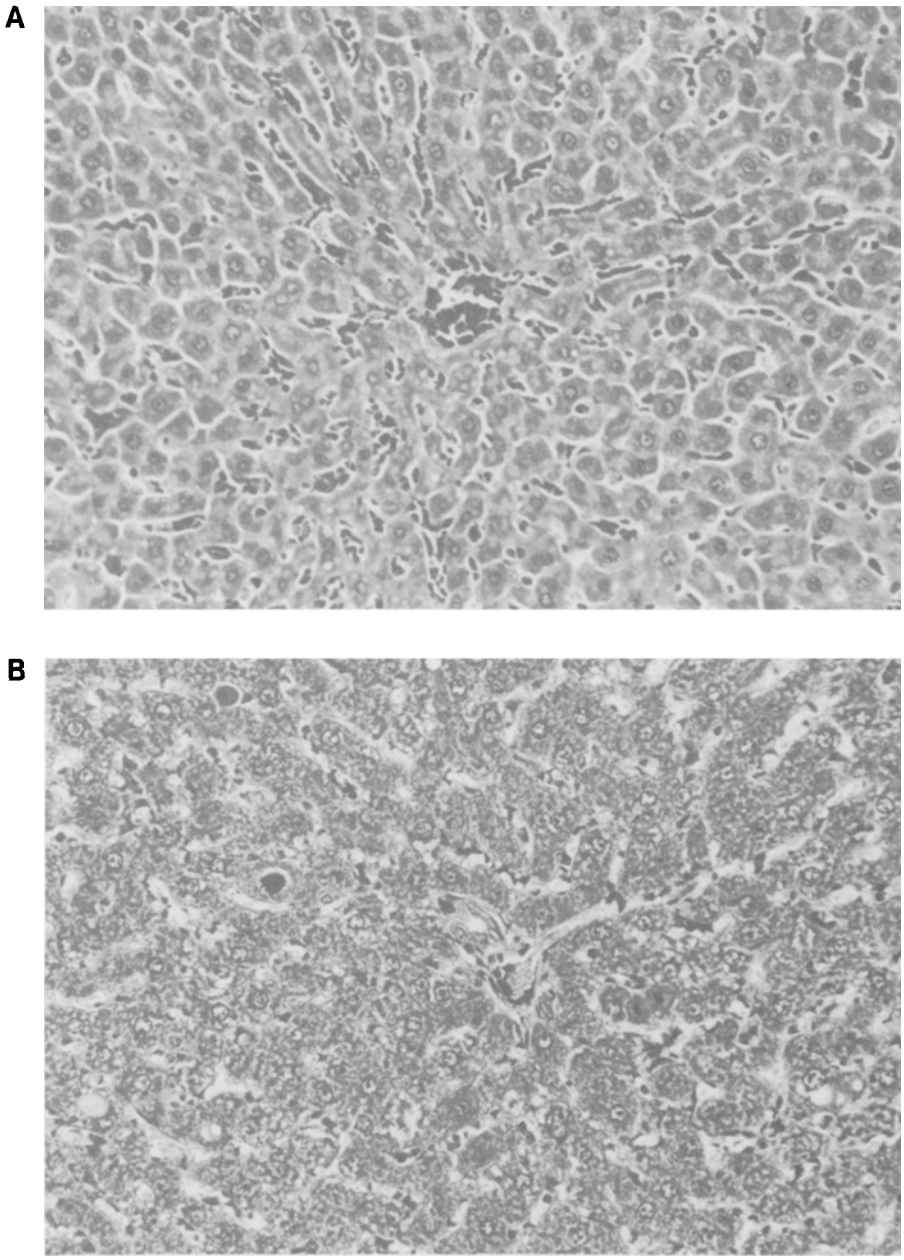

FIG. 2. Histopathology of the liver of a rat treated with 1,000 mg/kg of HNE (a) found dead 6 hr after gavage; and (b) killed at termination. (a) Although marked congestion is seen, mild liver cell necrosis is noticed around the central vein. H-E X250. (b) Moderate liver cell necrosis is seen diffusely and several mitoses are scattered. H-E X250.

weight of the two rats that died early in the experiment markedly decreased after treatment (from 164 g to 140 g and from 168 g to 1442 g, respectively). Body weight curves of the other animals are shown in Figure 1. Body weight gain of rats receiving 1,000 mg/kg and 300 mg/kg of HNE was reduced at the beginning of the experiment, but almost normalized at termination. Rats given 100 mg/kg showed no substantial change in body weight gain compared with the control group. Interestingly, the body weight of rats given 10 mg/kg of HNE was significantly higher than that of the control group ($p<0.05$) at the termination of the experiment, as is shown in Table 1. As for the absolute and relative organ weights of rats killed at the end of the experiment, there were no significant differences between the groups except that the testis of rats given 1,000 mg/kg of HNE was significantly heavier than that of control rats.

Histopathological findings of the liver and kidney are summarized in Table 2. Extensive acute tubular necrosis (moderate to severe) was seen in the kidneys of the dead rats. However, hepatic necrosis was observed only around the central vein of the liver (Fig. 2). The two rats that died early in the experiment showed hemorrhages in the endocardium and thymus, and congestion in the lung, spleen, testis and brain. The other rats given 1,000 mg/kg of HNE revealed moderate hepatic necrosis which was

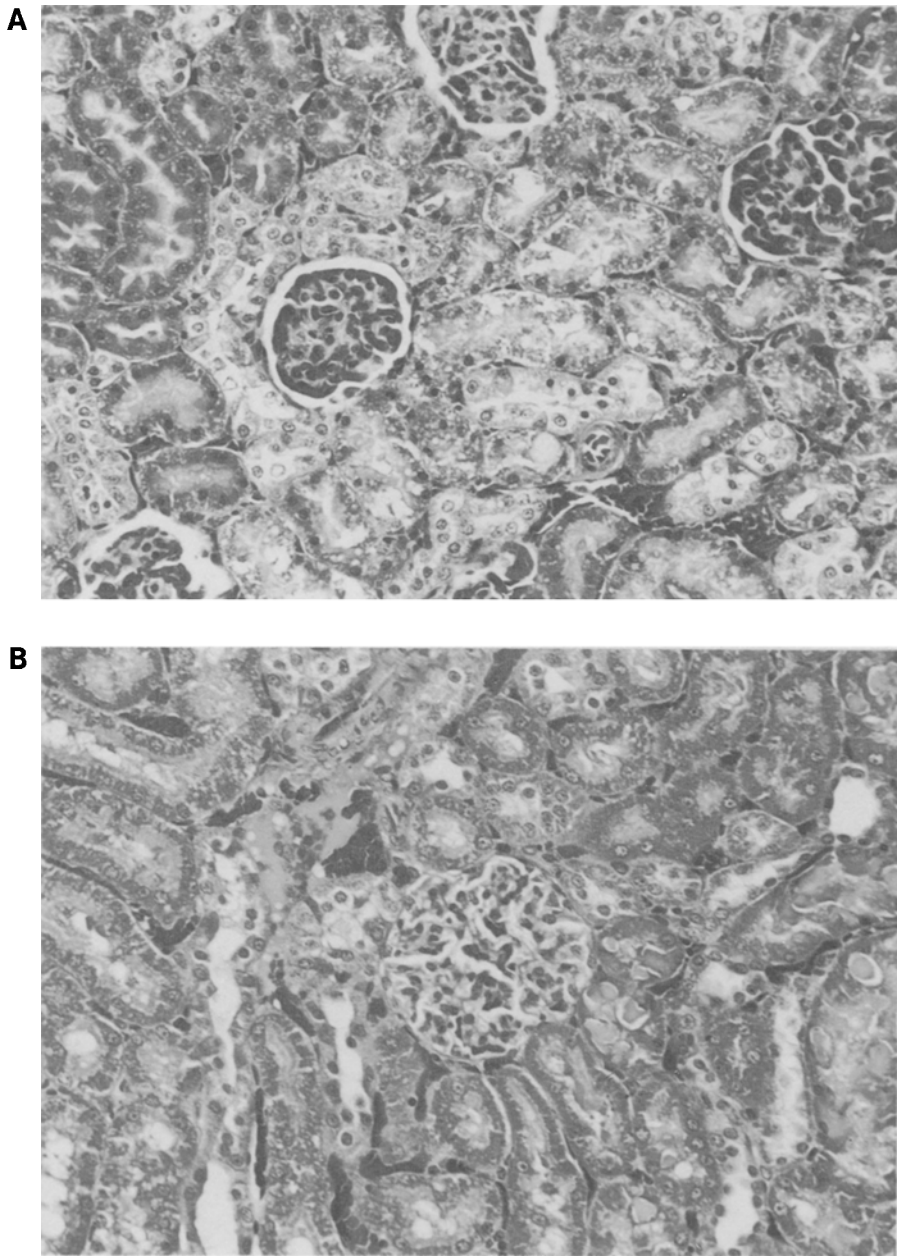

FIG. 3. Histopathology of the kidney of a rat treated with 1,000 mg/kg of HNE (a) found dead 6 hr after gavage; and (b) killed at termination. (a) Moderate to severe acute tubular necrosis is noticed mainly in the paraqcortical area. (b) Mild tubular necrosis is seen in the paracortical area. H-E X250.

seen diffusely, but most extensively, around the central veins. Such changes in the liver were recognized in all treated animals and the extent of lesions depended upon the dosage of HNE. Acute tubular necrosis was not significant in the kidney of rats in all groups killed at the termination of the experiment (Fig. 3). Thus, hepatotoxicity increased dose-dependently, but renal toxicity did not.

DISCUSSION

HNE is an endogenous aldehyde generated during lipid peroxidation, which is also present in small quantity in certain foods consumed by humans (19). Our results suggest that the LD_{40} of HNE given orally to male F344 rats is approximately 1,000 mg/kg body weight, which agrees with the LD_{50} (1,300 mg/kg) of *trans*-2-heptenal given orally to rats (9). However, a larger population of animals and oral doses higher than 1,000 mg/kg would be required for a more accurate estimation. Some autoxidation products of linoleic acid cause hepatotoxicity (20). Segall *et al.* (14) also have reported extensive hepatotoxicity of *trans*-4-hydroxy-2-hexenal, a reactive metabolite from the macrocyclic pyrrolizidine alkaloid senecionine, when it was injected into the portal veins of rats. HNE and *trans*-4-hydroxy-2-hexenal are homologous aldehydic products of lipid peroxidation. The former is produced from the ω-6 polyunsaturated fatty acids (PUFA), linoleic acid, arachidonic acid and γ-linolenic acid, whereas the latter is formed from the ω-3 PUFA, α-linolenic acid and docosahexaenoic acid (21–23). Our study shows for the first time that oral intake of a high dose of HNE can cause lethal renal damage before severe hepatic damage occurs. These results suggest that the secondary autoxidation product administered at a high dose overwhelmed the liver's capacity to serve as the first clearance (24). The time lapse before death occurs depends on the maximal incorporation time into rat kidney of the orally administered radioactive products (20). Tubular necrosis was not extensive in all the kidneys of rats killed at the end of the experiment, perhaps due to recovery from the lesion. Histochemical analysis of renal tubular damage at intermediate time points during the experiment could be useful to determine whether recovery from acute damage occurs. Although the incidence of mortality shows that a threshold for HNE toxicity in the kidney exists, the dose-dependent damage observed in the liver of rats sacrificed at the end of the experiment suggests that the liver is the primary target organ for HNE toxicity. Recently, Oarada *et al.* (25) have found that dietary lipid hydroperoxide causes severe lymphocyte depletion in the thymus. In our study, bleedings were noted in the thymus of the rats that died early in the experiment.

Animals may have adequate defense systems to detoxify aldehydic products of lipid peroxidation, such as HNE (26). HNE is a good substrate of cytosolic nicotinamide adenine dinucleotide (NAD)-dependent alcohol dehydrogenase, aldehyde dehydrogenase and glutathione transferase (27–29). However, the results of this study show that excessive HNE can cause acute and extensive renal or hepatic toxicity. Conjugation involving glutathione has been regarded as a major pathway for detoxification of HNE (5). White and Rees (30) have suggested that HNE toxicity is a result of increased lipid peroxidation which depletes glutathione levels. Measurement of glutathione would be helpful to determine whether depletion of this important antioxidant is necessary for acute renal toxicity of HNE to occur. Our study also shows that low doses of HNE appeared to increase body weight gain, which may be related to regulatory functions in cell division (31). HNE is a homologue of crotonaldehyde which has been known to induce liver tumors in F344 rats (32); therefore, chronic toxicity and carcinogenicity of HNE should be studied to assess its potential role in hepatocarcinogenesis. The results of this study also suggest the possibility of renal tumorigenesis by HNE in rats.

ACKNOWLEDGMENTS

We thank Dr. Michael Iatropoulos for useful suggestions in regard to the histopathological evaluations and Dr. Yong Xu and Ms. Yin Liu for excellent technical assistance.

Preparation and Properties of *gem*-Dichlorocyclopropane Derivatives of Long-Chain Fatty Esters

Marcel S.F. Lie Ken Jie* and **C.F. Wong**
Department of Chemistry, University of Hong Kong, Hong Kong

Methyl oleate (18:1) and linoleate (18:2) were readily transformed to the corresponding *gem*-dichlorocyclopropane derivatives in high yield, using triethylbenzylammonium chloride as the phase-transfer catalyst in the presence of aqueous NaOH and $CHCl_3$. Reaction of dichlorocarbene with methyl 12-hydroxystearate furnished methyl 12-chlorostearate (49%) and 12-*O*-formylstearate (19%). The hydroxy group in methyl ricinoleate was protected (*O*-tetrahydropyran-2′-yl) prior to dichlorocyclopropanation of the ethylenic bond. Removal of the protecting group allowed the hydroxy group to be converted to a chloride, *O*-acetyl, azido or *O*-formyl function. Treatment of methyl ricinoleate with thionyl chloride, followed by the reaction with dichlorocarbene gave the corresponding 12-chloro-dichlorocyclopropane derivative. The dichlorocyclopropane derivative of oleic acid was transformed to a C_{19} allenic fatty acid when treated with *t*-butyl lithium. However, the remaining dichlorocyclopropane derivatives, containing an additional functional group in the alkyl chain, failed to yield the corresponding allenic derivatives. All derivatives were characterized by a combination of spectroscopic and chromatographic techniques, including infrared, ^1H nuclear magnetic resonance (NMR), and ^{13}C NMR spectroscopy.
***Lipids* 27, 59–64 (1992).**

Cyclopropane fatty acids are more commonly found in microorganisms than in plants (1). Lactobacillic acid (*cis*-11,12-methyleneoctadecanoic acid) is commonly found in bacterial lipids (2,3) and mycolic acids are complex fatty acids of high molecular weights occurring in a wide range of micro-organisms containing one or more cyclopropane rings (4). Many eubacteria, such as *Escherichia coli*, modify their membrane phospholipids during the onset of the stationary phase by transforming the ethylenic centers in the fatty acid components to cyclopropane groups (5). *S*-Adenosylmethionine has been shown to effect the formation of the cyclopropane system from unsaturated fatty acid precursors. The function of these unusual fatty acids remains a matter of speculation. It has been postulated that the cyclopropane system preserves the configuration of the ethylenic bond in the fatty acid molecule and prevents autoxidation of the phospholipids in the organism (6,7). More recently, studies on the cloning and manipulation of the *E. coli* cyclopropane fatty acid synthetase gene have been reported (8,9). The relationship between cyclopropane synthetase and the formation of cyclopropane fatty acids by *Proteus vulgaris*, grown under various respiratory conditions, have also been studied (10).

Some long-chain cyclopropane fatty acids, such as dihydrosterculic acid (*cis*-9,10-methyleneoctadecanoic acid), have been identified in the lipid extract of *Euphoria longana* (11) and from *Litchi sinensis* (*Fam. Sapindaceae*) seeds (12). Dihydromalvalic acid (*cis*-8,9-methyleneheptadecanoic acid) has been found in the seed oil of *Hibiscus syracus* (*Fam. Malvaceae*) (13) and from *Brachychiton acerifolium* (*Fam. Sterculiaceae*) (14). A C_{10} cyclopropane fatty acid, *cis*-3,4-methylenedecanoic acid, has been identified in Cascarilla essential oil (15).

Gunstone and Perera (16) have synthesized the entire series of positional isomers of C_{18} cyclopropane fatty esters using the classical Simmons-Smith method (17). A recent modification to the cyclopropanation procedure involves the use of ultrasound to accelerate the rate of reaction (18–21). We report in this paper the preparation of *gem*-dichlorocyclopropane fatty ester derivatives of methyl oleate, linoleate, ricinoleate (12-hydroxy-*cis*-9-octadecenoate) and methyl 12-oxo-*cis*-9-octadecenoate. We have examined the nuclear magnetic resonance (NMR) spectroscopic properties of such dichlorinated cyclopropane fatty ester derivatives and have evaluated the procedure for obtaining allenic fatty esters *via gem*-dichlorocyclopropane intermediates (22). Only a few long-chain allenic fatty acids have been isolated from seed oils so far, and include laballenic acid [(*R*)-5,6-octadecadienoic acid] in the oil of *Leonotis nepetaefolia* (23) and lamenallenic acid (5,6 *trans*-16-octadecatrienoic acid) in the oil of *Lamium purpureum* (24).

A number of procedures have been reported for the synthesis of dichlorocarbene species for reaction with ethylenic bonds to obtain *gem*-dichlorocyclopropane derivatives, which involve anhydrous, homogenous reaction conditions (25,26). Kenney *et al.* (27) have prepared the dichlorocyclopropane derivatives of methyl oleate, elaidate and linoleate using an alkoxide in chloroform or in ethyl trichloroacetate. More recent developments have made use of phase-transfer catalysts, which not only enhance the yield of the products, but also permit reactions to take place under heterogenous conditions (28–31). We have adopted the phase-transfer catalytic method for the preparation of the *gem*-dichlorocyclopropane fatty ester derivatives as presented in Scheme 1, which shows the synthesis of *gem*-dichlorocyclopropane C_{18} derivatives from methyl oleate, linoleate and ricinoleate.

RESULTS AND DISCUSSION

Dichlorocarbene species were readily generated *in situ* by using a catalytic amount of triethylbenzylammonium chloride as the phase-transfer catalyst in the presence of aqueous NaOH and chloroform as described by Makosza and Wawrzyniewicz (28). By this method, methyl oleate and linoleate were transformed into the corresponding dichlorocyclopropane C_{18} derivatives **1** (78%) and **2** (93%), respectively.

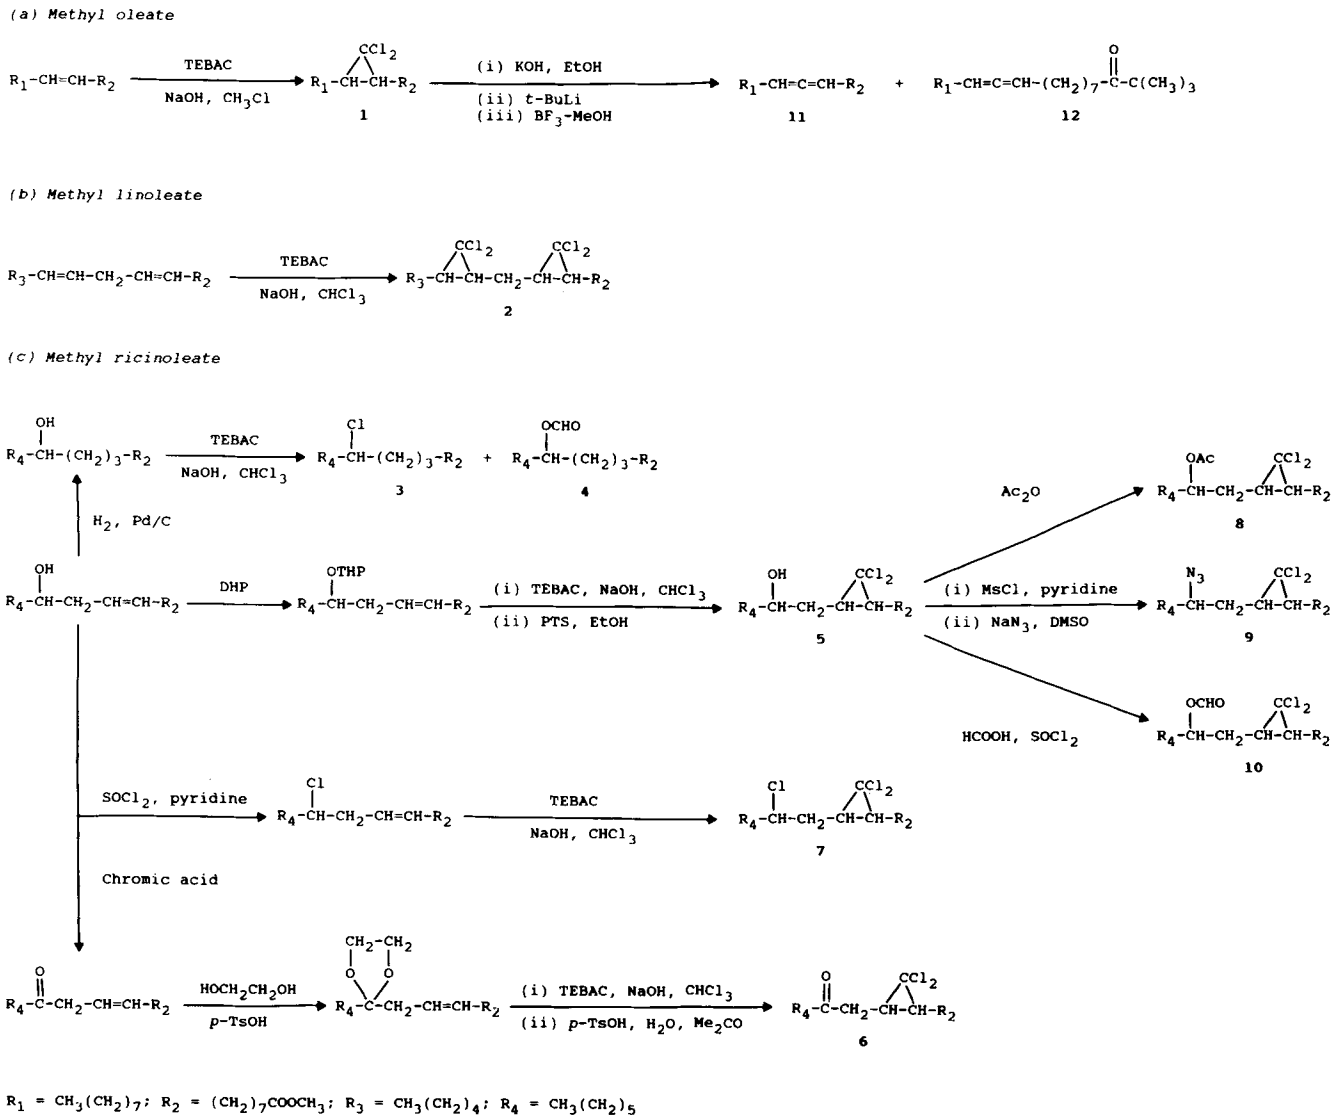

SCHEME 1

When methyl ricinoleate was reacted with dichlorocarbene, a complex mixture of products was obtained which could not be separated into individual components by silica gel thin-layer chromatography (TLC). The gas-liquid chromatographic (GLC) analysis of the crude product on SE-30 stationary phase showed the presence of at least three major components. The ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra of the crude product showed an unexpected signal at δ 8.1 (*s*) and 160.8 ppm, respectively, suggesting the presence of an *O*-formyl function (-OCH=O). Methyl ricinoleate was hydrogenated to yield methyl 12-hydroxystearate, and the latter compound was reacted with dichlorocarbene generated from a mixture of triethylbenzylammonium chloride, aqueous NaOH and chloroform. Silica column chromatographic separation of the isolated product gave three fractions—methyl 12-chlorostearate (3, 49%); 12-*O*-formylstearate (4, 19%); and unreacted 12-hydroxystearate (32%). From these results it became apparent that the electrophilic dichlorocarbene species reacted with the hydroxyl group to give an alkoxydichloro carbanion intermediate which, upon hydrolysis, yielded the *O*-formyl C_{18} derivative 4. The same alkoxydichlorocarbene intermediate could also lose a chloride ion by α-elimination to form an alkoxymonochlorocarbene, which gave rise to the chloro C_{18} derivative (3) by elimination of a molecule of carbonmonoxide *via* and S_Ni reaction as described by Tabushi *et al.* (32). In order to prevent the attack of the hydroxy group in methyl ricinoleate by the dichlorocarbene species, the hydroxy group was protected by converting it to the *O*-tetrahydropyran-2′-yl (OTHP) derivative. Dichlorocyclopropanation by the phase-transfer method of the OTHP-protected methyl ricinoleate was readily accomplished. Removal of the protecting group gave the desired dichlorocyclopropane-hydroxy C_{18} derivative 5 (83%) as an oil.

Since carbonyl functions are also susceptible to reaction with dichlorocarbene species (33), the keto group of

methyl 12-oxo-*cis*-9-octadecenoate was converted to the 1,3-dioxolane derivative prior to treatment with dichlorocarbene. The desired dichlorocyclopropane-keto C_{18} derivative **6** (76%) was subsequently obtained after removal of the protecting group of the keto function.

Treatment of methyl ricinoleate with thionyl chloride gave methyl 12-chloro-*cis*-9-octadecenoate, which reacted with dichlorocarbene to give the corresponding 12-chloro-dichloro-cyclopropane C_{18} derivatives (**7**, 95%). Further transformation of the hydroxy function of compound **5** furnished the corresponding *O*-acetyl- (**8**, 98%), azido- (**9**, 33%) and *O*-formyl- (**10**, 27%) dichlorocyclopropane derivatives, demonstrating the stability of the dichlorocyclopropane ring towards the various reagents used in these conversions.

When the free acid of compound **1** was treated with *t*-butyl lithium, the chlorine atoms of the dichlorocyclopropane system were eliminated to yield a labile carbene intermediate (cyclopropylidene), which ring-opened to give after esterification a C_{19} allenic ester (**11**, 82%). A small amount of 2,2-dimethyl-3-oxo-11,12-heneicosadiene (**12**, 18%) was also obtained as a result of an attack of the *t*-butyl anion on the carboxylic acid function of the substrate. However, reaction of the free acids of the remaining dichlorocyclopropane derivatives (**2**, **5–10**) with *t*-butyl lithium failed to yield the corresponding allenic derivatives.

The dichlorocyclopropane derivatives (**2**, **5–10**) were all found to be stable during GLC analysis with the dichlorocyclopropane system contributing *ca.* 3.1 carbon numbers to the equivalent chain length (ECL) value of the parent fatty ester on SE-30 stationary phase. The chemical shift of the methine protons of the dichlorocyclopropane ring appeared as a multiplet at δ 1.6–1.8, due to the effects of the two chlorine atoms. In the ^{13}C NMR spectrum of compound **1**, the chemical shifts of the carbon atoms of the dichlorocyclopropane ring appeared at 33.0 ppm (C-9, C-10) and at 66.0 ppm for the chlorine substituted quaternary carbon atom. The shielding effect of the dichlorocyclopropane system on the two adjacent methylene carbons caused these nuclei to shift to 24.8 ppm (C-8, C-11). In the case of the *bis*-dichlorocyclopropane derivative (**2**), the ^{13}C NMR spectrum showed two distinct signals at 65.0 and 65.1 ppm for the quaternary carbon nuclei of the dichlorocyclopropane ring. Difficulties remain in the absolute assignment of these two signals, but the signal at 65.0 ppm seems to be due to the quaternary carbon of the dichlorocyclopropane ring nearer to the terminal methyl group. The effect of the hydroxy group at C-12 in compound **5** caused the methine carbon of the ring at C-10 to be shifted upfield to 29.7 ppm, while the methine carbon at C-9 appeared at 32.8 ppm. The presence of the hydroxy group was also confirmed by the signal at 70.9 ppm for the methine carbon atom (C-12) attached to the hydroxy group. In compound **6** the ring methine carbon atoms appeared at 32.7 and 27.9 ppm for C-9 and C-10, respectively, while the shift of the keto carbon atom appeared at 207.8 ppm. Compound **7** was characterized by the deshielding effect of the chlorine atom on the attached carbon atom (C-12), which appeared at 62.8 ppm. The carbon shifts of the methyl and carbonyl carbon of the *O*-acetyl group in compound **8** appeared at 21.1 and 170.4 ppm, respectively. The *O*-acetyl function was also characterized in the ^1H NMR spectrum by the signal at δ 2.09(*s*,3H) for the methyl protons of the *O*-acetyl function and by the multiplet at δ 5.0 for the methine proton at C-12. In compound **9** the azido group gave a characteristic strong absorption band at 2100 cm^{-1} (N_3, stretching) in the infrared spectrum, and the ^1H NMR shift of the methine proton at C-12 appeared at δ 3.4(*m*). The effect of the azido group on the chemical shift of the adjacent carbon atoms was rather similar to that observed for the chlorine atom in compound **7**. The *O*-formyl group in compound **10** was characterized by the signal appearing at δ 5.1(*m*) for the methine proton of C-12 in the ^1H NMR spectrum. In the ^{13}C NMR spectral analysis, the shift of the C-12 carbon atom of compound **10** appeared at 73.4 ppm.

EXPERIMENTAL PROCEDURES

Methyl oleate, methyl linoleate, triethylbenzylammonium chloride, *p*-toluenesulfonic acid, *t*-butyl lithium and methanesulfonyl chloride were obtained from Aldrich Chemical Company (Milwaukee, WI). Pyridinium *p*-toluenesulfonate was prepared by reaction of *p*-toluenesulfonic acid and pyridine (34); methyl ricinoleate was isolated from castor oil and methyl 12-oxo-*cis*-9-octadecenoate was prepared from methyl ricinoleate by oxidation as previously described (35). Methyl 12-hydroxystearate was obtained by hydrogenation of methyl ricinoleate over palladium on charcoal in MeOH. GLC analyses were carried out on a Hewlett-Packard (Hewlett-Packard Inc., Palo Alto, CA) model 5970 gas chromatograph fitted with a 10 m × 0.53 mm SE-30 microbore column using nitrogen (20 mL/min) as the carrier gas under isothermal conditions (220°C) and a flame ionization detector. External methyl ester standards (12:0, 14:0, 16:0 and 18:0) were used as reference compounds, and the equivalent chain length (ECL) values were calculated accordingly for each isomer (36). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a JEOL (JEOL Ltd., Tokyo, Japan) model FX90Q (90 MHz) pulse Fourier transform spectrometer operating at 90 and 22.5 MHz, respectively. Samples were dissolved in $CDCl_3$, which served as both the internal lock and secondary reference.

Dichlorocyclopropanation of methyl oleate. A mixture of methyl oleate (0.2 g, 0.68 mmol), chloroform (1.4 mL), triethylbenzylammonium chloride (30 mg) and aqueous NaOH (50%, 1 mL) was stirred at room temperature for 12 hr. Conc. HCl (5 mL) was added and the reaction mixture was extracted with chloroform (2 × 10 mL). The organic extract was washed with water (10 mL) and dried (Na_2SO_4). The organic solvent was evaporated and the residue separated by silica gel chromatography using Solvent A as eluent. Evaporation of the solvent gave the dichlorocyclopropane C_{18} derivative **1** (0.21 g, 78%) as an oil (27). TLC, R_f 0.6 (Solvent B). GLC, ECL 21.8 (SE-30). IR (cm^{-1}): 1740 (s), 1440(m), 805(m), 780(m). ^1H NMR (δ): 0.9(*t*,3H), 1.2–1.6(*m*,26H), 1.6–1.8(*m*,2H, C*H* ring), 2.3(*t*,2H), 3.6(*s*,3H). ^{13}C NMR (ppm): C-1, 174.2; C-2, 34.1; C-3, 25.0; C-4/C-6, 29.1–29.5; C-7, 28.8; C-8, 24.8; C-9, C-10, 33.0; C-11, 24.8; C-12, 28.7; C-13/C-15, 29.1–29.5; C-16, 31.9; C-17, 22.7; C-18, 14.1; $COOCH_3$, 51.4; $>CCl_2$, 66.0.

Dichlorocyclopropanation of methyl linoleate. A mixture of methyl linoleate (0.2 g, 0.68 mmol), chloroform (3

mL), triethylbenzylammonium chloride (30 mg) and aqueous NaOH (50%, 2 mL) was stirred at room temperature for 12 hr. Isolation and silica gel column chromatography gave the *bis*-dichlorocyclopropane C_{18} derivative **2** (0.29 g, 93%) as an oil (26). TLC, R_f 0.6 (Solvent B). GLC, ECL 24.6 (SE-30). IR (cm^{-1}): 1740(s), 1460(m), 805(m), 790(m). ^1H NMR (δ): 0.9(*t*,3H), 1.2–1.6(*m*,22H), 1.6–1.8(*m*,4H), 2.3(*t*,2H), 3.6(*s*,3H). ^{13}C NMR (ppm): C-1, 174.2; C-2, 34.1; C-3, 24.9; C-4/C-6, 29.1–29.7; C-7, 28.6; C-8/C-14, 24.8; C-9, 33.1; C-10, C-12, 31.2; C-11, 20.7; C-13, 33.9; C-15, 28.4; C-16, 31.5; C-17, 22.5; C-18, 14.0; $COOCH_3$, 51.4; and $>CCl_2$ 65.0 and 65.1.

Reaction of methyl 12-hydroxystearate with dichlorocarbene. A mixture of methyl 12-hydroxystearate (2.5 g, 7.9 mmol), aqueous NaOH (50%, 20 mL), chloroform (30 mL) and triethylbenzylammonium chloride (70 mg) was stirred for 12 hr at room temperature. Conc. HCl (50 mL) was added and the reaction mixture was extracted with chloroform (2 × 30 mL). The organic extract was washed with water (2 × 20 mL) and dried (Na_2SO_4). The solvent was evaporated under reduced pressure to give a mixture of crude products (2.3 g). Preparative TLC separation of 200 mg of the crude product using Solvent B as developer gave three fractions (A–C). The least polar fraction (A) consisted of methyl 12-chlorostearate, **3** (56 mg, 24%) as an oil. TLC, R_f 0.6 (Solvent B). GLC, ECL 19.9 (SE-30). ^1H NMR (δ): 0.9(*t*,3H), 1.2–1.6(*m*,24H), 1.6–1.8(*m*,4H), 2.3(*t*,2H), 3.6(*s*,3H), 4.0(*m*,1H, C*H*Cl). ^{13}C NMR (ppm): C-1, 174.2; C-2, 34.1; C-3, 24.8; C-4/C-9, 29.1–29.5; C-10, 26.5; C-11, 38.6; C-12, 64.3; (>*C*HCl); C-13, 38.6; C-14, 26.5; C-15, 29.3; C-16, 31.7; C-17, 22.6; C-18, 14.1; $COOCH_3$, 51.4. Fraction B gave methyl 12-*O*-formylstearate, **4** (22 mg, 9%) as an oil. TLC, R_f 0.45 (Solvent B). GLC, ECL 20.6 (SE-30). ^1H NMR (δ): 0.9(*t*,3H), 1.2–1.6(*m*,24H), 1.6–1.8(*m*,4H), 2.3(*t*,2H), 3.6(*s*,3H), 5.0(*m*,12-*H*), 8.1(*s*, -OC*H*=O). ^{13}C NMR (ppm): C-1, 174.2; C-2, 34.1; C-3, 25.0; C-4/C-9, 29.1–29.5; C-10, 25.2; C-11, 34.1; C-12, 74.6; C-13, 34.1; C-14, 25.2; C-15, 29.3; C-16, 31.7; C-17, 22.6; C-18, 14.1; $COOCH_3$, 51.4; -O*C*H=O, 161.1. Fraction C consisted of unreacted methyl 12-hydroxystearate (37 mg, 17%). TLC, R_f 0.2 (Solvent B). GLC, ECL 20.7 (SE-30). IR (cm^{-1}): 3400(s, br), 1740(s).

Dichlorocyclopropanation of OTHP derivative of methyl ricinoleate. A mixture of methyl ricinoleate (1.1 g, 3.6 mmol), 3,4-dihydro-2*H*-pyran (0.45 g, 5.4 mmol), pyridinium *p*-toluenesulfonate (0.1 g) and CH_2Cl_2 (7 mL) was stirred at room temperature for 12 hr. Diethyl ether (50 mL) was added and the ethereal mixture was washed with brine (2 × 10 mL) and dried (Na_2SO_4). Evaporation of the solvent gave the tetrahydropyran-2′-yloxy derivative of methyl ricinoleate (1.4 g). The latter compound was dissolved in chloroform (30 mL) and stirred with triethylbenzylammonium chloride (30 mg) and aqueous NaOH (50%, 8 mL) for 12 hr at 50°C. Dil. HCl (2M, 30 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 30 mL). The extract was washed with water (20 mL) and dried (Na_2SO_4). The solvent was evaporated and the residue stirred with a solution of pyridinium *p*-toluenesulfonate (50 mg) in ethanol (20 mL) at 50°C for 4 hr. The solvent was evaporated under reduced pressure and the residue was extracted with diethyl ether (2 × 30 mL). The extract was washed with water (20 mL) and dried. Silica gel column chromatography gave the C_{18} dichlorocyclopropane-hydroxy C_{18} derivative **5** (1.6 g, 83%) as an oil. TLC, R_f 0.25 (Solvent B). GLC, ECL 24.3 (SE-30). ^1H NMR (δ): 0.9(*t*,3H), 1.2–1.6(*m*,20H), 1.6–1.8(*m*,6H), 2.3(*t*,2H), 2.6(*s*,1H, >CHO*H*), 3.65(*s*,3H), 3.8(*m*,1H, >C*H*OH). ^{13}C NMR (ppm): C-1, 174.3; C-2, 34.1; C-3, 24.9; C-4/C-6, 29.1–29.8; C-7, 28.5; C-8, 24.9; C-9, 32.8; C-10, 29.7; C-11, 32.6; C-12, 70.9, >*C*HOH; C-13, 37.7; C-14, 25.7; C-15, 29.3; C-16, 31.9; C-17, 22.6; C-18, 14.1, $COOCH_3$, 51.4; $>CCl_2$, 65.8.

Dichlorocyclopropanation of the 1,3-dioxolane derivative of methyl 12-oxo-cis-9-octadecenoate. A mixture of methyl 12-oxo-*cis*-9-octadecenoate (2 g, 6.5 mmol), ethylene glycol (18.5 mL), *p*-toluenesulfonic acid (0.1 g) and toluene (100 mL) was refluxed for 6 hr. The cooled reaction mixture was washed with water (50 mL) and dil. $NaHCO_3$ (10%, 30 mL) and dried (Na_2SO_4). The solvent was evaporated under reduced pressure. A mixture of chloroform (35 mL), triethylbenzylammonium chloride (0.1 g) and aqueous NaOH (50%, 30 mL) was added to the residue and stirred at 50°C for 1 hr and at room temperature for an additional 12 hr. Dil. HCl (2M, 100 mL) was added and the reaction mixture was extracted with chloroform (2 × 30 mL). The organic extract was washed with water (20 mL) and dried (Na_2SO_4). The solvent was evaporated under reduced pressure and the residue refluxed with *p*-toluenesulfonic acid (0.2 g), acetone (75 mL) and water (1 mL) for 1 hr. Water was added and the reaction mixture was extracted with petroleum ether (3 × 30 mL). The organic extract was washed with dil. $NaHCO_3$ (10%, 20 mL) and dried (Na_2SO_4). Silica column chromatographic separation gave dichlorocyclopropane-keto C_{18} derivative **6** (1.9 g, 76%) as an oil. TLC, R_f 0.5 (Solvent B). GLC, ECL 23.2 (SE-30). ^1H NMR (δ): 0.9(*t*,3H), 1.2–1.6(*m*,20H), 1.6–1.8(*m*,2H), 2.3(*t*,2H), 2.4(*t*,2H), 2.6(*t*,2H), 3.65(*s*,3H). ^{13}C NMR (ppm): C-1, 174.0; C-2, 34.1; C-3, 25.0; C-4/C-6, 28.5–29.3; C-7, 27.9; C-8, 25.2; C-9, 32.7; C-10, 27.9; C-11, 38.4; C-12, 207.8 (>C=O); C-13, 42.7; C-14, 23.9; C-15, 29.3; C-16, 31.8; C-17, 22.7; C-18, 14.2; $COOCH_3$, 51.4; $>CCl_2$, 65.2.

Dichlorocyclopropanation of methyl 12-chloro-cis-9-octadecenoate. A mixture of methyl ricinoleate (8.4 g, 28 mmol), thionyl chloride (4.3 g, 36 mmol) and pyridine (1 mL) was stirred at room temperature for 1 hr and refluxed for 30 min. Water (20 mL) was added and the reaction mixture was extracted with diethyl ether (3 × 30 mL). The organic extract was washed with dil. HCl (2M, 10 mL) and water (20 mL) and dried. Silica column chromatographic separation of the isolated product gave methyl 12-chloro-*cis*-9-octadecenoate (5.7 g, 62%) as an oil. A portion of the latter compound (0.2 g, 0.6 mmol) was stirred with chloroform (2 mL), triethylbenzylammonium chloride (20 mg) and aqueous NaOH (50%, 1.5 mL) at 50°C for 1 hr and at room temperature for an additional 12 hr. Dil. HCl (2M, 10 mL) was added and the reaction mixture was extracted with chloroform (2 × 15 mL). The organic extract was washed with water (10 mL) and dried. Silica column chromatographic purification of the product gave 12-chloro-dichlorocyclopropane C_{18} derivative **7** (0.24 g, 95%) as an oil. TLC, R_f 0.6 (Solvent B). GLC, ECL 23.3 (SE-30). ^1H NMR (δ): 0.9(*t*,3H), 1.2–1.6(*m*,20H), 1.6–1.8(*m*,6H), 2.3(*t*,2H), 3.7(*s*,3H), 3.9(*m*,1H). ^{13}C NMR (ppm): C-1, 174.2; C-2, 34.2; C-3, 25.0; C-4/C-6, 29.0–30.0; C-7, 28.8; C-8, 24.9; C-9, 33.0; C-10, 30.5; C-11, 34.1; C-12,

62.8; C-13, 38.7; C-14, 26.4; C-15, 29.5; C-16, 31.7; C-17, 22.6; C-18, 14.1; $COOCH_3$, 51.4; $>CCl_2$, 65.2.

Reaction of compound 5 with acetic anhydride. A mixture of compound **5** (0.16 g, 0.5 mmol) acetic anhydride (5 mL) and pyridine (1 mL) was stirred at room temperature for 12 hr. Water (10 mL) was added and the reaction mixture was extracted with petroleum ether (3 × 15 mL). The organic extract was washed with water (3 × 10 mL) and dried. Silica column chromatography of the isolated product gave the corresponding *O*-acetyl dichlorocyclopropane C_{18} derivative **8** (0.17 g, 98%). TLC, R_f 0.4 (Solvent B). GLC, ECL 23.7 (SE-30). ^1H NMR (δ): 0.9(*t*,3H), 1.2-1.6(*m*,20H), 1.6-1.8(*m*,6H), 2.09(*s*,3H), 2.3(*t*,2H), 3.7(*s*,3H), 5.0(*m*,1H). ^{13}C NMR (ppm): C-1, 173.9; C-2, 34.1; C-3, 25.0; C-4/C-6, 29.1-29.6; C-7, 28.5; C-8, 24.8; C-9, 32.6; C-10, 29.5; C-11, 29.4; C-12, 73.1; C-13, 33.9; C-14, 25.3; C-15, 29.3; C-16, 31.7; C-17, 22.5; C-18, 14.0; $COOCH_3$, 51.3; $>CCl_2$, 65.3; CH_3COO-, 170.4; CH_3COO-, 21.1.

Reaction of compound 5 with methanesulfonyl chloride followed by sodium azide. A mixture of compound **5** (0.3 g, 1.0 mmol), methanesulfonyl chloride (0.15 g, 1.3 mmol) and pyridine (10 mL) was stirred at 0-5°C for 2 hr. Cold dil. HCl (2M, 10 mL) was added and the reaction mixture was extracted with dichloromethane (2 × 30 mL). The organic extract was washed with dil. HCl (2M, 20 mL) and water (2 × 20 mL) and dried. The solvent was evaporated and the residue (0.29 g, 0.74 mmol) was stirred with sodium azide (50 mg, 0.77 mmol) in dimethylsulfoxide (10 mL) at 50°C for 4 hr. Water (50 mL) was added and the reaction mixture was extracted with diethyl ether (3 × 50 mL). The ethereal extract was washed with water (2 × 20 mL) and dried. Silica column chromatography of the isolated product gave azido-dichlorocyclopropane C_{18} derivative **9** (0.1 g, 33%) as an oil. TLC, R_f (Solvent B). GLC, ECL 23.8 (SE-30). IR (cm^{-1}): 2100 (s), 1740 (s). ^1H NMR (δ): 0.9(*t*,3H), 1.2-1.6(*m*,20H), 1.6-1.8(*m*,6H), 2.3(*t*,2H), 3.4(*m*,1H), 3.67(*s*,3H). ^{13}C NMR (ppm): C-1, 174.2; C-2, 34.1; C-3, 24.9; C-4/C-6, 29.0-29.5; C-7, 28.6; C-8, 25.1; C-9, 32.7; C-10, 29.6; C-11, 29.9; C-12, 62.1; C-13, 34.6; C-14, 26.1; C-15, 29.3; C-16, 31.7; C-17, 22.6; C-18, 14.1; $COOCH_3$, 51.4; $>CCl_2$, 65.4.

Reaction of compound 5 with formyl chloride. A mixture of formic acid (1.8 g, 39 mmol), pyridine (1.0 mL) and thionyl chloride (3.6 g, 30 mmol) was stirred at room temperature for 1 hr and heated at 80°C for an additional 1 hr. Compound **5** (0.3 g, 1.0 mmol) was added. The reaction mixture was stirred at 100°C for 1 hr and was left at room temperature for an additional 12 hr. Dil. HCl (2M, 20 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 30 mL). The extract was washed with water (20 mL) and dried. Silica gel preparative TLC (Solvent B) gave *O*-formyl dichlorocyclopropane C_{18} derivative, **10** (70 mg, 27%), as an oil. TLC, R_f 0.45 (Solvent B). GLC, ECL 24.0 (SE-30). ^1H NMR (δ): 0.9(*t*,3H), 1.2-1.6(*m*,20H), 1.6-1.8(*m*,6H), 2.3(*t*,2H), 3.65(*s*,3H), 5.1(*m*,1H), 8.1(*s*,1H). ^{13}C NMR (ppm): C-1, 174.2; C-2, 34.1; C-3, 25.0; C-4/C-6, 29.0-29.7; C-7, 28.5; C-8, 24.9; C-9, 32.8; C-10, 28.5; C-11, 29.5; C-12, 73.4; C-13, 33.9; C-14, 25.2; C-15, 29.3; C-16, 31.7; C-17, 22.6; C-18, 14.1; $COOCH_3$, 51.4; $>CCl_2$, 65.4; -OCH=O, 160.8.

Reaction of free acid of compound 1 with t-butyl lithium. A mixture of the free acid of compound **1** (0.23 g, 0.63 mmol) and anhydrous diethyl ether (10 mL) was cooled to −10°C under nitrogen. *t*-Butyl lithium (1.7M in pentane, 2 mL) was added and the reaction mixture stirred for 1 hr at room temperature. Dil. HCl (2M, 15 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 20 mL). The ethereal extract was washed with water (20 mL) and dried. The solvent was evaporated and the residue refluxed with BF_3/methanol complex (15%, w/w, 5 mL) and methanol (10 mL) for 15 min. Water (20 mL) was added and the reaction mixture was extracted with petroleum ether (2 × 20 mL). The organic extract was washed with water (10 mL) and dried. Silica gel chromatographic separation of the isolated product gave two main fractions. The more polar fraction (R_f 0.5; Solvent B) consisted of methyl 9,10-nonadecadienoate, **11** (81 mg, 82%) as an oil. GLC, ECL 19.1 (SE-30). IR (cm^{-1}): 1960 (w, C=C=C), 1740 (s, C=O). ^1H NMR (δ): 0.9(*t*,3H), 1.2-1.6(*m*,22H), 1.9(*m*, CH_2CH=C=$CHCH_2$, 4H), 2.3(*t*,2H), 3.66(*s*,3H), 5.1(*m*,2H, *CH*=C=*CH*). ^{13}C NMR (ppm): C-1, 174.3; C-2, 34.1; C-3, 25.0; C-4/C-8, 28.9-29.5; C-9, C-11, 90.8, 91.0; C-10, 203.8; C-12/C-16, 28.9-29.5; C-17, 31.9; C-18, 22.7; C-19, 14.1; $COOCH_3$, 51.4.

The less polar fraction (R_f 0.7; Solvent B) furnished 2,2-dimethyl-3-oxo-11,12-heneicosadiene **12** (18 mg, 18%). GLC, ECL 21.1 (SE-30). IR (cm^{-1}): 1960 (w, C=C=C), 1700 (s,C=O), 1460(s). ^1H NMR (δ): 0.9(*t*,3H), 1.1(*s*,9H, CH_3 of *t*-butyl), 1.2-1.6(*m*,22H), 1.9(*m*, CH_2HC=C=$CHCH_2$, 4H), 2.3(*t*,2H, CH_2C=O), 5.1(*m*,2H, *CH*=C=*CH*). ^{13}C NMR (ppm): C-1, C-2′, 26.4 (CH_3, *t*-butyl, 3C); C-2, 44.1; C-3, 216.1; C-4, 36.4; C-5, 24.0; C-6/C-10, 29.0-29.5; C-11, C-13, 90.0, 91.0; C-12, 203.8; C-14/C-18, 29.0-29.5; C-19, 31.9; C-20, 22.7; C-21, 14.1.

METHOD

The Quantitation of Long-Chain Acyl-CoA in Mammalian Tissue

Paul G. Tardi, Jagat J. Mukherjee and **Patrick C. Choy***
Department of Biochemistry and Molecular Biology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3E 0W3

Intracellular long-chain acyl-CoA esters are key metabolites in lipid metabolism. A rapid procedure was developed for the isolation of long-chain acyl-CoA from mammalian tissues. Acyl-CoA was extracted from the tissue with chloroform/methanol and separated from other lipid-containing metabolites by phase partition with solvents. The content and the molecular species of acyl-CoA were determined by gas-liquid chromatography. In rat liver and hamster heart, the total acyl-CoA content was estimated to be 83 ± 11 and 61 ± 9 nmol/g wet weight, respectively. The results obtained are comparable to those reported in previous studies. The relative ease of this procedure would permit the determination of acyl-CoA contents in a large number of samples.
Lipids 27, 65–67 (1992).

Acyl-coenzyme A (CoA) esters are intermediates involved in the acylation of lipids and proteins. The intracellular acyl-CoA content and composition have been shown to be important factors in determining the acyl group composition of phospholipids produced by reacylation (1–3). Acyl-CoA esters also act as modulators in the regulation of several enzyme systems (4,5) including the cardiac sodium pump (6) and protein kinase C (7). The identification of acyl-CoA as a metabolic regulator has led to the development of several assays for its quantitation (8). In general, the tissue is homogenized and proteins are precipitated from the homogenate. Subsequently, acyl-CoA is purified from the protein-free extract by column chromatography. Enzymatic or chemical analysis can then be employed for the quantitation of total acyl-CoA (9). The molecular species of the acyl-CoA can be determined by reverse-phase high-performance liquid chromatography (10,11). Since column chromatography is employed to purify acyl-CoA prior to its analysis, the procedure is not only time-consuming, but does not allow the simultaneous analysis of more than a few samples.

In the present study, a novel procedure was developed for the isolation of long-chain acyl-CoA in mammalian tissues. Acyl-CoA was extracted from tissue with chloroform/methanol and separated from other lipid-containing metabolites by phase partition. Subsequently, the total acyl-CoA content and the molecular species of acyl-CoA were determined by gas-liquid chromatography.

MATERIALS AND METHODS

[1-^{14}C]Oleoyl-CoA, [1-^{14}C]stearoyl-CoA, [1-^{14}C]palmitoyl-CoA, [1-^{14}C]arachidonoyl-CoA, [1-^{14}C]linoleoyl-CoA, [9,10(n)-^{3}H]palmitic acid, 1-palmitoyl-2-[1-^{14}C]oleoyl phosphatidylcholine, 1-[^{14}C]palmitoyl carnitine, tri-[9,10-^{3}H]olein, and cholesteryl [1-^{14}C]oleate were obtained from Amersham Canada Limited (Oakville, Canada). The radiolabeled compounds were purified by solvent partition or thin-layer chromatography before use. Aqueous liquid scintillant (EcoLite) was purchased from ICN Biomedicals Canada Ltd. (St. Laurent, Canada). BF_3 methanol (12% w/w) was obtained through Supelco Canada Ltd. (Oakville, Canada). Heptadecanoic acid methyl ester was purchased from Sigma Chemical Company (St. Louis, MO). Thin-layer chromatographic plates (Sil-G25) were produced by Macherey-Nagel and purchased through Brinkmann Instruments (Rexdale, Canada). All other chemicals were of reagent grade and were obtained through Canlab Division of Travenol Canada Inc. (Mississauga, Canada). Theoretical aqueous phase (TAP), containing chloroform/methanol/water (3:48:47, v/v/v) and theoretical organic phase (TOP), containing chloroform/methanol/water (86:14:1, v/v/v) were prepared as described by Sheltawy and Dawson (12).

Mature male Sprague-Dawley rats, 250 ± 100 g, and Syrian Golden hamsters, 120 ± 20 g, were obtained from Charles River Can. Inc. (St. Constante, Canada). The animals were fed the rodent diet RMH 3000 (Agway Inc., Syracuse, NY) and tap water *ad libitum*. Animals were sacrificed by decapitation, and organs were rapidly removed and placed in liquid nitrogen. The frozen tissue (1 g) was placed in a test tube containing 10 mL of chloroform/methanol/water (1:1.5:0.2, v/v/v). Labeled acyl-CoA (0.1 μCi) or 100 nmol of acyl-CoA was added as an internal standard. The tissue was homogenized by a PT-30 polytron generator. In some experiments, 1 μCi of labeled phosphatidylcholine, palmitic acid, palmitoyl carnitine, cholesteryl oleate or triolein was added prior to homogenization.

The homogenate was centrifuged at 2,000 × *g* for 5 min. The supernatant was removed, and the pellet was extracted twice with 5 mL of chloroform/methanol/water (1:1.5:0.2, v/v/v). The supernatants were pooled and 1 mg of butylated hydroxytoluene was added to minimize the oxidation of the unsaturated long-chain acyl-CoA. Chloroform and water were added until the ratio of $CHCl_3/CH_3OH/H_2O$ was 4:2:3 (v/v/v). Phase separation of the mixture was achieved by centrifugation at 2,000 × *g*. The aqueous phase, containing long-chain acyl-CoA, was removed and the organic phase was extracted twice with 10 mL of TAP. The pooled aqueous phases were reduced to 3 mL by evaporation under reduced pressure.

The pooled aqueous phase was shaken with 6 mL chloroform and 0.75 mL saturated $(NH_4)_2SO_4$, and centrifuged at 2,000 × *g* for 10 min. The organic phase (containing long-chain acyl-CoA and some white precipitate) was removed and the aqueous phase was reextracted twice with 10 mL of TOP. The organic phases obtained from the washes were pooled and centrifuged at 2,000 × *g* for 5 min (to pellet the white precipitate). The supernatant was reduced under N_2, and long-chain acyl-CoA was extracted back into the aqueous phase by the addition of

Abbreviations: BF_3, boron trifluoride; CoA, coenzyme A; DEGS, diethylene glycol succinate; TAP, theoretical aqueous phase; TLC, thin-layer chromatography; TOP, theoretical organic phase.

5 mL of TAP. After centrifugation, the aqueous phase was removed and the organic phase was re-extracted two times with 5 mL TAP. Vigorous mixing was essential for high acyl-CoA recovery during the extraction.

Samples obtained after phase partition were applied to a thin-layer chromatographic plate (G-25). The plate was developed in *n*-butanol/acetic acid/water (4:1:2, v/v/v). The fraction containing long-chain acyl-CoA (R_f 0.43) was identified by comparison with acyl-CoA standards. The R_f for long-chain acyl-CoA ($>C_{12}$) is different from hexanoyl-CoA and octanoyl-CoA (0.20), fatty acids (0.85), acyl carnitine (0.52), phosphatidylcholine (0.52) and phosphatidylethanolamine (0.65). The acyl-CoA in the fraction was eluted from the silica gel with 10 mL of the developing solvent.

Acyl-CoA content in the sample was determined by gas-liquid chromatography. The acyl groups in the sample were converted into methyl esters in the presence of boron trifluoride (13). Briefly, the solvent in the sample was evaporated under a stream of nitrogen, and 0.5 mL of boron trifluoride (BF_3) MeOH reagent was added to the dried sample. Methylation of the sample was carried out in a screw-capped tube which was heated at 96°C for 5 min. Subsequent to heating, 0.5 mL water and 1.5 mL petroleum hydrocarbon were added to the reaction mixture. The methyl esters formed were recovered in the petroleum hydrocarbon phase; the efficiency of methylation was better than 95%. The conversion of the acyl group to methyl ester by BF_3 appeared to be more efficient than the conversion to an alcohol by sodium borohydride (14). The methyl esters were analyzed on a Shimadzu Mini-2 gas-liquid chromatograph (Tekscience; Oakville, Canada) equipped with 15% DEGS (on 80/100 Chromosorb W/AW) columns. Heptadecanoic acid methyl ester was used as a standard for quantitation. The data obtained were analyzed by a Shimadzu Chromatopac CR601 integrator (Tekscience).

TABLE 1

Recovery of Radioactivity in Samples After Phase Partition[a]

Labeled compound added	Recovery (%)
Palmitoyl-CoA (16:0)	40 ± 4
Stearoyl-CoA (18:0)	43 ± 9
Oleoyl-CoA (18:1)	40 ± 6
Arachidonoyl-CoA (20:4)	39 ± 8
Palmitic acid	<0.1
Phosphatidylcholine	<0.1
Palmitoyl carnitine	<0.1
Cholesteryl oleate	<0.1
Triolein	<0.1

[a]Liver samples were homogenized and extracted as outlined in Materials and Methods. Radiolabeled lipid (1 μCi) was added to the sample prior to homogenization. The % radioactivity recovered in the sample after solvent partition is shown.

TABLE 2

Long-Chain Acyl-CoA Content and Distribution of Species in Samples After Phase Partition[a]

Acyl-CoA species	Distribution (%)
Myristoyl-CoA (14:0)	3 ± 2
Palmitoyl-CoA (16:0)	20 ± 5
Palmitoleoyl-CoA (16:1)	3 ± 2
Stearoyl-CoA (18:0)	33 ± 3
Oleoyl-CoA (18:1)	14 ± 6
Linoleoyl-CoA (18:2)	12 ± 4
Linolenoyl-CoA (18:3)	4 ± 2
Arachidonoyl-CoA (20:4)	8 ± 4
Others	3 ± 1
Total long-chain acyl-CoA	83 ± 11 nmol/g wet weight

[a]Acyl-CoA was isolated from rat liver homogenate by solvent partition as described in Materials and Methods. The resultant methyl esters were separated and quantitated by gas-liquid chromatography.

RESULTS AND DISCUSSION

The long-chain acyl-CoA in rat liver extract was found to partition in chloroform/methanol/water (4:2:3, v/v/v). The distribution of acyl-CoA in the aqueous and organic phases was monitored with labeled stearoyl-CoA, oleoyl-CoA and arachidonoyl-CoA. In all cases, over 95% of the radioactivity was found in the aqueous phase and less than 2% was recovered in the organic phase. When ammonium sulfate was added to the aqueous phase, a substantial portion of the labeled acyl-CoA was found in the organic phase. A 30% ammonium sulfate saturation in the aqueous phase was optimal for partitioning labeled CoA (68 ± 8%) into the organic phase. Most (72 ± 6%) of the labeled acyl-CoA in the organic phase was extracted back into the aqueous phase in the absence of ammonium sulfate. The overall recovery of acyl-CoA was 39–43% (Table 1). The yield obtained from this study is similar to that reported by Prasad *et al.* (15) but substantially higher than the value described by Olbrich *et al.* (16). Based on the results of Table 1, a 40% recovery was used to calculate the total acyl-CoA content.

The ability to separate long-chain acyl-CoA from other acyl-containing species by phase partition was examined. Labeled phosphatidylcholine, palmitic acid, triolein, cholesteryl oleate or palmitoyl carnitine was added to the tissue homogenate. After phase partition, the sample was analyzed for radioactivity. Less than 0.1% of the original radioactivity added to the homogenate was detected in the lipid fractions (Table 1). The results suggests that the long-chain acyl-CoA sample obtained after phase partition was not significantly contaminated with other lipid moieties.

The quantitation of long-chain acyl-CoA in the sample after phase partition was carried out by gas-liquid chromatography. The tissue homogenate was divided into two aliquots. An internal standard (100 nmol of acyl-CoA) was added to one aliquot prior to the isolation of acyl-CoA by phase partition. Subsequently, the acyl-CoA esters in the sample were converted into methyl esters and quantitated by gas-liquid chromatography. The quantity of each methyl ester species was determined by comparison with the methyl heptadecanoate standard.

The yield of acyl-CoA calculated from the internal standard (100 nmol of acyl-CoA) was in complete agreement with the values obtained from the labeled acyl-CoA (Table 1). The total long-chain acyl-CoA content as well as the distribution of the acyl species in rat liver are shown in Table 2. Our data (83 ± 11 nmol/g wet weight) are similar to those obtained in previous studies (15,17,18). However,

TABLE 3

Long-Chain Acyl-CoA Content and Distribution of Species in Samples After Thin-Layer Chromatography[a]

Acyl-CoA species	Distribution (%)
Myristoyl-CoA (14:0)	3 ± 2
Palmitoyl-CoA (16:0)	16 ± 6
Palmitoleoyl-CoA (16:1)	5 ± 2
Stearoyl-CoA (18:0)	35 ± 5
Oleoyl-CoA (18:1)	14 ± 4
Linoleoyl-CoA (18:2)	12 ± 4
Linolenoyl-CoA (18:3)	3 ± 2
Arachidonoyl-CoA (20:4)	6 ± 4
Others	6 ± 3
Total long-chain acyl-CoA content	81 ± 9 nmol/g wet weight

[a]Acyl-CoA was isolated from rat liver homogenate by solvent partition, followed by thin-layer chromatography as described in Materials and Methods. The resultant methyl esters were separated and quantitated by gas-liquid chromatography.

the value of arachidonoyl-CoA obtained in this study is lower than that reported by Prasad *et al.* (15). One possible explanation for this may be a difference in the diet of the animals used in the two studies. The rodent diet used in the present study contained a 7% lipid supplement whereas the diet used in the other study was a sucrose-casein based diet. It was reported by Masuzawa *et al.* (19) that the arachidonoyl-CoA level in the rat liver was significantly reduced (from 32% to 11%) by a diet supplemented with 10% soybean oil.

The requirement for further purification of the long-chain acyl-CoA after phase partition was also investigated. An aliquot of the acyl-CoA preparation obtained after phase partition was subjected to thin-layer chromatography with *n*-butanol/acetic acid/water (4:1:2, v/v/v) as solvent. Analysis of the chromatogram revealed that the R_f of acyl-CoA was different from the R_f values of free fatty acids, diacylglycerol, triacylglycerol and acyl carnitine (see Materials and Methods). The content and the composition of the acyl-CoA fraction obtained by thin-layer chromatography was analyzed by gas-liquid chromatography. As depicted in Table 3, the results obtained are similar to those found in the samples after phase partition (Table 2). Hence, the phase partition procedure alone appears to be adequate for the quantitation of acyl-CoA in a tissue extract.

In conclusion, phase partition is a rapid procedure for the determination of long-chain acyl-CoA content and composition in mammalian tissue. Using the same procedure, the analysis of long-chain acyl-CoA levels in the hamster heart was found to be 61 ± 9 nmol/g wet weight. The value obtained is similar to that reported for rat heart (19). The relative ease of the procedure would permit the determination of acyl-CoA content in a large number of samples. Analysis of long-chain acyl-CoA in smaller samples (biopsy samples) may also be feasible by increasing the sensitivity in gas-liquid chromatography.

Measurement of Bile Acid Synthesis in Man by Release of $^{14}CO_2$ from [26-^{14}C]Cholesterol: Comparison to Isotope Dilution and Assessment of Optimum Reference Cholesterol Specific Activity

John C. Mitchell, Bradford G. Stone and **William C. Duane***
Department of Medicine, VA Medical Center and University of Minnesota, Minneapolis, Minnesota 55417

Bile acid synthesis can be measured as release of $^{14}CO_2$ from [26-^{14}C]cholesterol divided by cholesterol specific activity, but this method has not been validated in human subjects. We made twelve comparisons of this CO_2 method to standard isotope dilution in six normal subjects and found a mean discrepancy of 6%. Linear regression analysis of one value with respect to the other revealed a correlation coefficient of 0.83 ($P < 0.001$), a Y-intercept close to zero (−4.98) and a slope close to 1 (1.06), suggesting good correspondence between the two methods. To assess the potential for error arising from use of serum cholesterol to estimate specific activity of cholesterol used for bile acid synthesis, we compared synthesis measured using serum free cholesterol specific activity to that measured using bile cholesterol specific activity, which is known to be near isotopic equilibrium with the precursor pool used for bile acid synthesis. Synthesis calculated in these two ways differed by less than 10%. The data indicate that the CO_2 method using either serum or bile cholesterol specific activity provides a valid estimate of bile acid synthesis in man.
Lipids 27, 68–71 (1992).

Bile acid synthesis is an important component of overall cholesterol homeostasis. In human subjects, bile acid synthesis is usually measured by Lindstedt isotope dilution kinetics (1) or fecal acidic sterol output (2). Both techniques are difficult and cannot be used to assess short-term changes in synthesis because sampling must be performed over periods of 4–10 days.

An alternative method, which enables measurement of short-term changes, is to quantitate synthesis by release of $^{14}CO_2$ from [26-^{14}C]cholesterol (3–5). During conversion of cholesterol to bile acid, carbon-26 is removed and quantitatively converted to CO_2. Output of $^{14}CO_2$ can be easily and accurately determined by quantitative collection of breath CO_2. Output of $^{14}CO_2$ is converted to bile acid production by dividing by specific activity of the cholesterol precursor pool used for bile acid synthesis.

Because this precursor pool specific activity is difficult to determine, it is usually approximated by substituting the specific activity of serum cholesterol (3–5). However, at least in certain circumstances, there is preferential use of newly synthesized cholesterol for bile acid synthesis (6). In that case, the specific activity of the cholesterol precursor pool used for bile acid synthesis would be lower than the specific activity of the serum cholesterol, and the calculated bile acid synthesis rate would be falsely low. An approach that might theoretically avoid this potential problem would be to use biliary cholesterol specific activity for calculation of bile acid synthesis because the pool of cholesterol used for bile acid synthesis appears to be in near equilibrium with the pool of cholesterol destined for secretion into bile (6).

In the present study we have assessed the accuracy of this CO_2 method in human volunteers by comparing it to the isotope dilution technique of Lindstedt. In addition, we have evaluated the possibility that biliary cholesterol specific activity might be superior to that of serum cholesterol for calculation of bile acid synthesis by the CO_2 method.

MATERIALS AND METHODS

Six male volunteers were studied. All had participated in two earlier studies of effects of lovastatin on biliary lipid secretion and bile acid synthesis (7,8). As part of one of these studies (7), each had had bile acid synthesis measured by isotope dilution, as originally described by Lindstedt (1), in two separate periods—once in a control period and once after ingesting lovastatin 40 mg b.i.d. for 5–6 weeks. As part of the other study (8), each volunteer had bile acid synthesis measured by the CO_2 method in the same two periods. This measurement was performed one week after the isotope dilution measurement.

The volunteers ranged in age from 51–68 years, in percent ideal body weight from 98–132%, and in serum cholesterol from 140–210 mg/dL. Two of the volunteers had hypertriglyceridemia (412 and 478 mg/dL) without hypercholesterolemia. Their results did not appear to differ from those of the other four subjects.

Informed consent was obtained from all volunteers prior to study. All study protocols were approved by the Subcommittee on the Use of Human Subjects in Research of the Minneapolis VA Medical Center.

Bile acid synthesis was measured as release of $^{14}CO_2$ from administered [26-^{14}C]cholesterol (New England Nuclear, Boston, MA) as described previously (5). Briefly, the subject was given 20–50 μCi of [26-^{14}C]cholesterol at least one week prior to study. Expired CO_2 was quantitatively collected by having the subject place his head in a plexiglass hood. Air from this hood was drawn rapidly through a series of collection traps containing a solution of phenethylamine to trap CO_2 and Liquifluor (New England Nuclear) to permit scintillation counting. Duplicate 8–10 min collections were done 30 min apart. All collections were performed at the same time of day, between 12 p.m. and 1:00 p.m., to avoid changes resulting from circadian variation. Bile acid synthesis was calculated by dividing output of $^{14}CO_2$ by specific activity of cholesterol. Unless otherwise stated, biliary cholesterol specific activity was used in this calculation.

*To whom correspondence should be addressed at VA Medical Center (111D), 1 Veterans Drive, Minneapolis, MN 55417.

Specific activities of both biliary and serum free cholesterol were measured by gas-liquid chromatography and liquid scintillation counting (5,9). For analysis of serum samples, free cholesterol was first isolated from a petroleum hydrocarbon (b.p. 30–60°C) extract by thin-layer chromatography using a solvent system of diethyl ether/heptane (55:45, v/v). Biliary cholesterol for measurement of specific activity was obtained during measurement of stimulated secretion rates of biliary lipids by the method of Grundy and Metzger (10).

RESULTS

Bile acid synthesis measured by isotope dilution averaged 105 ± 11% (mean ± SEM) of synthesis measured by the CO_2 method. Each of the individual measurements of these two variables is plotted in Figure 1, together with the regression line. Correlation coefficient for this regression was 0.83 ($P < 0.001$). The Y-intercept of the regression was close to zero (−4.98) and the slope was close to 1 (1.06), suggesting good correspondence between synthesis rates measured by the two methods over a fairly wide range of synthesis rates.

Bile acid synthesis by the CO_2 method calculated using the serum free cholesterol specific activity averaged 91 ± 4% of synthesis calculated using the bile cholesterol specific activity. The tendency for synthesis calculated using the serum cholesterol specific activity to be slightly lower than synthesis calculated using the bile cholesterol specific activity reflects the slightly lower specific activity of bile as compared to the serum free cholesterol reported earlier (8). As shown in Figure 2, however, the points clustered close to the line of identity suggesting little difference in values calculated by the two methods.

DISCUSSION

Measurement of bile acid synthesis as release of $^{14}CO_2$ from [26-^{14}C]cholesterol is considerably easier and quicker than measurement by isotope dilution or fecal acidic sterol balance. Until now, however, the method has not been validated in human subjects. Redinger *et al.* (4) compared this CO_2 method to fecal acidic sterol output in baboons and found the methods provided approximately equal values for bile acid synthesis in animals with an intact enterohepatic circulation.

In the present study we found reasonably good correspondence of bile acid synthesis measured by the CO_2 method as compared to standard isotope dilution (Fig. 1). The correspondence was not perfect, presumably in part because of the complexity of sampling and analysis, especially in the isotope dilution method. However, the observed average discrepancy of 6% between the two methods is small compared to the magnitude of changes in bile acid synthesis one is usually attempting to assess. Moreover, the apparent linear relationship between values returned by the two methods with a linear regression Y-intercept near zero and a slope near 1 suggests that synthesis rates over the range found in our subjects were measured equally well by either method. Thus the present study confirms the findings in baboons (4) and provides the first validation of this technique in human subjects.

Previous studies from our laboratory and others indicate that in normolipidemic subjects, isotope dilution and fecal acidic sterol balance yield comparable values for bile acid synthesis (11,12). However, there is some evidence that in hypertriglyceridemic subjects isotope dilution returns a higher rate of bile acid synthesis than fecal acidic sterol output (12). Two of our subjects had elevated triglycerides. In one of them synthesis by isotope, dilution was about 10% higher than by the CO_2 method in both control and lovastatin periods. In the other synthesis by isotope, dilution was actually lower than by the CO_2 method in both periods. Thus, these limited data do not suggest that isotope dilution overestimates bile acid synthesis compared to the CO_2 method in hypertriglyceridemic subjects.

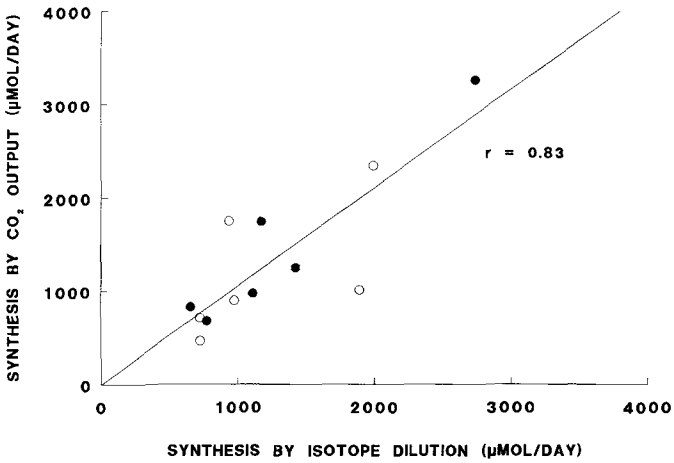

FIG. 1. Relationship between bile acid synthesis determined by isotope dilution *vs.* release of $^{14}CO_2$ from [26-^{14}C]cholesterol. The two methods correlated reasonably well ($r = 0.83$, $P < 0.001$) over about a four-fold range of synthesis rates. Moreover, the Y-intercept was close to zero (−4.98) and the slope was close to 1 (1.06), suggesting that there was no systematic bias of one method as compared to the other. Open circles represent the period of lovastatin ingestion, while closed circles represent the control period off lovastatin.

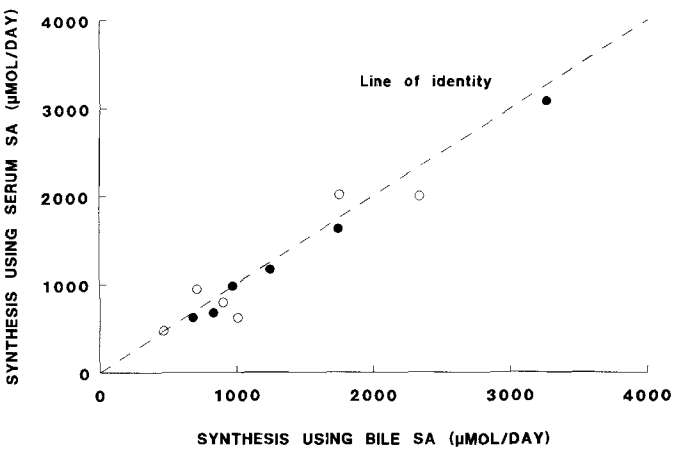

FIG. 2. Relationship of bile acid synthesis determined by the CO_2 method calculated with the biliary cholesterol specific activity *vs.* that calculated with the serum unesterified cholesterol specific activity. The two specific activities provided nearly identical values for bile acid synthesis, although there was a slight tendency for synthesis values calculated with the serum specific activity to be lower. As in Figure 1, open circles represent the lovastatin period and closed circles represent the control period.

We have previously reported that bile acid synthesis measured by the CO_2 method undergoes circadian variation (5). Therefore, in comparing this method to isotope dilution, which provides an average value of synthesis over four days, measurements of $^{14}CO_2$ output must be done at an appropriate time of day. We selected midday for determination of $^{14}CO_2$ output because our previous data suggest that this is the time most likely to correspond to mean daily synthesis (5). Nevertheless, in any individual, synthesis might be somewhat more or less than average at this time of day, which represents a potential for some variation and inaccuracy when using the CO_2 method to estimate mean daily synthesis.

It is also important in calculating bile acid synthesis by the CO_2 method to use the best possible estimate of cholesterol specific activity in the precursor pool destined for bile acid synthesis. Because cholesterol synthesis and bile acid synthesis take place in proximity to one another, newly synthesized cholesterol is likely to be disproportionately represented in this precursor pool. If so, the serum free cholesterol specific activity would be somewhat higher than that of the precursor pool and would yield a falsely low estimate of bile acid synthesis. A remedy for this potential problem is suggested by the observation that the precursor pool destined for bile acid synthesis and that destined for secretion into bile are near equilibrium (6). We therefore examined the possibility that the specific activity of biliary cholesterol might provide a better estimate than the serum cholesterol of the specific activity of the precursor pool used for bile acid synthesis. As reported earlier (8), serum free cholesterol specific activity did tend to be higher than that of biliary cholesterol, but the difference was less than 10%. Consequently, as shown in Figure 2, both the serum free cholesterol and the biliary cholesterol specific activity yielded reasonably accurate calculated values for bile acid synthesis.

In summary, these studies indicate that in human subjects with an intact enterohepatic circulation, the $^{14}CO_2$ technique provides a reasonably accurate measure of bile acid synthesis. Either serum or bile can be used to determine the reference cholesterol specific activity. The method has the advantages of easily and quickly providing a short-term measure of bile acid synthesis, but has the disadvantage of requiring administration of fairly large amounts of radioactive cholesterol (20–50 μCi). The method also provides no information about kinetics or pool sizes of bile acid.

APPENDIX

For purposes of illustration, the following is an example of calculations performed on one subject.

Bile Acid synthesis by isotope dilution (Lindstedt method). This measurement was carried out as described originally by Lindstedt (1), and later by our own laboratory (9). The evening prior to sampling, the subject was given 1.357×10^7 DPM of [24-^{14}C]cholic acid and 1.196×10^7 DPM of [24-^{14}C]chenodeoxycholic acid. Each of the subsequent four mornings (days 0.5, 1.5, 2.5 and 3.5), a sample of gallbladder bile was obtained and the specific activity of these two bile acids was measured in duplicate.

For cholic acid these specific activities were—12,690, 7193, 3783, and 1715 DPM/μmole. Linear regression of the natural logarithm of specific activity (y) *vs.* time after isotope administration (x) was performed and provided a slope of 0.665 day^{-1} (which is the fractional turnover of cholic acid) and a Y-intercept of 9.8331 (which is the natural logarithm of the specific activity at time zero). The antilog of the Y-intercept provided the specific activity at time zero:

$$\text{specific activity} = \exp(9.8331) = 18{,}640 \text{ DPM}/\mu\text{mole}$$

Dividing the specific activity at time zero into the administered amount of cholic acid administered yielded cholic acid pool size:

$$\text{pool} = (1.357 \times 10^7)/18{,}640 = 728 \ \mu\text{mole}$$

Finally multiplying the pool size by the fractional turnover of cholic acid yielded synthesis rate of cholic acid:

$$\text{synthesis} = (0.665) \times (728) = 484 \ \mu\text{mole/day}$$

Similar analysis was done for chenodeoxycholic acid yielding specific activities of 18,100, 12,860, 7527, 4204 DPM/μmole. Linear regression then yielded a slope of 0.491 day^{-1} and a Y-intercept of 10.1169. Again, taking the antilog of the Y-intercept provided a specific activity at time zero:

$$\text{specific activity} = \exp(10.1169) = 24{,}758 \text{ DPM}/\mu\text{mole}$$

Dividing that into the amount of labelled chenodeoxycholic acid administered yielded pool size of chenodeoxycholic acid:

$$\text{pool} = (1.196 \times 10^7)/24758 = 483 \ \mu\text{moles}$$

Multiplying this pool size by the fractional turnover of chenodeoxycholic acid yielded synthesis rate of chenodeoxycholic acid:

$$\text{synthesis} = (0.491) \times (483) = 237\ \mu\text{mole/day}$$

Finally, to obtain total bile acid synthesis by isotope dilution, synthesis rates for these two bile acids were summed:

$$\text{total synthesis} = 484 + 237 = 721\ \mu\text{mole/day}$$

Bile acid synthesis by CO_2 method. This measurement was carried out as previously described (5). Immediately following completion of four days of bile collection, the same subject was given about 25 μCi of [26-^{14}C]-cholesterol. One week later, we performed quantitative collections of breath $^{14}CO_2$ for three separate 8-min periods. In these 8-min collections, output of $^{14}CO_2$ averaged 2482 DPM. Multiplying by (1440/8) provided average daily output of $^{14}CO_2$ (= 446,760 DPM/day). On the same day, a sample of stimulated bile was obtained for measurement of cholesterol specific activity (= 630 DPM/μmole). Dividing daily output of $^{14}CO_2$ by this cholesterol specific activity yielded average daily bile acid synthesis rate:

$$\text{synthesis} = (446{,}760/(630) = 709\ \mu\text{mole/day}$$

COMMUNICATION

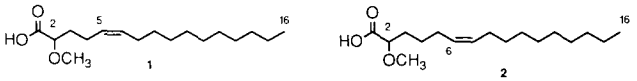
Two Novel Naturally Occurring α-Methoxy Acids from the Phospholipids of Two Caribbean Sponges

Néstor M. Carballeira* and **Juan A. Sepúlveda**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The novel (5Z)-2-methoxy-5-hexadecenoic acid (1) was identified in the phospholipids of the sponge *Tethya crypta* while the also novel acid (6Z)-2-methoxy-6-hexadecenoic acid (2) was found in the phospholipids of the Caribbean sponge *Spheciospongia cuspidifera*. The methoxy-fatty acids were mainly associated with phosphatidylethanolamine. The double bond positions were determined by gas chromatography/mass spectrometry on the corresponding dimethyldisulfide adducts and the double bond stereochemistry was ascertained by gas chromatography/Fourier transform infrared spectroscopy. The fatty acid composition of the two sponges is reported.
***Lipids* 27, 72-74 (1992).**

Phospholipids containing α-substituted fatty acids are quite rare in nature, but sponges have provided the most striking examples. Two particularly interesting examples have been the phospholipid-bound α-methoxy and α-hydroxy fatty acids. Ayanoglu *et al.* (1) reported that the African sponge *Higginsia tethyoides* contains α-methoxy acids, such as 2-methoxy-17-tetracosenoic acid (24:1n-7), 2-methoxy-19-hexacosenoic acid (26:1n-7), and 2-methoxy-21-octacosenoic acid (28:1n-7). We also recently encountered a series of phospholipids containing α-hydroxy fatty acids, namely 2-hydroxydocosanoic (22:0) and 2-hydroxytricosanoic (23:0) acids which were isolated from the sponge *Amphimedon compressa* (2). Ayanoglu *et al.* (3) have also described another class of demospongic acids, namely totally saturated 2-acetoxy C_{22}-C_{30} acids from the sponge *Polymastia gleneni*. These probably are the only examples of 2-oxo-substituted fatty acids in the phospholipids of sponges, mostly occurring in phosphatidylethanolamine.

We now wish to report the isolation and structure elucidation of the new phospholipid fatty acid (5Z)-2-methoxy-5-hexadecenoic acid (1) from the sponge *Tethya crypta*, and (6Z)-2-methoxy-6-hexadecenoic acid (2) which was found in the Caribbean sponge *Spheciospongia cuspidifera*.



SCHEME 1

EXPERIMENTAL PROCEDURES

T. crypta and *S. cuspidifera* were collected in July, 1989, near the shelf edge of La Parguera, Puerto Rico, at a depth of 15 m. The sponges (500 g) were washed in sea water, carefully cleaned of all nonsponge debris and cut into small pieces. Immediate extraction with 600 mL of chloroform/methanol (1:1, v/v) yielded the total lipids. The neutral lipids, glycolipids and phospholipids (100 mg) were separated by column chromatography on silica gel (60-200 mesh) using a procedure similar to that of Privett *et al.* (4). The phospholipid classes were fractionated by preparative thin-layer chromatography (TLC) using silica gel G and chloroform/methanol/water (25:10:1, v/v/v) as solvent. The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride (5) followed by column chromatographic purification and elution with hexane/diethyl ether (9:1, v/v). The resulting methyl esters were analyzed by gas chromatography/mass spectrometry using either a Hewlett-Packard 5995 A gas chromatograph/mass spectrometer (Hewlett-Packard, Palo Alto, CA) or a Hewlett-Packard 59970 MS ChemStation equipped with a 30 m × 0.32 mm nonpolar fused silica column (Supelco, Bellefonte, PA) with SPB™-1 as the bonded phase. Gas chromatography/Fourier transform infrared (FT-IR) spectra were recorded on a Nicolet (Madison, WI) 740 FT-IR spectrometer. For the location of double bonds, dimethyldisulfide derivatives were prepared by dissolving the esters (2 mg) in dimethyldisulfide (0.2 mL) and adding a solution (0.05 mL) of iodine in diethyl ether (60 mg/mL). The solution was heated at 50°C for 24 hr followed by the standard purification method (6). Hydrogenations were carried out in 10 mL of absolute methanol in the presence of catalytic amounts of platinum oxide (PtO_2). Mass spectral data for the key fatty acids described are presented here:

Methyl (5Z)-2-methoxy-5-hexadecenoate. MS (70 eV) *m/z* (relative intensity), 298 (M^+,1), 266 (M^+-CH_3OH,12), 239 ($M^+-CO_2CH_3$,5), 207 (1.7), 206 (2.6), 180 (1), 150 (3), 139 (3), 135 (3), 127 (2), 123 (4), 121 (4), 117 (2), 111 (12), 109 (8), 104 (100), 97 (16), 95 (13), 93 (16), 89 (9), 87 (6), 83 (12), 81 (14), 79 (11), 75 (5), 71 (7), 69 (14), 67 (16), 57 (10), 55 (21).

*Methyl 2-methoxy-5,6-*bis*(methylthio)hexadecanoate.* (3) MS (70 eV) *m/z* (relative intensity), 392 (M^+,4), 201 (31), 191 (100), 160 (10), 159 (91), 131 (52), 111 (17), 97 (23), 95 (11), 87 (18), 85 (13), 83 (19), 81 (13), 79 (13), 75 (15), 74 (17), 71 (27), 69 (26), 67 (19), 61 (33), 59 (17), 57 (20), 55 (39).

Methyl (6Z)-2-methoxy-6-hexadecenoate. MS (70 eV) *m/z* (relative intensity), 298 (M^+,1), 266 (M^+-CH_3OH,4), 239 ($M^+-CO_2CH_3$,20), 207 (6), 206 (7), 180 (6), 150 (11), 139 (5), 138 (8), 136 (10), 127 (8), 123 (13), 121 (12), 117 (6), 111 (18), 109 (19), 104 (100), 97 (21), 95 (39), 93 (17), 88 (12), 87 (16), 83 (18), 81 (35), 79 (19), 74 (16), 71 (30), 69 (25), 67 (37), 57 (22), 55 (48).

*Methyl 2-methoxy-6,7-*bis*(methylthio)hexadecanoate.* (4) MS (70 eV) *m/z* (relative intensity), 392 (M^+,3), 206 (9), 205 (100), 187 (37), 173 (37), 145 (23), 125 (12), 97 (32), 95 (16), 93 (11), 87 (64), 85 (12), 83 (28), 81 (21), 79 (12), 75 (11), 71 (45), 69 (27), 67 (29), 61 (44), 57 (19), 55 (46).

TABLE 1

Principal Fatty Acids from *Tethya crypta* and *Spheciospongia cuspidifera*[a]

Fatty acid	Abundance (%)	
	T. crypta	*S. cuspidifera*
Tetradecanoic (14:0)	3	7
4,8,12-Trimethyltridecanoic (16:0)	2	11
Pentadecanoic (15:0)[b]	5	—
9-Hexadecenoic (16:1)	3	2
Hexadecanoic (16:0)[b]	16	10
Heptadecanoic (17:0)	2	3
Octadecenoic (18:1)[c]	2	5
2-Methyloctadecanoic (19:0)	5	—
2-Methoxy-5-hexadecenoic (16:1)	2	—
2-Methoxy-6-hexadecenoic (16:1)	—	4
Octadecanoic (18:0)	5	5
Nonadecanoic (19:0)[b]	4	6
Eicosanoic (20:0)	3	5
Heneicosanoic (21:0)	2	2
2-Hydroxydocosanoic (22:0)	4	2
2-Hydroxytricosanoic (23:0)	1	1
2-Hydroxytetracosanoic (24:0)	2	5
2-Hydroxypentacosanoic (25:0)	4	2
5,9-Pentacosadienoic (25:2)	6	4
5,9-Hexacosadienoic (26:2)	15	18

[a]Some minor acids are not included in this table.

[b]These normally were a mixture of the branched iso-anteiso acids.

[c]Includes the Δ9 and Δ11 isomers.

RESULTS AND DISCUSSION

Capillary gas chromatography (GC) and gas chromatography/mass spectrometry (GC/MS) of the mixture gave the principal acids described in Table 1 for *T. crypta*, and *S. cuspidifera*. As can be seen from the Table, both *T. crypta* and *S. cuspidifera* possess a series of α-hydroxy fatty acids, the most abundant being those between C_{22}–C_{25} carbons long. *T. crypta* also has a rare 2-methyloctadecanoic acid, which tends to indicate the propensity of this sponge for phospholipids with α-substituted fatty acids. An unusual fatty acid methyl ester from *T. crypta* (2% abundance) was difficult to characterize due to the small amounts of this acid in the complex mixture of more than 25 fatty acid methyl esters. Capillary GC on a SPB™-1 30-m column and GC/MS became the principal tools for the characterization. The unknown ester exhibited unusual chromatographic properties, namely an equivalent chain length (ECL) of 17.20, which is unusual for the molecular weight of this methyl ester. The mass spectrum showed a molecular peak at *m/z* 298 (1%) and a base peak at *m/z* 104, arising from a McLafferty rearrangement (1). The additional 30 amu, when compared with the typical base peak of saturated fatty acid methyl esters at *m/z* 74, could only be accounted for by a methoxy group at the 2-position. Important for the characterization were also fragmentation ions at *m/z* 266 ($[M-MeOH]^+$, 2%), *m/z* 239 ($[M-COOCH_3]^+$, 5%), and *m/z* 207 ($[M-COOCH_3-CH_3OH]^+$, 2%). In fact, comparison of the mass spectrum with spectra for other 2-methoxy acids (1) confirmed that we have identified a novel 2-methoxyhexadecenoic acid. The double bond position was determined by preparing the corresponding dimethyldisulfide adduct, a convenient method for the location of double bonds by mass spectrometry (6,7). The mass spectrum of the corresponding dimethyldisulfide adduct afforded a molecular ion peak at *m/z* 392 (M^+, 4%). The double bond was readily determined to be at carbon 5 by the fragmentations at *m/z* 201 ($[C_{11}H_{22}SCH_3]^+$, 31%) and *m/z* 191 ($[C_8H_{15}SO_3]^+$, 100%) since this constitutes cleavage between carbons 5 and 6. There was also a prominent peak at *m/z* 159 (91%) corresponding to the *m/z* 191 fragment with the loss of methanol; these fragmentations are shown in 3 (Fig. 1). The experimental data thus support the structure of a (5Z)-2-methoxy-5-hexadecenoic acid (1) as the new compound. The capillary GC-FTIR spectrum showed hydrocarbon and ester bands at 3020, 2925, 2850 and 1743 cm^{-1}, respectively. There was no prominent absorption in the 980–968 cm^{-1} region, that would be indicative of *cis* rather than *trans* unsaturation.

The new methoxy fatty acid methyl ester (4% abundance) from *S. cuspidifera* also exhibited a long retention time in GC (ECL, 17.22), unusual for the molecular weight of this ester. The mass spectrum indicated a molecular weight of 298 (1%) and the same base peak at *m/z* 104 (McLafferty rearrangement). Other key fragmentations were also found at *m/z* 266 ($[M-MeOH]^+$, 6%), *m/z* 239 ($[M-COOCH_3]^+$, 5%) and *m/z* 207 ($[M-COOCH_3-CH_3OH]^+$, 6%. This suggested that the compound was identical to or an isomer of 1. The dimethyldisulfide adduct was again prepared and the mass spectrum unequivocally determined the double bond position to be at carbon 6. In this case, the molecular ion peak was also observed at *m/z* 392 (M^+, 3%) and the double bond was deduced from the prominent fragments at *m/z* 187 ($[C_{10}H_{20}SCH_3]^+$, 37%) and *m/z* 205 ($[C_9H_{17}SO_3]^+$, 100%), this constitutes cleavage between carbons 6 and 7 as exemplified in 4. There was also a prominent peak at *m/z* 173 (37%) corresponding to the 205 fragment with the

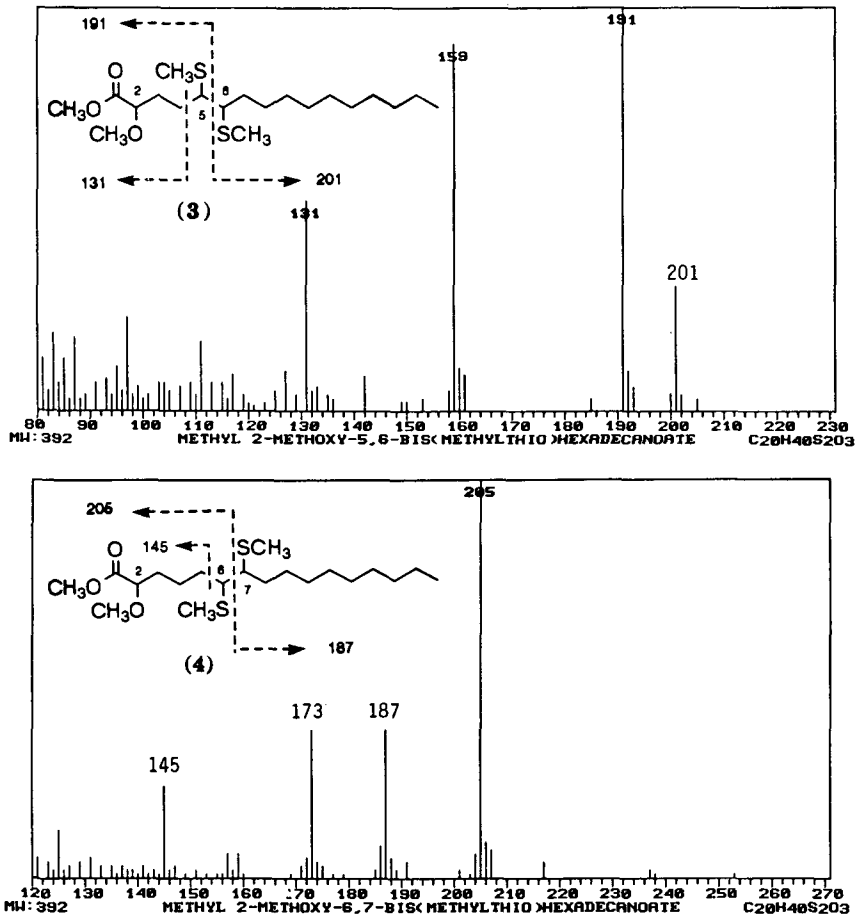

FIG. 1. Partial mass spectra of methyl 2-methoxy-5,6-*bis*(methylthio)hexadecanoate (3) and methyl 2-methoxy-6,7-*bis*(methylthio)hexadecanoate (4) displaying the key fragmentations used for the localization of the double bonds.

concomitant loss of methanol. The capillary GC-FTIR spectrum showed hydrocarbon and ester bands at 3020, 2925, 2850 and 1743 cm^{-1}, respectively. There was no prominent absorption in the 980-968 cm^{-1} region, indicating *cis* rather than *trans* unsaturation. The compound in question was thus (6Z)-2-methoxy-6-hexadecenoic acid (2) which is also unprecedented in nature.

The acids reported here were mainly associated with phosphatidylethanolamine. Naturally occurring 2-hydroxy fatty acids are known to possess the R configuration and the determination by Ayanoglu *et al.* (8) that methoxy fatty acids from sponges have the R configuration at the α-carbon tends to indicate that the compounds presented here also possess the R configuration. The biosynthetic origin of these novel acids is presently a matter of speculation, and much biosynthetic work is needed in order to put in perspective the origin of these novel α-methoxy acids.

ACKNOWLEDGMENTS

Dr. Vance Vicente from the United States Department of the Interior Fish and Wildlife Service collected and classified the sponges. We thank M. Mercado for preliminary work with the *T. crypta*. This work was supported by the National Science Foundation under Grant No. CHE-8715649 and the National Institutes of Health under Grant No. S06 RR08102-17.

Occurrence of Wax Esters and 1-*O*-Alkyl-2,3-diacylglycerols in Goat Epididymal Sperm Plasma Membrane

Ajay P.S. Rana[a,1], **Gopal C. Majumder**[a], **Suniti Misra**[b] and **Amitabha Ghosh**[c,*]
[a]Indian Institute of Chemical Biology, Jadavpur, Calcutta 700 032, [b]Department of Marine Science, Calcutta University, Calcutta 700 019 and [c]Department of Chemistry, Bose Institute, Calcutta 700 009, India

Two unusual lipid classes were detected by thin-layer chromatography in the neutral lipids derived from goat cauda-epididymal sperm plasma membrane. The lipids were identified as wax esters and 1-*O*-alkyl-2,3-diacylglycerols based on chromatographic properties, identity of their hydrolysis products, and infrared/^{1}H nuclear magnetic resonance spectral evidence. The membrane contained *ca.* 3 and 5 μg/mg protein of wax esters and alkyldiacylglycerols, respectively. The relative proportions of wax esters and alkyldiacylglycerols in the total neutral lipids were 1.5% and 2.4%, respectively. The lipids contained fatty acids with chain lengths of C_{14} to C_{22}. The major fatty acids of the wax esters were 14:0, 16:0, 16:1ω7, 18:0 and 18:1ω9. The fatty acids in alkyldiacylglycerol were 16:0, 18:0, 22:5ω3 and 22:6ω3. Alkyldiacylglycerol was particularly rich in docosahexaenoic acid (22:6ω3) representing 30% of the total fatty acids. The alcohols of wax ester were all saturated with C_{20}-C_{29} carbon chains. The deacylated products derived from alkyldiacylglycerols were identified as hexadecyl, octadecyl and octadec-9′-enyl glycerol ethers.
Lipids 27, 75–78 (1992).

The sperm surface undergoes marked alterations during the various developmental stages of the male gametes, such as epididymal maturation, uterine capacitation, and acrosomal reaction and fertilization that take place in the fallopian tube (1,2). The cell surface of spermatozoa is believed to play a vital role at these stages, although specific surface molecules that regulate sperm motility and fertility have not yet been identified (1,2). Lipids, being major constituents of the cell surface, may play a role in regulating cellular recognition, transmembrane signalling, species specificity and tissue immunity (3–5). The lipids of boar (6) and ram (7) sperm plasma membrane (PM) have been found to change markedly as the cells undergo maturation during the epididymal transit. These studies suggest that cell surface lipids may have a role in regulating sperm maturation.

While analyzing goat sperm PM lipids, two unusual neutral lipids were detected. This study describes their identification as wax esters and 1-*O*-alkyl-2,3-diacylglycerols (Alkyl-DAG).

MATERIALS AND METHODS

Materials. Polyethyleneglycol (15–20 KDa), dextran (average mol. wt. 229000), hog pancreatic lipase, 1-*O*-hexadecylglycerol, 1-*O*-octadecylglycerol and 1-*O*-hexadecyl-2,3-dipalmitoyl-*sn*-glycerol were obtained from Sigma Chemical Company (St. Louis, MO). Palmityl oleate was prepared synthetically (8). Trisil-Z was a product of Pierce Chemical Company (Rockford, IL). The polymer system containing 5.5% dextran and 4.2% polyethyleneglycol in 0.1M K-phosphate, pH 6.5, was prepared as reported previously (9). Spermatozoa were extracted from goat epididymides within 2–4 hr after slaughter of the animals.

Isolation of goat sperm plasma membrane. Highly motile spermatozoa were extracted from goat cauda-epididymides in a modified Ringers phosphate buffered saline medium that contained 119 mM NaCl, 5 mM KCl, 1 mM $CaCl_2$, 1.2 mM $MgSO_4$, 10 mM glucose, 16.3 mM K-phosphate, pH 6.9, and penicillin (50 units/mL) (10). PM was isolated by the aqueous two-phase polymer method described earlier (9). Our previous study had demonstrated that the membranes isolated by this method are very pure, as judged by electron microscopy and analysis of marker enzymes (9). Electron microscopy showed the predominantly vesicular structure of sperm membranes (see Fig. 4 in ref. 9). The specific activities of alkaline phosphatase and 5′-nucleotidase as plasma membrane markers were approximately 14-fold higher in the isolated membrane than in sperm homogenate. The membrane had no detectable activity of acrosin and glucose-6-phosphatase, the markers of the acrosome and endoplasmic reticulum, respectively. The specific activity of cytochrome oxidase, an enzyme marker of mitochondria, was nearly seven-fold lower in the membranes than in the sperm homogenate. These data demonstrate that the isolated sperm plasma membranes were barely contaminated with acrosomes, endoplasmic reticulum, or mitochondria (see Table 4 in ref. 9).

Isolation of neutral lipids. Total lipids of the sperm PM were extracted following the method of Folch *et al.* (11). The neutral lipids were separated from other lipids by silicic acid column chromatography according to Rouser *et al.* (12).

Fractionation of neutral lipids by thin-layer chromatography. Neutral lipids were fractionated by preparative thin-layer chromatography (TLC) (13,14). Preliminary identifications were done by comparing R_f values with those of reference compounds applied to the same plate. For identification of wax esters (WE) and Alkyl-DAG, synthetic palmityl oleate and 1-*O*-hexadecyl-2,3-dipalmitoyl-*sn*-glycerol, respectively, were used. The alkyldiacylglycerol fraction was further purified by preparative TLC (15) using petroleum hydrocarbon/benzene (95:5, v/v) as developing solvent.

Abbreviations: Alkyl-DAG, 1-*O*-alkyl-2,3-diacylglycerol; DAG, diacylglycerol; GLC, gas-liquid chromatography; PM, plasma membrane; TLC, thin-layer chromatography; TMS, tetramethylsilane; WE, wax ester.

Analysis of wax esters. Wax esters were hydrolyzed on TLC plates according to Misra *et al.* (8) using lipid-free (16) hog pancreatic lipase. After recovery of the alcohols and fatty acids, alcohols were analyzed as acetates and fatty acids as methyl esters by gas-liquid chromatography (GLC) as described previously (17,18).

Analysis of 1-O-alkyl-diacylglycerols. The Alkyl-DAG were refluxed with methanolic hydrogen chloride for 2 hr under anhydrous conditions (15), and the methyl esters and 1-*O*-alkylglycerols formed were separated by preparative TLC. Aliquots of 1-*O*-alkylglycerols were silylated using Trisil-Z and analyzed by GLC on a 3% OV-17 column (15). Authentic 1-*O*-alkylglycerol standards *viz.*, 1-*O*-hexadecyl-*sn*-glycerol and 1-*O*-octadecyl-*sn*-glycerol, were derivatized and used as GLC standards.

A portion of the 1-*O*-alkylglycerol fraction was acetylated (19) and subjected to argentation TLC on layers impregnated with 10% silver nitrate (20). Two bands were recovered, one corresponding to 1-*O*-hexadecyl-2,3-diacetyl-*sn*-glycerol (R_f 0.6) prepared by acetylation of authentic 1-*O*-hexadecyl-*sn*-glycerol, the other with a lower migration rate (R_f 0.45) containing one double bond. Portions of both bands, along with their catalytically reduced (21) products, were analyzed by GLC. A portion of the compound with R_f 0.45 was oxidized by permanganate/periodate reagent and the methyl esters of monocarboxylic acid were recovered from the TLC plate and analyzed by GLC (20).

Infrared (IR) and ^1H nuclear magnetic resonance (NMR) spectroscopy. ^1H NMR spectra of Alkyl-DAG were recorded on a JEOL FX-100 FT (Tokyo, Japan) instrument using $CDCl_3$ as solvent with tetramethylsilane (TMS) as internal standard. IR spectra of Alkyl-DAG were recorded in nujol on a Shimadzu (Tokyo, Japan) IR-408 spectrophotometer.

RESULTS

Two uncommon lipid bands were detected when the neutral lipids from sperm plasma membrane were analyzed by TLC. The R_f values of the bands were 0.85 and 0.68 when petroleum hydrocarbon/diethyl ether/glacial acetic acid (90:10:1, by vol) was used as the developing solvent. As described below, the PM-bound neutral lipids were identified as WE (R_f 0.85) and Alkyl-DAG (R_f 0.68). Sperm PM contained approximately 3 and 5 μg/mg protein of WE and Alkyl-DAG (Table 1), or 1.5% and 2.4% of total neutral lipids, respectively. The compounds were identified by comparison of their R_f values with those of the authentic standards. The structures were further confirmed by IR spectroscopy. IR showed characteristic strong ester bands at 1735 and 1180 cm^{-1} for both compounds and an *O*-alkyl ether band at 1110 cm^{-1} for Alkyl-DAG. The ^1H NMR (100 MHz) spectrum of alkyldiacylglycerol showed signals at 5.34 ppm (*m*, C*H* = C*H*), 5.18 (*m*, H-2), 4.24 (AB part of an ABX spectrum with J_{AB} = 12 Hz, J_{AX} = 6 Hz, J_{BX} = 4 Hz; H-3), 3.54 (*d*, *J* = 6 Hz, H-1), 3.4 (*t*, *J* = 6 Hz, H-1), 2.64 (*t*, *J* = 4 Hz, = CH-CH_2-CH=), 2.3 (*t*, *J* = 7 Hz, -CH_2COO), 2.04 (*m*, -CH_2-CH=CH-), 1.24 (broad *s*, CH_2) and 0.88 (*t*, *J* = 6 Hz, CH_3-CH$_2$). The ^1H NMR spectrum was in good agreement with that reported by Wood and Snyder (22), and more recently by Pakrashi *et al.* (23). Lipase hydrolysis (8) of wax esters yielded fatty acids and fatty alcohols which were identified and quantitated by GLC analysis and were found to be present in a 1:1 molar ratio. Hydrolysis of Alkyl-DAG yielded fatty acids and 1-*O*-alkylglycerols which were identified and quantitated by GLC analysis, and were found to be present in 2:1 molar ratio.

The trimethylsilyl derivatives of the 1-*O*-alkylglycerols gave three peaks in GLC analysis, two of which were identified as 1-*O*-hexadecyl- and 1-*O*-octadecylglycerols by comparison of their retention times with authentic compounds. The peak that appeared ahead of 1-*O*-octadecylglycerol was identified following argentation TLC. The acetylated 1-*O*-alkylglycerols were separated into two bands by argentation TLC. The band with R_f 0.6 yielded two peaks in GLC, corresponding to the acetyl derivatives of 1-*O*-hexadecyl- and 1-*O*-octadecylglycerol. The other band with R_f 0.45 showed IR absorption bands at 3030 and 1650 cm^{-1}, indicating the presence of *cis*-double bonds. Upon catalytic reduction, this band yielded 1-*O*-octadecyl-2,3-diacetate, having a retention time in GLC identical to that of authentic compound prepared by acetylation of 1-*O*-octadecylglycerol. Oxidation of the R_f 0.45 band with permanganate/periodate and analysis of the monocarboxylic fatty acid as methyl ester by GLC produced C-9 (9:0, nonanoic) acid. The data confirmed that the compound was 1-*O*-*cis*-octadec-9′-enylglycerol.

Table 2 shows the fatty acid composition of WE and Alkyl-DAG of sperm PM. The lipids contained fatty acids having chain lengths of C_{14} to C_{22}. The major fatty acids of the WE were 14:0, 16:0, 16:1ω7, 18:0 and 18:1ω9, whereas Alkyl-DAG were particularly rich in fatty acids having chain lengths of 16:0, 18:0, 22:5ω3 and 22:6ω3. The Alkyl-DAG possessed a markedly lower ratio of saturated/unsaturated fatty acids than the WE, primarily because of its unusually high content of docosahexaenoic acid (22:6ω3).

The composition of the alcohols derived from WE measured upon lipolysis is presented in Table 3. Carbon chain lengths were found to be from 20- to 29 carbons; major components were 24:0, 28:0 and 29:0 alcohols.

[b]Values within parentheses show % (w/w) of total lipids.

[c]Values within parentheses show % (w/w) of neutral lipids.

DISCUSSION

Wax esters and ether lipids, including Alkyl-DAG, are known constituents of mammalian cells (24,25). Plasma membranes of mammalian cells contain ether-linked

phospholipids and glycolipids (6,7). The present study reports the presence of both WE and Alkyl-DAG in PM of a mammalian cell type, namely the spermatozoon. The sperm PM preparations we used were highly pure, as evidenced by electron microscopy and marker enzyme analysis (9). It thus appears that contaminating trace amount of cellular organelles, if any, would not make an appreciable contribution to the observed WE and ether lipid contents of isolated sperm PM.

Little is known about the biological significance of these neutral lipids. However, it is known that ether linkages resist hydrolytic action by lipases (26) and are likely to retard the rate of hydrolysis of acyl moieties next to the ether bond (27).

Phosphatidylinositol and phosphatidylcholine are known to be involved in transmembrane signalling in response to various external stimuli such as hormones or neurotransmitters (4,5). DAG, as a second messenger, activates protein kinase C which, in turn, propagates the signal by phosphorylation of specific proteins (4). Stimulation of MDCK cells by the tumor promoter 12-*O*-tetradecanoylphorbol-13-acetate results in the production of 1-*O*-alkyl-2-acyl-glycerols by the phospholipase C mediated hydrolysis of phosphatidylcholine (28). 1-*O*-Hexadecyl-2-acetyl-*sn*-glycerol, a synthetic alkylacylglycerol, has been found to inhibit the growth of HL-60 promyelocytic leukemia cells and to stimulate their differentiation to macrophage-like cells (29). Recently Daniel *et al.* (30) have shown that the synthetic 1-*O*-alkyl-2-acylglycerols inhibit DAG-activated protein kinase C activity. Furthermore, it has been speculated that the biological activity of alkylacylglycerol may be expressed through its inhibitory action on protein Kinase C (30). Alkylacylglycerol could also be generated in PM by the action of lipases on Alkyl-DAG, and affect signal transduction.

[a]INRA, Station de Recherches sur la Qualité des Aliments de l'Homme, Unité de Nutrition Lipidique 21034 Dijon and [b]Faculté de Médecine, Laboratoire de Physiologie, 21000 Dijon Cedex, France

Primary cultures of newborn rat cardiomyocytes were grown in medium supplemented with cyclic fatty acid monomers (CFAM) which had been isolated from heated linseed oil. The cells were harvested, and lipids were extracted and fractionated using silica cartridges and high-performance liquid chromatography. The CFAM structures isolated from cellular lipids were determined and compared to those that had been supplemented to the medium, using gas-liquid chromatography coupled with mass spectrometry (GC/MS). We found that CFAM were incorporated into phospholipids and neutral lipids of cardiomyocytes. Furthermore, CFAM with a cyclopentyl ring structure were more abundant in cardiomyocytes than were the cyclohexyl ring isomers. Our data suggest that CFAM of the 5-carbon and 6-carbon ring series are metabolized differently in newborn rat cardiomyocytes.
Lipids 27, 79–81 (1992).

Oils and fats undergo chemical changes during heating, such as oxidation, polymerization, hydrolysis, isomerization and cyclization (1–4). Among the compounds formed, cyclic fatty acid monomers (CFAM), especially those formed from linolenic acid (5), are suspected to cause adverse health effects (6). In recent experiments with rats, high perinatal mortality was observed in pups whose mothers were fed high quantities of this type of CFAM (7). Other physiological effects of oils heated under extreme conditions may also be attributed to CFAM (8,9). Bird *et al.* (10,11) studied the effects on heart cell cultures of distillable, non-urea adductable fractions obtained from thermally oxidized fats. However, the composition of this fraction was not given and may have included oxidized components as well. Use of purified fractions of CFAM seems to be desirable to study the physiopathological effects of heated oils. However, feeding experiments require large quantities of purified material which would be time-consuming and expensive to prepare. Hence, cell cultures can serve as useful models.

As part of our ongoing work on the toxicity of different types of CFAM, the present study examines the incorporation of purified CFAM derived from linseed oil into heart cells.

MATERIALS AND METHODS

Cyclic fatty acid monomers were prepared from linseed oil heated at 275°C under nitrogen for 12 hr, as previously described (12). The oil was saponified, and the free fatty acids were esterified and purified from polar compounds (mainly polymers) by column chromatography on silicic acid. Urea fractionation was used to obtain the CFAM (99% pure).

The culture medium was Ham's F10 basal medium supplemented with 10% fetal bovine serum (Seromed, München, Germany) and 10% human serum (CTS, Dijon, France). CFAM in ethanol (100 mg/5 mL) were added to the medium using lipid-free bovine serum albumin (fraction V, Sigma, St Louis, MO) at 37°C, at a molar ratio CFAM/albumin of 6:1 (13). The medium containing the CFAM was then sterilized by filtration (Millex GS 0.22 μ, Millipore, Milford, MA).

Primary cultures of rat ventricular cells were prepared as previously described (14). The hearts from 2- to 4-day-old rats were aseptically removed, minced and washed 3 times in a cold Saline G solution (NaCl 8 g/L, KCl 0.4 g/L, KH_2PO_4 0.15 g/L, Na_2HPO_4 0.19 g/L and glucose 1.1 g/L; Prolabo, Paris, France), and one more time in the same solution for 10 min at 30°C in a shaking water bath. The fragments were then submitted to a 7-step (10 min each) trypsinization process (Trypsin, Difco, Detroit, MI; 0.1% in Saline G) at 30°C. The supernatants of the last 6 proteolytic treatments were pooled and diluted v/v in culture medium. The muscle to non-muscle cell ratio was increased by a two-step (30 and 150 min) selective adhesion procedure. The final cell suspension was diluted to 4×10^5 cells/mL in culture medium and seeded in 60-mm plastic Petri dishes (5 mL/dish). Cultures were maintained at 37°C in a humidified atmosphere (5% CO_2, 19% O_2 and 76% N_2). The culture medium was renewed 24 hr after seeding and thereafter every 48 hr.

Cells were separated into two groups, and incubated either in the same medium or in the CFAM containing medium (21.5 mg/L) for two days. Cells were then harvested by scraping with a rubber policeman and pelleted by centrifugation.

Total lipids were extracted from the medium according to Folch *et al.* (15) with two modifications. First, 10 mL of medium were extracted with 75 mL of solvent mixture and 5 mL of a 0.73% solution of sodium chloride (which takes into account the sodium chloride content of the medium). Secondly, 1 mL of formic acid was added, as suggested by Savary and Constantin (16), to break calcium soaps. Total cell lipids were similarly extracted except that no formic acid was used.

Phospholipids were separated from non-phosphorus lipids using a silica cartridge (Sep-Pak, Waters, Milford, MA) as described by Juaneda and Rocquelin (17). Phospholipid classes were obtained using high-performance liquid chromatography (HPLC) and ultraviolet (UV) detection (18).

Fatty acids were transesterified using boron trifluoride/methanol (19). Fatty acid methyl esters (FAME) were hydrogenated in chloroform/methanol solution (2:1, v/v) using platinum oxide (Merck, Darmstadt, Germany) as catalyst under 3 bars of hydrogen pressure. CFAM were then isolated *via* urea inclusion (20) and analyzed by gas-

TABLE 1

Cyclic Fatty Acid Monomers (CFAM) in Culture Medium and in Lipids of Rat Cardiomyocytes in Culture

	Total CFAM (% of total methyl esters)	Relative proportions of the major CFAM types[a] (% of total CFAM)					
		1	2	3	4	5	6
CFAM fraction		16.2	22.1	6.5	22.3	9.4	23.4
Culture medium	11.5	18.0	18.0	6.1	21.0	8.1	23.4
Neutral lipids of cardiomyocytes	4.6	23.4	42.5	7.8	11.0	8.0	7.3
Phospholipids of cardiomyocytes	2.0	31.6	37.9	6.3	9.5	9.3	5.3
Phosphatidylcholine	3.5	32.5	37.6	6.8	11.0	7.3	4.8

[a]Bold numbers refer to the CFAM structures shown in Figure 1. The values are the mean of two separate cultures (more than 100 Petri dishes each).

liquid chromatography/mass spectrometry (GC/MS). A Hewlett-Packard 5970 Mass Selective Detector coupled with a Hewlett-Packard 5890 gas chromatograph was used with a fused silica column (J and W Scientific, Rancho Cordo, CA) coated with DB Wax (30 m × 0.25 mm i.d., film thickness 0.5 μm). The temperature was programmed from 50 to 200°C at 20°C/min, held at 200°C for 25 min, then programmed from 200°C to 220°C at 20°C/min and held at 220°C until completion of analysis. Helium was the carrier gas, and splitless injection was used.

RESULTS AND DISCUSSION

The CFAM fraction we used in this study was obtained from heated linseed oil and contained approximately half cyclopentyl isomers and half cyclohexyl compounds (21). CFAM distribution in the medium was uniform, and the relative proportions of the CFAM structures in the medium (Table 1 and Fig. 1) resembled those in the original CFAM fraction. Cyclic fatty acid monomers were not detected in the lipids of cardiomyocyte control cultures or in the culture medium.

The cardiomyocytes grown in CFAM-containing medium exhibited high levels of CFAM in their cellular lipids (Table 1). Incorporation of CFAM into phospholipids was about half that incorporated into neutral lipids. The data also show that incorporation of CFAM is rather selective. The cyclohexyl isomers 4 and 6 were incorporated into neutral lipids and phospholipids to a lesser extent (15–18% of the total CFAM in cell lipids *versus* 44% in culture medium) than were other CFAM, similar to what has previously been observed in female rats and their offsprings fed the same CFAM (7). Differences in the incorporation of cyclopentyl *versus* cyclohexyl ring CFAM had been difficult to observe in earlier studies due to the poor separation of individual CFAM (22) by gas-liquid chromatography (GC) on packed columns.

The results presented in Table 1 illustrate the effect of ring size of the CFAM. However, other factors, such as *cis versus trans* configuration, or propyl *versus* butyl substitution on the ring can also contribute to the observed differences.

Among the methods used in the present study, the urea inclusion step is critical. When the straight-chain fatty acids are not removed by urea inclusion, a very large peak of methyl stearate can mask some of the CFAM (23).

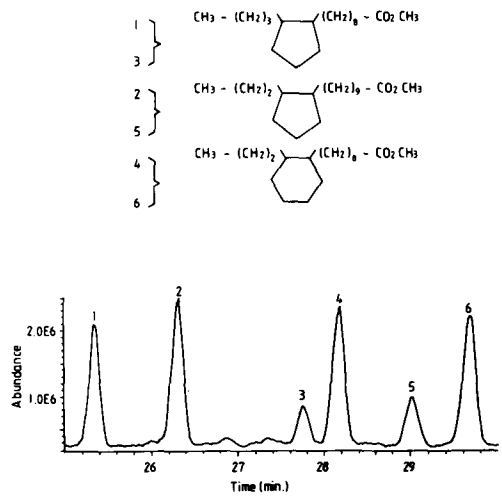

FIG. 1. Total ion chromatogram (GC/MS) of the hydrogenated CFAM from the cell culture medium. The structures are: 1 and 3, methyl 9-(2′-butylcyclopentyl)nonanoate; 2 and 5, methyl 10-(2′-propylcyclopentyl)decanoate; 4 and 6, methyl 9-(2′propylcyclohexyl)-nonanoate. Compounds 1, 2 and 4 have *trans* configuration, and compounds 3, 5 and 6 are the corresponding *cis* isomers.

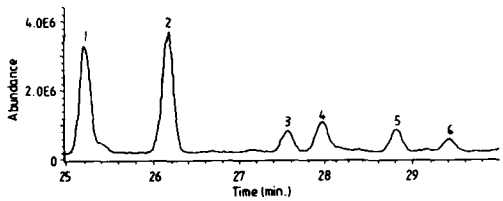

FIG. 2. Total ion chromatogram (GC/MS) of the hydrogenated CFAM derived from the phosphatidylcholine fraction of cultured rat cardiomyocytes. Peaks are identified as in Figure 1.

Sufficient enrichment of CFAM can be attained during urea inclusion when the proportions of urea and fatty acid methyl esters are at the optimum 3:1 ratio (7,12). When we attempted to quantify CFAM in individual phospholipid classes, accurate results were only obtained for the major phospholipid, namely phosphatidylcholine (Table

1, Fig. 2). For the lesser phospholipid classes, the large urea-to-fatty acid methyl ester ratio can cause CFAM losses due to trapping in the urea crystals. Special adaptation of the method will be required to accurately quantify low levels of CFAM in biological samples.

Gamma Linolenic Acid (GLA) Content of Encapsulated Evening Primrose Oil Products

Robert A. Gibson*, David R. Lines and **Mark A. Neumann**
Department of Pediatrics and Child Health, Flinders Medical Centre, Bedford Park (Adelaide) 5042, Australia

The fatty acid composition of 16 brands of evening primrose oil (EPO) capsules was determined by capillary gas chromatography. Fourteen of these EPO brands contained γ-linolenic acid (GLA) levels between 7% and 10% (mean, 8.7; range, 1.9–10.5%) and there was generally good agreement between the level of GLA claimed by the manufacturer and the level determined by analysis. Low levels of the monoenes 22:1 and 24:1 found in some brands may indicate contamination of EPO with borage oil.
Lipids 27, 82–84 (1992).

There is evidence that, in humans, either the conversion of linoleic acid (LA, 18:2n-6) to γ-linolenic acid (GLA, 18:3n-6) is blocked or the Δ6 desaturase responsible for the conversion is fully saturated. In either event, levels of GLA and other metabolites, including dihomo-γ-linolenic acid (DGLA, 20:3n-6) and arachidonic acid (AA, 20:4n-6), are unaffected by dietary supplementation with LA rich oils, but are elevated by consumption of evening primrose oil (EPO) which contains on average 9% GLA (1).

A number of clinical conditions have been treated orally with EPO, including pre-menstrual tension (2), rheumatoid arthritis (3) and breast disorders (4). Atopic eczema in children and adults is the condition showing the best result from oral EPO treatment (5). Based on a number of such studies (6), a product license has been granted to at least one pharmaceutical company under the label "Epogam" for the treatment of eczema.

In many countries, including Australia, numerous EPO brands are available in pharmacies and health food stores. We report here a systematic study on the fatty acids of a range of EPO products which we measured using sensitive capillary column gas chromatography.

MATERIALS AND METHODS

EPO capsules were obtained from pharmacies and health food stores in Sydney, Melbourne and Adelaide and, where possible, more than one batch number of each product was purchased. All capsules tested were in the soft gelatin form. The retail cost varied and ranged from A$ 0.19 to A$ 0.52 per capsule.

All EPO samples were tested against a standard that had been extracted from evening primrose seed in our laboratory. Seeds (5 g) were homogenized in 30 mL of petroleum hydrocarbon and the homogenate centrifuged. The supernatant was decanted and the sediment extracted twice with 30-mL washes of petroleum hydrocarbon. The combined supernatants were filtered and the solvent evaporated. Thin-layer chromatography (TLC) revealed that only triglycerides were present.

Fatty acid analysis. TLC showed that all commercial products were predominantly in the triglyceride form. EPO was removed from capsules and 1–2 μL added to glass vials without further purification. Five mL of a solution of 1% H_2SO_4 in methanol was added to each vial. Vials were sealed and heated at 70°C for 3 hr. After cooling, the resulting methyl esters were extracted with 2 mL n-heptane. The extract was transferred into 2-mL auto sampler vials containing anhydrous sodium sulfate. Fatty acid methyl esters were separated on a wide bore (0.56 mm) 50-m capillary column coated with SP 2340 (Supelco Inc., Bellefonte, PA) using a Hewlett Packard 5880 gas chromatograph (Hewlett Packard, Palo Alto, CA). Chromatographic conditions were those described in detail elsewhere (7). Helium was used as the carrier gas at a flow of 30 cm/sec. The oven temperature was increased from 120°C to 200°C at 5°C per min; injection temperature was held at 250°C; and flame ionization detector temperature was 300°C. Samples (1 μL) were injected using the split mode at a 30:1 ratio.

Variation. All products were sampled in triplicate. Variation in major peaks was less than 5%, while the variation in minor peaks (<1% of total fatty acids) was less than 15%. Analyses not meeting these ranges were rejected.

RESULTS AND DISCUSSION

A total of 16 brands of EPO were analyzed (Table 1). Our aim was to examine at least three batches of each brand, but these were not always available. Of the EPO brands examined most contained levels of GLA between 7–10%; exceptions were one batch of Bioglan (6.3%) and Moonkist (1.9%). There was generally good agreement between the level of GLA claimed by the manufacturer and that determined by analysis. The levels of the major fatty acid components of all the products were consistent with the range of values seen for genuine EPO in our laboratory. The very low level of GLA (1.9%) in Moonkist, a locally grown product, is thought to be due to climatic conditions. The high levels (>20%) of saturates measured in Nature's Own Plus are due to oils present in an added vitamin/mineral mix.

Examination of the minor components of the products showed interesting differences between brands. Several brands contained detectable amounts of C_{22} and C_{24} monounsaturated fatty acids (MUFA), which were not found in our laboratory standard EPO. While it is possible that these low levels of C_{22} and C_{24} MUFA are due to genetic differences among the various strains of evening primrose, we consider this unlikely. Analysis of oil extracted in our laboratory from seeds of evening primrose strains from Europe, China, Australia, New Zealand and North America has failed to reveal the presence of these MUFA.

[e] Includes 14:1, 15:1, 16:1, 17:1, 18:1, 20:1, 22:1 and 24:1.

TABLE 2

Fatty Acid Composition[a] of EPO, Borage and Safflower Oils

	GLA 18:3n-6	LA 18:2n-6	Total SFA[b]	Total MUFA[c]	20:1n-9	22:1n-11	24:1n-9
EPO	7.0	69.7	8.2	15.0	0.24	—	—
Borage	26.1	38.1	12.6	22.8	4.31	2.70	1.56
EPO/Borage (84:16)	9.8	64.9	8.8	16.4	0.79	0.46	0.25
Borage/Safflower (60:40)	9.8	60.9	10.8	18.3	1.94	1.27	0.90

[a] Values are means given as % weight of total fatty acids. [b] Includes 14:0, 15:0, 16:0, 17:0, 18:0, 20:0, 22:0 and 24:0. [c] Includes 14:1, 15:1, 16:1, 17:1, 18:1, 20:1, 22:1, and 24:1.

We investigated the possibility that some of the capsules contained blends of EPO and either borage or safflower oil (Table 2). Starting with an EPO sample with 7% GLA, blends of oils were prepared which were designed to achieve a GLA level of 10%. The fatty acid profile of the EPO/Borage oil blend (84:16) more closely matched the profile seen in some of the capsules than the Borage/Safflower blend (60:40).

GLA is the claimed active ingredient of EPO and, thus, consumers and researchers alike are interested in the GLA content of EPO products. Although the levels of GLA in the products tested in this study were in the range expected for EPO, minor constituents in some products suggested that some may contain contaminants of other oils.

Unlike marine oils (8), EPO is relatively easy to analyze (particularly by capillary gas chromatography) as it contains only two major polyunsaturated fatty acids (LA and GLA), and sometimes low levels of α-linolenic acid (18:3n-3) EPO is devoid of C_{22} and C_{24} MUFA that are present in some other GLA-containing oils, such as borage (9). Despite this, several of the products that we tested were found to contain amounts of 20:1, 22:1 and 24:1 consistent with a blend of borage and EPO (Table 2). It is interesting that most of the capsules thought to contain EPO/borage blends also contained GLA levels close to 10% of the total fatty acids. Whether this represents an attempt by manufacturers to supply oils with a standard GLA content or is the result of accidental contamination during pressing and/or extraction is unknown.

There are no reports of the comparative physiological or clinical effects of the various GLA containing oils in humans. Until this is done, the significance of capsules of EPO containing low levels of borage or other oils remains largely one of labelling.

Dietary Arachidonic and Linoleic Acids: Comparative Effects on Tissue Lipids

J. Whelan*, K.S. Broughton[1], M.E. Surette and J.E. Kinsella[2]
Lipids Research Laboratory, Institute of Food Science, Cornell University, Ithaca, New York 14853

The effects of preformed dietary arachidonic acid (AA, 20:4n-6) on murine phospholipid fatty acid composition in tissues capable (liver) and incapable (peritoneal exudate cells, PEC) of desaturating and elongating linoleic acid (LA, 18:2n-6) to AA were investigated. The results were compared with those obtained on matched animals on LA diets by either substituting or supplementing dietary LA with AA. Modest amounts of AA ethyl ester (0.5 wt%) included in the diet significantly increased tissue phospholipid AA levels by 39% and 57% in the liver and in PEC, respectively. The changes were further enhanced when dietary LA and AA intakes were equivalent, *i.e.*, 57% and 68% in liver and PEC, respectively. This enrichment was observed in all phospholipid classes analyzed, with the greatest impact on phosphatidylcholine. In addition, the doubling of dietary LA had little effect on tissue phospholipid AA levels. The data suggest that while the level of n-6 PUFA may have an important effect on tissue fatty acid composition, the type of n-6 PUFA in the diet could be of greater significance.
***Lipids* 27, 85–88 (1992).**

Arachidonic acid (AA, 20:4n-6) is one of the most abundant polyunsaturated fatty acids (PUFA) associated with mammalian phospholipids. While dietary n-6 PUFA are essential and beneficial, elevated intakes may contribute to the pathologies associated with a number of chronic diseases (1,2). When AA is liberated from membrane phospholipids, it can be enzymatically oxidized to a variety of eicosanoids, many of which are proinflammatory and proatherogenic (3–6).

The conversion of linoleic acid (LA, 18:2n-6) to AA is regulated by a number of mechanisms (7–11). Tissue AA levels may be influenced by the amount of LA consumed in the diet (12). LA is desaturated (*via* the Δ5 desaturase and Δ6 desaturase) and elongated to AA, primarily in the liver. As dietary LA intake increases, tissue AA levels also increase, but this process appears to be saturable (12–15). AA is an inhibitor of both the Δ5 and Δ6 desaturases (10,11); thus, it is conceivable that when AA is included in the diet, tissue AA levels could remain constant at the expense of desaturation and elongation of LA. However, the effects that preformed dietary AA has on the fatty acid composition of tissues capable (*e.g.* liver) and incapable (*e.g.*, peritoneal exudate cells, PEC) of converting LA to AA are not clear (16). This is an important consideration as the estimated daily intake of dietary AA in the United States is approximately 170 mg and, based on the AA content of commonly consumed foods, this intake could easily be tripled (17,18).

Few studies have evaluated the dietary effects of AA on tissue fatty acid composition. Mohrhauer and Holman (12) examined the effects of dietary AA on total hepatic fatty acid composition in the rat. However, AA ethyl ester administered orally *via* microsyringe was the only lipid provided in the dietary regimen (12). Studies on human subjects either failed to control the fatty acid content of the diet (19), provided no tissue fatty acid composition data (20), or examined plasma lipid composition only (19,21,22). Therefore, in the present study we have evaluated the effects of dietary AA on hepatic and extrahepatic (*viz.*, PEC) tissue fatty acid composition and compared the results with those obtained on matched animals on LA diets by either substituting or supplementing dietary LA with AA.

METHODS

Animals. Twenty CD-1 male mice (Charles River, Wilmington, MA) (18–20 g) were, upon arrival, randomly divided into four dietary groups (diets 1–4), five animals per group. All mice were maintained on Prolab Chow diet (Agway, RMF 1000, Syracuse, NY) for one week. Because the chow diet contained a small amount of 18:3n-3, an inhibitor of Δ6 desaturase, the mice were placed on a fat-free diet (ICN Biochemicals, Cleveland, OH) for one week, at which time they were placed on their experimental diets for two weeks.

Diets. All diets contained 10.5 wt% fat. The LA content of the diets, as supplied primarily by safflower oil (75% LA) (Hollywood Foods, Los Angeles, CA), was maintained at 2.0 wt% (Tables 1 and 2). The filler oils (6.5 wt%) consisted of high oleic acid sunflower oil (77% 18:1n-9) (SVO, Eastlake, OH) and tripalmitin (99% 16:0) (Sigma, St. Louis, MO) (Table 2). Each of the four diets contained an additional 1.5 wt% of fatty acid ethyl esters (NuChek Prep, Elysian, MN). Diets 1, 2 and 4 contained the ethyl esters of oleic acid (18:1n-9), linoleic acid (LA) and arachidonic acid (AA) respectively, while diet 3 contained 1.0 wt% 18:1n-9 plus 0.5 wt% AA. Diets were prepared in bulk, prepackaged in separate Whirl-Pak bags (NASCO, Atkinson, WI) and stored under nitrogen at −20°C. Water and food were provided *ad libitum* for two weeks. Fresh diets were provided daily and uneaten food was discarded to minimize oxidation prior to consumption. The fatty acid analysis of the diets is presented in Table 2.

Fatty acid analysis. Following two weeks on the experimental diets, the animals were sacrificed by diethyl ether inhalation and the peritoneal cavity was immediately washed (twice) with saline (0.9%) containing 1 mM ethylenediaminetetraacetic acid (EDTA). The peritoneal exudate cell population consisted primarily of resident macrophages (95%) and some mast cells (<5%). The cells were differentiated according to standard morphological

criteria using cytospin preparations stained with May-Grünwald-Giemsa stain. The peritoneal washes were pooled and centrifuged (700 × *g* for 4 min at 25°C) to pellet the PEC. The livers were perfused with cold (4°C) saline, removed, and homogenized in saline. The liver homogenates and pelleted PEC were resuspended in equal volumes of saline and chloroform/methanol (1:2, v/v) and the lipids were extracted sequentially with chloroform/saline (1:1, v/v) and chloroform (twice). The pooled extracts were evaporated to dryness under nitrogen and redissolved in chloroform. The PEC and liver phospholipids were separated from the neutral lipids by thin-layer chromatography (TLC) using a chloroform/methanol (8:1, v/v) solvent system. Fractions were made visible with 0.1% 8-hydroxy-1,3,6-pyrene-trisulfonic acid trisodium salt (Eastman Kodak, Rochester, NY) in methanol. The phospholipids were recovered from TLC plates by scraping the appropriate bands and resuspending in toluene. They were then saponified with 0.5 N KOH in methanol for 8 min at 86°C. Following acidification with 0.7 N HCl, the free fatty acids were extracted with equal volumes of hexane (twice), evaporated under nitrogen, and methylated with diazomethane. The fatty acid methyl esters were resuspended in hexane and analyzed by gas chromatography on a DB23 capillary column (0.25 mm × 30 m) (J&W Chromatography, Folsom, OH) with hydrogen as the carrier gas. The internal standard, pentadecanoic acid methyl ester, was added to each sample prior to the saponification step.

Fatty acid analysis of hepatic phospholipid classes. Following TLC separation of the hepatic phospholipids, the phospholipid classes were separated by a second TLC step using chloroform/methanol/acetic acid/water (25:20:3:0.3, by vol). Phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylinositol plus phosphatidylserine (PI + PS) were identified by comparison with standards. The appropriate bands were scraped from the TLC plates and the fractions were resuspended in toluene. The fatty acid composition of the isolated phospholipid classes was determined by the methods described above.

Statistical analysis. The analytical data were statistically evaluated by Duncan's protected least significant difference test using the MSUSTAT statistical package (Montana State University, Bozeman, MT). Significance was determined at $P<0.05$.

RESULTS

Food intake and weight gain were not significantly different between any of the dietary groups.

Fatty acid composition of liver total phospholipids. When dietary LA was doubled from 2 wt% (diet 1) to 4 wt% (diet 2) by adding LA ethyl ester, the LA content in liver phospholipids increased from 18.3 mol% to 21 mol%, respectively, with very little change in AA content or long chain n-6 PUFA content (C_{22} PUFA) (Table 3). However, when AA was included in the diet at 0.67 wt% (diet 3), hepatic phospholipids were significantly enriched in AA at the expense of LA (Table 3). The AA content of the tissue phospholipids from animals on diet 3 increased by 32% when compared to that of animals on diet 2, despite 30% less total n-6 PUFA in the diet. When AA was equivalent to the amount of LA in the diet (diet 4), tissue AA levels were enriched above those levels observed in the other three dietary groups; *i.e.*, there was a 57%, 48% and 13% increase *vs* diets 1, 2 and 3, respectively.

Fatty acid composition of liver phospholipid classes. When LA was increased in the diet (diet 1 *vs* diet 2), LA and AA levels in all phospholipid classes (PC, PE and PI + PS) changed little (Table 4), particularly in PE and PI

+ PS, with a slight but significant increase in PC. When AA was included in the diet, the relative content of AA almost doubled in PC of mice on diet 3 compared to diet 1 or diet 2, with a further increase of AA content in animals on diet 4. The LA levels in all phospholipid classes were approximately halved after the introduction of AA to the diet, with the greatest change also occurring in PC.

Fatty acid composition of peritoneal cell phospholipids. Dietary AA was very effective in altering the phospholipid fatty acid composition of the resident PEC (Table 3). The AA levels in PEC progressively increased with increasing dietary AA consumption, apparently at the expense of LA. Significantly, the doubling of dietary LA resulted in no significant change in peritoneal cell AA content.

DISCUSSION

Tissue AA can be derived from dietary LA *via de novo* synthesis, and this conversion appears to be highly regulated (7–11). This study showed that the doubling of dietary LA (diet 1 *vs* diet 2) resulted in a slight but insignificant increase in tissue AA levels in both the liver and PEC. Thus, as LA increased in the diet, its conversion to AA and eventual incorporation into tissue phospholipids was saturable. However, when AA was included in the diet, its effect on tissue phospholipid fatty acid composition was significant. Even when the dietary AA intake was one-third that of LA (diet 3 *vs* diet 2), tissue AA levels were significantly higher in the AA dietary group (diet 3), 32% and 39% in the liver and in PEC, respectively. These changes were even greater when dietary LA and AA intakes were equivalent (diet 1 *vs* diet 4), *i.e.*, 57% and 68% in the liver and in PEC, respectively. It is important to note that most of the effects of dietary n-6 PUFA on tissue 20:4n-6 levels came as a result of including modest amounts of 20:4n-6 in the diet (diet 3), with only a moderate increase when dietary 20:4n-6 was increased three-fold (diet 4). Therefore, while the level of dietary n-6 PUFA may be an important influence on tissue phospholipid fatty acid composition, the type of n-6 PUFA in the diet could be of greater significance (diet 2 *vs* diet 4).

Increasing dietary LA had little effect on AA content of hepatic phospholipid classes in any of the phospholipid fractions, but inclusion of AA in the diet resulted in significant enrichment of AA in all phospholipid classes. The data demonstrate that dietary AA is readily and preferentially incorporated into PC. This type of selectivity for AA has been observed elsewhere, under *in vitro* (13,23,24) and *in vivo* conditions (25).

Mice efficiently elongate and desaturate C_{18} PUFA to their C_{20} PUFA derivatives (26,27). Both mice and rats have relatively high Δ5 desaturase activity compared to a number of other species, including human (26). Low Δ5 desaturase activity would be one way of controlling tissue AA levels. Therefore, the impact of dietary AA on tissue AA content may be of great significance in those species which poorly elongate and desaturase LA to AA.

The enrichment of tissue phospholipids by dietary AA can be explained by a number of factors. Dietary AA does not have to be elongated and desaturated prior to tissue incorporation. Based on guinea-pig data, it has been estimated that as little as 0.01% of dietary LA may be converted to AA, with even a smaller percentage being incorporated into tissue phospholipids (28). Secondly, LA appears to be a relatively good substrate for β-oxidation in contrast to AA, which is a poor one. Studies evaluating the oxidation of a variety of ^{14}C-labelled PUFA revealed that only 14% of dietary AA is oxidized to [^{14}C]CO_2 (after 24 hr), in contrast to 48% for LA (25). Thirdly, C_{20} PUFA are preferentially incorporated into tissue phospholipids (13,23,24). The activities of liver acyl-CoA synthase and acyl CoA:1-acyl-*sn*-glycero-3-phosphocholine acyltransferase, key enzymes in phospholipid biosynthesis, exhibit relatively high specificity for AA when compared to other fatty acid, including LA (23).

In summary, the inclusion of AA in the diet, even in modest amounts, resulted in facile enrichment of tissue phospholipid AA content. This enrichment was observed in all phospholipid fractions (PC, PE, PS + PI), with the greatest impact on PC. Increasing dietary LA levels resulted in small increases in tissue AA content, but these changes were minimal compared with those observed with dietary AA. These results may be particularly relevant in species with limited desaturase activities, *e.g.*, human.

ARTICLE

Docosahexaenoic Acid in Developing Brain and Retina of Piglets Fed High or Low α-Linolenate Formula with and Without Fish Oil

L. Dianne Arbuckle[a,1] and **Sheila M. Innis**[b,2,*]

[a]Department of Human Nutrition and [b]Department of Pediatrics, University of British Columbia, Vancouver, British Columbia, Canada V5Z 4H4

Docosahexaenoic acid (22:6n-3) can be synthesized in the liver and/or brain from α-linolenic acid (18:3n-3) and is required in large amounts in structural membranes of developing brain and retina. The adequacy and efficacy of formulas containing 18:3n-3 and/or fish oil in providing 22:6n-3 for deposition was investigated in piglets fed formula from birth to 15 days. The test formulas contained high (HL) or low (LL) 18:3n-3 (3.9 or 0.7% of the total formula fatty acids, respectively), or low 18:3n-3 plus fish oil (LL+FO) to provide C_{20} and C_{22} n-3 polyunsaturated fatty acids (0.8% of total fatty acids). Fatty acid analyses of synaptic plasma membrane and retina ethanolamine phospholipids (EPL), which are especially enriched in 22:6n-3, were compared to those of 15-day-old piglets fed sow milk (SM). Feeding LL resulted in lower 22:6n-3 in synaptic plasma membrane. Fatty acid levels in HL and LL+FO piglets were equivalent to SM, with the exception of lower 22:5n-3 in the synaptic plasma membrane of LL+FO and in the retina of HL and LL+FO-fed piglets. Levels of 22:4n-6 were also lower in the retina of the LL+FO group. The results suggest formula 18:3n-3 is at least 24% as effective as C_{20} and C_{22} n-3 fatty acids as a source of membrane 22:6n-3. This study shows dietary 18:3n-3, as the only n-3 fatty acid, can support deposition of comparable percentage of 22:6n-3 to natural milk. Fish oil also supported tissue levels of 22:6n-3 similar to natural milk; however, lower 22:4n-6 may indicate possible inhibitory effects on n-6 metabolism.

Lipids 27, 89–93 (1992).

Docosahexaenoic acid (22:6n-3) is required in large amounts in phospholipids (PL) of cellular and subcellular membranes of the developing brain and retina. Prolonged dietary deficiency of n-3 fatty acids may result in decreased brain and retina 22:6n-3 (1–8) and impairment of normal visual function in rodents (9) and monkeys (7). The visual problems seem to persist even when the low brain and retina 22:6n-3 levels are restored (7). Altered visual acuity also has been demonstrated in premature infants fed formulas providing less than 1% of total fatty acids as α-linolenic acid (18:3n-3) and no C_{20} or C_{22} polyunsaturated fatty acids (PUFA) (10,11). In humans, the period of neuronal differentiation and maturation coincides with rapid C_{20} and C_{22} PUFA accretion in structural PL of the central nervous system (CNS) (12). The functional alterations suggest that tissue levels of 22:6n-3 may be important for normal development of the CNS.

Human breast milk typically provides 22:6n-3 and other C_{20} and C_{22} n-3 and n-6 PUFA, as well as about 8–17% of total fatty acids as linoleic acid (18:2n-6) and 0.5–1% of total fatty acids as 18:3n-3 (13). Infant formulas provide 18:2n-6 and 18:3n-3 but, in contrast to milk, they contain little or no C_{20} and C_{22} PUFA. Low levels of 22:6n-3 in red blood cell (RBC) and plasma PL of infants fed formula have led to the speculation that the desaturase enzymes required for the synthesis of C_{20} and C_{22} derivatives of 18:2n-6 and 18:3n-3 may be immature at birth (14,15) or that C_{20} and C_{22} PUFA, if synthesized, are unavailable to growing neural tissues (16). This has led to suggestions that 22:6n-3 is essential in the diet of the newborn (17,18), and to clinical trials with fish oil-supplemented formulas (10,11,19). Although effective in supplying 22:6n-3 for developing tissues (3,7,20–23), the high amount of eicosapentaenoic acid (20:5n-3) and minimal arachidonic acid (20:4n-6) in marine fish oils leads to increased 20:5n-3/20:4n-6 in liver and plasma PL (19–22,24). The subsequent decrease in 20:4n-6 availability, substrate competition between n-6 and n-3 fatty acids for cyclooxygenase and/or a change in membrane fluidity may have possible functional implications to, for example, xenobiotic (25) or eicosanoid (26) metabolism, or immune function (27).

Piglets fed from birth with formula containing 34% of total fatty acids as 18:2n-6 and 0.8% of total fatty acids as 18:3n-3 had lower 22:6n-3, but higher 22:5n-6 in brain (5), synaptosomes (4) and retina (8) than piglets fed natural sow milk. The low CNS 22:6n-3 may be explained by an inadequate dietary supply of 18:3n-3 or limited ability to desaturate n-3, but not n-6, fatty acids. The increase in 22:5n-6 in the CNS lipids of these piglets (4,5,8) as well as n-3 fatty acid-deficient rodents (1,2), chicks (28) and non-human primates (7) provides evidence of Δ4 desaturase activity in the newborn.

The ability of various amounts of 18:3n-3 as compared to n-3 PUFA to support deposition of 22:6n-3 in brain at comparable levels to natural milk cannot be studied in humans. The piglet is a suitable animal model for this study because the timing of the perinatal brain growth spurt (29) and brain and milk lipid fatty acids (4) are similar to that of humans. The objective of this study was to determine if formula containing either 18:3n-3 as the only n-3 fatty acid, in amounts approximately four-fold greater than the total n-3 fatty acids in milk, or similar 18:3n-3 to milk plus C_{20} and C_{22} n-3 PUFA from fish oil can support equivalent deposition of 22:6n-3 in the CNS to sow milk. The quantity of fish oil used was similar to that added to formulas in clinical studies (10,11,19). The

Abbreviations: ANOVA, analysis of variance; CNS, central nervous system; EPL, ethanolamine phospholipids; FO, fish oil; GLC, gas-liquid chromatography; HL, high α-linolenic acid; HPTLC, high-performance thin-layer chromatography; LL, low α-linolenic acid; PL, phospholipid; PUFA, polyunsaturated fatty acids; RBC, red blood cell; SM, sow milk; UI, unsaturation index.

four-fold greater 18:3n-3 was based on the work of Anderson *et al.* (28), which suggests 18:3n-3 was about four times less effective than 20:5n-3 and 22:6n-3 in supporting brain n-3 fatty acid deposition. The fatty acid analyses were restricted to synaptic plasma membrane and retina ethanolamine phospholipids (EPL), because these membranes are especially enriched in 22:6n-3 (30,31).

MATERIALS AND METHODS

Animals and diets. Male Yorkshire piglets of normal term gestation (116–118 days) were obtained from the University of British Columbia, Department of Animal Science and Pitt Ineffable Growers Ltd. (Pitt Meadows, B.C., Canada). Seven non-littermate piglets fed sow milk (SM) were kept on the farm and suckled from the sow. Six non-littermate piglets for each of the three formula groups were taken from the sow immediately *post partum*, prior to receiving colostrum. All animals were fed from birth to 15 days of age, representing at least two-thirds of the normal suckling period. Housing, feeding and provision of passive immunity with pig serum-derived immunoglobulin have been described previously (4). Spot heat lamps were attached to the cages to provide 24-hr light and heat for the first 7 days. An 0700-1900 hr light/1900–0700 hr dark cycle was maintained from 8–15 days to parallel lighting conditions of sow milk-fed piglets. The formula fats were blends of soy, coconut, corn, canola and/or high oleic acid sunflower oils, with or without marine oil. The fat contributed approximately 50% of dietary energy, similar to that provided by sow milk. The formulas supplied similar amounts of 18:2n-6, but with low (0.7% of the total fatty acids, LL) or high (3.9% of the total fatty acids, HL) 18:3n-3 or low 18:3n-3 with fish oil to provide 20:5n-3, 22:5n-3 and 22:6n-3 in amounts of 0.4, 0.1 and 0.3% of the total formula fatty acids, respectively (LL+FO) (Table 1). The formulas differed from sow milk in their higher percentage of fatty acids with C $\leqslant$ 14, lower percentage of 16:0 and absence of C_{20} and C_{22} n-6 PUFA. In contrast to LL+FO, LL and HL contained no detectable C_{20} and C_{22} n-3 PUFA. After opening, the liquid, read-to-feed formulas were kept at 4°C for no longer than 24 hr. The procedures used were approved by the University of British Columbia Animal Care Committee and conformed to the guidelines of the Canadian Council on Animal Care.

Sample collection and analyses. The non-fasted animals were sacrificed by intracardiac injection of 10 mL KCl (20 meq/10 mL) at 15 days of age. The cerebrum was immediately excised, weighed, minced and homogenized in 5 v/wt of 0.32 M sucrose/15mM Tris HCl (1mM EDTA, 1 mM $MgCl_2$ and 1.5 mM glutathione), pH 7.4. Synaptic plasma membranes were isolated by the method of Cruz and Gurd (33). Whole eyes were dissected within 15 min of death and kept on ice until retinas were removed with a gentle stream of ice-cold saline. All tissues were stored at −80°C until analysis.

Total lipids were extracted from all tissues according to Folch *et al.* (34). Lipid extracts were separated into PL classes on high-performance thin-layer chromatography (HPTLC) plates (Merck, Darmstadt, Germany) using chloroform/methanol/acetic acid/water (50:37.5:3.5:2, v/v/v/v) (35) as the solvent system. Synaptic plasma membrane and retina EPL fractions, containing diacyl, alkylacyl and alkenylacyl glycerophosphoethanolamine, were collected. Fatty acid methyl esters were prepared, then separated and identified by gas-liquid chromatography (GLC) (4) using authentic fatty acid methyl ester standards (Supelco Inc., Bellefonte, PA; and Nu-Chek-Prep, Inc., Elysian, MN).

Statistical analysis. Differences in the mean levels of each fatty acid among the diet groups were investigated using one-way analysis of variance (ANOVA) (36). Formal tests of differences among diets utilized Fisher's least significant difference and were based on least squares means and standard errors calculated from ANOVA. Bonferroni corrections within a fatty acid were used to determine which of these differences were significant ($P < 0.01$). All tests for differences between means were two-sided. Outliers for each fatty acid detected by residual analysis methods were removed and the analysis was repeated. All calculations were performed using the General Linear Model procedure in the Number Cruncher Statistical System, version 5.01 (Kaysville, Utah).

[a]The fatty acid composition of sow milk and formula was determined by direct 1-hr transesterification (100°C) with methanol/benzene (4:1, v/v) and acetyl chloride (ref. 32) and subsequent analysis by GLC.

[b]Values for sow milk are mean of 2 milk samples collected at 1- and 2-weeks lactation.

[c]nd, Not detected.

RESULTS AND DISCUSSION

Growth. The first 15 days of life are a period of exponential growth in the piglet. Body weight increased from about 1.2 kg to about 4.3 kg, while the total brain weight increased from about 27.9 g (5) to about 37.8 g over the 15 day study. This represents increases in body and brain weights of about 300% and 40%, respectively. Significant differences ($P < 0.05$) were not found among the four groups of piglets either in the final body (mean ± SEM: SM, 4.1 ± 0.4; LL, 4.3 ± 0.4; HL, 4.4 ± 0.3; and LL+FO, 4.3 ± 0.3 kg) or cerebrum (mean ± SEM: SM, 35.0 ± 1.0; LL, 34.1 ± 0.9; HL, 32.0 ± 0.6; and LL+FO, 33.3 ± 1.1 g) weight.

Effect of feeding low (LL) or high α-linolenate (HL) formula on tissue n-6 and n-3 fatty acids. The percentage of 22:5n-3, 22:6n-3, the ΣC_{20} and C_{22} n-3 PUFA and

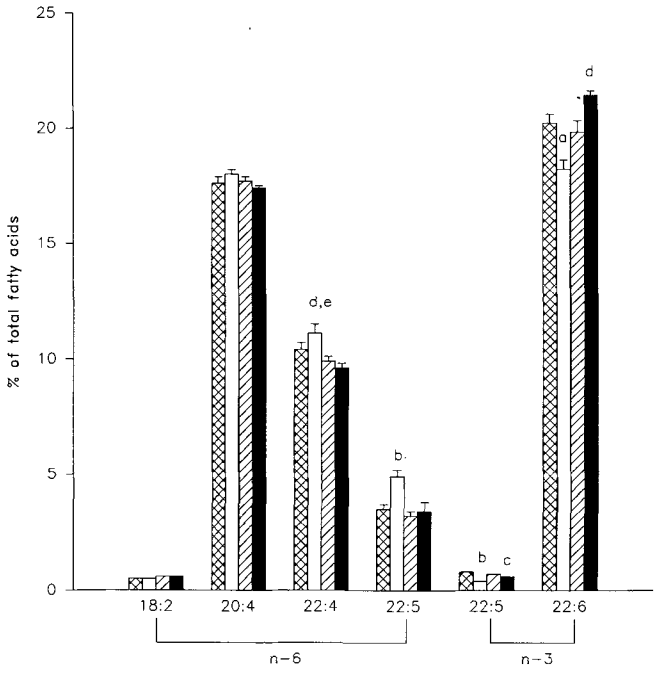

FIG. 1. Effect of dietary fatty acids on n-6 and n-3 fatty acids of synaptic plasma membrane ethanolamine phospholipids (EPL) of 15-day-old piglets fed: sow milk (SM), crossed bars; or formula containing 0.7% (LL, low linolenate), white bars; or 3.9% of total fatty acids as 18:3n-3 (HL, high linolenate), hatched bars; or 0.6% of total fatty acids as 18:3n-3 + 0.4, 0.1 and 0.3% of total fatty acids as 20:5n-3, 22:5n-3 and 22:6n-3, respectively (LL+FO, low linolenate + fish oil), black bars. Values are mean ± SEM (n=7, 6, 6, and 5, respectively). Values denoted with symbols represent statistically significant differences in the Fisher's least significant difference test, with Bonferroni correction, as follows: a, $P < 0.001$; and b, $P < 0.001$ *vs.* all other groups; c, $P < 0.001$ *vs.* SM; d, $P < 0.01$ *vs.* HL; and e, $P < 0.01$ *vs.* LL+FO.

22:6n-3/22:5n-6 were decreased and ΣC_{20} and C_{22} n-6 PUFA, specifically 22:5n-6, was increased in synaptic plasma membrane EPL of piglets fed LL as compared to SM (Fig. 1, Table 2). These changes are characteristic of neural tissues of rodents (1,2,37), non-human primates (7) and piglets (4,5,8) fed diets deficient in n-3 fatty acids. As in the synaptic plasma membrane, 22:5n-6 was increased and the ratio of 22:6n-3/22:5n-6 was decreased in the retina of LL compared to SM-fed piglets, although the percentage of 22:6n-3 was not significantly different (Table 2). In contrast, Hrboticky *et al.* (8) found significantly lower 22:6n-3 in the retina PE of piglets fed formula containing 34 and 0.8% of total fatty acids as 18:2n-6 and 18:3n-3, respectively. Possibly, competitive inhibition by the high levels of 18:2n-6 (18:2n-6/18:3n-3 ratio, 38:1) in the latter (8) compared to the LL formula (18:2n-6/18:3n-3 ratio, 22:1) may explain the difference in results. Despite the changes in individual C_{20} and C_{22} n-3 and n-6 fatty acids of piglets fed LL, the UI and ΣC_{20} and C_{22} PUFA within the structural PL of the neural tissues were similar among the groups (Table 2).

Levels of all fatty acids in the synaptic plasma membrane and retina EPL of piglets fed HL were equivalent to those of SM-fed piglets, with the exception of a lower retina 22:5n-3 in the HL group (Figs. 1 and 2, Table 2). The similar deposition of 22:6n-3 in neural tissues of HL and SM groups provides definitive evidence that, in this species, dietary 18:3n-3 can support synthesis and deposition of comparable amounts of 22:6n-3 in the absence of a dietary source of 22:6n-3. The higher amounts of 18:3n-3 in the HL formula may be necessary for adequate *de novo* synthesis of 22:6n-3 for deposition in structural membranes concomitant with probable oxidation of diet 18:3n-3 (38,39) to meet the high energy demands of the rapidly growing newborn. Whether or not a lower 18:2n-6/

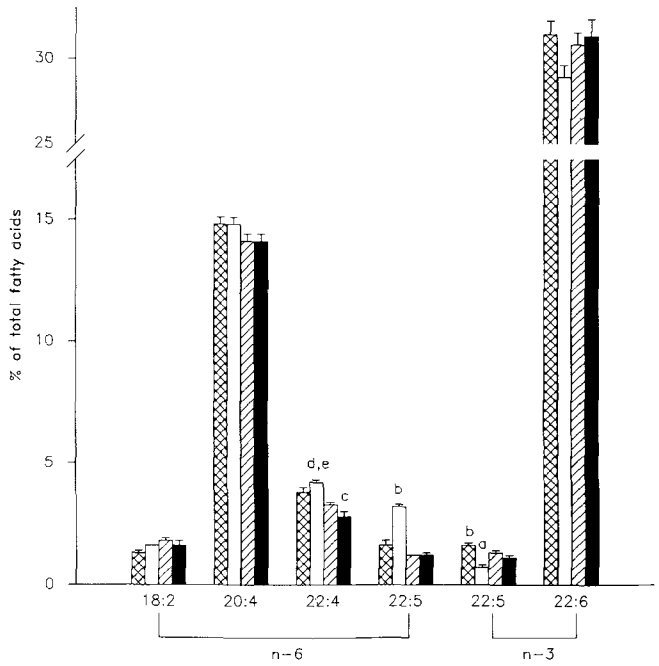

FIG. 2. Effect of dietary fatty acids on n-6 and n-3 fatty acids of retina ethanolamine phospholipids (EPL) of 15-day-old piglets fed sow milk (SM), crossed bars; or formula containing 0.7% (LL, low linolenate), white bars; 3.9% of total fatty acids as 18:3n-3 (HL, high linolenate), hatched bars; or 0.6% of total fatty acids as 18:3n-3 + 0.4, 0.1 and 0.3% of total fatty acids as 20:5n-3, 22:5n-3 and 22:6n-3, respectively (LL+FO, low linolenate + fish oil), black bars. Values are mean ± SEM (n=8, 5, 6 and 5, respectively). Values denoted with symbols represent statistically significant differences in the Fisher's least significant difference test, with Bonferroni correction, as follows: a, $P < 0.01$; and b, $P < 0.001$ *vs.* all other groups; c, $P < 0.001$ *vs.* SM; d, $P < 0.01$ *vs.* HL; and e, $P < 0.01$ *vs.* LL+FO.

18:3n-3 ratio than that in the LL formula (22:1) would facilitate assimilation of 22:6n-3 comparable to HL formula (18:2n-6/18:3n-3 ratio, 4:1) cannot be speculated from our results, but should be considered.

Diets supplying 0.44% of kcal as 18:3n-3 to newly hatched n-3 fatty acid deficient chicks have been shown to be inadequate to support normal levels of 22:6n-3 in brain and retina (28). This is in agreement with our results, showing that formula providing 0.3% of kcal as 18:3n-3 (LL) did not support normal 22:6n-3 deposition in the synaptic plasma membrane EPL. Recent studies have suggested the minimum dietary requirement for 18:3n-3 needed to achieve maximum levels of 22:6n-3 in rat total brain lipid is about 0.4% of kcal (1). Optimal amounts of 22:6n-3, however, do not appear to have been incorporated into the rat brain synaptosomes and retina in the latter studies until the diet 18:3n-3 intake was about 0.7% of kcal (1). This would allow a prediction that the HL formula, which provided 1.7% of kcal as 18:3n-3, would be an adequate source of n-3 fatty acids for the developing CNS. The results found support this prediction.

Effect of feeding formula containing low α-linolenate plus fish oil or high linolenate on tissue n-6 and n-3 fatty acids. Formulas containing low levels of fish oil to provide a diet source of 20:5n-3 and 22:6n-3 have been shown to be effective in maintaining plasma and RBC PL levels of 22:6n-3 in term (19) and preterm (10,11,24) infants similar to those found when human milk is fed. Further, addition of marine oils to diets containing limited 18:3n-3 are effective in supplying 22:6n-3 to developing piglet (20,21) and rodent (22,23) brain. Feeding the LL+FO formula resulted in similar ΣC_{20} and C_{22} n-3 PUFA and 22:6n-3, but lower 22:5n-3, in the synaptic plasma membrane and retina EPL to SM-fed piglets (Figs. 1 and 2, Table 2). The levels of 22:6n-3 were significantly higher in the synaptic plasma membrane EPL of the LL+FO group than in the HL group, however, values were not significantly different from those of the SM-fed piglets. Yamamoto *et al.* (2) reported similar levels of 22:6n-3 in brain between rats fed 8% of diet kcal as 18:3n-3 and rats fed 0.5% plus 0.3% of kcal as 18:3n-3 and C_{20} and C_{22} n-3 PUFA, respectively. In contrast, feeding diets containing fish oil to provide 5-6% of kcal as C_{20} and C_{22} n-3 PUFA resulted in a higher percentage of 22:6n-3 in cerebral cortex of monkeys (3) and brain microsomes of rats (40) than when a control diet providing 1-2% of kcal as 18:3n-3 was fed. Based on estimates of dietary requirements for 18:3n-3 of less than 1.0% of kcal (1), it seems possible that the elevation of C_{20} and C_{22} n-3 PUFA seen with fish oil supplementation at more than 5% of kcal reflects pharmacological changes rather than optimal physiology.

Our results indicate that 1.7% of dietary kcal as 18:3n-3 is as effective as 0.4% of kcal as C_{20} and C_{22} n-3 PUFA in achieving levels of 22:6n-3 in the growing piglet synaptic plasma membrane and retina. Thus, as suggested by others (28), our results show that dietary 18:3n-3 is at least 24% as efficient as C_{20} and C_{22} n-3 PUFA as a source of CNS 22:6n-3 in the newborn piglet.

The synaptic plasma membrane and retina EPL fatty acids contained less than 0.1% of total fatty acids as 20:5n-3, even in piglets fed HL or LL+FO formula (data not shown). Levels of 20:4n-6 were not altered in these CNS tissues by formula feeding (Figs. 1 and 2). Similarly, lack of accumulation of 20:5n-3 (3,20,21,40) and maintenance of 20:4n-6 in brain (20,21,37) have been reported following feeding with up to 8% of kcal as 18:3n-3 (37) or 0.4 to 6% of kcal as C_{20} and C_{22} n-3 PUFA (3,20,21,40).

The only significant difference found in the synaptic plasma membrane and retina EPL n-6 fatty acids among the SM, HL and LL+FO piglet groups was a lower 22:4n-6 in the retina EPL of LL+FO compared to SM-fed piglets (Fig. 2, Table 2). Whether or not this is related to the fish oil and has any physiological significance is unknown. It is known, however, that 22:4n-6 may be chain shortened (41), thus possibly contributing to the maintenance of membrane PL 20:4n-6.

In summary, the results of this study demonstrate that the provision of 1.7% of kcal as 18:3n-3 in formula containing 8% of kcal as 18:2n-6 is adequate for normal C_{20} and C_{22} n-3 and n-6 PUFA deposition in the CNS of term gestation piglets. The relatively high formula 18:3n-3, giving an 18:2n-6/18:3n-3 ratio of 4:1, did not result in any reduction in the normally high levels of C_{20} and C_{22} n-6 PUFA in CNS tissues examined. Small amounts (0.4% of kcal) of C_{20} and C_{22} n-3 PUFA were also effective in supporting 22:6n-3 deposition in the synaptic plasma membrane and retina and did not lead to accumulation of 20:5n-3 or loss of 20:4n-6.

ACKNOWLEDGMENTS

This work was supported by grants from the Medical Research Council of Canada (MRC-Industry Award) and the Canola Utilization Assistance Programme. The formulas were prepared and generously donated by Ross Laboratories (Columbus, OH). The assistance of France Rioux and the animal unit staff in the housing and care of piglets, and the help of Murray MacKinnon in statistical analysis, is gratefully acknowledged.

[Received March 6, 1991, and in revised form September 20, 1991; Revision accepted December 12, 1991]

Does a Threshold for the Effect of Dietary Omega-3 Fatty Acids on the Fatty Acid Composition of Nuclear Envelope Phospholipids Exist?

J.T. Venkatraman, T. Toohey and **M.T. Clandinin***
Nutrition and Metabolism Research Group, Departments of Foods & Nutrition and Medicine, University of Alberta, Edmonton, Alberta, Canada T6G 2C2

Existence of a dietary maximal level or threshold for incorporation of ω3 fatty acids into membrane phospholipids is of interest as it may further define understanding of the dietary requirement for ω3 fatty acids. To test whether feeding increasing levels of dietary ω3 fatty acids continues to increase membrane ω3 fatty acid content, weanling rats were fed a nutritionally adequate semipurified diet which provided increasing amounts of C_{20} and C_{22} ω3 fatty acids, such as 20:5ω3 and 22:6ω3. Dietary 20:5ω3 and 22:6ω3 were provided by substituting a purified shark oil concentrate of high 22:6ω3 content for safflower oil high in 18:2ω6. After four weeks of feeding, nuclear envelopes from four animals in each diet group were prepared, lipid was extracted and phospholipids separated. Arachidonic acid content in membrane phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol and phosphatidylserine was significantly reduced by feeding increased dietary levels of ω3 fatty acids. Decline of 20:4ω6 level in phospholipid tended to stabilize when the dietary content of total ω3 fatty acids reached 4–5% of total fatty acids. Above this level, dietary ω3 fatty acids did not result in a further decrease in membrane content of 20:4ω6. Increase in membrane phospholipid content of 20:5ω3 occurred as the dietary intake of ω3 fatty acids increased from 1.1% to 5% of total fatty acids. A dietary ω3 fatty acid level of 2.2–3% was sufficient to result in maximum incorporation of 22:6ω3 into membrane phosphatidylcholine and phosphatidylethanolamine, but not into phosphatidylinositol or phosphatidylserine.
Lipids 27, 94–97 (1992).

The role of dietary omega-3 fatty acids has been studied in a wide variety of membranes (reviewed in ref. 1). When eicosapentaenoic acid (20:5ω3) is fed to rats, 20:5ω3 and docosahexaenoic acid (22:6ω3) levels increase in membrane phospholipids. It is not clear whether 22:6ω3 increases in membrane solely as a consequence of *in vivo* conversion of 20:5ω3 to 22:6ω3 or because most sources of 20:5ω3 also contain some 22:6ω3. Thus, relatively little is known about the incorporation of dietary docosahexaenoic acid into membrane lipids. Recent experiments (2) have used various dietary levels of 18:3ω3 to discern a dietary threshold level of 0.4 to 2.4% of energy to produce significant changes in brain membrane 22:6ω3 and 22:5ω6 levels. Not only is minimum dietary levels of ω3 fatty acid required for incorporation of ω3 fatty acids into membrane lipid to affect integral membrane functions clearly of interest, it is central to current debate over the optimal fatty acid composition of infant formulas, and may help to establish dietary requirements for ω3 fatty acids.

Feeding diets high or low in polyunsaturated to saturated fats induces differences in fatty acid composition of the nuclear envelope phospholipid in the liver, altering functions involved in hormone binding (3), mRNA synthesis and nucleocytoplasmic exchange of macromolecules (4). Thus, diet-induced change in the composition of this membrane alters functions central to the activity of the cell.

The present study used a feeding model to determine whether gradual increase in dietary ω3 fatty acids, primarily 22:6ω3 and 20:5ω3, results in a continuous increase in the content of 20:5ω3 and 22:6ω3 in nuclear envelope phospholipids. We hypothesized that if a dietary threshold exists it would result in a maximum level of incorporation of ω3 fatty acid in membrane phospholipids.

MATERIALS AND METHODS

Animals and diets. Weanling Sprague-Dawley strain rats were fed one of eight nutritionally adequate semipurified diets that provided different levels of C_{20} and C_{22} ω3 fatty acids, such as 20:5ω3 and 22:6ω3 (Table 1) (5). The 18:3ω3 level of the diets was kept constant (Table 2). Dietary 20:5ω3 and 22:6ω3 were provided by substituting a purified shark oil concentrate of high 22:6ω3 content for safflower oil high in 18:2ω6 (Table 1). Data are expressed as a function of increasing dietary intake of ω3 fatty acid.

After four weeks of feeding, four animals from each diet were sacrificed by cervical dislocation. Livers were quickly removed and placed on ice. Subsequent procedures were done at 4°C unless stated otherwise.

Preparation of nuclear envelope. Nuclear envelopes were prepared from the purified nuclear pellet by subjecting nuclei to deoxyribonuclease (Sigma Chemical Co., St. Louis, MO) digestion and were purified by layering on a discontinuous sucrose gradient (6). Succinic dehydrogenase activity could not be detected in these preparations, indicating that membrane preparations were free of mitochondrial contamination. Contamination by lysosomes, plasma membranes and endoplasmic reticulum was also very low. Electron microscopic examination indicated that the nuclear envelope preparations were intact, with inner and outer membranes well preserved.

Extraction and analysis of lipids. Nuclear membrane lipids were extracted and phospholipids were separated (7,8). Lipids were identified and recovered; fatty acid methyl esters were prepared using boron trifluoride/methanol reagent (9). Saturated and unsaturated fatty acids of 14–24 carbons in chain length were analyzed by automated capillary gas-liquid chromatography using a fused silica column (Scientific Gas Engineering, Victoria, Australia, BP-20 column, 25 m × .25 mm ID) (10). Fatty acids analyzed included all saturated and unsaturated fatty acids of 14–24 carbons in chain length. Only major ω6 and ω3 fatty acids are listed.

[a] All dietary saturated and unsaturated fatty acids of C_{14} to C_{24} in chain length were analyzed; however, only major constituents are listed.

[b] Σω3, Total ω3 fatty acids.

Assays. Protein content was determined (11). Marker enzymes were measured (12) to determine the purity of nuclear envelope preparations. Data were assessed by regression procedures to determine the best fit line. Values (n ± SD) for each diet treatment are illustrated with the best fit line.

RESULTS AND DISCUSSION

Feeding diets of increasing ω3 fatty acid content altered the fatty acid composition of the nuclear envelope (Figs. 1 and 2). The degree of change which occurred in membrane composition was different for individual essential fatty acids. For example, increasing dietary content of ω3 fatty acids resulted in a relatively small change in the content of 18:2ω6 in phosphatidylcholine (Fig. 1) and phosphatidylinositol (Fig. 2). However, arachidonic acid content in membrane phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol and phosphatidylserine was significantly reduced by feeding increasing levels of ω3 fatty acid. Decline of the 20:4ω6 level in these phospholipids tended to reach a minimum level when the dietary content of total ω3 fatty acids reached 4–5% of total fatty acids (Figs. 1 and 2). Feeding levels beyond this point did not result in further decrease in membrane phospholipid content of 20:4ω6.

Increase in membrane phospholipid content of 20:5ω3 occurred as the dietary intake of ω3 fatty acids was increased from 1.1% to 5% of total fatty acids. Further increase in dietary ω3 fatty acid level did not result in increased incorporation of 20:5ω3 into phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol or phosphatidylserine. Dietary levels of 2.2–3% of total ω3 fatty acid were sufficient to result in maximum incorporation of 22:6ω3 into membrane phosphatidylcholine and phosphatidylethanolamine. For phosphatidylinositol, increase in 22:6ω3 content occurred as the dietary content of ω3 fatty acids, and thus dietary 22:6ω3 increased. It is clear that feeding a high level of 22:6ω3 alters membrane phospholipid content of 20:4ω6 and 20:5ω3 most effectively over the range of 1.1–5% of dietary fatty acid fed. By estimating the amount of dietary 20:5ω3 intake (see

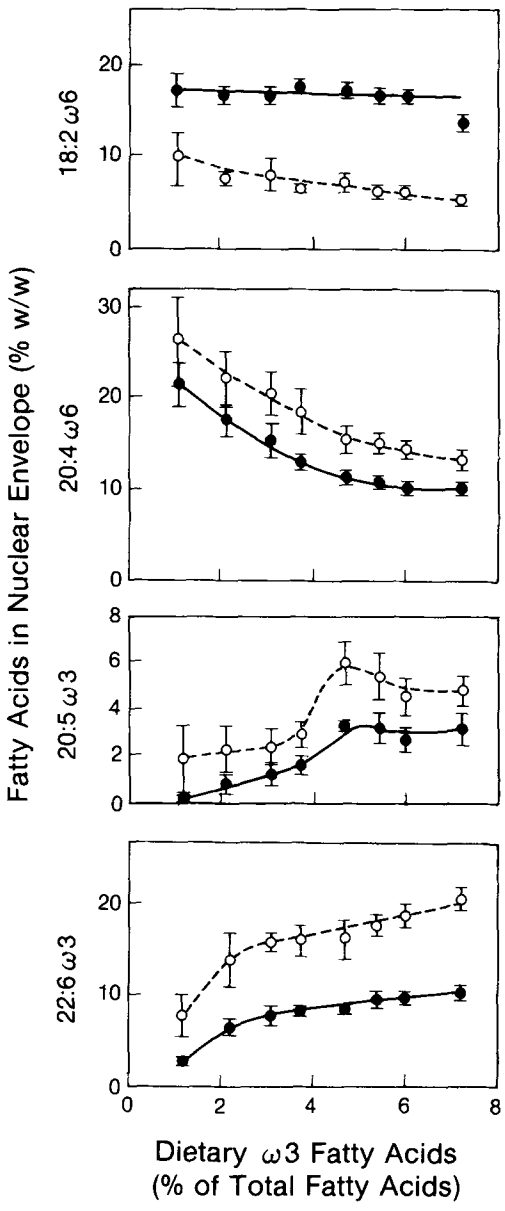

FIG. 1. Effect of increasing levels of dietary ω3 fatty acid on the fatty acid composition of the phosphatidylcholine (●) and phosphatidylethanolamine (○) fractions of rat liver nuclear envelope. The dietary fatty acid composition for each point illustrated can be determined from Table 2. The point closest to the intersect of the x and y axes is diet 1, with diets 2-8 following (Figs. 1 and 2).

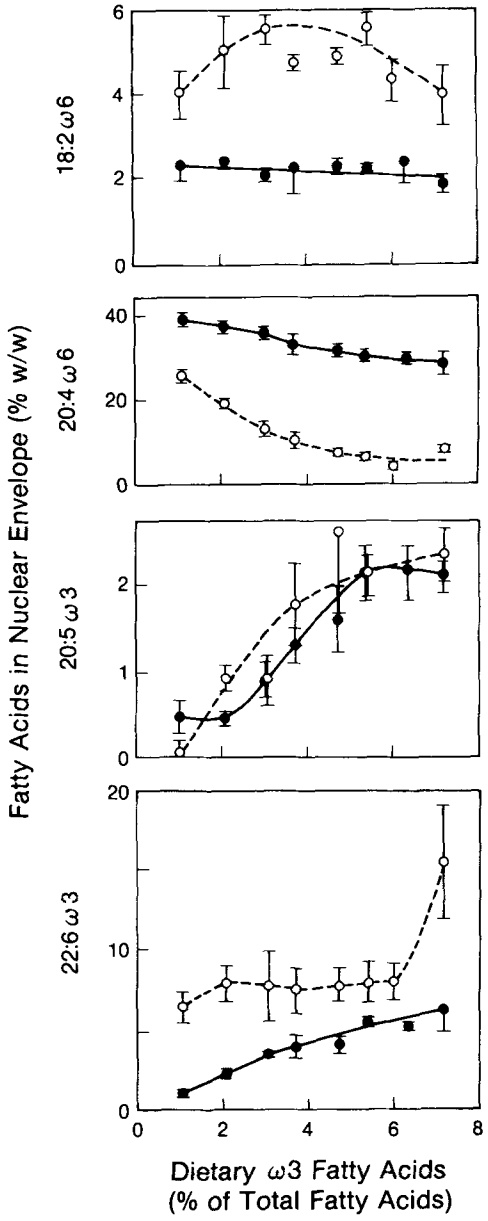

FIG. 2. Effect of increasing concentrations of dietary ω3 fatty acids on the fatty acid composition of the phosphatidylinositol (●) and phosphatidylserine (○) fractions of rat liver nuclear envelope.

scale in Figs. 1 and 2), it is apparent that a similar dietary intake of 20:5ω3 (0.79 to 0.83% of fatty acid) and 22:6ω3 (0.75-1.5% of fatty acid) is reflected in a plateau in membrane phosphatidylcholine and phosphatidylethanolamine content of 20:5ω3 and 22:6ω3 (Fig. 2). This suggests that increase in membrane content of 20:5ω3 and 22:6ω3 is primarily in response to the dietary level of these fatty acids fed and is not primarily attributable to synthesis from 18:3ω3 in the diet.

It is clear from the current study that a dietary threshold for the effect of dietary 20:5ω3 and 22:6ω3 on the fatty acid composition of nuclear envelope membrane phosphatidylcholine and phosphatidylethanolamine composition exists. The threshold level for both fatty acids is apparently similar and suggests that a maximal effect for dietary 20:5ω3 and 22:6ω3 on membrane phosphatidylcholine and phosphatidylethanolamine fatty acid composition occurs at a relatively low dietary concentration consistent with that observed for brain when the only ω3 fatty acid fed was 18:3ω3 (2).

The Effects of Dietary n-3/n-6 Ratio on Brain Development in the Mouse: A Dose Response Study with Long-Chain n-3 Fatty Acids

This study examines the effects of the ratio of n-3/n-6 fatty acids (FA) on brain development in mice when long-chain n-3 FA are supplied in the diet. From conception until 12 days after birth, B6D2F$_1$ mice were fed liquid diets, each providing 10% of energy from olive oil, and a further 10% from different combinations of free FA concentrates derived from safflower oil (18:2n-6), and fish oil (20:5n-3 and 22:6n-3). The range of dietary n-3/n-6 ratios was 0, 0.25, 0.5, 1.0, 2.0 and 4.0, with an n-6 content of greater than 1.5% of energy in all diets, and similar levels of total polyunsaturated fatty acids (PUFA). In an additional group of ratio 0.5, 18:2n-6 was partially replaced by its Δ6 desaturation product, 18:3n-6. Biochemical analyses were conducted on 12-day-old pup brains, as well as on samples of maternal milk. No obvious effects on overall pup growth and development were observed, apart from a smaller litter size at ratio 1. Co-variance analysis indicated that increasing the n-3/n-6 ratio was associated with slightly smaller brains, relative to body weight. We found that 18:2n-6 and 20:5n-3 were the predominant n-6 and n-3 FA in the milk; in the brain these were 20:4n-6 and 22:6n-3, respectively. Increasing dietary n-3/n-6 ratios generally resulted in an increase in n-3 FA, with a corresponding decrease in n-6 FA. The n-3/n-6 ratio of the milk lipids showed a strong linear relationship with the diet, but in the brain the rate of increase tended to decrease beyond 0.5 (phosphatidylcholine, PC) and 0.25 (phosphatidylethanolamine, PE), such that there was a significant quadratic contribution to the relationship. The partial replacement of dietary 18:2n-6 with 18:3n-6 raised levels of 20:4n-6 in milk, brain PC, and brain PE. These results indicate that the n-3/n-6 ratio of the phospholipids in the developing mouse brain responds maximally to maternal dietary long-chain n-3/n-6 ratios of between 0.25 and 0.5.
***Lipids* 27, 98–103 (1992).**

The membrane phospholipids of the central nervous system contain high levels of polyunsaturated fatty acids (PUFA), particularly arachidonic acid, 20:4n-6, and docosahexaenoic acid, 22:6n-3 (1). It is known that 22:6n-3, occurs at high concentrations in synaptic membranes (2) and in photoreceptor cells in the retina (3,4). These long-chain PUFA accrue rapidly in the brain during the prenatal and suckling periods (5–7), and are formed from their respective dietary precursors, 18:2n-6 and 18:3n-3, by the same series of desaturation and elongation reactions, with n-3 having the competitive advantage over n-6 compounds *in vitro* (8). Both fetal liver and brain have the metabolic capacity to synthesize long-chain PUFA (9,10). There is recent evidence suggesting that 18:3n-3 is converted in fetal and pup liver to 22:6n-3, which is then secreted into blood as lipoproteins, and incorporated selectively into nervous tissue (11). Studies in both developing rat and chick brain have demonstrated preferential uptake of 22:6n-3 over its precursors (12,13). Dose-response studies conducted by varying the amount of dietary 18:3n-3 during the developmental period (14), and in weanling animals (15–17), showed a decrease in brain 22:5n-6 and an increase in brain 22:6n-3 with increasing dietary 18:3n-3. Much of this effect appeared to be in comparison with an n-3 deficient group, with smaller differences at the higher dosage levels, suggesting regulatory limits. The relationship between brain FA composition and dietary long-chain n-3 FA may be different from that seen with dietary 18:3n-3. Feeding of fish oil to adult rats resulted in a rapid increase in levels of 22:5n-3 and 22:6n-3, as well as 20:5n-3 (which is usually present in brain only in trace amounts), with corresponding decreases in 22:5n-6, as well as 20:4n-6, suggesting that the brain may be vulnerable to an excess of long-chain n-3 PUFA (18,19). The developing brain, because of its affinity for long-chain n-3, may be particularly susceptible to such effects. There is particular concern that decreases in 20:4n-6 may be associated with adverse effects (20). Thus the present study investigated the relationship between the dietary long-chain n-3/n-6 ratio and the FA composition of the brain in developing mice. The n-3 FA were provided as the long-chain compounds found in fish oil, predominantly 20:5n-3 and 22:6n-3, and using ratios of 0, 0.25, 0.5, 1.0, 2.0 and 4.0. While the 0 group was clearly an n-3 deficient group, the values above 0.25 considerably exceeded current dietary recommendations (21), with the intent of challenging the regulatory capacity of the system. The study included two groups of ratio 0.5, one as part of the dose-response series where the n-6 was provided as 18:2n-6, and the other where a portion of the 18:2n-6 was replaced by 18:3n-6. Previous work comparing labelled dietary 18:3n-6 with 18:2n-6 showed increased incorporation into brain 20:4n-6 with 18:3n-6 (22). Therefore comparison of these two groups addressed whether levels of 20:4n-6 in the brain would increase in animals fed 18:3n-6 relative to those receiving the same amount of long-chain n-3, but only 18:2n-6 in the diet. The dietary treatments were imposed throughout gestation and lactation. The FA composition of milk lipids and pup brain phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions was determined on day 32 postconception (12 days after birth); other measurements included pup body and brain growth, as well as eye-opening score.

MATERIALS AND METHODS

Animals. Parents were 28- to 32-week-old B6D2F$_1$ hybrid mice purchased from Charles River Breeding Laboratories (St. Constant, P.Q., Canada). They were maintained under a reversed 12 hr light:12 hr dark schedule at 22 ± 1°C, with tap water and lab chow (PMI Lab Diet—formerly Purina—# 5001, St. Louis, MO) available *ad libitum* until breeding. The animals were group-housed in standard plastic cages containing Beta-Chip hardwood bedding (Northeastern Products Corp., Warrensburg, NY) and toilet tissue for nesting material.

Diets. Maternal animals were fed one of six liquid diets, each of which provided 20% of the calories from oil, but which varied in their n-3/n-6 ratio. The diet, as used in our previous studies (23–25), was specifically formulated for our use by BioServ, ref. # F2187 (Frenchtown, NJ). This provided 1 kcal/mL, with 20% of the calories from protein (fat-free casein), 20% from oil, 60% from carbohydrate (maltose-dextrin), supplemented with minerals and vitamins. The dietary oil mixtures were prepared in our laboratory from olive oil (13% 18:2n-6 as triglyceride), and free fatty acid concentrates, Safflower 70, derived from safflower oil and containing 69.7% 18:2n-6, and EPA 50, derived from fish oil concentrate and containing 41.2% 20:5n-3 and 6.1% 22:6n-3 (Callanish Ltd., Breasclete, Isle of Lewis, U.K.). The use of these free fatty acid concentrates in the formulation of the diets allowed us to provide high n-3/n-6 ratios (0.0, 0.25, 0.5, 1.0, 2.0, and 4.0), while ensuring similar levels of PUFA (approximately 8% of total dietary energy) (Table 1). All groups received sufficient n-6 FA (>1.5% of total dietary energy), such that we were studying only the effect of increasing n-3, and not that of n-6 deficiency. The n-6 was supplied as 18:2n-6, and the n-3 predominantly as 20:5n-3 and 22:6n-3. This design therefore addressed the effects of increasing the dietary n-3/n-6 ratio ((20:5n-3 + 22:6n-3)/18:2n-6) while keeping the total amount of saturated (SFA), monounsaturated (MUFA) and polyunsaturated fatty acids (PUFA) relatively constant; thus, as n-3 increased, n-6 decreased. The alternative of increasing n-3 while keeping n-6 constant would have had the problem of causing these other factors to vary concomitantly. A similar dietary formulation has been used in a recently published study of varying dietary n-6/n-3 ratio on the brain fatty acid (FA) composition in weanling rats (27). An additional group was fed a diet with a n-3/n-6 ratio of 0.5 and the same amount of EPA 50 as the 0.5 group. In this group, 18:2n-6 was replaced partially by 18:3n-6 (GLA 70, containing 19% 18:2n-6 and 68.7% 18:3n-6). Additionally, α-tocopherol was added to the oil mixtures, such that the prepared liquid diet contained 150 i.u. per liter.

Breeding protocol. Animals were mated daily, and checked for the presence of copulatory plugs after 7 hr. Pregnant dams were assigned randomly to each dietary condition on day 0, and all subsequent days were designated as "days post-conception." Dams were fed daily preweighed amounts of the liquid diet, based on 0.65 kcal/g body wt/day, until day 20. Fresh diet was prepared every two days, and diets and dietary oils were stored in the refrigerator under nitrogen at all times. Birth occurred on day 19 or 20, and all dams and litters were weighed on

[a] Calculations are based on GLC analysis of component oils (olive oil, 13% n-6; safflower 70, 70% n-6; EPA 50, 4% n-6, 56% n-3; GLA 70, 88% n-6).

[b] In this group the dietary 18:2n-6 was replaced partially by 18:3n-6.

[c] 18:4n-3, 20:4n-3, 22:5n-3.

day 20. At this time, litters were culled to six (three of each sex). From day 20 until day 32 post-conception, when the pups were tested, lactating mothers were fed the appropriate liquid diet *ad libitum* at 1.5 × strength (daily intake = 0.975 kcal/g). Differences in food intake among the groups were negligible. On day 32, two pups of each sex from each litter were assessed for eye-opening on a scale from 0 to 1 (detailed criteria available on request). One male and one female from each litter were then anaesthetized with Halothane and decapitated. The brains were extracted and trimmed by removal of the olfactory bulbs anteriorly and 2 mm below the medulla posteriorly. The two brains from each litter were pooled, weighed within two minutes to the nearest 0.1 mg, and frozen at −50°C until analysis of fatty acid composition. The hearts, livers and kidneys were also extracted, pooled and stored; these data are the subject of a separate report (26). The remaining pups were separated from the dams overnight, and on day 33 the dams were milked, following an adaptation of the procedure described by Mills *et al.* (27). The milk was also stored at −50°C. All tissue was coded so that biochemical analysis was done independently of knowledge of the treatment group.

Brain lipids. The homogenized brains were extracted according to a modified method of Bligh and Dyer (28), using chloroform/methanol (1:1, v/v), in the presence of 0.02% BHT (w/v). After separation and drying under nitrogen, the total lipids were fractionated by thin-layer chromatography, using silica gel plates (Analtech GF) and a chloroform/methanol/acetic acid/water (50/30/4/2, by vol) solvent system. The fatty acids of the resulting phospholipid fractions were methylated with 14% boron trifluoride in methanol, and analyzed on a gas chromatograph (Perkin-Elmer 8420, Norwalk, CT) equipped with a flame-ionization detector and a 15 m × 0.32 m (i.d.) capillary column (Supelco Wax 10, Bellefonte, PA). The temperature program for gas-liquid chromatography (GLC) consisted of a 2-min hold at 160°C, followed by a 2°/min increase to 190°C. After 10 min at 190°C the temperature was increased at 5°/min to 220°C, followed by a 2-min hold at 220°C. Fatty acids were identified by comparison of their retention times with those of authentic standards.

The concentration of total phospholipids, and the percent distribution of phospholipid subclasses were measured by high-performance liquid chromatography (System Gold, Beckman Canada, Mississauga, Ontario, Canada) using a Si Ultrasphere column (5 microns, 4.6 mm i.d. × 250 mm, Beckman) and a mass detector (ACS 750/14, Applied Chromatography Systems Ltd., Lutons, Bds., U.K.) as described previously (29).

Statistical analyses. The maternal and pup growth data were analyzed using the general linear model (GLM) provided by the Statistical Analysis System (SAS) to do analysis of variance (ANOVA). Individual group means were compared using Tukey's t-test; least squares means resulting from covariance analysis were compared using t-tests; the alpha level was set at 0.05. In the absence of a treatment by sex interaction, the litter mean score, collapsed across sex, was used as the unit of analysis for the data on pup growth and development. As the fatty acid determinations were conducted on the pooled brains from a litter, the litter also represents the unit of analysis for these measures. Regression analyses described the nature of the dose-response relationship between the dietary n-3/n-6 ratio and the n-3/n-6 ratio of milk and brain lipids. A linear model was used initially, and, when this proved significant, it was subsequently determined whether the inclusion of a quadratic component made a significant additional contribution. The sample sizes are shown in the respective tables.

RESULTS

Maternal variables and pup growth and development. Maternal weight gain did not differ among the groups during pregnancy, but litter size, as reflected by the number of live pups on day 20, was significantly different, $F(5,45) = 3.73$, $p < 0.01$, with ratio 1.0 having smaller litters (mean (pups) ±SEM: 5.3 ± 0.9) than ratio 0.25 (9.0 ± 0.5) and ratio 2.0 (9.1 ± 0.8). Neither pup weight on day 20 and day 32, nor eye-opening score, differed significantly. Brain weight showed a trend toward decreasing as the n-3/n-6 ratio increased, particularly at ratio 2.0. This was confirmed by a covariance analysis, where the least squares means of brain weight adjusted for body weight indicated a significant treatment effect, $F(5,41) = 3.08$, $p < 0.02$, with ratio 0.25 (mean (g) ± SEM: 0.347 ± 0.003), 1.0 (0.345 ± 0.003), and 2.0 (0.342 ± 0.003) being significantly lower than ratio 0 (0.356 ± 0.003. Ratio 4.0 (0.348 ± 0.003) was marginally lower than ratio 0, $p < 0.08$. Ratio 0.5 (3.353 ± 0.003) did not differ from any other group.

Lipid analysis. The n-3/n-6 ratio provides a summary of the outcome of the dietary treatment. There was a clear treatment effect on the milk lipids, $F(5,34) = 841.34$, $p < 0.0001$, brain phosphatidylcholine (PC), $F(5,40) = 191.6$, $p < 0.0001$, and brain phosphatidylethanolamine (PE), $F(5,41) = 164.9$, $p < 0.0001$. As is shown in Figure 1, the relationship between the n-3/n-6 ratio of the maternal diet and that of the milk was represented by a linear dose-response model. The pattern in the brain phospholipids

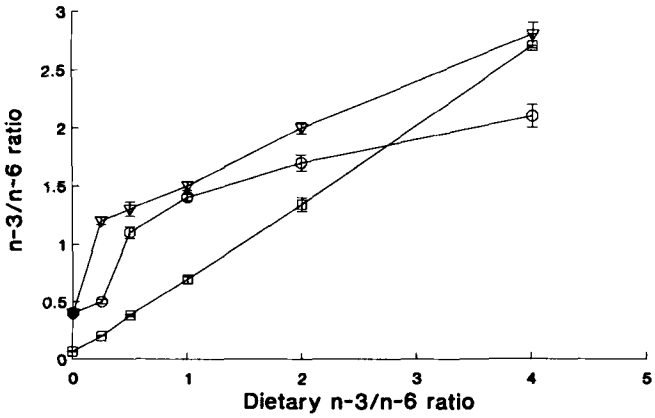

FIG. 1. Effects of maternal dietary n-3/n-6 ratio (x) on the n-3/n-6 ratio (y) of milk lipids (□) and pup brain phosphatidylcholine (PC, ○) and phosphatidylethanolamine (PE, ▽). Pregnant mice were fed diets of increasing n-3/n-6 ratio from conception to day 32 post-conception (12 days after birth). The values represent the group mean ±SEM. Regression analysis shows a linear relationship of the treatment with milk lipids ($y = 0.04 + 0.67x$, $r^2 = 0.99$) whereas in brain the relationship includes a quadratic component (PC: $y = 0.41 + 1.05x - 0.16x^2$, $r^2 = 0.90$; PE: $y = 0.70 + 0.88x - 0.09x^2$, $r^2 = 0.90$. In PC, all groups differ except 0.25 and 0.0: in PE all groups differ except 0.5 which does not differ from 0.25 and 1.0.

was somewhat different. In both the PC and PE fractions there was an initial steep increase, followed by increments which were smaller in magnitude, although still significantly different from each other. Thus the relationship with the dietary n-3/n-6 ratio included a significant quadratic component. In PC, all groups differed except 0.25 and 0.0; in PE all groups differed except 0.5 which did not differ from 0.25 and 1.0.

The values for individual FA are given in Tables 2, 3, and 4. From these it is clear that in both PC and PE the increase in the n-3/n-6 ratio was due to an increase in n-3, with a reciprocal decrease in n-6. In the milk lipids, 18:2n-6 and 20:5n-3 were the major FA. Their elongation products, 20:4n-6 and 22:6n-3, were the predominant n-6 and n-3 compounds, respectively, in the brain. Very little 18:2n-6 was observed in the brain, and 20:5n-3 was seen only in any appreciable amounts (>1%) in the PE fraction of the groups receiving n-3/n-6 ratios of 2 and 4. Conversely, 22:5n-6 was seen only at ratio 0 in both PC and PE. In contrast to other n-6 FA, levels of 20:3n-6 increased as the

[a]Values are expressed in % and represent group means ± SEM with n = number of litters.

[b]In this group the dietary 18:2n-6 was replaced partially by 18:3n-6.

Groups are significantly different by Tukey's t-test, $p < 0.05$: c, each group *vs* 0.25.; d, 1.0 *vs* 0.5; e, 2.0 *vs* 1.0; f, 4.0 *vs* 2.0; g, 0.5 (18:3n-6) *vs* 0.5 (18:2n-6).

dietary n-3/n-6 ratio increased. No consistent dose-response effects were observed on the levels of SFA in the brain. In PE and PC, levels of 18:1 increased with increasing levels of n-3; in the milk, levels of 18:1 decreased with increasing n-3, whereas those of 16:1 increased. Quantification of the individual phospholipid classes in the brain showed only a small range over the groups (wt%: PC: 30.5–34.8; PE: 26.1–28.2; PI: 2.3–2.8; PS: 7.7–8.6; SM: 3.1–4.9). Comparison of the two ratio 0.5 groups indicated that the effect of 18:3n-3 was to increase levels of 20:4n-6 in both milk and brain PC and PE. In PC, but not in PE, there was an accompanying slight decrease in levels 22:6n-3.

DISCUSSION

This study sought to examine the effects of varying maternal dietary long-chain n-3 to n-6 FA ratios on the incorporation of n-3 FA into the brains of the developing offspring. A question of particular interest was whether the brain would show the capacity to regulate its fatty acid composition at the higher dietary ratios. The results provide support for such regulation. While the brain showed continually increasing n-3/n-6 ratios with dietary increases, the maximum effect had occurred by 0.5 in PC and 0.25 in PE, with a significantly lower rate of increase beyond these values. Thus, as with the work done with 18:3n-3, the largest effect seen was in comparison with the deficient group. This is supported by the observation that 22:5n-6 was only present to any appreciable extent in the ratio 0 group.

Although 20:5n-3 was the major n-3 FA in the milk, 22:6n-3 predominated in the brain; levels of 20:5n-3 in the brain were generally low, exceeding 1% in PE only at the higher ratios. The companion study on the livers of these animals demonstrated that 22:6n-3 was also the major n-3 FA in the liver, with the maximum 22:6n-3 content seen at ratio 0.5 (26). Although only trace amounts of 20:5n-3 and 22:6n-3 were found in the milk of ratio 0, the brains of these pups showed 5.1% and 15.1% 22:6n-3 in PC and PE, respectively. These data show that there is considerable accretion of long-chain n-3 PUFA during prenatal brain growth, and that dietary n-3 deficiency during gestation may be offset partially by selective retention of 22:6n-3 by the dam, possibly in the liver (30). The absence of n-3 postnatally in the milk of these dams may be explained by depletion of these stores, or, alternatively, by mechanisms which vary in terms of promoting the availability of stored PUFA prenatally to the fetus as compared with postnatally to the milk. Increases in n-3 were generally accompanied by decreases in n-6, particularly of 20:4n-6, thereby reflecting the similar n-3/n-6 reciprocity in the diet. It was shown recently in rats that with a minimal level of 18:2n-6 (0.3% of calories) the amount of 20:4n-6 in the brain remained constant, and, beyond a minimum, was independent of levels of dietary 18:3n-3 (31). This suggests that the present effects on 20:4n-6 may be due specifically to long-chain n-3. Interestingly, levels of 20:4n-6 were increased in both milk and brain by partial replacement of dietary 18:2n-6 with 18:3n-6. There are two possible mechanisms which may account for this, both related to desaturase activity. It is known that 20:5n-3 and 22:6n-3 inhibit Δ6 and Δ5 desaturases (32,33), which reduces the formation of 20:4n-6 from 18:2n-6; the presence of large amounts of 18:2n-6 may result in substrate inhibition of the Δ6 desaturase (34). In both instances, the provision of 18:3n-6 would avoid the effects of a decline in Δ6 desaturase activity. In contrast with the other n-6, 20:3n-6 increased. This replicates our previous findings and suggests inhibition of Δ5 desaturase activity by FA derived from fish oil (23,25). The general absence of effects on the SFA is consistent with other work (35).

With respect to the increase in 18:1 seen with increasing n-3, a similar finding has been reported for chick brain (36).

The data on the milk lipids support previous work in showing an effect of maternal dietary PUFA composition (37,38); they also extend these findings by demonstrating the dose-response nature of this relationship. In contrast with the tendency of the n-3/n-6 ratio to level off in the brain, that of the milk lipids showed a strong linear increase with increasing dietary ratios. These results suggest therefore that it is the metabolism of the pup, not the dam, which is regulating either supply or incorporation into the developing brain.

No systematic effects on overall growth and development were observed, except at ratio 1.0, as seen by the smaller litter size. Also, relative to body weight, increasing the n-3/n-6 ratio resulted in a very small decrease in brain weight. We had shown previously that n-3 supplementation slightly accelerated eye-opening, and that this correlated positively with other indices of sensorymotor development (22). However, in the present study, no effect on the rate of eye-opening was observed.

The diets used in this study were clearly experimental in that they provided only long-chain n-3 FA, with no 18:3n-3, and the n-3/n-6 ratios beyond 0.25 were high. Moreover, species differences in desaturase activities (39) may limit the generalizability of these results. Nevertheless, the findings may be of relevance to questions concerning the provision of long-chain n-3 FA in human infant feeding. They suggest that provision of n-6 FA partially as 18:3n-6 may help to offset the decrease in 20:4n-6 observed with dietary long-chain n-3 FA. They also clearly support a trend toward regulatory limits on the incorporation of long-chain n-3 FA into the mouse brain, showing a maximum response to maternal dietary n-3/n-6 ratios of 0.25–0.5

ACKNOWLEDGMENTS

Financial assistance for this work was provided by research grants from the Natural Sciences and Engineering Research Council of Canada to P. Wainwright and D. Mills. The authors are indebted to R. Ward, B. Parker and A. Huang for technical assistance in lipid analysis, S. Levesque for help in feeding the animals, L. Albrecht and J. Cassaubon for secretarial support, and Dr. G. Bennett for statistical advice.

This report examines the distribution of n-3 and n-6 fatty acids in heart, kidney and liver phosphatidylcholine and phosphatidylethanolamine of suckling mice from dams fed a fat-supplemented diet with variable n-3/n-6 ratios. After conception and throughout the pregnancy and lactation period, dams were fed a fat-free liquid diet supplemented with 20% by energy of oil mixtures (fish oil concentrate, rich in 20:5n-3 and 22:6n-3, and safflower oil concentrate, rich in 18:2n-6). The diets contained similar amounts of combined n-3 and n-6 fatty acids but variable ratios of n-3 to n-6 fatty acids (0, 0.25, 0.5, 1, 2 and 4). In 12-day-old suckling mice, as the n-3/n-6 ratio in the maternal diet increased (up to approx. 0.5), the tissue levels of 20:5n-3, 22:5n-3 and 22:6n-3 increased, whereas those of 18:2n-6 and 20:4n-6 decreased. The responses were similar in both phospholipid subclasses, but varied between different tissues. Generally, the n-3/n-6 ratios were significantly greater in pup tissues than in milk fat, indicating preferential incorporation of n-3 over n-6 fatty acids into phospholipids during growth. However, the incorporation of n-3 fatty acids in pups was significantly suppressed whereas that of n-6 fatty acids was increased when 18:2n-6 was replaced by its Δ6-desaturation product, 18:3n-6 (concentrated from evening primrose oil), as the source of n-6 fatty acid. This result suggests that Δ6 desaturase activity in neonate tissues is low, and consequently, the metabolism of 18:2n-6 to longer chain n-6 fatty acids is reduced. The preformed long-chain n-3 fatty acids, which bypass Δ6-desaturation, were thus, preferentially incorporated into tissue phospholipids.
***Lipids 27,* 104–110 (1992).**

Two essential fatty acids, linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), represent the parent acids of n-6 and n-3 metabolites, respectively. It is generally agreed that both n-6 and n-3 fatty acids are metabolized by the same enzyme systems (1,2). Previously, the interaction between n-6 and n-3 fatty acids has been studied mostly on adult and post-weaned growing animals; few have been carried out on pre-weaning neonates. Since long-chain n-6 and n-3 fatty acids constitute the major structural components in neural tissues (3–5), and the active brain growth (spurt) in mice occurs immediately after birth, changes in fatty acid metabolism would have a profound effect on postnatal development.

Nutrients are supplied to the preweaning neonate solely from its mother's milk, and therefore, the quality and quantity of the milk fat dictate the fatty acid metabolism in neonates. In normal human and animal milk, the levels of n-3 fatty acids in comparison with n-6 fatty acids are very low. This may be a result of the abundant presence of n-6 fatty acids in the maternal diet which suppresses the metabolism and incorporation of n-3 fatty acids into milk fat and consequently limits the supply of n-3 fatty acids to the neonates through the milk. However, the long-chain n-3 fatty acid content of milk can be enriched through dietary supplementation of preformed long-chain n-3 fatty acids, such as eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), to the maternal diet (6). We have shown previously that increasing maternal n-3 fatty acid intake accelerates the behavioral development in neonates (7).

Increasing evidence has indicated that excessive and prolonged intake of long-chain n-3 fatty acids may produce some adverse effects in humans and animals (8). Since maternal dietary fat modulates the milk n-3 and n-6 fatty acid content, and the preweaned neonate obtains nutrients solely from its mother's milk, varying the fatty acid composition of the maternal diet would affect fatty acid metabolism in the preweaned neonate. In the preceding paper (9), we describe the changes of pup brain fatty acids in response to maternal diets supplemented with a constant level of combined n-3 and n-6 fatty acids but with variable n-3/n-6 ratios (0, 0.25, 0.5, 1, 2 and 4). In this communication, we report the changes of n-3 and n-6 fatty acids in heart, kidney and liver phospholipid subclasses of the same suckling mice (9). The n-3/n-6 ratios of 0.25 and 4 used are approximately 1- and 16-fold, respectively, of that reported in a previously published study (7).

MATERIALS AND METHODS

Male and female mice (B6D2 F_1 hybrid, 28–32 wk old) were purchased from Charles River Breeding Laboratories (St. Constant, Quebec, Canada). Mice were group-housed in a constant temperature (22°C) room with a reversed 12-hr light/12-hr dark cycle, and had free access to water and lab chow (Purina No. 5001). Animals were mated and conception was confirmed by the presence of a vaginal plug (day 0 post-conception). The pregnant dams were then housed individually in opaque plastic cages (29 × 18 × 13 cm) containing Beta-Chip hardwood bedding and toilet tissue for nesting material. The dams were randomly assigned to different experimental groups (number of animals in each group varied from 6 to 10), and fed a liquid diet (0.65 kcal/g body wt per day), supplemented with 20% by calories of 6 different oil mixtures. The composition of the liquid diet (F 2187) formulated by BioServ (Frenchtown, NJ) has been described previously (10). The diet contained (by energy) 20% fat-free casein, 20% fat, and 60% maltose-dextrin including mineral and vitamin mixtures. In addition, 4 IU/g oil of α-tocopherol (or approximately 96 IU/L diet) were also added to the diet (contains 56 IU/L), as antioxidant. The fat was prepared by mixing variable amounts of olive (containing 13% 18:2n-6), safflower (containing 69.7% 18:2n-6), and concentrated fish oils (containing 41.2% 20:5n-3 and 6.1% 22:6n-3, provided by Callanish Ltd., Bresclete, Isle of Lewis, Scotland), to provide constant combined n-3 and n-6 levels (approximately 40% of total fatty acids) but with variable n-3/n-6 ratios (0, 0.25, 0.5, 1, 2, and 4). In all diets, at least 1.5% (en) of n-6 fatty acids was provided to ensure that the

animals were free of essential fatty acid deficiency. The detailed fatty acid compositions of the oil mixtures are described in the preceding paper (9). The diets were freshly prepared every other day and stored under nitrogen at 5°C. In a separate group, dams (n = 6) were fed a diet with a n-3/n-6 ratio of 0.5 and a 18:3n-6 concentrate (containing 68.7% 18:3n-6 and 19% 18:2n-6, derived from evening primrose oil and prepared by Callanish Ltd.) as a source of n-6 fatty acid. The purpose of this manipulation was to examine whether the incorporation of n-3 and n-6 fatty acids might be affected by the ability of tissues to metabolize (Δ6-desaturate) 18:2n-6.

Birth occurred on day 19 or 20 (post-conception), and litters were culled to six (3 males and 3 females). From day 20 until day 32, the lactating dams were fed the appropriate diet at 0.975 Kcal/g of body weight/day. On day 32, two pups (one male and one female) in each litter were selected randomly, anesthetized with Halothane and then decapitated. The brain, liver, kidney and heart were excised, pooled and frozen at −50°C until lipid analysis. The brain samples and the remaining pups (n = 4 in each litter) were subjects of the behavioral study as described in the preceding paper (9). On day 33, all dams were milked under light anesthesia after receiving 0.4 IU/kg body weight of oxytocin following the procedure described previously (11).

Total lipids of all tissues and milk were extracted using a method described by Folch *et al.* (12). The liver, kidney and heart phospholipid subclasses, phosphatidylcholine (PC), phosphatidylethanolamine (PE) phosphatidylinositol and phosphatidylserine, were separated by thin-layer chromatography using the solvent system, chloroform/ethanol/water/triethylamine (4:5:1:4, by vol) (13). The lipid fractions were identified by comparison with authentic standards after visualization with 2′,7′-dichlorofluorescein (0.025% in ethanol). Milk fat and two major phospholipid subclasses (PC and PE) were transmethylated as described by Morrison and Smith (14). The fatty acid methyl esters were analyzed by gas-liquid chromatography using a Hewlett-Packard gas chromatograph (model 5890, Avondale, PA) equipped with a flame-ionization detector and a fused silica capillary column (0.25 mm i.d. × 15 m) coated with SP-2230 (Supelco Canada, Oakville, Ontario) as described previously (15). Fatty acids were identified by comparison of retention times with those of authentic standards (Nu-Chek Prep, Elysian, MN).

The concentration of total phospholipids, and the percent distribution of phospholipid subclasses were measured by high-performance liquid chromatography (System Gold, Beckman Canada, Mississauga, Ontario) using a Si Ultrasphere column (5 microns, 4.6 mm i.d. × 250 mm, Beckman) and a mass detector (ACS 750/14, Applied Chromatography Systems Ltd, Lutons, Bds, United Kingdom) as described previously (16).

One way analysis of variance was used to examine the relationship between the dietary n-3/n-6 ratios and fatty acid levels in tissue PC and PE. The effects of 18:2n-6

and 18:3n-6 in maternal diet on n-3 and n-6 fatty acid distribution in pup tissue phospholipids were assessed using the Student's t-test.

RESULTS

Table 1 shows the tissue phospholipid concentrations and distributions of phospholipid subclasses in 12-day-old (32-day postconception) suckling mice from dams fed a fat-supplemented liquid diet with variable n-3/n-6 ratios. Overall, no consistent differences were observed between various dietary groups. Body weight, liver, heart and kidney weights were also not significantly different between pups from dams fed different dietary fats (data not shown).

The changes in the major n-3 and n-6 fatty acids in liver PC and PE in response to changes in the n-3/n-6 ratio in the maternal diet are shown in Figure 1. Increasing the dietary n-3/n-6 ratio increased the levels of saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), and total n-3 fatty acids, but decreased those of polyunsaturated fatty acids (PUFA) and n-6 fatty acids. n-6 Fatty acids (18:2n-6 and 20:4n-6) decreased more rapidly when the dietary n-3/n-6 ratio increased from 0 to 0.5 than from 0.5 to 4. The major n-3 fatty acid in liver PC and PE was 22:6n-3, followed by 20:5n-3 and 22:5n-3. The levels of 22:6n-3 rose and reached a maximum very rapidly when only a small amount of long chain n-3 fatty acids was included in the diet (*i.e.*, when the dietary n-3/n-6 ratio increased from 0 to 0.5). When the dietary n-3/n-6 ratio increased from 2 to 4, 22:6n-3 levels remained maximal in PE, whereas they fell in PC. The levels of 20:5n-3 and 22:5n-3 increased very rapidly when the dietary n-3/n-6 ratio increased from 0 to 1, and leveled off when the n-3/n-6 ratio increased from 1 to 4.

In kidney (Fig. 2) and heart (Fig. 3) phospholipids, increasing the dietary n-3/n-6 ratio increased the levels of total n-3 fatty acids and decreased those of n-6 fatty acids, but did not significantly affect the levels of SFA, MUFA and PUFA. In general, the pattern of change of major n-3 and n-6 fatty acids in kidney (Fig. 2) and heart (Fig. 3) was similar to that in liver phospholipids (Fig. 1). Both 18:2n-6 and 20:4n-6 levels fell rapidly whereas 20:5n-3, 22:5n-3 and 22:6n-3 rose rapidly as the dietary n-3/n-6 ratio increased. The extent of change was considerably smaller for 18:2n-6 than for 20:4n-6. Among the n-3 fatty acids, 20:5n-3 in kidney PC reached the same level as 22:6n-3, when the n-3/n-6 ratio in the maternal diet exceeded 1. In kidney PE, the level of 20:5n-3 continued to rise and exceeded that of 22:6n-3. The major n-3 fatty acid in heart

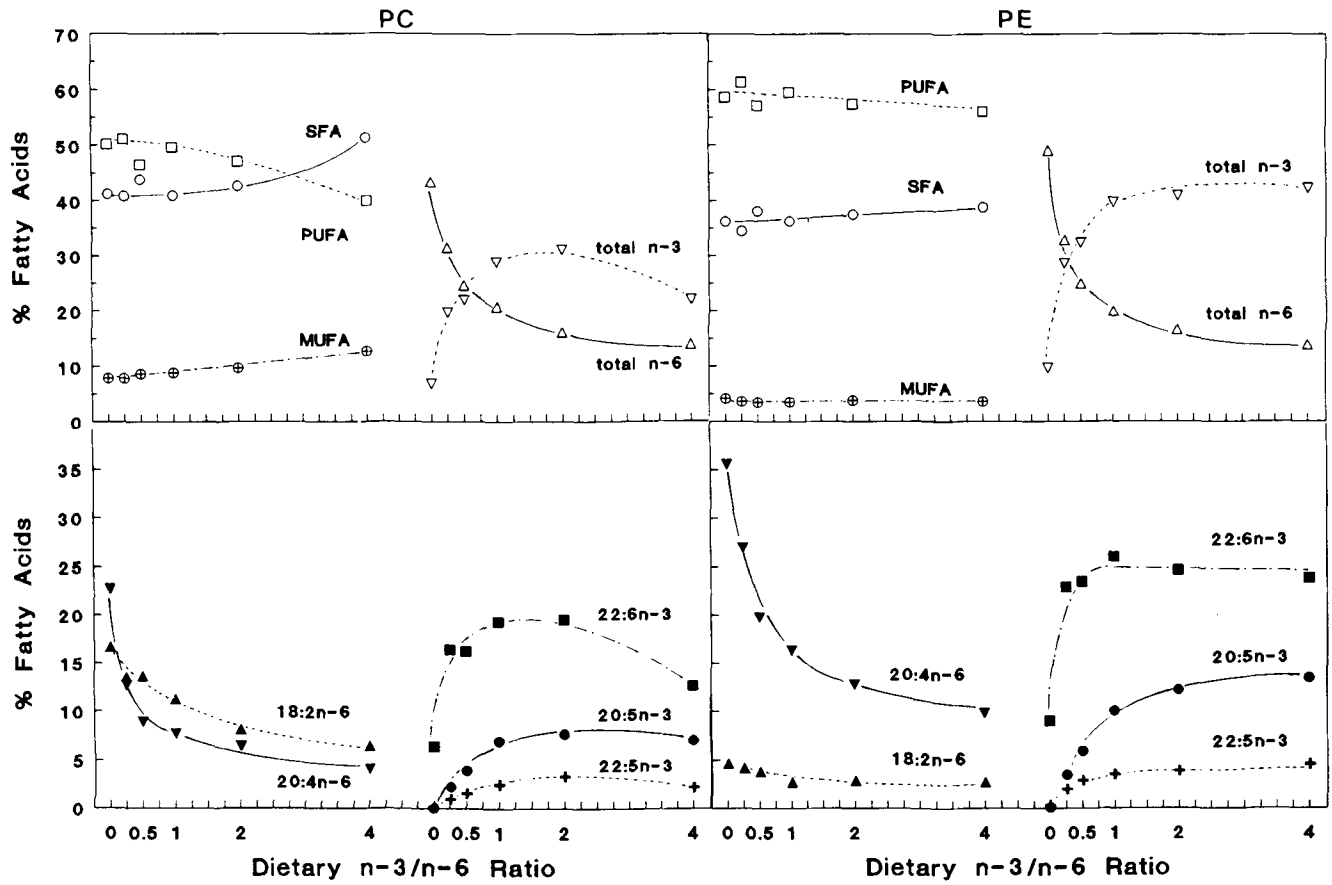

FIG. 1. The distribution (% of total fatty acids) of saturated (SFA, ○), monounsaturated (MUFA,⊕), polyunsaturated (PUFA, □), total n-3 (▽) and n-6 (△) fatty acids, and the major n-6 (18:2n-6, ▲; and 20:4n-6, ▼) and n-3 (20:5n-3, ●; 22:5n-3, +; and 22:6n-3, ■) fatty acids in liver phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of suckling mice from dams fed a liquid diet supplemented with 20% (energy) fats, but with variable n-3/n-6 ratios. Each data point represents the mean of 9, 9, 6, 10, 6, or 6 pooled samples of one male and one female pup from dams fed a diet with n-3/n-6 ratio at 0, 0.25, 0.5, 1, 2 or 4, respectively.

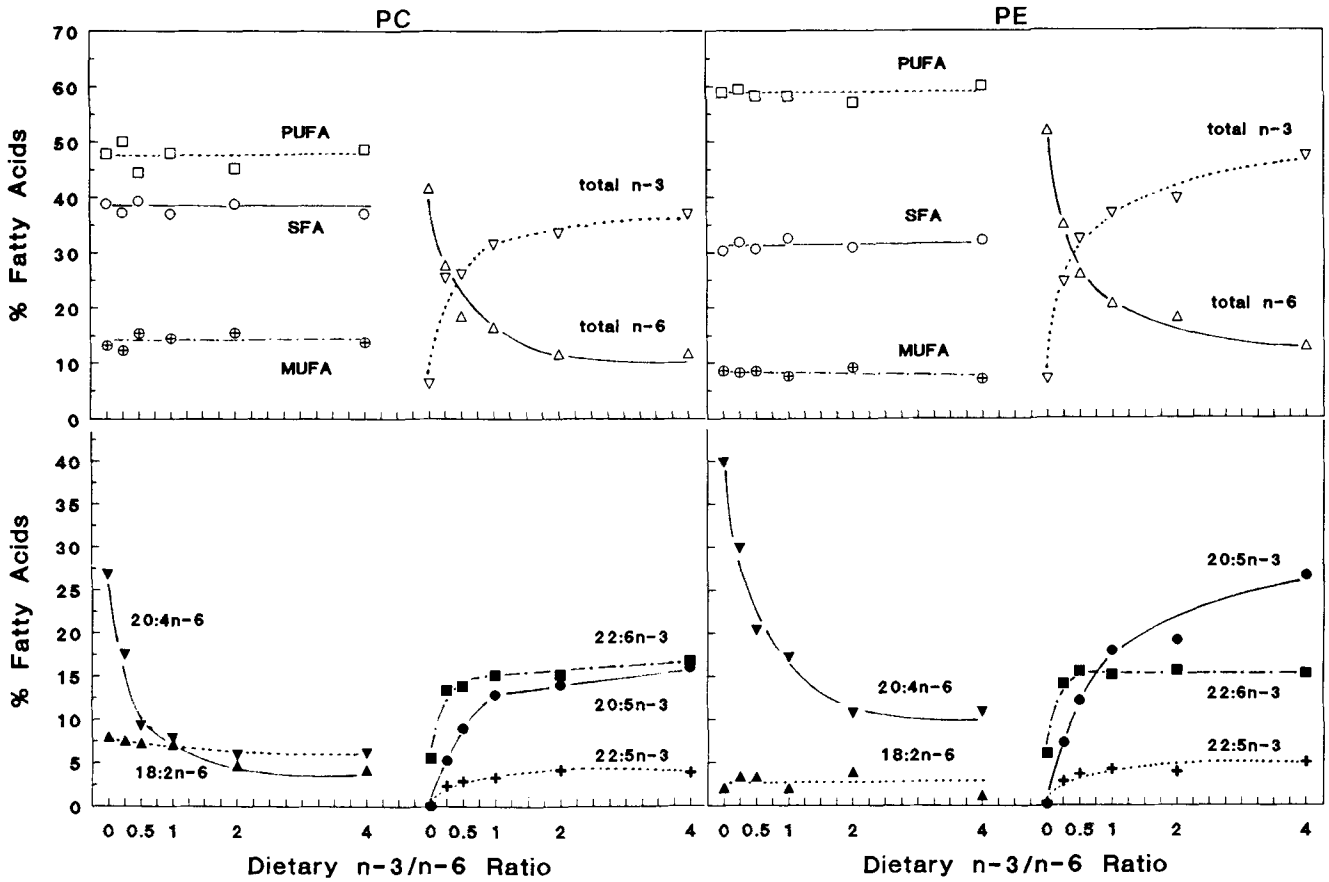

FIG. 2. The distribution (% of total fatty acids) of saturated (SFA, ○, monounsaturated (MUFA, ⊕), polyunsaturated (PUFA, □), total n-3 (▽) and n-6 (△) fatty acids, and the major n-6 (18:2n-6, ▲; and 20:4n-6, ▼) and n-3 (20:5n-3, ●; 22:5n-3, +; and 22:6n-3, ■) fatty acids in kidney phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of suckling mice from dams fed a liquid diet supplemented with 20% (energy) fats, but with variable n-3/n-6 ratios. Each data point represents the mean of 9, 9, 6, 10, 6, 6 pooled samples of one male and one female pup from dams fed a diet with n-3/n-6 ratio at 0, 0.25, 0.5, 1, 2 or 4, respectively.

phospholipids was 22:6n-3, followed by 22:5n-3. Both 22:5n-3 and 22:6n-3 rose rapidly to maximal levels when only a small amount of long-chain n-3 fatty acids was included in the diet (n-3/n-6 ratio ≥ 0.25). The levels of 20:5n-3 in heart phospholipids were low in comparison with the other two n-3 acids, and were less responsive to changes of n-3/n-6 ratios in the maternal diet.

Figure 4 illustrates the response of tissues in suckling mice to maternal dietary change, plotting the n-3/n-6 ratios in tissue PC and PE of suckling mice against the n-3/n-6 ratios in the maternal diet. These relationships were then compared with those of milk fat. Results indicate that there existed a linear relationship between the ratio of n-3/n-6 fatty acids in milk fat and that in the maternal diet. However, the increases of the n-3/n-6 ratios in response to the maternal dietary change were significantly greater than those of milk fat in tissue PC (except in liver PC, when the n-3/n-6 ratio in the maternal diet exceeded 4) and PE, and greater in the heart than in other tissue phospholipids.

Figure 5 shows the effects of maternal dietary supplementation of either 18:2n-6 or 18:3n-6 as the main source of n-6 fatty acids (n-3/n-6 ratio = 0.5) on the distributions of major n-6 and n-3 fatty acids in pup liver, kidney and heart PC and PE. In general, the levels of 20:3n-6 and 20:4n-6 were consistently greater whereas those of long-chain n-3 fatty acids (20:5n-3, 22:5n-3 and 22:6n-3) were consistently lower in pup tissue phospholipids from the dams fed an 18:3n-6 enriched diet than from those fed an 18:2n-6 enriched diet. These differences are again illustrated in Figure 6, where the sum of tissue n-6 and n-3 fatty acids and the n-3/n-6 ratios in these animals are compared.

DISCUSSION

Figures 1-3 show that the levels of 20:4n-6 in neonatal tissue phospholipids were significantly reduced when the n-3/n-6 ratio in the maternal diet was increased from 0 to 0.5. Pup tissue 20:4n-6/18:2n-6 ratios in all phospholipids fell in a similar fashion as maternal dietary n-3/n-6 ratio increased. The reduction of 20:4n-6 in tissue phospholipids may reflect a reduced conversion from 18:2n-6. Increasing dietary intake of 20:5n-3 and 22:6n-3 has been shown to inhibit the activity of Δ6 and Δ5 desaturases (17,18). However, when the dietary n-3/n-6 ratio increased 8-fold from 0.5 to 4, 20:4n-6 further decreased only to a limited extent in tissue phospholipids. This finding in conjunction

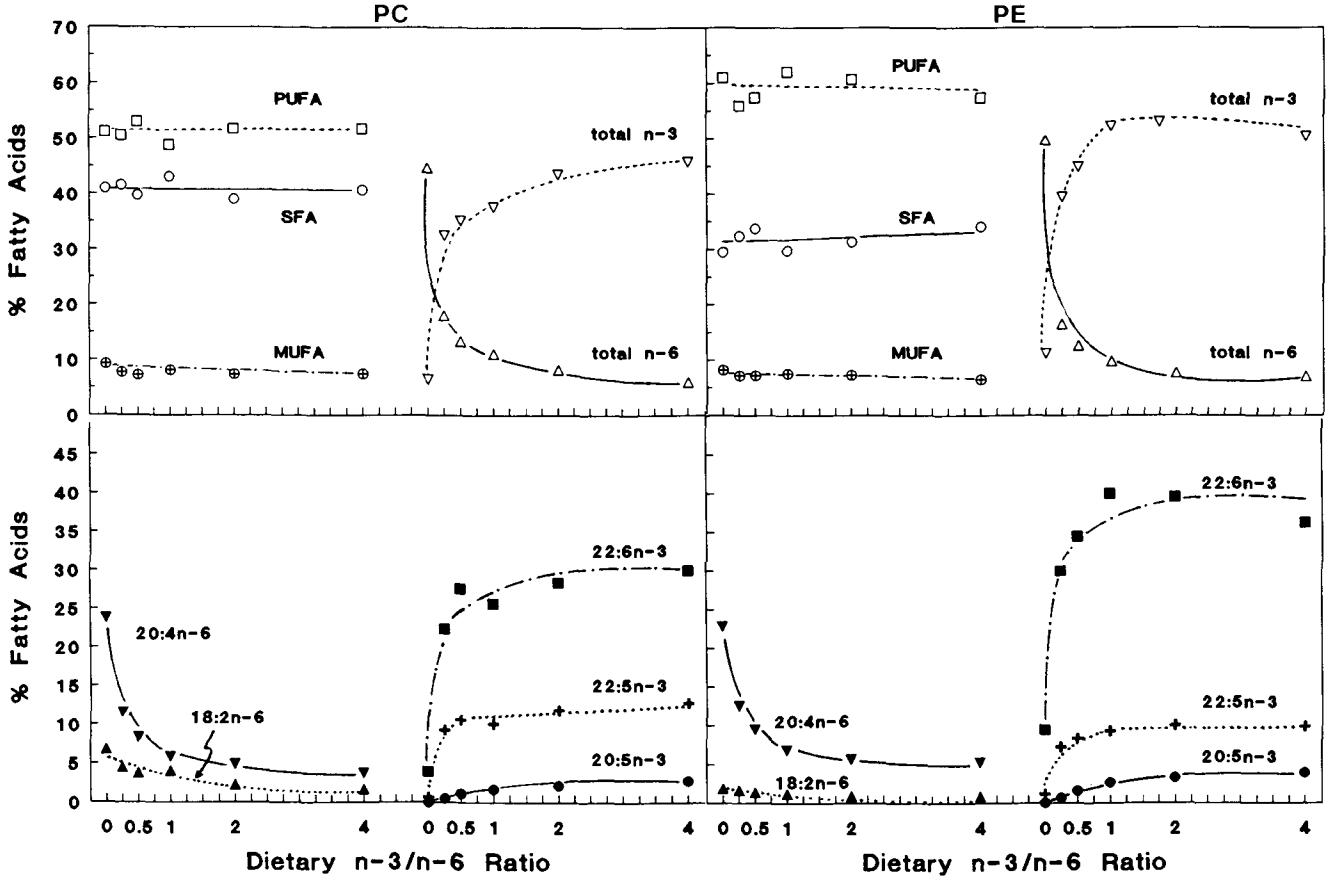

FIG. 3. The distribution (% of total fatty acids) of saturated (SFA, ○), monounsaturated (MUFA, ⊕), polyunsaturated (PUFA, □), total n-3 (▽) and n-6 (△) fatty acids, and the major n-6 (18:2n-6, ▲; and 20:4n-6, ▼) and n-3 (20:5n-3, ●; 22:5n-3, +; and 22:6n-3, ■) fatty acids in heart phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of suckling mice from dams fed a liquid diet supplemented with 20% (energy) fats, but with variable n-3/n-6 ratios. Each data point represents the mean of 9, 9, 6, 10, 6, 6 pooled samples of one male and one female pups from dams fed a diet with n-3/n-6 ratio at 0, 0.25, 0.5, 1, 2 or 4, respectively.

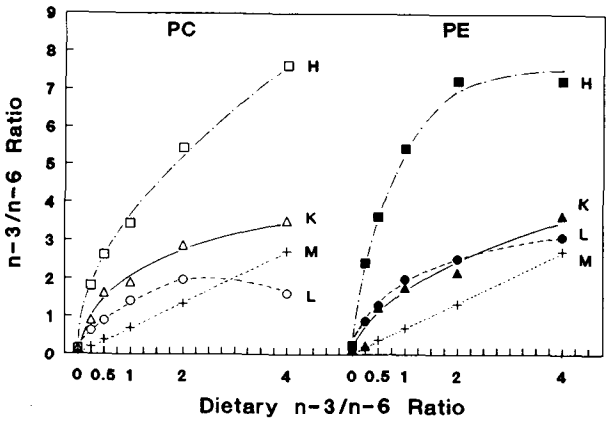

FIG. 4. The n-3/n-6 ratios in liver (L, ○, ●), kidney (K, △, ▲), and heart (H, □, ■) phosphatidylcholine (open symbols) and phosphatidylethanolamine (solid symbols) of suckling mice from dams fed a liquid diet supplemented with 20% (energy) fats, but with variable n-3/n-6 ratios (0, 0.25, 0.5, 1, 2 and 4). The n-3/n-6 ratios in milk fat (M, +) in response to n-3/n-6 changes in maternal diet are also shown.

with an insignificant change of the ratio of 20:4n-6/18:2n-6 in tissue phospholipids suggests that there was no further inhibition on the conversion of 18:2n-6 to 20:4n-6 in these dietary groups. The reduction of 20:4n-6 in tissue phospholipids was due to the fact that 20:5n-3 and 22:6n-3 competed with 20:4n-6 for incorporation into phospholipids. The competition between n-3 fatty acids and 20:4n-6 presumably outweighed the preferential effect of the phospholipid synthesis enzyme, acyltransferase, which favors the 20:4n-6 as substrate (19).

Figure 4 shows a direct relationship between milk fat and the n-3/n-6 ratio of the maternal diet. This relationship is in agreement with the report that milk fatty acid composition is regulated by the dietary n-3/n-6 ratio (6). However, at any given dietary n-3/n-6 ratio, the milk fat n-3/n-6 ratio is consistently lower than that of the maternal diet, suggesting that the dams preferentially incorporate n-6 fatty acids into milk fat over n-3 fatty acids. Despite this, the n-3/n-6 ratio in pup tissue phospholipids was consistently greater than that in milk fat. This suggests that milk long-chain n-3 fatty acids were more efficiently incorporated into and retained in

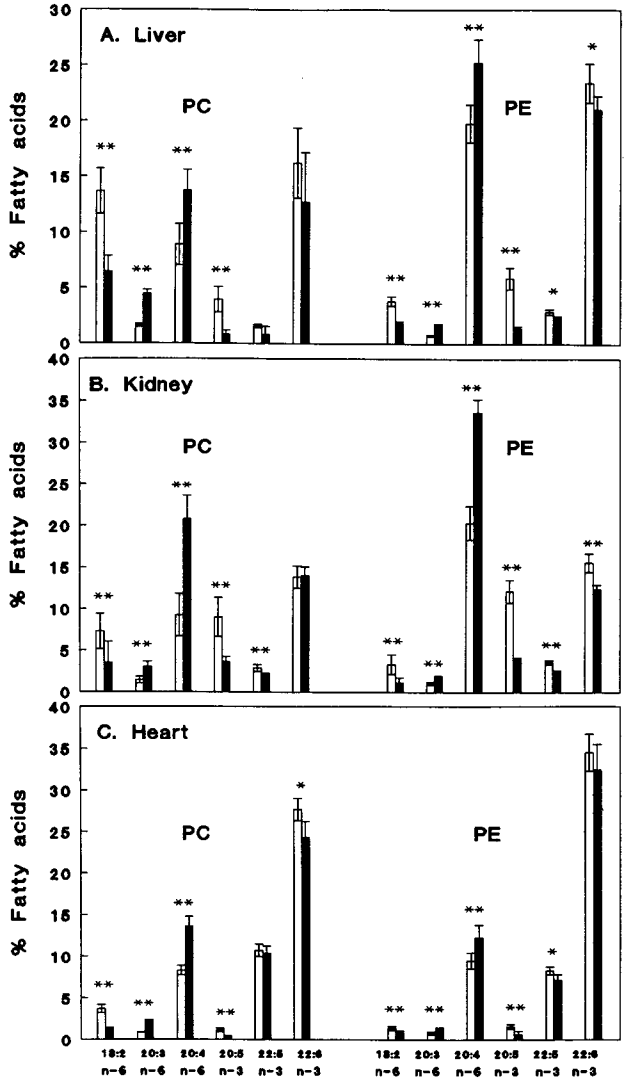

FIG. 5. The distribution (% of total fatty acids) of major n-6 (18:2n-6, 20:3n-6 and 20:4n-6) and n-3 (20:5n-3, 22:5n-3, and 22:6n-3) fatty acids in liver (panel A), kidney (panel B) and heart (panel C) phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of suckling mice from dams fed a liquid diet supplemented with 20% (energy) fat (n-3/n-6 ratio = 0.5). The source of n-3 fatty acids was from the concentrated fish oil while that of n-6 fatty acids was from either 18:2n-6 rich oil (□) or 18:3n-6 rich oil (■). Values represent means ± SD of 6 determinations. *, ** significantly different at $p<0.05$ or 0.01 respectively.

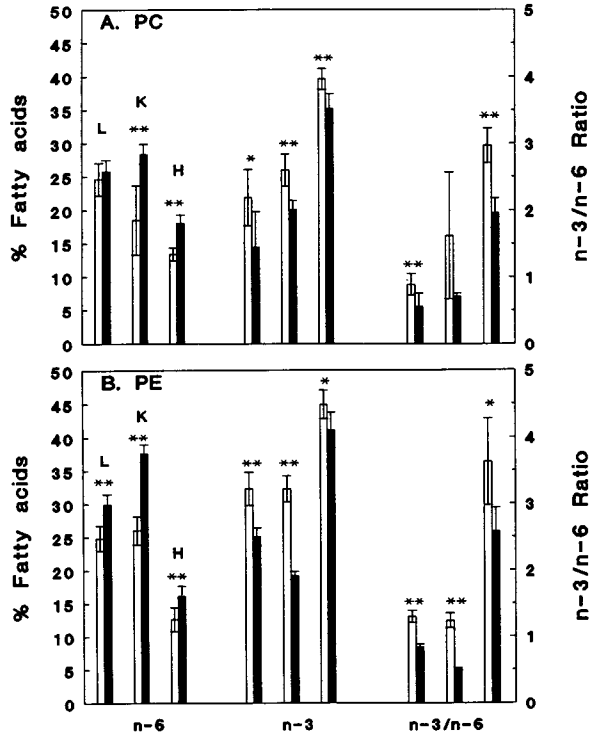

FIG. 6. The sum of n-6 and n-3 fatty acids and n-3/n-6 ratios in liver (L), kidney (K), and heart (H) phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of suckling mice from dams fed a liquid diet supplemented with 20% (energy) fats (n-3/n-6 ratio = 0.5). The source of n-3 fatty acids was from the concentrated fish oil while that of n-6 fatty acids was from either 18:2n-6 rich oil (□) or 18:3n-6 rich oil (■). Values represent means ± SD of 6 determinations. *, ** significantly different at $p<0.05$ or 0.01 respectively.

membrane phospholipids in the suckling mice than were milk n-6 fatty acids.

Figure 4 also shows the rate of increase of the n-3/n-6 ratio in different tissues in response to increasing the n-3/n-6 ratio in the maternal diet. The increased incorporation of n-3 fatty acids was compensated by a reduction in 20:4n-6 (and to a lesser extent, 18:2n-6). The change in heart phospholipids was the most striking among the three tissues examined (Fig. 3). The incorporation of n-3 fatty acids into heart tissues continued to rise at dietary n-3/n-6 ratios over 1.0. In kidney phospholipids, the n-3/n-6 ratios increased in parallel to but higher than those in milk fats. In liver phospholipids, the n-3/n-6 ratios leveled off when the n-3/n-6 ratios in the maternal diet exceeded 2. The difference in incorporation of n-3 and n-6 fatty acids might be regulated in part by the ability of tissues to metabolize 18:2n-6 and 18:3n-3. Heart tissue has only a limited ability for fatty acid desaturation (20); 20:4n-6 must be derived from plasma lipids after desaturation-elongation of 18:2n-6 in liver. When the supply of 20:4n-6 was reduced in milk from dams fed a diet with a high n-3/n-6 ratio, the high rate of acylation of 22:6n-3 and other n-3 fatty acids into heart phospholipids probably resulted from the high affinity of heart sarcoplasmic reticulum for n-3 PUFA (21–26). In kidney PE, the levels of 20:5n-3 continued to increase while 22:6n-3 reached and stayed at the maximal level (Fig. 2); this may be due to a portion of the 22:6n-3 being retroconverted into 20:5n-3 (27).

Previously, Sinclair (28) had shown that the uptake of labelled 22:6n-3 into brain lipids was greater in 16–17 day-old suckling rats than in adult rats. The accretion of n-3 fatty acids may depend upon the stage of growth as well as the activity of desaturation which tends to decrease as growth progresses (29). The view that low Δ6-desaturase activity may be responsible for higher incorporation of long-chain n-3 fatty acids is supported by comparing the

effect of dietary supplementation with 18:2n-6 and its Δ6 desaturation product, 18:3n-6 (Fig. 5 and 6). The incorporation of n-3 was significantly higher when the dietary source of n-6 fatty acids was 18:2n-6 in comparison with 18:3n-6. Since n-3 fatty acids (20:5n-3 and 22:6n-3) supplemented in the diet had already undergone Δ6 desaturation whereas the n-6 fatty acids (18:2n-6) had not, a decreased formation of 20:4n-6 reduces the ability of n-6 fatty acids to compete with preformed long-chain n-3 fatty acid for incorporation into tissue phospholipids (19).

Esterification of Fatty Acids by Bovine Intramuscular and Subcutaneous Adipose Tissues[1]

Kuen-Chiun Lin[2], H. Russell Cross and **Stephen B. Smith***
Department of Animal Science, Texas Agricultural Experiment Station, Texas A&M University, College Station, Texas 77843

Exogenous fatty acid esterification in intramuscular and subcutaneous adipose tissues from 72-hr fasted or *ad libitum* fed Angus cattle was investigated. Intramuscular (interfascicular) and subcutaneous adipose tissue snips were obtained from the longissimus dorsi muscle and were incubated with radioisotopically labeled fatty acids (palmitate, stearate, oleate, linoleate or linolenate) at three different concentrations (0.3 mM, 0.6 mM and 2.0 mM) to assess rates of fatty acid incorporation into glycerolipids. Rates of fatty acid esterification *in vitro* increased with fatty acid concentration in both intramuscular and subcutaneous adipose tissues. For all of the fatty acids investigated, triglycerides were the predominant products (60–85%). Subcutaneous adipose tissue had larger adipocytes and more actively ($P<0.05$) esterified fatty acids, with the exception of palmitate, than intramuscular adipose tissue. The rate of palmitate esterification was not different between tissues, although intramuscular adipose tissue esterified a greater proportion ($P<0.10$) of palmitate as triglyceride (85%) than did subcutaneous adipose tissue (75%). Relative rates of incorporation of fatty acids into lipids in intramuscular and subcutaneous adipose tissues were: palmitate > linolenate > linoleate > stearate. In general, 72-hr fasting did not significantly reduce the rates of fatty acid incorporation in bovine adipose tissues. Results of this study revealed that: i) rates of exogenous fatty acid incorporation into adipose tissue lipids were dependent on the medium fatty acid concentration and adipose tissue depot; and ii) the relative esterification rates of the various fatty acids *in vitro* did not necessarily reflect the proportion of these fatty acids in bovine adipose tissues.
***Lipids* 27, 111–116 (1992).**

Evidence has accumulated to indicate that intramuscular (interfascicular) adipocytes represent a cell population different from the more extensively investigated subcutaneous adipocytes. Subcutaneous adipose tissue synthesizes fatty acids *de novo* at four to ten times the rate observed for intramuscular adipose tissue (1–3), even at a constant cell volume (3). Additionally, glucose is utilized more readily for fatty acid biosynthesis in bovine intramuscular adipose tissue than in subcutaneous adipose tissue (1,3). Glucose, the primary source of glycerol 3-phosphate for glycerolipid biosynthesis, has been shown to stimulate lipogenesis in bovine subcutaneous adipose tissue (3–6). Furthermore, fatty acids of dietary origin are readily accumulated into the perirenal and omental adipose tissues from ruminants (7,8). It is possible that the dissimilarity in preference for lipogenic substrates between intramuscular and subcutaneous adipose tissues influences the rate of esterification of exogenous fatty acids into these tissues.

Fasting has been shown to cause a marked reduction in the rate of fatty acid esterification in adipose tissue from swine (9) and rats (10) *in vitro*. Up to 55% and 48% suppression of the esterification of palmitate and glyceride-glycerol synthesis, respectively, were observed in subcutaneous adipocytes from pigs fasted for 48 hr (9). In ruminants, studies on fasting focused primarily on its effect on fatty acid synthesis (11–13) and oxidation (14,15). There is no information concerning fatty acid uptake and incorporation into bovine adipose tissue *in vitro*.

This study was conducted to quantify rates of exogenous fatty acid esterification in bovine intramuscular and subcutaneous adipose tissues *in vitro*. The effect of short term fasting on the glycerolipid synthesis of these two adipose tissues was also investigated to document the feasibility of a fasting-refeeding scheme in modifying the fatty acid composition of bovine adipose tissues.

MATERIALS AND METHODS

Chemicals. Bovine insulin (25.8 USP IU/mg) and bovine serum albumin (fraction V; fatty acid-, nuclease- and protease-free) were purchased from Calbiochem (La Jolla, CA). Radioisotopically-labeled compounds, [9,10(n)-^{3}H]-palmitate, [9,10(n)-^{3}H]oleate and [1-^{14}C]linolenate, were supplied by New England Nuclear (Boston, MA); [1-^{14}C]-linoleate and [1-^{14}C]stearate were obtained from Amersham (Arlington Heights, IL). Sodium salts of fatty acids (palmitate, stearate, oleate, linoleate and linolenate) and glycerol lipid standards (triolein, diolein, and monoolein) were purchased from NuChek Prep (Elysian, MN). Sodium L-α-phosphatidate, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), D-glucose, Triton X-100 and 2,4,6-collidine were purchased from Sigma Chemical Co. (St. Louis, MO). Trichloroacetic acid (TCA) and Scinti-Verse II were from Fisher Scientific (Fairlawn, NJ), and osmium tetraoxide (OsO_4) was from J.T. Baker Chemical (Phillipsburg, NJ). All other chemicals used were reagent grade of high purity and available from commercial sources.

Animals. Twelve Angus cattle (6 steers and 6 heifers) of the same age group (16–18 months) were selected from a single commercial Angus herd and finished with a standard finishing diet (16). The Angus breed was used in this study because of their propensity to develop more intramuscular adipose tissue in the longissimus dorsi muscle than most breeds. After reaching market weight (approximately 440 kg), the cattle were transported to the Texas A&M University Beef Cattle Center approximately one week prior to slaughter. Unusual stress was minimized during transportation and relocation of the animals. Upon arrival, cattle were assigned randomly and divided equally into two groups. One group of the cattle (3 steers and 3

Abbreviations: BHT, 2,6-di-*tert*-butyl-4-methylphenol; HEPES, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; TCA, trichloroacetic acid.

heifers) was subjected to a 72-hr fasting period in the holding pen with free access to water prior to slaughter, whereas the other group, fed *ad libitum*, was slaughtered about 4 hr after removal from feed. Carcass characteristics were evaluated according to USDA grading standards (17) by trained Texas A&M University personnel.

Tissue preparation. Immediately after stunning and prior to the completion of bleeding, the 8–13th rib region of the longissimus dorsi muscle from the right side of the animal was removed (with subcutaneous adipose tissue attached) by cutting through the hide. The sample was placed in 37°C Krebs-Henseleit calcium (Ca^{+2})-free bicarbonate buffer (pH 7.4) with 5 mM glucose, gassed with oxygen/carbon dioxide (95:5; v/v) for 30 min. Intramuscular and inner layer subcutaneous (adjacent to the muscle) adipose tissue snips were carefully dissected from the longissimus dorsi muscle for tissue incubation and adipose tissue cellularity determinations (1).

Tissue incubations. The incubation procedures and medium as described by Deeth and Christie (18) were modified for use in this study. Maximum weight of the adipose tissue snips in the incubation was limited to 150 mg (2–3 mm thickness) to minimize factors which tend to reduce fatty acid uptake (19). Adipose tissue snips (weight ranged from 70 to 150 mg) were incubated in Krebs-Henseleit Ca^{+2}-free bicarbonate buffer (pH 7.4) that contained 10 mM HEPES, 5 mM glucose, 1.0 mU/mL insulin, and 40 mg fatty acid-free bovine serum albumin for each μmol fatty acid. The fatty acid to bovine serum albumin molar ratio of 1.7 (molecular weight of albumin assumed to be 68,000) was established in accordance with a previous report (20). The sodium salt of the free fatty acid palmitate (16:0), stearate (18:0), oleate (18:1n-9), linoleate (18:2n-6), or α-linolenate (18:3n-3) was emulsified into the buffer by 30 min stirring at 37°C (for oleate, linoleate and linolenate) or 45°C (for palmitate and stearate) under nitrogen gas followed by 30 min sonication using a Fisher Sonic Dismembrator (Model 300, Fisher Scientific) equipped with a micro-tip on setting 3.5.

As reported by Pothoven and Beitz (11), and Bell (21), plasma free fatty acid levels can fluctuate from 0.3 mM to 2.0 mM. Therefore, three different fatty acid concentrations (0.3, 0.6 and 2.0 mM) were used in this study to determine the fatty acid esterification capacity of the adipose tissues. In addition, the concentrations of the exogenous fatty acid added were sufficient to minimize the effects of any endogenous unesterified fatty acids in the tissues. After the fatty acids were dispersed, the incubation media were gassed with O_2/CO_2 (95:5, v/v) for 30 min. Incubations were carried out in 20-mL glass scintillation vials, in duplicate, in 3 mL incubation medium (pH 7.4) containing 0.5 μCi of [9,10(n)-^{3}H]palmitate, [1-^{14}C]stearate, [9,10(n)-^{3}H]oleate, [1-^{14}C]linoleate, or [1-^{14}C]linolenate.

After gassing vials with O_2/CO_2 for 30 sec and sealing with caps, incubations were conducted for 30 min at 37°C in a shaking water bath (Fisher Model 129) set at 120 strokes/min (20). Five mL 5% (w/w) TCA was added to each vial to terminate incubations. Blanks included for all incubations were terminated by addition of 5 mL 5% TCA before incubation. Tissues were removed from the incubation media and were rinsed once with 9 mL incubation buffer and twice with 9 mL saline (0.154 M NaCl). The snips were transferred to scintillation vials containing 5 mL chloroform/methanol (2:1, v/v). To minimize lipid oxidation, 0.1 mg/mL of 2,6-di-*tert*-butyl-4-methylphenol (BHT) was added to the extraction solvent. The vials were flushed with nitrogen gas and were cap-sealed and stored at −25°C for subsequent lipid extraction and analysis.

Adipose tissue lipids were extracted by a method modified from Folch *et al.* (22). Nonesterified fatty acids and protein residues were trapped and removed with consecutive 0.38 M Na_2CO_3 washes (20). Preliminary tests showed that the Na_2CO_3 washes removed more than 99.7% of nonesterified fatty acids from the lipid extract. The chloroform was evaporated under a nitrogen gas stream at 45°C in a Multi-Vap (Model 112) evaporator. The dried lipid samples were redissolved in 0.3 mL chloroform for subsequent lipid assays.

The esterified lipid products were characterized and quantitated by thin-layer chromatography as described by Christie (23). The plates (preadsorbent/scored/channeled 20 × 20 cm, 250 micron Silica Gel G, Analtech, Inc., Newark, DE) were activated at 12°C for 2 hr and cooled to ambient temperature in a vacuum desiccator before sample applications. An unlabeled carrier standard (10 μL) consisting of a mixture of diolein, phosphatidate, and nonesterified oleic acid was applied to the sample spots. The plates were developed in a hexane/diethyl ether/glacial acetic acid (85:25:2.5, v/v/v) solvent system. Separated lipids were visualized and identified by comparison to migration of reference standards in parallel channels after exposure to iodine vapors. Respective bands of triglycerides, diglycerides, monoglycerides and phospholipids for each sample were scraped into 6-mL plastic scintillation vials (Beckman, Fullerton, CA) and, after adding 5 mL scintillation fluid, lipid products were quantified by liquid scintillation spectrometry. Esterification rates of fatty acids were calculated on the basis of incubation medium specific activity and were expressed as nmol fatty acid esterified/10^5 adipose tissue cells/30 min.

Adipose tissue cellularity. Subcutaneous and intramuscular adipose tissue samples (90 to 120 mg) were stored at −25°C in screw cap vials. Frozen tissue samples were sliced to approximately 1 mm thickness on an ice-cold glass plate and transferred into 20 mL scintillation vials. The method modified by Etherton *et al.* (24) was used for determining adipose tissue cellularity (cell size and cells per g adipose tissue).

Mean adipocyte diameter was obtained by randomly measuring 150 fixed cells for each tissue sample using a Timbrell/Coulter Shearicon (25). Adipocyte volume data were obtained by calculation based on cell diameter. The number of adipocytes per unit adipose tissue weight (g) was measured using a Coulter Counter (Model ZBI). Mean adipocyte number for each sample was obtained from five readings.

Statistical analyses. Data were processed and analyzed using the Statistical Analysis System (SAS) program (26). Main effects (independent variables) included sex (steers and heifers), treatments (fed and fasted), adipose tissues (subcutaneous and intramuscular) from each animal, fatty acids (palmitate, stearate, oleate, linoleate and linolenate) for each tissue, and fatty acid concentrations (0.3 mM, 0.6 mM and 2.0 mM). Because these were split-split plot designs, appropriate error terms were used to test the respective main effects and their interactions. The Student-Newman-Keul's test was performed to compare the mean differences when the main effect was significant.

RESULTS AND DISCUSSION

Adipose tissue cellularity. In agreement with previous reports (1-3,27,28), subcutaneous adipocytes were larger ($P<0.05$) than intramuscular adipocytes (Table 1). This investigation was initially designed to characterize differences in fatty acid esterification between steers and heifers. However, sex of the animal had no effect on any aspect of adipose tissue cellularity (Table 1) or fatty acid esterification (data not shown). Nor was dietary restriction sufficient to affect adipose tissue cellularity or rates or patterns of fatty acid esterification ($P>0.10$). Similarly, no interactions ($P>0.10$) among the main effects, sex (steer and heifer), treatment (fasted and fed) and adipose tissue (intramuscular and subcutaneous adipose tissues) were detected for all aspects of adipose tissue cellularity. For this reason, only differences elicited by media fatty acid concentration and adipose tissue depot will be discussed.

Esterification as a function of fatty acid concentration. Fatty acid incorporation into the adipose tissue total lipids increased with fatty acid concentration (Fig. 1). With the exception of stearate, the increase in esterification generally was linear with fatty acid concentration up to 2.0 mM. This is similar to previous findings (20,29). The variability in rates at different concentrations of stearate may have been due to extreme insolubility of stearate in the buffer system. It is unlikely that this abnormality was caused by the detergent effect of the fatty acid (30), because the greatest rate of esterification for stearate was observed at 2.0 mM.

At the low concentrations of substrate fatty acids, it is possible that lipolysis could have diluted the intracellular pool of radioisotopically-labeled fatty acids. This would have been especially pronounced in the cattle fasted for two days. However, we observed no difference in rates of esterification of fatty acids between the fed and fasted steers (data not shown), suggesting that fatty acid pool dilution did not substantially affect the observed rates of incorporation. Virtually no effect of pool dilution would be anticipated for tissues incubated at 2.0 mM fatty acids, or for those fatty acids in low abundance in bovine adipose tissues (linoleate and α-linolenate; ref. 31).

For adipose tissues incubated with palmitate, oleate and linolenate, the triglyceride fraction decreased as the fatty acid concentration increased (from 80-85% of the total to 70-75% of the total; data not shown). This was generally accompanied with a relative increase in the percentage of diglyceride, phospholipid and monoglyceride fractions. The distribution of stearate and linoleate in glycerolipid fractions did not change with substrate concentration. A decrease in the proportion of triglycerides with increased diglycerides and phospholipids was also noted in ovine liver slices incubated with increasing concentrations of various fatty acids (32). The basis for the alteration of lipid distribution in response to the medium fatty acid concentration is not known.

Fatty acid esterification as a function of fatty acid species. To characterize the effects of the different exogenous fatty acids on esterification rates and lipid product distributions, data were pooled across fatty acid concentrations (Table 2). Palmitate, followed by oleate, were esterified more rapidly ($P<0.05$) than linoleate, linolenate and stearate by the adipose tissues *in vitro*. The incorporation rate tended to be higher for linolenate than for linoleate, though the difference ($P<0.10$) was noted only in subcutaneous adipose tissue (Table 2). Stearate had the lowest esterification rate among the five fatty acids. Similar results were observed in ovine adipose tissue (32), but the esterification rate of stearate was much higher than reported here. Another study (18) demonstrated that oleate, palmitate and stearate were esterified at similar rates when ovine adipose tissue was incubated with equimolar concentrations of the fatty acids. The discrepancy among studies may be due to differences in the fatty acid makeup of the incubation medium. Since fatty acids are stereospecifically esterified onto the glycerolipids (7,30, 33), incubation with mixtures of fatty acids would be more favorable for incorporation than with homogeneous fatty

TABLE 1

Intramuscular and Subcutaneous Adipose Tissue Cellularity of Fed and Fasted Steers and Heifers[a]

	Sex/treatment				Comparison within adipose tissue

[a] Adipose tissues were fixed by 3% (w/v) OsO_4 (in collidine buffer) and adipocytes were isolated in 8 M urea. The number of adipocytes per unit adipose tissue weight (g) was measured using a Coulter Counter (Model ZBI) equipped with a logarithmic range expander. Adipocyte diameter (d) for each tissue sample was obtained by randomly measuring 150 fixed cells using a Timbrell/Coulter Shearicon. Adipocyte volumes were obtained by calculation $[4/3\pi(d/2)^2]$ from the cell diameter data for each tissue sample. Values are expressed as mean ± SEM.

[b] Cells/g adipose tissue were not different ($P>0.05$) between intramuscular and subcutaneous adipose tissues.

[c] Cell volume was different ($P<0.05$) between intramuscular and subcutaneous adipose tissues.

[d] Not significant.

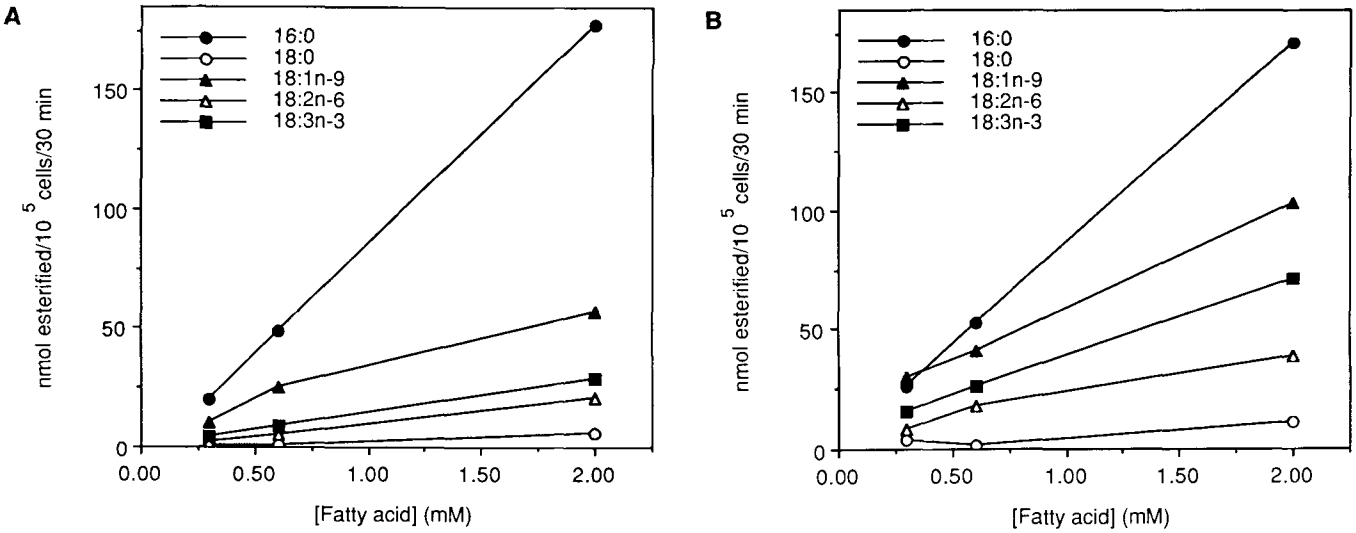

FIG. 1. The esterification of palmitate (16:0), stearate (18:0), oleate (18:1n-9), linoleate (18:2n-6) and α-linolenate (18:3n-3) into total lipids in bovine intramuscular adipose (A) and subcutaneous (B) adipose tissues incubated *in vitro*. Each data point is the mean of adipose tissues obtained from six steers and six heifers. The average SEM was 23% of the mean.

[a]Adipose tissue snips (70–150 mg) were incubated in 3.0 mL of Krebs-Henseleit Ca^{2+}-free bicarbonate buffer containing 10 mM HEPES, 5 mM glucose, 1.0 mU/mL insulin, fatty acid-free bovine serum albumin, fatty acid (palmitate, stearate, oleate, linoleate or linolenate) and 0.5 μCi of the labeled fatty acid. Data are pooled across fatty acid concentration. Means ± SEM are for three steers and three heifers with three concentrations fatty acid/animal.

Means within rows followed by different superscript letters (b,c,e,f,g) are different ($P<0.10$); means between the intramuscular (IM) and subcutaneous (SC) adipose tissues (d) are different ($P<0.10$).

acid media, as was used in the present investigation. The differences between the current study and previous investigations of ovine adipose tissue alternatively may reflect species differences. We have demonstrated that ovine and bovine subcutaneous adipose tissues differ in several aspects of *de novo* fatty acid biosynthesis (34).

Rates of esterification of stearate, oleate, linoleate and linolenate into triglycerides were higher ($P<0.10$) in subcutaneous adipose tissue than in intramuscular adipose tissue (calculated from data in Table 2). Conversely, the rate of palmitate incorporation into triglycerides was the same in intramuscular and subcutaneous adipose tissues. Regardless of the fatty acid substrate, subcutaneous adipose tissue consistently exhibited greater ($P<0.10$) rates of diglyceride production than did intramuscular adipose tissue. A similar trend was observed for phospholipids, although the differences were significant only for palmitate and oleate. The only differences ($P < 0.10$) noticed in

monoglycerides between the two adipose tissues were for oleate and linoleate.

The rates of fatty acid incorporation into total lipids (Table 2) were expressed per 10^5 adipocytes (*i.e.*, per metabolic unit). However, the volume of the subcutaneous adipocytes was over twice that of the intramuscular adipocytes (Table 1). If rates were expressed based on adipocyte volume, then the esterification of palmitate in intramuscular adipocytes would be over two-fold greater than the rate observed in subcutaneous adipocytes. This indicates that the enzymes of the triglyceride biosynthetic pathway are relatively more concentrated in the intramuscular adipocytes than in their subcutaneous counterparts.

The different rates of palmitate and linoleate esterification in the current study reflect the natural composition of these fatty acids in bovine adipose tissues (7,35,36). However, because ruminant animals biohydrogenate fatty acids before passage into the small intestine, very little linoleate is available for absorption. Thus, fatty acid availability, rather than rate of esterification, likely dictates the composition of bovine adipose tissues for many of the fatty acids.

There is no clear explanation for the higher oleate content (42–49% *vs.* 25–30% for palmitate) but lower esterification rate of oleate as compared to palmitate. It was reported that oleoyl-CoA at a high concentration (0.12–0.27 mM) reduced the activity of phosphatidate phosphohydrolase (37). The high concentration of oleate in bovine adipose tissue, relative to palmitate, may also reflect the active fatty acid elongase and stearoyl-CoA desaturase of that tissue (38), so that a large proportion of the palmitate synthesized *de novo* or absorbed from the diet would be converted to oleate.

With respect to the low stearate incorporation rate, the difficulty in dispersing the water-insoluble substrate as well as maintaining its emulsion stability, in part, could be the reason for both its low incorporation rate *in vitro* and the relatively lower concentration observed in bovine adipose tissue (39). Fatty acyl-CoA synthetase (EC 6.2.1.3) has a low affinity for stearate relative to its affinity for the other fatty acids (40). Stokes *et al.* (41) demonstrated that stearoyl-CoA was incorporated into triglycerides by the subcellular preparations from rat adipose tissue as efficiently as palmitoyl-CoA, but with stearate the incorporation rate was only about one-fifth that of palmitate, oleate and linoleate. On the basis of these observations, they concluded that this difference was at the level of acyl-CoA synthetase (41).

Fatty acid distribution in glycerolipids as a function of fatty acid species. Irrespective of the fatty acid species, triglycerides were the predominant products and amounted to 60–85% of total lipids esterified (Table 2). The subsidiary lipid class (9–20%) formed by the adipose tissue was diglycerides, and the remainder was accounted for by monoglycerides and phospholipids. Deeth and Christie (18) and Payne and Masters (32) reported similar findings in ovine omental adipose tissue incubated with the same fatty acids.

For stearate, linoleate and linolenate, subcutaneous adipose tissue tended to have a larger proportion of triglycerides but smaller proportions of diglycerides and phospholipids than did intramuscular adipose tissue, though the differences were not always significant (Table 2). In contrast, intramuscular adipose tissue deposited a larger proportion of palmitate as triglyceride than did subcutaneous adipose tissue. There were no differences ($P > 0.10$) in the distribution of oleate into these lipid products between the two adipose tissues. Except for linolenate, the variation in monoglyceride distributions in the two adipose tissues was not significant ($P > 0.10$).

The lipid products were distributed in a pattern parallel to the natural distribution of the lipid classes in adipose tissue, with triglycerides being the primary products followed, in descending order, by diglycerides, phospholipids and monoglycerides (9). Because the major role of adipose tissues is to assimilate and deposit fatty acids as triglycerides, it may be expected that the adipose tissues primarily synthesize triglycerides *in vitro*. The apparent accumulation of diglycerides could be an artifact arising from the time lag in the formation of triglycerides from diglycerides.

In summary, the different esterification activities between intramuscular and subcutaneous adipose tissues support the previous findings that adipose tissues from various anatomical origins are dissimilar in metabolic functions and processes (1–3,42,43). It has been shown that intramuscular adipose tissue can synthesize palmitate *in situ*, but at a much slower rate than subcutaneous adipose tissue (1,43,44). Because of its low endogenous synthetic capacity, intramuscular adipose tissue may rely more on exogenous sources of palmitate to supply substrate for glycerolipid assimilation than subcutaneous adipose tissue.

Anorexic Contribution to Increased Linoleate Mobilization and Oxidation in Lymphoma-Bearing Mice

Ram Kannan[a,1], **Minerva Gan-Elepano**[a] and **Nome Baker**[b,*]

[a]Liver Research Laboratory, Medical Research Services, Veterans Administration Wadsworth Medical Center, Los Angeles, California 90073 and UCLA School of Medicine, Los Angeles, California 90024 and [b]John Muir Cancer and Aging Research Institute, Walnut Creek, California 94596

To test for a regulatory defect in adipose triacylglycerol (essential) fatty acid mobilization in lymphoma-bearing mice, free [1-^{14}C]linoleic acid/mouse serum albumin was injected *iv* into lymphoma-bearing and control mice, adapted to a reversed light cycle, and studied in three dietary states in the dark period. Mean daily food intake decreased in mice with small and large tumor burdens. Plasma free fatty acid (FFA) oxidation rates, which approximate FFA mobilization rates, were estimated by multicompartmental analysis (CONSAM). Oxidation of linoleate to CO_2 was reduced significantly (85%) in *ad libitum* fed as compared to briefly fasted control mice but not in fed *vs.* fasted mice with large or small tumor burdens. However, plasma FFA oxidation rates to CO_2 did not differ in briefly fasted tumor-bearing and pair-fed control mice. When re-fed a 250-mg test meal, briefly fasted mice with small tumors suppressed plasma free linoleic acid oxidation, as did controls. During simulated night, mildly anorexic, tumor-bearing mice with small tumor burdens mobilized essential fatty acids much faster than controls. This could explain body fat loss. The abnormally rapid rates of FFA (free linoleic acid) mobilization at night probably result from anorexia rather than from inability of food to suppress fat mobilization.
***Lipids* 27, 117–123 (1992).**

Lymphoma-bearing mice reportedly have a potent, circulating lipid mobilizing factor (LMF) produced directly by the lymphoma cells. This factor was hypothesized to act by increasing the mobilization of linoleate, and presumably other fatty acids, stored in adipose tissue as triacylglycerol fatty acids (TGFA) (1,2). Such action could explain the loss of body fat, an aspect of cancer cachexia associated with this mouse lymphoma (1), and also enhance tumor growth, which is limited by the free linoleic acid transport rate in some experimental cancer models (3). However, no one, to our knowledge, has measured transport rates of free fatty acid (FFA), traced by free linoleic acid, in lymphoma-bearing mice to confirm that mobilization of this essential FA is actually increased.

Two studies of non-essential FA have been carried out in lymphoma-bearing mice, both of which failed to show any increase in FFA (free palmitic acid) mobilization and oxidation in briefly fasted lymphoma-bearing mice (4,5). Therefore, if an active LMF circulates in the lymphoma-bearing mice, it does not influence rates of adipose TGFA lipolysis in the fasted state. However, free palmitic acid is mobilized and oxidized more rapidly in *ad libitum* fed lymphoma-bearing mice than in controls, suggesting that LMF, if present, might interfere with regulatory processes that govern lipolytic activity in adipose tissue (5). Alternatively, diminished food intake, independent of LMF activity, could account for the abnormally rapid rates of FFA (free palmitic acid) mobilization in fed lymphoma-bearing mice (5).

In the present study we have used tracer techniques to test the hypothesis that FFA (free linoleic acid) transport and oxidation is increased in lymphoma-bearing mice, presumably due to the presence of a potent, circulating LMF. We have also monitored food intake throughout the tumor-growth period, as well as before and after adaptation to the reverse light cycle conditions under which the studies were carried out, in order to establish whether the hypothetical defect in essential FFA transport might result from anorexia. Finally, we have included a set of experiments designed to see whether lymphoma-bearing mice are capable of responding to a known small test meal by reducing their rates of FFA (free linoleic acid) transport and oxidation as do control mice.

MATERIALS AND METHODS

Materials. [1-^{14}C]Linoleic acid (58 mCi/mmol) was purchased from ICN Biochemicals, Inc. (Costa Mesa, CA) and was 99% pure. Aquasol was obtained from Dupont-NEN (Boston, MA). All solvents and chemicals used in CO_2 and FFA measurements were of reagent grade.

Animals and tumors. Seven-week-old male AKR/J mice (Jackson Laboratory, Bar Harbor, ME) were maintained on Purina Lab Chow and water *ad libitum*. The mice were divided into lymphoma-bearing and control groups. Mice in the tumor-bearing (TB) group were inoculated with 1×10^6 freshly harvested SL-3 tumor cells that had been maintained in culture (6). The cells were injected *ip* in 0.2 mL medium or phosphate buffer (5). The tumor usually developed in about two weeks and was detected by a palpable abdominal mass near the inoculation site and by decreased food intake by the animal.

Both control and TB mice were maintained on a reverse light cycle schedule which consisted of 12 hr of darkness (8:00 a.m.–8:00 p.m.), followed by 12 hr of light at night. Mice from both groups were kept on a reverse light cycle immediately after the tumor inoculation and were maintained under the same conditions throughout the study, but with additional minimal lighting required to inject the tracer and to execute the experiment.

Animals were housed individually and body weights and daily food intake were monitored in all but one study, as described previously (5). The TB mice were studied at two levels of tumor burden, "small" and "large" (see

Results for further description of the body weights, tumor sizes and average daily food intakes).

Experimental protocols. Four experiments listed below were carried out on separate populations of mice. Each study was conducted in the dark period after the mice had been adapted to a reversed light cycle for 2–3 weeks, the time allowed for tumor development. From these studies we were able to estimate the rates of plasma FFA transport and oxidation to CO_2, based on free linoleic acid as tracer, in the following—lymphoma-bearing animals with small or with large tumor burdens and their controls, fed *ad libitum;* tumor bearing (small burdens) and pair-fed controls in both the briefly fed state and after ingesting a small, known test meal.

In Experiments 1 (controls) and 2 (lymphoma-bearing mice with small burdens), free [1-^{14}C]linoleic acid disappearance from plasma and oxidation to breath $^{14}CO_2$ in unanesthetized mice that were fed *ad libitum* was measured. Fatty acid/mouse serum albumin complexes for all experiments were prepared as described previously (7). Each experiment was conducted in two parts, on consecutive days, at mid-day. The dose (1 μCi/mouse) in 0.2 mL of mouse serum was injected into the tail vein of unanesthetized mice in restraining cages. On the first day, only breath $^{14}CO_2$ was measured. On the second day, the same animals were used to measure plasma [^{14}C]FFA disappearance by collecting two retroorbital blood samples per mouse, from half of the mice at 0.5 and 2 min, and from the other half at 1 and 5 min plus the terminal sample at 10 min from all control and from TB mice with small burdens. The numbers of mice used in Experiments 1 and 2 were 9 and 8, respectively.

In Experiment 3, TB mice with large tumor burdens were studied under the same conditions as in Experiments 1 and 2, except that they were only injected with tracer once to study the kinetics of breath $^{14}CO_2$ appearance for 10 min. Immediately thereafter a terminal blood sample (only) was drawn to determine the percent of the injected [^{14}C]FFA dose remaining in the plasma.

In Experiment 4, we again measured the oxidation of plasma free [1-^{14}C]linoleic acid oxidation to CO_2 following *i.v.* injection of the tracer in control and in TB mice (small burdens), and the percentage of the injected tracer remaining in the plasma at 10–11 min. However, in this experiment the control mice were carefully pair-fed with the TB animals, and a different experimental protocol was followed. All of the mice were briefly fasted and then half were fed a single 250-mg test meal for 30 min immediately prior to the tracer study, and half were not fed. Four groups of mice (n=5/group) were used: pair-fed controls, briefly fasted, 4–6 hr; TB, briefly fasted; pair-fed controls, briefly fasted and then refed; and TB mice, briefly fasted and refed. All studies were carried out in the dark period, beginning at noon, as in the other experiments. Only a terminal blood sample, at 10–11 min, was collected immediately after the last breath $^{14}CO_2$ sample. Plasma FFA data (percent injected dose remaining and plasma FFA concentration) were obtained from this terminal sample. The mixing kinetics of plasma with extraplasma FFA were assumed to be the same as those of the corresponding *ad libitum* fed group.

Blood sampling. Retroorbital blood was obtained from an opthalmic venous sinus in heparinized capillaries (8,9). Only two blood samples per mouse (100 μL total volume) were taken prior to a third terminal sample. The capillaries were kept in ice and then centrifuged at 1,000 rpm for 1 min to separate plasma from red blood cells.

Chemical and radioactive analyses. Plasma [^{14}C]FFA was determined by adding 25–100 μL of plasma to 10 mL Aquasol and counting directly, without prior separation of FFA from other lipids. We confirmed in trial runs that the serum total neutral lipid radioactivity in the short time span (10 min) used in these experiments is entirely in the form of labeled FFA. Plasma FFA concentrations were determined using terminal blood samples according to the method of Hron and Menahan (10), as in our earlier studies (4,5,11). Total plasma [^{14}C]FFA radioactivity at each time was calculated by assuming a plasma volume of 4.0% of body weight (4).

Breath CO_2 measurement. The techniques used for measuring radioactivity and mass of CO_2 were those described in our earlier studies (5,12), namely, trapping in hyamine hydroxide solution, measuring the time needed for the expired CO_2 to titrate the latter to a phenolphthalein end point (12), and measurement of bicarbonate radioactivity by liquid scintillation counting (0.5 mL of the trapping agent in 10 mL Aquasol). Breath $^{14}CO_2$ was collected for 10 min, with measurements of radioactivity every 2 min, cumulatively.

Multicompartmental analyses. The tracer kinetic data that were analyzed consisted of the percentage of the injected dose of radioactive free linoleic acid remaining in the plasma as a function of time and the percentage of the injected dose appearing in breath $^{14}CO_2$ cumulatively during the first 10 min of the experiment. The disappearance of labeled FFA from the plasma has been shown in earlier studies (11) to represent primarily mixing of the tracer with extraplasma FFA (and FA-X) compartments. Only a part of the label appears in the breath during this period. The multicompartmental analysis, as indicated below, takes these complex mixing and metabolic processes into account.

Multicompartmental analyses were carried out using the SAAM and CONSAM programs (13,14) with a VAX 11-780 computer using the model shown in Figure 1 of Kannan *et al.* (5). The reader is referred to the latter study and to our previous studies (11) for the logic and assumptions used in developing and validating the model, as well as for data and parameters that define the mixing and turnover of the plasma and extraplasma bicarbonate/CO_2 compartments in TB and in control mice (5). We assumed here that the parameters obtained using CONSAM for the bicarbonate/CO_2 compartments of briefly fasted control and TB mice studied in the regular light cycle could be applied to the corresponding control and TB mice under all of the present conditions. Although the bicarbonate kinetics almost surely differ in the different dietary states, this should have no major impact on our estimates of the fractional rate of plasma FFA oxidation to CO_2, the parameter used to test our hypotheses.

Statistical analysis. The significance of the differences between mean values for any fractional rate constant or transport rate was assessed by constructing an approximate 95% confidence interval, as described earlier (5). Differences between means of plasma FFA pool sizes and of [^{14}C]FFA remaining in the plasma at 10 min were evaluated using Student's *t*-test.

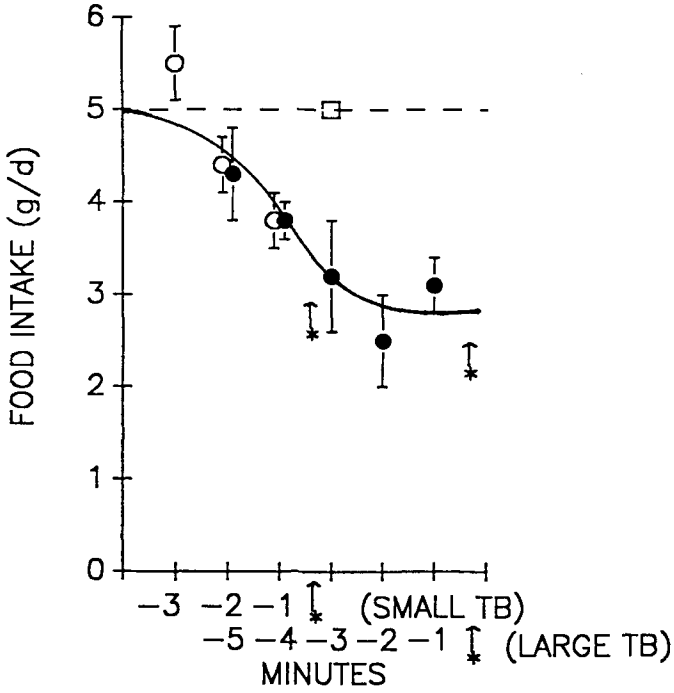

FIG. 1. Mean daily food intakes of lymphoma-bearing mice with small (○) and large (●) tumor burdens during the period immediately preceding the tracer studies. The mornings of the separate tracer studies (*i.e.*, during day 0) are indicated for each TB group by an arrow and asterisk. Separate populations of mice were used for each study. Data (□), broken line as reference, are also shown for control mice, some of which were later used for pair-feeding with the TB mice with small burdens, but before pair-feeding commenced. All mice were fed *ad libitum* and are the means of 8, 9, and 19 mice for the following groups, small tumors, large tumors, and controls, respectively. Food intakes have been normalized to 27 g body weight.

RESULTS

Mean body weights, food intake, inguinal fat pad, and tumor wet weights in control and lymphoma-bearing mice. Body weights of *ad libitum* fed mice on the morning of the linoleate oxidation studies averaged (± SE) 24.5 ± 0.52, 23.3 ± 1.9, and 26.9 ± 1.1 g for controls, mice with small tumor burdens, and mice with large tumor burdens, respectively; body weights were 29.5 ± 0.48 and 27.9 ± 0.70 g (fasted groups, mice with small tumor burdens, and pair fed controls, respectively) and 28.7 ± 0.89 and 24.0 ± 0.71 g (fasted-refed groups). Initial body weights, at tumor inoculation, when mice were first placed under reversed light cycle conditions averaged 25.4 and 22.6 g for the mice used in the fasted and fasted-refed studies, respectively.

Lymphoma-bearing mice with small burdens eat about the same amount of food as they do when first inoculated and when first placed on a reversed light cycle (5). However, during adjustment to the reversed light cycle, the daily food intake of both *ad libitum* fed controls and TB mice increases significantly; it then decreases in the TB mice, but not in the controls. This is shown in Figure 1. The food intake, normalized to 27 g body weight, the approximate mean body weight of all groups on the experimental day, increased from 4.3 ± 0.11 g/day in the first week of acclimatization (not shown in Fig. 1) to 5.0 ± 0.09 g/day ($p \leq 0.01$) three days prior to study (control mice). In Figure 1, day −1 represents food intake by mice with small and large tumor-burdens (and their pair-fed controls) from the day before the experiment to the day of the experiment. The mean daily food intake in TB mice with small tumor burdens fell significantly (from 5.0 or 5.5 to 3.6 g/day) during the three days prior to the experimental day (Fig. 1). Similarly, the mean food intake of mice with large tumor burdens fell during the five days preceding the experimental day. Thus, in mice with large tumor burdens, there was a 53% reduction in food intake (from 5.5 to 2.6 g/day) as compared to values measured six days earlier (Fig. 1). Pair-fed controls were offered and ate the same amount of food as the TB mice ate on the preceding day. Tracer studies of the pair-fed controls were done the day after those of TB mice so that pair-feeding could continue until the experimental day.

As in our earlier report (5), mice with small tumor burdens had solid *ip* tumors weighing less than 0.5 g and some gelatinous ascites material that was not quantified. Mice with large tumor burdens had an average of 2.5 ± 0.5 g solid tumor and their right inguinal fat pad weights were significantly lower than those of controls (20 ± 6 *vs.* 109 ± 12 mg/single fat pad, respectively). The inguinal fat pad weights of mice with small tumor burdens did not differ significantly from those of controls (5).

Plasma free [1-^{14}C]linoleic acid disappearance following i.v. *injection of tracer free linoleic acid/mouse serum albumin complex.* Early kinetics of plasma FFA (linoleic acid) mixing and removal during experiments of 10 min duration were studied in two groups of mice, those with small tumor burdens and controls, each group fed *ad libitum* (Fig. 2). The tracer remaining in plasma at 10 to

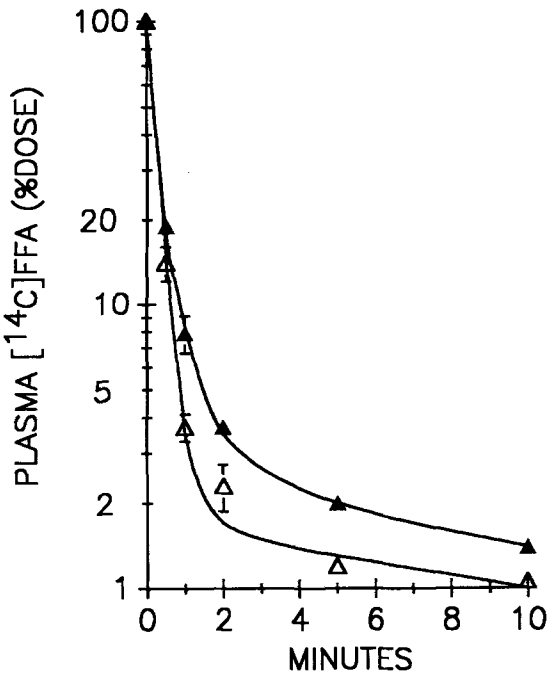

FIG. 2. Disappearance of plasma [^{14}C]FFA after *i.v.* injection of free [1-^{14}C]linoleic acid complexed to mouse serum albumin in lymphoma-bearing (▲) and control (△) mice fed *ad libitum*. Mice were adapted to a reversed light cycle and studied in the dark period. Ordinate: percent of injected ^{14}C dose remaining in the total plasma volume as FFA; data plotted semilogarithmically. Number of mice: controls, 9; tumor (small burdens), 8. Vertical bars, ± SE.

11 min, measured immediately after the studies of free [1-^{14}C]linoleic acid oxidation to breath $^{14}CO_2$ (below), was measured in each of the other groups. The percentage of the injected dose remaining in the plasma per mouse did not vary greatly among groups, and ranged [mean ± SE (n)] from 1.0 ± 0.06 (n=6) to 1.6 ± 0.015 (n=5) %. In all groups studied, an average of between 98.4% and 99.0% of the injected free linoleic acid dose was removed from the circulation in 10–11 min. This implies that mixing of plasma FFA with extraplasma FFA and with other rapidly exchanging FA-containing compartments, which dominates the early kinetic behavior of injected tracer FFA (11), occurred at similar rates in all of these groups. Accordingly, the early tracer FFA data between t = 0.5 and 5 min for the normal and TB mice fed *ad libitum* (shown in Figure 2) was assumed to approximate that of the normal and TB mice, respectively, in the other groups.

Kinetics of plasma free [1-^{14}C]linoleic acid oxidation to breath $^{14}CO_2$ in TB and control mice (reversed light cycles). In control mice fed *ad libitum,* the cumulative excretion of breath $^{14}CO_2$ was 85% lower than in those that were briefly fasted [6% *vs.* 30%, respectively (Fig. 3)]. However, oxidation of labeled linoleate to breath $^{14}CO_2$ was the same in the fed as in the briefly fasted lymphoma-bearing mice (Fig. 4). Thus, averages of 27% and of 30% of the injected dose were recovered as $^{14}CO_2$ at 10 min in *ad libitum*-fed TB mice with small and large tumor burdens, respectively (Fig. 4). This contrasts with the mean value of 6% for the *ad libitum*-fed control mice (Fig. 3), and is similar to the mean value of 30% for the briefly fasted TB mice with small tumors (Fig. 4).

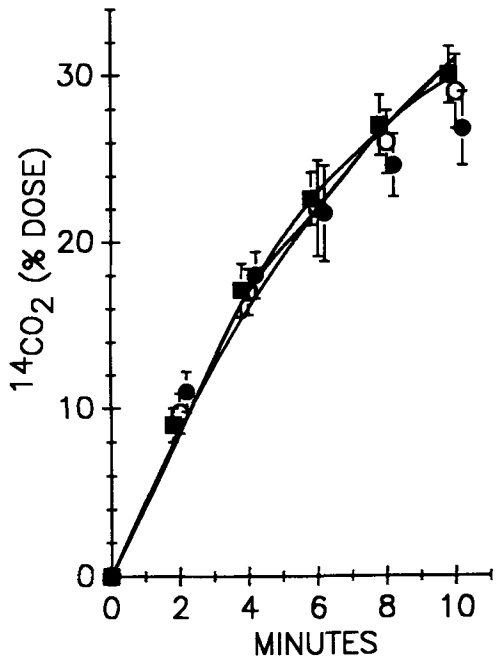

FIG. 4. Failure of lymphoma-bearing mice, both with large (○) and small (●) tumor burdens, to suppress plasma FFA (free linoleic acid) oxidation when fed *ad libitum,* compared to briefly fasted (■) TB mice with small tumor burdens (4–6 hr). See legend to Figure 3 for further details. Number of *ad libitum*-fed TB mice: small burden, 8; large burden, 8; number of fasted TB mice (small burden), 5. Vertical bars, ± SE.

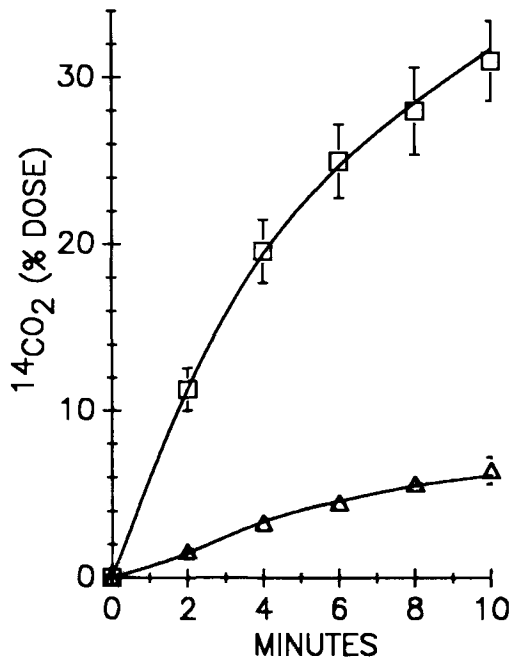

FIG. 3. Suppression of plasma FFA (linoleate) oxidation to CO_2 in *ad libitum*-fed (△) compared to briefly (4–6 hr) fasted (□) control mice. The cumulative breath $^{14}CO_2$ excretion patterns, expressed as the percentage of the injected dose, are shown for the two groups as a function of time following *i.v.* injection of tracer free [1-^{14}C]linoleic acid complexed to mouse serum albumin. Data are plotted on rectangular coordinates. Number of mice: fasted, 5; fed *ad libitum,* 9. Vertical bars, ± SE.

Although it would appear from the data presented in Figure 4 that the TB mice, even those with small tumor burdens, do not suppress the mobilization and oxidation of free linoleic acid when they eat, this was not the case when the study was repeated under conditions in which food intake was carefully controlled. As shown in Figure 5, when fed a small (250-mg) test meal, both TB (small tumor burdens) and control mice responded similarly with a prompt, significant reduction in the rate of injected tracer linoleate oxidation to breath $^{14}CO_2$. This suppression was accompanied by a significant decrease in the plasma FFA levels (Table 1).

Three control mice were pair-fed to TB mice with small tumor burdens throughout the period of adaptation to the reversed light cycle, which corresponded to the period of tumor growth. Since food intake decreased in the TB group as compared to controls fed *ad libitum* (Fig. 1), it was also reduced in the pair-fed control mice for several days. However, the pair-fed control mice were then allowed to eat *ad libitum* on the morning of the tracer experiment. These control mice oxidized free [1-^{14}C]linoleic acid to breath $^{14}CO_2$ at the same slow (suppressed) rate as did control mice that had not had their food restricted at any time [(mean ± SE) of 5.8 ± 1.2% *vs.* 6.4 ± 0.81% of the injected dose excreted as $^{14}CO_2$ in 10 min, respectively, unpublished observations and Fig. 3]. Therefore, we conclude that it is not the diminished food intake in the several days immediately preceding the tracer study, but rather the diminished food intake on the experimental morning (Fig. 1) that accounts for the *ad libitum*-fed TB mice having elevated rates of plasma essential and non-

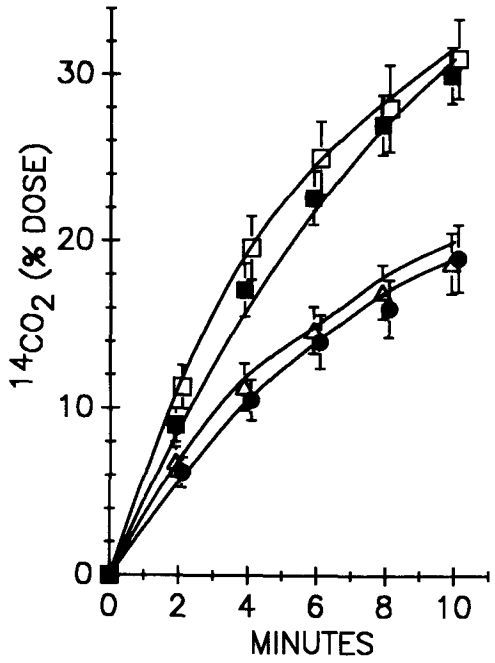

FIG. 5. Suppression of plasma FFA (free linoleic acid) oxidation to CO_2 in lymphoma-bearing and pair-fed control mice, briefly fasted and then fed a single, small test meal. Four groups of mice were used: briefly fasted, pair-fed controls (□); briefly fasted, pair-fed controls refed a 250-mg test meal (△); briefly fasted TB mice (■); and briefly fasted TB mice refed a 250-mg test meal (●). Data for the briefly fasted, pair-fed controls and TB mice are the same as those already presented in Figures 3 and 4. See legend to Figure 3 for further details. Number of mice, 5 per group. Vertical bars, ± SE.

essential (5) FFA oxidation and, therefore (11), elevated rates of adipose TGFA mobilization.

Multicompartmental analyses of the tracer (free linoleic acid) data. Plasma FFA pool sizes, the estimated fractional rates of plasma FFA oxidation to CO_2, and the plasma FFA oxidation rates (mass/time), which are assumed to approximate the net rates of plasma FFA replacement by mobilization of adipose TGFA to plasma FFA (11), are given in Table 1 and described in further detail below.

Control and TB mice fed ad libitum. The mean plasma FFA pool size of the *ad libitum*-mice with small tumor burdens was twice as high ($p \leq 0.001$) as that of the fed controls. The elevated plasma FFA pool sizes were associated with four-fold higher fractional rates of plasma FFA oxidation to CO_2 and nine-fold higher rates of plasma FFA flux in the mice with small tumor burdens (Table 1).

Mice briefly fasted or briefly fasted-refed a 250-mg test meal, with pair-fed controls. No significant differences in plasma FFA pool sizes were observed between briefly fasted TB and pair-fed control mice; therefore, the data were combined to obtain a best estimate for the population of briefly fasted animals. Similarly, there was no difference between the fasted-refed control and TB mice, and their plasma FFA data were also combined in order to obtain a best estimate of the pool sizes for the fasted-refed groups. Refeeding caused a significant 63% decrease ($p \leq 0.001$) in the mean plasma FFA levels of the combined TB and pair-fed control groups (Table 1).

This decrease in the mean plasma FFA pool size was consistent with the observed decreases in fractional rates of plasma FFA (linoleic acid) oxidation to breath CO_2

TABLE 1

Plasma FFA Pool Sizes, Fractional Rate Constants, and Replacement and Oxidation Rates in Lymphoma-Bearing and Control Mice Under Different Dietary Conditions[a]

Group	Pool sizes[b,c]	Fraction rate constants	Oxidation rates
Control			
Fed *ad libitum*	8.8 ± 0.43 (12[d]	0.20 ± 0.0086 (9)[d]	1.8 ± 0.13 (9)[d]
Briefly fasted	13 ± 0.49 (7)	1.1 ± 0.063 (5)	14 ± 0.90 (5)
Fasted-refed	4.8 ± 0.96 (9)	0.66 ± 0.050 (5)	3.2 ± 0.67 (5)
Tumor-bearing[e]			
Fed *ad libitum*	19 ± 1.6 (19)	0.84 ± 0.045 (8)	16 ± 1.6 (8)
Briefly fasted	13 ± 0.49 (7)	1.1 ± 0.057 (5)	14 ± 0.90 (5)
Fasted-refed	4.8 ± 0.96 (9)	0.75 ± 0.064 (5)	3.6 ± 0.79 (5)

[a] Plasma FFA pool sizes, μg-atoms FA-carbon/30 g body weight ± SE; fractional rate constants, per min ± SE; oxidation rates, μg-atoms FA-carbon/min/30 g body weight ± SE.

[b] Plasma FFA pool sizes, fractional rate constants, and oxidation rates correspond to M(1), L(10,1) and R(10,1), respectively, using the model and CONSAM analysis described earlier (5,11).

[c] Pool sizes of the *ad libitum*-fed groups have been published previously (5) and are taken from a separate group of animals adapted to the same conditions as those used for the tracer studies. Values for the briefly fasted control and TB groups did not differ significantly, as was also true for the briefly fasted-refed control and TB groups; therefore, the mean ± SE of both control and TB groups combined (*i.e.*, the combined fasted and the combined fasted-refed groups, respectively) are shown.

[d] Statistical analyses: pool sizes of control *vs.* TB groups, both fed *ad libitum*, were significantly different ($p \leq 0.001$); those of control and TB groups combined (the value shown in each case), fasted *vs.* fasted-refed, were also significantly different ($p \leq 0.001$); fractional rate constants of control *vs.* TB groups, both fed *ad libitum*, were significantly different ($p \leq 0.05$), as were those of control, fasted *vs.* fasted-refed groups ($p \leq 0.05$), and of the TB, fasted *vs.* fasted-refed groups ($p \leq 0.05$); oxidation rates (assumed equal to net plasma FFA transport rates) of control *vs.* TB groups, both fed *ad libitum*, were significantly different ($p \leq 0.05$), as were those of controls, briefly fasted *vs.* fasted-refed groups ($p \leq 0.05$), and of TB, briefly fasted *vs.* fasted-refed groups ($p \leq 0.05$).

[e] Small tumor burden group.

induced by feeding the small test meal to both control and tumor-bearing mice (Table 1). The fractional rates were reduced an average of 40% in controls ($p \leq 0.01$) and 32% in TB mice ($p \leq 0.01$). The fractional FFA oxidation rates did not differ in the fasted TB *vs.* fasted control groups, nor in the fasted-refed TB *vs.* fasted-refed control groups. This was also true for the oxidation rate (mass/time), where the oxidation rates fell from 14 units in both TB and control groups in the briefly fasted state to about 3–3.5 units in the fasted-refed state (Table 1). Thus, the net flux of FFA following the ingestion of a single 250-mg test meal decreased by 77% in both TB and pair-fed control mice ($p \leq 0.001$, each group, fasted *vs.* fasted-refed just 30 min after the mice began eating.

DISCUSSION

Lymphoma-bearing mice are thought to have a potent circulating lipid mobilizing factor (LMF) that causes them to lose their body fat (1). Initially, this was demonstrated using an essential FA, linoleate, to label the adipose TGFA of normal rats and by showing, indirectly, that linoleate was rapidly mobilized from these fat pads when plasma from lymphoma-bearing mice was injected into the normal mice (1). Therefore, one might expect lymphoma-bearing mice, who produce this LMF, to mobilize linoleate from their own adipose TGFA stores at an increased rate. However, no one has actually measured the rates of free linoleic acid transport and oxidation in lymphoma-bearing mice to confirm this hypothesis.

Our experiments indicate that, in lymphoma-bearing mice, linoleate is mobilized from adipose tissue and the free linoleic acid oxidized to CO_2 at the same rate as in controls if the mice are briefly fasted. This confirms earlier observations using a non-essential FA, palmitate (4,5). Therefore, if an active, circulating LMF is produced by this tumor (1), it does not appear to influence rates of adipose TGFA mobilization ("lipolysis") in the briefly fasted state.

However, FFA (free linoleic acid) transport and oxidation rates in lymphoma-bearing mice were greatly elevated over the control rates in the *ad libitum*-fed state. This had been shown to be the case for free palmitic acid in earlier studies with similarly maintained lymphoma-bearing mice (5). Although superficially these data indicated that ingestion of food failed to inhibit adipose tissue TGFA-linoleate mobilization in the tumor-bearing mice, additional data and experiments carried out in the present study strongly suggest that this was not the case. The appetites of the tumor-bearing mice were seriously impaired. Therefore, when fed *ad libitum* they apparently did not ingest enough nutrient to activate the mechanisms that normally inhibit adipose tissue TGFA lipolysis. However, after ingesting a small known test meal, previously fasted lymphoma-bearing mice responded promptly by inhibiting linoleate transport (from adipose tissue TGFA) to the same extent as did the controls.

This finding is consistent with our earlier studies of Ehrlich ascites tumor-bearing mice (15), but contrasts with those of Waterhouse and Kemperman (16), who studied human cancer subjects. The latter were shown to have a pronounced regulatory defect in their ability to suppress plasma FFA transport and oxidation when given many repeated small test meals of glucose (16,17).

Although decreased caloric food intake at night would account for body fat loss in anorexic tumor-bearing mice, additional direct and indirect effects of tumor- and macrophage-derived cytokines upon adipose tissue (18) cannot be ruled out. However, the physiological actions of cytokines would be difficult to demonstrate in anorexic animals. Other, potentially more suitable models to study cytokine action have been described in which TB rodents lose much of their body fat despite apparently normal caloric intakes (*e.g.*, refs. 19,20).

According to the hypothesis of Sauer and Dauchy (3), the rate of tumor growth (mitosis) is directly proportional to the rate of free linoleic acid transport to the tumor. Our data show that lymphoma-bearing mice are anorexic and have an abnormally rapid rate of free linoleic acid transport at night. Undoubtedly they supply linoleic acid and other essential FFA to their tumors much faster than would be the case if the animals were eating normally. However, as we have shown here, these TB animals clearly do not lack the metabolic regulatory processes that inhibit linoleate transport. Hypothetically, it should be possible to diminish cachexia, inhibit the rate of tumor growth, and thereby increase longevity of lymphoma-bearing mice, despite the reported existence of a circulating lipid mobilizing factor (1). This might be accomplished either by appropriate parenteral feeding or by overcoming their anorexia, *e.g.*, by blocking the inhibitory effects of TNF/cachectin (21) on appetite centers (22,23).

ACKNOWLEDGMENTS

We wish to thank Professor Esther Hays, UCLA Medical Center, Los Angeles, CA, for providing the tumor cells used in this study. Multicompartmental analyses were carried out using SAAM/CONSAM computer programs kindly provided by the National Heart, Lung, and Blood Institute-National Cancer Institute joint development project; we gratefully acknowledge their fine support. This work was supported by National Cancer Institute grant RO1-CA15813.

Urinary Response to *in Vivo* Lipid Peroxidation Induced by Vitamin E Deficiency

Hye-Sung Lee[1], **D.W. Shoeman** and **A. Saari Csallany***
Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

Experiments were carried out to measure the urinary excretion of free and conjugated malonaldehyde (MDA) and other thiobarbituric acid reactive substances (TBARS) in vitamin E deficient and vitamin E supplemented rats. From both dietary groups, six TBA positive fractions were isolated, in addition to that containing free MDA, by high-performance liquid chromatography (HPLC) on a TSK-GEL G-1000PW column. Three of the fractions isolated were found to be significantly increased in vitamin E deficiency. After acid hydrolysis, only one of the above compounds produced free MDA which indicated the presence of derivatized MDA. Only this fraction exhibited fluorescence at excitation 370 nm and emission 450 nm. The five other fractions formed 2,4-dinitrophenylhydrazones (2,4-DNPH), indicating the presence of carbonyl groups, but the derivatized MDA fraction did not. No significant differences were found in free MDA levels between the vitamin E deficient and the vitamin E supplemented groups.
Lipids 27, 124-128 (1992).

Lipid peroxidation is a degradative, free radical mediated process that primarily involves polyunsaturated fatty acids of biomembranes (1,2). The nonenzymatic autoxidation of polyunsaturated fatty acids is known to be accompanied by the formation of a complex mixture of products including aldehydes such as alkanals, alk-2-enals, 4-hydroxyalkenals, and malonaldehyde (3-5). Malonaldehyde (MDA), one of the most studied secondary products of lipid peroxidation, has been known to be of biological significance due to its reactivity with biomolecules including amino acids (6-8), proteins (9-14), and nucleic acids (15,16). Peroxidizing tissue samples produce significant amounts of thiobarbituric acid-reactive substances (TBARS). Several reports have indicated that a positive relationship exists between *in vivo* lipid peroxidation and urinary MDA levels. Draper *et al.* (17) showed, using high-performance liquid chromatography (HPLC) of the MDA/TBA complex, that urinary MDA excretion increased in response to vitamin E deficiency after administration of iron nitrilotriacetate. Gavino *et al.* (18) reported that a cod liver oil diet and iron overload induced increased excretion of TBARS in the urine of rats. Ekström *et al.* (19) demonstrated increased MDA (as measured by HPLC of its dinitrophenylhydrazone) excretion in urine from non-starved animals exposed to chloroform and found that there is good agreement between ethane exhalation and urinary MDA levels. A comprehensive review on malonaldehyde and TBA reactivity has recently appeared (20).

The present study was designed to separate, by HPLC, free MDA from other TBA test-positive materials of urine, to see whether other fractions were associated with vitamin E deficiency, and to determine whether they contained bound MDA.

MATERIALS AND METHODS

Animals and diets. Two groups of 10 Sprague-Dawley female, weanling rats were fed either a modified basal vitamin E-deficient diet developed by Draper *et al.* (21) adequate in all respects except for vitamin E (−E group) or a basal diet supplemented with 30 mg/kg of RRR-α-tocopheryl acetate (1.36 IU/mg, Sigma Chemical Co., St. Louis, MO) (NE group) for 38 wk. Diets and water were provided *ad libitum*. Sodium salt of sulfamerazine (Sigma) was added to drinking water (1 g/3.8 L) to prevent pulmonary infections.

Urine collection. At the 38th week of the experimental diets, the animals were individually held in stainless steel metabolic cages for 36 hr and had access to water *ad libitum*, but were deprived of food. To avoid direct effects of diet, the urine samples were collected during the final 24 hr into 50-mL graduated centrifuge tubes attached to urine collection funnels with screens to prevent contamination from feces. The tubes contained a few drops of toluene as a preservative. Urine volumes were accurately measured, and the samples were centrifuged to remove hair and stored at −70°C until analysis.

Thiobarbituric acid test of urine fractions. The levels of TBARS in urine samples were measured by the modified filtration procedure of Tarladgis *et al.* (22). Duplicate samples of 0.5 mL urine were mixed thoroughly with 3 mL of 5% trichloroacetic acid (TCA) and 1 mL of 0.06M TBA solution in screw-capped culture tubes. The mixtures were heated in an 80°C water bath for 90 min, cooled to room temperature, and centrifuged at 1360 × *g* for 15 min to remove a fine precipitate. The absorbance of the supernatant was read at 535 nm using a Beckman (Fullerton, CA) Model DU-8 spectrophotometer. MDA standards were freshly prepared from tetramethoxypropane (TMP) and treated in the same way as the test samples. The amounts of TBARS in urine were expressed as equivalents of MDA.

HPLC separation and free MDA determination of urine samples. Chromatographic separation and free-MDA analysis of urine samples were carried out by the HPLC method developed by Csallany *et al.* (23). Aliquots (2 to 3 mL) of urine were filtered through an Amicon cell equipped with a UMO5 ultramembrane (Amicon Corp., Danvers, MA) under 35 psi of nitrogen pressure. Fifty to 100 μL of clear filtrates were injected onto the HPLC system, which consisted of an Altex Model 110A solvent metering pump (Beckman Instruments, Berkeley, CA), Altex Model 210 sample injector (Beckman Instruments), Spectra-Physics Model SP-8400 variable wavelength detector (Spectra-Physics, Arlington, IL), and a Model SP-4100 computing integrator (Spectra-Physics).

HPLC separations were performed on a 7.5 mm i.d. ×

Abbreviations: −E, vitamin E deficient group; HPLC, high-performance liquid chromatography; NE group, 30 mg/kg of RRR-α-tocopherol acetate group; MDA, malonaldehyde; TBARS, thiobarbituric acid reactive substances; TMP, tetramethoxypropane; 2,4-DNPH, 2,4-dinitrophenylhydrazone.

30 cm Spherogel-TSK 1000 PW size exclusion [excluded volume 4.7 mL, total vol 9.7 mL, exclusion limit 1000 MW column (Beckman Instruments)] eluted with a mobile phase of 0.1 M phosphate buffer, pH 8.0, at a flow rate of 0.6 mL/min. Absorbance was monitored at 267 nm. Seven to eight urine samples from each dietary group were analyzed in duplicate measurements. The amount of free MDA was measured from peak area response, determined from a standard curve prepared with authentic MDA. The lowest amount of MDA that can be determined by this HPLC technique is approximately 1 ng per injection (23). The relationship between the other HPLC separated, urinary fractions and the dietary treatments was examined by comparing the mean peak areas (expressed as peak area/day/100 g body weight) of each urinary fraction between the two dietary groups.

Isolation of the individual urine fractions. Fractions were isolated from urine by pooling corresponding fractions from three 200 μL injections of rat urine. The pooled fractions were diluted uniformly to 5 mL. Pooled fractions were checked for homogeneity by re-injecting a 200-μL aliquot on the same HPLC system, and 4.5 mL of each fraction was lyophilized in a Virtis freeze dryer (Virtis Res. Equipment, Gardiner, NY).

TBA reactivity of the isolated fractions. Residues from 16 fractions were dissolved in 2 mL of deionized water and 1 mL aliquots (equivalent to 0.27 mL urine) were subjected to the TBA test procedure, described previously. The TBA chromophores in each urine fraction and that of standard MDA were extracted with 2 mL of n-butanol. Absorption spectra of the butanol extracts were measured over the wavelength range of 450–600 nm.

Absorption spectra of the "TBA test-positive" urine fractions. Lyophilized fractions (that had been shown previously to be "TBA test-positive") were dissolved in 2 mL deionized water. The absorption spectrum of each fraction was obtained against a blank prepared by the same procedure using a Beckman DU-8 spectrophotometer equipped with a wavelength scan compuset.

Fluorescence measurement of the "TBA test-positive" urine fractions. Lyophilized residues of "TBA test-positive" fractions were dissolved in 1.5 mL of HPLC grade water and filtered through a 0.45 μm Magna nylon 66 membrane filter (Micron Separation Inc., Honeoye Falls, NY). The filtrates (200 μL) were injected onto a Spherogel-TSK 1000 PW column, and fluorescence was determined with a Perkin-Elmer model 650-105 fluorescence spectrophotometer (Perkin-Elmer Co., Norwalk, CT) at 370 nm excitation and 450 nm emission, and 405 nm excitation and 465 emission.

Acidic hydrolysis of the fluorescent fraction. A lyophilized sample of the fluorescent fraction (retention time 19 min) was dissolved in 0.5 mL HPLC grade water, and then 1 mL of 10% trichloroacetic acid was added to bring the pH to 2.0. The acidic mixture was heated in a 80°C water bath for 90 min, cooled to room temperature, neutralized to pH 8.0 with 30 μL of saturated NaOH solution, and filtered through a Magna nylon 66 membrane filter. The filtrate of the hydrolyzed sample was analyzed for free MDA by the HPLC method described previously. The identity of the free MDA peak was confirmed by cochromatography of a mixture of the hydrolysate with authentic MDA.

Formation of 2,4-dinitrophenylhydrazones of "TBA test-positive" urine fractions. Lyophilized aliquots of the six "TBA test-positive" urine fractions were dissolved in 2 mL of HPLC grade water, and the 2,4-dinitrophenylhydrazones (DNPH) were prepared by the method described by Esterbauer *et al.* (24). Hexanal (Sigma), *trans*-2-heptenal (Aldrich Chemical Co., Milwaukee, WI), and acetone (Fisher Scientific, Fairlawn, NJ) were used as standards representative of an alkanal, 2-alkenal, and alkanone, respectively.

RESULTS AND DISCUSSION

In the present experiments vitamin E deficient rats excreted significantly higher levels of total TBARS in urine, calculated on the basis of 24-hr urine volume and rat body weight (BW), compared to vitamin E-supplemented rats (Fig. 1). This demonstrates that total urinary TBARS levels respond to the increased *in vivo* lipid peroxidation associated with vitamin E deficiency. However, the actual amount of urinary free MDA in both groups was much less than the total TBARS when expressed as equivalents of MDA. Furthermore, in spite of a large difference in total urinary TBARS levels between the vitamin E-deficient group and the normal group, the difference in free MDA levels in these two groups was not statistically significant (Fig. 1). These observations indicate that the amount of free MDA in the urine alone does not reflect *in vivo* lipid peroxidation. Although some investigators (16) have reported increased urinary MDA in the vitamin E-deficient rat, their results may not represent only free MDA present in the urine because of their assay method is based on the final measurement of the TBA derivative of MDA (only) by HPLC. MDA may be released from its derivatized forms by acid hydrolysis during analysis. We have reported previously that free MDA levels in liver tissue were 15 times higher in animals fed a vitamin E-deficient diet than in control animals (14). However, differences in urinary free MDA levels were not observed between the vitamin E-deficient animals and the control group in the present experiments. A possible explanation could be that most MDA is metabolized by the liver (25) and thus only a minor fraction of the available free MDA

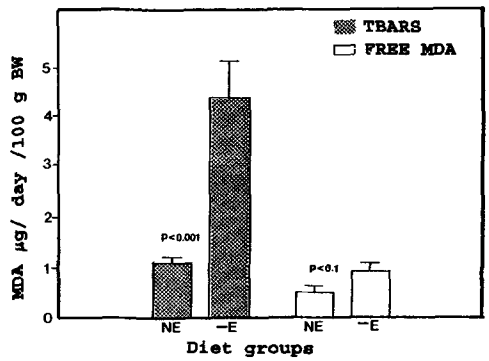

FIG. 1. Comparison of total urinary TBA-reactive substances (TBARS) and free malonaldehyde (MDA) levels in 38-wk old normal and vitamin E-deficient rats. Values represent the mean ± SEM of 10 animals per dietary group.

is excreted in the urine. Another possibility is that the reactivity of free MDA could lead to its combination with other compounds and to excretion in a derivatized form in the urine (26).

A typical HPLC chromatogram of a rat urine sample, separated by Spherogel-TSK 1000 PW column at 267 nm, is shown in Figure 2. Free MDA is well separated (R_t 44 min) from other compounds and this system has the additional advantage of allowing the fractionation of urine components according to molecular size as well. The retardation of MDA well beyond the total volume of the size exclusion column indicates that additional separation modes are available with this column. Other investigators have used anion exchange chromatography to fractionate the MDA-containing components of rat urine, and found that most (75%) of the MDA was present as *N*-α-acetyl-ε-(2-propenal)lysine (10).

The peak areas of the 13 major urine fractions were calculated on the basis of 24-hr urine volume and rat body weight (BW) to determine which of the urinary fractions responded to vitamin E deficiency (Fig. 3). Mean values were compared between vitamin E-deficient and control groups. The areas of six of these fractions (R_t 19,21,29,48,56, and 62) were larger in the vitamin E-deficient group than in the control group. This may indicate that the six urine fractions are vitamin E-deficiency dependent, and therefore may be related to *in vivo* lipid peroxidation.

Each HPLC separated and purified urine fraction was reacted with TBA reagent. Positive TBA test results among the sixteen purified individual urine fractions are shown in Table 1. Six fractions, in addition to the isolated MDA fraction (R_t 44), were found to be "TBA test-positive" regardless of the dietary treatments. The absorption spectra of TBA chromophores of these six fractions showed significant peaks near that of standard MDA. Accordingly, the level of total urinary TBARS reflects contributions at 533 nm of all the TBA chromophores of these fractions. Three of the "TBA test-positive" fractions (R_t 19,21, and 29) were significantly higher in vitamin E deficiency. The three fractions, therefore, appear to be responsible for the increased levels of TBARS in the urine of rats under these dietary conditions. *N*-α-acetyl-ε-(2-propenal)lysine has been reported (10,27) to be the major contributor to the TBARS of urine. This compound, as well as MDA conjugates of other amino acids, coelutes with the 19-min fraction found in the present study. The amount of this and other amino acid conjugates of MDA in fraction R_t 19, as well as the identity of the compounds in the other fractions, is currently under investigation. Absorption maxima of "TBA test-positive" urine fractions are shown in Table 1. All of these fractions showed characteristic absorption maxima in the ultraviolet (UV) range of 230–270 nm. Fraction R_t 44 (Table 1) was confirmed as MDA from its absorption maximum at 266 nm, which corresponds to that (267 nm) of standard MDA at neutral or alkaline pH. Three of the fractions (R_t 19,21, and 29), which are both "TBA test-positive" and are significantly increased in vitamin E deficiency, have their maximum absorptions at 230, 260, and 259 nm, respectively. Condensation products of MDA and primary amino groups of biomolecules have been known to possess fluorescence due to their Schiff's base type structure (8,28). The existence of Schiff's bases

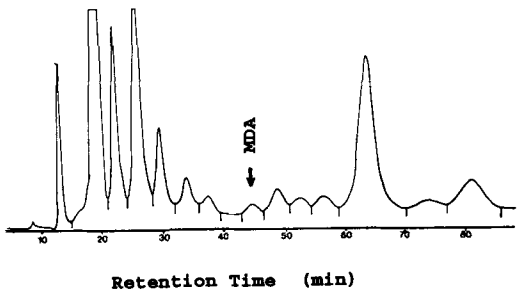

FIG. 2. Typical HPLC chromatogram of a rat urine sample. Separation conditions: Spherogel-TSK 1000PW size exclusion column; mobile phase, 0.1 M sodium phosphate buffer, pH 8.0; flow rate, 0.6 mL/min; monitoring wavelength 267 nm; ambient temperature.

in these "TBA test-positive urinary fractions was examined by measuring their fluorescence characteristics. Excitation and emission wavelengths at 370 nm/450 nm and 405 nm/465 nm were selected for the measurements of Schiff's bases derived from MDA and amino acids (8) and of Schiff's bases formed from MDA and albumin or other proteins (29), respectively. Only one fraction (R_t 19) was found to possess fluorescence at Ex 370 nm/Em 450 nm, indicating the presence of a Schiff's base (Table 2). The fluorescent urine fraction (R_t 19) was hydrolyzed under acidic conditions (pH 2.0) to confirm this possibility and the existence of MDA in a Schiff's base form. The HPLC chromatograms of this fraction prior to and after acid hydrolysis, cochromatography of MDA standard with the hydrolyzed fraction 19, and standard MDA are shown in Figure 4. Acidic hydrolysis of the fluorescent fraction (R_t 19) resulted in the release of free MDA. The presence of free MDA was confirmed by cochromatography of the hydrolysate with standard MDA. This result indicates that the fluorescent fraction (R_t 19) contains MDA as an acid-hydrolyzable Schiff's base-type derivative. The other "TBA test-positive" fractions were also hydrolyzed under the same conditions, but none of these fractions released free MDA after hydrolysis. Each fraction was examined

for the presence of MDA using the method of Bird *et al.* (30), whereby the TBA/MDA (2:1) complex is isolated by HPLC. Fraction (R_t 19) was the only urine fraction containing MDA in a derivatized form.

A variety of secondary carbonyl products such as alkanals, alk-2-enals, 4-hydroxyalkenals, MDA, and alkanones are produced by peroxidation of unsaturated fatty acids (5), and several of these products have been reported to react with the TBA reagent (31,32). Kosugi *et al.* (33) have studied the reaction of alk-2-enals with TBA and found that under certain conditions red pigments were produced which were indistinguishable spectrophotometrically from the 2:1 complex of TBA with MDA. These compounds also exhibited similar retention times during reverse-phase HPLC. The molar absorptivity of the TBA complex with MDA was much greater than that of the complexes with other aldehydes, however. Kosugi *et al.* (34) have more recently examined the products of the TBA reaction with various peroxidized lipids and concluded that the yield of the TBA/MDA (2:1) product, as measured by absorbance, fluorescent intensity and HPLC, was much greater than the MDA contents of the preparation as measured by direct chemical analysis. Thus, some products of lipid peroxidation may produce MDA during the measurement of the TBA reaction. As described previously, five of the "TBA test-positive" urine fractions obtained in this study contained no MDA in a derivatized form. The reactivities of these non-fluorescent fractions with the TBA reagent may have been due to the presence of carbonyl compounds other than MDA. The presence of carbonyl groups was tested by the formation of 2,4-dinitrophenylhydrazones. The absorption maxima of the derivatives of urine fractions and standard carbonyl compounds are listed in Table 2. The fluorescent fraction (R_t 19) was the only fraction that did not form a 2,4-DNPH. It should be noted that free MDA, a bifunctional aldehyde, yields a pyrazole derivative instead of a hydrazone when reacted with dinitrophenylhydrazine (35). The major absorption maxima of the derivatives of the four fractions (R_t 21,15,29,and 33) are quite similar to that of a derivative of acetone which may indicate the presence of keto groups in these fractions. The carbonyl groups present in the non-fluorescent urine fractions may be derived from short- or medium-chain secondary lipid peroxidation products and seem to be responsible for the reactivities of these fractions with the TBA reagent. Fur-

ther investigations are needed to reveal the identity of the vitamin E dependent, urinary TBA reactive carbonyl-containing compounds.

Although MDA may be an important product of lipid peroxidation *in vitro*, subsequent metabolism of this compound may complicate the use of free MDA excretion as a measure of lipid peroxidation *in vivo*. Others have found conjugated MDA in the urine to be increased in vitamin E deficiency (17) but this increase is superimposed upon the considerable background of conjugated MDA acquired from the diet. The present finding of substances which do not release MDA upon hydrolysis but are profoundly increased during vitamin E deficiency may provide more satisfactory measures of *in vivo* lipid peroxidation.

[Received June 8, 1991, and in final revised form November 6, 1991; Revision accepted December 28, 1991]

Separation and Spectral Data of the Six Isomeric Ozonides from Methyl Oleate

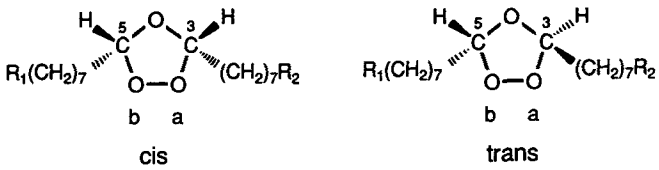
Mingdan Wu[a], Daniel F. Church[a], Thomas J. Mahier[b], Steven A. Barker[b] and William A. Pryor[a,*]
[a]The Chemistry Department and the Biodynamics Institute, Louisiana State University, Baton Rouge, Louisiana 70803-1800 and [b]The Department of Physiology, Pharmacology, and Toxicology, School of Veterinary Medicine, Louisiana State University, Baton Rouge, Louisiana 70803-8420

The structures of the products obtained on ozonation of methyl oleate have been re-examined. The assignments for the six isomeric ozonides of methyl oleate have been made by ^1H and ^{13}C nuclear magnetic resonance (NMR), which were consistent with the retention times observed in high-performance liquid chromatography; the assignments were confirmed by mass and infrared spectroscopy. Two triplets for the ozonide ring protons of the *cis* and *trans* isomers in the normal (MOO1) and the two cross ozonides (MOO1 and MOO3) can be resolved by 400 MHz NMR. For MOO1 and MOO3, where the two ring carbons are equivalent, two peaks for the ring carbons of each cross ozonides are resolved in the ^{13}C NMR spectra, one for the *cis* and one for the *trans* isomer. For MOO2, four peaks for the ring carbons are resolved in the ^{13}C NMR spectra, two for the *cis* and two for the *trans* isomer. *Lipids 27,* 129–135 (1992).

The Criegee mechanism for the reaction of ozone with alkenes in solution has been thoroughly investigated (1). The detection of cross ozonides and *cis* and *trans* isomers has been taken as evidence for the formation of carbonyl oxides as intermediates (1). Both *cis* and *trans* isomers of the normal ozonide, methyl 5-octyl-1,2,4-trioxolane-3-(8′-octanoate) (MOO2), and two cross ozonides, 3,5-dioctyl-1,2,4-trioxolane (MOO1) and dimethyl 1,2,4-trioxolane-3,5-(8′,8′-dioctanoate) (MOO3), produced upon ozonation of methyl oleate were first isolated in the early 1960's by Riezebos *et al.* (2) and Privett and Nickell (3,4). Later, Lorenz and Parks (5) identified similar isomers upon ozonation of smaller asymmetric alkenes. Subsequently, several papers (6–11) were published describing the cross ozonide yields and *cis* and *trans* ratios. Since the 1970's, a number of studies also have been concerned with the biological effects of fatty acid ozonides (12–21).

Lung surfactant and cell membrane lipids may be important targets for inhaled ozone (22–29), as oleate is one of the major unsaturated fatty acids in lung surfactants (30) and in cell membrane lipids (31). Hence, oleate ozonides may be formed upon inhalation of ozone-containing air.

The *cis* and *trans* isomers of the normal and cross ozonides of methyl oleate have previously been characterized by thin-layer chromatography (TLC), infrared (IR), and ^1H nuclear magnetic resonance (NMR) (2–4). A recent report from our laboratory also provided some ^1H NMR and ^{13}C NMR data for MOO2 (20). Scheme 1 shows the structures (and abbreviations) of the six isomeric ozonides of methyl oleate. We report here reversed-phase high-performance liquid chromatography (HPLC) retention times, UV, and high resolution ^1H and ^{13}C NMR spectral data for all six isomeric ozonides of methyl oleate, along with mass and FT-IR (Fourier transform-IR) spectral data for the normal and cross ozonides of methyl oleate.



Name of ozonide	Abbreviation	R_1	R_2	M.W.
"Cross"	MOO1	CH_3	CH_3	300
"Normal"	MOO2	CH_3	$-COOCH_3$	344
"Cross"	MOO3	CH_3COO-	$-COOCH_3$	388

SCHEME 1. The six isomeric ozonides from methyl oleate.

EXPERIMENTAL PROCEDURES

Materials. Methyl oleate (>99%) was purchased from Sigma Chemical Co. (St. Louis, MO). Both analytical TLC plates (PE Sil G/UV, F-254, 250 μm layer) and preparative TLC plates (Silica Gel 60A, F-254, 20 × 20 cm, 1000 μm layer) were purchased from Whatman International, Ltd. (Maidstone, England).

Preparation of the ozonation mixture from methyl oleate. Using a procedure modified from that described by Ewing *et al.* (20), 4.5 g of methyl oleate was dissolved in 80 mL of dry pentane in a 200-mL, three-neck flask connected to a trap containing a 10% KI sollution. The reaction vessel was then chilled in an ice-water bath. An Orec ozonator (Ozone Research & Equipment Corp., Phoenix, AR; Model 03V10-0) was used to generate a 1.2% (v/v) ozone-in-oxygen gas stream, which was bubbled at 200 mL/min through the chilled, continuously stirred reaction solution. Pentane was added to keep the volume of the reaction solution constant during ozonation. The reaction was stopped after about 3 hr when the KI solution in the trap became yellow. At the end of the reaction, the absence of methyl oleate was determined by TLC. Unreacted ozone was removed by slowly bubbling nitrogen through the reaction solution. The solvent was removed using a rotary evaporator under vacuum at room temperature, leaving about 4.8 g of an oily material with a unique smell.

Abbreviations: CI, chemical ionization; FT-IR, Fourier transform infrared; HPLC, high-performance liquid chromatography; IR, infrared; MOO1, one of the cross ozonides from methyl oleate (3,5-dioctyl-1,2,4-trioxolane); MOO2, the normal ozonide from methyl oleate (methyl 5-octyl-1,2,4-trioxolane-3-(8′octanoate)); MOO3, the second cross ozonide from methyl oleate (dimethyl 1,2,4-trioxolane-3,5-(8′,8′-dioctanoate)); MOO1, MOO2, and MOO3 refer to both *cis* and *trans* isomers (see Scheme 1 for structures of the six isomeric ozonides); NMR, nuclear magnetic resonance; TLC, thin-layer chromatography.

Analysis of the ozonation mixture. A Whatman analytical TLC plate was developed using a mobile phase of diethyl ether/petroleum hydrocarbon (1:9, v/v, bp 30–60°C). A Hewlett-Packard (Palo Alto, CA) chromatograph (Model HP 1090 LC chromatograph) with a reversed-phase Hewlett-Packard ODS Hypersil, 5 μm, 200 × 2.1 mm column was used. The mobile phase was 50% methanol/water, increased linearly to 100% methanol over 15 min, and then was held at 100% methanol for 10 min. The flow rate was 0.45 mL/min and the eluent was continuously monitored at 210 nm. Monitoring at 230 nm gave similar results.

Isolation of the cis/trans *pairs of the normal and cross ozonides.* The oily material from ozonation was separated into one pair of normal and two pairs of cross ozonides using fluorescence Whatman preparative TLC plates. The preparative TLC plate was developed using diethyl ether/petroleum hydrocarbon (5:95, v/v, bp 30–60°C).

Isolation of the cis *and* trans *normal ozonides.* A reversed-phase Hewlett-Packard ODS Hypersil, 5 μm, 200 × 4.6 mm column was used. The mobile phase, 93% methanol/water, was used isocratically at a flow rate of 1.0 mL/min.

Analysis of the ozonide yields from ozonation of methyl oleate in hexane. About 10 mg of methyl oleate was dissolved in 2.4 mL of hexane and ozonated for 2 min using 1.2% ozone-in-oxygen. The solvent was evaporated, methanol was added to give a total volume of 2.4 mL, and the solution was directly subjected to HPLC analysis. The ozonide yields were calculated using the external standard method (21) and the ratios of the *trans* to *cis* isomers were calculated using the ratios of corresponding HPLC peak areas.

Spectrometry. UV spectra were determined on a Hewlett-Packard HPLC instrument equipped with a diode array detector. For chemical ionization (CI) mass spectra, a unit-resolution Finnigan MAT mass spectrometer (model Finnigan TSQ 4500) was used with either methane or isobutane at 0.5 torr. The direct probe mode was used, and the source temperature was set at 50°C. For Fourier transform IR (FT-IR), a film was deposited on an NaCl disk, and spectra were obtained on a Perkin-Elmer FT-IR 1700X instrument with a 1 cm^{-1} resolution. ^1H NMR spectra were obtained at 400 MHz on a Bruker AM-400 NMR spectrometer equipped with an Aspect 3000 computer or at 200 MHz on a Bruker AC-200 NMR spectrometer; both instruments were also used for recording ^{13}C NMR spectra. The solvent was $CDCl_3$ for both ^1H and ^{13}C spectra. A trace amount of $CHCl_3$ in $CDCl_3$ served as a reference, giving rise to signals at 7.26 ppm in ^1H and at 77.00 ppm in ^{13}C NMR.

RESULTS AND DISCUSSION

Assignments of the normal and cross ozonides. Three types of methyl oleate ozonides can be identified by analytical TLC of the ozonation mixture (see Table 1); these correspond to one normal ozonide (MOO2) and two cross ozonides (MOO1 and MOO3), all of which consist of both *cis* and *trans* isomers (see Scheme 1 for structures). The assignments for the normal ozonide and cross ozonides isolated by preparative TLC are consistent with mass, IR, and NMR data. The mass spectral data provide the molecular weights of the protonated parent, $[M + H]^+$, for MOO1, MOO2, and MOO3. The IR data (see Table 2) show no carbonyl group for MOO1, one carbonyl for MOO2, and two carbonyls for MOO3 based on the absorption at *ca.* 1740 cm^{-1} (2).

TABLE 1

Normal TLC R_f Values and Reversed-Phase HPLC Retention Times (R_t), for Methyl Oleate d the Ozonides from Methyl Oleate

Spot or peak[a]	R_f[b]		R_t, min[c]
MMOO1	—	0.86	18.1 *(trans)* 17.9 *(cis)*
Methyl oleate	—	0.74	17.4
MOO2	0.53 *(trans)* 0.47 *(cis)*	0.51	16.3 *(trans)* 16.1 *(cis)*
MOO3	—	0.20	14.1 *(trans)* 13.9 *(cis)*

[a] See Scheme 1 for structures.

[b] R_f values in the first column are taken from ref. 35; R_f values in the second column are our data.

[c] Our data.

TABLE 2

IR Data for the Normal and Cross Methyl Oleate Ozonides and Methyl Oleate (in cm^{-1})

Ozonide[a]	The ring C-O bond[b]			Ester carbonyl[b]		
MOO1	1108	1110		N.A.[c]	N.A.	
MOO2	1109	1110	1109	1742	1730	1741
MOO3	1109	1110		1742 1734	1730	
Methyl oleate	N.A.			1744		

[a] See Scheme 1 for the structures.

[b] The first column lists our data; data in the second column are from ref. 2; data in the third column are from ref. 20.

[c] N.A., no absorptions.

The NMR data support the assignments of the normal and cross ozonides (Table 3). Neither ester methyl protons (*ca.* δ 3.66 ppm) nor ester carbonyl carbons (*ca.* δ 174 ppm) are detected in the NMR spectrum of MOO1, but there are two terminal methyl groups (δ 0.88 ppm, 6H) indicated in the ^1H spectrum and a peak at δ 14.05 ppm in the carbon spectrum. There is just one ester carbonyl in MOO2, as indicated by the absorption at δ 3.66 ppm (3H) and δ 174.2 ppm for the ester methyl protons and ester carbonyl carbon, respectively. Since δ 0.88 ppm (3H) and δ 14.06 ppm peaks corresponding to the terminal methyl protons and the terminal methyl carbon are detected for MOO2, one terminal methyl group is present in this ozonide. There are two ester methyls in MOO3 since δ 3.65 ppm (6H) and δ 174.2 ppm peaks are detected for the ester methyl protons and carbonyl carbons, but no terminal methyl since neither δ 0.88 ppm nor δ 14 ppm peaks are detected.

Assignment of the cis *and* trans *isomers.* Because the *cis* isomer has a larger dipole moment (32,33), the peak with shorter retention time in reversed-phase HPLC was assigned to the *cis* isomer and the peak with the longer

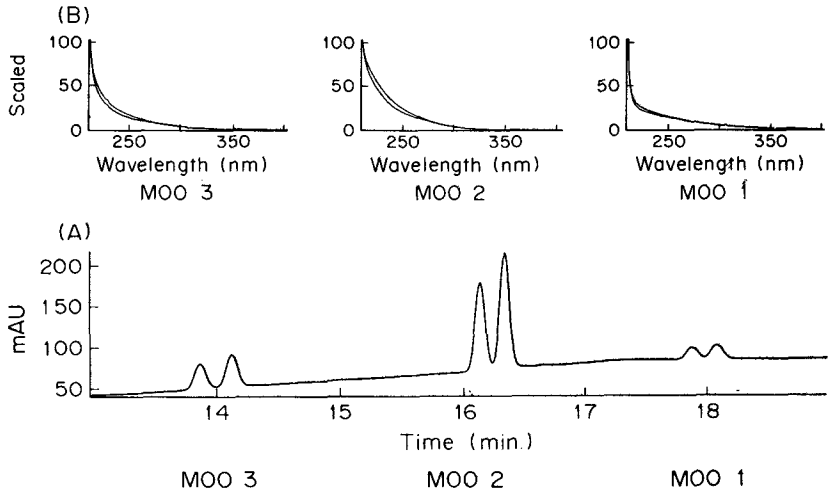

FIG. 1. A. Reversed-phase HPLC chromatogram for the six ozonides of methyl oleate. B. UV spectra for the six ozonides of methyl oleate. In the Figure, the *trans* isomer is always the top curve, whereas the *cis* isomer is always the bottom curve of the spectra.

retention time to the *trans* (see Table 1). This assignment is consistent with the literature (3,34,35), where the isomer with the smaller R_f value in normal-phase TLC is assigned the *cis* configuration and the isomer with the larger R_f value the *trans* form. The assignment was further confirmed by the faster rate of hydrolysis observed for the *cis* isomer (21), since the *cis* isomer has higher free energy and higher reactivity than the *trans*. Similarly, the *cis* ozonide was reported to undergo reduction faster than the *trans* form (36,37). Our ^1H NMR data support this assignment as well, since it is known that the ^1H resonance signal of the ring proton of the *cis* isomer occurs at lower field than that of the *trans* isomer (34).

Analytical yields determined by HPLC for the ozonides formed by ozonation of methyl oleate in hexane. Figure 1A shows a reversed-phase HPLC chromatogram for the six possible ozonides generated by ozonation of 0.013 M methyl oleate in hexane at 0°C under conditions where no methyl oleate is recovered. Each adjacent pair of peaks corresponds to a single TLC spot, in which the peak with the shorter retention time is assigned to the *cis* isomer.

The total ozonide yield in Figure 1A is 89% as measured by HPLC based on an external standard (21). The yields of the individual compounds are 9.9%, 66%, and 13% for MOO1, MOO2, and MOO3, respectively, in relative yields of 0.15:1.0:0.19. Riezebos *et al.* (2) reported relative yields of 1:2:1 for MOO1, MOO2, and MOO3 generated by ozonation of 0.34 M methyl oleate in light petroleum at 10°C. However, when they ozonized 0.017 M methyl oleate at −65°C, they could not detect any cross ozonides (2).

Using a 0.013 M solution of methyl oleate in hexane at 0°C, we obtain a *trans* to *cis* ratio of 1.3 for MOO2, compared to 1.1 by ozonation of 0.014 M methyl oleate in pentane at −70°C (3). Both the cross ozonide yield and the *trans* to *cis* ratio of each ozonide are higher at a higher ozonation temperature because of the "solvent cage effect" and equilibration between *syn*- and *anti*-carbonyl oxides (21).

The UV spectra of the ozonides. The UV spectra of all six ozonides are shown above the HPLC chromatogram (Fig. 1B). No strong characteristic absorptions were detected; the absorption is strongest in the vicinity of 200 nm and rapidly decreases with increasing wavelength. The normal ozonides of methyl oleate have broader absorption curves than the cross ozonides. For either MOO1, MOO2, or MOO3, the *cis* and *trans* isomers have similar absorption curves. For better sensitivity and baseline stability, a wavelength of 210 nm was chosen for HPLC detection. [Analysis at 230 nm gave similar results (21).]

Mass spectra and fragmentation patterns. Fragmentation patterns are suggested for MOO3 by heterolytic (Scheme 2A) and homolytic (Scheme 2B) decompositions, based on the mechanisms of acidolysis (38) and thermal decomposition (20) of the ozonides, as well as the fragments generated in mass spectra (21). Scission of the ring C-O, peroxy O-O, and ester methoxy CO-OCH_3 bonds occur in either case. The fragmentation pattern for MOO1 is illustrated in Scheme 2C, where ions **17**, **18**, and **19** are generated in the same way as ions **11**, **2**, and **7** in Schemes 2A and 2B, respectively. The fragmentation pattern for MOO2 is similar to the patterns shown in Schemes 2A, 2B, and 2C. When methane was used as the CI gas, the MOO3 spectrum showed the protonated parent ion, $[M + H]^+$, at *m/z* 389 (15%); and the methane adducts, $[M + C_2H_5]^+$ and $[M + C_3H_5]^+$ at *m/z* 417 (6.2%) and 429 (1.5%). The peak at *m/z* 371 (6.2%) is formed by dehydration of the protonated parent, $[M + H - H_2O]^+$, and 357 (6.2%) is derived from the protonated parent having two oxygen atoms less, $[M + H - O_2]^+$. Other fragments can be found in Schemes 2A and 2B. By using methane as the CI gas, the mass spectrum of MOO1 provides peaks at *m/z* 301 (18%) for the protonated parent of $[M + H]^+$ and at *m/z* 329 (1.0%) for methane adducts of $[M + C_2H_5]^+$. The peak at *m/z* 285 (14%) results from the loss of one oxygen atom from the protonated parent, $[M + H - O]^+$. Other fragments can be found in Scheme 2C. Using isobutane as the CI gas, MOO2 shows the protonated parent ion, $[M + H]^+$, at *m/z* 345 (3.0%); and the isobutane adduct, $[M + C_4H_9]^+$, at *m/z* 401 (0.05%). The peak at *m/z* 373 is derived from the isobutane adduct upon loss of a carbonyl, $[M + C_4H_9 - CO]^+$; and 317 (1.5%) is derived from the protonated parent upon loss of a carbonyl, $[M + H - CO]^+$. Other fragments are the same as those from both MOO1 and MOO3. The peak at *m/z* 141 (50%) in the spectra of MOO1 is ion **21**, possibly arising from hydride abstraction from the C_9 aldehyde $[18 - H]^+$. The peak at *m/z* 159 (100%) is the base peak for MOO1, and 187 (100%) is the base peak for both MOO2 and MOO3.

NMR studies on methyl oleate ozonides. As discussed earlier, the NMR peaks of the terminal methyl protons, ester methyl protons, terminal methyl carbon atoms, and ester carbonyl carbon atoms from ^1H and ^{13}C NMR spectra can be used to distinguish MOO1, MOO2, and MOO3. ^1H and ^{13}C NMR of the ozonide ring protons and carbons can distinguish the *trans* from the *cis* isomer. Figure 2 shows the 400 MHz ^1H and ^{13}C NMR spectra for the ozonide ring structures of a *cis* and *trans* mixture

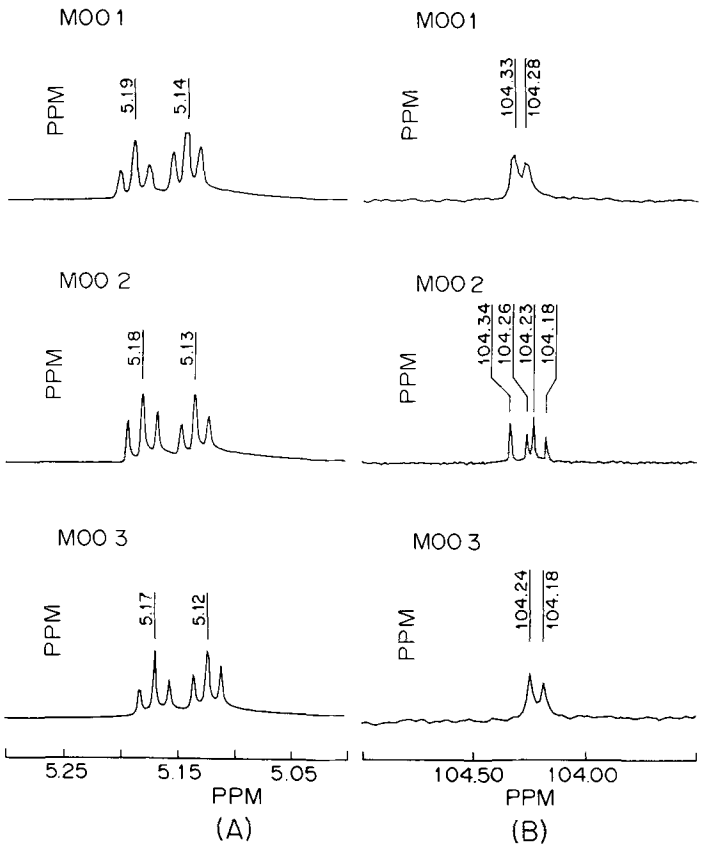

FIG. 2. The ^{1}H and ^{13}C NMR spectra for the ring protons of MOO1, MOO2, and MOO3 from the 400 MHz NMR spectrometer. In both ^{1}H and ^{13}C NMR spectra, the top one is for MOO1, the middle for MOO2, and the bottom for MOO3. A, ^{1}H NMR spectra; and B, ^{13}C NMR spectra.

of MOO1, MOO2, and MOO3. Both ^{1}H and ^{13}C NMR spectra of each individual isomer of either *cis*- or *trans*-MOO2 are reported elsewhere (21).

Assignments of the ozonide ring structures. From Table 3, the *trans* normal ozonide of methyl oleate (*trans*-MOO2) gives one triplet centered at δ 5.13 ppm (J = 4.8 Hz); the *cis* normal ozonide of methyl oleate (*cis*-MOO2) gives one triplet at δ 5.18 ppm (J = 5.2 Hz); and a mixture of the *trans* and *cis* isomers of MOO2 gives a set of two well resolved triplets at δ 5.13 ppm (J = 4.8 Hz) and δ 5.18 ppm (J = 5.2 Hz) (Fig. 2), which are not resolved on the 200 MHz NMR spectrometer (21). Previous studies only observed either δ 5.1 ppm for all six isomers (2) or δ 5.17 ppm (q) for MOO2) (20). Our assignments are consistent with the other physical properties of the ozonides based on the dipole moments (3,32,33). R_f values in normal-phase TLC, and R_t values in reversed-phase HPLC (Table 1). Based on the data from *trans*- and *cis*-MOO2, we assign the peaks at δ 5.19 and δ 5.17 ppm to the *cis* isomers for MOO1 and MOO3, and the peaks at δ 5.14 and δ 5.12 ppm to the *trans* isomers for MOO1 and MOO3, respectively (see Fig. 2A).

Since both MOO1 and MOO3 show either C-2 (for their *trans* isomers) or sigma (for their *cis* isomers) symmetry, the two ring carbons C-3 and C-5 (see Scheme 1) are equivalent in these cases. We observed two peaks at about δ 104 ppm for both MOO1 and MOO3 (Fig. 2B) due to the ring carbons; these peaks arise from the *trans* and *cis* isomers, not from carbons C-3 and C-5.

2D ^{1}H-^{13}C correlation experiments (21) supported these assignments. The results show that peaks at δ 104.34 and δ 104.23 ppm are produced by the *trans* isomers of MOO1 and MOO3 and that peaks at δ 104.26 and δ 104.18 ppm are produced by the *cis* isomers of MOO1 and MOO3, using the known values of the ring proton peaks of the corresponding *trans* and *cis* isomers. Thus, symmetry considerations, ^{13}C NMR, and 2D ^{1}H-^{13}C correlation experiments give consistent assignments for the ring carbons of MOO1 and MOO3.

We assigned the ^{13}C NMR peaks for carbons C-3 and C-5 in *trans*- and *cis*-MOO2 as follows. The structural environment of C-3 in *trans*- and *cis*-MOO2 is closer to that of C-3 (or C-5) in MOO3 rather than in MOO1, and the environment of C-5 in *trans*- and *cis*-MOO2 is closer to that of C-5 (or C-3) in MOO1 rather than in MOO3. Thus, we assigned δ 104.23 (*trans*-MOO2) and δ 104.18 ppm (*cis*-MOO2) for C-3 and δ 104.34 (*trans*-MOO2) and δ 104.26 ppm (*cis*-MOO2) for C-5 in MOO2. Most ^{13}C NMR signals for MOO2 agree with the results obtained by Ewing *et al.* (20,21). However, while Ewing *et al.* (20) detected only one peak at δ 106 ppm for the MOO2 ring carbons, we detected four MOO2 ring carbon peaks between δ 104.18 and δ 104.34 ppm. Complete assignments for the ozonide ring structures, including the terminal methyl, ester methyl, and ester carbonyl groups, are listed in Table 3. The NMR data for methyl oleate are also included in Table 3 for comparison.

Comparison of 400 MHz and 200 MHz NMR spectra. The 200 MHz ^{1}H NMR spectra of MOO1, MOO2, and MOO3 show an unresolved multiplet peak (partial-overlapped five lines) for the ring protons of both *cis* and *trans* isomers (21). The ^{13}C NMR spectra obtained at 50 MHz showed only one line for the ozonide ring carbons of both MOO1 and MOO3, and two lines for MOO2 (21). Thus, the AC-200 NMR spectrometer is not powerful enough to resolve these peaks, which may explain why previous work (2,20) gave incomplete assignments.

Lipids of the Earthworm *Lumbricus terrestris*

Phillip W. Albro*, Joanna L. Schroeder and **Jean T. Corbett**
Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina 27709

The lipid composition of the earthworm *Lumbricus terrestris* has been reexamined under conditions intended to avoid enzymatic and chemical alterations during storage, extraction, and fractionation procedures. The simple lipids included aliphatic hydrocarbons, steryl esters, glycerides, and at least nine different sterols, all thought to be derived from the diet. Free fatty acids, previously considered to be major components of worm lipids, comprised only 0.3% of the total lipid weight. Phospholipids included (in order of relative abundance) phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol, as well as sphingomyelin. Glycolipids included cerebrosides and sulfatides containing both glucose and galactose, and gangliosides containing glucosamine and sialic acid. The fatty acid compositions of these lipid classes appeared to be a mixture of what are considered typical plant, bacterial, and animal acids. Several fatty acids found in the worms, including *cis*-vaccenic and eicosapentaenoic acids, were essentially absent from the dietary components, and it is concluded that these acids were synthesized in the worms. The earthworm derives much of its lipid adventitiously, but exerts at least some control over its tissue lipid composition.
***Lipids 27,* 136–143 (1992).**

Earthworms are the major biomass in soil, constituting from 356 to 678 pounds per acre of arable land (1), and are widely used as a source of food and as an antipyretic (2,3). Charles Darwin estimated that the earthworms in an acre of land pass from 10 to 18 tons of earth and leaves through their intestines every year. In spite of their importance to agriculture, we know relatively little about the chemical composition of earthworms.

The general lipid composition of earthworms was reported by Lovern in 1940 (4), but the species was not identified. The neutral lipids of earthworms, especially the sterols, have been the subjects of considerable study (5–8), but the methodologies available at the time lacked sufficient resolving power for complete characterization. The few studies that have been made of earthworm phospholipids and glycolipids (8,9), while indicating a phospholipid class composition typical of animal species, have concluded that the glycolipids are very minor components and of limited variety.

The fatty acid composition of earthworm lipids is known to be quite complex (5,10,11). However, since high-resolution capillary column chromatography was not used in previous studies, it remained possible that the fatty acid distribution was even more complex than that reported.

These early studies of earthworm lipids were performed using worms dug from the soil at the time of analysis, with no attempt being made to control or characterize the dietary material or other environmental factors. The present work was undertaken in order to provide information on the lipid composition of the earthworm *Lumbricus terrestris* when the animals were maintained in the laboratory under controlled conditions, and precautions were taken to minimize the possibility for alterations before and during extraction and fractionation.

MATERIALS AND METHODS

Young earthworms (*L. terrestris,* "night crawlers"), sphagnum moss-based worm bedding, and worm feed (primarily based on corn meal) were obtained from Carolina Biological Supply Co. (Raleigh, NC). The bedding was extracted twice with chloroform and dried in a fume hood to ensure freedom from nematodes, to remove lipid-soluble polymeric material, and to delay the growth of mold. Worms were maintained at 12°C in glass chambers partially filled with moist bedding, and were fed a mixture of one part commercial worm feed, one part dried rabbit feces and two parts fresh coffee grounds (12). The chambers were in a dim light/dark cycle of 10 hr/14 hr. The worms were maintained in our laboratory for between three and six months after purchase.

The intestinal contents of the worms were partially voided by placing the worms for 24 hr in a chamber containing water and clean quartz gravel so they could be in or out of the water as they pleased. Worms taken for analysis weighed between 4 and 8 g, and had been obtained in the Spring of 1990. The worms were dropped into liquid nitrogen, and extracted while frozen.

Extraction involved the use of a stainless steel Waring blender canister to rapidly homogenize the worms in 20 volumes (v/w) of chloroform/methanol (2:1, v/v) at room temperature. This extract was filtered with suction through glass fiber filter paper (Reeve-Angel, Clifton, NJ) and the filter pad was reextracted with half the amount of chloroform/methanol used originally. The second extract was filtered through glass fiber paper and combined with the first. The combined extract was washed with 0.2 volumes of 1.2% aq. KCl by the method of Folch *et al.* (13). The lower phase was rotary evaporated under vacuum at 20°C, and the residue immediately weighed and fractionated. Results reported in this paper are the means for three batches of worms, five worms per batch, unless stated otherwise.

Fractionation of lipid classes. All solvents used in this study were (HPLC) grade, either MCB OmniSolv (EM Science, Cherry Hill, NJ) or glass distilled (Burdick & Jackson, Muskegon, MI). The extracted lipids were first separated into major classes by chromatography on columns of Unisil silicic acid (Clarkson Chemical Co., Williamsport, PA) prepared as hexane slurries. The

Abbreviations: CL, cardiolipin; ECL, equivalent chain length; GLC, gas-liquid chromatography; HPLC, high-pressure liquid chromatography; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; LPS, lysophosphatidylserine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; SPH, sphingomyelin; TLC, thin-layer chromatography; TMS, trimethylsilyl.

loading factor was 15 mg of lipid per g of adsorbent. Simple lipids were eluted as Fraction I with chloroform (20 mL/g silicic acid). Glycolipids were then eluted as Fraction II with chloroform/acetone (1:1, v/v), 10 mL/g silicic acid, and Fraction III with acetone, 10 mL/g. After a wash with chloroform (10 mL/g silicic acid) that did not elute additional lipid, phospholipids were eluted with methanol (10 mL/g silicic acid). Recovery averaged 95.6% of the weight of extract loaded onto the columns. All lipid fractions were stored under nitrogen without solvent at −20°C until processed further.

The simple lipid fraction (I) was examined by thin-layer chromatography (TLC) on 250 micron silica gel GF plates (Analtec, Inc., Newark, DE) using (a) hexane/benzene (9:1, v/v); and (b) hexane/diethyl ether/acetic acid (85:15:1.5, v/v/v) as developing solvents. Detection was with iodine vapors and by charring with sulfuric acid/nitric acid/water (5:4:3, v/v/v). Aliphatic hydrocarbons and steryl esters were separated from portions of Fraction I by chromatography on Florisil as described by Carroll (14).

Glycolipids (Fractions II and III) were examined by TLC in (c) chloroform/methanol/water (60:35:8, v/v/v) (15). The α-naphthol spray of Siakotos and Rouser (16) was used to detect carbohydrate-containing components. The hypochlorite-benzidine spray of Bischel and Austin (17) was used to detect sphingosine, and the resorcinol spray described by Svennerholm (18) was used to detect sialic acid. A molybdate spray was used to visualize phospholipid contaminants (19).

Phospholipids were separated by two-dimensional TLC on plates that had been pre-developed in acetone before activation. Plates were first developed in (d) chloroform/methanol/acetic acid/water (50:25:8:4, by vol.), dried, and developed in the second dimension in (e) diisobutyl ketone/acetic acid/water (8:5:1, v/v/v) using lined tanks. Fractions were detected with iodine vapors, scraped off, and analyzed for lipid phosphorus by the method of Bartlett (20). Corresponding regions were scraped from solvent-developed, but otherwise blank, plates to serve as background controls. Phospholipid class identifications were confirmed by one-dimensional TLC using chloroform/methanol/14% aq. ammonia (68:28:8, v/v/v). These plates were sprayed with molybdate for lipid phosphate, ammonia/silver nitrate for reducing lipids, ninhydrin for amino groups, and Dragendorff's reagent for choline-containing lipids (21). Identification was based on cochromatography with standards and appropriate color reactions with the selective spray reagents.

Reference standards for TLC included phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylcholine (PC), and mixed gangliosides (bovine origin), phosphatidylinositol (PI) and phosphatidylglycerol (PG) (soybean) were from Supelco (Bellefonte, PA); lysoPE (LPE), LPC, LPS, sphingomyelin (SPH), brain sulfatides and cerebrosides (bovine) were from Applied Science Laboratories (State College, PA), and cardiolipin (CL) from ICN Pharmaceuticals (Cleveland, OH).

Portions of Fraction V were chromatographed on columns of Silica Gel 60 (Brinkmann, EM Laboratories, Elmsford, NY) chloroform slurry. After a wash with 4 mL of chloroform per g of silicic acid, amino-phospholipids (mostly PE) were eluted with 7.5 mL of chloroform/methanol (4:1, v/v) per g and zwitterionic phospholipids (mostly PC) were eluted with 7.5 mL of chloroform/methanol (1:4, v/v) per g.

Other analytical methods. Glycolipids were quantified by the colorimetric anthrone assay following hydrolysis in ethanol/chloroform/2N HCl (22). Sterols and steryl esters were measured by a ferric chloride procedure that gives the same molar response for free and esterified sterols (23). Aliphatic hydrocarbons were estimated by weighing the residue from the hexane fraction off Florisil. Intrared spectra of thin films on salt plates or pressed KBr pellets were obtained using a Perkin-Elmer model 1320 Infrared Spectrophotometer (Perkin-Elmer, Norwalk, CT). UV/visible spectra were scanned on a Beckman DU-7 instrument (Beckman Instruments Co., Fullerton, CA). Plasmalogens were determined by the method of Gottfried and Rapport (24). Free fatty acids were quantified using the rhodamine assay of Chakrabarty *et al.* (25).

Glycolipids were hydrolyzed for analysis of the carbohydrate moieties after reflux for 2–3 hr in *tert*-butanol/water (2:1, v/v) containing 2N HCl. The fatty acids and alcohol were removed by adding 6 volumes of water and extracting three time with diethyl ether. The aqueous phase was frozen in a dry-ice/acetone bath and lyophilized prior to derivatization for gas chromatography. This is a modification of the established method of Radin *et al.* (22), in which substitution of *tert*-butanol for ethanol avoids the formation of alkylated artifacts while retaining the ability to dissolve lipids. The modified procedure gave complete release of sugars from standards of bovine brain sulfatides (data not shown).

Total sterols were obtained by saponifying the simple lipid fraction in 50% aqueous ethanol containing 2N KOH under reflux for 90 min. After adding water to reduce the ethanol to 25%, non-saponifiables were extracted twice with 5% diethyl ether in hexane. The aqueous phase was acidified with HCl and extracted with diethyl ether to recover the fatty acids.

Squalene, cholesta-3,5-diene, cholesteryl oleate, and the reference sterols cholesterol, stigmasterol, lanosterol, ergosterol, epicholesterol, β-cholestanol, desmosterol, β-sitosterol, campesterol, dihydrobrassicasterol, 7-dehydrocholesterol, and cholest-7-en-3β-ol were from Sigma Chemical Co. (St. Louis, MO). Reference sterols coprostanol, fucosterol, and brassicasterol were from Supelco.

Lipid fractions were converted to fatty acid methyl esters using BF_3/methanol (26) directly, except for the simple lipids, in which only the saponifiables were derivatized in order to prevent the formation of BF_3/sterol artifacts. Free sterols were converted to trimethylsilyl (TMS) derivatives in methylene chloride/methyl trimethylsilyl trifluoroacetamide (3:1, v/v) by heating for 15 min at 60°C. TMS derivatives of the monosaccharides derived from hydrolysis of glycolipids were made using Tri-Sil Z (27). Hydroxy-acid methyl esters were converted to TMS derivatives with *bis*-(trimethylsilyl) trifluoroacetamide/methylene chloride (1:2, v/v) at room temperature. All silylation reagents were obtained from Alltech Associates (Deerfield, IL).

Gas-liquid chromatography. All separations were performed using a Varian model 3700 gas chromatograph with hydrogen flame ionization detection and splitless injection (Varian Associates, Inc., Palo Alto, CA). Quantification (molar percentages) was based on peak areas as reported by a Hewlett-Packard model 3390A electronic integrator (Hewlett-Packard, Cupertino, CA).

TMS derivatives of sterols were chromatographed on a 25 m × 0.25 mm fused silica capillary column

containing a 0.2-micron layer of RSL-150 methyl silicone (Alltech, Deerfield, IL) at 250°C, with helium as carrier gas at 20 psig. Identifications were confirmed on a more polar column, 25 m × 0.25 mm, coated with a 0.2-micron layer of DB-1701 (Alltech), at 200°C. In addition, the TMS derivatives were examined by GLC/mass spectrometry on a Kratos Concept 1SQ mass spectrometer (Kratos Analytical, Ramsey, NJ) using the 70-eV electron impact ionization mode. Samples were introduced through a 30 m × 0.25 mm DB-5 capillary column programmed from 150–250°C at 4°C/min.

Fatty acid methyl esters were determined on a 25 m × 0.25 mm fused silica capillary column coated with RSL-950 (Alltech, equivalent to SP 2340), cyanosilicone, at 140°C. Identifications were based on direct cochromatography with standards, confirmed by cochromatography on the methyl silicone column described above and, where feasible, reconfirmed on a packed column of 5% Apiezon L on 100/120 mesh Gas Chrom Q, 2 m × 3 mm, with helium as carrier at 30 mL/min at 205°C.

TMS derivatives of hydroxyacid methyl esters were analyzed on the methyl silicone column with a temperature program from 150 to 250°C at 2°C/min. Identifications were confirmed by GLC/mass spectrometry using a 15 m × 0.25 mm DB-5 column programmed from 40–325°C at 10°C/min. Electron impact ionization (70 eV) mass spectra were generated as for the sterols above.

Reference fatty acid methyl esters included all those (normal, branched, hydroxy, cyclic) available from Applied Science Laboratories, Supelco, Sigma, and Analabs, Inc. (North Haven, CT). Additional confirmation of the identifications of the fatty acid methyl esters involved chromatography before and after catalytic hydrogenation over platinum oxide in n-heptane, and separate analysis of the reconstituted methyl esters after separation of the mercurimethoxy derivatives according to the number of double bonds (28).

RESULTS

Six worms were extracted individually, giving a mean lipid content of 1.23% ± 0.20% (S.D.) of worm fresh weight. The extractable lipid from three batches of worms was distributed among chromatographic fractions as shown in Table 1.

Simple lipids. Aliphatic hydrocarbons were quantified by weight only, since the composition of this fraction has been examined in great detail by GLC/mass spectrometry previously (29). Squalene was not detected on TLC in solvent (a); if present, it must have amounted to less than 1% of the lipid. The data in Table 1 for sterols and steryl esters are lower limits, as some of the minor components do not give a strong color reaction with ferric chloride. Free fatty acids were extremely low, probably because of the precautions taken to prevent artifactual hydrolysis. If the lipid extract was stored in chloroform for one month at −20°C prior to fractionation, most of the PE and at least part of the PC were converted to lyso forms with a major increase in free fatty acids (data not shown).

Glycerides were the major components in the simple lipid fraction. TLC showed that most of the glyceride was a triglyceride, with a barely detectable level of diglyceride also being observed.

TABLE 1

Lipid Class Composition of *L. terrestris*[a]

Lipid fraction	Total lipid (%) ± S.D.
Simple Lipid (Fr. I)	(29.0 ± 1.5)
Hydrocarbons	1.25 ± 0.05
Steryl esters	3.0 ± 0.10
Free fatty acids	0.32 ± 0.01
Sterols	3.75 ± 0.08
Glycerides	20.7 ± 1.1
Glycolipid (Fr. II)	(6.6 ± 0.3)
Glycolipid (Fr. III)	(4.8 ± 0.4)
Phospholipid	(59.5 ± 1.3)
Phosphatidylethanolamine	19.8 ± 0.6
Phosphatidylcholine	23.8 ± 0.7
Phosphatidylserine	4.6 ± 0.14
Phosphatidylinositol	4.0 ± 0.12
Sphingomyelin	2.1 ± 0.06
Lysophosphatidylethanolamine	3.3 ± 0.1
Lysophosphatidylcholine	2.1 ± 0.07

[a]Results are expressed as weight percentage of total extractable lipids. SD, standard deviation between batches. Numbers in parentheses are for the weights of the fractions from Unisil silicic acid chromatography. Phospholipid values based on phosphorus × 25. Sterols and free fatty acids based on colorimetric assay. Glycerides by weight difference. Extractable lipid amounted to 1.23 ± 0.20% of the worm fresh weight (average of six determinations).

Sterols. Table 2 shows the distribution of sterols found after saponification and trimethylsilylation. It was not possible to distinguish between R- and S-isomers of the 25-alkyl-substituted sterols. For example, the component labeled brassicasterol could also include its isomer crinosterol. Except for these optical isomers, which are not resolved under GLC conditions, resolution of the TMS derivatives was excellent and much better than we observed for the free sterols (not shown). Ergosterol was lost if the lipid extract was stored without protection from light, although it was much more stable after saponification and isolation of the nonsaponifiables.

Glycolipids. The two glycolipid fractions from the Unisil columns could be fractionated cleanly by TLC if the extract was processed while fresh. If build-up of free fatty acids through spontaneous hydrolysis on storage was allowed to occur, the glycolipid fractions smeared badly. Most of the dark pigment in the lipid extract eluted in Fraction II with chloroform/acetone (1:1, v/v). This material is not lipid, even though it is lipid soluble, and it has not been characterized in the present study.

Fraction II contained material chromatographing (TLC) with bovine cerebrosides. This material gave a double spot, as is always seen when the fatty acids include a mixture of normal and hydroxylated forms (30). These spots were positive for carbohydrate with the naphthol spray, and positive for sphingosine with the hypochlorite-benzidine reagent. Hydrolysis and GLC analysis of the TMS derivatives gave only glucose and galactose in a ratio of 2.39 to 1, indicative of a mixture. In contrast, similar treatment of bovine cerebroside and sulfatide gave only galactose. Fraction II also contained a very slight amount of carbohydrate/sphingosine positive material chromatographing with sulfatide, as well as a small amount of sterol carryover from Fraction I.

TABLE 2

Distribution of Total Sterols[a]

Sterol	RRT[b] RSL150	Area %, TMS deriv.	Characteristic mass peaks (m/z) [% rel. abundance]
Cholesterol	1.000	66.9 ± 2.8	458 [100], 443 [15], 368[87], 353 [32], 329 [94], 129 [71]
β-Cholestanol	1.036	1.7 ± 0.3	460 [100], 445 [17], 370 [85], 331 [16], 129 [39]
Desmosterol	1.092	8.6 ± 1.4	456 [92], 441 [41], 366 [45], 343 [87], 327 [57], 129 [100], 60 [99]
Brassicasterol	1.118	8.8 ± 0.6	470 [82], 455 [8], 380 [36], 341 [19], 329 [8], 255 [27], 129 [41], 71 [100]
Ergosterol	1.200	3.1 ± 0.3	468 [100], 453 [7], 378 [15], 363 [83], 337 [45], 253 [20], 69 [52]
Campesterol	1.288	6.3 ± 0.9	472 [100], 457 [15], 382 [74], 367 [25], 343 [80], 129 [61]
Stigmasterol	1.388	3.6 ± 0.2	484 [56], 469 [6], 394 [24], 379 [6], 343 [15], 255 [23], 100 [100]
β-Sitosterol	1.582	1.0 ± 0.1	486 [100], 471 [11], 396 [71], 381 [22], 357 [74], 129 [64], 70 [37]
Isofucosterol	1.634	0.2 ± 0.2	Tentative, much background interference.

[a]Nonsaponifiable lipids derivatized with methyl trimethylsilyl trifluoroacetamide in methylene chloride and analyzed by gas chromatography on a 25-m capillary column coated with methyl silicone (RSL-150), under isothermal conditions. Identifications confirmed on a 25-m capillary column of DB 1701 and by GC/mass spectrometry (EI-70 eV). For details, see Materials and Methods.

[b]RRT, retention time relative to that of cholesterol TMS, on the RSL-150 capillary column.

Fraction III contained significant amounts of both material chromatographing with sulfatide and material chromatographing with bovine gangliosides (double spots in both cases). The latter, but not the former, reacted positively with the resorcinol-copper sulfate reagent for sialic acid, as well as the naphthol and hypochlorite-benzidine reagents. Refluxing for 2 hr in 66% *tert*-butanol containing 2N HCl hydrolyzed glycosidic bonds, but did not hydrolyze the amide bonds of standard *N*-acetyl-glycosamine or *N*-acetyl-neuraminic acid. Fraction III gave glucose, galactose, *N*-acetyl-glucosamine, and sialic acid in an apparent ratio of 2.29:1:1.69:1.02. This mixture confirmed the presence of gangliosides in Fraction III.

Infrared spectra of Fractions II and III showed amide at ~1645 cm^{-1}, S=O at 828, and S-O at ~1368 and/or 1182 cm^{-1}, as well as strong -OH absorption in the 3300-3400 cm^{-1} region. This confirmed the presence of sulfatides in both fractions (31).

The anthrone assay for hexoses indicated that Fraction II contained approximately 390 nmole of hexose per mg of fraction weight, with 720 nmole hexose per mg in Fraction III. Amino sugars do not contribute to this assay, so Fraction III would have contained a total of 1.3 micromoles of monosaccharide-equivalent per mg of fraction weight. If we assume a mean molecular weight of 760 for typical cerebrosides, and assume that sulfatides are minor components in Fraction II, then it is possible to estimate that cerebrosides amounted to approximately 1.9% of the total lipid weight (upper limit). Both glucose- and galactose-containing lipids would be included in this estimate. The bulk of the weight of Fraction II not included in glycolipid was due to pigment (almost absent from Fraction III).

We were not able to estimate a mean molecular weight for Fraction III glycolipids. Moreover, the exact proportion of sulfatide to ganglioside is not known for these preparations. Therefore, we can only report that sulfatides plus gangliosides comprised approximately 4.6% of the total extractable lipid. We cannot state that glycosyl glycerides were absent, but all the naphthol-positive spots we detected were also positive for sphingosine.

Phospholipids. The phospholipid distribution is also shown in Table 1. The two major classes were PC and PE, with PS, PI, SPH, and lyso forms as minor components. CL, PG, and phosphatidyl-*N*-methylethanolamine were not detected, although they could have been present below our limits of detection. Phosphate assays indicated that Unisil fraction V could not have contained significant amounts of material lacking lipid phosphorus (not shown). Thus phospholipid was the most abundant class of extractable lipids in these worms (about 60% of the total lipid by weight).

The iodination assay (23) indicated that only 3.7% of the phospholipid was present in the form of plasmalogen (vinyl ether). We did not assay for saturated ether-containing lipids.

Fatty acids. The fatty acid compositions of various lipid fractions are summarized in Tables 3 and 4. Infrared spectra of the methyl ester preparations showed no indication of *trans* double bonds, keto groups, or epoxides. Traces of dimethylacetals were indicated by small peaks at 1195 and 1122 cm^{-1} (32). Very low levels of the dimethyl acetals of palmitaldehyde and stearaldehyde were detected in the methyl ester preparations derived from the total phospholipids (not shown). Hydroxyacids were clearly present in the phospho- and glycolipid fractions, and were separated from the simple fatty acids (as methyl esters) on silicic acid (33). The individual hydroxyesters were identified on the basis of their GLC retention parameters before and after reaction with *bis*(trimethylsilyl) trifluoroacetamide (34,35), and confirmed by GLC/mass spectrometry. In no case were hydroxy acids other than 2-hydroxy acids detected. We particularly looked for ricinoleic acid, but did not find it. All of the hydroxyacid methyl esters (as TMS derivatives) gave mass spectra in which the base peak was either *m/z* 73 or the ion corresponding to M-59 (loss of $COOCH_3$), with only a very weak (~1%) molecular ion, a strong peak at M-15, and a minor peak at M-31. The spectra closely matched those published for the 2-hydroxyacid methyl ester TMS derivatives from brain (35).

The complexity of the fatty acid mixtures is apparent from Table 3. Acids typical of animals (arachidonic, other C_{20} polyenes) were abundant, as were characteristic plant acids (pristanic and phytanic), and bacterial acids (vaccenic, branched saturated). It was not possible to

[a] Fatty acid methyl esters analyzed by capillary GLC on RSL-950 at 140°C. All identifications are based on cochromatography with known standards. The identifications were confimred on RSL-150 and Apiezon L columns. ECL, equivalent chain length on RSL-950 column. Analytical data are presented as percentage of non-hydroxylated fatty acids in a given fraction for those acids comprising at least 0.1% of the total. A "T" indicates that at least one of the three batches analyzed had 0.1% of that component.

[b] Fatty acids designated as number of carbon atoms:number of double bonds. n, Normal; i, iso; a, anteiso; br, unidentified branching pattern; cyc, cyclopropane ring in chain at the specified location; Me, branch methyl group at specified location. "Unknown" indicates a component for which we lacked a matching standard.

[c] Fractions from Unisil silicic acid columns or (steryl esters) from Florisil. See Materials and Methods for details.

[d] This peak includes trimethyltridecanoate with the anteisopentadecanoate.

rationalize the fatty acid compositions solely on the basis of the worm diet (Table 5). None of the dietary components contained more than a trace of vaccenic acid, yet vaccenic acid equaled or exceeded oleic acid in the worms. The worms contained branched acids and hydroxy acids that were not detected in the diet. One of the most abundant fatty acids in the worms, eicosa-11-enoic acid, was no more than a trace component of the diet.

Steryl esters contained primarily saturated fatty acids, with less than 1% being polyunsaturated. The glycerides had a fatty acid composition similar to that of the mixed diet, except for increased amounts of branched saturated acids. Linoleic acid was high in the glycerides, but C_{20} polyenes were almost absent. The phospholipids contained C_{20} polyenes as the main components, with fatty acid compositions more reminiscent of animal than of plant lipids. At the same time, the high levels of vaccenic acid, branched acids, and cyclopropanoid acids in the phospholipids suggested a partial bacterial origin.

DISCUSSION

The lipid content of *L. terrestris* reported here, 1.23 ± 0.20% of the worm fresh weight, may be compared to the 1.2–2.5% reported by Hansen and Czochanska (10), 0.65–3.5% (average 1.25%) reported by Cerbulis and Wight

[b]Number of carbon atoms:number of double bonds (Δ position of first double bond, if known).

Taylor (5), and the 1.2–1.3% reported by Lovern (4). The lipid content reportedly depends on the season of the year in which the worms are collected (10,11) which, in turn, may depend upon the organic composition of the soil at those seasons. If that is the case, then the present data for worms maintained on a fixed diet may be independent of the season in which the worms were procured.

Cerbulis and Wight Taylor (5) and Nooner *et al.* (29) reported that aliphatic hydrocarbons amounted to 3% of the total lipid weight. Our finding hydrocarbons to comprise only 1.25% of the total lipid weight may reflect the fact that the worm bedding was free of organic extractables in our study, while the worms studied previously (5) were collected directly from the soil just prior to analysis.

Lovern (4) and Cerbulis and Wight Taylor (5) had reported that earthworm lipids did not contain triglycerides. The absence of glycerides was later shown by Hansen and Czochanska (36) to be an artifact resulting from cold storage of dead worms prior to extraction. It would not be surprising for hydrolysis of lipids to have also occurred during the extremely prolonged (four days) room temperature extraction procedure of Cerbulis and Wight Taylor (5). However, it was still accepted that earthworm lipids were rich in free fatty acids (10,11). We found that storage of the extracted lipids at −20°C, for even a few days prior to fractionation, resulted in decomposition of the phospholipids (especially PE) to give lysophosphatides and free fatty acids. Under the conditions of extraction and immediate fractionation described here, free fatty acids were not seen on TLC of the lipids, and were only detectable (at 0.3% of the total lipid) by colorimetric assay. However, it is also possible that the soil in which the worms were living contained a high level of free fatty acids in the earlier studies.

Previous reports that ergosterol was the second most abundant sterol in the earthworm, amounting to 23% or more of the sterol fraction (see references in 4), were based on methods incapable of separating the wide variety of sterols actually present. Cerbulis and Wight Taylor (5) observed the presence of at least six different sterols in *L. terrestris*; however, gas chromatography of the free sterols on a packed column did not provide sufficient resolution to permit quantification. We can confirm the presence of five of the six sterols reported previously (5), but we did not detect γ-sitosterol. We found ergosterol to be only the sixth most abundant sterol present, behind cholesterol, brassicasterol, desmosterol, campesterol, and stigmasterol. Four of the sterols found in the present study (dihydrocholesterol, desmosterol, brassicasterol, and isofucosterol) have not been reported previously in *Lumbricus*. Dihydrocholesterol and desmosterol are common animal sterols, and the former was reported to occur in *E. foetida* (8), as well as in the cricket *A. domesticus* (37). The compound here identified as desmosterol may correspond to what was thought to be 7-dehydrocholesterol on the basis of cochromatography (8). These two sterols are not separated on non-polar columns. However, the intense peaks at *m/z* 343 and 69 in the mass spectrum of this compound clearly show the second double bond to be at C-24 rather than C-7 (38). Brassicasterol occurs in *Mollusca* (39) and *Perichaeta* (40), and was tentatively identified in *Eisenia* (8). Campesterol, stigmasterol and isofucosterol are generally considered characteristic of plants. The relatively low level of ergosterol found in the present study

may reflect the low level of fungal metabolites available to our worms.

Since it has been shown by Wootton and Wright (41,42) that *L. terrestris* has a block in sterol biosynthesis such that mevalonic acid can be incorporated into squalene but not into sterols, and since common soil bacteria do not produce sterols (43), it must be assumed that the sterols found in earthworms are derived as such from the organic matter in their diet. It is not surprising, therefore, that many of the sterols found in the worms are typical plant sterols. No lanosterol or lathosterol was detected, again suggesting the absence of *de novo* synthesis of sterols in *Lumbricus.*

Phospholipids were reported to comprise 33–44% (4), 25–41% (5) or 59.5% (this study) of the total extractable lipid of *L. terrestris.* Hansen and Czochanska (11) reported 57.6% phospholipid in *L. rubellus* and *Allolobophora caliginosa* lipids. The two lowest values were from the studies in which hydrolysis of the lipids almost certainly had occurred prior to analysis, suggesting that the higher value is more likely correct. That the two most abundant phospholipids were PC and PE (in that order) was also the case for *Eisenia foetida* (8) and the purified chloragosomes of *L. terrestris* (44). *E. foetida* reportedly also contained PS (8), but not PI, while both PS and PI (but not SPH) were found in isolated nerve tissue from *L. terrestris* (9).

Okamura *et al.* (9) reported finding only a trace of glucocerebroside and no other glycolipids in the nerve tissue of *L. terrestris.* Hansen and Czochanska (11) reported that glycolipids (uncharacterized) comprised 2.3% of the extractable lipid from *L. rubellus* and *A. caliginosa.* Glycolipids were only trace components of the lipids of *E. foetida* (8), but phospholipids were also extremely low in this species (11%). It has been reported that the large amount of polar pigment extracted from earthworms can interfere in the detection of gangliosides (8). This pigment mixture is thought to consist of coumarols and flavonols (44). Since the pigment was separated from the sialic acid-containing lipids under our chromatographic conditions, we may have escaped the interference problem. Glycolipids, as determined both directly on a weight basis and by colorimetric and gas chromatographic determination of the monosaccharides after hydrolysis, amounted to at least 6.7% of the extractable lipid in the present study. This is a lower limit, since it is probable that some of the gangliosides would have been lost in the aqueous phase of the Folch extraction (45).

Detailed studies of the fatty acid compositions of total lipids, lipid fractions, or individual phospholipids were reported for *L. terrestris* by Cerbulis and Wight Taylor (5), for a mixture of *L. rubellus* and *A. caliginosa* by Hansen and Czochanska (10,11), and for nerve tissue from *L. terrestris* by Okamura *et al.* (9). Hydroxy fatty acids were not reported in any of these studies.

Early studies (5) indicated that *L. terrestris* contained fatty acids from C_{11} to C_{27} in length, with significant amounts of monoenes, traces of dienes, and no fatty acids with more than two double bonds except a C_{16} acid with four double bonds. Polyunsaturated acids were also not detected in *L. terrestris* nerve tissue (9). In contrast, polyunsaturated acids, especially arachidonic acid and a C_{20} acid with five double bonds ($\omega 3$), were major components in the lipids from *L. rubellus* and *A. caliginosa* (11). We found polyunsaturated fatty acids to be major components of the phospholipids of *L. terrestris,* suggesting that the prolonged extraction time (5) or extensive manipulation involved in isolating nerve tissue (9) may have permitted autooxidation to have occurred, depleting these components in the earlier studies of this species. We found no indication of acids with conjugated double bonds, keto groups, or epoxy groups in the present study. Table 3 shows only about half the fatty acids actually observed in this study; many others occurred, but at levels below 0.1% of the total (below our limit of reliable quantification).

The occurrence of simple branched and isoprenoid fatty acids reported here is in agreement with what was reported for *L. rubellus* and *A. caliginosa* (11). In combination with the major presence of *cis*-vaccenic acid, the cyclopropanoid C_{17} acid and the polyunsaturated C_{20} and C_{22} acids, these fatty acids suggest a combination of plant, bacterial, and animal origins. Since several of the major fatty acids, including vaccenic acid and eicosapentaenoic acid, could not be traced to the worm diet, it is necessary to conclude that fatty acid synthesis does occur in worms (possibly with help from the intestinal flora) and that worms do exert some control over the fatty acid composition of their lipids. This is consistent with the observations of Wootton and Wright (41), who found incorporation of radioactivity from ^{14}C-labeled mevalonic acid into fatty acids in *L. terrestris.*

Hydroxy fatty acids were found in the phospholipid fraction and in both fractions of glycolipids in the present study. Those in the phospholipid fraction may have been associated with sphingomyelin, although that component was not separately isolated. The hydroxy acids in the glycolipid fractions support the conclusion that the glycolipids did indeed include sphingolipids. This observation is in contrast to the results found for isolated *L. terrestris* nerve tissue, where sphingolipids were essentially absent (9). Whether the absence of sphingolipids in the studies of nerve tissues indicates that they are localized elsewhere, or whether the fact that the worms were killed with hot water and the extraction performed at 70°C (9) may have, in some way, prevented the recovery of sphingolipids is not known.

PE and PS from worm nerves were reported to contain high concentrations of plasmalogens (9). We found only traces of plasmalogens in the total worm phospholipids, suggesting that plasmalogens may be negligible components of *L. terrestris* lipids in tissues other than nerves.

It is clear that misleading results will be obtained for the lipid composition of worms if precautions are not taken to prevent enzymatic, chemical (hydrolytic), photochemical and oxidative alteration during storage of dead worms, extraction, and/or storage of the lipid extracts. These alterations seem to include extensive hydrolysis of triglycerides and PE, loss of polyunsaturated fatty acids, and destruction of photosensitive sterols. The remarkable complexity of the lipid mixture from earthworms can only be observed if such alterations are strenuously avoided.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to Steve McGowan for obtaining the mass spectra of TMS derivatives.

COMMUNICATION

Changes in Fatty Acid Composition of Phospholipids from Liver Microsomes and Nuclei in Rats Fed a Choline-Free Diet

Randhir Kapoor[a], **Amiya K. Ghoshal**[a,*] and **Emmanuel Farber**[a,b]
[a]Department of Pathology and [b]Department of Biochemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A8

Male F-344 rats were fed a choline-free (CF) diet, and changes in phospholipid content, phospholipid fatty acids and phospholipase A_2 activity in liver nuclei and microsomes were examined during the first 72 hr. Both nuclei and microsomes showed a decrease in phosphatidylcholine (PC) content. Microsomes showed an increase in PC arachidonate while nuclei showed a decrease. Also, microsomes showed increased activity of phospholipase A_2 (PLA_2) while nuclei did not. These observations are consistent with the hypothesis that the absence of diene conjugates in liver microsomes in the rats on the CF diet may reflect the increased rate of removal of peroxidized fatty acids by phospholipase A_2.
Lipids 27, 144-146 (1992).

Rats fed a choline-free (CF) diet devoid of any added or known carcinogen, including aflatoxin B_1, develop liver cancer (1-3). The liver cells show a highly reproducible sequence of early biochemical and biological changes. Triglyceride accumulation begins at 8 hr and nuclear lipid peroxidation at 24 hr. Lipid peroxidation, as measured by the formation of diene conjugates (4), is seen in liver nuclei but not in liver microsomes 24 hr to 63 days on the dietary regimen (4,5). This is followed by DNA alterations, liver cell death, and liver cell proliferation by 5 days, and initiation of hepatocarcinogenesis by 10 wk (4-10).

It has been reported that the microsomes prepared from rats fed a CF diet show characteristic alterations in phospholipid composition (6). In view of the difference in observed appearance of diene conjugates in nuclei but not in microsomes (4,5) and the suggested relevance of nuclear lipid peroxidation to initiation of liver carcinogenesis (7), it became important to determine whether nuclei show the same changes as microsomes in their phospholipid content on feeding a CF diet. Also, because of the differential effect of phospholipase A_2 on the removal of peroxidized arachidonic acid from phospholipid (8), it was of interest to determine whether this enzyme shows different responses to a CF diet in nuclei and microsomes.

MATERIALS AND METHODS

Animals. Male Fischer 344 rats (Charles River Breeding Laboratories, Wilmington, MA), weighing 150 to 160 g, were used. The rats wre maintained on Purina Rodent Laboratory Chow (catalogue 5001) for 1 wk on a 12 hr day/night cycle. They were given food *ad libitum* and were acclimatized to their new environment for 1 wk before the start of the experiments.

Diet and chemicals. The choline-free (CF) and choline-supplemented (CS) diets were obtained from Dyets (Bethlehem, PA). The CF and CS diets were the same as described previously (2). Both diets contained 1800 mg L-methionine per kg, but only the CS diet had added choline (8.0 g choline chloride per kg diet). Diets were stored at 5°C, were analyzed regularly to detect potential contamination with aflatoxin B_1, nitrosamines and other potential mutagens (2), and were provided fresh to the rats on alternate days to minimize deterioration at room temperature.

1-Palmitoyl-2-[9′,10′(N)-^{3}H]palmitoyl-*sn*-glycero-3-phosphocholine (sp. act., 58.0 Ci/mmole) was obtained from New England Nuclear (Dupont Canada Inc., Mississauga, Ontario, Canada). Phosphatidylcholine, phosphatidylethanolamine, butylated hydroxytoluene (BHT), Triton X-100, bovine serum albumin, calcium chloride and glycine were purchased from Sigma Chemical Co. (St. Louis, MO). Chloroform, methanol and n-hexane were purchased from Caledon Labs (Mississauga, Ontario, Canada).

Experimental design. Animals were divided into two groups of 12 animals each. One group was fed the CS diet while the other was given the CF diet after an overnight fast. A set of 3 animals each from both groups were sacrificed after 1, 2 or 3 days on the respective diets.

Preparation of subcellular organelles and assays. The livers were excised from the diethyl ether-anaesthetized rats, washed in ice-cold normal saline, and rapidly processed for the preparation of nuclei and microsomes. All subsequent steps were carried out at 4°C. Liver nuclei were isolated by the method of Blobel and Potter (9), with the addition of 1 mM EDTA (ethylenediaminetetraacetic acid) to the sucrose/TKM buffer. The purified nuclei were washed three additional times with 0.25 M sucrose/TKM buffer [5 mM Tris-HCl (pH 7.4 at 4°C), 2.5 mM KCl, 5.0 mM $MgCl_2$ and 0.24 M sucrose containing 1 mM EDTA] by sedimentation at 700 × *g* for 10 min and resuspension in 1 mL of the same buffer. The purity of the nuclei was monitored by light and electron microscopy as well as by biochemical markers assay as described (5). A 10% liver homogenate (w/v) in 0.25 M sucrose/TKM buffer, containing 1 mM EDTA (pH 7.4), was prepared for microsome separation. Homogenates were centrifuged at 10,000 × *g* for 10 min in a Sorval RC 5B centrifuge and then for 60 min in a Beckman ultracentrifuge (model L5-75, Beckman Instruments Inc., Palo Alto, CA) at 100,000 × *g* using a 60 Ti rotor to yield a microsomal pellet, which was then suspended in 1 mL of the TKM buffer.

Phospholipase A_2 activity in liver homogenate, nuclei and microsomes was assayed essentially by the method of Katsumata *et al.* (10). The constituents in the final 1-mL incubation mixture were 100 μmoles of glycine NaOH buffer, 2-3 mg of subcellular organelle protein, 2.5 μmoles of sodium deoxycholate, 2 μmoles of $CaCl_2$, 10 μg of bovine serum albumin and 150 nmoles of substrate. The mixture was incubated at 37°C for 1 hr and radioactive palmitic

acid was extracted with 10 mL hexane containing 0.1% acetic acid in the presence of anhydrous sodium sulfate (0.5 g/mL). Activity of phospholipase A_2, as counts per minute per mg protein, was directly determined based on the radioactivity present in the hexane phase.

Lipids were extracted with chloroform/methanol (2:1, v/v) by the method of Folch *et al.* (11). Total phospholipids were quantitated by the method of Bartlett (12) as modified by Marinetti (13). Aliquots of the extracts were removed and chromatographed in duplicate along with standards for the separation and analysis of phospholipid classes by one-dimensional thin-layer chromatography (TLC) on Silica Gel G60, using the solvent system chloroform/methanol/7N ammonium hydroxide (230:90:15, v/v/v). Individual phospholipids were made visible under ultraviolet (UV) light after spraying the TLC plates with 1,6-diphenylhexatriene and were identified by comparison with co-chromatographed standards. The phospholipid bands were scraped from the plates and quantitated by phosphorus assay upon digestion in the presence of the gel. The fatty acid composition of phospholipid classes was measured upon methanolysis of the individual phospholipid classes for 12 hr in 4% H_2SO_4 in methanol at 90°C. The methyl esters were extracted with hexane.

Gas-liquid chromatography (GLC). GLC of the methyl esters was carried out on a Hewlett-Packard model 5880 (Mississauga, Ontario, Canada) automatic gas chromatograph using a level IV terminal and a 10 mM open granular glass capillary column (0.25 mm i.d.) with its wall coated with SP-2330 liquid phase (68% cyanopropyl and 32% phenylsiloxane) supplied by Supelco (Bellefonte, PA). Injector temperature was 270°C. Separations of fatty acid methyl esters were under temperature programming from 100 to 160 at 20°C/min and then at 2°C/min, or alternatively from 100 to 180°C at 20°C/min and then at 2°C/min, using hydrogen as carrier gas. The peaks were identified by reference to cochromatographed standards (14).

RESULTS

In the nuclear fraction (Table 1), the relative content of phosphatidylcholine as percentage of the total phospholipid, after 24, 48 and 72 hr on the CF diet, is decreased by 14 to 18%. Phosphatidylethanolamine (PE) shows a relative increase by 28 to 48%, while the phosphatidylcholine/phosphatidylethanolamine ratio is decreased by 33 to 43%. The total phospholipid content in each group remained the same over the 72-hr period.

In the microsomal fraction (Table 2), the pattern of decreasing phosphatidylcholine (PC), increasing PE and decreasing PC/PE is similar to that in the nucleus. Although the increase of PE at 24 hr is smaller than at 48 and 72 hr, it is not clear whether this is biologically significant in view of the small number of animals used. However, the values at all three time points and for each determination parallel very closely those seen in the nuclear fraction. The total phospholipid content in each group remained the same over the 72-hr period.

Associated with the changes in the quantities of PC and PE are alterations in the composition of some fatty acids. In the nuclear fraction (Fig. 1), the largest changes involve linoleic (18:2) and arachidonic (20:4) acids which show decreases of over 50% and about 40%, respectively, in the PC fraction and much smaller changes in PE. Several other fatty acids show small decreases or increases in both phospholipids.

The fatty acid compositions of PC and PE from microsomes show several differences (Fig. 2). The most striking is a large increase (about 40%) in arachidonic acid in the PC fraction. In contrast, there is a decrease in linoleic acid similar to that seen in the nuclei. In PC, 16:0, 16:1 and 18:0 decrease in the microsomes while the nuclear

fraction shows increases. The variations in all the fatty acid determinations were well within ± 2 standard deviations.

Table 3 lists the activities of phospholipase A_2 (PLA_2) in the total liver homogenate and in the nuclear and microsomal fractions from animals fed the CS or the CF diets. The total homogenate shows a significant increase of about 50% and the microsomes of 34% in the animals fed the CF diet for 72 hr as compared to those on the CS diet. In contrast, the nuclear fraction shows a much lower activity as compared to the microsomes and whole homogenate and no significant difference between the values for the CF and CS animals at 72 hr.

DISCUSSION

The early changes observed in the phospholipid pattern (PC and PE) in the hepatic nuclear membrane of the rats on CF and CS diets are similar to those previously described for microsomes (6). However, the fatty acid patterns of PC and PE are quite different, especially in respect to the arachidonic acid content of microsomes and nuclei, as the latter show a decrease while the former show an increase. This may reflect different responses of PLA_2 in nuclei and microsomes to the feeding of a CF diet. The microsomes have twice the activity of the nuclei in the control animals and show a significant increase within 72 hr on the CF diet. A more rapid removal, especially of peroxidized arachidonic acid (8) from the microsomes and subsequent repair could account for observed differences between microsomes and nuclei in the generation of diene conjugates.

In the presence of peroxidized arachidonic acid in the phospholipid, the preferred target of PLA_2 is not arachidonate but its peroxidized form (8). In choline deficiency, peroxidized fatty acids could be removed by phospholipase A_2 and subsequently replaced by arachidonic acid in the microsomes. In the presence of a much lower level of activity of phospholipase A_2 in the nuclei, and without increase in activity in the animals fed the CF diet, the peroxidized arachidonic acid could remain in the nuclear membrane and thus become detectable as diene conjugates in this fraction.

ACKNOWLEDGMENTS

Supported by research grants from the National Institutes of Health (CA 41537), Medical Research Council of Canada (MT-5994) and National Cancer Institute of Canada. The authors are grateful for the valuable advice of Dr. A. Kuksis of this University in respect to fatty acid analysis. We thank Lori Cutler for excellent secretarial assistance.

Levels of Thiobarbituric Acid Reactive Substances and the Cytocidal Potential of Gammalinolenic and Docosahexaenoic Acids on ZR-75-1 and CV-1 Cells

M.E. Bégin[a,*] and **G. Ells**[b]

[a]Centre de Recherche Lipergen, Sherbrooke, Québec, Canada J1J 3H3 and [b]Efamol Research Institute, Kentville, Nova Scotia, Canada B4N 4H8

To clarify the mechanism by which gammalinolenic acid (GLA) is more tumoricidal than docosahexaenoic acid (DHA), we have compared the incorporation of the respective exogenously added ethyl esters GLAe and DHAe into the phospholipids of tumorigenic ZR-75-1 and non-tumorigenic CV-1 cells relative to the ability of the cells to survive and to accumulate thiobarbituric acid reactive substances (TBARS). GLA and DHA were incorporated in the phospholipids to the same extent, but GLA disappeared more rapidly than DHA in both cell lines. GLAe induced about twice as much intracellular TBARS as DHAe in both cell lines, but killed ZR-75-1 cells four times more effectively than DHAe. DHAe induced 11–15 fmoles malondialdehyde-equivalents (MDA-eq)/cell in both ZR-75-1 and CV-1 cells, whereas GLAe induced 5–6 times more TBARS in ZR-75-1 cells (26–30 fmoles MDA-eq/cell) than in CV-1 cells (5–6 fmoles MDA-eq/cell). The results show that there is no difference in GLA and DHA incorporation into phospholipids, but that their metabolism differs in the two cell types. The data also suggest that the cytocidal potential is related to TBARS levels in a nonlinear fashion. The relationship between excess prostaglandin production and excessive cell death due to GLA is discussed.

Lipids 27, 147-149 (1992).

Previous studies have shown that gammalinolenic acid (GLA, 18:3n-6) kills tumorigenic cells at concentrations that are not cytocidal to non-tumorigenic cells (1,2). In contrast, docosahexaenoic acid (DHA, 22:6n-3) at the same concentrations affects tumorigenic and non-tumorigenic cells to a similar extent and kills significantly less cells than GLA (1,3). Using ZR-75-1 and CV-1 cells as model test systems, it was shown that GLA-induced cytotoxicity was associated with increased generation of oxygenated free radicals and with lipid peroxidation (4–6).

In cell free systems, the rate of fatty acid peroxidation is generally related to the number of double bonds. Since DHA (with 6 double bonds) would be more readily peroxidized than GLA (with three double bonds) (7,8), the difference observed between the cytocidal potential of GLA and DHA would suggest that the tumoricidal effects of GLA would only be related in part to autoxidation. It appears reasonable to assume that observed differences in tumoricidal effects also reflect differences in the uptake and the metabolic pathways between GLA and DHA. In the present study, we compare the incorporation of exogenously added DHAe and GLAe into the phospholipids of ZR-75-1 and CV-1 cells with the ability of the cells to survive and to accumulate TBARS.

Abbreviations: DHA, docosahexaenoic acid; DHAe, docosahexaenoic acid ethyl ester; GLA, gammalinolenic acid; GLAe, gammalinolenic acid ethyl ester; MDA-eq, malondialdehyde-equivalent; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substances.

MATERIALS AND METHODS

Materials. Ethyl esters of GLA (GLAe) and DHA (DHAe) (>99% pure) were purchased from NuChek Prep (Elysian, MN). 1,1,3,3-Tetramethoxypropane was obtained from Aldrich (Milwaukee, WI).

Fatty acids. Ethyl esters of GLA and DHA were dissolved in absolute ethanol and stored as stock solutions (10 mg/mL) under a nitrogen atmosphere at −75°C. For experiments, dilutions were freshly prepared from stock solutions using growth medium so that the final ethanol concentration equaled 0.2%.

Cells. Human breast (ZR-75-1) carcinoma cells and established normal simian kidney cells (CV-1) were obtained from the American Type Culture Collection. Stock cultures were grown in glass bottles in bicarbonate-buffered Dulbecco's modified Eagle medium containing 10% fetal calf serum, 2 mM glutamine, 50 μg gentamicin/mL and 2.5 μg fungizone/mL of growth medium. The same serum was used throughout; it contained less than 0.1 μg/mL of GLA and DHA.

Cell viability counts. Cells were seeded at 1×10^4 cells/well in 24-well tissue culture plates as previously described (1). One day after seeding, one set of cultures was supplemented with 20 μg/mL (*ca.* 60 μM) of GLAe or DHAe and incubated in 0.5 mL of growth medium at 37°C in a 5% CO_2 humidified incubator without medium change for the duration of the experiment. Unsupplemented control cultures received 0.2% final concentration of ethanol and were incubated in parallel. The concentration of added ethanol in the control cultures was equivalent to the concentration of ethanol present in supplemented cultures. Supplemented and unsupplemented cultures were examined in parallel after identical incubation periods. Cell viability counts were determined by trypan blue exclusion in a Neubauer hemacytometer. Before counting, the cells were detached following treatment with trypsin-EDTA solution, pooled, and centrifuged in their respective culture medium. The percentage of dead cells was evaluated as the number of stained cells × 100/total number of cells.

Intracellular TBARS levels. Cultures were made from 5×10^4 cells seeded in 35-mm culture dishes. One day after seeding, the medium was removed and the cultures were supplemented with 20 μg/mL of GLAe or DHAe, or kept unsupplemented, and incubated in 2 mL of growth

medium as described above. At the indicated times, cells were detached by trypsinization, washed in PBS, and assayed for TBARS according to the method of Gavino *et al.* (9). Briefly, 1 mL of 20% trichloroacetic acid was added to 2 mL of cells resuspended in PBS, pH 7.0. Two mL of 0.67% TBA was added. This mixture was incubated for 20 min at 90°C and centrifuged at 1200 × *g* for 10 min at 4°C. The absorbance of the supernatant was measured at 532 nm using PBS as a reference. Absorbance was converted to pmoles MDA-eq from a standard curve using 1,1,3,3-tetramethoxypropane as the source of malondialdehyde. All experiments were done at least in triplicate.

TBARS levels in cell-free cultures. Two mL of growth medium in 35-mm culture dishes were supplemented with 20 μg/mL of GLAe or DHAe and incubated as described above. Culture dishes containing growth medium (but without GLAe or DHAe supplementation) were incubated in parallel under otherwise similar conditions. At the indicated time points, the medium was assayed for TBARS according to the method of Gavino *et al.* (9) as described above. Growth medium was used as a reference. All experiments were done in triplicate.

Phospholipid fatty acids. Cell cultures seeded with 6 × 10^6 cells per 243 × 243 × 18 mm Bio-Assay dish (Nunc) were challenged with GLAe or DHAe, as described above. At 1, 3 and 7 days after supplementation, the cells were trypsinized and washed three times with PBS, pH 7.0. Lipids were extracted from cell pellets which had been resuspended in 0.1 volume of PBS with chloroform/methanol (2:1, v/v) containing 0.02% butylated hydroxytoluene (BHT) in 16 × 125 mm tubes. After centrifugation, the lower phase was taken to dryness and redissolved in 100 μL of high-performance liquid chromatography (HPLC) grade chloroform. The total phospholipid fraction was separated by thin-layer chromatography using a solvent system consisting of hexane/diethyl ether/acetic acid (80:20:1, v/v/v). Methyl esters were prepared by treatment of samples with 14% boron trifluoride in methanol and the relative fatty acid composition was determined by gas-liquid chromatography according to Manku *et al.* (10).

Statistical analysis. The results are expressed as mean ± SD. One-way analysis of variance (ANOVA) was used to test significant variations between the fatty acid treatments. Statistical significance was analyzed by two-tailed Student's *t*-test.

RESULTS AND DISCUSSION

Table 1 shows that both ZR-75-1 and CV-1 cells had incorporated GLA and DHA into their phospholipids to the same extent at day 1 after supplementation. The levels of GLA were maximal in both ZR-75-1 and CV-1 cells after the first day of supplementation and decreased significantly thereafter. In contrast, the proportion of DHA was maximal at day 3 and decreased thereafter in both cell lines at a slower rate than was seen for GLA. After day 1, the proportion of DHA remained 2–10 times higher than the levels of GLA in both cell lines.

Table 2 demonstrates that more TBARS were found in cells supplemented with the fatty acids than in unsup-

plemented cells. GLAe induced about 5–6 times more TBARS in ZR-75-1 cells than in CV-1 cells. In contrast, the TBARS levels found in ZR-75-1 and CV-1 cells exposed to DHAe were the same and reached about half the TBARS levels found in GLAe-supplemented ZR-75-1 cells. Conversely, DHAe as compared to GLAe generated the greatest accumulation of TBARS in a cell-free system (Table 3).

The percentage of dead cells were highest in ZR-75-1 cells treated with GLAe. This cytocidal effect corresponded to the higher TBARS levels in ZR-75-1 cells as compared to those in CV-1 cells. Lower TBARS levels with DHA corresponded to lower cytocidal activity in relation to GLA. However, higher TBARS with DHA-treated cells did not affect cytotoxicity relative to untreated controls.

The data show that there is no difference in GLA and DHA incorporation into phospholipids, but that their metabolism differs in the two cell types and that the cytocidal potential relates nonlinearly to TBARS levels. The nature of the TBARS has not been established here but it is plausible that hydroperoxide and endoperoxide degradation products account chiefly for the TBARS levels detected in the fatty acid-supplemented cells. It is well recognized that both GLA and DHA produce hydroperoxides by nonenzymatic mechanisms, such as autoxidation processes, but GLA can also be metabolized to dihomogammalinolenic acid and, to some extent, to arachidonic acid, both of which enzymatically give rise to prostaglandins, whereas DHA is a potent inhibitor of prostaglandin synthesis (11). Thus, the ability of GLA to produce endoperoxide and endoperoxide breakdown products suggests that the difference observed in GLA and TBARS levels might be associated with prostaglandin synthesis and that they may contribute to the cytocidal effects. Another possibility is that DHA could influence the availability of arachidonic acid for endoperoxides (12). Although plausible, this hypothesis is less likely because previous studies have demonstrated that eicosanoid synthesis is not involved in the cytocidal effects of GLA (4,13). Thus, a different radical-driven process developing in parallel or concurrently to prostaglandin synthesis and/or autoxidation may be operative (4,5). Whether or not this relates to the gradual accumulation of conjugated trienes, which has been reported to be associated with lethal treatments, remains to be determined (14). The results substantiate the hypothesis that n-6 and n-3 polyunsaturated fatty acids induce cytotoxic effects by differing mechanisms (13,15).

To differentiate between these possibilities, and because of the uncertainties in comparing tissues of different origins, the use of genetically-related tumorigenic and non-tumorigenic cells would be desirable. Using a series of closely-related tumorigenic and non-tumorigenic cell lines, we have confirmed that tumorigenic cell lines were more sensitive than corresponding non-tumorigenic cell variants to GLA challenge (2,16). Hence, these cell lines should prove suitable for comparing possible mechanisms of the cytocidal mode of action of GLA, DHA and other n-6 and n-3 polyunsaturated fatty acids.

Phospholipid Composition of Cultured Human Endothelial Cells

Eric J. Murphy[a,*], Laurie Joseph[b,1], Ralph Stephens[b] and Lloyd A. Horrocks[a]
[a]Department of Medical Biochemistry and Neuroscience Program and [b]Department of Pathology, The Ohio State University, Columbus, Ohio 43210

Detailed analyses of the phospholipid compositions of cultured human endothelial cells are reported here. No significant differences were found between the phospholipid compositions of cells from human artery, saphenous and umbilical vein. However, due to the small sample sizes, relatively large standard deviations for some of the phospholipid classes were observed. A representative composition of endothelial cells is: phosphatidylcholine 36.6%, choline plasmalogen 3.7%, phosphatidylethanolamine 10.2%, ethanolamine plasmalogen 7.6%, sphingomyelin 10.8%, phosphatidylserine 7.1%, lysophosphatidylcholine 7.5%, phosphatidylinositol 3.1%, lysophosphatidylethanolamine 3.6%, phosphatidylinositol 4,5-bisphosphate 1.8%, phosphatidic acid 1.9%, phosphatidylinositol 4-phosphate 1.5%, and cardiolipin 1.9%. The cells possess high choline plasmalogen and lysophosphatidylethanolamine contents. The other phospholipids are within the normal biological ranges expected. Phospholipids were separated by high-performance liquid chromatography and quantified by lipid phosphorus assay.
***Lipids* 27, 150-153 (1992).**

Phospholipids, and particularly the polyphosphoinositides, play an important role in endothelial cell receptor function. Stimulation of the bradykinin receptor has been shown to affect polyphosphoinositide turnover in endothelial cells (1,2). This turnover is mediated by the combined action of phospholipase C and diacylglycerol lipase on the polyphosphoinositides, thereby releasing arachidonic acid (3,4). Several alternative pathways have been proposed for arachidonic acid release in endothelial cells. These include the action of phospholipase A_2 (5,6) and a combined calcium independent phospholipase A_1 and lysophospholipase pathway (4). In other cell systems, decreases in choline plasmalogen have been linked to bradykinin receptor activation (7).

Plasmalogen hydrolysis has been implicated in several receptor mechanisms which result in release of arachidonic acid (8). Phosphatidylcholine (PtdCho) is a major contributor of arachidonic acid following thrombin stimulation (6) or stimulation by the calcium ionophore A23187 (9). These decreases in PtdCho may be due to the hydrolysis of choline plasmalogen (7,8) or the receptor mediated breakdown of PtdCho (10,11). Regardless, these receptor mechanisms all involve the degradation of membrane phospholipids resulting in the release of arachidonic acid for eicosanoid formation (12-17).

Partial phospholipid compositions of endothelial cells have been reported for different species (5,18-25). However, in order to better understand the role of phospholipids in receptor function, the complete and detailed phospholipid composition of endothelial cells needs to be known. In the present study, the phospholipid compositions of human endothelial cells from three vascular sources were compared in order to determine whether phospholipid composition is dependent upon the vascular source. This report is the first to describe the simultaneous extraction and high-performance liquid chromatography (HPLC) separation of plasmalogens and polyphosphoinositides from cultured cells.

MATERIALS AND METHODS

Three vascular sources were used to establish separate human endothelial cell cultures. Cells were isolated from cadaver aorta artery, from bypass patient's saphenous vein, and from newborn umbilical veins by treating the luminal surface with 0.1% type II collagenase (26). The cells were plated on human fibronectin coated glass tissue culture flask (23 cm^2) containing M-199 media Gibco (Gaithersburg, MD) supplemented with 10% fetal bovine serum, 150 μg/mL endothelial cell growth factor (27), 90 μg/mL Na-heparin (28), and antibiotics. The cells in a flask upon reaching confluency were split and plated on 100-mm glass cell culture plates. Cells were used from passage 5 through 12. Their endothelial origin was confirmed by the presence of factor VIII antigen (29).

Confluent cells were extracted using n-hexane/2-propanol (3:2, v/v) (30). The use of this extraction method avoids the use of toxic solvents, decreases the amount of extractable protein, and avoids the loss of water-soluble phospholipids. Prior to extraction the medium was removed and the cells were washed with two 3-mL portions of cold PBS buffer to remove traces of medium. The plates were immediately placed upon dry ice prior to extraction and frozen to minimize membrane damage and activation of acylhydrolases during extraction (31). Two 3-mL aliquots of n-hexane/2-propanol (3:2, v/v) were used to extract the lipids from the cells. The initial aliquot was added to the frozen cells which were subsequently removed from the plate by using a Teflon cell scraper. The second aliquot was used to rinse the plate. Most cellular debris was removed by filtration through glass wool. The extracts were kept under N_2 to minimize auto-oxidation of lipids.

Extracts were stored at −20°C. Prior to phospholipid separation, the cells were subjected to ultrafiltration using a Rainin 0.2 μm Nylon filter (Woburn, MA). The sample was dried under nitrogen and redissolved in a known

Abbreviations: Cer*P*Cho, sphingomyelin; Gpl, glycerophospholipid; HAE, human arterial endothelial; HPLC, high-performance liquid chromatography; HSVE, human saphenous vein endothelial; HUVE, human umbilical vein endothelial; lysoPtdCho, lysophosphatidylcholine; lysoPtdEtn, lysophosphatidylethanolamine; PlsCho, choline plasmalogen; PtdCho, phosphatidylcholine; PlsEtn, ethanolamine plasmalogen; PtdEtn, phosphatidylethanolamine; Ptd_2Gro, cardiolipin; PtdIns, phosphatidylinositol; PtdIns4*P* phosphatidylinositol 4-phosphate; PtdIns(4,5)P_2, phosphatidylinositol 4,5-bisphosphate; PtdOH, phosphatidic acid; PtdSer, phosphatidylserine; TLC, thin-layer chromatography.

volume of n-hexane/2-propanol/water (3:2, + 5.5% by volume) prior to high-performance liquid chromatography (HPLC).

The cell extracts were separated into major phospholipid classes by HPLC. Solvents used were HPLC grade n-hexane and 2-propanol from E.M. Science (Cherry Hill, NJ). Solvents were filtered through a 0.5-μm Millipore FH-type Nylon filter (Bedford, MA) and degassed. Solvent A was n-hexane/2-propanol (3:2, v/v), solvent B was n-hexane/2-propanol/water (3:2 + 5.5% by volume). Water was purified using a Millipore water purification system. The HPLC instrument consisted of two Altex (Berkeley, CA) 100A pumps, an Altex 420/421 controller and an Altex model 210 injection port. The Dupont Zorbax Silica column (4.6 mm × 250 mm 5–6 μm; Wilmington, DE) was maintained at a constant temperature of 34°C using a Jones chromatography heating block (Columbus, OH). An ISCO (Lincoln, NE) V4 ultraviolet (UV) variable wave length detector was used to detect peaks at 205 nm.

The chromatographic procedure (32) permitted the separation of the major phospholipids including the separation of the acidic phospholipids phosphatidylserine (PtdSer) and phosphatidylinositol (PtdIns) as well as the resolution of lysophosphatidylethanolamine (lysoPtdEtn). The polyphosphoinositides were also separated (33). Retention times for each phospholipid class were according to polarity with the elution order being from least polar to most polar. The lower limit of sensitivity was 100 nmol of injected lipid phosphorus.

Plasmalogens were separated by HPLC after acidic hydrolysis (34). The ethanolamine glycerophospholipid (EtnGpl) and choline glycerophospholipid (ChoGpl) peaks were collected, dried under N_2, and then inverted over 5 drops of concentrated hydrochloric acid in a test tube cap for two minutes. This caused hydrolysis of the alkenyl ether bond of the plasmalogens while the alkylacyl and diacyl bonds remained intact. The sample was reextracted and rechromatographed utilizing the same separation procedure as used in the initial separation.

The alkylacyl and diacyl fractions were then collected and subjected to alkaline hydrolysis in 2 mL of 0.1 M NaOH in methanol. After 15 min the reaction was terminated by addition of 1 mL of ethyl formate (35). Cleavage of the alkali-labile ester linkage caused formation of glycerophosphocholine or glycerophosphoethanolamine and of alkylglycerophosphocholine or alkylglycerophosphoethanolamine. The products were separated following extraction of the methanol phase with chloroform/isobutanol/water (4:2:3, v/v/v) followed by centrifugation to facilitate phase separation. The top layer contained glycerophosphocholine or glycerophosphoethanolamine, the bottom layer contained the ether lysophospholipids.

Phospholipid classes were quantitated by measuring lipid phosphorus (36).

RESULTS

The compositions of human saphenous vein (HSVE), human umbilical vein (HUVE) and human arterial endothelial cells (HAE) are reported in Table 1. LysoPtdEtn represented an abnormally high mole percentage of the total lipid phosphorus in the cells from all sources. The polyphosphoinositide values are also reported. No statistically significant differences in the proportions of phospholipid classes were found between the various sources of endothelial cells. The most important finding is the high lysoPtdEtn level seen in all three sources.

Because no differences were found between the major phospholipids from various sources, the plasmalogen content of only the HUVE cells was determined. The PlsEtn content was 40.5% of the EtnGpl and the PlsCho content was 11.6% of ChoGpl. These values represent 7.1% and 5.0% respectively of the total lipid phosphorus. The compositions of the choline and ethanolamine glycerophospholipid subclasses are listed in Table 2.

The amount of lipid phosphorus injected onto the column was at or below the desirable lower limit of sensitivity (100 nmol) due to the small sample sizes available from

TABLE 1

Phospholipid Composition of Cultured Human Endothelial Cells[a]

	HUVE n = 12 × S.D.	HSVE n = 10 × S.D.	HAE n = 12 × S.D.
Ptd_2Gro	2.60 ± 2.88	2.06 ± 1.05	1.08 ± 0.85
PtdEtn+	17.63 ± 1.98	16.86 ± 3.11	19.06 ± 3.78
PtdOH	2.37 ± 3.09	1.81 ± 1.64	1.56 ± 0.76
PtdIns	1.90 ± 3.09	2.99 ± 2.21	4.26 ± 2.31
lysoPtdEtn	3.12 ± 3.36	5.26 ± 2.22	2.54 ± 2.07
PtdSer	5.36 ± 2.70	8.86 ± 1.76	7.15 ± 2.87
PtdCho+	42.76 ± 6.26	39.03 ± 6.56	39.12 ± 3.92
Cer*P*Cho	8.91 ± 2.69	10.52 ± 2.39	12.96 ± 5.04
PtdIns4P	1.56 ± 1.75	1.19 ± 0.94	1.90 ± 1.83
lysoPtdCho	7.53 ± 5.04	8.07 ± 4.68	7.02 ± 4.84
$PtdIns4,5P_2$	1.24 ± 0.94	1.99 ± 1.05	2.09 ± 1.26

[a]Values are mole % of total phospholipid. Tukey's multiple comparison test was used for statistical evaluation. +PtdEtn and PtdCho represent the sum of alkenylacyl, alkylacyl and diacyl fractions. Abbreviations are: Cer*P*Cho, sphingomyelin; HAE, human arterial endothelial; HSVE, human saphenous vein endothelial; HUVE, human umbilical vein endothelial; lysoPtdCho, lysophosphatidylcholine; lysoPtdEtn, lysophosphatidylethanolamine; PlsCho, choline plasmalogen; PtdCho, phosphatidylcholine; PlsEtn, ethanolamine plasmalogen; PtdEtn, phosphatidylethanolamine; Ptd_2Gro, cardiolipin; PtdIns, phosphatidylinositol; PtdIns4*P*, phosphatidylinositol 4-phosphate; PtdIns(4,5)P_2, phosphatidylinositol 4,5-bisphosphate; PtdOH phosphatidic acid; PtdSer phosphatidylserine.

TABLE 2

Composition of Ethanolamine and Choline Glycerophospholipid Subclasses[a]

	EtnGpl class (%)	Total Gpl (%)
Diacyl	45.2 ± 1.4	8.0
Alkenylacyl	40.5 ± 1.9	7.1
Alkylacyl	14.3 ± 0.5	2.5
	ChoGpl class (%)	**Total Gpl (%)**
Diacyl	78.4 ± 1.1	33.5
Alkenylacyl	11.6 ± 0.9	5.0
Alkylacyl	10.0 ± 1.6	4.3

[a]The values are means ± standard deviations. For EtnGpl and ChoGpl, n = 4. Abbreviations are: EtnGpl, ethanolamine glycerophospholipid; ChoGpl, choline glycerophospholipid; and Gpl, glycerophospholipid.

the cultures. Thus, the variability between samples increases especially for phospholipid classes that represent a small percentage of total lipid phosphorus.

DISCUSSION

The purpose of this study was to determine the phospholipid composition of human endothelial cells in culture and the dependence of this composition on the vascular source. The separation of phospholipids by HPLC allows for good recovery of all phospholipids, improved phosphorus determination and detection of smaller changes in phospholipid composition with statistical significance due to a lower variance than based on thin-layer chromatography (TLC) (37). The extraction procedure used permits a good recovery of phospholipids while minimizing the amount of protein in the extract. The procedure increases polyphosphoinositide recovery and avoids the need for a two-phase system which can cause losses of lysoglycerophospholipids (30). Freezing the cells prior to extraction decreases the mechanical trauma incurred by the cells during their removal from the plates (31). Hence, our values should represent more closely the actual composition of the cells in culture.

Several papers have reported partial phospholipid compositions of endothelial cells from various vascular sources and species (5,19–25). A composition of 25.3% PtdEtn, 36.3% PtdCho and 12.8% Cer*P*Cho in HUVE cells has been reported by Rastogi and Nordøy (19), which is similar to our data. A plasmalogen content in HUVE cells of 42.5% PlsEtn in EtnGpl and 6.8% PlsCho in ChoGpl has been reported by Blank *et al.* (22). However, their values for the choline glycerophospholipid diacyl (88.6%) and alkylacyl (4.6%) subclasses differ from our values of 78.4% and 10%, respectively. The reported values for the two ethanolamine glycerophospholipid subclasses were 52.6% for the diacyl and 4.9% for the alkylacyl fractions (22). Our values were 45.3% and 14.3% for the diacyl and alkylacyl subclasses, respectively. These differences may reflect the different methodologies used to quantitate the EtnGpl and ChoGpl subclasses.

Values for the proportions of choline and ethanolamine glycerophospholipid subclasses reported by Takamura *et al.* (25) also differ from our values. The differences could be due to the different methodology used to separate the subclasses. The reported phospholipid compositions for both umbilical vein and arterial endothelial cells (25) are also considerably different from our values. Phospholipid separations by TLC usually have lower recoveries than HPLC separations (our recoveries are 98.3% ± 3), and TLC may not completely resolve all classes of phospholipids because of the lower number of theoretical plates.

Values for PtdEtn and PtdCho composition from rat and human brain endothelial cells (24) compare closely to our values, although a difference exists in Cer*P*Cho contents with 20.4% and 17.0% for rat and human brain, respectively, compared with our value of 10.8%. The difference may be due the fact that the cells were freshly isolated, and not cultured. Isolated rat brain endothelial cells have 46.3% PlsEtn in EtnGpl (18), which is close to our value. The polyphosphoinositide content of endothelial cells has not been reported previously for any species. Guinea pig brain contains 0.58% PtdIns4*P* and 2.58% PtdIns (4,5)P_2 (38). Our values are within this range. Our data compare favorably to several literature values for the partial phospholipid composition of endothelial cells from various species and vascular sources and are the first to include polyphosphoinositides.

The cells exhibited a high lysoPtdEtn and a relatively high lysoPtdCho content. The position of the fatty acid was not determined. Regardless of fatty acid position, these lysophospholipids are known to have detergent properties on cellular membranes (39). High concentrations of endogenous lysophospholipids are generally assumed to increase membrane fluidity and to give rise to subtle changes in cellular surface. The high levels in human endothelial cells may be related to the apparent ease of thrombosis (40). Increases in membrane fluidity may also cause the cell membrane to be more susceptible to mechanical damage accounting for the observed morphological changes such as crater formation in endothelial cells (41). High levels of lysolipid may modulate the effect of injury and interaction of the endothelium with various hormones (42) because lysophospholipids can alter the functioning of membrane-bound enzymes (39,43).

Endothelial cells play a major role in vascular homeostasis (40). In order to understand the lipid metabolism of endothelial cells, the basic phospholipid composition must be known. It has been hypothesized that lipid composition varies with vascular source based on observations of ultrastructural differences depending on vessel size and location (19). In this study no dependence of phospholipid composition on vascular source was found. However, it should be noted that in some phospholipid classes the standard deviations were high. This is especially true for phospholipids which make up a small percentage of the total phospholipids. Differences in phospholipid classes molecular species dependent upon vascular source were not ruled out.

ACKNOWLEDGMENTS

We thank Diana Carter for her help in the preparation of the manuscript, Patrick Vaccaro for providing the tissues, Mark Armeni for assistance in cell culture and extraction procedures, Lynda Titterington for growing the cells, Robert Hancock for assistance in the statistical calculations, and Laura Dugan for her advice with the HPLC separations. This work was supported in part by National Institutes of Health research grant NS-10165.

[Received July 9, 1990, and in revised form December 27, 1991; Revision accepted December 28, 1991]

Unusual Tetraene Sterols in Some Phytoplankton

G.W. Patterson*[,a], P.K. Gladu[b], G.H. Wikfors[c] and W.R. Lusby[d]

[a]Department of Botany, University of Maryland, College Park, Maryland 20742, [b]Department of Biology, Lindsey Wilson College, Columbia, Kentucky 42728, [c]NOAA, National Marine Fisheries Service, Northeast Fisheries Center, Milford, Connecticut 06460 and [d]Insect Neurobiology and Hormone Laboratory, Agricultural Research Service, U.S. Department of Agriculture, Beltsville, Maryland 20705

Sterols were analyzed from four phytoplankton strains which are under investigation as possible sources of food for oysters in culture. One strain of *Pyramimonas* contained only 24-methylenecholesterol as a major sterol component. *Pyramimonas grossii, Chlorella autotrophica* and *Dunaliella tertiolecta* each contained a complex mixture of C_{28} and C_{29} sterols with Δ^7, $\Delta^{5,7}$ and $\Delta^{5,7,9(11)}$ nuclear double bond systems. Sterols were found both with and without the C-22 side chain double bond. Ergosterol and 7-dehydroporiferasterol were the principal sterols in each of the latter three species, which also contained the rare tetraene sterols, 24-methylcholesta-5,7,9(11),22-tetraen-3β-ol and 24-ethylcholesta-5,7,9(11),22-tetraen-3β-ol.
***Lipids* 27, 154–156 (1992).**

Most marine invertebrates examined have a complex sterol composition attributed to lack of sterol synthesis in the animal and incorporation of a wide variety of dietary sterols into the animal tissue (1). The oyster (*Crassostrea virginica*) has been shown to contain over forty sterols (2–4), but it cannot synthesize any of them from acetate (5–7). Recent research shows a strong correlation between oyster growth rate and the type and amount of dietary sterol present (8).

Approximately 60% of total oyster sterol is cholesterol, 24-methylenecholesterol and 24-methyl-22-dehydrocholesterol (2). The latter two sterols are found in specific diatoms (9) occurring in the estuarine environments, and several diatoms are known to provide a good food source for oysters (10). The source of the oyster's cholesterol has not been identified and most phytoplankton do not contain more than trace quantities of it (9).

The work described here is part of an effort to improve our knowledge of the effect of dietary sterol on oyster growth rates by examining a wide range of phytoplankton with varied sterol composition which are within the size range utilized by the oyster.

MATERIALS AND METHODS

Axenically cultured algae (strains 580, De, and 78) obtained from the Milford microalgal culture collection were prepared for analysis as previously described (11). Pyram 2 was a gift from Jeff Johanson of the Solar Energy Research Institute (Golden, CO). Dry algal samples (0.3–1.0 g) were extracted with $CHCl_3$/MeOH and sterols were isolated from the non-saponifiable lipid (11). Sterols were analyzed on a 30 m × 0.25 μm fused silica capillary column with a 0.25 mm film of SPB-1 (Supelco, Bellefonte, PA) at 255°C in a Varian Model 3500 chromatograph equipped with a Varian Model 8100 autosampler, an on-column injector, and a hydrogen flame detector (Varian Associates, Palo Alto, CA). Each unknown was injected alone and with a cholesterol standard for relative retention time (RRT) determination. Sterol identity was confirmed by electron impact gas chromatography/mass spectrometry (GC/MS) with a 30 m × 0.32 mm i.d. fused silica capillary column with a 0.25 mm film of DB-1.

RESULTS AND DISCUSSION

Pyramimonas sp. had a simple sterol composition of 99% 24-methylenecholesterol and 1% cholesterol (Table 1). However, the compositions of *Pyramimonas grossii, Chlorella autotrophica* and *Dunaliella tertiolecta* were complex. The principal sterols of *D. tertiolecta* and *C. autotrophica* have been identified previously as ergosterol and 7-dehydroporiferasterol (7,12), but detailed sterol analyses were not reported in either case. In *D. tertiolecta* the side chain methyl and ethyl of these compounds were determined by ^{13}C nuclear magnetic resonance spectrometry to be oriented in the β position (12). Side chain stereochemistry of *C. autotrophica* was not determined, but in other *Chlorella* species where it was determined, the C-24 methyl and ethyl groups were also β-oriented (9,13).

In this work, capillary gas chromatography confirmed the presence of major peaks for the above two sterols but

TABLE 1

Abundance of Sterols in Four Cultured Algae[a]

Sterol	RRT	Species[b] 1	2	3	4
Cholesterol	1.00	—	—	—	1
24-Methylenecholesterol	1.20	—	—	—	99
9(11)-Dehydroergosterol	1.08	3	1	1	—
Ergosterol	1.18	36	22	31	—
5-Dihydroergosterol	1.23	1	5	3	—
Ergost-5,7-dienol	1.35	3	—	—	—
Ergost-7-enol	1.41	20	8	4	—
Stigmasta-5,7,9(11),22-tetraenol	1.33	3	2	2	—
7-Dehydroporiferasterol	1.46	23	46	53	—
Stigmasta-7,22-dienol	1.51	1	9	4	—
Stigmasta-5,7-dienol	1.66	1	—	—	—
Stigmast-7-enol	1.71	6	4	1	—

[a]Abundances are expressed as % of total sterol. RRT are relative to cholesterol. C-24 orientation was not determined for any compound.

[b]Cultures were obtained from the Milford Culture Collection (strain No. in parentheses) except for *Pyramimonas* sp., which was from the Solar Energy Research Center.

1, *Chlorella autotrophica* (580); 2, *Dunaliella tertiolecta* (De); 3, *Pyramimonas grossi* (78); 4, *Pyramimonas* sp. (Pyram 2).

Abbreviations: GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; RRT, relative retention time.

also detected the presence of a number of additional compounds. GC/MS enabled the identification of 7(8)-monoene sterols and 7,22-diene sterols with 28 and 29 carbon atoms (Table 1). In each case mass spectra were identical with those of reference compounds isolated from *Chlorella emersonii* (14). A small amount of 14α-methyl-5α-stigmast-9(11)-enol was identified in *Chlorella autotrophica* by comparison of its mass spectra with those reported by the Akihisa group (15,16). The 24α-epimer of this sterol (all sterols of *Chlorella* to date are 24β) has been reported in *Cucumis sativa* (15), and 14-methyl-5α-ergost-9(11)-enol has been reported recently in *Chlorella vulgaris* (16). Also detected were C_{28} and C_{29} tetraene sterols with GC retention times shorter than for the corresponding trienols ergosterol and 7-dehydroporiferasterol.

Tetraene sterols are not common, but a number of them are known to occur in living organisms. Cholesta-5,7,22,24-tetraenol has been isolated from *Tribolium confusum*, where it is an intermediate in the dealkylation of stigmasterol to cholesterol (17). Known tetraethenoid C_{28} sterols include 14-dehydroergosterol from a strain of *Aspergillus niger* (18), 24-dehydroergosterol from yeast (19), 25(27)-dehydroergosterol (protothecasterol) from the colorless alga, *Prototheca* (20), and 9(11)-dehydroergosterol from *Giberella fujikuroi*, *Candida lipolytica* and *Chlorella vulgaris* (16,21,22). The tetraene sterol reported here from *Chlorella*, *Dunaliella* and *Pyramimonas* has gas chromatographic characteristics (Table 1) and mass spectra identical to those of a synthetic sample of 9(11)-dehydroergosterol provided by Nes (20). Major mass spectra peaks were observed for the free sterol at *m/z* (rel. abundance), 394(8), 376(17), 361(3), 251(100) and 69(100).

Each of the algae containing 9(11)-dehydroergosterol also contained a C_{29} tetraene. Gas chromatographic retention times were 1.23 times those of the C_{28} tetraene in each case (Table 1), which is the increase expected for the addition of an extra carbon at C-28. Mass spectra of the tetraene from each alga were identical and were very similar to those of the C_{28} tetraene, especially with respect to the dominant base peak at *m/z* 251. This compound is identified as 24-ethylcholesta-5,7,9(11),22-tetraenol, a compound to our knowledge not previously reported to occur in nature. Species previously shown to produce C_{28} tetraenes did not produce C_{29} sterols (16,18–22). *Chlorella autotrophica*, *D. tertiolecta* and *P. grossii* each produces a mixture of C_{28} and C_{29} monoenes, dienes, trienes and tetraenes.

Gibberella produced 9(11)-dehydroergosterol only in stationary phase cultures (19). It should be pointed out that the cultures examined here also were harvested from the stationary phase. Detailed analyses from log phase cultures of these algae are not available. Such data may be important in the culture of algae for oyster rearing, because recent data from our laboratories indicate a correlation between algal sterol composition and the growth rates of oysters fed unialgal diets (8).

Neither the metabolic origin nor the role of 9(11)-dehydroergosterol is known. Its accumulation in stationary phase cultures prompts speculation of a new pathway *via* parkeol (lanosta-9(11),24-dien-3β-ol) or alternately by the dehydrogenation of ergosterol. The sterol composition of *D. tertiolecta* determined here is in agreement with that reported in previous work (12). It should be noted that while two other *Dunaliella* species have been reported to contain principally $\Delta^{5,7}$-sterols (23,24), *D. minuta* has 24-methylenecholesterol and 24-methylcholesterol as principal sterols (25), and *D. acidophila* contains 24-ethylcholesterol and 24-ethylidenecholesterol as its major sterols (26). An unialgal diet of *D. tertiolecta* supports moderate growth of oysters (27). Because sterol composition varies widely from species to species, the comparative nutritional value of these species is of great interest.

In our studies, oysters grew more poorly on *P. grossii* than on *D. tertiolecta* (G.H. Wikfors, unpublished data). We have no nutritional data on *Pyramimonas* sp. It is interesting to note that (as is the case with *Dunaliella*), sterol composition varies widely with species in *Pyramimonas*. In contrast with the species of *Pyramimonas* studied here, Volkman (28) has found isofucosterol to be the principal sterol of *Pyramimonas gelidicola*. In many phytoplankton taxa, names and taxonomic affinities of species are in a constant state of flux. More work, especially on taxonomy, will be necessary to determine whether these three genera have the variety of sterols they now appear to have.

ARTICLE

Inhibition of Cholesterol Synthesis by Cyclopropylamine Derivatives of Squalene in Human Hepatoblastoma Cells in Culture

W.A. Van Sickle*, M.R. Angelastro, P. Wilson, J.R. Cooper, A. Marquart and **M.A. Flanagan**
Marion Merrell Dow Research Institute, Cincinnati, Ohio 45215

Two squalene derivatives, trisnorsqualene cyclopropylamine and trisnorsqualene *N*-methylcyclopropylamine, were synthesized and tested for inhibition of lanosterol and squalene epoxide formation from squalene in rat hepatic microsomes, and for the inhibition of cholesterol synthesis in human cultured hepatoblastoma (HepG2) cells. Trisnorsqualene cyclopropylamine inhibited [^{3}H]-squalene conversion to [^{3}H]squalene epoxide in microsomes (IC_{50} = 5.0 μM), indicating that this derivative inhibited squalene mono-oxygenase. Trisnorsqualene *N*-methylcyclopropylamine inhibited [^{3}H]squalene conversion to [^{3}H]lanosterol (IC_{50} = 12.0 μM) and caused [^{3}H]-squalene epoxide to accumulate in microsomes, indicating that this derivative inhibited 2,3-oxidosqualene cyclase. Cholesterol biosynthesis from [^{14}C]acetate in HepG2 cells was inhibited by both derivatives (IC_{50} = 1.0 μM for trisnorsqualene cyclopropylamine; IC_{50} = 0.5 μM for trisnorsqualene *N*-methylcyclopropylamine). Cells incubated with trisnorsqualene cyclopropylamine accumulated [^{14}C]squalene, while cells incubated with trisnorsqualene *N*-methylcyclopropylamine accumulated [^{14}C]squalene epoxide and [^{14}C]squalene diepoxide. The concentration range of inhibitor which caused these intermediates to accumulate coincided with that which inhibited cholesterol synthesis. The results indicate that cyclopropylamine derivatives of squalene are effective inhibitors of cholesterol synthesis, and that substitutions at the nitrogen affect enzyme selectivity and thus the mechanism of action of the compounds.
Lipids 27, 157–160 (1992).

Hypercholesterolemia is a major risk factor for the development of atherosclerotic vascular disease. Reducing the rate of cholesterol synthesis has been shown to be an effective therapeutic approach to lowering elevated serum cholesterol levels (1). However, the only drug currently available for the treatment of hypercholesterolemia which acts by inhibiting cholesterol synthesis is mevinolin (Lovastatin). This drug inhibits 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in the pathway of cholesterol biosynthesis (2). Two other enzymes in this pathway, squalene mono-oxygenase and 2,3-oxidosqualene cyclase, are also potential therapeutic targets of drugs intended to reduce sterol synthesis (3–8). Because of their position in the biosynthetic sequence, inhibition of either of these enzymes avoids potential problems caused either by reduced synthesis of polyisoprene units or the accumulation of sterol intermediates. Also, partial inhibition of 2,3-oxidosqualene cyclase may cause cells to accumulate oxysterols (9), which act to inhibit cholesterol synthesis indirectly by reducing transcription of the gene encoding for HMG-CoA reductase and by increasing the rate of HMG-CoA reductase degradation (10). We report here that two structurally similar squalene analogues inhibit these enzymes. Trisnorsqualene cyclopropylamine inhibits microsomal squalene mono-oxygenase, and trisnorsqualene *N*-methylcyclopropylamine inhibits microsomal 2,3-oxidosqualene cyclase. Furthermore, we show that both compounds inhibit cholesterol biosynthesis in a human cultured hepatoblastoma cell line, and that this inhibition apparently occurs because of blockade of the respective targeted enzyme.

Abbreviations: FBS, fetal bovine serum; HBSS, Hanks buffered salt solution; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; HPLC, high-performance liquid chromatography; LPDS, lipoprotein-deficient bovine serum; MEM, minimal essential medium.

MATERIALS AND METHODS

Materials. Male Sprague Dawley rats were purchased from Harlan (Indianapolis, IN). Human hepatoblastoma cells (HepG2; ATCC # HB8065) were purchased from American Type Culture Collection (Rockville, MD). Fetal Bovine Serum (FBS), Eagle's Minimal Essential Medium (MEM), T-160 culture flasks and 24-well cluster plates, Hanks Balanced Salt Solution (HBSS), MEM non-essential amino acids (10 mM), trypsin/EDTA (0.25%/1.0 mM), penicillin, streptomycin and glutamine (200 mM) were purchased from GIBCO (Grand Island, NY). Lipoprotein-deficient bovine calf serum (LPDS) was from Biomedical Technologies Inc. (Stoughton, MA). Cholesterol, squalene, lanosterol, FAD, NADPH and Tween-80 were from Sigma (St. Louis, MO). Methanol, hexane, isopropanol and tetrahydrofuran were purchased from Burdick and Jackson (Muskegan, MI). Flo-Scint II scintillation fluid was from Radiomatic (Tampa, FL). [7-^{3}H(N)]Cholesterol (21.0 Ci/mmole), [4,8,12,13,17,21-^{3}H]squalene (28.9 Ci/mmole) and [2-^{14}C]acetic acid (57 mCi/mmole) were from DuPont/New England Nuclear (Wilmington, DE). [^{3}H]Squalene was purified by high-performance liquid chromatography (HPLC) prior to use. Trisnorsqualene cyclopropylamine was prepared by reductive amination of trisnorsqualene aldehyde with cyclopropylamine (8). Subsequent reduction amination of formaldehyde with trisnorsqualene cyclopropylamine gave the expected *N*-methyl derivative. The products were purified by flash chromatography on silica gel. Structures obtained were consistent with spectral data.

Enzyme assays. Rat hepatic microsomes were used as the source of enzymes (11). Squalene mono-oxygenase activity was determined by monitoring the conversion of [^{3}H]squalene to [^{3}H]squalene epoxide, and 2,3-oxidosqualene cyclase activity was determined by monitoring the conversion of [^{3}H]squalene to [^{3}H]lanosterol (11). Trisnorsqualene cyclopropylamine and trisnorsqualene *N*-methylcyclopropylamine were dissolved in methanol and mixed with 100 μL of a solution of 0.1% Tween-80 and 0.6 mM [^{3}H]squalene (sp. act. 5,000 dpm/nmole) in

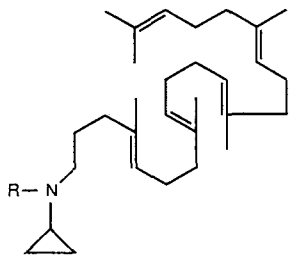
acetone. The solvents were evaporated under N_2 gas, and the residue was dissolved in a mixture of 1.0 mg microsomal protein, 7.0 mg cytosolic protein and 0.01 mM FAD in 0.1 M Tris-HCl, pH 7.4. The volume was adjusted to 950 μL with Tris buffer, and tubes were pre-incubated for 10 min at 37°C. Fifty μL of buffer were added to tubes designated as blanks, and 50 μL of 20 mM NADPH in buffer was added to all other tubes. All tubes were then incubated at 37°C for 45 min. Following incubation, 1.0 mL water was added and products were extracted twice, each time into 2.0 mL hexane. The hexane extracts were combined and dried under N_2 gas. The residue was dissolved in 60 μL tetrahydrofuran/methanol (1:1, v/v) and finally transferred to 200 μL minivials for HPLC analysis.

High-performance liquid chromatography. Samples (45 μL) were injected onto a 3.9 × 300 mm Waters μBondapak ODS column (Waters Associates, Milford, MA) and fractionated isocratically using a solvent of 7% water in methanol delivered at 1.5 mL/min. Peaks were monitored at 200 to 350 nm with a Waters 990 diode array detector, and for radioactivity with a Radiomatic FLO-1β flow-through scintillation detector (Radiomatic) connected in series with the diode array detector. Counting efficiencies were determined by injecting known amounts of either [^{3}H]- or [^{14}C]cholesterol into the HPLC system without an attached column but otherwise using conditions identical to those used for samples. Counting efficiencies were 23% for ^{3}H and 49% for ^{14}C. Recovery of [^{3}H]cholesterol from cell extracts (see below) was 91%.

Cell culture. Stock cultures of HepG2 cells were treated for 5.0 min with trypsin/EDTA at room temperature to detach the cells. The cells were suspended in MEM containing 1.0 mM non-essential amino acids, 2.0 mM L-glutamine, 1.0 mM pyruvate, 100 units/mL penicillin, 100 μg/mL streptomycin and 10% FBS. They were seeded at 3 × 10^5 cells/well into 24-well cluster dishes and incubated with 1.0 mL medium at 37°C in an atmosphere of 5% CO_2 + 95% air for 24 hr. The cells were then washed twice with HBSS, the medium was replaced with one that contained 5% LPDS instead of FBS, and the cells were incubated for 17 hr prior to the start of an experiment. Drugs were added in 10 μL ethanol to the media. Control cultures received 10 μL of ethanol. Four hours later, 4 × 10^5 dpm of [^{14}C]acetate was added, and the cells were allowed to incubate for an additional 18 hr. The cells were then washed, and 1.0 mL of hexane/isopropanol (3:2, v/v) was added to each well to extract cell lipids. Squalene, squalene monoepoxide, squalene diepoxide (15 μg each), cholesterol and lanosterol (60 μg each) were added to the extracts. [^{3}H]Cholesterol (5,000 dpm) was also added to extracts as a radioactive standard to estimate recovery and to correct for differences in retention times between the ultraviolet (UV) and radioisotope detectors caused by their physical separation. The extracts were dried under N_2 gas, and redissolved in 1.0 mL of 5% KOH in 90% ethanol. The extracts were then incubated for 60 min at 70°C. One mL water was added, and the nonsaponified material was extracted twice, each time into 2.0 mL hexane. The hexane extracts were dried, and the residue was finally dissolved in THF/M for HPLC analysis. Identification of metabolites was based on their retention times against authentic standards. The cell protein residue left in the culture wells after lipid extraction was dissolved in 0.3 N NaOH at 4°C overnight. The protein content of this solution was measured by the method of Lowry *et al.* (12). Results (dpm/peak) were normalized to cell protein, and expressed as relative proportions of total radioactive metabolites. Cell toxicity was estimated by light microscopic examination of the cultures and by measurements of cell protein per well. Drug-treated cultures were indistinguishable from controls.

RESULTS

Trisnorsqualene *N*-methylcyclopropylamine (Fig. 1) increased [^{3}H]squalene epoxide and decreased [^{3}H]-



R= H; trisnorsqualene cyclopropylamine

R= CH_3; trisnorsqualene N-methylcyclopropylamine

FIG. 1. Structures of trisnorsqualene cyclopropylamine and trisnorsqualene *N*-methylcyclopropylamine.

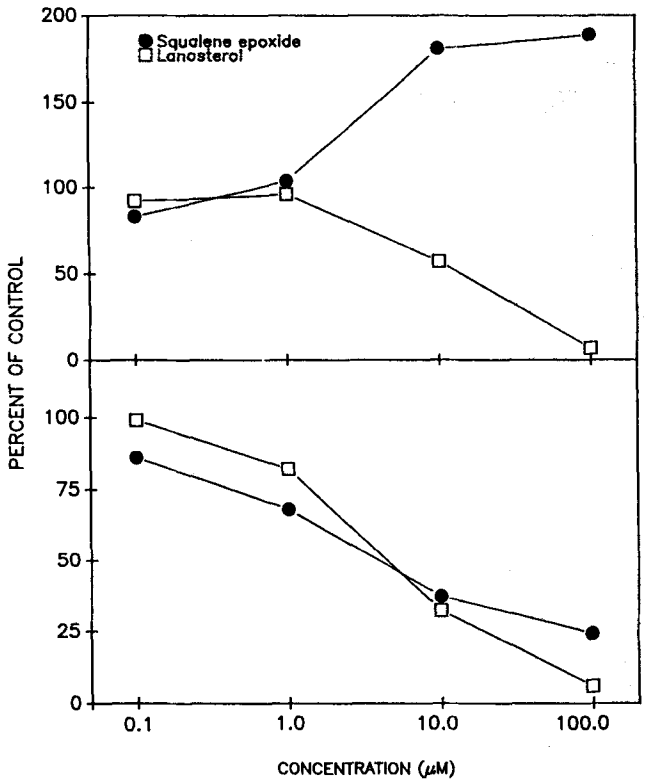


FIG. 2. Effects of increasing concentrations of either trisnorsqualene *N*-methylcyclopropylamine (top panel) or trisnorsqualene cyclopropylamine (bottom panel) on [^{3}H]squalene conversion to [^{3}H]squalene monoepoxide and [^{3}H]lanosterol by rat hepatic microsomes.

lanosterol production in the microsomal assay, both effects indicating that this compound inhibited 2,3-oxidosqualene cyclase (Fig. 2, top panel). The effect of the compound was dose-dependent, as shown in Figure 2, top panel. The calculated 50% of inhibitory concentration (IC_{50}) for inhibition of lanosterol synthesis was 12 μM. Trisnorsqualene cyclopropylamine (Fig. 1) inhibited [^{3}H]squalene conversion to [^{3}H]squalene epoxide (Fig. 2, bottom panel), indicating that it inhibited squalene mono-oxygenase. This compound also inhibited lanosterol synthesis (Fig. 2, bottom panel) as expected, since it blocked formation of the substrate for 2,3-oxidosqualene cyclase. Trisnorsqualene cyclopropylamine also acted in a dose-dependent manner (Fig. 2, bottom panel). The calculated IC_{50} for inhibition of squalene epoxide synthesis was 5 μM.

Because trisnorsqualene cyclopropylamine and its *N*-methyl analogue inhibited squalene mono-oxygenase and 2,3-oxidosqualene cyclase, respectively, in hepatic microsomes, it was of interest to determine if these compounds would affect the same enzymes and block cholesterol biosynthesis in intact hepatocytes. Trisnorsqualene cyclopropylamine caused an accumulation of squalene in HepG2 cells at concentrations greater than 0.1 μM (Fig. 3). Associated with the squalene accumulation was a corresponding decrease in [^{14}C]cholesterol synthesis (IC_{50} = 1.0 μM). At concentrations greater than 1.0 μM squalene monoepoxide accumulated, indicating that trisnorsqualene cyclopropylamine may also inhibit 2,3-oxidosqualene cyclase. Neither squalene diepoxide nor lanosterol levels exceeded background levels over the concentration range tested.

Trisnorsqualene *N*-methylcyclopropylamine also caused a dose-dependent inhibition of [^{14}C]cholesterol synthesis as shown in Figure 4 (IC_{50} = 0.5 μM). This inhibition of cholesterol synthesis was associated not with an accumulation of squalene, however, but with an accumulation of squalene mono- and diepoxide. Squalene monoepoxide levels began to increase at 0.01 μM drug concentration, and continued to rise until 1.0 μM. Squalene diepoxide levels exceeded background levels at drug concentrations greater than 0.01 μM, and at 1.0 μM and above exceeded those of squalene monoepoxide. These results

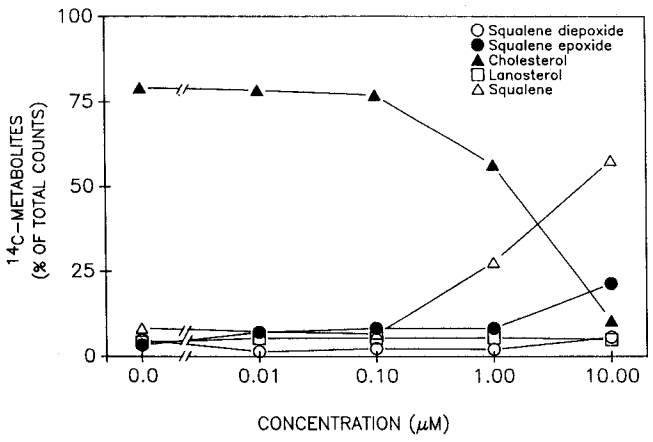

FIG. 3. Effects of increasing concentrations of trisnorsqualene cyclopropylamine on the conversion of [^{14}C]acetate to the indicated ^{14}C-labeled metabolites in cultured HepG2 cells.

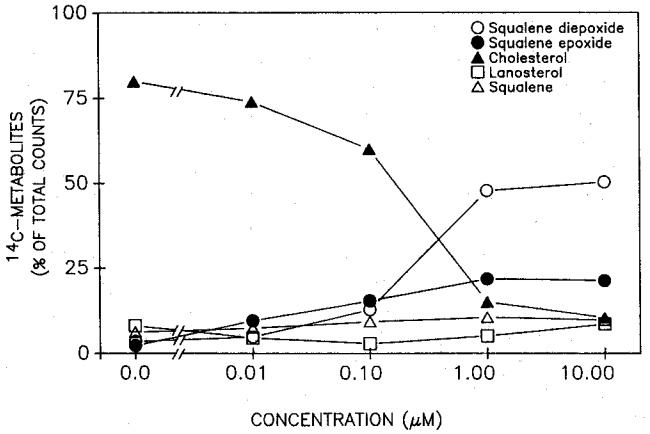

FIG. 4. Effects of increasing concentrations of trisnorsqualene *N*-methylcyclopropylamine on the conversion of [^{14}C]acetate to the indicated ^{14}C-labeled metabolites in cultured HepG2 cells.

suggest that this compound inhibited 2,3-oxidosqualene cyclase rather than squalene mono-oxygenase.

DISCUSSION

Our results confirm a recent report (8) that trisnorsqualene cyclopropylamine inhibits microsomal squalene mono-oxygenase. We found that this compound inhibited rat hepatic microsomal squalene monooxygenase with an IC_{50} of 5 μM, a result which is similar to that for the porcine microsomal enzyme (8). In addition, we found that the *N*-methyl derivative of trisnorsqualene cyclopropylamine inhibited rat hepatic microsomal 2,3-oxidosqualene cyclase. This compound did not inhibit the porcine hepatic microsomal enzyme (8). There are no apparent reasons other than species differences which could account for this difference in inhibitory activity. However, our results showing the accumulation of squalene epoxides in cultured HepG2 cells incubated with the *N*-methyl derivative confirm the results of our microsomal enzyme assay.

The two compounds studied here differ only in a methyl substitution on the nitrogen, yet they inhibited two different enzymes, both in hepatic microsomes and cultured hepatocytes. Trisnorsqualene cyclopropylamine and its *N*-methyl derivative are secondary and tertiary amines, respectively, and this structural difference appears to account for the difference in enzyme specificity. Trisnorsqualene cyclopropylamine could inactivate squalene mono-oxygenase through a mechanism involving aminium radical formation, followed by cyclopropane ring opening and alkylation of the enzyme's active site. Such a mechanism has been proposed to account for inhibition of monoamine oxidase and cytochrome P-450 by cyclopropylamines (13). Alkylation by trisnorsqualene cyclopropylamine is unlikely, however, because it has been shown that inhibition of porcine squalene mono-oxygenase by this compound is reversible (8). The *N*-methyl derivative, by virtue of being a positively charged tertiary amine at pH 7.4, may mimic a carbocationic intermediate formed during formation of the A ring of lanosterol and thereby competitively inhibit 2,3-oxidosqualene cyclase (14–16). The *N*-methyl derivative neither inhibited microsomal squalene mono-oxygenase, nor did it cause squalene accumulation in HepG2 cells. Considering the inhibition of

squalene mono-oxygenase by trisnorsqualene cyclopropylamine, it is not clear why the *N*-methylcyclopropylamine derivative did not also inhibit squalene mono-oxygenase, though the methyl group may sterically hinder access of the compound to the enzyme's active site.

When HepG2 cells were incubated with trisnorsqualene *N*-methylcyclopropylamine, squalene diepoxide accumulated to levels exceeding those of squalene monoepoxide (see Fig. 4). This is consistent with the ability of squalene mono-oxygenase, or another polyisoprene oxygenase, to catalyze an epoxidation of squalene monoepoxide to form the diepoxide in intact cells. Therefore, in the presence of an inhibitor of 2,3-oxidosqualene cyclase, such as trisnorsqualene *N*-methylcyclopropylamine, squalene diepoxide rather than squalene monoepoxide is the terminal product.

Trisnorsqualene cyclopropylamine caused squalene monoepoxide to accumulate in the HepG2 cells, although at concentrations 10-fold higher than those required to cause squalene accumulation. This suggests that the compound inhibits 2,3-oxidosqualene cyclase, but with a potency at least 10-fold less than for inhibition of squalene mono-oxygenase. It also indicates that squalene mono-oxygenase is incompletely inhibited at these concentrations. Inhibition of 2,3-oxidosqualene cyclase by trisnorsqualene cyclopropylamine would be consistent with the known ability of various azasqualene analogues to inhibit this enzyme (3).

Both compounds inhibited cholesterol synthesis in HepG2 cells. Associated with this inhibition was cellular accumulation of the substrates for squalene mono-oxygenase and 2,3-oxidosqualene cyclase when the cells were incubated with trisnorsqualene cyclopropylamine and trisnorsqualene *N*-methylcyclopropylamine, respectively. [^{14}C]Acetate would not have incorporated into these substrates if the inhibition of cholesterol synthesis was due to blockade of an enzyme(s) upstream in the reaction sequence to either of the two target enzymes. Furthermore, for each compound the curve describing the decrease in cholesterol synthesis overlapped the curve describing enzyme substrate accumulation. If inhibition of cholesterol synthesis was due to blockade of enzyme(s) downstream in the reaction sequence to the target enzymes, these curves would have been separated due to the higher drug concentration required to block the target enzymes relative to the downstream step(s). This correlation of substrate accumulation with inhibition of cholesterol synthesis, however, does not prove that other enzymes in the cholesterol biosynthetic sequence are unaffected. Nevertheless, these results combined with those showing direct inhibition of microsomal enzymes suggest that trisnorsqualene cyclopropylamine and trisnorsqualene *N*-methylcyclopropylamine inhibit cholesterol synthesis in cells by mechanisms involving the inhibition of squalene mono-oxygenase and 2,3-oxidosqualene cyclase, respectively.

Effects of n-3 and n-6 Fatty Acids on Tumor Necrosis Factor Cytotoxicity in WEHI Fibrosarcoma Cells

Ole-L. Brekke[a], Terje Espevik[b], Tora Bardal[a] and Kristian S. Bjerve[a,*]
[a]Department of Clinical Chemistry and [b]Institute of Cancer Research, University Hospital, University of Trondheim, N-7006 Trondheim, Norway

Modulation by fatty acids of the cytotoxic effect of recombinant tumor necrosis factor alpha (TNF) toward WEHI 164 mouse fibrosarcoma cells has been examined. Preincubating the highly TNF-sensitive WEHI clone 13 cells for 44 hr with 50 μmol/L of 20:5n-3, 22:6n-3, 18:3n-6, 20:3n-6 or 20:4n-6 reduced cell survival 22 hr after challenge with TNF (40 ng/L) by 65%, 72%, 60%, 98% and 85%, respectively. In comparison, 18:3n-3, 18:2n-6 and 18:1n-9 had only negligible effects on TNF-induced toxicity. Different extent of fatty acid incorporation into cell total phospholipids or triglycerides could not explain the observed effects on TNF cytotoxicity, and the enhanced cytotoxicity could therefore not be explained merely by an increased unsaturation of the cell membranes. In addition to the fatty acid supplied, preincubation with 18:2n-6, 18:3n-6 or 18:3n-3 also enriched the cells with 20:2n-6, 20:3n-6 and 20:3n-3, respectively, most likely due to chain elongation. The results suggest that the WEHI cells have a low Δ6 desaturase activity, and that n-6 and n-3 acids must have at least 3 or 4 double bonds, respectively, to enhance TNF cytotoxicity in WEHI cells. Dexamethasone partly inhibited TNF-induced cytotoxicity, while cyclooxygenase, thromboxane synthetase or lipoxygenase inhibitors had no or negligible effects. The antioxidant butylated hydroxyanisole (BHA) completely inhibited TNF-induced cytotoxicity, while the structurally and functionally similar antioxidant butylated hydroxytoluene had no such effect, indicating that BHA does not block TNF cytotoxicity through its antioxidant effect. The results suggest that TNF cytotoxicity involves, directly or indirectly, metabolism of long-chain polyunsaturated fatty acids, and we speculate that fatty acid metabolites are involved.
Lipids 27, 161-168 (1992).

Human mononuclear phagocytes mediate a large number of immunological responses, and are probably part of the immunological defense against cancer *in vivo* (1). Tumor necrosis factor (TNF) seems to be a major effector molecule in the monocyte-mediated lysis of cancer cells *in vitro* (2), and recombinant TNF depresses growth and kills some sensitive cancer cells *in vitro* (3). Studies by Urban *et al.* (4) indicate that cancer cells resistant to TNF are resistant to macrophage-mediated killing. Both TNF-sensitive and -resistant cells have high-affinity receptors for TNF (5). Activators of protein kinase C decrease the number of TNF receptors on the cell surface (6), thereby inhibiting TNF-mediated cytotoxicity. The observed difference between cancer cell lines in sensitivity to TNF has partly been attributed to high-molecular-weight components in the TNF receptor itself (7), and partly to differences in the intracellular concentration of glutathione (8). The cellular mechanisms involved in TNF-mediated cytotoxicity are largely unknown, although several reports indicate that 20:4n-6 metabolism is involved (9,10). It has been shown that TNF induces release of 20:4n-6 from cell membrane phospholipids, and also that some phospholipase A_2 inhibitors protect against TNF-induced cytotoxicity (11). This indicates that activation of phospholipase(s) may be involved in TNF-induced cytotoxicity.

Studies from Japan and Greenland eskimos suggest that a diet enriched in n-3 fatty acids is related to a low incidence of breast and colon cancer (12). In addition, animal studies have indicated that the growth of some tumors is affected by the fatty acid composition of the diet (13,14). It has also been found that the fatty acid composition of cancer cells affects their sensitivity to antibody plus complement mediated killing *in vitro* (15). These observations could indicate that the fatty acid composition of cancer cells' membrane lipids might affect their sensitivity to TNF-mediated cytotoxicity. We have therefore enriched the TNF-sensitive WEHI 164 fibrosarcoma cell line with saturated and unsaturated fatty acids, and investigated how this affects the cellular sensitivity to TNF.

MATERIALS AND METHODS

Materials. RPMI-1640, fetal calf serum, L-glutamine, trypsin solution, gentamicin sulfate, actinomycin D, sodium dodecyl sulfate (SDS), and Dulbecco's phosphate buffered saline were obtained from Gibco (Paisley, U.K.). Oleic, alpha-linolenic, eicosapentaenoic, arachidonic, linoleic, gamma-linolenic and palmitic acid, dexamethasone, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), nordihydroguaretic acid (NDGA), butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) were obtained from Sigma (St. Louis, MO). Docosahexaenoic and dihomogamma-linolenic acids were purchased from Nu Chek Prep. (Elysian, MN). The purity of all fatty acids was better than 95% (w/w). Dichloro-(R)fluorescein was from B.D.H. Lab., Chemicals Division (Poole, England). Adsorbosil plus-1 softlayer preadsorbent thin-layer chromatography (TLC) plates and the SGE BPX 70 capillary column were obtained from Alltech (Deerfield, IL). Absolute ethanol was obtained from Vinmonopolet A/S (Oslo, Norway). Ascorbic acid, methanolic base and the SP2330 capillary column were from Supelco (Bellefonte, PA). Chloroform, n-hexane, isooctane, toluene, isopropanol and methanol of chromatographic quality were obtained from E. Merck (Darmstadt, Germany). Diethyl ether and acetic acid of p.a. quality were also obtained from E. Merck. Recombinant murine TNF alpha

(8×10^7 U/mg protein) was generously provided by Genentech Inc. (San Francisco, CA).

Cell culture. The WEHI 164 cell line (termed WEHI parental cells) was obtained from Dr. H. W. Löms Ziegler-Heitbrock (University of Munich, Germany). The highly TNF-sensitive WEHI 164 clone 13 cells (WEHI clone 13) were previously isolated (16) from the WEHI parental cells. WEHI 164 parental and clone 13 cells were grown in RPMI-1640 medium containing 10% (v/v) heat-inactivated fetal calf serum, 2 mmol/L L-glutamine and 40 mg/L gentamicin (FCS-M). The cells were grown in 95% air and 5% CO_2 in a humidified atmosphere. Fatty acids dissolved in ethanol were added as indicated; the final ethanol concentration was 0.025% (v/v). Controls containing 0.025% ethanol were always included and had no effect on TNF cytotoxicity. Concentration and purity of the ethanolic fatty acid stock solutions were checked by capillary gas-liquid chromatography (GLC) after methylation with BF_3/methanol (17) using nonadecanoic acid as internal standard.

Viability. After incubation of the WEHI cells with 50 μmol/L of different fatty acids in FCS-M for 44 hr, the viability was at least 95% as determined by trypan blue exclusion.

MTT assay. A modification of the method described by Mosmann (18) was used. If not otherwise indicated, cells were cultured in 75-cm^2 flasks (Costar 3275), trypsinized and seeded at a density of 2×10^3 cells/well in 96-well microplates (Costar 3598) using 100 μL medium/well. After 4-hr incubation, 100 μL FCS-M containing the appropriate fatty acid supplement was added. Half the medium was replenished after 22 hr to avoid depletion of the added fatty acid, and cells were tested for TNF sensitivity after a total preincubation time of 44 hr. At this time, all cells were in logarithmic phase of growth (results not shown). Cell growth was slightly suppressed by 50 μmol/L of 22:6n-3, 20:5n-3, 20:4n-6 and 20:3n-6 both when measured with the MTT assay and by cell counting using a Coulter ZF cell counter (Coulter Electronics LTD, Dunstable Beds, England). After 44-hr preincubation, the medium was changed to 200 μL fatty acid-free FCS-M containing TNF as indicated. Cell survival was then measured after 22-hr further incubation, using the MTT assay as previously described (16). Wells containing medium but no cells were used to correct for background absorbance. Cell survival was calculated as: 100 × (OD in wells with TNF)/(OD in wells without TNF).

To test whether fatty acid enrichment of WEHI cells affected the MTT assay, cells were preincubated with 50 μmol/L fatty acid or 0.025% (v/v) ethanol for 44 hr. The cells were then transferred into fatty acid-free FCS-M and 22 hr later seeded into microplates containing FCS-M and 1 mg/L of actinomycin D. The MTT assay was then performed immediately. Neither ethanol, 18:1n-9, 20:4n-6, 20:5n-3, nor 22:6n-3 without TNF had any effect on the MTT assay (results not shown).

Chromium release assay. The chromium release assay was a modification of the method described by Brunner *et al.* (19). WEHI clone 13 cells were trypsinized, and 1×10^6 cells were seeded as non-adherent cultures in 1400 mm microbiological petri dishes (Nunc A/S, Roskilde, Denmark) in 10 mL FCS-M. Four hours later, the indicated fatty acid was added to the cells in a total volume of 20 mL FCS-M. After preincubation with fatty acids for 44 hr, cells were pelleted at +4°C (200 × *g*, 8 min), and resuspended in FCS-M (+4°C). Thereafter, 4×10^6 cells were incubated with 150 μCi $Na_2{}^{51}CrO_4$ (specific activity of 11 GBq/mg chromium, Institutt for Energiteknikk, Kjeller, Norway) for 60 min at 37°C in a total volume of 0.75 mL. The cells were then washed three times in +4°C FCS-M (200 × *g*, 8 min). The labeled cells were seeded at 1×10^4 cells/well in microplates (Costar 3598) in 200 μL of medium containing TNF and/or the test compounds. The supernatants were harvested after 16-hr further incubation using a supernatant collecting system (Skatron A/S, Lier, Norway). Percent specific lysis was calculated as: $100 \times (E - S)/(T - S)$, where E is cpm released from cells added TNF, S is cpm released spontaneously from cells added medium only, and T is cpm released after complete lysis of the cells added 50 μL 2.5% (w/v) of SDS.

Fatty acid analysis. Total lipids from fetal calf serum were extracted with n-butanol and separated into phospholipids, free fatty acids and neutral lipids on Bond Elut aminopropyl columns (Varian SPP., Harbor City, CA) after adding diheptadecanoylglycerophosphocholine, nonadecanoic acid and trinonadecanoin as internal standards and BHT as antioxidant (20). Phospholipids were transmethylated with BF_3/methanol in Teflon-lined screw-capped tubes filled with N_2, at 100°C for 30 min, and fatty acid methyl esters (FAME) were extracted into isooctane and analyzed by GLC as previously described (21). Free fatty acids were methylated with BF_3/methanol, extracted into hexane, and dissolved in isooctane after evaporation under N_2. Neutral lipids were taken to dryness by N_2, dissolved in toluene, and transmethylated with methanolic base at 80°C for 20 min. The reaction was stopped by addition of water. After extraction into n-hexane and evaporation under N_2, FAME were dissolved in isooctane and analyzed by GLC.

Triglyceride and total phospholipid fatty acids in WEHI clone 13 cells were quantitated after washing the cells twice at +4°C in Dulbecco's phosphate buffered saline (without calcium and magnesium) and extracting the lipids according to Bligh and Dyer (22). BHT (10 μg) was added to each sample as antioxidant, and trinonadecanoin and diheptadecanoylglycerophosphocholine were used as internal standards. Lipid classes were separated on TLC plates activated at 110°C for one hour and prewashed with hexane/diethyl ether (80:20, v/v). Triglycerides and total phospholipids were separated using hexane/diethyl ether/acetic acid (80:20:1, v/v/v), containing 0.001% (w/v) BHT, as solvent (23). The lipids were made visible under ultraviolet (UV)-light after spraying with 0.001% (w/v) dichlorofluorescein in ethanol. The phospholipid and triglyceride fractions were identified by comparison with standards, scraped into Teflon-capped tubes, and transmethylated with methanolic base for 20 min at 80°C under N_2; FAME were thereafter extracted twice into n-hexane, taken to dryness under a stream of N_2, and finally dissolved in isooctane. One μL of the mixture was injected into the Hewlett-Packard 5890A GLC (Avondale, PA) equipped with a SP2330 capillary column as previously described (21), but using a splitless injection technique. The SP2330 column does not separate 20:4n-6 and 20:3n-3. The samples were therefore reanalyzed on a SGE BPX 70 column to calculate the content of 20:4n-6 and 20:3n-3. Initial temperature was 80°C on both columns. The purge vent was opened after 3 min, and after 3.2 min the

temperature was programmed at 40°C/min to 170°C. After a 1 min hold, the temperature was programmed at 1.5°C/min to 210°C. Total run time was 52 min.

Statistics. Analysis of variance (ANOVA) was performed using the SPSS-PC+ version 4.0 (SPSS Inc., Chicago, IL) or the SAS statistical packages version 6.0 (SAS Institute Inc., Cary, NC).

RESULTS

Preincubation of WEHI 164 clone 13 cells with 12.5 to 50 μmol/L of different fatty acids influenced the cellular sensitivity to TNF-induced cytotoxicity. When 40 ng/L of TNF was added to cells preincubated with fatty acid free FCS-M, cell survival decreased to 43% (Fig. 1). In comparison, preincubation with 50 μmol/L 20:3n-6 or 20:4n-6 followed by addition of TNF, decreased cell survival to 1 and 7%, respectively. Their precursor 18:3n-6 was equally effective at 25 μmol/L, but slightly less effective than 20:3n-6 and 20:4n-6 at 50 μmol/L. In comparison, 20:5n-3 and 22:6n-3 were slightly less effective than 20:3n-6 and 20:4n-6, decreasing cell survival to 15 and 12% at 50 μmol/L, respectively. Preincubating the cells with 18:1n-9, 18:3n-3 or 18:2n-6 had negligible effects on TNF-induced toxicity, while both 16:0 and 20:1n-9 at 50 μmol/L decreased cell survival to approximately 34%.

Preincubation of WEHI clone 13 cells with 20:4n-6 increased the sensitivity to TNF-induced cytotoxicity in a time-dependent way. The WEHI clone 13 cells received either control medium, 18:2n-6 or 20:4n-6 at increasing time intervals before challenge with TNF (Fig. 2). Preincubation with 50 μmol/L 20:4n-6 decreased cell survival from 64% to 45%, 34% and 26% after 24, 48 and 72 hr preincubation time, respectively. In comparison, preincubation with control medium or 18:2n-6 had no or only small effects. In this experiment, 18:2n-6 or 20:4n-6 was also added simultaneously with TNF to cells that had been preincubated with control medium only. Again, 18:2n-6 had no effect, while 20:4n-6 reduced cell survival from 64% to 55% (Fig. 2). The WEHI cells preincubated in control medium only were more resistant to TNF at day 3 than day 2 after seeding, explaining the higher survival of control cells in this experiment compared to Figure 1.

The fatty acid composition of total phospholipids and triglycerides in WEHI clone 13 cells preincubated with 50 μmol/L of different fatty acids is shown in Tables 1 and 2, respectively. Fatty acid analysis showed that enrichment with 18:1n-9 and 18:2n-6 slightly decreased the concentration of 20:3n-6 and 20:4n-6 in cell phospholipids. Enrichment with 18:3n-6 increased 20:3n-6 in both phospholipids and triglycerides nearly as much as enrichment with 20:3n-6, while 18:3n-6 increased 20:4n-6 significantly only in the triglyceride fraction. In comparison, 18:3n-3 increased 20:3n-3 and decreased both 20:3n-6 and 20:4n-6 in total phospholipids. Interestingly, 22:6n-3 had no effect on the level of 20:3n-6 or 20:4n-6, while 20:5n-3 decreased both 20:3n-6 and 20:4n-6 in total phospholipids. Preincubation with 20:4n-6 decreased both 20:5n-3 and 22:6n-3 in the total phospholipids. With a few exceptions, the triglyceride fatty acids changed rather similarly as did the phospholipid fatty acids (Table 2). While 18:3n-3 increased 18:3n-3, 20:3n-3 and 20:5n-3, but decreased 22:6n-3 in the phospholipid fraction, it increased both 18:3n-3, 20:3n-3, 20:5n-3 and 22:6n-3 in the triglycerides. Further, preincubation with 20:5n-3 increased 20:5n-3 and 22:5n-3 to the same extent, and at the same time reduced 22:6n-3 in the phospholipid fraction, while both 22:5n-3 and 22:6n-3 increased in the triglycerides.

Fatty acid analysis showed that the unsupplemented FCS-M contained very low concentrations of both n-3 and n-6 fatty acids in the free fatty acid fraction, where 16:0, 18:0 and 18:1n-9 comprised 74% of total free fatty acids (Table 3). In comparison, the total n-3 and total n-6 fatty acids comprised 7.5% and 11.2%, respectively. A similar

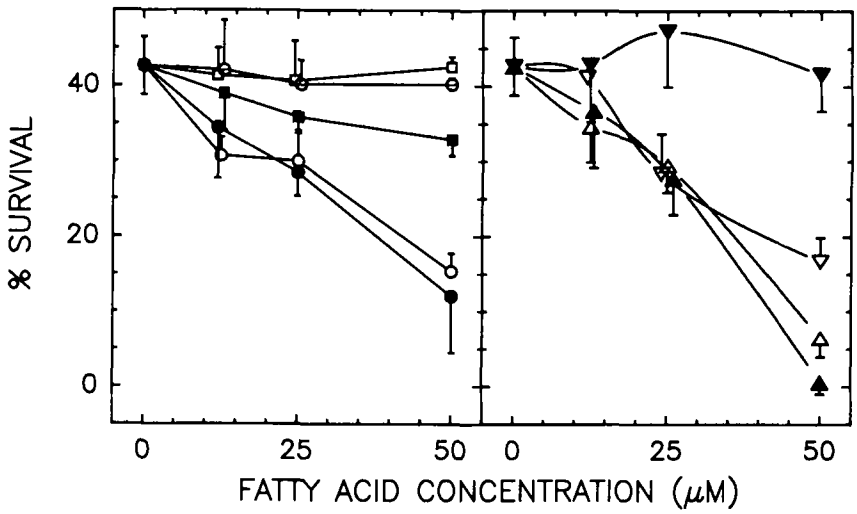

FIG. 1. Effect of different fatty acids on TNF-induced cytotoxicity in WEHI 164 clone 13 cells. Cells were preincubated for 44 hr with or without fatty acids at the concentrations indicated. TNF (40 ng/L) was then added, and percent cell survival was quantitated by the MTT assay as described in Materials and Methods. Results are from one of two similar experiments and are given as the mean of quadruplicate determinations, with SD shown as vertical bars. A: Effect of 16:0 (■), 18:1n-9 (□), 18:3n-3 (⊖), 20:5n-3 (○) and 22:6n-3 (●). B: Effect of 18:2n-6 (▼), 18:3n-6 (▽), 20:3n-6 (▲) and 20:4n-6 (△).

[a]WEHI clone 13 cells were incubated for 44 hr in FCS-M supplemented with 50 μM fatty acids as indicated. Results are expressed as % of total fatty acids or as $\mu g/10^6$ cells, and given as mean ± SD from one experiment performed in triplicate.

[b]Not detected.

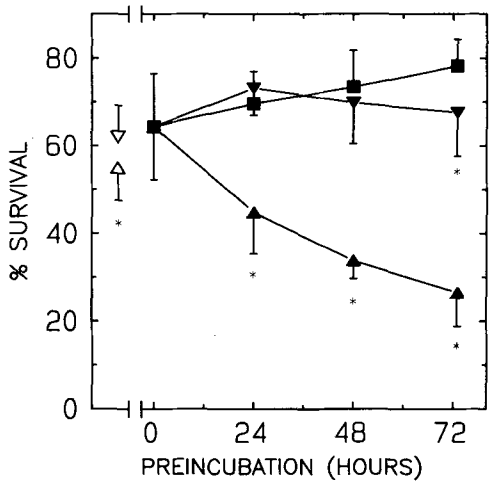

FIG. 2. Effect of preincubating WEHI clone 13 cells with 18:2n-6 and 20:4n-6. All cells were preincubated for 72 hr in microplates. At the indicated time points before challenge with TNF, the medium was changed from control medium (■,△,▽) to medium containing 50 μmol/L 18:2n-6) (▼) or 50 μmol/L 20:4n-6 (▲). At the end of preincubation, TNF (40 ng/L) was added in control medium (■,▲,▼) or in medium containing 50 μmol/L 18:2n-6 (▽) or 50 μmol/L 20:4n-6 (△). Cell survival was measured by the MTT assay 22 hr later. Results are from two experiments, each with 8 parallels, and are expressed as mean ± SD of 16 determinations. *P < 0.05 as compared to control at each time point. Data were analyzed by one-way analysis of variance using Duncan multiple comparison test.

fatty acid distribution was found in the phospholipids, while neutral lipids contained relatively more 18:1n-9 and n-6 fatty acids. The low concentrations of free fatty acids in the culture medium imply that addition of 50 μmol/L of a single fatty acid dramatically changed the composition of free fatty acids available to the cells.

Preincubation of WEHI clone 13 cells with increasing concentrations of 20:5n-3 decreased the TNF concentration that reduces cell density by 50% (ED_{50}) for TNF dose-dependently (Fig. 3). When 20:5n-3 increased from 0 to 50 μmol/L, the ED_{50} for TNF decreased tenfold, from 25 ng/L to 2.5 ng/L. A similar dose-response relationship was obtained by preincubating with increasing concentrations of 20:4n-6 or 22:6n-3 (results not shown). The absolute effect of these fatty acids changed relatively little with increasing concentrations of TNF, but was most pronounced at TNF concentrations around ED_{50}. The relative effect, however, varied with the concentration of TNF. At 0.04 ng/L TNF, 50 μmol/L 20:5n-3 reduced cell survival by 15%, while it was reduced by 65% compared to the control at 40 ng/L TNF.

Preincubation of WEHI clone 13 cells with 50 μmol/L of 20:4n-6 or 22:6n-3 decreased the ED_{50} for TNF similarly to 20:5n-3 (Fig. 4). In WEHI clone 13 cells, 50 μmol/L 22:6n-3 decreased the ED_{50} for TNF from 25 ng/L to 2.5 ng/L, while 20:4n-6 and 20:5n-3 both decreased ED_{50} to 1 ng/L (Fig. 4). In the less TNF-sensitive parental WEHI 164 cell line, 22:6n-3 decreased ED_{50} five-fold from 2.2 μg/L to 0.43 μg/L, while 20:4n-6 and 20:5n-3 at

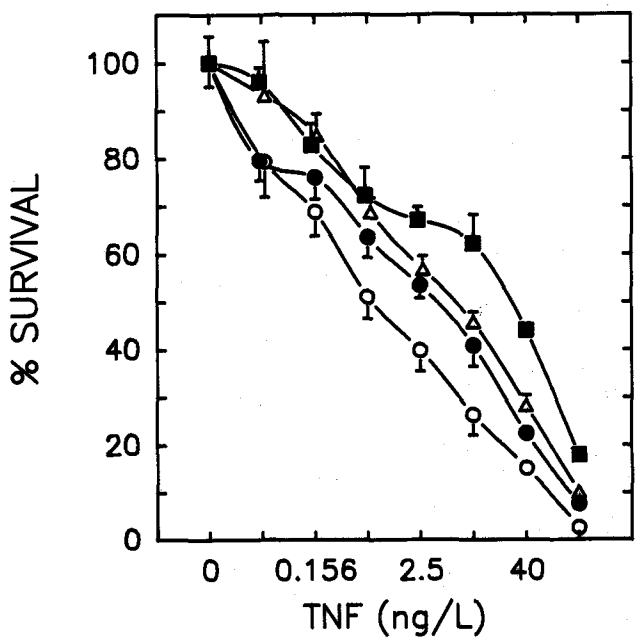

FIG. 3. Effect of increasing concentrations of 20:5n-3 on the ED_{50} for TNF in WEHI clone 13 cells. Cells were preincubated with the indicated concentrations of 20:5n-3 for 44 hr. Thereafter, the medium was removed and TNF was added in four-fold dilutions as indicated. Cell survival was measured by the MTT assay 22 hr later. In wells without TNF, the mean optical density was 1.13, 1.18, 1.14 and 1.07 after preincubation with control, 12.5, 25 and 50 μmol/L 20:5n-3, respectively. Results are from one of two similar experiments, and given as mean ± SD of quadruplicates. No addition (■), 12.5 μmol/L (△), 25 μmol/L (●), 50 μmol/L (○).

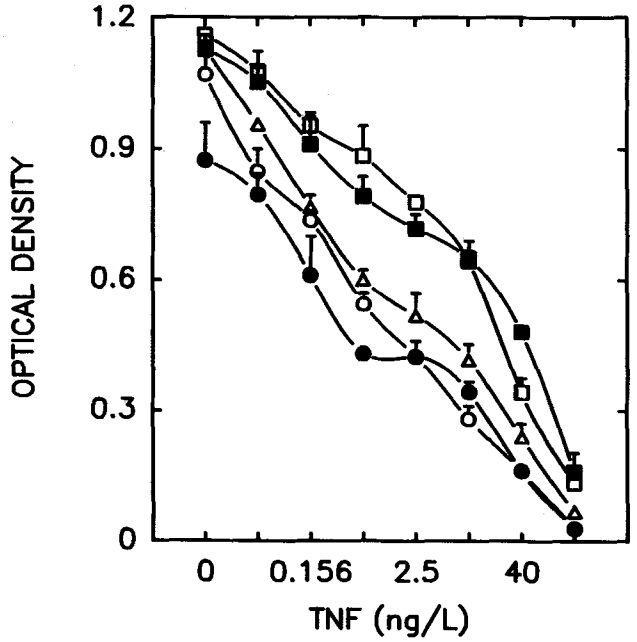

FIG. 4. Effect of enriching WEHI clone 13 cells with different fatty acids on the sensitivity to TNF. WEHI clone 13 cells were preincubated in microplates for 44 hr with or without the indicated fatty acid (50 μmol/L) supplementation, before changing to medium containing TNF in four-fold dilutions. Cell survival was measured by the MTT assay as described in Materials and Methods. Results are expressed as optical density and are given as mean ± SD of quadruplicates. Cells were preincubated with no addition (■), 18:1n-9 (□), 20:4n-6 (△), 20:5n-3 (○) or 22:6n-3 (●).

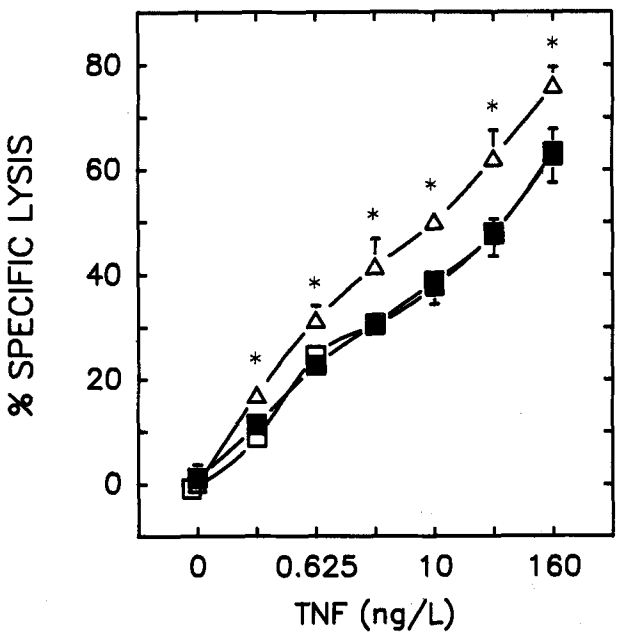

FIG. 5. TNF-induced cytolysis of WEHI clone 13 cells as measured using a 16 hr ^{51}Cr release assay as described in Materials and Methods. Cells were preincubated for 44 hr with no addition (■), 50 μmol/L 18:1n-9 (□) or 50 μmol/L 20:4n-6 (△). The spontaneous release in control, 18:1n-9- and 20:4n-6-treated cells was 23%, 24% and 27% of total release, respectively. Results are expressed as mean ± SD, and are from two experiments, each performed in triplicate. *$P < 0.05$ as compared to control. Data were analyzed by one-way analysis of variance (Scheffe F-test).

50 μmol/L decreased ED_{50} to 0.7 and 0.6 μg/L, respectively (results not shown). In Figure 4 the results are presented as optical density instead of percent survival to show that some of the fatty acids slightly decreased cell density. To further confirm that varying cell density did not invalidate the results, control experiments were performed with a constant cell density per well. Again, both 20:4n-6 and 22:6n-3 increased the sensitivity to TNF, while 18:1n-9 had no effect (results not shown), indicating that varying cell densities did not explain the effect on ED_{50}.

When the change in TNF sensitivity was measured using a 16-hr chromium release assay, 20:4n-6 decreased ED_{50} for TNF from approx. 57 ng/L to 10 ng/L, while 18:1n-9 had no effect (Fig. 5), which is similar to the results obtained using the MTT assay.

To test whether the increased sensitivity to TNF was connected with eicosanoid synthesis or free radical formation, the effect of enzyme inhibitors and antioxidants was examined (Table 4). Dexamethasone, but not indomethacin, decreased the cytotoxic effect of TNF in both fatty acid-enriched and in non-enriched cells. Further, the thromboxane synthetase inhibitor carboxyheptylimidazole had no effect. The relatively specific 5-lipoxygenase inhibitor NDGA did not inhibit TNF-induced cytotoxicity and was itself slightly toxic at 25 μmol/L when tested in the absence of TNF (results not shown). The water-soluble antioxidant ascorbic acid had no effect on TNF-induced toxicity (results not shown). The lipid soluble antioxidant BHT did not inhibit TNF-induced cytotoxicity and was toxic itself at 100 μM. In comparison, the antioxidant BHA (100 μM) totally inhibited TNF-induced cytotoxicity in both control cells as well as in cells enriched with fatty acids. This suggests that BHA does not block TNF-induced cytotoxicity through its antioxidant effect.

DISCUSSION

The present study shows that the sensitivity to TNF-induced cytotoxicity in WEHI 164 fibrosarcoma cells can be modified by preincubating the cells with different polyunsaturated fatty acids. Although polyunsaturated fatty acids inhibited the growth of WEHI cells slightly also in the absence of TNF, this could not explain the observed, increased sensitivity to TNF. Preincubation with polyunsaturated fatty acids could increase the sensitivity to TNF through several mechanisms, as discussed below.

Yamauchi *et al.* (24) showed that TNF stimulated the production of hydroxyl radicals in the TNF-sensitive U-937 cells, indicating that lipid peroxidation may be involved in TNF-mediated cytotoxicity. The observed increase in sensitivity to TNF in WEHI cells preincubated with 18:3n-6, 20:3n-6, 20:4n-6, 20:5n-3 or 22:6n-3, could therefore reflect an increased unsaturation of the cell membranes, thereby rendering the cells more susceptible to peroxidation from TNF-induced radical formation. This report indicates, however, that preincubation with polyunsaturated fatty acids selectively increases TNF-induced

TABLE 4

Effect of Inhibitors of Arachidonate Metabolism on TNF-Mediated Cytotoxicity

Additions	(μmol/L)	Fatty acid present during preincubation[a]

[a] WEHI clone 13 cells were preincubated with 50 μmol/L of the indicated fatty acid before labeling with ^{51}Cr as described in Materials and Methods. The cells were then challenged with TNF (40 ng/L) in the presence of the compounds indicated 16 hr before measuring specific cell lysis. The results are from two independent experiments and are given as mean ± SD of six determinations. The spontaneous release varied between 21 and 26% of total.

[b] $P < 0.05$ when compared to cells preincubated with ethanol only. Data were analyzed by one-way analysis of variance using Duncan multiple comparison test.

[c] $P < 0.05$ when compared to the control in each fatty acid treatment. Data were analyzed by one-way analysis of variance using Duncan multiple comparison test.

cytotoxicity in WEHI cells, and that this increase probably does not reflect merely the increased unsaturation of the cellular lipids.

Preincubating the WEHI cells with 50 μmol/L 18:3n-3 had negligible effects on TNF-induced cytotoxicity, while 18:3n-6 and 20:3n-6 reduced cell survival by 60 and 98%, respectively (Fig. 1). The trienoic fatty acid 20:3n-6 was thus considerably more effective in potentiating TNF cytotoxicity than the more unsaturated fatty acids 20:5n-3 and 22:6n-3, which reduced cell survival by 65 and 72%, respectively, at the same concentration. These results indicate that there is no direct correlation between the degree of unsaturation of the fatty acid added to the cells, and the effect on TNF-induced cytotoxicity.

Preincubation with 18:2n-6 had only small effects on the sensitivity to TNF even after 72-hr preincubation (Fig. 2). We speculate that the small effect of 18:2n-6 could be explained by a low activity of the Δ6 desaturase, the rate-limiting enzyme in the conversion of 18:2n-6 to 18:3n-6, 20:3n-6 and 20:4n-6 (25). The fatty acid analysis indicated that preincubation with 18:2n-6 did not increase 18:3n-6 and 20:4n-6 in total phospholipids. By comparison, preincubation with 18:3n-6 increased both 20:3n-6 and 20:4n-6 in total phospholipids. However, the increased sensitivity to TNF was not related only to 20:3n-6 or 20:4n-6, since preincubation with 20:5n-3 decreased both 20:3n-6 and 20:4n-6 in total phospholipids and simultaneously increased the sensitivity to TNF. The fatty acid analysis also showed that preincubation with 18:1n-9, 18:2n-6, 18:3n-3 and 18:3n-6 increased cellular 20:1n-9, 20:2n-6, 20:3n-3 and 20:3n-6, respectively, most likely due to chain elongation.

Incubation of WEHI 164 clone 13 cells with 20:5n-3 or 20:4n-6 increased the sensitivity to TNF dose- and time-dependently. Hepburn *et al.* previously reported that addition of 20:4n-6 simultaneously with TNF had no effect on TNF-induced cytotoxicity. We found that adding 20:4n-6 for 22 hr simultaneously with TNF reduced cell survival by only 14%. In comparison, preincubating the cells with 20:4n-6 for 24 hr before challenging the cells with TNF in the absence of 20:4n-6 reduced cell survival by 30% (Fig. 2). This may suggest that the increased sensitivity to TNF is not mediated by free unesterified 20:4n-6 present in the culture medium or intracellularly, and we therefore speculate that 20:4n-6 has to be incorporated into the cellular lipids in order to increase the susceptibility to TNF. A similar conclusion was recently published by Reid *et al.* (26) who showed that an adipogenic cell line was more sensitive to TNF after enrichment of choline- and ethanolamine-containing phospholipids with 20:4n-6.

The fatty acids were not present simultaneously with TNF in most of our experiments. Therefore we possibly underestimated the fatty acid effects since simultaneous addition of 20:4n-6 and TNF increased TNF toxicity slightly. Preincubation of WEHI clone 13 cells with 50 μmol/L 20:4n-6 in microplates decreased the ED_{50} for TNF to approximately 4% of control cells (Fig. 4). However, preincubation with 50 μmol/L 20:4n-6 in the petri dishes in the ^{51}Cr release experiments decreased the ED_{50} for TNF to approximately 18% of control cells (Fig. 5). The fatty acid concentration was identical in both types of experiments, but due to differences in cell counts, only 1 pmol fatty acid was added per cell in the ^{51}Cr

release experiments compared to 7.5 pmol/cell in the microplate experiments. This may explain at least some of the difference.

The effect of polyunsaturated fatty acids on TNF-induced cytotoxicity in WEHI cells may possibly be mediated by free radicals, and we therefore tested the effect of antioxidants. Other investigators have shown that incubation with 20:3n-6, 20:4n-6, 20:5n-3 and 22:6n-3 may increase free radical generation (27), inhibit growth, and even kill some cancer cell lines *in vitro* (28,29). Further, it has been reported previously that some, but not all, free radical scavengers can partly inhibit TNF-induced cytotoxicity (30,31). In the present study, the antioxidant BHA completely blocked TNF-induced cytotoxicity in both control as well as in fatty acid-enriched cells (Table 4), while the structurally and functionally very similar antioxidant BHT did not inhibit TNF-induced cytotoxicity. The results suggest that BHA does not block TNF-induced cytotoxicity in WEHI cells through its antioxidant effect, but through some other unknown mechanism. We therefore speculate that BHA functions as a specific enzyme inhibitor.

Previous reports have suggested that TNF-induced cytotoxicity is linked to arachidonic acid metabolism (10), and we therefore tested several other enzyme inhibitors. BHA has been reported to inhibit both the lipoxygenase enzyme(s) (32) and cyclooxygenase (33). However, since the relatively specific 5-lipoxygenase inhibitor NDGA had no effect, while in comparison the antioxidant and lipoxygenase inhibitor BHA completely blocked TNF-induced toxicity, this may suggest that if a lipoxygenase is involved in TNF-induced toxicity, it may be different from the 5-lipoxygenase. It is unlikely that BHA blocks TNF-induced cytotoxicity due to inhibition of the cyclooxygenase, since indomethacin did not inhibit TNF cytotoxicity in these cells. The lack of effect of carboxyheptylimidazole suggests that thromboxane synthetase metabolites are not involved in TNF-mediated cytotoxicity in WEHI clone 13 cells. The inhibitory effect of dexamethasone on TNF-mediated cytotoxicity is in agreement with the report by Kull (9). The effect of dexamethasone may result from inhibited phospholipase A_2 activity as indicated by other reports (11), and/or from lowering the affinity for TNF to its receptor (9).

The present report is in agreement with the report by Hori *et al.* (34) who showed that TNF-insensitive diploid FS-4 fibroblasts became sensitive to the cytotoxic effect of TNF in the presence of 20:4n-6 or 20:5n-3. They also showed that the cytotoxic effect of TNF in the presence of 20:4n-6 was completely abolished by indomethacin. As indomethacin had no effect on TNF-induced cytotoxicity in WEHI cells, this may suggest that TNF-induced cytotoxicity in diploid fibroblasts and WEHI fibrosarcoma cells involves different mechanisms.

In conclusion, our report indicates that the sensitivity to TNF in WEHI 164 fibrosarcoma cells can be increased selectively by preincubation with long-chain polyunsaturated fatty acids. The results suggest that the increased sensitivity to TNF is not only due to an increased unsaturation of cell membranes. Further, free 20:4n-6 seems to be less potent than 20:4n-6 incorporated into cell lipids. Future studies should clarify if it is the fatty acids themselves, some fatty acid metabolites, or other effects of fatty acids that increase the sensitivity to TNF-induced cytotoxicity. Further investigations are also needed to evaluate if a diet enriched in such fatty acids in any way is associated with resistance against cancer *in vivo*.

[Received August 31, 1990, and in final revised form November 18, 1991; Revision accepted January 23, 1992]

The Effect of Dietary Supplementation with Eicosapentaenoic Acid on the Phospholipid and Fatty Acid Composition of Erythrocytes of Marmoset

Robert A. Gibson[a,*], Mark A. Neumann[a], Sharon L. Burnard[b], Josephine A. Rinaldi[b], Glen S. Patten[b] and Edward J. McMurchie[b]

[a]Department of Paediatrics, Flinders Medical Centre, Bedford Park, S.A., 5042 and [b]CSIRO, Division of Human Nutrition, Glenthorne Laboratory, O'Halloran Hill, S.A., 5158 Australia

Adult male marmoset monkeys were fed eicosapentaenoic acid (20:5n-3) as the ethyl ester in diets containing either 32% (reference diet, no added cholesterol) or 7% (atherogenic diet with 0.2% added cholesterol) linoleic acid (18:2n-6) for 30 wk. No changes were seen in the level of phosphatidylcholine (PC) or phosphatidylethanolamine (PE) but minor changes were observed in both the sphingomyelin (SPM) and phosphatidylinositol plus phosphatidylserine (PI + PS) fractions of erythrocyte lipids. The extent of total n-3 fatty acid incorporation into membrane lipids was higher in atherogenic diets (polyunsaturated/monounsaturated/saturated (P/M/S) ratio 0.2:0.6:1.0) than reference diets (P/M/S ratio 1:1:1) and this was true for both PE (33.4 ± 1.0% *vs* 24.3 ± 1.1%) and PC (9.3 ± 0.5% *vs* 4.9 ± 0.3%). Although suitable controls for cholesterol effects were not included in the study, earlier results obtained with marmosets lead us to believe such effects were probably small. Regardless of basic diet (atherogenic, reference), 20:5n-3 was preferentially incorporated into PE (10.8 ± 0.2%, 6.0 ± 0.02%) while smaller amounts were incorporated into PC (6.9 ± 0.4%, 3.2 ± 0.2%). The major n-3 polyunsaturated fatty acid found in PE in response to dietary 20:5n-3 was the elongation metabolite 22:5n-3 in both the atherogenic (17.7 ± 0.7%) and reference (14.3 ± 1.0%) dietary groups; 22:6n-3 levels were less affected by diet (4.7 ± 0.3% and 3.9 ± 0.2%, respectively). The results can be interpreted to indicate an inverse relationship between the amount of dietary 18:2n-6 and incorporation of 20:5n-3 into erythrocyte membrane phospholipids regardless of whether the major dietary n-3 fatty acid was α-linolenate (18:3n-3) or 20:5n-3. This interpretation is supported by theoretical calculations.

Lipids 27, 169–176 (1992).

The n-3 polyunsaturated fatty acid eicosapentaenoic acid (20:5) and docosahexaenoic acid (22:6) which are present in marine oils have unique lipid lowering potential in humans and animals (1,2). Fish oil has been shown to lower triglyceride levels in both normal and hypertriglyceridemic subjects (3). In the rat, the hypotriglyceridemic effect is probably mediated by 20:5n-3 while 22:6n-3 may be responsible for lowering of plasma cholesterol levels (4). Although investigations into the effect of n-3 polyunsaturated fatty acids on blood cells have tended to focus on platelets (5,6) or neutrophils (7,8), changes in phospholipid fatty acids and membrane function of erythrocytes have also been examined. For example, dietary n-3 fatty acids have been shown to affect both the deformability of red cells (9,10) and the fluidity of erythrocyte membranes from human subjects (11,12). Similar studies on rats have failed to demonstrate changes in erythrocyte deformability despite an increase in n-3 polyunsaturated fatty acids in membrane phospholipids (13).

Many beneficial effects of marine oil consumption by humans are now attributed to incorporation of 20:5n-3 into cell membranes (1,2). However, because 20:5n-3 incorporation into liver phospholipids has been shown to be less when fish oil was fed with safflower oil than when it was fed with beef tallow (14), co-ingestion of other fats, particularly those rich in linoleate (18:2n-6) must be considered in order to maximize 20:5n-3 incorporation.

Interpretation of results from animals fed marine oils has often been difficult due to the presence of several n-3 polyunsaturated fatty acids in these oils. The availability of a source of ethyl esters derived from fish oil which contained over 70% 20:5n-3 and no 22:6n-3, made it possible to determine the effect of dietary 20:5n-3 on the fatty acid composition of individual phospholipids of the marmoset red blood cell in the absence of other n-3 polyunsaturated fatty acids. We demonstrate that dietary 20:5n-3 is preferentially incorporated into erythrocyte phosphatidylethanolamine (PE), and this incorporation is greatest when dietary 18:2n-6 is reduced as in an atherogenic-type diet.

MATERIALS AND METHODS

Marmosets. Adolescent male common cotton-eared marmosets (*Callithrix jacchus jacchus*), approximately 16 to 26 mon old at the start of the experiment, were divided into four groups of equivalent age and weight. Marmosets were paired for optimum growth and social behavior and kept in aluminum alloy marmoset cages in a room with fluorescent light and 30 min of ultraviolet irradiation daily. The temperature was maintained at 26°C and the humidity at 50%. Marmosets were maintained on the various dietary lipid regimes described below for a period of 30 wk and were sacrificed under anaesthesia by injection of Saffan, 1.5 mL per kg body weight (alphaxalone, 9 mg/mL; alphadolone acetate, 3 mg/mL; Glaxo, Sydney, Australia), into the femoral artery.

Marmoset diets. Four high-fat dietary regimes of equivalent energy value were used. These diets were chosen to examine the effect of 20:5n-3 (as the ethyl ester) when administered in combination with diets differing significantly in their polyunsaturated/monounsaturated/saturated (P/M/S) fatty acid ratio. The normal colony diet for marmosets consisted of a 1:1 mixture of greyhound chow (Arnott Harper's Ltd., Adelaide, Australia) and primate meal (Milling Industries Ltd., Adelaide, Australia). The overall composition of this diet with regard to all nutrients has previously been described (15), and contained approximately 4.5% fat. The fatty acid composition of the normal colony diet (shown in Table 1) was used as the basis

*To whom correspondence should be addressed.

Abbreviations: ATH, atherogenic diet; EPA, eicosapentaenoic acid; FID, flame-ionization detector; HUFA, highly unsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; P/M/S, polyunsaturated/monounsaturated/saturated ratio; REF, reference diet; SPM, sphingomyelin.

for the preparation of the four experimental diets described below.

The reference (REF) diet consisted of the colony diet supplemented with 5.5% (by weight) sunflower seed oil (Nuttelex, Melbourne, Australia), 1.5% olive oil (SA Olive Oil Co., Adelaide, Australia) and 3.0% sheep kidney (perirenal) fat (Noarlunga Meat Works, Noarlunga, Australia). The final fat blend achieved a P/M/S ratio of 1.1:1.1:1.0. Addition of 0.8 (w/w) 20:5n-3 ethyl ester concentrate (containing 75% 20:5n-3 and 0.2% α-tocopherol; supplied by Dr. Yasushi Tamura, Chiba University Medical School, Chiba, Japan) changed the P/M/S ratio to 1.1:1.0:1.0 (REF + eicosapentaenoic acid (EPA) diet). The atherogenic (ATH) diet consisted of the colony diet supplemented with 10% sheep kidney fat and 0.2% (w/w) cholesterol (Ajax Chemical Co., Adelaide, Australia) which achieved a P/M/S ratio of 0.14:0.6:1.0. The addition of 0.8% (w/w) 20:5n-3, ethyl ester concentrate to the ATH diet gave a P/M/S ratio of 0.2:0.6:1.0 (ATH + EPA diet). The fatty acid compositions of the 20:5n-3 concentrate and of the experimental diets are shown in Table 1. All additions (*i.e.* oils, fat, cholesterol and concentrate) were thoroughly mixed with the crushed colony diet before the respective diets were repelleted. A two-week supply of each diet was prepared and frozen at −20°C in a N_2 atmosphere. Aliquots of these diets were thawed for each daily feeding and replaced daily. Animals were fed *ad libitum*.

Collection of erythrocytes. Immediately after the animals were killed, blood was collected from the aorta by a heparinized syringe, and centrifuged to separate plasma and erythrocytes as previously described (16). Erythrocytes were washed three times by centrifugation in phosphate buffered saline, and lipids were extracted immediately.

Lipid extraction. Lipids were extracted by the methods described elsewhere (16). Briefly, one volume of washed erythrocytes was extracted with 4 vol of boiling 2-propanol containing the antioxidant butylated hydroxyanisole (0.1% of the estimated lipid weight), and the mixture was boiled for 30 sec. After cooling, 8 vol of chloroform and 2 vol of water were added, and the mixture was shaken. Following centrifugation, the lower organic phase was collected and the aqueous phase was re-extracted with an additional 4 vol of chloroform. The combined organic phases were dried over anhydrous sodium sulfate.

Separation of total phospholipids and phospholipid classes. Total phospholipids were separated from neutral lipids by thin-layer chromatography on silica gel H plates using petroleum hydrocarbon acetone (3:1, v/v) as the developing solvent. Individual phospholipid classes (as % of total phospholipids) were separated on Whatman LK5D thin-layer chromatography plates (Maidstone, England) developed in one direction in a solvent system of chloroform/ethanol/water/triethylamine (30:34:8:35, by vol) as described by Touchstone *et al.* (17). All phospholipids were clearly separated except phosphatidylinositol (PI) and phosphatidylserine (PS) which were only present in trace amounts; samples were pooled as indicated in Table 2.

Fatty acid analysis of erythrocyte total phospholipids and phospholipid classes. Phospholipid bands isolated by thin-layer chromatography were scraped directly into glass vials containing 1% (v/v) H_2SO_4 in methanol and heated for 3 hr at 70°C. The resulting methyl esters were extracted into heptane and dried over sodium sulfate prior to analysis by gas chromatography. Analyses of fatty acid methyl esters of the total phospholipids and the major phospholipid classes of marmoset erythrocytes were performed using capillary gas chromatography (Hewlett-Packard HP 5880 gas chromatograph; Hewlett-Packard, Palo Alto, CA). The column was a 50-m glass column

[a]Fatty acids are designated by the number of carbon atoms followed by the number of double bonds. The particular unsaturated fatty acid series is shown as (n-x) which refers to the first double bond counting from the terminal methyl group of the fatty acid. Fatty acid values shown above represent the average obtained from at least five separate extractions and analyses of the respective diet or oil. tr, (trace), present at less than 0.5%; n.d., not detected. REF, reference; EPA, eicosapentaenoate; ATH, atherogenic; ATH + EPA, atherogenic plus eicosapentaenoate; U.I., unsaturation index, as defined in reference (24).

coated with SP2340 (Supelco Inc., Bellefonte, PA) prepared by Chromolytic Technology Ltd. (Boronia, Victoria, Australia). Methyl esters were separated using helium as carrier gas at a flow of 25 cm/sec with a temperature gradient of 120°C to 200°C at 5°C per minute. The injection/split temperature was 250°C and the flame-ionization detector (FID) temperature was 300°C. Fatty acids were identified using authentic lipid standards supplied by Nuchek Prep (Elysian, MN).

Quantitative diet-tissue relationships. It has been reported (18,19) that the amounts of certain 20 and 22 carbon n-3, n-6 and n-9 highly unsaturated fatty acids (HUFA) that are maintained in membrane phospholipids fit saturable hyperbolic relationships to the dietary supply of precursors and can be described by the following equations (Equation 1, 2 and 3):

$$\text{n-6 as \% HUFA} = \frac{100}{1 + \frac{HC6}{en\%H6}\left(1+\frac{en\%H3}{HC3}\right)} + \frac{100}{1 + \frac{PC6}{en\%P6}\left(1 + \frac{en\%P3}{PC3} + \frac{en\%H3}{HI3} + \frac{en\%O}{Co} + \frac{en\%P6}{Ks}\right)} \quad [1]$$

$$\text{n-3 as \% HUFA} = \frac{100}{1 + \frac{HC3}{en\%H3}\left(1+\frac{en\%H6}{HC6}\right)} + \frac{100}{1 + \frac{PC3}{en\%P3}\left(1 + \frac{en\%P6}{PC6} + \frac{en\%H6}{HI6} + \frac{en\%O}{Co} + \frac{en\%P3}{Ks}\right)} \quad [2]$$

$$\text{n-9 as \% HUFA} = \frac{100}{1 + K\left(1 + \frac{en\%P6}{PC6} + \frac{en\%H6}{HI6} + \frac{en\%P3}{PC3} + \frac{en\%H3}{HI3}\right)} \quad [3]$$

The variables are: en%P6 = energy % as 18:2n-6; en%P3 = energy % as 18:3n-3; en%H6 = energy % as 20:4n-6; and en%H3 = energy % as 20:5n-3. The fitted constants are: PC3 = 0.0685; HC3 = 1.0; HI3 = 0.0115; PC6 = 0.17; HC6 = 0.8; HI6 = 0.02; Co = 10; Ks = 0.17; and K = 3.9. The equation predicts the level of certain n-6 (20:3, 20:4), n-3 (20:5, 22:5) and n-9 (20:3) HUFA in tissues based on the level of dietary fatty acids including these same HUFA as well as the level of dietary 18:2n-6 and 18:3n-3. Note that 22:6n-3, a major constituent of some tissues, is not predicted by the equations.

Statistical analysis. All data are presented as the mean ± standard error of the mean for the indicated number of samples (n) for each dietary group. Multiple comparisons were made between dietary groups by unpaired t-tests with $p < 0.05$ being considered significant.

Chemicals. Solvents were of the highest analytical grade and were redistilled and gassed with N_2 before use. All other chemicals were of the highest reagent grade available.

RESULTS

By mixing the various fats and oils in the proportions indicated in Materials and Methods, two high-fat diets of equal energy value were produced which differed markedly in their P/M/S ratio and hence in their proportion of 18:2n-6 without affecting the level of α-linolenate (18:3n-3). Addition of the 20:5n-3 concentrate to these diets resulted in about 3% of the total dietary fatty acids available as 20:5n-3 (Table 1). Body weights of marmosets (g) at the start and finish of the experiment for each dietary group were (mean ± SEM): REF (N = 8) 353 ± 7, 364 ± 10; REF + EPA (n = 8) 332 ± 9, 326 ± 9; ATH (n = 10) 324 ± 8, 335 ± 12; ATH + EPA (n = 10) 313 ± 9, 307 ± 12.

The proportions of marmoset erythrocyte phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were not altered by the dietary supplements. PC remained at about 40% of the total erythrocyte phospholipids, while PE was about 32% (mean values) (Table 2).

The proportion of sphingomyelin (SPM) was reduced in all dietary groups in comparison to the REF diet; however this difference was only statistically significant when compared to the ATH + EPA group. In comparison to the REF group, the proportion of PI + PS was significantly elevated in the three other dietary groups with the proportion being about double that of the control. The increase in phosphatidylinositol plus phosphatidylserine (PI + PS) therefore appeared to be at the expense of SPM.

Eicosapentaenoic acid (20:5n-3) was significantly incorporated into the total phospholipids of erythrocyte membranes in those animals receiving 20:5n-3 supplements (Table 3). Interestingly the incorporation of 20:5n-3 in the ATH + EPA group (10%) was approximately double that of the REF + EPA group (5.4%). Accompanying this increase in the proportion of 20:5n-3 was an increase in the proportion of its elongation product docosapentaenoic acid (22:5n-3) but its Δ4 desaturase metabolite, 22:6n-3, did not increase.

In the REF + EPA group, the proportion of 22:5n-3 actually exceeded that of 20:5n-3 (Table 3). Together these changes resulted in a marked increase in the proportion of the total n-3 polyunsaturated fatty acids in both 20:5n-3 supplemented groups. Also accompanying the increase in 20:5n-3 was a concomitant decrease in the proportions of 18:2n-6 and arachidonic acid (20:4n-6) in the REF + EPA and ATH + EPA diet groups. The combined decrease in these two n-6 polyunsaturated fatty acids approximated the increase in the proportion of 20:5n-3 with 20:5n-3 supplementation. As a result, the n-6/n-3 polyunsaturated fatty acid ratio markedly decreased in the two EPA-supplemented diet groups.

TABLE 2

Effect of Dietary Lipid Supplementation on the Proportion of Major Phospholipids of Marmoset Erythrocytes[a]

Phospholipid class	REF[b] (n = 8)	REF + EPA (n = 8)	ATH (n = 10)	ATH + EPA (n = 10)
PC	41.8 ± 1.1	40.8 ± 1.6	39.6 ± 0.9	40.1 ± 0.8
PE	31.5 ± 0.7	31.8 ± 1.4	31.8 ± 1.1	32.5 ± 0.9
SPM	23.1 ± 1.4	19.7 ± 1.4	20.8 ± 1.8	20.1 ± 0.8
PI + PS	3.6 ± 1.1[c]	7.7 ± 1.5	7.8 ± 0.9	7.3 ± 1.1

[a]Data are presented as the mean ± SEM for the indicated number of animals (n) in each dietary group. Values for PI + PS were determined from 2 pooled samples per diet group each representing 4 individual animals.

[b]% of total phospholipids.

[c]Significantly different from the other three dietary groups at $P < 0.05$.

U.I.	151	170	153	183

[a]Data are presented as the mean ± SEM for samples from the indicated number of animals (n) in each dietary group. Fatty acids are designated as in Table 1. Only those fatty acids present at >0.5% of the total (w/w) are reported. Values without a common superscript are significantly different at $p < 0.05$. Statistical significance was not determined for those values without a superscript.

Differences in the fatty acid composition of total phospholipids were also evident when comparing the basic diets which differed in their P/M/S ratio (Table 3). For example, relatively higher levels of 18:2n-6 and lower levels of monounsaturates were apparent in the REF and REF + EPA dietary groups (P/M/S; 1:1:1) compared to the ATH and the ATH + EPA diet groups (P/M/S; 0.2:0.6:1.0). The level of erythrocyte membrane lipid saturation was not markedly altered despite the large differences in the extent of lipid saturation between the REF- and the ATH-based experimental diets (Table 1).

Changes in the fatty acid profile of erythrocyte PE were qualitatively and quantitatively similar to those occurring in the total erythrocyte phospholipids (Table 4).

Thus the proportions of 20:5n-3, 22:5n-3 and total n-3 polyunsaturated fatty acids were increased, and the proportions of 18:2n-6, 20:4n-6, total n-6 polyunsaturated fatty acids, and the n-6/n-3 decreased with 20:5n-3 supplementation in both the REF and ATH diet groups. Accumulation of 22:5n-3 into the PE fraction was well above that of 20:5n-3 in the diets supplemented with 20:5n-3 but the level of 22:6n-3 was increased only in the REF + EPA diet relative to REF. The proportion of saturated fatty acids was not greatly influenced as a result of feeding the atherogenic diet. The changes in PC as a result of 20:5n-3 supplementation were similar in most respects to those in PE, however the extent of incorporation of 20:5n-3 was not as great (Table 5).

PC also had higher levels of saturated fatty acids, 18:2n-6 and very much less 20:4n-6. The fatty acid profile of marmoset erythrocyte SPM was characteristic of this phospholipid species in having a high proportion of saturated fatty acids, particularly 16:0, lower proportions of 18:2n-6 and 20:4n-6, and the presence of both long-chain

[a]Data are presented as the mean ± SEM for samples from the indicated number of animals (n) in each dietary group. All other details are as described in Table 1. Only those fatty acids present at >0.5% of the total (w/w) are reported. Data were analyzed as described for Table 3.

saturated (20:0, 22:0; 24:0) and monoenoic (24:1n-9) fatty acid (Table 6).

Although n-3 supplementation increased the proportion of 20:5n-3, the final proportion remained at less than 1% of the total SPM fatty acids. The proportion of 18:2n-6 decreased as a result of 20:5n-3 supplementation in both diet groups. The proportion of saturated fatty acids in SPM was increased in the ATH and ATH + EPA diet groups in comparison to the REF and REF + EPA diet groups due mainly to an increase in the proportion of 18:0. Reliable measures of the constituent fatty acids in the PI + PS fractions could not be obtained due to the low levels of these phospholipids in marmoset erythrocyte membranes.

By fitting the dietary fatty acids as energy percent values into the equation devised by Lands *et al.* (18 and Lands, W.E.M., personal communication) along with the appropriate constants, it was possible to compare the levels predicted from the equations with the level of n-3, n-6 and n-9, 20 and 22 carbon HUFA observed in erythrocyte total phospholipids (Fig. 1). There was good agreement between actual and predicted n-3 HUFA for all

[a]Data are presented as the mean ± SEM for samples from the indicated number of animals (n) in each dietary group. All other data are as described in Table 1. Only those fatty acids present at >0.5% of the total (w/w) are reported. Data were analyzed as described for Table 3.

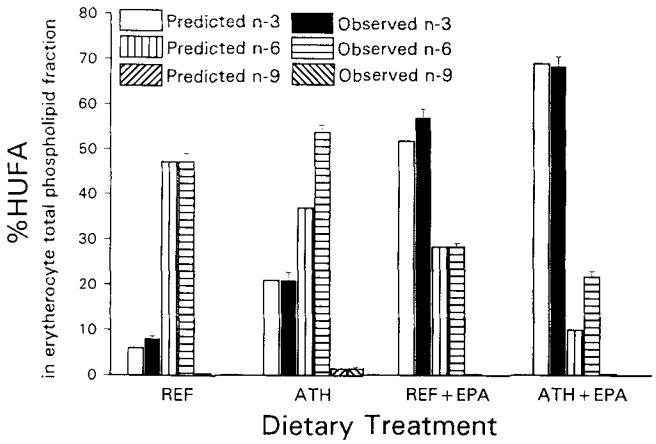

FIG. 1. Predicted levels of n-3, n-6 and n-9 highly unsaturated fatty acid (HUFA) levels in erythrocyte total phospholipids compared to actual levels observed in membrane extracts of marmosets fed different diets. Error bars indicate standard deviation of mean values.

dietary treatments. The level of n-6 HUFA was accurately predicted in both the REF and REF + EPA diets but poorly predicted in the two ATH-based diets.

DISCUSSION

This study was designed to compare the incorporation of EPA into erythrocyte membranes in two contrasting basal diets namely an atherogenic diet high in saturates containing 0.2% cholesterol and a reference diet rich in linoleate and low in cholesterol. Thus the elevated n-3 incorporation in the ATH group could be accounted for by cholesterol effects, polyunsaturate effects, or both. Without having done direct comparisons any explanation of the results obtained in our study can only be tentative. However there is suggestive evidence from earlier studies carried out in the marmoset that the effect of dietary cholesterol on tissue membrane fatty acid composition is too small to account for the effects seen in the current study. For example when we fed marmosets a reference type diet (P/M/S, 0.5:1:1), addition of 0.5% cholesterol resulted in only small inconsistent changes to both the n-3 and n-6 polyunsaturates of heart ventricle membranes (19). Furthermore in a separate study, marmosets fed a diet with a fatty acid composition identical to the atherogenic diet of the present study but with only 0.05% cholesterol were found to contain erythrocyte fatty acid patterns similar to the present study (16). For example the levels of fatty acids for the present study compared with the earlier study (16) were 18:2n-6 (13.0 ± 0.2, 12.6 ± 0.5) 20:4n-6 (11.4 ± 0.1, 11.9 ± 0.3) 22:5n-3 (4.1 ±

0.1, 3.7 ± 0.1) and 22:6n-3 (3.1 ± 0.1, 4.4 ± 0.2). Thus it is likely that cholesterol fed at a level of 0.2% (present study) will have caused only minimal changes in the erythrocyte membrane composition. It is interesting to note in this regard that the effect of cholesterol on plasma fatty acids may be species specific. For example 1% cholesterol added to the diet resulted in a decrease in plasma 20:4n-6 in rabbits (21). Interestingly, the dietary treatments employed in this study did not result in altered membrane cholesterol levels despite modulation of plasma levels (22).

The Lands equation (18 and Lands, W.E.M., personal communication) accurately predicted the increase in n-3 incorporation in the two ATH-based diets as well as the two REF-based diets (Fig. 1). Since deviations from predictions could be expected if factors other than those included in the equation (such as cholesterol) were influencing the equation, we take this to indicate that the increased incorporation of EPA into erythrocyte membranes in the two ATH-based diets was a result of reduced n-6 fatty acids in the diet rather than the presence of cholesterol. However it is clear that the equation did not accurately predict the level of n-6 HUFA in membrane total phospholipids of the ATH-based diets. This may indicate a perturbation in the membrane composition due to cholesterol.

Our interpretation of the results of this study is that in marmoset monkeys the incorporation of n-3 polyunsaturates into erythrocyte membranes is particularly sensitive to the presence of other fatty acids in the diet. Specifically we believe that the results indicate that the level of dietary 18:2n-6 over and above the level normally required to prevent essential fatty acid deficiency in animals (23) reduced n-3 incorporation. For example, in animals receiving EPA-supplemented diets the levels of 20:5n-3 in all erythrocyte phospholipid fractions from animals fed diets low in 18:2n-6 were about twice the level seen in membrane phospholipids of animals fed high 18:2n-6 diets. Interestingly the levels of 20:5n-3 in membranes of animals receiving unsupplemented atherogenic diets were 6–8 fold that seen in the reference or high 18:2n-6 group indicating that the effect applies to both endogenously synthesized, as well as supplemented, 20:5n-3. As has been mentioned, this effect can be predicted from the Lands equations (18 and Lands, W.E.M., personal communication) which quantify the interaction between n-3 and n-6 dietary fats.

Despite parallels that can be seen in some human studies, there have been few attempts to specifically test the strong effect of dietary 18:2n-6 on n-3 fatty acid incorporation into tissues or to measure these diet-induced changes in erythrocyte membranes in animals. However work with rats has shown that 20:5n-3 accumulates to a greater extent in serum and liver lipid fractions when n-3 fatty acids are fed in combination with saturated fatty acids than with 18:2n-6-rich diets (14,24). Indeed Lee and Sugano (25) have shown that in rats fed 18:3n-3, incorporation of 20:5n-3 into plasma and liver PC is more sensitive to dietary 18:2n-6 than is the incorporation of 22:6n-3.

The low 18:2n-6 (ATH) diet used in this study increased the proportion of 20:4n-6 found in erythrocyte total phospholipids and PE while it reduced the level of membrane 18:2n-6. We have observed similar effects in rats (26) implying that 18:2n-6 competes with both 20:4n-6 and 20:5n-3 for incorporation into the phospholipid molecule. The introduction of 20:5n-3 to both the ATH and REF diets further reduced the level of both 20:4n-6 and 18:2n-6 incorporation into the total phospholipids and PE fraction indicating a complex interrelationship between n-6 and n-3 fatty acids in these conditions. Indeed other studies have indicated that in rats, where a constant dietary intake of 18:2n-6 is maintained, dietary 18:3n-3 and 20:5n-3 can both independently result in increased incorporation of 18:2n-6 and decreased incorporation of 20:4n-6 into plasma and liver phospholipids (27). A study done in healthy women showed a similar relationship between these n-3 and n-6 polyunsaturated fatty acids associated with plasma cholesteryl esters (28).

A further effect observed in the 20:5n-3-treated groups was the reduction in the proportion of 20:3n-6, the precursor of the 1-series eicosanoids, to a level of 20–30% of that seen in the reference diet groups. Reductions in 20:3n-6 levels have been reported in tissue phospholipids of rats fed fish oil (29) and in the plasma of rheumatoid human subjects consuming 20:5n-3 (30); however, such changes were not observed in erythrocyte phospholipids (9). This may be a reflection of n-6 levels in the diets of these subjects, as it has been shown that it is possible to increase tissue 20:3n-6 levels in fish oil fed animals by enriching the diets with 18:3n-6 (31,32).

One of the most significant results for animals fed 20:5n-3 was the large increase in the proportion of 22:5n-3 in both the erythrocyte total phospholipids and in the PE fraction. However there was little change in 22:6n-3, Δ4 desaturase product of 22:5n-3. A similar trend has been observed in platelet phospholipids from atherosclerotic patients fed 20:5n-3 ethyl ester (33). Such an effect would be masked in subjects fed fish oils containing 22:6n-3. Whether this effect is due to poor conversion of 22:5n-3 or limited incorporation sites for 22:6n-3 into erythrocyte phospholipids is not clear from these results although the existence in rat liver of a Δ4 desaturase has recently been questioned (34). Certainly, the 30-wk feeding period employed in our study is sufficient to maximize diet-induced changes in erythrocyte membranes.

Overall, the most significant result of the present study was the increased incorporation of 20:5n-3 and 22:5n-3 in animals fed atherogenic diets compared to those consuming diets rich in 18:2n-6. Although directly comparable experiments have not been carried out in humans, there is evidence that incorporation of n-3 polyunsaturated fatty acids into plasma lipids and platelets of humans is inversely correlated with the level of dietary linoleate (35). Our results are therefore relevant to dietary studies on the effects of 20:5n-3 containing oils, on vascular disease risk factors (1,2) and arthritis (36).

ACKNOWLEDGMENTS

We thank Mr. G. Cook for overseeing the marmoset breeding program, Mr. J. Greenfield for care of the animals and preparation of the diets, and Dr. J. Clarke for veterinary care. We also thank Dr. Y. Tamura for supplying the EPA concentrate. This work was supported in part from a grant-in-aid from the National Heart Foundation of Australia (to EJM).

[Received September 21, 1990, and in revised form November 18, 1991; Revision accepted January 2, 1992]

Monoenoic Fatty Acids in Human Brain Lipids: Isomer Identification and Distribution

D.W. Johnson*, K. Beckman, A.J. Fellenberg, B.S. Robinson and **A. Poulos**
Department of Chemical Pathology, Adelaide Medical Centre for Women and Children, North Adelaide, South Australia, 5006, Australia

The carbon chain length distribution and the double bond positional isomer composition of the monoenoic fatty acids of the lipids of total human brain tissue have been determined using gas chromatography and gas chromatography/mass spectrometry of the fatty acid methyl and picolinyl esters. The even chain length monoenoic C_{16} to C_{28} fatty acids contain predominantly two positional isomer series, the n-7 and n-9 *cis* homologues, whose relative proportion varies significantly with chain length. The odd chain length long-chain fatty acids consist of n-8 and n-10 isomers, whereas the odd chain length very long-chain (more than 22 carbon) fatty acids are n-7 and n-9 isomers. ***Lipids 27,*** **177–180 (1992).**

The ratio of monoenoic fatty acids to saturated fatty acids in the lipids of human brain tissue is low at birth, rapidly increases when the process of myelination begins, and reaches a plateau by three years of age. Monoenoic fatty acids originate mostly from *de novo* synthesis and a small portion is derived from the diet. Two major double bond positional isomer series, the n-7 and n-9 homologues, have been identified. The reason for the existence of double bond positional isomers and whether each isomer has a different function is presently unclear. Studies with *cis* n-8 octadecenoic acid in animal (1) and human (2) tissues suggest that some positionally isomeric monoenoic fatty acids are metabolized by different routes. Monoenoic fatty acids may also play a role in the biosynthesis of saturated fatty acids (3).

Surprisingly, analyses of the double bond positional isomer series of the monoenoic fatty acids present in human brain, which would provide information to contribute to an understanding of the biosynthetic pathways of monoenoic fatty acids, have not been reported. A limited identification of isomer series of mixtures of monoenoic fatty acids has been achieved by GC analysis of the products after reductive ozonolysis. This approach, however, gives an average of all carbon chain lengths present.

A composite technique, described in this paper, coupled the identification capability of gas chromatography/mass spectrometry (GC/MS) and the quantitation capability of gas chromatography (GC) to achieve the dual requirements of analyzing double bond position and carbon chain length distribution of the total monoenoic fatty acids in whole human brain.

MATERIALS AND METHODS

Brain samples were obtained from male children aged 4, 5, 7 and 13 years who died in accidents, a male aged 53 years who suffered a cardiac tamponade, and a female aged 85 years who died from cardiorespiratory failure. The rat brain was obtained from a 14-day-old Porton rat, killed by decapitation.

Lipids were extracted according to Folch *et al.* (4) from 1-g samples of whole brain, containing similar amounts of white and grey matter, and were transesterified with 0.27 M sulfuric acid in methanol. Fatty acid methyl esters were isolated by preparative thin-layer chromatography (TLC) as previously described (5), and applied under nitrogen as 4 cm zones to silver nitrate impregnated silica gel 60 plates prepared by the method of Inomata *et al.* (6). A monoenoic fatty acid methyl ester standard was applied as reference at both edges of the plate and the chromatogram was developed in hexane/diethyl ether (95:5, v/v). After development, the plates were briefly air dried and sprayed with 0.2% (w/v) dichlorofluorescein in ethanol to locate the monoenoic methyl esters. That zone was scraped from the plate and eluted with 10 mL of chloroform/methanol (2:1, v/v). Dichlorofluorescein was removed by washing with dilute ammonia solution, and the chloroform solution was separated, dried and evaporated in a glass tube. This technique (argentation chromatography) separates monoenoic methyl esters from saturated (top of TLC plate) and polyenoic (bottom of TLC plate) methyl esters. To the monoenoic methyl ester fraction was added 1 mL of ethanol and 0.5 mL of 10% (w/v) potassium hydroxide in water, and the mixture was heated at 80°C for 4 hr. The solution was cooled, acidified with 0.5 mL concentrated hydrochloric acid, and extracted with 3 mL of hexane. The hexane extract, containing monoenoic fatty acids, was evaporated to dryness and 0.1 mL of thionyl chloride was added. After 5 min, excess thionyl chloride was removed in a stream of nitrogen and 0.05 mL of 3-pyridylcarbinol/acetonitrile (1:9, v/v) was added. The acetonitrile was removed in a stream of nitrogen after 10 min and 0.05 mL tetrahydrofuran was added. One μL of this solution was injected into the GC/MS.

The GC/MS was a JEOL JMS DX-303 single beam double focusing mass spectrometer (Tokyo, Japan) equipped with a Hewlett-Packard 5890 gas chromatograph (Avondale, PA) and a JEOL JMA DA5000 data system. Esters were separated using a splitless injector, heated at 270°C, coupled to a Scientific Glass Engineering (SGE, Melbourne, Australia) BP-1 bonded phase silica column (12 m × 0.22 mm i.d., 0.25 μm phase thickness) directly inserted into the mass spectrometer source. For analyses of both methyl and picolinyl esters, the gas chromatograph was temperature programmed from 160°C to 320°C at 4°C/min, and then maintained at 320°C for 10 min. The mass spectrometer was operated in the electron impact mode at an ionization voltage of 70 eV and a source temperature of 250°C.

The GC was a Perkin Elmer Sigma 2 model (Norwalk, CT) equipped with a splitless injector system, a flame ionization detector and a Hewlett Packard 3396A integrator (Avondale, PA). Esters were separated on a nonpolar BP-1 bonded phase silica column (SGE, Melbourne,

Australia; 25 m × 0.33 mm i.d., 0.25 μm phase thickness) and a polar BPX70 (SGE) bonded phase silica column (25 m × 0.33 mm i.d., 0.25 μm phase thickness).

Samples of monoenoic fatty acids and methyl esters were obtained from NuChek Prep (Elysian, MN). Others, including 26:1n-9, 27:1n-9 and 28:1n-7 were synthesized (7).

RESULTS

Whole brain tissue, comprising approximately equal amounts of white and grey matter, from six normal individuals ranging in age from 4- to 85-years-old was extracted and the lipids were transesterified. The fatty acid methyl esters were resolved by TLC and analyzed by GC on both a polar and a non-polar capillary column, and then by GC/MS. The monoenoic fatty acid methyl esters were identified by GC/MS, by selective scanning of molecular ions and molecular ions less 32 amu (atomic mass units), and their percentage composition was determined by GC using an electronic integrator. The monoenoic fatty acids comprised 27.9% ± 0.9% S.D. of the total long-chain fatty acids (assuming a non-discriminatory response by the GC detector).

Each sample was then subjected to argentation chromatography and again analyzed by both GC and GC/MS. Both BP1 nonpolar and BPX70 polar chromatography columns were employed to ensure unambiguous assignment of the monoenoic fatty acid methyl esters. Small amounts of saturated fatty acids, principally methyl palmitate and methyl stearate, and other contaminants were present but they did not interfere with the analysis. The carbon chain length distribution of the monoenoic fatty acids is summarized in Table 1. To ensure that the relative composition of the monoenoic fatty acids was not significantly altered during argentation chromatography, the ratios of C_{26}/C_{18} monoenoic fatty acids before and after purification were compared. They were found to differ by between 4 and 10% in the 6 brain samples.

The double bond positional isomers of the mixture of monoenoic fatty acids were then identified by mass spectral fragmentation analysis of fatty acid derivatives. The 3-picolinyl esters first used by Harvey (8,9) and subsequently by Christie *et al.* (10–12) for the analysis of monoenoic long-chain fatty acids of animal and marine origin were chosen as the most suitable of the many available (13–17).

Initial attempts to prepare the picolinyl derivatives of the monoenoic fatty acids by reacting the acid chlorides with 3-pyridylcarbinol in acetonitrile were disappointing. The picolinyl derivatives, especially those of the very long-chain acids, were poorly soluble in acetonitrile. When this solvent was replaced by tetrahydrofuran, GC/MS response improved dramatically. The picolinyl derivatives of a series of monoenoic fatty acid standards (16:1n-7, 18:1n-9, 20:1n-9, 20:1n-12, 22:1n-9, 24:1n-9, 26:1n-9, 27:1n-9 and 28:1n-7) were prepared. The mass spectra of the picolinyl derivatives indicate cleavage of the terminal methyl group (loss of 15 amu) and then sequential cleavages of methylene groups (14 amu) until the double bond is reached, when there is a loss of 26 amu. In addition, the intensities of the two ions from cleavage two and three carbon atoms before the double bond are significantly higher. These ions have been rationalized by Harvey (8) and by Christie (18) as arising from cleavage after abstraction of an allylic hydrogen from either side of the double bond. This doublet of intense ions was shown to be the most reliable way of assigning the position of the double bond in the monoenoic fatty acid standards and then in the brain monoenoic fatty acids. For example, the spectrum of the picolinyl derivative of 19:1n-8, shown in Figure 1A, has a gap of 26 amu between *m/z* 262 and 288 and two strong ions at *m/z* 302 and 316, while the mass spectrum of the picolinyl derivative of 19:1n-10, shown in Figure 1B, has a gap of 26 amu between *m/z* 234 and 260 and two strong ions at *m/z* 274 and 288.

The GC/MS total ion chromatograms of the mixtures of picolinyl derivatives of the brain monoenoic fatty acids were extremely complex. Many peaks arose from side reactions of the reagents but, fortunately, few of them obscured the monoenoic fatty acid derivatives, which possessed intense ions at *m/z* 92, 108, 151 and 164, as well as prominent molecular ions. The picolinyl derivatives give broader peaks than the methyl esters and there is poorer separation of the isomers. Spectra taken on the leading and trailing edges of the peaks were, however, diagnostic of the two isomeric forms in all of the doublet peaks analyzed. Figure 1 shows two mass spectra, taken six seconds apart, of the picolinyl derivative of 19:1 fatty acid isolated from normal brain and assigned as the n-8 (A) and n-10 (B) isomers. The order of elution was the same as for methyl esters, *i.e.*, the lower numbered positional isomer eluted first on the non-polar column and last on the polar column. For this reason quantitation of the isomeric forms of the monoenoic fatty acids was performed using the methyl esters. Figure 2 shows the purified monoenoic fatty acid methyl esters from a normal adult brain and their isomer assignments. The monoenoic fatty acid isomer distribution of the six brain samples are presented in Table 2. A realistic level of isomer detection would be 5% of the total for each carbon chain number, so minor amounts of other isomers may well be present.

The monoenoic fatty acid composition of a 14-day-old rat brain (near the onset of myelination) was determined by the same procedure (data not shown), and the only noticeable difference from normal human brain was a

[a]The distribution (expressed as a percentage) of the monoenoic fatty acid isomers with the same carbon chain length in six specimens of human brain.

greatly reduced proportion of 16:1n-7 fatty acid, which probably reflects the diet different from that of humans.

DISCUSSION

The fatty acid composition and isomer distribution of human brain that we measured at ages 4, 5, 7, 13, 53 and 85 years were remarkably consistent. This does not contradict the accepted view that there is a reduction in monoenoic fatty acids with age because percentage composition, and not fatty acid concentration, per g of brain tissue was determined. The even numbered carbon chain monoenoic fatty acids contain predominantly n-7 and n-9 series isomers, which may originate from dietary palmitoleic acid (16:1n-7) and oleic acid (18:1n-9). The ratio of amounts of the two isomer series at each even carbon chain number is not constant, but varies in a cyclical pattern with increasing carbon chain number. The n-7/n-9 ratio has maxima at 16, 22 and 28 carbon atoms and minima at 18 and 24 carbon atoms, which indicates that the two series are metabolized differently.

The odd numbered carbon chain monoenoic long-chain fatty acids contain mostly n-8 and n-10 isomers. Long-chain n-10 fatty acids are biosynthesized in skin sebaceous glands and in cultured fetal rabbit lung tissue (19). The origins of the n-8 and n-10 isomers in the brain are therefore probably biosynthetic and the fatty acids are not directly derived from the diet. The odd numbered carbon chain monoenoic very long-chain fatty acids (*e.g.*, 25:1 and 27:1) consist only of n-7 and n-9 isomers. These result from one carbon shortening by α-oxidation of the longer, even chain, monoenoic fatty acids.

No *trans* monoenoic fatty acids were identified for which there is an explanation. Studies by Ohlrogge *et al.* (2) had shown that the most abundant *trans* octadecenoic fatty acid in brain, the n-8 isomer, was less than 1% of the total octadecenoic fatty acids, *i.e.*, well below our detection limit. Furthermore, Cook (20) had shown that no *trans* monoenoic fatty acids longer than C_{18} were present in brain.

Brain is a complex mixture of organelles, cells and cellular components including neurons, synaptosomes, astrocytes, oligodendrocytes, myelin, microsomes and mitochondria. The method described has been successful in defining the monoenoic fatty acid composition and distribution of a representative sample of these. Processes involving synthesis and differential metabolism of monoenoic fatty acids, either in normal brain or diseased brain, may occur in specific cell (or cell component) types. Provided that methods will become available to isolate purified cells (or cell components), our method can be scaled down as much as ten-fold to adjust for smaller sample sizes.

Effects of Polyphenolic Natural Products on the Lipid Profiles of Rats Fed High Fat Diets

T. Yugarani[a], B.K.H. Tan[b], M. Teh[c] and N.P. Das*[,a]

Departments of [a]Biochemistry, [b]Pharmacology and [c]Pathology, Faculty of Medicine, National University of Singapore, Singapore 0511, Republic of Singapore

Male Wistar rats were fed a high fat diet (HFD) containing 2.5% cholesterol and 16% lard supplemented with polyphenolic natural products namely quercetin, morin or tannic acid (100 mg/rat/day) for 4, 7 and 10 wk. Rats fed HFD without the supplements served as control. The effects of these compounds on blood lipid profiles, enzymes, liver fat and aorta of the rat were studied. In rats fed HFD containing tannic acid, plasma total cholesterol (TC), low density lipoprotein cholesterol (LDLC) and triglyceride (TG) were reduced by 33.3%, 29.6% and 65.1%, respectively, at week 10. High density lipoprotein cholesterol (HDLC) concentration was not altered. Fat deposition was also decreased in the liver of these rats. Morin significantly reduced plasma TG (65.1%) and liver fat only at week 7 while at week 10 it reduced plasma TC and LDLC by 30.9% and 29.3% respectively. The plasma HDLC concentration was increased by 47.3% at week 4 but no effect was seen at weeks 7 and 10. In the rats fed HFD containing quercetin, plasma HDLC was increased by 28.6% at week 7 but at week 10, plasma LDLC was increased by 21.2%. Quercetin did not cause any significant changes on the plasma TC, TG and liver fat at weeks 4, 7 and 10. Plasma alanine aminotransferase, alkaline phosphatase and bilirubin in control and treated groups were not significantly different. However, hepatic lipase activity in rats fed tannic acid was significantly lower. Aortae of all groups of rats showed no abnormalities. The present report indicates that tannic acid and morin are effective in reducing plasma and liver lipids when supplemented with a high fat diet in rats.

Lipids 27, 181-186 (1992).

Coronary heart disease (CHD) is one of the most prevalent causes of death in the United States (1). Hypercholesterolemia is an important etiological factor in CHD. Studies have shown that the risk of developing CHD is linearly related to serum cholesterol concentration (2) and low density lipoprotein cholesterol (LDLC; ref. 3), while high density lipoprotein cholesterol (HDLC) exerts a protective effect (4). Other complications of hypercholesterolemia include the development of premature atherosclerosis and atherothrombotic brain infarction (1). Dietary lipids have been reported to cause atherosclerosis in various animal models (5-8). In rats, cholesterol feeding increased low density lipoprotein (LDL) and decreased high density lipoprotein (HDL; ref. 9).

Abbreviations: ALAT, alanine aminotransferase; ANOVA, analysis of variance; AP, alkaline phosphatase; ATP, adenosine triphosphate; BF_3, borontrifluoride; BHT, butylated hydroxytoluene; CHD, coronary heart disease; EDTA, ethylenediaminetetraacetate; G1, group 1; G2, group 2; G3, group 3; G4, group 4; G5, group 5; HDLC, high density lipoprotein cholesterol; HFD, high fat diet; HFD + M, high fat diet + morin; HFD + T, high fat diet + tannic acid; HFD + Q, high fat diet + quercetin; LDLC, low density lipoprotein cholesterol; NADH, reduced nicotinamide adenine dinucleotide; ND, normal diet; TC, total cholesterol; TG, triglyceride.

The polyphenolic natural products namely flavonoids and tannic acid (hydrolyzable tannin; Fig. 1) are ubiquitous in plants and are easily accessible to animals and man through their diets (10). It is estimated that the average American (USA) adult dietary intake of these natural products is about 1 g/day comprised of mixed flavonoids (11). These polyphenolic substances have been effectively used to treat certain human diseases (12,13). Flavonoids increased the survival time of rats when fed together with either a thrombogenic or atherogenic diet (14). In *in vitro* studies, they have exhibited antithrombotic effects (15).

Quercetin, found commonly in vascular plants (16), reduced plasma total cholesterol (TC) when maintained in colloidal suspension *in vitro* (17) but not plasma total cholesterol (TC) in rats (18). It is also non-toxic (19) and non-carcinogenic (20). Morin is structurally related to quercetin (a flavonol; Fig. 1). Tannins are commonly found in food (21) and in herbal medicine (22). Tannic acid (a hydrolyzable tannin) occurs in the bark and fruits of many plants (23) and is non-toxic when fed to rats at dietary levels of less than 5% (24).

In view of the limited reports on the biological effects of polyphenolic natural products on rats fed atherogenic diets (14), it was felt useful to carry out a study in order to evaluate the effects of some of these compounds namely quercetin, morin and tannic acid when supplied as food supplements (100 mg/rat/day) to rats fed high cholesterol and lard diets. The single dose was selected because our preliminary investigation (data not shown) had indicated it to be the most ideal dosage to use. Single dosage studies

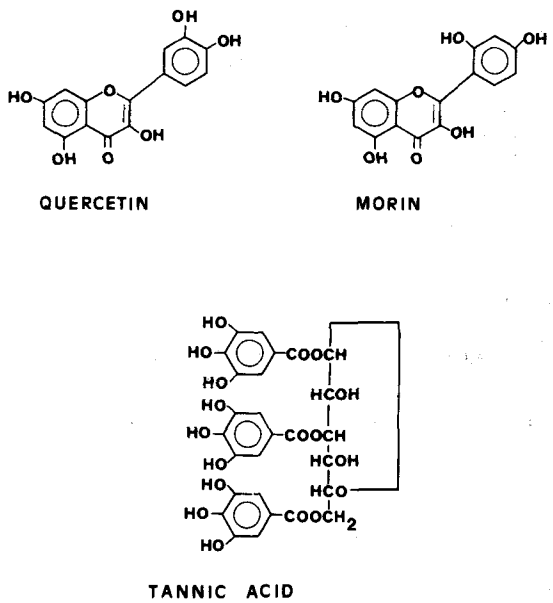

FIG. 1. Structure of polyphenolic compounds used in the present study.

have been used to study the effects of other compounds on serum and liver cholesterol (25,26). Any beneficial effects of these natural products may provide a basis for future investigations for the possible treatment of lipid disorder resulting from high fat dietary intake. Their reported non-toxicity in animals rendered the compounds useful for the present study.

MATERIALS AND METHODS

Chemicals. Cholesterol was purchased from E. Merck (Darmstadt, Germany). Morin and tannic acid were obtained from Extrasarsyntex (Ganey, France). Quercetin was supplied by Sigma Chemical Co. (St. Louis, MO).

Animals and treatment. Male Wistar rats, body weight approximately 180 g were used. The rats were divided into five groups, each group comprising nine rats as follows: Group 1 (G1)—normal diet; Group 2 (G2)—high fat diet (HFD) without supplement; Group 3 (G3)—HFD with quercetin; Group 4 (G4)—HFD with morin; and Group 5 (G5)—HFD with tannic acid. The compositions of the diets and their fatty acid contents are given in Tables 1 and 2, respectively. The normal diet was adopted from Griffith's (27) earlier report because it was necessary to use a natural diet which contained a low level of flavonoids and other phenolic compounds. During the first week of the experiment, each rat consumed about 7 g/day of the powdered diet. This amount was increased by 1 g weekly. Each polyphenol (100 mg/rat/day) was mixed thoroughly into the diet prior to feeding. At the end of 4, 7 and 10 wk, 3 rats were taken from each group, weighed and then decapitated. Whole blood was collected into tubes containing ethlenediaminetetraacetate (EDTA) and centrifuged to obtain plasma. The plasma was either analyzed immediately or stored at −70°C until analyses were carried out.

Tissue preparation. The fresh liver from each rat was partly cut into 2-mm sections and preserved in 10% formalin. Further 10-μm sections were made and stained with Oil Red 'O' for examination of fat distribution. A sample of liver (1 g) was used for the determination of TC and triglyceride (TG). TC and TG were extracted according to the method of Haug and Hostmark (28). Hepatic lipase was extracted from the remaining fresh liver according to our earlier reported method (29). Thoracic aorta was removed from each rat and preserved in 10% formalin. Each aorta was subsequently cut into 10 equal sized sections, dehydrated and paraffin embedded. Using a microtome, each section was further cut into 8-μm slices. The slices were stained with hemotoxylin and eosin (H and E) and examined under a light microscope for evidence of atherosclerotic changes.

Lipid analysis. The concentrations of plasma LDLC, HDLC, TC, and TG and of liver TG and TC were determined using commercially available diagnostic kits from Boehringer Mannheim GmbH (Singapore) according to the protocol supplied.

Briefly, cholesteryl esters were enzymatically cleaved by cholesterol esterase to liberate cholesterol and free fatty acids. The enzyme-liberated cholesterol and the endogenous free cholesterol were oxidized by cholesterol oxidase to form Δ^4 cholestenone and hydrogen peroxide (H_2O_2). The H_2O_2 generated was reacted with 4-aminophenazone and phenol (catalyzed by peroxidase) to form a pink complex. The color intensity was read at 500 nm.

LDL in plasma was reacted with polyvinyl sulfate which resulted in the formation of the LDLC precipitate. The supernatant was taken to determine the total cholesterol concentration. From the difference between plasma TC and TC in the supernatant after centrifugation, the LDLC value was calculated.

For the determination of HDLC, phosphotungstic acid and $MgCl_2$ were added to the sample to precipitate chylomicrons, very low density lipoprotein (VLDL) and LDL. The HDL remained in the supernatant after centrifugation and the cholesterol content was determined as described above.

TG was hydrolyzed by lipase to form free fatty acids and glycerol. The glycerol was reacted with glycerol kinase in the presence of adenosine triphosphate (ATP) to form glycerol-3-phosphate. The glycerol-3-phosphate was oxidized by glycerol phosphate oxidase to form dihydroxyacetonephosphate and H_2O_2. The H_2O_2 was complexed with 4-aminophenazone and phenol, and the pink color formed was read at 500 nm.

Enzyme and bilirubin analysis. Activities of the enzymes alkaline phosphatase (AP) and alanine aminotransferase (ALAT) in plasma, hepatic lipase, and plasma total bilirubin concentrations were determined using diagnostic kits from Boehringer Mannheim GmbH.

Briefly, in the determination of AP, the substrate *p*-nitrophenyl phosphate was hydrolyzed to phosphate and *p*-nitrophenol by the enzyme. The formation of *p*-nitrophenol was then measured at 405 nm. In the determination of ALAT, the sample was added to the test reagent which contained a mixture of α-oxoglutarate and L-alanine as substrate. α-Oxoglutarate and L-alanine were acted upon by ALAT to form glutamate and pyruvate,

TABLE 1

Compositions of the Diets

Contents	Normal diet (g/100 g)	High fat diet (g/100 g)
Wheat flour	70.7	52.6
Milk powder	23.6	23.2
Dried yeast powder	3.5	3.5
Sodium chloride	1.2	1.2
Multivitamins[a]	1.0	1.0
Cholesterol powder	0	2.5
Pork lard	0	16.0

[a]Vitamin composition is given in our earlier report (29).

TABLE 2

Fatty Acid Composition of Experimental Diets and Lard (% of total fatty acids)

Fatty acid	Normal diet	High fat diet	Lard
10:0	4.0	2.0	—
12:0	4.8	2.2	—
14:0	12.3	6.3	2.1
16:0	27.3	27.9	28.3
18:0	10.3	12.6	14.9
18:1n-9	18.2	29.6	37.4
18:2n-6	9.2	9.7	10.6
18:3n-6	5.7	3.5	—

respectively. The pyruvate was further converted to lactate in an irreversible reaction by lactate dehydrogenase in the presence of reduced nicotinamide adenine dinucleotide (NADH) and the decrease in absorbance due to the utilization of NADH was followed at 340 nm.

Hepatic lipase hydrolyzed triolein (in test reagent) to form monoglyceride and oleic acid. The decrease in turbidity due to the hydrolysis of triolein was also measured at 340 nm.

Total bilirubin in plasma was coupled with diazotized sulfanilic acid in the presence of caffeine to give an azo dye which absorbed at 580 nm.

Diet fatty acid analysis. The lipids in the rat diets were extracted using chloroform/methanol (2:1, v/v) containing 0.02% butylated hydroxytoluene (BHT) as an antioxidant. The chloroform layer, which contained the lipids, was removed and saponified with methanolic KOH and concentrated HCl. The free fatty acids were extracted into n-hexane and then methylated using borontrifluoride (BF_3)/methanol (30). The fatty acid methyl esters were analyzed on a Varian model 3400 gas chromatograph equipped with a flame ionization detector and a fused silica capillary column (DB-1; from J & W Scientific, Folsom, CA). A programmed run over the temperature range of 150°-250°C, on-column injection, and oxygen-free nitrogen as carrier gas were used.

Statistical analysis. Values of the biochemical parameters in each group are expressed as mean ±SEM. One way analysis of variance (ANOVA; ref. 31) followed by Duncan's Multiple-Range Test (32) were used to evaluate the significance of differences found between mean values. P values < 0.05 were considered to be statistically significant.

RESULTS AND DISCUSSION

Food intake in all the five groups of rats were unaffected by the experimental diet. The rats in each group consumed all the allotted amount of food daily. Since hypercholesterolemia was induced in the experimental group of rats by feeding cholesterol and lard, the G1 normal diet (ND) rats were used as a comparison to G2 (HFD) in order to determine at which time interval (week 4, 7 or 10) blood cholesterol was significantly increased. Feeding of the HFD for 4 wk did not significantly induce hypercholesterolemia in G2 (Fig. 2). However, at week 7 the plasma TC in G2 was significantly increased in comparison to G1. The plasma cholesterol concentration was presumably stabilized in G2 after 7 wk because there was no further increase at week 10. In contrast to this, plasma TC in G1 did not fluctuate significantly from week 4 to 10 with an average concentration of 76.4 ± 2.1 mg/100 mL.

The G2 (HFD without supplement) rats were used as control for the test groups G3–G5. In G5, plasma TC was significantly reduced by 26.4% and 33.3% at week 7 and 10, respectively (Fig. 2). In G4, plasma TC was only significantly reduced at week 10 (30.9%), thus indicating that morin is able to reduce plasma cholesterol upon prolonged intake.

All the rats showed progressive increase in body weight from weeks 4–10. However, body weights did not differ significantly amongst groups (G1–G5) during the 10 wk period (Table 3). Therefore, the reduction in plasma TC in G4 and G5 cannot be attributed to weight loss or lower

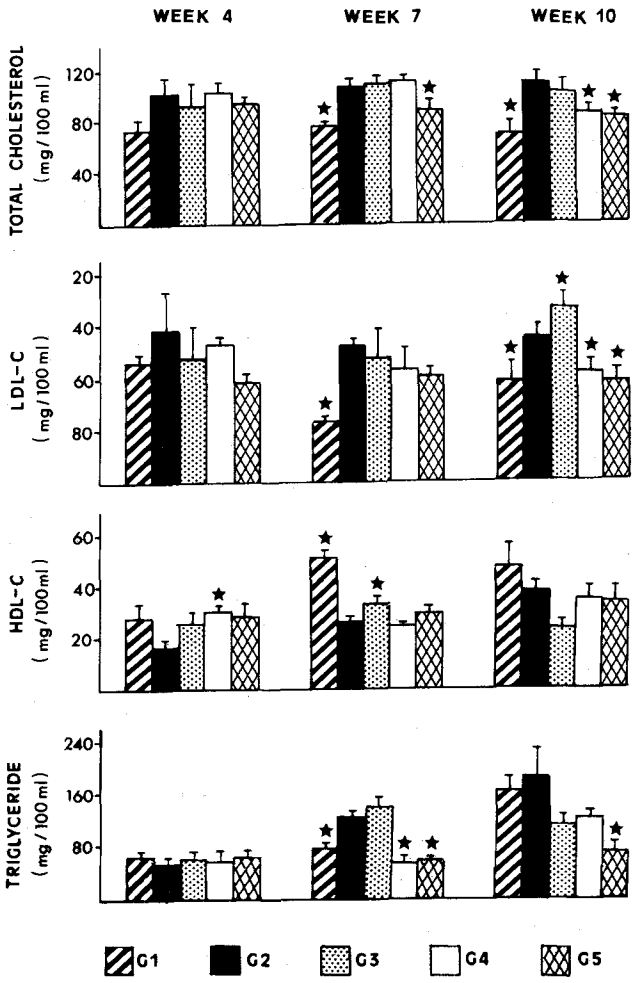

FIG. 2. Concentration of plasma total cholesterol, LDL-C, HDLC-C and triglyceride. Values are expressed as mg/100 mL plasma. ★ denotes a statistically significant difference between G2 and other groups ($p < 0.05$).

TABLE 3

Average Body Weight Increases (measured as percentage)[a]

Animal groups	% Increase in body weight		
	Week 4	Week 7	Week 10
G1 (ND)	36.3 ± 1.6[a]	58.6 ± 14.1[a,b]	89.2 ± 9.5[a]
G2 (HFD)	48.3 ± 5.3[a]	73.0 ± 5.4[a]	85.6 ± 7.8[a]
G3 (HFD + Q)	38.4 ± 6.3[a]	74.8 ± 1.8[a]	100.0 ± 3.1[a]
G4 (HFD + M)	47.6 ± 11.0[a]	61.7 ± 4.6[a]	100.0 ± 8.2[a]
G5 (HFD + T)	46.5 ± 5.6[a]	73.0 ± 8.2[a]	88.5 ± 5.7[a]

[a]In each experiment, values in the same column without common superscript letters denote significant difference ($p < 0.05$). Values are mean ± SEM of three animals.

weight gain of the rats in these two groups. In contrast, large reductions in body weight have been associated with reduced blood lipids (33). Quercetin (G3) did not cause any significant changes on plasma TC concentration at weeks 4, 7 or 10 (Fig. 2). Basarkar and Hatwalne (18) have also reported that feeding of quercetin did not lower plasma

TC in rats. However, in *in vitro* experiments, quercetin reduced plasma cholesterol when maintained in colloidal suspension (17).

The plasma LDLC concentration in G1 was significantly lower than in G2 at weeks 7 and 10 (Fig. 2). At week 10, LDLC in G4 and G5 were significantly reduced by 29.3% and 29.6%, respectively while in G3 a significant increase occurred (21.2%; Fig. 2). No significant differences were observed at weeks 4 and 7. Plasma concentration of LDLC is largely dependent on the rates of its production and removal from the circulation (34). LDLC is produced from very low density lipoprotein (VLDL) which is secreted by the liver and most of the plasma LDLC is removed *via* a hepatic receptor mediated process (35,36). A reduction in plasma LDLC by morin or tannic acid as observed in the present study suggests that these compounds may interfere with either one of these processes or both.

Plasma HDLC concentration in G1 and G3 were significantly higher (50.0% and 28.6%, respectively) than in G2 at week 7, but not at weeks 4 or 10 (Fig. 2). In G4 though HDLC was significantly increased by 47.3% at week 4, this effect was not sustained in the subsequent weeks (7 and 10). No significant difference was observed in plasma HDLC concentration in G5 when compared to control (G2) at weeks 4, 7 or 10. Mahley and Holcombe (9) have reported an increase in LDL and a decrease in HDL following cholesterol feeding in the rats. Cholesterol transport to extrahepatic tissues is primarily ensured by LDL while HDL has an important role in reversing the cholesterol transport process, whereby excess cholesterol is removed from peripheral tissues to the liver for excretion (37).

It is interesting to note that tannic acid is able to reduce LDLC and TC without affecting the HDLC level. Thus, there is a significant increase in the HDLC to TC ratio for this group of rats when compared to the control group (G2; Table 4). This ratio is suggested to be a more useful index for determining the quality and effects of fat on health. We have also recently reported a high ratio value on rats fed refined, bleached and deodorized palm oil (29).

Joslyn and Glick (24) have shown that tannic acid is non-toxic at dietary concentration of 5% or less. They also observed that tannic acid toxicity depended on the initial body weight of the rats used. Rats with a higher initial body weight showed greater resistance to tannic acid toxicity. In the present investigation we have fed less than 1.5% dietary concentration of tannic acid to rats with an initial body weight of about 180 g. We have observed no weight loss nor death throughout the experimental period and all the rats appeared to be normal and healthy.

No significant differences were observed in plasma TG concentration between all groups at week 4. At week 7, plasma TG concentration in G2 was significantly higher than in G1 (52.4%) indicating that the increase of TG in G2 is of dietary origin and the TG level appeared to be stabilized from week 7 onward because no significant difference was observed at week 10. The plasma TG of G4 and G5 were lower than G2 by 65.1% and 56.6%, respectively, at week 7. At week 10, plasma TG in G5 was further reduced (65.1%). It has been reported that enrichment of diet with n-3 fatty acids also reduces plasma TG concentrations in the rat (38). Perhaps morin or tannic acid may have acted in the similar process as the n-3 fatty acids.

The significant increase in liver weight (Table 5) without a significant increase in body weight (Table 3) of rats in G2–G5 in comparison to G1 (normal diet fed rats) is probably due to higher fat deposition resulting from a higher fat intake. Microscopic examination of the liver supports this conclusion for there was a minimal amount of fat deposited in the liver of normal diet fed rats (Fig. 3a). The tannic acid fed group (G5) showed less fat deposition (but higher than G1) in the liver when compared to G2–4 (Fig. 3b & c). This indicates that tannic acid is able to reduce the infiltration of fat into the liver cells of rats fed high fat diet.

Analysis of the liver TG and TC content at week 7 (Table 6) showed liver TC in G1 and G5 to be significantly lower than G2. In G1 and G4 the liver TG content was significantly lower than in G2 (Table 6). Although there was a significant decrease in liver TG of G4, this effect was not manifested in liver weight or liver fat distribution. Data for liver cholesterol and TG contents at weeks 4 and 10 were not obtained. Sugano *et al.* (39) observed reductions in liver cholesterol concentration of rats when fed with chitosan and cholesterol, and they have explained the reduction as a result of chitosan interfering with cholesterol absorption. It may be pertinent to suggest that tannic acid may also interfere with cholesterol absorption.

The liver plays an important role in the catabolism of cholesterol. Conversion of cholesterol to bile acids occurs exclusively in the liver and represents the major pathway for the elimination of cholesterol from the body (40). Retention of biliary constituents due to bile duct obstruction was reported to show an initial rise in plasma bilirubin accompanied by an increase in AP and ALAT (41) as

TABLE 4

Ratio of HDL Cholesterol to Total Cholesterol[a]

Animal groups	Week 4	Week 7	Week 10
G1 (ND)	0.35 ± 0.06[a]	0.67 ± 0.12[b]	0.68 ± 0.14[b]
G2 (HFD)	0.28 ± 0.04[a]	0.24 ± 0.05[a]	0.34 ± 0.09[a]
G3 (HFD + Q)	0.29 ± 0.04[a]	0.30 ± 0.05[a]	0.23 ± 0.04[a]

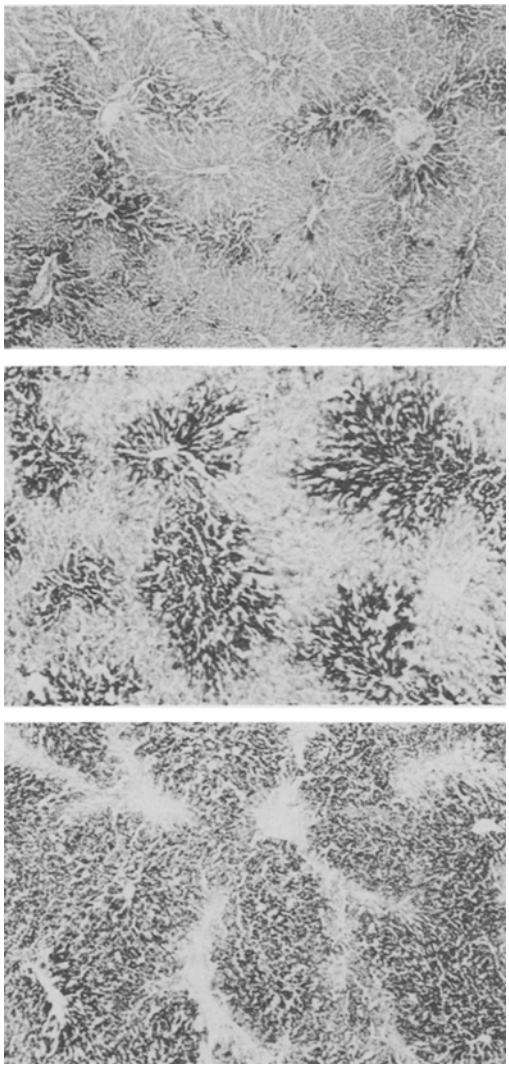

FIG. 3. a) Liver of a rat fed normal diet for 10 wk shows minimal deposition of fat in the hepatocytes. (Oil Red O stain, 75×). b) Liver of a rat fed high fat diet supplemented with tannic acid (100 mg/rat/day) for 10 wk shows moderate deposition of fat in the hepatocytes with sparing of the centrilobular hepatocytes. (Oil Red O stain, 80×). c) Liver of a rat fed high fat diet without polyphenolic compounds supplement for 10 wk shows severe and panlobular involvement of hepatocytes. (Oil Red O stain, 75×). Liver of rats fed high fat diet with quercetin (100 mg/rat/day) and morin (100 mg/rat/day) for 10 wk also showed similar appearance.

TABLE 6

Liver Total Cholesterol and Triglyceride Concentration at Week 7[a]

Animal group	Total cholesterol (mg/g liver)	Triglyceride (mg/g liver)
G1 (ND)	2.2 ± 0.1[b]	15.9 ± 1.5[b]
G2 (HFD)	26.6 ± 0.9[a]	42.9 ± 10.9[a]
G3 (HFD + Q)	18.6 ± 2.6[a]	45.1 ± 3.6[a]
G4 (HFD + M)	22.3 ± 2.2[a]	29.5 ± 2.0[b]
G5 (HFD + T)	15.9 ± 0.9[b]	33.1 ± 5.9[a]

[a]In each experiment, values in the same column without common superscript letters denote significant difference ($p < 0.05$). Values are mean ± SEM of three animals.

well as cirrhosis of the liver (42). Others have shown increases in tissue levels of AP due to diet induced hyperlipidemia (43). In contrast, the present study showed no significant differences in the activities of plasma AP, ALAT and bilirubin concentration in all groups of rats. The activities ranged from 47.2 ± 5.2 to 52.8 ± 3.2 U/L and 40.3 ± 4.8 to 45.1 ± 4.1 U/L for ALAT and AP, respectively. The total bilirubin concentration ranged from 11.0 ± 2.5 to 15.2 ± 2.7 mg/100 mL. Thus, these results indicate that feeding of a diet high in cholesterol and lard content or a cholesterol and lard diet supplemented with polyphenolic compounds does not cause bile retention or liver cirrhosis.

Hepatic lipase activity in G1 and G5 were significantly lower than in G2 at weeks 7 and 10 (Fig. 4). Jansen and Hulsmann (44) have suggested an involvement of hepatic lipase in the delivery of cholesterol to the liver. They have proposed that cholesterol is taken up from peripheral cells by a phospholipid rich HDL and subsequently delivered to the liver *via* a mechanism involving the depletion of phospholipid from HDL by hepatic lipase. Along this line, others have proposed that the increase in hepatic lipase activity could contribute to increases in liver cholesterol (45). Our findings are in agreement with these reports as increased hepatic lipase activity in G2, G3 and G4 correlates well with increased liver cholesterol concentration at week 7 (correlation coefficient, $r = +0.632$).

Atherosclerotic plaques were not observed in the aorta of the five groups of rats. Microscopic examination of the H and E stained paraffin sections of the thoracic aorta showed smooth, intact intimal lining with no evidence of raised fatty plaques or proliferation of smooth muscle cells, thereby demonstrating the absence of atherosclerosis in all the groups of experimental rats.

In summary, the present study has shown that both tannic acid and morin can cause favorable changes in plasma lipid profiles of the type that have been correlated with CHD. Tannic acid reduced fat deposits in liver cells at nontoxic concentrations. Thus, tannic acid has a potential to avert complications arising from high fat intake. Further studies need to be carried out to unravel the mechanism of the observed hypolipidemic effect of tannic acid.

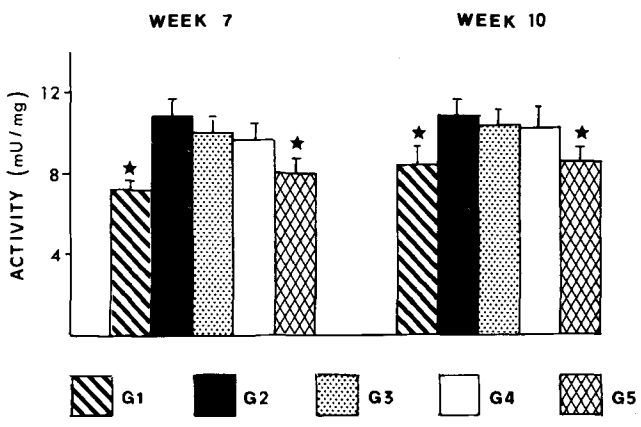

FIG. 4. Hepatic lipase activity of rats at weeks 7 and 10. Values are expressed as mU/mg protein. ★ denotes a statistically significant difference between G2 and other groups ($p < 0.05$).

Microsomes from the liver of sea bass (*Dicentrarchus labrax*) were shown to hydroxylate lauric acid at subterminal positions. The cytochrome P-450 system converted lauric acid to several mono-hydroxylated metabolites including ω-1 hydroxylaurate, which was the major metabolite (44% of total products). In addition, ω-2, ω-3, ω-4 and a small amount (2.3%) of ω hydroxylaurates were found. Reaction products were identified using thin-layer chromatography (TLC) and gas chromatography/mass spectrometry (GC/MS). Oxidation reactions were dependent upon O_2 and NADPH, and did not occur with boiled microsomes or in the presence of a mixture of CO/O_2. Hydroxylation proceeded linearly up to 20 min at 28°C for protein concentrations below 380 μg. Treatment of fish with benzo(*a*)pyrene (BP) (20 mg/kg) drastically increased xenobiotic metabolism (ECOD, EROD and BPMO activities), but no difference in laurate hydroxylase activity was observed between untreated and treated fish. Starvation strongly enhanced laurate hydroxylase activity, and resumption of feeding reduced by half this increase of activity. In all of the experiments we did not observe any modification of the regioselectivity of lauric acid hydroxylation by this microsomal in-chain hydroxylating system. We suggest that cytochrome P-450 enzymes involved in lauric acid and xenobiotics metabolism are regulated independently.

Lipids 27, 187-191 (1992).

Cytochrome P-450 enzymes are involved in many essential reactions, including the metabolism of fatty acids. The physiological significance of the metabolism of fatty acids, prostaglandins and leukotrienes by monooxygenases remains uncertain. Lauric acid hydroxylases are widely distributed and cytochrome P-450 is a component of these monooxygenase systems found in most living organisms. Differences, depending on enzyme source and isozyme multiplicity, appear in the regiospecificity of the oxidation of lauric acid. Hydroxylation occurs at the terminal methyl end and/or in the chain of the molecule. A more pronounced difference exists between organisms which catalyze ω hydroxylation of lauric acid, *i.e.* mammals (1), amphibians (2), plants (Leguminosae) (3), insects (4), and yeasts (5), and those which hydroxylate fatty acids exclusively in the aliphatic carbon chain, *i.e.* fish (6), plants (other than Leguminosae) (7), fungi (8), and bacteria (9).

The specificities and physiological roles of these enzyme systems are not completely understood. It has been reported that rat liver microsomes probably contain three cytochrome P-450 systems involved in ω and ω-1 hydroxylation of fatty acids (10). Rabbit liver microsomes are likely to contain multiple forms of fatty acid ω-1 hydroxylase, and the cDNA of one of them has been cloned in yeast cells (11). Recently, Williams and co-workers (6) described the high regioselectivity of lauric acid hydroxylation at ω-1 position by liver and kidney microsomes from untreated rainbow trout. Antibodies raised against a purified cytochrome P-450 from trout (trout $P450LM_2$), active toward aflatoxin B_1, inhibited laurate hydroxylation in both liver and kidney microsomes. Treatment of fish with β-naphthoflavone decreases the rate of laurate oxidation but strongly enhances 7-ethoxyresorufin *O*-de-ethylase (EROD) activities. Very recently, Miranda *et al.* (12) reinvestigated the catalytic activity of hepatic cytochrome P-450 from untreated trout and demonstrated that lauric acid can be hydroxylated at both ω and ω-1 positions. Each type of oxidation was carried out by a highly regiospecific P-450, designated LMC_1 (laurate ω hydroxylase) and LMC_2 (laurate ω-1 hydroxylase). Other enzyme systems hydroxylating lauric acid, from carp (13) and *Tilapia aurea* (14), have been described but metabolites have not been fully characterized.

Most of the relevant publications on monooxygenases from fish concern the oxidation of xenobiotics. Few studies have been conducted on the metabolism of endogenous substrates except for those on sex hormones. The objective of our present study was to compare the *in vitro* metabolism of fatty acids and of xenobiotics by microsomal monooxygenases from the liver of sea bass. Using lauric acid as a model substrate for monooxygenases that hydroxylate fatty acids, we have identified the reaction products by a combination of thin-layer chromatography (TLC) and reverse phase high-performance liquid chromatography (RP-HPLC) methods, and have characterized the laurate metabolites by gas chromatography/mass spectrometry (GC/MS). Laurate hydroxylase activities and the ratio of metabolites formed from fish farm sea bass and from a wild type are compared. We also report the effects of starvation, feeding and treatment with benzo(*a*)pyrene (BP) on xenobiotics metabolism and laurate oxidation from liver microsomes of farm sea bass.

MATERIALS AND METHODS

Chemicals. Lauric acid (sodium salt), NADPH, glucose 6-phosphate, glucose 6-phosphate dehydrogenase and benzo(*a*)pyrene were purchased from Sigma-Chimie (La Verepillière, France). Radiolabeled [1-^{14}C]lauric acid (spec. act. 56 Ci/mol) was from C.E.A. (Gif/Yvette, France). *N,O-bis*(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane (BSTFA + 1% TMCS) was from

Abbreviations: BP, benzo(*a*)pyrene; BPMO, benzo(*a*)pyrene monooxygenase; ECOD, 7-ethoxycoumarin *O*-de-ethylase; EROD, 7-ethoxyresorufin *O*-de-ethylase; GC/MS, gas chromatography/mass spectrometry; LAH, lauric acid hydroxylase; RP-HPLC, reverse phase high-performance liquid chromatography; TLC, thin-layer chromatography.

Pierce-Europe (Oud-Beijerland, The Netherlands). Acetonitrile (HPLC grade) and silica gel plates (G60 F254, 0.25 mm) were from Merck (Darmstadt, Germany).

Fish. Sea bass (*Dicentrarchus labrax*), obtained from two local fish farms, were conditioned for 3 wk in 600-L tanks, and fed a commercial sea bass diet (Aqualim) before the experiments. Wild sea bass were caught in the Mediterranean Sea (Banyuls, France). During experiments, marine fish were placed in a glass tank containing 120 L of synthetic sea water (20g/L, 20°C) under a 12-hr light/12-hr dark cycle. Water was oxygenated and cleaned through activated charcoal filters with a pump delivering 1000 L/hr.

Sea bass from the farm "Les poissons du Soleil" (Balaruc-les-Bains, France), weighing 71 ± 6 g, were starved 48 hr and then treated with a single intraperitoneal injection (100 μL) of sterilized maize oil (control) or 100 μL of sterilized maize oil containing benzo(*a*)pyrene to give a dose of 2 mg/kg or 20 mg/kg body weight. The fish were sacrificed 14 hr after injection and hepatic microsomes were prepared.

In a second experiment, sea bass from the farm "Aquamed" (Théoule-sur-mer, France), weighing 69 ± 4 g, were divided into three groups. One group was denied food for 2 mo. The second group was fed the Aqualim diet *ad libitum* throughout the experiment. The third group was denied food for 2 mo and then fed again the Aqualim diet for 2 wk.

Microsomal preparations. Hepatic microsomes were prepared by differential centrifugation. The fish were sacrificed by severing their spinal cords. The livers (about 1 g) were immediately removed and washed with 150 mM KCl solution. The minced livers were homogenized in 5 vol (1:5, g/mL) of 250 mM sucrose/10 mM Hepes buffer (pH 7.4) using a Potter-Elvehjem homogenizer (Poly-LABO, Strasbourg, France). The homogenates were centrifuged at 12,000 × *g* for 15 min in a Beckman J2-21 centrifuge (Fullerton, CA). Resultant supernatants were centrifuged again at 105,000 × *g* for 60 min in a Beckman L5-50 ultracentrifuge. Microsomal pellets were resuspended in 2.5 mL of 250 mM sucrose/10 mM Hepes buffer (pH 7.4) containing 20% glycerol, and were stored in liquid nitrogen until assayed.

Measurement of enzyme activities. Lauric acid hydroxylase was assayed as previously described (15). The standard assay was contained in a final volume of 0.2 mL, 0.1–0.3 mg microsomal proteins, 0.1 M sodium phosphate buffer pH 7.4, 1 mM NADPH, 6.7 mM glucose-6-phosphate, 0.4 U glucose-6-phosphate dehydrogenase, 2.12 μM [1-^{14}C]lauric acid and sodium laurate to make a final concentration 100 μM. A rapid procedure was generally used to measure enzyme activity, and to analyze the compounds formed. The reaction mixture incubated at 28°C was stopped after 20 min by adding 200 μL of acetonitrile containing 0.2% acetic acid. After cooling 5–10 min on ice and a rapid centrifugation (1500 × *g*, 5 min), 50–100 μL of supernatant was injected in a RP-HPLC column or spotted on silica gel plates.

When larger quantities of metabolites were needed for GC/MS analysis, the whole procedure was scaled up tenfold. The reaction was stopped and immediately extracted twice with 10 mL of benzene/diethyl ether (9:1, v/v). After filtration over anhydrous Na_2SO_4 and drying under vacuum, samples were dissolved in a small volume of methanol and subjected to RP-HPLC or TLC analysis.

For carbon monoxide enzyme inhibition, the phosphate buffer used in the standard assay was saturated by bubbling CO for 1 hr into the buffer. Inhibition studies were performed by adding 50 and 100 μL of phosphate buffer saturated with CO to the incubation medium (final volume of 200 μL) in capped tubes. Control experiments were performed as described for the standard assay in open and capped tubes. No difference in lauric acid hydroxylase (LAH) activities was observed between open or capped tubes using these conditions.

Ethoxyresorufin *O*-dealkylase (EROD) and ethoxycoumarin *O*-dealkylase (ECOD) activities were measured according to Burke and Mayer (16) and Ullrich and Weber (17), respectively. Benzo(*a*)pyrene monooxygenase (BPMO) activity was determined by 3-hydroxybenzo(*a*)pyrene formation as described by Nebert and Gelboin (18). Assays were performed at 30°C using a fluorimetric method with a Kontron SFM 25.

All enzymatic assays were linear as a function of time and protein concentration under the conditions used for enzyme measurements.

Statistical analysis. Statistical data analysis was by Student's t-test (19).

Chromatographic conditions. RP-HPLC analyses were carried out on a 15 cm × 4.6 mm Beckman Ultrasphere ODS 5 μm C18 column as described (15). To measure radioactivity distribution, lauric acid and hydroxylated reaction products were injected either in 20 μL of methanol or directly in 50–100 μL of reaction medium containing 50% acetonitrile. Samples were developed (2 mL/min) using an initial mobile phase of acetonitrile/water/acetic acid (25/75/0.2, v/v/v) to elute the hydroxylated products. Residual lauric acid was eluted using a linear gradient (0 to 100%) of acetonitrile/water/acetic acid (80:20:0.2, v/v/v) 35 min after injection at the same flow rate for 20 min. Radioactivity of RP-HPLC effluents was monitored with a computerized on-line solid scintillation counter (Ramona-D RAYTEST, Straubenhardt, Germany).

For quantitative evaluation, 100-μL aliquots of incubation medium were spotted on silica TLC plates. The plates were developed (15 min longer than for solvent migration to the top of the plate) in a system of diethyl ether/light petroleum hydrocarbon (b.p. 40–60°C)/formic acid (70:30:1, v/v/v). After detection of the radiolabeled metabolites with a thin-layer linear analyzer (Berthold LB 511, La Garenne-Colombes, France), the areas corresponding to ω plus ω-1 hydroxylaurates (Fig. 1, peak A) and to ω-4, ω-3 and ω-2 hydroxylaurates (Fig. 1, peak B) were scraped into counting vials, and radioactivity was measured with an Intertechnique SL 4000 liquid scintillation counter (Intertechniques, Plaisir, France).

Gas chromatography/mass spectrometry. Products formed were first separated in two radioactive peaks by the TLC procedure described above. Radioactive compounds contained in peaks A and B (Fig. 1) were scraped off the plates and eluted twice from the silica with 10 mL of benzene/diethyl ether (1:1, v/v). An aliquot of each was subjected to RP-HPLC analysis (Fig. 2, B and C) with the appropriate mobile phase as described above. Prior to GC/MS analysis, the metabolites of lauric acid were methylated and silylated using a procedure described previously (15). Samples in a mixture of hexane/BSTFA (1:1, v/v) were injected (1–2 μL) in the splitless mode, and

were run on a capillary column (30 m × 0.25 μm coating thickness) packed with 1% SE 30 on Chromosorb W-AW DMCS (Supelco-France, Paris). The oven temperature was programmed from 80 to 200°C at a rate of 3°C/min. The gas chromatograph was interfaced with an LKB 9000S mass spectrometer with an LKB 2130 computer on-line system (LKB Produkter, Bromma, Sweden). Spectra were obtained in the EI mode at 70 eV.

Spectroscopic assays. Spectrophotometric hemoprotein determinations were carried out on a Shimadzu MPS 2000 instrument (Roucaire, Strasbourg, France). Microsomal amounts of cytochromes P-450 and b_5 were measured by the method of Omura and Sato (20) using the following extinction coefficients: 91 mM^{-1} cm^{-1} for the 450–490 nm absorbance difference, and 185 mM^{-1} cm^{-1} for the 424–409 nm absorbance difference, respectively. Microsomal protein concentrations were determined according to Lowry *et al.* (21) using bovine serum albumin as standard.

RESULTS

Microsomal incubations with lauric acid. As previously shown for cytochrome P-450 catalyzed hydroxylation of lauric acid, both molecular oxygen and NADPH were essential for hydroxylation of lauric acid by liver microsomes from sea bass. Carbon monoxide, which interacts with the active site of cytochrome P-450 enzymes, inhibited hydroxylation suggesting the involvement of cytochrome P-450 in both reactions. The reaction was linear up to 20 min at 28°C for protein concentrations below 380 μg of liver microsomal proteins (not shown).

The mixture of reaction products was resolved by TLC into two major radioactive peaks (Fig. 1, A and B). When compounds eluted from the TLC zone A were analyzed by RP-HPLC, two metabolites with retention times corresponding to ω-1 and ω hydroxylaurates (peaks 1 and 5, respectively) were eluted (Fig. 2, B). Elution of compounds containing zone B showed three metabolites with reten-

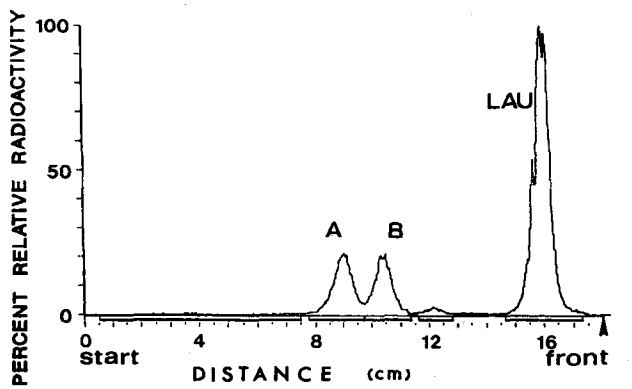

FIG. 1. TLC analysis upon microsomal incubation of [1-^{14}C]lauric acid. Radiolabeled metabolites extracted from the microsomal incubations of farm sea bass (fed throughout) with lauric acid (LAU) were subjected to TLC analysis on Silica Gel G (see Materials and Methods). Compounds in zones A (ω and ω-1 hydroxylaurate) and B (ω-2, ω-3 and ω-4 hydroxylaurate) were scraped off the plate and eluted. Aliquots were subjected to RP-HPLC (Fig. 2) and mass spectrometry.

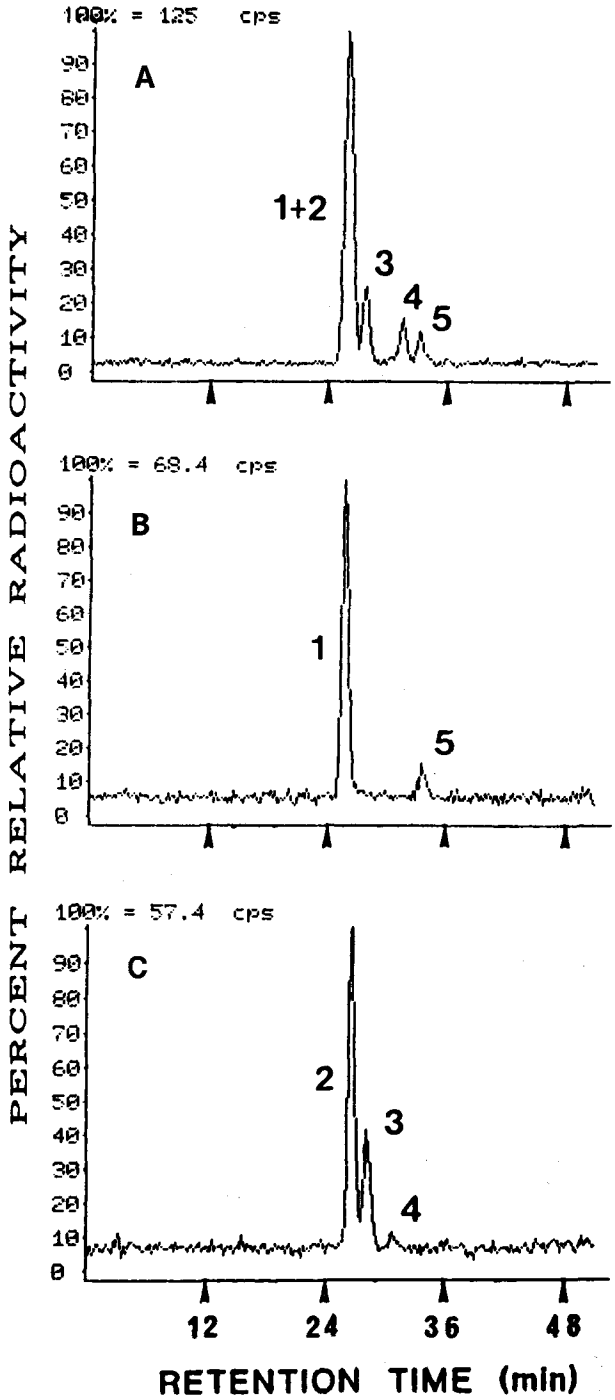

FIG. 2. RP-HPLC analysis of hydroxylated metabolites from microsomal incubations with [1-^{14}C]lauric acid. Microsomes from farm sea bass (fed throughout) were aerobically incubated with radiolabeled laurate and NADPH. (A) Total hydroxylated metabolites formed by microsomal incubation. (B) Hydroxylated metabolites eluted from zone A of TLC plate (Fig. 1). (C) Hydroxylated metabolites eluted from zone B of TLC plate (Fig. 1). Radiolabeled metabolites eluted from RP-HPLC column were: peak 1, ω-1 hydroxy-; peak 2, ω-2 hydroxy-; peak 3, ω-3 hydroxy-; peak 4, ω-4 hydroxy- and peak 5, ω hydroxylaurate. Forty min after starting analysis, a linear gradient of 80% acetonitrile was applied to elute residual substrate (not shown). Conditions of incubation, TLC and RP-HPLC analyses are described under Materials and Methods.

TABLE 1

Effects of Starvation, Feeding and Treatment with BP on Monooxygenase Activities and Contents of Cytochromes P-450 and b_5 in Hepatic Microsomes from Sea Bass[a]

[a]Data are expressed as means ±SD for five individuals. EROD, ECOD and LAH activities are expressed in nmol min^{-1} mg^{-1} protein and BPMO in pmol min^{-1} mg^{-1} protein. Cytochrome P-450 and cytochrome b_5 contents are in nmol mg^{-1} protein. N.S., not significant. N.D., not determined. Fish farm origin and conditions of treatments and microsomal incubations are described in Materials and Methods.

[b]Significant at $P < 0.001$.

[c]Significant at $P < 0.005$.

[d]Effects due to treatment are significant at $P < 0.05$.

tion times observed (7) for ω-2, ω-3 and ω-4 hydroxylaurates (Fig. 2, C; peaks 2-4, respectively). When an aliquot of the supernatant (containing 50% acetonitrile) from incubated microsomes was directly analyzed by RP-HPLC, only four radioactive compounds were eluted (Fig. 2, A) showing that ω-1 and ω-2 hydroxylaurates were not resolved under these RP-HPLC conditions.

Characterization and distribution of metabolites. GC/MS analyses and electron impact (70 eV) studies of the methyl ester trimethylsilyl derivatives of the reaction products formed by untreated sea bass microsomes were performed as described elsewhere (3,7). Mass spectra of the methylated and trimethylsilylated derivatives showed typical fragment ions expected from monohydroxylated fatty acids (22) including: *m/z* 287 $[M-15]^+$, *m/z* 271 $[M-31]^+$, *m/z* 255 $[M-47]^+$, *m/z* 146 $[CH_2 = C(OSi-(CH_3)_3)-OCH_3]^+$, *m/z* 159 $[(CH_3O = C(OSi-(CH_3)_3)CH = CH_2]^+$ and the base peak at *m/z* 73 (TMS) which were commonly present in all hydroxylated lauric acid metabolites. From the results of the mass spectrometry studies, peaks in Figure 2 were identified as: *m/z* (relative intensity %); peak 1, 11-hydroxydodecanoic acid (*m/z* 117 (100), *m/z* 255 (9) *m/z* 258 (10)); peak 2, 10-hydroxydodecanoic acid (*m/z* 131 (100), *m/z* 273 (41)); peak 3, 9-hydroxydodecanoic acid (*m/z* 145 (100), *m/z* 259 (36)); peak 4,8-hydroxydodecanoic acid (*m/z* 159 (60), *m/z* 245 (34)) and peak 5, 12-hydoxydodecanoic acid (*m/z* 89 (43), *m/z* 103 (45), *m/z* 255 (100), *m/z* 287 (73)). The proportion of each monohydroxylaurate formed as a percentage of the bulk of hydroxylated metabolites was calculated from peak areas to be 44.0%, 35.6%, 14.5%, 3.5% and 2.3% for 11-hydroxy-, 10-hydroxy-, 9-hydroxy-, 8-hydroxy- and 12-hydroxylaurate, respectively. These results obtained with starved or BP-treated farm fish show that starvation, which increases laurate hydroxylase activity, does not change the regioselectivity of the oxidative attack of laurate in sea bass microsomes.

Effects of fish treatments on monooxygenase activities. Hepatic microsomal mixed function oxidase activities were measured in sea bass treated with two doses of BP. After a single intraperitoneal injection with 20 mg/kg body weight, EROD, ECOD and BPMO activities were significantly induced (2-3 fold) in liver microsomes (Table 1). However, at 2 mg/kg body weight, no significant induction of these activities was observed. No significant increase of laurate hydroxylase activity was observed after BP treatment.

Fish that were not fed for two months showed a significant decrease in EROD and BPMO activities (1.5- and 2-fold respectively, Table 1). In contrast, both ECOD and laurate activities were enhanced approximately three times by starvation.

Compared to control (fed throughout), resumption of feeding results in a significant increase in EROD, ECOD and BPMO activities (3.8, 5.3 and 2.3, respectively, Table 1). By contrast, laurate hydroxylase activity decreased when compared to that of starved fish, but remained 1.8-fold higher than that of control fish.

No significant variation in the microsomal amount of cytochromes P-450 and b_5 was observed.

The levels of cytochrome P-450 enzyme activities from wild fish were similar to those of farm fish.

DISCUSSION

Little information is available concerning the metabolism of endogenous substrates in marine fish. The present work demonstrates that a microsomal fraction from sea bass catalyzes both in-chain hydroxylation of lauric acid at ω-2, ω-3 and ω-4 positions and penultimate hydroxylation at ω-1 with nearly identical efficiency. Our results further confirm that microsomes from fish liver catalyze principally ω-1 hydroxylation of lauric acid. Analysis of the regioisomeric composition of the monohydroxylated metabolites formed by microsomes showed that oxygenation at ω-1, ω-2, ω-3, and ω-4 occurred in a nearly 3:2.5:1:0.2 molar ratio. These reactions are not fish-specific because microsomes from other living organisms such as plants, fungi and bacteria produced a similar pattern of reaction products. In addition, a very low level of ω-hydroxylaurate (2-3% of total metabolites) was also detected under our experimental conditions.

Strong evidence in support of the involvement of cytochrome P-450 in laurate hydroxylation is provided by the microsomal localization of the hydroxylase, the requirement of cofactors such as O_2 and NADPH, and the inhibitory effects of carbon monoxide. C-9, C-10 and C-11 are the major targets of oxidative attack in lauric acid in sea bass liver microsomes. No evidence is available that

hydroxylation of all positions, including the very low attack at the terminal methyl end, is catalyzed by the same hydroxylase. However no difference in the molar ratio of hydroxylated metabolites from laurate was observed between liver microsomes from control, starved and BP-treated fish. Moreover, microsomes from wild sea bass produced a hydroxylaurate profile identical to that of farm sea bass. Similar reactions products, with respect to substrate specificity, have been found with reconstituted rat liver microsomes containing a constitutive cytochrome P-450 enzyme (P450 IIC_{11}) or an isoform (P450 IA_1), inducible by β-naphtoflavone. These two isoforms were able to catalyze either ω and ω-1 hydroxylation (major reaction product) of arachidonic acid and its oxidation to ω-2, ω-3 and ω-4 hydroxyarachidonate (23).

In mammals, starvation, or a diet enriched in long-chain saturated fatty acids, is known to strongly enhance fatty acid hydroxylation activities. As shown in Table 1, the starvation of sea bass results in similar effects, increasing (about 3 times) laurate hydroxylation. Resumption of feeding after fasting decreases LAH activities (Table 1); however, they remain higher than in control (fed throughout) sea bass. Cytochrome P-450-dependent oxidation at the methyl end of fatty acids has been described as the first step of a metabolic process ending with excretion of short-chain dicarboxylic acids. In contrast, the biological significance of in-chain hydroxylases, which do not fit this catabolic scheme, remains obscure, and more studies are needed on the metabolic capacity of fish P-450 to understand the physiological roles of enzymes catalyzing in-chain hydroxylations of mid-chain fatty acids.

BP treatment at 2 mg/kg had no effect on EROD, ECOD and BPMO activities in liver microsomes from sea bass. At 20 mg/kg, BP treatment resulted in a significant increase of all activities. These results are similar to those obtained by Jimenez and Burtis (24) with bluegill sunfish. In addition, our results show that the strong induction of monooxygenase activities involved in xenobiotics metabolism is not paralleled by an increase of laurate hydroxylase activities (Table 1). These results suggest that cytochrome P-450 forms involved in xenobiotics and fatty acid metabolism are regulated independently. In addition, lauric acid seems to be metabolized by P-450 forms which are not induced by BP.

Starved fish exhibited lower levels of EROD and BPMO activities than control animals, but ECOD activity was slightly enhanced. Similar alterations in liver microsomal enzyme activities, involved in xenobiotics metabolism, have been reported by Jimenez *et al.* (25) during starvation of bluegill sunfish. However in our study, when feeding of sea bass was resumed, laurate hydroxylase activity was depressed, but ECOD, EROD and BPMO activities were induced. Ankley and Blazer (26) and Ankley *et al.* (27) reported that diet can be a significant factor influencing mixed function oxidase activities in channel catfish. But, to the best of our knowledge, modification of laurate activity in starved fish has not been demonstrated before. It would therefore appear that cytochrome P-450 systems involved in laurate hydroxylation are regulated independently of those implicated in detoxification (ECOD, EROD and BPMO) of foreign compounds.

Inhibition of Ferrous-Induced Lipid Peroxidation by Pyrimido-Pyrimidine Derivatives in Human Liver Membranes

J.P. de la Cruz*, T. Carrasco, G. Ortega and F. Sanchez de la Cuesta
Department of Pharmacology and Therapeutics, School of Medicine, University of Málaga, 29071 Málaga, Spain

The effects of pyrimido-pyrimidine derivatives (dipyridamole, RA-642, and RA-233) on lipid peroxidation, using d-α-tocopherol as standard, were studied in enriched membrane fractions from human and rat hepatocytes. Equimolar concentrations of ferrous sulfate and ascorbic acid were used to induce lipid peroxidation. The amount of peroxidized lipids observed in membrane fractions from human liver was smaller than in those from rat liver. In both species, however, pyrimido-pyrimidine derivatives, except for RA-233 in rat liver, inhibited lipid peroxidation dose-dependently in the following sequence: RA-642 > dipyridamole > d-α-tocopherol RA-233.
Lipids 27, 192–194 (1992).

Oxygen-derived free radicals (ODFR) have been associated with the etiology of certain pathological processes, such as ischemia re-perfusion syndrome (1,2), diabetic vasculopathy (3), cataracts (4), and liver disorders (5). The development of drugs that prevent the formation and/or cell damage by ODFR is a fundamental objective of current research (6).

Our group reported that dipyridamole, a pyrimido-pyrimidine derivative, which acts as a vasodilator and platelet aggregation inhibitor (7), reduces the incidence of post-thrombolysis re-perfusion arrhythmias (PTRA) (8) and of renal excretion of proteins in different types of glomerulonephritis (GMN) (9); PTRA and GMN are associated with ODFR cell membrane damage. We also reported that dipyridamole inhibits lipid peroxidation induced by hydroxyl anions (HA) in cell membranes of different rat tissue (10), an effect that had been previously observed by Iuliano *et al.* (11) using chemical substrates.

The aim of the present study was to assess the antiperoxidative effect of dipyridamole in liver cell membranes from humans, as distinct from those of rats, and to compare this effect with that of two other chemical congeners, RA-233 (Mopidamole) and RA-642, using d-α-tocopherol as standard.

MATERIALS AND METHODS

Materials. Dipyridamole (2,6-*bis*-(diethanolamino)-4,8-dipiperidinopyrimido-[5,4-d]pyrimidine) was obtained from Boehringer Ingelheim S.A. (Barcelona, Spain). RA-233 (2,6-*bis*(diethanolamino)-4-piperidinopyrimido[5,4-d]pyrimidine) and RA-642 (2,6-*bis*(2-hidroxiethyl-2-metoxiethylamino)-4,8-*bis*(diethylamino)pyrimido[5,4-d]pyrimidine) were donated by Dr. Karl Thomae (Biberach an der Riss, Germany). Malondialdehyde *bis*-diethylacetal was obtained from Aldrich-Chemie (Steinheim/Albuch, Germany), and d-α-tocopherol and all other reagents were obtained from Sigma Chemical Co (St. Louis, MO).

Preparation of membrane fractions. Enriched membrane fractions from human and rat liver were used in this study. Human liver samples (n = 6) were obtained from specimens of partial hepatectomies carried out on patients with traumatic liver injury due to traffic accidents. The normal characteristics of the liver tissue were confirmed by histopathological examination. Informed consent was obtained for all patient samples. Rat liver samples were obtained from six 3- to 4-month-old male Wistar rats.

All samples were diluted 1:10 (v/v) in buffer containing 50 mM Tris, 100 mM NaCl, 0.5 mM KCl, 3.1 mM $CaCl_2$, 1 mM $MgSO_4$, 0.55 mM KH_2PO_4, and 3.20 M sucrose (pH 7.4). The samples were minced and homogenized in a Braun potter at 600 strokes/min, then centrifuged at 1,000 × *g* for 10 min at 4°C. The pellet was discarded and the supernatant was centrifuged at 20,000 × *g* for 20 min at 4°C. The supernatant was removed, and the pellet was diluted (1:10, v/v) in the buffer mentioned above without sucrose. Crushed ice surrounded the samples throughout the procedure.

Measurement of lipid peroxidation. The products resulting from the thiobarbituric acid reaction, most of which were malondialdehyde (MDA) reaction products, were taken as indicators of lipid peroxidation in membrane fractions. A modification of a method described by R. Zimmerman (personal communication) was followed. Briefly, membrane concentrates were diluted (1:4, v/v) in the above-mentioned buffer solution but with 20 mM Tris, and were divided into 1.7-mL aliquots. Then 0.1 mL of the buffer (in the assays without inhibitors) or 0.1 mL of different concentrations of pyrimido-pyrimidine derivatives were added. Ferrous sulfate (0.1 mL) and 0.1 mL of ascorbic acid (FeAs) in increasing equimolar concentrations were added in baseline assays (without drugs); 75 μM of FeAs was used in experiments with drugs. FeAs was used to induce lipid peroxidation *via* the formation of HA (11,12).

Test tubes were incubated at 37°C for 45 min while being continuously shaken. Blanks which contained only tissue were incubated at 4°C. Subsequently the reaction was stopped and MDA was analyzed using 1 mL of 0.5% thiobarbituric acid in 20% trichloroacetic acid. The products used in the samples were added to the blanks. After agitation, the samples were incubated at 100°C for 15 min and then centrifuged at 1,000 × *g* for 15 min at 4°C. The amount of malondialdehyde (MDA) produced was determined by measuring the spectrophotometric absorbance of the supernatant at 532 nm.

The absorbances were compared to those of a standard of malondialdehyde *bis*-diethyl-acetal. The protein content of the samples was determined using the method described by Lowry *et al.* (13); the results are expressed in nmol of MDA/mg protein.

Statistical analyses were carried out using the Epistat program. The Student's t-test was applied for comparison

of nonpaired variables. Statistical significance was set at $p < 0.05$.

RESULTS

Production of MDA in cell membranes. Incubation of equimolar concentrations of FeAs with liver cell membranes caused the dose-dependent production of MDA (Fig. 1) which reached a maximum of 13.5 ± 2.3 nmol/mg of protein with human liver and of 18.2 ± 2.1 nmol/mg of protein with rat liver ($p = 0.014$). These maximum values were attained at 75 μM FeAs in both species. An FeAs concentration of 14.60 ± 1.17 μM with human liver and 14.96 ± 1.20 μM with rat liver produced 50% of the maximal MDA values. This species difference was not statistically significant ($P = 0.889$).

Inhibition of MDA production. Dipyridamole, RA-642 and d-α-tocopherol inhibited lipid peroxidation dose-dependently in rat (Fig. 2) and human liver membrane fractions (Fig. 3). In both cases, the sequence of effectiveness was RA-642 > dipyridamole > d-α-tocopherol. Peroxidation was inhibited in a concentration range of 10^{-7}M for RA-642, 10^{-6}M for dipyridamole, and 10^{-5}M for d-α-tocopherol.

When rat liver was incubated with 5 mM mopidamole, peroxidation was inhibited by only 37.8 ± 3.5%; a dose-dependent inhibition within a concentration range of 10^{-5} –10^{-3}M was observed in human liver. Table 1 shows the concentrations which inhibited MDA baseline production by 50% (IC-50).

DISCUSSION

Lipid peroxidation induced by free radicals has been associated with the development of certain liver lesions which occur upon administration of toxic substances or drugs (14) and in some liver disorders (5). Moreover, measurement of MDA after ferrous-induced peroxidation in organic samples has been proposed as a method to examine lipid peroxidation induced by HA (11,12). Our present results reflect the degree of peroxidation in human liver cell membranes induced by hydroxyl anions.

TABLE 1

Values of 50% Inhibition (IC-50) of Ferrous-Induced Lipid Peroxidation

Compound	IC-50 (μM) Human liver membranes	IC-50 (μM) Rat liver membranes	p[a]
RA-642	0.85 ± 0.09	0.64 ± 0.05	0.0874
Dipyridamole	6.69 ± 0.77[b]	4.99 ± 0.31[c]	0.0865
d-α-Tocopherol	33.79 ± 6.83[d]	31.11 ± 5.87[e]	0.7760
Mopidamole	820 ± 60.2[f]	>5000	—

[a]Student's t-test (differences between human and rat values) [b]$p = 0.00088$, [c]$p = 0.00028$, *versus* RA-642 values [d]$p = 0.0056$, [e]$p = 0.0061$ *versus* RA-642 values, and $p = 0.0012$, $p = 0.0021$, *versus* dipyridamole values [f]$p < 0.00001$ *versus* dipyridamole, RA-642 and d-α-tocopherol values.

We observed that ferrous salts induced MDA production with similar effective concentration, 50% (EC-50) values for rat and human liver membranes. However, human liver tissue produced smaller absolute amounts of

MDA than did rat liver. The protein content was similar in both types of tissue samples (0.45 ± 0.02 mg/mL in rat liver and 0.48 ± 0.06 mg/mL in human liver, p = 0.34). According to Bosmann and Hemsworth (15), the membranes used in the present study would be expected to consist of similar morphological components in both rat and human liver. We therefore attribute observed differences in MDA production to species differences.

In the present study, we describe the inhibition of HA-induced lipid peroxidation in enriched fractions of human liver cell membranes. The results obtained with dipyridamole are consistent with data on rat tissue earlier published by our group (10), by Iuliano *et al.* (11) using a chemical fatty acid peroxidation model, and by Slater *et al.* (16) using CCl_4-poisoned rat liver microsomes. Our findings are also consistent with the results obtained by Keppler and Novacky (17) who reported that dipyridamole prevented bacterial killing by paraquat, which produces ODFR. The inhibition by dipyridamole of HA-induced lipid peroxidation is also in agreement with the inhibition by dipyridamole of proteinuria in glomerulonephritis (9), the reduction of the incidence of post-thrombolysis re-perfusion arrhythmias after a single i.v. dose of 10 mg of dipyridamole (8), and the prevention of the inhibition of prostacyclin synthesis in an experimental diabetes model (18). All these processes have been associated with ODFR production. Thus, dipyridamole appears to affect superoxide or HA formation. This was also suggested by Iuliano *et al.* (11), who showed that dipyridamole caused a decrease in the reduction of cytochrome C (Cyt C), and by our group who reported that the administration of dipyridamole decreased the reduction of nitroblue tetrazolium (NBT) produced by phenazine methosulfate in rat lens (19). Reduction of Cyt C and NBT is induced by superoxide anion formation. This would be consistent with a possible scavenger type action on superoxide anions by dipyridamole.

RA-642 has been shown to be 7.9 times more potent than dipyridamole in human tissue and 7.8 times more potent in rat tissue, while dipyridamole was 5 times more potent than d-α-tocopherol in human tissue and 6.2 times more potent in rat tissue (Table 1). We therefore conclude that RA-642 has a potent antiperoxidative effect.

Mopidamole exerts its antiperoxidative effect in human liver tissue in the mM range which is higher than the concentration required for inhibition of platelet aggregation in humans (3-5 μM) (20,21).

We conclude that in humans, pyrimido-pyrimidine derivatives, and mainly dipyridamole and RA-642, inhibit lipid peroxidation induced by ODFR. RA-642 is a new and potent antioxidant which should prove useful in the study of processes in which ODFR are involved.

α-Tocopherol Oxidation Mediated by Superoxide Anion (O_2^-). I. Reactions in Aprotic and Protic Conditions

A. Saari Csallany* and **Yeong L. Ha**[1]
Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

The reaction of α-tocopherol (α-T) with superoxide anion (O_2^-) in both dry acetonitrile and in aqueous acetonitrile solution is described. The O_2^- was generated by the electrochemical reduction of molecular oxygen in acetonitrile, using tetrabutylammonium bromide as an electrolyte. α-T was reacted with O_2^- either in dry acetonitrile or in a 10% aqueous acetonitrile solution. In dry acetonitrile, α-T was oxidized to a very unstable primary intermediate, which was further oxidized to a secondary, more stable intermediate. The formation of the secondary intermediate depended upon the presence of molecular oxygen. This intermediate readily converted into two compounds in equimolar amounts (designated A and B). The primary, very unstable intermediate was readily reduced again to α-T by treatment with $LiAlH_4$ or ascorbic acid. However, the secondary intermediate or the stable oxidation products could not be reduced to α-T. In the 10% aqueous acetonitrile, α-T was oxidized to α-tocopheryl quinone, α-tocopherol dimer and α-tocopherol dihydroxy dimer, and an unknown compound. In the aqueous medium, no intermediates were formed by the action of O_2^-. The results of this study indicate that the reaction of α-T with O_2^- under aprotic conditions is different from that observed under protic conditions.
Lipids 27, 195–200 (1992).

The superoxide anion (O_2^-) is produced in biological systems and foods by enzymatic (1,2) or non-enzymatic reactions (3,4). It is relatively stable under anhydrous conditions, but not in aqueous media. O_2^- has been found to have detrimental effects on cells and cell constituents (5). Several studies have shown α-tocopherol (α-T) involvement in the prevention of membrane lipid peroxidation caused by O_2^-. The protective effect of α-T is thought to be due to the scavenging action of α-T which results in its oxidation by free radicals. Inconsistencies in α-tocopherol oxidation products formed under protic (aqueous) conditions and aprotic (anhydrous) conditions have previously been reported (6–10). These inconsistencies might be attributed to the instability of O_2^- under aqueous conditions and suggest that there may be differences in the reaction mechanism of α-T with O_2^- under anhydrous and aqueous conditions.

The objectives of this study were to compare the oxidation of α-T with O_2^- under protic and aprotic conditions, and to isolate the oxidation products arising under both conditions.

MATERIALS AND METHODS

Reagents. Acetonitrile (spectral grade, 0.006% water; Burdick and Jackson, Muskegon, MI), mercury (electro grade, 99.9999%; Alfa Products, Danvers, MA), ethyl acetate high-performance liquid chromatography (HPLC) grade; Fisher Scientific Company, Itasca, IL), hexane (HPLC grade; Fisher Scientific Company), isopropanol (HPLC grade; Fisher Scientific Company), tetrabutylammonium bromide (Fisher Scientific Company), α-tocopherol (Eastman Kodak Company, Rochester, NY), and oxygen (99.999%; Air Products Inc., Minneapolis, MN) were used in this study. In all experiments, doubly distilled water was used. α-Tocopheryl quinone (TQ) was synthesized and purified by the method of Eggitt and Norris (11). α-Tocopherol dihydroxy dimer (DHD) and α-tocopherol dimer (D) were synthesized according to Csallany *et al.* (12). Purification of the above compounds was carried out by the method of Ha and Csallany (13). All other chemicals used were reagent grade.

Generation of O_2^-. The O_2^- was generated by electrochemical reduction of molecular oxygen (O_2), as described by Fee and Hildenbrand (14), with slight modifications. One-tenth M tetrabutylammonium bromide (TBAB) in acetonitrile was used as a supporting electrolyte. The TBAB was recrystallized from ethyl acetate and dried overnight in a vacuum desiccator. The electrolytic cell (H-shape) contained 60 mL of the electrolyte and the compartments were separated by a sintered glass disc 1 cm in diameter. The anode was a coil of platinum wire and the cathode was a pool of mercury. O_2 was dried by passing it through both concentrated H_2SO_4 and $CaCl_2$, and bubbled continuously through the cathode compartment for 30 min with a velocity of one bubble/sec. The O_2^- was generated using a 2 mA current for 20 min. The concentration of O_2^- was determined by measuring the optical density at 250 nm, as described by Fee and Hildenbrand (14). Electrolysis was carried out in a dry-glove box (Prospect, Kansas City, MO) that was continuously purged with dry nitrogen.

Reaction conditions. Unless otherwise specified, the following conditions were used for the reaction of α-T with O_2^- in both dry acetonitrile and aqueous acetonitrile solutions. One μmole of α-T was dissolved in 100 μL acetonitrile, and was reacted with 3 mL O_2^- solution (5.2×10^{-6} M) for 1 min. The reaction was carried out in screw-capped test tubes (20 cm × 1.5 cm) in a dry-glove box. Each reaction was repeated four times. After completing each reaction, the unreacted α-T and its oxidation products were extracted 3 times with 3 mL of hexane. The combined extracts were dried over anhydrous sodium sulfate and concentrated to 3 mL under N_2 at room temperature for HPLC analysis. The HPLC analysis of α-T and its oxidation products was performed on a normal-phase column (5 μm Ultrasphere-Si, Beckman Instruments Inc., Berkeley, CA) using a mobile phase of hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v) (13). The HPLC equipment used was a model 110A solvent metering pump (Beckman Instruments, Inc.) and an Altex Model 210 solvent injector equipped with a 100-μL loop (Beckman Instruments, Inc.).

Stability of O_2^-. The stability of O_2^- in the presence of water was determined. Water was added to quartz cuvet-

Abbreviations: α-T, α-tocopherol; D, α-T dimer; DHD, α-T dihydroxy dimer; HPLC, high-performance liquid chromatography; O_2^-, superoxide anion; O.D., optical density; TBAB, tetrabutylammonium bromide; TQ, α-tocopheryl quinone.

tes (1 cm × 1 cm) containing 3 mL O_2^- solutions to produce 0, 1, 5, and 10% per volume water concentrations. Dismutation of O_2^- was determined by measuring the rate of change of optical density (O.D.) at 250 nm, using a Beckman model DU-8 Spectrophotometer equipped with a DU-8 kinetic Compuset module (Berkeley, CA).

Formation of intermediates in dry acetonitrile. To determine the formation of the very unstable primary intermediate product, α-T was reacted with the O_2^- solution. The primary intermediate and the secondary intermediate products exhibited maximum absorbance at 350 and 235 nm, respectively. The optical density of the reaction mixture was monitored at 350 nm for the formation of the primary oxidation product and 235 nm for the formation of the secondary, more stable oxidation product of α-T. The disappearance of α-tocopherol (α-T) was monitored at 292 nm as a function of time (1/3, 1, 2, 3, 4, 5, and 10 min) using a Beckman DU-8 Spectrophotometer equipped with a kinetic Compuset module. The primary intermediate product reached a maximum concentration at 20 sec. A one-minute reaction time was used for the production of the secondary intermediate.

Reduction of the primary intermediate. One-μmole samples of α-T were each reacted with 3 mL O_2^- solution for 20 sec. The reaction mixtures were reduced immediately with $LiAlH_4$ reagent according to the method of Csallany *et al.* (15) or with 0.6 g ascorbic acid for 5 min. After reduction, the reaction mixtures were extracted with hexane, the extracts were washed with distilled water and analyzed by HPLC for α-T and its oxidation products. Control samples were treated identically, except that they were not treated with the reducing agents.

Reduction of the secondary intermediate. Four one-μmole samples of α-T were each reacted with 3 mL O_2^- solution for one min and extracted with hexane. One sample was used as a control without further treatment, and the remaining samples in hexane were treated with either $LiAlH_4$, (15) ascorbic acid or 1 mL of 0.1 M HCl. The mixtures then were extracted with hexane, which was washed with distilled water, and the samples were analyzed for α-T and its oxidation products by HPLC.

Formation of stable α-T oxidation products (A and B). The formation of two stable α-T oxidation products (compounds A and B) with O_2^- in dry acetonitrile was carried out in the same way as that of the secondary intermediate product (reaction time 1 min). The unstable secondary oxidation product was converted quantitatively to compounds A and B by evaporating the solvent hexane or by washing the solvent with water. Compounds A and B were then separated by HPLC.

Reduction of the compounds A and B. Compounds A and B were treated with $LiAlH_4$ or ascorbic acid identically as described for the primary and secondary intermediates and were analyzed by HPLC for possible conversion into α-T.

Effect of molecular oxygen. A three-mL aliquot of the O_2^- solution, was reacted with one μmole α-T for 1 min and then used as control. Other aliquots of the O_2^- solution were purged with nitrogen for 6 min to remove the remaining O_2. This solution was reacted with one μmole α-T for 1 min with or without further nitrogen purge. Each reaction mixture was assayed for α-T and its oxidation products as described above.

Reaction of α-T with O_2^- in aqueous acetonitrile solution (protic conditions). Samples of one μmole α-T were reacted with 3 mL O_2^- solution for 0, 0.5, 1, 5 and 10 min in the presence of various concentrations of water (1, 5 and 10%). The samples were extracted with hexane and then analyzed by HPLC as described above.

RESULTS

Stability of O_2^-. The relationship between the O_2^- dismutation rate and water content is shown in Figure 1. The O_2^- was quite stable in absolute acetonitrile and remained at a constant level during the test period. The O_2^- was partly dismutated by the addition of a small amount of water to the solution, with a dismutation rate proportional to the water content. With a 10% water concentration, O_2^- declined nearly to zero within one minute. These results are in agreement with those of Ozawa and Hanaki (16), who observed that O_2^- dismutation was positively correlated with the water content in the reaction medium.

Reaction of α-T with O_2^- in dry acetonitrile (aprotic conditions). A very unstable primary intermediate product was formed during the reaction of α-T with O_2^- in dry acetonitrile, which was monitored by measuring the optical density changes at 350, 292, 235 nm as a function of time (Fig. 2). The rapid increase in the primary product (350 nm) was concomitant with a dramatic fall in α-T concentration (292 nm). Maximum absorption for the primary intermediate was observed at about 20 sec, after which it slowly disappeared. Its disappearance was followed by increased absorption at 235 nm (secondary inter-

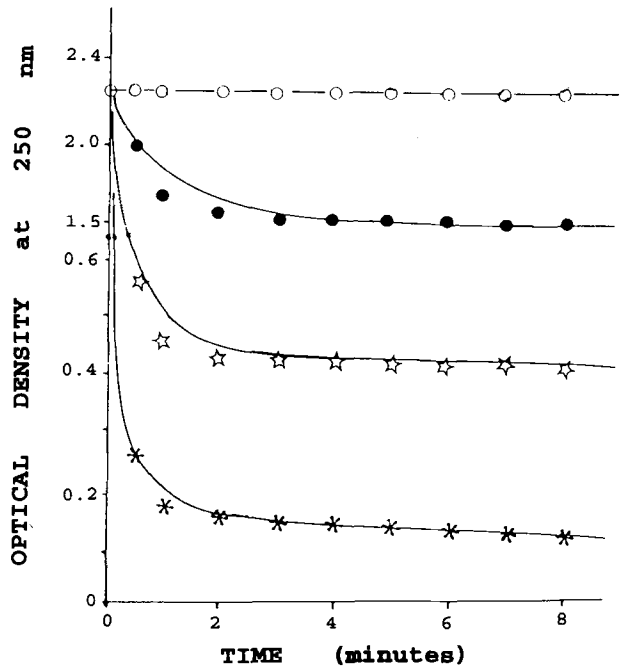

FIG. 1. Stability of O_2^- in acetonitrile containing various concentrations of water; 0 (○), 1% (●), 5% (☆), and 10% (*) water. O_2^- was generated electrochemically at 2 mA for 20 min.

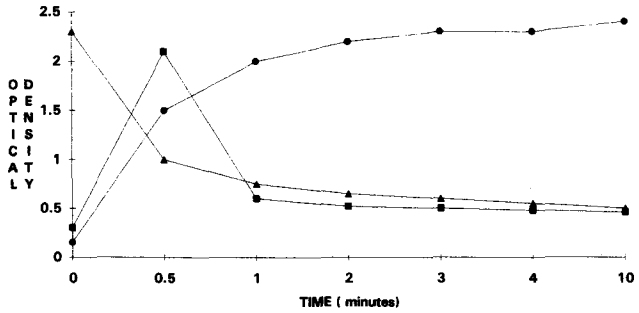

FIG. 2. Changes in optical density during the reaction of α-T with O_2^- under aprotic conditions. The primary intermediate product absorbs maximally at 350 nm (■), secondary intermediate product at 235 nm (●), and α-tocopherol at 292 nm (▲).

mediate) with a maximum intensity at 1 min. The data indicate that the reaction of α-T with O_2^- under aprotic conditions produced two distinct intermediates within 1 min. The primary product was easily reduced back to α-T by treatment with either $LiAlH_4$ or ascorbic acid, as shown in Figure 3 and Table 1. The primary intermediate product disappeared completely when the reaction mixture was treated with the reducing agents, and 91% and 58% of α-T were regenerated from the primary intermediate product when treated with $LiAlH_4$ or ascorbic acid, respectively. The limited solubility of ascorbic acid in acetonitrile may be responsible for its lower effectiveness compard to $LiAlH_4$. When no reducing agents were added, approximately 85% of the α-T converted to compounds A and B.

The α-T oxidation products produced by the reaction of α-T with O_2^- in dry acetonitrile are shown in Figure 4. Retention times were 12.8, 15.2 and 16.4 min for the α-T secondary intermediate, compound A, and compound B, respectively. The secondary product was measured at 235 nm maximum absorbance. This compound slowly converted in hexane at room temperature to compounds A and B, and also readily converted to these compounds (A and B) when washed with water or when the solvent was evaporated under nitrogen. Compounds A and B also exhibited maximum absorbance at 235 nm, and were found to be slightly more polar than the parent compound α-T. Compounds A, B, and the secondary intermediate product were not converted to α-T when treated with either $LiAlH_4$, ascorbic acid or 0.1M HCl.

The greatest conversion of α-T into the secondary intermediate product was obtained when no nitrogen was bubbled through the reaction mixture before and during the reaction of α-T with O_2^- in dry acetonitrile (Fig. 5). When the O_2^- solution was purged with nitrogen for 5 min before the reaction with α-T, considerably less secondary product formed. When the nitrogen purge was continued during the reaction of O_2^- with α-T for an additional one minute (total 6 min), the least amount of secondary product was produced. These results seem to indicate that O_2 may also be involved in α-T oxidation. Matsumoto and colleagues (17,18) observed that when O_2 was evacuated from the reaction medium, the reaction rate of an α-T model compound, 2,2,5,7,8-pentamethylchroman, with O_2^- was markedly inhibited. Nanni *et al.* (8) reported

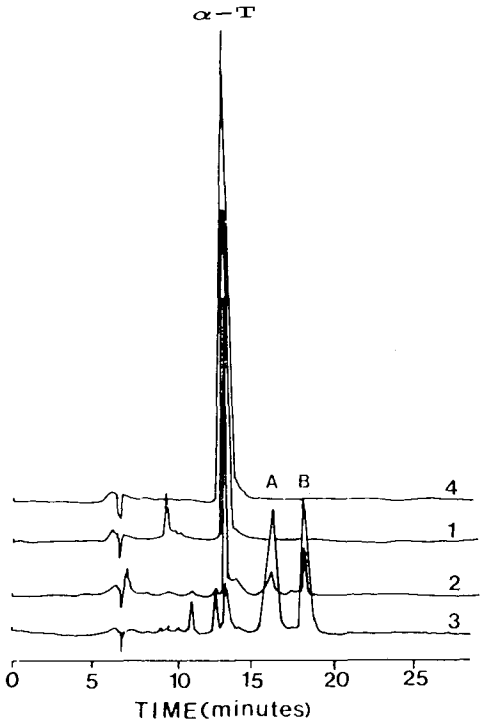

FIG. 3. HPLC tracings of the reduction products of the primary oxidation product of α-T after treatment with $LiAlH_4$ (1) or ascorbic acid (2). The primary oxidation product in the absence of reducing agent converts to compounds A and B during analysis (3). Standard α-T is shown for comparison (4). A 5 μm Ultrasphere-Si column, 250 mm × 4.6 mm i.d. was eluted with hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v) at a flow rate of 0.4 mL/min. Detection was at 234 nm for compounds A and B and 292 nm for α-T; the sensitivity was 0.05 AUFS at both wavelengths.

that O_2 may be produced during the reaction of α-T with O_2^- and may be involved in α-T oxidation reactions as well.

Reaction of α-T with O_2^- in an aqueous acetonitrile solution (protic conditions). The disappearance of α-T was measured during the reaction with O_2^- in the presence of various amounts of water (1, 5 and 10%) in acetonitrile over a period of time and compared with a control α-T sample which contained no O_2^- and water (Fig. 6). In the presence of 1% of water (1 min reaction time), α-T quickly disappeared and produced an intermediate similar to that

Chromatogram 1; secondary intermediate, S. Chromatogram 2; stable end-products compound A, A and compound B, B.

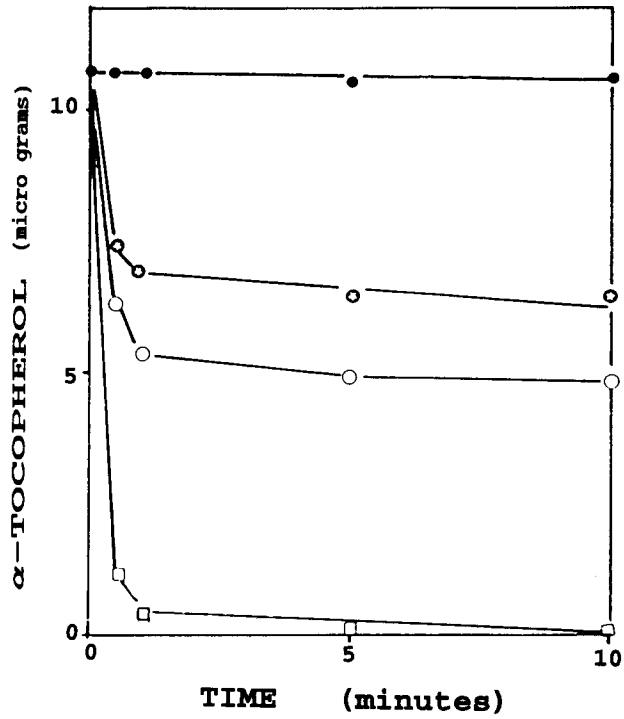

FIG. 6. Disappearance of α-T from the reaction mixture of α-T with O_2^- in the presence of various concentrations of water: 1% water (○), 5% water (○), 10% water (□) and 0% water and no O_2^- (●).

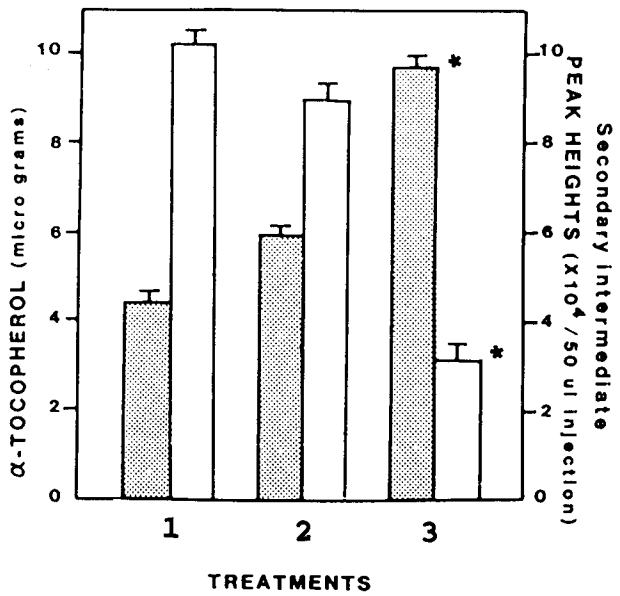

FIG. 5. Effects of N_2 purge on the reaction of α-T with O_2^- in dry acetonitrile. Treatments: 1, no nitrogen purge; 2, 5 min nitrogen purge before reaction; 3, nitrogen purge 5 min before reaction and 1 min during reaction. Shaded bars represent α-T and open bars represent secondary intermediate product. * = Differ statistically, Tukey's w significant test, $X < = 0.05$.

seen with the reaction of O_2^- itself. This result indicates that a 1% water concentration in acetonitrile is not sufficient to dismutate O_2^-. The higher reaction rate, in 10% water than in 5% water, suggests that 10% water in acetonitrile was more effective in dismutating O_2^- under the experimental conditions used. A typical HPLC separation of the products of the reaction of α-T with O_2^- in a 10% aqueous acetonitrile solution (Ultrasphere-Si column) is shown in Figure 7. Four α-T oxidation products were isolated, and three of them were identified as α-T dimer (D), α-T dihydroxy dimer (DHD) and α-T quinone (TQ) by both co-chromatography and ultraviolet spectrometry. Co-chromatography of the samples spiked with pure D, DHD and TQ did not change retention times and peak shapes when compared to the pure compounds alone. Peak heights and areas were increased proportionately to the amounts of standards added. The ultra-violet spectra of these compounds in hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v) were identical to their corresponding standards (Table 2). Hence, the products of the oxidation of α-T with O_2^- were different in anhydrous acetonitrile (Fig. 4) and in the presence of 10% water in acetonitrile.

DISCUSSION

Two unstable α-T intermediate products were produced during the reaction of α-T with O_2^- in dry acetonitrile. The first intermediate was found to be very unstable (20 sec) and converted readily to the second intermediate. The

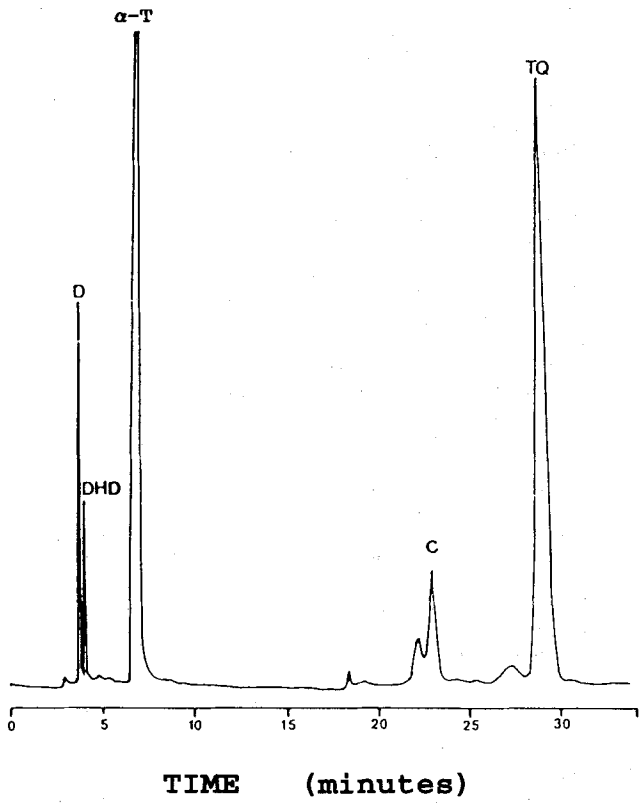

FIG. 7. A typical HPLC tracings of α-T oxidation products produced by the reaction of α-T with O_2^- in a 10% aqueous solution. The identified peaks are: D, α-T dimer; DHD, α-T dihydroxy dimer; α-T, α-tocopherol; TQ, α-tocopheryl quinone; and C, unknown compound. The HPLC conditions were as described for Figure 3.

TABLE 2

Adsorption Maxima[a] of Standards and Isolated α-Tocopherol Oxidation Products from the Reactions of α-Tocopherol with O_2^- in the Presence of 10% water

Compounds	Standards (nm)	Isolated compounds (nm)
α-Tocopherol dimer	298.5	298.6
α-Tocopherol dihydroxy dimer	291.2	291.0
α-Tocopherol	292.0	291.8
α-Tocopheryl quinone	268.0	267.8

[a]Maxima were determined in the hexane/chloroform/isopropanol (95:45:0.5, v/v/v) mixture used as mobile phase in HPLC.

secondary intermediate was more stable than the first intermediate, but also converted in about equal quantities of two stable end products, compounds A and B. The primary intermediate product was easily reconverted to α-T by treatment with $LiAlH_4$ or ascorbic acid. It may be concluded that the primary intermediate product is an α-tocopheroxy radical or an α-tocopheroxy anion. Ozawa and Hanaki (10,16,19) observed yellow color development during the reaction of an α-tocopherol model compound with O_2^-, and identified this compound as an α-chromanoxy radical by electron spin resonance (10,16,19). However, the chromanoxy radical seemed to be more stable than the primary intermediate product of α-T produced in the present experiments. According to Nanni *et al.* (8) the possibility exists for the formation of an α-tocopheroxy anion by the action of O_2^-. It has also been suggested that, in the presence of glutathione or ascorbic acid, α-T could be regenerated after being oxidized to an α-tocopheroxy radical by O_2^- (9,20). However, none of these studies provided direct evidence that α-T was the end product of the regeneration procedures. One of the interesting aspects of the present study is the demonstration of α-T regeneration from the primary intermediate product which was produced by the reaction of α-T with O_2^- in an aprotic condition. When O_2^- is produced by membrane-bound enzymes such as NADPH reductase (2,21) or by the H_2O_2 disproportionation reaction (22), α-T acts as a scavenger. If an α-tocopheroxy anion is formed by O_2^-, it could be reduced back to α-T in the presence of ascorbic acid, making α-T again available for scavenging action.

The secondary intermediate product (absorption maximum 273 nm) could not be converted to α-T by treatment with $LiAlH_4$ or ascorbic acid. It has been reported that α-tocopherone (absorption maximum 240 nm in methanol) produced from the reaction of α-T with O_2^- (20) or free radicals (3) can be reduced again to α-T by treatment with reducing agents, and can be oxidized to α-tocopheryl quinone by treatment with acid (23).

It is concluded that the secondary intermediate produced by the reaction of α-T with O_2^- under aprotic conditions is not identical to α-tocopherone because the secondary intermediate thus produced is not convertible to α-T by reducing agents nor is the secondary intermediate oxidized to α-tocopheryl quinone in the presence of acid. Production of the secondary intermediate product required O_2 in the reaction media (Fig. 5). The secondary intermediate product converted readily to equal amounts of compounds A and B in the presence of water or during sample handling. Compounds A and B were stable end products of the reaction of O_2^- under aprotic conditions.

The first step of α-T reaction with O_2^- in the aprotic media resulted in the formation of the primary intermediate product. If O_2^- in an aprotic solution acts as a Bronsted base, then phenolic compounds such as α-T (8,17,24) could be converted to α-tocopheroxy anions. The second step is the oxidation of the primary intermediate to the secondary intermediate product, mediated by the presence of O_2. The involvement of O_2 in α-T oxidation has been observed by several other investigators (8,24,25). Depending upon the reaction conditions, α-T was selectively oxidized (especially in the presence of base). The final step in the oxidation of α-T is the conversion of the secondary intermediate into the stable end products A and B.

By contrast, when α-T was reacted with O_2^- in a 10% aqueous acetonitrile solution, neither the primary intermediate product, the secondary intermediate product, nor compounds A and B were formed, rather, α-tocopherol dimer (D), α-tocopherol dihydroxy dimer (DHD), α-tocopheryl quinone (TQ) and an unknown compound were formed instead. The principal fate of O_2^- in an aqueous solution is its dismutation which results in the formation of hydroxy radical and/or singlet oxygen (5,22,26–28). Dimer, DHD, α-T trimer, and TQ are formed by the reaction of α-T with free radicals (12,23,29), in addition, TQ may be formed by reaction with singlet oxygen (30,31).

It has also been reported that TQ is produced by the reaction of α-T with O_2^- generated from the xanthine oxidase system (9). However, O_2^- dismutation must have occurred in that system in the presence of water. Therefore, TQ formation may be attributable to the formation of hydroxy free radicals. In the present experiments, α-tocopheryl quinone was not found to be produced by the direct action of O_2^-.

In summary, when α-T was reacted with O_2^- in dry acetonitrile, a very unstable intermediate product was formed. This compound could easily be converted into α-T by treatment with either $LiAlH_4$ or ascorbic acid. The primary intermediate product changed into the secondary product which was isolated by HPLC. The secondary product then converted in the presence of oxygen into two stable end products. When α-T reacted with O_2^- in a 10% aqueous acetonitrile solution, α-T dimer, α-T dihydroxy dimer, α-T quinone and an unknown compound were produced. The present experiments demonstrate that the reaction of α-T with O_2^- under aprotic conditions produces completely different oxidation products than does the reaction under protic conditions.

α-Tocopherol Oxidation Mediated by Superoxide Anion (O_2^-). II. Identification of the Stable α-Tocopherol Oxidation Products

Yeong L. Ha[1] and **A. Saari Csallany***
Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

The present paper describes the identification of two stable end products of α-tocopherol oxidation that were previously detected among the products of the reaction of α-tocopherol with superoxide anion (O_2^-) under aprotic conditions. One compound, previously designated compound A, was identified as *trans*-7-hydroxy-*trans*-8,8a-epoxy-α-tocopherone, and the other, designated compound B, was identified as *cis*-7-hydroxy-*cis*-8,8a-epoxy-α-tocopherone. It was also observed that under protic conditions (10% water in acetonitrile) the reaction of α-tocopherol with O_2^- did not produce compounds A and B, but rather α-tocopheryl quinone, α-tocopherol dimer, α-tocopherol dihydroxy dimer, and the previously designated compound C. Compound C was identified in the present study as α-tocopheryl-quinone-2,3-epoxide.
Lipids 27, 201-205 (1992).

Following the first report by Fridovich (1) on the production of superoxide anion (O_2^-) in biological systems, several laboratories became interested in the reaction of α-tocopherol (α-T) with O_2^- under various conditions (2-11). Recent studies from our laboratory (12) showed that the reaction of α-T with O_2^- proceeded by different mechanisms under aprotic and protic conditions. By use of high-performance liquid chromatography (HPLC) (12), two stable unidentified compounds (A and B) were isolated from the reaction products of α-T with O_2^- under aprotic conditions, while α-tocopheryl quinone, α-tocopherol dimer, α-tocopherol dihydroxy dimer and an unidentified compound C were isolated from the reaction products of α-T with O_2^- under protic conditions (13). In the present paper, the identification of compounds A, B and C is reported.

MATERIALS AND METHODS

Reagents. Acetonitrile (spectral grade, 0.0006% water; Burdick and Jackson, Muskegon, MI), mercury (electro grade 99.999%; Alfa Products, Danvers, MA), ethyl acetate (HPLC grade; Fisher Scientific Company, Itasca, IL), hexane (HPLC grade; Fisher Scientific Company), isopropanol (HPLC grade; Fisher Scientific Company), tetrabutylammonium bromide (Fisher Scientific Company), α-tocopherol (Eastman Kodak Company, Rochester, NY), and oxygen (99.999%; Air Products, Inc., Minneapolis, MN) were used in this study. In all experiments, doubly distilled water was used. All other chemicals were reagent grade.

Instrumentation. HPLC separation of α-tocopherol (α-T) and its oxidation products was performed on a 5 μm Ultrasphere-Si, 250 mm × 4.6 mm, i.d., column (Beckman Instruments Inc., Berkeley, CA), using a mobile phase of hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v) as described previously (12,13). Ultraviolet (UV) spectra were recorded with a Beckman model DU-8 spectrophotometer. Mass spectral (MS) analyses were carried out with a Kratos MS-25 instrument (Manchester, England) equipped with a Data General Eclipse s/120 data system. For electron impact mass spectroscopy (EI-MS), the ion source temperature was 230°C, and the ionizing voltage was 70 eV. For chemical ionization mass spectroscopy (CI-MS), a 220 eV ionization voltage with isobutane as the reagent gas was used. ^{1}H nuclear magnetic resonance (NMR) spectra were obtained at 300 MHz with a Nicolet 300 WB Fourier transform (FT) NMR spectrometer equipped with a Nicolet 1280 data system (Shamburg, IL). Infrared (IR) spectra were recorded using a Nicolet 60S FT IR spectrometer equipped with a triglycine sulfate (TGS) detector.

Reaction of α-T with O_2^- (aprotic conditions). One μmole of α-T was dissolved in 100 μL dry acetonitrile and reacted with 3 mL of O_2^- solution (5.2×10^{-6}M) for one minute. The reaction mixture was extracted three times with 3 mL of hexane, the combined extracts were washed three times with 3 mL of water and dried over anhydrous sodium sulfate. The dried hexane extract was then concentrated to about 3 mL under a stream of nitrogen.

Reaction of α-T with O_2^- (protic conditions). The procedure was the same as described above, except that the 3 mL of O_2^- solution contained 10% water (v/v). Reaction conditions have been described in detail previously (13).

High-performance liquid chromatography (HPLC). The concentrated hexane extracts were analyzed by HPLC as described previously (12,13).

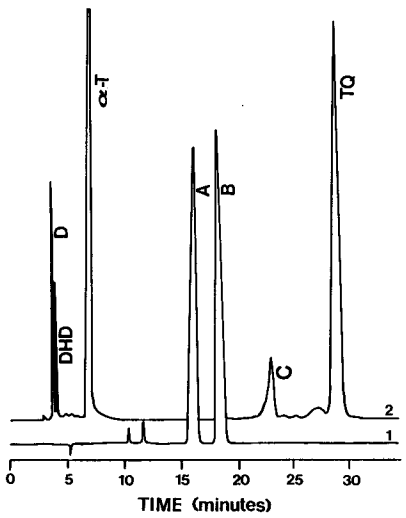

FIG. 1. HPLC separation of compounds A and B (tracing 1). HPLC separation of α-tocopherol dimer (D), α-tocopherol dihydroxy dimer (DHD), α-tocopherol (α-T), compound C (C), and α-tocopheryl quinone (TQ) (tracing 2).

Abbreviations: $CDCl_3$, deuterated chloroform; CI-MS, chemical ionization mass spectroscopy; EI-MS, electron impact mass spectroscopy; FT, Fourier transform; HPLC, high-performance liquid chromatography; IR, infrared; NMR, nuclear magnetic resonance; O_2^-, superoxide anion; TGS, triglycine sulfate; α-T, α-tocopherol; UV, ultraviolet.

RESULTS AND DISCUSSION

The reaction of α-T with O_2^- in dry acetonitrile produced two unstable intermediate and two stable end products (13). The stable end products (Compounds A and B) were isolated and purified by HPLC (Fig. 1, Chromatogram 1). Several fractions containing these compounds were individually collected, combined, and dried under nitrogen. The residues were redissolved in methanol for UV and MS, in carbontetrachloride for IR, and in deuterated chloroform ($CDCl_3$) for NMR analyses.

The ultraviolet absorption maxima of compounds A and B were found to be at 235 nm and 234 nm and the molar absorptivities (ε) were 3060 and 3100, respectively, indicating that both compounds A and B contained a conjugated enone system (5,14,15). Infrared spectral analyses showed the presence of a hydroxyl group (3586 cm^{-1}) and a carbonyl group (1720 cm^{-1}) in both compounds.

CI-MS data of compounds A and B are shown in Figure 2. The molecular weight of both compounds was 462 daltons. Ion ($M^+ + 1$) appeared at *m/z* 463 indicating the addition of two atoms of oxygen to α-T. The EI-MS of these compounds were almost identical (Fig. 3); their distinct features were not sufficient to pinpoint structural differ-

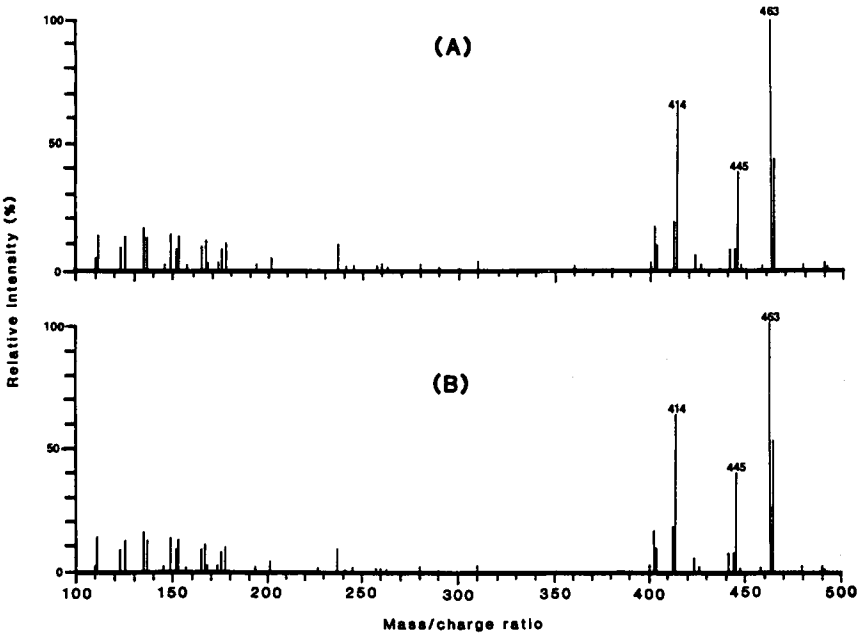

FIG. 2. CI-MS of compounds A and B.

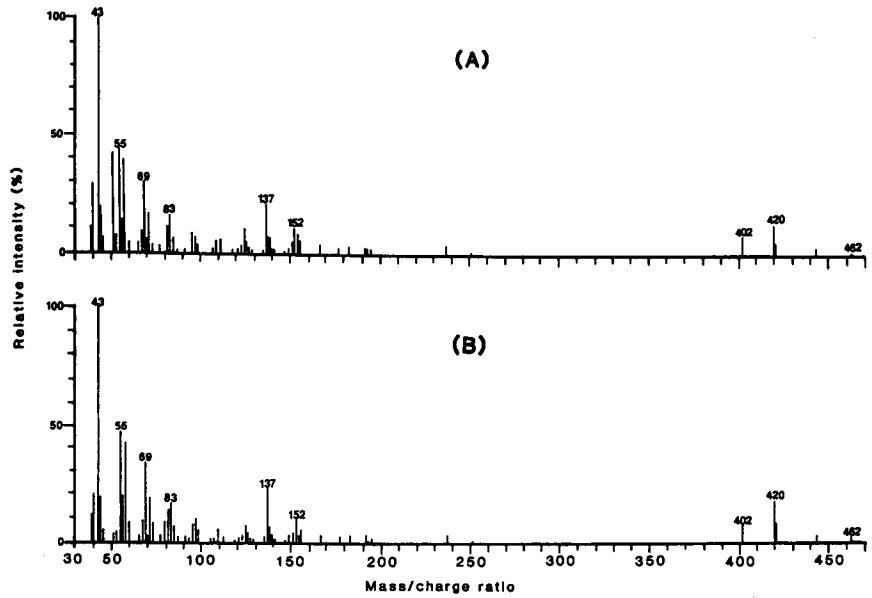

FIG. 3. EI-MS of compounds A and B.

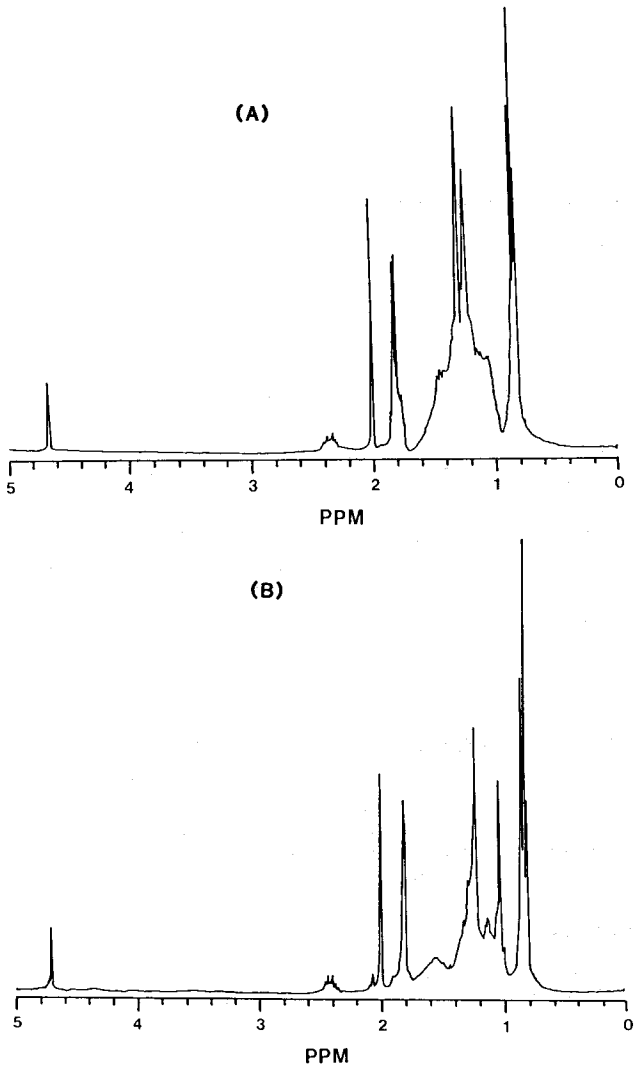

FIG. 4. NMR spectra of compounds A and B in $CDCl_3$.

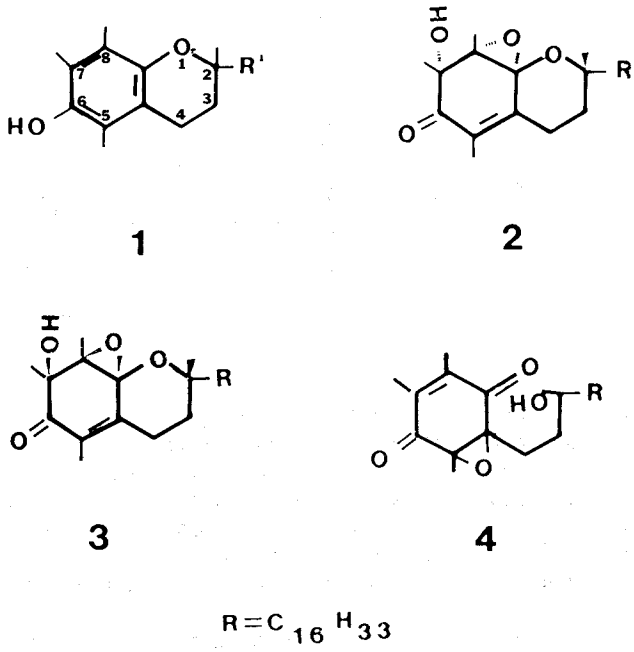

FIG. 5. Structures of α-tocopherol (1); compound A, *trans*-7-hydroxy-*trans*-8,8a-epoxy-α-tocopherone (2); compound B, *cis*-7-hydroxy-*cis*-8,8a-epoxy-α-tocopherone (3); compound C, α-tocopheryl-quinone-2,3-epoxide (4).

ences. Based on UV, IR, CI-MS and EI-MS analysis, it was concluded that both compounds A and B have a chromane ring structure, and contain an epoxide group and a hydroxyl group, as well as a ketone group at the C-6 position.

The NMR spectra for compounds A and B are shown in Figure 4. The signal assigned to a hydroxyl proton was observed at 4.70 ppm in the spectra of both compounds. Substantial differences in the NMR spectra were observed in the 1–3 ppm region. The methyl protons assigned to C-2 of compound A appeared at 1.04 ppm, those of compound B appeared at 1.30 ppm. The other proton signals of the two compounds were quite similar. The hydroxyl protons of compound A or B were shielded, indicating that the hydroxyl group may be located between a ketone group (C-6) and an epoxide group on the phenol ring thus maintaining an enone system. The chemical shift of the hydroxyl group in 2,2′,5,7,8-pentamethyl-5-hydroxy-α-chromanone was observed by Matsuo *et al.* at 3.5 ppm (5). Matsumoto and Matsuo (6) reported that the chemical shift of the hydroxyl group in 2,2′,5,7,8-pentamethyl-4a,5-7;8-diepoxy-8a-hydroxy-α-chromanone appeared at 3.05 ppm. Both 8a- and C-5 positions, therefore, can be ruled out as the hydroxyl positions in compounds A and B. Hence, C-7 appears to be the likely position for the hydroxyl group, and 8 and 8a for the epoxide group in both compounds. Compounds A and B seem to be isomers of 7-hydroxy-8,8a-epoxy-α-tocopherone. The compound contains at least three asymmetric centers at the C(2)-CH_3, C(7)-OH, and C(8),C(8a)-epoxide positions, respectively (Fig. 5, compound 2). This appears to indicate the possible existence of eight stereoisomers; however, only four isomers are formed due to ring fusion (*cis* and *trans* ring). Grams *et al.* (16) have shown that a model compound 4a, 5-epoxy-8a-methoxy-α-tocopherone exhibited *cis*-methoxy, *cis*-epoxy and *trans*-epoxy isomers to the C(2)-methyl group with a *cis* ring fusion; and *trans*-methoxy, *cis*-epoxy and *cis*-methoxy, *trans*-epoxy isomers to the C(2)-methyl groups with *trans*-ring fusion. Since the hydroxyl groups of both compounds A and B appeared at 4.70 ppm, the configuration of these compounds could be either *trans*-hydroxyl, *trans*-epoxy or *cis*-hydroxyl, *cis*-epoxy to the C(2)-CH_3 belonging to the *cis* ring fusion described above. The protons at 1.04 ppm of the C(2)-methyl group of compound A were deshielded compared to those at 1.30 ppm of compound B. Hence, compound A is proposed to be *trans*-7-hydroxy-*trans*-8,8a-epoxy-α-tocopherone (Fig. 5, compound 2) whereas compound B is proposed to be *cis*-7-hydroxy-*cis*-8,8a-epoxy-α-tocopherone (Fig. 5, compound 3).

The reaction of α-T with O_2^- under protic conditions (10% water in acetonitrile) resulted in the formation of α-tocopheryl quinone, α-tocopherol dimer, α-tocopherol dihy-

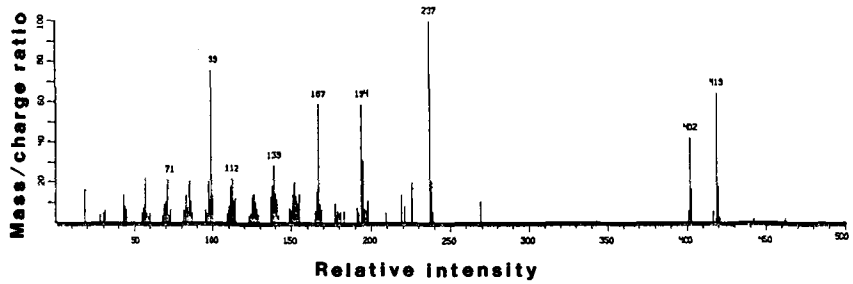

FIG. 6. EI-MS of α-tocopherol quinone-2,3-epoxide isolated by HPLC.

droxy dimer and an unidentified compound designated to be compound C (13). Figure 1 (Chromatogram 2) illustrates a typical HPLC separation of these compounds. To obtain enough material for identification, the middle portions of peak C from several HPLC separations were combined. The pooled fractions were dried under nitrogen, redissolved in methanol, and used for UV and MS analyses (Fig. 6).

An ultraviolet absorption maximum was found at 274 nm, indicating the presence of a dione conjugated double-bond system and suggesting that the chromane ring was opened. EI-MS spectra showed peaks at *m/z* 462 (M^+, 3%), 444 ($M^+ - H_2O$, 5%), 419 ($M^+ - CH_3 - CO$, 65%), and 237 ($M^+ - C_{16}H_{33}$, 100%) (Fig. 6) indicating that this compound contains one hydroxyl group (444, $M^+ - H_2O$) and a carbonyl group (419, $M - CH_3 - CO$). Furthermore, the 237 *m/z* fragment (M − R sidechain $C_{16}H_{33}$) indicates that the phenolic part of the chroman ring contains one additional oxygen. The EI-MS of α-tocopheryl quinone shows a fragment at *m/z* 221 ($M - C_{16}H_{33}$) which contains one less atom of oxygen than does compound C (16,17). Based on the data in both spectra, compound C was identified as an α-tocopheryl quinone-2,3-epoxide (Fig. 5, compound 4). The UV and MS spectral data for this compound are in agreement with the data of Grams and Inglett (17) reported for α-tocopheryl quinone-2,3-epoxide.

The principal fate of O_2^- in aqueous solution is its dismutation *via* disproportionation reactions resulting in the formation of a hydroxyl free radical (•OH) (18–21). The formation of singlet oxygen O_2^- under the above conditions remains to be controversial. Active oxygen species seem to be responsible for the formation of α-tocopherol dimer, α-tocopherol dihydroxy dimer, α-tocopheryl quinone and α-tocopheryl quinone-2,3-epoxide. Several investigators have observed the formation of α-tocopheryl quinone, dimer, dihydroxy dimer and trimer of α-tocopherol, by the reaction of α-T with hydroxy free radicals. α-Tocopheryl quinone and α-tocopheryl quinone-2,3-epoxide may be formed from the reaction of α-T with singlet oxygen (22–25). However, if O_2^- dismutation results in hydroperoxy radical (HOO•) formation, this active oxygen species could be responsible for the reaction products formed under protic conditions.

In summary, the reaction of α-T with O_2^- under anhydrous (aprotic) conditions resulted in the formation of an unstable intermediate which was converted to a somewhat more stable second intermediate (13) that, in the presence of molecular oxygen, is proposed to convert to *trans*-7-hydroxy-*trans*-8,8a-epoxy-α-tocopherone and *cis*-7-hydroxy-*cis*-8,8a-epoxy-α-tocopherone. The results are in good agreement with the findings of Matsumoto and Matsuo (4) who isolated hydroxy chromanones after reacting α-tocopherol with potassium superoxide in tetrahydrofuran. In the presence of water (protic conditions), O_2^- dismutates to active oxygen species which lead to the formation of α-tocopheryl quinone, α-tocopherol dimer, α-tocopherol dihydroxy dimer and α-tocopheryl quinone 2,3-epoxide. The present results demonstrate the difference in the reaction of α-T with O_2^- under anhydrous conditions and in the presence of water.

METHOD

A Sensitive and Specific Radioimmunoassay for Platelet-Activating Factor[1]

Chang-jin Wang and **Hsin-Hsiung Tai***
Division of Medicinal Chemistry and Pharmaceutics, College of Pharmacy, University of Kentucky, Lexington, Kentucky 40536-0082

A platelet-activating factor (PAF) analog with a reactive ω-aldehyde group at the *sn*-1 position was synthesized. The hapten-thyroglobulin conjugate was used to immunize rabbits to produce specific antibodies to PAF. The purified immunoglobulin G (IgG) fraction was found to bind stereospecifically to tritiated PAF and to crossreact minimally with lysoPAF, plasmalogens, and other phospholipids. The radioimmunoassay detected as little as 20 pg of PAF per assay tube and was used to explore agonist-induced synthesis of PAF in rabbit neutrophils. Calcium ionophore A23187 at 1 μM induced PAF synthesis peaking at 2 min and reaching basal levels after 5 min. *N*-Formyl-Met-Leu-Phe (FMLP) at 0.1 μM also stimulated rapid synthesis and degradation of PAF with a peak at 5 min. Both A23187 and FMLP stimulated PAF synthesis in a dose-dependent manner. The radioimmunoassay should be applicable to the quantitation of PAF in biological samples.
Lipids 27, 206–208 (1992).

Platelet-activating factor (PAF) is a potent phospholipid mediator with a wide spectrum of biological activities, including platelet aggregation and secretion, neutrophil aggregation and chemotaxis, hypotension, bronchoconstriction, and vascular permeability (1). The fact that the naturally occurring stereoisomer (R), but not the (S) isomer is effective in stimulating platelets and neutrophils suggests the involvement of a specific PAF receptor (2). PAF is capable of triggering biological effects at concentrations as low as 0.1 nM or less indicating that endogenous production of this potent mediator by activated cells can be extremely low.

Quantitation of PAF primarily relies on its ability to trigger rabbit platelet aggregation or labeled serotonin secretion (3). The bioassays, however, have an inherent variability as even the manner in which the platelets and assay samples are prepared can affect the results. Therefore, the development of a specific, sensitive and reproducible PAF assay, such as a radioimmunoassay, for PAF is urgently needed.

We describe here the conjugation of a novel PAF analog to thyroglobulin, and the production of specific PAF antibodies. The antibodies served as the basis for developing a radioimmunoassay. The biosynthesis of PAF in rabbit neutrophils in response to stimulation by calcium ionophore and chemotactic peptide was followed using the radioimmunoassay.

[1]Based on a paper originally presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

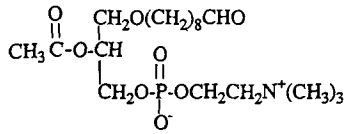
Abbreviations: CPL, choline plasmalogen; FMLP, *N*-formyl-methionyl-leucyl-phenylalanine; IC_{50}, 50% maximal binding; IgG, immunoglobulin G; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; lysoPAF, lyso platelet-activating factor, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetal-*sn*-glycero-3-phosphocholine; RIA, radioimmunoassay.

MATERIALS AND METHODS

Materials. PAF, lysoPAF, *rac*-PAF, A23187, *N*-formyl-Met-Leu-Phe (FMLP), bovine thyroglobulin, bovine serum albumin, sodium cyanoborohydride, and complete and incomplete Freund adjuvant were obtained from Sigma (St. Louis, MO). Other phospholipids were purchased from Serdary Research Laboratories (London, Ontario, Canada). The Affi-Gel protein A MAPS II Kit was supplied by Bio-Rad (Richmond, CA). Polyethylene glycol 6000 was obtained from Union Carbide (New York, NY). Goat anti-rabbit IgG was supplied by Calbiochem (San Diego, CA). New Zealand white rabbits were purchased from a local farm. 1-*O*-[Alkyl-1′,2′-^{3}H]PAF (40–45 Ci/mmol) was purchased from DuPont-NEN (Boston, MA). The PAF analog 1-*O*-(ω-nonanal)-2-acetyl-*sn*-glycero-3-phosphocholine—compound 1 (Scheme 1) was synthesized by a 10-step procedure reported elsewhere (4).



SCHEME 1

Production and purification of PAF antibodies. Conjugation and immunization were carried out essentially as described (4). Briefly, bovine thyroglobulin (30 mg) was dissolved in 2 mL of H_2O, and 10 mg of freshly prepared compound 1 in 0.5 mL of CH_3OH was added. After 30 min, 3 mg of sodium cyanoborohydride was added. The reduction was allowed to continue for 24 hr at 4°C. The mixture was then dialyzed against H_2O for 24 hr with the water being changed three times. The conjugate (1 mg) in 1 mL of H_2O was emulsified with an equal volume of complete Freund adjuvant and injected intradermally into the back of a female rabbit (8–10 wk old) at multiple sites. Booster injections at the same dose were carried out at monthly intervals. the rabbit was bled through an ear vein 7–14 days following each booster injection. Plasma was obtained from blood after centrifuging the blood at 2,000 × *g* for 10 min. Plasma (1 mL) was mixed with 1 mL of the binding buffer for the Affi-Gel protein A MAPS II Kit. The clear solution after filtration was applied onto a 2-mL Affi-Gel protein A column equilibrated with the binding buffer. The column was washed with 5 mL of the binding buffer which eluted plasma proteins other than immunoglobulinG (IgG). The IgG fraction was eluted with 2 mL of the elution buffer from the kit and extensively dialyzed against H_2O. The IgG fraction was used for radioimmunoassay.

Isolation of rabbit neutrophils. Rabbit neutrophils were isolated as described previously with some modifications (5). More than 98% of the neutrophils were viable as verified by trypan blue staining.

Incubation conditions and PAF extraction. Neutrophils (1×10^6) in 0.5 mL of Hanks balanced salt solution containing 0.1% bovine serum albumin were stimulated with appropriate concentrations of A23187 or FMLP at 37°C. The reaction was terminated at the time indicated by adding 1.9 mL of $CHCl_3/CH_3OH/CH_3COOH$ (1:2:0.04, v/v/v). The phases were separated by the procedure of Bligh and Dyer (6), and the lower layer was removed and evaporated under a stream of nitrogen. For PAF determinations (in duplicates), the residue was dissolved in the radioimmunoassay buffer.

Radioimmunoassay of PAF. The assay was carried out as previously described (4). The assay was run, in duplicates, in 12×75 mm conical polypropylene tubes. The standard assay buffer, 0.1 M sodium phosphate buffer pH 7.0 containing 0.15 M NaCl, 0.05% bovine serum albumin, and 0.005% Tween 20, was used for diluting antibodies, PAF standard, samples, and labeled PAF. The assay mixture contained 0.2 mL of PAF standard or sample, 0.04 mL of appropriately diluted antibodies, 0.04 mL of tritiated PAF (*ca.* 15,000 cpm), and 0.02 mL of goat anti-rabbit IgG in a final volume of 0.4 mL of the standard assay buffer. The mixture was incubated at 4°C overnight, and IgG was precipitated by adding 2 mL of cold 4% polyethylene glycol 6000. After centrifugation at 3,000 rpm for 30 min at 4°C, the supernatant was removed and the precipitate was resuspended in 1 mL of H_2O. The radioactivity of the suspension was determined by liquid scintillation counting. The concentration of PAF was estimated from standard curve.

RESULTS AND DISCUSSION

PAF does not possess functional groups that can readily be conjugated to proteins. The synthesis of a PAF analog with reactive conjugatable function is a prerequisite for the preparation of a hapten-protein conjugate. We synthesized an aldehydic PAF analog (compound 1, Scheme 1) which reacted readily with thyroglobulin. Subsequent reduction with sodium cyanoborohydride provided a stable conjugate. We have chosen a shorter alkyl chain at *sn*-1, which is structurally distinct from most phospholipids, for eliciting immune response.

Rabbits produced detectable antibodies against the PAF analog conjugate after injection over 2 mon. Binding of tritiated PAF to antibodies was not detected when crude antiplasma was diluted and used for incubation. However, binding was observed when the IgG fraction of the antiplasma or acidified antiplasma was used. The lack of binding by crude antiplasma may be due to rapid deacetylation of the labeled PAF by acetylhydrolase which has been reported to be present in plasma (7). Since the purified IgG fraction showed higher binding and less nonspecific background than acidified plasma, the IgG fraction was routinely used in the radioimmunoassay.

The radioimmunoassay of PAF described here can detect 20 pg of PAF per assay tube at a final antibody dilution for 1 to 1,000 (Fig. 1). The concentration of PAF which inhibits 50% maximal binding (IC_{50}) is 300 pg, as shown in Figure 1 and Table 1. Racemic PAF gave an IC_{50} of 600 pg, *i.e.* twice as much as IC_{50} of PAF indicating stereospecific binding of the antibodies. The specificity of the antibodies was further examined by measuring competitive binding of various phospholipids

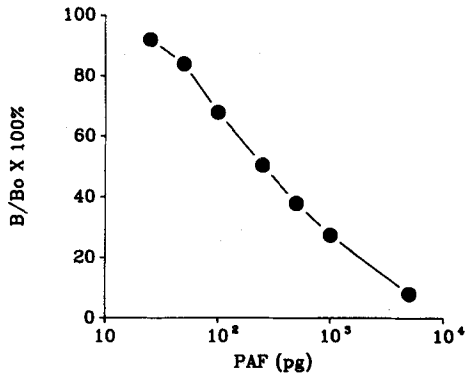


FIG. 1. Standard displacement curve for PAF. The radioimmunoassay was carried out as described in Materials and Methods. B_0 represents % binding of labeled PAF in the absence of unlabeled PAF. B represents % binding of labeled PAF in the presence of the indicated amount of unlabeled PAF.

TABLE 1

Crossreaction of Anti-PAF Antibodies with Phospholipids[a]

Phospholipids	IC_{50}	% Crossreaction
PAF	300 pg	100
rac-PAF	600 pg	50
LysoPAF	>50 μg	<0.02
PC	>25 μg	<0.04
LysoPC	>50 μg	<0.02
PI	>50 μg	<0.02
LysoPI	>15 μg	<0.06
CPL		ND
PE		ND
LysoPE		ND
PS		ND
LysoPS		ND

[a]ND, not detectable; CPL, choline plasmalogen; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; lysoPAF, lysoplatelet-activating factor, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine.

including lysoPAF and plasmalogens with labeled PAF. Only insignificant crossreaction with lysoPAF and the other phospholipids was observed, indicating that the antibodies recognize the acetyl moiety of PAF. PAF was also found to be released to an insignificant extent into extracellular space (8). Therefore, quantitation of the total amount of PAF synthesized requires lipid extraction from the cells. The Bligh and Dyer method (6) was shown to effectively extract PAF and was therefore used in the present study. Since the antibodies did not appear to cross react with any of the phospholipids other than PAF, the crude extract was dissolved in the buffer and directly used for the radioimmunoassay. The validity of the assay was ascertained by measuring PAF in increasing volumes of the extract and by examining whether the PAF levels measured increased in a linear manner. A linear correlation was observed. Furthermore, when known amounts of PAF were added to an extract, the recovery of added PAF as measured by radioimmunoassay (RIA) was essentially quantitative ($87 \pm 8\%$; $n = 7$).

When rabbit neutrophils were stimulated with 1 μM

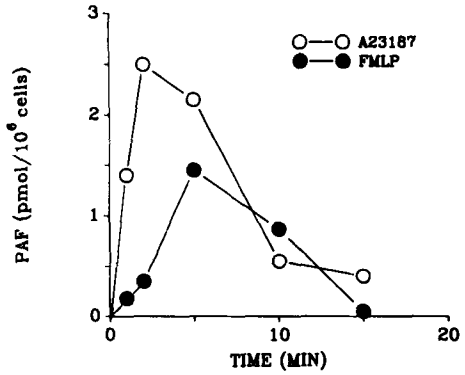

FIG. 2. Time course of PAF synthesis in rabbit neutrophils following stimulation by A23187 or FMLP. Rabbit neutrophils (2×10^6/mL) were stimulated by 1 μM A23187 or by 0.1 μM FMLP for the indicated length of time. Extraction and radioimmunoassay of PAF were carried out as described in Materials and Methods.

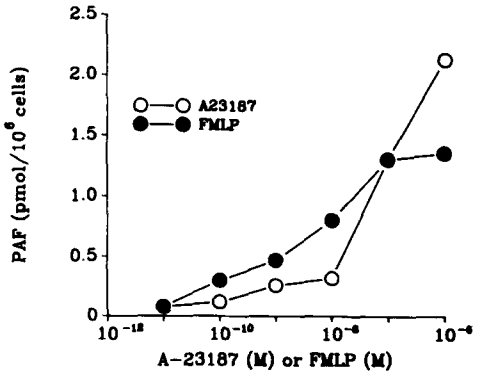

FIG. 3. Concentration dependent PAF synthesis in rabbit neutrophils following stimulation by increasing concentrations of A23187 or FMLP. Rabbit neutrophils (2×10^6/mL) were stimulated by the indicated concentrations of A23187 for 2 min or of FMLP for 5 min. Extraction and radioimmunoassay of PAF were carried out as described in Materials and Methods.

calcium ionophore A23187, rapid synthesis and accumulation of PAF was observed peaking at 2 min as shown in Figure 2. The level of PAF decreased to near basal after 10 min of stimulation. Similarly, 0.1 μM FMLP stimulated rabbit neutrophils to synthesize PAF with a peak at 5 min. Again the level of PAF returned to near basal 15 min after stimulation. Stimulation of rabbit neutrophils by A23187 or FMLP was found to be concentration-dependent as shown in Figure 3. A significant increase in PAF synthesis could be observed with 0.1 nM FMLP or 1 nM A23187, and near maximal synthesis was achieved at 1 μM FMLP or 10 μM A23187. A23187 appeared to be the more potent agonist for inducing PAF synthesis. The peak levels of PAF were in the range of 1.5–2.5 pmol/10^6 cells. The figures are similar to those reported for human neutrophils stimulated with FMLP (9) and for rat hepatic Kupffer cells following A23187 stimulation (10), but were significantly lower than those reported for human endothelial cells stimulated with thrombin (8).

Antibodies against PAF have been described in some previous reports. In one study, rabbits were immunized with liposomes containing PAF. However, the antibodies showed poor specificity and affinity for PAF (11). In another study, an acetylhydrolase resistant analog, an *N,N*-dimethylcarbamoyl derivative of ω-carboxylated PAF was synthesized and conjugated to bovine serum albumin (12). Although the conjugate elicited antibody production, the antibodies showed some crossreaction with lysoPAF. An approach similar to ours of synthesizing an aldehydic analog of PAF for antibody production was published during the course of our study (13). The authors employed a different synthetic route to synthesize dimethoxy PAF analogs which were then converted to the corresponding aldehydes by acid hydrolysis. The antibodies showed good specificity, but lower sensitivity (2.5 ng per assay tube). The radioimmunoassay described herein represents a specific and sensitive method capable of quantitating PAF in biological samples.

REVIEW

Metals and Lipid Oxidation. Contemporary Issues[1]

K.M. Schaich[2]
Department of Food Science, Cook College, Rutgers University, New Brunswick, New Jersey 08903

Lipid oxidation is now recognized to be a critically important reaction in physiological and toxicological processes as well as in food products. This provides compelling reasons to understand what causes lipid oxidation in order to be able to prevent or control the reactions. Redox-active metals are major factors catalyzing lipid oxidation in biological systems. Classical mechanisms of direct electron transfer to double bonds by higher valence metals and of reduction of hydroperoxides by lower valence metals do not always account for patterns of metal catalysis of lipid oxidation in multiphasic or compartmentalized biological systems. To explain why oxidation kinetics, mechanisms, and products in molecular environments which are both chemically and physically complex often do not follow classical patterns predicted by model system studies, increased consideration must be given to five contemporary issues regarding metal catalysis of lipid oxidation: hypervalent non-heme iron or iron-oxygen complexes, heme catalysis mechanism(s), compartmentalization of reactions and lipid phase reactions of metals, effects of metals on product mixes, and factors affecting the mode of metal catalytic action.
***Lipids 27,* 209-218 (1992).**

Metal catalysis of lipid oxidation has been recognized for decades. Early research focussed on oxidation of food lipids, and it was in this area that there was intense research effort during the 1960s. Most attention at that time was given to determining lipid oxidation kinetics and catalytic mechanisms of the metals, including which metals, which chelates or complexes, and which valence states were most active (1-11). During the early 1970s, the feeling that the research of the 1960s had discovered all the answers led to metal catalysis of lipid oxidation being considered, for the most part, passé. However, during the late 1970s and early 1980s, the realization that metals play an important, if not critical role in oxidative cytotoxicity reawakened interest in metal catalysis (12-19). Oxidative cytotoxicity refers to pathological processes presumed to be caused by reduced forms of oxygen including H_2O_2, $O_2^{\cdot-}/HO_2^{\cdot}$ (may react directly or dismutate to H_2O_2), $HO^{\cdot}$ from reduction of H_2O_2, and lipid alkoxyl or peroxyl radicals. Production of these radicals is driven catalytically by the trace levels of iron, copper, and perhaps other redox-active metals present in tissues (14,15,18,20,21). Indeed, many scientists feel that participation of metals is *obligatory* for toxic fluxes of radicals which may overwhelm natural defense mechanisms in some diseases and in chemical and drug toxicities (18,20,22,23).

Largely due to the interest of the toxicologists, research on metal catalysis of lipid oxidation has been renewed and revitalized during the 1980s. Food scientists, too, are finding new problems with metals relative to the stability of lipids, particularly in multiphasic foods. Several contemporary issues in metal catalysis have evolved from attempts to understand and explain why oxidation kinetics, mechanisms, and products in molecular environments which are both chemically and physically complex (as in foods and tissues) often do not follow the classical patterns predicted from model system studies.

The general chemical mechanisms for metal catalysis of lipid oxidation are quite familiar (3,24-27).

DIRECT INITIATION

1) by higher valence state metals, via electron transfer and formation of lipid alkyl radicals (2,24). Iron and copper (28) are known to behave this way, as do Mn, Ni, and Co (29,30). For LH representing an unsaturated lipid molecule

$$M^{(n+1)+} + LH \rightarrow M^{n+} + L^{\cdot} + H^{+} \quad [1]$$

2) by lower valence state metals. a) *via* formation of metal-oxygen transition complexes ($M^{(n+1)+} \ldots O_2$), particularly in non-polar solvents (2,3)

$$M^{n+} + O_2 \rightarrow (M^{(n+1)+} \ldots O_2) \rightarrow \begin{cases} M^{(n+1)+} + O_2^{\cdot-} & [2a] \\ \xrightarrow{LH} L^{\cdot} + (M^{n+1)+} \ldots {}^{-}O_2H) & [2b] \\ \xrightarrow{LH} L^{\cdot} + M^{n+} + HO_2^{\cdot} & [2c] \\ \xrightarrow{LH} LO^{\cdot} + (M^{(n+1)+} \ldots OH^{-}) & [2d] \\ \xrightarrow{(M^{n+}LH)} HO_2^{\cdot} + (M^{(n+1)+}L^{-}) + M^{n+} & [2e] \end{cases}$$

b) *via* metal autoxidation, which produces reactive oxygen species, $O_2^{\cdot-}/HO_2^{\cdot}$ and H_2O_2

$$M^{n+} + O_2 \rightarrow M^{(n+1)+} + O_2^{\cdot-} \xrightarrow{H^{+}} HO_2^{\cdot} \quad [3]$$

$$O_2^{\cdot-}/HO_2^{\cdot} \rightarrow H_2O_2 + O_2 \quad [4]$$

Reaction of $O_2^{\cdot-}$ with double bonds of unsaturated fatty acids was proposed as early as 1962 (4), but pulse radiolysis studies have shown that it is $HO_2^{\cdot}$ rather than $O_2^{\cdot-}$ that reacts with unsaturated fatty acids (31,32), and

[1]Based on a paper presented at the Symposium on Metals and Lipid Oxidation, held at the AOCS Annual Meeting in Baltimore, MD, April, 1990.

[2]Mailing address: Department of Food Science, P.O. Box 231, Rutgers University, New Brunswick, NJ 08903.

Abbreviations: ADP, adenosine diphosphate; EDTA, ethylenediaminetetraacetic acid; EPR, electron paramagnetic resonance; NHE, normal hydrogen electrode; NMR, nuclear magnetic resonance; SOD, superoxide dismutase; TBA, thiobarbituric acid.

the reaction is slow ($k = 300 - 1700\ M^{-1}\ sec^{-1}$) (31,33, 34). Reaction of $O_2^{\cdot}$ /$HO_2^{\cdot -}$ with lipid hydroperoxides has been reported (35), but a later study showed that scrupulously demetalled LOOH is not decomposed by $O_2^{\cdot -}$ (36).

More important is the reduction of H_2O_2 to yield hydroxyl radicals, HO$^{\cdot}$ (37), which initiate lipid oxidation by hydrogen abstraction ($k = 8 \times 10^9\ M^{-1}s^{-1}$ for linolenate) (32,38)

$$M^{n+} + H_2O_2 \rightarrow M^{(n+1)+} + HO^{\cdot} + OH^- \quad [5]$$

$$HO^{\cdot} + LH \rightarrow L^{\cdot} + H_2O \quad [6]$$

INDIRECT INITIATION, PROPAGATION, OR CHAIN BRANCHING

Catalysis by some metals (Fe, Cu, Ni) occurs by oxidation (39,40) or reduction (41) of preformed lipid hydroperoxides (LOOH) to form chain-carrying LO$^{\cdot}$ and LOO$^{\cdot}$ radicals. Using iron as an example

$$LOOH + Fe^{3+} \rightarrow LOO^{\cdot} + H^+ + Fe^{2+} \quad [7]$$

$$LOOH + Fe^{2+} \rightarrow LO^{\cdot} + OH^- + Fe^{3+} \quad [8]$$

According to traditional theory, these hydroperoxide decompositions increase the rate of chain re-initiation or propagation because the rates of hydrogen abstraction by LO$^{\cdot}$ and LOO$^{\cdot}$ are much faster than the rates of *ab initio* L$^{\cdot}$ formation (24). Recent evidence, however, has suggested that secondary epoxyallylic radicals from LO$^{\cdot}$ rearrangements may be more likely chain carriers under some conditions (42).

The redox potentials of other metals such as Mn and Co are too low to effect LOOH decomposition in aqueous systems (41), but they may catalyze hydroperoxide decomposition in non-polar media by formation of metal-hydroperoxide complexes (1,40,43).

$$Co^{3+} + LOOH \rightarrow (LOOHCo)^{3+} \rightarrow Co^{2+} + LO_2^{\cdot} + H^+ \quad [9]$$

$$Co^{2+} + LOOH \rightarrow (LOOHCo)^{2+} \rightarrow Co^{3+} + LO^{\cdot} + OH^- \quad [10]$$

Inhibitory effects of metals are also known, usually when metals are present at higher concentrations (10,25, 43–46). The inhibition is thought to result from oxidation and reduction of free radicals by iron and copper (24,37, 47,48) and from metal complexation of free radicals by Co (43,49). Either mechanism results in interruption of the free radical chain and reduction in the overall oxidation rate.

$$\text{(Fe, Cu)} \quad L^{\cdot} + M^{(n+1)+} \rightarrow (L^{\cdot} \ldots M^{(n+1)+}) \text{ (stable)} \quad [11a]$$

$$\text{(Fe, Cu)} \quad L^{\cdot} + M^{(n+1)+} \rightarrow M^{n+} + L^+ \rightarrow \text{products} \quad [11b]$$

$$L^{\cdot} + M^{n+} \rightarrow M^{(n+1)+} + L^- \quad [12]$$

$$\text{(Co, Mn)} \quad R^{\cdot} + MA_n \rightarrow R\text{-}MA \quad [13]$$

where R$^{\cdot}$ may be L$^{\cdot}$, LO$^{\cdot}$, LOO$^{\cdot}$, etc.

These mechanisms have been derived from studies conducted in relatively simple chemical model systems of defined composition with controlled reaction conditions. Biological systems, on the other hand, are more complicated. They have multiple reaction environments in membranes and aqueous phases, and natural materials have complex compositions which are difficult to reproduce and control precisely. Metal catalysis of lipid oxidation in these complex biological systems is not as uncomplicated as classical mechanisms would suggest.

For example, both valence forms of metals have catalytic activity, and the factors affecting the balance or dominance between direct initiation reactions and re-initiation by hydroperoxide decompositions are poorly understood. Also, problems in the interpretation of mechanisms in complex biological systems have arisen when the reaction kinetics or the products did not obviously fit these classical mechanisms. This has been particularly true for toxicological studies which tried to determine whether HO$^{\cdot}$ produced from H_2O_2 in Fenton reactions (37,47) initiate oxidation of membrane lipids.

Clearly, new understandings of metal catalysis of lipid oxidation in biological systems must be sought. Issues needing clarification are, by their nature, complex and interdisciplinary, and solutions will require input from many different fields: metallochemistry, electrochemistry, organic chemistry, physical chemistry, biochemistry, physiology and toxicology, food chemistry. To provide a context and to stimulate renewed consideration of mechanisms along with new research approaches, the following overview of contemporary issues in metal catalysis of lipid oxidation is offered. A summary of these issues is presented in Table 1. While the discussion will focus on iron because it is the dominant redox-active metal in biological systems, most of the issues are relevant also to other redox-active metals.

HYPERVALENT IRON OR IRON-OXYGEN COMPLEXES

One of the major, and perhaps one of the most controversial, contemporary issues in regard to mechanisms of lipid oxidation is whether hypervalent iron (iron valence of +4 to +6, Table 2) or other iron-oxygen complexes form and are catalytically active in biological systems in the absence of a protein or other macromolecular prosthetic group. If they do form, what are the necessary conditions, and how do the kinetics and products of their reactions compare with those produced in classical Fe^{3+}/Fe^{2+} reactions?

Originally proposed by Hochstein *et al.* (50), the principal proponents of this theory applied to biological systems have been proposed by Aust and colleagues (51–55). Based on repeated observations that maximum lipid oxidation occurs when Fe^{2+} and Fe^{3+} are present in a 1:1 ratio, they proposed a mechanism in which the species actively catalyzing lipid oxidation in the presence of H_2O_2 is ferryl iron or mixed metal-O_2 complexes [Fe^{2+}-O_2-Fe^{3+}] rather than HO$^{\cdot}$. Recently, these authors have modified their proposed mechanism, contending that 1:1 ratios of ferric and ferrous iron facilitate redox cycling of the iron. Details of this theory and a review of their work are presented in this issue (56).

Authentic hypervalent iron complexes have long been recognized as active forms of heme proteins and porphyrin

TABLE 1

Summary of Contemporary Issues Which Need to Be Clarified Regarding Metal Catalysis of Lipid Oxidation

1. HYPERVALENT NON-HEME IRON OR IRON-OXYGEN COMPLEXES:
   - Under what conditions do they form in biological systems?
   - Do they catalyze lipid oxidation?
   - What are the characteristic kinetics and lipid products?
2. HEME CATALYSIS MECHANISM(s):
   - Hydroperoxide reduction, oxidation by hypervalent iron, or other mechanisms?
3. COMPARTMENTALIZATION OF REACTIONS AND LIPID PHASE REACTIONS OF METALS:
   - Where does metal catalysis occur in multiphase systems?
   - Are lipid phase reactions of metals significant?
   - Do catalysis mechanisms and oxidation products differ depending on phase?
4. EFFECTS OF METALS ON PRODUCT MIXES:
   - Does metal catalysis influence isomeric hydroperoxide distributions, alkoxyl radical scission reactions, intramolecular rearrangements to epoxides, etc.?
5. FACTORS AFFECTING THE MODE OF METAL CATALYTIC ACTION—direct initiation *vs* chain propagation (reinitiation), mechanism, reaction location, overall course of oxidation:
   - Chelator—partition coefficients, redox potentials, pK_a.
   - Reaction conditions—metal concentrations, pH, presence/absence of water and reducing agents, oxygen tension, type of lipid.
   - Membrane surface charge.

compounds. Hypervalent iron states also have been identified and characterized spectroscopically in numerous enzymes and in iron complexes in organic solvents, but little is known about hypervalent iron in aqueous solutions. Physical chemists have expressed great skepticism that hypervalent iron occurs in non-heme small molecular complexes under physiological conditions on the grounds that hypervalent iron complexes require *macro*molecular complexers or a very high pH for formation and stabilization. Thus, hypervalent iron should not be a significant reactant since in complex biological systems decay of hypervalent states to Fe^{3+} would be essentially instantaneous, eliminating any enhanced catalytic capability.

There have been a few reports based on electron paramagnetic resonance (EPR) (57,58) and kinetic spectroscopic (59) evidence for the formation of hypervalent iron in small molecular complexes. However, the hypervalent iron indeed decayed very rapidly to its ferric form. In other reports, hypervalent iron was thought to be formed in olefin microemulsions, but only at high (10:1) hydroperoxide/iron ratios (60); 1:1 ratios yielded conventional Fenton chemistry.

Bielski (61) studied the stability and reactivity of synthetic Fe^{4+}, Fe^{5+}, and Fe^{6+} complexes in aqueous solutions, and found that all the complexes were strong oxidants at high pH. Fe^{+4} and Fe^{+5} were significantly more reactive than Fe^{+6}, due to substantial free radical character of the Fe–O bonds in the ferryl/perferryl species. Proton sources in solvent or substrate markedly increased decay rates of the hypervalent states.

While Bielski's results suggest that hypervalent iron states, *if* they form in contact with lipids in biological systems, should be particularly potent initiators of lipid oxidation, three critical issues must still be addressed to understand the practical importance of these complexes: i) Under what conditions do these hypervalent states form in small molecules under physiological conditions? What is the source of oxygen, is it dissolved molecular oxygen or hydrogen/hydroperoxides? What pH? What complexing agents? If aprotic solvents stabilize hypervalent states, may the hydrophobic lipid phases of membranes be preferential sites for hypervalent iron formation and activity? ii) Do hypervalent iron complexes actually catalyze lipid oxidation? Under what conditions? What are the rate constants? iii) How do the kinetics, mechanisms, and products differ from normal autoxidation or Fe^{2+}/Fe^{3+} catalyses? Are hypervalent iron processes distinguishable from other oxidations?

HEME CATALYSIS MECHANISM(S)

Early observations that heme compounds were catalytically active in the ferrous form and that no valence change of the iron occurred in the process led Tappel (5,62) to propose a mechanism by which lipid hydroperoxides form activated complexes through a coordinate bond between the ferrous heme and the hydroperoxide function. At the time, no distinction could be made between radical scission of the hydroperoxide,

$$\text{LOOH} + \text{Heme-Fe}^{2+} \rightarrow \text{Heme-Fe}^{2+} + \text{LO}^{\bullet} + {}^{\bullet}\text{OH} \quad [14]$$

and reductive scission followed by secondary oxidation of ions to immediately recycle the ferric to ferrous heme (5).

$$\text{LOOH} + \text{Heme-Fe}^{2+} \rightarrow \text{Hematin-Fe}^{3+} + \text{LO}^{\bullet} + \text{OH}^{-} \quad [15a]$$

$$\text{or Hematin-Fe}^{3+} + \text{LO}^{-} + {}^{\bullet}\text{OH} \quad [15b]$$

$$\text{Hematin-Fe}^{3+} + \text{OH}^{-} \rightarrow \text{Heme-Fe}^{2+} + {}^{\bullet}\text{OH} \quad [16a]$$

$$+ \text{LO}^{-} \rightarrow \text{Heme-Fe}^{2+} + \text{LO}^{\bullet} \quad [16b]$$

Tappel's mechanism is historically important, as it explained most observations for many years. Recent

advances in analytical techniques have enabled others to provide amplifications and mechanistic details to Tappel's theory. Bruice (63) has presented evidence that in aqueous solution radical scission dominates with the alkoxyl radical being released and the ·OH remaining bound to the heme compound, while in organic solvents radical scission occurs followed by secondary electron transfer such that products are equivalent to those which would be produced by reductive O–O bond cleavage. However, not all hemes follow this mechanism, so a diagnostic probe to distinguish which heme compounds decompose hydroperoxides by mechanisms yielding alkoxyl radicals has been developed using 10-hydroperoxy linoleic acid (64,65).

However, reductive scission of hydroperoxides alone does not adequately explain differences between catalytic efficiencies or the specific product mixes of different hemes (26,66). Also, recent EPR studies have shown clearly that ferric as well as ferrous hemes are active catalysts, yielding peroxyl radicals from hydroperoxides (67,68). Inconsistencies in pro-oxidant effects of hemes continue to be reported, probably because multiple mechanisms of heme catalysis exist, even for individual hemes, determined by reaction conditions and components and by the specific heme compounds involved.

Contemporary studies have provided evidence for at least four mechanisms by which heme compounds may catalyze lipid oxidation in addition to the straightforward electron transfers described in Reactions 7 and 8.

One mechanism is the formation of hypervalent iron complexes which oxidize lipids directly. In the discussion about hypervalent iron above, the qualifications "small molecule" or "non-heme" were repeatedly used because it is known clearly that ferryl iron is formed by peroxidase (69) and other heme proteins and is the active oxidizing form of these enzymes (70,71). Ferryl complexes are also formed in catalase (69,72), cytochrome P-450 (73), myoglobin (74,75), hemoglobin (57,58,76), and model porphyrins (63,77–79), although less is known about the catalytic activity of ferryl forms of these proteins.

All of these heme proteins have been shown to catalyze lipid oxidation, and by analogy to the above it seems logical to question whether hypervalent iron may be involved in this activity, formed *via* either heme-oxygen, heme-hydrogen peroxide, or heme-lipid hydroperoxide complexes. The requirement for at least one of these oxygen sources in order for catalysis of lipid oxidation to occur has been noted in tissue (80) and chemical model reaction systems (81). Observations that metmyoglobin catalysis in air was markedly accelerated as pH was increased, especially above pH 7 (81), is consistent with this hypothesis since hypervalent iron complexes are more stable at high pH (61). Hypervalent iron activity may also explain observations that hemoglobin catalyzes oxidation of linoleic acid and ester (82) and phospholipids in liposomes (83) without induction periods, and that haptoglobin inhibits hemoglobin-stimulated lipid oxidation (84). Reduction of hypervalent iron or prevention of its formation may contribute to antioxidant effects of high heme concentration (85) and the reducing agents ascorbic acid and cysteine (85).

A second mode of heme catalysis may involve an indirect mechanism in which HO· attacks lipids to initiate autoxidation chain reactions. The HO· arises from either a) the autoxidation of ferrous heme iron to produce $O_2^{\cdot-}$ and H_2O_2, which is then reduced to HO· by adventitious iron (86,87); or b) heme-catalyzed reduction of H_2O_2 added or produced *in situ* (88).

A third possible mechanism for catalysis of lipid oxidation by hemes is photosensitization, either *via* free radicals or singlet oxygen (89). Ten years ago this concept was proposed on theoretical grounds (26) and recently some experimental verification for Type I (free radical) sensitization has been published (90).

Recent observations suggest that a fourth mode of heme catalysis is also possible in systems containing H_2O_2: HO· attacks hemoglobin (or other heme proteins) and releases iron which then catalyzes lipid oxidation as non-heme iron (91,92).

Of these mechanisms, hypervalent iron states seem to account best for many characteristics of heme catalysis of lipid oxidation documented but incompletely explained in the previous literature. Nevertheless, several issues still require clarification, including which valence states of hemes are involved, whether different hemes catalyze lipid oxidation by different mechanisms, what conditions favor activity of hypervalent iron as opposed to direct reduction of hydroperoxides or any of the other mechanisms which have been proposed, and which molecular regions are involved in the electron transfers, *i.e.* whether the iron atom, porphyrin ring, or apoprotein (93) is involved.

COMPARTMENTALIZATION OF REACTIONS AND LIPID PHASE REACTIONS OF METALS

Apparent inconsistent effects of iron on oxygen radical reactions and lipid oxidation in biological systems have been observed, but this may be expected since cells, tissues, membranes, and organelles, by their nature, lack the precisely controlled conditions and defined composition of laboratory test tube reactions. For example, adenosine diphosphate (ADP), ethylenediaminetetraacetic acid (EDTA), and histidine complexation of iron may have pro- or antioxidant activity or no effect on lipid oxidation depending on the source and preparation of tissues, cells, membranes or purified lipid, the solvents used, the concentrations of metal complexes, the presence or absence of oxygen sources, and how the effects are measured. Because we need to be able to predict and control metal reactions in foods and in living tissue, we have cogent and compelling reasons to understand the molecular bases for these inconsistencies and thus to determine the physical and chemical factors which affect iron activity in complex, multiphase, and often compartmentalized systems.

One critical physical aspect which cannot be ignored is that biological systems are always at least *bi*phasic, inhomogeneous systems, *i.e.* a hydrophilic, protic aqueous phase and a hydrophobic lipid phase which may have both protic and aprotic regions. Because of the bilayer structure of the membrane, initiation of lipid oxidation must necessarily occur in the membrane interior region, where the lipid chains are located. However, in typical experimental designs, metal reagents are added to an external aqueous phase. Reactions occurring in the aqueous phase can initiate lipid oxidation only if reactive intermediates or products diffuse to the surface or into the lipid bilayer of the membrane. Because of their high reactivity, HO· generated in the aqueous phase have little, if any, chance of initiating oxidation of lipids in membranes or in lipid

phases in food products. Water-soluble chelators or free radical interceptors such as mannitol, superoxide dismutase (SOD), and catalase can be effective against reactants in the aqueous phase, but are unlikely to affect oxidations occurring in the hydrophobic regions of lipid bilayers.

This paradox highlights a third important issue regarding metals and lipid oxidation: Where does metal catalysis of lipid oxidation occur in a multiphase system? What reactions of metals occur in lipid phases and how do their mechanisms, kinetics, and products differ from aqueous phase or interface reactions of metals?

Traditional chemistry holds that catalysis in a biphasic system will occur at the phase interface or at the membrane surface. Thus, any chelators or reaction conditions which increase the binding of metals to the membrane, creating "ill-placed" metal (94), should increase the catalytic effectiveness of the metal. It is well-known, for example, that copper binds readily to membrane proteins and mediates site-specific reactions at those locations (22,95,96). Iron also has surface binding sites on proteins (97,98) and binds to the phosphoric acid moieties of phospholipids (99–101). This binding contributes to rapid iron uptake by membranes, and to reduction of lipid hydroperoxides near those sites. Zinc (102–104) and other metals can displace iron from these sites, but whether aqueous phase $HO^{\cdot}$ interceptors and metal chelators have access to and can compete with binding sites on the membrane surface remains to be determined.

Considering that lipid molecules themselves are the final targets and participants in lipid oxidation, surprisingly little attention has been given to the reactions which may occur in the hydrophobic lipid region of the membrane (or lipid phases of foods), catalyzed by metal complexes, H_2O_2, reducing agents, or other reactants which diffuse or solubilize there. This may be partially attributed to a general expectation that metals are not soluble in hydrophobic media. Nevertheless, fatty acid complexation of metals has long been known to occur and is responsible for a major proportion of metal contamination of refined food oils. In recent studies determining lipid partitioning into lipid phases, fatty acids solubilized metals at concentrations of micromolar or higher, depending on the chelating or complexing agent; complexation of metals through the carboxylic acid groups was very likely involved (105). ADP and (des)ferrioxamine were surprisingly potent solubilizers, a characteristic which may partially explain why ADP as a chelator is unusually effective in enhancing lipid oxidation in membranes, and why desferrioxamine is not always protective against oxidative damage in tissues.

Iron complexes were 10-100× less soluble in the aprotic methyl esters of fatty acids, but even 10^{-8} M concentrations of iron were sufficient to drive oxidations detectable within minutes (seconds in some cases) by EPR spin trapping in these pure lipid phases (105).

Why should lipid phase reactions be critical? Reactions of metals occurring in the lipid phase, whether direct initiation, Fenton generation of $HO^{\cdot}$, or decomposition of LOOH, would be inaccessible to water-soluble interceptors. Thus, negative results in experiments using inhibition of lipid oxidation by water-soluble agents to derive mechanisms can be misinterpreted; rather than the causal connection being absent, the causal location may be wrong.

Perhaps an even more important reason is that Fenton and other iron reactions in aprotic solvents such as acetonitrile or lipid esters may not proceed as they would in water or protic organic solvents. Several factors may contribute to these reaction differences. First, the electrochemistry of iron (196) and the reactions of product oxyl radicals ($O_2^{\cdot-}/HO_2^{\cdot}$, $HO^{\cdot}$, $RO^{\cdot}$, and $ROO^{\cdot}$) in aprotic organic solvents differ from their aqueous counterparts. Ferric oxidation of hydroperoxides, which are relatively weak in aqueous solutions, are accelerated in aprotic solvents such as acetonitrile (107,108). Changes in the ligand structure and solvation state of the metal may shift electron transfer from an outer sphere (free radical) to an inner sphere (peroxide complex) process (39), thus altering oxidation mechanisms and products (108). Fe^{2+} has long been known to autoxidize much more rapidly (109), and hypervalent iron states form more readily and are more stable in aprotic solvents. Recent evidence that ferric iron is not easily reduced in aprotic fatty acid methyl esters (Schaich, K.M., unpublished data) is consistent with observed iron behavior in other aprotic organic solvents (110).

These observations may be extrapolated to membranes. Because the acyl chains forming the hydrophobic region of the lipid bilayer should be aprotic while the phosphate regions near the surface should be protic, the mechanisms of metal catalysis and the processes of lipid oxidation in these two regions are very likely to be different.

In research with Fenton and metal reactions in lipid phases, reactions in protic fatty acids have been shown to clearly differ from those in aprotic esters (105). EPR spin trapping studies of Fenton reactions (Fe^{3+}, H_2O_2, and hydroxylamine as a reducing agent) in lipid phases showed rapid Fenton reactions generating $HO^{\cdot}$ which could be trapped in fatty acids, but in fatty acid esters Fenton reactions were slower and $HO^{\cdot}$ were never trapped; instead, complex multiple-species spectra were produced.

Initial EPR spectra in lipid esters showed mixtures of radicals (105). Because Fe^{3+} reduction was inhibited and its oxidations were accelerated in the lipid phases, three oxidation reactions competed to produce the initial radicals: i) oxidation of H_2O_2 to $HO_2^{\cdot}$; ii) direct oxidation of unsaturated lipids to yield lipid peroxyl radicals (oxygen was present); and iii) oxidation of traces of preformed lipid hydroperoxides to peroxyl radicals. At later reaction stages, an unusual spectrum appeared; this was assigned to an epoxyallylic radical species.

Additional evidence that metal reactions in lipid or other non-aqueous aprotic phases do not follow classical aqueous reaction pathways has been provided in new reports showing production of ketones at the alkoxyl radical carbon (111,112) or a variety of epoxide or other rearrangement products rather than scission products when lipid hydroperoxides are reduced by iron complexes (113) or by ultraviolet light (114) in aprotic solvents. Similarly, in a reaction system containing $FeCl_3$, H_2O_2, and olefins in acetonitrile, epoxide and dioxetane products were formed rather than peroxy radicals, hydroxylation or scission products (115). An Fe^{III}-oxene [$Fe^{III}(O)$] species was proposed as the active catalyst in the latter study.

Another possible explanation for differences in oxidation mechanism in different media is offered by observations that linoleic acid and linoleate-containing phospholipids autoxidized neat, in chlorobenzene, or in buffered

vesicular systems yield hydroperoxides with very different *cis,trans* to *trans,trans* ratios (116–118). The *cis,trans/trans,trans* isomer ratios decreased as lipid concentrations increased, as hydrogen donating ability of the solvent decreased, and as intermolecular lipid associations increased. Analogous hydroperoxide patterns have been observed following *in vivo* lipid peroxidation (119). Thus, molecular conformations of hydroperoxides in lipid phases may facilitate isomerization and intramolecular rearrangements over scission reactions. A third factor which may favor intramolecular rearrangement is a reduction in the rate of intermolecular hydrogen abstraction by LOO$^{\bullet}$ due to the viscosity of lipid phases (120).

Additional research will be needed to determine definitively which effects of solvent have the dominant influence on metal catalyses of lipid oxidation: alteration of the electrochemistry of iron complexes, proton transfer mediation, changes in lipid conformations and molecular associations, or still other factors as yet unrecognized.

EFFECTS OF METALS ON PRODUCT MIXES

Numerous studies have documented the classical breakdown of oxidizing lipids into mixtures of hydroperoxides, aldehydes, ketones and other carbonyl compounds, alkanes and carboxylic acids *via* scission reactions of the lipid alkoxyl radicals (121,122, and references therein). Less attention has been given to internal rearrangements of hydroperoxides to epoxides and related product (113, 114,123,124), and very little research has focussed on determining what factors influence scission reactions and whether metal catalysis alters reaction pathways and product distribution. How metals and metal-solvent interactions affect the overall course of lipid oxidation and the scission reactions which produce malonaldehyde and similar reactive aldehydes, and how metals influence the dominance of scission reactions yielding carbonyls *versus* rearrangement reactions yielding epoxides in different environments are specific issues which have received little attention.

Why is this important? Metals affect not only the rate of initiation and total extent of lipid oxidation, but also the degree of chain branching and secondary reaction, and the nature of termination reactions, *i.e.* metals determine which final products are formed.

The thiobarbituric acid (TBA) test is a measure of lipid oxidation commonly used as a measure of the effectiveness of metals in catalyzing lipid oxidation. This test provides very convenient analyses because the products are water-soluble, eliminating the need for tedious lipid extractions. However, the TBA test depends on the production of "expected" scission products, predominantly malonaldehyde, although cyclic peroxides and dihydroperoxides of 18:3 and higher fatty acids are also known to react (125,126). Malonaldehyde is only produced in secondary scissions of fatty acids with three or more double bonds, and it is a relatively minor breakdown product. Media or reactants may alter the oxidation pathways, increasing or even eliminating cyclization reactions and malonaldehyde production.

For example, in the presence of water, metals increase both the breakdown of LOOH products to alkoxyl radicals and α- and β-scissions of alkoxyl radicals to aldehydes, other carbonyl compounds, and alkanes. Indeed, some versions of the TBA test include an iron reagent to accelerate these scission reactions and the subsequent formation of malonaldehyde from a secondary scission reaction.

In contrast, dominant products of metal-catalyzed oxidations in neat lipid phases or in aprotic solvents appear to be rearrangement products rather than scission products (113). As discussed above, whether this results predominantly from different catalytic species (*e.g.*, iron^{III}-oxenes or hypervalent iron) or rather from direct solvent influences on proton transfers (114) and molecular associations or conformations remains to be determined.

Internal rearrangements to epoxides, hydroxyepoxides, and hydroperoxyepoxides are facilitated by close alignment and association of the lipid chains, such as would be found in oriented monolayers in dry foods and in the bilayers of membranes (127,128). Solvent also plays a critical role. As discussed above, reactions of metals in lipid phases or in lipids dissolved in aprotic solvents do not produce classical distributions of lipid scission products. The epoxide and other rearrangement products observed with the cited metal-lipid reactions are consistent with reports that olefin hydroperoxide-metal complexes yield scission products in coordinating solvents but shift increasingly to epoxide production as the hydrogen donating power of the solvent decreases (129) and the epoxides are stabilized (124).

Also, heme catalyses do not yield classical distributions of hydroxy, aldehyde, and alkane products. Multiple reaction mechanisms are recognized for many heme compounds (130) producing keto, epoxyhydroxy, trihydroxy, and other non-scission compounds as dominant products.

The practical implications of these differences are enormous for both food chemistry and toxicology. A few obvious ones can be mentioned. First, given the considerations outlined above, serious questions must be raised regarding the validity of using malonaldehyde production as an indicator of metal catalysis in a lipid phase or in compartmentalized multiphase systems such as cells. Another implication: the secondary carbonyl and alkane products resulting from scission reactions are important sources of flavors and odors, some characteristic and most undesirable, from oxidized lipids (121). If a way could be found to block this pathway, shelf-life could be extended.

Reconsideration of mechanisms by which membrane lipid oxidation is involved in biological damage processes also seems to be warranted. Lipid free radical species (20, 131–138), hydroperoxides (139–141), and carbonyl oxidation products (135,136,142–147) have commonly been blamed for co-oxidation and crosslinking of critical cellular macromolecules (136) such as tocopherols (143,148), proteins, nucleic acids (149–153), and carcinogens (154,155). Nonetheless, many lipid rearrangement products, particularly the hydroperoxyepoxides, also have been found to be cytotoxic and perhaps carcinogenic. Whether the rearrangement products are also capable of crosslinking remains to be determined, but in light of Gardner's identification of methyl linoleate epoxy adducts with cysteine catalyzed by $FeCl_3$ (124,156,157) crosslinking capability would certainly be expected. Since lipid rearrangement products would be expected to form in membrane bilayers, where proteins and nucleic acids are also bound, epoxy-mediated lipid complexation to these critical macromolecules may provide an important mechanism for the cytotoxicity and cancer promoting activity of oxidized lipids.

FACTORS AFFECTING METAL CATALYSIS

In my own studies of metal reactions in lipid phases, oxidation kinetics have proven to be complex and dependent on a number of factors, including the specific metal complex or chelator used, the valence state of the metal, the concentration of the metal, the oxygen tension of the system, the types of lipid (protic or aprotic), and the presence of contaminating preformed hydroperoxides. These are all factors well known to affect the overall kinetics of lipid oxidation, but it is less understood how these and other system variables affect the mechanism and course of metal catalysis.

Solvents, especially water, affect metal catalysis in a variety of ways. As noted above, water and other hydrophilic solvents facilitate LO$^{\bullet}$ scission reactions in solution (158). However, it is known from research of Karel and others (8,9,159) that there are also conditions in which water inhibits LOOH decompositions. Two hypotheses previously advanced to explain these actions are i) hydration of metals, thus inhibiting electron transfers to and from the metals, and ii) hydrogen bonding between water and hydroperoxides, providing stabilization. Recent nuclear magnetic resonance (NMR) studies of water-lipid hydroperoxide-metal complexes and their effects on hydroperoxide decomposition kinetics have corroborated these mechanisms (160).

Chelators and complexing agents are critical determinants of the catalytic mode and effectiveness of metals. Chelators vary in their metal affinities, their charge and solubility in lipids, and thus how they partition between lipid and aqueous phases. They differ in the valence state of iron they stabilize, the metal coordination sites they occupy, and the type of electron transfer reactions they mediate (161). They also vary in the redox potentials of their complexes (Table 3) (162,163), and hence how they poise metals for redox cycling in the presence of cellular reducing agents. These should be obvious considerations, but they are often ignored when interpreting effects of different metal complexes, particularly in multiphase systems. The net effects of chelators may be complex and seemingly contradictory.

For example, EDTA complexation of iron removes "free" or weakly complexed iron from solution. It also lowers the Fe^{3+}/Fe^{2+} redox potential from 0.77 V to 0.12 V *vs* normal hydrogen electrode (NHE). Thus, by changing the localization of iron and by limiting the capability of Fe as an oxidizing agent, EDTA can markedly reduce *ab initio* (LH → L$^{\bullet}$) initiation of lipid oxidation. However, the lower redox potential makes EDTA-iron a better reducing agent, so EDTA-Fe^{2+} chelates reduce lipid hydroperoxides faster than uncomplexed iron. In the presence of reducing agents to recycle the iron, EDTA complexation may even result in a marked acceleration of chain propagation and branching reactions (LOOH → LO$^{\bullet}$ + $^{\bullet}$OH, and LO$^{\bullet}$ + L'H → L$^{\bullet}$ + LOH). The net effect of EDTA results from the balance between these actions in individual systems, and has led to apparently contradictory reports of EDTA effects on lipid oxidation (164).

Several other chelators deserve attention. Picolinic acid, a metabolic product of tryptophan, is a strong metal chelator and is potentially very important as a physiological chelator. Picolinates have received attention recently since the iron chelates are very effective at producing HO$^{\bullet}$, at least at low H_2O_2/chelate ratios (1:1) (165). At higher hydroperoxide ratios, a mechanism more like that with hypervalent iron dominates (111,112). With such behavior, it is imperative that we understand the redox chemistry of this molecule and its chelates. Reaction characteristics of picolinate complexes have been described by Sawyer (112).

ADP, histidine, bipyridyl, orthophenanthroline, and nitriloacetic acid are all chelators which have shown multiple, sometimes contradictory, effects on lipid oxidation in various systems. The first two are physiological chelators and the latter three are chelators known to be toxic to humans. Lipophilicity, singlet oxygen scavenging, hypervalent iron facilitation have been proposed as possible explanations for the actions of these chelators, but the mechanisms of their actions remain incompletely understood.

A characteristic of chelators which has received little general recognition is that HO$^{\bullet}$ and perhaps also lipid oxyl radicals, formed in the reaction cage of peroxide reduction, react with some chelators to form chelator free radicals which are themselves reactive. EDTA, for example, forms four different free radicals, most of which are strongly reducing and hence may be important determinants in the course of catalyzed oxidations (166). TRIS and phosphate (167) in buffers and desferrioxamine (168, 169; Schaich, K.M., manuscript in preparation) are known to form reactive radicals when attacked by HO$^{\bullet}$. These complexing agents are very likely to be both targets and initiators for lipid oxyl radicals.

Still another factor which may potentially have great importance for lipid oxidation in living systems is charge on chelators and on membrane surfaces. Surface charges

affect molecular access and binding as well as the dynamics of electron transfer reactions through lipid phases, and thus may be particularly important for porphyrin catalyses (170). Also, the electrostatic environment (the total effective charge) surrounding the binding site of a metal can markedly affect the redox potential and other thermodynamic properties of the metal (171). The net effect often results from a complex competition between several individual effects and thus may be difficult to predict. Nevertheless, these various effects of charge need to be understood and considered when interpreting mechanisms of metal action in complex systems.

Some very elegant studies have shown distinctly different behaviors in membranes or micelles incubated with Fenton reagents, depending on the surface charge of the vesicles (172–176). Negatively charged vesicles repelled metals, so direct initiation of lipids could not be effected. However, mutual repulsions of charged groups at the surface created more open molecular packing, so small molecules from the aqueous phase were able to penetrate the lipid layers and mediate reactions there. For example, $HO^{\cdot}$ generated near the surface was able to penetrate into the hydrophobic regions of the vesicles and initiate oxidation of lipids there, and this oxidation could be effectively inhibited by α-tocopherol and by water-soluble $HO^{\cdot}$ scavengers. In contrast, vesicles with negative surface charges bound metals, which reacted with traces of lipid hydroperoxides in the vesicles to initiate new oxidation chains. Water-soluble radical scavengers had little or no effect on this LOOH reaction, and tocopherol actually accelerated lipid oxidation in these vesicles because it recycled the Fe^{3+}, thus maintaining LOOH reductions. Effects of chelators in these systems could be explained by the changes in metal distribution and binding attributable to chelator charges (177).

SUMMARY

The five contemporary issues presented in this paper show clearly that metal catalyses of lipid oxidation in complex, often multiphasic or compartmentalized reaction systems are not straightforward. They often do not fit the classical electron transfer mechanisms for metal catalysis which have been accepted for decades. New understandings must be developed to more accurately explain the kinetics, mechanisms, and products of metal-catalyzed lipid oxidation in complex environments. Definitive evidence for intermediates in proposed mechanisms must be sought, and consideration must be given to all physical and chemical properties of reactants and reaction environments when interpreting mechanism from kinetic and product data. New integrative approaches and expertise from many different scientific disciplines will be necessary to elucidate the many factors affecting and controlling metal reactions in complex, multiphase systems.

ACKNOWLEDGMENTS

Support for the author's unpublished work cited and for the preparation of this manuscript was provided by the New Jersey Agricultural Experiment Station Project No. 10116.

Redox Cycling of Iron and Lipid Peroxidation[1]

Giorgio Minotti[a] and **Steven D. Aust**[b,*]
[a]Institute of General Pathology, Catholic University School of Medicine, 00168 Rome, Italy and [b]Biotechnology Center, Utah State University, Logan, Utah 84322-4700

Mechanisms of iron-catalyzed lipid peroxidation depend on the presence or absence of preformed lipid hydroperoxides (LOOH). Preformed LOOH are decomposed by Fe(II) to highly reactive lipid alkoxyl radicals, which in turn promote the formation of new LOOH. However, in the absence of LOOH, both Fe^{2+} and Fe^{3+} must be available to initiate lipid peroxidation, with optimum activity occurring as the Fe^{2+}/Fe^{3+} ratio approaches unity. The simultaneous availability of Fe^{2+} and Fe^{3+} can be achieved by oxidizing some Fe^{2+} with hydrogen peroxide or with chelators that favor autoxidation of Fe^{2+} by molecular oxygen. Alternatively, one can use Fe^{3+} and reductants like superoxide, ascorbate or thiols. In either case excess Fe^{2+} oxidation or Fe^{3+} reduction will inhibit lipid peroxidation by converting all the iron to the Fe^{3+} or Fe^{2+} form, respectively. Superoxide dismutase and catalase can affect lipid peroxidation by affecting iron reduction/oxidation and the formation of a (1:1) Fe^{2+}/Fe^{3+} ratio. Hydroxyl radical scavengers can also increase or decrease lipid peroxidation by affecting the redox cycling of iron.
Lipids 27, 219–226 (1992).

Lipid peroxidation is the process in which molecular oxygen is incorporated into unsaturated lipids (LH) to form lipid hydroperoxides (LOOH). However, the direct reaction of lipids with oxygen is spin-forbidden because the ground state of lipids is of singlet multiplicity whereas that of oxygen is of triplet multiplicity (1). Lipid peroxidation must therefore occur *via* reactions that by-pass the spin barrier between lipids and oxygen. These reactions are promoted by some type of "initiator" (I$^\bullet$) that overcomes the dissociation energy of an allylic bond and thus causes hydrogen abstraction and formation of a lipid alkyl radical (L$^\bullet$). Lipid alkyl radicals can rapidly add oxygen to form lipid peroxyl radicals (LOO$^\bullet$) which eventually liberate LOOH *via* hydrogen abstraction from a neighboring allylic bond (2).

$$I^\bullet + LH \rightarrow IH + L^\bullet \quad \text{initiation} \quad [1]$$

$$L^\bullet + O_2 \rightarrow LOO^\bullet \quad O_2 \text{ addition} \quad [2]$$

$$LOO^\bullet + LH \rightarrow LOOH + L^\bullet \quad \text{propagation} \quad [3]$$

Externally generated oxidants are required to initiate lipid peroxidation, but once started, the reaction will proceed *via* propagation to form new LOOH. Transition metals can substantially enhance the propagation of lipid peroxidation. For example, Fe^{2+} will reductively cleave LOOH to highly reactive alkoxyl (LO$^\bullet$) radicals, which in turn abstract hydrogen from lipids to form new lipid alkyl radicals (3). This reaction is referred to as LOOH-dependent lipid peroxidation (3).

$$Fe^{2+} + LOOH \rightarrow Fe^{3+} + LO^\bullet + OH^- \quad [4]$$

$$LO^\bullet + LH \rightarrow LOH + L^\bullet \quad [5]$$

The realization that numerous diseases may involve lipid peroxidation as a common pathogenic mechanism (4) has prompted interest in identification of possible initiators (see Eq. 1). Both iron and partially reduced species of dioxygen have been implicated in the formation of initiators, although with very different interpretations concerning the mechanism of their involvement.

One very popular theory dictates that lipid peroxidation is initiated by $^\bullet$OH (5–8), the most potent oxidant that can be formed from oxygen ($E^\circ = 1.6$ V) (9). This is thought to occur *via* the Haber-Weiss reaction, that consists of $O_2^{-\bullet}$ dependent Fe^{3+} reduction and subsequent Fe^{2+}-catalyzed H_2O_2 cleavage to $^\bullet$OH (10).

$$O_2^{-\bullet} + Fe^{3+} \rightarrow O_2 + Fe^{2+} \quad [6]$$

$$2O_2^{-\bullet} + 2H^+ \rightarrow 2H_2O_2 + O_2 \quad [7]$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + {}^\bullet OH \quad [8]$$

Ferrous iron-promoted breakdown of H_2O_2 (Eq. 8) is best known as the Fenton reaction, and the Haber-Weiss reaction may alternatively be referred to as $O_2^{-\bullet}$ driven Fenton reaction, with this terminology illustrating that $O_2^{-\bullet}$ is required for the formation of both Fe^{2+} (*via* reduction of Fe^{3+}, Eq. 6) and H_2O_2 (*via* dismutation, Eq. 8) (10). According to this interpretation, the inhibition of lipid peroxidation by superoxide dismutase (SOD), catalase or hydroxyl radical ($^\bullet$OH) scavengers is viewed as supporting evidence of initiation of lipid peroxidation *via* Fenton chemistry and the $^\bullet$OH (6,7) As an alternate proposal for the initiation of lipid peroxidation however, some investigators have proposed that iron oxygen complexes can substitute for $^\bullet$OH in the initiation of lipid peroxidation, provided that both Fe^{2+} and Fe^{3+} are involved in the formation of this complex (11–20). This alternate interpretation implies that $O_2^{-\bullet}$ and H_2O_2 are required not to form $^\bullet$OH but rather to promote the Fe^{3+} reduction or Fe^{2+} oxidation from which the appropriate Fe^{2+}/Fe^{3+} initiating species originates. Consistent with this proposal, the effects of SOD, catalase and $^\bullet$OH scavengers have been found to vary depending on their effects on the iron valence state (15,20). Furthermore, $O_2^{-\bullet}$ and H_2O_2

independent mechanisms for the redox cycling of iron and the initiation of lipid peroxidation have been described (18,20).

In this article we describe and discuss some mechanisms for the redox cycling of iron and their relevance to the initiation of lipid peroxidation by either $^{\bullet}OH$ or equally effective iron/oxygen complexes.

FERROUS IRON OXIDATION AND LIPID PEROXIDATION

Lipid peroxidation can be studied in incubations containing unchelated Fe^{2+} and either commercially available fatty acids or microsomal phospholipid liposomes. Ferrous iron *per se* may promote or not promote lipid peroxidation, depending on whether lipids contain preformed LOOH. In the presence of preformed LOOH, Fe^{2+} will catalyze what we have previously referred to as LOOH-dependent lipid peroxidation (3), a reaction resembling propagation rather than initiation mechanisms. In the absence of preformed LOOH, or when the concentration of LOOH is so low that they may not react with Fe^{2+} to an appreciable rate, H_2O_2 can be used to promote Fenton reaction and $^{\bullet}OH$ formation. We observed that in model systems including $FeCl_2$ and microsomal phospholipid liposomes with very little, if any, LOOH contamination, the inclusion of H_2O_2 promoted lipid peroxidation, as evidenced by formation of malondialdehyde (MDA) (Table 1). The reaction was inhibited by catalase, but the addition of $^{\bullet}OH$ scavengers either inhibited or stimulated MDA formation. These effects were not due to the ability of mannitol and benzoate to scavenge $^{\bullet}OH$, but could be explained by the ability of these compounds to interfere with Fe^{2+} oxidation. Thus, lipid peroxidation was inhibited by mannitol, which minimizes Fe^{3+} formation, whereas lipid peroxidation was stimulated by benzoate, which facilitates Fe^{3+} formation (see also Table 1). Collectively, these observations have led us to question the involvement of $^{\bullet}OH$ in lipid peroxidation and the effects of $^{\bullet}OH$ scavengers therein. We have proposed that: (i) Fe^{2+} dependent peroxidation of LOOH-free lipids is mediated by an oxidant that also requires Fe^{3+}, (ii) the role of H_2O_2 is that of oxidizing Fe^{2+} to Fe^{3+} rather than of serving as precursor of $^{\bullet}OH$, and (iii) chemicals referred to as $^{\bullet}OH$ scavengers must be used with great caution, since they can interfere with lipid peroxidation by modulating the rate of Fe^{2+} oxidation.

TABLE 1

Effects of Catalase, $^{\bullet}OH$ Scavengers and Detergents on Fe^{2+} and H_2O_2 Dependent Lipid Peroxidation[a,b]

System	Fe^{2+} oxidation (%)	nmol MDA/mL/min
Fe^{2+}	0	0.0
Fe^{2+}, H_2O_2	50	3.8
+ catalase	0	0.0
+ mannitol	30	0.7
+ benzoate	85	5.5
Fe^{2+}, H_2O_2, Lubrol-PX	53	6.1
+ catalase	0	0.0
+ mannitol	39	2.8
− benzoate	92	8.2

[a] Incubations contained microsomal phospholipid liposomes (1 μmol lipid phosphate/mL) ± 0.1% Lubrol-PX, in 50 mM NaCl, pH 7.0, 37°C. Where indicated, additions were made as follows: $FeCl_2$, 0.2 mM; H_2O_2, 0.1 mM; catalase, 400 U/mL; mannitol, 25 mM; benzoate, 25 mM. Ferrous iron oxidation was monitored as disappearance of 1,10-phenanthroline chelatable Fe^{2+} in lipid-free incubations and values are those determined at 30 sec. NaCl was chromatographed on Chelex-100 to remove contaminating metals, and catalase was chromatographed on Sephadex G-25 to remove the antioxidant thymol and other contaminants. MDA formation was determined by thiobarbituric acid test within the linear phase of the reactions (4–6 min.).

[b] Data taken in part from Minotti and Aust (15).

In principle, our skepticism concerning the participation of $^{\bullet}OH$ in lipid peroxidation agrees with the criticism that $^{\bullet}OH$ is a short-lived radical with diffusion-limited reactivity (21). As such, $^{\bullet}OH$ would not migrate from the aqueous phase of incubations to the hydrophobic membrane compartments where the allylic bonds of fatty acids are buried. For example, any $^{\bullet}OH$ generated in the aqueous bulk of incubations can react with residual Fe^{2+} and H_2O_2 (Eqs. 9–10) or can undergo bimolecular recombination to water (Eq. 11), thus self-precluding from reaction with lipids (8,9).

$$^{\bullet}OH + Fe^{2+} + H^+ \rightarrow Fe^{3+} + H_2O \quad [9]$$

$$^{\bullet}OH + H_2O_2{}^{\bullet} \rightarrow HO_2{}^{\bullet} + H_2O \quad [10]$$

$$^{\bullet}OH + {}^{\bullet}OH \rightarrow H_2O_2 \quad [11]$$

However, Schaich and Borg (8,22) have found that critical amounts of iron and H_2O_2 can partition from water into lipids. They have therefore proposed that Fenton reaction may take place in the lipids, so that "site specific" reaction of $^{\bullet}OH$ with juxtaposed allylic bonds would prevail over nonproductive side reactions in the aqueous phase. Viewed in this context, stimulation or inhibition of lipid peroxidation by benzoate or mannitol might simply reflect spurious and diverging effects of these compounds on $^{\bullet}OH$-dependent reactions that occur in the aqueous phase and either "consume" Fe^{2+} and H_2O_2 (*cf.* Eqs. 9–10) or evolve H_2O_2 (*cf.* Eq. 11). Mannitol and benzoate would affect lipid peroxidation by affecting the concentration of Fe^{2+} and H_2O_2 that migrate from water to lipids and promote the intramembranous formation of $^{\bullet}OH$.

In order to validate or disprove this hypothesis, we have studied Fe^{2+} and H_2O_2-dependent peroxidation of phospholipid liposomes dispersed in nonionic detergent Lubrol-PX. In this system, the detergent served to modify lipid configuration and facilitated the partitioning of both iron and $^{\bullet}OH$ scavengers from water to lipids (6,23). This would facilitate the formation of $^{\bullet}OH$ in closest proximity of the allylic bond, thus minimizing reactions of $^{\bullet}OH$ in the aqueous phase and nonspecific interferences of $^{\bullet}OH$ traps therein. As shown in Table 1, Lubrol-PX caused a substantial increase of lipid peroxidation, although it did not modify the extent of Fe^{2+} oxidation. This indicates that Lubrol-PX stimulates lipid peroxidation mainly by increasing the accessibility of iron to lipids. However, the effects of catalase, mannitol and benzoate on Fe^{2+} oxidation and formation of MDA were the same as observed in incubations lacking the detergent (see also Table 1). Therefore, we must reiterate the earlier contention that the initiation of lipid peroxidation by Fe^{2+} is mediated by

TABLE 2

Effect of Preincubating Fe^{2+} with H_2O_2 on Fe^{2+} Oxidation and Lipid Peroxidation[a,b]

Preincubation time (sec)	Fe^{2+} oxidation (%)	nmol MDA/mL/min
0	0	0.0
15	39	3.9
30	50	4.3
60	68	2.7
120	88	0.9
240	100	0.0

[a] Hydrogen peroxide (0.1 mM) and $FeCl_2$ (0.2 mM) were preincubated in 50 mM NaCl, pH 7.0, 37°C, for the time required to achieve the indicated extents of Fe^{2+} oxidation, measured as described in legend to Table 1. At the end of preincubation, catalase (400 U/mL) was included to scavenge any remaining H_2O_2, and microsomal phospholipid liposomes (1 μmol lipid phosphate/mL) were included to study lipid peroxidation.

[b] Data from Minotti and Aust (15).

oxidants that provide Fe^{3+}. Thus, in this system H_2O_2 must be available to ensure Fe^{2+} oxidation, whereas mannitol and benzoate will modulate lipid peroxidation by decreasing or increasing Fe^{3+} formation, irrespective of their ability to intercept $^{\bullet}OH$ in either aqueous or lipid environments.

To quantitate how much Fe^{3+} is required for the initiation of lipid peroxidation using Fe^{2+}, we studied liposome incubations containing various amounts of Fe^{2+} and Fe^{3+} generated by reacting Fe^{2+} with H_2O_2 for increasing periods of time. As shown in Table 2, the rate of lipid peroxidation was highest when approximately 50% of Fe^{2+} had been oxidized to Fe^{3+}. Lipid peroxidation did not occur when all of the iron remained in the reduced form nor when H_2O_2 had oxidized all the Fe^{2+} to Fe^{3+}. These results suggested to us that only a fraction of Fe^{2+} must be converted to Fe^{3+}, with optimum activity occurring as the Fe^{2+}/Fe^{3+} ratio approaches unity.

FERROUS IRON AUTOXIDATION AND LIPID PEROXIDATION

The autoxidation of Fe^{2+} may represent an alternate means to generate Fe^{3+} and thus initiate lipid peroxidation. Iron autoxidation consists of direct electron transfer from $Fe^{2+}+$ to molecular oxygen, leading to formation of $O_2^{-\bullet}$ and Fe^{3+} (Eq. 12). Alternatively, and perhaps more likely (1), two Fe^{2+} can autoxidize at the expense of one molecule of oxygen, thus causing the formation of H_2O_2 and two Fe^{3+} (Eq. 13).

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^{-\bullet} \quad [12]$$

$$2Fe^{2+} + O_2 + 2H^+ \rightarrow 2Fe^{3+} + H_2O_2 \quad [13]$$

In order for iron to autoxidize, the reduction potential of the Fe^{2+}/Fe^{3+} couple must be lower than that of the $O_2^{-\bullet}/O_2$ couple (−0.33 V) (24). It is generally assumed that the redox potential of Fe^{2+}/Fe^{3+} couple is −0.77 V (25) and that chelators with oxygen donor atoms and greater affinity for Fe^{3+} lower this value (26). However, ^{-}OH ligation of the iron may *per se* lower the redox potential of Fe^{2+} by about 0.66 V, thus making the autoxidation of "free" Fe^{2+} theoretically feasible (1). However, even in such a case, chelators will dictate the rate of iron autoxidation. For example, unchelated Fe^{2+} and ethylenediaminetetraacetic acid (EDTA) chelated Fe^{2+} have a similar redox potential (−0.11 V) (1), yet $FeSO_4$ or $FeCl_2$ will autoxidize very slowly whereas EDTA/Fe^{2+} will autoxidize very rapidly, provided that these reactions are studied at neutral pH and in an inert solution like NaCl (27).

It is a frequent misconception that unchelated Fe^{2+} autoxidizes rapidly, but this contention does not take into account that several laboratory buffers chelate iron and modify its redox chemistry, ultimately favoring Fe^{2+} autoxidation. Phosphate buffers are perhaps the most effective in causing Fe^{2+} autoxidation (1), and this may explain some conflicting reports in the literature. For example, we have already mentioned that unchelated Fe^{2+} cannot peroxidize LOOH-free liposomes incubated in NaCl, but others have shown that Fe^{2+} may quite effectively promote the peroxidation of liposomes incubated in phosphate buffers (28). Irrespective of different LOOH contaminations of liposomes prepared in different laboratories, it is quite possible that lipid peroxidation in phosphate-buffered incubations is mediated by Fe^{2+} autoxidation and formation of the Fe^{3+} also required for initiation rather than by decomposition of LOOH by Fe^{2+} alone.

There are some basic aspects of ligand-affected iron autoxidation that must be kept in mind for rigorous interpretation of lipid peroxidation experiments. First of all, iron autoxidation increases with the chelator/Fe^{2+} ratio, with the extent of autoxidation strictly depending on the chelator being used. For example, EDTA/Fe^{2+} autoxidizes much more rapidly than citrate/Fe^{2+} and the autoxidation of approximately 50–70% of the iron will therefore occur at very different chelator/Fe^{2+} ratios (1:1 for EDTA/Fe^{2+} *vs* 20:1 for citrate/Fe^{2+}) (16,27). Second, in the presence of ligands Fe^{2+} autoxidation may not be significantly inhibited by catalase (16,20,27). Direct consequences of these mechanisms of iron autoxidation on the initiation of lipid peroxidation are exemplified in Table 3. The data indicate that both citrate/Fe^{2+} and

TABLE 3

The Effects of Chelators on Iron oxidation and Lipid Peroxidation[a,b]

Chelate	Fe^{2+} oxidation (%)		nmol MDA/mL/min	
	− catalase	+ catalase	− catalase	+ catalase
EDTA/Fe^{2+}				
(1:1)	75	63	1.4	1.3
(20:1)	100	100	0.0	0.0
Citrate/Fe^{2+}				
(1:1)	19	16	0.3	0.4
(20:1)	63	48	1.0	1.2

[a] Incubations contained microsomal phospholipid liposomes (1 μmol lipid phosphate/mL) in 50 mM NaCl, pH 7.0, 37°C. Reactions were started by addition of chelates at different chelator/$FeCl_2$ ratios. The concentration of Fe^{2+} was 200 μM. Where indicated, catalase (400 U/mL) was included. Iron oxidation was measured as described in the legend to Table 1 and values are those determined at 30 sec. MDA formation is expressed as initial rates.

[b] Data from Minotti and Aust (16,27).

EDTA/Fe^{2+} catalyzed lipid peroxidation, yet the EDTA/Fe^{2+} ratio had to be 1:1 and the citrate/Fe^{2+} ratio had to be 20:1. This is because lipid peroxidation occurred when only a critical fraction of Fe^{2+} was converted to Fe^{3+}. Very little, if any, lipid peroxidation occurred with either 20:1 EDTA/Fe^{2+} or 1:1 citrate/Fe^{2+} ratios, which caused too extensive or too moderate autoxidation, respectively, and thus shifted the Fe^{2+}/Fe^{3+} ratios toward values that were not permissive to lipid peroxidation (see also Table 3). By contrast, EDTA and citrate/Fe^{2+} dependent lipid peroxidation were largely insensitive to the addition of catalase, as were the autoxidation rates of the two chelates (Table 3). This underscored a substantial difference from systems in which H_2O_2 dependent and hence catalase-inhibitable oxidation of unchelated Fe^{2+} was mandatory to form the necessary Fe^{3+} (*cf.* Table 1).

The observation that catalase cannot affect iron autoxidation must be examined from different viewpoints. One possibility might be that the vast majority of Fe^{3+} forms *via* Eqs. 12–13, with very minor contribution by subsequent reactions of residual Fe^{2+} and the H_2O_2 formed by oxygen reduction. Another possibility might be that H_2O_2 does participate in Fe^{3+} formation yet the access of catalase to the site of reaction between Fe^{2+} and H_2O_2 is made sterically unfavorable by some type of "cage effect" (29) of the chelator being used.

Although speculative in nature, this latter possibility should not be neglected, because we have found that exogenously added H_2O_2 can react with citrate/Fe^{2+} and that simultaneous addition of catalase prevents this reaction (16). Therefore, one may not rule out that ligand-affected Fe^{2+} autoxidation would be paralleled by H_2O_2 dependent Fe^{2+} oxidation (see Table 3). Irrespective of any further speculation on the difference between exogenously added or endogenously formed H_2O_2 for reaction with chelated iron, it is noteworthy that the addition of H_2O_2 can either stimulate or inhibit citrate/Fe^{2+} dependent lipid peroxidation, depending on the citrate/Fe^{2+} ratio. With a low citrate/Fe^{2+} ratio and very moderate Fe^{2+} autoxidation, the addition of H_2O_2 was found to expedite Fe^{3+} formation and approach Fe^{2+}/Fe^{3+} ratios that favored lipid peroxidation (see Table 4). With a high citrate/Fe^{2+} ratio and more extensive Fe^{2+} autoxidation, the addition of H_2O_2 caused the formation of too much Fe^{3+}, thereby shifting the Fe^{2+}/Fe^{3+} ratio toward values that were not permissive to lipid peroxidation (Table 4). In either case, the simultaneous addition of catalase prevented the reaction of H_2O_2 with citrate/Fe^{2+}, changed the Fe^{2+}/Fe^{3+} ratio, and either stimulated or inhibited lipid peroxidation. These results confirmed the role of H_2O_2 in forming Fe^{3+} from Fe^{2+}, with ultimate effects on lipid peroxidation depending on the ratio of Fe^{2+}/Fe^{3+}.

Some investigators have noted that unchelated Fe^{2+} can very rapidly promote lipid peroxidation of "intact" microsomes, irrespective of the presence or absence of an oxidant like H_2O_2 or chelators favoring the autoxidation of Fe^{2+} (28). The occurrence of lipid peroxidation in incubations containing microsomes and Fe^{2+} but neither H_2O_2 or chelators has been taken as evidence against the requirement for both Fe^{2+} and Fe^{3+}, which was first observed in liposomal systems. In this respect, Table 5 shows that all of the exogenously added $FeSO_4$ was recovered from incubations containing liposomes but not from incubations containing microsomes from which these same liposomes have been prepared. Microsome-induced ferrous iron disappearance was inhibited by anaerobiosis but not by catalase, as was the autoxidation of EDTA/Fe^{2+} or citrate/Fe^{2+} (*cf.* Table 3 and Table 5). It is difficult to propose that Fe^{2+} would react with preformed LOOH of "intact" microsomes but not of their extracted lipids. We would rather propose that microsomes, but not liposomes, favor reaction of Fe^{2+} with oxygen and formation of the Fe^{3+} required for initiation of lipid peroxidation (see Table 5). Studies are in progress to identify the nonlipid microsome components that cause iron oxidation. Irrespective of the precise nature of these components, however, it is imperative to recognize microsome-induced Fe^{2+} oxidation as an additional mechanism for Fe^{3+}

TABLE 4

Effects of H_2O_2 on Citrate/Fe^{2+} Dependent Lipid Peroxidation[a,b]

Citrate/Fe^{2+} ratio	System	nmol MDA/mL/min	% Change
1:1	Complete	0.3	
	+ H_2O_2	1.3	+ 333
	+H_2O_2 + catalase	0.4	+33
20:1	Complete	1.4	
	+ H_2O_2	0.3	−79
	+H_2O + catalase	1.3	−7

[a] Complete systems contained citrate (at the indicated citrate/Fe^{2+} ratios) and microsomal phospholipid liposomes (1 μmol lipid phosphate/mL) in 50 mL NaCl, pH 7.0, 37°C. Where indicated, 10 μM H_2O_2 and catalase (400 U/mL) were included in the reaction mixtures. Fe^{2+} concentration was 200 μM. Values of MDA formation are given as initial rates.

[b] Data from Minotti and Aust (16).

TABLE 5

Iron Oxidation and Lipid Peroxidation: Comparison of Microsomal *vs* Liposomal Systems[a]

System	Fe^{2+} oxidation (%)	nmoles MDA/mL/min
Fe^{2+} + liposomes	4	0.0
Fe^{2+} + microsomes	48	1.2
Fe^{2+}, microsomes, catalase	46	1.2
Fe^{2+} + microsomes (anaerobic)	3	0.1

[a] Incubations contained $FeSO_4$ (60 μM) and either microsomes (0.6 mg protein/mL) or microsomal phospholipid liposomes (0.6 μmol lipid phosphate/mL) in 50 mM NaCl, pH 7.0, 37°C. In experiments with microsomes, iron oxidation was measured at 5 min as disappearance of bathophenanthroline chelatable Fe^{2+} in 105,000 × *g* supernatants of incubations, as described (20). In experiments with liposomes, aliquots of incubations were mixed with bathophenanthroline and formation of bathophenanthroline/Fe^{2+} complex was determined spectrophotometrically upon addition of Tween 80 to eliminate turbidity, as described in (17). Where indicated, incubations were made anaerobic by means of argon plus glucose (5 mM) and glucose oxidase (10 U/mL); catalase was also included to scavenge H_2O_2 produced by glucose oxidase reaction. Microsomes were calcium-aggregated and chromatographed on Sepharose CL-2B to remove contaminants like SOD, catalase and ferritin (see also ref. 20). Values of MDA formation are given as initial rates.

formation and lipid peroxidation. This will aid the understanding and interpretation of results obtained by different investigators under various experimental conditions.

FERRIC IRON REDUCTION AND LIPID PEROXIDATION

Lipid peroxidation can also be studied in incubations containing ferric iron and reductants. One very popular system of lipid peroxidation relies on xanthine oxidase and adenosine diphosphate (ADP)/Fe^{3+} (30). The xanthine oxidase reaction generates $O_2^{-\bullet}$ as a reductant for Fe^{3+}. However, the xanthine oxidase reaction also generates H_2O_2, either *via* $O_2^{-\bullet}$ dismutation or *via* the direct two-electron reduction of molecular oxygen (31). Therefore, xanthine oxidase dependent generation of an iron reductant is accompanied by the generation of an iron oxidant. Keeping in mind that lipid peroxidation requires both Fe^{2+} and Fe^{3+}, one can easily anticipate that xanthine oxidase and ADP/Fe^{3+} dependent lipid peroxidation will be inhibited by SOD, which prevents Fe^{3+} reduction, and will be enhanced by catalase, which prevents Fe^{2+} oxidation back to Fe^{3+} (Table 6). We have determined that xanthine oxidase dependent generation of $O_2^{-\bullet}$ at a rate of approximately 50 μM/min will reduce 100 μM ADP/Fe^{3+} at a rate of 6 or 22 μM/min, depending on whether catalase is omitted or included to scavenge H_2O_2, respectively (32). This quantitation confirms that the inclusion of xanthine oxidase with Fe^{3+} rapidly makes both Fe^{3+} and Fe^{2+} available to lipids, especially when catalase is included to prevent Fe^{2+} reoxidation. The relatively high stoichiometry of $O_2^{-\bullet}$ generation *vs* Fe^{2+} formation (~5:1) that persists even in the presence of catalase indicates that some Fe^{2+} invariably oxidizes to Fe^{3+}. It is possible that ADP/Fe^{3+} reduction results in the formation of an ADP/Fe^{2+} complex, which in turn autoxidizes in a catalase-insensitive manner. Nonetheless, it should also be noted that ADP/Fe^{2+} autoxidizes quite moderately as compared to other chelates, *e.g.*, citrate/Fe^{2+} or EDTA/Fe^{2+} (*cf.* refs. 16,18,27). Therefore ADP/Fe^{2+} autoxidation may not preclude formation of an appropriate Fe^{2+}/Fe^{3+} ratio. Another possibility is that $O_2^{-\bullet}$ may also serve as an oxidant for Fe^{2+}, thereby maintaining iron within a continuous $Fe^{3+} \rightarrow Fe^{2+} \rightarrow Fe^{3+}$ cycle (1,32).

Thomas and Aust (33) and Saito *et al.* (34) have described ferritin- and transferrin-dependent lipid peroxidation systems in which xanthine oxidase is required to form $O_2^{-\bullet}$ and promote the reductive release of iron from these proteins. As a general feature, rates of iron release are less than one-tenth or one-fifth of rates of ADP/Fe^{3+} reduction (*cf.* refs. 32–34). Therefore, catalase must be included to prevent H_2O_2 from causing the complete oxidation of the released Fe^{2+} and inhibiting the formation of a suitable Fe^{2+}/Fe^{3+} ratio. The Fe^{3+} required to combine with Fe^{2+} and initiate lipid peroxidation will form *via* catalase-insensitive autoxidation of the released Fe^{2+}, which is favored by ADP included to facilitate iron release, perhaps *via* disruption of the ternary complex of iron-binding proteins (34), and also to chelate the released iron (33). However, excess ADP will cause the autoxidation of too much Fe^{2+}, thereby shifting the Fe^{2+}/Fe^{3+} ratio toward values that are not permissive to lipid peroxidation. As a result of the equilibrium between Fe^{2+} release and Fe^{2+} autoxidation, Saito *et al.* (34) have shown that xanthine oxidase and transferrin dependent lipid peroxidation is enhanced by low concentrations of ADP but inhibited by high concentrations of this same chelator, irrespective of the presence or absence of catalase to remove H_2O_2 (34).

It has been suggested that $O_2^{-\bullet}$ dependent Fe^{3+} reduction and lipid peroxidation can also be achieved by replacing xanthine oxidase with "autoxidizable" compounds like thiols and ascorbate (35,36). However, others have shown that "autoxidation" of thiols and ascorbate at the expense of molecular oxygen is neither thermodynamically or kinetically feasible unless iron is present to serve as direct one electron acceptor (1,18,27,37). Thus, ascorbate or thiol oxidation is mediated by direct electron addition to Fe^{3+}. Subsequent reactions of Fe^{2+} with oxygen can eventually form $O_2^{-\bullet}$. In agreement with this interpretation, Table 6 indicates that replacing xanthine oxidase with glutathione or ascorbate resulted in SOD-insensitive lipid peroxidation, indicative of $O_2^{-\bullet}$ independent ADP/Fe^{3+} reduction. Moreover, results presented in Table 6 indicate that catalase did not inhibit ascorbate or glutathione dependent lipid peroxidation, perhaps indicating either that ADP/Fe^{2+} autoxidized so slowly that H_2O_2 could not accumulate to oxidize more Fe^{2+} and prevent initiation; or that H_2O_2 was formed in such a way that it could not be intercepted by catalase. Overall, it seems that lipid peroxidation is mediated by ADP/Fe^{3+} reduction and that ADP/Fe^{2+} would in turn combine with residual ADP/Fe^{3+} to form some type of Fe^{2+}/Fe^{3+} complex.

Ascorbate is an effective iron reductant, therefore relatively minor changes in its concentration will result in substantial changes in the Fe^{2+}/Fe^{3+} ratio and lipid peroxidation. For example, 25 μM ("low") ascorbate reduces some Fe^{3+} to Fe^{2+} and promotes lipid peroxidation, whereas 50 μM ("high") ascorbate reduces too much

TABLE 6

Ferric Iron-Dependent Lipid Peroxidation: Comparison of Xanthine Oxidase *vs* Glutathione and Ascorbate Systems[a]

System	nmol MDA/mL/min	% Change
Xanthine oxidase[b]	1.2	
+ SOD	0.3	−75
+ catalase	1.6	+33
Glutathione[c]	1.3	
+ SOD	1.4	+8
+ catalase	1.3	—
Ascorbate[d]	0.7	
+ SOD	0.7	—
+ catalase	0.7	—

[a] Incubations contained microsomal phospholipid liposomes (1 μmol lipid phosphate/mL) in 50 mM NaCl, pH 7.0, 37°C. Lipid peroxidation was assayed as malondialdehyde (MDA) formation (3).

[b] System contained 0.11 mM ADP, 0.1 mM $FeCl_2$, 0.33 mM xanthine and 0.05 U/mL xanthine oxidase. SOD and catalase were added at 100 and 400 U/mL, respectively (27). Xanthine oxidase was chromatographed on Sephadex G-25 to remove ammonium sulfate and other contaminants.

[c] System contained 0.11 mM ADP, and 0.1 mM $FeCl_3$ and 1 mM glutathione. SOD and catalase were added at 100 and 400 U/mL, respectively (27).

[d] System contained 0.25 mM ADP, 0.05 mM $FeCl_3$ and 12.5 μM ascorbate. SOD and catalase were added at 15 U/mL (17).

TABLE 7

Ascorbate-Dependent Lipid Peroxidation[a,b]

System	nmol MDA/mL/min	% Change
"Low" ascorbate	0.77	
+ H_2O_2	0.60	−22
"High" ascorbate	0.16	
+ H_2O_2	0.92	+475

[a] Incubations contained microsomal phospholipid liposomes (1 μmol lipid phosphate/mL) and ADP/Fe^{3+} (250 μM-50 μM) in 50 mM NaCl, pH 7.0, 37°C. Reactions were started by addition of either "low" (25 μM) or "high" (50 μM) ascorbate and lipid peroxidation was assayed as malondialdehyde (MDA) formation (3). Where indicated, 50 μM H_2O_2 was also included in the reaction mixtures.
[b] Data from Miller and Aust (18).

Fe^{3+} to Fe^{2+} and inhibits lipid peroxidation (Table 7). Very similar observations have been made with thiols like cysteine or dithiothreitol, which also promote moderate to excessive iron reduction upon minor increase in their concentration (38). Glutathione is a much weaker reductant than is ascorbate, cysteine or dithiothreitol (*cf.* refs. 18,38). Therefore, glutathione may not achieve the complete reduction of iron and inhibition of lipid peroxidation, even when it is used at rather high concentrations. Not surprisingly, both glutathione and ascorbate were capable of promoting lipid peroxidation, yet the concentration of glutathione was approximately 80-fold that of ascorbate (*cf.* legend to Table 6). From another viewpoint, concentrations of glutathione favoring lipid peroxidation were 20-fold those of ascorbate that inhibited lipid peroxidation (*cf.* Tables 6 and 7). One can use H_2O_2 to modulate the balance of reduced *vs* oxidized iron and either inhibit or stimulate lipid peroxidation. For example, with "low" concentration of ascorbate and partial Fe^{3+} reduction, the addition of H_2O_2 will reconvert more Fe^{2+} to Fe^{3+}, thereby inhibiting lipid peroxidation (Table 7). With "high" concentration of ascorbate and extensive or eventually complete Fe^{3+} reduction, the addition of H_2O_2 will oxidize some Fe^{2+} to Fe^{3+}, thereby stimulating lipid peroxidation (Table 7). These experiments indicate that reductants/oxidants can facilitate or prevent lipid peroxidation by virtue of their ability to modulate the Fe^{2+}/Fe^{3+} ratio. In particular, the effects of H_2O_2 on ascorbate dependent lipid peroxidation indicate that its ability to stimulate or inhibit will solely depend on how much iron is maintained in the Fe^{3+} form to achieve the formation of appropriate Fe^{2+}/Fe^{3+} ratios.

POSSIBLE EXPLANATIONS FOR THE REQUIREMENT FOR BOTH FE^{2+} AND FE^{3+}

The results described thus far indicate that the simultaneous availability of Fe^{2+} and Fe^{3+} determines whether lipid peroxidation will occur. The diverging effects of $^{\bullet}OH$ scavengers and the observations that SOD and catalase can either stimulate, inhibit or not affect lipid peroxidation apparently rule out any major role for $^{\bullet}OH$ in initiation of lipid peroxidation. These and other considerations, such as the previously mentioned diffusion-limited reactivity of $^{\bullet}OH$, have led Bucher *et al.* (11), Minotti and Aust (15,16,27) and Braughler *et al.* (12–14) to propose that lipid peroxidation is mediated by some type of iron/oxygen complex comprised of both Fe^{2+} and Fe^{3+}, and perhaps oxygen. All attempts by our laboratories to characterize this elusive complex have been unsuccessful so far. But studies of Co^{2+} or Co^{3+} dependent reactions have shown that the formation of oxygen-bridged complexes of reduced and oxidized metals is feasible (39).

Other investigators (40,41) have proposed that the iron/oxygen complex involved in lipid peroxidation can be best described as the perferryl ion ($Fe^{3+}O_2^{-\bullet}$), which forms *via* the following reactions of Fe^{2+} with oxygen, or the reduction of Fe^{3+} with $O_2^{-\bullet}$.

$$Fe^{2+} + O_2 \rightleftharpoons Fe^{2+}O_2 \rightleftharpoons Fe^{3+} + O_2^{-\bullet} \qquad [14]$$

Interestingly, Goddard and Sweeney (42) and Ursini *et al.* (43) have noted that the requirement for both Fe^{2+} and Fe^{3+} may underlie the initiation by perferryl iron rather than by ferrous/dioxygen/ferric complex(es) for at least two reasons. First, perferryl iron formation and reaction with lipids best occur with chelators and chelator/Fe^{2+} ratios that favor only moderate Fe^{2+} autoxidation and generate an equilibrium between $Fe^{2+}O_2$ and $Fe^{3+}O_2^{-\bullet}$ (43). Second, excess Fe^{2+} would compete with lipids as electron donors for $Fe^{3+}O_2^{-\bullet}$, thereby inhibiting hydrogen abstraction and lipid peroxidation (42,43). This proposed competition between lipids and excess Fe^{2+} for perferryl ion seems consistent with our findings that lipid peroxidation is maximal when critical amounts of Fe^{2+} oxidize to Fe^{3+} (Tables 3–5). Therefore, the perferryl ion model of lipid peroxidation is intriguing and deserves experimental attention. However, excellent rates of lipid peroxidation have been observed in incubations containing H_2O_2 and unchelated Fe^{2+}, which may not autoxidize to generate the equilibrium of $Fe^{2+}O_2$ with $Fe^{3+}O_2^{-\bullet}$ (Tables 1 and 2). Furthermore, SOD did not inhibit lipid peroxidation induced by Fe^{3+} plus ascorbate or glutathione (Table 6) nor that induced by Fe^{2+} chelates (11,16) perhaps indicating that an $O_2^{-\bullet}$-centered radical like perferryl ion may not be involved in either of these systems. Xanthine oxidase dependent lipid peroxidation is inhibited by SOD (Table 5) because Fe^{3+} reduction is mediated by $O_2^{-\bullet}$ in this system, regardless of whether Fe^{2+} is subsequently utilized to form the perferryl ion or a ferrous/dioxygen/ferric complex. Overall, there seem to be some positive but also some negative considerations to support the initiation by perferryl ion rather than by a ferrous/dioxygen/ferric complex.

Schaich and Borg (8) have proposed that irrespective of the nature of the reactive species which abstracts hydrogen from lipids, excess Fe^{2+} would compete as electron donors for $LOO^{\bullet}$ and $LO^{\bullet}$, thereby inhibiting both the formation of first LOOH and subsequent LOOH dependent propagation. As an additional criticism, it has been emphasized that most lipid peroxidation systems rely on high concentrations of iron, which not only fail to reproduce *in vivo* situations but also exaggerate the "antioxidant" effects by Fe^{2+} (8). The validity of this criticism is somehow weakened by previous observations that the requirement for both Fe^{2+} and Fe^{3+} is evident in ferritin and transferrin dependent systems, *i.e.*, systems mediated by physiological iron storage proteins *via* the reductive mobilization and subsequent autoxidation of

very low amounts of Fe^{2+} (33,34). We therefore conclude that Fe^{2+} oxidation is required not to decrease the concentration of Fe^{2+} as an antioxidant, but rather to increase the concentration of some type of oxidant that requires Fe^{3+}. Similar observations have recently been made for the initiation of lipid peroxidation by nonheme iron embedded in the microsomal milieu (20). However, lack of information on the precise structure of microsome-bound iron does not justify extensive discussion of these latter observations in the present article.

The importance of attaining an optimal Fe^{2+}/Fe^{3+} ratio in the initiation of lipid peroxidation was originally proposed and reiterated by relatively few investigators (11-16,27). An overview of the recent literature, however, reveals that similar results have been obtained by other research groups (44-47). Nevertheless, the mechanism of lipid peroxidation remains a matter of controversy. For example, it is certainly true that lipid peroxidation can be promoted by the direct addition of appropriate amounts of Fe^{2+} and Fe^{3+} yet Aruoma *et al.* (28) have found that Pb^{2+} and Al^{3+} can replace Fe^{3+} in the initiation of lipid peroxidation. This latter finding has been taken as evidence against the initiation of lipid peroxidation by a specific Fe^{2+}/Fe^{3+} complex. However, these investigators did not investigate the effects of Pb^{2+} or Al^{3+} on Fe^{2+} oxidation or the subsequent Fe^{2+}/Fe^{3+} ratio. This report also did not address the usual hypothesis that the $^{\bullet}OH$ was responsible for lipid peroxidation. It should be noted, however, that Pb^{2+} and Al^{3+} have also been found to inhibit the lipid peroxidation promoted by ADP/Fe^{3+} and either ascorbate or the reduced nicotinamide adenine dinucleotide phosphate (NADPH) dependent microsomal electron transport system, and that the reasons for such discrepancies have remained unexplained (28). Thus, the participation of Al^{3+} and Pb^{2+} in iron-dependent lipid peroxidation remains confined in very narrowed experimental conditions, whereas the formation of some type of Fe^{2+}/Fe^{3+} complex appears to mediate the initiation of lipid peroxidation in several model systems. We believe that the identification of intracellular low molecular weight iron complexes and the characterization of the mechanisms by which the cell regulates the redox state of these complexes and perhaps their interaction with other metals remain absolute prerequisites to further investigations in this field.

In conclusion, we have presented evidence that lipid peroxidation is mediated by some type of Fe^{2+}/Fe^{3+} complex which can be formed by Fe^{3+} reduction or by Fe^{2+} oxidation, and that these latter reactions can occur and be affected by various mechanisms.

ARTICLE

Peroxide Dependent and Independent Lipid Peroxidation: Site-Specific Mechanisms of Initiation by Chelated Iron and Inhibition by α-Tocopherol[1]

Kenji Fukuzawa* and **Tomohito Fujii**
Faculty of Pharmaceutical Sciences, Tokushima University, Tokushima 770, Japan

Peroxidation of linoleic acid (LA) was catalyzed by Fenton reagent (H_2O_2 and Fe^{2+}) in positively charged tetradecyltrimethylammonium bromide (TTAB) micelles, but not in negatively charged sodium dodecylsulfate (SDS) micelles. However, more hydroxyl radicals formed *via* the Fenton reaction were trapped by *N-t*-butyl-α-phenylnitrone (PBN) in SDS micelles than in TTAB micelles. Generation of linoleic acid alkoxy (LO) radicals by Fe^{2+} *via* reductive cleavage of linoleic acid hydroperoxide (LOOH) resulted in peroxidation of LA and formation of PBN-LO· adducts in SDS micelles, but not in TTAB micelles. This LOOH dependent lipid peroxidation could be catalyzed in TTAB micelles in the presence of a negatively charged iron chelator, nitrilotriacetic acid (NTA). LO radicals formed by the LOOH dependent Fenton reaction were also trapped by PBN at the surface of TTAB micelles in the presence of NTA, but not in its absence. The consumption of a spin probe, 16-(*N*-oxyl-4,4′-dimethyloxazolidin-2-yl)stearic acid (16-NS) during the LOOH dependent Fenton reaction in the presence of NTA was higher in TTAB micelles of LA than in those of lauric acid (LauA), although the rates and amounts of LO radicals formed in the two types of fatty acid micelles were similar. The rates of 5-NS consumption in LA and LauA micelles were almost the same, and were lower than the rate of 16-NS in LA micelles. NTA-Fe^{2+} initiated peroxidation of LA in TTAB micelles without a lag time in the presence of LOOH, but after a lag period, peroxidation occurred without LOOH. α-Tocopherol inhibited peroxidation of LA catalyzed by Fenton reagent by scavenging OH radicals in TTAB micelles. In contrast, α-tocopherol enhanced free Fe^{2+} induced LOOH dependent lipid peroxidation through the regeneration of Fe^{2+} in SDS micelles. However, it inhibited NTA-Fe^{2+} induced LOOH dependent lipid peroxidation in TTAB micelles. The rate and amount of α-tocopherol oxidized by the Fe^{2+} induced, H_2O_2 dependent Fenton reaction were almost the same in TTAB micelles of LA and LauA. The oxidation of α-tocopherol by the NTA-Fe^{2+} induced, LOOH dependent Fenton reaction was greater and faster in LA micelles than in LauA micelles, although the rates of LO radical production in the two types of micelles were the same. During NTA-Fe^{2+} induced, LOOH dependent lipid peroxidation, α-tocopherol inhibited more effectively the consumption of 16-NS than 5-NS. The results are discussed in relation to the location of iron, the unsaturated bonding region of LA, the OOH group of LOOH, the radical trapping site of PBN, the spin sites of 5-NS and 16-NS, and the phenolic hydroxyl group of α-tocopherol in micelles with different charges.
***Lipids* 27, 227–233 (1992).**

Lipid peroxidation is generally thought to cause functional abnormalities and pathological changes in biological systems. Transition metals, such as iron, are involved in the production of reactive oxygen species, such as the hydroxyl radical (·OH), lipid alkoxy radical (RO·), and the iron-oxygen species responsible for initiation of lipid peroxidation. The ·OH and RO· are derived from hydrogen peroxide (H_2O_2) and lipid hydroperoxide (ROOH), respectively, by Fenton and Fenton-like reactions:

$$H_2O_2 + Fe^{2+} \rightarrow \cdot OH + Fe^{3+} + OH^- \quad [1]$$

$$ROOH + Fe^{2+} \rightarrow RO\cdot + Fe^{3+} + OH^- \quad [2]$$

Ferrous chelates alone also initiate lipid peroxidation without requiring hydroperoxides such as H_2O_2 or ROOH, and the initiating species may be a perferryl (1) or ferryl (2) ion or a ferrous-ferric-oxygen (3,4).

Vitamin E (tocopherol), well known as one of the most effective natural lipophilic antioxidants, scavenges ·OH and free lipid radicals such as RO· and hydroperoxy radicals (ROO·).

Samuni *et al.* (5) proposed a "site-specific" Fenton mechanism in which the binding of a transition metal to the biological target is a prerequisite for OH radical mediated cell damage. Schaich and Borg (6) also suggested that the solubility of iron complexes in the lipid phase of membranes is a critical determinant of the catalytic effectiveness to initiate lipid peroxidation. Recently, we confirmed the "site-specific" mechanism of initiation by free and chelated iron, and the inhibition by α-tocopherol of peroxide dependent and independent peroxidation of LA in positively and negatively charged micelles (7–10). In this paper, we describe the dependence of the mechanism on the location of the iron, the unsaturated bonding region of LA, the OOH group of LOOH, and the OH group of α-tocopherol in micellar membranes. The results are discussed with reference to the site of the ·OH, LO· and LOO· and to their scavenging by α-tocopherol.

MATERIALS AND METHODS

Materials. 5- and 16-(*N*-oxy-4,4′-dimethyloxazolidin-2-yl)-stearic acid were purchased from Aldrich Chemical Co. (Milwaukee, WI). *N-t*-Butyl-α-phenylnitrone was from

[1]Based on a paper presented at the Symposium on Metals and Lipid Oxidation, held at the AOCS Annual Meeting in Baltimore, MD, April 1990.

Sigma Chemical Co. (St. Louis, MO). Nitrilotriacetic acid and lauric acid were obtained from Nakarai Chemicals (Tokyo, Japan). Linoleic acid, triphenylphosphine and α,α′-dipyridyl were purchased from Wako Pure Chemical Industries (Tokyo, Japan). α-Tocopherol (>99% pure) was supplied by Eisai Pharmaceutical Co. (Tokyo, Japan). All other reagents were of analytical grade.

Preparation of LOOH. LOOH was prepared by the method of O'Brien (11) and purified by column chromatography as described by Gamage *et al.* (12).

Preparation of fatty acid micelles. Linoleic acid or lauric acid was dispersed in the form of mixed micelles with TTAB or SDS as described previously (9). Briefly, a solution of 25 μmol LA or LauA in chloroform was placed in a test tube, and the solvent was evaporated under nitrogen. The lipid film was dissolved in 5 mL of 50 mM TTAB or SDS solution, vortexed and then sonicated in a Branson sonic bath. When necessary, contaminating LOOH in LA was reduced to the corresponding LOH by treatment of LA with TPP in chloroform solution (13) just before the preparation of micelles.

Lipid peroxidation assay. Lipid peroxidation was measured by monitoring oxygen consumption with a Clark type electrode (8). Consumption was calculated assuming an oxygen concentration of 253 nmol/mL in the initial incubation mixture at 25°C. The pH of the mixture was adjusted by HCl or NaOH. The concentrations of the components of the reaction mixtures and the incubation conditions are given in the figure legends. LOOH formed was also determined iodometrically by the method of Buege and Aust (14) with slight modification.

Measurement of ferrous iron concentration. Ferrous iron was determined colorimetrically with α,α′-dipyridyl (15). Forty μL of 375 mM α,α′-dipyridyl solution in ethanol was added to 3 mL of incubation mixture, and absorbance at 520 nm was measured.

Measurement of α-tocopherol. Oxidation of α-tocopherol was assayed by measuring the change in ultraviolet (UV) absorbance as reported previously (16).

Measurement of electron spin resonance (ESR) spectra. The free radicals formed by reaction with H_2O_2 or LOOH and Fe^{2+} were detected by spin trapping methods with PBN (9). Two *N*-oxyl-4,4′-dimethyloxazolidine derivatives of stearic acid, 5-NS and 16-NS, were used as spin labels to probe the hydrophobic interior of the TTAB micelles at different depths. The PBN and NS labeled micelles were prepared as follows: a solution of 10 μmol of fatty acid and 10 or 25 μmol of PBN or 50 nmol of 5-NS or 16-NS in chloroform was placed in a test tube, and the solvent was evaporated under nitrogen. The resulting film of PBN or NS was dispersed in a SDS or TTAB solution. The reaction was started by the addition of $FeSO_4$ to the micellar solution. The mixture was then transferred to a flat rectangular ESR cell, and the ESR spectra of PBN-adducts were recorded under the following conditions: microwave power, 8 mW; magnetic field, 3377 G; and scan range, 50 G. Hyperfine splitting parameters and *g* values were determined by direct comparison with a known standard, Fremy's salt. The ESR spectra of 5-NS and 16-NS were recorded under the following conditions: microwave power, 8 mW; magnetic field, 3374 G; scan range, 25 G; and modulation width, 1.0 G. The concentrations of spin probes in the TTAB micelles were determined from their ESR signals using a standard calibration chart.

RESULTS

The effects of H_2O_2, LOOH, Fe^{2+} and NTA on the peroxidation of LA were studied in TTAB and SDS micelles (Fig. 1). When LA without LOOH was solubilized in positively charged TTAB micelles, lipid peroxidation was strongly induced by H_2O_2 and Fe^{2+} (H_2O_2 dependent lipid peroxidation). This peroxidation was inhibited 30% and 13% by 50 mM mannitol and *t*-butanol, respectively. In negatively charged SDS micelles, however, H_2O_2 dependent lipid peroxidation was not induced. Rather the addition of free Fe^{2+} resulted in the peroxidation of LA in the presence of LOOH instead of H_2O_2 in SDS micelles (LOOH dependent lipid peroxidation), but not in TTAB micelles. LOOH dependent lipid peroxidation in TTAB micelles was induced by Fe^{2+} in the presence of the negatively charged iron chelator NTA.

Figure 2 shows the oxidation of Fe^{2+} associated with H_2O_2 and LOOH dependent peroxidation of LA. In TTAB micelles, Fe^{2+} was oxidized concurrently with

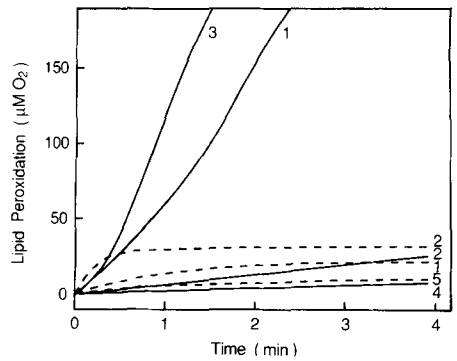

FIG. 1. Peroxide-dependent peroxidation of LA in TTAB micelles (—) at pH 3.5 and in SDS micelles (——) at pH 5.0 (1) H_2O_2, LA and Fe^{2+}, (2) LOOH, LA and Fe^{2+}, (3) LOOH, LA, NTA and Fe^{2+}, (4) LA, NTA and Fe^{2+}, and (5) LA and Fe^{2+}. The LA (25 μmol) was pretreated with 0.5 μmol TPP to remove contaminating LOOH (0.31 μmol). The concentrations of reactants were 5 mM LA, 62 μM LOOH, 100 μM H_2O_2, 30 μM $FeSO_4$, 30 μM NTA, 100 μM TPP, and 50 mM SDS or TTAB. Reactions were started by the addition of Fe^{2+} to the reaction mixtures at 25°C. The amounts of LOOH formed during the 2-min incubation were 143.5 μM (line 1), 47.5 μM (line 2), 388.4 μM (line 3), and 5.4 μM (line 4) in TTAB micelles, and 7.5 μM (line 1) and 20.5 μM (line 2) in SDS micelles.

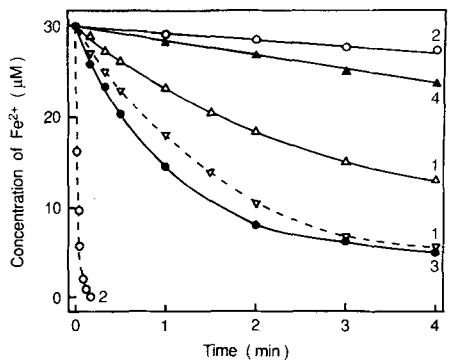

FIG. 2. Oxidation of Fe^{2+} during peroxidation of LA in TTAB micelles (—) and SDS micelles (——). (1) H_2O_2, LA and Fe^{2+}, (2) LOOH, LA and Fe^{2+}, (3) LOOH, LA, NTA and Fe^{2+}, and (4) LA, NTA and Fe^{2+}. The concentrations of reactants and reaction conditions were the same as in Figure 1.

H_2O_2 dependent lipid peroxidation. However, in SDS micelles, Fe^{2+} was also oxidized by H_2O_2 although there was no H_2O_2 dependent lipid peroxidation. During LOOH dependent lipid peroxidation in SDS micelles, free Fe^{2+} was rapidly oxidized in the absence of NTA. However, NTA was necessary in TTAB micelles for the oxidation of Fe^{2+} associated with the LOOH dependent peroxidation of LA.

Figure 3 shows the ESR spectra of PBN adducts formed in the presence of H_2O_2 and LOOH in SDS and TTAB micelles. In SDS micelles, an ESR spectrum attributed to PBN-OH• adducts was observed, while peroxidation of LA was not induced by the addition of H_2O_2 and Fe^{2+}. However, there was little production of PBN-OH• adducts in TTAB micelles while H_2O_2 dependent lipid peroxidation was initiated. With LOOH, a strong ESR spectrum of PBN adduct trapping of alkoxy radical (PBN-LO•) was observed upon addition of free Fe^{2+} to SDS micelles, but was barely seen in TTAB micelles. However in TTAB micelles, an ESR spectrum of PBN-LO• adducts appeared after the addition of Fe^{2+} in the presence of NTA and LOOH.

Nitroxide radicals (NS) such as 5-NS and 16-NS labeled at different positions in liposomal membranes are reported to be lost, possibly by reacting with radicals formed during peroxidation of membrane lipids (17):

$$NS + LO\cdot \text{ or } LOO\cdot \rightarrow \text{Non-radical products} \quad [3]$$

Therefore, to determine the sites at which LO• and LOO• are generated during LOOH dependent lipid peroxidation induced by Fe^{2+} and NTA in TTAB micelles, we examined the consumption of their spin probe radicals. As shown in Table 1, the amount of 16-NS consumed was much greater than that of 5-NS during LOOH dependent lipid peroxidation. Furthermore, the rate and extent of loss of 16-NS by the LOOH dependent Fenton-like reaction were higher in micelles containing LA than in micelles containing lauric acid (LauA). There was little difference in the rate and extent of loss of 5-NS in LA micelles and LauA micelles.

As shown in Figure 4, addition of NTA and Fe^{2+} induced rapid peroxidation of LA in TTAB micelles in the

TABLE 1

Decrease of ESR Signals of 16-NS and 5-NS Induced by Reaction of LOOH with NTA-Fe^{2+} and Inhibition by α-Tocopherol[a]

	% Remaining NS		% Inhibition by α-Toc[b]	
	16-NS	5-NS	16-NS	5-NS
LA	42.7 ± 5.3	64.7 ± 5.8	67.7	21.9
LauA	64.4 ± 3.6	64.9 ± 3.9		

[a] The concentrations of reactants were 50 μM 5-NS or 16-NS, 10 mM LA or LauA, 2 mM LOOH, 0.2 mM NTA, 0.2 mM $FeSO_4$, and 100 mM TTAB. The incubation time was 2.5 min. Other reaction conditions were the same as in Figure 1.

[b] Inhibitions are shown as decreases of ESR signals of 16-NS and 5-NS in the presence of 50 μM α-tocopherol (as percentages of those in its absence).

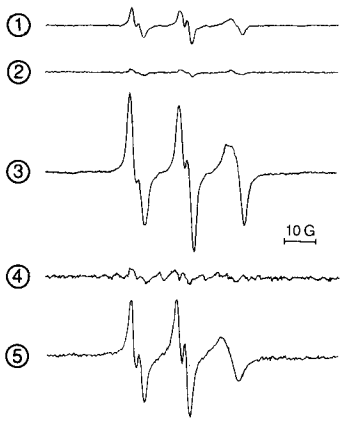

FIG. 3. ESR spectra of the PBN spin adducts. (1) H_2O_2 and Fe^{2+} in SDS micelles, (2) H_2O_2 and Fe^{2+} in TTAB micelles, (3) LOOH and Fe^{2+} in SDS micelles, (4) LOOH and Fe^{2+} in TTAB micelles, and (5) LOOH, NTA and Fe^{2+} in TTAB micelles. Spectra were recorded 30 min after addition of Fe^{2+} at room temperature. The concentrations of reactants in the H_2O_2 system were 25 mM PBN, 2 mM H_2O_2, 0.2 mM Fe^{2+} and 50 mM SDS or TTAB. ESR parameters of spectrum (1) (PBN-OH•); A_N = 15.52 G, A_H = 3.04 G, g = 2.00600. Modulation width, 0.5 G. The concentrations of reactants in the LOOH system were 25 mM PBN, 1.7 mM LOOH, 0.2 mM NTA, 0.2 mM Fe^{2+} and 50 mM SDS or TTAB. ESR parameters of spectrum (3) (PBN-OL•); A_N = 14.77 G, A_H = 3.24 G, g = 2.00560. Modulation width, 0.5 G. ESR parameters of spectrum (5) (PBN-OL•); A_N = 15.39 G, A_H = 2.18 G, g = 2.00600. Modulation width, 1.6 G.

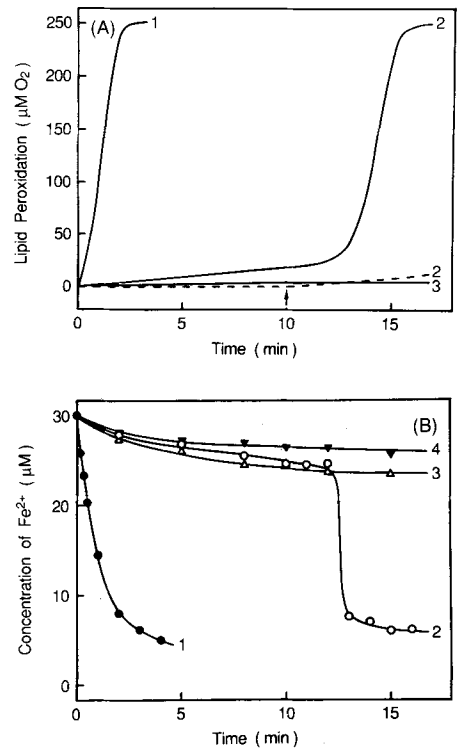

FIG. 4. (A) Peroxidation of LA induced independently of peroxides by chelated Fe^{2+} with NTA, and (B) associated oxidation of Fe^{2+} in TTAB micelles at pH 3.5. (1) LOOH, LA, NTA and Fe^{2+}, (2) LA, NTA and Fe^{2+}, (3) LauA, NTA and Fe^{2+}, and (4) LauA and Fe^{2+}. Reactions were started by addition of Fe^{2+} to the reaction mixtures except for reaction 2 shown by the dotted line, in which Fe^{2+} was added at the time indicated by an arrow. LA (25 μmol) was pretreated with 0.25 μmol TPP. The LOOH concentration was 15.4 μM. The concentrations of other reactants and conditions were the same as in Figures 1 and 2.

presence of LOOH, with associated rapid oxidation of Fe^{2+}. In the absence of LOOH, peroxidation was induced by NTA and Fe^{2+} after a long lag time; the associated oxidation of Fe^{2+} was slow but significant during the lag period and rapid after the lag time. However, the addition of Fe^{2+} after preincubation of TTAB micelles in the presence of NTA for a period corresponding to the lag time did not induce the peroxidation of LA. These results are summarized in Table 2.

α-Tocopherol inhibited H_2O_2 and LOOH dependent lipid peroxidation in TTAB micelles but accelerated LOOH dependent lipid peroxidation in SDS micelles (Fig. 5). In SDS micelles, Fe^{3+} also strongly initiated LOOH dependent lipid peroxidation in the presence of α-tocopherol, but not in the absence of α-tocopherol (data not shown). Figure 6 shows that α-tocopherol was oxidized and free Fe^{3+} was reduced by the interaction of the two in SDS micelles, but α-tocopherol did not react with NTA-Fe^{3+} or free Fe^{3+} in TTAB micelles.

The consumption of 5-NS and 16-NS during LOOH dependent lipid peroxidation in TTAB micelles was also inhibited by α-tocopherol. As shown in Table 1, α-tocopherol inhibited the loss of 16-NS more than of 5-NS.

Figure 7 indicates the time course of oxidation of α-tocopherol during the H_2O_2 and LOOH dependent Fenton reactions in TTAB micelles. The oxidation rates and amounts of α-tocopherol induced by H_2O_2 and Fe^{2+} in LauA and LA micelles were similar, but those induced by LOOH and NTA-Fe^{2+} were greater in LA micelles than in LauA micelles.

Table 3 shows the fluorescence intensities of α-tocopherol in SDS and TTAB micelles and in alcohols of different chain length. The organic solvents affected the fluorescence intensity, which increased as the chain length of the alcohol increased. The fluorescence intensity of α-tocopherol in TTAB micelles was as strong as that in ethanol containing 1% H_2O, but the fluorescence was only about 30% as much in SDS micelles than it was in TTAB micelles. The fluorescence in TTAB micelles decreased in the presence of the membrane probes such as 5-NS and 16-NS (data not shown), which have been used to determine the location of chromophores in membranes by measuring their quenching efficiencies (18). The Stern-Volmer plots of quenching of α-tocopherol fluorescence were linear; no difference in quenching was observed between 5-NS and 16-NS (9).

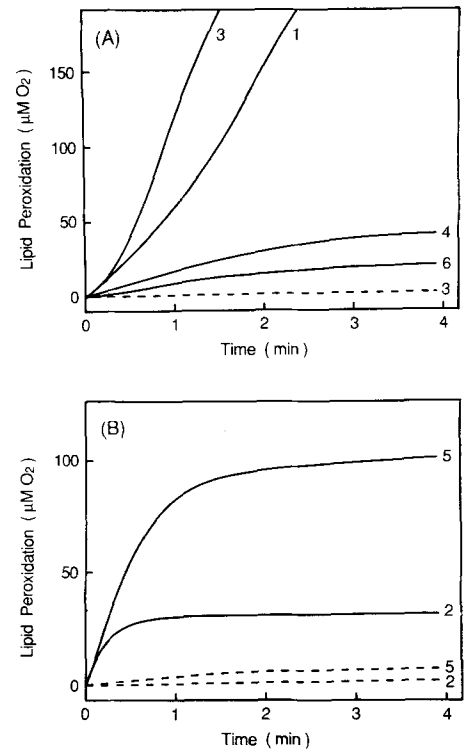

FIG. 5. Effect of α-tocopherol on the H_2O_2 and LOOH dependent peroxidation of LA in (A) TTAB micelles and in (B) SDS micelles. (1) H_2O_2, Fe^{2+} and LA, (2) LOOH, Fe^{2+} and LA or LauA, (3) LOOH, Fe^{2+}, NTA and LA, (4) H_2O_2, Fe^{2+}, α-Toc and LA, (5) LOOH, Fe^{2+}, α-Toc and LA or LauA, and (6) LOOH, Fe^{2+}, NTA, α-Toc, and LA. Solid lines and dotted lines show the systems containing LA and LauA, respectively. The concentration of α-Toc was 100 μM. The concentrations of other reactants were the same as in Figure 1.

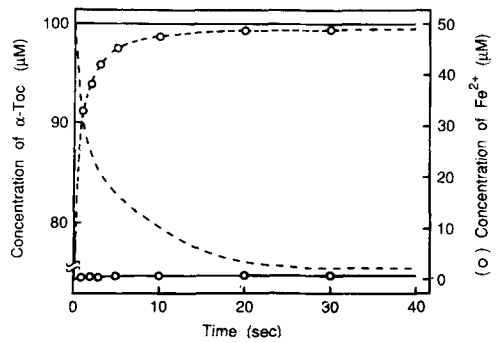

FIG. 6. Time courses of oxidation of α-tocopherol and reduction of free Fe^{3+} or Fe^{3+} chelated with NTA by their interaction in TTAB micelles (—) with and without NTA and in SDS micelles (——) without NTA. The concentrations of reactants were 100 μM α-Toc, 50 μM $FeNH_4(SO_4)_2$, 50 μM NTA and 50 mM TTAB or SDS.

DISCUSSION

In TTAB micelles, the peroxidation of LA was induced after addition of H_2O_2 and Fe^{2+}, but PBN-OH• adducts

TABLE 2

Peroxide Dependent and Independent Initiation of Lipid Peroxidation, and Formation of Initiators and Their PBN-Adducts by Fe^{2+} and NTA-Fe^{2+} in SDS and TTAB Micelles

Micelle system	Initiation of lipid peroxidation			PBN adduct formation		Formation of initiator (oxidation rate of Fe^{2+}; μM/min)

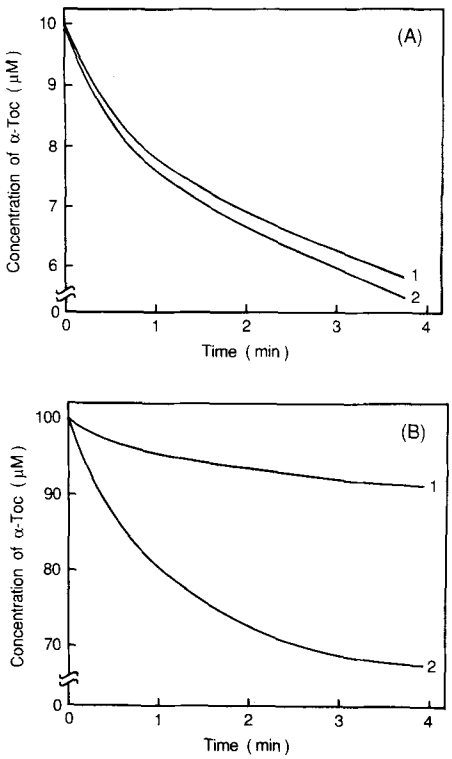

FIG. 7. Oxidation of α-tocopherol in (A) H_2O_2 and (B) LOOH systems in TTAB micelles. (1) LauA, and (2) LA. The concentrations of reactants were (A) 10 μM α-Toc, 0.1 mM H_2O_2, 5 mM fatty acid and 10 μM $FeSO_4$, and (B) 100 μM α-Toc, 100 μM LOOH, 5 mM fatty acid, 50 μM NTA and 50 μM $FeSO_4$.

were not formed (Figs. 1 and 3). The OH radical formed by the reaction of H_2O_2 and Fe^{2+} [1] (Fig. 2) is probably responsible for the initiation [eq. 4] of peroxidation of LA. The processes are then propagated by a chain reaction [eqs. 5 and 6] in TTAB micelles; the processes are inhibited by OH-radical scavengers.

$$LH + \cdot OH \rightarrow L\cdot + H_2O \quad [4]$$

$$L\cdot + O_2 \rightarrow LOO\cdot \quad [5]$$

$$LOO\cdot + LH \rightarrow LOOH + L\cdot \quad [6]$$

In positively charged TTAB micelles, Fe^{2+} is present in the inner water phase and the outer bulk water phase, but not at the positively charged surface. Therefore, some of the ·OH formed in the inner hydrophobic region may react with the unsaturated moiety of LA in the micelles resulting in the initiation of lipid peroxidation. However, since a radical trapping site of PBN is present at the surface, it cannot interact with ·OH. At the surface, ·OH is not formed because no Fe^{2+} is present.

By contrast, PBN-OH· adducts were observed in SDS micelles, but H_2O_2 dependent lipid peroxidation was not induced (Figs. 1 and 3). Because positively charged Fe^{2+} is present at the surface of negatively charged SDS micelles resulting from ionic interaction with the sulfate group of SDS, ·OH is also formed at the surface. Therefore, ·OH can react with the radical trapping site of PBN at the surface, but cannot react with the unsaturated moiety of LA located in the inner hydrophobic region.

The LOOH dependent initiation of lipid peroxidation by free Fe^{2+} and the concurrent oxidation of Fe^{2+} were observed in negatively charged SDS micelles but not in positively charged TTAB micelles (Figs. 1 and 2). Fridovich (19) suggested that polyanionic plasma membranes contain some bound Fe^{2+}, and that ROOH dependent lipid peroxidation can occur when traces of lipid hydroperoxide are present. In SDS micelles, the positively charged Fe^{2+} located at the negatively charged micelle surface plays a role in the initial breakdown of LOOH, which may also be present on the surface, to form LO· [eq. 7] for the chain reaction [eqs. 8, 5 and then 6].

$$LOOH + Fe^{2+} \rightarrow LO\cdot + Fe^{3+} + OH^- \quad [7]$$

$$LH + LO\cdot \rightarrow L\cdot + LOH \quad [8]$$

In contrast, Fe^{2+} may not be able to react with LOOH in TTAB micelles because Fe^{2+} is not located in the positively charged surface of the membranes, and consequently LOOH dependent peroxidation of LA is not initiated. These conclusions are supported by the finding that an ESR spectrum of PBN-LO· adducts was observed in SDS micelles but not in TTAB micelles after the addition of Fe^{2+} to LOOH (Fig. 3). In the presence of NTA, however, LOOH dependent peroxidation of LA and

TABLE 3

Relative Fluorescence Intensities and UV Absorbances of α-Tocopherol in Different Solvents[a]

Solvent system	Fluorescence			UV absorption	
	Relative intensity[b]	Excitation maximum (nm)	Emission maximum (nm)	Absorbance	Absorption maximum (nm)
SDS micelles	30.9	295	326	0.325	293
TTAB micelles	100	295	326	0.325	295
Ethanol	184.8	295	326	0.326	292
Ethanol (1% H_2O)	90.8	295	330	0.326	292
Butanol	214.8	295	328	0.325	292
Octanol	271.9	295	324	0.325	292

[a]A solution of 0.5 μmol α-tocopherol in chloroform was evaporated under nitrogen, and the residue was dissolved in 5 mL of organic solvents or dispersed in 5 mL of 50 mM SDS or TTAB solution with a vortex mixer and sonicator.

[b]Relative fluorescence intensities of α-tocopherol were calculated as percentages of that in TTAB micelles.

PBN-LO· adduct formation were catalyzed by Fe^{2+} in TTAB micelles with concurrent oxidation of Fe^{2+} (Figs. 1–3). Fe^{2+} probably binds to negatively charged NTA located at the positively charged surface of TTAB micelles and then reacts with the OOH group of LOOH at the membrane surface.

The site of the propagation reaction of LOOH dependent oxidation of LA catalyzed by NTA and Fe^{2+} in TTAB micelles was investigated by following the consumption of the spin probes 5-NS and 16-NS (Table 1). More 16-NS than 5-NS was consumed during LOOH dependent peroxidation, indicating that more radicals are present in the deeper regions of the micelles. The consumption of 16-NS during the LOOH dependent NTA-Fe^{2+}-catalyzed Fenton-like reaction [eq. 7] was greater in LA micelles than in LauA micelles. This difference may be due to a LOO· because 16-NS may react with LO· and LOO· in LA micelles but only with LO· in LauA micelles. Decreases in 5-NS during the LOOH dependent Fenton-like reaction were similar in LA and LauA micelles indicating that 5-NS reacts mainly with LO·. These results suggest that the LO· formed at the membrane surface from LOOH [eq. 7] penetrates into the hydrophobic region and abstracts the methylene hydrogen from LA [8]. The propagation reaction [eq. 6] may take place in the deeper regions of the membrane because the LOO· regenerated reacted mainly with 16-NS.

In TTAB micelles in the absence of LOOH, NTA-Fe^{2+} induced peroxidation of LA after a lag period. A small amount of LOOH was probably formed independently of preformed peroxides by NTA-Fe^{2+}, and then rapid peroxidation of LA occurred dependent upon the LOOH accumulated during the lag period associated with the rapid oxidation of Fe^{2+}. The addition of Fe^{2+} after preincubation did not induce peroxidation of LA. The amount of LOOH formed without NTA and Fe^{2+} during preincubation with LA might not have been sufficient to catalyze the LOOH dependent peroxidation of LA. The autoxidation rate of Fe^{2+} was significantly increased by iron chelators such as NTA and diethylenetriaminepentaacetic acid with concomitant O_2 uptake in the absence of LA (data not shown). Therefore, a ferric-oxygen complex may be the initiating species of peroxide-independent lipid peroxidation. However, this remains to be established.

It is uncertain whether the chromanol group of α-tocopherol in membranes is located at the surface (17,20) or in the inner hydrophobic region (21,22). The fluorescence intensity of α-tocopherol decreased as the polarity of the solvent increased (Table 3). The much lower fluorescence intensity of α-tocopherol in SDS micelles than in TTAB micelles (Table 3) indicated that the chromanol group is present in a more polar environment in SDS micelles than in TTAB micelles. Since α-tocopherol was rapidly oxidized by Fe^{3+} in SDS micelles, a phenolic hydroxyl group of α-tocopherol may be associated with the SO_3^- group of SDS through hydrogen bonding and exposed at the membrane surface. In TTAB micelles, however, the membrane probe 16-NS quenched intrinsic α-tocopherol fluorescence as effectively as 5-NS did. This suggests that the chromanol moiety of α-tocopherol is uniformly distributed in the shallow and the deep hydrophobic regions of TTAB micelles.

α-Tocopherol inhibited H_2O_2 dependent and LOOH dependent peroxidation of LA catalyzed by free and chelated Fe^{2+}, respectively, in TTAB micelles, but enhanced free Fe^{2+} induced LOOH dependent lipid peroxidation (Fig. 5). The enhancing effect of α-tocopherol in SDS micelles may be due to its regeneration of Fe^{2+} from Fe^{3+} [eq. 9],

$$\alpha\text{-Toc} + Fe^{3+} \rightarrow \alpha\text{-Toc}\cdot + Fe^{2+} \qquad [9]$$

because i) α-tocopherol rapidly reduced Fe^{3+} to Fe^{2+} in SDS micelles, but not in TTAB micelles (Fig. 6), ii) α-tocopherol caused Fe^{3+} to induce LOOH dependent peroxidation of LA in SDS micelles, whereas this peroxidation was not induced by Fe^{3+} in the absence of α-tocopherol, and iii) the fluorescence intensity of α-tocopherol was much lower in SDS micelles than in TTAB micelles (Table 3).

No significant difference was observed in the rates of oxidation of α-tocopherol by H_2O_2 and Fe^{2+} in TTAB micelles containing unsaturated LA or saturated LauA (Fig. 7A). These results indicate that in this system α-tocopherol inhibits the H_2O_2 dependent peroxidation of LA by scavenging ·OH [eq. 10] rather than free lipid radicals [eqs. 11,12].

$$\cdot OH + \alpha\text{-Toc} \rightarrow \alpha\text{-Toc}\cdot + H_2O \qquad [10]$$

$$LOO\cdot + \alpha\text{-Toc} \rightarrow \alpha\text{-Toc}\cdot + LOOH \qquad [11]$$

$$LO\cdot + \alpha\text{-Toc} \rightarrow \alpha\text{-Toc}\cdot + LOH \qquad [12]$$

By contrast, as shown in Figure 7B, much more α-tocopherol was oxidized during the NTA-Fe^{2+} catalyzed LOOH dependent Fenton reaction [eq. 7] in TTAB micelles containing LA, in which LO· and LOO· are generated [eq. 7, 5], than in TTAB micelles containing LauA, in which only LO· is produced [eq. 7]. These findings suggest that α-tocopherol inhibits the LOOH dependent peroxidation of LA catalyzed by NTA-Fe^{2+} in TTAB micelles mainly by scavenging LOO· [11] in the deep inner hydrophobic membrane regions, where 16-NS was almost completely consumed by LOO· (Table 2). In the presence of α-tocopherol, the LO· initially formed by a Fenton-like reaction [eq. 7] may be lost in the following three reactions: i) interaction of LO· [13], ii) reaction with α-tocopherol [12], and iii) reaction with LA to form LOO· [8, 5], which is also reduced by α-tocopherol [11]. Since the concentration of LA is much higher than the concentrations of LOOH and α-tocopherol, reactions [8] and [11] may progress preferentially to reactions [12] and [13].

$$LO\cdot + LO\cdot \rightarrow \text{Stable product} \qquad [13]$$

Our results and conclusions on the effects of α-tocopherol on H_2O_2 and LOOH dependent peroxidation of LA in SDS and TTAB micelles are summarized in Table 4.

The Inhibitory Effect of Water on the Co^{2+} and Cu^{2+} Catalyzed Decomposition of Methyl Linoleate Hydroperoxides[1]

H. Chen[2], D.J. Lee* and E.G. Schanus[3]
Department of Food Science and Human Nutrition, Washington State University, Pullman, Washington 99164-6376

The inhibitory effect of water on the decomposition of methyl linoleate hydroperoxides (MLHP) catalyzed by Co^{2+} and Cu^{2+} was studied in a model system using proton nuclear magnetic resonance (NMR) spectroscopy. MLHP were prepared by photoxidation and purified by chromatographic methods. Proton NMR spectroscopy was used to measure reaction rates by monitoring changes in the intensity of the OOH signal. The rate constant of the reaction was obtained by plotting the natural logarithm of MLHP concentration *vs* time. In the first part of the study, no transition metals were added to the model system, so that the effect of water could be attributed to the interaction between water and MLHP only. The rate constant of the reaction (K) was found inversely proportional to the concentration of water. There was a downfield chemical shift of both hydroperoxide and water peaks in the NMR spectra when water was added. As temperature increased to 40°C, the difference in K between the systems with 0% and 2% water disappeared. It is proposed that the hydroperoxides were solvated with water which retarded their decomposition. When Co^{2+} was added to the model system, K decreased as the concentration of water increased from 0% to 1.5%. As temperature increased from 18°C to 40°C, differences between the K for 0% and 2% water disappeared. A similar phenomenon was observed in reactions catalyzed with Cu^{2+}. These findings would support a mechanism in which the protective effect of water involves both the solvation of OOH and hydration of the metal catalyst.
Lipids 27, 234-239 (1992).

Lipid autoxidation, a free radical chain reaction, is a recognized problem in preserving food stuffs and involves unsaturated lipids reacting with oxygen. The mechanism of lipid autoxidation has been studied by several research groups and reviewed (1-4). The overall reaction consists of four major stages: initiation, propagation, chain branching and termination.

Decomposition of lipid peroxides plays an important role in autoxidation of unsaturated lipids. First, during the propagation stage, hydroperoxide decomposition occurs with alkoxy and/or peroxyl radicals as reaction products being formed. These radicals in turn abstract hydrogens from fatty acids to form more hydroperoxides and perpetuate the chain reaction. Chain propagation accelerates autoxidation because the reactions of alkoxy and peroxyl radicals with lipid molecules are faster than *ab initio* formation of free radicals by light, heat, or other energy sources. Second, the volatile breakdown products from the reaction are directly responsible for undesirable flavors in rancid foods. The autoxidation of lipids and the generation, synthesis and decomposition of lipid peroxides have been studied extensively during the past two decades (5-17).

Transition metals, such as iron, copper and cobalt, are found in many foods and are important elements in the decomposition of lipid peroxides. Because of their unpaired electron(s) in 3d or 4s orbital, transition metals readily lose or gain an electron so they serve as excellent catalysts of the reaction. The role of transition metals in the decomposition of lipid peroxides has been investigated and reviewed (18-22).

Water retards lipid autoxidation in many dehydrated and low moisture foods (23,24). The shelf life of oat flakes containing 2-6% water was less than two weeks compared with eight months for flakes with 10% moisture (25). Several hypotheses have been offered to explain this inhibitory effect (26-28). The presence of water could slow autoxidation by the following mechanisms: (a) lowering diffusion rate of oxygen; (b) lowering effectiveness of metal catalysts; (c) promoting non-enzymatic browning which produces antioxidants; and (d) excluding air from the surface of food. Because of the complexity of food systems, however, the effect of water observed in the studies cited above does not support or rule out any single one of these possibilities.

The effect of water on lipid autoxidation has been investigated in model systems using methyl linoleate as substrate (29-32). Based on systematic studies, Karel (33) suggested the following events occurred during autoxidation which retarded degradation of lipid peroxides: (a) hydrogen-bonding of amphipolar hydroperoxides at the lipid-water interface lowered the total effective hydroperoxide concentration; and (b) hydration of metal reduced the effectiveness of the catalysts.

This study was undertaken to provide data to validate earlier hypotheses and to increase our understanding of how water interacts with hydroperoxides and transition metals to retard lipid autoxidation. A new model system was developed that contained methyl linoleate hydroperoxides (MLHP), transition metals and various amounts of water in fully deuterated acetone (acetone-d_6). Proton nuclear magnetic resonance (NMR) was used to monitor the reaction by measuring the area of the OOH peak. The area of this peak is proportional to the concentration of MLHP in the system, and thus changes as decomposition occurring can be measured. The inhibitory effect of water was investigated by: (a) studying the interaction between water and lipid peroxides; and (b) investigating the interaction between water and transition metals.

MATERIALS AND METHODS

Materials. The following chemicals were used to prepare and purify MLHP: methyl linoleate (NuChek Prep, Elysian, MN); rose bengal (cert.) (Eastman Kodak, Rochester, NY); silicic acid (n-hydrate, J.T. Baker Chemical Co., Phillipsburg, NJ), hexane and methanol. Fully deuterated acetone (acetone-d_6) (Wilmand Glass Co., Buena, NJ) was used as solvent in the model system. Cobalt(II)chloride, $CoCl_2 \cdot 6H_2O$ (crystal) and Cu(II)chloride, $CuCl_2 \cdot 2H_2O$ (crystal) (J.T. Baker) were used as catalysts.

Preparation of MLHP. The photoxidation method reported by Schenk and Schults-Elte (34) was modified slightly to synthesize MLHP. Three grams of methyl linoleate, 0.05 g rose bengal and 70 mL of methanol were mixed in a 150-mL Erlenmeyer flask. The mixture was transferred to a 100-mL fritted glass funnel connected to an oxygen tank. Two 300-W spotlights were used as an energy source for the photochemical reaction. Temperature was maintained at 2°C using a refrigerated water bath covered with a glass baking dish containing water to act as an infrared light filter. Water was added to compensate for evaporation during the 18-hr reaction. When the reaction was stopped, the methanol was removed under vacuum in a rotary evaporator.

Purification of MLHP was done by column chromatography (35). Silicic acid (70 g) was activated in a 110°C oven for 12 hr, cooled in a desiccator, transferred to a 500-mL beaker and mixed with enough hexane to form a slurry. The slurry was packed into a 400 mm × 25 mm glass column and washed with 500 mL of hexane. Products from the photochemical reaction were loaded onto the column in a minimal volume of hexane/diethyl ether (15:5, v/v). Five hundred milliliters of hexane/diethyl ether (95:5, v/v) were used to elute non-polar compounds and unreacted methyl linoleate. MLHP were eluted with 500 mL of hexane/diethyl ether (80:20, v/v). A drop-controlled fractionator was used to collect MLHP in disposable culture tubes. Thin-layer chromatography served to identify tubes containing MLHP (36). ^1H NMR spectrometry was employed to confirm the presence of MLHP in combined fractions. High-performance liquid chromatography (HPLC) was used to further purify MLHP. Ten microliters of the MLHP mixture were loaded onto a silica gel semipreparative column (10 mm × 300 mm). The elution solvent was 1.2% isopropanol and 98.8% hexane (v/v). The flow rate of the solvent was 4 mL/min. The wavelength of the ultraviolet (UV) detector was set at 245 nm. Solvent in the collected MLHP fraction was evaporated with a rotary evaporator. The purified MLHP was transferred to small glass vessels, flushed with nitrogen, and stored at −22°C.

Preparation of model system. The model system was prepared in an NMR tube using 50 μL of acetone-d_6 as solvent. To investigate the interactions between MLHP and water, the solvent was replaced with various amounts of distilled water (v/v) to arrive at a final concentration of water of 0%, 0.5%, 1.0%, 1.5%, or 2.0%. Interactions between transition metals and water were studied by replacing a like volume of acetone-d_6 in the system with a solution of cobalt(II)chloride or copper(II)chloride dissolved in acetone-d_6.

Experimental procedure. The proton NMR spectrum of MLHP shown in Figure 1 was recorded on a JEOL FX90Q FT-NMR spectrometer (Tokyo, Japan) operating at 89.90 MHz. Complete identification and interpretation of the spectra of methyl linoleate and MLHP have been previously reported by Gunstone and Norris (37), Chan (3), Chan and Levette (15), and Frankel *et al.* (8). The OOH peak appeared downfield at 10.40 ppm. The peak at 3.65 ppm can be assigned to OCH_3, and was chosen as a reference peak for measuring OOH peak areas. The area for OOH protons was integrated using the operating disk FAFT72 in the JEOL computer. Since the initial concentrations of OOH were known, the areas of OOH at any given time could be converted into molar concentrations. For each data point, three readings were taken. The average standard deviation was 0.011. All measurements were conducted at 18°C unless specified otherwise.

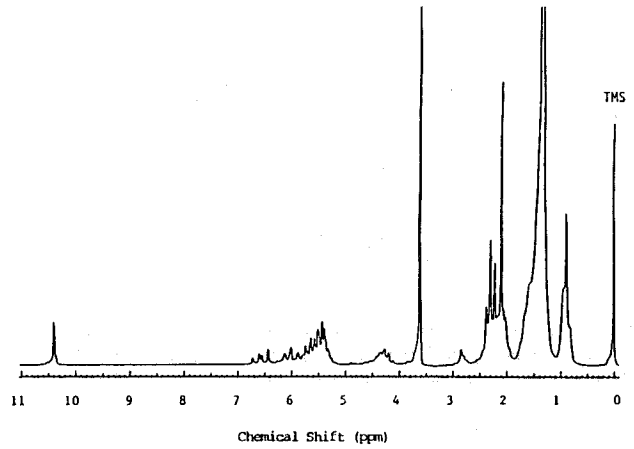

FIG. 1. Proton NMR spectrum of MLHP (89.90 MHz). Peak of OOH appeared at 10.40 ppm. Peak at 3.65 ppm was assigned to OCH_3 and was used as reference for the measurement of the peak area of OOH.

To determine the apparent rate constant for the reaction, K, the natural logarithm of the concentration of MLHP was plotted against time. The slope of the straight line is K. All statistical analyses, such as linear regression correlation coefficient (r^2) and confidence level, were carried out using the statistical program, MSUSTAT, on an IBM computer.

RESULTS AND DISCUSSION

For convenience of discussion, our results are presented in two parts: (i) solvation of MLHP; and (ii) hydration of metals. In the first part, transition metals were not involved so that the effect of water could be attributed to the solvation of MLHP only. In the second part, water, MLHP and metals were present in the same system; so the effect of water could be attributed to solvation of MLHP and to hydration of metals.

Solvation of MLHP. The apparent rate constant, K, for the decomposition of MLHP, as affected by various concentrations of water, is shown in Figure 2. K decreased linearly as the concentration of water increased, indicating that water acts as an inhibitor of the reaction.

A downfield shift of the OOH and water signals in the NMR spectra was observed when water was added to MLHP. The extent of the shift was dependent on the concentration of water in the system (Fig. 3 and Table 1). The

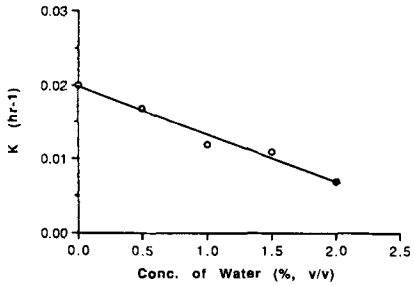

FIG. 2. Plot of apparent rate constant (K) *vs* concentration of water in MLHP decomposition in the absence of metals. Duplicate experiments were carried out ($r^2 = 0.94$, confidence level >99%).

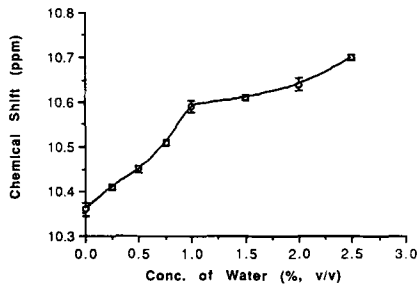

FIG. 4. Change in chemical shift of NMR peak of OOH *vs* increased concentration of water. Standard deviations of the measurements are shown by the error bar.

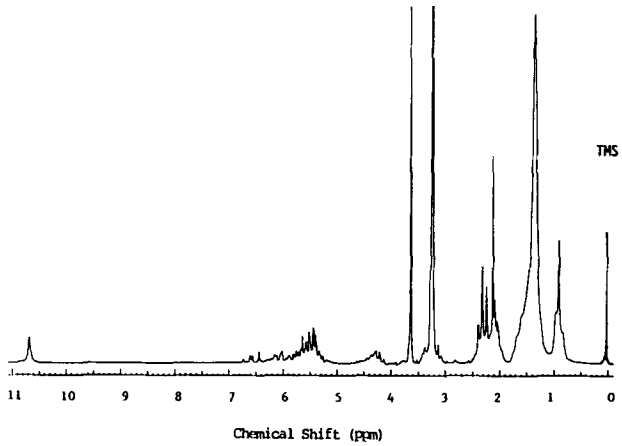

FIG. 3. Proton NMR spectrum of MLHP (89.90 MHz). The model system contained 2% H_2O. Peak for OOH was shifted from 10.40 ppm to 10.65 ppm (Fig. 1). Peak for water appeared at 3.25 ppm.

TABLE 1

Change in Chemical Shift of NMR Peak of Water After Mixing with MLHP

Conc. of H_2O (%, v/v)	Chemical shift (ppm)[a]		
	Before mixing	After mixing	Change
0.25	2.85	2.90	0.05
0.50	2.90	2.95	0.05
0.75	2.93	3.00	0.07
1.00	2.95	3.10	0.15
1.50	3.00	3.15	0.15
2.00	3.10	3.25	0.15

[a]Standard deviation range of the measurements was ±0.007 to 0.014.

observed change in chemical shift can be explained by interaction between the OOH protons and water molecules. Hydrogen bonding would be expected to alter shielding of these protons which would result in the observed downfield shifts. This explanation is supported by the nonlinear change in chemical shift with increasing amounts of water in the system (Fig. 4), in contrast to the linear change that would be expected if replacement of acetone-d_6 was the cause. When the chemical shift was plotted against water concentration (Fig. 4), the curve obtained was somewhat bimodal. Water concentration above 1.0% caused less change per unit increase than at concentrations below 1.0%. This finding supports the mechanism proposed by Karel (4) and by Barclay and Ingold (5) that polar hydroperoxides form water-peroxide complexes which alter the path of the reaction.

This would be expected if hydrogen bonding occurred between the peroxide group and two molecules of water. The molar concentration corresponding to 1% water in the system is approximately twice that of MLHP in the system. The addition of more water would not change the equilibrium of the reaction toward the bound state as rapidly as when water concentrations were lower and more binding sites on the hydroperoxide molecules were free. The preferential bonding between water and one of the isomers in the mixture could also account for the observed non-linear response to increased water concentrations. However, the fact that the oxidation rate and response to water of the 13-hydroperoxy-*cis*-9, *trans*-11-octadecadienoate isomer, separated by using the method by Chan and Levett (15), was nearly identical to that of the MLHP mixture does not support this hypothesis. The chemical shift of the NMR peak for water was observed to revert back toward initial values as the reaction progressed and the concentration of hydroperoxide decreased (Table 2). The formation and subsequent decay of water-OOH hydrogen

TABLE 2

NMR Chemical Shifts of Water and Hydroperoxide Peaks in Various Systems

System	Chemical shift (ppm)[a]	
	OOH	H_2O
Acetone-d_6 + 2% H_2O		3.15
Acetone-d_6 + 2% H_2O + Co^{2+} (100 ppm)		3.85
Acetone-d_6 + Co^{2+} (100 ppm) + MLHP	10.4	
Acetone-d_6 + MLHP	10.4	
Acetone-d_6 + 2% H_2O + MLHP	10.6	3.20
Acetone-d_6 + 2% H_2O + MLHP + Co^{2+} (100 ppm)	10.6	3.40

[a]Standard deviation range of the measurements was ±0.007 to 0.014.

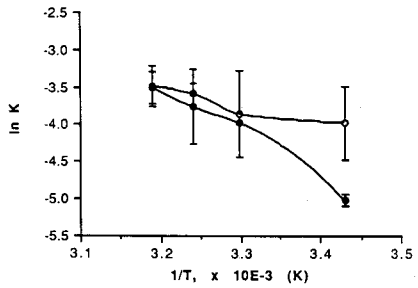

FIG. 5. Plot of K *vs* temperature for reactions in the absence of metals: ○, 0% H_2O; ●, 2% H_2O. Standard deviation of the measurements are shown by the error bar.

bonds could explain this observation. The results support the proposals of Karel (4) and Barclay and Ingold (5) that polar hydroperoxides form water-peroxide complexes which slow their decomposition.

To further support our findings, the effect of temperature on the reaction with 0% and 2.0% water was investigated. At 18°C, the apparent rate constant (K) for MLHP decomposition in the absence of water was twice that of the one with 2.0% water (Fig. 5). The reaction rate of the system with water was more temperature-dependent than the one without water, and the difference in K disappeared at 30°C and the plotted lines met at 40°C.

A possible explanation of this is that at 18°C most of the peroxide moieties were complexed with water, as indicated by the chemical shifts of the water and peroxide peaks. As temperature increased, the hydrogen bonds were weakened and the equilibrium shifted toward more free water and more free peroxide moieties. This would explain the near-linear temperature response of the 2% water system. Unfortunately, neither the NMR signals for water at different temperatures, nor the effect of temperature at lower water concentrations have been determined so far; so this explanation remains tentative. The influence of temperature on hydrogen bonding has been studied previously. Luck (38) reported that as temperature increased, hydrogen bonding between water and alcohol decreased; but this observation was made over a much wider temperature range than used in the present study.

Hydration of metals. The effect of water on the reaction catalyzed by Co^{2+} (Fig. 6) was attributed to both solvation and hydration. Adding 0.5% water to the model system reduced K by 55%. Water concentrations above 0.5% had decreasing effects on reaction rates, which were reduced by 67% and 80% by 1.0% and 1.5% water, respectively. No additional inhibitory effect was found when 2.0% water was added to the system. The supposition that hydration of the metal ion reduces the reaction rate is supported by these results. When 100 ppm Co^{2+} was added to a system containing acetone-d_6, 2% water and no MLHP, a chemical shift in the NMR spectrum of the water peak to 3.85 was observed. This indicated the water was complexing with the metal ion. Decomposition of hydroperoxides catalyzed by metal ions as proposed by Chan (3) involves the exchange of electrons; a) $ROOH + M^{(n+1)} \leftrightarrow ROO^* + H^+ + M^{n+}$, and; b) $ROOH + M^{n+} \leftrightarrow RO^* + OH^- + M^{(n+1)}$. Hydration of metals can reduce their effectiveness as catalysts (19). Pokorny (18) reported that transition metal ions, such as Co^{2+}, are normally surrounded by water molecules and can form polymeric micelles. This can inhibit electron transfer from the outer layer of the metal to the oxidizing form of molecule. Increasing amounts of water in the model system could increase the degree of hydration with subsequent reduction in reaction rates. At 1.5% water, the molar concentration of added water is one-half that of the Co^{2+} ion and is the same when maximum inhibition occurs. This supports the formation of a complex containing two cobalt ions per water molecule.

Experiments to determine the effects of temperature on reactions catalyzed by Co^{2+} and Cu^{2+} with 0% and 2.0% water in the system were conducted. Results (Fig. 7) were similar to those obtained with a non-catalyzed system (Fig. 5). At 18°C, there were differences in the rate constants between the systems with and without water. The

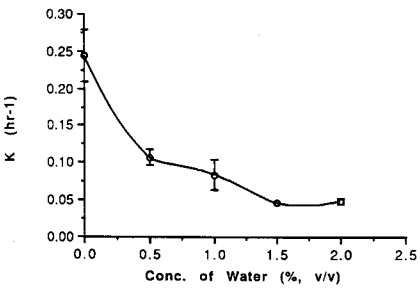

FIG. 6. Change in K *vs* concentrations of water in systems containing 100 ppm Co^{2+}. Standard deviations are shown by error bars.

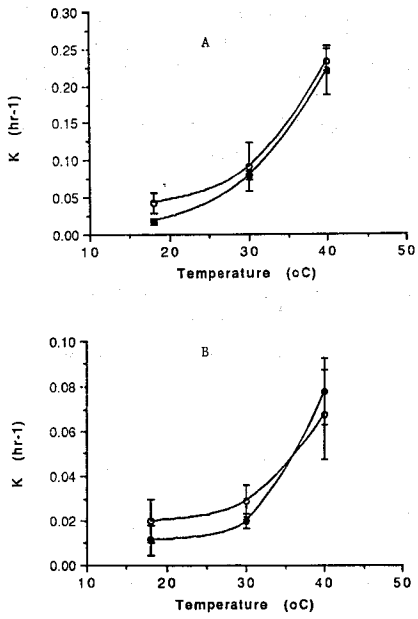

FIG. 7. Plot of K *vs* temperature for reactions catalyzed by Co^{2+} and Cu^{2+}. (A) ○, 0% H_2O and Co^{2+}; ●, 2% H_2O and Co^{2+}. (B) ○, 0% H_2O and Cu^{2+}; ●, 2% H_2O and Cu^{2+}. Concentration of Co^{2+} and Cu^{2+}: 10 ppm. Standard deviation of the measurements are shown by the error bar.

systems with 2.0% water were more temperature-dependent and with both catalysts the K of the reactions increased faster than in systems with no water. Near 30°C, or slightly above, the rates in the Co^{2+} catalyzed reactions were nearly the same for both systems. This effect of temperature on the reactions would be expected if there is an interaction of water and metal which inhibits the reaction at 18°C, but which is disrupted as temperatures increase.

The observed differences between the reactions catalyzed with Co^{2+} and Cu^{2+} could be due to the fact that they catalyze redox reactions by different mechanisms. Copper normally catalyzes *via* direct electron transfer while cobalt more easily forms complexes with polar compounds, such as oxygen and hydroperoxides. The differences in heat of hydration could also account for part of the observed differences. Hydration heat of Cu^{2+} is approximately 11 kcal/mole greater than that for Co^{2+} (39). The data obtained in this study do not enable us to determine which, if either, explanation is correct, but the addition of water inhibited the reactions catalyzed with copper as well as those catalyzed with cobalt.

Transition metals do not exist in the free state but are always surrounded by solvents, such as water, and oxidation products, such as lipid peroxides, to form polymeric micelles (18). The complex formed can stop or slow the electron transfer between the metals and the organic substrate. Hill and McAuley (21) have described how such a complex would interfere with the oxidative decarboxylation of carboxylic acid. Waters (20) indicated that the ease of electron transfer depends on the equilibrium constant for the ligand-displacement process. A MLHP-metal-water complex may actually have been formed in the model system during MLHP degradation.

Indirect evidence for the formation of such a complex is found in the NMR data presented in Tables 2 and 3. The data presented in Table 2 indicate a) that water was bound to Co^{2+} through coordination bonding, which caused a downfield shift of the proton in the presence of water; b) that there was no direct interaction between the peroxide OOH groups and Co^{2+} since the chemical shift of the OOH proton did not change when the two were mixed in the absence of water; and, c) that water interacted with MLHP and Co^{2+} causing a downfield shift of both the protons of water and the OOH groups. Two possible explanations for these findings are; i) Co^{2+} was hydrated to form a water-metal complex and, in an independent reaction, water was bound to OOH groups *via* hydrogen bonding to form a water-hydroperoxide complex. The physical barrier these water complexes create would slow electron transfer from catalyst to substrate and inhibit the reaction; ii) previous studies and our experimental data indicate the possibility that Co^{2+} was bound to water with water molecules surrounding the Co^{2+} ion. Hydrogen bonding of the water molecules with the oxygens of the OOH group of MLHP occurred to form a metal-water-MLHP complex. This is supported by the chemical shift data presented in Table 3. In the reaction with 0.5% water, the chemical shift of the water peak was 2.95 ppm before Co^{2+} was added (0 hr). After mixing (0.25 hr), the peak was downshifted to 3.50 ppm. This is obviously due to a change in the chemical environment of the water protons, which could be caused by water-cobalt complex forming hydrogen bonds with the peroxide OOH group to form a water-MLHP-Co^{2+} complex. As MLHP decomposed, the amount of hydrogen bonding between water and MLHP lessened and the protons in water became more shielded causing the NMR water peak to shift back toward its original position. In our experiments, at the end of the reaction the chemical shift of the water peak was 3.00 ppm. Similar observations were made at other water concentrations. The association between the change in the chemical shift of the water peak and the decomposition of MLHP can be explained by a mechanism involving a metal-water-MLHP complex. It is difficult to explain the chemical shift returning to the original value as the reaction progressed if the binding of water with Co^{2+} and hydroperoxides are separate events. The possible role of breakdown products remains to be determined.

This study demonstrated that in a model system the decomposition of MLHP was inhibited by water concentrations of 0.5% to 2.0%, and NMR spectral data provided evidence for water molecules complexing with hydroperoxides and binding with the metal catalysts, Co^{2+} and Cu^{2+}. We propose that formation of a metal-water-hydroperoxide complex is involved in the inhibition by water. Further studies are needed to verify these findings and their interpretation.

TABLE 3

Change in Chemical Shift of NMR Peak of Water *vs* Time in Decomposition of MLHP Catalyzed by Co^{2+}

Time (hr)	Chemical shift (ppm)[a]			
	0.5% H_2O	1.0% H_2O	1.5% H_2O	2.0% H_2O

ARTICLE

Relationship Between Translocation of Long-Chain Acyl-CoA Hydrolase, Phosphatidate Phosphohydrolase and CTP:Phosphocholine Cytidylyltransferase and the Synthesis of Triglycerides and Phosphatidylcholine in Rat Liver

Daniel Asiedu*, Jon Skorve, Abraham Demoz, Nina Willumsen and **Rolf K. Berge**
Laboratory of Clinical Biochemistry, University of Bergen, Haukeland Sykehus, 5021 Bergen, Norway

Translocation of long-chain acyl-coenzyme A hydrolase from the microsomal fraction to the cytosolic fraction was promoted in cell-free extracts of rat liver by palmitic acid, oleic acid, tetradecylthioacetic acid, and tetradecylthiopropionic acid, and by their CoA esters. The CoA esters were more effective than the non-esterified acids in the translocation of the enzyme. Treatment of normolipidemic rats with sulfur-substituted non-β-oxidizable fatty acid analogues resulted in a transitory increase in hepatic concentration of long-chain acyl-CoA. Longer feeding times almost normalized the hepatic long-chain acyl-CoA content. Microsomal long-chain acyl-CoA hydrolase activity was inhibited, whereas the activity of the cytosolic form was stimulated. The rise in enzyme activity coincided with a reduction in liver content of triglyceride and an increase in hepatic phospholipid content. The results suggest that the activity of long-chain acyl-CoA hydrolase in the cytosol may control the amount of acyl-CoA thioesters in the liver. Esterified and non-esterified fatty acids caused *in vitro* translocation of phosphatidate phosphohydrolase and cytidine 5′-triphosphate (CTP):phosphocholine cytidylyltransferase from the cytosolic fraction to the microsomal fraction. However, the translocation of these two enzyme systems was not obtained *in vivo*. The activity of phosphatidate phosphohydrolase decreased in microsomal and cytosolic fractions while the activity of cytidylyltransferase in these fractions increased. The activities of soluble phosphatidate phosphohydrolase and long-chain acyl-CoA hydrolase appeared to be inversely correlated. The results imply that in cytoplasm, long-chain acyl-CoA hydrolase may compete with the biosynthetic enzymes for the acyl-CoA substrate, thus influencing the rate of lipid synthesis. The reduced hepatic triglyceride content observed in tetradecylthioacetic acid-treated rats is probably due to reduced triglyceride synthesis, which is mediated by an inhibition of phosphatidate phosphohydrolase accompanied with translocation and stimulation of long-chain acyl-CoA hydrolase. Development of fatty liver as an effect of tetradecylthiopropionic acid is probably due to accelerated triglyceride biosynthesis, which is mediated by a stimulation of phosphatidate phosphohydrolase and a decrease in cytosolic palmitoyl-CoA hydrolase activity.
Lipids 27, 241–247 (1992).

Abbreviations: BCMTD, 3-thiadicarboxylic acid; CETTD, tetradecylthiopropionic acid; CMOTD, tetradecyloxyacetic acid; CMS, carboxymethyl cellulose; CMTTD, tetradecylthioacetic acid; CoA, coenzyme A; CTP, cytidine 5′-triphosphate; EDTA, (ethylenedinitrolo)tetraacetic acid; HEPES, *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid); P, microsomal fraction; S, soluble fraction.

Long-chain acyl-CoA hydrolase (palmitoyl-CoA hydrolase), phosphatidate phosphohydrolase and cytidine 5′-triphosphate (CTP):phosphocholine cytidylyltransferase are ubiquitous enzymes (1–5). They are found in both the cytoplasm and the cell membrane (6–14). Palmitoyl-CoA hydrolase also occurs in organelles involved in oxidation of fatty acids such as mitochondria (15,16) and peroxisomes (16–18), and its distribution between the different cell compartments can be modified (19). This has been observed in the rat liver after starvation or repeated administration of peroxisome proliferators such as clofibrate, tiadenol (17,20), and partially hydrogenated fish oils (21,22), conditions which increase the hepatic concentration of long-chain acyl-CoA (19,23). Thus, increased long-chain acyl-CoA hydrolase activity in cytosol during peroxisome proliferation is apparently a consistent phenomenon, exhibiting a close correlation with induction of peroxisomal β-oxidation (14).

Treatment of normolipidemic rats with sulfur-substituted non-β-oxidizable fatty acids, which are peroxisome proliferators (19), results in a reduction in the liver content of triglycerides (24) and an increase in phospholipid levels (25). This is accompanied by an increase in CTP:phosphocholine cytidylyltransferase activity and a decrease in phosphatidate phosphohydrolase activity. The results may indicate that the biosynthesis of triglycerides and phospholipids are coordinately regulated (25).

Both phosphatidate phosphohydrolase and CTP:phosphocholine cytidylyltransferase have been reported to exist in two interconvertible forms—a microsomal form and a cytosolic form (1,2,8–11). It is thought that the cytosolic form, which is a functionally inactive reservoir, can become metabolically activated when translocated to the endoplasmic reticulum in which the synthesis of glycerolipids occurs (7,8). As long-chain fatty acids and their CoA esters are able to promote translocation of these two enzymes, increased synthesis of glycerolipids, particularly triglycerides, may help to limit the rise in the concentration of fatty acyl-CoA esters in the liver (2,26) and prevent them from becoming toxic. If the rise in concentration of fatty acyl-CoA esters is not limited, the formation of a fatty liver can result.

The most dramatic effect observed after the administration of 3-tetradecylpropionic acid, which is able to undergo one cycle of β-oxidation, was the development of fatty liver (19). Since long-chain acyl-CoA hydrolase also appears to be important in the regulation of long-chain acyl-CoA, the aim of the present investigation was to examine whether *in vitro* translocation also occurs for this enzyme. We were also interested in determining whether the 3- and 4-sulfur substituted fatty acids and their CoA esters interfere with the translocation process of phosphatidate phosphohydro-

lase and CTP:phosphocholine cytidylyltransferase. In addition, we examined whether changes in the activities of phosphatidate phosphohydrolase, CTP:phosphocholine cytidylyltransferase and long-chain acyl-CoA hydrolase activities and their subcellular distribution are affected by and related to the increase in concentration of hepatic long-chain acyl-CoA by feeding 3-thiadicarboxylic acid, tetradecylthioacetic acid and tetradecylthiopropionic acid to rats.

The present data support the concept that induction of long-chain acyl-CoA hydrolase activity, particularly in the cytosolic form, is a protective adaption against unfavorable levels of acyl-CoA. Furthermore, our results imply that acyl-CoA hydrolase may compete with the biosynthetic enzymes for the acyl-CoA substrate, thus influencing the rate of lipid synthesis.

MATERIALS AND METHODS

Chemicals and drugs. [1-^{14}C]Palmitoyl-CoA and [^{3}H]-glycerol 3-phosphate were purchased from the Radiochemical Centre (Amersham, England). 1,10-*Bis*(carboxymethylthio)decane (3-thia-dicarboxylic acid) (BCMTD), tetradecylthioacetic acid (CMTTD), tetradecylthiopropionic acid (CETTD) and the CoA esters of the monocarboxylic acids were prepared as described earlier (27). The synthesis of tetradecyloxyacetic acid also has been described previously (J. Skorve, D. Asiedu, M. Solbakken, R.K. Berge, unpublished data). Table 1 shows the structure of the different compounds. All other chemicals were obtained from common commercial sources and were of reagent grade.

Animals and treatments. Male Wistar rats from Møllegaard Breeding Laboratory (Ejby, Denmark), weighing 170–180 g, were housed individually in metal wire cages in a room maintained at 12-hr light-dark cycles at a constant temperature of 20 ± 3°C. The animals were acclimatized for at least one week under these conditions before the start of the experiment. The fatty acid analogues were suspended in 0.5% sodium carboxymethyl cellulose (CMS) and administered by gastric intubation in a volume of 1 mL once a day at a dose of 150 mg/day/kg body weight. The control animals received only CMS. All animals had free access to water and food (17,19). In some experiments the rats were fed *ad libitum* the diet supplemented with tetradecyloxyacetic acid at a dose of 400 mg/day/kg body weight for 5 days.

Preparation and treatment of subcellular fractions. The livers from individual rats were homogenized in ice-cold sucrose-medium (0.25 M sucrose in 10 mM HEPES buffer, pH 7.4 and 1 mM EDTA), and the resulting nuclear and postnuclear fraction were used as the total homogenate (19). For further analytical differential centrifugation experiments, postnuclear fractions from three animals were pooled (19,24,25) before microsomal and cytosolic enriched fractions were isolated. Variation in the response from animal to animal was estimated separately in the group of control animals for selected enzymes and lipids.

A postperoxisomal fraction obtained from rat liver homogenates after centrifugation using a time integral of 4.3×10^9 min^{-1} (t = 30 min, r_{min} = 4.8 cm and r_{max} = 14.6 cm) (16,21) was incubated with various fatty acids and CoA esters with or without bovine serum albumin for 10 min at 37°C (7,8). Microsomal and cytosolic fractions were isolated after centrifugation at a time integral of 7.4×10^{10} min^{-1} (t = 60 min, r_{min} = 6.6 cm and r_{max} = 15.2) at 4°C (7,8,16,21).

Analytical methods. Protein was assayed with Bio-Rad protein assay kit (Bio-Rad, Richmond, CA). The enzymatic activities of CTP:phosphocholine cytidylyltransferase (28), and long-chain acyl-CoA hydrolase (using palmitoyl-CoA as substrate) at a concentration of 60 μM (5,19) were determined as earlier described. The phosphatidate phosphohydrolase activity was measured as phosphate release in the absence and presence of 5 mM $MgCl_2$ (29). The activity of the phosphohydrolase was also measured as diacylglycerol formation. The assay conditions were identical in the presence of 5 mM $MgCl_2$, as earlier described (29). The reaction was stopped by adding 1 mL of chloroform/methanol (1:2, v/v), and the diacylglycerol formed was extracted into the chloroform phase. The diacylglycerol was quantitated with a diacylglycerol assay reagent system from Amersham. Free CoASH and acid-insoluble CoA (the CoA-thioesters of native fatty acids and/or the CoA thioesters of the drugs) were measured in liver extracts processed as described previously (23).

RESULTS

Translocation of long-chain acyl-CoA hydrolase from membrane to cytoplasm in vitro. The addition of increasing concentrations of oleoyl-CoA to a post-light mitochondrial fraction of rat liver caused a progressive decrease in specific activity of palmitoyl-CoA hydrolase in the microsomal fraction (Fig. 1). By comparison, oleoyl-CoA increased the activity in the soluble fraction (Fig. 1). Palmitoyl-CoA was comparable to oleoyl-CoA in this respect (Table 2), but the CoA esters of the sulfur-substituted fatty acid analogues, tetradecylthioacetic acid and tetradecylthiopropionic acid, were more effective than the CoA esters of "normal" fatty acids in facilitating the translocation (Table 2). Clofibroyl-CoA was less effective in facilitating the translocation when compared with controls to which

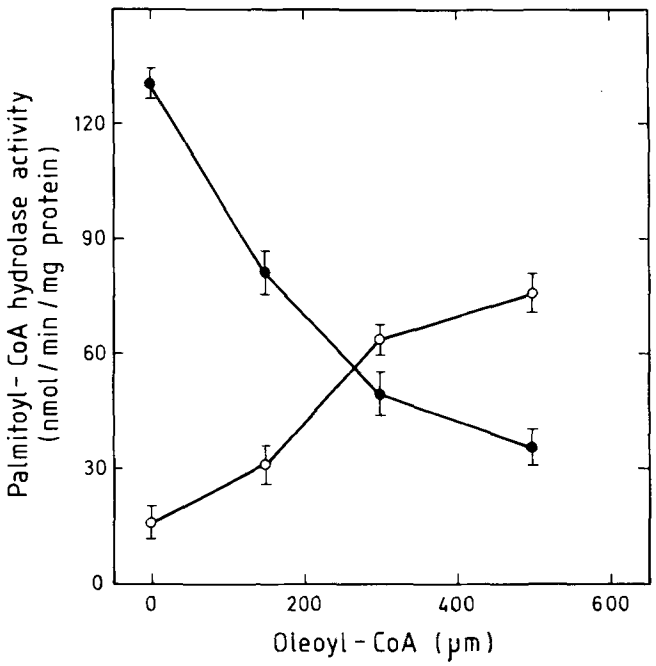

FIG. 1. Effect of oleoyl-CoA on the activity of long-chain acyl-CoA hydrolase in the microsomal (●) and soluble (○) fraction of rat liver. The post-light mitochondrial supernatant of rat liver was incubated for 10 min at 37°C at the concentrations of oleoyl-CoA indicated. The values are the means ± SD of three independent experiments. For details, see Materials and Methods.

no fatty acid had been added. Evidence is presented in Table 2 that the unesterified fatty acids were less effective than their CoA esters in promoting the translocation of palmitoyl-CoA hydrolase from a membrane-associated compartment to the soluble fraction. In the presence of albumin, palmitoyl-CoA and oleoyl-CoA caused increased specific activity of palmitoyl-CoA hydrolase in the cytosolic fraction (Table 2). Furthermore, addition of fatty acyl-CoA at concentrations similar to those generated *in vivo* by feeding the various fatty acids (Table 4) was effective in facilitating the translocation of palmitoyl-CoA hydrolase (Table 3). Thus, the rlease of long-chain acyl-CoA hydrolase from microsomes is not simply an artefact due to the detergent action of the CoA-esters.

The activity of rotenone-insensitive NADPH-cytochrome c reductase in the cytosolic fraction was less than 2% of the activity present in the liver homogenates. The activity of lactate dehydrogenase in the particulate fraction after resuspension and centrifugation was less than 2% of the total activity present in the homogenate. No increased reductase activity in the cytosolic fraction was observed after addition of the different CoA esters. Thus, the low cross contaminations were irrelevant for the measurement of the cellular distribution of palmitoyl-CoA hydrolase. The CoA esters seem to release certain microsome-associated proteins more or less selectively.

Translocation of long-chain acyl-CoA hydrolase from membrane to cytoplasm in vivo. Treatment of rats with 3-thiadicarboxylic acid and tetradecylthioacetic acid at a dose of 150 mg/day/kg body weight for 5 days resulted

TABLE 2

Effects of Fatty Acid and their CoA Esters on the Activity of Long-Chain Acyl-CoA Hydrolase in the Microsomal and Cytosolic Fractions in Liver of Untreated Rats[a]

	Long-chain acyl-CoA hydrolase activity

[a] Post-light mitochondrial fraction was incubated with the fatty acids and their CoA esters with or without albumin, as indicated, for 10 min at 37°C. Microsomal and soluble fractions were then prepared as described in Materials and Methods. The hydrolase activity was measured with palmitoyl-CoA as substrate at a concentration of 60 μM. The total hydrolase activity in microsomal and soluble fractions relative to the post-mitochondrial fraction was in the range of 96 to 111%. The tabulated values are expressed as means ± ranges of two independent experiments.

[b] $P < 0.05$ between control (no addition) and addition.

TABLE 3

Effects of CoA Esters on the Activity of Long-Chain Acyl-CoA Hydrolase in the Microsomal and Cytosolic Fractions of Liver in Alkyloxyacetic Acid (400 mg/day/kg body weight) Treated Rats for Five Days[a]

Additions	Long-Chain acyl-CoA hydrolase activity

	2	93.2 ± 3.1[b]	233.5 ± 3.6[b]	144.9 ± 30.1[b]	91.6 ± 8.6[b]	1.58
	3	85.5 ± 1.9[b]	356.9 ± 2.8[b]	39.7 ± 8.5	125.9 ± 10.2[b]	0.32
	7	83.7 ± 4.2[b]	641.9 ± 8.6[b]	51.1 ± 10.1[b]	201.1 ± 15.6[b]	0.25
Tetradecylthiopropionic acid	1	80.2 ± 5.2[b]	78.4 ± 4.1[b]	30.1 ± 2.2	61.8 ± 3.1	0.49
	3	78.3 ± 3.6[b]	76.6 ± 3.2[b]	31.6 ± 6.2	78.4 ± 14.1	0.40
	7	75.3 ± 4.5[b]	66.5 ± 6.1[b]	38.6 ± 9.1	77.6 ± 13.6	0.50
	14	69.9 ± 2.6[b]	96.9 ± 4.2	61.6 ± .8[b]	61.4 ± 5.2	1.00

[a]The tabulated values of CoA derivatives (nmol/g liver) represent means ± SD of 12 control animals and 3 rats of 2 feeding groups. The acyl-CoA hydrolase activities are presented relative to those of control animals equaling 100% (n = 6). In controls the mean acyl-CoA hydrolase activity of the microsomal and soluble fractions was 154.4 ± 2.8 nmol/min/mg protein and 16.8 ± 2.8 nmol/min/mg protein, respectively.

[b]$P < 0.02$ between control and treated rats.

in a progressive increase in the activity of cytosolic palmitoyl-CoA hydrolase accompanied by decreasing microsomal enzyme activity (Table 4). Administration of palmitic acid was less effective in facilitating the translocation, but at higher palmitic acid doses increased activity of palmitoyl-CoA hydrolase in the cytosolic fraction was observed (30,31). The activity of the enzyme in the microsomal fraction was decreased (31). Administration of tetradecylthiopropionic acid decreased the activities of microsomal and cytosolic long-chain acyl-CoA hydrolase (Table 4).

The results of Table 4 show that repeated administration of 3-thiadicarboxylic acid and tetradecylthioacetic acid increased the hepatic concentration of long-chain acyl-CoA, which was already apparent during the first days of treatment. Increased CoASH levels were observed within longer feeding periods and the ratio of long-chain acyl-CoA to CoASH was maximally increased after two days of feeding. Subsequently, after seven days of feeding 3-thiadicarboxylic acid, the ratio was essentially normalized (Table 4). In agreement with earlier observations (30), no redistribution of long-chain acyl-CoA and free CoASH

was observed in tetradecylthiopropionic acid treated animals (Table 4). Repeated administration of the β-oxidizable sulfur acid tended to increase the concentration of long-chain acyl-CoA after 14 days of feeding (Table 4).

Translocation of phosphatidate phosphohydrolase and CTP:phosphocholine cytidylyltransferase to the microsomal fraction in vitro. The activities of Mg^{2+}-dependent phosphatidate phosphohydrolase (Table 5), as well as CTP:phosphocholine cytidylyltransferase (Table 6), were increased in the microsomal fraction after addition of esterified or non-esterified fatty acids. In most cases, the CoA esters of the thio fatty acids, as well as the CoA esters of "normal" fatty acids, were more effective than the non-esterified fatty acids in stimulating the enzyme activities (Tables 5 and 6). In contrast, the activities of the cytosolic forms of phosphatidate phosphohydrolase (Table 5) and CTP:phosphocholine (Table 6) tended to decrease after additions of CoA esters. Thus, a translocation of phosphatidate phosphohydrolase and CTP:phosphocholine cytidylyltransferase from the cytosolic to the microsomal fraction

[a]The enzyme activities are presented relative to those of control animals equaling 100%. The tabulated values are the means ± SD of 12 control animals and 6 treated rats. In control animals the mean phosphatidate phosphohydrolase activity in the microsomal and cytosolic fractions was 13.9 ± 1.8 nmol/min/mg protein and 7.1 ± 1.4 nmol/min/mg protein, respectively. The mean CTP:phosphocholine cytidylyltransferase activity in the microsomal and cytosolic fractions was 4.2 ±0.2 nmol/min/g liver and 44.1 ± 3.0 nmol/min/g liver, respectively.

was promoted in the cell-free extract of rat liver by fatty acid and their CoA esters (Tables 5 and 6). In addition, evidence is presented in Tables 5 and 6 that both enzymes can translocate from cytosol to microsomes *in vitro* in the presence of added esterified or unesterified sulfur-substituted fatty acid analogues. Clofibroyl-CoA was less effective than tetradecylthioacetic-CoA and tetradecylthiopropionic-CoA in facilitating the translocation (Tables 5 and 6).

Cellular distribution of phosphatide phosphohydrolase and CTP:phosphocholine cytidylyltransferase in vivo. Repeated administration of 3-tetradecylthioacetic acid and 3-thiadicarboxylic acid caused a decrease in the activities of microsomal and cytosolic Mg^{2+}-dependent phosphatidate phosphohydrolase (Table 7), whereas the microsomal and soluble CTP:phosphocholine cytidylyltransferase activities were stimulated. Thus, no translocation *in vivo* of these enzymes from the cytosolic compartment to the microsomal compartment was observed after repeated administration of sulfur-substituted fatty acid analogues.

DISCUSSION

In agreement with earlier observations (3–11), esterified and unesterified fatty acids can cause phosphatidate phosphohydrolase (Table 5) and CTP:phosphocholine cytidylyltransferase (Table 6) to translocate from the cytosol and to associate with microsomal membranes *in vitro*. The present results demonstrate that the two enzymes also can be translocated to the endoplasmic reticulum by sulfur-substituted fatty acid analogues. The CoA-esters of these peroxisome proliferating acids appeared to be more effective than their unesterified acids in facilitating the translocation (Table 5).

Translocation of phosphatidate phosphohydrolase and CTP:phosphocholine cytidylyltransferase *in vivo* could not be demonstrated in our study (Table 7). Moreover, the phosphohydrolase activity was inhibited in 3-thiadicarboxylic acid and tetradecylthioacetic acid treated animals despite the increase in long-chain acyl-CoA content (Table 4). The reason for the discrepancy *in vivo* compared to the *in vitro* studies is not clear. It cannot be explained by the effect of Mg^{2+} or the assay conditions, as decreased cytosolic and microsomal phosphatidate phosphohydrolase activity *in vivo* was observed in the absence of Mg^{2+} (assayed as phosphate formation) (29) and in the presence of Mg^{2+} (assayed as diacylglycerol formation) (Table 7). Furthermore, in the presence of Mg^{2+}, measured phosphate formation equaled diacylglycerol formation in most cases (Table 5). However, the activity of Mg^{2+}-independent phosphatidate phosphohydrolase was much lower than the Mg^{2+}-dependent enzyme activity in the cytosolic fractions (Table 5). As subcellular fractionation itself causes no redistribution of the phosphohydrolase, observed differences between *in vivo* and *in vitro* data suggest that other mechanisms for stimulation and inhibition must also be considered.

The present study confirms earlier observations that treatment with sulfur-substituted fatty acid analogues, which are classified as hypolipidemic peroxisome proliferating agents (19,24), cause inhibition of the phosphatidate phosphohydrolase activity coupled with stimulated CTP:phosphocholine cytidylyltransferase activity (25). In our study, an inhibition of the latter enzyme activity was accompanied by a stimulation of the former (Table 7). Thus, a coordinated regulation of triglyceride and phospholipid biosynthesis appears to exist (25). Taken together, the activity of phosphatidate phosphohydrolase may be important in regulating the rate of triglyceride synthesis (25). However, it is not sufficient to limit the rise in the concentration of acyl-CoA esters in the liver (Table 4), as has been suggested (7,26).

The present study demonstrates that esterified and unesterified fatty acids and sulfur-substituted fatty acids may promote translocation of long-chain acyl-CoA hydrolase from the microsomal fraction to the cytosolic fraction (Fig. 1 and Table 2). The CoA esters were more effective than the free acids (Table 2). The *in vitro* effects observed with fatty acyl-CoA derivatives, particularly as

they affect the release, could simply be artefacts that occur at the concentrations used, *e.g.*, due to detergent action, certain microsome-associated proteins may be released more or less selectively. However, relatively low concentrations of CoA esters (Table 3), at *in vitro* fatty acyl-CoA concentrations similar to those generated upon *in vivo* feeding of the various acids (Table 4) (30,31), were able to promote translocation of long-chain acyl-CoA hydrolase (Table 3).

Changes in enzyme activities can be attributed to inhibition or activation as well as to compartmental translocation. Fatty acyl-CoA hydrolase activity can be changed by treating the *in vitro* systems with high concentrations of the same and different CoA esters. The hydrolase assay was run at an optimal palmitoyl-CoA concentration, and addition of different esterified and non-esterified CoA esters did not interfere with the assay; recoveries of enzyme activities in soluble and microsomal fractions were close to 100% (between 92 and 111%). The changes in long-chain acyl-CoA hydrolase activity do not appear to involve inhibition or activation of the enzyme, but more likely translocation between compartments.

The *in vivo* data on redistribution of long-chain acyl-CoA hydrolase between microsomal and cytosolic fractions, which may be promoted by long-chain acyl-CoA (Table 4), were comparable with the *in vitro* data (Tables 2 and 3). Treatment with tetradecylthiopropionic acid resulted in no changes in the distribution of CoASH between the free and acylated forms, and in no redistribution of the hydrolase activities (30) (Table 4). Both the microsomal and cytosolic hydrolase activities were decreased (Table 4). This suggests that the activity of long-chain acyl-CoA hydrolase in the cytosol may control the amount of acyl-CoA ester in the liver.

Reduction in the triglyceride content of the liver and an increase in hepatic phospholipid concentrations have been observed in 3-thiadicarboxylic acid and tetradecylthioacetic acid treated rats (25). In contrast, repeated administration of tetradecylthiopropionic acid led to a drastic increase in the hepatic triglyceride content. It is conceivable that increased activity of cytosolic long-chain acyl-CoA hydrolase may limit the increase in the concentration of long-chain acyl-CoA and, thereby may protect the cells against a toxic detergent effect and formation of fatty liver.

The rise and fall in long-chain acyl-CoA hydrolase activity in cytosol (Table 4) coincided with a decreased and increased concentration of hepatic triglycerides, respectively (25). Thus, the long-chain acyl-CoA hydrolase in cytoplasm may compete with the biosynthetic enzymes for the acyl-CoA substrate, thus influencing the rate of lipid synthesis. The reduced hepatic triglyceride content observed in non-β-oxidizable fatty acid-treated rats is probably due to reduced triglyceride synthesis which is mediated by translocation and stimulation of long-chain acyl-CoA hydrolase and inhibition of phosphatidate phosphohydrolase. Development of fatty liver of tetradecylthiopropionic acid (24,25) is probably due to accelerated triglyceride synthesis which is mediated by an increase in the availability of CoA esters along with enzymatic inhibition (long-chain acyl-CoA hydrolase) (Table 4) and mitochondrial β-oxidation (25,30,31) and stimulation (phosphatidate phosphohydrolase) (25). Thus, the palmitoyl-CoA hydrolase activity may play an important role in regulating substrate availability, *i.e.*, fatty acids, as a major determinant of the rate of triglyceride biosynthesis. To what extent the palmitoyl-CoA hydrolase serve as an intracellular buffer preventing great fluctuation in the concentration of fatty acyl-CoA is presently unknown.

[Received September 6, 1991; Revision accepted January 3, 1992]

Transfer of Liposomes Containing Dolichol into Isolated Hepatocytes

Örjan Tollbom[a,c,*], **Tadeusz Chojnacki**[a,d] and **Gustav Dallner**[a,b]

[a]Department of Biochemistry, Arrhenius Laboratory, University of Stockholm, S-106 91 Stockholm, and [b]Division of Basic Research in Dementia, Clinical Research Center at Huddinge Hospital, Karolinska Institutet, S-141 86 Huddinge, Stockholm, [c]Department of Cell Biology, Faculty of Health Sciences, Linköping University, S-581 83 Linköping, Sweden, and [d]Institute of Biochemistry and Biophysics, Polish Academy of Sciences, Warsaw 02-532, Poland

Isolated rat hepatocytes were preincubated with egg lecithin liposomes containing [^{3}H]dolichol and [^{3}H]-dolichyl ester, and the intracellular levels and distributions of these lipids were subsequently determined after incubation in a liposome-free medium. [^{3}H]Dolichol was recovered initially mainly in microsomes, and no increase with time in the low level of this compound in the mitochondrial/lysosomal fraction could be observed. A small portion of the labeled dolichol was esterified in the endoplasmic reticulum and transferred to the lysosome-containing fraction. [^{3}H]Dolichyl linoleate was initially localized in microsomes and supernatant, but later accumulated in the mitochondria/lysosomes. Dolichyl linoleate was found in the membrane of microsomes, in the membrane and lumen of lysosomes, and in the soluble cytoplasm. Exogenous dolichol recovered in microsomes was not phosphorylated to any significant extent. Liposomal phosphatidylcholine also showed preferential accumulation in microsomes after incubation with hepatocytes. These results indicate that exogenous or endogenously formed dolichyl esters are transferred from the endoplasmic reticulum to lysosomes, probably through the cytoplasm. It appears that fatty acids play a role in targeting these lipids to their intracellular locations.
Lipids 27, 248-254 (1992).

Dolichol is synthesized in the endoplasmic reticulum and also in the peroxisomes, but it is present in all membranes and in the cytoplasm (1-4). Studies to date have concentrated on the details of the biosynthetic mechanism and the influence of dolichol on stability, fluidity and permeability in model membranes and on its stimulating effects on membrane fusion (5-8). The phosphorylated form is an obligatory intermediate in glycoprotein synthesis, which has been studied in great detail (9).

The broad distribution of dolichol, its rapid rate of synthesis and the large variation in the amounts present under different experimental conditions indicate that the uptake and intracellular transport of dolichols are important factors which appear to contribute to the homeostasis of cell life. It seems of importance to study these processes using a suitable experimental system in which uptake can be followed. Isolated hepatocytes take up lipids from liposomes in the medium and a large portion of this exogenous lipid becomes subsequently associated with intracellular organelles (10). The components of liposomes may be internalized by a process involving the uptake of individual components, instead of entire particles. The uptake of micellar lipids depends greatly on the cell type, and lipid uptake by many cells in culture proceeds rather slowly (11).

Using such a system, several questions concerning the intracellular fate of dolichol can be answered. These include how dolichol initially distributes in the cell, how it is redistributed from its initial location to other membranes, whether it is incorporated into membranes or distributed within the organelle and, finally, whether dolichol is modified during uptake or intracellular transport.

The receptor-mediated uptake of low density lipoproteins by hepatocytes has been studied extensively (12). In this process, lipids enter the cell *via* the phagosomal-lysosomal system, where they are processed before discharge into the cytoplasm and before further translocation into intracellular membrane systems. When dolichol is injected into the blood of rats, it ends up in the phagosomal hepatic lysosomes, where it remains for at least 6 days without being transferred to other organelles (13).

Dolichol transport occurs not only within the cell, but dolichol is also discharged through the endoplasmic reticulum (ER)-Golgi system into the blood, where it participates in the formation of high density lipoprotein (14). Like cholesterol, dolichol appears in the bile, and this route of excretion is believed to make a major contribution to dolichol turnover (15,16). The half-life of dolichol in the endoplasmic reticulum is about 80-120 hr, while in lysosomes it ranges between 120 and 140 hr (17). These half-lives are about the same as those found for other neutral and phospholipids, suggesting that active breakdown of polyisoprenoids may occur in the liver. In fact, breakdown products of dolichol were recently found in bile (18,19). Attempts to identify metabolites of this process have so far not been successful (20,21). Uptake of extracellular dolichol and its subsequent intracellular translocation may provide a system for investigating the breakdown process (10,11).

In a number of physiological and pathophysiological conditions, such as in aging (22-25), under drug treatments (26), exposure to plasticizer (27), and under various experimental (28-30) and human pathological conditions (31-34), considerable alterations in the amount, nature and distribution of polyisoprenoids in cells and tissues are observed. Obviously, the uptake, transport and discharge of dolichols can be considerably modified by an as-yet-unknown mechanism.

In the present study, we have incubated isolated rat hepatocytes with egg lecithin liposomes containing polyisoprenoids. The uptake and distribution of the lipids in the membranes and the lumen of subcellular organelles were analyzed and metabolic modifications of dolichol were investigated.

MATERIALS AND METHODS

Animals and cells. In all experiments, livers of non-starved Sprague-Dawley rats (330-360 g) were used. For the isolation of hepatocytes, the livers were first perfused with

*To whom correspondence should be addressed.

Abbreviations: EGTA, ethyleneglycol-*bis*(β-aminoethyl ether)-*N,N,N',N'*-tetraacetic acid; ER, endoplasmic reticulum; HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography.

150 mL Hanks buffer containing 0.5 mM ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid (EGTA) and 2% albumin (35). In the subsequent perfusion, 100 mL Hanks buffer containing 0.12% collagenase (type V, Boehringer, Mannheim, Germany) and 2 mM calcium chloride was employed. The perfusion times were 10 and 15 min with the first and second medium, respectively. The perfusion media were bubbled with carbogen gas (95% oxygen, 5% carbon dioxide) and warmed to 37°C before use. For dissociation of hepatocytes, the livers were shaken in Krebs-Henseleit buffer. The isolated cell suspension was centrifuged and after resuspension the same buffer was centrifuged at $80 \times g$ for 5 min. The yield from one liver was about 400×10^6 hepatocytes.

Subcellular fractionations. For subcellular fractionation, the cells were disrupted by sonication with a fine tip on a Heat System sonifier (Farmingdale, NY) using the lowest setting (36). The cell suspension in 0.25 M sucrose had a protein concentration of 30 mg/mL and was cooled in an ice-water bath. The sonication time was 1 min employing a 50% pulse. For preparation of the mitochondrial/lysosomal fraction, debris and nuclei were first removed by centrifugation at $480 \times g$ for 10 min. The supernatant was decanted and, after further centrifugation at $4300 \times g$ for 20 min, the pellet obtained was resuspended in 0.25 M sucrose and washed by centrifugation at $4300 \times g$ for 15 min. The washing procedure was repeated and the final mitochondrial/lysosomal pellet was resuspended in 0.25 M sucrose.

For the preparation of lysosomes, the $480 \times g$ supernatant was centrifuged at $48000 \times g$ for 12 min and the pellet was resuspended in 57% metrizamide adjusted to pH 7.3. The discontinuous gradient above the particle suspension was prepared according to Wattiaux *et al.* (37) and, after centrifugation at $100,000 \times g$ for 3 hr, the two bands on the top and bottom of the upper 20% metrizamide layer were collected and designated as lysosomes. The purified mitochondrial fraction, between the 57% and 37% metrizamide layers, was also collected.

For the preparation of microsomes, the suspension of disrupted cells was centrifuged at $10,000 \times g$ for 20 min and the supernatant was recentrifuged at $105,000 \times g$ for 60 min to obtain the microsomal pellet. The supernatant fraction was obtained by an additional centrifugation of the microsomal supernatant at $105,000 \times g$ for 2 hr.

The separation of microsomal and lysosomal membranes and luminal contents was achieved by sonication of the particle suspension for 1 min with a 50% pulse, followed by centrifugation at $105,000 \times g$ for 2 hr.

Marker enzyme activities were measured in mitochondria (cytochrome c oxidase), microsomes (NADPH-cytochrome c reductase), lysosomes (acid phosphatase) and plasma membranes (AMPase). The respective values were used to calculate the percentage contamination (on a protein basis) of the fractions isolated from hepatocytes (10,36,38). Mitochondria, lysosomes and plasma membranes contributed 0.5, 6 and 3%, respectively, of the total microsomal protein. The contamination of mitochondria ("lysosomes free") with microsomal protein, lysosomes and plasma membranes was 3, 3 and 1%, respectively. The lysosomal fraction contained 1, 9 and 2% mitochondria, microsomes and plasma membranes, respectively.

Microsomes prepared from hepatocytes were placed on a discontinuous sucrose gradient containing $MgCl_2$, as described earlier (36). Measurement of marker enzymes revealed that contamination with mitochondria, lysosomes and plasma membranes was 0.5, 4 and 1%, respectively. Thus, this gradient centrifugation removed a large portion of the plasma membrane contamination. The acid phosphatase activity not associated with organelles was also measured and it was found that 4% of the total activity of the homogenate was localized in the supernatant. Consequently, the majority of lysosomes in the homogenate were intact.

Protein was measured by the Biuret method, using bovine serum albumin as standard (39).

Preparation of liposomes. Twenty mg of egg lecithin (Lipid Products, South Nutfield, England) dissolved in chloroform/methanol (2:1, v/v) was mixed with 1 μmol [1-^{3}H]dolichol-19,[1-^{3}H]dolichyl-19 linoleate or 1,2-dipalmitoyl-*sn*-glycero-3-phospho[*methyl*-^{3}H]choline. The solvent was evaporated first under nitrogen and then *in vacuo*. The lipid residue was supplemented with 4.5 mL of 0.9% NaCl and sonicated for 10 min with a 50% pulse in an ice-water bath under nitrogen. This suspension was centrifuged at $105,000 \times g$ for 30 min before use. The liposomal suspension was prepared freshly each day.

Incubation. For incubations the cells from one liver were suspended in 40 mL Krebs-Henseleit buffer and supplemented with 2 mL of the liposomal suspension or 2 mL fatty acid/albumin complex (see below). The incubation was performed in a water bath at 37°C with continuous rotation. The mixture was also gassed with a continuous stream of carbogen. The incubation was terminated by cooling and centrifugation at $50 \times g$ for 4 min, after which the cells were washed four times with 20 mL of 0.9% NaCl solution. The final pellet was suspended in 0.25 M sucrose for subcellular fractionation.

Lipid extraction. Lipids from isolated subfractions were extracted with 20 vol of chloroform/methanol (2:1, v/v). Dolichol-23 and dolichyl-23 palmitate were added as internal standards. Partition was achieved with water, and the chloroform layer was then evaporated to dryness. The lipid residue was dissolved in methanol and applied to a Supelco C-18 cartridge (Bellefonte, PA). After washing with methanol, the dolichol and the dolichyl esters were eluted with hexane. After evaporation of the solvent, the lipids were dissolved in a small volume of hexane and analyzed by thin-layer chromatography (TLC) or by high-performance liquid chromatography (HPLC).

In order to isolate dolichyl-P, the subcellular fractions were subjected to alkaline hydrolysis by mixing 1 mL of the fraction with 2 mL methanol and 1 mL of 60% KOH. Dolichyl-23 phosphate was added as an internal standard. The mixture was heated at 80°C for 45 min. Lipids were subsequently extracted with chloroform/methanol/water (1:1:0.3, v/v/v). The extract was poured onto a column of DEAE-Sephadex (acetate form) and washed with the same solvent to elute uncharged molecules. Dolichyl-P was eluted with chloroform/methanol/water (1:1:0.3, v/v/v) containing 200 mM ammonium acetate. After partition, the chloroform phase was washed 3 times with theoretical upper phase in order to remove ammonium acetate. After evaporation of the solvent, dolichyl-P was dissolved in a solution (see below) containing 20 mM phosphoric acid and subjected to HPLC.

Chromatography. Separations by HPLC were done on a Hewlett-Packard (Palo Alto, CA) Hypersil ODS 3 μm

reversed phase column. A convex gradient (No. 1, Shimadzu solvent program, Kyoto, Japan) from the initial 2-propanol/methanol/water (40:60:5, v/v/v) in pump system A to 50% hexane/2-propanol (70:30, v/v) in pump system B was employed at a flow rate of 1.5 mL/min and with a program time of 25 min, and the absorbance of the eluate was monitored at 210 nm. Dolichols were well separated from dolichyl esters, which had longer retention times. Dolichyl-P was separated by HPLC as described earlier (16). The radioactivity in the dolichol, dolichyl-P and dolichyl ester fractions was determined by scintillation counting.

Chemicals. Dolichol-19 and dolichol-23 were isolated from autopsy specimens of human liver using reversed phase column chromatography. Dolichyl-19 linoleate was synthesized by esterification of dolichol-19 with the corresponding acyl chloride (40). For phosphorylation of dolichol-23, the method described by Danilov and Chojnacki was used (41). Labeling of dolichol-19 with tritium was achieved with NaB^3H_4 (14 Ci/mmol, New England Nuclear, Boston, MA), according to Keenan and Kruczek (42). The palmitic acid used in incubations was first complexed with albumin. Then, 75 μCi of [^{14}C]palmitic acid (57 mCi/mmol (The Radiochemical Centre, Amersham, England) and 7 mg of unlabeled palmitic acid were mixed, the pH adjusted to 9.5 and, after evaporation, the mixture was resuspended in 1 mL 0.9% NaCl (70°C, 20 min). Finally, the albumin complex was prepared by mixing 1 mL of the fatty acid solution with 1 mL 0.9% NaCl containing 200 mg fatty acid-free albumin at pH 7.4 (43). 1,2-Dipalmitoyl-*sn*-glycero-3-phospho[*methyl*-^{3}H]choline (72 Ci/mmol) was purchased from The Radiochemical Centre.

RESULTS

In agreement with previous studies, hepatocytes isolated by the collagenase method were found to effectively take up lipids from liposomes present in the incubation mixture (10). The chemical composition and surface charge of the liposomes had no great effect on the rate of uptake and, for this reason, egg lecithin was used as the major liposomal lipid in all experiments. The uptake of unilaminar vesicles was much more effective than was uptake of multilaminar liposomes. Care was taken to use liposomes that were prepared freshly by sonication. In control experiments the liposomes were added to hepatocytes. The hepatocytes were then fractionated and radioactivity associated with the microsomes was determined. Liposomes were also added to hepatocyte homogenates, which were fractionated and microsomes were analyzed. In neither case was a sizeable amount of radioactivity associated with the microsomal fraction, which excluded the possibility that cofractionation of liposomes had occurred.

Uptake of [^{3}H]dolichol. Hepatocytes take up measureable amounts of liposomal lipids within 30 min of incubation. In these uptake experiments, radioactive dolichol-19 was mixed with non-labeled dolichol to obtain a liposomal content of 2%. After 30 min of incubation, most of the dolichol had entered the cells and was associated with the microsomal fraction, whereas its concentration in the mitochondrial/lysosomal fraction was relatively low (Fig. 1A). The hepatocytes were then washed and the incubation was continued in the absence of liposomes. After 30 additional min of incubation, the microsomal dolichol concentration decreased rapidly, while the low level of radioactivity in the mitochondria/lysosomes was unchanged. After a 30-min incubation with liposomes, a portion of the dolichol in the microsomes became esterified with a fatty acid. It is known that the acyl-CoA:dolichol acyltransferase is localized in the endoplasmic reticulum (38) (Fig. 1B). The amount of dolichyl ester increased during the first 60 min of incubation, followed by a decrease during the next 30 min. In contrast to dolichol, dolichyl esters did not remain at the original low levels in lysosomes, but

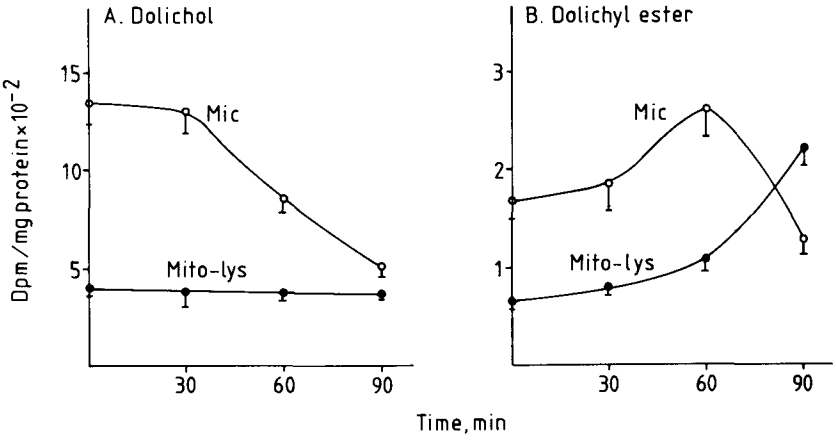

FIG. 1. Distribution and esterification of liposomal [^{3}H]dolichol in hepatocytes. Hepatocytes were incubated with liposomes containing [^{3}H]dolichol for 30 min. After this pulse labeling, the cells were recentrifuged, washed, and post-incubated for 90 min and the microsomes and mitochondrial/lysosomal fractions were prepared. Time 0 represents the start of the post-incubation period. The amounts of labeled dolichol (A) and dolichyl ester (B) were determined. The values are the means of 7 experiments; the vertical bars represent SEM.

increased continuously until after 90 min levels had increased 3-fold.

In some experiments, isolated microsomes were centrifuged on a $MgCl_2$-containing gradient, as described in Materials and Methods, which removed two-thirds of the plasma membrane contamination. There was no decrease in the [^{3}H]dolichol content in microsomes which had been purified in this manner, which shows that the label is not associated to any great extent with plasma membranes.

Uptake of [^{3}H]dolichyl linoleate. The previous experiment demonstrated that dolichyl ester, but not free dolichol, appears to be transported from the endoplasmic reticulum to the lysosomes (38). Therefore, experiments with dolichyl ester were also performed. When hepatocytes were incubated with liposomes containing [^{3}H]-dolichyl-19 linoleate, the amount of radioactive dolichyl ester recovered in microsomes increased rapidly (Fig. 2A). In the initial period, the level of the radioactive ester in the mitochondria/lysosomes was very low and an increase was observed only during the second half of the incubation period. A 5-min pulse gave relatively low labeling in the microsomes, and during the postincubation without liposomes radioactivity increased during the first 5 min followed by a decrease during the next 10 min (Fig. 2B). During the initial period of post-incubation, no significant increase in radioactivity associated with dolichyl ester could be observed in mitochondria/lysosomes and no free dolichol was detectable in the two organelle fractions studied.

Hepatocytes were also incubated with liposomes containing dolichyl esters for 30 min and relocation events were followed during a subsequent 100-min post-incubation period in the absence of liposomes. The microsomal labeling increased during the first 40 min of post-incubation, followed by a rapid and continuous decrease (Fig. 3A). The pattern of labeled polyisoprenoids in the supernatant was very similar to that found in microsomes. In the mitochondrial/lysosomal fraction, the initial low labeling increased rapidly and after 100 min was 5 times higher than the initial value. The initial low concentration of the labeled free dolichol in lysosomes increased rapidly during the entire incubation period (Fig. 3B). As concluded previously, the esterase activity specific for dolichyl esters is associated with lysosomes (44). The low levels of labeled free dolichol in the microsomes and supernatant did not change significantly.

After incubating hepatocytes for 80 min with liposomes containing [^{3}H]dolichyl-19 linoleate, the isolated microsomes and lysosomes were further treated to separate the membranes from the luminal contents (Table 1). In microsomes, both dolichyl ester and its hydrolysis product dolichol were present only in the membrane fraction. About half of both of these lipids was recovered in the lysosomal membrane and half in the luminal content. Clearly, dolichyl linoleate is transported from the endoplasmic reticulum, either through the cytoplasm or in a membrane-associated form, to the lysosomes, where it is recovered to a large extent in the soluble luminal compartment.

Phosphorylation of [^{3}H]dolichol. Hepatocyte microsomes contain a CTP-kinase, which is capable of phosphorylating dolichol under *in vitro* conditions (45). The liposomal system we used here is suitable for examining whether this kinase functions in hepatocytes *in vivo*. In our system only 2–3% of the total [^{3}H]dolichol appeared to be in phosphorylated form. Thus, this experiment suggests that in isolated hepatocytes exogenous dolichol is not phosphorylated to any significant extent.

Esterification with [^{3}H]palmitic acid. In preliminary experiments it was found that [^{3}H]palmitic acid presented to hepatocytes as a complex with albumin is effectively transferred to the cytoplasm and used in various types of enzymatic reactions. Hepatocytes were incubated with the [^{3}H]palmitic acid complex for 90 min, during which time labeled dolichyl ester accumulated both in the

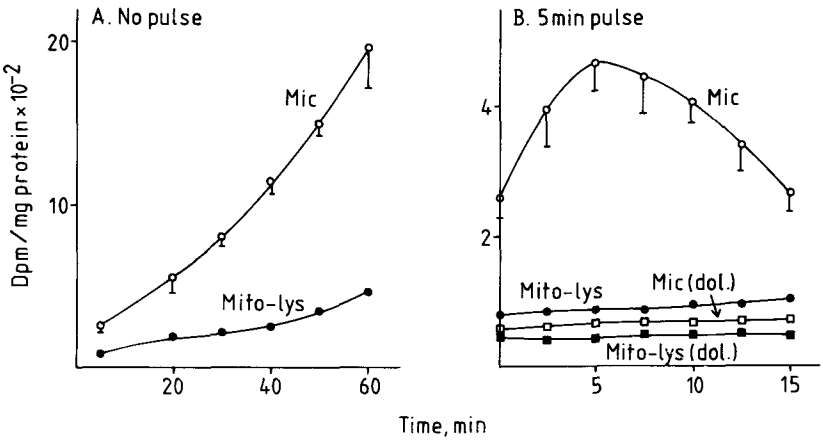

FIG. 2. Transfer of liposomal [^{3}H]dolichyl linoleate into hepatocytes. A. Liposomes containing dolichyl ester were present in the hepatocyte mixture throughout the entire incubation period. B. The hepatocyte suspension was incubated with the liposomes for 5 min followed by centrifugation and washing of the cells. The time periods given in the figure represent incubation times with the resuspended cells after the 5-min pulse labeling and subsequent washing. The values are the means of 9 experiments; the vertical bars represent SEM.

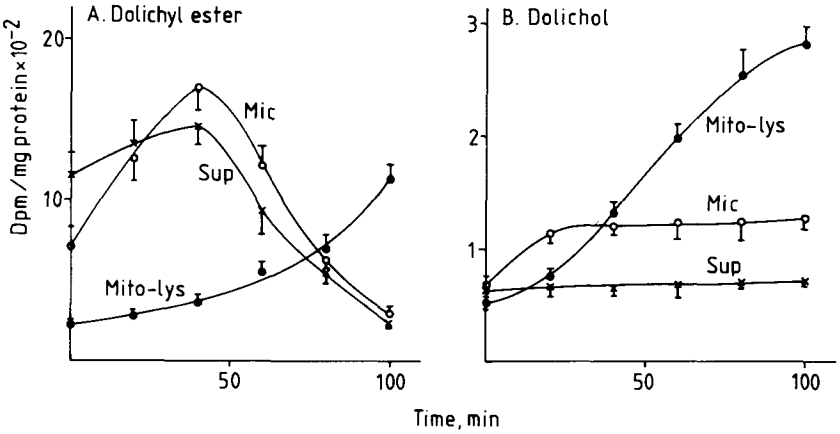

FIG. 3. Distribution and partial hydrolysis of liposomal [^{3}H]dolichyl linoleate in hepatocytes. Hepatocytes were incubated with liposomes containing [^{3}H]dolichyl linoleate for 30 min. After this pulse labeling, the cells were recentrifuged, washed, and post-incubated for 100 min. A. Distribution of [^{3}H]dolichyl ester in hepatocyte fractions. B. Appearance of nonesterified [^{3}H]dolichol in the isolated fractions. The values are the means of 7 experiments; the vertical bars represent SEM.

TABLE 1

Recovery of Liposomal [^{3}H]Dolichyl Linoleate in Subcellular Fractions from Hepatocytes[a]

	dpm/mg protein

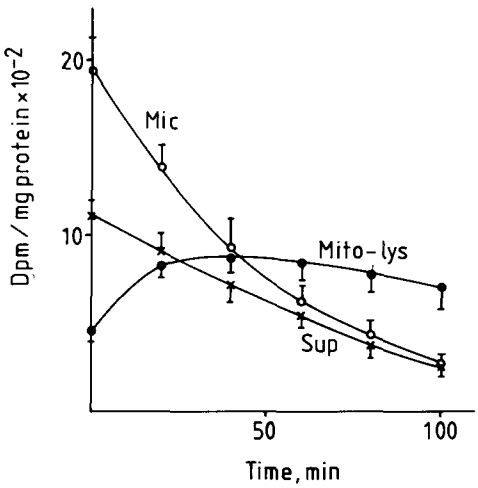

FIG. 4. Esterification of endogenous dolichol after incubation of hepatocytes with [^{3}H]palmitic acid-albumin complex. Hepatocytes were incubated with [^{3}H]palmitic acid for 90 min, followed by centrifugation and washing of the cells. The resuspended hepatocytes were post-incubated for 100 min. The values are the means of 6 experiments; the vertical bars represent SEM.

microsomes and in the supernatant (Fig. 4). In the following post-incubation period the concentrations of the radioactive lipid in both these fractions decreased rapidly during the initial 40 min and a concomitant increase in the mitochondrial/lysosomal fraction was observed. Thus, dolichyl ester synthesized within the hepatocyte exhibited a behavior similar to that of dolichyl ester supplied exogenously. Similar experiments were also performed using [^{3}H]mevalonate as biosynthetic precursor and the results obtained were similar to those described with [^{3}H]palmitic acid (data not shown).

Uptake of phosphatidyl[^{3}H]choline. The experiments with dolichol and dolichyl ester demonstrated preferential initial association of both lipids with the endoplasmic reticulum and subsequent transfer to the lysosomes. The question arose as to whether this behavior is typical for dolichols or is also seen with other lipids, such as phospholipids. Egg lecithin liposomes containing phosphatidyl[^{3}H]choline were therefore incubated with hepatocytes for 30 min (Fig. 5). The high level of labeled phospholipid in microsomes further increased during the first 40 min of post-incubation without liposomes followed by a continuous decrease in this fraction. The low levels of radioactivity in the mitochondrial-lysosomal fraction and in the supernatant were unchanged during the entire 100-min period (pre- and postincubation) studied. Thus, phosphatidylcholine supplied exogenously to the hepatocytes showed the same pattern of distribution as that described for dolichol.

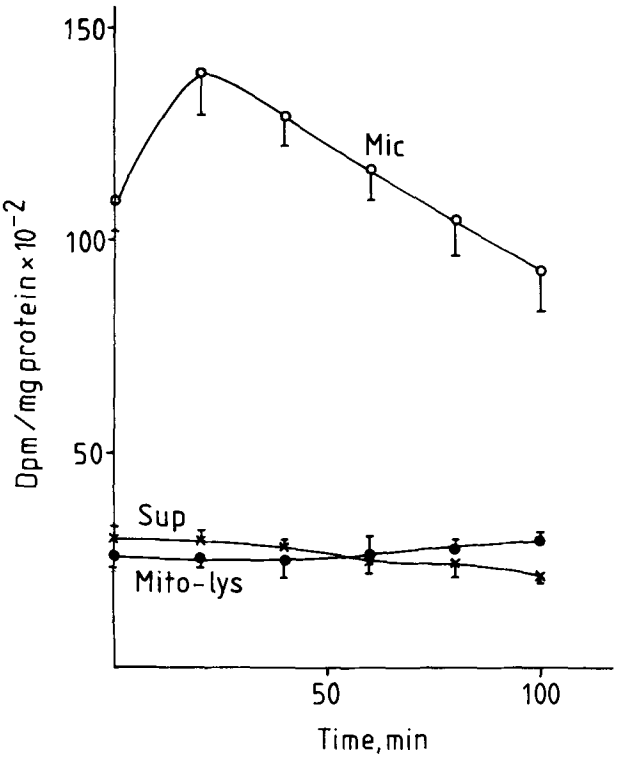

FIG. 5. Uptake of labeled phosphatidylcholine into hepatocytes. Hepatocytes were incubated for 30 min with liposomes containing 1,2-dipalmitoyl-*sn*-glycero-3-phospho[*methyl*-^{3}H]choline. The values show the distribution of label in the fractions during the post-incubation period. The values are the means of 6 experiments; the vertical bars represent SEM.

DISCUSSION

Hepatocytes isolated by EGTA-collagenase procedures are known to be of high quality, and a large number of metabolic and biosynthetic studies have been performed with these cells (46). Upon incubation with liposomes, the cells take up liposomal lipid components very efficiently and the rate of uptake greatly exceeds that observed with other types of cells (11). Interestingly, all lipid components of liposomes seem to be translocated into the cells, as observed here for free and esterified dolichol and phosphatidylcholine. This system seems suitable for studying the uptake of various lipids by hepatocytes since the process appears independent of the composition or the net charge of the lipids. A great number of experiments have demonstrated that during the 2–3 hr incubation, the cells appear to retain their normal metabolic capacity and that preincubation followed by washing allows efficient pulse labeling.

Previous investigations have shown that dolichol is taken up by cells, but the mechanism of its uptake has not been investigated in detail. The broad subcellular distribution of dolichol demonstrates that both the extracellularly supplied lipid and that synthesized in the cell are distributed effectively and do not remain only at one subcellular location. The transport mechanism for dolichol in the cell is not known, mainly because of the lack of suitable experimental systems. Our purpose was to supply the cell with highly labeled dolichol and to follow its appearance at various locations and to thereby obtain information on dolichol transport.

The experiments in this study have shown that the lipids appear first in the microsomes and that initially there is no uptake into mitochondria/lysosomes. Previous investigations had demonstrated that the mitochondrial dolichol content is low (47). Obviously, some incorporation of dolichol and dolichyl ester into mitochondria occurred in our system, but incorporation into lysosomes is much higher. Since the changes observed for the mitochondrial-lysosomal fraction reflect lysosomal changes, we used the combined fraction to deduce the events in lysosomes, as has previously been done (26). The uptake, evidently, is not receptor-mediated and does not involve the usual type of endocytosis. Liposomes rather appear to interact with the hepatocyte plasma membrane and with the individual lipid components in these structures not as liposomal membrane as such, but in micellar or carrier-bound form, to be transported to the endoplasmic reticulum.

One of the aims of our study was to find out in which form dolichol is transported within the cell. Upon incubation with dolichol, a small portion of the free dolichol became esterified in the endoplasmic reticulum and the dolichyl ester became transferred to the lysosomes within about 1–2 hr. These results are in agreement with previous investigations, where dolichol esterification and lysosomal transport were studied after metabolic labeling (38). Dolichol is esterified in the endoplasmic reticulum and the main purpose of this acylation appears to be to supply the lipid with a signal for further transport (48). Additional support for this idea of targeting was obtained when hepatocytes were incubated with the [^{3}H]palmitic acid—albumin complex. The early decrease in microsomal labeled dolichyl ester was paralleled by a concomitant increased labeling in lysosomes, again indicating that the ester is translocated.

In preincubated hepatocytes, microsomes had a high content of dolichyl ester, which, upon further incubation, decreased while the content in lysosomes increased. Evidence in support of the transport from the endoplasmic reticulum to lysosomes would be the demonstration of a precursor-product relationship, which is not possible at present.

Subfractionation of microsomal vesicles demonstrated that the translocated lipid is present mainly in the membrane. This may indicate that the lipid is transported *via* a membrane flow process, which is known to operate in the production of primary lysosomes, an organelle originating from the trans-Golgi reticulum. However, the presence of the dolichyl ester in the soluble cytoplasm during the post-incubation period suggests a cytoplasmic route of transfer. When microsomal esterification was monitored using [^{3}H]palmitic acid, dolichyl ester appeared rapidly in the cytoplasm, which suggests that the main mechanism operative in dolichyl ester transfer from the endoplasmic reticulum to lysosomes is a cytoplasmic transport and not a membrane flow.

Further transport of lysosomal luminal dolichol is of considerable interest. Lysosomal cholesterol is to a large extent transported to the bile (49) and it appears that such excretion occurs also with dolichol (15,16). There is experimental evidence that newly synthesized dolichol appears as free alcohol in the bile. According to this

mechanism, dolichol receives a fatty acid targeting signal in the endoplasmic reticulum, which is followed by its transport to the lysosomes. After hydrolysis by the specific lysosomal esterase, dolichol is translocated to the bile, either in unchanged or in metabolized form.

The exogenous dolichol recovered in microsomes is not phosphorylated to any significant extent, which indicates that the microsomal CTP-kinase does not produce dolichyl-P. This result is in agreement with previous investigations with hepatocytes from adult rats (50,51). In primary cell cultures where the mevalonate pathway was inhibited by compactin, only about 10% of the normal amount of dolichyl-P was found to be synthesized by phosphorylation of free dolichol (52). Pulse-labeling experiments with hepatocytes led also to the conclusion that dolichyl-P in these cells arises by *de novo* synthesis. In contrast, under conditions where the requirement for dolichyl-P is increased, such as during embryonic development and carcinogenesis, the CTP-kinase may play a role in dolichol phosphorylation (53,54). Consequently, it would be of interest in the future to conduct similar liposome/hepatocyte experiments with cells prepared from newborn animals or neoplastic tissue.

It is evident that liposomal lipids are transferred to the plasma membrane and, subsequently, to the cytoplasm by a mechanism which results in preferential incorporation into the endoplasmic reticulum. This pathway differs markedly from the receptor mechanism for the lysosomal uptake of low density lipoprotein, which has been studied in detail. Clearly, both mechanisms are operating for both phospholipids and neutral lipids. By monitoring these two processes, one may obtain detailed information about the distribution and excretion of lipids in hepatocytes.

Effect of Ethanol on Platelet Phospholipase A_2

Christopher D. Stubbs* and **Raphael Rubin**
Department of Pathology and Cell Biology, Thomas Jefferson University, Philadelphia, Pennsylvania 19107

Platelet aggregation is known to be inhibited by ethanol, and this has been suggested to be one of the attenuating effects of ethanol in cardiovascular disease. Recent studies have implicated an inhibition of phospholipase A_2 induced arachidonic acid release, since the production of prostanoids that are formed from arachidonic acid and are involved in the aggregation process has been shown to be diminished by ethanol. Phospholipase A_2 is found in platelets in both a cytosolic form, from where it may translocate to the plasma membrane to release arachidonic acid, and in a secretory form which is released extracellularly upon activation. In the present study, the effect of ethanol on the secretion of phospholipase A_2 and on its activity was determined. It was found that ethanol inhibited phospholipase A_2 secretion but not its activity. By contrast, the activity of the cytosolic form of phospholipase A_2 was inhibited by ethanol.
Lipids 27, 255-260 (1992).

There is considerable evidence that ethanol exerts an inhibitory effect on platelet aggregation (1-8), and it is possible that this could contribute to its attenuating effect in cardiovascular disease (reviewed in ref. 9). A number of studies have shown that ethanol inhibits the synthesis of prostanoids including thromboxane A_2, which is involved in the aggregation process (1-7). These findings would imply that ethanol reduces the level of arachidonic acid release. Indeed addition of exogenous arachidonic acid is known to alleviate the effect of ethanol (*e.g.*, see ref. 6).

The release of arachidonic acid may be due to the action of one or both of two enzymes, phospholipase C and phospholipase A_2. Phospholipase C activation would lead to the release of inositol 1,4,5-triphosphate and diacylglycerol. Inositol 1,4,5-triphosphate then induces an increase in intracellular Ca^{2+}, and the diacylglycerol activates the regulatory protein kinase C. Arachidonic acid is then formed by the breakdown of diacylglycerol by diglyceride lipase. However, this pathway accounts for only a minor proportion of arachidonic acid release. The major source of arachidonic acid in platelets is phospholipids in which arachidonic acid resides in the *sn*-2 position and is released by the action of phospholipase A_2 (*e.g.*, see ref. 10,11). Recently, an inhibition by ethanol of the release of arachidonic acid has been demonstrated, and an effect on phospholipase A_2 was thereby implicated (12,13).

There is evidence for existence of more than one form of phospholipase A_2 in platelets (discussed in recent reviews, see ref. 14,15). Two types of phospholipase A_2 have been recognized, a cytosolic form of 90 kDa molecular weight (16-20) and a secretable, 14 kDa "type II" form (21-26; see also reviews 14,15). The cytosolic form can be translocated to the membrane surface as a result of an increase in intracellular Ca^{2+}, and it appears to be identical to a number of unknown membrane associated forms of the enzyme (27).

There is also evidence for arachidonoyl phospholipid species specificity of the cytosolic form of phospholipase A_2 in the platelet (16,19,28). However, platelet phospholipase A_2 can also hydrolyze other species (18,29-31), and if pre-labeled glycerol is used, all phosphatidylcholine (PC) species were found to be hydrolyzed to similar extents (29, 30). A lack of selectivity is also consistent with the observation that a partially purified rabbit platelet phospholipase A_2 did not show acyl-chain selectivity (32). Although in a recent study it was found that while the arachidonoyl PC species were hydrolyzed more rapidly than the linoleoyl PC species, in a mixture of the two species both were equally hydrolyzed (18). In spite of these latter observations, the release of the fatty acids from stimulated platelets, determined as mass changes in individual molecular species, does appear to show some arachidonoyl phospholipid species selectivity (16). An arachidonic acid selective phospholipase A_2 has recently been cloned (27). Taken together, above studies suggest that the phospholipase A_2, which is selective for arachidonate phospholipid species, may be compartmentalized in a manner which optimizes the release of arachidonic acid upon stimulation. This would fit in with the other observation that selectivity was best observed with minimal perturbation of the membranes (33). This may also imply that there may exist more than one cytosolic form of phospholipase A_2.

The secretable form of phospholipase A_2 is located in α-granules (21,25), as was shown by recent immunochemical-labelling studies (23). Detailed characteristics of the secretory phospholipase A_2, including substrate specificity, Ca^{2+} requirement, heat stability, and pH optimum, have been described (22,26). Studies in which phospholipase A_2 from rat and human platelets were compared have revealed that the level of secretion, or activity, of the rat phospholipase A_2 is much greater (22). At present there is no evidence for any fundamental differences between the rat and human phospholipase A_2 and it is entirely possible that observed differences in activity are due to the presence of an endogenous inhibitor.

While ethanol has been shown to inhibit the release of arachidonic acid from stimulated platelets (12,13), it is not known whether the effect is specific for the cytosolic form of the enzyme. To investigate the locus of ethanol action, the effects of ethanol on both forms of phospholipase A_2 were examined. Rat platelets were used since the secretory phospholipase A_2 is more readily obtained. The results revealed that ethanol inhibited the secretion of phospholipase A_2 but not its activity. By contrast, the cytosolic phospholipase A_2 was inhibited, although the effect was not specific to arachidonate.

MATERIALS AND METHODS

Materials. Male Sprague-Dawley rats (100-200 g) were obtained from Charles River Laboratories (St. Constant, Quebec, Canada). Thrombin, prostacyclin, indomethacin,

*To whom correspondence should be addressed at Room 271 JAH, Thomas Jefferson University, 1020 Locust Street, Philadelphia, PA 19107.

Abbreviations: ATP, adenosine triphosphate; C_6-NBD-PC, *1*-palmitoyl-2-*N*-(7-nitrobenzo-2-oxa-1,3-diazol-4-yl)amino)hexanoylglycerophosphocholine; EGTA, ethyleneglycol-*bis*(β-aminoethyl ether)-*N,N,N',N'*-tetraacetic acid; HA, hexanoic acid; HEPES, *N*-[2-hydroxyethyl]-piperazine-*N'*-[2-ethanesulfonic acid].

and arachidonic acid were obtained from Sigma (St. Louis, MO); lipid standards and *1*-palmitoyl-*2*-*N*-(7-nitrobenzo-2-oxa-1,3-diazol-4-yl)amino)hexanoyl-glycerophosphocholine (C_6-NBD-PC) was from Avanti Polar Lipids (Birmingham, AL); 6-(*N*-(7-nitrobenzo-2-oxa-1,3-diazol-4-yl)amino) hexanoic acid) was from Molecular Probes (Eugene, OR). The radiolabeled lipids [5,6,8,9,11,12,14,15-^{3}H]arachidonic acid (206 Ci/mmol),*1*-stearoyl-*2*-[5,6,8,9,11,12,14,15-^{3}H]arachidonoyl-*sn*-glycero-3-phosphocholine (120 Ci/mmol) and 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (53.8 mCi/mmol) were from Amersham International (Arlington Height, IL). Solvents and other reagents were from Fisher Scientific (Pittsburg, PA).

Platelet preparation. Blood was taken by cardiac puncture from rats anesthetized by nembutol. The blood was anticoagulated with 0.38% (w/v) sodium citrate and centrifuged at 140 × *g* for 20 min at room temperature. The platelet-rich plasma was further centrifuged at 600 × *g* for 20 min and the pellet washed and resuspended in 10 mM (*N*-[2-hydroxyethyl]piperazine-*N'*-[2-ethanesulfonic acid] (HEPES) pH 7.4 buffer with 5 mM NaH_2PO_4, 1 mM $MgSO_4$, 5 mM KCl, 145 mM NaCl, 10 mM dextrose, and 0.1 mM ethyleneglycol-*bis*(β-amino ethyl ether)-*N,N,N',N'*-tetraacetic acid (EGTA).

Phospholipase assay. For the release of arachidonic acid from activated platelets, [^{3}H]arachidonic acid was preincorporated by incubation of platelets with buffer containing 1 mg/mL fatty acid free albumin and [^{3}H]arachidonic acid (1 μCi/2 × 10^8 cells) for one hr in a shaking water bath; arachidonic acid not incorporated was removed by a centrifugation step. The cells were washed and finally resuspended in HEPES buffer pH 6.4 containing prostacyclin at 5–8 × 10^8 cells/mL. After incubation with thrombin (2U/10^6 cells) for 15 min, chloroform/methanol was added to the cells to stop the reaction and to extract lipids (34). The lipids from the chloroform phase (which included 0.01 mg/mL butylated hydroxytoluene to minimize oxidation) were then applied to a Silica Gel 60 plastic backed thin-layer chromatography (TLC) plate (EM Reagents, Cherry Hill, NJ) and separated using chloroform/methanol/acetic acid/H_2O (90:8:1:0.8, by vol). The phospholipids remained at the origin, and the location of arachidonic acid was verified by comparison with a standard. Corresponding regions were cut out, and radioactivity was determined using Budget-Solve scintillation fluid (Research Products Int., Mt. Prospect, IL).

The assay of the secreted phospholipase A_2 was performed using C_6-NBD-PC as the substrate, as previously described (35). Briefly, a suspension of C_6-NBD-PC (0.8 nmol) in buffer was added to platelets (0.4 mL, 2 × 10^8 cell/mL) or to the supernatant obtained from activated platelet suspensions (see above) in the presence of 1 mM Ca^{2+}. After 15 min, the reaction was terminated by addition of chloroform/methanol (34). The method depends on the release of the fluorescent fatty acid NBD-hexanoic acid from the *sn*-2 position and its recovery in the upper aqueous phase after the addition of chloroform/methanol, while the unhydrolyzed C_6-NBD-PC remains in the lower chloroform phase. The NBD-hexanoic acid was recovered from the upper aqueous phase and was easily quantified by virtue of its fluorescence relative to a standard.

Phospholipase A_2 activity of the particulate fraction of broken cell preparations was determined using vesicles consisting of natural phospholipids (100 μM) prepared from liver microsomes (36) / C_6-NBD-PC / *1*-stearoyl-*2*-[^{3}H]arachidonoyl-*sn*-glycerophosphocholine /*1*-palmitoyl-*2*-[^{14}C]oleoyl-*sn*-glycerophosphocholine (93:5:1:1, molar). The vesicles were made by mixing the components in a test tube, removal of the solvent by a stream of nitrogen, and addition of buffer. The suspension was then vortexed for 2 min to obtain a multilamellar vesicle suspension. The vesicles were added to the platelet phospholipase A_2, with 1 mM Ca^{2+}, and incubated at 37°C for 30 min. The reaction was terminated as described above. The release of radiolabeled arachidonic and oleic acid was determined by TLC of the lower chloroform phase. The release of NBD-hexanoic acid was determined as described above. TLC separations were carried out using Merck HPTLC plates (Darmstadt, Germany) as described previously (37). The positions of the phospholipids and fatty acids were verified by the use of lipid standards and were visualized by exposure to iodine vapor. The lipids were then scraped from the plate and radioactivity was counted as described above using an ^{3}H and ^{14}C dual window.

RESULTS

In previous studies with human platelets it was shown that the release of arachidonic acid is inhibited by ethanol (13,14). The experiments were repeated here using rat platelets, and essentially the same results were obtained (Fig. 1). The secretory phospholipase A_2 of rat platelets has been studied in some detail by others (22–26); its activity is somewhat higher than that of human platelets making it the system of choice for present study.

For study of the secretory phospholipase A_2 it was important to ascertain that cytosolic phospholipase A_2 was not able to hydrolyze the substrate. One way to separate the platelets from secreted phospholipase A_2 is by centrifugation. However, activated platelets are somewhat fragile. To be certain that membrane fragments from activated platelets would not remain in the supernatant with the secreted phospholipase A_2, high speed centrifugation would have been required to segregate the two. In addition, an unstimulated control would be difficult to obtain because centrifugation itself may cause stimulation. To avoid these complications, the phospholipase A_2 substrate C_6-NBD-PC was used. This substrate, while being rapidly taken up into the external bilayer leaflet of the plasma membrane, crosses the plasma membrane to the inner leaflet only very slowly (38), so it normally would not be hydrolyzed by cytosolic phospholipase A_2. While it is conceivable that flip-flop of phospholipids in the activated platelets may have allowed some access of the cytosolic phospholipase A_2 to C_6-NBD-PC, in a sonicated "particulate" preparation (from which the soluble or secreted phospholipase A_2 had been removed by centrifugation) while efficiently hydrolyzing natural PC substrates, only marginal activity against C_6-NBD-PC was noted (see below). Therefore the contribution of cytosolic phospholipase A_2 (in the inner leaflet) to the hydrolysis of any C_6-NBD-PC which had crossed to the cytosolic side should have been negligible. Separation of the stimulated platelets from the secreted phospholipase A_2 was therefore not obligatory. The assay also offers other advantages as previously detailed (39).

The optimal concentration of thrombin required for the phospholipase A_2 secretion is shown in Figure 2. It was

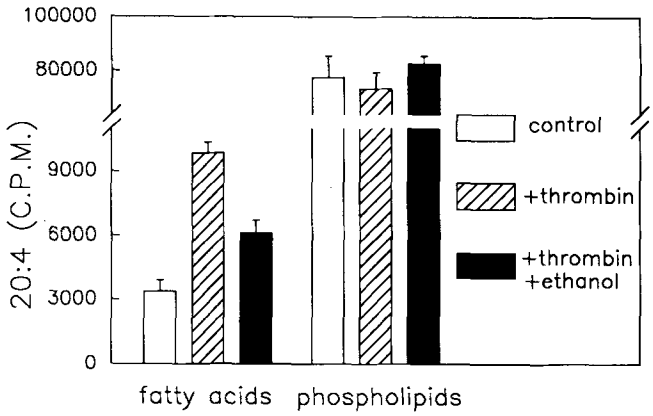

FIG. 1. Effect of ethanol (100 mM) on thrombin (0.2 U/mL) stimulated release of arachidonic acid from rat platelet membrane phospholipids. Results are expressed as the arachidonate released in the form of free fatty acid and the arachidonate remaining esterified to the platelet phospholipids (CPM, mean of ⩾ 3 experiments ± SD, details are as described in Materials and Methods).

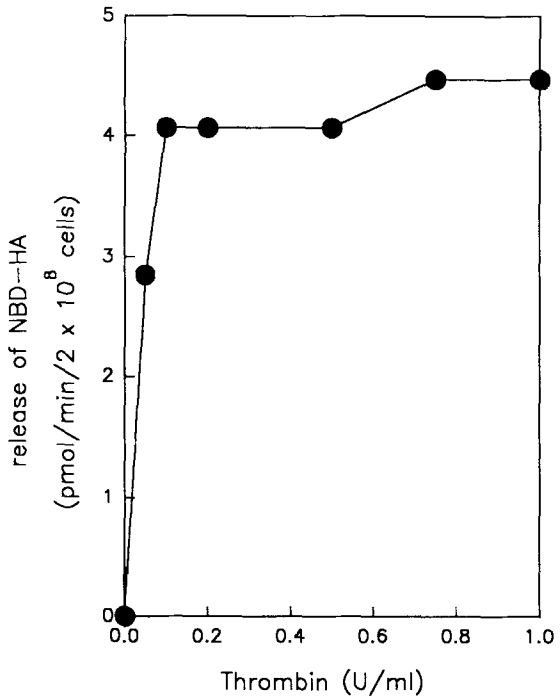

FIG. 2. The thrombin concentration dependence of the secreted phospholipase A_2, assessed by the hydrolysis of C_6-NBD-PC (details as described in Materials and Methods).

found that phospholipase A_2 activity increased with thrombin concentration to ~ 2 U/mL after which it reached a maximum. The secretory phospholipase A_2 could also be obtained by sonication in the absence of thrombin or Ca^{2+}.

In order to confirm that the phospholipase A_2 activity detected with activated platelets using C_6-NBD-PC was soluble, the cells were pelleted by centrifugation (600 × *g* for 10 min) and the supernatant and the pellet was examined for phospholipase A_2 activity. It was found that phospholipase A_2 was indeed released from the cells since activity was recovered in the supernatant (see Fig. 3). The phospholipase A_2 release, after thrombin stimulation, was extremely rapid, occurring in seconds. The phospholipase A_2 release showed no further increase, as demonstrated by recovering the released phospholipase A_2 at different time points after activation (Fig. 3). There was a slight apparent decrease of activity with time after the initial secretion, which may have been due to some re-incorporation of NBD-hexanoic acid (NBD-HA) (released by the phospholipase A_2) into other membrane phospholipids prior to the centrifugation of the cells. It should be noted that the activity was higher after sedimentation than in cell suspensions. Thus activation by the centrifugation procedure may have activated resilient platelets that had not activated by thrombin alone and required the extra stimulus, or the centrifugation released trapped phospholipase A_2. It is also not possible to exclude that some cytosolic phospholipase A_2 may have been released. However, if C_6-NBD-PC is a poor substrate for cytosolic phospholipase A_2, as evidence suggests, and considering that the total level of activity of this phospholipase A_2 was much lower than that of the secreted form, this should not have been a significant factor. To confirm that the released phospholipase A_2 was soluble, the supernatant was also centrifuged at 100,000× *g* for 60 min. Examination of the supernatant still revealed the presence of phospholipase A_2 (7.8 pmol NBD-HA/min/2 × 10^6 cell, similar to the activity obtained after low speed centrifugation) showing that it was the secreted form. The production of NBD-hexanoic acid, indicative of phospholipase A_2 activity was confirmed using TLC and respective standards. Although the centrifugation procedure was effective for measuring the time course of phospholipase A_2 release and to demonstrate that the released phospholipase A_2 was soluble, problems in using centrifugation with platelets for studying the secreted phospholipase A_2 point to the advantage of using the C_6-NBD-PC substrate.

To explore the effect of ethanol on the phospholipase A_2 secretion, thrombin activated platelets were examined by addition of ethanol prior to stimulation. The phospholipase A_2 activity and/or amount of phospholipase A_2 released was reduced as shown in Figure 4.

The effect of ethanol on the secretory phospholipase A_2 (*after* activation) was also investigated to determine if the amount of phospholipase A_2 secreted, or its activity, was affected by ethanol. Platelets were subjected to 5 × 15 sec bursts of ultrasonication (with 15 sec pauses) using a Fisher Sonicator at 50% full power with a microtip probe, followed by ultracentrifugation at 100,000 × *g* for one hr and separation into soluble and particulate fractions. To the soluble and particulate fractions, respectively, was added a PC vesicle suspension containing labeled arachidonoyl, oleoyl and NBD-hexanoyl PC (as described in Materials and Methods). Hydrolysis of the three substrates was simultaneously determined and is shown in Figure 5. The results reveal that there was only a marginal effect of ethanol on the secretory phospholipase A_2 *activity* for all three substrates, as distinct from an inhibition of *secretion* of phospholipase A_2. The rate of hydrolysis of phospholipase A_2 in the particulate fraction was much lower than that for the secretory phospholipase A_2. This may have been due to a lesser amount of phospholipase A_2, a lower activity, or to difficulties in sub-

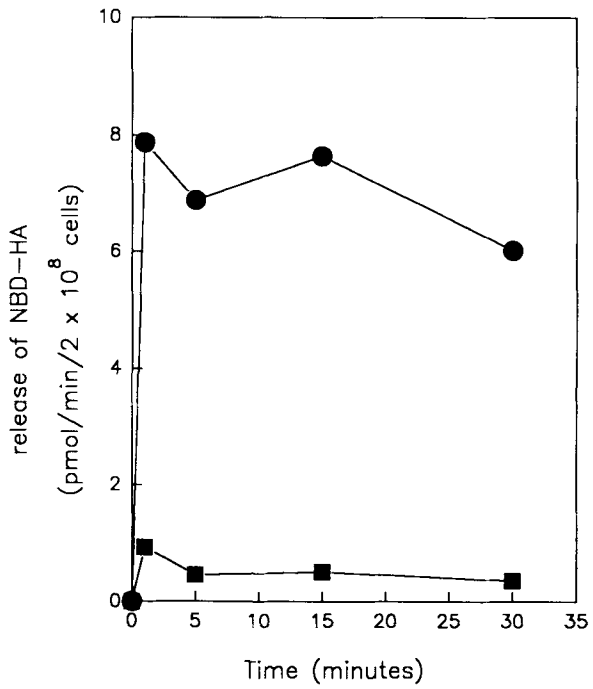

FIG. 3. The phospholipase A_2 activity (using the substrate C_6-NBD-PC) recovered in the supernatant [filled circle] from platelets stimulated using thrombin (0.2 U/mL and 1mM Ca^{2+}) at different times of stimulation separated as described in Materials and Methods.

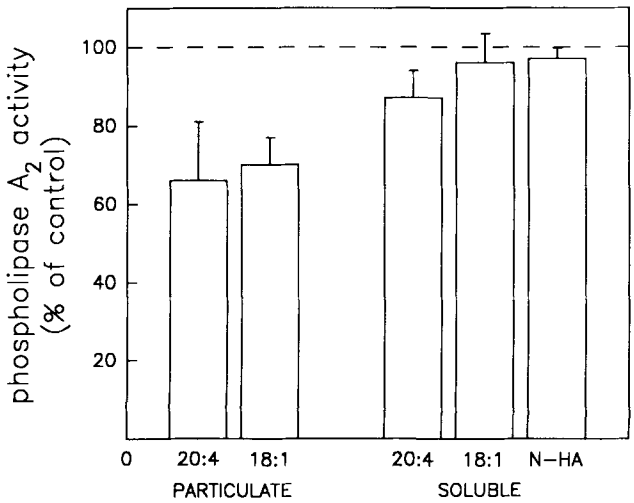

FIG. 5. Effect of ethanol (100 mM) on the activity of membrane associated phospholipase A_2 and on the phospholipase A_2 secreted from thrombin stimulated platelets. The results are expressed as the activity of phospholipase A_2 (in the presence of 100 mM ethanol) as a percentage of the activity in the absence of ethanol (soluble: 2.5ϱmol NBD-HA, 3.8ϱmol 18:1 and 3.2ϱmol 20:4/min/10^8 cells; particulate: 0.14ϱmol 18:1 and 0.12ϱmol 20:4/min/10^8 cells). The phospholipase A_2 activity was determined against PC multilamellar vesicles consisting of natural phospholipids (100 μM, prepared from liver microsomes, C_6-NBD-PC,*1*-stearoyl-*2*-[^{3}H]arachidonoyl-glycerophosphocholine and *1*-palmitoyl-*2*-[^{14}C]oleoyl-glycerophosphocholine (93:5:1:1 molar, details as described in Materials and Methods). The results are the mean of three determinations from one of two replicate experiments.

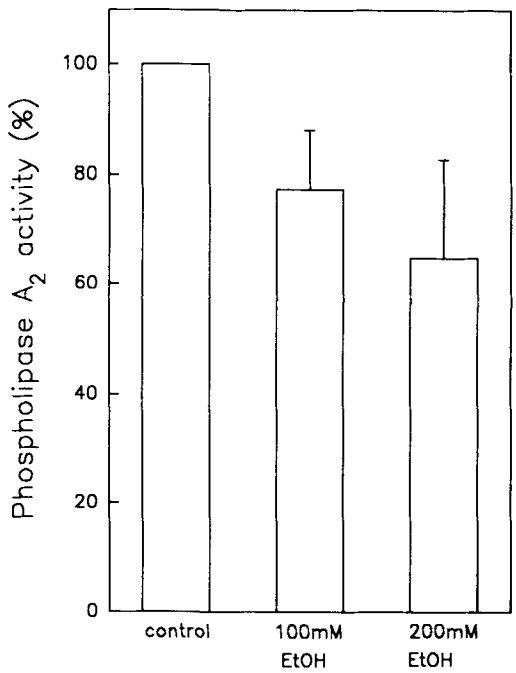

FIG 4. Effect of ethanol on the thrombin induced secretion phospholipase A_2, assessed by the hydrolysis of C_6-NBD-PC. The results are expressed as the activity of phospholipase A_2 as a percentage of the control (4.25ϱmol NBD-HA/min/10^8 cells). The activities in the presence of ethanol were significantly different from the control at the 0.05% level according to the paired t-test; the results are the mean of three experiments ± SD (details as described in Materials and Methods).

strate accessibility by the cytosolic phospholipase A_2. Alternatively, this could have been due to the cytosolic phospholipase A_2 being released in the course of the sonication process, although the level of phospholipase A_2 obtained by sonication and thrombin were similar. In addition, the rate of C_6-NBD-PC hydrolysis in the particulate fraction was too low to be accurately measured, possibly due to a preference of the cytosolic phospholipase A_2 for the natural PC substrates. The important finding was that while ethanol did not affect the secretory phospholipase A_2 activity, ethanol inhibited the hydrolysis of arachidonoyl- and oleoyl-PC in the particulate fraction as shown in Figure 5.

DISCUSSION

In previous studies it had been shown that ethanol inhibited the release of arachidonic acid from human platelets (13,14). To determine which of the two forms of phospholipase A_2 might be responsible, the effects of ethanol on both the secretory and cytosolic forms were examined. It was found that ethanol inhibited secretion of the secretory form of phospholipase A_2 but not its activity. By contrast, the cytosolic phospholipase A_2 was inhibited by ethanol.

We were able to demonstrate that rat platelets secrete phospholipase A_2 upon thrombin induced stimulation, confirming previous observations (21–26), but using C_6-NBD-PC as substrate. The use of C_6-NBD-PC in the investigation of platelet phospholipase A_2 is a novel and useful approach offering a convenient assay system, how-

ever, for phospholipid specificity studies, conventional methods with radiolabeled lipids are still advantageous. Next, it was demonstrated that ethanol inhibits the release of arachidonic acid from activated rat platelets as was previously demonstrated for human platelets (13, 14). The release of arachidonate resulting from platelet activation is normally considered to arise from the action of a cytosolic phospholipase A_2 after being bound to the plasma membrane. It should be noted, however, that the secreted phospholipase A_2 could potentially act on the external leaflet of the platelet membrane and could induce the release of arachidonate, a point worthy of future study.

In the present study, inhibition by ethanol of the secretion of phospholipase A_2 was observed. Ethanol is known to inhibit the secretion of 5-hydroxytryptamine and adenosine triphosphate (ATP) in stimulated human platelets (13,14), and it is therefore reasonable to explain the inhibition of phospholipase A_2 secretion by such a mechanism. Prior to the present study involvement of the secretory phospholipase A_2 had not been established. The mechanism whereby ethanol inhibits the secretion process is unknown; however, it has been shown that thrombin induced secretory granule centralization and fusion is inhibited by ethanol (14,40). Some experiments were performed to determine the secreted phospholipase A_2 from human platelets (results not shown); however, it was found that only very small amounts were released. This is consistent with the results of other studies (22). This shows that the rat platelet is a more useful model to determine the effects of ethanol on the secreted form of phospholipase A_2.

When the activity of the cytosolic phospholipase A_2 was examined, ethanol was found to inhibit its activity in terms of the release of *sn*-2 oleic or arachidonic acid from phosphatidylcholine. This contrasted with the lack of an effect of ethanol on the secretory form of the enzyme. The inhibition of the cytosolic form of phospholipase A_2 could occur either directly by action of ethanol on the enzyme itself or indirectly by acting on the various other regulatory mechanisms that occur in the platelet. There are relatively few studies on the effect of alcohol on phospholipase A_2. In one study concerned with venom phospholipase A_2, a slight stimulatory effect rather than an inhibition was found; however, the form of the enzyme differs greatly from the cytosolic phospholipase A_2 (41). Notwithstanding possible differences between the secreted phospholipase A_2 of rat and human platelets, there is no evidence to suggest that the membrane associated cytosolic forms of phospholipase A_2 differ to any extent so that an inhibition of human platelet membrane associated phospholipase A_2 by ethanol might be expected.

At present we can only speculate as to the mechanism of the inhibition by ethanol of membrane associated phospholipase A_2. As a pointer to further studies, it is worth noting that there is increasing evidence for a G-protein and/or protein kinase C involvement with (cytosolic/membrane associated) phospholipase A_2 in other tissues (42,43) as well as in platelets (44–46). It is quite possible that ethanol acts at the level of these proteins, as demonstrated, for example, for a G-protein association with phospholipase C in turkey erythrocytes (47). Other possibilities include protein kinase C which may regulate platelet phospholipase A_2 *via* phosphorylation, again probably *via* a G-protein (44,48,49).

Sphingomyelin membranes were prepared with different levels of oxidative damage caused by *tert*-butyl hydroperoxide (TBH). Temperature-induced changes in membrane hydrocarbon chain packing (phase transitions) were monitored using infrared spectroscopy. Lipid phase transition characteristics were evaluated from thermodynamic parameters fitted to the experimental transition curve data. At temperatures below the lipid phase transition T_c, hydrocarbon chains pack in an ordered state whereas above the T_c the hydrocarbon chains pack in a disordered state. Compared to the non-oxidized control, the packing of the hydrocarbon chains of mildly oxidized sphingomyelin (<10 nmol TBH/mg lipid) was no different at all temperatures below the T_c, and was more ordered above the T_c. The hydrocarbon chains of strongly oxidized sphingomyelin (>10 nmol TBH/mg lipid) were more disordered at temperatures above and below the T_c compared to the control samples. These results suggest that lipid oxidation has a dual effect on lipid order. A more ordered or disordered state may result depending on the degree of oxidation and the state of lipid order prior to oxidation. These results could be important for explaining the structural changes in oxidized membranes high in sphingomyelin such as those found in the ocular lens and liver plasma membranes.
Lipids 27, 261-265 (1992).

Lipid oxidation has been implicated in a number of pathological processes (1-4, and references therein) and is believed to alter protein structure and membrane function (5-10). The function of biological membranes is directly affected by the conformation and packing of the lipid components (11). An increase in the passive permeability of membranes has been attributed to conformational changes caused by lipid oxidation (12-17). Several studies have demonstrated that lipid oxidation orders the lipid matrix (18-27).

Of particular interest is the role of lipid oxidation in the process of cataractogenesis in the ocular lens (1). We have shown that low levels of oxidative damage induced by *tert*-butyl hydroperoxide (TBH) cause sphingomyelin, the major phospholipid of the lens membrane, to become more disordered (28). Both the headgroup and acyl chain regions of the bilayer were deranged (28). These results appear to be contrary to those reported for lipids that are fluid at physiological temperature (18-27). The purpose of this report is to determine the cause(s) of this disparity and to develop a general structural model that could explain previous and current results.

METHODS

Liposome preparation and oxidation. Liposome bilayer vesicles were prepared by dispersing sphingomyelin in an aqueous buffer consisting of 5 mM 4-(2-hydroxyethyl)-1-piperazine-ethanesulfonic acid and 100 mM KCl at pH 7.4. Sphingomyelin from bovine brain (99%) and all reagents were obtained from Sigma Chemical Co. (St. Louis, MO), and were used without further purification. Samples, each having approximate concentrations of 1 mg lipid per mL of buffer, were treated with TBH at 2-35 nmol/mg lipid. TBH-treated liposomes are hereafter referred to as "treated samples". The sphingomyelin from these samples was partitioned into chloroform at low temperature in an argon atmosphere to prevent auto-oxidation of hydrocarbon chains as described previously (28). This protocol removes any water-soluble secondary oxidation products in the aqueous phase. The extracted lipid was then dried under a stream of argon. Absorption spectra indicated that at least 99% of the lipid partitioned into the lower $CHCl_3$ phase.

Instrumentation and preparation of samples for spectroscopy. Liposomes were prepared by dispersing dried lipid samples, as described above, in a buffer at 150 mg/mL lipid. Thin films of samples were prepared by sandwiching 3 μL of sample placed between 13-mm diameter AgCl plates with a 0.015-mm spacer. Samples were warmed to 70°C for one hour to assure complete hydration. The sample was cooled from 70 to 0°C; then heated from 0 to 70°C. Temperature was changed at a rate of 0.1°C per min to avoid hysteresis and was controlled within ±0.1°C. Hysteresis, in this case is the lagging behind of transition properties, such as fluidity, when a sample is heated or cooled too quickly. The sample was allowed to equilibrate at a given temperature for 5 min before a spectral measurement was made. Infrared spectra were measured every 5°C which took about 2 min per spectrum. The spectra were acquired on a Nicolet 7199C Fourier transform infrared spectrometer (Cincinnati, OH), equipped with a triglycine sulfate detector. One hundred interferograms were co-added and apodized with a triangular function. The resulting effective spectral resolution was 2 cm^{-1}. The frequency of the lipid acyl chain CH_2 symmetric stretching band was measured with a precision of ±0.06 cm^{-1}. This precision was calculated from a set of independent measurements from four different preparations of the same sample.

Statistical evaluation of the lipid phase transition. It is difficult to measure and assess the accuracy of parameters such as relative cooperativity by visual inspection of lipid phase transitions curves. To circumvent these problems, a non-linear regression analysis was used to evaluate the parameters P_1, P_2, P_3 and P_4 from experimental phase transition data pairs (vibrational frequency in wavenumbers, temperature in K). The errors in the fitted parameters are usually greater than the precision by which the frequencies are measured. The function used in the fitting algorithm given below has been used previously (29):

$$\text{frequency} = P_1 + P_2/[1 + (P_3/T)^{P_4}] \qquad [1]$$

P_1 is the minimum wavenumber for the phase transition and represents the most ordered state of the transition.

*To whom correspondence should be addressed.

Abbreviations: TBH, *tert*-butyl hydroperoxide; UV, ultraviolet.

P_2, the magnitude of the phase transition, is the net change in wavenumber and represents the change in the number of *trans*-to-*gauche* rotomers. P_3 is the transition temperature and indicates the temperature at which half of the population of lipid molecules has undergone the phase change. P_4 is the relative cooperativity and describes the degree by which one lipid affects the state of order of adjacent lipids.

The enthalpies of the lipid phase transitions were calculated from Arrhenius plots (ln% *gauche* rotomers *vs* 1/T) as described previously (29).

The maximum frequency is a parameter that quantifies the maximum disorder of the hydrocarbon chains. It is calculated as the sum of P_1 and P_2, and represents the maximum frequency at an infinitely high temperature (see equation above).

RESULTS AND DISCUSSION

Fourier transform infrared spectroscopy was used to measure structural changes which resulted from oxidative damage induced by TBH treatment. Infrared spectroscopic techniques are not troubled by the limitations of spin probe techniques used to study oxidative damage on lipid structure (18-24,26,27). These limitations include: the influence of the probe on adjacent lipid molecules (30), the uncertainty of the location of the probe (31), the ineffectiveness of the probe at higher concentrations of cholesterol (32), such as those found in lens membranes (33), and the chemical modification of the probe (34). At best, spin probe studies only infer the order of lipid membranes and are not a direct measure of lipid conformation, environment and bilayer packing.

At lower temperatures, lipid hydrocarbon chains are usually in an ordered phase (gel phase), the fatty acyl carbons are in an all *trans* conformation, and van der Waals interactions and bilayer packing are maximized. At higher temperatures, lipids often form a disordered phase (liquid crystalline phase) where a number of C-C *gauche* rotomers are introduced diminishing van der Waals interactions between hydrocarbon chains (35,36). Thus upon increasing temperature, many lipid bilayer membranes undergo a change from an ordered to a disordered phase. The frequency of the CH_2 stretching band near 2850 cm^{-1} increases as the disorder and number of gauche rotomers increase. This band was used in this study to monitor the order of the lipid hydrocarbon chains as a function of temperature. From temperature *vs* lipid order curves, phase transition parameters were determined.

Figure 1 shows temperature-induced phase transitions for a suspension of sphingomyelin vesicles prior to (lower curves) and after (upper curves) oxidation. The gel-to-liquid crystalline phase transition was observed at about 36°C for the untreated lipid. The broad phase transition curves corresponding to samples treated with concentrations greater than 10 nmol TBH/mg lipid indicated the absence of a sharp phase transition over the temperature range measured. For this reason, above 10 nmol TBH/mg lipid, the T_c could not be assessed. However, other parameters were evaluated independently of the T_c. Below 8 nmol TBH/mg lipid, a linear increase in oxidative damage (28) caused no significant change in the transition temperature (Fig. 2A).

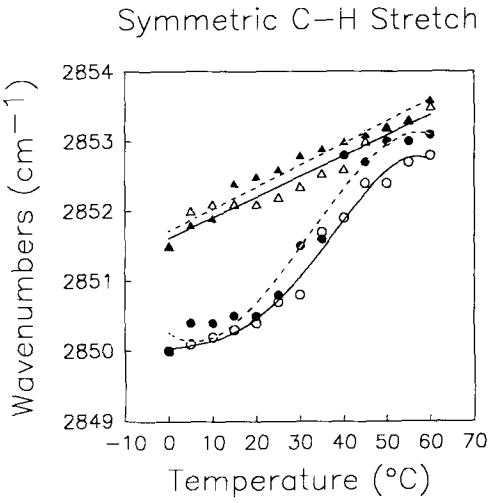

FIG. 1. Change in frequency of the CH_2 symmetric stretching band with temperature for sphingomyelin membranes: before (circles), and after (triangles) treatment with 20 nmol TBH/mg lipid. Closed symbols and dashed lines are for the cooling curves. Open symbols are for the heating curves. Higher wavenumber values indicate a more disordered membrane.

We have shown that the conjugated diene content increases linearly, and quantitatively with TBH concentrations between 0 and 50 nmol TBH/mg sphingomyelin (28). Precise quantification of the conjugated diene content measured by ultraviolet (UV) absorption at 241 nm is impeded by spectral interference due to bands corresponding to isolated double bonds and ketones. Consequently, the initial number of conjugated dienes is an approximation and is about 1 conjugated diene in 50 moles sphingomyelin. We have determined precisely that treatment of sphingomyelin with TBH (from 0 to 30 nmol TBH/mg sphingomyelin) causes a linear increase in the content of conjugated dienes. Four moles of conjugated dienes are formed per 50 moles of sphingomyelin when 1 mg of sphingomyelin is treated with 30 nmol TBH.

Mild oxidation, <10 nmol TBH/mg lipid. It is evident from Figure 2B that for concentrations below 10 nmol TBH/mg sphingomyelin, increasing lipid oxidation decreases the maximum C-H stretching frequency, which implies a decrease of acyl chain *gauche* rotomers, a measure of lipid disorder. Thus when sphingomyelin is in the disordered phase, oxidation levels below 10 nmol TBH/mg lipid order the membrane. These results are in accordance with those obtained using invasive probe techniques (18-27). This ordering effect with mild levels of oxidation is shown in Step 2b of Scheme 1. It is possible, for example, that at mild levels of lipid oxidation (<10 nmol TBH/mg lipid) *trans* double bonds are formed which may rigidify the bilayer (26,37). One would expect the transition enthalpy of the system to increase due to this type of stabilization. The transition enthalpy in fact remains constant with mild oxidation (Fig. 3). This disparity may be explained by a decrease in the magnitude of the phase transition (Fig. 2C). The decrease indicates that a smaller percentage of lipids are involved in the transition equilibrium 3 compared to that in equilibrium 1 (Scheme 1). The lack of significant change in the cooperativity (Fig. 2D) below 10 nmol TBH/mg lipid indicates

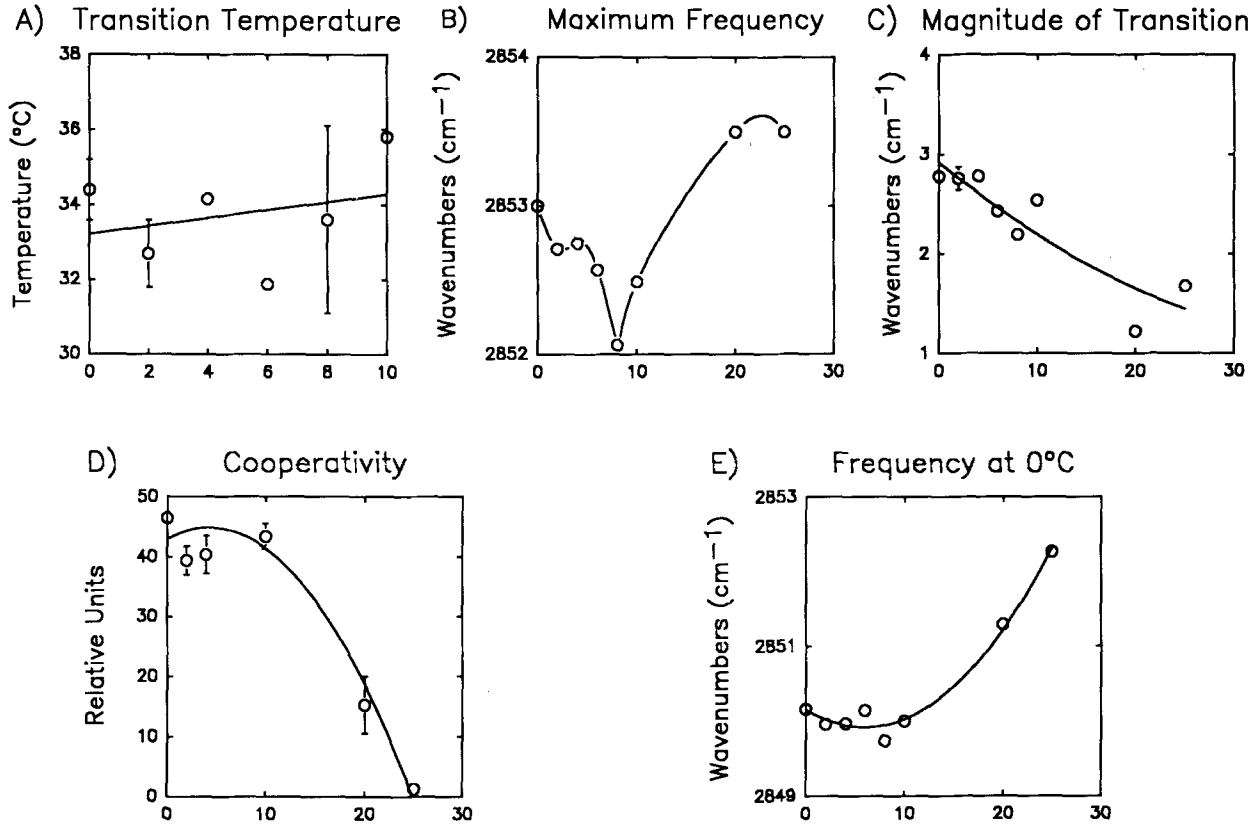

FIG. 2. The thermodynamic parameters were determined using non-linear regression analysis (see Methods) applied to phase transition curves such as those shown in Figure 1. X-axis is the concentration of TBH in nmol/mg lipid. Error bars are given for all data points unless the error is smaller than the symbol. In Figure 2A, the error bar for the data point corresponding to an abscissa value of 10 is ±7.

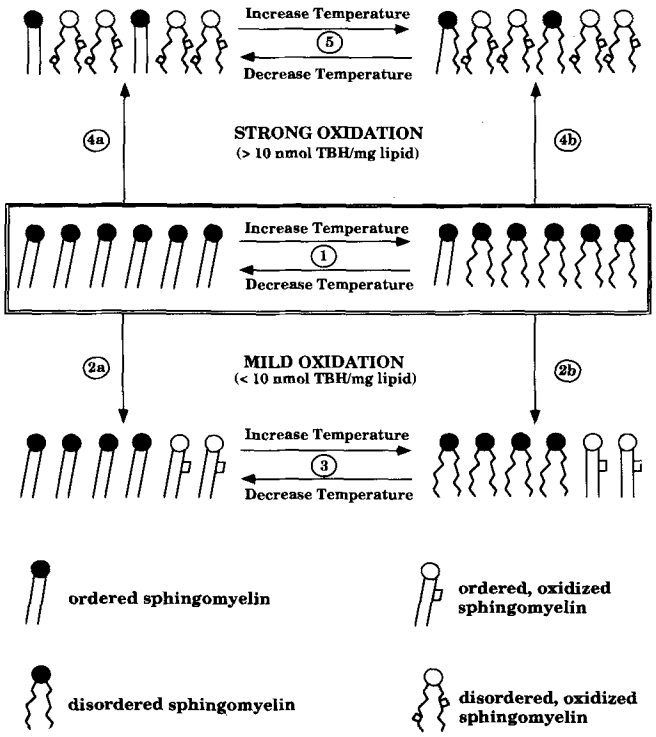

SCHEME 1

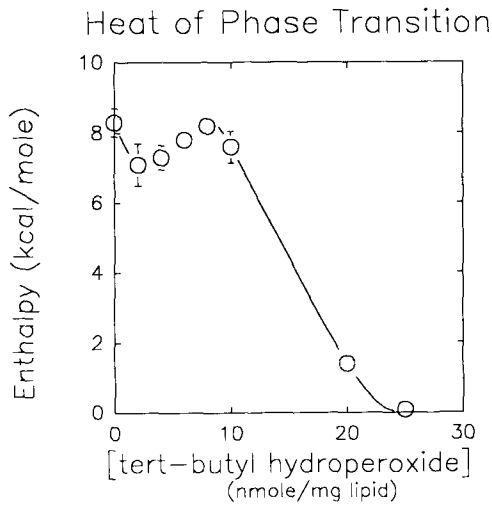

FIG. 3. The enthalpy of the lipid phase transitions was calculated from an Arrhenius plot (ln % *gauche* rotomers *vs* 1/T).

that the ordered oxidized lipids are laterally phase separated from the fluid lipids. The frequency at 0°C (Fig. 2E) does not change, indicating that mild oxidation has no effect on sphingomyelin in the ordered state (Scheme 1, Step 2a).

Strong oxidation, >10 nmol TBH/mg lipid. A small change in the maximum frequency (Fig. 2B) with strong oxidation indicates that at this level of lipid oxidation, packing of the hydrocarbon chains in the disordered phase is affected only slightly by oxidation. This is represented in Scheme 1, Step 4b. It should be noted that oxidation may have a more dramatic effect on the headgroup or interface region, packing, and/or may affect the dynamics of lipid motion. All of these parameters are not detected by merely measuring hydrocarbon chain structure. The observed increase in the frequency at 0°C (Fig. 2E) for high levels of oxidation may be considered as a disordering of the bilayer (Scheme 1, Step 4a). This disordering of the ordered phase at higher levels of oxidation has not been reported previously and may be caused by the disruption of van der Waals interactions by the introduction of hydrophilic peroxy groups into the hydrophobic lipid acyl chain environment. It is apparent that this increase in the level of disorder can overcome the ordering effect of *trans* bond formation observed at lower levels of oxidation. This is a unique finding and implies that natural membranes that are highly ordered, such as the ocular lens membranes, would become more fluid with increasing oxidation. We have observed this in a preliminary study of cataractous lens membranes (38) where lipids have been shown to contain a higher degree of oxidation than normal lens lipids (1). Oxidized disordered lipids in an ordered lipid matrix would be expected to increase the passive permeability of these membranes (39). An increase in passive permeability is observed during cataractogenesis (40-42).

A decrease in cooperativity (Fig. 2D) indicates that below the transition temperature, the unoxidized lipid is not laterally phase separated but dispersed in a fluid lipid matrix (Scheme 1, equilibrium 5). A decrease in the enthalpy (Fig. 3) and magnitude (Fig. 2C) of the phase transition indicates that fewer lipid molecules undergo an order to disorder phase change (Scheme 1, equilibrium 5) as compared to the mildly oxidized membranes (Scheme 1, equilibrium 3) and untreated membranes (Scheme 1, equilibrium 1). When membranes are highly oxidized and close to their maximum state of disorder, a slight disordering of the hydrocarbon chains is observed (Scheme 1, Step 4b).

Dimyristoyl phosphatidylcholine was used as a control since this phospholipid has no double bonds and is not oxidized with TBH. None of the thermodynamic parameters for dimyristoyl phosphatidylcholine were influenced by TBH treatment (Table 1). Thus all of the effects of TBH on sphingomyelin appear to be due to oxidative perturbation.

We have shown that lipid oxidation has a dual effect on lipid order in that it may result in a more ordered or a more disordered state depending on the degree of oxidation and the state of lipid order prior to oxidation. These studies will serve as a foundation to explain structural changes caused by oxidative damage to native membranes that are high in sphingomyelin, such as lens and liver plasma membranes.

TABLE 1

Thermodynamic Parameters for the Order to Disorder Phase Transition of Dimyristoyl Phosphatidylcholine Membranes Before and After Treatment with Oxidant

	Untreated	Treated with oxidant (20 nmol TBH/mg lipid)
Minimum frequency (cm^{-1})	2849.9 ± 0.2	2850.5 ± 0.1
Maximum frequency (cm^{-1})	2853.2 ± 0.3	2853.5 ± 0.2
Phase transition magnitude (cm^{-1})	3.3 ± 0.2	3.0 ± 0.2
Phase transition temperature (°C)	31 ± 0.9	29 ± 0.7
Cooperativity	119 ± 65	122 ± 46

Lecithin:cholesterol acyltransferase (LCAT) activity levels were determined, as function of plasma total cholesterol (TC) in 13 normocholesterolemic (TC < 85 mg/dL) and in 28 hypercholesterolemic (TC > 98 mg/dL) pigs. The normocholesterolemic group consisted of pigs that carried apo-B allelic genes other than *Lpb*^{5} and or *Lpb*^{8}. The hypercholesterolemic group consisted of *Lpb*$^{5/x}$ and *Lpb*$^{5/8}$ heterozygous and *Lpb*$^{5/5}$ homozygous animals. The data reported in this study show that the LCAT activity in the plasma of hypercholesterolemic (HC) pigs (79 ± 43 units) was significantly lower ($p < 0.0005$) compared to the normocholesterolemic controls (175 ± 45 units). Furthermore, LCAT activity was positively correlated with TC in the normocholesterolemic group ($r = +0.54$; $p < 0.05$), whereas it was negatively correlated with TC in the hypercholesterolemic group ($r = -0.73$; $p < 0.001$). Additional data obtained from incubation experiments suggest that the lower LCAT activity in hypercholesterolemic pigs may be due, at least in part, to inhibition of LCAT activity by components found in the lipoprotein-deficient fractions of the plasma of hypercholesterolemic pigs.
Lipids 27, 266-269 (1992).

Except for the rare cases of monogenic hypercholesterolemia in humans and in rabbits, involving defects in low density lipoprotein (LDL) receptor function (1,2), the biochemical mechanisms underlying the elevation of LDL and/or cholesterol remain largely unexplained. Studies during the last two decades have shown that apolipoproteins and specific enzymes play a central role in plasma lipid metabolism. Mutations in structural genes, therefore, could produce polymorphic proteins resulting in modified rates of enzymatic reactions and subsequently defective catabolism of lipoproteins.

Rapacz and coworkers (3-5) have identified extensive apolipoprotein-B (apoB) polymorphism in pigs including eight *apoB* alleles. One of these (*Lpb*^{5}) showed association with inherited hypercholesterolemia and atherosclerosis. Although the *Lpb*^{5} animals develop hypercholesterolemia even on a low fat diet, they exhibit normal LDL receptor function (4). Although the *Lpb*^{5} allele was highly correlated with the hypercholesterolemic phenotype, the variations in apoB and cholesterol levels observed in the offspring of the hypercholesterolemic parents suggest that the hypercholesterolemic phenotype is of a *polygenic nature.* Consequently, it is likely that factors other than ApoB polymorphism contribute to the hypercholesterolemia and its phenotypic variation. This paper reports on the first investigation of lecithin:cholesterol acyltransferase (LCAT), in normal (LC) and genetically hypercholesterolemic (HC) pigs. The data reported in this study show that the LCAT activity in the plasma of HC pigs is considerably lower than that found in their normal counterparts. Additional studies suggest that the lower enzyme activity may be due, at least in part, to the presence of an LCAT inhibitor in the plasma of the HC pigs.

MATERIALS AND METHODS

Chemicals and reagents. [1,2-^{3}H]Cholesterol (40.7 Ci/mmole) was from Amersham (Arlington Heights, IL). Crystalline bovine serum albumin (essentially fatty acid free) and cholesterol standard and Aquacide IA were from Calbiochem (San Diego, CA). Enzymatic kits for cholesterol assays were from Boehringer Mannheim (Indianapolis, IN). All other chemicals were obtained from Fisher Scientific Company (Pittsburgh, PA) and were of reagent grade or better.

The animals. The animals used in this study were selected from the experimental herd of the Immunogenetics Laboratory at the University of Wisconsin, Madison, where the majority of the immunogenetically defined apolipoprotein mutant genes, including eight apoB alleles, have been identified (4) and are being preserved through propagation of a relatively small group of pigs. A total of 41 pigs, 23 females and 18 males, ranging from 5-36 months of age, were used. Preliminary studies on ten pigs indicated significant differences between the LCAT activity of the normal and hypercholesterolemic pigs with different *Lpb* genotypes. This observation prompted the increase of the sample size to include all available animals with elevated LpB to a total of 28; eight *Lpb*$^{5/5}$ homozygotes, five *Lpb*$^{5/8}$ and fifteen *Lpb*$^{5/x}$ heterozygotes. The group of animals with normal LpB levels was increased by random selection to a total of 13 pigs all carrying the *Lpb*^{x} alleles (*Lpb*^{1}, *Lpb*^{2}, *Lpb*^{3}, *Lpb*^{4}, *Lpb*^{6} and *Lpb*^{7}).

Collection of samples. Blood was collected into a syringe containing 10% Na_2 EDTA, pH 7.2 (1 mL/60 mL of blood, 0.004 M final concentration) from the jugular vein of pigs that had been fasted overnight, and the sample was cooled immediately to less than 4°C. Plasma was obtained by centrifugation at 2000 × *g* for 30 min at 4°C and shipped on wet ice to the Fort Worth laboratory within 24 hr by courier.

Preparation of lipoprotein-deficient plasma fractions. Endogenous LCAT activity was inhibited by the addition of diisopropylfluorophosphate (DFP; 1 mM final concentration) to the plasma. The lipoproteins were then separated by ultracentrifugal flotation for 48 hr upon

adjusting the density to 1.225 g/mL (6). The lipoprotein-deficient infranatants were isolated, dialyzed against 0.01 M Tris-HCl buffer (pH 7.4) containing 0.15 M NaCl and 0.01% EDTA, and adjusted to the volume of the original plasma sample.

Measurement of cholesterol. Total cholesterol was determined with the Abbott VP (Chicago, IL) biochromatic analyzer using the Abbott reagent kits. Unesterified cholesterol in whole plasma and total cholesterol in the lipoprotein-depleted plasma fractions were determined using an enzymatic assay with reagents supplied by Boehringer Mannheim.

Measurement of LCAT activity. Individual plasma samples were analyzed according to the method of Glomset and Wright (7) which was modified to employ human plasma high density lipoprotein (HDL) instead of heat-inactivated plasma as the substrate. HDL from human plasma was prepared (8) and labeled with [^{3}H]-cholesterol as described previously (9). Briefly, the isolated HDL was treated with diisopropylfluorophosphate (DFP) to suppress endogenous LCAT activity. A mixture of bovine serm albumin and [^{3}H]cholesterol was prepared and added to the HDL preparation to result in approximately 500,000 dpm/mL. Bovine serum albumin was added to the substrate to a final concentration of 2%. The labeled HDL substrate solution was stored at 4°C and was stable for at least two months. This was ascertained by standard plasma samples being run along with the test samples for each run (10). The volume of the substrate used was 200 μL and the enzyme reaction was initiated by the addition of 5 μL of plasma. This high dilution of the plasma sample in the large substrate aliquot (1:40) was used in order to minimize the contribution of the free cholesterol introduced into the assay mix with the aliquots of the plasma. The incubation time for the LCAT assay was selected to yield a linear rate of cholesterol esterification so that no more than 10% of the total available free cholesterol was converted to cholesteryl ester. These conditions have been found to be adequate to assure the linearity and the reproducibility of the assay. All LCAT assays were performed using a single preparation of the [1,2-^{3}H]cholesterol labeled HDL substrate. The incubations (16 hr) were carried out in duplicates at 37°C with an average error of less than 5% between duplicates. The rate of cholesterol esterification (LCAT units) was calculated by multiplying the fractional rate (% cholesterol esterification/time) by the free cholesterol concentration present in the respective assay mixtures; including free cholesterol in the substrate (271 nmole of FC/mL) plus the free cholesterol originating from the aliquot of pig plasma (used as the enzyme source). Blank incubations (HDL substrate only) resulted in % cholesteryl ester values of 0.2%. These blank values were routinely subtracted from the assay results.

RESULTS AND DISCUSSION

Plasma lipids and LCAT assays. Plasma samples from a total of 41 pigs were used in this study. Of these, 13 were arbitrarily designated as normocholesterolemic (total cholesterol (TC) < 85 mg/dL) and 28 as hypercholesterolemic (TC > 98 mg/dL). The normocholesterolemic (LC) group was made up of animals with genotypes which carried the following apoB alleles: Lpb^1, Lpb^2, Lpb^3, Lpb^4, Lpb^6 and Lpb^7. The HC group consisted of $Lpb^{5/8}$ and $Lpb^{5/x}$ heterozygous and $Lpb^{5/5}$ homozygous animals. Total cholesterol (TC), free (unesterified) cholesterol (FC) and LCAT activity were determined. Table 1 shows the plasma cholesterol values and the LCAT activity for the normocholesterolemic (LC) and hypercholesterolemic (HC) pigs separated into male and female groups. Among the LC animals, TC ranged from 50 to 84 mg/dL (mean = 66 ± 9.2 mg/dL) and LCAT activity from 70 to 253 units (mean = 175 ± 45 units). In the hypercholesterolemic group, TC ranged from 98-409 mg/dL (mean = 249 ± 93 mg/dL) and LCAT activity from 38-195 units (mean = 79 ± 43 units). Figure 1 shows the LCAT activity (measured using an exogenous, substrate) as the function of TC in the plasma of LC pigs. A positive trend in LCAT activity was observed with increasing plasma TC as indicated by the linear correlation coefficient ($r = +0.54$; $p < 0.05$). However, the same relationship for the data obtained for the samples of the HC pigs revealed a *negative* trend ($r = -0.73$, $p < 0.001$) as shown in Figure 2.

The effectiveness of LCAT in the plasma has been assessed by either measuring its ability to esterify

TABLE 1

Plasma Cholesterol and LCAT Activity

Experimental group (no. in group)	Age (mo)	TC (mg/dL)	FC (mg/dL)	% EC	LCAT (LCAT units)
a) Normocholesterolemic pigs ($Lpb^{x/x}$)					
Males (7)	13.6 ± 6.3 (6-24)	60.3 ± 6.6 (50-68)	14.4 ± 1.9 (13-18)	75.5 ± 5.6 (64-80)	162 ± 51.8 (70-212)
Females (6)	11.5 ± 7.3 (6-24)	72.8 ± 7.1 (64-84)	18.8 ± 2.2 (16-22)	74.3 ± 3.32 (70-79)	188.8 ± 40.7 (137-253)
b) Hypercholesterolemic pigs ($Lpb^{5/x}$ and $Lpb^{5/5}$)					
Males (11)	12.5 ± 7.3 (54-27)	234.9 ± 80.8[a] (128-384)	67.3 ± 26.9[a] (30-124)	72.1 ± 3.1 (68-77)	65.5 ± 17.6[a] (42-102)
Females (19)	10.1 ± 7.7 (5-36)	257.8 ± 101[a] (98-409)	75.9 ± 36.2[b] (24-134)	71.6 ± 3.5 (64-77)	88.1 ± 52.1[a] (38-195)

[a]$p < 0.0005$; [b]$p < 0.005$; denotes significance of difference from values in the corresponding control group.

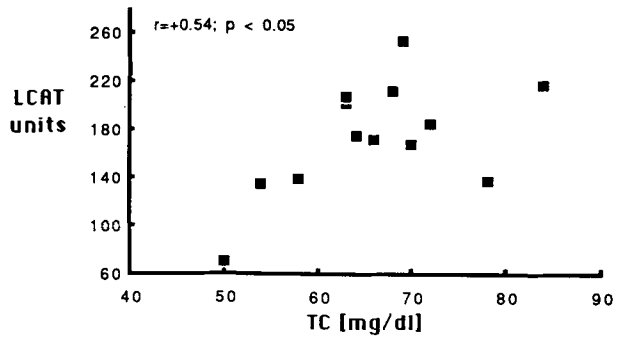

FIG. 1. LCAT activity as a function of total cholesterol (TC) concentration in the plasma of normocholesterolemic (LC) pigs. The data are representative of two separate sets of determinations.

endogenous plasma cholesterol (10) or by the esterification of *exogenous* cholesterol in artificially prepared substrates (11). Although lower (12-14) and higher (14) rates of *endogenous* cholesterol esterification have been reported for a number of pathological states, the levels of circulating LCAT activity for these cases (as measured with an exogenous substrate) have been generally found to be normal. The few exceptions to these are congenital LCAT deficiency (15), parenchymal liver disease (16), and perhaps advanced renal disease (17). Therefore, it was unexpected to find significantly lower LCAT activity ($p < 0.0005$) in the plasma of hypercholesterolemic pigs (79 ± 43 units) as compared to their normocholesterolemic controls (175 ± 45 units). Examination of the LCAT activity (with an exogenous substrate), as a function of TC levels, revealed even more striking differences between the HC and LC pigs (Figs. 1 and 2). We have shown earlier that the circulating LCAT activity *increased* essentially linearly as a function FC (or TC) in a number of mammalian species (18). We have now confirmed such a trend in a group of 12 of 13 normocholesterolemic (LC) pigs (Fig. 1). Lower plasma cholesterol levels observed in males older than 12 months compared to females of the same age is in agreement with the general trend observed in both LC and HC pigs (3). However, the LCAT activity in the plasma of hypercholesterolemic (HC) pigs showed a *decreasing* trend with increasing TC levels especially up to TC values of 200 mg/dL (Fig. 2). Such a lower LCAT activity could be due to a number of factors including decreased synthesis or increased removal of the enzyme by the liver or to the presence of an LCAT inhibitor in the HC pigs. Only the latter possibility was investigated, as currently we have no means to measure LCAT enzyme protein levels directly by an immunoassay in pig plasma.

The lower LCAT levels particularly in the plasma of the HC pigs resulted in a lower percentage of esterified cholesterol in the plasma. Although the differences shown for % cholesteryl ester (CE) in Table 1 are not significant, the difference between HC and LC animals does become significant when the males and females are combined into one group (% CE = 75 ± 4.5 for the LC group and 71.8 ± 3.3 for the HC group; $p < 0.05$). Furthermore, there was a rather strong positive correlation ($r = 0.52$; $p < 0.005$) between LCAT activity and % CE in the plasma (Fig. 3).

Incubation studies. Preliminary experiments were conducted to investigate whether the lower LCAT activity in HC pigs was due to the presence of a circulating inhibitor. Plasma samples (1 mL each) from 10 HC pigs were pooled, treated with DFP and subjected to ultracentrifugation to obtain the lipoprotein-deficient infranatant ($d > 1.225$ g/mL). Increasing amounts of the dialyzed lipoprotein-deficient infranatants (obtained from HC and LC pigs) were preincubated (30 min; 25°C) with 100 μL of LC plasma containing active LCAT. Following the preincubation period, 5 μL aliquots were transferred to the assay mix to measure the residual LCAT activity. Although the lipoprotein-deficient infranatants contained a limited amount of total cholesterol (<10 mg/dL), this contributed less than 2% to the free cholesterol pool in the assay mix. The data presented in Figure 4 show that whereas the lipoprotein-deficient infranatant from the HC pigs inhibited LCAT activity, similar preparations obtained from the plasma of LC pigs had no such effect.

The etiology of hypercholesterolemia in the *Lpb*^{5} pigs has not yet been fully elucidated. Consequently, the present studies examined relevant aspects of lipoprotein metabolism to learn more about the mechanism of the

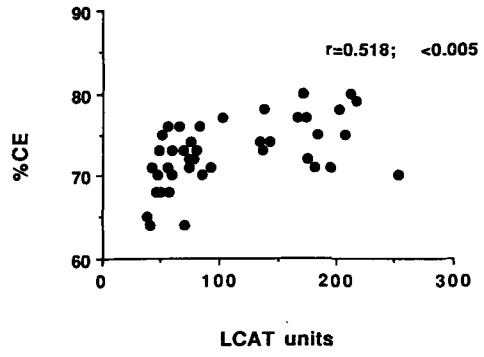

FIG. 3. Percent plasma cholesteryl esters as a function of CAT activity. Includes observations made with both normocholesterolemic (LC) and hypercholesterolemic (HC) pig plasma samples.

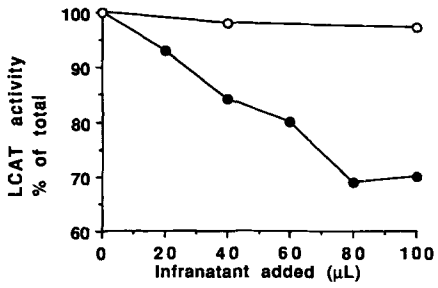

FIG. 4. Inhibition of LCAT activity in the plasma of a normocholesterolemic (LC) pig by lipoprotein-free infranatant prepared from the plasma of hypercholesterolemic (HC) pigs. Plasma samples pooled from HC pigs were treated with DFP and the lipoprotein-deficient infranatant (d > 1.225) was isolated by ultracentrifugation. Exhaustive dialysis followed (0.01 M Tris-HCl; pH 7.4 containing 0.15 M NaCl and 0.1% EDTA) to remove the unreacted DFP. Control infranatants from LC pigs were also prepared using the same DFP treatment and dialysis as for the HC infranatants and brought to the original volume of the plasma. Increasing amounts of the infranatants from HC pigs (■) and from LC pigs (□) were preincubated with 100 μL of LC plasma (30 min, 25°C). Following the incubation with the infranatants, 5 μL aliquots were transferred to the assay mixture to measure the residual LCAT activity. The data are representative of four separate experiments.

abnormal plasma cholesterol accumulation in these animals. The enzyme LCAT has been known to contribute to reverse cholesterol transport by converting the free cholesterol on the surface of the circulating lipoprotein particles to cholesteryl esters. As a result, most of the plasma cholesterol is made unavailable for exchange with membrane cholesterol pools; instead, it is targeted for removal by hepatic lipoprotein receptors. The physiological and clinical consequences of prolonged absence (15) or lower than normal (19,20) LCAT activity have been well documented and are characterized by the storage of free cholesterol in a number of tissues including the arteries (21). In this communication, we report for the first time, reduced LCAT activity associated with hypercholesterolemia and premature atherosclerosis in genetically inbred pigs. The mechanism underlying this decreased LCAT activity and its relationship to hypercholesterolemia and atherosclerosis is yet to be established.

Oxysterols in Cultured Bovine Aortic Smooth Muscle Cells and in the Monocyte-Like Cell Line U937

Jae Eun Pie and **Christine Seillan***
Laboratoire de Nutrition et Sécurité Alimentaire, INRA-CRJ, 78352 Jouy-en-Josas Cédex, France

Oxysterols in cultured bovine aortic smooth muscle cells and in the monocyte-like cell line U937 were analyzed by gas-liquid chromatography. The following products were detected: 7α- and 7β-hydroxycholesterol, 7-ketocholesterol, cholesterol-α-epoxide, cholesterol-β-epoxide, cholestanetriol, and 20- and 25-hydroxycholesterol. The proportions of oxidized cholesterol varied from 1 to 3% of total cholesterol. The concentrations of oxysterols were lower when the smooth muscle cells were maintained in a vitamin E-enriched medium, and were higher in U937 cells when the cells were activated with phorbol myristate acetate. The cell oxysterol content appears to be regulated by factors that inhibit or enhance free radical generation. The concentrations of oxysterols found in cells may serve as an indicator of the extent of lipid peroxidation.
Lipids 27, 270–274 (1992).

The presence of oxygen radicals has been linked to a number of human diseases, and the damaging effects of free radicals, particularly in the vascular system, have attracted increasing attention (1,2). One of the major consequences of free radical mediated reactions is lipid peroxidation. Unsaturated fatty acids, as constituents of membrane phospholipids, are easy targets of oxidative processes and several methods have been developed to measure fatty acid oxidative end products (1). Cholesterol, a major cell membrane component of animal tissue, also can easily undergo oxidation, but measurement of oxidized cholesterol is rarely performed. Recent studies have shown that cholesterol can be oxidized after photoxidation of red blood cell membranes (3,4) or upon CCl_4 poisoning of rat liver (5). Using our recenty developed method which allows simple and reliable quantification of oxysterols and cholesterol by gas-liquid chromatography (GLC) (6), we analyzed the oxysterol contents of cultured cells derived from the vascular system, namely bovine aortic smooth muscle cells and U937 cells, a monocyte-like cell line that grows easily and generates oxidant species when activated. Indeed, it seemed particularly interesting to investigate oxysterol formation in these cells because oxysterols can modify various parameters of vascular physiology. They recently have been shown to alter endothelial permeability (7), and to change arachidonic acid metabolism and fatty acid distribution in smooth muscle cells (8,9). The present report describes the oxysterol contents of cultured bovine aortic smooth muscle cells and U937 cells, and the effects of protective culture conditions and oxidant stress on the formation of oxidized cholesterol.

MATERIALS AND METHODS

Reagents. Cholesterol, cholestanol, cholestanetriol, cholesterol-α-epoxide, 20-hydroxycholesterol, 7-ketocholesterol and 19-hydroxycholesterol, butylated hydroxytoluene (BHT), phorbol myristate acetate (PMA) and α-tocopherol were obtained from Sigma Chemical Co. (St. Louis, MO). Cholesterol-β-epoxide came from Research Plus (Bayonne, NJ), and 25-hydroxycholesterol and 7α- and 7β-hydroxycholesterol were purchased from Steraloids Inc. (Wilton, NH). All standards were found to be pure as determined by GLC analysis. Culture reagents were obtained from Flow Laboratories (Irvine, U.K.).

Cell cultures. Bovine aortic smooth muscle cells were cultured as described elsewhere (8). Cells from explants of bovine aortic media were used up to the eighth passage. The culture medium used was RPMI 1640 20 mM *N*-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid) (HEPES) supplemented with 10% heat-inactivated fetal bovine serum, 50 U/mL penicillin, 50 μg/mL streptomycin, 1 μg/mL amphotericin B and 2 mM L-glutamine. The same batch of fetal bovine serum was used throughout the study. The monocyte-like cell line U937 was obtained from the European cell culture collection (Salisbury, U.K.). Cell suspensions were maintained at a density ranging from 0.3 to 0.9×10^6 cells/mL in the same culture medium used for smooth muscle cells.

Cultures in vitamin E-enriched medium. Smooth muscle cells were obtained as described above. After the first passage, the cultures were divided into two parts. The control cells were maintained in the usual culture medium, and the other cells were maintained in the culture medium containing 1 μg/mL of α-tocopherol. Vitamin E stock solutions at 0.1 mg/mL of acetone were stored at −20°C and diluted in pure ethanol. The vitamin solution was added in the medium each time the medium was changed, throughout the maintenance of the culture. The final ethanol concentration was not higher than 0.5% (v/v) and did not affect cell viability.

Activation of U937 cells with PMA. The cells were rinsed once with RPMI without fetal bovine serum by centrifugation, and resuspended in the same medium. The PMA was stored at −20°C in 1 mg/mL of acetone, diluted in ethanol at the desired concentrations, and added into the medium. Cell suspensions were divided into 75-cm^2 culture flasks and incubated for 60 min at 37°C. At the end of the incubation, the cell suspensions were recovered and the adhering cells were detached with 10 mL per flask of a trypsin-EDTA solution.

Lipid extraction. Total lipids were extracted from the samples by the Folch procedure (10). Smooth muscle cells

Nomenclature: Cholestanetriol, cholestane-3β,5α,6β-triol; cholestanol, 5α-cholestan-3β-ol; cholesterol, cholest-5-en-3β-ol; cholesterol-α-epoxide, 5,6α-epoxy-5α-cholestan-3β-ol; cholesterol-β-epoxide, 5,6β-epoxy-5α-cholestan-3β-ol; 7α-hydroxycholesterol, cholest-5-ene-3β,7α-diol; 7β-hydroxycholesterol, cholest-5-ene-3β,7β-diol; 19-hydroxycholesterol, cholest-5-ene-3β,19-diol; 20-hydroxycholesterol, cholest-5-ene-3β,20α-diol; 25-hydroxycholesterol, cholest-5-ene-3β,25-diol; 26-hydroxycholesterol, cholest-5-ene-3β,26-diol; 7-ketocholesterol, 3β-hydroxycholest-5-en-7-one.

from 5-75 cm^2 flasks were trypsinized and pooled, and 10-mL samples of the cell suspension were extracted with 30 mL of chloroform/methanol (2:1, v/v) containing 0.002% BHT (w/v) and the internal standards for the quantification of the cholesterol oxides (10 μg of 19-hydroxycholesterol) and cholesterol (200 μg of cholestanol). U937 cell suspension was similarly extracted—30×10^6 cells were necessary for each sample. Approximately 1 g of aortic media fragments was extracted with 20 mL of chloroform/methanol (2:1, v/v) containing BHT and the internal standards. The suspension was mixed vigorously for 30 min, and once the organic phase was recovered, the extraction was repeated under the same conditions. Lipids extracts were evaporated under nitrogen.

Quantification of cholesterol and oxysterols. Lipids extracts were saponified overnight at room temperature with 20 mL of 1N KOH in methanol. The unsaponifiable fractions were deposited on a silica thin-layer chromatography (TLC) plate and developed in hexane/diethyl ether (70:30, v/v) to separate oxysterols from cholesterol. The extracts of scraped silica gel were derivatized as previously described (6). The sterols were quantified by GLC analysis on a Girdel 30 gas chromatograph (Suresnes, France) with a flame ionization detector. The GLC conditions were: A 30-m fused silica DB5 column (J&W Scientific, Folsom, CA) with a film thickness of 1.0 μm; oven temperature, 280°C and 270°C for oxysterols and cholesterol, respectively; detector at 310°C; injector at 300°C; flow rate of helium, 1 mL/min; and pressure 12 psi.

Verification of the identity of the substances detected by GLC analysis. To verify the identity of the substances detected by GLC by relative retention time, the following experiment was performed. Lipid extracts from 10 pooled 75-cm^2 culture flasks were processed as described above up to the TLC step. Once the silica was recovered and extracted, the extracts were deposited again on a silica TLC plate, and developed in 100 mL of hexane/diethyl ether/ethyl acetate (50:50:50, v/v/v). Once developed and dried, the plates were sprayed with rhodamin (1 mg/mL in ethanol). Four bands of silica were recovered and extracted separately. These bands corresponded to migration areas of standards run in parallel. The extracts were derivatized and analyzed under usual GLC conditions.

Statistics. Results are expressed as mean ± SD. The significance of differences between groups was assessed by using one-way analysis of variance and Student's *t*-test.

RESULTS AND DISCUSSION

We quantified cholesterol and oxysterols with good reproducibility and satisfactory recoveries using our method (6). Different oxysterols were detected in the lipid extracts obtained from smooth muscle cells and U937 cells; Table 1 links the range of amounts found in the samples and the proportions of the different oxysterols expressed as percentages of the total cholesterol contained in the sample. Under our conditions, the detection limit was 0.05 μg/18×10^6 U937 cells or 0.05 μg/mg protein of smooth muscle cells. Typical GLC profiles are shown in Figure 1. As shown in Table 1 and Figure 1, eight compounds were detected in the smooth muscle cell cultures. The most abundant species were cholesterol-β-epoxide, 7-ketocholesterol and cholesterol-α-epoxide. The high standard deviations were due to differences in the cultures analyzed. In spite of these large variations, we consistently found low amounts of 7α- and 7β-hydroxycholesterol in these cells. In contrast, both substances were more abundant in U937 cell extracts, where 7-ketocholesterol was consistently found in the highest proportion. In this cell line, 25-hydroxycholesterol was not detected. As shown in Table 1, the profile of oxysterols detected in the cells differed from the profile of these compounds in the serum. In light of the differences noticed between the two cell types, and because both cultures were maintained in the same medium, it seems probable that the oxysterols found in the cells do not only originate from the medium.

Low amounts of oxysterols in the samples and lack of sensitivity prevented us from using mass spectrometry to verify the identity of the substances detected by GLC (6). Therefore, we analyzed the samples using a further TLC step. Figure 2 shows the migration of pure compounds in the system used. For the smooth muscle cell extracts, silica gel was scraped in four bands as shown in Figure 2 and the content of each band was analyzed by GLC. Figure 2 shows a typical GLC profile obtained for band III from a cell sample. This band corresponded

TABLE 1

Quantification of Oxysterols in Cultures of Smooth Muscle Cells and U937 Cells[a]

	Smooth muscle cells	U937 cells	Fetal calf serum
Cholesterol	0.23 ± 0.06	0.14 ± 0.03	0.31 ± 0.01
7α-Hydroxycholesterol	0.15 ± 0.07 (0.06)	0.27 ± 0.10 (0.19)	0.40 ± 0.03 (0.13)
7β-Hydroxycholesterol	0.12 ± 0.06 (0.05)	0.27 ± 0.10 (0.19)	0.40 ± 0.01 (0.13)
7-Ketocholesterol	1.49 ± 0.51 (0.64)	1.08 ± 0.41 (0.76)	1.78 ± 0.04 (0.57)
Cholesterol-α-epoxide	1.18 ± 0.49 (0.50)	0.34 ± 0.12 (0.24)	0.30 ± 0.02 (0.09)
Cholesterol-β-epoxide	1.89 ± 0.82 (0.81)	0.51 ± 0.09 (0.36)	0.08 ± 0.01 (0.02)
Cholestanetriol	0.25 ± 0.12 (0.11)	0.17 ± 0.09 (0.12)	N.D.
20-Hydroxycholesterol	0.66 ± 0.29 (0.28)	0.53 ± 0.13 (0.37)	0.07 ± 0.01 (0.02)
25-Hydroxycholesterol	0.48 ± 0.17 (0.20)	N.D.	0.06 ± 0.01 (0.02)

[a]Results are expressed in g/sample of cells or g/mL of serum for cholesterol, and in μg/sample of cells or μg/mL of serum for oxysterols. Numbers in parentheses indicate the proportion for each oxysterol expressed as percentage relative to total cholesterol. Each sample consisted of 5-75-cm^2 culture flasks for smooth muscle cells and of 30×10^6 cells for U937 cells. N.D., not detectable. Mean ± SD (n = 15 for the cell extracts, n = 3 for the serum).

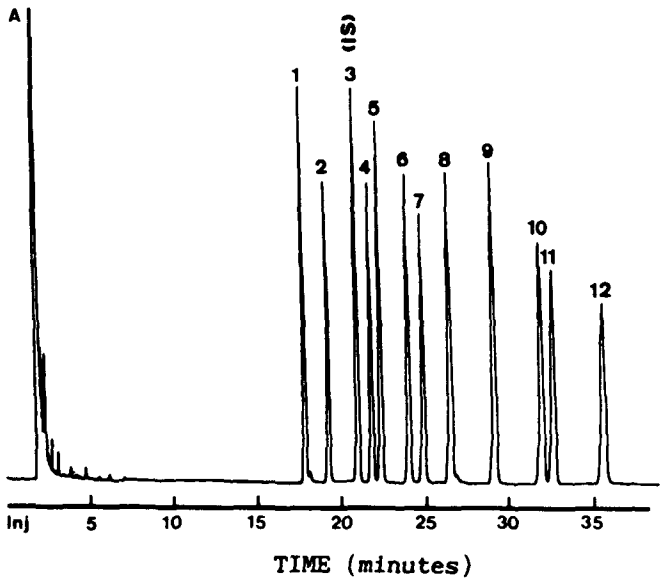

FIG. 1A. GLC profiles of standards.

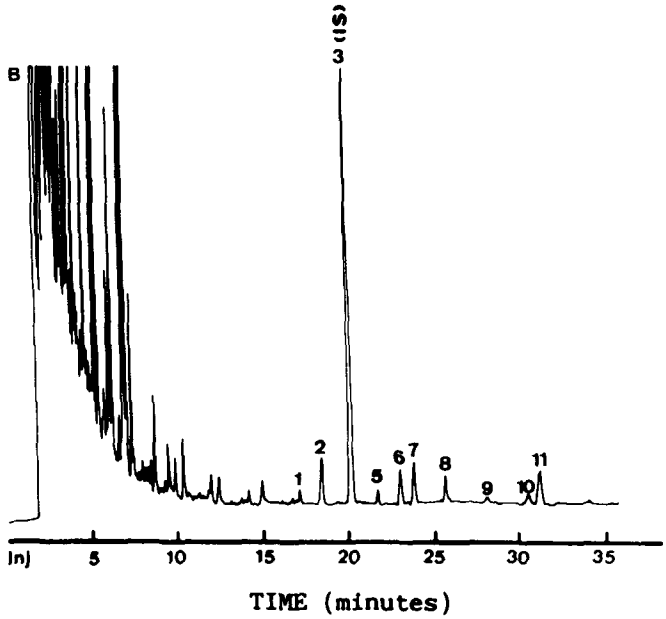

FIG. 1B. Smooth muscle cells.

to the area of migration of 7-ketocholesterol, cholesterol-α-epoxide, cholesterol-β-epoxide and 25-hydroxycholesterol. The GLC profile shows four peaks with the same retention times as the four oxysterols. Thus the presence of these substances in the cell samples was confirmed. Using this method we could obtain confirmation of the presence of the eight oxysterols detected by GLC.

We also performed experiments to verify that the oxysterols were not produced artifactually during analysis.

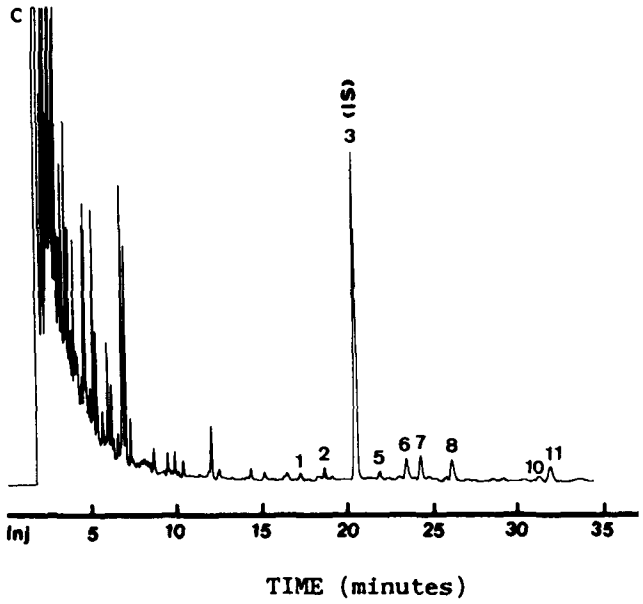

FIG. 1C. U937 cells. 1, 7α-Hydroxycholesterol; 2, cholesterol; 3, 19-hydroxycholesterol; 4, cholesta-3, 5-diene-7-one; 5, 7β-hydroxycholesterol; 6, cholesterol-β-epoxide; 7, cholesterol-α-epoxide; 8, 20-hydroxycholesterol; 9, cholestantriol; 10, 25-hydroxycholesterol; 11, 7-ketocholesterol; 12, 26-hydroxycholesterol.

The results are presented in Table 2. The cholesterol added to the sample was first purified by TLC to remove any contaminating oxysterols. As seen in the table, when a cell sample was spiked with cholesterol no increase in the amounts of oxysterols could be observed. Cholesterol was stable throughout the analysis, and the oxysterols detected were not derived by spontaneous oxidation occurring during sample processing.

Since the sum of oxysterols represented a significant portion of cell sterols, we analyzed the oxysterol content of media from bovine aortas and compared them to the data obtained on cells maintained *in vitro*. The results for three different aortas are shown in Table 3. Only four oxysterols, in relatively low amounts, could be detected in each sample, since the sum of these compounds represented only 0.4% of total sterol. There were fewer primary oxysterols detected than in cells maintained *in vitro*, since 7-ketocholesterol was not always present and there was no 7α- and 7β-hydroxycholesterol. Thus, as expected, in cultured cells, cholesterol is more oxidized. Indeed, cell cultures are exposed to intense oxidative conditions, such as high O_2 concentrations. Furthermore, culture media contain iron and copper salts or HEPES buffer that can enhance oxygen radical generation (11,12).

The oxysterol content of cultured cells was investigated next to see whether it can be modulated by factors that either inhibit or stimulate free radical formation. Smooth muscle cells were cultured in vitamin E-enriched medium. The concentration chosen (1 μg/mL) did not affect cell growth, while at 2 μg/mL, vitamin E blocked cell division without any sign of cytotoxicity. The cell content of oxidized cholesterol was significantly reduced in cells maintained in vitamin E-enriched medium. After 13 days of repeated exposure to α-tocopherol, the ratio of oxysterols to cholesterol dropped from 3.5% (controls) to 1.7%. Reductions in the total amount of oxysterols varied from 50 to

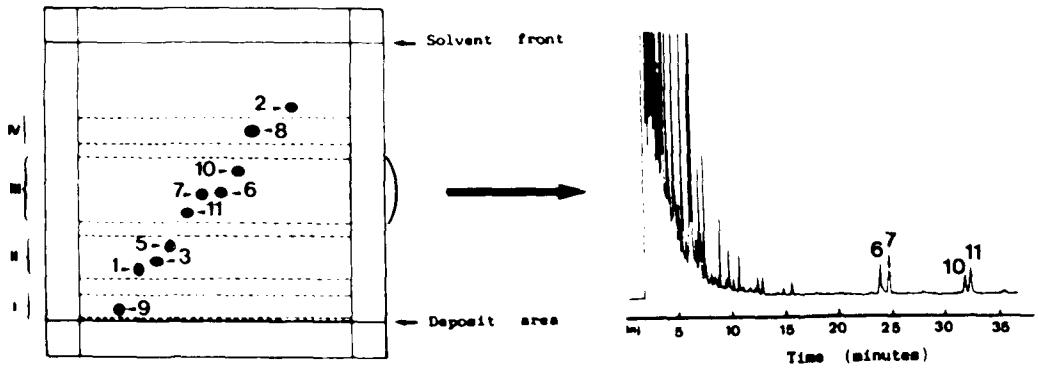

FIG. 2. Verification of the identity of the substances detected by GLC analysis. Unsaponifiable fractions of cell extracts were developed in hexane/diethyl ether/ethyl acetate (50:50:50, v/v/v) using silica gel plates, and standards were simultaneously run on a separate plate (left). For the cell samples, four bands of silica corresponding to migration areas of standards were recovered, extracted, and analyzed by GLC. A typical profile of the content of band III of a cell sample is shown (right). Oxysterols have been numbered in the same way as in Figure 1.

TABLE 2

Control of the Stability of Cholesterol During the Analysis[a]

	Cell extract	Cell extract + cholesterol
Cholesterol	0.18 ± 0.05	1.54 ± 0.62
7α-Hydroxycholesterol	0.11 ± 0.02	0.10 ± 0.01
7β-Hydroxycholesterol	0.07 ± 0.01	0.06 ± 0.02
7-Ketocholesterol	1.39 ± 0.25	1.46 ± 0.25
Cholesterol-α-epoxide	1.30 ± 0.52	1.28 ± 0.45
Cholesterol-β-epoxide	1.63 ± 0.53	1.68 ± 0.60
Cholestanetriol	0.32 ± 0.18	0.24 ± 0.20
20-Hydroxycholesterol	0.34 ± 0.08	0.32 ± 0.10
25-Hydroxycholesterol	0.58 ± 0.10	0.61 ± 0.12

[a]Smooth muscle cells from 10–75-cm^2 flasks were pooled and lipids were extracted. The sample was divided into two parts and pure cholesterol was added into one of the samples. Analysis was performed as described in Materials and Methods. Results are expressed in g/sample for cholesterol and μg/sample for oxysterols. Mean of four experiments ± SD.

85%. The oxysterols were not equally reduced, as shown in Figure 3. Oxysterols oxidized on the side chain were not reduced as much as the others. The reductions noted for 20- and 25-hydroxycholesterol varied from 0 to 33%, while they were consistently higher than 50% for the other products.

When U937 cells were exposed for a short time to 100 ng/mL of PMA, the oxysterol content of the cells increased markedly, as shown in Figure 4. The concentration of 7α- and 7β-hydroxycholesterol doubled after exposure to PMA, and an increase in 20-hydroxycholesterol, 7-ketocholesterol and the two cholesterol epoxide isomers was also observed. When BHT was added to the incubation medium containing PMA, the PMA induced increases were suppressed, as shown in Figure 4. Thus, the increases noted for different oxysterols after PMA stimulation seem to be the result of free radical generation.

Our experiments have shown that cell oxysterols derive partly from radical generation and spontaneous cholesterol autooxidation. Nevertheless, it is probable that they have diverse origins and that they also partly derive from enzymatic pathways. For instance, the failure to reduce 20- and 25-hydroxycholesterol after repeated exposure to vitamin E suggests that they do not derive from radical generation. Our method includes saponification of the lipid extract, and the data obtained do not provide any information on the distribution between free and esterified sterols. Also, we only analyzed the total amount of oxysterols and cholesterol present in the cells and the data do not provide any insight into the distribution of the sterols between membranes and cytosols. It would be of interest to focus more precisely on the oxysterol content of plasma membranes and to assess the modifications

TABLE 3

Quantification of Cholesterol and Oxysterols in Media from Bovine Aortas[a]

	Cholesterol	Cholesterol-β-epoxide	Cholesterol-α-epoxide	20-Hydroxycholesterol	7-Ketocholesterol
Aorta 1	0.65 ± 0.01	1.19 ± 0.07	1.26 ± 0.08	0.23 ± 0.03	0.17 ± 0.01

[a]Results are expressed in g/g of tissue for cholesterol and in μg/g of tissue for oxysterols. Mean ± SD (n = 3); N.D., not detected.

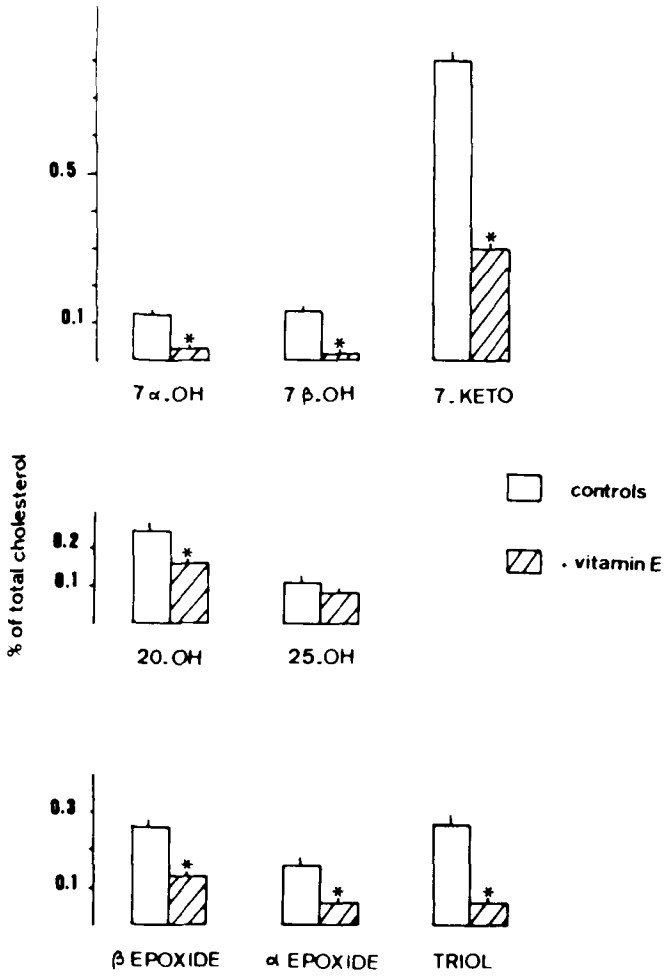

FIG. 3. Effect of vitamin E enrichment of culture medium on the oxysterol content of smooth muscle cells. Vitamin E was added at 1 μg/mL to the culture medium each time the medium was changed throughout the maintenance of the culture. Each oxysterol is expressed as a percentage relative to total cholesterol. The data are the result of a typical experiment. Similar results were found in three separate experiments. *Significantly different from controls at $P < 0.05$. Abbreviations: 7α-OH, 7α-hydroxycholesterol, 7β-OH, 7β-hydroxycholesterol; 7-keto, 7-ketocholesterol; 20-OH, 20-hydroxycholesterol; 25-OH, 25-hydroxycholesterol; β-epoxide, cholesterol-β-epoxide; α-epoxide, cholesterol-α-epoxide; triol, cholestanetriol.

of plasma membrane cholesterol after exposure to oxidant or protective factors. Indeed, it has been shown that oxysterol inclusion in the plasma membranes can modify membrane fluidity (13), permeability to ions (14,15) and enzymatic activities (16). Our results show that changes were detectable under both conditions, either protective or oxidant. Since we analyzed whole cell extracts, an underestimation of the plasma membrane changes is probable. Nevertheless, it seems that the quantification of oxysterols can serve as an important indicator of lipid peroxidation and that our method is a reliable tool in assessing the changes induced by free radical formation.

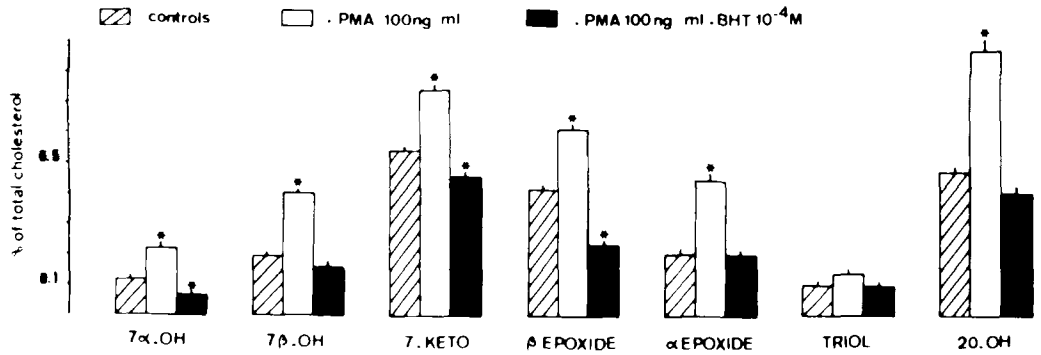

FIG. 4. Effect of PMA induced activation on oxysterol content of U937 cells. U937 cells were incubated at 37°C for 60 min in RPMI without fetal bovine serum either alone (controls) or with PMA or PMA plus BHT at the concentrations indicated above. The oxysterols are expressed as percentage of total cholesterol. The data are the results of a typical experiment. Similar data were obtained in three separate experiments. *Significantly different from control value at $P < 0.05$. The abbreviations used are the same as in Figure 3.

Phospholipids in *Trypanosoma cruzi:* Phosphoinositide Composition and Turnover

G. Racagni, M. García de Lema, C.E. Domenech and **E.E. Machado de Domenech***
Departamento de Biología Molecular, Facultad de Ciencias Exactas, Físico-Químicas y Naturales, Universidad Nacional de Río Cuarto, Córdoba, Argentina

The polyphosphoinositides from *Trypanosoma cruzi* were isolated by preparative thin-layer chromatography (TLC) and identified. When myo-[^{3}H]inositol was present in the culture medium for five days, analyses showed the presence of phosphatidylinositol (PI), lysophosphatidylinositol (lysoPI), phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2). Short-term incubation with $^{32}P_i$ led to higher percentages of incorporation into phosphatidylethanolamine (PE), lysophosphatidylethanolamine (lysoPE) and PI compared to the other glycerophospholipids. The phosphoinositides (PI, PIP and PIP_2) contained a larger proportion of unsaturated than saturated fatty acids. High proportions of 18:2 were found in the three phosphoinositides analyzed, whereas the major saturated fatty acid was 18:0. Water-soluble inositol phosphates (IP, IP_2 and IP_3) were also identified.
Lipids 27, 275–278 (1992).

Phosphoinositides are minor constituents of eukaryotic cells and are located in the plasma membrane. Phosphatidylinositol (PI) is the most abundant representative, whereas phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2) often occur in trace amounts only (1,2). External signals such as hormones, neurotransmitters, growth factors, or light can cause changes in phosphatidylinositol metabolism in many organisms (1–5). In the parasitic protozoa, the role of phosphoinositides is not well understood. Some of the trypanosomatidae are pathogenic, and a most important representative is the etiological agent of American trypanosomiasis (Chagas' disease) with a life cycle involving mammalian and insect hosts. Both, the lipid composition of *Trypanosoma cruzi* and the presence of phosphatidylinositol (PI) in this organism have been reported previously (6). However, the presence of polyphosphoinositides had not been demonstrated. In our study on *Trypanosoma cruzi*, various forms of phosphoinositides were found, and the hydrolysis of phosphatidylinositol bisphosphate (PIP_2) was examined.

MATERIALS AND METHODS

Organisms. The Tulahuen strain of *Trypanosoma cruzi* was used in this study. The epimastigote forms were grown at 28°C in a modified Warren medium (7) consisting of 37 g/L Brain/Heart Infusion (Merck, Darmstadt, Germany), 0.1% hemine (Sigma Chemical Co., St. Louis, MO) using 1 g of hemine in 50 mL of 0.2 M NaOH, 10% calf serum (GEN S.A., Buenos Aires, Argentina) and 1,000,000 U penicillin per 4×10^7 parasites or cells/mL. Growth was followed by measuring the weight of the harvested cells and the number of mobile cells per mL of culture medium. Cells in the logarithmic phase of growth were harvested by centrifugation at $6,400 \times g$ for 10 min and washed three times with Krebs-Ringer-TRIS (KRT) buffer (25 mM HCl-TRIS, pH 7.2; 1.2 mM $MgSO_4$; 2.6 mM $CaCl_2$; 4.8 mM KCl; 120 mM NaCl; and 100 mM glucose).

Radioisotope incorporation. Millipore sterilized myo-2-[^{3}H]inositol (1.2 μCi/mL) was added to the culture medium and growth was allowed to proceed for 5 days at 28°C. The parasites were then harvested according to the method described above, and the lipids were extracted. In other experiments, the cells harvested in the logarithmic phase were incubated with [^{32}P]orthophosphate (100 μCi/250 mg of cells) at 37°C for 3 hr. Cells were then harvested by centrifugation at $500 \times g$ for 20 min and processed for lipid extraction.

Lipid extraction. Total lipids were extracted from the washed parasites according to Bligh and Dyer (8). The lipid extract was washed with neutral upper-phase chloroform/methanol/0.1 M KCl (3:48:47, v/v/v) (9). After washing, the lipid extract was dried under a stream of nitrogen and redissolved in a suitable volume of chloroform/methanol (9:1, v/v).

Phospholipid separation and quantification. Phospholipids were separated by preparative thin-layer chromatography. Glass plates (20 × 20 cm) were coated with a slurry of 40 g Silica Gel H (Merck) in 90 mL of a solution of 0.01% Na_2CO_3 and 2 mM EDTA. Potassium oxalate, 1%, was added according to Jolles *et al.* (10). Prior to use, the plates were activated at 110°C for 60 min. An aliquot of the total lipid extract was applied onto the chromatoplate and developed with solvent A, chloroform/methanol/acetic acid/water (50:30:8:4, by vol), or solvent B, chloroform/methanol/4N NH_4OH (54:42:12, v/v/v). The developed chromatograms were exposed to iodine vapors, marked, and the fractions were removed from the plates for phosphorus determination (11,12).

The position of radiolabeled lipids was determined by autoradiography on Agfa-Gevaert Curix X-ray film. Spots were scraped off the plates, and fractions were counted in a liquid scintillation counter (6,13).

Gas-liquid chromatography (GLC) and thin-layer chromatography (TLC) of methyl esters of fatty acids. Fatty acid methyl esters were prepared from the lipid extract with 14% borontrifluoride in methanol (14). The methyl esters of fatty acids were separated by $AgNO_3$-TLC on the basis of their degree of unsaturation as described by Cook (15). The methyl esters were analyzed by GLC on a Varian 2100 gas chromatograph equipped with a flame-ionization detector (Varian, Palo Alto, CA). A column with 10% SP-2330 on 100/120 of Chromosorb WA W (Supelco, Bellefonte, PA) was operated at 180–190°C; the carrier gas was nitrogen. Peaks were identified by comparison with

Abbreviations: DAG, diacylglycerol; EDTA, (ethylenedinitrilo) tetraacetic acid; GLC, gas-liquid chromatography; KRT buffer, Krebs-Ringer-Tris buffer: PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PKC, protein kinase C; PS, phosphatidylserine; TRIS, 2-amino-2-(hydroxymethyl)-1,3-propanediol; TLC, thin-layer chromatography.

those of standard fatty acid methyl esters. When standards were unavailable, peaks were assigned based on semilogarithmic plots of their relative retention times.

Elution of phosphatidylinositol from silica gel. Radioactive and nonradioactive phosphatidylinositol were eluted from thin-layer chromatograms according to the Holub procedure (16).

Incorporation of phosphorus into PI from [γ-^{32}P]ATP. *Trypanosoma cruzi* epimastigote forms homogenate was prepared from 200 mg cells in 10 vol (w/v) of 25 mM TRIS-HCl, pH 7.4, 0.30% Triton-X100 and centrifuged for 10 min at 800 × *g* (5°C) to remove heavy particulate matter. The supernatant was again centrifuged for 30 min at 12,000 × *g* (5°C). According to the method of Traynor-Kaplan *et al.* (17), 104 mg of the last sediment was resuspended in 25 mM TRIS-HCl, pH 7.4, to carry out the phosphorylation (18) and was then added to a reaction mixture containing 17 mM $MgCl_2$, 30 mM 2-mercaptoethanol, 0.15% Triton-X100 and 1 mM ATP[γ-^{32}P]ATP (specific activity 500–1000 cpm/pmol). Following incubation for 20 min at 30°C, the reaction was terminated by the addition of a cooled solution of nonradioactive 7 mM ATP and 20 mM (ethylenedinitrilo) tetraacetic acid (EDTA). Acidified methanol/chloroform was then added to extract the phospholipids.

Materials. All solvents (Merck) were of analytical grade. Phospholipid standards were obtained from Sigma Chemical Co.; [^{32}Pi]phosphoric acid, carrier-free, and [γ-^{32}P]ATP were kindly provided by Dr. Luis Beaugé, Instituto Martín Ferreyra (Córdoba, Argentina). Myo-[^{3}H]inositol (12.8 Ci/mmol) was purchased from New England Nuclear (NEN). Polyphosphoinositides were prepared from ox brain as described by Lees (19).

RESULTS AND DISCUSSION

[^{32}P]P_i was mainly incorporated into phosphatidylethanolamine (PE), lysoPE and PI. Table 1 illustrates the [^{32}P]P_i incorporation into lipids which were separated on oxalate impregnated silica gel thin-layer plates using chloroform/methanol/4N NH_4OH (54:42:12, v/v/v) as developing solvent. In addition significant quantities of the polyphosphoinositides PIP and PIP_2 and lysoPI were identified for the first time in *T. cruzi.*

The phosphoinositides accounted for 14.71% of total cellular lipid phosphorus (500–600 μgP_i/g cells) and were distributed as follows: PI, 63%; PIP, 10%; PIP_2, 8%, and lysoPI, 19%. (The phosphorus content in μgPi/g cells, in PIP and PIP_2 was divided by 2 and 3, respectively.) The PI content in respect to total phospholipids was similar to values found by others (6,20). Although phosphatidylinositol constitutes only 9.30 ± 1.61% of the total cellular phospholipids, and phosphatidylinositol 4-phosphate and phosphatidylinositol 4,5-bisphosphate are represented at even smaller percentages, [^{32}P]P_i was substantially incorporated into these lipids, and they showed a high turnover rate.

In previous studies, PC, PE and PI were the major phospholipids that were identified in whole *T. cruzi* epimastigotes (6,20,21) and in other flagelates (22,23). In our study, phosphatidylcholine (PC), PE, PI and lysoPE (10.46 ± 3.95%) were the major phospholipids found; the relative proportions of PC (21.00 ± 3.00%) and PE (11.06 ± 1.85%) were somewhat different from those reported earlier. Phosphatidic acid (PA) (5.00 ± 1.50%), as previously shown (20), lysoPC (4.43 ± 1.50%) and the polyphosphoinositides described earlier were also identified in *T. cruzi.*

TABLE 1

Phospholipid Turnover and Phosphoinositide Composition of *Trypanosoma cruzi* Epimastigote Forms[a]

Phospholipids	R_f	% of Incorporation [^{32}P][b]	% of Incorporation [^{3}H]inositol[c]
PE	0.75	30.0 ± 4.8	—
PC	0.62	8.5 ± 3.8	—
PI	0.55	13.9 ± 2.2	94.8 ± 3.0
LysoPE	0.52	27.4 ± 3.8	—
LysoPC	0.45	1.9 ± 1.0	—
LysoPI	0.39	4.3 ± 0.6	1.7 ± 1.3
PIP	0.33	8.0 ± 2.0	1.8 ± 0.4
PIP_2	0.14	6.0 ± 1.6	1.7 ± 0.7

[a]Results are expressed as mean ± SE for n = 3. Phospholipids from *T. cruzi* epimastigotes were resolved by TLC using chloroform/methanol/4N NH_4OH (54:42:12, v/v/v) for developing.

[b][^{32}P]P_i (100 μCi/250 mg of cells) was incubated with epimastigote forms (3.0 × 10^7/mL) for 3 hr at 37°C. Phospholipids and radioactivity were determined as described in Materials and Methods.

[c]Myo-[^{3}H]inositol 1.2 μCi/1.0 × 10^6 cells were incubated for 5 days.

An unidentified phospholipid fraction (5.00 ± 1.50%) that migrated between PIP_2 and the origin was present in whole cells. However, structural characterization of this unidentified phospholipid has not yet been completed.

Inositol phospholipids and phosphatidic acid are of interest because of their response to cell stimulation in various types of cells (24,25). Preliminary experiments with *T. cruzi* cells showed similar effects (Machado de Domenech, E.E., Garcia, M., Garrido, M., and Racagni, G., manuscript in preparation). Furthermore, the presence of PIP and PIP_2 would indicate the presence of kinases responsible for PI phosphorylation in *T. cruzi,* which had not been demonstrated previously (see below).

^{3}H-Labeled lipid bands were observed migrating with PI, PIP and PIP_2 in cells grown for five days in the presence of myo-[^{3}H]inositol (not shown). These bands seem to represent authentic phosphoinositides. Our long-term (five days) myo-[^{3}H]inositol labeling experiments (Table 1) indicate that there is a very small amount of inositol incorporated into PIP and PIP_2 compared to the large PI pool in epimastigotes of *T. cruzi,* as has been observed in other membranes (22,26). One to two percent of the myo-[^{3}H]inositol added was incorporated into epimastigotes. The PIP_2 amount was approximately equal to PIP in this protozoa; however, in *C. fasciculata* and yeast, PIP was much more abundant than PIP_2 (22).

In other experiments, radioactive phosphate from [γ-^{32}P]ATP was incorporated into PI to form a phosphorylated product that co-migrated with PIP in thin-layer chromatography. PIP on the plate was localized by autoradiography and by comparison with an authentic standard (results not shown here).

Labeling of PI, PE and lysoPE may indicate that these lipids were formed from rapidly labeled precursors, as suggested by Palmer (22) for *C. fasciculata.* Another possibility is that phosphatidylethanolamine serves as the precursor of phosphatidylcholine *via* methylation as has been

TABLE 2

observed in some protozoa (27). Serine has been shown to be a good lipid precursor in *T. cruzi* (28). A decarboxylase may also be present in this organism, as was suggested for *C. fasciculata* (22). The increased incorporation of ^{14}C into lipids, when the hydroxymethyl carbon is specifically labeled, suggests that in *T. cruzi* transmethylation may play a role in phospholipid synthesis (28).

The upper phase of the lipid extraction was used for the isolation and identification of inositol phosphates by paper chromatography using n-propanol/concentrated ammonia/water (5:4:1, v/v/v) for developing. Our unlabeled standard was inositol 2-monophosphate which has an R_f value equal to that of inositol 4-phosphate (0.44). We therefore, could not distinguish the two. The inositol phosphate ratios observed for IP, IP_2 and IP_3 in *T. cruzi* were 1:1.24:1.67, respectively. Glycerophosphate and glycerophosphoinositol were identified by their R_f values of 0.53 and 0.61, respectively, as reported by Lapetina and Siess (29).

Some significant changes were observed in the relative percentages of fatty acid composition of the total lipids from *T. cruzi* (Table 2) compared to those found by others in epimastigote forms (29–31). *T. cruzi* total lipids contain only a small amount of arachidonic acid (1.5%). Major components were C_{18} and C_{16} acids as in *Leishmania donovani* (32). The major esterified fatty acids of PI, PIP and PIP_2 were different from those of mammalian phosphoinositides but similar to those of leishmania (26). In *T. cruzi*, however, relative increases in the C_{18} acids (except 18:2) and relative decreases in C_{16} acids were observed. The absence of arachidonic acid in these phospholipids (PIP and PIP_2) and its importance as a second messenger (33) and activator of protein kinase C (PKC) (34) might suggest that other unsaturated fatty acids may be able to replace arachidonic acid in certain of its roles. Moreover, several other unsaturated fatty acids, such as oleic acid and linoleic acid (35), are also effective stimulators of PKC. Wooten and Wrenn (36) reported that in pancreatic acinar cells linolenic acid activates this enzyme much more effectively than arachidonic or linolenic acid. Assuming that this is correct, this would point at the potential importance of some unsaturated fatty acids other than arachidonic acid in this type of organism.

LysoPC is both a stimulator of the kinase at low concentration and an inhibitor at high concentrations when acting together with Ca^{2+} and phosphatidylserine (PS) or Ca^{2+}, phosphatidylserine (PS) and diacylglycerol (DAG) (37). LysoPC-mediated activation of PKC is synergistic with that of DAG, but additive to that of oleic acid. Since the PC content of membranes is higher than that of PI, the potential capacity of the cells to generate free fatty acids and lysoPC is considerably greater than that for DAG.

ACKNOWLEDGMENTS

We are grateful to Dr. Luis Beaugé, Instituto Martín Ferreyra (Córdoba, Argentina) for providing the $[^{32}P]P_i$ and $[\gamma\text{-}^{32}P]ATP$ and to Donna Balegno for help with the manuscript. This work was supported in part by a grant from the Consejo de Investigaciones Científicas y Tecnológicas de la Provincia de Córdoba (CONICOR) (Córdoba, Argentina) and the Secretaría de Ciencia y Técnica, Programa Nacional de Enfermedades Endémicas, Argentina.

Effects of Dietary n-3 Fatty Acid-Enriched Chicken Eggs on Plasma and Tissue Cholesterol and Fatty Acid Composition of Rats

Zhirong Jiang and **Jeong S. Sim***
Department of Animal Science, University of Alberta, Edmonton, Alberta, Canada T6G 2P5

The purpose of this study was to examine the effects of feeding n-3 polyunsaturated fatty acid (PUFA)-enriched chicken eggs on plasma and liver cholesterol levels and fatty acid composition in rats. Eggs were collected from laying hens fed diets containing 10% flax seed (Hn-3), 12% sunflower seed (Hn-6), or wheat and soybean meal control (CON). Yolk powders were prepared and fed at the 15% level to weanling female Sprague-Dawley rats for 28 days. Consumption of n-3 PUFA-enriched yolks significantly reduced both plasma and liver total cholesterol. Liver total lipids and phospholipids of rats fed Hn-3 diet were enriched with linolenic, eicosapentaenoic, and docosahexaenoic acids with a concomitant reduction of arachidonic acid in liver phospholipids. The plasma cholesterol of rats fed yolk powders enriched with n-6 PUFA (mainly linoleic acid) was reduced to the same extent as in those fed the n-3 enriched, but the liver cholesterol was significantly increased, indicating differential effects of dietary n-3 and n-6 PUFA. The results demonstrated that the cholesterolemic and tissue lipid modulating properties of chicken eggs could be modified in a favorable way by altering the fatty acid composition of yolk lipids through manipulation of laying hen diets.
Lipids 27, 279–284 (1992).

The past decade has witnessed a burst of interest in dietary n-3 polyunsaturated fatty acids (PUFA) and a growing consensus that consumption of n-3 PUFA is associated with a reduced incidence of coronary heart disease (1,2). α-Linolenic acid (LNA), the major plant n-3 fatty acid, exhibited beneficial effects similar to those of the longer chain n-3 fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) that occur in fish oil (3–6). It was thus suggested that 800 to 1100 mg per day of LNA and 300 to 400 mg per day of a combination of EPA and DHA are needed to prevent n-3 fatty acid deficiency in the elderly (7). Recently, the Canadian government adopted a recommendation that both n-6 and n-3 PUFA are essential nutrients and that the dietary supply should be at least 3 and 0.5%, respectively, of energy intake (8). The absolute amount of dietary n-3 fatty acids should be increased, and the ratio of n-6 to n-3 PUFA be reduced (9,10).

An alternate way to provide n-3 PUFA is by enriching the lipid components of animal products with n-3 PUFA since a major proportion of dietary fat in the Western world is of animal origin. The chicken egg appears to be quite suitable for this purpose (11,12). Preliminary studies from our laboratory have demonstrated that feeding full-fat flax seeds to laying hens greatly increased n-3 PUFA of the yolk (13,14). No studies, however, have reported the dietary effects of the n-3 PUFA-enriched eggs on lipid metabolism.

*To whom correspondence should be addressed.

Abbreviations: AA, arachidonic acid; CON, control diet; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; Hn-3, diet high in n-3 PUFA; Hn-6, diet high in n-6 PUFA; LA, linoleic acid; LNA, α-linolenic acid; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; TC, total cholesterol.

The present study was conducted to examine the lipid modulating property of n-3 PUFA-enriched eggs which were collected from laying hens fed diets containing flax seed. Eggs collected from laying hens fed a diet containing sunflower seed, and thus enriched with n-6 PUFA, were also included for comparison.

MATERIALS AND METHODS

Laying hen diets and yolk powder preparation. Single Comb White Leghorn pullets, 22 wk of age, were transferred to the test diets (Table 1), and the lighting was increased from 8 to 13 hr per day for the first wk, to 14 hr per day during the second wk, and maintained at 14 hr per day thereafter. The laying hen test diets containing 10% full-fat flax seed, 12% sunflower seed, or soybean meal plus animal tallow were provided *ad libitum*. The fatty acid composition of eggs was monitored, and the changes in fatty acid composition of the yolks were found to reach a plateau by 2 wk after feeding the test diets (data not shown). Ten dozen eggs laid during the sixth week were then collected from each treatment. The eggs were hard-boiled, and the yolks were separated, pulverized and dried at room temperature. Yolk powders thus obtained contained 96.3% dry matter. The fatty acid compositions of the yolk powder preparations were determined by gas chromatography (Table 2).

Animals and diets. Twenty-one female Sprague-Dawley rats, 4 wk of age, were housed individually in metabolic wire cages in a room with controlled temperature (21°C), humidity (60%) and lighting (12-hr light-dark cycle). Water and feed were provided *ad libitum*. After feeding a commercial diet (Wayne Rodent Blox, Continental Grain Company, Chicago, IL) for three days, they were divided into three groups with seven rats each, in such a manner that the mean body weight of each group was similar.

Three rat test diets were prepared by mixing 85% basal mix with 15% egg yolk powders (Table 3). The test diets contained yolk powders prepared from eggs laid by laying hens fed rations containing 10% flax seed (Hn-3, diet high in n-3 PUFA), 12% sunflower seed (Hn-6, diet high in n-6 PUFA), or soybean meal plus animal tallow (CON). The diets were stored at 4°C in dark plastic bags. Fresh feed was provided every two days, and feed consumption and body weight gain were measured weekly.

Sample preparation and analyses. At the end of the 28-day feeding trial, rats were fasted overnight and sacrificed by decapitation the following morning (09:00 to 11:00 hr). Trunk blood was collected into Na^+-heparin coated tubes. Rat liver tissue was quickly excised, blotted dry, weighed, and stored at −20°C for lipid analyses. Plasma was separated by centrifugation at 2,000 × *g* for 30 min. Plasma total cholesterol (TC) content was measured by an enzymatic method (15).

A portion (1.0 g) of the median lobe of rat liver was homogenized with a mixture of $CHCl_3$ and CH_3OH (2:1, v/v) (16) with 2 mg 5-α-cholestane added as an internal standard, and the liver total lipid content was determined gravimetrically. Liver cholesterol was determined

[a]Yolk powders were prepared from eggs of laying hens fed diets containing 10% full-fat flax (Hn-3), 12% sunflower seed (Hn-6), or soybean meal plus animal tallow (CON).

by gas chromatography as described previously (17). Aliquots of the liver lipid extracts were dried under nitrogen and converted to their methyl esters by incubation with a mixture of BF_3/methanol (10% BF_3 in methanol), hexane and methanol (35:20:45, v/v/v) at 90°C for 30 min (18). Liver phospholipids were separated on silica gel G plates (Sigma Chemical Co., St. Louis, MO) by developing the plates in a solvent mixture of hexane, diethyl ether and acetic acid (80:20:1, v/v/v) for 30 min. The regions corresponding to the phospholipid standards were scraped into screw-capped tubes and methylated directly in the same way as for the liver total lipids. The methyl esters of fatty acids of liver total lipids and phospholipids were separated and quantified by gas chromatography equipped with an on-column injector (Varian 3400, Varian Associates Inc., Sunnyvale, CA) using a DB-23 fused capillary column (30 m × 0.25 mm i.d.) (J & W Scientific, Folsom, CA). A two-stage column temperature program was used. The initial temperature was set at 70°C for 0.3 min, increased to 180°C at 30 C/min and held for 10 min. Then the column temperature was elevated to 230°C at a rate of 5°C/min and held at the final temperature for 3 min. Helium was used as the carrier gas. The flame ionization detector was set at 240°C.

Statistical analysis. Data were analyzed by one-way analysis of variance (ANOVA). Treatment means were further analyzed by Duncan's multiple range test (19).

RESULTS

Fatty acid profiles of yolk lipids. The fatty acid composition of the yolk powders was readily modified by the laying hen test diets (Table 2). Yolk powders from laying hens fed diets containing flax seed contained 6.1 times the total n-3 PUFA of the control. LNA was the major n-3 PUFA deposited in Hn-3 yolks, although considerable amounts of EPA and DHA were also found in these yolks. Feeding flax seed to laying hens also slightly increased yolk LA and decreased yolk arachidonic acid (AA) content. On the other hand, yolk powder from laying hens fed sunflower seed diet more than doubled the n-6 linoleic acid (LA) in place of oleic acid. Consequently, the ratios of LA/LNA and Σn-6/Σn-3 PUFA were dramatically decreased in Hn-3 yolk powders, and increased in Hn-6 yolk powder preparation, when compared to the control.

Rat performance and organ weights. Rat test diets did not affect the daily feed consumption or body weight gain, nor the absolute weight or the percentage of body weight of liver and heart tissues (Table 4), indicating that enrichment of yolks with either n-3 or n-6 PUFA did not adversely affect the overall feeding values of the yolk.

TABLE 4

Initial Body Weight, Daily Body Weight Gain and Feed Consumption, Liver and Heart Weights of Rats Fed Test Diets

Diet[a]	Initial wt (g)	Net gain (g/rat/day)	Feed consumption (g/rat/day)	Liver wt (g)	Heart wt (g)
Hn-3	80.3	4.6	16.5	7.08	0.91
Hn-6	82.7	4.6	16.6	7.71	0.89
CON	82.7	4.4	16.7	7.21	0.86
SEM	2.19	0.13	0.45	0.27	0.04

[a]The test diets used yolk powders prepared from eggs of laying hens fed diets containing 10% full-fat flax (Hn-3), 12% sunflower seed (Hn-6), or soybean meal plus animal tallow (CON). Female Sprague-Dawley rats were fed test diets for a period of 28 days (n = 7).

Plasma and liver total cholesterol levels. Feeding the Hn-3 diet significantly reduced plasma total cholesterol (TC) as well as liver cholesterol content in rats (Fig. 1). On the other hand, the Hn-6 diet reduced plasma TC level to the same extent as did the Hn-3 diet, but elevated hepatic cholesterol concentration significantly. As the weight of the rat liver was not affected by dietary treatments (Table 4), the Hn-3 diet thus significantly reduced the hepatic cholesterol pool while the Hn-6 augmented this pool when compared to the control diet. Liver total lipid content was also highest in rats fed the Hn-6 diet (Fig. 1).

Fatty acids of liver total lipids and phospholipids. The fatty acids of liver total lipids were changed by rat test diets (Table 5). Significantly higher contents of LNA and its metabolites EPA, docosapentaenoic acid (DPA), and DHA, were found in liver total lipids of rats fed Hn-3 than those fed the control diet (CON). In rats fed the n-6 PUFA-enriched yolk powder diet, neither total nor individual n-3 PUFA were changed when compared to the control fed group. The Hn-6 diet, although it increased LA content significantly, had no effect on the AA level of liver total lipids.

The LNA content of liver phospholipids was not affected by dietary treatments (Table 6). EPA in liver phospholipids of rats fed the Hn-3 diet was 0.9% of total fatty acids, a significant increase over those in Hn-6 or CON fed rats. Hn-3 feeding compared to CON feeding also increased DHA and reduced AA contents significantly in liver phospholipid fraction. Slightly higher LA content found in the liver phospholipids of rats fed the Hn-3 diet might be the result of a slightly higher LA content in the Hn-3 yolks (Table 2). The Hn-6 diet increased the LA content of liver phospholipids, but did not elevate the AA content. When compared to the liver total lipids, liver phospholipids were particularly rich in longer chain metabolites of LA and LNA, such as AA, EPA, and DHA.

DISCUSSION

Since n-3 fatty acids play important roles in human health and disease, and particularly in cardiovascular disease, major nutritional advisory groups have recommended to increase the intake of n-3 fatty acids and to lower the dietary n-6 to n-3 fatty acid ratio (7–10). In the present study, we employed chicken eggs to provide the much

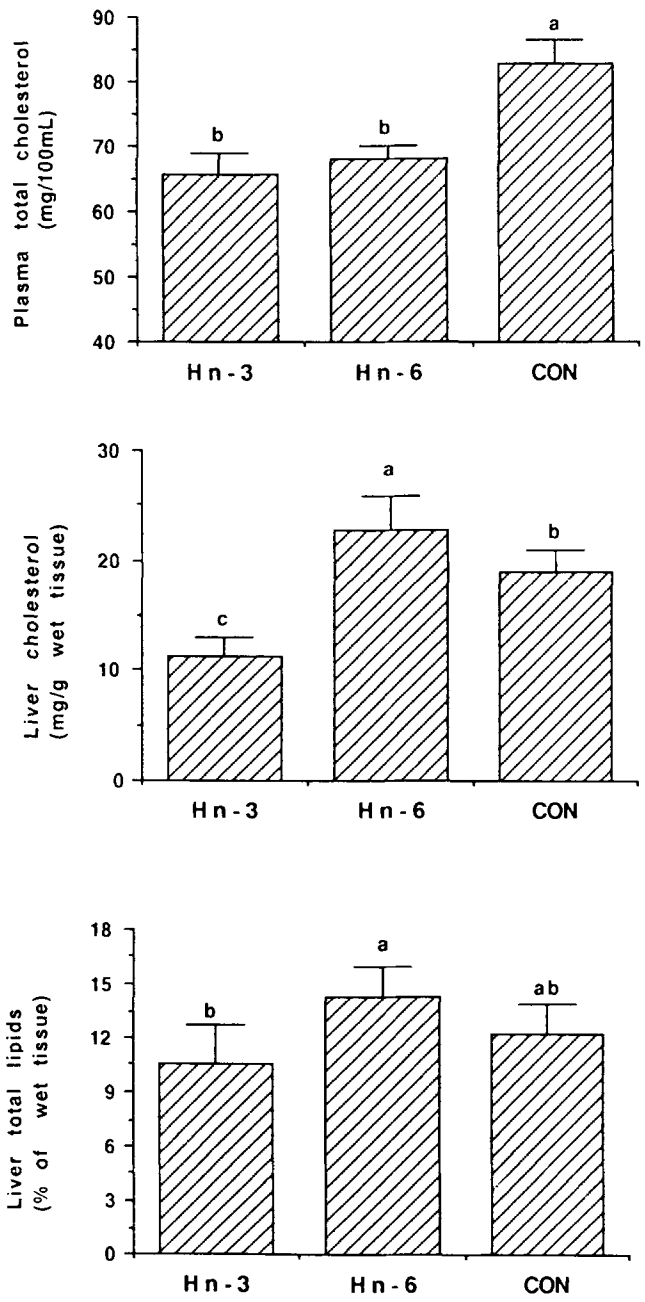

FIG. 1. Plasma and liver cholesterol levels and liver total lipid content of rats at the end of 28-day feeding trial (mean ± SEM, n = 7). The test diets used yolk powders prepared from eggs laid by laying hens fed diets containing 10% flax seed (Hn-3), 12% sunflower seed (Hn-6), or animal tallow control (CON). Bars without a common letter differ significantly ($P < 0.05$).

needed n-3 PUFA and to lower the n-6 to n-3 ratio. A large egg from laying hens fed the 10% flax diet, for example, provided about 450 mg of n-3 PUFA, one-third of which was due to longer chain n-3 PUFA such as EPA, DPA, and DHA. Furthermore, the n-6 to n-3 ratio was reduced from 8.2 in regular eggs to 1.4 in n-3 PUFA-enriched eggs.

The intake of n-3 PUFA-enriched eggs reduced not only the plasma total cholesterol level, but also the liver cholesterol content. In contrast, while the plasma cholesterol content of rats was reduced to the same extent as in those fed the Hn-3 diet, Hn-6 feeding resulted in the accumulation of more cholesterol in rat liver tissue. Thus eggs enriched with n-3 PUFA were more potent than those enriched with n-6 PUFA in reducing the body cholesterol pool. This discrepancy was attributable to the different effects of dietary LNA and LA on cholesterol metabolism in rats. The accumulation of cholesterol in hepatic tissue was also observed in rats fed vegetable oils rich in LA (3,20,21).

The increase of n-3 or n-6 PUFA in yolks was in place of monounsaturated fatty acids (MUFA, Table 2). A hypocholesterolemic effect of dietary MUFA was reported in human subjects (22). In the present study, however, replacement of MUFA by n-3 and n-6 PUFA resulted in a significant reduction in plasma cholesterol level, indicating that dietary n-3 or n-6 PUFA were more potent than dietary MUFA in lowering plasma cholesterol in rats. Previous studies have also revealed that substitution of MUFA for saturated or n-6 PUFA resulted in higher plasma and liver cholesterol levels in rats (23–26).

When dietary n-3 PUFA were provided exclusively as LNA from vegetable oils such as flax and canola oils, a concentration higher than 12% of total fatty acids was needed to effect a lower plasma cholesterol in rats (3,4,27). In the present study, the Hn-3 diet contained 7.9% total n-3 PUFA but still lowered plasma and liver cholesterol significantly. The n-3 PUFA-enriched yolks contained 2.4% EPA, DPA, and DHA in addition to 5.5% LNA, while flax, soybean and canola oils contained LNA as the only n-3 PUFA. The longer chain n-3 PUFA (EPA and DHA) might be more potent than LNA in lowering plasma cholesterol (28,29). In addition, the major portion of the longer chain n-3 PUFA (EPA, DPA, and DHA) in the n-3 yolks resided in phospholipid classes, particularly in phosphatidylethanolamine (30). Dietary phospholipids were reported to have a specific and systemic influence on cholesterol metabolism (31,32), and the degree of the unsaturation of dietary phospholipids directly influenced rat plasma cholesterol levels (32). The enrichment of yolk phospholipids with EPA, DPA, and DHA might thus enhance the ability of lipid modification by n-3 PUFA-enriched yolks. Furthermore, female rats were used in this study. The plasma cholesterol of female rats was more responsive to dietary manipulation than that of male ones (33,34).

The consumption of the n-3 PUFA-enriched yolks not only diminished the body cholesterol pool, but more importantly enriched liver total lipids and phospholipids with LNA, EPA, DPA, and DHA (Table 5,6). In addition, the AA content of liver phospholipids was reduced. The reduction of AA content could be attributable to the inhibition of AA synthesis by the n-3 PUFA in the Hn-3 diet and/or a lower dietary AA content of Hn-3 yolks. Both the enrichment with n-3 PUFA and the reduction of the AA content in tissue phospholipids are considered to have ameliorating effects on atherosclerosis (2).

When rats were fed n-6 PUFA-enriched yolk powders, the LA content of liver total lipids and phospholipids increased, whereas the AA content was not affected. In general, increasing the dietary intake of LA tended to elevate tissue AA content. However, often no further increase of tissue AA content was observed due to the de-

TABLE 5

Major n-3 and n-6 Fatty Acids of Rat Liver at the End of the Feeding Trial[a]

Fatty acid	Dietary treatment

crease of tissue Δ6 desaturase activity when diet was rich in LA (3,35,36).

In conclusion, the cholesterolemic and lipid modulating properties of dietary egg yolks could be modified by altering the fatty acid composition of yolk lipids through nutritional manipulation of laying hens. The n-3 PUFA-enriched animal products (eggs and meats) could become an important dietary source of nutritionally important n-3 PUFA. Caution, however, must be exercised in extrapolating the rat data to man. Further studies with human subjects appear therefore warranted.

METHOD

Effects of *bis* Homoallylic and Homoallylic Hydroxyl Substitution on the Olefinic ^{13}C Resonance Shifts in Fatty Acid Methyl Esters[1]

Philip E. Pfeffer[a,*], Philip E. Sonnet[a], Daniel P. Schwartz[a], Stanley F. Osman[a] and David Weisleder[b]
[a]U.S. Department of Agriculture, ARS, Eastern Regional Research Center, Philadelphia, Pennsylvania 19118 and [b]U.S. Department of Agriculture, ARS, NCAUR, Peoria, Illinois 61604

Substitution of a hydroxyl group at the *bis* homoallylic position (OH group located three carbons away from the olefinic carbon) in C_{18} unsaturated fatty acid esters (FAE) induces a 0.73 ± 0.05 ppm upfield and a 0.73 ± 0.06 ppm downfield shift on the δ and ε olefinic ^{13}C resonances relative to the unsubstituted FAE, respectively. If the hydroxyl group is located on the carboxyl side of the double bond of the *bis* homoallylic hydroxy fatty acid esters (BHAHFA), the olefinic resonances are uniformly shifted apart by [|1.46+|Δδdb$_u$||] where Δδdb$_u$ represents the absolute value of the double bond resonance separation in the unsubstituted FAE and 1.46 ppm is the sum of the absolute values of the δ and ε shift parameters. With hydroxyl substitution on the terminal methyl side of the double bond, the olefinic shift separation is equal to [|1.46−|Δδdb$_u$||]. In homoallylic (OH group located two carbons away from the olefinic carbon) substituted FAE the γ and δ induced hydroxyl shifts for the *cis* double bond resonances are +3.08 and −4.63 ppm, respectively while the *trans* double bond parameters are +4.06 and −4.18 ppm, respectively. The double bond resonance separation in homoallylic hydroxy fatty acid esters (HAHFA) can be calculated from the formula [|7.71−|Δδdb$_u$||] for *cis* and [|8.24−|Δδdb$_u$||] for the *trans* case when the OH substitution is on the carboxyl side of the double bond. Conversely, when the OH resides on the terminal methyl side, the double bond shift separations for *cis* and *trans* isomers are [|7.71+|Δδdb$_u$||] and [|8.24+|Δδdb$_u$||], respectively. The derived shift parameters can verify the positions of both the double bond and hydroxyl substitution from the olefinic resonance separation in long-chain fatty acid derivatives, obviating the need for destructive analytical methods.
***Lipids* 27, 285–288 (1992).**

Although there are a number of articles concerning the ^{13}C nuclear magnetic resonance (NMR) assignments of fatty acid structures (1,2) including unsaturated fatty acids (3–6) and hydroxy fatty acids (7), no attempts have been made to systematize the ^{13}C NMR assignments of unsaturated hydroxy fatty acids. Spectral assignments for methyl ricinoleate, methyl ricinelaidate, and homoallylic hydroxy fatty acid esters (HAHFA) have been mentioned by Rakoff *et al.* (8) and so have assignments of methyl 12-hydroxy-10-octadecenoate by Frankel *et al.* (9).

[1] Reference to brand or firm name does not constitute endorsement by the United States Department of Agriculture over others of a similar nature not mentioned.

Abbreviations: BHAFA, *bis* homoallylic fatty acid esters; FAE, fatty acid esters; HAHFA, homoallylic fatty acid esters; NMR, nuclear magnetic resonance; THP, tetrahydropyranyl.

Earlier work by Tulloch and Mazurek (7) demonstrated that the position of hydroxylation in saturated fatty acids could be pinpointed by examining the induced shifts in natural abundance ^{13}C spectra of the hydroxylated and adjacent carbon resonances. In these spectra the carbon carrying the hydroxyl group (α carbon) was found to shift 42.2 ppm downfield, the β carbon downfield 7.80 ppm, and γ and δ shifted upfield 4.0 and 0.6 ppm, respectively. Batchelor *et al.* (5) have undertaken an extensive investigation of the electric field effects of the carboxyl group on the ^{13}C double bond resonances and of the effects of other substituents such as cyclopropane and additional double bonds on saturated and unsaturated carbon resonances in long-chain fatty acid derivatives (1). Their findings demonstrated that of the two unsaturated carbons, the carbon nearest the carboxylate head group consistently had the higher field ^{13}C chemical shift. It was also revealed that the separation of the double bond ^{13}C resonances uniquely depends upon the position of the double bond relative to the carboxyl group. These observations were attributed to a linear electric field effect induced by the terminal carboxyl group. In the present work we report the results of hydroxyl substitution on the chemical shift separation of unsaturated carbon resonances in long-chain fatty acid esters together with some strategies for exploiting derived shift parameters for structural identification of these derivatives.

MATERIALS AND METHODS

Materials. Unsaturated and hydroxy-substituted fatty acids and esters such as those of petroselinic, ricinoleic, ricinelaidic, oleic, and elaidic acids were obtained commercially. Most of the ^{13}C NMR data were taken from various literature sources (3,4,7–9). Chemical shift assignments for the unsaturated carbon resonances in *cis* and *trans* HAHFA, methyl 12-OH-9-octadecenoate, were obtained from Rakoff *et al.* (8). Methyl 9-hydroxy-12-octadecenoate (isoricinoleate) was obtained by extracting seeds of *Holarrhena antidysenterica* (NU-46607) and purification as described (10).

NMR spectroscopy. ^{13}C NMR spectra were obtained with a 9.3T JEOL GX-400 NMR spectrometer (Peabody, MA) operating at 100.4 MHz. All spectra were obtained with a 25KHz spectral width, 16K data points, a 15 μsec 90 degree pulse, and a 5 sec repetition rate. Samples were examined in $CDCl_3$. All resonances were referenced to $CDCl_3$ at 77.00 ppm relative to external TMS which is assigned a value of 0.00 ppm. Reported chemical shifts are ±0.03 ppm.

Mass spectrometry. Mass spectra were obtained on a Hewlett-Packard 5990B GC/MS fitted with an Ultra (methyl silicone) 12-m capillary column (Hewlett-Packard,

Palo Alto, CA). The column was temperature programmed from 150° to 250°C at 4°C per min.

Methyl 10-hydroxy-6-octadecenoate and methyl 9-hydroxy-5-octadecenoate were synthesized by the following procedure: The synthesis of the δ-6,7-structure began with 5-chloro-1-pentanol that was protected as a tetrahydropyranyl (THP) ether, and was then treated with lithium acetylide in dimethyl sulfoxide (iodide catalyst). The resulting alkyne was cyanoethylated (1:butyllithium, ethylene oxide; 2:methanesulfonyl chloride, triethylamine, 3:sodium cyanide, dimethyl sulfoxide), and the resulting nitrile was then condensed with n-octylmagnesium bromide to produce a ketoalkyne of the correct chain length bearing a THP-protected primary alcohol. Deprotection (methanolic HCl) gave a ketoalkynol that was oxidized to the acid (chromic acid, acetone) and esterified (methanol, boron trifluoride). This ketoalkyne ester was reduced at the carbonyl by sodium borohydride and hydrogenated to a *cis*-alkene over palladium on carbon in methanol. The δ-5,6-structure was synthesized in analogous fashion using 4-chloro-1-butanol and 1-bromononane as alternate starting materials. The positions of the hydroxyl group and double bonds were verified by oxidative cleavage and mass spectrometry. Double bond position was determined by the chromic acid micro column technique (11). The scission products (carboxylic acids) were identified by comparison of retention times with standards using gas-liquid chromatography, and also by mass spectrometry. The hydroxyl group was localized by mass spectrometry after hydrogenation of the double bond (12).

RESULTS AND DISCUSSION

Figure 1 gives a schematic representation of the two types of unsaturated hydroxy fatty acids examined in this study. Each of these two structures, *bis* homoallylic (BHAHFA), OH located three carbons away from the olefinic carbon and homoallylic (HAHFA), OH located 2 carbons away from the olefinic carbon fatty acid esters, can contain a hydroxyl substituent on the terminal methyl side [a] or carboxyl side [b] of the double bond. Table 1 lists as an example the observed ^{13}C chemical shifts for the newly synthesized BHAHFA II methyl 9-OH-*cis*-5-octadecenoate, methyl 10-OH-*cis*-6-octadecenoate as well as the previously isolated methyl 9-OH-*cis*-12-octadecenoate (isoricinoleate) and the corresponding unsaturated methyl esters from which they are derived (3). The incremental ^{13}C shifts due to the substitution of the hydroxyl group

[a]ppm. [b]Reference 3.

are given for each structure. Note that the OH induced shifts in the BHAHFA associated with the ^{13}C resonances representing the adjacent saturated carbons are similar to those reported earlier (7). However, the double bond carbon resonances, those δ and ε to the OH substituted carbon, have undergone a relatively large shift change as compared to their saturated counterparts, presumably because of the greater polarizability of the unsaturated carbons by the electric field originating at the molecular dipole of the OH group (1,5).

Table 2 lists the observed OH induced shift parameters for the double bond carbon resonances in HAHFA Ia,b and BHAHFA IIa,b. The values represent the average difference in chemical shift between the olefinic carbon resonances in the substituted and non-substituted esters. By combining the shift separation values for the monounsaturated fatty acid methyl esters as given in Table 3 with the shift parameters in Table 2 we can predict the double bond resonance separation in type IIa and b BHAHFA (Fig. 2 and 3). Figure 2 illustrates when the OH group is on the terminal methyl side of the double bond, the double bond resonance separation shows a continuous narrowing as the double bond position moves from carbon 12 to 6. The narrowing in the olefinic shift separations results from the upfield movement (−0.73 ppm) of the lower field shift (δ carbon) and the downfield movement (+0.73 ppm) of the higher field olefinic resonance (ε carbon). Therefore, in type IIa structures with unsaturation in positions 6–12, the double bond resonance assignments

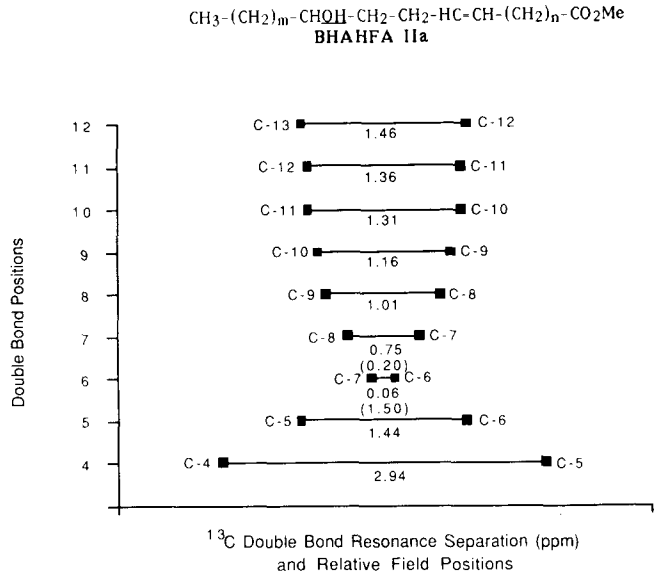

FIG. 2. Predicted and actual ^{13}C double bond resonance separations, chemical shift assignments and relative field positions for BHAHFA when the OH group is on the terminal methyl side of the double bond (type IIa). Value given in parentheses over the line is the actual shift separation value.

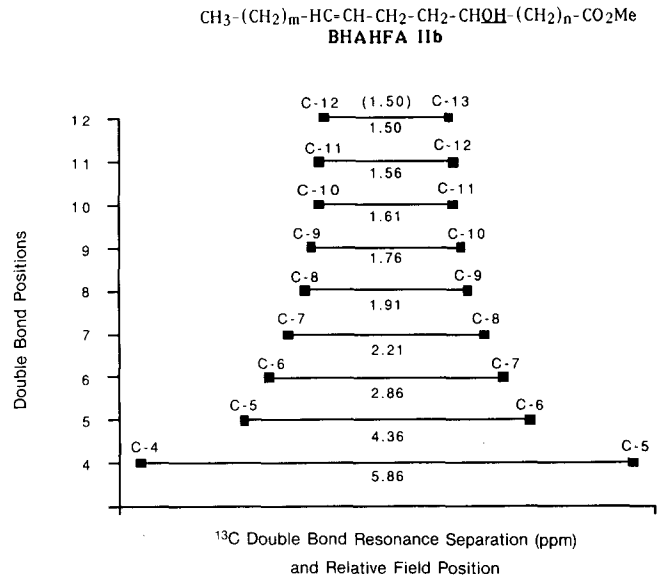

FIG. 3. Predicted and actual ^{13}C double bond resonance separations, chemical shift assignments and relative field positions for BHAHFA when the OH group is on the carboxyl side of the double bond (type IIb). Value given in parentheses over the line is the actual shift separation value.

[a]Based on shifts given by Bus *et al.* (4).

are opposite to those reported for the unsubstituted monounsaturated counterparts (5). That is, in type IIa compounds (double bond positions 6–12 and beyond) the higher field olefinic resonance represents the olefinic carbon farthest from the carboxyl group. At the 6-position the olefinic shift separation reaches a minimum (0.1 ppm) due to the countering dipolar effects of the terminal carboxyl group (5). Beyond the 6-position *e.g.*, double bond

positions 4, 5, etc. the higher and lower field olefinic resonance assignments revert to those previously established for the corresponding fatty esters (3). In essence, these shifts have crossed over each other.

In Figure 3 we observe that the predicted double bond shift assignments for type IIb compounds do not change from the corresponding unsubstituted precursors (4,5), since the upfield resonance (δ) moves upfield (−0.73 ppm) and the downfield resonance (ε) moves downfield (0.73) with OH substitution on the carboxyl side of the double bond. Since no shift crossovers can occur in this example, only a smooth increment in double bond resonance separation is observed as the double bond moves from C-12 to C-4.

To calculate the double bond shift separation in BHAHFA we use the following:

$$\text{For type IIa} \qquad \Delta\delta db_s = [||\varepsilon\text{-}\delta| + |\Delta\delta db_u||] \qquad [1]$$

Where $\Delta\delta db_s$ is the double bond resonance separation in the BHAHFA, $|\varepsilon\text{-}\delta|$ is 1.46 ppm for *cis* type II fatty acid esters and $\Delta\delta db_u$ is the observed ^{13}C shift separation in the monounsaturated analogues.

$$\text{For type IIb} \qquad \Delta\delta db_s = [||\varepsilon\text{-}\delta| - |\Delta\delta db_u||] \qquad [2]$$

HAHFA double bond resonance separations are given by:

$$\Delta\delta db_s = [||\gamma\text{-}\delta| - |\Delta\delta db_u||] \qquad [3]$$

For type Ia *cis* or *trans* where $|\gamma\text{-}\delta|$ is equal to 7.71 and 8.24 ppm for the *cis* and *trans* isomers, respectively (Table 2). For type Ib the same equation as above applies except the sign is positive:

$$\Delta\delta db_s = [||\gamma\text{-}\delta| + |\Delta\delta db_u||] \qquad [4]$$

Predicted shift separations for *cis* and *trans* type a or b HAHFA are given in Table 3. In most instances one can pinpoint the position of hydroxyl substitution in long-chain fatty acid derivatives directly from the documented α shift (7). Having established this position, it is easy to ascertain if a double bond is located within 3 or 2 carbons from this site as well as on which side of the double bond it resides. Note that it is not possible to determine if we have type a or b substitution in either BHAHFA or HAHFA derivatives when the double bond is at the 12-position since the chemical shifts are identical for the olefinic carbons in the spectra of the corresponding unsubstituted fatty acid esters (FAE). Also, we have not accounted for possible effects of H-bonding of the OH group with the carboxyl when OH substitution is found at the C-4 or position closer to the carboxyl group. ^{13}C chemical shift data available from the literature on allylic hydroxy FAE do not appear to show the same predictable shift increments exhibited by derivatives I and II.

The shift parameters described in this work can be useful for the non-destructive identification of structures of type Ia,b and IIa,b FAE. It is particularly valuable when sample size is limited and material cannot be sacrificed for destructive analyses. While alternative NMR methods such as 2D INADEQUATE experiments (13) are often used to elucidate such structures, they require orders of magnitude of more sample and time than is required for this simple analysis.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Frank Gunstone for his help in locating some of the references to the ^{13}C shift assignments of some allylic and homoallylic FAE.

Chemiluminescence Detection of 8a-Hydroperoxy-tocopherone in Photooxidized α-Tocopherol

Teruo Miyazawa*, Toyonobu Yamashita and **Kenshiro Fujimoto**
Department of Food Chemistry, Tohoku University, Tsutsumidori Amamiyamachi 1-1, Aoba-ku, Sendai 981, Japan

Photosensitized oxidation products of α-tocopherol were analyzed by reversed phase high-performance liquid chromatography (CL-HPLC) in combination with chemiluminescence detection, to measure hydroperoxide derivatives. An intense peak was observed on the chemiluminescence chromatogram, corresponding to 8a-hydroperoxy-α-tocopherone (α-tocopherol hydroperoxide), the identity of which was confirmed by ^1H nuclear magnetic resonance and mass spectrometry. Observed peak intensities correlated with the peroxide value of oxidized α-tocopherol. As little as 50 pmol of 8a-hydroperoxy-α-tocopherone was detectable. The CL-HPLC method, which is specific for the detection of hydroperoxides, should prove useful in studies on tocopherol oxidation in foods and biological systems.
Lipids 27, 289–294 (1992).

Tocopherol (Toc) has received much attention as a very important antioxidant both in foods and biological systems (1,2). Toc is known to react with singlet molecular oxygen ($^1O_2$) whereby $^1O_2$ is chemically and physically quenched by Toc (3,4). Toc-quinone and Toc-quinone epoxide have been reported to be formed by $^1O_2$ oxidation of Toc in several model systems (5–7). The occurrence of Toc-quinone in rat liver also has been reported (8,9). However, details of the oxidation mechanism of Toc with oxygen radicals and with electrically excited species of $^1O_2$ are not fully understood.

Clough *et al.* (3) suggested that $^1O_2$ oxidation of Toc takes place *via* formation of 8a-hydroperoxy-tocopherone (Toc-OOH) as an intermediate. Matsumoto *et al.* (10) demonstrated by X-ray analysis that the reaction of 2,2,5,7,8-pentamethyl-chroman-6-ol (a model compound for Toc) with $^1O_2$ gives rise to 8a-hydroperoxy-2,2,5,7,8-pentamethyl-chroman-6-one, which is an important precursor of Toc oxidation products. Recently, Yamauchi *et al.* (11) reported that 8a-hydroperoxy-α-tocopherone was generated by radical initiated oxidation of α-Toc. Hydroperoxidic Toc has been characterized by its mass spectrum, infrared spectrum, and by ^1H and ^{13}C nuclear magnetic resonance (NMR) spectroscopy. No evidence has been published on the occurrence of hydroperoxy-tocopherones in biological systems. An established method that would be specific for the detection of the hydroperoxide group of Toc-OOH is not presently available.

Miyazawa and co-workers (12–15) have described a chemiluminescence detection high-performance liquid chromatographic (CL-HPLC) method for the assay of phospholipid hydroperoxides present in plasma and tissues. In the present study, we have applied the CL-HPLC method for the assay of Toc-OOH formed during the reaction of α-Toc with photochemically-generated $^1O_2$. We observed the appearance of a chemiluminescence peak that we ascribed to Toc-OOH, and 8a-hydroperoxy-tocopherone was identified as the principal chemiluminescent product.

Abbreviations: CL, chemiluminescence; FAB-MS, fast atom bombardment mass spectrometry; HPLC, high-performance liquid chromatography; NMR, nuclear magnetic resonance; $^1O_2$, singlet oxygen; TLC, thin-layer chromatography; Toc, Tocopherol; Toc-OOH, tocopherol hydroperoxides.

MATERIALS AND METHODS

CL-HPLC system. The CL-HPLC system used in the present study to detect Toc-OOH was essentially the same as that reported by Miyazawa (12). It consisted of a Reodyne model 7125 sample injector and a Wakopak NU-ODS-10 column (4.6 × 250 mm, packed with 10 μm Nucleosil-ODS-Si; Wako Pure Chemical Co., Osaka, Japan) coupled to a Jasco 875 UV detector (Japan Spectroscopic Co., Tokyo, Japan). Methanol was used as the mobile phase for HPLC at a flow rate of 1.1 mL/min, which was controlled by a Jasco 880 PU pump. Column eluate was first monitored at 240 nm by a UV detector. After UV detection, the column eluate was mixed with a chemiluminescence (CL) reagent consisting of cytochrome c (10 mg/L) and luminol (1 mg/L) in 50 mM borate buffer (pH 9.3) (12). The flow rate of the CL reagent was 1.0 mL/min. The generated CL was monitored with a Chemiluminescence Analyzer OX-7 or CLD-100 (Tohoku Electronic Ind. Co., Sendai, Japan) equipped with a spiral teflon flow cell (cell vol., *ca.* 200 μL) (12–15). Chromatograms based on UV and CL detection were recorded simultaneously with a Sekonic SS-250F multiple recorder. All CL-HPLC assays were performed at 20°C in a temperature-controlled room.

Photooxidation of α-Toc. d-α-Toc (116 μmol; gift from Eisai Co., Tokyo, Japan) was dissolved in 25 mL of methanol containing 0.8 mg methylene blue (Wako Pure Chemical Co., Osaka, Japan) as a photosensitizer. The reaction mixture was placed in a beaker (200 mL) cooled with ice-cold water, and photoirradiated for 0 to 11 hr at 12.5°C. The light source, a 500-W photoreflector lamp (Toshiba Electronics Co., Tokyo, Japan), was held at a 50-cm distance above the surface of the reaction mixture. After photooxidation, the reaction mixture was passed through a silica gel column (20 × 150 mm, Wako Pure Chemical Co.) using methanol as eluant to also remove methylene blue. Toc and its oxidized products were recovered from the methanol extract under reduced pressure by rotary evaporation. The oxidation products of Toc were redissolved in 20 mL of methanol, and a 20-μL portion was subjected to CL-HPLC assay.

The hydroperoxide concentration was determined by KI reduction (16,17). The residual Toc in the photooxidized sample was measured by reversed phase HPLC using a Wakopak NU-ODS-10 column and fluorescence detection at Ex. 298 nm and Em. 325 nm (Jasco FP 210).

$NaBH_4$ reduction of photooxidized α-Toc. A 2-mL portion of the 10-hr photooxidized α-Toc was reacted in methanol with 100 μmol $NaBH_4$ (Wako Pure Chemical Co.) for 1 hr. The reaction products were recovered in the chloroform layer after adding chloroform and water to the

reaction mixture. The chloroform layer was dried, the residue redissolved in 2 mL of methanol, and 20-μL portions of the extract were subjected to CL-HPLC and α-Toc assay.

Thin-layer chromatography (TLC) of photooxidized α-Toc. The photooxidation products of α-Toc were applied to a TLC plate (DC-Kieselgel 60, Merck, Darmstadt, Germany) using hexane/diethyl ether (55:45, v/v) as the developing solvent. Spots were visualized either by charring with 50% sulfuric acid, or by spraying with 1% dimethyl-*p*-phenylenediamine/methanol solution. The hydroperoxide group containing compound gives a purple spot in TLC with the dimethyl-*p*-phenylenediamine reagent (18).

NMR and mass spectrometry. The chemiluminescent product that was revealed by CL-HPLC of photooxidized α-Toc was isolated by HPLC and characterized by ^{1}H NMR (Jeol JNM-GSX-270 NMR spectrometer) in $CDCl_3$ at 27°C. Isolated products were further analyzed by fast atom bombardment mass spectrometry (FAB-MS; Jeol JMN-HX-105 mass spectrometer). To avoid decomposition of the hydroperoxide of oxidized Toc, the chemiluminescent compound was collected by HPLC using a Jasco RPC-PO-based polymethacrylate column (4.6 × 150 mm, Japan Spectroscopic Co., Hachiohji, Tokyo, Japan) and methanol/water (95:5, v/v) as the mobile phase at a flow rate of 1.0 mL/min.

RESULTS

Figure 1 shows a typical chromatogram of 3-hr photooxidized α-Toc as obtained by CL-HPLC with OX-7 as the chemiluminescence detector. On the UV (240 nm) chromatogram, three major peaks were observed for oxidized Toc. The peak components were isolated by using normal-phase and reversed-phase HPLC, and were identified by ^{1}H NMR and mass spectrometry as being the same oxidation products as those found by Grams *et al.* (5) upon photoirradiation of α-Toc; that is, methoxy-tocopherone (8a-methoxy-α-tocopherone), epoxy-methoxy-tocopherone (mixture of *cis* or *trans*-4a,5-epoxy-*cis* or *trans*-8a-methoxy-α-tocopherone), α-Toc, and 8a-hydroperoxy-α-tocopherone (Toc-OOH). By comparison, on the CL chromatogram only a single intense peak was observed.[1] This single peak on the CL chromatogram was resolved under UV detection into an overlapping multiplet of 4 or 5 peaks. Rechromatography by CL-HPLC of an individual component that had been isolated from the multiplet fraction in UV-HPLC confirmed that only peak 1 is chemiluminescent (Fig. 1).

The intense CL peak completely disappeared when the photooxidized α-Toc was reacted with $NaBH_4$ (Fig. 2). Frei *et al.* (19) reported that chemiluminescence of ubiquinol did not disappear after reaction with $NaBH_4$ (19). This suggests that the CL peak observed in our experiment is not due to quinone derivatives such as Toc-quinone or Toc-quinone epoxide. When we examined authentic Toc-quinone by CL-HPLC, CL peaks due to Toc-quinone were not noted on the CL chromatograms (data not shown).

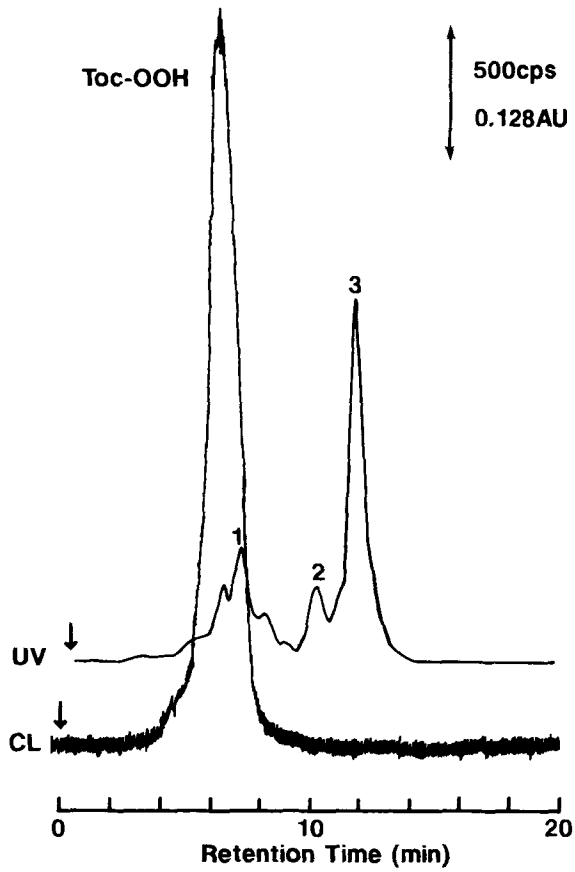

FIG. 1. Typical CL-HPLC chromatogram of the photooxidation products of α-Toc. Twenty-five mL of a methanolic solution containing 116 μmol *d*-α-Toc and 0.8 mg methylene blue were photoirradiated for 3 hr. The oxidation products were then treated as described in Materials and Methods and were injected into a CL-HPLC instrument equipped with an OX-7 detector. The main peaks identified were: 1, Toc-OOH (8a-hydroperoxy-α-tocopherone); 2, unoxidized α-Toc + 8a-methoxy-α-tocopherone; and 3, epoxy-8a-methoxy-α-tocopherone.

TLC of 2-hr photoirradiated α-Toc showed seven fractions (R_f 0.65, 0.63, 0.59, 0.49, 0.40, 0.37 and 0.22) upon charring with 50% sulfuric acid. α-Toc gave a spot at R_f 0.49 under the same conditions. By comparison, two spots (R_f 0.40 and 0.37) were identified as hydroperoxide-containing products as they gave positive results with the dimethyl-*p*-phenylenediamine reagent. These two fractions seemed to be the two epimeric products of 8a-hydroperoxy-tocopherone as previously reported by Yamauchi *et al.* (11,20). The structural characterization of the two fractions was further pursued by NMR and mass spectrometry.

The ^{1}H NMR spectrum of the chemiluminescent peak component isolated by HPLC clearly indicated the presence of a hydroperoxide group (Fig. 3). The proton signal due to the hydroxyl group (4.18 ppm) observed for α-Toc disappeared, and a doublet (7.34, 7.37 ppm) that can be ascribed to the hydroperoxide protons of the epimers was detected at lower field. The hydroperoxide signal disappeared after reduction of Toc-OOH with $NaBH_4$ (data

[1]When the new chemiluminescence detector CLD-100 was used, CL sensitivity improved; several small luminescent peaks ascribed as analogues of Toc-OOH appeared on the CL chromatogram (data not shown). However, these peaks showed little absorbance by UV detection, and were difficult to isolate and identify.

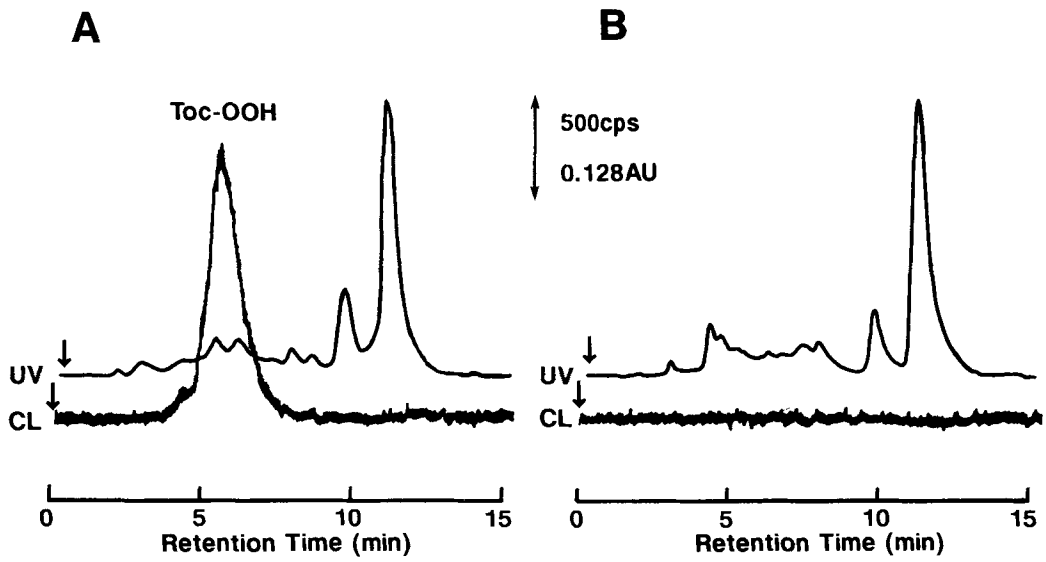

FIG. 2. Effect of $NaBH_4$ reduction of photooxidized α-Toc on CL-HPLC pattern. A, Photooxidized α-Toc; B, $NaBH_4$ reduction products of photooxidized α-Toc.

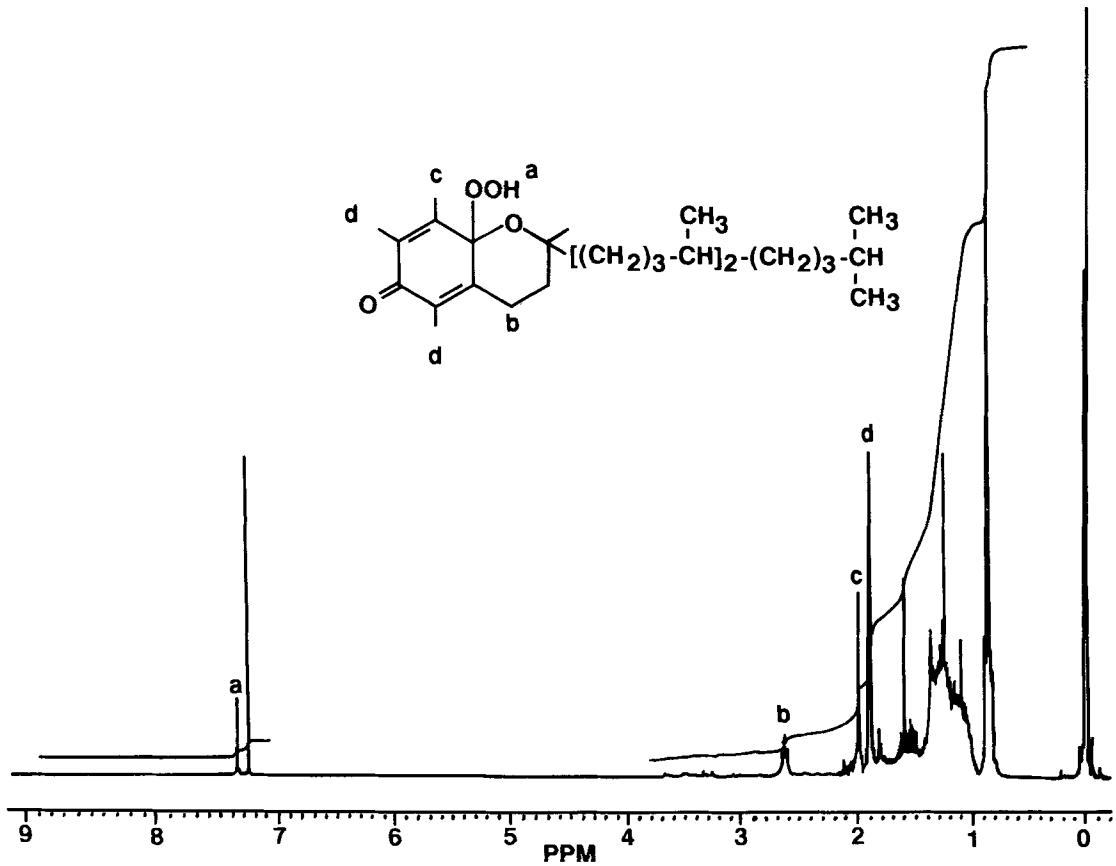

FIG. 3. ^1H NMR spectrum of the chemiluminescent product, 8a-hydroperoxy-α-tocopherone, from photooxidized α-Toc. The chemiluminescent product was isolated from photooxidized *d*-α-Toc prior to NMR analysis.

not shown). The methyl protons of the phytyl side chain appeared as a series of doublets at about 0.8 ppm (Fig. 3). The molecular weight of the chemiluminescent product was determined to be 462 by FAB-mass spectrometry, as expected for 8a-hydroperoxy-α-tocopherone. We therefore concluded that the chemiluminescent peak component, which we detected by CL-HPLC of the $^1O_2$/Toc oxidation products, was 8a-hydroperoxy-α-tocopherone.

Figure 4 shows the time-course of Toc-OOH formation, the changes in peroxide value (theoretical 4328 meq/kg for 8a-hydroperoxy-α-tocopherone), and the residual amount of α-Toc, when 116 μmol of α-Toc dissolved in methanol was subjected to photooxidation. After 30 min of photoirradiation, 90% of α-Toc remained, and just a small CL peak ascribed to Toc-OOH (corresponding to 9.1 μmol) was observed on the CL chromatogram. After 3-hr photooxidation, Toc had been completely oxidized. During this time, the increase in peroxide value of the oxidized Toc was proportional to the appearance of Toc-OOH in CL-HPLC. After 3-hr oxidation, 87.0 μmol of Toc-OOH (equivalent to 75.0% of initial α-Toc) was formed and the peroxide value of the oxidized Toc reached 3480 meq/kg. The decrease in Toc-OOH and peroxide value of oxidized Toc observed after the 3-hr photoirradiation is ascribed to the breakdown of Toc-OOH.

In order to improve sensitivity and to lower the detection limit of 8a-hydroperoxy-α-tocopherone, we also used the new chemiluminescence detector CLD-100, instead of OX-7. With the CLD-100, it was possible to extend the detection limit to as low as 50 pmol of 8a-hydroperoxy-α-tocopherone with our CL-HPLC system (Fig. 5). A mixture of cytochrome c (10 mg/L) and luminol (2 mg/L) in 50 mM borate buffer (pH 10.0) was favored as the CL reagent for measuring Toc-OOH. We found that at higher luminol concentration and pH, the sensitivity was generally increased, but under these conditions background was also increased. Therefore, the optimal concentration of luminol should be carefully chosen.

DISCUSSION

Toc is known to be the principal antioxidant in lipophilic biological systems and is thought to play an important role in protecting biomembranes from radical-induced injury. In rats, the molecular ratio of α-Toc to polyunsaturated fatty acids in liver and kidneys was reported to be below 0.001 (21). Tappel (22) suggested that ascorbic acid and/or reduced glutathione can synergistically regenerate Toc from Toc radicals. Similarly, Niki *et al.* (23) reported that in liposomal model systems ascorbic acid can regenerate Toc from its radical forms. Yamauchi *et al.* (20) suggested that 8a-hydroperoxy-tocopherone (Toc hydroperoxide) is convertible to Toc by ascorbic acid.

However, researchers have generally failed to detect Toc hydroperoxide among Toc oxidation products, because no selective and sensitive detection method had been applied until now. In this paper, we describe (for the first time) the hydroperoxide-specific detection of Toc-OOH with a CL-HPLC system and report that 8a-hydroperoxy-α-tocopherone can be identified as a prominent single peak in CL-HPLC.

Toc has been reported to inhibit chemiluminescence and has been shown to appear as a quenching peak in CL chromatograms (19). However, no quenching due to Toc (Rt, 9.8 min) was apparent on the chromatogram shown in Figure 1. This is because the base line was low under our conditions as methanol was used as HPLC solvent at a low luminol concentration. We should also emphasize

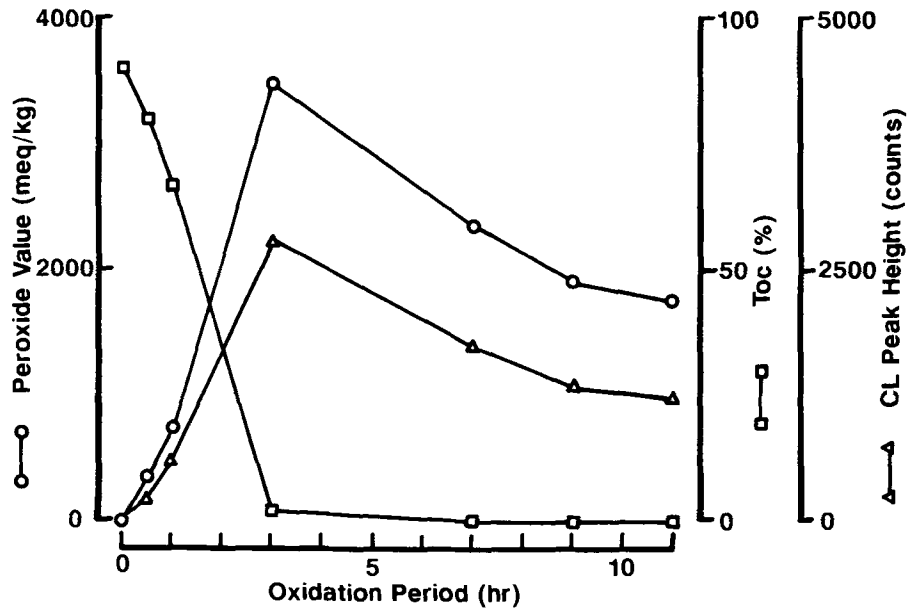

FIG. 4. Photooxidation time dependent changes of residual α-Toc, 8a-hydroperoxy-α-tocopherone (Toc-OOH) and peroxide value of oxidized α-Toc.

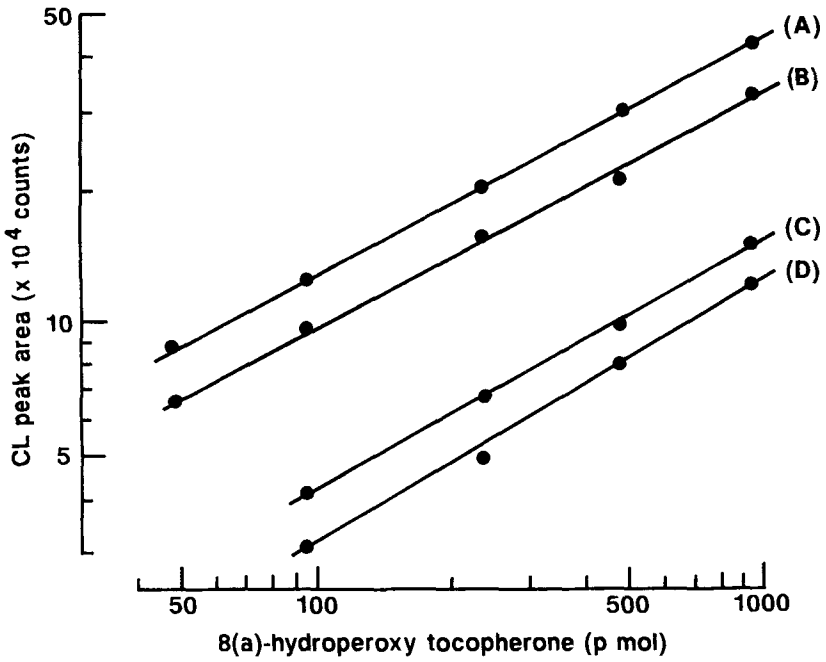

FIG. 5. Calibration curves of 8a-hydroperoxy-α-tocopherone. Photooxidized α-Toc was assayed by CL-HPLC using a CLD-100 analyzer and a RPC-PO polymethacrylate column. The mobile phase was methanol (flow rate, 1.1 mL/min). Four types of luminescent post column reagents (flow rate 1.0 mL/min) were tested: A, cytochrome c (10 mg/L) and luminol (2 mg/L) in 50 mM borate buffer (pH 10.0); B, cytochrome c (10 mg/L) and luminol (1 mg/L) in 50 mM borate buffer (pH 10.0); C, cytochrome c (10 mg/L) and luminol (2 mg/L) in 50 mM borate buffer (pH 9.3); and D, cytochrome c (10 mg/L) and luminol (1 mg/L) in 50 mM borate buffer (pH 9.3).

that α-Toc does not affect the chemiluminescence of 8a-hydroperoxy-α-tocopherone (Rt, 6.6 min) because of their different retention times.

Clough *et al.* (3) reported that 8a-hydroperoxy-α-tocopherone, which is a yellowish material, decomposed when passed through a silica gel column. This was confirmed in our experiments. For example, when we tested silica gel and ODS silica gel columns to isolate the peroxidized Toc with various solvent systems as eluants, we could not isolate the hydroperoxidic compound. Even in silica gel TLC at −25°C, it was impossible to isolate Toc-OOH. Despite decomposition of Toc-OOH during normal-phase silica gel column chromatography, in CL-HPLC chemiluminescent response was observed when a reversed-phase ODS column was used (Fig. 1). This implies that part of Toc-OOH is not destroyed and emits light, which allows the use of the ODS silica gel column for the detection of Toc oxidation products. Nevertheless, for complete protection of Toc-OOH, we prefer a polymer type column, such as the RPC-PO-based polymethacrylate column (Japan Spectroscopic Co., Tokyo, Japan). In the polymer column, Toc-OOH was more stable than in the silica gel column, and the detection limit was 50 pmol using the CLD-100 detector (Fig. 5).

We showed that the retention time of Toc-quinone was similar to that of Toc-OOH (Rt, 6.6 min) on the ODS silica gel column in CL-HPLC. However, Toc-quinone did not give a chemiluminescent peak. α-Toc quinone and α-tocopheryl-quinone-epoxide together with 8a-hydroperoxy-α-tocopherone have been reported to be formed by the reaction of α-Toc and photochemically generated $^1O_2$ (5–7). Grams *et al.* (5) reported that the major oxidation products were methoxy-tocopherone and epoxy-methoxy-tocopherone when Toc was reacted with $^1O_2$ in methanol. In our study, we detected methoxy-tocopherone and epoxy-methoxy-tocopherone together with Toc-OOH, and confirmed that only Toc-OOH is a chemiluminescent product (Fig. 1). It was thought that formation of methoxy adducts *via* Toc-OOH is a major oxidation pathway, while Toc quinone formation was a minor reaction when Toc oxidation with $^1O_2$ was performed in the methanol. Our results on methoxy adduct formation are, in principle, consistent with the findings of Grams *et al.* (5).

In the ^1H NMR spectrum that we measured at 27°C, the hydroperoxide protons of the epimers of 8a-hydroperoxy-α-tocopherone occurred at 7.34 and 7.37 ppm (Fig. 3), whereas those of the epimers at −25°C were reported at 8.9 ppm (3). As we proceeded to rather high temperatures, the hydroperoxide protons of Toc-OOH seemed to shift upfield, which may be the result of weakened hydrogen bonding with the oxygen at position-1 in the chroman ring.

Although oxidation processes of Toc with superoxide anion (24,25), singlet oxygen (20,26,27) and *t*-butyl hydroperoxide (28–30) have been studied extensively, detailed mechanisms have not yet been elucidated, especially for *in vivo* systems. Winterle *et al.* (31) reported that α-Toc formed 8a-alkylperoxy-α-tocopherones *via* reaction of alkylperoxyl radicals with α-tocopheroxyl radicals. Adduct

formation of peroxyl radicals and tocopheroxyl radicals was also reported by Liebler *et al.* (32) and Yamauchi *et al.* (11,20,33). These peroxyl radical dependent oxidation pathways of α-Tbc may also involve the formation of 8a-hydroperoxyl tocopherone as an intermediate which one should be able to detect by the present chemiluminescence assay. The CL-HPLC method should prove useful for the study of oxidoreductive reactions of tocopherols in foods and biological systems.

[Received November 18, 1991; Revision accepted February 18, 1992]

An Extended Method for Separating and Quantitating Molecular Species of Phospholipids

Margaret G. Wiley, Marek Przetakiewicz, Mareyuki Takahashi and **John M. Lowenstein***
Graduate Department of Biochemistry, Brandeis University, Waltham, Massachusetts 02254

An improved and extended method for separating and quantitating molecular species of four phospholipid classes is presented. Crude lipid extract is first separated into phospholipid classes on a silica column. Each phospholipid class is then separated into molecular species without derivatization using high-performance liquid chromatography on columns packed with octadecyl silica. Quantitation of individual species is achieved by measuring absorbance at 205 nm. Factors for converting absorbancies to mol fractions have been determined. Quantitation by absorbance at 205 nm agrees well with quantitation by gas chromatography which is preferred to quantitation by phosphate analysis. One hundred phospholipid species have been identified. A table of relative retention times of molecular species is provided. Examples of quantitative analyses of species composition are presented. *Lipids 27,* **295–301 (1992).**

Fatty acids are attached to the 1- and 2-position of the glycerol moiety of phospholipids in a pattern that is charactistic of the particular class of phospholipid, of the source from which the lipid is derived, and of the dietary history of the organism. High-performance liquid chromatography (HPLC) has made possible the separation of each class of phospholipid into its molecular species, *i.e.,* the particular combination of fatty acids found in the 1- and 2-positions. Such separation can be accomplished on the intact phospholipid (1–3), or after it has been modified. In the latter case, the lipid is typically treated with bacterial phospholipase C to produce the corresponding mixture of diacylglycerol species which are then derivatized to form acetyl (4), benzoyl (5,6), 3,5-dinitrobenzoyl (7–9), or 1-anthroyl (10) derivatives. Trialkylsilyl derivatives of diacylglycerols also have been used (11,12). The amino groups of intact phosphatidylserine and phosphatidylethanolamine have been derivatized with 2,4,6-trinitrobenzenesulfonic acid or 1-fluoro-2,4-dinitrobenzene (13). These derivatives are separated into molecular species by HPLC. Earlier efforts to separate and quantitate molecular species have been reviewed by Smith and Jungalwala (1).

We report here an improved and extended method for separating and quantitating the molecular species of four phospholipid classes by high-performance liquid chromatography of the underivatized phospholipids. Quantitation is achieved by continuous absorbance measurement at 205 nm. Appropriate conversion factors have been determined for converting peak areas into mol fractions. The method of quantitation by absorbance agrees well with quantitation by gas-liquid chromatography (GLC). In cases where the HPLC resolution of molecular species is incomplete, the complex peak is analyzed and quantitated further by capillary GLC. The use of underivatized phospholipids makes it easier to preserve polyunsaturated fatty acids and avoids time-consuming enzymatic and chemical steps. For the present purpose, no attempt was made to separate alkenylacyl, alkylacyl and diacyl glycerophospholipids from each other prior to molecular species analysis.

Abbreviations: BHA, butylated hydroxyanisole; CL, cardiolipin; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; LPC, lysophosphatidylcholine; NL, neutral lipids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; RRT, relative retention time; SM, sphingomyelin.

MATERIALS AND METHODS

Materials. HPLC grade solvents and absolute ethanol were obtained from Fisher Scientific (Medford, MA) and U.S. Industrial Chemicals Co. (Tuscola, IL), respectively. Choline chloride was obtained from Sigma Chemical Co. (St. Louis, MO). Fatty acid methyl ester standards were purchased from Nu-Chek Prep, Inc. (Elysian, MN) and Applied Science (State College, PA). Ultrapure perchloric acid was purchased from Alfa Products (Danvers, MA).

Extraction of lipids. Total lipids from heart and liver of rats were extracted with chloroform/methanol (2:1, v/v) as described by Folch *et al.* (14). The tissue was weighed, homogenized in chloroform/methanol in an Omnimixer (Omni Corp. International, Waterbury, CT) and allowed to stand overnight under N_2 at room temperature before being filtered. C3H cells were washed, centrifuged at low speed, and extracted in similar fashion. The washed lipid extract was dried under a stream of N_2 and redissolved in 1 mL of isopropanol/hexane/ethanol (4.9:3.7:1.15, v/v/v) per g wet weight of tissue. The extract was stored under nitrogen at −20°C.

Separation of phospholipid classes. Column chromatography was performed on a Gradient Liquid Chromatograph (Model 334, Beckman Instruments, Fullerton, CA) equipped with an Variable Wavelength Spectrophotometer (Model 100-40, Hitachi Instruments, Elmsford, NY) and a Computing Integrator (Model 3390A, Hewlett Packard Co., San Fernando, CA).

Lipids were separated into phospholipid classes on columns packed with 10 μm particle-size LiChrosphere Si 100 (EM Science, Cherry Hill, NJ) by a modification of the method of Hax and van Kessel (15). Column dimensions were 4.6 × 250 mm for the small column (S) and 10 × 250 mm for the large column (L). The solvent mixtures used for eluting the lipids contained isopropanol/hexane/ethanol/1 mM ammonium phosphate/acetic acid in the proportions shown in Table 1. The solvent mixtures were filtered through a Millipore filter, type FH, pore size 0.5 μm (Millipore Corp., Bedford, MA), and then degassed. The column was equilibrated with 15 column bed volumes of Solvent A prior to use.

Lipid extract equivalent to 0.04–0.15 g wet weight of tissue was injected onto column S, which was then eluted according to the protocol shown in Table 1. The absorbance of the eluate was measured continuously at 205 nm and peak areas were integrated. Lipid extract equivalent to 0.2–0.5 g wet weight of tissue was injected onto column

TABLE 1

Elution Protocol for Class Separations

Time (min)	Solvents[a] A (%)	B (%)	Description
Column S ("Small", flow rate 1 mL/min)			
0-40	100	0	Isocratic
40-64	100-80	0-20	Linear gradient
64-104	80-0	20-100	Linear gradient
104-150	0	100	Isocratic
Column L ("Large", flow rate 3 mL/min)			
0-24	100	0	Isocratic
24-42	100-70	0-30	Linear gradient
42-66	70-50	30-50	Linear gradient
66-86	50-0	50-100	Linear gradient
86-120	0	100	Isocratic

[a]The solvents contained isopropanol/hexane/ethanol/1 mM ammonium phosphate/acetic acid in the following proportions, by volume: A, 490:370:115:25:0.4, and B, 490:370:60:80:0.4.

L, which was also eluted according to the protocol shown in Table 1. The absorbance of the eluate was measured continuously at 205 nm and peak areas were integrated. A typical elution pattern for lipids from rat heart is shown in Figure 1. Fractions of the eluate were collected and stored under Ar at −20°C. The 10 × 250 mm LiChrosphere Si 100 column exhibits virtually the same resolution at a flow rate of 6 mL/min, but the higher flow rate results in a shorter column life.

For consecutive runs, the LiChrosphere column was regenerated after each run with at least 10 column bed volumes of Solvent A, followed by two injections of 1.0 mL of absolute ethanol. The column was then washed with Solvent A until base line absorbance was achieved, before injecting the next sample. Before storing the column and

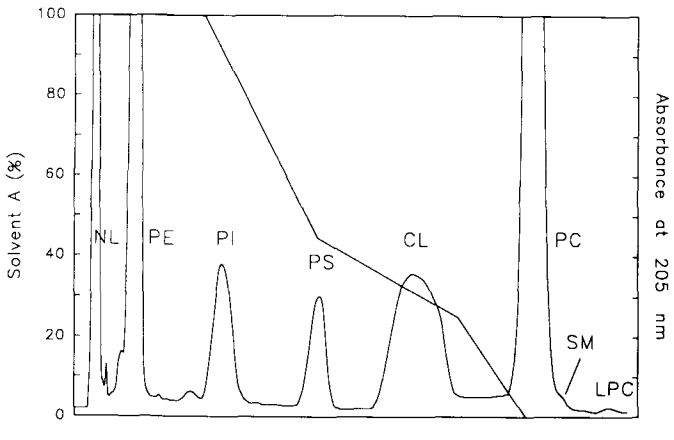

FIG. 1. Separation of phospholipid classes from rat heart. The column (10 × 250 mm) was packed with silica (LiChrospher Si 100). Extraction of lipids, application to the column, and elution conditions were as described under Materials and Methods. NL, neutral lipids; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; CL, cardiolipin; PC, phosphatidylcholine; SM, sphingomyelin; LPC, lysophosphatidylcholine. For the compositions of Solvents A and B, see Materials and Methods. Full scale absorbance = 1.0.

before using it again, the column was washed with 15 column bed volumes of absolute ethanol.

If for any reason the column is not regenerated properly, phosphatidylserine (PS) may not separate completely from phosphatidylinositol (PI) during the class separation. This is readily detected during the molecular species separation of PS. The major PI species of 18:0-20:4ω6 then runs between the PS species 16:0-20:4ω6 and 18:0-20:5ω3, in a position not normally occupied by any PS species.

Sphingomyelin (SM) overlaps at the tail of the phosphatidylcholine (PC) peak (Fig. 1). If SM is a minor constituent, this is of little consequence in the molecular species analysis of phosphatidylcholine (PC). If SM is not a minor constituent, this is easily detected in the molecular species chromatogram of PC by the appearance of the 16:0 molecular species peak of SM (hereafter 16:0-SM). With 10 × log relative retention time (RRT) for the 16:0-22:6ω3 species of PC defined as 1.000, the 10 × log RRT for 16:0-SM is 0.930. Molecular species of PC to be expected in this region are shown in Table 2. In most analyses of mammalian phospholipids we have observed low amounts or no molecular species of PC in this region. An exception is 18:1-20:5ω3, which occurs in animals on a diet rich in eicosapentaenoate-containing fat or diets giving rise to 20:5ω3. Complete separation of PC from SM is achieved by re-running the PC/SM mixture on the same column (*i.e.*, LiChrosphere Si-100) using acetonitrile/methanol/water (80:12:8, v/v/v) as isocratic eluent. These proportions are similar to those used by Juaneda and Rocquelin (16).

Separation of molecular species. Fractions from the class separations which contain a particular phospholipid were pooled, dried under a stream of N_2, and redissolved in 0.5 to 2 mL methanol/water/acetonitrile (90.5:7.0:2.5, v/v/v) per g wet weight of liver. A portion of the resulting solution (100-500 μL) was injected onto a 4.6 × 250 mm column packed with octadecyl silica (5 μm particle size Ultrasphere ODS or Dynamax-300A; Rainin Instrument Co., Woburn, MA). For phosphatidylethanolamine (PE), PC and PI species, the column was eluted with methanol/286 mM aqueous choline chloride/acetonitrile (90.5:7.0:2.5, v/v/v) using a flow rate of 1 mL/min instead of the 2 mL/min recommended by Patton *et al.* (2). This change resulted in better resolution of the peaks. A flow rate of 0.5 mL/min gave an even better resolution. For PS species, the column was eluted with methanol/25 mM KH_2PO_4/acetonitrile/phosphoric acid (90.5:7.0:2.5:0.1, by volume), to which was added 0.42 g choline chloride per 100 mL. The mixture is similar to that used by Patton *et al.* (2), except that phosphoric acid is used in place of acetic acid. This change results in substantially better resolutions. Absorbance of the eluate was measured at 205 nm and recorded continuously. Fractions were collected and stored under N_2 at −20°C.

Gas-liquid chromatography. Fractions obtained during the species separations were dried under a stream of N_2 and transmethylated with 2% HCl in methanol, which was generated from acetyl chloride and "Lipopure" methanol (Alltech Associates, Deerfield, IL). The reagent (2-3 mL) was added to the dry sample, and the tube was sealed under nitrogen. The mixture was incubated at 70°C with occasional shaking for 60 min. The mixture was then diluted with 0.2*N* HCl and extracted four times with petroleum hydrocarbon. Alternatively, the transmethylation was carried out with 0.5*N* sodium methoxide in

TABLE 2

Relative Retention Times for Molecular Species of Phospholipids[a]

[a] The columns used were packed with octadecyl silica (Ultrasphere or Dynamax-300A; bed dimensions 4.6 mm diameter × 250 mm long; particle size 5 μm). The column was eluted with methanol/286 mM choline chloride/acetonitrile (90.5:7.0:2.5, v/v/v) at a flow rate of 1 mL/min. The data shown are average relative retention times of molecular species of phospholipids obtained from liver and heart of rats and from C3H cells grown in culture. The animals were kept on diets of laboratory chow ("Rat, mouse, hamster 3000," Agway Inc., Syracuse, NY), or diets containing 5% of either corn oil (Fleischmann's) or menhaden oil (MaxEpa, Schering) as the sole source of fat for two weeks. The cells were grown in Dulbecco's minimum essential medium supplemented with different long chain fatty acids for two weeks.

[b] RRT, relative retention time. The retention times are relative to the elution time of the species 16:0-22:6ω3.

[c] Mixed isomers of ω9 and ω7.

[d] Plasmalogens are indicated by "p".

methanol, freshly prepared with clean sodium metal and "Lipopure" methanol. The concentration was checked by titration with 0.2*N* HCl. The reagent (0.5 mL) was added to the dry sample and the tube was then sealed under nitrogen. The mixture was incubated at 50°C for 15 min. Acidification and extraction were done as before. The last step in preparing samples for GLC consists of drying the fatty acid methyl ester solution in petroleum hydrocarbon over anhydrous sodium sulfate. We have found that certain batches of anhydrous sodium sulfate obtained from different manufacturers can produce peaks in the gas chromatograms that are artifacts. A single recrystallization of the sodium sulfate from hot water, followed by drying in an oven at 150°C, was sufficient to remove the unidentified materials responsible for the artifacts. Fatty acid methyl esters were identified and quantitated by gas-liquid chromatography on a 50-m glass capillary column coated with Silar-5 CP, using methyl heptadecanoate as internal standard (17). Fatty aldehydes derived from plasmalogens were identified as dimethyl acetals. No attempt was made to identify alkyl ethers. The elution position of the 16:0-16:0 species, which has negligible absorbance at 205 nm, was determined and quantitated by GLC.

RESULTS

Typical elution patterns of species separations are shown in Figures 2–5. Zero time is the point at which the solvent front is observed by the detector. Relative retention times (RRT) of molecular species are shown in Table 2. RRT values were calculated relative to a retention time for 16:0-22:6ω3 of 1.000. In some instances it may be more convenient to use 18:0-20:4ω6 (10 × log RRT = 1.247; RRT = 1.766) as reference instead of 16:0-22:6ω3 (10 × log RRT = 1.000; RRT = 1.000, by definition). However, with the aid of Table 2, any identified species can be used as

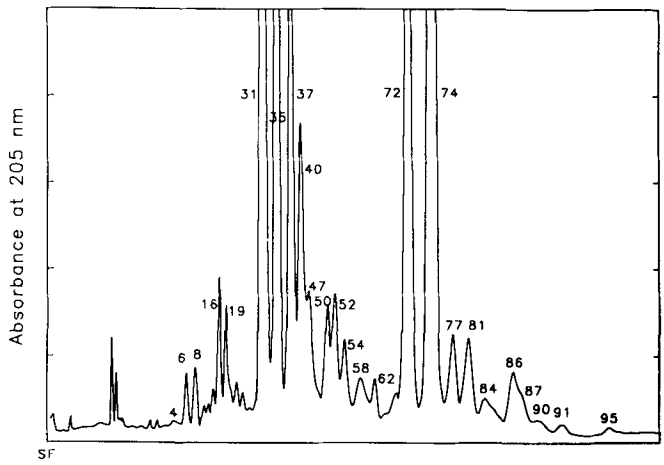

FIG. 2. Separation of molecular species of PE from rat liver. The column used was packed with octadecyl silica (Dynamax-300A). Elution conditions were as described under Materials and Methods, with a flow rate of 0.5 mL/min. Species are identified by the numbers assigned in Table 1. Full scale absorbance = 0.05.

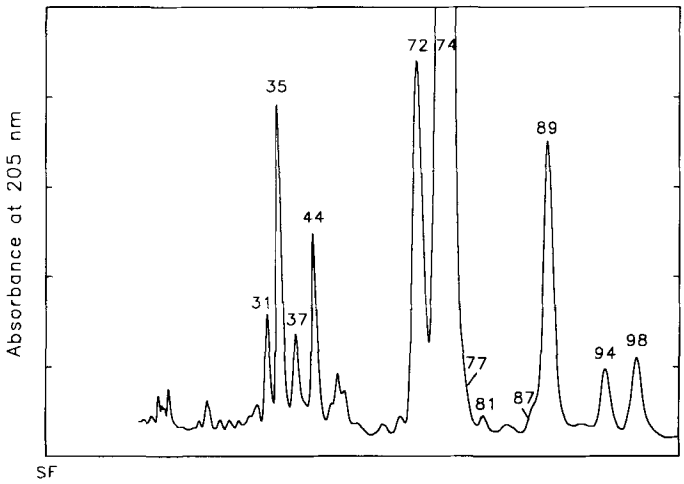

FIG. 4. Separation of molecular species of PS from rat liver. Elution and other details were as described in the legend to Figure 2, except that the flow rate was 1.0 mL/min.

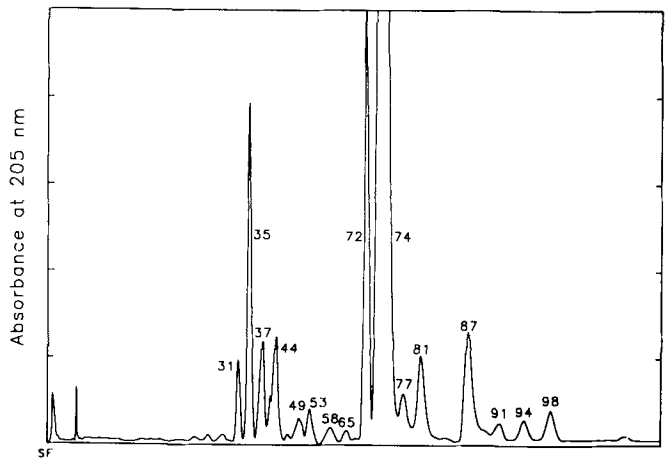

FIG. 3. Separation of molecular species of PI from rat liver. Elution and other details were as described in the legend to Figure 2.

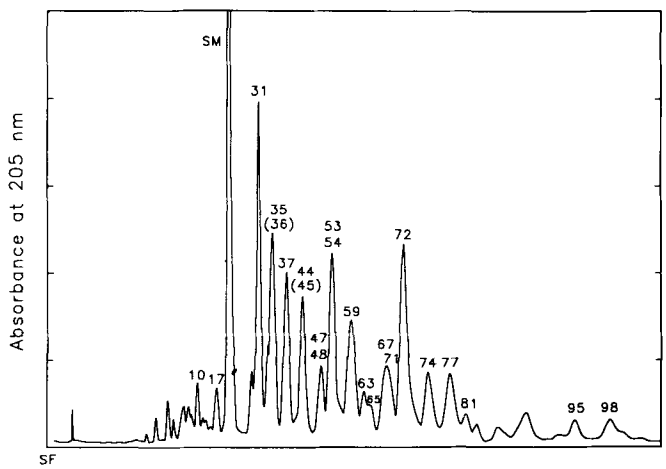

FIG. 5. Separation of molecular species of PC from rat liver. Elution and other details were as described in the legend to Figure 2, except that the flow rate was 1.0 mL/min. PC was used without separating it from SM, in order to illustrate the position of the 16:0-SM peak in the PC species chromatogram.

reference for identifying other species, or for confirming the identity of other species.

All species were identified initially by GLC after transesterification. Graphs of log (relative retention time of the species) *vs.* the equivalent chain length of the fatty acid found in the 1-position yielded a straight line for a given fatty acid in the 2-position (2). Repetition of this plotting method for different fatty acids in the 2-position yielded a series of parallel straight lines (Fig. 6). The equivalent chain length of saturated fatty acids is equal to the actual chain length. The equivalent chain length of unsaturated fatty acid and plasmalogens was determined as described in the legend to Figure 6. These graphs are used to identify molecular species in routine analyses. If conditions for regenerating and running the reverse phase HPLC column are kept constant, the relative retention times remain the same within ±2% and usually within ±1%. When changes in relative retention times do occur, the slopes of all lines change together in such a manner that they remain parallel. A slight change in the slopes may change the order in which peaks that run closely together are eluted. However, in practice we have found it unnecessary to construct new charts of relative retention times.

Conversion factors. The molecular species separated by reverse phase chromatography were quantitated by converting the areas of the ultraviolet absorbance peaks into chemical amounts. This necessitated the determination of conversion factors. The conversion factors for different peaks were obtained by dividing the area of the peaks by the chemical amounts in the peaks, which were determined by quantitative GLC using internal standards (17) or total phosphorus analysis. To carry out the latter, species peaks were taken to dryness, 0.4 mL $HClO_4$ was added, and the mixture was refluxed for 2–10 min depending on the amount of phospholipid. Orthophosphate was then measured by the method of Sanui (18). Table 3 shows

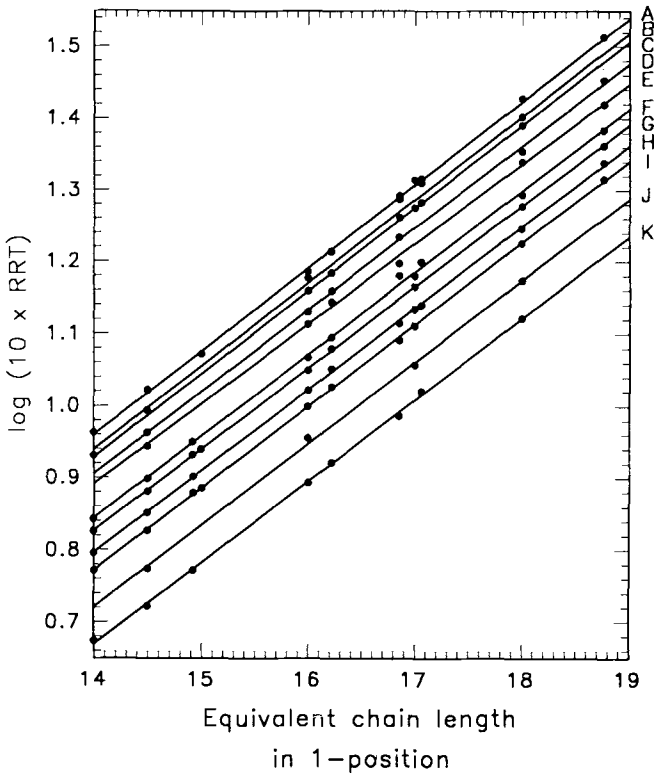

FIG. 6. Plot of log (10 × relative retention time) *vs.* equivalent chain length of fatty acids in 1-position of glycerophospholipids. The molecular species were identified as described in the text. Relative retention times for the same fatty acid in the 2-position were grouped together and plotted as a function the equivalent chain length in the 1-position. Linear regression lines are shown for each group. For saturated fatty acids in the 1-position, the equivalent chain length is equal to the actual chain length. For unsaturated fatty acids and alkenyl groups in the 1-position (plasmalogens) the equivalent chain length was determined to be as follows by drawing the best fitting vertical lines through the corresponding points on the individual regression lines: 16:1ω7, 14.50; 18:2ω6, 14.92; 18:1ω9&7, 16.22; 16:0p, 16.86; 18:1ω9p, 17.06; 18:0p, 18.77. Fatty acids in the 2-position were as follows: A, 18:1ω9&7 and 22:4ω6; B, 20:2ω6; C, 20:3ω9; D, 22:5ω6; E, 20:3ω6; F, 22:5ω3; G, 18:2ω6; H, 20:4ω6; I, 22:6ω3; J, 16:1ω7; and K, 20:5ω3.

conversion factors obtained with species containing 1,2, 4 and 6 double bonds. The conversion factors were plotted *vs.* the number of double bonds and the conversion factors for species with three and five double bonds were interpolated on the resulting graph. Table 3 also shows conversion factors that were determined for two species of plasmalogens. The conversion factor for 16:0-20:4 and 18:0-20:4 is 7.56. This yields a value of 7.56 ÷ 4 = 1.89 per double bond. The conversion factor for 18:0p-20:4 is 11.90, thus the additional vinyl ether double bond has a conversion factor of 11.90 − 7.56 = 4.34, and the vinyl ether linkage absorbs 4.34 ÷ 1.89 = 2.30 times more strongly than the aliphatic double bonds at 205 nm. The conversion factor for 16:0-22:6ω3 and 18:0-22:6ω3 is 10.4. This yields a value of 10.4 ÷ 6 = 1.73 per double bond. The conversion factor for 18:0p-22:6ω3 is 14.5; thus the additional vinyl ether double bond has a conversion factor of 14.5 − 10.4 = 4.1, and the vinyl ether linkage absorbs 4.1 ÷ 1.73 = 2.37 times more strongly than the aliphatic double bond at 205 nm. The two separate determinations agree within 3%. Gross (19) found that the vinyl ether bond absorbs 2.9 times more strongly at 203 nm than the aliphatic double bond. For molecular species containing two unsaturated fatty acids, the conversion factor was calculated by assuming that the conversion factors of the two fatty acids were additive. The conversion factors used by us have the dimension of 10^{-5} × area (in arbitrary units) per nmol phospholipid. The molecular species shown in Table 3 were quantitated by GLC. Two molecular species, 18:0-18:1 and 18:0-20:4ω6, were also quantitated by phosphorus analysis, with the same results.

The amount of each molecular species present is calculated as follows. The area of each peak is divided by the corresponding conversion factor to yield corrected areas (CA). The corrected areas are added to yield the total corrected area (TCA). The amount of each molecular species is then calculated in mol% using 100 × CA/TCA.

Depending on the composition of the lipid class, some molecular species eluted as overlapping peaks (Table 2 and Figs. 2-5). The fractions containing the overlapping peaks were analyzed by GLC. Methylheptadecanoate was used as internal standard to quantitate these species. The amount of each species so obtained was multiplied by its conversion factor, and then the areas were added to yield a calculated area for the peak in question. The calculated area agreed well with the integrated area of the peak, further validating this method of quantitation.

A template of a table which contains the molecular species shown in Table 2 has been created using the computer program Excel (Microsoft Corp., Redmont, WA). Quantitative molecular species analyses are recorded into this table. The template contains a series of equations, each of which calculates the total amount of a particular fatty acid in all molecular species. For example, all molecular species containing 16:0 are summed. This is repeated for each fatty acid and the total fatty acid composition in mol% is then calculated. The individual equations for each summation are stored in the table template and the calculations are made automatically. Lastly, the fatty acid composition in mol% obtained from the molecular species separation is compared with that obtained by GLC. When occasional discrepancies occurred between the two types of analyses during the development of the method, they were found to be due to misidentification of a molecular species in the HPLC chromatogram.

Representative results. Molecular species analyses of PS from livers of rats that were kept on two different diets are shown in Table 4. The method detailed here has been used to analyze the molecular species of PE, PI, PS and PC of C3H cells grown in media containing different fatty acid supplements (20).

DISCUSSION

The quantitative method described here does not require enzymatic or non-enzymatic degradation to diacylglycerols followed by derivatization. This presents a considerable saving in time and effort and eliminates errors due to incomplete degradation and derivatization as well as the potential for isomerization of diacylglycerol intermediates. The conversion factors used in calculating the actual amounts of each molecular species differ widely; however, the quantitative data obtained are highly reproducible and agree well with quantitative analyses

TABLE 3

Conversion Factors[a]

Double bonds per molecule	Species	Class	Conversion factors
			Measured values
1	16:0-18:1ω9 + ω7	PC	0.62 ± 0.07 (7)
2	18:0-18:2ω6	PC, PE	2.63 ± 0.19 (11)
4	16:0-20:4ω6	PC, PI	7.56 ± 0.27 (25)
4	18:0-20:4ω6	PC, PE, PI, PS	
6	16:0-22:6ω3	PC, PE	10.4 ± 0.8 (16)
6	18:0-22:6ω3	PC, PE	
			Interpolated values
3	16:0-20:3ω6		5.25
3	18:0-20:3ω6		
5	16:0-20:5ω3		9.32
5	18:0-20:5ω3		
5	16:0-22:5ω6 or ω3		
5	18:0-22:5ω6 or ω3		
			Measured values
5[b]	18:0p-20:4ω6	PE	11.9 ± 0.6 (3)
7[b]	18:0p-22:6ω3	PE	14.5 ± 0.4 (3)

[a]Areas of individual peaks were obtained by integrating the absorbance at 205 nm as a function of time. The area of each peak was then divided by the amount of phospholipid in the peak, which was determined by quantitative GLC. For further details, see Materials and Methods. Conversion factors are expressed as $10^{-5} \times$ area of peak (in integrator units) per nmol phospholipid ± standard deviation (number of determinations). The numerical values of these units depend on the integrator; however, the ratios of these values are constant and are used to calculate the mol% of each species.

[b]Including vinyl ether double bond.

	Σω6/Σω3	12.9	0.17

[a]Species are grouped in order of the position of the first double bond counted from the ω carbon atom of the fatty acid in the 2-position. Male rats were fed diets containing 0.025% BHA and 5% of either corn or fish oil (MaxEPA) as sole source of fat for two weeks. Results show mean ± S.D. for nine or five analyses, respectively. The animals were 53-days-old when analyzed. Only those species are shown which occurred in excess of 1 mol% in livers of animals on at least one of the two diets. A blank space indicates that the species was not detected in animals on one of the diets.

performed on the molecular species peaks. The separation of molecular species of phospholipids by HPLC also has been coupled to detection and identification by chemical ionization mass spectrometry (21).

The molecular species separations described in Figures 2–5 were run using octadecyl silica columns with an internal diameter of 4.6 mm. This required amounts of PE, PS and PI found in 50–250 mg of liver or heart. Preliminary work shows that the method can be adapted to octadecyl silica columns with an internal diameter of 1 mm with similar or better resolution. this makes possible the separation and quantitation of molecular species of phospholipids in 10–15 mg wet weight of tissue or cells.

No attempt was made to separate alkenylacyl, alkylacyl and diacyl glycerophospholipids from each other. The major species of alkenylacyl phospholipids were readily detected among the diacyl glycerophospholipids. Alkylacyl molecular species each account for a small fraction of the total molecular species (22). If necessary, alkenylacyl, alkylacyl and diacylglycerolipids can be separated from each other as described by Nakagawa and Horrocks (23). However, this involves removing the polar head group with bacterial phospholipase C, followed by acetylation, prior to molecular species analysis. The molecular species composition of cardiolipin (Fig. 1), which we did not investigate, has been studied by Teng and Smith (24) and Wolff *et al.* (25).

COMMUNICATION

α-Helical Requirements for Free Apolipoproteins to Generate HDL and to Induce Cellular Lipid Efflux

Hitoshi Hara, Hiroko Hara, Akira Komaba and **Shinji Yokoyama***
Lipid and Lipoprotein Research Group, Department of Medicine, University of Alberta, Edmonton, Alberta, Canada T6G 2S2

The structural requirement has been studied for apolipoproteins in their free form to interact with cells, to generate high density lipoprotein (HDL), and to cause cellular lipid efflux (*J. Biol. Chem. 266*, 3080-3086, 1991). It is shown that human apolipoprotein (apo) A-IV and apolipophorin III of *Manduca sexta* cause cholesterol efflux from cholesterol-loaded mouse peritoneal macrophages and reduce intracellularly accumulated cholesteryl ester as a result of forming HDL-like particles with cellular lipids, as do apoA-I, A-II and E. On the other hand, similar to apoC-III, reduced-and-carboxymethylated human apoA-II had no such effect. Thus, apolipoproteins seem to require at least four amphiphilic helical segments per molecule to express this function.
***Lipids 27*, 302-304 (1992).**

Removal of cholesterol from cells is the initial step of cholesterol transport from peripheral tissues to the liver, and high density lipoprotein (HDL) has been shown to function as an efficient acceptor of cellular cholesterol *in vitro* (1-5). When incubated with human plasma, cellular cholesterol taken up appears first in a minor HDL subfraction, "pre-βHDL", and then in other HDL fractions (6).

We have demonstrated that free apolipoproteins (apo) A-I, A-II and E in solution interact with macrophages and generate HDL-like particles with pre-β electrophoretic mobility, resulting in the release of cellular cholesterol and in lower levels of cellular cholesteryl ester (7). The K_m values of the reaction seem to be consistent with the putative free apolipoprotein concentrations in plasma or in peripheral lymph, since those values are as low as 0.25% of the apoA-I concentration in plasma (7-9). Thus, this reaction may play a physiological role in the first step of cholesterol removal from cells and appears consistent with the finding that cellular cholesterol appears first in "pre-βHDL" (6).

This reaction was observed with apoA-I, A-II and E while apoC-III did not show such an effect (7) although the latter protein binds to lipids as strongly as do the three former apolipoproteins (10-12). It appears that some parameter related to apolipoprotein chain length, such as the number of amphiphilic helical segments (11,13-15), may be one of the determining factors for formation of HDL-like particles rather than the presence of specific domains that would be required for the interaction. In order to test this hypothesis, complementary experiments were carried out with a series of apolipoproteins, including human apoA-IV, reduced-and-carboxymethylated human apoA-II (CMapoA-II) (16), and insect apolipophorin III (apoLpIII) from *Manduca sexta* (17).

*To whom correspondence should be addressed.

Abbreviations: apo, apolipoprotein; apoLpIII, apolipophorin III; CM, reduced and carboxymethylated; HDL, high density lipoproteins; SDS-PAGE, polyacrylamide gel electrophoresis in the presence of sodium dodecylsulfate.

MATERIALS AND METHODS

ApoA-I, A-II and apoE were isolated from human plasma as previously described (10,12). ApoA-IV was isolated from fresh human plasma according to the method described by Weinberg and Scanu (18). The bottom fraction of the density 1.21 g/mL adjusted with NaBr was dialyzed against 5 mM Na-phosphate buffer, pH 7.4, containing 0.15 M NaCl, and then diluted with the same volume of the buffer, to which NaCl was added at 0.28 g/mL. The fraction was then mixed with 20% Intralipid (KabiVitrum Canada, Newmarket, Ontario) at a ratio of 3:1 (v/v) and incubated at 37°C for 1 hr. The lipid emulsion was isolated by centrifugation and delipidated with ethanol/diethyl ether (1:3, v/v). Protein was applied to a DEAE/cellulose column using a gradient from 50 to 90 mM Tris-HCl, pH 8.2, containing 8 M urea. The fraction containing apoA-IV was rechromatographed under the same condition to obtain pure apoA-IV, which was identified as a single band with a molecular weight of 45,000 in polyacrylamide gel electrophoresis in the presence of 1% sodium dodecylsulfate (SDS-PAGE). ApoLpIII was isolated from hemolymph of *Manduca sexta* (17) and kindly provided by Dr. Robert Ryan, Lipid and Lipoprotein Research Group, University of Alberta, Edmonton, Alberta, Canada. The protein migrated as a single band in SDS-PAGE. ApoA-II was reduced and carboxymethylated by iodine acetate in the presence of β-mercaptoethanol as previously described (16,19). The modified apoA-II migrated as a single band with an apparent molecular weight of 8700 in SDS-PAGE. All apolipoproteins were lyophilized and stored under argon at −75°C. Aqueous solutions of each protein were prepared in a manner as described previously (10, 12,17). Protein concentrations of the solution were determined by absorbance at 280 nm using the specific molar extinction coefficient for each protein.

Low density lipoprotein (LDL) was labeled with [1,2-^{3}H]-cholesteryl oleate (45.4 Ci/mmol, Amersham, Arlington Heights, IL) as described (7,20) and then acetylated (7,21). Mouse peritoneal macrophages were obtained from ICR mice by peritoneal lavage, and approximately 2×10^6 cells were placed in each dish (3.5 cm). Cells adhering to the dishes were incubated with labeled acetylated LDL for 24 hr (and with the [*methyl*-^{3}H]choline chloride, Amersham, when phospholipids were also labeled), and then for another 24 hr without lipoprotein at 37°C (7). The cells were then exposed to the apolipoprotein solutions in the medium at 37°C for a certain period of time (7). The lipids were extracted from the medium and the cells, analyzed by thin-layer chromatography, and radioactivity in free and esterified cholesterol (and in each choline-containing phospholipid when labeled) was determined as previously described (7). Specific radioactivities of free and esterified cholesterol were determined for a few experimental points in each series of the experiment, based on quantitation of the lipids by gas chromatography. An average value was used for calculation of cholesterol levels of

other experimental points based on radioactivity (7). To determine the density of the peak for cholesterol, the medium was analyzed by sucrose density gradient ultracentrifugation as previously described (7).

RESULTS AND DISCUSSION

Figure 1 shows the change in cellular cholesterol and its efflux into the medium resulting from incubation of the cells with apoLpIII and apoE. The release of free cholesterol from cholesterol-loaded macrophages into the medium was demonstrated with both apolipoproteins. The reciprocal decrease in intracellular cholesterol was demonstrated for esterified cholesterol. In both cases, the rates were dose-dependent showing a saturation kinetics profile. K_m values obtained from double reciprocal plots were 1-1.5 $\times$ 10^{-6} M and 4 $\times$ 10^{-7} M for apoLpIII and apoE, respectively. The results were highly consistent with those previously reported for apoA-I, A-II and E (7). Figure 2 shows the release of free cholesterol into the medium as mediated by apoA-II, CMapoA-II, and by apoA-IV. Substantial efflux of free cholesterol was demonstrated with apoA-II consistent with previous work (7), but CMapoA-II did not cause cholesterol release from the cells. On the other hand, apoA-IV was shown to be capable of removing cellular cholesterol. Analysis of the medium in case of apoLpIII by density gradient ultracentrifugation showed peaks for free cholesterol, phosphatidylcholine and sphingomyelin all at the density of 1.1 g/mL (Fig. 3), consistent with the results previously obtained with apoA-I, A-II and E (7).

All these apolipoproteins contain amphiphilic α-helical segments of some 22-24 amino acid residues which are thought to be responsible for interactions with lipids (11, 13-16,22,23). Table 1 lists the apolipoproteins examined

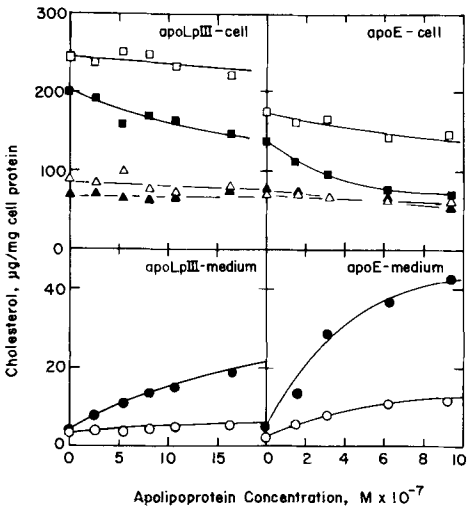

FIG. 1. Release of free cholesterol from macrophages and reciprocal decrease in intracellular cholesterol induced by apolipoproteins. Cholesterol-loaded macrophages were exposed to a solution of human apoE or apoLpIII of *Manduca sexta* for 6 hr (open symbols) or 24 hr (closed symbols). Free cholesterol in the medium (circles), and free and esterified cholesterol in the cells (triangles and squares, respectively) were determined as described in the Methods section (8). Cell protein per dish was 43.8 $\pm$ 5.0 μg for apoLpIII and 81.8 $\pm$ 10.3 μg for apoE.

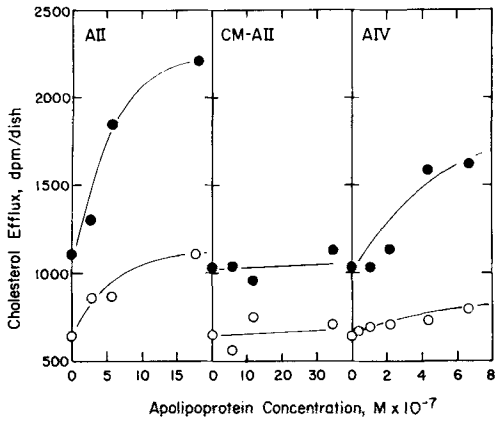

FIG. 2. Apolipoprotein-induced release of cholesterol from macrophages into the medium. ApoA-II, left; CMapoA-II, middle; apoA-IV, right. Cholesterol-loaded macrophages were incubated with apolipoproteins for 6 hr (open circles) or 24 hr (closed circles). Specific radioactivity of cholesterol is approximately 4000 dpm per μg of total cellular cholesterol. Cell protein per dish was 25.6 $\pm$ 2.9 μg.

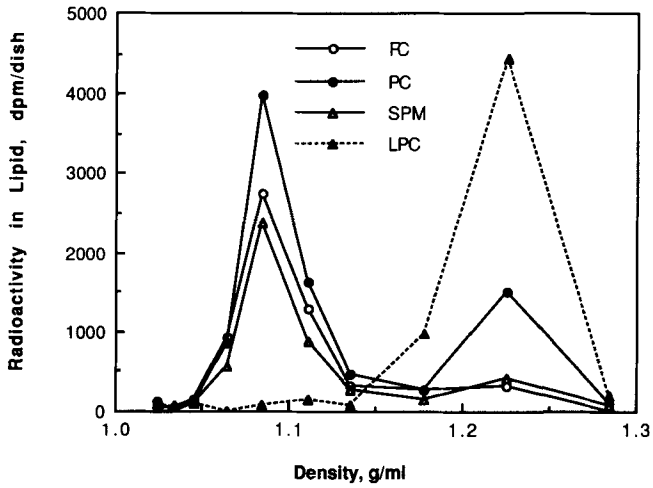

FIG. 3. Density gradient ultracentrifugation of the medium containing apoLpIII after incubation with macrophages labeled with [^{3}H]cholesterol and [^{3}H]choline. Cell protein per dish was 15.3 $\pm$ 1.1 μg. Symbols: free cholesterol, (○); phosphatidylcholine, (●); sphingomyelin, (△); lysophosphatidylcholine (▲).

TABLE 1

Cellular Cholesterol Efflux Induced by Free Apolipoproteins and Their Number of Amphiphilic Helices

Apolipoprotein	Number of amino acid residues	Number of helices[a] (reference)	Cholesterol release from macrophages[b]
ApoA-IV	376	≈ 12 (22)	+
ApoE	299	8 (15)	+
ApoA-I	243	6 (14)	+
ApoLpIII	166	5 (23)	+
ApoA-II	77 × 2	≈ 4 (11)	+
CMapoA-II	77	≈ 2	−
ApoC-III	79	≈ 2 (13)	−

[a] Number of amphiphilic helical segments of 20 to 24 amino acids per molecule as predicted (references).

[b] Capability of apolipoproteins to generate HDL and to cause cellular lipids efflux upon interaction with cholesterol-loaded macrophages.

and gives the putative number of such segments in each molecule. The data suggest that apolipoproteins with more than four such segments are capable of removing cellular cholesterol by generating HDL-like particles, whereas those with two or less such segments can not.

ApoC-III and CMapoA-II both contain at most only two amphiphilic helical segments. ApoC-III is in a random structure and does not self-associate in aqueous solution (10,12,24). However, it binds to the lipid surface as strongly as do other apolipoproteins whereby an amphiphilic helical structure is induced (10–12). Human apoA-II is a disulfide-linked homodimer and its carboxymethylation generates two identical monomers which differ from the original monomer only by the modified cystein at residue 6. CMapoA-II strongly self-associates in aqueous solution, thereby inducing a helix, and binds to the lipid surface (16). However, neither generate HDL-like particles upon interaction with macrophages.

Most vertebrate apolipoproteins except apoB, including those examined in this study, are likely to belong to a gene family under the same evolutionary tree (25,26) having common structure of multi-segments of amphiphilic helices. However, sequence homology is not strikingly high among them, so that it seems difficult to postulate that these apolipoproteins interact with the cells *via* a specific domain. ApoA-I, A-II and A-IV complexed with phospholipid reportedly bind to the same membrane "receptor site" and promote cholesterol efflux from adipocytes (27). This may argue against specific interactions between these apolipoproteins and membrane protein(s). Furthermore, cholesterol removal has been demonstrated with insect apoLpIII from *Manduca sexta*, which is poorly homologous to human apolipoproteins in terms of amino acid sequence (28), but is similar in function to human apolipoproteins in regard to physicochemical properties (28,29) based on its amphiphilic helical segments (23). It is therefore unlikely that any specific domain, such as a recognition site for a cell membrane protein, could be required for interaction of free apolipoproteins with cholesterol-loaded macrophages to generate HDL-like lipoproteins under removal of cellular cholesterol.

Thus, it seems that lipid-protein interactions mediated by amphiphilic helices are mainly responsible for generation of HDL upon interaction with the cell surface. However, not all the parameters for lipid-protein interaction of apolipoproteins directly correlate with this. ApoA-I, A-II, A-IV and E spontaneously generate disc-like particles with certain phospholipids such as dimyristoyl phosphatidylcholine (27,30–32), but CMapoA-II does not form typical "discs" even with this phospholipid (33). However, apoC-III does form the disc-like particles with dimyristoyl phosphatidylcholine although it has a peptide chain of about the same length as dose CMapoA-II, and both are incapable of causing cellular lipid efflux (34). The apparent dissociation constants of apoA-I, A-II, C-II and C-III are all in the same order when they are measured for the surface of phospholipid/triglyceride microemulsion having a diameter of 26 nm (10), while the dissociation constant of apoE is significantly higher (12). Therefore, we cannot completely rule out a more specific interaction between the membrane and certain apolipoproteins as a contributing mechanism for the generation of HDL.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Robert O. Ryan, Lipid and Lipoprotein Research Group, University of Alberta, for valuable discussions, and Miss Lisa Main for technical assistance. The work was supported by a Research Grant from the Alberta Heart and Stroke Foundation, by International Scientific Research Program for Joint Research of the Ministry of Education, Science and Culture of Japan, and by a research fund provided by Sankyo Co. Ltd.

Inhibition of Myocardial Lipoprotein Lipase by U-57,908 (RHC 80267)

Rogayah Carroll and **David L. Severson***
MRC Signal Transduction Group, Faculty of Medicine, The University of Calgary, Calgary, Alberta T2N 4N1, Canada

U-57,908 (RHC 80267) was shown to inhibit lipoprotein lipase (LPL) activity in cardiac myocytes from rat hearts; the concentrations required for inhibition to 50% of control activity were 1.1 μM and 2.5 μM for myocyte homogenates and a post-heparin medium preparation, respectively. The inhibition of LPL activity by U-57,908 was not changed when the concentration of the triolein substrate and apolipoprotein CII activator in the assay was reduced. The availability of U-57,908 as a potent and selective LPL inhibitor may provide a useful experimental approach in studies on lipoprotein metabolism.
Lipids 27, **305–307 (1992).**

Lipoprotein lipase (LPL) catalyzes the hydrolysis of the triacylglycerol component of circulating lipoproteins (1). A selective inhibitor of LPL activity that could be utilized with either intact cell and organ preparations or under *in vitro* conditions would be useful. Antibodies to LPL have been utilized to inhibit LPL activity bound to the surface of the capillary endothelium in perfused hearts (2) or to cultured vascular endothelial cells (3), but inhibitory antibodies are not generally available for experimental use.

U-57,908, *i.e.* cyclohexanone-*O,O'*[(1,6-hexanediyl)-*bis*-(iminocarbonyl)]dioxime, which was formerly designated RHC 80267 (4), has been characterized as a potent inhibitor of diacylglycerol (DAG) lipase activity in extracts of platelets (4), pancreatic islets (5), cardiac myocytes (6) and gastric smooth muscle (7). In contrast, the activities of phospholipase A_2 (4,5,7), phospholipase C (4,5) and DAG kinase (6,7) are not reduced by U-57,908 (RHC 80267). Consequently, U-57,908 has been utilized to determine whether the degradation of DAG, derived from phospholipids, by a DAG lipase pathway (8) could release arachidonic acid. The supply of free arachidonic acid regulates a variety of biological processes such as hormone secretion (5,9) and prostanoid biosynthesis (7). In an investigation of the ability of U-57,908 to inhibit DAG metabolism in isolated cardiac myocytes, U-57,908 was observed to inhibit LPL activity in myocyte homogenates (6). Therefore, our objective in this investigation was to further characterize the inhibition of LPL activity from cardiac myocytes by U-57,908.

MATERIALS AND METHODS

Preparation of cardiac myocytes. Calcium-tolerant cardiac myocytes were isolated from the hearts of male Sprague-Dawley rats (200–300 g), essentially as described by Kryski *et al.* (10). The freshly isolated myocytes were resuspended in Joklik minimal essential medium supplemented with 1.2 mM $MgSO_4$, 1 mM carnitine, 1.5 mM $CaCl_2$ and 1% (w/v) defatted albumin (10) to a cell density of 4×10^5 cells/mL. A cell pellet was collected by centrifugation and sonicated (6×30 s, using a BraunSonic (B. Braun Instruments, San Francisco, CA) 1510 sonicator at 75 W) into 0.25 M sucrose, 1 mM ethylenediaminetetraacetic acid (EDTA), 10 mM *N*-(2-(hydroxyethyl)piperazine-*N'*(2-ethanesulfonic acid) (HEPES), pH 7.4, to give a homogenate for the assay of cellular LPL activity. In some experiments, myocytes (4×10^5 cells/mL of Joklik medium) were incubated for 30 min with 5 U/mL heparin (11) to displace LPL bound to the cell surface; after centrifugation, the supernatant (post-heparin medium) was collected for LPL assays.

LPL assay. The activity of LPL in myocyte homogenates (sonicated cells) and in the post-heparin incubation medium was assayed with a sonicated [^{3}H]triolein (glycerol-[9,10-^{3}H]trioleate) substrate emulsion (12). The standard assay conditions were: 0.6 mM [^{3}H]triolein (1 mCi/mmol), 25 mM piperazine-*N,N'-bis*(2-ethanesulfonic acid) (PIPES), pH 7.5, 0.05% (w/v) defatted albumin, 50 mM $MgCl_2$, 1 μg/mL apolipoprotein CII as the LPL activator, and either 20 μL homogenate or 100 μL of post-heparin medium. After a 30-min incubation at 30°C, the release of [^{3}H]oleic acid was determined by liquid-liquid partitioning (12). All assays were performed in duplicate; LPL activity was linear with respect to incubation time (10–40 min) and the content of myocyte sonicates or post-heparin medium, and is routinely expressed as nmol oleate released per hour per 10^6 cells. Lipase activity in myocyte homogenates determined in the absence of apolipoprotein CII and in the presence of anti-LPL antibody is less than 10% of apolipoprotein CII-stimulated (LPL) activity (13). Therefore, other tissue lipases do not contribute significantly to LPL assays with sonicated cardiac myocytes.

Materials. [^{3}H]Triolein was purchased from Amersham Canada (Oakville, Ontario, Canada). Human apolipoprotein CII and U-57,908 were generous gifts from Dr. P. Connelly (University of Toronto, Toronto, Ontario, Canada) and Dr. D. R. Morton (The Upjohn Company, Kalamazoo, MI), respectively. A 1-mM stock solution of U-57,908 was prepared in dimethylsulfoxide; control assays contained appropriate quantities of solvent which had no effect on LPL activity.

RESULTS AND DISCUSSION

U-57,908 inhibited LPL activity concentration-dependently in myocyte homogenates (Fig. 1), confirming previous results from this laboratory (6). LPL activity was reduced to less than 5% of control at 10 μM U-57,908; a concentration of 1.1 μM resulted in a 50% inhibition of control activity. LPL in myocyte homogenates has been reported to be predominantly particulate after differential centrifugation (13).

LPL can be released from surface binding sites on cardiac myocytes into the medium following incubation with heparin (11,14). Soluble LPL in the post-heparin medium

Abbreviations: DAG, diacylglycerol; EDTA, ethylenediaminetetraacetic acid; HEPES, *N*-(2-hydroxyethyl)piperazine-*N'*(2-ethanesulfonic acid); LPL, lipoprotein lipase; PIPES, piperazine-*N,N'-bis*(2-ethanesulfonic acid); U-57,908, cyclohexanone-*O,O'*[(1,6-hexanediyl)-*bis*(iminocarbonyl)]dioxime.

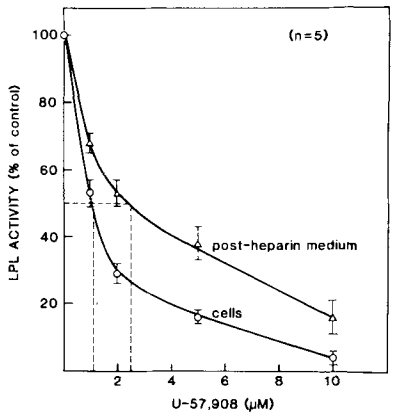

FIG. 1. Concentration-dependent inhibition of LPL activity by U-57,908. LPL activity in myocyte homogenates (○) or post-heparin medium (△) was determined in the presence of the indicated concentrations of U-57,908. Results are the mean ± S.E. ($n = 5$) and are expressed as the percentage of control activity determined in the absence of U-57,908. Absolute values of LPL activity corresponding to 100% control were 1190 and 156 nmol/hr/10^6 cells for myocyte homogenates and post-heparin medium, respectively.

was less sensitive to inhibition by U-57,908 (inhibition to 50% of control at 2.5 μM U-57,908) than the enzyme in cell sonicates (Fig. 1). Nevertheless, both preparations of LPL from cardiac myocytes were more sensitive to inhibition by U-57,908 than DAG lipase. The activity of DAG lipase in a variety of preparations was inhibited to 50% of control activity at U-57,908 concentrations ranging from 3.5–6 μM (4–6).

The inhibition of myocardial LPL activity by U-57,908 was constant when the time of incubation was varied from 10–40 min, so that the assay time-course was still linear in the presence of the inhibitor. Preincubation of post-heparin medium with 5 μM U-57,908 followed by a five-fold dilution into the assay indicated that the inhibition was reversible.

The inhibition of LPL in either myocyte homogenates or post-heparin medium by 2 μM U-57,908 was not changed when the triolein substrate concentration was reduced from 0.6 mM (standard assay conditions) to 0.1 mM (Table 1), suggesting that U-57,908 is not likely to be a competitive inhibitor of LPL activity with respect to substrate. The inhibition of DAG lipase activity in a microsomal subcellular fraction from cardiac myocytes by U-57,908 was also reported to be non-competitive with respect to dioctanoylglycerol as substrate (6).

The inhibitory effect of U-57,908 on LPL activity was also unchanged when assays were performed with a sub-optimal concentration (0.1 μg/mL) of apolipoprotein CII as the LPL activator (Fig. 2). Similar results were obtained when two concentrations of chicken serum (0.5% and 2%, v/v) replaced apolipoprotein CII in the LPL assay (results not shown).

In summary, U-57,908 was a potent and effective inhibitor of LPL activity, as assessed under a variety of *in vitro* assay conditions (varying concentrations of triolein substrate and apolipoprotein CII activator) with two different enzyme preparations (cell homogenates and post-heparin medium) from cardiac myocytes. LPL catalyzes the release of fatty acids from the *sn*-1 and *sn*-3 positions of triacylglycerols (15). Therefore, U-57,908 appears to be a relatively selective inhibitor for the release of fatty acids from the primary positions of acylglycerol substrates, since U-57,908 was a potent inhibitor of the hydrolysis of the *sn*-1 position of a 1-palmitoyl-2-oleoyl-*sn*-glycerol substrate (DAG lipase activity) but was much less effective as an inhibitor of 2-monoacylglycerol lipase activity in cardiac myocytes (6). Rindlisbacher *et al.* (16) have also reported that U-57,908 (RHC 80267) inhibited DAG lipase activity (*sn*-1 hydrolysis) but not 2-monoacylglycerol lipase activity in plasma membranes from adrenal chromaffin cells. LPL is bound to the luminal surface of capillary endothelial cells where the enzyme has its functional role in lipoprotein metabolism (1). U-57,908 may provide a particularly useful experimental tool as an LPL inhibitor in

TABLE 1

Effect of Triolein Substrate Concentration on the Inhibition of LPL Activity by U-57,908

Preparation	U-57,908 (μM)	LPL activity[a] (nmol/hr/10^6 cells) 0.6 mM Triolein	0.1 mM Triolein
Cell sonicate	0	1330	569
	2	294 (22%)[b]	138 (24%)
Post-heparin medium	0	156	60
	2	70 (45%)	28 (46%)

[a] Results are the mean from 2 experiments.

[b] Percentage of control activity measured in the absence of U-57,908.

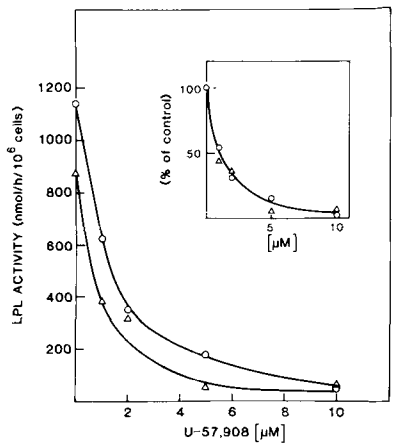

FIG. 2. Effect of apolipoprotein CII on the inhibition of LPL activity by U-57,908. LPL activity (nmol/hr/10^6 cells) in a myocyte homogenate was determined in the presence of either 0.1 μg/mL (△) or 1 μg/mL apolipoprotein CII (○) and the indicated concentrations of U-57,908. Insert: LPL activity, expressed as a percentage of the respective control, is replotted as a function of the concentration of U-57,908. Similar results were obtained in a second experiment.

perfused organs and tissues, because cellular uptake of the inhibitor will not be necessary, and therefore, any potential effect of concurrent inhibition of intracellular DAG lipase on cellular function will be minimized. The demonstration that U-57,908 can be an effective LPL inhibitor *in vivo* is an important future research objective.

Glycolipids of a Human Glioma Cell Line Bearing Receptors for Platelet-Derived Growth Factor (PDGF)

Allan J. Yates*, **Javier D. Agudelo** and **Ching-Ching Sung**
Division of Neuropathology, Department of Pathology, The Ohio State University, Columbus, Ohio 43210

Glycolipids of U-1242 MG were characterized because results of previous studies showed that exogenous gangliosides, especially G_{M3}, inhibit PDGF-stimulated growth of this human glioma cell line. G_{M3} and G_{M2} are the major gangliosides; both separate as doublets with thin-layer chromatography. The major neutral glycolipid is glucocerebroside with nonhydroxy fatty acids, but paragloboside, ceramide dihexoside, globoside, and asialoG_{M2} (G_{A2}) are also present. The coexistence in U-1242 MG of these gangliosides and the PDGF receptor, whose mitogenic signal is modulated by G_{M3} in these cells, suggests a possible functional relationship among them with respect to growth regulation.
Lipids 27, 308-310 (1992).

Growth inhibition was one of the first described biological responses of cultured cells to exogenously added gangliosides, and it has been suggested that this may be mediated through the ability of gangliosides and their metabolites to affect protein phosphorylation by regulating several different protein kinases and phosphatases (1-3). Bremer *et al.* (4,5) have shown that gangliosides can inhibit i) growth of 3T3 fibroblasts stimulated by platelet-derived growth factor (PDGF), and ii) autophosphorylation of the receptors for PDGF and epidermal growth factor (EGF). The potency to cause these effects varied among different gangliosides, but G_{M3}, a major ganglioside in fibroblasts, was one of the most effective. U-1242 MG is a cell line derived from a human malignant astrocytoma. Its major current point of interest is that it bears receptors for PDGF (6,7) and responds mitogenically to PDGF, suggesting that PDGF may be a biological mitogen for this glioma (8). If gangliosides are biological regulators of the PDGF receptor, then it would be expected that gangliosides which have been found to be more effective in inhibiting PDGF-stimulated growth and autophosphorylation of the PDGF receptor, such as G_{M3}, might be prevalent in U-1242 MG cells. In this paper we describe the results of glycosphingolipid analyses of this cell line which show that this is the case.

MATERIALS AND METHODS

For biochemical analyses, U-1242 MG cells were seeded into 150-cm^2 plastic cell culture flasks (Corning, Corning, NY) in Eagle's minimal essential medium containing 10% calf serum at 10,000 cells/cm^2. Cultures were maintained in a humidified atmosphere of 95% air and 5% CO_2 at 37°C; culture media were changed every third day. When cultures were subconfluent they were harvested using 0.01% trypsin in 0.01% EDTA, and before the cells were pelleted, aliquots of cell suspension were removed for total protein determinations [using the method of Bradford (9)] and for quantitation of cell numbers. Total lipids were extracted from cell pellets by homogenizing them in chloroform/methanol/water (5:5:1, by vol) and by separating the non-lipid residue by centrifugation. Ganglioside and neutral glycolipid fractions were purified using methods previously described in detail (10,11). The procedure involves an initial Folch partition, followed by three sequential washes of the lower phase with theoretical upper phase containing water but no KCl. Triplicate aliquots of washed lower phase were weighed using a Cahn microbalance. Neutral glycolipids were purified from the lower phase by silicic acid column chromatography and alkaline methanalysis. Individual neutral glycolipids were separated and quantitated using high-performance liquid chromatography (HPLC) (10). Cerebrosides were qualitatively identified on the basis of their hexose content using thin-layer chromatography (TLC) on borate impregnated silica gel plates (12,13), and detected by spraying with diphenylamine followed by heating (14). Immunostaining for galactocerebroside was performed after separating the neutral glycolipids on aluminum backed silica gel 60 high-performance thin-layer chromatography (HPTLC) plates (Merck, Darmstadt, Germany) in the solvent system chloroform/methanol/water (65:25:4, v/v/v). This was done using the monoclonal antibody O1, provided by Dr. S.E. Pfeiffer (15), and the Avidin-Biotin alkaline phosphatase kit (Vector Laboratories, Burlingame, CA) (16). Paragloboside was detected in a similar way using the antibody F1H11 from Dainabot (Chiba, Japan) (17). The pooled upper phases were desalted using a C_{18} reversed phase column, and total gangliosides were quantitated using the resorcinol reaction (18). Gangliosides were separated using HPTLC and quantitated using scanning densitometry. The usual solvent system was chloroform/methanol/0.2% $CaCl_2$ (55:45:10, v/v/v), but to separate *N*-acetylneuraminic acid (NeuAc) from *N*-glycolyl-neuraminic acid (NeuGc) containing gangliosides, the solvent system used was chloroform/methanol/5M ammonium hydroxide/0.4% $CaCl_2.2H_2O$(50:50:4:5, by vol). Immunostaining for NeuGc-containing G_{M3} was performed as described above for galactocerebroside, but using the monoclonal antibody 2-39M (19). Antibody 2-39M, directed against NeuGc containing G_{M3}, was provided by Dr. Kenneth Lloyd. The NeuGc-containing G_{M3} standard used as a positive control was from Matreya, Inc. (Pleasant Gap, PA).

RESULTS AND DISCUSSION

The amounts of total gangliosides and neutral glycolipids in U-1242 MG cells are shown in Table 1. The values for

TABLE 1

Amounts of Total Gangliosides and Neutral Glycolipids in U-1242 MG Cells[a]

Gangliosides			Neutral glycolipids		
Per mg protein	Per mg total lipids	Per 10^7 cells	Per mg protein	Per mg total lipid	Per 10^7 cells
1.03 ± 0.13	8.8 ± 3.4	5.2 ± 1.1	1.1 ± 0.37	8.7 ± 1.02	6.7 ± 1.27

[a]Results for gangliosides are expressed as nmoles sialic acid, for neutral glycolipids as nmoles glycolipid. Values represent the means ± SEM for three separate experiments.

both lipid classes expressed on the basis of total lipid and total protein are within the same range previously reported for the few other human glioma cell lines studied (10,11,20-22). G_{M3} and G_{M2} were the major gangliosides making up 57% and 43%, respectively, of the total gangliosides, with only trace amounts (not quantitated) of one which migrated just behind G_{D1a} and another behind G_{D1b}. G_{M1} was not detected. Both of the major gangliosides in U-1242 MG migrated as doublets (Fig. 1). In the basic solvent system, the faster migrating of the G_{M3} doublet comigrated with G_{M3} containing *N*-acetylneuraminic acid, while the other comigrated with *N*-glycolylneuraminic acid-containing G_{M3}. However, on immuno-TLC, neither ganglioside reacted with monoclonal antibody 2-39M, which is specific for NeuGc-containing G_{M3}. Therefore, it seems most likely that these G_{M3} gangliosides separate on the basis of either their sphingosine or fatty acid composition. The G_{M2} doublet migrated as a single band in the basic system, indicating that both of the G_{M2} bands in the neutral system contain only one type of sialic acid, probably NeuAc. The proportions of these gangliosides are shown in Table 2.

This relatively simple ganglioside pattern is remarkable, because other human glioma cell lines previously reported have had significant amounts of disialogangliosides (22), and some even had trisialogangliosides (23,24). The presence of G_{M1} has been variable in previously reported human glioma cell lines, but gangliotetraose oligosaccharide cores have been present in all others studied (11,20,22-24).

The major neutral glycolipid in U-1242 MG is cerebroside which eluted on HPLC with a retention time equal to that of cerebroside containing nonhydroxy fatty acids (Table 3). It is approximately five times more prevalent than the cerebroside which coeluted with cerebroside containing hydroxy fatty acid (HFA). On immuno-TLC none of the cerebroside reacted with the O1 antibody (which reacted strongly with the galactocerebroside control). On borate impregnated TLC plates all of the cerebroside from U-1242 MG migrated with glucocerebroside. Therefore, the major neutral glycolipid in these cells is glucocerebroside, the majority of which contains nonhydroxy fatty acids. Glucocerebroside is both an anabolic precursor and a catabolic degradation product of all of the gangliosides and neutral glycolipids found in this cell line. Whether it has a biological role other than an intermediate metabolite of other glycolipids is presently unknown.

U-1242 MG cells also contain lesser amounts of ceramide dihexoside (CDH), asialo-G_{M2} (G_{A2}), and globoside (glob) (Table 3). CDH, G_{A2}, G_{M3} and G_{M2} are all closely related metabolically. Therefore it is conceivable that changes in the activities of sialytransferases and sialidases

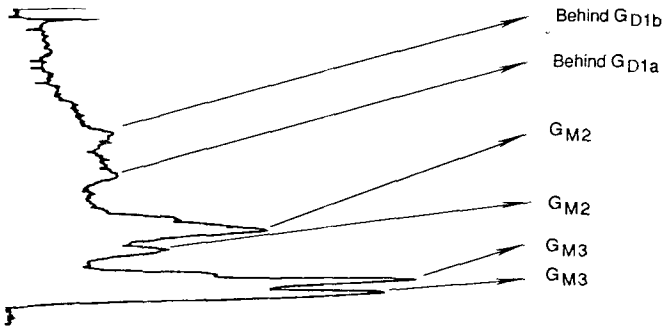

FIG. 1. Densitometric scan of gangliosides from U-1242 MG. A mixture of purified gangliosides (1 μg sialic acid) isolated from U-1242 MG was spotted on an HPTLC plate and developed in chloroform/methanol/0.2% $CaCl_2$ (55:45:10, v/v/v). The plate was air-dried, sprayed with the resorcinol spray, and fractions were made visible by heating on an aluminum plate at 95°C. The HPTLC plate was scanned using a Shimadzu CS-910 scanning densitometer (Shimadzu, Tokyo, Japan).

involved in their interconversions could modulate the functions of the PDGF receptor by altering the concentrations of these glycolipids in the plasmalemma. Paragloboside migrated as a triplet on both HPLC and HPTLC with approximately equimolar amounts in each band. Its identity was proven further by visualizing all three bands on immuno-TLC with the antibody F1H11. One major difference between the neutral glycolipids of this human glioma cell line and the other four described in the literature (10) is the presence of modest amounts of paragloboside in U-1242 MG which was not detected in any of the others. However, immunodetection was not used previously. The relationship of the neutral glycolipid composition to the function of the PDGF receptor, if any,

TABLE 3

Neutral Glycolipid Composition of U-1242 MG[a]

Glycolipid	Per mg protein	Per mg total lipid	Per 10^7 cells	Molar %
NHF cerebroside	0.45 ± 0.16	3.6 ± 0.51	2.7 ± 0.71	40
HFA cerebroside	0.01 ± 0.032	0.80 ± 0.09	0.60 ± 0.14	8.9
CDH	0.17 ± 0.06	1.35 ± 0.24	1.0 ± 0.29	15.0
G_{A2}	0.037 ± 0.015	0.27 ± 0.081	0.23 ± 0.088	3.4
Globoside	0.11 ± 0.034	0.84 ± 0.09	0.66 ± 0.18	10.0
Paragloboside	0.247 ± 0.0081	1.91 ± 0.25	1.50 ± 0.44	23.0

[a]Values are means ± SEM for three separate experiments and represent nmoles of each glycolipid. At least three chromatograms were obtained for each specimen, and values were averaged.

is unknown. Although sphingosine is an inhibitor of protein kinase C (reviewed in ref. 25), there is little evidence that any neutral glycolipid has an effect on the activity of any protein kinase.

G_{M3}, which comprises 57% of the total ganglioside in U-1242 MG cells, is a relatively potent inhibitor of both PDGF-stimulated growth of U-1242 MG (8) and Swiss 3T3 fibroblasts (4). G_{M3} also inhibits autophosphorylation of the PDGF receptor (4). Of relevance to the present study is the finding that sialosylparagloboside (SPG) was inactive in both respects (4). Although paragloboside is present in U-1242 MG, no SPG was found. The ganglioside composition reported here is compatible with the possibility that G_{M3} could play a role in regulating the degree of autophosphorylation of the PDGF receptor, thus modulating signal transduction of the PDGF signal for mitogenesis in U-1242 MG cells.

The pattern of gangliosides reported here for U-1242 MG cells has not been seen in all human glioma lines studied so far, nor have PDGF receptors been found in all glioma cell lines examined (6,7). Thus, it is possible that glioma cells whose growth is influenced by PDGF may have ganglioside and neutral glycolipid contents similar to those described here for U-1242 MG. If this proves to be the case, then the glycolipid composition of glioma cells could play a role in their growth by modulating the function of the PDGF receptor and, thus, might be a marker for cells which interact with PDGF. This would have implications of both biological and clinical importance, and the U-1242MG cell line could be used as a model system to investigate the molecular mechanisms involved in the interactions of ganglioside with the PDGF receptor in human glioma cells.

ACKNOWLEDGMENTS

The authors would like to thank Drs. Kenneth Lloyd and S.E. Pfeiffer for helpful discussions and the antibodies 2-39M and O1, respectively. We are also grateful to Dainabot (Chiba, Japan) for antibody F1H11. We also thank Ms. Julie Dolin for photographic assistance and Ms. Eleanor Borem for secretarial services. Liver Lipid Profiles of Adults Taking Therapeutic Doses of Aspirin

Joseph L. Rabinowitz[a,*], Daniel G. Baker[a], Thelma G. Villanueva[a], Aurora P. Asanza[b] and David M. Capuzzi[a]
[a]Veterans Affairs Medical Center, University of Pennsylvania and Medical College of Pennsylvania, Philadelphia, Pennsylvania 19104 and [b]University of East, Quezon City, Philippines

The distributions of lipids of hepatic specimens obtained at autopsy from 7 adult patients who had been taking large amounts of aspirin for arthritis were compared to 7 control samples obtained from livers of autopsied adults without prior liver disease. The total neutral lipid levels of control livers were approximately one-third lower than those observed for livers of patients on aspirin. In addition, the phospholipid content of control specimens was significantly greater than that of livers from adult patients that had been on a high dose of aspirin for a long time. Examination of individual lipid classes showed that the concentrations of free fatty acids, triacylglycerols, and mono- and diacylglycerols were highest in livers of patients with aspirin exposure, and that all phospholipids were diminished. Phosphatidylcholines and phosphatidylethanolamines showed the greatest decrease. These results suggest that the livers of patients taking large amounts of aspirin may accumulate fatty acids and neutral lipids due to an impairment in the oxidation of fatty acids by hepatocytes. The data obtained also suggest that needle biopsy of the liver with measurement of distribution of hepatic lipids, perhaps together with histopathologic examination, may provide useful diagnostic information.
Lipids 27, 311-314 (1992).

Acetylsalicylic acid (aspirin) has been shown to affect the liver adversely under a number of clinical conditions. High-dose aspirin can elevate liver transaminases in patients with rheumatoid arthritis and systemic lupus erythematosis (1). Aspirin inhibits not only cyclooxygenase but also several other enzymes involved in respiratory burst and in lipid mobilization (2,3). Biopsies show mononuclear cell infiltration of the portal triads with occasional focal necrosis, but the lipid compositions of such hepatic tissues have not been analyzed previously.

In addition to aspirin toxicity in rheumatoid arthritis, aspirin has been implicated in the development of Reye's syndrome. Although this condition has been extensively studied since it was first described, the etiology and pathogenesis of the syndrome remain unclear. Mitochondrial changes in various organ systems, including the liver, brain, kidney, skeletal muscle, pancreas, and myocardium have been reported (4).

Other syndromes that have been ascribed to high aspirin intake (5) are characterized by lowered activities of mitochondrial enzymes involved in ureagenesis (orithine transcarbamylase and carbamylphosphate synthetase) and gluconeogenesis (pyruvate carboxylase), and of enzymes associated with the tricarboxylic acid cycle (citrate synthetase, glutamate dehydrogenase, succinic dehydrogenase, malic dehydrogenase, and isocitrate dehydrogenase). Further evidence of mitochondrial injury derives from the occurrence of dicarboxylic acids in both serum and urine in several disorders including dicarboxylic aciduria, isovaleric acedemia, and others (6-9).

Biochemical abnormalities in lipid metabolism may account for some of the pathogenic features of this condition. Stimulated lipolysis from adipose tissues with impaired hepatic oxidation of mobilized fatty acids and panlobular microvesicular fatty changes have been found in various stages of Reye's syndrome and in alcoholics (10-13). Also, some patients taking therapeutic doses of aspirin tend to be hypoketotic, and dicarboxylic acids can be detected in serum and urine specimens. These metabolic derangements may suggest compromised hepatic mitochondrial β-oxidation of fatty acids.

This study was undertaken to characterize and quantify the major lipid classes found in the liver of patients taking high-dose aspirin and to compare with those found in adult control specimens obtained at autopsy. The study indicates that the pattern of distribution of hepatic lipids found in adult patients on high-dose aspirin differs greatly from that observed in liver specimens obtained from adult control subjects which points toward a metabolic impairment in hepatic mitochondrial fatty acid oxidation. The results obtained also show a striking similarity between the lipid distribution in livers of adults on high-dose aspirin and reported hepatic lipid distributions in children with Reye's syndrome.

MATERIALS AND METHODS

Patients. Liver biopsies were obtained from seven patients with severe rheumatoid arthritis who had been taking between 3.25 and 5.85 g of aspirin daily for many years. All patients died from myocardial infarctions, had no history of ethanol intake, and had no known liver function abnormalities at the time of death. Patients had no other known medical problems and none were obese. Controls biopsy specimens were obtained from age-matched patients who also died of myocardial infarction but had not been on aspirin and likewise had no known liver disease or ethanol abuse history. T.G.V. and A.P.A. selected the patients and obtained 1-2 g biopsies from the center of the liver 1-2 days after the demise of the patient.

Lipid assays. Lipid standards were purchased from Applied Sciences (State College, PA) and were tested for purity by thin-layer chromatography (TLC) and gas-liquid chromatography. The liver specimens were extracted twice with 100 mL of chloroform/methanol (2:1, v/v); additional extractions did not yield additional lipid material. The extracts were washed with 5 mL of 0.1 M KCl solution (14).

One aliquot of the extract was subjected to silicic acid (BioSil A, 100-200 mesh) column chromatography to separate the neutral lipids (by chloroform elution) from the phospholipids (by methanol elution). Individual lipid classes were obtained from the neutral lipids and from the phospholipids by TLC. Silica Gel G plates were developed with petroleum hydrocarbon/diethyl ether/glacial acetic

Abbreviations: MCAD, medium chain acylcoenzyme A dehydrogenase; SEM, standard error of the mean; TLC, thin-layer chromatography.

acid (90:10:1, v/v/v) for the separation of neutral lipids. Phospholipids were separated by TLC on Silica Gel H plates using chloroform/methanol/acetic acid/water (200:120:25:15, by vol) as developed solvent. Known amounts of authentic standards were applied and developed alongside each experimental sample. Iodine vapor was used to localize lipid spots. The stained areas were then scraped from the plates and transferred to individual test tubes containing 2 mL of concentrated sulfuric acid. The tubes were heated at 200°C for 15 min, cooled by immersion into ice, and 3 mL of water was added. Following centrifugation for 5 min at 3000 rpm to remove the silica gel, each solution was decanted into a quartz cuvette. The charred lipids were quantitatively assayed by use of a Beckman DB Spectrometer (Beckman, Fullerton, CA) set at 375 nm by comparison with known standards treated in the same manner. The sum of the data from all charred fractions was defined to total 100%. Other details of the methods used for lipid assay have been described previously (15).

Total lipid content of control cases was 65.0 ± 1.3 mg/g wet weight of liver. The total lipid content of the specimens obtained from the liver of patients that had been taking a high dose of aspirin was 80.1 ± 3.1 mg/g wet weight.

RESULTS AND DISCUSSION

The lipid distribution of liver specimens obtained at autopsy from seven rheumatoid patients that had been taking a high dose of aspirin are shown in Tables 1–4. Specimens were also obtained from livers of seven control subjects who showed no evidence of any disease affecting the liver.

Examination of the total lipids extracted from livers of control subjects compared to those obtained from specimens of rheumatoid patients on high dose aspirin revealed that about half the total lipids from controls comprised neutral lipids and half comprised phospholipids (Tables 1 and 3). By contrast, approximately two-thirds of the lipids found in high aspirin specimens were neutral lipids whereas only about one-third were phospholipids (Tables 2 and 4).

Table 1 shows the distribution of neutral lipids extracted from liver tissue specimens obtained from control patients. The mean of total neutral lipids was 49.5 ± 1.0% which differs markedly from the mean of 65.6 ± 0.7% for rheumatoid patients on high-dose aspirin (Table 2). A most striking difference was observed in the hepatic content of free fatty acids from the controls (12.6 ± 1.5%) which was less than half that (27.4 ± 2.4%) for rheumatoid patients on high-dose aspirin. The data in Table 2 also describe the neutral lipids for each specimen from patients on high-dose aspirin. The data illustrate the greater accumulation of hepatic neutral lipids in these patients compared to control subjects.

In Tables 3 and 4 we present the phospholipid compositions of specimens of liver tissue obtained from control subjects and from rheumatoid patients on high-dose

aspirin, respectively. The mean percentage of hepatic phospholipids for patients on high-dose aspirin was 34.1 ± 0.6% while that for controls indicated a much higher phospholipid content, namely 50.5 ± 1.0%. The largest disparity in phospholipid subclasses was observed for phosphatidylethanolamine (6.0 ± 1.5% in patients *versus* 13.5 ± 0.4% in controls) and for phosphatidylcholine (6.0 ± 0.4% in patients *versus* 14.4 ± 1.1% in controls). There also was a dramatic decline in cardiolipin levels for patient samples (0.3 ± 0%) which was only half that found in controls (0.6 ± 0.1%). The other phospholipid subclasses did not differ significantly between the two groups of specimens studied.

In the present study, lipid analyses of hepatic autopsy specimens from rheumatoid patients who had been taking high doses of aspirin have indicated significant differences from those of similar specimens from autopsied control subjects. The data suggest that a major metabolic impairment of fatty acid oxidation may exist in patients taking a high dose of aspirin. The increased neutral lipids and free fatty acids found in the liver specimens from these patients would be consistent with decreased oxidative capacity.

Mitochondrial morphologic changes, metabolic changes, and a clinical presentation similar to rheumatoid patients taking a high dose of aspirin have previously been described for patients with medium-chain acyl-coenzyme A dehydrogenase (MCAD) deficiency, an inherited defect in mitochondrial β-oxidation of fatty acids (16). This supports the notion that a relationship may exist between abnormalities in fatty acid oxidation and the observed clinical signs and symptoms.

ARTICLE

The Effect of Borage Oil Consumption on the Composition of Individual Phospholipids in Human Platelets

D. Edward Barre and **Bruce J. Holub***
Department of Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada N1G 2W1

The effect of supplementation with borage oil containing γ-linolenic acid (GLA, 18:3n-6) on the levels and fatty acid compositions of individual human platelet phospholipids was evaluated. For this purpose, male volunteers were given an average daily intake of 5.23 g of GLA (as borage oil) for 42 days, after which the supplement was withdrawn for an additional 42-day period. No significant differences were found in the relative amounts of the choline phospholipids (PC), ethanolamine phospholipids (PE), phosphatidylserine (PS), phosphatidylinositol (PI), and sphingomyelin (SPH) at days 0, 22, 43, 64, and 85. However, marked differences were observed in the fatty acid compositions of all the phospholipids including a marked, and reversible, rise in the level of dihomo-γ-linolenic acid (DGLA, 20:3n-6), without a significant elevation in arachidonic acid (AA, 20:4n-6) and decreases in n-3 polyunsaturated fatty acids. In the case of PC, a net rise in DGLA of 1.8 mol% was observed by day 22 (from 2.1 to 3.9 mol%). The DGLA/AA ratios at day 43 exhibited considerable variability across phospholipids with PC > PS > PE = PI; the PC, PE, PS, and PI accounted for 67.6, 16.7, 12.9, and 2.6%, respectively, of the total DGLA in platelet phospholipids. Interestingly, despite the lack of DGLA in SPH, this phospholipid exhibited a marked enrichment in nervonic acid (NA, 24:1n-9) from 16.2 to 24.7 mol% upon borage oil consumption. The observed alterations may represent biochemical strategies for adaptation to dietary fatty acid modifications and the regulation of platelet membrane functioning.
Lipids 27, 315–320 (1992).

The activation of human platelets plays an intimate role in the sequence of events leading to arterial thrombosis and atherosclerotic cardiovascular disease (for reviews, see refs. 1–4). In this regard, the fatty acid compositions of platelet phospholipids are of particular interest since arachidonic acid (AA, 20:4n-6), upon release *via* phospholipase activities in stimulated platelets, is converted into thromboxane A_2 (TxA_2), a potentiator of platelet aggregation and a vasoconstrictor compound (5,6). With respect to nutritional modification of platelet fatty acid composition and prevention of arterial thrombosis, considerable interest in fish/fish oils containing n-3 polyunsaturated fatty acids has arisen (7,8). Both dietary eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) (9) have been shown to have the ability to partially replace AA and other unsaturated fatty acids in various human platelet membrane phospholipids. Separation of the individual phospholipids from the platelets of humans consuming n-3 polyunsaturated fatty acids has revealed considerable individual variability in the degree of EPA and DHA enrichment, including AA replacement (10–13). For example, phosphatidylinositol (PI) is greatly enriched in AA and resilient to replacement of AA by EPA in contrast to choline (PC) and ethanolamine phospholipids (PE).

Recently, there has been considerable interest in the potential health benefits of dietary supplementation with γ-linolenic acid (GLA, 18:3n-6) found in evening primrose oil (14), black currant seed oil (15), and borage oil (16). In the latter oil, the level of GLA is approximately 22% which greatly surpasses the levels in evening primrose and black currant seed oil. The ratio of GLA/linoleic acid is approximately 7-fold that present in primrose oil.

The consumption of GLA can provide for the enrichment of cells and tissues including platelets in dihomo-γ-linolenic acid (DGLA, 20:3n-6) (14–19) derived *via* fatty acid elongation. The suggested health benefits of consuming dietary GLA are based on a potentially increased availability of DGLA, without an accompanying rise in the Δ5 desaturase product, AA (20). Interest in increasing the DGLA/AA ratio in mammalian cells is based on the expected increase in the biosynthesis of PGE_1 relative to the AA derived eicosanoids, including TxA_2, in terms of platelet reactivity (20, 21). *In vitro* studies have indicated that PGE_1 has a significant anti-aggregatory effect (20,21). Whereas some information is available on the effect of dietary supplementation with DGLA or evening primrose oil containing GLA on the fatty acid composition of total or selected platelet phospholipids found in animal models (22,23) and in isolated human trials (17,24,25), no data are available in the literature on the effect of dietary GLA on the fatty acid composition of the various phospholipids including sphingomyelin (SPH) found in the platelets of human volunteers. SPH was of particular interest since the EPA/DHA enrichment of platelet phospholipids observed in human subjects ingesting fish oil was accompanied by a significant rise in nervonic acid (NA, 24:1n-9) in SPH (10).

MATERIALS AND METHODS

Subjects and experimental design. The subjects were 6 healthy male volunteers with a mean age of 33 years and a body weight of 73.1 kg. They claimed to have abstained from medication, alcohol, tobacco, and fish, and to have otherwise maintained their normal dietary habits from 2 wk prior to day 0 up to day 85. The Human Ethics Committee of the University of Guelph gave certification for the study and the subjects signed an informed consent.

The borage oil capsules (PGE Canada, Saskatoon, Canada) were consumed on a per kg body weight basis (71.6 mg of GLA/kg/day) for 42 consecutive days starting on day 1, after which the supplement was removed for a subsequent 42-day period. The borage oil capsules each contained 1 g of oil (21.8 wt% GLA and 10 IU of α-tocopherol) and were consumed on average in the amount of

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; GLA, γ-linolenic acid; DGLA, dihomo-γ-linolenic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; NA, nervonic acid; PC, choline phospholipids; PE, ethanolamine phospholipids; PI, phosphatidylinositol; PRP, platelet-rich plasma; PS, phosphatidylserine, SPH, sphingomyelin; Tx, thromboxane.

24 capsules/day which provided the equivalency of 5.23 g (mean intake) of GLA daily. No significant change was found in the percent GLA in the encapsulated borage oil during storage based on routine analysis. The subjects gave blood for platelet isolation on consecutive days 0, 22, 43, 64, and 85.

Platelet isolation. Approximately 70 mL of blood were drawn from the antecubital veins into siliconized vacutainer tubes containing 1/6 volume of acid-citrate-dextrose (ACD) as an anticoagulant (26). Platelet-rich plasma (PRP) was prepared by centrifuging the blood at 111 × *g* for 15 min at 30°C. PRP was then centrifuged at 2000 × *g* for 15 min at 37°C. The derived platelet pellet was suspended in platelet suspension I (PS-I) consisting of Tyrodes buffer (NaCl, 137 mM; KCl, 2.7 mM; $NaHCO_3$, 12 mM; NaH_2PO_4, 0.4 mM; MgCl, 1 mM; $CaCl_2$, 2mM; glucose, 5.5 mM; pH 7.35; osmolarity, 290–300 mOsm; 0.35% albumin; HEPES, 2.5 mM), heparin (50 units/mL) and apyrase (30 μg/mL). PS-I was incubated for 10 min at 37°C and then centrifuged at 1200 × *g* for 10 min (27). The latter platelet pellet was suspended in Tyrodes buffer, and washed platelet suspensions were prepared according to Skeaff and Holub (28) based on the method of Mustard *et al.* (27). Final platelet concentrations were adjusted to 2×10^9/mL with Tyrodes buffer (see above) using a Coulter counter (Model ZM, Coulter Electronics of Canada, Ltd., Burlington, Ontario, Canada).

Platelet phospholipid analyses. Platelets were extracted according to Bligh and Dyer (29) using 3.75 mL of chloroform/methanol (1:2, v/v), 1.25 mL of chloroform, and 1.25 mL of water for 1 mL of platelet suspension. The methods for the thin-layer chromatographic separation of the individual phospholipids and determination of their fatty acid compositions by gas-liquid chromatography were as described (30). Conversions of the determined fatty acid amounts (mols) into phospholipid employed factors of 0.5, 0.75, 0.5, 0.5, and 1.0 in the case of PC, PE, phosphatidylserine (PS), PI, and SPH, respectively. There are approximately equal amounts of diacyl and alkenylacyl PE; as well up to 94% of the PC has been reported to be diacyl (31). This gives a rounded conversion factor of 0.5 for PC.

Statistical analyses. The data were assessed with a randomized complete block design using Tukey's Honestly Significant Difference test (32) to determine individual differences across various sampling times. The level of significance was selected at $P < 0.05$.

RESULTS

The fatty acid composition of the borage oil is shown in Table 1. The major fatty acids were oleic, linoleic (LA, 18:2n-6), and GLA. The wt percentage of GLA was 21.8% which agreed very well with the manufacturer's data claiming 22.0% (PGE Canada).

Borage oil consumption for 42 days did not change the relative contributions of the individual phospholipids to the total over the periods of consideration (see Fig. 1).

The fatty acid compositions of all the individual phospholipid classes were changed significantly by borage oil supplementation (Tables 2–6). In the case of PC (Table 2), there was a notable rise ($p < 0.05$) in DGLA which reached 3.9 mol% (from 2.1 mol%) by day 22. A rise in GLA (from 0.07 to 0.3 mol%) was also noted. Interestingly,

[a]The values represent the means ± SEM (n = 5) of randomly selected capsules.

there was no change in AA while a moderate reduction in LA was observed. Conversely, there was a statistically significant decrease in the level of the n-3 polyunsaturated fatty acids including α-linolenic acid (ALA, 18:3n-3), and EPA with no significant decrease in DHA. This was manifested in an increased ratio of DGLA/AA. The aforementioned alterations attained by day 22 showed no further change at day 43; these fully reverted to entry values by day 85.

In the case of PE (Table 3), PS (Table 4), and PI (Table 5), similar trends in DGLA were seen as for PC (Table 2) but to varying degrees. A decrease in DHA was observed in PE and PS following borage oil consumption for 42 days (Tables 3 and 4). In terms of ratios, the DGLA/AA ratio rose from 0.02 to 0.05 in the case of PE (Table 3), 0.1 to 0.2 (PS) (Table 4), and 0.01 to 0.05 (PI) (Table 5).

Interestingly, SPH (Table 6) contained no detectable AA at day 0 and, upon supplementation with borage oil containing GLA, no enrichment of this phospholipid in DGLA nor AA accumulation was found. However, there was a substantial enrichment of this phospholipid in NA without an accompanying rise in other monoenes (18:1 and 22:1) at day 22. Cessation of borage oil supplementation returned the NA levels to entry values.

It was determined (Fig. 2) that 67.6% of the DGLA in phospholipid resided within PC with PE, PS, and PI accounting for 16.7, 12.9, and 2.6%, respectively.

DISCUSSION

The consumption of borage oil containing GLA significantly affected the fatty acid compositions of the n-6 plus n-3 series and DGLA/AA ratios of the individual phospholipids of human platelets. However, it did not alter the relative levels of the individual phospholipid classes as a percentage of the total phospholipid. The DGLA/AA ratios varied across the phospholipids (Tables 2–5) with PC > PS > PE = PI. The level of GLA consumption averaged approximately 1.8% of daily calories. Normal human intakes are approximately 38% of calories as fat in North America currently. In corresponding trials with fish oils containing n-3 polyunsaturated fatty acids (EPA and DHA), no corresponding alterations in the dis-

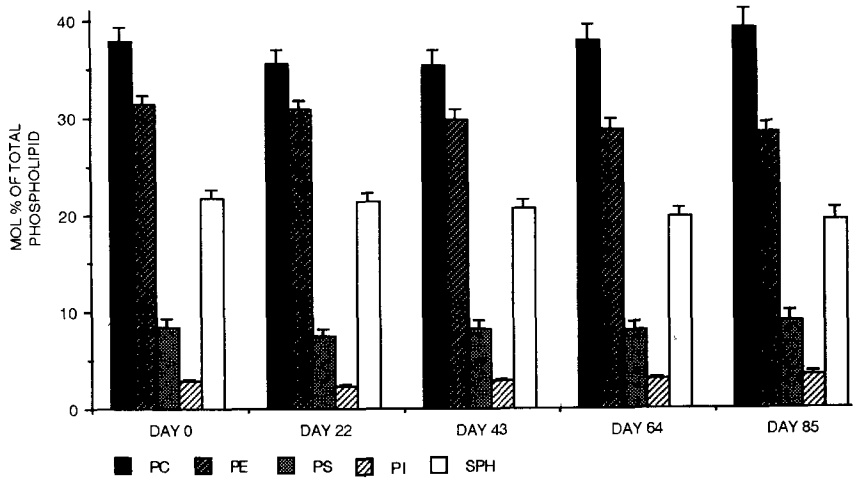

FIG. 1. Percentage mass contributions of individual platelet phospholipids before, during, and after borage oil consumption. Values are means ± SEM n = 6). No significant differences were found for a given phospholipid at all time points ($p > 0.05$).

[a]Borage oil consumption occurred consecutively from days 1 to 42 inclusive. Values are means ± SEM for six subjects. Values across a given row with different superscript letters are significantly different ($P < 0.05$). Other minor fatty acids have been omitted from the table.

tributions of individual phospholipids were found in platelets (10).

The fatty acid composition of each of the individual phospholipids at day 0 (Tables 2–6) was similar to literature values for healthy subjects (10,33). The increased GLA and DGLA in PC was apparently due to the consumption of high amounts of GLA and its metabolism *via* fatty acid elongation to DGLA (16,34). The noted (see Results) diminution in n-3 polyunsaturated fatty acid levels (EPA and DHA) in platelet phospholipids may reflect a decreased conversion of α-linolenic acid (ALA) to DHA by desaturation/elongation reactions. The decreased levels of n-3 fatty acids, including ALA, and n-6 fatty acids, *e.g.* LA in PC, may also reflect their replacement by DGLA in phospholipids *via* deacylation/reacylation. Interestingly, the AA-rich phospholipid PI was more resilient to enrichment with DGLA upon borage oil consumption compared to PC. The net mol% rise in DGLA, day 43 relative to day 0, averaged 1.2 mol% in the case of PI compared to 1.7, 1.1, and 1.2% in PC, PE, and PS, respectively. Whether this discrimination reflects the availability of DGLA to phospholipid biosynthetic reactions in the megakaryocyte or selectivity in the enzymic reactions involved remains to be investigated. Previous studies with dietary fish oils containing n-3 fatty acids have shown a marked resilience of platelet PI with respect to EPA entry (10,35).

The observation that AA levels in the various individual phospholipids (PC, PE, PS, PI) were unchanged upon borage oil ingestion may reflect in part the reported low activity of the Δ5 desaturase activity in human platelets (36) and a very limited exchange of AA-containing phos-

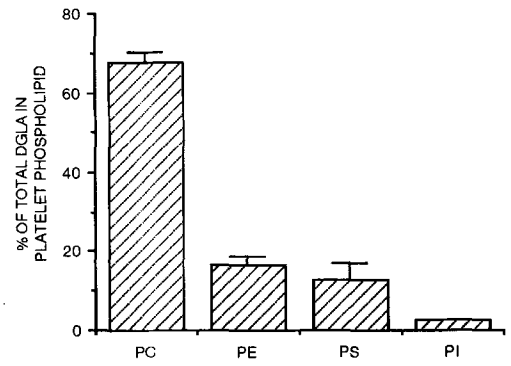

FIG. 2. Percentage contributions of individual platelet phospholipids to the total mass of DGLA in phospholipid at day 43. Values are means ± SEM (n = 6).

pholipid from plasma to platelet. In contrast, a significant rise in the AA level as found in human plasma phospholipid following the consumption of dietary evening primrose oil and/or borage oil containing GLA (17,37,38) may arise from a higher Δ5 desaturase activity in human liver.

The mass distribution of DGLA among the various phospholipids (Fig. 2) was in the order of PC >> PE > PS >> PI with no significant contribution from SPH. In contrast to the DGLA distribution, previous studies with dietary fish oils in humans have indicated that the order for the mass distribution of EPA was PE >> PC >> PS > PI (11) and for DHA was PE >> PC > PS >> PI (13).

Of considerable interest in this investigation was the marked alteration in the fatty acid composition of SPH: notably, the marked rise in NA upon borage oil ingestion without any detectable accumulation of DGLA or AA in this particular phospholipid. The rise in NA was accompanied by a significant decrease in 22:0 as well as 20:0, and 22:1 to a lesser extent without any significant decrease in 24:0. It is possible that the altered fatty acid compositions of the other phospholipids (PC, PE, PS, PI) induced by dietary borage oil may alter membrane fluidity which impacts upon the membrane-bound desaturase activity ultimately responsible for the formation of NA and/or enzymic reactions involved in SPH turnover. The possibility exists therefore that the altered fatty acid composition in sphingomyelin may play a role in maintaining membrane fluidity and function in response to the altered fatty acid composition of non-sphingomyelin phospholipids. Such may be imparted in the stabilizing effect of SPH species containing NA. It is also possible that the presence of 24:1n-9 and 22:1 in the borage oil could contribute to the rise of NA in SPH.

In conclusion, borage oil containing GLA was found to have a significant impact on the fatty acid composition of platelet membrane phospholipids with considerable differences being exhibited across the individual phospholipids. The increased DGLA levels and DGLA/AA ratios without an accompanying rise in AA (in the case of PC, PE, PS, PI), similar to the findings of other studies using evening primrose oil (17-19), and the marked rise in NA in SPH were of particular interest. The biochemical factors regulating these compositional shifts and the potential physiological significance of such alterations remain to be investigated.

This study was undertaken to determine the effect of various lipid emulsions on the hepato-biliary system in rats. Rats were randomly divided into six groups and infused continuously for 48 hr with either long-chain triglycerides (LCT), medium-chain triglycerides (MCT) or a mixture of MCT and LCT. One group infused with physiological saline solution served as controls. Throughout this period the rats received a fat free diet *ad libitum*. During the last hour of lipid infusion bile was collected for determination of bile flow and composition. Subsequently, the rats were sacrificed and the morphology and lipid content of the liver determined. Only LCT lipid emulsions induced morphological changes and increased liver cholesterol content. In two rats infused with radiolabeled LCT, no labeled cholesterol was found in the liver, indicating that the excess hepatic cholesterol level may originate from enhanced cholesterol mobilization to the liver. Biliary cholesterol and phospholipid concentrations in LCT-treated rats were also elevated, as was the lithogenic index, whereas the other emulsions had no such effects. None of the emulsions affected the plasma liver function tests or bile flow. We therefore conclude that the lithogenicity of the bile in rats is directly related to the lipid components of the total parenteral nutrition and the type of triglyceride infused.
***Lipids* 27, 321-325 (1992).**

Total parenteral nutrition (TPN) may result in the impairment of liver functions and the development of gallstones (1-5). The role of the lipid emulsion contained in the TPN in these complications is a controversial issue (6-10). One study in humans has indicated a possible involvement of the fat emulsion in causing abnormal liver function (6), but other reports showed that isocaloric substitution of glucose with fat emulsion did not alter the normal values of liver enzymes (7-9). Capron *et al.* (10) suggested that intestinal bacterial overgrowth with the production of endotoxin or hepatotoxic bile acids might explain some of the liver dysfunctions associated with TPN. Other investigators suggested that this complication might be prevented by oral supplements (11).

An increased incidence of cholelithiasis associated in patients with TPN has also been noted (2). Gimmon *et al.* (12) found that continuous administration of TPN solutions supplemented with long-chain triglycerides (LCT) to rats caused an increase in the lithogenicity of their bile independent of the route of administration, whether oral or intravenous. A recent study in rats (13) found that only TPN supplemented by LCT lipid emulsion of polyunsaturated fatty acids induced a significant increase in biliary cholesterol and phospholipid levels. In contrast, Innis (14), as well as Heyman *et al.* (15), reported that lipid-containing TPN reduced bile flow in rats, with no changes in bile composition. Other reports (16,17) have claimed that fat infusion to rats resulted in a decreased molar concentration of cholesterol and bile lithogenicity. The reason for these discrepancies is not clear.

In an attempt to define the role of lipid emulsions on liver function and bile lithogenicity, we studied the effect of short-term infusion of various lipid emulsions on liver function, bile composition and lithogenicity in rats which were fed with a fat-free oral diet. The rat was selected as a model since it has already been investigated in many TPN studies, although it lacks a gallbladder. This study indicates that infusion of the commonly used emulsion with long-chain triglycerides results in an increase in hepatic cholesterol content and in biliary cholesterol and phospholipids, whereas no such effects were observed in rats infused with medium-chain triglycerides (MCT) or mixtures of MCT and LCT.

MATERIALS AND METHODS

Experimental model. Male Sprague-Dawley rats (Mollegaard Ltd., Skensved, Denmark) of 230-270 g were housed in individual metabolic cages, at a controlled temperature (22 ± 3°C), light cycle (18.00-06.00 hr darkness) and relative humidity (40-60%). They were allowed water and standard rat pellets (R3 Ewos AB, Sodertalje, Sweden) *ad libitum* for a week before the experiment. A permanent central venous catheter was positioned under general anesthesia (Hypnorm, 0.5 mL/kg *i.m.*) in the lower part of the superior *vena cava* after its introduction in the right internal jugular vein. The catheter was then tunneled subcutaneously to the back of the rat and threaded through a metallic spiral connected to a ball bearing at the top of the metabolic cage. This permitted free movement of the rats, which were fitted with a harness (18). Infusions were started on the seventh day after the operation. Animals were checked daily for general health and body weight.

Study design. A total of 65 animals were randomly assigned to six experimental groups. All animals received infusions at a rate of 35 mL/kg/day. Group A was infused with saline and served as controls. Groups B-F were infused with lipid emulsions all containing 20% TG emulsified by 1.2% egg phosphatidylcholine (PC) and 2.5% glycerol in serile water. The fatty acid composition of the various emulsions is given elsewhere (19). Group B received a LCT lipid emulsion containing long-chain

Abbreviations: ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CSI, cholesterol saturation index; LCT, long-chain triglycerides; LDH, lactate dehydrogenase; LLL, long, long, long-chain fatty acyl triacylglycerols; MCT, medium-chain triglycerides; MLL, medium, long, long-chain fatty acyl triacylglycerols; MML, medium, medium, long-chain fatty acyl triacylglycerols; MMM, medium, medium, medium-chain fatty acyl triacylglycerols; PC, phosphatidylcholine; TG, triglycerides or triacylglycerols; TPN, total parenteral nutrition.

triglycerides (TG) (C_{14}-C_{24}) (Endolipid 20%, B. Braun, Melsungen, Germany). Group C was infused with LCT lipid emulsion (Intralipid 20%, Kabi, Sweden) containing long-chain TG (C_{14}-C_{24}). Group D received MCT/LCT lipid emulsion (Lipofundin MCT/LCT 20%, B. Braun, Melsungen, Germany), containing a mixture of equal amounts (w/w) of LCT (C_{14}-C_{24}) and MCT (C_6-C_{12}). Group E was infused with a "structured lipid" emulsion (MCT + LCT 20% Kabi) containing 75 mole% of MML + MLL and 25 mole% of MMM + LLL. Group F was infused with MCT 20% lipid emulsion (Kabi, Sweden) containing medium-chain fatty acids (C_6-C_{12}).

In addition, two rats underwent the same protocol and were infused with radiolabeled [^{14}C]LCT emulsion prepared with 2 mL of Intralipid 20% containing (4 μCi/mL) glycerol tri-[1-^{14}C]oleate per 100 mL Intralipid. The administered activity was approximately 2.75 μCi/kg body weight/day.

During the infusion period for 48 hr all the rats had free access to water and semisynthetic fat-free pwoder diet containing 20% casein supplemented with 0.3% L-methionine, minerals and trace elements (20) (Table 1). After 48 hr of infusion the rats were anesthetized with Hypnorm 0.5 mL/kg and Ketamin HCl (*i.m.*), a midline laparotomy was performed, the common bile duct was cannulated with a polyethylene catheter (PE 10), and the abdomen was closed. During the last hour of infusion, bile was collected while the rats remained anaesthetized and the infusions continued at the same rate. The effect of anesthesia and bile salt reabsorption on bile composition were minimized by limiting this procedure to one hour. The rate of bile flow was measured with a stopwatch. After completing collection of bile for one hour, the bile was frozen at −70°C for a maximum of four weeks before determination of cholesterol, phospholipids and bile-salts concentrations. Four rats (one of each of the following groups: Endolipid, Intralipid, structured and MCT) were withdrawn from the study due to technical problems in collecting bile.

Liver function. At the end of the study the animals were killed by cardiac aspiration and aliquots of blood were taken for determination of serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), bilirubin, alkaline phosphatase (ALP) and lactate dehydrogenase (LDH). These liver function tests were performed by standard photometric techniques (21).

The liver was excised and weighed. Approximately 1 g of liver was placed in a 10% buffered formaldehyde solution for histologic examination. The rest of the liver was frozen at −70°C for later total cholesterol determination.

Bile analysis. Bile acid concentration was determined enzymatically (22), cholesterol was determined by the method of Abell *et al.* (23), and phospholipid phosphorus was measured as described by Bartlett (24). The cholesterol saturation index (CSI) was calculated using the critical tables of Carey (25).

Liver structure. For light microscopy studies, portions of fresh liver obtained at the time of death were fixed in formaldehyde 10% and stained with hematoxylin-eosin and oil-red. Quantitative evaluation of fatty liver infiltration was estimated on slides under light microscopy as percentage of hepatocytoplasm infiltrated with fat globules as described by Leevy (26).

Hepatic cholesterol and radioactive cholesterol in liver and bile. Liver samples of 1 g were homogenized with 4 mL of saline using an Ultra-Turrax (Janke and Kunkel Ika-Werk, Staufen, Germany). The homogenates were then extracted with chloroform/methanol according to Bligh and Dyer (27), and cholesterol was determined by the method of Abell *et al.* (23). For determination of radiolabeled cholesterol, the isolated lipids were first passed through a silicic acid column. Triglycerides and cholesteryl esters were eluted with hexane/diethyl ether (9:1, v/v); cholesterol, fatty acids and diglycerides were eluted with chloroform. To isolate cholesterol, the chloroform eluate was subsequently subjected to alkaline hydrolysis. Cholesterol and fatty acids were extracted into hexane and separated by thin-layer chromatography, employing hexane/diethyl ether/methanol/acetic acid (90:20:2:3, by vol.) as solvent. The zone corresponding to cholesterol was scraped into a scintillation vial and counted using a Kontron Scintillation Spectrometer (Hemile, Switzerland). The amount of cholesterol present in the sample was determined according to Abell *et al.* (23), yielding information on cholesterol recovery.

To isolate radioactive biliary cholesterol, bile lipids were extracted with chloroform/methanol (27). One half of this sample was used for thin-layer chromatography and counted using a Kontron Scintillation Spectrometer, the other half was quantitatively analyzed for cholesterol as previously described.

Statistical analysis. Significance of differences were tested using ANOVA with multiple comparison (Dunnet's tests). All data represent average values ± SD.

TABLE 1

Composition of Fat-Free Diet (g/kg) Supplied During the Infusion Period

Vitamin free casein	200
L-methionine	3
Sucrose	250
Wheat starch	250
Glucose	223.7
Cellulose powder	10
Vitamin mix I[a]	5
Vitamin mix II[b]	5
Mineral mix[c]	53.3

[a] Per 5 g vitamin mix I, choline chloride, 2.0 g; and sucrose, 3.0 g.

[b] Per 5 g vitamin mix II, thiamine mononitrate, 5 mg; riboflavin, 8 mg; pyridoxine HCl, 5 mg; niacinamide, 40 mg; Ca-pantothenate, 40 mg; *p*-aminobenzoic acid, 2 mg; biotin, 4 mg; folic acid, 2 mg; vitamin B12, 30 μg; inositol, 100 mg; and sucrose to 5 g.

[c] Per 53.3 g mineral mix, NaCl, 6.97 g; KH_2PO_4, 19.46 g; $MgSO_4 \cdot 7H_2O$, 5.87 g; $CaCO_3$, 19.08 g; $FeSO_4 \cdot 7H_2O$, 1.35 g; $MnSO_4 \cdot H_2O$, 0.20 g; $ZnSO_4 \cdot 7H_2O$, 82 mg; $CuSO_4 \cdot 5H_2O$, 24 mg; $CoCl_2 \cdot 6H_2O$, 1 mg; $Na_2SO_4 \cdot 10H_2O$ 1/1000 (with sucrose), 234 mg; and KI, 39 mg.

RESULTS

This paper presents the effect of short-term infusion of various lipid emulsions on liver morphology and on the lipid composition of the heptobiliary system. Five groups of rats were infused with different lipid emulsions and compared with a control group that was infused with a saline solution. All the rats were fed with a fat-free oral diet *ad libitum* (Table 1), while being infused with the various solutions. It is of note that the control group, which was deprived of any dietary lipids while receiving

saline infusion, consumed approximately 15% more food than all the other groups (Table 2) to compensate for the lack of calories; over the 48-hr experiment this group showed a weight gain similar to that of the other rats (Table 2). There were no significant differences in weight between the various groups either before or after the 48 hr of infusion (Table 2).

None of the infusion regimens affected liver weight or enzymes (Table 3). Morphologic studies of the liver with light microscopy revealed no cell necrosis or granulomatos changes in any of the groups. Fatty infiltration was apparent only in the liver of rats infused with LCT emulsions (Endolipid™ and Intralipid®); no such effect was observed in rats infused with either MCT or mixtures of MCT and LCT.

The plasma bilirubin levels were not altered by infusion of either MCT or mixtures of MCT and LCT (Table 3). Similar bilirubin levels were observed in rats treated with the Endolipid (LCT) emulsion. In contrast, there was significant hyperbilirubinemia in those rats infused with Intralipid (Table 3), in apparent contradiction with the findings of Gimmon *et al.* (12), who observed no such effect.

Another significant effect of both LCT emulsions (Intralipid and Endolipid) was the increase of hepatic cholesterol level (Table 3). The level of hepatic cholesterol in the LCT-treated rats was significantly higher (by 30–50%) than in the control group ($P < 0.05$; Table 3). Infusion of structured MCT + LCT emulsion, MCT or Lipofundin MCT/LCT did not affect hepatic cholesterol content (Table 3).

None of the emulsions affected the rate of bile secretion (Table 4). However, infusion of LCT emulsions (either Intralipid or Endolipid) caused a significant elevation (by approximately 70%; $P < 0.01$) of biliary cholesterol and a somewhat smaller increase (approximately 50%; $P < 0.05$) in biliary phospholipid concentrations (Table 4). Following these LCT infusions, the CSI of the bile of all 20 rats (both Intralipid and Endolipid groups taken together) was significantly higher ($P < 0.05$) than after infusion of saline to the control group (Table 4). Neither MCT nor MCT/LCT, nor the "structured" lipid emulsion had any such effect on bile lipids (Table 4). It is of interest that although the average increase of hepatic cholesterol concentration was quantitatively similar to that observed for

TABLE 2

Weight and Food Intake of the Rats[a]

[a]Cholesterol levels were significantly higher in groups B or C in comparison to group A ($P < 0.01$).

[b]The biliary phospholipid levels in groups B or C were significantly higher ($P < 0.05$) than in group A.

[c]The cholesterol saturation index (CSI) was calculated on the basis of Carey's tables (ref. 25).

[d]The CSI in groups B and C were significantly higher than in group A ($P < 0.05$) only when taken together.

biliary cholesterol, no correlation (R = 0.5; P = 0.46) was found between the levels of hepatic and biliary cholesterol in the individual rats.

In an attempt to clarify the mechanism responsible for the effect of LCT lipid emulsions on bile composition, we infused radiolabeled Intralipid (2.75 μCi/kg/day) in two rats following the same protocol and determined the radioactivity of cholesterol in their liver and bile after completion of the infusions. No radioactive cholesterol was found in these samples although large quantities of cholesterol were detected, with efficient recovery of cholesterol in the experiment (greater than 90%), and in spite of the infusion-induced elevation of hepatic and bile cholesterol levels.

DISCUSSION

The effect of lipid infusion on bile composition in rats is a controversial and problematic issue (12–17). The present study was designed so that the rats were fed a fat-free diet while being infused with various lipid emulsions. This protocol minimized the potential effects of starvation and of non-lipid components of TPN on hepatic and bile composition and enabled us to evaluate the net effect of lipid.

The results obtained in this study show that short-term infusion of long chain triglycerides caused fatty infiltration of the liver and resulted in a significant increase of hepatic cholesterol as well as in elevation of biliary cholesterol and phospholipids. No such effects were observed in rats infused with either MCT or mixtures of MCT and LCT. These results are consistent with the finding (28–30) that the infused MCT-containing emulsions are oxidized more rapidly and are therefore accumulated to a lesser extent in the liver than are LCT emulsions. These results concur with those described by several other groups (28–30), but contradict a recent report (31) that MCT induced greater fat infiltration of the liver than did LCT lipid emulsion.

Since the infused emulsions do not contain cholesterol, the excess cholesterol in the liver and bile observed following infusion of LCT may be due either to cholesterol mobilization by emulsion remnants from extrahepatic sources to the liver or increased *de novo* synthesis of cholesterol in the liver (19,32). The latter possibility is unlikely in light of the absence of radiolabeled cholesterol in the liver or bile of rats infused with [^{14}C]LCT, in spite of the infusion-induced elevation of hepatic and biliary cholesterol level. It would appear that the excess hepatic and biliary cholesterol following lipid infusion resulted mainly from mobilization of cholesterol to the liver from extrahepatic tissues, commonly denoted as "reverse cholesterol transport" (19). This conclusion accords with previous reports on the relative efficiency of LCT and MCT remnants in mobilizing cholesterol to the liver (33); MCT and its mixtures with LCT are more efficiently metabolized in the liver (28,29), but have a lower ability to mobilize cholesterol to the liver than do LCT (19,33–35). Indeed, MCT-containing emulsions did not cause a significant increase of hepatic cholesterol in rats, lending further support to our conclusions.

A point of interest is the lack of correlation between the increase in hepatic and biliary cholesterol in individual rats. This may result from the complex effect of other factors on bile composition (35,36). More specifically, biliary cholesterol secretion is regulated by numerous factors, including synthesis, esterification of cholesterol in the liver and the existence of different intracellular pools as suggested by Nervi *et al.* (37). Therefore, because of this complexity, individual differences in the metabolic fate of excess hepatic cholesterol may obscure any correlation between hepatic and biliary cholesterol levels.

Hepatic phospholipids newly synthesized from long-chain fatty acids have been reported to make only a small contribution to the total biliary output (36,38). The elevation of biliary phospholipids, observed in this study following LCT infusion, is therefore likely to originate from an extrahepatic source.

The effect of lipid infusion on bile lithogenicity as expressed by the CSI is rather complex. Neither MCT nor mixtures of MCT and LCT affected the levels of any of the biliary lipids. Thus, neither of them altered the CSI (25). The LCT induced elevation of cholesterol could have been expected to increase the CSI, whereas the opposite could have been expected from the increase in biliary phospholipids. A slight and insignificant increase was observed in the CSI of the bile of rats infused with either Intralipid or Endolipid when compared to the control group. However, when the LCT lipid emulsions (Intralipid

and Endolipid groups) were taken together a significant increase in the CSI of the bile was observed. This is despite the increase in biliary phospholipids, which in itself should have reduced the CSI (25).

In conclusion, the results reported here show that short-term infusion of LCT emulsions (but not of MCT, nor of various mixtures of LCT and MCT) in the rat cause a significant increase of both hepatic and biliary cholesterol, probably *via* a cholesterol mobilization mechanism. The effects of LCT infusion on bile composition observed in the present study in rats are similar to those found in our previous study carried out on human subjects (39). However, in the human, in contrast to the rat, MCT/LCT lipid emulsions caused an even more pronounced elevation of both biliary cholesterol and phospholipid (39). We suggest that the difference in effectiveness of MCT/LCT infusion on biliary lipids observed in humans and in rats may be ascribed to a difference between the species (40). The data presented here may contribute to our understanding of the role of lipids in the hepatobiliary abnormalities associated with total parenteral nutrition.

[Received October 21, 1991, and in revised form March 3, 1992; Revision accepted March 16, 1992]

Effect of Dietary Fish Oil on the Rate of Very Low Density Lipoprotein Triacylglycerol Formation and on the Metabolism of Chylomicrons

Ana Maria P. Lottenberg, Helena C. F. Oliveira, Edna R. Nakandakare and **Eder C.R. Quintão***
Division of Nutrition and Dietetics, and Laboratories of Medical Investigation (LIM), Hospital of the University of São Paulo Medical School, São Paulo, Brazil

The mechanism by which ω3 fatty acids lower plasma triacylglycerol levels was investigated. Rats were fed fish oil, olive oil (10% fat by weight) or a nonpurified diet (4% fat by weight) for 15 days. Lipoprotein lipase was inhibited by intra-arterial administration of Triton WR 1339 to estimate hepatic triacylglycerol output. Rats fed the olive oil diet showed a higher rate of triacylglycerol formation than rats fed the ω3 fatty acid diet or the low-fat diet. All three groups showed identical rates of removal from plasma of intraarterially administered artificial chylomicrons that had simultaneously been labeled with cholesteryl [1-^{14}C]oleate and [9,10(n)-^{3}H]triolein. Liver radioactivity and total fat content were lowest in rats fed the fish oil diet, indicating that ω3 fatty acids were preferentially metabolized in liver. Chylomicrons obtained from donor rats fed either fish oil containing [^{14}C]cholesterol or olive oil containing [^{3}H]cholesterol were removed at similar rates when infused together intraarterially into recipient animals. A slower formation of plasma very low density lipoprotein triacylglycerols in rats fed fish oil is probably due to a faster rate of oxidation of the fatty acid chains in the liver resulting in decreased plasma triacylglycerol concentrations.
Lipids 27, **326-330 (1992).**

The role that dietary ω3 eicosapentaenoic and docosahexaenoic acids of marine oils play in the prevention of coronary heart disease has been studied extensively (1,2). Fish oils are known to lower plasma triacylglycerol (TG) levels and very low density lipoprotein (VLDL) levels both in humans (3-5) and in experimental animals (6), although the mechanisms that are involved are not clearly understood.

Fish oil has been shown to retard *in vivo* hepatic production of VLDL triacylglycerol in humans (5,7-10) and in roosters (11), as well as in perfused liver (12,13) and in cultured hepatocytes (14-16). Less evidence is available in support of the enhancing effect of fish oil on the removal of plasma VLDL (7,9). Fish oil can also influence chylomicron metabolism, although similar intestinal absorption rates for eicosapentaenoic acid and oleic acid have been reported (17). However, the results of chylomicron metabolism studies are not entirely conclusive. When analyzed between 25 and 90 min, the disappearance rate of eicosapentaenoic acid enriched chylomicrons, that had been infused in the bloodstream of rats, was slower than that of oleic acid enriched particles. At 10 min, no difference in turnover rates was observed between the two types of chylomicrons (18). Chylomicron clearance rates in perfused rat hearts were similar for particles made from ω3 fatty acid with those made from oleic acid (19).

We set out to determine whether the fats affected metabolism because the particles differed in fatty acid composition or because the dietary fats by themselves modified lipoprotein lipase activity and the splanchnic organ receptors for chylomicron particles. In our study, native chylomicrons from animals fed fish oil and [^{14}C]cholesterol, or olive oil and [^{3}H]cholesterol, were injected into rats fed a nonpurified low-fat diet. Also, the plasma disappearance rates of intra-arterially infused artificial chylomicrons simultaneously labeled with cholesteryl [1-^{14}C]oleate and [9,10(n)-^{3}H]triolein were compared in rats fed fish oil, olive oil and low fat. Triacylglycerol mass and radioactivity were measured in the liver and spleen of the animals at the end of the artificial chylomicron infusion experiment. Finally, the effect of the different diets on hepatic secretion of triacylglycerol and on the metabolism of chylomicrons was examined after inhibition of the enzyme lipoprotein lipase by Triton WR 1339.

MATERIALS AND METHODS

Experimental protocol. Adult male Wistar rats, weighing approximately 230 g, were divided into three experimental groups of 10 animals each. The animals were fed for 15 days (% by weight) 10% fish oil, 10% olive oil, or a nonpurified diet containing 4% fat (Control, provided by Novilab, São Paulo, Brazil). Both fat enriched diets contained (% by weight): fat (10%), casein (10%), cellulose (3.5%), saline mixture (3.5%), vitamin supplement (1.0%), choline bitartrate (0.2%), D,L-methionine (0.3%), and starch (71.5%).

Body weights (mean ± SD) of rats in experimental groups (initial and final, respectively) were: controls (195 ± 19 and 244 ± 33), fish oil (250 ± 22 and 264 ± 28), and olive oil (235 ± 58 and 268 ± 38).

Commercially available fish oil (MaxEPA, Seven Seas Ltd., Marfleet, England) contained 18.6% eicosapentaenoic acid, 12.1% docosahexaenoic acid, 15.2% oleic acid, 22.95% saturated fatty acids and 31.3% unidentified unsaturated fatty acids. Olive oil was composed of 77.5% oleic, 7.6% linoleic, 2.3% stearic, 10% palmitic, and 0.6% unidentified fatty acids. After fasting overnight, rats were treated with Triton WR 1339 (Tyloxapol, Sigma Chemical Co., St. Louis, MO; 600 mg/kg body weight), which was administered through an intra-arterial catheter, to evaluate hepatic production of triacylglycerols (20).

Rats were infused intra-arterially with chylomicrons that had been simultaneously labeled with cholesteryl [1-^{14}C]oleate and [9,10(nn)-^{3}H]triolein (21,22) (NEN Research Products, Boston, MA). To follow the effect of various diets on the rate of chylomicron removal from plasma, a chylomicron-like emulsion was used which consisted of (% by weight) 2% cholesterol, 23% phosphatidyl-

choline (Lipid Products, Surrey, U.K.), 6% cholesteryl oleate and 69% triolein (NuChek Prep, Inc., Elysian, MN). Lipids were dispensed from stock solutions into vials and radioactive materials were added. After evaporation of solvents under a nitrogen stream, the vials were placed overnight in a vacuum desiccator at 4°C to remove residual solvent. Lipids were emulsified by sonication in 8 mL of 2.785 M NaCl solution (density = 1.100 g/mL), at approximately 55°C using a Branson Cell Disruptor (Branson Ultrasonics Corp., Danbury, CT) and a 1-cm probe at a continuous output of 70–80 W. Crude emulsions were purified by ultracentrifugation using an SW-41 rotor (Beckman ultracentrifuge, model L7-55, Beckman Instruments, Palo Alto, CA) at 12,000 rpm (density gradient 1.100–1.006) at 20°C for 15 min. After the first run, the coarse lipid that floated to the top was removed by aspiration and replaced with a corresponding volume of fresh 1.006 g/mL solution. The chylomicron-like emulsion was again ultracentrifuged at 36,000 rpm for 25 min. The emulsion particles floating to the top were then aspirated and used for the analyses and metabolic studies. The lipid composition of the emulsions was determined by standard procedures. Cholesterol was analyzed by the enzymatic Chod-Pap method (Boehringer Mannheim, Mannheim, Germany). Triacylglycerols were measured using the enzymatic Biodiagnostica kit (São Paulo, Brazil). Phospholipids were assayed by the Bartlett method (23). Chylomicron composition was (% by weight): cholesterol, 1.9%; phospholipids, 10.4%; cholesteryl ester, 11.2%; and triacylglycerol 76.5%.

Approximately 159 μg of chylomicron triacylglycerol was infused into each rat together with cholesteryl (1-^{14}C)oleate (0.34 μCi) and [9,10(n)-^{3}H]triolein (1.17 μCi). Blood samples were drawn sequentially, and 10 min later the liver and spleen were rapidly removed and analyzed for triacylglycerol total fat and radioactivity levels.

Native chylomicrons drawn from the pooled intestinal lymph of donor rats that had been fed fish oil and [^{14}C]-cholesterol, or olive oil and [^{3}H]cholesterol, were pooled and pulse infused intra-arterially into recipient rats fed the non-purified diet to measure the rates of disappearance of both chylomicron species from plasma. Each rat received 8.45 mg of chylomicron triacylglycerols from each dietary source containing ^{14}C (0.43 μCi) and ^{3}H (0.93 μCi). In these experiments adult male Wistar rats were subjected to intestinal lymph duct catheterization under pentobarbital anesthesia (5 mg/100 g of body weight) and restrained in Bollman-type metabolic cages. A single dose of fish oil or olive oil containing radioactive cholesterol was administered to each rat by gavage 24 hr later. The intestinal lymph was collected on ice in 0.01% sodium ethylenediaminetetraacetic acid (EDTA) over a period of 24 hr while the animals drank 5% glucose solution in saline *ad libitum*. For native chylomicron separation, the lymph was submitted to ultracentrifugation at 24,500 rpm at 20°C (density = 1.006 g/mL) using an SW 41 rotor (Beckman ultracentrifuge model L3-50, Beckman Instruments). Chylomicrons were harvested with a Pasteur pipette and were used within 24 hr.

Plasma analyses. Blood was drawn after carotid catheterization. In the Triton WR 1339 experiment, blood was sequentially drawn over a 90 min period and triacylglycerols were measured enzymatically (Biodiagnostica). Triacylglycerols secreted by the liver were calculated by linear regression of the plasma triacylglycerol concentration data on the ordinate as related to time (on the abscissa) according to the equation $y = a + bx$, where b is the angular coefficient of the minimum square straight line, expressed in mg/100 mL/min.

In the artificial chylomicron infusion experiments, blood was drawn at 2, 4, 6, 8 and 10 min and plasma (100 μL) was extracted with chloroform/methanol (2:1, v/v). Radioactivity in the triacylglycerol and cholesteryl ester fractions was measured as previously described (21). In the natural chylomicron infusion experiment, ^{14}C and ^{3}H radioactivities were measured in blood samples drawn as described above; plasma aliquots were counted using a toluene-phosphor solution and a Beckman LS-100 beta scintillation counter (Beckman Instruments, Inc.) (24).

The fractional removal rate for each isotope in the plasma was computed from a monoexponential curve fitting after plotting the plasma radioactivity log values (on the ordinate) against time in minutes (on the abscissa). A monoexponential least square line as drawn ($y = a \cdot e^{bx}$), where b represents the angular coefficient which is the fractional removal rate expressed in minutes (21).

Tissue analyses. Aliquots of liver and spleen (1g) were extracted with 30 mL of a solution of chloroform/methanol (2:1, v/v). After filtration and addition of water (7 mL), the upper water phase was discarded. A solution of chloroform/methanol/water (3:48:47, v/v/v; 4 mL) was then added, and the water phase discarded. The solvents were evaporated under a stream of nitrogen. The extracted lipids were purified by thin-layer chromatography (TLC) on silica gel using the solvent system hexane/diethyl ether/acetic acid (70:30:1, v/v/v). The cholesteryl ester and triacylglycerol bands were identified in an iodine chamber and eluted with diethyl ether. Radioactivity was determined in a toluene phosphor scintillation solution. An aliquot of the extracted tissue fat was used for the gravimetric measurement of total fat and triacylglycerols using the enzymatic kit (Biodiagnostica; Clinical Chem. Industry, São Paulo, Brazil).

RESULTS

Triacylglycerol and cholesterol concentrations in plasma after 15 days on each diet are shown in Table 1. Although plasma lipids were measured in the fasting state, the plasma triacylglycerol level was much higher in the olive oil group than in the fish oil and control groups. Plasma cholesterol concentration was slightly, but significantly, higher in the fish oil fed rats than in the olive oil fed and control animals. Thus fish oil reduced plasma triacylglycerol concentration, but increased the plasma cholesterol level, in agreement with results reported by others for humans and animals (25,26).

Figure 1 shows the increase in plasma triacylglycerol level with time after intraarterial administration of Triton WR 1339. Formation of liver triacylglycerol was significantly lower in controls and in fish oil fed rats than in olive oil fed animals. Fractional removal rates of the artificial chylomicrons are shown in Table 2. The plasma fractional catabolic rate (FCR) of [9,10(n)-^{3}H]triolein measures the triacylglycerol lipolysis and the particle removal rates altogether, while the FCR of cholesteryl [1-^{14}C]oleate measures the particle removal rate only. The FCR of both radioactive moieties did not differ among the three ex-

TABLE 1

Plasma Levels of Triacylglycerols and Cholesterol in Rats After 15 Days of Dietary Treatment[a]

Experimental groups	Triacylglycerols	Cholesterol
Controls (n = 7)	94.3 ± 19.6	56.3 ± 9.4
Fish oil (n = 9)	98.3 ± 34.3	75.2 ± 14.3
Olive oil (n = 7)	170.4 ± 48.1	62.7 ± 11.8

[a]Mean mg/dL ± SD. Statistical comparisons between groups by Student's t-test was as follows:

Controls × fish oil	NS	$p < 0.005$
Controls × olive oil	$p < 0.005$	NS
Fish oil × olive oil	$p < 0.005$	$p < 0.05$

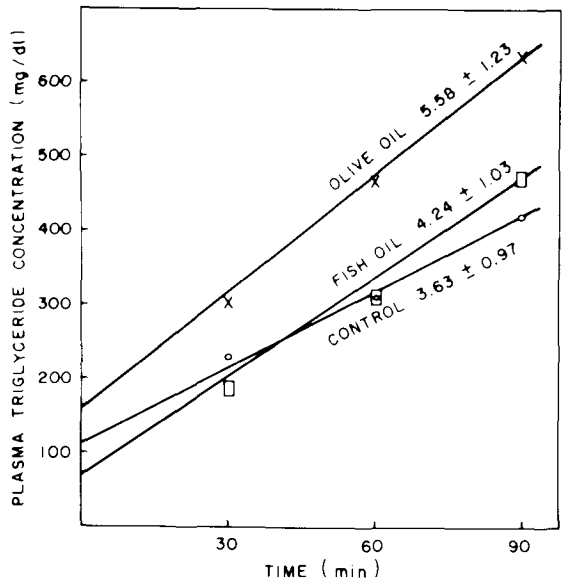

FIG. 1. Plasma triacylglycerol secretion rate. Variation of plasma triacylglycerol concentration after intra-arterial pulse infusion of Triton WR-1339. Control group: circles (n = 7); olive oil group: crosses (n =); fish oil group: squares (n = 9). Statistical comparisons: controls × olive oil ($p < 0.01$); control × fish oil (p = not significant); olive oil × fish oil ($p < 0.05$). For calculation of secretion rates, see text.

Fractional Catabolic Rates of Artificial Chylomicrons Doubly Labeled with Cholesteryl [1-^{14}C] oleate [^{14}C-CE] and [9,10(n)-^{3}H] triolein [^{3}H TG] Pulse Infused Intra-Arterially[a]

Experimental groups	^{14}C-CE	^{3}H-TG
Controls (n = 10)	0.23 ± 0.09	0.36 ± 0.14
Fish oil (n = 10)	0.21 ± 0.04	0.34 ± 0.11
Olive oil (n = 10)	0.21 ± 0.04	0.28 ± 0.07

[a]Mean min^{-1} ± SD. Differences between experimental groups by Student's t-test were not significant.

perimental dietary groups. Prolonged periods of feeding the diets did not interfere with the rate of metabolism of the artificial chylomicrons in plasma.

After the simultaneous intra-arterial injection into control rats, the fractional removal rate of the native chylomicrons containing radioactive cholesterol, labeled either with ^{3}H or ^{14}C (min; mean ± SD), was 0.07 ± 0.03 for those made from fish oil (labeled with [^{14}C]cholesterol) and 0.08 ± 0.03 for those made from olive oil (labeled with [^{3}H]cholesterol). The liver radioactive contents, as measured after artificial chylomicron administration, were different among the experimental groups (Table 3). Control rats had the highest liver cholesteryl [1-^{14}C]oleate content, while the fish oil fed group had the lowest. The liver content of [9,10(n)-^{3}H]triolein was lower in fish oil and olive oil fed rats than in control rats. Lower levels of [^{3}H]triacylglycerols were also present in the spleen of control rats as compared to the fish oil and olive oil fed groups. However, it is difficult to interpret the spleen results in view of the extremely low radioactivity values as compared to the liver data. More total fat and triacylglycerol were present in the liver of the olive oil fed group than in the fish oil fed rats; the control livers showed the lowest values (Tables 4 and 5).

DISCUSSION

Our data show that lower liver triacylglycerol output is the major plasma triacylglycerol lowering mechanism of dietary fish oil, which is in agreement with previous reports (7-11, 13-16).

Feeding different fats modified the chylomicron composition, but may also have affected the number of liver chylomicron receptors or lipoprotein lipase activity. These changes may thus have affected the rate of chylomicron metabolism. In order to distinguish between these two alternatives, native chylomicrons containing radioactive cholesterol were obtained from the intestinal lymph of olive oil and of fish oil fed rats and simultaneously infused intra-arterially into recipient rats that had been on a non-purified diet. The metabolism in plasma of chylomicron particles made of olive oil was indistinguishable from that of chylomicron particles made of fish oil, as their FCR were identical. Similar results were suggested in a previous study where infused rat mesenteric lymph chylomicrons had been enriched with either [^{14}C]oleic acid or [^{14}C]eicosapentaenoic acids (18).

Artificial chylomicrons were removed from the plasma at similar rates independent of the diet. Therefore, liver receptors for chylomicrons and the activity of enzymes (lipoprotein lipase) that delipidated the large particles were not influenced by the regular feeding of different types of fats.

The liver is the major organ that metabolizes chylomicron remnants (27,28); therefore after a 10-min period, similar fractions of the injected radioactive artificial chylomicrons should have been found in the liver with all three experimental dietary groups. However, the liver radioactivity values were much higher in the low fat (control) rats than in the other two groups. The liver of fish oil fed rats contained the smallest radioactive concentration of the three groups (Table 3) and much less total fat (Table 4) or triacylglycerol mass than the olive oil

Controls × olive oil	NS	$p < 0.001$
Fish oil × olive oil	$p < 0.001$	NS

TABLE 5

Liver Triacylglycerol Mass (mean ± SD) as Measured at the End of the Artificial Chylomicron Infusion

Experimental groups[a]	Total (mg)	mg/g Liver weight
Controls (n = 10)	37.0 ± 8.3	4.3 ± 0.6
Fish oil (n = 10)	45.7 ± 11.5	4.1 ± 0.9
Olive oil (n = 10)	136.7 ± 36.6	12.2 ± 4.1

[a]Statistical comparisons between groups by Student's t-test were as follows:

Controls × fish oil	$p < 0.05$	NS
Controls × olive oil	$p < 0.001$	$p < 0.001$
Fish oil × olive oil	$p < 0.001$	$p < 0.001$

fed rats when values were expressed per unit of liver weight (Table 5).

The present experiments demonstrate that rats fed dietary fish oil rather than olive oil have a slower VLDL-TG production in liver, a normal plasma catabolic rate of radioactive chylomicrons, a decreased liver concentration of the infused radioactive chylomicrons, and a smaller liver concentration of total fat and of triacylglycerol. The data above are in agreement with a slower production of VLDL-TG in the presence of a normal entrance into the liver of the fat dietary origin. If the exit of fat from the liver were impaired while the local synthesis rate of triacylglycerol were maintained, liver fat would have been stored during fish oil feeding. However, the liver fat content was remarkably small in the fish oil fed group compared to that in the olive oil fed group. Therefore, fish oil must stimulate fatty acid oxidation, impair triacylglycerol synthesis, or both.

Previous studies have shown that in the liver ω3 fatty acids are preferentially oxidized as compared to acid of the ω6 series (13,29). Finding little radioactive triacylglycerol in the liver indicates that chylomicrons taken up are more rapidly metabolized into products that are no longer fatty acids; however, slower synthesis of triacylglycerols cannot be ruled out. Dietary fish oil has been found to reduce the activity of certain liver enzymes, such as diacylglycerol hydrolase (30), diacylglycerol acyltransferase (31), phosphatidate phosphohydrolase (29,30), and acetyl-CoA carboxylase (32). Faster oxidation of fish oil derived fatty acids in liver has also been demonstrated in earlier studies (13,33).

Plasma cholesterol concentration was higher in the fish oil group than in the olive oil fed rats (Table 1). Since the fish oil brand used in our study (MaxEPA) contained 4.6 mg cholesterol/g, and the animals consumed approximately 20 g of diet/day, their daily cholesterol intake was approximately 9–10 mg. This intake may have increased the plasma cholesterol concentration in rats (34). In past studies with normal subjects, fish oil treatment did not influence plasma cholesterol concentrations (35,36), but

increased low density lipoprotein (LDL) cholesterol levels (37). Studies with hypercholesterolemic individuals have shown reduced plasma cholesterol concentrations after fish oil treatment (25). The number of LDL receptors was decreased and the number of high density lipoprotein (HDL) receptors was increased in rats fed fish oil as compared to animals fed sunflower oil (38). In rats fed a nonpurified diet, the largest share of plasma cholesterol was found in HDL. Further studies are needed to explain whether and how dietary fish oil influences LDL and HDL metabolism both in humans and in animals.

Derivatives of Di-*O*-octanoylglycerol and Mono-*O*-octylglycerol as Modulators of Protein Kinase C and Diacylglycerol Kinase Activities

Jacqueline Goddat[a], Hervé Coste[b], Isabelle Vilgrain[b], Edmond Chambaz[b] and Hugues Driguez[a,*]
[a]CNRS-CERMAV, 38041 Grenoble and [b]INSERM (U244), LBIO/DRF, CEN-Grenoble, 38042 Grenoble, France

Twelve analogs of 1,2-di-*O*-octanoylglycerol modified at C-3 and three quaternary *N*-alkyl-ammonium derivatives of glycerol were synthesized. The compounds were tested *in vitro* as potential modulators of the calcium activated, phospholipid dependent protein kinase C (PKC) and diacylglycerol (DAG) kinase activities in order to understand the molecular interactions of these enzymes with their natural activators, inhibitors, or substrates. PKC activity was assayed by measuring histone H_1 phosphorylation, and the compounds synthesized were tested either in the presence (inhibitors) or in the absence (activators) of 1,2-di-*O*-octanoylglycerol analogs with the phosphatidylserine/Ca^{2+} mixture. DAG kinase activity was measured by the incorporation of phosphate into 1,2-di-*O*-oleoyl-*sn*-glycerol in the presence of the various analogs synthesized. In regard to PKC activity, the assays revealed that 1,2-di-*O*-octanoylglycerol analogs are inactive when modified at C-3 with groups which do not permit hydrogen bonding. Under our conditions, di-*O*-octanoylthioglycerol, which has been reported as inactive, was able to activate PKC in the presence of phosphatidylserine. It has been shown to give a synergistic activation with diacylglycerol and had no affinity for the phorbol ester receptor binding site, suggesting that *O*-octanoylthioglycerol interacts with the enzyme at a different site from the phorbol ester receptor binding site. PKC and DAG kinase activities are inhibited by *N*-alkyl-ammonium compounds (IC_{50} 24 μM) only when either two 8-carbon alkyl or acyl chains are present at the 1- and 2-positions of the glycerol backbone. The fact that these compounds have a strong effect on the binding of [^{3}H]phorbol 12,13-dibutyrate to protein kinase C, and also inhibit DAG kinase, may suggest binding to the DAG site of the regulatory domain of PKC.
***Lipids 27,* 331-338 (1992).**

Protein kinase C (PKC) is a calcium/phospholipid regulated enzyme which is activated by phorbol esters and diacylglycerols (1). This kinase has emerged as a pivotal regulatory enzyme in cellular signal transduction in response to a large number of external stimuli (2). However, the exact mode of molecular recognition between these activators and the enzyme is still not fully understood (3,4). Previous work has established that 1,2-di-*O*-octanoyl-*sn*-glycerol is an effective activator of PKC activity (5); however, this enzyme also can be activated very efficiently with phorbol ester or with phosphatidylserine (PS) and phosphatidylinositol 4,5-bisphosphate (PIP_2) (6). A number of 1,2-di-*O*-octanoylglycerol analogs have been used to show the importance in the activation process of an hydroxyl group at the 3-position and of the acyl groups at the 1- and 2-positions of the glycerol structure (7,8). On the other hand, natural *O*-alkyl-*O*-acylglycerols and synthetic di-*O*-alkylglycerols also have been shown to inhibit phorbol ester and di-*O*-acylglycerol stimulated PKC activity (9–11). Certain amino compounds may inhibit PKC by interfering with PS, di-*O*-acylglycerol and/or ATP (12–14). After completion of the present work, quaternary ammonium derivatives of *O*-alkylglycerols, with a short chain at the 2-position have been reported to inhibit PKC (15). We therefore reasoned that specific modulators of PKC should be structural analogs of 1,2-*O*-acyl or *O*-alkylglycerol with a function at C-3 that would permit hydrogen bonding as donor or acceptor.

MATERIALS AND METHODS

Materials. Octanoyl chloride and 3-dimethylamino-1,2-propanediol were purchased from Janssen Chimica (Belgium). 3-Amino-1,2-propanediol and 3-mercapto-1,2-propanediol were from Fluka (Mulhouse, France). Other reagents were obtained from Sigma Chimie (L'isle d'Abeau Chesnes, France) or from Aldrich Chimie (Strasbourg, France). The routes of chemical synthesis for compounds shown in Figure 1 are presented in Schemes 1 and 2.

General. In the present paper, "usual work-up" implies dilution of the reaction mixture with dichloromethane and successive washings with ice-cold aqueous solutions of potassium hydrogen sulfate (10%), saturated sodium hydrogen carbonate, and ice-cold water. Aqueous washings were then extracted again with dichloromethane, and the aqueous-washed organic phase was dried (Na_2SO_4) and then evaporated under reduced pressure below 45°C. Thin-layer chromatography (TLC) was done on layers of silica gel (Merck F254, Merck, Darmstadt, Germany) with detection by UV light and/or by charring with H_2SO_4/MeOH/H_2O, and/or dipping into 1% α-cyclodextrin in aqueous methanol (3%), followed by exposure to iodine vapors, and/or dipping into aqueous potassium bichromate (5%) in sulfuric acid (40%). Chromatographic purifications were done under pressure using dry kieselgel 60 (230–400 mesh) columns. Mass spectra were recorded on a Nermag R-10-10C instrument using positive or negative fast-atom bombardment (FAB^+ or FAB^-) with a glycerol matrix, or using DCl/NH_3 techniques. ^{13}C NMR spectra were recorded at 25.18 MHz on a Bruker (Karlsruhe, Germany) WP100 spectrometer. Chemical shifts are given from tetramethylsilane (TMS) in $CDCl_3$ or relative to acetone (31.09 ppm) in D_2O.

3-N-Acetylamino-1,2-di-octanoyloxy-propane (2). 3-Aminopropane-1,2-diol (0.5 g, 5.5 mmol) was selectively *N*-acetylated by treatment at 0°C with acetic anhydride in methanol (7.7 mL, 10% v/v). At 0°C, octanoyl chloride (3.5 mL, 20 mmol) was added dropwise, and methanol

An analytical sample was obtained after bulb-to-bulb distillation (90°C/0.01 mmHg). *Anal.* Calcd for $C_{21}H_{39}NO_5$: C, 65.42; H, 10.19; N, 3.63. Found: C, 65.24; H, 10.26; N, 3.63.

3-N-Dimethylamino-1,2-di-octanoyloxy-propane (**3**). 3-Dimethylaminopropane-1,2-diol (1 g, 8.4 mmol) was esterified as described for the preparation of **2**. Compound **3** was isolated by chromatography (ethyl acetate/hexane, 1:3, v/v) in 91% yield. ^{13}C NMR ($CDCl_3$) ppm: 174.1, 173.4 (CO); 69.4 ($CH\text{-}O$); 64.1 ($CH_2\text{-}O$); 59.6 ($CH_2\text{-}N$); 46.2 (NCH_3); 34.6, 34.3, 31.8, 29.2, 29.1, 25.1, 22.8, 14.2 (C_7H_{15}). MS (FAB^+) *m/z* 372 $[M + H]^+$; 327 $[M + H - N(CH_3)_2]^+$; 244 $[M - COC_7H_{15}]^+$; 226 $[M - HOCOC_7H_{15}]^+$. An analytical sample was obtained after bulb-to-bulb distillation (80°C/0.01 mmHg). *Anal.* Calcd for $C_{21}H_{41}NO_4$: C, 67.88; H, 11.12; N, 3.77. Found: C, 67.78; H, 11.11; N, 3.91.

1,2-Dioctanoyloxy-3-pyrrolidino-propane (**4**). 3-Pyrrolidino-propane-1,2-diol (1 g, 6.8 mmol) was treated as described for the preparation of **2**. Chromatography (ethyl acetate/hexane, 1:4, v/v) afforded **4** in 96% yield. ^{13}C NMR ($CDCl_3$) ppm: 173.6, 173.2 (CO); 70.4 ($CH\text{-}O$); 64.1 ($CH_2\text{-}O$); 56.1 ($CH_2\text{-}N$); 54.7 ($CH_2\text{-}N$); 23.7 ($CH_2\text{-}CH_2$); 34.5, 34.3, 31.8, 29.9, 29.1, 25.1, 22.7, 14.1 (C_7H_{15}). MS (DCl/NH_3) *m/z* 398 $[M + H]^+$. *Anal.* Calcd for $C_{23}H_{43}NO_4$: C, 69.47; H, 10.90; N, 3.52. Found: C, 69.22; H, 10.74; N, 3.50.

1,2-Dioctanoyloxy-3-piperidino-propane (**5**). 3-Piperidino-propane-1,2-diol (1 g, 6.28 mmol) was treated as described for the preparation of **2**. Chromatography (ethyl acetate/hexane, 1:10, v/v) gave **5** (85%). ^{13}C NMR ($CDCl_3$) ppm: 173.5, 173.4 ($CO\text{-}C_7H_{15}$); 69.1 ($CH\text{-}O$); 64.2 ($CH_2\text{-}O$); 58.8 ($CH_2\text{-}N$); 55.0 ($CH_2\text{-}N$); 25.6 ($CH_2\text{-}CH_2N$); 23.8 ($CH_2\text{-}C_2H_4N$); 34.2, 33.9, 31.4, 28.7, 28.6, 24.5, 22.2, 13.5 (C_7H_{15}). MS (DCl/NH_3) *m/z* 412 $[M + H]^+$. *Anal.* Calcd for $C_{24}H_{45}NO_4$: C, 70.03; H, 11.02; N, 3.40. Found: C, 69.76; H, 10.81; N, 3.33.

1,2-Dioctanoyloxy-propane-3-thiol (**6**). This compound was obtained from 1,2-dioctanoyloxy-3,3′-dithio*bis*-propane (**7**). Compound **7** was synthesized as described (16), and obtained in 60% yield after chromatography on silica gel (ethyl acetate/hexane, 1:20, v/v). ^{13}C NMR ($CDCl_3$) ppm: 173.3, 173.1 ($CO\text{-}C_7H_{15}$); 63.6 ($CH_2\text{-}O$); 69.7 ($CH\text{-}O$); 39.5 ($CH_2\text{-}S$); 34.4, 34.2, 31.8, 29.2, 29.1, 25.0, 22.7, 14.2 (C_7H_{15}). MS (FAB^+ PEG200 matrix) *m/z* 718 M^+; 575 $[M\text{-}OCOC_7H_{15}]^+$. *Anal.* Calcd for $C_{38}H_{70}O_8S_2$: C, 63.47; H, 9.81; S, 8.91. Found: C, 63.19; H, 9.94; S, 8.89.

Compound **7** (0.2 g, 0.27 mmol) was dissolved in ethanol (6 mL) and treated with dithioerythrol (86 mg, 0.55 mmol) in the presence of aqueous ammonia (29%, 11 μL). The reaction was carried out at 25°C for 15 min. After evaporation, the residue was dissolved in hexane (20 mL) and washed with water (6 mL, four times). The organic phase was dried and evaporated, and **6** was obtained in 95% yield. ^{13}C NMR ($CDCl_3$) ppm: 173.4, 173.0 ($CO\text{-}C_7H_{15}$); 72.2 ($CH\text{-}O$); 63.1 ($CH_2\text{-}O$); 25.0 ($CH_2\text{-}S$); 34.4, 34.2, 31.8, 29.2, 29.0, 25.0, 22.7, 14.1 (C_7H_{15}). MS (DCl/NH_3) *m/z* 378 $[M + NH_4]^+$; 361 $[M + H]^+$; 217 $[M + H - OCOC_7H_{15}]^+$. An analytical sample was obtained after bulb-to-bulb distillation (85°C/0.01 mmHg). *Anal.* Calcd for $C_{19}H_{36}O_4S$: C, 63.29; H, 10.06; S, 8.89. Found: C, 63.39; H, 10.36; S, 8.97.

3-Acetylthio-1,2-dioctanoyloxy-propane (**8**). Compound **6** (0.1 g, 0.28 mmol) was acetylated with acetic anhydride/pyridine (2 mL, 1:1, v/v). After usual work-up, the residue was purified by chromatography (ethyl acetate/hexane, 1:10, v/v), and **8** was obtained in 80%. ^{13}C NMR ($CDCl_3$) ppm: 173.4, 173.1 ($CO\text{-}C_7H_{15}$); 170.0 ($CO\text{-}CH_3$); 69.9 ($CH\text{-}O$); 63.6 ($CH_2\text{-}O$); 29.6 ($CH_2\text{-}S$); 30.5 ($CH_3\text{-}COS$); 34.3, 34.2, 31.8, 29.2, 29.1, 25.0, 22.7, 14.2 (C_7H_{15}). MS (FAB^+) *m/z* 403 $[M + H]^+$; 327 $[M - SCOCH_3]^+$. *Anal.* Calcd for $C_{21}H_{38}O_5S$: C, 62.65; H, 9.51; S, 7.96. Found: C, 62.89; H, 9.51; S, 8.14.

1,2-Dioctanoyloxy-3-methylthio-propane (**9**). 3-Methylthiopropane-1,2-diol (1 g, 8.18 mmol) was acylated as described for the synthesis of **2**. The expected compound was isolated in 86% yield after chromatography (dichloromethane/hexane, 2:3, v/v). ^{13}C NMR ($CDCl_3$) ppm: 173.4, 173.1 ($CO\text{-}C_7H_{15}$); 70.0 ($CH\text{-}O$); 63.8 ($CH_2\text{-}O$); 34.6

(CH_2-S); 16.2 (CH_3-S) 34.4, 34.2, 31.7, 29.1, 29.0, 25.0, 22.7, 14.2 (C_7H_{15}). MS (DCl/NH_3) *m/z* 392 $[M + NH_4]^+$; 327 $[M - SCH_3]^+$. An analytical sample was obtained after bulb-to-bulb distillation (78-80°C/0.01 mmHg). *Anal.* Calcd for $C_{20}H_{38}SO_4$: C, 64.13; H, 10.22; S, 8.56. Found: C, 64.12; H, 10.23; S, 8.77.

1,2-Dioctanoyloxyl-3-fluoro-propane (**10**). The preparation of 3-fluoro-propane-1,2-diol was carried out following the procedure used by Ghangas and Fondy (17) starting from glycerol. This compound was then acylated as described for 2, and was obtained in 59% yield after chromatography (hexane/diethyl ether, 2:1, v/v). ^{13}C NMR ($CDCl_3$) ppm: 173.6 (*C*O); 81.3 (*C*H_2-F, $J_{CF} = 174$ Hz); 69.6 (*C*H-O, $J_{CF} = 21.7$ Hz); 61.3 (*C*H_2-O, $J_{CF} = 7$ Hz); 34.1, 31.7, 29.1, 28.9, 24.9, 22.6, 14.0 (C_7H_{15}). MS (DCl/NH_3) *m/z* 364 $[M + NH_4]^+$. An analytical sample was obtained after bulb-to-bulb distillation (55°C/0.01 mmHg). *Anal.* Calcd for $C_{19}H_{35}FO_4$: C, 65.86; H, 10.18. Found: C, 65.42; H, 10.13.

3,4-Dioctanoyloxy-butane-2-ol (**11**, *Scheme 1*). Treatment of *meso*-erythrol (7.32 g, 60 mmol) in DMF (50 mL) with 2,2-dimethoxypropane (9.5 mL, 78 mmol) in the presence of *p*-toluenesulfonic acid (165 mg) for 15 min at 80°C afforded after neutralization with triethylamine (4 mL) and chromatography (ethyl acetate/hexane, 1:1, v/v) 3,4-*O*-isopropylidene-butane-1,2-diol (**11a**, 57%). ^{13}C NMR ($CDCl_3$) ppm: 109.4 (*C*$(CH_3)_2$)); 75.8 (*C*H-O); 72.5 (*C*H-OH); 66.5 (*C*H_2-O); 63.7 (*C*H_2-OH); 26.6, 25.2 (C-(*C*$H_3)_2$). MS (DCl/NH_3) *m/z* 163 $[M + H]^+$; 145 $[M - OH]^+$.

Compound **11a** (3.38 g, 20.9 mmol) was dissolved in dichloromethane/pyridine (16 mL; 10:1, v/v) and tosyl chloride (4.3 g, 22 mmol) and pyridine (16 mL) was added dropwise. After stirring for 24 hr at room temperature, the mixture was evaporated to dryness. Usual work-up and chromatography (ethyl acetate/hexane, 1:3, v/v) afforded 3,4-*O*-isopropylidene-1-tosyloxy-butane-2-ol (**11b**) in 78% yield. ^{13}C NMR ($CDCl_3$) ppm: 127.9, 129.9, 132.5 (C_6H_4); 109.4 (*C*-$(CH_3)_2$); 75.1 (*C*H-O); 71.8 (*C*H-OH); 70.6 (*C*H_2-OTS); 66.6 (*C*H_2-O); 26.6, 25.2 (C-(*C*$H_3)_2$); 21.6 (*C*H_3-C_6H_4). MS (DCl/NH_3) *m/z* 334 $[M + NH_4]^+$; 317 $[M + H]^+$; 301 $[M - CH_3]^+$; 131 $[M - CH_2OTS]^+$.

Displacement of the tosyl group of **11b** (4 g, 12.65 mmol) by iodine using sodium iodide (13.7 g, 91 mmol) in DMF (50 mL) was achieved by stirring for 4 hr at 80°C. Usual work-up and chromatography (ethyl acetate/hexane, 1:3, v/v) afforded 1-iodo-3,4-*O*-isopropylidene-butane-2-ol **11c** in 64% yield. ^{13}C NMR ($CDCl_3$) ppm: 109.3 (*C*-*C*$H_3)_2$); 77.7 (*C*H-O); 72.1 (*C*H-OH); 66.7 (*C*H_2-O); 26.9, 25.2 (C-(*C*$H_3)_2$); 12.7 (*C*H_2-I).

Compound **11c** (0.5 g, 1.9 mmol) was dissolved in ethanol (20 mL) containing triethylamine (0.8 mL) and was hydrogenated in the presence of Pd/C (10%, 0.5 g, 6 at.) for 20 hr at room temperature. After removing the catalyst, evaporation of the solvent and purification by gel chromatography (ethyl acetate/hexane, 1:3, v/v), 3,4-*O*-isopropylidene-butane-2-ol (**11d**) was isolated in 61% yield. ^{13}C NMR ($CDCl_3$) ppm: 109.3 (*C*-$(CH_3)_2$); 79.6 (*C*H-O); 67.1 (*C*H_2-OH); 64.8 (*C*H_2-O); 26.6, 25.4 (C-(*C*$H_3)_2$); 18.5 (*C*H_3). MS (DCl/NH_3) *m/z* 164 $[M + NH_4]^+$; 147 $[M + H]^+$; 131 $[M - CH_3]^+$.

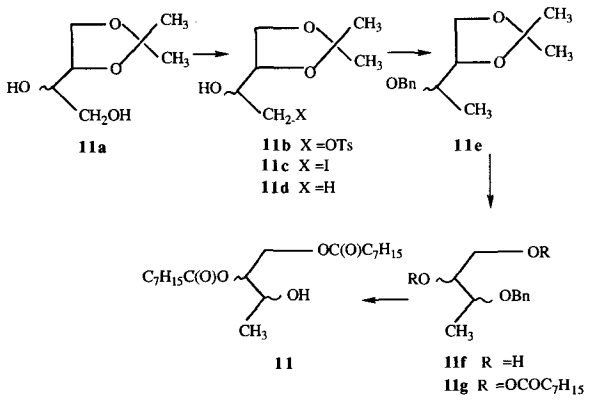
Compound **11d** (0.1 g, 0.68 mmol) was dissolved in DMF (7 mL). Sodium hydride (0.75 mmol) was added followed by benzyl bromide (97 μL, 0.8 mmol) and tetrabutylammonium iodide (25 mg) as described (18). The mixture was stirred for 12 hr at room temperature. Evaporation, usual work-up, and chromatography (ethyl acetate/hexane, 0.5:20, v/v) led to 3-benzyloxy-1,2-*O*-isopropylidene-butane (**11e**, 75% yield). ^{13}C NMR ($CDCl_3$) ppm: 139.4, 129.1, 128.4 (C_6H_5); 109.7 (*C*-$(CH_3)_2$); 79.2 (*C*H-O*C*H_2); 75.8 (*C*H-O); 71.2 (O-*C*H_2-C_6H_5); 66.9 (*C*H_2-O); 26.2, 24.9 (C-(*C*$H_3)_2$; 15.8 (*C*H_3). MS (El) *m/z* 236 M^+; 221 $[M - CH_3]^+$; 178 $[M - OC(CH_3)_2]^+$; 91 $[CH_2C_6H_5]^+$.

Tetrafluoroboric acid (35%) in H_2O (119 μL, 0.59 mmol) was added to a stirred solution of compound **11e** (93 mg, 0.39 mmol) in acetonitrile (5.5 mL) as described (19). After stirring for 30 min at room temperature, triethylamine (120 μL) was added, and the solvent was evaporated. The residue gave after chromatography (ethyl acetate/hexane, 1:1, v/v) 3-benzyloxy-butane-1,2-diol (**11f**) in 87% yield. ^{13}C NMR (D_2O) ppm: 138.4, 129.4, 128.9 (C_6H_5); 76.3 (*C*H-O*C*H_2); 74.5 (*C*H-OH); 71.5 (O-*C*$H_2C_6H_5$); 63.3 (*C*H_2-OH); 15.2 (*C*H_3). MS (DCl/NH_3) *m/z* 214 $[M + NH_4]^+$; 197 $[M + H]^+$; 91 $[CH_2C_6H_5]^+$.

3-Benzyloxy-1,2-di-octanoyloxy-butane (**11g**). **11f** afforded after treatment with octanoyl chloride, as described for **2**, and chromatography (ethyl acetate/hexane, 0.5:20, v/v) compound **11g** in 53% yield. ^{13}C NMR ($CDCl_3$) ppm: 163.7, 163.2 (*C*O); 138.0, 128.6, 127.9 (C_6H_5); 73.7, 73.6 (*C*H-O); 71.4 (O-*C*H_2-O); 34.6, 34.3, 31.9, 29.3, 29.1, 25.1, 22.7, 14.2 (C_7H_{15}). MS (DCl/NH_3) *m/z* 466 $[M + NH_4]^+$; 449 $[M + H]^+$; 305 $[M - OCOC_7H_{15}]^+$.

3,4-Dioctanoyloxy-butane-2-ol (**11**). Catalytic hydrogenation (6 at.) over Pd/C (10%, 94 mg) for 24 hr in ethyl acetate (20 mL) of **11g** (94 mg, 0.2 mmol) led to **11** (52%) contaminated with its 2,4 isomer (20%, as estimated by NMR). ^{13}C NMR ($CDCl_3$) ppm: 174.1, 173.4 (*C*O); 75.4 (*C*H-O); 66.9 (*C*H-OH); 62.3 (*C*H_2-O) 19.0 (*C*H_3); 34.6, 34.3, 31.8, 29.2, 25.1, 22.8, 14.2 (C_7H_{15}). MS (DCl/NH_3) *m/z* 376 $[M + NH_4]^+$; 359 $[M + H]^+$; 341 $[M + H - H_2O]^+$. *Anal.* Calcd for $C_{20}H_{38}O_5$: C, 67.00; H, 10.68. Found: C, 67.08; H, 10.59.

*N-(1,2-Dioctanoyloxy-3-propyl-*N,N,N-*trimethylammonium iodide* (**12**). To a cold solution of compound **3** (0.3 g, 0.8 mmol) in diethyl ether (10 mL) was added methyl iodide (0.25 mL, 4 mmol). After a few minutes at room temperature, the compound which separated was filtered off by suction and recrystallized from ether at 4°C (54%; m.p. 142-144°C). ^{13}C NMR ($CDCl_3$) ppm: 173.2, 172.8



SCHEME 1

N-(1-Octanoyloxy-2-ethyl)-N,N,N-trimethylammonium iodide (**15**). To a solution of 2-*N,N*-dimethylamino-ethanol (5 g, 56 mmol) in diethyl ether (20 mL) was added octanoyl chloride (9.59 mL, 56 mmol) and the reaction was stirred overnight at room temperature. The precipitate was collected and dried to give 2-*N,N*-dimethylamino-1-octanoyl-ethane hydrochloride (98%). ^{13}C NMR ($CDCl_3$) ppm: 173.1 (*CO*); 58.2 (*CH*$_2$-O); 56.1 (*CH*$_2$-N); 43.5 (N-(*CH*$_3$)$_2$); 34.0, 31.6, 29.0, 28.9, 24.7, 22.6, 14.0 (*C*$_7$H$_{15}$). *Anal.* Calcd for $C_{12}H_{26}CINO_2 \times 0.5H_2O$: C, 55.26; H, 10.43; N, 5.37. Found: C, 55.49; H, 10.17; N, 5.40. The salt was stirred in methanol with Dowex (OH)$^+$ resin for a few minutes. After filtration and evaporation, the compound was treated as already described for the synthesis of **12**. Compound **15** was obtained in 47% yield (m.p. 132-134°C). *Anal.* Calcd for $C_{13}H_{28}INO_2 \times 0.5H_2O$: C, 42.63; H, 7.98; I, 34.64; N, 3.82. Found: C, 42.72; H, 7.86; I, 34.40; N, 3.91.

2,3-O-Isopropylidene-1-octyloxy-propane-2,3-diol (**17**). This compound was obtained following the procedure by Baumann and Mangold (20), but starting with octyl methanesulfonate and glycerol derivative **16** and using toluene as solvent. The expected compound **17** was obtained in 76% yield after chromatography (hexane/ethyl acetate, 40:1, v/v). ^{13}C NMR ($CDCl_3$) ppm: 109.8 (*C*(CH$_3$)$_2$); 74.9 (*CH*-O); 71.9 (*CH*$_2$-O-*CH*$_2$); 67.0 (*CH*$_2$-O); 25.6, 25.0 (C(*CH*$_3$)$_2$); 31.5, 29.2, 29.0, 28.8, 26.3, 22.2, 13.5 (*C*$_7$H$_{15}$). MS (EI) *m/z* 245 [M + H]$^+$; 229 [M − CH$_3$]$^+$.

3-Octyloxy-propane-1,2-diol (**18**). Compound **17** (0.6 g, 2.5 mmol) was treated at 100°C in acetone (2 mL) in the presence of aqueous 1N HCl (3 mL) for 30 min. After neutralization, 1-octylglycerol **18** can be used without purification for the next step. An analytical sample is obtained by filtration through silica gel (hexane/ethyl acetate, 3:1, v/v). ^{13}C NMR ($CDCl_3$) ppm: 72.5 (*CH*$_2$-OC$_8$H$_{17}$); 72.0 (O-*CH*$_2$-C$_7$H$_{15}$); 70.8 (*CH*-OH); 64.3 (*CH*$_2$-OH); 32.0, 29.7, 29.6, 29.4, 26.2, 22.8, 14.2 (*C*$_7$H$_{15}$). 1-Octyloxy-3-tosyloxy-propane-2-ol (**19**). The above compound **18** (2.4 mmol) was dissolved in pyridine (5 mL), chilled at 4°C, and tosyl chloride (1.5 eq.) was added. The resulting mixture was stirred for 20 hr at room temperature. After usual work-up, **19** was obtained in 37% yield after chromatography (hexane/ethyl acetate, 9:1, vwv). ^{13}C NMR ($CDCl_3$) ppm: 145.9, 130.6, 128.7 (*C*$_6$H$_4$); 71.9, 70.8 (*CH*$_2$-O-*CH*$_2$); 70.6 (*CH*-OH); 68.4 (*CH*$_2$-OTS); 21.1 (*CH*$_3$-C$_6$H$_4$); 31.4, 29.1, 28.8, 25.6, 22.2, 13.5 (*C*$_7$H$_{15}$). MS (DCl/NH$_3$) *m/z* 376 [M + NH$_4$]$^+$; 359 [M + H]$^+$; 187 [M − OTS]$^+$. *Anal.* Calcd for $C_{18}H_{30}O_5S$: C, 60.30; H, 8.43; S, 8.94. Found: C, 60.17; H, 8.36; S, 8.71.

1-Azido-3-octyloxy-propane-3-ol (**20**). The displacement of the tosyl group was achieved by treatment of **19** (0.25 g, 0.69 mmol) with lithium azide (0.13 g, 2.8 mmol) in DMF (10 mL) at 60°C for 12 hr. The solvent was evaporated; usual work-up of the residue and chromatography (ethyl acetate/hexane, 1:9, v/v) afforded **20** (95%). ^{13}C NMR ($CDCl_3$) ppm; 72.0 (*CH*$_2$-O-*CH*$_2$); 69.8 (CH-OH); 53.7 (*CH*$_2$-N$_3$); 32.0, 29.7, 29.6, 29.4, 26.2, 22.8, 14.2 (*C*$_7$H$_{15}$). MS (DCl/NH$_3$) *m/z* 247 [M + NH$_4$]$^+$; 230 [M + H]$^+$.

1-Azido-2-methyloxy-3-octyloxy-propane (**21**). Compound (**20**) (60 mg, 0.26 mmol) was treated with sodium hydride (12 mg, 50% in oil dispersion) in DMF (3 mL). After 30 min at room temperature, methyl iodide (0.28 mmol) was added and the mixture was heated at 50°C for 12 hr, diluted with dichloromethane, and washed with ice-cold water. Compound **21** was obtained in 68% yield after chromatography (hexane/ethyl acetate, 15:1, v/v). ^{13}C NMR ($CDCl_3$) ppm: 79.6 (*CH*-OCH$_3$); 72.0, 69.9 (*CH*$_2$-O-*CH*$_2$); 51.9 (*CH*$_2$-N$_3$); 32.0, 29.8, 29.6, 29.4, 26.2, 22.9, 14.2 (*C*$_7$H$_{15}$). MS (DCl/NH$_3$) *m/z* 261 [M + NH$_4$]$^+$; 244 [M + H]$^+$.

1-N,N-Dimethylamino-2-methoxy-3-octyloxy-propane (**22**). The azido compound **21** (66 mg, 0.27 mmol) was treated as described (21) for 12 hr with pyridine/ammonia-saturated methanol (3.6 mL; 1:1, v/v) in the presence of triphenyl phosphine (180 mg). The reaction mixture was diluted with diethyl ether (50 mL) and washed with aqueous 1N HCl (50 mL). To the aqueous phase, NaOH (1N) was added (until slightly basic), and this phase was extracted with chloroform (3 times). The organic layer was dried, filtered and concentrated to yield the expected amino compound in 73% yield. This compound was used for the next step without characterization and was *N,N*-dimethylated following the procedure recently described (22). Compound **22** was obtained in 70% after chromatography (ethyl acetate/methanol, 3:7, v/v). ^{13}C NMR ($CDCl_3$) ppm: 78.9 (*CH*-OCH$_3$), 71.9 (*CH*$_2$-O-*CH*$_2$-C$_7$H$_{15}$); 61.1 (*CH*$_2$-N); 57.9 (O-*CH*$_3$); 46.3 (N(*CH*$_3$)$_2$); 32.0, 29.9, 29.6, 29.4, 26.3, 22.8, 14.1 (*C*$_7$H$_{15}$). MS [FAB$^+$] *m/z* 246 [M + H]$^+$.

N-(1-Octyloxy-2-methoxy-3-propyl)-N,N,N-trimethylammonium iodide (**23**). This compound was prepared in 80% yield as described for the synthesis of **12** (m.p. 99°C). ^{13}C NMR ($CDCl_3$) ppm: 74.7 (*CH*-O); 72.1 (O-*CH*$_2$-C$_7$H$_{15}$); 68.1 (CH$_2$-O); 67.6 (CH$_2$-N); 58.5 (O-CH$_3$); 55.4 (N(*CH*$_3$)$_3$); 31.8, 29.4, 29.2, 26.0, 22.6, 14.0 (*C*$_7$H$_{15}$). MS (FAB$^-$) *m/z* 514 [M + I]$^-$; 127 [I]$^-$; (FAB$^+$) *m/z* 260 [M − I]$^+$. *Anal.* Calcd for $C_{15}H_{34}INO_2$; C, 46.51; H, 8.84; I, 32.76; N, 3.61. Found: C, 46.62; H, 8.93; I, 32.20; N, 3.52.

1-Amino-3-octyloxy-propane-2-ol (**24**). Reduction of the azido group of **20** (75 mg, 0.32 mmol) was done as described for compound **21**. Compound **24** was obtained in

93% yield. ^{13}C NMR ($CDCl_3$) ppm: 77.1 (*C*H-OH); 73.2 (*C*H_2-O); 71.9 (*C*H_2-C_7H_{15}); 44.6 (*C*H_2-N); 31.9, 29.8, 29.5, 26.3, 22.8, 14.2 (C_7H_{15}). MS (DCI/NH_3) *m/z* 204 $[M + H]^+$; 185 $[M - NH_3]^+$.

*2-Acetyloxy-1-*N,N-*dimethylamino-3-octyloxy-propane* (25). Compound 24 was *N,N*-dimethylated as already described for the synthesis of 22, the resulting product was acetylated with acetic anhydride/pyridine mixture (1:1, v/v), and 25 was obtained in 65% yield after purification (ethyl acetate/methanol, 7:3, v/v). ^{13}C NMR ($CDCl_3$) ppm: 171.0 (*C*O); 71.6 (*C*H-O); 70.5, 70.6 (*C*H_2-O-*C*H_2); 59.7 (*C*H_2-N); 46.0 (N(*C*H_3)$_2$) 21.3 (*C*H_3); 31.8, 29.6, 29.4, 29.2, 26.0, 22.6, 14.0 (C_7H_{15}). MS (FAB^+) *m/z* 274 $[M + H]^+$.

N-*(2-Acetyloxy-1-octyloxy-3-propyl)*-N,N,N-*trimethylammonium iodide* (26). *N*-Alkylation of compound 24 was accomplished as described for the synthesis of 23. Compound 26 was obtained in 82% yield (m.p. 128–129°C). ^{13}C NMR ($CDCl_3$) ppm: 170.3 (*C*O); 72.3 (*C*H-O); 67.6 (*C*H_2-O-*C*H_2); 67.1 (*C*H_2-N); 55.1 (N(*C*H_3)$_3$); 21.4 (*C*H_3); 32.0, 29.7, 29.5, 29.4, 26.2, 22.8, 14.2 (C_7H_{15}). MS (FAB^-) *m/z* 542 $[M + I]^-$; (FAB^+) *m/z* 288 $[M - I]^+$. *Anal.* Calcd for $C_{16}H_{34}INO_3$: C, 46.26; H, 8.25; I, 30.55; N, 3.37. Found: C, 46.21; H, 8.38; I, 30.30; N, 3.30.

*1-*N,N-*Dimethylamino-2-octanoyloxy-3-octyloxy-propane* (27). Compound 24 (63 mg, 0.3 mmol) was *N,N*-dimethylated as already described for the synthesis of 22, and the resulting product was acylated with octanoyl chloride (1.3 eq; 62 μL) in pyridine/dichloromethane (3:1, v/v). Usual work-up and purification (hexane/ethyl acetate, 7:3, v/v) afforded 27. ^{13}C NMR ($CDCl_3$) ppm: 173.4 (*C*O); 71.5 (*C*H-O); 70.6, 70.4 (*C*H_2-O-*C*H_2); 46.0 (N(*C*H_3)$_2$); 34.5, 31.8, 31.7, 29.6, 29.4, 29.2, 29.1, 29.0, 26.0, 25.0, 22.6, 22.5, 14.1, 14.0 (C_7H_{15}). MS (EI) *m/z* 358 $[M + H]^+$; 213 $[M - OCOC_7H_{15}]^+$. *Anal.* Calcd for $C_{21}H_{43}NO_3$: C, 70.53; H, 12.12; N, 3.91. Found: C, 70.48; H, 12.38; N, 4.0.

N-*(2-Octanoyloxy-1-octyloxy-3-propyl)*-N,N,N-*trimethylammonium iodide* (28). *N*-Alkylation of compound 27 was performed as described for the synthesis of 23. Compound 28 was obtained in 38% yield after crystallization in diethyl ether (m.p. 126–128°C). ^{13}C NMR ($CDCl_3$) ppm: 172.9 (*C*O); 72.0 (*C*H_2-C_7H_{15}); 69.4 (*C*H-O); 67.3 (*C*H_2-O); 66.6 (*C*H_2-N); 54.7 (N(*C*H_3)$_3$); 34.3, 31.8, 31.6, 29.4, 29.3, 29.2, 29.0, 28.8, 26.0, 24.7, 22.6, 22.5, 14.1, 14.0 (C_7H_{15}). MS (FAB^-) *m/z* 626 $[M + I]^-$; (FAB^+) *m/z* 373 $[M - I]^+$. *Anal.* Calcd for $C_{22}H_{46}INO_3$: C, 52.89; H, 9.28; I, 25.4; N, 2.80. Found: C, 53.10; H, 9.47; I, 25.50; N, 2.90.

Protein kinase C. Protein kinase C was purified from bovine brain according to Walton *et al.* (23). A final specific activity of 90 nmol of phosphorus transferred per min per mg protein was obtained. Protein kinase C was routinely assayed by measuring ^{32}P transferred from [γ^{32}P]ATP to histone H_1 according to Vilgrain *et al.* (24). Briefly, the reaction was run in a final volume of 80 μL of 50 mM Tris-HCl, pH 7.4, containing 50 ng of enzyme, $CaCl_2$ 100 μM, $MgCl_2$ 10 mM, histone H_1 37.5 μg/mL, phosphatidylserine 31 μM, and 1,2-dioleoyl-*sn*-glycerol 0.5 μM. Phosphatidylserine and 1,2-dioleoyl-*sn*-glycerol were dispersed by sonication in 50 mM Tris-HCl, pH 7.4, containing 0.5 mM ethylenediaminetetraacetic acid (EDTA). Synthetic compounds were dissolved in dimethylsulfoxide (final concentration, 0.1%). After addition of 10 μM [γ^{32}P]ATP (1250 cpm/pmol), the sample was further incubated for 10 min at 30°C. The reaction was terminated by the addition of 12% trichloroacetic acid (TCA) in the presence of casein as carrier protein. After centrifugation for 5 min at 5000 rpm, the supernatant was discarded and the pellet was washed twice with 2.5 mL of TCA. The final pellet was resuspended in 100 μL of 1N NaOH, and ^{32}P incorporation was measured by scintillation counting in Aquasol (New England Nuclear, Boston, MA).

[^{3}H]PDBU binding assay. [^{3}H]PDBU binding was measured using the polyethylene glycol precipitation method (25). The reaction was carried out in a final volume of 100 μL of 50 mM Tris-HCl, pH 7.4, containing 0.5 mg of purified PKC, $CaCl_2$ 100 μM, bovine serum albumin 0.2 mg/mL, phosphatidylserine 250 μg/mL, and [^{3}H]-PDBU 10 nM (15.8 Ci/mmol) for 30 min at 30°C and then cooled to 4°C for 1 hr to ensure precipitation by polyethylene glycol 6000 (final concentration, 12%) in the presence of bovine γ-globuline (1 mg). After centrifugation at 14,000 rpm, the pellet was dissolved in 20 μL of 1N NaOH and the radioactive [^{3}H]PDBU was determined by scintillation counting. Non-specific binding was measured in the presence of 30 μM unlabeled PDBU.

Diacylglycerol kinase assay. DAG kinase was purified from pig brain according to Kanoh *et al.* (26). A final specific activity of 0.8 μmol of phosphatidate produced per min per mg protein was obtained. The diacylglycerol kinase assay was carried out in a final volume of 40 μL 100 mM Tris-HCl, pH 7.5, buffer containing 10 mM NaF, 1 mM dithiothreitol (DTT), 8 mM $MgCl_2$, 0.5 mM deoxycholate, 5 μM diolein, 200 μM [γ^{32}P]ATP (125 cpm/pmol) and 50 ng of enzyme. Synthetic compounds were dissolved in DMSO (final concentration, <0.1%). Labelled phosphatidate was extracted as described (27) and counted by scintillation counting.

RESULTS AND DISCUSSION

The aim of this study was to investigate both the ability of analogs of di-*O*-octanoylglycerol (1) to act as specific activators, inhibitors or substrates of PKC and DG kinase, and to examine the possible involvement of the 3-hydroxyl group of 1,2-diacylglycerols in bringing about these efforts. All compounds studied were racemic mixtures. Hence, no information was acquired as to the relative activities of the enantiomers.

Ganong *et al.* (8) suggested the involvement of the 3-hydroxyl group by demonstrating that a deoxy compound, or substitution of this group by chloride or by bulky groups produced inactive compounds. Earlier efforts (28, 29) to rationalize structure-activity relationships of potent activators of PKC had been based on their conformational properties. Also, Brockerhoff (3) had suggested formation of an intermediary complex involving the 3-hydroxy group as a proton donor to the enzyme. It also was proposed that the ester groups acted as acceptors of protons from the protein. Since a hydroxyl group can act as a proton acceptor and can donate its hydrogen to a proton acceptor, such as the solvent or a protein, we considered it of interest to examine the effect of substitution of the hydroxyl group with groups that are polar, apolar or amphiphilic in characters.

Substituted nitrogen derivatives were prepared first. These compounds (2–5) were easily obtained by acylation of commercially available precursors. All were inactive under our experimental conditions (IC 50 > 100 μM). The

sulfur containing compounds 6–9 were readily synthesized. Although compounds 7–9 were inactive, compound 6 with a free thiol at C-3 proved to be a potent activator of PKC (Fig. 2A). At a concentration of 40 μM, both diacylglycerol and thiol 6 produced about the same activation with A_{50} values of approximately 5 μM and 18 μM, respectively. For compound 6, the dose-dependent activation was without saturation up to 40 μM.

Compound 6 had been tested previously as activator or antagonist of PKC. However, it was reported to be inactive (8). A likely explanation for this would be that the thiol had undergone autoxidation to disulfide 7, which we have found inactive. Although compound 6 proved to be first analog of di-*O*-octanoylglycerol 1 which significantly promoted PKC activation, the compound did not displace the [^{3}H]PDBU binding at concentrations up to 30 μM (Fig. 2B). This conclusion was supported by the synergistic action of the thiol with diacylglycerol. Activation of PKC was observed (Fig. 2C, curve a) when compound 6 was used at constant concentration (20 μM) and diacylglycerol was added in a concentration range of 0–40 μM. The theoretical curve for an additive effect is represented by curve b. The lack of coincidence of these plots suggests that 6 binds to a site different from the PDBU binding site.

Racemic mixtures of the fluoro compound 10 and the C-methyl derivative of 1 (11) were essentially inactive. During our work, the optically pure isomers of 11 were measured by Wender *et al.* (30) and only one isomeric form was shown to be slightly active. In view of the inactivity displayed by fluoride 10, the hydroxyl group of 1 appears to donate its hydrogen to hydrogen bonding with the receptor site responsible for PKC activation.

Structurally dissimilar hydrophobic compounds with free or protonated amino groups have been reported to be potent inhibitors of PKC by interfering with phosphatidylserine (12,31). Furthermore, very recently quaternary ammonium analogs of alkyl glycerols with short alkyl chains at C-2 were found to reverse PS activation of PKC (15). These compounds are structurally related to choline phosphoglycerides and their *in vivo* turnover does not involve the phosphatidylinositol cycle. Keeping in mind a selective regulation of this pathway, we have synthesized a series of quaternary ammonium derivatives of 1,2-di-*O*-octanoylglycerols 12–14 (Fig. 1), a 1,2-di-*O*-alkyl-glycerol (23) and 1-*O*-alkyl-2-*O*-acyl-glycerols (26 and 28) (Scheme 2). The choline analog 15 also was prepared. All these cationic compounds were tested for *in vitro* inhibition of PKC and DG kinase. The results, shown in Table 1, indicate that the activation of all these compounds with two C-8 chains were not significantly different, in that all caused a half-maximum inhibition at ~20 μM for both enzymes. As expected, substitution of an acyl chain of 12 by an alkyl chain at C-1 to produce 28 did not alter the activity. However, contrary to the reported behavior of *O*-alkylglycerol derivatives (15), both the 2-*O*-methyl and 2-*O*-acetyl analogs of 28 (23 and 26) were inactive under our conditions, as was compound 15. As shown in Figure 3, the inhibition of PKC is due to competition for the receptor site for 1. Since [^{3}H]PDBU binding was inhibited by 12–14 and 28 in a dose-dependent fashion, it seems unlikely that the inhibitory effects described in this paper can be explained by either detergent effects or by competition with other agents (ATP, PS, or substrates). The results appear to be

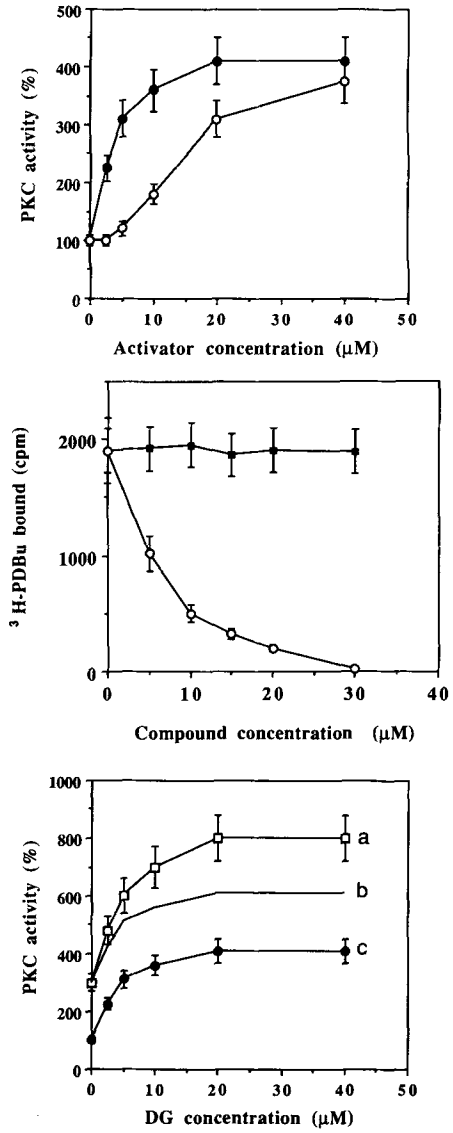

FIG. 2. Effect of 1,2-di-*O*-acylglycerol and 1,2-di-*O*-octanoyl-thioglycerol on PKC activity and [^{3}H]PDBU binding. A. PKC activity was assayed as described in Materials and Methods. Enzyme (500 ng) was incubated in the presence of [γ^{32}P]ATP and histone H_1 for 20 min at 30°C with increasing concentrations of 1,2-di-*O*-acylglycerol (closed circle) or 1,2-di-*O*-octanoyl-thioglycerol 6 (open circle) from 0–40 μM. Incorporation of radioactivity into H_1 was counted after TCA precipitation with casein as carrier protein. The results are expressed as % of control where control is the enzyme activity in the presence of phosphatidylserine/Ca^{2+}. B. [^{3}H]PDBU binding was assayed as described in Materials and Methods in a final volume of 100 μL containing 500 μg of enzyme, phosphatidylserine 250 μg/mL, 10 nM [^{3}H]PDBU (15.8 Ci/mol), and 100 μM $CaCl_2$ in the presence of increasing concentrations of di-*O*-acylglycerol (open circle) or 1,2-di-octanoyl-thioglycerol 6 (closed circle) from 0–30 μM. Specific binding was determined by counting [^{3}H]PDBU after PEG 6000 precipitation in the presence of bovine-γ globuline as carrier protein. Results are expressed as cpm of [^{3}H]PDBU counted. Data points are the mean of triplicate determinations ± SEM as indicated. C. Effects of 1,2-di-*O*-octanoyl-thioglycerol on PKC activation by 1,2-di-*O*-acylglycerol. The enzyme activity was determined as described in A with increasing concentrations of 1,2-di-*O*-acylglycerol, in the absence of compound 6 (closed circle) (curve c), or in the presence of 20 μM thioglycerol (open square) (curve a); curve b is the theoretical curve for an additive effect. Data are expressed as % of control where control is the PKC activity in the presence of phosphatidylserine/Ca^{2+}.

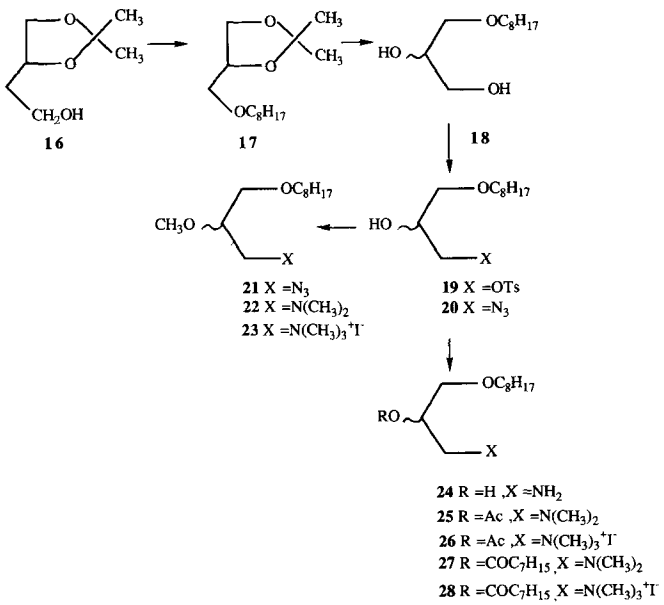

SCHEME 2

TABLE 1

Effect of *N*-Alkylammonium Derivatives of 1,2-Di-*O*-octanoylglycerol on PKC and DAG Kinase Activities[a]

Compounds	IC_{50} (μM) PKC	DAG K
12	23	18
13	25	30
14	20	20
15	>100	>100
23	>100	>100
26	>100	>100
28	20	20

[a]PKC activity was tested as described in Materials and Methods using a mixture of *sn*-1,2-diolein/PS/Ca^{2+} activators + the indicated compounds. DAG kinase activity was assayed using *sn*-1,2-diolein as substrate in the presence of the compounds indicated.

best explained by interactions at or near the DAG binding site.

ACKNOWLEDGMENTS

We are grateful to Dr. F. Hyafil (Glaxo Research Center, France) for support and helpful discussions. A post-doctoral fellowship to H.C. and a Ph.D. scholarship to J.G. were also provided by Glaxo Laboratories. We want to thank Professor R. U. Lemieux (University of Alberta, Edmonton, Canada) for careful review of this manuscript.

Effect of Dietary Fats on Some Membrane-Bound Enzyme Activities, Membrane Lipid Composition and Fatty Acid Profiles of Rat Heart Sarcolemma

A. Vajreswari* and **K. Narayanareddy**[1]
National Institute of Nutrition, Indian Council of Medical Research, Jamai Osmania P.O., Hyderabad - 500 007, A.P., India

The effect of various dietary fats on membrane lipid composition, fatty acid profiles and membrane-bound enzyme activities of rat cardiac sarcolemma was assessed. Four groups of male weanling Charles Foster Young rats were fed diets containing 20% of groundnut, coconut, safflower or mustard oil for 16 weeks. Cardiac sarcolemma was prepared from each group and the activities of Na^+,K^+-ATPase, 5′-nucleotidase, Ca^{2+}-ATPase and acetylcholinesterase were examined. ATPase activities were similar in all groups except the one fed coconut oil, which had the highest activities. Acetylcholinesterase activity was also similar in all the groups, however, it was significantly higher in the group fed mustard oil. No significant changes were observed among the groups in 5′-nucleotidase activity, in the cholesterol-to-phospholipid molar ratio and in sialic acid content. The coconut, safflower and mustard oil diets significantly increased cholesterol and phospholipid contents and the lipid-to-protein ratio of cardiac sarcolemma as compared to feeding the groundnut oil diet. The fatty acid composition of membrane lipids was quite different among the various groups, reflecting the type of dietary fat given. The total unsaturated-to-saturated fatty acid ratio was not different among the various groups; however, the levels of some major fatty acids such as palmitic (16:0), oleic (18:1) and linoleic (18:2) acids were significantly different. Cardiac sarcolemma of the group fed safflower oil had the highest polyunsaturated fatty acid content. The results suggest that dietary fats induce changes not only in the fatty acid composition of the component lipids but also in the activities of sarcolemmal enzymes involved in the regulation of cardiac function.
***lipids* 27, 339–343 (1992).**

The activities of membrane-bound enzymes are dependent on the lipid milieu surrounding the protein, and some enzymes, such as NA^+,K^+-ATPase (adenosine triphosphatase) and adenylate cyclase, have specific requirements for certain phospholipids (1). Dietary fat has been shown to affect the lipid composition of various tissues (2), including that of cardiac membranes (3), which may induce changes in the activities of membrane-bound enzymes (4). Cardiovascular health and disease are greatly dependent on the quality and quantity of dietary fat, and therefore it is of interest to study their effects at the cellular level.

Abbreviations: AMP, adenosine monophosphate; ATP, adenosine triphosphate; ATPase, adenosine triphosphatase; CFY, Charles Foster Young; DTNB, 5,5′-dithio*bis*(2-nitrobenzoic acid); EDTA, ethylenediaminetetraacetic acid; EFA, essential fatty acid; EGTA, ethyleneglycol*bis*(β-aminoethyl ether)-*N,N,N′,N′*-tetraacetic acid; PUFA, polyunsaturated fatty acids.

Na^+,K^+-ATPase and Ca^{2+}-ATPase play significant roles in the contraction and relaxation cycles of the cardiac muscle by maintaining normal ion levels within the myocytes (5). Changes in the properties of these ion pumps due to changes in the lipid microenvironment may, in turn, influence cardiac function. In fact, the failure of the cell membrane to maintain normal transmembrane ionic distribution through ion pumps is considered to be a major event in the pathogenesis of ischemia and arrythmias (6,7).

Although dietary fat is known to alter the structural lipids of various cell membranes and, in turn, to induce changes in membrane function, the exact mechanisms by which these effects are brought about are not clear. However, membrane fatty acid composition (8), cholesterol-to-phospholipid ratio (9) and optimal bilayer thickness (10) are considered important factors in bringing about these effects.

In previous studies the effect of highly saturated vegetable and animal fats (coconut oil and sheep kidney fat) on lipid composition and membrane-bound enzymes of cardiac sarcolemma has been compared to the effect of highly unsaturated dietary fats, such as safflower oil or sunflower oil (3,11–14). In the present study, we have examined the effects of several dietary vegetable oils, which markedly differ in their fatty acid composition, on the lipid composition and function of cardiac sarcolemma.

MATERIALS AND METHODS

All chemicals used were obtained from Sigma Chemical Co. (St. Louis, MO). All solvents were of analytical grade.

Four groups of male, weanling, Charles Foster Young (CFY) rats were fed semi-purified diets containing groundnut, coconut, safflower or mustard oil at 20% by weight of the diet for 16 weeks. The composition of the diet was similar to AIN-76 A (15,16), except that the oil content was increased from 5 to 20% at the expense of starch as adapted earlier (17). Rats were killed by decapitation, hearts were removed and washed several times with ice-cold homogenizing medium containing 0.25 M sucrose, 0.2 mM ethylenediaminetetraacetic acid (EDTA) and 0.1 M Tris-HCl buffer (pH 7.6). Cardiac sarcolemma was isolated from pooled rat hearts (n = 8–16) according to the method of Andrew and Appel (18), except that the membranes were not subjected further to sucrose density gradient centrifugation. The $105,000 \times g$ pellet was suspended in 0.25 M sucrose buffer with 10 mM Tris-HCl (pH 7.4). These membrane preparations were enriched in Na^+,K^+-ATPase and 5′-nucleotidase.

5′-Nucleotidase (EC 3.1.3.5) activity was measured according to Aronson and Touster (19) in a medium containing 100 mM glycine-NaOH buffer (pH 8.75), 3 mM sodium-AMP and 10 mM $MgCl_2$.

Na^+,K^+-ATPase (EC 3.6.1.3) activity was assayed according to Post and Sen (20), except that ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N′,N′*-tetraacetic acid (EGTA)

was included in the reaction mixture. The reaction medium contained 50 mM Tris-HCl buffer (pH 7.4), 140 mM NaCl, 14 mM KCl, 3 mM $MgCl_2$, 3 mM Tris-ATP and 1 mM EGTA in a final volume of 0.5 mL. Ouabain (when required) was added at 1.0 mM concentration. Na^+,K^+-ATPase activity was calculated by subtracting the activity obtained with ouabain from that obtained without ouabain.

Ca^{2+}-ATPase (EC 3.6.1.3) activity was determined as described by Dhalla *et al.* (21) in a medium containing 50 mM Tris-HCl (pH 7.4) 3 mM $CaCl_2$ and 3 mM Tris-ATP. The blank contained 1 mM EGTA instead of $CaCl_2$.

Acetylcholinesterase (EC 3.1.1.8) activity was estimated according to the method of Ellman *et al.* (22), except that the reaction was stopped after 15-min incubation by the addition of an equal volume of absolute ethanol. The assay mixture contained 50 mM Tris-HCl buffer (pH 7.4), 0.2 mM Tris-EDTA, 0.1 mM 5,5′-dithio-*bis*(2-nitrobenzoic acid) and 1 mM acetylthiocholine iodide.

Lipids were extracted from the sarcolemma membrane preparations with chloroform/methanol (23). Cholesterol (24), phospholipids (25), sialic acid (26) and protein (27) were determined according to published procedures. Total lipids of cardiac sarcolemmal membranes were transesterified (28) and the fatty acids were analyzed by gas chromatography using an instrument (Model 3700, Varian Associates, Walnut Creek, CA) equipped with a flame ionization detector and an electronic integrator (Model 4270, Varian). A stainless steel column (12 ft. × 1/8 inch) was packed with 10% Silar 10C coated on Chromosorb-W, 80–100 mesh (Supelco Inc., Bellefonte, PA). Carrier gas was nitrogen at 20 mL/min. Temperature of the column was maintained at 180°C, and that of the injector and detector at 200°C. Fatty acids were identified by comparison with an authentic standard mixture (GLC-68B) obtained from Nu-Chek Prep (Elysian, MN).

All data were statistically analyzed by analysis of variance, and the level of significance was determined at $P < 0.05$.

RESULTS

The fatty acid compositions of the various dietary fats used in the experiment are shown in Table 1. Safflower oil has a very high proportion of linoleic (18:2) acid and very low amounts of saturated fatty acids. Coconut oil is characterized by a considerable proportion of short-chain fatty acids and high levels of saturated fatty acids which account for nearly 90% of total fatty acids. Mustard oil is unique in that it has erucic (22:1) acid constituting 50% of the total fatty acids. Groundnut oil has nearly 21% saturated fatty acids, 38% oleic (18:1) acid and 38% linoleic (18:2) acid. Thus all four diets differ markedly in total saturated, mono- and polyunsaturated fatty acids (PUFA).

The dietary fat had no influence on the cholesterol-to-phospholipid ratio; however, significant differences were observed in the absolute amounts of cholesterol and phospholipids among various groups (Table 2). Cardiac sarcolemma of safflower, mustard and coconut oil-fed groups displayed higher levels of cholesterol than did the groundnut oil-fed group. The plasma membranes of cardiac tissue of the mustard oil-fed group showed the highest levels of phospholipids, while those of the groundnut oil-fed group exhibited the lowest levels. Elevated amounts of cholesterol and phospholipids resulted in higher lipid-to-protein ratios in the cardiac sarcolemma of coconut, safflower and mustard oil-fed groups as compared to the groundnut oil-fed group. Sialic acid contents of cardiac membranes were not significantly different among the groups.

Substantial changes occurred in the fatty acid patterns of cardiac membrane lipids among the various groups (Table 3). Coconut oil diet, which was rich in saturated

5′-nucleotidase	55.7 ± 5.8[b]	63.7 ± 6.0[b]	67.1 ± 10.3[b]	53.1 ± 3.9[b]

[a]All enzyme activities are in μmoles P_i/mg protein/hr, except acetylcholinesterase, which is in μmoles thiocholine/mg protein/hr. Values are mean ± SEM of 4–8 observations/group; each sample was obtained from 8–16 rat hearts from each group.

[b,c]Means in a horizontal row not sharing a common superscript are different from each other ($P < 0.05$).

fatty acids, induced in the cardiac membranes an increase in monounsaturated fatty acids, especially 18:1, and a concomitant decrease in 18:2 as compared to the safflower oil group. The safflower oil diet, which was rich in PUFA, significantly reduced the 18:1 level and consequently decreased the total monounsaturated fatty acid content. Higher levels of PUFA, especially 18:2, were found in the cardiac sarcolemma of the safflower oil-fed group than in the coconut oil-fed group.

The cardiac sarcolemma of the mustard oil-fed group was characterized by the presence of significant proportions of eicosenoic (20:1) acid and 22:1, as well as a high 18:2 level and a low palmitic (16:0) acid level. No significant differences in the arachidonic (20:4) acid level or in the unsaturated-to-saturated fatty acid ratio of the cardiac sarcolemma were observed among the groups.

Plasma membranes obtained from cardiac tissue of the four dietary groups were examined for their purity by measuring the activities of marker enzymes. The preparations were enriched with 5′-nucleotidase and Na^+,K^+-ATPase. The membrane preparations showed nearly 27–34-fold enrichment in 5′-nucleotidase activity over that of a total tissue homogenate, and the activity of this enzyme remained unaffected by dietary variation. Contamination of the sarcolemma with mitochondrial and microsomal membranes was found to be minimal as assessed by determining azide-sensitive ATPase and K^+-stimulated Ca^{2+}-ATPase (29). Furthermore, there were no differences in the yield of membrane protein among the various groups (data not shown). However, it is evident from Table 4 that the activities of other sarcolemma-bound enzymes such as Na^+,K^+-ATPase and Ca^{2+}-ATPase were elevated in the coconut oil-fed group whereas the cardiac membranes of mustard oil-fed group had the highest acetylcholinesterase activity.

DISCUSSION

Earlier studies have indicated that the lipid composition of cardiac sarcolemma is modified by including or removing certain fats (3,11–14,30) of plant or animal origin from diets. However, the effect of other commonly used

dietary lipids, such as groundnut and mustard oil, on cardiac sarcolemma was not clear until now.

Analyses of cardiac membrane lipids indicated that the various dietary fats altered the lipid-to-protein ratio and the fatty acid composition of membrane lipids, while the cholesterol-to-phospholipid ratio remained unaltered. However, increases were observed in the absolute amounts of cholesterol and phospholipids of the cardiac membranes of the coconut, safflower and mustard oil-fed groups as compared to the groundnut oil-fed group. Further, the presence of elevated levels of cholesterol in these groups suggests that the concentration of cholesterol in the cardiac membranes is independent of the PUFA content of the diet, as has been observed with liver microsomal membranes (31). Feeding fats of different fatty acid composition does not appear to alter the ratio of unsaturated-to-saturated fatty acids, suggesting that membranes generally display a considerable degree of homeostasis with respect to this parameter. This homeostasis suggests an important role for membrane lipids in regulating membrane and cellular functions.

Although no differences in the unsaturated-to-saturated fatty acid ratios were observed, the proportions of some major fatty acids of cardiac membrane lipids were significantly different between the groups. The cardiac sarcolemmal preparations from the safflower oil-fed group were characterized by higher levels of PUFA than those of the other groups. However, no significant differences were apparent in the concentration of 20:4, which may be due to the remarkable ability of cardiac tissue to conserve this fatty acid. In fact, even in severe essential fatty acid (EFA) deficiency the heart, unlike other organs, tends to maintain high levels of 20:4 (32). The higher level of PUFA in this safflower oil-fed group was mainly due to a significantly higher level of 18:2. The lower levels of PUFA (both in the groundnut and coconut oil-fed groups) were offset by concomitant increases in 18:1. Further, the cardiac membranes of the mustard oil-fed group exhibited significantly lower level of 16:0 than did those of the other three groups.

Increased PUFA content is generally thought to induce higher membrane disorder, and this trend should be apparent in the cardiac sarcolemmal membranes of safflower oil-fed group. However, in these membranes, the higher membrane disorder appears to have been compensated for by the presence of higher levels of cholesterol. Although no differences were found in the fatty acid composition of the cardiac sarcolemma between the groundnut and coconut oil-fed groups, the membranes of the latter group showed a higher lipid-to-protein ratio than those of the former group. The cardiac membranes of the coconut oil-fed group displayed higher activities of a majority of the assayed enzymes in comparison to the other groups. These observations, along with those of earlier researchers (13, 14,33–35), indicate that an optimal lipid-to-protein ratio rather than the presence of highly unsaturated fatty acids are important for the activities of many membrane-bound enzymes (33).

As judged by the activities of 5′-nucleotidase, Na^+,K^+-ATPase and cholesterol-to-phospholipid ratio, our preparations of cardiac membranes appear to be more highly purified than the sarcolemmal preparations that were used in earlier studies (35–37).

Awad and Chattopadhyay (3) reported a decrease in the activities of 5′-nucleotidase, phosphodiesterase and *p*-nitrophenylphosphatase in cardiac sarcolemma of rats fed coconut oil as compared to those of a safflower oil-fed group, and they attributed this effect to changes in the fatty acid composition of the membrane. However, the results of the present study show that the activity of 5′-nucleotidase was unaffected by dietary manipulation of membrane fatty acid composition, consistent with data reported by others (38,39).

Na^+,K^+-ATPase activity of cardiac sarcolemma was distinctly higher in the coconut oil-fed group than in the other three groups in which the enzyme showed similar activities. Increases in Na^+,K^+-ATPase activity were also reported for homogenates of salivary glands and kidneys of animals fed saturated fats, such as butter and hydrogenated coconut oil, as compared to safflower oil-fed animals (39). A similar increase in the activity of Na^+,K^+-ATPase has been reported for liver plasma membranes (40) and brain synaptosomes (41) of EFA-deficient animals. The activities of Mg^{2+}-ATPase and Ca^{2+}-ATPase of sarcolemma were higher in the coconut oil and safflower oil-fed groups than in the other two groups. Surprisingly, two dietary fats with diverse fatty acid compositions exerted similar stimulatory effects on the activities of these two enzymes. The mechanisms by which these effects on membrane-bound enzyme activities are brought about are not clearly understood. Enhanced enzyme activities have been attributed to an increase in enzyme protein (42), changes in membrane bilayer thickness (43) and changes in lipid-to-protein ratio (33,44,45). Further studies are required to cast more light on the influence of various dietary fats on these membrane parameters.

The enhanced activity of acetylcholinesterase in the mustard oil-fed group may result in decreased levels of acetylcholine which would affect neuromuscular function. The importance of surface phenomena (46) and the role of sialic acid (47,48) in determining the activity of this enzyme have been recognized. The insertion of membrane proteins into the lipid core may be dependent on the transmembrane potential (49,50), which could be maintained by sialic acid by virtue of its negative charge (48). However, no differences in sialic acid content were found in the cardiac membranes of the groups, thereby suggesting the existence of other regulatory mechanisms.

The results of the present study suggest that the impact of dietary fats on the activities of membrane-bound enzymes can be mediated through factors such as fatty acyl composition of the membrane lipids and lipid-to-protein ratio of the membrane.

ACKNOWLEDGMENTS

We thank Dr. B. S. Narasinga Rao and Dr. Vinodini Reddy for their interest in this study; the staff of LAISC, Hyderabad for supplying weanling rats; Dr. K. Visweswara Rao for advice in statistical analysis; and Dr. M. S. Bamji for help in the preparation of the manuscript. Technical assistance of G. L. Nageswara Rao and Armugam is appreciated.

Effect of Prenatal and Postnatal Exposure to Ethanol on Rat Central Nervous System Gangliosides and Glycosidases

V.V.T.S. Prasad[1]
Department of Biochemistry, Faculty of Science, M.S. University of Baroda, Baroda, 390 002, India

We investigated the effect of maternal alcohol consumption on cell number, gangliosides and ganglioside catabolizing enzymes in the central nervous system (CNS) of the offspring. Virgin female rats of the Charles Foster strain were given 15% (v/v) ethanol in drinking water one month prior to conception and during gestation and lactation. At 21 days postnatal age, the offspring were sacrificed and the brains were separated into cerebrum, cerebellum and brain stem to investigate possible regional variations. Compared to controls, wet weight of cerebrum, cerebellum and brain stem, and of spinal cord was decreased in the pups exposed to alcohol. DNA and protein contents were also found to be lowered in all the CNS regions of the pups exposed to alcohol. Conversely, maternal alcohol consumption was found to increase the concentration and the content of total ganglioside *N*-acetylneuraminic (NANA) in CNS of the pups. In addition, alcohol treatment was found to induce alterations in the proportions of individual ganglioside fractions. Interestingly, these alterations are somewhat different than those observed in the neonatal brain and spinal cord of the pups subjected to prenatal alcohol exposure. The alterations in the proportions of ganglioside fractions were shown to be region-specific. Maternal alcohol consumption resulted in decreased activities of sialidase, β-galactosidase, β-glucosidase and β-hexosaminidase. The results suggest that the alcohol-associated increases in ganglioside concentration may be at least partly due to the decreased activities of ganglioside catabolizing enzymes.
Lipids 27, 344–348 (1992).

Alcohol consumption during pregnancy is detrimental to the fetus, and the nervous system has been shown to be affected most (1). Clusters of abnormalities observed in children exposed to alcohol *in utero* are described as fetal alcohol syndrome (FAS). The complete spectrum of abnormalities of FAS includes pre- and postnatal growth retardation, microcephaly, facial dysmorphology and central nervous system (CNS) dysfunction (2,3). To study the effects of alcohol on rat brain development, it is necessary to expose the offspring to alcohol during both pre- and postnatal periods, as rats, unlike humans, are born relatively immature with respect to their brain development (4).

The plasma membrane appears to be the primary target of the effects of alcohol; hence much research in this area has been focused on lipids, which are major constituents of neural membranes. However, most studies have been confined to cholesterol and phospholipids, which are important for maintaining membrane integrity and fluidity. Neural membranes (5), particularly those of brain, also are rich in gangliosides (6) which play an important role in a wide variety of cellular events, ranging from cell differentiation (7) to neuronal transmission (8). Despite their suggested importance, information on the effects of alcohol on CNS gangliosides is scanty and is mostly restricted to adult rats. There are no studies on the effects of pre- and postnatal alcohol exposure on the enzymes involved in the catabolism of gangliosides.

We have reported the effects of prenatal exposure to alcohol on rat brain gangliosides at birth. However, growth spurt in rat brain development (9) and the rapid phase of accumulation of gangliosides (10) occur during the postnatal period. As the brain is a heterogeneous organ, the present study was designed to follow the effects of pre- and postnatal exposure to alcohol on the cell number and protein content, and on gangliosides and their catabolizing enzymes in cerebrum, cerebellum, brain stem and spinal cord of pups at weaning.

MATERIALS AND METHODS

Experimental design and animals. Virgin female rats of the Charles Foster strain weighing 180–200 g were divided into two groups. A control group (CT) was given a 20% casein diet and drinking water *ad libitum,* and a second group of rats (AL) was given 20% casein diet and 15% alcohol (ethanol) in drinking water *ad libitum.* The rats were fed a semi-synthetic diet containing 20% sucrose, 20% casein, 7% ground nut oil (peanut oil), 0.3% DL-methionine, 0.2% choline bitartrate, 48% sago, 3.5% mineral mixture, and vitamin mixture (11). Both groups of rats were maintained on the respective regimen for four weeks prior to breeding and during gestation and lactation. After birth, pups were culled randomly and nursed in litters of eight. Pups were sacrificed by decapitation, at 21 days postnatal age, after the body weights had been recorded. Intact whole brains and spinal cords were quickly dissected and the weights were recorded. Whole brains were separated into cerebrum, cerebellum and brain stem on ice-cold glass plates. Tissue samples for DNA, protein and enzyme assays were processed immediately; the samples for ganglioside analysis were stored until use in a chloroform/methanol (1:1, v/v) mixture at −20°C.

Estimation of maternal plasma alcohol levels. Tail blood samples from the mothers were collected in the morning after birth. Alcohol was assayed using alcohol dehydrogenase (12). Blood ethanol concentration was found to be 87.3 ± 10 mg/dL (mean ± SD).

Estimation of DNA and protein. DNA was extracted by the method of Schneider (13) and was estimated according to the method of Burton (14). Protein was estimated by the method of Lowry *et al.* (15) using bovine serum albumin as standard.

Analysis of gangliosides. Total gangliosides were isolated and purified by the method of Seyfried *et al.* (16), and ganglioside *N*-acetylneuraminic acid (NANA) was assayed by the method of Warren (17) as modified by

[1]Current address: CINN Research Laboratory, Columbus Hospital, 2520 N. Lake View Avenue, Chicago, IL 60614.

Skoza and Mohos (18). The details of these methods are described elsewhere (19). The ganglioside nomenclature used is that of Svennerholm (20). For the separation of individual gangliosides (GQ_1, GD_{1b}, GD_{1a}, GT_{1b} and GM), 20 × 20-cm glass plates coated with silica gel G were developed by one ascending run with chloroform/methanol/water containing 0.02% $CaCl_2 \times 2H_2O$ (58:38:9, v/v/v). Ganglioside bands marked after exposure to iodine vapors were scraped from the plates and NANA in the individual ganglioside fractions was estimated as described earlier. Since the concentration of monosialogangliosides such as GM_2 and GM_3 was extremely low, the bands corresponding to all monosialogangliosides were pooled and the fraction was designated GM. The bands were confirmed as gangliosides by using resorcinol-HCl reagent on a duplicate set, and the identity of individual ganglioside bands was confirmed by simultaneously running a commercially obtained reference bovine brain ganglioside mixture (Sigma, St. Louis, MO) (19).

Enzyme assays. A 10% (w/v) homogenate for enzyme assays was prepared by homogenizing the tissue with ice-cold, glass-distilled water for three minutes at 2000–3000 rpm using a Potter-Elvehjem homogenizer while cooling with ice. Activities of β-D-galactosidase (EC 3.2.1.23) and β-D-glucosidase (EC 3.2.1.21) were assayed according to the method of Gatt and Rapport (21). Total β-D-hexosaminidase (EC 3.2.1.30) activity was assayed according to the method of Frohwein and Gatt (22). Units for the abovementioned enzymes are defined as nmol of *p*-nitrophenol liberated per minute under the assay conditions used. Sialidase (EC 3.2.1.18) activity, using endogenous substrate alone, was assayed according to the method of Irwin *et al.* (23). The enzyme unit for sialidase is defined as nmol of NANA liberated per minute under assay conditions. Statistical comparison between group means was by Student's *t*-test (24). Differences between values were considered significant for $p < 0.01$.

RESULTS

In preliminary studies we found that providing a 15% (v/v) alcohol solution as the sole water source had no effect on the total calorie or water intake of rats (data not shown). However, higher concentrations of alcohol did cause a significant decrease in food and water intake. The data obtained for tissue weights, and DNA and protein levels in the CNS regions of 21-day-old pups exposed to alcohol *in utero* and during lactation are presented in Table 1. Pre- and postnatal exposure of rat pups to alcohol caused significant deficits in cerebrum, cerebellum, brain stem and spinal cord weights as compared to controls. The tissue weight loss was more severe in brain stem followed by cerebellum and cerebrum, in that order. The deficits in tissue weights were 11, 15, 29 and 16% in cerebrum, cerebellum, brain stem and spinal cord, respectively.

DNA content (mg DNA/total tissue) showed a significant decrease in all CNS tissues of the pups exposed to alcohol when compared to the control pups. DNA content in cerebrum, cerebellum, brain stem and spinal cord of the alcoholic pups was 84, 88, 83 and 66% of control values, respectively. These deficits in DNA contents were reflected in the reduced cell number. The reductions in cell numbers of pups exposed to alcohol were 16, 12, 17 and 34% of controls in cerebrum, cerebellum, brain stem and spinal cord, respectively. Similarly, protein content (mg/total tissue) showed a significant decrease in all CNS regions.

Administration of alcohol to rats during gestation and lactation caused an increase in total ganglioside NANA concentration (μg NANA/g tissue) in cerebrum, cerebellum, brain stem and spinal cord of the pups when compared to controls (Table 2). The increase in total ganglioside concentration was 35, 47, 61 and 27%, respectively, in cerebrum, cerebellum, brain stem and spinal cord, compared to control values. Despite reduced tissue weights, the content of total ganglioside NANA (μg NANA/total tissue) was significantly higher in cerebrum, cerebellum and brain stem of alcoholic pups when compared to controls.

Alcohol was also found to induce alterations in the proportions of individual ganglioside fractions, and the changes were found to be region-specific. In general, alcohol-induced alterations in the proportions of GQ_1, GT_{1b} and GD_{1a} were more pronounced. In cerebrum, the proportions of GT_{1b} and GM showed an increase, GQ_1 and GD_{1a} showed a decrease, and GD_{1b} was unaffected by exposure of pups to alcohol. On the other hand, in cerebellum, alcohol increased the proportions of GQ_1, GD_{1b} and GM and decreased the proportion of GT_{1b} without affecting the proportions of GD_{1a}. However, in brain stem the proportions of GQ_1 and GT_{1b} showed a significant increase and GM showed a decrease in pups exposed to alcohol. The proportions of GD_{1a} and GD_{1b}, which were unaltered in brain stem, showed an increase in the spinal cord of the alcoholic pups. However, the proportions of GQ_1 and GM showed a decrease in spinal cord due to alcohol.

Sialidase, β-glucosidase, β-galactosidase, pH 3.1 and β-hexosaminidase activities decreased in cerebrum, cerebellum, brain stem and spinal cord of the pups due to maternal alcohol consumption (Table 3). A similar decrease was observed in the β-galactosidase, pH 4.5 activity in cerebrum, cerebellum and brain stem following exposure to alcohol. However, alcohol was found to increase β-galactosidase, pH 4.5 activity in the spinal cord of alcoholic pups as compared to control pups. Sialidase, β-hexosaminidase, β-glucosidase, β-galactosidase, pH 3.1 and β-galactosidase, pH 4.5 activities, in cerebrum of alcohol exposed pups were only 65, 70, 69, 91, and 89% of control values. The corresponding values in cerebellum, brain stem and spinal cord were 78, 85, 75, 84 and 94%; 66, 61, 75, 78 and 77%; and 70, 88, 82, 93 and 77%, respectively.

DISCUSSION

In the present study rat pups were exposed to alcohol by feeding mothers with 15% alcohol one month before gestation, and during gestation and lactation. Alcohol consumed by the mother during gestation reaches the fetus as there is no placental barrier to alcohol (25); after birth, pups were exposed to alcohol through the mother's milk (26).

Alcohol-associated deficits in DNA content observed in the present study correlate well with the reported decrease in the incorporation of labeled thymidine into fetal tissues (27) and with impaired cellular multiplication observed *in vitro* due to alcohol (28). Alcohol also was found to decrease the levels of zinc and folate (29,30), which are required for DNA synthesis. Taken together the studies suggest that alcohol-associated cell loss may be due to

[c] Enzyme units/g tissue.

impairment in DNA synthesis. Postnatal alcohol exposure has been shown to induce neuronal cell loss in hippocampus and cerebellum (31) and to delay the maturation of oligodendrocytes (32). Deficits observed in CNS cell numbers of the alcoholic pups are in line with a 29% cell loss in the cerebellum reported by Burns *et al.* (33) following the administration of alcohol (4 g/Kg body weight) between 6-16 days postnatal. In the present study, the cell loss was found to be 16, 12, 17 and 34% in cerebrum, cerebellum, brainstem and spinal cord, respectively, when compared to the controls. Alcohol also was found to decrease the protein content. This loss in protein content could be attributed to alcohol related impairment in the uptake of amino acids across the placenta (34,35) and in protein synthesis (36).

In contrast, the concentration of total ganglioside NANA (μg NANA/g tissue) and content (μg NANA/total tissue) was higher in all brain regions following exposure to alcohol. This increase in ganglioside concentration is in agreement with the reported increase in adult mouse (37) and rat (38) brain ganglioside concentration following chronic alcohol administration. In this context it may also be relevant to note that chronic alcohol treatment increases the intracellular fluid volume (39,40) and that maternal alcohol consumption increases water and sodium content in the fetus (41) and increases brain cell size of the offspring (33).

Although alcohol tends to fluidize biological membranes, chronic exposure to alcohol increases order in membranes by increasing the concentration of cholesterol (42). It is believed that the increase in cholesterol content, following chronic exposure to alcohol, is to confer rigidity to the membranes to counteract the fluidizing effects of alcohol. An increase in gangliosides has been shown to reduce the integrity of lipid bilayers (43) and to increase the sensitivity of liposomes to alcohol (44). Alcohol also was found to increase the content of unsaturated fatty acids of phospholipids in the synaptosomal fraction (45). Such an increase in the unsaturated fatty acids would also increase membrane fluidity.

It is of interest to note that the alcohol induced alterations in the proportions of individual gangliosides that were observed in the present study are somewhat different than the alterations observed in the neonatal pups subjected to alcohol exposure *in utero* (19). In addition, the changes in the ganglioside proportions are region-specific. For example, trisialoganglioside GT_{1b} showed an increase in cerebrum and brain stem and a decrease in cerebellum following exposure to alcohol. On the other hand, disialoganglioside GD_{1a} showed a decrease in cerebrum and an increase in spinal cord due to alcohol. Polysialoganglioside GQ_1 showed a decrease in cerebrum and spinal cord and an increase in cerebellum and brain stem of pups exposed to alcohol. Monosialogangliosides (GM) showed an increase in cerebrum and a decrease in the myelin rich regions, such as brain stem and spinal cord, due to alcohol. This decrease in monosialoganglioside (GM) is consistent with the reported decrease in monosialoganglioside GM_1 in myelin of 24-day-old rat pups born of mothers fed 6.6% (v/v) ethanol diet prior to breeding and during gestation (46). In addition, postnatal alcohol exposure was found to delay the acquisition of myelin by rat optic nerve (47).

In conclusion, it would appear that the changes in gangliosides observed can have profound implications in various surface events, such as cell differentiation, cell-to-cell interaction, and synaptogenesis, as gangliosides are located on the outer layer of the plasma membrane with their negatively charged polysaccharide chains protruding towards the extracellular space.

ACKNOWLEDGMENTS

This research was supported by the University Grants Commission's (New Delhi, India) special assistance program to the Department of Biochemistry, M.S. University, Baroda, India. The author is thankful to Prof. K. K. Rao for his suggestions and to Mr. Ravindran Pillai for his help in preparing the manuscript.

Reaction of Dipyridamole with the Hydroxyl Radical

Luigi Iuliano[a,*], Domenico Praticò[a], Andrea Ghiselli[b], Maria S. Bonavita[a] and Francesco Violi[a]
[a]University of Rome "La Sapienza", First Clinical Medicine Institute and [b]National Institute of Nutrition, Rome, Italy

Dipyridamole [2,6-*bis*-diethanolamino-4,8-dipiperidinopyrimido-(5,4-d)pyrimidine], a well known platelet aggregation inhibitor, shows powerful hydroxyl radical scavenging activity by inhibiting OH•-dependent salicylate and deoxyribose degradation. Steady-state competition kinetics experiments with deoxyribose were carried out to evaluate the second-order rate constant for the reaction between hydroxyl radical and dipyridamole. OH• radicals were generated either by a Fenton-type reaction or by X-ray irradiation of water solutions. A second-order rate constant $k_{(Dipyridamole + OH\cdot)}$ of $1.72 \pm 0.11 \times 10^{10}$ M^{-1} s^{-1} and of $1.54 \pm 0.15 \times 10^{10}$ M^{-1} s^{-1} was measured by Fenton chemistry and by radiation chemistry, respectively. Mannitol was used as an internal standard for hydroxyl radicals in steady-state competition experiments with deoxyribose. A rate constant $k_{(Mannitol + OH\cdot)}$ of $1.58 \pm 0.13 \times 10^9$ M^{-1} s^{-1} and $1.88 \pm 0.14 \times 10^9$ M^{-1} s^{-1} was measured in the Fenton model and in the water radiolysis system, respectively. Both these rate constants are in good agreement with the published data obtained by the "deoxyribose assay" and by pulse radiolysis.
Lipids 27, 349–353 (1992).

There is a large amount of data which support the involvement of oxygen free radicals (OFR) in various human diseases and in aging (1). One of the most important OFR species is the highly reactive hydroxyl radical, which causes tissue injury through a variety of pathways including the initiation of lipid peroxidation, DNA damage and inactivation of proteins. The use of antioxidants to prevent the deleterious effects of OFR could be one approach in the therapy of several of these diseases. Consistent with this, a number of therapeutic agents may actually exert some of their beneficial effects by scavenging OFR (2–5).

Dipyridamole (Fig. 1) is a drug that is currently used in the treatment of cardiovascular diseases because of its vasodilating activity and its ability to inhibit platelet aggregation. Dipyridamole also has been shown to inhibit lipid peroxidation (6,7) and to scavenge OFR (7). A better understanding of the antioxidant activity of dipyridamole will be useful to elucidate its pharmacological action.

This study was designed to investigate the reaction of dipyridamole with the hydroxyl radical. Measurements involving this radical are complicated because of its high reactivity and its participation in a multitude of reactions. It is therefore useful to employ complementary techniques to examine the same reaction. To study the interaction between OH• and dipyridamole, two types of assays were used. In the first, hydroxyl radicals were generated in aqueous solution *via* an ascorbate-modified Fenton reaction where the metal catalyst was bound to EDTA to produce "free" OH• in solution (8). In the second system, OH• radicals were generated by radiation-induced decomposition of water. To further evaluate the results, control experiments were carried out in the presence of the well-characterized hydroxyl radical scavenger mannitol.

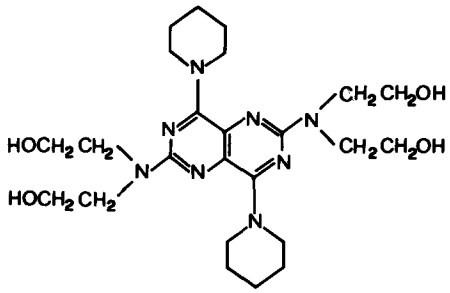

FIG. 1. Structure of dipyridamole.

MATERIALS AND METHODS

Dipyridamole was donated by Boehringer Ingelheim Italia (Reggello, Italy). Deoxyribose, salicylate, 2,3-dihydroxybenzoate, 2,5-dihydroxybenzoate and 3,4-dihydroxybenzoate were from Aldrich (Steinheim, Germany). High-performance liquid chromatography (HPLC)-grade solvents were all purchased from Carlo Erba (Rome, Italy). All other reagents were of the highest grade available from Merck (Darmstadt, Germany). Water of high purity (≥18 MOhms) was obtained by treating doubly distilled water in a Milli-Q (Millipore, Bedford, MA) purifying system.

OH• production by Fenton-like chemistry. Incubations for 1 hr at 37 °C were carried out in Falcon polypropylene sterile-tubes (Becton-Dickinson, Milan, Italy). The reaction mixtures contained, in a final volume of 1 mL, the reagents (added in the following order): KH_2PO_4/KOH buffer (20 mM),deoxyribose (2.8 mM), EDTA (104 μM), $FeCl_3$ (100 μM), H_2O_2 (1 mM), and ascorbate (100 μM). The pH was 7 for mannitol experiments and 5 for experiments with dipyridamole, because dipyridamole is insoluble above pH 5.5. Stock solutions of Fe^{3+}, H_2O_2 and ascorbate were made up in water immediately before use.

OH• production by water radiolysis. Irradiation was with X-rays in an atmosphere of air. The solutions contained 2.8 mM deoxyribose and 10 mM potassium phosphate as buffer in Falcon polystyrene-sterile tubes. The tubes were placed in the X-ray source (Stabilipan, Siemens, Erlangen, Germany) at 22 °C. The dose rate (11.3 Gy/min) was determined by Fricke dosimetry (9). Most irradiation treatments lasted 20 min. At the end of the irradiation period, reaction mixtures were treated as described above for the determination of malonaldehyde derived from the OH•attack on deoxyribose.

Measurement of OH•-dependent deoxyribose degradation. To the reaction mixture was added 1 mL of 2.8% trichloroacetic acid plus 1 mL of thiobarbituric acid (1% w/v in 50 mM NaOH) and the mixture was heated for 20

Abbreviations: EDTA, ethylenediaminetetraacetic acid; OFR, oxygen free radicals; TBA, thiobarbituric acid.

min at 100°C. The chromogen was measured at 532 nm on an HP 8542A diode array spectrophotometer (Hewlett-Packard, Palo Alto, CA).

Measurement of OH•-dependent salicylate oxidation. At the end of the irradiation time, 500 μL of each sample was placed on ice and 10 μL of 3,4-dihydroxybenzoic acid (internal standard) plus 25 μL of 1 M HCl were added, and the mixture was vortexed. The resulting solution was extracted with 5 mL of HPLC grade diethyl ether by mixing thoroughly for 1 min and then centrifuged for 5 min at 2,000 × *g*. The organic phase was collected, evaporated to dryness under nitrogen, and reconstituted with 2.0 mL of HPLC mobile phase. The samples were injected for HPLC analysis immediately after reconstitution.

Reverse phase HPLC separations were carried out on a 5 ODS Spherisorb 250 mm × 4.6 mm i.d. analytical column, using a Perkin Elmer series 410 LC pump equipped with a Perkin Elmer SEC-4 solvent environmental control (Perkin Elmer Co., Norwalk, CT). The mobile phase consisted of 90% (v/v) 30 mM sodium citrate, 27.7 mM acetate buffer (pH 4.75) and 10% (v/v) methanol, according to Grootveld and Halliwell (10). The mobile phase was filtered through a Millipore filter of 0.45 μm pore size and continuously purged with He gas during elution. The flow rate was 1 mL/min; the injection loop was 50 μL. The column eluate was monitored with an LC4B amperometric detector (Bioanalytical Systems, West Lafayette, IN) equipped with a Bioanalytical Systems detector cell. The detector potential was set at +0.76 V *vs.* an Ag/AgCl reference electrode. The output of the detector was registered on an Isco Chemresearch Data Management System (Lincoln, NE). The range was set at 10 nA. Concentrations were determined from calibrations with standard solutions of 2,3-dihydroxybenzoate and 2,5-dihydroxybenzoate, using 3,4-dihydroxybenzoate as internal standard. The retention times relative to salicylate (12 ± 0.4 min) were 0.45, 0.49 and 0.66 for 2,3-dihydroxybenzoate, 2,5-dihydroxybenzoate and 3,4-dihydroxybenzoate, respectively.

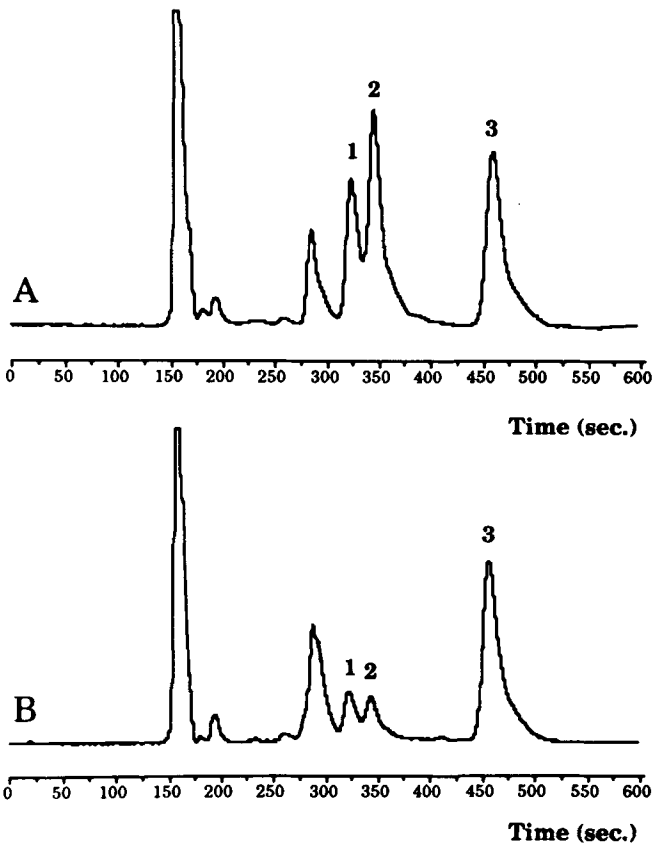

FIG. 2. Inhibition of OH•-dependent salicylate oxidation by dipyridamole. HPLC analysis of 10 μM salicylate after exposure to OH•, in the absence (A) or presence (B) of dipyridamole (100 μM). Peak identification: 1, 2,3-dihydroxybenzoate; 2, 2,5-dihydroxybenzoate; and 3, 3,4-dihydroxybenzoate (internal standard).

RESULTS

The reaction of dipyridamole with OH• was monitored by following the inhibition of OH•-dependent salicylate oxidation in the water radiolysis system. OH• attacks the salicylate molecule and gives addition products measured by reverse phase HPLC:

$$OH\bullet + \text{salicylate} \rightarrow \text{dihydroxybenzoates} \quad [1]$$

Figure 2, upper panel, shows the chromatographic profile of 10 μM salicylate after exposure to OH•, the 2,3- and 2,5-dihydroxybenzoates generated were identified as peaks 1 and 2, respectively. The lower panel of Figure 1 shows the same experiment carried out in the presence of dipyridamole, which lowers the amounts of 2,3- and 3,5-dihydroxybenzoates formed according to reaction [2].

$$OH\bullet + \text{dipyridamole} \rightarrow \text{products} \quad [2]$$

Neither dipyridamole nor its oxidation product could be detected with the HPLC column/solvent combination, and the exact nature of the reaction product is still unknown. However, product formation was indicated through observed changes in the optical spectrum of dipyridamole (Figs. 3 and 4); the characteristic absorption maximum at 404 nm disappeared gradually upon exposure to OH•. The existence of an isosbestic point suggested that a single product was formed during the reaction. Addition of the hydroxyl radical scavenger sodium formiate slowed down the dipyridamole degradation considerably, consistent with the involvement of OH• in the process (Fig. 4). In a series of parallel experiments it was found that dipyridamole also inhibited salicylate oxidation in the Fenton system (not shown).

The magnitude of the OH• scavenging activity of dipyridamole was investigated by steady-state competition kinetics experiments in order to measure the rate constant of reaction [2]. Deoxyribose was used in competition kinetic experiments as reference substance:

$$OH\bullet + \text{deoxyribose} \rightarrow \text{malondialdehyde} \quad [3]$$

The use of deoxyribose as detector in competition experiments was proposed by Halliwell *et al.* (8) and has proved a reliable alternative to pulse radiolysis. The amount of malonaldehyde generated (11) in reaction [3] was measured by the thiobarbituric acid (TBA) test.

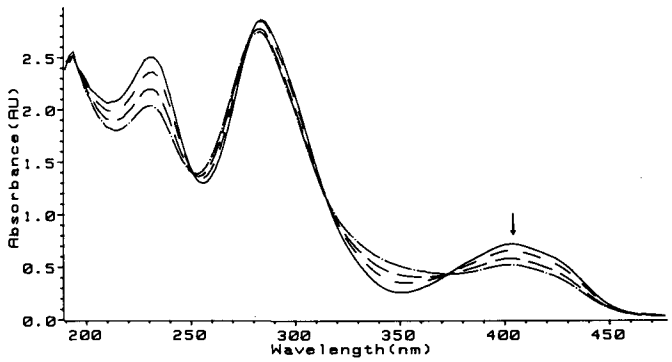

FIG. 3. Changes of the dipyridamole spectrum upon increasing exposition to OH•. Dipyridamole (100 μM) was irradiated at a rate of 11.3 Gy/min in 10 mM phosphate, pH 5, 22°C, in air atmosphere.

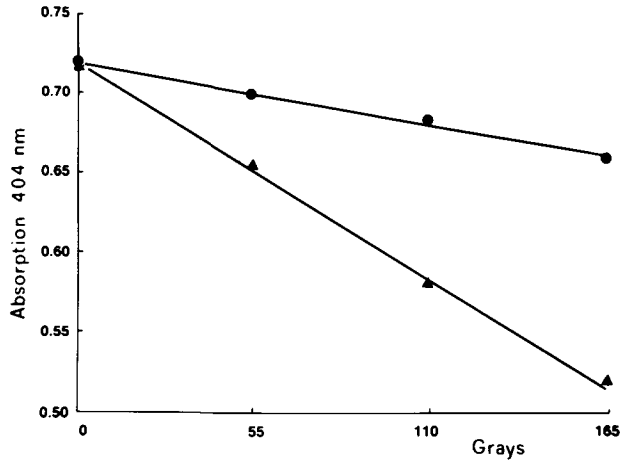

FIG. 4. Time course of absorbance loss (404 nm), in the absence (triangles) or presence (circles) of 100 mM sodium formiate, as hydroxyl radical scavenger. Experimental conditions as in Figure 3.

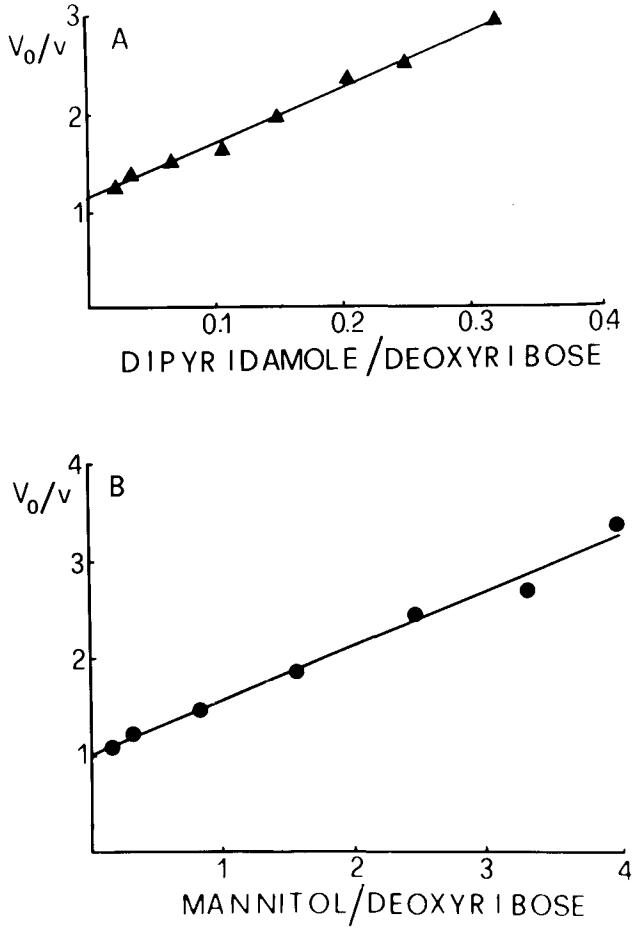

FIG. 5. Competition plots of dipyridamole (plot A) or mannitol (plot B), and deoxyribose with a Fenton-type reaction as OH• source. Concentration of deoxyribose was 2.8 mM, pH 5 for dipyridamole, pH 7 for mannitol. See Materials and Methods for details. Each point represents the mean of three separate experiments carried out in triplicate, error bars are not shown as they do not exceed the size of the symbols.

The rate of the absorption change (V_0) of deoxyribose, in the absence of competitor molecules, was taken as a measure of the rate of reaction, which is given by:

$$V_0 = k_3[\text{deoxyribose}][OH\bullet]$$

In the presence of different concentrations of the competitor dipyridamole, the rate of reaction (v) is:

$$v = V_0 \frac{k_3\,[\text{deoxyribose}]}{k_3\,[\text{deoxyribose}] + k_2\,[\text{dipyridamole}]}$$

A minor transformation yields a linear equation:

$$\frac{V_o}{v} = 1 + \frac{k_2}{k_3}\,\frac{[\text{dipyridamole}]}{[\text{deoxyribose}]}$$

Plotting V_0/v against [dipyridamole]/[deoxyribose] gives a straight line intersecting the ordinate at unity. The rate constant for the reaction of dipyridamole with OH• can be obtained from the slope assuming a k_3 of 3.1×10^9 M^{-1} s^{-1} (8). Figure 5 shows competition experiments with deoxyribose carried out in the Fenton chemistry system. Plot A refers to dipyridamole; from the slope a $k_{(\text{Dipyridamole} + OH\cdot)}$ of 1.72×10^{10} M^{-1} s^{-1} was calculated (mean value). Figure 6 summarizes the data of analogous experiments which were carried out with irradiation generated OH•. Also in this case, the data from experiments carried out in the presence of dipyridamole (plot A) give a straight line, from which a rate constant of 1.54×10^{10} M^{-1} s^{-1} was calculated (mean value).

Competition experiments were also carried out with mannitol as internal standard since the bimolecular rate constant for the reaction of mannitol with OH• is known from pulse radiolysis measurements. We obtained a $k_{(\text{Mannitol} + OH\cdot)}$ of 1.58×10^9 M^{-1} s^{-1} (Fig. 5B) and 1.88×10^9 M^{-1} s^{-1} (Fig. 6B); these values (Table 1) are very similar to the published rate constants obtained by the "deoxyribose assay" and by pulse radiolysis (8,12).

DISCUSSION

It has been reported that dipyridamole scavenges OH• in experiments using deoxyribose as detector molecule for

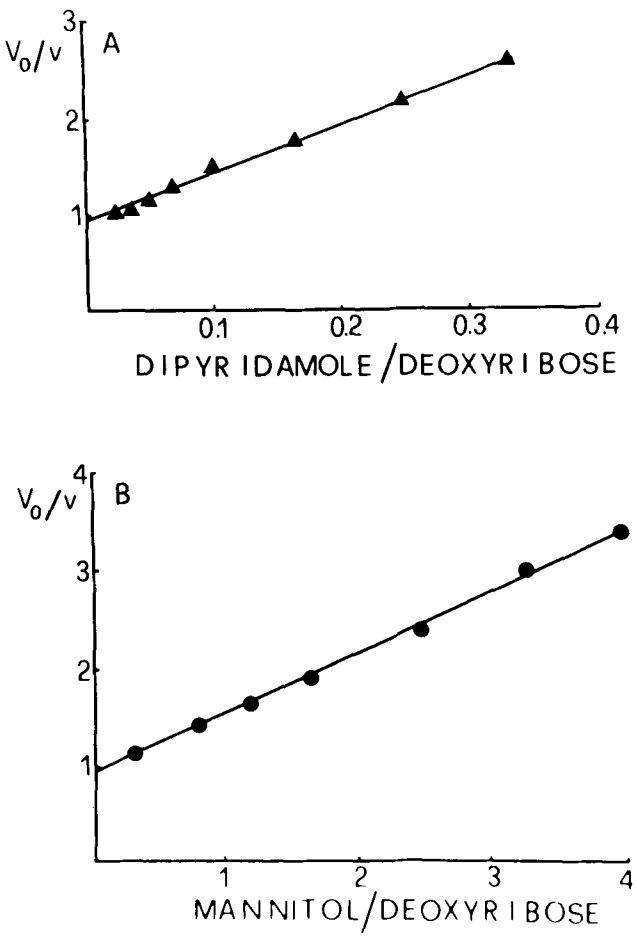

FIG. 6. Competition plots of dipyridamole (plot A) or mannitol (plot B), and deoxyribose with X-rays as radical source of OH•. Concentration of deoxyribose was 2.8 mM. X-radiolysis: 11.3 Gy/min, at 22°C in air atmosphere; pH 5 for dipyridamole, pH 7 for mannitol. Each point represents the mean of three separate experiments carried out in triplicate.

TABLE 1

Second Order Rate Constants for the Reaction of OH• with Dipyridamole and Mannitol

	Rate constant
Dipyridamole[a]	$1.39\text{-}1.93 \times 10^{10}$
Mannitol[a]	$1.45\text{-}2.02 \times 10^{9}$
Mannitol[b]	$1.0\text{-}2.0 \times 10^{9}$
Mannitol[c]	$1.0\text{-}1.8 \times 10^{9}$

hydroxyl radicals (7). Here we report further evidence on the OH•-scavenging activity of dipyridamole. The drug is able to prevent the hydroxylation reaction of salicylate. The formation of both 2,3-dihydroxybenzoate and 2,5-dihydroxybenzoate, monitored by HPLC, dependent on hydroxyl radicals generated during water radiolysis, is inhibited by dipyridamole. The reaction of dipyridamole with the hydroxyl radical also is shown by the spectral changes, the more evident of which is the gradual disappearance of the absorption maximum at 404 nm. The rate of reaction of dipyridamole with the hydroxyl radical is considerable ($>10^{10}$ M^{-1} s^{-1}), as determined by the "deoxyribose assay" (8), and is of possible biological interest. Competition kinetics with deoxyribose were carried out both in a Fenton system and with X-radiolysis in order to ensure the validity of the "deoxyribose assay" under our experimental conditions. Second-order rate constants for the reaction of dipyridamole with OH• of 1.72×10^{10} M^{-1} s^{-1} and of 1.54×10^{10} M^{-1} s^{-1} were measured by Fenton chemistry and by radiation chemistry, respectively. Considering the very different nature of the two models, the agreement between the calculated constants is excellent.

Additional support was given by the use of a second internal standard, mannitol, of which the measured rate constants in both the Fenton and radiation chemistry system corresponded to those reported in the literature. The high rate constant (Table 1) for the reaction of dipyridamole with OH• might be attributed to the presence of numerous hydrogen atoms which are abstractable by OH•. In this connection it is interesting that dipyridamole can be considered a carrier of four alcohol groups and so has a resemblance with other OH•-containing scavengers such as mannitol and deoxyribose. An alternative explanation is the occurrence of an addition reaction occurring at the bi-pyrimidine ring with subsequent rupture or saturation. The addition reaction is consistent with the loss of the 404 nm band upon irradiation, however, further studies are needed to elucidate the exact mechanism of the reaction.

The mechanisms of dipyridamole are not yet fully understood even though the drug is already in use in clinical practice as an antiplatelet drug (13). The antioxidant activity of dipyridamole and the powerful scavenging of OH• could be linked to its antithrombotic and vasodilating activity since OFR have been reported to have a role in coronary heart disease (14,15), in platelet activation (16,17) and in the regulation of vascular tone (18,19). The antioxidant activity of dipyridamole could be further utilized therapeutically in other cases where an OFR-mediated mechanism of pathology is involved. Another use could be as *in vivo* OH• probe for conditions such as reperfusion injury where the involvement of OFR has been recognized by measuring OFR by the electron spin resonance spin-trapping technique (14,15).

ACKNOWLEDGMENTS

We would like to thank J.Z. Pedersen for useful criticism and suggestion and C. Piccheri for technical assistance. This work was supported by a grant from the Andrea Cesalpino Foundation.

Fluorospectroscopic Analysis of the Fluorescent Substances in Peroxidized Microsomes of Rat Liver

Yoshiyuki Minamide, Toshiharu Horie* and **Shoji Awazu**
Department of Biopharmaceutics, Tokyo College of Pharmacy 1432-1, Horinouchi, Hachioji, Tokyo 192-03, Japan

The fluorescent substances formed in rat liver microsomes in the course of lipid peroxidation were investigated by fluorescence techniques. The fluorescence emitted from peroxidizing microsomes continuously increased as lipid peroxidation progressed, while the steady-state fluorescence anisotropy increased and then reached a plateau. A similar increase was observed in the steady-state fluorescence anisotropy of 1,6-diphenyl-1,3,5-hexatriene in peroxidizing microsomes. The fluorescence from peroxidized microsomes consisted of at least three species having short, middle or long fluorescence lifetimes. The lifetimes and relative amplitudes of fluorescence were unaffected by the extent of lipid peroxidation. Both fluorescence of the chromolipids extracted and the proteins isolated from peroxidized microsomes had the same characteristics in fluorescence lifetimes as the fluorescence from whole peroxidized microsomes. Thus, these lipids and proteins appear to be the major biological substances responsible for the fluorescence emanating from whole peroxidized microsomes. Furthermore, fluorescent substances formed in microsomes seem to increase in quantity rather than change in quality as lipid peroxidation progresses. *Lipids 27,* **354–359 (1992).**

Lipid peroxidation has gained considerable attention due to its serious effects on biological systems. Lipid peroxidation produces various products. Fluorescent substances are one type of characteristic products formed upon lipid peroxidation and they can be observed in artificial phospholipid membranes (1) as well as in biological membranes, such as liver microsomes (2), hepatocytes (3) and red blood cells (4). Tappel (5) and Fletcher *et al.* (6) suggested that lipofuscin, an age pigment, accumulates in tissues in the course of lipid peroxidation in biological membranes. The fluorescence of lipofuscin has been ascribed to reaction products of malondialdehyde (MDA) with amino compounds (5,6). However, some other reactions also have been proposed to form fluorescent substances (7,8). Thiobarbituric acid-reactive substances (TBARS) produced in the membranes during lipid peroxidation, which are commonly used for measuring lipid peroxidation, are mostly released into the medium, with little remaining in the membranes (9–11). However, the fluorescent substances are retained in the membranes and little of it is released into the aqueous phase. The fluorescence emitted from peroxidizing membranes continuously increases as lipid peroxidation progresses, whereas the generation of TBARS ceases at an early stage of lipid peroxidation (11). Therefore, fluorescent substances can be quite useful for evaluating *in vitro* and *in vivo* lipid peroxidation.

Fluorescent substances are commonly characterized by their fluorescence patterns. Shimasaki *et al.* (12) demonstrated that the fluorescence patterns of fluorescent products formed in rat liver phosphatidylcholine liposomes containing glycine during lipid peroxidation were similar to those of conjugated Schiff bases (13) and of the age-related fluorescent substances (14). Fluorescence polarization and lifetime measurements on fluorescent substances were made by Malshet *et al.* (15), and such measurements were found useful for characterizing these substances.

Malshet *et al.* (15) did their measurements on the chloroform/methanol-extractable fluorescent substances. However, the fluorescent substances formed in peroxidizing microsomes not only consist of fluorescent chromolipids but also of fluorescent proteins (11,16). We have previously detected the fluorescence emitted from peroxidized microsomes (11) by a technique which simultaneously gives information on both fluorescent chromolipids and proteins in peroxidized membranes. Most recently, we also have succeeded in determining the lifetimes of fluorescence emitted from peroxidized microsomes without prior extraction (17).

The present study was undertaken to further clarify the properties of fluorescent substances and to analyze the formation of fluorescent substances in peroxidizing microsomes by fluorescence polarization and lifetime measurements.

MATERIALS AND METHODS

Materials. L-Ascorbic acid, $FeSO_4 \cdot 7H_2O$, ethylenediaminetetraacetic acid (EDTA) sodium salt, dithiothreitol and glycerol were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). 1,6-Diphenyl-1,3,5-hexatriene (DPH) and Sephacryl S-400 (superfine) were obtained from Sigma Chemical Co. (St. Louis, MO) and Pharmacia Fine Chemicals (Uppsala, Sweden), respectively. All other reagents were of analytical grade.

Microsomes. Rat liver microsomes were isolated from 170- to 250-g male Wistar rats treated with phenobarbital as previously described (11). The microsomes obtained were suspended in 0.1 M sodium phosphate buffer, pH 7.4. The protein concentration of microsomes was determined by the method of Lowry *et al.* (18) using bovine serum albumin as the standard.

Lipid peroxidation. The microsomes (2 mg protein/mL) were incubated with 0.2 mM ascorbic acid and 10 μM $FeSO_4$ at 37°C. Peroxidation was terminated by adding 1 mM EDTA to the reaction mixture at designated times. The extent to which lipid peroxidation proceeded was determined by the formation of TBARS according to the method of Buege and Aust (19) and expressed as nmoles of MDA equivalents/mg protein. Two milliliters of thiobarbituric acid stock reagent was added to 1.0 mL of the microsome suspension (0.5 mg protein/mL), and boiled for 15 min. The mixture was then cooled and centrifuged at 1,000 × *g* for 10 min, and the precipitate was removed. The absorbance of the samples was determined at 535 nm with a standard curve using tetraethoxypropane.

*To whom correspondence should be addressed.

Abbreviations: DPH, 1,6-diphenyl-1,3,5-hexatriene; EDTA, ethylenediaminetetraacetic acid; MDA, malondialdehyde; TBARS, thiobarbituric acid-reactive substances.

Extraction of membrane lipids from peroxidized microsomes. Membrane lipids were extracted from the microsomes according to the procedures of Koster and Slee (2). The samples were extracted with chloroform/methanol (1:2, v/v). After centrifugation, chloroform/water (1:1, v/v) was added to the supernatant. The chloroform layer was separated and evaporated under vacuum. Then liposomes were prepared from the extracted lipids according to Bangham *et al.* (20) using a slightly modified method.

Separation of microsomal membrane proteins. Microsomal proteins were separated as previously described (16). The microsomes exposed to the peroxidation reaction *in vitro* for 0, 1 and 5 hr were solubilized according to Imai *et al.* (21). Glycerol (20%), 2% cholic acid and 1 mM dithiothreitol were added to the peroxidized microsomes to solubilize the membranes. The reaction mixture was stirred for 1 hr under cooling with ice and then centrifuged for 1 hr at 105,000 × *g*. Ten mL of the supernatant was applied to a Sephacryl S-400 (superfine) column (Excel column SD 1000) that had been equilibrated with 0.1 M sodium phosphate buffer, pH 7.4, containing 20% glycerol, 1 mM EDTA, 1 mM dithiothreitol and 0.5% cholic acid. The rate of elution with the same buffer was 20 mL/hr. Each five mL of the effluent was fractionated. The proteins in the effluent were determined by their absorbance at 280 nm, using a Pharmacia Single Path Monitor UV-1 and by the fluorescence at the excitation wavelength, 355 nm, and emission wavelength, 430 nm, using a Hitachi fluorescence spectrophotometer 650-60 (Tokyo, Japan).

Fluorescence measurements. Control and peroxidized microsomes (0.2 mg protein/mL) in 0.1 M sodium phosphate buffer, pH 7.4, containing 50% glycerol and 1 mM EDTA were measured for fluorescence at 37°C, using the Hitachi fluorescence spectrophotometer 650-60. A cut-off filter (390 nm) was placed on the emission side for each measurement.

Labeling of microsomes with DPH. The microsomes were labeled with DPH as previously described (22). One-half mL of the microsomes (2 mg protein/mL) was incubated for 20 min at 37°C with 4.5 mL of 10 μM DPH in 0.1 M sodium phosphate buffer containing 1 mM EDTA.

Fluorescence anisotropy measurements. Microsomes exposed to the peroxidation reaction *in vitro* for designated reaction times (0–14 hr) were used to measure fluorescence anisotropy. Fluorescent substances and DPH were used as intrinsic and extrinsic fluorophores, respectively. The steady-state fluorescence anisotropy for microsomes in 0.1 M sodium phosphate buffer, pH 7.4, containing 50% glycerol and 1 mM EDTA, was measured at 37°C with the Hitachi fluorescence spectrophotometer 650-60. The samples (0.2 mg protein/mL) were excited by vertically polarized light at 355 nm for fluorescent substances and at 360 nm for DPH. The vertically and horizontally polarized components of fluorescence, which were designated as I_V and I_H, respectively, were measured at 430 nm and 450 nm through the cut-off filter (390 nm) for fluorescent substances and DPH, respectively. Polarizers were used to select the appropriate polarized components for the excitation and emission. The steady-state anisotropy, r^s, was obtained by:

$$r^s = \frac{I_V - GI_H}{I_V + 2GI_H} \quad [1]$$

where G is the ratio of the sensitivity of the detection system for vertically and horizontally polarized light, and is equal to the ratio I_V/I_H obtained by exciting with horizontally polarized light.

Effects of temperature on fluorescence anisotropy. Microsomes were exposed to lipid peroxidation for 0, 1, 5 and 14 hr. The steady-state fluorescence anisotropy of DPH in peroxidizing microsomes was measured by changing the temperature between 5 and 45°C.

Fluorescence lifetime measurements. Fluorescence lifetimes were measured at room temperature using a Horiba fluorescence lifetime instrument (NAES-550) (Kyoto, Japan) which measured lifetime by time-correlated photon counting using a hydrogen flash lamp (17). The samples were excited at 355 nm using a filter of $CuSO_4$ solution (250 g/L) on the excitation side, and the emission light was selected using a cut-off filter (420 nm). These measurements were carried out for the following three samples: i) peroxidized microsomes in 0.1 M sodium phosphate buffer, pH 7.4, containing 50% glycerol and 1 mM EDTA; ii) liposomes made from the extracted lipids in the same buffer as above; and iii) fluorescent protein fractions in 0.1 M sodium phosphate buffer, pH 7.4, containing 20% glycerol, 1 mM EDTA, 1 mM dithiothreitol and 0.5% cholic acid. The fluorescence decay curve can be described by the exponential expression:

$$F(t) = \Sigma A_i \exp(-t/\tau_i) \quad [2]$$

where F(t) is the fluorescence at time t, A_i is a relative amplitude of component i which represents the fractional contribution to the fluorescence decay curve and τ_i is the fluorescence lifetime of component i.

Time-resolved decay of the fluorescence anisotropy. The time-resolved decays of anisotropy for the fluorescence emitted from the peroxidized microsomes were measured at room temperature using the fluorescence lifetime instrument. The samples were excited at 355 nm and the emission light was selected using a cut-off filter (420 nm). Polarizers were used to select the appropriate polarized components for excitation and emission. The time-resolved decays of vertically polarized [$I_V(t)$] and horizontally polarized [$I_H(t)$] components of the emission were measured when excited by vertically polarized light. The time-resolved anisotropy [r(t)] is calculated by:

$$r(t) = \frac{I_V(t) - GI_H(t)}{I_V(t) + 2GI_H(t)} \quad [3]$$

Assuming that the rotations of the molecules are symmetric (isotropic) and unhindered, the rotational correlatoin time of the fluorophore, ϕ, is obtained by:

$$r(t) = r_o \exp(-t/\phi) \quad [4]$$

where r_o is the anisotropy which would be observed in the absence of rotational diffusion.

Ultraviolet light irradiation. The samples in the cuvettes for the fluorescence measurements were irradiated with ultraviolet light, using a sterilizing lamp (Toshiba GL 10; wavelength, 253.7 nm; output, 1.8 W) prior to all fluorescence measurements, as previously described (11). The samples in the cuvettes were irradiated at a close distance so that the cuvettes and the lamp nearly touched. All

fluorescence measurements were carried out on 0.2 mg protein/mL of microsomes.

RESULTS

Steady-state fluorescence anisotropy. The fluorescence emitted from microsomes undergoing lipid peroxidation continuously increased over the entire period of the peroxidation reaction (Fig. 1A). The EDTA used to terminate the peroxidation reaction did not affect the fluorescence (data not shown). The generation of TBARS would have been completed well before the end of this long-term experiment (9,11). The steady-state fluorescence anisotropy of the fluorescent substances in the peroxidized microsomes increased with lipid peroxidation and then reached a plateau (Fig. 1B). The fluorescence anisotropy of DPH increased in the same manner as that of the fluorescent substances as lipid peroxidation progressed, as has been shown previously (22).

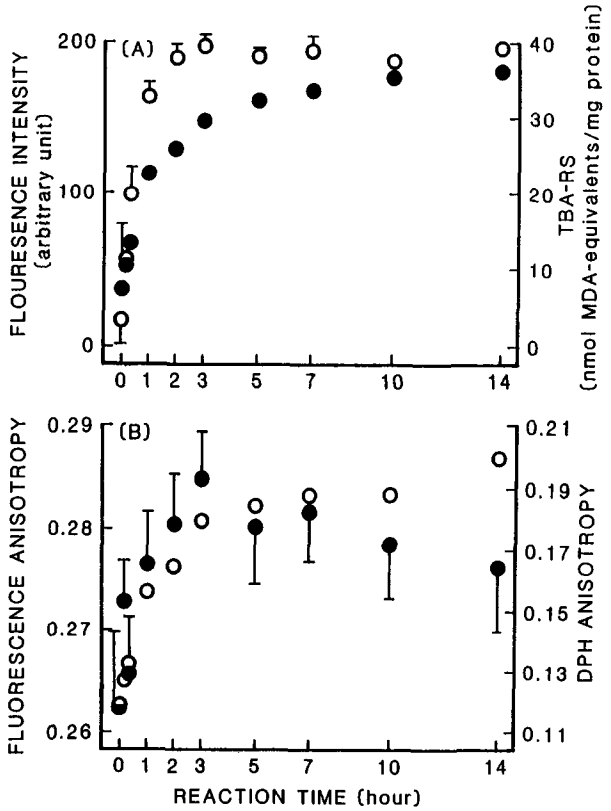

FIG. 1. Time course of chemical and physical changes occurring in microsomes during lipid peroxidation. Lipid peroxidation was induced at 37°C by the addition of 0.2 mM ascorbic acid and 10 μM $FeSO_4$ to the microsome suspension (2 mg protein/mL) and terminated by adding 1 mM EDTA to the reaction mixture at designated times. The following was plotted against lipid peroxidation reaction time: A, formation of fluorescent substances (●) and TBARS (○). B, steady-state fluorescence anisotropy of the fluorescence emitted from microsomes (●) and from DPH in microsomes (○). The data points of TBARS represent the mean values ± SEM of three determinations expressed as MDA-equivalents per mg protein of microsomes. The data points of fluorescence anisotropy represent the mean values ± SEM of six determinations. Where absent, SEM was smaller than the symbols.

Effect of temperature on DPH fluorescence anisotropy. The effect of temperature on the steady-state fluorescence anisotropy of DPH in peroxidized microsomes was examined by changing the temperature between 5 and 45°C (Fig. 2). Eichenberger *et al.* (23) reported a continuous decrease in the DPH anisotropy between 5–37°C for both control and peroxidized rat liver microsomes, suggesting that both types of microsomes were in the liquid-crystalline state over the entire temperature range. In the present study, the control microsomes showed a continuous decrease between 5–45°C. However, the microsomes exposed to lipid peroxidation did not show such a linear decrease. The microsomes exposed to lipid peroxidation for a longer period of time (5 and 14 hr) especially showed a biphasic anisotropy decrease, that is, two lines with different slopes below and above 25–30°C.

Fluorescence lifetime. Fluorescence lifetimes of the fluorescent substances formed in peroxidized microsomes were measured for further characterization. A time-resolved decay of the fluorescence emitted from the microsomes undergoing lipid peroxidation for 5 hr is shown in Figure 3. The data were automatically analyzed according to equation [2] using the built-in program of the fluorescence lifetime instrument. The data of fluorescence decay were fitted best to the fluorescence decay of a three-exponential equation, which was estimated by Chi square (χ^2). The fluorescence lifetimes (τ_i) and relative amplitudes (A_i) of three components are given in Table 1. All decays of the fluorescence from the microsomes undergoing lipid peroxidation for other reaction times also were fitted best to a three-exponential equation. The value of each parameter was plotted against peroxidation reaction time (Fig. 4). The results indicated that at least three species of fluorophore with different fluorescence lifetimes were present. Furthermore, fluorescence lifetime and relative amplitude of each component remained unchanged during the lipid peroxidation process.

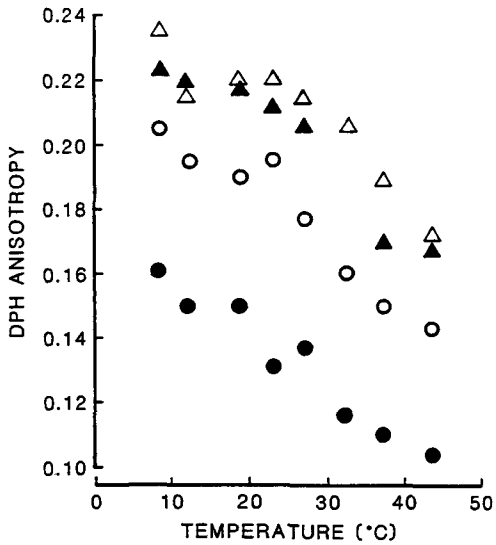

FIG. 2. Temperature dependence of steady-state fluorescence anisotropy of DPH in microsomes. Lipid peroxidation was induced under the conditions given for Figure 1. The microsomes were exposed to lipid peroxidation for 0 hr (●), 1 hr (○), 5 hr (▲)) and 14 hr (△).

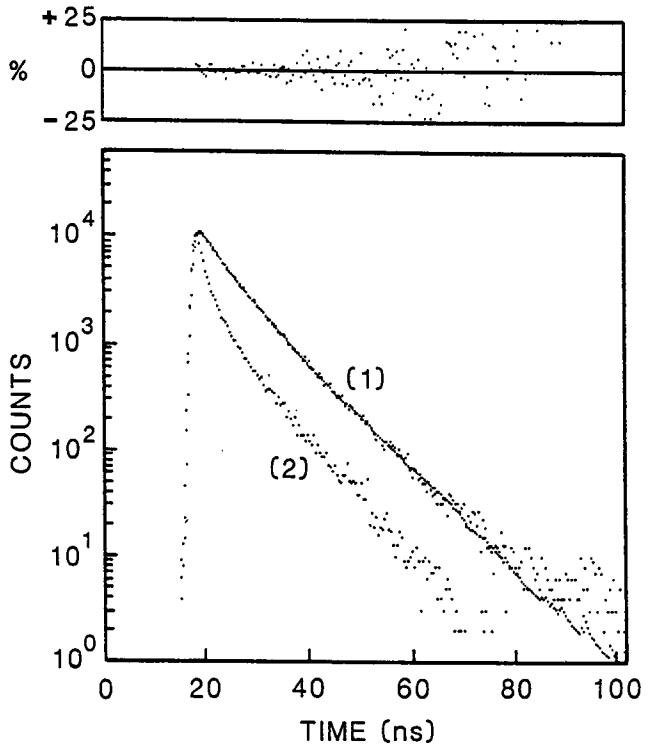

FIG. 3. Fluorescence decay of the fluorescence emitted from peroxidized microsomes. Measurement and analysis of the time-resolved decay of microsomes exposed to lipid peroxidation for 5 hr under conditions given for Figure 1 were carried out as described in Materials and Methods. The decay was fitted best by three components of fluorescence lifetimes. 1, Fluorescence decay (dots: observed values), fitted curve (——); and 2, lamp profile. The residuals of the experimental decay from the fitted curve are shown in the upper trace (%). Chi square (χ^2) in the decay curve was 1.59.

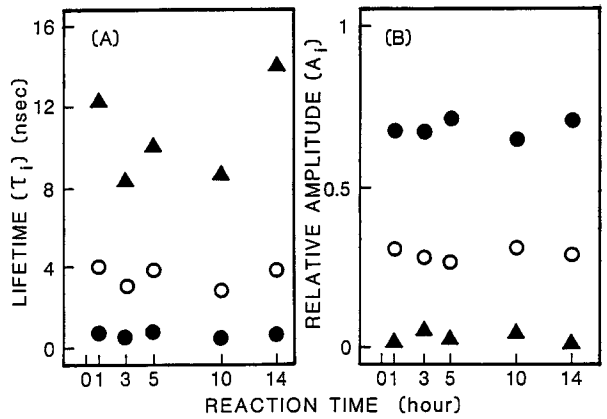

FIG. 4. Fluorescence lifetimes and relative amplitudes of the fluorescence from peroxidized microsomes. Measurement and analysis of the time-resolved decays of the fluorescence from microsomes exposed to lipid peroxidation for various reaction times under the conditions given for Figure 1 were carried out as described in Materials and Methods. All decays gave three components of fluorescence lifetimes. Fluorescence lifetimes and relative amplitudes were plotted against lipid peroxidation reaction time in panels A and B, respectively. Component of fluorescence lifetime: Short fluorescence lifetime (●); middle fluorescence lifetime (○); long fluorescence lifetime (▲).

TABLE 1

Fluorescence Lifetimes and Relative Amplitudes of Peroxidized Microsomes, Lipids and Proteins[a]

Component i	1		2		3	
	τ_1	(A_1)	τ_2	(A_2)	τ_3	(A_3)
Microsomes	0.8	(0.71)	3.9	(0.26)	10.1	(0.03)
Fluorescent chromolipids	0.9	(0.77)	3.7	(0.20)	11.5	(0.03)
Fluorescent proteins	1.0	(0.64)	4.2	(0.32)	12.5	(0.04)

[a]The microsomes underwent lipid peroxidation for 5 hr. The fluorescent chromolipids were extracted from the treated microsomes, and the fluorescent proteins were solubilized and isolated from these microsomes. τ_i, Fluorescent lifetimes; A_i, relative amplitudes.

Fluorescence lifetime of fluorescent lipids. One type of components of fluorescent substances formed in peroxidized microsomes is known to be chromolipids which are extractable with organic solvents (2-4,11). In order to characterize the fluorescent chromolipids by measuring fluorescence lifetimes, liposomes were made from the extracts of microsomes exposed to lipid peroxidation for 5 hr. Fluorescence decays of the extracted chromolipids were analyzed according to equation [2] and were found to fit best with a three-exponential equation. The fluorescence lifetime and relative amplitude for each component are given in Table 1. The extracted chromolipids from the microsomes exposed to lipid peroxidation for 1 and 10 hr gave similar results in regard to fluorescence lifetime and relative amplitude of each of the components.

Fluorescence lifetime of the fluorescent proteins. The microsomal proteins are another important type of component which can contribute to the fluorescence emitted from peroxidized microsomes (16). The microsomes undergoing lipid peroxidation were solubilized with cholic acid and fractionated by the Sephacryl S-400 gel column chromatography. The elution pattern of proteins solubilized from the microsomes after peroxidation for 5 hr is shown in Figure 5. The F-fraction containing the fluorescent proteins was used for the fluorescence lifetime measurements; the fluorescence of this F-fraction increased as lipid peroxidation progressed (16). The fluorescence decays of the fluorescent proteins (F-fraction) were analyzed according to equation [2] and fitted best with a three-exponential equation. The parameters obtained by this analysis are given in Table 1. Similar values were obtained for the microsomes exposed to lipid peroxidation for 1 hr. Thus, the values were quite independent of lipid peroxidation time.

Time-resolved decay of the fluorescence anisotropy. Finally, the time-resolved decays of anisotropy for the fluorescence from peroxidized microsomes were examined (Fig. 6). The decays are defined as given in equation [3]. The fluorescence decays of anisotropy were analyzed only for the short component of the fluorescence lifetime, using equation [4]. The calculated rotational correlation times of the fluorophore in microsomes exposed to lipid peroxidation for 1, 5 and 10 hr were 45, 71 and 93 ns, respectively.

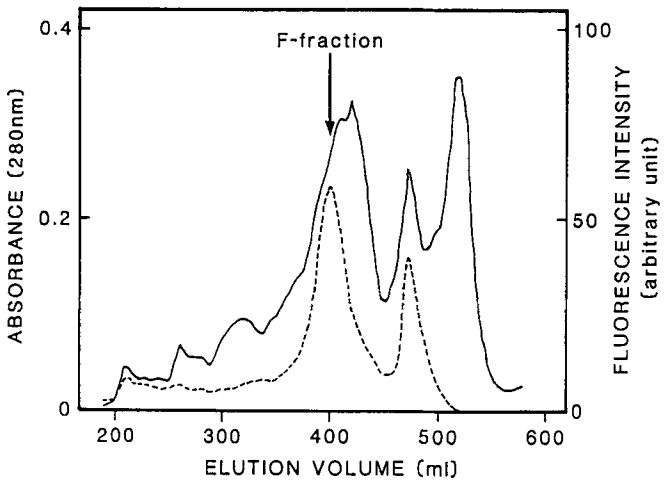

FIG. 5. Fractionation of fluorescent proteins of peroxidized microsomes. The proteins solubilized from microsomes exposed to lipid peroxidation for 5 hr were fractionated on a Sephacryl S-400 gel column. Each fraction of the effluent (5 mL) was determined by the absorbance at 280 nm (——) and the fluorescence (excitation wavelength, 345 nm; emission wavelength, 430 nm) (- - -). The fraction containing fluorescent proteins indicated by an arrow was designated F-fraction.

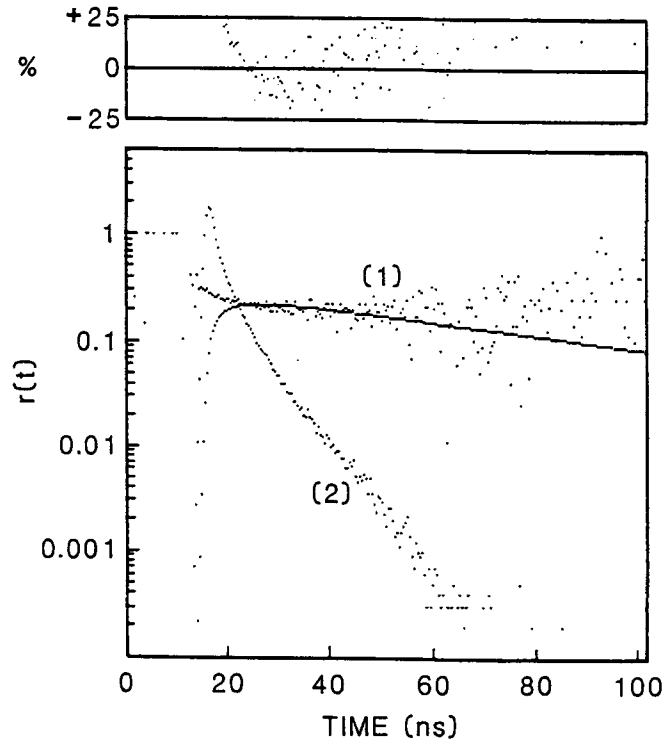

FIG. 6. Time-resolved fluorescence anisotropy decay of the fluorescence from peroxidized microsomes. Measurement and analysis of the time-resolved fluorescence anisotropy of the fluorescence emitted from microsomes exposed to lipid peroxidation for 5 hr were carried out as described in Materials and Methods. 1, Fluorescence anisotropy (dots: observed values), fitted curve (——); and 2, lamp profile. The time-resolved anisotropy was analyzed only for the short component, because the photon counts were insufficient for analyzing other components accurately. The residuals of the experimental decay curve from the fitted curve are shown in the upper trace (%).

DISCUSSION

Lipid peroxidation in biological membranes is accompanied by the formation of fluorescent substances and is suggested to induce the accumulation of lipofuscin in tissues (5,6,24). Fluorescence measurements *in situ* directly on peroxidized microsomes is a very useful approach to studying the changes that occur in membranes upon lipid peroxidation (11). Peroxidized lipids and proteins are the two major components giving rise to fluorescence in peroxidized microsoms (11,16), and the present technique can simultaneously provide information on both types of fluorescent materials without prior separation.

The formation of fluorescent substances showed a pattern which was quite different from that of TBARS formation. We found that the fluorescence emitted from peroxidized microsomes increased continuously during the entire process of lipid peroxidation (Fig. 1A) (11). This increase may be due to an increase of amount of fluorescent substances present and/or to an increase in the fluorescence quantum yield of fluorescent substances produced.

The time-resolved fluorescence decays were measured to characterize the fluorescent substances. The fluorescence from peroxidized microsomes consisted of at least three components of about 1, 4 and 10 ns lifetimes. The peroxidation time did not alter these lifetimes and the relative amplitudes (Fig. 4). Thus, the continuing increase in fluorescence from peroxidized microsomes thus appears to be not due to a change in the quality of the fluorescent substances, but due to an increase in quantity.

The major chemical components of fluorescent substances formed in peroxidized microsomes are the fluorescent chromolipids (2,11) and proteins (16). The time-resolved fluorescence decays of these two major types of membrane components were examined to reveal how these components contribute to the fluorescence from whole peroxidized microsomes. Both fluorescent chromolipids extracted and fluorescent proteins isolated from peroxidized microsomes had three species of fluorescence lifetime. Each lifetime value and the respective relative amplitude obtained from the fluorescent chromolipids and proteins were similar to those of the fluorescence emitted from whole peroxidized microsomes. Interestingly, the values for the fluorescence lifetimes and relative amplitudes of the fluorescent chromolipids and proteins were not affected by the peroxidation time, which was the same as in whole peroxidized microsomes. This confirms that the fluorescent substances increase in their amount rather than change in their quality as lipid peroxidation progresses. Furthermore, each of three different lifetime components increases with progressing lipid peroxidation, keeping their relative ratio constant throughout.

The steady-state fluorescence anisotropy for the fluorescence from whole peroxidized microsomes has now been measured for the first time (Fig. 1B). The anisotropy showed a saturable increase with increasing lipid peroxidation. This increase can possibly be attributed to a change in the fluorescent substances themselves and/or in the microenvironment surrounding the fluorescent substances. The fluorescence anisotropy of DPH indicated decreasing fluidity of the microsomal membranes upon lipid peroxidation (22,23,25). This change in fluidity possibly may contribute to the increased anisotropy of the fluorescence from peroxidized microsomes, because both

fluorescent substances and DPH showed a similar profile for the anisotropy *vs.* peroxidation time (Fig. 1B). This increase of the fluorescence anisotropy for peroxidized microsomes evidently is not due to a change in the fluorescence lifetimes, because the lifetimes were unchanged during lipid peroxidation. Furthermore, the rotational correlation times increased with lipid peroxidation. These results indicate that the rotational motion of the fluorophore in peroxidized microsomes is depressed upon lipid peroxidation. The decreased fluidity of microsomal membranes appears to affect the rotational motion of the fluorophores in microsomes. Moreover, a change in the fluorescent substances themselves, *e.g.*, the molecular size and/or shape, would affect the rotational motions of the fluorophores.

The occurrence of lipid peroxidation in microsomes inactivates membrane-bound enzymes such as glucose-6-phosphatase and UDP glucuronyltransferase (22,26). The microsomal monooxygenase system also is affected by lipid peroxidation (25,27,28). Cytochrome P-450 may be involved in fluorscent proteins formed in peroxidized microsomes (16). Thus, formation of fluorescent substances may affect various physiological functions of microsomes not only through a change in physical properties of the microsomal membranes, but also through a transformation of enzymes into fluorescent substances.

A Study of the Composition of Fish Liver and Body Oil Triglycerides

Alister S. McGill and **Colin F. Moffat***
Ministry of Agriculture, Fisheries and Food, Torry Research Station, Aberdeen, Scotland AB9 8DG

Silver-ion high-performance liquid chromatography (Ag^+-HPLC) was used to study the range and variations in molecular species of triglycerides from industrial, retail and laboratory extracted fish oils. These were contrasted with a typical plant oil. Selected fish oils were fractionated and the fatty acid distribution of the fractions determined by gas-liquid chromatography. Fish oils gave a characteristic Ag^+-HPLC profile, typified by sharp, intense peaks at the start of the chromatogram and broad, multiple nongaussian peaks for the late eluting components. Triglycerides ranging from those that were wholly saturated to those containing 16 double bonds were isolated. Cod (*Gadus* spp.), saithe (*Pollachius virens*) and monkfish (*Squatina squatina*) liver oils gave similar triglyceride profiles. Mackerel (*Scomber scombrus*), capelin (*Mallotus villosus*) and herring (*Clupea harengus*) body oils gave characteristic triglyceride profiles which were associated with high concentrations of 20:1 and 22:1 fatty acids. Only small amounts of these particular triglycerides were observed for menhaden (*Brevoortia* spp.), South African anchovy (*Engraulis capensis*) and Indian sardine (*Sardinella longiceps*) oils, all of which contained minor amounts of these acids. The latter oils contained highly unsaturated triglycerides, whereas only traces of these were noted for the former. Chromatography with Ag^+-HPLC can be used for the rapid screening of fish oils and for selecting those oils rich in polyunsaturated acids that may be suitable for enrichment. Cottonseed oil gave well-defined and discrete peaks. Similar peaks were observed in the chromatogram of Omega-combination, a mixture of primrose and fish oils. Thus, fish, plant and a mixture of these oils can be readily distinguished.
Lipids 27, 360–370 (1992).

An intense interest in the health benefits of fish oils was stimulated in the early 1970s by the research of Dyerberg and co-workers (1–4). The n-3 polyunsaturated fatty acids (PUFA) *cis*-5,8,11,14,17-eicosapentaenoic acid (EPA, 20:5) and *cis*-4,7,10,13,16,19-docosahexaenoic acid (DHA, 22:6) are the active components of such oils [for reviews of n-3 biochemistry and clinical applications, see (5,6)]. A substantial number of fish oil nutritional supplements are available (7), many of which are defined as "concentrates." There is considerable interest in producing fish oils enriched with PUFA for use as pharmacological agents, but a better understanding of the triglyceride composition of crude and refined fish oils is required.

Abbreviations: Ag^+-HPLC, silver-ion high-performance liquid chromatography; BHT, butylated hydroxytoluene; BP, British Pharmacopoeia; CLO, cod liver oil; DHA, *cis*-4,7,10,13,16,19-docosahexaenoic acid; EPA, *cis*-5,8,11,14,17-eicosapentaenoic acid; GLC, gas-liquid chromatography; GLC/MS, gas-liquid chromatography/mass spectroscopy; HPLC, high-performance liquid chromatography; PUFA, polyunsaturated fatty acid(s); TLC, thin-layer chromatography; TMAH, tetramethylammonium hydroxide; UCM, unresolved complex mixture.

High-performance liquid chromatography (HPLC), both normal and reversed-phase, has been increasingly used to study lipids and more specifically triglycerides (8–12). Silver ions have been added to the solvent (13) to modify selectivity. Detection has always been a problem in HPLC, but the advent of the mass (light-scattering) detector has greatly facilitated the use of HPLC for lipid analysis (14–18). Christie (19,20) has developed a method for the analysis of triglycerides using silver-ion high-performance liquid chromatography (Ag^+-HPLC) and mass detection. This technique permits rapid and reproducible analyses of triglycerides which can be separated on the basis of the number of double bonds per triglyceride. The large range of fatty acids present in fish oils results in a complex mixture of molecular species of triglycerides, but Laakso *et al.* (21) have utilized a silver ion column to study the triglycerides in oils from Atlantic herring (*Clupea harengus*), the closely related Baltic herring, and sand eel (*Ammodytes* spp.). A more detailed study of fish oil triglycerides requires more than one chromatographic technique, and Laakso and Christie (22) have combined silver-ion and reverse-phase HPLC to study the triglycerides of Atlantic herring.

In the work described here, a range of industrial, retail and laboratory-extracted fish oils were analyzed by gas-liquid chromatography (GLC) and Ag^+-HPLC with the aim of studying the range and variations in molecular species of triglyceride present in such oils. More detailed investigations of the triglyceride composition of three of these fish oils included GLC analysis of fractions isolated by HPLC. Through an increased understanding of the triglyceride composition of fish oils, the ultimate aim is to develop a rapid and economic method for enriching fish oils and from the HPLC profile predict the suitability of a crude fish oil for enrichment.

MATERIALS AND METHODS

Chemicals. Hexane, methanol and acetonitrile were purchased from Rathburn Chemicals Ltd. (Walkerburn, Scotland). Acetone and 1,2-dichloroethane were "Hipersolv" grade from BDH Chemicals Ltd. (Poole, England). Copper(II)sulfate, sodium sulfate and orthophosphoric acid were "AnalaR" grade reagents from BDH Chemicals Ltd. Chloroform and diethyl ether were Pronalys AR reagents from May and Baker (Dagenham, England). Tetramethylammonium hydroxide (TMAH, 20% solution in methanol) was obtained from Aldrich Chemical Company Ltd. (Dorset, England). All lipid standards and boron trifluoride (15% solution in methanol) were purchased from Sigma Chemical Company Ltd. (Poole, England).

Fish oils. Cod (*Gadus* spp.) liver oil BP, saithe (*Pollachius virens*) liver oil, monkfish (*Squatina squatina*) liver oil, a Russian fish oil of unknown provenance, and orange roughy (*Hoplostethus atlanticus*) oil were provided by Isaac Spencer and Co. Fleetwood (1920) Ltd. (Fleetwood, England). Menhaden (*Brevoortia* spp.) oil was obtained from the Zapata Haynie Corporation (Reedville, Virginia). Sun'n'Sea cod liver oil (Cupal Ltd., Blackburn, England) and Seven Seas cod liver oil (Seven Seas Health Care Ltd., Hull, England; batch 81159) were purchased

from a local retailer, as were Marine 25 and Omega-combination oil capsules which had been prepared by Callanish Ltd. (Breasclete, Isle of Lewis, Scotland). Oil from Nile perch (*Lates albertianus*), a Chilean fish oil, South African anchovy (*Engraulis capensis*) oil and Indian sardine (*Sardinella longiceps*) oil were provided by Dr. R. Hardy and Mr. P. Howgate, Torry Research Station (Aberdeen, Scotland).

Cottonseed oil. Cottonseed oil (batch Q80505) was purchased from Larodan AB (Malmo, Sweden).

Extraction of oil from capelin, mackerel, cod livers and herring. Whole capelin (*Mallotus villosus*) were defrosted and minced in a Kenwood Chef mincer. The mince (474.3 g) was mixed with sodium sulfate (142.3 g) and centrifuged at 1150 × *g* for 20 min at 3°C (Fisons MSE Coolspin centrifuge, Crawley, England). The resulting oil was poured off and passed through a layer of sodium sulfate under a nitrogen atmosphere. The yield was 16.9 g (3.6%).

A single mackerel (*Scomber scombrus*) caught off the north of Scotland in October was defrosted under cold running water, and the head and tail were removed. The fish was minced, and the mince (390.9 g) was mixed with sodium sulfate (117 g); the sample was treated as for the capelin. The yield was 24.6 g (6.3%).

Cod (*Gadus morhua*) livers taken from cod landed at Gourden, northeast Scotland in mid-December were thawed, homogenized and weighed. Anhydrous sodium sulfate (30%, w/w) was intimately mixed with the homogenate and the mixture was treated as before. The oil was stored in 15-mL aliquots under a nitrogen atmosphere at −28°C. This sample was coded CLO 3/4.

Fresh herring (*Clupea harengus*), caught off the west coast of Scotland during July, were gutted, filleted and the fillets minced. The fish muscle mince (50 g) was extracted by the method of Bligh and Dyer (23) in the presence of butylated hydroxytoluene (BHT) and the oil stored at −60°C under nitrogen.

Silver-ion high-performance liquid chromatography of fish oils. HPLC analyses were performed with a Vista 5500 liquid chromatograph (Varian UK Ltd., Surrey, England) together with an ACS Model 750/14 mass detector (Applied Chromatography Systems, Macclesfield, England). The Vista 5500 was programmed using a Varian Vista 402 Data Station which also recorded the chromatograms. The HPLC column (25 cm × 0.46 cm) was packed with Nucleosil™ 5SA (HPLC Technology Ltd., Cheshire, England) using a Shandon column packer (Shandon Scientific Ltd., Cheshire, England) and conditioned with silver ions according to the method of Christie (19).

The triglycerides were resolved using a complex ternary solvent system comprised of 1,2-dichloroethane (A), acetone (B), and acetone/acetonitrile (75:25, v/v; C). The specific gradient was dependent on the condition of the column. Typical parameters are given in Table 1. The flow rate of the mobile phase was 1 mL/min.

The fish oils were dissolved in 1,2-dichloroethane and 50 μL (600 μg) were injected onto the column. The retention times of triglycerides with varying degrees of unsaturation were assessed using tripalmitin, 1,2-dioleoyl-3-palmitoyl-*rac*-glycerol, 1,3-distearoyl-2-oleoyl-*rac*-glycerol, 1,2-dipalmitoyl-3-oleoyl-*rac*-glycerol, triolein, trilinolenin and triarachidonin. The standard triglycerides were run on their own and mixed with the Russian fish oil.

The resolution of the column deteriorated progressively over 50 hr of analysis and was influenced by the column standing overnight in 1,2-dichloroethane. Thus, once the gradient had been established, the fish oils were analyzed on a continuous basis using an autosampler. At regular intervals, the column performance was assessed using the Russian fish oil. In addition, blank injections of 1,2-dichloroethane were made to ensure that no carry-over of sample was occurring with the autosampler.

TABLE 1

Typical Gradient Conditions for Elution of Triglycerides from Fish Oils[a]

Time (min)	Solvent		
	% A	% B	% C
0.0	100	0	0
15.0	50	50	0
20.0	20	60	20
30.0	0	75	25
33.0	0	60	40
50.0	0	40	60
55.0	0	0	100
75.0	0	0	100
80.0	100	0	0
100.0	100	0	0

[a]The period from 75.0 to 100.0 min was required to recondition the column. A, 1,2-dichloroethane; B, acetone; C, acetone/acetonitrile (75:25, v/v).

The retention times for wax esters were determined using palmityl palmitate, oleyl palmitate, oleyl oleate and orange roughy oil (95% wax esters). A similar analysis was carried out on a sample of free fatty acids prepared by saponification of cod liver oil (Seven Seas, batch 81159) with ethanolic potassium hydroxide (1 mol/L).

Fractionation of fish oils by HPLC. Fish oils were chromatographed as already described, the detector output being recorded on a Chromjet integrator (Spectra Physics, Ltd., Hemel Hempstead, England). A stream-splitter (Thames Chromatography, Berkshire, England) was then adjusted such that 30% of the column eluant was directed to the detector and a second sample of the same fish oil was chromatographed. Fractions were collected manually, according to the times obtained from the preliminary run but with slight variations being made in accordance with the actual emerging HPLC profile. The fractions were stored in screw-capped tubes at −65°C until they were methylated, using TMAH. The three oils treated in this way were the Russian fish oil, Indian sardine oil and a Seven Seas cod liver oil (batch 811509).

Preparation of methyl esters. Fatty acid methyl esters of the fish oils were prepared using boron trifluoride in methanol as described previously (24). Preparation of methyl esters from the HPLC fractions was performed by base-catalyzed transesterification using TMAH (25). Methyl tricosanoate (100 μL; 60 μg/mL) was added as a standard to assess recoveries prior to the TMAH (0.2 mL) and the reaction mixture was shaken at room temperature using an IKA-VIBRAX-VXR (Janke and Kunkel, Surrey, U.K.) for 4 min. The extracted methyl esters were dissolved in hexane (0.2–0.4 mL) and stored at −60°C until they were analyzed by GLC.

Gas-liquid chromatography and gas-liquid chromatography/mass spectroscopy (GLC/MS). GLC analyses of

fatty acid methyl esters were performed on a Hewlett-Packard 5880A capillary gas chromatograph (Hewlett-Packard Co., Palo Alto, CA) as described previously (24). Individual fatty acids were identified by reference to a standard fish oil (EEC interlaboratory calibration study). GLC/MS analyses of the fatty acid methyl esters were performed using an Autospec high-resolution mass spectrometer (VG Analytical, Manchester, England) as described previously (24).

Thin-layer chromatography (TLC). Fish oils were analyzed by thin-layer chromatography on LHP-K linear high-performance TLC plates (Whatman Labsales Ltd., Kent, England). The samples (4 mg/mL) were applied using Drummond microcaps (1 μL; Drummond Scientific Company, Broomall, PA) and the plate developed with hexane/diethyl ether/acetic acid (70:30:1, v/v/v). The lipids were visualized by spraying with copper(II)sulfate (10%, w/v) in aqueous orthophosphoric acid (80%, v/v) followed by heating at 180°C for 10 min. The samples were run against authentic standards.

RESULTS

Fatty acid compositions of the fish oils and cottonseed oil. The fatty acid compositions of the fish oils and of a cottonseed oil are summarized in Table 2.

[a]The percentages include the total for various isomers where appropriate (*e.g.* 20:4n-6 and 20:4n-3). Branched and odd-numbered carbon fatty acids, other than 15:0, are not included; hence the totals do not sum to 100%. Tr, trace (<0.3%).

[b]In evening primrose oil, the 18:3 is the *all-cis*-6,9,12-octadecatrienoic acid.

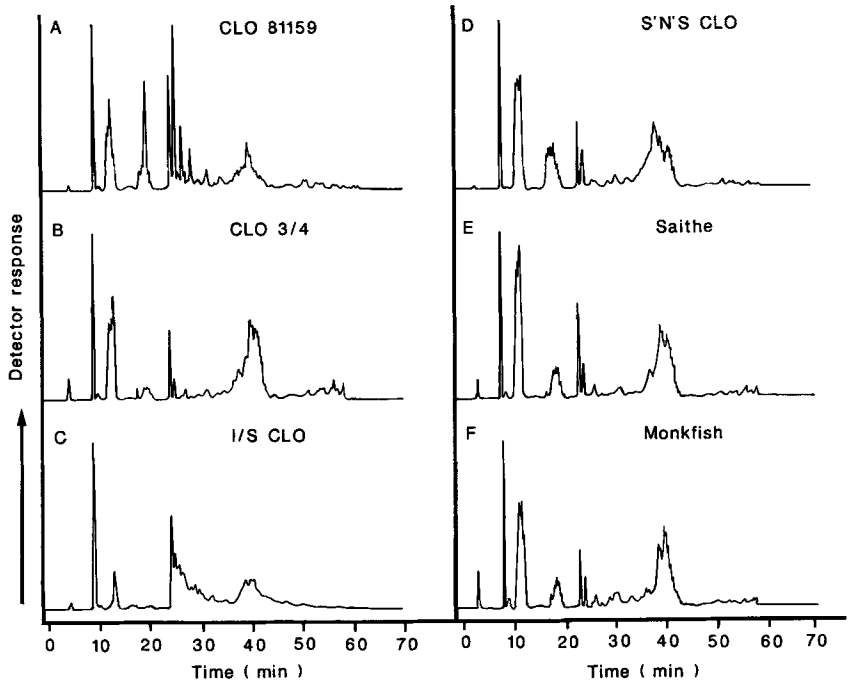

FIG. 1. Silver-ion HPLC of the triglycerides from fish liver oils. A, Seven Seas cod liver oil (batch 81159); B, laboratory-extracted cod liver oil (CLO); C, Isaac Spencer cod liver oil; D, Sun'n'Sea cod liver oil; E, saithe liver oil and F, monkfish liver oil. The oils (120 mg) were dissolved in 1,2-dichloroethane (10 mL). Injections (50 μL, 600 μg) were performed automatically to ensure reproducible reconditioning of the column and enabled all oils to be analyzed on a continuous basis. This ensured that the retention times of specific triglycerides remained constant.

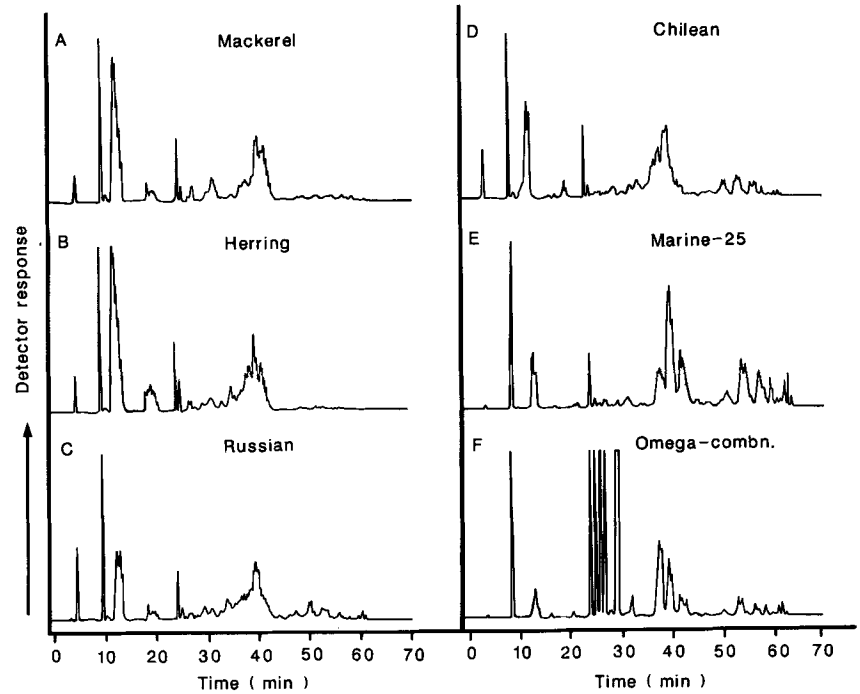

FIG. 2. Silver-ion HPLC of triglycerides from fish body oils. A, mackerel; B, herring; C, Russian fish oil; D. Chilean fish oil; E, Marine-25; F, Omega-combination. The Omega-combination includes both fish and plant oils.

Commercial cod liver oils are refined and clarified by filtration at 0°C (26). The removal of saturated triglycerides produces subtle differences between natural cod liver oil triglycerides and those purchased retail. Variations in the fatty acid composition resulting from season (27), fishing ground and sex (28) mean that direct comparison of the fatty acid composition of various cod liver oils is of little relevance, although typical ranges are recognized for specific fatty acids (27,28). The Issac Spencer cod liver oil, which was produced from cod caught off Iceland, was exceptional in that the level of eicosenoic acid (20:1) was extremely low (1.1%) while that for hexadecanoic acid (16:0) was very high. The presence of two unidentified components, which eluted after 22:6, resulted in the tabulated fatty acids adding up to only 90.8%. Adjustment of the figures by excluding these compounds did not produce a significant increase in the level of 20:1.

The mackerel and capelin body oils, and the herring fillet oil, contained large quantities of 20:1 and docosenoic acid (22:1). This contrasts with the oils produced industrially from the bodies of the fish from other regions, which contained only trace amounts of 20:1 and no 22:1. The Indian sardine oil, the South African anchovy oil, and the menhaden fish oil thus contained very small amounts of these monoenoic acids. These results are similar to those of Ackman (29,30). The lipid from Nile perch, a freshwater fish, was a very soft solid at room temperature, and the combined percentage for 20:5 and 22:6 (8.0%) was considerably less than for the marine fish oils.

Marine 25, a fish oil concentrate, contained the highest percentage of EPA (28.9%) of any of the fish oils, but the proportion of DHA (5.4%) was relatively low. Omega-combination contained a mixture of fish oil and evening primrose oil. The presence of the plant oil was reflected in the amount of *cis,cis*-9,12-octadecadienoic acid (18:2) in this oil. Furthermore, the octadecatrienoic acid is the *cis,cis,cis*-6,9,12-18:3 isomer (31).

TLC analysis of the fish oils. Trace amounts of wax esters, free fatty acids and sterols were detected in the fish oils.

Ag^+-HPLC of the fish oils and cottonseed oil. The liver oils (Fig. 1 A–F), with the exception of the Isaac Spencer cod liver oil (Fig. 1C), gave similar overall profiles. The commercial cod liver oils gave only a small trisaturated triglyceride peak (4 min) compared to the laboratory oil. This would be expected for a cold-cleared oil. The peaks centered at 9 min and 11.5 min were coincident with the standards 1,2-dipalmitoyl-3-oleoyl-*rac*-glycerol and 1,2-dioleoyl-3-palmitoyl-*rac*-glycerol, respectively.

An unresolved complex mixture (UCM), centered around 40 min, was a characteristic feature of the chromatograms. Cod liver oil 3/4, which contained at least 1.5 times as much 20:5 and 22:6 as the other liver oils, had the most significant peaks eluting after 50 min. These peaks were all of low amplitude. This was a result of the low concentration of triglycerides that contain highly unsaturated fatty acids and also of a decrease in detector response. The response of the mass detector is not constant for the different molecular species of triglyceride. The limit of detec-

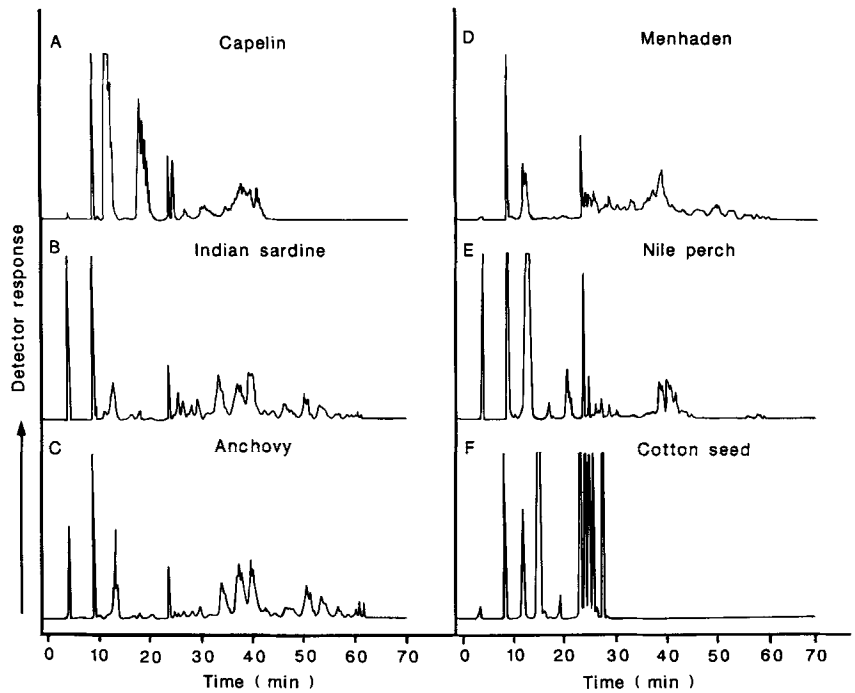

FIG. 3. Silver-ion HPLC of triglyceride from fish oils and cottonseed oil. A, capelin; B, Indian sardine; C, South African anchovy; D, menhaden; E, Nile perch; F, cottonseed.

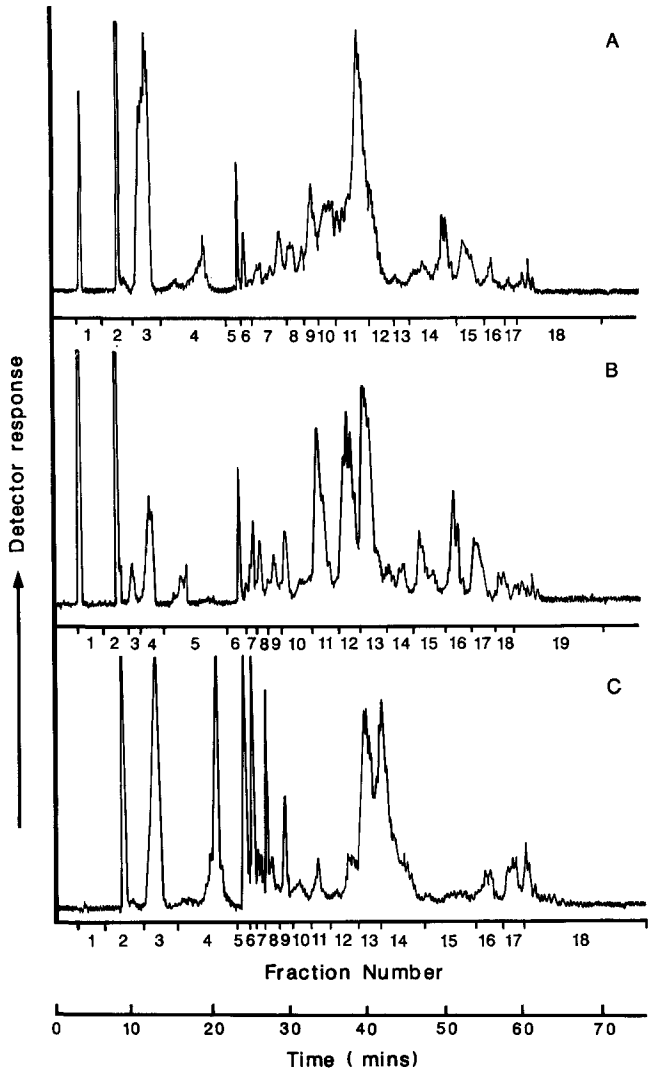

FIG. 4. HPLC of A, Russian fish oil; B, Indian sardine oil and C, Seven Seas cod liver oil (batch 811509) triglycerides. The column eluant passed through a stream-splitter and fractions were collected and numbered as indicated in the diagram. An incrased integrator sensitivity was used to provide greater detail of the triglyceride patterns.

tion was 1.5 μg and 0.8 μg for trilinolenin and tripalmitin, respectively. The equivalent figure for palmityl palmitate was 0.8 μg. In addition, 2.6 μg trilinolenin gave 4267 integrator counts, which was one-tenth of the response from an equivalent amount of tripalmitin (Moffat, Colin, unpublished results). Although a linear response was observed for the wax ester and a given triglyceride between the limit of detection and 25 μg, the response decreased for concentrations in excess of 25 μg. In addition, the gradients of the regression lines for the plots of detector response against amount of triglyceride increased going from trilinolenin to tripalmitin. In the case of trilinolenin, the detector response was proportional to the square root of the concentration over the range 25 to 500 μg.

The mackerel, herring, Russian and Chilean fish oils gave similar overall patterns (Fig. 2A–D). The chromatogram for the herring fish oil was similar to that obtained by Laakso *et al.* (21). Marine 25 (Fig. 2E) contained 32.3% pentaenoic acids and 5.4% hexaenoic acids. This oil gave several large peaks eluting after 50 min.

Christie (19) has shown that vegetable oils such as palm oil give more discrete peaks than fish oils when using a silver-loaded column. Omega-combination contained both fish oil and a primrose oil as clearly illustrated by the HPLC separation (Fig. 2F). Both the fish oil derived triglycerides with their characteristic non-gaussian peak profiles and the discrete peaks typical of a plant oil, as exemplified by the cottonseed oil (Fig. 3F), and observed for corn oil, peanut oil and olive oil (Moffat, Colin, unpublished results) were evident.

Capelin oil (Fig. 3A) contained substantial peaks around 10–13 min and 16–20 min. No triglycerides were eluted after 50 min. This corresponded with the high monoenoic acid (62.5%) and low pentaenoic/hexaenoic acid (12.2%) content of the oil. In contrast, the Indian sardine oil, which contained only 18.6% monoenes, gave small triglyceride peaks between 10 and 13 min with only a trace of triglycerides around 18 min (Fig. 3B). The triglyceride profile for the anchovy oil (Fig. 3C) was similar to the Indian sardine oil while the menhaden oil (Fig. 3D) was more like the Chilean fish oil (Fig. 2D).

Triglycerides containing three saturated acids, two saturated and one monoenoic acid, one saturated and two monoenoic acids dominated the HPLC profile for the Nile perch oil (Fig. 3E). Small peaks from highly unsaturated triglycerides were also apparent.

Several of the fish oils contained small amounts of free fatty acids but their contribution to the HPLC traces were negligible. This is because these acids are eluted as two broad peaks covering a restricted section of the chromatograms (15–25 min). Furthermore, the detector response to free fatty acids was approximately one-third that of the triglycerides. Thus, the sharp peaks that were evident on the HPLC chromatograms of the fish oils between 15 and 25 min were not due to free fatty acids.

Analysis of the fractions collected from the Russian, Indian sardine and cod liver oils. The molecular fractions were collected from the Russian, Indian sardine and cod liver oils, as shown in Figure 4. The fatty acid compositional data of the numbered fractions is presented in Tables 3, 4 and 5, respectively. The use of TMAH to methylate the fractions excluded the trace amounts of free fatty acids from the GLC analysis.

The first fraction in all three oils contained only saturated acids which included, for the Indian sardine oil, a significant quantity of 20:0 (3.4%). The saturated acids in Fraction 2 constituted 60.7%, 70.5% and 56.9% of the total for the Russian, Indian sardine and cod liver oils, respectively. The remainder of the acids for this fraction in the Russian and Indian sardine oils were monoenoic, with the percentages obtained for the Indian sardine being very close to those obtained by Laakso *et al.* (21) for Atlantic herring and sand eel. The cod liver oil Fraction 2 included 18:2. The subsequent peak (Fraction 3, Fig. 4C) contained no dienoic acids, only saturated fatty acids and monoenes; 18:1 constituted 35.3% (Table 5). This peak corresponded to triglycerides containing two monoenoic and one saturated fatty acid per glyceride. Thus, 18:1 constituted approximately 30% of the acids from Fraction 3 of the Russian oil (Table 3) and Fraction 4 of the Indian sardine oil (Table 4). Only a trace of 20:1 was present when

TABLE 3

[a]The percentages of the saturated (S), monoenoic (M), dienoic (Di), trienoic (Tri), tetraenoic (Tet), pentaenoic (P) and hexaenoic (H) acids were summed to assess the overall double bond distribution in the triglycerides. Tr, trace.

[b]Includes the n-6 and n-3 isomers.

[c]Area units detected for 23:0 added as a standard to assess recoveries. Fractions 2 and 3 were diluted by a factor of 2.

the total fatty acid composition was determined for the Indian sardine oil, but this fatty acid was measurable in Fraction 4 and one other fraction.

The introduction of more highly unsaturated fatty acids resulted in a loss in base-line resolution and the presence of unresolved complex mixtures. This second phase of the chromatogram was preceded, in all cases, by a sharp peak (Fraction 5, Russian and cod liver oils; Fraction 6, Indian sardine oil). The triglycerides from these fractions contained between 20 and 25% dienoic acids (16:2 and 18:2), while approximately one-third of the acids were saturated and approximately 40% were monoenoic. A large proportion of the triglycerides were probably in the form saturated/monoenoic/dienoic (exact positions not stated). The cod liver oil fraction 5 also contained 16:3 and 16:4. Fraction 6 of this oil (Fig. 4C, Table 5) did not contain these acids. Instead, it contained approximately two-thirds monoenes and one-third dienes. Trienoic acids were present in Fraction 6 of the Russian oil (Fig. 4A, Table 3) and Fraction 7 of the Indian sardine oil (Fig. 4B, Table 4), 16:3 being the major trienoic acid.

A greater variation in peak distribution was observed for peaks which eluted after 27 min. This was a result of the difference in fatty acid composition of the oils. Fractions 7–12 of the Russian oil (Fig. 4A, Table 3) all contained approximately one-third monoenoic acids with the exception of Fraction 9. An increasing range of polyenoic acids was evident in these fractions including 20:5 (from Fraction 8) and 22:6 (from Fraction 10). The average number of double bonds in each triglyceride molecule was 6.9, 7.8 and 8.8 for Fractions 10, 11 and 12, respectively. These fractions also contained the widest range of fatty acids. More detailed examination of these triglycerides requires complementary analysis as illustrated by Laakso and Christie (22). Fraction 8 contained the highest proportion of tetraenoic acids of any fraction. When the percentage tetraenoic acid was plotted against the fraction number, two distinct peaks were observed with maxima at Fraction 8 and Fraction 13. Between these maxima, the percentage decreased to practically zero (Fig. 5). This phenomenon was observed for all other acids when grouped according to the number of double bonds. The pentaenoic acids peaked at Fractions 10 and 15 while DHA peaked at Fractions 12 and 16. In both cases the intermediate values did not drop as low as was observed for the tetraenoic acids. The percentage constituted by the tetraenoic and pentaenoic acids rose, as if toward a third maximum, going from Fraction 16 to 18. Such a maximum was observed for the dienoic acids.

From Fraction 15 onward, the combined percentages for the pentaenoic and hexaenoic acids were greater than 68%. Thus, all these triglycerides contained a minimum of two fatty acids, each of which contained at least five double bonds. Fraction 18 contained only traces of fatty acids

[a]The percentages of the saturated (S), monoenoic (M), dienoic (Di), trienoic (Tri), tetraenoic (Tet), pentaenoic (P) and hexaenoic (H) acids were summed to assess the overall double bond distribution in the triglycerides. Tr, trace.

[b]Area units detected for 23:0 added as a standard to assess recoveries. Fraction 2 was diluted by a factor of 2.

with less than four double bonds. In addition, the percentages obtained for the pentaenoic/hexaenoic acids indicated that there were triglycerides substituted at all three positions by fatty acids with a minimum of five double bonds.

The triglyceride fractions from the Indian sardine oil containing polyenoic acids (Fractions 8 to 19; Fig. 4B, Table 4) were derived from more distinct peaks. Fraction 8 contained the highest percentage of 16:3 of any fraction from the three oils. Fraction 9 contained the first of the quantifiable tetraenoic acids (16:4, 18:4 and 20:4). Fraction 10 was a composite fraction, which contained a small proportion of EPA.

Fractions 11–13 (Fig. 4B) were collected from three major composite peaks. Fraction 11 contained 34.8% pentaenoics, primarily EPA, and 52.6% saturated fatty acids. Thus, the bulk of the triglycerides were saturated/pentaenoic. Approximately one-third of the acids from Fraction 12 were saturated, and an equivalent proportion contained five double bonds. In this oil, DHA was first detected in Fraction 12.

From Fraction 13 onward, of the sardine oil, there was a steady decrease in the percentage of saturated acids. The percentages of pentaenoic acids attained a maximum in Fraction 16. All triglycerides from Fraction 16 onward contained two acids with at least five double bonds per acid. This was the same as was observed for the Russian oil. Fraction 19 contained measurable amounts of 18:1, 16:3 and trace amounts of the saturated acids 14:0 and 16:0.

Plotting the combined area percentages for the acids containing a specific number of double bonds against the fraction number again gave discrete peaks except for pentaenoic acids.

The earlier-eluting cod liver oil triglycerides gave sharper, more intense peaks relative to the corresponding fractions in the two preceding fish oils. Examples of this were the peaks which comprised Fractions 7, 8 and 9 (Fig. 4C). The largest percentage for 18:3 obtained in a fraction of any of the oils was found in cod liver oil Fraction 9. Fraction 10 was a low broad peak. The fatty acid composition was approximately one-third saturated fatty acid, one-third monoenes with the remaining third comprised of di-, tri- and tetraenoic acids.

Cod liver oil EPA first appeared in Fraction 11, where it comprised 4.4% of the fatty acids. The DHA was first identified in Fraction 13 and comprised 26.6% of Fraction 14. Fraction 15 was characterized by a large percentage of tetraenoic acids.

The saturated acid content diminished markedly over the last three fractions of the Russian fish oil and Indian sardine oil. The content of both saturated and monoenoic acids was sustained in the cod liver oil such that there was a significant population of both groups of fatty acids in the final fraction. This was probably due to the influence of a large peak present at the start of Fraction 18

[a]The percentages of the saturated (S), monoenoic (M), dienoic (Di), trienoic (Tri), tetraenoic (Tet), pentaenoic (P) and hexaenoic (H) acids were summed to assess the overall double bond distribution in the triglycerides. Tr, trace.

[b]Area units detected for 23:0 added as a standard to assess recoveries. Fractions 2 and 3–5 were diluted by a factor of 1.5 and 2, respectively.

and the presence of the tail end of a small unresolved complex mixture.

Despite the differences between the cod liver oil and the other two oils, plotting the combined area percentage of the acids with equivalent number of double bonds against fraction number gave similar results with distinct peaks for the individual double bond types.

DISCUSSION

In this study, the fatty acid and triglyceride distributions of industrial, retail and laboratory-extracted fish oils have been investigated using a combination of GLC and Ag^+-HPLC. The objective was to study the range and variations in molecular species of triglyceride present in such oils and to investigate the potential of utilizing Ag^+-HPLC for assessing the nature of fish oils. No attempt was made to isolate the triglycerides free of the trace amounts of wax esters, free fatty acids or sterols found to be present in the fish oils by TLC. The emphasis was on utilizing the oil directly. The potential for interference from these compounds was assessed by carrying out HPLC analysis on appropriate standards. The saturated wax ester, palmityl palmitate, was eluted just before the trisaturated triglyceride peak; the two peaks were not totally resolved. Monounsaturated wax esters, typified by oleyl palmitate, were located between the trisaturated and monounsaturated triglyceride peaks. Oleyl oleate had a retention time greater than for triglycerides which contained two monoenoic acids per molecule. Orange roughy oil, which contained mainly wax esters, gave essentially two peaks when analyzed by Ag^+-HPLC. The retention times were the same as those of oleyl palmitate and oleyl oleate. Thus, the wax esters are grouped according to degree of saturation and the retention times were independent of chain length. Close examination of the trisaturated triglyceride peak in the chromatograms from Issac Spencer and Sun'n'Sea cod liver oils revealed a shoulder on the leading edge of the peak. This was probably due to the saturated wax esters. There was no evidence for saturated, or any other, wax esters in the oils chosen for fractionation.

From the results obtained during this study and those of Laakso *et al.* (21), it was apparent that the triglyceride composition of all fish oils is extremely complex. The composition of the triglycerides range from those containing only saturated acids to those containing up to at least 16 double bonds.

Although there is insufficient information from this study to conclude whether or not Ag^+-HPLC can be used to fingerprint specific fish oils, there is good evidence that the body oils examined in this work can be categorized as belonging to one of two groupings. The mackerel oil (admittedly from one fish), herring and capelin oils were similar to each other but different from menhaden, South African anchovy and Indian sardine oils. The former were

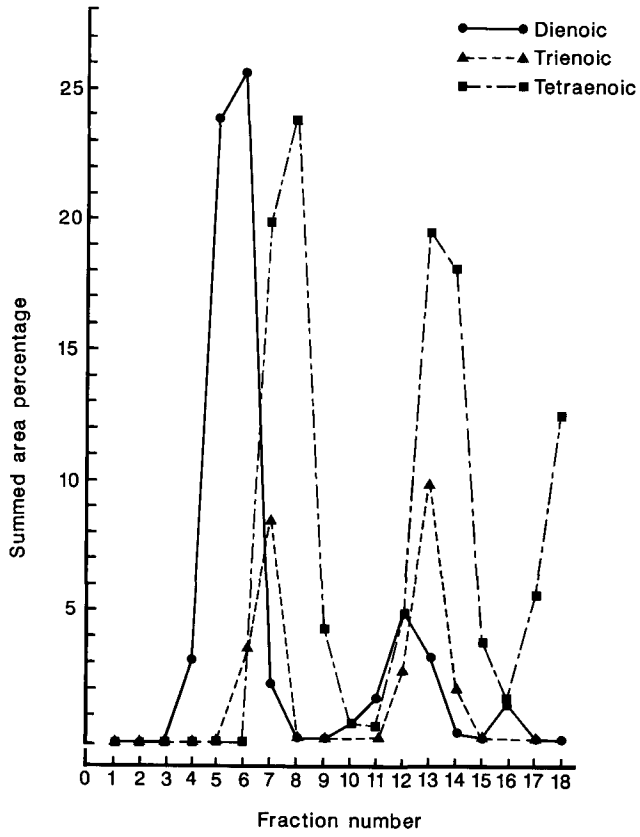

FIG. 5. Plot of summed area percentage of fatty acids with equivalent number of double bonds against fraction number for dienoic, trienoic and tetraenoic acids from the Russian fish oil derived fractions.

characterized by a large peak between 11 and 13 min with a second, smaller, peak between 17 and 21 min. These two peaks were typified by a high proportion of monoenoic acids. Oils where these peaks were very small or absent (Indian sardine, South African anchovy and menhaden oils) contained a very small proportion of 20:1 and 22:1. It can also be seen from the triglyceride profiles that peaks eluting after 50 min, which correspond to the polyunsaturated triglycerides, are either absent or present in trace amounts for mackerel, herring and capelin, whereas significant amounts are to be found in the menhaden, South African anchovy and Indian sardine profiles.

The Chilean oil gave an HPLC profile more akin to the latter group of oils whereas that of the Russian oil appeared to encompass both. The distribution of the 20:1 and 22:1 in the Chilean and Russian oils followed the expected pattern. As far as the liver oils were concerned, the Isaac Spencer cod liver oil was identified as being atypical from its triglyceride pattern. This interpretation was reinforced by its unusual fatty acid composition.

From the results obtained in this study, it is apparent that Ag^+-HPLC can be used to characterize fish oils. The distinctive peak shapes and triglyceride distribution of the fish oil profiles contrast markedly with those from plant oils. Thus, Ag^+-HPLC can be used to rapidly differentiate between triglycerides from plant and fish oils or to check for adulteration.

The method, as presented, was reproducible, but reconditioning of the column or a change of column required a reevaluation of the solvent gradients. In addition, accurate and reproducible retention times for the early eluting peaks were only achieved if the time permitted for reequilibration of the column with the starting solvent remained constant. This favored the use of an autosampler as did the time of analysis. In addition, after an overnight stop a blank run had to be performed before any triglyceride analysis could be carried out.

Marine 25 was described as a concentrate. This fish oil contained a high proportion of 20:5 and 22:6, but triglycerides which contained three saturated fatty acids or two saturated fatty acids and one monoenoic fatty acid per triglyceride were still present. From the work carried out in this study, it was apparent that the triglyceride distributions follow a similar pattern for fish oils. A method which removed from a fish oil all the triglycerides with structures equivalent to those eluted in the first 29 min of a typical chromatogram would yield an enriched oil, with maximal amounts of 20:5 and 22:6 being retained. The residual product should also have some commercial value. Chromatography with Ag^+-HPLC could be utilized to assess the suitability of a fish oil for such an enrichment process. This line of research is being actively pursued in this laboratory.

Lipid Composition and Mitochondrial Respiration in Warm- and Cold-Adapted Sea Bass

Gianni Trigari*, Maurizio Pirini, Vittoria Ventrella, Alessandra Pagliarani, Fabiana Trombetti and Anna Rosa Borgatti

Department of Biochemistry, Section of Veterinary Biochemistry, University of Bologna, Bologna, Italy

The response to cold of liver and heart membrane lipid composition and mitochondrial respiration in reared sea bass (*Dicentrarchus labrax* L.) was investigated. Fish acclimation was followed during the natural seasonal cycle from August to March. The data on the fatty acid composition of liver and heart polar lipids and on total lipids of liver mitochondria and microsomes did not indicate any increase in unsaturation in response to cold. The enzyme complexes of the liver and heart mitochondrial respiratory chain showed a repeated negative compensation for cold acclimation. The constancy of the break in the Arrhenius plot of liver cytochrome oxidase (EC 1.9.3.1.) was consistent with the lack of homeoviscous adaptation of membrane lipids. A thermoadaptive strategy based on the reduction of sea bass metabolic activity is suggested. *Lipids 27,* **371-377 (1992).**

Various physiological and biochemical mechanisms have evolved in poikilotherms to counter the effects of thermal variation on physical properties of cells and body fluids. A number of studies have been carried out to identify the temperature-activated mechanisms involved in maintaining homeostasis. Changes in the unsaturation of membrane lipids have generally been implicated in membrane viscotropic regulaton and thus in the modulation of membrane-bound enzyme activities (1-5). However variations in the membrane cholesterol content (6) and in the ratio of phospholipid classes (3,7), interactions between the polar heads of phospholipids (8) and/or lipids and proteins (8,9), as well as direct temperature effects on protein chains (2), have been shown to contribute to homeoviscous adaptation. These studies have been mainly carried out on winter-active freshwater teleosts. In some poikilotherms, the slowing of life activities, similar to that characteristic for hibernating mammals, was described as another adaptational strategy (2,10).

The purpose of our study was to examine whether behavioral adaptation in the sea bass (*Dicentrarchus labrax* L.) is accompanied by changes in membrane lipid composition and/or by variations in the activity of membrane-bound enzymes, such as mitochondrial respiratory complexes. The choice of the sea bass was based on the following observations: below 10°C, this species strongly reduces motility and stops eating (11); its marine origin implies reduced capability to synthesize polyunsaturated fatty acids (PUFA) (12). Our experiments were carried out following the seasonal cycle to obtain more reliable results than one could obtain by artificial, season-independent cold-acclimation studies. Thus, our experimental design reproduced the natural conditions, fast included, by overwintering sea bass in Northern Italy (11).

Abbreviations: BSA, bovine serum albumin; EDTA, ethylenediaminetetraacetate; FA, fatty acids; GLC, gas-liquid chromatography; LCA, long-term cold-adapted; MUFA, monounsaturated fatty acids; PL, phospholipids; PUFA, polyunsaturated fatty acids; SCA, short-term cold-adapted; SFA, saturated fatty acids; TL, total lipids; TMPD, *N,N,N',N'*-tetramethyl-*p*-phenylendiamine dihydrochloride; Tris, Tris-(hydroxymethyl)aminomethane; WA, warm-adapted.

MATERIALS AND METHODS

Reagents. Solvents, acid-washed Chromosorb W 60-80 mesh and diethyleneglycolsuccinate were purchased from Carlo Erba (Milan, Italy). Silver nitrate and Tris were obtained from Merck (Darmstadt, Germany). Silicic acid, 100 mesh and 14% boron trifluoride in anhydrous methanol were purchased from Mallinkrodt (St. Louis, MO) and from BDH, Laboratory Chemical Division (Poole, United Kingdom), respectively. Fatty acid-free bovine serum albumin (BSA), sodium ethylenediaminetetraacetate (Na_2EDTA), respiratory substrates, and inhibitors were from Sigma Chemical Co. (St. Louis, MO). Standards for fatty acid analyses were obtained from Sigma and from Applied Science Laboratories Inc. (State College, PA). All chemicals were reagent grade. Quartz-double distilled water was used for all solutions in the preparation of subcellular fractions and in the mitochondrial respiratory activity tests.

Animals and diets. Adult sea bass (*Dicentrarchus labrax* L.) weighing about 100 g, reared in a commercial hatchery in Valle Campo-Comacchio (Ferrara, Italy), were used. Fish were fed a pelleted diet to which lipids had been added as oil mixture (cod liver oil/raw linseed oil/grape seed oil/corn oil, 2:1:1:1, by vol) amounting to 10% (13). Total dietary total lipid content was slightly higher (11.2%, w/w) due to the lipid content of other dietary components. The fatty acid pattern of the diet is shown in Table 1. Other details of diet composition were reported by Corti *et al.* (13).

Experimental design. As shown in Figure 1 fish were kept at approximately 22°C, from August until mid-October (warm-adapted or WA) and fed to satiation (2.5% of wet body weight/day). Following the seasonal lowering of environmental temperature, the water temperature gradually decreased to 10°C. Food consumption gradually decreased with temperature and became undetectable. The daily ration was therefore gradually lowered to 0.5% of wet body weight and maintained until the end of the experiment. Fish sacrificed in December, after a month of acclimation at temperatures around 10-11°C to test the short-term cold adaptation to the threshold temperature of food uptake among sea bass (11), were defined as short-term cold-adapted (SCA). Fish were then kept at approximately 7°C until March to test the long-term adaptation at a temperature similar to that faced by reared sea bass during winter in Northern Italy (7). This adaptation was performed under two conditions as follows. Fish were randomly divided into two groups. The first group was kept in seawater tanks and diet was provided (Expt. 1). In parallel, the second group was maintained at the same

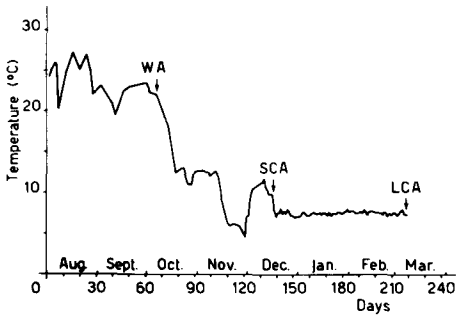

FIG. 1. Temperature regimen during the experiment. Samplings are indicated by arrows.

temperature in synthetic-seawater tanks, but was not fed (Expt. 2). Since at this temperature sea bass usually do not eat (11), the two experiments were aimed at ascertaining whether any differences exist between fasting (Expt. 1) and starved (Expt. 2) sea bass. Data from both experiments were not significantly different; therefore, the results from long-term cold-acclimated (LCA) fish are reported as averages of Expts. 1 and 2. The water temperature in the tanks was measured at the same hour each day during the entire experiment. Fish mortality, which was calculated as percentage of the initial number at the end of each acclimation period, was about 0.9% up to December and nil thereafter (Viviani, R., personal communication).

Sampling procedures. Fish were randomly selected and killed at the end of each experimental period. Samples consisted of 80 WA, 40 SCA and 80 LCA fish (60 from Expt. 1 and 20 from Expt. 2). Liver and heart were removed immediately after death. Part of each tissue was stored in the dark under nitrogen at −20°C for lipid analysis. Another portion was immediately used for the preparation of subcellular fractions.

Preparation of the mitochondrial and microsomal fractions. In each preparation, the liver and heart from 10–20 animals were repeatedly rinsed in ice-cold medium A (0.25 M sucrose, 5 mM sodium ethylenediaminetetraacetate (Na_2EDTA), 16.5 mM Tris-HCl, pH 7.4) and homogenized with an Ultraturrax in medium B (0.25 M sucrose, 1 mM Na_2EDTA, 24 mM Tris-HCl, 0.5 mg/mL fatty acid-free bovine serum albumin (BSA), pH 7.6). The mitochondrial fraction was obtained by differential centrifugation using the method of Lyons and Raison (14) modified as follows. The homogenate was centrifuged at 750 × *g* for 10 min, and then the supernatant was filtered through a double layer of gauze (30 mesh) and centrifuged at 10,000 × *g* for 10 min. The mitochondrial pellet was resuspended in medium B and centrifuged at 13,000 × *g* for 10 min. Part of the sample was frozen in liquid nitrogen for lipid analysis, and another part was immediately used for the respiratory tests. The post-mitochondrial supernatant from the liver was further centrifuged at 90,000 × *g* for 90 min. The pellet was resuspended and twice washed by centrifuging at the same speed for 40 min. The resulting microsomal fraction was stored in liquid nitrogen until use. All steps were carried out at 0–4°C. Protein in the various fractions was evaluated by the biuret method (15). The purity of microsomal and mitochondrial fractions was routinely tested by determining (Na^+, K^+)-ATPase (EC 3.6.1.3) and cytochrome oxidase (EC 1.9.3.1) as enzymatic markers for plasma membrane and mitochondria, respectively. The negligible specific activity of (Na^+, K^+)-ATPase in the mitochondrial fraction and of the cytochrome oxidase in microsomes indicated no appreciable mutual contamination of the fractions under study.

Determination of mitochondrial respiratory activities. The respiratory activity of liver and heart mitochondria was evaluated polarographically with a Clark electrode using a Yellow Springs Instrument Model 53 oxygen monitor (Yellow Springs, OH). The three sites of oxidative phosphorylation were tested at 20°C by using as substrates, respectively, glutamate, succinate and ascorbate + *N,N,N′,N′*-tetramethyl-*p*-phenylendiamine dihydrochloride (TMPD) under the conditions previously described (16). The respiratory control ratio (RCR) and adenosine diphosphate (ADP):Oxygen (O) ratio were calculated as described by Estabrook (17). The Arrhenius plot of the liver cytochrome oxidase system was drawn by plotting the state 3 respiratory activity data using ascorbate + TMPD as substrate in the temperature range of 3–40°C as reported by Borgatti *et al.* (18). The above assay was not carried out on heart because of insufficient mitochondrial material.

Lipid analyses. Lipids were extracted according to Folch *et al.* (19) from each liver mitochondrial and microsomal preparation containing 100–300 mg protein, from 1–5 g liver and heart pooled from 5 fish, and from 5 g of the diet. Total lipids (TL) were determined gravimetrically. Phospholipids (PL) were quantitatively evaluated by colorimetric determination of phosphorus (20) according to the method of Bartlett (21), as modified by Marinetti (22). Tissue lipid extracts were separated into neutral lipids and

polar lipids according to Marks *et al.* (23). Activated silicic acid in the maximal ratio of 1 g per 50 mg PL was added to total lipids. After removal of neutral lipids by triplicate extraction with diethyl ether, polar lipids were obtained by triplicate extraction with methanol. A complete separation was obtained. The saponification of TL and polar lipids, the extraction of the fatty acids (FA), and the methylation using 14% BF_3 in methanol were carried out as previously described (24). Methyl esters of FA were analyzed by gas-liquid chromatography (GLC) and also by chromatography on silicic acid columns impregnated with 25% $AgNO_3$ and by catalytic hydrogenation. GLC was done on a Dani (Monza, Italy) 3600 gas chromatograph using a glass column (2 m × 4 mm) filled with acid-washed Chromosorb W 60–80 mesh and 20% (w/w) diethyleneglycolsuccinate. The carrier gas was nitrogen. The GLC operating conditions and the methods of identification of FA were reported previously (25). Methyl esters of FA separated by GLC are given as weight percentages of total FA. The unsaturation index (I) and the ratio I × 100/Σ saturated fatty acids (SFA) were calculated according to Bloj *et al.* (26).

Statistics. Results are presented as mean ± standard error (SE). Statistical significance of differences between differently acclimated groups was determined by the Student's t-test.

RESULTS AND DISCUSSION

Effect of cold-acclimation on lipid composition. Changes in lipid class composition have been reported as one of the possible responses to temperature lowering (27,28). The content of total lipids (TL) and phospholipids (PL) of liver, heart and liver mitochondria and microsomes, shown in Table 2, indicates that only in the liver TL and PL levels were changed by cold exposure. The observed increase of liver TL in SCA probably reflects fat storage to face the winter. This would be consistent with previous studies which have shown that eel accumulates triglycerides as energy source before fasting for the winter (28). A TL increase was found by Roche and Pérès (27) in cold-acclimated *Dicentrarchus labrax* fed during the entire experiment. However, other cold acclimation studies (29) that were carried out under conditions of forced starvation and independent of season showed no TL variation. The PL increase in LCA is probably related to the consumption of previously stored neutral lipids. Other studies have indicated a widespread tendency of PL to increase after long-term cold-exposure (at least one month) (27,28).

No variations in TL and PL levels are apparent in heart and liver subcellular fractions consistent with the lack of fat storage function of this tissue. The constancy of TL and PL levels in liver mitochondrial and microsomal fractions is also in line with literature reports on cold acclimated teleosts (6,9,30).

The analysis of fatty acid composition was focused on liver and heart polar lipids and on total lipids of liver mitochondrial and microsomal fractions.

Liver polar lipids (Table 3) show only little variation related to cold acclimation, namely an increase of 20:5n-3 and thus of Σn-3, and a decrease of 18:1 resulting into a lowering of monounsaturated fatty acids (MUFA). The decrease of MUFA is consistent with that reported for trout liver (31).

Heart polar lipids show a rather constant fatty acid composition (Table 3). The observed decreases in 18:0, 18:1 and MUFA and the increase of 22:6n-3 during cold acclimation are insufficient to affect the unsaturation parameters.

When the acclimation temperature is lowered, liver mitochondrial and microsomal FA (Table 4) show a progressive increase in 18:2n-6 and a decrease in 22:6n-3 with a consequent increase in Σn-6 and a decrease in the unsaturation parameters, Σn-3 and the n-3/n-6 ratio. Some of these data are at odds with many literature reports that show an overall increase in unsaturation parameters during cold adaptation (3,4,6,8). In carp liver, cold was shown to promote a decrease in 22:6n-3 and in the n-3/n-6 ratio, which consistent with previous findings was counterbalanced by an increase in n-6 long-chain polyunsaturated fatty acids (PUFA) due to Δ6 desaturation of linoleic acid. Consequently membrane unsaturation increased (7). By contrast, in cold acclimated sea bass, an increase in 18:2n-6, which is not further desaturated and elongated, together with a decrease in 22:6n-3 contributed to lower unsaturation parameters. The high level of 18:2n-6 may have been due to dietary intake which is higher in reared fish than in wild ones (27).

Membrane fatty acid composition has received the most attention as possible site of homeoviscous adaptation (1–4). The lack of an increase in unsaturation parameters during cold adaptation, which is at odds with other literature reports, may have been due to differences in the experimental design of our studies and of those reported earlier. The differences lie in the experimental conditions

and in the species used. Roche and Pérès (27) reported a cold-promoted unsaturation increase of liver triglycerides in 12°C-acclimated sea bass. As the unsaturation increase was due to changes in different FA depending on the season, the authors concluded that cold acclimation processes were ruled by an internal clock not only that would be susceptive to the environmental temperature but also to the season. Moreover, at 12°C, sea bass were eating and thus, in our opinion, could adequately select dietary FA in response to thermal stress. The dietary intake of FA is crucial in marine teleosts because of the poor efficiency of PUFA biosynthesis (3,9,12,31–34).

These observations clearly strengthen our case to carry out experiments on cold-acclimation by following the seasonal cycle and to reproduce the natural winter conditions of reared sea bass in Northern Italy (11). The apparent lack of classical cold-adaptational mechanisms, *i.e.* a SFA decrease and a long-chain PUFA increase (1–5), suggests that such mechanisms do not represent the main strategy of sea bass to cold adaptation, and that other processes are likely to be involved.

Most cold acclimation studies have been carried out on winter-active freshwater teleosts such as the trout. These species exhibit far different features from the carnivorous and prevalently marine sea bass. In the literature on trout, feeding and normal activity were maintained during the whole experiment. However, below 10–12°C, sea bass strongly reduce food intake, as well as activity, and rest quite immobile at the bottom (12). Such a species-specific behavior may be related to a different, cold-directed metabolic modulation. The trout, not a strictly carnivorous species, shares with other freshwater teleosts the biosynthetic enzymes capable of forming long-chain n-3 and n-6 PUFA from the precursors 18:3n-3 and 18:2n-6 (3). Conversely, the sea bass is only able to synthesize long-chain PUFA to a limited extent as are most marine teleosts (3,9,12,31–34). These differences may explain the differential responses to low temperatures between the sea bass and freshwater teleosts.

Effect of cold acclimation on mitochondrial respiratory activities. Liver and heart mitochondrial oxidative activities show a clear thermoacclimation response (Table 5). However, the response to cold appears to depend on the tissue and the complexes involved.

State-3 and state-4 respiratory activities increase in liver mitochondria of LCA fish when glutamate is used as substrate, remain invariable with succinate, and decrease with ascorbate + TMPD. Thus RCR and ADP:O ratio values are generally constant.

Heart mitochondria exhibit a more homogenous behavior with all substrates; generally both state-3 and state-4 respiratory activities decrease in SCA and LCA groups. The ADP:O ratio is generally constant and RCR exhibits an increase with glutamate as a result of nonparallel variations undergone by states 3 and 4. Moreover the disappearance of coupling with ascorbate + TMPD during prolonged cold exposure may be related to the low RCR and its greater susceptibility to various perturbations (16). The overall decrease of mitochondrial respiratory activity during cold acclimation, excluding glutamate oxidation in liver mitochondria, strongly contrasts with literature reports. Acclimation indices (cold-acclimated/warm-acclimated) of enzymes involved in energy production are reported to be greater than 1 (2,30,35,36). Fish respiratory-chain enzymes are quoted as representative of positive compensation (2). The sea bass behavior may have an adaptive significance as it may reflect a cold-promoted reduction of all physiological activities and thus of energy requirements. This would be consistent with the less active succinate oxidation in slow fish with respect to fast

[g] Not detectable because all mitochondrial preparations were uncoupled.

swimmers (37). In nature the reduction of life processes during winter may represent a strategy adopted by sea bass to face unfavorable environmental conditions.

Results different from the commonly reported positive compensation in cold acclimation were found by Wodtke (38) in carp liver. He demonstrated that a transient increase in mitochondrial succinate oxidation rate, shown immediately (two days) after cold transfer, disappeared after prolonged (one month) exposure at 10°C.

The dependence on assay temperature of liver mitochondrial respiratory activity with ascorbate + TMPD as substrate (cytochrome oxidase) is shown as Arrhenius plot (Fig. 2). All plots are discontinuous with a break at about 20°C. The break is always clearly detectable as the ratio of the two activation energies below (Ea_2) and above (Ea_1) the break is approximately 2.0. Although various authors (14,39-43) have reported linear Arrhenius plots for fish membrane-bound enzymes, the occurrence of a break, as in the homeotherms (2), is widely documented (5,18,37,38,44,45). The temperature of discontinuity of the Arrhenius plot, in turn, is related to the temperature range of the phase transition of membrane lipids, and is generally influenced by the acclimation temperature, which is lowered in cold-acclimated fish as a result of an increase in PUFA (2,37,38,44). Thus, in the present experiments, the break constancy is consistent with the observed lack of substantial variations in the unsaturation parameters of the FA. The higher position of the WA plot with respect to positions of the SCA and LCA plots confirms the decrease in activity during cold-acclimation. Most of the decrease occurs during the first cold-adaptation period (SCA fish). Over the temperature range tested, the enzyme activities determined at high and low temperatures are never lower than those predicted on the basis of the linearity of both the upper and lower parts of the Arrhenius plots. The results suggest a similar thermosensitivity in differently acclimated sea bass (WA, SCA and LCA groups), at least in the temperature range considered. The temperature of discontinuity and both activation energies do not show any significant variations that can be attributed to cold acclimation.

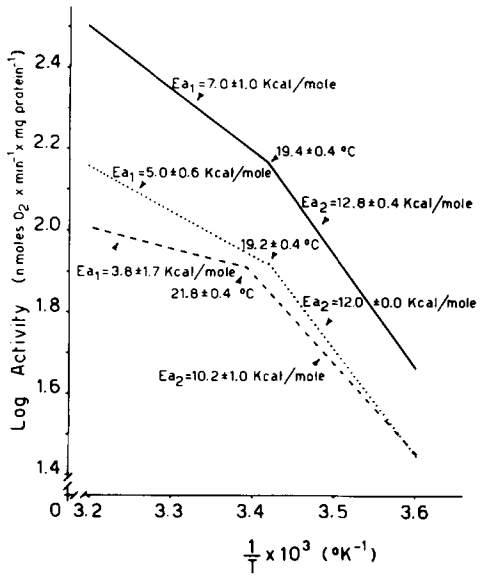

FIG. 2. Arrhenius plot of liver cytochrome oxidase system of WA ——, SCA ····· and LCA —— — fish in the temperature range 40-3°C. Ea_1, Ea_2, activation energies, expressed as Kcal/mole, above and below the temperature of discontinuity. The slopes were calculated from the average activation energies. The point of intersection corresponds to the average temperature of discontinuity (x-axis) and Log enzyme activities (y-axis) from two series of determinations of enzyme activity with no significant variations. In each series of determinations the lines were the best fit from least squares linear regression analysis.

METHOD

Improved Resolution of ^{31}P Nuclear Magnetic Resonance Spectra of Phospholipids from Brain

G. Capuani[a], T. Aureli[a], A. Miccheli[b], M.E. Di Cocco[b], M.T. Ramacci[a] and M. Delfini[b,*]
[a]Institute for Research on Senescence, Sigma Tau, 00040 Pomezia (Rome) and [b]Department of Chemistry, University of Rome "La Sapienza", Rome, Italy

A method is described wherein the resolution of ^{31}P nuclear magnetic resonance spectra of the lipophilic fraction from a Bligh-Dyer extract of rat brain can be enhanced. The lipids are dispersed as micelles in aqueous solution with sodium deoxycholate, and spectral resolution is further optimized by adjusting the pH and by removing ions from the solution. The application of the method to the study of aging in rat brain serves as an example.
Lipids 27, 389-391 (1992).

Changes in phospholipid metabolism which occur in rat brains with aging have been demonstrated previously by ^{31}P nuclear magnetic resonance (NMR) (1,2). However, the studies were mainly concerned with the water-soluble metabolites, such as phosphocholine, glycerophosphocholine, phosphoethanolamine and glycerophosphoethanolamine. To obtain complementary data on more hydrophobic metabolites, including the phospholipids of neural membranes, is of considerable interest.

The Bligh-Dyer modified method has been shown to be most useful for extracting lipids (3,4). Although it gives a water-soluble fraction that produces sufficiently well-resolved ^{1}H and ^{31}P NMR spectra, the resolution achieved for the lipophilic fraction is usually not satisfactory. This makes qualitative and quantitative evaluation by NMR difficult.

In order to overcome these difficulties, a number of techniques have been proposed, including the formation of mixed micelles in aqueous medium by means of detergents (5-7), as well as the use of cesium-containing reagents (8).

In the present paper we report results obtained on rat brain extracts in a study on aging. The simple procedure we describe gives good spectral resolution of the phospholipid ^{31}P NMR signals obtained on the organic phase of the Bligh-Dyer extract.

MATERIALS AND METHODS

Six adult (6 months) and 12 aged (24 months) Fischer 344 male rats (Charles River, Calco, Italy) were sacrificed as previously described (9). The brains were separated from the cerebella and were crushed and pulverized at liquid N_2 temperature. The extraction was done with $CHCl_3$/CH_3OH/H_2O (2:2:1, v/v/v) following the technique by Bligh and Dyer (3) as modified by Miccheli *et al.* (4). The organic phase was separated and then washed with an equal volume of aqueous 100 mM ethylenediaminetetraacetic acid (EDTA) (Sigma Chemical Co., St. Louis, MO) at pH 7. The solution was dried under N_2 until the solvent was completely evaporated, and sodium deoxycholate (Sigma) was added to the lipid residue in a 3:1 (w/w) ratio. The sample obtained was then taken up in D_2O (99.95%; Farmitalia Carlo Erba, Milan, Italy) and an aliquot of a 100 mM Na_3PO_4 stock solution was added as internal reference. The pH was adjusted with 0.1 M NaOH to achieve the best resolution of spectral lines (about 11.4). The dispersion containing about 40 mM total phospholipids was sonicated in a bath sonicator at alternating 30 second intervals until an opalescent appearance was attained (5).

Proton decoupled ^{31}P NMR spectra were measured on a Varian XL-300 spectrometer (Varian Associates, Palo Alto, CA) operating at 121.4 MHz using an acquisition time of 1.5 seconds, a pulse length of 10 μs (45° pulse), and a pulse delay of 1.5 seconds. To ensure that complete relaxation had occurred, control spectra were measured with a pulse delay of 80 seconds; no differences in peak intensities were observed.

The chemical shifts of the phosphorus signals were measured relative to phosphonitrilic chloride (trimer) in benzene as an external reference. Values are reported in parts per million (ppm) relative to H_3PO_4, 85% (trimer, 20.8 ppm) (10). Assignments were made based on chemical shift values reported in literature and by comparison with pure standards.

Statistical analyses were by Student's *t*-test. The difference between two means was considered insignificant when $P > 0.05$.

RESULTS AND DISCUSSION

Figure 1a shows the ^{31}P NMR spectrum of the organic phase of the Bligh-Dyer extract from an adult rat brain redissolved in $CDCl_3$/CD_3OD (2:1, v/v). Figure 1b shows a spectrum of an analogous sample in aqueous dispersion after treatment with sodium deoxycholate. Seven major signals are present in the lower spectrum (Fig. 1b) which can be assigned to phosphatidic acid (PA), PO_4^{3-}, phosphatidylethanolamine (PtdEtn) + PtdEtn plasmalogen, phosphatidylserine (PtdSer), sphingomyelin (CerCho), phosphatidylinositol (PtdIns) and phosphatidylcholine (PtdCho) + PtdCho plasmalogen. The assignments and chemical shift values are listed in Table 1. All signals show a half-height bandwidth of less than 8 Hz.

In the $CDCl_3$/CD_3OD spectrum (Fig. 1a), the peak at 1.31 ppm corresponds to the overlapping signals of PtdEtn and PtdSer. However, these two signals are well resolved in the spectrum (Fig. 1b) of the deoxycholate

^{31}P NMR Chemical Shifts of the Major Phospholipids from Rat Brain[a]

	Chemical shift (ppm)
PA	4.621
PO_4^{3-}	3.509
PtdEtn	0.989
PtdSer	0.855
CerCho	0.657
PtdIns	0.168
PtdCho	0.044

[a]ppm from H_3PO_4 (85%); for sample preparation, see Materials and Methods (data from Fig. 1b).

treated sample in water (0.989 and 0.855 ppm, respectively). In Figure 1a, the signal corresponding to CerCho is only a shoulder of the PtdEtn/PtdSer peak, while it is well-resolved at 0.657 ppm in the spectrum obtained after deoxycholate treatment. The signal corresponding to PtdIns is not visible in the $CDCl_3/CD_3OD$ spectrum, while it occurs as a low intensity peak at 0.168 ppm after treatment of the sample with detergent.

Meneses and Glonek (8) had previously analyzed (by NMR) phospholipid mixtures from animal and plant extracts by using another approach to minimize aggregation, which produced spectral half-height bandwidths of 1.8–3.2 Hz at a magnetic field strength of 11.75 T. Although this technique gave qualitative and quantitative data comparable to those obtained by chromatographic techniques, sample preparation is more complex. Use of detergents with an excess of EDTA to form micelles in aqueous medium was described by London and Feigenson (5). However, their spectra, measured at pH 8, did not show optimal resolution, particularly for PtdEtn, PtdSer and CerCho. Sappey Marinier *et al.* (6) employed a similar approach and evaluated the effect of pH and detergent/phospholipid ratio using Triton X-100 as detergent. The presence of metal cations appeared to be responsible for the wider bandwidths and for observed differences in chemical shift values reported by these authors.

The technique described here seems to provide an excellent alternative to previous methods. The absence of cations minimizes various ion effects on the polar phospholipid headgroups which contributes to a reduction in bandwidth of signals obtained on micelles formed by sonication in the presence of deoxycholate. The resolution thus attainable allows the qualitative and quantitative determination of the different phospholipid components.

Sotirhos *et al.* (11) had obtained ^{31}P spectra with a similar resolution on egg and liver extracts using hexane/propanol (3:2, v/v) as solvent. The Bligh-Dyer extraction, however, offers distinct advantages as it is quantitative, and eliminates lipid hydrolysis which can occur in the presence of perchloric acid (4). In addition, the Bligh-Dyer method gives a hydrophilic and a lipophilic phase from the same sample, each of which lend themselves to further study.

The possibilities offered by the present deoxycholate method allowed us to examine various cerebral extracts from adult (6 months) and aged (24 months) rats. The data obtained are reported in Table 2. The concentrations are expressed as percentages of total phosphorus content. The comparison between the phospholipid levels in the two populations shows no significant differences in PtdEtn, PtdSer, PtdIns and PtdCho, while a significant increase (+31.77%; $p < 0.005$) in CerCho levels is observed in the aged rats.

An increase in CerCho associated with an increase in PtdSer during the developmental process in rat brain was previously reported by Wells and Dittmer (12). This was assumed to be the result of an active myelination process.

TABLE 2

Phospholipid Composition of Bligh-Dyer Extract from Adult and Aged Rat Brains[a]

	Adult (n=6)		Aged (n=12)	
	Mean	SD	Mean	SD
PA	1.02	0.17	1.35	0.13
PtdEtn	43.92	2.09	43.08	1.67
PtdSer	11.68	0.98	11.92	1.03
CerCho[b]	2.99	0.54	3.94	0.66
PtdIns	2.78	1.11	3.24	0.79
PtdCho	34.76	2.65	34.01	1.37

[a]Values are expressed as percent of total phosphorus content.
[b]$P < 0.005$.

Variations in CerCho metabolism are known to occur in various pathological states, including cancer, atherosclerosis and Niemann-Pick disease (13).

Our present data do not allow us to clarify the causes of the observed phenomenon. Increased CerCho levels may be the result of decreased sphingomyelinase activity during aging, as it has been proposed for similar variations observed in aorta and in the lens of the eye (14,15).

ACKNOWLEDGMENTS

The authors wish to thank Prof. F. Conti for helpful discussions, and Mrs. L. Mattace for help with the English.

One-Step Synthesis of Radioactive Acyl-CoA and Acylcarnitines Using Rat Liver Mitochondrial Outer Membrane as Enzyme Source[1]

A.K.M. Jalaluddin Bhuiyan[2] and **S.V. Pande***

Laboratory of Intermediary Metabolism, Clinical Research Institute of Montreal and Department of Experimental Medicine, University of Montreal, Montreal, Quebec H2W 1R7, Canada

Rat liver mitochondrial outer membrane enriched preparations have proven to be a convenient enzyme source for synthesizing coenzyme A (CoA) and carnitine esters of radioactive fatty acids. These membranes are simple to isolate and they retain acyl-CoA ligase and carnitine palmitoyltransferase activities well upon storage. Enzyme purification is not required. A novel aspect of the present procedure is that the same enzymatic incubation step allows both the acyl-CoA and the acylcarnitine esters to be obtained simultaneously when carnitine is present, but produces acyl-CoA ester only when carnitine is not included. Under the conditions described, the conversion of [1-^{14}C]octanoic acid to the respective esters was about 95%; the corresponding figure for [1-^{14}C]palmitic acids was over 70%. The procedure seems suitable for synthesizing the labeled CoA and carnitine esters from a variety of radioactive fatty acids.

Lipids 27, 392–395 (1992).

Metabolic fatty acid studies frequently require the use of radioactive coenzyme A (CoA) and carnitine esters. However, these derivatives are not readily available even for some of the more common fatty acids. Also, several chemical methods that have been described do not give high yields when working with submicromolar quantities (see refs. 2 and 3). While procedures for synthesizing acyl-CoA esters of radioactive fatty acids have been described (4–6), micromethods for synthesizing labeled acyl carnitines in acceptable radioisotopic yields are not available.

We describe here a novel enzymatic procedure using an outer membrane enriched preparation of rat liver mitochondria as the source of the fatty acyl-CoA ligase and carnitine acyltransferase activities. The procedure allows us to obtain the fatty acyl esters of carnitine and CoA by the same incubation. The system yields acyl-CoA ester alone when carnitine is not included. The procedure is relatively simple, does not require purification of enzymes, and gives radioisotopic yields of 70–95% with [1-^{14}C]-palmitic acid and [1-^{14}C]octanoic acid, respectively, as substrates.

EXPERIMENTAL PROCEDURES

Isolation of an outer membrane enriched preparation from mitochondria. Rat liver mitochondria and outer membrane enriched preparations are isolated by previously described procedures, except for minor modifications (7–10). The isolation procedures are carried out at 0–4°C. Freshly removed rat livers (*ca.* 60 g) are washed, minced, and a 15% (w/v) homogenate is prepared in 210 mM mannitol, 70 mM sucrose, 0.1 mM ethylenediaminetetraacetic acid (EDTA), and 10 mM *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) (pH 7.4). The homogenate is centrifuged for 10 min at 500 × *g* and the resulting supernatant is spun at 1500 × *g* for 5 min, then at 8,000 × *g* for 10 min. The supernatant, along with the lightly packed layer on the surface of the pellet, is aspirated off and the pellet is rinsed twice with a small volume of the homogenizing medium to further remove the lightly packed material. The pellet is suspended in fresh homogenizing medium and then centrifuged for 3 min at 500 × *g* to sediment any remaining blood cells, etc. The supernatant is then spun at 8,000 × *g* for 10 min. The resulting pellet is suspended in fresh homogenizing medium, recentrifuged for 10 min at 8,000 × *g*, then rinsed as above to remove the lightly packed material. The rinsed pellets are finally suspended in 10 mL of the homogenizing medium yielding a mitochondrial fraction that contains 750–950 mg protein.

To obtain outer membrane enriched vesicles (OMV) by the swelling/shrinking procedure, the above mitochondrial suspension is diluted to 300 mL with 20 mM potassium phosphate, pH 7.2, containing 0.02% bovine serum albumin, and left at 0°C for 20 min. Then 37 mL of 15 mM ATP and 37 mL of 15 mM $MgCl_2$ are added. After 4 min at 0°C, the suspension is spun at 35,000 × *g* for 20 min, and the pellets are suspended in about 100 mL of 20 mM potassium phosphate (pH 7.2) containing 0.02% bovine serum albumin, 1.5 mM ATP, and 1.5 mM $MgCl_2$. The suspension is spun at 4,000 × *g* for 10 min, and the pellet is discarded. The supernatant is recentrifuged at 150,000 × *g* for 60 min. The resulting pellets are suspended in 3.8 mL of 20 mM potassium phosphate (pH 7.2), and 0.6-mL aliquots are layered separately, in six centrifuge tubes (SW 60Ti rotor) on top of a sucrose gradient; the sucrose gradient consists, from bottom to top, of 1 mL of 51.3% sucrose in 20 mM potassium phosphate, 1 mL of 37.7% sucrose in 20 mM potassium phosphate, and 1 mL of 25.3% sucrose in 20 mM potassium phosphate. The tubes are centrifuged at 115,000 × *g* for 60 min. The first top band containing mostly outer membrane fragments with fatty droplets is aspirated off. The second band from top, at the interphase of 25.2% and 37.7% sucrose, is collected, diluted 1:4 with chilled 20 mM potassium phosphate (pH 7.4) having protease inhibitors (0.5 mM phenylmethanesulfonyl fluoride, 25 μg/mL leupeptin, 20 μg/mL pepstatin) and spun again at 150,000 × *g* for 60 min. The pellet obtained is suspended, by gentle vortexing, in 1 mL of 250 mM sucrose and 5 mM potassium phosphate (pH 7.2) containing protease inhibitors as above, to obtain an outer membrane enriched preparation (OMV) containing 10–15 mg protein.

Abbreviations: CoA, coenzyme A; CPT_o, outer carnitine palmitoyltransferase; EDTA, ethylenediaminetetraacetic acid; HEPES, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; OMV, outer membrane enriched vesicles.

The OMV thus prepared show a parallel enrichment of the specific activities of the outer membrane marker, monoamine oxidase, and of the malonyl-CoA sensitive carnitine palmitoyltransferase which is 12–20-fold enriched over the activity in the mitochondrial preparation (9). Aliquots of OMV are stored at −80°C, and can be used for acyl-CoA and acylcarnitine syntheses for at least three months (the longest period tested). The palmitoyl-CoA synthetase activity of these OMV is about 625 nmol/min/mg protein (9). The specific activity of outer carnitine palmitoyltransferase (CPT_o) with palmitoyl-CoA as substrate varies from 40 to 70 nmol/min/mg under the assay conditions described previously (9) at 2 mM carnitine. The CPT_o specific activity with octanoyl-CoA as substrate is 150–230 nmol/min/mg when assay conditions are as described by Murthy *et al.* (11), except that the concentration of potassium phosphate is 100 mM and that of carnitine is 5 mM. No noticeable change in activities is found following storage of OMV preparations at −80°C for 3 months.

Synthesis of palmitoyl-CoA and palmitoylcarnitine. The reaction system contains, in 1 mL, 250 mM potassium phosphate (pH 7.4), 1.9 mM CoA, 5 mM ATP, 1 mM L-carnitine, 10 mM $MgCl_2$, 1 mg bovine serum albumin, 185 nmole [1-^{14}C]palmitate (10 μCi), and OMV corresponding to 50 μg of protein. Incubations are carried out for 90 min at 37°C with shaking. Reactions are stopped by the addition of 50 μL of 5 M HCl, and chilling. Unused palmitic acid is removed by extracting four times with 3-mL portions of diethyl ether. The aqueous phase is then extracted three times with 3-mL portions of water-saturated butanol. The combined butanol phases are washed twice with 2 mL of butanol-saturated water and are then lyophilized. The residue is taken up in 2 mL of 80% (v/v) methanol, its pH is brought to 5–6 with 1 M KOH, and then the solution is passed through a DEAE Sephacel column (acetate form, 5 mm × 50 mm, equilibrated with 80% methanol). A further 6 mL of 80% methanol is then passed through the column to complete palmitoylcarnitine elution. The palmitoyl-CoA is then eluted from the DEAE Sephacel column with 9 mL of 80% methanol containing 10 mM acetic acid and 0.5 M ammonium acetate. The solvent is evaporated under a stream of nitrogen, and the material is lyophilized. The radioactive palmitoyl-CoA thus obtained, while radioisotopically pure, shows some carryover of CoA as a contaminant. A CoA-free product is obtained, if desired, by using a further high-pressure liquid chromatographic step (HPLC) as described later in Results and Figure 2. The palmitoyl-CoA peak is collected and the acetonitrile is evaporated under a stream of nitrogen. The aqueous residue is lyophilized, and the dried material is extracted with methanol/butanol (1:1, v/v), leaving behind potassium phosphate.

Synthesis of octanoyl-CoA and octanoylcarnitine. The reaction system contains, in 1 mL, 250 mM potassium phosphate (pH 7.4), 1.9 mM CoA, 5 mM ATP, 1 mM L-carnitine, 10 mM $MgCl_2$, 170 nmole [1-^{14}C]octanoic acid (10 μCi), and 50 μg OMV protein. Incubations are for 90 min at 37°C with shaking. Reactions are stopped by the addition of 50 μL of 5 M HCl, and chilling. Unused octanoic acid is removed by extracting four times with 3-mL portions of diethyl ether. The pH of the aqueous phase is brought to 5–6 by addition of 1 M KOH, and then the solution is passed through a DEAE Sephacel column (acetate form, 5 mm × 50 mm, equilibrated with 80% methanol). Six mL of 80% methanol is further passed through the column to completely elute octanoylcarnitine and carnitine together. Nine mL of 80% methanol containing 10 mM acetic acid and 0.5 M ammonium acetate is then passed through the column to elute octanoyl-CoA and CoA together.

The octanoylcarnitine is separated from free carnitine by blowing off the methanol under nitrogen, dissolving the residue in 1 mL of water, and extracting the aqueous phase three times each with 3 mL of water-saturated butanol. The combined butanol phases are washed twice with 2 mL of butanol-saturated water and are then lyophilized to obtain octanoylcarnitine.

For isolating octanoyl-CoA, the ammonium acetate eluent is lyophilized, the residue is taken up in 1.5 mL of water, and pH is adjusted to 5–6. If a CoA-free product is desired, aliquots are further purified by HPLC (see below). Otherwise the solution is applied onto a 3-mL, open, pre-packed C_{18} reverse phase column (Supelclean of Supelco, Oakville, Ontario, Canada; washed with water, methanol, then water). The eluent is passed through the column three more times, then the column is washed with 2 mL of acetonitrile/50 mM potassium phosphate (5:95, v/v; pH 5.6). This elutes most of the CoA. Octanoyl-CoA is next eluted with 5–6 mL of acetonitrile/50 mM potassium phosphate (60:40, v/v; pH 5.6). The eluent contains radioisotopically pure octanoyl-CoA (see Results and Fig. 2), but a variable CoA contamination is frequently found upon analyzing the product by reversed phase HPLC. When a CoA-free product is desired, it is obtained by omitting the above open column step. The material is instead purified by reversed phase HPLC (see Fig. 2 for details). The octanoyl-CoA peak is collected, and the eluent is removed by a stream of nitrogen. The residual aqueous phase is lyophilized and the dried residue is extracted with methanol/butanol (1:1, v/v) to eliminate potassium phosphate.

RESULTS AND DISCUSSION

Table 1 shows that with [1-^{14}C]octanoic acid and [1-^{14}C]-palmitic acid, the incubation produced the corresponding esters of CoA or of CoA and carnitine in isotopic yields of about 95 and 74%, respectively. These yields were not noticeably affected by variations in incubaton time (from 30 to 180 min) or by variations in the quantity of OMV protein used (from 5 to 200 μg). Yields started to decline only when more than 300 μg of protein was present; yields were 68% with 1 mg OMV protein. Use of a high salt concentration, *i.e.*, 250 mM potassium phosphate, at the incubation step made it possible to lower the quantity of OMV protein to 5 μg and still obtain optimal yields of the acyl esters (Table 1). This is likely the result of an activating/stabilizing effect of the salt on the outer carnitine palmitoyltransferase (12) and acyl-CoA ligase activities (13). With freshly dissolved samples of CoA, inclusion of 5 mM dithiothreitol did not change product yields.

Table 1 shows also that comparable yields of the CoA esters alone, of about 73 and 92% with palmitic and octanoic acids, respectively, are obtained when carnitine is not added. When carnitine is included, the final reaction mixture contains the acyl-CoA and acylcarnitine products;

TABLE 1

Conversion of Palmitic and Octanoic Acids to their CoA and Carnitine Esters as Effected by the Quantity of OMV Protein and Incubation Time[a]

[1-^{14}C]Fatty acid	OMV protein (μg)	Incubation time (min)	Carnitine	% Conversion to	
				Acyl-CoA ester	Acyl-CoA + acylcarnitine
Palmitic acid[b]	60	120	+		73-79
Palmitic acid	60	120	−	71-75	—
Octanoic acid[c]	1000	90	+	—	66-70
Octanoic acid	400	120	+	—	85-90
Octanoic acid	25-200	90	+	—	95 ± 2.1 (n=7)
Octanoic acid[b]	5-30	90	+	—	94 ± 7.1 (n=6)
Octanoic acid	30-60	90	−	94-97	—
Octanoic acid	300	15	+	—	65
Octanoic acid	300	30-180[d]	+	—	87-95

[c]With 100 mM potassium phosphate (pH 7.4).

[d]Six time points in between.

in several mixtures that were analyzed, the two acyl esters were found present in about equal proportions with both [1-^{14}C]palmitic acid and [1-^{14}C]octanoic acid.

Figure 1 shows the characterization of the synthesized [1-^{14}C]palmitoylcarnitine and [1-^{14}C]octanoylcarnitine as *p*-bromophenacyl derivatives by HPLC. In both cases, a single radioactivity peak emerged in the area expected, indicating that the acylcarnitines synthesized were radioisotopically pure. Similarly, HPLC of the [1-^{14}C]-palmitoyl-CoA and [1-^{14}C]octanoyl-CoA preparations (see Fig. 2 for details) showed that each of these products emerged at the expected retention time with 91-96% recovery of the radioactivity applied. No other radioactivity peaks were detected, confirming the radiopurity of the acyl-CoA products synthesized.

For the synthesis of acylcarnitines and acyl-CoA esters, we found the OMV of rat liver mitochondria to be a convenient source of the required enzyme activities. Firstly, the OMV are relatively simple to isolate and their use obviates the need for purifying the enzymes, and particularly the carnitine palmitoyltransferase. Secondly, OMV show high specific activities of the acyl-CoA ligase and the outer carnitine palmitoyltransferase (CPT_o) (see Methods and ref. 9), so that microgram quantities of OMV suffice for preparing microCurie quantities of the products. Thirdly, OMV acyl-CoA ligase and CPT_o activities are stable during storage as long as repeated freeze-thawing is avoided. No noticeable change in enzyme activities was observed following three months of storage of the OMV in the frozen state (−80°C) or as lyophilized material (the latter was reconstituted with water before use). The radioisotopic yields of the acyl-CoA and acylcarnitine esters obtained with frozen or lyophilized OMV preparations were similar to those obtained with freshly isolated OMV (74 ± 4% with [1-^{14}C]palmitic acid and 95 ± 6 [n = 8] with [1-^{14}C]octanoic acid). Fourthly, the OMV preparations showed little acyl-CoA hydrolase activity. Fifthly, use of OMV allows the acyl-CoA and acylcarnitine both to be synthesized simultaneously.

The details of the incubation and product isolation conditions described here are those found optimal for obtaining CoA and carnitine esters of palmitic and octanoic acids. The same procedure should, however, allow the CoA and carnitine esters of other fatty acids to be obtained in a like manner inasmuch as the acyl-CoA ligase and CPT_o of OMV show broad substrate specificity and the isolation steps also should be applicable for isolating the corresponding esters of other fatty acids. The methods should be of particular interest to those involved in studies on fatty acid oxidation. Several metabolic disorders related to impaired fatty acid oxidation recently have been recognized (17), the investigation of which frequently requires CoA and carnitine esters of different fatty acids.

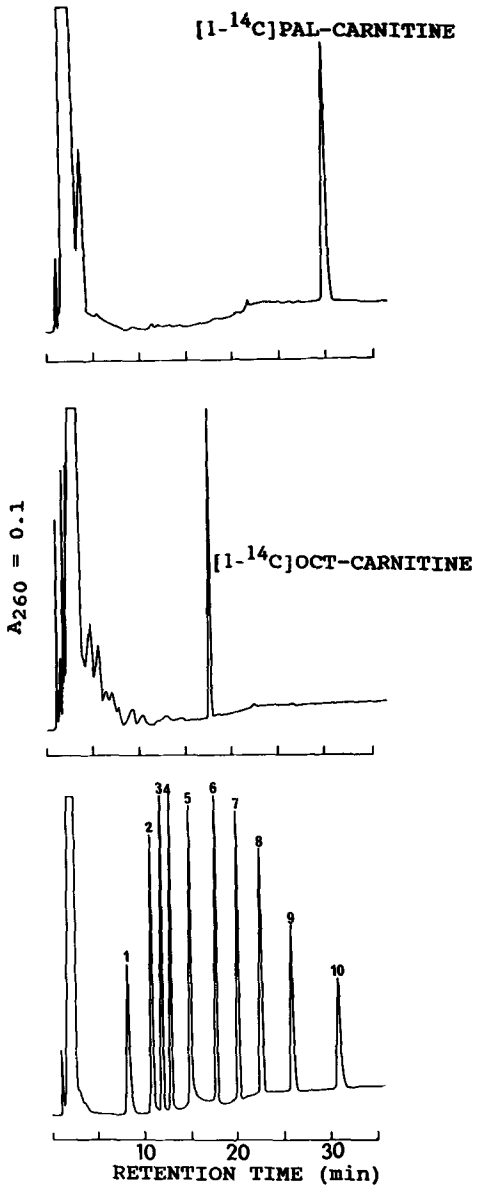

FIG. 1. Characterization of synthesized acylcarnitines as *p*-bromophenacyl derivatives by reversed phase HPLC. The *p*-bromophenacyl derivatives of the carnitines were prepared as in (14) and were resolved as in (15), except for minor modifications. A ternary gradient of acetonitrile (A), water (B) and 0.15 M triethylamine phosphate (pH 5.6) (C) was used as follows: Isocratic 70% (v/v) A, 28% B, 2% C, 6 min; linear gradient 70–80% A, 28–18% B, 2% C, 4 min; linear gradient 80–90% A, 2–10% C, 15 min; linear gradient 90–93% A, 10–7% C, 10 min; linear gradient 93–70% A, 0–28% B, 7–2% C, 5 min. The flow rate was 1.5 mL/min. A Varian 9010 solvent delivery system with a Supelcosil LC-8 (5 micron) column (25.0 cm × 4.6 mm) was used for HPLC. The top two panels show results obtained with the [1-^{14}C]palmitoylcarnitine and [1-^{14}C]octanoylcarnitine synthesized. The bottom most panel shows results obtained with a standard mixture of acylcarnitines that contained: 1, carnitine; 2, acetylcarnitine; 3, propionylcarnitine; 4, butyrylcarnitine; 5, hexanoylcarnitine; 6, octanoylcarnitine; 7, decanoylcarnitine; 8, dodecanoylcarnitine; 9, tetradecanoylcarnitine; and 10, hexadecanoylcarnitine.

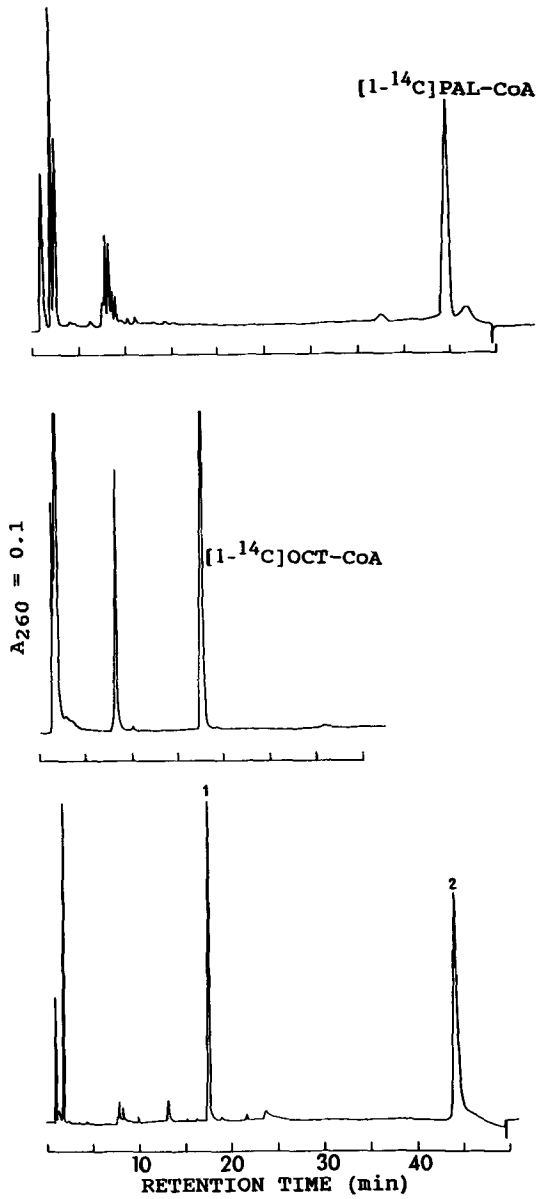

FIG. 2. Purification and characterization of synthesized acyl-CoA esters by reversed phase HPLC. The HPLC system is as in Figure 1, but an LC_{18} column was used. Acyl-CoA esters were resolved (16) by the following gradient of acetonitrile in 50 mM KH_2PO_4 (pH 5.3): Isocratic 5% (v/v), 5 min; isocratic 10%, 0.1 min; linear gradient 10–30%, 9.9 min; linear gradient 30–50%, 30 min; linear gradient 50–5%, 5 min. The flow rate was 2.0 mL/min. The top two panels show the results obtained with the synthesized [1-^{14}C]palmitoyl-CoA and [1-^{14}C]octanoyl-CoA, while the bottom most panel shows results with a standard mixture of octanoyl-CoA (peak 1) and palmitoyl-CoA (peak 2).

COMMUNICATION

High-Performance Liquid Chromatographic Separation of Enantiomeric Benzyl Glycerides[1]

Thomas A. Foglia* and **Kazuhito Maeda**[2]
U.S. Department of Agriculture, ARS, Eastern Regional Research Center, Philadelphia, Pennsylvania 19118

The enantiomeric resolution of a series of 1,2-diacyl- and 1,2-mixed acid-diacyl-3-benzyl-*rac*-glycerols was investigated by high-performance liquid chromatography (HPLC). Of the racemic benzylglycerols studied, the 1-*O*-benzyl-2,3-*O*-iso-propylidene-*rac*-glycerol, 1-acyl-3-benzyl-*rac*-glycerol and 2-acyl-3-benzyl-*rac*-glycerol structures could be resolved into their enantiomers. The latter were resolved on a silica (10 μm) column coated with cellulose tribenzoate by isocratic elution with hexane/isopropanol mixtures as mobile phase. The effects of para substitution of the benzyl moiety on the resolution of the acylbenzylglycerols by this HPLC method were evaluated.
***Lipids* 27, 396–399 (1992).**

1,2-Diacyl-*sn*-glycerols are activators of protein kinase C (PKC), an enzyme which plays an important role in signal transduction (1–5). To investigate the structural requirement of diacylglycerols as protein kinase C activators, enantiomeric 1,2-diacyl-*sn*-glycerols have been synthesized (4,5). Typical synthetic methods for the synthesis of enantiomeric 1,2-diacyl-*sn*-glycerols require optically active precursors, such as D-mannitol (6,7). The procedures typically involve a number of synthetic steps, produce relatively low yields, and cause racemization during synthesis.

A variety of chiral stationary phase (CSP) high-performance liquid chromatography (HPLC) columns have been developed recently and have been used to separate chiral compounds into their optical isomers (8). CSP HPLC columns also have been used on a preparative scale to isolate pure enantiomers (9). Thus, it may be easier to separate by HPLC selected racemic intermediates into their enantiomers, rather than to synthesize enantiomers from optically active compounds as starting materials. Using this approach, we recently reported the separation of enantiomeric alkyl glycerol ethers on a cellulose tribenzoate CSP HPLC column (10).

In the present study, we investigated the enantiomeric separation of several synthetic intermediates that are encountered in the synthesis of 1,2-diacylglycerols. We investigated the separation of 1,2-monoacid-diacylglycerols as well as of 1,2-mixed acid-diacylglycerols because different synthetic routes are required for their preparation.

MATERIALS AND METHODS

Materials. Oleic acid (99%, Extra Oleic 99) was obtained from Nippon Oil & Fats Co. (Tokyo, Japan). All other reagents used for the syntheses were obtained from Aldrich Chemical Co. (Milwaukee, WI). *n*-Hexane and isopropanol used for HPLC were obtained from American Burdick & Jackson (Muskegon, MI).

Analytical system. The HPLC system used in this study was a Beckman Model 110A instrument (Beckman Instruments, San Ramon, CA) which was connected to an ultraviolet detector (Spectroflow 773, Kratos Instruments, Ramsay, NJ) and an HP 3396A integrator (Hewlett-Packard, Avondale, PA); a Waters Differential Refractometer Model R 401 detector (Waters Associates, Milford, MA) was used as required. The analytical HPLC column used was a Microsorb Si, 4.6 mm i.d. × 25 cm, 5 μm silica column (Rainin Instrument Co., Woburn, MA). The preparative silica column was a Dynamax Macro Si, 10 mm i.d. × 25 cm, 8 μm (Rainin Instrument Co.). The CSP HPLC column was a Bakerbond Chiralcel OB, 4.6 mm i.d. × 25 cm stainless steel column prepacked with 10 μm silica coated with cellulose tribenzoate (J.T. Baker, Phillipsburg, NJ). Columns were eluted isocratically with n-hexane/isopropanol (varying in composition from 96:4 to 99:1, v/v). In the case of the analytical column and the CSP column, sample concentrations were 1% (w/v) in mobile phase as solvent; injection volumes were 20 μL, and the flow rate was 0.5 or 1 mL/min. For preparative separations, sample concentrations were 50% (w/v), injection volumes were 100 μL, and the flow rate was 5 mL/min.

Syntheses. As shown in Figure 1, 1-*O*-benzyl-2,3-*O*-isopropylidene-*rac*-glycerol **2a** was synthesized by benzylation of racemic glycerol acetonide **1** with benzyl chloride in the presence of aq. NaOH and tetrabutylammonium bromide (11). 1-*O*-(4-Substituted-benzyl)-2,3-*O*-isopropylidene-*rac*-glycerols **2b–d** were obtained in a similar manner.

As illustrated in Figure 2, 1-benzyloxy- and 1-(4-substituted-benzyloxy)-2,3-epoxy-propanes **5a–c** were obtained by benzylation of epichlorohydrin **4** with benzyl or 4-substituted benzyl alcohols in the presence of aq. NaOH and tetrabutylammonium bromide. 1-*O*-Benzyl- and 1-*O*-(4-substituted-benzyl)-3-acyl-*rac*-glycerols **6a–c** were obtained by acylation of **5a–c** with fatty acid in the presence of tetraethylammonium bromide (12). Their 2-acyl-isomers **7a–c**, formed as co-products in the latter reaction, were separated and purified by preparative HPLC on the silica column.

All compounds were identified by infrared (IR) and ^{13}C nuclear magnetic resonance (NMR) spectroscopy, and purity confirmed by analytical HPLC (Table 1).

RESULTS AND DISCUSSION

Enantiomeric HPLC separation of synthetic intermediates for enantiomeric 1,2-monoacid-diacyl-glycerol. We previously reported that racemic glycerol acetonide **1** (Fig.

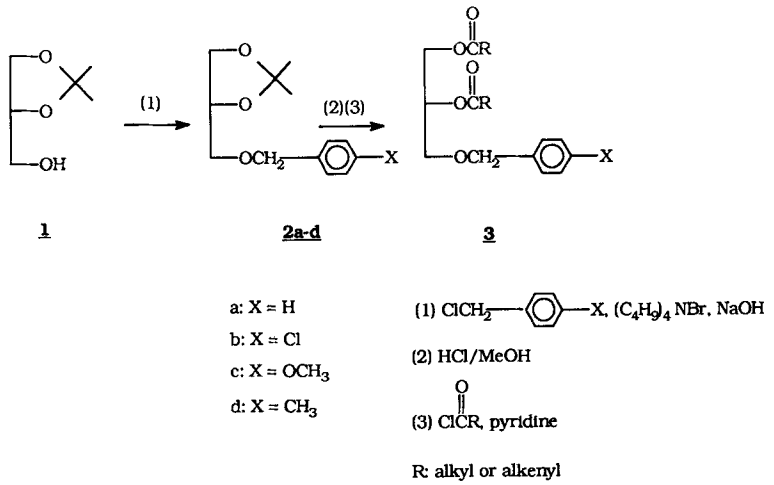

FIG. 1. Synthesis of racemic 1,2-diacylglycerols.

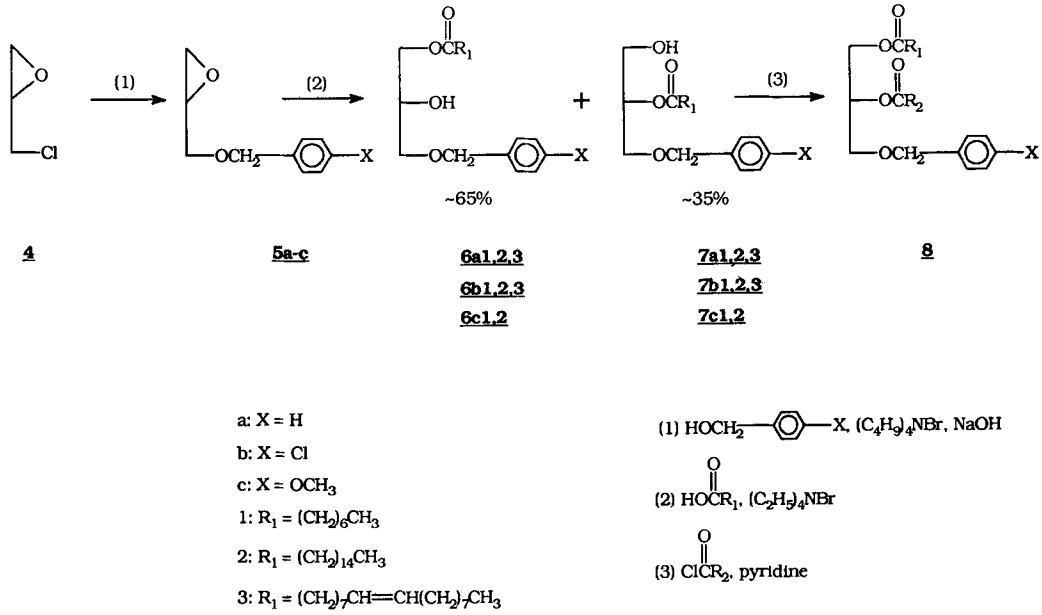

FIG. 2. Synthesis of racemic 1,2-mixed-acid-diacylglycerols.

1) and its 1-*O*-benzyl derivative **2a** (Fig. 1) can be separated into their enantiomers using a cellulose tribenzoate CSP HPLC column (abbreviated as "OB" below) (10). However, the enantiomers of glycerol acetonide may not be suitable synthetic intermediates for preparative isolation because they tend to racemize, and compound **2a** does not completely resolve into its enantiomer, which is required for preparative purposes (10). In an attempt to improve the enantiomeric resolution of **2a**, we prepared 4-substituted-benzyl analogs **2b–d** (Fig. 1) and examined their enantiomeric separation using the CSP HPLC column. Table 2 gives the chromatographic data obtained in the present study on the resolution of 1-*O*-benzyl and 1-*O*-(4-substituted-benzyl)-*rac*-glycerols. The separation factor (α) and resolution (R_s) values observed for **2a–d** were in the following order: compound **2c>2b>2d>2a**, which corresponds to a para substituent order of OCH_3>Cl>CH_3>H. Interaction between the phenyl moieties of the sample compound and the chiral stationary phase have been often cited in describing the mechanism of chiral recognition. It has been reported that electron-donating substituents on the phenyl moieties of the cellulose tribenzoate CSP (13) or the analyte compounds (14) improve the effective chiral recognition of the CSP. However, from our results for compound 2 (Fig. 1), it appears that the stronger the electron-donating substituent (*e.g.* OCH_3) or the electron-withdrawing (*e.g.* Cl) substituent effect on the phenyl moiety, the better an enantiomeric resolution is achieved.

We also examined the enantiomeric separation of several racemic 1,2-monoacid-diacyl-3-benzyl- or (4-substituted-benzyl-glycerols **3** (Fig. 1) on the CSP column; however, none of these intermediates could be separated into enantiomers.

TABLE 2

Enantiomeric Separation of 1-Benzylglycerols 2a–d

Compound	Capacity factor K′	Separation factor α	Resolution R_s
2a	3.31	1.19	0.70
2b	3.19	1.50	1.23
2c	11.08	1.54	1.46
2d	3.36	1.50	0.82

Because a desirable base-line separation (R_s>1), a criterion that must be met to resolve enantiomers, was obtained with **2b** and **2c**, we considered these compounds useful as synthetic intermediates for preparing diacylglycerols in which both acyl residues are the same (Fig. 1).

Enantiomeric HPLC separation of synthetic intermediates for the preparation of enantiomeric 1,2-mixed acid-diacyl glycerols. The synthetic scheme used for preparing racemic 1,2-mixed acid-diacylglycerols is shown in Figure 2 (11,12). Compounds **6a–6c** are candidates for separation into their enantiomers because they contain the requisite functional groups, namely an ester, a hydroxy group and an aromatic ring. We have previously shown that these structural features enhance the enantiomeric separation on the CSP column (10). In the present study, we also prepared several 1-*O*-benzyl- and 1-*O*-(4-substituted-benzyl)-3-acyl-glycerols **6a–c,1-3** to examine their enantiomeric separation on the CSP column. The 2-acyl isomers **7a–c,1-3**, which are formed as co-products, were purified and isolated by preparative HPLC and their enantiomeric separation was also investigated.

Table 3 gives the chromatographic data for the racemic 1-acyl and 2-acyl-3-benzyl-glycerols prepared in this study. Compounds **6a–c,1-3** were separated only partially into their enantiomers or were not separated at all on the CSP column. On the other hand, the corresponding 2-acyl isomers **7a–c,1-3** were resolved into their enantiomers with a good separation factor (α) and resolution (R_s) and with most giving a base-line separation (R_s>1). These results demonstrate that an ester group at the 2-position of the glycerol backbone contributes more substantially to the enantiomeric separation than does an ester group at the 3-position of the glycerol backbone. This is in agreement with our previous study where we reported that 1-*O*-hexadecyl-2-*O*-benzyl-*rac*-glycerol was successfully separated into its enantiomers by the CSP column, whereas the corresponding 3-benzyl isomer was not resolved at all (10). From our previous results and based on the present data, it is concluded that a selected functional group, *e.g.*, the ester or benzyl group, needs to be attached at the 2-position of the glycerol backbone to accomplish a successful enantiomeric separation on a CSP column.

The effect of the substituents on the phenyl moiety on enantiomeric separation was less clear because, in the case of the octanoyl and oleoyl glycerols **7a1** and **7a3**, the nonsubstituted benzyl derivatives showed better enantiomeric separation than the substituted benzyls **7b1** and

TABLE 3

Enantiomeric Separation of 1(2)-Acyl-3-benzylglycerols 6 and 7

	rac-Glycerol position			Enantiomeric separation		
	1[a]	2	3	K′	α	R_s
6a,1	phenyl		octanoyl	10.7	1.19	0.83

7c,1	4-methoxyphenyl	octanoyl		26.4	1.33	1.04
7a,2	phenyl	palmitoyl		2.8	1.0	0.4
7b,2	4-chlorophenyl	palmitoyl		7.2	1.34	1.13
71,3	phenyl	oleoyl		4.8	1.60	1.40
7b,3	4-chlorophenyl	oleoyl		6.3	1.82	1.17

[a]The phenyl moiety referred to is that of the benzyl group located at position-1 of glycerol (see Fig. 2).

7b3. We also attempted to separate several racemic 1,2-mixed acid-diacyl-3-benzyl- or (4-substituted-benzyl)-glycerols 8 using the CSP column. However, enantiomeric separation was not achieved.

Based on the present data we conclude that 2-acyl-3-benzyl-glycerols, such as compounds **7a–c** (Fig. 2, Table 3), have the best potential as intermediates for the preparative enantiomeric separation of the racemic compounds. Because the 2-acyl-3-benzyl-glycerols are co-products of the synthetic pathway we have used (Fig. 2), alternate synthetic routes by which the 2-acyl isomers are obtained as major products are under investigation.

REVIEW

Dietary Ether Lipid Incorporation into Tissue Plasmalogens of Humans and Rodents

Arun K. Das[a], Ronald D. Holmes[b], Golder N. Wilson[c] and Amiya K. Hajra[a,*]
[a]Mental Health Research Institute and Department of Biological Chemistry and [b]Department of Pediatrics, University of Michigan, Ann Arbor, Michigan 48104 and [c]Department of Pediatrics, University of Texas, Southwestern Medical Center, Dallas, Texas 75235

Chronic feeding of 1-*O*-octadecyl-*sn*-glycerol (batyl alcohol) to patients suffering from congenital deficiency in tissue ether glycerolipids showed an increase in the plasmalogens content of their erythrocytes. However, nothing is known about the ether lipid content of other tissues in these patients. Feeding 1-*O*-heptadecyl-*sn*-glycerol to young rats showed that this uncommon ether lipid was incorporated to a high extent into the plasmalogens of all tissues except brain. Comparative studies with other precursors, such as 3-*O*-heptadecyl-*sn*-glycerol, heptadecanol and heptadecanoic acid, indicated a stereospecific incorporation of the dietary 1-*O*-alkyl-*sn*-glycerols into tissue plasmalogens without cleavage of the ether bond. Dietary ether lipids were also shown to be transferred from mothers to suckling rats, but not from pregnant rats to fetuses. The implication of these results to possible dietary ether lipid therapy for patients suffering from peroxisomal disorders is discussed.
Lipids 27, 401–405 (1992).

In mammals, 1-*O*-alkyl-*sn*-glycerols derived from dietary ether glycerolipids are absorbed without cleavage of the ether bond (1). This was first shown by Bergström and Blomstrand (2) who fed radioactive 1-*O*-[1'-^{14}C]hexadecyl-*rac*-glycerol (chimyl alcohol) to rats and showed that it was completely absorbed by the intestine. About half of the radioactive lipids recovered from the lymphatic fluid were shown to be either chimyl alcohol or its esterified derivatives, and the rest of the radioactivity was recovered in palmitic acid. Using human subjects, a similar finding was reported by Blomstrand and Ahrens (3). Apparently after absorption, all of the unnatural isomer (*sn*-3-alkyl) and part of the natural (*sn*-1-alkyl) isomer were oxidized in the intestinal mucosal cells to form palmitic acid (4). This was demonstrated later by Paltauf (5) who administered labeled natural (1-*O*-hexadecyl-*sn*-glycerol) and unnatural (3-*O*-hexadecyl-*sn*-glycerol) glycerol ether isomers to rats and showed that only the natural isomer was incorporated into intestinal mucosal lipids. Paltauf also showed that the exogenous alkylglycerol was further metabolized to plasmalogens in intestinal mucosal cells (5). Mangold (1) and Bandi *et al.* (6) reported similar findings by feeding rats glycerol ethers which contained unnatural (18:2, 18:3) alkyl chains. These works have found that dietary ether glycerolipids are not only incorporated into membrane ether lipids of intestinal mucosal cells, but a small portion is also transported to liver and incorporated into plasmalogens in that tissue (6). Reichwald and Mangold (7) fed rats 1-alkyl glycerols having unnatural, odd-numbered and polyunsaturated alkyl groups (13:0, 15:0, 17:0, 19:0, 19:1 and 19:2) and studied their incorporation into lipids of intestinal mucosal cells. They found that although all of these glycerol ethers are incorporated into alkylacyl-glycerophosphoethanolamine (GPE) and alkylacyl-glycerophosphocholine (GPC), only the glycerol ethers containing 17:0, 19:0 and 19:1 chain lengths are converted into the corresponding ethanolamine and choline plasmalogens. Weber (8) showed that dietary 1-*O*-dodecyl-*rac*-glycerol is incorporated into the alkylglycerolipids, but not into the plasmalogens, of all tissues in mice.

These studies from different laboratories established that mammals can utilize dietary glycerol ethers to make membrane ether lipids in different tissues. In recent years, the possible incorporation of exogenous ether lipids into tissue plasmalogens has assumed clinical significance because of the discovery of a number of genetic diseases involving ether lipid deficiency (9–11).

Heymans *et al.* (12) first reported the almost complete absence of ether lipids in the tissues of patients suffering from Zellweger cerebrohepatorenal syndrome. This deficiency of ether lipids is due to the absence of peroxisomes in the tissues of these patients (13). Peroxisomes have been shown to be the site for synthesis of ether lipids (14). It has been demonstrated that the activity of dihydroxyacetone phosphate acyltransferase (DHAPAT), which catalyzes the biosynthesis of the precursor of ether lipids, acyl dihydroxyacetone phosphate (acyl DHAP) (Fig. 1), is very low in the tissues of Zellweger patients (15–17). The activity of the enzyme catalyzing the synthesis of the ether bond, *i.e.*, alkyl DHAP synthase (Fig. 1), is also somewhat low in these patients (15,17,18). The deficiency of these peroxisomal enzymes, required for the *de novo* biosynthesis of the ether bond in ether glycerolipids, results in a decreased amount of plasmalogens in the tissues of Zellweger patients. The same enzymes have also been shown to be deficient in a number of other genetic diseases involving peroxisomal disorders, such as neonatal adrenoleukodystrophy (19), infantile Refsum disease (20), rhizomelic chrondrodysplasia punctata (9) and others (21). On the other hand, the activity of the key enzyme necessary for the utilization of exogenous 1-*O*-alkyl-*sn*-glycerol, *i.e.*, alkyl glycerol kinase (Fig. 1), was shown not to be deficient in these patients (15). Considering that the enzymes that catalyze the conversion of 1-alkyl-*sn*-glycerol-3-phosphate to membrane ether glycerolipids and plasmalogens are localized not in peroxisomes (14,22) but in the endoplasmic reticulum (Fig. 1), it is expected that exogenous alkyl glycerols might be incorporated into tissue ether lipids in these patients. This has been shown to be the case in cultured skin fibroblasts

obtained from Zellweger patients where the labeled alkyl glycerols, added to the culture medium, are incorporated into cellular plasmalogens, but the labeled long-chain alcohols are not (23,24).

ORAL ETHER LIPID THERAPY IN PATIENTS WITH ETHER LIPID DEFICIENCY

The findings summarized above led us to hypothesize that oral administration of ether lipids to patients with peroxisomal disorders might rectify the tissue ether lipid deficiency (15,25). Our group has given several patients with peroxisomal disorders an ether lipid suspension containing 400 mg 1-*O*-octadecyl-*sn*-glycerol (batyl alcohol) and 200 mg sodium deoxycholate in 100 mL of water. Each patient received 5–10 mg/kg daily of batyl alcohol (25). Case histories for three patients are described below.

Patient 1. NR was born on May 26, 1983, following a full-term gestation. Birth weight was 3.13 kg (50%), length 54 cm (95%) and head circumference 34.5 cm (50%). He was evaluated at 7 weeks of age because of failure to thrive and was noted to have hypotonia and enlarged anterior and posterior fontanels with diastasis of the sagittal suture. Hepatomegaly was present at age 4 months and serum aminotransferase levels were elevated. Percutaneous liver biopsy showed abnormal lobular architecture with fibrous septa extending from portal tracts into the surrounding parenchyma. By 8 months of age he could not visually fix on objects and had wandering nystagmus. Ophthalmologic evaluation revealed bilateral punctate cortical and plaque-like nuclear changes, optic atrophy and retinal degeneration.

A skin biopsy was performed at 1 year of age and fibroblasts were cultured, harvested and assayed for the activity of the peroxisomal membrane enzyme, dihydroxyacetone phosphate acyltransferase (DHAPAT). The activity was 30% of control. Plasma levels of C_{26} very long-chain fatty acids and the ratio of C_{26}/C_{22} assayed at 20 months of age were elevated in a pattern diagnostic of neonatal adrenoleukodystrophy.

Dietary supplementation with batyl alcohol was started in August, 1984, and continued through May, 1987. The child is currently enrolled in special education classes with a level of development equivalent to a young toddler. He has not yet developed clinical or laboratory evidence of adrenal insufficiency (normal cortrosyn stimulation test at age 8 1/2 years).

Patient 2. EZ was born at 40 weeks gestation by emergency cesarean section on September 28, 1982, because of fetal distress and maternal hypertension. Birth weight was 2.5 kg and length 53 cm. At 6 months of age she was evaluated for failure to thrive, hypotonia and hepatomegaly. A liver biopsy was performed and sections of the liver showed bridging fibrosis and paucity of intrahepatic bile ducts without cholestasis.

She was re-evaluated at age 2 years because of failure to thrive, delayed development, seizures, hypotonia and persistent hepatomegaly with elevated levels of serum aminotransferases. Her facies was not dysmorphic, although there was a high-arched palate. Because of these findings, fibroblasts cultured from a skin biopsy were assayed for DHAPAT. The activity of fibroblast DHAPAT was 0.125 nmol/min/mg protein (control value = 0.2 nmol/min/mg protein). The reference non-peroxisomal enzyme glycerol-3-phosphate acyltransferase had values of 0.89 nmol/min/mg (control = 0.81 nmol/min/mg protein). Erythrocyte plasmalogen content was assayed at age 3 years and was abnormal (Table 1).

She was given a suspension of batyl alcohol from July, 1985, until February, 1989. There were no adverse effects.

TABLE 1

Erythrocyte Ethanolamine Plasmalogen Concentration Before and After Administration of Batyl Alcohol[a]

	Ethanolamine plasmalogen (% of total phospholipids)		
	Patient no. 1	Patient no. 2	Patient no. 3
Pretreatment value	4.0	1.3	4.1
Post-treatment value	10.6	11.2	7.5

[a]Erythrocyte phospholipid composition was analyzed by two-dimensional thin-layer chromatography as previously described (30). The percentage of ethanolamine plasmalogen is shown here. Most of the other phospholipid percentages were the same as normal except for phosphatidylethanolamine, which was increased. The ethanolamine plasmalogen contents of normal subjects varies from 10% to 15% of the total phospholipids. For further details, see text and ref. 25.

She is presently attending a school for developmentally handicapped children and is beginning to walk. There is marked speech delay.

Patient 3. CB was born on January 14, 1986, following full-term gestation. Hypotonia and strabisimus were present at birth. He was evaluated at age 4 months because of failure to thrive, and was noted to have a dysmorphic facies and hepatomegaly. Plasma very long chain fatty acid levels were elevated and the activity of fibroblast DHAPAT was determined to be 40% of control value. These findings supported the diagnosis of neonatal adrenoleukodystrophy.

A cortrysn stimulation test was performed in March, 1988. The result was abnormal and hydrocortisone replacement therapy was started. In October, 1988, he developed a diffuse, erythematous skin rash, associated with elevation of plasma phytanic acid.

An oral suspension of batyl alcohol was prescribed in October, 1986, and continued to January, 1989. The erythrocyte plasmalogen content was measured before and after treatment with batyl alcohol. The results are summarized in Table 1.

At the present time, he is attending a special education program for hearing-impaired and vision-impaired children. He has marked developmental delay and is not yet able to walk.

The results presented in Table 1 show that erythrocyte plasmalogen levels are increased in these patients after oral feeding of batyl alcohol for a few months. In one patient, who was under oral batyl alcohol therapy for three months, the chain length distribution of the alk-1′-enyl moiety of ethanolamine plasmalogens from erythrocytes was analyzed. An increase in the 18:0 moiety (68% *vs.* 50% in normal controls) was observed, suggesting that the dietary batyl alcohol was absorbed, metabolized and incorporated into the erythrocyte plasmalogens of this patient.

Administration of oral ether lipids represents a potential treatment for patients with peroxisomal disorders. Although none of the patients reported in this series have the severe Zellweger phenotype associated with multiple peroxisomal enzyme deficiency, they all share clinical features typically seen in patients with peroxisomal dysfunction: failure to thrive, delayed development, hypotonia, facial dysmorphia and hepatomegaly. Each of these patients has a documented defect of plasmalogen synthesis and oxidation of fatty acids. These infants have exhibited subjective improvement of nutritional status, liver function, retinal pigmentation and motor tone and repletion of deficient red cell ethanolamine plasmalogens since receiving batyl alcohol. However, it is not possible to separate these changes from the natural history of untreated disease. Wanders *et al.* (26) have documented increasing plasmalogen levels in Zellweger's syndrome as a function of age. This may be due to the intake of natural alkylglycerols present in food. Horrocks (27) estimated that the average adult consumes 10–100 mg of batyl alcohol each day.

INCORPORATION OF DIETARY ALKYLGLYCEROL INTO PLASMALOGENS OF DIFFERENT TISSUES IN RATS

The increase in the plasmalogen level in erythrocytes of patients after feeding batyl alcohol indicated that dietary ether lipids may also be incorporated into different tissues of these patients. However, a direct demonstration of such an increase in tissues of these patients was not feasible. There are also no reports of incorporation of dietary ether lipids into plasmalogens of different tissues of animals except in intestinal mucosa (1,5) and, to a small extent, in liver of rats (6). By contrast, there are reports of nonincorporation of exogenous tracer doses of labeled ether lipids into tissue plasmalogens of animals (28,29). Therefore, to determine whether dietary ether lipids are utilized to synthesize membrane ether lipids of different tissues, we administered 1-*O*-heptadecyl-*sn*-glycerol to young rats. The odd chain heptadecyl moiety is practically absent in normal ether glycerolipids, but it is very similar to the alkyl and alk-1′-enyl groups of tissue lipids that are mainly composed of 16:0, 18:0 and 18:1 chains. By feeding rats (19-d-old) 1-*O*-heptadecyl-*rac*-glycerol (1–2% mixed with food) for 5 to 10 days, we found a very high (46–60%) incorporation of the C_{17}-moiety at the C-1 position of ethanolamine plasmalogens in most tissues of these rats (30). However, the total plasmalogen content of the tissues did not increase. These results show that dietary alkyl glycerol ethers are not only absorbed and converted to plasmalogens in intestinal tissue, but are also transported to other organs where they are metabolized and deposited as membrane plasmalogens. The incorporation of the exogenous ether lipids into tissue plasmalogens is quite high, much higher than reported previously (7). This is probably due to our use of young growing rats for these experiments, as opposed to the use of adult rats by other authors. Recently, Blank *et al.* (31) reported a similar observation. These authors fed 1-*O*-alkyl-2,3-diacetyl-*sn*-glycerol, containing 65% 18:1 and 17% 16:1 alkyl groups, to rats, and found an increase in the 18:1 group of alkyl and alk-1′-enyl side chains of ether phosphoglycerides in liver, kidney and lung. There was an increase in the alkyl glycerol ether content but, as we have found, no change in the plasmalogens content of these tissues (31). We further investigated the mode of incorporation of dietary ether lipids into tissue lipids by feeding different precursors of ether lipids, such as heptadecanoic acid, heptadecanol, 1-*O*-heptadecyl-*sn*-glycerol and 3-*O*-heptadecyl-*sn*-glycerol, to young rats. The results are summarized in Figure 2. It is seen that 1-*O*-heptadecyl-*sn*-glycerol is the best precursor, whereas its unnatural optical isomer, 3-*O*-heptadecyl-*sn*-glycerol, is incorporated only to a very small extent. Apparently, the *sn*-3 isomer is oxidized to heptadecanoic acid (the mono-oxygenase oxidizing the ether bond is non-stereospecific, see ref. 32) which is further utilized. This conclusion is supported by the higher percentage of incorporation of heptadecanol and heptadecanoic acid than of the *sn*-3 isomer (Fig. 2). The relative incorporation rates, *i.e.* 1-*O*-heptadecyl-*sn*-glycerol $\gg$ heptadecanol > heptadecanoic acid > 3-*O*-heptadecyl-*sn*-glycerol (Fig. 2), suggest that the pathway shown (Fig. 1) for the incorporation of different precursors into ether lipids is operative in all tissues. These results and results from other laboratories (7,8,31) indicate that most exogenous long chain ether lipids incorporate into alkylglycerol ether lipids, but the subsequent conversion to plasmalogens occurs only in lipids containing alkyl chain lengths between C_{15} and C_{19} (saturated or monounsaturated). Thus, it appears that, physiologically, the 1′-alkenyl chain lengths are restricted to a narrow range,

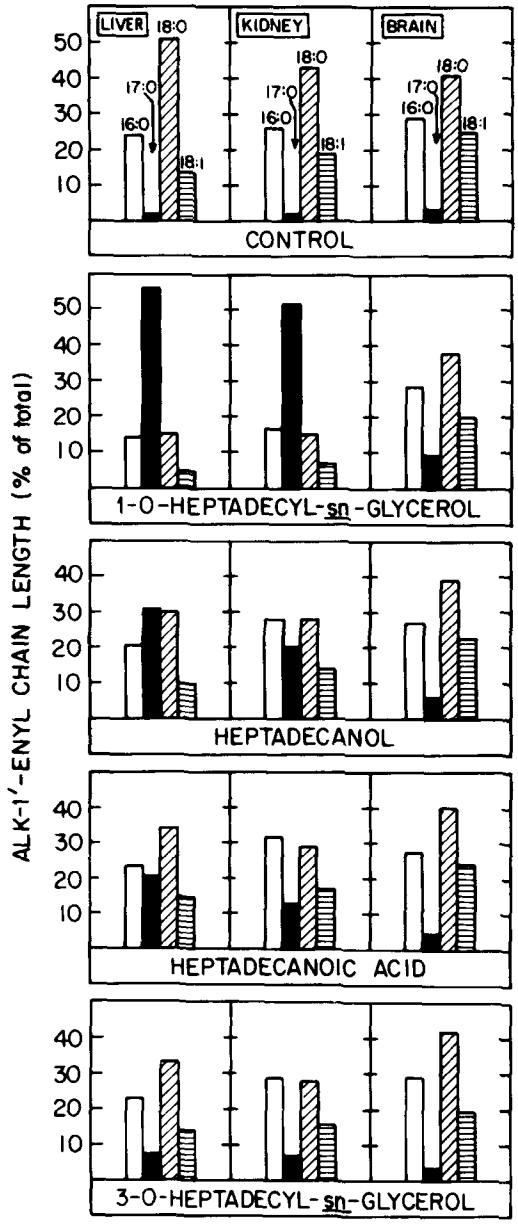

FIG. 2. Incorporation of dietary 1-*O*-heptadecyl-*sn*-glycerol, heptadecanol, heptadecanoic acid and 3-*O*-heptadecyl-*sn*-glycerol into ethanolamine plasmalogen of the tissues of 19-day-old rats. Rats were fed either powdered food mixed with the indicated compounds (1%, w/w) or only the powdered food alone (control group) for 5 days, and then the chain length distributions of the alk-1'-enyl group at C-1 position of ethanolamine plasmalogen of liver, kidney and brain were analyzed, as described previously (30).

not only by the specificity of the acyl-CoA reductase (33), but also by the chain length specificity of the dehydrogenase which converts 1-*O*-alkyl phosphoglycerides to 1-*O*-[1'-alkenyl]phosphoglycerides (34). The nature of the ether lipids transported from intestine to liver or to other organs is a matter of speculation. However, it is plausible that esterified alkylglycerols (ether analogs of triglycerides) are transported from the intestine (2–4) and liver to other organs and that these alkylglycerol derivatives are utilized after partial or complete hydrolysis of the ester bonds. Neutral lipids, whose chromatographic migration rate is similar to alkyldiacylglycerol, were found to be present in the liver and kidney of animals who were chronically fed heptadecylglycerol (Das, A.K., and Hajra, A.K., unpublished observation; see also ref. 31).

The results of our animal feeding experiment show that dietary ether glycerolipids are effectively utilized to synthesize membrane ether lipids in most tissues. However, in brain the incorporation of the exogenous ether lipid precursor was always very low (ref. 30 and Fig. 2). This could possibly be due to either a low rate of ether lipid synthesis in brain after myelination is complete, or to the fact that the ether lipid precursors cannot cross the blood-brain barrier. To resolve this question, ether lipids should be fed to rats before the start of myelination (<10 d old). It is difficult, however, to feed large amounts of ether lipids to these suckling rats. Therefore, we fed pregnant female rats powdered food containing 0.5% (w/w) 1-*O*-heptadecyl-*sn*-glycerol on the fifth day before delivery, and continued until the fourteenth day after the pups were born. The babies were allowed to suck the mother's milk which, when analyzed, was found to contain 1-*O*-alkyl-2,3-diacyl-*sn*-glycerols. When the tissues of the babies (14-d-old) were analyzed, 28% of liver and 17% of kidney alk-1'-enyl groups of ethanolamine plasmalogen were found to contain the 17:0 moiety. These values were lower than those obtained by direct feeding of heptadecylglycerol (30). In brain, a low (2%) incorporation of 17:0 in the alkenyl chain was also observed. It is not clear whether this low incorporation into brain lipid is due to the blood-brain barrier or to the lower consumption of heptadecylglycerol by the babies. In another experiment, we found no incorporation of the 17:0 moiety in the tissues of newborn babies whose mothers had been fed 1-*O*-heptadecylglycerol for 20 days during pregnancy, though the mothers' tissues contained a high percentage (40–60%) of the heptadec-1'-enyl moiety in the ethanolamine plasmalogens. This indicates that ether lipids are not transported across the placenta from mother to fetus.

From these results, it is evident that dietary ether lipids can be directly utilized by mammals to synthesize membrane alkyl glycerolipids and plasmalogens in most tissues. Although the utilization of the exogenous ether lipids for the formation of brain plasmalogens is somewhat questionable, there was a low but reproducible incorporation of 1-*O*-heptadecyl-*sn*-glycerol into brain ether lipids (ref. 30, Fig. 2). It is possible that the exogenous ether lipids would be more effectively utilized if there were no endogenous formation of ether lipids. Increasing the dose might result in higher incorporation of ether lipids in all tissues of the patients. Oral ether lipid therapy may never relieve all of the syndrome associated with these diseases because of multiple peroxisomal enzyme defects (10,22). But, in mild cases, where the main problem is the deficiency of ether lipids, oral ether lipid therapy may prove helpful. Alkyl glycerols are fairly innocuous compounds which have been shown to be nontoxic even at high doses (1), and no harmful effects are expected when these compounds are chronically administered to the patients. Oral ether lipid therapy should be attempted to alleviate some of the symptoms associated with these peroxisomal disorders.

ARTICLE

Characterization of a Cytosolic Protein in Rat Liver Inhibiting Neutral Cholesteryl Ester Hydrolase

J.H. Shand and D.W. West*
Hannah Research Institute, Ayr, KA6 5HL, Scotland

Neutral cholesteryl ester hydrolase activity (EC 3.1.1.13) present in microsomes isolated from lactating rat mammary glands was found to be inhibited by a factor (or factors) occurring in the cytosolic fraction of male rat liver. The inhibitor was heat-labile, non-dialyzable, destroyed by proteolysis, and was stable following preparation of an acetone/diethyl ether powder of the cytosolic fraction. The protein also inhibited the activity of hormone-sensitive lipase (HSL) (from bovine adipose tissue) and esterase from *Candida cylindracea*, but seemed to be more active against the neutral hydrolase found in rat liver microsomes. For the mammary gland microsomal cholesteryl ester hydrolase, the extent of the inhibitory effect was dependent on the concentration of the cytosolic protein, 50% inhibition being achieved by about 100 μg of cytosolic protein, and on the method of initiating the enzyme assay. Kinetic analysis indicated that, under circumstances where the reaction was initiated by the addition of substrate, the inhibition was characterized as "uncompetitive." When an inhibitor/substrate complex was allowed to form in the absence of enzyme, an element of "competitive" inhibition was introduced into the reaction. Food withdrawal reduced the activity of the inhibitor in liver by 56%, but activity was fully restored by short-term re-feeding. In contrast, feeding a diet high in fat led to a 34% increase in activity. The present findings suggest that the inhibitory factor(s) may be involved in the regulation of the hydrolysis of cholesteryl esters in the liver and also in other cell types. *Lipids* 27, 406–412 (1992).

Hepatic cholesteryl esters, which derive primarily from the uptake and degradation of plasma lipoproteins, are hydrolyzed in liver cells through the action of the enzyme cholesteryl ester hydrolase (CEH). The resulting free cholesterol, as well as the endogenously synthesized sterol can be catabolized, re-esterified for storage, or secreted from the liver. In addition, recent studies on CEH regulation suggest that cholesteryl ester metabolism may play a role in steroid hormone synthesis (1–3). Thus, free and esterified cholesterol are subject to constant turnover, and the enzyme CEH plays an important role in controlling the supply of free sterol from its storage form. At least three CEH activities have been described that are located in different hepatic subcellular compartments (4–7). It is known that lysosomal CEH, which has an optimum pH in the acidic range, is required for the hydrolysis of exogenous cholesteryl ester, internalized as lipoproteins into cells by receptor-mediated endocytosis (8–10). Recent research has indicated that the neutral CEH of macrophages (11), adrenal cortex (12), corpus luteum (13), mammary gland (14) and heart (15) are identical to the hormone-sensitive lipase of rat adipose tissue, and it has been suggested that all of the neutral CEH in tissues are the same enzyme (16). There is now considerable evidence that these enzymes are under hormonal control and that this hormonal activation is mediated by a covalent phosphorylation of the enzyme catalyzed by cyclic adenosine monophosphate (AMP)-dependent protein kinase (16,17). The activity of the cytosolic neutral CEH in the liver is also reported to be increased by cyclic AMP-dependent phosphorylation (18), but is extremely low in contrast to the enzyme of adipose tissue and adrenal cortex (12). This is in spite of the fact that the liver is thought to be the major site of cholesteryl ester hydrolysis in the rat.

The liver does, however, contain a neutral CEH that is activated by bile salts at levels higher than their critical micelle concentration (19), and it is possible that the effect of these bile salts could be to increase the efficiency with which cholesteryl ester substrate is presented to the enzyme (20,21). There is considerable evidence that the activity of various CEH is markedly affected by the manner in which the substrate is presented to the enzyme. Cholesteryl esters are insoluble in aqueous media and the substrate is usually presented either as a solution in ethanol or acetone, or suspended in a mixed micelle with bile salts and phospholipids (20). This raises the possibility that within the cell the activity of the neutral CEH may also be controlled by the manner in which the enzyme interacts with its substrate. An inhibitor of lysosomal acid CEH, which does not affect the neutral hydrolase, has been reported to exist in the cytosolic fraction of rat liver (22) and in cultured fibroblasts (23), and more recently this same enzyme has been shown to be inhibited by apolipoprotein A-I (24).

We have re-investigated the cytosolic fraction of rat liver and have now shown that this fraction does contain a highly active inhibitor of neutral CEH that appears to function by interfering with the presentation of substrate to enzyme.

MATERIALS AND METHODS

Materials. [1-^{14}C]Oleic acid (1.95 GBq/mmol) and [9,10(n)-^{3}H]oleic acid (74-370 GBq/mmol) were purchased from Amersham International (Amersham, Bucks, U.K.). Cholesteryl [9,10(n)-^{3}H]oleate was synthesized from cholesterol and [9,10(n)-^{3}H]oleic acid by a modification of the method of Swell and Treadwell (25). [9,10(n)-^{3}H]Oleic acid (10 mg) was dissolved in oxalyl chloride (0.5 mL) and heated at 50°C for 24 h. The excess reagent was removed in a stream of nitrogen and a solution of cholesterol (30 mg) and pyridine (100 μL) in dry toluene (2 mL) was added. The mixture was kept at 50°C overnight and the excess solvent and reagents again evaporated off. The final product was purified by thin-layer chromatography (TLC) and gave a product with specific activity of (42 mCi/mmol). All biochemicals were purchased from Sigma Chemical Co. (Poole, Dorset, U.K.) or from BCL (Lewes, Sussex, U.K.).

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; AMP, adenosine monophosphate; BSA, bovine serum albumin; CEH, cholesteryl ester hydrolase; EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycol-*bis*(2-aminoethyl)tetraacetic acid; HSL, hormone-sensitive lipase; MES, 2-(*N*-morpholino)ethanesulfonic acid; M_r, relative molecular weight; NEM, *N*-ethylmaleimide; TRIS, tris(hydroxymethyl)aminomethane; TLC, thin-layer chromatography.

Preparation of the inhibitory factor from rat liver. Male Wistar rats (280–330 g) were maintained in an alternating light cycle of 12 h (light from 0800) and were fed *ad libitum* on a CRM(X) breeding diet (Special Diet Services, Manea, Cambridgeshire, U.K.). Starved rats were deprived of food for 24 h or 48 h, and starved/re-fed rats were allowed food for 2 h after 48 h starvation. One group of rats was given a high-fat diet (26), comprising potato crisps, cheese crackers and chocolate chip cookies, in addition to chow, for 2 wk prior to use. Animals were killed by cervical dislocation at 0930 (except where indicated in the text) and the livers excised and homogenized (Polytron, Kinematica, Luzern, Switzerland; PMA20N probe, 17000 rpm, 30 sec) in 4 volumes of ice-cold medium consisting of 50 mM 2-(*N*-morpholino)-ethanesulfonic acid (MES), 50 mM tris(hydroxymethyl)aminomethane (TRIS)/HCl buffer pH 7.2, 1 mM ethylenediaminetetracetic acid (EDTA), 1 mM ethyleneglycol-*bis*(2-aminoethyl)tetraacetic acid (EGTA), and 1 mM dithiothreitol (Buffer A). The homogenate was centrifuged at 10,000 × *g* for 10 min and the resulting supernatant centrifuged at 100,000 × *g* for 60 min. The clear supernatant below the floating fat layer was carefully removed and either stored in liquid nitrogen or converted into an acetone/diethyl ether powder by addition to 10 volumes of ice-cold acetone. The resultant precipitate was recovered by centrifugation (5,000 × *g*, 5 min) and washed with cold acetone and diethyl ether before being dried in a vacuum desiccator. The dried powder was stored at −20°C. Before use it was extracted in a volume of Buffer A equivalent to that of the original solution and dialyzed or passed through a column of Sephadex G15 (Pharmacia LKB Biotechnology, Uppsala, Sweden).

Partial purification of the inhibitory material. The 100,000 × *g* supernatant was acidified to pH 5.2 with 1 M acetic acid and after standing for 30 min in ice was centrifuged 100,000 × *g* for 15 min. The pH of the resultant supernatant was re-adjusted to pH 7.2 with 1 M TRIS, and ammonium sulfate was added to bring the solution to 70% saturation. After 60 min in ice, the suspension was again centrifuged (10,000 × *g*, 15 min) and the precipitate dissolved in a minimum volume of Buffer A. An acetone/diethyl ether powder was prepared from this solution as detailed above.

Gel filtration chromatography. The 100,000 × *g* supernatant from the homogenized liver or the dialyzed extract of the acetone/diethyl ether powder (3 mL) was applied to a column (24 × 900 mm) of Sephacryl S-300HR (Pharmacia) equilibrated in the Buffer A. Fractions of 2.5 mL were collected and 140 μL of every second fraction assayed under standard conditions for activity with respect to inhibition of the neutral CEH in a mammary microsomal preparation.

Interaction with phenyl sepharose. A sample of phenyl sepharose (Pharmacia) was equilibrated with Buffer A in a small column. The column was centrifuged to remove excess buffer and the phenyl sepharose (100 mg) added to small tubes together with the solution containing inhibitory activity (120 μg). After 60 min in ice, the tubes were centrifuged (9,000 × *g*, 5 min) and the supernatant assayed for remaining inhibitory activity.

Heat stability. To test the heat stability of the inhibitory material, an extract of the acetone/diethyl ether powder was heated at 95°C for 5 min. After centrifugation (9,000 × *g*, 5 min) to remove precipitated protein, the remaining inhibitory activity was assayed.

Influence of proteolysis. An extract of the acetone/diethyl ether powder (400 μg) was incubated at 37°C with trypsin (30 μg). After 15 min, proteolysis was terminated by the addition of soybean trypsin inhibitor (60 μg) and the resultant solution assayed for inhibitory activity. Control incubations where the trypsin inhibitor was added before the trypsin were also included.

Influence of N-ethyl maleimide. A sample of the acetone diethyl ether powder extract was passed through a column of Sephadex G-15, equilibrated in 50 mM TRIS/50 mM MES buffer (pH 7.0), to remove dithiothreitol and the resultant solution incubated at 37°C with *N*-ethyl maleimide (2 mM). After 15 min, the reaction was stopped by the addition of dithiothreitol (5 mM) and the extract again passed through a small column of Sephadex G-15 equilibrated with Buffer A. The efficiency of the inhibitor in the acetone/diethyl ether powder was assayed before and after this treatment.

Preparation of rat mammary and liver microsomes. Microsomes were prepared from the mammary glands of rats in mid-lactation as previously described (27) and from the liver of virgin female rats according to the method of Polokoff *et al.* (28). They were stored at −80°C as a suspension in Buffer A.

Assay of CEH. Neutral CEH activity in the mammary microsomal membranes (100 μg) was routinely assayed using Buffer A containing bovine serum albumin (BSA) (2%, w/v). The inhibitory fraction (10–120 μg) was included in the assay mixture (final volume 200 μL) and the reaction was initiated by the injection of an ethanolic solution of cholesteryl [9,10(n)-^{3}H]oleate (20 nmol, 200,000 dpm). Where indicated, the reaction was also initiated by the addition of the microsomal membranes, suspended either in Buffer A or in a solution of BSA in Buffer A, to the incubation tubes containing all of the other assay constituents. In all instances the final assay mixtures were identical. After 20 min at 37°C the reaction was terminated and the extent of hydrolysis of the substrate determined as previously described (27). Assays were performed in triplicate and appropriate controls without microsomes were incubated concurrently to correct for background and possible CEH activity in the cytosolic fractions. Where indicated, taurocholate was present at a final concentration of 1 mM. Where the activity of the CEH in the liver microsomes was assayed, the microsomal protein concentration was kept below 250 μg/mL and the incubation period was increased to 30 min (7).

Protein measurement. The protein concentrations were determined by the dye-binding technique of Bradford (29) using crystalline BSA as standard.

RESULTS

The neutral CEH activity in both mammary and liver microsomes was markedly inhibited when the cytosolic fraction from liver was included in the assay (Figs. 1 and 2). Although the inhibitory effect was dependent on the concentration of cytosolic protein, total inhibition of the enzyme activity was not observed (Fig. 1). The reduction in esterase activity was not due to dephosphorylation of the enzyme by phosphatases in the liver cytosolic fraction (16) since incubation of the mammary microsomes

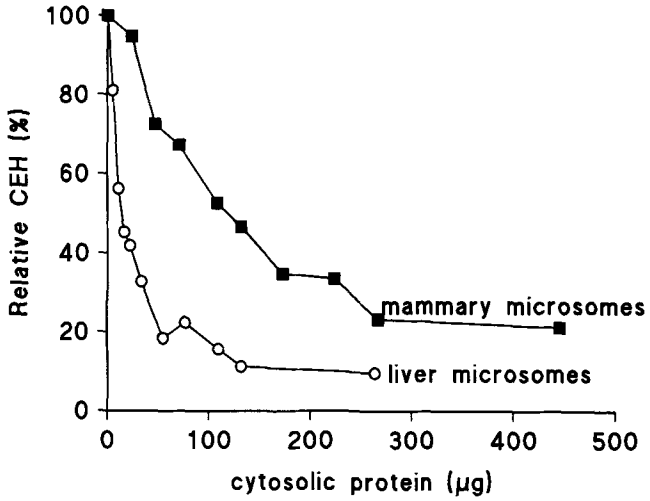

FIG. 1. Inhibitory effect of the cytosolic fraction from rat liver on the CEH in microsomes isolated either from lactating rat mammary glands or from rat liver. The assay for CEH activity was performed, as described in Materials and Methods, in the presence of varying amounts of an extract of an acetone/diethyl ether powder of rat liver cytosol. The mammary microsomal enzyme hydrolyzed 486 pmol of cholesteryl oleate per min per mg of protein, while the liver microsomal enzyme hydrolyzed 90.6 pmol cholesteryl ester per min per mg of protein.

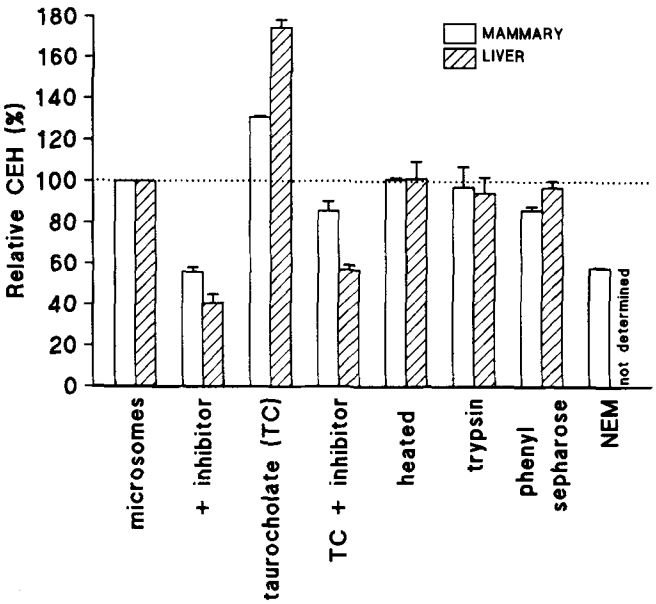

FIG. 2. The effect of various treatments on the inhibition of CEH by hepatic cytosolic factors. The assay for CEH activity in both mammary (100 μg) and liver (23.5 μg) microsomes was performed, as described in the Materials and Methods section, in the presence and absence of a dialyzed extract of an acetone/diethyl ether powder of liver cytosol (enzyme/inhibitor = 1:1 for mammary, 1:1.9 for liver). Where indicated, the inhibitor was heated, or was treated with *N*-ethyl-maleimide (NEM), phenyl sepharose, or trypsin as detailed in Materials and Methods. The assay was also performed in the presence of taurocholate (1 mM) with and without the inhibitor. The results are the means ± SEM of triplicate determinations and are expressed relative to the activity (100%) of the microsomal CEH. The mammary enzyme hydrolyzed 548.7 ± 8.93 pmol of cholesteryl oleate per min per mg protein while the activity of the liver enzyme was 73.3 ± 3.1 pmol cholesteryl oleate hydrolyzed per min per mg of protein.

TABLE 1

Partial Purification of Cytosolic Inhibitor[a]

	Total protein (mg)	Specific activity (μg protein for 50% inhibition)	Purification
Homogenate	14300	770.5	1.0
pH 5.2 supernatant	5555	271.0	2.8
Acetone precipitate	3141	66.7	11.6

[a]Rat livers (100 g) were homogenized in 4 vol of ice-cold medium consisting of 50 mM TRIS, 50 mM MES, pH 7.2, 1 mM EDTA, 1 mM EGTA and 1 mM dithiothreitol. The pH 5.2 supernatant and the acetone precipitate were then prepared as detailed in Materials and Methods. The specific activity was taken as the amount of protein necessary for 50% inhibition of the neutral CEH activity in 100 μg of mammary gland microsomal membranes.

with a sample of partially-purified rat liver phosphoprotein phosphatase (30) had no effect on its CEH activity. The inhibitory activity was retained on dialysis but was heat-labile, being totally destroyed by treatment of the cytosolic fraction at 95°C (Fig. 2). It was also completely abolished following incubation of the material with trypsin (Fig. 2). Adjustment of the pH of the cytosol to 5.2 did not cause precipitation of the inhibitory activity (Table 1). It also survived the preparation of an acetone/diethyl ether powder (Table 1). This treatment, which removes endogenous lipid, indicates that inhibition was not an artefact arising from alterations in the specific activity of the substrate by cholesteryl esters in the fraction. The bulk of the cytosolic activity was bound to phenyl sepharose indicating its hydrophobic characteristics (Fig. 2). The neutral CEH was stimulated by low concentrations (1 mM) of taurocholate, but the presence of the bile salt did not prevent the inhibition produced by the cytosolic material (Fig. 2). The cytosolic factors also inhibited the activity of bovine adipose tissue hormone-sensitive lipase (HSL) (reduced from 270.17 nmol/min/mg protein to 73.4 nmol/min/mg protein by 125 μg of cytosolic protein) and the activity of the CEH from *Candida cylindracea* (EC 3.1.1.13) (reduced from 2194 nmol/min/mg protein to 1075 nmol/min/mg protein by 62.6 μg of cytosolic protein).

Variation in the method of initiating the hydrolysis of the cholesteryl esters affected both the rate of the reaction and the extent to which it was inhibited by the cytosolic factors. When the reaction was initiated by the addition of the mammary gland microsomes, either as a suspension in buffer or as a suspension in a solution of BSA, the rate of hydrolysis by the neutral CEH was slower than that observed under the normal conditions of the assay (*i.e.*, initiation by injection of an ethanolic solution of the substrate). Nevertheless, when the mixture of microsomes and BSA was used to initiate the reaction, the inhibitory effect was significantly enhanced (Table 2). Similar, but less marked effects were obtained with the liver microsomal enzyme.

Injection of an ethanolic solution of cholesteryl oleate into aqueous medium results in the formation of a finely dispersed suspension of the substrate. Enhancement of the precipitation of this suspension would not, however, explain the increased efficiency of inhibition because the presence of the inhibitor actually diminished such sedimentation (Table 3). Initiation of the reaction in this manner allowed the inhibitor to react with the substrate, in

TABLE 2

Neutral CEH Activity. Effect of Method of Initiating Assay[a]

Initiation	Neutral cholesteryl esterase activity (pmol/min/mg protein)		Percentage activity remaining
	Control	Plus inhibitor	
(a) Substrate	548.72 ± 8.93	242.09 ± 12.49	44.2 ± 2.28
(b) Microsomes	339.80 ± 11.16	128.85 ± 6.78	37.9 ± 1.99
(c) Microsomes plus BSA	380.40 ± 11.37	50.30 ± 1.25	14.9 ± 1.0

[a]The reaction was initiated by addition of (a) an ethanolic solution of cholesteryl [9,10(n)-^{3}H]oleate (20 nmol, 200,000 dpm), (b) a suspension of mammary microsomes (100 μg), or (c) a suspension of mammary microsomes (100 μg) in bovine serum albumin (4 mg) to the remaining constituents of the assay. Where indicated, the assay contained 99.6 μg of an extract of an acetone/diethyl ether powder of rat liver cytosol. The mixtures were incubated for 20 min before the reaction was terminated and the extent of hydrolysis determined as described in Materials and Methods. The results given are the means ± SEM for triplicate determinations and are expressed in terms of the pmol of cholesteryl oleate hydrolyzed per min per mg microsomal protein.

TABLE 3

Influence of Hepatic Cytosolic Protein on Amount of Cholesterol Oleate Retained in Aqueous Solution[a]

Cytosolic protein (μg)	Cholesteryl ester in supernatant (nmol)
None	9.02 ± 0.12 (45.1%)
22.0	14.70 ± 0.24 (73.5%)
43.9	14.52 ± 0.35 (72.6%)
65.9	14.64 ± 0.02 (73.2%)

[a]An ethanolic solution of cholesteryl [9,10(n)-^{3}H]oleate (10 μL, 20 nmol, ≈200,000 dpm) was added to an aqueous solution containing 50 mM TRIS, 50 mM MES, pH 7.2, 2 mM dithiothreitol, and varying amounts of the extract of an acetone/diethyl ether powder of rat liver cytosol in a total volume of 200 μL. After 15 min at 37°C, the solution were centrifuged (9,000 × *g*, 2 min) and the radioactivity in duplicate aliquots of the supernatant determined. The results are the means ± SEM of triplicate determinations.

the absence of microsomes and BSA, prior to the assay, and this may be the explanation for its increased efficiency. The results from Table 3 would suggest that around 5.6 nmol of cholesteryl ester could be bound by the inhibitory fraction at 37°C, effectively reducing the amount of cholesteryl ester available to the microsomal CEH.

Kinetic analysis. A Lineweaver-Burk plot of the data obtained with the mammary microsomal preparation demonstrated that, when the reaction was initiated by the addition of substrate, the presence of the inhibitory activity produced a plot of 1/V against 1/S that was parallel to the plot obtained in its absence (Fig. 3a). Thus, both the K_m and the V_{max} were reduced (Table 4) indicating that inhibition was "uncompetitive" (31). However, when the reaction was initiated by addition of microsomes, the slope of the line, derived in the presence of the inhibitor, was much steeper than that observed in its absence (Fig. 3b). The increase in K_m and the decrease in V_{max} (Table 4) was consistent with a "mixed" type of inhibition (31). Essentially the same phenomena were observed with the liver microsomal enzyme when the method of initiation of the reaction was varied (Table 4).

TABLE 4

CEH Activity in Microsomes Isolated from Rat Mammary Gland and Liver. Variation of Kinetic Parameters with the Method of Initiation of the Reaction in the Presence and Absence of the Liver Cytosolic Inhibitor[a]

Enzyme source	Initiation by addition of	K_m (μM)		V_{max} (pmol/min/mg)	
		Control	Inhibited	Control	Inhibited
Mammary gland	Microsomes	9.71	33.78	198.2	34.3
	Substrate	20.68	10.18	1060.0	524.3
Liver	Microsomes	30.68	35.36	78.0	50.3
	Substrate	26.27	17.96	70.0	48.1

[a]For the mammary gland enzyme the kinetic parameters were calculated from the data shown in Figures 3a and 3b. For the liver microsomal enzyme the parameters were calculated from similar plots, which are not shown.

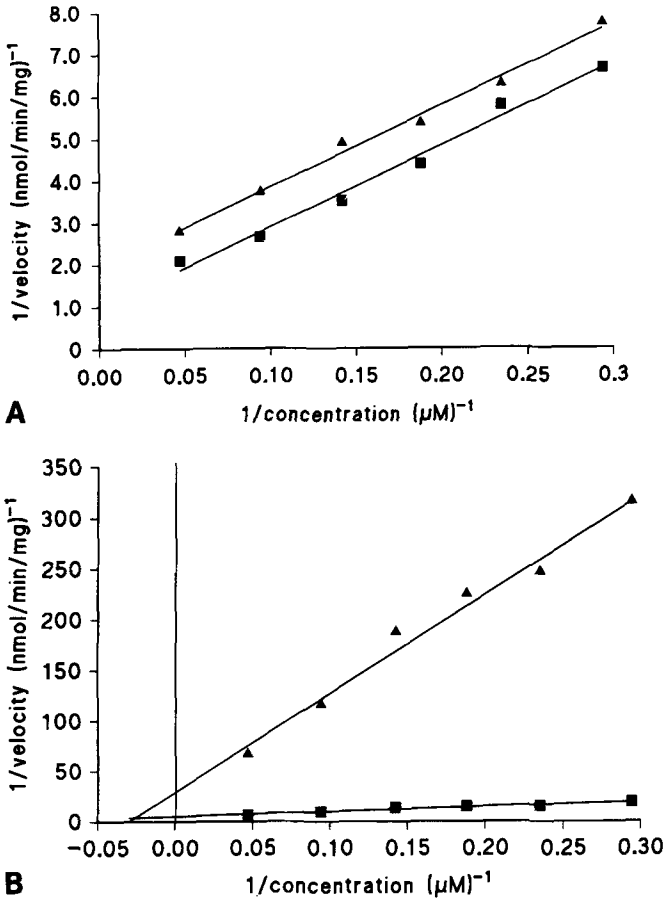

FIG. 3. Inhibitory effect of the cytosolic fraction on neutral CEH in rat mammary gland microsomes (100 μg). Lineweaver-Burk plots of cholesteryl ester hydrolysis in the presence (▲) or absence (■) of the cytosolic protein (50 μg). (a) Reaction initiated by the addition of an ethanolic solution of cholesteryl oleate. (b) Reaction initiated by the addition of rat mammary gland microsomal membranes suspended in an aqueous solution of BSA as detailed in Materials and Methods. The microsomal enzyme activity (pmol cholesteryl ester hydrolyzed per min per mg protein) was 484.8 ± 33.4 in (a) and 159.2 ± 3.5 in (b) at a substrate concentration of 21 μM.

Gel filtration. The liver cytosol was fractionated by Sephacryl S-300HR (Pharmacia) gel filtration and the inhibitory activity in the fractions assayed against the neutral CEH present in the mammary microsomes (Fig. 4a).

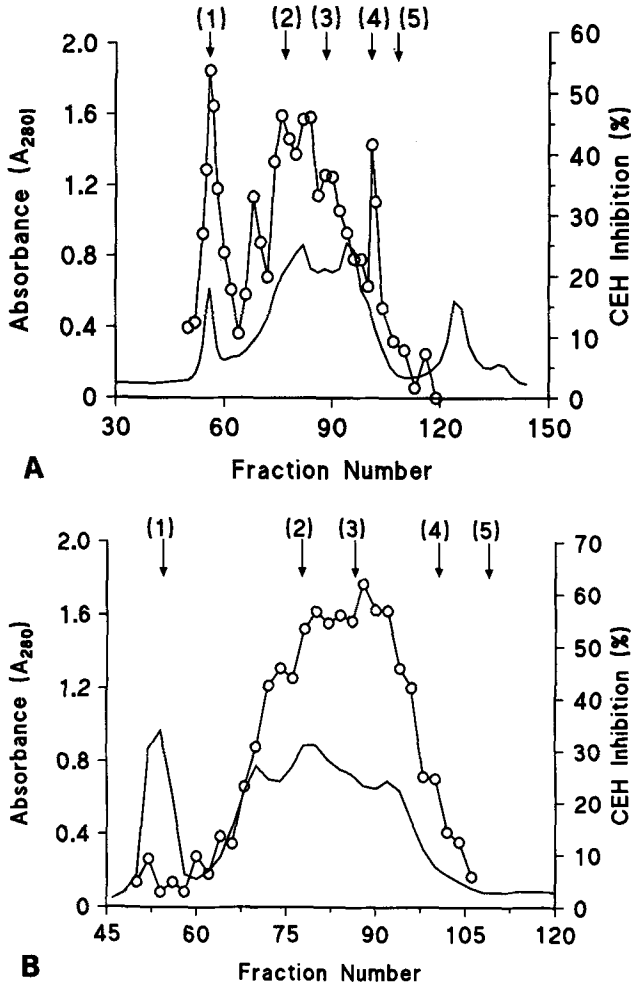

FIG. 4. Gel filtration of (a) liver cytosol (b) extract of acetone/diethyl ether powder on Sephacryl S-300HR. The samples were added to a column of Sephacryl S-300HR equilibrated with 50 mM TRIS, 50 mM MES, pH 7.2, 1 mM EDTA, 1 mM EGTA, and 1 mM dithiothreitol at 4°C, and the inhibitory activity in duplicate aliquots of every other fraction determined against the mammary microsomal CEH in the standard assay system, as detailed in Material and Methods. Absorbance at 280 nm (—); inhibitory activity on neutral CEH (-O-). The column was calibrated with the following markers: (1) Blue Dextran 2000; (2) potato amylase (mol wt 200,000); (3) bovine serum albumin (mol wt 66,000); (4) carbonic anhydrase (mol wt 29,000); (5) cytochrome C (mol wt 12,400).

The inhibitory activity eluted over a wide molecular weight range with peaks of activity at M_r 510,000; 220,000; 110,000; and 57,000. A similar multiplicity of peaks was reported by Tanaka and co-workers (22) for a liver cytosolic inhibitor of lysosomal acid CEH. Interestingly, a major peak of activity eluted in the void volume, suggesting the presence of high molecular weight lipoprotein complexes. This interpretation was enhanced when an acetone/diethyl ether powder was prepared from the cytosol and again fractionated on the Sephacryl S-300HR column (Pharmacia). In this instance, very little inhibitory activity eluted in the void volume of the column (Fig. 4b).

Nutritional and diurnal effects. In order to make meaningful comparisons between the different groups of animals, the results are expressed in terms of the amount of cytosolic protein required to achieve 50% inhibition of the neutral CEH in the mammary microsomes under standard assay conditions. The same preparation of mammary microsomal enzyme was employed throughout to prevent possible variations in sensitivity to the inhibitor in different microsomal samples, from obscuring the inhibitory effects of the different liver cytosols. In addition, all of these studies employed extracts of the acetone/diethyl ether powders prepared from the 100,000 × *g* cytosolic fractions of the livers to avoid the possibility that variations in activity could arise from alterations in the hepatic concentrations of cholesteryl esters.

TABLE 5

Inhibition of Neutral CEH in Mammary Microsomes by Hepatic Cytosolic Factors. Influence of Diurnal Variation and Nutritional Status of Animals on Amount of Cytosolic Inhibitor Protein[a]

Animal treatments	Time of sampling	Protein (μg)
Controls	0930	107.20 ± 3.70 (12)
No treatment	1400	97.99 ± 5.52 (5)
No treatment	0200	102.34 ± 4.12
24 h food withdrawal	0930	95.10 ± 5.76
48 h food withdrawal	0930	167.20 ± 7.40*
48 h food withdrawal then 2 h re-feeding	0930	109.32 ± 9.51
Cafeteria feeding	0930	71.20 ± 2.01*

[a]Acetone/diethyl ether powders were prepared from the cytosolic fraction of each of the rat livers as described in Materials and Methods. Extracts of these powders were used as the source of the inhibitory material, and the results are expressed as μg of protein required to achieve 50% inhibition of the neutral CEH activity in mammary gland microsomes. Values are the means ± SEM for six animals, except where indicated by the number in parentheses. Statistically significant differences (Student's *t*-test) between treatments and controls are indicated by $*P < 0.001$.

In the livers of the normally-fed male rats, approximately 100 μg of cytosolic protein was required for 50% inhibition of the neutral CEH in the mammary microsomes (Table 5). Withdrawal of food for 24 h did not alter the inhibitory activity of the liver cytosols, but withholding food for 48 h caused a marked reduction in this activity (indicated by an increase in the amount of protein required to produce 50% inhibition of the microsomal CEH activity). Re-feeding for as little as 2 h restored inhibitory activity to that of the controls. Feeding animals on a high-fat cafeteria-style diet resulted in a decrease in the amount of protein required for 50% inhibition, reflecting an increase in the inhibitory activity of the cytosolic fraction. There was no apparent diurnal variation in the concentration of the inhibitor since the livers of animals taken at the mid-light and mid-dark time points showed essentially the same amount of inhibitory activity which was not different from that exhibited by the control animals sampled 1.5 h into the light phase (Table 5).

DISCUSSION

The concentration of cholesteryl ester in cells is controlled by a balance between synthesis and hydrolysis (32), and a number of disease states are characterized by an accumulation of cholesteryl esters (33-35). Most studies on this problem have concentrated on the synthetic side of this balance, and inhibitors of the enzyme acyl-CoA:cho-

lesterol acyltransferase (ACAT) have been widely employed (36,37). The hydrolytic side of the equation has received less attention, although recent publications have reported studies on a series of synthetic inhibitors of the neutral CEH (38,39). The present work demonstrates that the hepatic cell contains a cytosolic factor(s) that inhibits a number of neutral CEH. Moreover, the higher sensitivity of the liver microsomal CEH to the hepatic cytosolic inhibitor(s) suggests that there may be some degree of tissue specificity in its action. The presence of these naturally occurring inhibitor(s) that can be altered under physiological conditions is potentially of great significance. Moreover, their presence in the cytosol provides an explanation for the reported low activity of hepatic cytosolic neutral CEH (18). The hepatic cytosolic esterase activity *in vivo* could be much higher than that measured *in vitro* due to compartmentalization of the inhibitor and enzyme. This would fit more with the role of the liver as a major site of cholesteryl ester hydrolysis in the rat.

The physiological significance of the inhibitor is also indicated by its variation in response to nutritional changes. Its reduction after 48 h food withdrawal would result in increased hydrolysis of the cholesteryl ester stores reflecting a requirement for maximum utilization of hepatic cholesteryl esters. Cafeteria-feeding (26) would give rise to the opposite situation, leading to maximum storage of cholesteryl esters and, hence, an increased requirement for inhibition of cholesteryl ester hydrolysis. The increase in inhibitory activity within 2 h of re-feeding the starved animal argues against re-synthesis of the inhibitor(s) as a means of increasing its efficiency and implies that other mechanisms control its activity. The activities of neutral forms of CEH in a number of tissues are elevated following phosphorylation by cAMP-dependent protein kinase (16), and analogy with the inhibitors that control the activity of a number of cellular phosphatases (40,41) would suggest modification of the activity of the inhibitor by a similar mechanism. This proposal is currently under investigation.

Interpretation of the mode of action of the inhibitor(s) is complicated by the fact that the substrate is insoluble in aqueous medium and the enzyme would consequently act at a lipid-water interface. The activity of the neutral CEH can be varied by the manner of presentation of the substrate (20,31); the difficulties of assessing inhibitory activities under these circumstances have been recently discussed (42). Nevertheless, consideration of the kinetic parameters reported here suggests certain possibilities. The parallel reduction in K_m and V_{max}, observed when both enzyme and inhibitor were present at the start of the reaction, is stated to be characteristic of an "uncompetitive" form of inhibition (31). The decrease in V_{max} indicates that the activity of the enzyme present in the mixture had been decreased. This could arise from binding of the inhibitor to the enzyme-substrate complex leading to a decrease in its rate of breakdown to free enzyme and products (31). The observed proportionate reduction in K_m is in agreement with this interpretation.

Injection of an ethanolic solution of cholesteryl oleate into aqueous buffer results in the formation of a fine suspension and the hydrophobic nature of the inhibitor, indicated by its binding to phenyl sepharose (Fig. 2), would allow it to form a soluble complex with this suspended substrate (Table 3). When microsomes were then added to initiate the reaction, competition occurred between the free and the bound substrate for the binding sites on the enzyme, leading to an increase in the value for K_m. However, the simultaneous reduction in V_{max} indicates that the resultant inhibition is not of a purely "competitive" type, but is modified by an element of the "uncompetitive" inhibition observed in the previous situation. The bulk of these studies have used a mammary microsomal preparation which is identical to the hormone-sensitive lipase/neutral cholesteryl esterase present in other tissues (14). The inhibitory properties are thus likely to have wider implications than just as a control mechanism in the liver, and we have preliminary evidence that similar inhibitory properties are associated with cytosolic factors from a number of macrophage cell lines. The development of these cells into the foam cells of atherosclerotic lesions by variations in the activity of the inhibitor is an intriguing possibility.

ACKNOWLEDGMENTS

We wish to thank Dr. S. Yeaman, Newcastle University, U.K., for the sample of purified hormone-sensitive lipase from bovine adipose tissue. The research was funded by the Scottish Office Agriculture and Fisheries Department.

The Inhibition of Neutral Cholesteryl Ester Hydrolase by a Cytosolic Protein Factor in Female Rat Liver: The Influence of Varying Hormonal and Nutritional Conditions on the Inhibitory Activity

J.H. Shand and **D.W. West***
Hannah Research Institute, Ayr, KA6 5HL, Scotland

A cytosolic protein, that is inhibitory to neutral cholesteryl ester hydrolase, has been investigated in the livers of female rats using microsomes isolated from the mammary gland of lactating rats as an enzyme source. To facilitate comparisons, inhibitory activity is expressed in terms of the amount (μg) of cytosolic protein required to reduce esterase activity by 50% and is compared to the hepatic content of both cholesterol and cholesteryl esters. The experiments revealed a sexual difference in the level of inhibitory activity, with the livers of both suckling and mature male animals containing less of the material than the corresponding females. Alterations in the physiological status of the females, such as pregnancy and lactation, led to a decrease in the activity of the protein. This was reversed by blocking lactation with a combination of an antiserum to rat growth hormone and the anti-prolactin drug, bromocriptine, but not by premature weaning of the animals. Food withdrawal for 24 hr also had the effect of increasing inhibitory activity. In general the cholesteryl ester content of the livers correlated with the level of inhibitory activity. Thus the activity of the cytosolic inhibitor of neutral cholesteryl ester hydrolase responded to changes in both the hormonal and the nutritional status of the female animal. It is suggested that the presence of the greater cholesteryl ester hydrolase inhibitory activity in the female liver may help to explain the lower risk of coronary heart disease in premenopausal females by facilitating increased hepatic storage of the sterol in the form of the ester.
Lipids 27, 413–417 (1992).

Hepatic cholesteryl esters, which derive primarily from the uptake and degradation of plasma lipoproteins, are hydrolyzed in liver cells through the action of the lysosomal enzyme cholesteryl ester hydrolase (CEH) having optimal activity at acid pH (1–3). The resulting free cholesterol, as well as that endogenously synthesized, can be catabolized, re-esterified for storage in cytoplasmic lipid droplets, or secreted from the liver in lipoprotein particles. Although the hydrolysis of the plasma-derived lipoprotein cholesteryl ester is mediated by the lysosomal esterase, the cholesteryl ester in the lipid droplets is hydrolyzed by a neutral CEH located in the cytosolic compartment. Free and esterified cholesterol are subject to constant turnover (4) and the neutral CEH thus plays an important role in controlling the supply of free sterol from its storage form. There is considerable evidence that the activity of this neutral CEH in a number of tissues is under hormonal control mediated by a covalent phosphorylation of the enzyme catalyzed by cyclic AMP-dependent protein kinase (5–7). In addition, we have recently described a protein factor in hepatic tissue that inhibits the activity of the neutral cholesteryl esterase (8). Since the activity of the inhibitory material varies under different nutritional and hormonal conditions, this provides a second mechanism for controlling the breakdown of cholesteryl esters and, hence, the output of hepatic cholesterol into the circulation.

Since high levels of plasma cholesterol are one of the factors associated with coronary heart disease, understanding the mechanism by which the activity of this inhibitory material is controlled may help to provide insight into the mechanisms which control plasma cholesterol levels.

Although these original experiments were performed with hepatic tissue from male rats, there is substantial documentary evidence that the hepatic metabolism of cholesterol differs considerably between the male and the female of the species. The two female hormones, estradiol and progesterone, have been reported to modulate cholesteryl ester hydrolysis in the rat (9–13), although the biochemical basis underlying this regulatory effect is not understood. It has, nevertheless, led to the suggestion that the lower risk of coronary heart disease in premenopausal females, in comparison with males of an equivalent age, is due to the presence of estrogens (14). We have therefore extended our investigations to female rats and here show that the livers of these animals do contain the inhibitory material, but in a more active form than that present in the livers of equivalent male rats. This may provide some explanation for the lower plasma cholesterol in females. Furthermore, in confirmation of our results with the male rats, we demonstrate that manipulation of the nutritional and hormonal status of the female rats also produces changes in the activity of the hepatic inhibitor and, hence, alters hepatic cholesterol metabolism.

MATERIALS AND METHODS

Materials. [1-^{14}C]Oleic acid and [9,10(n)-^{3}H]oleic acid were purchased from Amersham International (Amersham, Bucks, U.K.). Cholesteryl [9,10(n)-^{3}H]oleate was synthesized from cholesterol and [9,10(n)-^{3}H]oleic acid as previously described (8), and had a specific activity of (42 mCi/mmol). All biochemicals were purchased from Sigma Chemical Co. (Poole, Dorset, U.K.) or from BCL (Lewes, Sussex, U.K.).

Preparation of the inhibitory factor from rat liver. Wistar rats were maintained in an alternating light cycle of 12 hr (light from 0800) and were fed *ad libitum* on a CRM(X) breeding diet (Special Diet Services, Manea, Cambridgeshire, U.K.). Female rats were killed at two stages of pregnancy (day 12 and day 20) and in early lactation (day 2) and mid-lactation (day 10–14). Animals which had failed to mate were used as controls for the pregnant and lactating animals. Animals at mid-lactation also were treated with bromocriptine (0.5 mg) or anti-rat growth hormone (220 mg), or a combination of the two given as two injections per day (at 0900 and 1700 h) for

two successive days. Control animals were given injection carrier alone. Where indicated, rats were deprived of food for 24 h. Animals were killed by cervical dislocation at 0930 and the livers excised and frozen in liquid nitrogen. They were homogenized and the acetone/diethyl ether powders prepared from the 100,000 × *g* supernatants of the homogenates as described (8).

Preparation of mammary microsomes. Microsomes were prepared from the mammary glands of rats in mid-lactation as previously described (15) and were stored at −80°C as a suspension in the medium used for the homogenization of the livers.

Assay of CEH. Neutral CEH activity in the microsomal membranes (100 μg) was routinely assayed in the presence and absence of the inhibitory fraction (40–120 μg) as described previously (8).

Protein measurement. The protein concentrations were determined by the dye-binding technique of Bradford (16) using crystalline bovine serum albumin as standard.

RESULTS

In order to make meaningful comparisons beween the different groups of animals, all of the assays were carried out using the same batch of mammary microsomal membranes. The results are then expressed in terms of the amount of cytosolic protein calculated to be necessary to achieve 50% inhibition of the neutral CEH in the mammary microsomes, under standard assay conditions. Thus, a smaller figure represents an increase in the amount of the inhibitory material present in the livers of the experimental animals. Moreover, since we have demonstrated previously that the activity of the inhibitory material was not affected by preparation of an acetone/diethyl ether powder from the liver cytosols, this methodology was adopted here. This has the advantage that residual cholesteryl esters were removed from the cytosol, and any variation in the hepatic content of this lipid could not affect the specific activity of the cholesteryl oleate used in the esterase assay. Furthermore, residual estradiol and progesterone also were removed to nullify the reported direct inhibitory effects of these hormones (10).

In comparison with the females, 35.6% more of the male hepatic cytosolic protein was required to achieve 50% inhibition of the mammary microsomal CEH (Table 1). The results indicate that the inhibitor in the livers of male rats was less potent than that in the female rats. This variation in inhibitory properties of the cytosols of adult male and female livers did not lead to significant differences in the levels of hepatic free and esterified cholesterol (Table 2). There was no evidence of an age-related variation in inhibitory activity in adult animals since the livers of young female rats (170–190 g) exhibited essentially the same activity as the livers of mature animals (280–320 g) (Table 1). However, the inhibitory activity in the livers of the 13-day-old suckling rats was significantly higher than that in the livers of adult animals. The differential noted between adult male and adult female animals was emphasized in these sucklings, where 42.8% more male cytosolic protein was required to achieve the same inhibition as that obtained with the females.

Effect of pregnancy and lactation. Since it is well established that female hormones have a marked effect on hepatic cholesterol metabolism, the effect of pregnancy and lactation on the activity of the hepatic inhibitory material was investigated. The effectiveness of the inhibitory activity showed a steady decline throughout pregnancy and lactation (Table 2). However, it was only in the livers of the animals at mid-lactation (day 10–14) that the differences from the mature controls achieved significance. In comparison with the controls, the mid-lactating animals required 31% more of the cytosolic protein to achieve 50% inhibition of the CEH activity in the

TABLE 1

The Influence of Sex and Age on the Activity of the Hepatic Inhibitor of Neutral CEH[a]

Animals	Age/weight	Inhibitor activity (μg of protein for 50% inhibition)
Adult males	300–340 g	107.20 ± 3.70(12)
Adult females	170–190 g	79.04 ± 1.62(5)[c]
Adult females	280–320 g	79.31 ± 3.82(4)[c]
Suckling males	13 days	81.80 ± 2.14(3)[e]
Suckling females	13 days	57.22 ± 4.76(3)[b,d]

[a]The results are the means ± SEM for the number of animals shown in parentheses and are expressed in terms of the amount of cytosolic protein required to accomplish a 50% inhibition of the mammary gland neutral CEH under standard assay conditions. Significant differences (Student's t-test) between males and females are indicated by [b], $P > 0.01$; [c], $P > 0.001$; and between adults and sucklings by [d], $P > 0.01$; and [e], $P > 0.001$.

TABLE 2

The Influence of Pregnancy, Lactation and Premature Weaning on the Hepatic Content of Free and Esterified Cholesterol and on the Activity of the Hepatic Inhibitor of Neutral CEH[a]

Condition	Inhibitory activity (μg protein for 50% inhibition)	Cholesterol (mg/100 g of tissue)	Cholesteryl (mg/100 g of tissue)
Virgins (av. 180 g)	79.04 ± 1.62(5)	151.3 ± 5.4	88.0 ± 7.0
Virgins (av. 300 g)	79.31 ± 3.82	n.d.	n.d.
Pregnant (day 12)	85.84 ± 3.67	159.8 ± 2.8	81.0 ± 1.2
Pregnant (day 20)	88.10 ± 2.79	138.3 ± 1.5	74.3 ± 0.5
Lactation (day 2)	92.41 ± 5.50	148.3 ± 4.1	81.5 ± 3.0
Lactation (day 12)	103.64 ± 3.04(15)[c]	173.8 ± 2.7[b]	95.3 ± 1.6
Litter-removed	104.92 ± 4.28(9)[c]	125.5 ± 4.3[b,e]	84.0 ± 2.4[d]
Male rats	107.20 ± 3.70(12)	166.8 ± 4.2	74.0 ± 5.0

[a]Litter-removed were without pups for 48 h prior to sampling. The results are the means ± SEM for four animals except where indicated by the numbers given in parenthesis. Inhibitory activity is expressed in terms of the amount of cytosolic protein required for 50% inhibition of the mammary CEH under standard conditions, n.d., not determined. Statistical differences (Student's *t*-test) are relative to the virgin animals [b], $P > 0.01$; [c], $P > 0.001$; between mid-lactators and litter-removed; [d], $P > 0.01$; [e], $P > 0.001$. The results for male animals are included for comparison.

TABLE 3

The Influence of Short-Term Starvation and Insulin Deprivation on the Hepatic Content of Free and Esterified Cholesterol and on the Activity of the Hepatic Inhibitor of Neutral Cholesterol Ester Hydrolase[a]

Condition	Inhibitory activity (μg protein for 50% inhibition)	Cholesterol (mg/100 g of tissue)	Cholesteryl ester (mg/100 g of tissue)
Pregnant (day 20) (24 h starved)	74.99 ± 1.95[d]	189.3 ± 6.5[e]	100.3 ± 2.7[e]
Lactation (day 12) (24 h starved)	85.09 ± 3.44(3)[e]	166.0 ± 3.3	87.8 ± 1.9
Streptozotocin	121.64 ± 3.58[c]	186.8 ± 4.5[b]	104.8 ± 4.7

[a]The starved animals had food withdrawn for 24 h prior to sampling. Streptozotocin (65 mg/Kg) was administered by intraperitoneal injection and the livers taken 3 h later. The results are the means ± SEM for four animals at each condition, except where indicated in parenthesis. Statistical differences (Student's *t*-test) expressed relative to the virgin females are indicated by [b], $P > 0.01$; [c], $P > 0.001$; expressed relative to the appropriate non-starved animals are indicated by [d], $P > 0.01$; [e], $P > 0.001$.

microsomes. The level of inhibitory activity in these mid-lactating animals was therefore similar to that seen in adult males. This was reflected in increases in the amount of free cholesterol present in the livers of the animals in mid-lactation although the cholesteryl ester content was not significantly altered.

Short-term starvation (24 h) of the late pregnant animals resulted in significant increases in the inhibitory activity (Table 3), to levels closer to those seen in the virgin animals. This was correlated with a highly significant increase in the hepatic cholesterol and cholesteryl ester content. Similar treatment (24-h starvation) of the mid-lactating animals also increased inhibitory activity but, in these animals, only a small decrease in cholesterol and cholesteryl ester content was observed. For comparison, starvation of male rats for 24 h had no effect on the hepatic inhibitory activity (8).

Influence of insulin. Lactating animals are hypoinsulinemic (17) suggesting that insulin may have an effect on the inhibitory activity. Short-term hypoinsulinemia has been induced in experimental animals following an injection of streptozotocin (17–19), and this technique was employed to investigate the influence of insulin on the inhibitory activity. Three hours after an injection of streptozotocin, the activity of the cytosolic inhibitor was significantly reduced with 69% more cytosolic protein being required to achieve 50% inhibition of the mammary microsomal esterase (Table 3). Furthermore, the drug significantly increased the hepatic concentration of free cholesterol and also appeared to increase cholesteryl ester levels. In contrast, short term (1 h) injections of insulin and glucose into mid-lactating animals did not alter inhibitory activity (results not shown). Thus, although reductions in insulin plasma levels do apparently influence the activity of the inhibitory material, other factors are also important.

Effect of growth hormone and prolactin. The mammary gland in the lactating rat extracts large amounts of circulating triacylglycerols and cholesterol to provide lipids for milk secretion. Inhibition of this secretory activity, which can be achieved by reducing the plasma levels of growth hormone and/or prolactin, would be expected to have marked effects on hepatic lipid metabolism. Rats in mid-lactation were therefore treated for two days, either with an antiserum to growth hormone or with the anti-prolactin drug, bromocriptine, or with a combination of the two agents. Although both bromocriptine and the antiserum individually produced a reduction in milk yield (20), neither was able to promote any alteration in the activity of the inhibitory material in the livers (Table 4). However, when the two agents were administered simultaneously, a 29% increase in the activity of the inhibitory material was observed. This brought it to the level that was found in the livers of non-lactating animals. The complete cessation of milk production in the mammary gland, produced by the simultaneous injection of these two anti-hormone agents, is similar to that obtained when the animals are prematurely weaned (21). However, removal of the litters for 48 h prior to sampling made no difference to the effectiveness of the inhibitory material in the liver, which remained at the same level as that found in the mid-lactating animals (Table 2). Although the two anti-hormone agents did not change inhibitor activity when administered separately, individually they caused significant decreases in the hepatic level of both cholesterol and cholesteryl ester. However, with the combined administration of the antiserum and bromocriptine, hepatic cholesterol levels were unaltered from controls, whereas cholesteryl ester levels were increased, as was consistent with the enhanced activity of the inhibitor.

DISCUSSION

The results presented here indicate that the hepatic inhibitor of neutral CEH, identified in a previous report (8), is more active in the female liver than in the male liver. Sexual differences in rat hepatic cholesterol metabolism have been attributed to the action of the female sex hormones estradiol and progesterone (9,14,22–26). Administration of ethinylestradiol to rats results in an increase in hepatic esterified cholesterol and an apparent decrease in CEH activity (9,10,26). The increased inhibitory activity seen in the female livers would therefore correlate with this effect of the estrogen and may help

TABLE 4

The Activity of the Inhibitory Cytosolic Protein Factor in the Livers of Rats in Mid-Lactation: Influence of Variation in Serum Prolactin and Growth Hormone Levels[a]

Treatment	Inhibitory activity (μg protein for 50% inhibition)	Cholesterol (mg/100 g of tissue)	Cholesteryl ester (mg/100 g of tissue)
Control	103.64 ± 3.04(15)	173.8 ± 2.7	95.3 ± 1.6
Antiserum to growth hormone	106.50 ± 12.60(5)	152.5 ± 6.7[b]	76.0 ± 4.7[c]
Bromocriptine	107.70 ± 9.40(6)	156.0 ± 2.7[c]	82.8 ± 2.1[c]
Antiserum + bromocriptine	80.30 ± 4.20(11)[c]	181.5 ± 3.1	104.3 ± 3.3[b]

[a]Rats in mid-lactation were treated with the various combinations of agents and the livers analyzed for inhibitor activity and cholesterol and cholesteryl ester content as described in Materials and Methods. The results are the means ± SEM for four animals except where indicated by the numbers in parenthesis. Inhibitory activity is expressed in terms of the amount of cytosolic protein required to achieve 50% inhibition of the mammary microsomal CEH under standard conditions. Significant differences, analyzed by Student's *t*-test, are indicated between treatments and controls: [b], $P > 0.05$; and [c], $P > 0.002$.

to explain some of the well documented differences in cholesterol metabolism between the sexes. In spite of the difference in inhibitor activity between males and females, there was no significant difference in their hepatic cholesteryl ester contents. This may reflect the fact that these were untreated animals, whereas the reported increases in cholesteryl ester content resulted from treatment with pharmacological doses of the estrogens (26). Alternatively, it may reflect the presence of separate pools of free and esterified cholesterol (27–34), only some of which are influenced by the inhibitor.
