Progesterone increases the biliary output of cholesterol (35) and inhibits the activity of acyl-CoA:cholesterol acyltransferase (ACAT), the enzyme responsible for cholesterol esterification (36,37). High progesterone levels occur in late pregnancy, so the observed decrease in hepatic cholesterol content is consistent with the proposition of increased biliary output of the sterol. Replenishment of the hepatic cholesterol pool may involve an increase in CEH activity, a suggestion supported both by the decrease in the hepatic cholesteryl ester content and by the reduction in inhibitor activity. It is interesting to note that young women taking oral contraceptives (high in progesterone) are more susceptible to gallstones (38), raising the possibility that variations in the activity of this inhibitor is a factor in the etiology of this disease.

The results obtained with pregnant animals following 24-h starvation are also consistent. The reduction in biliary output would increase the hepatic cholesterol content and provide more substrate for ACAT, leading to a greater cholesteryl ester content. The effect of a higher inhibitory activity on the esterase would ensure that this increased level of cholesteryl ester was maintained.

Hepatic cholesterol synthesis is increased in lactation (39), but the hyperphagia associated with this physiological state (17) imposes an additional requirement for cholesterol for increased secretion of very low density lipoproteins (VLDL) (40,41). This correlated with the decreased inhibitory activity in these animals which would permit increased hydrolytic breakdown of the stored cholesteryl esters. Following short-term starvation (24 h), VLDL secretion would be diminished and hepatic storage of the esterified sterol would assume a greater importance. Thus, inhibitory activity was increased in response.

Bromocriptine has been reported to decrease mammary lipoprotein lipase (LPL) activity, but not the accumulation of lipid by the mammary gland (42), indicating that continued secretion of hepatic VLDL was required. Therefore, it was not surprising that the level of hepatic inhibitory activity in the lactating animals was unaltered when this drug was administered. More paradoxical was the lack of change in inhibitory activity following removal of the pups, since this was reported to cause a massive decrease in lipid accumulation in the mammary gland (42). However, in weaned animals, the LPL activity of white adipose tissue was increased and lipid deposition in the adipose tissue became predominant (42). The level of inhibitory activity in the liver may thus reflect a continued demand for cholesterol, for VLDL secretion, and this correlates with the reduction in free and esterified cholesterol in the liver.

The effects of injecting bromocriptine together with the antiserum were more puzzling. This treatment was reported to reduce milk yield (20) and to both reduce mammary LPL activity and elevate adipose tissue LPL to a level similar to that obtained on litter removal (Clegg, R.A., unpublished data). In the current experiments an increase in hepatic cholesteryl ester was observed concomitant with a decrease in inhibitor activity. No explanation for this difference between the litter removal and the anti-hormone treatments can be provided, although it should be noted that the two physiological conditions are not identical. The pups continued to suckle during the anti-hormone treatment and the mammary gland was depleted of milk, whereas weaning led to an accumulation of milk. Alternatively, since the liver has specific receptors for both prolactin and growth hormone, the observed result may arise from a direct effect on the liver, due to

removal of these hormones, rather than from a secondary effect related to the hepatic secretion of cholesterol.

The differences in inhibitor activity in the suckling animals are also interesting since sex differences in cholesterol metabolism normally only become apparent after puberty at about 6-7 weeks of age (43). Suckling animals, nevertheless, do show large sexual differences in the hepatic enzymes that metabolize steroids (25,44-46). Thus, the observed variations in the inhibitory activity in these animals suggests that the inhibitor is of fundamental importance, and may function not only in the control of hepatic cholesterol metabolism, but also possibly in controlling other aspects of steroid metabolism. Finally, the lower risk of coronary heart disease in premenopausal women when compared with males of equivalent age has been repeatedly confirmed by clinical and epidemiologic studies. The evidence that the female liver contains a more highly active inhibitor of the hepatic CEH, leading to increased hepatic storage of cholesterol as the ester, may help to provide an explanation for some of these differences. If this were proven then pharmacological manipulation of this inhibitory activity may constitute an important advance in the treatment of a number of diseases characterized by altered cholesterol metabolism.

ACKNOWLEDGEMENTS

We thank Dr. D.J. Flint, Hannah Research Institute, Ayr, for the antiserum to rat growth hormone. The research was funded by the Scottish Office Agriculture and Fisheries Department.

[Received October 31, 1991; Revision accepted March 27, 1992]

Cholestane as a Digestibility Marker in the Absorption of Polyunsaturated Fatty Acid Ethyl Esters in Atlantic Salmon[1]

Salmonid fish require long-chain n-3 fatty acids in their diet. The digestibility of different chemical forms of fish oil fatty acids, fed as triacylglycerols, free fatty acids or ethyl esters, was examined in 300 g farmed Atlantic salmon (*Salmo salar*) using cholestane as an indicator of fat absorption *in lieu* of the chromium oxide (Cr_2O_3) which is commonly used as a marker in digestibility studies. It was established that the two digestibility markers gave similar results. Conveniently, cholestane does not require a separate analysis if fatty acids are to be determined by appropriate gas-liquid chromatography. The long-chain polyunsaturated fatty acids were particularly well absorbed, the apparent digestibility being 90–98% when feeding triacylglycerols or free fatty acids. However, the digestibility of monounsaturated fatty acids (75–94%) was lower, and lower still for saturated fatty acids (50–80%). Ethyl esters of fatty acids were significantly less well absorbed ($P < 0.05$) than were the corresponding fatty acids in free acid or triacylglycerol form. Irrespective of dietary fat type, only free fatty acids were identified in feces, indicating total hydrolysis of triacylglycerols and ethyl esters.
***Lipids* 27, 418–424 (1992).**

Ethyl esters or free fatty acids are the most economical forms in which highly concentrated marine n-3 fatty acids are available in bulk (1,2). Some researchers have assumed that ethyl esters of n-3 fatty acids are efficiently absorbed by humans and rats (3–5). As ethyl esters are not a natural food, it is possible that they are not hydrolyzed by lipases as efficiently as are natural fats in humans and in animals (6–8). On the basis of previous *in vitro* work (9) it has been assumed that long-chain n-3 polyunsaturated fatty acid esters with ethylenic bonds near the carboxyl group may be resistant to pancreatic lipolysis in mammals. This may reduce absorption and lower transfer of these fatty acids to lymph and blood (10). However, others have suggested that once triacylglycerols containing n-3 fatty acids are hydrolyzed, the n-3 fatty acids liberated are totally absorbed *in vivo* (6,7,11). Indeed, since the digestion *in vivo* may go on for hours, the rate of lipolysis *in vitro* may have little influence on the total amount of fat absorbed.

Polvi (12) observed that ethyl esters were absorbed by Atlantic salmon, although the absorption efficiency was not determined. She also noted that growth was less than with triacylglycerol oils. It has been established that the physiological specificity of hydrolysis by fish intestinal juices is markedly different from that of human pancreatic lipase, for example (13,14). The products of intraluminal hydrolysis of triacylglycerols in mammals are monoacylglycerols and fatty acids. In salmonids, monoacylglycerols are, to a large extent, hydrolyzed into fatty acids and glycerol (13). Recent work with cod (*Gadus morhua*) has isolated a bile salt dependent lipase capable of 1,3-hydrolysis of trioleoylglycerol, and also capable of hydrolyzing methyl esters of fatty acids (15). However, another enzyme, a nonspecific lipase different from pancreatic lipase, that competes effectively with lipase as a major fat digestive enzyme in fish, may be involved (13,14). An additional example of hydrolysis is that of wax esters, important food components for clupeid fish (16,17), but also digested by cod (18). If more than one lipase is present in the gastrointestinal tract of fish (13) there exists the possibility of equally rapid and complete absorption of fatty acids fed as triacylglycerols or as ethyl esters. Although the digestibility of dietary lipids in triacylglycerol form has been discussed (19), there are no reports on the absorption of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) when fed to fish in either ethyl ester or free fatty acid form.

In digestibility studies, inert markers or indicators such as chromium oxide (Cr_2O_3) are commonly used (20). However, Cr_2O_3 is not without some problems (21), and has one serious disadvantage in that it has to be determined by an analysis separate from fat or fatty acids. In lipid nutrition, a marker preferably should be recovered along with lipids, and also be determined readily by lipid analytical techniques. The hydrocarbon squalene has been examined as a digestibility marker for absorption of other hydrocarbons in rats by Albro and Fishbein (22). It is established that, in general, the extent to which alkanes are absorbed by mammals decreases with chain length and with increasing melting point (22,23). Unfortunately, alkanes are often present in both plant and animal food sources (24), but cholestane appeared to be a xenobiotic and offered a suitable set of physical and chemical properties for this role.

The objectives of the present study were to investigate cholestane as a suitable marker for lipid digestibility studies with fish, and to determine the absorption of ethyl esters of fatty acids and especially of the polyunsaturated fatty acids of marine oils.

MATERIALS AND METHODS

Fish and diets. Two experiments were conducted. The first experiment was designed to examine the suitability of cholestane as an indicator of fat absorption, the second to apply this marker in a digestibility study. In both studies, Atlantic salmon smolts (averaging 300 g each) were acclimated to feed, aquaria and standardized experimental conditions (25). Seawater was supplied to each tank at a flow rate of 3 L per min and maintained at 15 ± 1°C in a flow-through system. The photoperiod (12

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; EE, ethyl ester; FFA, free fatty acid; GC, gas chromatography; TLC/FID, thin-layer chromatography with flame ionization detection.

h daily) was controlled automatically. Feeding to satiety was by hand (twice) during the lighted period.

In a preliminary study, a commercial diet containing 16% fat was supplemented with herring oil containing cholestane (Sigma, St. Louis, MO), to increase the fat level of the diet to 22% and to provide cholestane at 0.25% of diet lipid. After three days of feeding, fish were anaesthetized by immersion in seawater containing MS 222 (ethyl *m*-aminobenzoate methanesulfonate). Blood samples (1 mL) were drawn from the caudal artery in a heparinized syringe, and feces were collected from the rectal region of three fish by applying gentle pressure to the surface of the fish from the ventral fins towards the anus.

In the main study, a casein-gelatin based purified diet (Table 1) was used to determine the digestibility of marine oil fatty acids which were supplied in three different chemical forms in the diet. Twenty-five Atlantic salmon smolts per tank in each of five tanks were fed five separate test diets (Table 1) with four of the diets differing only in lipid source (15% of diet). The following four lipid supplements were tested: 15% Menhaden oil (Diet 1); 15% free fatty acids of menhaden oil (Diet 2); 15% ethyl esters of menhaden oil (Diet 3); and 15% of a mixture (1:1) of ethyl esters of menhaden oil and of corn oil (Diet 4). Cholestane was dissolved in the various lipid supplements (before they were mixed with the basal diet) to give a level of 0.7 mg/g diet (equal to 0.5% of fatty acids). The fifth diet, with 15% menhaden oil, was prepared by incorporating chromic oxide (Fisher Scientific Ltd., Fairlawn, NJ) at a level of 0.5% as a standard digestibility marker instead of cholestane. The first five days constituted an acclimation period and no feces were collected during this period. After five days fish were anaesthetized and feces were collected. Feces were stripped from respective groups of approximately 12 fish at one time (a.m. and p.m. subsamples of approximately 5 g each were obtained from each tank on each day and pooled). This procedure was repeated on the same fish after three days. Feces samples were immediately frozen at −30°C until required for analysis.

Preparation of ethyl esters, free fatty acids and analysis of diets. The ethyl esters and free fatty acids were made from menhaden oil according to Christie (26), and Nadenicek and Privett (27), respectively, with minor modification. An Iatroscan TH-10 Mark III TLC/FID (thin-layer chromatography with flame ionization detection; Newman-Howells Associates Ltd., Penybont Uchaf, Great Britain) was used to determine the chemical purity of the ethyl esters and free fatty acids prepared from menhaden oil. The procedure was basically that described by Parrish and Ackman (28). The Iatroscan also was used for quantification of lipid classes in feces. Area measurements were performed with a SP4200 computing integrator. The air flow was 2 L/min and the detector hydrogen flow rate 160 mL/min. The recording chart speed was 16 cm/min and the scanning speed 0.42 cm/s. The yield of ethyl esters and free fatty acids was 85%, and the chemical purities 99% and 89%, respectively.

Lipid and fatty acid analysis. Duplicate samples of each experimental diet (20 g) were weighed, placed in a beaker with 70 mL of water and sonicated for 15 min. The solution was then mixed in a Waring Blendor for chloroform/methanol extraction of lipid by the method of Bligh and Dyer (29). Lipids were extracted from feces and plasma by the Folch method as modified by Christie (26, and references therein). Dilute hydrochloric acid solution (3N) was added to the last extraction of the feces, to destroy any calcium soap present. Total lipids were examined for lipid classes by Chromarod-Iatroscan (only μg being required), with development in hexane/diethyl ether/formic acid (97:3:1, vol/vol/vol). The recovered lipids were transesterified and/or esterified by the method of Morrison and Smith (30). Recovered methyl esters of fatty acids and the cholestane were determined simultaneously by capillary gas chromatography (GC) in a Perkin-Elmer model 900 gas chromatograph (Perkin Elmer, Norwalk, CT) fitted with a SUPELCOWAX-10 (bonded polyethylene glycol) fused silica column, dimension 30 m × 0.32 mm, phase thickness 0.2 μm (Supelco Canada Ltd., Oakville, Ontario, Canada). Helium pressure was set at 76 kPa. The temperature program used was isothermal at 195°C for 8 min, followed by an increase at 3°C/min to 240°C, and a final isothermal hold of 20 min. For the determination of fatty acid composition the weight percentage of each fatty acid was calculated according to Ackman and Eaton (31). Peaks were identified by comparing the retention times with those of standard mixtures of known fatty acid methyl esters. Cholestane was used to calculate digestibility by the equation:

$$D(\%) = 100 - \frac{\text{(area chol-feed)}}{\text{(area chol-feces)}} \times \frac{\text{(area fa-feces)}}{\text{(area fa-feed)}} \times 100$$

where areas are obtained from peaks of GC chromatograms (chol-feed, cholestane in feed; chol-feces, cholestane in feces; fa-feed, fatty acid in feed; fa-feces, fatty acid in feces).

TABLE 1

Composition of the Experimental Diets in the Exploratory Phase

Feed ingredients	Amount (w/w %)
Casein	40.0
Gelatin	8.0
Dextrin	9.5
Starch	8.3
D-glucose	4.0
Carboxymethylcellulose	2.0
Alpha cellulose	5.0
Vitamin mixture[a]	1.0
Mineral mixture[b]	4.0
Amino acid-mixture[c]	3.0
Choline chloride	0.2
Lipid supplement[d]	14.93
Cholestane[e,f]	0.07

[a]Supplied vitamins at following levels: (I.U. or mg/kg) Thiamin, 50; riboflavin, 60; d-calcium pantothenate, 200; biotin, 1; folic acid, 20; vitamin B_{12}, 0.1; niacin, 250; pyridoxine, 40; ascorbic acid, 1000; inositol, 400, vitamin A, 8000 I.U.; vitamin D_3, 2400 I.U.; vitamin E, 300 I.U.; and vitamin K, 40.

[b]Supplied minerals at following levels: (mg/kg) Manganese, 50; iron, 60; zinc, 120; and copper, 25.

[c]Amino acids supplied at following levels (%): DL-methionine, 0.5; L-arginine-HCl, 1.0; and betaine amino acid additive, 1.5 (Finnstim, Finnish Sugar Ltd., Finland).

[d]Lipid supplements had the following forms. Diet 1, menhaden oil; Diet 2, free fatty acids of menhaden oil; Diet 3, ethyl esters of menhaden oil; Diet 4, ethyl esters of menhaden oil and triacylglycerols of corn oil (1:1); and Diet 5, menhaden oil.

[e]Cholestane was dissolved in lipid supplements 1–4 prior to mixing.

[f]Diet 5 contained chromic oxide instead of cholestane.

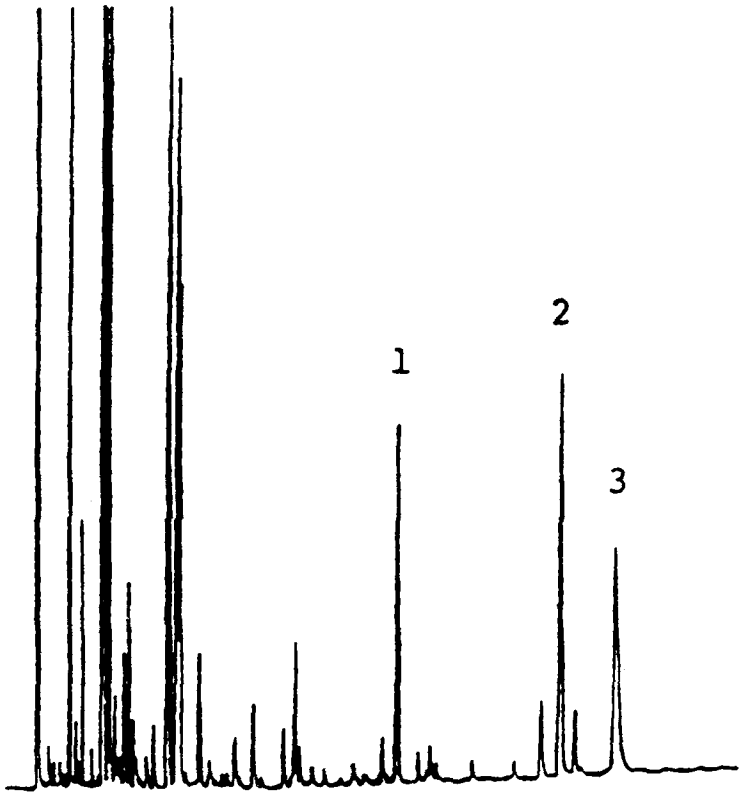

FIG. 1. Gas-liquid chromatogram of methyl esters of fatty acids recovered from feces of Atlantic salmon on a fish oil diet. Peak designations: 1, Eicosapentaenoic acid; 2, docosahexaenoic acid; and 3, cholestane. Other peaks represent saturated, monounsaturated and polyunsaturated fatty acids common in fish oil.

Chromic oxide analysis. Chromic oxide in Diet 5 and in the associated feces was determined according to the method of Arthur (32).

Statistics. Data sets were analyzed by analysis of variance and two-sample *t*-tests. Differences were considered significant if $P < 0.05$. The arcsin transformation (33) was used where statistical comparisons were performed on proportion data. The F-test was used to determine whether the standard deviations of the sample were significantly different ($P < 0.05$).

RESULTS AND DISCUSSION

Cholestane as a digestibility marker. Cholestane ($C_{27}H_{40}$, MW 372.65, m.p. 80°C) was selected on the basis of its physical and chemical properties, such as lipid solubility and the absence of interference with the analysis of fatty acid methyl esters on "bonded" polyglycol wall-coated open-tubular gas chromatography columns (Fig. 1). Cholestane has not been used previously as a digestibility marker. Squalane has been recommended as a lipid digestibility marker in rats (22), but squalane was unsuitable because of the possibility of interference with the analysis of longer-chain fatty acid methyl esters when analyzed by GC on the SUPELCOWAX-10 column. Chromic oxide, the most commonly used digestibility marker (20,21), is not fat soluble and must be determined separately from fat and fatty acids.

In a preliminary study, after feeding diets supplemented with cholestane for three days, cholestane was found to be highly concentrated in the fecal fatty acids, 3.0% *vs.* 0.3% in those of the feed. Cholestane was detected in fish plasma lipids at very low levels (Table 2). To estimate the absorption of cholestane, it was assumed that a dietary lipid steady state was achieved in plasma concentrations of cholestane after continuous feeding of diets *ad libitum* for three (or five) days, and that plasma n-3 polyunsaturated fatty acids were mostly freshly absorbed (34) and represented dietary fat. From this viewpoint, cholestane is calculated to be absorbed at less than 5% of n-3 polyunsaturated fatty acids. The proportion of cholestane absorbed could reflect the various other types of lipids present in the diet. In this context, the results of the preliminary study could be applied with confidence to Diets 1 and 2 based on triacylglycerols. The similarity of results for ethyl esters only and ethyl esters plus triacylglycerols (Table 3) suggests that cholestane was equally suitable for other high-fat diets.

Comparison of cholestane and chromic oxide as digestibility markers. The digestibility of fatty acids in the form of triacylglycerols was not significantly ($P > 0.05$) different when using either chromic oxide or cholestane. However, the standard deviation was observed to be higher for all of the fatty acids except one, and significantly higher ($P < 0.05$) for three fatty acids when using chromic oxide (Table 4). To determine fatty acid absorption with cholestane as a digestibility marker, the proportion of cholestane and fatty acids in the feed could be com-

TABLE 2

Representative Total Fatty Acid Profiles (w/w %) of the Fatty Acids in the Diet, Feces and Plasma of Atlantic Salmon and Cholestane Area Relative to Fatty Acids After Feeding a Commercial Diet Supplemented with Cholestane for Three Days[a]

[a]Data are the mean of two determinations.
[b]Ratio of carbon atoms to double bonds.
[c]Methyl group on C_7.
[d]Number of carbon atoms from the methyl end of the acyl chain to the nearest double bond.
[e]Isomers not separated.
[f]Hydrocarbon marker was added to the diet at a level of 0.25% of lipid or 0.277% of fatty acids.

pared directly to that in the feces. Therefore, cholestane was accepted as a convenient and suitable indicator of fat absorption.

Fatty acid absorption by Atlantic salmon. The apparent digestibility of total fatty acids (84%), fed either as triacylglycerols or as free fatty acids (Table 4), is in agreement with results from Austreng *et al.* (19), who observed digestibility of total fatty acids in rainbow trout to be 84–90%. The long-chain n-3 polyunsaturated fatty acids were particularly well absorbed, the apparent digestibilities being 90–97% when fed either as triacylglycerols or as free fatty acids (Table 3). The digestibility of monounsaturated fatty acids was 75–94%, depending on the chain length. However, the absorption was lower for saturated fatty acids, diminishing from 70% for 14:0 to 50% for 18:0 (20:0 was present at very low levels in the diet, and was difficult to determine accurately). The poor absorption of saturated fatty acids compared to unsaturated analogs of equivalent chain length (Fig. 2) is in agreement with results in rats observed by Carroll (35), and was recently confirmed by de Schrijver *et al.* (36) for C_{18} fatty acids. Lie and Lambertsen (18) examined gut and intestinal contents and considered that specificity of enzyme is a factor in discrimination among fatty acids absorbed by cod (*Gadus morhua*). The reason for preferential absorption of polyunsaturated fatty acids is not obvious, as the longer and more unsaturated fatty acids have been observed to be more slowly hydrolyzed by pancreatic lipase *in vitro* (9). In rats fed fish oils, however, these fatty acids appear almost immediately (30 min) in the lymph (37), so *in vitro* studies can be unreliable guides.

The absorption of the fatty acids esterified to glycerol was inversely correlated with the melting points of the fatty acids (R = 0.92), where the digestibility decreased with increasing melting points (Fig. 3). This has been reported by other investigators (19,38). Austreng *et al.* (19) examined the digestibility of fatty acids of different melting points in mink and in trout, using chromic oxide as the marker. One possible explanation for the low absorption of saturated fatty acids lies in the calcium present in intestinal fluids. This has been reported to affect the fatty acid absorption. Gacs and Barltrop (39) observed both the solubility of fatty acid calcium soaps and the absorption of calcium to be inversely correlated with chain length and the degree of saturation of the dietary fatty acids. The solubility in intestinal fluid could control the final rate of absorption.

The absorptions of EPA and DHA fed as ethyl esters were significantly less ($P < 0.05$) than the absorption of the triacylglycerols and free fatty acid forms of these same long-chain polyunsaturated fatty acids. This was observed when feeding ethyl esters at the 15% level and also at the 7.5% level (Fig. 4, Table 3). This is in agreement with the conclusions of El Boustani *et al.* (6) and of Lawson and Hughes (7), who observed incorporation of EPA and DHA, fed as ethyl esters, into plasma triacylglycerols in humans, and found that the incorporation was lower than when they were administered as triacylglycerols or as free fatty acids. Such "pulse" feeding is not apt to yield the same results as feeding over extended time periods (36). The superior absorption of the ethyl ester of EPA (Fig. 4) as compared to that of DHA is matched by that for methyl esters exposed to the cod lipase (15) at 37°C, where the activity towards EPA was nearly ten-fold that towards DHA. This appeared to be related to fatty acid chain length rather than to the frequently discussed position of the double bond nearest the carboxyl group (40).

When digestibility was calculated for total fatty acids and lipids, the total fatty acids were not absorbed nearly as well ($P < 0.05$) when fed as ethyl esters as when fed as triacylglycerols or free fatty acids (Table 3). This was emphasized by the significantly ($P < 0.05$) higher dry weight (Table 5) in the feces from fish fed ethyl esters (Diets 3 and 4). The absorptions of fatty acids of triacylglycerols and of actual free fatty acids were not significantly different (Table 3). In rats, free acids were not as well absorbed as the same acids in triacylglycerol form (36).

The apparent digestibilities obtained from the first and second fecal collections were not significantly ($P > 0.05$)

TABLE 3

Apparent Digestibilities in Atlantic Salmon of Fatty Acids in Various Chemical Forms[a,b]

Fatty acid	Diet 1 (%)	Diet 2 (%)	Diet 3 (%)	Diet 4 (%)

Lipids[c]	85.9 ± 2.2	86.2 ± 2.5	77.3 ± 1.9[b]	78.1 ± 1.2[b]

[a]Diet 1, triacylglycerols; Diet 2, free fatty acids; Diet 3, 15% ethyl esters; and Diet 4, 7.5% ethyl esters/7.5% corn oil. Data are the mean ± SD of four determinations of the proportion (%) of the fatty acids, except for the group fed ethyl esters 15% (two determinations).

[b]Significantly ($P < 0.05$) different from triacylglycerols and free fatty acids.

[c]Digestibility of lipids is determined by comparing the proportion of lipid and cholestane content of dry weight feed and feces.

TABLE 4

Comparison of Digestibility (%) in Atlantic Salmon of Fatty Acids When Fed as Triacylglycerols, Determined by Using Cholestane or Chromic Oxide as the Marker[a,b]

Fatty acids	Cholestane (%)	Chromic oxide (%)
14:0	78.3 ± 0.4	77.4 ± 5.1[c]
16:0	64.6 ± 2.8	58.0 ± 8.6[c]
16:1n-7	93.5 ± 2.9	92.4 ± 3.3
18:0	52.3 ± 4.1	46.2 ± 10.6[c]
18:1n-9	90.5 ± 3.6	86.9 ± 3.4
18:2n-6	90.8 ± 3.1	90.7 ± 5.4
18:3n-3	93.7 ± 2.1	92.9 ± 2.4
20:5n-3	96.8 ± 1.9	95.1 ± 2.4
22:6n-3	91.0 ± 4.8	87.5 ± 5.8

[a]Data are the mean ± SD of four determinations.

[b]No significant ($P > 0.05$) difference was observed between the mean of the two groups for any fatty acid.

[c]SD is significantly different ($P < 0.05$) from SD observed when using cholestane.

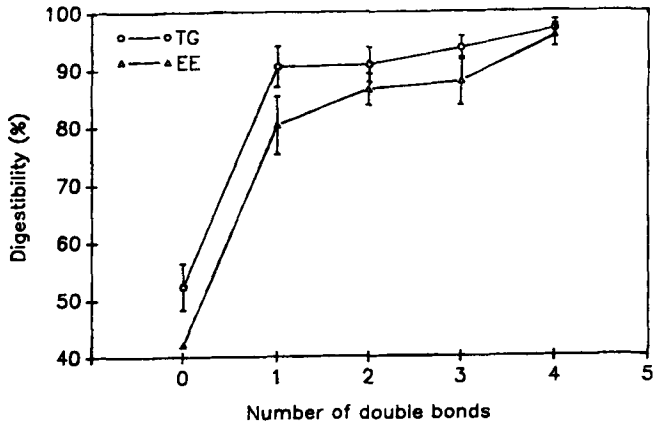

FIG. 2. Digestibility (%) in Atlantic salmon of fatty acids composed of 18 carbons fed as triacylglycerols (TG) and ethyl esters (EE), plotted as a function of their unsaturation. Data are the mean ± SD of four determinations.

different, except for the group fed ethyl esters only (Diet 3). This group had diarrhea at the second collection and the results from this fecal collection were excluded from calculations. The fatty acids in the feces were in the free acid form in all of the groups (Fig. 5), except for the group fed ethyl esters only, at the second time of fecal collection (data excluded). Therefore, all of the dietary lipids were totally hydrolyzed as predicted by Yang *et al.* (40). The diet which contained both corn oil triacylglycerol and marine oil fatty acid ethyl esters (Diet 4) did not show any difference in absorption from the diet which contained the latter as ethyl esters only (Diet 3). This indicates that the added triacylglycerol in Diet 4 did not facilitate the dissolution of the ethyl esters into the intestinal micelles, or otherwise promote digestibility. Such a dissolution step is thus not a rate-limiting factor in absorption. The differences in absorption of fatty acids or ethyl esters could still result from impairment at the ethyl ester hydrolysis step. This was complete (Fig. 5), but could have been completed too late to provide for completion of absorption. The digestive process in fish (13,15,16,18) may not be totally explainable in terms of mammalian pancreatic lipase activity *in vitro* (36,40).

It can be concluded that dietary fatty acids, as ethyl

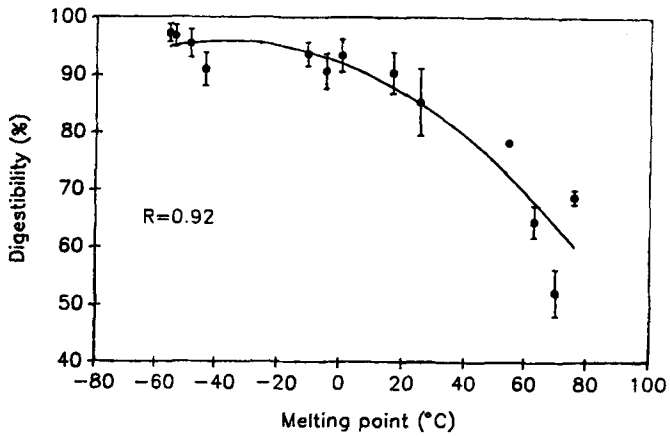

FIG. 3. Digestibility (%) in Atlantic salmon of fish oil fatty acids fed as triacylglycerols, plotted as a function of their melting point. Data are the mean ± SD of four determinations. For one point, the SD was too small to mark.

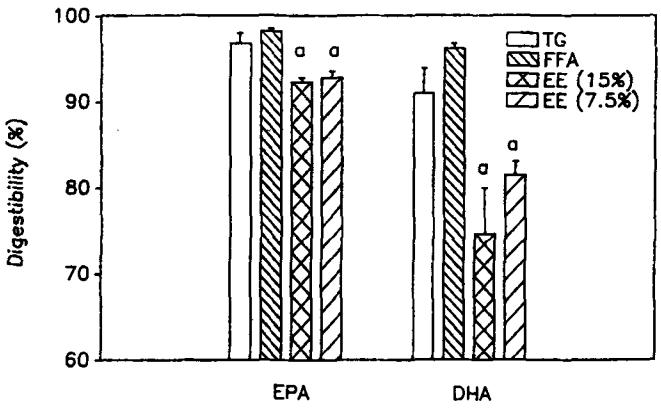

FIG. 4. Digestibility in Atlantic salmon of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in different chemical forms; triacylglycerols (TG), free fatty acids (FFA), and ethyl esters (EE). Data are the mean ± SD of four determinations, except for the group fed 15% ethyl esters (two determinations). [a]Mean is significantly ($P < 0.05$) different from mean digestibility when feeding free fatty acids and triacylglycerols.

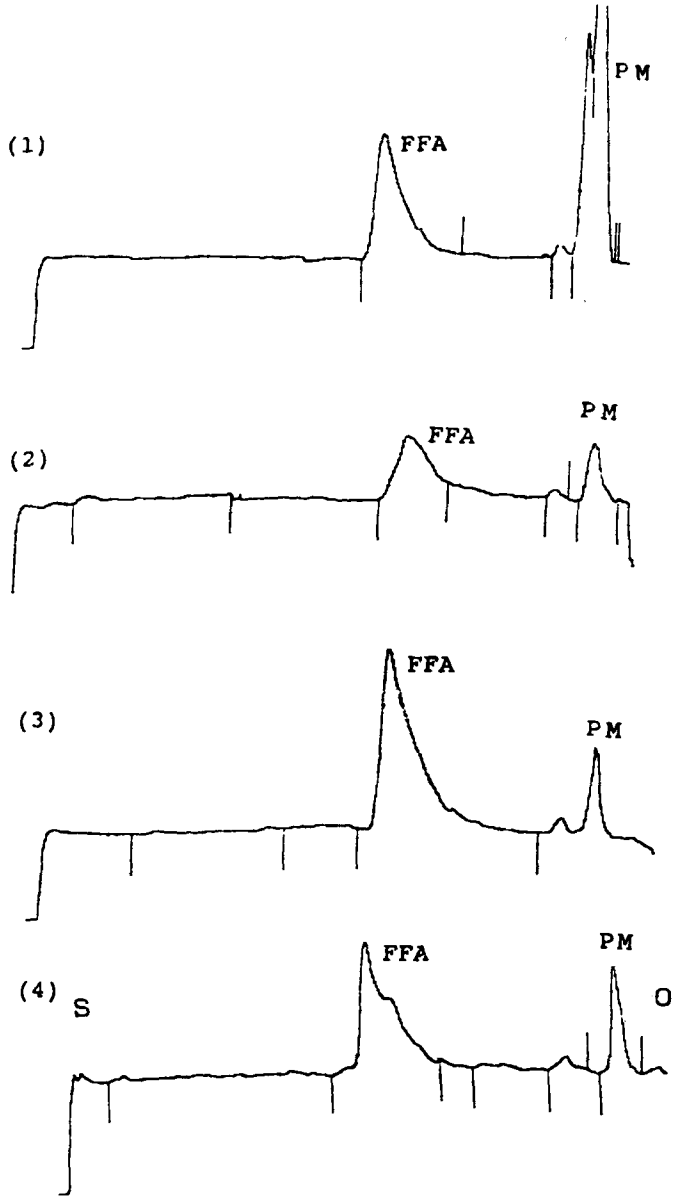

FIG. 5. TLC/FID chromatograms of the classes in lipids of feces of Atlantic salmon when fed; (1) triacylglycerols (TG), (2) free fatty acids (FFA), (3) ethyl esters (EE) and (4) a 1:1 mixture of triacylglycerols and ethyl esters (TG/EE). PM refers to polar materials, all soluble in chloroform and, hence, lipids. The origin of scan (0) and stop at end (S) are marked. Ethyl esters (not shown) are more mobile than FFA on silica gel Chromarods and were only observed in the one feces sample from fish with diarrhea. Triacylglycerols (not shown) were not observed, but would have appeared between PM and FAA.

Dry Weight and Lipid Content of Feces from Atlantic Salmon, Fed Four Different Diets[a]

Diet	Dry weight (%)[b]	Lipid (%dwb)[c]
1	13.5 ± 0.8	6.1 ± 0.7
2	10.9 ± 1.3	5.2 ± 1.0
3	16.8 ± 1.5	6.2 ± 0.1
4	15.9 ± 2.5	9.1 ± 0.8

[a]Diet 1, triacylglycerols; Diet 2, free fatty acids; Diet 3, 15% ethyl esters; and Diet 4, 7.5% ethyl esters/7.5% corn oil.
[b]Data are the mean ± SD of 4 determinations.
[c]Data are the mean ± SD of 2-4 determinations.

esters, are not absorbed as well by Atlantic salmon as the same fatty acids fed in free acid form or as triacylglycerols. Subsequent deposition of fatty acids from ethyl esters, for example, in muscle phosphatidylcholine (41), appeared to be normal (12). The preferred form for concentrate administration should therefore be free fatty acids. Cholestane is especially convenient and useful as a marker for studying the digestibility of fatty acids in any form, and lends itself especially well to total saponification of feces *in lieu* of lipid extraction (42).

ACKNOWLEDGMENTS

The assistance of Andrew Harris in conducting feeding trials and the advice of S.F. O'Keefe and N.C. Shantha is gratefully acknowledged. The authors wish to thank D.J. Scarrett and J.D. Castell for critical review of the manuscript. This work was supported by the Natural Sciences and Engineering Research Council of Canada.

[Received December 4, 1991; Revision accepted April 26, 1992]

Comparison of the Effects of Dietary Fish Oils with Different n-3 Polyunsaturated Fatty Acid Compositions on Plasma and Liver Lipids in Rats

I. Banerjee, S. Saha and **J. Dutta***
Department of Chemistry, Bose Institute, Calcutta 700 009, India

The effects of dietary fish oils with different n-3 polyunsaturated fatty acid compositions on plasma lipid profiles in rats have been studied. Forty-eight male rats, previously maintained on a cholesterol-free diet for 15 days, were fed for 60 days with diets supplemented with 10% fat of either marine hilsa fish (*Hilsa ilisa*, family clupeidae) or fresh-water chital fish (*Notopterus chitala*, family notopteridae). The diets had similar levels of total saturated (35–41%), monounsaturated (43–47%) and n-3 polyunsaturated (9–10%) fatty acids. Cholesterol contents of the diets were adjusted to 0.85%; γ-linolenic acid (3.3%) in chital oil and eicosapentaenoic acid (4.9%) in hilsa oil diets were the major n-3 contributors. The percentage of eicosapentaenoic acid in the chital oil diet was 0.57 times that of the hilsa oil diet, but the eicosapentaenoic (EPA) to arachidonic acid (AA) ratio in the latter (4.08) was 3.2 times that of the former (1.27). Sixty days of hilsa oil diet feeding decreased the levels of cholesterol (53.3 ± 2.9 to 50.0 ± 1.1 mg/dL), triacylglycerol (75.7 ± 3.8 to 64.3 ± 2.6 mg/dL) and phospholipid (55.8 ± 1.5 to 51.7 ± 3.1 mg/dL) in rat plasma. Similar treatment with chital oil diet elevated the plasma cholesterol level (53.3 ± 2.9 to 62.3 ± 7.6 mg/dL) while triacylglycerol and phospholipid contents remained unaltered. Both the dietary treatments decreased the levels of linoleic and arachidonic acids in liver but only under the hilsa oil diet did the eicosapentaenoic acid percentage increase markedly (0.8 ± 0.06% to 5.5 ± 0.06%) at the expense of arachidonic acid. This study strongly suggests that the hypolipidemic effect depends on the composition of the n-3 polyunsaturated fatty acids rather than on the total n-3 polyunsaturated fatty acid content of the dietary fish oil.
Lipids 27, 425–428 (1992).

A high plasma cholesterol level and the occurrence of coronary heart disease are strongly interrelated (1). Dietary supplementation with polyunsaturated fat is associated with a reduction in the incidence of occlusive vascular diseases including both atherosclerosis and thrombosis (2,3). Administration of marine fish oils rich in n-3 polyunsaturated fatty acids (PUFA), especially eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), decreased plasma cholesterol and triacylglycerol contents in normolipidemic and hyperlipidemic human subjects (4–6) and also in rats (7–12). Feeding of such oils was found to reduce platelet aggregability (4,5,13–15), thus lowering the chance of thrombosis, a major factor in heart attacks and strokes.

Abbreviations: AA, arachidonic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; NEFA, non-esterified fatty acids; PUFA, polyunsaturated fatty acids; RT, retention time.

The n-3 PUFA of dietary fish oils are generally considered the main causative factor for the aforesaid hypolipidemic effect, but the data so far obtained are still insufficient to determine whether this effect is due to an increased intake of n-3 PUFA or due to the specific distribution of the three prostaglandin-producing PUFA, dihomo-γ-linolenic acid (20:3n-6), arachidonic acid (AA; 20:4n-6), and EPA (20:5n-3) of fish oil.

In this communication, we compare the plasma lipid lowering effects of the oils of two fishes, one of marine and the other of fresh water origin. Both fish oil diets contained similar amounts of total saturated acids (principally 16:0), total monunsaturated acids (mainly 16:1 and 18:1), n-3 PUFA, docosapentaenoic acid (DPA; 22:5n-3) and DHA (22:6n-3). So it is expected that the effects exerted by these factors on plasma lipid profile would be the same for the two fish oil supplemented diets. But the EPA/AA ratios of these two oils differ considerably. Our aim was to find out whether the effectiveness of a dietary fish oil in producing the hypolipidemic effect depends upon the quantity or the type of n-3 PUFA in the oil.

MATERIALS AND METHODS

Fish and fish oil. Hilsa fish (*Hilsa ilisa,* English hilsa shad) of the clupeidae family were collected from the river Ganges near Calcutta. Chital fish *(Notopterus chitala)* of the notopteridae family were purchased from a Calcutta market. Both fish were collected during the months of June to August, and are considered excellent food sources.

Oils were extracted from the flesh of both fish. Flesh only from the belly flap of chital fish was used because this portion of the body is richer in fat content than the rest. By contrast, fat in hilsa fish is more or less evenly distributed. Hilsa fish with minimum egg content were selected because egg formation depletes the lipid reserves of the fish (16).

Chopped fish flesh was extracted with acetone (1 L/kg) in a Soxhlet extractor for 8–10 h, the resulting emulsion was broken by adding 250 mL each of chloroform and water. The lower phase containing the fat was washed three times with water and dried overnight over anhydrous Na_2SO_4. Solvent was removed under reduced pressure and finally by flushing with N_2. The oil was stored in air-tight amber-colored bottles under N_2 at −20°C. A nitrogen atmosphere was maintained, whenever possible, during the entire operation to minimize oxidation of the oil.

Total fat contents of wet flesh of chital and hilsa fish were 8.38% and 15.9%, respectively. Cholesterol contents of the oils were 8.5% and 8.1% for chital and hilsa oils, respectively. Cholesterol (0.4 g) was added to each 100 g of hilsa oil in order to make the two dietary oils equal in cholesterol content.

Animals and diets. Fifty-four male Charles Foster rats (100 g, average weight) were maintained on a semisynthetic standard diet for 15 days. The composition of the diet in weight percent was casein 20, starch 40, sucrose

20.15, cellulose 5, U.S.P. salt mix XIV 4.5, vitamin mix 0.15 (17), choline chloride 0.2, BHT 0.002, and groundnut oil 10. Starch, cellulose and casein were defatted by Soxhlet extraction with *n*-hexane for 12 h. This dietary treatment was meant to standardize the animals before starting the actual experiments with fish oil supplemented diets. After 15 days, 6 rats were killed for analyses (these are the 0-day data in the tables). The remaining 48 rats were divided into two groups of 24 rats each, such that the average weights per group were similar. Experimental diets were prepared by adding 10 g of either hilsa or chital oil to 90 g of fat-free basal diet mix as described above. Fatty acid compositions of the three diets are presented in Table 1.

Animals were housed individually in cages in an airconditioned animal house (20–23°C) and fed experimental diets *ad libitum* for 60 days. Food was given twice a day (8 a.m. and 8 p.m.); uneaten food was discarded. Diets were prepared twice a week and stored under a N_2 atmosphere at −20°C. Food intake and body weights were recorded every other day. On the 15th, 30th, 45th and 60th days of feeding, 6 rats from each dietary group were killed for analyses.

Lipid analysis. The animals were fasted for 12 h and killed by drawing blood from the abdominal aorta under light diethyl ether anaesthesia. Blood was collected into plastic syringes and anticoagulated with 3.8% trisodium citrate (9 vol blood and 1 vol citrate). Plasma was separated by centrifuging the blood at 1500 × *g* for 10 min. Plasma from 2 rats was pooled together so that 3 sets of data were produced for each group. Whenever necessary, liver tissue was excised, rinsed thoroughly with ice-cold physiological saline and kept frozen at −20°C until analysis. An aliquot of plasma was extracted using a one-step procedure (18) for quantitation of plasma lipids. Total cholesterol, phospholipid and triacylglycerol contents of plasma were determined using standard procedures (19–21). Plasma non-esterified fatty acid (NEFA) concentration was measured using a micromethod (22), developed in this laboratory.

For fatty acid analyses, plasma and liver tissues were extracted according to the method of Bligh and Dyer (23). Total lipids were transmethylated in the presence of 5% methanolic HCl (24).

Fatty acid compositions were determined by gas-liquid chromatography of methyl ester using 15% diethyleneglycol-succinate polyester on 100–120 mesh Gaschrom W (Hewlett-Packard, Avondale, PA) columns, packed in 6 ft × 1/8 inch (o.d.) stainless-steel tubes. The flow rate of the carrier gas (nitrogen) was 30 mL/min; the injection port and detector were maintained at 200°C. The column temperature was held at 170°C for 1 min and then programmed at 2.5°/min to 200°C. A dual-column, fully computerized gas chromatograph with dual flame-ionization detectors (FID) (Hewlett-Packard, Model 5840A) was used. The compositions in Tables 1, 3 and 4 are expressed as weight percentages (wt%) and represent the average of three separate analyses. Fatty acid peaks were identified by comparing the corresponding retention times (RT) with those of standard methyl esters.

Statistical analysis of data. The results are expressed as mean ± SD. Statistical significance was analyzed by Student's *t*-test.

EPA/AA	—	1.27	4.08

[a]The fat-free basal diet was supplemented with 10% by weight of the respective oils. The basal diet contained the following components (g/kg diet): casein, 200; starch, 400; sucrose, 201.5; cellulose, 50; U.S.P. salt mix. XIV, 45; vitamin mix, 1.5 (17), choline chloride, 2.0; BHT, 0.02. At least three random samples of each diet were analyzed; trace, trace amount (less than 0.1%).

RESULTS

The fatty acid compositions of the diets are presented in Table 1. Groundnut oil supplemented standard diet contained mainly oleic acid (18:1, 44.5%) and linoleic acid (18:2n-6, 32.8%). The n-3 fatty acid contents of both fish oil diets were essentially the same (approximately 10%). However, the chital oil diet was high in γ-linolenic acid (18:3n-3), while the hilsa oil diet was rich in EPA.

The fish oil diets differed considerably in n-3/n-6 ratios (0.83 in chital oil diet and 2.81 in hilsa oil diet) and EPA/AA ratios (1.27 in chital oil diet and 4.08 in hilsa oil diet).

The fatty acid composition of the hilsa oil diet closely resembles that of the Eskimo diet (25,16), being rich in monoenoic acid (57.3%), but low in polyenoic (19.2%) fatty acids, has a very low AA content (0.4%), and contains almost the same proportion of EPA as does the hilsa oil diet (4.6% in Eskimo diet and 4.9% in hilsa oil diet).

Body weights and food consumption. All rats appeared healthy after the 8-week feeding regimen. There was no significant difference in weight gain under the two different fish oil treatments, and food consumption during the feeding trial was also similar (data not shown).

Lipid contents of rat plasma. Plasma total cholesterol, triacylglycerol and total phospholipid contents significantly increased within 15 days in rats fed the fish oil diets (Table 2). However, on the 60th day total cholesterol,

TABLE 2

Effect of the Two Fish Oil Diets on Plasma Total Cholesterol, Triacylglycerol, Total Phospholipid and Non-Esterified Fatty Acid Concentration of Rats[a]

Lipids	0-day	Chital oil Days on test				Hilsa oil Days on test

[a]Each value represents the mean ± SD; n = 6; $P < 0.05$.

[b]Non-significance of the difference between 0-day data and that due to each fish oil feeding.

[c]Non-significance of the difference between the two fish oil feeding data for a specific day.

triacylglycerol, total phospholipid and NEFA became significantly lower under the hilsa oil dietary regimen than they were upon chital oil feeding. The lowering of cholesterol was significant even on the 30th day of the experiment.

Fatty acid composition of plasma and liver lipids. The 18:2n-6 and 20:4n-6 contents of plasma total lipids under the two fish oil diets were very similar (Table 3), even though chital oil contains about 10 times more 18:2n-6 (3.4%) than does hilsa oil (0.3%). Therefore, a certain level of essential fatty acids, 18:2n-6 and AA, was retained in the plasma within the experimental period, despite very low percentages of these two fatty acids in the hilsa oil diet.

Though both dietary fish oils significantly reduced AA content of liver total lipids (Table 4), the extent of the decrease was larger with the hilsa oil diet, which has a higher EPA/AA ratio in comparison to the chital oil diet.

Ratio			
n-3/n-6	0.07	0.29	0.66
EPA/AA	0.05	0.09	0.64

[a]Each value represents mean ± standard deviation of three separate determinations. Values without a common superscript are significantly different ($P < 0.05$); trace, trace amount.

EPA is the major n-3 PUFA in hilsa oil but not in chital oil. There was a considerable difference in the EPA content of liver lipids under the two fish oil diets (5.5 ± 0.6% for hilsa oil diet and only 1.2 ± 0.1% for chital oil diet). As a result, the EPA/AA ratio in the liver total lipids under hilsa oil treatment was about 7 times higher than it was under chital oil treatment.

DISCUSSION

Several studies have demonstrated the effects of n-3 PUFA, especially EPA and DHA, on plasma lipid profile, platelet function and eicosanoid formation (6,14,25-27). However, in fish oil feeding studies different fish oils containing various types and amounts of n-3 PUFA have been used, making a true evaluation of the effect of any particular n-3 PUFA difficult. The present experiments were carried out to study the effect of a specific composition of n-3 PUFA on the plasma and liver lipid profiles in rats. The hypolipidemic effects of two fish oil diets having similar proportions of total saturated acids, monounsaturated acids, n-3 PUFA, 22:5n-3, and 22:6n-3, and the same amounts of cholesterol (adjusted), were compared. The fish oils were chosen so they would differ considerably in their EPA/AA ratios.

We found a substantial difference between the effects of these two fish oil diets on plasma lipid profiles. Hilsa oil diet decreased the total cholesterol, triacylglycerol, phospholipid and NEFA contents to significantly lower levels than did the chital oil diet. This difference is most noticeable between the plasma total cholesterol levels, although the same amount of cholesterol was present in the two diets.

The hilsa oil diet increased the EPA level and decreased the AA level in liver lipids. These changes were more pronounced than the corresponding changes due to the chital oil diet, although both diets contained similar amounts of n-3 PUFA. The main difference between the fatty acid composition of these two fish oils is in their EPA/AA ratios. Although the level of EPA in hilsa oil is not very high (4.9%), the EPA/AA ratio in hilsa oil (4.08) is 3.2 times higher than that of chital oil (1.27). Thus, the higher EPA/AA ratio in the hilsa oil diet appears to have facilitated the greater enrichment of tissue lipids with EPA at the expense of AA than was observed with the chital oil diet. The study also pointed out the importance of n-3 PUFA composition over PUFA amount to assess the hypolipidemic effect of a fish oil diet.

Diets with a high PUFA content have been recommended by several medical and nutritional boards because of the lipid-lowering effect of PUFA in plasma. However, the high PUFA containing fish oils are apt to be oxidized during extraction, purification and storage. Cost-effective measures, such as processing under a nitrogen atmosphere and the addition of antioxidants (vitamin E, BHT), can minimize oxidation. Hilsa fish oil is lower in total PUFA content than are other fish oils, but it is a good source of C_{20} and C_{22} n-3 PUFA. The moderate n-3 PUFA content of this oil is sufficient to exert its hypolipidemic effects. The low total PUFA content of this oil would also be expected to make it less susceptible to autoxidation and should therefore better lend itself to food processing than would other highly unsaturated fish oils.

Abnormal Lipid and Fatty Acid Compositions of Kidneys from Mice with Polycystic Kidney Disease

H.M. Aukema[a], T. Yamaguchi[a], H. Takahashi[b], B. Celi[a] and B.J. Holub[a,*]

[a]University of Guelph, Department of Nutritional Sciences, Guelph, Ontario, Canada N1G 2W1 and [b]Laboratory Animal Center, Fujita Health University, Toyoake, Japan

Renal cyst development in polycystic kidney disease (PKD) involves hyperplastic growth and extensive membrane alterations, suggesting abnormal membrane composition and function. Using thin-layer and gas-liquid chromatography, we analyzed the lipid components of the kidneys from 120-day-old DBA/2FG-*pcy (pcy)* having PKD as compared to normal DBA/2J (DBA) mice. At sacrifice, kidneys from *pcy* mice were four times larger than DBA controls, indicating that extensive renal cyst growth had occurred. The ratios of cholesterol/phospholipid, choline glycerophospholipid (GPC)/ethanolamine glycerophospholipid (GPE) and alkenylacyl GPE/diacyl GPE were higher (by 25%, 41% and 72%, respectively) in the cystic kidneys, while total phosphatidylinositol (PI), GPE and cardiolipin (DPG) were lower (by 13%, 23% and 27%, respectively). With respect to fatty acid compositions, there were significantly lower levels of docosahexaenoic acid (DHA, 22:6n-3) and higher levels of adrenic acid (AdA, 22:4n-6) in the phospholipids of *pcy* mouse kidneys. These changes were not present in serum, indicating that they were not generalized differences. Interestingly, the lower level of DHA in GPE was found to be associated with the alkenylacyl, but not the diacyl species. The fatty acids comprising the product/substrate ratio for the Δ4 desaturase activity were lower across all phospholipids, indicating a possible abnormality in polyunsaturated fatty acid metabolism in this model of PKD. These lipid abnormalities may influence membrane-mediated events such as receptor activation, signal transduction, ion transport and enzyme activities. The renal pathophysiologies associated with PKD may be related to the tissue lipid abnormalities described herein.

Lipids 27, 429–435 (1992).

Cell proliferation is influenced by membrane properties such as enzyme activities, permeability, ion transport and fluidity which are influenced by the phospholipid environment (1–3). As a result, altered lipid composition is seen in abnormal cellular proliferation such as in tumor growth. In particular, factors known to influence membrane fluidity, such as docosahexaenoic acid (DHA, 22:6n-3) levels in membrane phospholipid and the cholesterol/phospholipid ratios, have been shown to be altered in tumor cells (4–8). Phospholipid methylation also appears to be increased in tumor cells (9), and elevated choline glycerophospholipid (GPC)/ethanolamine glycerophospholipid (GPE) ratios have been demonstrated in high metastatic compared to low metastatic cell lines (10,11). In addition, tumor cells often exhibit altered metabolism of ether lipids and increased content of this unique class of lipid (8, 12–16).

In polycystic kidney disease (PKD), renal tissue becomes grossly enlarged as cysts proliferate in all parts of the nephron, particularly the tubules (17). Although these cysts are filled with fluid instead of cellular material, renal cysts are comparable to slow-growing adenomas in many respects (18). In addition to fluid accumulation, epithelial cell hyperplasia is an essential feature of PKD (19,20). Hyperplasia of epithelial cells has been shown in many cysts (19,21,22), and it has been reported that the earliest changes noted in the development of cysts are proximal tubule cell hyperplasia and tubule dilatation (23,24). Polyps are also a common feature of cyst epithelial cells in both genetic and non-genetic forms of the disease, as well as chemically-induced models of PKD (19,21,25–28). Cystic lesions have also been seen in kidneys of rats fed a carcinogen to induce renal adenocarcinoma (29).

The recent availability of a mouse model of PKD (30,31) provides an opportunity to evaluate any lipid abnormalities in the kidneys of these diseased animals. Since cyst development involves hyperplastic growth and extensive membrane alterations, we have determined the lipid characteristics of the kidneys from DBA/2FG-*pcy (pcy)* mice (including individual phospholipids, their subclasses and fatty acid profiles) as compared to the corresponding DBA/2J (DBA) controls. The present findings indicate several lipid abnormalities in this model of PKD, including alterations in cholesterol/phospholipid and GPC/GPE ratios, DHA levels in individual phospholipids and ether phospholipid compositions.

EXPERIMENTAL PROCEDURES

Animals and lipid extraction. Male DBA and *pcy* mice (n = 4 per group) were weaned at 30 days and maintained on lab chow (Ralston Purina, St. Louis, MO) until 120 days of age, at which time the animals were sacrificed following an overnight fast. Blood samples were taken by heart puncture and the serum was frozen in liquid nitrogen. The kidneys were also removed, weighed and frozen. The right kidneys were homogenized in 5 mL of chloroform/methanol (2:1, vol/vol) and lipids from both kidney and serum were extracted by the Folch method (32). Known aliquots of the lipid extracts were taken for analysis of total phospholipid and triacylglycerol (TG), individual phospholipids and the subclasses of GPC and GPE.

Lipid analysis. Following saponification of the lipid extracts, serum and renal cholesterol concentrations were determined enzymatically using the Cholesterol High Performance CHOD-PAP method (Boehringer Mannheim Canada, Dorval, Quebec, Canada).

For analysis of renal and serum total phospholipid and TG, a measured aliquot of the lipid extract was spotted on Merck silica gel 60HR thin-layer chromatography

(TLC) plates (British Drug House, Toronto, Ontario, Canada), and developed in heptane/iso-propyl ether/acetic acid (60:40:3, by vol) (33). Chloroform/methanol/acetic acid/water (50:37.5:3.5:2, by vol) (34) was used as the developing solvent to separate the individual phospholipids in another measured aliquot of the lipid extract. Fatty acid methyl esters (FAME) were then prepared and analyzed by gas-liquid chromatography (GLC) as described (34). Phospholipids were quantified by dividing the amount (in nmol) of fatty acids for each fraction by the number of fatty acids per molecule, taking into consideration that the alkylacyl or alkenylacyl phospholipid subclasses contain only one fatty acid per molecule whereas the diacyl contain two.

GPC and GPE subclass analysis. The subclasses of GPC and GPE were analyzed by a modification of the method of Renkonen (35). Briefly, GPC and GPE were separated by TLC and eluted as described (36). Each extract was evaporated under nitrogen and the residual phospholipid was resuspended in 1 mL of diethyl ether. To this solution was added 1.5 mL of a 17.5 mM Tris buffer (pH 7.3) containing 40 units of phospholipase C (*Bacillus cereus,* type V; Sigma Chemical Co., St. Louis, MO) and 0.5 mL 1% $CaCl_2$ (37). This mixture was incubated by gentle agitation at 37°C for 16 h to completely hydrolyze all three subclasses of phospholipid. The resulting diradylglycerols produced were extracted 3 times with 2 mL diethyl ether; following solvent evaporation, they were resuspended in 1 mL acetic anhydride and 4–5 drops of pyridine to produce diradylglycerol acetates. After heating for 75 min at 80°C, 1 mL of methanol was added (on ice). This mixture was completely dried down, and 2 mL of water and 3 mL of diethyl ether/methanol/acetic acid (60:40:1, by vol) were added. The diradylglycerol acetates were extracted twice with 3 mL of petroleum ether (b.p. 38–56°C) and subsequently separated by triple-development TLC. The first and third developments were in toluene and the second development was in hexane/diethyl ether (4:1, vol/vol). This system readily separates the 1,2-diacyl, any 1,3-diacyl, alkylacyl and alkenylacyl glycerol acetates produced (R_f values of 0.25, 0.33, 0.39 and 0.47, respectively). Only trace amounts of 1,3-diacyl glycerol acetate were detected, indicating that isomerization of the diradylglycerol and diradylglycerol acetates was minimal during this procedure. The resolved bands were scraped into test tubes containing monopentadecanoic acid as an internal standard, and the fatty acids were analyzed as FAME following transmethylation (34). For the alkenylacyl fractions, TLC was used to separate the FAME from the dimethyl acetals derived from the vinyl ether linked fatty aldehydes. After developing the TLC plate in toluene, the FAME were eluted from the gel scrapings by adding 2 mL methanol, 2 mL petroleum ether and 1 mL water, and after removing the upper phase, were dissolved in hexane for GLC.

Statistical analysis. Statistical differences between data obtained from *pcy* (diseased) and DBA (control) mouse kidneys and serum were determined using Student's unpaired *t*-test, except the GPC/GPE ratios and kidney weight data, which were compared using the Mann-Whitney test for non-parametric data. Significance of correlations was determined using Fisher's tables (38).

RESULTS AND DISCUSSION

At sacrifice, kidneys from *pcy* mice were obviously enlarged and discolored compared to normal DBA kidneys. Overall, the *pcy* (right) kidneys were four times larger than the DBA controls (means ± SE: 0.51 ± 0.13 g for *pcy* compared to 0.12 ± 0.01 g for DBA, $P < 0.05$), indicating that extensive renal cyst growth had already occurred in these mice.

Total phospholipid, TG and cholesterol levels were similar (as nmol/kidney) in *pcy* compared to DBA kidneys (Table 1). On the other hand, total phospholipid and cholesterol levels were higher (by 123% and 35%, respectively) in serum from *pcy* mice, while TG levels were similar (Table 1). Although it has not been specifically shown in human PKD (39), elevated serum lipids can contribute to impaired renal functioning (40,41), and the elevated serum lipid levels seen herein may possibly be associated with the development of renal deterioration in *pcy* mice.

The higher cholesterol/phospholipid ratio in the *pcy* kidney (by 25%, Table 1) is similar to that reported for tumor cells (5–7). Membrane viscosity is increased with increased cholesterol/phospholipid levels (6,42); thus membrane-mediated events related to cell growth, such as receptor activation, signal transduction and ion transport, possibly may be altered as a result.

Table 2 gives the phospholipid compositions of the DBA and *pcy* mouse kidneys. Lower levels of GPE, phosphatidylinositol (PI), cardiolipin (diphosphatidylglycerol, DPG) and a higher GPC/GPE ratio were found in *pcy* mouse kidneys compared to normal kidneys. The lower levels of PI seen in *pcy* kidneys possibly may be of relevance to the recognized involvement of inositol phospholipid metabolism in membrane signalling associated with cell proliferation and growth (43), as well as the

generation of two intracellular second messengers, diacylglycerol [a protein kinase C activator (44)] and inositol trisphosphate [involved in intracellular Ca^{++} mobilization (45)]. The lower levels of DPG (by 27%) may reflect cellular/mitochondrial differences (see below). The higher GPC/GPE ratio found in *pcy* kidneys is also of interest because elevated GPC/GPE ratios have been reported in high-metastatic tumor cells (10,11).

The relative amounts of diacyl GPE and alkenylacyl GPE were also altered in *pcy* kidneys (Table 3): Calculations from Tables 2 and 3 show that diacyl GPE is 36% lower in *pcy* kidneys, while the level of alkenylacyl GPE is conserved, resulting in a relative enrichment of this ether phospholipid. The relatively higher level of ether lipid content in *pcy* kidneys follows a general trend of ether lipid enrichment in neoplastic cells (8,12–16). While the biochemical function of plasmalogenic phospholipid (specifically alkenylacyl GPE) has not been fully elucidated, it has been suggested to function as a cellular antioxidant (46). Lipid peroxidation and free radical formation recently have been implicated in the progression of renal disease (47,48). Alkenylacyl GPE may therefore have a function in PKD in relation to oxidative tissue damage, or may be related to alterations in membrane packing.

With respect to the GPC/GPE ratio and the two major subclasses of GPE, namely diacyl GPE and alkenylacyl GPE, significant correlations ($P < 0.05$) with kidney weight were noted in *pcy* kidneys. The relative proportion of GPC (total), as well as the GPC/GPE ratio were found to correlate positively with kidney weight (cystic involvement). Conversely, the relative proportion of GPE (total) correlated negatively with kidney weight (data not shown). With respect to the GPE subclasses, the proportion of alkenylacyl GPE and diacyl GPE correlated positively and negatively, respectively, with kidney weight. The relative levels of these classes of phospholipids may therefore be used as possible markers for the extent of cystic involvement in *pcy* kidneys.

The fatty acid profile of the DBA kidney total phospholipid (Table 4) is in general agreement with previous reports on mouse kidney (49,50). While minor differences were found in various fatty acids, of particular interest was the finding of significantly lower levels of DHA in the *pcy* mouse kidney (by 22% overall) and higher levels of adrenic acid (AdA, 22:4n-6). Minor differences also were observed in the TG fraction. The corresponding data for the serum phospholipid and TG (Table 5) did not mimic the differences seen in mouse kidney, indicating that the renal abnormalities are not generalized. No significant difference was found in the level of DHA in the serum phospholipid, and a moderately higher level of DHA in serum TG was found in *pcy* relative to DBA animals. The lower amounts of DHA in the renal phospholipid from the *pcy* animals may reflect an impaired uptake and entry of DHA into kidney phospholipid, and/or an impaired conversion of α-linolenic acid to DHA *via* desaturation/elongation reactions and/or altered retroconversion of DHA.

The most consistent alterations in fatty acid compositions in *pcy* mouse kidneys across individual phospholipids were lower levels of DHA and higher amounts of AdA, as shown in the fatty acid profiles of PI, phosphatidylserine (PS), total GPE and total GPC (Tables 6–8). The resulting higher n-6/n-3 ratio in the total phospholipid and individual phospholipids in the *pcy* relative to DBA mouse kidneys (Fig. 1) are of some interest in view of the association of high dietary n-6/n-3 intakes with tumorigenicity (51).

The Δ4 desaturase activity (potential), as measured by the product/substrate levels, was found to be consistently lower across all phospholipids in *pcy* compared to DBA mouse kidneys (Fig. 2). A diminution of the Δ4-desaturase activity also has been implicated in Zellweger's syndrome (52,53), a disease characterized by an absence of peroxisomes in hepatocytes and renal proximal tubules (54,55). Zellweger's syndrome has been associated with PKD (56),

indicating that they may have some common lipid abnormalities. Recently, it has been reported that the Δ4 desaturase enzyme is not present in rat hepatocytes (57). The proposed pathway for conversion of 22:5n-3 to DHA is 22:5n-3 → 24:5n-3 → 24:6n-3 → DHA, with the last step being analogous to peroxisomal β-oxidation of long-chain fatty acids. If this pathway is present in murine renal cells, an abnormality in this pathway may also explain the higher 22:4n-6 plus 22:5n-3 to 22:5n-6 plus 22:6n-3 ratio in *pcy* mouse kidneys.

With respect to the potential relevance of the lower DHA levels in phospholipid to PKD, reduced levels of DHA have been reported in the lipids of a high metastatic cell line when compared to one of low metastatic potential (8) and in hepatoma cells compared to normal hepatocytes (4). Both the lower levels of renal DHA and the higher cholesterol/phospholipid ratio (Table 1) seen in *pcy* mice may result in a decrease in membrane fluidity, possibly altering membrane-mediated events. In a mouse model of essential fatty acid deficiency, Sun and Sun (58) documented a decrease in brain DHA level and an increase in Na^+K^+ATPase activity. Surette and colleagues (59) reported that dietary DHA increased mouse microsomal DHA content and decreased the specific activity of Na^+K^+ATPase by 48%. In this regard, altered DHA and cholesterol/phospholipid levels seen herein may be associated with the elevation of the activity of this membrane-bound enzyme in PKD (60).

The higher level of AdA in the kidney phospholipid of the *pcy* mouse kidney relative to the DBA is of interest because AdA can be metabolized by the kidney *via* the cyclooxygenase enzyme to produce dihomo-prostaglandins and dihomo-thromboxane, unlike other tissues enriched in AdA, such as the adrenal glands, brain and testis (61). Furthermore, the production of these AdA-derived eicosanoids was found to be augmented in the hydronephrotic kidney (61). The potential implications of increased levels of AdA in the kidney phospholipid in relation to the formation/function of these unique eicosanoids in PKD remains to be evaluated.

Fatty acid analysis of sphingomyelin (SPH) revealed only modest differences between the *pcy* and DBA mouse kidneys; these included a higher level of arachidic acid (20:0) in the former group (Table 9).

Unlike the other kidney phospholipids, DPG exhibited higher relative levels of DHA in the *pcy* kidneys (Table 9) and a lower n-6/n-3 fatty acid ratio (Fig. 1). As a mitochondrial phospholipid, these fatty acid alterations in DPG, as well as the lower levels of DPG in *pcy* (Table 2), may be associated with possible mitochondrial changes in PKD. In this regard, renal mitochondria are reduced compared to hepatic mitochondria in cisplatin-induced nephrotoxicity (62). Cisplatin administration has been shown to induce renal cyst growth (63). The inability of renal tissue

to replace damaged mitochondria possibly may explain why the kidneys (and not livers) are susceptible to cyst formation in the *pcy* mouse. The lower level of DPG in the *pcy* kidneys (Table 2) was of some interest as well, because the maintenance of mitochondrial carnitine palmitoyl transferase activity in mammalian membranes requires the presence of DPG (64).

Interestingly, separation of the total GPE into the diacyl and alkenylacyl subclasses (Table 7), revealed that the lower GPE level of DHA in the *pcy* kidney was associated with the alkenylacyl GPE (lower by 30%) and not the diacyl GPE (which exhibited no difference in DHA content). The biochemical basis for this phenomenon (including the availability of DHA-containing precursors or enzyme specificities leading to alkenylacyl and diacyl GPE biosynthesis and breakdown) and significance to PKD remain to be investigated. The higher level of AdA seen in total kidney phospholipid (Table 4) was maintained in the total GPE, diacyl GPE and alkenylacyl GPE (Table 7). The lower level of DHA and higher levels of AdA, as well as arachidonic acid, were consistent in total GPC and the two subclasses, diacyl GPC and alkylacyl GPC (Table 8). An evaluation of platelet-activating factor involvement in PKD, *via* its formation from renal alkylacyl GPC, remains to be studied. Platelet-activating factor synthesis has been implicated recently in a number of renal pathophysiologies (65).

In conclusion, mouse *pcy* kidneys are characterized by several lipid abnormalities often seen in neoplastic cells, such as a higher cholesterol/phospholipid and GPC/GPE

ratios, lower DHA levels, and relative enrichment of ether phospholipid (notably alkenylacyl GPE). The higher cholesterol/phospholipid and GPC/GPE ratios and lower DHA levels may alter membrane fluidity, thereby altering membrane functions related to cell growth, such as receptor activation, signal transduction, ion transport and enzyme activities. The possible influence of nutritional modification (*e.g.*, dietary DHA supplementation) on the lipid abnormalities exhibited in this model of PKD remains to be evaluated.

[Received September 13, 1991; Revision accepted April 22, 1992]

Characterization of Triacylglycerols in the Seeds of *Aquilegia vulgaris* by Chromatographic and Mass Spectrometric Methods

Mustafa Demirbüker[a], Lars G. Blomberg[a,*], N. Urban Olsson[b], Magnus Bergqvist[a], Bengt G. Herslöf[b] and Fernando Alvarado Jacobs[c]

[a]Department of Analytical Chemistry, University of Stockholm, S-106 91 Stockholm, [b]Karlshamns LipidTeknik AB, S-104 65 Stockholm and [c]Swedish Pulp and Paper Research Institute, S-114 86 Stockholm, Sweden

A combination of analytical techniques is generally necessary to properly characterize complex lipid materials. Chromatographic separation in conjunction with spectroscopic characterization was utilized for the analysis of the triacylglycerols in the seeds of *Aquilegia vulgaris*. Reversed-phase high-performance liquid chromatography (HPLC), micropacked argentation supercritical fluid chromatography (SFC), and combinations of the two techniques were used. The fatty acid profile was determined by gas chromatography/mass spectrometry of the picolinyl esters and by gas chromatography/flame-ionization detection of the methyl esters. The major components were also identified by direct inlet mass spectrometry. The excellent selectivity of packed fused silica argentation SFC for the separation of triacylglycerols was demonstrated.

Lipids 27, 436–441 (1992).

Essential fatty acid (EFA) deficiency in mammals caused by an unbalanced diet can lead to conditions such as scaly dermatitis, interactable eczema and excessive transdermal loss of body water (1–3). Dietary supplementation of essential fatty acids, mainly linoleic and α-linolenic acids, normally reverses these conditions. Columbinic acid (Cb), 6*c*,9*c*,13*t*-18:3, has been found in abundance in the seeds of the Sierra Meadowrue *(Thalictrum polycarpum)* (4) and in the seeds of the Columbine *(Aquilegia vulgaris)* (5,6). This fatty acid exhibits EFA properties similar to linoleic acid and α-linolenic acid in mammals. This indicates that columbinic acid undergoes metabolic conversion by utilizing enzyme systems that generally metabolize arachidonic acid (7). It has also been shown that the major lipoxygenase product of columbinic acid, 13-hydroxyoctadecatrienoic acid, can reverse scaly dermatitis in EFA deficient rats (7).

The fatty acid profile of the seed oil of the *Aquilegia vulgaris* has been determined (8), but the molecular species pattern of the triacylglycerols, which has important physicochemical and bioavailability implications, has not yet been investigated.

Triacylglycerols have been extensively characterized by gas chromatography (GC) and high-performance liquid chromatography (HPLC) (9,10). The applicability of GC is, however, limited by the thermal stability of the triacylglycerols. Thermal degradation and/or polymerization of polyunsaturated triacylglycerols takes place at the temperatures necessary for their elution (9–13).

*To whom correspondence should be addressed.

Abbreviations: C, 9*c*,13*t*-18:2; Cb, columbinic acid; EFA, essential fatty acids; FID, flame-ionization detector; GC, gas chromatography; HPLC, high-performance liquid chromatography; L, linoleic acid; MS, mass spectrometry; O, oleic acid; P, palmitic acid; +EI, positive electron impact; S, stearic acid; SFC, supercritical fluid chromatography; TG, triacylglycerol; UV, ultraviolet.

Excellent separations of triacylglycerol species have been obtained by HPLC in the reversed phase mode and on columns impregnated with silver nitrate (10). It was demonstrated by Christie and coworkers (14–17) that highly stable argentation columns can be prepared by silver nitrate impregnation of columns packed with a silica-based cation exchanger. The separation of molecular species is, however, oftentimes incomplete, and quantification can become difficult in such cases. The separation can be improved by a two-step procedure, *e.g.* by HPLC/GC (18) or HPLC/HPLC (19).

Micropacked argentation columns have recently been utilized for the separation of triacylglycerols using supercritical fluids as the mobile phase (20,21). It was also discovered that the Ag^+-modified, silica-based cation exchanger is very stable at elevated temperatures. This significantly increases the possibilities to optimize separation conditions, and temperature can thus be used to control silver/olefin complex formation. Further, microcolumns prepared from fused silica capillary tubing provide rapid and efficient heat transfer, which is a requirement for successful temperature programming.

Detection may be a problem when silica-based cation exchangers are being used as column packing material in microcolumn supercritical fluid chromatography (SFC). A polar modifier must be added to the mobile phase in order to elute triacylglycerols. The presence of such an additive precludes the use of flame-ionization detection; thus detection had to be by ultraviolet (UV) detector in the present work. This detector has a widely varying response for triacylglycerols dependent on the degree of unsaturation of the constituent fatty acyl chains.

In the present study, the triacylglycerol molecular species of the seed oil of *Aquilegia vulgaris* have been characterized by reversed phase HPLC, micropacked argentation SFC, direct inlet mass spectrometry (MS), and GC/MS of the picolinyl esters of the constituent fatty acids.

EXPERIMENTAL PROCEDURES

Materials. Seeds from *Aquilegia vulgaris* (Fröcentralen, Landskrona, Sweden) were cold-pressed to obtain the oil, which was analyzed without further purification.

Reversed phase HPLC. Fractionation of the triacylglycerols of the seed oil into molecular species was performed by HPLC at room temperature, utilizing a 250 mm × 10 mm column packed with Lichrospher 100, RP 18, 5 μm (Merck, Darmstadt, Germany). The seed oil was dissolved (50 mg/mL) in ethanol/isooctane (3:1, vol/vol). A volume of 200 μL was injected into the chromatograph with HPLC grade, degassed methanol/acetone (1:1, vol/vol) as the mobile phase. The solvent flow, which initially was set to 2.5 mL/min, was increased to 4 mL/min after 50 min. The total run time was 60 min. Detection was by means of a light-scattering detector (ACS, Macclesfield, United

Kingdom) operated at a dispersion pressure of 22 psi and a nebulizer temperature of 50°C. Between the outlet of the column and the detector, a split valve (1:4) was installed. Fractions representing molecular species were collected from four consecutive runs and the corresponding fractions subsequently combined. An aliquot of each fraction was derivatized to the corresponding methyl esters and analyzed by gas chromatography to determine the fatty acid composition.

Analytical HPLC was done on a 150 mm × 4.6 mm column packed with Ultraspher 100, ODS, 5 μm (Beckman Instruments, San Ramon, CA). The column was held at 25°C throughout the analysis. The solvent delivery system consisted of two Shimadzu (Kyoto, Japan) LC-6A HPLC pumps and a Shimadzu SCL-6A gradient control unit. A binary solvent gradient from (A) acetonitrile to (B) acetonitrile/ethanol/isooctane (2:2:1, vol/vol/vol) was applied over 60 min at a constant flow of 1 mL/min. Detection was with a light-scattering detector (Cunow, Cergy St. Christophe, France) operated at a dispersion pressure of 30 psi and a nebulizer temperature of 60°C.

Fatty acid methyl esters. Fatty acid methyl esters were analyzed as described earlier (22) utilizing an alkali methanolysis derivatization procedure in conjunction with a GC separation method. However, in the present work, the analytes were separated on a DB-Wax column, 30 m × 0.25 mm, film thickness 0.25 μm (J & W, Folsom, CA). Helium was used as carrier gas. On-column injection was at 130°C, after 2 min, programmed at 50°C/min to 150°C and then programmed at 3.3°C/min.

GC/MS of picolinyl esters. Picolinyl esters were prepared according to Christie and coworkers (23–25). The esters were analyzed by GC/MS using an ion trap detector (Varian ITS, Sunnyvale, CA) connected to a Varian 3400 gas chromatograph. The column used was a Supelcowax 10, 30 m × 0.25 mm, film thickness 0.25 μm (Supelco, Bellefonte, PA). Helium was used as carrier gas. On column injection was at 80°C, after 1 min, programmed at 50°C/min to 200°C, then programmed at 3.6°C/min. Fraction A was derivatized and analyzed.

Micropacked argentation SFC. The chromatographic system consisted of a Lee Scientific (Salt Lake City, UT) 600 Series SFC and μ-UV detector; detection was at 210 nm. Columns were prepared from fused silica capillary tubing, 330 mm × 250 μm i.d. and 430 μm o.d. (Polymicro Technologies, Phoenix, AZ). All columns were packed with Nucleosil 5 SA (Macherey Nagel, Düren, Germany). After packing, the columns were rinsed with 400 μL of 0.1 M silver nitrate (21).

The mobile phase consisted of carbon dioxide/acetonitrile/isopropanol (92.8:6.5:0.7, by mol%). Critical parameters for this mixture have been reported earlier (20). The mobile phase mixture was prepared in the SFC pump as described previously (26). Mobile phase velocity was 3.5 mm/s. Seed oil of *Aquilegia vulgaris* and fractions thereof, obtained from HPLC, were analyzed. Solutes were dissolved in HPLC-grade pentane at concentrations of 30 mg/mL. The injector was equipped with an internal loop, 200 nL, and injection was performed using a timed split of 0.2 s. Furthermore, a split ratio of 1:1 was applied. Using these conditions, *ca.* 60 nL was allowed to enter the column.

Direct inlet mass spectroscopy. Mass spectrometric analysis of triacylglycerols was carried out on a Triple Stage Quadrupol (TSQ) 4600 (Finnigan Mat, San José, CA) equipped with a water-cooled TIC controlled solid inlet system (Finnigan Mat, Bremen, Germany). The ion source temperature was 150°C. Ionization energy was 70 eV. Direct inlet temperature was programmed from 50°C to 450°C at 10°/s. The solvent was evaporated prior to introduction into the MS.

RESULTS AND DISCUSSION

In this study, the triacylglycerols (TG) of the seeds of *Aquilegia vulgaris* were characterized in terms of molecular species composition and fatty acid profile. This was accomplished by (i) a traditional approach utilizing preparative reversed phase HPLC to fractionate groups of molecular species similar in chain length and unsaturation, followed by subsequent fatty acid determination of each collected fraction, and (ii) the novel technique of micropacked argentation-SFC by which separation is achieved mainly according to degree of unsaturation.

The analytical HPLC chromatogram of the triacylglycerols is shown in Figure 1, and the preparative chromatogram in Figure 2. Note that the acyl groups are given in an arbitrary sequence and do not denote any specific position at the glycerol moiety. Fractions, as indicated in Figure 2, were collected for further analysis. All the

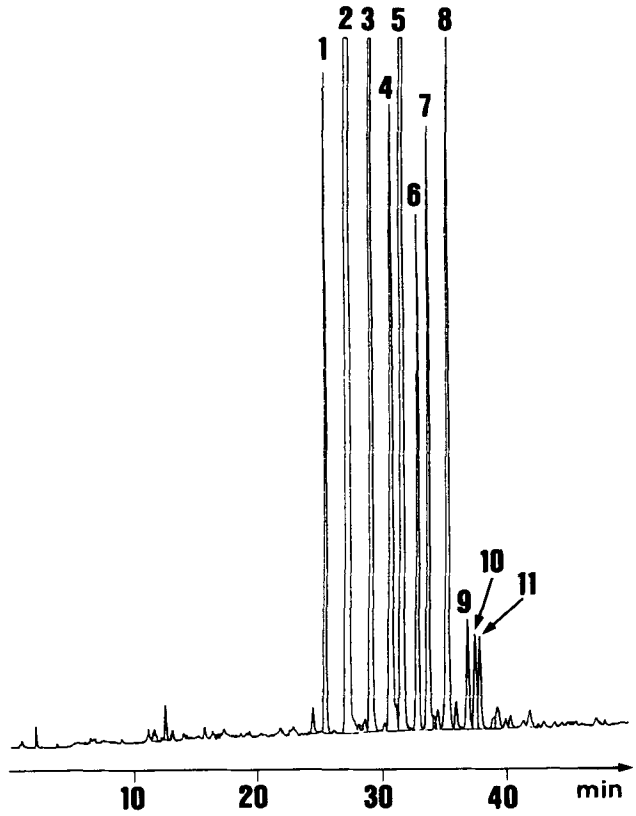

FIG. 1. Analytical reversed phase high-performance liquid chromatogram of the triacylglycerols present in the seed oil of *Aquilegia vulgaris*. Column: Ultrasphere 100, ODS, 5 μm (150 × 4.6 mm). FIG. 2. Preparative reversed-phase high-performance liquid chromatogram of the triacylglycerols present in the seed oil of *Aquilegia vulgaris*. Column: Lichrosphere 100, RP 18, 5 μm (250 × 10 mm). Conditions: see text, reversed-phase HPLC. The main components of each fraction are given in Table 1.

fractions were thus analyzed by SFC/UV; the purpose of this was to control the peak purity and to establish the elution order. Some of the fractions were derivatized to picolinyl esters which made it possible to determine the position of the double bonds in the acids by GC/MS (23–25). A mass spectrum of the picolinyl esters of columbinic acid is shown in Figure 3. The fatty acid picolinyl ester was obtained by hydrolysis of Fraction A. The peaks at $m/z = 218$, 258 and 298 indicate the positions of the double bonds (see Scheme 1).

The fatty acid profiles of the oil and its different HPLC fractions were quantitatively analyzed by means of GC/FID (flame-ionization detector) of the methyl esters derived from TG. The results are given in Table 1. It can be noted that there is some overlap between the different fractions. The composition of the oil was in good agreement with published data (8,27).

The fractions were further analyzed by direct inlet MS in the positive electron impact mode (+EI). This technique provides information concerning the chain length and the number of double bonds (28–32). The fragmentation of

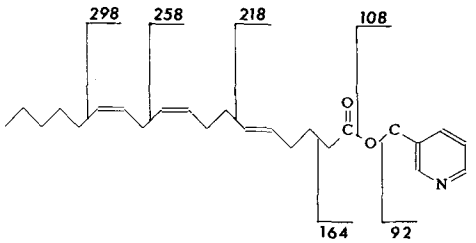

SCHEME 1

triacylglycerols has been extensively investigated (28–32). Characteristic ions corresponding to M^+, $[M - RCOO]^+$, $[RCO + 128]^+$, $[RCO + 74]^+$ and $[RCO]^+$ are being formed. R represents the aliphatic chain of the constituent fatty acids.

The results are summarized in Table 2. The main components of the fractions have been definitively identified from the ions $[RCO]^+$, $[RCO - 1]^+$ and $[M - OCOR]^+$. Molecular weight is indicated by $[M]^+$. Under the ionization conditions applied, saturated TG give relatively small M^+ ions (32); the intensity of M^+ is, however, increased with increasing degree of unsaturation in the TG. Considering the stability of the ions $[RCO + 128]$, saturated fatty acids give the highest intensities, and the intensities of unsaturated fatty acids are decreasing with an increasing degree of unsaturation. A mass spectrum of Fraction C is given in Figure 4.

Separation of the oil by microcolumn argentation SFC is shown in Figure 5. Elution in HPLC as shown in Figures 1 and 2 is obtained according to partition number, while separation, as performed in Figure 5, depends on the number and position of double bonds. Furthermore, some separation according to chain length is indicated in Figure 5, *e.g.*, CbCbP (where P is palmitic acid) from CbCbS (where S is stearic acid). Oil from *Aquilegia vulgaris* has a relatively simple composition, and all major components could be separated on the SFC column. The peaks in Figure 5 have been identified with some different degree of certainty. Identification of the major peaks was by direct inlet MS of the fractions (Table 2) and injection of the same fractions onto the micro SFC system. Trilinolein was tentatively identified on the basis of the fatty acid profile of Fraction E and the retention time of a standard. The separation of Fraction E on microcolumn argentation SFC is shown in Figure 6. LLL (where L is linoleic acid) was recently detected also in meadowfoam oil (25,27). Further, the presence of LPP, LOP (where O is oleic acid), LLP, LLS, LOO and LLO in the oil was indicated by minor peaks in Figure 5 having the same retention as observed for these TG under identical SFC conditions, *e.g.* in soybean oil (21). Finally, TG containing the acid 9*c*,13*t*-18:2 (C) may be indicated in Figure 5. Tentative identification was based on fatty acid profiles (Table 1) and retention times.

In reversed-phase HPLC, TG having identical carbon numbers and numbers of double bonds are eluted according to the position of the double bonds (10). The highest content of the acid 9*c*,13*t*-18:2 was observed in Fraction D (Table 1). It seems that 9*c*,13*t*-18:2 is derived from species such as 9*c*,13*t*-18:2, 9*c*,13*t*-18:2, and 6*c*,9*c*,13*t*-18:3. The retention of this species in reversed-phase HPLC is higher than for CbLL, and therefore, it has been collected in Fraction D rather than in Fraction C. Separation of Fraction D on argentation SFC revealed a small peak right after the elution of CbCbO. In argentation chromatography, *trans*-isomers migrate ahead of corresponding *cis*-isomers (9). It may thus be speculated that the peak preceding CbLL consists of 9*c*,13*t*-18:2, 9*c*,13*t*-18:2, and 6*c*,9*c*,13*t*-18:3. Similarly, Peaks 2 and 9 may contain the species 9*c*,13*t*-18:2, 6*c*,9*c*,13*t*-18:3, 16:0, and 9*c*,13*t*-18:2, 6*c*,13*t*-18:3, 9*c*-18:1, respectively.

This study has shown that the seeds of *A. vulgaris* are a rich source of columbinic acid and that this acid is incorporated in the majority of molecular species of triacylglycerols. The biological implications of this would merit further investigations.

With the recent introduction of micropacked argentation-SFC, an alternative route of lipid separation has

emerged. The solubility properties of the mobile phase, *i.e.* the supercritical medium, places this type of chromatography in an interesting experimental domain. Even though the full potential of micropacked argentation-SFC is yet to be exploited, it has proven to be a worthy addition to the family of lipid analytical methods.

Autoxidation of Polyunsaturated Triacylglycerols. IV. Volatile Decomposition Products from Triacylglycerols Containing Linoleate and Linolenate[1]

E.N. Frankel[2], E. Selke, W.E. Neff* and K. Miyashita[3]
National Center for Agricultural Utilization Research, U.S. Department of Agriculture, Peoria, Illinois 61604

Trilinoleoylglycerol (LLL), trilinolenoylglycerol (LnLnLn) and four synthetic triacylglycerols were autoxidized and the volatile products were investigated to determine the effect of fatty acid glyceride position on the mechanism of hydroperoxide decomposition. Capillary gas chromatography provided a sensitive method to follow the volatile oxidation products of mixtures of LLL and LnLnLn and of synthetic triacylglycerols containing linoleate and linolenate in different known positions. The relative amount of linoleate oxidation was determined by analyzing for hexanal, 2-heptenal and 2,4-decadienal, and the relative amount of linolenate oxidation by analyzing for 2,4-heptadienal and 2,4,7-decatrienal. The volatiles from pure monohydroperoxides of LLL and LnLnLn were compared with those of the corresponding triacylglycerols by capillary gas chromatography. Significant differences in the distribution of volatile products were observed depending on the triacylglycerols precursor. A 1:1 mixture of LLL and LnLnLn autoxidized at 40°C showed an equal contribution of linolenate and linoleate volatiles at a peroxide value of 34. The synthetic triacylglycerols LLnL and LLLn (L, linoleic; Ln, linolenic acid) formed initially about the same total volatiles, whereas LnLnL formed more volatiles than LnLLn. The ratio Ln to L volatile products was the same for the diL triacylglycerols, and higher for LnLnL than for LnLLn. This new information should permit us to better understand the influence of triacylglycerol structure on the relative oxidative stability of unsaturated triacylglycerols.
***Lipids* 27, 442-446 (1992).**

Much work has been reported on the volatile oxidation products of unsaturated fats because they cause rancidity in foods and cellular damage in the body. Decomposition of lipid hydroperoxides creates a wide range of carbonyl compounds, hydrocarbons, furans and other materials that contribute to flavor deterioration of foods (1,2). These materials are also implicated in biological oxidation. Interaction of some of these degradation products with DNA, proteins and enzymes may be involved in cell-damaging reactions (3-5). Although lipid hydroperoxides are the recognized precursors of volatile secondary products, relatively little information is available on the mechanism of their decomposition. Much attention has been given to the effects of processing on oxidative stability of fats and oils, but less attention has been given to the effect of triglyceride structure of polyunsaturated vegetable oils.

In the previous papers of this series, the major autoxidation products of trilinoleoylglycerol (LLL) and trilinolenoylglycerol (LnLnLn) were separated and characterized (6,7). In the preceding paper of this series, four synthetic triacylglycerols containing linoleate and linolenate were autoxidized and the relative amounts of autoxidation products from L and Ln components were investigated by high-performance liquid chromatography (HPLC) techniques (8). This paper describes a study of the effect of triacylglycerol structures on the types and amounts of volatile oxidation products to clarify their contribution to flavor and oxidative deterioration of vegetable oils. Capillary gas chromatography was used as a sensitive method to follow the distribution of volatile oxidation products and to determine the corresponding unsaturated fatty acid precursors.

EXPERIMENTAL PROCEDURES

Materials. LLL and LnLnLn (99+ % purity) were purchased from NuChek Prep, Inc. (Elysian, MN). LLLn, LLnL, LnLnL and LnLLn were synthesized and purified as described previously (9).

Autoxidation. Freshly chromatographed triacylglycerols were autoxidized at 40°C and the pure monohydroperoxides were prepared as described previously (6,7). Peroxide values (PV) were determined by the ferric thiocyanate method (10).

Capillary gas chromatography. The direct injection capillary gas chromatographic (GC) technique was used to analyze volatile decomposition products (11). By this technique samples of oxidized triacylglycerol or monohydroperoxides were injected into a glass insert inside the injector port that was packed with glass wool and heated at 180°C. The volatiles formed were swept into the GC capillary column cooled to −65°C and held for 5 min while the injector was in the splitless mode. The temperature was then programmed to 270°C at 5°C per min, using a fused silica capillary DB-1701 (14% cyanopropylphenyl; 60 m × 0.32 mm) column (J&W, Folsom, CA). The GC conditions were the same as described previously (11).

RESULTS

To investigate the volatiles from triacylglycerols containing linoleic and linolenic acids at different glycerol locations, pure monohydroperoxides of LLL and LnLnLn were decomposed at 180°C under conditions of direct injection GC. Volatile GC analyses of LLL hydroperoxides are compared with those of LnLnLn hydroperoxides in Table 1. Direct injection GC of LLL hydroperoxides produced pentane, hexanal, pentanal, 2-heptenal, 2-octenal and 2,4-decadienal as major volatiles. Direct injection GC of LnLnLn hydroperoxides produced propanal, 2,4-heptadienal and 2,4,7-decatrienal as major volatiles. Other significant volatiles included acrolein, 1-penten-3-ol, 2-pentenal, 2-/3-hexenal and ethyl furanone.

To establish characteristic volatiles of linoleate and linolenate components of triacylglycerols, oxidized LLL, LnLnLn and an equal mixture of LLL and LnLnLn were analyzed quantitatively by direct injection GC at peroxide

L Volatiles		100		0		52
Ln Volatiles		0		100		48
Ln/L Volatiles						0.92

[a]Determined by direct injection capillary GC (see Experimental Procedures). Peroxide values for LLL, 22.6; LnLnLn, 31.5; LLL + LnLnLn, 34.3. Peak area (× 1000). Average standard deviation of duplicate analyses is 1.2% for LLL, 2.3% for LnLnLn and 1.3% for LLL + LnLnLn. Integrated values for 2,4-decadienal, 2,4-heptadienal and 2,4,7-decatrienal represent summation of two peaks for each volatile due to the presence of *cis,trans* and *trans,trans* isomers.

values ranging from 22.6 to 34.3. The main volatiles produced from linoleate and linolenate are summarized in Table 2. The main volatiles derived from LLL included pentane, hexanal, 2-heptenal and 2,4-decadienal. The main volatiles derived from LnLnLn included propanal, 2,4-heptadienal and 2,4,7-decatrienal. In the mixture of LLL and LnLnLn, the ratio of linolenate to linoleate volatiles was 0.92 at peroxide value of 34. Therefore, at this peroxide value, the linolenate and linoleate volatiles had about equal contribution to the total decomposition products.

The major volatiles formed from synthetic diL triacylglycerols, LLLn and LLnL, autoxidized at 40°C included in decreasing order: 2,4-decadienal, 2,4-heptadienal, hexanal, 2-heptenal and 2,4,7-decatrienal (Figs. 1a and 1b). The major volatiles formed from synthetic diLn triacylglycerols LnLnL and LnLLn, autoxidized at 40°C included in decreasing order: 2,4-heptadienal, 2,4-decadienal, 2,4,7-decatrienal, hexanal, and 2-heptenal (Figs. 1c and 1d).

The effect of peroxide value on the relative concentrations of these major volatiles is depicted in Figures 2a–e. Among the five volatiles compared, only hexanal showed significant differences between the four triacylglycerols. Hexanal is a major volatile derived from linoleate. Initially, this volatile was formed in larger amounts from LnLLn than LnLnL (Fig. 1a). On the other hand, hexanal was formed in larger amounts from LLLn than from LLnL. Therefore, in the pair of triacylglycerols containing two Ln, more hexanal is formed when L is in the 2 position than when it is in the 1 or 3 position. In the other pair of triacylglycerols containing two L, more hexanal is formed when L is in the 1 and 2 positions than when it is in the 1 and 3 positions.

2,4-Decadienal and 2-heptenal are also volatiles that come from linoleate. No significant differences were found in formation of these two volatiles between the two sets of synthetic triacylglycerols (Figs 2b and 2c). The position of L in these triacylglycerols, therefore, has no effect on the formation of 2,4-decadienal and 2-heptenal. 2,4-Heptadienal and 2,4,7-decatrienal are important volatiles that come from linolenate. No significant differences in the formation of these two volatiles were found between the two sets of synthetic triacylglycerols (Figs. 2d and 2e). The data indicate, therefore, that there is no effect of the position of Ln in these triacylglycerols on the formation of 2,4-heptadienal and 2,4,7-decatrienal.

Figure 3a compares total volatile formation from the synthetic diL triacylglycerols with the corresponding 2:1 mixture of LLL/LnLnLn. About the same amounts of total volatiles were produced by the two synthetic triacylglycerols, and initially both generated less total volatiles than did the 2:1 mixture of LLL/LnLnLn. In contrast, larger differences in total volatiles were observed from the synthetic diLn triacylglycerols and the corresponding 1:2 mixture of LLL/LnLnLn (Fig. 3b). At peroxide values larger than 20, LLnLn produced more total volatiles than the corresponding LnLLn, and both produced more total volatiles than the 2:1 mixture of LLL/LnLnLn. Therefore, the position of Ln in the 1 and 2 position seems to be more important in total volatile formation than that of L in producing total volatiles.

Figure 4 compares the ratios of Ln/L volatiles for the synthetic triacylglycerols. The two diL triacylglycerols show no effect in the relative positions of linoleate in the triacylglycerols. However, the ranges of ratios of Ln/L volatiles for LLLn and LLnL were both higher than the Ln/L ratio in the substrate of 0.5 (Table 3). Therefore, more Ln than L volatiles were produced by LLLn and LLnL than expected from the Ln/L substrate ratio. The Ln/L volatile ratio of the corresponding LLL/LnLnLn mixture of 2:1 was even higher than the Ln/L substrate ratio. On the other hand, the two diLn triacylglycerols show a small difference in the ratio of Ln/L volatiles (Fig. 4). At the beginning and end of the oxidation range, LLnLn pro-

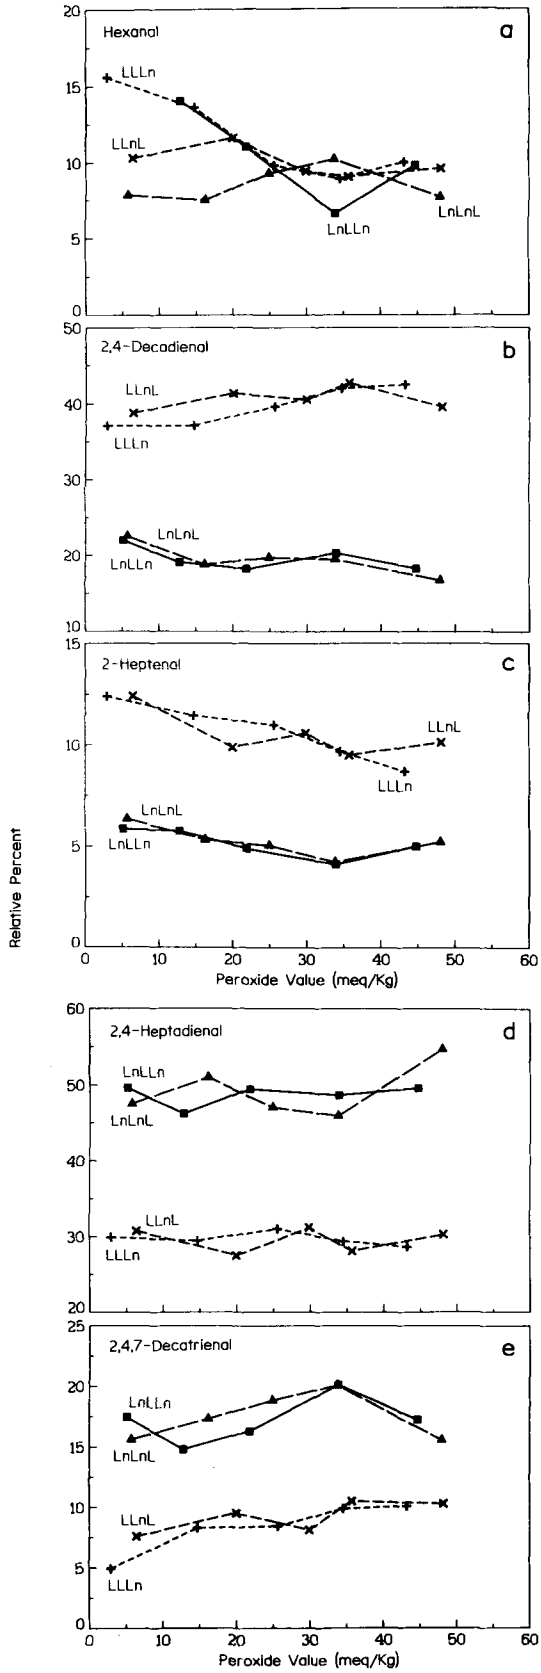

FIG. 2. Autoxidation of synthetic triacylglycerols at 40°C. Analyses by direct injection gas chromatography at 180°C. (a) Hexanal formation; (b)2,4-decadienal formation; (c) 2-heptenal formation; (d) 2,4-heptadienal formation; (e) 2,4,7-decatrienal formation.

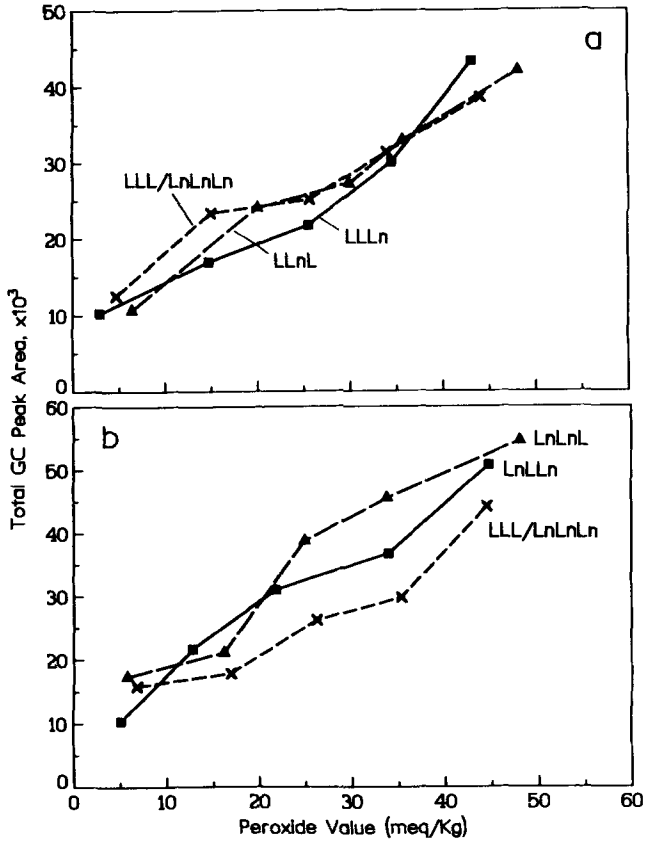

FIG. 3. Autoxidation of synthetic triacylglycerols at 40°C. Analyses by direct injection gas chromatography at 180°C. (a) LLLn, LLnL and a 2:1 mixture of LLL/LnLnLn; (b) LnLnL, LnLLn and a 1:2 mixture of LLL/LnLnLn.

TABLE 3

Relation Between Ratios of Substrates and Volatile Compounds from Synthetic Triacylglycerols and Mixtures of LLL and LnLnLn Oxidized at 40°C[a]

Triacylglycerols	Substrate ratio Ln/L	Volatile compounds Ln/L
LLLn	0.5	0.54-0.65
LLnL	0.5	0.59-0.68
LLL/LnLnLn (2:1)	0.5	0.66-0.84
LnLnL	2.0	1.93-2.37
LnLLn	2.0	1.95-2.21
LLL/LnLnLn (1:2)	2.0	2.37-2.76

[a]Ranges of volatile Ln/L ratios taken from Figure 4.

duced a larger ratio of Ln/L products than the corresponding LnLLn. The ranges of ratios of Ln/L volatiles for LnLnL and LnLLn were about the same as the Ln/L substrate ratio of 2.0 (Table 3). Therefore, the Ln and L volatiles produced by LLLn and LLnL are in the same range as expected from the Ln/L substrate ratio. However, the Ln/L volatile ratio of the corresponding LLL/LnLnLn mixture of 1:2 was significantly higher than the Ln/L substrate ratio. It appears, therefore, that volatile formation from known mixtures of LLL and LnLnLn does not conform to that of the synthetic triacylglycerols. Although

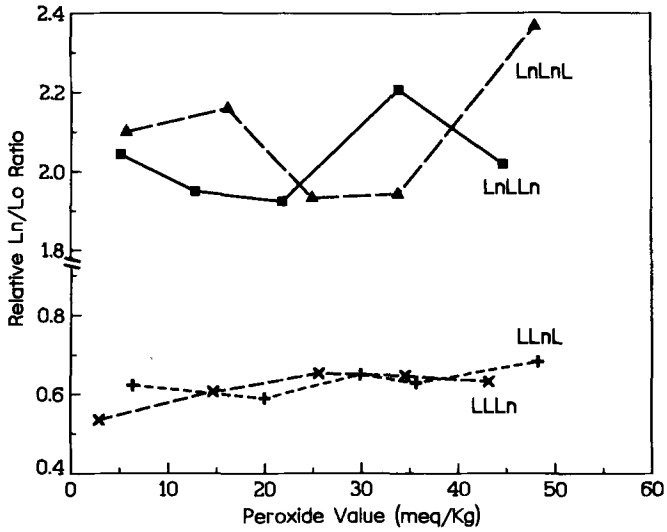

FIG. 4. Autoxidation of synthetic triacylglycerols at 40°C. Analyses by direct injection gas chromatography at 180°C. Relative Ln/L volatile product ratio. Ln volatiles include 2,4-heptadienal and 2,4,7-decatrienal; L volatiles include hexanal, 2,4-decadienal and 2-heptenal.

these mixtures of LLL and LnLnLn have been useful in developing the analytical methodology to distinguish between L and Ln volatiles, they have poor predictive value on volatile formation from triacylglycerols containing L and Ln in different positions.

DISCUSSION

Capillary GC provided a sensitive method to follow the volatile oxidation products of mixtures of LLL and LnLnLn, and of synthetic triacylglycerols containing L and Ln in different known positions. Significant differences in the distribution of volatile products were observed depending on the triacylglycerol precursor. We measured the relative amount of linoleate oxidation by analyzing for hexanal, 2-heptenal and 2,4-decadienal, and the relative amount of linolenate oxidation by analyzing for 2,4-heptadienal and 2,4,7-decatrienal. Mixtures of trilinolein and trilinolenin (1:1) autoxidized at 40°C showed an equal contribution of linolenate and linoleate volatiles at a peroxide value of 34 (Table 2).

The synthetic triacylglycerols LLnL and LLLn initially formed about the same amounts of total volatiles and ratio of linolenate to linoleate products. On the other hand, LnLnL formed more volatiles and a slightly higher ratio of linolenate to linoleate products than LnLnL. In our previous paper (8), when synthetic triacylglycerols were oxidized at 40°C, peroxide formation decreased in the following order: LnLnL > LnLLn > LLnL > LLLn. The oxidation product ratios of linolenate/linoleate showed the following trend: LnLnL > LnLLn >> LLnL = LLLn. We suggested that competitive interactions between two Ln are higher than between Ln and L in adjacent triacylglycerol positions.

In the present work, smaller differences were found in total volatile formation between the synthetic triacylglycerols, and thus smaller effects of the relative positions of L and Ln than in our previous study (8) of peroxide formation using the same set of triacylglycerols. The volatile decomposition products from autoxidized triacylglycerols showed a larger total volatile formation from LnLnL than from LnLLn, but no difference between LLnL and LLLn. The product ratio of Ln/L volatiles showed the same order as that of the peroxide formation (8), *i.e.*, LnLnL > LnLLn >> LLnL = LLLn. Therefore, in the diLn triacylglycerols, two adjacent Ln substituents produced more volatiles than when they are separated by one L substituent. In diL triacylglycerols, the relative acyl position of L had no effect on volatile formation. As for peroxide formation (8), LnLn interactions are apparently also more important for volatile formation than LnL interactions. These interactions are, however, not as significant in the diL triacylglycerols. This new information may permit us to evaluate better the precursors of oxidative deterioration in unsaturated lipids, and to understand the influence of triacylglycerol structure on the relative stability of lipids.

Oxidation of the α-Tocopherol Model Compound 2,2,5,7,8-Pentamethyl-6-chromanol in the Presence of Alcohols

Cacang Suarna, Manuel Baca and **Peter T. Southwell-Keely***
School of Chemistry, University of South Wales, Kensington, N.S.W. 2033, Australia

Oxidation of the vitamin E model compound, 2,2,5,7,8-pentamethyl-6-chromanol (1b) by *t*-butyl hydroperoxide in chloroform has been studied in the presence of ethanol, heptanol and cholesterol. In the absence of an alcohol, the major products were the spirodimer (13b) and spirotrimer (14b) of 1b, together with 1H,2,3-dihydro-3,3,5,6,9,10,11a(R)-heptamethyl-7a(S)-(3-hydroxy-3-methylbutyl)-pyrano[2,3-a] xanthene 8(7aH), 11(11aH) dione (6b). In the presence of ethanol, heptanol and cholesterol, the major products were 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (16b), 5-heptoxymethyl-2,2,7,8-tetramethyl-6-chromanol (17) and 5-cholesteroxymethyl-2,2,7,8-tetramethyl-6-chromanol (18). However, when water was present in a homogeneous reaction, the most rapidly formed product was 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (5b). Compounds 13b, 14b, 16b, 17 and 18 are formed *via* a quinone methide intermediate, and compound 5b is formed *via* a phenoxylium ion. The phenoxylium species appears to be the preferred intermediate when water is present, whereas the quinone methide species is preferred in the absence of water.
Lipids 27, 447–453 (1992).

It has been shown recently that some of the oxidation procuts of α-tocopherol (1a) and of its model compound, 2,2,5,7,8-pentamethyl-6-chromanol (1b), are themselves antioxidants (1). If such compounds are formed *in vivo*, the antioxidant activity of 1a would not necessarily be lost on oxidation, which could help to explain its remarkable efficiency. Oxidation products of 1a and 1b are believed to be formed either through an intermediary phenoxyl radical (2a or 2b; Scheme 1), through a phenoxylium ion (3a or 3b; Scheme 1) or through a quinone methide (8a or 8b, Scheme 1). All of the products with antioxidant activity are derivatives of 8a (or 8b), derivatives of 3a (or 3b) have no antioxidant activity (1). Therefore, the intermediate through which the oxidation proceeds determines whether or not antioxidant activity can be prolonged, and the type of intermediate is determined by the nature of the oxidant and/or of the solvent in which the reaction occurs. Thus the oxidation of 1a and 1b, in an inert, nonpolar solvent, such as petroleum, leads to derivatives of 8a (or 8b) (2,3) such as dimers, trimers and 5-benzoyloxymethyl derivatives (2,4–6). By contrast, oxidation in a protic solvent, such as ethanol, can give derivatives of 3a (or 3b) (7–9), such as quinones (10), 8a-hydroxy-tocopherones (11), 8a-alkoxy-tocopherones (7,12) and quinone epoxides (13), and also derivatives of 8a (or 8b), such as 5-alkoxymethyl compounds (14,15).

We have never observed products of 2a,2b, but have found that products of 3a,3b and of 8a,8b are present in all oxidation reactions, and it was the aim of the present work to study the rate of product formation under conditions of varying solvent polarity.

EXPERIMENTAL PROCEDURES

Compound 1b, 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (10b), 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (5b), the spirodimer of 1b (13b), the spirotrimer of 1b (14b), and 1,2-*bis*(2,2,7,8-tetramethyl-6-chromanol-5)ethane (15b) were synthesized to satisfactory purity by established methods (2,5,10,16,17).

The following compounds were isolated from oxidation reactions of 1b: 5-Formyl-2,2-7,8-tetramethyl-6-chromanol (12b) (15); 1H-2,3-dihydro-3,3,5,6,9,10,11a(R)heptamethyl-7a(S)-(3-hydroxy-3-methylbutyl)-pyrano[2,3-a]xanthene-8(7aH), 11(11aH) dione (6b) (18); 5-ethoxymethyl-2,2-7,8-tetramethyl-6-chromanol (16b) (14); 5-heptoxymethyl-2,2,7,8-tetramethyl-6-chromanol (17) (19); 5-cholesteroxymethyl-2,2,7,8-tetramethyl-6-chromanol (18) (19); and 2,2,7,8-tetramethylchroman-5,6-dione (11b) (20).

High-performance liquid chromatography (HPLC) employed a Waters Associates (Milford, MA) 501 (Solvent A) and 6000A (Solvent B) pump, U6K injector, with 2 mL loop, a 660 solvent programer, an ETP Kortec (Sydney, Australia) K 95 variable wavelength detector (set at 290 nm for these experiments), a National Pen Recorder (Matsushita, Yokohama, Japan) VP-6513 A, and a SIC Chromatocorder 12 (Alphatech, Tokyo, Japan) integrator. Separations were performed by linear program (from 7 to 65% Solvent B in 0–40 min) on a Lichrosorb (Merck, Darmstadt, Germany) Si 60, 10 μm column (300 × 4.6 mm; packed in the School of Chemistry, University of New South Wales, Sydney, Australia) at a flow rate of 1 mL/min. The oxidation products had the following retention times (in min) in this system: 18, 3.78; 17, 4.10; 14b, 4.14; 13b, 4.70; 12b, 5.22; 16b, 6.19; 1b, 8.68; 15b, 10.68; 11b, 19.90; 5b, 24.82; 6b, 31.28 (21). Compounds 17 and 14b would have been incompletely separated if they had occurred in the same reaction (*e.g.*, reaction 4 below). However, no trace of 14b or 13b was seen in reaction 4, which had been studied previously by thin-layer chromatography (TLC) (Suarna, C., and Southwell-Keely, P.T., unpublished observations). Solvents A and B were hexane/chloroform (9:1, vol/vol) and hexane/chloroform/ethyl acetate (4:1:5, vol/vol/vol), respectively. Solvents were passed through an Activon (Sydney, Australia) 0.45 μm filter, degassed (Waters Associates pump) and sonicated (Branasonic 12, Branson, Danbury, CT).

Reaction 1. Oxidation of 1b *by t-butyl hydroperoxide in chloroform saturated with water.* A solution of 1b (55.1 mg, 0.25 mmol) in chloroform saturated with water (30 mL) was prepared; an aliquot (2 mL) was taken for analysis as the zero time reaction. *t*-Butyl hydroperoxide (27.0 mg, 0.279 mmol) was added to the remaining solution, and the solution was heated at 60 ± 2°C for 6 h.

18 R"= Cholesteryl-

SCHEME 1

Aliquots (2 mL) of the reaction mixture were removed for analysis at 15, 30, 45, 60, 90, 120, 150, 180, 240, 300 and 360 min. Each 2 mL aliquot was washed with 5% ferrous sulfate (3 × 1 mL; to destroy unreacted hydroperoxide) and with distilled water (4 × 1 mL). The aliquots were dried (Na_2 SO_4), and the solvent was removed *in vacuo*. The dried samples were kept over silica gel and under nitrogen at −20°C until ready for analysis. For HPLC, the dried samples were diluted to 2.0 mL with Solvent A and filtered through a 0.45 μm nylon filter (Activon).

Reaction 2. Oxidation of **1b** *by t-butyl hydroperoxide in chloroform containing 20% ethanol.* In a similar manner

to the previous reaction, **1b** (54.9 mg, 0.25 mmol) in a mixture of chloroform (24 mL) and absolute ethanol (6 mL) was oxidized by *t*-butyl hydroperoxide (26.4 mg, 0.27 mmol) at 60 ± 2°C. Aliquots (2 mL) of the reaction mixture were taken at the same intervals for analysis.

Reaction 3. Oxidation of **1b** *by t-butyl hydroperoxide in chloroform containing 18.5% ethanol and 1.5% water.* In a similar manner to the first reaction, **1b** (55 mg, 0.25 mmol), in a mixture of chloroform (24 mL), absolute ethanol (5.55 mL) and water (0.45 mL), was oxidized by *t*-butyl hydroperoxide (27.2 mg, 0.28 mmol) at 60 ± 2°C. Aliquots (2 mL) of the reaction mixture were taken at the same intervals as before for analysis.

Reaction 4. Oxidation of **1b** *by t-butyl hydroperoxide in chloroform containing 20% heptanol.* In a manner similar to the first reaction, **1b** (55 mg, 0.25 mmol), in a mixture of chloroform (24 mL) and heptanol (6 mL), was oxidized by *t*-butyl hydroperoxide (24.1 mg, 0.25 mmol) at 60 ± 2°C. Aliquots (2 mL) of the reaction mixture were taken at the same intervals as before for analysis.

Reaction 5. Oxidation of **1b** *by t-butyl hydroperoxide in chloroform containing cholesterol.* In a manner similar to the first reaction, **1b** (55 mg, 0.25 mmol), in a mixture of chloroform (24 mL) and cholesterol (97 mg, 0.25 mmol), was oxidized by *t*-butyl hydroperoxide (24.0 mg, 0.25 mmol) at 60 ± 2°C. Aliquots (2 mL) of the reaction mixture were taken at the same intervals as before for analysis.

RESULTS

Figure 1 shows that *t*-butyl hydroperoxide oxidizes **1b** very slowly when water is present in a heterogeneous system, recording a 50% loss of **1b** in 100 min and almost complete loss in 360 min. Seventeen products were formed, eight of which have been identified and are shown in Figure 1. The nine additional unknown compounds are not shown. The major product after 360 min was the spirodimer **13b** (40%), and minor products included the pyranoxanthene **6b** (12%), the spirotrimer **14b** (10%), aldehyde **12b** (4.5%), quinone **5b** (3.5%), the 5-ethoxymethyl compound **16b** (2%), the chroman-5,6-dione **11b** (1.5%) and the dihydroxy dimer **15b** (1.6%).

Oxidation of **1b** in the presence of 20% ethanol gives a much faster reaction, with a 50% loss of **1b** in 30 min and almost complete loss in 90 min (Fig. 2). Concomitant with the loss of **1b** is the formation of **16b**, which reaches a maximum of 60% in 90 min and is by far the major product (Fig. 2). The formation of **5b** is unusual in that it forms rapidly (though not as rapidly as **16b**) and reaches a maximum of 4% in the first 30 min (Fig. 2). It then declines, reaching a minimum in 120 min and appears to form again, attaining 3.5% after 360 min. Compounds **11b** and **12b** appear to be secondary products which build up slowly with time reaching 5.7 and 2.7%, respectively, after 360 min (Fig. 2). Three, as yet unidentified, compounds (retention times 4.29, 7.42 and 26.44 min, respectively) also were noted in the reaction (Fig. 2).

Oxidation of **1b** in the presence of 18.5% ethanol and 1.5% water (a homogeneous system) gave an even faster reaction, with a 50% loss of **1b** in 20 min and complete loss in 90 min (Fig. 3). The dominant product early in the reaction was **5b**, which reached a maximum of 50% after 90 min but then fell and was only 17% at 300 min. Compound **16b** was a minor product early in the reaction (8%

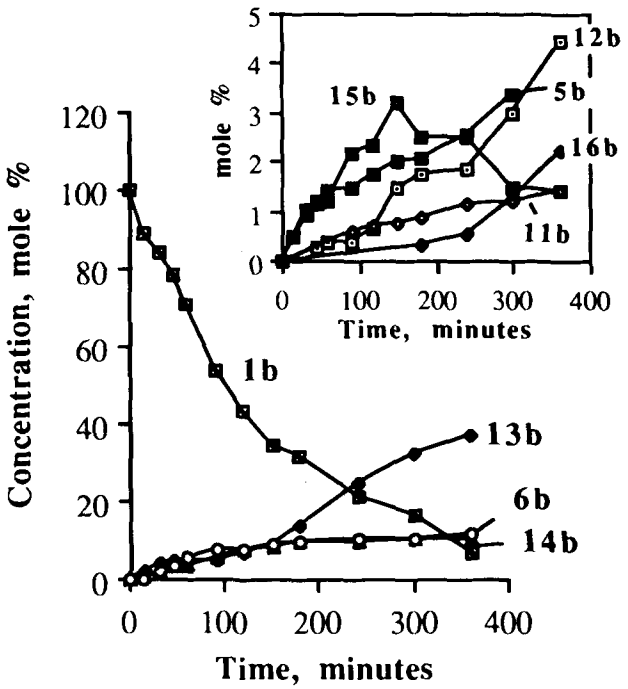

FIG. 1. Formation of oxidation products in the reaction between *t*-butyl hydroperoxide and 2,2,5,7,8-pentamethyl-6-chromanol (1b) in chloroform saturated with water. Products are numbered as in Scheme 1.

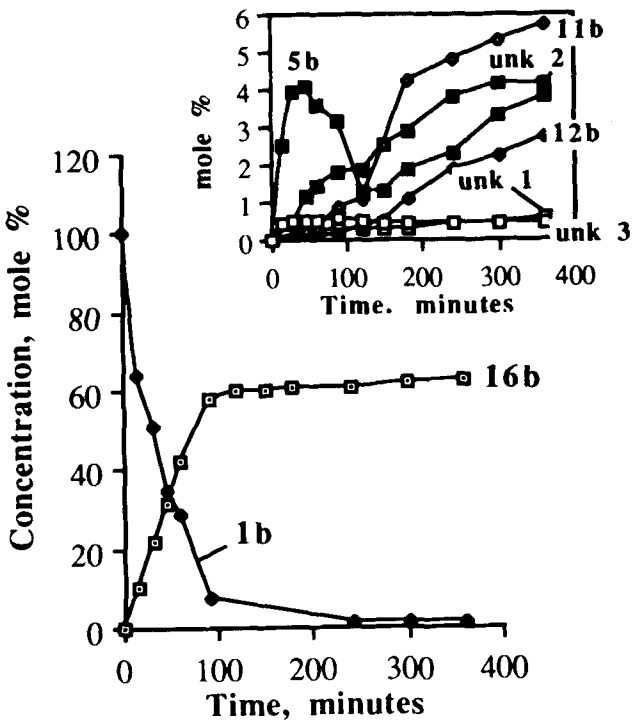

FIG. 2. Formation of oxidation products in the reaction between *t*-butyl hydroperoxide and 2,2,5,7,8-pentamethyl-6-chromanol (1b) in chloroform containing 20% ethanol. Products are numbered as in Scheme 1.

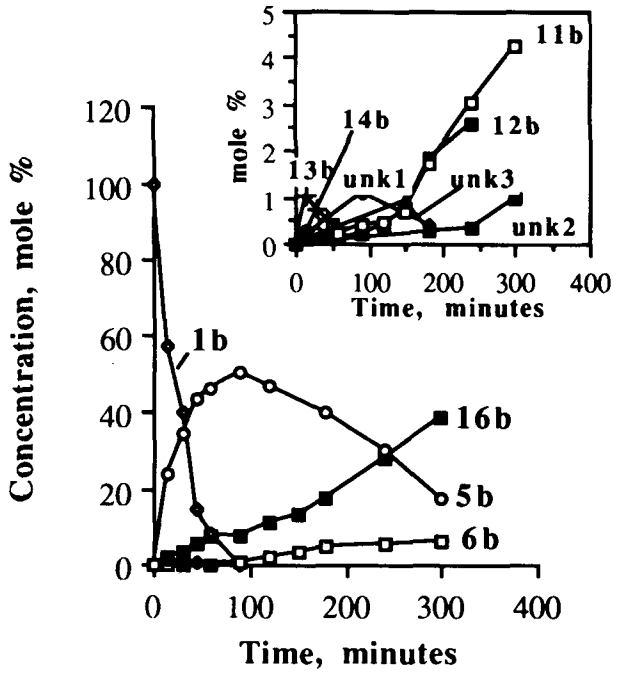

FIG. 3. Formation of oxidation products in the reaction between *t*-butyl hydroperoxide and 2,2,5,7,8-pentamethyl-6-chromanol (1b) in chloroform containing 18.5% ethanol and 1.5% water. Products are numbered as in Scheme 1.

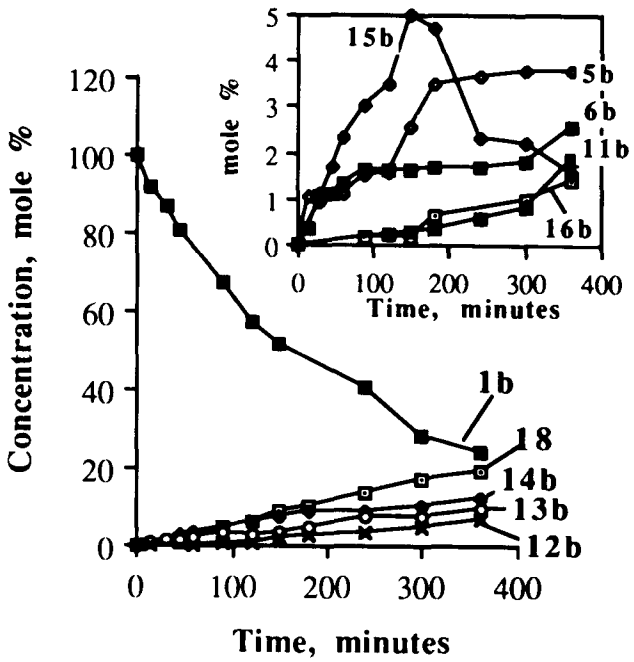

FIG. 4. Formation of oxidation products in the reaction between *t*-butyl hydroperoxide and 2,2,5,7,8-pentamethyl-6-chromanol (1b) in chloroform containing 20% heptanol. Products are numbered as in Scheme 1.

after 90 min) but rose steadily to be the major product (39%) at 300 min (Fig. 3).

Oxidation of **1b** in the presence of 20% heptanol gave the most rapid reaction with 85% loss in 15 min and complete loss in 45 min (Fig. 4). Matching the loss of **1b** was the rapid formation of **17**, which reached 47% in 45 min and a maximum of 64% in 150 min. Compound **5b** also was formed rapidly in the early stages, reaching 18% in 15 min but then dropping to zero in 90 min. Minor products **12b** (2.4% in 300 min) and **11b** (3% in 90 min) were formed again.

Oxidation of **1b** in the presence of cholesterol was a very slow reaction with 50% loss in 150 min and 75% loss in 360 min (Fig. 5). Compound **18** was the major product which was formed at a slow but steady rate to yield 19% after 360 min. As in reaction 1, there was a large number of products of smaller amount ranging from **14b** (12%) to **15b** (1.6%).

DISCUSSION

Oxidation of **1a** and **1b** proceeds by loss of a single electron to form the phenoxyl radicals **2a,2b** (22–24), which may lose a further electron to form the phenoxylium ions **3a,3b** or alternatively dimerize to **7a,7b** followed by disproportionation of the dimers to form one molecule of quinone methide **8a,8b** and one molecule of **1a,1b** (25–27). Since **3a,3b** are the protonated forms of **8a,8b**, respectively, it is likely that an equilibrium exists between the **3** and **8** species. Compounds **2a,2b**, **3a,3b** and **8a,8b** are unstable intermediates and products of each are known. Thus, peroxyl radicals can react with the mesomeric form of **2a** to form **9a** (R′ = O-alkyl) (28–31). Compound **3a** can react with alcohols to form **9a** (R′ = alkyl) (12), or it may react

with water to form **4a**, the precursor of **5a** and **6a** (11). Compounds **8a,8b** are the most versatile intermediates and are the precursors of a wide variety of compounds. They may undergo: i) Diels-Alder polymerization to form **13a, 13b** and **14a,14b** (2,5); ii) Diels-Alder addition to form **6a,6b** (18); iii) nucleophilic addition of water to form **10a,10b** (15), the precursors of **11a,11b** and **12a,12b**; iv) nucleophilic addition of alcohols to form **16a,16b, 17, 18** and other homologs (14,19); or v) disproportionation to form **15a,15b** (5,32).

Previous results have demonstrated that *t*-butyl hydroperoxide is a very weak oxidant for **1b** and will not oxidize it at all unless there is an attendant nucleophile, such as an alcohol or water (14,15). Reaction 1 shows that, even in the presence of a very small amount of water, substantial though slow reaction occurs to form a large number of products.

Products of reaction 1 which are derivatives of the quinone methide **8b** include **11b, 12b, 13b, 14b, 15b** and **16b**. The major derivative of the phenoxylium ion **3b** is **5b**. The pyrano-xanthene **6b** is a derivative of both **8b** and **3b** since it is formed by reaction of **8b** with **5b**. On this basis, derivatives of **8b** account for 64% of **1b** after 360 min, while derivatives of **3b** account for 9.5%. It would seem that the neutral **8b**, much less polar than the ionic **3b**, is the intermediate favored by the nonpolar solvent chloroform. The concentration of dimer **13b** is four times that of the trimer **14b**. By contrast, when **1a** was oxidized by autoxidizing methyl linoleate, the trimer **14a** was the major product and the dimer **13a** the minor product (33). Also, in simpler molecules, the trimer is the preferred product (27). Formation of the trimer probably depends on whether other reactions are available to **8a,8b**. In the present reaction, addition of **8b** to **5b** to form **6b**, and addition of water to **8b** leading ultimately to **11b** and **12b**, compete successfully with trimerization.

Alkaline ferricyanide is the reagent which has been used most in the preparation of spirodimers **13a,13b** (4,5), and a comparison of its oxidizing power with that of *t*-butyl hydroperoxide is interesting. Even taking into account the more concentrated reaction mixtures used in previous work (4,5), alkaline ferricyanide is a much more effective oxidant than *t*-butyl hydroperoxide, producing approximately the same yield of dimer in 3 min at room temperature as that produced by *t*-butyl hydroperoxide in 360 min at 60°C. If one compares the rate of formation of (**5b** + **6b**) with that of (**11b** + **12b**), it is clear that water would prefer to add to **3b** rather than to **8b**.

Formation of compound **16b** (2% after 360 min) requires explanation. Compound **16b** is formed by the reaction of ethanol with **8b**. However, this reaction contains no ethanol and the chloroform solvent was purified to remove the ethanol stabilizer. This concentration of **16b** can be accounted for by assuming that compound **1b** was contaminated by 0.4% (w/w) ethanol of crystallization. Detection of this concentration of ethanol in the ^{1}H NMR (nuclear magnetic resonance) spectrum of **1b** would have required a 1000-fold peak enhancement which was not performed at the time.

There have been a number of studies involving the oxidation of **1a** with alkylperoxyl radicals (28–31). In each case mixed peroxide products such as **9a** (R′ = O-alkyl) have been reported and, in several cases, isolated (29–31). *t*-Butylperoxyl radical reacts with **1b** to form epoxide peroxides of **9b** (R′ = O-*t*-butyl), which are sufficiently stable that they can be isolated by chromatography on silica gel (34). By contrast, *t*-butoxyl radical produces **13b, 14b** and **15b**, but does not produce compound **9b** (R′ = *t*-butyl) or its epoxides (34), presumably because the bulky *t*-butyl group cannot be accommodated so close to the birdgehead (8a) position (12). We have never observed compound **9b** (R′ = O-*t*-butyl) or its epoxides, either in the present reactions or in our previous reactions involving **1b**. This suggests that the oxidant in our reactions was not the *t*-butylperoxyl radical, but the *t*-butoxyl radical.

After 45 min of reaction 2 (containing 20% ethanol), **16b**, a derivative of **8b**, accounted for 33% of **1b**, while **5b**, a derivative of **3b**, accounted for 4% of **1b**. After 90 min, derivatives of **8b**, (**11b, 12b** and **16b**), accounted for 60%, and derivatives of **3b**, (**5b**) accounted for 1% of **1b**. Thus **8b** was again the overwhelmingly favored intermediate despite the much more polar solvent (20% ethanol) which, one might imagine, would favor **3b**. The rate of formation of **5b** was much more rapid in reaction 2 (4% after 30 min) than in reaction 1 (3% after 300 min), even though there was more water (0.7%) in reaction 1 than in reaction 2 (0.2%). The reason for this must be that in reaction 2, the water was in a homogeneous solution, and therefore more available for reaction, whereas in reaction 1, it was in a heterogeneous solution, on the surface of the chloroform, and therefore less available for reaction.

No trace was found of 8a-ethoxy 2,2,5,7,8-pentamethylchroman-6(8aH)-one (**9b**, R′ = CH_3CH_2). It is doubtful that it was formed at all since very little of its breakdown product, **5b**, was noted in the reaction. Thus, these results differ significantly from those observed by Goodhue and Risley (6,12) who oxidized **1a** with benzoyl peroxide. They found 5-benzoyloxymethyl-γ-tocopherol (a derivative of **8a** with structure analogous to **16a, 16b, 17** and **18**) as major product in nonpolar solvents, such as benzene and hexane. However, they found alkoxy homologs of **9a** (R′ = alkyl) (derivatives of **3a**) as the major products in alcohol solvents. The reasons for the differences between our present results and those of Goodhue and Risley (6,12) may have to do with the substrate or with the oxidant. First, we have used **1b** as substrate, whereas they used **1a**. It is not known whether the phytol side chain of **1a** has an influence on the formation of compound **9a**. However, compound **9a** (R′ = alkyl) is well known (12), whereas compounds **9b** (R′ = alkyl) does not appear to have been reported. Second, our oxidant was probably the *t*-butoxyl radical, whereas Goodhue and Risley used the benzoyloxyl radical (BzO•, derived from benzoyl peroxide). When BzO• reacts with **1a**, it forms benzoic acid (BzOH) and **2a** (Eq. [1]):

$$\text{BzO}\bullet + \mathbf{1a} \rightarrow \text{BzOH} + \mathbf{2a} \qquad [1]$$

Compound **2a** disproportionates to form **8a**, as described above. In nonpolar solvents such as benzene and hexane, BzOH acts as a nucleophile and adds to **8a** to form 5-benzoyloxymethyl-γ-tocopherol. However, in protic solvents such as alcohols, it is possible that an equilibrium exists between **3** and **8** (Scheme 1), both of which are capable of reacting with ethanol. Results of reaction 2 suggest that ethanol prefers to react with **8** rather than with **3**. However, if a stronger acid such as BzOH is present,

it may push the **8a** ↔ **3a** equilibrium towards **3a** and thus favor the formation of **9a**.

In our system, the oxidant is probably the *t*-butoxyl radical (*t*-BuO•) which would react with **1b** to form *t*-butanol and **2b** (Eq. [2]):

$$t\text{-BuO}\bullet + \mathbf{1b} \rightarrow t\text{-BuOH} + \mathbf{2b} \qquad [2]$$

Compound **2b** disproportionates to form **8b** as before. *t*-Butanol can act as a nucleophile and add to **8b** to form 5-*t*-butoxymethyl-2,2,7,8-tetramethyl-6-chromanol (analogous to **16b**, **17** and **18**) (19). However, it does not do so in this case, probably because of the overwhelming, competing excess of ethanol which reacts with **8b** to form **16b**. It would appear that neither *t*-butanol nor ethanol is a sufficiently strong acid to drive the **8b** ↔ **3b** equilibrium towards **3b** and, hence, compound **9b** (R′ = CH_3-CH_2) does not form.

There seems to be no relationship between the strength of the oxidant and the type of derivative formed. Thus benzoyl peroxide, which is a stronger oxidant than *t*-butyl hydroperoxide (35), and ferric chloride, which is weaker than *t*-butyl hydroperoxide or benzoyl peroxide, both give rise to **9a**, whereas *t*-butyl hydroperoxide gives rise to **16b**–**18**. Reaction temperature does not appear to be a factor since the benzoyl peroxide reactions were run at 60°C or higher and the present reactions were run at 60°C, whereas the ferric chloride reactions were run at −10°C (7).

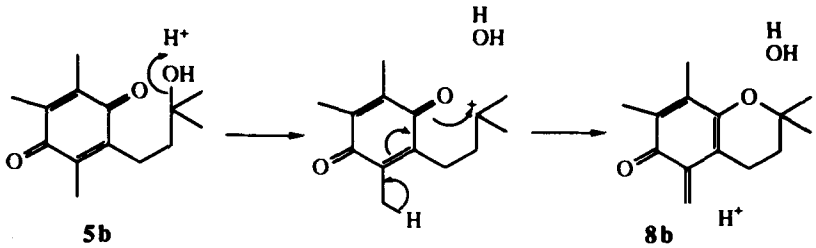
In reaction 3 (containing 18.5% ethanol and 1.5% water), **5b** is formed most rapidly and dominates the early phase of this reaction even though the molar concentration of water is one-fifth that of ethanol, whereas products of **8b** (**11b**, **12b** and **16b**) are formed much more slowly and dominate the later stages. Clearly, both **3b** and **8b** are present at the same time but the increase in water from 0.2% in reaction 2 to 1.8% in reaction 3 heavily favors **3b**. It is possible that water is able to shift the **8b** ↔ **3b** equilibrium towards **3b** because of the much greater ability of water to solvate the ionic **3b** rather than the neutral **8b**.

The results of reactions 1–3 and others (28–31,34) suggest that the first-formed products **2a**,**2b** can react with peroxyl radicals, if present, to form **9a**,**9b** (R′ = O-alkyl). If no species are present which can react directly with **2a**,**2b** they will either lose an electron to form **3a**,**3b** or disproportionate to form **8a**,**8b**. Protic solvents will promote the formation of the **8** ↔ **3** equilibrium. The high yield of **16b** and absence of **9b** (R′ = CH_3CH_2) in reaction 2 suggests that **3** is formed in the sequence **2** → **7** → **8** ↔ **3** rather than the more direct **2** → **3**. If **3** were formed in the sequence **2** → **3**, one would expect **9b** rather than **16b** to be the major product in reaction 2.

In reaction 3, one might ask how **16b** can continue to be formed after **1b** is completely destroyed, since **1b** is the source of **8b**, which reacts with ethanol to form **16b**. Since the concentration of **5b** falls as **16b** rises, one might suspect that **5b** is being converted into **16b**. Compound **5b** is completely stable when heated with *t*-butyl hydroperoxide at 60°C in chloroform. However, **5b** is easily converted into **16b** when heated at 60°C in ethanol in the absence of *t*-butyl hydroperoxide but in the presence of acid (Kohar, I., and Southwell-Keely, P.T., unpublished observations). In order for **5b** to be converted into **16b**, it must proceed through **8b** (Scheme 2). The source of acidity for the **5b** ↔ **8b** conversion in reaction 3 is probably the formation of **5b** itself. Thus, when **3b** reacts with water to form **4b**, the precursor of **5b**, a proton is liberated. Another possible source of **16b** is 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (**10b**), which is formed by reaction of water with **8b**. Compound **10b** can react with ethanol to form **16b** (Kohar, I., and Southwell-Keely, P.T., unpublished observations). For reasons which are not completely understood, but which are related to its lability, particularly to acid, **10b** is very difficult to detect by HPLC. However, **10b** must be present since **11b** and **12b** are formed from it. Minor secondary products included **6b** (6% after 300 min), **11b** (4%) and **12b** (3%), each of which began to increase as **5b** began to decline. Each is probably formed as a consequence of the **5b** ↔ **8b** interconversion described above. Again, no trace of **9b** (R′ = CH_3-CH_2) was observed in this reaction. However, it is possible that **9b** may have been formed and converted into **5b**.

Reaction 4, which contained heptanol as the nucleophile, gave the most rapid reaction, the highest yield of any product (**17**, 65%) and the simplest mixture of products, despite the fact that the concentration of heptanol in reaction 4 was only one-third, on a molar basis, that of ethanol in reaction 2. It would appear that the more nonpolar the attacking nucleophile, the more rapid the rate of reaction is likely to be. In the first 15 min, production of **5b** was almost as fast as that of **17**, but it then decreased rapidly while production of **17** continued to increase. Again, as in reaction 2, no trace of **9b** (R′ = CH_3-$(CH_2)_6$) was found. The continuing formation of **17** after **1b** had been completely destroyed may have been due to conversion of **5b** into **8b** under the influence of acid (as in reaction 3), followed by reaction of **8b** with heptanol.

Reaction 5, with cholesterol as the attacking nucleophile, was the slowest reaction of all. However, this would be expected from the much lower molar ratio of cholesterol



SCHEME 2

to **1b** (1:1) as compared with ethanol to **1b** (430:1) and heptanol to **1b** (170:1). Due to its lack of solubility in chloroform, it was necessary to use a much lower concentration of cholesterol than those of the other alcohols. In addition, one might expect a reduction in reaction rate from a large, bulky secondary alcohol (cholesterol) as compared with smaller, less bulky primary alcohols. Nevertheless, the major product was **18** and derivatives of **8b** dominated the reaction. Taken together, the concentration of **13b** and **14b** just exceeded that of **18**, showing that when the nucleophile is large and bulky, polymerization of **8b** competes well with nucleophilic addition, whereas nucleophilic addition predominates with a smaller, more reactive and/or more concentrated nucleophile.

ACKNOWLEDGMENTS

Thanks are due to N. Juranario for recording the infrared spectra, and to H. Stender for the NMR spectra, and to J. Brophy for the mass spectra.

***Tris*(*N,N*-dimethyl)amide of phosphorous acid activated by addition of iodine at an optimal molar ratio of 1.05:0.05 was used as a phosphorylating reagent to synthesize cholecalciferyl-3-*O*-(1-2-isopropylidene-*rac*-glycero-3-*O*-)-thiophosphate and cholecalciferyl-3-*O*-(1,2-dipalmitoyl-*rac*-glycero-3-*O*-)thiophosphate of methyl alcohol, 2-dimethylaminoethanol, 3-dimethylamino-1-propanol and 1,2-isopropylidene-*rac*-glycerol in a "one-pot procedure" in overall yields of 60–80%. Activation of the reaction with an equimolar mixture of imidazole and carbon disulfide at the triester formation step permits selective phosphorylation at room temperature. The compounds synthesized represent new triester phospholipid model compounds in which (in addition to glycerol and another requisite alcohol) a steroid and an element other than oxygen are bond to phosphorus.**

***Lipds* 27, 454–457 (1992).**

Synthetic model phospholipids containing phosphate triester linkages are of considerable interest to elucidate their chemical, biochemical and pharmacological properties. The synthesis of a triester phospholipid that includes (in addition to glycerol and another alcoholic moiety) a biological active lipid has not been reported as of yet.

In the present paper we describe the synthesis of asymmetrical triester glycerothiophosphates containing vitamin D_3 (Fig. 1). These types of compounds represent new model structures in which a biologically important element other than oxygen also is bonded to phosphorus.

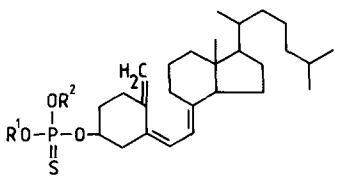

FIG. 1. Triester thiophosphates of vitamin D_3: R^1 = 1,2-isopropylidene-*rac*-glyceryl, or 1,2-dipalmitoyl-*rac*-glyceryl; R^2 = methyl, 2-dimethylaminoethyl, 3-dimethylaminopropyl or 1,2-isopropylidene-*rac*-glyceryl.

MATERIALS AND METHODS

Tris(*N,N*-dimethyl)amide of phosphoruous acid **1** was prepared and freshly distilled as described (1). Cholecalciferol (**a**), 1,2-isopropylidene-*rac*-glycerol (**b**), 1,2-dipalmitoyl-*rac*-glycerol (**c**), methyl alcohol (**d**), 2-dimethylaminoethanol (**e**) and 3-dimethylamino-1-propanol (**f**) were obtained commercially (Aldrich, Milwaukee, WI; Merck, Darmstadt, Germany; Sigma, St. Louis, MO) and were better than 98% pure. All other reagents were purchased from Janssen (Stockholm, Sweden) and were better than 98% pure. Benzene (Merck) was dried over sodium and freshly distilled prior to use. Reaction conditions were kept strictly anhydrous.

All processes were monitored by analytical thin-layer chromatography (TLC) on pre-coated aluminum sheets of Silica Gel 60 F_{254} (Merck). High-performance liquid chromatography (HPLC) was done (Gilson 305 System, equipped with a Gilson 131 refractive index detector; Medical Electronics, Middleton, WI) using a Polygosil 60-7 silica gel column (Scandinaviska Genetik AB, Sweden; 250 × 10 mm). Chloroform (System A), chloroform/methanol (90:10, vol/vol; System B), chloroform/methanol (80:20, vol/vol; System C) and n-heptane/ethyl acetate (80:20, vol/vol; System D) were used as mobile phases.

^{13}C Nuclear magnetic resonance (NMR) spectra were recorded on a Varian XL-300 (Palo Alto, CA) spectrometer at 75.43 MHz. ^{13}C Chemical shifts are reported in ppm relative to tetramethylsilane (TMS). ^{31}P NMR spectra were recorded on the same instrument at 121.42 MHz. ^{31}P Chemical shifts are reported in ppm relative to 85% phosphoric acid (external), where a positive sign is downfield from the standard. Infrared (IR) spectra were recorded on a Perkin-Elmer FT-IR 1750 (Beaconsfield, England) spectrometer. Peak positions are reported in cm^{-1}. Satisfactory microanalyses were obtained for **1abdS, 1acdS, 1aceS, 1abfS** and **1ab²S**: C, ±0.25; H, ±0.10; P, ±0.10; S, ±0.11.

*Cholecalciferyl-3-O-(1,2-isopropylidene-*rac*-glycero-3-O-)-(methyl-O-)thiophosphate,* **1abdS**: *Representative procedure.* A mixture of iodine (0.025 g, 0.1 mmol) and the *tris*(*N,N*-dimethyl)amide of phosphorous acid (**1**; 0.343 g, 2.1 mmol) in benzene (50 mL) was heated at 70°C in a stream of argon for approximately 15 min until the precipitate dissolved. Cholecalciferol (**a**; 0.769 g, 2.0 mmol) was added, and the mixture was kept under these conditions for 10 min to give **1a**. 1,2-Isopropylidene-*rac*-glycerol (**b**; 0.264 g, 2.0 mmol) was then added and the reaction system was heated at 70°C for 1.5 h to give **1ab**. The solution was cooled to room temperature (20–25°C) and added to a mixture of methyl alcohol (**d**; 0.064 g, 2.0 mmol), imidazole (0.136 g, 2.0 mmol) and carbon disulfide (0.152 g, 2.0 mmol) in benzene (50 mL). After 2 h at 20–25°C, the resultant triester phosphite **1abd** was transformed to the thiophosphate **1abdS** by adding sulfur (0.067 g, 2.1 mmol) at 20–25°C for 30 min. The solvent was removed under vacuum, and the compound was isolated by HPLC (System D) in pure form. Yield of **1abdS**: 0.98 g (80%); $n_D^{40} = 1.5098$; R_f (System A), 0.55; $C_{34}H_{57}O_5PS$ (609.0). ^{13}C NMR-{H} ($CDCl_3$) δ 11.9 ppm (C-18); 22.5 (C-26); 22.8 (C-27); 73.9 (*d*, C-3, $J = 9$ Hz); 112.9 (C-19); 117.4 (C-7); 122.9 (C-6); 133.7 (C-8); 142.6 (C-5); 144.1 (C-10): *cholecalciferyl-3-O-fragment;* 25.2, 26.7 (CH_3C); 66.2 (CH_2CHCH_2OP); 67.6 (*m*, CH_2CHCH_2OP); 77.2 (*m*, CH_2CHCH_2OP); 109.7 (CH_3C): *1,2-isopropylidene-*rac*-glycero-3-O-fragment;* 54.4 (*m*, CH_3OP). ^{31}P NMR-{H} ($CDCl_3$) δ 69.2 ppm (m). IR (KBr, film) ν 3030 (CH=);

Cholecalciferyl-3-O-(1,2-dipalmitoyl-rac-glycero-3-O-)(methyl-O-)thiophosphate, **lacdS**. The derivative was synthesized using cholecalciferol (**a**; 0.769 g, 2.0 mmol), 1,2-dipalmitoyl-*rac*-glycerol (**c**; 1.138 g, 2.0 mmol) and methyl alcohol (**d**; 0.064 g, 2.0 mmol), and then purified in the same way as described for **labdS** (variant I).

A mixture of the 1,2-isopropylidene-*rac*-glycero-3-*O*-thiophosphate derivative (**labdS**; 1.218 g, 2.0 mmol), palmitoyl chloride (1.100 g, 4.0 mmol), and zinc chloride (0.050 g) was kept at 20–25°C for 24 h. The resulting product was dissolved in diethyl ether (25 mL). The solution was placed on a diethyl ether-filled column of aluminium oxide (30 g; Brockmann II; basic) and the column was washed with diethyl ether (300 mL). The solvent was distilled off and the compound **lacdS** was isolated by HPLC (System D) in pure form (variant II). Yield of **lacdS**: 1.53 g (73%); $n_D^{40} = 1.4761$; R_f (System A), 0.67 (variant I); 0.79 g (38%); $n_D^{40} = 1.4766$; R_f (System A), 0.67 (variant II); $C_{63}H_{113}O_7PS$ (1045.8). ^{13}C NMR-{H} ($CDCl_3$) δ 12.1 ppm (C-18); 22.6 (C-26); 22.8 (C-27); 71.9 (*d*, C-3, $J = 9$ Hz); 112.9 (C-19); 117.6 (C-7); 123.2 (C-6); 133.1 (C-8); 142.3 (C-5); 144.2 (C-10); *cholecalciferyl-3-O-fragment;* 61.8 (CH_2CHCH_2OP); 65.5 (*m*, CH_2CHCH_2OP); 76.5 (*m*, CH_2CHCH_2OP): *glycero-3-O-fragment;* 14.1 (C-16); 173.0, 173.3 (C-1): *palmitoyl-fragment;* 54.5 (m, CH_3OP). ^{31}P NMR-{H} ($CDCl_3$) δ 69.6 ppm (*m*). IR (KBr, film) ν 3030 (CH=); 1740 (C=O); 1640 (C=C); 1010, 830 (PO-C, P-OC); 720 cm^{-1} (P=S).

Cholecalciferyl-3-O-(1,2-dipalmitoyl-rac-glycero-3-O-)(2-dimethylaminoethyl-1-O-)thiophosphate, **laceS**. The compound was prepared using cholecalciferol (**a**; 0.769 g, 2.0 mmol), 1,2-dipalmitoyl-*rac*-glycerol (**c**; 1.138 g, 2.0 mmol) and 2-dimethylaminoethanol (**e**; 0.178 g, 2.0 mmol) following the procedures described for **labdS**. The triester formation stage took 4 h. The crude derivative was purified by HPLC (System B). Yield of **laceS**: 1.69 g (76%); $n_D^{40} = 1.4898$; R_f (System B) 0.68; $C_{66}H_{120}NO_7PS$ (1102.9). ^{13}C NMR-{H} ($CDCl_3$) δ 12.0 ppm (C-18); 22.6 (C-26); 22.8 (C-27); 72.8 (*d*, C-3, $J = 9$ Hz); 112.9 (C-19); 117.6 (C-7); 122.9 (C-6); 133.8 (C-8); 142.3 (C-5); 144.2 (C-10): *cholecalciferyl-3-O-fragment.* 61.8 (CH_2CHCH_2OP); 65.6 (*m*, CH_2CHCH_2OP): *glycero-3-O-fragment;* 14.1 (C-16); 172.5, 172.9 (C-1): *palmitoyl-fragment;* 45.4 (CH_3N); 58.5 (CH_2N); 65.8 (*m*, CH_2OP): *aminoethyl-1-O-fragment.* ^{31}P NMR-{H} ($CDCl_3$) δ 67.5 ppm (m). IR (KBr, film) ν 3030 (CH=); 1746 (C=O); 1647 (C=C); 1005, 831 (PO-C, P-OC); 720 cm^{1-} (P=S).

Cholecalciferyl-3-O-(1,2-isopropylidene-rac-glycero-3-O-)(3-dimethylaminopropyl-1-O-)thiophosphate, **labfS**. The compound was synthesized using cholecalciferol (**a**; 0.769 g, 2.0 mmol), 1,2-isopropylidene-*rac*-glycerol (**b**; 0.264 g, 2.0 mmol) and 3-dimethylamino-1-propanol (**f**; 0.206 g, 2.0 mmol) in the same way as described for **laceS**. The derivative was isolated by HPLC (System C) in pure form. Yield of **labfS**: 0.82 g (60%); $n_D^{40} = 1.5097$; R_f (System C), 0.14; $C_{38}H_{66}NO_5PS$ (680.1). ^{13}C NMR-{H} ($CDCl_3$) δ 12.0 ppm (C-18); 22.5 (C-26); 22.8 (C-27); 73.9 (*d*, C-3, $J = 9$ Hz); 113.0 (C-19); 117.4 (C-7); 122.8 (C-6); 133.6 (C-8); 142.9 (C-5); 143.9 (C-10): *cholecalciferyl-3-O-fragment;* 25.2, 26.8 (CH_3C); 66.0 (CH_2CHCH_2OP); 68.0 (*m*, CH_2CHCH_2OP); 74.8 (m, CH_2CHCH_2OP); 109.3 (CH_3C): *1,2-isopropylidene-rac-glycero-3-O-fragment;* 29.1 (*m*, $OCH_2CH_2CH_2N$); 45.9 (CH_3N); 55.1 (CH_2N); 66.8 (m, 10.2 CH_2OP): *aminopropyl-1-O-fragment.* ^{31}P NMR-{H} ($CDCl_3$) δ 67.7 ppm (*m*). IR (KBr, film) ν 3030 (CH=); 1646 (C=C); 1360, 1370 (*gem*-CH_3); 1005, 835 (PO-C, P-OC); 711 cm^{-1} (P=S).

Cholecalciferyl-3-O-bis(1,2-isopropylidene-rac-glycero-3-O-)thiophosphate, **lab^{2}S**. The intermediate **lab** was prepared using cholecalciferol (**a**; 0.769 g, 2.0 mmol) and then 1,2-isopropylidene-*rac*-glycerol (**b**; 0.264 g, 2.0 mmol) as described for **labdS**. Treatment of a solution of 1,2-isopropylidene-*rac*-glycerol (**b**; 0.264 g, 2.0 mmol), imidazole (0.136 g, 2.0 mmol) and carbon disulfide (0.152 g, 2.0 mmol) in benzene (50 mL) with the intermediate **lab** at 20–25°C for 4 h afforded the triester phosphite **lab^2**. Transformation to thiophosphate **lab^{2}S** was accomplished by reaction with sulfur (0.067 g, 2.1 mmol) at room temperature for 30 min (variant I).

The intermediate **1a** was prepared using cholecalciferol (**a**; 0.769 g, 2.0 mmol) as described for **labdS**. The cooled solution (20–25°C) was then added to a mixture of 1,2-isopropylidene-*rac*-glycerol (**b**; 0.529 g, 4.0 mmol), imidazole (0.272 g, 4.0 mmol) and carbon disulfide (0.304 g, 4.0 mmol) and the reaction system was left at room temperature for 6 h. The transformation to thiophosphate **lab^{2}S** was performed by adding sulfur (0.067 g, 2.1 mmol) at 20–25°C for 30 min (variant II).

The purification procedures were identical with those described for **labdS**. Yield of **lab^{2}S**: 1.08 g (76%); $n_D^{40} = 1.5079$; R_f (System D), 0.28 (variant I); 1.00 g (70%); $n_D^{40} = 1.5085$; R_f (System D), 0.25 (variant II); $C_{39}H_{65}O_7PS$ (709.1). ^{13}C NMR-{H} ($CDCl_3$) δ 12.1 ppm (C-18); 22.7 (C-26); 22.8 (C-27); 73.9 (*d*, C-3, $J = 9$ Hz); 116.1 (C-19); 123.2 (C-7); 125.6 (C-6); 134.6 (C-8); 145.1 (C-5); 150.0 (C-10): *cholecalciferyl-3-O-fragment;* 25.3, 26.7 (CH_3C); 66.3 (CH_2CHCH_2OP); 67.8 (*m*, CH_2CHCH_2OP); 76.4 (*m*, CH_2CHCH_2OP); 109.8 (CH_3C): *1,2-isopropylidene-rac-glycero-3-O-fragment* (Fig. 2). ^{31}P NMR-{H} ($CDCl_3$) δ

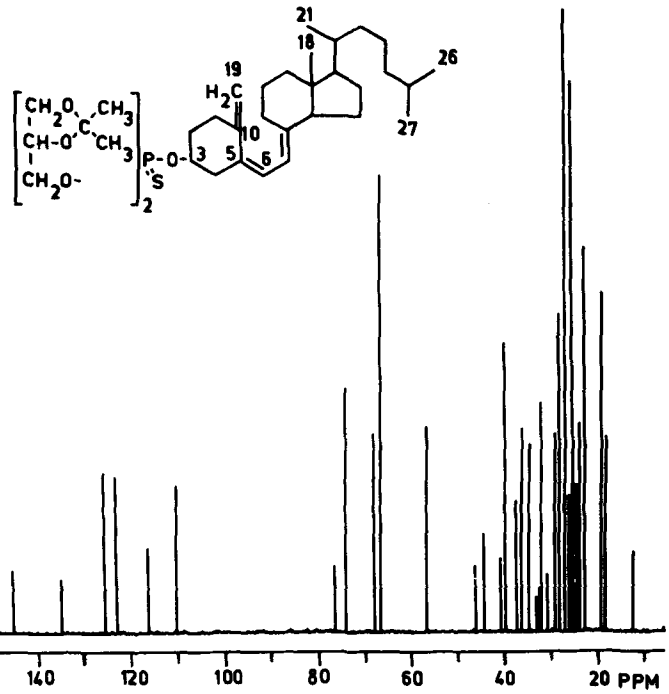

FIG. 2. Proton-decoupled 75.43 MHz ^{13}C NMR spectrum of cholecalciferyl-3-*O*-*bis*(1,2-isopropylidene-*rac*-glycero-3-*O*-)thiophosphate.

68.0 ppm (*m*). IR (KBr, film) ν 3030 (CH=); 1640 (C=C); 1368, 1378 (*gem*-CH_3); 1004, 838 (PO-C, P-OC); 710 cm^{-1} (P=S).

RESULTS AND DISCUSSION

As we have previously shown, changes in the glycerol fragment (1,3-benzylidene-, 1,2-isopropylidene-, 1,3-dioleoyl-, and 1,2-dioleoyl-*rac*-glyceryl), in the position of P–O bonding (glycero-2-O-P-, or glycero-3-O-P-), and in molecular mass had little influence on the stability of the diester glycerothiophosphates of vitamin D_3 (2). In the present report, we examined the possibility of preparing glycerothiophosphates of vitamin D_3 which possess a triester structure. Cholecalciferol **a**, 1,2-isopropylidene-*rac*-glycerol **b**, 1,2-dipalmitoyl-*rac*-glycerol **c**, methyl alcohol **d**, 2-dimethylaminoethanol **e** and 3-dimethylamino-1-propanol **f** were selected as substrates of phosphorylation.

As discussed earlier, the phosphorylation of steroids using conventional reagents is frequently accompanied by a variety of side reactions (3). The acyclic triamides of phosphorous acid, after activation with iodine, afford an opportunity to avoid these problems (3–5). In this case, the *tris*(*N,N*-dimethyl)amide of phosphorous acid **1** with iodine at an optimal molar ratio of 1.05:0.05 was used as reagent.

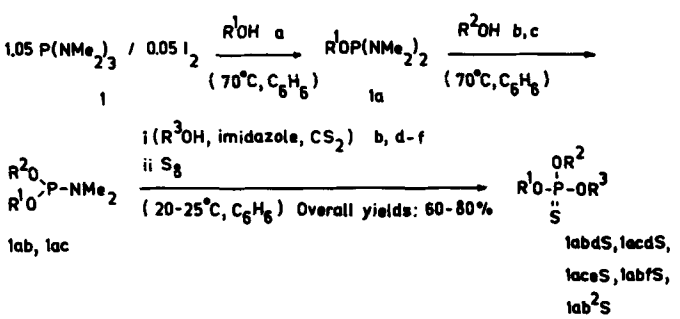
The synthesis was carried out according to the method recently proposed by us (5). The hexamethylphosphorus triamide **1** was reacted with cholecalciferol **a** in stoichiometric amounts at 70°C for 10 min to give the monoester **1a** in close to quantitative yield (Scheme 1). The scheme shows for **a**, **1a**, **1ab**, **1ac**, **1abdS**, **1acdS**, **1aceS**, **1abfS**, and **1ab²S**: R^1 = cholecalciferyl; **b**, **1ab**, **1abdS**, **1abfS**, and **1ab²S**: R^2 (or R^3) = 1,2-isopropylidene-*rac*-glyceryl; **c**, **1ac**, **1acdS**, and **1aceS**: R^2 = 1,2-dipalmitoyl-*rac*-glyceryl; **d**, **1abdS**, and **1acdS**: R^3 = methyl; **e** and **1aceS**: R^3 = 2-dimethylaminoethyl; **f** and **1abfS**: R^3 = 3-dimethylaminopropyl. This was proven earlier by transformation of the phosphite **1a** to the corresponding thiophosphate derivative (2).

The high selectivity of phosphorylation at the monoester formation stage permits the synthesis of asymmetrical diesters in a "one-pot" procedure. The *bis*(*N,N*-dimethylamido)phosphite **1a** was used as the initial key intermediate in order to avoid transesterification under experimental conditions. The crude intermediate **1a** was treated with an equivalent amount of the glycerol derivatives **b** or **c** at 70°C for 1.5 h. In preliminary studies we established that this type of diester phosphite also can be obtained directly in high yields (2). The consecutive treatment of an equimolar mixture of the third substrate **b**, **d**, **e** or **f**, imidazole and carbon disulfide with an equivalent amount of the crude diester intermediate **1ab** or **1ac** and sulfur at room temperature for 2–4 h or 30 min, respectively, afforded the triester thiophosphates **1abdS**, **1acdS**, **1aceS**, **1abfS** and **1ab²S** in good overall yields. The monoester phosphite **1a** also can be reacted directly with two equivalents of the 1,2-isopropylidene-*rac*-glycerol **b** (Scheme 2). In this way we resynthesized compound **1ab²S** (for **1a** and **1ab²S**: R^1 = cholecalciferyl; **b** and **1ab²S**: R^2 = 1,2-isopropylidene-*rac*-glycerol).

Our attempts to obtain the *bis*(1,2-dipalmitoyl-*rac*-glycero-3-*O*-)thiophosphate and the 1,2-dipalmitoyl-*rac*-glycero-3-*O*-(1,2-isopropylidene-*rac*-glycero-3-*O*-)thiophosphate derivatives of vitamin D_3 failed. The monoester **1a** did not react with two equivalents of 1,2-dipalmitoyl-*rac*-glycerol **c**. The same substrate **c** also was not coupled with the activated diester amidophosphite (type **1ab** or **1ac**) at the last synthetic step. This is probably due to sterical hindrance. The successful synthesis of **1ab²S** would support this hypothesis.

The 1,2-isopropylidene glycerothiophosphate triester can directly be transformed to the corresponding 1,2-diacylglycero-3-*O*- derivatives. For example, treatment of the cholecalciferyl-3-*O*-(1,2-isopropylidene-*rac*-glycero-3-*O*-)-(methyl-*O*-)thiophosphate **1abdS** with two equivalents of palmitoyl chloride in the presence of catalytic amounts of zinc chloride, led to conversion of this triester to its 1,2-dipalmitoyl analogue **1acdS** (Scheme 3; for **1abdS** and **1acdS**: R^1 = cholecalciferyl). However, by this method (6) the target compound was obtained only in low yield (38%).

Pronounced downfield shifts were observed for the olefinic carbons of the steroid moiety (C-5 to C-8, C-10, C-19) only in the ^{13}C NMR spectrum of the *bis*(1,2-isopropylidene-*rac*-glycero-3-*O*-)thiophosphate derivative **1ab²S**. In comparison with the other compounds synthesized, C-10 and C-7 were most strongly affected (~5.9 ppm), while the downfield shift was less pronounced for C-19 (~3.2 ppm), C-6, C-5 (~2.7 ppm) and C-8 (~0.9 ppm). It is suggested that the observed spectral features are related to the specific configuration of the phosphorus substituent $(RO)_2P$–, which can induce



SCHEME 1

marked conformational distortions of the steroid framework. Such long range substituent effects in steroid systems have been discussed extensively (7).

METHOD

A Colorimetric Assay for Measuring Cell-Free and Cell-Bound Cholesterol Oxidase

Joseph Kreit[a,*], Gérard Lefebvre[a], Abdelhak Elhichami[b], Pierre Germain[a] and Mohamed Saghi[b]

[a]Laboratoire de Microbiologie Industrielle et Alimentaire, Ecole Nationale Supérieure d'Agronomie et des Industries Alimentaires (ENSAIA), 54505 Vandoeuvre-Lès-Nancy Cedex, France and [b]Laboratory of Microbiology, Faculty of Sciences, Rabat, Morocco

Cholesterol oxidase (cholesterol:oxygen oxidoreductase, EC 1.1.3.6) catalyzes the conversion of sterol Δ^5-3β-alcohol to the corresponding Δ^4-3-ketone with the reduction of oxygen to hydrogen peroxide. *Rhodococcus* species GK 1, a soil isolated microbe, produces an extracellular and a membrane-bound cholesterol oxidase; the latter is bound to the outer surface of the microbial cell membrane. A simple and sensitive assay is described to measure the two enzyme types; no enzyme extraction is needed for measuring the membrane-bound cholesterol oxidase. In this assay, hydrogen peroxide is reduced by the chromogen 2,2′-azino-*bis*(3-ethylbenzothiazoline-6-sulfonate) (ABTS) in the presence of horseradish peroxidase, and the increased absorbance is followed continuously at 600 nm ($\varepsilon_m = 1.82 \times 10^4$ $M^{-1} \cdot cm^{-1}$ at pH 7.0 and 30°C). The standardized assay medium contained 46.9 mM sodium-potassium phosphate buffer pH 7.0, 0.16% Triton X-100, 312.5 μM ABTS, 50 μg peroxidase (12.5 units at 25°C), 6.25% isopropanol, 306.3 μM cholesterol or other sterols (kept in solution with isopropanol), and cholesterol oxidase. Oxidation of one molecule of cholesterol by cholesterol oxidase gives one molecule of hydrogen peroxide which reacts with two molecules of ABTS. The method is reproducible and the results correlate well with those obtained by measuring the absorbance of Δ^4-cholest-3-one at 240 nm ($\varepsilon_m = 1.40 \times 10^4$ $M^{-1} \cdot cm^{-1}$ at pH 7.0 and 30°C) and by the method of Allain *et al.* (*Clin. Chem. 20*, 470–475, 1974). In terms of efficiency, simplicity, and time saved, this coupled assay is expected to be a useful method for monitoring microbial production of cholesterol oxidase on an industrial scale, and for determining cholesterol or other sterols in biological fluids.

***Lipids 27*, 458–465 (1992).**

3β-Hydroxysteroid oxidase catalyzes the conversion of the Δ^5-3β-hydroxyl group of sterol to the corresponding Δ^4-3-ketone with concomitant reduction of oxygen to hydrogen peroxide. The enzyme is commonly known as cholesterol oxidase (cholesterol:oxygen oxidoreductase, EC 1.1.3.6). Preparations of cholesterol oxidase have been commercially produced from several microbial agents and used for steroid analysis, and particularly for the clinical estimation of plasma cholesterol (1–4).

In many microorganisms, such as *Nocardia* species (4,5) and *Rhodococcus* strains isolated from food of animal origin (butter, bacon, pork fat, and chicken fat) (6), cholesterol oxidase was shown to be an intrinsic membrane-bound type which can be extracted from cells by treatment with nonionic surfactant, such as Triton X-100. In contrast, extracellular cholesterol oxidase was isolated from the broth filtrates of various microorganisms such as *Streptomyces violascens* (7) and *Streptoverticillium cholesterolicum* (8). The microbe *Rhodococcus* species GK1, which we isolated from soil, degraded soybean sterols rapidly during growth and produced very large quantities of membrane-bound cholesterol oxidase. An extracellular form of the enzyme was also detected in the broth filtrate of this strain (Kreit, J., Lefebvre, G., and Germain, P., manuscript in preparation).

The present paper describes an assay for measuring cell-free and cell-bound cholesterol oxidase activities. The procedure is based on the use of 2,2′-azino-*bis*(3-ethylbenzothiazoline-6-sulfonate) and peroxidase for the reduction of the hydrogen peroxide generated by the cholesterol oxidase reaction. The data show that the method is efficient and simple, and may be useful for monitoring enzyme production on an industrial scale, and for determining sterols in biological fluids.

MATERIALS AND METHODS

Chemicals. Cholesterol, 4-cholesten-3-one, stigmasterol, Carbowax (Polyethylene glycol 6000), phenol and isopropanol were obtained from Fluka AG (Buchs, Switzerland). An alternative commercial source for isopropanol was Carlo Erba (Milan, Italy). β-Sitosterol was purchased from Serva (Heidelberg, Germany). A nonanalytical grade of soybean β-sitosterol (containing other sterols) was supplied by Merck (Darmstadt, Germany), and used only for culturing. 4-Aminoantipyrine (AAP), bovine serum albumin, Lubrol PX and Triton X-100 were purchased from Sigma Chemical Co. (St. Louis, MO). 2,2′-Azino-*bis*(3-ethylbenzothiazoline-6-sulfonate (ABTS), crystallized diammonium salt, and horseradish peroxidase (POD), lyophilized, salt free, 250 units/mg protein at 25°C, were obtained from Boehringer Mannheim (Mannheim, Germany). Hydrogen peroxide, a solution of about 30%, was obtained from Prolabo (Paris, France), and Lubrol WX from Supelco Inc. (Bellefonte, PA). All other chemicals were of analytical grade and were obtained from commercial sources. The buffer solution used was 0.05 M sodium-potassium phosphate (a mixture of Na_2HPO_4 and KH_2PO_4) buffer, pH 7.0–7.1.

Apparatus. Absorbance measurements and spectra were performed by using a Pye Unicam PU 8600 UV/Vis (Pye Unicam Ltd., Cambridge, England), or a Varian DMS 80 UV/Vis (Varian Techtron Pty. Ltd., Melbourne, Australia) spectrophotometer.

Hydrogen peroxide determination. The initial concentration of H_2O_2 in commercial solutions was determined by titration with potassium permanganate ($KMnO_4$) in acidified medium at 0–1°C (9).

Microorganism and cultivation. The strain GK 1, an *ac-*

Abbreviations: AAP, 4-aminoantipyrine; Abs, absorbance; ABTS, 2,2′-azino-*bis*(3-ethylbenzothiazoline-6-sulfonate) diammonium salt; CV, coefficient of variation; EU, enzyme unit; POD, peroxidase (donor: H_2O_2 oxidoreductase, EC 1.11.1.7); UV, ultraviolet.

tinomycete isolated from a polluted soil (Nancy, France) and identified as *Rhodococcus* species, was used. The strain was cultured in a mineral salt medium containing, 3 g $(NH_4)_2SO_4$, 4.16 g Na_2HPO_4, 1.2 g KH_2PO_4, 0.05 g yeast extract, 0.8 mg thiamine per liter, and other mineral ingredients (10). The pH of the medium was adjusted to 7.0 and nonanalytical β-sitosterol (5 g/L) was added as a fine powder directly to the culture flask. Sterilized medium was inoculated and the microbial growth maintained semiaerobically in Erlenmeyer flasks at 30°C with shaking. Microbial growth was stopped in the primary stage of the stationary phase (after about 100 hr of cell growth). Cells were harvested by centrifugation, washed with cooled buffer containing isopropanol (5%) and resuspended in the buffer at 0.5 to 0.8 g wet biomass (the wet weight is about 4 times the dry weight) for 10 mL.

Preparation of cholesterol oxidase solutions. Supernatant from the microbial culture (broth filtrate) was clarified by centrifugation at 56 600 × *g* for 30 min at 5°C, and used as extracellular enzyme source. Cell-bound cholesterol oxidase was extracted by magnetic stirring of the cellular suspension containing 1% Triton X-100 (v/v) for 30 min at room temperature. The enzymic solution was collected by centrifugation and further clarified by recentrifugation at 56 600 × *g* for 30 min.

Concentration of enzyme solutions. When required, cholesterol oxidase solutions were concentrated by protein precipitation with solid ammonium sulfate at 60% saturation. The mixture was stirred for 30 min at 0°C, and then left at this temperature for several hours. The precipitate was collected by centrifugation, dissolved in a small portion of the phosphate buffer and dialyzed overnight against the same buffer at 2–4°C.

Conservation and stability of the enzyme. The cellular suspensions and the enzyme solutions were maintained at 0–2°C. There was no loss in the enzyme activity of these fractions after one month of conservation. The enzyme fractions retained full activity over 2 hr at 30°C.

Standard assays of cholesterol oxidase. The enzyme activity was measured at 30°C and pH 7.0 by estimation of either 4-cholesten-3-one or H_2O_2; both are produced stoichiometrically by the enzyme reaction.

Estimation of 4-cholesten-3-one is based on its ultraviolet (UV) absorption. The enzyme was assayed in a final volume of 3.2 mL containing 150 μmoles sodium-potassium phosphate buffer, 0.16% Triton X-100 (v/v), 0.98 μmole cholesterol (0.2 mL of cholesterol solution in isopropanol), and an appropriate amount of enzymic samples. The reagents were added directly into the spectrophotometer cuvette (1 cm path length). The assay medium was mixed by inversion after adding the substrate and again after adding the enzyme. The cholesterol solution must be deposited onto the surface of the assay medium, and mixing must be rigorous to allow formation of stable detergent-cholesterol micelles giving rise to a clear medium. The rate of increase in absorbance was monitored continuously at 240 nm. The control assay was either without cholesterol or without cholesterol oxidase. Under these conditions, a value of 1.40×10^4 $M^{-1} \cdot cm^{-1}$ was determined for the molar absorption coefficient (ε_m) of 4-cholesten-3-one. Under the same conditions, a value of 38 $M^{-1} \cdot cm^{-1}$ was estimated for ε_m of H_2O_2 at 240 nm. This value is very small and has no effect on cholesterol oxidase evaluation.

H_2O_2 was measured under the conditions mentioned above except that 1 μmole ABTS and 50 μg POD were added to the assay medium (3.2 mL final volume) before cholesterol addition. H_2O_2 produced during the enzyme reaction oxidizes ABTS in a reaction catalyzed by POD. The rate of color formation due to the oxidized ABTS was followed continuously at 600 nm. Commercial H_2O_2 was used under these conditions to determine ε_m of the color; the value obtained was 1.82×10^4 $M^{-1} \cdot cm^{-1}$ with respect to H_2O_2 concentration.

One unit of cholesterol oxidase activity is defined as the amount of enzyme producing 1 μmole of 4-cholesten-3-one (or H_2O_2) per min.

Solution of 2% Triton X-100, 10 μmoles/mL ABTS and 1 mg/mL POD were prepared separately in 0.05 M phosphate buffer pH 7.0 and kept at 2–4°C. These preparations were stable for about 1 year.

Protein determination. Protein was determined by the Biuret method (11). Bovine serum albumin was used as standard. Triton X-100 did not affect the protein determination.

RESULTS AND DISCUSSION

Stadtman and coworkers (12,13) described a microbial dehydrogenase (cholesterol oxidase) for use in a cholesterol assay based on measuring increased absorbance at 240 nm due to formation of 4-cholesten-3-one. Much has been published on this subject, and major efforts have been made to overcome the fact that cholesterol is not water-soluble (14,15). We set out to find conditions for such an assay which would be relatively simple. We studied the effect of isopropanol and of detergents on the solubility of cholesterol in the test medium and on enzyme activity. The essential observations made in this study are summarized here.

Cholesterol oxidase was assayed in the presence of 6 to 35 percent isopropanol, with cholesterol amounts ranging from 6.5 to 260.9 μM, by following the rate of change in absorbance at 240 nm. Only a small amount of substrate (less than 65.2 μM) can be used with 10% isopropanol as higher concentrations result in the formation of cholesterol crystals. Cholesterol was better dissolved in 35% isopropanol; however, the assay was still not adequate.

Secondly, we investigated the effect of the nonionic detergent, Triton X-100, on the cholesterol oxidase assay. The purpose of this was to determine the Triton amounts that would allow formation of stable mixed micelles of detergent and substrate without inhibiting the enzyme. The test mixture contained phosphate buffer, cholesterol oxidase, 6.25% isopropanol, Triton X-100 (0.05–0.35%) and cholesterol (3.8–312.5 μM). Favorable results were obtained with 0.15 to 0.20% Triton X-100 in the assay medium.

The conditions for the standard assay reported in Materials and Methods were derived from the experiments described above. Due to the significant absorption of both Triton X-100 and protein at 240 nm, the assay requires a more sophisticated UV spectrophotometer with good resolution. We therefore tried to replace Triton with either Lubrol WX or Lubrol PX nonionic detergents which do not interfere with UV absorption measurements. Triton X-100, however, was better at keeping cholesterol in solution and maintaining assay linearity. The 4-cholesten-3-

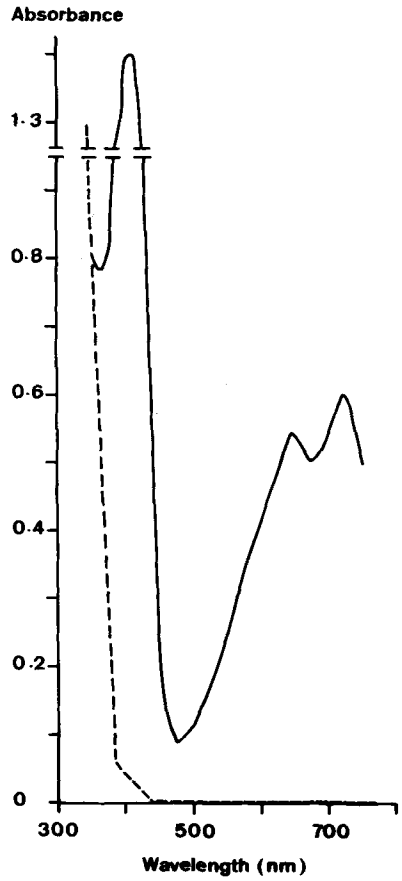

FIG. 1. Visible absorption spectra of ABTS. ABTS (0.136 μmole) was oxidized under the standard assay conditions of the cholesterol oxidase assay in the presence of 14 μmoles H_2O_2 (cholesterol and cholesterol oxidase were absent). After 5 min, when all ABTS was oxidized (the absorbance at 600 nm became constant), a wavelength scan of the cuvette (1 cm path length) was recorded against distilled water (——). For the reduced ABTS spectrum (———), H_2O_2 (or POD) was omitted from the assay medium.

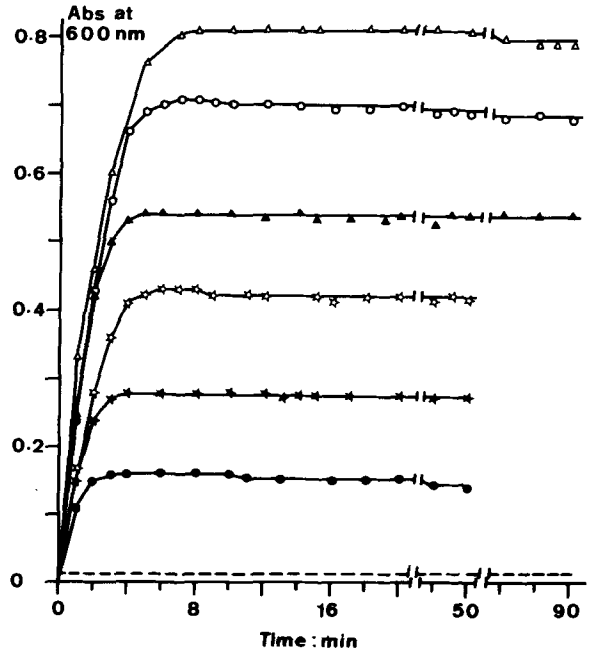

FIG. 2. Stability of final color produced by ABTS oxidation. The standard assay medium contained 0.028 enzyme unit (EU) of cholesterol oxidase (Triton extract, 32 μg protein) and cholesterol. Concentrations of cholesterol (in μmole/assay) were: ●, 0.025; ★, 0.049; ☆, 0.074; ▲, 0.098; ○, 0.123; △, 0.15. The control (———) was without cholesterol. Absorbance was followed against distilled water.

one produced in these studies was identified by gas chromatography (data not shown).

Alternatively, a colorimetric assay method was worked out for measuring cholesterol oxidase activity. In this assay, H_2O_2 produced by the oxidase reaction is used to oxidize the chromogen ABTS in a reaction catalyzed by POD. POD has a high specificity for the electron acceptor H_2O_2. However, it has a low specificity for the electron donor. Several chromogens, such as pyrogallol, *O*-dianisidine, 4-aminophenazine, 3,3′-diaminobenzidine, guaiacol, and ABTS are enzyme active substrates serving as electron donors. In their report on peroxidase steady-state kinetics, Childs and Bardsley (16) stated that most of the electron donors that have been used are much less efficient than ABTS. Since ABTS is also chemically stable and nontoxic, we chose it for the coupled assay of cholesterol oxidase. The optimum amounts of ABTS and POD for the standard assay we determined are those described in Materials and Methods. The validity of the coupled assay for cell-free and cell-bound cholesterol oxidase was ascertained as described below.

Visible absorption spectra of oxidized and reduced

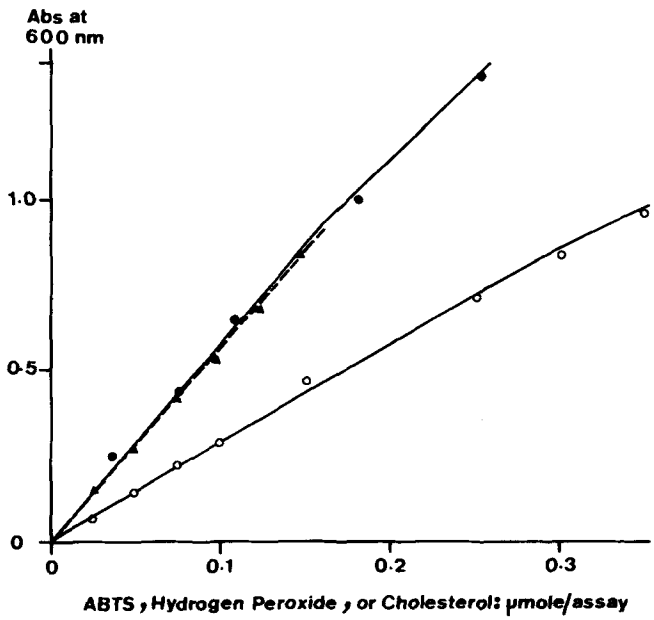

FIG. 3. Plots of oxidized ABTS absorbance for various concentrations of ABTS, H_2O_2, or cholesterol. The standard assay medium (in a cuvette of 1 cm path length) contained 0.361 μmole H_2O_2 for limiting amounts of ABTS (○), or 1 μmole ABTS for limiting concentrations of H_2O_2 (●); cholesterol and cholesterol oxidase were absent. One μmole of ABTS was used for limiting amounts of cholesterol (▲).

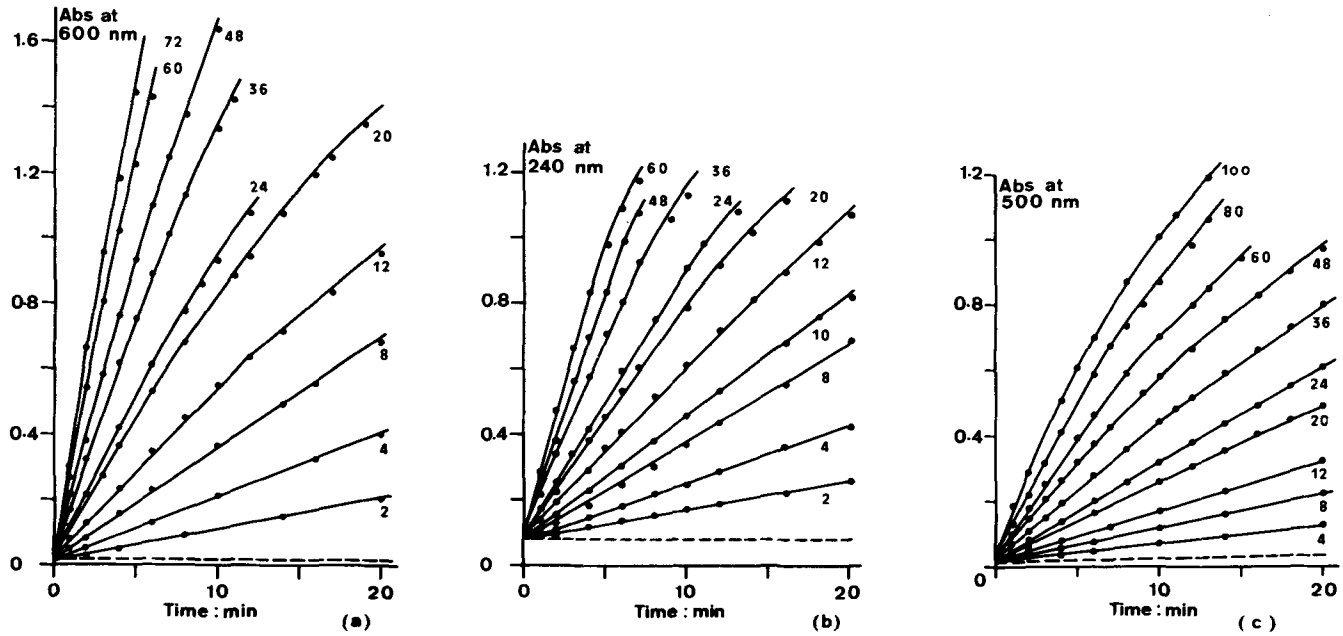

FIG. 4. Measurement of cell-free cholesterol oxidase: comparison studies. Portions from an enzymic Triton extract (1.2 mg protein per mL) were assayed by either the ABTS assay (a), the UV absorption method (b) or by the method of Allain *et al.* (1) (c). The data in panel 4c were obtained using 3.2 mL of final volume containing 280 μmoles phosphate buffer pH 7.0, 44.8 μmoles phenol, 2.53 μmoles AAP, 100 μg POD, 0.16% Triton X-100, 0.98 μmole cholesterol (in 0.2 mL isopropanol) and the enzyme extract. The protein amounts (μg/assay) used are indicated on the plots. Control assays (———) were without cholesterol oxidase. Absorbance was followed against: (a,c) distilled water, (b) the assay medium devoid of cholesterol (or cholesterol together with the enzyme for the control assay).

ABTS were defined with limited amounts of this compound. Figure 1 shows an example of the type of spectra observed. Oxidized ABTS has an absorption maximum at 415 nm ($\varepsilon_m = 3.3 \times 10^4$ $M^{-1} \cdot cm^{-1}$) together with lesser maxima at 640 nm ($\varepsilon_m = 1.25 \times 10^4$ $M^{-1} \cdot cm^{-1}$) and 725 nm ($\varepsilon_m = 1.40 \times 10^4$ $M^{-1} \cdot cm^{-1}$) and a shoulder at 580 nm. Reduced ABTS did not absorb to a significant extent in the range of 400 to 750 nm. The wavelengths at which absorptions are maximal were considered appropriate for measuring the chromogen in the oxidase system. We used a wavelength between 600 and 650 nm for the present purpose ($\varepsilon_m = 0.91 \times 10^4 - 1.24 \times 10^4$ $M^{-1} \cdot cm^{-1}$ with respect to ABTS concentration).

The color stability of oxidized ABTS was examined under the standard conditions of the cholesterol oxidase assay. With limited amounts of cholesterol, 0.025–0.15 μmole per assay, the chromogen absorbance became maximal in 2 to 10 min (Fig. 2) and stayed constant during the time of the test (90 min). When ABTS was the limited factor (0.03 to 0.35 μmole per assay) instead of cholesterol, the final color was stable for 20 min; beyond this time the decline in color absorbance became notable reaching 10% of the original value after an additional 10 min. The same stability of the chromogen color was observed for the limited amounts of ABTS when 0.36 or 14 μmoles H_2O_2 per assay were used instead of cholesterol and cholesterol oxidase. With limited amounts of H_2O_2, 0.03 to 0.2 μmole per assay (cholesterol and cholesterol oxidase were absent), the final color of the chromogen was stable for the entire time of the test (30 min).

The redox capacity of ABTS with H_2O_2 as electron acceptor was investigated under the standard conditions of the cholesterol oxidase assay. Experiments carried out for this purpose were done with limited amounts of either cholesterol or ABTS or H_2O_2; an example is shown in Figure 3. The molar absorption coefficient obtained for oxidized ABTS is 0.91×10^4 $M^{-1} \cdot cm^{-1}$ at 600 nm. A double value was estimated for this coefficient with respect to the concentration of either H_2O_2 or cholesterol instead of ABTS. This result indicated that one molecule of cholesterol (5-cholesten-3β-ol), catalyzed by the oxidase, generated one molecule of H_2O_2 which, in turn, reacted with two molecules of ABTS. Thus, the following reaction scheme can be postulated:

$$\text{5-Cholesten-3}\beta\text{-ol} \xrightarrow{O_2} \text{4-Cholesten-3-one} + H_2O_2$$

$$H_2O_2 + 2\ \text{ABTS} \longrightarrow 2\ H_2O + 2\ \text{ABTS}^+$$

The accuracy of the ABTS assay was examined by measuring cell-free cholesterol oxidase of *Rhodococcus* species and by comparing the results with those obtained by the UV absorption method (standardized assay) and by the AAP assay of Allain *et al.* (1). According to the last procedure, H_2O_2 generated by the enzymic oxidation of cholesterol is measured by the oxidative coupling of AAP with phenol catalyzed by POD to yield a quinoneimine dye with a maximum absorption at 500 nm ($\varepsilon_m = 5.33 \times 10^4$ $M^{-1} \cdot cm^{-1}$). The method of Allain *et al.* (1) has been widely used for measuring cholesterol oxidase (7,8,17,18); so we chose it for comparison as a currently available assay. However, in this assay Carbowax failed to keep cholesterol in clear suspension at the enzyme-

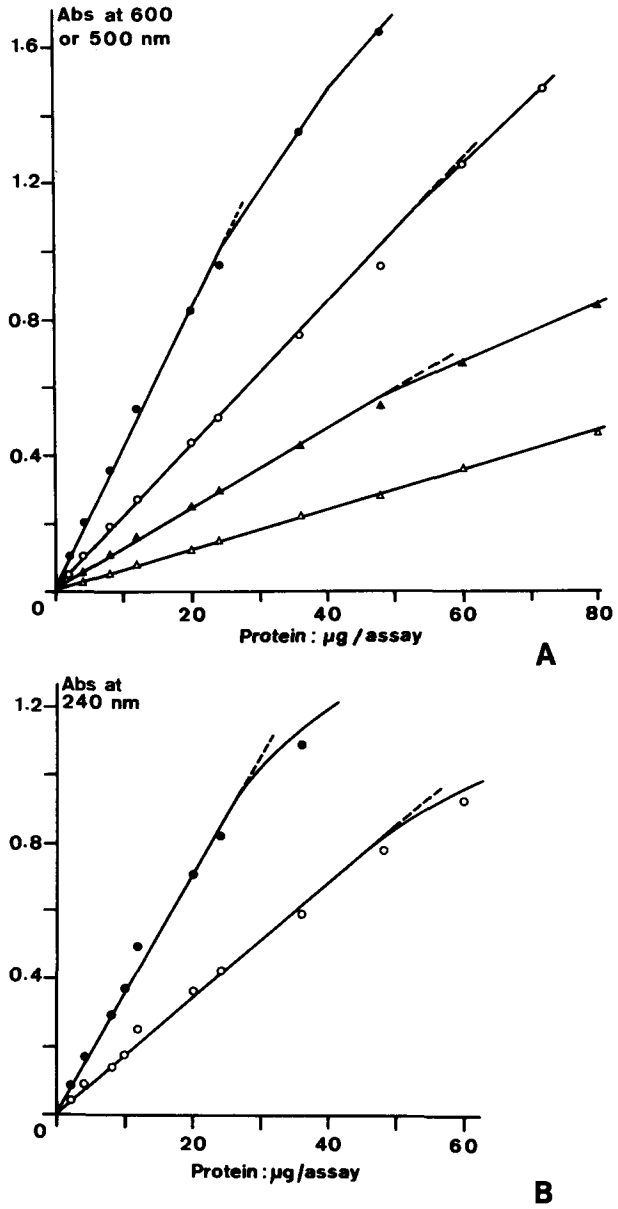

FIG. 5. Cell-free cholesterol oxidase measurement: comparison studies. Data on enzyme activities were derived from Figure 4 for the reaction time of 5 min (empty symbols) and of 10 min (full symbols). a: ○, ●, ABTS assay; △, ▲, AAP assay; b: UV absorption method.

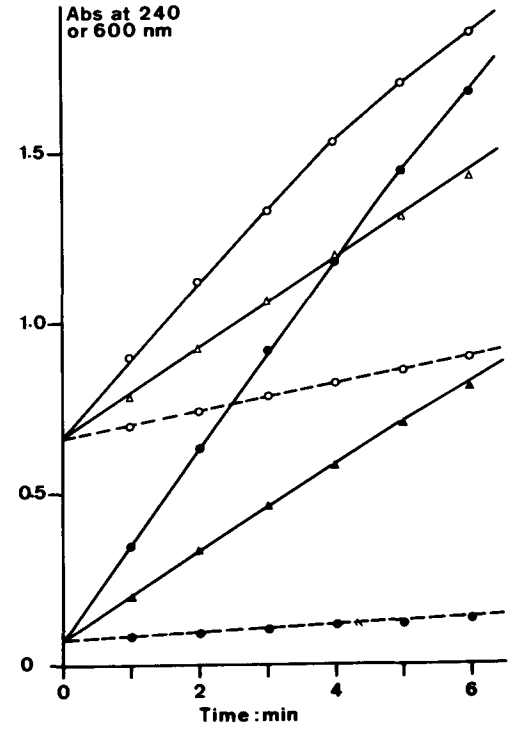

FIG. 6. Activity measurements of cholesterol oxidase with β-sitosterol. The enzyme (37.5 and 75 µg of a Triton extract) was assayed with 0.98 µmole β-sitosterol as substrate. Control assays (dashed lines) were performed without the enzyme. ●, ▲, ABTS assay; the absorbance was followed at 600 nm against distilled water. ○, △, UV absorption method; the absorbance was followed at 240 nm against the test medium devoid of the substrate (or the substrate together with the enzyme for the control assay).

saturating concentrations. Thus, we replaced it with Triton X-100. The results obtained are shown in Figures 4 and 5. The UV absorption method and the ABTS assay were linear up to 0.9 and 1.0 absorbance unit, respectively. This is better than what was observed with the AAP assay (linear up to 0.6 abs. units). The control of the ABTS assay with cholesterol as substrate showed a very low absorbance (0.0 to 0.02) against distilled water. When β-sitosterol (or stigmasterol) was used instead of cholesterol, the control assay exhibited a linear change in absorbance at 240 nm and 600 nm owing to the increasing turbidity of the sterol (Fig. 6). This change in absorbance was subtracted from that of the assays for estimating the enzymatic activities.

The ABTS assay and the UV absorption method are reproducible with good precision. Two series of enzyme measurements were performed in parallel by these two methods (Table 1). We found a coefficient of variation of 2.3 to 2.4% and 3.2 to 3.7% for the former and the latter method, respectively. The calculated regression line and correlation coefficient (r) indicated excellent agreement between the method of Allain *et al.* (1) and the present coupled assay ($r > 0.998$).

The present coupled assay appeared to be better than the AAP assay in terms of simplicity and the use of nontoxic material. Phenol and AAP used in the reference procedure are toxic and harmful. The ABTS assay is 3.4 times more sensitive than the AAP assay (ratio of the molecular absorption coefficients: $1.82 \times 10^4/5.33 \times 10^3$).

Methods described in the literature for monitoring microbial cholesterol oxidase production during cell fermentation are indirect procedures. They are based upon incubation of whole cells with colloidal suspensions of cholesterol, followed by extraction and determination of either the reaction product, 4-cholesten-3-one, or the remaining substrate. This determination has been made by Liebermann-Burchard assay (for cholesterol) (4), UV absorption (19), or gas chromatography (Kreit, J., Lefebvre, G., and Germain, P., manuscript in preparation). Proce-

TABLE 1

Reproducibility of Cell-Free Cholesterol Oxidase Measurements[a]

Methods	Experiment number	Means		Standard deviation		Coefficient of variation (CV) (%)
		Abs. units	EU/mg	Abs. units	EU/mg	
UV assay	1	0.347	0.881	0.013	0.032	3.7
	2	0.682	0.866	0.022	0.027	3.2
ABTS assay	1	0.432	0.844	0.010	0.019	2.3
	2	0.858	0.838	0.021	0.020	2.4

[a]Ten determinations were made in each experiment under standard conditions; 0.02 mL (18 μg protein) from an enzymic Triton extract was used per assay. All reagents were independently added into the spectrophotometer cuvette; the reaction lasted 5 min in Experiment 1 and 10 min in Experiment 2. EU, enzyme unit.

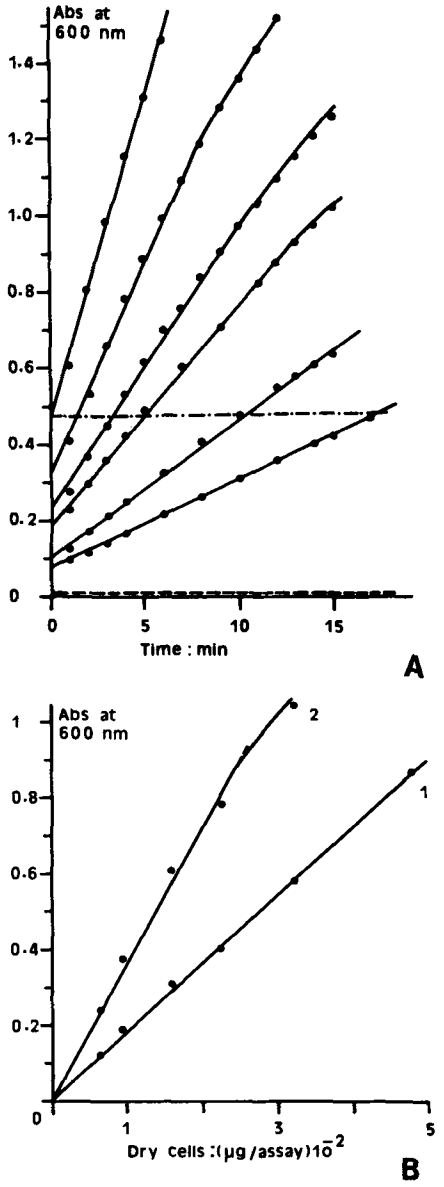

FIG. 7. Measurement of cell-bound cholesterol oxidase activity. a: A cell suspension (cell dry weight: 12.8 mg/mL) was appropriately diluted and then aliquots were assayed by the ABTS assay method. The control was either without cholesterol (—·—·—) or without cells (———). Absorbance was monitored against distilled water. b: Data derived from a. The enzymic activity is per assay of 5 min (1) and of 10 min (2).

dures based on extraction of cholesterol oxidase from cells and assay of the cell-free enzyme have also been reported (6,15). All these methods consist of several steps involving complex experimental conditions; to our knowledge, no suitable direct procedure exists for measuring cell-bound cholesterol oxidase.

In the nocardioform bacteria, cholesterol oxidase has an amphipathic structure consisting of an enzymicly active portion and a hydrophobic portion which allows incorporation of the enzyme into the bacterial cell membrane (5 and Kreit, J., Lefebvre, G., and Germain, P., manuscript in preparation). The enzymicly active site is free in the membrane outer compartment and can exhibit full activity. Direct measurement of the cell-bound enzyme is then possible provided reagents can diffuse inside the microbial cell wall to the enzymicly active site, and again outside the wall after catalysis. This is the case with the present coupled assay for measuring cell-bound cholesterol oxidase of *Rhodococcus* species. When portions of the cell culture or cell suspension were assayed, the rate of enzymic activity was proportional to the cell concentration in the test medium (Fig. 7). Turbidity caused by cells in the assay mixture is acceptable up to 0.5 absorbance unit. The accuracy of the present colorimetric method was investigated using whole cells of the bacterium (Table 2). We found a precision (CV—coefficient of variation) of 3.6% and 3.9% for enzyme activities (in abs. units) with a mean value of 0.585 and 0.311, respectively.

Different enzymic fractions were assayed using the two methods with either cholesterol or β-sitosterol as substrate (Table 3). The enzyme activity values obtained with the ABTS assay correlate well with those obtained in parallel by the UV absorption assay. Cholesterol oxidase in conjugated fractions was measured by the ABTS assay, and recovery of the enzyme was calculated for each fraction tested. As shown in Table 4, the final amount of enzyme in the extracts (or the cell suspension) plus the growth filtrate is comparatively similar to that of the microbe culture from which the fractions were prepared. Assuming that preparation of the fractions was achieved without loss of enzyme activity, the data demonstrate the validity of the coupled assay to measure cell-bound cholesterol oxidase as well as the cell-free enzyme.

Based on kinetic studies, the Michaelis-Menten constant (K_m) and the activation energy (E_a) of the oxidase

TABLE 2

Precision of Cell-Bound Cholesterol Oxidase Measurements by the ABTS Assay Method[a]

Cell fractions	Means		Standard deviation		Coefficient of variation (CV) (%)
	Abs. units	EU/mL	Abs. units	EU/mL	
Cell suspension	0.585	0.823	0.021	0.030	3.6
Complete culture	0.311	0.273	0.012	0.011	3.9

[a]Ten determinations were made for each cell fraction under standard conditions. Cell suspension as described in Figure 7, 0.32 mg dry cells (in 0.1 mL) was used per assay. Complete culture: diluted 5 times; 0.2 mL of the dilution was used per assay. Reaction time, 5 min. EU, enzyme unit.

TABLE 3

Cholesterol Oxidase Measurements by the ABTS Assay and the UV Absorption Method[a]

Experiment number	Substrate	Cholesterol oxidase activity (EU/mg)	
		ABTS assay	UV absorption
1	cholesterol	0.871	0.906
2	cholesterol	0.919	0.878
	β-sitosterol	0.592	0.549
3	cholesterol	1.054	1.130
4	cholesterol	0.045	0.051
	β-sitosterol	0.031	0.034

[a]In the standardized assay medium, 0.98 μmole of either cholesterol or β-sitosterol was used. Experiments were performed with different Triton extracts (1,2), a concentrated fraction of a Triton extract (3), and a growth filtrate (4); ε_m of 4-sitosten-3-one at 240 nm was considered to be the same as that of 4-cholesten-3-one. EU, enzyme unit.

TABLE 4

Recovery of Cholesterol Oxidase in Conjugated Fractions As Evaluated by the ABTS Assay Method[a]

Fractions	Volume (mL)		Cholesterol oxidase activity				Recovery (%)	
			EU/mL		Total (EU)			
	Exp. 1	Exp. 2	Exp. 1	Exp. 2	Exp. 1	Exp. 2	Exp. 1	Exp. 2
Culture	200	180	0.230	0.306	46.0	55.1	100	100
Growth filtrate	192	174	0.027	0.052	5.2	9.0	11	16
Cell suspension	50	30	0.870	1.500	43.5	45.0	95	82
Extract 1	46	28	0.840	1.350	38.6	37.8	89	84
Extract 2	46	28	0.132	0.180	6.1	5.0	14	11

[a]Recovery of the enzyme in the extract fractions was calculated relative to that of the cell suspension. Two Triton treatments of cell suspensions were generally sufficient for cholesterol oxidase total extraction. EU, enzyme unit.

catalyzing cholesterol were determined by the ABTS assay and, for comparison, by the UV absorption method. In both cases, K_m was about 2×10^{-5}M (from Lineweaver-Burk plots) at pH 7.0 and 30°C and E_a (calculated according to the Arrhenius equation) was about 11 Kcal/mole at pH 7.0. These kinetic data further confirmed the validity of the coupled assay for studying cholesterol oxidase activity.

The present paper represents the first report describing the use of ABTS as chromogen for cholesterol oxidase measurement. The method affords a simple and highly sensitive assay to measure cell-free and cell-bound cholesterol oxidase activities. In terms of efficiency and speed, this assay is expected to be particularly useful for monitoring microbial production of cholesterol oxidase during cell fermentation. Furthermore, the assay represents a novel approach for measuring sterols in biological fluids.

COMMUNICATION

The Effect of Amino Acids on Choline Uptake and Phosphatidylcholine Biosynthesis in Mammalian Hearts

Monroe Chan, Karmin O, Adrian S. Man and **Patrick C. Choy***
Department of Biochemistry and Molecular Biology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3E 0W3

The uptake of choline in mammalian hearts in the presence of amino acids was examined. Isolated hamster, guinea pig, rat and rabbit hearts were perfused with labeled choline in the presence and absence of amino acids. Neutral amino acids enhanced choline uptake in the hamster heart, but not in the guinea pig, rat and rabbit hearts. Phosphatidylcholine biosynthesis in these hearts was not affected by the presence of amino acids. Choline uptake in the hamster myocytes was also enhanced by neutral amino acid. The enhancement of choline uptake suggests a direct interaction between the amino acid and the transport of choline into the myocardiac cells. The different responses in choline uptake to neutral amino acids indicate that the regulation of choline uptake in the hearts may be different between mammalian species.
Lipids 27, 466–469 (1992).

Phosphatidylcholine is the major phospholipid in mammalian tissues (1). The principal route for its biosynthesis in the heart and isolated cardiac myocytes is the cytidine-5′-diphosphocholine (CDPcholine) pathway (2–4). Exogenous choline is actively transported into the heart, and rapidly phosphorylated into phosphocholine. Phosphocholine is converted to CDPcholine by the action of cytidine-5′-triphosphate:phosphocholine cytidylyltransferase. The CDPcholine produced is condensed with 1,2-diacylglycerol for the formation of phosphatidylcholine (3). Although the control of the CDPcholine pathway is usually mediated *via* the rate-limiting step of the pathway catalyzed by the cytidylyltransferase, modulation of choline uptake may contribute to the overall regulation of phosphatidylcholine biosynthesis (3).

A number of compounds including hemicholinium-3 (5,6), benzylcholine and chlorocholine (7) have been identified as potent inhibitors of choline uptake. The influence of amino acids on choline uptake and phosphatidylcholine biosynthesis in renal cortical slices has been reported (8). Recently, neutral amino acids were found to enhance choline uptake in the isolated hamster heart, but not to affect phosphatidylcholine biosynthesis (9). However, the ability of neutral amino acids to enhance choline uptake in the hearts of other mammalian species was not studied. Choline in the perfusate was transported across the endothelial cells and the intercellular fluid prior to uptake by the myocardial cells; thus the direct action of amino acid on choline uptake in these cells had not been demonstrated.

In the present report, the effect of amino acids on choline uptake in isolated guinea pig, rat and rabbit hearts were studied and compared with the hamster heart. The ability of the neutral amino acid to enhance choline uptake in isolated hamster and rat myocytes was examined.

Abbreviations: CDPcholine, cytidine-5′-diphosphocholine; TLC, thin-layer chromatography; CTP, cytidine-5′-triphosphate.

MATERIALS AND METHODS

Materials. Choline iodide, phosphocholine chloride, cytidine 5′-diphosphocholine (CDPcholine), amino acids and all cell culture media were purchased from Sigma Chemical Co. (St. Louis, MO). [Methyl-^{3}H]choline was obtained from NEN division of Dupont (Mississauga, Canada). Thin-layer chromatographic plates (Sil-G25) were a product of Macherey-Nagel (Düren, Germany), and were obtained through Brinkman (Rexdale, Canada). Collagenase (type II) was purchased from Worthington-Miles (Freehold, NJ). Earle's Balanced Salt solution was obtained from Flow Laboratories (Mississauga, Canada). All other chemicals were of the highest grades available and were obtained from the Canlab division of Baxter (Mississauga, Canada).

Methods. Syrian golden hamsters (110 ± 20 g) and guinea pigs (280 ± 20 g) were obtained from Charles River Inc. (Charles River, Canada). Sprague-Dawley rats (230 ± 10 g) and New Zealand White rabbits (1.8 ± 0.5 kg) were obtained from the central animal care unit of the University of Manitoba (Winnipeg, Canada). Hearts were removed from the animals immediately after decapitation, and perfused in Langendorff mode with Krebs-Henseleit buffer containing labeled choline (2). Perfusion time was 60 min at 37°C and the flow rate of the perfusate was 6–8 mL/g heart weight which would produce an aortic pressure of 60–80 mm Hg. The perfusate was saturated with 95% O_2/5% CO_2 and contained 10 μM [methyl-^{3}H]choline (0.35 μCi/mL)/1 mM amino acid. Hearts perfused with labeled choline in the absence of amino acid were used as controls. Subsequent to perfusion, the heart was homogenized in 10 mL $CHCl_3$/CH_3OH (1:1, vol/vol). The homogenate was centrifuged at 2,000 × *g* for 10 min, and the pellet was reextracted twice with the same solvent. An aliquot of the pooled extract was used to determine total choline uptake. Water and chloroform were added to the remainder of the lipid extract in order to reach a ratio of 4:2:3 (vol/vol/vol) for $CHCl_3$/CH_3OH/H_2O. Subsequent to phase separation, the volumes of both upper and lower phases were reduced by evaporation *in vacuo*. An aliquot of the upper phase was analyzed for radioactivity in the choline-containing metabolites by thin-layer chromatography (TLC) with a solvent containing CH_3OH/0.6%-NaCl/NH_4OH (10:10:1, vol/vol/vol). An aliquot of the lower phase was analyzed for radioactivity in the phosphatidylcholine fraction by TLC with a solvent containing $CHCl_3$/CH_3OH/H_2O/CH_3COOH (70:30:4:2, by vol).

Myocytes from the rat heart were isolated by the procedure of Langer *et al.* (10). The viability of the cells was tested by trypan blue exclusion and myogenic activity. Over 90% of the cells in the petri dish were viable and in rod shape. The isolation of myocytes from the hamster

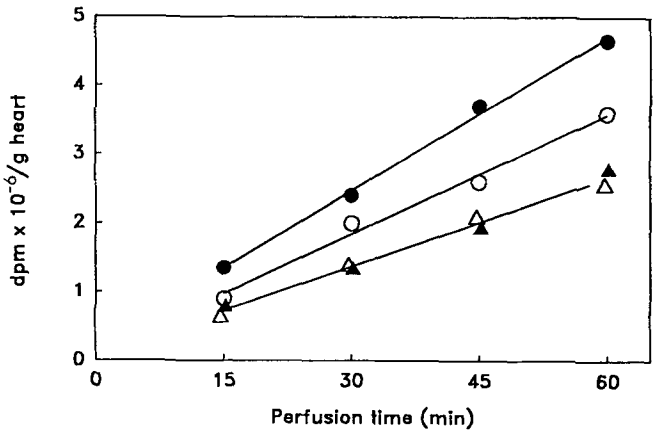

FIG. 1. Time course of choline uptake in hamster and rat hearts in the presence of L-alanine. Hamster (●,○) and rat (▲,△) hearts were perfused in Krebs-Henseleit buffer containing 10 μM labeled choline in the presence (filled symbols) and absence (open symbols) of 1 mM L-alanine for 15–60 min. Total choline uptake was determined in the tissue extract after perfusion. Each time point represents the mean of three separate experiments.

heart required a slight modification of the preceding method. Briefly, the hamster heart was perfused with a modified Jokliks-MEM buffer where sodium bicarbonate was replaced by potassium bicarbonate. The heart was perfused in the modified Jokliks-MEM buffer containing 2.5 mg/mL collagenase for 15 min. Digested tissues were suspended in the same buffer and gently agitated to dislodge the cells. Free myocytes were separated from the other cells by sedimentation. The cells were washed with the modified Jokliks-MEM buffer and incubated with the same buffer for 20 min. The cells were washed with M199 buffer, and subsequently with M199 buffer containing 5% fetal calf serum. The cell suspension was distributed to ten 60-mm petri dishes and the dishes were incubated for 60 min at 37° to allow the attachment of myocytes onto the dish. Over 90% of the cells in the dish were viable.

In the labeling study, myocytes were incubated with Earle's buffer containing 0.1 μM [methyl-^{3}H]choline (2.5 μCi/mL) for 60 min. Subsequently, the cells were washed three times with ice-cooled Earle's buffer. After the wash, 2 mL of 50% methanol was added, and the precipitate was removed by centrifugation. An aliquot of the extract was used for the determination of total uptake. Chloroform and water were added to the extract to cause phase separation. An aliquot of the lower phase was analyzed for radioactivity in the phosphatidylcholine fraction by TLC.

Protein content was determined by the method of Lowry *et al.* (11). Radioactivity was determined by scintillation counting using channels' ratio calibration method. Student's *t*-test was used for statistical analysis.

RESULTS

The time course of choline uptake by hamster and rat hearts in the presence of 1 mM L-alanine was examined. Hearts were perfused with 10 μM labeled choline (0.35 μCi/mL) in Krebs-Henseleit buffer for 15–60 min at 37°C. Subsequent to perfusion, the amounts of radioactivity in the tissue extracts were determined. As depicted in Figure 1, choline uptake was enhanced at all time points by L-alanine in the hamster heart but not in the rat heart. In a separate study, choline uptake in guinea pig and rabbit hearts were not enhanced by 1 mM L-alanine at 30 and 60 min of perfusion.

The effect of other amino acids on choline uptake in hamster, rat, guinea pig and rabbit hearts was also studied. In the presence of 1 mM L-aspartate, no change in choline uptake was observed in all hearts when compared with the control (Table 1). In the presence of 1 mM glycine or L-alanine, the uptake of choline was elevated in the hamster heart but not in guinea pig, rat or rabbit hearts. The choline uptake in the guinea pig, rat or rabbit hearts was not affected when the level of L-lysine, L-aspartate, L-alanine or glycine was elevated to 5 mM.

The effect of amino acids on the labeling of phosphatidylcholine was examined. Subsequent to perfusion, the phosphatidylcholine fraction was isolated from the tissue extract by TLC, and the amount of radioactivity in this fraction was determined (Table 2). As expected, no significant change was observed in the labelling of phosphatidylcholine in the guinea pig, rat or rabbit heart when amino acid was present in the perfusate. Although choline uptake was enhanced in the hamster heart perfused with neutral amino acids, there was no corresponding increase in the labeling of phosphatidylcholine. Analysis of the choline-containing metabolites revealed that the metabolites in the CDPcholine pathway were not affected by L-alanine in guinea pig, rat or rabbit hearts. An accumulation in the labeling of phosphocholine was found in the hamster heart perfused with L-alanine (Table 3). The increase in the labeling of phosphocholine quantitatively

Control	0.40 ± 0.01 (4)	0.10 ± 0.01 (4)
+ L-alanine	0.38 ± 0.03 (4)	0.10 ± 0.02 (4)

[a]Myocytes from hamster and rat hearts were incubated with 0.1 μM of labelled choline (2 μCi/mL) for 60 min. The radioactivities in the cell extracts and in phosphatidylcholine after the incubation were determined. The values represent the mean ± standard deviation (number of determinations in parentheses).

[b]$P < 0.05$ when compared with control.

accounted for the increase in labelled choline uptake in the presence of the neutral amino acid.

The ability of neutral amino acid to enhance choline uptake in myocytes was investigated. Myocytes were isolated from hamster and rat hearts by collagenase digestion, and incubated with 0.1 μM labeled choline (2 μCi/mL) for 60 min in the presence of L-alanine. Since the viability of the hamster myocytes might not be identical from one batch of cells to another, the variation might affect the ability of the cells to take up choline. The results obtained from two separate batches are shown in Table 4. Choline uptake in hamster myocytes was enhanced by L-alanine in both batches. Analysis of the choline-containing metabolites revealed that their distribution pattern (the accumulation of label in the phosphocholine fraction) was similar to that obtained from the isolated hamster heart. As a control study, the effect of L-alanine on choline uptake in rat myocytes was investigated. The presence of L-alanine did not enhance the uptake of choline in rat myocytes.

DISCUSSION

The uptake of choline by the low-affinity Na^+-independent transport system in non-neural cells has been documented (12). In the hamster heart, the uptake of choline follows Michaelis-Menten kinetics and appears to consist of a single uptake system (2). We have shown earlier that the choline uptake in the hamster heart was enhanced by neutral amino acids (9). We have also demonstrated in the same study that the presence of more than one neutral amino acid did not produce a synergistic effect on the choline uptake (9). The present study suggests that the enhancement of choline uptake by amino acids may be limited to the hamster heart. The inability of neutral amino acids to modulate choline uptake in the guinea pig, rat and rabbit hearts was not caused by the duration of perfusion or amino acid concentration and implies that the regulation of the uptake mechanism is not the same between mammalian species. Interestingly, the hamster heart (and myocytes) also displays a higher rate of choline uptake than hearts from the other animals. The reason for the higher rate of choline uptake in the hamster heart is not known.

Since choline uptake in guinea pig, rat and rabbit hearts was not affected by the presence of amino acids, the rate of phosphatidylcholine biosynthesis in these hearts should not be affected. This postulation was confirmed by the analysis of labeling in phosphatidylcholine and choline-containing metabolites. The ability of the hamster heart to maintain phosphatidylcholine biosynthesis during enhanced choline uptake was documented in previous studies (9). The accumulation of labelled phosphocholine in the hamster heart and in the hamster myocytes clearly reflects the ability of the rate-limiting step of the CDPcholine pathway to regulate phosphatidylcholine biosynthesis (3). At present, the exact mechanism for the modulation of choline uptake by neutral amino acids in the hamster heart is not known. One explanation is that neutral amino acid facilitates the transport of choline across the endothelial wall of the blood vessels and causes an increase in choline concentration in the intercellular fluid. The higher concentration of choline in the intercellular fluid may cause an increase in choline uptake by the myocardial cells. However, the ability of neutral amino acids to enhance choline uptake in the hamster myocytes eliminates this possibility and suggests that such an enhancement is a result of the direct modulation of the choline transport site by amino acids.

ACKNOWLEDGMENT

The study was supported by the Medical Research Council of Canada.

Changes in Lipid Content, Fatty Acid Composition and Lipoprotein Lipase Activity in Dry Goat Omental Adipose Tissue According to Tissue Site

P. Bas*, F. Gallouin and **P. Morand-Fehr**
Station de Nutrition et Alimentation (INRA), de l'INA-PG, 75005, Paris, France

Water and lipid contents, fatty acid distribution, and lipoprotein lipase activity were determined in 11 samples taken from the *Omentum Majus* of five dry Alpine goats. Samples were chosen to standardize sampling sites using geometric guide marks representative of different adipose tissue sites. Sample location explained between 20% and 30% of the total variance in water and lipid contents and in lipoprotein lipase activity, and from 5.5% to 45.4% of the total variance in fatty acid distribution. Increased sample thickness was associated with an increase in lipid content and in saturated fatty acid percentages. Samples taken in proximity of the omentum tissue attached to the rumen and abomasum had the highest content. We furthermore found that the levels of 18:2n-6, 18:1n-7, and of branched chain fatty acids were high close to a pila of the rumen which also corresponded to high lipoprotein lipase activity. Concomitant high levels of 16:1n-7, 17:1n-8, and 18:1n-9 may reflect high levels of Δ9 desaturase activity. *Lipids 27*, 470–473 (1992).

At the onset of lactation, high-producing dairy females are in a negative energy balance. They mobilize lipids from fat deposits, especially from visceral adipose tissue (1,2). There are great differences between animals, within the same species, the same breed, and even on the same diet, in the ability of an animal to mobilize and restore fat deposits.

The composition and metabolic characteristics of most adipose deposits are well documented in goats (3–6), but there is a general lack of information on the variations that exist within each deposit. In pig and cattle subcutaneous adipose tissue, there is an increase in unsaturation and a decrease in lipogenic enzyme activities with increased proximity to the skin (7–10). In goats, subcutaneous adipose tissue is scarce, but visceral adipose deposits are relatively large (3,11).

The purpose of this study was to compare lipid contents, fatty acid compositions, and lipoprotein lipase activity at different locations of omental tissue in dry goats in order to gain a better understanding of the representativeness of a sample in respect to tissue site.

MATERIALS AND METHODS

Animals and diets. Five dry Alpine does were given free access to lucerne hay, plus 400 g of a cereal based concentrate. Goats, at approximately 4.4 (SD = 1.8) years of age, were slaughtered after an overnight fast between 9:00 a.m. and 10:00 a.m. by stunning and bleeding. Mean live weight was 57.9 kg (SD = 10.6). Immediately after slaughter, the *Omentum Majus*, the perirenal adipose tissue and the mesenteric adipose tissue were removed and weighed. The empty body weight of goats was determined as live weight minus the weight of faeces, digesta, and urine. From each goat, 11 samples were taken from the *Omentum Majus*. These samples were chosen to be representative of the different parts of the adipose tissue. In order to standardize the sampling site for each goat, geometric guide marks were used (Fig. 1). Samples weighing between 5 and 10 g were taken and immediately placed into weighed bags and frozen at −50°C until further analysis.

Chemical analysis. Water and lipid contents were determined ater 48-h freeze-drying and by reflux extraction with hexane (12) using a Soxtec HT extractor (Perstorp, Bezons, France), respectively.

Fatty acid analysis. Fatty acids were butylated in the presence of 3% hydrochloric acid in butanol (vol/vol) as previously described (11). After elimination of excess butanol by washing with distilled water, the fatty acid butyl esters were analyzed by gas-liquid chromatography on a model 300 C Girdel apparatus (Delsi-Nermag, Argenteuil, France). The glass capillary column, 50 m × 0.25 mm, i.d. was coated with carbowax-20 M. The capillary tubing was dynamically coated with the liquid phase in methylene chloride, 20% w/v, using a 2-cm plug of high purity mercury. Peak areas were measured using a Delsi model Icap 10-5 computing integrator (Delsi-Nermag). Peaks were identified on the basis of their equivalent chain lengths (13) as determined by interpolation between two consecutive even-straight-chain saturated fatty acids and compared with those of standards (Sigma, St. Louis, MO) analyzed under the same conditions as well as based on literature values (14–18). Fatty acids of all samples were analyzed as such and following hydrogenation. Hydrogenation was done according to Poukka *et al.* (19) using 1 to 10 mg of butyl esters dissolved, in a conical tube, using 8 mL of butanol to which 20 mg of Adams' platinum oxide catalyst (Touzart et Matignon, Vitry-sur-Seine, France) was added. A slight hydrogen-stream was passed over the solution for 1 h.

Enzyme assay. For each sample, 1 g of frozen crude tissue was homogenized in cold (4°C) heparinized ammoniacal buffer (pH 8.30 at 20°C) using a Sorvall (Norwalk, CT) omni-mixer. Lipoprotein lipase activity was measured in the supernatant according to Chilliard (20).

Statistical analysis. The data were analyzed using the general linear models (GLM) and the discriminant analysis (DISCRIM) procedures provided by the Statistical Analysis System (SAS) (21). Analysis of variance of each dependent variable was performed with the main effect model where the 5 goats and the 11 locations of the samples represented two main factors of variations. The comparison between the location of the samples was performed by the multiple comparison procedure using

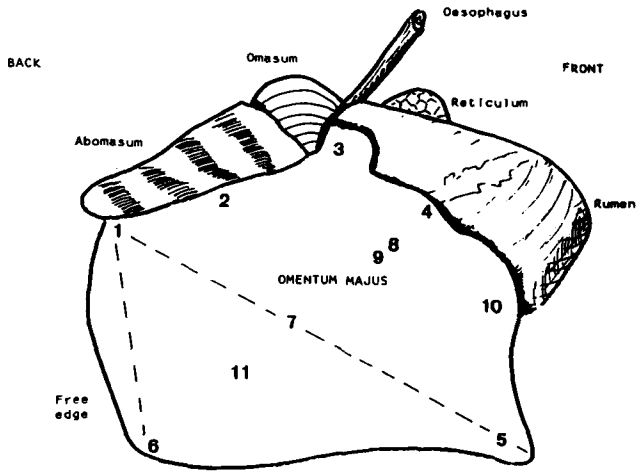

FIG. 1. Location of the samples taken from the *Omentum Majus* (OM) of dry Alpine goats. (1) At the bottom of the abomasum, near the pylorus; (2) near the attached part of the OM, on the *curvature dorsalis* of the abomasum; (3) near the upper part of the abomasum; (4) in front of the spleen, near the *pila longitudinalis* and the *sulcus caudalis*; (5) at the end of the free side of the OM, on the opposite side of sample (1), at the point near the *saccus caecus caudoventralis* of the rumen; (6) at the end of the free side of the OM, on the opposite side of sample (3), near the jejunum; (7) in the middle of the diagonal line between sample (1) and sample (5); (8) between sample (4) and sample (7), on a fatty nodule; (9) between sample (4) and sample (7), on a very thin part of the OM; (10) between sample (4) and sample (5), on the cranial part of the OM, near its connection to the rumen; (11) between sample (6) and sample (7), in a thin area including a blood vessel.

t-test equivalent to Fisher's least-significant difference. The comparisons between the sample locations based on their fatty acid profile were evaluated by discriminant analysis using Mahalanobis distances.

RESULTS

In the five dry goats, the weight of the visceral adipose tissues represented 14.8% (SD = 2.2%) of the empty body weight. Omental tissue was much heavier than the other visceral adipose tissues, representing 48.8% (SD = 5.4%) of the total weight of the three visceral adipose tissues. The coefficient of variation of the omental tissue weight was lower than that of the other visceral adipose tissues (10.8, 22.9 and 30.3%, respectively, for omental, perirenal and mesenteric adipose tissues).

The means of water and of lipid contents, lipoprotein lipase (LPL) activity, and fatty acid percentages for the 55 analyzed samples are reported in Table 1. The means of the 11 samples from each goat omental tissue varied from 91.2% (w/w) to 94.2% (w/w) in lipid content. The higher the lipid content, the smaller were the variations between samples from different sites.

Each determined component of goat omental tissue significantly differed between sample location (Table 2). For water and lipid contents, the analyzed samples could be divided into at least three groups. The group containing samples 4, 9 and 11 was characterized by the highest water content (7.0% w/w) and the lowest lipid content (91.2% w/w) (Table 2, and Fig. 2). The other extreme was represented by samples 2, 3 and 10 which showed the lowest water content (4.6% w/w) and the highest lipid content (94.2% w/w).

LPL activity was high in sample 4 (40 nmol · min^{-1} · g^{-1}) and to a lesser extent in sample 10 (25 nmol · min^{-1} · g^{-1}). LPL activity was the lowest in sample 2 (12 nmol · min^{-1} · g^{-1}).

Total variance with location for fatty acid percentages ranged from 5.5% for 17:0 to 45.4% for 16:1n-7 (Table 1). Variance for 16:1n-7 by location was much greater than variance between goats. Both sources of variations contributed almost equally to the variances observed for

[e]Lipoprotein lipase activity (nmol • $min^{-1} \cdot g^{-1}$ of crude tissue).

18:0, 18:1n-9, and branched-chain saturated fatty acids (BCFA).

Total straight-chain saturated fatty acid levels were significantly higher in samples 10, 5, 3, and 2 than in the other samples. These four samples contained high levels of the major saturated fatty acids 16:0 and 18:0, sample 5 had a low level of 15:0, sample 3 had a low level of 14:0, and sample 2 had low levels of 14:0, 15:0, and 17:0. By contrast, the highest levels of total monounsaturated fatty acids were found in samples 4 and 9 due to high 16:1n-7, 17:1n-8, and 18:1n-9 levels. The percentages of the other monoenoic fatty acids, for example, 16:1n-9 and 18:1n-7, were elevated in sample 4 but not in sample 9. Moreover, sample 4 had the highest BCFA content and a high 18:2n-6 level.

The total-sample correlation coefficient for all omental samples (n = 55) calculated between 18:1n-9 on one hand, and 14:0, 15:0, 16:0, 16:1n-9, 16:1n-7, 17:1n-8, 18:0, and 18:2n-6 levels on the other hand, were highly significant (−0.583, −0.595, −0.683, +0.491, +0.710, +0.856, −0.820, and +0.633, respectively). The correlation between 18:1n-9 and 18:1n-7 was very weak (+0.197). Overall, unsaturated fatty acid percentages were positively correlated to LPL activity (+0.418, +0.392, +0.579, +0.497, +0.313, and +0.289 for 16:1n-9, 16:1n-7, 17:1n-8, 18:1n-9, 18:1n-7, and 18:2n-6, respectively; $P < 0.05$). By contrast even-numbered saturated fatty acids (ESFA) levels were negatively correlated to LPL (−0.398, −0.560, and −0.319, respectively, for 14:0, 16:0, and 18:0). The mean thickness of the samples was strongly correlated with water and lipid contents, and the levels of 16:1n-7, 17:1n-8, 18:0, and 18:1n-9 (−0.581, +0.558, −0.479, −0.401, +0.548, and −0.483, respectively).

In regard to the fatty acid profile of each sample location, most samples could be pooled with neighboring ones due to their similar profiles, although samples 4, 9, and 11 were quite dissimilar.

DISCUSSION

Variations in composition within the omentum have not been reported previously for goats or other domestic animals. Observed variations in water content, in lipid content, in LPL activity, and in fatty acid composition between samples from different locations appear to be characteristic for the tissue site. It also seems that the thickness of the sample relates to variations in composition as the three thinner samples had the lowest lipid and saturated fatty acid contents. Samples in close proximity to the attachment site to the rumen and abomasum had increased lipid contents and decreased water contents in comparison to samples distant from the attachment site. Sample 4 was an exception with its high water content, its low lipid content, and its highest levels of monoenoic fatty acids, BCFA, and 18:2n-6, and its very high LPL activity being twice as high as in other samples. This appears to indicate a high metabolic activity at the sample 4 site. The large amounts of dietary fatty acids, for example 18:2n-6, or of 18:1n-7 which are produced in the rumen during microbial hydrogenation of polyunsaturated fatty acids from the diet (22,23), or BCFA which are derived from lipids of rumen microorganisms, emphasize the importance of lipogenesis by uptake of fatty acids from the bloodstream involving lipoprotein lipase. High levels of 16:1n-7, 17:1n-8, and 18:1n-9 may reflect a very active endogenous Δ9 desaturase. Thick samples such as fatty nodules with a high lipid content and a high level of saturated fatty acids seem to point toward a low metabolic activity (24).

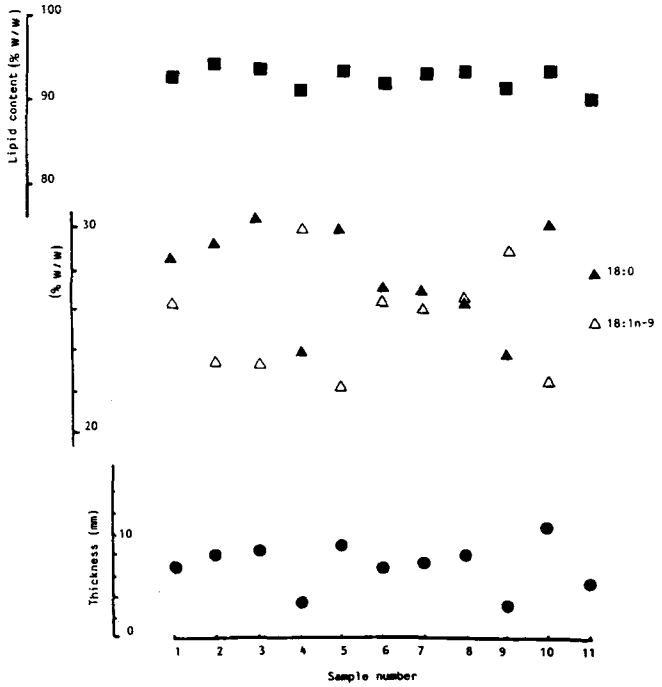

FIG. 2. Variation of some characteristics of goat *Omentum Majus* in dry Alpine goats.

On account of the significant variations observed within the omental tissue, care in the selection of the sampling site appears to be in order. Unless the whole tissue cannot be analyzed, an easily definable sample site should be chosen. The sample which seems to best fit this criterion is sample 5; it is located where the omental tissue forms a sac at its periphery.

Low-Density Lipoprotein Turnover in Inbred Strains of Rabbits Hypo- or Hyperresponsive to Dietary Cholesterol

G.W. Meijer[a,*], A.F.H. Stalenhoef[b], P.N.M. Demacker[b], M.J.T.M. Mol[b], L.F.M. Van Zutphen[a] and A.C. Beynen[a]

In two inbred strains of rabbits with high or low response of plasma cholesterol to dietary cholesterol, low density lipoprotein (LDL) apolipoprotein (apoLDL) kinetics were determined with the use of a heterologous tracer isolated from a Watanabe heritable hyperlipidemic (WHHL) rabbit. On a diet without added cholesterol, the total clearance of apoLDL (which equals apoLDL production) did not differ significantly between rabbits of both strains. After the feeding of a diet containing 0.1% cholesterol for six weeks, plasma LDL cholesterol, plasma apoLDL and liver cholesterol concentrations rose significantly in the hyperresponsive but not in the hyporesponsive rabbits. Cholesterol feeding depressed the total fractional catabolic rate (FCR) of apoLDL in the hyper- but not in the hyporesponsive rabbits; this was attributed to a decrease of receptor-dependent FCR while receptor-independent FCR was similar in the two strains. On the diet containing cholesterol, the receptor-mediated absolute catabolic rate (ACR) of apoLDL did not differ between hyper- and hyporesponsive rabbits but receptor-independent ACR of apoLDL was higher in hyperresponders. It is concluded that the higher plasma apoLDL levels in hyperresponsive rabbits fed the 0.1% cholesterol diet are caused by a higher production of apoLDL and not by a lower flux of apoLDL through the receptor-mediated pathway.
Lipids 27, 474-477 (1992).

Among humans and various animal species, individuals can differ in their susceptibility to dietary cholesterol (1). Hyporesponders showing only minor changes in their plasma cholesterol concentrations can be discriminated from hyperresponders showing high degrees of cholesterolemia. The underlying cause for this individual variation in response is poorly understood. Studies with inbred rabbits (2,3) indicate that in hyperresponders the efficiency of intestinal cholesterol absorption is increased. After cholesterol feeding, the higher efficiency of cholesterol absorption in hyperresponders leads to increased fluxes of chylomicron-remnant cholesterol into the liver. This might cause higher liver cholesterol concentrations in hyper- than in hyporesponders. The liver is the major organ for low-density lipoprotein (LDL) clearance (4) and there is an inverse relationship between cellular cholesterol concentrations and the number of LDL receptors on the cell membrane (5). Thus, cholesterol feeding might lead to a greater reduction of receptor-mediated LDL clearance in hyper- than in hyporesponders. This in turn would explain the higher degree of hypercholesterolemia in cholesterol-fed hyperresponders compared with their hyporesponsive counterparts. In the present study this idea was put to the test.

MATERIALS AND METHODS

Animals and diets. Rabbits, aged 9-25 mon, of two inbred strains were used. The IIIVO/JU strain has previously been shown to be hyporesponsive and the AX/JU strain to be hyperresponsive to dietary cholesterol (2,6,7). The rabbits had been fed a commercial diet (LKK-20®, Hope Farms, Woerden, The Netherlands) and were housed individually as described (2). Three male and three female rabbits of each of the two strains were either fed a diet without added cholesterol or a high-cholesterol diet. Males and females have been shown to have comparable cholesterolemic responses to cholesterol feeding. A purified diet was formulated so as to keep dietary cholesterol concentration as low as possible. This diet consisted of (g/kg): soybean protein isolate, 102; methionine, 2; dextrose, 64.3; alfalfa meal, 560; molasses, 100; corn oil, 10; coconut fat, 90; $CaCO_3$, 10; NaH_2PO_4, 5; Na_2CO_3, 10.3; $MgCO_3$, 1.4; NaCl, 5; $KHCO_3$, 18; mineral premix, 10; vitamin premix, 12. The composition of the vitamin and mineral premix has been described (7). The purified diet without added cholesterol was fed for four weeks prior to and during the LDL turnover measurement period. To maintain palatability, the high-cholesterol diet was the commercial chow to which 0.1% (w/w) of cholesterol was added. This amount of cholesterol is low compared with the amounts generally used in cholesterol feeding studies with rabbits. In this way, induction of pathological changes would be prevented (8). The high-cholesterol diet was fed for six weeks prior to and during the apoLDL turnover measurement period. Upon analysis, the diet without added cholesterol and the high-cholesterol diet were found to contain 8 and 141 mg of cholesterol/100 g diet, respectively. The rabbits were given 75 g of diet at 9 a.m. each day. This amount was completely consumed within 4 h. Tap water was provided *ad libitum*. The rabbits were allowed to practice cecotrophy.

Isolation, radiolabelling and reductive methylation of LDL. Additional details of the procedures used have been described previously (9). Five days before apoLDL turnover measurement, 70-80 mL of blood was taken by heart puncture from a WHHL rabbit fed the commercial diet. LDL was isolated from serum by sequential ultracentrifugation in a fixed angle rotor at 168,000 × *g* for 22 hr between densities 1.020 and 1.055 as described (9). For administration to rabbits fed the diet without added cholesterol, this LDL was labelled with ^{131}I by a modification (10) of the method of McFarlane (11). For injection into rabbits fed the high-cholesterol diet, a por-

tion of the LDL was labelled with ^{131}I and another portion with ^{125}I. Subsequently, the ^{125}I-labelled LDL was chemically modified by reductive methylation following a 60-min reaction sequence (12). Methylation of lysine residues has been shown to abolish the binding of LDL to the LDL receptor without affecting non-receptor-mediated processes (10,13). Free iodine was removed by column chromatography on Sephadex G-25 M (columns PD-10, Pharmacia Fine Chemicals, Uppsala, Sweden). As estimated by a colorimetric method based on reaction of 2,4,6-trinitrobenzene-1-sulfonic acid with primary amines (14), 63% of the lysine residues had been methylated. The efficiency of labelling was 50–60%; more than 95% of the radioactivity could be precipitated by 10% trichloroacetic acid and 80–85% by 50% isopropanol.

LDL turnover studies. Two turnover studies were carried out exactly as described (9). One study was done with the animals fed the diet without added cholesterol and another with rabbits fed the high cholesterol diet; the interval between the two studies was 11 wk. ^{131}I-labelled native LDL was diluted with 0.15 M NaCl in the absence (study with rabbits fed the diet without added cholesterol) or presence (study with cholesterol-fed rabbits) of ^{125}I-labelled methyl-LDL and mixed with serum derived from a rabbit of the same strain and fed the same diet as the recipients. This mixture was kept overnight at 4°C after which 1 mL was injected into a marginal ear vein of each of the recipients; the amount of injected radioactivity was 13.8–15.5 μCi (0.51–0.57 MBq) for ^{131}I and 12.8–13.3 μCi (0.47–0.49 MBq) for ^{125}I. The amount of apoLDL injected into the rabbits fed the diet without added cholesterol was less than 0.4% of their estimated apoLDL pool. For the cholesterol-fed animals, this amount was lower than 0.2%. Blood samples drawn 3 min after injection were used to calculate plasma volume by measuring isotope dilution. Blood samples (2–2.5 mL in 4 mg ethylenediaminetetraacetic acid (EDTA) were taken at regular intervals for 72 h. Total plasma radioactivity of ^{131}I and ^{125}I was counted in a Philips PW 4800 automatic gammacounter (Eindhoven, The Netherlands). During blood sampling, the feeding schedule was not changed. Within two hours after taking the last blood samples, the rabbits were killed by administration of pentobarbital, and their livers removed.

The fractional catabolic rate (FCR) was obtained from bi-exponential analysis of the plasma radioactivity decay curves, assuming a simple two-compartment model where plasma LDL equilibrates with an extravascular compartment and where all irreversible loss of apoLDL occurs from the plasma compartment (15,16). Decay of ^{125}I-labelled LDL was used to calculate the receptor-independent FCR. The difference between decay of ^{131}I- and ^{125}I-labelled LDL was taken to calculate the receptor-dependent FCR. The absolute catabolic rate (ACR) was calculated from the FCR and the apoLDL pool size; the apoLDL pool size was obtained from the plasma volume and the apoLDL concentration by multiplication, and expressed relative to body weight. Under steady-state conditions, the ACR equals the production rate.

Analytical methods. After an overnight fast, blood was taken from an ear artery and mixed with EDTA (1 g/L) for lipoprotein analysis. Lipoproteins were isolated by sequential centrifugation in a Kontron fixed angle rotor JFT45 (Hemile, Switzerland) in a Beckman L7/55 ultracentrifuge (Fullerton, CA) at 168,000 × *g* for 20 h at 14°C as described previously (17). LDL was isolated at the density range 1.025–1.055 g/mL. ApoLDL was determined as total protein in LDL.

Total cholesterol was determined with an enzymatic, commercially available test kit (Boehringer, Mannheim, Germany). Protein was determined according to the method described by Lowry *et al.* (18). Liver samples (1–2 g) were homogenized in two volumes of distilled water, and cholesterol was extracted and analyzed according to Abell *et al.* (19).

Statistical analyses. Comparisons between the hypo- and hyperresponsive strain and between animals of the same strain fed either the diet without added cholesterol or the high-cholesterol diet were evaluated by Student's *t*-test. For data with no normal distribution, the Mann-Whitney U test was used. A two-sided *P* value of less than 0.05 was set for statistical significance. Results are expressed as means ± SD.

RESULTS

Plasma lipoproteins and liver cholesterol. Initial plasma total cholesterol concentrations and those after feeding the diet without added cholesterol were higher in the hyporesponsive rabbits (Table 1). When fed the diet without added cholesterol, there were no significant dif-

TABLE 1

Cholesterol and ApoLDL in Plasma and Liver Cholesterol of Hypo- and Hyperresponsive Rabbits Fed Either a Diet Without or with Added Cholesterol[a]

Measure	Diet without added cholesterol		Diet with added (0.1%) cholesterol	
	Hypo-	Hyper-	Hypo-	Hyper-
Plasma total cholesterol (mM)				
Initial	0.98 ± 0.23	0.64 ± 0.22[b]	1.17 ± 0.18	0.57 ± 0.19[b]
Final	2.04 ± 0.65	0.79 ± 0.36[b]	2.16 ± 0.27	4.87 ± 1.27[b,c]
LDL cholesterol (mM)[d]	0.24 ± 0.17	0.20 ± 0.18	0.39 ± 0.15	2.34 ± 1.06[b,c]
ApoLDL (mg/dl)[d]	17.5 ± 6.0	15.4 ± 4.7	20.5 ± 3.4	59.9 ± 23.2[b,c]
Liver cholesterol (μmol/g)	6.4 ± 0.9	9.3 ± 1.4[b]	8.1 ± 1.7	14.7 ± 2.8[b,c]

[b]Significant difference between hypo- and hyperresponsive rabbit strain fed the same diet.

[c]Significantly different from rabbits of the same strain but fed the cholesterol-free diet.

[d]At the administration of the tracer(s).

ferences in plasma LDL cholesterol and apoLDL levels between the two strains, whereas liver cholesterol concentrations were significantly higher in the hyperresponders.

Feeding the high-cholesterol diet caused more pronounced increases of plasma total cholesterol concentrations in the hyperresponsive rabbits than in the hyporesponders. The strain difference in response to dietary cholesterol was larger for LDL-cholesterol and apoLDL concentrations in plasma. Cholesterol loading increased group mean liver cholesterol concentrations in both strains, the increase being larger in the hyperresponders.

LDL catabolism. Plasma cholesterol concentrations did not change over the 72 h of measuring apoLDL turnover (data not shown), consistent with reaching a steady state. The size of plasma apoLDL pools in hypo- and hyperresponders fed the diet without added cholesterol was similar (7.8 ± 2.3 *vs.* 8.2 ± 3.4 mg/kg; means ± SD, n = 6). On the high-cholesterol diet, plasma apoLDL pools had significantly increased in both strains, the final value being significantly greater in the hyperresponders (Table 2). On the diet without added cholesterol, total FCR of apoLDL did not differ significantly between the two strains (Fig. 1): 1.63 ± 0.37 and 1.71 ± 0.44 pools/day for hypo- and hyperresponders, respectively (means ± SD, n = 6). Compared with the diet without added cholesterol, the high-cholesterol diet caused a decrease of the mean total FCR of apoLDL in the hyper- but not in the hyporesponders (Table 2). Receptor-independent FCR of apoLDL did not differ significantly between hypo- and hyperresponders fed cholesterol. Receptor-dependent FCR of apoLDL was significantly lower in hyperresponsive rabbits fed the diet containing cholesterol when compared with their hyporesponsive counterparts (Table 2). When fed the diet without added cholesterol, there was no significant difference in ACR of apoLDL between hypo- and hyperresponsive rabbits (12.1 ± 2.1 *vs.* 14.2 ± 7.1 mg/kg/day; means ± SD, n = 6). Dietary cholesterol produced a significantly larger ACR of apoLDL in both rabbit strains, the difference being more pronounced in the hyperresponders.

DISCUSSION

The present study provides further insight into the metabolic differences between hypo- and hyperresponsive inbred rabbits. On the diet without added cholesterol, hyperresponsive rabbits had slightly higher liver cholesterol concentrations but did not differ significantly from hyporesponders as to LDL-cholesterol levels, apoLDL pools and total FCR of apoLDL. On the high-cholesterol diet, LDL-cholesterol, apoLDL and liver cholesterol concentrations became higher in the hyper- than in the hyporesponsive rabbits. Cholesterol feeding depressed total FCR of apoLDL in the hyper- but not in hyporesponsive rabbits. This was due to a decrease of both receptor-dependent and receptor-independent FCR of apoLDL, although the latter was not significantly different between hypo- and hyperresponders.

Since apoLDL pools were significantly higher in the hyperresponders, the observed reduction of the receptor-dependent FCR in this strain cannot be taken as unequivocal evidence that there had been depression of the number of LDL receptors (20). The ACR can provide additional information in this context. Although the calculated ACR values may be biased because a heterologous tracer LDL was used, they may still serve to compare the two rabbit strains. The decreased receptor-dependent FCR of apoLDL in cholesterol-fed hyper- *vs.* hyporesponders, in combination with the increased apoLDL pools in the former, led to receptor-dependent ACR values that were identical for hyper- and hyporesponders fed the high-cholesterol diet. Thus, in cholesterol-fed hypo- and hyperresponders the flux of apoLDL through the receptor-dependent pathway was similar. This could imply that in the two strains the number of LDL receptors was similar while the concentration of circulating LDL particles was sufficiently high to saturate the receptors. Thus, after cholesterol feeding there was no difference in LDL receptor activity in the two strains. Alternatively, it could be proposed that the LDL receptors in cholesterol-fed hyperresponders are less active than in cholesterol-fed hyporesponders. Despite the three-fold larger apoLDL pool in the hyperresponders, the LDL receptors in these rabbits were not able to remove more LDL from the cir-

culation than those in the hyporesponders. This resulted in a lower receptor-mediated FCR of apoLDL in cholesterol-fed hyperresponders. It is possible that the feeding of a higher amount of cholesterol than that used in the present study would induce a clear-cut difference between hypo- and hyperresponders as to depression of LDL receptors.

There was a direct relation between total ACR of apoLDL and plasma apoLDL pools for individual rabbits ($r = 0.87$; $n = 24$; $P < 0.0005$). Thus, it may be concluded that the higher plasma apoLDL concentration in the hyperresponders was caused by a higher production of apoLDL. Since the flux of LDL through the receptor-dependent pathway was not influenced, a new steady state could only be reached by increasing receptor-independent removal of LDL. Indeed, receptor-independent removal (ACR) of apoLDL was higher in the hyper- than in the hyporesponsive rabbits.

We conclude that the earlier reported (2,3) higher efficiency of intestinal cholesterol absorption in hyperresponsive rabbits causes liver cholesterol to increase more markedly in hyper- than hyporesponsive rabbits in response to cholesterol feeding. There was a positive correlation between liver cholesterol concentration and total ACR of apoLDL ($r = 0.71$; $n = 24$; $P < 0.0005$). Possibly, the higher liver cholesterol levels in hyperresponders cause a higher production rate of apoLDL, which accounts for the increase of LDL in plasma. The number of LDL receptors in hypo- and hyperresponders fed a diet with 0.1% cholesterol is similar and, maybe because they are saturated with LDL, the absolute amount of apoLDL taken up by the cells is also similar. Because of the increased LDL concentration in hyperresponders, the amount of apoLDL taken up by the receptor-independent pathway in these animals is increased.

Effect of 25-Hydroxycholesterol on Cholesteryl Ester Formation in Caco-2 Cells

Hidenobu Kusuhara*, Osafumi Shimada and Jun Inui
Research Laboratories, Yoshitomi Pharmaceutical Industries, Ltd., Iruma-shi, Saitama 358, Japan

Incubation of Caco-2 cells, a human intestinal cell line, with 25-hydroxycholesterol (25-HOC) markedly enhanced cellular cholesteryl ester formation determined by incorporation of [^{14}C]oleic acid into intracellular cholesteryl [^{14}C]oleate. The stimulation by 25-HOC of cholesteryl ester formation was suppressed by staurosporine, a kinase inhibitor, but not by cycloheximide or actinomycin D. The specific activity of microsomal acyl-coenzyme A:cholesterol acyltransferase (ACAT) increased two-fold in cells treated with 10 μM 25-HOC for 5 h. ACAT activity decreased when microsomes were incubated without sodium fluoride, a phosphatase inhibitor, but the decrease in ACAT activity in cells stimulated with 25-HOC was more pronounced. The results suggest that protein phosphorylation may be involved in the stimulation of cholesteryl ester formation by 25-HOC in Caco-2 cells.
Lipids 27, 478–480 (1992).

Oxygenated derivatives of cholesterol, such as 25-hydroxycholesterol (25-HOC) and 7-ketocholesterol, are potent regulators of intracellular cholesterol metabolism (1). In cultured cells, these sterols have been shown to suppress 3-hydroxy-3-methylglutaryl-coenzyme A reductase activity and low density lipoprotein receptor activity mainly by the repression of transcriptional expression of the genes through sterol regulatory elements (1).

It has also been reported that oxygenated sterols stimulate the formation of cholesteryl esters in several cultured cell lines including human fibroblasts (2), rat hepatocytes (3) and rat intestinal cells (4). This stimulation is caused by an increase in the activity of microsomal acyl-coenzyme A:cholesterol acyltransferase (ACAT) which catalyzes the formation of long-chain fatty acyl esters of cholesterol. ACAT plays an important role in cholesterol absorption in the intestine and in foam cell formation in arteries; however, the precise mechanism of enhancement of ACAT activity by oxygenated sterols is not clear.

In the present study, the effects of 25-HOC on cholesteryl ester formation were studied in Caco-2 cells, a cell line derived from human intestine, to further explore the mechanism of stimulated cholesteryl ester formation in human intestinal cells. The results confirm that 25-HOC stimulates cholesteryl ester formation in this cell line through enhancement of microsomal ACAT activity. In addition, it appears that protein phosphorylation is involved in this type of stimulation.

Abbreviations: ACAT, acyl-coenzyme A:cholesterol acyltransferase; AD, actinomycin D; BSA, bovine serum albumin; CHX, cycloheximide; DMEM, Dulbecco's modified Eagle medium; 25-HOC, 25-hydroxycholesterol; STP, staurosporine; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. [1-^{14}C]Oleic acid, [1-^{14}C]oleoyl-coenzyme A and [4,5-^{3}H]leucine were purchased from New England Nuclear (Boston, MA). Oleic acid, oleoyl-coenzyme A, cholesterol and 25-hydroxycholesterol were purchased from Sigma Chemical Co. (St. Louis, MO). Staurosporine was from Kyowa Hakko, Inc. (Tokyo, Japan). All other chemicals were reagent grade.

Assay of cholesteryl ester formation. Caco-2 cells were obtained from the American Type Culture Collection (Rockville, MD) and cultured at 37°C in 95% air/5% CO_2 in Dulbecco's modified Eagle medium (DMEM) supplemented with 20% fetal calf serum and antibiotics. Cholesteryl ester formation was estimated according to Brown *et al.* (5). Briefly, cells grown to confluence in 12-well plates (Costar, Cambridge, MA) were washed and treated with or without 25-HOC in DMEM at 37°C for 2 h. Cells were then incubated for 3 h with 100 μM [1-^{14}C]oleic acid (sp. act. 110MBq/mmol) and 20 μM fatty acid-free bovine serum albumin (BSA; the molecular weight of BSA was assumed to be 60,000). Intracellular lipids were extracted with *n*-hexane/2-propanol (3:2, vol/vol) and separated by thin-layer chromatography (TLC). Radioactivity was scanned on the TLC plates with a Berthold Automatic TLC-Linear Analyzer LB285 (Labor Berthold, Wildbad, Germany) to measure incorporation of labeled oleic acid into cholesteryl esters. Cholesterol and 25-HOC were dissolved in ethanol; staurosporine was dissolved in dimethyl sulfoxide. The final concentration of solvents in the medium was 1%.

Assay of [^{3}H]leucine incorporation into cells during cholesteryl ester formation. Cells grown on 12-well plates were incubated for 3 h with [^{14}C]oleic acid, BSA and [^{3}H]leucine (75 KBq, sp. act. 37 GBq/mmol). After lipids were extracted, the residue was washed twice with cold 5% trichloracetic acid and solubilized in 1 mL of 1 N NaOH. [^{3}H]Leucine incorporated into the cells was determined by liquid scintillation counting of the solution after neutralization. Cycloheximide and actinomycin D were dissolved in DMEM.

Assay of ACAT. Caco-2 cells were grown to confluence in 225-cm^2 flasks (Costar), and treated with 10 μM 25-HOC for 5 h. Microsomes were prepared as 100,000 × *g* pellets from cell homogenates by sequential centrifugation. ACAT activity was measured as described (2). After 5 min preincubation at 37°C, microsomes (40 μg of protein) were incubated with 20 μM [^{14}C]oleoyl-CoA (sp. act. 220 Bq/mmol) and 20 μM BSA for 10 min in 154 mM potassium phosphate buffer (pH 7.4), in a total volume of 500 μL. Lipids were extracted with chloroform/methanol (2:1, vol/vol) and incorporation of radioactivity into cholesteryl esters was determined as described above. Protein was determined by the method of Lowry *et al.* (6) with BSA as the standard.

Statistical analysis. The unpaired Student's *t*-test was used to determine significance.

RESULTS AND DISCUSSION

Figure 1 shows the time course of cholesteryl ester formation in Caco-2 cells. Intracellular cholesteryl [^{14}C]-oleate increased with incubation time and reached the maximum at 5 h. When cells were treated with cholesterol or 25-HOC, cholesteryl [^{14}C]oleate formation increased (Fig. 2). 25-HOC was more potent than cholesterol. When 10 μM 25-HOC was present, the formation of cholesteryl esters was twice that of controls.

As shown in Figure 3, cholesteryl ester formation was stimulated by 120%, while incorporation of [^{3}H]leucine into 5% trichloracetic acid-insoluble material decreased when cells were treated with 25-HOC. Upon addition of cycloheximide or actinomycin D to the culture which had received 25-HOC, the incorporation of [^{3}H]leucine into the cells decreased by 87% or 40%, respectively. However, the stimulation of cholesteryl ester formation was not

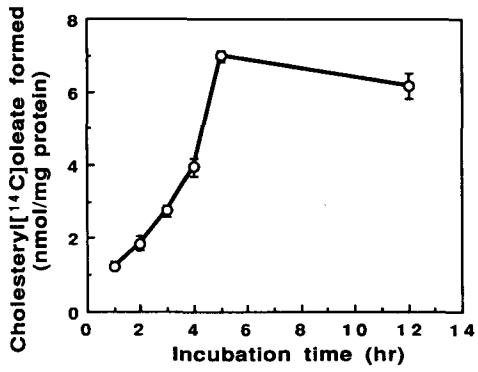

FIG. 1. Intracellular cholesteryl ester formation in Caco-2 as a function of incubation time. Caco-2 cells, grown to confluence in 12-well culture plates, received 1 mL of DMEM containing 100 μM [^{14}C]-oleic acid and 20 μM BSA at 0 h. Lipids were extracted from cells with *n*-hexane/2-propanol and the amount of cholesteryl [^{14}C]oleate was determined after separation on thin-layer plates. The data are the mean and SD from triplicate assays.

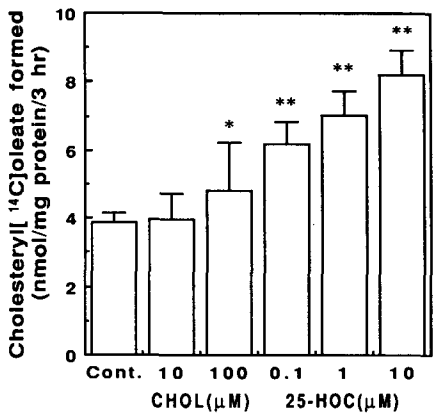

FIG. 2. Effects of exogenous cholesterol (CHOL) and 25-hydroxycholesterol (25-HOC) on cholesteryl ester formation in Caco-2 cells. Cells were treated with the indicated amount of sterols for 2 h. They were then incubated 3 h with [^{14}C]oleic acid and BSA. The data are the mean and SD from triplicate assays, *, $P < 0.05$; **, $P < 0.01$, *vs.* control.

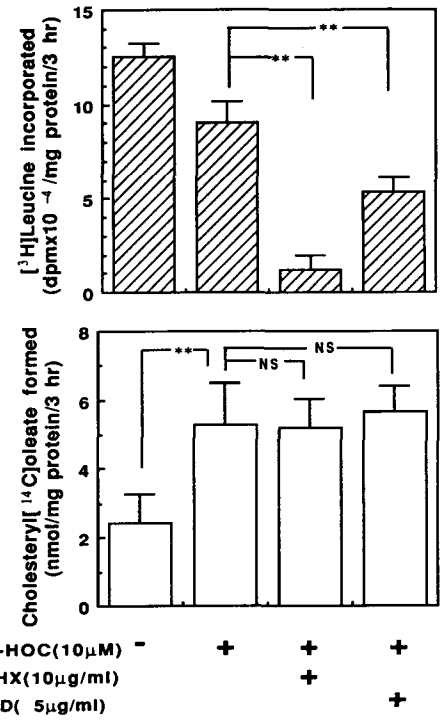

FIG. 3. Effects of cycloheximide (CHX) and actinomycin D (AD) on the stimulation of cholesteryl ester formation by 25-hydroxycholesterol (25-HOC) in Caco-2. Cells were treated with 10 μM 25-HOC plus cycloheximide (10 μg/mL) or actinomycin D (5 μg/mL) for 2 h. They were then incubated for 3 h with [^{14}C]oleic acid, BSA and [^{3}H]leucine. After lipids were extracted, cells were solubilized in 1 mL of 1 N NaOH. [^{3}H]Leucine incorporated in the cells was determined by counting the radioactivity of the solution after neutralization. The data are the mean and SD from triplicate assays, **, $P < 0.01$; NS, not significant.

affected by these inhibitors. This shows that protein synthesis is not required for stimulation of cholesteryl ester formation in Caco-2 cells.

Figure 4 shows the effect of staurosporine, an inhibitor of protein kinases, on the stimulation of cholesteryl ester formation by 25-HOC. The formation of cholesteryl esters was suppressed by staurosporine only when 25-HOC was present. This suggests that protein phosphorylation is involved in the stimulation of cholesteryl ester formation.

The specific activity of ACAT in microsomes prepared from cells treated with 10 μM 25-HOC was 202 $\pm$ 21 pmol cholesteryl [^{14}C]oleate/mg protein/min (n = 5), whereas ACAT activity of controls was 105 $\pm$ 30 pmol cholesteryl [^{14}C]oleate/mg protein/min (n = 5). The difference is statistically significant ($P < 0.01$). ACAT activity in control microsomes was 92 $\pm$ 4 pmol cholesteryl [^{14}C]oleate/mg protein/min (n = 3) and 90 $\pm$ 14 pmol cholesteryl [^{14}C]oleate/mg protein/min (n = 3) when incubated with or without 10 μM 25-HOC for 1 h, respectively. This suggests that ACAT activity would not be enhanced by microsomal enzymes during the incubation with 25-HOC.

It has been reported that ACAT activity in rat liver and intestine can be modulated by phosphorylation/dephosphorylation (7,8). Gavey *et al.* (8) have demonstrated that ACAT can be inactivated by incubation without phosphatase inhibitors and reactivated by incubation with a

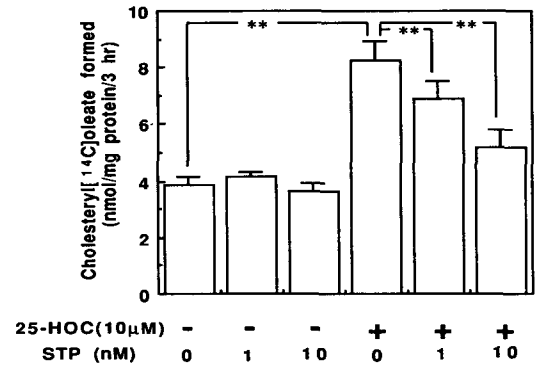

FIG. 4. Effects of staurosporine (STP) on the stimulation of cholesteryl ester formation by 25-hydroxycholesterol (25-HOC). Cells were treated with 10 μM 25-HOC and the indicated amount of staurosporine. The data are the mean and SD from triplicate assays, **, $P < 0.01$.

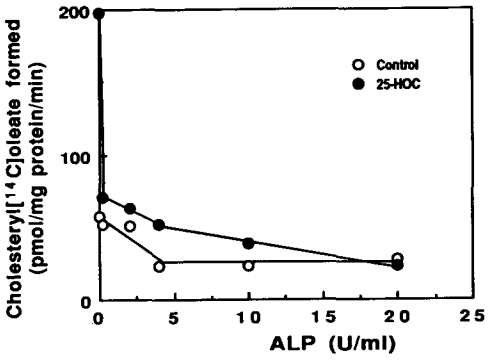

FIG. 6. Inactivation of microsomal ACAT by incubation with exogenous phosphatase. Microsomes (40 μg protein) were preincubated at 37°C for 30 min with the indicated amount of *E. coli* alkaline phosphatase in 154 mM potassium phosphate buffer (pH 7.4), in a total volume of 200 μL, prior to ACAT assay. The data are the average of duplicate determinations.

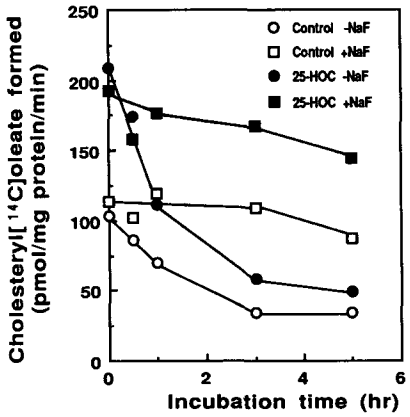

FIG. 5. Inactivation of microsomal ACAT by incubation without sodium fluoride. Microsomes (40 μg protein) were preincubated with or without 100 mM NaF in 100 mM imidazole buffer (pH 7.4) at 37°C for 5 min, in a total volume of 200 μL. Then the ACAT assay was carried out by incubation upon addition of 20 μM [^{14}C]oleoyl-CoA and 20 μM BSA in 154 mM potassium phosphate buffer (pH 7.4) at 37°C for 10 min, in a total volume of 500 μL. The reaction was stopped by addition of 5 mL of chloroform/methanol (2:1, vol/vol). Lipids were extracted and separated on thin-layer plates. The data are the average of duplicate determinations.

partially purified kinase. Figure 5 shows the stability of ACAT activity in Caco-2 microsomes when incubated with or without 100 mM sodium fluoride, a phosphatase inhibitor, at 37°C. ACAT activity in microsomes decreased in the absence of NaF, with the decrease in the microsomes from cells treated with 25-HOC being more notable. The decrease in microsomal ACAT activity was suppressed by NaF. ACAT activity in microsomes was also sensitive to *E. coli* alkaline phosphatase as shown in Figure 6. The activity in microsomes from cells treated with 25-HOC fell to almost the same value as that in microsomes from control cells, when incubated with 20 units/mL of phosphatase for 30 min. These results indicate that ACAT in the cells treated with 25-HOC is more sensitive to endogenous and exogenous phosphatases than ACAT in control cells. This and the data from Figure 3, suggest that formation of cholesteryl esters in Caco-2 cells may be stimulated by 25-HOC through either stimulation of phosphorylation or suppression of dephosphorylation of ACAT; however, phosphorylation of the protein remains to be demonstrated.

Occurrence of a Novel Sterol, 24,25-Methylenecholest-5-en-3β-ol, in *Mortierella alpina* 1S-4

Sakayu Shimizu*, **Hiroshi Kawashima**[1], **Masaru Wada** and **Hideaki Yamada**
Department of Agricultural Chemistry, Kyoto University, Kyoto 606, Japan

24,25-Methylenecholest-5-en-3β-ol, which has not been reported previously to exist in nature, was isolated from mycelia of an arachidonic acid-producing fungus, *Mortierella alpina* 1S-4. Desmosterol, ergosta-5,24(25)-dien-3β-ol and ergosta-5,25-dien-3β-ol were also found in the fungus, but ergosterol and cholesterol were not detected.
***Lipids* 27, 481–483 (1992).**

Sterols with a cyclopropane (or cyclopropene) ring have been reported to exist in sponges or coelenterates, *i.e.*, gorgosterol (5) (1–3), 23-demethylgorgosterol (6) (4), calysterol (7) (5), papakusterol (8) (6), and petrosterol (9) (7,8). They are all contained in marine lower organisms. On the other hand, many of 24-methylsterols are found in plants and fungi (9).

During the course of our studies on the lipid metabolism in an arachidonic acid-producing zygomycetous fungus, *Mortierella alpina* 1S-4, (10–20), we found that the fungus produces a novel sterol with a cyclopropane ring, 24,25-methylenecholest-5-en-3β-ol (4) besides desmosterol (1) and 24-methylsterols, *i.e.*, ergosta-5,25-dien-3β-ol (2) and ergosta-5,24(25)-dien-3β-ol (3). To our knowledge, the occurrence of such a cyclopropane sterol in nature has not been reported. We reported here the isolation and identification of sterol 4 from the fungal mycelia.

MATERIALS AND METHODS

Chemicals. Desmosterol was purchased from Sigma Chemical Co. (St. Louis, MO). Cholesterol and ergosterol were purchased from Wako Pure Chemicals (Osaka, Japan). All other chemicals used in this work were of analytical grade and commercially available.

Microorganism, medium and cultivation. Mortierella alpina 1S-4 (AKU 3998; Faculty of Agriculture, Kyoto University, Kyoto, Japan) (10,17) was used. The fungus was cultivated in a medium (20 mL, pH 6.0) containing 2% glucose and 1% yeast extract in a 100-mL flask for 6–8 days at 28°C with reciprocal shaking (120 strokes/min).

Extraction and analysis of sterols. Fungal mycelia obtained on suction filtration were washed with water and then dried at 100°C for 2 h. Fifty mg of dried mycelia was incubated with 5 mL of 33% KOH/methanol (1:4, vol/vol) at 70°C for 1 h. After extraction with 10 mL of *n*-hexane, followed by evaporation, the unsaponifiable fraction was analyzed by gas-liquid chromatography (GLC) or high-performance liquid chromatography (HPLC). The analytical conditions were as follows. GLC: apparatus, GC-7A (Shimadzu, Kyoto, Japan) equipped with a flame ionization detector; column, ULBON HR-1 (0.25 mm × 25 m) (Shinwakakou, Kyoto, Japan); column temperature, 280°C; injection port temperature, 300°C; carrier gas, He (2 mL/min); make-up gas, N_2 (60 mL/min); split ratio, 30:1. HPLC: pump, LC-6A (Shimadzu); column, A-302 (S-5 120A ODS) (Yamamura Chemical Lab., Kyoto, Japan); detector, SPD-6A (Shimadzu); wave length, 210 nm; mobile phase, acetonitrile/methanol/water (19:19:2, vol/vol/vol); flow rate, 1.5 mL/min; column temperature, 35°C. Cholesterol was used as an internal standard for both GLC and HPLC analyses.

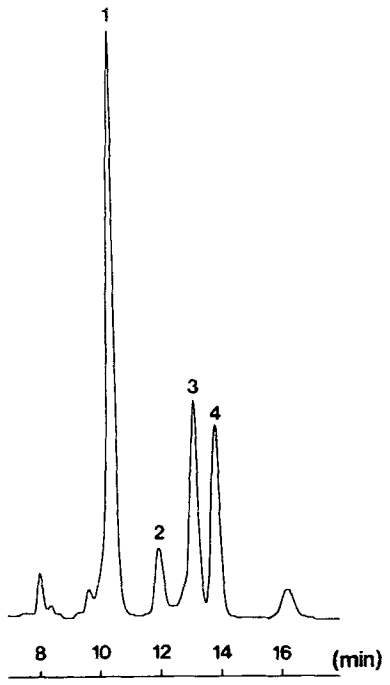

FIG. 1. HPLC chromatogram of the unsaponifiable fraction of mycelia of *Mortierella alpina* 1S-4.

Determination of the structure of the isolated sterols. Each mycelial sterol was isolated by HPLC using the conditions described above except for the following: column, Cosmosil 5C18 (10 × 250 mm, Nakalai Tesque, Kyoto, Japan); mobile phase, acetonitrile/methanol (1:1, vol/vol); and flow rate, 3.5 mL/min. Mass spectra of the isolated sterols were measured with Hitachi (Tokyo, Japan) MK-80 instrument (ionization potential, 70 eV). ^1H Nuclear magnetic resonance (NMR) spectra were recorded in $CDCl_3$ on a Nicolet (Fermont, CA) NT-360 (360 MHz) with tetramethylsilane as an internal standard.

RESULTS AND DISCUSSION

The nonsaponifiable fraction obtained from mycelia of *Mortierella alpina* 1S-4 was analyzed by HPLC and GLC. Four major peaks were detected by HPLC analysis (Fig. 1). They all were different from the common fungal sterols,

ergosterol and cholesterol. Four sterols (1–2 mg each) were isolated by HPLC on a reversed phase column and examined by mass spectrometry (MS) and ^{1}H NMR analyses (Table 1). The ^{1}H NMR spectrum of the C_{27} sterol (1) indicates Δ^5 and Δ^{24} double bonds and is shown to be identical with that of authentic desmosterol (cholesta-5,24-dien-3β-ol) (Fig. 2). Compounds 2 and 3 were determined to be C_{28} sterols with two double bonds, *i.e.*, ergosta-5,25-dien-3β-ol and ergosta-5,24(25)-dien-3β-ol, respectively. The ^{1}H NMR spectrum of compound 4 showed signals at δ −0.16 and 0.37 ppm (Table 1), indicating that this compound contains a cyclopropane ring. The data in Table 1 suggest that compound 4 is 24,25-methylenecholest-5-en-3β-ol; the data are identical with those of the synthetic compound prepared by addition of dichlorocarbene to desmosterol, followed by metal reduction (21,22). This is the first report on the existence of compound 4 in nature and of the occurrence of a sterol with a cyclopropane ring in a fungus. The sterols with a cyclopropane (or cyclopropene) ring reported previously are different from compound 4 in regard to the location of the cyclopropane (or cyclopropene) ring, *i.e.*, 22,23-cyclo- (gorgosterol (5) and 23-demethylgorgosterol (6)), 23,24-cyclo- (calysterol (7)), 24,26-cyclo- (papakusterol (8)) or 26,27-cyclo-structure (petrosterol (9)). The biosynthetic route to 24-methylsterols involving *S*-adenosylmethionine has previously been elucidated (9), but the synthesis of compound 4 is still unclear.

LETTER TO THE EDITOR

Comments on Essential Fatty Acid Deficient Rats Fed Hydrogenated Oil

Dear Sir:

In their recent paper, Holman *et al.* (1) reported that partially hydrogenated soybean oil (PHSBO) induced the formation of measurable amounts of unusual polyunsaturated fatty acids (PUFA) in rat liver phospholipids in a manner similar to a parallel experiment where fully hydrogenated coconut oil was fed to cause an essential fatty acid deficiency (EFAD). We have reviewed this publication, conferred with the two senior authors (1), and retrieved the compositional data on the particular type of PHSBO which was used in this study that industry had prepared for the Holman group. This letter seeks to clarify and explain the results obtained by Holman *et al.* (1).

First, it must be noted that no data were presented in the paper as to the fatty acid compositions of the fats employed (1). This unfortunately precludes replication of the experiments or direct analysis of the results. However, in private conversations, both H. J. Dutton and R. T. Holman confirmed that their PHSBO treatment group received only the PHSBO supplied by industry. No supplemental essential fatty acid (EFA) was added to this diet. Industry records (Kuss, G., private communication) show that the PHSBO samples used in this study contained a high *trans* isomer level (45–48% of total fatty acids) with essentially no linoleic acid (0–0.8% of total fatty acids). This level of linoleic acid in the diet (est. 0–0.08%) is, at best, well below the 0.6% recommended by the National Research Council (NRC) for EFA adequacy in the rat (2). Thus, although the authors noted (1) "... the PHSO contained sufficient linoleic acid ... to prevent dermatitis of EFAD," the rats in question certainly did not have adequate EFA in their diets based on industry analyses and NRC recommendations. Furthermore, examination of the data in Table 1 (1) reveals that both the EFAD and PHSBO diets produced 20:3/20:4 ratios of 2.8 and 1.3, respectively, in liver phospholipids; these are far in excess of the 0.4 maximum first described by Holman in 1960 (3) as the upper limit of EFA adequacy. Ratios in excess of 0.4 are indicative of EFAD. Based on all of these facts and the similarities of the results obtained in the two experimental diets, we believe the data reported resulted from EFAD in both groups of rats and that a so-called "isomeric" effect with the PHSBO has not been demonstrated.

A similar PHSBO was used by Kummerow *et al.* (4,5) in feeding studies on swine which led to severe aortic atherosclerosis in pigs fed only the PHSBO as their dietary fat. However, later repetition (6,7) of these studies in which adequate EFA was provided revealed no significant atherosclerosis in the swine fed the PHSBO. In addition, Zevenbergen *et al.* (8) conducted a study, not cited by Holman *et al.* (1), which was similar to Holman *et al.*'s (1) study in that rats were fed a PHSBO diet with limited amounts of EFA. Importantly, Zevenbergen *et al.* (8) demonstrated that supplementation of the PHSBO diet with 2 energy percent of linoleic acid prevented undesirable effects on mitochondrial function and tissue lipid polyunsaturated fatty acid composition associated with high amounts of *trans* fatty acids in the diets with limited EFA.

Finally, we believe that Holman *et al.*'s (1) concern that "large-scale hydrogenation of vegetable oils ... (induces) significant partial deficiencies of EFA" is completely unwarranted. The NRC's Food and Nutrition Board (9) has concluded that EFAD is simply not a health problem for the average adult in the U.S. because the "minimally adequate intake of linoleic acid ... (3 to 6 g/day) ... is more than met by diets in the United States. ..."

In spite of the great significance for humans that was attributed to these data (1), we believe that these conclusions are without basis in fact and that repetition of the experiments with added EFA will reveal that there is no significant "isomeric" effect. Further, as we (10,11) and the NRC (12) have emphasized, the findings of the Federation of American Societies for Experimental Biology (FASEB) committee (13) are still valid, and there is no hazard associated with the typical intake of hydrogenated fats in U.S. diets (11,14) where adequate EFA is present.

Essential Fatty Acid Deficient Rats Fed Hydrogenated Oil —A Response

Dear Sir:

Our recent report, that ingestion of partially hydrogenated soybean oil (PHSO) is accompanied by unusual isomeric polyunsaturated fatty acids (PUFA) in the livers of rats (1), has prompted T. H. Applewhite and J. E. Hunter to respond in the preceding Letter to the Editor of this journal. They believe that the data we reported "resulted from EFAD in both groups of rats and that a so-called 'isomeric' effect with PHSO has not been demonstrated."

The PHSO furnished to us by industry for these studies contained 45 to 48% *trans* unsaturated acids but a maximum of 0.8% *cis,cis*-linoleic acid by their analyses. Our attempt to measure the linoleic acid content of the 18:2 fraction from the PHSO sample failed because the complexity of the mixture exceeded the limits of our method. Accepting their analysis, 10% of PHSO in the diet could thus have provided no more than 0.08% of linoleic acid in the diet, or approximately 0.16% of calories. This, indeed, was well below the 0.6% of calories recommended by the National Research Council (NRC) committee.

The purpose of our study was to detect, identify and measure the individual 18:2 isomers in liver lipids of rats in two models of essential fatty acid deficiency (EFAD) known or suspected to develop elevated levels of unusual isomers of 18:2, and to compare them with controls receiving adequate linoleic acid. Our results indicate that, indeed, unusual positional isomers of 18:2, 20:2, 20:3 and 20:4 can and do occur in the liver of rats made essential fatty acid (EFA) deficient by low EFA and high saturated fat or high levels of unusual isomers of 18:1.

The major difference between the diet groups was that EFAD rats received high levels of 12- to 16-carbon saturated fatty acids, whereas the PHSO group received high levels of positionally isomeric *cis* and *trans* 18:1 fatty acids. The 45–48% of *trans* isomers measured by the donor of the sample must have been accompanied by 22.5 to 24% of *cis*-positional isomers as well, for hydrogenation yields an equilibrium mixture of about 2 parts *trans* to 1 part *cis*. Total *cis*- and *trans*-18:1 positional isomers comprised two-thirds of the dietary fatty acids, and both groups of isomers are substrates for liver microsomal desaturases (2).

The two models *did not* induce the same pattern of positional isomers of 18:2 and 20:2 in liver phospholipids despite their common feature of low or deficient levels of linoleic acid. The saturated fat diet used to induce EFA deficiency produced several endogenously synthesizable 18:2 and 20:2 isomers which were identified. The PHSO diet, containing 6.75 to 7.2% of isomeric 18:1 acids, induced some of the same 18:2 and 20:2 isomers, but *additional isomers also appeared* which were not found in simple EFA deficiency. Isomeric 18:1, and perhaps isomeric 18:2, provided by PHSO are the most plausible precursors of some of the isomers of 18:2 and 20:2 peculiar to PHSO-fed rat liver (2).

Both saturated fatty acids (EFAD diet) and positionally isomeric 18:1 (PHSO diet) suppressed the content of essential arachidonic acid in the liver phospholipids (PL), indicating impairment of EFA metabolism, as had been reported previously for rats fed low EFA and high isomeric 18:1 (3,4).

Positionally isomeric 18:1 present in dietary, partially hydrogenated fat interfere with the normal metabolism of polyunsaturated fatty acids (PUFA) by providing alternative substrates for desaturation and elongation, the products of which compete with naturally-occurring PUFA at several steps in the metabolic cascade. This effect becomes pronounced when the diet contains an inadequate level of linoleic acid. We are fully aware that the products of positional isomers of 18:1, as well as the products from oleic acid, are suppressed by increase of dietary linoleic acid, a preferred substrate (5). The proportions of competing substrates and their affinities for the enzymes govern the proportions of the products, and, in our opinion, even when linoleic acid is "adequate" by committee standards, unusual isomers of PUFA can be produced from unusual isomers of 18:1. Our point is that unusual isomers of PUFA become measureable when EFA intake is low.

In quoting our statement that "Large-scale hydrogenation of vegetable oils . . . (induces) significant partial deficiencies of EFA," Applewhite and Hunter did not include the main point of our concern: Linolenic acid, now known to be an essential fatty acid, is abundant in natural soybean oil but is severely diminished in hydrogenated products. The remainder of our statement was: "It would seem wise to preserve the essential nutrients and to avoid producing inhibitors of their metabolism by hydrogenation. Evidence is growing for the essentiality of ω3 PUFA and the occurrence of deficiencies of ω3 acids in humans under stress conditions (ref. 6 here). It would therefore, be wise economy to use oils containing linolenic acid directly as foods and to avoid their hydrogenation."

ARTICLE

Linoleic Acid Metabolism in the Red Alga *Lithothamnion corallioides*: Biosynthesis of 11*(R)*-Hydroxy-9*(Z)*,12*(Z)*-octadecadienoic Acid

Mats Hamberg[a,*], **William H. Gerwick**[b] and **Per Arvid Åsen**[c]

[a]Department of Physiological Chemistry, Karolinska Institutet, S-104 01 Stockholm, Sweden, [b]College of Pharmacy, Oregon State University, Corvallis, Oregon 97331 and [c]Department of Botany, Kristiansand Museum, N-4602 Kristiansand, Norway

Incubation of [1-^{14}C]linoleic acid with an enzyme preparation obtained from the red alga *Lithothamnion corallioides* CROUAN resulted in the formation of 11-hydroxy-9*(Z)*,12*(Z)*-octadecadienoic acid as well as smaller amounts of 9-hydroxy-10*(E)*,12*(Z)*-octadecadienoic acid, 13-hydroxy-9*(Z)*,11*(E)*-octadecadienoic acid and 11-keto-9*(Z)*,12*(Z)*-octadecadienoic acid. Steric analysis showed that the 11-hydroxyoctadecadienoic acid had the *(R)* configuration. The 9- and 13-hydroxyoctadecadienoic acids were not optically pure, but were due to mixtures of 75% *(R)* and 25% *(S)* enantiomers (9-hydroxyoctadecadienoate), and 24% *(R)* and 76% *(S)* enantiomers (13-hydroxyoctadecadienoate). 11-Hydroxyoctadecadienoic acid was unstable at acidic pH. In acidified water, equal parts of 9*(R,S)*-hydroxy-10*(E)*,12*(Z)*-octadecadienoate and 13*(R,S)*-hydroxy-9*(Z)*,11*(E)*-octadecadienoate, plus smaller amounts of the corresponding *(E),(E)* isomers were produced. In aprotic solvents, acid treatment resulted in dehydration and in the formation of equal amounts of 8,10,12- and 9,11,13-octadecatrienoates. The enzymatic conversion of linoleic acid into the hydroxyoctadecadienoic acids and the ketooctadecadienoic acid was oxygen-dependent; however, inhibitor experiments indicated that neither lipoxygenase nor cytochrome P-450 were involved in the conversion. This conclusion was supported by experiments with $^{18}O_2$ and $H_2{}^{18}O$, which demonstrated that the hydroxyl oxygen of the hydroxyoctadecadienoic acids and the keto oxygen of the 11-ketooctadecadienoic acid were derived from water and not from molecular oxygen.

Lipids 27, 487–493 (1992).

Studies carried out during the last years have documented the importance of lipoxygenases in the metabolism of polyunsaturated fatty acids in marine algae (for a review, see ref. 2). The majority of oxylipins thus produced are formed by sequences that involve arachidonic acid 12-lipoxygenase in the initial step. An example of this is the conversion of arachidonic acid into 12*(R)*,13*(S)*-dihydroxy-5*(Z)*,8*(Z)*,10*(E)*,14*(Z)*-eicosatetraenoic acid (12*(R)*,13*(S)*-diHETE) (3), a transformation that occurs by initial lipoxygenase-catalyzed oxygenation of arachidonic acid into 12*(S)*-hydroperoxy-5*(Z)*,8*(Z)*,10*(E)*,14*(Z)*-eicosatetraenoic acid (12*(S)*-HPETE), followed by hydroperoxide isomerase-catalyzed conversion of the hydroperoxide into the diol fatty acid (1).

Guerriero *et al.* (4) recently isolated the ethyl esters of an array of oxylipins from the calcareous red algae *Lithothamnion corallioides* and *Lithothamnion calcareum.* Apart from the previously known esters of 5-, 11-, 12- and 15-hydroxyeicosatetraenoic acids (5-, 11-, 12- and 15-HETE), three new esters oxygenated at C-13 were obtained, *i.e.,* ethyl 13-hydroxy-5*(Z)*,8*(Z)*,11*(Z)*,14*(Z)*-eicosatetraenoate, ethyl 13-hydroxy-5*(Z)*,8*(Z)*,11*(Z)*,14*(Z)*,17*(Z)*-eicosapentaenoate and ethyl 8-hydroxy-13-keto-5*(Z)*,9*(E)*,11*(E)*,14*(E)*-eicosatetraenoate. The unusual structures of the three latter compounds prompted an investigation of the metabolism of ^{14}C-labeled polyunsaturated fatty acids in *Lithothamnion.* The present work is concerned with transformations of [^{14}C]linoleic acid in the presence of an enzyme preparation of *Lithothamnion corallioides* and with the reaction mechanism.

EXPERIMENTAL PROCEDURES

Linoleic acid was purchased from NuChek Prep, Inc. (Elysian, MN). [1-^{14}C]Linoleic acid was obtained from Amersham Laboratories (Amersham, U.K.) and added to the unlabeled acid to provide a specimen having a specific radioactivity of 5.3 kBq/μmol. 9*(R,S)*-HOD, 9*(R,S)*-hydroxy-10*(E)*,12*(E)*-octadecadienoic acid, 13*(R,S)*-HOD and 13*(R,S)*-hydroxy-9*(E)*,11*(E)*-octadecadienoic acid were prepared by treatment of the corresponding hydroperoxides (5) with sodium borohydride. Methyl 11-hydroxy-12-octadecenoate was obtained by deoxygenation of methyl 11-hydroxy-12,13-epoxyoctadecanoate (Hamberg, M., unpublished data). [9,10,12,13-$^2H_4$]Linoleic acid was prepared by partial deuteriation of 9,12-octadecadiynoic acid as described previously (6). The isotopic composition of the sample was 93% tetradeuteriated and 7% trideuteriated molecules. $^{18}O_2$ (97–98%) was obtained from Cambridge Isotope Laboratories (Woburn, MA) and $H_2{}^{18}O$ (98.7 atom%) was purchased from Isotec, Inc. (Miamisburg, OH).

Enzyme preparation. The red alga *Lithothamnion corallioides* CROUAN was collected at 10–15 m depth in a semi-exposed sound on the Southern coast of Norway in June, 1991, and kept at −77°C. Batches of about 90 g of frozen algae were crushed and ground in a mortar with liquid nitrogen. The coarse powder (85 g) was added to 0.09 M potassium phosphate buffer, pH 7.4 (85 mL), and homogenized at 0°C with an Ultra-Turrax (Janke and Kunkel, Staufen, Germany). The homogenate was centrifuged at 9,300 × *g* for 15 min and the resulting supernatant was further centrifuged at 105,000 × *g* for 60 min.

Abbreviations: ETYA, 5,8,11,14-eicosatetraynoic acid; GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; 12*(R)*,13*(S)*-diHETE, 12*(R)*,13*(S)*-dihydroxy-5*(Z)*,8*(Z)*,10*(E)*,14*(Z)*-eicosatetraenoic acid; 5-HETE, 5-hydroxy-6*(E)*,8*(Z)*,11*(Z)*,14*(Z)*-eicosatetraenoic acid; 11-HETE, 11-hydroxy-5*(Z)*,8*(Z)*,12*(E)*,14*(Z)*-eicosatetraenoic acid; 12-HETE, 12-hydroxy-5*(Z)*,8*(Z)*,10*(E)*,14*(Z)*-eicosatetraenoic acid; 15-HETE, 15-hydroxy-5*(Z)*,8*(Z)*,11*(Z)*,13*(E)*-eicosatetraenoic acid; 9-HOD, 9-hydroxy-10*(E)*,12*(Z)*-octadecadienoic acid; 13-HOD, 13-hydroxy-9*(Z)*,11*(E)*-octadecadienoic acid; 12*(S)*-HPETE, 12*(S)*-hydroperoxy-5*(Z)*,8*(Z)*,10*(E)*,14*(Z)*-eicosatetraenoic acid; MC, (−)-menthoxycarbonyl; Me_3Si, trimethylsilyl; NDGA, nordihydroguaiaretic acid; TLC, thin-layer chromatography. The term "oxylipin" was introduced recently (ref. 1) as an encompassing term for oxygenated compounds which are formed from fatty acids by reaction(s) involving at least one step of mono- or dioxygenase-catalyzed oxygenation.

Ammonium sulfate fractionation carried out with the high speed supernatant provided precipitates obtained at 0-30%, 30-55% and 55-80% saturation. The 30-55% precipitate, which contained more than 90% of the linoleic acid oxidizing activity, was dissolved in potassium phosphate buffer and used as the enzyme source. The protein concentration (7) was 2 mg/mL. If desired, the 30-55% ammonium sulfate precipitate could be stored at −30°C for several weeks without loss of activity.

Incubations and treatments. [1-^{14}C]Linoleic acid (300 μM) was stirred with enzyme preparation at 22°C for the times indicated. Five volumes of methanol were added and the mixture diluted with water, acidified to pH 4, and rapidly extracted with two portions of diethyl ether. The combined ether phases were washed until neutral reaction and dried over magnesium sulfate. The product obtained after evaporation of the ether was esterified by treatment with diazomethane and subjected to thin-layer radiochromatography. Recovery of radioactivity from added labeled substrate was 90-95%.

Chemical methods. Hydrogenation was carried out with palladium on calcium carbonate as the catalyst (8). Preparation of (−)-menthoxycarbonyl (MC) derivatives and procedures for oxidative ozonolysis and steric analysis of MC derivatives by gas-liquid chromatography (GLC) were performed as described (9,10).

Chromatographic and instrumental methods. Thin-layer chromatography (TLC) was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck (Darmstadt, Germany). The solvent systems consisted of mixtures of ethyl acetate/hexane in the proportions indicated. Thin-layer argentation chromatography was performed with plates coated with Silica gel G/$AgNO_3$ (9:1, w/w) and a solvent system consisting of ethyl acetate/hexane (25:75, vol/vol). Radioactivity on TLC plates was determined with a Berthold Dünnschichtscanner II (Wildbad, Germany) interfaced with a Macintosh SE/30 PC. GLC was carried out with a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm). Gas chromatography/mass spectrometry (GC/MS) was performed with a Hewlett-Packard Model 5970B mass selective detector connected to a Hewlett-Packard Model 5890 gas chromatograph. Ultraviolet spectroscopy was carried out with a Hewlett-Packard Model 8450A diode array spectrophotometer, and infrared spectra were obtained with a Perkin-Elmer (Überlingen, Germany) model 257 infrared spectrrophotometer. Radioactivity was measured with a Packard (Downers Grove, IL) Tri-Carb Model 4450 liquid scintillation counter.

RESULTS

Isolation of products formed from linoleic acid. Figure 1A shows a thin-layer radiochromatogram of the esterified product obtained following incubation of 300 μM [1-^{14}C]-linoleic acid with the enzyme preparation at 22°C for 20 min. The reaction product consisted of three compounds (Compounds A_1, A_2 and A_3) having a polarity typical for hydroxyoctadecadienoates, as well as a fourth compound (Compound B; $R_f = 0.52$), which migrated like a ketooctadecadienoate. Compound B was directly obtained in a purity which was satisfactory for structural analysis. In order to obtain Compounds A_1-A_3 in pure form, a broad

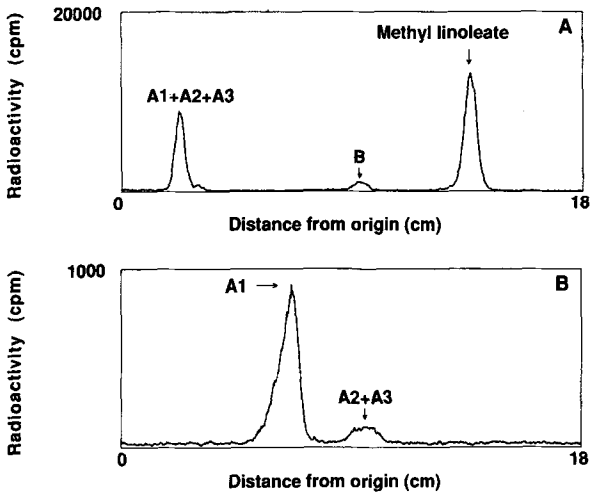

FIG. 1. A: Thin-layer radiochromatogram of esterified product obtained following incubation of [1-^{14}C]linoleic acid (300 μM) with enzyme preparation (2 mL) at 22°C for 20 min. Solvent system, ethyl acetate/hexane (1:9, vol/vol). B: Thin-layer argentation radiochromatogram of material present in zone of compounds $A_1 + A_2 + A_3$ in A. Solvent system, ethyl acetate/hexane (25:75, vol/vol).

zone of silica gel containing these compounds was scraped off and the material subjected to thin-layer argentation chromatography. As seen in Figure 1B, this resulted in separation of a major hydroxyoctadecadienoate (Compound A_1; $R_f = 0.37$) from two minor hydroxyoctadecadienoates (Compounds A_2 and A_3). The two latter compounds were separated on plain silica gel using a solvent system of ethyl acetate/hexane (2:8, vol/vol; Compound A_2, $R_f = 0.39$; Compound A_3, $R_f = 0.44$).

Structure of Compound A_1. Compound A_1 accounted for 71% of the reaction product formed from linoleic acid. The UV spectrum of Compound A_1 did not show any specific absorption band in the region 200-320 nm, demonstrating the absence of a conjugated diene structure. Infrared spectroscopy showed absorption bands at *inter alia* 3350-3620 cm^{-1} (hydroxyl) and 1735 cm^{-1} (ester carbonyl). No band was observed in the region 950-1000 cm^{-1}, thus excluding the presence of *(E)* double bond(s). Analysis of the Me_3Si derivative of Compound A_1 by GC/MS showed a single peak having a C-value of 19.41. The mass spectrum (Fig. 2) showed prominent ions at *inter alia m/e* 382 (M, 38%), 311 [M − 71; loss of $\cdot(CH_2)_4$-CH_3, 32], and 225 ([CH=CH-CH($OSiMe_3$)-CH=CH-$(CH_2)_4$-CH_3]$^+$, 44). The spectrum was similar to those of the Me_3Si derivatives of the methyl esters of 9- and 13-hydroxyoctadecadienoic acids (9- and 13-HOD). Catalytic hydrogenation performed on Compound A_1 provided methyl 11-hydroxy-stearate as judged by GC/MS analysis of the Me_3Si derivative. Prominent ions appeared at *m/e* 371 (M − 15; loss of $\cdot CH_3$, 4%), 339 [M − (15 + 32), 19], 287 [Me_3SiO^+=CH-$(CH_2)_9$-$COOCH_3$, 100], and 201 [Me_3SiO^+=CH-$(CH_2)_6$-CH_3, 71].

The data mentioned indicated that Compound A_1 was a methyl octadecadienoate having a hydroxyl group at C-11. In order to determine the absolute configuration of C-11 and the positions of the double bonds, a sample of Compound A_1 (250 μg) was stirred with palladium on calcium carbonate (5 mg) in ethyl acetate (3 mL) under

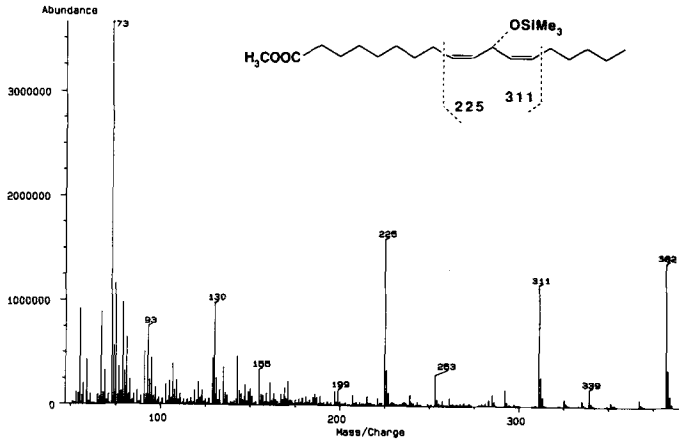

FIG. 2. Mass spectrum of the Me_3Si derivative of methyl 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate (Compound A_1).

hydrogen gas for 3 min. The partially hydrogenated product obtained was a mixture of 11-hydroxystearate, two isomeric 11-hydroxyoctadecenoates, and unreacted methyl 11-hydroxyoctadecadienoate as judged by GC/MS analysis. Oxidative ozonolysis performed on the MC derivatives yielded methyl hydrogen azelate (from methyl 11-hydroxy-9,12-octadecadienoate and methyl 11-hydroxy-9-octadecenoate), the MC derivative of 2*(R)*-hydroxynonanoic acid (from methyl 11-hydroxy-9-octadecenoate), as well as the MC derivative of methyl hydrogen 2*(S)*-hydroxy-1,12-dodecanedioate (from methyl 11-hydroxy-12-octadecenoate). On the basis of the results obtained, Compound A_1 was assigned the structure of methyl 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate.

Structures of Compounds A_2 and A_3. Compounds A_2 and A_3 each accounted for 5% of the product formed from linoleic acid. The UV spectra of the two compounds showed a strong absorption band at 234 nm (solvent, methanol; $\varepsilon = 26{,}000$), indicating the presence of a conjugated diene structure. The C-value of the Me_3Si derivatives found on GLC analysis of Compounds A_2 and A_3 was 19.81 [references, Me_3Si derivatives of the methyl esters of 9-HOD (C-19.81), 13-HOD (C-19.81), 9-hydroxy-10*(E)*,12*(E)*-octadecadienoic acid (C-20.20), and of 13-hydroxy-9*(E)*,11*(E)*-octadecadienoic acid (C-20.36)]. The mass spectra of the Me_3Si derivative of Compounds A_2 and A_3 were identical with those of the corresponding derivatives of the methyl esters of 9- and 13-HOD, respectively. Prominent ions were observed at *m/e* 382 (M), 311 [M − 71; loss of $\cdot(CH_2)_4$-CH_3] and 225 {due to the ion Me_3SiO^+=CH-$(CH{=}CH)_2$-$(CH_2)_4$-CH_3 in the spectrum of the derivative of 9-HOD, due to the ion [$(CH{=}CH)_2$-$CH(OSiMe_3)$-$(CH_2)_4$-CH_3]$^+$ in the spectrum of the derivative of 13-HOD}. The fragmentation patterns of the derivatives of 9- and 13-HOD were similar; however, the intensity of the *m/e* 225 ion was greater than that of the *m/e* 311 ion in the spectrum of the derivative of 9-HOD, whereas the reverse was true in the spectrum of the derivative of 13-HOD. Catalytic hydrogenation of Compounds A_2 and A_3 produced methyl 9- and 13-hydroxystearates, respectively, as demonstrated by GC/MS. Oxidative ozonolysis performed on the MC derivative of Compound A_2 yielded the MC derivative of methyl hydrogen 2-hydroxysebacate [*(R)/(S)*, 75:25], while the same treatment of the MC derivative of Compound A_3 afforded methyl hydrogen azelate plus the MC derivative of 2-hydroxyheptanoic acid [*(R),(S)*, 24:76]. Thus, Compound A_2 was methyl 9-hydroxy-10*(E)*,12*(Z)*-octadecadienoate [75% of the *(R)* enantiomer], whereas Compound A_3 was identical to methyl 13-hydroxy-9*(Z)*,11*(E)*-octadecadienoate [76% of the *(S)* enantiomer].

Structure of Compound B. Compound B accounted for 13% of the reaction product formed from linoleic acid. The UV spectrum showed a strong absorption band at 255 nm (solvent, methanol; $\varepsilon = 17{,}000$). Mass spectrometric analysis of Compound B showed a molecular ion at *m/e* 308 (6%), as well as high intensity ions at *m/e* 277 (M − 31; loss of $\cdot OCH_3$, 6), 211 [M − 97; loss of $\cdot$CH=CH-$(CH_2)_4$-CH_3, 16], 183 [M − 125; loss of $\cdot$CO-CH=CH-$(CH_2)_4$-CH_3, 16], 151 {[CH=CH-CO-CH=CH-$(CH_2)_4$-CH_3]$^+$, 42}, and 125 [O^+≡C-CH=CH-$(CH_2)_4$-CH_3, 36]. Catalytic hydrogenation of Compound B yielded methyl 11-ketostearate as judged by GC/MS. The data mentioned indicated that Compound B was a methyl 11-ketooctadecadienoate. The ultraviolet spectroscopic data further suggested that the two double bonds were not present as a conjugated diene, but were part of a 3-keto-1,4-pentadiene structure.

Proof for the location and geometry of the double bonds was obtained by an experiment in which the products formed from Compound B upon sodium borohydride reduction were analyzed. Thus, Compound B (240 μg) was treated with $NaBH_4$ (30 mg) in methanol (3 mL) at 22°C for 30 min. Analysis by TLC showed two bands of similar intensity. The more polar material was identified as methyl 11-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate by GC/MS using the authentic compound as reference. The less polar material was due to a 1:1 mixture of methyl 11-hydroxy-9-octadecenoate (C-value of Me_3Si derivative, 19.54; prominent ions at *m/e* 369 (M − 15; loss of $\cdot CH_3$, 1%), 337 [M − (15 + 32), 4] and 285 [Me_3SiO^+=CH-CH=CH-$(CH_2)_7$-$COOCH_3$), 100]) and methyl 11-hydroxy-12-octadecenoate (C-value of Me_3Si derivative, 19.65; prominent ions at *m/e* 369 (M − 15; loss of $\cdot CH_3$, 2%), 337 [M − (15 + 32), 5], and 199 [Me_3SiO^+=CH-CH=CH-$(CH_2)_4$-CH_3, 100; mass spectrum identical with that of the Me_3Si derivative of the authentic compound]. The positions of the hydroxyl group and of the double bond in the two hydroxyoctadecenoates were established by oxidative ozonolysis performed on the MC derivatives. This treatment afforded methyl hydrogen azelate and the MC derivative of 2*(R,S)*-hydroxynonanoic acid (from the MC derivative of methyl 11-hydroxy-9-octadecenoate) and the MC derivative of methyl hydrogen 2*(R,S)*-hydroxy-1,12-dodecanedioate (from the MC derivative of methyl 11-hydroxy-12-octadecenoate). On the basis of the data presented, Compound B was assigned the structure methyl 11-keto-9*(Z)*,12*(Z)*-octadecadienoate.

Acid-induced conversions of methyl 11(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate.* A solution of methyl 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate (250 μg) in dimethoxyethane (5 mL) was treated with water (10 mL) and 2 M HCl (0.1 mL) at 22°C for 15 min. Analysis of the product by TLC and GC/MS demonstrated complete conversion of the methyl 11-hydroxyoctadecadienoate into four isomeric hydroxyoctadecadienoates. These compounds were identified, using the authentic materials as references, as the methyl esters of 9-HOD (43%), 13-HOD (43%),

9-hydroxy-10*(E)*,12*(E)*-octadecadienoic acid (7%) and 13-hydroxy-9*(E)*,11*(E)*-octadecadienoic acid (7%). The four hydroxyoctadecadienoates were racemic as shown by oxidative ozonolysis performed on the MC derivatives, which produced the MC derivatives of methyl hydrogen 2*(R,S)*-hydroxysebacate and 2*(R,S)*-hydroxyheptanoic acid.

In another experiment, methyl 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate (27 μg) in methanol (3 mL) was treated with 2 M HCl (2 μL) at 23°C. This treatment was accompanied by the appearance of a UV absorption band with λ_{max} = 234 nm (ε = 27,000). As shown in Figure 3, appearance of the absorption band was rapid. Disappearance of the 11-hydroxyoctadecadienoate in the acidified methanol solution followed first order kinetics with a half-life time of 32 s. The products formed were analyzed by GC/MS and found to be a 1:1 mixture of 9-methoxy-10,12-octadecadienoate [base peak at *m/e* 167, due to CH_3O^+=CH-(CH=CH)$_2$-(CH$_2$)$_4$-CH$_3$] and 13-methoxy-9,11-octadecadienoate [base peak at *m/e* 253, due to CH_3O^+=CH-(CH=CH)$_2$-(CH$_2$)$_7$-COOCH$_3$]. GC/MS analysis of the hydrogenated derivatives was in full accordance with these structures.

The following experiment was carried out in order to investigate the fate of methyl 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate in an acidified aprotic solvent. Methyl 11-hydroxyoctadecadienoate (18 μg) in acetonitrile (3 mL) was treated with 70% (w/w) perchloric acid (5 μL). The UV spectrum recorded after 1 min at 23°C showed absorption bands indicative of a conjugated triene, *i.e.*, at 259 nm, 269 nm (ε = 50,000), and 280 nm [Fig. 4; reported for 9*(Z)*,11*(E)*,13*(E)*-octadecatrienoic acid: bands at 261, 270 and 281 nm; and for 9*(E)*,11*(E)*,13*(E)*-octadecatrienoic acid: bands at 258, 268 and 279 nm (11)]. GC/MS analysis of the material showed two pairs of peaks, *i.e.*, at C-18.99 (21%) and 19.11 (21%), and at C-19.41 (29%) and 19.45 (29%). The mass spectra recorded on these peaks showed an intense molecular ion at *m/e* 292, but were otherwise relatively non-informative. Catalytic hydrogenation performed on the product yielded a single compound, *i.e.*, methyl stearate (*m/e* 298). It was thus clear that the product formed upon acid treatment of methyl 11-hydroxy-

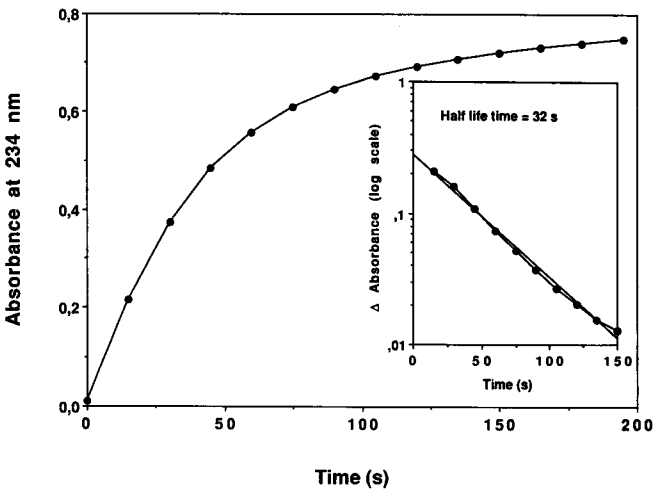

FIG. 3. Appearance of absorbance at 234 nm upon treatment of methyl 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate (27 μg) in methanol (3 mL) with 2 μL of 2 M HCl. Inset: Plot of change in absorbance at 234 nm (log scale) *vs.* time.

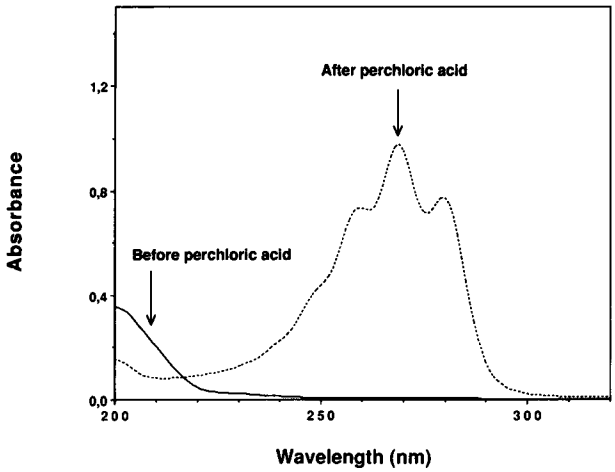

FIG. 4. UV spectra recorded on a solution of 18 μg of methyl 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoate in 3 mL of acetonitrile before (solid line) and 1 min after (dashed line) addition of 5 μL of 70% (w/w) perchloric acid.

octadecadienoate in acetonitrile was due to four isomeric methyl octadecatrienoates. It appeared that the two factors causing separation of the octadecatrienoates upon GLC were different positions of the triene moiety, and geometrical isomerism of the triene. The geometrical configurations of the conjugated trienes were not determined; however, the fact that oxidative ozonolysis performed on the octadecatrienoate mixture yielded equal amounts of methyl hydrogen suberate and methyl hydrogen azelate localized the conjugated triene structures in the carbon chain, and demonstrated that the octadecatrienoates were due to equal amounts of methyl 8,10,12- and 9,11,13-octadecatrienoates.

Incubation of 11-hydroxy- and 11-ketooctadecadienoates. Figure 5A shows the time course of the formation of oxidized products (9-, 11- and 13-hydroxyoctadecadienoic acids plus 11-ketooctadecadienoic acid) from linoleic acid when incubated with the enzyme preparation. As seen, oxidation proceeded linearly in the time interval 0–30 min and then leveled off because of depletion of substrate. No oxidation was observed when heat-inactivated enzyme was used. In order to obtain information of possible interconversions between the 11-oxygenated products, samples of [1-^{14}C]11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoic acid and [1-^{14}C]11-keto-9*(Z)*,12*(Z)*-octadecadienoic acid were prepared by incubation of [1-^{14}C]linoleic acid and isolated as the free acids by silicic acid open column chromatography. The 11-ketooctadecadienoic acid thus obtained was radiochemically pure, whereas the 11-hydroxyoctadecadienoic acid was contaminated with 14% of a mixture of equal parts of 9- and 13-HOD. Re-incubation of [1-^{14}C]11-ketooctadecadienoic acid (100 μM) with the enzyme preparation at 22°C for 20 min did not result in conversion into hydroxyoctadecadienoate(s) or other products. Similar re-incubation of [1-^{14}C]11-hydroxyoctadecadienoic acid resulted in a low yield (5%) of 11-ketooctadecadienoic acid. Slow conversion of 11-hydroxyoctadecadienoic acid into 11-ketooctadecadienoic acid was confirmed by a time-course study (Fig. 5B). Significant formation of 9- and 13-HOD from 11-hydroxyoctadecadienoic acid was not observed.

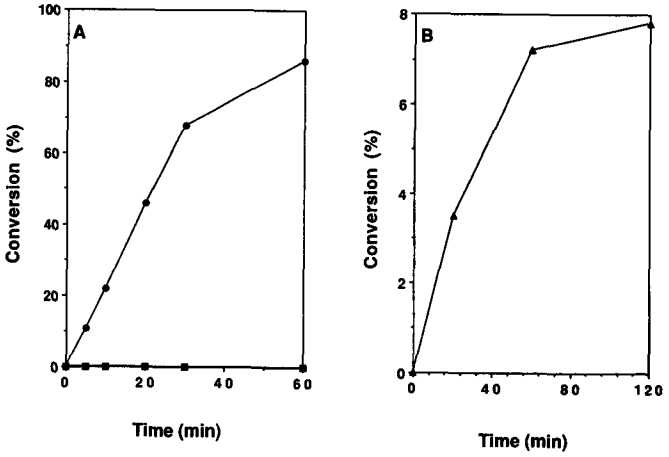

FIG. 5. A: Time course of the oxidation of linoleic acid into 9-, 11- and 13-hydroxyoctadecadienoic acids and 11-ketooctadecadienoic acid. Enzyme preparation (10 mL; -●-●-●-) or heat-inactivated (95°C, 10 min) enzyme preparation (10 mL; -■-■-■-) were stirred with [1-^{14}C]linoleic acid (300 μM) at 22°C and aliquots of 2 mL were removed at times indicated. The percentage conversion of linoleic acid into the three hydroxyoctadecadienoic acids and the 11-keto-octadecadienoic acid was determined by thin-layer radiochromatography. B: Time course of the conversion of 11-hydroxyoctadecadienoic acid into 11-ketooctadecadienoic acid. Enzyme preparation (8 mL) was stirred with [1-^{14}C]11-hydroxyoctadecadienoic acid (100 μM) at 22°C and aliquots of 2 mL were removed at times indicated. The percentage conversion into 11-ketooctadecadienoic acid was determined by thin-layer radiochromatography.

In order to facilitate interpretation of results obtained with linoleic acid incubated in the presence of $^{18}O_2$ and $H_2{}^{18}O$ (see below), re-incubations of 11-hydroxy- and 11-ketooctadecadienoic acids (100 μM) were also carried out with enzyme preparation dissolved in potassium phosphate buffer (1.6 mL) and $H_2{}^{18}O$ (0.4 mL). As seen in Table 1, 11-ketooctadecadienoic acid, either produced from 11-hydroxyoctadecadienoic acid or recovered following incubation of 11-ketooctadecadienoic acid, contained a small fraction of solvent ^{18}O (incorporation, 7-8% of the theoretical). As expected, 11-hydroxyoctadecadienoic acid recovered following incubation of this hydroxy acid did not contain any ^{18}O in the C-11 hydroxyl group.

^{18}O experiments. Linoleic acid (300 μM) was incubated at 22°C for 20 min with the enzyme preparation under an atmosphere of $^{18}O_2$. As seen in Table 2, the 11-hydroxy- and 11-ketooctadecadienoic acids produced were completely devoid of ^{18}O. A small (2.5%) incorporation was observed in 9- and 13-HOD. As a check, following aspiration of the reaction mixture at the end of the incubation period, the incubation vessel was injected with linoleic acid and soybean lipoxygenase. The linoleic acid 13-hydroperoxide thus formed was reduced into 13-HOD. Mass spectrometric analysis of the Me_3Si derivative of the methyl ester of this compound showed satisfactory incorporation of ^{18}O.

In another experiment, linoleic acid was stirred with the enzyme preparation in the presence of $H_2{}^{18}O$. As seen in Table 2, the resulting 11-hydroxy- and 11-ketooctadecadienoates showed virtually complete incorporation of ^{18}O in the hydroxyl and keto groups, respectively. Incorporation of ^{18}O in 9- and 13-HOD was extensive but not complete, *i.e.*, 79-86% of the theoretical.

Incubation of [9,10,12,13-$^2H_4$]linoleic acid. Enzyme preparation (2 mL) was stirred at 22°C for 20 min with 300 μM [9,10,12,13-$^2H_4$]linoleic acid. The hydroxyoctadecadienoates were isolated and converted into the Me_3Si derivatives. Selected monitoring of the ions *m/e* 225, 226, 227, 228 and 229 showed that 11-hydroxyoctadecadienoic acid, as well as 9- and 13-HOD, were due to 93% of tetradeuteriated and 7% trideuteriated molecules. This isotopic composition was the same as that of the incubated deuteriated linoleic acid, thus showing that the hydrogens at carbons 9, 10, 12 and 13 were retained in the conversion of linoleic acid into the three hydroxyoctadecadienoic acids.

Effect of anaerobiosis and enzyme inhibitors. Conversion of linoleic acid into oxidized products was strictly dependent on the presence of oxygen (Table 3). Furthermore, sodium azide in 5 mM concentration inhibited the reaction. The lipoxygenase inhibitor nordihydroguaiaretic acid gave only weak inhibition, and two other well-established lipoxygenase inhibitors, 5,8,11,14-eicosatetraynoic acid and esculetin, were without effect. One cytochrome P-450 inhibitor, metyrapone, lacked inhibitory effect, whereas another one, SKF-525A, gave moderate inhibition when tested in 1 mM concentration. Furthermore,

TABLE 1

Isotope Composition of Compounds Isolated Following Incubation of 11-Hydroxy- and 11-Ketooctadecadienoic Acids with Enzyme Preparation in the Presence of $H_2{}^{18}O$

	Isotope composition (%)[b]			
	11-Hydroxyoctadecadienoic acid		11-Ketooctadecadienoic acid	
Compound incubated[a]	$^{18}O_0$	$^{18}O_1$	$^{18}O_0$	$^{18}O_1$
11-Hydroxyoctadecadienoic acid	100	0 (0)	98.5	1.5 (7)
11-Ketooctadecadienoic acid	—	—	98.4	1.6 (8)

[a] Enzyme preparation (1.6 mL) and $H_2{}^{18}O$ (98.7 atom%, 0.4 mL) were stirred at 22°C for 20 min with 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoic acid (100 μM) or 11-keto-9*(Z)*,12*(Z)*-octadecadienoic acid (100 μM). Five volumes of methanol were added and the products isolated and derivatized as described in the text.

[b] The isotopic compositions were determined by selected monitoring of the following ions: *m/e* 225 and 227 ($[CH=CH-CH(OSiMe_3)-CH=CH-(CH_2)_4-CH_3]^+$, Me_3Si derivative of the methyl ester of 11-hydroxyoctadecadienoic acid, and *m/e* 151 and 153 ($[CH=CH-CO-CH=CH-(CH_2)_4-CH_3]^+$; methyl ester of 11-ketooctadecadienoic acid. The dwell time used for data acquisition was 50 ms. Numbers in parentheses indicate content of ^{18}O relative to the content of ^{18}O in the water of the incubation mixture.

TABLE 2

Isotope Composition of Compounds Isolated Following Incubation of Linoleic Acid with Enzyme Preparation in the Presence of $^{18}O_2$ and $H_2{}^{18}O$

Compound analyzed[a]	Isotope composition (%)			
	Incubation with $^{18}O_2$[b]		Incubation with $H_2{}^{18}O$[c]	
	$^{18}O_0$	$^{18}O_1$	$^{18}O_0$	$^{18}O_1$
11-Hydroxyoctadecadienoic acid	100.0	0	80.1	19.9 (101)
9-HOD	97.5	2.5	83.0	17.0 (86)
13-HOD	97.5	2.5	84.5	15.5 (79)
11-Ketooctadecadienoic acid	100.0	0	80.6	19.4 (98)

[a]The isotopic composition was determined by selected monitoring of the ions *m/e* 225 and 227 (hydroxyoctadecadienoates), and 151 and 153 (11-ketooctadecadienoate).

[b]Enzyme preparation (10 mL) in a sealed vessel was purged with argon and evacuated in five cycles. $^{18}O_2$ (97–98 atom%, 0.1 L) was introduced, and the reaction was started by injection of linoleic acid (300 μM. The mixture was stirred at 22°C for 20 min and then added to five volumes of methanol. Products were isolated and derivatized as described in the text.

[c]Enzyme preparation (4 mL) and $H_2{}^{18}O$ (98.7 atom%, 1 mL) was stirred at 22°C for 20 min with 300 μM linoleic acid. Five volumes of methanol were added and the products isolated and derivatized as described in the text. Numbers in parentheses indicate percentage content of ^{18}O relative to the content of ^{18}O in the water of the incubation mixture.

TABLE 3

Effect of Anaerobiosis and Enzyme Inhibitors on the Oxidation of Linoleic Acid

Condition[a]	Conversion (% of control)[b]
Control	100
Heat-treated enzyme (95°C, 10 min)	0
Anaerobiosis	< 1
Sodium azide (5 mM)	22
SKF-525A (1 mM)	50
Diethyldithiocarbamate (1 mM)	63
NDGA (0.1 mM)	75
2,2′-Dipyridyl (1 mM)	100
Esculetin (0.1 mM)	101
Metyrapone (1 mM)	101
ETYA (0.1 mM)	101

[a]The enzyme preparation was stirred at 22°C for 5 min with inhibitor and then stirred for additional 20 min in the presence of [1-^{14}C]-linoleic acid. Anaerobiosis was accomplished by repeated argon-purging and evacuation of the enzyme preparation contained in a sealed vessel.

[b]The control incubation showed 49% conversion into the three hydroxyoctadecadienoic acids and the ketooctadecadienoic acid.

slight inhibition was noted in the presence of the copper-chelating agent, diethyldithiocarbamate.

DISCUSSION

Several mechanisms exist for introduction of molecular oxygen in the formation of oxylipins. A quantitatively large part of oxylipins is formed by sequences that are initiated by lipoxygenase-catalyzed oxygenation. Compounds formed in this way include leukotrienes and lipoxins formed by initial 5-lipoxygenation of arachidonic acid in animal tissue (12), jasmonic acid and a host of other biologically active compounds formed by initial 9- and 13-lipoxygenation of linoleic and α-linolenic acids in plants (13), and a variety of products formed in algae by initial 12-lipoxygenation of arachidonic and eicosapentaenoic acids (2). Prostaglandins and thromboxanes constitute a group of oxylipins which is formed by initial dioxygenation catalyzed by prostaglandin endoperoxide synthase (14). Oxylipins also may be biosynthesized by cytochrome P-450-catalyzed monooxygenation, in animal (15) as well as in plant tissue (16,17). An additional, recently discovered mechanism of biosynthesis of oxylipins consists of hydroperoxide-dependent epoxidation of fatty acids and hydroxy acids in higher plants (18,19). The present study is concerned with transformation of linoleic acid into hydroxy and ketooctadecadienoic acids in the red alga *Lithothamnion corallioides* by a mechanism which appears to be distinct from previously recognized mechanisms of oxylipin biosynthesis.

The major compound formed from linoleic acid upon incubation with the enzyme preparation of *Lithothamnion* was found to have the structure 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoic acid (Fig. 6). This novel hydroxy acid was related to 13-hydroxyarachidonate and 13-hydroxyeicosapentaenoate recently isolated as natural products from *Lithothamnion* (4), and also to the methyl ester of 11-hydroperoxylinoleic acid, which had been obtained earlier by chemical synthesis (20). The transformation of linoleic acid into 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoic acid demonstrated in the present paper constitutes the first example of an enzymatic reaction in which oxygen is introduced into a *bis*-allylic methylene group of a polyunsaturated fatty acid. Interestingly, the oxygen incorporated originated in water rather than dioxygen. This was an unexpected result, and a number of control experiments were performed in order to verify it. For example, that the lack of incorporation of ^{18}O in 11-hydroxyoctadecadienoic acid biosynthesized from linoleic acid under $^{18}O_2$ was not due to technical problems with the $^{18}O_2$ incubations or with the ^{18}O-gas itself was shown by a control experiment in which linoleic acid was incubated with soybean lipoxygenase using the same atmosphere of $^{18}O_2$

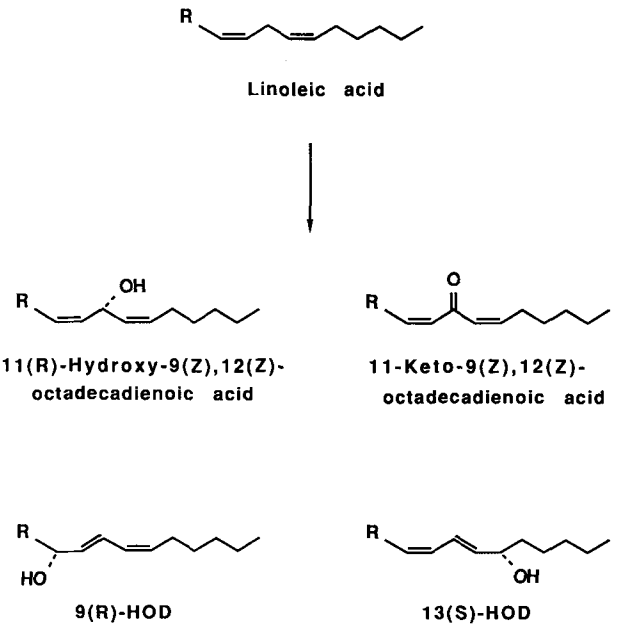

FIG. 6. Transformations of linoleic acid in *Lithothamnion corallioides*. The major enantiomers of the 9- and 13-HOD isolated are shown. R = $(CH_2)_7$-COOH.

as that used for the *Lithothamnion* incubation. The linoleic acid 13-hydroperoxide thus produced showed the expected incorporation of ^{18}O. Furthermore, that the incorporation of ^{18}O into 11-hydroxyoctadecadienoic acid formed from linoleic acid in the presence of $H_2{}^{18}O$ was not due to secondary chemical or enzymatical exchange of ^{18}O into 11-hydroxyoctadecadienoic acid was apparent from an experiment in which 11-hydroxyoctadecadienoic acid was separately incubated with the enzyme preparation in the presence of $H_2{}^{18}O$. No incorporation of ^{18}O in the re-isolated 11-hydroxyoctadecadienoic acid could be detected (Table 1).

The *bis*-allylic alcohol group present in 11-hydroxyoctadecadienoic acid made the compound sensitive to acid. In acidified protic solvents, 11-hydroxyoctadecadienoic acid underwent rapid solvolysis to produce 9- and 13-substituted derivatives having one pair of conjugated double bonds. In aprotic solvents elimination of water took place with the formation of derivatives having a conjugated triene structure. Fatty acids containing conjugated triene and tetraene structures, *e.g.*, elaeostearic and parinaric acids, occur naturally in plants (21). Possibly the facile dehydration of 11-hydroxyoctadecadienoate into conjugated triene acids may have relevance for the biosynthesis of such compounds.

Two other hydroyoctadecadienoates, *i.e.*, 9- and 13-HOD, were obtained as minor compounds following incubation of linoleic acid with *Lithothamnion*. Undoubtedly, part of these compounds was formed non-enzymatically from 11-hydroxyoctadecadienoic acid during the incubation period and the isolation procedure. However, steric analysis showed that the 9- and 13-HOD isolated were not racemates, but due to *ca.* 75% of the *(R)* and *(S)* enantiomers, respectively. It thus seemed likely that *ca.* 50% of the 9- and 13-HOD were formed as the racemic compounds by chemical solvolysis of 11-hydroxyoctadecadienoic acid, while the remaining 50% were formed as the pure *(R)* and *(S)* compounds, respectively, by enzymatic oxidation of linoleic acid. Interestingly, this oxidation occurred by a non-lipoxygenase mechanism as judged by the extensive incorporation of ^{18}O from $H_2{}^{18}O$, but not from $^{18}O_2$, in the hydroxyl groups of 9- and 13-HOD (Table 2). A fourth compound isolated following incubation of linoleic acid, 11-keto-9*(Z)*,12*(Z)*-octadecadienoic acid, was apparently formed by enzymatic oxidation of 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoic acid (Fig. 5B). As expected from its formation from 11-hydroxyoctadecadienoic acid, the oxygen of the C-11 keto group of 11-ketooctadecadienoic acid was derived from water, and not from dioxygen (Table 2).

The transformation of linoleic acid into 11*(R)*-hydroxy-9*(Z)*,12*(Z)*-octadecadienoic acid was oxygen-dependent (Table 3), involved incorporation of 1 atom of oxygen from water (Table 2), and was not inhibitable, or only moderately so, by lipoxygenase and cytochrome P-450 inhibitors (Table 3). If the transformation occurred by a single enzymatic step it followed, per definition, that the enzyme involved was not an oxygenase. It may be speculated that an oxidase was responsible for the conversion; however, it is apparent that further studies on the enzyme(s) involved in the transformation are necessary before any conclusions as to the mechanism may be drawn. Such work is in progress in our laboratory.

The incorporation of [1-^{14}C]18:3n-3 (LNA) and [1-^{14}C]-22:6n-3 (DHA), and the metabolism *via* the desaturase/elongase pathways of [1-^{14}C]LNA and [1-^{14}C]20:5n-3 (EPA) were studied in brain cells from newly-weaned (1-month-old) and 4-month-old turbot. The rank order of the extent of net incorporation of both LNA and DHA into glycerophospholipids was total diradyl glycerophosphocholines (CPL) > total diradyl glycerophosphoethanolamines (EPL) > phosphatidylserine (PS) and phosphatidylinositol (PI) and was independent of the polyunsaturated fatty acid added, the age of the fish and the time of incubation. However, the rate of incorporation of LNA into total lipid, CPL, EPL and PS was significantly greater than the rate of incorporation of DHA, and there was a significantly greater amount of DHA incorporated into EPL than LNA. There was no significant difference between the amounts of LNA and DHA incorporated into total lipid, CPL, PS and PI. Therefore, little preferential uptake and incorporation of DHA into brain cells was apparent. In 24-h incubations, on average 1.1% and 8.5% of radioactivity from [1-^{14}C]LNA and [1-^{14}C]EPA, respectively, were recovered in the DHA fraction. Therefore, LNA cannot contribute significantly to brain DHA levels in the turbot but EPA can. There were no significant differences between the amounts of radioactivity from either [1-^{14}C]LNA or [1-^{14}C]EPA recovered in the individual products/intermediates of the desaturase pathways in brain cells from 30-day-old and 120-day-old turbot.
***Lipids* 27, 494-499 (1992).**

Neural tissues from all vertebrates are characterized by high levels of n-3 polyunsaturated fatty acids (PUFA), especially docosahexaenoic acid (DHA; 22:6n-3) (1). Despite the high level of n-3 PUFA in all their tissues, this phenomenon is evident also in fish brain and retina where total n-3 PUFA and DHA levels are elevated above the levels found in non-neural tissues (2). DHA is tenaciously retained by neural tissues during dietary deprivation of n-3 PUFA in mammals (3) and two generations of deprivation are required to reduce significantly DHA levels in brain and retina (4-7). Depletion of neural DHA levels was accompanied by alterations in physiological parameters and functional defects such as reduced visual acuity and impaired learning abilities (4-7). This research established a critical role for DHA in neural tissue functions in mammals (8,9) and the nutritional importance of n-3 PUFA during neural development in mammals is now increasingly recognized (10,11).

It is unclear how much brain DHA is derived from endogenous biosynthesis from α-linolenic acid (LNA; 18:3n-3) in the brain and how much is obtained preformed from the liver or dietary sources (8). *In vivo* production of DHA from LNA has been demonstrated in rat brain (12) but other evidence suggests that much of the DHA in mammalian brains results from the accumulation of preformed DHA during neural development (13-15). Some of this DHA may be obtained directly as maternal DHA and some may be produced in the liver from maternal LNA (16). Until recently this has been a virtually unstudied area in fish. However, we have recently demonstrated that DHA accumulates rapidly in brains from farmed turbot in the period immediately following weaning onto dry pellet food relatively rich in DHA (17). Prior to weaning from a diet relatively deficient in DHA, the turbot brains have low levels of DHA, so that the increase in brain DHA levels appears to be dependent upon the provision of dietary DHA (18).

Previously, it was shown that turbot require dietary C_{20} and C_{22} PUFA for optimal growth (19) and that turbot, aged 10 mon, could not convert dietary [1-^{14}C]LNA to DHA (20). Deficient Δ5 fatty acid desaturase activity and/or C_{18}-C_{20} elongase has been demonstrated in turbot in both intact fish (21) and cells in culture (22,23), although the Δ4 fatty acid desaturase responsible for the conversion of eicosapentaenoic acid (EPA; 20:5n-3) to DHA appeared to be active in the systems studied. Brain tissue or cells have not been investigated in any of the previous studies.

In the present study, we have investigated n-3 PUFA metabolism in brain cells from rapidly growing and developing turbot. Specifically, we have studied the metabolism of [1-^{14}C]DHA, [1-^{14}C]EPA and [1-^{14}C]LNA in brain cells from newly-weaned (1-month-old) and 4-month-old turbot. We aimed to determine i) if there was a differential uptake and incorporation of DHA into brain cells, ii) the extent to which LNA and EPA could contribute to brain DHA levels and iii) if these processes were affected by age and development of the fish.

MATERIALS AND METHODS

Experimental animals. Juvenile turbot (*S. maximus*) were obtained from a commercial turbot hatchery (Golden Sea Produce, Hunterston, Ayrshire, Scotland) and were maintained in 2-m circular tanks supplied with filtered, recirculating sea water. Temperature was 10 ± 2°C, and the fish were given commercial diets as used in the hatchery

Abbreviations: ANOVA, analysis of variance; BHT, butylated hydroxytoluene; BSA, bovine serum albumin; CPL, total diradyl glycerophosphocholines; DHA, 4,7,10,13,16,19-docosahexaenoic acid (22:6n-3); EPA, 5,8,11,14,17-eicosapentaenoic acid (20:5n-3); EPL, total diradyl glycerophosphoethanolamines; GC, gas chromatography; HBSS, Hank's balanced salt solution; HPTLC, high-performance thin-layer chromatography; LNA, 9,12,15-octadecatrienoic acid, α-linolenic acid (18:3n-3); PI, (diacyl)phosphatidylinositols; PS, (diacyl)phosphatidylserines; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography.

(17,18). Two ages of turbot were studied. The younger group were newly-weaned fish of approximate age 30 days and the older group were fish that had been weaned for 3 mon (approximately 120 days old).

Preparation of isolated brain cell suspensions. Fish were killed by cutting the spinal cord immediately posterior to the brain. Entire brains were removed into ice-cold Hank's balanced salt solution (Ca^{2+}- and Mg^{2+}-free and supplemented with 1.75% NaCl)(HBSS) and finely chopped. A mixed brain cell suspension was produced by sequential mechanical sieving of the chopped tissue through sterile nylon gauzes of 100 and 30 μm essential as described by McCarthy and De Vellis (24). The suspension was centrifuged at 300 × *g* for 10 min at 4°C and the cell pellet resuspended in Dulbecco's modification of Eagle's medium supplemented with 4 mM glutamine, antibiotics (50 IU/mL penicillin and 50 μg/mL streptomycin) and 0.35% NaCl. Cells were resuspended in 6.5 mL and 3 mL of medium for incorporation time-course and metabolic experiments, respectively. The numbers of fish used in each incorporation time-course and metabolic experiment were 36 and 18, respectively, for 30-day turbot. For 120-day-old turbot the numbers of fish per experiment as above were 15 and 7, respectively. Viability was assessed by trypan blue exclusion at the beginning and end of each experiment (6 h for incorporation experiments and 24 h for metabolic experiments). The cell numbers remained constant throughout the incubation periods but viability of the cells decreased from >86% upon preparation of the suspension to <72% after 6 h incubation (Table 1). The viability was not affected by a further 18 h incubation.

Incubation of brain cells with ^{14}C-labelled PUFA. For incorporation experiments, 2.75 mL of brain cell suspension had 0.6 μCi of either [1-^{14}C]LNA or [1-^{14}C]DHA added, carrier-free, in 15 μL ethanol (final conc., 4.0–4.5 μM PUFA and 0.55% ethanol). For metabolic experiments, 1 mL of suspension had 0.25 μCi of either [1-^{14}C]LNA or [1-^{14}C]EPA added, carrier free in 6 μL ethanol (final conc. 4–5 μM PUFA and 0.6% ethanol). Incubations were performed in a shaking water bath at 15°C.

Lipid extraction. Samples of suspension (0.5 mL and 1 mL in incorporation and metabolic experiments, respectively) had 5 mL ice-cold HBSS containing 1% fatty acid-free bovine serum albumin (BSA) added. After mixing, the samples were centrifuged at 500 × *g* for 2 min and the supernatants aspirated. The cells were washed once more with HBSS as above and total lipid extracted essentially according to Folch *et al.* (25) as described previously (26). Lipid content of each suspension was determined in a 0.5 mL sample extracted in parallel, with the total lipid content determined gravimetrically.

Incorporation of radioactivity into glycerophospholipid classes. Samples of total lipid had 50 μg of unlabelled turbot brain lipid added as carrier and were then applied in 1-cm streaks to high-performance thin-layer chromatography (HPTLC) plates. Polar lipid classes were separated using methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) (27). Lipids were visualized by brief exposure to iodine vapor, marked, and the iodine removed under vacuum. Individual classes were scraped into scintillation minivials, 2.5 mL of Ecoscint A (National Diagnostics, Manville, NJ) added, and radioactivity determined using a Packard 2000CA Tri-Carb liquid scintillation analyzer (Downers Grove, IL).

TABLE 1

Protein and Lipid Contents, and Viability of Brain Cells During 24-h Incubations of Brain Cell Suspensions from 30- and 120-day-old Turbot *Scophthalmus maximus*[a]

	Age of turbot	
	30-days-old	120-days-old
Protein content (mg/mL)	0.91 ± 0.14	0.81 ± 0.13
Lipid content (mg/mL)	0.65 ± 0.08	1.33 ± 0.42
Lipid /protein ratio	0.71 ± 0.04	1.64 ± 0.22
	Time of incubation	
	0 h	6 h	24 h
Cell number (10^6/mL)	1.4 ± 0.1	1.6 ± 0.2	1.6 ± 0.1
Cell viability (%)	86.2 ± 2.6	71.7 ± 3.4	71.3 ± 3.5

[a]Values are means ± SD of at least six suspensions.

Incorporation of radioactivity into PUFA. Fatty acid methyl esters from total lipid were prepared by acid-catalyzed transmethylation at 50°C for 16 h (28) and extracted and purified as described previously (2). Methyl esters were separated by a combination of argentation thin-layer chromatography (TLC) and radio gas chromatography (GC), and radioactivity in the fatty acid methyl ester fractions was determined as described in detail previously (29,30). All solvents contained 0.01% butylated hydroxytoluene (BHT) as antioxidant.

Protein content. Samples of 0.5 mL of each suspension were taken into NaOH/sodium dodecylsulfate for protein determination essentially according to Lowry *et al.* (31).

Statistical analysis. All results are the means of at least three experiments ± 1 SD. The data were checked for homogeneity of the variances by the Bartlett test and, where necessary, the data were log-transformed before further statistical analysis. The kinetics of the incorporation of [1-^{14}C]LNA and [1-^{14}C]DHA into various lipids were determined by non-linear regression analysis and fitted to the 1st order rate equation $y = A(1\text{-}e^{-kt})$, where A is the limit and k is the rate constant. Differences between means were analyzed by one-way analysis of variance (ANOVA) followed by Tukey's multiple comparison test. The effects on the kinetics of incorporation due to different [^{14}C]PUFA in brain cells from turbot of different ages were analyzed by a model I two-way ANOVA.

Materials. [1-^{14}C]PUFA (all 50–55 mCi/mmol and 99% pure were obtained from NEN, DuPont (U.K.) Ltd. (Stevenage, U.K.). BHT, fatty acid-free BSA and silver nitrate were from Sigma Chemical Co. Ltd. (Poole, U.K.). Medium, HBSS, glutamine and antibiotics were obtained from Northumbria Biologicals Ltd. (Northumberland, U.K.). TLC (20 × 20 cm × 0.25 mm) and HPTLC (10 × 10 cm × 0.15 mm) plates, precoated with silica gel 60 (without fluorescent indicator), were obtained from Merck (Darmstadt, Germany). All solvents were HPLC grade and were obtained from Rathburn Chemicals (Walkerburn, Scotland).

RESULTS

The lipid/protein ratio was significantly greater in the older fish indicating that there was considerable bio-

bsynthesis and/or accumulation of lipid in the turbot brains during this period of development (Table 1).

The time-courses for the incorporation of [1-^{14}C]LNA and [1-^{14}C]DHA into brain cells from 30- and 120-day-old turbot are shown in Figure 1. Under the conditions of the experiments, the incorporations had reached maxima by 2 h in the case of LNA and 4 h for DHA. The time courses for the incorporation of [1-^{14}C]LNA and [1-^{14}C]DHA into individual glycerophospholipids are shown in Figures 2 and 3, respectively. The rank order of incorporation into the glycerophospholipids was total diradyl glycerophosphocholines (CPL) > total diradyl glycerophosphoethanolamines (EPL) > (diacyl)phosphatidylserine (PS) and (diacyl)phosphatidylinositol (PI), and was independent of ^{14}C-labelled PUFA, age of the fish, and time of incubation (Figs. 2 and 3).

The kinetics of the incorporation of [1-^{14}C]LNA and [1-^{14}C]DHA into total lipid and individual glycerophospholipids were determined and analyzed statistically. The rate of incorporation of [1-^{14}C]LNA into total lipid, CPL, EPL and PS was significantly greater than the rate of incorporation of [1-^{14}C]DHA (Table 2, Figs. 1-3). This was also apparent for PI, but as some of these data were only in duplicate the statistical analysis could not be performed. In almost every case the rates of incorporation were lower in brain cells from the older fish, but the errors involved made these data not statistically significant.

The ANOVA analysis showed that, under the conditions of the experiments, there was no significant difference between the amounts of [1-^{14}C]LNA and [1-^{14}C]DHA incorporated into total lipid, CPL, PS and PI (Table 2). However, there was significantly greater incorporation of [1-^{14}C]DHA into EPL than [1-^{14}C]LNA. In particular, the incorporation of [1-^{14}C]DHA into EPL in brain cells from 30-day turbot was more than double the incorporation of [1-^{14}C]LNA into EPL in both 30- and 120-day-old turbot (Table 2, Figs. 1-3). As with the rate of incorporation, although the amount of incorporation of both labelled PUFA generally tended to be lower in brain cells from older fish, there was no statistical significance to the differences. The two-way ANOVA showed that there was no interrelationship between the effects of PUFA and age of the fish (Table 2).

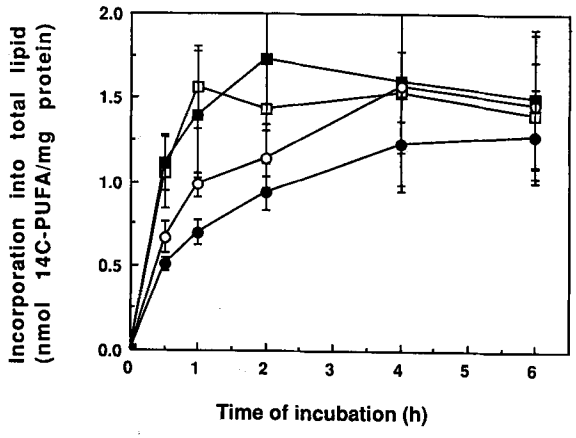

FIG. 1. Incorporation of [^{14}C]18:3n-3 and [^{14}C]22:6n-3 into total lipid of brain cells from turbot at 30 days and 120 days after hatching. Isotopes were added to cell suspensions to final fatty acid concentrations of 4.0–4.5 μM and incubations were performed at 15°C. Samples were withdrawn and analyzed as described in Materials and Methods. Results are means ± SD (n = 3). (□,■)[^{14}C]18:3n-3; (○,●)[^{14}C]22:6n-3. Open symbols, 30 days; closed symbols, 120 days.

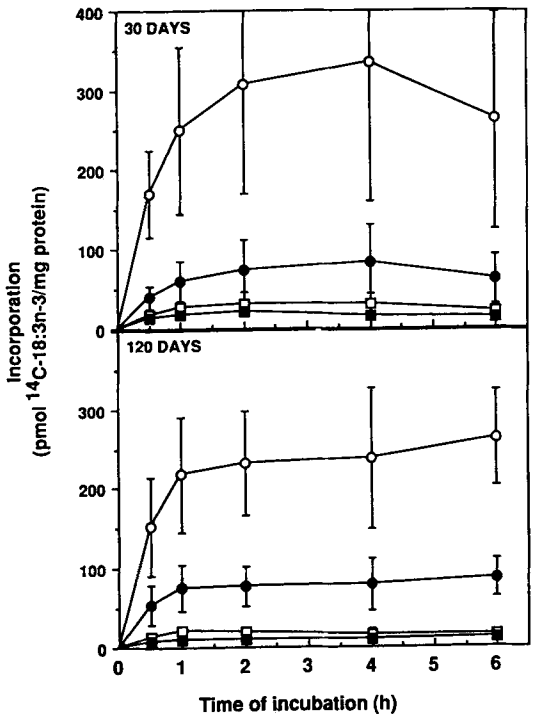

FIG. 2. Incorporation of [^{14}C]18:3n-3 into glycerophospholipid classes in brain cells from turbot at 30 days and 120 days after hatching. Incubation conditions as in Figure 1. Analyses performed as described in Materials and Methods. Results are means ± SD (n = 3). (○), total diradyl glycerophosphocholine; (●), total diradyl glycerophosphoethanolamine; (□), phosphatidylserine; (■), phosphatidylinositol.

The metabolism of [1-^{14}C]LNA and [1-^{14}C]EPA *via* the desaturase pathways over a 24-h period are shown in Table 3. In brain cells from 30-day-old turbot, only 5% of radioactivity from [1-^{14}C]LNA was recovered in products/intermediates of the normal desaturase/elongase pathway with only half of that percentage appearing as products beyond the Δ5 desaturase step (Table 3). The dead-end product 20:3n-3 accounted for the largest single percentage of metabolized [1-^{14}C]LNA. Over 12% of incorporated [1-^{14}C]EPA was chain elongated to 22:5n-3 with 7% being further desaturated *via* Δ4 desaturase activity to DHA in brain cells from 30-day-old turbot (Table 3).

There were lower percentages (significantly so with labelled LNA) of radioactivity recovered in the precursor fatty acid fractions in the brain cells from 120-day-old turbot (Table 3). However, there were no significant differences between the amounts of radioactivity from either labelled PUFA recovered in the individual products/intermediates of the desaturase pathways in brain cells from 30-day-old and 120-day-old turbot.

DISCUSSION

The results of the present study strongly suggest that there is no preferential uptake and incorporation of DHA into juvenile turbot brain cells. Furthermore, under

TABLE 2

identical experimental conditions, although the initial rate of incorporation of LNA was greater than that of DHA, both PUFA were incorporated to approximately the same final level. No data on the incorporation of DHA into fish brains or brain cells are available for comparison. Furthermore, although the rapid and specific accumulation of DHA (and 20:4n-6) into mammalian brains during development is well established (13–15,32), there are few data comparing directly the incorporation of different PUFA into brains or brain cells in mammals. However,

[a]Values show the radioactivity found in each fatty acid fraction expressed as a percentage of total radioactivity recovered and are means ± SD (n = 3).

[b]The differences between values at 30 and 120 days were significantly different ($P < 0.05$) as determined by Student's *t*-test; n.d., not determined.

the uptake of i.v.-injected ^{14}C-labelled DHA into brains of 15-day-old rats was greater than the uptake of LNA, 18:2n-6 and 16:0 (33). Similarly, in primary cultures of rat neurons, the incorporation of DHA exceeded that of LNA (34).

The absolute level of incorporation of both LNA and DHA was lower in the turbot brain cells than previously found in mammalian systems although there is considerable variation between different studies. Yavin and Menkes (35) reported an incorporation of approximately 4–5 nmol [1-^{14}C]LNA/mg protein after 3 h incubation in cultures of dissociated rat cerebrum cells, about 3 times the level of incorporation found with [1-^{14}C]LNA in the turbot brain cell suspensions in the present study. In a recent study, [1-^{14}C]DHA and [1-^{14}C]LNA were incorporated into rat neurons in primary culture to levels of 150 and 75 mmol/mg protein, respectively, after 8 h incubation (34). These differences could be the results of different concentrations of labelled PUFA (7 μM and 18 μM, respectively, in the previous studies compared with 4.0–4.5 μM in the present study), incubation temperature (37°C with the mammalian cells and 15°C with the turbot cells), cell profiles in the different preparations, or inherent differences between mammalian and fish cells.

The distribution of incorporated [1-^{14}C]DHA and [1-^{14}C]LNA in glycerophospholipids in the present study was similar to that obtained previously in other fish cells and several mammalian neural cells. The rank order of the distribution of incorporated [1-^{14}C]LNA was CPL > EPL > PS/PI in primary cultures of rainbow trout astrocytes (29) and established cell cultures from rainbow trout gonad, Atlantic salmon fry and turbot fin (30). The incorporation of DHA was not investigated in these studies. In turbot injected i.v. with ^{14}C-labelled DHA and LNA, the pattern of incorporation for both PUFA was CPL > EPL > PS/PI (21). This rank order was also found with the incorporation of ^{14}C-labelled LNA in primary rat astroblast cultures (36) and in cultured dissociated cells from rat cerebrum (35). In rats injected i.v. with ^{14}C-labelled DHA, 80–85% of radioactivity in the brain after 4 h was recovered in CPL/EPL (37).

Although the distribution of [1-^{14}C]DHA and [1-^{14}C]-LNA between the glycerophospholipids was qualitatively similar in the present study, quantitatively there was a difference in that significantly more DHA was incorporated into EPL. Previously, it was shown in rats with intracerebral injections of ^{14}C-labelled DHA and ^{3}H-labelled 20:4n-6 that DHA was selectively incorporated into EPL compared to 20:4n-6 (38). The relatively high concentration of EPL in neural tissues compared with non-neural tissues in both mammals and fish (2) combined with the high concentration of DHA in EPL means that the bulk of neural DHA is present in EPL. This may imply some special role for EPL in neural tissue functions.

The present study showed that LNA could not contribute significantly to DHA levels in juvenile turbot brains. This was, perhaps, expected as previous work on turbot showed that little or no labelled DHA was produced from injected ^{14}C-labelled LNA in juveniles (21) or 10-month-old fish (20). Similarly, only 1% on average of ^{14}C-labelled LNA was converted to DHA in turbot fin cells in culture (30). However, significant amounts (6–7%) of labelled DHA were produced from ^{14}C-labelled EPA in the present study on turbot brain cells and approximately 14% of radioactivity from injected ^{14}C-labelled EPA was recovered in the DHA fraction in juvenile turbot after 48 h (21). Overall, the data from the present study using [1-^{14}C]EPA and [1-^{14}C]LNA show that juvenile turbot brain expresses the same range of fatty acid desaturase activities as found previously in whole fish and in fin cell cultures, *i.e.* Δ6 and Δ4 desaturase activities are expressed whereas Δ5 desaturase activity is very low or lacking.

There are no data from neural tissues of fish that do not lack Δ5 desaturase activity, *i.e.* trout or salmon, with which to compare the turbot data from the present study. However, in rats, radioactivity from intracranially injected ^{14}C-labelled LNA was recovered in DHA of the brain (12). In cultures of dissociated cells from rat cerebrum incubated with ^{14}C-labelled LNA, 10–25% of the radioactivity was recovered in DHA (35,39). In rat brain, the conversion of LNA to DHA has been localized in the astroglial cell fraction (34), whereas rat neurons and mouse brain microvascular endothelial cells both lacked Δ4 desaturase activity (34,40).

Desaturase activities are known to vary, generally decreasing, with increasing age of animals (41–44). In prenatal rat pups injected intracranially with ^{14}C-labelled LNA, only 1% of the radioactivity in the brain was recovered in DHA (45). Similarly, in brain microsomes from neonatal monkeys (and up to 2 years old), very little DHA was produced from EPA (46). In the present study, significant amounts of labelled DHA were produced in the turbot brain cells, but there was no difference between 1-month-old and 4-month-old turbot in the metabolism of either [1-^{14}C]EPA or [1-^{14}C]LNA *via* the desaturase pathways. In contrast, in pre-weaned turbot of <1 mon of age, there was no evidence for significant conversion of EPA to DHA *in vivo* (17,18) perhaps reflecting a lower level of Δ4 desaturase activity in pre-juvenile and, possibly, larval turbot.

The present study has strongly suggested that the accumulation of DHA in turbot brain during development is not due to specific uptake and incorporation of DHA and that endogenous desaturation of LNA cannot contribute to brain DHA levels. This confirms our previous conclusions, from studies on lipid and fatty acid compositions of developing turbot brain, that the level of DHA in the brain was markedly dependent upon the level of DHA in the diet (17,18). We conclude, therefore, that a strictly carnivorous marine fish such as the turbot is heavily dependent on a substantial dietary input of DHA for normal neural and visual development. The implications of this conclusion for precise prey selection by early larval turbot in nature, and for the provision of an adequate diet for larval turbot in mariculture, are considerable.

[Received October 30, 1991; Revision accepted May 21, 1992]

5c,11c,14c-Eicosatrienoic Acid and 5c,11c,14c,17c-Eicosatetraenoic Acid of *Biota orientalis* Seed Oil Affect Lipid Metabolism in the Rat

Ikuo Ikeda[a,*], Takayuki Oka[a], Kazunori Koba[a], Michihiro Sugano[a] and Marcel S.F. Lie Ken Jie[b]

[a]Laboratory of Nutrition Chemistry, Kyushu University School of Agriculture 46-09, Hakozaki, Fukuoka 812, Japan and [b]Department of Chemistry, University of Hong Kong, Hong Kong

The effects of 5c,11c,14c-eicosatrienoic acid (20:3BSO) and 5c,11c,14c,17c-eicosatetraenoic acid (20:4BSO), polyunsaturated fatty acids (PUFA) contained in *Biota orientalis* seed oil (BSO), on lipid metabolism in rats were compared to the effects of fats rich in linoleic acid (LA) or α-linolenic acid (ALA) under similar conditions. The potential effect of ethyl 20:4BSO as an essential fatty acid also was examined in comparison with the ethyl esters of LA, ALA and γ-linolenic acid (GLA). BSO- and ALA-rich fat decreased the concentration of plasma total cholesterol, high density lipoprotein cholesterol, triglyceride and phospholipid as compared to LA-rich fat. BSO was more effective in reducing plasma cholesterol concentrations than was the ALA-rich fat. Dietary BSO markedly decreased the hepatic triglyceride concentration as compared to the LA-rich or ALA-rich fats. Aortic production of prostaglandin I_2 tended to decrease in rats fed BSO or ALA-rich fat compared to those fed the LA-rich fat. Adenosine diphosphate-induced platelet aggregation was similar in the three groups. The proportion of arachidonic acid (AA) in liver phosphatidylcholine (PC) of rats fed BSO was lowest compared to that of rats fed ALA-rich or LA-rich fats. Administration of 20:4BSO, ALA or GLA to essential fatty acid-deficient rats decreased the ratio of 20:3n-9 to AA in liver PC to the same extent; administration of LA was more effective. The results indicate that the effects of specific PUFA contained in BSO on lipid metabolism are different from those of LA and ALA. It is also suggested that 20:4BSO may exhibit some essential fatty acid effects.

***Lipids* 27, 500-504 (1992).**

Biota orientalis seeds have been used for many years in Chinese medicine. The oil extracted from the seeds contains anomalous n-6 and n-3 polyunsaturated fatty acids (PUFA), 5c,11c,14c-eicosatrienoic (20:3BSO) and 5c,11c,14c,17c-eicosatetraenoic (20:4BSO) acids (1,2). While 20:3BSO lacks the double bond at position 8 of arachidonic acid (AA), 20:4BSO lacks the double bond at position 8 of eicosapentaenoic acid (EPA). Although different PUFA are known to have different metabolic effects in mammals (3), no information is available on the biological effects of the PUFA occurring in BSO. In the present study, we examined the effect of specific PUFA occurring in *Biota orientalis* seed oil (BSO) on serum and liver lipid concentrations, platelet aggregation and prostaglandin formation in rats. The effect of 20:4BSO as an essential fatty acid also was assessed in essential fatty acid (EFA)-deficient rats.

Abbreviations: AA, arachidonic acid; ADP, adenosine diphosphate; ALA, α-linolenic acid; BSO, *Biota orientalis* seed oil; 20:3BSO, 5c,11c,14c-eicosatrienoic acid (n-3); EFA, essential fatty acid(s); EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; GLC, gas-liquid chromatography; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; LA, linoleic acid; PC, phosphatidylcholine(s); PE, phosphatidylethanolamine(s); PGI_2, prostacyclin; PUFA, polyunsaturated fatty acid(s); TLC, thin-layer chromatography; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Materials. BSO was extracted with hexane from *Biota orientalis* seed purchased from herb shops in Guangzhou, China, and was purified to a grade of refined edible oils by the general purification processes through the courtesy of Nihon Yushi Co. (Tokyo, Japan). Linseed, high oleic safflower and safflower oils were obtained from Nisshin Oil Mills Co. (Tokyo, Japan), Fuji Oil Co. (Tokyo, Japan) and Linol-Yushi (Tokyo, Japan), respectively. Purified ethyl linoleic acid (LA), ethyl α-linolenic acid (ALA) and ethyl γ-linolenic acid (GLA) (>98% purity) were obtained from Idemitsu Chemicals (Tokyo, Japan). After BSO was saponified and the fatty acids were converted to ethyl esters, ethyl 20:4BSO was separated and purified by preparative high-performance liquid chromatography (HPLC) at Nisshin Oil Mills Co. The preparation was 85.3% pure and contained 12.0% ALA and 2.7% LA as impurities.

Animals and diets. Male Sprague-Dawley rats (4-wk-old in Exp. 1, and 3-wk-old in Exp. 2) obtained from Seiwa Experimental Animals (Fukuoka, Japan) were housed individually and kept in a room at controlled temperature (22-24°C) and lighting (8:00 a.m. to 8:00 p.m.). In Exp. 1, the rats were divided into 3 groups of 6 animals each and fed the experimental diets for 24 days. The basal diet was prepared according to the formula recommended by the American Institute of Nutrition (4) and contained (by weight percent): Casein 20, fat 10, vitamin mixture 1.0, mineral mixture 3.5, choline bitartrate 0.2, DL-methionine 0.3, cholesterol 0.5, sodium cholate 0.125, cellulose 5.0, corn starch 15 and sucrose to 100. A mixture of 90% safflower oil and 10% high oleic safflower oil was used as the LA-rich fat, and a mixture of 85% linseed oil and 15% safflower oil was used as the ALA-rich fat. The fatty acid compositions of the fats are shown in Table 1.

TABLE 1

Fatty Acid Composition of Dietary Fat[a]

Dietary fat	Fatty acids (weight %)						
	16:0	18:0	18:1	18:2n-6	18:3n-3	20:3BSO	20:4BSO
ALA[b]	4.9	2.8	17.3	25.7	49.1	—	—
LA[c]	6.1	2.4	18.4	72.6	—	—	—
BSO	5.2	4.6	17.5	23.9	32.1	4.8	8.9

[a]20:3BSO, 5c,11c,14c-eicosatrienoic acid; and 20:4BSO, 5c,11c,14c,17c-eicosatetraenoic acid.

[b]ALA-rich fat.

[c]LA-rich fat.

In Exp. 2, 70 rats were divided into 2 groups. Twelve rats were fed the basal diet supplemented with 1.4% safflower oil, and 58 rats were given a fat-free diet. The composition of the basal diet was the same as in Exp. 1, except for the exclusion of fat, cholesterol and sodium cholate. After 66 days on the diets, 6 rats given the safflower oil-supplemented diet and 5 rats fed the fat-free diet were killed. The rest of the rats, fed a fat-free diet, were divided into five groups. Four groups of 12 rats each were given 100 mg/day (orally) of either ethyl LA, ethyl ALA, ethyl GLA or ethyl 20:4BSO, and 6 rats in each group were killed after consecutive administration of the ethyl esters for 3 and 10 days while they were continuously given a fat-free diet. Six rats fed the safflower oil-supplemented diet and five rats fed the fat-free diet were given a glucose solution which contained the same amount of calories as 100 mg of fatty acid ethyl esters, and were killed after 10 days. In both experiments, after 7-h fasting from 6:00 a.m. to 1:00 p.m., rats were anesthetized with diethyl ether. Blood (9 mL) was collected from the abdominal aorta in a syringe containing 1 mL of 3.8% trisodium citrate and indomethacin (final concentration of 0.1 mM).

Lipid analyses. Liver, plasma and epididymal adipose tissue were extracted in 20 vol of chloroform-methanol (2:1, vol/vol) according to Folch *et al.* (5). Liver and plasma cholesterol, triglyceride and phospholipid were measured as described previously (6). Liver phosphatidylcholine (PC), phosphatidylethanolamine (PE), triglyceride and cholesteryl ester, as well as plasma cholesteryl ester and triglyceride were separated by thin-layer chromatography (TLC), and the fatty acid compositions were analyzed by gas-liquid chromatography (GLC) on a SILAR 10C column (Nihon Kuromato Kogyo, Tokyo, Japan) (7). Fatty acid compositions of total lipids in epididymal adipose tissue also were analyzed by GLC.

Prostaglandin analyses. The thoracic aortas were incubated in Krebs-Henseleit bicarbonate buffer (pH 7.4) at 25°C for 30 min and the concentration of 6-keto prostaglandin $F_{1\alpha}$ in the medium was measured with a commercially available radioimmunoassay kit (NEK-008, New England Nuclear, Boston, MA) (8). The concentration of 11-dehydro-thromboxane B_2 in plasma also was measured with a commercial kit (NEK-042, New England Nuclear) as described previously (9).

Statistical analysis. All data were analyzed by Duncan's new multiple range test (10).

RESULTS

Experiment 1

Body weight, food intake and liver weight. As shown in Table 2, no significant differences were found in body weight gain, food intake and relative liver weight among the three groups.

Plasma and liver lipids. The concentration of plasma and liver lipids is shown in Table 3. The concentration of plasma total cholesterol was lowest in the BSO group and highest in the LA-rich fat group, and intermediate in the ALA-rich fat group. The difference between each group was significant. The concentrations of plasma high density lipoprotein (HDL) cholesterol and phospholipid were significantly lower in rats fed ALA-rich fat or BSO than in those fed LA-rich fat. A similar tendency was observed in the concentration of plasma triglyceride.

The concentration of liver triglyceride in the BSO group was significantly decreased by more than 50% relative to the ALA-rich or LA-rich fat groups. The concentration of liver cholesterol was similar in the three groups, whereas that of liver phospholipid was higher in the BSO group than in the other two groups.

Prostaglandin I_2 and platelet aggregation. Aortic production of prostacyclin (PGI_2) measured as 6-keto-prostaglandin $F_{1\alpha}$ significantly decreased in rats fed BSO as compared to those fed LA-rich fat (Fig. 1). The production in rats fed ALA-rich oil also tended to be lower than in those fed LA-rich fat. There was no difference in the

[c,e,f,g]Values not sharing a common superscript letter are significantly different at $P < 0.05$.
[b]ALA-rich fat.
[d]LA-rich fat.

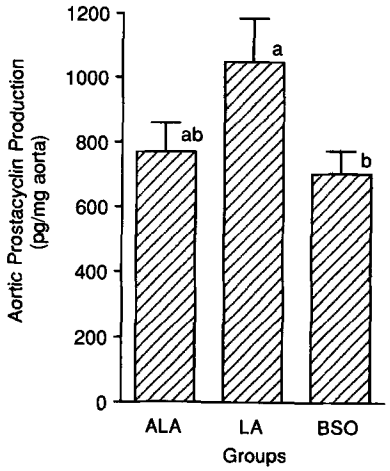

FIG. 1. Effect of ALA- and LA-rich fats and BSO on aortic prostacyclin production in rats. Prostacyclin was measured as a 6-keto-prostaglandin $F_{1\alpha}$. Data are means ± SE of six rats. Values not sharing a common letter are significantly different at $P < 0.05$.

maximum platelet aggregation induced by 5 μM adenosine diphosphate (ADP) among the three groups (32.7 ± 6.0%, 33.1 ± 4.1% and 39.0 ± 4.0% in the ALA-rich fat, LA-rich fat and BSO groups, respectively; mean ± SE of six rats).

Fatty acid compositions. Fatty acid compositions of liver PC and PE are shown in Table 4. The proportions of LA in the respective phospholipid fractions were similar among the three groups. The proportion of AA was lower when the dietary fat was BSO or ALA than when it was LA. BSO decreased AA more markedly than ALA-rich fat in liver PC, but not in PE. The same tendency was observed in plasma PC (data not shown). The proportion of EPA in both phospholipid fractions was considerably higher in rats fed ALA-rich fat than in those fed BSO; essentially no EPA was detected in rats fed the LA-rich fat. However, the proportions of 22:5n-3 and 22:6n-3 were not too different between the ALA-rich fat and the BSO groups. The proportion of LA in triglyceride and cholesteryl ester of liver was significantly lower in the BSO and ALA-rich fat groups than in the LA-rich fat group, but no difference between the BSO and ALA-rich fat groups was found (data not shown).

The fatty acid composition of epididymal adipose tissue total lipids reflected that of the dietary fat, as shown in Table 5. The proportions of LA and AA were significantly higher in the LA-rich fat group than in the ALA-rich fat or the BSO groups.

Incorporation of 20:3BSO and 20:4BSO into various lipid fractions is summarized in Table 6. Markedly higher incorporation of 20:3BSO, as compared to 20:4BSO, was seen in the phospholipid fractions of plasma and liver. In contrast, more 20:4BSO was incorporated than 20:3BSO in liver cholesteryl ester. Incorporation of these two PUFA into liver triglyceride was marginal.

Experiment 2

Fatty acid compositions of liver PC at the end of the experiment (feeding PUFA for 10 days) are shown in Table 7. The effect of PUFA on the fatty acid composition was more pronounced after consecutive administration for 10 days than after 3 days. The proportion of AA significantly decreased, and that of 20:3n-9 increased in liver PC of rats fed the fat-free diet. ALA was the most effective in decreasing the proportion of 20:3n-9, while it simultaneously decreased AA. The ability of 20:4BSO to decrease 20:3n-9 was equal to that of LA. The increase in AA in the liver PC fraction was most evident when LA was administered. When GLA or 20:4BSO was administered, the proportion of AA was similar to that of the fat-free group. ALA administration resulted in the lowest AA values. The high 20:3n-9/AA ratio in the fat-free group was apparently

reduced by the administration of LA. THe effects of administering GLA, ALA or 20:4BSO were similar and were less than that of LA. The same tendency was observed in the fatty acid composition of liver PE (data not shown). Various PUFA did not show a different effect on plasma and liver lipid concentrations, the production of aortic PGI_2 or platelet thromboxane A_2 (data not shown).

DISCUSSION

Our results show that BSO lowered plasma cholesterol more effectively than the fats rich in either LA or ALA. The effect of BSO can be ascribed to 20:3BSO and 20:4BSO, because the content of PUFA in the dietary fats was adjusted to be the same. A reduction in plasma triglycerides and phospholipids also was observed in rats fed BSO as compared to those fed LA-rich fat, although the efficacy was comparable to that of ALA-rich fat. The most specific effect of BSO was seen in liver triglyceride. The concentration of liver triglyceride in the BSO group was less than half that in the LA-rich and ALA-rich fat groups. The observation suggests that BSO specifically inhibits the synthesis of triglyceride and/or promotes the catabolism of triglyceride in the liver. The decrease in liver triglyceride may cause reduced synthesis and secretion of very low density lipoprotein (VLDL) into plasma (11). This may be the reason why BSO decreased plasma cholesterol concentration more efficiently than fat rich in LA or ALA. However, since the plasma triglyceride concentration in rats fed BSO was comparable to that in the ALA-rich fat group, the plasma clearance rate of VLDL triglyceride in the BSO group might be different from that in the ALA-rich fat group. Although EPA synthesized from ALA depresses the secretion of VLDL and decreases

[c-f]Values not sharing a common superscript letter are significantly different at $P < 0.05$.

the plasma concentration of triglyceride and cholesterol in rats, it does not decrease the concentration of liver triglyceride significantly (12). These observations point towards a specific effect of BSO on hepatic triglyceride metabolism.

The hypocholesterolemic effect of LA, the most ubiquitous n-6 PUFA, is widely accepted, although the precise mechanism is still under debate (13). It has been reported that excessive intake of LA may result in various side-effects, including promotion of carcinogenesis, increased lithogenecity, acceleration of cell aging, immunodepression, and lowering of HDL cholesterol (14,15). These effects can be mostly, but not entirely, explained by the overproduction and imbalance of specific prostaglandin(s). Therefore, PUFA having a cholesterol-lowering effect and not serving as a substrate for 2-series prostaglandins may be more useful. EPA contained in fish oil has been reported to exert a hypotriglyceridemic and hypocholesterolemic effect, and it interferes with the production of the 2-series prostaglandins in rats (16). However, fish oil is extremely sensitive to peroxidation and is not a good dietary source because of its unpleasant odor. BSO lowered plasma cholesterol without increasing prostaglandin synthesis; therefore, it can be a useful hypolipidemic fat compared to the usual n-3 PUFA, such as EPA and ALA.

The proportion of AA in plasma and liver PC decreased in rats fed ALA-rich fat or BSO, suggesting interference with desaturation and elongation of LA to AA. The reduction of AA in liver and plasma PC of the BSO group was more pronounced than in the ALA-rich group. The reduction of tissue AA may be related to the decrease in aortic PGI_2 synthesis. Since BSO and ALA-rich fat decreased PGI_2 synthesis to the same extent as compared to LA-rich fat, it is quite apparent that BSO has an effect similar to that of ALA.

Incorporation of 20:3BSO and 20:4BSO into various lipid fractions was specific; more 20:3BSO than 20:4BSO was incorporated into liver PC, PE and plasma PC, whereas the opposite was true for incorporation into liver cholesteryl esters and adipose tissue triglycerides. The proportions of these fatty acids in plasma cholesteryl ester and triglyceride were comparable to those of dietary BSO. These fatty acids were essentially not incorporated into liver triglyceride. The metabolic consequence of such a tissue and lipid-specific incorporation of these anomalous PUFA is not obvious at present. However, it is plausible that the deposition of a considerable amount of 20:3BSO into membrane phospholipids causes an alteration in membrane properties and function.

The ability of 20:4BSO to act as an essential fatty acid was assessed by the reduction in the ratio of 20:3n-9/AA in liver PC, which was comparable to that of GLA or ALA, and less than that of LA. ALA most effectively decreased the proportion of both AA and 20:3n-9, suggesting a greater depression by ALA of the desaturation and elongation of oleic acid, as well as LA (17). Although 20:4BSO, another n-3 PUFA, also tended to decrease AA and 20:3n-9, the effect was less than that of ALA. In contrast, BSO was more effective in decreasing AA than ALA-rich fat in the liver PC fraction in Exp. 1. The difference can be explained by the difference in the essential fatty acid status or in the composition of fat given between these two experiments. In Exp. 1, dietary fat contained the mixture of LA, ALA, 20:3BSO and 20:4BSO, in contrast to ethyl 20:4BSO in Exp. 2.

The improvement of skin symptoms due to administration of PUFA was not evident in these experiments. It has been reported that n-3 PUFA, when compared to LA, are less effective in improving skin symptoms resulting from essential fatty acid deficiency (18,19).

The results in Exp. 1 showed that 20:3BSO and/or 20:4BSO contained in BSO have some specific effects on lipid metabolism in rats. It also was suggested that 20:4BSO may function as an essential fatty acid, as would ALA and GLA, as judged by the decrease in the ratio of 20:3n-9/AA. Therefore, BSO may become useful as a beneficial dietary PUFA to prevent lipid disorders.

ACKNOWLEDGMENT

The authors wish to thank Dr. S. Samman, Human Nutrition Unit, University of Sydney, for his valuable comments in the preparation of the manuscript.

Phospholipid Fatty Acyl Distribution of Three Fungi Indicates Positional Specificity for n-6 *vs.* n-3 Fatty Acids

Andrew Kendrick and **Colin Ratledge***
Department of Applied Biology, University of Hull, Hull HU6 7RX, United Kingdom

Phospholipids of the fungi *Conidobolus nanodes, Entomophthora exitalis* and *Saprolegnia parasitica* were extracted and analyzed. The phospholipid content was the same (2.4%) for the three species and was independent of the total lipid content. Phospholipase A_2 degradation of individual phospholipid classes showed an asymmetrical distribution of polyunsaturated fatty acids (PUFA) between the two fatty acyl positions of glycerol. There was a predominance of n-6 PUFA at position 2 and a predominance of n-3 PUFA at position 1. With *C. nanodes* and *E. exitalis*, 20:5n-3 is derived from 18:3n-3 and is located predominantly at position 1. In *S. parasitica* 20:5n-3 is synthesized from 18:3n-6 *via* 20:4n-6 and is located predominantly at position 2. It is suggested that the asymmetrical distribution of PUFA between positions 1 and 2 of glycerol points towards different sites of synthesis of the two classes of PUFA, and that cross-over between PUFA of the different types is prevented by the *sn*-1 or *sn*-2 positional specificity of the desaturases.
***Lipids* 27, 505–508 (1992).**

Phospholipids are highly versatile membrane components that can, for example, regulate changes in membrane fluidity in response to changes in growth temperature, oxygen deprivation or salinity (1). When working with the fungus *Entomophthora exitalis,* we observed changes in phospholipid composition with respect to the proportion of the phospholipid classes that were present and to the degree of fatty acyl unsaturation in response to changing growth temperatures (2). The phospholipid fraction of this organism, compared to the neutral, glycolipid and sphingolipid fractions, contains the highest proportion of polyunsaturated fatty acids (PUFA) (2–4). This difference in distribution of PUFA between lipid classes could either reflect a functional necessity of phospholipids within the various cell membranes, or indicate that phospholipids are the sites of PUFA biosynthesis, or both. Phospholipids have actually been shown to serve as substrates for fatty acyl desaturation in eukaryotic organisms, including yeasts (5,6) and plants where, for example, in barley *(Hordeum vulgare)* oleate is desaturated to linoleate and then to linolenate while being a constituent of phosphatidylcholine (PC) (7).

The three fungi selected for this work were part of a survey of PUFA-producing fungi (2,3). All displayed a predominance of PUFA in the phospholipid fractions as described above. All three fungi are members of the lower fungi or phycomycetes (8). *Saprolegnia parasitica* is an Oomycetes and has been reported as being able to synthesize eicosapentaenoic acid (EPA) from arachidonic acid (AA) (9,10), *i.e.,* it possesses a Δ17 desaturase. *Entomophthora exitalis* and *Conidiobolus nanodes* are both Zygomycetes (8) and have been reported (11–13) as producing long-chain PUFA of both the n-6 type (*e.g.,* AA) and the n-3 type [*i.e.,* EPA and docosahexaenoic acid (DHA)]. We therefore felt that the analysis of the positional distribution of the fatty acyl groups in glycerol positions 1 and 2 of the phospholipids of these fungi may help in a better understanding of PUFA biosynthesis in fungi in general.

Abbreviations: AA, arachidonic acid; DHA, docosahexaenoic acid; EDTA, ethylenediaminetetraacetic acid disodium salt; EPA, eicosapentaenoic acid; GLA, gamma-linolenic acid; MES, 4-morpholinoethanesulfonic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid.

MATERIALS AND METHODS

Micro-organisms and growth. The strains of fungi examined were *Conidiobolus nanodes* (IMI 92299), *Entomophthora exitalis* (NRRL 3742) and *Saprolegnia parasitica* (ATCC 22284). The fungi were cultivated in semi-defined nitrogen-limiting growth media which combined (g/L): Glucose, 30; KH_2PO_4, 7.0; Na_2HPO_4, 2.0; $MgSO_4 \cdot 7H_2O$, 1.5; yeast extract (Oxoid) 1.5; $CaCl_2 \cdot 2H_2O$, 0.1; $FeCl_3 \cdot 6H_2O$, 0.008; $ZnSO_4 \cdot 7H_2O$, 0.001; $CuSO_4 \cdot 5H_2O$, 0.0001; $Co(NO_3)_2 \cdot 6H_2O$, 0.0001; $MnSO_4 \cdot 5H_2O$, 0.0001 and diammonium tartrate, 3.3. The fungi were grown for 72 h in 800 mL media contained in 1-L vortex-aerated reagent bottles. *C. nanodes* and *E. exitalis* were grown at 30°C and *S. parasitica* was grown at 24°C. Lipids were extracted with chloroform/methanol (2:1, vol/vol), fractionated using a column of silicic acid, and fatty acids were analyzed as methyl esters by gas chromatography as previously described (3).

Thin-layer chromatographic analysis of phospholipids (3). Separation of phospholipids was achieved on 0.25 mm Silica Gel G plates (Anachem, Luton, Bedshire, U.K.) (20 × 20 cm) using chloroform/methanol/water/acetic acid (65:43:3:1, by vol) for development. Spots were visualized by staining with 2′,7′-dichlorofluorescein (0.1% w/vol in ethanol) and viewed under UV light. Phospholipids were identified by comparison with authentic standards (Sigma Chemical Co., St. Louis, MO). The appropriate regions of the plate were scraped off, and phospholipids were extracted with 50 mL of chloroform/methanol (1:1, vol/vol). Silica Gel G was removed by filtration and was washed with 50 mL chloroform/methanol (1:1, vol/vol). The organic phases were pooled and the solvent was removed by rotary evaporation.

Phospholipase A_2 degradation of phospholipids (9). Phospholipids (5–10 mg) were dissolved in diethyl ether (5 mL) containing hexadecyltrimethylammonium bromide (20 mg); 10 mM 4-morpholinoethenesulfonic acid (MES) buffer, pH 7.0, containing 1 mM ethylenediaminetetraacetic acid (EDTA) and 100 units phospholipase A_2 (porcine pancreas; Sigma), was added (1 mL) and the mixture was shaken vigorously for 3 h at 37°C. The aqueous phase was removed and washed with diethyl ether (3 × 50 mL). The ether washings were combined with the ether layer, the solvent was evaporated and the residue (the free fatty acids) was redissolved in a minimal volume of diethyl ether, weighed after evaporation of the solvent, and stored

at −20°C. The aqueous layer was mixed with ethanol (20 mL), the solvent was removed by rotary evaporation and the residue of lysophospholipids was redissolved in a minimal volume of diethyl ether and stored at −20°C.

RESULTS

The phospholipid contents of the three fungi examined were similar at 2.5% w/w of biomass (Table 1), and appeared to be independent of the total lipid content. In each case, the main component of the extracted lipid was triacylglycerol (data not given, see ref. 3).

The distribution of fatty acids between the *sn*-1 and *sn*-2 positions of the phospholipids was examined for each fungus (Tables 2, 3 and 4). With one exception, position

[a]Expressed as percentage (w/w) of total fatty acids present.

2 contained a greater proportion of PUFA than position 1, the exception being PC isolated from *E. exitalis*.

A further pattern emerges when the fatty acid profiles are expressed as n-3 and n-6 PUFA at each position. In the fungi *C. nanodes* (Table 2) and *E. exitalis* (Table 3), n-3 PUFA predominate at position 1 and n-6 PUFA at position 2. In *S. parasitica*, the only n-3 PUFA evident is EPA (Table 4), which is fund preferentially at position 2 along with the n-6 PUFA, AA. It has been shown previously that *S. parasitica* belongs to a group of organisms that can synthesize EPA from AA (9,10), *i.e.*, they possess a Δ17 desaturase. Accordingly, if the two groups of PUFA are reclassified, either as derivatives of gamma-linolenic acid (GLA) (*i.e.*, n-6 PUFA) or α-linolenic acid (*i.e.*, n-3 PUFA), a consistent pattern of fatty acyl distribution can now be discerned for all three fungi—position *sn*-1 contains predominantly PUFA derived from α-linolenic acid, and position *sn*-2 contains predominantly PUFA derived from GLA.

DISCUSSION

Predominance of PUFA at position 2 of phospholipids has been reported previously to the fungus *Phycomyces blakesleeanus* (14), which is classed as a lower fungus and produces only n-6 PUFA, and also in rat (15), rainbow trout (16) and mosses (9). No evidence has been presented to explain such a distribution resulting from *de novo* phospholipid biosynthesis, *i.e.*, the transfer of CDPcholine to specific 1,2-diacylglycerol species with a preference of n-3 in position 1 and n-6 in position 2. Neither has asymmetrical distribution of different PUFA classes been reported in a 1,2-diacylglycerol.

Phospholipids in eukaryotic systems other than animals are accepted as the most likely form in which fatty acids exist for desaturation (5–7). The results obtained here could be viewed as evidence for separate sites of n-3 and n-6 PUFA synthesis on phospholipid molecules (positions 1 and 2, respectively). This theory is supported by comparing the positional distribution of fatty acids of the fungi *C. nanodes* and *E. exitalis* with the fungus *S. parasitica*. In the former fungi, EPA is derived from α-linolenic acid, 18:3n-3, and is located predominantly at position 1. In the latter fungus, EPA is derived from GLA 18:3n-6, and is located predominantly at position 2. The change in positional distribution in response to the changed mode of EPA synthesis would support the theory of n-3 and n-6 PUFA biosynthesis at positions 1 and 2, respectively. By extension of this argument, as both 18:3 isomers will be derived from 18:2 (*c*9,*c*12), the Δ6 desaturase must act primarily on the acyl group at position 2 and the Δ15 desaturase must act on the acyl group at position 1. This prediction has been confirmed in plants by work with borage *(Borage officinalis)* preparations which has revealed that, although linoleate is present at both positions of PC, only linoleate at position 2 acts as a substrate for the Δ6 desaturase to give GLA (17). We have recently made a similar observation for the formation of GLA in *Mucor circinelloides*, except that phosphatidylethanolamine (PE) is used as the acyl carrying phospholipid (Kendrick, A.J., and Ratledge, C., unpublished work).

In *C. nanodes* and *E. exitalis*, the PUFA which predominate are the n-6 type (3). Of the three phospholipid types present, PC had the lowest proportion of n-6 PUFA. Further work with borage preparations (18) has shown that, although other phospholipid types are substrates for desaturation, only PC is actively turned over and is involved in the supply of fatty acids for other cellular lipids (14). If PC is similarly turned over in *C. nanodes* and *E. exitalis* then it could be predicted that the n-6 PUFA content of this phospholipid would be lower than that of the other phospholipid types and, indeed, this has been shown to be the case in this work.

The present observations allow us to speculate that n-6 and n-3 PUFA diverge from their common precursor of 18:2 not only by there being two distinct desaturases (the Δ6 and the Δ15, respectively), but by these enzymes acting at different sites on the phospholipid carrying the 18:2 residues. Thus, one can understand how each series of n-6 and n-3 PUFA is created without spurious introduction of double bonds into the wrong position. The two series of PUFA are kept distinct and separate by virtue of their differential attachments to the phospholipid carrier. Cross-over from n-6 to n-3 thus remains minimized. The only exception comes with *Saprolegnia parasitica* for the final conversion of 20:4n-6 (AA) to 20:5n-3 (EPA), which occurs with a Δ17 desaturase acting upon AA at the *sn*-2 position. The presence of this enzyme in this fungus has already been described by Gellerman and Schlenk (10) and, more recently, in *Mortierella alpina* (19). (The stereospecific distribution of PUFA on the phospholipids of the latter mold has not been carried out to verify if it fits in with the pattern observed here.) In the other two fungi studied here there is no evidence for cross-over, and EPA is seemingly synthesized from 18:3n-3, probably *via* 20:3n-3 and 20:4n-3, which remain attached to the *sn*-1 position in the phospholipids.

The proof of this hypothesis will need to await the isolation and detailed study of the appropriate desaturases. Nevertheless the analyses recorded here offer an explanation for the origin of n-6 and n-3 PUFA in the same fungal organism, and possibly in those plants that produce both n-6 and n-3 PUFA. It would clearly be of interest to see whether this hypothesis was of general applicability in fungi and in plants. An examination of the stereospecific distribution of PUFA in ascomycete and basodiomycete fungi (the "fungi imperfect" and "higher fungi"), which produce only n-3 PUFA, should be extremely revealing. If our hypothesis holds, such fungi would be expected to have 18:3n-3, and any other n-3 PUFA, located only at the *sn*-1 position of the appropriate phospholipid involved in the desaturase reactions, as this would be the site of action of the Δ15 desaturase.

Inhibitory Effect of Curcumin on Fatty Acid Desaturation in *Mortierella alpina* 1S-4 and Rat Liver Microsomes

Sakayu Shimizu*, Saeree Jareonkitmongkol, Hiroshi Kawashima[1], Kengo Akimoto[1] and Hideaki Yamada
Department of Agricultural Chemistry, Kyoto University, Sakyo-ku, Kyoto 606, Japan

An extract of rhizomes of *Curcuma longta* L. (turmeric) inhibited the desaturation of dihomo-γ-linolenic acid (DGLA) in the arachidonic acid (AA) producing fungus *Mortierella alpina* 1S-4. The factor responsible for this phenomenon was isolated and identified as curcumin (diferuloyl methane). Mycelial DGLA levels increased about two-fold (22.3 mg/g dry weight) with a concomitant decrease in AA levels when the fungus was cultivated with curcumin. The 50% inhibitory concentration against Δ5 desaturase was 27.2 μM. Curcumin also inhibited rat liver microsomal Δ5 and Δ6 desaturases.
Lipids 27, 509–512 (1992).

Polyunsaturated fatty acids (PUFA), especially those of the C_{20} series, such as dihomo-γ-linolenic acid (8,11,14-*cis,cis,cis*-eicosatrienoic acid, DGLA), arachidonic acid (5,8,11,14-*cis,cis,cis,cis*-eicosatetraenoic acid, AA) and 5,8,11,14,17-*cis,cis,cis,cis,cis*-eicosapentaenoic acid, are not only important precursors of prostaglandins, but they also regulate membrane fluidity as primary components of biological membranes and affect various physiological activities. In higher animals, PUFA of the ω6 and ω3 series cannot be synthesized unless linoleic acid (ω6) or α-linolenic acid (ω3) is supplied in the diet. Thus, compounds that regulate the metabolism of these PUFA are of profound interest, as they may not only serve as important means of clarifying the physiological significance of PUFA biosynthesis, but they also may be useful as new types of drugs.

We have reported previously (1,2) that sesamin and other lignan compounds found in sesame seeds inhibit the conversion of DGLA to AA (Δ5 desaturation). In the present study we tested several extracts of crude drugs and spices for their effects on the fatty acid composition of the AA producing fungus, *Mortierella alpina* 1S-4. We found that the DGLA/AA ratio in the fungus increased significantly when grown in a medium supplemented with an ethanol-extract of turmeric. In this paper we report the isolation and characterization of the inhibitory constituent responsible for this phenomenon and its effect on the desaturation system of this fungus, as well as on rat liver microsomal desaturases.

MATERIALS AND METHODS

Chemicals. Curcumin was purchased from Wako Pure Chemicals (Osaka, Japan). Turmeric, other spices and crude drugs were obtained from a local market. Radiolabeled fatty acids were obtained from Amersham International (Buckinghamshire, U.K.). All other reagents were of analytical grade.

Microorganism and cultivation. Mortierella alpina 1S-4 (3,4) was inoculated as a spore suspension into a 10-mL flask containing 2 mL of medium A (2% glucose and 1% yeast extract, pH 6.0) or medium B (4% glucose and 1% yeast extract, pH 6.0) and then incubated at 28°C with reciprocal shaking at 120 strokes/min, unless otherwise noted. When crude drugs and spices were tested for their effects on the fatty acid composition of the fungus, 0.5 g of each test substance was first extracted twice with 5 mL of ethanol. The extract was evaporated to dryness and then redissolved in a small volume of ethanol. The extracts were mixed with sterile medium A at concentrations of 0.1–1% (w/vol) when the fungus was inoculated and grown as described above. The ethanol concentrations were usually less than 5%.

Fatty acid analysis. Mycelial cells were harvested by suction filtration, washed with distilled water and dried at 100°C overnight for subsequent fatty acid analysis by gas-liquid chromatography (GLC) after transmethylation with methanolic HCl as detailed elsewhere (3,5).

Cell-free extract. Washed mycelia (*ca.* 7 g) of *M. alpina* 1S-4 were suspended in 1 mL of 50 mM potassium phosphate buffer, pH 7.4, containing 1 mM dithiothreitol and ground in an ice-cooled mortar with 2 g of sea sand for 50 min. One mL of buffer was added 10, 20, 30 and 40 min later. After centrifugation (10,000 × *g*, 4°C, 30 min), the supernatant was used as the enzyme solution.

Preparation of rat liver microsomes. Microsomes were prepared from male Wistar rats maintained on a pellet diet for 8 wk as described previously (2).

Assay of desaturase activities. The cell-free extract of *M. alpina* 1S-4 was assayed for Δ5 desaturase activity by using radiolabeled DGLA as previously described (2). Rat liver microsomal Δ5, Δ6 and Δ9 desaturase activities were measured by the method of Svensson (6) using radiolabelled DGLA, linoleic acid and stearic acid, respectively, as substrates.

Other methods. Protein concentrations were determined by the method of Bradford (7). Mass spectra were recorded on a Hitachi (Tokyo, Japan) M-80B at 70 eV. ^1H nuclear magnetic resonance (NMR) spectra were measured with Nicolet (Fermont, CA) NT-360 using CD_3OD as solvent and tetramethylsilane as internal standard.

RESULTS

Screening of Δ5 desaturation inhibitors. The effects of 62 crude drugs and 67 spices on the fatty acid profile of *M. alpina* 1S-4 were tested. The effects of some crude drugs and spices (which are commonly known and easily obtainable in Japan) on DGLA and AA production of the fungus are given in Table 1. Considering the DGLA/AA ratios of the fungus grown in the presence of the extracts as an index for the estimation of Δ5 desaturation inhibitory activity, we found that the DGLA/AA ratio of the fungus cultured with turmeric extract was 0.43. [a]*M. alpina* 1S-4 was grown in medium B supplemented with the turmeric extract at 28°C for 7 d. All values are means of two determinations.

[b]The ethanol extract obtained from 0.5 g of turmeric was resuspended in 4 mL ethanol, then the indicated volumes were added to 2 mL of sterile medium A.

was about double that of the control (0.21). However, those cultured with the other extracts (including those not shown in Table 1) ranged from 0.20 to 0.29. The extracts which resulted in DGLA/AA ratio higher than 0.27 (or 1.3-fold that the control) were tested again as to their dose-dependent effects on the DGLA/AA ratio, but none of them except for turmeric extract was found to be positive (data not shown). As shown in Table 2, the presence of turmeric extract of up to 20 μL in the culture medium did not affect fungal growth, but some inhibitory effect was observed with 50 μL. The levels of palmitic acid, oleic acid and DGLA appeared to increase to some extent, whereas those of AA decreased markedly. Mycelial DGLA concentration reached 28.7 mg/g dry mycelia, a value approximately 1.7 times that of the control (no supplement).

Isolation and identification of the inhibitory component. In order to characterize the active compound(s) responsible for this inhibition, we eluted the ethanol extract through silica gel with successive solvent systems of *n*-hexane/ethyl acetate (95:5 and 90:10, vol/vol) and methanol. Based on the elution profile at 254 nm, the extract was separated into eight fractions. The inhibitory effects of each fraction were monitored by growing the fungus in medium B supplemented with each fraction (0.01–0.1% w/vol culture broth), followed by analysis of the fatty acid profile. The fungus grown in the presence of the methanol-luted fraction accumulated about twice as much DGLA (27.9 mg/g dry mycelia) than did controls (14.7 mg/g dry mycelia). DGLA concentrations were about 12–14 mg/g dry mycelia in fungi grown with the other fractions. This fraction was separated into several bands in reverse phase thin-layer chromatography (TLC, $KC_{18}F$; Whatman, Fairfield, NJ) using 70% methanol as the developing solvent. Therefore, this fraction was subfractionated on a reverse phase column packed with octadecylsilane-bonded silica gel (Nakarai Chemicals, Kyoto, Japan) using various concentrations of aqueous methanol as eluent. Seven subfractions were obtained which were separately tested for their effects on the fatty acid profile of the fungus as described above. One fraction, comprised of a yellow pigment, showed a similar effect to that found in the crude extract. The DGLA/AA ratio of the fungus grown with this fraction was 0.26, and that of the control was 0.13. On the other hand, the DGLA/AA ratios of fungi grown with the other fractions were 0.12–0.16. The yellow fraction was homogeneous in reverse phase TLC as judged by UV detection (254 nm). Mass spectra showed the molecular ion at *m/z* 368 (relative intensity 27%); the other major fragmentation ion peaks were 350 (28), 338 (3), 320 (5), 272 (9), 244 (6), 232 (12), 217 (17), 203 (5), 190 (42), 177 (100), 161 (8), 150 (26), 145 (34), 137 (50), 131 (27), 117 (22), 103 (15), 89 (27), 77 (23), 65 (13), 51 (13) and 39 (8). ^1H NMR showed signals (δ, ppm) at 3.91 (*s*, 6H, CH_3), 5.96 (*s*, 1H, C=C), 6.62 (*d*, 2H, C=C), 6.81 (*d*, 2H, Ar), 7.12 (*d*, 2H, Ar), 7.21 (*s*, 2H, Ar) and 7.57 (*d*, 2H, C=C). These data agree well with those of authentic standard and they correspond to those of the enol form of curcumin, the structure of the keto form of which is shown in Figure 1.

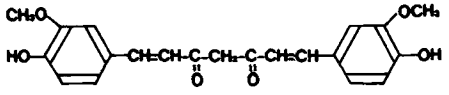

FIG. 1. Chemical structure of curcumin.

Effects of curcumin on DGLA production. Commercially obtained curcumin was dissolved in ethanol and added to sterilized medium B on which *M. alpina* 1S-4 was grown at 28°C for one week. As shown in Figure 2, the production of DGLA increased dose-dependently. The DGLA production rate was about 0.42 mg/mL culture broth per 0.1 mg/mL of curcumin. A higher concentration of curcumin inhibited fungal growth (data not shown).

Effect of curcumin on the conversion of DGLA to AA in vitro. The effect of curcumin on the conversion of DGLA to AA was investigated *in vitro* using a cell-free extract of the fungus. As shown in Figure 3a, increasing concentrations of curcumin markedly reduced the conversion of DGLA to AA. The 50% inhibitory concentration against Δ5 desaturase was 27.2 μM. On the other hand, the inhibition against Δ6 desaturase was less than 10% (data not shown). This result is consistent with the observation that the mycelial DGLA level of the fungus increased with a concomitant decrease in AA on growth in the presence of curcumin.

Inhibition effect in rat liver microsomes. Since curcumin inhibited Δ5 desaturation in the fungus, we further tested its effect on the desaturation systems of animals using rat liver microsomes (Fig. 3b). Unlike sesamin, which inhibits Δ5 desaturation in a specific manner (2), curcumin not only inhibited Δ5 desaturation, but the conversion of linoleic acid to γ-linolenic acid, *i.e.*, Δ6 desaturation. In the presence of 80 μM curcumin, the inhibition of Δ5 and Δ6 desaturation was 49% and 18%, respectively.

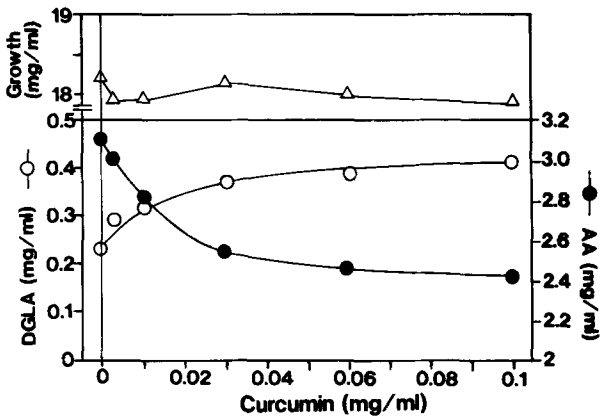

FIG. 2. Effects of curcumin on the production of DGLA and AA by *M. alpina* 1S-4. Curcumin was added as an ethanol solution to sterile medium B at the final concentrations indicated, then *M. alpina* 1S-4 was cultured at 28°C for one week. All value are means of three determinations, the standard deviation being less than 10%.

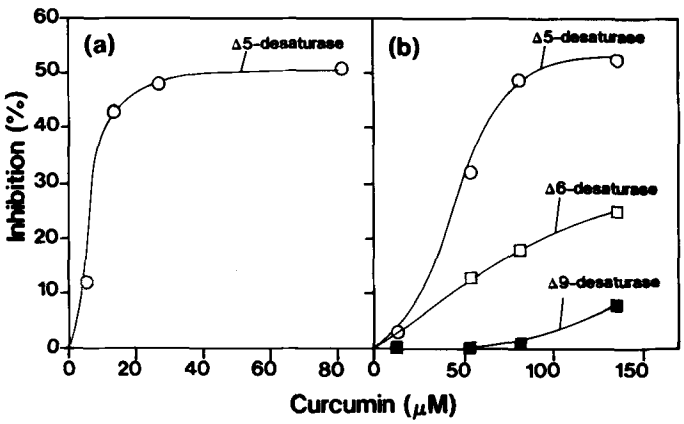

FIG. 3. Effects of curcumin on the Δ5 desaturase activities in cell-free extract of *M. alpina* 1S-4 (a) and rat liver microsomes (b). The reaction was done at 28°C (a) or 37°C (b), using the respective labeled fatty acids as substrate under the conditions described previously (2). The percentage of inhibition was calculated from the amount of radiolabeled fatty acids formed as compared with the control (no curcumin addition). The specific activity of Δ5 desaturase in the fungal cell-free extract was 24 pmol/min/mg protein, and those of rat microsomal Δ5, Δ6 and Δ9 desaturases were 131, 19 and 38 pmol/min/mg protein, respectively. All values are means of three determinations, the standard deviation being less than 10%.

DISCUSSION

These studies were undertaken to screen for Δ5 desaturation inhibitors from natural sources. Since the fatty acid composition can be expected to reflect desaturation activity in cells, we performed the screening by growing a potent AA producer, *M. alpina* 1S-4, in the presence of the test materials, followed by analysis of the fungal fatty acids. We found that curcumin, the major component of turmeric (*Curcuma longta*, L.) (8), mainly inhibited Δ5 desaturation in *M. alpina* 1S-4 fungus. However, in rat liver microsomes, curcumin markedly inhibited Δ6 desaturation. Curcumin has been studied intensively by many investigators and has been shown to have inflammatory activity (9–17), as well as showing inhibitory effects on mammalian 5-lipoxygenase and cyclooxygenase (18). However, as far as we know, there has been no report on its effect on the fatty acid desaturation system.

Except for our earlier paper (2), there has been no report demonstrating the occurrence of desaturase inhibitors in nature. Some unnatural desaturase inhibitors have been synthesized, and most of them are analogs of fatty acids which nonspecifically inhibit any of the desaturases involved in PUFA biosynthesis. For example, several *trans*-octadecenoic acids are competitive inhibitors of Δ9, Δ6 and Δ5 desaturases of rat liver microsomes (19,20). A kinetic study of the inhibition mode of curcumin was not done, but the inhibition is probably not competitive. On a structural basis, curcumin should not compete with any fatty acid for any desaturase.

The enzyme Δ5 desaturase converts DGLA to AA with the result that a precursor for the 1-series prostaglandins is converted to a precursor for the 2-series. Since curcumin inhibited the Δ5 desaturase, it may be able to influence the balance of the two fatty acids and, therefore, alter various metabolic pathways. It would be of interest to investigate the effect of curcumin on the fatty acid desaturation (or biosynthesis) in humans, since curcumin is a component of an edible spice that is widely consumed.

Nonesterified Fatty Acids in Normal and Diabetic Rat Sciatic Nerve

Jyotiprakas Chattopadhyay, Ed W. Thompson and **Harald H.O. Schmid***
The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

Alloxan-induced diabetes in rats results in elevated levels of nonesterified fatty acids (NEFA) in whole sciatic nerve and its endoneurium. Increases in NEFA levels are more pronounced in whole diabetic nerve (40% over control) than in its endoneurial portion (20–30%). Alterations in the composition of phospholipid fatty acids are observed as well, including an increase in linoleate (18:2n-6) in endoneurial phosphatidylethanolamine and a decrease in arachidonate (20:4n-6) in both phosphatidylethanolamine and phosphatidylinositol of diabetic nerve.
Lipids 27, 513–517 (1992).

Peripheral neuropathy is a common complication of human diabetes mellitus as well as of chemically-induced or genetically determined diabetes in experimental animals (1–3). Common functional changes induced by diabetes in peripheral nerve include reduced conduction velocity, action potential and axonal transport, whereas morphological changes can include segmental demyelination (2). The underlying physiological and biochemical alterations induced by diabetes appear to be related to the microenvironment of the nerve, including blood flow and oxygen delivery (4) and changes in *myo*-inositol and inositol phospholipid metabolism (5). Reduced blood flow and hypoxia observed in diabetic rat sciatic nerve (6) were recently correlated with the generation of oxygen free radicals and the accumulation of lipid peroxidation products (7).

Ischemia and hypoxia are often associated with the liberation of fatty acids from complex lipids by the action of lipolytic enzymes, a process which is especially pronounced in the central nervous system (8). In addition, alterations in fatty acid metabolism are an important component of diabetes mellitus (9) and we have previously observed significantly elevated levels of nonesterified fatty acids (NEFA) in the myocardium of alloxan-diabetic rats (10). There exists, however, very little information on the amount or composition of NEFA in peripheral nerve in general (11–13) and none regarding diabetic animals. In order to examine whether changes in nonesterified fatty acids may play a role in the development of diabetic neuropathy, we have measured their levels and composition in the endoneurium and in whole sciatic nerve from normal and alloxan diabetic rats. The results are reported here.

EXPERIMENTAL PROCEDURES

Experimental animals and induction of diabetes mellitus. Male Sprague-Dawley rats of 150–180 g were obtained from a commercial colony (Bio Lab Corporation, St. Paul, MN) and housed in separate cages within a modern animal care facility. All animals had free access to food (Purina #5001, St. Louis, MO) and water throughout the study and were exposed to a 12 h light/12 h dark cycle. Diabetes was induced in each animal by a single injection of 4% alloxan monohydrate (Sigma Chemical Company, St. Louis, MO) in sterile saline into a tail vein at a dosage of 55 mg/kg body weight as described previously (10,14). Control animals received the appropriate volume of sterile saline. Nonfasting plasma glucose levels were measured three days later and at monthly intervals by enzymatic assay (Sigma) coupling the reactions of glucose oxidase and peroxidase. Glycosylated hemoglobin was measured according to the method of Abraham *et al.* (15) using Isolab affinity columns (Isolab, Inc., Akron, OH). Alloxan-injected rats with plasma glucose levels greater than 300 mg/dL and showing little or no weight gain were considered insulin deficient, and saline-injected animals with glucose levels below 150 mg/dL and normal rates of weight gain were used as controls. Any animal not meeting those criteria (*i.e.*, with plasma glucose level between 150 and 300 mg/dL or hyperglycemic but weight gaining) was excluded from the study. These limited criteria for inclusion of animals, used routinely in our studies of experimental diabetes, were selected (10,14) to minimize experimental variations due to differing severities of diabetes which we have shown to affect myocardial complications (16).

In accord with standards of proper animal care, efforts were made throughout the study to minimize or eliminate any unnecessary discomfort to the experimental animals. A diabetic rat of this model will normally remain active and able to groom itself. Food and water consumption and urine output will be above normal. In these experiments, any animal which showed a sudden or significant chronic weight loss, developed anuria, or became lethargic or unable to eat or drink was removed from the study and sacrificed by CO_2 inhalation.

At the intervals described below, diabetic and nondiabetic rats were moderately anesthetized by subcutaneous injection of sodium pentobarbital (50 mg/kg body weight) and brought to full anesthesia by intraperitoneal injection at the same dosage. The skin and superficial fascia of the right thigh of each rat were incised to expose the sciatic nerve from the point where it emerged from the gluteal muscles, past its separation into tibial, peroneal, and sural divisions, to the points where these passed deep to peripheral musculature. This portion was quickly excised and prepared for lipid analysis as described below. The animal was then killed by decapitation while still under anesthesia.

Preparation of sciatic nerve tissue. Experiment 1: Age-matched diabetic and nondiabetic control animals were killed 8 wk after the induction of diabetes. The excised sciatic nerve was washed in saline on cooled (15°C) dental wax, freed of adherent blood vessels and connective tissue, frozen in liquid N_2, weighed, and prepared for lipid analysis. Experiment 2: Age-matched diabetic and nondiabetic control animals were killed 21 wk after induction of diabetes. Upon removal, the nerve was washed in cooled saline, and the epineurium and perineurium were

Abbreviations: GC, gas chromatography; NEFA, nonesterified fatty acids; TLC, thin-layer chromatography.

stripped away by the procedure of Dyck *et al.* (17). The remaining endoneurium was weighed and prepared for lipid analysis.

Analysis of sciatic nerve lipids. Total lipids were extracted from sciatic nerve endoneurium or total sciatic nerve according to the procedure of Folch *et al.* (18). Briefly, nerve tissue was homogenized in cold methanol containing butylated hydroxytoluene using a Dounce homogenizer and then extracted with chloroform/methanol (2:1, vol/vol) containing 10 μg of heptadecanoic acid as internal standard. The phases were separated by adding 0.2 vol of 0.9% NaCl to the mixture which was again vortexed to remove water soluble contaminants. The residual tissue and upper aqueous layer were re-extracted with chloroform/methanol/water (86:14:1, vol/vol/vol). The pooled chloroform layer was evaporated under N_2 and the lipids redissolved in chloroform for further analysis. Aliquots were assayed for lipid phosphorus according to Bartlett (19).

A portion of the lipid extract was analyzed for NEFA after addition of diazomethane (20) using heptadecanoic acid as an internal standard. Briefly, the lipid extract was dried down under N_2, dissolved in freshly prepared diethyl ether/methanol (9:1, vol/vol), and treated with a solution of diazomethane in diethyl ether for 10–15 min. Fatty acid methyl esters were subsequently purified by silicic acid column chromatography and analyzed by gas chromatography using a Packard (Downers Grove, IL) model 428 gas chromatograph equipped with a Supelco (Bellefonte, PA) 2330 packed column and flame ionization detector. Column temperature was programmed from 180°C to 235°C at 2°C/min and the detector and injection port temperatures were 260°C and 250°C, respectively. The peaks were identified by comparison with standards obtained from NuChek Prep (Elysian, MN) and aliquots were hydrogenated to confirm the identity of unsaturated fatty acids. Peak areas were quantitated with a Spectra-Physics (San Jose, CA) SP4270 computing integrator.

Another portion of the lipid extract was applied to a small column of silicic acid and eluted with 10 mL chloroform (neutral lipids), 20 mL acetone (glycolipids) and 10 mL methanol (phospholipids). The phospholipid classes were quantified by phosphorus assay (19) after separation by two-dimensional thin-layer chromatography (TLC) (21) as described previously (22). For the analysis of their constituent fatty acids, phospholipid classes were isolated by one-dimensional TLC on layers of silica gel H containing 7.5% magnesium acetate using chloroform/methanol/ammonium hydroxide/water (65:35:5:1, by vol) as developing solvent. Choline and ethanolamine phospholipids were further purified by TLC on silica gel H using chloroform/methanol/water (65:25:4, vol/vol/vol). Ethanolamine plasmalogens were hydrolyzed in HCl-saturated diethyl ether, and the resulting lysophosphatidylethanolamines were separated from the nonhydrolyzed diacyl analogs by TLC. Purified phospholipids were transesterified with 0.2 N NaOH in methanol at 45°C for 1 h. Methyl esters were extracted into hexane and analyzed by gas chromatography (GC) as described above.

Statistics. All values between diabetic and non-diabetic groups in Experiments 1 and 2 were compared by two-tailed, unpaired Student's *t*-test, with significance indicated by $P \leq 0.05$.

RESULTS

Effects of alloxan-induced diabetes. As demonstrated by the data of Table 1, diabetic animals exhibited severe hyperglycemia, elevated levels of glycosylated hemoglobin and plasma lipids, increased water intake and essentially no weight gain compared to nondiabetic control rats. The wet weight of the endoneurium was reduced in diabetic animals, but increased moderately when corrected for body weight due to the marked loss of adipose tissue (14,16) which offsets continued growth of lean body mass to yield little or no net weight gain in this model.

NEFA content and composition of sciatic nerve. As shown in Table 2, Experiment 1 demonstrated that the total amount of sciatic nerve NEFA was significantly higher in diabetic rats than in age-matched non-diabetic control animals when expressed relative to either wet

[b]Significant difference between control and diabetic group ($P \leq 0.05$).

weight or total lipid phosphorus. When the NEFA composition of the nerve was examined, a modest decrease in palmitoleic acid (16:1) and increase in linoleic acid (18:2n-6) were noted in nerve from diabetic animals. The levels of arachidonic acid (20:4n-6) and tetracosanoic acid (24:0) were also reduced although these changes were not statistically significant.

NEFA content and composition of sciatic endoneurium. Based on the results of Experiment 1, Experiment 2 was designed to examine the effects of prolonging the diabetic interval and to focus more specifically on the endoneurial portion of the sciatic nerve by removing the perineurium and epineurium, which are primarily connective tissue. The results are presented in Table 3. Removal of the connective tissue sheaths significantly reduced the total NEFA content in samples from both normal and diabetic animals, although the effect was greater when expressed per μmol of lipid phosphorus, reflecting the relatively large amount of phospholipids in the neurolemma and myelin sheath. Compared to whole nerve, diabetes induced a smaller increase in endoneurial NEFA and considerable variation in their composition.

The phospholipid class composition in diabetic nerve was the same as that of normal nerve with the exception of phosphatidylinositol which was reduced in diabetic nerve (data not shown). This agrees with our previous observations in the streptozotocin diabetic rat model (22). The fatty acid composition of individual endoneurial phospholipids of normal and diabetic nerve is shown in Table 4. Modest differences were observed in fatty acids containing 16 to 20 carbons. Within all of the phospholipid classes examined in this study, of potential significance is the elevation of linoleate (18:2n-6) in phosphatidylethanolamine and the reduction of arachidonate (20:4n-6) in phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol. As in Tables 2 and 3, the relatively large standard deviations indicated marked within-group

variations in the effects of insulin deficiency on sciatic nerve lipids.

DISCUSSION

We have shown that alloxan-induced diabetes results in elevated levels of nonesterified fatty acids (NEFA) in rat sciatic nerve. Based on total lipid phosphorous, NEFA levels in both whole nerve and sciatic endoneurium were as much as 40% higher than in control nerves. However, differences between diabetic and control nerve were far less pronounced than previously observed in myocardial tissue whose NEFA levels increased about three-fold within 5 days of alloxan administration (10).

There exists very little information on the amounts and composition of NEFA in the peripheral nervous system. Berry *et al.* (11) reported the NEFA content of cat sciatic nerve as approximately 5 μmol/g wet weight, about twice our present data, and Yao *et al.* (13) found endoneurial NEFA of rat sciatic nerve to be about 43 nmol/mg dry weight. Because sciatic nerve contains 60–70% water (23), our own data would show NEFA levels to be about 2–3 nmol/mg dry weight, at least an order of magnitude lower than those reported by Yao *et al.* (13). NEFA levels are notoriously difficult to determine and are subject to a number of experimental variabilities (10,24). These can include overestimation due to *post mortem* lipolysis or due to transesterification of ester lipids which may be co-purified with NEFA. Methylation with diazomethane avoids this possibility and does not require isolation of NEFA prior to derivatization. We rigorously standardized our procedures of nerve preparation and extraction using low temperatures and minimal time periods between surgery and lipid extraction. It is not clear whether anesthesia or the surgical procedure itself could affect NEFA levels. However, such effects would most likely be the same in normal and diabetic nerve. *Post mortem* lipolysis appears to occur rapidly in the central nervous system (8,23) but was reported to be much slower in peripheral nerve (13). Our present data are in general agreement with the lowest NEFA values obtained for brain and other mammalian tissues (10,25,26). We believe that presentation of NEFA levels on the basis of total lipid phosphorus is more meaningful than data based on wet or dry weight because it takes into account an easily measurable parameter of membrane lipids.

In contrast to diabetic heart (10), the elevation of NEFA levels in diabetic nerve over normal controls was relatively minor. In the endoneurial portion, which is of primary interest as the functional unit of the nerve, this elevation amounted to about 20–30%, was well reproducible and could be reduced to normal levels by insulin treatment (data not shown). However, we also observed some variation of NEFA levels in sciatic nerves of normal rats including a consistent increase with age (data not shown). It is interesting to note that a much greater portion of labeled acetate was found to be incorporated into NEFA rather than more complex lipids by endoneurial preparations from older rats than by those of younger rats (27). It is therefore unlikely that NEFA are involved in the etiology of diabetic neuropathy.

We found only small proportions of polyunsaturated fatty acids among endoneurial NEFA. Thus, the expected increase of linoleic (18:2n-6) acid at the expense of arachidonic (20:4n-6) acid observed in a number of diabetic tissues (28–30) is measurable only among the acyl groups of more complex lipids and occurs together with other alterations in phospholipid fatty acid compositions (Table 4). These data are in general agreement with earlier results obtained with streptozotocin-diabetic rat sciatic nerve (31). Some of the changes in phospholipid acyl groups appear to be due to decreased desaturase activity in diabetic tissue (32,33), including the Δ6 desaturase catalyzing the conversion of linoleic (18:2n-6) to γ-linolenic (18:3n-6) acid (28,33). These relatively minor changes may be important, however, because certain dietary polyunsaturated fatty acids (34,35), including γ-linolenic acid (36), were shown to have beneficial effects in both experimental and human diabetic neuropathy (34–37). Thus, the relationship between endoneurial phospholipid acyl composition and the functional consequences of diabetic neuropathy deserves further study.

[Received January 24, 1992; Revision accepted May 5, 1992]

Changes in Fatty Acid Composition of Plasma and Oviduct Lipids During Sexual Maturation of Japanese Quail

The fatty acid (FA) compositions of plasma and oviduct phospholipids (PL) and triglycerides (TG) were studied throughout the natural sexual development of the Japanese quail. In the oviduct, PL concentration increased rapidly during the period of active oviduct cell proliferation and then remained at a constant level during the phase of cellular hypertrophy. Oviduct and plasma TG concentrations were 2- and 10-fold higher, respectively, in fully developed animals than in immature ones. During natural sexual maturation of the quail, the FA compositions of PL and TG were markedly modified both in plasma and in oviduct. These qualitative changes occurred predominantly during the period of intense cellular proliferation of oviduct cells, and also were observed in immature animals injected with physiological doses of estradiol. In oviduct PL, the proportions of 20:4n-6 and 22:4n-6 decreased significantly (from 20 to 10% and 3.5 to 0.7%, respectively) whereas those of 18:2n-6 increased (from 8.5 to 21%). In contrast, the plasma PL proportions of 20:4n-6, 22:4n-6 and 18:2n-6 were decreased significantly and the percentage of 18:1n-9 doubled, suggesting that the oviduct is able to utilize certain plasma FA to a greater extent than others. Changes in plasma and oviduct lipid composition occurring in the quail during sexual development may be attributed to estradiol, which stimulates hepatic Δ9 desaturase and inhibits the oviduct Δ6 desaturase. The changes in FA composition observed in oviduct phospholipids are discussed in relation to eicosanoid production and cellular proliferation.
***Lipids 27,* 518–525 (1992).**

In many animals, including mammals and birds, steroid hormones affect the growth and differentiation of specific target organs, such as the uterus or oviduct, and induce changes in lipid metabolism in these organs. In the uterus, estradiol stimulates the synthesis of all lipid classes (1,2), increases the rate of 20:4n-6 incorporation into phospholipids (PL) and neutral lipids (3) and enhances phosphatidylinositol metabolism (4,5). Estradiol also stimulates phospholipase A_2 activity (6,7) and increases the production of oxygenated eicosanoids (8,9). These effects appear a few hours after hormonal treatment and precede the proliferation of target cells. Prostaglandins and leukotrienes may play various physiological roles in the regulation of parturition in mammalian species, including the vascular changes associated with menstruation in primates (10) and the control of luteolysis and uterine contractility (11). These compounds may also be implicated in the proliferation of estradiol target cells as shown in *in vivo* and *in vitro* studies. Essential fatty acid deficiency delays the onset of puberty in the female rat, probably due to a reduced availability of arachidonic acid (12). The nature of dietary fat influences the developmental growth of the mammary gland in immature estradiol-stimulated mice; animals fed a 19% menhaden oil plus 1% corn oil diet have altered mammae development as compared to controls (13). Linoleic acid stimulates the growth of human breast cancer cell lines in culture (14). This effect is inhibited by n-3 polyunsaturated fatty acids (PUFA) and seems to be more dependent upon the production of leukotrienes than prostaglandins (15).

In the present study, changes in the fatty acid (FA) compositions of plasma and oviduct lipids were examined in Japanese quail during natural and estradiol-induced sexual development in relation to the proliferative state of the tissue.

MATERIALS AND METHODS

Chemicals. Glycerol tri-[1-^{14}C]palmitate (52 mCi/mmol), cholesteryl [1-^{14}C]oleate (50 mCi/mmol), [9-10(n)^{3}H]oleic acid (5 Ci/mmol) and 1-stearoyl 2-[1-^{14}C]arachidonyl phosphatidylcholine (50 mCi/mmol) were purchased from Amersham France (Les Ullis, France). Heptadecanoic and pentadecanoic acids, di-17:0 phosphatidylcholine, tri-17:0 triglyceride, 17:0 cholesteryl ester and standard fatty acid methyl esters (FAME) were from Sigma (St. Louis, MO). All solvents used were reagent grade.

Animals. Female Japanese quail (*Coturnix coturnix japonica*; 17–55-days-old) were maintained in groups at a constant temperature (23°C) on a daily cycle of light (14 h) and darkness (10 h). Chicken powder chow (UAR 115, Villemoisson, France) and water were provided *ad libitum*. Under these conditions, the sexual maturation of the quail started after 21 days and reached the laying state at about 45 days. Hormonal treatment was performed in immature quail (17-days-old) only. Estradiol benzoate (0.05 mg/kg and 0.5 mg/kg dissolved in olive oil) was injected intramuscularly in a total volume of 0.1 mL. Controls received the vehicle alone. Treated and control animals were sacrificed 24 h after the last injection. Animals were fasted for 16 h before being killed by decapitation. Heparinized blood was collected and the resulting plasma was stored at −30°C until analysis. The oviduct was excised and the magnum (secretory portion of the oviduct) was dissected, weighed and used immediately or stored in liquid nitrogen until lipid analysis.

Lipid analysis. The magnum (70–250 mg of pooled or individual tissues) was homogenized using a glass-glass tissue homogenizer (Kontes P22, Poly Labo P. Block, Strasbourg, France) in 6 mL of chloroform/methanol (2:1, v/v) containing 0.01% butylated hydroxytoluene (BHT) and internal standards (10–30 μg of 17:0 fatty acid, di-17:0 phosphatidylcholine, tri-17:0 triglyceride and 17:0 cholesteryl ester). The homogenate was kept at 18°C for 30 min

Abbreviations: BHT, butylated hydroxytoluene; DMA, dimethylacetal; EB, estradiol benzoate; FFA, free fatty acids; FAME, fatty acid methyl ester; GLC, gas-liquid chromatography; MUFA, monounsaturated fatty acids; PG, prostaglandins; PL, phospholipids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TG, triglycerides; TLC, thin-layer chromatography.

and then centrifuged. The resulting pellet was homogenized with 6 mL of chloroform/methanol (2:1, vol/vol) and centrifuged. The two supernatants were combined, and the lipid extract was washed with 3 mL of 0.73% NaCl. The chloroform layer was removed, dried under vacuum and the residue redissolved in an appropriate amount of chloroform/methanol (1:1, vol/vol) containing 10–15 nCi of each radioactive standard listed in the chemical section. Total lipid extracts from 0.5 mL plasma were prepared according to the procedure of Folch *et al.* (16); internal standards (10–30 μg of 17:0 fatty acid, di-17:0 phosphatidylcholine, tri-17:0 triglyceride and 17:0 cholesteryl ester) and radioactive standards were added to samples during the extraction. Control assays (without tissue or plasma) were carried out for each series of experiments.

The various lipid classes were separated by thin-layer chromatography (TLC) using silica gel 60 plates (20 × 20 cm, 0.25 mm, Merck, Darmstadt, Germany) and hexane/diethyl ether/acetic acid (80:20:2, vol/vol/vol) as the developing solvent. The radioactive bands were detected using a Berthold LB 511 (Wildbad, Germany) TLC analyzer, the gel corresponding to each lipid class was scraped off and the fatty acids were directly converted to methyl esters by adding 1 mL of 10% boron trifluoride in methanol to each tube and heating at 90°C for 45 min. The FAME were extracted twice with 2 mL of heptane after adding 1 mL water to each tube. The heptane extract was removed, concentrated under N_2, and a known amount (10–40 μg) of pentadecanoic methyl ester was added to each sample as an internal standard. FAME were analyzed with a Girdel 3000 (Suresnes, France) gas-chromatograph, equipped with a Ross injector that was coupled with a CR 5A integrator (Shimadzu, Kyoto, Japan). The capillary column was a CP Wax 52 CB (0.32 mm × 50 m; Chrompack, Middelburg, The Netherlands), and the temperature was programmed from 160°C to 230°C at 1.2°C/min; helium was used as carrier gas (20 cm/s). FAME were identified by comparison with the relative retention time of known standards. The percentage and concentration of each fatty acid were computed using the internal standard (pentadecanoic acid) and correction for recovery determined for each lipid class by means of 17:0 internal standards.

Statistical analysis. Data are expressed as mean ± SEM. Since fatty acids were measured as proportions, comparison of the different groups could not be done directly by standard methods. Data were transformed according to the following formula $y_i = \log (x_i/x_d)$, where x_d is a fixed component and x_i the percentage of the fatty acid in the study (17,18). For convenience, we chose palmitic acid as x_d. Statistical significance ($\alpha = 0.05$) was tested using Mann-Whitney or Kruskal-Wallis nonparametric rank tests. Non-linear regression analysis of data concerning the FA composition of PL and triglycerides (TG) *vs.* magnum weight was performed with an IBM PS/2 computer using the program COSY (19).

RESULTS

As shown in Table 1, total PL and TG concentrations increased significantly, both in plasma and oviduct, during natural sexual development of the quail. In contrast, plasma and tissue concentrations of free fatty acids remained at a constant level. Tissue and plasma PL and TG concentrations were measured in naturally developing birds to determine whether the observed changes occurred at a particular state of the sexual growth or were continuous throughout the period of sexual maturation. They were plotted (Fig. 1) *vs.* the corresponding magnum wet weight, which is the best criterion to determine the degree of sexual maturation of an individual (20,21). In oviduct, PL and TG concentrations increased only during the beginning of sexual maturation (up to about 300–400 mg magnum weight). Further growth of the tissue was then associated with constant levels of PL and TG. In contrast, a small increase in plasma PL and TG concentrations was observed during the beginning of sexual maturation, whereas these parameters increased rapidly thereafter (up to about 1.5 g magnum weight).

Treatment of immature quail for three consecutive days with a physiological dose of estradiol benzoate (EB; 0.05 mg/kg) resulted in oviduct growth (Table 1). In EB-treated animals, plasma and oviduct PL and TG concentrations were similar to those observed in naturally developing animals exhibiting the same magnum weight (Fig. 1). A higher dose of EB (0.5 mg/kg) induced a drastic increase in plasma and tissue TG levels (Table 1, Fig. 1b). In contrast, plasma and oviduct PL levels were similar (Fig. 1a) in EB-treated and in non-treated animals.

[d]Values within a column are statistically different ($P < 0.05$) from those of the immature group.

[e]21-Day-old quail treated with 0.05 mg/kg of estradiol benzoate for three consecutive days.

[f]21-Day-old quail treated with 0.5 mg/kg of estradiol benzoate for three consecutive days.

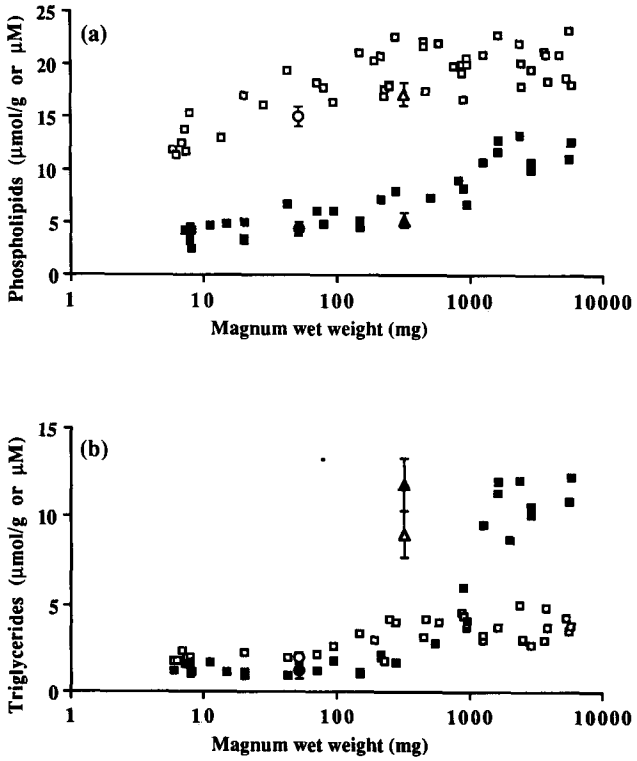

FIG. 1. Total phospholipid and triglyceride concentrations in plasma and oviduct during natural and estradiol-induced sexual development of the quail. (a) Total phospholipid concentration in oviduct (□) and plasma (■). (b) Triglyceride concentration in oviduct (□) and plasma (■). Each point represents an individual animal except for estradiol benzoate-treated birds (○ and ●, 0.05 mg/kg; △ and ▲, 0.5 mg/kg), where the mean ± SEM of six animals are reported. Results are expressed as μmol/g for oviduct and μM for plasma and are plotted against magnum wet weight.

As indicated in Table 2, the FA composition of total PL in both plasma and oviduct changed during the natural sexual development of the quail. In plasma, the most changes occurred in the proportions of monounsaturated fatty acids (MUFA) and PUFA of the n-6 series. The proportions of 16:1n-7 and 18:1n-9 were significantly increased (+211 and +106%, respectively) in laying quail, whereas 16:1n-9 and 18:1n-7 remained at a constant level throughout the maturation period. The proportions of 18:2n-6, 20:4n-6 and 22:4n-6 were significantly reduced (−19, −37 and −55%, respectively). Decreases in the proportions of 18:0 (−19%), 20:5n-3 (−50%) and 22:5n-3 (−48%) also were observed. In the oviduct, the proportion of saturated fatty acids (SFA) was significantly decreased due to a lower level of 18:0 (−36%). Levels of 16:1n-7 and 18:1n-9 were increased (+194% and +14%, respectively) but 16:1n-9 and 18:1n-7 remained unchanged. Total n-6 PUFA was not significantly affected. However, 20:4n-6 (−51%) and 22:4n-6 (−80%) significantly decreased and 18:2n-6 (+146%) increased. The level of 22:6n-3 increased (+41%) while 20:5n-3 and 22:5n-3 decreased, but not significantly. The natural sexual maturation of the oviduct also was associated with an alteration of the dimethylacetal (DMA) composition—18:0 DMA increased (+56%) in laying quail, whereas 16:0 DMA decreased (−48%).

Individual FA composition of plasma and tissue PL also was studied in naturally developing animals from the immature to the laying states (Fig. 2). For convenience, FA showing no trend or those found in very low proportion (≤2%) were not listed. The FA composition of the oviduct PL was closely related to the degree of sexual development of the quail. The percentages of 20:4n-6 and 22:4n-6 decreased continuously as the magnum weight increased (*i.e.*, as the tissue sexually matured); in contrast, the proportion of 18:2n-6 increased throughout the study. The proportion of 18:0 decreased little, the proportion of 18:1n-9 remained virtually constant. For all the FA showing a systematic trend in oviduct PL, various mathematical models were used to describe the results. In all cases, the best model fitting the data was of the form $y = a + be^{kx}$ (where y and x represented the FA percentage and the magnum weight in mg, respectively) and the calculated coefficients of determination were greater than 0.77. According to this model, the rate of change in the proportion of an individual FA occurred mainly during the beginning of the developmental period. DNA synthesis has been shown to exhibit a similar exponential model during the natural maturation of the oviduct (21).

Comparison of plasma (Fig. 2b) and oviduct (Fig. 2a, Table 2) FA profiles showed that some FA (18:0, 20:4n-6, 22:4n-6) varied similarly in plasma and tissue, but 18:2n-6 and 18:1n-9 exhibited a very different pattern. Thus, 18:2n-6 increased in oviduct and decreased in plasma, whereas 18:1n-9 was markedly increased in plasma and was at an essentially constant level in oviduct PL. As indicated in Figure 2 and Table 2, in both plasma and oviduct, estradiol injected in immature quail induced (qualitatively and quantitatively) FA modifications in PL similar to those observed during natural development. Nevertheless, the highest EB dose used (0.5 mg/kg) induced a significant accumulation of 22:6n-3 in oviduct PL (Table 2) which was more pronounced than that observed in naturally developing or laying quail.

The FA compositions of TG in plasma and oviduct during the sexual development of the quail are reported in Table 3 and Figure 3. In the oviduct, the proportions of 18:0 and 20:4n-6 decreased continuously during the natural sexual maturation of the tissue (Fig. 3a) and were significantly reduced (−24 and −74%, respectively) in laying quail as compared to the immature group (Table 3). The proportions of other major FA (principally 18:1n-9 and 18:2n-6) were not significantly modified during this period. The FA composition in plasma TG was quite different than that of the tissue. The proportions of 18:0 and 20:4n-6 decreased in plasma, but to a greater extent (−41 and −90%, respectively) than in the oviduct. Furthermore, 16:1n-7 and 18:1n-9 increased throughout the developmental period (Table 3 and Fig. 3b), and were found in significantly higher proportions in laying quail (+101 and +44%, respectively) than in immature animals. Moreover, the proportion of 18:2n-6 decreased steadily as the maturation of the oviduct progressed and was about half in laying as compared to immature quail. Treatment of immature quail with estradiol, at any dosage used, induced qualitative changes in the FA composition of plasma TG similar to those observed in naturally developing birds presenting the same degree of oviduct maturation (Fig. 3b). In contrast, the FA composition of oviduct TG depended upon the dose injected. A physiological EB dose reproduced the

changes observed during natural oviduct development, whereas a higher dose induced a significant accumulation of MUFA and a significant decrease of n-6 PUFA.

DISCUSSION

The natural sexual maturation of the female quail is characterized by significant proliferation and differentiation of oviduct cells resulting in a marked increase in oviduct weight (from 15 mg for 21-day-old immature quails to more than 10 g for 45-day-old mature animals). Oviduct growth and maturation are clearly related to increasing levels of circulating estradiol and progesterone (20,21). During this overall period, three phases may be considered and characterized by magnum weight. The first phase (up to about 250–300 mg magnum weight) consists of a very active proliferation of epithelial cells associated with a regular increase in the circulating level of estradiol and a constant low level of progesterone. During the second phase (up to 1.5 g magnum weight), the rate of cellular proliferation decreases while cellular differentiation and egg white synthesis take place. This phase is related to increasing levels of estradiol and progesterone. At the end of this period, cellular proliferation and differentiation are arrested and further growth of the magnum (up to 5–6 g) involves only accumulation of secretory products. This third phase is associated with a constant level of estradiol and increasing values of plasma progesterone.

PL and TG concentrations increased significantly, both in plasma and oviduct, during natural sexual development of the quail (Table 1 and Fig. 1). Our observations are in agreement with studies on mammalian (22,23) and avian (24,25) species showing that sexual hormones influence general lipid metabolism by acting upon both the liver (25–27) and adipose tissue (28) to produce an increase in plasma lipids (22,24). Plasma PL and TG levels increased significantly when plasma estradiol level increased (first and second phase of natural sexual maturation) and were constant thereafter, suggesting that progesterone did not significantly affect these parameters in the quail. Changes

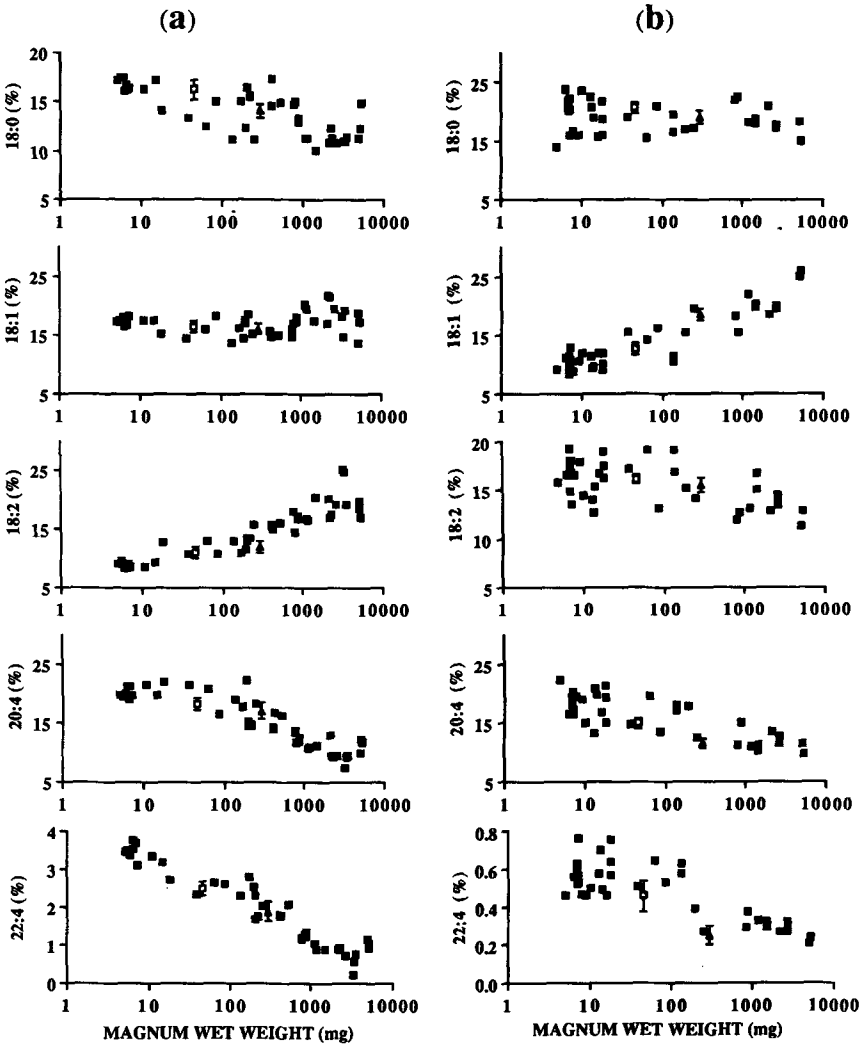

FIG. 2. Fatty acid compositions of total phospholipids of plasma and oviduct during natural and estradiol-induced sexual development of the quail. The percentage of some fatty acids found in the oviduct (a) and plasma (b) are plotted *vs.* the magnum weight during the natural (■) or estradiol-induced (□, △) sexual development. Each point represents an individual animal except for estradiol benzoate-treated birds (□, 0.05 mg/kg; △, 0.5 mg/kg), where the mean ± SEM of six animals are reported.

in the lipid content of the oviduct appeared more rapidly than in plasma. This observation suggests that estradiol has a specific effect on lipid metabolism in the target tissue, and that it takes place during the intense proliferation of the oviduct cells.

The FA composition of plasma lipids was markedly affected, with only minor differences between PL and TG classes. These modifications may be attributed mainly to estradiol, since estradiol injected into immature animals induced qualitatively the same changes as those observed in naturally developing animals, in which both progesterone and estradiol levels are increased (20,21). The proportions of 18:1n-9 and 16:1n-7 were increased, whereas the proportion of 18:0 was reduced, confirming earlier studies in chicken showing that estradiol stimulated hepatic Δ9 desaturase activity (25). Conversely, since 16:1n-9 and 18:1n-7 were not altered, this suggests that the corresponding retroconversion and elongation were not enhanced, but even decreased, by estradiol.

In both PL and TG classes, the oviduct FA composition did not exactly reflect that of plasma lipids, suggesting that the oviduct is able to take up some plasma FA (for example, 18:2n-6 and 18:0) to a greater extent than others (18:1n-9) which were accumulated in plasma. All n-6 PUFA were significantly reduced in plasma, whereas in the oviduct the decreased proportions of 20:4n-6 and 22:4n-6 were compensated by an elevation of 18:2n-6. This suggests that, during the natural or estradiol-induced development of the quail oviduct, the utilization of 20:4n-6 and 22:4n-6 may be greatly enhanced and/or that the metabolic conversion of 18:2n-6 into C_{20} PUFA may be inhibited. Since no accumulation of 18:3n-6 and 20:3n-6 occurred in the tissue, it is likely that Δ6 desaturase activity was not stimulated by estradiol. This may explain why 20:3n-9 was

not increased, although 18:1n-9 was increased. In contrast, the lower proportion of 18:2n-6 in plasma lipids may be the consequence of either estradiol induction of the hepatic Δ6 desaturase activity or a specific uptake of this FA by the oviduct.

Extensive literature exists dealing with the metabolism of 20:4n-6 in estradiol target cells (3,29,30). In the models used, 20:4n-6 was mainly converted to prostaglandins and leukotrienes (7,8,31), which have been implicated in specific physiological responses (9,10) and in cellular proliferation (32). Since estradiol stimulates phospholipase A_2 activity (6) and increases 20:4n-6 turnover (3) and oxygenated eicosanoid production (7), all these effects may contribute to the important decrease in 20:4n-6 levels in the oviduct lipids.

Changes in the FA composition in the oviduct were more pronounced during the phase of intense cellular proliferation of the oviduct cells than during the phase of cellular hypertrophy taking place during the final maturation of the oviduct. Metabolites from 20:4n-6 may, therefore, be important for cellular proliferation of estradiol target cells. Two lines of evidence support this hypothesis. First, the addition of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) to the culture medium of primary explants of rabbit endometrial cells results in an increase in the rate of cellular proliferation (32). Neither PGE_1 nor PGE_2 affects the rate of proliferation when added alone, but either PGE_1 or PGE_2 reverse the stimulation obtained with $PGF_{2\alpha}$. In this system, PGE_1 increases cAMP, whereas $PGF_{2\alpha}$ stimulates the breakdown of phosphatidylinositol 4,5-bisphosphate (33, 34). Previous studies from our laboratory have shown that, in quail oviduct, the regulation of cAMP level is essential for the control of cellular proliferation. Low levels of cAMP are required for cell replication, whereas high levels are associated with an arrest of cellular proliferation (35, 36). Second, the growth and development of the mammary gland in mice are affected by the type of dietary fat. Animals fed a low fat diet or a fish oil diet had altered mammae development (13). This inhibitory effect has been observed only in estradiol-treated mice, the mammae of which were in a state of intense proliferation. Furthermore, *in vitro* growth of estrogen-responsive cells is stimulated by 18:2n-6 (14,15) and inhibited by 22:6n-3 or 20:5n-3. These effects are dependent upon oxygenated eicosanoid

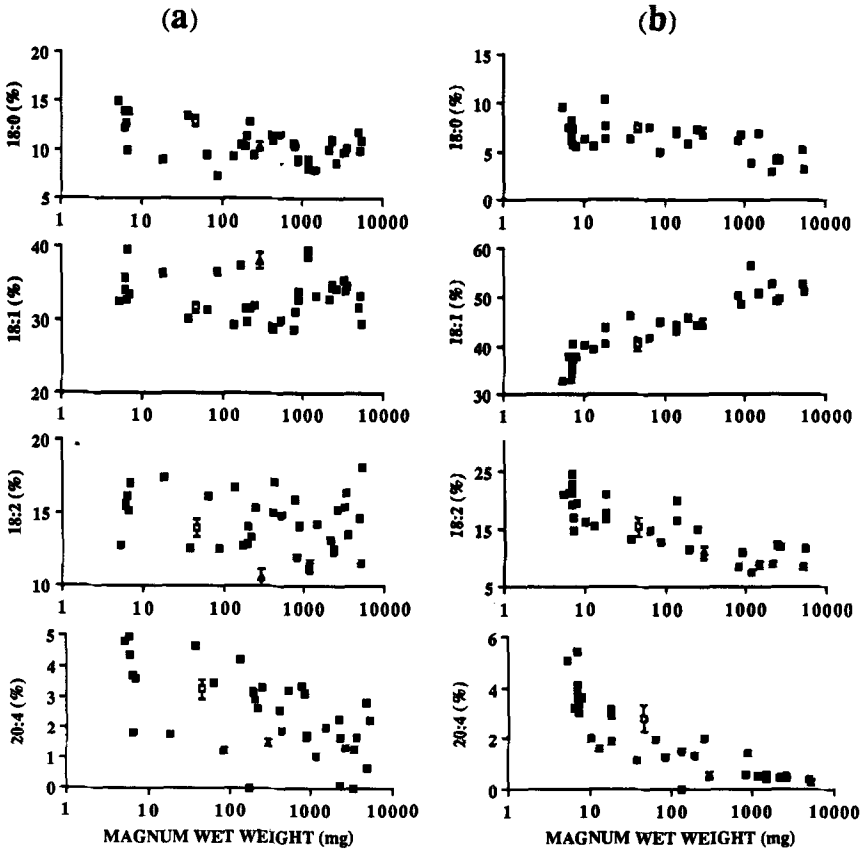

FIG. 3. Fatty acid compositions of triglycerides in plasma and oviduct during natural and estradiol-induced sexual development of the quail. Dietary Fat and Fatty Acids Modulate Cholesterol Cholelithiasis in the Hamster

Bertram I. Cohen*, Erwin H. Mosbach, Nariman Ayyad, Shigeo Miki[1] and Charles K. McSherry
Departments of Surgery, Beth Israel Medical Center and the Mount Sinai School of Medicine of the City University of New York, New York, New York 10003

We tested two hypotheses, i) whether the type and the amount of fat in the diet will affect the formation of cholesterol gallstones in the hamsters, and ii) whether palmitic acid, a major fatty acid component of butterfat, can act as a potentiator of cholesterol cholelithiasis in the hamster. Young, male golden Syrian hamsters (Sasco) were fed a semipurified diet containing casein, corn starch, cellulose and cholesterol (0.3%) to which various types and amounts of fat (butterfat, olive oil, menhaden oil, corn oil) were added. All diets contained 2% corn oil to supply essential fatty acids to the growing hamsters. No deaths or illness occurred during the experiment. Animals fed the semipurified diet plus 4% butterfat (group 1) had a gallstone incidence of 63%. Replacement of butterfat with either olive oil, corn oil or menhaden oil prevented the formation of cholesterol gallstones entirely (groups 2–4). When total butterfat was increased from 4% to 8% (group 8), the incidence of cholesterol gallstones increased to 80%. Substitution of 4% olive oil (group 5), corn oil (group 6), or menhaden oil (group 7) for the additional 4% butterfat significantly reduced gallstones to 35%, 45% and 30%, respectively. The replacement of 4% butterfat with 1.2% palmitic acid gave the highest incidence of cholesterol gallstones (95%). These results suggest that butterfat (and one of its components, palmitic acid) intensifies gallstone formation in this model whereas mono- and polyunsaturated fats act as inhibitors of cholesterol cholelithiasis. A fatty acid, possibly palmitic acid, appears to act as lithogen in our model.
Lipids 27, 526–532 (1992).

Cause-and-effect relationships between disease and specific dietary components have been sought over the past two decades. Some types of cancer, particularly colon cancer, have been found to be associated with the ingestion of various types and amounts of fat and/or fiber (1–5). Cholesterol cholelithiasis has been studied in a similar way (6–11) but the dietary factors which influence the course of this disease remain in doubt. Various medical and surgical treatments for cholelithiasis have recently been described, including bile acid therapy (11,12), extracorporeal shockwave lithotripsy (13,14), solvent dissolution (15), and laparoscopic cholecystectomy (16). However, to prevent stone formation, it would be important to clarify the role of the diet in the etiology of cholesterol cholelithiasis.

Many investigators have used hamster models to study gallstone disease (17–23). Because of its size, bile acid composition, and limited hepatic cholesterol synthesis, the hamster is a useful model for human cholelithiasis. Dam (17) fed growing hamsters fat-free diets to obtain cholesterol gallstones. These animals often became ill, lost weight, developed diarrhea and died during the experiment. The dietary manipulations Dam reported, however, suggested a relationship between various fats, carbohydrates and gallstones. A second hamster model (18) was reported to develop cholesterol gallstones on a chow diet supplemented with cholesterol and estrogen. This model was not reproducible in our laboratory (20).

We discovered that young Sasco hamsters develop cholesterol gallstones in a predictable manner when fed a semipurified diet containing 4% butterfat and 0.3% cholesterol (24). This model has enabled us to demonstrate that Sasco hamsters form cholesterol gallstones faster than animals from either Charles River or Harlan Sprague-Dawley when fed our semipurified diet (24). The role of a specific dietary component, namely butterfat, was thought to be essential for stone formation; however, whether the amount or type of fat or a component of the fat could alter gallstone incidence in our model was unclear.

In the present study, we examined, for the first time, whether substitution of various fats for butterfat, including olive oil, corn oil, or menhaden oil, altered the incidence of cholesterol cholelithiasis in the hamster. We also examined if substitution of palmitic acid for butterfat would affect cholelithiasis. All diets contained 2% corn oil to prevent a deficiency of essential fatty acids. Our model previously produced a cholesterol gallstone incidence of 55–65% after a 5- to 10-wk feeding period (24). We also attempted to increase the incidence of gallstones by doubling the amount of butterfat from 4% to 8%. The aim of this study was three-fold: to elucidate the role of i) different fats, ii) total fat, and iii) a specific component of butterfat (palmitic acid), on cholesterol cholelithiasis in Sasco hamsters.

MATERIALS AND METHODS

Compounds. Cholesterol was obtained from Sigma Chemical Company (St. Louis, MO) and found to be greater than 98% pure by gas-liquid chromatography (GLC) after preparation of the trimethylsilyl (TMS) ether derivative. Butterfat, olive oil, corn oil and menhaden oil were obtained from Dyets Premier (Bethlehem, PA). 3α,7α-Dihydroxy-12-keto-5β-cholanoic acid was purchased from Steraloids (Wilton, NH). Palmitic acid (99%) was obtained from Sigma Chemical Company.

Animals and diets. Male golden Syrian hamsters (*Mesocricetus auratus*), weighing between 48 and 50 g, were purchased from Sasco Laboratories (Omaha, NE). All 200 animals were quarantined for one week, during which time they were fed Purina chow and water *ad libitum*. The animals were divided into eight experimental groups and fed the following diets (prepared in pelleted form and color coded by Dyets): group 1 (40 animals) received the standard lithogenic diet containing (g/kg) casein, 200; corn oil, 20; butterfat, 40; corn starch, 434; dyetrose (a soluble

Abbreviations: CH, cholesterol; CSI, cholesterol saturation index; FT-IR, Fourier transform infrared spectroscopy; GLC, gas-liquid chromatography; LDL, low-density lipoprotein; SPD, semipurified diet; TMS, trimethylsilyl.

starch), 146; fiber, 100; cholesterol, 3; salt mix, 50; vitamin mix, 5; choline chloride, 2. The animals in groups 2, 3 and 4 (20 animals/group) were fed a similar diet with the exception that different types of fat were substituted for butterfat (4%): group 2, 4% olive oil; group 3, 4% corn oil; group 4, 4% menhaden oil. Animals in groups 5–8 (20 animals/group) were given 8% fat in the diet (80 g fat/kg food): group 5, 4% olive oil plus 4% butterfat; group 6, 4% corn oil plus 4% butterfat; group 7, 4% menhaden oil plus 4% butterfat; group 8, 8% butterfat. Animals in group 9 were fed a diet where 4% butterfat (in group 1) was replaced by 1.2% palmitic acid. The fatty acid composition of the diets for groups 1–9 is shown in Table 1. All diets contained 2% corn oil to prevent deficiency of essential fatty acids. The lithogenic diet (group 1) contained a total of 1.3% palmitic acid.

The hamsters were fed the experimental diets and water *ad libitum* for a period of 6 wk and were maintained under an alternating 12-h light and dark cycle. All animals were fasted for 24 h prior to sacrifice to ensure an adequate quantity of bile for analyses. The hamsters were anesthetized with 20–30 mg of ketamine hydrochloride (Bristol Labs, Syracuse, NY) and blood was obtained by cardiac puncture for determination of serum cholesterol; the animals were killed by exsanguination. The gallbladders were exposed and examined visually for the presence of cholesterol gallstones. If present, these stones were easily seen through the gallbladder wall. Cholesterol gallstones were analyzed using diffuse reflectance on a Perkin-Elmer Fourier transform infrared (FT-IR) spectrometer 1710 (Perkin-Elmer, Norwalk, CT) attached to a Perkin-Elmer 7500 computer. Bile was removed and quantitated with a Hamilton syringe (Hamilton Co., Reno, NV) (bile volume ranged from 35–50 μL/animal). All bile samples were centrifuged at 3000 × *g* for 15 min to remove suspended cholesterol crystals; the bile was then immediately divided into aliquots for determination of the biliary lipids. The liver was excised and weighed. An aliquot was removed for determination of cholesterol.

Analytical techniques for bile, liver and plasma. A portion of bile was hydrolyzed in 2 N NaOH for determination of biliary cholesterol. 5α-Cholestane (100 μg/sample) was added prior to GLC (3% SE-30 column) to quantify the cholesterol as the trimethylsilyl ether derivative (24). Biliary bile acids were hydrolyzed with 2 N alkali (24) by autoclaving the samples; the bile acids were extracted and quantitated with a SPB-5 capillary column (15 m, 0.25 μ, Supelco, Bellefonte, PA) attached to a Hewlett-Packard (Avondale, PA) 5890A gas chromatograph controlled by a Hewlett-Packard 3365A workstation with Chemstation software (G12022-10045). Biliary phospholipid concentration was determined using the Biochemical Diagnostics phospholipid kit B (Wako Pure Chemical Industries, Ltd., Osaka, Japan). The cholesterol saturation index (CSI) was calculated as described earlier (24,25).

Calculations and statistics. All data are presented as the mean ± standard deviation or standard error of the mean. Differences in gallstone incidence were determined using chi square (26). Statistical differences among groups were calculated using one-way analyses of variance to determine the F statistic. Student's unpaired *t*-test was applied to those values where the F statistic was significant ($P < 0.05$) (26).

RESULTS

The hamsters in each experimental group were fed diets containing either i) 4% fat (groups 1–4), ii) 8% fat (groups 5–8), or iii) 1.2% palmitic acid, in place of 4% fat which was added to the standard semipurified diets. All diets contained in addition 2% corn oil to assure that there was no deficiency in essential fatty acids. The fatty acid composition of all diets (groups 1–9) is summarized in Table 1; the data include the fatty acids present in the dietary fat (if any) and corn oil.

Animals were fed the experimental diets for 6 wk. They were divided into groups (group 1, 40 animals; groups 2–9, 20 animals/group) to assure an adequate number for statistical comparisons. The hamsters gained weight throughout the 6-wk feeding period (Table 2). No animals died during the experiment. The hamsters fed the 4% fat plus 2% corn oil (groups 1–4) gained less weight than animals fed 8% fat plus 2% corn oil (groups 5–8). The weight gain was only moderately related to the food intake which was 9–13 g/d. The largest increase in weight occurred in animals fed 8% butterfat (group 8); the small-

est increase observed in hamsters fed 4% menhaden oil. [The palmitic acid group (group 9) gained weight at about the same rate as the lithogenic controls (group 1).]

The incidence of cholesterol gallstones and biliary cholesterol crystals is summarized in Table 3. Gallbladders were removed and dissected at sacrifice and visually examined for the presence of stones. Animals fed the lithogenic diet, which contained 4% butterfat (group 1), had a stone incidence of 63%. These stones were composed entirely of cholesterol as seen by polarized light microscopy and confirmed by FT-IR spectroscopy. The substitution of either olive oil, corn oil or menhaden oil (groups 2–4, respectively) for butterfat resulted in a complete prevention of both cholesterol gallstones and crystals (gallstone incidence, 0%). When total butterfat was increased from 4% to 8% (group 8), gallstone incidence increased to 80%. The addition of 4% olive oil, corn oil, or menhaden oil to the lithogenic diet (which contained 4% butterfat, group 1) resulted in a significant decrease of gallstone occurrence (from 80%, group 8) to 35%, 45% and 30%, respectively (groups 5–7) (Table 3). When we replaced the 4% butterfat in the lithogenic diet with 1.2% palmitic acid (group 9), gallstones increased significantly (from 63% to 95%, $P < 0.01$). As in groups 1–4, all gallstones in groups 5–9 were composed entirely of cholesterol, as determined by both polarized light microscopy, FT-IR and GLC of a stone sample (after preparation of the TMS ether derivative). The addition of the various dietary fats in groups 5–7 suppressed gallstone incidence from that obtained with butterfat alone (group 8).

Cholesterol levels in liver, serum and bile were determined at the time of sacrifice; the results are summarized in Table 4. All liver cholesterol levels were greatly elevated above those previously obtained with the cholesterol-free semipurified diet alone [5 mg/g (24)]. The highest liver cholesterol was present in group 5 (lithogenic diet plus 4% olive oil, 108.8 mg/g) and the lowest in group 9 (semipurified diet plus 0.3% cholesterol plus 1.2% palmitic acid, 40.3 mg/g). With either 4% fat (groups 1–4), 8% fat (groups 5–8), or palmitic acid (group 9), the ani-

[d]Differs significantly from groups 1-7, $P < 0.01$.

mals given menhaden oil had the highest serum cholesterol levels (group 4, 379 mg/dL; group 7, 612 mg/dL). Biliary cholesterol was elevated above that of animals fed the semipurified diet alone (24) and ranged from a low of 3.34 mg/mL (group 9) to a high of 9.53 mg/mL (group 8).

The biliary lipids and cholesterol saturation indices are summarized in Table 5. The mol% cholesterol was highest in the animals given 8% butterfat (group 8) (11.8). This was the highest mol% cholesterol observed for any hamsters fed in this experiment. Animals fed 4% corn oil (group 3) had the lowest mol% cholesterol (6.7). The mol% phospholipid ranged from 17.6 (group 1) to 23.0 (group 7). All groups had cholesterol saturation indices of 1 or above. The highest value was in group 9 where stone incidence was greatest (CSI, 1.82); in this group biliary lipids were only 5.0 g/dL.

Biliary bile acids were analyzed by capillary gas chromatography after preparations of the methyl ester/acetate derivatives and are summarized in Table 6. Cholic acid was the major component in the bile of each group [range (%), 34.0-50.5]. Chenodeoxycholic acid was most prominent in group 1 (33.2%) and lowest in group 4 (23.9%). Other bile acids included deoxycholic, hyodeoxycholic, murideoxycholic, and allocholic acids. The percent of hyodeoxycholic and murideoxycholic acids tended to be higher with 8% dietary fat. The animals in which palmitic acid (group 9) was substituted for butterfat (group 1) had the lowest bile acid concentration (28.7 mg/mL); however, the

[a]Bile samples were aliquoted at sacrifice. See experimental section for details. Numbers are mean ± standard error of the mean. CA. cholic acid; CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; HDCA, hyodeoxycholic acid; MDCA, murideoxycholic acid. Other bile acids include lithocholic acid, allocholic acid, plus unidentified bile acids, each of which is less than 5%.
[b]Differs significantly from groups 1-8, $P < 0.01$.

percent of the various biliary bile acids was similar to group 1.

DISCUSSION

The hamster model of cholesterol cholelithiasis developed in our laboratory has remained reproducible for several years; gallstone incidence occurs in 45-65% of the animals fed the lithogenic diet (24) for 6 wk. All animals remained healthy during the feeding of this nutritionally adequate diet. The composition of the hamster diet was similar in nutritional content to one described by the National Research Council (27). This assured stone development in healthy animals. Other investigators have used the Sasco hamster to produce gallstones (28,29); the stones produced (cholesterol or pigment) seemed to vary with the dietary components.

The objectives of the current investigation were twofold: to determine if i) the type and the amount of dietary fat, and ii) a particular fatty acid (palmitic acid) affect the development of cholelithiasis. A link between fatty acid(s) and cholelithiasis has been sought but never established (17). The types of diets we used varied in composition with respect to the amount of saturated and unsaturated fatty acids (Table 1). A major saturated fatty acid in all of our diets was palmitic acid (16:0); the dietary concentration of palmitic acid was highest in groups 1 and 8 (as well as group 9) and lowest in the corn oil containing diets (groups 3 and 6). Palmitic acid was known to alter cholesterol metabolism in hamsters by enhancing high density lipoprotein cholesterol and low density lipoprotein receptor mesenger-ribonucleic acid (30,31). There have been no known studies on the effect of palmitic acid on cholelithiasis.

The mechanism by which fats or their individual components alter gallstone formation remains open to questions. In the current experiment, the bile of all hamsters was supersaturated (lithogenic index greater than 1.0) yet only cholesterol (and not pigment) gallstones formed by feeding certain fats to the animals (Table 3). Since the only dietary change among the groups was the administered fat, we assume that this modification affected the incidence of cholelithiasis. Several possibilities for this result can be suggested. First, the bile may contain a protein(s) which prevents (or extends the time of) nucleation of cholesterol crystals. Such proteins have been identified in bile of man (32-35). In man, large quantities of bile are available for analysis, while fasted hamsters, at sacrifice, usually have only 35-50 μL of bile per animal in their gallbladder at sacrifice. Different dietary fats may change the type or amount of bile protein. In studies of only 20 animals/group, the total amount of bile available was insufficient for analysis of the biliary lipids and isolation of individual proteins (or classes of proteins). In this experiment, we chose to determine the biliary lipids and the cholesterol saturation index (CSI). Second, the reason for absence of cholesterol crystals and/or gallstones in bile may be by alterations of the types of cholesterol carriers in the bile (vesicles, micelles, liquid crystals). We did not observe liquid crystals (multilamellar structures in bile under polarized light microscopy); however, vesicles of smaller size (monomeric unilamellar structures) could have been present but remained undetected (36). Vesicular structures solubilize more cholesterol than micelles (36-38). These structures could explain why some hamster biles, even though supersaturated, do not form stones or crystals. Quantitative analyses of vesicles in bile also require 1-2 mL of hepatic bile or 1 mL of gallbladder bile (36-38). The small volume of bile obtained in hamsters thus makes it extremely difficult to determine the vesicular content of bile. Furthermore, the accuracy of the current methodology for quantitation of vesicles and micelles

has been questioned (39). An improved analytical method to separate vesicles from micelles has been described but to date has only been useful for model bile (40).

Nutritional changes can affect cholesterol metabolism as well as cholelithiasis. A recent review by Grundy and Denke (41) pointed out that nutritional factors, such as saturated fatty acids, cholesterol and excess caloric intake, tend to affect serum low-density lipoprotein (LDL) levels in man. Similar factors appear to play a role in increasing the relative cholesterol content (lithogenic index) in bile in our hamster model of cholelithiasis. However, a high biliary cholesterol content *per se* may not be the sole determinant of cholelithiasis. Total fat intake can affect animal weight and can conceivably promote gallstone formation (by increasing cholesterol adsorption). We observed that hamsters ingesting 8% fat gained more weight than those consuming 4% fat (Table 2); food intake (g/d) in both sets of animals was similar. Nevertheless, several groups of animals on 8% fat had a significantly lower incidence of cholesterol stones than others (groups 5 and 6 *vs.* group 8). The gain in weight (44 g/6 wk) of the animals in group 9 (1.2% palmitic acid) was similar to that of the lithogenic control group (group 1, 35 g/6 wk). Gallstone incidence was 95% in group 9 and 63% in group 1. Thus, weight gain seemed to be unrelated to the development of cholelithiasis. The gain in total body weight, as well as total caloric intake alone, does not seem to predict the development of stones in this model.

Interestingly, animals in group 9 where total fat intake was only 3.2% (2% corn oil and 1.2% palmitic acid) had the highest incidence of cholesterol gallstones as well as the highest cholesterol saturation index (1.82). The total lipids in the bile of animals in group 9 were only 5.0 g/dL, about one-half of the value obtained for the control group (group 1, 10.5 g/dL). The decreased concentration of bile acids and phospholipid in the presence of elevated biliary cholesterol produced an elevated cholesterol saturation index which may explain the enhanced lithogenic stimulus exerted by palmitic acid, at least in part. This is the first report that a specific fatty acid caused a very high incidence of pure cholesterol gallstones. It has been reported that palmitic acid affects serum proteins, *i.e.*, it enhanced high density lipoprotein production (30). In addition, biliary phospholipids may alter cholesterol nucleation (42). Since different dietary fats are known to alter the fatty acid composition of biliary phospholipid in prairie dogs (43), it is interesting to speculate that a similar phenomenon may be occurring in this hamster model. It is also possible that in our model palmitic acid may affect the concentration or composition of nucleating/antinucleating proteins in bile leading to increased cholelithiasis. Further studies are needed to clarify these points.

Cholesterol in various body tissues increased with the intake of dietary fat. The amount of cholesterol in liver, plasma and bile of Sasco hamsters fed a semipurified diet containing no added dietary fat was 5.0 mg/g, 182 mg/dL and 1.84 mg/mL, respectively (25), well below the values in animals given dietary fat and cholesterol. There was no correlation between the concentration of cholesterol in liver or serum and the incidence of cholesterol gallstones. For example, hamsters in the lithogenic control group (group 1) had a mean liver cholesterol level of 78.4 mg/g and the incidence of cholesterol stones was 63%. Animals in groups 2–4 had no gallstones, yet liver cholesterol ranged from 71.7 to 92.1 mg/g. In general, serum cholesterol increased when dietary fat was increased (groups 1–4 *vs.* groups 5–8). In all groups, biliary cholesterol levels were higher and bile was supersaturated with cholesterol when dietary fat was increased, but only certain fats potentiated the formation of gallstones. We suggest that under the experimental conditions employed the concentrations of cholesterol in liver and serum were not predictive of relative biliary cholesterol concentrations, cholesterol saturation indices, or cholelithiasis.

[Received January 29, 1992; Revision accepted June 8, 1992]

Changes in Blood Lipids and Fibrinogen with a Note on Safety in a Long Term Study on the Effects of n-3 Fatty Acids in Subjects Receiving Fish Oil Supplements and Followed for Seven Years

Reginald Saynor* and **Timothy Gillott**
Sheffield Cardiothoracic Laboratory, Northern General Hospital, Sheffield S5 7AU, England

The present study was designed to assess the effectiveness of the n-3 fatty acids in modifying serum total, low density lipoprotein and high density lipoprotein (HDL) cholesterol, as well as serum triglycerides, over a seven-year period. Changes in plasma fibrinogen were recorded and long term safety assessed. A total of 365 subjects with ischemic heart disease (IHD), hyperlipidemia or a strong family history of IHD had their diet supplemented with MaxEPA (Seven Seas Ltd., Hull, England) fish oil containing 18–19% eicosapentaenoic acid. Venous blood samples were taken at regular intervals for lipid and fibrinogen assays and routine clinical chemistry and hematological profiling. Current medication was recorded and no further dietary modification was attempted. Triglyceride and fibrinogen were significantly reduced, whereas a significant reduction in total cholesterol occurred only in the subjects with a pre-oil level > 6.5 mmol/L. HDL cholesterol significantly increased over the study period. Clinical chemistry and hematological profiles were not adversely affected, and platelet count did not change significantly. The type of lipid changes observed were those usually considered antiatherogenic. Reducing fibrinogen may result in beneficial changes in the pathological processes leading to thrombotic occlusion. The consumption of MaxEPA by our patients over a seven-year period did not indicate any adverse effects.
Lipids 27, 533–538 (1992).

In recent years, much attention has been focused on dietary fish and fish oil as a means of improving various coronary heart disease risk factors (1). A high dietary intake of n-3 fatty acids is thought to be responsible for the low incidence of ischemic heart disease in Eskimos living in the Umanak district of Greenland (2). A low incidence of ischemic heart disease also has been reported in coastal-dwelling Turks and Japanese populations consuming a diet rich in n-3 fatty acids (3–6). Blood lipids, in particular, appear to be altered by the regular consumption of n-3 fatty acids. In 1980 we first reported (7) a significant reduction in serum triglyceride in normal volunteers taking MaxEPA (Seven Seas Ltd., Hull, England) a natural marine triglyceride rich in eicosapentaenoic (EPA) and docosahexaenoic acids (DHA). This finding was subsequently confirmed by both open (8–10) and controlled studies in healthy subjects and in patients with ischemic heart disease (11,12). In a further double-blind crossover study on hypertriglyceridemic patients, many of whom suffered previous myocardial infarcts, we demonstrated a significant superiority of n-3 over n-6 fatty acids in reducing serum triglyceride and total cholesterol and increasing high density lipoprotein cholesterol (HDL-C) (13). The bleeding time in Eskimos has been shown to be higher than in the Danes, a group with which the Eskimos have been compared (14,15). Other work has demonstrated an increased bleeding time after the consumption of fish oil in British subjects with ischemic heart disease (16). Re-occlusion after angioplasty has been significantly reduced in patients taking MaxEPA in addition to aspirin and persantin (17) and, indeed, many of the reported properties of fish oil would suggest a potential role in the prevention of coronary thrombosis. This open prospective study was designed to answer two important questions. What are the long-term effects of regular fish oil supplements to the diet on serum triglyceride, serum total cholesterol, low density lipoprotein (LDL) cholesterol and high density lipoprotein (HDL) cholesterol, as well as plasma fibrinogen and platelet count? Secondly, are there any undesirable long-term side effects as judged by clinical chemistry and hematology profiling?

PATIENTS AND METHODS

Three hundred and sixty-five subjects participated in the study (304 males and 61 females), with an age range of 18–76 years and a median age of 51 years. Of these, 47.2% had suffered a myocardial infarction and 1.9% had had a stroke prior to joining the study. A total of 49.2% had angina pectoris as assessed by history of symptoms, 3.8% diabetes mellitus and 6.1% intermittent claudication. Because most of these patients (73%) had hyperlipidemia and, in view of the pre-existing other high risk factors, it was not considered ethical to give them a placebo; hence the study was conducted as an open trial. Hyperlipidemia was defined as a triglyceride level in excess of 2.0 mmol/L and/or a total cholesterol level in excess of 6.5 mmol/L. The data reported on serum lipids covers a seven-year period. Plasma fibrinogen was measured by an outside laboratory, and at four years the method of measurement was changed. The measurement of this parameter was therefore discontinued. Seventy-five subjects withdrew from the study over seven years. The commonest reasons for withdrawal were moving away from the area and dislike of the taste of the fish oil, which was taken by spoonful since capsules of MaxEPA were not yet available. On joining the study, 199 patients were receiving medication for cardiovascular disorders, including treatment for angina and hypertension. Nine had been taking clofibrate but discontinued this before joining the study. No patients taking aspirin or lipid lowering medication were included in the study. Patients joined the study throughout the seven years. The 365 patients were studied for 1 mo; 343 for 3 mo; 300 for 6 mo; 258 for 12 mo; 216 for 18 mo; 204 for 24 mo; 163 for 30 mo; 146 for 36 mo; 126 for 42

mo; 109 for 48 mo; 84 for 60 mo; 61 for 72 mo; and 40 for 84 mo. Data from patients dropping out of the study were not included.

MaxEPA. The oil used in this study was a refined natural triglyceride concentrate, deodorized and blended from marine body oils. Dodecyl gallate (100 ppm) was added to the oil to retard oxidation and α-tocopherol acetate (1000 ppm was present to reduce the risk of vitamin E deficiency in the recipient. An advantage of this particular fish oil was the low concentrations of vitamins A and D present. The concentration of vitamin A was less than 100 IU/g, and less than 15 IU/g of vitamin D. The MaxEPA used here contained 18.6% EPA and 12.1% DHA.

Blood sampling. Serum for lipid and routine biochemical estimations was separated from venous blood withdrawn with the minimum of stasis after a 12–14 h fast. Blood for hematological estimations was collected into ethylenediaminetetraacetic acid (EDTA). Two blood samples for lipid measurement were taken at seven-day intervals before supplementation of the diet with MaxEPA, and further samples were taken at 1, 3, 6, 12, 18, 24, 30, 36, 42, 60, 72 and 84 mo after starting MaxEPA. In order to avoid diurnal lipid changes, all blood samples were taken between 9:00 and 10:00 a.m.

Dose. During the first year of study, each participant was asked to take 10 mL of MaxEPA (1.8 g EPA) twice daily with food. No further modification of diet was attempted and, to try to avoid the complicating effects of other, concomitant dietary manipulations, patients were encouraged to stay on the same diet as when they first joined the study. Subsequently, the dose was reduced to 10 mL once daily.

Laboratory assays. The method chosen for the measurement of serum triglyceride in the present study was the enzymatic assay after saponification with ethanol/potassium hydroxide (18–20). The glycerol present in serum before and after hydrolysis with ethanol/potassium hydroxide was converted to glycerol-3-phosphate and adenosine diphosphate (ADP) with adenosine triphosphate (ATP) and glycerokinase (GK) (ATP:glycerol 3-phosphotransferase). The ADP reacts with pyruvate kinase (PK) (ATP:pyruvate 2-*O*-phosphotransferase), and added phosphoenolpyruvate to give pyruvate which is reduced to lactate with reduced nicotinamide adenine dinucleotide (NADH) with lactate dehydrogenase (LDH) (L-lactate:NADH oxidoreductase). Triglyceride was determined by direct measurement of free glycerol which was subtracted from the total glycerol measured after alkaline hydrolysis of serum. The difference corresponds to the neutral fat content. The determination of triglyceride is dependent on a double enzymatic measurement of glycerol. No significant interference was observed from mono- and diglycerides which are present in the serum only in trace amounts. The decrease in extinction due to the oxidation of NADH was measured at 340 nm. Total serum cholesterol was measured by an enzymatic method using cholesterol oxidase (21–23). Esterified cholesterol is broken down into free cholesterol and fatty acid by enzymatic cleavage with cholesterol esterase. Cholestenone and hydrogen peroxide are produced as a result of the action of cholesterol oxidase on cholesterol. The amount of hydrogen peroxide produced is directly proportional to the amount of cholesterol present in the serum. After addition of color reagent the absorbance is read at a wavelength of 500 nm. The reagents used in both the above methods were supplied by Boehringer Mannheim U.K. Ltd. (Lewes, England). HDL-C was measured by the method described above after polyanion precipitation of the apoB-containing lipoproteins (very LDL, LDL) with sodium heparin and manganese chloride (24,25). Failure of the precipitate to sediment occurred in samples containing very high levels of very low density lipoprotein (VLDL). In order to measure HDL cholesterol in these samples it was necessary to dilute the serum with an equal volume of 0.01 M Tris-HCl buffer, pH 7.6, after which the measurement was made as described above. Polyacrylamide gel electrophoresis was used on both precipitate and supernatant to ensure complete and specific isolation of HDL. To prospectively assess the long-term safety of MaxEPA, routine clinical chemistry and hematological profiles were measured by the respective laboratories of this hospital using the Technicon H6000 and Vickers SP120 instruments (Technicon Co., Tarrytown, NY). Platelets were counted on a Coulter counter and plasma fibrinogen was measured by the Coagulation Laboratory (26). The Friedewald formula (27) was used to calculate LDL cholesterol, namely LDL-C = (total cholesterol − HDL-C) − triglycerides ÷ 2.19 mmol/L.

Statistics. A method based on piecewise linear interpolation (28), carried out for each individual patient, was used on each of the following variables—serum triglyceride, total cholesterol, HDL-C, LDL-C and plasma fibrinogen.

RESULTS

Serum triglyceride levels in the group of subjects with raised baseline levels (mean 3.76 mmol/L) fell significantly within one month, as did the triglyceride levels in the group with "normal" baseline levels (mean 1.35 mmol/L). In both groups the changes were significant at the 0.1% level. This highly significant decrease in triglyceride continued to the end of the study at seven years. Normal levels were defined as < 2.0 mmol/L. The results are shown in Figure 1.

Serum cholesterol in the group of subjects with raised baseline levels (mean 8.15 mmol/L) was reduced at 1 mo by 0.44 mmol/L, and by 3 mo had reached 0.54 mmol/L (significant at 0.1% level). At the end of seven years the reduction in cholesterol was 1.25 mmol/L. Normal levels were defined as 3.8 to 6.5 mmol/L. The group with a baseline < 6.5 mmol/L (mean 5.64 mmol/L) showed small increases at months 18 to 36, but this change was not significant at the 5% level. However, by the end of the study the cholesterol level in this group had fallen by 0.4 mmol%L (not significant). The results can be seen in Figure 2.

At each timepoint mean HDL cholesterol levels showed an increase from baseline levels (mean 1.22 mmol/L). These increases are shown in Figure 3. Furthermore, at each timepoint a majority of subjects were found to have increased levels of HDL cholesterol (significant at 0.1% level for each timepoint). The magnitude of change did not appear to differ greatly between the group with low baseline levels and the group with normal baseline levels. At each timepoint, mean LDL cholesterol levels demonstrated little or no change from the baseline levels

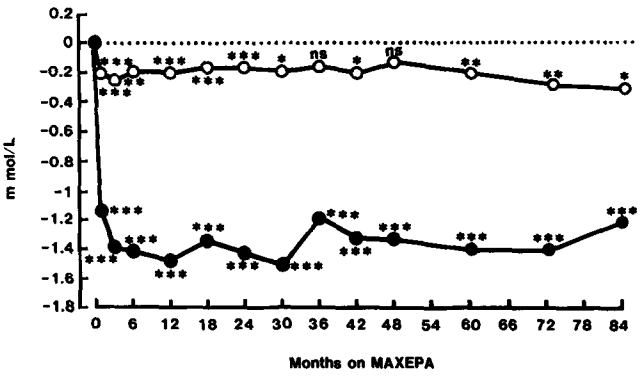

FIG. 1. Serum triglycerides before and during treatment with MaxEPA are shown as a mean change from baseline expressed in mmol/L. The mean level of the subjects with a pre-treatment triglyceride of < 2.0 mmol/L as illustrated by an open circle demonstrates a reduction significant at 0.1% level (***) for the first two years of study, after which changes show significance at a 1% (**) or a 5% level (*). No significant change is apparent at 36 and 48 mo. Changes observed in the subjects with a mean triglyceride level of > 2.0 mmol/L (●) indicate a reduction with significance at the 0.1% level (***) throughout the seven years of study.

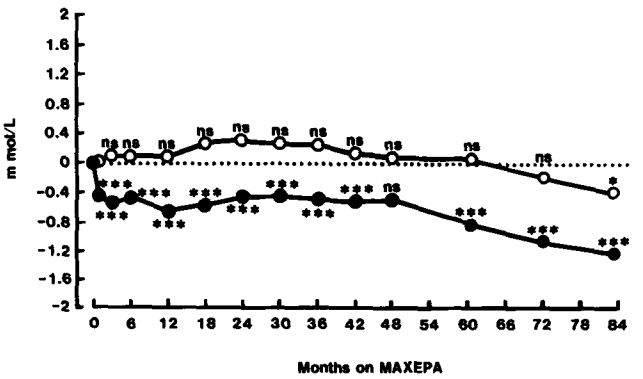

FIG. 2. The mean total serum cholesterol for two groups of subjects before and during seven years of treatment with MaxEPA is shown. In the group with a pre-treatment level of < 6.5 mmol/L (○) no significant change was observed until the final point at 84 mo, when a reduction in cholesterol was observed with a significance at 5% level. However, the group of subjects with a pre-treatment mean total serum cholesterol > 6.5 mmol/L (●) experienced a reduction in cholesterol significant at 0.1% level (***), at all except the 48 mo point during study.

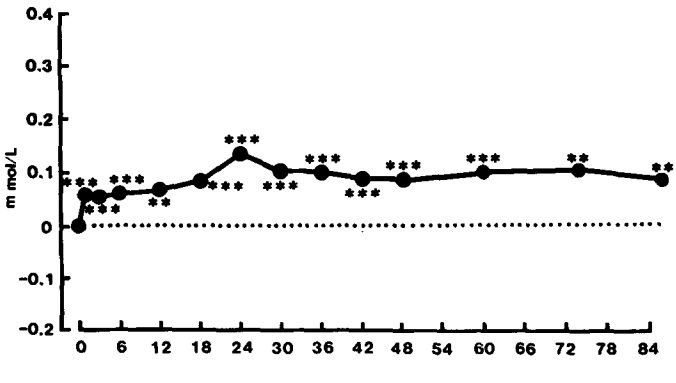

FIG. 3. The high density lipoprotein cholesterol increased within a few weeks of starting treatment with MaxEPA, and at most timepoints the change was significant at 0.1% level (***). At points 12, 72 and 84 mo the increase was significant at a 1% level (**).

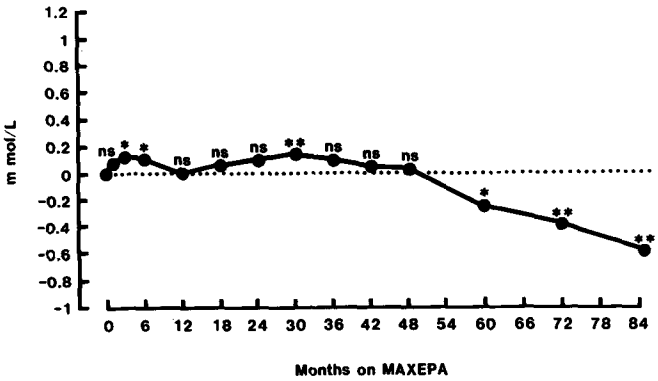

FIG. 4. Low density lipoprotein cholesterol increased at 3, 6 and 30 mo after starting treatment with MaxEPA with significance at 5% (*), 1% (**) levels, respectively. At all other points no significant change was observed until 60 mo through to the end of the study when a significant decrease in LDL cholesterol was apparent. At 60 mo this change was significant at 5% (*) level, at 72 and 84 mo the change was significant at a 1% (**) level.

with the exception of 3, 6 and 30 mo, where a significant increase occurred at the 5% level at the first two points and at 1% at the latter. However, at the end of seven years the LDL cholesterol had fallen by 0.6 mmol/L (significant at 1% level). Changes are shown in Figure 4.

Plasma fibrinogen levels demonstrated mean reductions from baseline levels at each timepoint and these tended to increase in magnitude as time progressed (Fig. 5). After 1 mo, the mean fibrinogen level was reduced by 0.14 g/L, at 6 mo the observed mean reduction from the baseline levels was 0.33 g/L, and at 48 mo the mean reduction was 0.89 g/L (significant at the 0.1% level). No significant change was observed in the mean platelet count during this study (Fig. 6). At the start of the study MaxEPA was not available in capsule form and it was not possible to find a placebo oil with similar taste. It was therefore decided to conduct an open study with a control group. With the exception of taste, as indicated by a number of patients withdrawing from the study, MaxEPA was found to be without apparent side-effects over seven years of medication. Although up to 17.5% of patients had minor disturbances of routine chemical and hematological parameters, none had more than two changes outside the normal range (Table 1). The changes were small and inconsistent and were felt to be of no significance. No change in any parameter could be attributed to MaxEPA.

DISCUSSION

A recent editorial sounded a cautionary note on both the safety and long-term efficacy of fish oil in lowering plasma triglyceride (29). A study using a different fish oil concentrate (Omega-500, Omegacaps, St. Louis, MO) 15 g daily had failed to sustain the initial reduction in plasma triglyceride in 16 patients over 6 mo of study (30). Our much longer study, with larger numbers of patients, found MaxEPA to be safe and to show a persistent reduction in triglyceride concentrations, which was as effective after seven years as during the initial period of study. The only side effect to lead to a number of patients withdraw-

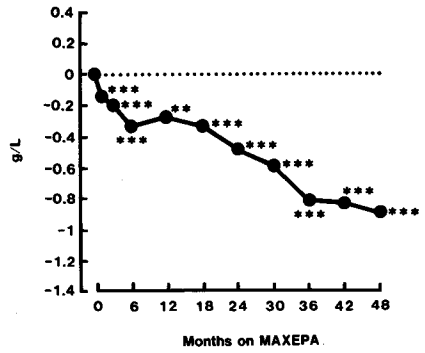

FIG. 5. Plasma fibrinogen, measured for the first 48 mo after starting treatment with MaxEPA, fell significantly at each timepoint. Only at 12 mo was the change significant at the 1% level (**), at every other point the significance was at the 0.1% level (***).

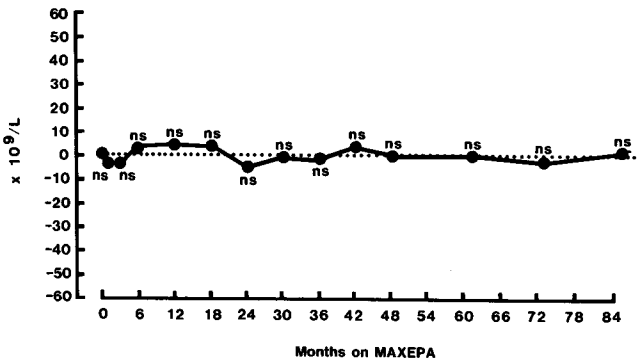

FIG. 6. Platelet numbers were reduced during the first three months after starting treatment with MaxEPA. This reduction did not reach significance. For the remaining period of study there was not significant change in platelet count, which remained close to the baseline level.

ing from the study was the taste of the oil. We cannot explain the reduction in long term efficacy in the Omega-500 trial, where the maintenance dose of n-3 fatty acids was 3.9 g/day. One possible explanation for these differences might lie in the different composition of fish oil produced by different manufacturers. The mechanism by which fish oil reduced plasma triglyceride has been discussed at length elsewhere (16,31–33).

Hypertriglyceridemia is an univariate risk factor for ischemic heart disease, but its role as an independent risk factor is still controversial. In general, hypertriglyceridemia combined with low HDL cholesterol suggests an increased risk of coronary disease. However, a strong relationship between non-fasting VLDL levels and cardiovascular mortality in both men and women has been reported (34). This suggests that triglyceride-rich lipoprotein in random samples is an important predictor of both total and cardiovascular mortality.

Hypertriglyceridemia also has been associated with depressed fibrinolysis, an important factor in ischemic heart disease (35). An association between hypertriglyceridemia and increased plasma concentrations of fibrinogen has been reported to be partially corrected by reducing plasma triglycerides (36). Most myocardial infarcts are the result of thrombotic occlusion. A number of prospective studies have shown plasma fibrinogen to be a highly significant risk factor in the development of coronary heart disease (37–41). In one of these studies (41), platelet aggregability was strongly associated with plasma fibrinogen concentration. A strong correlation has been reported between decreased red cell filterability, high triglyceride, high fibrinogen and low HDL-C levels. The present work suggests a positive correlation between triglyceride and fibrinogen. Reducing triglyceride and maintaining a low plasma level of fibrinogen may result in a lessening of its adverse effects on hemorrheology and damage to the arterial wall. The foregoing would appear to suggest a link, directly or indirectly, between serum triglyceride, plasma fibrinogen and platelet aggregation

TABLE 1

Clinical Chemistry and Hematological Measurements on Patients[a]

Variable (normal range)	No. of patients	No. of patients with at least one value below range	No. of patients with at least one value above range
Sodium (134–144 mmol/L)	211	7 (3.3%)	23 (10.9%)
Potassium (3.8–5.2 mmol/L)	211	15 (7.1%)	35 (16.6%)
Calcium (2.2–2.6 mmol/L)	211	18 (8.5%)	21 (10.0%)
Creatinine (35–120 mmol/L)	211	5 (2.4%)	37 (17.5%)
Urea (2.8–8.0 mmol/L)	211	10 (4.7%)	15 (7.1%)
Albumin (36–50 mmol/L)	209	2 (1.0%)	20 (9.6%)
Bilirubin (1–24 mmol/L)	207	0 (0%)	13 (6.2%)
Leucocytes (3.5–11.5 10^9/L)	283	7 (2.5%)	14 (4.9%)
Hemoglobin (F: 12.3–16.5 g/dL) (M: 13.0–18.0 g/dL)	283	15 (5.3%)	19 (6.7%)

[a]No patient had more than two results outside normal range.

which would not only lead to a hypercoagulable state but might also stimulate atherogenesis. It is suggested that the pathological processes leading to thrombotic occlusion may be modified beneficially by increasing the level of n-3 series fatty acids in the circulating blood. Although this was an open study, patients were specifically asked not to change their usual eating habits and the authors have no evidence to suggest that these instructions were not followed. The reduction in total serum cholesterol over seven years in patients with raised baseline levels was both consistent and significant. However, LDL cholesterol changed little over the first four years of study with the exception of three points, at which a significant increase was observed. After four years the LDL cholesterol was significantly reduced. We are unable to explain the LDL pattern, except to point out that the significant fall at years five, six and seven was accompanied by a significant reduction in total cholesterol. These changes, if confirmed by further studies, could suggest the possibility of an anti-atherogenic role for n-3 fatty acids.

Increases in HDL cholesterol were highly significant at each time point and may be related to the fall in serum triglycerides. The increased HDL-C is suggestive of an enhanced removal of cholesterol, and that a shift in body cholesterol from the serum to the tissue pool is not the mechanism by which the total cholesterol is reduced. The ingestion of n-3 fatty acids appears to lead to a reduction in triglyceride-rich VLDL and, consequently, it appears likely that the synthesis and release of apo A-I from endothelial cells is increased. This probably leads to increased conversion of discoid to spherical HDL due to activating effect of the apoprotein on lecithin:cholesterol acyltransferase (LCAT). It is also possible that an increase in HDL synthesis occurs by stimulation of the end process of HDL formation, allowing for a greater rate of apo A-I incorporation into the final HDL. Although changes in platelet count did not reach significance, about 50% of subjects experienced a reduction in platelet numbers. The incorporation of n-3 fatty acids into the platelet membrane lipids leads to the partial replacement of arachidonic acid in the membrane by EPA which, in turn, leads to the weak aggregating agent, thromboxane A_3, instead of the potent aggregator A_2 (41), thereby reducing the tendency to thrombosis. The study presented here suggests that beneficial changes can be elicited in the concentration of blood lipids. It is interesting that in the long term, both total and LDL cholesterol are reduced significantly. LDL cholesterol was reduced by 0.6 mmol/L after seven years, from an initial level of 4.66 mmol/L. Changes after the end of the study were insignificant. Many patients continued taking MaxEPA, prescribed by their general practitioner, after the end of the study and continued attending our lipid clinic. No significant weight change was observed but it is possible that, despite asking patients not to change diet, the much publicized benefit of using polyunsaturated fats to help lower cholesterol influenced some patients from the mid-1980's. These changes, together with a reduction in the concentration of plasma fibrinogen, may lead to a slowing-down in atheroma formation. Furthermore, a reduction in fibrinogen together with changes induced in thromboxane production demonstrated by other researchers suggests the possibility of a reduction in thrombus formation. Long term safety of MaxEPA consumption in the doses used in this study and assessed by the methods described would appear to suggest no cause for concern.

The Effect of Beta Blocking Drugs on Lipid Peroxidation in Rat Heart *in Vitro*

R.R. Jenkins*, C.M. Del Signore, P. Sauer and C. Skelly
Department of Biology, Ithaca College, Ithaca, New York 14850

Beta-adrenergic receptor blocking drugs include a structurally related class of drugs that are employed clinically to treat a variety of cardiovascular disorders. Since these drugs exert additional nonspecific effects including membrane stabilization, representative samples including atenolol, dilevolol, labetolol, metoprolol and propranolol were studied to determine their influence on lipid peroxidation. Homogenates or liposomes of adult rat hearts were incubated in the presence of various concentrations of propranolol or equivalent concentrations of dilevolol, labetolol, metoprolol or atenolol. Lipid peroxidation was stimulated with 50 μM $FeSO_4$, 5 μM *t*-butyl hydroperoxide (homogenates) or 0.2 mM citrate $FeSO_4$ (liposomes) plus O_2. Lipid peroxidation, as assessed by both the thiobarbituric acid reaction and chemiluminescence, was reduced in a dose-dependent manner as the propranolol concentration was increased from 1 to 10 mM. The five beta-adrenergic receptor blocking drugs reduced lipid peroxidation both in crude homogenates and in liposomes; their effectiveness was related to their lipophilicity. Dilevolol, propranolol, labetolol and metoprolol at a concentration of 20 mM reduced lipid peroxidation by 45%, 37%, 35% and 28%, respectively. The hydrophilic blocker atenolol was ineffective in reducing lipid peroxidation even at elevated concentrations. Lipophilic beta-blocking drugs apparently are capable of exerting an antioxidant effect in protecting membrane lipids against peroxidation. *Lipids 27,* 539–542 (1992).

Series of clinical trials have recently demonstrated that beta-adrenergic receptor blocking drugs (beta blockers) reduce mortality subsequent to acute myocardial infarction. Beta blockers include a class of structurally related *N*-isopropyl amines. The drugs exert their specific receptor blockade by competing for membrane receptor sites. However beta blockers have also been shown to exhibit a variety of nonspecific effects. For instance, they reduce O_2 consumption and alter the metabolism of the myocardium (1), reduce calcium entry (2), exert local anesthetic activity (3), exert antiarrhythmic action in heart tissue (4) and stabilize membranes (5).

The mechanisms by which the nonspecific effects are exerted are poorly understood. The membrane-stabilizing properties of the drugs may be related to the degree of lipophilicity of certain blockers. The lipophilic characteristic of these compounds seems to be related to their aromatic ring structure. For instance, the *n*-octanol and buffer distribution coefficients range from 20.2 for the propranolol, 11.5 for labetolol, 0.98 for metoprolol and 0.0015 for atenolol (6). Presumably, the greater lipophilicity of propranolol may be due to its naphthalene moiety. In addition, beta blockers are cationic amphiphiles, and that characteristic may enable them to interact with phospholipids (7).

A vast literature implicates oxygen centered radicals as initiators of lipid peroxidation (8,9). The process of lipid peroxidation results in a variety of detrimental changes in cell biology including altered electrophysiological changes that may lead to an increased susceptibility to arrhythmias (10). Since the beneficial effects of beta blockers extend to the central nervous system (5) as well as to the gastric mucosa (11), the beneficial action of the drugs might operate through a mechanism unrelated to membrane receptor blockade. The following experiments were conducted to determine whether beta blockers might protect myocardial tissue by reducing its susceptibility to lipid peroxidation.

MATERIALS AND METHODS

Male Sprague-Dawley-derived rats (200–250 g), originally obtained from Harlan Sprague Dawley (Indianapolis, IN), were housed in standard wire cages and maintained on a 12-h day/12-h night cycle. Rats were given standard rat chow and water *ad libitum.* All animals were sacrificed between 0800–1000 h. The animals were anesthetized with sodium pentobarbital (42 mg/kg), and the hearts were perfused with 100 mL of ice-cold 0.9% NaCl. Hearts were prepared for analysis either as homogenates with 1 g of tissue to 9 mL of 1.15% KCl, or as liposomes. Liposomes were prepared according to the method of Pederson *et al.* (12) by sonicating lipids that had been extracted from heart homogenates according to the method of Folch *et al.* (13). The samples were covered with argon and were maintained in an ice bath until used.

All solutions were made in twice distilled water and passed through Chelex 100 to remove iron (14). Heart tissue susceptibility to lipid peroxidation was determined by incubating aliquots of homogenates for various periods of time either in the presence of a beta blocking drug (at various concentrations) or an equal volume of 0.9% saline. Homogenates received either 100 μL of 50 μM $FeSO_4$, 5 μM *t*-butyl hydroperoxide or an equal volume of H_2O, and were gassed with O_2/CO_2 (95/5%) for 30 s prior to being tightly capped and incubated at 37°C for 1 h. Liposomes were stimulated with 100 μL of 1:1 (vol/vol) citrate Fe^{2+}/citrate Fe^{3+} (0.2 mM). The 0.2 mM citrate Fe solutions were made fresh daily according to the method of Minotti and Aust (15). Thiobarbituric acid reactive substances (TBARS) were assayed by the method of Ohkawa *et al.* (16). Malondialdehyde (MDA) was prepared by the method of Kwon and Watts (17) from 1,1,3,3-tetraethoxypropane (Sigma Chemical Company, St. Louis, MO), and was used as an internal standard.

Ultraweak chemiluminescence was analyzed using a single photon counting technique similar to that of Boveris *et al.* (18). The system consisted of a photomultiplier tube (EMI-GENCOM, 96586, THORN EMI-GENCOM, Fairfield, NJ) housed in a thermoelectric cooler (EMI-GENCOM, Fact 50). The tube output was set through an

Abbreviations: MDA, malondialdehyde; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substances.

amplifier-discriminator to a counter (EMI-GENCOM, C10) and the data were subsequently transferred to an Apple IIe computer for analysis. The system was calibrated against carbon-14 according to the method of Woodland Hastings and Weber (19). The homogenates or liposomes were placed in a specially constructed 15 × 5 × 50 mm lucite cuvette. During the assay, the 2.5-mL volumes were gently stirred and were continually gassed with O_2/CO_2 (95/5%). Chemiluminescence was stimulated by the addition of $FeSO_4$, citrate Fe or *t*-butyl hydroperoxide as in the TBARS assay. The effect of epinephrine on the TBARS and chemiluminescence assays was measured with epinephrine bitartrate (Sigma Chemical Company). Where appropriate, data are referenced to protein which was determined by the method of Bradford (20).

Values are expressed as mean ± SE. Data were analyzed by analysis of variance followed by the Newman-Keuls test when appropriate. Significance was established at the 0.05 level.

RESULTS

Figures 1 and 2 illustrate a dose-dependent relationship between propranolol, chemiluminescence and TBARS. When propranolol was included in the reaction at a final concentration of 0.01, 0.1, 1 or 10 mM, chemiluminescence and TBARS were significantly reduced relative to the iron stimulated condition. Good agreement was found between the two parameters measured. A regression analysis of the data yielded an r = 0.86.

In order to determine whether the observed inhibitory effect was limited to iron stimulated peroxidation or to propranolol, five beta-blocking agents were tested with peroxidation induced by including *t*-butyl hydroperoxide (5 μM) in the incubation. The data in Figure 3 demonstrate that the drugs dilevolol, propranolol, labetolol, and metoprolol all significantly reduced TBARS relative to the

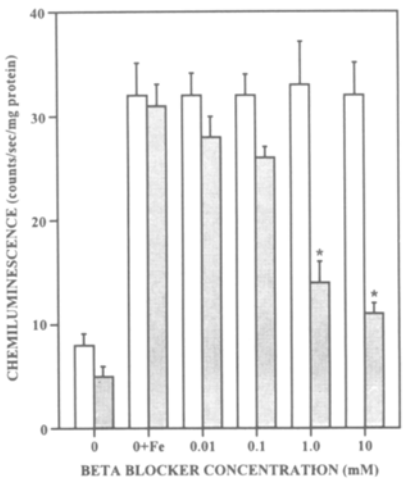

FIG. 1. Inhibition of iron stimulated chemiluminescence from heart homogenates (10% w/v) by mM concentrations of propranolol. Reaction contained 0.5 mL homogenate (10% w/v), 100 μL $FeSO_4$ (50 μM), 5 μL antifoam, 1.795 mL sodium phosphate buffer and 100 μL propranolol or H_2O. Control = 0 with no iron or propranolol, 0 + Fe = iron and no propranol. Data were analyzed by analysis of variance followed by the Newman-Keuls test. Asterisk indicates values significantly different from Fe stimulated values ($P \leq 0.05$).

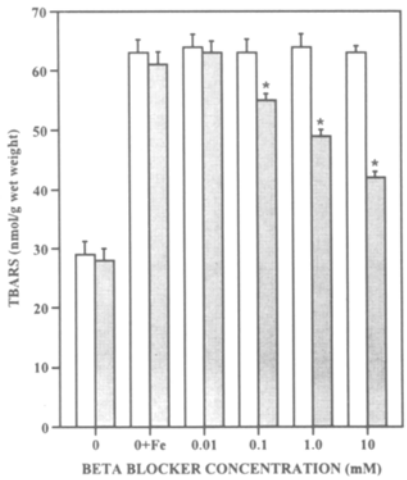

FIG. 2. Inhibition of iron stimulated thiobarbituric acid reactive substance (TBARS) formation from heart homogenates by propranolol. Reaction mixture is as in Figure 1. Data are means ± SE. Asterisk indicates values significantly different from Fe stimulated values ($P \leq 0.05$).

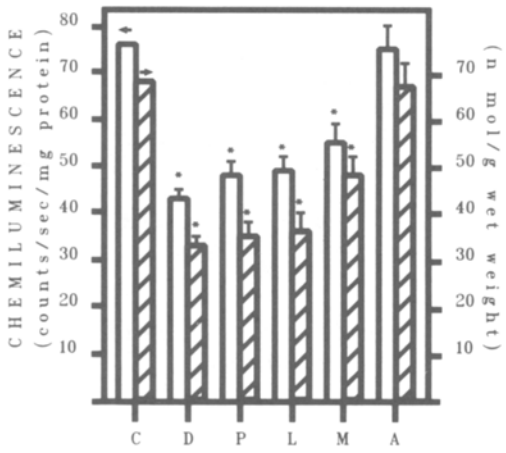

FIG. 3. Inhibition of chemiluminescence (open bars) and thiobarbituric acid reactive substance (TBARS—slash bars) from heart homogenates resultant from incubation with 100 μL of either 20 mM atenolol (A), dilevolol (D), labetolol (L), metoprolol (M) or propranolol (P). Remainder of the reaction mixture is as in Figure 1. Asterisk indicates values significantly different from Fe stimulated values ($P \leq 0.05$).

t-butyl hydroperoxide stimulated condition. Dilevolol which produced a 52% reduction was most effective. Propranolol and labetolol were equally effective in reducing TBARS by 47% and chemiluminescence by 37%. Dilevolol and metoprolol resulted in a 45% and 28% reduction in chemiluminescence, respectively, while atenolol was ineffective in altering TBARS and chemiluminescence. The drugs similarly reduced iron stimulated lipid peroxidation (data not shown).

As the previous data were derived from crude homogenates, additional experiments were conducted to determine whether propranolol would exert a similar effect in lipids extracted from heart homogenates. Figure 4 demonstrates that the drugs' effectiveness in inhibiting lipid

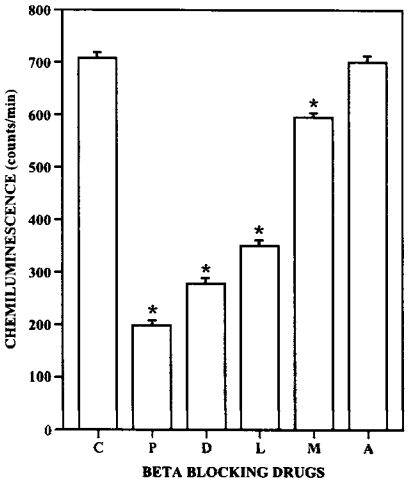

FIG. 4. The effect of 100 μL of either 20 mM atenolol (A), dilevolol (D), labetolol (L), metoprolol (M) or propranolol (P) on liposomal chemiluminescence stimulated by 100 μL of 1:1 (vol/vol) citrate Fe^{2+}/citrate Fe^{3+} (0.2 mM). Remainder of reaction mixture is as in Figure 1. Data are means ± SE. Asterisk indicates significantly different from citrate Fe stimulated control ($P \leq 0.05$).

peroxidation in liposomes was similar to that observed in crude homogenates with the exception that propranolol, rather than dilevolol, was most effective. In addition, Figure 5 illustrates that the inhibitory effect was related to the length of time that liposomes had been preincubated with propranolol prior to stimulating peroxidation by introducing citrate $FeSO_4$ into the reaction.

Propranolol at a final concentration of 10 mM was included with an MDA standard to determine whether propranolol simply interfered with the chemistry of the TBARS formation. Table 1 demonstrates that the treatment failed to reduce TBARS. Furthermore, Table 1 also demonstrates that epinephrine or propranolol added to homogenates at the end of the incubation period did not alter TBARS values.

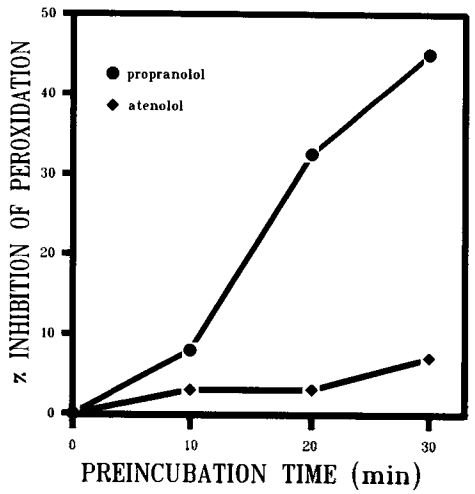

FIG. 5. Relationship between the length of time heart homogenates were preincubated with atenolol or propranolol prior to stimulation with Fe and the % reduction in lipid peroxidation from Fe stimulated controls.

TABLE 1

Influence of Propranolol or Epinephrine on the Thiobarbituric Acid Reaction (TBARS) with Peroxidized Heart Homogenates and Malondialdehyde (MDA) Standards

	Control[a]	Epinephrine[b]	Propranolol
Heart	58.0 ± 2.1[c]	60.3 ± 2.8	59.2 ± 3.1
MDA	0.19 ± 0.1	0.18 ± 0.1	0.21 ± 0.2

[a] Heart control was homogenate stimulated with $FeSO_4$ (as in Fig. 1). MDA control is 6 nmol standard.

[b] Incubation medium contained 10 μg epinephrine per mL or 10 mM propranolol.

[c] Units of measurements are TBARS (nmol/g wet weight) for heart and absorbance for MDA.

DISCUSSION

Meerson and his colleagues (10) were the first to show that inderal (propranolol) resulted in a reduction of catecholamine-induced lipid peroxidation. More recently, beta blockers have been shown to reduce lipid peroxidation of sarcolemma (21,22) and microsomal membranes (23). The present studies confirm the previous findings that the effectiveness of the beta blockers is related to the compounds' lipophilicity (24). Furthermore, our data demonstrate that the inhibition of lipid peroxidation is related to a more general action of the drug and not to a specific receptor blocking mechanism.

Beta-adrenergic blocking drugs have been reported to provide protection against damage in various tissues and conditions. For instance, while there was no benefit from propranolol administration begun 8.5 h post-myocardial infarction (25), the benefits of adrenergic blocker administration prior to tissue insult have been well documented. Several groups have reported that patients who were given beta-blockers prior to surgery suffered less myocardial damage than those taken off blockers prior to surgery (26). Propranolol has also been shown to exert a nonspecific membrane-stabilizing effect on erythrocyte membranes (27). In addition, propranolol administration was associated with a reduction in gastric mucosal damage (11) as well as a reduction in cerebral infarct size in cats subsequent to middle cerebral artery occlusion (28).

Until recently the beneficial influence of beta-adrenergic blocking drugs that could not reasonably be attributed to receptor mediated effects has been explained as nonspecific effects on mitochondrial coupling (29), blood pressure reduction (7) or reduced energy demands (30). A growing body of evidence implicates oxygen centered radical events in membrane injury and malfunction. Barsacchi *et al.* (31) have correlated oxidative stress with decreased contractile function in hearts. Furthermore, pretreatment of hydroperoxide perfused hearts with the radical scavenger butylated hydroxytoluene reduced arrhythmias and the accumulation of malondialdehyde (32).

Arouma *et al.* (23) have recently shown that beta blockers do not act as antioxidants. Beta blockers may exert their non-specific membrane stabilizing effect by reducing lipid peroxidation. Cruickshank and Neil-Dwyer (24) have shown that the beneficial influence of beta-blockers was related to the degree of their lipophilicity. More recently Ondrias *et al.* (33) have confirmed that

eleven beta-blocking drugs interacted with membranes in a structure-dependent manner which was related to their lipophilicity. The partition coefficients for the drugs used in this study were in direct agreement with the order of effectiveness in reducing lipid peroxidation, with the hydrophilic drug atenolol being least effective and dilevolol, the R,R-isomer of labetolol, being the most effective. We interpret the fact that beta-blockers required a preincubation period to be effective as evidence that they exert a lipid peroxidation blocking action. The lipophilic beta-blocking drugs may intercalate into the lipid matrix and reduce the propagation phase of lipid peroxidation in a manner similar to that proposed for tocopherol (34).

Ascorbate and Phenolic Antioxidant Interactions in Prevention of Liposomal Oxidation

Craig E. Thomas*, Larry R. McLean, Roger A. Parker and David F. Ohlweiler
Marion Merrell Dow Research Institute, Cincinnati, Ohio 45215

Efficient prevention of membrane lipid peroxidation by vitamin E (α-tocopherol) may involve its regeneration by vitamin C (ascorbate). Conceivably, the efficacy of antioxidants designed as therapeutic agents could be enhanced if a similar regeneration were favorable; thus, a model membrane system was developed which allowed assessment of interaction of phenolic antioxidants with ascorbate and ascorbyl-6-palmitate. Ascorbate alone (50–200 μM) potentiated oxidation of soybean phosphatidylcholine liposomes by Fe^{2+}/histidine-Fe^{3+}, an effect which was temporally related to reduction of Fe^{3+} generated during oxidation. Addition of 200 μM ascorbate to α-tocopherol-containing liposomes (0.1 mol%) resulted in marked, synergistic protection. Accordingly, in the presence but not absence of ascorbate, α-tocopherol levels were maintained relatively constant during Fe^{2+}/histidine-Fe^{3+} exposure. Probucol (4,4′-[(1-methylethylidine)*bis*(thio)][*bis*[2,6-*bis*(1,1-dimethylethyl)]phenol), an antioxidant which prevents oxidation of low density lipoproteins, and its analogues MDL 27,968 (4,4′-[(1-methylethylidene)*bis*(thio)]-*bis*[2,6-dimethyl]phenol) and MDL 28,881 (2,6-*bis*(1,1-dimethylethyl)-4-[(3,7,11-trimethyldodecyl)thio]phenol) prevented oxidation but exhibited no synergy with ascorbate. Ascorbyl-6-palmitate itself was an effective antioxidant but did not interact synergistically with any of the phenolic antioxidants. Differential scanning calorimetry revealed significant differences among the antioxidants in their effect on the liquid-crystalline phase transition of dipalmitoyl phosphatidylcholine (DPPC) liposomes. Both α-tocopherol and MDL 27,968 significantly reduced the phase transition temperature and the enthalpy of the transition. MDL 28,881 had no effect while probucol was intermediate. The potential for ascorbate or its analogues to interact with phenolic antioxidants to provide a more effective antioxidant system appears to be dictated by structural features and by the location of the antioxidants in the membrane.
Lipids 27, 543–550 (1992).

Vitamin E (α-tocopherol) functions as the major lipophilic antioxidant in biological systems by virtue of its ability to react with lipid peroxyl radicals to terminate the peroxidative process (1). The resultant tocopheroxyl radical can be further oxidized to a number of non-radical products including tocopherol quinone and 8a-(alkyldioxy)tocopherones (2–4). As the loss of a critical cellular defense mechanism by irreversible oxidation would be extremely deleterious to cells, one would expect relatively high cellular levels of α-tocopherol which are accompanied by high turnover rates. However, in most tissues the ratio of α-tocopherol to polyunsaturated fatty acids is on the order of 1:1000 and, furthermore, in certain tissues the biological half-life of α-tocopherol is quite long (5,6). For these reasons, it has been speculated that other cellular reductants interact with partially oxidized α-tocopherol which would, in effect, greatly increase the protective capacity of a cell by enabling a presumably much larger reductant pool to participate in termination reactions.

In vitro studies have suggested that α-tocopherol may be recycled by interaction with glutathione (GSH) or ascorbate. Protection against lipid peroxidation in microsomes (7,8) mitochondria (9) and nuclei (10) has been afforded by GSH, and one possible explanation for the protection was the enzyme catalyzed recycling of α-tocopherol (7). Mitochondria also possess a free radical reductase which uses nicotinamide adenine dinucleotide, reduced (NADH) as a source of reducing equivalents to reduce chromanoxyl radicals (11). Alternatively, in support of an earlier proposal by Tappel (12), direct reduction of the tocopheroxyl radical by ascorbate has been demonstrated (13,14). This regeneration of α-tocopherol by ascorbate has been assumed to be responsible for their observed synergistic protective effect in model lipid peroxidation systems (15,16). However, it has been questioned whether ascorbate can effectively compete with secondary oxidation reactions of the tocopheroxyl radical or whether it reduces another oxidized intermediate such as a tocopherone cation (2).

In the design of antioxidants for treatment of disorders related to membrane lipid oxidation, it may be desirable to prepare compounds which can interact with ascorbate as does α-tocopherol. Many studies have evaluated α-tocopherol analogues in an attempt to define the chemical and structural properties of the molecule which make it ideally suited as a lipophilic peroxyl radical trap (17,18). Moreover, α-tocopherol derivatives have been evaluated for the ability of their respective chromanoxyl radicals to interact with ascorbate (19). In general, as the alkyl groups *ortho* to the phenoxyl radical of the α-tocopherol derivatives increase in size, the second order rate constant for the interaction decreases appreciably, probably due to steric hindrance. These results are of interest as most synthetic antioxidants such as probucol and butylated hydroxytoluene (BHT) are di-*tert*-butyl compounds. *In vivo*, other additional effects such as positioning of the antioxidant in the membrane and reduction of oxidized intermediates other than the tocopheroxyl radical (2) are likely to be of importance. The purpose of this study was to compare the ability of α-tocopherol and three synthetic lipophilic antioxidants to interact synergistically with ascorbate or ascorbyl-6-palmitate in the prevention of iron-induced oxidation of liposomal membranes. Probucol was

Abbreviations: BHT, butylated hydroxytoluene; DPPC, dipalmitoyl phosphatidylcholine; DSC, differential scanning calorimetry; EDTA, ethylenediaminetetraacetic acid; GSH, reduced glutathione; MDL 27,968, 4,4′-[(1-methylethylidene)*bis*(thio)]*bis*[2,6-dimethyl]-phenol; MDL 28,881, 2,6-*bis*(1,1-dimethylethyl)-4-[3,7,11-trimethyldodecyl)thio]phenol; NADH, nicotinamide adenine dinucleotide, reduced; probucol, 4,4′[(1-methylethylidene)*bis*(thio)]*bis*[2,6-*bis*(1,1-dimethylethyl)]phenol; TBARS, thiobarbituric acid reactive substances; T_m, phase transition temperatures.

evaluated as it is an effective antioxidant in low density lipoproteins (20) and prevents atherosclerosis in animal models (21–23). To address the issue of *ortho* substitution, MDL 27,968 was chosen as it contains methyl, rather than di-*tert*-butyl, groups. MDL 28,881 has a similar substitution at the *ortho*-position but contains an acyl chain similar to α-tocopherol which may allow assessment of membrane positioning as a determinant of synergistic interaction with ascorbate.

MATERIALS AND METHODS

Probucol (4,4′-[(1-methylethylidene)*bis*(thio)]*bis*[2,6-*bis*-(1,1-dimethylethyl)]phenol) and its analogues MDL 28,881 (2,6-*bis*(1,1-dimethylethyl)-4-[(3,7,11-trimethyldodecyl)-thio]phenol) and MDL 27;968 (4,4′-[(1-methylethylidene)-*bis*(thio)]*bis*[2,6-dimethyl]phenol) were synthesized by Marion Merrell Dow (Cincinnati, OH) and the Dow Chemical Company (Midland, MI), respectively (24). The structures of these 3 compounds and α-tocopherol are shown in Figure 1. The α-tocopherol and δ-tocopherol were obtained from Kodak (Rochester, NY). Soybean phosphatidylcholine (Type III-S), Ferrozine, ferrous chloride, ferric chloride, ethylenediaminetetraacetic acid (EDTA), histidine, trichloroacetic acid, butylated hydroxytoluene, ascorbic acid, ascorbyl-6-palmitate, and thiobarbituric acid were purchased from Sigma (St. Louis, MO). Dipalmitoyl phosphatidylcholine (DPPC) was a product of Avanti Polar Lipids (Birmingham, AL). All other chemicals were obtained from commercial sources and were of the highest grade available.

Liposome preparation and oxidation. Liposomes comprised primarily of single bilayers were prepared by ethanol injection essentially as described by Kremer *et al.* (25). Soybean phosphatidylcholine and, where indicated, the phenolic antioxidants or ascorbyl-6-palmitate were dried under a stream of N_2. Typically, the material was reconstituted in 100 μL of ethanol and injected using a Hamilton syringe (Reno, NV) into 10 mL of 10 mM Tris/50 mM NaCl, pH 7.0 at 37°C while mixing. The final concentration of the phosphatidylcholine was 0.5 mM and the antioxidants included at various mol% relative to the phospholipid concentration. The final lipid concentration is 0.5 mM, thus for all antioxidants 0.1 mol% is equivalent to 0.5 μM. Incubations were carried out at 37°C in 25 mL beakers under an air atmosphere in a metabolic shaking incubator. Fe^{2+} was prepared in ice-cold, nitrogen-purged, doubly distilled, deionized water and kept on ice to minimize autoxidation. The histidine-Fe^{3+} was prepared as a stock solution (25 mM histidine/5 mM $FeCl_3$) in 10 mM Tris/50 mM NaCl and the pH adjusted to approximately 6.5. Above this pH, the complex began to dissociate as evidenced by Fe^{3+} precipitation. When added to the incubation mixture at pH 7.0, no precipitate was evident. Where appropriate, ascorbate was added to the incubations just prior to initiation of oxidation with Fe^{2+} (50 μM) and histidine-Fe^{3+} (250 μM histidine/50 μM Fe^{3+}). An assessment of oxidation was achieved by measurement of thiobarbituric acid reactive substances (TBARS). At the indicated times, a 1-mL aliquot of the incubation mixture was removed and added to a tube containing 2 mL of 0.67% thiobarbituric acid in 0.25 N HCl and 10% trichloroacetic acid (2:1, vol/vol) and 0.033% BHT (26). The samples were heated at 100°C for 20 min and centrifuged after cooling. The absorbance of the supernatant at A_{532} minus A_{580} to account for any turbidity was read, and TBARS were quantitated by comparison to a standard curve of malondialdehyde equivalents generated by acid catalyzed hydrolysis of 1,1,3,3-tetraethoxypropane. Each experiment was repeated at least twice with differences in TBARS formation between duplicate samples generally less than 10%.

Iron oxidation/reduction. The concentration of Fe^{2+} in the incubations was determined by removing 0.9 mL and adding to 0.1 mL of 10 mM ferrozine [3-(2-pyridyl)-5,6-*bis*(4-phenyl-sulfonic acid)-1,2,4-triazine]. The absorbance of the ferrozine/Fe^{2+} complex was read at 564 nm and compared to a standard curve prepared from known amounts of Fe^{2+}. The reduction of histidine-Fe^{3+} by ascorbate was assessed by incubating histidine-Fe^{3+} (500 μM histidine/100 μM Fe^{3+}) with 200 μM ascorbate for 0–15 min. Aliquots (0.9 mL) of the reaction mixture were taken at various times and analyzed for Fe^{2+} content.

α-Tocopherol determination. The content of α-tocopherol in liposomes was determined by high-performance liquid chromatography using fluorometric detection (5) with some minor modification (27). One-mL aliquots of liposomes containing 0.1 mol% α-tocopherol were removed at various intervals and added to 1 mL of 0.1 M sodium dodecylsulfate. δ-Tocopherol (500 pmoles) in ethanol was added as an internal standard followed by 2 mL of ethanol and vigorous mixing. The tocopherols were extracted into 2 mL of heptane and the tubes centrifuged at low speed for 5 min. The heptane layer was removed, dried under N_2, and the material reconstituted in methanol. Chromatography was performed using an LKB (Bromma, Sweden) 2150 pump, a Waters (Milford, MA) 712 wisp autoinjector and a McPherson (Acton, MA) FL-749 spectrofluorometer. The mobile phase consisted of methanol/water (98:2, vol/vol) and was run at a flow rate of 0.75 mL/min. A Shodex (Waters, Milford, MA) ODSpak C18 reverse phase column (15 cm × 4.6 mm, 5 μm) was used and fluorometric detection performed with excitation at 210 nm and

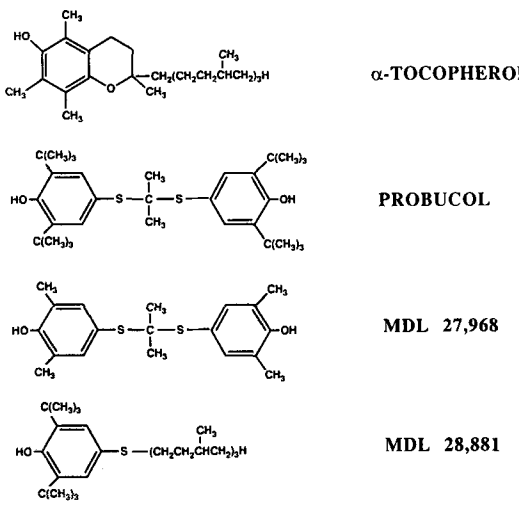

FIG. 1. Structures of α-tocopherol and other phenolic antioxidants.

emission monitored using a 270 nm cut-off filter. The retention time for δ-tocopherol was approximately 9 min and 10.5 min for α-tocopherol with a detection limit of approximately 50 pmol. Quantitation of α-tocopherol was by comparison to the peak area of δ-tocopherol. All extractions were done on ice and in capped tubes to minimize oxidation of the tocopherols.

Differential scanning calorimetry (DSC). Mixtures of DPPC and various mole fractions of antioxidants were prepared by mixing the lipid and antioxidant in chloroform/methanol (1:1, vol/vol), drying under N_2 and vacuum, and swelling in 0.15 M NaCl, 20 mM Tris-HCl, 1 mM EDTA, 0.1% sodium azide, pH 7.4 for 1 h at ~50°C. The final concentration of DPPC was 0.5 mg/mL. DSC was performed on a Microcal MC-2 differential scanning calorimeter (Northampton, MA) at a scan rate of 60°C/h. DPPC alone was scanned at 20°C/h. The differential voltage signal from the thermopiles, the temperature of the heat sink and the time were recorded at 10 s intervals on an IBM-PC-AT computer with a PASCAL program written by MIRAC (Cincinnati, OH). The data were converted to cal/g°C after dividing by the scan rate and the weight of sample. Enthalpies were calculated by numerical integration; the phase transition temperatures (T_m) correspond to the temperatures at which the heat capacities reach maximum values during the transitions.

RESULTS

Incubation of soybean phosphatidylcholine liposomes with Fe^{2+}/histidine-Fe^{3+} resulted in immediate oxidation as has been reported for other Fe^{2+}/Fe^{3+} mixtures (Fig. 2) (28). Following the initial 2 min time period, TBARS formation increased relatively slowly. Histidine-Fe^{3+} was utilized as ascorbate can influence the Fe^{2+}/Fe^{3+} redox balance and thereby inhibit lipid peroxidation independent of a recycling α-tocopherol. Ascorbate is apparently incapable of reducing histidine-Fe^{3+} (29) and, in agreement, we observed no ascorbate oxidation with histidine-Fe^{3+} and no subsequent appearance of Fe^{2+} (data not shown).

The incorporation of increasing amounts of α-tocopherol in the liposomes led to a successive delay in the onset of oxidation which eventually proceeded at a rate similar to that observed in the first two minutes of incubation in the absence of α-tocopherol (Fig. 2A). The addition of ascorbate (50–200 μM) resulted in a slight inhibition of oxidation at 2 min, yet the rate of oxidation remained relatively constant leading to an overall increase in TBARS formation relative to that observed in the absence of ascorbate (Fig. 2B). This is noteworthy as the potential exists for ascorbate to interact with the initiating species or, at high concentrations, to directly terminate peroxidation which could lead to the erroneous conclusion that ascorbate was recycling α-tocopherol. The stimulation by ascorbate in this model system is likely explained by the data shown in Figure 3. In the absence of liposomes Fe^{2+} autoxidation was minimal in our buffer system but the addition of liposomes to Fe^{2+}/histidine-Fe^{3+} led to complete oxidation of the Fe^{2+} within 2 min. Thus, no reducing equivalents remained to propagate the peroxidative process. Inclusion of ascorbate (50–200 μM) delayed depletion of a pool of Fe^{2+} for greater than 10 min which agrees with the continued rise in TBARS formation.

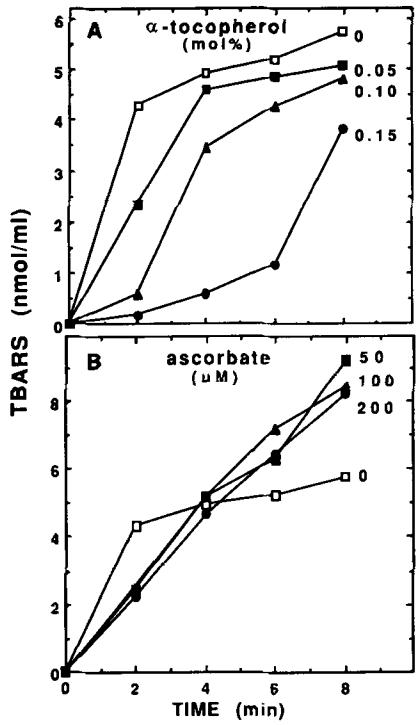

FIG. 2. Effect of varying α-tocopherol or ascorbate concentrations on liposomal peroxidation. Liposomes (0.5 mM) were oxidized with Fe^{2+}/histidine-Fe^{3+} in the presence of α-tocopherol (0–0.15 mol%; Panel A) or ascorbate (0–200 μM; Panel B). Aliquots were removed at various timepoints and analyzed for TBARS as described in detail in Materials and Methods. Data points represent the averages of 2–4 separate incubations.

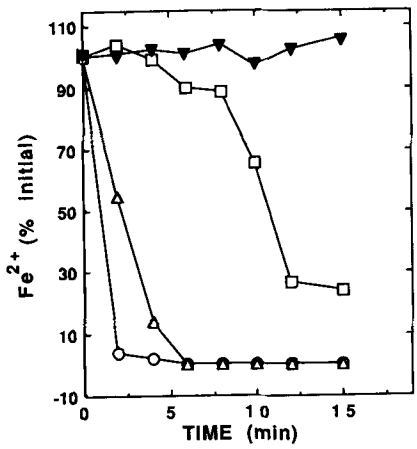

FIG. 3. Effect of ascorbate or α-tocopherol on Fe^{2+} concentrations in liposomes oxidized with Fe^{2+}/histidine-Fe^{3+}. Fe^{2+} concentrations were determined in the absence of liposomes (▼) or with liposomes and Fe^{2+}/histidine-Fe^{3+} (○) in the presence of 200 μM ascorbate (□), or 0.1 mol% α-tocopherol (△). The average initial concentration of Fe^{2+} for all incubations was 52.9 ± 2.2 μM (mean ± SE). Determinations at each timepoint were done in duplicate.

Similarly, the lag in TBARS formation induced by 0.1 mol% α-tocopherol was reflected in a slightly slower rate of Fe^{2+} oxidation. As ascorbate does not reduce histidine-Fe^{3+}, these results suggest that ascorbate can

reduce Fe^{3+} generated by Fe^{2+} oxidation. The net effect is to continue to provide a source of reducing equivalents which catalyzes peroxidative reactions.

For each of the four phenolic antioxidants, a series of concentration curves were obtained such as that shown for α-tocopherol in Figure 2A. From these curves a concentration of each antioxidant was chosen such that peroxidation was delayed only slightly. This allowed for a clearer distinction between synergistic, or merely additive effects, when interaction with ascorbate was evaluated. As observed in Figure 4, 0.4 mol% was the concentration chosen for MDL 27,968 and MDL 28,881 while probucol was 0.3 mol% and α-tocopherol was 0.1 mol%. The presence of 200 μM ascorbate led to a significant increase in TBARS in the absence of a phenolic antioxidant, but a complete suppression of oxidation in the presence of 0.1 mol% α-tocopherol (Fig. 4A). With MDL 27,968 and probucol, the presence of ascorbate led to only a slight lag period before peroxidation began which again reached a level greater than twice that observed in the absence of ascorbate (Fig. 4B and 4C). In the liposomes containing 0.4 mol% MDL 28,881, a lag period of 6 min was observed with ascorbate, at which point peroxidation increased in a linear fashion to eventually exceed that of the control incubation (Fig. 4D).

The lag period preceding the onset of oxidation is characteristic of chain terminating antioxidants and correlates with oxidation of the antioxidant (15). This finding is corroborated by the results in Figure 5A which demonstrate that, in the absence of ascorbate, a marked increase in TBARS formation correlated with the loss of α-tocopherol. When ascorbate was included in the incubation containing 0.1 mol% α-tocopherol, the levels of α-tocopherol remained relatively constant over the 15 min time period and, accordingly, no TBARS formation was observed.

The lack of interaction of antioxidants other than α-tocopherol with ascorbate may be due to differences in interaction with and orientation in the liposomes. An evaluation of the interaction of the antioxidants with phospholipids was performed by examining their effect on the liquid-crystalline phase transition of DPPC using differential scanning calorimetry. As shown in Figure 6, probucol, α-tocopherol and MDL 27,968 broaden T_m of DPPC with α-tocopherol having the most dramatic effect on the enthalpy of the transition (Fig. 7A). Both α-tocopherol and MDL 27,968 reduced T_m approximately 4°C at a concentration of 20 mol% (Fig. 7B). In contrast, MDL 28,881 had relatively little effect on either T_m or the enthalpy of the transition.

The inability of ascorbate to provide synergistic protection with antioxidants other than α-tocopherol could also be related to physical constraints imposed by compartmentation of ascorbate in the aqueous phase and the antioxidant within the hydrophobic membrane region. Therefore, the effect of a lipophilic ascorbate analogue, ascorbyl-6-palmitate, was tested in the liposomal system. As demonstrated in Figure 8, ascorbyl-6-palmitate itself provides good protection against iron-induced oxidation which limited the concentration which could be tested in synergy experiments to 0.25 or 0.5 mol%. With all four phenolic antioxidants, the addition of ascorbyl-6-palmitate resulted in the induction of only a slight lag period (Fig. 9).

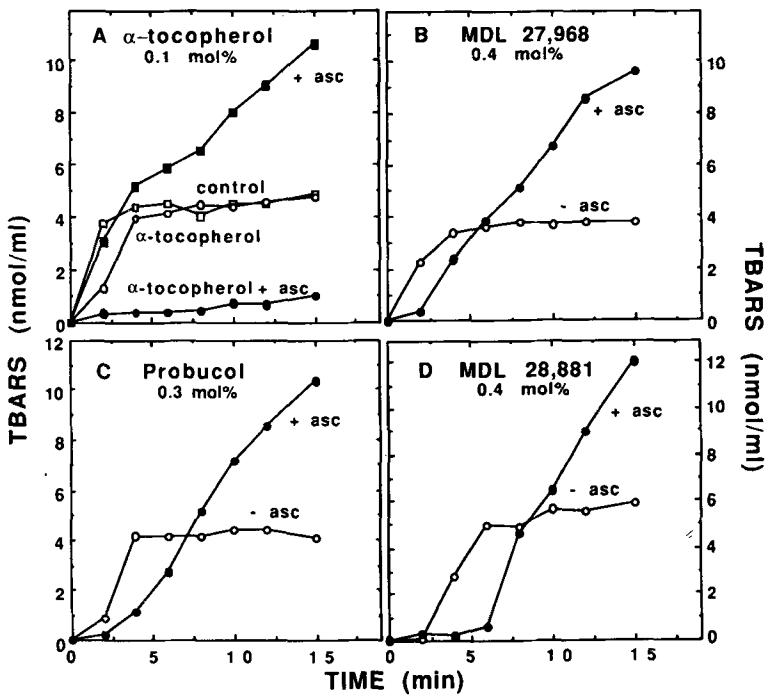

FIG. 4. Effect of ascorbate on peroxidation of phenolic antioxidant-containing liposomes. Liposomes containing the phenolic antioxidants were oxidized with Fe^{2+}/histidine-Fe^{3+} in the absence (open symbols) or presence (closed symbols) of 200 μM ascorbate. Incubations were sampled at various timepoints for TBARS as detailed in Materials and Methods. Values are the average of two incubations. In Panel A, control incubations without α-tocopherol are included (open squares) and with ascorbate (closed squares).

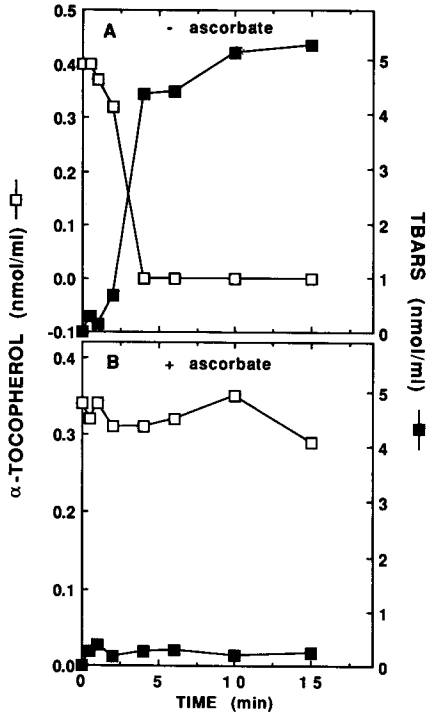

FIG. 5. α-Tocopherol and TBARS concentrations in liposomes undergoing peroxidation in the presence or absence of ascorbate. Liposomes contained 0.1 mol% α-tocopherol and, either no (panel A) or 200 μM (panel B) ascorbate. At the indicated time, the reaction mixtures were sampled for the determination of α-tocopherol (□) and TBARS (■) as outlined in Materials and Methods. Each data point represents the average of two separate incubations for both α-tocopherol and TBARS with values varying less than 10%.

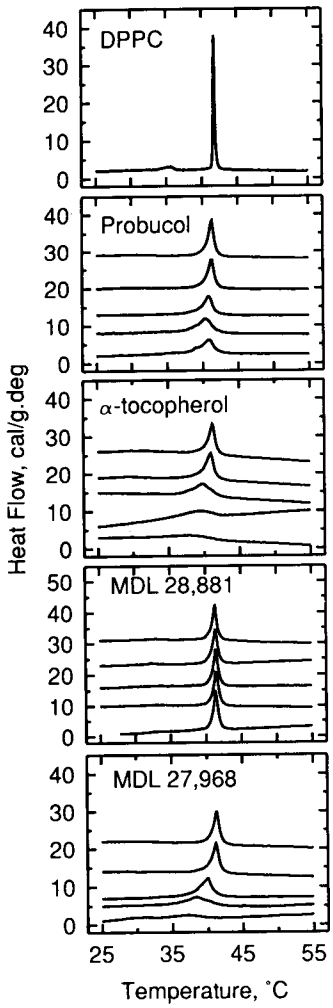

FIG. 6. DSC of mixtures of antioxidants with DPPC. Antioxidants were mixed with DPPC and prepared as liposomes at mol fractions of 1, 2, 5, 10 and 20 mol%. The scans are in order from top to bottom with increasing concentrations of antioxidants. Two separate DPPC/antioxidant mixtures were prepared and scanned for each concentration.

DISCUSSION

The present study confirms the extremely effective interaction between ascorbate and α-tocopherol in prevention of lipid oxidation (15,30). In the presence of very low amounts of α-tocopherol, ascorbate totally prevented oxidation while in the absence of α-tocopherol it greatly potentiated overall TBARS production. This is a dramatic illustration of the potent antioxidant capacity of these agents acting in concert to not only inhibit oxidation induced by Fe^{2+}/histidine-Fe^{3+}, but to completely counteract the significant enhancement of peroxidation induced by the ability of ascorbate to maintain Fe^{2+} levels. In the absence of ascorbate, Fe^{2+}/histidine-Fe^{3+} treatment led to a complete loss of α-tocopherol within the first few min which was accompanied by TBARS formation (Fig. 5). In the presence of ascorbate, α-tocopherol levels remained relatively constant throughout the 15 min of incubation and no significant oxidation of the liposomes was noted. Importantly, the use of Fe^{2+}/histidine-Fe^{3+} as an initiating system minimizes the potential for ascorbate, at the concentrations used herein, to exert antioxidant effects independent of recycling of α-tocopherol.

In contrast to α-tocopherol, the other three phenolic antioxidants did not interact synergistically with ascorbate. Both probucol and MDL 28,881 have *tert*-butyl substituents in the *ortho* positions which may present steric hindrance to the ascorbate (19). MDL 27,968 is similar to probucol except that methyl, rather than *tert*-butyl groups, are the *ortho* substituents yet there was still no apparent interaction. There are several possible explanations for this finding. One is that MDL 27,968 is situated in the membrane such that a phenoxyl radical is not oriented to the aqueous side. This may result from the lack of a phytyl tail which has been suggested to align α-tocopherol parallel with fatty acyl chains of the bilayer, thus orienting the chromanol ring toward the outer regions (reviewed in ref. 31). The similarity in the effects of α-tocopherol and MDL 27,968 on the T_m of DPPC suggests that MDL 27,968 also orients itself in the membrane but its lack of a hydrocarbon chain may cause it to be buried within the membrane, thus limiting access to ascorbate. Such differences may be indicated by the difference in the enthalpy of transition for α-tocopherol relative to MDL 27,968. Precedence for such an effect was provided by Takahashi *et al.* (32) who demonstrated that the rate of interaction between ascorbate and spin probes decreased as the nitroxide radical was increasingly buried in the bilayer.

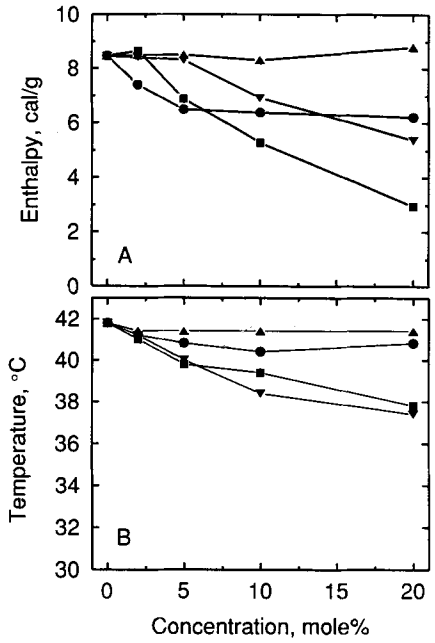

FIG. 7. Enthalpies and temperatures of the liquid-crystalline phase transition of DPPC liposomes doped with antioxidants. Enthalpies (A) and temperatures (B) were calculated for liposomes comprised of DPPC and the various antioxidants. (●) Probucol, (■) α-tocopherol, (▲) MDL 28,881 and (▼) MDL 27,968.

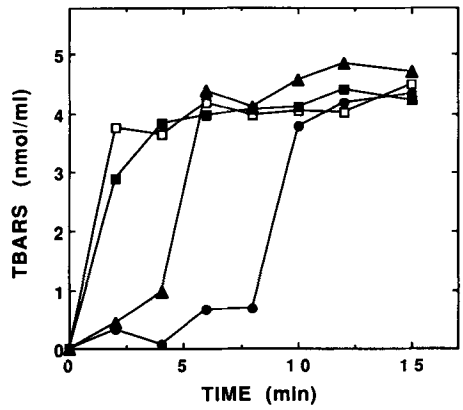

FIG. 8. Influence of ascorbyl-6-palmitate on TBARS formation. Liposomes containing various concentrations of ascorbyl-6-palmitate were treated with Fe^{2+}/histidine-Fe^{3+} and sampled at various times for TBARS. The concentrations (mol%) of ascorbyl-6-palmitate were (□) 0, (■) 0.25, (▲) 0.5 and (●) 0.75. Values represent the average of 2-3 determinations.

MDL 28,881 contains a phytyl tail as does α-tocopherol but does not interact well with phospholipids. One interpretation of the data is that the bulkiness of the *tert*-butyl groups causes the ring portion of MDL 28,881 to reside outside the membrane and thus have less of an effect on

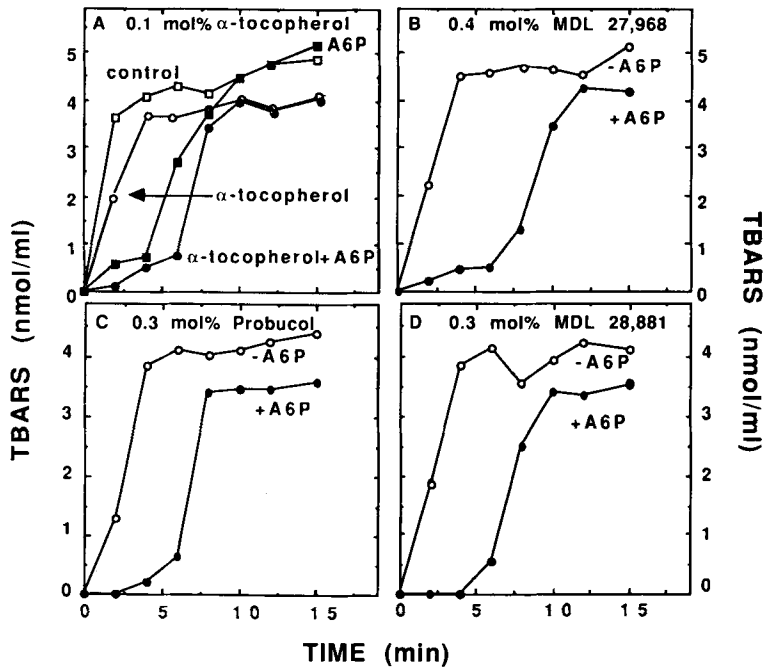

FIG. 9. Effect of ascorbyl-6-palmitate on peroxidation of phenolic antioxidant-containing liposomes. Phenolic-antioxidant containing liposomes were oxidized with Fe^{2+}/histidine-Fe^{3+} in the absence (open symbols) or presence (closed symbols) of 0.25 mol% ascorbyl-6-palmitate. Aliquots were taken at the indicated times for analysis of TBARS as described in Materials and Methods. Data points represent the mean of at least two incubations. In Panel A, control incubations without α-tocopherol are included (open squares) and with ascorbate (closed squares).

the DPPC. We have observed similar DSC scans with MDL 73,335, a tocopherol analogue in which the acyl chain has been replaced with an ethyl amino group (33) which considerably decreases its interaction with DPPC (Thomas, C.E., McLean, L.R., Parker, R.A., and Ohlweiler, D.F., unpublished observations). This would render the phenoxyl radical of MDL 28,881 accessible to ascorbate, and there did appear to be a slight, greater than additive effect when the antioxidants were combined (Fig. 4D).

Another explanation is suggested by the studies of Burton and co-workers (17) which demonstrated that positioning of the pair of pi electrons of the oxy substituent *para* to the hydroxyl group in an orientation perpendicular to the plane of the ring imparts stability to the phenoxyl radical. Such structural stability is lacking in MDL 27,968 and, additionally, it does not have the *ortho-tert*-butyl substituents which greatly stabilize the phenoxyl radicals of probucol and MDL 28,881. The corresponding decrease in the half-life of the phenoxyl radical of MDL 27,968 would lessen the likelihood of its reduction by ascorbate.

The possibility that the phenolic antioxidants other than α-tocopherol may orient in the membrane in a manner which precludes access to ascorbate led us to evaluate a lipophilic derivative of ascorbate, ascorbyl-6-palmitate, for possible interaction with these antioxidants. We observed that ascorbyl-6-palmitate itself was a relatively potent antioxidant (Fig. 8), in agreement with Pryor *et al.* (34) who studied its effect on O_2 uptake in micelles. However, when added to phenolic antioxidant-containing liposomes, no dramatic, synergistic interactions were observed (Fig. 9). The lack of synergy with α-tocopherol can be rationalized by the orientation of its phenoxyl radical toward the aqueous environment. The absence of synergy with probucol and MDL 28,881 may again indicate that bulky groups as *ortho* substituents prevent reduction of the phenoxyl radical as reported for 6-*O*-steroyl-ascorbate (19). On the other hand, Kagan *et al.* (35) recently reported that ascorbyl palmitate could reduce the phenoxyl radical of BHT and related analogues as determined by electron spin resonance spectroscopy. Clearly, physical accessibility of the reductant to the phenoxyl radical is a critical determinant of synergistic antioxidant activity in a membrane system.

It must also be considered that the lack of synergy could be due to an insufficient amount of ascorbyl-6-palmitate. However, several lines of evidence argue against this. First, the concentration of ascorbate required to totally prevent oxidation in the presence of α-tocopherol was much lower than the 50–200 μM used in these studies. The actual ascorbate concentrations required could not be determined as they were below the limit of detection of our assay which was approximately 14 μM. Secondly, in the absence of ascorbate, 0.2–0.3 mol% of α-tocopherol provided complete protection against oxidation. With 0.25 or 0.5 mol% ascorbyl-6-palmitate (1.25 or 2.5 μM), and with 0.1 mol% α-tocopherol, we observed no synergistic interaction. Thus, if even only 20–40% of the added ascorbyl-6-palmitate reacted with the α-tocopherol, this should have provided the same results as 0.2–0.3 mol% α-tocopherol and totally prevented oxidation. Together these findings suggest that in liposomal membranes interaction between ascorbyl-6-palmitate and α-tocopherol is restricted, probably due to physical inaccessibility.

It is clear from these studies that ascorbate and α-tocopherol interact synergistically to prevent iron-induced liposomal oxidation. Importantly, oxidation of liposomes with Fe^{2+}/histidine-Fe^{3+} minimizes the possibility that ascorbate is directly interacting with other radicals to spare the α-tocopherol as ascorbate actually stimulates peroxidation by reducing the Fe^{3+} generated during peroxidation. It cannot be determined, however, whether ascorbate recycles α-tocopherol from the tocopheroxyl radical or from 8a-(alkyldioxy)-tocopherones which constitute approximately half of the α-tocopherol oxidized by peroxyl radicals in liposomes (4). Nonetheless, this system may provide a facile means by which to evaluate synthetic antioxidants for synergistic interaction with ascorbate in a model which resembles biological membranes and may have more relevance than studies conducted in solution (19,36). However, evaluation of ascorbate reduction of phenoxyl radicals as studied by electron spin resonance spectroscopy would provide some useful information regarding the effect of *ortho*-substitution and complement the peroxidation studies described herein. The three synthetic antioxidants tested to date did not interact synergistically with ascorbate or ascorbyl-6-palmitate, a phenomenon which appears attributable to their structural and physical characteristics. Further experimentation will be required to determine the criteria which allow recycling of phenolic antioxidants by ascorbate and/or analogues thereof.

ACKNOWLEDGMENT

We thank Debbra Wagner for typing the manuscript.

^{31}P NMR of Tissue Phospholipids: Competition for Mg^{2+}, Ca^{2+}, Na^+ and K^+ Cations

Thomas E. Merchant[a] and **Thomas Glonek**[b,*]

[a]Department of Radiation Oncology, Memorial Sloan-Kettering Cancer Center, New York, New York 10021 and [b]Magnetic Resonance Laboratory, Chicago College of Osteopathic Medicine, Chicago, Illinois 60615

Phosphatidylcholine (PC), phosphatidylethanolamine (PE), ethanolamine plasmalogen (EPLAS), sphingomyelin (SPH), phosphatidylinositol (PI), phosphatidylserine (PS), cardiolipin (CL), phosphatidylglycerol (PG) and phosphatidic acid (PA) were dispersed together in Cs(ethylenedinitrilo)tetraacetic acid-scrubbed chloroform/methanol solution, and high resolution ^{31}P nuclear magnetic resonance spectra were recorded. In separate titration experiments, Mg^{2+} and Ca^{2+} were added to the dispersed phospholipid mixture to determine the relative interaction potentials of each of the phospholipids for each of the added cations. The association of cations with individual phospholipids was indicated by ^{31}P chemical-shift changes, signal broadening, signal quenching or a combination of these. The titrations revealed that CL had the highest, and PA the next highest, interaction potential for Mg^{2+} cations. In contrast, PS and PA had the highest, and CL the next highest, interaction potential for Ca^{2+}. Considering only interactions with Ca^{2+} ions, the phospholipids can be divided into three distinct groups: PS and PA (high interaction potential); CL, PI and PG (intermediate interaction potential); and EPLAS, PE, SPH and PC (essentially no interaction potential). The two phospholipids with the least interaction potential for either of the alkaline-earth cations were PC and SPH. Na^+ and K^+ ion interactions with PA, CL, PI and PG were unique and resulted in positive chemical-shift changes relative to the chemical shifts in the presence of Cs^+ ions. Relative to both Cs^+ and K^+ ions, chemical shifts in the presence of Na^+ ions were deshielded $\delta >$ 0.1 ppm in the order PA > CL > PI > PG.

Lipids 27, 551-559 (1992).

Investigations have attempted to gauge the nature of interactions between membrane phospholipids and inorganic cations, and particularly Ca^{2+} (1-10). From these studies differing conclusions have been derived, as data interpretation is complicated because of the complexity of the lamellar, vesicular or micellar structures that phospholipids produce in aqueous media (6). Moreover, the procedures that have been employed to probe the interactions of phospholipids with cations either in aqueous media or organic solvents, have limited such analyses to the examination of one or two phospholipids at a time.

Observation of phospholipids by ^{31}P nuclear magnetic resonance (NMR) spectroscopy in a hydrated chloroform/methanol medium circumvents many of these analytical limitations (9,11). Using this approach, more than 15 different phospholipid functional groups have been monitored simultaneously, thus permitting competitive binding to be monitored between phospholipid polar head groups and inorganic cations (9).

^{31}P NMR recognizes interactions of phospholipids with cations depending on the type of complex formed, on the nuclear properties of the cation and on the chemical equilibria that exist. The signal from a phosphate interacting with a cation will undergo a chemical-shift change that may be either positive or negative (9,12,13). The signal may typically broaden due to shorter ^{31}P NMR relaxation times (9,14-16). The signal may be quenched, that is, extensively broadened; such broadened ^{31}P NMR signals can be detected by wide-line spectroscopic methods (6).

In the present study, mixtures of approximately equivalent amounts of phospholipids in solution were allowed to interact with a fractional equivalent of a single inorganic cation and were monitored by ^{31}P NMR. The hypothesis was that the cation will interact with the phospholipid polar head group with which it has the highest interaction potential. Should two or more polar head groups exhibit nearly equivalent interaction potentials for a given cation, the cation will be partitioned between these groups, with the remaining phospholipids being essentially non-interactive, *i.e.*, unaffected chemically and spectroscopically.

Phosphatidylcholine (PC), choline plasmalogen (CPLAS), phosphatidylethanolamine (PE), ethanolamine plasmalogen (EPLAS), phosphatidylserine (PS), phosphatidylinositol (PI), phosphatidylglycerol (PG), cardiolipin (CL), sphingomyelin (SPH), phosphatidic acid (PA) and an unidentified phospholipid isolated from human lens (U) (17), were selected for this interaction study. Mg^{2+}, Ca^{2+}, Na^+, K^+ and Cs^+ were the cations selected. Similar studies involving interactions with Al^{3+} have already been carried out (18).

METHODS

Phospholipid preparations of high purity were obtained from Sigma Chemical Co. (St. Louis, MO), P-L Biochemicals, Inc. (Milwaukee, WI) and Life-Science Resources (Milwaukee, WI).

Phospholipid-alkaline-earth-ion titrations. From stock solutions of specific phospholipids in chloroform, approximately 4 μmole each of PC, PE, EPLAS, PS, SPH, PI, CL, PG and PA were combined in a total volume of 3 mL of chloroform containing 20% benzene-d_6 (Reagent A). To this solution, 1 mL of methanol containing 20% aqueous 0.2 M Cs(ethylenedinitrilo)tetraacetic acid (EDTA), pH 6, was added (Reagent B). The mixture was stirred, transferred to a 10-mm NMR tube, and allowed to separate into

Abbreviations: CL, cardiolipin; CPLAS, choline plasmalogen; EDTA, (ethylenedinitrilo)tetraacetic acid; EPLAS, ethanolamine plasmalogen; ^{31}P NMR, phosphorus-31 nuclear magnetic resonance; PC, phosphatidylcholine; PA, phosphatidic acid; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; SPH, sphingomyelin; U, unidentified phospholipid.

two phases, an organic phase and an upper aqueous phase (9). A Teflon™ NMR vortex plug was inserted into the NMR tube so that the aqueous phase was slowly extruded through the breather port of the vortex plug and could be aspirated from the tube. The aqueous phase (containing EDTA) was removed as completely as possible, to minimize residual EDTA contamination of the sample. Prior to adding metal ions, a ^{31}P NMR spectrum was recorded to measure the relative proportions of the phospholipids present (Fig. 1). The cations were introduced into the sample after withdrawing the vortex plug by injecting 1–10 μmoles of 1M aqueous cation solution into the chloroform phase by microliter syringe. The vortex plug was then partially re-inserted into the tube, and the sample was mixed by tipping the tube several times. Subsequently, the vortex plug was repositioned for NMR analysis. During the titrations, a minimal aqueous phase was generated by the addition of the aqueous alkaline-earth chloride solutions which accumulated above the chloroform layer; this aqueous phase was allowed to remain in contact with the chloroform phase throughout the titration, so that equilibria were maintained. However, only the organic phase was visible to the receiver coil.

A series of ion concentrations was measured so that each phospholipid resonance could be followed throughout its course. When signal congestion occurred, computerized deconvolution and integration routines were used to aid in signal analysis (17).

The stability of pH and the stability with time of the measured NMR parameters, including chemical shifts, signal widths and integrated signal areas, were taken as evidence that chemical equilibration had been achieved (19). Upon incremental cation addition, the samples were mixed thoroughly for several minutes to allow for a fine dispersion of the aqueous phase in the organic phase. Final NMR data were recorded, usually within 1 min, when no further changes with time were detectable. The time interval between sample mixing and NMR measurements, however, was nominally greater than 10 min.

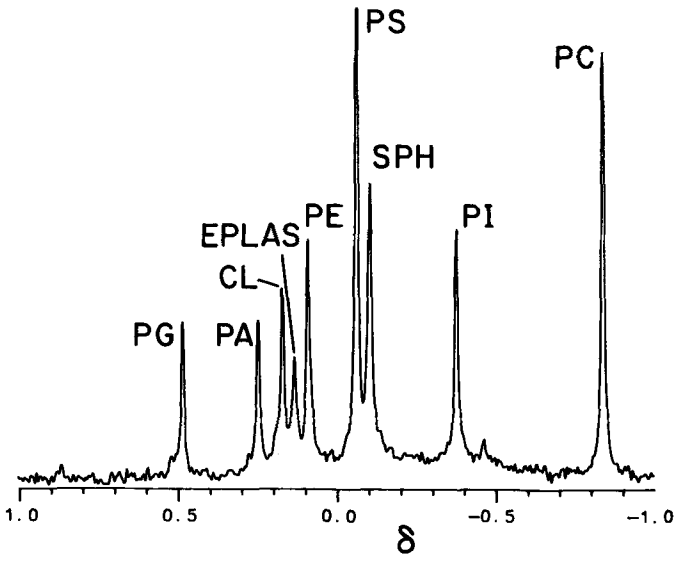

FIG. 1. ^{31}P NMR spectrum of a total rat heart lipid extract in which the endogenous signals of PG and PA have been enhanced by the addition of the pure phospholipids: PG, phosphatidylglycerol; PA, phosphatidic acid; CL, cardiolipin; EPLAS, ethanolamine plasmalogen; PE, phosphatidylethanolamine; PS, phosphatidylserine; SPH, sphingomyelin; PI, phosphatidylinositol; and PC, phosphatidylcholine.

The benzene-d_6 in the chloroform phase provided the internal NMR reference for field-frequency stabilization (9). The initial phospholipid profile was adjusted so that each component phospholipid resonance exhibited a small, but measurable, difference in amplitude. This was done to enhance signal visibility so that signals could be followed as they crossed over one another during titrations. The differences in the concentrations of the phospholipids were less than 10%.

The selectivity of some phospholipids, particularly CL, PA and PS, for alkaline earth cations was high enough that only one phospholipid at a time showed a change in chemical shift in the course of a titration. For example, all PA was noted to bind the ions before the tritration of other phospholipids began; thus, small concentration differences between the phospholipids were irrelevant.

Precipitates did not form until samples were very heavily loaded with alkaline earth cations. Titrations were not carried out beyond the point where precipitation began. Other titrations were carried out using samples containing two, three or four phospholipids in equal molar ratios to verify various observaqtions made on the rather complex nine-component phospholipid system. The simpler systems gave results that were qualitatively identical to those observed on the nine-component phospholipid system. However, quantitative differences were observed, particularly between those phospholipids interacting strongly with Mg^{2+} and Ca^{2+} ions.

Alkali ion phospholipid preparations. The chloroform/methanol/aqueous-Cs-EDTA phospholipid mixture used in this study was formulated for the analysis of phospholipids by ^{31}P NMR spectroscopy (9,11). When formulated using the Cs salt of EDTA at pH 6, the second part of the two-part reagent (referred to as Reagent B), consisting of methanol/aqueous 0.2 M Cs-EDTA, is stable at room temperature indefinitely. When formulated using the K salt, the solution is reasonably stable for about 1 h before the K-EDTA salts begin to crystallize from the solution. The corresponding Na-EDTA preparation is unstable, crystallization of Na-EDTA salts proceeds rapidly after mixing the methanol and aqueous salt solutions to generate the methanolic-EDTA scrubbing reagent. Nevertheless, a short period of time (less than 1 min) exists when the Na reagent can be used for quantitative measurements.

Upon mixing Reagent B with Reagent A, the reaction mixture separates into two phases, a major chloroform phase and a minor aqueous phase containing some methanol. The Na salts of EDTA remain soluble in this aqueous phase for at least 10 min before crystallizing from the solution. This permits the sample to be scrubbed thoroughly.

Common stock solutions of pure phospholipids and mixtures of phospholipids in chloroform were used to provide the samples for the alkali metal ion chemical-shift analysis. Prior to preparation of the NMR samples using the NMR scrubbing reagent described above, the samples in chloroform/methanol (2:1, vol/vol) were pre-washed with 0.06 M EDTA solution having the appropriate alkali metal cation at pH 6 and allowed to separate into two liquid phases overnight (9). The chloroform phase was then withdrawn from the separatory funnel, evaporated to dryness

by rotary evaporation at 40°C, and dissolved in the chloroform Reagent A prior to mixing with Reagent B for ^{31}P NMR analysis.

^{31}P NMR spectroscopy. The NMR spectrometer used in this investigation was a multinuclear GE 500 NMB system operating at 202.4 MHz for ^{31}P. Analytical samples were placed in standard, 10-mm (spinning) NMR sample tubes and analyzed using procedures previously published (9). Chemical shifts (δ) are reported in ppm relative to 85% orthophosphoric acid (20,21); however, the primary internal standard was benzene-d_6 used for field-frequency locking purposes. At the beginning of each tritration, the chemical-shift offset value was set to position the PC resonance at −0.84 ppm (9).

RESULTS

A representative ^{31}P NMR spectrum of the nine phospholipid classes examined in this study is shown in Figure 1. The sample is a complex rat heart total lipid extract to which additional PG and PA were added. The principal resonance signals examined in this study are identified (9).

Calcium titrations. Because the interaction of Ca^{2+} ions with phospholipids does not result in noticeable broadening of phospholipid resonance signals, Ca^{2+} ion interactions will be described first. Information derived from spectra in which signals are not completely broadened out permits straight-forward interpretations (12,13, 15,22). Chemical-shift changes to the first titration end point are large with Ca^{2+} relative to the precision of the NMR chemical-shift measurements (202.4 MHz) which gives a high degree of certainty to extrapolations of the linear segments of the resultant chemical-shift titration plots. A typical chemical-shift excursion to the first end point is *ca.* 1 ppm; the precision of the NMR chemical-shift measurement is ±0.001 ppm. The phospholipid solutions also can accept relatively high Ca^{2+} ion levels before precipitation occurs. This allows the titrations to be carried to sufficiently high Ca^{2+} concentrations to firmly establish titration end points.

Titration of phospholipid preparations with aqueous $CaCl_2$ causes the phospholipid signals to be shifted upfield to lower δ values, *i.e.,* in the direction of increased shielding. In this regard, these titrations are similar to pH titrations on phosphates, where the δ value of resonance groups accepting the proton shifts upfield with lower pH levels (16,20,22,23). Phospholipid ^{31}P NMR signals are not quenched by Ca^{2+} ions. Further, noticeable signal broadening does not occur until just prior to precipitate formation. For each phospholipid, a data set for δ as a function of added Ca^{2+} ion can be obtained.

To quantitatively relate the relative chemical-shift change of one phospholipid to that of another, two types of normalization procedures and one correction are required to adjust the data sets. i) Each phospholipid shows a characteristic resonance on the δ scale dependent on the functional group. ii) The magnitude of the upfield shift excursion of each resonance upon Ca^{2+} addition depends on the phospholipid, *i.e.,* the maximum excursion of the chemical-shift per transition is a function of the structure of the complex formed (24-26). Generally, the shift transition to the first end-point is about −1.5 ppm, but may vary among phospholipids over a range of −1.5 ± 0.5 ppm. iii) Initially, the reaction solvent is biphasic. The liquid phases must be allowed to separate to allow removal of the minor aqueous phase before a titration can begin. Otherwise, the residual EDTA present in the aqueous phase will take up the initial Ca^{2+} ions, which would result in a shift of the titration curves towards higher Ca^{2+} levels.

The application of correction and normalization procedures is illustrated in Figure 2. The example is for a pure preparation of PS in the NMR phospholipid reagent (4 μmoles in 3.0 mL). The first step is to normalize the chemical-shift data set so that the curve passes through zero change in the chemical shift ($\Delta\delta$) at the 0 point in the Ca^{2+} ion titration. The intrinsic chemical shift of pure PS in the NMR solvent is −0.050 ppm relative to 85% phosphoric acid (9). To normalize the PS data set, 0.050 ppm is therefore added to each value in the original data set. This normalization is carried out for each phospholipid data set. For PA and CL, which exhibit fundamental δ values of 0.317 and 0.193 ppm, respectively, values of −0.317 and −0.193 are added. This procedure results in a curve similar to the top curve in Figure 2. Such a curve passes through zero on the ordinate, which corresponds to the change in chemical shift, $\Delta\delta$, with no Ca^{2+} ions added. Metal-ion titration curves exhibit two or more linear segments with corresponding transition zones, which are typical of phosphate ^{31}P NMR spectroscopic titrations (12-14,22,27,28).

The residual EDTA in the sample chelates the alkaline earth cations that were added initially (29). Extrapolation of the first linear segment of the top curve to the ordinate gives the amount of curve displacement resulting from

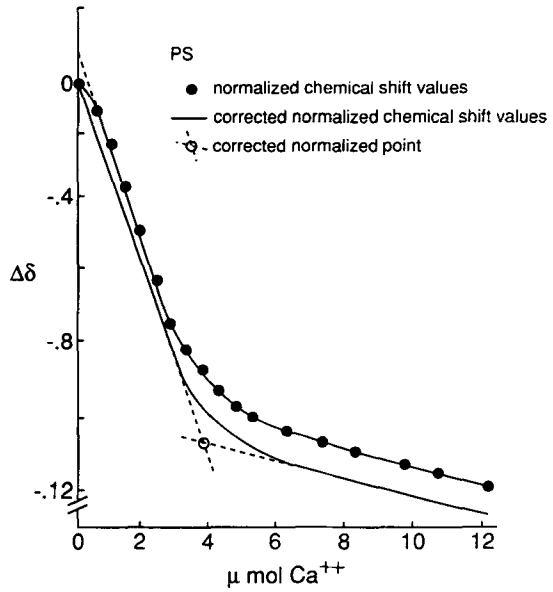

FIG. 2. The ^{31}P NMR chemical shift of PS (4 μmoles/3 mL) as a function of added aqueous $CaCl_2$ (1 M, pH 7.2). The top curve shows the measured chemical-shift difference from the 0-point chemical-shift value (δ 0.193 ppm) of PS. The bottom curve was derived from the top curve after correcting for the error (0.084 ppm) introduced by residual EDTA in the sample. The intersecting extrapolated lines indicate the chemical-shift-difference value and the Ca^{2+} ion concentration corresponding to the first detectable end-point in the titration. Precipitation occurs at Ca^{2+} levels in excess of 25 μmoles.

the residual EDTA in the sample, *e.g.*, 0.084 ppm for PS. The intrinsic-shift-normalized data set is then corrected for this displacement by subtracting 0.084 ppm from each titration-point value. These data correspond to the lower curve in the Figure, which represents the chemical-shift effect of titrating a pure, uncontaminated sample of PS by the indicated quantities of Ca^{2+} ions.

Extrapolation of the linear segments of this corrected curve through the transition zone yields a point corresponding to a hypothetical one-to-one complex of Ca^{2+} and phospholipid (12,13,28). Most important, the total chemical-shift displacement corresponding to formation of this complex (−1.106 ppm in this instance for PS) also is obtained.

Perfect agreement with theory would have the intersection in Figure 2 occur at 4 μmoles added Ca^{2+} ions. Further, at higher than 4 μmole Ca^{2+}, the curve would be horizontal if no further interactions of the phospholipid with Ca^{2+} ions were to take place. The negative slope of the second line segment indicates the presence of additional Ca^{2+}-ion-phospholipid interactions.

The corresponding first-transition chemical-shift displacements for CL and PA are −1.690 and −1.590 ppm, respectively. These are considerably larger values than the −1.106 ppm displacement exhibited by PS (9). To compare the relative interaction potential of these three phospholipids for Ca^{2+} ions, the curves need to be normalized a second time for the displacement corresponding to the initial Ca^{2+}-phospholipid interaction. This is done by dividing each $\Delta\delta$ value of a normalized-corrected data set by the total chemical-shift excursion derived from the extrapolated line segments obtained above. Multiplying these fractional values by 100 yields a scale in percent of total chemical-shift change, as illustrated in Figure 3. For PS, CL and PA these devisors are $\Delta\delta$ −1.106, −1.690 and −1.590 ppm, respectively.

Figure 3 shows the relative effect on chemical shift of titrating a sample containing 3 μmole each of PS and CL with Ca^{2+} ions with the data being displayed as percent of chemical-shift change. The curves have shapes similar to that of the lower curve in Figure 2. In these instances, the extrapolated line segments correspond to 100% of the first transition. The observation that the initial segment of the CL curve is shifted to lower Ca^{2+} ion concentrations relative to that of PS indicates that in this system, composed of two pure phospholipids in an organic solvent, CL has the higher interaction potential for Ca^{2+} by a factor of about 1.5 (8.0 μmoles Ca^{2+} *vs.* 5.4 μmoles Ca^{2+}).

Figure 4 presents similar data for PS, CL and PA as components of the complex phospholipid mixture consisting of total rat heart lipids that have been supplemented with PG and PA. Only the initial linear segments of the curves are given. When using the rat heart lipid mixture (which contains neutral lipids, other non-phosphorus polar lipids, as well as phospholipids), the most avid Ca^{2+} binding phospholipids are PS and PA; CL is much less effective in binding Ca^{2+} ions in the total rat heart lipid system than in the pure lipid system containing PS and CL shown in Figure 3. In this instance, PS and PA have the higher interaction potential for Ca^{2+} relative to CL by a factor of 4.7. The PS and PA plots are similar to those obtained using systems containing only pure phospholipids. Therefore, the binding of Ca^{2+} to PS and PA is only slightly affected by other lipids present.

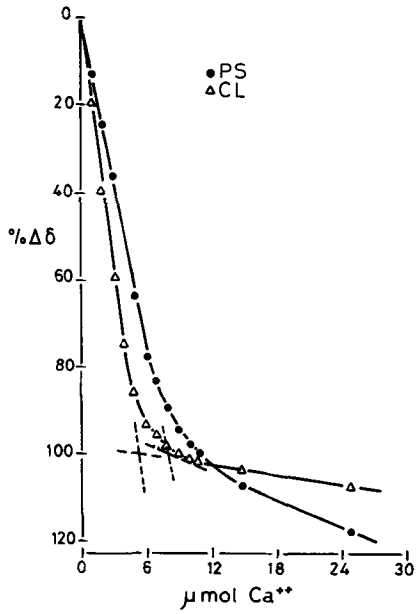

FIG. 3. Percent ^{31}P NMR chemical-shift change of a mixture of PS and CL as a function of added $CaCl_2$. Each phospholipid is 1 mmolar, total solvent volume is 3 mL. The intersecting extrapolated lines at 100% change in chemical-shift indicate the Ca^{2+} ion concentration corresponding to the first end-point in the titration of each phospholipid. In such a plot, the phospholipid with its end-point corresponding to the lowest Ca^{2+} concentration is the more avid Ca^{2+} sequestrant. Precipitation of the sample occurs at Ca^{2+} levels in excess of 25 μmoles.

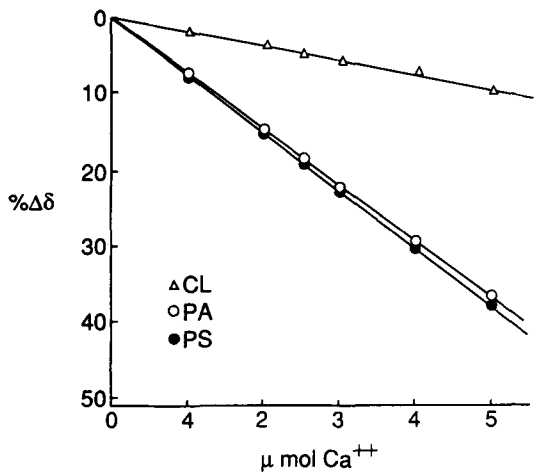

Fig. 4. Percent ^{31}P NMR chemical-shift change of PS, CL and PA, contained in a complex mixture of rat heart lipids, as a function of added $CaCl_2$. Only the initial linear segment of each curve is shown.

However, in the complex rat heart lipid mixture, some other lipid component appears to interfere with the ability of CL to bind Ca^{2+}.

For PG, PI, PE, EPLAS, SPH and PC, end points cannot be determined with reasonable accuracy. The chemical shifts of these phospholipids simply change linearly with added Ca^{2+} ion until precipitation occurs. The titration plots are illustrated, along with the initial linear segments

of the PS, PA and CL curves, in Figure 5. If it is assumed that titration with Ca^{2+} will change all of the phospholipid chemical shifts by about −1.0 ppm, which is a reasonable first approximation, then the relative slopes of the titration line segments presented in Figure 5 give an approximation of the relative interaction potentials of the indicated phospholipids for Ca^{2+} ions. For the complex rat heart lipid system, the phospholipids can be divided into three distinct groups: i) The net charge-neutral zwitterionic phospholipids, PC, SPH, EPLAS and PE, which have a low interaction potential for Ca^{2+}; ii) the anionic phospholipids, PI, PG and CL, which have an intermediate interaction potential; and iii) PS and PA, which have a high interaction potential.

Magnesium titrations. Unlike Ca^{2+}, Mg^{2+} interactions with phospholipids result in a marked broadening of the ^{31}P NMR signal, which can be of sufficient magnitude to quench the phospholipid signal. Therefore, titration curves, such as those presented in Figures 2–5 for Ca^{2+}, usually cannot be obtained for Mg^{2+} with the precision required. However, relative binding interaction potentials of phospholipids with Mg^{2+} ions can be obtained. When the Mg^{2+} ions are added to the sample, the NMR signal of the phospholipid having the highest interaction potential for Mg^{2+} will disappear from the spectral profile first, followed by the signals of other phospholipids according to their binding potential for Mg^{2+} ions until either all the phospholipid signals are quenched or precipitation occurs.

Negative (upfield) chemical-shift changes are observed in the course of Mg^{2+} ion titrations, but these are small compared to those obtained in the Ca^{2+} titrations. For example, in titrating the complex rat heart lipids to the point just prior to precipitation, the following total chemical-shift changes $\Delta\delta$ were observed for those signals that had not been quenched or excessively broadened—PG, −0.032; EPLAS, 0.000; PE, −0.002; SPH, −0.005; PS, −0.078; PI, −0.027; and PC, −0.003 ppm.

Of the nine phospholipids studied, two (CL and PA) showed signal quenching or marked signal broadening upon interaction with Mg^{2+}. The first interaction with Mg^{2+}, which was stoichiometric, became apparent as total quenching of the CL resonance. Subsequently, progressive broadening of the PA signal was observed until precipitation occurred. The remaining phospholipids were essentially unaffected by added Mg^{2+} throughout the observable titration range.

The quenching of the CL resonance by Mg^{2+} is illustrated in Figure 6. The mixture is composed of PA, CL and PS, in the relative amounts indicated by the peak heights shown in the top spectrum, which was obtained on the reagent-scrubbed preparation just prior to Mg^{2+} addition. Total phospholipid content of the sample is approximately 9 μmoles phosphorus. The bottom spectrum, obtained after addition of 3 μmoles Mg^{2+}, shows that the CL resonance has been broadened nearly to the point of extinction (quenched); the PA resonance is slightly broadened, and the PS signal is little affected by added Mg^{2+} ions. Between the two extremes, spectral changes are continuous, at 90 μmoles added $MgCl_2$, precipitation occurs.

During titration of the sample shown in Figure 6, chemical-shift changes occurred that were proportional to

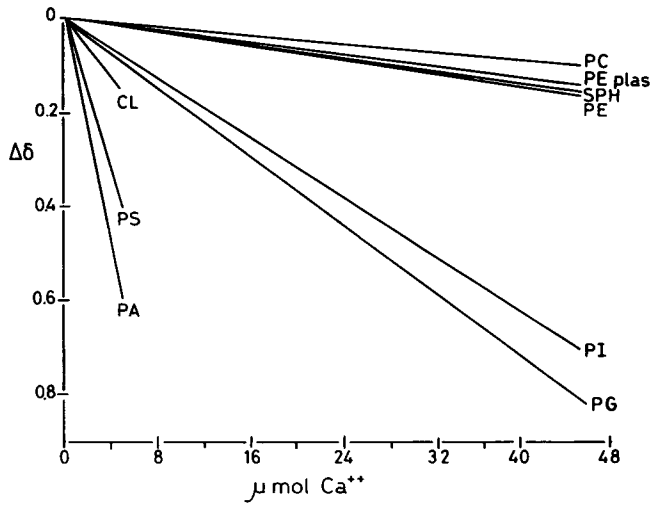

FIG. 5. ^{31}P NMR chemical-shift change of phospholipids in a complex mixture of rat heart lipids as a function of added $CaCl_2$. Only the initial linear portions of the PC, CL and PA curves are plotted. Precipitation occurs at Ca^{2+} levels in excess of 45 μmoles.

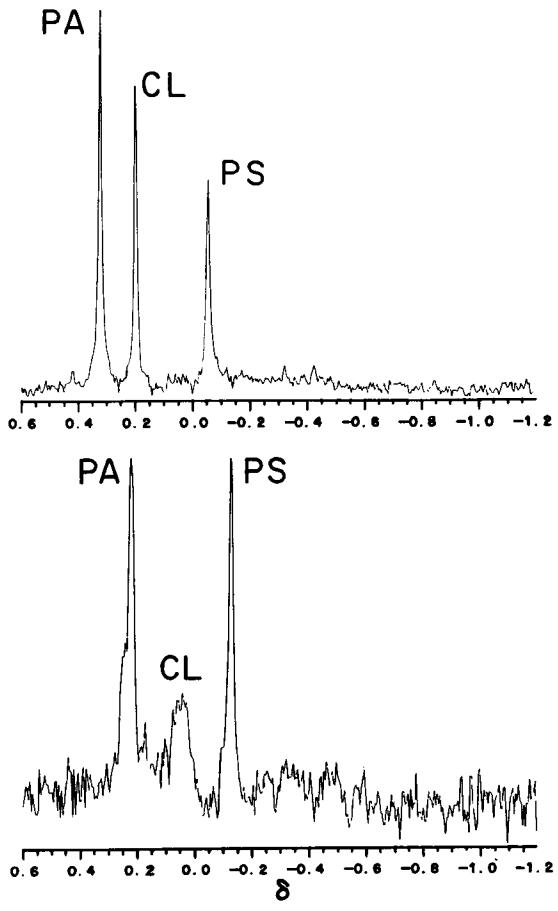

FIG. 6. ^{31}P NMR spectra of a mixture of PA, CL and PS, showing the Mg^{2+} ion quenching of the CL signal and the initial broadening of the PA signal. The top spectrum is that of the phospholipid mixture before addition of $MgCl_2$. The bottom spectrum is that of the same mixture at the point in the Mg^{2+} ion titration just prior to total Mg^{2+} quenching of the CL resonance. Associated with the signal-broadening effects of added Mg^{2+} ions are shifts of the phospholipid resonances to lower δ values.

the amount of added Mg^{2+}. The greatest chemical-shift change was exhibited by CL (−0.15 ppm), followed by PA (−0.10 ppm), followed by PS (−0.07 ppm).

Partition of Mg^{2+} and Ca^{2+} between CL and PS. The above data illustrate that CL shows a preference for Mg^{2+}, while PS shows a preference for Ca^{2+}. In a system containing both CL and PS, as well as Mg^{2+} and Ca^{2+} cations, Mg^{2+} will associate primarily with CL, while Ca^{2+} will associate primarily with PS. This is illustrated in Figure 7.

The top spectrum of Figure 7 was obtained on a sample containing CL and PS. Two well-resolved signals occur. Titration of this sample with an equimolar mixture of Mg and Ca chlorides results in a continuous conversion of the top to the bottom spectrum, with precipitation taking place just after the bottom spectrum was recorded. The CL resonance at this point became substantially broadened, which is a characteristic of Mg^{2+} binding to CL, but not of Ca^{2+} binding to CL. The PS resonance shifted upfield by −0.221 ppm. The direction of the chemical-shift change of PS is characteristic of both Mg^{2+} and Ca^{2+} interactions with PS. The magnitude of the change, however, indicates that Ca^{2+}, and not Mg^{2+}, is the interacting alkaline-earth cation. Using the quenching of the CL signal as the best index of Mg^{2+} binding and knowing the relative concentrations of the reacting components, one can calculate that approximately 90% of the added Mg^{2+} is associated with CL in this binary phospholipid system. On the other hand, it is then reasonable to assume that PS is binding 90% of the added Ca^{2+} ions.

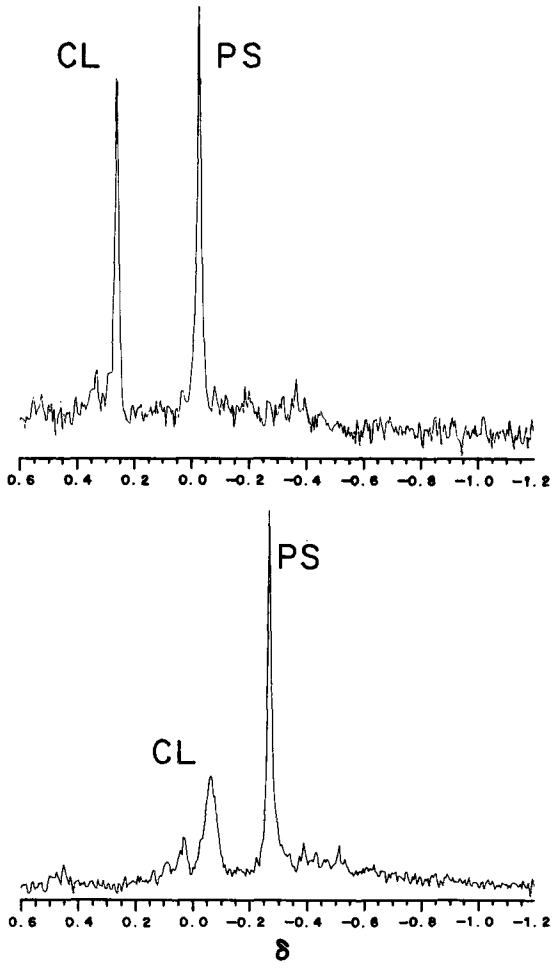

FIG. 7. ^{31}P NMR spectra of a phospholipid sample containing nearly equimolar quantities of CL and PS in the chloroform/methanol NMR reagent. The top spectrum was obtained on the phospholipids prior to the addition of alkaline-earth cations (counter cation, Cs^+). The bottom spectrum was obtained after titrating the sample with an equimolar mixture of the Mg and Ca chlorides to a point just prior to alkaline-earth precipitation of the phospholipids. The CL resonance of the bottom spectrum at δ −0.07 ppm shows the characteristic broadening that results from the interaction of CL with Mg^{2+} ions. Both signals are shifted to lower δ values as a result of the phospholipids interacting with the added alkaline-earth titrating reagent.

Parallel phospholipid interactions with Na^+, K^+ and Cs^+. As the anionic phospholipids are capable of distinguishing between group (II), alkaline-earth, and group (III) (18), cations, with CL preferring to complex with Mg^{2+} and PS preferring to complex with Ca^{2+}, the question arises whether these phospholipids could also distinguish between group (I), alkali ions, such as Na^+, K^+ and Cs^+. Such a distinction would be reminiscent of the selectivity of polyphosphates for alkali metal ions (12,28). The ^{31}P NMR chemical shifts of the anionic phospholipids depend on whether the counter cation is K^+, Cs^+ or $(Me)_4N^+$, but the neutral-zwitterionic phospholipids do not exhibit such an ion-dependence in their ^{31}P NMR chemical shifts (9). As the authors of that study (9) did not report phospholipid chemical shifts with Na^+ as the counter cation, these data have now been added in Table 1.

The data listed in Table 1 were obtained on phospholipids that had been thoroughly washed with Cs^+, K^+ or Na^+ EDTA solutions prepared from the free-acid form of EDTA and 10 M solutions of the corresponding alkali metal hydroxides. The samples also contained the appropriate alkali EDTA Reagent B solution set to pH 7.

Table 1 gives the chemical shifts of the phospholipid in the presence of the alkali metal ions indicated and the absolute differences between the respective chemical shifts. Except for PS, the most negative chemical shifts are obtained for each of the phospholipids with Cs^+ as the alkali ion. Shifts obtained for K^+ are similar to those obtained for Cs^+, with the exceptions that PI, PE, PG and PA resonate at higher chemical-shift values in the presence of K^+. The remaining phospholipids give rise to chemical-shift changes that are small or not large enough to be detected.

When comparing chemical shifts of individual phospholipids in the presence of Cs^+ and Na^+, the anionic phospholipids, PI, CL, PG and PA, yield chemical-shift changes that are greater than δ 0.100 ppm, a finding that also applies to K^+ *vs.* Na^+. PE and EPLAS show a small, positive shift change when either Cs^+ or K^+ are compared to Na^+. The greatest change in comparing Cs^+ or K^+ to Na^+ is exhibited by PA. In order of decreasing magnitude, the chemical-shift change upon switching the counter cation from Cs^+ or K^+ to Na^+ is PA > CL > PI > PG.

Interaction with Na^+ causes a considerable broadening of the PA resonance, from a nominal value of 6 Hz at half-height in the presence of Cs^+ or K^+ to a value >40 Hz in the presence of Na^+. The signal broadening effect

TABLE 1

^{31}P NMR Chemical Shifts and Chemical-Shift Differences of Phospholipids in the Presence of Cs^+, K^+ and Na^+

	^{31}P Chemical shift (pH 7)					
	Chemical shifts (δ)			Difference in δ between cations (ppm)

becomes more pronounced with sample dilution, such that at low concentrations the PA signal becomes difficult to detect.

DISCUSSION

One of the many useful features of NMR spectroscopy is that complex mixtures can be directly analyzed (19,21,30). Thus, for example, in examining the spectrum of rat heart phospholipids, all of the common phospholipids can be qualitatively and quantitatively analyzed in a single sample (Fig. 1). This advantage of NMR spectroscopy was exploited in the titration experiments presented herein, because it appeared likely that the lipids would interact (and, for example, aggregate) (9,11) in ways that would alter their chemical and physical properties. Therefore, the focus of this study was not the measurement of phospholipid-alkaline-earth interactions on single phospholipids, but the measurement of phospholipid/Ca^{2+} and phospholipid/Mg^{2+} interactions in complex lipid mixtures.

Interactions with Ca^{2+}. Phospholipids interacting with Ca^{2+}, as measured on the rat heart lipid preparations, fall into three groups (Fig. 5)—PS and PA; CL, PI and PG; and EPLAS, PE, SPH, and PC. Both PS and PA (at pH 7.2) are anionic phospholipids that possess two negative charges per headgroup or per molecule. The anionic phospholipids CL, PI and PG possess one negative charge per phosphate group. Both PI and PG also possess one negative charge per molecule, and the head groups of both are polyols. By contrast, CL carries two negative charges. CL is not a polyol, but contains one free hydroxyl group in the polar head. Of the remaining phospholipids tested, EPLAS, PE, SPH and PC possess zwitterionic polar head groups that, at physiological pH, are electrically neutral. Interactions of Ca^{2+} with this group of neutral phospholipids are minimal. Interactions of PS and PA with Ca^{2+} are the strongest and appear to be medium-independent. The intermediate group is represented by the polyols PI and PG. The phospholipid CL represents a special case because in these mixtures of lipids in organic solvents, CL behaves like a mono-anionic polyol. By itself, or with one or two other phospholipids, CL behaves like a di-anionic phospholipid (Fig. 4). The observed hermaphroditic behavior of CL in organic solvents could be relevant to its biological function.

CL can be viewed in either of two ways: i) As the diphospho, di-anionic molecule; or ii) as the mono-phospho, mono-anionic half-molecule. Viewed as the half-molecule, CL is similar to a polyol with a low interaction potential for Ca^{2+} ions. Viewed as the whole molecule, CL is a dianion with a high interaction potential for Ca^{2+} ions. The key functional group in this coordination complex appears to be the lone and unique β-hydroxyl group on the central glycerol moiety. As diagrammed by Shah and Schulman (2), this hydroxyl group may form a co-ordinate covalent bond with Ca^{2+} in the Ca^{2+}/CL complex. Formation of this bond promotes the participation of the two PO_4 groups, thereby facilitating the observed Ca^{2+}-ion-induced compression of aqueous CL monolayers (2).

Intramolecular hydrogen-bonding of this hydroxyl with one of the CL phosphate groups would have the effect of interdicting formation of the Ca^{2+}/CL complex. It is known that hydrogen bonds form readily with the PO^4 group of phosphate diesters. From crystallographic evidence (20) and molecular mechanics calculations (31), bonding can be either to the equivalent ionic oxygen pair (32) or to the ester oxygen pair; either type being formed with nearly equal probability. In the absence of spatial constraints, both types of bonding may occur in the same complex.

Insertion of a second lipid between the CL fatty acid side-chain pairs would also have the effect of interdicting formation of the Ca^{2+}/CL complex by lowering the probability of both phosphate groups being suitably oriented for Ca^{2+} complex formation. Moreover, complexation would be inhibited further if this interstitial lipid also contained a hydroxyl group available for hydrogen-bonding to the remaining phosphate group of the CL phosphate pair. An excellent candidate for such a lipid is cholesterol. High cholesterol levels of 20% by weight are required for

the expression of the enzymatic activities of the cardiac sarcolemmal Na^+-Ca^{2+} exchanger or the Na^+,K^+-ATPase reconstituted into PC/PS vesicles. The sterol requirement is highly specific for cholesterol (32). Cholesterol, therefore, may act as an inhibitor of Ca^{2+}/CL complex formation in these organic solutions by keeping the CL polar head group in an extended form, or by interacting with one of the CL phosphates through a hydrogen bond.

Interactions with Mg^{2+}. Two of the phospholipids, CL and PA, interact strongly with Mg^{2+} ions, the other phospholipids tested interact weakly or not at all. CL is by far the strongest complexing lipid, with PA not interacting with Mg^{2+} until essentially all of the CL has been Mg^{2+}-saturated. Unlike complexation with the Ca^{2+}, complexation with the Mg^{2+} does not appear to be dependent on the presence of other lipids in the medium. The Mg^{2+} ion complex, therefore, is stronger than the Ca^{2+} ion complex and should form preferentially in the presence of Ca^{2+} ions. It is known that Mg^{2+} has a strong propensity to assume a six coordination, whereas Ca^{2+} preferentially assumes a coordination greater than six. Also, water molecules attached to magnesium ions are held more rigidly than those attached to calcium ions, with Ca^{2+} more readily exchanging water for negative ligands (32).

The above hypothesis was tested in the partitioning experiment presented in Figure 7, where the ^{31}P NMR signal quenching effect of Mg^{2+} was expressed only for the CL signal. The signal of PS exposed to both Mg^{2+} and Ca^{2+} ions only exhibits the alkaline-earth ion upfield shift, but undergoes no signal broadening. The phospholipids CL and PS in combination, therefore, are capable of partitioning Ca^{2+} and Mg^{2+} ions between them in the organic solvent without the participation of other factors. In a study (18) reported on Al^{3+} as the interacting cation, the most avid Al-complexing phospholipid was found to be PA, with CL following PA, and PS following CL.

Interactions with the alkali metal ions Na^+, K^+ and Cs^+. The studies on the ability of phospholipids to discriminate between the alkaline-earth cations in organic solvent were extended (12) to include the alkali metal ions, Na^+, K^+ and Cs^+ (Table 1). The ^{31}P NMR chemical shifts of four phospholipids, PA, CL, PI and PG, responded to the presence of Na^+ ions in the solvating medium by exhibiting more positive chemical-shift values, *i.e.*, the resonance chemical-shift positions became deshielded in the presence of Na^+ relative to their positions in the presence of Cs^+ or K^+ ions. All four phospholipids are net negatively charged anions having no zwitterionic component. Three of these, PI, PG and CL, represent a family with free hydroxyl groups present in the polar head group moiety.

The phospholipid undergoing the greatest chemical-shift change upon switching from Cs^+ to either K^+ or Na^+ is PA. PA being a phosphomonoester, its chemical shift is influenced by two factors: i) Coordination of the phosphate to the cation; and ii) the pK_a of the phosphate group. Alkali metal cation coordination of the phosphate will alter the average bond angles of the phosphate, the magnitude of the average π-bond contribution of the phosphate group to the complex and the magnitude of the average σ-bond contribution, all of which contribute to the ^{31}P NMR chemical shift (24–26). Phosphomonoesters are weak acids having pK_a values in the pH range of 6–8 (23). A change in the pK_a upon coordination of an alkali metal cation (18,33) will alter the ratio of the acid and base forms of the phosphate and, thereby, the average chemical shift of the phosphate functional group. The relative contribution of factors i) and ii) to the phosphate chemical-shift change upon switching counter-cations cannot be rigorously assessed. All that can be said is that the chemical shifts change upon switching from Cs^+ to K^+ and Na^+ ions. Whether the PA phosphate exhibits a preference for one cation over another cannot be determined from the data presented in Table 1 alone.

For the phospholipids PI, PG and CL, the interpretation of shift data is more certain. Because these phospholipids are phosphodiesters, they are strong acids at physiological pH, and a shift contribution by factor ii) does not exist. Moreover, because the chemical shifts of these phosphates change little or not at all upon switching from Cs^+ to K^+ cations, in a first approximation the assumption can be made that factor i) also does not change upon switching between these cations or, at least, that there are internal compensations (unlikely) among the three components of factor i) that cause the chemical-shift values to be the same.

Upon switching from either Cs^+ or K^+ to Na^+, CL, PI and PG undergo a marked and characteristic chemical-shift change which decreases in the order CL > PI > PG. Clearly, among all the phospholipids tested, these three interact with the Na^+ ion in a distinctive manner, and this interaction is not due simply to the existence of a net negative charge. The phospholipid PS has a net negative charge under the conditions of measurement, and PS does not undergo a Na^+-induced chemical-shift change. Thus, in the organic solvent used in this study, the three anionic phospholipids, CL, PI and PG, interact with Na^+ in a characteristic manner that is similar among these three phospholipids and different from Na^+ interactions with all of the other phospholipids.

In a first approximation, two effects can be invoked to explain the relative Na^+-induced chemical-shift changes among CL, PI and PG: i) the number of potential coordinating groups per polar head; and ii) the relative electronegativity of these coordinating groups. Phosphodiester phosphates possesses four potential coordinating ligands at physiological pH, the two equivalent ionic oxygen atoms and the two linking ester oxygens, which are similar, but not equivalent, in phospholipids. The polar head group moiety of phospholipids also contains potential coordinating sites in addition to that of the linking ester oxygen. These are the hydroxyl groups of the glycerol and inositol residues for CL, PI and PG.

Bearing in mind that the chemical shift observed in high-resolution ^{31}P NMR represents the weighted time-averaged sum of the contribution of all possible coordination complexes, an argument based simply on the numbers of available coordination sites has merit. PI and PG each contain similar phosphodiester groups possessing four potential coordinating moieties; however, in their polar head groups, PI has available five hydroxyl groups for coordination to Na^+, whereas PG has only two such groups available. In aggregate, therefore, PI possesses nine potential coordinating groups and PG six such groups, and this difference in the number of available coordinating groups may account for the difference in the (average) chemical shielding of the phosphorus atoms of PI and PG upon interacting with NA^+ ions.

CL contains two phosphodiester groups per molecule (eight potential coordinating groups) but only one hydroxyl group on the central glycerol moiety. The total number of potential coordinating groups, therefore, is nine, just as in PI. The chemical-shift change for the CL phosphates upon interaction with Na^+, however, is nearly twice that for the PI phosphate. In this instance, the difference in shielding may be attributed to the relative electronegativity of the phosphodiester groups over that of the inositol hydroxyl groups.

In the organic solvent used in this study, CL, PI and PG interact in a specific manner with Na^+ cations and may be capable of distinguishing Na^+ ions from among the other cations present in this and other media. For example, the three phospholipids as functional components of the plasma membrane may recognize Na^+ specifically and may be capable of distinguishing (34) Na^+ cations from among other cations present.

METHOD

The Determination of Tissue Ethanolamine Levels by Reverse-Phase High-Performance Liquid Chromatography

Christopher R. McMaster and **Patrick C. Choy***
Department of Biochemistry and Molecular Biology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3E 0W3

A rapid and sensitive procedure for the determination of ethanolamine levels in mammalian tissues is reported. Ethanolamine was extracted from the tissue with a chloroform/methanol mixture, followed by phase separation. The aqueous phase was subjected to charcoal chromatography and the eluant was derivatized with phenylisothiocyanate. The amount of phenylthiocarbamyl (PTC) ethanolamine in the tissue extract was determined by reverse-phase high-performance liquid chromatography. Quantitation of PTC ethanolamine was linear between 0.1–10 nmol. The pool sizes of ethanolamine in hamster heart, liver and kidney were found to be 1.07, 0.92 and 1.11 μmol/g wet weight, respectively. The sensitivity of the method would allow the determination of ethanolamine in very small tissue samples.
Lipids 27, 560–563 (1992).

Ethanolamine is the precursor for the *de novo* biosynthesis of phosphatidylethanolamine in eukaryotic cells (1). Recently, the role of ethanolamine in the glycosyl phosphatidylinositol membrane anchors has been demonstrated (2). Although ethanolamine can be synthesized *in vivo via* decarboxylation of phosphatidylserine (3), the majority of cellular ethanolamine appears to originate from extracellular sources. The active uptake of ethanolamine by the liver (4), heart (5,6), brain (6), kidney (6), and by cell cultures (7) has been documented. Changes in extracellular ethanolamine have been shown to cause alterations in the intracellular concentrations of ethanolamine which, in turn, may play a role in the direct regulation of phosphatidylethanolamine biosynthesis (7). Changes in ethanolamine levels also may affect the choline uptake and phosphatidylcholine biosynthesis in the heart (8) and retinal tissues (9).

In earlier studies, the level of ethanolamine in a tissue extract was determined using an automatic amino acid analyzer. Briefly, a protein-free tissue extract was obtained and ethanolamine was separated from other metabolites by ion-exchange chromatography. The amount of ethanolamine eluted from the column was quantitated spectrophotometrically after ninhydrin reaction. The method was initially developed for the analysis of ethanolamine levels in serum (10) and later adapted for the determination of ethanolamine levels in tissues (5,11). The major limitation of this method was the difficulty in completely separating ethanolamine from other cellular metabolites. In addition, the sensitivity of the assay was not high enough to allow the determination of ethanolamine levels in very small tissue samples (5). To circumvent these difficulties, several other methods for ethanolamine determination were reported (12–17). However, these methods were typically designed for the quantitation of ethanolamine under very specific conditions and could not be easily adapted for the general determination of ethanolamine in mammalian tissues. In the present study, we report a rapid and sensitive procedure for the determination of intracellular ethanolamine by reverse-phase high-performance liquid chromatography (HPLC).

Abbreviations: HPLC, high-performance liquid chromatography; PTC, phenylthiocarbamyl; PITC, phenylisothiocyanate.

MATERIALS AND METHODS

Materials. [1-^{3}H]Ethanolamine hydrochloride (8.8 Ci/mmol) was purchased from Amersham International Ltd. (Oakville, Ontario, Canada). Phenylisothiocyanate (PITC) and standard amino acid mixtures were obtained from Pierce Chemical Company (Rockford, IL). Pyridine and triethylamine were from Fisher Scientific (Ottawa, Ontario, Canada). Acetonitrile (HPLC-grade) and other chemicals were purchased from the Canlab division of the Baxter Diagnostics Corporation (Mississauga, Ontario, Canada). Activated charcoal and ethanolamine were from Sigma Chemical Company (Toronto, Ontario, Canada). Celite was a product of Supelco Inc. (Oakville, Ontario, Canada).

Preparation of tissue sample. Syrian golden hamsters weighing 120 ± 20 g were used, and sacrificed by decapitation. Tissue samples of 0.25 g were removed and homogenized in 10 mL of chloroform/methanol (1:1, vol/vol). In some experiments, 1 μCi of labelled ethanolamine was added to the homogenate. The homogenate was allowed to sit at room temperature for 30 min and was then centrifuged at 1,000 × *g* for 10 min. The supernatant was decanted and the pellet was extracted twice with 5 mL of chloroform/methanol (2:1, vol/vol) each time. The extracts were pooled, and the ratio of chloroform/methanol/0.9% KCl in the extract was adjusted to 4:2:3 (vol/vol/vol). The mixture was centrifuged at 250 × *g* to facilitate phase separation. An aliquot (5 mL) of the aqueous phase was evaporated to dryness under a stream of nitrogen, and the sample was dissolved in 0.5 mL of 10 mM sodium phosphate buffer, pH 7.4. The sample solution was applied to a 2 × 0.5 cm charcoal/celite (1:2, w/w) column equilibrated with 10 mM sodium phosphate solution (pH 7.4) containing 2% ethanol. Ethanolamine was eluted from the column with 10 mL of the same buffer. The volume of the eluant was reduced by evaporation.

Coupling of ethanolamine with PITC. Coupling was accomplished by a modified method of Heinrikson and Meredith (18). The buffer in the sample was removed *in vacuo* with a Savant (Farmingdale, NY) SC100 vacuum concentrator, and 200 μL coupling buffer containing acetonitrile/pyridine/triethylamine/water (10:5:2:3, by vol) was added. The solvent in the mixture was removed *in vacuo* and the sample was redissolved in another 200 μL of coupling buffer. The coupling reaction was started by the addition of 5–20 μL PITC and the reaction mixture was allowed to sit at room temperature for 15 min. The

solvent in the reaction mixture was evaporated *in vacuo* and the resulting products were dissolved in 250 μL of water/acetonitrile (7:2, vol/vol).

Analysis of phenylthiocarbamyl ethanolamine by HPLC. A Pharmacia LKB (Uppsala, Sweden) SuperPac Spherisorb 3 μm ODS2 column (4 × 125 mm) equipped with a 3 μm ODS guard cartridge was used in this study. The column was equilibrated with 12.5 mM potassium phosphate, pH 6.4, at a constant flow rate of 1.0 mL/min. After sample application (20 μL), the column was washed for 5 min with the equilibration buffer, followed by a 30-min wash with a linear gradient of 0–40% acetonitrile. After completion of the run, the column was washed with acetonitrile for 10 min and re-equilibrated with the equilibration buffer. The absorbance of the eluant was monitored at 254 nm with an Isco (Lincoln, NE) UV detector equipped with an HPLC cell. Data were collected in the first 30 min of the run, and the area of each peak was analyzed using a Beckman (Mississauga, Ontario, Canada) 450 Data System.

RESULTS AND DISCUSSION

The conversion of ethanolamine into its phenylthiocarbamyl (PTC) derivative was investigated. Known amounts (0.1–2.5 μmol) of ethanolamine were used to react with PITC to form PTC ethanolamine. After the reaction, the unreacted PITC was removed by evaporation *in vacuo* and the amount of PTC ethanolamine formed was determined spectrophotometrically. Based on the molar extinction coefficient of PTC amino acids at 254 nm (18), over 98% of the ethanolamine in the reaction mixture was converted into PTC ethanolamine. The ability to separate and identify PTC ethanolamine by reverse-phase HPLC was examined. Under the conditions outlined in Materials and Methods, PTC ethanolamine was eluted as a single peak with a retention time of 17.5 min (Fig. 1A). When a PTC amino acid mixture (derived from a standard amino acid mixture) was applied to the column, none of the amino acid derivatives displayed a retention time between 16.5–18.5 min (Fig. 1B). When a mixture of PTC ethanolamine and PTC amino acids was applied to the column, PTC ethanolamine was eluted as a single peak with a retention time of 17.5 min (Fig. 1C). The amount of PTC ethanolamine applied *vs.* peak area obtained by reverse-phase HPLC was examined. The quantitation of PTC ethanolamine by peak area was found to be linear when 0.10–10.0 nmol PTC ethanolamine was applied to the column (Fig. 2). The sensitivity of the determination could be further enhanced by an increase in the sensitivity of the detector unit.

A chloroform/methanol mixture was used for the extraction of ethanolamine from the tissue. The tissue was homogenized in 40 vol of chloroform/methanol (1:1, vol/vol) and the homogenate was centrifuged to obtain a clear extract. The pellet was re-extracted twice with chloroform/methanol (2:1, vol/vol). A 0.9% KCl solution was added to the pooled extract to cause phase separation. When labelled ethanolamine was added to the tissue homogenate, 99% of the radioactivity was recovered in the aqueous phase. The partition of ethanolamine into the aqueous phase eliminated the contamination of lipid material in the sample. However, the aqueous phase contained nucleotides and other metabolites whose absorbance at UV range could interfere with the analysis of PTC ethanolamine. The majority of these metabolites were removed by charcoal chromatography. The efficiency of the column to remove these contaminants (99.5%) was monitored by determining the absorbance of the sample at 260 nm and 280 nm before and after charcoal chromatography. The yield of ethanolamine was 93% (Table 1).

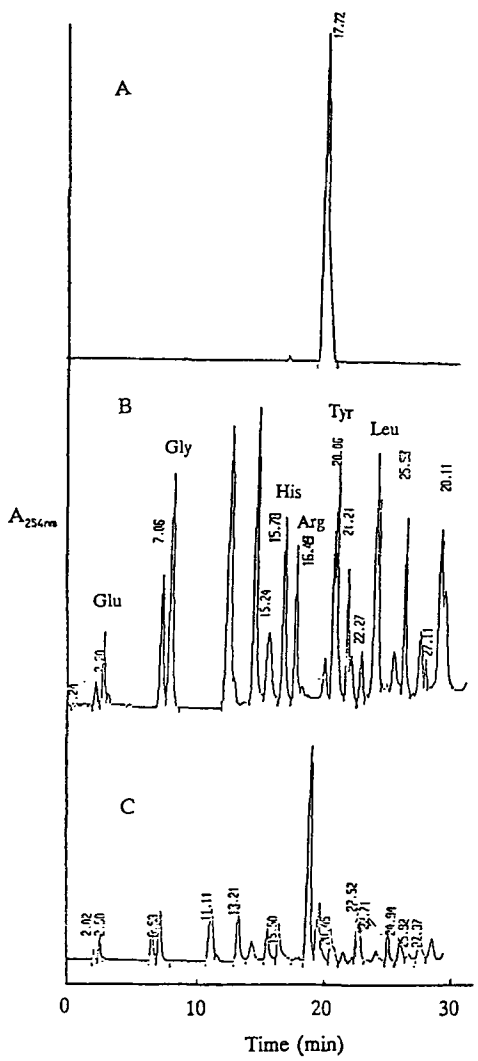

FIG. 1. Separation of PTC ethanolamine by reverse-phase HPLC. Subsequent to sample application (20 μL), the column was washed for 5 min with 12.5 mM potassium phosphate buffer, pH 6.4, followed by 30 min wash with a linear gradient of 0–40% acetonitrile. The flow rate was 1 mL per min, and the numbers shown are the retention times for each peak. A, PTC ethanolamine; B, PTC amino acids; and C, mixture of PTC ethanolamine and PTC amino acids.

For measuring ethanolamine content, two aliquots were taken from the aqueous phase of each sample. A known amount of ethanolamine (100 nmol), which served as an internal standard, was added to one of the aliquots. Both aliquots were reacted with PITC to obtain the PTC derivatives. After reaction, the preparation was resuspended in 250 μL of water/acetonitrile (7:2, vol/vol), and a 20 μL fraction was analyzed by reverse-phase HPLC. A typical chromatogram is shown in Figure 3A. The chromatogram of an identical sample containing the internal standard is depicted in Figure 3B. The internal standard resulted in an increase in the size of the peak correspond-

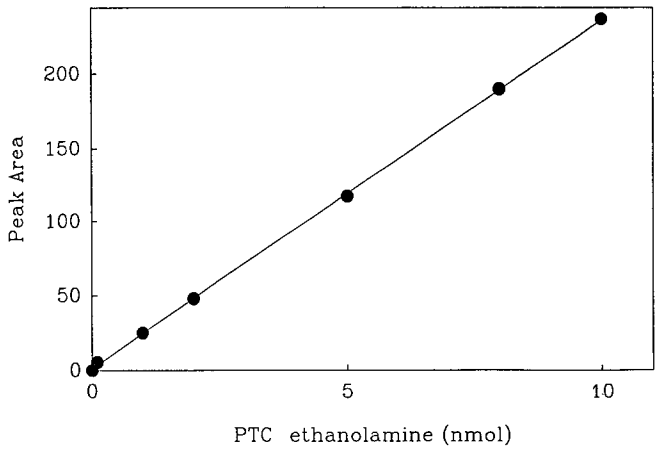

FIG. 2. The quantitation of standard PTC ethanolamine by reverse-phase HPLC. Known amounts of PTC ethanolamine were applied to the column and the corresponding peak areas detected at 254 nm are depicted. Each point is the mean of two separate determinations.

TABLE 1

Ethanolamine Recovery During Pool Size Analysis[a]

Procedure	% Yield[b]
Tissue homogenate	100
Aqueous phase	99
Charcoal chromatography	93

[a][1-^{14}C]Ethanolamine (1 μCi) was added to the tissue homogenate, and the yield after each step was calculated from the amount of radioactivity recovered.
[b]The values are the mean of three separate experiments.

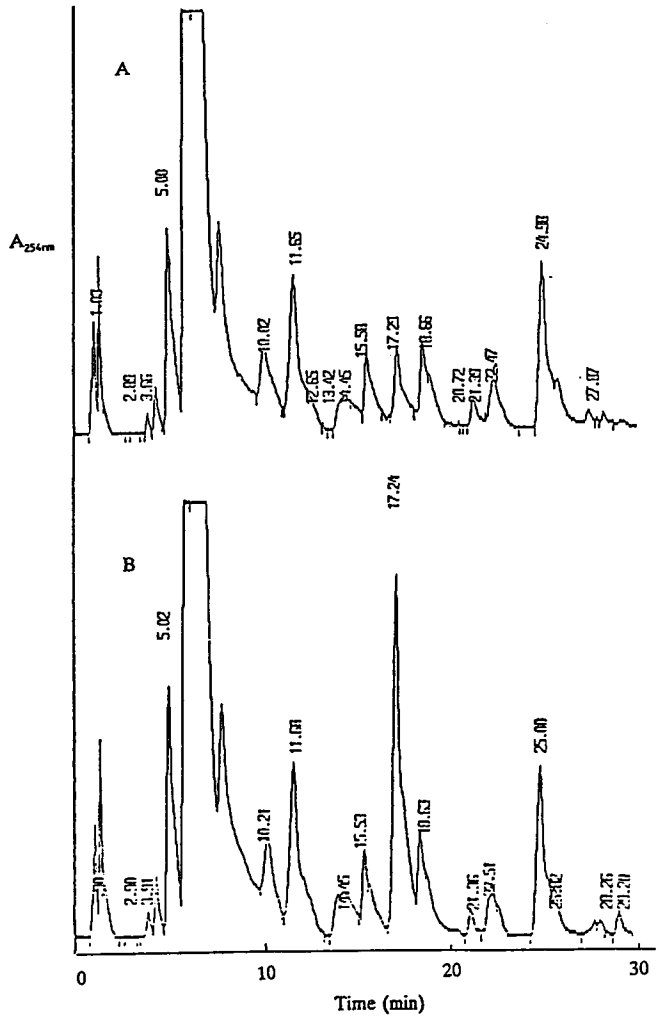

FIG. 3. The quantitation of ethanolamine in hamster heart. Ethanolamine was extracted from the tissue and derivatized to PTC ethanolamine. The derivatized tissue extract was analyzed by reverse-phase HPLC. A, The elution profile of the tissue extract; and B, the elution profile of the tissue extract containing an internal standard of ethanolamine.

ding to the authentic PTC ethanolamine standard with retention time of 17.5 min. The increased peak area of the sample containing the internal standard was 8 nmol (Fig. 2), which corresponds to the amount of internal standard we added to the sample. Our result indicates that all the ethanolamine in the sample was being derivatized to PTC ethanolamine. In some samples, labelled ethanolamine was added to the tissue homogenate and the sample was processed and derivatized as mentioned in Materials and Methods. The eluant from the HPLC was collected into 0.5-mL fractions, and the radioactivity in each fraction was determined. The fraction corresponding to the 17.5 min time point contained the radioactivity which further confirms this peak as PTC ethanolamine.

The pool sizes of ethanolamine in hamster heart, liver and kidney are shown in Table 2. There was no significant difference in the ethanolamine pools between the major hamster tissues. The value obtained for hamster liver was substantially higher than the previously reported value (0.3 μmol/g) for cat liver (11), but the value for the hamster heart was significantly lower than that (5.2 μmol/g) reported earlier (5). The difference in liver ethanolamine could be explained by variation between species. The difference in ethanolamine level in the heart might arise from the methods of quantitation. In the earlier study (5), the amount of ethanolamine was determined by the calibration factor of an amino acid, whereas internal and external standards of ethanolamine were used for calibration in the present study.

TABLE 2

Pool Sizes of Ethanolamine in Hamster Tissues[a]

Tissue	Pool size of ethanolamine
Heart	1.07 ± 0.07
Liver	0.92 ± 0.15
Kidney	1.11 ± 0.32

[a]Each value represents the mean ± SD of three separate sets of experiments, each determined in duplicate. The pool sizes of ethanolamine in hamster tissues are expressed as μmol/g wet weight.

Recently, the determination of ethanolamine in bovine aortic endothelial cells (7) and fetal bovine serum (7) by HPLC equipped with a C_{18} column was reported. Ethanolamine was converted to 2,4-dinitrobenzylethanolamine, and the product was quantitated by reverse-phase

HPLC. However, the sensitivity and specificity of this assay was not defined to allow comparison with the present study. The determination of ethanolamine by PITC derivatization and subsequent reverse-phase HPLC is a facile and rapid procedure to examine the pool sizes of ethanolamine in mammalian tissues. The sensitivity of this procedure is high enough for the determination of ethanolamine in biopsy samples (10–50 mg).

COMMUNICATION

Production of Eicosapentaenoic Acid by Freshwater *Vibrio*

Einar Ringø*, Jens Petter Jøstensen and **Rolf Erik Olsen**[1]
The Norwegian College of Fishery Science, University of Tromsø, N-9001 Tromsø, Norway

Arctic charr, *Salvelinus alpinus* (L.), were fed a moist pellet diet based on casein, dextrin and coconut oil in fresh water. The diet contained substantial amounts of saturated fatty acids, especially 12:0. Polyunsaturated fatty acids in the n-3 series were not detected in the diet, but analysis of the intestinal liquor stripped from the charr showed that eicosapentaenoic acid (EPA, 20:5n-3) accounted for 3.5% of fatty acids in total lipid. Colony forming units (CFU) of aerobic microorganisms were approximately 10^4 per mL intestinal liquor. Seventeen bacterial strains isolated from the intestinal liquor were screened for EPA production. Four isolates contained a high proportion of EPA in their total lipid. These isolates belong to the species *Vibrio*.
***Lipids* 27, 564-566 (1992).**

Bacteria are generally considered not to contain polyunsaturated fatty acids (PUFA); instead such fatty acids are only believed to be formed *de novo* by photosynthetic organisms (1). However, the presence of linoleic acid (18:2n-6) in cellular lipids has been demonstrated in *Vibrio cholera* (2), several *Vibrio* species (3) and in three bacterial species of the human pathogen *Yersinia* (4,5). Eicosapentaenoic acid (20:5n-3) has been reported as a membrane constituent in several marine bacterial species: deep-sea bacteria (6), *Alteromonas* sp. (7) *Shewanella Alteromonas putrefaciens* (8,9) and *Flexibacter* (10). These observations may indicate that microorganisms contain PUFA more frequently than earlier suggested.

No investigations to date have reported that freshwater bacteria contain PUFA. The focus of our study was therefore to investigate whether bacteria isolated from freshwater fish contain PUFA or not.

MATERIALS AND METHODS

Fish. Alevins of Arctic charr, *Salvelinus alpinus* (L.), were reared on commercial feed (Tess Elite Pluss, Skretting LTD, Stavanger, Norway) from the initial feeding stage to an average weight of approximately 10 g. Thereafter the fish were fed the artificial diet.

Diet. The diet consisted of a moist pellet based on casein, dextrin and coconut oil. The composition of the diet is given in Table 1. A detailed description of the different premixes and vitamins added to the diet is given by Olsen *et al.* (11). The diet components were thoroughly mixed, pelleted, and stored at −80°C prior to use.

TABLE 1

Ingredients (g/kg dry weight) of the Diet[a]

Ingredients	
Casein	706.5
Dextrin	170.0
Gelatin	17.0
Premix I	30.0
II	1.7
III	1.8
IV	20.0
Coconut oil	53.0

[a]A detailed description of the added premixes and vitamins is given by Olsen *et al.* (11).

Experimental conditions. We examined 30 Arctic charr in our study, following the experimental design of Ringø and Nilsen (12). This study was undertaken under a natural photoperiod at 70°N from October to April with an average water temperature of 6.0°C ± 1.0°C.

Sampling of intestinal liquor. Ten fish, each weighing about 40 g, were stripped after having been anesthetized in 0.3% benzocaine. The belly of the fish was pressed and intestinal liquor was extruded through the rectum. The intestinal liquor was separated from the fecal pellet after standing for 2 min.

Lipid analyses of diet and intestinal liquor. Analyses of diet and intestinal liquor were carried out in triplicate. Lipids were extracted by the method of Bligh and Dyer (13). Methyl esters of fatty acids were prepared by H_2SO_4 catalyzed transesterification of total lipid in methanol (14), and were analyzed by gas chromatography (Hewlett-Packard, Model 5890 A, Waldbronn 2, Germany) using a SP 2330 capillary column (30 × 0.25 mm i.d.) and helium as carrier gas. The temperature program employed was 60°C for 1 min, followed by an increase of 30°C/min to 180°C for 7 min and thereafter 5°C/min to 240°C. Individual fatty acids were identified by comparison with known standards (Supelco 4-7019, 4-7042, 4-7033, 4-5589, Supelco, Bellefonte, PA) and quantitated using a Hewlett-Packard 3393A integrator. Eicosapentaenoic acid (20:5n-3) was identified by gas chromatography-mass selective detector (GC-MSD) using a 5970 MSD (Hewlett-Packard) connected to a Hewlett-Packard work station 9000-300, and further confirmed by gas chromatography-mass spectrometry (GC-MS) using conditions described elsewhere (15).

Isolation of microorganisms. Total viable counts were performed on TSAg plates containing TSA (tryptic soy agar) 40 g/L and 5 g/L glucose. Intestinal liquor was diluted in sterile 0.9% saline; 0.1 mL vol of appropriate dilutions were spread on the surface of the TSAg plates. The plates were incubated at 12°C, and inspected daily for up to 4 wk. After enumeration, a representative selection of colonies was subcultured on TSAg plates. After

confirmation of culture purity, bacteria isolates were identified to species level by standard biochemical tests (16).

Lipid analyses of microorganisms. Seventeen bacterial isolates, isolated from intestinal liquor at 12°C were grown in lipid-free TSBg medium at 12°C to an optical density (OD_{600}) of approximately 0.7. Thereafter, sterile culture medium (TSBg) was inoculated with 0.5% (vol/vol) of each bacterial isolate and the cultures were maintained at 12°C. Microorganisms were harvested in stationary growth phase. The bacteria were centrifugated at 5.000 rpm for 15 min in a Sorvall centrifuge (model RC2-B), and then suspended in 5 mL methanol. The bacterial cells were sonicated for 1 min and extracted with chloroform/methanol (2:1, vol/vol). The extract was left at 12°C for several hours, and then the solvent was evaporated (17). Methyl esters were prepared as described above.

RESULTS AND DISCUSSION

Fatty acid compositions of the lipids from diet and intestinal liquor are presented in Table 2. The diet had a high content of saturated fatty acids which accounted for approximately 90% of total fatty acids. The major saturated fatty acid was 12:0 (about 41% of total fatty acids). Smaller proportions of the monoene fatty acids (16:1n-7 and 18:1n-9) were also detected. Polyunsaturated fatty acids were not detected in the dietary lipids. Eicosapentaenoic acid (EPA; 20:5n-3) was, however, detected in intestinal liquor, at a level of 3.5% of total fatty acids (Table 2). In addition, high proportions of 20:1 (7%) and 22:1 (9%) were detected. Colony forming units (CFU) of aerobic microorganisms in intestinal liquor were approximately 10^4 when the intestinal liquor was incubated on TSAg plates at 12°C. The EPA productivity of 17 bacterial isolates, isolated from intestinal liquor was tested. Four bacterial isolates tested produced EPA when grown aerobically in a lipid-free TSBg medium. These bacterial isolates belong to *Vibrio* spp. The highest production of cellular EPA, approximately 10% of total fatty acids, was detected in *Vibrio* isolate B10 (Table 3). The relative high quantity of EPA is of bacterial origin, because neither EPA nor other polyunsaturated fatty acids (PUFA) were detected in the growth medium (results not shown). Moreover, fatty acid composition of a *Vibrio* spp. isolated from the intestinal liquor not producing EPA is presented in Table 3.

The proportion of EPA detected in cellular lipid of *Vibrio* isolate B10 in the present study was considerably lower than the values reported for several deep-sea bacteria (25–37%) (6) and for marine bacteria *Shewanella Alteromonas putrefaciens* (24%) (8).

Erwin and Bloch (18) demonstrated that cyanobacteria contained 18:3 PUFA, but C_{20} and C_{22} PUFA were not found in this group. Based upon the observation of Erwin and Bloch (18), and their own observation that C_{20} and C_{22} PUFA were present in deep-sea bacteria (6), DeLong and Yayanos (6) put forth a hypothesis that the genes for PUFA biosynthesis evolved separately in deep-sea bacteria. However, since the freshwater *Vibrio* examined in the present study contained a relatively high proportion of C_{20} long-chain PUFA, the ability to synthesize PUFA may be more universal than generally believed.

TABLE 2

Fatty Acid Composition (%) of the Diet and Intestinal Liquor[a]

	Diet[b]	Intestinal liquor

Catalytic Deuteration of Alkynols and Their Tetrahydropyranyl Ethers[1]

Henry Rakoff* and **William K. Rohwedder**
Food Quality and Safety Research, National Center for Agricultural Utilization Research, ARS U.S. Department of Agriculture, Peoria, Illinois 61604

To ascertain the effect of a replaceable hydrogen on deuterium incorporation, 2-pentynol, 2-hexynol, 3-hexynol, their tetrahydropyranyl (THP) ethers, and the mono- and di-THP ethers of 3-hexyne-1,6-diol were deuterated catalytically with deuterium gas. The differences in percent d_4 (using Wilkinson's catalyst, *tris*(triphenylphosphine)-chlororhodium) or percent d_2 (using Lindlar's catalyst, Pd on $CaCO_3$ poisoned with a lead salt) measured for the alcohols and their THP ethers were, in general, less than 4% with either catalyst. Noticeable exceptions occurred during the deuteration over Wilkinson's catalyst of 2-pentynol and 2-hexynol; extensive scatter resulted in a substantial decrease in percent d_4. This scatter was not observed with the corresponding THP ethers.
Lipids 27, 567–569 (1992).

Over the years we have synthesized (1–4) a number of fatty acids labelled with deuterium. The deuterium was introduced catalytically either with Wilkinson's catalyst, *tris*(triphenylphosphine)chlororhodium, or Lindlar's catalyst, Pd on $CaCO_3$ poisoned with a Pb salt. These catalysts have proven useful for the preparation of multigram quantities of fatty acids with high isotopic purities. From early observations we concluded that substantially greater deuterium incorporation and less scatter could be obtained by elimination of replaceable hydrogens on the molecule prior to the catalytic deuteration. Elimination of the hydroxy hydrogen was accomplished by converting alkynols to their tetrahydropyranyl (THP) ethers. The objective of this study was to measure the increase in percent d_2 or percent d_4 that would be realized by deuterating the THP ether rather than the alcohol.

EXPERIMENTAL PROCEDURES

Materials. *Tris*(triphenylphosphine)chlororhodium was obtained from Strem Chemical Company (Newburyport, MA). Lindlar catalyst and quinoline were purchased from Aldrich Chemical Company (Milwaukee, WI). 3-Hexynol, 2-hexynol and 2-pentynol were obtained from Farchan Laboratories (Gainesville, FL). Deuterium (99.5%) was purchased from Matheson (Joliet, IL). The mono-THP ether of 3-hexyne-1,6-diol was prepared according to Raphael and Roxburgh (5).

Mass spectral analyses. The deuterated pentynol and hexynols, and their THP ethers were analyzed by gas chromatography-mass spectrometry using a Hewlett-Packard (Avondale, PA) model HP 5890 Series II Gas Chromatograph and a Hewlett-Packard model HP 5988A mass spectrometer. The samples were ionized by the chemical ionization technique using isobutane as the reagent gas. The data were recorded using selected ion monitoring (SIM) of the most prominent peaks. The masses chosen for SIM included all mass numbers in the prominent peak clusters of both the non-deuterated standards and the deuterated compounds. A sample of the nondeuterated standard compound was run prior to the deuterated compound. The deuterium distribution was calculated by solving the simultaneous equations set using the unknown deuterium distribution values, the pattern of intensities of the standard and the measured mass intensities (6). Since there was some separation of the deuterated components, with the compound with the highest number of deuterium atoms eluting first, the gas chromatograms were cut very broadly, down to the baseline.

Deuteration with Wilkinson's catalyst. Benzene (50 mL) was placed in a 100 mL round-bottom flask equipped with a magnetic stirrer and attached to an apparatus designed for maintaining one atmosphere of pressure and for measuring the amount of gas absorbed. The system was evacuated and flushed with nitrogen (3X) and with deuterium (2X). Stirring was stopped, *tris*(triphenylphosphine)chlororhodium (0.2 g) was added and the system was evacuated and flushed twice with deuterium. Stirring was started and as the catalyst was reduced, the solution developed the color of iced tea. The stirrer was stopped, the substrate (1 g) was added and the system was evacuated and flushed twice with deuterium. Stirring was resumed and continued until absorption of deuterium ceased (1.5–3 h). Benzene was removed on the rotary evaporator, the residue was diluted with hexane (30 mL) and the reddish precipitate was separated by filtration and by passage through a SEP PAK silica cartridge. Removal of the solvent left the product.

Deuteration with Lindlar's catalyst. The substrate (1 g) was dissolved in hexane (50 mL) in a 100 mL round-bottom flask equipped with a magnetic stirrer and attached to an apparatus designed for maintaining one atmosphere of pressure and for measuring the amount of gas absorbed. Lindlar's catalyst (100 mg) and quinoline (50 μL) were added and the system was evacuated and flushed twice with deuterium. Stirring was continued until deuterium absorption ceased (30–60 min). The reaction mixture was filtered through a pad of Celite, washed with 5 mL cold 5% HCl, 5 mL saturated $NaHCO_3$, and 2×5 mL H_2O, and dried over anhydrous sodium sulfate. Removal of the solvent left the product.

The reaction of 2-pentynol and 2-hexynol with deuterium over Lindlar catalyst was very slow, and repeated additions of catalyst were required for it to proceed.

RESULTS AND DISCUSSION

Catalytic hydrogenation of alkynes and alkenes over heterogeneous (insoluble) catalysts usually results in isomerization (7,8). Several homogeneous (soluble) catalysts

[1]The mention of firm names or trade products does not imply that they are endorsed or recommended by the U.S. Department of Agriculture over other firms or similar products not mentioned.

Abbreviations: SIM, selected ion monitoring; THP, tetrahydropyranyl.

have been reported to not give isomerization. One of the most common is Wilkinson's catalyst, *tris*(triphenylphosphine)chlororhodium (9–11). The preferred solvent for this catalyst is benzene because it has been noted (12,13) that positional and geometric isomerizations do not occur in this solvent but do occur in alcohol or benzene alcohol solutions (13,14). Table 1 lists the deuterium contents obtained from the catalytic deuteration with Wilkinson's catalyst of several alkynols and their THP ethers. Deuteration of 3-hexynol and its THP ether (1-1 and 1-2) gave high d_4 values; the difference in d_4 incorporation was about 4.5%. Deuteration of the mono- and di-THP ethers of 3-hexyne-1,6-diol (1-3 and 1-4) likewise gave high d_4 values; the difference in this case was less than 2%. For these compounds there is little to be gained by preparing and reducing the THP ether rather than by reducing the alkynol directly. With 2-hexynol and 2-pentynol and their THP ethers (1-5 through 1-8) the situation is quite different. With the THP ethers high d_4 incorporation was obtained; better than 90% in both cases. With the alcohols, 2-pentynol and 2-hexynol, however, there was extensive scatter and low values of d_4. Meese and Borstel (15) reported extensive scattering due to allenic rearrangements during heterogeneous catalytic deuteration of the THP ether of 2-butynol in ethyl acetate. Homogeneous catalytic deuteration of this THP ether with Wilkinson's catalyst in ethyl acetate did not produce any scrambling. They did not investigate the deuteration of 2-butynol with this catalyst. To prepare pentanol-2,2,3,3-d_4 or hexanol-2,2,3,3-d_4, the route through the THP ether is obviously to be preferred.

Lindlar's catalyst is a popular catalyst for semihydrogenation of the triple bond (16). Table 2 lists the deuterium contents obtained from catalytic deuteration with Lindlar's catalyst of several alkynols and their THP ethers. Deuteration with Lindlar's catalyst of 2-pentynol was carried out in three different solvents, hexane, diethyl ether, and benzene (2-1, 2-2, and 2-3) to see if the nature of the solvent would affect deuterium content. For the solvents studied, the choice of solvent had little or no effect. Deuteration of the THP ether of 2-pentynol (2-4) gave a product with 97% d_2, about 4% more than with 2-pentynol. With 2-hexynol and its THP ether (2-5 and 2-6), a difference of about 6% in d_2 content was obtained. With 2-pentynol and 2-hexynol it was necessary to add three separate 100 mg portions of Lindlar's catalyst before the reduction proceeded. Quinoline was not used in 2-1 and 18% overreduction to the saturated compound occurred.

Deuteration with Lindlar's catalyst of 3-hexynol and its THP ether (2-7 and 2-8) gave di-deuterated products differing by less than 4% in d_2 content. With the mono- and di-THP ethers of 3-hexyne-1,6-diol (2-9 thru 2-11), no difference was observed in percent d_2 in the products. Entries 2-9 and 2-10 also illustrate that there was no solvent influence on the percent d_2 obtained.

In summary, a high percentage of d_4 incorporation was

achieved in deuteration with Wilkinson's catalyst of a 3-alkynol, its THP ether or of the THP ether of a 2-alkynol. With the 2-alkynols, however, there was extensive scatter of the deuterium atoms. With the Lindlar catalyst, the position of the triple bond in both the alkynols and their THP ethers had little or no effect on deuterium content.

ACKNOWLEDGMENT

We thank R.O. Adolf for helpful discussions.

ARTICLE

Purification and Characterization of an Extracellular Lipase from the Fungus *Rhizopus delemar* [1]

Michael J. Haas[a,*], **David J. Cichowicz**[b] and **David G. Bailey**[a]

[a]Eastern Regional Research Center, U.S. Department of Agriculture, Philadelphia, Pennsylvania 19118 and [b]Department of Chemistry, LaSalle University, Philadelphia, Pennsylvania 19141

The complete purification and characterization of an extracellular lipase (acylglycerol acylhydrolase, EC 3.1.1.3) from *R. delemar* is described. The final product was homogeneous as judged by electrophoresis in denaturing polyacrylamide gels and by isoelectric focusing, and was shown by means of an activity stain to be lipolytic. The purified enzyme had a monomer molecular weight of 30,300, an isoelectric point of 8.6, and approximately one monosaccharide moiety per molecule. *N*-Terminal sequence data (28 residues) and the amino acid composition of the lipase indicated that it corresponds to the product of a lipase-encoding cDNA previously isolated from *R. delemar*. Optimal activity occurred between pH 8.0 and 8.5. The activity and stability of the enzyme were maximum at 30°C. Divalent cations were required for activity, with barium, calcium and manganese conferring maximum activity. Activation by calcium was maximal at and above 10 mM. The lipase was not inactivated by reducing agents, sodium fluoride or phenylmethylsulfonyl fluoride. It was resistant to *N*-ethylmaleimide, and inactivated by *p*-chloromercuribenzoic acid in a manner which was not reversed by cysteine.
***Lipids* 27, 571-576 (1992).**

In biological systems, lipases (acylglycerol acylhydrolases, EC 3.1.1.3) initiate the catabolism of fats and oils by hydrolyzing the fatty acyl ester bonds of acylglycerols. Work from several laboratories has established that the activities of lipases are not limited to this reaction. They also catalyze the synthesis and transesterification of glyceride (1-4) and phosphoglyceride (5,6) ester bonds, and the synthesis and hydrolysis of a variety of non-glyceride esters (7-12). In addition, lipases are active in both aqueous and non-aqueous solvent systems (1,4,10,11,13,14). It has therefore become evident that lipases have considerable biotechnological potential for the general synthesis and hydrolysis of esters (13-17).

Lipases differ from one another in their physical properties and biochemical features, such as substrate specificities, optimal reaction conditions, requirements for activators, and sensitivity to inhibitors (18,19). The mycelial fungus *Rhizopus delemar* produces at least three extracellular lipases (20, 21) which exhibit very high selectivity for the hydrolysis of primary, but not secondary, esters (22). Partially purified mixtures of these enzymes have been employed in a variety of reactions including ester (23) and glyceride synthesis (4,24,25), glyceride restructuring (2,26), and the exchange of the acyl groups of phospholipids (6).

The development of new uses for lipases as applied catalysts would be fostered by their purification and characterization. We report here the purification of one of the extracellular lipases of *R. delemar*. This enzyme corresponds to the product of a lipase-encoding (*LIP*) cDNA recently isolated from this organism (27).

MATERIALS AND METHODS

Enzyme production. Rhizopus delemar, ATCC 34612, was obtained from the American Type Culture Collection (Rockville, MD). The progeny of single spores were used as inocula for enzyme production. Growth medium contained 0.5% Casamino Acids (Difco, Detroit, MI), 30 mM glycerol, trace elements (28) and 5 μg biotin/L in a basal salts medium (29). Media were inoculated with 0.1% (vol/vol) of spore suspension (10^6 spores/L) and shaken at 150 rpm for 36 h at 30°C. The mycelia were then removed by filtration through cheesecloth, and the filtrates were stored at −20°C.

Enzyme purification. Culture filtrate was thawed in two and three liter batches and filtered through Whatman #1 paper. Sodium azide was added to a final concentration of 0.03% (wt/vol). Protease inhibitors were added to the final following concentrations: Phenylmethylsulfonyl fluoride (PMSF, 0.2 mM), pepstatin (1 μM), leupeptin (1 μM) and ethylenediaminetetraacetic acid disodium dihydrate (EDTA, 1 mM). The solution was applied at room temperature to an oleic acid affinity chromatography column (prepared as described below) with a bed volume of 20 mL at a cross sectional flow rate of 0.4 cm/min. Effluent was collected at intervals during loading and checked for lipase activity. When lipase adsorption fell below 40% of input, the column was chilled to 4°C and washed at a rate of 1 mL/min with: (i) 100 mL of 0.86 M NaCl in Buffer 1 (10 mM sodium phosphate, pH 6.0, containing the same inhibitors as were added to crude enzyme), (ii) 100 mL of Buffer 1, and (iii) a linear gradient of Triton X-100 from 0 to 0.5% in 320 mL of 10 mM sodium phosphate, pH 6.0. Fifteen-mL fractions were collected during the gradient.

Lipase-containing fractions from the affinity chromatography step were pooled and applied at 4°C to a CM-Sephadex C25 column (2.6 × 51.5 cm, Pharmacia LKB, Piscataway, NJ) equilibrated in Buffer 2 (10 mM sodium phosphate, pH 6.0, 1 mM EDTA). The column was washed with 400 mL of Buffer 2, followed by a linear gradient of NaCl from 0 to 0.5 M in 1 L of Buffer 2. The flow rate was 1 mL/min throughout. Fifteen-mL fractions were collected during the NaCl gradient.

A rapid and sensitive assay, wherein the hydrolysis of olive oil by lipase induces a change in the fluorescence of rhodamine B (Sigma, St. Louis, MO), was used to track lipase during purification (30). Two- to 100-μL aliquots of

[1]Mention of brand or firm names does not constitute an endorsement by the U.S. Department of Agriculture over others of a similar nature not mentioned.

Abbreviations: BME, β-mercaptoethanol; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid disodium dihydrate; IEF, isoelectric focusing; kDa, kilodaltons; NEM, *N*-ethylmaleimide; PCMB, *p*-chloromercuribenzoic acid; pI, isoelectric point; PMSF, phenylmethylsulfonyl fluoride; PVP, polyvinylpyrrolidone; SDS-PAGE, polyacrylamide gel electrophoresis in sodium dodecyl sulfate; U, units of lipase activity; UV, ultraviolet.

potentially lipolytic samples were applied to an agar-solidified emulsion of olive oil and rhodamine B in a Petri dish. The dish was then incubated at room temperature for 5 to 60 min, whereupon active fractions could be detected by their bright fluorescence under ultraviolet (UV) light.

Synthesis of affinity chromatography resin. Oleic acid (1 mol free acid, Sigma), Affi-Gel 102 (20 mL, Bio-Rad Laboratories, Richmond, CA), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (10 mmol, Bio-Rad) were gently mixed overnight at room temperature in 28 mL of 70% aqueous dimethylformamide. The pH was held at 4.2 by the addition of 1N HCl with a constant titrating pH meter. The resin was washed in a column with 700 mL 80% ethanol, followed by two series of (a) 400 mL 0.1 N NH_4OH, and (b) 400 mL 80% ethanol. These were followed by 400 mL 0.1N NH_4OH, and 400 mL 80% methanol. Finally, the column was washed with 1 L 10 mM sodium phosphate, pH 6.0 containing 0.03% sodium azide. The continuous-service life of this resin exceeded two years.

Electrophoretic methods. 0.1% SDS-12% PAGE was performed according to Laemmli (31). The molecular weight of lipase was determined by reference to the mobilities of proteins of known molecular mass (Dalton Mk VII-L, Sigma).

Electrofocusing was performed on a PhastSystem (Pharmacia LKB) according to the manufacturers' directions using IEF 3-9 PhastGels (Pharmacia LKB) pre-equilibrated in a solution of 4M urea, 0.5% Nonidet P-40, and 4% pH 8-10.5 Pharmalytes (Pharmacia LKB). The isoelectric point (pI) of lipase was estimated by comparison of its mobility to those of standard proteins (High pI Calibration Kit, Pharmacia LKB) included on each gel.

Proteins were detected in gels by silver staining (32). Isoelectric focusing (IEF) gels were incubated 5 min in 20% trichloroacetic acid before staining, to eliminate interference by ampholytes.

Lipase activity was detected following IEF by placing the gel onto a solid lipase detection medium (30) containing olive oil and rohdamine B, incubating at room temperature for 100 min, and examining the medium under UV light for bright pink bands.

Determination of lipase activity. Lipolytic activity was quantitated by a continuous titrimetric assay using emulsified olive oil as substrate. A maximum of 0.58 mL of enzyme was added to 5 mL of pre-neutralized emulsion containing 18% (wt/vol) olive oil, 4.2% (wt/vol) gum arabic and 15 mM $CaCl_2$. A titrating pH meter (Radiometer, Copenhagen, Denmark) was employed to maintain the pH at a preset value by the addition of 0.1 N NaOH. Unless stated otherwise, incubations were carried out at 26°C with a set point pH of 7.5. Enzyme activity was calculated from the maximal rate of base addition, assuming molar equivalence between fatty acid release and base consumption. A unit of activity was defined as the release of one μmole of fatty acid per min under these conditions.

Purified lipase was dialyzed against deionized water prior to characterization. In determinations of the pH dependence of activity, the set point pH of the pH meter was adjusted to the values of interest. A thermostatted, water-jacketed reaction chamber was employed in determining the temperature dependence of activity. The effect of storage temperature on activity was measured by preincubating the enzyme at the desired temperature and assaying residual activity at 26°C. For investigations of the effect of cations upon lipase activity, 0.5% (wt/vol) polyvinylpyrrolidone [average mol. wt.: 360 kilodaltons (kDa), Sigma] replaced gum arabic as the emulsifier, and $CaCl_2$ was omitted from the assay mixture.

The calcium content of the gum arabic used as a substrate emulsifier was determined on a Perkin-Elmer (Norwalk, CT) PE 5000 Atomic Absorption Spectrophotometer with reference to $CaCl_2$ solutions of known concentrations.

Protein determination. Protein concentrations were determined according to Bradford (33) using the Bio-Rad Protein Assay Kit. For samples containing Triton X-100, the bicinchoninic acid assay (34) (Pierce, Rockford, IL) was employed. Bovine-γ-globulin was used as the standard in both assays.

Sugar content determination. The phenol-sulfuric acid method (35) was used to determine the degree of glycosylation of the purified lipase, using mannose as the reference standard. As another means of assessing the degree of glycosylation, individual samples of lipase were treated with endoglycosidase F and with *N*-glycosidase F (both from Boehringer Mannheim, Indianapolis, IN) (36), and examined for an alteration in electrophoretic mobility, relative to untreated lipase, by SDS-PAGE.

Amino acid analysis. Pure lipase was incubated in 5.7 N HCl for 24 h at 110°C. The amino acid compositions of the resulting hydrolysates were determined with a Beckman (Palo Alto, CA) Model 119CL amino-acid analyzer according to the manufacturers' instructions.

Amino acid sequence determination. N-Terminal sequence analysis was performed by automated Edman degradation using instrumentation, reagents and protocols from Applied Biosystems (Foster City, CA). A Model 470A gas-phase protein sequencer equipped with an online 120A PTH-analyzer and a Model 900A Control/Data Analysis Module were employed.

RESULTS AND DISCUSSION

Production and purification of lipase. We have produced and have purified to homogeneity an extracellular lipase from *R. delemar.* Glycerol was the main carbon source for the growth of the organism. In the majority of published papers describing lipase production, triglycerides have been the carbon source. However, there are disadvantages to their use, including media turbidity (which complicates measurement of the growth of the culture by optical methods), the insolubility of the fatty acids released by enzymatic hydrolysis, and the difficulty of removing unhydrolyzed triglyceride from solution prior to enzyme purification. We have found glycerol to be an acceptable carbon source for lipase production, resulting in enzyme levels comparable to those obtained with triglycerides, without the difficulties noted above.

Lipase eluted as a single peak from the oleic acid resin, during the Triton X-100 gradient, at a Triton concentration of approximately 0.25%. The output of two or three affinity chromatography run was routinely combined and taken to the CM-Sephadex step. Lipase eluted from this cation exchange column as a single sharp symmetrical peak at 0.25 M NaCl, the approximate mid-point of the gradient. The results of a typical purification are sum-

TABLE 1

Purification of *Rhizopus delemar* Extracellular Lipase

Step	Protein (mg)	Activity (U)	Specific activity (U/mg)	Purification (-fold)

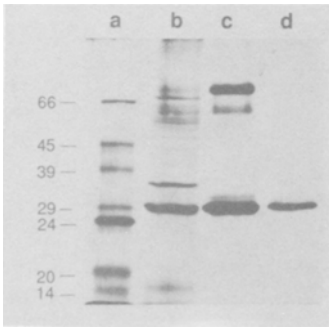

FIG. 1. SDS-PAGE of *R. delemar* lipase at various stages of purification. Proteins were detected by silver staining. Lane a, 2.25 μg of molecular mass marker preparation; lane b, 37.5 μg of culture filtrate; lane c, 3 μg of pooled lipase-positive fractions eluted from oleic acid affinity chromatography column; lane d, 1 μg of pooled lipolytic material obtained by CM-Sephadex column chromatography. The masses of the molecular weight marker proteins (kDa) are indicated in the left margin.

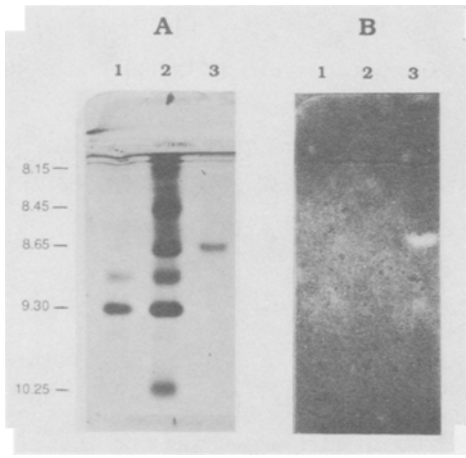

FIG. 2. Isoelectric focusing (IEF) of the purified lipase. (A) Silver stained IEF gel. Lane 1, 0.1 μg of trypsinogen standard; lane 2, 0.433 μg of IEF standard protein preparation; lane 3, 98 ng of pure lipase. The pI values of the standard proteins are indicated in the left margin. (B) Activity stain for lipase. An IEF gel identical to the one in Panel A was inverted onto lipase indicator media containing olive oil and rhodamine B, incubated for 100 min at room temperature, and photographed under UV light. The bright band indicates the site of lipase activity.

marized in Table 1. A 10.3-fold increase in specific activity was achieved, with a 30% recovery of activity. Purified preparations typically had specific activities of approximately 8000 units of lipase activity (U)/mg.

Enzyme characterization. As judged by polyacrylamide gel electrophoresis in sodium dodecyl sulfate (SDS-PAGE) (Fig. 1) and IEF (Fig. 2A), the final lipase preparation was homogeneous. When an IEF gel was incubated on lipase indicator media, a single fluorescent band was produced (Fig. 2B). The position of this band corresponded to that of the single protein band seen on IEF gels (Fig. 2A). Therefore, the purified protein is a lipase.

The molecular weight of the lipase, calculated by SDS-PAGE, was 30.3 kDa (Fig. 1). The isoelectric point was 8.6 (Fig. 2).

Amino acid composition and N-*terminal sequence.* The amino acid composition of the purified lipase (Table 2), indicates a minimum molecular weight of 29,762 (Trp was not determined). This agrees with the value determined by SDS-PAGE (above). As reported for other lipases, the protein is not enriched in hydrophobic residues, despite the fact that its natural substrates are very hydrophobic.

Two nmol of purified lipase were subjected to *N*-terminal sequence determination. A low background was obtained throughout this operation, indicating that the preparation was very homogeneous. The *N*-terminus was not blocked. The sequence we determined is shown in Scheme 1. An identical sequence is encoded within the *R. delemar* lipase cDNA (27). Based on the gene sequence, the predicted molecular mass for the mature protein with this *N*-terminus is 29,592. This agrees with the value cal-

culated for the pure lipase from SDS-PAGE data (above), and with that predicted from the amino acid composition of the enzyme (Table 2). In addition, the amino acid composition of the purified lipase agrees with that predicted from the cDNA sequence (27). We conclude that the lipase described here corresponds to the product of the cloned *LIP* cDNA and that it is initially synthesized as a larger polypeptide which is proteolytically cleaved to produce mature lipase.

The predicted pI of the mature lipase, calculated from the *LIP* cDNA, is 8.01 (27). The difference between this value and the pI determined here for the isolated fungal protein (8.6) may be related to the inclusion of urea and NP-40 in the IEF gel. These additives were absolutely required to detect lipase protein on the gels.

Pure lipase was determined to contain 0.53% carbohydrate. This corresponds to 0.88 monosaccharide residues per molecule. In agreement with this observation, neither endoglycosidase F nor *N*-glycosidase F treatment caused any alteration in the SDS-PAGE mobility of the lipase. In addition, the molecular weight of lipase, determined by SDS-PAGE of either crude (Haas, M.J., unpublished) or purified enzyme (above), is virtually identical to those calculated from the amino acid composition of the enzyme (above) and predicted from the sequence of the cloned lipase gene (27). All evidence therefore indicates that the lipase isolated here lacks substantial glycosylation. By contrast, a glycosylation level of 5–10% appears to be more typical of fungal lipases (37,38). Since the oleic acid affinity chromatography column was run at a low flow rate, this step of the purification required several weeks. It is possible that the lipase was initially glycosylated but that its carbohydrate moieties were removed during this operation by glycosidases endogenous to the crude enzyme preparation.

Properties of the lipase. The pH dependence of the activity of the pure enzyme is shown in Figure 3. Optimal activity occurred at slightly alkaline pH, with peak activity between pH 8.0 and 8.5. The enzyme exhibited 80% or more of maximal activity between pH 7.3 and 9.1. The fact that the lipase is maximally active near its pI may indicate that the binding of this enzyme to its hydrophobic substrate is best when its net charge is zero.

Lipase activity is temperature sensitive (Fig. 4). Maximum activity occurred at 30°C, with 80% of this value exhibited between 25 and 38°C. At and above 45°C, the activity fell to 0 within the first two min of incubation.

The thermal stability (15 min) of the lipase is illustrated in Figure 5. The enzyme was unstable above 30°C. Approximately 50% of the activity was lost during a 15 min preincubation at 42°C. Above 50°C, the enzyme was completely inactivated during a 5-min preincubation.

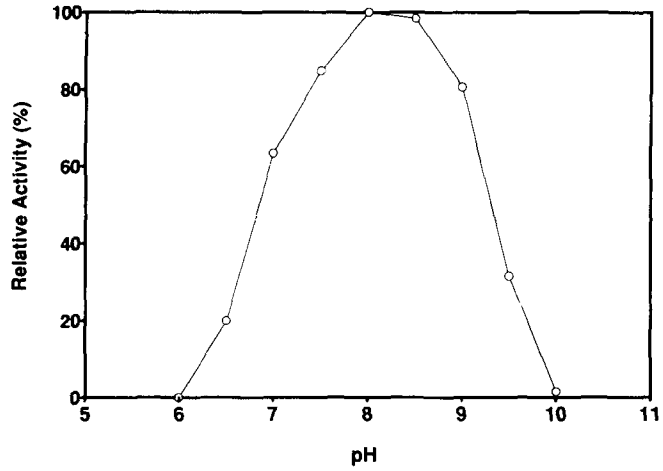

FIG. 3. The effect of pH on the activity of the pure lipase. The activity was assayed titrimetrically at various pH values as described in Materials and Methods, using olive oil as the substrate and gum arabic as emulsifier. Activities are expressed relative to that of the most active sample.

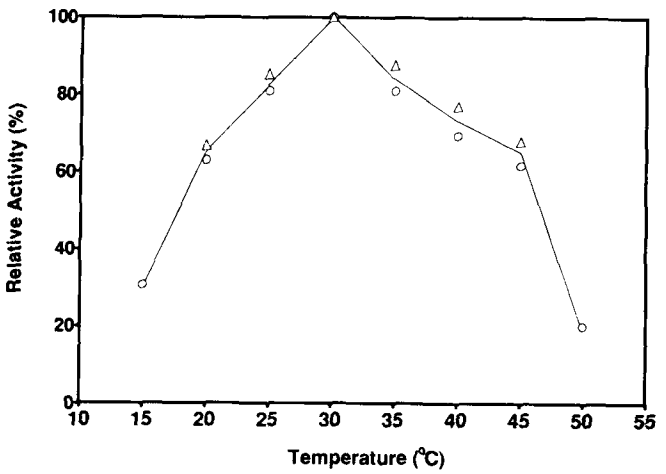

FIG. 4. Dependence of lipase activity upon temperature. Activity was assayed titrimetrically in a thermostatted, water-jacketed reaction vessel as described in Materials and Methods, using olive oil as the substrate and gum arabic as the emulsifier. The results of duplicate determinations are shown. Activities are expressed relative to that of the most active sample.

Some lipolytic enzymes require calcium for activity (18). It has been postulated that this stimulation is mediated through electrostatic interactions which mask repulsions either between the enzyme and its emulsified substrate or between the enzyme and product free fatty acids. To measure the effects of calcium and other ions, lipase activity was assayed in substrate emulsions where gum arabic, which contains inorganic ions, was replaced by the ion-free emulsifier PVP. The effects of the chloride salts of various cations, at concentrations of 10 mM, upon lipase activity were examined. With no additions, lipase activity was undetectable. Barium, calcium and man-

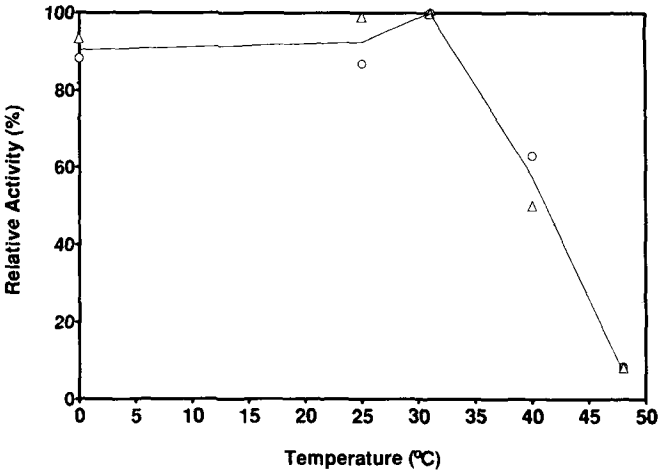

FIG. 5. Thermal stability of the lipase. Aliquots of enzyme were incubated at desired temperatures for 15 min. Lipolytic activity was then assayed titrimetrically at 26°C as described in Materials and Methods. The results of duplicate determinations are shown. Activities are expressed relative to that of the most active sample.

ganese (at 10 mM) substantially restored lipase activity (4400–5300 U/mg). Moderate amounts of activity were recovered in the presence of zinc, cobalt, copper and magnesium (700–3300 U/mg). No activity was detected upon the addition of sodium, potassium or ammonium salts.

The response to calcium was further investigated by testing its effects at several concentrations. Lipase activity rose steadily in PVP-emulsified systems as the calcium concentration increased, and was maximal above 10 mM. Gum arabic contains calcium. By atomic absorption spectroscopy, it was determined that the calcium concentration of gum arabic-emulsified assay mixtures was 68 mM. Nonetheless, the further addition of $CaCl_2$ stimulated the enzyme. Evidently, only a fraction of the calcium introduced by gum arabic is able to effect lipase activity. The stimulation by added $CaCl_2$ was maximal at and above 10 mM, resulting in an approximately three-fold increase in activity over that seen in the absence of added $CaCl_2$.

The effect of enzyme inhibitors upon lipase activity is shown in Table 3. The enzyme is resistant to the disulfide bond reducing agents dithiothreitol (DTT) and β-mercaptoethanol (BME). The predicted amino acid sequence of the *R. delemar* lipase is highly homologous to that of *Rhizomucor miehei*, which contains three disulfide bonds (27,42). The *R. delemar* lipase contains Cys at sites corresponding to the six Cys residues involved in disulfide formation in the *R. miehei* enzyme. It is reasonable to postulate that the *R. delemar* enzyme also has three disulfide bonds. The resistance of the *R. delemar* lipase to inactivation by reducing agents indicates that these disulfides are either inaccessible or are not essential for activity.

The enzyme was resistant to *N*-ethylmaleimide (NEM) (Table 3), consistent with the postulate that its sulfhydryls are involved in disulfide bonds. However, 2 mM *p*-chloromercuribenzoic acid (PCMB) did inhibit the lipase. Activity was only partially restored by cysteine (Table 3), suggesting that PCMB inhibition is due to action at some

TABLE 3

[a]The activities are expressed as the mean and standard deviation of two determinations.

secondary site within the enzyme rather than to an interaction with a sulfhydryl group.

Sodium fluoride inhibits some lipases (39), while others are resistant to its effects (40). The *R. delemar* enzyme was not inhibited by fluoride (Table 3).

A serine-containing pentapeptide sequence has been postulated to form part of the active site of lipases, with the serine playing an active role in catalysis (41). The *R. delemar* lipase gene contains sequences encoding this conserved pentapeptide (27). However, the purified lipase was resistant to phenylmethylsulfonyl fluoride (PMSF), a potent serine-directed inhibitor (Table 3). Similar resistance has been reported for the *R. miehei* lipase (42), and attributed to a protective burying of the active site serine within the enzyme. Presumably this is also the case for the closely related *R. delemar* enzyme.

This is the first description of the complete purification and characterization of a *Rhizopus* lipase for which the cognate gene has also been isolated and analyzed. The size, pI and amino acid composition of the lipase reported here corresponds to those predicted for a peptide encoded by an internal portion of the cloned *LIP* cDNA (27). This correspondence led to the conclusion (27) that the lipase is initially synthesized as a precursor of molecular mass 42.1 kDa which undergoes proteolytic maturation to a smaller species with molecular mass of approximately 30 kDa.

The molecular mass of the *R. delemar* lipase is similar to that of a lipase from *Rhizomucor miehei* (38,42), and about 10 kDa smaller than that reported to date for a *Rhizopus* lipase. Iwai's group reported the partial purification of three extracellular lipases from *R. delemar* (20,21). The enzyme we have isolated is similar to their lipase C in terms of stability and pH and temperature requirements. However, the molecular mass of lipase C, determined by gel filtration, was 45 kDa, 15 kDa larger than the enzyme we have isolated. This larger molecular weight may be an overestimate of the true mass, since gel filtration was observed to overestimate the mass of another lipase, that from *R. miehei* (38). Alternatively, lipase C may have retained an associated glycopeptide during purification, as was demonstrated for *Rhizopus arrhizus* lipase (43–45). This lipase was isolated as a heterodimer consisting of a lipolytic fragment with a molecular mass of approximately 34 kDa, and a non-lipolytic glycopeptide of 8.5 kDa. The two fragments were separated by treat-

ments such as acid precipitation, but this resulted in the inactivation of the lipase (45). Considering the close relationship between members of the genus *Rhizopus* (46), it seems probable that the *R. delemar* lipase is produced in a similar fashion, with the C lipase described by Iwai's group representing the heterodimer form of the enzyme we have isolated. The purification method here appears to allow the preparation of glycopeptide-free lipase which retains activity.

It is conceivable that the glycopeptides attached to the *R. arrhizus* lipases isolated by Laboureur and Labrousse (43) and Semeriva *et al.* (44,45) are lipase propeptides which remain associated with the enzyme after proteolytic maturation. Chiba *et al.* (47) reported the isolation of a lipase from a commercial preparation of crude *R. delemar* enzyme. The molecular weight of the enzyme was 41.3 kDa, similar to those of the enzymes studied by Laboureur and Labrousse (43) and Semeriva *et al.* (44,45). In size this enzyme corresponds to the prolipase encoded by the cloned *R. delemar* lipase gene (27). However, its amino acid composition (47) differs substantially from that predicted for the *R. delemar* prolipase (27). Therefore, it is unlikely that the glycopeptides found with some *Rhizopus* lipases are lipase propeptide fragments which have remained associated with the enzyme after proteolytic maturation of a precursor form of the enzyme.

ACKNOWLEDGMENTS

We thank Deborah Woolf, Dominic Esposito and Karen Kolaetis for excellent technical assistance, and Dr. Harold Farrell for the determination of the amino acid composition of the lipase.

Reversible ATP-Dependent Inactivation of Adipose Diacylglycerol Acyltransferase

M.A. Rodriguez*, C. Dias and **T.E. Lau**
University of Ottawa, Department of Biochemistry, Ottawa, Ontario, Canada K1N 6N5

Diacylglycerol acyltransferase from rat adipose tissue is shown to be inactivated by 30 to 40% upon incubation with adenosine 5′-triphosphate (ATP) and Mg^{2+}. The activity responsible for this inactivation is associated with the cytosolic fraction, specific for ATP, prevented when ATP is substituted by β,γ-methylene-ATP, and partially blocked by 1 mM ethylenediaminetetraacetate or 40 mM NaF, but not by inhibitors of adenosine 3′,5′-cyclic-monophosphate (cAMP)-dependent protein kinase and/or protein kinase C (PKC). The cytosolic activity cannot be mimicked by (cAMP)-protein kinase nor by PKC. Inactivated diacylglycerol acyltransferase from ATP/cytosol-treated microsomes can be reactivated by incubation with partially purified protein phosphate from rat liver, and can be inactivated again by further addition of ATP in the presence of cytosol. The results suggest the existence in adipose tissue of a protein kinase other than cAMP-protein kinase or PKC, which may be involved in the regulation of triacylglycerol synthesis.
Lipids 27, 577–581 (1992).

Incorporation of fatty acids into adipose tissue triacylglycerols plays a central role in lipid metabolism. Although it is well established that this process is under hormonal control, the precise molecular events involved in the regulation have yet to be elucidated. *In vitro* experiments suggest that some triacylglycerol synthetic enzymes from the heart and the liver may be regulated by a phosphorylation-dephosphorylation mechanism (1–3). We have recently reported the presence of an enzyme activity in adipose tissue which in the presence of adenosine 5′-triphosphate (ATP) inactivates glycerolphosphate acyltransferase (GPAT) (4). A second key enzyme in triacylglycerol synthesis, diacylglycerol acyltransferase (DGAT), is shown here to be reversibly modified by a cytosolic enzyme activity in the presence of ATP and Mg^{2+}.

MATERIALS AND METHODS

Materials. All substrates, nucleotides, fatty acid-free bovine serum albumin (BSA) the catalytic subunit of adenosine 3′,5′-cyclic monophosphate (cAMP)-protein kinase from bovine heart, staurosporine, amiloride and 1-(5-isoquinolinylsulfonyl)-3-methylpiperazine dihydrochloride[1] (H7 analogue) were obtained from the Sigma Chemical Co. (St. Louis, MO). Rat brain protein kinase C was from Calbiochem Co. (San Diego, CA). L-[2-^{3}H]Glycerol-3-phosphate (10.6 Ci/nmol, 1 Ci = 37 GBq) and [1-^{14}C]oleoyl CoA (58 Ci/mol) were from New England Nuclear (Lachine, Quebec, Canada). Universol (liquid scintillation cocktail) was obtained from ICN biomedicals (Mississauga, Ontario, Canada), and Sephadex G-25 was purchased from Pharmacia Inc. (Baie d'Urfe, Quebec, Canada).

Protein phosphatase was partially purified from rat liver up to the ethanol precipitation step of the method by Brant *et al.* (6) for phosphorylase phosphatase purification. The ethanol precipitate was extracted twice with 25 mM Tris-HCl (pH 7.5) buffer containing 1 mM ethylenediaminetetraacetate (EDTA) and 1 mM DL-dithiothreitol (DTT). The extract was then dialyzed against the same buffer, concentrated, added to one volume of glycerol and kept at −90°C.

Epididymal adipose tissue from eight male Sprague-Dawley rats (Charles River Canada Inc., St. Constant, Quebec, Canada), fed *ad libitum*, were homogenized and fractionated as previously described by Walsh *et al.* (4). The 16,000 × *g* supernatant (postmitochondrial supernatant) was resolved into cytosol and microsomes by centrifugation at 100,000 × *g* for 1 h. The microsomes were washed once and resuspended in a 10 mM Tris-HCl (pH 7.5) buffer containing 0.25 M sucrose and 1 mM DTT to a final concentration of 1–2 mg protein/mL. Both fractions were stored in aliquots at −90°C. Amounts of microsomes used in the experiments are indicated through this paper as mass of microsomal protein.

Methods. DGAT was assayed as previously described (7) by incubating the microsomes (10–20 μg) for 6–8 min at 37°C with 20 μM [1-^{14}C]oleoyl-CoA (10 Ci/mol) and 150 μM 1,2-dioleoyl-*sn*-glycerol (delivered in 5 μL acetone) in 0.5 mL of 0.1 M Tris-HCl (pH 7.5), containing 1 mM DTT, 10 mM $MgCl_2$ and 5 μM BSA (TMB Buffer). The reaction was stopped by the addition of 1.5 mL of isopropanol/heptane (1:1, vol/vol). The organic phase was washed three times with 0.75 mL of isopropanol/heptane (4:1, vol/vol) and 0.75 mL of 0.05% KOH. A 0.75-mL aliquot from the organic (heptane) phase was counted in 7.5 mL of Universol in an LKB-Wallac (Turku, Finland) 1215 Rack Beta counter.

Glycerolphosphate acyltransferase (GPAT) was assayed as previously described (4). NADPH-cytochrome reductase was assayed with cytochrome-C as described by Phillips and Langdom (8). All enzyme assays were performed in duplicate. Protein concentrations were measured by the dye binding method of Bradford (9), using BSA as a standard.

ATP-treated microsomes were prepared by incubation of microsomes (0.4 mg/mL) with 0.4 mg/mL cytosol, 1 mM ATKP, 10 mM Mg^{2+}, and 2 mM DTT in 100 mM Tris-HCl (pH 7.5) for 10 min at room temperature. ATP was then removed in a Sephadex G-25 (fine) column (4 mL

[1]This compound was mistakenly listed by Sigma as H7 (1-(5-isoquinolinylsulfonyl)-2-methylpiperazine) and found to be a PKC inhibitor, although less potent than H7 (5).

Abbreviations: ADP, adenosine 5′-diphosphate; AMP, adenosine 5′-phosphate; AMP-PCP, β,γ-methylene-ATP; ATP, adenosine 5′-triphosphate; BSA, fatty acid-free bovine serum albumin; cAMP, adenosine 3′,5′-cyclic monophosphate; Cl-Ph-S-cAMP, 8-(4-chlorophenylthio)-cAMP; CTP, cytidine 5′-triphosphate; DGAT, diacylglycerol acyltransferase; DTT, DL-dithiothreitol; EDTA, ethylenediaminetetraacetate; GPAT, glycerolphosphate acyltransferase; GTP, guanosine 5″triphosphate; H-7 analogue, 1-(5-isoquinolinylsulfonyl)-3-methylpiperazine dihydrochloride; ITP, inosine 5′-triphosphate; PKC, protein kinase C; PPase, protein phosphatase; UTP, uridine 5′-triphosphate.

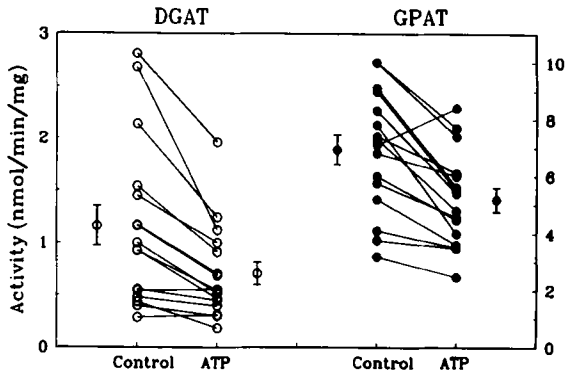

FIG. 1. Postmitochondrial supernatant inactivation with ATP. Adipose tissues from 16 animals were homogenized and 100 μL of the postmitochondrial supernatants (300–600 μg) were incubated for 15 min at 37°C with and without 1 mM ATP in 0.25 mL of 0.1 M Tris-HCl pH 7.5) buffer containing 2 mM DTT, 20 mM $MgCl_2$ 10 μM BSA (50 μM for GPAT). After preincubation, substrates were added (in 250 μL of 0.1 M Tris-HCl) for DGAT (○) and GPAT (●) activity determination as described in Methods.

(4 mL gel/mL sample) spun at 400 × *g* for 1 min in an IEC (Needham Heights, MA) HN-S11 centrifuge. NADPH-cytochrome reductase activity was used as an internal standard for evaluation of microsomal recovery.

RESULTS

Figure 1 illustrates the consistent decrease in both DGAT and GPAT activities observed when post-mitochondrial supernatant from rat adipose tissue was incubated with ATP. GPAT activity (6.9 ± 0.5 nmol•min^{-1}•mg^{-1}) showed a significant reduction of 25 ± 3% (n = 16, $p < 10^{-6}$, paired *t*-test), which correlates well with our previous results (4). DGAT activity (1.2 ± 0.2 nmol•min^{-1}•mg^{-1}) on the other hand, showed a slightly higher degree of inactivation: 35 ± 4% (n = 16, $p < 10^{-7}$). Two animals did not follow the general trend and showed increases of 7 and 1% for DGAT activity while GPAT activity increased by 12 and 26%, respectively. One animal also showed an increase in GPAT activity (18%) with a concurrent decrease in DGAT activity (58%). No statistical correlation was found between GPAT and DGAT inactivation. Addition of 50 mM NaF to the homogenization buffer resulted in no change of either GPAT or DGAT specific activities nor in the ATP-dependent inactivation.

Upon fractionation of the postmitochondrial supernatant into microsomal and cytosolic fractions, the activity responsible for DGAT inactivation was found to be associated with the soluble fraction (Table 1) as previously observed for GPAT inactivation (4). In the absence of cytosol, microsomes from different preparations showed no significant inactivation of DGAT activity. By contrast, in the presence of the cytosolic fraction, a significant reduction of 33 ± 2% in DGAT activity was observed. The degree of DGAT inactivation varied from 28 to 45% and depended on both the cytosol and the microsomal preparations.

As previously demonstrated for GPAT activity (4), microsomal DGAT is significantly stimulated by the cytosolic fraction from 4.3 ± 0.7 to 7.3 ± 0.8 nmol•min^{-1}•mg^{-1} ($P < 0.04$; Table 1). The cytosolic effect on both DGAT activity and its ATP-dependent inactivation is concentration dependent (Fig. 2). Higher concentration of cytosolic protein seems to be required for maximal DGAT inactivation than for stimulation. Boiling of the cytosol for 5 min abolished both of these effects (not shown).

Results in Table 1 and Figure 2 may suggest that the ATP effect on DGAT activity could be due to prevention of cytosolic stimulation of DGAT. However, this assumption does not explain the results in Figure 1, nor the observation that some cytosolic preparations show no capacity for DGAT stimulation while still being able to inactivate the enzyme in the presence of ATP. Preincubation of microsomes with cytosol previous to the addition of ATP does not affect the degree of inactivation. Moreover, preincubation of the cytosol with ATP and Mg^{++} does not modify its capacity for both stimulation and ATP-dependent inactivation of DGAT activity (not shown), suggesting that ATP does not inactivate a cytosolic stimulatory factor.

In contrast with what we observed for GPAT inactivation (4), ATP-dependent inactivation of DGAT did not display a lag time and was detectable after a one-minute incubation (Fig. 3). Therefore, the cytosolic activity responsible for DGAT inactivation appears to have a substantially higher rate than DGAT itself.

We investigated the nucleotide specificity of the cytosolic activity responsible for DGAT inactivation (Table 2) and the results paralleled our earlier findings for GPAT (4). The specificity is such that ATP cannot be substituted by any of the other nucleotides tested. AMP-PCP (β,γ-methylene-ATP) was not a substrate for the DGAT inactivation, suggesting that cleavage of the β,γ-phosphodiester bond of ATP is involved in the reaction. Maximal effect of ATP was observed at concentrations of 0.5 mM or higher (not shown).

The effect of several kinase inhibitors on the ATP-

TABLE 1

Cytosolic Contribution to DGAT Inactivation[a]

Microsomes/cytosol	DGAT (nmol•min^{-1}•mg^{-1})		Inactivation

[a]Microsomes (20 μg in average) alone or with cytosol (100 μg in average) were incubated (in duplicate) for 10 min at 37°C in 0.4 mL of TMB buffer followed by addition of substrates for DGAT assay. n.s., Not significant.
[b]For paired *t*-test.
[c]Number of independent experiments.

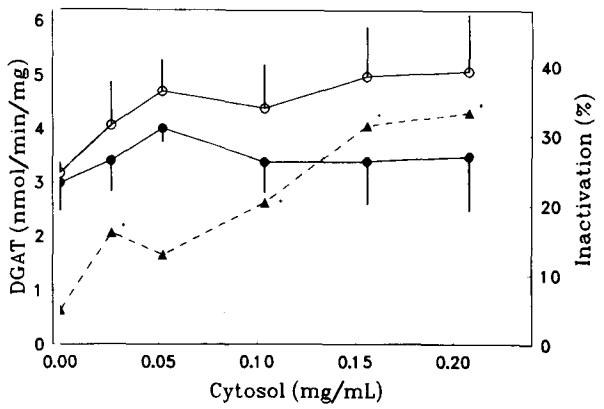

FIG. 2. Cytosol dependence of DGAT inactivation. Microsomes (15–20 μg protein) were incubated for 10 min at 37°C with increasing amounts of cytosol in the presence (●) and absence (○) of 1 mM ATP in 0.4 mL of TMB buffer containing 60 mM sucrose, 0.25 mM EDTA. Following addition of substrates, DGAT activity (left axis) was determined as described in Methods, and percent DGAT inactivation calculated for each cytosol concentration (▲, right axis). Four independent experiments were performed. DGAT activity values are given as the means with their SE. Percent DGAT inactivation values were calculated for each experiment and analyzed by paired *t*-test for significant inactivation. Points represents means values of inactivation and were labeled with * when $P < 0.05$.

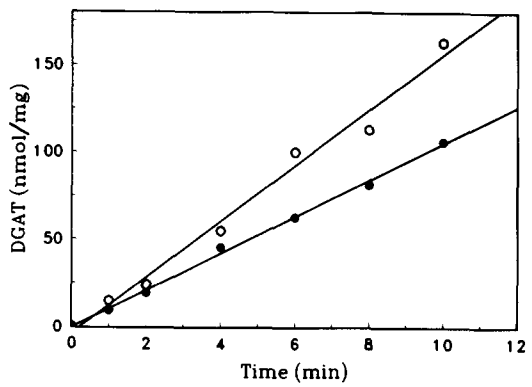

FIG. 3. Time dependence of DGAT inactivation. Microsomes (14 μg in average) with added cytosol (70 μg in average) were assayed for DGAT activity at different incubation times in the presence (●) and absence (○) of 1 mM ATP. Results represent the average of two independent experiments and are fitted by linear regression.

dependent inactivation of DGAT (Table 3) was tested at a non-saturating concentration of ATP (0.2 mM). Partial blockage of the inactivation was achieved only when the incubation mixture contained 1 mM EDTA (with no Mg^{2+}) or 40 mM NaF. Although amiloride seemed to have an effect, statistical analysis indicated no significant difference from the control. Stimulators of cAMP-dependent protein kinases, such as cAMP and 8-(4-chlorophenylthio)-cAMP, did not increase the degree of DGAT inactivation. Moreover, substitution of cytosol by the catalytic subunit of the cAMP-protein kinase or protein kinase C (PKC), did not result in a significant inactivation by ATP: 17 ± 6.3% (n = 4, $P > 0.1$) and −4 ± 15% (n = 4, $P > 0.4$), respectively *vs.* 13 ± 7.1% (n = 4, $P > 0.05$) for the microsomes alone.

As observed for GPAT, we were unable to reactivate the

TABLE 2

Nucleotide Specificity[a]

Nucleotide	DGAT (%)	*P*

[a]Microsomes (18 μg in average) with added cytosol (100 μg in average) and the indicated inhibitor/activator were incubated in the presence and absence of 0.2 mM ATP as for Table 1, and assayed for DGAT activity. The corresponding decrease in DGAT activity caused by ATP is given as mean ± SEM for the number of independent experiments indicated in brackets. The *P* values were calculated using a *t*-test with the control (no inhibitor/activator) as reference.

[b]With no Mg^{2+} in the incubation buffer.

ATP-treated microsomal DGAT by incubation with either adipose tissue or liver cytosols and Mg^{2+}. However, reactivation was achieved by incubation with a crude preparation of protein phosphatase from the liver (Fig. 4). The reactivation effect is Mg^{++} dependent and is reduced by 70% in the presence of 40 mM NaF but it is insensitive to 0.1 μM okadaic acid (Rodriquez, M.A., and Lay, T.E., unpublished results).

The reversibility of the phosphatase-dependent DGAT reactivation was also investigated. ATP/cytosol-treated microsomes incubated for 10 min at 37°C in the presence of the phosphatase resulted in a 118 ± 21% reactivation. Another 10-min incubation at 37°C upon addition of cytosol and 1 mM ATP resulted in a 45 ± 4% inactivation, or a 83% reversion of the reactivation (average of six independent experiments). Our liver protein phosphatase preparation was also able to stimulate DGAT activity in untreated microsomes (144 ± 25%, n = 10) and the effect was significantly ($P < 0.02$, by paired *t*-test) reduced by the adipose cytosol (stimulation of 99 ± 27%, n = 10).

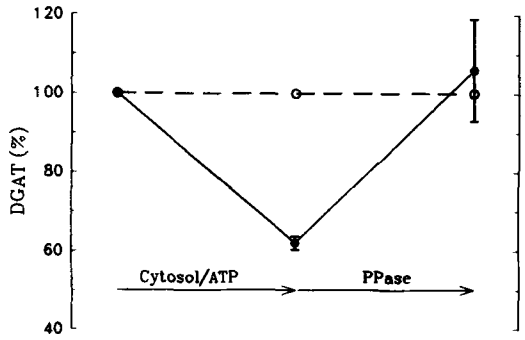

FIG. 4. Reactivation of ATP treated microsomes. Microsomes (0.36 mg/mL) and cytosol (0.36 mg/mL) were incubated in TMB buffer for 10 min at 21°C in the presence of 1 mM ATP, followed by centrifugation on Sephadex G-25 and DGAT determination as described in Methods. Partially purified protein phosphatase from rat liver was added to the remaining filtrate (0.7 mg/mL) and incubated again for 10 min at 37°C, then assayed for DGAT activity. A control (○) was run in parallel without ATP. DGAT activity in the sample (●) is expressed as percentage of the control. Results are the mean ± SEM for three independent experiments. PPase, protein phosphatase.

DISCUSSION

Our results indicate the presence in adipose tissue of an ATP-dependent activity that *in vitro* reduces both glycerolphosphate acyltransferase and diacylglycerol acyltransferase activities by 30 to 40%. As previously shown for GPAT inactivation (4), the activity responsible for DGAT is associated with the cytosolic fraction, is heat sensitive, requires Mg^{2+} and an intact, cleavable β,γ-phosphodiester bond on the ATP. DGAT activity from ATP-treated microsomes can be restored to control levels by incubation with a crude preparation of liver protein phosphatase. New addition of ATP and cytosol results in reinactivation close to the level for ATP-treated microsomes. These observations support the hypothesis of a soluble protein kinase involved in the regulation of adipose tissue DGAT, as has been suggested for microsomal GPAT (4).

DGAT inactivation was not affected by the inhibitors of PKC and/or cAMP-dependent protein kinase such as H-7 analogue (5), staurosporine (10), amiloride (11,12) or cAMP-protein kinase inhibitor. Furthermore, since the stimulation of DGAT was not observed by the addition of Ca^{2+}, cAMP or the cAMP analogue chlorophenylthio-cAMP, and because neither PKC from rat brain nor the catalytic subunit of cAMP-dependent protein kinase from bovine heart could replace the cytosolic activity, the postulated DGAT kinase is neither PKC nor cAMP-protein kinase.

Modulation of DGAT activity in liver by a phosphorylation-dephosphorylation mechanism was suggested previously by Haagsman and coworkers (3,13). Rat liver microsomes were shown to be inactivated *in vitro* by incubation with ATP, Mg^{++} and the liver cytosolic fraction, but not with cAMP-protein kinase and its substrates (3). The authors reported reactivation of DGAT activity from ATP-trated liver microsomes upon incubation with liver cytosol. Also they observed a decrease in DGAT activity of tissue homogenized in the presence of 40 mM NaF. By contrast, we were unable to detect either of these latter effects in adipose tissue. We did find a consistent stimulation of both DGAT (Table 1) and GPAT (4) activities by the cytosolic fraction. Similar stimulation has been previously reported in different laboratories although the mechanism of stimulation has not yet been demonstrated (14-17).

Regulation of adipocyte microsomal GPAT by cAMP-protein kinase has been suggested by Nimmo and coworkers (18-20), but other laboratories have been unable to observe any GPAT inactivation upon incubation of rat adipocyte microsomes with cAMP-protein kinase and its substrates (4,21). We have consistently observed cytosol and ATP-dependent inactivation of GPAT.

Inactivation of both DGAT and GPAT enzymes show similar nucleotide dependence and specificity, as well as similar response to protein kinase inhibitors. Although inactivation of both enzymes cannot be reversed by the addition of cytosol alone, they can both be reversed by our preparation of protein phosphatase from liver. Whether or not GPAT and DGAT are substrates of the same protein kinase remains to be established.

Since DGAT in ATP and cytosol-treated microsomes can be reversibly reactivated by our crude preparation of phosphorylase phosphatase from liver, and since this reactivation is dependent on Mg^{++} and sensitive to NaF, a protein phosphatase (likely PPase 2C) is implicated in the process. The ability of the protein phosphatase preparation to stimulate DGAT activity of untreated microsomes indicates that the DGAT enzyme is already in a partially inactivated form. Prevention of the latter stimulation by the adipose cytosol, and the failure of cytosol to reactivate ATP-treated microsomes may both be direct results of the reported phosphatase inhibitors present in adipose tissue (19,22). Consequently, future experiments will try to resolve the adipose tissue protein phosphatase from these inhibitors.

Reversible or Irreversible Modification of [^{3}H]PAF Binding on Rabbit Platelet Membranes Differentiates Various PAF Receptor Antagonists[1]

M.T. Domingo, F. Piro, C. Broquet, E. Auclair, P.E. Chabrier* and P. Braquet
Institut Henri Beaufour, 91952 Les Ulis, France

[^{3}H]Platelet-activating factor (PAF) binding to rabbit platelet membranes was examined before and after 20 min preincubation at 25°C in the presence of PAF, lysoPAF, or of five different PAF receptor antagonists (L 652731, BN 52021, WEB 2086, BN 52111 and BN 52115). When platelet membranes were not washed after preincubation with PAF or PAF antagonists, no significant specific binding of [^{3}H]PAF was observed, which suggests full occupancy of the binding sites. When membranes were extensively washed, full recovery of specific [^{3}H]PAF binding was attained with L 652731 and partial recoveries (60%, 55% and 30%) were reached with BN 52021, WEB 2086 and PAF, respectively; no recovery was seen with the dioxolanes BN 52111 and BN 52115. Scatchard analysis of the binding data indicated that no significant change in the dissociation constant (K_d) and maximum number of binding sites (B_{max}) occurred after preincubation of platelet membrane with L 652731, whereas a reduction of B_{max} was observed when PAF and BN 52021 were measured. When platelet membranes were preincubated with WEB 2086, B_{max} and K_d significantly increased. The data suggest differing binding properties for PAF and the PAF antagonists. Some of the PAF antagonists may tightly bind to the PAF receptor site(s) and/or irreversibly modify or downregulate PAF recognition sites. Our results also suggest that the interaction of PAF receptor antagonists with PAF receptor can be divided into at least two components, namely a reversible component and an irreversible one. *Lipids 27*, 582–586 (1992).

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycerophosphocholine) (1,2) is a biologically active phospholipid released by a variety of cell types, such as macrophages, leukocytes, basophils, platelets and endothelial cells, upon appropriate stimulation. PAF appears to be involved in inflammatory disorders in lung (3,4), heart (5,6) and other organs (7,8). The structural requirements for PAF biological activity are highly specific, which led to the notion that PAF action is mediated through specific receptor(s).

Specific binding for [^{3}H]PAF has been described in many organs and cell types including platelets (9–11), lung tissue (12), polymorphonuclear neutrophils (13,14), endothelial cells, liver (15), brain (16,17) and the eyes (18). Different characteristics for the PAF binding sites in these tissues have been described, which suggests existence of multiconformational states of one type of receptor or populations of multiple receptors (15). [^{3}H]PAF binding has been shown to be specific, saturable and displaceable by unlabeled PAF (10) or PAF receptor antagonists, including CV 3988 (19), L 652731 (20), WEB 2086 (21), BN 52111, BN 52115 (22) kadsurenone (23) and BN 52021 (24).

[^{3}H]PAF binding to intact human platelets is prevented by preincubation of platelets with unlabeled PAF, suggesting a downregulation of the PAF binding sites (25,26). We further investigated the effect on [^{3}H]PAF binding of preincubation of rabbit platelet membranes with increasing concentrations of PAF and five different PAF-receptor antagonists structurally unrelated to PAF. These antagonists include: The terpenoid BN 52021, the tetrahydrofurane L 652731, the triazolothienobenzodiazepine WEB 2086 and two PAF-related molecules, BN 52111 and BN 52115.

MATERIALS AND METHODS

Materials. Synthetic [^{3}H]PAF in ethanol with a specific activity of 59.5 Ci/mmole was purchased from New England Nuclear (Boston, MA). Unlabeled PAF and lysoPAF were purchased from Calbiochem (San Diego, CA) or Bachem (Bubendorf, Switzerland), solubilized in ethanol and stored at −80°C. BN 52021 was solubilized in dimethylsulfoxide (DMSO). L 652731 and WEB 2086, kindly provided by Merck Sharp and Dohme (St. Louis, MO) and Boehringer Ingelheim (Ingelheim/Rhein, Germany), were also solubilized in DMSO. BN 52111 and BN 52115 were solubilized in water. The chemical structures of the compounds are given in Figure 1.

Preparation of platelet membranes. Rabbit blood (6 vol) was collected from the central ear artery and added to 1 vol of ACD solution (citric acid 1.4 g, sodium citrate 2.5 g, dextrose 2 g per 100 mL of distilled water). After centrifugation at 150 *g* for 15 min, the platelet-rich plasma (PRP) was carefully removed and centrifuged again for 15 min at 1000 × *g*. The platelet pellet was collected and successively washed by centrifugation in i) a 37°C prewarmed Tyrode buffer containing heparin (50 U/mL), apyrase (0.3 U/mL) and ethylenediaminetetraacetic acid (EDTA; .2 mM); ii) 10 mM Tris, 150 mM NaCl, 5 mM $MgCl_2$, 2 mM EDTA, pH 7.4 buffer; and iii)the latter buffer sodium-free at pH 7. The platelet pellet was then resuspended in the latter buffer, quickly frozen in liquid nitrogen and slowly thawed at room temperature; the whole process was repeated at least three times as described by Hwang *et al.* (27). The lysed platelets were centrifuged at 100,000 × *g* for 30 min in a Beckman (Palo Alto, CA) model L8-55 ultracentrifuge (50.2 Tirotor). The platelet membrane homogenate was stored at −80°C and used within 5 days. Protein content was determined by the Bradford method (28) using Biorad (Paris, France) protein assay reagents and bovine serum albumin (BSA) as a standard.

Preincubation of platelet membranes with PAF, lysoPAF and PAF-antagonists. For the preincubation pro-

cedure, the membrane homogenate was suspended in a solution containing 10 mM Tris, 5 mM $MgCl_2$, 2 mM EDTA, 10^{-4} M phenylmethylsulfonyl fluoride (PMSF), trasylol (100 U) per mL and BSA 0.025% at pH 7 (buffer A). The membrane homogenate was then preincubated for 20 min at 25°C in presence or in the absence of lysoPAF (10^{-6} M), PAF (10^{-6} M) or a PAF antagonists (10^{-5} M).

After preincubation, the membranes were centrifuged at 100,000 × *g* for 40 min in Buffer A. The pellet was washed five times by centrifugation at 100,000 × *g* for 30 min in the same buffer. Finally, the platelet pellet was suspended in Buffer A and used for the binding assay.

[^{3}H]PAF binding assay. One hundred to 150 μg of membrane protein was added to a final volume of 1 mL of 10 mM Tris, 5 mM $MgCl_2$, BSA 0.025% pH 7 buffer containing 1 nM [^{3}H]PAF and was incubated for 90 min at 0°C with or without unlabeled PAF (10^{-6} M). The bound [^{3}H]PAF was separated from the free [^{3}H]PAF by immediate filtration through Whatman (Hillsboro, OR) GF/B glass-fiber filters under vacuum (Brandel system, Beckman). The reaction tubes and the filters were washed 3 times with 5 mL of precooled buffer solution. Filters were transfered to polyethylene vials filled with 10 mL liquid scintillation fluid (Instagel, Packard, Fullerton, CA). The radioactivity was measured with an LKB (Piscataway, NJ) β counter with 45% efficacy.

RESULTS

[^{3}H]PAF binding to platelet membranes. Binding of [^{3}H]PAF to rabbit platelet membranes was specific, saturable and of high affinity. A high specific binding representing 60-70% of the membrane-associated radioactivity was obtained under our experimental conditions, which included Mg^{2+} ions in the binding buffer solution.

Before interpreting any change of PAF binding in rabbit platelet membranes, the effect of storage at −80°C on the PAF binding capacity was investigated (Table 1). Some differences were noted when we compared fresh and frozen preparations; in the subsequent studies, we used frozen membranes with well-reproducible [^{3}H]PAF binding characteristics.

Comparative displacement of [^{3}H]PAF from rabbit platelet membrane with PAF, lysoPAF and PAF antagonists. [^{3}H]PAF on platelet membranes was fully displaced by PAF, L 652731, BN 52111, BN 52115, BN 52021 and WEB 2086 with IC_{50} of 2 nM, 20 nM, 35 nM, 35 nM, 200 nM and 150 nM, respectively (n=4) (Fig. 2). The maximum displacement obtained with lysoPAF at the highest concentration used (10^{-6}M) was 20%.

Regulation of PAF binding by PAF and lysoPAF. When the membranes were not washed after 20-min preincubation of platelet membranes with PAF (10^{-6} M) followed by a 90-min incubation period with [^{3}H]PAF at 0°C, no significant specific binding was observed, which suggests full occupancy of the PAF binding sites (Fig. 3). Five extensive washings of the membranes after preincubation with PAF resulted in a partial recovery (30%) of [^{3}H]PAF binding. Increasing concentrations of PAF (10^{-9} M, 10^{-8} M, 10^{-7} M) decreased the number of binding sites con-

Frozen membranes (5 days) (n=9)	4.73 ± 0.13	1.25 ± 0.07

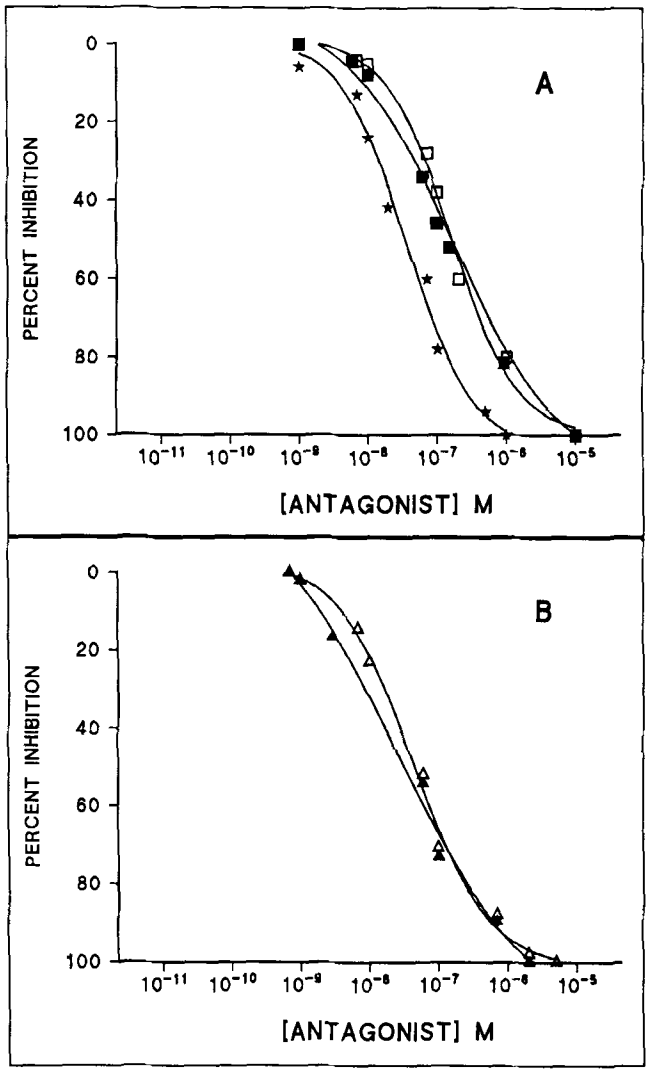

FIG. 2. A, Potencies of L 652731 (★) IC_{50} = 2 ± 0.2 10^{-8} M, BN 52021 (□) IC_{50} = 2 ± 0.1 10^{-7} M to inhibit [^{3}H]PAF specific binding in rabbit platelet membranes. B, Potencies of BN 52111 (▲) IC_{50} = 3.5 ± 0.05 10^{-8} M and BN 52115 (△) IC_{50} = 3.5 ± 0.04 10^{-8} M to inhibit [^{3}H]PAF specific binding in rabbit platelet membranes. The experiments were performed in tris 10 mM, $MgCl_2$ 50 mM, BSA 0.025% pH 7, and each point is the average of four different experiments.

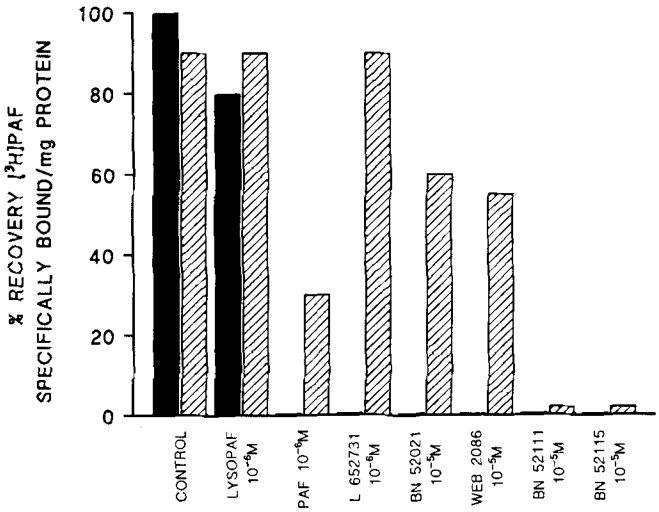

FIG. 3. Percent recovery of [^{3}H]PAF specific binding after five extensive washes (hatched bar) and without wash (solid bar) in rabbit platelet membranes preincubated in the presence of PAF, lysoPAF, L 652731, BN 52021, WEB 2086, BN 52111 and BN 52115.

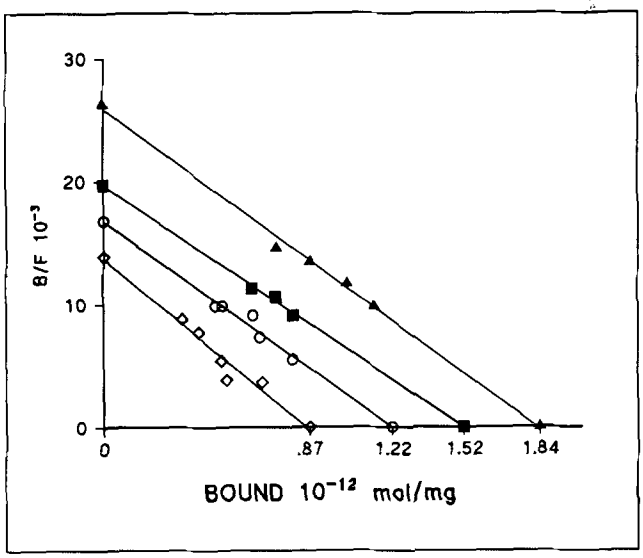

FIG. 4. Scatchard plot analysis of [^{3}H]PAF binding after preincubation with increasing concentrations of PAF:control (▲), PAF 10^{-9} M (■), 10^{-8} M (○), 10^{-7} M (□). The experiments were performed in tris 10 mM, $MgCl_2$ 5 mM, BSA 0.025%, pH 7.

centration-dependently, without significantly changing the affinity. The K_d and B_{max} values obtained are presented in Figure 4. A time-course study with 10^{-6} M PAF revealed that the effect was time-dependent; the apparent B_{max} was decreased by 50% after 15 min and reached a plateau (−70%) after 20 min.

After preincubation with lysoPAF (10^{-6} M), without washing the membranes, the [^{3}H]PAF specific binding to the membranes represented about 80% of that of the control, which suggests that only 20% of the PAF binding sites were occupied. After washing the platelet membranes, 100% of the specific binding was recovered.

Modulation of PAF binding sites by PAF antagonists. When the membranes were not washed after 20-min preincubation with L 652731, BN 52021, WEB 2086, BN 52111 or BN 52115, followed by 90-min incubation at 0°C with [^{3}H]PAF, no significant [^{3}H]PAF specific binding was obtained. Extensive washing of the membranes after preincubation resulted in full recovery of the specific binding when L 652731 was used, partial recoveries (60% and 55%) when BN 52021 and WEB 2086 were used and no recovery when BN 52111 and BN 52115 were used (Fig. 3). Scatchard plot analysis of the binding data indicated that preincubation of the membranes with L 652731 followed by extensive washings did not modify [^{3}H]PAF binding characteristics (Fig. 5A). A significant increase in K_d and decrease in B_{max} were observed for BN 52021 (Fig. 5B), and a significant decrease in K_d value was observed for WEB 2086 (Fig. 5C).

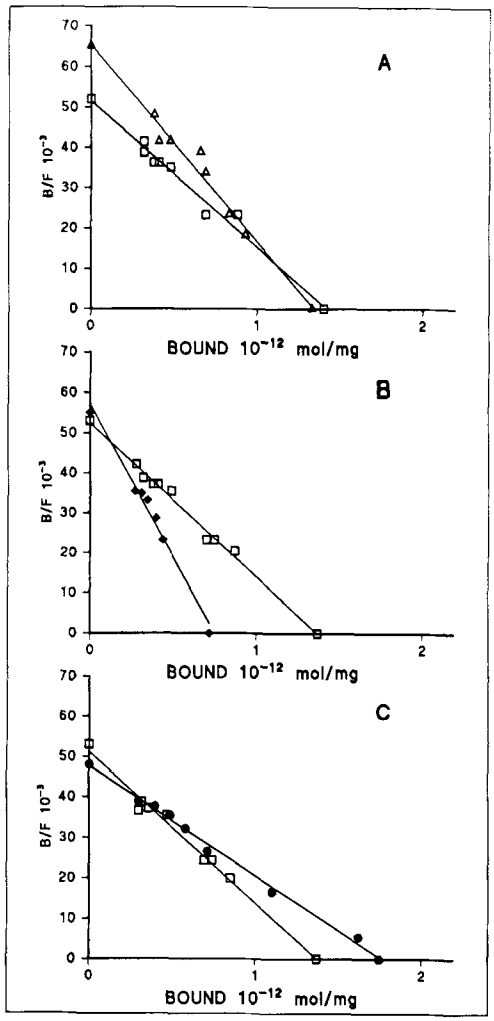

FIG. 5. Scatchard plot analysis of [^{3}H]PAF binding in rabbit platelet membranes after preincubation with A, buffer (□) and L 652731 (△); B, buffer (□) and BN 52021 (◆); C, buffer (□) and WEB 2086 (●).

DISCUSSION

The characteristics of PAF binding to rabbit platelet membranes were studied before and after 20-min preincubation at 25°C in the presence of PAF, lysoPAF or five competitive PAF antagonists. All the binding experiments were performed using frozen membrane preparations (5 days maximum), for which [^{3}H]PAF binding characteristics are well defined.

Preincubation of the membranes with increasing concentrations of PAF followed by extensive washings progressively decreased specific binding. Scatchard plot analysis of the data revealed a concentration-dependent downregulation of PAF binding sites, without significant change in the dissociation constant (K_d). This effect has previously been described in intact human platelets, for which no recovery of the binding was observed after preincubation of the cells with an excess of unlabeled PAF (25,26). In our experiments, 30% of the specific binding was recovered, even at the highest concentration of PAF (10^{-6} M). This discrepancy may be due to our experimental conditions (membrane preparation *vs.* intact cells) or to an easier dissociation of bound [^{3}H]PAF from its recognition sites. Increasing the preincubation time from 20 to 45 min still resulted in 30% recovery in PAF binding.

Preincubation of the membranes with various PAF receptor antagonists revealed profound differences in [^{3}H]-PAF binding. Preincubation with L 652731 followed by extensive washing did not affect [^{3}H]PAF binding capacity, which suggests that the interaction of this antagonist with the PAF receptor site is fully reversible (29).

Under the same conditions, except that L 652731 was replaced by BN 52021, only 60% of the specific binding was recovered. Scatchard plot analysis of the binding data showed that exposure of the membranes to BN 52021 decreased the maximum number of binding sites by 50%, with a slight increase of the affinity of [^{3}H]PAF for the receptor. When plasma membranes were incubated with WEB 2086, the 55% specific binding recovered corresponded to a decrease in the affinity of [^{3}H]PAF for the receptor and to an increase in the maximum number of sites.

When BN 52111 or BN 52115 were used no recovery was observed, suggesting that the interaction of each of these two compounds with PAF binding sites is probably irreversible.

These results may allow us to distinguish three classes of PAF-receptor antagonists—fully reversible, partially reversible and totally irreversible. The interaction of the various antagonists with the PAF receptor appears to be dependent on their chemical structure rather than on their relative affinity for this receptor. The partially reversible and irreversible compounds may bind tightly to the PAF receptor and thus are difficult to wash out; they may also change or regulate, as PAF itself does, the binding characteristics of PAF in platelet membranes. It is also conceivable that the antagonists structurally unrelated to PAF recognize different components of PAF binding.

It is of interest to note that BN 52111 and BN 52115 are structurally related to PAF and exhibit a long lasting effect *in vivo* (30). Indeed, structure-activity relationships have been established demonstrating the necessity for a long alkyl group and for a charge transfer group to express maximal antagonistic and irreversible action (22).

The Origin of Palmitic Acid in Brain of the Developing Rat

B. Noelle Marbois[a], Henry O. Ajie[b], Rose A. Korsak[a], Dilip K. Sensharma[b] and John Edmond[a,*]
[a]Department of Biological Chemistry, UCLA School of Medicine and [b]Department of Chemistry and Biochemistry, The College of Letters and Science, Los Angeles, California 90024

A rat milk substitute containing lower amounts of palmitic and oleic acid in the triacylglycerols in comparison to natural rat milk was fed to artificially reared rat pups from day 7 after birth to day 14. Pups reared by their mother served as controls. Free trideuterated (D_3) palmitic acid [$(C^2H_3)(CH_2)_{14}COOH$, 98 atom % D] and free perdeuterated (D_{31}) palmitic acid [$C_{15}{}^2H_{31}COOH$, 99 atom % D] in equal quantity were mixed into the triacylglycerols of the milk substitute in an amount equal to 100% of the palmitic acid in the triacylglycerols. A control milk substitute contained unlabeled free palmitic acid in an amount equal to 100% of the palmitic acid in the triacylglycerols of the milk substitute. The objective was to determine if palmitic acid in the diet contributed significantly to the palmitic acid content of developing brain and other organs. The methyl esters of the fatty acids were analyzed by gas chromatography and the palmitic acid methyl ester was examined by fast atom bombardment mass spectrometry. The proportion of deuterated methyl palmitate as a percentage of total palmitate was determined; 32% of the palmitic acid in liver and 12% of the palmitic acid in lung were trideuterated and perdeuterated palmitic acid in approximately equal amounts. The brain, by contrast, did not contain the deuterated palmitic acid moiety. Quantitation of palmitic acid and total fatty acids revealed a significant accumulation in organs in the interval from 7 to 14 days of age. Under our experimental conditions, labeled palmitic acid does not enter the brain. Consequently, we conclude that the developing brain produces all required palmitic acid by *de novo* synthesis.
Lipids 27, 587-592 (1992).

Any substance which enters the brain must do so through capillary endothelial cell membranes or pores within these membranes, as adjacent cells possess tight junctions which prevent the passage of high molecular weight substances (1). Lipid soluble substances are assumed to directly penetrate the membranes of the cells marking the blood brain barrier, while lipid insoluble substances such as glucose are assumed to enter *via* specialized pores, utilizing additional transport proteins which have high affinity for such substances (1). Recent evidence also suggests that the glycoprotein coated surface proteins of these cells lend immense negative charges, repelling most particles (2).

Many studies have been carried out to determine the penetration of labeled fatty acids past the blood brain barrier. These studies can be classified into three general types: labeled fatty acids were i) injected into the carotid artery (3); ii) injected into some other body site, for example, the femoral artery (4), the jugular vein (5), the peritoneal cavity (6,7) or the stomach (8); iii) administered orally (9-12). In a recent study, adult rats were fed a diet deficient in essential fatty acids and then fed free octadeuterated arachidonic acid (12). Gas chromatographic/mass spectrometric analyses of fatty acids from their organs showed that 26.6% of the arachidonic acid of brain lipids was in the octadeuterated form (12). This study indicated that deuterium labeled arachidonic acid crosses the blood brain barrier. The present study was designed to determine if the abundant saturated fatty acid, palmitic acid, could gain access to the rapidly growing brain when supplied in the diet.

MATERIALS AND METHODS

Animals. Pregnant Sprague Dawley rats (second or third litter experience) were obtained from Bantin and Kingman (Fremont, CA) at 14 days of gestation and the time of parturition carefully noted. Postnatal day 0 was the calendar day on which the rat pups were born. Litters remained undisturbed until day 5. Animals were selected and artificially reared as described previously (13). The artificially reared rats numbered seven; four were fed deuterium labeled free palmitic acid added to the milk (D-milk) and three were fed a control milk (C-milk) containing unlabeled free palmitic acid in an amount equal to the deuterated free palmitic acid in D-milk.

At 14 days of age artificially reared (AR) and maternally reared (MR) pups were anesthetized with pentobarbital (50 mg/mL) at a dosage of 50 mg/kg body weight. The thorax was dissected open and then blood was taken from the right atrium into a syringe containing 0.1 mL heparin (1000 units/mL). The animal was then perfused slowly through the left ventricle with 30 mL of 38°C phosphate buffered saline containing heparin (5 mL/L) and 1% sodium sulfate (1.0 mL/L). Brain, lung and liver were removed and weighed after the perfusion. The weight of lung tissue varied markedly according to how much saline was trapped in the organ.

Four MR rats were sacrificed by decapitation on day 7 and day 14; MR rat pups killed on day seven were not perfused, as heart tissue was too delicate to withstand perfusion. Brain, liver and lung from these animals were handled as described above.

Rat milk substitute. The basic procedure for the preparation of Rat Milk Substitute (RMS) has been described extensively (13). A protein-rich premilk, which contained minimal fat of mammalian origin, was constituted from a custom prepared casein-rich protein powder (Ross Laboratories, Columbus, OH). The milk fat was constituted from a mixture of four oils of vegetable origin in the ratio 1:1:2:8, by weight, with soy oil: MCT (medium chain triacylglycerol supplied by Mead Johnson, Evansville, IN); safflower oil: MCT (Captex no. 8323, custom prepared (13) by Capital City Products, Janesville, WI) to yield a fat blend low in palmitic and oleic acids as compared to the fat of rat milk. Vitamins, minerals and other constituents

Abbreviations: AR, artificially reared; FAB-MS, fast atom bombardment mass spectrometry; HPLC, high-performance liquid chromatography; MCT, medium-chain triacylglycerol; MR, maternally reared; RMS, rat milk substitute.

were added to yield a milk substitute which closely resembled rat milk in its gross and detailed composition (13). The gross composition of the milk substitute was as follows in g/L, protein 95; carbohydrate 34; fat 122; ash 11.

The rat milk substitute, without added free palmitic acid, contained 310 mg palmitic acid/100 g fat and 524 mg oleic acid/100 g fat. This milk substitute was shown to contain a total triacylglycerol content of 10.7 g/100 g of milk, with palmitic and oleic acids comprising 2.9% and 4.9% of the total fatty acids (Ross Laboratories). An additional 310 mg of deuterium labeled free palmitic acid (Cambridge Isotope Laboratories, Woburn, MA) was added per 100 g of fat to the oil mixture during preparation of the milk substitute (D-milk). Of this 310 mg, 155 mg was trideuterated free palmitic acid (98 atom % D), with the ω methyl being fully deuterated. The other 155 mg was perdeuterated free palmitic acid (99 atom% D). Unlabeled free palmitic acid (310 mg/100 g fat), 99% pure (Sigma Chemical Company, St. Louis, MO), was added to the control milk (C-milk). Other than containing labeled or unlabeled free palmitic acid, the C-milk and D-milk substitutes were identical in composition.

Preparation of fatty acid methyl esters. Organs from 7- and 14-day-old MR and AR rats were saponified overnight in one volume of 30% KOH (w/vol) at 70°C in glass tubes which were sealed with Teflon-lined caps. Fatty acids were extracted as described previously (14) and their methyl esters prepared (15). The derivatized fatty acids were then taken to dryness under N_2 gas and dissolved in 600 μL hexane for gas chromatography or 500 μL methanol for high-performance liquid chromatography (HPLC).

HPLC. Samples of 100–250 μg methyl esters of fatty acids in methanol from each of the organs were applied to an HPLC column equilibrated with HPLC grade, methanol/H_2O (95:5, vol/vol). The column, AXXI-CHROM C-18 (ODS), 5 μm, 4.6 mm i.d., 250 mm long (Cole Scientific Inc., Calabasas, CA) was fitted with a compatible RP-18 "Newguard" precolumn, 3.2 mm × 15 mm (Brownless Labs Inc., Santa Clara, CA) and was operated at 34°C. The HPLC system consisted of the model 110A Altex pump, Rheodyne injection valve with 100 μL injection loop, Hitachi model 100-30 spectrophotometer, Shimadzu model C-RIA Chromatopak and Eldex column temperature control unit (Cole Scientific Inc.). Esters of fatty acids were eluted from the column with methanol/H_2O (95:5, vol/vol) at a flow rate of 0.7 mL per minute and detected at 220 nm. Fractions were collected in solvent rinsed glass vials on an LKB model 2112 Redirac fraction collector (LKB-Produkter, Bromma, Sweden) set at 3 min per vial. The fraction containing palmitate and oleate was collected as a single peak in a single vial, retention time 18 min, and care was taken to ensure that the entire peak was included. These fractions were dried and transferred in hexane to 1 mL borosilicate conical vials ready for analysis by mass spectrometry and capillary gas chromatography to check for the presence of perdeuterated methyl palmitate.

Fast atom bombardment mass spectrometry. A double focusing sector field mass spectrometer (Model MS-9) made by Associated Electrical Industries (Manchester, U.K.) was used for the analysis of all samples. A custom-built FAB gun was retrofitted into the source chamber of this mass spectrometer (Chemical Instrumentation Division, Chemistry Department, UCLA, Los Angeles, CA). In all the analyses, a xenon beam of 5 kvolts energy was used. The FAB target consisted of a stainless steel tip of 2.5 mm diameter. Mass spectral ion signals were processed in real time by a computerized data system interfaced with the mass spectrometer. About 2 microliters of *m*-nitrobenzyl alcohol coated on the tip served as a matrix. The sample to be analyzed was dissolved in hexane. One microliter of this solution was placed onto the probe tip that was already coated with *m*-nitrobenzyl alcohol. Good protonated parent ion signals were detected with samples as low as 2 to 5 picomoles. In experiments to assess limits of detection of labeled palmitic acid in the presence of unlabeled palmitic acid, a range of mixtures of D_0 palmitic acid with D_3 palmitic acid, and D_0 palmitic acid with D_{31} palmitic acid were examined. Trideuterated and perdeuterated palmitic acid were observed at the lowest proportion tested; at 0.02% of D_0 palmitic acid (data not shown).

Absolute ion peak intensity and percent base peak intensity of the protonated parent ion $[M + 1]^+$ were used to quantitate the mixture of trideuterated, perdeuterated and unlabeled palmitates. Standards containing variable quantities of each palmitate were also analyzed to ensure a proper determination of the percentages of each type of palmitate. These mixtures were derivatized and collected by HPLC in a manner identical for the purification of samples from organs.

Gas chromatography. Known aliquots of fatty acids from each tissue were dried prior to methanolysis and a precisely known amount of an internal standard of heptadecanoic acid methyl ester (17:0, 99% pure, AllTech Associates Inc., Deerfield, IL) was added. Amounts added were estimated to be equal to the palmitate content of the sample. Methanolysis then proceeded as previously described for the preparation of samples for HPLC. Standards of fatty acid methyl esters were obtained from Supelco Inc. (Bellefonte, PA) and included palmitate, oleate and linoleate.

The capillary column used was 10% carbowax, 0.5 μm film thickness, 30 m long with an internal diameter of 0.32 mm (Cole Scientific Inc.). A Shimadzu Gas Chromatograph model GC-14A connected to an Axxiom Chromatography Data-System model 727 was used. Helium was used as the carrier gas at 0.6 kg/cm^2 column pressure. Injector temperature was 175°C, FID 200°C, initial oven temperature 140°C for 0.5 min isothermally before the temperature program was introduced. A temperature rate increase of 4°C/min to 190°C and isothermal conditions at 190°C for 5 min were followed by a second temperature rate increase of 3°C/min from 190°C to a final temperature of 223°C. This temperature was maintained isothermally for 15 or 30 min to complete the program, depending upon which tissue samples were analyzed. Profiles for fatty acid methyl esters for brain and liver were obtained in 54 min and for lung in 39 min.

Statistics. Chromatographic analyses of the methyl esters of fatty acids from organs were done a minimum of two times and area percent of peaks and concentrations were calculated for each using the internal standard. Mean and standard error were calculated for the data from brain and liver for palmitate, oleate and linoleate. The percentages of total fatty acids contributed by palmitate, oleate and linoleate were calculated.

Differences between animal groups were analyzed by a

nested mixed model program (16) for analysis of variance, where group (AR and MR) and individual animal contributions to variances were analyzed. This design treated the two groups (AR and MR) as fixed while animals were nested within the groups and treated as random.

Because many comparisons between means were made, a cut off value for significance was set at $P < 0.02$, to decrease the chance of random acceptance of the null hypothesis in error which is possible, with an alpha level of 0.05. All other statistical comparisons were with Student's *t*-test for the difference between means with a significance level of $\alpha = 0.05$.

RESULTS

Weight gain. Animals reared by their mothers or by the artificial rearing system showed no significant differences between the means for weight gain. MR animals were weighed on days 6, 8, 11 and 13. The confidence intervals for AR animals on these days *vs.* those for MR are overlapping and not significantly different by the Student's *t*-test ($\alpha = 0.05$) (data not shown).

Distribution of deuterium labeled palmitic acid. Table 1 shows results which were obtained by fast atom bombardment mass spectrometry for palmitate from organs. Palmitic acid from animals receiving C-milk contained only the nondeuterated form of palmitate, as confirmed by the FAB mass spectrum showing a base peak at *m/z* 271 that corresponds to the protonated molecular ion $[M + 1]^+$ of the methyl ester of nondeuterated palmitate. The mass spectra of palmitate from animals receiving D-milk showed the presence of nondeuterated palmitate as base ion at *m/z* 271 for all samples. Palmitate from liver and lung, however, contained trideuterated (*m/z* 274) and perdeuterated (*m/z* 302) palmitates. The amount of each palmitate as a percentage of total was calculated from their contribution as percent base intensity. Their percentages in liver were 17.5 ± 2.4 and 15.2 ± 2.3 (mean ± SD) of total palmitate, for trideuterated and perdeuterated palmitate, respectively. In lung they amounted to 7.4 ± 1.1% and 5.2 ± 0.5% of total palmitate, respectively. Palmitic acid from brain, by contrast, contained no perdeuterated palmitic acid and showed only a trace of the molecular ion representing trideuterated palmitic acid. The presence of an ion, *m/z* at 274, that is, $[M + 1]^+$, the base ion for trideuterated palmitate, in brain palmitic acid may account for 0.48 ± 0.21% of the total palmitate. However, the ion at M + 1 for trideuterated palmitate can contain a contribution from nondeuterated palmitate (*m/z* at 271, $[M + 1]^+$) at M + 4, an isotopomer of nondeuterated palmitate. This small contribution is confirmed by a comparison with the spectrum of palmitate from brain of control animals (see Table 1, columns 5 and 6).

Palmitate from the D-milk was analyzed by fast atom bombardment-mass spectrometry and the results are presented in Table 2. The amount of deuterated free palmitic acid added to D-milk was based on the palmitic acid content of the triacylglycerol in a milk substitute prepared earlier for analyses by Ross Laboratories. The rat milk substitute for this study was formulated to contain the same nutrient composition. The data presented in Table 2, showing a greater proportion of palmitic acid as deuterated palmitic acid than calculated in the milk substitute, indicate that the amount of natural palmitic acid was lower in the milk prepared for this experiment.

Palmitic acid and total fatty acids in brain and liver. Tables 3 and 4 show the amounts of palmitic acids, total fatty acids and deuterated palmitic acids in brain and liver. There were no significant differences between the groups for palmitic acid and total fatty acids in brain and liver except for an increased amount of total fatty acids in the liver of the AR animals (*P* value <0.03). This difference arose because the livers from AR animals were heavier than livers from control animals (data not shown).

Table 4 shows the mass of deuterium labeled palmitic acid incorporated into brain and liver. Palmitic, oleic and

	M	1.20 (0.6)	2.70 (0.9)	2.90 (1.6)	3.35 (0.6)	0.67 (0.1)	0.00

[a] Animals were fed either D-milk or C-milk and the total fatty acids were obtained from brain, liver and lung. The methyl esters of fatty acids were prepared and purified by HPLC and the palmitate fractions examined by fast atom bombardment mass spectrometry (see Materials and Methods). Data are presented as the mean ± SD. Four animals were fed D-milk and three animals were fed C-milk.

[b] Percent base intensity is obtained from the absolute intensity for a particular ion or ion fragment, expressed as a percentage of the absolute intensity of the ion identified as the base peak.

[c] D_0, D_3 and D_{31} are natural, trideuterated and perdeuterated palmitic acids, respectively. The mass (M) of their methyl esters is 270, 273 and 301, respectively.

TABLE 2

Analyses of Palmitates from D-Milk by FAB-MS[a]

Palmitate	Base intensity (%)[b]			Absolute[c] intensity	Amount of palmitate present as % of total	
	M	M + 1[d]	M + 2	M + 1	By analysis[e]	By weighing[f]
D_0[g]	4.3	100	31.5	2039	42.5	50.3
D_3	6.7	71.9	12.9	1446	30.5	24.7
D_{31}	7.6	64.0	4.8	1304	27.1	25.0

[a] Palmitic acid was isolated from a sample of the milk substitute, purified and prepared for analyses as described in Materials and Methods. The values are averages from quadruplicate analyses.

[b] See Table 1.

[c] The absolute intensity of the base peak $[M + 1]^+$ for each palmitate in the sample, natural, trideuterated and perdeuterated palmitate.

[d] The base peak in the mass spectra of palmitate is at $[M + 1]^+$, because the molecular ion is protonated.

[e] The absolute intensity for $[M + 1]^+$ for each form of palmitate was summed and the contribution by each expressed as a percentage; the values for the amount of each palmitic acid in the milk is the average of the duplicate analyses from one milk sample.

[f] The amounts added by weighing, corrected for purity, as indicated by the supplier, were summed and the contribution by each expressed as a percentage. The mass of natural palmitate already present in the milk was calculated from an analysis provided by Ross Laboratories (Columbus, Ohio).

[g] D_0, D_3 and D_{31} are natural, trideuterated and perdeuterated palmitate, respectively.

TABLE 3

Palmitate and Total Fatty Acids in Brain and Liver[a]

	Palmitate			Total fatty acids		
Group[b]	MR	MR	AR	MR	MR	AR
Age in days	7	14	14	7	14	14
(n)	4	4	7	4	4	7
Brain mg/brain	2.5 ± 0.1	5.6 ± 0.4	5.7 ± 0.5	6.4 ± 0.3	18.6 ± 0.1	18.2 ± 0.6
Liver mg/liver	2.8 ± 0.3	5.5 ± 0.1	5.1 ± 0.7	9.0 ± 0.2	20.2 ± 0.3	26.4 ± 0.6

[a] Fatty acids were extracted from organs of rat pups in the MR group who served as controls and in the AR groups who were fed either unlabeled palmitic acid or the deuterated palmitic acids in the milk substitutes as described in Materials and Methods.

[b] MR groups are the mother reared controls, AR groups are the artificially reared groups. The fatty acids were separated by capillary gas chromatography as described in Materials and Methods. Values are mg per organ and expressed as the mean with standard deviation; (n) shows the number of animals in each group.

TABLE 4

The Amount of Natural and Deuterated Palmitic Acid in Liver and Brain of Animals Fed D-Milk[a]

Palmitate	D_0[b]	D_3	D_{31}
		mg/g wet weight	
Liver	4.00 ± 0.42	0.69 ± 0.13	0.59 ± 0.11
Brain	4.94 ± 0.42	0.03 ± 0.01	0.00

[a] The data are derived from liver and brain of animals fed deuterated palmitic acid (Table 3). Palmitic acid was isolated from organs, purified and prepared for analyses by FAB-MS and capillary gas chromatography as described in Materials and Methods. Values are means with standard deviation and are calculated from the results of the analyses by capillary gas chromatography and the proportion of each as determined by analyses by FAB-MS (Materials and Methods, Tables 1 and 2).

[b] D_0, D_3 and D_{31} are natural, trideuterated and perdeuterated palmitate, respectively.

linoleic acids, as a percent of total fatty acids in rat milk, the rat milk substitute and the brain, liver and lung of MR and AR rats are shown in Table 5. Although the amounts of palmitic and oleic acids in the fat of the milk substitute were reduced by about 88% and 72%, respectively, while linoleic acid was increased by about 225% from the amounts in rat milk, there was no difference in the concentration of these fatty acids in the brains of AR and MR rats. A similar statement cannot be made for the liver and lung of these animals, because, with the exception of oleic acid in lung, the amounts of each of these fatty acids in liver and lung of AR rats were significantly different from the amounts in liver and lung of MR rats (Table 5).

DISCUSSION

There were design aspects to our study which bear highlighting. Our approach takes into consideration the

TABLE 5

Fatty Acids in Milk and Organs[a]

	Milk		Organs					
			Brain		Liver		Lung	
Group	Rat milk[b]	RMS[c]	AR	MR	AR	MR	AR	MR
Fatty acids	Percentage of total fatty acids							
Palmitate	18.4-32.6	2.9	27.9 ± 0.2	26.4 ± 0.4	17.2 ± 0.5[d]	23.6 ± 0.4[d]	32.3 ± 0.7[e]	35.1 ± 0.2[e]
Oleate	15.2-20.4	4.9	12.9 ± 0.2	11.2 ± 0.1	7.1 ± 0.1[f]	5.8 ± 0.2[f]	17.6 ± 0.6	19.8 ± 0.2
Linoleate	6.0-11.4	19.6	1.7 ± 0.1	1.3 ± 0.1	27.6 ± 0.6[g]	16.3 ± 0.3[g]	20.0 ± 0.5[h]	15.3 ± 0.2[h]

[a]Fatty acids were isolated from the rat milk substitute and organs, purified and prepared for analyses by capillary gas chromatography as described in Materials and Methods. The data are from animals whose organs were analyzed for their fatty acid content as shown in Tables 1 and 3. Superscripts d-h, for liver and lung, values with the same superscript letter for a particular fatty acid are significantly different, $P < 0.02$, see section on statistics (Materials and Methods).

[b]Percentages taken from ref. 13.

[c]Percentages taken from the analysis of the rat milk substitute by Ross Laboratories (Columbus, OH). The number of animals in each group is given in Table 3. Values are mean ± SEM.

concern expressed by Pardridge and Mietus (3) that lipids such as cholesterol or palmitate should be presented to the blood brain barrier as a component of normal circulating lipids at this interface, otherwise the outcome may be artifactual. In our study, deuterated free palmitic acid from the milk was subjected to normal digestion, absorption and intestinal processing and transport, and was presented within the natural milieu of the various circulating lipoproteins to the cellular interface of organs such as liver, lung and brain. It was shown by studies on humans that deuterium labeled fatty acids were freely absorbed and transported (17-20). The seven-day exposure of the organs to deuterated palmitic acid, in our study, was long enough to allow for extensive equilibration of deuterated palmitic acid into accessible compartments. It was considered important to perfuse the animals to decrease the possibility of contamination from label carried by blood and trapped within organs before organs were removed. There is the possibility however, that label within the cells of the capillary network permeating the brain and other organs is a source of contamination; the capillary endothelial cellular network was included with brain when brain lipids were extracted, yet it is considered to be extra cerebral tissue. A final highlight is that the mass spectrometry technique of fast atom bombardment finds selectively and unambiguously the stable isotopic form of the substance which is fed and is to be quantitated.

Blood brain barrier. Mead and associates (4,10,21) performed many experiments to determine if brain incorporated palmitic acid directly. Their conclusion that labeled palmitic acid, injected intraperitoneally or administered orally, became incorporated into brain lipids was developed from analysis of the percent of radioactivity present in the carboxyl carbon, *vs.* other carbons within the fatty acyl chain of brain palmitic acid. Since the palmitic acid in brain acquired and retained a higher carboxyl radioactivity, it seemed that much of it was probably incorporated unchanged (4,21). Theoretically, if palmitic acid was formed in brain by *de novo* synthesis there would be a random distribution of radioactivity within the carbon chain from uptake of radioactive acetate transported to brain after β-oxidation of radioactive palmitic acid in extra neural organs such as the liver. Earlier, it was observed that there was a relative carboxyl activity of 20.7% for the carboxyl carbon of palmitic acid in brain from weanling rats after the injection of labeled acetate (10). Since palmitic acid is made up of eight "acetyl-units," the expected relative carboxyl activity should be 12.5%. This difference suggests that the carboxyl terminus of palmitic acid, when synthesized from radioactive acetate, exchanges more rapidly than the other labeled two carbon units within the hydrocarbon chain. Thus it is not feasible to distinguish with certainty, the proportion of the palmitic acid which is unchanged [1-^{14}C]palmitic acid as fed and palmitic acid which has been preferentially labeled on the carboxy-terminus through an exchange with the radioactive acetate pool.

Other investigators studying uptake of radioactive palmitic acid into brain have found varying levels of oxidation products. In a study in which the oxidation of [1-^{14}C]palmitic acid and other metabolites was compared in various brain areas, little incorporation of label into amino acids associated with the Krebs cycle was observed (6). Another study using filtered whole blood containing albumin bound [U-^{14}C]palmitic acid showed a quantitative oxidation of palmitic acid to $^{14}CO_2$ of only 2.8% (22). It was suggested this small amount of oxidation could be occurring in extra cerebral tissues (22). A brief survey of the relevant literature revealed many investigations which showed that varying amounts of radioactively labeled palmitic acid can access brain (3,4,6,8,10,21).

The only previous study in which a deuterium labeled saturated fatty acid was used in a study of transport across the blood brain barrier was done more than fifty years ago (9). In this study the unsaturated fatty acids in linseed oil were hydrogenated with deuterium. The treatment yields a fat containing about 90 percent deuterated stearic acid with either 2, 4 or 6 deuterium atoms from the oleic, linoleic and linolenic acids respectively. The fat was fed to adult male rats by stomach tube; then brain, liver, intestine and the remaining carcasses were examined for their content of deuterium labeled fatty acids. A very low uptake of deuterium labeled fatty acid into brain and a large deposition into liver and other organs were observed (9). Waelsch and associates (9,23,24) concluded that

"the brain synthesizes the fatty acids it needs, wholly or in large part, and does not depend on an external source of supply."

Perdeuterated and deuterated substances are known to have access to the brain (25–29) and have been used to study the half lives of rapidly metabolized drugs, because they are not degraded as quickly as the unlabeled forms (26–29). During the seven-day period of our study, a large net increase in fatty acids and palmitic acid occurred in the liver and to a greater extent in brain. In addition, the effect of an altered fatty acid composition in the fat of the milk substitute as compared to maternal milk, had a profound influence on the content of palmitic, oleic and linoleic acids in liver and in lung. By contrast, the concentration of these fatty acids was not altered in the brain.

Our study shows under the experimental conditions which prevailed an absolute exclusion of perdeuterated palmitic acid from brain tissue. Although it is possible that a very small amount of trideuterated palmitic acid may have been trapped in the brain capillary endothelial cell network, it is clear from our study that trideuterated palmitic acid does not access the brain. By contrast, octadeuterated arachidonic acid does access the adult brain to accumulate in significant amounts (12). It is logical to suggest that unsaturated fatty acids which can be produced from palmitic and stearic acid may also be biosynthesized in brain to meet its needs, consequently, we speculate that a selective transport system across the blood brain barrier may exist for the essential fatty acids. We conclude that the brain synthesizes *de novo* all the palmitic acid it requires.

ACKNOWLEDGMENTS

We thank Chris Rhodes, Ph.D., for advice on HPLC and methyl ester preparation procedures and Scott Komo, statistician, Mental Retardation Research Center, UCLA, for his help with the statistical analyses. We thank Ross Laboratories, Columbus, Ohio for the analyses of the composition of the fat in the rat milk substitute and for their interest in our study. This study was supported by United States Public Health Service Awards HD 11496 and HD 06576, which are gratefully acknowledged.

[Received February 17, 1992; Revision accepted June 1, 1992]

Arachidonic Acid Biosynthesis in Non-Stimulated and Adrenocorticotropin-Stimulated Sertoli and Leydig Cells

Graciela E. Hurtado de Catalfo[1], Elisabet C. Mandon[1] and Irma N.T. de Gómez Dumm[1,*]
Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Médicas, 1900-La Plata, Argentina

The biosynthesis of arachidonic acid in Sertoli and Leydig cells isolated from the testes of mature rats has been investigated. Both types of cells incorporated [2-^{14}C]eicosatrienoic acid from the incubation medium and transformed it into arachidonic acid. The administration of adrenocorticotropin (ACTH) to the rats decreased the Δ5 desaturating activity in the isolated testicular cells, while ACTH produced no changes in the uptake of the substrate. Similar results were obtained when ACTH was added to the incubation medium of cells isolated from non-hormone treated rats. The total fatty acid composition of the Sertoli cells isolated from ACTH-treated rats showed a significant increase in the relative percentage of 18:2n-6 and a decrease in the C_{20} and C_{22} polyenes. This may indicate that ACTH exerts an inhibitory effect on Δ6, Δ5 and Δ4 desaturase activities. Addition of corticosterone to the incubation medium also produced a significant decrease in arachidonic acid biosynthesis. Because ACTH is known to stimulate the release of corticosterone *in vivo*, both hormones may act cumulatively in the regulation of arachidonic acid metabolism in Sertoli and Leydig cells.
***Lipids* 27, 593–598 (1992).**

Polyenoic acids derived from linoleic or α-linolenic acids are important components of testicular tissue. Rat testes contain relatively large amounts of polyunsaturated fatty acids (PUFA), mainly arachidonic and docosa-4,7,10,13,16-pentaenoic acids (1–3). The distribution of these fatty acids among the different cell types of the testes is not uniform. Thus, rat spermatids contain much more docosa-4,7,10,13,16-pentaenoic acid (22:5n-6) than do spermatocytes (4). Sertoli cells contain much lower levels of 22:5n-6 (5), and Leydig cells contain only very small amounts (6).

The pathways of polyunsaturated fatty acid biosynthesis have been studied rather extensively in whole testes and in mixtures of various testicular cells. These studies have generally shown that the main route of polyenoic fatty acid biosynthesis follows an alternating sequence of desaturation and elongation reactions, the former of which are thought to be catalyzed by fatty acid desaturases (7–9). The conversion of linoleate to arachidonate by rat Sertoli cells in primary cultures was more recently reported by Coniglio and Sharp (10). Studies carried out with subcellular fractions of whole testes demonstrated the presence of a microsomal Δ6 desaturase that converts linoleic acid to γ-linoleic acid, and a microsomal Δ5 desaturase which synthesizes arachidonic acid (20:4n-6) from eicosa-8,11,14-trienoic acid (20:3n-6) (11,12).

There is substantial evidence that fatty acid composition plays an important role in the normal differentiation of germinal cells. During sexual maturation, the testes accumulate large quantities of 22-carbon polyenes (13,14). Their levels decrease significantly when spermatogenesis is impaired (14). Moreover, in adult rats polyunsaturated fatty acid biosynthesis is markedly affected by nutritional and hormonal deficiencies (15,16).

The control of testicular function is a multihormonal process that requires the functional integrity of the hypophysis and eventual hormonal stimulation of the seminiferous tubules by Leydig cell-derived testosterone. Hypophysectomy is followed by a regression of the germinal epithelium (17) with a concomitant decrease in acyl-CoA synthetase activity (18). The administration to rats of the hypophyseal hormone adrenocorticotropin (ACTH), whose primary target organ is the adrenal gland, depresses acyl-CoA synthetase activity in adrenal and in adipose tissues (19,20), and inhibits PUFA biosynthesis in liver and in isolated adrenocortical cells (21). ACTH-secreting tumors, chronic stress accompanied by ACTH hypersecretion and prolonged administration of ACTH have been shown to produce a decrease in serum testosterone levels (22–25). The presence of pro-opiomelanocortin-derived peptides, particularly ACTH, has been demonstrated in testicular tissues. These hypophysis-derived peptides are probably responsible for the increases in cyclic adenosine monophosphate (cAMP) observed in Sertoli (26) and Leydig cells (27).

The steroidogenic capacity of Leydig cells is essential for sustaining spermatogenesis; however, this function can be modulated by Sertoli cell-secreted factors (28). Sertoli cells are also involved in the maintenance and nutrition of the germinal cells (29).

Considering that polyunsaturated fatty acid biosynthesis has been mainly studied in whole testes, that individual testicular cells are highly specialized, and that each type is essential for completion of spermatogenesis, the experiments reported here have two major objectives: (i) To demonstrate the ability of isolated Sertoli and Leydig cells to synthesize arachidonic acid; and (ii) to investigate the participation of the pituitary-adrenal axis in the biosynthesis of arachidonic acid in the isolated cells.

MATERIALS AND METHODS

[2-^{14}C]Eicosa-8,11,14-trienoic acid (47.7 mCi/mmol, 98% radiochemically pure) was purchased from Amersham International (Amersham, U.K.). Unlabeled eicosa-8,11,14-trienoic acid was supplied by Nu-Chek Prep (Elysian, MN). Bovine serum albumin (essentially free of fatty acids), trypsin, DNAse type I and diBucAMP were purchased from Sigma Chemical Co. (St. Louis, MO). Collagenase was obtained from Worthington Biochemical Corp. (Freehold, NJ). ACTH was from Elea Laboratories

(Buenos Aires, Argentina). All other chemicals used were of analytical grade.

Animals and experimental design. The adult male Wistar rats used (300–350 g body weight) were maintained in a temperature-controlled environment at 24 ± 1°C and subjected to a daily 12-h light/12-h dark cycle, with midnight being the midpoint in the dark period. The animals were housed in cages with free access to water and chow pellets (Cargill, type C). The rats were fasted for 24 h, then refed with the commercial diet for 2 h, and killed 12 h after the refeeding period.

Three series of experiments were performed using isolated Sertoli and Leydig cells. First, the ability of cells to incorporate eicosa-8,11,14-trienoic acid from the medium into cellular lipids and to transform it to arachidonic acid was examined with cells from four control (*i.e.*, non-hormone treated) rats. Second, the same parameters were measured in isolated cells after the administration of a single dose of ACTH to four rats. The ACTH was injected intraperitoneally at a dose of 4.5 IU per rat 30 min before sacrifice. The control group (also four rats) received saline solution instead of the hormone at the same time point. Third, we studied the effect of ACTH (250 μIU/per flask), diBucAMP (0.5 mM) and corticosterone (0.8 μM), which were added to the incubation medium, on 20:3n-6 uptake and its conversion to 20:4n-6 in cells isolated from four untreated rats. Corticosterone was initially dissolved in ethanol and then added to the incubation medium; the final ethanol concentration was 0.01% (vol/vol). The same concentration of ethanol was present in the medium of control cells.

Isolation of testicular cells. Rats were killed by decapitation with minimal handling. Testes were immediately removed, decapsulated and weighed.

Separation of dispersed Leydig cells. Leydig cells were isolated after mechanical shaking with collagenase in 25-mL flasks (Falcon, Division of Beckton Dickinson Co., Oxnard, CA) according to the procedure of Suescun *et al.* (30). Decapsulated testes were treated with collagenase (0.3 mg/mL) at a ratio of 1 mg/g of tissue using a metabolic incubator at 34°C for 10 min with gentle, constant shaking. The incubation was stopped by dilution with cold medium. The supernatant was filtered through a double layer of nylon mesh and centrifuged at 800 × *g* for 10 min, after which the pellet was resuspended in 5 mL of medium. Cell viability, as judged by trypan blue exclusion (31), was 85–90%. After counting the cells in a hemocytometer, cell concentrations was adjusted to 10^6cell/mL. The entire procedure for the isolation of Leydig cells took 50 min.

To perform incubations in a medium as simple as possible, Medium 199, the original medium described by Suescun *et al.* (30) was replaced with Krebs Ringer bicarbonate glucose (KRBG 0.1%), albumin (0.1%), pH 7.4, in all experiments.

Preparation of Sertoli cells. The remaining collagenase-treated testicular tissue was chopped at right angles and used for isolating Sertoli cell aggregates following treatment with trypsin and collagenase, as described by Dorrington *et al.* (32). The testis fragments were treated with a solution containing (per g of testis) 25 mL of 0.25% trypsin in KRBG-1% DNAse medium (Buffer A). After 20 min of incubation at 34°C in a metabolic shaker (80 oscillations/min), the dispersed material was passed through a double layer of nylon mesh to remove undigested testicular remnants. The filtrate was centrifuged at 2000 × *g* for 5 min, and the supernatant was discarded. In order to inhibit trypsin activity, the sediment was washed twice with 25 mL of Swim's S-77 medium with 10% calf serum and twice with the same volume of Buffer A. The sediment was then resuspended in 20 mL of 0.05% collagenase (prepared in Buffer A) per g of initial tissue weight and incubated at 34°C for 20 min, followed by low-speed centrifugation (2000 × *g*) for 5 min. The pellet was washed twice with KRBG, and the Sertoli cell aggregates finally obtained were resuspended in 5 mL of KRBG. The entire procedure for the preparation of Sertoli cells took approximately one hour. Sertoli cells were examined for viability (85–90%), counted as described for the Leydig cells, and immediately used. The recovery of Leydig and Sertoli cells was about 5–7 × 10^6 cells per testis.

Cytologic studies. A drop of approximately 2 μL from a pellet of either Sertoli or Leydig cell preparations was placed on slides. The drop was spread over the slide, allowed to dry until the visible liquid evaporated, and then immediately fixed in Bouins for 1 h. The smears were stained with hematoxylin-eosin, dehydrated and mounted.

Cells were counted under a light microscope, using a grid of 8 × 8 mm that was placed in the eye-piece, at a magnification of 100 times. The results showed that the Leydig cell preparation consisted of 79% Leydig cells and of 21% spermatids, spermatocytes and small cytoplasmic fragments. The Sertoli cell preparation consisted of 80% Sertoli cells and 20% spermatocytes and small cytoplasmic fragments.

Incubation procedure. Aliquots of isolated cell suspensions (10^6 cells per tube) were incubated in a final volume of 3 mL of KRBG in siliconized glassware in a metabolic shaker (80 oscillations/min) at 34°C under an atmosphere of 95% O_2/5% CO_2 for various time periods. In the first series of experiments, the cells were incubated for 3 h with a mixture of 10 nmoles of [2-^{14}C]eicosa-8,11,14-trienoic acid and increasing amounts of unlabeled eicosa-8,11,14-trienoic acid up to a concentration of 40 μM, or with eicosa-8,11,14-trienoic acid at a concentration of 15 μM (10 nmoles of the labeled acid and 35 nmoles of the unlabeled acid) for 30 to 180 min. In all experiments the acid was added as its sodium salt bound to defatted albumin according to Spector *et al.* (33).

In the second series of experiments, both types of cells were incubated for 180 min in the presence of the substrate at a concentration of 15 μM. In the third series of experiments, Leydig cells, as well as aggregated Sertoli cells, were preincubated in the presence or absence of either ACTH, dibutyryl cAMP (diBucAMP), corticosterone or the alcoholic vehicle for 30 min. At the end of this period, 15 μM of eicosa-8,11,14-trienoic acid was added to the medium and the cells were incubated for 3 h under the conditions established in the first series of assays.

Analytical methods. At the end of the incubation periods, suspended cells were collected into cold tubes and rapidly centrifuged. The cell pellets were washed twice with cold KRBG solution and resuspended in a final volume of 5 mL. An aliquot of the suspension was used to determine the viability of the cells and the amount of cellular protein (34). The viability remained constant up to the end of the incubation period. The rest of the cell suspension was centrifuged at 2000 × *g* for 5 min. The cells were saponified at 85°C with 2 mL 10% KOH in

ethanol plus 0.5 mL methanol for 45 min. After acidification of the solution, the fatty acids were extracted with light petroleum hydrocarbon (b.p. 30–40°C) and esterified with methanolic 3N HCl for 3 h at 68°C. An aliquot of the medium (1.5 mL) was treated identically to obtain the fatty acid methyl esters.

The radioactivity of the recovered methyl esters was determined in a Beckman liquid scintillation counter (Model L5-3133 P, Fullerton, CA) with 96.7% efficiency for ^{14}C. The distribution of radioactivity among the fatty acids was determined in a gas-liquid radiochromatograph equipped with a Panax proportional counter and a Suroscribe 2S recorder (Panax Equipment Ltd., Redhill, Surrey, England). The column was packed with 10% SP-2330 coated on Chromosorb WAW-DMCS (100–200 mesh; Supelco, Bellefonte, PA). Percentage conversion was calculated from the distribution of radioactivity between substrate and products measured directly on the radiochromatogram. The composition of fatty acid methyl esters was determined by gas-liquid chromatography using a Hewlett-Packard chromatograph (model 5840 A, Palo Alto, CA) equipped with a flame ionization detector. The column was packed as described for radiochromatography. The oven temperature was programmed from 140 to 220°C at 3°C/min to separate methyl esters ranging from 12 to 22 carbon fatty acids. Retention time and peak areas were determined electronically using a Hewlett-Packard Recording Integrator. Identification of methyl esters was by comparison with known methyl ester standards. All results were tested for statistical significance by Student's *t*-test compared with the respective controls.

RESULTS

Incorporation and conversion of [2-^{14}C]eicosa-8,11,14-trienoic acid into arachidonic acid in Sertoli and Leydig cells. Figure 1 shows how increasing concentrations of the substrate modified the steady-state level of incorporation of labeled eicosatrienoic acid and its subsequent transformation into arachidonic acid by Sertoli (panel A) and Leydig (panel B) cells. Precursor acid was taken up by both types of cells. The amount of label incorporated after 3 h incubation followed a hyperbolic curve that became saturated at approximately 15 μM. The uptake of 20:3n-6 by the Leydig cells increased progressively up to 7.5 μM substrate. A similar pattern was obtained for Sertoli cells when the substrate concentration reached 5 μM. After this point the rate of incorporation increased more slowly, and at the highest concentrations of substrate studied (40 μM), the amount of fatty acid incorporated was similar in both cell types.

Arachidonic acid was not further elongated and/or desaturated as indicated by the absence of significant amounts of label in total cellular higher PUFA methyl esters. In all experiments, the only labeled acid found in the incubation medium was 20:3n-6, indicating that the arachidonic acid formed in the cells was fully integrated into complex membrane lipids. Approximately 15% of the eicosatrienoic acid incorporated was transformed into arachidonic acid. The amount of 20:4n-6 formed by Leydig cells was nearly twice that synthesized by Sertoli cells.

The time curves of incorporation and desaturation of eicosatrienoic acid by Sertoli and Leydig cells incubated with 15 μM substrate are shown in Figure 1 (panels C and D). In both types of cells, 20:3n-6 was rapidly incorporated

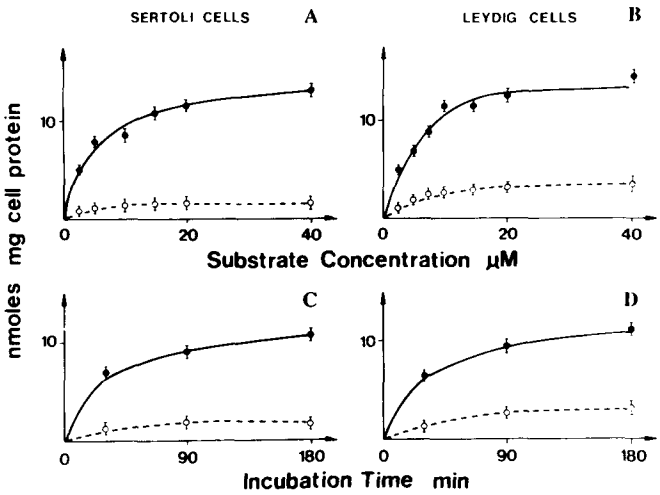

FIG. 1. Incorporation of [2-^{14}C]eicosa-8,11,14-trienoic acid (closed circles) and desaturation to arachidonic acid (open circles), as a function of substrate concentration (upper panel) and incubation time (lower panel) in Sertoli (left) and Leydig (right) cells isolated from control rats. Values are the mean ± SEM of four incubations. The incubation time used in the upper panel (A and B) was 180 min, while the concentration of the substrate added in the experiments showed in the lower panel (C and D) was 15 μM. Other incubation conditions are described in the Materials and Methods section.

during the initial 30 min of incubation. The incorporation reached a plateau soon thereafter. In Sertoli and Leydig cells, eicosatrienoic acid was partially converted into arachidonic acid, about 15% and 25% respectively; the values remained constant after 30 min of incubation.

Effect of in vivo *administration of ACTH on the incorporation and desaturation of [2-^{14}C]eicosa-8,11,14-trienoic acid into arachidonic acid in isolated Sertoli and Leydig cells.* Incorporation of labeled 20:3n-6 into the Sertoli or Leydig cells isolated from ACTH-treated rats was similar to that seen in the same cell types isolated from non-hormonally-treated animals (Fig. 2). By contrast, the transformation of 20:3n-6 into 20:4n-6 was decreased by 48% and 40%, respectively, in Sertoli and Leydig cells after prior treatment of the animals with ACTH.

Effect of addition of ACTH and diBucAMP to the incubation medium of isolated Sertoli and Leydig cells obtained from untreated rats. To test whether the inhibitory effect of ACTH on the biosynthesis of arachidonic acid also was produced in cells isolated from untreated rats, the hormone was added to the incubation medium. Figure 3 shows the incorporation and desaturation of [2-^{14}C]-eicosa-8,11,14-trienoic acid in the isolated cells 210 min after the addition of ACTH to the medium. We also tested the effect of addition of diBucAMP to the incubation medium under the same conditions. Neither the hormone nor the cyclic nucleotide modified the incorporation of eicosatrienoic acid into either cell type. However, both agents caused a significant decrease in arachidonic acid biosynthesis in both Sertoli and Leydig cells as compared with replicate cells incubated in the absence of ACTH and diBucAMP (Fig. 3).

Effect of addition of corticosterone to the incubation medium of Sertoli and Leydig cells isolated from untreated rats. Figure 4 shows the effect of the hormone or its vehicle on the incorporation and transformation of

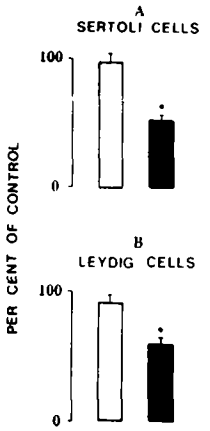

FIG. 2. Effect of ACTH administered to intact rats on the incorporation (open columns) and desaturation (filled columns) of [2-^{14}C]eicosa-8,11,14-trienoic acid in Sertoli (panel A) and Leydig (panel B) cells after 3 h of incubation. One hundred percent corresponds to control values: 10.02 ± 0.015 nmol/mg protein incorporated and 2.006 ± 0.102 nmol/mg protein desaturated by Sertoli cells (A); and 15.22 ± 0.63 nmol/mg protein incorporated and 2.292 ± 0.150 nmol/mg protein desaturated by Leydig cells (B). The incubation conditions were as described in the Materials and Methods section. Values are the mean of four incubations ± SEM. Asterisk represents significant difference relative to the respective control $P < 0.001$.

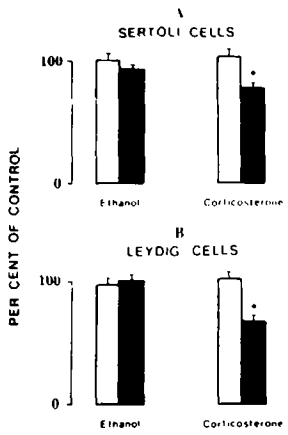

FIG. 4. Effect of the addition of corticosterone or its vehicle to the incubation medium on the incorporation (open columns) and desaturation (filled columns) of [2-^{14}C]eicosa-8,11,14-trienoic acid in isolated Sertoli (A) and Leydig (B) cells obtained from untreated rats. One hundred percent corresponds to 10.94 ± 0.30 nmol/mg protein incorporated and 2.189 ± 0.053 nmol/mg protein desaturated by Sertoli (A); and 10.39 ± 0.16 nmol/mg protein incorporated and 2.145 ± 0.195 nmol/mg protein desaturated by Leydig (B) cells. The incubation conditions were as described in the Materials and Methods section. Values are the mean of four incubations ± SEM. Asterisk indicates a significant difference from the respective controls $P < 0.01$.

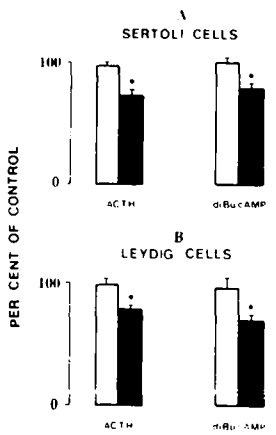

FIG. 3. Effect of addition of ACTH (250 μ IU/per flask) and diBucAMP (0.5 mM) to the incubation medium on the incorporation (open columns) and desaturation (filled columns) of [2-^{14}C]eicosa-8,11,14-trienoic acid in Sertoli (panel A) and Leydig (panel B) cells obtained from untreated rats. One hundred percent corresponds to 10.48 ± 0.020 nmol/mg protein incorporated and 2.094 ± 0.076 nmol/mg protein desaturated by Sertoli cells (A); and 13.08 ± 0.27 nmol/mg protein incorporated and 2.207 ± 0.172 nmol/mg protein desaturated by Leydig cells (B). The incubation conditions were described in the Materials and Methods section. Values are the mean of four incubations ± SEM. Asterisk indicates a significant difference from the respective controls $P < 0.01$.

[2-^{14}C]eicosa-8,11,14-trienoic acid in Sertoli (Fig. 4A) and Leydig (Fig. 4B) cells after 210 min of incubation. Corticosterone inhibited the production of arachidonic acid by both types of cells in the absence of any change in substrate incorporation. Ethanol modified neither the incorporation nor the transformation of eicosatrienoic acid (Fig. 4).

Effect of ACTH on the fatty acid composition of total lipids in Sertoli and Leydig cells. The relative percentages of total fatty acids of Sertoli cells obtained from untreated rats either not incubated or incubated for 3 h in the presence of 20:3n-6 are shown in Table 1. In the untreated cells, the major components in the non-essential fatty acid series were 16:0 and 18:1 (approximately 20%), while in the essential fatty acid series 22:5n-6 and 20:4n-6 were most abundant. After 3 h of incubation in the presence of the labeled precursors the only significant difference observed was a small increase in 20:3n-6.

ACTH treatment of the rats produced significant changes in the fatty acid composition of the Sertoli cells when compared to cells obtained from untreated animals. The relative abundance of 16:1 and 18:2n-6 increased, while the proportions of 20:4n-6, 22:5n-6, 22:5n-3 and 22:6n-3 decreased markedly. In contrast, addition of ACTH, corticosterone or diBucAMP *in vitro* produced no significant differences in the total fatty acid composition when compared to cells incubated in the absence of either the hormones or the nucleotide. No significant changes in the total amount of fatty acids were observed among the different groups. The values for the control rats were 23.1 ± 0.8 μg/10^6 cells.

The total fatty acid profile of the non-incubated Leydig cells indicated that 16:0, 18:0, 18:1 and 20:4n-6 acids were the major components, while the percentage of 22:5n-6 was approximately 2-3%. The results agree with those published (6) and, thus, are not shown here. Although 3 h of incubation produced a small, though significant, increase in 20:3n-6, the other fatty acids remained unchanged.

The administration of ACTH to the rats and the addition of ACTH or diBucAMP to the incubation medium did not produce significant changes in the amount or composition of total fatty acids of Leydig cells. The total

amount of fatty acids in the control group was 23.9 ± 1.1 $\mu g/10^6$ cells. For this reason, the results are not reported here.

DISCUSSION

The testis is a steroidogenic tissue which consists of a heterogeneous population of cell types. Most previous studies on the biosynthesis of polyunsaturated fatty acids in testis were done without accounting for the metabolic peculiarities of the individual cell types. In the present studies we have used isolated cells, because they are valuable models in which environmental conditions can be controlled more rigidly and complex interactions between the cells can be minimized. The synthesis of arachidonate from linoleate has previously been documented in primary cultures of Sertoli cells from young rats in which both Δ6 and Δ5 desaturating activities work in concert (10). Our experiments have further characterized the desaturase activity of these cells and of Leydig cells by demonstrating the conversion of eicosa-8,11,14-trienoic acid to arachidonate. Hence, an active complex of Δ5 desaturase appears to be operative in both cell types. The Δ5 desaturase activity in the testicular cells differs from that in liver and in other steroidogenic tissues, such as the adrenal gland (35). The amount of 20:3n-6 transformed into 20:4n-6 is higher in adrenocortical cells (35) than in Sertoli or Leydig cells (Fig. 1). Adrenocortical cells transformed 50% of the fatty acid that was incorporated into arachidonate, while in testicular cells the percentage was less than 20%. The amount of 20:3n-6 incorporated in both types of testicular cells was reflected in a significant increase in the relative percentage of 20:3n-6, as is apparent in the fatty acid profile (Table 1). Considering that these cell types have high levels of arachidonic acid and that the amount of 20:3n-6 that was further desaturated was about 20% of that incorporated, an increase in the relative percentage of 20:4n-6 was not expected after only 3 h of incubation. Such observations are consistent with a relatively sluggish Δ5 desaturase activity in the two cell types. Under similar experimental conditions, either hepatocytes or adrenocortical cells showed both a lesser increase in eicosatrienoic acid incorporation and a more pronounced enhancement in arachidonic acid synthesis when compared to the isolated testicular cells (see Fig. 1, this paper; also Fig. 1, ref. 35, and Figs. 1 and 3, ref. 36). In all these separate studies with cell cultures from the three tissues, the radioactive precursor was the same fatty acid (*i.e.*, 20:3n-6). Therefore, differences in arachidonic acid formation appear to be due to a more pronounced Δ5 desaturase activity in the adrenal and liver than in the testicular cells.

PUFA biosynthesis is regulated by the hypophysis through the production of ACTH. This was previously demonstrated in various tissues, including the liver and the adrenal gland (21). The results obtained in this work showed that ACTH also diminishes the biosynthesis of arachidonic acid in Sertoli and Leydig cells (Figs. 2 and 3). This effect was apparent when rats were treated with ACTH, or when the hormone was added to the incubation medium of the isolated testicular cells. The inhibition produced by the hormone *in vivo*, however, was greater than that evoked in isolated cells. The *in vivo* effect was reflected accordingly in the fatty acid composition of Sertoli cells. In order to more accurately assess the activity of the arachidonate-synthetic pathway, we analyzed the 20:4/18:2 ratio in these cells and found a 50% decrease in the cells isolated from the hormone-treated rats. In hepatocytes and adrenal cells, ACTH produced an inhibition in both Δ6 and Δ5 desaturating activities (21). The inhibition of the former also can be inferred from the fatty acid composition; we found an accumulation of 18:2n-6 and a diminution in the amount of 20:3n-6 (Table 1) after hormone treatment. Control Sertoli cells before incubation contained 1.4% 20:3n-6. After 3 h of incubation, the relative percentage of 20:3n-6 increased to 3.1%, but was decreased by 16% when Sertoli cells were isolated from ACTH-treated rats. Since this decrease occurred even when the precursor 18:2n-6 accumulated after hormonal intervention, the depression observed in the level of 20:3n-6 *in vivo* must depend on a lesser conversion of 18:2n-6 to 18:3n-6 in addition to diminution in 20:3n-6 desaturation that we measured directly. Moreover, the low

percentages observed in 22:5n-3 and 22:6n-3 also are an indirect indication of a depression in Δ4 desaturase activity. Similar results were obtained when the effect of ACTH on the production of higher homologs formed from α-linolenic acid was studied in adrenocortical cells (37).

In contrast to Sertoli cells, the total fatty acid composition of Leydig cells showed no significant changes after either *in vivo* or *in vitro* exposure to the hormone in spite of the significant depression observed in Δ5 desaturation activity (Figs. 2 and 3).

The most common signal-transducing system mediating ACTH stimulation involves cAMP. In the present work, we have shown that the addition of diBucAMP to the incubation medium of Sertoli and Leydig cells mimicked the inhibition produced by ACTH on the formation of arachidonic acid (Fig. 3). This may indicate that cAMP could well be a second messenger for the action of ACTH on polyunsaturated fatty acid biosynthesis in testicular cells. The inhibition produced by either ACTH or diBucAMP *in vitro* was smaller than that evoked when the hormone was injected directly into the rats. This quantitative discrepancy may imply that at least one other effector participates in the depression of Δ5 desaturation.

Glucocorticoids directly inhibit the biosynthesis of arachidonic acid in several tissues (21,38,39). On the other hand, it is well-known that ACTH increases the plasma levels of corticosterone several-fold. This hormone, in turn, could potentiate the *in vivo* effect of ACTH on Δ5 desaturating activity. We found that the addition of corticosterone to the incubation medium blocked the biosynthesis of arachidonic acid in both Sertoli and Leydig cells (Fig. 4). We thus conclude that the higher inhibition of polyunsaturated fatty acid biosynthesis observed after *in vivo* treatment with ACTH may arise, at least in part, from a concerted effect of both hormones.

[Received August 27, 1990; Revision accepted April 4, 1992]

Glucocorticoid and Mineralocorticoid Hormones Depress Liver Δ5 Desaturase Activity Through Different Mechanisms

María J.T. de Alaniz[1] and **Carlos Alberto Marra**[1,*]

Instituto de Investigaciones Bioquímica de La Plata (INIBIOLP), Facultad de Ciencias Médicas, Universidad Nacional de La Plata, 1900-La Plata, Argentina

The effects of 11-deoxycorticosterone and aldosterone on liver Δ5 desaturase activity were examined. Both steroid hormones significantly depressed the conversion of [1-^{14}C] eicosatrienoic acid to arachidonic acid. However, the mechanism of action of each of these hormones was different. The effect of 11-deoxycorticosterone was mediated by a soluble protein present in the liver cytosolic fraction. The biological activity of this protein, having a molecular weight lower than 25 kDa, was impaired by trypsin digestion. To determine whether the inhibitory protein was induced through glucocorticoid or mineralocorticoid receptor occupancy, cultured Morris minimal deviation hepatoma cells were pre-treated with the antiglucocorticoid cortexolone or the mineralocorticoid receptor antagonist spironolactone. The results obtained demonstrated that only glucocorticoid receptor structures were involved in the induction of this regulatory protein. The inhibitory response evoked by aldosterone was mediated by a different mechanism. In the case of aldosterone, the inhibitory action affected the microsomal membranes and was not mediated by a soluble protein messenger.

Lipids 27, 599–604 (1992).

Polyunsaturated fatty acid biosynthesis in liver is regulated by glucocorticoids. The administration of these hormones to rats has been shown to increase Δ9 desaturase activity (1) and to decrease Δ6 and Δ5 desaturase activities (2,3). In addition, the incubation of Morris minimal deviation hepatoma cells (HTC), or of hepatocytes from normal rats with dexamethasone, provoked a strong depression in the conversion of eicosatrienoic acid to arachidonic acid (4,5). However, the regulatory mechanisms of fatty acid biosynthesis are still poorly understood.

We have demonstrated that the regulatory action of glucocorticoid hormones on the fatty acid desaturase activities depends on a protein factor whose biosynthesis is brought about by hormonal induction (1,3). Although 11-deoxycorticosterone (DOC) does not have an 11-β-hydroxy group, which is thought to be essential for glucocorticoid activity (6), we have previously demonstrated that in HTC cells this hormone can induce a soluble regulatory factor that stimulates Δ9 desaturase activity (7). Two species of adrenocortical hormone receptors have been defined: i) Those receptors associated with mineralocorticoid function which have a high affinity for aldosterone (ALDO) and a lower affinity for corticosterone (8); and ii) those receptors associated with glucocorticoid function which have a high affinity for corticosterone and a lower affinity for aldosterone (9,10).

The aim of the present study was to assess the effectiveness of DOC or aldosterone in depressing liver Δ5 desaturase activity. In addition, we set out to determine whether induced inhibition of Δ5 desaturase was specific for glucocorticoid receptor occupancy. Taking into account that DOC can exert glucocorticoid hormone-type effects (11), we also compared the ability of DOC and aldosterone to induce the above-mentioned inhibitory protein factor in the presence or absence of cortexolone or spironolactone. The compounds were chosen because they are antagonists for gluco- and mineralocorticoid receptors, respectively (12,13).

MATERIALS AND METHODS

Chemicals. Radioactive [1-^{14}C]eicosa-8,11,14-trienoic acid (59.0 mCi/mmol, 98% radiochemically pure) was purchased from New England Nuclear (Boston, MA). Unlabeled eicosatrienoic acid was purchased from NuChek Prep (Elysian, MN). NADH, ATP, coenzyme A (CoASH) and other co-factors, HEPES (*N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid), bovine serum albumin, trypsin type III, trypsin soybean inhibitor type I, delipidated bovine serum albumin, 11-deoxycorticosterone (hemisuccinate) (DOC), ALDO, spironolactone and cortexolone (Reichstein substance S 21-acetate) were from Sigma Chemical Co. (St. Louis, MO). Dexamethasone (sodium phosphate salt) was from Merck, Sharp and Dhome (Buenos Aires, Argentina).

Animals and their treatment. Adult female Wistar rats weighing 160–180 g were housed two per cage in a thermostatically controlled room at 22 ± 2°C. Food (Cargill type "C", Rosario, Argentina) and water were available *ad libitum*. Cargill standard pelleted diet, type "C", consisted of (in calories): 56.7% carbohydrates, 10.4% lipids and 32.9% protein, vitamins and minerals. The fatty acid relative percentages of this diet were 21.4% palmitic,2.1% palmitoleic, 8.2% stearic, 24.9% oleic, 37.7% linoleic and 0.2% arachidonic. The rats were divided in groups of four animals each. One group was injected intraperitoneally with a single dose of DOC (1.0 μmol/kg body weight). Another group of rats was injected with ALDO (1.0 μmol/kg body weight), and the last group (control rats) was injected only with the vehicle in which the hormone was dissolved (ethanol, 20 mM). All rats were killed by decapitation without anesthesia 24 h after the injection. In order to avoid individual differences among the nutritional status of the animals, the rats were fasted for 24 h, fed for 2 h, and then killed 12 h after the end of the feeding period.

Isolation of crude microsomes. Livers (processed individually) were rapidly excised and immediately placed

Abbreviations: ALDO, aldosterone; CoASH, coenzyme A (sodium salt); DOC, 11-deoxycorticosterone (hemisuccinate); Dx, dexamethasone (sodium phosphate salt); GLC, gas-liquid chromatography; H, Sp fraction containing proteins with MW higher than 25 kDa; HEPES, *N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid; HTC, Morris minimal deviation hepatoma cells number 7288 c; IMEM-Zo, improved minimal essential medium-zinc option; L, Sp fraction containing proteins with MW lower than 25 kDa; M, crude liver microsomes; Me, extracted liver microsomes; Sp, soluble proteins obtained by washing crude microsomes; Spa, specific activity; T-Sp, Sp fraction proteolized by incubation with trypsin.

in ice-cold homogenizing solution (14). The excised livers were homogenized in 3 mL of homogenizing medium for each gram of liver and centrifuged at 10,000 × *g* for 20 min at 2–4°C. The pellet was discarded and the supernatant was centrifuged again (110,000 × *g* for 60 min) at 1–2°C. The supernatant from the second centrifugation was used as cytosol fraction. The pellets were resuspended in cold homogenizing solution up to a final protein concentration of 50 mg/mL, and were used as crude microsomes from DOC-treated (M_{DOC}), ALDO-treated (M_{ALDO}) or control (M_C) rats.

Microsome extraction. In some experiments, extracted microsomes from rat liver (Me) were obtained following the procedure described previously (15). Briefly, crude microsomes from control or hormonally-treated rats in the proportion of 5 mg protein per 3 mL of standard extraction solution (15) were shaken at 0–2°C under air for 15 min. The standard extraction solution contained 0.25 M sucrose, 0.04 M phosphate buffer (pH 7.40), 0.04 M NaCl, 0.15 M KCl, 0.004 M *N*-acetylcysteine, 0.04 M NaF, 0.3 mM nicotinamide and 15 mM $MgCl_2$. The suspension was then centrifuged at 110,000 × *g* (1–2°C) for 60 min in a L-2-65 ultracentrifuge (Beckman Instruments, Palo Alto, CA). Two fractions, one corresponding to the extracted microsomes (Me) and the other to the supernatant soluble fractions (Sp), were obtained. Sp fractions obtained by washing microsomal suspensions from control or hormonally-treated rats routinely contained 40–45% of proteins associated with crude microsomal fractions.

Hepatoma cultured cells. Culture cells used in these experiments came from Morris minimal deviation hepatoma number 7288 c, a solid hepatoma from which the ascites tumor line (HTC cells) had been derived (16). HTC cells were maintained and grown *in vitro* at 37°C in confluent layer attached to glass on Swim's 77 (S-77) medium supplemented with 10% (vol/vol) calf serum, using conventional sterile conditions, as previously described (17).

Cytosol fractions from control or hormone-treated HTC cells. When HTC cells were in logarithmic phase (approximately 72 h), Swim's 77 was replaced by Richter's improved minimal essential medium-zinc option (IMEM-Zo) (18). In the first series of experiments, several culture flasks were supplemented with DOC, dexamethasone (Dx) or ALDO at a final concentration of 10^{-6}M. In some experiments the cells were maintained under these conditions for 12 h, harvested as indicated above, processed separately (control, DOC, Dx or ALDO-treated cells) and pelleted by centrifugation at 4°C (1,000 × *g* for 10 min). Each pellet was washed three times with 10 mL of cold, steroid-free IMEM-Zo medium and resuspended in 5 mL of the same ice-cold homogenizing solution use for the isolation of liver microsomes (14). The cells were homogenized immediately in a small, stainless-steel hand homogenizer and centrifuged at 110,000 × *g* for 60 min. The supernatants obtained were used as cellular (control or hormone-treated) cytosol fractions. In a second series of experiments, cytosol fractions of steroid-treated HTC cultures were prepared following the procedures described above, except that the cells were incubated with DOC (10^{-6}M) for 12 h, after pre-incubation or not with either cortexolone (10^{-4}M) or spironolactone (10^{-4}) for 2 h.

Isolation of light (L) and heavy (H) fractions from microsomal soluble proteins (Sp). Aliquots (4 mL) of soluble proteins (Sp) extracted from microsomes of control or DOC-treated rats were applied, without further manipulation, to Centriflo CF-254 filter cones (Amicon Co., Lexington, MA) and centrifuged in the cold at 1,600 × *g* for 55 min. The ultrafiltrates of Sp_C or Sp_{DOC} were collected separately and used as L-control or L-DOC Sp fractions. These fractions contained 95% of the soluble proteins with molecular weights of 25 kDa or less. The ultrafilter cones were rinsed three times (2 mL each time) with cold homogenizing solution, and the filtrates obtained after centrifugation were discarded. The remaining protein fractions in the cones were resuspended in homogenizing medium (3 mL) and used as H-control or H-DOC Sp fractions. These fractions contained proteins with molecular weights higher than 25 kDa.

Fatty acid desaturase activity assay. Δ5 Desaturase activity was measured by estimation of the percentage conversion of [1-^{14}C]eicosa-8,11,14-trienoic acid to arachidonic acid. Liver microsomal protein (5 mg) was incubated with 100 nmol of a mixture of labeled and unlabeled eicosatrienoic acid (0.25 μCi/tube) at 37°C for 10 min in a shaking water bath. The incubation medium (1.5 mL) contained the same solution used for the extraction of microsomes except that in the desaturase activity assay 3.5 mM ATP, 0.2 mM CoASH and 1.5 mM NADH were added.

Under these experimental conditions the desaturase enzyme was completely saturated with the substrate (19). In some experiments, cytosol fractions from steroid-treated HTC cells or Sp fractions from microsomes of hormone-injected rats were added to the incubation medium (0.60 mg protein per tube). In all cases the final volume of incubation was 1.5 mL. The reaction was started by addition of an aliquot of crude of extracted liver microsomal suspension. It was stopped by addition of 2 mL of 10% (w/vol) KOH in ethanol plus 500 μL/tube methanol to facilitate the subsequent extraction step. The fatty acids were recovered after saponification of the incubation mixture, and were methylated as described elsewhere (1).

Radioactivity of the recovered methyl esters (> 98%) was determined in a Beckman liquid scintillation counter (model LS-3133, Beckman Instruments, Palo Alto, CA) with 96% efficiency for ^{14}C. Distribution of radioactivity among the fatty acid methyl esters was measured by gas-liquid chromatography (GLC) as detailed in a previous study (5). The chromatographic peaks were identified by comparison of the relative retention times with those of standards chromatographed under the same conditions. Percentage conversion was calculated from the radioactivity distribution between substrate and product, and was measured directly on the radiochromatogram (20). The column was packed with 10% SP-2330 on Chromosorb WAW-DMCS (100–200 mesh) (Supelco Inc., Bellefonte, PA).

Trypsinization of soluble fractions. A solution of 6 mg trypsin (type III) in 0.25 mL phosphate buffer (pH 7.4) was added to each 6 mL Sp corresponding to 0.6 mg protein per mL, and the mixture was incubated for 60 min at 37°C. Proteolysis was stopped by the addition of 12 mg trypsin soybean inhibitor (type I).

RESULTS

Table 1 shows the changes that occurred in liver Δ5 desaturase activity 24 h after the injection of 1 μmol/kg

TABLE 1

Effect of Steroid Treatment on Microsomal Rat Liver Δ5 Desaturase Activity

Microsomes[a]	Δ5 Desaturase activity: Spa = nmol desat. / min•mg/prot.	% Change compared to control
M_C	0.58 ± 0.02[b]	
M_{DOC}	0.22 ± 0.02[c]	62 ± 3
M_{ALDO}	0.19 ± 0.03[c]	69 ± 5

[a]Five mg of microsomal protein from control (M_C) and deoxycorticosterone (M_{DOC})- or aldosterone (M_{ALDO})-treated rats were incubated at 37°C for 10 min in a shaking water bath with 100 nmol of a mixture of labeled and unlabeled eicosatrienoic acid (0.25 μCi/tube).

[b]The results are given as the means of four animals per group ± SEM.

[c]Determined significantly different from M_C using Student's *t*-test ($P < 0.001$).

TABLE 2

Effect of the Addition of Soluble Proteins (Sp) or Cytosol to Rat Liver Microsomes on Δ5 Desaturase Activity[a]

	Crude microsomes (M)		
	M_C	M_{DOC}	M_{ALDO}
None	29.6 ± 1.0[b]	14.9 ± 0.8	18.7 ± 1.1
	Extracted microsomes (Me)		
	Me_C	Me_{DOC}	Me_{ALDO}
None	20.7 ± 0.8	10.3 ± 0.6	8.1 ± 0.3
Sp_C	28.6 ± 0.9	15.4 ± 0.7	20.4 ± 0.2
Sp_{DOC}	13.7 ± 0.9	4.8 ± 0.3	—
Sp_{ALDO}	28.6 ± 0.7	—	21.2 ± 0.8
$Cytosol_C$	29.0 ± 0.7	16.1 ± 0.8	21.8 ± 0.5
$Cytosol_{DOC}$	12.0 ± 0.5	3.3 ± 0.5	—
$Cytosol_{ALDO}$	26.9 ± 0.5	—	18.9 ± 1.0

[a]Soluble proteins (0.6 mg protein/tube) or cytosol (0.6 mg protein/tube) from control (C), DOC-treated (DOC) or ALDO-treated (ALDO) rats were added to crude (M) or extracted (Me) microsomal (5 mg of microsomal protein) in 1.5 mL of incubation medium. For details see Materials and Methods.

[b]The results are the mean of three determinations expressed as percent conversion of eicosatrienoic acid to arachidonic acid ± SEM. Incubation conditions were as described in Table 1.

body weight of DOC or ALDO into rats. Both hormones significantly decreased the conversion of eicosatrienoic acid to arachidonic acid.

A number of experiments were designed in order to establish whether the mechanism of DOC or ALDO action is mediated by the induction of a regulatory protein present in the cytosolic fraction of the cells. In the first one, the effect on Δ5 desaturase activity caused by the addition of liver microsome soluble fractions from control or DOC-injected rats to crude microsomes was determined. As shown in Table 2, liver Δ5 desaturase activity was strongly depressed by extraction of microsomes (from control or DOC-treated rats) with a low ionic strength solution, but in control microsomes the depression observed was considerably higher.

The addition of 0.6 mg of soluble fraction obtained from control livers (Sp_C) to extracted microsomes of untreated animals (Me_C) restored almost 100% of Δ5 desaturase activity. A similar effect was observed with the addition of liver cytosol from control rats. However, soluble protein and cytosol obtained from DOC-treated animals were unable to restore the desaturation capacity of washed microsomes (Me_C or Me_{DOC}), instead they significantly decreased enzyme activity.

When extracted microsomes from hormonally-treated rats (Me_{DOC}) were incubated with soluble fractions or cytosol obtained from control rats, Δ5 desaturase activity increased to values observed with whole microsomes from DOC-injected animals. Conversely, when extracted soluble protein or liver cytosol from hormonal treated animals was added to Me_{DOC}, the conversion of eicosatrienoic acid to arachidonic acid was significantly depressed and Δ5 desaturase activity was the lowest measured. Soluble proteins or liver cytosol fractions were added to complete or extracted microsomes from control or ALDO-treated animals in similar experiments (Table 2). DOC strongly depressed the conversion of eicosatrienoic acid to arachidonic acid both in complete or in extracted-liver microsomes.

The addition of 0.6 mg protein of soluble fraction from control liver (Sp_C) to extracted microsomes of untreated animals (Me_C) restored the Δ5 desaturase activity to values obtained with crude microsomes from control rats. A similar effect was observed with added soluble protein fractions from aldosterone-treated rats (Sp_{ALDO}) or cytosolic fractions from control or aldosterone-injected animals.

When extracted microsomes from hormonally-treated rats (Me_{ALDO}) were incubated with soluble fractions from control or aldosterone-injected animals (Sp or cytosol), Δ5 desaturase activity only increased to values observed with crude microsomes from treated animals (M_{ALDO}). Therefore, the conversion of eicosatrienoic acid to arachidonic acid in liver microsomes from aldosterone-injected rats was significantly depressed (as compared to control animals), even after the addition of the different soluble fractions tested.

Results from the incubation of [1-^{14}C]eicosatrienoic acid with control crude microsomes or control-extracted microsomes plus cellular cytosolic fractions of control or hormonally-treated isolated cells are shown in Table 3. When the 110,000 × *g* supernatant from homogenates of control or ALDO-treated HTC cells was added to extracted liver microsomes (Me_C), Δ5 desaturase activity that was previously reduced by washing microsomes with a low ionic strength solution, increased. Conversely, the addition of cytosolic fractions from Dx- or DOC-treated HTC cells to extracted microsomes from control rats, inhibited rather than restored Δ5 desaturating capacity.

The effect of trypsin digestion of soluble fractions from control and DOC-treated rats on Δ5 desaturase activity is shown in Table 4. Proteolysis inhibited the capacity of the control soluble fraction to reactivate the fatty acid desaturation of extracted microsomes from control animals. The ability to reactivate the Δ5 desaturase reaction was not impaired when the control soluble fraction was treated with trypsin that had previously been inactivated by trypsin inhibitor. As shown in Table 3, the soluble fraction from DOC-treated animals significantly reduced the Δ5 desaturase capacity of Me_C. This inhibition was stronger than that produced by washing crude micro-

TABLE 3

Effect of the Addition of Cytosol from Hormonally-Treated HTC Cells to Rat Liver Microsomes on Δ5 Desaturase Activity[a]

	% Conversion 20:3n-6 to 20:4n-6
Crude microsomes (M_C	31.5 ± 0.9[b]
Extracted microsomes (Me_C	20.8 ± 0.5
Me_C + cytosol from control HTC cells	28.7 ± 0.8
Me_C + cytosol from DOC-treated HTC cells	15.6 ± 0.4
Me_C + cytosol from ALDO-treated HTC cells	29.1 ± 0.6
Me_C + cytosol from Dx-treated HTC cells	13.0 ± 0.3

[a]Cytosol fraction from control (C), deoxycorticosterone (DOC) or aldosterone (ALDO)-treated HTC cells, were added (0.6 mg protein/tube) to 5 mg of extracted liver microsomal protein (Me) from control rats. Final incubation medium was 1.5 mL. See Materials and Methods for experimental details.

[b]Data are expressed as percent conversion of [1-^{14}C]eicosa-8,11,14-trienoic acid to arachidonic acid and are given as mean of three individual determinations ± SEM. Analyses of the samples were done as described in Materials and Methods.

TABLE 4

Effect of Trypsin-Treated Soluble Fractions on Δ5 Desaturase Activity of Extracted Microsomes from Control (C) Rats[a]

	% Conversion 20:3n-6 to 20:4n-6
Crude microsomes from control rats (M_C)	35.8 ± 1.7
Extracted microsomes from control rats (Me_C)	15.1 ± 1.3
Me_C + Sp_C	31.2 ± 1.8
Me_C + T-Sp_C	16.2 ± 1.5
Me_C + Sp_C + (trypsin + trypsin inhibitor)[b]	30.9 ± 2.2
Me_C + Sp_{DOC}	9.7 ± 0.7
Me_C + T-Sp_{DOC}	15.6 ± 1.4
Me_C + Sp_{DOC} + (trypsin + trypsin inhibitor)[b]	9.8 ± 1.2

[a]Desaturation activity was measured by incubation of 5 mg of liver extracted microsomal protein (Me_C) plus 0.6 mg per tube of soluble proteins from control (Sp_C) or 11-deoxycorticosterone-injected (Sp_{DOC}) rats. In some tubes trypsin-treated Sp fractions (T-Sp) from control or DOC-injected rats were added (0.6 mg/tube).

[b]Sp treated with trypsin previously inhibited by trypsin inhbitor. In all cases, the final volume of incubation was 1.5 mL. The results are expressed as percent conversion of eicosatrienoic acid to arachidonic acid and are the mean of three individiual determinations ± 1 SEM.

TABLE 5

Effect of Addition of the H-Cytosolic or L-Cytosolic Fractions from Control (C), Deoxycorticosterone (DOC)-Treated Rats to Extracted Liver Microsomes (Me) from Control Rats, on Δ5 Desaturase Activity[a]

	% Conversion 20:3n-6 to 20:4n-6
Crude microsomes (M_C)	32.3 ± 1.1
Extracted microsomes (Me_C)	20.1 ± 0.8
Me_C + H-Sp fraction from control rats	33.3 ± 0.6
Me_C + H-Sp fraction from DOC-treated rats	30.9 ± 1.3
Me_C + L-Sp fraction from control rats	29.8 ± 0.5
Me_C + L-Sp fraction from DOC-trated rats	14.0 ± 0.3

[a]H- and L-fractions were prepared by ultracentrifugation. For details see Materials and Methods. Data are expressed as percent conversion of [1-^{14}C]eicosatrienoic acid to arachidonic acid and are the mean of three determinations ± SEM.

TABLE 6

Effect of Pre-Treatment of HTC Cells with the Antiglucocorticoid Cortexolone or the Antimineralocorticoid Spironolactone on the Action of Deoxycorticosterone (DOC) on Eicosatrienoic Acid Desaturation[a]

	% Conversion 20:3n-6 to 20:4n-6
Crude microsomes from control rats (M_C)	29.8 ± 1.3
Extracted microsomes from control rats (Me_C)	18.5 ± 0.9
Me_C + cytosol from control HTC cells	27.6 ± 0.8
Me_C + cytosol from cortexolone-treated HTC cells	25.8 ± 1.1
Me_C + cytosol from spironolactone-treated HTC cells	25.4 ± 1.4
Me_C + cytosol from DOC-treated HTC cells	11.0 ± 1.2
Me_C + (cortexolone DOC-[b]-treated HTC cells	25.0 ± 0.9
Me_C + (spironolactone DOC)[b]-treated HTC cells	10.6 ± 1.0

[a]Desaturation of [1-^{14}C]eicosa-8,11,14-trienoic acid (100 nmol, 0.25 μCi per tube) was measured by incubating 5 mg of extracted microsomes (Me_C) with 0.6 mg per tube of cytosol from control or 11-deoxycorticosaterone (DOC)-treated HTC cells.

[b]In these experiments, after the incubation with cortexolone (10^{-4}M) or spironolactone (10^{-4}M) for 2 h, DOC was added (10^{-6}M) to the same flasks and the cells were incubated with the two hormones for another 12 h. Cytosolic fractions were prepared as described in Materials and Methods. In all cases, the final incubation volume was 1.5 mL. The results are given as the mean of three independent determinations ± SEM.

somes with a low ionic strength solution. The depression of Sp_{DOC} disappeared after proteolysis of the factor with trypsin, unless the trypsin had been previously inactivated by trypsin inhibitor.

Table 5 provides additional data concerning the nature of the Δ5 desaturase inhibitory factor induced by DOC. The depressive effect of different soluble proteins (Sp) was tested. The proteins were extracted from liver microsomes of control or DOC-treated rats, segregated by ultrafiltration according to their molecular weights (> or < than 25 kDa), and their effects on the conversion of eicosatrienoic acid to arachidonic acid were tested. The Sp fraction containing protein with MW higher than 25 kDa (H-Sp) restored the Δ5 desaturation capacity of extracted microsomes. This effect was observed not only with the H-Sp fraction from control livers, but also with the same fraction of DOC-treated rats. By comparison, the addition of the L-Sp fraction (MW < 25 kDa) from control rats to extracted microsomes did not re-establish the enzymatic activity lost after washing the microsomes. The L-fraction from DOC-treated rats inhibited rather than returned Δ5 desaturase activity to values obtained with crude microsomes (M_C) (Table 5).

HTC cells were treated with cortexolone or spironolactone to determine which steroid receptors were involved in the mechanism by which the protein factor inhibits Δ5 desaturase activity. As can be seen in Table 6, when HTC cells were pre-treated with the antiglucocorticoid cortexolone, the inhibitory action of DOC on Δ5 desaturase ac-

tivity was abolished and the values obtained in the conversion of eicosatrienoic acid to arachidonic acid were similar to those obtained with the addition of control cytosol to Me_C. By contrast, pre-treatment of HTC cells with the antimineralocorticoid spironolactone did not modify the inhibitory action of DOC on Δ5 desaturase activity, and the percent conversion obtained was similar to that obtained when cytosol from DOC-treated HTC cells was added directly to Me_C.

DISCUSSION

Previous biochemical studies of dexamethasone action in the biosynthesis of arachidonic acid in liver have emphasized the possible role of hormone-induced gene activation. This activation also produced an enhancement in the synthesis of specific proteins (1,7) that lead to an inhibition in Δ5 and Δ6 desaturase enzymes and, at the same time, to an increase in Δ9 desaturase. Another steroid hormone, 11-deoxycorticosterone, is able to induce a regulatory protein factor that modulates Δ9 desaturating reactions in hepatoma tissue culture cells (HTC) (Marra, C.A., and M.J.T. de Alaniz, unpublished data). Recent studies on aldosterone have, in general, emphasized its action as an active transepithelial sodium carrier (21–23). Our study provides the first evidence that aldosterone affects the biosynthesis of arachidonic acid in liver.

Although treatment of rats with dexamethasone (3), DOC or ALDO decreased Δ5 desaturase activity in liver (Table 1), the mechanism of action for these hormones is not the same. DOC is able to synthesize a soluble inhibitory factor that is loosely bound to microsomes (3). In the present study, this factor also was found in a soluble fraction obtained after washing crude microsomes from DOC-treated rats, with a low ionic strength solution (Table 2).

The results in Table 1 suggest that a protein factor participates in the regulatory effect of DOC on the conversion of eicosatrienoic acid to arachidonic acid. Isolated cells exposed to dexamethasone or DOC produced this regulatory protein, while trypsin digestion impaired its biological activity. The hormonally-induced factor present in the cytosolic fraction of treated cells strongly depressed liver microsomal Δ5 desaturase activity (Table 3). The production of this inhibitory agent by isolated cells can be detected *in vitro*, where the interference of many complex physiological interaction does not occur as it does when the hormonal effect was tested in the whole animal.

Experiments have begun in an attempt to isolate a soluble factor responsible for the inhibition of the conversion of eicosatrienoic acid to arachidonic acid by separating the factor into light and heavy fractions. Table 5 shows that the inhibitory activity of Δ5 desaturase enzyme took place in a soluble fraction containing protein of MW lower than 25 kDa (L-Sp). However, further research is needed to characterize this protein.

The effect of aldosterone on the conversion of eicosatrienoic acid to arachidonic acid was different from those of DOC and dexamethasone. The former seems not to be mediated by a protein soluble factor induced by the hormone (Table 2), because the recovery of Δ5 desaturase activity for Me_C or Me_{ALDO} obtained by addition of soluble protein or liver cytosol from ALDO-treated rats was similar to that obtained by addition of the same fractions from control rats.

The treatment of rats with aldosterone significantly depressed Δ5 desaturase activity in both crude and extracted liver microsomes. The mechanisms by which ALDO exerts its effect on arachidonic acid biosynthesis seems to be different from those evoked by DOC (Table 2) and dexamethasone (3). The effect of aldosterone on Δ5 desaturase activity would be the consequence of the modification of the microsomal membrane properties which would take further action on the Δ5 desaturase activity. No protein messenger, induced by the hormone, would be involved in this mechanism. A similar mechanism of action was proposed previously to explain the regulatory effect displayed by testosterone on desaturase activities (24). We have already reported that the treatment of rats for 24 h with aldosterone significantly alters the fatty acid composition of liver microsomal membranes (25). The most important changes observed were a decrease in the percent distribution of palmitic, stearic, arachidonic, docosapentaenoic and docosahexaenoic acids, with a concomitant increase in the fractional composition of palmitoleic, oleic and linoleic acids. These modifications were reflected in a significant increase in the monoenoic/saturated fatty acid ratio and a decrease in the arachidonic/linoleic ratio. Since aldosterone has been found to be able to modify the fatty acid composition of liver microsomal membranes (25), it may be suggested that its inhibitory effect on Δ5 desaturase would be the direct consequence of such changes. However, whether the dexamethasone- or DOC-induced inhibition of Δ5 desaturase enzyme is mediated through glucocorticoid receptor occupancy is not known. DOC may, indeed, function as a glucocorticoid, inducing certain enzyme activities in HTC cells (11), and it is known that it is more effective than other steroids in displacing glucocorticoids from their receptors (26,27). We therefore suggest that the diminished conversion of eicosatrienoic acid to arachidonic acid evoked by DOC may be due to the production of a counteracting protein mediator released or activated in response to hormonal action through glucocorticoid receptor occupancy. In the present study we have demonstrated that glucocorticoid receptor structures are involved in the depression of Δ5 desaturase activity by DOC, because the inhibition of eicosatrienoic acid desaturation provoked by this hormone was blocked by pre-treatment of HTC cells with the antiglucocorticoid cortexolone (Table 6).

It is generally accepted that spironolactone is able to displace mineralocorticoid hormones from their receptor sites, and thereby antagonize hormone action (13,28). In our study using spironolactone (Table 6), mineralocorticoid receptors were not involved in the mechanism by which aldosterone or DOC depressed Δ5 desaturase activity.

In conclusion, the data presented here provide good evidence that DOC, which exerts physiologic and metabolic effects different from those of dexamethasone, can display similar mechanisms of action for the inhibition of arachidonic biosynthesis. We postulate that this inhibitory response is mediated by a soluble protein with a MW lower than 25 kDa. The induction of this regulatory factor requires glucocorticoid receptor occupancy and protein synthesis. Moreover, our results show that deoxycorticosterone and aldosterone depress Δ5 desaturase activity by different mechanisms of action.

Effects of Various Dietary Fats on Cardiolipin Acyl Composition During Ontogeny of Mice[1]

Alvin Berger[a], M.E. Gershwin[b] and J. Bruce German[a,*]

[a]Department of Food Science and Technology and [b]Division of Rheumatology and Immunology, University of California at Davis, Davis, California 95616

Cardiolipin (CL) is a unique mitochondrial phospholipid, containing up to 85 wt% 18:2n-6 in mammals. The influence of maternal dietary fatty acids on the acyl composition of offspring CL has not been examined previously. Adult female mice were thus fed diets rich in 18:1n-9 (olive oil), 18:2n-6 (safflower oil), 18:3n-3 (linseed oil) or 20:5n-3 and 22:6n-3 (fish oil/safflower, 9:1, w/w), for a five month period, encompassing two breeding cycles. Offspring from the second breeding cycle were then fed these diets. The acyl composition of CL, phosphatidylcholine and phosphatidylethanolamine from liver and heart was evaluated from mice killed 3, 18 and 42 days after parturition. The primary nutrient sources at these three time points were transplacental nutrients, breast milk and the diet, respectively. Maternal diet was found to influence the acyl composition of CL *via* both placental transfer of fatty acids and breast milk. Fish oil feeding resulted in replacement of a substantial portion of 18:2n-6 with 22:6n-3; after 42 days, the area% of 18:2n-6 in heart CL was reduced from 62% in safflower oil fed mice to 12%. In comparison to fish oil feeding, linseed oil feeding resulted in a much lower accumulation of 22:6n-3. Olive oil feeding resulted in substantial replacement of 18:2n-6 with 18:1n-9 (18:2n-6 was reduced from 62% to 31%). Physiologically, these findings are relevant because changes in CL acyl composition may influence the activity of associated inner mitochondrial membrane enzymes.

Lipids 27, 605–612 (1992).

Cardiolipin (CL) [1′-(1,2-diacyl-*sn*-glycero-3-phosphoryl)-3′-(1″,2″-diacyl-*sn*-glycero-3″-phosphoryl)-*sn*-glycerol; or 1,3-*bis*(3-*sn*-phosphatidyl)glycerol] is a unique mitochondrial phospholipid. In mammals, CL may contain up to 85 wt% 18:2n-6 (1–3). CL is known to be associated with several inner mitochondrial membrane proteins (4–9), most notably cytochrome *c* oxidase (10–12). The four fatty acid chains of CL may exert a variety of biophysical effects. There is evidence from both feeding studies (13–15) and *in vitro* studies with CL derivatives (2,10,11,16–18) that modulation of the acyl chain of CL can influence the activity of associated inner mitochondrial membrane proteins. We have demonstrated that alteration of the acyl moiety of CL can influence the binding to antiphospholipid antibodies (aPL) *in vitro* (19). These effects of acyl modification of CL are nutritionally relevant since the acyl moiety of CL can be altered by diet (13,15,20–24).

The influences of long-term maternal fat consumption on the CL acyl composition of offspring tissues during ontogeny has not been studied previously. We were specifically interested in the extent to which dietary fatty acids of the n-9 and n-3 series could displace the predominating n-6 fatty acid, 18:2n-6, from CL.

MATERIALS AND METHODS

Experimental animals. The initial experimental animals were four-week-old, murine-pathogen-free, female and male Swiss Webster mice, weighing 25–30 g initially (Bantin and Kingman, Fremont, CA). There were nine female mice per treatment housed in groups of five and four in 27 × 17 × 13 cm clear plastic cages with bedding. Males were fed a non-purified diet (Rodent Laboratory Chow® #5001, Purina Mills, St. Louis, MO) and were housed in groups of four. The dams received the non-purified diet for two weeks, followed by the experimental diets for a five-month period which encompassed two breeding cycles, five weeks apart. First pregnancies are characterized by large variations in the number of pups born and by cannibalism. Hence, offspring from the second pregnancy were analyzed.

During mating periods, one male was added to the cage of three females for a three-day period. Two weeks later, males were re-introduced to those non-pregnant females (as determined by vaginal plugs and weight gain) in a 1:1 ratio for one week. On day 14 of gestation, pregnant mice were housed individually. This breeding scheme resulted in 5–9 successful pregnancies per treatment. Litters were randomly normalized from 10–15 pups to 10 pups on day 3 *postpartum*. On day 18, the dams were removed, and the litters were culled to 6. On day 42, the remaining pups were killed by CO_2 intoxication. Tissues were analyzed from dams, and from pups which were killed 3, 18 and 42 days after parturition. The primary nutrient sources at these three time points were transplacental nutrients, breast milk and the diet, respectively.

Experimental diets. The experimental diets consisted of fat-free AIN 76A meal diets (25) (Dyets Inc., Bethlehem, PA) modified by addition of either 10 wt% safflower oil (Dyets Inc.), linseed oil (Spectrum Marketing, Petaluma CA), olive oil (G. Sensat, extra virgin #5, Specialty Food and Beverage Sales, West Milford, NJ), or a 9:1 (w/w) mixture of vacuum deodorized menhaden oil (National Institute of Health Biomedical Test Material Lot #L89195BB, Bethesda, MD) and safflower oil (Table 1). The fat-free diet mix, safflower oil and olive oil were stored refrigerated, linseed and fish oils were stored at −70°C under N_2. To minimize oxidation, all oils contained 0.02 wt% *tert*-butylhydroquinone (Aldrich Chemical Co., Milwaukee, WI). The diets were prepared in a commercial mixer in 5-kg lots, sealed under N_2 in freezer bags in 250-g quantities, and stored at −70°C.

Mice received *ad libitum* amounts of fresh feed in ceramic feed cups each evening in a humidity-controlled room with a dark cycle from 1800–0700 hours. Uneaten food was discarded each evening. Deionized water was provided *via* a pressure sensitive nozzle. Feed cups,

cages and bedding were cleaned every 2–4 d as needed.

Lipid analysis. Tissue lipids were extracted (26), separated by high-performance thin-layer chromatography (HPTLC) (27) and then methylated (28). Fatty acid methyl esters (FAME) were resolved by gas chromatography and detected with a flame ionization detector as previously described (21), except for the modifications listed below.

To analyze day 42 livers by HPTLC, it was necessary to first remove neutral lipids. Lipid extracts from 300 mg of liver were dissolved in 2 mL of hexane, and applied to pre-washed 100 mg silica columns equipped with stainless steel frits and 10-mL reservoirs (Analytichem International, Harbor City, CA). Columns were mounted to a Supelco Visiprep™ Solid Phase Extraction Vacuum Manifold (Bellefonte, PA). Neutral lipids were eluted with 12 mL of $CHCl_3$. CL, phosphatidylserine, phosphatidylinositol and phosphatidylethanolamine (PE) were eluted with 4 mL of $CHCl_3/CH_3OH$ (2:1, vol/vol), and phosphatidylcholine (PC) and sphingomyelin were eluted with 4 mL CH_3OH.

For gas chromatography, FAME were injected with a Hewlett-Packard (HP) model 7673 autosampler and resolved with an HP gas chromatograph Model 5890A equipped with a DB-23 capillary column (25 m × 0.25 μm i.d., 50% cyanopropyl phase, 0.25 μm film thickness; J&W Scientific, Folsom, CA). Integrator data were electronically transferred to a Macintosh™ computer, where the data were automatically sorted based on the retention time of standard FAME (NuChek Prep, Elysian, MN), and then converted to area percentages in Microsoft Excel® (Redmond, WA).

Statistics. Results are expressed as area% and were evaluated with analysis of variance (ANOVA) (29) using the statistical package Super ANOVA (Abacus Concepts, Berkeley, CA).

RESULTS

Gestational length, litter size, survivorship and growth parameters. Diet did not have a significant effect on the gestational period, the litter size or the average weight of offspring killed on day three after adjusting for litter size ($P > 0.44$). Interestingly, the number of "successful pregnancies" (out of nine dams per treatment) were: Nine, fish oil; seven, linseed; six, safflower; and five, olive. A pregnancy was considered successful if all of the following criteria were met: i) The dam became pregnant after three exposures to a male; ii) at least six healthy pups were born; and iii) after culling to 10 pups on day three, at least six healthy offspring survived to weaning on day 18. Non-successful pregnancies were characterized by still births, maternal abandonment, cannibalism and large variation in pup size within the litter.

Safflower oil fed dams were found to gain weight at a slightly faster rate than dams from all other groups (analysis of the residuals of a third-order polynomial regression equation; $P < 0.05$). There were also small, but statistically significant, differences in the body weights of the offspring for the various treatments ($P < 0.01$; ANOVA with litter as a nested factor). Body weights ranged from 8.2–10.6 g at 18 d, and from 30.1–33.5 g at 42 d for the various dietary treatments. Dietary fat intake had no significant effect on the relative organ weights (organ weight/body weight) of liver and kidney of day 18 mice, but did elicit small but significant effects ($P < 0.05$) on relative brain, spleen and thymus weights. These data are discussed in detail elsewhere (Berger, A., German, J.B., Keen, C., Ansari, A., and Gershwin, M.E., manuscript submitted for publication).

Influence of age and diet on acyl modification of hepatic and cardiac CL. The CL acyl composition of the pups was

[a]Abbreviations are as follows: Saf, safflower oil fed group; Oli, olive oil fed group; Lin, linseed oil fed group; and Fish, fish oil fed group. Results are expressed as the mean area percent of each fatty acid in CL. 18:1n-9+7 Denotes the sum of 18:1n-9 and 18:1n-7. These isomers were combined since their chromatographic separation was not reliable. When 18:1n-9 was considered alone in the analyses, the statistical trends were identical. Generally, there were highly significant differences ($P < 0.0001$) between the time points and between organs. For simplicity, Tables include one-way ANOVA evaluation of the diet effects at each time point.

[b]Due to limited tissue availability on day 3, it was necessary to pool day 3 hearts from several mice. This resulted in an n of 1 for fish and linseed, 2 for safflower and 5 for olive oil. Statistical significance was thus achieved only when differences were quantitatively large. n Ranged from 3-6 for days 18-42.

[c]Includes 14:0, 14:1n-5, 16:1n-7, 18:3n-6, 20:0, 22:0, 24:0, 20:1n-9, 22:1n-9 and 24:1n-9.

[d,e,f,g]Values within each time point sharing a superscript or lacking a superscript are not significantly different at $P > 0.05$ (Fisher's protected least significant difference). No statistics were performed on the combined fatty acids in the "Others" category.

found to depend on the age of the pups, the diet consumed by both the dams and the pups and the tissue examined.

Age dependency was evident in all dietary groups (Tables 2 and 3). Levels of 18:1 (18:1n-9 plus 18:1n-7) and 20:4n-6 (though only in the heart) were higher at birth and these acids were increasingly replaced with other fatty acids (most notably 18:2n-6) through day 18 and 42 (Tables 2 and 3).

There was also clear evidence that maternal diet influenced the acyl composition of CL in newborn (day 3) and in nursing (day 18) pups. In liver and heart CL, mice fed the n-6 rich safflower oil had higher levels of 18:2n-6 and its metabolites 22:5n-6 and 20:2n-6 at birth, and increasingly higher levels at each respective time point. Mice fed olive oil had higher levels of 18:1. Mice fed linseed oil had higher levels of 18:3n-3 and its metabolites 22:6n-3 and 20:3n-3 (except cardiac CL from day 3 mice). Mice fed fish oil had higher levels of 22:6n-3. Relative to safflower oil feeding, the feeding of all other diets resulted in strikingly lower levels of 18:2n-6. The accumulation of the elongation products 20:2n-6 and 20:3n-3 declined between days 18 and 42 (Tables 2 and 3).

The acyl composition of heart CL was extremely sensitive to the difference between feeding of 18:3n-3 (linseed oil) and 20:5n-3 and 22:6n-3 (fish oil). As compared to mice fed fish oil, mice fed linseed oil for 42 d accumulated much less 22:6n-3 (48% *vs.* 16%, respectively, in the heart) but, interestingly, accumulated more 22:5n-3.

The accumulation of 22:6n-3 in CL was also tissue specific. In comparison to the heart, the liver accumulated less 22:6n-3 at all time points following fish oil feeding and there was a similar accumulation of 22:6n-3 after 42 d feeding with both linseed oil and fish oil. Hepatic levels of 22:6n-3 were not maximized until day 42.

Comparison of the acyl composition of CL, PC and PE. Historically, CL has been considered to elicit a high degree of acyl chain selectivity due to the predominance of 18:2n-6 (1). It was therefore interesting to compare the acyl composition of CL as a function of age and diet to PC and PE, which are thought to accumulate dietary fatty acids with less discrimination. A similar pattern of incorporation of the various dietary fatty acids into CL, PC and PE from the two organs was evident at day 18, however, there were some remarkable differences (Tables 4 and 5). Following feeding of the various n-9, n-6 and n-3 fatty acids, 18:1 and 18:2n-6 were generally present at lower levels in PC and PE, whereas 20:4n-6, 22:5n-6, 20:5n-3 and 22:5n-3 were higher, relative to CL. Hepatic levels of 22:6n-3 were higher in PC and PE than CL on day 18. The dramatically higher level of 22:5n-3 in cardiac PC and PE observed with linseed oil feeding relative to fish oil feeding was not apparent in CL. It is also notable that in cardiac PE, the summed area% of 20:5n-3, 22:5n-3 and 22:6n-3 were equivalent after linseed and fish oil feeding. In PE, 22:6n-3 largely replaced 20:4n-6 and 22:5n-6, whereas 22:6n-3 replaced 18:2n-6 in CL.

Selectivity of incorporation of various fatty acids. Since the experimental diets contained differing amounts of 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3 and 22:6n-3, in order to assess the selectivity for incorporation of these dietary fatty acids into the CL pool, a variable termed the "relative selectivity index" was developed (Table 6). The precursor fatty acids were considered to be 18:1n-9 (olive oil), 18:2n-6 (safflower oil), 18:3n-3 (linseed oil) and the summed quantity of 18:3n-3, 20:5n-3, 22:5n-3 and 22:6n-3

(fish oil). After 42 days, 22:6n-3 derived from precursors in fish oil (as opposed to 18:3n-3) was incorporated into cardiac CL with twice the selectivity of 18:2n-6, whereas 18:1n-9 showed less selectivity for incorporation than 18:2n-6. Conversely, in the liver, there was twice the selectivity for incorporation of 18:2n-6 than 22:6n-3.

DISCUSSION

Age and diet related replacement of monoenoic acids with linoleate. Independent of diet, all the experimental groups were born with a higher content of 18:1 in CL that was gradually replaced with other fatty acids derived from breast milk and the diet. The observed decreases in 18:1 and 16:1n-7, and increases in 18:2n-6 from birth through the post-weaning period have been reported in rats (30–35) and in humans (36), and may result from decreased endogenous fetal synthesis of these monoenes from acetate with age, along with increased supply of 18:2n-6 (and other maternal fatty acids) *via* placental transfer, breast milk and the diet (present study and ref. 34). In contrast to our results, rabbit heart mitochondria examined three days postnatally recently were reported to have a higher content of 18:2n-6 (92%) in CL than adult heart mitochondria (84%) (37).

Accumulation of 22:6n-3 from fish and linseed oil feeding. The substantial accumulation of 22:6n-3 in CL following fish oil feeding has been reported in some studies (13,38,39), but not in others (23,40). Factors that may account for this discrepancy are differences in the species and age of the experimental animals; the tissues examined (1); the amount of food consumed; the feeding duration (13,23); the levels of n-3 polyenoic acids in the diet (39); and the amount of competing n-9 and n-6 dietary fat-

[b]n Ranged from 3–6 for the heart and liver.

ty acids (41). Another factor is that CL could be contaminated with free fatty acids during its chromatographic separation. The very high levels of 22:6n-3 incorporated into cardiac CL in the present study reflects the long-term feeding of a diet rich in n-3 polyenoic acids, but is not dependent on the fact the diet was fed through two generations, since similarly high levels of 22:6n-3 were observed in the CL of adult mice fed fish oil for five months (data not shown). The observed reductions in 18:2n-6 with fish oil feeding were not entirely due to diminished supply of 18:2n-6 in the diet. Our selectivity data, along with the demonstration that fish oils can decrease the content of 18:2n-6 in CL to a greater extent than essential fatty acid deficient diets or hydrogenated corn oil diets (15), suggests that 22:6n-3 may actively compete with 18:2n-6 for incorporation into CL.

The greater accumulation of 22:6n-3 in CL from the heart than the liver is an indication that there was selective uptake or retention by the heart since isolated heart myocytes cannot elongate 20:5n-3 or desaturate 22:5n-3 (42). Cardiac binding proteins may have high selectivity for 22:6n-3, accounting for rapid uptake of this fatty acid into heart cells (43). Decreased retroconversion (44), high selectivity for acyltransferases (45), decreased phospholipase action (46) and diminished mitochondrial oxidation (47) may also contribute to the higher level of 22:6n-3 maintained in cardiac CL.

The apparent selective uptake of 22:6n-3 into heart CL was evident during the transfer of both maternal transplacental and breast milk derived 22:6n-3. As compared to the heart (in linseed oil fed mice) there were higher levels of 18:3n-3 in CL from the liver of day three pups, and lower levels of 22:6n-3. This is an indication that there was selective uptake of placental 22:6n-3 in the heart. In fish oil fed mice, levels of 22:6n-3 were maximized by day 18 in the heart, but not until day 42 in the liver. This suggests that 22:6n-3 derived from breast milk, or released from other organs such as adipose tissue and liver, was selectively retained by heart cells. These results emphasize the importance of evaluating the phospholipid acyl moiety of more than one tissue in dietary lipid studies.

The lesser accumulation of 22:6n-3 in cardiac CL with linseed oil feeding relative to fish oil feeding (23,24) suggests that one or more steps in the conversion of 18:3n-3 to 22:6n-3 are regulated, or at least limiting. Recent evidence suggests that 20:5n-3 may be metabolized to 22:6n-3 *via* the following pathway: 5,8,11,14,17-20:5 → 7,10,13,16,19-22:5 → 9,12,15,18,21-24:5 → 6,9,12,15,18,21-24:6 → 4,7,13,16,19-22:6 (48). In short-term feeding experiments, the quantitative differences in 22:6n-3 incorporation into CL with linseed and fish oil feeding are less obvious (23). This suggests that longitudinal feeding studies need to be conducted with graded amount of n-3 fatty acids provided.

In cardiac PE, the fact that levels of 22:5n-3 were considerably higher after linseed oil feeding as compared to fish oil feeding suggests that the conversion of 22:5n-3 to 24:5n-3 may be limiting. There was no evidence from our gas chromatographic analyses that 24:5n-3 or 24:6n-3 accumulated.

Accumulation of 18:1n-9, 18:3n-3, 20:3n-3 and 20:2n-6. The extensive incorporation of 18:1n-9 into CL has been reported in rats fed 20 wt% olive oil (31) or triolein (18) for 4–5 months, but not in shorter-duration experiments (23). Oleate also has been found to increase in CL after feeding rapeseed oil and essential fatty acid deficient or low linoleic acid diets (3).

The minor accumulation of 18:3n-3 (21,49) and 20:3n-3 (24) in CL after feeding linolenate sources has been reported previously. The fact that 20:2n-6 (following safflower oil feeding) and 20:3n-3 (following linseed oil feeding) accumulated in day 18, but not day 42, mice suggests that these fatty acids were either more available during breast feeding (day 18) than during dietary ingestion (day 42); or that the Δ6 desaturase may not have been fully active in day 18 mice. There is some evidence from *in vitro* studies that "dead end" elongation products may accumulate under conditions when the desaturase system is not active (50–52).

[a]Calculated as the ratio of the mol%, wt% or area% of 18:1n-9 (δ), 22:1n-9 (φ), 18:2n-6 (θ), or 22:6n-3 (Ω) in CL divided by the respective mol%, wt% or area% of the designated precursor fatty acid.
[b]FO, fish oil.

Mechanisms of acyl specificity in cardiolipin. Linoleate is known to be a major fatty acid in CL from a variety of mammalian tissue sources except for rat brain, lung and testes (1,53). Our data indicate that 18:2n-6 accumulates in CL because it is very abundant in most animal diets, and that other fatty acids, such as 18:1n-9 and 22:6n-3, may replace 18:2n-6 when provided in sufficient amounts in the diet. There is not a uniquely high selectivity for incorporation (Table 6) or retention of this fatty acid in CL pools. Rather, it has been shown that 18:2n-6 levels in CL change dynamically in response to dietary 18:2n-6 supply (20,22,32,54,55). Interestingly, we found that a marine shark (brown smoothhound shark, *Mustelus henlei*) caught in Tomales Bay, Northern California, had only 3 area% 18:2n-6 in heart CL, but had high levels of n-9 monoenoic acids (49% 18:1), and n-3 polyenoic acids (12% 22:5n-3, 18% 22:6n-3) (unpublished data). These data likely reflect the fact that sharks consume a diet low in 18:2n-6 and high in n-3 polyenoic acids.

The assumed high selectivity of 18:2n-6 for CL has not been demonstrated *in vitro* (1). Schlame and Rüstow (2) have provided some evidence that monolysoCL can be

enriched with 18:2n-6 when 1-palmitoyl-2-linoleoyl PC is present in the incubation system (1-palmitoyl-2-docosahexaenoyl PC was not evaluated). This observation, and the fact that CL is synthesized from inner mitochondrial membrane precursors that are not particularly rich in 18:2n-6, suggests that extensive retailoring of CL may occur (56,57).

The replacement of 18:2n-6 with 22:6n-3 and 18:1n-9 suggests that the enzymes responsible for remodeling and maintaining acyl specificity in CL (phospholipases and acyltransferases) can recognize and select for fatty acids of different unsaturation and different chain length. In other phospholipids, fatty acids that are more structurally similar may replace one another (*e.g.*, 20:5n-3 may replace 20:4n-6; and 22:6n-3 may replace 22:5n-6) (42).

There appears to be no special selectivity for incorporation of 22-carbon fatty acids (compare 22:1n-9 and 22:6n-3; Table 6). Wolff and Entressangles (3) suggest that there may be selectivity for double bond positions 8 and 11 in both 18- and 20-carbon fatty acids, based on the results of depletion studies. This selectivity is difficult to discern from dietary feeding studies. The following fatty acids are more abundant in CL relative to other phospholipids or can be enriched in CL by dietary means: 16:1n-7, 18:1n-7, 18:1n-9, 18:2n-6, 5*t*,9*c*,12*c*-octadecatrienoate, 20:2n-6, 20:3n-3, 22:1n-9 and 22:6n-3 (21,58–61). The following dietary fatty acids are incorporated into CL to a lesser extent: 16:0, Monoenoic acids with the double bond in the *trans* conformation (22,62), 18:3n-3, 18:3n-6 (49), 5,11,14-eicosatrienoate, 5,11,14,17-eicosatetraenoate (61), 20:3n-6 (49) and 22:1n-11 (62).

Dietary fatty acids thus appear to be extensively incorporated into the CL class in their intact form, or after one round of "dead end" elongation (*e.g.*, 18:1n-7, 20:2n-6, 20:3n-3), but not after they have been desaturated. For example, 18:2n-6, but not its desaturation/elongation products 20:3n-6, 20:4n-6, 22:4n-6 and 22:5n-6, is extensively incorporated into CL. Similarly, with essential fatty acid deficiency, 18:1n-9, 18:1n-7 and 16:1n-7 (synthesized endogenously) accumulate to a greater extent than 20:3n-9 and 20:3n-7 (3,15,63).

Physiological consequences of replacing 18:2n-6 with other fatty acids in CL. In the inner mitochondrial membrane, CL is associated with several key enzymes (4–9), the most studied being cytochrome *c* oxidase (10–12). There is evidence from dietary studies (13–15) that modulation of the acyl chain of CL can influence the activity of associated inner mitochondrial membrane proteins. Yamaoka *et al.* (13) found that in rats fed fish oil, 18:2n-6 was largely replaced with 22:6n-3 in hepatic and cardiac CL, and there was a 50% decrease in the activity of cytochrome *c* oxidase. Cytochrome *c* oxidase activity (and possibly other inner mitochondrial membrane enzyme activities) may therefore be modulated by dietary fat intake *via* alterations in the acyl composition of CL. Dietary fat is not known to alter the absolute amount of CL in organs (15,23,31,38,39,64). The results of *in vitro* studies with CL derivatives similarly indicate that the acyl chains of CL, as well as the phosphate moiety and the free 2′-hydroxyl group on the headgroup glycerol, are important in the associations of CL with inner mitochondrial membrane proteins (2,10,11,16–18).

CL, or a related acidic phospholipid may also bind to aPL, possibly bound to plasma β_2-globulin (65). aPL are prevalent in patients with systemic lupus erythematosus and other disorders, and have been correlated to thrombosis, thrombocytopenia, neurological disorders and ischemic heart disease (65). The recent demonstration that passive transfer of aPL to mice can result in fetal loss suggesting that aPL may have direct effects on pregnancy outcome (66). Alteration of the acyl moiety of CL can influence the *in vitro* binding to aPL (19,67,68).

There are several lines of evidence to suggest that the oxidation of CL may affect the activity of associated enzymes: i) Free radical-induced lipid peroxidation of mitochondrial particles is known to lead to the formation of more polar species of CL (as well as PC and PE), and to decreased activities of inner mitochondrial NADH oxidase and NADH-cytochrome *c* reductase (69,70); ii) peroxidation of CL/PC vesicles by addition of superoxide radical ions has been demonstrated to decrease the binding of ferricytochrome *c* to cytochrome *c* oxidase in the tertiary complex (CL-ferricytochrome *c*-cytochrome *c* oxidase) (71); and iii) cytochrome *c*-(Fe^{3+})-H_2O_2 induced peroxidation of mitochondrial membranes may preferentially affect CL, to which cytochrome c binds (72). Malis *et al.* (73) found mitochondrial membranes derived from fish oil fed rats to have enhanced phospholipase A_2-mediated release of fatty acids, and a corresponding reduced NADH coenzyme Q reductase activity after exposure to Ca^{2+} and reactive oxygen species, relative to control membranes. Although the acyl composition of CL was not examined in this study, the feeding of fish oils to rats would result in significant incorporation of 22:6n-3 into mitochondrial CL and to the formation of tetra-docosahexaenoyl molecular species (15). CL rich in 22:6n-3 could thus have been a phospholipid target of the reactive oxygen species in the studies of Malis *et al.* (73).

In summary, we have demonstrated that 18:1n-9 present in olive oil and 22:6n-3 present in fish oil can replace a significant portion of 18:2n-6 in hepatic and cardiac CL of newborn mice. These fatty acids will continue to accumulate during nursing and active feeding of the offspring, provided they are fed in sufficient quantities and for a long enough duration. The major difference between linseed oil (rich in 18:3n-3) and fish oil feeding (rich in 22:6n-3) was that 22:6n-3 accumulated extensively in heart CL only when fed as intact 22:6n-3. Levels of 20:5n-3 and 22:5n-3 were equivalent or greater with linseed oil feeding in CL, PC and PE. These findings may be relevant to human populations who consume diets rich in 18:1n-9 (Mediterraneans), 18:2n-6 (Americans) and 20:5n-3/22:6n-3 (Eskimos and individuals ingesting fish and fish oils). Physiologically, these findings may be important because alterations in CL acyl moiety may influence the activity of associated inner mitochondrial membrane enzymes. The ramifications of altering the acyl composition of CL during development have never been investigated.

ACKNOWLEDGMENTS

Surface Components of Chylomicrons from Rats Fed Glyceryl or Alkyl Esters of Fatty Acids: Minor Components[1]

L.Y. Yang[a], A. Kuksis[a,*], J.J. Myher[a] and H. Pang[b]
[a]Department of Biochemistry and Banting and Best Department of Medical Research, University of Toronto, Toronto, Canada M5G 1L6 and [b]The Carbohydrate Research Center, University of Toronto, Toronto, Canada M5S 1A8

The lipid class, fatty acid and molecular species composition of the minor polar surface components of rat lymph chylomicrons were determined during absorption of menhaden oil and corn oil or of the corresponding fatty acid ethyl esters. In addition to the previously reported minor polar lipids (sphingomyelin, phosphatidylserine, phosphatidylinositol, phosphatidic acid and lysophosphatidylcholine), we identified phosphatidylglycerol, dimethylphosphatidylethanolamine, ceramide and cholesteryl sulfate in the chylomicrons from both oil and ester feeding. The dietary fatty acids were found to be incorporated to a variable extent into the different phospholipid classes, the proportions of which remained the same during both types of feeding. No evidence was obtained for the presence of the minor glycerophospholipids characteristic of the lysosomal membranes (*e.g., bis*-phosphatidic, lyso*bis*phosphatidic and semilyso*bis*-phosphatidic acids), although special efforts were made to identify them. These results indicate that the chylomicrons arising from the monoacylglycerol and phosphatidic acid pathways of triacylglycerol biosynthesis become enveloped in closely similar monolayers of phospholipids. Hence, all triacylglycerols may be secreted from the villus cells *via* a common mechanism as suggested by the previously demonstrated convergence (at the 2-monoacylglycerol stage) of the monoacylglycerol and the phosphatidic acid pathways of mucosal triacylglycerol formation [Yang, Y.L., and Kuksis, A. (1991) *J. Lipid Res. 32*, 1173–1186].
Lipids 27, 613–618 (1992).

We have obtained evidence for an apparent convergence (at the 2-monoacylglycerol stage) of the phosphatidic acid and the monoacylglycerol pathways of triacylglycerol biosynthesis in the rat intestinal mucosa (2). In support of such a common final pathway, we have demonstrated identical apoprotein (3) and major glycerophospholipid (4,5) composition of the chylomicrons generated from oil (monoacylglycerol pathway) and ester (phosphatidic acid pathway) feeding. Since the mechanism proposed for the convergence involves the conversion of the triacylglycerol products of the phosphatidic acid pathway, which are stored and cannot be secreted, into 2-monoacylglycerols by a lysosomal lipase, we have sought evidence of a lysosomal membrane contact by analyzing the minor phospholipids of the chylomicrons for the presence of lysosomal lipids. Lysosomes are known (6) to contain *bis*-monoacylglycerophosphate (*bis*-lysophosphatidic acid) as a characteristic component, which overlaps with phosphatidic acid in the acidic thin-layer chromatography (TLC) systems commonly employed in phospholipid analyses (7). These compounds can be readily resolved in alkaline solvent systems (6). Previous studies (8) had occasionally noted unusually high proportions of phosphatidic acid in rat chylomicrons and prechylomicrons, but a contamination with the polyglycerophosphates had not been considered.

The present study demonstrates that the previously identified "phosphatidic acid" fraction (8) recovered from rat lymph chylomicrons contains significant amounts of other previously unidentified compounds, which can be resolved in an alkaline TLC system, and that the *bis*-phosphatidic acid derivatives are not among them. The results extend the demonstration of the similarity in the surface composition of the chylomicrons from the oil and ester feeding to the minor phospholipids, which had not been assessed previously.

MATERIALS AND METHODS

Animals, surgical procedures and diets. Retired male breeder rats (350–400 g) received 1 mL of menhaden oil or corn oil or the corresponding fatty acid ethyl esters by stomach fistula, and lymph collections were made from the thoracic duct over a period of 2–24 h, as previously described (3,4). Lymph chylomicrons were isolated by ultracentrifugation (3).

Isolation and quantitation of phospholipid classes. Total lipid extracts of chylomicrons were obtained with chloroform/methanol (2:1, vol/vol) and were resolved into neutral and polar lipids by TLC using heptane/isopropyl ether/acetic acid (60:40:4, vol/vol/vol) as the developing solvent (5), which carried the triacylglycerols near the solvent front and retained the phospholipids at the origin. The phospholipids were recovered from the origin by extraction with chloroform/methanol/water/acetic acid (50:39:10:1, by vol) (9). After concentration, the lipids were separated into individual phospholipid classes by TLC using either chloroform/methanol/acetic acid/water (75:45:12:6, by vol) (10) or a double development system (11)—chloroform/methanol/ammonium hydroxide/water (65:35:1:3, by vol) and chloroform/methanol (95:5, by vol) in the same direction. The phospholipid classes from all feedings were identified by reference to standards and those from corn oil feeding also were analyzed by fast atom bombardment-mass spectrometry (FAB-MS). The phospholipid clases were quantitated on the basis of the fatty acid content using heptadecanoic acid as an internal standard. Gel scrapings containing individual phospholipid classes were subjected to acidic methanolysis using 6% H_2SO_4 in methanol at 80°C for 2 h. After addition of the internal standard, the fatty acid methyl esters were analyzed by gas-liquid chromatography (GLC) (5). Cholesteryl sulfate was quantitated by measuring cholesterol in relation to the content of dimethylphosphatidylethanolamine (DMPE).

[1]Part of this work was presented at the Annual AOCS Meeting, Baltimore, MD, April, 1990 (ref. 1).

Abbreviations: CL, cardiolipin; DMPE, dimethylphosphatidylethanolamine; FAB-MS, fast atom bombardment-mass spectrometry; GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; GP, glycerophosphate; LPC, lysophosphatidylcholine; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; SPH, sphingomyelin; TLC, thin-layer chromatography; VLDL, very low density lipoprotein.

FAB-MS. Fast atom bombardment-mass spectra were obtained using a VG-Analytical ZAB-SE instrument with a VG-11/250 data system (VG Analytical Ltd., Manchester, England). The samples were dissolved in chloroform, and triethylamine was used as matrix for negative ion analysis. The bombardment was effected with xenon atoms at 8 kV anode potential and 1.2 mA anode current.

Acetolysis. In order to determine if the unknown phospholipids contained one or two fatty acids per glycerol molecule, various samples were subjected to acetolysis (12). The products of acetolysis were separated by TLC using petroleum ether/diethyl ether (4:1 by vol) as mobile phase.

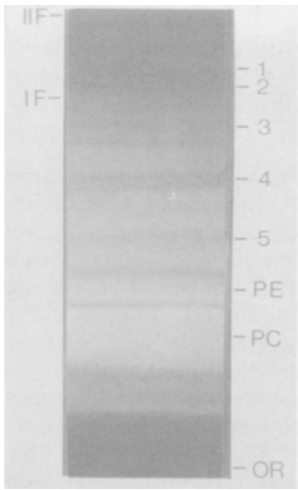

FIG. 1. TLC separation of total phospholipids from lymph chylomicrons. OR, origin; PC, phosphatidylcholine; PE, phosphatidylethanolamine; 1, ceramides; 2, monoacylglycerols plus hydroxyceramides; 3, unknown phospholipid; 4, dimethylphosphatidylethanolamine plus cholesteryl sulfate; 5, phosphatidylglycerol. IF, first solvent front; IIF, second solvent front. Solvent system: First, chloroform/methanol/NH_4OH/water (65:35:1:3, by vol); second, chloroform/methanol (95:5, vol/vol).

RESULTS

Identification of minor polar lipids. Figure 1 indicates the presence of five fast moving bands in the basic TLC system used to examine the minor phospholipids in the chylomicrons from corn oil feeding. These bands migrate close to the solvent front in the acidic TLC system, and in the past apparently have been pooled with phosphatidic acid (8). The R_f values of the unknowns (TLC Bands 3 and 4) correspond closely to those of standard *bis*-monoacylglycerodiacylglycerophosphate (*bis*-semilysophosphatidic acid) and *bis*-monoacylglycerophosphate, respectively. However, acetolysis failed to reveal any monoacylglycerol diacetates, thus eliminating the possible presence of these polyglycerophosphates as major components of these fractions. Only diacylglycerol acetate (TLC Band 3) and diacylglycerol and cholesteryl acetate (TLC Band 4), and diacylglycerol acetate (TLC Band 5) were present as confirmed by gas chromatography/mass spectrometry (GC/MS). The triacetylglycerol also expected in TLC Band 5 was lost due to evaporation. TLC Bands 1 and 2 were rechromatographed in a neutral system, where they could be shown to run with R_f values corresponding to ceramides (TLC Band 1) and monoacylglycerols (TLC Band 2), and a component more polar than monoacylglycerols. The identity of the ceramides and monoacylglycerols was confirmed by GLC (13). Finally, all the minor polar lipid fractions from the initial TLC separation were examined by FAB-MS. TLC Band 1 gave a FAB mass spectrum with prominent $[M-H]^-$ ions at *m/z* 536 and 648, indicating the presence of palmitoyl and lignoceroyl sphingosines, respectively. Other species corresponding to the 22:0, 23:0 and 24:1 amides were present also. These species matched those reported in the literature for the free ceramides of rat intestinal mucosal lipids (14). TLC Band 2, which corresponded in R_f value to *bis*-phosphatidic acid, gave a FAB mass spectrum with prominent $[M-H]^-$ ions at *m/z* 554 and 666, indicating the presence of palmitoyl and lignoceroyl hydroxysphinganine, respectively. Other species corresponding to the 22:1, 22:0, 18:0 and 20:0 hydroxysphinganines also were present. The composition of the hydroxyceramides from rat intestine has been reported (14). The FAB-MS of TLC Band 3, which corresponded in R_f value to the *bis*-semilysophosphatidate, remained unidentified although some characteristics of a glycerophospholipid could be discerned. TLC Band 4, which corresponded in R_f value to *bis*-monophosphatidate (*bis*-lysophosphatidate), gave an FAB mass spectrum with prominent $[M-H]^-$ ions at *m/z* 742 and 770, which indicated the presence of the 16:0–18:2 and 18:0–18:2 species of DMPE, respectively. The fragmentation ions at *m/z* 255, 279, 281 and 283 corresponded to the $[RCOO]^-$ ions of 16:0, 18:2, 18:1 and 18:0 fatty acids. The fragment ions $[PA-H]^-$ at *m/z* 671 and 699 indicated the presence of 16:0–18:2 and 18:0–18:2 diacylglycerophosphates, or phosphatidic acids (PA), respectively. In addition, this TLC band contained a prominent ion $[M-H]^-$ at *m/z* 465, which corresponded to cholesteryl sulfate. The presence of cholesteryl sulfate in this TLC band was confirmed by a GC/MS demonstration of cholesteryl acetate among acetolysis products of this fraction (results not shown). The complex FAB-MS of TLC Band 4 is given in Figure 2. The FAB mass spectrum of TLC Band 5, which migrated between cardiolipin (CL) and phosphatidylethanolamine (PE), gave prominent ions $[M-H]^-$ at *m/z* 745 and 773, which corresponded to the 16:0–18:2 and 18:0–18:2 species of phosphatidylglycerol (PG), respectively. The fragment ions at *m/z* 255, 279, 281 and 283 were due to the $[RCOO]^-$ ions of 16:0, 18:2, 18:1 and 18:0 fatty acids. The fragment ions $[PA-H]^-$ at *m/z* 671 and 699 are due to the 16:0—18:2 and 18:0—18:2 diacylglycerophosphates (GP) or phosphatidic acids, while the fragment ions $[GP-H]^-$ at *m/z* 153 and 171 are due to glycerophosphate. The FAB-MS of PG was similar to the FAB-MS published previously for natural PG (15).

Phospholipid class composition. Table 1 gives the relative proportions of the phospholipid classes isolated from the chylomicrons during the peak of absorption (2–8 h) of menhaden oil and its fatty acid ethyl esters. The values represent best estimates derived from TLC separations obtained with the acidic and basic solvent systems and GLC following appropriate derivatization. In both instances the major components are phosphatidylcholine (PC; 80%) and PE (8%), with much smaller amounts of phosphatidylinositol (PI; 2.5%), phosphatidylserine (PS;

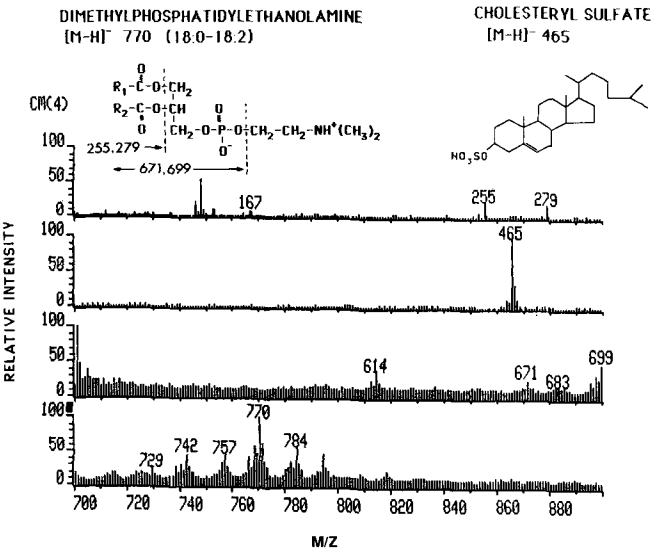

FIG. 2. FAB-MS of DMPE and cholesteryl sulfate. The general structure and cleavage fragments are indicated in the Figure. The ions at *m/z* 742 and 770 correspond to the parent ions of the 16:0-18:2 and 18:0-18:2 species of DMPE, respectively. The ions at *m/z* 671 and 699 correspond to the fragment ions of the corresponding species of PA. The fragment ions at *m/z* 225, 279, 281 and 283 correspond to the 16:0, 18:2, 18:1 and 18:0 fatty acids. The prominent ion at *m/z* 465 is due to cholesteryl sulfate, which was also present in this TLC fraction. FAB-MS conditions are as given under Methods. The individual panels are displayed independently of each other.

TABLE 1

Relative Proportions of Polar Surface Lipid Classes in Chylomicrons from Rats Receiving Menhaden Oil or Corresponding Fatty Acid Ethyl Esters[a]

Polar lipid classes	Source of chylomicrons (mole %)	
	Oil-fed	Ester-fed
Phosphatidylcholine	78.7 ± 1.2	80.6 ± 1.0
Phosphatidylethanolamine	8.1 ± 1.7	7.7 ± 0.2
Phosphatidylinositol	2.7 ± 0.5	2.5 ± 0.4
Phosphatidylserine	0.1 ± 0.0	0.1 ± 0.0
Phosphatidic acid	1.1 ± 0.3	0.9 ± 0.2
Sphingomyelin	0.5 ± 0.2	0.5 ± 0.1
Lysophosphatidylcholine	1.0 ± 0.1	1.4 ± 0.1
Phosphatidylglycerol	1.6 ± 0.2	1.3 ± 0.2
Dimethylphosphatidylethanolamine	1.3 ± 0.5	1.0 ± 0.2
Cholesteryl sulfate	1.5 ± 0.4	1.4 ± 0.5
Ceramides	0.3 ± 0.1	0.3 ± 0.1
Hydroxyceramides[b]	0.2 ± 0.1	0.2 ± 0.0
Monoacylglycerols	0.4 ± 0.3	0.3 ± 0.1
Unknown phospholipid	2.4 ± 1.0	1.9 ± 0.7
PC/FC ratio	8.6 ± 2.0	7.4 ± 1.1

[a]PC/FC, phosphatidylcholine/free cholesterol, X ± SD from 4-6 determinations.
[b]Acylated hydroxysphinganines.

0.1%), PA (1%), sphingomyelin (SPH; 0.5%), lysophosphatidylcholine (LPC; 1%), PG (1.5%) and DMPE (1%). In addition, the chylomicrons contain other polar lipids, such as cholesteryl sulfate (1.5%), ceramide (0.3%), hydroxyceramides (0.2%) and an unidentified minor phospholipid (2%). There are no significant differences between the major phospholipids of chylomicrons when menhaden oil was fed intact or as its fatty acid ethyl ester. Except for the contribution of the unknown and the minor lipids, these values are comparable to those observed earlier during mustard seed oil feeding (4).

Table 2 compares the fatty acid composition of SPH and LPC in the chylomicrons collected at the peak of absorption (2-8 h) of menhaden oil and its fatty acid ethyl ester feeding. Both SPH and LPC have high proportions of 16:0 (50% for SPH and 37% for LPC), 18:0 (17% for SPH and 33% for LPC), and small amounts of 14:0, 16:1, 18:1 and 18:2, along with very small amounts of the polyunsaturated fish oil fatty acids.

Table 3 compares the fatty acid composition of PG and DMPE from chylomicrons collected 2-8 h after menhaden oil or its fatty acid ethyl ester feeding. The oil feeding resulted in more dietary fatty acids in these phospholipids, as indicated by the higher proportion of 18:2 detected and attributed to an incomplete clearance of corn oil used in pre-feeding (5). In other respects, both feedings show comparable effects on the fatty acids of PG and DMPE.

Table 4 gives the fatty acid composition of PA and the unknown lipid fraction. PA was isolated from just above the origin during the phospholipid resolution in a basic TLC system. There are minor differences between the two feedings in the fatty acid composition of these esters. The major acids are of endogenous origin, with very small amounts of the dietary polyunsaturated fatty acids being present. The identity and significance of the unknown lipid requires further investigation.

The ceramides of chylomicrons collected during the peak absorption of menhaden oil and its ethyl ester showed very similar fatty acid composition (data not shown). The two types of ceramides contain significant proportions of 14:0, 16:0 and 18:1, in addition to the saturated long-chain acids. The small amounts of the polyunsaturated dietary fatty acids recovered from these ceramides probably represented minor contamination with glycerophospholipids.

DISCUSSION

The composition of the common chylomicron phospholipids established in this study is comparable to that observed earlier by Myher *et al.* (4) during mustard seed oil absorption. Further, these values are similar to those obtained by Redgrave (8), who reported 6% PA. In the present study, the sum of PA plus minor low polarity phospholipids accounted for 6.4% of total. The phospholipid class composition of the chylomicrons clearly differs from that of the mucosal microsomes reported by Redgrave (8) as 45% PC, 20% PE, 16% LPC, 8% SPH and 8% PI, as well as from that of the prechylomicrons, which showed intermediate composition between that of the microsomes and the chylomicrons, except for 10% PA. The PA levels of the chylomicrons or intestinal mucosal cells analyzed in our laboratory never exceeded 1%. Apparently phosphorus containing lipids other than PA had been included in the higher estimates, as suggested by the present study. The microsomal PE also contained 11-16% alkylacyl and 4-8% alkenylacyl subclasses (16), which occurred in the chylomicrons to less than 5-6% (5). Likewise, the phospholipids of the chylomicrons are different from those of whole villus cells (17) and of rat plasma (18). The

present results clearly exclude the origin of the major chylomicron phospholipids by transfer from any of the above sources as well as by extensive equilibration with any plasma lipoproteins that may have filtered into lymph. These findings would make a significant lysosomal contribution unlikely in view of the absence of the polyglycerophospholipids from the chylomicrons.

In view of the above results, it is necessary to look to other explanations for the origin of the peculiar composition of chylomicron phospholipids. The relative absence of PE and the acidic phospholipids from the surface of the chylomicrons would suggest a selective loss based on monolayer stability during the passage of the chylomicrons from the site of initial assembly to the point of secretion. This would result in a preferential retention of PC, which is known to more readily form phospholipid

TABLE 4

Fatty Acid Composition of PA and Unknown Phospholipid of Chylomicrons from Rats Receiving Menhaden Oil or Corresponding Fatty Acid Ethyl Esters[a]

[a]X ± SD from 4-6 determinations.

monolayers at the oil-water interface (19) than PE, PS, PI or LPC (20). It is not known whether this effect extends to the oil-water interface involved in the chylomicron secretion and to what extent the monolayer stability may be influenced by interaction with apoprotein B and other apoproteins also present on the chylomicron surface.

In an earlier study O'Doherty *et al.* (21) demonstrated the need of PC during fat absorption in choline deficient rats with bile fistula, and suggested a requirement for a continued supply of a phospholipid surfactant. More recently, Vance *et al.* (22) reported evidence for a possible need of PC biosynthesis during VLDL secretion by rat liver. The present results obtained on the minor polar lipids of the chylomicrons are consistent with a biosynthesis of surface active components, because several of the newly identified lipids are precursors of phospholipids and sphingolipids. Thus, DMPE is an intermediate in PC synthesis *via* PE methylation pathway, which is known to be active in endoplasmic reticulum and the Golgi of hepatocytes during very low density lipoprotein (VLDL) secretion (22,23). It is believed to contribute some 20–40% of the cellular PC. The methylation pathway of PE has been claimed to be activated in the liver of the choline deficient rat (24). The fatty acid composition of DMPE was similar to that of PE collected at the same time and reported previously (5). This was in agreement with the work of Vance (23), which had shown that the DMPE of the rat liver VLDL possesses a fatty acid composition similar to that of PE. The fatty acid composition of PC is not achieved until after complete methylation of PE to PC and a probable acyl exchange. A biosynthetic involvement of DMPE is favored by the rapid appearance of dietary fatty acids in this lipid during fat absorption, as shown in the present work.

The presence of free ceramides in the chylomicrons would suggest a possible role in the biosynthesis of glycosphingolipids, which are known to be synthesized in mucosal cells (25), although they were not analyzed in the present work. These ceramides are less likely to be precursors of sphingomyelin, the chylomicron content of which is not increased. The isolation of substantial amounts of cholesteryl sulfate from the chylomicrons is a new finding, but fully consistent with the hypothetical need for surfactants. Cholesteryl sulfate has been reported in plasma low density lipoproteins by Epstein *et al.* (26) and Nakamura *et al.* (27). It is known to serve as a membrane stabilizer (27). In recessive X-linked ichtyosis patients, which lack cholesterol sulfatase, the abnormal amount of the accumulating steroid causes desquamation, as characterized by scaly skin and corneal opacity (27). Hence, the specific biosynthesis of PC, reflecting a need for surfactant during chylomicron formation and secretion would appear to provide the most logical explanation for its enrichment in the chylomicrons, along with other minor surfactants. We have previously demonstrated a general increase in glycerophospholipid synthesis in response to fat absorption by villus cells (17). The present study indicates that a further investigation of surfactant synthesis during chylomicron formation and secretion would be justified.

The present study provides further evidence for the similarity in the surface lipids of chylomicrons formed *via* the phosphatidic acid and the monoacylglycerol pathways of triacylglycerol biosynthesis. These results lend credibility to the hypothesis that the two synthetic pathways yield only one final triacylglycerol product which is packaged and secreted as chylomicrons (2).

Effects of Dietary Saturated Fat on Erucic Acid Induced Myocardial Lipidosis in Rats

J.K.G. Kramer[a,*], F.D. Sauer[a], M.S. Wolynetz[b], E.R. Farnworth[a] and K.M. Johnston[1]

Male Sprague-Dawley rats were fed for one week diets containing 20% by weight fat/oil mixtures with different levels of erucic acid (22:1n-9) (~2.5 or 9%) and total saturated fatty acids (~8 or 35%). Corn oil and high erucic acid rapeseed (HEAR) oil were fed as controls. The same hearts were evaluated histologically using oil red O staining and chemically for cardiac triacylglycerol (TAG) and 22:1n-9 content in cardiac TAG to compare the three methods for assessing lipid accumulation in rat hearts. Rats fed corn oil showed trace myocardial lipidosis by staining, and a cardiac TAG content of 3.6 mg/g wet weight in the absence of dietary 22:1n-9. An increase in dietary 22:1n-9 resulted in significantly increased myocardial lipidosis as assessed histologically and by an accumulation of 22:1n-9 in heart lipids; there was no increase in cardiac TAG except when HEAR oil was fed. An increase in saturated fatty acids showed no changes in myocardial lipid content assessed histologically, the content of cardiac TAG or the 22:1n-9 content of TAG at either 2.5 or 9% dietary 22:1n-9. The histological staining method was more significantly correlated to 22:1n-9 in cardiac TAG ($r = 0.49$; $P < 0.001$) than to total cardiac TAG ($r = 0.40$; $P < 0.05$). The 22:1n-9 content was highest in cardiac TAG and free fatty acids. Among the cardiac phospholipids, the highest incorporation was observed into phosphatidylserine, followed by sphingomyelin. With the addition of saturated fat, the fatty acid composition showed decreased accumulation of 22:1n-9 and increased levels of arachidonic and docosahexaenoic acids in most cardiac phospholipids, despite decreased dietary concentrations of their precursor fatty acids, linoleic and linolenic acids.
Lipids 27, 619–623 (1992).

Erucic acid (22:1n-9) in the diet has been shown to cause myocardial lipidosis, particularly in rats, and to a lesser extent in other species (1–4). On continuous feeding, lipidosis reaches a maximum at 4 to 7 days and decreases thereafter. Diets with >10% 22:1n-9 in the oil/fat portion result in increased myocardial lipidosis as assessed histologically with appropriate fat-soluble dyes, increased triacylglycerol (TAG), and incorporation of 22:1n-9 into cardiac lipid classes.

The occurrence of myocardial lipidosis is less consistent when diets containing <10% 22:1n-9 in the oil portion are fed, and results are dependent on which method is used to assess the lipid accumulation. Some investigations have reported increased myocardial lipidosis with 10% 22:1n-9 in the dietary oil (5,6); others with 8% (7), 6% (8), 5% (9), and 2% (10–12). Furthermore, some researchers have reported myocardial lipidosis in rats fed high fat diets containing no 22:1n-9 with such oils as corn (11–13), peanut (8,9), soybean (14) and sunflower (7,15), and with lard (16) and lard/corn oil (12).

Dietary saturated fatty acids (SFA) have been shown to improve growth rate in rats (17–19), reduce incidence and/or severity of myocardial necrosis in male rats (19–22), improve pathogenic characteristics in ducklings (18), as well as reduce myocardial lipidosis in rats fed diets rich in 20:1n-9, but not with 22:1n-9 (23). The reason may have been that the dietary content of 22:1n-9 was too high in these diets, *i.e.*, 30 and 70% (23). No other studies were designed to test the effects of different levels of SFA on myocardial lipidosis in rats in the presence of much lower dietary concentrations of 22:1n-9, and the effects of TAG and the composition of fatty acids in the heart.

The present study was designed to test if SFA would influence the incidence and/or severity of myocardial lipidosis in male rats fed <10% 22:1n-9, to determine if dietary SFA influence the relative concentration of other fatty acids in cardiac lipids in the presence of different levels of dietary 22:1n-9, and to compare the results of histological and chemical assays.

EXPERIMENTAL PROCEDURES

Male Sprague-Dawley rats (Charles River Canada Inc., St. Constant, Quebec, Canada), weighing 124.1 ± 0.7 g, were fed one of six diets (10 rats/diet) for one week. The test oil mixtures were prepared by mixing canola oil, high erucic acid rapeseed (HEAR) oil and cocoa butter in proportions to give oils with about 2.5 and 9% 22:1n-9, each with a low (8%) and a high content (35%) of total SFA. The ratios of oils used and the fatty acid composition of all test oils are shown in Table 1. Semisynthetic diets were prepared containing oil at 20% by weight as described previously (19); diets were fed *ad libitum*.

After one week on the test diet, rats were anesthetized with CO_2 and killed by decapitation. Hearts were removed immediately. Hearts were bisected longitudinally along the median plane. Half the heart was fixed in 10% neutral buffered formalin and the other half placed on dry ice for total lipid extraction (24). Following formalin fixation, the tissue was frozen in liquid nitrogen, sectioned longitudinally on a cryostat at −20°C and stained with oil red O. The percent of tissue area stained was estimated by examining fields under 200-fold magnification, judging the percent of each field involved in lipidosis and averaging the percentages, to arrive at a percent involvement for each heart section.

The cardiac lipids were separated by 3-directional thin-layer chromatography (TLC) (25) on silica gel H plates (Analtech Inc., Newark, DE), first direction, chloroform/methanol/28% aqueous ammonia (65:25:5, vol/vol/vol); second direction, chloroform/methanol/acetone/acetic acid/water (50:10:20:15:5, by vol); and third direction (for

[a]Diets contained two different levels of erucic acid (22:1n-9) and two different levels of saturated fatty acids (SFA). The dietary oil mixtures were prepared by mixing canola oil (0.8% 22:1n-9), high erucic acid rapeseed (HEAR) oil (42.9% 22:1n-9), and cocoa butter in the ratio of 96:4:0 (A), 54:4:42 (B), 81:19:0 (C) and 39:19:42 (D) by weight, respectively.

neutral lipids only) hexane/diethyl ether/acetic acid (85:15:1, vol/vol/vol). The lipid classes were visualized under ultraviolet (UV) light after spraying the plates with a 2′,7′-dichlorofluorescein solution in methanol. Lipid fractions were scraped off the plate, and methyl heptadecanoate (NuChek Prep, Elysian, MN) was added as internal standard (26). The lipid/silica gel mixtures were transmethylated with anhydrous HCl/CH_3OH (5% by wt). The resultant fatty acid methyl esters were purified by TLC (hexane/diethyl ether/acetic acid, 85:15:1, vol/vol/vol) and quantitated by gas liquid chromatography (GLC) using fused silica capillary columns (27). Cholesterol was determined colorimetrically (26).

Analysis of variance was used to assess treatment differences; factors in the model were level of dietary SFA, 22:1n-9 and their interaction. Treatment effects were considered significant at $P < 0.05$. Because of heterogeneity of variances, data were also analyzed after a logarithm transformation. Since the statistical inferences were unchanged, only the results based on the original data were presented. The relationships among several of the response criteria were evaluated by computing the partial correlation coefficient after adjusting for treatment effects.

RESULTS

There were no significant differences in weight gain of rats fed the four oil mixtures and corn oil (55.3 ± 2.2 g). Rats fed the HEAR oil diet gained significantly ($P < 0.05$) less (49.4 ± 1.8 g). The heart weights were similar for all groups (0.72 ± 0.2 g). Total heart lipids were higher for the HEAR oil group (59.5 ± 3.2 mg/g wet weight) compared to all other groups, which showed no significant differences among each other (27.7 ± 1.0 mg/g wet weight). Among the rats fed the 4 test oil mixtures, there were no significant effects on weight gain, heart weight or total heart lipids, related to their dietary differences in 22:1n-9 and total SFA.

The histological results indicated trace myocardial lipidosis in most rats fed corn oil (Table 2). Compared to rats fed corn oil, the incidence and severity was slightly higher in rats fed oils with about 2.5% 22:1n-9, but the differences were not significant ($P > 0.05$). Oils with about 9% 22:1n-9 produced significantly increased myocardial lipidosis compared to rats fed oils with about 2.5% 22:1n-9. The areas most affected were the right and left ventricles near the base of the heart. Among the four test oil mixtures, there was a significant effect ($P < 0.001$) for dietary 22:1n-9, but not for total SFA. In contrast, myocardial lipidosis in HEAR oil-fed rats was very extensive throughout the whole heart. For an illustration, see Figure 2 in reference (28).

The cardiac lipid classes were not significantly different among the diets (results not shown), except for TAG which was significantly increased in HEAR oil-fed rats (Table 2). Among the four test oil mixtures, there was no significant effect related to dietary 22:1n-9 or total SFA, but there was a significant interaction ($P < 0.05$).

The 22:1n-9 content in cardiac TAG was directly related to the dietary content of 22:1n-9 (55 to 89% of diet), but the content of SFA had no effect (Table 2). This was not the case among the cardiac phospholipids, which showed a significant decrease in 22:1n-9 accumulation in several of the major cardiac phospholipids with an increase in dietary SFA (Table 3). The exception was cardiac sphingomyelin (SP), which showed a significant increase of 22:1n-9 with increased SFA.

Dietary 22:1n-9 accumulated in all lipid classes (Table 3). The highest accumulation was found in cardiac TAG, free fatty acids (FFA), phosphatidylserine (PS) and SP. Generally, the increase in dietary 22:1n-9 did not affect the relative concentration of other cardiac fatty acids including total SFA and arachidonic acid (20:4n-6), but the C_{22} polyunsaturated fatty acids (PUFA) content appeared to decrease, on occasion significantly. The addition of SFA to the oil mixtures, however, showed generally

little effect on the relative concentration of other fatty acids, except for the decrease in 22:1n-9 already pointed out, and the expected increase in total SFA of cardiac TAG (Table 3).

Based on the partial correlations, histological staining was highly correlated ($P < 0.01$) with 22:1n-9 in cardiac TAG (Table 2), as well as all other cardiac phospholipids ($P < 0.001$), except SP (results not shown). Furthermore, after adjusting for diets, the histological staining was positively correlated to other monounsaturated fatty acids (18:1n-9 and 20:1n-9) and linoleic acid (18:2n-6) and negatively correlated to SFA (14:0, 16:0, 18:0, 20:0 and 24:0); correlations were often significant for 16:0, 18:2n-6 and 20:1n-9 (results not shown). In cardiac SP, only 18:1n-9 showed a significant ($P < 0.05$) and positive correlation to histological staining.

DISCUSSION

The results of this study indicate that sparsely dispersed lipid droplets were readily detected by histological staining in most rat hearts examined (Table 2). Dietary 22:1n-9 exacerbated lipid droplet formation, but it did not appear to be the only cause, since the hearts of rats fed corn oil, which contained no 22:1n-9, also showed evidence of increased myocardial lipidosis. This confirms earlier observations by some investigators of trace myocardial lipidosis in rats fed high fat diets containing such oils as corn, peanut, soybean and sunflower, all of which contain no 22:1n-9 (7–9,11–15). The histological technique (staining with oil red O) is sensitive and will detect localized lipid accumulation, which in these hearts occurs mainly in the right and left ventricles near the base of the heart. At moderate to low severity of myocardial lipidosis, there are large differences in lipidosis responses between animals on the same diet (see SEM, Table 2), which depends on where the section was taken.

Even though these lipid droplets consist of TAG (1–4), myocardial lipidosis could not be confirmed by chemical analyses as increased TAG, even when the other half of the same heart was investigated. In order to detect increased TAG by chemical analyses, it appears that lipidosis needs to be dispersed over the entire heart, not simply in localized areas as shown by oil red O. Similar results were obtained recently by correlating myocardial lipidosis to cardiac TAG in newborn piglets fed milk replacer diets containing different oils (29). It should be noted that normal hearts contain about 4 mg/g wet weight intracellular TAG present as droplets, which are generally not visible after staining with oil red O and examining the sections using a light microscope. However, the lipid droplets in normal heart tissue can be seen using electron microscopy (9,15,30,31). Based on these results, it would appear that 22:1n-9 increased the droplet size, such that the droplets can be detected with oil red O, without significantly increasing the level of cardiac TAG (Table 2).

[a]Diets A, B, C and D are mixtures of canola oil (0.8% 22:1n-9), high erucic acid rapeseed (HEAR) oil (42.9% 22:1n-9) and cocoa butter; ratios shown in Table 1. The erucic acid (22:1n-9) and saturated fatty acid (SFA) content of the diets are shown.

[b]LSD, least significant difference. Means within a row which differ by more than the LSD are significantly different at $P < 0.01$.

[c]Significance due to differences in erucic acid (22:1n-9) or saturated fatty acids (SFA). n.s., Not significant ($P > 0.05$); *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$.

[d]For abbreviations of lipid classes see Footnote to title page.

[e]Number of rats/diet.

Erucic acid in cardiac TAG showed a higher correlation with oil red O staining than cardiac TAG (Table 2). However, the value of 22:1n-9 in cardiac TAG should be considered an overestimation of lipid droplets, since 22:1n-9 was incorporated into all cardiac TAG, but not all cardiac TAG was detected histologically using a light microscope. The correlation of oil red O to 22:1n-9 in cardiac TAG would therefore appear to be a reliable indicator, since 22:1n-9 at higher dietary concentrations will cause myocardial lipidosis.

It is evident from the results of this study that dietary SFA do not affect the incidence and/or severity of myocardial lipidosis at either 2.5 or 9% 22:1n-9, as measured by any of the three methods (Table 2). This suggests that 22:1n-9 acts independently in causing myocardial lipidosis at low (<10%; this study) or high (>30%; see ref. 23) concentrations of 22:1n-9. However, even though no discernible effects were observed in myocardial lipidosis and/or accumulation of cardiac TAG, the fatty acid profile of heart lipids showed distinct changes due to increased SFA. These include a general reduction in the incorporation of 22:1n-9 into several cardiac phospholipids, and increased concentrations of 20:4n-6 and C_{22} PUFA (Table 3), despite lower dietary levels of the precursor fatty acids, linoleic (18:2n-6) and linolenic (18:3n-3) acids (Table 1).

The question remains, what is the minimum level of dietary 22:1n-9 that will cause myocardial lipidosis? Such a question might imply that only 22:1n-9 induces myocardial lipidosis; this is not the case. A number of conditions are known to cause accumulation of lipid droplets such as stress, hypoxia, intoxication (9,15), including the first

consumption of maternal milk (13,29) and fasting (32). The problem is further complicated by the fact that vegetable oils fed at 20% by weight of the diet, even though they do not contain 22:1n-9, also cause trace myocardial lipidosis in rats (7-9,11-15) and pigs (29). From several studies using neonatal pigs, it appears that levels of more than 5% 22:1n-9 in the dietary oil caused increased myocardial lipidosis (29). On the other hand, results from this and other studies (9-12) with rats would suggest that levels of about 2 to 3% 22:1n-9 already show increased myocardial lipidosis. Species differences may account for the differences in sensitivity.

Increments of Dietary Linoleate Raise Liver Arachidonate, But Markedly Reduce Heart n-6 and n-3 Fatty Acids in the Rat

Franca Marangoni, Cristina Mosconi, Gerardina Galella and **Claudio Galli***
Institute of Pharmacological Sciences, University of Milan, 20133 Milan, Italy

Four diets containing 20% of energy (en%) as fat and with linoleic acid contents of 1.9, 3.1, 7.7 and 10.1 en%, respectively, were fed to one-month-old male rats for three months. The fatty acid profiles and the levels of the major n-6 and n-3 fatty acids in the lipids of plasma, liver, heart and kidney were measured. We found that with increasing concentrations of 18:2n-6 in the diet, linoleic acid rose in plasma and in all organs, but long-chain n-6 and n-3 fatty acids responded differently. In liver, arachidonic acid increased and n-3 fatty acids were not significantly affected; in heart, both arachidonic and docosahexaenoic acids were progressively reduced; and in kidney, there was no change of n-6 and n-3. The results indicate that incremental changes in dietary linoleate affect the levels of polyunsaturated fatty acids in liver and extrahepatic organs differently.
Lipids 27, 624–628 (1992).

The effect of diets with different linoleic acid (LA) contents, on the levels of polyunsaturated fatty acids (PUFA) in tissue lipids has been examined in experimental animals (1,2). Most studies, however, have been aimed mainly at investigating the changes of fatty acid (FA) profiles of tissue and plasma lipids after feeding different types of fats containing markedly different proportions of saturated FA, monounsaturated FA and PUFA (n-6 and n-3). Thus, the relationships between changes in LA, the major essential FA in the diet, and the accumulation of LA and its derivatives in tissues were not specifically investigated. An additional difficulty in evaluating the data available is due to the lower fat content in rodent diets when compared to human diets.

The relationships between the intakes of LA, the most abundant PUFA in the diet and in tissues, and the levels of arachidonic acid (AA), the major product of LA metabolism, in tissues and organs, are of special nutritional interest. Over the last decades, several expert panels have, in fact, recommended an increase in LA intakes up to 7 to 10 percent energy (en%), quite above the minimum requirement. *In vitro* studies indicate a high rate of production of the long-chain, highly unsaturated fatty acids in liver (3–10). However, in feeding studies, it is difficult to predict the relationships between different intakes of LA and the levels of n-6 highly unsaturated fatty acids (HUFA) in tissues and organs, since these appear to change differently in the liver and in other organs.

To explore the relationships between levels of LA in the diet and those of n-6 and n-3 PUFA in different tissues, we have fed defined diets, with a fat content of 10% (w/w), corresponding to 20.6 en%, and LA contents ranging between 2 to 10 en%, to groups of rats. The levels of LA and of the long-chain PUFA of the n-6 and n-3 series in plasma, liver and extrahepatic organs (heart and kidney) have then been measured. The major findings were that increasing levels of dietary LA, within the range of recommended intakes for humans, resulted in elevation of LA in all tissues. AA accumulated in the liver, whereas it decreased in the heart, with LA levels greater than 3.1 en% while docosahexaenoic (DHA) acid decreased progressively with increasing dietary LA levels. In the kidney, PUFA were minimally affected by changes of dietary LA.

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; CE, cholesteryl esters; DHA, docosahexaenoic acid; EFA, essential fatty acids; en%, percent energy; EPA, eicosapentaenoic acid; FA, fatty acids; HUFA, highly unsaturated fatty acids; LA, linoleic acid; PL, phospholipids; PUFA, polyunsaturated fatty acids; TG, triglycerides; GOT, glutamic-oxalacetic transaminase; LDH, lactic dehydrogenase; GPT, glutamic-pyruvic transaminase.

MATERIALS AND METHODS

Animals and diets. Four groups (six animals/group) of male rats of the Charles River strain were fed *ad libitum* the diets under study for a period of three months, starting at one month of age. Animals were individually caged in the first three weeks of treatment, in order to evaluate individual food consumption and body growth; subsequently, they were kept three animals/cage.

The four semisynthetic diets used were prepared according to AIN (AIN-76™) recommendations (Piccioni S.p.A., Gessate, Italy), had adequate protein, carbohydrate, vitamin and micronutrient contents, and contained 10% (w/w) fat (20.6% of the energy) supplied by one of four types of margarines. Margarines (Star S.p.A., Agrate Brianza, Italy) were prepared by interesterification of different proportions of sunflower seed oil, partially hydrogenated soybean oil, hydrogenated palm oil, and hydrogenated coconut butter. The LA content (percentage of FA) of the four margarines was 9.4, 14.9, 36.7 and 48.2%, respectively, corresponding to 1.9, 3.1, 7.7 and 10.1% of the energy provided by the diets. Diets were kept at 4°C in tightly closed plastic bags in a nitrogen atmosphere. To minimize oxidative alterations, feeds were replaced every day. The detailed composition of the diets is presented in Table 1.

TABLE 1

Fatty Acid Percent Composition of Fats in Experimental Diets[a]

Fatty acids	Diets			
	A	B	C	D
14:0	6.3	5.0	2.4	1.3
16:0	45.8	55.8	35.2	23.6
18:0	5.5	3.1	3.8	3.2
16:1	0.2	0.1	0.1	0.1
18:1	21.0	20.9	21.7	23.4
trans isomers	11.8	0.2	0.2	0.1
18:2n-6	9.4	14.9	36.7	48.2
18:2n-6 (as en%)	1.9	3.1	7.7	10.1

[a]All diets contained (en%): 17.4 protein, 20.9 fat, 61.7 carbohydrates, for a total of 430 Kcal/100 g diet.

At the end of the three months feeding period, animals were fasted overnight and killed after diethyl ether anesthesia. Blood was collected by intracardiac puncture using sodium citrate as anticoagulant. The following organs were removed and weighed: liver, heart, kidney, spleen, testicles and brain. The tissues were kept in small, air-tight containers at −20°C until analyzed.

Lipid extractions. Tissues were thawed, finely minced and 1-g aliquots of the homogeneous paste were homogenized in an Ultra Turrax (T-25 IKA, Staufen, Germany) tissue homogenizer, using chloroform/methanol (2:1, vol/vol) (11), containing 5 μg/μL of butyl hydroxytoluene for extraction. The lipid extract was concentrated under N_2 and the lipid concentration in aliquots was determined by the use of a Microbalance (C-31, Cahn Instruments, Cerritos, CA). Plasma lipids were extracted from diluted samples by stepwise addition of methanol and chloroform, and by collection of the organic layer after phase separation. Lipids were extracted from finely powdered diet samples following the same procedure as described for tissues.

Lipid analysis. Neutral (cholesteryl esters, triglycerides) and polar (total phospholipids [PL]) lipid classes in plasma lipid extracts were separated by thin-layer chromatography on prewashed silica gel (HR 60, Merck, Darmstadt, Germany) plates using hexane/diethyl ether/acetic acid (70:30:2, vol/vol/vol) as developing solvent. Compounds were detected on plates dried under N_2 by brief exposure to iodine vapors, the spots were scraped off, and the silica collected in vials for preparation of methyl esters.

Fatty acid methyl esters were prepared from total lipid extracts of the organs and from the separated lipid classes by transesterification with 3N methanolic HCl (Supelco, Bellefonte, PA). Methyl esters were analyzed on a Dani 8510 (Monza, Italy) gas chromatograph, equipped with a flame ionization detector, using chemically bonded Supelco Wax 10 (Supelco) column (30m, 0.32 mm i.d., 0.25 μm film) and temperature programming (140–210°C). Peaks were identified by comparison with pure reference compounds, and the percentage distribution of fatty acid methyl esters was quantified with a Shimadzu C-R 6A (Kyoto, Japan) recording integrator. The fatty acids were quantified relative to nonadecanoic acid (19:0) as internal standard, and calibration curves were obtained with reference compounds. The *trans* isomers present in margarine A and in lipid extracts from the same dietary group were separated by gas-liquid chromatography (GLC) analysis (data not reported).

Other assays. Glutamic-oxalacetic transaminase (GOT), lactic dehydrogenase (LDH) and glutamic-pyruvic transaminase (GPT), marker enzymes of liver function, were determined by standard assays. Plasma cholesterol and triglycerides (TG) were measured by enzymatic assays.

Statistical methods. The data for each tissue were submitted to one-way analysis of variance (ANOVA) and single comparisons between values at different levels of dietary LA were carried out according to Bonferoni *t*-test (12). Regression analysis was done for each tissue.

RESULTS

The diets used in this study were equicaloric and had an adequate composition (Table 1) of major and minor nutrients. The fat component consisted of one of four different margarines (A–D) with increasing levels of LA from 9.4 to 48.2 wt%; oleic acid contents, around 20%, were the same in all the diets, saturated acids ranged between 23.6 and 55.8%, with the lowest contents in the margarines which had the highest LA concentrations. Margarine A contained 11.8% *trans* isomers, mainly as elaidic acid.

Body growth, weekly weight gains, and caloric efficiencies [weight increments (g)/consumed diet (g)] (not shown) did not differ among groups. After three months of treatment, animals were sacrificed and organ weights, as percentage of body weights, plasma levels of cholesterol and TG levels of lipids in organs, and levels of enzymes markers of liver function, were determined. These parameters did not differ among groups.

The fatty acid composition of plasma, liver, heart and kidney total lipids were measured, but they are not reported here. In general, LA levels reflected those in the diet, but significant differences were observed for the long-chain PUFA in the various organs.

The relationships between LA intakes and the levels of n-6 and n-3 FA in plasma, liver and extrahepatic organs are shown in Figures 1–5. The values are expressed as μg/mg of plasma or tissue lipids and are superimposable with those expressed on a fresh weight basis, since levels of total lipids in tissues were not affected by dietary LA.

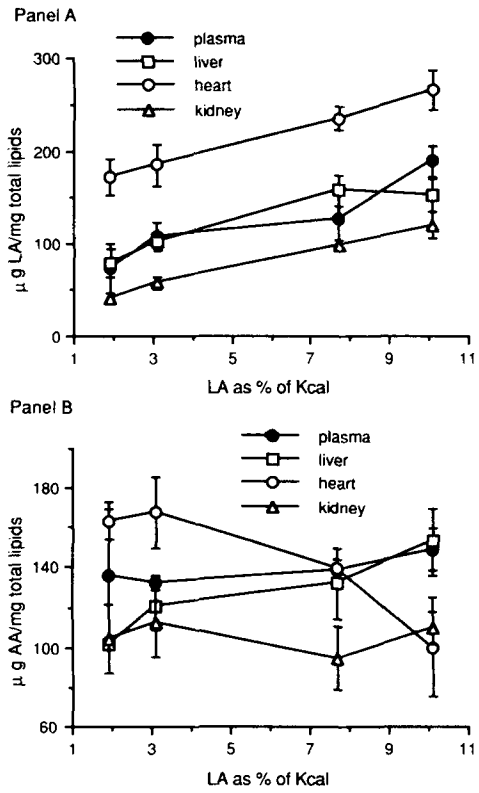

FIG. 1. Panel A. Levels (μg/mg of total lipids) of linoleic acid (LA) in plasma, liver, heart and kidney total lipids, with increasing levels of linoleic acid in the diet, as percentage of calories. Panel B. Levels (μg/mg of total lipids) of arachidonic acid (AA) in plasma, liver, heart and kidney total lipids, with increasing levels of linoleic acid in the diet, as percentage of calories.

The relationships between LA intakes and levels (μg/mg of total lipids) of LA and AA in plasma and different organs are shown in Figure 1. Changes of LA in all tissues (Panel A) followed similar trends, although the concentrations in the heart were almost twice those in the other tissues. Statistical analysis shows significant differences among values at different LA levels in the diet. One-way ANOVA shows statistically significant differences ($P < 0.05$ and $P < 0.01$) in all four tissues at different LA concentrations in the diet. The Bonferoni *t*-test shows, more specifically, that LA concentrations at the lowest dietary levels are always statistically different ($P < 0.05$) from those at the highest dietary levels. In liver, the LA concentration at the lowest dietary LA level is statistically different from the value at 7.7% LA in the diet. In all tissues, regression analysis of LA changes *vs.* increments in the diet indicate statistically significant linear correlations. The concentrations of AA in tissues (Panel B) varied according to different dietary LA levels; in the liver the concentration at 10 en% LA was significantly higher than at the lowest dietary LA levels, whereas in the heart AA concentration at 10 en% LA was significantly lower than at 1.9 and 3.1 en%. Regression analysis shows a statistically significant ($P < 0.05$) linear regression. In plasma and in the kidneys, there were no substantial changes, with increasing dietary LA.

When LA levels were measured in individual lipid classes of plasma and liver (Fig. 2), it appeared that LA accumulation in plasma (Panel A) occurred mainly in TG, up to a dietary LA concentration of 7.7 en%, whereas in liver (Panel B) LA increased mainly in PL, with a maximal concentration at 10 en% LA. Total AA in plasma (Fig. 3, Panel A) changed minimally with increasing LA in the diet, whereas in the liver (Panel B) AA concentration was significantly higher ($P < 0.0$) at 10 en% LA than at the lowest LA level in the diet.

Changes of n-3 FA in plasma and organs with increasing LA intakes also followed different trends. In plasma (Fig. 4, Panel A) both eicosapentaenoic acid (EPA) and DHA did not appreciably change up to 7.7 en% LA in the diet, but EPA rose with higher LA intake. In the liver (Panel B), EPA was marginally changed by different LA intakes, whereas DHA levels rose at 7.7 en% LA in the diet, and were very similar in the other groups. In the kidneys (Fig. 5) EPA and DHA levels remained constant, whereas in the heart EPA did not change, but DHA declined markedly and progressively, with a 50% reduction from the highest to the lowest concentrations. When DHA values were plotted against dietary LA, in the heart (not shown) a negative linear correlation, with a coefficient of 0.9, was obtained.

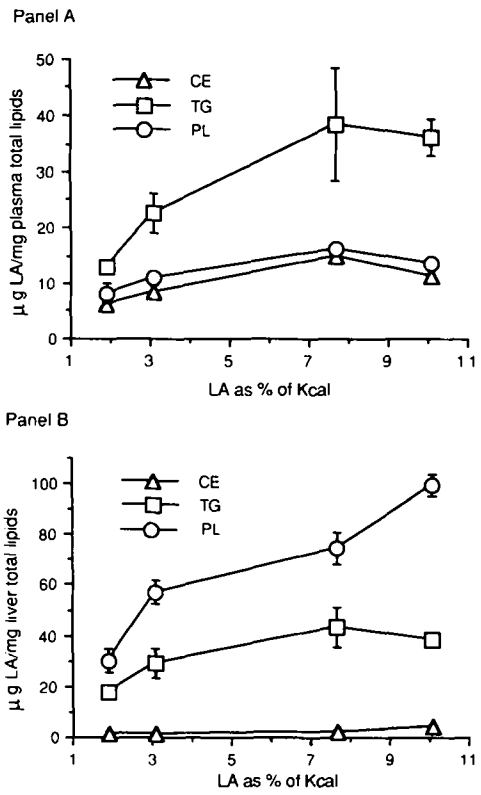

FIG. 2. Panel A. Levels (μg/mg of total liids) of linoleic acid (LA) in the major plasma lipid classes, with increasing levels of linoleic acid in the diet, as percentage of calories. Panel B. Levels (μg/mg of total lipids) of linoleic acid (LA) in the major lipid classes in the liver, with increasing levels of linoleic acid in the diet, as percentage of calories. CE, cholesteryl esters; TG, triglycerides; PL, phospholipids.

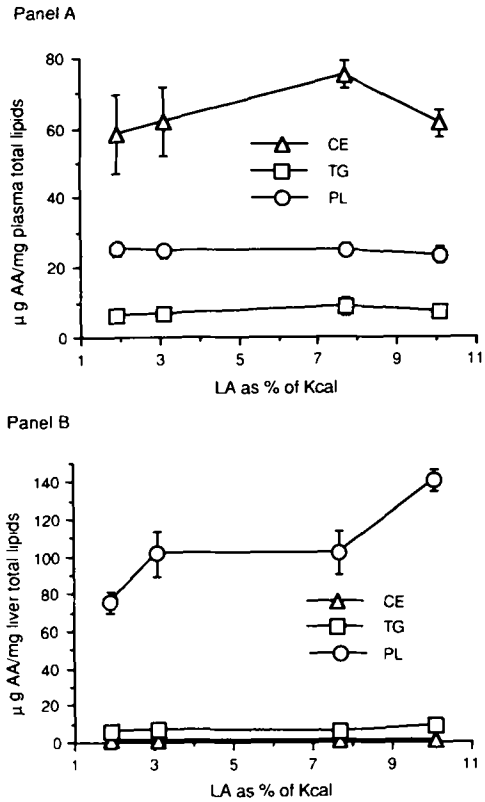

FIG. 3. Panel A. Levels (μg/mg of total lipids) of arachidonic acid (AA) in the major lipid classes in plasma, with increasing levels of linoleic acid in the diet, as percentage of calories. Panel B. Levels (μg/mg of total lipids) of arachidonic acid (AA) in the major lipid classes in the liver, with increasing levels of linoleic acid in the diet, as percentage of calories. CE, cholesteryl esters; TG, triglycerides; PL, phospholipids.

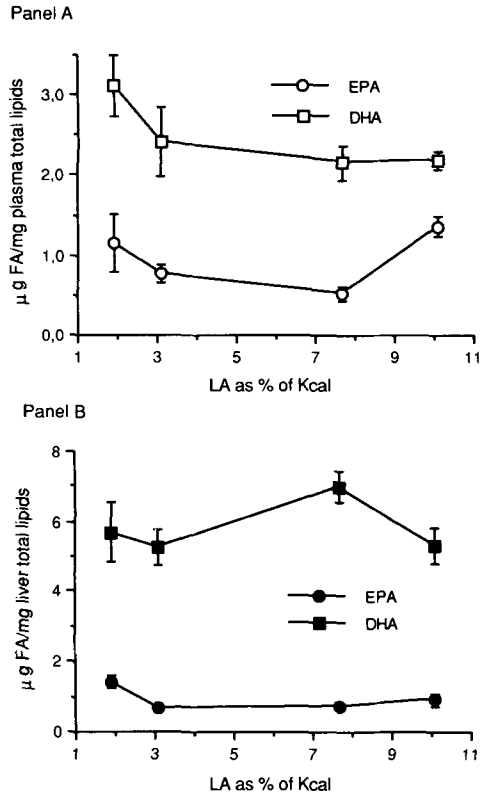

FIG. 4. Panel A. Levels (μg/mg of total lipids) of the n-3 fatty acids EPA and DHA in plasma total lipids, with increasing levels of linoleic acid in the diet, as percentage of calories. Panel B. Levels (μg/mg of total lipids) of the n-3 fatty acids EPA and DHA in liver total lipids, with increasing levels of linoleic acid in the diet, as percentage of calories.

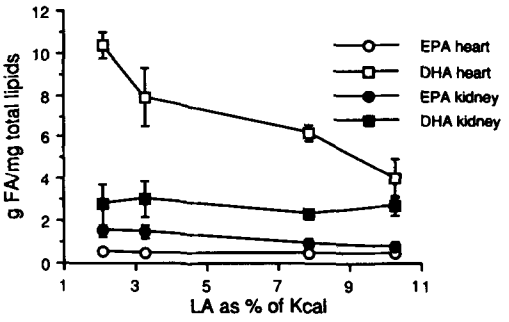

FIG. 5. Levels (μg/mg of total lipids) of the n-3 fatty acids EPA and DHA in heart and kidney total lipids, with increasing levels of linoleic acid in the diet, as percentage of calories.

DISCUSSION

During the last ten years, the effects of diets containing different types of fats and oils, and hence with different levels of LA, on plasma and tissue FA have been explored in a number of studies. The major conclusions that have generally been drawn are: i) the levels of PUFA in plasma and tissue lipids reflect the dietary intake, ii) dietary FA also influence the activity of the enzymes (especially desaturases) (13,14) in PUFA metabolism. Moreover, the direct contribution of preformed long-chain PUFA, such as AA (15) or the n-3 FA (16), present in the diet, to the endogenous pools of PUFA has only recently been appreciated. In the adult, the accumulation of AA in extrahepatic organs appears to be based mainly on processes such as delivery from the liver and uptake by cells, due to the very low activity of the desaturases and elongases in most tissues (17,18).

Very few studies have been directly devoted to investigating the effects of increasing levels of LA in the diet. In rodents it has been shown that the liver acts as a store of AA to be supplied to extrahepatic organs during essential fatty acid (EFA) deficiency (19,20); furthermore, when LA was increased to 10–11 en%, AA in various extrahepatic cells was reduced (21,22–24). Thus, in extrahepatic cells, remodelling of phospholipids (PL) through FA replacement, seems to prevail over the metabolic conversion of short-chain to long-chain PUFA, when LA is increased in the diet.

In our study when LA in the diet was raised from 2 to 10% of the energy, changes in LA, AA and n-3 FA in plasma, liver and organs such as heart and kidneys were distinctly different. In all tissues, increasing dietary LA resulted in a parallel increase in LA levels as expected. A detailed analysis of the changes of n-6 and n-3 PUFA in the different tissues revealed instead that elevation of AA, the major desaturation and elongation product of 18:2n-6, with increasing dietary LA, occurred only in the liver, mainly in the PL fraction, with reduction in the heart and practically no change in plasma and in the kidneys.

Our data, in agreement with Mohrhaurer and Holman (25), show that liver AA increased with increasing 18:2 in the diet, suggesting that there was no inhibition of LA conversion to AA. The lowering effect of dietary LA, at energy levels just above the minimal requirement, on heart AA has not been reported previously. Significant decline of both AA, at LA concentration in the diet greater than 3 en%, and of DHA, at LA concentration in the diet above 2 en% were observed in the heart. Similar effects were observed in previous studies using much higher concentrations of LA in the diet (23,24). In general, modifications of AA levels in heart lipids were also observed in animals fed different types of fats (26,27) but these studies have limited their comparisons to only a few scattered levels of dietary LA, and observed the reduction of long-chain PUFA in the heart only at very high amounts of dietary LA.

We have observed that in the heart the long-chain n-6 and n-3 FA were progressively replaced by a greater supply of dietary LA, the total amount of PUFA in heart structural lipids being held constant. Calculations of the total levels of n-6 and n-3 PUFA at 3 en% LA in the diet indicate that they are much higher in the heart (360 μg/mg lipid) than in the liver and the kidneys (228 and 173 μg/mg lipid, respectively). This observation and the findings of a reduction of long-chain PUFA in the heart with dietary LA levels above the minimum tested suggest that in the heart maximal PUFA levels are reached with dietary LA levels as low as 1.9 en%.

The accumulation of LA differentially affected the levels of n-3 FA in the liver and other organs. In the liver, there was no appreciable change in EPA and DHA levels, suggesting that the elevation of n-6 FA did not affect the n-3 fatty acid pool. The lack of decline of n-3 FA in the liver, in spite of the deficiency of n-3 in the diet, suggests that

under these conditions the liver was retaining n-3 FA and not supplying n-3 acids to extrahepatic organs. In the kidneys, n-3 levels, as well as those of 20:4n-6, were not appreciably modified by diet-induced accumulation of 18:2. In addition, we did not detect, in plasma and organs of the group fed the diet containing the *trans* FA isomers, an effect of these compounds on the levels of n-6 and n-3 PUFA.

The reduction of n-3 FA in the heart in addition to the fall of AA with increasing 18:2 in the diet may reflect inhibition of n-3 uptake by extrahepatic cells. This effect of high LA on n-3 levels in the heart could have significant consequences in regard to the recommendations for LA consumption. High LA intakes have been recommended for the prevention of atherosclerotic risk factors, but the reduction of DHA in the heart induced by high dietary 18:2 may bring about functional changes. In fact, a relationship between lower DHA levels in heart muscle and lower contraction force and greater sensitivity to arrhythmogenic agents have been reported (28,29).

In conclusion, our data show that when LA intake is increased there is an accumulation of AA only in the liver. In other organs, such as heart, the major changes are a decline in highly unsaturated FA of both the n-3 and n-6 series, and this in turn may differently influence AA-dependent processes in various organ.

ACKNOWLEDGMENTS

Incorporation of n-3 Fatty Acids of Fish Oil into Tissue and Serum Lipids of Ruminants

John R. Ashes[a,*], Brian D. Siebert[b], Suresh K. Gulati[a], Abla Z. Cuthbertson[b] and Trevor W. Scott[a]
CSIRO, [a]Division of Animal Production, Prospect, N.S.W., 2148 and [b]Division of Human Nutrition, O'Halloran Hill, S.A., 5148, Australia

This study examines the biohydrogenation and utilization of the C_{20} and C_{22} polyenoic fatty acids in ruminants. Eicosapentaenoic (20:5n-3) and docosahexaenoic (22:6n-3) acids were not biohydrogenated to any significant extent by rumen microorganisms, whereas C_{18} polyenoic fatty acids were extensively hydrogenated. The feeding of protected fish oil increased the proportion of 20:5 from 1% to 13–18% and 22:6 from 2% to 7–9% in serum lipids and there were reductions in the proportion of stearic (18:0) and linoleic (18:2) acids. The proportion of 20:5 in muscle phospholipids (PL) increased from 1.5% to 14.7% and 22:6 from 1.0% to 4.2%; these acids were not incorporated into muscle or adipose tissue triacylglycerols (TAG). In the total PL of muscle, the incorporated 20:5 and 22:6 substituted primarily for oleic (18:1) and/or linoleic (18:2) acid, and there was no consistent change in the porportion of arachidonic (20:4) acid.
Lipids 27, 629–631 (1992).

The diets of grazing ruminants contain only 3–4% lipid, of which the galactosylglycerols are principal components and 18:3n-3 is the dominant fatty acid (1–3). For hand-fed ruminants, the principal feedstuffs are cereal grains, where the lipid content is also 3–4%, but 18:2n-6 is the major constituent fatty acid (3). Rumen microorganisms have evolved an effective capacity to hydrolyze complex lipids and hydrogenate the constituent C_{18} unsaturated fatty acids to *trans* monoenes and stearic acid (1). Ruminal hydrogenation can be prevented by encapsulating the oil in a matrix of aldehyde-treated protein (3) as has been done with sunflower oil resulting in significant incorporation of the constituent fatty acids, *e.g.* 18:2n-6 into the triacylglycerols (TAG) and phospholipids (PL) of ruminants (4).

The long-chain polyunsaturated fatty acids of fish oil (20:5 and 22:6) are known to be effective in reducing the risk of coronary heart disease as they are antithrombotic (5) and antiarrhythmic (6). For this reason it has been suggested that it might prove useful to introduce n-3 C_{20} and C_{22} into the tissues of meat animals (7). This study examines the biohydrogenation and utilization of the C_{20} and C_{22} polyenoic fatty acids in ruminants.

METHODS

Animals and diets. Both sheep and cattle were used in the experiments. The sheep used were 18–24-month-old Merino wethers of approximately 35 kg body weight. The cattle used were 12–18-month-old European × British crossbred steers of approximately 300 kg body weight. Both species were fed a basal diet composed (w/w) of the following: 30% wheaten chaff, 30% maize, 20% lupin, 15% wheat screenings, 2.5% calcium carbonate and 2.5% sodium chloride. This diet was supplemented with fish oil ("MAXEPA", Scherer Pty Ltd, Melbourne, Australia), which had been encapsulated in a matrix of formaldehyde-treated protein to prevent ruminal hydrogenation (8) and loss of appetite that occurs in ruminants when the amount of dietary fat exceeds 2 to 3% (3). The protected fish oil (PFO) supplement contained 40% fat and had the following major fatty acid composition: 16:0, 18.2%; 18:1, 12.4%; 20:5, 17.6%; 22:6, 11.5%.

Two sheep were fed the basal ration and four sheep were supplemented with PFO and fed at 20% and 30% by weight of the diet. Animals were introduced to the diets over a period of one week with the total amount of treated supplement being gradually increased during that time. One steer received the basal ration and two were supplemented with PFO. Samples (100 mg) of muscle (*Longissimus dorsi*) were removed from the cattle by biopsy technique prior to offering the supplements and at weekly intervals for four weeks. Both the sheep and cattle were slaughtered after five weeks of feeding and muscle and adipose tissues (subcutaneous) were sampled and frozen prior to fatty acid analysis.

Analytical methods. Biohydrogenation and lipolysis of fish oil and sunflower oil supplements were assessed using procedures described previously (8). Blood samples were taken by jugular vein puncture; serum was separated and fatty acid analysis performed using procedures described elsewhere (4). In brief, muscle and adipose tissue lipids were extracted into chloroform/methanol (2:1, vol/vol) containing 0.01% (w/v) butylated hydroxytoluene. Neutral lipids and phospholipids (PL) of muscle were separated by thin-layer chromatography (TLC) on silica gel G plates (200 × 200 × 0.25 mm) using hexane/diethyl ether/acetic acid, 70:30:1 (vol/vol/vol). Individual PL were separated by TLC using procedures previously described (9). Areas of gel corresponding to the triacylglycerols (TAG) and PL were scraped off the plate and the lipid extracted (10). Fatty acid methyl esters were prepared (11) and analyzed by gas chromatography (Varian model 3400, Palo Alto, CA) using a 25-m × 0.25-mm fused silica capillary column (BPX70, SGE Pty Ltd, Melbourne, Australia). Fatty acids were identified by comparison of retention times with standard fatty acid methyl ester (FAME) mixtures.

RESULTS

Comparison of lipolysis and biohydrogenation of fish oil and sunflower oil by rumen microorganisms. Incubation of freeze-dried preparations (not treated with aldehyde) of fish oil-casein (1:1, w/w) and sunflower oil-casein (1:1, w/w) with rumen microorganisms for 24 h under anaerobic conditions resulted in complete lipolysis of TAG to free fatty acids (Fig. 1). Despite this, negligible hydrogenation of the n-3 C_{20} and C_{22} fatty acids could be demonstrated

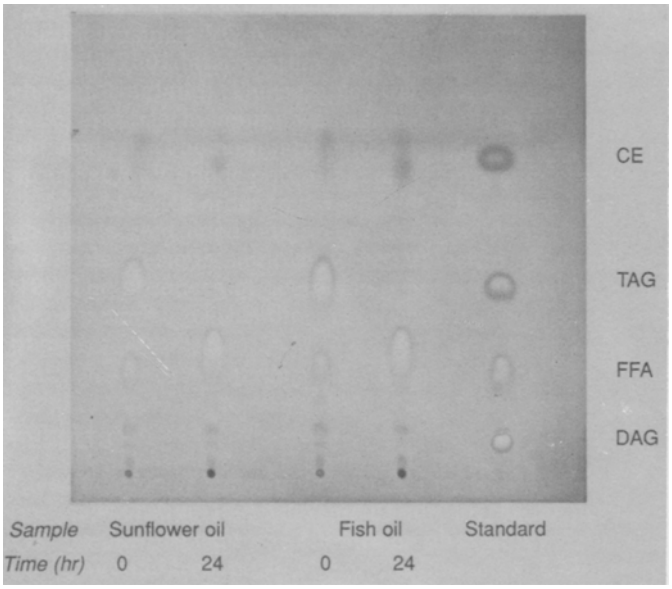

FIG. 1. One-dimensional TLC separation of lipid extracts from rumen incubations. Rumen contents from sheep (10 mL) were anaerobically incubated for 24 h at 37°C with freeze-dried preparations of sunflower oil-casein (1:1, w/w) and fish oil-casein (1:1, w/w), 50 mg, not protected with aldehyde (9). Individual lipids, *i.e.* cholesteryl esters (CE), triacylglycerols (TAG), free fatty acids (FFA) and diacylglycerols (DAG) were visualized by spraying with 2,7-dichlorofluoroscein.

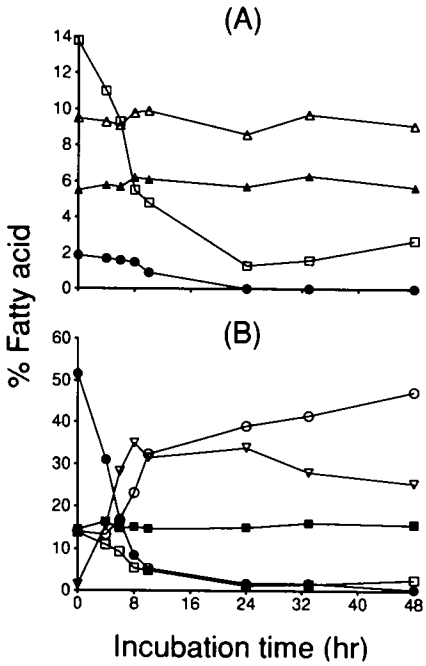

FIG. 2. Comparison of the hydrogenation of C_{18}, C_{20} and C_{22} unsaturated fatty acids by rumen microorganisms. Freeze-dried preparations (100 mg) of (A) fish oil-casein (1:1, w/w) and (B) sunflower oil-casein (1:1, w/w), not treated with aldehyde, were anaerobically incubated with sheep rumen contents at 37°C. Fatty acids were analyzed as described in the text. In (A), 16:0 and 18:0 are not shown and account for 45% of the total fatty acids. (■) 16:0, (○) 18:0, (□) 18:1 *cis*, (▽) 18:1 *trans*, (●) 18:2, (△) 20:5 and (▲) 22:6.

when these fish oil preparations were incubated with strained rumen liquor obtained from sheep, for up to 48 h under anaerobic conditions (Fig. 2a), whereas the 18:1 and 18:2 present in the fish oil were hydrogenated by rumen microorganisms as demonstrated by the increase in the intermediary 18:1 *trans* (2.6% to 4.8%) and an increase in 18:0 (12.7% to 16.3%, data not shown). For comparison Figure 2b shows the biohydrogenation of C_{18} unsaturated fatty acids of sunflower oil with 18:1 *trans* and 18:0 being the principal end-products.

The extent of hydrogenation of 20:5 and 22:6 was assessed by incubating the freeze-dried preparations of fish oil-casein (not treated with aldehyde) with rumen microorganisms removed from the sheep 30 days after the start of fish oil supplementation. During a 24-h incubation under anaerobic conditions, the proportions of 20:5 and 22:6 in the total rumen incubation contents were virtually unchanged, *viz.* 13% *versus* 13.3% and 7.9% *versus* 7.0% for 20:5 and 22:6, respectively.

Fatty acid composition. The composition of the major fatty acids in serum lipids of sheep is illustrated in Table 1; inclusion in the diet of the fish oil supplement increased the proportion of 20:5 and 22:6. For example the 20:5 content of serum lipids increased from 1 to 13% after feeding 20% fish oil supplement and reached 18% in the sheep receiving 30% fish oil supplement (Table 1). Similarly the proportion of 22:6 increased in response to the level of supplementation and the total n-3 serum fatty acids increased 5- to 7-fold (Table 1). The proportion of 20:4n-6 was unchanged and there were decreases in the proportion of 18:0 and 18:2 (Table 1).

Analysis of the fatty acid composition of adipose tissue from sheep fed the fish oil supplements revealed that 20:5 or 22:6 was not detectable (Table 1). The proportion of 20:5 and 22:6 increased 3–4-fold in the total muscle PL of sheep (Table 1) and cattle as a result of including the PFO in the diet. In sheep, the mean values of the proportion of 20:5 for the 20% and 30% supplementation were not significantly different, but when these values were pooled the mean of supplemented animals (11.0%) were significantly different ($P < 0.05$) to that of unsupplemented animals (2.4%). In individual cattle, the values of 20:5 increased at similar rates over the 5-week period, reaching 15.6% and 16.7% for 20% and 30% supplementation, respectively, from a base of 4.1%. In sheep, there were reductions in the proportion of 18:1 and no consistent change in 20:4.

Analysis of the choline PL of muscle from sheep fed PFO clearly indicated that the proportion of 20:5 increased and there was a reduction in the content of 18:1. The 20:5 content rose to a mean value of 11.4% when 20% fish oil supplement was fed in the diet to two animals and to a mean of 15.4% when 30% was fed. The 18:1 value fell to 18.1% from 24.6% when 30% was fed.

DISCUSSION

The study demonstrated that the C_{20} and C_{22} fatty acids of fish oil, even when not protected, are not hydrogenated to any significant extent. This is in contrast to oils containing C_{18} fatty acids where extensive hydrogenation occurs (1–3). Furthermore hydrogenation of the C_{20} and C_{22} fatty acids could not be detected in rumen microbial lipids of sheep, even after feeding fish oil supplements for 30 d. The inability of rumen microorganisms to hydrogenate

[a]Sheep were fed PFO as 20% and 30% by weight of the diet for 35 days.
[b]n.d., not detectable.

the 20:5 and 22:6 compared to the C_{18} fatty acids is not the result of the fish oil inhibiting lipase activity in the rumen, because the degree of lipolysis of sunflower oil and fish oil was similar, and is therefore probably due to the absence of specific enzymes or steric factors.

The feeding of PFO increased the proportion of 20:5 and 22:6 in the serum total lipids with corresponding reductions in the proportions of 18:0 and 18:2. Increases of 20:5 and 22:6 occurred in sheep and cattle muscle PL, but not in adipose tissue or muscle TAG. In previous studies, feeding or infusing cod liver oil in an unprotected form increased the proportion of C_{20} and C_{22} unsaturated fatty acids in serum and milk (12–14). Therefore it appears that ruminants are able to incorporate n-3 C_{20} and C_{22} fatty acids of fish oil into milk fat, but not into TAG of adipose tissue or muscle. It is clear that ruminants are able to preferentially incorporate 20:5 and 22:6 into PL and do so by substitution of the 18:1 and/or 18:2 fatty acids. This pattern of substitution is similar to that observed in rats (15) and marmoset monkeys (16) and indicates a preferential incorporation of n-3 over n-6 fatty acids. However the proportion of 20:4 is unchanged in both serum and muscle PL, which would suggest that the Δ6 desaturase activity was not inhibited by the elevated 20:5 content. This contrasts with the finding of Garg *et al.* (15), who showed that the feeding of a fish oil and hydrogenated tallow supplement to rats increased the 20:5 content of serum total lipids to 16% and reduced the 20:4 content from 15% to 6%.

In summary, the n-3 C_{20} and C_{22} fatty acids of fish oil are not hydrogenated in the rumen but are incorporated into muscle PL. However, because the PL fraction represents only a small proportion of the fat in ruminant meat, it does not appear to offer a means of providing humans with a significant source of these fatty acids.

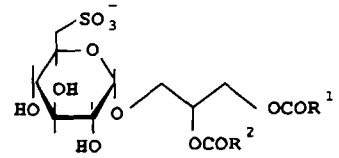
Comparison of Sulfoquinovosyl Diacylglycerol from Spinach and the Purple Bacterium *Rhodobacter sphaeroides* by Fast Atom Bombardment Tandem Mass Spectrometry

Douglas A. Gage[a,*], **Zhi-Heng Huang**[a] and **Christoph Benning**[b]
[a]MSU-NIH Mass Spectrometry Facility, Department of Biochemistry, and [b]MSU-DOE Plant Research Laboratory, Michigan State University, East Lansing, Michigan 48824

Isolated sulfoquinovosyl-diacylglycerol (SQD) from spinach and the purple bacterium *Rhodobacter sphaeroides* provide two sources of very different molecular species of SQD. We were able to demonstrate by fast atom bombardment-collisionally activated dissociation tandem mass spectrometry in the negative ion mode that the sulfoquinovosyl head group of the plant and bacterial lipids can be characterized by the common fragmentation pattern found in the spectra of both samples. Differences in the acyl functions from the two sources were also identified by this technique. SQD specific fragments are found at *m/z* 299, 283, 241, 225, 165 and 80 which indicate the presence of the sulfoquinovosyl moiety. The two predominant molecular species found in spinach contain palmitic and linolenic ($[M-H]^-$ at *m/z* 815) or two linolenic acids ($[M-H]^-$ at *m/z* 837) in the *sn*-1 and *sn*-2 positions, while the two major species of the bacterial lipid contain palmitic and 18:1 (vaccenic) acids ($[M-H]^-$ at *m/z* 819) or stearic and 18:1 (vaccenic) acids, ($[M-H]^-$ at *m/z* 847), respectively.
Lipids 27, 632-636 (1992).

Approximately thirty years ago, Benson and co-workers (1) discovered that $^{35}SO_4$-labeled extracts from various higher plants, algae, and a purple non-sulfur bacterium harbored significant amounts of a sulfur containing lipid. They determined the structure to be 1-*O*-(*α*-6′,6-deoxy-aldohexopyranosyl-6′-sulfonic acid)-3-*O*-diacylglycerol, **1** (2). The 6-deoxy-6-sulfo-glycose is also known as sulfoquinovose. The two major fatty acids found in the sulfoquinovosyl diacylglycerol (SQD) in higher plants are palmitic acid and linolenic acid (3). In SQD of *Rhodobacter sphaeroides*, a purple non-sulfur bacterium, the place of linolenic acid is taken by vaccenic acid (18:1, *cis* Δ11), a monounsaturated 18-carbon fatty acid commonly found in bacteria (4). Positional analysis of the fatty acyl groups of SQD in higher plants had previously revealed an interesting difference compared to the galactolipids monogalatosyl diacylglycerol (MGD) and digalactosyl diacylglycerol (DGD) (3). Chloroplastic lipids such as MGD and DGD contain palmitic acid preferentially in the *sn*-2 position and linolenic acid in the *sn*-1 position, whereas SQD contains palmitic acid in the *sn*-2 as well as in the *sn*-1 position of the glycerol backbone (3).



1

SQD occurs in all higher plants, including ferns and mosses and in various classes of algae such as hemoflagellata, phytoflagellata, red algae, brown algae and green algae. SQD has also been reported to be a constituent of cyanobacteria and some species of purple non-sulfur bacteria, including *R. sphaeroides* (5). The amounts, measured in percent of ether extractable lipids, vary from 2.6% in *R. sphaeroides* up to 18.3% in the brown algae *F. vesiculosa* (5). Leaves of higher plants usually contain around 5% SQD of the extractable lipids (6). A large amount of organic sulfur exists as SQD, which therefore plays an important role in the global sulfur cycle (7). The exclusive occurrence of SQD in photosynthetic organisms, its subcellular localization in photosynthetic membranes, and the unique structure of the sulfonic acid head group, indicated early on that SQD may play a critical role in photosynthesis. Indirect evidence has been accumulated which supports this idea (8,9).

To date, few direct methods for the analysis of sulfoquinovosyl-diacylglycerols have been reported. An early study by Budzikiewicz and co-workers (10) employed electron impact mass spectrometry (EIMS) to analyze the permethylated derivative of SQD, but the spectra contain a very weak molecular ion (~0.1% relative abundance). A single fragment indicative of the sulfoquinovosyl moiety is present at *m/z* 367, but other ions only permit the total weight of the two acyl groups to be determined. By this approach, it is not possible to characterize the two acyl groups or their relative positions. Here we report the use of fast atom bombardment-mass spectrometry (FAB-MS) and fast atom bombardment-collisionally activated dissociation-tandom mass spectrometry (FAB-CAD-MS/MS) in the negative ion mode as diagnostic methods to analyze mixtures of SQD molecular species and to identify the presence of the sulfoquinovosyl head group in lipids from two different sources. In addition, we demonstrate that FAB-CAD-MS/MS can be directly used to characterize the composition of the two acyl groups and possibly their relative positions.

MATERIALS AND METHODS

Preparation of SQD. Spinach leaves (500 g) obtained from a local store were blended in 1.2 L of chloroform/methanol/water (5:5:1, vol/vol/vol). Solids were separated by filtration and re-extracted with 440 mL chloroform/methanol/H_2O (5:5:1, vol/vol/vol). The two combined filtrates were phase partitioned with 600 mL 1M KCl, 0.2M phosphoric acid. The dried chloroform phase yielded about

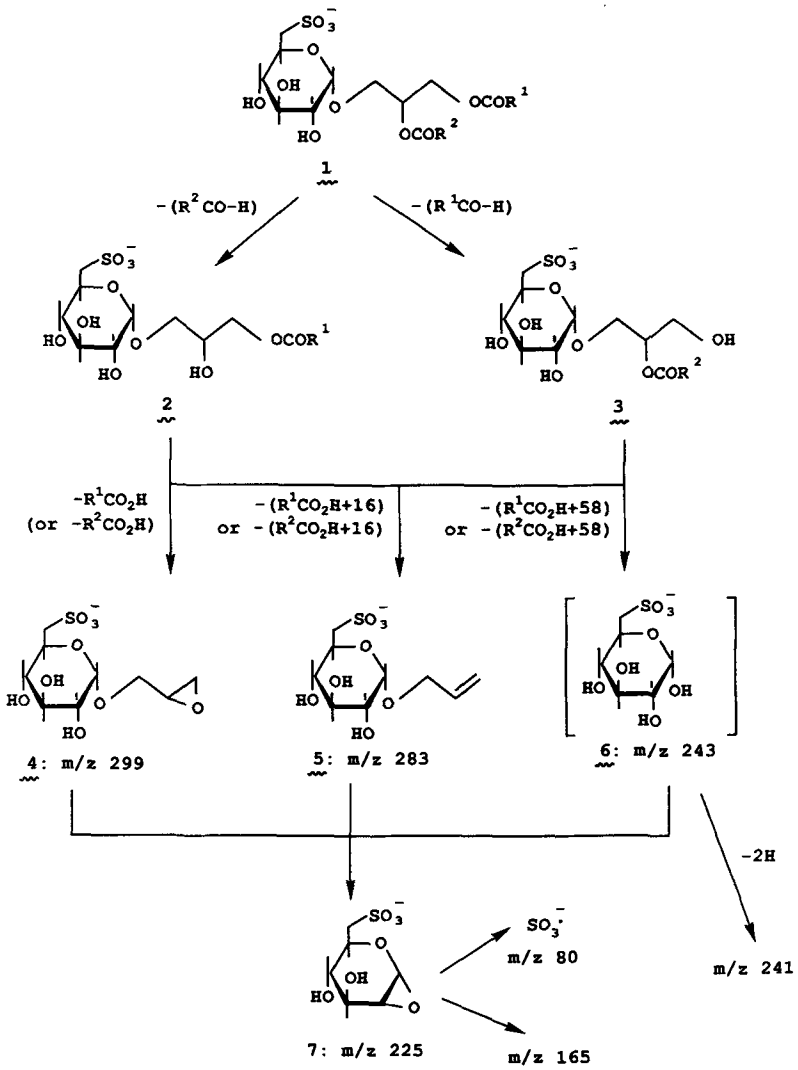
Abbreviations: B/E, ratio of magnetic sector field strength to electrostatic analyzer energy; DGD, digalactosyl diacylglycerol; EIMS, electron impact mass spectrometry; FAB-MS, fast atom bombardment mass spectrometry; FAB-CAD-MS/MS, fast atom bombardment-collisionally activated dissociation-tandem mass spectrometry; GC, gas chromatography; MGD, monogalactosyl diacylglycerol; MS/MS, tandem mass spectrometry; *m/z*, mass to charge ratio; SQD, sulfoquinovosyl diacylglycerol; TLC, thin-layer chromatography.

4.5 g of lipids. This material was purified according to O'Brien and Benson (11). Similarly, SQD was extracted and purified from 20 g of *R. sphaeroides* (2.4.1) cells grown photoheterotrophically in Sistrom's medium (12), except that lipid extraction volumes were cut in half. As a final purification step, thin-layer chromatography (TLC) was employed to remove contaminating phosphatidylglycerol. Baker Si 250 silica gel plates were first soaked in 0.15 M ammonium sulfate. Following complete drying in air, the plates were activated for 2.5 h at 120°C and after application of lipid extract, developed in acetone/benzene/water (91:30:8, vol/vol/vol). The SQD band was scraped off the plate after visualizing with iodine vapor and the lipid was eluted using chloroform/methanol (1:1, vol/vol). In addition, this TLC system was used to monitor the purity of SQD throughout the purification procedure.

Mass spectrometry. Approximately 1.0 μg of the sulfolipid sample dissolved in chloroform/methanol (1:1, vol/vol) was mixed with 2 μL of triethanolamine matrix on the FAB probe tip. Ions were produced by bombardment with a beam of Xe atoms (6 keV) or Cs^+ ions (12 keV) in a JEOL HX-110 double focusing mass spectrometer (JEOL USA, Peabody, MA) operating in the negative ion mode; no differences were observed in spectra acquired by neutral beam (Xe°) or charged cesium beam (Cs^+) bombardment. The accelerating voltage was 10 kV and the resolution was set at 1000. For FAB-CAD-MS/MS, helium was used as the collision gas in a cell located in the first field-free region. The helium pressure was adjusted to reduce the abundance of the parent ion by 50%. A JEOL DA-5000 data system generated linked scans at a constant ratio of magnetic to electrical fields (B/E). The instrument was scanned in two minutes from *m/z* 0–1500. Data presented were acquired in a single scan, although data acquired on subsequent scans were found not to differ.

RESULTS AND DISCUSSION

Comparison of molecular species of sulfolipid found in samples of spinach and R. sphaeroides. The negative FAB spectra of the two sulfolipid samples obtained from spinach and *R. sphaeroides* displayed prominent peaks for the $[M-H]^-$ ions (1, Scheme 1) of the individual molecular species present (Fig. 1). Two predominant molecular



SCHEME 1

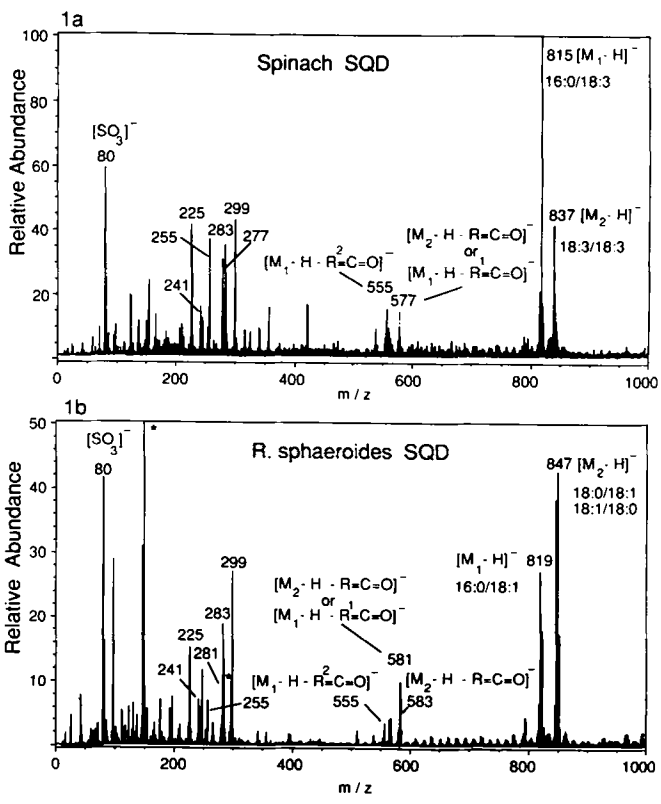


FIG. 1. The negative FAB mass spectra of spinach SQD (Fig. 1a) and *R. sphaeroides* SQD (Fig. 1b). Each spectrum dislays $[M-H]^-$ ions representing the molecular species present. The two predominant molecular species in each spectrum are designated by the nomenclature referring to the acyl group positions, *sn*-1/*sn*-2 (minor species are discussed in the text). Confirmation of the assignment of particular acyl groups to a particular molecular species in a mixed sample, however, requires MS/MS analysis of the individual $[M-H]^-$ ions (see Fig. 2). Other fragments in the spectra at *m/z* 80, 225, 241, 283 and 299 are characteristic of the sulfoquinovosyl glycerol moiety. Triethanolamine matrix ions at *m/z* 148 and 297 are designated with an asterisk in Figure 1b. Because of the higher concentration of SQD in the spinach sample (Fig. 1a), these matrix ions are suppressed.

species were found in the spinach sample at *m/z* 815 and 837 (Fig. 1a), which were interpreted as sulfoquinovosyl diacylglycerol containing two acyl functions corresponding to a total fatty acid composition (carbon atoms and double bonds) of 34:3 and 36:6, respectively. The $[M-H]^-$ ions of minor molecular species were also observed at *m/z* 813, 817 and 839; these likely differed from the major molecular species in the degree of acyl group unsaturation. This interpretation was consistent with previously reported data obtained by conventional gas chromatography (GC) analysis of the fatty acid composition of spinach sulfolipid, where palmitic and linolenic acids were the main acids detected (38.9 and 45% of the total, respectively) and linoleic, 16:1, oleic, 16:3 and stearic acids were minor components (6.1, 5.4, 1.9, 1.5 and 1.2%, respectively) (13,14). Corresponding fragments representing the carboxylate anions ($RCOO^-$) of these fatty acyl groups in the low mass region of the FAB spectrum (*e.g*, major ions at *m/z* 255 and 277 for 16:0 and 18:3, respectively) supported the GC data. However, note that if a sample is contaminated with free fatty acids, these low mass ions may be misleading. Fragments in the spectrum were also found at *m/z* 555 and 577 as a result of the loss of one fatty acyl group in the form of its ketene analog (R=C=O) (2 and 3, Scheme 1) suggesting the presence of an 18:3 acyl group in both molecular species ($[M-H-260]^-$ in Fig. 1a). The negative FAB spectrum of bacterial sulfolipid showed two principal species of sulfoquinovosyl diacylglycerol with $[M-H]^-$ ions at *m/z* 819 and 847 (Fig. 1b), which correspond to two molecular species containing either fatty acyl groups totalling 34:1 or 36:1. The presence of other molecular species was indicated by ions at *m/z* 817 (34:2), 821 (34:0), 845 (36:2), and 849 (36:0). The fatty acid composition obtained by GC analysis of *R. sphaeroides* SQD indicated palmitic, stearic and vaccenic acids are the primary acyl groups present (8). The later compound, typical of bacteria, is an eighteen carbon *cis*-Δ11 acid. Again, carboxylate anions in the FAB spectrum at *m/z* 255, 281 and 283 lend support to the GC data and the interpretation of the molecular ion clusters. As in the previous spectrum, loss of a fatty acyl moiety (as the ketene analog, R=C=O) resulted in the formation of ions at *m/z* 555, 581 and 583 (2 and 3, Scheme 1) which are consistent with the presence of palmitoyl, stearoyl and vaccenoyl (or an 18:1 isomer) acyl groups (loss of 238, 266 or 264, respectively from the $[M-H]^-$ ions.). In addition, the spectra of both the spinach and bacterial sulfolipid both showed common fragment peaks at *m/z* 299, 283, 241, 225 and 80, which were suspected to be characteristic of SQD.

FAB-CAD-MS/MS analysis of molecular ions and high mass fragments of sulfolipid. In order to further characterize the molecular species in the two samples, two B/E linked scans of the $[M-H]^-$ ions of the major species found in the spinach sample (*m/z* 815) and the bacterial sample (*m/z* 847) were obtained (Fig. 2). Collisionally activated dissociation induced the formation of a number of fragments between *m/z* 600–800 at intervals of about 14 mass units. These correspond to fragmentation along the fatty acyl chains and represent charge-remote fragmentation (15) similar to that reported in the CAD-MS/MS spectra of phospholipids (16). Although in principle these fragments could be used to locate sites of unsaturation (15), the contribution of overlapping fragments from both acyl groups makes interpretation problematic. In each spectrum, two prominent fragments are observed in the middle mass range which result from loss of the acyl groups as their corresponding free acids (−RCOOH). These fragments confirm the identities of the two acyl groups in the spinach SQD species as palmitoyl and linolenoyl and in the main *R. sphaeroides* SQD molecular species as palmitoyl and vaccenoyl (or an 18:1 isomer). The relative intensity of these two fragments may provide evidence for the relative positions of the two acyl functions. By analogy to phosphatidylcholine, loss of the *sn*-2 acyl group is expected to be favored (17), thus yielding a more abundant $[M-H-R^2COOH]^-$ fragment (see Fig. 2). However, in the case of these SQD samples, we have no independent determination of the acyl group positions (but see 14). In the low mass range, fragments characteristic for the sulfoquinovosyl glycerol group were found. Both spectra showed a similar pattern of fragments with ions at *m/z* 299 (weak), 283, 241, 225, and 80 (weak). These identical loss mass daughter ions were detected when B/E linked scans were performed on precursor ions at *m/z* 555 (Fig. 3a) and 577 for spinach and on those at *m/z* 581 (Fig. 3b) and 555 for the bacterial sample, which represent

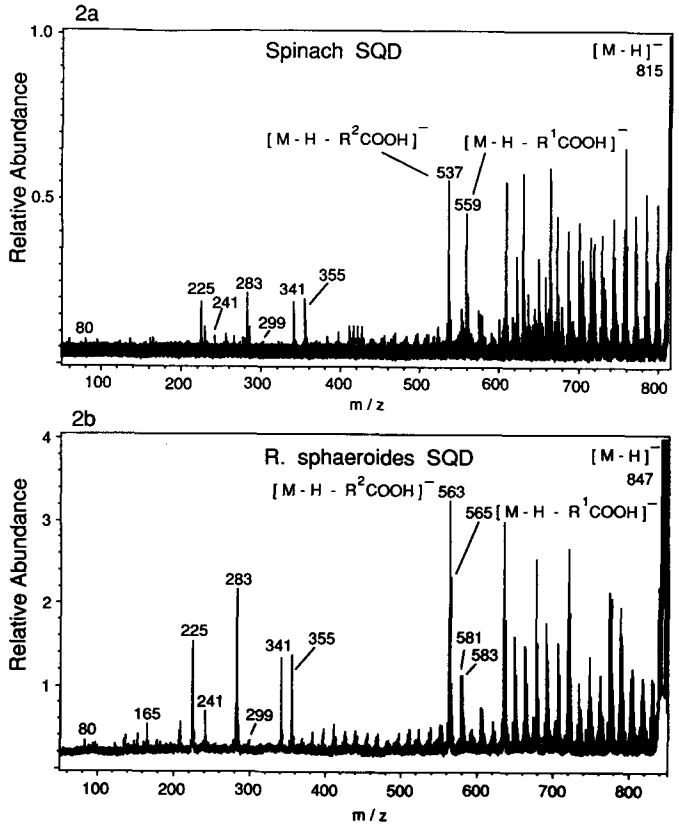

FIG. 2. FAB-CAD-MS/MS of the prominent $[M-H]^-$ ions representing the most abundant SQD molecular species in spinach (Fig. 2a) and *R. sphaeroides* (Fig. 2b). The precursor ion at *m/z* 815 in Figure 2a yields fragments in the high mass end of the spectrum from remote site fragmentation (15) along the acyl group chains. Two prominent daughter ions at *m/z* 537 and 559 result from loss of a linolenoyl and a palmitoyl group, respectively, as their corresponding free acids (RCOOH). Ketene losses are much less favored under these experimental conditions (cf. Fig. 1). Low mass fragments from the $[M-H]^-$ ion at *m/z* 847 in the bacterial SQD sample (Fig. 2b) are identical to those observed in the spectrum of the SQD molecular species from spinach (Fig. 2a). The daughter ions at *m/z* 563 and 565 show that the acyl groups in this case are stearoyl and vaccenoyl (or another 18:1 isomer).

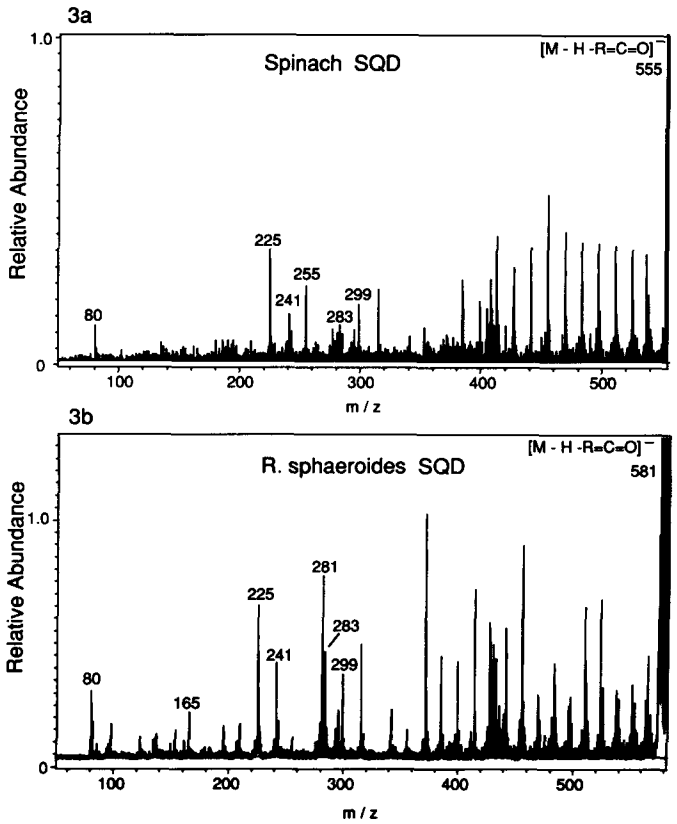

FIG. 3. FAB-CAD-MS/MS of the $[M-H-R=C=O]^-$ ions at *m/z* 555 in the spinach sample (Fig. 3a), representing monoacyl SQD with a palmitoyl group and at *m/z* 581 in the *R. sphaeroides* sample (Fig. 3b), representing monoacyl SQD containing a vaccenoyl function. Fragments are observed in both spectra at *m/z* 80, 225, 241, 283 and 299 which are characteristic of sulfoquinovosylglycerol (see Scheme 1). In addition, the more concentrated *R. sphaeroides* sample displays another diagnostic peak at *m/z* 165. The spectrum of each sample contains a peak for the carboxylate anion of their respective acyl groups at *m/z* 255 (palmitate) in Figure 3a and at *m/z* 281 (vaccenate) in Figure 3b. Other fragments in the high mass region are formed by remote site fragmentation along the acyl chain (15,16).

the respective molecular species following the loss of one fatty acyl group as the ketene analog (2 and 3, Scheme 1). The appearance of the same fragments in all these spectra lends support to the notion that these ions are related to the sulfoquinovosyl glycerol moiety, rather than to the acyl groups. The structure and formation of these fragments were further investigated by additional FAB-CAD-MS/MS experiments described below.

FAB-CAD-MS/MS of sulfolipid specific fragments. In any SQD, loss from the $[M-H]^-$ ion of one acyl group as the free acid and the second acyl group as its ketene analog should yield an ion of mass 299. This could be represented as the ion 4 in Scheme 1. The B/E linked scan of the ion at *m/z* 299 in the negative FAB spectrum of the spinach sample showed fragments at *m/z* 225, 165, and 80. Consistent with the hypothetical structure of the ion at *m/z* 299, the ion at *m/z* 225 likely represents the epoxysulfoquinovosyl fragment (7, Scheme 1) formed by the loss of the deoxyglycerol moiety in 4 (m/z 299), while *m/z* 80 represents the sulfonyl anion. The absence of a fragment at *m/z* 241 suggested that this ion was derived from the molecular ion or the products resulting from the loss of one acyl group, but that its direct formation from fragment at *m/z* 299 was not favored. The proposed formation of the observed fragments of the ion at *m/z* 299, 4 is shown in Scheme 1. A structure for the ion at *m/z* 165 could not be proposed. This latter ion was not observed in the B/E linked scan of the ion at *m/z* 241 (see below). Analysis of the ion at *m/z* 283, the deoxy analog of 4, provided similar results, yielding major fragments at *m/z* 225, 165 and 80. The proposed structure for this ion, 5, is shown in Scheme 1. The absence of stearic acid in the fatty acid analysis excludes the possibility that this peak represents the stearic carboxylate anion. Further, the daughter ion spectrum of this ion is quite distinct from that of stearate.

The sulfoquinovose sugar anion has a mass of 243. Consistently in all the spectra discussed above, a key ion was observed at *m/z* 241, although the ion at *m/z* 243 was present in less abundance (Fig. 1). It is proposed that the former ion represents a stable fragment ion formed by loss of two hydrogens during cleavage of the sugar residue (structure 6, Scheme 1). The same phenomenon has been

observed for sulfated sugar head groups from animal lipids where an analogous fragment is seen at *m/z* 257, 2 mass units below the intact anion of a sulfated hexose (18). A small fragment at *m/z* 241 is also seen in the negative FAB spectrum of these 6-*O*-sulfated hexosyl lipids, but the ion at *m/z* 257 is twenty times more abundant. In addition, these compounds can be distinguished from SQD by the dominant fragment found in their spectra at *m/z* 97, $[HSO_4]^-$ (19). B/E linked scans on the precursor at *m/z* 241 from the spinach and the bacterial SQD samples showed a comparable pattern. Since parent ion selection is not precise with B/E scans on a double focusing instrument, the daughter ion at *m/z* 225 was proposed to be the dehydrated product of the minor sulfoquinovosyl ion at *m/z* 243, while the ion at *m/z* 80 corresponded to the SO_3^- radical anion (Scheme 1). The most abundant fragment at *m/z* 161 resulted from the loss of a neutral SO_3 group. Based on the limited available information, it was not possible to propose a precise structure for the latter fragment.

To complete the series of daughter ion scans and to confirm the identity of the proposed fragments, FAB-CAD-MS/MS scans for the ions *m/z* 225 and *m/z* 80 from the spinach sample were obtained. The fragment at *m/z* 225, as part of the sulfoquinovosyl head group, produced the SO_3^- fragment at *m/z* 80. In addition, several other fragments, including that at *m/z* 165, were generated. The ion at *m/z* 80 gave rise to the SO_2 ion with a mass of 64, confirming that this ion represents the sulfonate group.

CONCLUSION

The results indicate that FAB-MS is a useful technique for characterizing the composition of molecular species of sulfoquinovosyl diacylglycerol lipids. Prominent molecular ions are produced and key high mass fragments resulting from loss of the ketene analog of the *sn-2* acyl group provide information about the composition. Significant fragments are also present in the low mass end of the spectra which are characteristic of sulfoquinovosyl diacylglycerol. FAB-CAD-MS/MS can be used to confirm the identity of individual molecular species and to elucidate the fragmentation pathway of these compounds.

Based on the results obtained in this study, several diagnostic fragments from the negative FAB-MS of sulfolipid are proposed: first, the sulfoquinovose head group specific ions with masses of 225, 7, and 241/243, 6, and second, the sulfoquinovose glycerol specific deacylation products at *m/z* 283 and 299. The latter ion is sometimes weak in the B/E spectrum of the $[M-H]^-$ or $[M-H-R=C=O]^-$ ions. Since the daughter ion at *m/z* 299 did not give rise to the ion at *m/z* 241, and since the B/E linked scans using these two ions as precursors revealed distinct fragmentation patterns, it was postulated that both ions were produced in competing reactions from the molecular ion or monodeacylation products.

Comparison of linked B/E scans of the high mass ions and, in particular, of the head group specific ion at *m/z* 241, revealed similar fragmentation patterns for the spinach and bacterial sulfolipid, strongly suggesting that the sulfolipid found in both organisms is sulfoquinovosyl diacylglycerol. The data supported and extended earlier findings obtained by Wood *et al.* (4) and Radunz (6), who identified the sulfolipid in *R. sphaeroides* by co-chromatography with standards. However, it should be pointed out that the mass spectrometric technique used does not distinguish between the sulfoquinovose sugar and its stereoisomers. Future work in our laboratory with these compounds will focus on characterizing the positions of acyl group unsaturation from the high mass fragments in the FAB-CAD-MS/MS spectra.

ACKNOWLEDGMENTS

This work was funded, in part, by Research Excellence Funds from the State of Michigan. Mass spectral data were acquired at the MSU-NIH Mass Spectrometry Facility which is supported by a NIH grant (RR-00480) to J.T. Watson.

Positional Analyses of Triacylglycerol Fatty Acids in the Milk Fat of the Antarctic Fur Seal (*Arctocephalus gazella*)

Donald L. Puppione[a,*], Cindy M. Kuehlthau[b], Ronald J. Jandacek[b] and Daniel P. Costa[a]
[a]Long Marine Laboratory, Institute of Marine Science, University of California, Santa Cruz, California 95064 and [b]The Procter and Gamble Company, Miami Valley Laboratories, Cincinnati, Ohio 45239

The positional distribution of fatty acids has been determined for the milk triacylglycerols of the Antarctic fur seal, *Arctocephalus gazella*. Of particular interest was the positional distribution of the polyunsaturated n-3 fatty acids in milk triacylglycerols (TG). In adipocytes of pinnipeds, TG are synthesized with the n-3 fatty acids primarily in the *sn*-1,3 positions. To determine the positional distribution, extracts of enzymatically digested lipids were separated by thin-layer chromatography, and the constituent fatty acids were separated and quantified by gas-liquid chromatography. Monoenoic and saturated fatty acids comprised over 75% of the total, the ratio of monoenoic to saturated fatty acids being 2:1. The percent content of the long-chain n-3 fatty acids, 20:5, 22:5 and 22:6, ranged between 15-20%. The positional analyses revealed that at the *sn*-2 position of milk TG, saturated fatty acids were in excess (57%), and the content of n-3 fatty acids was less than 5%. More than 80% of the n-3 fatty acids in milk were located in the *sn*-1,3 positions. The data indicate that in pinnipeds TG are synthesized in the mammary gland and adipose tissue with fatty acids having similar positional distributions.
Lipids 27, 637-639 (1992).

As a group, pinnipeds produce milk with an exceptionally high fat content (1-10), ranging from 19% in the Galapagos sea lion (1) to 61%, the highest value reported for any mammal, in the hooded seal (2). In the milk of the various species, 18:1 (17-47%), 16:0 (9-22%) and 16:1 (6-19%) (6-8,11-17) consistently were found to be the predominant three fatty acids. The polyenoic n-3 (20:5, 22:5 and 22:6) and the monoenoic (20:1 and 22:1) fatty acids common to the marine food web comprised between 15-40% of the total fatty acids in the milk of pinnipeds (6-8,11-13,16,17). Rather than being synthesized *de novo*, the polyenoic and most likely the long-chain monoenoic fatty acids are derived from the diet of the lactating female.

Brockerhoff and co-workers (18-20) showed that the fatty acid positional distribution in stored triacylglycerols (TG) were different in pinnipeds than in cold blooded organisms. Therefore, we were interested in determining whether the mammary gland of pinnipeds adaptively arranged the fatty acids in the milk TG to mimick the positional distribution in the stored fat of prey animals. To answer this question and to gain a better understanding of the utilization and processing of lipids in these animals, the positional distribution was determined for the fatty acids in the milk of the Antarctic fur seal (*Artocephalus gazella*). Our data on the milk TG indicate that there is no such adaptation. Overall, the positional distribution of the fatty acids is very similar to data reported previously for seal blubber (18-20).

METHODS

Milk samples (30-120 mL) were collected on Bird Island, South Georgia (54, 00'S, 38, 02'W) from four fur seals marked on the date of parturition. At the time of collection, the animals, which could be approached to within 1-2 m, were captured with a rope noose attached to a 3-m pole. Captured animals were then restrained using a specially constructed board as described by Gentry and Holt (21). Once restrained, females were weighed and then injected with 40 units of Oxytocin. After a few minutes, milk was manually expressed from the teat into plastic vials. Samples were kept frozen at −20°C until lipid analyses were carried out.

The milk lipids were extracted with chloroform/methanol (2:1, vol/vol). Extracts were weighed to obtain the percent lipid in the milk and then analyzed by thin-layer chromatography (TLC). The total fatty acids in the lipid extracts were methylated with boron trifluoride after undergoing saponification (22). The distribution of fatty acid methyl esters was determined by gas-liquid chromatography. Methyl esters were separated on a Durabond 225 column (0.00025 × 30 m, J&W Scientific, Folsom, CA) in a Hewlett-Packard (Kennet Square, PA) model 5890a equipped with a hydrogen flame detector. Column temperature was 220°C. The carrier gas was helium and the flow rate was 1.42 mL/min. The detector and injection port temperatures were 350°C. The resulting peak areas were measured electronically with a Hewlett-Packard 3392a and normalized to give values as weight percent of total fatty acid.

To determine the positional fatty acid distribution, the lipid extracts were first hydrolyzed with porcine pancreatic lipase (steapsin) in a 1.0 M Tris buffer (pH 8.0) as described by Mattson and Volpenhein (23). Following extraction, the enzymatic digestion products, 2-monoacylglycerols and free fatty acid released from the 1- and 3-positions, were separated by TLC. Using fatty acid and monoglycerol standards, both the digestion products and completion of the reaction could be monitored. The monoglycerols and free fatty acids were scraped from the plate and recovered after a subsequent TLC separation with only the standards being visualized with iodine vapor. Methylation of fatty acids and analyses of the resulting methyl esters for each of the recovered fractions were done as described above.

RESULTS

Analyses by TLC confirmed that the extracted lipid from fur seal milk consisted almost exclusively of TG. Although milk samples were obtained at different stages of the lactation cycle and the overall fat content in the milk varied from 30-52% (Table 1), individual variations in the percent content of the major fatty acids were quite small

Positional Distribution of Fatty Acids in Fur Seal Milk[a]

	sn-2 Position	*sn*-1,3 Positions
Saturated fatty acids		
14:0	11.4 (±4.3)	3.6 (±1.5)
16:0	44.9 (±1.8)	8.4 (±0.5)
18:0	0.5 (±0.05)	2.6 (±0.2)
Monoenoic fatty acids		
16:1	13.8 (±0.9)	9.2 (±1.2)
18:1	17.5 (±4.0)	41.5 (±3.9)
20:1	0.2 (±0.21)	5.7 (±1.0)
22:1		1.5 (±0.4)
Polyenoic fatty acids Group 2[b]		
18:2	2.2 (±0.3)	1.4 (±0.08)
18:3	0.6 (±0.17)	0.7 (±0.08)
20:4	0.3 (±0.19)	0.5 (±0.15)
Polyenoic fatty acids Group 2[c]		
20:5	2.2 (±0.4)	9.7 (±2.5)
22:5	0.2 (±0.26)	2.8 (±0.2)
22:6	1.6 (±0.8)	7.5 (±1.3)
Totals	95.4	95.1

[a] Percent content values are means obtained from the analyses of four individual samples of fur seal milk. Standard deviations are given in parentheses.

[b] Polyenoic fatty acids Group 1 consists of polyunsaturated fatty acids commonly found in the diet of terrestrial animals.

[c] Polyenoic fatty acids Group 2 consists of polyunsaturated fatty acids commonly found in the diet of marine animals.

(values are listed in Table 2). The fatty acids with less than 20 carbons comprised over 70% of the total. The remaining portion consisted primarily of 20:5 and 22:6, with the ratio of 20:5 to 22:6 varying from 1:2.2. The percentage of any one of the polyenoic fatty acids in Group 1 never exceeded 1.7%.

When the distribution at the *sn*-2 position was examined, a definite pattern could be discerned. Over 85% of these fatty acids were in order of relative amounts 16:0, 18:1, 16:1 and 14:0. From the data in Table 3, it can be calculated that 73% of 16:0 and 61% of 14:0 in milk TG were located at the *sn*-2 position. The corresponding values for 16:1 and 18:1 were 43% and 17%, respectively. A random arrangement would correspond to a value of 33% at the *sn*-2 position. In contrast, the percent content at the *sn*-2 position for any of the polyenoic fatty acids of Group 2 was low. At the *sn*-1,3 positions, 20% of the fatty acids in the TG of fur seal milk were 20:5, 22:5 and 22:6.

DISCUSSION

The high fat content in pinniped milk is related to their amphibious existence, which separates lactation on shore from feeding at sea (9,10). In the family *Otariidae*, consisting of fur seals and sea lions, lactation on shore is interspersed between feeding trips to sea. These periods of foraging typically last between 1 and 7 d and then are followed by a suckling period of 1 to 3 d on shore (10). In the case of the Antarctic fur seal, while at sea the female will derive 52% of her calories from the fat stored in krill (25). Such a diet enables the seal to provide her pup with milk enriched in lipids (26).

Our current study is the first to report on the partial positional distribution of the n-3 fatty acid in the milk of a pinniped. The polyenoic n-3, as well as the monoenoic C_{20} and C_{22} fatty acids, also common to the marine food web, were located primarily in the *sn*-1,3 positions. The *sn*-2 position contained a high percentage of 16:0 (45%). Overall, the distribution was essentially the same as reported previously for the TG of seal blubber (18–20). In seals, the *sn*-2 position was found to contain mostly saturated fatty acids, 14:0 and 16:0, with lesser amounts of monoenoic acids, 16:1 and 18:1. The n-3 fatty acids comprised only a small percentage of the fatty acids at this position and were located primarily at the *sn*-1,3 positions. On the other hand, in fish and invertebrate TG, the n-3 fatty acids were located primarily at the *sn*-2 position, and 14:0 and 16:0 were the two major fatty acids at the *sn*-1,3 positions (18,19). There was no adaptation in the mammary gland to provide suckling pups with dietary fats with positional distributions mimicking those found in future prey animals in the ocean.

Prior to our study, the fatty acids in the milk TG had been reported for three other species of otariids or

eared seals, the Northern fur seal *(Callorhinus ursinus)* (8), the California sea lion *(Zalophus californianus)* (16) and the Galapagos fur seal *(Arctocephalus galapagoensis)* (17). Many more studies have been done on phocids or earless seals (3,6,7,11-16). Our data on the total fatty acid composition are in general agreement with these other studies which show the milk fat to be enriched, particularly in monoenoic and saturated fatty acids (7,8,11-17). In most studies, including our own, the ratio of monoenoic to saturated fatty acid was approximately two. Exceptions to this trend were data obtained on the milk of the harp seal *(Pagophilus groenlandicus)*, hooded seal *(Cystophora cristata)* and the California sea lion. In the seal studies (3,6), the milk had a low content of saturated fatty acids resulting in the ratio having a value greater than 3.8. However, values reported by Cook and Baker (13) for harp seal milk agree with data obtained in other species. In the study of the California sea lion milk, the relative amounts of saturated and monoenoic acids were almost equal and the resulting ratio was slightly greater than one (16). Observed differences in the fatty acid composition of milk TG may be related to variations in the composition of the dietary fat of these animals. The long chain polyenoic acids are at comparable levels in both the milk and the principal prey, *Euphausia superba* (24), of the Antarctic fur seal (see Table 2).

In addition to obtaining data on the major energy source of suckling fur seals, our study may provide insights into ways to supplement infant formula diets with n-3 fatty acids. There is growing evidence that the n-3 fatty acids are essential in the neonatal period in humans (27,28). Studies have been done with formulas supplemented with fish oils as a source of 20:5 and 22:6 n-3 fatty acids (28). We currently are extending our studies of neonatal pinnipeds to determine whether variations in the location of n-3 fatty acids in dietary marine fats may be important. By studying animals before and after weaning, when they are switched to a diet of fish, we can determine the effects on both plasma membranes and lipoproteins, in particular on the size and number of chylomicra. Having natural diets with fats differing in the positional distribution of n-3 fatty acids, neonatal pinnipeds provide us with a unique animal model for addressing some of these issues.

ACKNOWLEDGMENTS

D. P. Costa was supported by Division of Polar Programs National Science Foundation Grants 8311799 and 8618820. Logistic support generously was provided by the British Antarctic Survey, Cambridge, England. J. Mastro assisted in the collection of milk samples in the field. Many thanks go to J. P. Croxall of the British Antarctic Survey for making our studies at Bird Island possible.

The Fatty Acids of the Sponge *Dysidea fragilis* from the Black Sea

W.W. Christie[a,*], Elizabeth Y. Brechany[a], K. Stefanov[b] and S. Popov[b]
[a]Hannah Research Institute, Ayr, KA6 5HL, Scotland and [b]Institute of Organic Chemistry, Bulgarian Academy of Sciences, Sofia 1113, Bulgaria

The fatty acid composition of the sponge, *Dysidea fragilis*, from the Black Sea has been determined by analytical gas chromatography, silver ion high-performance liquid chromatography and gas chromatography/mass spectrometry. More than a hundred different fatty acids were identified, of which many were similar to those in sponges from tropical seas. On the other hand, some of the fatty acids identified have not been found previously in sponges or other marine sources and perhaps are new to science. These include 13-methyl-tetradec-4-enoic and 14-methyl-hexadec-6-enoic acids, together with demospongic acids, *i.e.* 5,9,17-tetracosatrienoic, 5,9,17-pentacosatrienoic and 5,9,19-pentacosatrienoic acids. From the elution behavior on silver nitrate chromatography, all the double bonds were of the *cis*-configuration.
***Lipids* 27, 640–644 (1992).**

Sponges are relatively primitive multicellular organisms which are known to contain a unique variety of distinctive fatty acids in the membrane phospholipids in unusual molecular species (reviewed by Djerassi and Lam (1)). In particular, these include the demospongic acids, *i.e.*, C_{24} to C_{30} fatty acids with 5,9-diunsaturation and often a further double bond in the terminal part of the molecule. Most of the published work has dealt with species from the Caribbean Sea or the Pacific Ocean. The Black Sea is an inland sea with reduced salinity (approximately half) compared to the oceans or the Mediterranean Sea; it also has a high concentration of hydrogen sulfide, reaching near saturation levels at depths below 200 m.

In this study, total fatty acids of a sponge, *Dysidea fragilis* (Family, Dysideidea; Order, Dictyoceratida), from the Black Sea have been examined by methods involving fractionation of the complex mixtures by degree of unsaturation by high-performance liquid chromatography (HPLC) in the silver ion mode, followed by gas chromatography/mass spectrometry (GC/MS) of the picolinyl ester derivatives. The methodology has been improved somewhat from an earlier study of the fatty acids of certain Black Sea invertebrates (2).

MATERIALS AND METHODS

Sample. The sponge *Dysidea fragilis* was collected from the Black Sea, at depths of 2 to 10 m, near the town of Pomorie in Bulgaria in August 1989. Samples were washed in tap water and immediately immersed in ethanol for transport to the laboratory. Lipids were extracted with chloroform/methanol (2:1, vol/vol) and saponified, the non-saponifiables were removed, and the acids were methylated with methanol containing 1% sulfuric acid (3). The yield of lipid was 0.36% of the wet weight of the sponge (from 10 sponges, total weight 160 g). Voucher specimens were deposited in the Museum of Natural History, Sofia, Bulgaria by Dr. St. Andreev.

Analytical gas chromatography. For analytical purposes, a Carlo Erba Model 4130 capillary gas chromatograph (Erba Science, Swindon, U.K.), fitted with split/splitless injection, and equipped with a capillary column (0.25 mm i.d. × 25 m in. length) of fused silica coated with Carbowax 20M (Chrompack UK Ltd., London, U.K.), was used with the methyl ester derivatives. After holding the temperature at 170°C for 3 min, it was temperature-programmed at 3°C/min to 225°C, then was held at this point for a further 17 min. Hydrogen was the carrier gas. Components were quantified by electronic integration. Equivalent chain length (ECL) values were determined isothermally at 170°C (C_{13} to C_{22} components) or at 200°C (C_{23} to C_{27} components).

Silver ion high-performance liquid chromatography. A Spectra-Physics Model 8700 solvent delivery system was used (Spectra-Physics Ltd., St. Albans, U.K.), together with a Cunow model DDL 21 detector (Severn Analytical Ltd., Shefford, Beds, U.K.). A stream-splitter (approx. 10:1) was inserted between the column and the detector to enable collection of fractions. The silver ion column, Chrom-Spher Lipids™, was kindly donated by Dr. Stephan Rose of Chrompack Ltd. (Middelburg, Netherlands) and was prepared as described elsewhere (4). For micro-preparative purposes, 1–2 mg of methyl esters were applied to the column in 10 μL of dichloroethane. The column was eluted using a binary gradient procedure with mixtures of dichloromethane/dichloroethane (1:1, vol/vol) (Solvent A) and dichloromethane/dichloroethane/methanol/acetonitrile (45:45:5:5, by vol) (Solvent B). There was a linear gradient from 100% A to 95% A/5% B over 15 min then to 80% A/20% B over a further 25 min and finally to 50% A/50% B over another 10 min at a flow-rate of 1 mL/min.

Gas chromatography/mass spectrometry. The fatty acids were subjected to GC/MS as the picolinyl esters prepared essentially by the method of Balazy and Nies (5). A Hewlett-Packard Model 5890 gas chromatograph attached to a Hewlett-Packard Model 5970 Mass Selective Detector (Hewlett-Packard Ltd., Wokingham, U.K.) was used. The picolinyl esters were analyzed on a fused-silica capillary column (25 m × 0.25 mm i.d.), coated with a cross-linked 5% phenylmethylsilicone (CP-Sil 8™, Chrompack UK Ltd., London, U.K.), and injected onto the column at 70°C (held for 0.5 min), temperature-programmed to 210°C at 60°C/min, held there for 3 min, raised again to 280°C at 2°C/min, then held for a further 40 min. The column outlet was connected directly to the ion source of the mass spectrometer, which was operated at an ionization energy of 70 eV.

RESULTS

In the present study, the total fatty acids from the sponge *Dysidea fragilis* were analyzed, as opposed to those of the phospholipid fraction, which has a high proportion of choline and ethanolamine plasmalogens (Stef-

*To whom correspondence should be addressed.

Abbeviations: ECL, equivalent chain length; GC, gas chromatography; HPLC, high-performance liquid chromatograhy; MS, mass spectrometry.

anov, K., unpublished). As anticipated, the GC trace of the methyl ester derivatives of the fatty acids was highly complex, with well over 100 distinct peaks being resolved, many with much longer retention times than are normally seen in fatty acid methyl esters derived from mammalian tissues. GC/MS of picolinyl esters has been proven of great value for the determination of fatty acid structures in complex samples (for reviews, see refs. 3,6), but some loss of resolution is inevitable when they are subjected to GC separation; their high polarity and molecular weight make it advisable to use non-polar stationary phases, especially when the samples contain fatty acids with a higher molecular weight than normal. Therefore, the methyl ester derivatives were fractionated by silver ion HPLC for examination by analytical GC, and for conversion to the picolinyl esters for GC/MS. This approach has assisted greatly in the elucidation of many complex samples of natural origin (2,7–9). The chromatographic trace from the silver ion HPLC is shown in Figure 1, and the points where fractions were collected are indicated. Resolution was achieved mainly according to the number of double bonds in each component, and partly by their configuration and position. Ten fractions were collected for derivatization and analysis by GC/MS. Those fatty acids identified, and their relative proportions and equivalent chain lengths (28) are given in Table 1 together with references to previous reports of their occurrence in sponges and marine invertebrates. Ninety different fatty acids were identified and are listed if they occur at a concentration of 0.05% or greater, and a further 13 fatty acids were detected in even smaller proportions.

The saturated fatty acids (fraction 1) were mainly 14:0, 16:0 and 18:0 with small amounts of other straight-chain fatty acids and *iso*- and *anteiso*-methyl branched acids. In addition, there was a small amount of 4,8,12-trimethyl-13:0, which is common in marine invertebrates, phytanic acid, other monomethyl-branched components, and a cyclopropane fatty acid, some of which do not appear to have been reported to occur in sponges.

The second minor fraction contained monoenoic acids, which probably have double bonds of the *trans*-configuration (insufficient material was available for confirmation), since they eluted well ahead of the conventional *cis*-monoenes. The 6-16:1 and 9-16:1 fatty acids were identified.

cis-Monoenes were in the third fraction and the main components were conventional positional isomers of 16:1, 18:1, 20:1 and 22:1, together with related odd-chain components. There were also high proportions of C_{24} to C_{26} monoenes, some of which do not appear to have been reported previously for sponges. Small amounts of monoenes with double bonds in position 5, that may be related biosynthetically to the dienes and trienes described below, were found. In addition, monoenoic fatty acids with methyl branching were identified, some of which appear to be novel. The most abundant of these was 15-methyl-hexadec-6-enoic acid, which has been reported previously to occur in human *Vernix caseosa* (29) and which was recently confirmed in human cerumen by mass spectrometry of its picolinyl ester (30), but has not been found before in marine invertebrates. As an example, Figure 2 shows the mass spectrum of the picolinyl ester derivative of 14-methylhexadec-6-enoic acid, which has not been found before in marine samples. The molecular ion

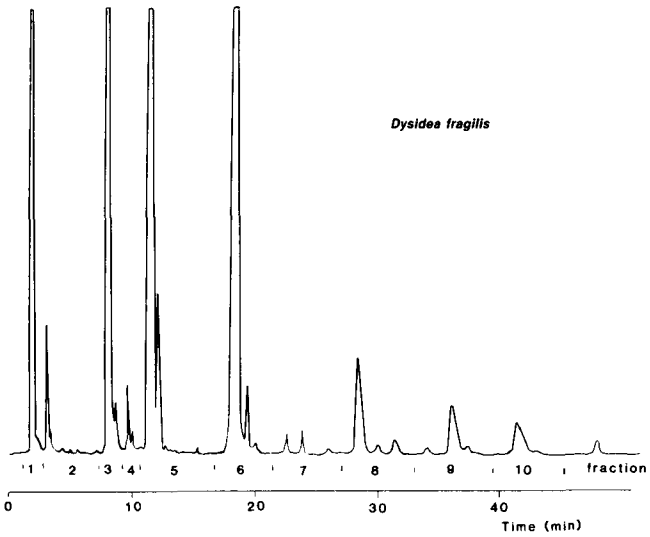

FIG. 1. Silver ion HPLC of methyl esters of the fatty acids from *Dysidea fragilis*. See Materials and Methods for experimental details. Numbered fractions were collected between the points indicated.

(m/z = 359) is that expected of a C_{17} monoenoic acid (although the GC retention time was appreciably less than that of most 17:1 isomers). The gap of 28 amu between m/z = 302 and 330 is indicative of an *anteiso*-methyl branch (31), while the abundant ion at m/z = 246 is a characteristic marker for a double bond in position 6 (32). Isomeric compounds, in which either the position of the methyl branch or of the double bond varied, and homologues of this acid were also found, *i.e.*, 13-methyl-4-14:1 and 15-methyl-9-16:1. The former had a molecular ion at m/z = 331, a gap of 28 amu between m/z = 288 and 316 for the iso-methyl branch; the double bond in position 4 was indicted by a prominent ion at m/z = 218 while the base peak was at m/z = 151 (32). Only the 15-methyl-9-16:1 fatty acid appears to have been reported previously to occur in marine sources (12,24).

The minor fraction 4 contained mainly non-methylene-interrupted dienes, many but not all of which were similar to those in the following fraction, a finding that suggests that one of the double bonds might be of the *trans* configuration. Insufficient material was available to confirm this hypothesis.

Fraction 5 contained most of the dienoic components, including conventional methylene-interrupted fatty acids of the n-4 and n-6 families, such as 18:2n-6, and dienes with more than one methylene group between the double bonds and up to 27 carbon atoms in the chain ("demospongic acids"). With most of the latter group, the first double bond was in position 5 and there were two central methylene groups, *i.e.*, the most common isomers were 5,9-dienoic acids. The mass spectrum of the picolinyl ester derivative of 5,9-hexacosadienoic acid is illustrated in Figure 3A, as an example. As usual, there was an abundant molecular ion (m/z = 483). The most important diagnostic feature was an ion formed by cleavage between the two methylene groups separating the double bonds which, being very unusual, for a picolinyl ester, has an odd mass number, *i.e.* in this instance at m/z = 219 (33). A

[a]The number of carbons listed does not include the methyl branch In addition, trace amounts of 13-methyl-16:0, 21:0, 22:0, 23:0, 24:0, *trans*-monoenes (6-16:1 and 9-16:1), *cis*-monoenes (13-methyl-14:1, 4-16:1, 7-17:1, 13-22:1 and 16-23:1) and 24:5n-3 were identified.

[b]For common fatty acids, such as 16:0, only a representative reference is given.

similar feature was reported for the spectrum of the picolinyl ester of 5,9,12-octadecatrienoic acid (34). In addition, gaps of 26 amu between *m/z* = 178 and 204, and between 232 and 258, confirmed the presence of double bonds in positions 5 and 9, respectively. The presence of a regular series of ions 14 amu apart, from *m/z* = 258 to 468, indicated that there were no further double bonds or any branch points in the chain. Fatty acids with the 5,9-dienoic structure have been found in many sponges from tropical seas (1). Related fatty acids were present with an *iso*-methyl branch, *i.e.*, 23-methyl-5,9-24:2 and 24-methyl-5,9-25:2, which have been found previously in sponges (26,17). In addition, several fatty acids were found in which there were more than two methylene groups between the double bonds. Interpretation of the mass spectrum of the picolinyl esters of these fatty acids is sometimes less straight-forward, but is relatively simple when comparison with model compounds is possible, as was here (2,33). Most, if not all of these compounds have previously been found in other sponges or marine invertebrates.

Fraction 6 from the silver ion column is a trienoic fraction in which the double bonds all have more than one methylene group separating them. The most abundant single component was 5,9,19-hexacosatrienoic acid, and the mass spectrum of the picolinyl ester is shown in Figure 3B. The molecular ion at *m/z* = 481 was prominent, and the ions diagnostic for the 5,9-double bonds were clearly seen, as in the previous example. However, a gap of 26 amu between *m/z* = 370 and 396 confirmed the presence of the double bond in position 19. Regular series of ions 14 amu apart between *m/z* = 258 and 370 and between *m/z* = 396 and 466 showed that no double bonds or branch points were present in other parts of the molecule. Again, this

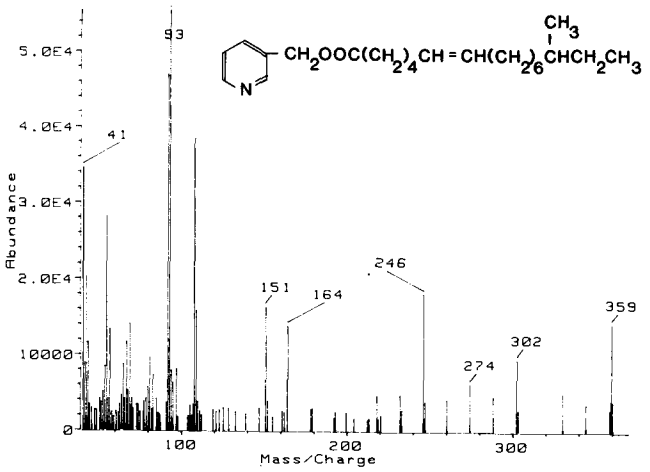

FIG. 2. Mass spectrum of the picolinyl ester of 14-methylhexadec-6-enoic acid.

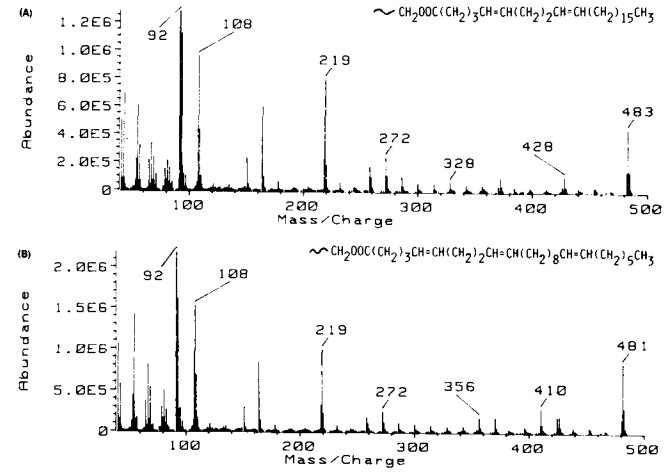

FIG. 3. Mass spectra of the picolinyl esters of 5,9-hexacosadienoic acid (A) and 5,9,19-hexacosatrienoic acid (B).

fatty acid has been found in sponges from tropical seas (1). However, certain of the other isomers and homologues, that were found albeit in small amounts, *i.e.* 5,9,17-24:3, 5,9,17-25:3, 5,9,19-25:3, do not appear to have been reported previously. It was not easy to obtain definitive mass spectra from components present in such small amounts, but identification was simple by comparison with the spectrum of the abundant homologue illustrated (Fig. 3B). Thus molecular ions at m/z = 453 and 467 were obtained for the 24:3 and 25:3 homologues, respectively, ions for the 5,9-double bond system or an isolated 19-double bond were present in the same positions, while the gap of 26 amu for the double bond in position 17 was between ions at m/z = 342 and 368.

Fraction 7 from the silver ion column contained three distinct peaks, from which six components emerged upon GC/MS of the picolinyl derivatives. These were found to be the common range of C_{16} to C_{20} trienoic acids with methylene-interrupted double bonds, *i.e.* mainly of the n-6 and n-3 families found in marine oils. Similarly, fraction 8 contained three peaks of which the first and most abundant was arachidonic acid, with 18:4n-3, 20:4n-3 and 22:4n-6 also identified. Fractions 9 and 10 then were found to contain the common range of penta- and hexaenoic acids, respectively.

DISCUSSION

In spite of its remoteness from species in the major oceans of the world, the sponge *Dysidea fragilis* contains many of the well-known demospongic acids found in the tropical seas around the United States of America (1) and apparently in Siberian and Arctic waters (35–39). The most abundant components found in this instance are common to many species, but it does appear to be unusual for so many different demospongic acids to be found in one species. Three trienoic acids, 5,9,17-24:3, 5,9,17-25:3 and 5,9,19-25:3, do not appear to have been recorded previously. From the chromatographic behavior on silver ion HPLC and by analogy with other such acids, the double bonds are presumed to be of the *cis*-configuration. Carballeira *et al.* (18) have stated that "it is very rare to find three consecutive acids with the 5,9-unsaturation together in the same sponge" (18). In this species, four such dienoic (24:2, 25:2, 26:2 and 27:2) together with two branched isomers and three consecutive trienoic acids (plus two isomers) were detected.

It has also been suggested (18) that sponges may be selective as to which of the isoprenoid fatty acids, 4,8,12-trimethyltridecanoic and 3,7,11,15-tetramethylhexadecanoic (phytanic), were incorporated into their tissues. In *Dysidea fragilis*, both of these were found.

A number of long-chain monoenoic fatty acids with double bonds in positions 5, 7 and 9 were found, that do not appear to have been recorded previously, but they can be presumed to have biosynthetic relationships to the demospongic acids. In addition, several branched-chain monoenoic acids with *cis*-double bonds in positions 4 and 6, *i.e.* 13-methyl-4-14:1, 14-methyl-6-16:1 and 15-methyl-6-16:1, of which the first two may be new to science, were detected. These do not have any obvious biosynthetic relationship to the other fatty acids found, and they were not detected in comprehensive studies of other Black Sea organisms (2,7).

Some adventitious contamination with marine algae which adhere to the sponge can occur, so there is a possibility that some of the fatty acids in the sample could have come from this source. However, no sponges which were obviously contaminated were collected. Algae also serve as a food for sponges so their fatty acids may be incorporated into sponge lipids by this route, though an examination of the composition of a number of marine algae from the Black Sea (7) showed mainly the polyunsaturated fatty acids of the n-3 and n-6 families. Some of the branched-chain, and especially the cyclopropane fatty acids, may have come from bacteria in the food chain or as symbionts (40,41).

The methodology utilized in this study is extremely powerful, and gave detailed structural information permitting complete structure elucidations of more than a hundred different fatty acids in this single species. Virtually every component present at a concentration of more than 0.05% was identified. Some of these do not appear to have been found previously in nature. Mass spectro-

metry of picolinyl esters (6) enables identification of fatty acids with much greater ease than has been possible with pyrolidides which have been used hitherto, especially with sponges. In addition, preliminary fractionation by silver ion HPLC affords clean fractions that greatly improves the resolution attainable on GC/MS.

ACKNOWLEDGMENTS

Dr. S. Andreev of the Museum of Natural History of the Bulgarian Academy of Sciences, Sofia, Bulgaria collected and classified the sponge. This research was funded in part by The Scottish Office Agriculture and Fisheries Department and by Project 344 with the Ministry of Science and Higher Education of Bulgaria.

To identify lipid ester core aldehydes (aldehydes still bound to parent lipid molecules) among the secondary products of peroxidation, we have prepared reference standards of cholesteryl esters, diacylglycerols and the common glycerophospholipids (GPL) containing an aldehyde function. We subjected the unsaturated lipid esters to hydroxylation with osmium tetroxide and to carbon-carbon bond cleavage with periodic acid. The resulting aldehyde esters (mainly 5-oxovalerates and 9-oxononanoates of cholesterol and the glycerolipids) were isolated and purified by thin-layer chromatography (TLC) and reverse-phase high-performance liquid chromatography (HPLC). Liquid chromatography/mass spectrometry (LC/MS) was used to identify the cholesteryl and other neutral lipid ester aldehydes as the dinitrophenylhydrazones (DNPH). The choline (CGPL) and ethanolamine (EGPL) glycerophospholipids containing core aldehydes were identified by fast atom bombardment mass spectrometry (FAB-MS) and by gas chromatography/mass spectrometry (GC/MS) of the aldehyde-containing diacylglycerol moieties following dephosphorylation with phospholipase C and preparation of the methoximes (MOX) and the trimethylsilyl (TMS) ethers. The lipid esters containing the C_5 and C_9 aldehydes are chemically stable compounds with excellent chromatographic properties yielding mass spectra characteristic of the parent compounds. The overall yield of the core aldehydes was 10–20% of the unsaturated starting material.
Lipids 27, 645–650 (1992).

Recently much attention has been focused on the role of lipid peroxidation in many pathological conditions (2). Analysis of specific products of lipid peroxidation is crucial for the identification of pathological mediators in these instances. The initial step of lipid peroxidation is the conversion of polyunsaturated fatty acids into hydroperoxides. The hydroperoxides are then decomposed into aldehydes by homolytic scission of the two carbon bonds on either side of the hydroperoxy group (3). Because polyunsaturated fatty acids in biological systems are found in glycerophospholipids (GPL), triacylglycerols and cholesteryl esters, cleavage of the carbon-carbon bonds of the hydroperoxides would theoretically yield two types of aldehydes: a water-soluble aldehyde derived from the methyl terminal of the unsaturated fatty acid and a lipid soluble core aldehyde still containing most of the parent lipid molecule. The latter group of aldehydes, lipid ester core aldehydes, have rarely been studied as part of the peroxidation process (4). An exception is provided by the identification of 5-oxovaleroyl glycerophosphocholine (GPC) among the *in vitro* peroxidation products of 2-arachidonoyl GPC (5). In addition, GPC with azelaic acid in the *sn*-2 position has been isolated as one of the cytotoxic products generated during oxyhemoglobin-induced peroxidation of unsaturated choline glycerophospholipids (CGPL) (6). However, the core aldehydes of diacylglycerols, triacylglycerols and CGPL have been obtained in the past by ozonolysis and reductive cleavage during structural investigations of natural glycerolipids (7). In order to facilitate the studies on the core aldehydes in peroxidation mixtures, we have prepared model compounds from unsaturated cholesteryl esters, diacylglycerols and the common GPL, and have investigated methods for their rapid isolation and identification.

MATERIALS AND METHODS

Materials. The palmitic, oleic and arachidonic acid esters of cholesterol, 1-palmitoyl-2-oleoyl glycerophosphoethanolamine (GPE), egg yolk phosphatidylcholine (PC), phospholipase C *(Clostridium welchii),* and periodic acid were from Sigma Chemical Co. (St. Louis, MO). Methoxylamine HCl (MOX reagent), trimethylsilylchloride (TMSC), *N,O-bis*(trimethylsilyl)trifluoroacetamide (BSTFA) and 1-fluoro-2,4-dinitrobenzene were from Pierce Chemical Co. (Rockford, IL). Osmium tetroxide was obtained from British Drug Houses, Ltd. (Toronto, Canada), while 2,4-dinitrophenylhydrazine was from Aldrich Chemical Co. (Milwaukee, WI). Propionitrile was from Romil (Loughborough, England). Other solvents and chemicals were of reagent grade or better quality and were obtained from local suppliers.

Preparation of cholesteryl oxoalkanoates. Cholesteryl 5-oxovalerate and cholesteryl 9-oxononanoate were prepared from cholesteryl arachidonate and cholesteryl oleate, respectively. To a solution of 1.5 mg of the unsaturated cholesteryl ester in 0.2 mL of pyridine/dioxane (1:8, vol/vol), 0.2 mL of a dioxane solution of osmium tetroxide (10 mg/mL) was added. After 2 h at room temperature, 6 mL of a suspension of sodium sulfite (made by adding 8.5 mL of 16% sodium sulfite to 2.5 mL of methanol) was added and mixed (8). After 1.5 h at room temperature, the mixture was centrifuged and lipids were extracted from the residue with chloroform/methanol (2:1, vol/vol). The lipid extracts containing the alcohols were evaporated under nitrogen and dissolved in 0.5 mL 95% ethanol. To this solution, 0.5 mL of 1% periodic acid in 95% ethanol was added, mixed and left at room temperature for 1 h

[1]Part of this work was presented at the Annual AOCS Meeting, Chicago, IL, May, 1991 (see ref. 1).

(9). The mixtures were diluted with 2 mL of chloroform and washed three times with water. The lower chloroform phase containing the cholesteryl ester core aldehydes was evaporated under nitrogen and the aldehydes were purified by thin-layer chromatography (TLC) on silica gel H using heptane/diisopropyl ether/glacial acetic acid (60:40:4, vol/vol/vol) as the developing solvent. The lipids were localized by spraying the plate with 2',7'-dichlorofluorescein in methanol or with Schiff's reagent (10). The fluorescent silica gel zones were scraped off the plate and eluted with chloroform/methanol (2:1, vol/vol). The extracts were reduced to a small volume and the lipid fractions characterized (see below).

Preparation of oxoalkanoates of GPL. The 1-palmitoyl-2-(9-oxononanoyl)- and 1-stearoyl-2-(9-oxononanoyl)-GPC were prepared from egg yolk PC as described for the preparation of the cholesteryl ester core aldehydes. The core aldehydes derived from PC were purified by TLC on silica gel H using chloroform/methanol/water (65:35:6, vol/vol/vol) as the developing solvent. The fluorescent silica gel zones were scraped off the plate and the lipids were eluted with chloroform/methanol (2:1, vol/vol). The phospholipid extract was reduced to a small volume and hydrolyzed with phospholipase C for 1 h at 37°C as previously described (11). After solvent evaporation, the diacylglycerol core aldehydes were characterized by various chromatographic and mass spectrometric methods. The 1-palmitoyl-2-(9-oxononanoyl) GPE was prepared as described for the corresponding PC-derived core aldehyde, except that the PE was first converted to the dinitrophenyl (DNP) derivative by treatment with 1-fluoro-2,4-dinitrobenzene to facilitate detection of cleavage product in high-performance liquid chromatography (HPLC) (12). The core aldehyde was purified by TLC using chloroform/acetone/methanol/acetic acid/water (50:20:10:10:5, by vol). The UV absorbing silica gel zones were scraped off and extracted with chloroform/methanol (2:1, vol/vol). After solvent evaporation, the core aldehyde of the DNP-GPE product was characterized before and after derivatization.

Preparation of methoxime (MOX) derivatives. The MOX derivatives were obtained by heating the core aldehydes with 100 μL of the methoxylamine·HCl reagent at 60°C for 3 h (13). The reaction mixture was evaporated under nitrogen and the residue extracted with 5 mL of hexane and washed with water. The solvent layer was dried over sodium sulfate and evaporated to a small volume before gas-liquid chromatography (GLC) and gas chromatography/mass spectrometry (GC/MS).

Preparation of dinitrophenylhydrazone (DNPH) derivatives. The lipid ester core aldehydes were converted into the 2,4-DNPH derivatives using a modification of the method of Esterbauer and Chesseman (14). The aldehydes were treated with 0.5 mL of freshly prepared 2,4-dinitrophenylhydrazine in 1N HCl (0.5 mg/mL), mixed vigorously and kept in the dark for 2 h at room temperature and 1 h at 4°C. The reaction mixture was extracted with chloroform/methanol (2:1, vol/vol) and the recovered hydrazones were purified by TLC using a double development with dichloromethane (up to a height of 10 cm) and, after solvent evaporation, in the same direction with toluene (up to 17 cm). The ultraviolet (UV) absorbing silica gel zones were scraped off, extracted with methanol and reduced to a small volume. The DNPH derivatives of the CGPL core aldehydes recovered from the origin of the TLC plate were treated with phospholipase C for 2 h at 37°C, and the released DNPH derivatives of the diacylglycerol core aldehydes were purified by TLC using chloroform/methanol (95:5, vol/vol) as the developing solvent.

GLC and GC/MS. The core aldehydes of the cholesteryl esters and diacylglycerols, as well as their trimethylsilyl (TMS) ethers and MOX derivatives were resolved on basis of molecular weight by GLC on non-polar capillary columns as described by Myher and Kuksis (15). The TMS ethers were prepared by treating the lipid fractions or their MOX derivatives with a silylating reagent made up of one part BSTFA + 1% TMSC and one part pyridine for 30 min at room temperature. Nonpolar capillary GC/MS with electron impact (EI) or chemical ionization (CI) with ammonia was performed as previously reported (16).

HPLC and liquid chromatography/mass spectrometry (LC/MS). Reverse-phase HPLC with the DNPH derivatives of the core aldehydes was performed on a Supelcosil LC-18 column (250 mm × 4.6 mm) (Supelco, Inc., Bellefonte, PA) using acetonitrile/isopropanol (4:1, vol/vol) (1.0 mL/min) or a linear gradient of 30–90% propionitrile in acetonitrile (1.5 mL/min) as the eluting solvent (17). The peaks were monitored at 358 nm with a variable wavelength detector. Reverse-phase HPLC of the DNP-phosphatidylethanolamine (PE) core aldehydes was performed on a Supelcosil LC-18 column using 10 mM ammonium acetate, pH 5.0, and methanol as the mobile phase, beginning with a 5-min isocratic elution at 84% methanol, followed by a linear increase to 87% methanol within 15 min (12). Elution was monitored by measuring absorptivity at 348 nm and fractions were collected for fast atom bombardment-mass spectrometry (FAB-MS) examination.

FAB-MS. FAB-MS on the DNP-GPE core aldehydes and their diethyl acetals was performed using thioglycerol as the matrix as previously described (18).

RESULTS AND DISCUSSION

Characterization of cholesteryl ester core aldehydes. Figure 1 shows the TLC separation of the osmium tetroxide/periodic acid oxidation products of the palmitic, oleic and arachidonic acid esters of cholesterol. Lane A shows the osmium tetroxide oxidation products of cholesteryl palmitate. In addition to the band corresponding to the original cholesteryl ester (R_f 0.83), there is a more slowly migrating band representing the ester containing an oxidized sterol ring (R_f 0.26). Lane B contains the osmium tetroxide/periodic acid oxidation products of cholesteryl oleate. Separate bands are seen for the C_9 aldehyde (R_f 0.41) and its diethyl acetal (R_f 0.57), as well as the osmic acid ester (R_f 0.31) of cholesteryl dihydroxyoctadecanoate. Lane C contains the oxidation products of cholesteryl arachidonate. In this instance, the band corresponding to the original ester did not contain any residual cholesteryl arachidonate, the fluorescence being due to some other component of low mass. There were also bands near the origin of the TLC plate, which were subsequently shown to be due to the sterol ring oxidation products of the oxoester (Kamido, Kuksis, Marai and Myher, 1992, unpublished data). The bands with intermediate retention values were due to the C_5 aldehyde (R_f 0.28) and its diethyl acetal (R_f 0.34). There are other minor bands which have thus far remained unidentified. The band in

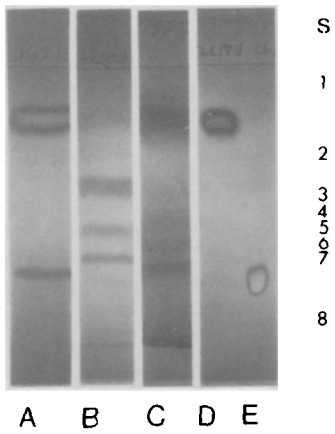

FIG. 1. TLC separation of osmium tetroxide/periodic acid oxidation products of palmitic (A), oleic (B) and arachidonic (C) acid esters of cholesterol. Lanes D and E contain cholesteryl oleate and free cholesterol, respectively. The lipid bands are identified as follows: 1, cholesteryl ester; 2, diethyl acetal of cholesteryl ester C_9 core aldehyde; 3, cholesteryl ester C_9 core aldehyde; 4, diethyl acetal of cholesteryl ester C_5 core aldehyde; 5, osmic acid ester of cholesterol dihydroxyoctadecanoate; 6, cholesteryl ester C_5 core aldehyde; 7, free cholesterol and oxo-cholesteryl palmitate; 8, origin and unidentified more polar oxidation products. Solvent system: heptane/diisopropyl ether/glacial acetic acid (60:40:4, vol/vol/vol). Lipid fractions were located by spraying with 2′,7′-dichlorofluorescein and Schiff's reagent (10).

Lane D is due to standard cholesteryl oleate (R_f 0.83) while that in Lane E is due to free cholesterol (R_f 0.26). The identity of the TLC fractions was established by chromatographic and mass spectrometric methods.

Figure 2 shows the nonpolar capillary GLC profiles of the C_5 (Fig. 2A) and C_9 (Fig. 2B) cholesteryl ester core aldehydes recovered from the TLC bands with R_f values 0.28 and 0.41, respectively, when analyzed as the free aldehydes. A single peak is seen for the C_9 oxidation product of cholesteryl oleate, while cholesteryl arachidonate gives, in addition to the major C_5 peak, one or two smaller peaks, which were not identified. A preparation of the MOX and TMS derivatives resulted in a uniform shifting of these peaks to slightly higher retention times, while a GC/MS examination of the peaks with ammonia CI gave pseudomolecular ions corresponding to $[M + NH_4]^+$ of the core aldehyde and its MOX derivatives, along with the ions for the cholesterol ring at *m/z* 369.

Figure 3 gives the full mass spectra for the cholesterol C_9 core aldehyde and its MOX derivative as obtained by ammonia CI. The aldehyde (Fig. 3A) gives ions for the ammonium adduct at *m/z* 558 and the cholesterol ring at *m/z* 369 and *m/z* 386. The ability to form the methoxime derivative supports the presence of an aldehyde function in these molecules. The ion at *m/z* 555 in Figure 3B is due to the loss of methanol from the methoxime ($[M + NH_4 - 32]^+$). The C_5 core aldehyde and its MOX derivative gave corresponding characteristic ions for the major peak. GLC examination of the TLC fractions corresponding to the diethyl acetals yielded peaks with retention times greater than those of the corresponding core aldehydes. These peaks showed signs of decomposition at the elevated temperatures necessary for steryl ester elution, and were not examined further. These TLC bands failed to yield the hydrazones or MOX derivatives. GLC analysis of the TLC band corresponding to the osmic acid ester of cholesteryl oleate diol was unstable during high temperature GLC, as indicated by the formation of variable peak proportions with retention times lower or greater than those of the parent cholesteryl oleate. The osmium tetroxide ester is an intermediate in the hydroxylation of polyunsaturated fatty acid esters and is not completely reduced with sodium bisulfite to the *cis* vicinal-diol. The presence of the diethyl acetals was attributed to their formation during the periodate cleavage of the fatty chain between the vicinal hydroxyl groups, since the reaction was carried out in 95% ethanol with HIO_4 being a strong acid.

Figure 4 shows the reverse-phase HPLC resolution of the DNPH derivatives of the C_5 and C_9 cholesteryl ester core aldehydes. A single peak is obtained for the C_9

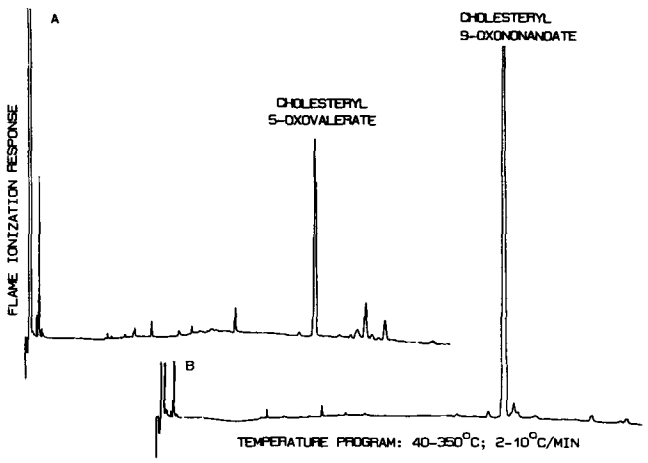

FIG. 2. Nonpolar capillary GLC separation of the C_5 (A) and C_9 (B) cholesteryl ester core aldehydes (free form) after recovery by TLC. GLC conditions, column (8 m × 0.30 mm); temperature program, 40–350°C; detector, FID.

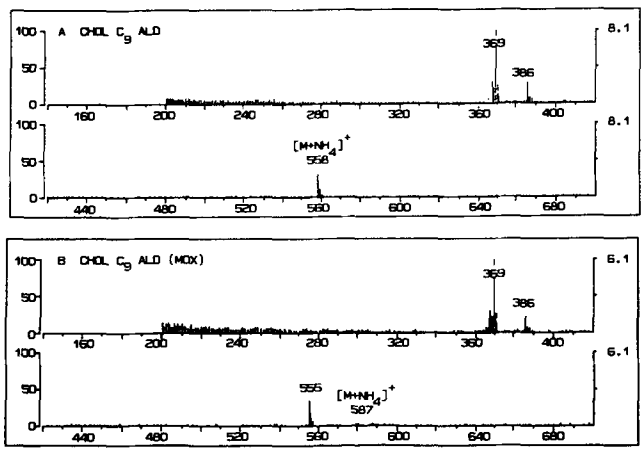

FIG. 3. Full mass spectra of cholesteryl 9-oxononanoate as obtained by GC/MS with ammonia CI. A, free aldehyde; B, methoxime (MOX). GC/MS conditions, nonpolar capillary column (8 m × 0.30); temperature program, as in Figure 2; mass spectra, GC/MS *via* direct capillary column inlet in the positive ammonia ionization mode.

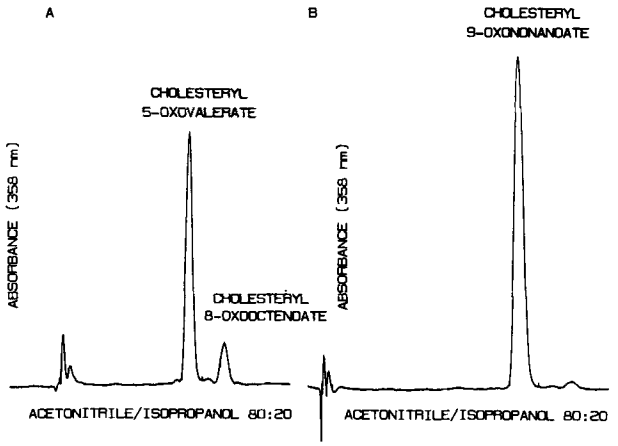

FIG. 4. Reverse-phase HPLC resolution of cholesteryl ester core aldehydes as the DNPH derivatives. A, 5-oxovalerate; B, 9-oxononanoate. HPLC conditions were as given in Materials and Methods. The retention time of the C_9 aldehyde was 15 minutes.

aldehyde, while the C_5 aldehyde gives also a minor peak for the 8:1 aldehyde, as established by LC/MS. Figure 5 shows the full negative CI mass spectra of the DNPH derivatives of the C_5 and C_9 cholesteryl ester core aldehydes. Only the molecular ions are seen. A correct molecular ion was also obtained for the 8:1 aldehyde among the oxidation products of the cholesteryl arachidonate. A GLC examination of the more polar oxidation products of the cholesteryl esters recovered near the origin of the TLC plate yielded peaks, which corresponded to cholesteryl esters with oxygenated sterol rings. The ring oxidation products obtained from the unsaturated fatty acid esters of cholesterol were identical to those derived from cholesteryl palmitate employed as a control. Saponification of these fractions revealed the presence of mixed cholestane triols, as well as other unidentified oxygen-containing sterols. On the basis of the total lipid profiles of the unsaturated cholesteryl ester oxidation products, the overall yield of the C_5 and C_9 core aldehydes was estimated to be about 10% (chromatograms not shown).

Characterization of diacylglycerol core aldehydes. The native and osmium tetroxide/periodic acid oxidized egg yolk PC were resolved by TLC using chloroform/methanol/water (65:35:6, vol/vol/vol) as solvent. Because of its greater polarity, the oxidized PC (R_f 0.26) was clearly resolved from the native PC (R_f 0.33) (chromatoplate not shown). Any residual PC, however, overlapped with the diethyl acetals of the PC-derived core aldehydes. There were minor fluorescent bands near the origin of the TLC plate, which were not further characterized. The identity of the core aldehydes was established by dephosphorylation of the PC-derived core aldehydes or their DNPH derivatives with phospholipase C followed by GC/MS or LC/MS.

Figure 6 shows the separation of the diacylglycerols containing the core aldehydes as the TMS and the MOX-TMS derivatives by nonpolar capillary GLC. Two major peaks are seen, which were shown by GC/MS to be due to the 9-oxononanoyl esters of palmitoyl and stearoylglycerols. The presence of the aldehyde function was indicated by the shift of both peaks to longer retention times following conversion to the MOX derivatives. Figure 7 gives the GC/EIMS spectra of the TMS ethers (Fig. 7A) of 1-palmitoyl-2-(9-oxononanoyl)-*sn*-glycerol and its MOX derivative (Fig. 7B). In neither instance was the molecular ion seen. However, readily detectable were the $[M - 15]^+$ ions due to loss of a methyl group from the TMS ethers. The *m/z* 145 ion represents $[CH(O)CHCH_2OSi(CH_3)_3]^+$, while the ion at *m/z* 129 represents $[CH_2CHCHOSi(CH_3)_3]^+$. The *m/z* 385 and 301 ions in Figure 8A are due to $[M - RCOO(C_9ALD)]^+$ and $[M - RCOO(C_{16})]^+$, respectively, while the *m/z* 229 and 313 ions are due to

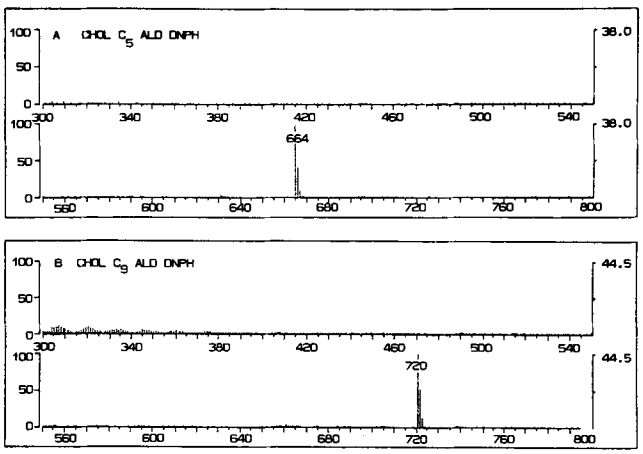

FIG. 5. Full mass spectra of cholesteryl ester core aldehyde DNPH derivatives as obtained by reverse-phase LC/MS with negative CI. A, 5-oxovalerate; B, 9-oxononanoate. LC/MS conditions were as given in Materials and Methods.

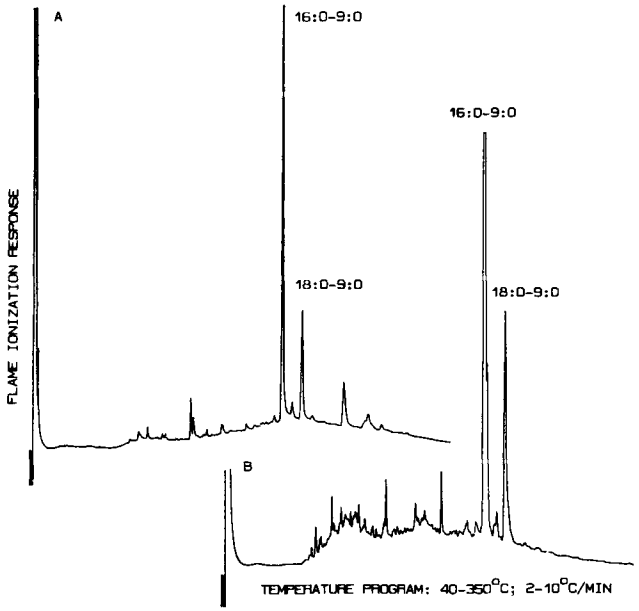

FIG. 6. Nonpolar capillary GLC profiles of diacylglycerol moieties of oxidized egg yolk PC containing core aldehydes. A, TMS ethers; B, MOX-TMS ethers. GLC conditions were as in Figure 2.

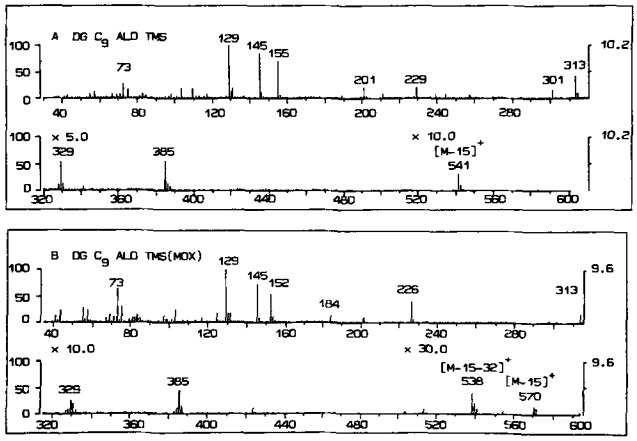

FIG. 7. Full mass spectra of 1-palmitoyl-2-(9-oxononanoyl)-*sn*-glycerol as obtained by GC/MS with EI ionization. A, TMS ether; B, MOX-TMS ether. GC/MS conditions as in Figure 2.

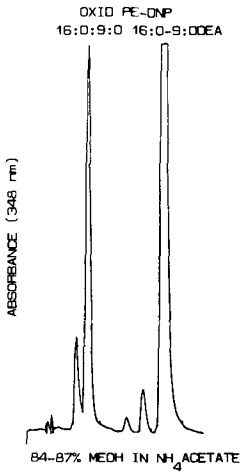

FIG. 8. Reverse-phase HPLC resolution of 1-palmitoyl-2-(9-oxononanoyl)-GPE-DNP; 16:0-9:0, C_9 core aldehyde of PE DNP; 16:0-9:0 DEA, diethyl acetal of C_9 core aldehyde of PE DNP. HPLC conditions as given in Materials and Methods. The retention time of the 16:0-9:0 diethyl acetal was 10 minutes.

$[RCO(C_9ALD) + 74]^+$ and $[RCO(C_{16}) + 74)]^+$, respectively. The *m/z* 155 is due to $[RCO(C_9ALD)]^+$. The *m/z* 538 ion in Figure 7B is due to loss of methanol from the MOX group in $[M - 15]^+$, while the *m/z* 385 and 329 ions are due to $[M - RCOO(C_9ALDMOX)]^+$ and $[M - RCOO(C_{16}) - H]^+$, respectively. The *m/z* 226 and 313 ions are due to $[RCO(C_9ALDMOX) - CH_3OH + 74]^+$ and $[RCO(C_{16}) + 74]^+$, respectively. The *m/z* 184 and *m/z* 152 ions are due to $[RCO(C_9ALDMOX)]^+$ and $[RCO(C_9ALDMOX) - CH_3OH]^+$ fragments, respectively. Two peaks were seen also in the LC/NCIMS (NCI, negative chemical ionization) profile of the DNPH derivatives of the diacylglycerol core aldehydes prepared from the oxidized egg yolk PC. The single negative ions produced for each peak corresponded to the $[M]^-$ of palmitoyl-9-oxononanoyl and stearoyl-9-oxononanoylglycerol DNPH (chromatograms and mass spectra not included). The total ion current profile was similar to that of the UV absorption profile, while the peak ratios corresponded to the ratios of the 16:0/18:0 fatty acids in the egg yolk PC from which the oxidation products were derived.

Characterization of GPE core aldehyde. Osmium tetroxide/periodic acid oxidation of the DNP derivative of synthetic 16:0-18:1 GPE gave two bands on TLC: one corresponding mainly to the core aldehyde (R_f 0.53) and another one (R_f 0.60) corresponding to the diethyl acetal of the core aldehyde. Figure 8 shows the reverse-phase HPLC profile of the diethyl acetal band which was cross-contaminated with small amounts of the core aldehyde. The major peaks were separately collected and examined by FAB-MS.

Figure 9 shows the pertinent portions of the FAB-MS spectra of the core aldehyde esters containing the free aldehyde and the diethyl acetal functions. The ion *m/z* 796 in Figure 9A represents $[M + Na]^+$ of the free aldehyde molecule, while the *m/z* 870 and 865 ions in Figure 9B represent the $[M + Na]^+$ and $[M + NH_4]^+$, respectively. The *m/z* 824 ion is due to loss of ethanol from the diethyl acetal group of $[M + Na]^+$, while the *m/z* 802 ion is due to $[M + H - C_2H_5OH]^+$. The presence of the DNP group on the ethanolamine moiety of GPE allowed the UV monitoring of the presence of non-aldehyde peaks formed as minor byproducts in the oxidation reaction. These were considered to be the acids and their ethyl esters of the core aldehydes, but were not further identified. On the basis of the reverse-phase HPLC profiles of the total reaction mixture, the overall yield of the C_5 and C_9 core aldehydes of the DNP-PE was estimated at about 20% of the unsaturated starting material.

In conclusion, this study reports the synthesis and characterization of 5-oxovaleric and 9-oxononanoic acid esters of cholesterol and the common GPL, PC and PE. The core aldehydes are characterized by chromatographic

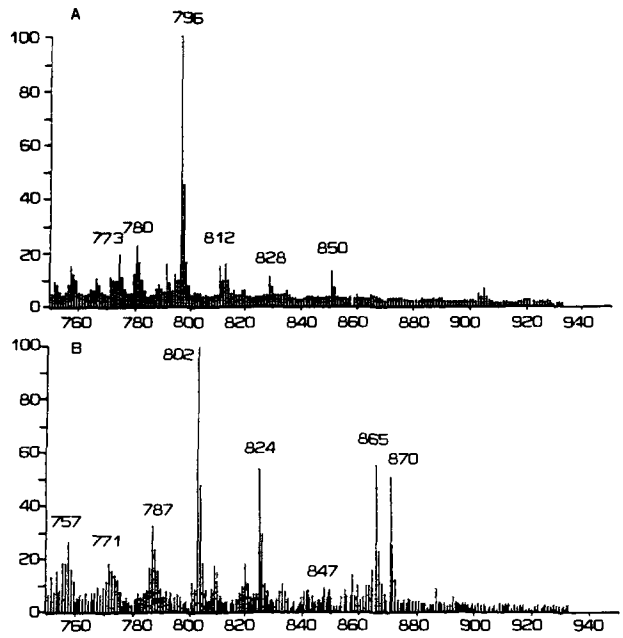

FIG. 9. FAB-MS spectra of 1-palmitoyl-2-(9-oxononanoyl)-GPE-DNP. A, free aldehyde; B, diethyl acetal. FAB-MS conditions were as given elsewhere (18).

and mass spectrometric methods in the form of various derivatives, which clearly distinguish them from closely related byproducts formed during synthesis. The semisynthetic lipid ester core aldehydes provide reliable standards for the isolation and identification of the common lipid ester core aldehydes among the secondary peroxidation products of natural cholesteryl esters and glycerolipids.

Seawater Fatty Acids and Lipid Classes in an Urban and a Rural Nova Scotia Inlet[1]

Christopher C. Parrish[a,*], Guy Bodennec[b], Ena J. Macpherson[c] and Robert G. Ackman[c]
[a]Ocean Sciences Centre and Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1C 5S7, [b]IFREMER, Centre de Brest, 29280 Plouzané, France and [c]Canadian Institute of Fisheries Technology, Technical University of Nova Scotia, Halifax, Nova Scotia, Canada B3J 2X4

Seawater samples collected in the summer of 1989 in Nova Scotia inlets were analyzed for lipid content to examine water quality. One inlet, the Northwest Arm, is located adjacent to an urban center, while the other, Ship Harbour, is located in an uninhabited area and contains three commercial mollusk farms. Lipids in the dissolved and particulate fractions were measured by Chromarod-Iatroscan thin-layer chromatography with flame ionization detection and by gas chromatography. Samples collected near the urban center had higher levels of particulate hydrocarbons (28 ± 15 μg/L) than those collected in the relatively pristine environment (11 ± 1 μg/L). The urban center samples also had higher levels of particulate free aliphatic alcohols (14 ± 5 *vs.* 8 ± 1 μg/L) and free fatty acids (5 ± 1 *vs.* <0.5 μg/L), suggesting degradation of wax esters and other fatty acid esters. Dissolved and particulate matter fatty acids contained a higher proportion of monounsaturated acids near the urban center (33–35 *vs.* 25–29% of the total fatty acids). The essential fatty acids 20:5n-3 (eicosapentaenoic acid) and 22:6n-3 (docosahexaenoic acid), presumably of algal origin, were more prominent in the pristine environment (up to 3.5%), where mollusk aquaculture is practiced. Fatty acid markers of toxic algae were virtually absent (<0.2%) in samples taken from both locations.
Lipids 27, 651–655 (1992).

Lipids are present in seawater in organisms, in detritus, and in the operationally defined "dissolved" fraction. Lipid class data from extracts of dissolved and particulate matter are useful as indicators of pollution, certain types of organisms, or of anabolic or catabolic processes (1), while certain fatty acids may be used as marker or signature compounds for specific organisms (2,3). Markers of particular interest in eastern Canada are the polyunsaturated fatty acids associated with marine dinoflagellates (2) and the marine diatom *Nitzschia pungens* (4). Certain dinoflagellates have long been known to cause paralytic shellfish poisoning in this region, while *Nitzschia pungens* was the source of domoic acid present in cultivated blue mussels which caused a recent outbreak of amnesic shellfish poisoning here (5,6). There is currently a global increase in reports of such catastrophic blooms; areas affected include polluted coastal waters and aquaculture sites (7). Thus we measured fatty acids and lipid classes in seawater samples collected from two such areas represented by two inlets on the coast of Nova Scotia in eastern Canada. One inlet, the Northwest Arm, is surrounded by a city; the other, Ship Harbour, is located in a relatively uninhabited area used for blue mussel farming.

MATERIALS AND METHODS

Seawater samples. Samples from the Northwest Arm, a small marine inlet about 5 km long surrounded by the City of Halifax, were collected in the Aquatron Laboratory of Dalhousie University. Water was pumped from a depth of about 12 m in the arm, through an underground fiberglass pipeline to the Aquatron Laboratory. Samples of unfiltered water were collected around noon on July 17, 21 and 25 and on August 2, 1989. The average water temperature over the four sampling days was 12 ± 3°C.

Samples were also collected on August 3, 1989 from Ship Harbour, a marine inlet located about 80 km east of Halifax. Ship Harbour is about 8 km long, and is surrounded by six freshwater lakes from which five rivers drain into various points of the harbor. Ship Harbour is the site of three farms for blue mussels, *Mytilus edulis*; it has no major settlements or heavy industry located on its shores. Samples were taken around 3 p.m. at 0.5 m, near the center of the harbor. The water temperature was 21°C.

Chlorophyll *a* was determined in a Turner fluorometer according to Strickland and Parsons (8). Salinity was measured using a Guildline Autosal (Smiths Falls, Ontario, Canada) and the nutrients were run on a Technicon Autoanalyser II (Tarrytown, NY).

Lipid class analyses. Dissolved and particulate lipid classes were measured as described previously (9). Briefly, samples collected in precleaned and sample-rinsed amber glass solvent bottles were screened through a 75 μm metal sieve, then filtered onto precombusted Gelman A/E glass fiber filters (Gelman Sciences, Ann Arbor, MI). After addition of the internal standard, *n*-octadecan-3-one, "dissolved" lipids were extracted with dichloromethane and "particulate" lipids (see Discussion) were extracted with dichloromethane/methanol (2:1, vol/vol). The extracts were washed with distilled water to remove non-lipid material, dried over anhydrous sodium sulfate, and concentrated under nitrogen. The concentrated lipid extracts were spotted onto Chromarods-SIII for thin-layer chromatographic separation of lipid classes. Samples were focused (10) into a narrow band on the silica gel surface by developing to the origin in acetone, and then lipid classes were separated in a step-wise procedure using developing systems of increasing polarity. Neutral lipids were separated in two solvent systems containing hexane, diethyl ether and formic acid, 99:1:0.05 (vol/vol/vol) followed by 80:20:0.1. Polar lipids were then separated into "acetone-mobile polar lipids" and phospholipids using 100% acetone and a mixture of chloroform, methanol and water (65:35:4). Lipid classes were measured by flame ionization detection in an Iatroscan MK III (Newman-Howells Assoc., Wales, U.K.); the signal was recorded on a Spectra-Physics computing integrator (SP 4270;

[1]O.S.C. contribution 173.

Abbreviations: br, branched-chain; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; FA, fatty acid; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry.

Spectra-Physics, St. Albans, U.K.). They were quantified using calibration curves obtained from scans of authentic standards (Sigma, St. Louis, MO).

Fatty acid analyses. Fatty acids in the August samples were measured by gas chromatography (GC) as methyl esters (11). Separations were performed on a fused silica capillary column (30 m × 0.32 mm i.d.) coated with Supelcowax-10 (Supelco Inc., Bellefonte, PA) in a Perkin-Elmer Model 8420 gas chromatograph (Perkin-Elmer, Norwalk, CT). Fatty acids were identified by comparing their retention times, both before and after catalytic hydrogenation over PtO_2, with those of standard mixtures of well-established composition. Some identities were also confirmed by GC/mass spectrometry (MS) using a Finnigan MAT (San Jose, CA) Ion Trap detector (12).

RESULTS

The temperature and salinity data (Table 1) from the two Nova Scotia inlets suggest a significant oceanic contribution to the source of the seawater samples from the Northwest Arm and a significant freshwater contribution to the upper water layer of Ship Harbour. The salinity of the Northwest Arm water was greater than that measured throughout the water column in nearby Bedford Basin during the spring or summer (13,14). Bedford Basin, which is normally described as a marine inlet, is connected to the Northwest Arm *via* Halifax Harbour.

TABLE 1

Salinity, Nutrients and Chlorophyll *a* in Nova Scotia Inlets in August 1989

	Northwest Arm[a]	Ship Harbour[b]
Salinity (‰)[c]	31.65 ± 0.05	18.42 ± 1.19
Phosphate (μmol/L)	0.99 ± 0.04	0.24 ± 0.02
Nitrate (μmol/L)	0.99 ± 0.02	0.17 ± 0.03
Chlorophyll *a* (μg/L)	0.26 ± 0.12	0.24 ± 0.03

[a]Mean ± SD of three separate samples collected on August 2.
[b]Mean ± SD of three separate samples collected on August 3.
[c]Parts per thousand.

Both the nutrient and chlorophyll *a* concentrations were low in the two inlets suggesting post-algal bloom conditions; they were similar to those measured in Bedford Basin after spring blooms (15) though the nitrate and chlorophyll *a* concentrations (Table 1) were even lower than post-bloom in Bedford Basin. Chlorophyll *a* concentrations (Table 1) were also lower than measured during the summer in Bedford Basin (13,16).

Total particulate lipids present in the Northwest Arm samples were at a concentration of 156 ± 59 μg/L (mean ± SD, n = 4). Total dissolved lipids were present at a level of 87 ± 33 μg/L over the four-week sampling period. There was no continuous trend in the total lipid data for the four sampling days.

The average levels of total dissolved and particulate lipids in Ship Harbour were 156 μg/L and 83 μg/L, respectively, in the August samples. The individual lipid class concentrations for Ship Harbour were generally similar to those measured in the Northwest Arm samples (Table 2), except in the case of particulate hydrocarbons, free fatty acids and free aliphatic alcohols which were lower in Ship Harbour, and dissolved free fatty acids and acetone-mobile polar lipids which were higher.

Detailed GC and GC/MS analyses of the total fatty acids in the August samples revealed the presence of 33–40 identifiable fatty acids (Table 3). Particulate lipids from the Northwest Arm showed the widest spectrum of fatty acids, suggesting a greater variety of sources. GC/MS analyses also indicated that several hydrocarbons and phthalates of unknown origin occurred in the concentrates.

DISCUSSION

Representatives from as many as 16 lipid classes have been found in the dissolved and particulate fractions of seawater (1). These fractions are obtained by firstly passing samples through a screen (50–250 μm mesh) to remove larger zooplankton, and then by filtering through glass-fiber filters (0.7–1.2 μm pore size) to separate dissolved and particulate material. Lipids present in dissolved and particulate matter in coastal waters are derived from various

TABLE 2

Dissolved and Particulate Lipid Class Concentrations (μg/L ± SD) in Nova Scotia Inlets During the Summer of 1989

	Northwest Arm[a]		Ship Harbour[b]

sources (17,18). Biogenic and anthropogenic inputs of such compounds occur directly in aquatic environments (15) or they are transported from further afield by ocean currents (19), by rivers (20) or in airborne particulate matter (21).

We compare here dissolved and particulate lipid data from two inlets where sources for the lipids are likely to be different. We also compare these data with published data from another inlet, Bedford Basin, located on the same coast. Bedford Basin has been the site of several studies involving lipid analyses (9,13-16,22). By contrast with these previous studies, in this study we measured not only the complete suite of lipid classes in both dissolved and particulate matter, but also the complete spectrum of fatty acids in these two fractions.

The concentrations of particulate lipids in the Northwest Arm were similar to those measured near the center of Bedford Basin after the spring bloom (15,22). The concentrations of dissolved lipids, however, were lower than measured during bloom periods in Bedford Basin (15) where dissolved lipids were usually present at higher concentrations than were the particulate lipids. It is possible that sampling the Northwest Arm water through a pipeline had in some way upset the natural balance between dissolved and particulate lipids, although the fear had been that dissolved lipid concentrations would be biased upward as a result of cell lysis.

The lack of a trend in the Northwest Arm total lipid data extended to the time series data for all but one of the lipid classes. For this reason, all the Northwest Arm lipid class data have been averaged in order to more easily compare with the Ship Harbour lipid data (Table 2). Such a grouping seems reasonable as the week to week variability in the Northwest Arm data was close to the sample to sample analytical variability for Ship Harbour. The standard deviation for the Northwest Arm data is similar to that obtained from triplicate Ship Harbour samples, though it is larger for the time series in all but one case (Table 2).

The hydrocarbon figures for Ship Harbour were similar in magnitude to the 10 μg/L of C_{14}-C_{21} hydrocarbons measured in nearby Jeddore Harbour (23). High levels of branched-chain (br) hydrocarbons in Jeddore Harbour were thought to have been derived from diesel fuels. These hydrocarbons are, however, normal constituents of blue-green algae (24), and a strong summer input of complex hydrocarbons from algae cannot be ruled out. The origins of the Ship Harbour hydrocarbons (Table 2) may thus be quite diverse. The average particulate hydrocarbon concentration measured in the Northwest Arm samples is not only higher than measured in Ship Harbour, but it is also higher than averages measured in Bedford Basin (14,15) and much higher than averages measured over the Scotian Slope (14). Urban runoff is a possible contributor to these high total particulate hydrocarbon levels (20).

Free fatty acids, free aliphatic alcohols and acetone-mobile polar lipids were present at different concentrations in the Ship Harbour and Northwest Arm samples. Such classes, which contain indicators of lipid degradation (1), might be expected in a post-bloom situation. High concentrations of particulate wax and steryl esters (Table 2) also might be expected in this situation; the levels of this zooplankton indicator class (1) were the same in the Northwest Arm and Ship Harbour samples, but were

higher than over the Scotian Slope or in Bedford Basin (14,15). It is not clear why certain degradation indicators were more prominent in one fraction in one location than in the other, although it is likely that such differences are related to anthropogenic inputs to the Northwest Arm.

The oceans are a repository for many fatty acids because of the multitude of marine flora and fauna. The presence of the long-chain saturated fatty acids 19:0 and 20:0 in a Newfoundland bay has been noted (25). Here we show that 22:0, 23:0 and 24:0 are also present in marine dissolved or particulate matter (Table 3). Such saturated fatty acids may originate in crustacean faecal matter (26). The proportions of branched-chain C_{15} fatty acids were 3–5 times higher in the Nova Scotian inlets (Table 3) by comparison with the Newfoundland bay (25). Such fatty acids are believed to be of bacterial origin and it is notable that the levels of odd carbon number branched-chain fatty acids tend to be higher in the samples taken from the urban inlet (Table 3). The levels of these fatty acids are more similar to those found in Jeddore Harbour, Nova Scotia where br C_{15} and br C_{17} were in the range 0.6–1.7 wt% in the August sample (23). The high levels of unbranched 15:0 (2.9–4.1 wt%) in dissolved and particulate material (Table 3) compare well with previous measurements of 15:0 (23,25). This saturated fatty acid is easily identified and quantified and, because it is ubiquitous in marine phytoplankton (27), it may be a useful indicator of algal blooms.

In contrast to C_{15} fatty acids, the even-chain saturated fatty acids 14:0, 16:0 and 18:0 are found at significant levels in most marine samples. It is thus not surprising that these unbranched fatty acids contribute significantly to the total fatty acid pool in both dissolved and particulate matter from both locations (Table 3). The levels, in μg/L, of these fatty acids are also likely to be similar. The total levels of the acyl lipid classes where fatty acids are a major component of the lipid structure (wax and steryl esters, triacylglycerols, free fatty acids and phospholipids) are in the range 36–61 μg/L. Thus, the levels of the major saturated fatty acids are likely to be similar in the dissolved and particulate samples from each location. This suggests a ubiquitous source, presumably algae.

The monoethylenic fatty acids include 14:1 at about half the level of 14:0. In lipids extracted from most marine animals, 14:1 is a very minor component (<0.5% of the fatty acids) and its presence in seawater is not clearly explainable. The 16:1 and 18:1 fatty acids are also ubiquitous and not remarkable qualitatively or quantitatively; however, 20:1 and 22:1 are usually associated with copepod lipids (25,28) and were not previously found in the coastal seawater sample that had been screened to remove zooplankton (25). These long-chain monoene fatty acids were also absent from suspended particulate matter collected at oceanic stations (29), but they were present in particulate matter collected in Bedford Basin after screening through 163 μm bolting cloth (16). Bedford Basin is connected to the Northwest Arm, thus the source of the 20:1 and 22:1 is probably the same in the two studies and may be related to high wax and sterol ester levels (Table 2).

The polyunsaturated fatty acids are all minor constituents, although the Ship Harbour dissolved lipid sample had rather higher quantities of 20:5n-3 (eicosapentaenoic acid—EPA) and 22:6n-3 (docosahexaenoic acid—DHA). The level of these polyenoic acids was also slightly higher in the particulate matter from Ship Harbour. The significant levels of these labile fatty acids, which are abundant in marine phytoplankton (27), suggest that an algal bloom was just decaying in Ship Harbour. The high concentration of dissolved free fatty acids in this water (Table 2) would support this contention. Whether this had already taken place in the Northwest Arm is difficult to assess because of the deeper water source. After EPA and DHA, the most important polyenes were 18:2n-6 and 16:3n-4 (Table 3). Both these fatty acids could have been synthesized by any of several phytoplankton common in these waters. Two polyunsaturated fatty acids that are notable, at least from a public health perspective, because of their virtual absence from the extracts are 18:5n-3 and 16:4n-1. The first is a marker for marine dinoflagellates (2) which has been reported to be an ichthyotoxin (30), while the second is a major contributor to the fatty acids of the toxic marine diatom *Nitzschia pungens* (4). These seawater data thus provide a baseline showing a normal fatty acid and lipid class distribution against which samples taken during catastrophic blooms could be compared. Good baseline data for coastal areas are important in view of the global increase in geographic extent and variety of toxic algal blooms (7).

ACKNOWLEDGMENTS

ARTICLE

Studies on the Transfer of Tocopherol Between Lipoproteins

Maret G. Traber*, Jerome C. Lane, Nora R. Lagmay and Herbert J. Kayden
Department of Medicine, New York University School of Medicine, New York, New York 10016

The net transfer of labeled α-tocopherol from donor to acceptor lipoproteins at physiological concentrations was investigated. Labeled lipoproteins were isolated i) following *in vitro* addition of [3,4-^{3}H] *all rac*-α-tocopherol to plasma, or ii) from plasma obtained 12–16 h after ingestion by normal subjects of an oral dose (100 mg each) of 2*R*,4′*R*,8′*R*-α-[5,7-(C^2H_3)$_2$]tocopheryl acetate and 2*S*,4′*R*,′R-α-[5-C^2H_3]tocopheryl acetate. A constant amount (on a protein basis) of labeled lipoprotein was incubated with an increasing amount of unlabeled acceptor lipoprotein for 2 h at 37°C. No discrimination between stereoisomers of α-tocopherol was detected. Labeled VLDL and labeled LDL (very low and low density lipoproteins, respectively) tended to retain their labeled tocopherol. Labeled high density lipoproteins (HDL) readily transferred the labeled tocopherol to VLDL (>60% transferred), while the transfer to LDL was dependent upon the ratio of labeled HDL/LDL with a lower net transfer at higher ratios. This dependency of the distribution of tocopherol upon the ratio of HDL/LDL was also observed *in vivo*. The tocopherol/mg HDL protein was measured in 11 subjects with varying HDL levels. As the % HDL in the plasma increased from 14 to 50%, the tocopherol/HDL protein also increased (r^2 = 0.37, $P < 0.05$).
***Lipids* 27, 657–663 (1992).**

Vitamin E absorption and transport has been studied using deuterated tocopherols. The ratio of deuterated/total α-tocopherol following an oral dose of the labeled material to humans peaks first in chylomicrons, then in very low density lipoproteins (VLDL), and then simultaneously in low and high density lipoproteins (LDL and HDL, respectively) (1). Studies of the discrimination between tocopherols have demonstrated that there is a specific mechanism in the liver for the incorporation of *RRR*-α-tocopherol into VLDL (2–4), and that this mechanism is essential for the maintenance of normal plasma α-tocopherol concentrations (5). However, we have also found that independent of this specific mechanism there is transfer of tocopherols to LDL and HDL during catabolism of the triglyceride-rich lipoproteins. This latter transfer mechanism is sufficient to maintain normal plasma levels of α-tocopherol, when large doses of vitamin E are given to patients with familial isolated vitamin E deficiency, who do not have normal secretion of α-tocopherol in VLDL (5).

The present paper describes a series of *in vitro* incubation studies using lipoproteins labeled with radioactive or deuterated tocopherols then mixed and incubated with unlabeled lipoproteins to determine whether tocopherol transfers between lipoproteins in the absence of other mediators. Previously, Massey (6) has studied the transfer of tocopherol and cholesterol between lipoproteins and liposomes and demonstrated that cholesterol transfers more readily than does tocopherol. Kayden and Bjornson (7) and Bjornson *et al.* (8) demonstrated that tocopherol readily exchanges between lipoproteins and erythrocytes, and that the order of the rate of exchange was HDL > LDL > VLDL. Granot *et al.* (9) have demonstrated that tocopherol transfer between lipoproteins is not assisted by neutral lipid transfer protein. All of these studies have employed the use of lipoproteins labeled *in vitro* with radioactive tocopherol. Potentially, this label might not equilibrate with the lipoproteins similarly to metabolically incorporated tocopherols. Therefore, we first devised our experiments using lipoproteins isolated from serum incubated with radioactive tocopherol, then we verified our results using lipoproteins isolated from plasma obtained 12–16 h following the oral administration of deuterated tocopherols.

MATERIALS AND METHODS

Radioactive tocopherol. Before use, [3,4-^{3}H] *all rac*-α-tocopheryl acetate (a gift from Dr. W. Cohn, Hoffmann La Roche, Basel, Switzerland) was subjected to alkaline hydrolysis in the presence of excess ascorbic acid followed by extraction with hexane. The [^{3}H]α-tocopherol was then used immediately for the labeling of plasma (described below). More than 95% ^{3}H was found to coelute with an authentic sample of added unlabeled *all rac*-α-tocopherol in high-performance liquid chromatography (HPLC) (10).

To label the plasma with [^{3}H]tocopherol, a modification of the method used by Goodman *et al.* (11) for labeling plasma with radioactive cholesterol was devised. Approximately 15 μCi of [^{3}H]tocopherol in hexane was dried under nitrogen and immediately resuspended in acetone (200 μL). The sample was mixed vigorously with a vortex mixer, then was taken up into a syringe and forcibly injected under the surface of approximately 11 mL of plasma in a scintillation vial. The vial was flushed with nitrogen, sealed and incubated in the dark at room temperature overnight. The vial was then flushed with nitrogen for 1 h to allow the acetone to evaporate. The lipoproteins (VLDL, LDL and HDL) were isolated by the micro-method of lipoprotein isolation described below.

Deuterated tocopherols. The syntheses and analysis of deuterated α-tocopherols have been described previously (12,13). Drs. Keith Ingold and Graham Burton (National Research Council, Ottawa, Ontario, Canada) provided the tocopherols labeled with deuterium and carried out the analyses. An oral dose containing 100 mg of each 2*R*, 4′*R*,8′*R*-α-[5,7-(C^2H_3)$_2$]tocopheryl acetate, a source of hexadeuterated α-tocopherol with natural stereochemistry, and 2*S*,4′*R*-α-[5-C^2H_3]tocopheryl acetate, a source of trideuterated α-tocopherol with unnatural stereochemistry, was consumed by each subject. 2-*Ambo*-α-[5,7,8-(C^2H_3)$_3$] tocopherol (d_9-tocopherol), used as an internal standard, was added in known amount to each plasma, or lipoprotein sample, immediately prior to lipid extraction (1,14). The lipid extracts were purified by passage through an

Abbreviations: EDTA, ethylenediaminetetraacetic acid; GC/MS, gas chromatography/mass spectrometry; HDL, high density lipoproteins; HPLC, high-performance liquid chromatography; LDL, low density lipoproteins; VLDL, very low density lipoproteins.

analytical high-performance silica gel column. The amounts of d_3-, d_6-, d_9- and unlabeled (d_0) α-tocopherols in the tocopherol fractions collected were determined by gas chromatography/mass spectrometry (GC/MS) after conversion to their trimethylsilyl ethers (12,14). The absolute concentrations of d_0-, d_3- and d_6-α-tocopherols were obtained by comparing the respective peak areas with the peak area of the added d_9-α-tocopherol, as described previously (1,2,5,12,14).

Subjects. This study was carried out with the approval of the Institutional Review Board of New York University Medical Center. Three normal control subjects gave written informed consent and had no abnormalities of lipid or lipoprotein metabolism. These subjects consumed both deuterated tocopherols with the evening meal, then a blood sample (150 mL) was drawn into 0.05% ethylenediaminetetraacetic acid (EDTA) on the morning of the following day. The plasma was separated from the erythrocytes by centrifugation and immediately used for the isolation of lipoproteins labeled with deuterated tocopherols. Plasma for the isolation of unlabeled lipoproteins was obtained from the New York Blood Center (New York, NY).

Eleven subjects participated in the analysis of the distribution of α-tocopherol and cholesterol in lipoproteins. These subjects had a variety of abnormalities of lipoprotein metabolism which resulted in different levels of HDL cholesterol (Table 1). Following an overnight fast, two blood samples were collected; one serum sample for the analysis of cholesterol and HDL cholesterol by the clinical laboratory, and one plasma sample for the isolation of lipoproteins by the micro-method described below and the measurement of tocopherol by HPLC (10).

Lipoprotein isolation. Two separate protocols were used to isolate lipoproteins by ultracentrifugation: i) a macro-method was used to isolate the lipoproteins from the plasma prior to incubation; and ii) a micro-method was used to isolate the lipoproteins following incubation, or from small volumes of plasma. A precipitation technique was also used to re-isolate lipoproteins following incubation, as described below.

In the macro-method the lipoproteins were isolated by sequential ultracentrifugation by the method of Havel *et al.* (15) using a 50.2 Ti rotor in a L5-65 Beckman ultracentrifuge (Beckman Instruments, Inc., Palo Alto, CA) at 100,000 × *g* for 4 h for isolation of VLDL and LDL and for 48 h for isolation of HDL with plasma adjusted with solid KBr to the following densities: VLDL ($d < 1.019$), LDL ($1.019 < d < 1.063$) and HDL ($1.063 < d < 1.21$). The lipoprotein fractions were dialyzed extensively against saline (0.15 M NaCl, 0.3 mM EDTA, pH 7.4), were filtered with a 0.45 μm^2 sterile filter unit (Nalge Co., Rochester, NY), the protein contents were determined by the method of Lowry *et al.* (16) with the addition of diethyl ether to remove lipids from the aliquots used for analysis. The lipoprotein fractions were stored at 4°C for less than two weeks prior to the incubation studies.

In the micro-method of lipoprotein isolation a TL 100 Beckman ultracentrifuge was used to isolate the indicated lipoprotein fractions by centrifugation at 435,680 × *g* using a fixed angle rotor (TLA 100.2) with density changes achieved by adding solid KBr. For isolation of lipoproteins for incubations, the densities above were used with a 2 h centrifugation to isolate VLDL, or LDL, and a 4 h centrifugation to isolate HDL. The lipoprotein fractions were dialyzed, and the protein contents were determined as described above. The labeled lipoproteins were filtered using a sterile 0.45 μm^2 syringe filter (Gelman Sciences, Ann Arbor, MI), were stored at 4°C and used within two days of isolation.

TABLE 1

Characteristics and Plasma Tocopherol and Cholesterol Concentrations of Subjects[a]

		Tocopherol		Cholesterol

[a]Shown in Figure 5.

The micro-method was used to re-isolate lipoproteins following incubation. VLDL were separated from LDL or HDL at d = 1.006 g/mL, while LDL was separated from HDL at d = 1.063. The lipoprotein fractions labeled with deuterated tocopherols were frozen and stored at −70°C until shipped by overnight freight on dry ice to the National Research Council in Ottawa, Canada, for analyses of the tocopherols. The radioactively labeled samples were counted as described below.

In some experiments, following incubation (described below) to rapidly re-isolate apolipoprotein (apo) B-containing lipoproteins from HDL, a manganese-heparin precipitation technique was used (17). Briefly, a stock solution was added to each tube such that the final concentrations were: heparin (14 mg/mL) and manganese chloride (0.092 M). The samples were mixed, allowed to stand at room temperature for 10 min, then the tubes were centrifuged for 1 min at 10,000 × *g* and the supernatant (HDL fraction) was transferred to scintillation vials for counting in ACS (Aqueous Counting Scintillant, Amersham, Arlington Heights, IL) using a Beckman LS 7000 scintillation counter. To dissolve the precipitate, 100 μL of 1 M Na citrate was added to each tube and the solution was transferred to scintillation vials for counting, as above.

Incubation protocol. Various combinations of labeled and unlabeled lipoproteins based on protein ratios (as described in the figure legends) were incubated together in a uniform volume (<2 mL) in sterile, plastic tubes in a 37°C water bath with gentle agitation for 2 h, or the indicated interval. The amount of labeled lipoprotein was kept constant, while varying amounts of the unlabeled lipoprotein were added to achieve the indicated protein ratios, then saline (0.15 M NaCl, 0.3 mM EDTA, pH 7.4) was added such that the total volume for the series of protein levels was constant. No other proteins or plasma components were added. Following the incubation, the lipoproteins were re-isolated using the micro-isolation method or the precipitation technique as described in the legends.

The % tocopherol transferred was calculated from the amount of labeled tocopherol (either ^3H or ^2H) in the acceptor lipoprotein fraction divided by the total labeled tocopherol recovered in the donor and acceptor fractions.

RESULTS

Shown in Figure 1 are the time courses (up to 24 h) of the [^{3}H]tocopherol distribution into HDL from labeled LDL, or the reverse, at the indicated donor to acceptor protein ratios. When labeled LDL was incubated with HDL up to 24 h, about 80% of label remained in LDL. By contrast, when labeled HDL was incubated with LDL up to 24 h, about 75% of the label had transferred to LDL. Most of this transfer occurred prior to 30-min. Previously, Massey (6) demonstrated that equilibration of labeled tocopherol from HDL to LDL took place in less than 1 h. Since most of the transfer occurred within the first 2 h, the subsequent incubations were carried out for 2 h.

Shown in Figure 2 are the results of a representative experiment of three in which [^{3}H]tocopherol-labeled donor lipoproteins were incubated with acceptor lipoproteins at protein ratios from 0.33 to 3. Little [^{3}H]tocopherol transferred from labeled VLDL to either LDL or HDL, irrespective of the amount of acceptor (Fig. 2A and C). Similarly, when labeled LDL was the donor at a donor-to-acceptor ratio of 0.5, 17% of the [^{3}H]tocopherol transferred to HDL, while at a ratio of 3, only 7% was transferred (Fig. 2D). Unlike LDL and VLDL, HDL readily donated tocopherol. When labeled HDL was incubated with LDL at a donor-to-acceptor ratio of 0.5 (shown as LDL/labeled HDL = 2, Fig. 2B), 78% of the [^{3}H]tocopherol was transferred to LDL, while at a donor-to-acceptor ratio of 3 (shown as LDL/labeled HDL = 0.3, Fig. 2B), 56% was transferred.

Although this experimental protocol was carried out several times with similar results, it seemed possible that a systematic error was taking place. To isolate the apo B-containing lipoproteins from HDL, a manganese-heparin precipitation technique was used. Since the lipoproteins were labeled *in vitro*, it seemed possible that this procedure might have denatured the lipoproteins and these denatured labeled lipoproteins were precipitated by the reagent and thus were artificially increasing the apparent transfer from HDL to apo B-containing lipoproteins, and were increasing the amount of label retained by apo B-containing lipoproteins, when incubated with HDL. Therefore, in the studies described below metabolically labeled lipoproteins were used—deuterated tocopherols were administered orally to subjects, then plasma was obtained 12–16 h later, and the lipoproteins were isolated before and after incubation using ultracentrifugation techniques.

Figure 3 shows the data from one of three separate experiments in which different donors provided plasma for the incubations; the three experiments yielded similar results. The subject was given both *RRR-* and *SRR-α*-tocopherols labeled with different amounts of deuterium, but only the d_6-*RRR-α*-tocopherol results are shown because the relative transfers of *SSR-* were identical to those of *RRR-α*-tocopherol. Thus, transfer between lipoproteins during 2 h *in vitro* incubations does not result in discrimination between stereoisomers of *α*-tocopherol.

When VLDL was used as a donor of deuterated tocopherols (Fig. 3A and C), only 6–12% was detected in LDL or HDL after a 2-h incubation. LDL was a somewhat better donor of the d_6-tocopherol (Fig. 3 D and F). At a donor-to-acceptor protein ratio of 0.25, 32% of the d_6-tocopherol transferred to HDL, and 27% transferred to VLDL. When the amount of acceptor was decreased to a donor/acceptor ratio of 2, these percentages decreased to 14% and 11%, respectively. By contrast, HDL functioned well as a donor of d_6-tocopherol. At a donor-to-acceptor protein ratio of 0.25, ~90% of the d_6-tocopherol was transferred to VLDL (Fig. 3B), and 87% to LDL (ratio LDL/labeled HDL = 2, Fig. 3E). However, when the amount of acceptor was decreased, less d_6-tocopherol was transferred. For example, at a donor-to-acceptor ratio of 2, 59% was transferred to VLDL (Fig. 3B) and 40% to LDL (LDL/labeled HDL = 0.5, Fig. 3E).

The labeled and unlabeled tocopherol contents of the lipoproteins at the end of the incubation period (from the experiment shown in Fig. 3) are shown in Figure 4. In the incubation of labeled HDL with VLDL (Fig. 4A), the

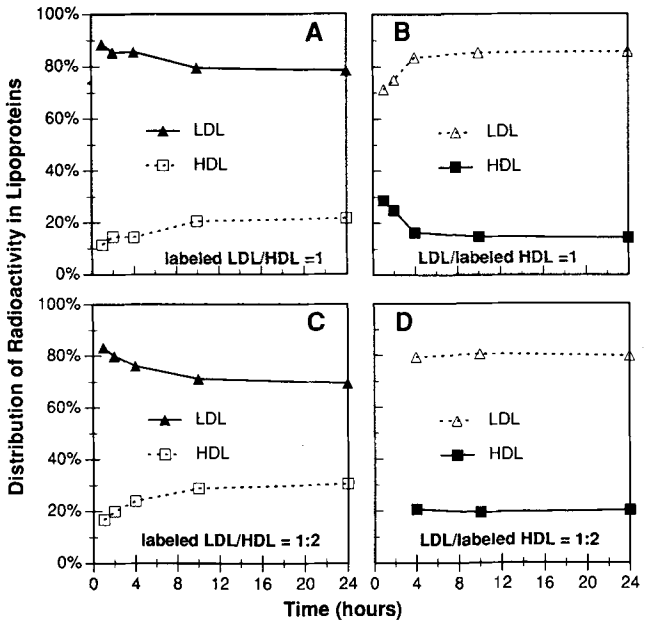

FIG. 1. Time course of the net transfer of [^{3}H]tocopherol between LDL and HDL. Plasma was labeled with [^{3}H]tocopherol and then lipoproteins were isolated by manganese-heparin precipitation as described in Materials and Methods. A constant amount (100 μL) of labeled LDL (4.2 μg protein/μL, 17 ng α-tocopherol/μL, 62.1 cpm/ng tocopherol) was mixed with unlabeled HDL (15.7 μg protein/μL, 17.4 mg tocopherol/μL) at labeled LDL/HDL protein ratios of 1 and 0.5 and volumes were adjusted to 1 mL with saline. Similarly, a constant amount (100 μL) of labeled HDL (5.2 μg protein/μL, 10.9 ng α-tocopherol/μL, 102 cpm/ng α-tocopherol) was mixed with unlabeled LDL (3.26 μg protein/μL, 11.3 ng tocopherol/μL) at labeled HDL/LDL protein ratios of 1 and 2 and volumes were adjusted to 1 mL. Mixtures were incubated in the dark in a 37°C water bath with constant gentle mixing, then 0.2 mL aliquots were taken at the indicated intervals. Immediately, LDL was precipitated from each aliquot by the addition of manganese-heparin (14 mg heparin/mL, 0.092 M Mn), the samples centrifuged, and the HDL supernatants removed and counted. LDL precipitates were resuspended in 1M Na citrate and counted. Shown are the % [^{3}H]tocopherol transferred calculated as the cpm in the acceptor lipoprotein as a fraction of the total cpm per time point.

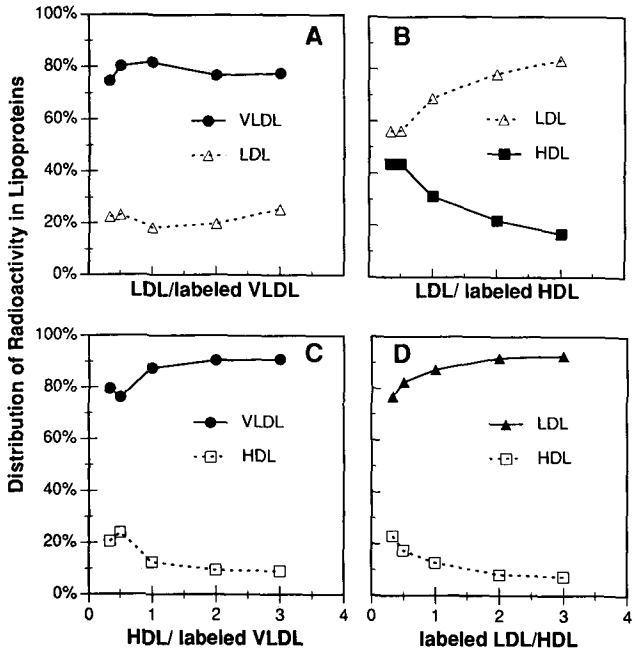

FIG. 2. Transfer of [^{3}H]tocopherol between lipoproteins at various protein ratios. Lipoproteins were labeled and isolated by manganese-heparin precipitation as described in Materials and Methods. A constant amount (260 μL) of labeled LDL (2.0 μg-protein/μL, 10.8 ng α-tocopherol/μL, 12.2 cpm/ng α-tocopherol) was mixed with unlabeled HDL (15.7 μg protein/μL, 17.4 ng α-tocopherol/μL) at labeled LDL/HDL protein ratios of 0.33, 0.5, 1, 2 and 3 and volumes adjusted to 1 mL with saline. Similarly, a constant amount (260 μL) of labeled HDL (6.6 μg protein/μL, 10.1 ng α-tocopherol/μL, 8.4 cpm/ng α-tocopherol) was mixed with unlabeled LDL (3.26 μg protein/μL, 11.3 ng tocopherol/mL) at the same protein ratios and volumes. For the transfer from VLDL to HDL (labeled VLDL -> HDL) two similar experiments are shown, but with different amounts of tocopherol in the donor VLDL. In the first experiment a constant amount (130 μL) of labeled VLDL (1.13 μg protein/μL, 7.9 ng α-tocopherol/μL, 50.7 cpm/ng α-tocopherol) was mixed with either unlabeled LDL or HDL (protein contents as above) at the same protein ratios (labeled VLDL/HDL or labeled VLDL/LDL) as above. In the second experiment (shown as a dotted line) a constant amount (85 μL) of labeled VLDL (2.39 μL, 9.6 ng α-tocopherol/μL, 19.6 cpm/ng α-tocopherol) was mixed with the same unlabeled HDL as above. Mixtures were incubated for 2 h as in Figure 1. After incubation, LDL and VLDL were separated from HDL by precipitation with Mn-heparin, VLDL was separated from LDL by the micro-method of ultracentrifugation described in the Methods section, and lipoprotein fractions were counted and the % [^{3}H]tocopherol transferred was calculated as described in Figure 1.

large amount of unlabeled tocopherol in the acceptor VLDL might be the reason for the nearly complete transfer of d_6-tocopherol from HDL to VLDL. However, the range of levels of unlabeled tocopherol in VLDL in this incubation was similar to that in the labeled LDL incubation with VLDL, shown in Figure 4D. The fact that a majority of d_6-tocopherol remained in LDL, despite the large quantities of unlabeled tocopherol in VLDL, suggests that the structure and composition of the donor lipoproteins (HDL *vs.* LDL) is more important than the content of unlabeled tocopherol in the acceptor lipoproteins. This is further amplified in Figure 4F showing the incubation of labeled VLDL with LDL at a protein ratio of 0.5. Here the d_0-tocopherol concentrations in LDL and VLDL are equal, yet the d_6-tocopherol remains in VLDL.

It is also interesting to compare the transfers between LDL and HDL. As shown in Figure 4C, when labeled LDL was incubated with HDL, the d_0-tocopherol content varied from double in the acceptor HDL to less than 10% of the LDL tocopherol, but this had relatively little effect on the transfer of d_6-tocopherol to HDL with most being retained in LDL; a small amount of d_6-tocopherol increased in HDL with increasing d_0-tocopherol in the acceptor HDL. By contrast, the transfer from labeled HDL to LDL (or VLDL) did closely parallel the amount of unlabeled tocopherol in the acceptor (Fig. 4B and A, respectively).

The results of these studies suggested that the amount of tocopherol in HDL *in vivo* might be dependent upon the ratio of circulating LDL to HDL in the plasma. That is, the higher the LDL concentration in the plasma, the greater the transfer of tocopherol to LDL and thus the lower the tocopherol per HDL particle, and conversely in subjects with a high proportion of HDL to LDL, the tocopherol per HDL particle might be increased. Therefore, the lipoprotein distribution of plasma tocopherol in 11 subjects undergoing routine evaluations of their lipid levels was also carried out. The characteristics of these subjects are shown in Table 1. To be noted is the wide range of HDL values. The fraction of plasma cholesterol in HDL (% HDL) ranged from 14 to 50%. Shown in Figure 5 are the tocopherol/protein and the cholesterol/protein ratios in HDL as a function of the % HDL cholesterol in the plasma. There was a significant correlation (r^2 = 0.366, $P < 0.05$) between the ng tocopherol/mg HDL protein and the % HDL cholesterol, while the relationship between the cholesterol/protein ratio and % HDL cholesterol was not correlated. Furthermore, neither the tocopherol/protein ratio, nor the cholesterol/protein ratio in LDL was correlated with the % LDL cholesterol in these subjects (data not shown).

DISCUSSION

We demonstrate that within a 2-h incubation, apo B-containing lipoproteins, both LDL and VLDL, retain a majority of the labeled tocopherol and do not readily donate it to other lipoproteins. Less than 40% of the labeled tocopherol was found in acceptor lipoproteins even at high-acceptor-to-donor ratios (Fig. 2 and 3). By contrast, HDL was found to readily donate labeled tocopherol either to LDL or to VLDL. Patients with abetalipoproteinemia are lacking apolipoprotein-B containing lipoproteins and transport lipids solely in HDL. These patients seldom have vitamin E levels more than one-tenth of control values. Thus, it is likely that HDL readily transfers tocopherol to tissues in these patients.

The ability of HDL to donate tocopherol was demonstrated using two different means of labeling the lipoproteins with tocopherol, both an *in vitro* technique using [^{3}H]tocopherol and *in vivo* metabolic labeling using deuterated tocopherols. Furthermore, two isolation techniques were used to isolate the lipoproteins following incubation. In the precipitation technique, the apo B-containing lipoproteins are precipitated, while in the ultracentrifugation technique the apo B lipoproteins are floated to the top of the tube. Since the two different methodologies yielded similar results, the conclusion that HDL readily donates tocopherol to LDL or VLDL is independent of

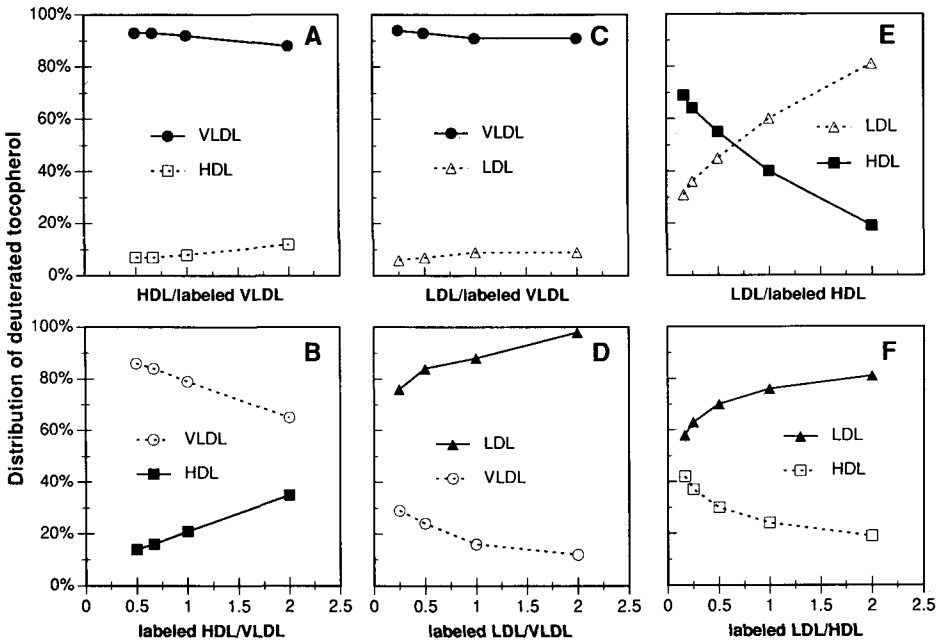

FIG. 3. Transfer of deuterium-labeled tocopherol between lipoproteins. Lipoproteins were isolated by ultracentrifugation from the plasma of a normal human subject who ingested 100 mg each of d_6-*RRR*-alpha-tocopheryl acetate (2*R*,4′*R*,8′*R*-α-[5,7-(C^2H_3)$_2$]tocopheryl acetate) and d_3-*SRR*-α-tocopheryl acetate (2*S*,4′*R*,8′*R*-α-]5-C^2H_3]tocopheryl acetate) as described in Materials and Methods. The Figure is representative of three experiments with similar results; only d_6-*RRR* values are shown, as d_6-*RRR* and d_3-*SRR*-α-tocopherol transfer values were similar. The protein (pro) and tocopherol contents of the starting lipoproteins per mL were: labeled VLDL 1.1 mg pro, 24.2 nmol d_0 and 8.6 nmol d_6; labeled LDL 1.1 mg pro, 20.7 nmol d_0 and 6.1 nmol d_6; labeled HDL 10.5 mg pro, 38.9 nmol d_0 11.34 nmol d_6; unlabeled VLDL 1.3 mg pro and 79.0 nmol d_0; LDL 2.7 mg pro and 33.6 nmol d_0; and HDL 7.3 mg pro and 13.7 nmol d_0. Labeled HDL (100 μL) was mixed with unlabeled VLDL at labeled HDL/VLDL protein ratios of 0.5, 0.67, 1 and 2, then taken to a volume of 1.7 mL; and with unlabeled LDL at labeled HDL/LDL protein ratios of 0.5, 1, 2, 4, and 6, then taken to a volume of 0.85 mL. Labeled VLDL (400 μL) was mixed with unlabeled HDL at labeled VLDL/HDL protein ratios of 0.5, 1, 1.5 and 2, then taken to a volume of 0.525 mL; and with unlabeled LDL at labeled VLDL/LDL protein ratios of 0.5, 1, 2 and 4, then taken to a volume of 0.725 mL. Labeled LDL (250 μL) was mixed with unlabeled VLDL at labeled LDL/VLDL protein ratios of 0.25, 0.5, 1 and 2, then taken to a volume of 2 mL; or labeled LDL (300 μL) was mixed with unlabeled HDL at labeled LDL/HDL protein ratios of 0.167, 0.25, 0.5, 1 and 2, then taken to a volume of 0.8 mL. All incubations were performed at 37°C in the dark for 2 h. At the end of the incubation period, the lipoproteins were immediately isolated by the micro-ultracentrifugation technique, and tocopherols in each fraction were measured as described in Materials and Methods. The % distribution of the d_6-tocopherol is calculated as the d_6-tocopherol in each lipoprotein as a fraction of the total d_6-tocopherol recovered at each protein concentration.

the isolation technique used. Furthermore, in data not shown, use of the precipitation technique following incubation of deuterated tocopherols also led to the same conclusions.

It is interesting that the stereochemistry of the 2-position did not affect the transfer of tocopherol between lipoproteins. As noted, but not shown, both *RRR* and *SRR*-α-tocopherol exchanged in an identical manner between the lipoproteins, suggesting that the structural differences between these two α-tocopherols were not sufficient to alter exchange rates. However, in one preliminary experiment we studied the exchange of deuterated cholesterol and d_6-*RRR*-α-tocopherol lipoproteins with unlabeled lipoproteins using an identical protocol to that described in Figure 3. When labeled LDL was incubated with HDL, although 80% of the labeled tocopherol remained in LDL, the labeled cholesterol equilibrated with about 50% in each fraction. These data suggest that the equilibration of tocopherol between lipoproteins is not dependent generally upon lipid flux, but is specific for each lipid studied, and is dependent upon the lipid and protein composition of the donor and acceptor lipoproteins. This is consistent with the studies of Granot *et al.* (9), who found that transfer of vitamin E remained relatively constant (40–55%) while triglyceride transfer ranged from 20 to 80%. Lund-Katz *et al.* (18) in their studies of cholesterol exchange between HDL and LDL concluded that their kinetic data was consistent with desorption of cholesterol from the donor lipoprotein into the aqueous phase, then cholesterol diffusing through the aqueous phase to the acceptor. The exchange of cholesterol from the core of HDL to the surface was not rate limiting for this exchange. From our data and the known characteristics of lipoproteins (19), we can hypothesize as to why tocopherol is more likely to be transferrd by HDL than the apo B-containing lipoproteins. A tocopherol molecule on the surface of HDL is perhaps more likely to desorb into the aqueous-phase than into the core, because although the HDL core is cholesteryl ester-rich (81 mol% *vs.* 19 mol % triglycerides), HDL is a relatively small lipoprotein (175,000–360,000 MV) with about 50% of the weight as protein, and 2–5% of the surface

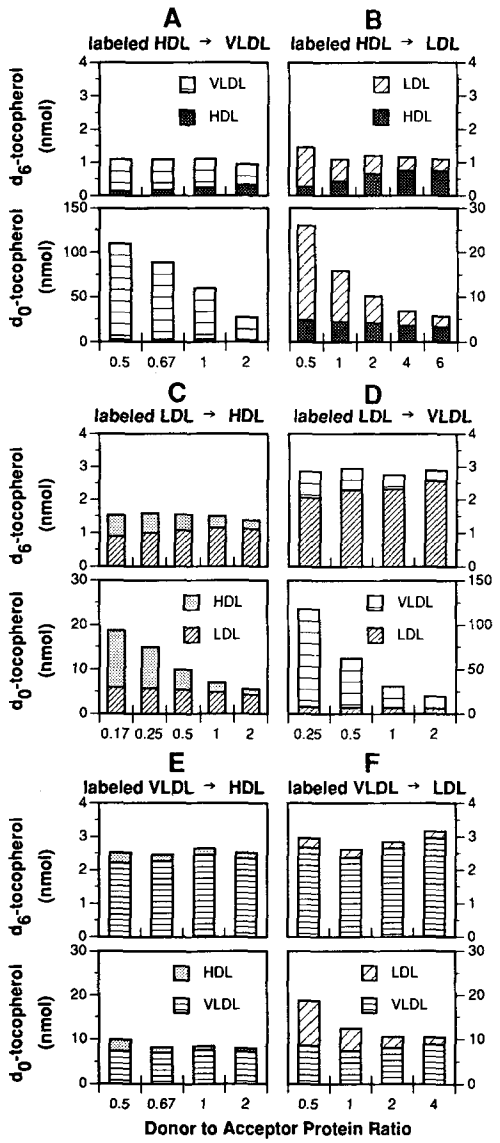

FIG. 4. Tocopherol contents of lipoprotein fractions from Figure 3. Each pair of graphs depicts the absolute amounts of d_6- and d_0-α-tocopherol (nmol) measured in each lipoprotein fraction after incubation and isolation, shown in Figure 3. Donor lipoproteins are shown with a denser pattern.

components are protein (on a mol% basis) LDL, which is 10 times larger than HDL 2,300,000 MW), has less protein on the surface (0.2%) but has the same distribution of core lipids. Thus, tocopherol is less likely to desorb into the aqueous phase, as the larger lipid core in LDL acts as a sink for the tocopherol. A tocopherol molecule on the surface of VLDL (10,000,000–80,000,000 MW) is most likely to dissolve in the core, which is 95 mol% triglyceride, than to desorb into the aqueous phase. Thus, we suggest that a tocopherol molecule moves readily between surface and core, and within the core, but not between the surface and the aqueous phase. By similar mechanisms, if either LDL or VLDL functions as the acceptor, then it is likely that there will be little transfer back to the donor lipoproteins, but if HDL acts as a tocopherol acceptor, the tocopherol will readily transfer back to the donor. Thus,

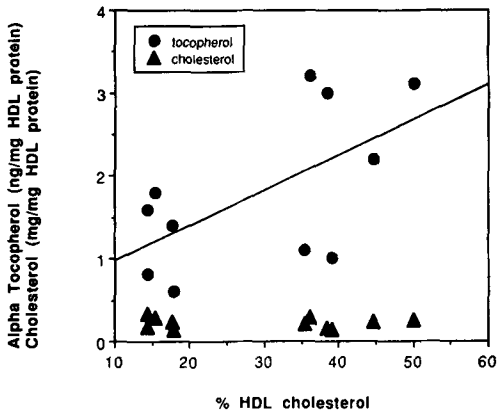

FIG. 5. Tocopherol and cholesterol concentrations per HDL protein, as a function of % HDL cholesterol in the plasma of human subjects. Following an overnight fast, blood samples were collected from 11 human subjects. The tocopherol content of HDL based on the nmol/mg HDL protein was significantly correlated with the proportion of HDL expressed as a % of total plasma cholesterol (r^2 = 0.366, $P < 0.05$), while the cholesterol content was not (r^2 = 0.039).

the net transfer of tocopherol from HDL will be enhanced by the larger lipid core of VLDL compared to LDL, while the transfer from VLDL will not be influenced by the acceptor because little tocopherol will escape the VLDL (as shown in Fig. 3).

Based on the observation that the HDL tocopherol was dependent upon the ratio of LDL/HDL, we investigated the tocopherol content of lipoproteins isolated from subjects with LDL/HDL protein ratios varying from 0.3 to 1.6. We found that as the fraction of HDL cholesterol increased in the plasma the amount of tocopherol per protein in HDL also increased. Although only 11 subjects were investigated, this was a statistically significant phenomenon. Thus, a person who has a high HDL level is likely to retain more tocopherol in their HDL fraction, than those with a high LDL. Both Behrens and Madere (20) and Clevidence and Lehmann (21) have reported that HDL α-tocopherol is related to HDL protein concentrations. The physiological importance of this observation needs further investigation. These *in vitro* studies also have relevance to the *in vivo* studies of tocopherol transport in lipoproteins. It is likely that transfer of tocopherol to HDL occurs *in vivo* during the catabolism of chylomicrons, because there is transfer of surface and core components between chylomicrons and HDL during the action of lipoprotein lipase. From the *in vitro* incubations described in the present study, it is clear that the tocopherol in HDL is readily transferred to both VLDL and LDL. At the highest labeled HDL/VLDL protein ratio tested (2:1), 65% of the d_6-tocopherol in HDL was transferred to VLDL, with greater proportions at higher VLDL concentrations (Fig. 3B). Thus, VLDL, and perhaps chylomicron remnants, present in the circulation during chylomicron catabolism, are likely to serve as tocopherol acceptors, returning plasma tocopherol to the liver during triglyceride-rich lipoprotein uptake.

In conclusion, this study has demonstrated that tocopherol in HDL readily transfers to apo B-containing lipoproteins, with little return of tocopherol from the

apolipoprotein B-containing lipoproteins to HDL. The transfer of tocopherol from HDL to LDL appears to depend upon the ratio of the lipoproteins present; with tocopherol transferring to LDL at LDL/HDL ratios of one or greater. An increased proportion of tocopherol/protein was found in HDL isolated from subjects with a high proportion of HDL in their plasma.

ACKNOWLEDGMENTS

The authors are most appreciative of the collaboration with Drs. Keith Ingold and Graham Burton and their staff at the National Research Council, Ottawa, Ontario, Canada, for providing deuterated tocopherols and cholesterol, in carrying out the analyses of the deuterated tocopherols (Eva Lusztyk) and for helpful discussions. Supported in part by grants from the U.S. Public Health Service (No. HL 30842) and from the Natural Source Vitamin E Association.

Lipoprotein Receptor Mediated Metabolism of [^{14}C]Arachidonic Acid Labeled Chylomicron Remnants by Hep G2 Cells

Qi Chen[a], Claes-Henrik Florén[b] and Åke Nilsson[a,*]

[a]Research Department I and Department of Internal Medicine, University Hospital, S-221 85 Lund and [b]Department of Internal Medicine, Malmö General Hospital, S-214 01 Malmö, Sweden

During lipolysis of chylomicron triacylglycerol by lipoprotein lipase, arachidonic acid (AA) esters are hydrolyzed at a slower rate than the predominant 16–18 carbon fatty acid esters. The further metabolism of the AA that is hereby enriched in the chylomicron remnant acylglycerols has not been investigated. In the present study, we examined the low density lipoprotein (LDL) dependent and independent metabolism of [^{14}C]AA present in chylomicron remnants in the human hepatoma cell line Hep G2. Mesenteric duct cannulated rats were fed [^{14}C]AA and [^{3}H]cholesterol in corn oil, and the chyle obtained was injected intravenously into hepatectomized rats to form chylomicron remnants labeled with [^{14}C]AA in the triacylglycerol (TG) and with ^{3}H in the cholesteryl ester portion. The remnants were then incubated with Hep G2 cells. The uptake of [^{14}C]AA within 2–4 h was similar to that of [^{3}H]cholesteryl ester. After uptake into the cells, [^{14}C]AA was preferentially incorporated into phospholipids, a high proportion being found in phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol. [^{14}C]AA and [^{3}H]cholesteryl ester uptake were influenced to similar extents by factors unknown to regulate the LDL receptor and by an anti-LDL receptor antibody. Addition of compactin thus increased the uptake of [^{14}C]AA by 50% in 4 h and mevalonolactone decreased the uptake by 86%. Using an anti-LDL receptor antibody, 25.0% of [^{3}H]cholesterol/cholesteryl ester and 37.7% of [^{14}C]AA binding to the cells at 4°C were blocked. There was no lipolysis of [^{14}C]TG or [^{14}C]diacylglycerol by lipase secreted into the medium during incubations. The study shows that after the uptake of chylomicron remnants by Hep G2 cells, which in part occurs *via* the LDL receptor, AA is liberated from the acylglycerols and is preferentially incorporated into phospholipids.

***Lipids* 27, 664–668 (1992).**

Significant amounts of arachidonic acid (AA) are transported by chyle lipoproteins. Most of this AA must originate from bile phosphatidylcholine (PC) which, in the rat, contains about 20% AA at the *sn*-2 position (1). In thoracic duct cannulated rats, the output of AA in chyle was 1.2 μmol/h during fasting, and 2.4 and 1.9 μmol/h after feeding moderate doses of Intralipid® or cream (2). A considerable part of this AA was in chyle phospholipids (2) which may be metabolized by lipoprotein lipase (LPL) (3,4) or transferred to high density lipoproteins (HDL) (5) and metabolized by hepatic lipase (6,7) or lecithin:cholesterol acyltransferase (LCAT) (8,9). A major part of the AA was, however, still incorporated into the chyle triacylglycerol (TG) (2).

During lipolysis of chylomicron TG by LPL, the AA esters exhibited a relative resistance to LPL (10). AA was therefore enriched in TG and in 2,3-diacylglycerol (DG) of the chylomicron remnants formed, the hydrolysis being somewhat more efficient when hepatic lipase was combined with LPL during the incubation (10). The metabolism of the remnant particles may thus have a more important role in the tissue distribution of AA than in that of the predominant dietary 16–18 carbon fatty acids. Chylomicron remnants are rapidly cleared and catabolized in hepatocytes (11) by an endocytotic process (12) that is mediated by apolipoprotein E and modulated by apolipoprotein C and phospholipids (13–18). The role of the LDL receptor in the remnant clearance is uncertain. Remnants are taken up *via* the low density lipoprotein (LDL) receptor in cultured hepatocytes (19), but both a normal (20) and a delayed remnant clearance (21,22) has been reported in Watanabe heritable hyperlipidemic rabbits (WHHL), which lack the LDL receptor. Another pathway which involves binding of apolipoprotein E of the remnant particles may be the predominant pathway *in vivo* (23). The uptake by this pathway might depend on the LDL receptor related protein (LRP), which has thus been considered a hypothetical remnant receptor (24,25). LRP recently was found to be identical to the alpha 2 macroglobulin receptor (26). In this study the metabolism of [^{14}C]AA present in chylomicron remnant acylglycerols was examined in the human hepatoblastoma cell line Hep G2. This cell line expresses LDL receptors (27) as well as LRP, and also secretes the enzyme hepatic lipase (28,29). The purpose was to obtain further information about the pathways by which the remnant AA is taken up and further metabolized by liver cells.

MATERIALS AND METHODS

Cell culture. The hepatoblastoma cell line Hep G2 was obtained from American Tissue Culture Collection (Rockville, MD). Cells were cultured at 37°C in 75-cm^2 flasks in RPMI 1640 (Gibco Laboratories, Santa Clara, CA) containing 10% fetal calf serum (heat inactivated at 56°C for 30 min, from Flow Laboratories Irvine, Ayrshire, Scotland), in the presence of benzyl penicillin (100 U/mL) and streptomycin (100 μg/mL). The cells were grown in humidified air with 5% CO_2 and were subcultured approximately once a week at a split ratio of 1:6.

Cells were trypsinized and then seeded into plastic Petri dishes. The medium (RPMI 1640 with 10% fetal calf serum without antibiotics) was routinely changed after two days. Preincubations with different additions indicated were started after a week. During the incubation with remnants, cells were grown in serum-free medium with 0.5% human serum albumin. The cells were routinely screened for mycoplasma using a kit with a specific

DNA probe from Gen-Probe Inc. (San Diego, CA). No mycoplasma was found.

Preparation of labeled chylomicron remnants. Mesenteric lymph duct cannulations were performed according to Warshaw (30) and a feeding fistula was inserted with the tip placed in the proximal duodenum. The rats were treated postoperatively, as described earlier (31). They were fed 1.0 mL corn oil containing 20 mg unlabeled cholesterol, 500 μCi (1.85 MBq) [1,2-^{3}H]cholesterol and 10 μCi [1-^{14}C]AA (51.3 mCi/mmol). Radioactive cholesterol and radioactive AA were obtained from Amersham International (Amersham, U.K.) and New England Nuclear (Boston, MA). The fat diets were divided into three doses and given through the feeding fistula over 2 h. Lymph was collected and stored at 4°C in the presence of 2 mM Na_2-EDTA (ethylenediaminetetraacetate; ref. 32). Chylomicron remnants were prepared by injecting chyle into eviscerated rats (33). After 30 min, blood was drawn from the abdominal aorta using Na_2-EDTA as anticoagulant. The density of the plasma was adjusted to 1.063 g/mL by adding a stock solution (d = 1.35 g/mL, 354 g/L KBr and 153 g/L NaCl). Plasma was then layered under saline (d = 1.006 g/mL) and centrifuged in a Beckman L5-65 ultracentrifuge (Fullerton, CA) with a SW Ti 40 rotor at 32,000 rpm (120,000 × *g*) for 12 h. The top layer containing chylomicron remnants was collected under sterile conditions and used within 24 h. The particles prepared by injecting chyle into eviscerated rats had lost 67.5% of their original TG content, as estimated from the change in the [^{14}C]TG/[^{3}H]cholesteryl ester ratio in chylomicron remnants in comparison to that of the injected chyle. The proportion of [^{3}H]cholesterol in cholesteryl ester of chylomicron remnants was 75.5%. The specific activity of the radioactively labeled cholesterol ranged between 5.3–6.4 dpm ^{3}H/ng cholesterol.

Incubation of chylomicron remnants with Hep G2 cells. The labeled chylomicron remnants were incubated with Hep G2 cells either at 37°C for up to 4 h or at 4°C for 2 h. At 37°C both the uptake and net degradation of chylomicron remnant cholesteryl esters by the cells were measured. At 4°C only binding of chylomicron remnants to cells was measured. After the incubation period the cells were washed twice with 2 mL ice cold phosphate buffered saline (PBS) containing 0.2% bovine serum albumin and then twice with 2 mL PBS without albumin. The cells were scraped off the dishes with a rubber policeman during repeated additions (2 × 1 mL) of methanol/water (2:1, vol/vol). Lipids were extracted from cells and media with chloroform/methanol (1:2, vol/vol) (34). Nonpolar lipids were separated by thin-layer chromatography on silica gel G plates, which were developed in light petroleum/diethyl ether/acetic acid (80:20:1, vol/vol/vol). Plates were developed in chloroform/methanol/acetic acid/water (100:80:12:1.2, by vol) to separate phospholipids. Spots were made visible by staining with iodine vapor, and scraped into vials. Methanol/water (1 mL; 1:1, vol/vol) and Instagel/toluene (9 mL; 1:1, vol/vol) were added, and radioactivity was determined in a Packard TC 460 CD Liquid Scintillation System (Packard Instruments, Downers Grove, IL) using the computerized external standard for quench correction.

Net hydrolysis of chylomicron remnant cholesteryl esters was calculated as described earlier (31). The percentage net hydrolysis of radioactive cholesteryl ester was calculated from the decrease in radioactivity (dpm) of cholesteryl ester, and the increase in that of free cholesterol in both cells and medium as follows:

$$\% \text{ net hydrolysis} = 100 - \frac{\% \text{ cholesterol as ester after incubation} \times 100}{\% \text{ cholesterol as ester before incubation}}$$

The percentage net hydrolysis was then multiplied by the dpm cholesteryl ester added to the dish to obtain dpm cholesteryl ester hydrolyzed. No measurable net hydrolysis of lipoprotein cholesteryl ester was observed in the cell-free controls. The uptake of chylomicron remnant cholesteryl ester (Fig. 1) is the amount of cholesteryl ester found in the washed cells as a percentage of added ^{3}H to the medium plus the percentage of net hydrolysis of [^{3}H]cholesteryl ester. The percentage of AA uptake in Figure 1 and Table 1 was calculated as follows:

$$\% \text{ AA uptake} = \frac{^{14}\text{C dpm in cells after incubation}}{^{14}\text{C dpm in remnants before incubation}} \times 100$$

LDL receptor antibody. The monoclonal anti-LDL receptor antibody (clone C7) was obtained from Amersham (Buckinghamshire, England). This antibody blocks LDL receptor mediated uptake of LDL in cultured human fibroblasts (35). In earlier experiments we have shown that approximately 50% of the LDL binding to Hep G2 cells is blocked (36).

Chemical assays. Triacylglycerol and cholesterol were determined using the commercial enzymatic kits from Boehringer Mannheim (Mannheim, Germany). The protein contents of the cells and of LDL were determined by the Lowry method (37) using human serum albumin as a standard.

RESULTS

When chylomicron remnants were incubated with Hep G2 cells, uptake of ^{3}H-labeled cholesteryl ester, ^{3}H-labeled cholesterol and ^{14}C-labeled AA occurred. The time courses for the uptakes of [^{14}C]AA and of [^{3}H]cholesteryl ester were similar (Fig. 1). The uptake of AA as a percentage of added label to the medium differs from that of cholesteryl ester during the first 1 h incubation ($P < 0.05$). The uptake of [^{14}C]AA and of [^{3}H]cholesteryl ester after 2 and 4 h did not differ.

The effects of factors which are known to influence cellular cholesterol content and LDL receptor levels on the uptake of chylomicron remnants were examined. When cells were incubated for 24 h with LDL to increase cellular cholesterol contents, AA uptake decreased to 3.8%, compared to 5.7% in controls (Table 1). When cellular cholesterol synthesis was stimulated by adding mevalonolactone, AA uptake decreased even more (Fig. 2). After incubation of the cells with lipoprotein-deficient medium (Table 1) or with compactin (Fig. 2), AA uptake increased by approximately 50%. The variation of AA uptake under these conditions closely followed that of cholesteryl ester

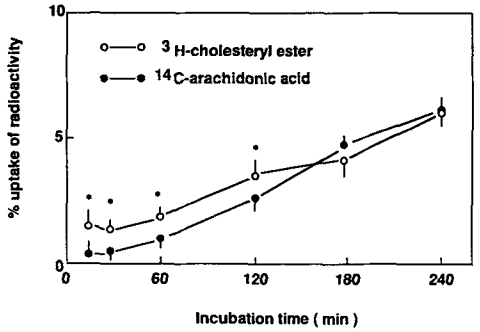

FIG. 1. Time course of uptake of [^{14}C]AA and [^{3}H]cholesteryl ester by Hep G2 cells. Chylomicron remnants (50 μL, 2.7 μg of cholesteryl ester and 28.5 μg of TG), 1.7-2.1 × 10,000 dpm of ^{3}H and 1.3-5.4 × 1,000 dpm of ^{14}C were added to each dish of Hep G2 cells and incubated for various time intervals. After the incubation, cells and medium were treated as described in Materials and Methods. Each time point represents the mean of five dishes. $*P < 0.05$.

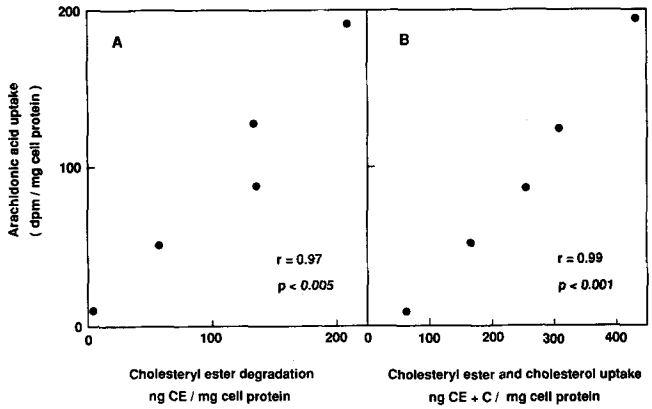

FIG. 3. Correlations between cholesteryl ester degradation and AA uptake (A) and cholesteryl ester and cholesterol uptake and AA upotake (B) in Hep C2 cells. Cells were preincubated under different conditions for 48 h. As in Figure 2, cells were incubated with 50 μL of chylomicron remnants containing 10 μg cholesteryl ester for 4 h. Each point is the mean of two dishes. Results are from one of similar experiments.

TABLE 1

Uptake of [^{14}C]Arachidonic Acid by Hep G2 Cells[a]

Preincubation conditions	AA uptake	
	dpm/mg Cell protein	% of AA added
1% Fetal calf serum	39.1	5.7
10% Fetal calf serum LDL 200 μg	25.8	3.8
Serum free medium	47.5	6.9
10% Lipoprotein-deficient serum	52.0	7.6

[a]Data are means of five observations. Cells were preincubated with different additions as indicated for 24 h. Then medium was changed to RPMI + 0.5% human serum albumin and incubated with 100 μL chylomicron remnants containing 2.7 μg cholesteryl ester for 4 h.

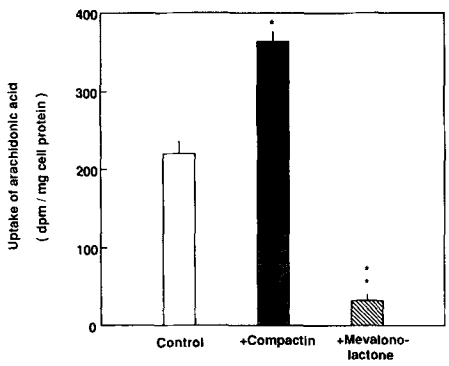

FIG. 2. Effects of compactin and mevalonolactone on uptake of AA in Hep G2 cells. Cells were preincubated in 10 mM Hepes RPMI medium plus 1% fetal calf serum (control) and with medium, FCS and compactin 20 μM (final conc.) or mevalonolactone 10 mM (final conc.). Cells were incubated at 37°C for 4 h with 70 μL chylomicron containing 4.0 μg cholesteryl ester. Uptake of AA was calculated as described in Materials and Methods. $*P < 0.01$, $**P < 0.001$. Results are from one of similar experiments.

degradation (r = 0.97, $P < 0.005$) and cholesterol plus cholesteryl ester uptake (r = 0.99, $P < 0.001$) (Fig. 3).

Addition of an anti-LDL receptor antibody (5 μg/mL) decreased the binding of chylomicron remnants. In eight different experiments 25.0 ± 17.0% (mean ± SE) of ^{3}H-labeled cholesterol plus cholesteryl ester binding to the cells at 4°C was blocked. The corresponding figure for [^{14}C]AA binding was 37.7 ± 23.4%.

After AA had been taken up by the cells, it was reincorporated mainly into the phospholipids. In chylomicron remnants 0.9% of the [^{14}C]AA was found in phospholipids. After incubation with cells, the proportion of ^{14}C found in phospholipids in the medium was increased. After a 4-h incubation, the proportion of cellular ^{14}C radioactivity in phospholipids was 76.0% (Table 2); of this radioactivity, 52.5% was in PC, 31.1% in phosphatidylethanolamine (PE) and 14.6% in phosphatidylinositol (PI) (Table 3). The proportion of the ^{14}C found in TG in the medium after 4-h incubation remained similar to that of the added remnants, and there was only a slight decrease in the proportion found in DG (Table 2). No increase was observed in the proportion of ^{14}C found as free fatty acids in the medium.

DISCUSSION

The present study shows that [^{14}C]AA present in acylglycerols (TG and 2,3-DG) of chylomicron remnants is taken up by Hep G2 cells. The major part of the added remnant [^{14}C]AA was in TG and DG, whereas most of the cellular AA was in phospholipids (Table 2). A net degradation of [^{14}C]acylglycerols and a preferential incorporation of [^{14}C]AA into PC, PE and PI thus occurred (Table 3).

Earlier studies indicate the existence of two types of lipoprotein receptor in liver cells: i) a remnant receptor capable of high-affinity binding of triglyceride-rich lipoproteins and HDL-E, but not of apolipoprotein E-free

TABLE 2

Incorporation of Arachidonic Acid (AA) into Phospholipids (PL): Percentage Distribution of [^{14}C]AA Among Different Lipid Fractions[a]

	PL	1,2-X-DG	Free fatty acids (FFA)	TG

TABLE 3

Distribution of [^{14}C]AA among Phospholipid Classes in Hep G2 Cells[a]

Synthesis of PL	Distribution (%)
Phosphatidic acid	0
Phosphatidylethanolamine	31.1 ± 0.8
Phosphatidylinositol	14.6 ± 0.9
Phosphatidylserine	1.8 ± 0.2
Phosphatidylcholine	52.5 ± 1.3
Lysophosphatidylcholine	0

[a]Data are means ± SE of four observations. Hep G2 cells were incubated with 100 μL chylomicron remnants in RPMI medium + 0.5% human serum albumin for 4 h. AA, arachidonic acid; PL, phospholipid.

LDL, and ii) a LDL receptor capable of high-affinity binding of LDL HDL-E (38) and remnants. *In vivo* the hepatocytes catabolize rat chylomicron remnants by an endocytotic process after the lipoprotein is bound with high affinity to the cells (12). The Hep G2 cells express both LDL receptors and LRP which might be identical with the remnant receptor and with the alpha 2 macroglobulin receptor (26). In an earlier study, the uptake of chylomicron remnant [^{3}H]cholesteryl ester by Hep G2 cells was in part inhibited by an anti-LDL receptor antibody and was influenced by factors altering cell cholesterol contents and, thereby, the LDL-receptor levels, such as mevalonolactone and the hydroxy methyl glutaryl coenzyme A (HMG-CoA) reductase inhibitor compactin (36).

In this study, the time course for the uptake of remnant [^{14}C]AA was similar to that for the uptake of remnant cholesteryl ester, suggesting that the [^{14}C]TG uptake occurred by uptake of the whole remnant particles, possibly by receptor mediated endocytosis (Fig. 1). The percentage of [^{14}C]AA uptake was somewhat lower than that of total [^{3}H] radioactivity, but this may be due to some uptake of unesterified cholesterol by exchange processes. In addition, a certain percentage of AA may be oxidized to CO_2 and H_2O or further metabolized by the cells to prostanoids.

The addition of compactin and mevalonolactone caused significant changes in AA uptake (Fig. 2), which were correlated with changes in uptake of chylomicron remnant cholesteryl ester (Fig. 3B). For example, mevalonolactone inhibited [^{14}C]AA uptake by 86% and [^{3}H] cholesteryl ester uptake by 64%. Also, when the remnant binding of cholesteryl ester and cholesterol was blocked by an anti-LDL receptor antibody, a similar decrease in the uptakes of cholesterol and of AA was observed. The study thus supports the idea that LDL receptors are important for the uptake and degradation of chylomicron remnant [^{14}C]AA-acylglycerols in Hep G2 cells. Because the uptake was only in part inhibited by the anti-LDL antiserum, however, the participation of other pathways must be postulated. Whether the uptake that did not depend on the LDL recepor was mediated by LRP remains to be established.

Hep G2 cells also secrete enzymes participating in lipoprotein metabolism such as hepatic lipase (28,29) and LCAT (39). In this study, the percentage of distribution of [^{14}C]AA in different lipid fractions in the medium remained constant during incubation (Table 2). Thus, there is no evidence for hydrolysis of [^{14}C]AA labeled remnant TG and DG in the medium. The data therefore indicate that the [^{14}C]acylglycerols were hydrolyzed after uptake by the cells, which is consistent with a role of the lipoprotein receptors rather than secreted hepatic lipase.

In summary, the data indicate that the AA of remnant acylglycerols is metabolized in Hep G2 cells by a lipoprotein receptor mediated uptake which is succeeded by liberation of AA from the acylglycerols, probably by lysosomal enzymes, and a preferential reincorporation into PC, PE and PI. Because considerable amounts of AA are secreted daily in rat bile and reabsorbed, this metabolic pathway may be important also for the transport of AA *in vivo*. Like the study of Habenicht *et al.* (40), who found that platelet-derived growth factor stimulated fibroblasts to metabolize AA of LDL to eicosanoids, this study stresses the potential physiological importance of the lipoprotein receptors in the transport of eicosanoid precursors.

ACKNOWLEDGMENTS

We thank Asta Lundquist for technical assistance. The gift of compactin from Dr. Akira Endo is gratefully acknowledged. Myogenic Differentiation of the Muscle Clonal Cell Line BC3H-1 Is Accompanied by Changes in Its Lipid Composition

M.F. Pediconi, L.E. Politi, C.B. Bouzat, E.B. De Los Santos and **F.J. Barrantes***

Phospholipid and neutral lipid composition was studied in the course of myogenic differentiation of the clonal cell line BC3H-1. Total phospholipid content increased during differentiation, predominantly in the major classes of choline and ethanolamine glycerophospholipids. The contents of other lipids, such as triacylglycerols, diminished more than 50% during this period. The content and distribution of fatty acids also underwent marked differentiation-dependent changes. The polyunsaturated (tetrapenta- and hexaenoic) fatty acid species of several phospholipid classes diminished during differentiation, especially those in choline, serine and inositol glycerophospholipids. Most noticeable were the changes in phosphatidylserine; long-chain fatty acids having 20 to 22 carbon atoms and 4 to 6 double bonds decreased from about 30 to about 10 mol%. Although increased levels of saturation in other phospholipid fatty acyl chains appear to accompany the myogenic changes of BC3H-1 cells, some unsaturated fatty acids, such as oleic acid (18:1), increased by as much as 80% during the same period, suggesting the activation of a Δ9 desaturase. Sphingomyelin contained only saturated and monoenoic fatty acids and exhibited a four- to five-fold decrease in its content of monoenoic acyl groups. Diacylglycerols became enriched in arachidonate and docosahexaenoate. The amount of cholesterol and its esters increased slightly during differentiation of BC3H-1 cells. The data show that several metabolic pathways change during myogenic differentiation of the BC3H-1 clonal cell line, particularly *de novo* biosynthetic pathways, elongation/desaturation reactions, and acyl chain turnover. As a consequence of this, the lipid composition of the myoblast form of the BC3H-1 cell, in which the nicotinic acetylcholine receptor and other cell surface receptors are expressed, is thus different from that of the nondifferentiated cell.
***Lipids* 27, 669–675 (1992).**

The nicotinic acetylcholine receptor (AChR) is one of the best characterized cell surface receptors (reviewed in ref. 1). The role of lipids in the maintenance of the structure and function of the AChR is becoming increasingly apparent (reviewed in refs. 2 and 3). The AChR is sensitive to the chemical nature of its lipid environment, and this has been experimentally demonstrated in *in vitro* studies in which the protein was reconstituted in lipid vesicles of different compositions, varying in the proportions of synthetic phospholipid species, fatty acyl chain lengths and degree of unsaturation, and in phospholipid/cholesterol ratio (4–6). With this strategy, the need for cholesterol and negatively charged phospholipids in i) the preservation of ligand-induced affinity transitions of the AChR and ii) the ability of the protein to translocate ions, *i.e.*, its gating property, was clearly established (4–5). The notion of the functional dependence of AChR on its lipid milieu has been complemented, and its relevance reinforced, by the discovery of an "annulus" of immobilized lipid molecules on the hydrophobic surface of the AChR protein as established by electron spin resonance techniques (reviewed in ref. 3).

As a natural extension of our *in vitro* studies, it is one of the aims of our current research to define *in situ*, in intact cellular systems, the chemical and physical characteristics of the lipids that constitute the immediate surrounding of the nicotinic AChR protein and those which form the rest of the bilayer, and also to study *in situ* the effect of lipids on the ligand binding and channel gating properties of the AChR. The clonal muscle cell line BC3H-1, originally derived by Schubert *et al.* (7) from a nitrosoethylurea-induced mouse cranial neoplasm, is a useful model toward this goal because lipid composition can be studied before and after cell surface expression of the AChR, one of the processes accompanying differentiation of the BC3H-1 cells (8). In addition, chemical changes which may occur can be correlated with the functional properties of the plasmalemma-assembled protein (Bouzat, C.B., Politi, L.E., Pediconi, M.F., de los Santos, E.B., and Barrantes, F.J., manuscript in preparation). In the present study, the content and composition of glycerophospholipids (neutral and polar classes), cholesterol and its esters (free and esterified forms of this sterol) and sphingomyelin were analyzed before and after cell differentiation. The results show a significant diminution in the content of neutral glycerolipids (triacylglycerols), an increase in various glycerophospholipids, predominantly the major classes of choline and ethanolamine glycerophospholipids, and changes in the content and distribution of their constituent fatty acids, which may be relevant to the structural and functional properties of the AChR and/or other membrane proteins whose expression changes in the course of cell differentiation.

MATERIALS AND METHODS

Materials. Fetal calf serum was purchased from CEVAN (Buenos Aires, Argentina).

Cell culture. Cells from the clonal cell line BC3H-1 (7) were grown unless otherwise specified in either 100-mm plastic Petri dishes or glass flasks at 37°C, essentially as described by Patrick *et al.* (8), in Dulbecco modified Eagle's medium containing 10% fetal calf serum in a Heraeus Cytoperm incubator maintained at 37°C with a 5% CO_2/95% air mixture. After the cultures reached confluency, the serum concentration was lowered to 0.5% to accelerate differentiation. Cells were analyzed 4–5 days thereafter. Differentiation was assessed by the changes in morphology (ref. 8, see also Fig. 1) and by the appearance of nicotinic AChR protein as assessed by binding assays using [^{125}I]α-bungarotoxin as described elsewhere (8). The maximum number of binding sites before and at

Abbreviations: AChR, acetylcholine receptor; DMA, dimethylacetals; FFA, free fatty acid; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PS + CDP-DAG, phosphatidylserine plus cytidine diphosphate-diacylglycerol; PPI, polyphosphoinositides; Sph, sphingomyelin; TAG, triacylglycerol; TLC, thin-layer chromatography.

day-4 after differentiation were nil and 1.20 ± 0.10 pmol/mg protein, respectively.

Lipid extraction, isolation and quantitation. Cells were homogenized in a Potter-Elvehjem (Thomas type) homogenizer with chloroform/methanol (2:1, vol/vol) and extracted with this solvent mixture for 2–3 h at 20°C. The crude extracts were subsequently centrifuged, and the supernatants were washed according to the method of Folch *et al.* (9). The protein residues were then extracted with acidified solvents (10) to ensure complete recovery of polyphosphoinositides. The acidic extracts were washed and neutralized as described elsewhere (11). Phosphatidic acid (PA), phosphatidylserine + cytidinediphosphate-diacylglycerol (PS + CDP-DAG), phosphatidylinositol (PI), phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were isolated by two-dimensional thin-layer chromatography (TLC) (12) of the neutral extracts. Plasmenyl-PC and plasmenyl-PE were determined as described previously (13). Polyphosphoinositides were separated from neutral and from acidic extracts by means of TLC on potassium oxalate-impregnated plates of silica gel H using the solvent system described by Shaik and Palmer (14). Standards of phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-*bis*phosphate (PIP_2) (Sigma, St. Louis, MO) were chromatographed in parallel with the samples. Neutral lipids such as triacylglycerols (TAG), diacylglycerols (DAG), and free fatty acids (FFA) were separated on silica gel G plates (Merck, Darmstadt, Germany) using hexane/diethyl ether/acetic acid (70:30:2, vol/vol/vol) as solvent system.

Transmethylation and gas-liquid chromatographic analysis of fatty acid derivatives. Thin-layer plates were sprayed with 2′,7′-dichlorofluorescein and viewed under ultraviolet light. The fractions were scraped into tubes containing eicosanoic acid as internal standard for gas-liquid chromatography. Fatty acid methyl esters were prepared according to the method of Morrison and Smith (15), using boron trifluoride (14% in methanol; Sigma) and subjected to gas-liquid chromatography using two (2 m × 0.2 cm inner diameter, 80–100 mesh) Chromosorb W-A/W columns (Supelco, Bellefonte, PA), in a Varian (Palo Alto, CA) 3700 chromatograph. The columns were connected to flame-ionization detectors operated in the dual-differential mode. The initial and final oven temperatures were 160°C and 220°C, respectively, and the rate of increase was 5°C/min. Injector and detector temperatures were 220°C and 230°C, respectively, and N_2 (30 mL/min) was the carrier gas. Chromatograms were quantitated with a CDS-111 Varian integrator. Peaks were identified by comparison of retention times with those of standards.

Other analytical methods. Total cholesterol content was determined by an enzymatic-colorimetric method (Wiener Laboratories, Rosario, Argentina). The method is based on the action of cholesteryl ester hydrolase, cholesterol oxidase, and a peroxidase coupled to a colorimetric assay. The content of free cholesterol was determined by a modification of the above-mentioned method using a mixture of enzymes without cholesteryl ester hydrolase. Phospholipid phosphorus was determined after treatment with perchloric acid of an aliquot of the total lipid extract or from the spots of the phospholipids isolated by two-dimensional TLC (12). Total protein content of the same samples was determined by the method of Lowry *et al.* (16) using bovine serum albumin as standard. Statistically significant differences were determined by the Student's *t*-test (two tailed).

Scanning electron microscopy. BC3H-1 cells were fixed overnight at 4°C in 0.37% formaldehyde and 0.5% glutaraldehyde in tissue culture medium. The cells were then washed with 0.1 M phosphate buffer, pH 7.2, and dehydrated with 75% acetone and 100% acetone (3 × 10 min each). The tissue was then incubated with Freon 113 diluted 1:3, 2:3 and 3:1 (vol/vol/vol) with acetone (15 min in each solution), in order to further dehydrate the tissue in a critical point chamber (Polaron, Watford, England) for 1 h. Samples were subsequently metalized with gold (200 Å) in a sputter coater model 3 (Pelco, Ted Pella Inc., Tustin, CA). The tissue was finally oriented for observation with a scanning electron microscope (JEOL 35 CF, JEOL, Tokyo, Japan) at 5 kV. Photographs were taken using Kodak SO-163 electron image film (Kodak, Rochester, NY).

RESULTS

Cholesterol and phospholipid distribution in BC3H-1 cells before and after differentiation. The muscle clonal cell line BC3H-1 undergoes marked morphological and biochemical changes during differentiation. One manifestation of the developmental changes is the expression of cell surface receptors, including the nicotinic AChR (8). This protein is absent from the plasmalemma at the predifferentiated stage, in which the cell exhibits a fibroblast-like morphology and reaches levels of about 300 fmol [^{125}I]α-bungarotoxin sites/35 mm dish at day 3 of differentiation, when the cell has already acquired the spindle-shaped, elongated, typical muscle-like morphology (Fig. 1). The maximum number of specific binding sites (1.20 ± 0.10 pmol/mg protein), as assessed by the [^{125}I]α-bungarotoxin assay, was reached at day-4 after differentiation, whereas no specific binding sites were detected 12 to 24 h after cell plating.

When the total phospholipid and cholesterol content in the BC3H-1 cells was measured at these two stages, we found that phospholipid content increased by about 40% upon differentiation (Table 1). Cholesterol and cholesteryl ester levels apparently increased by the same proportion as did phospholipids, but the increase was found not to be statistically significant (Table 1).

Further differences between non-differentiated and differentiated BC3H-1 cells became apparent when comparing the content and composition of individual phospholipids (Fig. 2). The major phospholipids of BC3H-1 cells, choline and ethanolamine glycerophospholipids, increased by 50% and 40%, respectively, after differentiation. Acidic phospholipids such as phosphatidylserine (PS), PI and sphingomyelin (Sph) did not change significantly during the same period.

Polyphosphoinositides (PPI) were found in quantities comparable to those of other cultured cells; PIP and PIP_2 represented less than 10% of the total phosphoinositide pool (Fig. 2). The BC3H-1 differentiated cells are thus relatively richer in phospholipids than the non-differentiated ones, with the two major classes (PC and PE) increasing most significantly.

Fatty acid composition of phospholipids in BC3H-1 cells. The fatty acid compositions of PC, PE and Sph are shown in Table 2 while those of PS and PI are presented in Table 3. PC exhibited characteristically very high

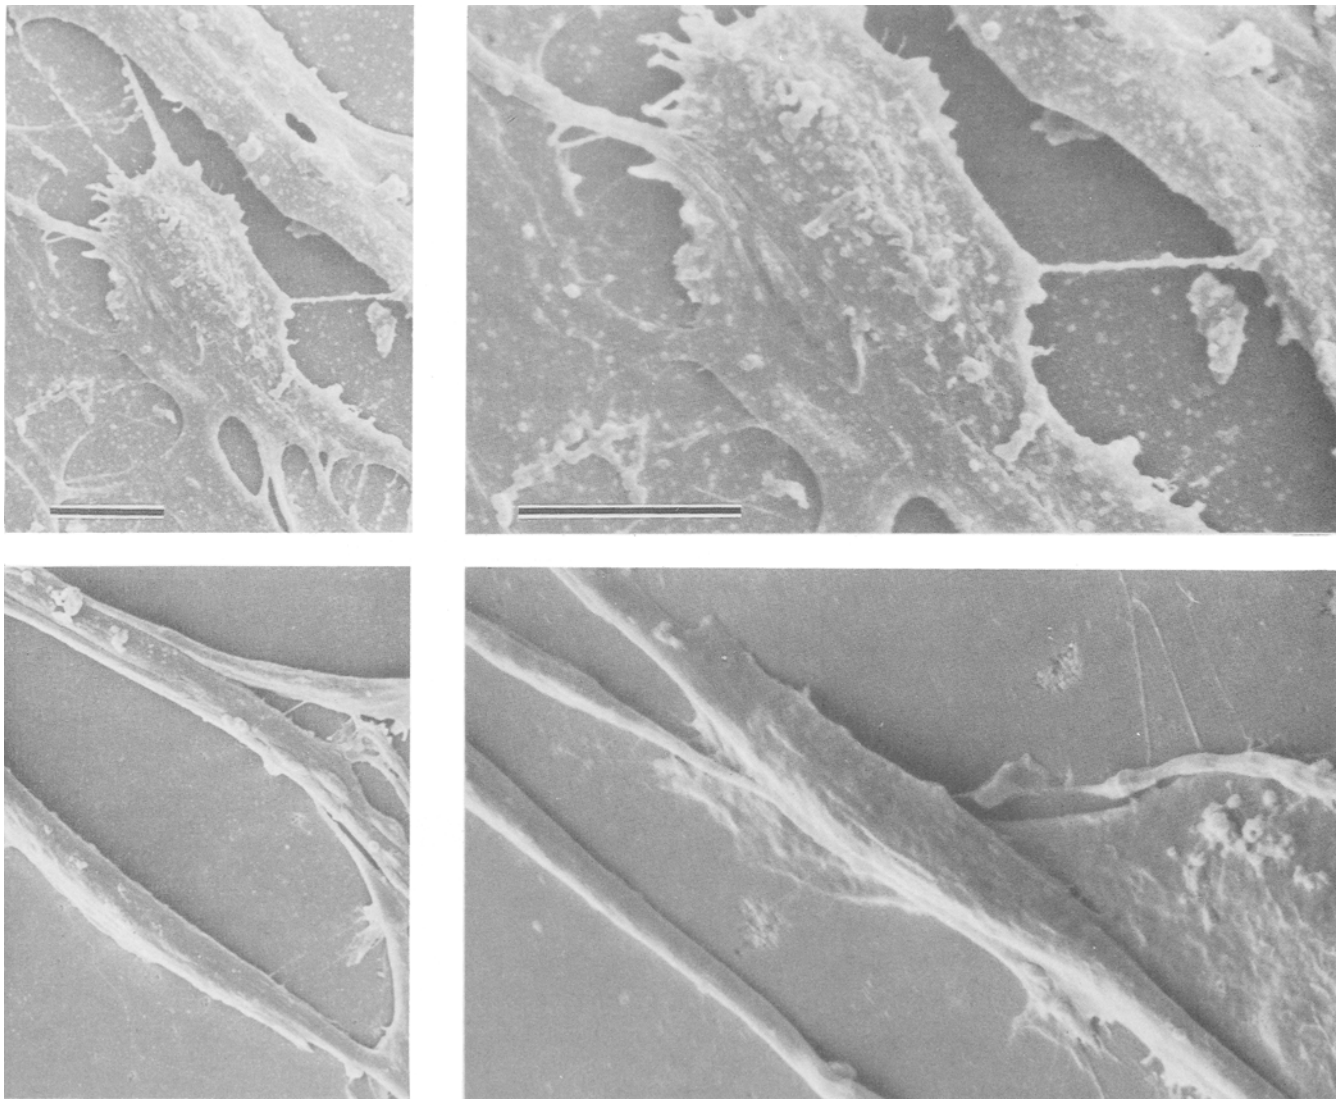

FIG. 1. Scanning electron micrographs of BC3H-1 cells before (upper panel) and four days after (lower panel) differentiation. The bars indicate 10 μm.

TABLE 1

Phospholipid and Sterol Content of BC3H-1 Cells[a]

Lipid	Undifferentiated	Differentiated
Phospholipids (n=5)	268.0 ± 25.0	369.0 ± 38.0[b]
Cholesterol (n=3)	94.8 ± 21.0	124.5 ± 14.1
Cholesteryl esters (n=3)	31.8 ± 11.2	42.9 ± 10.8
Cholesteryl ester/ cholesterol ratio	0.34	0.34
Phospholipid/cholesterol ratio	2.83	2.96

[a]Data are the mean ± SD, expressed in nmol lipid/mg protein. The molecular weight of cholesteryl oleate (651.1) was used as the average molecular weight for all cholesteryl esters.
[b]Statistically significant differences ($P < 0.005$).

saturated/unsaturated fatty acid ratios before differentiation, mainly due to the increased percentage of palmitate. Only 11% of the polyunsaturated long-chain fatty acids (C_{20}-C_{22}) were found before differentiation. Furthermore, the percentage of polyunsaturated fatty acids decreased by about 50% thereafter.

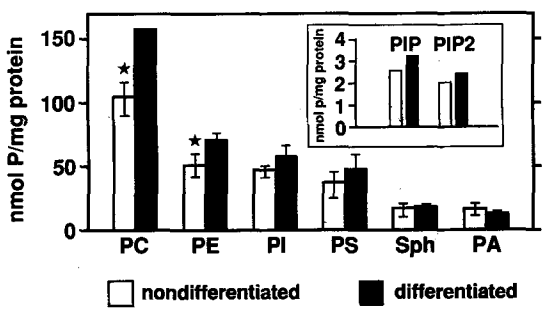

FIG. 2. Phospholipid content of BC3H-1 cells. Data represent the content of phospholipid P (nmol P/mg protein) of phospholipid classes expressed as mean value ± SD of six individual samples from two different experiments. Values for PIP and PIP_2 are from pooled samples (three samples each) from two different experiments. The lipids were extracted according to Folch *et al.* (9) and Uma and Ramakrishnan (10). Major phospholipids and PPI were isolated by the methods of Rouser *et al.* (12) and Shaik and Palmer (14), respectively. The size of the individual phospholipid pools was determined by measuring the lipid P content in each chromatographic spot.

[a]Data are mean ± SD (mol%) of five samples from two different experiments for undifferentiated cells and cells differentiated in 0.5% fetal calf serum (condition "A"), and of two samples for cells grown in 10% fetal calf serum (condition "B") in the medium. Values corresponding to sphingomyelin are from three separate samples.

[b]Statistically significant differences ($P < 0.05$).

Phosphatidylethanolamines displayed a unique feature among the phospholipid classes in that they maintained the same hydrocarbon chain composition during differentiation. As a consequence, PE showed approximately the same proportion of long-chain fatty acids with four or six double bonds (the sum of these acyl groups is 27.2 and 25.4 mol% in non-differentiated and differentiated cells, respectively). Very low levels of docosapentaenoate and docosahexaenoate were found in PE with respect to the total fatty acyls (Table 2).

Among the minority lipids, Sph displayed a fatty acid profile exclusively made up of saturated and monoenoic species, which accounted for its low degree of unsaturation (Table 2). Sph was one of the lipid classes exhibiting considerable changes in the proportion of saturated and monoenoics after differentiation (0.7 at the initial, undifferentiated stage and 2.1 after differentiation). Sph was mainly esterified with palmitic and oleic acids; 24:1 (which predominates in this lipid in mammalian tissues) was only the third or fourth most important fatty acid in BC3H-1 cells. The marked decrease in the content of 26:0 after differentiation (from 8.5 to 1.0 mol%, Table 2) is also noteworthy.

The analysis of acyl groups present in PS and PI also showed drastic changes in polyunsaturated fatty acids in the course of myogenic differentiation (Table 3). The results reveal that in addition to the increase in saturated fatty acids, such as palmitate (more than a two-fold increase), long-chain fatty acids having 20 to 22 carbon atoms and 4 to 6 double bonds decreased from about 30 to about 10 mol%. This constituted the most important change in acyl group content detected for all phospholipids analyzed. Thus, although increased levels of saturation in phospholipid fatty acyl chains appear to accompany the myogenic differentiation of BC3H-1 cells, some unsaturated species, such as oleic acid, increase by as much as 80% during the same period, suggesting a compensatory mechanism involving the activation of a Δ9 desaturase. Before BC3H-1 cell differentiation, PI has a characteristic fatty acid profile as found in mammalian tissue, with stearate and arachidonate accounting for more than 50% of the total. PI exhibited variations different to those observed with other glycerophospholipids: no increases in saturated fatty acids (16:0 and 18:0) were apparent; after cell differentiation, however, the relative proportion of oleic (18:1) and arachidonic (20:4) fatty acyl moieties changed noticeably (Table 3).

Differentiation of BC3H-1 cells is a reversible process which can be induced either by removal of growth factors from the culture medium or by allowing cells to reach confluency. The most commonly used procedure consists of decreasing the serum concentration in the culture medium, thus eliminating the inhibition exerted by the serum on protein synthesis and cell proliferation (17). In order to assess whether the changes in fatty acid composition of the cells were determined by the lipids present in the culture medium, fatty acid analyses were carried out on the phospholipids extracted from cells differentiated with low (0.5%) and high (10%) fetal calf serum. In low (0.5%) calf serum, BC3H-1 cells attained differentiation within 3 to 4 days, as judged by i) the typical morphological changes (cf. Fig. 1) and ii) the appearance of α-bungarotoxin sites on the plasmalemma of intact cells (see above). The results presented in Tables 2 and 3 indicate that the

TABLE 3

Composition of Acyl Chains in Phosphatidylserine and Phosphatidylinositol During Differentiation of BC3H-1 Cells[a]

[b]Statistically significant differences ($P < 0.05$).

observed changes in the fatty acid composition of phospholipids in BC3H-1 cells are not due to the growth medium conditions but are related to the myogenic developmental change itself.

The contribution of plasmalogens to the total PE pool were 68 and 74%, while for PC plasmalogens constituted 55% and 51% of the total before and after differentiation, respectively. The composition of ether-linked aliphatic chains in PC and PE varied during the course of myogenic differentiation (Fig. 3). Mature cells became richer in 16:1 and 18:1 dimethylacetals in both PC and PE, while the proportion of 16:0 diminished significantly in both phospholipids.

Fatty acid composition of triacylglycerols, diacylglycerols and free fatty acids in BC3H-1 cells. Though small, the pools of acylglycerols play an important role as acyl group donors for fatty acid turnover. We thus investigated their content and composition in differentiating BC3H-1 cells. As shown in Table 4, triacylglycerols decreased by 50% during differentiation (11.2 ± 0.3 μg/mg protein before and 4.1 ± 0.1 μg/mg protein after, respectively). Diacylglycerols increased during this process (1.8 to 2.96 μg/mg protein), whereas free fatty acids remained constant (26 and 21 μg/mg protein before and after differentiation, respectively). Oleate, palmitate, stearate and linoleate accounted for more than 75% of all acyl chains in triacylglycerols. Palmitate, stearate and oleate were the main components in both diacylglycerols and free fatty acids. The 20:3n-9 decreased in triacylglycerols while it increased in diacylglycerol and free fatty acid pools during differentiation (Table 4).

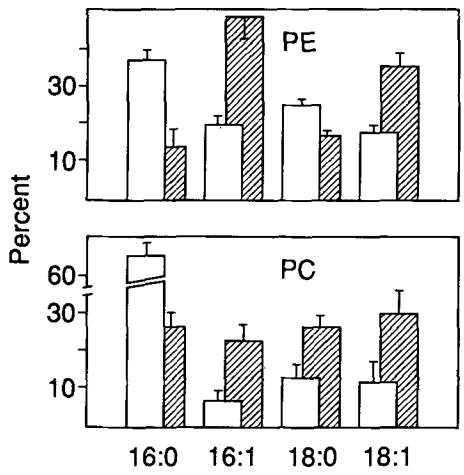

FIG. 3. Percentage distribution of ether-linked moieties in choline and ethanolamine glycerophospholipids. The relative contribution of C_{16} and C_{18} dimethylacetals found in PC and PE in undifferentiated (empty bars) and differentiated (dashed bars) BC3H-1 cells is shown. One-hundred percent corresponds to the sum of the content of the four DMA shown in the figure. Each bar represents the mean ± SD of determinations carried out in three different cultures. All differences are statistically significant ($P < 0.025$).

DISCUSSION

Important changes in the metabolism and expression of many proteins and other molecular constituents of cell membranes occur during cell differentiation. In BC3H-1 cells, differentiation-related changes involve the expression of a variety of muscle specific gene products, including the muscle form of the enzyme creatine kinase (7) and the AChR protein (8), among others. Cell membranes also exhibit substantial changes in absolute mass and turnover during cell differentiation (18,19). The developmentally-regulated appearance of insulin receptors and insulin-mediated effects on lipid metabolism in BC3H-1 cells (20) is a particularly clear manifestation of the importance of membrane phenomena associated with lipid metabolism in this nonfusing cell line. The overall lipid composition of the BC3H-1 cells reported here resembles that of other cell lines (21,22), and the changes undergone during differentiation in the majority of phospholipid

classes exhibit the same type of increases observed with other cells in culture (21–23). No relative changes in the phospholipid/cholesterol content were apparent (Table 1), in contrast with the variations in this ratio reported for some cells (23). The proportion of cholesteryl esters in BC3H-1 cells is, however, higher than that found in other AChR-containing cells such as electrocytes (24). The present work shows that during differentiation a net decrease in TAG and an increase in PL occurred. Similar observations were reported by Sauro and Strickland (25) in muscle cells. L6 myoblasts, but not differentiated L6 myotubes, accumulate large stores of neutral lipids, in accordance with previous findings showing the activation of a lysosomal triacylglycerol lipase after differentiation (26).

The most important differentiation-related changes in BC3H-1 lipids were found in the phospholipid fatty acid moieties. Phospholipids become richer in 18:1 and poorer in C_{20} and C_{22} polyenoic acids. Decreased levels of arachidonate, 22:4n-6, and 22:5 from both the n-3 and n-6 series, and 22:6n-3 have been reported for other transformed cell lines (19). Interestingly, neuroblastoma and astrocytoma established cell lines have been reported to display a decreased ability to elongate and desaturate long-chain fatty acids in comparison to normal brain cells (27). Tables 2 and 3 show that a net decrease on the polyunsaturated fatty acids takes place in BC3H-1 cells upon differentiation, especially in PS, PC and PI. In these cells, the desaturases may be subjected to different pressures in the undifferentiated and differentiated stages. Both 18:3 and 20:1 methyl esters co-migrate under the present chromatographic conditions. It is not possible, therefore, to unambiguously ascertain which is the fatty acid that increased in PC after differentiation (see Table 2). If this change were due to 18:3, as it is the precursor of other C_{20} and C_{22} polyunsaturated fatty acids, it would reflect the accumulation of this series precursor. The three- and five-fold decrease observed for 18:1 and 24:1, respectively, in Sph monounsaturated fatty acids suggests, however, that other metabolic pathways, specifically fatty acid turnover, may also be modified in the course of differentiation. In fact, the response of desaturases to dietary alterations appears to indicate that Δ6 and Δ5 desaturases are less dramatically influenced by fluctuations in the availability of dietary substrates than the Δ9 desaturase (28). The two former desaturases may be subjected to inhibitory mechanisms in differentiated, but not in undifferentiated, stages of BC3H-1 cell development.

The fatty acyl profile in neutral glycerides and free fatty acids remained relatively constant during differentiation. This is surprising if one considers these pools as a "reservoir" of fatty acid constituents for membrane phospholipids. Acyltransferases and various lipases, especially phospholipases, are responsible for the uptake, distribution and release of fatty acids from glycerophospholipids. The diminished amounts of long-chain polyunsaturated fatty acids in BC3H-1 phospholipids may be consistent with their reported deleterious effects on some types of cells in culture. For example, polyunsaturated fatty acids of the n-3 and n-6 series have been shown to inhibit the growth of a mammary adenocarcinoma and a leukemic T cell line, respectively (29,30). The relative composition of the fatty acid pool varied with differentiation of the BC3H-1 cells. Thus, eicosatrienoate increased about five-fold, pointing to the activation of a lipase or inactivation of an acyltransferase during development.

Physical consequences are likely to derive from the changes in the chemical composition of membranes occurring in the BC3H-1 cells. High proportions of 18:1 together with a low percentage of 20:4n-6 and C_{22} polyunsaturated fatty acids with six double bonds should be associated with a more "ordered" bilayer upon differentiation. Physical rearrangement of membrane lipids has also been reported to occur during differentiation of red blood cells (18). The immature cells contain regions of more disordered, loosely packed lipids, that are discarded after enucleation (31). A similar change may take place in

the BC3H-1 cell, with concomitant changes in membrane fluidity.

Previous studies from our laboratory (4,5; see also ref. 3 for review) demonstrated the essential need for some phospholipids such as PE, in combination with cholesterol, for the preservation of AChR functional properties *in vitro*. In the present work we have observed that the size and composition of phospholipid pools like that of PE increase or are maintained during differentiation of BC3H-1 cells. Also, the degree of saturation of this phospholipid, that plays an important role in the affinity states and ion translocation phenomena of the AChR (5,32), seems to be preserved in the differentiated BC3H-1 cell that expresses cell surface receptor. Cholesterol levels are also critical for the preservation of other AChR properties (4), and we report here that its level is maintained during differentiation (cf. Table 1). The cholesterol/cholesteryl ester ratio also remained constant upon differentiation of BC3H-1 cells (cf. Table 1). Electrophysiological work carried out since submission of the present paper (Bouzat, C.B., Politi, L.E., de los Santos, B.E., Pediconi, M.F., and Barrantes, F.J., unpublished results, and ref. 33) appears to confirm our working hypothesis; changes in the proportions and in the quality of the lipids in the AChR environment *in situ*, using the BC3H-1 model system, exert marked effects on the channel gating properties of this rapid ligand-operated receptor.

Dietary deficiency of essential fatty acids of the n-3 and n-6 series is known to promote a compensatory increase in polyenoic fatty acids of the n-9 series in the lipids of mammalian tissues. In the present study long-chain n-9 polyenes were found to be normal components of the epididymis and especially of sperm isolated from that tissue, in healthy, well-fed, fertile rats maintained on essential fatty acid-sufficient diets. The n-9 polyenes occurred in large concentrations in the choline glycerophospholipids (CGP), the major phospholipid class of spermatozoa in epididymal *cauda*, and were highly concentrated in plasmenylcholine, the major subclass of CGP. The uncommon polyene 22:4n-9 was found in the highest proportion, followed in order of relative abundance by 22:3n-9, 20:3n-9 and 24:4n-9. These polyenes were probably derived from oleate (18:1n-9) in much the same way as long-chain polyenes of the n-6 and n-3 series are derived from linoleate (18:2n-6) and linolenate (18:3n-3), respectively.

***Lipids* 27, 676-680 (1992).**

In the absence of dietary essential fatty acids of the n-6 and n-3 series, animals synthesize oleate (18:1n-9) derived polyenoic acids (1,2). The most familiar of these compounds is 20:3n-9, first identified by Mead and Slaton (3), and known to be formed from 18:1n-9 when there is not sufficient 18:2n-6 in the diet to synthesize ample 20:4n-6. Rats given diets having hydrogenated coconut oil as the only source of fat for five months accumulated 20:3n-9 in place of 20:4n-6 in erythrocytes and produced small, but measurable amounts of two minor fatty acids behaving chromatographically as 22:3n-9 and 22:4n-9 (4). Holman (1) demonstrated that competitive interactions occur such that n-3 acids suppress the metabolism of n-6 polyenes, n-6 acids suppress the metabolism of n-3 polyenes less strongly, and both suppress the formation of long-chain n-9 polyenes. Brenner and Peluffo (5) showed that the desaturase acting on 18:1n-9 in liver is inhibited by 18:2n-6 and 18:3n-3. These studies support the widely accepted view that long-chain n-9 polyenes do not normally accumulate in mammalian tissues except under n-6 and n-3 polyenoic fatty acid deficient conditions.

In the present paper an unexpected departure from this view is described. Large amounts of long-chain n-9 polyenes were found as normal acyl groups of a major lipid in essential fatty acid sufficient, healthy laboratory rats. The fatty acids in question occur in the epididymal tissue and are highly concentrated in the spermatozoa isolated from the caudal region of the epididymis.

Abbreviations: CGP, choline glycerophospholipid; DMDC, dimethyldicarboxylate; EGP, ethanolamine glycerophospholipids; FAME, fatty acid methyl esters; GLC, gas-liquid chromatography; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Male Albino Wistar rats (weight, 350-370 g) were killed by decapitation, the epididymal tissue was carefully dissected, and the proximal (*caput*) and distal (*cauda*) sections were isolated. Spermatozoa were prepared essentially as previously reported (6,7), by cutting the epididymal sections into small pieces, gently stirring the pieces in a salt-containing suspension medium (pH 7.4), and filtering through a fine mesh cloth. After several washings, the sperm cells were collected from the filtrates by centrifugation. Lipid extracts from whole epididymis or from spermatozoa were prepared and washed using the procedures described by Folch *et al.* (8). Phospholipids were resolved into classes by thin-layer chromatography (TLC) (9) and the diradyl-choline and -ethanolamine glycerophospholipids (CGP, EGP) from the epididymal *cauda* were eluted from the absorbent with chloroform/methanol/acetic acid/water (50:39:1:10, by vol) (10) for further analyses. A portion of each lipid fraction was exposed for 1 min to 0.5N HCl in chloroform/methanol (2:1, vol/vol), which released the aldehydes from the *sn*-1 position of the plasmenyl subclasses, yielding lysophosphatidylcholine and lysophosphatidylethanolamine. The lyso derivatives were separated from the unreacted lipids, mostly phosphatidylcholine and phosphatidylethanolamine, by TLC for fatty acid analysis.

Fatty acid methyl esters (FAME) were prepared by transesterification with BF_3/methanol (11). FAME were separated into fractions according to unsaturation by argentation TLC (using silica gel G/$AgNO_3$, 5:1, w/w, with chloroform/methanol, 95:5, vol/vol as solvent). FAME were then analyzed by gas-liquid chromatography (GLC) on glass columns (2 m × 2 mm i.d.) packed with 15% OV-275 on WAW, 100-200 mesh (Varian, Sunnyvale, CA), with nitrogen as the carrier gas. For fatty acid compositional analyses, a linear (5°C/min) temperature program was employed, the initial and final column oven temperatures were 160 and 220°C, respectively. Injector and flame ionization detector temperatures were 220 and 230°C, respectively, and the electrometer was operated in the dual-differential mode.

Unsaturated FAME fractions in methanol were hydrogenated by bubbling H_2 in the presence of palladium oxide through the solution (12). After adding water, the saturated FAME were recovered in hexane and analyzed by GLC. Oxidative ozonolysis was done by bubbling O_3 into ice-cold BF_3/methanol solutions of FAME (13). Water was added and the products were extracted with a small volume of hexane and subjected to TLC (hexane/diethyl ether, 95:5, vol/vol). This separated the methyl ester derivatives of monocarboxylic from those of dicarboxylic acids (the main products of fragmentation of the fatty acid molecules at their double bonds under these conditions). The products were recovered from the silica gel by adding a small volume of water and partitioning

with a small volume of CS_2, the solvent in which all samples were injected into the gas chromatograph.

The food pellets (Purina Lab Chow) routinely fed to the rats were analyzed by GLC. Nearly 40% of the total fatty acids in the diet was 18:2n-6, 24.4% was 18:1n-9 and 4.6% was 18:3n-3. Other fatty acids were 18.5% 16:0, 2.2% 16:1 and 5.4% 18:0. Variations in the 18:2/18:1 ratio in the diet did not significantly affect the fatty acid composition of the major sperm lipids.

RESULTS

Analysis of the fatty acids of rat epididymal and spermatozoal lipids showed abundant proportions of unfamiliar long-chain polyunsaturated components. These compounds, in parallel with known n-6 and n-3 polyenes, were subjected to a series of analytical tests to establish their identity (Fig. 1). When resolved by argentation TLC, the unusual fatty acids migrated as trienoic and tetraenoic FAME. Under both isothermal and temperature-programmed GLC conditions (Fig. 1, panels A and B), their elution behavior corresponded to that of 20, 22 and 24 carbon polyenes. The fatty acids tentatively identified as 20:3n-9, 22:3n-9, 22:4n-9 and 24:4n-9 always eluted ahead of the corresponding n-6 isomers, as would be expected from a polar stationary phase, as the one used in this experiment. When catalytic hydrogenation was performed on portions of the tri-, tetra- and pentaenoic FAME fractions, only 20-, 22- and 24-carbon saturated products were obtained, thus confirming the assigned chain lengths.

The trienoic and tetraenoic FAME fractions isolated from *cauda* sperm plasmenylcholine by argentation TLC were used as the sources of 22:3 and 22:4, respectively, to establish the position of the double bonds in both fatty acids. Ozonolysis of an unsaturated fatty acid in the presence of ice-cold BF_3/methanol (13) oxidatively cleaves the double bonds to yield (the methyl esters of) a monocarboxylic and a dicarboxylic acid whose number of carbons is diagnostic of the position of the double bond(s) in the original compound. For example, dimethyl azelaidate (C_9) was, as expected, the main dimethyldicarboxylate (DMDC) formed from 18:1n-9 and from 18:2n-6 (see Scheme 1). Arachidonate (20:4n-6), in turn, yielded low but

$$CH_3\text{-}(CH_2)_7\text{-}CH{=}CH\text{-}(CH_2)_7\text{-}COOCH_3 \rightarrow$$

$$CH_3\text{-}(CH_2)_7\text{-}COOCH_3 + H_3COOC\text{-}(CH_2)_7\text{-}COOCH_3$$

SCHEME 1

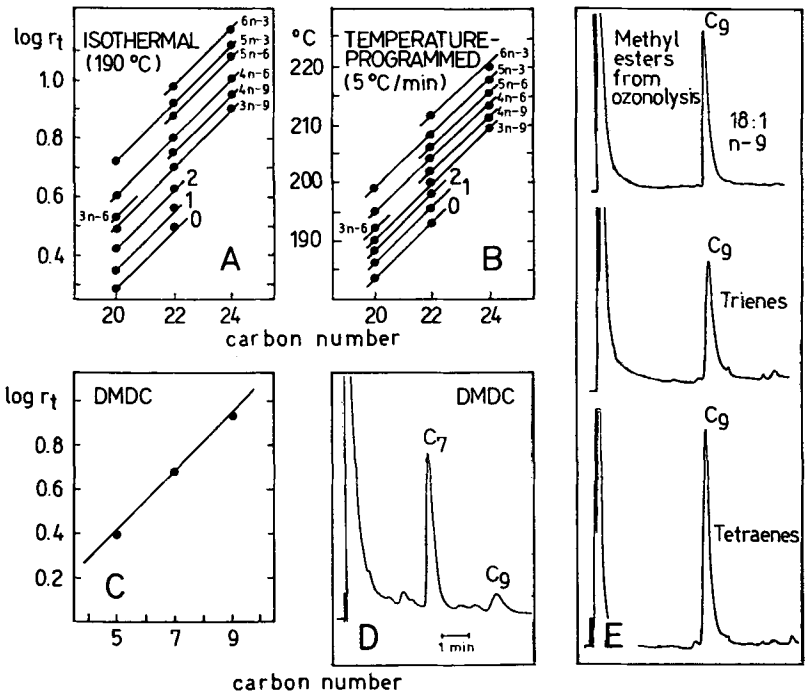

FIG. 1. Gas-liquid chromatographic analysis of FAME and of the fragments produced after oxidative ozonolysis of the trienoic and tetraenoic fatty acids from rat sperm plasmenylcholine. Glass columns packed with a polar stationary phase (OV-275, Varian) were used. A, Logarithms of retention times (r_t) of FAME as a function of their number of carbons under an isothermal condition. B, Elution temperatures, using a linear temperature program, *vs.* the number of carbons in the same compounds. C, Behavior of DMDC obtained after ozonolysis of known fatty acids (20:4n-6, 22:5n-3 and 18:1n-9) under isothermal conditions (120°C). D, DMDC obtained from the trienoic fraction of rat sperm plasmenylcholine. E, GLC of the short-chain methyl ester derivatives (temperature programmed at 10°C/min, with an initial temperature of 50°C) obtained after ozonolysis of oleate and of the trienoic and tetraenoic fractions from rat spermatozoa plasmenylcholine. The product was almost exclusively methyl nonanoate in all cases.

detectable amounts of the expected C_5 derivative, and 22:5n-3 [previously isolated from mammalian (bovine) retina to be used as a standard] gave the predictable C_7 DMDC (Fig. 1, panel C). These served for comparison of the products formed after ozonolysis of the FAME from rat sperm plasmenylcholine. The major DMDC from its trienoic FAME fraction had seven carbons (Fig. 1, panel D), thus allowing identification of the fatty acid parent as 7,10,13-docosatrienoate, or 22:3n-9.

Naturally occurring fatty acids having four carbons between the carboxyl end and their first double bond, such as 22:6n-3, 22:5n-6 and 22:4n-9 (4,7,10,13,16,19-docosahexaenoate, 4,7,10,13,16-docosapentaenoate and 4,7,10,13-docosatetraenoate, respectively) yield a four carbon DMDC from the carboxyl end and a C_3, C_6 and C_9 methyl ester, respectively, from the methyl end (in addition to dimethyl malonate). Small amounts of the C_4 DMDC were produced from the 22:4n-9 from rat sperm, probably because the present conditions were not satisfactory for the analysis of short-chain volatile derivatives. However, considering the other main product of ozonolysis, virtually the only methyl ester produced from the plasmenylcholine tetraenoic fraction was methyl nonanoate (Fig. 1, panel E). This was also the main methyl ester produced by ozonolysis from the trienoic fraction, confirming the presumption that the major polyenoic fatty acids of both fractions belonged to the oleic acid series. Thus, the major trienoic and tetraenoic components of plasmenylcholine from *cauda* spermatozoa could be conclusively identified as 22:3n-9 and 22:4n-9 (7,10,13-docosatrienoic and 4,7,10,13-docosatetraenoic acids, respectively).

The fatty acid composition of each of the two main phospholipid classes, EGP and CGP (together totaling about 80% of the total phospholipids) of *caput* and *cauda* epididymis differed significantly from that of spermatozoa isolated from such regions (Fig. 2). In both stages of maturation, sperm cells were much richer in fatty acids with longer chains (C_{22}, C_{24}) and with more double bonds (four, five) than the corresponding epididymal regions. The percentages of 22:3n-9 and 22:4n-9 were several-fold larger in CGP of caudal epididymal spermatozoa than in CGP from *cauda* epididymis (Table 1), showing that sperm cells were the main contributors to the n-9 polyenes observed in the latter epididymal region. Interestingly, the opposite was true for the EGP, in which the percentages of the same acyl chains were lower in spermatozoa than in the corresponding epididymal regions.

The fatty acid compositions of the two major lipids of spermatozoa also were affected differently by epididymal maturation. Comparing the sperm cells from *caput vs.* those from *cauda* regions, it was clear that their epididymal progression resulted in a significant increase in the percentage of long (C_{22} and C_{24}) polyenoic fatty acids of the n-9 series (Fig. 2). Such an increase was specifically observed in CGP (from ~3% to ~25% of the total fatty acids of this phospholipid). Since CGP represented nearly 50% of the total phospholipid of spermatozoa, this change in fatty acids significantly affected the fatty acid composition of the spermatozoon. In fact, when the total fatty acids of sperm were analyzed, the sum of the n-9 polyenes was observed to change from less than 2% in *caput* to about 12% in *cauda* sperm (data not shown), demonstrating that CGP was the major contributor of such fatty acids. Consistently n-9 polyenes were either minor components or virtually absent from other lipid classes. An interesting exception was phosphatidylinositol, which accounted for only 4% of the total phospholipid, but contained more than 15% n-9 polyenes (14).

The plasmalogens of EGP and CGP of both epididymis and spermatozoa were richer than the corresponding phosphatidyl subclasses in n-9 polyenes (Table 1). The contribution of plasmalogens to the total EGP and CGP in spermatozoa differed from that in the corresponding epididymal regions. Thus, plasmenylethanolamine and plasmenylcholine in *cauda* epididmis accounted for

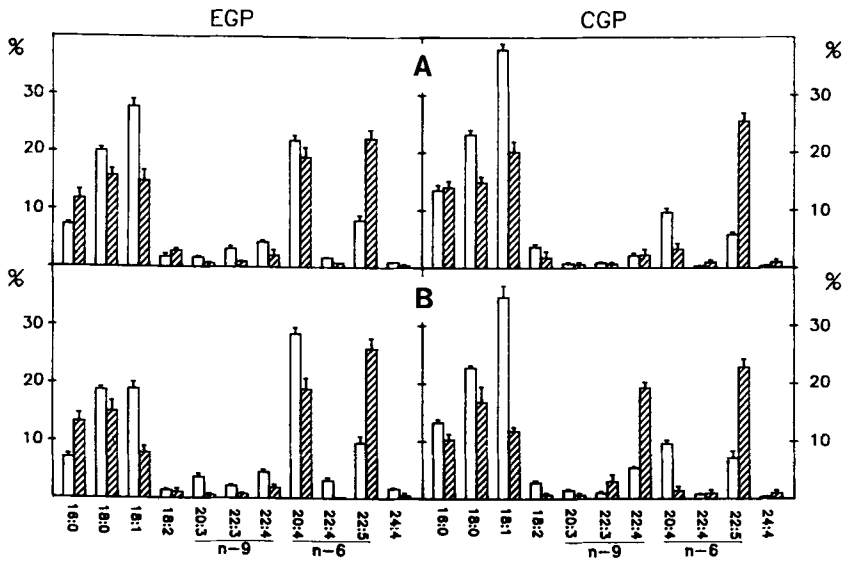

FIG. 2. Fatty acid composition of EGP and CGP from epididymal tissue (open bar) and epididymal spermatozoa (hatched bar). A, *caput*; and B, *cauda*. Phospholipids were isolated by TLC and fatty acids (as methyl esters) were analyzed by GLC. Results are given as percentages of the total fatty acids in each lipid (mean values ± SD from three and four individual samples for epididymal tissue and spermatozoa, respectively).

TABLE 1

Fatty Acids of Major Subclasses of Ethanolamine and Choline Glycerophospholipids from *Cauda* Epididymis and Epididymal Spermatozoa[a]

	Phosphatidylethanolamine		Plasmenylethanolamine		Phosphatidylcholine		Plasmenylcholine

[a] Results are given as percentages (wt%) of the fatty acids depicted (mean values ± SD from three and four individual samples, for epididymis and epididymal spermatozoa, respectively).

[b] Not detectable under the present GLC conditions (either too small for detection or not resolved from a closely eluting larger peak).

52.9 ± 2.3 and 17.8 ± 2.0%, and in the spermatozoa isolated from such region the same plasmalogens accounted for 42.1 ± 6.1 and 52.1 ± 4.1% of the total EGP and CGP, respectively. More than 60% of the fatty acids of plasmenylcholine, the major phospholipid of sperm from *cauda* epididymis, was accounted for by n-9 polyenes (Table 1).

DISCUSSION

The results presented here reveal some as yet uncharacterized features of the fatty acid composition of lipids of rat epididymis and epididymal spermatozoa. In addition to well-known polyenes such as 22:5n-6, mature rat spermatozoa are shown to be rich in uncommon long and very long polyenes of the n-9 series, the major one being 22:4n-9. The fact that rat sperm lipid classes are rich in polyenoic fatty acids is consistent with previous work in other animal species, such as the bull (15) and boar (16). However, whereas 22:5n-6 and 22:6n-3 are the major polyenes in the lipids of epididymal spermatozoa in these species, accounting for virtually all the acyl chains of the ether-linked choline and ethanolamine glycerophospholipids, the abundance of 22:4n-9 in plasmenylcholine appears to be a characteristic of rat sperm cells.

Mammalian spermatozoa are released from the testes with a generous supply of lipids rich in polyunsaturated fatty acids. During their journey through the epididymis, these cells undergo a series of maturational changes which include, among others, alterations in polyenoic fatty acids composition (Fig. 2). In the present study, polyenoic acids of the n-9 series of sperm were minor components of other tissues of rat, including testes, in agreement with what has long been known for testicular lipids, exceedingly rich in 22:5n-6 (17). Even taking into account that the epididymal tract is composed of many cell types, the amounts of 20:3n-9, 22:3n-9 and 22:4n-9 found in its glycerophospholipids were high in comparison with other rat tissues. The epididymis contains an active layer of androgen-dependent epithelial cells responsible for many of the molecular changes that lead to the functional maturity of spermatozoa. Such cells might also participate in metabolic activities resulting in the characteristic lipid pattern of mature spermatozoa, perhaps including the synthesis of 22:4n-9 and related fatty acids. It is interesting that for some lipids, like EGP, these fatty acids are more abundant in the epididymis than in sperm (Fig. 2 and Table 1).

The unusual polyenes of rat epididymis and sperm extend and fit into what is known about naturally occurring polyenoic fatty acids. The structural and metabolic relationship between n-9 polyenes and the more familiar and ubiquitous n-3 and n-6 polyenes are likely to be as summarized in Scheme 2. In liver, these conversion were

Enzymatic step	Oleate (n-9)	Linoleate (n-6)	Linolenate (n-3)	Position of first double bond from carboxyl end

SCHEME 2

studied in detail by Bernert and Sprecher (18). The presence of Δ9, Δ6 and Δ5 desaturases may account for all the major polyunsaturated fatty acids that occur in liver. A Δ8 desaturase activity, which is absent in liver (19), but has been demonstrated in rat testes (20), could lead to precursors of 22:4n-9, 22:5n-6 and 22:6n-3 through an alternative route, as shown in Scheme 3.

Enzymatic step	Oleate (n-9)	Linoleate (n-6)	Linolenate (n-3)
	18:1n-9	18:2n-6	18:3n-3

	20:1n-9	20:2n-6	20:3n-3
Δ8 Desaturation	↓	↓	↓
	20:2n-9	20:3n-6	20:4n-3

SCHEME 3

The most highly unsaturated members of each of the three series (namely 22:4n-9, 22:5n-6 and 22:6n-3) have in common that they are the products of an enzymatic activity that results in the presence of a double bond at C_4. Unsaturations are not known to occur in positions closer to the carboxyl end in naturally occurring long-chain fatty acids of mammalian membranes, and only 22-carbon fatty acids exhibit such a feature. The properties and regulation of this putative Δ4 desaturase have not yet been studied as thoroughly as those of the other desaturases. The vertebrate retina and the reproductive tract, rich in 22:6n-3, 22:5n-6 and 22:4n-9, seem to be the tissues of choice to investigate its activity.

Further elongation of 22-carbon polyenes to very long polyenoic fatty acids (C_{24} and longer) occurs in the reproductive tract (21) and in other tissues, such as retina (22). Polyenoic acids having 24-37 carbon atoms of the n-3 and n-6 series have been shown to occur in ejaculated spermatozoa of various mammals (23) and are predominantly associated with sphingomyelin (24). Similar very long polyenoic fatty acids have been observed in phosphatidylcholine from the retina of several vertebrates (12), including the rat (25). Given the presence of the unusually long 24:3n-9 and 24:4n-9 in rat spermatozoa observed in this study, longer polyenes of the n-9 series could be expected to be found in the future.

It is worth noting that long-chain n-9 polyenes do not occur in large proportions in sperm cells of species other than the rat (15,16,23). Among the explanations for the abundance of n-9 polyenes in rat spermatozoa in the presence of a normal supply of 18:2n-6 and 18:3n-3 in the diet is the possibility that the lipid metabolism in the rat epididymal tract is so demanding as to partially exhaust the n-6 and n-3 polyenoic precursors. This may result in a "local" deficiency of such polyenes within the epididymis, forcing the tissue to resort to the synthesis of such n-9 counterparts. In fact, the process of spermatogenesis in the rat is very active and continuous throughout the animal life. In addition to being non-renewable through synthesis *in situ*, essential fatty acids like 18:2n-6 could partly be unavailable if they are esterified in certain lipid classes or consumed in the synthesis of higher polyenes, such as 22:5n-6. The possibility of an important demand of essential fatty acids resulting in an extensive formation of n-9 polyenes in the rat still does not explain the remarkable selectivity observed in this study in the distribution of polyenes among major sperm lipid classes and subclasses. The finding of such an abundant natural source of long-chain n-9 polyenoic fatty acids as rat sperm apparently contradicts the widely accepted view that large amounts of these polyenes can only be observed in lipids of tissues from animals undergoing dietary deficiencies of fatty acids of the n-6 and n-3 series, showing that they can be normal, physiological components of certain cells.

Isolation and Characterization of Novel 2-Hydroxy Fatty Acids from the Phospholipids of the Sponge *Smenospongia aurea*

Néstor M. Carballeira*, Anastacio Emiliano, Jaime Rodriguez and **Elba D. Reyes**
Department of Chemistry, University of Puerto Rico, San Juan, Puerto Rico 00931-3346

The Caribbean sponge *Smenospongia aurea* revealed the presence of six novel branched α-hydroxy fatty acids: 2-hydroxy-17-methyloctadecanoic acid, 2-hydroxy-21-methyldocosanoic acid, 2-hydroxy-22-methyltricosanoic acid, 2-hydroxy-22-methyltetracosanoic acid, 2-hydroxy-24-methylpentacosanoic acid, and 2-hydroxy-23-methylpentacosanoic acid. These novel α-hydroxy fatty acids were associated with phosphatidylethanolamine. The sponges *Aplysina lacunosa* and *Aplysina fistularis* also contained considerable amounts of α-hydroxy fatty acids, the very long-chain 5,9,23-tricontatrienoic acid (30:3), and phytanic acid. The sterol composition of the three sponges was also studied. It indicated that *A. lacunosa* and *A. fistularis* contained large amounts of aplysterol and verongulasterol, while *S. aurea* did not show any of these sterols. The results are discussed in terms of the taxonomy of the species.
Lipids 27, 681-685 (1992).

Sponges belonging to the genus *Smenospongia* and *Aplysina* have shown interesting morphological similarities that warrant a closer scrutiny of their secondary metabolites (1). The Caribbean sponge *Smenospongia aurea* (Hyatt, 1875) contains the 5-bromo- and 5,6-dibromo-*N,N*-dimethyltryptamines, aureol, and 6-bromoaplysinopsin as well as 6-bromo-4′-*N*-demethylaplysinopsin (1). The *Aplysina* species, identified as *Aplysina lacunosa* (Pallas, 1766) and *Aplysina archeri* (Higgin, 1875), were also shown to contain mixtures of these metabolites and/or bromotyrosine derived compounds. An earlier report indicated similar results for *S. aurea* and *Smenospongia (= Polyfibrospongia) echina* (2). It is of interest that the sponge previously known as *Spongia fenestra* or *Aplysina aurea* was reclassified as *Smenospongia aurea* (Hyatt) by Wiedenmayer (3).

Our research group studied the phospholipid fatty acid composition of the sponges *Verongula gigantea* and *Aplysina (= Verongia) archeri* and concluded that the similarity in their phospholipid fatty acid composition could be used as a chemotaxonomic tool (4). The key similarities in the phospholipids were the presence of predominantly saturated fatty acids, of considerable quantities of 3,7,11,15-tetramethylhexadecanoic (phytanic) acid and of the very long-chain 5,9,23-tricontatrienoic acid, and of considerable amounts of 2-hydroxy fatty acids. The sterol composition of these sponges was also similar, in particular because both sponges contained aplysterol, verongulasterol, and 25-dehydroaplysterol (5,6). However, the question still remains whether the Caribbean sponge *S. aurea* contains a lipid composition similar to other *Aplysina* sponges.

Literature published in this area prompted us to further study other sponges from the genus *Aplysina*, in particular *Aplysina lacunosa* and *Aplysina fistularis*, in search of similar lipid metabolites which could serve as a sound chemotaxonomic base. We also studied the lipids of the sponge *Smenospongia aurea* in order to compare these with the lipids of sponges of the family Aplysinidae. It was likely that *S. aurea* would contain α-hydroxy fatty acids. We also felt that this type of study could also lead to a better understanding of the metabolism of α-hydroxy fatty acids in sponges in the future.

EXPERIMENTAL PROCEDURES

Aplysina lacunosa was collected on May 25, 1989, at a depth of 24 m. *Aplysina fistularis* and *Smenospongia aurea* were collected March 22, 1991, at 12 m near the shelf edge of La Parguera, Puerto Rico. The sponges were placed in dry ice for transportation to the laboratory. They were freeze-dried on a Labconco Freeze Dryer 4.5 (Model 77510; Kansas City, MO). For extraction, approximately 180 g of dry sponge was carefully cleaned of all nonsponge debris and cut into small pieces. Extraction with 600 mL of chloroform/methanol (1:1, vol/vol) yielded total lipids. The neutral lipids, glycolipids and phospholipids (1.5 g) were separated by column chromatography on silica gel (60-200 mesh) using the procedure of Privett *et al.* (7). The sterols were obtained from the neutral lipids fraction by chromatography on a silica gel column using diethyl ether/hexane (1:1, vol/vol) as solvent. The sterol mixtures were recrystallized two times, the first time in MeOH, the second time in CH_3CN. Final separation was achieved using a Waters Associates high-performance liquid chromatography (HPLC) system (M510 pump; Waters 410 differential refractometer), with an Altex Ultrasphere ODS-2 column (25 cm × 4.6 mm i.d.) and methanol as solvent. The phospholipid classes were separated by preparative thin-layer chromatography (TLC) on silica gel G using chloroform/methanol/water (25:10:1, vol/vol/vol) as solvent. The fatty acid methyl esters from phospholipids were obtained by reaction with methanolic hydrogen chloride (8) followed by purification by column chromatography and elution with hexane/diethyl ether (9:1, vol/vol). The resulting methyl esters were analyzed by gas chromatography/mass spectrometry (GC/MS) using a Hewlett-Packard 5995A GC/MS (Hewlett-Packard, Palo Alto, CA) or a Hewlett-Packard 59970 MS ChemStation equipped with a 20 m × 0.32 mm nonpolar fused silica column (Supelco, Bellefonte, PA) with SPB™-1 as the bonded phase. Hydrogenations were carried out in 10 mL of absolute methanol in the presence of catalytic amounts of platinum oxide (PtO_2). ^1H NMR and ^{31}P NMR spectra were recorded on a General Electric GN-300 (300 MHz) spectrometer in $CDCl_3$. Mass spectral data for the key fatty acids studied are presented below.

Lithium aluminum hydride reduction. The fatty acid methyl esters (5 mg) were placed in a 50-mL three-necked round-bottomed flask at −78°C in 20 mL of dry THF. Excess $LiAlH_4$ was added and the mixture was left to stir overnight. For the work-up, 10–15 mL of ethyl acetate followed by 10 mL of distilled water were added to destroy excess $LiAlH_4$. The solution was then acidified with H_2SO_4 followed by diethyl ether extraction (2 × 15 mL). The ether extract was dried over anhydrous $MgSO_4$, filtered, and the solvent was evaporated to dryness, affording the corresponding 1,2-diols in almost quantitative yield.

Oxidative cleavage of the 1,2-diols. The 1,2-diols (2–3 mg) were dissolved in 2 mL of *t*-BuOH followed by the addition of 1 mL of a solution of $NaIO_4/KMnO_4$ in distilled water and 1 mL of K_2CO_3 in water. The mixture was stirred vigorously for 1 h, followed by acidification with conc. H_2SO_4. The excess oxidant was destroyed by adding $Na_2S_2O_3$ until the solution remained colorless. The organic extract was taken up with diethyl ether (3 × 4 mL), dried over anhydrous Na_2SO_4, and the solvent was evaporated to dryness affording the corresponding fatty acids.

RESULTS

Phospholipid fatty acid compositions of *Smenospongia aurea, Aplysina lacunosa* and *Aplysina fistularis* are presented in Table 1. The main phospholipids in the sponges were phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), and phosphatidylcholine (PC). PE was the principal phospholipid, while PC was a minor component. ^{31}P nuclear magnetic resonance (NMR) was used to analyze the phospholipid mixture as we did previously (4). The phospholipid fatty acid composition of these sponges represented a series of predominantly saturated fatty acids with considerable amounts of *anteiso* and *iso* acids. Phytanic (3,7,11,15-tetramethylhexadecanoic) acid was present in *ca.* 4% relative abundance in *S. aurea*, 9.4% abundance in *A. lacunosa*, and 9% abundance in *A. fistularis*. The mass spectrum of the phytanic acid methyl ester showed a base peak at *m/z* 101 (100%) and peaks at *m/z* 171 (15%) and *m/z* 241 (2%) indicating branching consistent with its structure (9). A second key fatty acid common to all three sponges was the very long chain 5,9,23-triacontatrienoic acid (30:3). This fatty acid was identified by its retention times in capillary gas chromatography (GC), equivalent chain length (ECL), and by mass spectral comparison with an authentic sample (10).

Each of the three sponges contained α-hydroxy fatty acids (Table 1). *A. lacunosa* contained a series of α-hydroxy acids (10% of the total fatty acid mixture) ranging in length from 15 to 23 carbon atoms, *A. fistularis* contained α-hydroxy acids from 19 to 24 carbon atoms (7% of the total fatty acid mixture), while *S. aurea* showed the most complete series of α-hydroxy acids ranging in length from 17 to 26 carbon atoms (29% of the total fatty acid mixture). These findings substantially extend current knowledge on α-hydroxy acids in sponges (4). In particular, *S. aurea* contained six novel branched α-hydroxy acids which were characterized as 2-hydroxy-17-methyloctadecanoic acid (1), 2-hydroxy-21-methyldocosanoic acid (2), 2-hydroxy-22-methyltricosanoic acid (3), 2-hydroxy-22-methyltetracosanoic acid (4), 2-hydroxy-24-methylpentacosanoic acid (5), and 2-hydroxy-23-methylpentacosanoic acid (6). All contained either *iso* or *anteiso* terminal methyl

(6) n = 19

branching. Characterization of these acids was by GC retention times, GC/MS, chemical degradation to the known saturated *iso*/*anteiso* saturated compounds, and nuclear magnetic resonance spectroscopy. A representative example is the characterization of 2-hydroxy-21-methyldocosanoic acid methyl ester, which showed a very characteristic MS spectrum with a molecular ion at *m/z* 384 (5%, $C_{24}H_{48}O_3$). The identification of an $M^+ - COOCH_3$ fragmentation ion at *m/z* 325 (5%) strongly

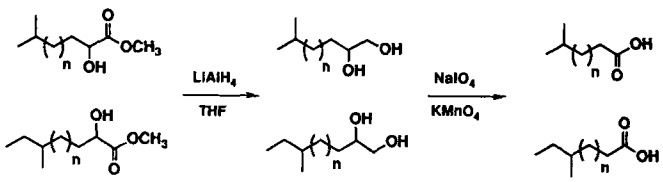
suggested α-substitution. Lack of significant peaks at *m/z* 74 and *m/z* 104, but the presence of fragmentation ions at *m/z* 90 (36%) and *m/z* 103 (11%) derived by McLafferty rearrangement, indicated the presence of the α-hydroxy structure. This was further confirmed by the long retention time in capillary GC with an ECL value of 23.88 found. The Fourier transform infrared (FTIR) spectrum of the mixture displayed a band between 3100 and 3600 cm^{-1}, supporting the presence of a hydroxy group. ^1H NMR of the 2-hydroxy fatty acid methyl esters showed the signal of the methoxy group of the ester at 3.78 ppm, while the signal of the methoxy group of a normal fatty acid methyl ester appears at 3.66 ppm. This downfield shift is consistent with α-hydroxy substitution. Moreover, the signal of the hydrogen at position 2 in the 2-hydroxy fatty acid methyl esters was observed between 4.1 and 4.2 ppm as expected for α-hydroxy fatty acid methyl esters. The identification of the entire series of long-chain α-hydroxy esters from *S. aurea* was possible based on a plot of retention time *vs.* number of carbon atoms. Three different families of α-hydroxy fatty acid methyl esters could thus be discerned.

The methyl branching in the novel α-hydroxy fatty acids was unequivocally determined by chemical degradation to the corresponding known *iso* and *anteiso* non-hydroxylated saturated fatty acids. The sequence used is shown in Scheme 1. The process resulted in a chain shortening



SCHEME 1

of the α-hydroxy esters by one carbon atom, while the non-hydroxylated saturated esters were unaffected. Hydrogenation of the mixture with PtO_2 in MeOH followed by $LiAlH_4$ reduction afforded the corresponding saturated 1,2-diols which were then cleaved and oxidized with $NaIO_4/KMnO_4$ to afford the corresponding nonhydroxylated fatty acid with one carbon less. These acids were then esterified with HCl/MeOH in order to obtain the corresponding fatty acid methyl esters. In all cases, the fatty acid methyl esters thus obtained corresponded to the saturated *iso* or *anteiso* methyl esters with one carbon less as shown by their ECL values as well as by GC coinjection with authentic standards. For example, the 2-hydroxy-22- and 23-methyltetracosanoic acid methyl esters (*ai*-25h:0 and *i*-25h:0) were transformed into the corresponding 23- and 24-methyltricosanoic acid methyl esters (*ai*-24:0 and *i*-24:0) by the sequence of reactions outlined above. The former methyl ester showed an ECL value of 23.63 and the latter an ECL value of 23.72. Similar results were obtained for the 2-hydroxy-23- and 24-methylpentacosanoic acid methyl esters (*ai*-26h:0 and *i*-26h:0) which were also transformed into the corresponding 22- and 23-methyltetracosanoic acid methyl esters (*ai*-25:0 and *i*-25:0) with ECL values of 24.75 and 24.63, respectively. By means of a series of recrystallizations from CH_3CN, we were able to isolate the 2-hydroxytetracosanoic acid methyl ester from *A. fistularis,* thus permitting the measurement of the optical rotation in methanol which was found to be a small positive number ($[\alpha]_D = +4.0°$). Therefore, α-hydroxy fatty acids from sponges seem to belong to the D-series.

A series of saturated aldehydes was also characterized which arose from 1-*O*-alk-1-enyl-2-acyl glycerophospholipids, commonly known as plasmalogens (11). While *S. aurea* produced only two aldehydes, namely octadecanal (18:0) and tetracosanal (24:0), *A. lacunosa* produced a more complete series of aldehydes ranging in length from 11 to 27 carbon atoms and accounting for 25% of the total long-chain components of the phospholipids of this sponge. Heptacosanal (27:0) is the longest aldehyde yet derived from sponge plasmalogens (11). The aldehydes were characterized as their dimethyl acetals. Dimethyl acetals normally do not afford a molecular ion in electron impact mass spectrometry (EIMS), but an ion equivalent to $[M - 31]^+$ (loss of a methoxy group) permits determination of the molecular weight. As an example, heptacosanal dimethyl acetal displayed a $[M - 31]^+$ peak at *m/z* 409 (0.5% abundance) and a base peak at *m/z* 75 ($C_3H_7O_2^+$).

The sterols from the three sponges were also isolated, using reverse-phase high-performance liquid chromatography (HPLC) for the final separation. The particular sterols were characterized by 300 MHz ^1H NMR, MS, and by comparison with authentic samples. The *Aplysina* sponges contained, as their major sterol 24*S*,26-dimethyl-25*S*-cholest-5-en-3β-ol (12). From *A. fistularis,* the following sterols were isolated and characterized: cholesterol (12% of the total sterol mixture), 24-methylcholesta-5,22-dien-3β-ol (5%), 24-methylcholest-5-en-3β-ol (5%), 24-ethylcholesta-5,22-dien-3β-ol (3%), 24-ethylcholest-5-en-3β-ol (29%), (24*R*,25*S*)-24,25-dimethylcholest-5-en-3β-ol (39%), and (24*R*)-24,26,27-trimethylcholesta-5,25-dien-3β-ol (6%). Similar results were obtained for *A. lacunosa* where 24*S*,26-dimethyl-25*S*-cholest-5-en-3β-ol (aplysterol) accounted for 39% of the total sterol mixture. On the other hand, in *S. aurea* we could detect neither aplysterol nor verongulasterol. The sterol mixture of *S. aurea* consisted of cholesterol (61% of the total sterol mixture), 24-methylcholesta-5,22-dien-3β-ol (10%), 24-methyl-cholest-5-en-3β-ol (5%), 24-ethylcholesta-5,22-dien-3β-ol (2%), and 24-ethylcholest-5-en-3β-ol (22%).

DISCUSSION

We observed that sponge phospholipid can contain α-hydroxy fatty acids ranging in length from 15 to 26 carbons. We also showed that sponges, such as *S. aurea,* are able to synthesize unusual very long chain branched α-hydroxy fatty acids and introduce them into their phospholipids. A series of *iso* and *anteiso* α-hydroxy fatty acids from 14 to 17 carbon atoms in length were previously identified in the phosphatidylethanolamines from *Nocardia leishmanii* (13); the 2-position of PE was exclusively substituted by branched α-hydroxy acids, while the 1-position contained chiefly *iso*-C_{16}, *iso*-C_{17}, and *anteiso*-C_{17} acids. A similar pattern was earlier reported for the lipids of *Streptomyces sioyaensis,* where 2-hydroxy-13-methyltetradecanoic acid was the main α-hydroxy acid, which was also found in the β-position in PE (14). A more

recent report showed that 2-hydroxy fatty acids, such as 2-hydroxy-15-methylhexadecanoic acid, are also found in PE from myxobacteria. Essentially two types of PE were encountered: one contained the nonhydroxy fatty acids, while the other contained 50% hydroxy fatty acids next to nonhydroxy fatty acids (15). *S. aurea* showed a similar picture except that *S. aurea* can synthesize longer chain fatty acids.

A second conclusion from our work relates to the chemotaxonomy of the sponges studied here. The phospholipid fatty acid compositions of *A. lacunosa* and *A. fistularis* were found to be quite similar to the ones reported for other sponges belonging to the family of the Aplysinidae, *i.e., Aplysina archeri* and *Verongula gigantea* (4). *S. aurea* also possesses a very similar fatty acid composition, except that more saturated *iso* and *anteiso* fatty acids were found in this sponge. The most interesting finding, however, was the difference in sterol composition between the *Smenospongia* and *Aplysina*. In both *A. lacunosa* and *A. fistularis* we found aplysterol to be the main sterol of both sponges (39% of the total fatty acid composition) and verongulasterol to be a minor constituent. We previously had obtained similar results for *A. archeri* and *V. gigantea* (5,6). *S. aurea*, on the other hand, showed a common sponge sterol composition, and no traces of aplysterol and/or verongulasterol were detected. Therefore on the basis of their sterol composition, the *Smenospongia* and *Aplysina* represent a different genus.

ACKNOWLEDGMENTS

Dr. Vance Vicente from the United States Department of the Interior Fish and Wildlife Service, classified the sponges. [Received March 25, 1992, and in revised form June 15, 1992; Revision accepted July 24, 1992]

A Facile Synthesis of 4-Hydroxy-2(*E*)-nonenal

H.W. Gardner*, R.J. Bartelt and D. Weisleder
National Center for Agricultural Utilization Research, Agricultural Research Service, USDA, Peoria, Illinois 61604

A facile, efficient synthesis of 4-hydroxy-2(*E*)-nonenal is presented as an alternative to the approaches published previously, which either employed four to six separate steps or furnished low yields. The commercially available 3(*Z*)-nonenol was sequentially oxidized into 3,4-epoxynonanol by 3-chloroperoxybenzoic acid followed by oxidation of the alcohol by periodinane to afford 4-hydroxy-2(*E*)-nonenal by this two-step procedure in 48 ± 7% yield.
***Lipids* 27, 686–689 (1992).**

4-Hydroxy-2(*E*)-nonenal (4HNE), a product of lipid peroxidation, is well-known for its biological effects, which include genotoxicity and cytotoxicity. Recently, Esterbauer *et al.* (1) have published a comprehensive review concerning 4HNE and related aldehydes.

A number of synthetic strategies for 4HNE and its homologs have been developed. Previous procedures had utilized variations of the Grignard reaction (2–6), isomerization of 2-yne-1,4-diols with a ruthenium catalyst (7), a method *via* 1,3-*bis*(methylthio)allyl-lithium (8) and a sequence of addition/elimination/substitution reactions performed on the corresponding saturated aldehyde (9,10). The present communication describes a facile two-step synthesis of 4HNE starting from 3(*Z*)-nonenol.

MATERIALS AND METHODS

Materials. 3(*Z*)-Nonenol (95%), 3-chloroperoxybenzoic acid (80–85%), hexanal (99%), 2-nonanone (99+%), pyridinium chlorochromate (98%), 2-iodobenzoic acid (98%), *O*-benzylhydroxylamine hydrochloride and potassium bromate were from Aldrich Chemical Company (Milwaukee, WI); $CHCl_3$ (high-performance liquid chromatography [HPLC] grade, 99.9%) was from Mallinckrodt (Paris, KY). All other chemicals and solvents were either reagent or HPLC grade. Thin-layer chromatography (TLC) plates were Silica Gel 60 F-254 (20 × 20 × 0.25 cm) from Merck (Darmstadt, Germany).

*Synthesis of 4-hydroxy-2(*E*)-nonenal.* To a solution of 3 (*Z*)-nonenol (0.5 mmol) in 2 mL $CHCl_3$ was added a 1.2 molar excess of 80–85% 3-chloroperoxybenzoic acid (130 mg). The solution was kept at room temperature for 1 h after which 2 mL of 10% $NaHCO_3$ was added with vigorous stirring for 45 min. As expected, the water washed $CHCl_3$ layer contained 3,4-epoxynonanol as determined by ^1H NMR and ^{13}C NMR spectrometry. The ^1H NMR data are given as chemical shift in ppm (δ) downfield from tetramethylsilane (TMS) and (number of protons, multiplicity, coupling constant in Hz and carbon assignment) are as follows: 3.84 (3H, *m* and brs, C-1 and probably OH); 3.09 (1H, apparent overlapping *dd* and *dd*, *J* values determined by simulation $J_{2a,3}$ = 4.4, $J_{2b,3}$ = 8.4, $J_{3,4}$ = 4.4, C-3); 2.95 (1H, apparent overlapping *dd* and *dd*, *J* values determined by simulation $J_{3,4}$ = 4.4, $J_{4,5a}$ = 5.7, $J_{4,5b}$ = 6, C-4); 1.87 and 1.67 (2H, *m*, C-2); 1.51 (4H, *m*, C-5,6); 1.32 (4H, *m*, C-7,8); 0.87 (3H, *t*, C-9). The ^{13}C NMR data are given relative to TMS in chemical shift in ppm (δ) and carbon assignment: 60.6, C-1; 56.9, C-4; 55.1, C-3; 31.6, C-7; 30.5, C-2; 27.8, C-5; 26.1, C-6; 22.5, C-8; 13.9, C-9. The assignments were confirmed by two-dimensional proton-carbon correlation spectroscopy, correlative spectroscopy (COSY) and distortionless enhancement by polarization transfer (DEPT) experiments (data not shown).

Subsequently, the alcohol group of 3,4-epoxynonanol was oxidized to the corresponding aldehyde by the reagent, periodinane. Periodinane was prepared by $KBrO_3$-H_2SO_4 oxidation of 2-iodobenzoic acid into the cyclic tautomer of 2-iodoxybenzoic acid followed by acetylation to the triacetate as described (11). In actual practice, the washed $CHCl_3$ layer containing 3,4-epoxynonanol from the previous step was dewatered for direct oxidation by periodinane in $CHCl_3$ without any other clean-up. Typically, the $CHCl_3$ layer was percolated through a 0.5 i.d. × 6 cm column (Pasteur pipette) packed with anhydrous Na_2SO_4, and the epoxynonanol was washed from the column with $CHCl_3$ to give a total volume of 5 mL (other dewatering procedures can be used). The $CHCl_3$ solution containing 3,4-epoxynonanol was oxidized by a molar excess of periodinane based on the starting 0.5 mmol 3(*Z*)-nonenol (generally a 2 molar excess, 1 mmol). An excess of periodinane is recommended because the reagent is sensitive to moisture (11). Various batches of periodinane could be checked for oxidation potential by reacting with an alcohol, such as 3(*Z*)-nonenol, and assessing conversion to the aldehyde by GLC. Also, it should be noted that certain suppliers of $CHCl_3$ add to their formulation as much as 1% ethanol as a preservative, in which case the alcohol must be removed before use. After the oxidation mixture was stirred for 20 min at room temperature, 14 mL of diethyl ether and 4 mL of 1.3 M NaOH were added, and the mixture was vigorously agitated for about 15 s. The aqueous NaOH layer containing most of the spent periodinane was removed, and an additional 5 mL of 1.3 m NaOH were added with vigorous stirring or vortexing for 10 min. The NaOH layer was removed, and the organic phase was washed with 5 mL of H_2O. Evaporation of solvent afforded crude 4HNE which gave the following ^1H NMR data in chemical shift, ppm (δ), and (number of protons, multiplicity, coupling constant in Hz, and carbon assignments): 9.56 (1H, *d*, *J* = 7.9, C-1); 6.29 (1H, *ddd*, *J* = 7.9, 15.7, 1.6, C-2); 6.81 (1H, *dd*, *J* = 15.7, 4.7, C-3); 4.42 (1H, *dtd*, *J* = 6.5, 4.7, 1.6, C-4). Except for minor differences, the ^1H NMR spectrum was in agreement with previously published data (12). The Fourier transform-infrared (FT-IR) spectrum gave the following diagnostic absorptions (cm^{-1}): 3438 m, br, OH; 2933 s, CH; 2863 m, CH; 2732 w, aldehyde CH; 1690 s, carbonyl; 1127 and 1077 m, hydroxyl CO; 976 s, *E*-olefin. An electron impact-mass spectrometry (EI-MS) furnished the following

Abbreviations: COSY, correlative spectroscopy; DEPT, distortionless enhancement by polarization transfer; EI-MS, electron impact-mass spectrometry; FT-IR, Fourier transform-infrared; GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; 4HNE, 4-hydroxy-2(*E*)-nonenal; HPLC, high-performance liquid chromatography; IR, infrared; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography; TMS, tetramethylsilane; UV, ultraviolet.

major ions [*m/z* (% relative intensity, ion structure)]: 127 (3, M^+-CHO); 109 (7, M^+-CHO-H_2O); 99 (9); 86 (13); 85 (12); 71 (12); 57 (78); 43 (100); 41 (45).

Formation of O-benzyloximes of 4HNE. Yields of 4HNE were determined by gravimetric analyses of the *O*-benzyloximes of 4HNE synthesized with *O*-benzylhydroxylamine reagent (4 molar excess of *O*-benzylhydroxylamine based on the reactant, 3*Z*-nonenol). The *O*-benzylhydroxylamine reagent was prepared by a method previously described for *O*-pentafluorobenzylhydroxylamine reagent (13). The *syn* and *anti* oximes were extracted from the reagent by $CHCl_3$ and isolated by TLC as described below. Trimethylsilyloxy derivatives were prepared for gas chromatography/mass spectrometry (GC/MS) by reaction with chlorotrimethylsilane/hexamethyldisilazane/pyridine (3:2:2, vol/vol/vol).

Chromatographic analysis. The purity of 4HNE was assessed by TLC using two different solvents: Solvent A, $CHCl_3/CH_3OH$ (99:1, vol/vol) and Solvent B, hexane/diethyl ether/acetic acid (50:50:1, vol/vol/vol); 4HNE R_f 0.14–0.15 and 0.33, respectively. Detection was by sequential viewing of 4HNE by ultraviolet (UV) absorption, followed by visualization of an orange spot after spraying with 0.4% 2,4-dinitrophenylhydrazine in 2N HCl. Other nonaldehydic components were visualized by spraying with vanillin/ethanol/H_2SO_4 (160:40:1, wt/vol/vol) and charring. 3(*Z*)-Nonenol and 3,4-epoxynonanol were analyzed by TLC using hexane/diethyl ether (3:2, vol/vol) as developing solvent [3(*Z*)-nonenol R_f 0.37; 3,4-epoxynonanol R_f 0.12]. *O*-Benzyloximes of 4HNE (*syn* and *anti*) were isolated by preparative TLC using hexane/ethyl acetate (4:1, vol/vol). Just prior to TLC, the excess *O*-benzylhydroxylamine was reacted with hexanal to avoid close migration of the hydroxylamine with the 4HNE oximes. The *syn* and *anti* oximes were detected by UV absorbance of two closely migrating bands centered at about R_f 0.30, and the TLC scrapings were eluted with ethyl acetate.

Gas-liquid chromatography (GLC) was completed with a Spectra-Physics (San Jose, CA) Model SP-7100 gas chromatograph equipped with an open tubular capillary column (12 m × 0.22 mm) coated with SE 30. The carrier gas flow was about 1 mL/min, and the temperature was programmed from 100–140°C at 5°C/min. 3(*Z*)-Nonenol, 3,4-epoxynonanol, and 4HNE eluted after 1.8, 3.5 and 3.9 min, respectively.

Open-column liquid chromatography was completed with a 1 cm i.d. × 10 cm column packed with SilicAR CC-4 (Mallinckrodt) slurried in hexane. Components of the product mixture were eluted with 60 mL each of 5, 10, 20 and 30% diethyl ether in hexane. HPLC was accomplished with a 9.4 × 250 mm Zorbax Sil 5μ spherical particle column (Dupont Instruments, Wilmington, DE) using hexane/acetone (87:13, vol/vol) elution at 1.5 mL/min and UV-detection at 218 nm.

Spectral analyses. ^1H and ^{13}C NMR spectra were obtained in C^2HCl_3 solution with a Bruker Model WM-300 spectrometer. Electron ionization-mass spectrometry (EI-MS) was done on a Hewlett-Packard (Palo Alto, CA) Model HP 5970 mass-selective detector equipped with a coupled gas chromatograph. The gas chromatograph was equipped with a fused silica capillary column (15 m × 0.25 mm) coated with a bonded nonpolar DB-1 (J&W Scientific, Rancho Cordova, CA). For elution of product mixtures containing 4HNE, the column temperature was held at 50°C for 4 min, and then programmed at 10°/min using a carrier gas flow of about 0.5 mL/min. A temperature program from 120°C–200°C at 10°C/min was employed to elute the trimethylsilyloxy derivative of 4HNE-*O*-benzyloxime. Infrared (IR) spectra were obtained from a liquid film sandwiched between KBr plates using a Galaxy 6020 series FT-IR spectrometer from Mattson Instruments (Madison, WI). IR absorptions are described in terms of wave number (cm^{-1}), intensity and assignment, in that order, using the following abbreviations: w, weak; m, medium; s, strong; and br, broad.

RESULTS

The synthetic method employed first epoxidation of 3(*Z*)-nonenol by 3-chloroperoxybenzoic acid followed by oxidation of the alcohol to the aldehyde by periodinane (theoretically affording 3,4-epoxynonanal). However, epoxyaldehydes, analogous to 3,4-epoxynonanal, are known to be readily converted to the corresponding hydroxy-2-ene aldehydes by conditions as mild as silica gel in diethyl ether (14) or triethylamine in diethyl ether (15), and accordingly the 3,4-epoxynonanal conversion to 4HNE would be expected to proceed by mild treatment with either acid or base (16). As discussed below, it seems certain that the NaOH wash ostensibly used to remove spent periodinane (2- iodobenzoic acid) was responsible for the conversion of 3,4-epoxynonanal to 4HNE (Fig. 1). 4HNE was synthesized by this simple two-step procedure without change of the $CHCl_3$ solvent and without chromatographic purification. As illustrated by the two-dimensional proton-carbon correlation nuclear magnetic resonance (NMR) spectrum (Fig. 2), there was little evidence for significant impurities in the crude product. Carbon assignments were confirmed by DEPT. Chromatographic purification by either preparative TLC, open-column liquid chromatography (elution volume 140–180 mL) or, preferably, HPLC (retention time, 35 min) is recommended to eliminate minor impurities. As indicated by GC-MS, impurities probably were methyl 2-iodobenzoate, nonadienal and 3-oxononanal (data not shown); however, the latter two could have been partially or wholly produced by the GLC conditions.

Ordinarily, it was most convenient to assess the product yield by GLC of the underivatized product mixture, which afforded an estimate of 60% yields. However, due to the possibility of artifact formation on the GLC column and lack of response factors, these uncertainties prompted us to determine the yield of the reaction by gravimetric determination of the *O*-benzyloxime derivative of 4HNE which afforded a calculated overall yield of 48 ± 7% (n = 7).

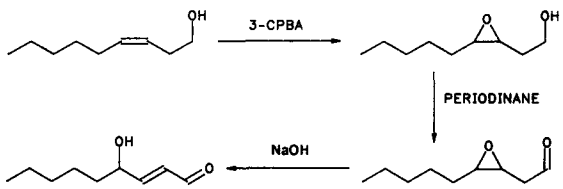

FIG. 1. Synthetic route to 4-hydroxy-2(*E*)-nonenal from 3(*Z*)-nonenol; 3-CPBA, 3-chloroperoxybenzoic acid.

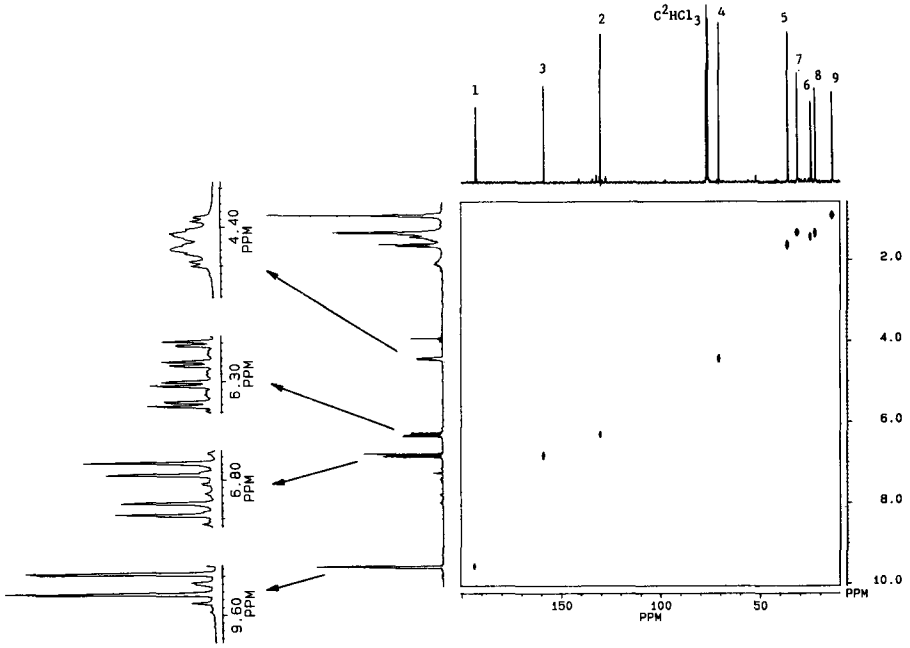

FIG. 2. Two-dimensional proton-carbon correlation NMR of crude synthetic 4-hydroxy-2(*E*)-nonenal (no chromatographic purification).

The *O*-benzyloxime of 4HNE was determined to be authentic by GC-MS of the trimethylsilyloxy derivative which afforded very similar spectra for both *syn* and *anti* isomers. The last eluting and most abundant isomer gave the following ions [*m/z* (% relative intensity, ion structure)]: 333 (3, M^+); 262 (15, $M^+ - CH_3(CH_2)_4$); 242 (42, $M^+ - CH_2C_6H_5$); 226 (14, $M^+ - OCH_2C_6H_5$); 91 (100, $CH_2C_6H_5$); 73 (47, trimethylsilyl).

As briefly mentioned above, we were able to observe a compound consistent in properties with the hypothetical intermediate, 3,4-epoxynonanal. When the organic layer containing the periodinane oxidation products was briefly treated with NaOH for 15 s and then washed with water instead of further agitating with NaOH for 10 min, a compound comprising about 60% of the total GLC peak area was detected at a retention of 2.4 min, compared to a 3.9 min retention time for 4HNE. Further agitation with NaOH for 10 min resulted in disappearance of the peak at retention of 2.4 min with a corresponding increase in the 4HNE peak. Furthermore, this intermediate was detected by TLC as a 2,4-dinitrophenylhydrazine reactive spot, which did not absorb UV, and migrated at a somewhat larger R_f value than 4HNE. GC-MS of this compound suggested that the intermediate was in fact 3,4-epoxynonanal giving the following major ions [*m/z* (% relative intensity, ion structure)]: 138 (0.1, $M^+ - H_2O$); 127 (2.6, $M^+ - CHO$); 113 (2.4, $M^+ - CH_2CHO$); 99 (22); 85 (5, $M^+ - (CH_2)_4CH_3$); 83 (37); 71 (25); 57 (56); 55 (100, $CH{=}CHCHO$); 43 (53, CH_2CHO); 41 (81).

Periodinane oxidation of the alcohol, 3,4-epoxynonanol, to 4HNE was determined to be somewhat superior to another oxidation agent of alcohols, pyridinium chlorochromate (17). GLC of the products of pyridinium chlorochromate oxidation indicated that the yield of 4HNE was only about 30% of the total peaks detected. Furthermore, a relatively large GLC peak detected at 2.4 min retention was indicative of 3,4-epoxynonanal. A 10 min NaOH treatment of the mixture dissolved in organic solvent, as described above for the periodinane oxidation, led to disappearance of the 2.4 min peak with a corresponding increase in the 4HNE peak. Although NaOH treatment apparently improved the yield of 4HNE, other unidentified GLC peaks were also observed even after alkali treatment. Possibly, the relatively long time (1 h) used for oxidation leads to epoxide opening and further oxidation. That 4HNE was produced by pyridinium chlorochromate oxidation was proved by TLC of the product mixture by sequentially using solvents B and A and obtaining a ^1H NMR spectrum of the isolate. Despite its apparent drawbacks, the pyridinium chlorochromate method does provide an alternative to periodinane oxidation if one can tolerate the increased impurities and loss in yield. With some effort expended on varying the conditions of pyridinium chlorochromate oxidation, it may be possible to further improve the yields.

A more direct route to 4HNE would appear to be direct epoxidation of 3(*Z*)-nonenal; however, aldehydes, such as 3(*Z*)-nonenal, are sensitive to the common epoxidizing reagent, 3-chloroperoxybenzoic acid. For example, reaction of hexanal with this reagent under the conditions used here largely oxidized the aldehyde into hexanoic acid (data not shown).

DISCUSSION

Previous methods for synthesis of 4HNE and its homologs usually employed variations of the Grignard reaction as a synthetic strategy (2-6). Although these methods required four to five steps, the overall yields were generally good, in the 50-78% range (2-5). A procedure offered an alternative to 4HNE in six steps employing conversion of nonanal by a series of addition, elimination

and substitution reactions (9,10), and 4-hydroxyhexenal has been prepared *via* 1,3-*bis*(methylthio)allyl-lithium and propanal in 61–62% yield (8). A potentially promising one-step procedure used to convert dodec-2-yne-1,4-diol into 4-hydroxy-2(*E*)-dodecenal by a ruthenium catalyst in 44% yield would appear to be limited by the availability of non-2-yne-1,4-diol (7). The two-step synthesis reported here does not require a change of solvent, only provided that the $CHCl_3$ solvent be reasonably dried after the epoxidation step prior to reaction with periodinane. Due to the relatively clean conversion, chromatographic purification was straightforward.

The current synthesis of 4HNE was designed to mimic a proposed biosynthetic pathway by plants. Recently, it was shown that a soybean preparation containing hydroperoxide lyase activity mainly converted 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid into 9-oxononanoic acid and 4HNE (18). Although a good yield of 3(*Z*)-nonenal was anticipated from the hydroperoxide lyase activity, this compound was only a minor product. This observation implied that the soybean preparation was converting 3(*Z*)-nonenal into 4HNE. One hypothesis is that a hydroperoxide-dependent peroxygenase or epoxygenase was epoxidizing 3(*Z*)-nonenal followed by conversion into 4HNE. Such enzymes from soybean (19) and *Vicia faba* (20) are known to epoxidize unsaturated fatty acids using as oxidants lipid hydroperoxide or H_2O_2. Recently, it was shown that 13*S*-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid and the alcohol, 3(*Z*)-nonenol, supplied to the soybean preparation produced 3,4-epoxynonanol (Gardner, H.W., unpublished). Accordingly, it seemed plausible that the peroxygenase could be responsible for the formation of 4HNE from 3(*Z*)-nonenal *via* 3,4-epoxynonanal. This seemed to be an especially attractive possibility in light of the hypothesis of Pryor and Porter (16) that conversion of 3,4-epoxynonanal may be one of the origins of 4HNE during peroxidation of lipids. In fact, their hypothesis was the key to suggesting such a biosynthetic pathway to 4HNE and the current method of synthesis. Experiments with *Vicia faba* hydroperoxide-dependent epoxygenase indicated that the conversion of 3(*Z*)-nonenal to 4HNE involves two separate reactions, one of which was shown to be catalyzed by the hydroperoxide-dependent epoxygenase (Gardner, H.W., and Hamberg, M., communicated at the 8th International Conference on Prostaglandins and Related Compounds, Montreal, Canada, July 26–31, 1992).

Specificity of Soybean Lipoxygenase-1 in Hydrated Reverse Micelles of Sodium *bis*(2-Ethylhexyl)sulfosuccinate (Aerosol OT)

Tatyana N. Shkarina[1], Hartmut Kühn and Tankred Schewe*
Institute of Biochemistry of the Medical School (Charité), Humboldt University, D-O-1040 Berlin, Germany

Soybean lipoxygenase-1 (EC 1.13.11.33) was purified by fast protein liquid chromatography on a MONO Q column and studied with respect to the conversion of linoleic and arachidonic acids in reverse micelles of sodium *bis*(2-ethylhexyl)sulfosuccinate in *n*-octane. In this system the specific activities were lower by one order of magnitude than those in the corresponding aqueous system. High-performance liquid chromatography analyses indicated the predominant formation of 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid (13-HpODE) from linoleic acid and of 15*S*-hydroperoxy-5*Z*,8*Z*,11*Z*,13*E*-eicosatetraenoic acid (15) from arachidonic acid both in the aqueous system and in the reverse micelles. After sedimentation of the hydrated reverse micelles by ultracentrifugation, both linoleic acid and 13-HpODE were found to be enriched in the micelles with only small amounts of these compounds present in *n*-octane. It is proposed that substrates and products of the lipoxygenase reaction are located mainly in the surfactant shell of the hydrated reverse micelles and reach the micelle-entrapped enzyme by diffusion into the aqueous interior space.
Lipids 27, 690–693 (1992).

Reverse micelles are formed when suitable amphiphilic molecules such as AOT [sodium *bis*(2-ethylhexyl)sulfosuccinate] are dissolved in nonpolar organic solvents; they differ from normal micelles in that the polar head groups are oriented toward the interior of the spheroidal aggregates. In reverse micelles, water and other polar compounds, including enzymes, can be encapsulated. The physical chemistry of hydrated reverse micelles of AOT in *n*-octane has been studied in detail by several research groups (1,2).

Several authors (3–6) have shown that commercially available soybean lipoxygenase-1 (EC 1.13.11.33) of low activity oxygenates linoleic acid in reverse micelles. The reaction products have not been identified, a step that is required to characterize the specificity of the reaction. In the aqueous system, soybean lipoxygenase-1 oxygenates polyenoic fatty acids containing an n-8 doubly allylic methylene to their corresponding n-6 hydroperoxy derivatives (for details see ref. 7). In this case the methyl end of the substrate appears to be a signal for the site of initial hydrogen abstraction. Under special conditions, such as change in pH or absence of doubly allylic methylene in the corresponding position, an inverse binding of the substrate at the active site of the enzyme is also possible (7). Thus, soybean lipoxygenase-1, which is an arachidonate "15-lipoxygenase", converts 15*S*-hydroperoxy-5*Z*,8*Z*,11*Z*,13*E*-eicosatetraenoic acid (15-HpETE) to 5*S*,15*S*-dihydroperoxy-6*E*,8*Z*,11*Z*,13*E*-eicosatetraenoic acid (8).

In an earlier study with reverse micelles of AOT, it was proposed that linoleic acid is incorporated into the micelle with the carboxylic group being directed toward the aqueous cavity containing the enzyme, and that only the substrate intercalated in the boundary surfactant layer would be transformed by the lipoxygenase (4). Such an assumption would imply that the carboxylic group, rather than the methyl tail, of the fatty acid molecule is accessible for the enzyme. In this case the lipoxygenase should act as "5-lipoxygenase" forming 5-HpETE and 9-HpODE from arachidonic acid and linoleic acid, respectively. The aim of the present study was to clarify whether the regio- and stereospecificities of highly active soybean lipoxygenase-1 in hydrated reverse micelles of AOT are identical to those in an aqueous system or whether inverse binding of the substrate occurs at the active site of the enzyme.

MATERIALS AND METHODS

Chemicals. AOT (Aerosol OT; dioctylsulfosuccinate, sodium salt; sodium *bis*(2-ethylhexyl)sulfosuccinate; research grade) was purchased from Serva (Heidelberg, Germany). *n*-Octane was purified by shaking three times with 0.03–0.04 volumes of 20% sulfur trioxide in concentrated sulfuric acid (oleum), followed by repeated washes with concentrated sulfuric acid, water, 2% NaOH, and again with water until neutral. After drying over anhydrous sodium sulfate, the solvent was distilled by means of a Vigreux column and shown to be spectrally pure in the ultraviolet (UV) region. Linoleic acid (analytical grade) and arachidonic acid (research grade) were obtained from Serva. Since the linoleic acid contained detectable amounts of oxygenation products, as judged from both thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC), it was purified on a silica gel column with *n*-hexane/diethyl ether (9:1, vol/vol) as developing solvent.

Purification of lipoxygenase. Fifty grams of air-dried vegetable soybeans, variant *Dorado* (VEB Saat- und Pflanzgut, Quedlinburg, Germany) were homogenized by means of a rotating knife-homogenizer (coffee grinder). The soya flour was defatted three times at −18 to −21°C (ice/NaCl mixture) with 100 mL acetone each. The defatted flour (about 42 g) was extracted with 7.5 vol of oxygen-free sodium acetate buffer, pH 4.5, for 1 h under shaking. The extract was centrifuged [Sorvall angle centrifuge (Newton, CT) at 16,000 × *g*, 15 min, 4°C] and the pellet was discarded. The lipoxygenase was precipitated by ammonium sulfate at a saturation of 0.63 at 0°C. The precipitate was dissolved in 0.01 M Tris buffer (pH 6.8) and dialyzed against the same buffer and frozen in small portions in liquid nitrogen until use.

Final purification was performed at 22°C by fast protein liquid chromatography using an analytical MONO Q HR5/5 column; (Pharmacia-LKB, Freiburg, Germany);

Abbreviations: AOT, Aerosol OT, dioctylsulfosuccinate sodium salt, sodium *bis*(2-ethylhexyl)sulfosuccinate; 13-HpODE, 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid; 15-HpETE, 15*S*-hydroperoxy-5*Z*,8*Z*,11*Z*,13*E*-eicosatetraenoic acid; DNP, 2,4-dinitrophenol; MOPS, 4-morpholino-propanesulfonic acid; HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography, UV, ultraviolet.

16 mg protein of the ammonium sulfate precipitate were applied. 4-Morpholino propanesulfonic acid (MOPS) buffer (0.01 M), pH 6.8, was used as starting solution, elution was by a gradient of NaCl (up to 0.2 M) in the same buffer. The buffers were degassed before use by sonication. Soybean lipoxygenase-1 was eluted at 0.18 M NaCl and shown to be 94% pure by polyacrylamide gel electrophoresis in sodium dodecylsulfate using a 10–20% gradient gel and Coomassie blue staining. Its turnover number immediately after purification at 25°C with linoleic acid as substrate was 350 s^{-1}. The preparation was devoid of lipoxygenase-2 and -3 as judged by the lack of aerobic formation of oxodienoic acids absorbing at 285 nm in water (9). For comparison, a commercial preparation of soybean lipoxygenase (Serva) was used which exhibited a turnover number of only 12 s^{-1}. 15-Lipoxygenase from rabbit reticulocytes was prepared as described (10).

Lipoxygenase assay. The activity of soybean lipoxygenase-1 in the aqueous system was measured at 25°C either spectrophotometrically at 234 nm (most experiments) or oxygraphically (experiment in Fig. 1) in 0.1 M borate buffer pH 9.0 with either linoleic acid or arachidonic acid as substrate. The substrate solutions were prepared by mixing 0.53 M stock solution in methanol with an equal volume of 0.53 M KOH and addition to 50 vol of borate buffer. The clear substrate solution was added to the assay mixture to a final concentration of 200 μM.

For activity measurements in the reverse micellar system at 25°C, the substrate fatty acid was dissolved in 1 mL of 0.05 M AOT in *n*-octane. Unless stated otherwise, a final concentration of 1.25 mM linoleic acid was used. Thereafter, 20 μL of 0.1 M sodium borate buffer, pH 9.0, was added and the mixture was vigorously shaken until optically transparent. After a preincubation period of 2 min, the reaction was started by addition of 2 μL of enzyme solution (final concentration, 20 nM). These conditions correspond to a hydration degree (molar ratio of water/AOT; w_0 value) of 25, which has been reported to afford maximal lipoxygenase activity (4,5). The reaction was followed by means of a Shimadzu UV-2100 spectrophotometer (Duisburg, Germany) at 245 nm. Measurements at the absorbance maximum of the conjugated dienes were not possible, owing to the high absorbance of AOT at this wavelength.

The oxygenation rates were estimated from the absorbance changes using molar absorption coefficients of 23,000 $M^{-1}cm^{-1}$ at 234 nm and 14,500 $M^{-1}cm^{-1}$ at 245 nm, respectively. The molecular activities of the lipoxygenase were calculated from the oxygenation rates and the protein concentrations in the assay samples presuming a molecular mass of 100,000 for soybean lipoxygenase-1.

Analytical methods. The reaction products from linoleic acid or arachidonic acid were identified by straight-phase HPLC using a Shimadzu instrument coupled to a Hewlett-Packard diode array detector 1040 A (Bad Homburg, Germany) on a Zorbax-SIL column (250 × 4.6 mm, 5 μm particle size; DuPont, Wilmington, DE) with the solvent system *n*-hexane/isopropanol/acetic acid (100:2:0.1, vol/vol/vol), and a flow rate of 2 mL/min. The absorbance at 235 nm (conjugated dienes) was recorded. For identification of the enantiomers, the methyl esters of the hydroxypolyenoic fatty acids (obtained by reduction of the hydroperoxy compounds by triphenylphosphine and subsequent methylation with diazomethane) were separated by chiral-phase HPLC on a dinitrobenzoyl phenylglycine column (chiral phase ionicly linked to silica gel, 260 × 4.6 mm, 5 μM particle size, Baker Chemical Co., Gross-Gerau, Germany) with the solvent *n*-hexane/isopropanol (100:0.25, vol/vol) at a flow rate of 1 mL/min (11). The compounds were generally identified by co-injection of authentic standards which were prepared and purified by HPLC and identified as described earlier (11).

The concentrations of linoleic acid and 13-HpODE (13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid) were determined by reverse-phase HPLC on a Nucleosil C18 column (KS system, 250 × 4 mm, 5 μm particle size; Macherey-Nagel, Düren, Germany) with the solvent methanol/water/acetic acid (10:10:0.1, vol/vol/vol) at a flow rate of 1 mL/min; linoleic acid and 13-HpODE were detected at 205 nm and 235 nm, respectively. The chromatograms were quantified by integration of peak areas.

Sedimentation of the reverse micelles. A 5-mL sample of the lipoxygenase assay mixture in reverse micelles of AOT (see above) was centrifuged at 180,000 × *g* for 2.5 h at 25°C in a Beckman L8-70 ultracentrifuge (Palo Alto, CA; swing-out rotor) before or 20 min after addition of lipoxygenase. In the latter case, oxygen gas was bubbled through the mixture before ultracentrifugation to avoid anaerobic conditions owing to the continuation of the lipoxygenase reaction. Moreover, 0.21 mM 2,4-dinitrophenol (DNP) as a marker for aqueous reverse micelles was added to the samples before ultracentrifugation. After ultracentrifugation, fractions of 0.5 mL were collected by means of a syringe and analyzed for DNP (optical density at 345 nm) and for linoleic acid and 13-HpODE (reverse-phase HPLC, see analytical methods).

RESULTS

In agreement with other authors (3–6) we found that soybean lipoxygenase-1 is active in hydrated reverse micelles of AOT. The reaction toward linoleic acid or arachidonic acid was linear for 15–20 min (not shown), indicating that neither depletion of substrate fatty acid, nor of oxygen, nor time-dependent inactivation of enzyme occurred under these conditions. The molecular activities of the enzyme in the aqueous and in the organic system containing reverse micelles are listed in Table 1. It is evident that in the aqueous system both the highly active purified enzyme and the commercially available preparation are more active than in the organic system by one order of magnitude.

One possible reason for the comparatively low activities in hydrated reverse micelles might be the inhibition of the lipoxygenase by AOT, which was shown to occur in the aqueous system; 50% inhibition was observed at about 1.5 mM AOT (Fig. 1). In this experiment, the lipoxygenase activity was assayed oxygraphically because of the turbidity that occurred in the aqueous system at high concentrations of AOT. The inhibition did not depend on the concentration of linoleic acid in the range between 0.16 and 1.0 mM. This observation argues against a competition between substrate and AOT for the active site of the enzyme. For this reason, the inhibition by AOT cannot account for the $Ks_{0.5}$ values in the reverse micellar system which have been reported to be two orders of magnitude higher than in the aqueous system (4,5).

	Own preparation	Serva	Serva
Medium	$V_m(s^{-1})$	$V_m(s^{-1})$	$V_m(s^{-1})$
0.1 M Sodium borate buffer, pH 9.0	100[a]	12	18
Reverse micelles of 0.05 M AOT in *n*-octane (w_0 = 24)	6.8	3.3	5.3

[a]Actual value after storage of the purified enzyme for five months.

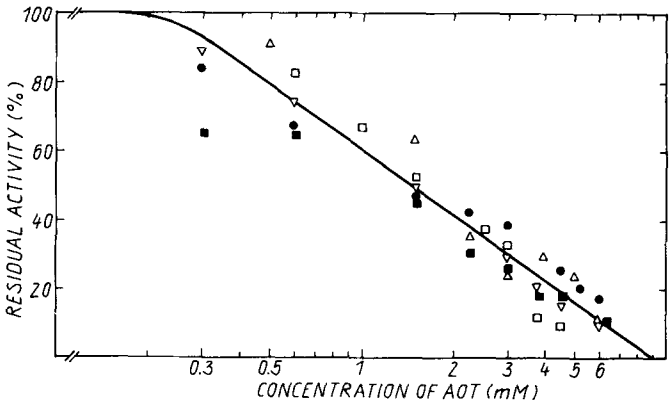

FIG. 1. Inhibition of soybean lipoxygenase-1 by AOT in 0.1 M borate buffer, pH 9.0, using commercial enzyme (Serva). Lipoxygenase activity was measured oxygraphically with linoleic acid as substrate at concentrations of 0.16 mM (□), 0.20 mM (△), 0.32 mM (▽), 0.48 mM (●), and 1.0 mM (■).

We failed to observe a reaction of the 15-lipoxygenase from rabbit reticulocytes in hydrated reverse AOT micelles under various experimental conditions (not shown). In the aqueous system we observed complete inhibition of this enzyme at AOT concentrations as low as 0.1 mM. We conclude, therefore, that the reticulocyte 15-lipoxygenase may be completely inhibited by AOT in the organic micellar system.

The reaction products of soybean lipoxygenase-1 from linoleic and arachidonic acids in both the aqueous system and the organic system containing reverse micelles were identified by straight-phase high-pressure liquid chromatography (Fig. 2 and Table 2). In both systems, products turned out to be nearly exclusively 13-HpODE and 15-HpETE as judged by co-injection of authentic standards. Separate experiments using chiral-phase HPLC indicated that in all cases (both with the commercial enzyme and the highly active enzyme) the *S* enantiomer was formed exclusively (Table 2). Thus, the specificity of soybean lipoxygenase-1 in hydrated reverse AOT micelles is actually identical to that in aqueous systems.

To estimate the distribution of substrate and product in the *n*-octane/H_2O/AOT system, the hydrated reverse micelles were sedimented by ultracentrifugation. DNP was added as a marker for the micelles, since this compound is known to be exclusively entrapped in the reverse micelles (12). After ultracentrifugation, fractions were collected and analyzed for DNP, linoleic acid and 13-HpODE. The data are compiled in Table 3. It is evident that both linoleic acid and 13-HpODE are strongly associated with the reverse micelles (bottom fractions 8 and 9). The two compounds appear to differ, however, with respect to their concentration in the *n*-octane phase. While 13-HpODE

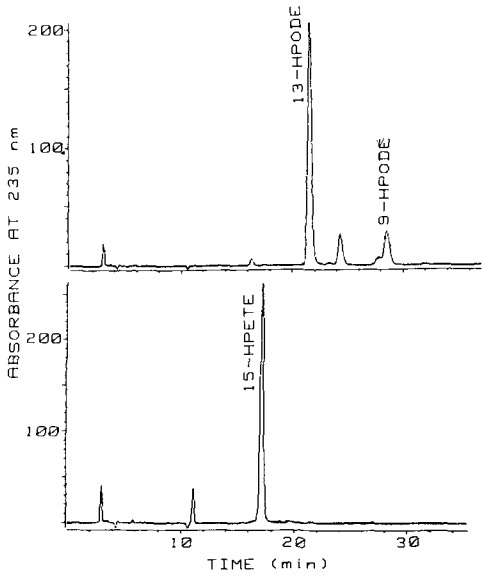

FIG. 2. Straight-phase HPLC of the dioxygenation products from linoleic (upper panel) and arachidonic acid (lower panel) in hydrated reverse micelles of AOT in *n*-octane. Purified soybean lipoxygenase-1 (20 nM) was incubated with the substrate fatty acid (see Materials and Methods) for 20 min at 25°C. Aliquots were directly applied to the HPLC column.

Dioxygenation Products from Linoleic and Arachidonic Acids in an Aqueous System and in an Organic System Containing Reverse Micelles of AOT[a] (w_0 = 23)

	Products (%) from		
	Linoleic acid		Arachidonic acid
Medium	13-HpODE	9-HpODE	15-HpETE
0.1 M Sodium borate buffer (pH 9.0)	95 (96:4 *S/R*)[b]	5 (50:50 *S/R*)	>98 (99% *S*)
Reverse micelles of AOT in *n*-octane	>98 (99:1 *S/R*)	—	>98 (>99% *S*)

[a]Soybean lipoxygenase-1 (50 nM in the aqueous system, 200 nM in the organic system) was incubated at 25°C with the substrate fatty acid for either 5 min in the aqueous system or 20 min in the organic system. The reaction products were extracted from the aqueous system twice with diethyl ether and analyzed by straight-phase HPLC. From the organic system, aliquots were directly applied onto the HPLC column.

[b]The percentages of the *S* and *R* enantiomers are given in parentheses. For analysis, the hydroperoxy fatty acids were reduced with triphenylphosphine followed by methylation of the carboxylic group with diazomethane. The hydroxypolyenoic acid methyl esters obtained were repurified by straight-phase HPLC and thereafter separated by chiral-phase HPLC (see Materials and Methods).

TABLE 3

Distribution of 2,4-Dinitrophenol, Linoleic Acid and 13*S*-Hydroperoxy-9*Z*,11*E*-octadecadienoic acid (13-HpODE) in Reverse Micelles of AOT (w_o = 23) After Ultracentrifugation

[a]The distribution of linoleic acid in a sample without enzyme was similar (not shown).

[b]The concentration of the bottom fraction was set as unity; absolute values: DNP, A_{345} = 8.40; linoleic acid, 123 mg/mL; and 13-HpODE, 0.67 mg/mL.

largely follows the sedimentation course of DNP indicating nearly exclusive localization in the micelles, linoleic acid exhibits about four-fold higher relative concentrations in the upper fractions containing only small amounts of reverse micelles, which suggests a low but detectable concentration of linoleic acid in *n*-octane.

The experiment described in Table 3 does not discriminate between the possibilities of a preferred localization in the AOT monolayer or in the aqueous interior space. However, in a separate experiment we found that in the two-phase system *n*-octane/0.1 borate buffer (pH 9.0) containing AOT, almost the entire amount of linoleic acid is located, after phase separation, in a milky interphase, whereas only small amounts were present in both the *n*-octane and the aqueous phases (not shown). This observation argues against a preferential localization of linoleic acid in the aqueous interior of the micelles.

DISCUSSION

The data presented here indicate that the specificity of the reaction of soybean lipoxygenase-1 in hydrated reverse micelles of AOT is identical to that in aqueous systems. The data further show that the substrate fatty acid is preferentially incorporated into the micelles rather than dissolved in *n*-octane. It is reasonable to assume that the polyenoic fatty acid is preferably localized in the AOT monolayer (surfactant shell) of the reverse micelles, as is known for naphthoic acid, which is also a nonpolar carboxylic acid (2). Considering their solubility properties, a preferred localization of fatty acids in the aqueous interior of the AOT micelles appears rather unlikely. The results of the analysis of lipoxygenase products in the reverse micelles are in line with the assumption that the fatty acid reaches the active site of the enzyme by diffusion from the surfactant shell into the aqueous interior. The alternate possibility that the enzyme directly reacts with the fatty acid intercalated in the surfactant shell can be excluded. In the latter case, the carboxylic group of the fatty acid would be primarily accessible for the enzyme, which would lead to the formation of 9-HpODE and 5-HpETE, respectively.

The much lower activity of soybean lipoxygenase-1 in hydrated reverse micelles of AOT than in water differs from the behavior of a variety of other enzymes showing superactivity in the organic system (13,14). The reason for this peculiarity of lipoxygenases is not clear. Both inhibition of lipoxygenases by AOT and limited substrate diffusion to the active site of the enzyme may play a role. A dose-dependent inhibition of soybean lipoxygenase-1 by AOT was demonstrated in the aqueous micellar system. It is, however difficult to extrapolate from these conditions to those that exist in hydrated reverse micelles. Moreover, one cannot extrapolate the lipoxygenase activity in reverse micelles of AOT to conditions without inhibition by AOT.

Despite the disadvantage of low activity, the reaction of soybean lipoxygenase-1 in hydrated reverse micelles of AOT may be useful for the preparation of certain hydroperoxy fatty acids. During our study we observed that the product from linoleic acid, namely 13-HpODE, was stable for several days after the end of the reaction in reverse micelles, whereas in the aqueous system there is a rapid destruction of the hydroperoxy compound unless special precautions are taken.

ACKNOWLEDGMENTS

The authors are grateful to Mrs. A. Ostareck-Lederer for preparing the enzyme during her thesis work, as well as to Professor S.M. Rapoport for valuable discussions. This work was supported by a fellowship of the Deutscher Akademischer Austauschdienst to T.N.S. and in part by a grant from the Federal Ministry for Research and Technology of the F.R.G. (Support No. 0319786A).

Cell Membranes and Multilamellar Vesicles: Influence of pH on Solvent Induced Damage

Myra K. Jacobsohn[a,b,*], **Melanie M. Lehman**[b] and **Gert M. Jacobsohn**[a]

[a]Department of Biological Chemistry, Hahnemann University, Philadelphia, Pennsylvania 19102 and [b]Department of Biology, Beaver College, Glenside, Pennsylvania 19038

Pigment leakage from sheep and horse erythrocytes and from red beet tissue induced by non-polar solvents was determined as a function of pH. The results were compared to disruption of multilamellar vesicles (MLV) composed of phospholipids with equimolar cholesterol under identical conditions of solvent exposure and pH. Solvent access to cholesterol was used to measure vesicle disruption. MLV were made from 1,2-dioleoyl phosphatidylethanolamine, sphingomyelin (SP) and various phosphatidylcholines to simulate the major lipid components of membranes. Pigment leakage from erythrocytes caused by petroleum hydrocarbon (b.p. 60–80°C) was maximal at pH 2–4 and at pH 10, but minimal at pH 6.8; alcohols caused less pigment leakage than petroleum hydrocarbon. Betacyanin leakage from beet tissue induced by petroleum hydrocarbon was maximal at pH 2, with very little leakage at pH 4, 6.6 and pH 10. Alcohols caused minimal damage to beet tissue above pH 2. Cholesterol removal by petroleum hydrocarbon from MLV of mixed lipid composition was maximal at pH 2–4, reduced at pH 6.8 and minimal at pH 10. Lipid mixtures in which fatty acyl side chains of one phospholipid were of a different length than the other lost more sterol than mixtures in which the acyl side chains were of identical chain length. MLV with more than 25% SP lost more sterol than those with less or no SP. Results show that in mixtures of phospholipids, SP exposes the hydrocarbon phase of a bilayer to solvent extraction, a property that was also observed in native membranes. Erythrocyte membranes, which contain SP, were more severely damaged by petroleum hydrocarbon than beet cells, which have none. Membranes from erythrocytes were more prone to solvent disruption at pH 10 than MLV, but they were more resistant at physiological pH. It is suggested that conformational changes in membrane proteins due to shifts in pH cause exposure of hydrophobic portions of surrounding lipids to the environment. At neutral pH, the native conformation of proteins is expected to stabilize the bilayer of membranes.

***Lipids 27,* 694–700 (1992).**

We have applied a simple physico-chemical procedure to study the stability of bilayers formed from single or mixed phospholipids. The criterion for stability was the capacity of bilayers to retain cholesterol upon exposure to a non-polar solvent. The assumption was that if phospholipids form stable bilayers, the polar head groups would repel the solvent and allow for only limited extractability of cholesterol. If the packing of the bilayer was unstable, or if the lipids formed a reverse hexagonal phase, cholesterol would become accessible to the non-polar solvent and the sterol would be extracted. This method was used previously to study the influence of side chain mobility, head group type and pH on the stability of bilayers (1,2). Results showed that at moderately acid to neutral pH, phospholipids with mobile side chains and/or those with ethanolamine-containing head groups form unstable bilayers from which cholesterol and phospholipids are readily removable, which may be a manifestation of reverse hexagonal phase formation (3). Conditions which would cause the head groups to occupy more space, *i.e.,* like charges and increased hydration, would increase the stability of bilayers.

In the present study, we compared the effect of organic solvents upon pigment leakage from whole cells to disruption of the lipid structure of multilamellar vesicles (MLV) caused by the same solvents. Leakage of betacyanin from beet root cells and of hemoglobin from erythrocytes were used as indicators of disruption of cell membranes. Pigment leakage was compared to cholesterol extraction from mixed lipid MLV under similar conditions of pH and solvent exposure. Cell membranes were expected to differ from model systems because native membranes include substantial amounts of protein which may be subject to conformational changes by pH and because the lipid compositions of model vesicles were not exact duplicates of those in membranes.

MATERIALS AND METHODS

Fresh beets were purchased from a local market. Sheep and horse erythrocytes were obtained from Environmental Diagnostics (Burlington, NC). Blood cells were washed at least three times with isotonic phosphate buffer, pH 6.8, prior to use and were made up to a uniform 50% suspension in the same buffer. Cells were held at 4°C until use.

Dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) and dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) were purchased from Avanti Polar Lipids (Alabaster, AL); bovine brain sphingomyelin (SP) was obtained from P-L Biochemicals (Milwaukee, WI); dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) was from Sigma Chemical Co. (St. Louis, MO). Cholesterol was recrystallized twice from methanol. [4-^{14}C]Cholesterol was obtained from Amersham (Arlington Heights, IL). The purity of phospholipids was checked by thin-layer chromatography on silica gel G plates developed with chloroform/methanol/water (65:25:4, vol/vol/vol) and visualized with iodine vapors. All other substances and solvents were reagent grade and were used without further purification.

Stability of cell membranes. The stability of beet root membranes was determined by a modification of the method described by Grunwald (4). Cores were cut from beets with a cork borer (#4) and sectioned freehand with a razor blade into 3-mm slices. The end slices from each core were discarded and the remaining slices were washed under cold running tap water for several hours or overnight. To initiate an experiment, 10 root slices were placed

in each of fifteen 100-mL beakers, with 9.0 or 10.0 mL of a designated sucrose-buffer solution. Buffers were 0.4 molal with respect to sucrose. The buffers used were 0.1 M KH_2PO_4 and phosphoric acid at pH 2.0; 0.1 M 2-(*N*-morpholino)ethanesulfonic acid (MES)/NaOH at pH 4.0; KH_2PO_4/NaOH at pH 6.6 or 6.8; 0.1 M cyclohexylaminopropanesulfonic acid (CAPS)/NaOH at pH 10.0. For controls, beet root slices were incubated in 10.0 mL of a sucrose-buffer; for solvent treated samples, they were incubated in 9.0 mL of a sucrose-buffer with 1.0 mL of either methanol, ethanol, a 2:1 (vol/vol) mixture of chloroform/methanol, or petroleum hydrocarbon (b.p. 60–80°C). The organic solvents were added at the start of an experiment. At time zero and periodically thereafter, the absorbance of betacyanin at 535 nm was determined. All incubates were kept at 22–23°C in a constant temperature bath with continuous shaking. Incubations continued for 2 h, and all experiments were run in duplicate.

For experiments on erythrocytes, incubations were carried out at room temperature. The same series of buffers described for the beet cell experiments were used except that pH 6.8 was substituted for pH 6.6 and the buffers were made isotonic with NaCl. Experiments were initiated by addition of 200 μL of a 50% red cell suspension. The contents of each tube were mixed immediately after addition of red cells and were agitated by vortexing briefly every 20 s. After 10 min, the tubes were centrifuged for 10 or 20 min in a benchtop centrifuge to sediment unlysed cells, membranes and denatured hemoglobin. Absorbance of supernatants was read at 590 nm. All experiments were run in triplicate.

Stability of multilamellar vesicles. The effect of pH on pigment leakage from cells or vesicles was compared to the loss of cholesterol from bilayers prepared from pure lipids. MLV were prepared from phospholipids in approximately similar proportions to those reported in the literature for that type of cell. Phosphatidylcholine (PC), phosphatidylethanolamine (PE) and SP lipids with equimolar amounts of sterol, to which [4-^{14}C]cholesterol (22,000 cpm) had been added, were incorporated into MLV. The procedure for making and incubating MLV and extracting them with petroleum hydrocarbon has been described previously (2). A slight change in the procedure was made in that lipid films were suspended in 0.4 mL of appropriate buffer solutions for 10 min prior to vortexing with glass beads, and the samples were left undisturbed for 45 to 60 min prior to extraction with solvent. In some of the experiments, the three sequential petroleum hydrocarbon extracts of each sample were assayed individually. Extracted cholesterol was determined by scintillation counting of the residue left, after evaporation of the solvent, in Ecoscint fluid (National Diagnostics, Manville, NJ). The pattern of cholesterol removal from the vesicles revealed information about the environment of the hydrocarbon components of the bilayers.

RESULTS

Betacyanin leakage from beet root cells. Incubation of beet root slices in sucrose-buffer solutions with and without organic solvents for a period of 2 h showed that near maximum amounts of pigment leakage due to chloroform/methanol (C/M) occurred within 30 min after the start of the experiment. Data for pH 6.6 are shown in Figure 1. Pigment leakage with other solvents increased linearly over the 2 h time span with leakage caused by solvents only slightly higher than that observed in samples with no solvent (Fig. 1, insert). In the beet cell and later in the erythrocyte experiments, we observed that pigment leaking from cells was affected by pH. Hemoglobin turned brown and precipitated at low pH, while betacyanin slowly turned yellow at high pH. Denatured hemoglobin exhibited maximum absorbance at 590 nm. Betacyanin was measured immediately at the end of incubation. Alterations in the pigments due to pH were reflected in changes in absorbance. In order to compare samples at one pH with the others, we assigned pigment leakage due to C/M as the maximum (100%) that could be obtained from cells at any given pH. Pigment leakage from all other samples, including controls with no organic solvent, were compared to C/M samples at the same pH and expressed as percent of maximum leakage. We calculated the percentage of maximum damage based upon pigment leakage after 30 min of incubation. The experiment was repeated twice and yielded the same pattern of results each time, but absolute values for pigment leakage differed with different batches of beets.

Results for one experiment are depicted in Figure 2. At pH 2.0, the samples without organic solvent showed considerable pigment leakage. Addition of any organic solvent increased the amount of betacyanin leakage, but ethanol and petroleum hydrocarbon caused the most damage. At pH 4.0 and 6.6, none of the samples with or without organic solvent showed any significant amount

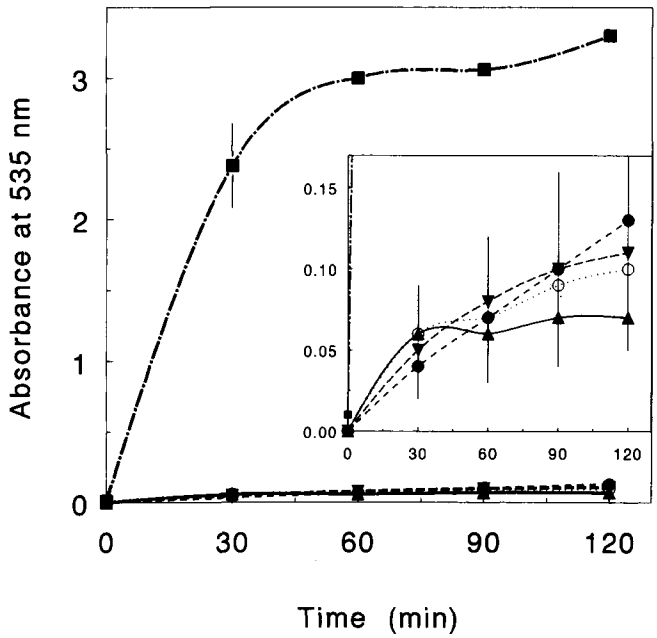

FIG. 1. Effect of solvents on betacyanin leakage from beet root tissue at pH 6.6 as function of time. Pigment leakage was measured by the increase in absorbance at 535 nm of the sucrose-phosphate buffer. Organic solvents were present to the extent of 10% of the volume of the suspending medium. The insert shows data on an expanded ordinate. All points are averages for three independent experiments. Standard deviations are within symbols or are shown by vertical bars. ▲, Buffer alone; ○, methanol; ▼, ethanol; ●, petroleum hydrocarbon; ■, chloroform/methanol (2:1, vol/vol).

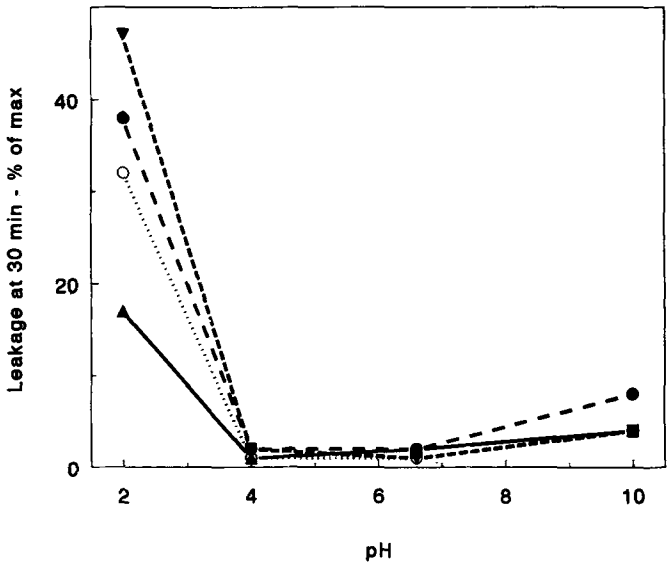

FIG. 2. Effect of solvents on betacyanin leakage from beet root tissue as function of pH at 30 min. Absorbance at 535 nm of samples exposed to an organic solvent at a given pH was compared to absorbance at the same pH and wavelength of samples exposed to chloroform/methanol (2:1, vol/vol). Organic solvents were present to the extent of 10% the volume of the suspending medium. Conditions are described under Materials and Methods. All points are averages for three independent experiments. Standard deviations are included within symbols or are shown by vertical bars. ▲, Buffer alone; ○, methanol; ▼, ethanol; ●, petroleum hydrocarbon.

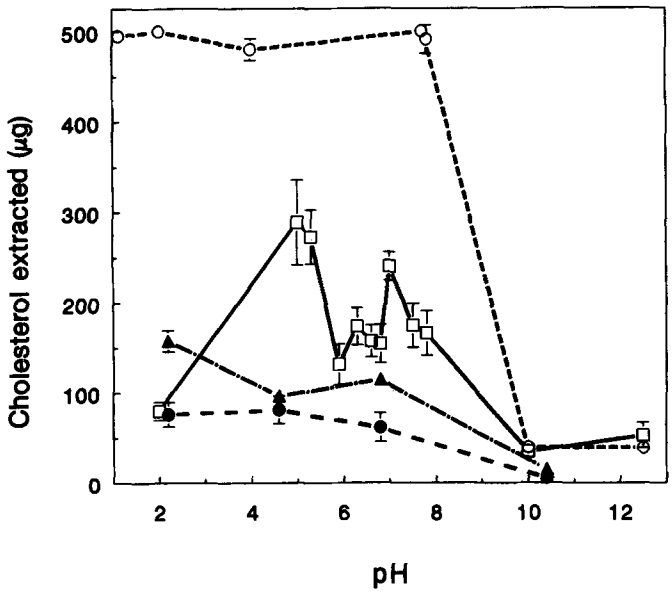

FIG. 3. Cholesterol extraction from MLV of DOPC/cholesterol (1:1, molar ratio), DOPE/cholesterol (1:1, molar ratio), DOPC/DOPE/cholesterol (1:1:2, molar ratio) or SP/DOPC/DOPE/cholesterol (0.5:0.5:1:2, molar ratio) related to the pH of the suspension media. MLV were prepared from pure phospholipids with [4-^{14}C]cholesterol equimolar to total phospholipids. The MLV were extracted three times with petroleum hydrocarbon. Details are given in the Methods section. Plots show the sum of cholesterol removed in all extracts. Experiments were done in triplicate and averages are indicated. Standard deviations are included in the symbols or are shown by vertical bars. □, DOPC; ○, DOPE; ▲, DOPE/DOPC; ●, SP/DOPC/DOPE.

of pigment leakage compared with leakage caused by C/M. At pH 10.0, pigment leakage from samples without organic solvent increased slightly, but organic solvents caused little, if any, additional leakage. Except at pH 2.0, organic solvents did not significantly aggravate damage due to changes in pH.

In order to compare the behavior of beet cells with that of pure lipid bilayers, MLV of lipids similar to those found in beet root tissue were prepared. Phospholipid analysis of beet root tissue reported by Beiss (5) showed that PC constituted 35% of the lipid and PE 17%, with phosphatidylserine (PS) and phosphatidic acid making up the balance. A combination of DOPC/DOPE/cholesterol (1:1:2, molar ratio) was used as an analog to beet cell membranes. We have previously found the extractability characteristics of MLV made from PC with two 18:1 side chains (DOPC) to be very similar to those of PC with one 16:0 and one 18:1 side chain (2). These MLV lost decreasing amounts of cholesterol upon extraction as the pH increased. At pH 2.2, about 150 μg or 30% of the sterol were lost; at pH 4.6 and 6.8, 100 μg or 20% was lost and at pH 10.4, less than 50 μg or 10% was lost (Fig. 3). While this pattern of data was similar to that observed with whole cells, a minimum of cholesterol extraction did not occur in the physiological range, nor were the properties of the mixed lipid vesicles an intermediate between the characteristics of the single lipid components. To determine whether similarity of head groups or of acyl side chains was responsible for the characteristics of the lipid vesicles, MLV of DPPC and DOPE (1:1) with equimolar cholesterol were prepared and studied for cholesterol loss to nonpolar solvent. Results are shown in Figure 4. These mixed lipid vesicles had much the same characteristics with respect

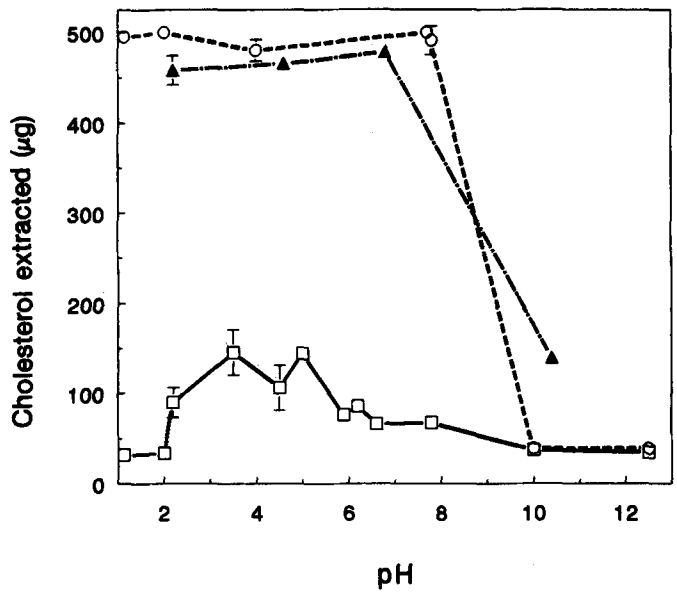

FIG. 4. Cholesterol extraction from MLV of DPPC/cholesterol (1:1, molar ratio), DOPE/cholesterol (1:1, molar ratio) and DPPC/DOPE/cholesterol (1:1:2 molar ratio) as function of pH of suspending media. Legend as in Figure 3. □, DPPC; ○, DOPE; ▲, DPPC/DOPE.

to cholesterol extraction as those prepared from DOPE alone. More than 450 μg or 90% of the cholesterol was extracted at pH values below 6.8. At pH 10.4, 150 μg or 30% of the cholesterol was extracted, but this was more than

the amount extracted from single species vesicles. Data from these experiments and those reported earlier (2) indicate that acyl side chain length and unsaturation are important parameters in determining the stability of lipid bilayers.

Hemoglobin leakage from erythrocytes. Hemoglobin leakage from sheep and horse erythrocytes was determined after 10 min of incubation in isotonic buffer solutions of pH comparable to those used in the beet root experiments. Results for sheep erythrocytes are shown in Figure 5. At pH 2.0, buffered samples showed about 40% of maximum pigment leakage. Organic solvents did not greatly increase the leakage of pigment, except for petroleum hydrocarbon, which caused a maximum of 55% leakage. At pH 4.0 the differences were much more pronounced. At this pH the buffered red cells exhibited less pigment leakage than at pH 2.0, but about 20% more than was observed with betacyanin leakage from beet root cells. Methanol and ethanol did not increase pigment leakage from erythrocytes, but petroleum hydrocarbon showed nearly twice as much leakage as buffer incubated samples (40% *vs.* 20%). At pH 6.8, untreated and ethanol treated samples showed no pigment leakage, while methanol and petroleum hydrocarbon caused 8 to 10% leakage. At pH 10.0, there was virtually no leakage from samples with alcohols, but the ones incubated with petroleum hydrocarbon showed almost as much pigment loss as the C/M exposed samples (>80%).

Results with horse erythrocytes (Fig. 6) were similar to those with sheep erythrocytes with some notable exceptions. At pH 4.0, no hemoglobin leaked from buffered samples and very little leakage was observed with methanol or ethanol. Petroleum hydrocarbon, however, caused even more leakage than at pH 2.0. At pH 6.8, neither the buffered nor methanol or ethanol samples showed any pigment leakage, while petroleum hydrocarbon caused about 10% of maximum pigment leakage. At pH 10.0 there was no pigment leakage from buffered samples and very little from methanol or ethanol, but the leakage caused by petroleum hydrocarbon rose to 35%. This was less than half the damage observed in sheep erythrocytes with the same solvent.

The lipid compositions of membranes from sheep and horse erythrocytes differ considerably. The predominant phospholipids in sheep erythrocyte membranes have been reported to be SP (51.0%) and PE (26.2%) (6). We confirmed the absence of PC by isolating sheep erythrocyte ghosts, extracting the lipids with C/M, and analyzing them by thin-layer chromatography (TLC) (Jacobsohn, M.K., Lehman, M.M., and Jacobsohn, G.M., unpublished observations). Horse erythrocyte membranes contain 42.4% PC, 13.5% SP and 22.4% PE (6). The remainder of the phospholipid was mainly phosphatidylserine (PS). We measured cholesterol extractability from MLV of SP and mixtures of SP with PE or PC plus equimolar amounts of sterol and compared the data to hemoglobin leakage from erythrocytes.

Data on petroleum hydrocarbon extraction of cholesterol from vesicles of SP are shown in Figure 7. A mixture of SP/DOPE/cholesterol (1:1:2, molar ratio) allowed petroleum hydrocarbon to extract more than 480 μg or 95% of the sterol at pH <6.8, 460 μg or 92% at pH 6.8 and 250 μg or 50% at pH 10.4. The latter was unexpected because neither DOPE nor SP vesicles lost more than 10% of their cholesterol to petroleum hydrocarbon at this pH (Fig. 7). It should be pointed out, however, that there was considerable variation in the amount of sterol extracted at pH 6.8 from vesicles of SP and DOPE. Values ranging from a high of 92% to a low of 16% were observed. We

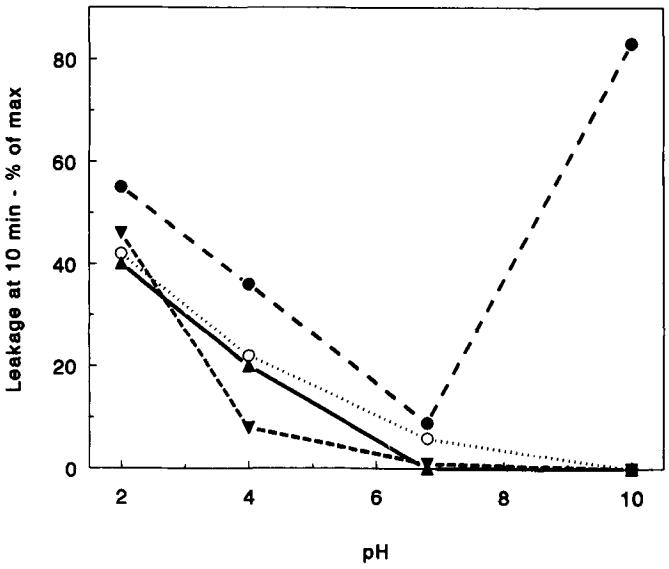

FIG. 5. Effect of solvents on hemoglobin leakage from sheep erythrocytes as function of pH at 10 min. Washed sheep erythrocytes were incubated in isotonic buffers of varying pH with or without an organic solvent. Organic solvents were present to the extent of 10% the volume of suspending media. Hemoglobin in the buffer was measured by absorbance at 590 nm and compared to similar leakage caused by chloroform/methanol, taken as 100%. Conditions are described in Materials and Methods. All points are averages for three independent assays. Standard deviations are within symbols or are shown by vertical bars. ▲, Buffer alone; ○, methanol; ▼, ethanol; ●, petroleum hydrocarbon.

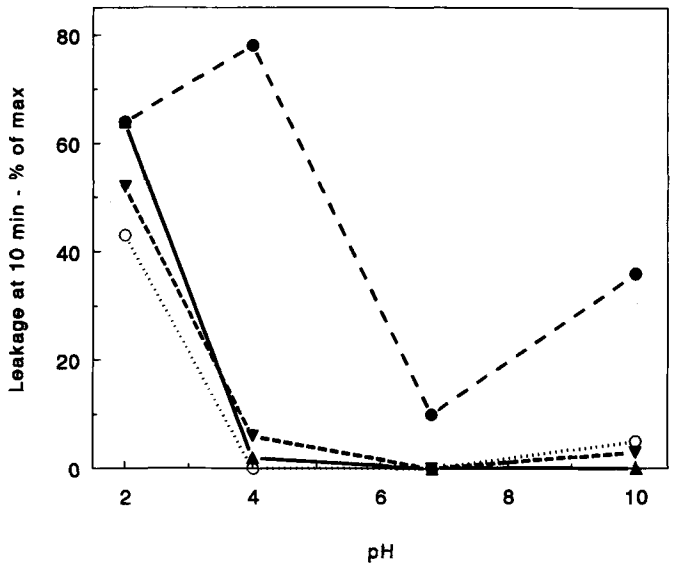

FIG. 6. Effect of solvents on hemoglobin leakage from horse erythrocytes as function of pH at 10 min. Washed horse erythrocytes were incubated in isotonic buffers of varying pH. Remainder of legend as in Figure 5. ▲, Buffer alone; ○, methanol; ▼, ethanol; ●, petroleum hydrocarbon.

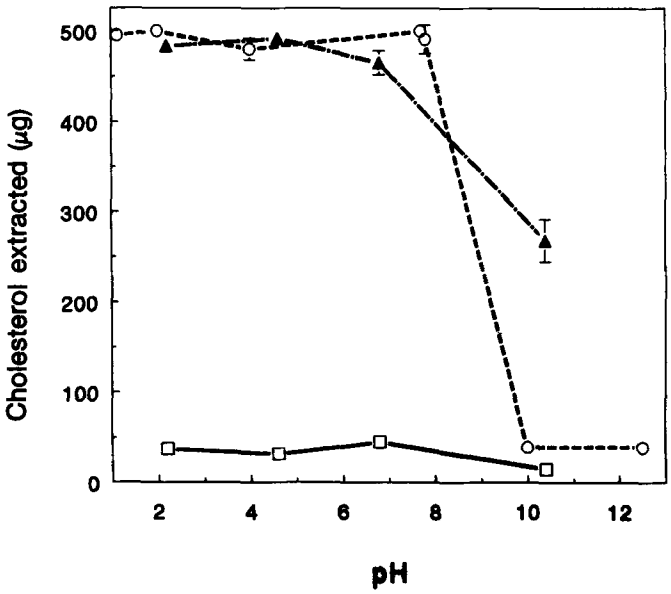

FIG. 7. Cholesterol extraction from MLV of SP/cholesterol (1:1, molar ratio), DOPE/cholesterol (1:1, molar ratio), and SP/DOPE/cholesterol (1:1:2, molar ratio) as function of pH of suspending media. Legend as in Figure 3. □, SP; ○, DOPE; ▲, SP/DOPE.

did observe consistency among the samples of any one batch of MLV. The differences suggested that the lipids did not always assume the same initial phase state (see below). MLV of SP/DOPC/DOPE/cholesterol (0.5:0.5:1:2, molar ratio) showed that 60 to 75 μg or 12 to 15% of the sterol was extracted with petroleum hydrocarbon at pH values below 10 and only 10 μg or 2% at pH 10.4 (Fig. 3).

The results of the three experiments revealed a number of interesting similarities and differences among the cell types. All of the cells displayed extensive pigment leakage at pH 2.0, and the presence of solvent tended to increase the amount of pigment lost. The beet cells were relatively insensitive to pH damage above pH 2.0, while sheep erythrocytes were stable only in the physiological range. Horse erythrocytes were more sensitive to pH changes than beet root cells, but less sensitive than sheep erythrocytes.

Extractability of cholesterol from MLV. Previous studies of cholesterol extraction from MLV made from single species of phospholipids had shown more cholesterol was extractable with petroleum hydrocarbon at low pH than at high pH (1). Phosphatidylcholines with long saturated acyl side chains were an exception in that they were unaffected by solvent extraction over the entire pH range. All of the phospholipids we examined were resistant to solvent extraction at high pH. While the pattern of pigment leakage from beet root cells with petroleum hydrocarbon followed the pattern of cholesterol loss from MLV, sheep and horse erythrocytes were much more sensitive to petroleum hydrocarbon extraction at high pH. We thought that the differences might be related to the lipid composition of the membranes.

Since lipid conformations, such as reverse hexagonal, (H_{II}) phases, would be expected to display different patterns of cholesterol extraction than bilayer phases, the amount of cholesterol removed from each of the MLV at each step of the extraction process was quantitated over the range of pH values used in the whole cell studies. Figure 8A shows the extraction pattern for cholesterol alone in various buffers. The first extraction removed 90% or more sterol from the buffers, with most of the remainder in the second extraction. The pH of the buffer had no effect upon the amount of cholesterol removed in each extraction. Figure 8B gives the extraction pattern for vesicles of SP/DOPE/cholesterol (1:1:2, molar ratio). At pH 6.8 and below, the extraction patterns for MLV that lost large amounts of sterol are very similar to those of cholesterol alone, with 68 to 77% of the sterol removed in the first extraction and indicating that sterol was accessible to the solvent at the outset. At pH 10.4, the pattern changed, with 17% of the cholesterol removed in the first extraction and 3 to 5% removed in each of the subsequent extractions. Elevation of pH rendered the lipids less accessible to the solvent. As noted earlier, at pH 6.8 there was variability in the amount of sterol extracted from SP/DOPE vesicles, but there was consistency with each subsequent extraction from the same vesicles. The results for DOPC/DOPE vesicles are shown in Figure 8C. For pH 2.2, 4.6 and 6.8, the results are similar to those observed with SP/DOPE at pH 10.4, Figure 8B. Fifteen to 22% of the sterol was removed in the first extraction, with an additional 5 to 8% being removed in each of the subsequent extractions. Relatively little sterol was exposed to the solvent initially, and the solvent itself did not make the lipid more accessible. At pH 10.4, the amount of sterol removed in each of the three extractions was virtually the same, less than 1% of the total. Figure 8D shows the results for vesicles of SP/DOPC/DOPE/cholesterol (0.5:0.5:1:2, molar ratio). At pH 2.2, 4.6 and 6.8, the amounts of cholesterol removed by each extraction were small but increased gradually with subsequent extractions, indicating that the lipid structure was altered by the solvent. At pH 10.4, the

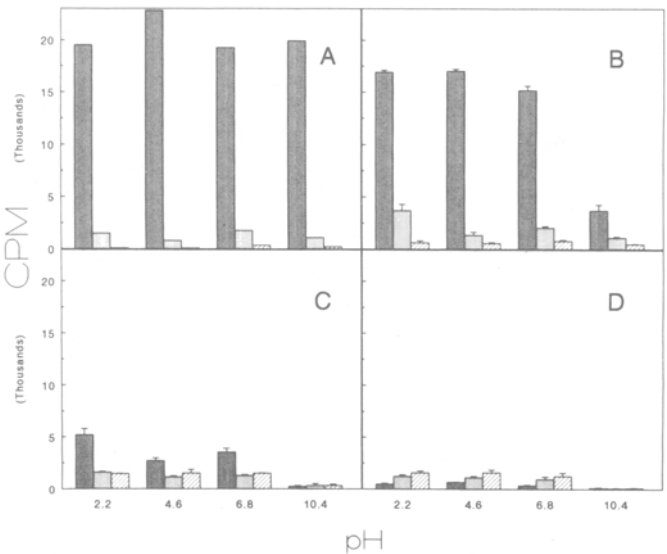

FIG. 8. Cholesterol removal from buffer and from suspensions of MLV by three successive petroleum hydrocarbon extracts as function of pH. Extractions by the organic solvent were assayed separately and are shown by vertical bars. A. Buffer only; B. MLV prepared from SP/DOPE/cholesterol (1:1:2, molar ratio); C. MLV prepared from DOPC/DOPE/cholesterol (1:1:2, molar ratio); and D. MLV prepared from SP/DOPC/DOPE/cholesterol (0.5:0.5:1:2, molar ratio). Crossed-hatched bars, 1st extraction; narrow lined bars, 2nd extraction; wide-lined bars, 3rd extraction.

amounts extracted were very low and did not increase from the first to the third extract. The extraction patterns at pH 10.4 indicated a more stable structure for vesicles of any given lipid composition, but the patterns at lower pH values suggest significant differences in the phase structures assumed by various combinations of lipids. SP particularly appears to promote configurations that make the hydrophobic portion of amphipathic lipids more accessible to a nonpolar solvent.

DISCUSSION

Studies on pigment leakage from beet root cells and erythrocytes show that pH can be a significant cause of damage to cell membranes. Natural membranes in the absence of solvent suffered more disruption at low pH than at high pH but none at physiological pH. In the presence of a highly nonpolar solvent, damage to cell membranes was influenced by pH, and the degree of disruption was related to the phospholipid composition of the membranes. The least disruption with organic solvents occurred at physiological pH. Solvents caused more damage to membranes containing SP than to those without this lipid and the disruption was proportional to the amount of SP in the membrane. Cholesterol extraction from MLV constructed with varying proportions of SP showed that petroleum hydrocarbon extracted more sterol from MLV at low pH than at high pH, with vesicles containing the highest proportions of SP showing the greatest loss of sterol. Vesicles in which the acyl side chains of phospholipids were equivalent in length and unsaturation were more stable than those in which the acyl side chains were different, as is evident by the difference in sterol retention among DPPC/DOPE, DOPC/DOPE and SP/DOPE vesicles. The pattern of cholesterol extraction from MLV suggests fundamental differences among bilayers formed by different combinations of phospholipids, some of which may be related to the presence of H_{II} phases. The notable difference between vesicles and cell membranes was the lack of maximum stability at physiological pH in the vesicles. None of the mixed lipid vesicles were resistant to petroleum hydrocarbon extraction of sterol at pH 6.8, whereas cells leaked a minimum of pigment at this pH.

The observation that pH and solvent induced instability of cell membranes and MLV was related to SP content was completely unexpected. Studies from other laboratories have shown that SP has as great or greater affinity for cholesterol than any other phospholipid (7–9), and even at low mole percent dehydroergosterol interacts preferentially with SP if the SP is the more fluid lipid in a mixture (10). Studies of cholesterol retention by SP vesicles reported here yielded the same result. We expected that membranes containing SP would be more stable than others since vesicles prepared entirely from SP lost almost no cholesterol by solvent extraction. The explanation of why membranes and vesicles of SP mixed with other phospholipids are more easily damaged by solvent stress at the ends of the pH scale most likely derives from disparity in their head groups coupled with differences in the conformation of their paraffin side chains.

Although the hydrocarbon portion of sphingosine is structurally similar to the acyl group at C-1 of the glycerol moiety of glycerophospholipids, it is shorter and carries a *trans* double bond at C-4. Further, the fatty acid attached to the amine group of sphingosine, which is analogous to the C-2 group of glycerophospholipids, can vary, but the predominating species reported from a variety of mammalian sources are 16:0, 18:0, 18:1, 20:4 and 22:6 (11). In most glycerolipids, the substituent on C-2 is an 18:1 or 18:2 fatty acid (11). The differences in hydrocarbon chain length and unsaturation may contribute to structural instability in SP-containing mixed lipid structures.

Another factor which may be involved in instability of bilayers containing SP is the asymmetric distribution of lipids within membranes. Weakly acidic phospholipids, such as PS, tend to accumulate on the basic side of a transmembrane gradient (12). In the absence of a gradient, the distribution of lipids in large vesicles is thought to be equal (13–15). Since the vesicles in the present investigation were prepared and processed in buffers of uniform pH and ion concentration and did not contain acidic phospholipids, it is unlikely that asymmetry in lipid distribution was induced. In our experiments with whole cells, pH induced lipid shifts within membranes may have occurred because of their PS content. Exposure to alkaline buffers would create pH gradients which can cause shifts in lipid distribution. Of the cells examined, beet membranes contain the highest proportion of PS, but these membranes were least affected by high pH. Thus it appears unlikely that shifts in lipid distribution within membranes would be a major cause of damage.

Indication that different phase states are assumed by the various mixed lipids in MLV was obtained from the extraction studies, based upon the following assumptions. If the phospholipids were initially in an H_{II} phase, then petroleum hydrocarbon would have ready access to sterol intercalated among the acyl side chains and to the side chains themselves. The partition coefficient for cholesterol would be close to that expected for cholesterol without phospholipid and the pattern of extraction should be similar to that of cholesterol alone in buffer. If the lipids were in a stable bilayer, each solvent extraction should remove small but constant amounts of cholesterol because the head groups of the phospholipids would protect the sterol. If the bilayer had an unstable structure, the head groups of the phospholipids might have gaps between them, or hydrogen bonding of head groups might draw a limited portion of the phospholipid into an H_{II} phase. Rand *et al.* (16) have described such behavior for mixtures of DOPC and DOPE at neutral pH. In such cases, the initial extraction with non-polar solvent would be expected to remove a relatively small amount of sterol from the vesicles, but invasion of solvent into the core of the bilayer would cause disordering, and more lipid would be removed with each subsequent extraction.

Data obtained for petroleum hydrocarbon extraction of cholesterol from mixed lipid vesicles exhibited all of the predicted patterns. Cholesterol was extractable from SP/DOPE vesicles in the same manner as from buffer, indicating that the hydrophobic portions of the vesicles were readily accessible to the solvent. At pH 10.4, the amount of extractable cholesterol was reduced, suggesting that the sterol had become inaccessible to the solvent, *i.e.*, that the orientation of the phospholipid phase had assumed a bilayer structure. Vesicles of DOPC/DOPE at pH 6.8 and below were similar to SP/DOPE vesicles at pH 10.4, except that the third extraction consistently

removed somewhat more sterol than the second extraction. This pattern is seen more clearly in the SP/DOPC/DOPE vesicles at pH 6.8 and below where the amounts increased slightly from the 1st to the 3rd extraction. At pH 10.4, only small amounts of sterol could be extracted, demonstrating that these vesicles were extremely resistant to solvent extraction. The present experiments provide, for the first time, evidence that SP promotes exposure of hydrophobic elements when it is combined with other lipids at a neutral pH or below.

The most striking observation was the stability of biological membranes at physiological pH compared to mixed lipid vesicles of defined composition. The MLV examined in these experiments lacked PS and trace phospholipids, and the fatty acyl composition of the major lipids was not equivalent to that of native membranes. While these discrepancies may account for some of the differences between MLV and cell membranes, we consider this unlikely to be the whole explanation. Evidence obtained in the present studies suggests that other factors, including proteins, may be responsible for the differences.

Pigment leakage from whole cells caused by petroleum hydrocarbon at pH 2 and at pH 10 was greater than would have been predicted from the cholesterol loss from analogous lipid vesicles. DOPC/DOPE vesicles lost less than 30% of their cholesterol at pH 2 upon extraction with petroleum hydrocarbon, but beet cells lost twice that percentage of pigment in the presence of solvent. The nearly complete extraction of pigment from erythrocytes observed at pH 2.0 was probably due to a combination of denaturation of membrane proteins and changes in lipid configuration. The observations with horse erythrocytes at pH 4 and 10 are also instructive. MLV with a lipid ratio similar to that of horse erythrocyte membranes lost about 20% of their cholesterol to the solvent at pH 4 but the erythrocytes leaked nearly 80% of their pigment under the same conditions. At pH 10, cholesterol extraction from MLV was negligible, but loss of pigment from erythrocytes was close to 40% of maximum. Loss of pigment from sheep erythrocytes was 80% of maximum at pH 10. If the effect of high pH is to denature protein but to maintain the lipid bilayer intact, petroleum hydrocarbon should not cause more pigment leakage than methanol and ethanol. Although petroleum hydrocarbon is a better solvent for the alkyl portion of membranes than alcohols, the negatively charged head groups at high pH would prevent access of petroleum hydrocarbon to the core of the membrane. Damage to membrane proteins induced by pH may influence the conformation of lipids to make the paraffin chains more accessible to a non-polar solvent.

Liu *et al.* (15,17) have noted that DOPE/oleic acid liposomes are stable over a wide range of pH and salt concentration when incubated with human plasma. They suggested that proteins from plasma insert into the core of lipid bilayers and found evidence of increased microviscosity in the core when protein was present. Hui and Sen (18) have found that lipids with non-cylindrical molecular shapes are associated with a high protein content of membranes. Sunamoto *et al.* (19) have reported that a PC analog of SP facilitated the insertion of glycoprotein into dimyristoyl phosphatidylcholine vesicles and also reduced the fluidity at the bilayer surface. Studies of fibroblasts by fluorescence recovery after photobleaching showed that lateral diffusion of phospholipids was nearly ten times slower in protein-containing membranes than in pure liposomes and that lipid diffusion in membranes is limited to the bulk phase between protein domains (20). Boggs *et al.* (21) have shown that myelin basic protein, lipophilin, preferentially binds phosphatidylserine in mixed PS-PC bilayers. Evidence suggests that proteins interact selectively with phospholipids, but once the proteins are in place, they exert an ordering effect on lipids that extends beyond their immediate domain. Changing the conformation of a protein by raising or lowering the pH from its optimal range may potentiate the formation of lipid phase structures that expose the hydrophobic portion of the bilayer to external influences.

The study of mixed lipid vesicles has proved to be a useful model in interpreting some of the characteristics of cell membranes under pH or solvent stress, but it has also underscored the limitations of extrapolating the properties of lipid bilayers to the dynamics of biological membranes. Predictions about the properties of membranes based on studies of single species of phospholipids or even combinations of two or more lipids are not always an indicator of how a cell membrane will behave. Other factors, most likely proteins, may modify lipid interactions, but the role of proteins *vis-a-vis* lipid structure is not sufficiently understood.

Evaluation of an Oleic Acid Water-in-Oil-in-Water-Type Multiple Emulsion as Potential Drug Carrier *via* the Enteral Route

Noriyuki Oba*, Hisao Sugimura, Yasuhiko Umehara, Masayuki Yoshida, Taizo Kimura and Takaji Yamaguchi

The First Department of Surgery, Hamamatsu University School of Medicine 3600 Handa-cho, Hamamatsu 431-31, Japan

A water-in-oil-in-water (W/O/W) emulsion composed of oleic acid was used as a carrier of carboxyfluorescein (CF) *via* the enteral route, as a model for future drug transport. The absorption of CF in the small intestine of rats given the emulsion (W/O/W group) was compared with the absorption in a group administered CF alone (CF group), and a group administered a mixed micelle of oleic acid and a surface-active agent in CF solution (MM group). Higher amounts of CF were absorbed in the W/O/W and MM groups than in the CF group. At 120 min, the amount of CF remaining in the intestinal tract was smaller in the MM group than in the W/O/W group. In the early period, CF excretion into bile was higher in the MM group than in the W/O/W group, but from 120 to 360 min, CF excretion in the W/O/W group was higher than in the MM group (non-specific). The blood CF level was significantly higher at 240 and 360 min in the W/O/W group than in the other two groups. The highest concentration in lymph was found in the W/O/W group. The W/O/W emulsion was considered superior to the micelles because it maintained a higher blood level of CF over long periods and transferred it to the lymph. This suggests that the W/O/W emulsion is applicable as a drug carrier *via* the enteral route. *Lipids 27,* 702–705 (1992).

Water-in-oil-in-water (W/O/W)-type multiple emulsions are a system of dispersed oil drops containing even smaller water droplets. Scientists working in the pharmaceutical field have been particularly interested in the development of slow-release drug delivery systems (1,2) or in selectively transferring drugs into the lymphatic system using W/O/W emulsions (3). However, there have been few applications of this type of emulsion as a drug carrier *via* the enteral route. Only Engel *et al.* (4) have attempted to enclose insulin in a W/O/W emulsion to improve intestinal absorption. In the present study, carboxyfluorescein (CF) and a W/O/W-type multiple emulsion composed of oleic acid were used as a model for drug delivery. The potential usefulness of the emulsion as a carrier was evaluated.

MATERIALS AND METHODS

Materials. CF and oleic acid were purchased from Eastman Kodak Co. (Rochester, NY) and Wako Pure Chemical Co. (Osaka, Japan), respectively. Glycerol fatty acid ester (GE; Sunsoft No. 818 NSM, Taiyo Chemical Co., Yokkaichi, Japan) and polyoxyethylene sorbitan monolaurate (Tween 20) (PSM, Wako Pure Chemical Co.) were used as surface agents. Both are currently used as food additives.

*To whom correspondence should be addressed.

Abbreviations: AUC, area under the concentration-time curve; CF, carboxyfluorescein; C_{MAX}, maximum concentration; GE, glycerol fatty acid ester; Kel, constant elimination rate; MM, mixed micelles; PSM, polyoxyethylene sorbitan monolaurate (Tween 20); t-MAX, time of maximum concentration; W/O/W, water-in-oil-in-water.

Preparation of emulsions. To prepare the W/O emulsion, 6 mL of CF solution containing phosphate buffer (pH 7.4) was added to a mixture of oleic acid and GE (CF solution/oleic acid/GE, 3:5:2, vol/vol/vol) and stirred for about 15 min in an ice-bath using a hand mixer (below 5°C). The W/O emulsion (7 mL) was dispersed in 93 mL of 0.2% saline solution containing 1.0% polyoxyethylene sorbitan monolaurate (PSM) and then stirred with a Bio-Mixer (higher speed mixer, Nippon Seiki Co., Tokyo, Japan, at 5°C, 6000 rpm) for about 5 min. To determine the total CF content of the W/O/W emulsion, 0.1 mL of 12.5% Triton X-100 was added to 0.1 mL of the emulsion, which was then acidified with 3 mL of 1 N HCl. CF was extracted with 6 mL isoamyl alcohol. After centrifugation, 5 mL of the organic phase was mixed and shaken with 4 mL of $Na_2CO_3/NaHCO_3$ buffer solution (pH 10). The aqueous phase was separated by centrifugation and measured fluorometrically. Then the W/O/W system was filtered through a 0.22-μm microfilter (Millex-GV, Nippon Millipore Industrial Co., Yonezawa, Japan) to separate the external water and the particles. The CF concentration in the separated external water was measured. Fluorescein in the CF solution was measured using a Shimazu Spectrofluorometer (Kyoto, Japan) at an emission wavelength of 515 nm and an excitation wavelength of 490 nm.

A mixed micelle solution of oleic acid and one of the surface-active agents was prepared as follows. Oleic acid (3.5 mL) was added to 96.5 mL of solution dissolved in phosphate buffer (pH 7.4) containing PSM (1.0%). The mixture was stirred with a Bio-Mixer for the same period of time as in the preparation of the W/O/W emulsion (at 5°C, 6000 rpm).

Absorption experiments. Male Wistar rats (weighing 180–200 g) were divided into three groups according to the mode of CF delivery. The first (CF group) consisted of rats given CF dissolved in phosphate buffer solution. The second group contained rats given CF in the W/O/W emulsion (W/O/W group), and the third CF in a solution with mixed micelles of oleic acid and surfactant (MM group).

The rats were then anesthetized intraperitoneally with pentobarbital (2.5 mg/100 g). The bile duct was cannulated with a polyethylene tube (i.d. 0.28 mm, e.d. 0.61 mm, Becton Dickinson Co., Parsippany, NJ) and bile was collected to avoid any reabsorption of CF in the bile. A similar-sized polyethylene tube for collection of blood was inserted into a femoral artery and then tunneled through the subcutaneous tissue to exit at the back. A polyethylene tube (i.d. 1.25 mm, e.d. 2.00 mm, Atom Co., Tokyo, Japan) was also inserted into the duodenum, and the distal end of the ileum was ligated. The surgical procedure was completed within 40 min, and then the rats were placed in Bollman cages. They remained anesthetized for about 50 min.

The test solutions, each containing 0.20 mg of CF in 5 mL, were introduced into the duodenum. Bile and blood samples were collected periodically.

Blood and bile assays for CF. Blood (0.04 mL) was mixed with 4 mL of isotonic phosphate-buffered saline, pH 7.4, containing 0.01% potassium chloride, and centrifuged to remove red blood cells (5). The concentration of CF in the supernatant was determined by the fluorometric procedure described above. Bile was diluted with phosphate buffer (pH 7.4) and assayed in the same manner.

Assay of CF remaining in the small intestine. Rats were killed periodically and the small intestine was excised from each animal. The intestine was then homogenized and the remaining CF was extracted and assayed by the method of Hashida *et al.* (6).

CF concentration in lymph. The thoracic duct was cannulated, and CF was given in the same manner as described above. Lymph from the thoracic duct was obtained for assay as described above, except that 0.1 mL of lymph was collected.

Effect of changes in oleic acid concentration on absorption of CF. Alteration of the volume of the W/O emulsion varied the concentration of oleic acid (40, 80, 120 mM) and thus modified the concentration of entrapped CF. The total CF concentration in the W/O/W emulsion was maintained at 0.02 mg/mL, and the volume administered was 5 mL.

RESULTS

The diameter of the W/O/W emulsion droplets was measured by microphotography, it ranged from 0.25 to 20 μm (Fig. 1, Table 1). Each droplet contained many smaller water droplets. The entrapping efficiency of CF was 89.5 ± 4.0% (mean ± SD) and did not change when the emulsion was stored at 5°C for 7 d.

Concentration of CF in blood. The CF concentrations in the blood of rats in the three groups were compared. The CF level increased more steeply, and blood levels were significantly higher in the MM and W/O/W groups than in the CF group. In the W/O/W group, the blood levels of CF at 240 and 360 min were higher than in the other two groups (Fig. 2).

TABLE 1

Size of the W/O/W Emulsion Particles[a]

Size (μm)	Frequency (%)
0.5	11.4
0.5–1.0	21.1
1.0–2.0	37.8
2.0–3.0	20.2
3.0–4.0	5.6
4.0–5.0	1.6
5.0–6.0	1.8
6.0	0.5

[a]The sizes of 1200 emulsion particles were measured by microphotography.

The maximum concentration (C_{MAX}) and area under the concentration-time curve (AUC) were significantly higher in the W/O/W and MM groups than in the CF group, but there was no significant difference between the former two groups (Table 2).

Amount of CF secreted into bile. No difference in bile volume was found among the three groups (Table 3). The W/O/W and MM groups delivered CF to bile more efficiently than the CF group. In the early period (0–120 min), the amount of CF in the MM group was higher than that in the W/O/W group. From 120 to 360 min, the W/O/W group had higher levels of CF than the MM group, but not to a significant extent (Fig. 3, Table 4).

Amount of CF remaining in the small intestine. The amount of CF remaining in the small intestine was lower in the W/O/W and MM groups than in the CF group

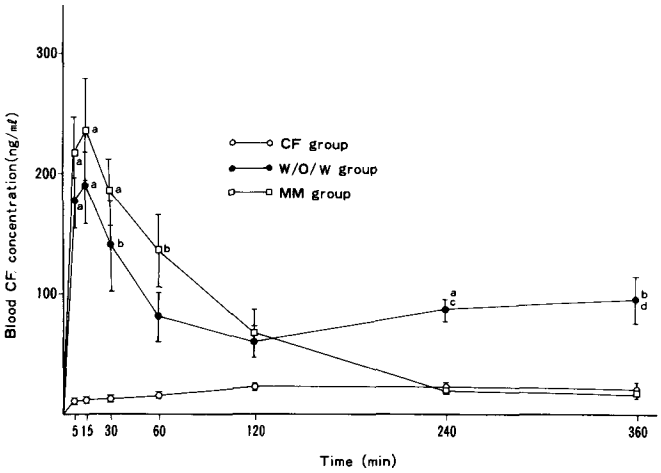

FIG. 2. Carboxyfluorescein (CF) concentration in blood. Rats were divided into three groups according to the mode of CF delivery. (○), CF dissolved in buffer solution (CF group); (●) CF in water-in-oil-in-water (W/O/W) emulsion (W/O/W group); (□) CF in a solution with mixed micelles of oleic acid and surfactant (MM group). Values represent means ± SEM of five animals. Statistical analysis was done by Student's *t*-test. Significantly different from CF group, $^aP < 0.01$, $^bP < 0.05$; from MM group, $^cP < 0.01$, $^dP < 0.05$.

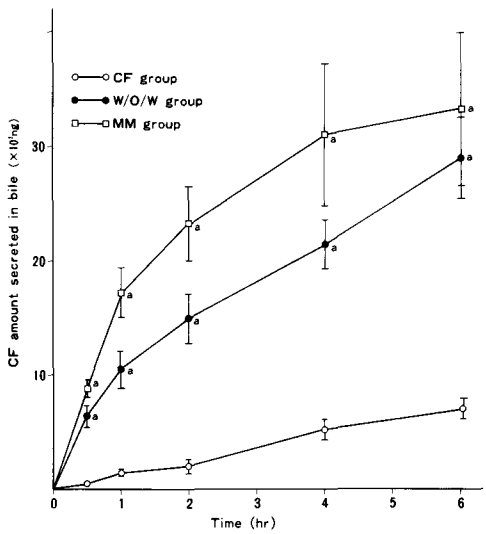

FIG. 3. Amount of carboxyfluorescein (CF) secreted into bile. (○), CF group; (●), water-in-oil-in-water group; (□), mixed micelle group. Values represent means ± SEM of five animals. Significantly different from CF group $^aP < 0.01$, $^bP < 0.05$.

throughout the course of the experiment. At 2 h after administration, the MM group had a lower amount of CF than the W/O/W group ($P < 0.05$), but no significant differences were observed at subsequent time points (Fig. 4).

Amount of CF in lymph. The CF content of lymph was significantly higher in the W/O/W group than in the other two groups, except at 4-6 h (Table 5, Fig. 5). However, throughout the experiment, the CF concentration in lymph was lower than that in plasma in all groups.

Effect of oleic acid concentration on absorption. In the early period, the CF level was elevated in each group (40,

[d]The value is significantly different from the W/O/W group ($P < 0.05$).

TABLE 5

Relationship Between Oleic Acid Concentration and Absorption Efficiency[a]

Oleic acid concentration	C_{MAX} (ng/mL)	AUC_{0-360} (ng·min/mL)	t-MAX (min)	K_{el} (h^{-1})
40 mM	121.7 ± 25.3	11399.8 ± 3266.3	21.0 ± 13.1	0.659 ± 0.068[b,d]
80 mM	144.4 ± 42.0	17102.6 ± 4075.6	16.3 ± 5.2	0.391 ± 0.029[c]
120 mM	125.0 ± 9.0	22412.9 ± 2542.8	17.5 ± 4.3	0.258 ± 0.032

[a]Values represent mean ± SEM of four animals. The values are significantly different from the 120 mM group ([b]$P < 0.01$, [c]$P < 0.05$). [d]The values are significantly different from the 80 mM group ($P < 0.05$). Abbreviations: C_{MAX}, maximum concentration; AUC, area under the concentration-time curve; t-MAX, time of maximum concentration; Kel, constant elimination rate.

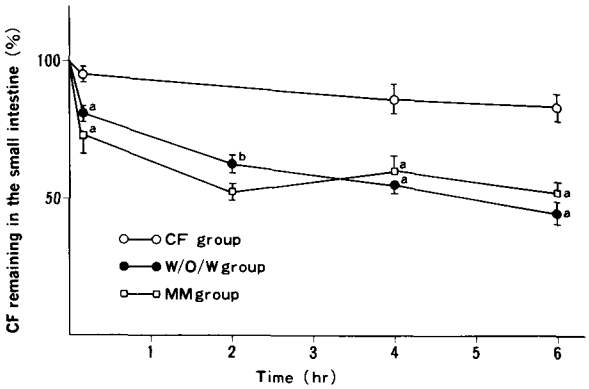

FIG. 4. Amount of carboxyfluorescein (CF) remaining in the small intestine. (○), CF group (n = 5); (●), water-in-oil-in-water group (n = 5–6); (□), mixed micelle group (n = 5–7). Significantly different from CF group [a]$P < 0.01$, from MM group [b]$P < 0.05$.

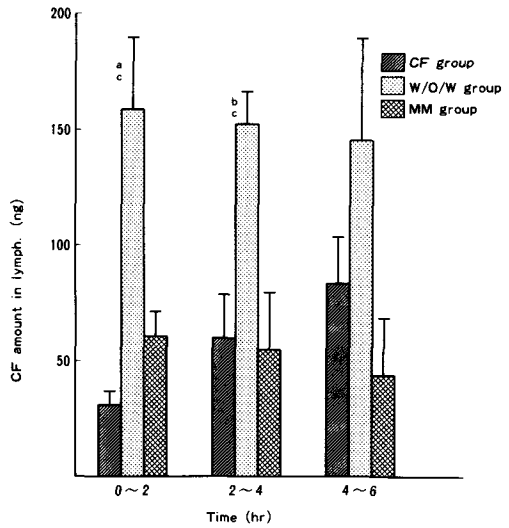

FIG. 5. Amount of carboxyfluorescein (CF) in lymph. Values represent means ± SEM of four animals. Significantly different from CF group [a]$P < 0.01$, [b]$P < 0.05$; from MM group [c]$P < 0.05$.

80, 120 mM) with no significant differences among the groups. After 120 min, in the 80 mM and 120 mM oleic acid groups, the levels of CF in blood were significantly higher than in the CF group, but the 40 mM group showed no difference from the CF group after 2 h (Fig. 6). The C_{MAX} and t-MAX values for the three groups did not differ, but the AUC increased in proportion to the concentration of oleic acid. Kel (constant elimination rate) fell significantly in proportion to the concentration of oleic acid (Table 6).

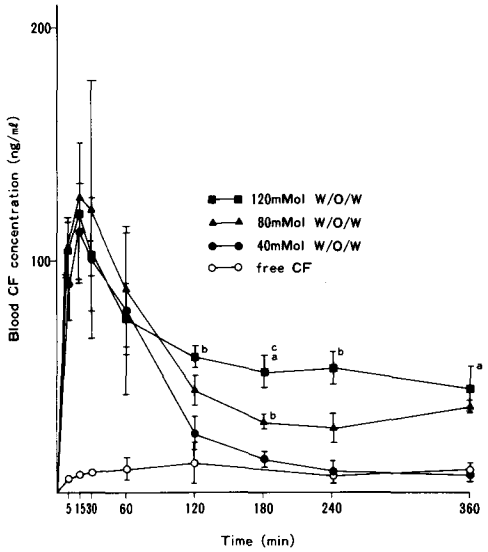

FIG. 6. The effect of changes in the oleic acid concentration on the absorption of carboxyfluorescein (CF). The concentration of oleic acid as a constituent of the water-in-oil-in-water emulsion was varied: (■), 120 mM; (▲), 80 mM; (●), 40 mM; (○), free CF. Total quantity of CF was controlled at 0.1 mg/5 mL/rat. Significantly different from 40 mM [a]$P < 0.01$, [b]$P < 0.05$; from 80 mM [c]$P < 0.05$.

TABLE 6

Lymph Volume Collected (mL)

MM[a]	0.43 ± 0.12	0.64 ± 0.04	0.48 ± 0.06

[a]CF, carboxyfluorescein; W/O/W, water-in-oil-in-water; MM, mixed micelles.

DISCUSSION

A W/O/W-type multiple emulsion was used as a carrier of CF *via* the enteral route for the following reasons. Multiple emulsions already have been used orally (7). Because of their low viscosity, they are easy to handle and to drink (8). Furthermore, drugs can be enclosed both easily and efficiently with multiple emulsions (9). The behavior of an emulsion is largely dependent on the lipid that constitutes the oil phase (8). If the emulsion is composed of unsaturated fatty acids, an absorption-promoting action may be obtainable (9–11). W/O/W emulsions enter the lymphatic system easily and reach regional lymph nodes selectively (11).

In the present study, when an oleic acid W/O/W emulsion was administered into rat small intestine, a larger amount of CF was absorbed in the W/O/W group than in the CF group. The MM group had more CF left in the intestinal tract at 120 min, but no significant differences were observed at later time points. The W/O/W group was superior to the MM group in transferring CF to the blood at the later time points, and transferred CF to the lymphatic system more efficiently than the other two groups.

The details of the absorption promoting action remain obscure. The number and size of particles may affect the absorption of CF. More particles were found in W/O/W emulsion and the particle diameter was smaller; therefore, the W/O/W emulsion may be more advantageous than micelles. Blood levels of CF dropped quickly when an oleic acid concentration of 40 mM was used. This decline may be related to the number of particles.

Some anticancer drugs produce considerable side-effects following intravenous administration, and are difficult to absorb *via* the digestive tract. If such a drug could be enclosed in oleic acid W/O/W emulsion and delivered to the liver and the lymphatic system efficiently, then treatment and prophylaxis of liver metastasis and nodal involvement could be improved. Thus, for administration of such a drug, W/O/W emulsions could be more advantageous than micelles. Also, oleic acid W/O/W emulsions would be superior to micelles for lymphatic transfer of anticancer drugs.

In administering W/O/W emulsions to the digestive tract, alteration in stability due to pH, intestinal peristalsis, saliva and gastric juice pose a problem. Fusion has been shown to take place in a dopamine W/O/W emulsion (soybean oil and egg yolk lecithin) in an acid environment (13). However, W/O/W emulsions can be stabilized by gelatinization of the internal aqueous phase in the emulsion (14). Therefore, some emulsions which are stable in the stomach environment are available (13), and these could overcome the problem of instability. If such stability could be achieved for oleic acid W/O/W emulsion, it could be an excellent drug carrier.

ACKNOWLEDGMENTS

We thank Professor Yukio Harada for his helpful advice and also Taiyo Chemical Co. for donating the glycerol ester.

[Received November 7, 1991; Revision accepted July 8, 1992]

Omega-3 Fatty Acid and Cholesterol Content of Newly Hatched Chicks from α-Linolenic Acid Enriched Eggs

G. Cherian and **J.S. Sim***
Department of Animal Sciences, University of Alberta, Edmonton, Alberta, Canada T6G 2P5

Egg yolk was enriched with α-linolenic acid (18:3n-3) by feeding laying hens diets containing flax, canola or soybean seeds. Fertilized eggs were incubated and the fatty acid composition of whole body, liver, plasma, brain and the cholesterol content of plasma and liver tissue of the hatched chicks were studied. Eggs enriched with 18:2n-6 fatty acids by feeding hens diets containing sunflower seeds were used as the controls. Feeding flax enriched ($P < 0.05$) egg yolk and the developing progeny with 18:3n-3, 20:5n-3, 22:5n-3 and 22:6n-3. Feeding sunflower seeds resulted in an increase ($P < 0.05$) of 18:2n-6, 20:4n-6, 22:4n-6 and 22:5n-6. The predominant polyunsaturated fatty acid of the brain was docosahexaenoic acid (22:6n-3) which was higher ($P < 0.05$) in the flax and canola fed group. The cholesterol content of the liver tissue was lower ($P < 0.05$) in chicks hatched from hens fed flax seeds. This study indicates that 18:3n-3 and 18:2n-6 in the maternal diet are potent modulators of long-chain polyunsaturated n-3 or n-6 fatty acid and of cholesterol content in the developing progeny.
Lipids 27, 706–710 (1992).

The essentiality of dietary n-3 fatty acids in the development of brain tissue is well documented (1,2). Docosahexaenoic acid (DHA) is the major n-3 polyunsaturated fatty acid (PUFA) in the brain (3). Diets deficient in n-3 fatty acids have resulted in inferior learning ability in rats (4) and neurological disorders in humans (5). The precursor of DHA is linolenic acid (LNA, 18:3n-3). LNA is desaturated and elongated to form long-chain PUFA of the n-3 series such as eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA) and docosahexaenoic acid (DHA) (6). Plant oil seeds such as flax and canola are a rich source of LNA.

The enrichment of chicken egg with n-3 fatty acids by incorporating flax and canola seeds or their oils in laying hens' diets has been well documented (7–10). During incubation of a fertile egg, the lipids of the yolk serve as an energy source and supply fatty acids for the synthesis of membrane lipids of the developing chicken embryos (11). Unlike the mammalian fetus, the chicken embryo is not dependent on maternal fatty acids through circulation. Maternal fatty acids can cross the placenta and may, for example, contribute up to 50% of fetal fatty acids during late gestation in the rat (12). Instead, we chose the hen, the fertilized egg and the hatched chick because when a fertilized egg is incubated, the developing embryo is in a "contained" environment. The laying hen, the fertilized egg and the hatched chick were considered useful to study n-3 fatty acid transfer from the egg to the developing embryo and its impact on the lipid metabolism of the progeny.

The hypocholesterolemic effect of n-3 fatty acids from fish oil (13,14) and from linseed oil has been established in human trials (15) and also in experimental animals (16). However, n-3 fatty acids in eggs and its effect on the plasma and/or tissue cholesterol content in the developing progeny has not been reported. The objective of the present study was to determine to which extent dietary n-3 or n-6 fatty acids can be incorporated into egg yolk and to examine its effect on the fatty acid and cholesterol content of the progeny (hatched chick).

MATERIALS AND METHODS

Fatty acid modulation. Single comb white leghorn (SCWL) laying hens were housed in cages (30 × 40 cm) and were assigned to test diets containing 10% ground flax seed, 10% ground canola seed or 16% ground soybean seed, and were compared to birds fed 12% sunflower seed serving as controls (Table 1). The fatty acid composition of the diets is shown in Table 2. The hens were artificially inseminated on consecutive days with 0.05 mL of pooled semen sample. Fertilized eggs were collected for six days

Abbreviations: ANOVA, analysis of variance; CE, eggs from hens fed diets containing ground canola seed; CAC, chicks hatched from hens fed diets containing ground canola seed; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; FE, eggs from hens fed diets containing ground flax seed; FXC, chicks hatched from hens fed diets containing ground flax seed; GC, gas chromatograph; HMG-CoA, 3-hydroxy-3-methyl-glutaryl coenzyme A; LNA, α-linolenic acid; MUFA, monounsaturated fatty acid(s); PUFA, polyunsaturated fatty acid(s); SBC, chicks hatched from hens fed diets containing ground soybean seed; SBE, eggs from hens fed diets containing ground soybean seed; SFC, ground sunflower; SCWL, single comb white leghorn; SFE, eggs from hens fed diets containing ground sunflower seed.

after two weeks on experimental diets and incubated in a forced-air incubator (Robbins Incubator Company, Denver, CO). The eggs were incubated at 37°C at a relative humidity of 64% and turned once per hour for eighteen days. They were then transferred to hatchers and incubated for three days at 37.2°C and at a relative humidity of 64%.

Sample collection and analyses. Eggs from laying hens fed ground flax seed (FE), ground canola seed (CE), ground soybean seed (SBE) and the ground sunflower seed (SFE) were collected and the yolks were separated, weighed and kept frozen till analysis. On the day of hatching, 10 newly hatched chicks from laying hens fed diets containing ground flax (FXC), ground canola (CAC), ground soybean seed (SBC) or ground sunflower (SFC) were weighed and killed by decapitation. Five chicks from each treatment were ground in chloroform/methanol (2:1, vol/vol) (17) solution with a polytron (Brinkman Instruments, Westbury, NY). From the remaining five chicks, blood, brain and liver tissues were collected. Blood samples were centrifuged at 3000 rpm in a Beckman centrifuge (Beckman Instruments, Mississauga, Ontario, Canada) and plasma was separated. Total lipids were extracted from yolk, whole chicks, liver, plasma and brain by the method of Folch *et al.* (17). Aliquots of the lipid extracts were dried under nitrogen and were converted to fatty acid methyl esters using a mixture of boron trifluoride, hexane and methanol (35:20:45, vol/vol/vol) (18). Fatty acid methyl esters were separated and quantified by automated gas chromatography (Model 3400, Varian Associates, Inc., Sunnyvale, CA) using a DB-23 fused capillary column (30 m × 0.25 mm). The initial column temperature was set at 70°C for 3 min, increased to 180°C at 30°C/min, and held for 10 min. Then the column temperature was elevated to 230°C at a temperature of 5°C/min and held at the final temperature for 3 min. Helium was used as the carrier gas at a flow rate of 1.5 mL/min. The fatty acid results were expressed on a percentage basis. Plasma cholesterol was measured by the enzymatic method using a commercial kit (Sigma Chemicals Co., St. Louis, MO). For liver cholesterol determination, an aliquot of the total lipid extract was dried under nitrogen along with the internal standard 5α-cholestane, and the cholesterol content was measured by gas chromatography (GC) (19).

Statistics. Data were analyzed by one-way analysis of variance (ANOVA). Significant differences between treatment means were determined with Duncan's multiple range test (20).

RESULTS

The total lipid and fatty acid composition of the diets are shown in Table 2. The only sources of n-3 or n-6 fatty acids in the diet were 18:3n-3 and 18:2n-6. The total n-3 and n-6 fatty acids in the diet were 27.2, 11.4, 5.0, 3.3% and 19.8, 25.4, 37.3, and 45.0 for flax, canola, soybean and the sunflower based diets, respectively. The fatty acid composition of egg yolk was significantly modified by the laying hen test diets (Table 3). Feeding ground flax seed enriched the egg yolk with LNA and its metabolites such as EPA and DHA resulting in the total incorporation of 8.29% of n-3 fatty acids compared with 2.83% for canola seed, 1.66% for soybean seed and 1.11% for ground sunflower seed. LNA was the major n-3 fatty acid in the yolk of hens fed diets containing ground flax or canola

[a]Superscripts a–d: means with no common superscripts within the same rows are significantly different ($P < 0.05$). Data are presented as mean ± SEM, n = 5. FE, CE, SBE, SFE represent eggs from hens fed diets containing ground flax, canola, soybean or sunflower seeds, respectively. nd, Not detectable. Percent of total lipids is represented on the last line entry (Lipids).

[b]Laying hens fed ground flax seed (FE), canola seed (CE), soybean seed (SBE) and sunflower seed (SFE).

seed, although considerable amounts of EPA and DHA were found in these yolks. Conversely, incorporation of 12% sunflower seeds in the laying hen's diet resulted in a significant increase in 18:2n-6 and arachidonic acid (20:4n-6) at the expense of oleic acid (18:1n-9). Consequently, this resulted in a decrease in monounsaturated fatty acid (MUFA) (data not shown) content and a higher total n-6/n-3 ratio in the SFE eggs. The 20:4n-6 content of FE eggs was significantly ($P < 0.05$) lower than the canola group at 0.82 and 1.37%, respectively.

The total lipid fatty acid composition of whole body, plasma and liver tissue was modified by the egg yolk lipid composition (Table 4). Significantly higher contents of LNA and its metabolites such as EPA, DPA and DHA were found in the total body lipids, plasma lipids and liver lipids of the hatched chicks from n-3 fatty acid enriched FE, CE and SBE than those hatched from n-6 fatty acid enriched SFE eggs. The chicks hatched from FE, CE and SBE had significantly reduced 18:2n-6 and 20:4n-6 contents. In contrast, the chicks hatched from n-6 fatty acid enriched eggs (SFE) had significantly higher levels of 18:2n-6 and its metabolites, such as 20:4n-6, 22:4n-6 and 22:5n-6, in all tissues examined. The total lipid content of the whole body and the liver was not affected. However, plasma total lipids were significantly reduced in the FXC and CAC chicks when compared with SBC and SFC chicks.

The brain fatty acid composition of the newly hatched chicks is shown in Table 5. Compared to SBC and SFC chicks, CAC and FXC chicks had elevated concentration of EPA, DPA and DHA. The effect was most pronounced with respect to DHA which is the major polyunsaturated fatty acid in chick brain. The concentrations of 18:2n-6, 22:4n-6 and 22:5n-6 were significantly higher in the SFC

FXC, CAC, SBC and SFC represent chicks hatched from hens fed diets containing ground flax, canola, soybean or sunflower seeds, respectively.

chicks. Except for the FXC chicks, the level of 20:4n-6 in brain was not influenced by the yolk fatty acid composition. The level of MUFA in the brain lipids was not affected by yolk fatty acid composition (data not shown).

The chicks hatched from FE eggs enriched with n-3 fatty acids significantly reduced liver cholesterol levels (Table 6). Cholesterol levels in the heart, brain and plasma were not affected by the yolk fatty acid composition.

DISCUSSION

The present study indicates that the presence of n-3 or n-6 fatty acids in the laying hen diet can enrich the egg yolk lipids and further the tissues of the hatched chicks with n-3 and n-6 fatty acids. The increased supply of dietary 18:3n-3 tended to increase the levels of the long-chain n-3 fatty acids such as EPA, DPA, DHA associated with a corresponding reduction in the level of 20:4n-6 in the egg yolk.

The major n-3 fatty acid in liver and brain was DHA. The low LNA and higher DHA levels in liver of n-3 fatty acid enriched FXC and CAC compared to SFC indicate the importance of liver in supplying DHA to the developing brain. Similar levels of DHA in the liver tissue of FXC and CAC chicks further support this observation because the brain of the FXC and CAC chicks had similar DHA levels. Moreover, DHA was a major fatty acid in the chick plasma. Liver and plasma have been shown to provide DHA to the developing brain in rat pups when the maternal diet was enriched with 18:3n-3 (21). Despite the changes in the fatty acid composition of the brain tissue, the total PUFA content (n-6 plus n-3) remained constant in this tissue. Similar observations have been reported for other species, such as the rat (22,23,2) and pig (24).

The chicks hatched from eggs enriched with n-3 fatty acids (FE) reduced plasma and liver cholesterol and plasma total lipids. In contrast, chicks hatched from eggs enriched with n-6 fatty acids showed a similar reduction in plasma cholesterol with an accumulation of cholesterol in the liver. However, this reduction was not evident in the chicks hatched from SBE eggs which might be due to the lower levels of n-3 fatty acids in the SBE eggs. Thus, n-6 and n-3 fatty acids in egg yolk affected cholesterol metabolism in the developing progeny differently. The n-6 fatty acids caused a redistribution of cholesterol from the plasma to the liver pool. Diets rich in n-6 fatty acids have been reported to increase cholesterol esterification. This

increased esterification further increases the capacity of hepatic cells to take up more free cholesterol from circulating plasma (16,25). The rate-limiting step in cholesterol synthesis is 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) (26). Haave *et al.* (27) reported an increased activity of this enzyme in the fetal liver of rat pups when the dam's diet was high in n-6 fatty acids. Differential effects of n-3 and n-6 fatty acids causing redistribution of cholesterol have been reported when rats were fed egg yolks enriched with n-3 or n-6 fatty acids (28) or linseed and sunflower oil (16). However, the enrichment of n-3 and n-6 fatty acid in the egg and their effect on the developing chick have not been reported.

In summary, the type of fat fed to laying hens can affect the fatty acid composition of the yolk and also the fatty acid and cholesterol content of the developing progeny. Whether changes in fatty acid accretion during development due to alteration of yolk fatty acid composition may cause long-term changes in cholesterol metabolism in the chick requires further study. In view of the significant impact of the maternal diet on fetal accretion of PUFA, it will be important to assess the net synthesis of these fatty acids and the appropriate amount of precursor for optimal tissue accretion. The omega-3 fatty acid enriched egg and the newly hatched chick model could be used to study the transfer, uptake and synthesis of polyunsaturated fatty acids during development.

Effect of Dietary Linoleic Acid Content on the Distribution of Triacylglycerol Molecular Species in Rat Adipose Tissue

Yung-Sheng Huang*, X. Lin, R.S. Smith, P.R. Redden, D.K. Jenkins and **D.F. Horrobin**
Efamol Research Institute, Kentville, Nova Scotia, Canada B4N 4H8

The present study examined the effect of varying dietary linoleate intake (0.01, 0.24, 2.4, 24, 80 or 160 g/kg diet) for 24 weeks on the distribution of triacylglycerol (TG) molecular species in rat epididymal adipose tissue. Adipose TG fractions were purified by thin-layer chromatography and separated into different molecular species by reverse-phase high-performance liquid chromatography. The identification of TG species was based on fatty acid composition, retention time and the theoretical carbon number. When the dietary 18:2n-6 content was equal to or less than 24 g/kg, no significant amounts of n-6 fatty acids (mainly 18:2n-6) were observed in adipose tissue TG despite the fact that the levels of 20:4n-6 in liver phospholipids increased significantly. There were 12 major molecular species in adipose tissue when the dietary 18:2n-6 content was less than 2.4 g/kg. When the dietary 18:2n-6 content reached 24 g/kg, an additional six TG species containing one, two or three molecules of 18:2n-6 were observed. The levels of TG molecules containing two or three 18:2n-6 residues were further increased when the diet contained very large amounts of linoleic acid (160 g/kg). Conversely, those TG species containing only one 18:2n-6 residue became less abundant. It is suggested that the accumulation of these linoleate-rich TG molecular species in adipose tissue, particularly di- and trilinoleoyl containing TG, is the result of an adequate or an excessive intake of linoleic acid.
***Lipids* 27, 711–715 (1992).**

Adipose tissue is the most important extrahepatic tissue regulating *in vivo* lipid metabolism. This tissue is rich in triacylglycerols (TG), whose fatty acid composition is modulated by *in situ de novo* synthesis and the influx of fatty acids from the diet or from the *de novo* synthesis in the liver (1–3). During early development, adipose tissue is very active in fatty acid synthesis (4–6). However, as animals grow older, the amount of fatty acid synthesis *in situ* declines, while the deposition of lipid from exogenous fat increases (7–10). As a result, dietary fat intake modulates the fatty acid composition of adipose tissue in mature animals.

In recent years, it has become well established that high levels of plasma cholesterol correlate closely with a high risk of coronary heart disease, and that dietary polyunsaturated fatty acids (mainly linoleic acid, 18:2n-6) can lower plasma cholesterol levels (11). As adipose tissue fatty acid composition reflects the history of dietary linoleic acid intake, it has been suggested that low adipose tissue linoleic acid is a risk factor in coronary heart disease (12,13). Previously, such assessments were based on overall linoleic acid content. The exact distribution of linoleic acid in TG species could not be routinely examined because of a lack of simple and effective techniques for the separation of TG species. Using $AgNO_3$-thin layer chromatography ($AgNO_3$-TLC) followed by gas-liquid chromatography (GLC), Bugaut (14) has examined the adipose tissue TG molecular species in rats fed a diet containing coconut oil. In the present paper we examined whether changes in dietary linoleic acid content would affect the distribution of linoleic acid containing TG in adipose tissue. The separation of TG species was carried out using a simple reverse-phase high-performance liquid chromatography (HPLC) method with a new isocratic solvent system (isopropranol/acetonitrile, 35:65, vol/vol).

MATERIALS AND METHODS

Weanling male Sprague-Dawley rats (3-wk-old) were purchased from the Charles River Breeding Laboratories (St. Constant, Quebec, Canada). Animals were randomly divided into six groups of six each and maintained *ad libitum* on a fat-free semi-purified diet (Teklad Test Diet, Madison, WI) supplemented with 20% (by weight) of fat containing 0.005, 0.12, 1.2, 12, 40 and 80% of linoleic acid (equivalent to 0.01, 0.24, 2.4, 24, 80 and 160 g/kg in the diet). The fat was prepared by mixing different proportions of safflower oil (containing 80% 18:2n-6) and hydrogenated coconut oil (containing no significant amount of n-6 fatty acids). The detailed composition of the fat-free diet has been described previously (15). Briefly, the diet contained 20% vitamin-free casein, 69.7% sucrose, 5% cellulose, 3.5% mineral mix (AIN-76), 1% vitamin mix, 0.5% calcium carbonate and 0.3% DL-methionine. After 24 weeks on the respective diet, all animals were killed in the fed state by exsanguination under light diethyl ether anaesthesia. Livers and the epididymal fat pads were excised, rinsed in cold saline, blotted, weighed, and frozen at −20°C.

Total tissue lipids were extracted, and the TG fraction was purified by TLC using hexane/diethyl ether/acetic acid (80:20:1, vol/vol/vol) as the mobile phase. The purified adipose tissue TG fraction (1–2 mg dissolved in 5–10 μL chloroform) was then fractionated, according to the number of double bonds and acyl carbons, into different molecular species by HPLC using a Beckman System Gold programmable solvent module 126 (Beckman Instruments, Palo Alto, CA). Two identical reverse-phase columns, Supelcosil LC-18 (5 μ, 250 mm × 4.6 mm i.d.; Supelco, Bellefonte, PA), maintained at 30°C in a programmable column oven, were used as the stationary phase, while isopropanol/acetonitrile (35:65, vol/vol) was used isocratically as the mobile phase (flow rate 2 mL/min). For preparative analysis, the eluting TG components were detected using a UV detector (Model 166, Beckman) at 210 nm. The presence of isopropanol (which has a UV cut-off value at 210 nm) in the mobile phase caused some UV absorption (approximately 0.34 units). However, the background value was automatically offset and only the net absorbance changes were shown in the computer monitor. The eluting TG components monitored with UV detector were then collected. A known amount of triheptadecanoin

Abbreviations: GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; L, linoleic acid (18:2n-6); O, oleic acid (18:1n-9); P, palmitic acid (16:0); PL, phospholipids; Po, palmitoleic acid (16:1n-7); S, stearic acid (18:0); TG, triacylglycerols; TLC, thin-layer chromatography.

(tri-17:0) was added as an internal standard to each collection prior to methylation and GLC analysis. Identification of TG species was achieved by examining their fatty acid composition analyzed on a fused silica capillary column (Supelcomega, 50 m × 0.25 mm i.d.; Supelco) in a Hewlett-Packard Model 5890 gas-liquid chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame ionization detector (16). For quantitation, the eluting TG components were detected using a mass (light scattering) detector (ACS model 740/14, Applied Chromatography System Ltd., Macclesfield, England). The settings on the mass detector were those described previously (17). The output signal integration and data analysis were performed on an IBM PS/2 computer (model 50) using Gold Software (version 3.1, Beckman). The response of the mass detector to different molecular species was compared to the value determined by GLC analysis using the added internal standard (tri-17:0), and the correction factor for each molecular species was then derived. A computer program described by Merritt *et al.* (18) was modified and used to determine the TG molecular species. The computation was based on random probability calculations (19,20) using the fatty acid composition of the purified TG fraction, and on the retention time, which has a direct logarithmic relation to the theoretical carbon number (21). It should be noted that the present system could not resolve positional TG isomers having the same acyl groups but in different positions (*e.g.*, OOL, OLO and LOO). Peaks identified could represent a mixture of the corresponding isomers. One-way analysis of variance was used to assess the significance of differences between groups fed different levels of linoleic acid.

RESULTS

Figure 1 shows the changes of two major n-6 fatty acids, 18:2n-6 (panel A) and 20:4n-6 (panel B), in liver and adipose tissue TG and phospholipids (PL) in response to different dietary linoleate levels. In liver and adipose tissue PL, 18:2n-6 constituted a small proportion of total fatty acids. However, the levels of 18:2n-6 were increased as the dietary linoleate content increased. The levels of 20:4n-6 were similarly increased in both tissues (Fig. 1, panel B). However, the magnitude of change was significantly lower in adipose tissue PL than in liver PL. In adipose tissue and liver TG, the levels of 18:2n-6 also were very low and were not significantly affected by increasing the dietary linoleate content up to 2.4 g/kg. As shown in Figure 1, the levels of 18:2n-6 in animals fed 2.4 g/kg (as compared with those fed either 0.01 or 0.24 g/kg linoleic acid) were increased by only a small fraction, despite a 240- and 10-fold increase in the dietary supply of linoleic acid. When the dietary linoleate content reached 24 g/kg diet, the levels of 18:2n-6 in adipose tissue and liver TG were increased significantly. Similarly, the levels of 20:4n-6 in liver and adipose tissue TG, undetectable when dietary linoleate content was less than 24 g/kg, were increased slightly in liver TG but not in adipose tissue TG, when dietary linoleate exceeded 24 g/kg (Fig. 1, panel B). The detailed fatty acid composition of adipose tissue TG from animals fed diets supplemented with linoleate at three different levels (0.01, 24 and 160 g/kg) is shown in Table 1.

Figure 2 shows two typical HPLC chromatograms of adipose tissue TG species from rats fed a diet containing

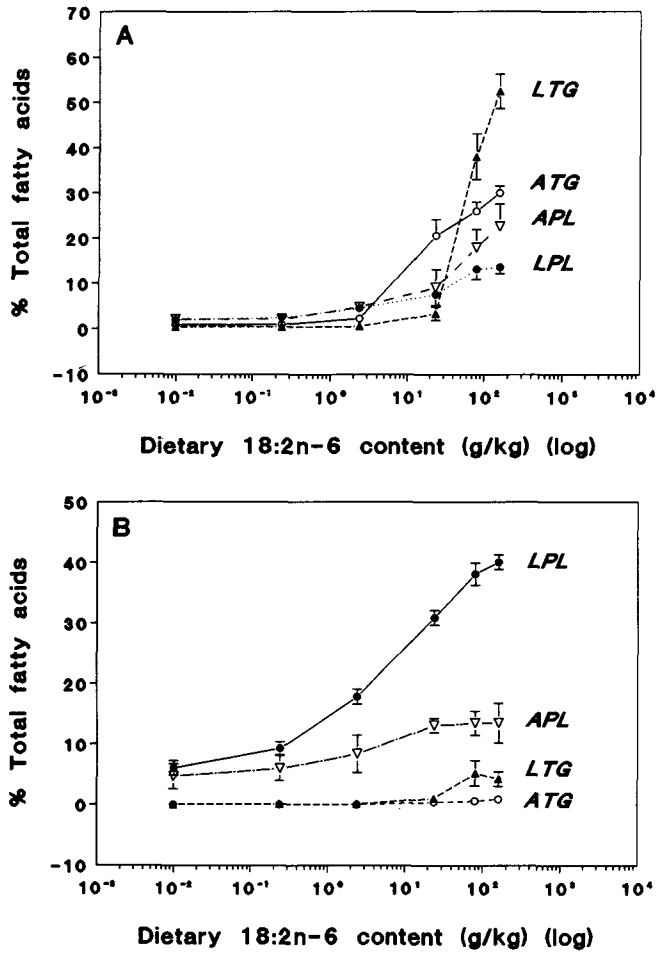

FIG. 1. The levels (mol% of total fatty acids) of 18:2n-6 (panel A) and 20:4n-6 (panel B) in liver phospholipids (LPL), liver triacylglycerols (LTG), and epididymal fat phospholipids (APL) and triacylglycerols (ATG) of rats fed a fat-free diet supplemented with linoleic acid at a level of 0.01, 0.24, 2.4, 24, 80 or 160 g/kg (in log) for 24 weeks (mean ± SD of six animals).

linoleic acid at a level of 0.01 and 24 g/kg. It is evident that the separation of various TG species based on theoretical carbon number and degree of unsaturation was satisfactory. The random and experimental distributions

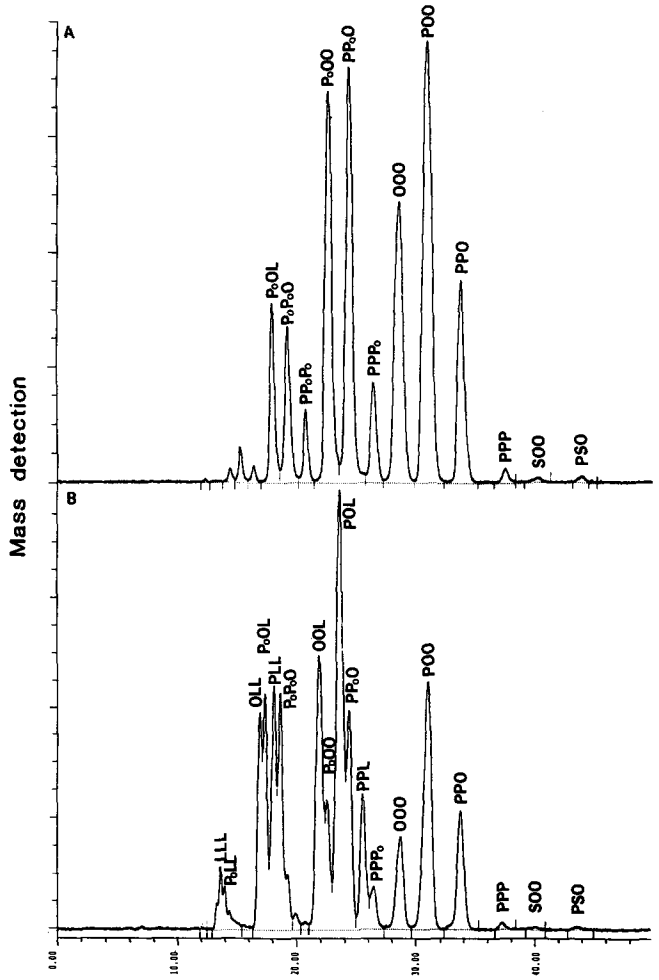

FIG. 2. Typical HPLC chromatograms of adipose tissue triacylglycerol molecular species from rats fed a diet containing linoleic acid at a level of 0.01 g/kg (panel A) or 24 g/kg (panel B).

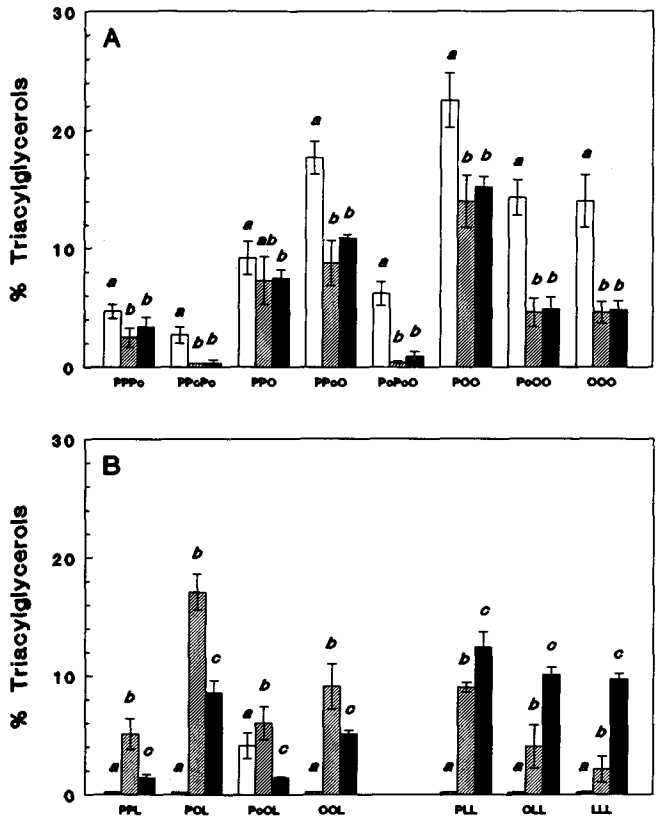

FIG. 3. Distribution (mol%) of linoleoyl deficient (panel A) or linoleoyl containing (panel B) triacylglycerol molecular species in epididymal fat pads from rats fed a diet supplemented with linoleic acid at a level of 0.01 (white bars), 24 (hatched bars) or 160 (black bars) g/kg for 24 weeks (mean ± SD of six animals). ^{a,b,c}Data with different superscripts are significantly different at $P < 0.05$. Abbreviations: P, palmitic, 16:0; Po, palmitoleic, 16:1n-7; S, stearic, 18:0; O, oleic, 18:1n-9; L, linoleic, 18:2n-6.

of TG molecular species in epididymal adipose tissue from rats fed low linoleic acid (0.01 g/kg diet) or linoleic acid-supplemented diet (24 and 160 g/kg diet) for 24 weeks are shown in Table 2. The distribution of major linoleic acid-deficient (panel A) and linoleic acid-containing (panel B) TG molecular species in epididymal adipose tissue are shown in Figure 3. In animals fed linoleic acid-sufficient diets (24 and 160 g/kg) as compared with those receiving lower amounts (0.01, 0.24 and 2.4 g/kg), the levels of linoleic acid containing TG molecular species, such as LLL, OLL, PLL, OOL, POL, and PPL, were significantly increased, whereas the levels of PoPoO, PoOO, PPoO, PPPo, OOO and POO were decreased. There were no significant differences between the overall levels of linoleoyl containing TG molecular species (52.4 *vs.* 49.6% of total TG) in rats receiving 24 and 160 g/kg of linoleic acid in the diet. However, the higher the dietary linoleic acid content, the greater the increase in the levels of TG species containing two or three molecules of 18:2n-6 (*e.g.*, PLL, OLL and LLL). This increase was at the expense of the levels of mono-linoleoyl containing TG species (*e.g.*, PPL, POL, and OOL), which were lower in adipose tissue from rats fed 160 g/kg than those fed 24 g/kg linoleic acid.

DISCUSSION

The results in Figure 1 show that the levels of 20:4n-6 in both adipose tissue and liver PL were increased as dietary linoleate content increased. On the other hand, the levels of 20:4n-6 in liver and adipose TG were very low when dietary linoleate content was below 2.4 g/kg. This suggests that at this level (2.4 g/kg) most of the linoleic acid taken up by the animal was metabolized and used in the synthesis of membrane PL (3,22–24). When dietary linoleate content exceeded 24 g/kg, the increased 18:2n-6 levels in both liver and adipose TG indicated that the dietary linoleate was likely to have exceeded the minimum requirement for PL synthesis, and some was incorporated into TG for storage. Thus, based on the present results, the minimum linoleate requirement of the animals was estimated to be 0.5–5% of total calories. This is in agreement with a previous report in which Holman (25) estimated the requirement to be 1–2% of total calories.

The use of HPLC to determine TG species in this study shows the unequivocal changes in mono- and di- or trilinoleoyl containing TG species (Fig. 3). When dietary 18:2n-6 content was below 24 g/kg (0.1, 0.24 or 2.4 g/kg), adipose tissue predominantly contained the non-linoleoyl containing TG, and only trace amounts of the linoleoyl containing TG. The latter became significant only when

[a]Fatty acid abbreviations: M, myristic; P, palmitic; Po, palmitoleic; S, stearic; O, oleic; L, linoleic; X, non-linoleic. Theoretical distribution (>0.5%) of triacylglycerol molecular species was calculated from total fatty acid composition (shown in Table 1) based on 1,2,3-random.

dietary linoleate content reached 24 g/kg. Since increasing the levels of linoleoyl containing TG reduced only a portion of non-linoleoyl containing TG in adipose tissue, this suggests that the increased influx of dietary linoleate might have partially suppressed endogenous fatty acid synthesis. There is ample evidence to demonstrate that dietary 18:2n-6 suppresses endogenous fatty acid synthesis in liver (26,27), but not in adipose tissue (28,29), and that feeding a linoleic acid-rich diet limited the contribution of *de novo* synthesized fatty acids from liver to the adipose tissue fatty acid store (see review, ref. 30). In the present study, we observed that the proportion of non-linoleoyl containing TG in adipose tissue was reduced to the same extent in animals given diets containing either moderately or extremely high levels (24 or 160 g/kg) of linoleic acid (Fig. 3, panel A). This finding suggests that the *in situ* formation of non-linoleoyl containing TG in adipose tissue was not affected by the dietary linoleate content. Thus, a decrease in the level of non-linoleoyl containing TG was probably the result of a reduced influx of *de novo* synthesized fatty acids from liver in conjunction with a significant increase in the formation of linoleoyl containing TG in adipose tissue. Nelson *et al.* (31) have shown that dietary linoleate is rapidly incorporated into adipose tissue TG in animals fed a linoleate-rich diet. Comparison between animals fed diets containing low and moderate levels (2.4 and 24 g/kg) of linoleic acid showed that the level of 18:2n-6 in adipose tissue TG was increased in parallel with the dietary linoleate content. However, when linoleic acid was increased from 24 to 160 g/kg (> six-fold increase), the level of 18:2n-6 in adipose tissue TG was increased by only 45% (Table 1). In other words, increases in the level of 18:2n-6 in adipose tissue are less pronounced once the linoleate content in the diet exceeds 24 g/kg, or equivalent to 5% of total calories. This value is therefore greater than the minimum dietary requirement. As dietary linoleate content increased from moderate to high levels (from 24 to 160 g/kg), the levels of di- and trilinoleoyl containing TG in adipose tissue were increased two-fold (32.2 *vs* 15.1%), whereas those of monolinoleoyl containing TG were decreased concomitantly two-fold (37.3 *vs.* 17.4%). This finding suggests that the additional linoleic acid molecules might have replaced fatty acids, such as 16:0, 16:1 or 18:1 in the monolinoleoyl containing TG, and converted them to di- or trilinoleoyl containing TG. Thus, the ratio of poly- to monolinoleoyl containing TG molecular species may be a useful indicator for assessing the level of dietary linoleate intake and its adequacy. Moreover, in comparison with the theoretical distribution calculated on basis of 1,2,3-random linoleate distribution, the observed levels of polylinoleoyl containing TG were increased (Table 2). It appears that upon an

increase in supply, linoleic acid was incorporated more readily into TG molecules already containing one or two 18:2n-6 residues than into those containing no linoleic acid.

In conclusion, we observed that the proportion of linoleoyl containing TG in adipose tissue increased only when the dietary linoleate content reached a certain level (24 g/kg). A further increase in dietary linoleic acid had only a moderate effect on the overall adipose tissue fatty acid composition, but it significantly modified the distribution of linoleic acid among adipose tissue TG molecular species; the proportion of monolinoleoyl containing TG species was decreased, whereas that of polylinoleoyl containing TG species was increased.

Site-Specific Differences in the Fatty Acid Composition of Human Adipose Tissue

P.C. Calder[a,*], D.J. Harvey[a], C.M. Pond[b] and E.A. Newsholme[a]

[a]Department of Biochemistry, University of Oxford, Oxford OX1 3QU and [b]Department of Biology, The Open University, Milton Keynes MK7 6AA, United Kingdom

The fatty acid composition of triacylglycerols from fifteen distinct adipose depots taken from each of seven adult male human subjects was compared. Oleic, palmitic, linoleic, stearic, myristic, palmitoleic and vaccenic acids accounted for more than 90% of the triacylglycerol fatty acids in all sites from all subjects; a number of other fatty acids were also identified and quantified. There were large differences in the average fatty acid composition between individual subjects. There were no site-specific differences in the proportions of myristic (3.8–4.7% of triacylglycerol fatty acids), palmitic (23–29%), linoleic (6.7–9.8%) or vaccenic (4.1–4.7%) acids or in the proportions of any of the less abundant fatty acids. There were some significant site-specific differences in the proportions of palmitoleic, oleic and stearic acids. The calf depot contained more palmitoleic acid (6.41 ± 1.09%) than the trapezius (3.12 ± 0.55%), perirenal (3.59 ± 0.50%) and mesenteric (3.70 ± 0.43%) depots, more oleic acid (42.13 ± 1.27%) than the trapezius (36.03 ± 2.18%), perirenal (36.50 ± 1.56%) and breast (37.13 ± 1.55%) depots and less stearic acid (5.18 ± 0.89%) than the trapezius (8.57 ± 0.97%), perirenal (8.49 ± 0.75%), mesenteric (7.87 ± 0.42%), breast (8.02 ± 0.75%) and clavicular (8.34 ± 0.78%) depots. The buttock depot contained less stearic acid (6.06 ± 0.65%) than the perirenal, mesenteric and clavicular depots, while the anterior thigh depot contained less stearic acid (6.07 ± 0.70%) than the perirenal depot. These findings indicate that, while most human adipose depots differ little in fatty acid composition, some sites, in particular the calf, perirenal, trapezius and mesenteric depots, have site-specific properties.
***Lipids* 27, 716–720 (1992).**

A number of studies have documented differences between human adipose depots with respect to adipocyte size (1–6) and metabolism (1–8), including lipoprotein lipase activity (1), sensitivity of lipolysis to catecholamines and to starvation (2,7,8), sensitivity to the antilipolytic effect of insulin (3), high density lipoprotein metabolism (5), glycolytic capacity (6) and adenylate cyclase activity and its sensitivity to adrenaline (7). Despite these structural and metabolic differences between adipose depots, it is generally assumed that the fatty acid composition of all adipose tissue within an individual is the same (9). Several studies have compared the fatty acid composition of different human adipose depots (10–15) and, although some of these studies did not detect any site-specific differences, some consistent differences have been reported. The adipose depots investigated in these studies were chosen on the basis of surgical accessibility. As a result, previous studies have compared a limited number of sites, usually two (11,14), three (10,12,15) or four (12). Furthermore, some of the earlier studies compared different depots from only a small number of subjects, in some cases from a single individual (10,12). To determine the true extent of site-specific differences in fatty acid composition, a large number of depots from a number of individuals should be compared. In this study we investigated the fatty acid composition of fifteen distinct adipose depots from seven subjects. The adipose depots examined included those studied previously (10–15) and those believed, on the basis of their anatomical relations with other tissues (see ref. 16), to be homologous with depots that are frequently studied in laboratory rodents (17–20) and other mammals (21–25). To our knowledge, this investigation of site-specific differences in human adipose tissue fatty acid composition is the most extensive yet performed.

Abbreviations: BSTFA, *N,O*-bis-(trimethylsilyl)trifluoroacetamide; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry.

MATERIALS AND METHODS

Materials. Solvents were obtained from Fisons Scientific Apparatus (Loughborough, Leics., U.K.) and were redistilled before use. *N,O-bis*-(Trimethylsilyl)trifluoroacetamide (BSTFA) was obtained from Sigma Chemical Co. (Poole, Dorset, U.K.). An ethereal solution of diazomethane was prepared from Diazald (Aldrich Chemical Co., Gillingham, Dorset, U.K.).

Source of adipose tissue. Adipose tissue samples were taken at *post mortem* examination from seven fresh, adult male cadavers for whom death had been sudden and/or accidental (for example, road traffic accident, drowning). The seven subjects were aged 31, 35, 27, 25, 46, 63 and 47 years, respectively (mean ± SD age 39 ± 13 years). All subjects lived in Southwest England. Subjects who had died from chronic illnesses were excluded from the study. The samples were collected within 24 h of death and were individually sealed and stored at −20°C until analysis. The adipose depots sampled included eight superficial (buttock, breast, clavicular, abdominal wall, anterior thigh, medial thigh, posterior arm, anterior arm), three intermuscular (popliteal, under the trapezius muscle, calf), three intraabdominal (perirenal, mesenteric, omental) and one intrathoracic (pericardial) sites. The calf depot, although not anatomically intermuscular, is included here as an intermuscular site because it is homologous with an intermuscular depot in other mammals (16).

Lipid extraction and fatty acid analysis. Total lipid was extracted using chloroform/methanol (2:1 vol/vol) as described by Folch *et al.* (26). Triacylglycerols were separated from phospholipids by chromatography through a column of activated silicic acid prewashed with chloroform. Triacylglycerols were eluted from the column with chloroform. Triacylglycerol fatty acids were obtained by saponification with methanolic 0.5 M KOH for 120 min at 70°C and were extracted into ethyl acetate. After evaporation to dryness, fatty acid methyl esters were prepared by reaction with an excess of diazomethane in diethyl ether (27).

Fatty acid methyl esters (dissolved in methyl acetate) were separated by gas chromatography (GC) in a Hewlett-Packard (Hewlett-Packard Ltd., Bracknell, Bucks., U.K.) 5890A gas chromatograph fitted with a 50 m × 0.3 mm bonded phase OV-1 fused silica capillary column, film thickness 0.52 μm. Helium at 2.0 mL/min was used as the carrier gas, and the split/splitless injector was used in the split mode with a split ratio of 15:1. Injector and detector temperatures were both 300°C, and the column oven temperature was programmed from 130–380°C at 2°C/min. The separation was recorded with a Servoscribe chart recorder and quantitative data were recorded with a Hewlett-Packard 3390A recording integrator. Fatty acid methyl esters were identified by comparison with standards or by gas chromatography/mass spectrometry (GC/MS) of fatty acid trimethylsilyl or picolinyl esters.

Trimethylsilyl esters of fatty acids were prepared by heating with BSTFA for 10 min at 60°C. Picolinyl esters of fatty acids were prepared by the method of Harvey (28,29). GC/MS data were obtained with a VG (Fisons Instruments, Manchester, U.K.) 70/70F mass spectrometer interfaced to a Varian (Varian Associates, Sunnyvale, CA) 2440 gas chromatograph fitted with a SGE split/splitless injection system operated in the split mode with a split ratio of 10:1. The column was a 25 m × 0.2 mm OV-1 bonded phase fused silica capillary, film thickness 0.33 μm, terminating 10 mm inside the mass spectrometer ion source. Helium at 1 mL/min (determined in the absence of the mass spectrometer vacuum) was used as the carrier gas. The injector, transfer line and ion source temperatures were 300, 300 and 280°C, respectively. The column oven temperature was programmed from 180–350°C at 2°C/min. The accelerating voltage, electron energy, trap current and scan speed used were 4 kV, 70 eV, 1 mA and 1 s/decade, respectively. Spectra were recorded with a VG 11/250 data system.

Data presentation and statistics. All data are presented as mean ± SE for the indicated number of samples. Statistical significance was determined using the two-tailed unpaired Student's *t*-test; a value for *P* of less than 0.05 was considered to indicate a statistically significant difference.

RESULTS

Fatty acid analysis. Between 25 and 30 fatty acids were positively identified in most samples from each of the subjects. However, seven fatty acids comprised more than 90% of the triacylglycerol fatty acids in all sites from all subjects. These were oleic (18:1n-9), palmitic (16:0), linoleic (18:2n-6), stearic (18:0), myristic (14:0), palmitoleic (16:1n-7) and vaccenic (18:1n-7) acids. The next most abundant fatty acids were lauric (12:0) and eicosamonoenoic (20:1n-9) acids, which comprised 0.3–1.0% and 0.4–1.0%, respectively, of the fatty acids present in the samples. The proportion of arachidonic acid (20:4n-6) was 0.1–0.3%. Most samples also contained quantifiable amounts of 14:1n-5 (0.2–0.5%), 15:0 (0.2–0.7%), 16:1n-8 (0.1–0.4%), 17:1n-8 (0.3–0.8%), 17:0 (0.2–0.7%), 20:1n-6 (0.1–0.3%), 20:0 (0.1–0.4%) and 22:1n-9 (0.1–0.2%) and trace amounts (<0.1% of fatty acids) of 10:0, *i*-15:0, *ai*-15:0, 16:1n-6, *ai*-17:0, 18:1n-5, 19:1n-10, 19:1n-8, 20:2n-7, 20:1n-7 and 22:0. In addition, many of the samples contained an eighteen carbon fatty acid whose structure has not yet been elucidated. Neither α- nor γ-linolenic acids (18:3n-3 and 18:3n-6, respectively) were detected in any of the samples.

Intersubject differences in fatty acid composition. The average proportions of the seven major fatty acids in all sites of each subject are shown in Table 1. There were significant differences in the proportion of each of these fatty acids between several of the subjects (Table 1). The greatest differences were in the proportions of palmitoleic and linoleic acids, which varied by up to three-fold between the subjects.

Site-specific differences in fatty acid composition. The proportions of each of the seven major fatty acids in each adipose depot from all subjects are shown in Table 2. There were no consistent site-specific differences in the proportions of myristic, palmitic, linoleic or vaccenic (Table 2) or in the proportions of any of the less abundant fatty acids (data not shown). There were, however, some significant site-specific differences in the proportions of palmitoleic, oleic and stearic acids (Table 2). These differences are summarized in Table 3.

Fatty acid composition data may be summarized in a variety of ways, such as proportions of saturated, monounsaturated and polyunsaturated fatty acids, as a saturated fatty acid/unsaturated fatty acid ratio or as the index of unsaturation, which takes into account the degree of unsaturation of the fatty acids. The fatty acid composition of each of the adipose depots studied is thus summarized in Table 4; data for all identified fatty acids, not only the seven major fatty acids, were used. No site-specific differences in the overall proportions of saturated or polyunsaturated fatty acids, in the saturated/unsaturated fatty acid ratio or in the index of unsaturation were found. There were, however, some site-specific differences in the proportion of monounsaturated fatty acids: the calf adipose

TABLE 3

Summary of the Site-Specific Differences in Human Adipose Tissue Fatty Acid Composition

Fatty acid	Site-specific differences
Palmitoleic	Calf > Trapezius, Perirenal, Mesenteric
Oleic	Calf > Trapezius, Perirenal, Breast
Stearic	Calf < Trapezius, Perirenal, Mesenteric, Breast, Clavicular Buttock < Perirenal, Mesenteric, Clavicular Anterior thigh < Perirenal

Pericardial (n = 5)	43.9 ± 4.8	48.7 ± 3.4	7.1 ± 0.9	0.79 ± 0.17	62.9 ± 4.7

[a]Data are mean ± SE from the indicated number of subjects. The index of unsaturation was calculated as the sum of (% unsaturated fatty acid × number of double bonds). Statistical significance ($P < 0.05$) is indicated by [b]*vs.* calf, [c]*vs.* trapezius, [d]*vs.* perirenal, [e]*vs.* mesenteric, [f]*vs.* breast, [g]*vs.* clavicular.

depot contained significantly more monounsaturated fatty acid than the trapezius, perirenal, mesenteric, breast and clavicular adipose depots (Table 4).

DISCUSSION

This study reports the fatty acid composition of triacylglycerols from fifteen distinct adipose depots taken from seven adult male human subjects. The fatty acid composition of a number of these sites has not been reported previously and, to our knowledge, this study represents the largest survey of possible site-specific differences in the fatty acid composition of human adipose tissue yet performed. In accord with previous studies (9–15,30), the major fatty acids found in all adipose depots were oleic, palmitic, linoleic, stearic, myristic and palmitoleic acids; these accounted for approximately 90% of the fatty acids present in each depot. Oleic acid was the most abundant fatty acid, comprising 35 to 45% of the fatty acid in each depot. This is less than the generally accepted proportion of oleic acid in adipose tissue, which is usually reported to be between 45 and 55% (9,12–15,30). However, in this study an isomer of oleic acid, vaccenic acid, accounted for a further 4–5% of fatty acid in each depot (Tables 2). It is likely that in earlier reports oleic and vaccenic acids were included under the single description of "18:1." Indeed, where oleic acid has been specifically referred to separately, its contribution to the adipose fatty acid content is 40–45%, while isomers of oleic acid contributed a further 6–8% (11). These proportions are in agreement with the current study. The proportions of the other major fatty acids reported here are in general agreement with those reported previously (9,12–15,30). In addition to the seven major fatty acids, a number of other fatty acids were identified and quantified. Neither α- nor γ-linolenic acids were detected in the current study, although previous studies have reported that human adipose tissue contains linolenic acid (9,15,30). The content of linolenic acid isomers reported by these earlier studies covers a rather wide range: Malcom *et al.* (15) report that linolenic acid comprises 0.6% of the fatty acid, although it is not clearly identified as n-3 or n-6 or both; Wood *et al.* (30) report that α-linolenic comprises 3% and γ-linolenic 0.2% of fatty acids, although it is stated that neither GC peak was pure linolenic acid; while Field *et al.* (9) give a value of 0.6% for α-linolenic and no value for γ-linolenic.

As has been reported previously (see ref. 31), there was great variation in adipose tissue fatty acid composition between the different subjects (Table 1). The proportions of palmitoleic and linoleic acids differed over a three-fold range between subjects, while the proportions of myristic, palmitoleic, vaccenic and stearic acids differed two-fold between subjects. Adipose tissue fatty acid composition is affected by diet (31), and it is likely that the differences reported here are the result of dietary variation between the subjects; we have no dietary information on any of the subects used in this study.

Site-specific differences in the proportions of palmitoleic, oleic and stearic acids were found (Tables 2 and 3), but the proportions of myristic, palmitic, linoleic and vaccenic acids did not vary between sites (Tables 2). There were no differences in the fatty acid composition of the intraabdominal adipose depots, while the only significant difference between the superficial sites was in the

proportion of stearic acid in the buttock and clavicular depots. The compositions of two intermuscular depots (calf and trapezius) differed greatly from one another. There were a number of differences in the proportions of palmitoleic, oleic and stearic acids between intermuscular (calf) and intraabdominal (perirenal, mesenteric), intermuscular (calf) and superficial (breast, clavicular) and intraabdominal (perirenal, mesenteric) and superficial (buttock, anterior thigh) depots (Tables 2). These differences indicate that some adipose depots, especially calf, trapezius, perirenal and mesenteric, have particular site-specific properties.

Because the rate of adipose tissue triacylglycerol-fatty acid turnover is low, the fatty acid composition of adipose tissue is believed to reflect the dietary fat intake of an individual over the previous twelve months (31). The fact that we (Tables 2 and 3) and others (10-15) find site-specific differences in adipose tissue fatty acid composition indicates that either not all adipose depots turn over their triacylglycerols at the same rate, or that factors other than diet can influence the fatty acid composition of some depots. It is possible that the sites which have been identified as having different fatty acid compositions have specific functions that may dictate the composition of the depot fat. Alternatively, differences in metabolic activity between adipose depots may cause variation in the fatty acid composition. Some site-specific metabolic differences between human adipose depots have been documented (1-8), although only a limited number of anatomical sites have been compared in most studies. A number of metabolic differences between the homologous depots in other mammals have been described (17-25). Interestingly, it has been found that different bovine adipose depots selectively incorporate different fatty acids (24), which would result in different fatty acid compositions. Furthermore, there is a difference in the fatty acid composition between inner and outer regions of the superficial fat depots of both the polar bear (23) and reindeer (25), suggesting that such differences occur within depots, as well as between depots.

Some site-specific differences in human adipose tissue fatty acid composition have been reported previously (10-15), although these studies were often based on a limited number of subjects and anatomical sites (see Introduction). Some studies reported site-specific differences in the proportion of stearic acid only (10) or in the proportions of palmitoleic and stearic acids only (11,12). The current study confirms some of these previous findings, for example that the perirenal depot contains more stearic acid than the buttock depot (10). In addition to differences in palmitoleic and stearic acids, more recent studies have reported some differences in the proportions of myristic, palmitic and oleic acids (13-15). This study did not find any site-specific differences in the proportions of myristic or palmitic acids (Table 2), although there were some differences in the proportions of oleic acid (Tables 2 and 3).

Inhibition of Phenytoin Bioactivation and Teratogenicity by Dietary n-3 Fatty Acids in Mice[1]

Stan Kubow*
School of Dietetics and Human Nutrition, Macdonald Campus of McGill University, Ste. Anne de Bellevue, Quebec, Canada H9X 3V9

Evidence suggests that the teratogenicity of the anticonvulsant drug phenytoin (DPH) can result from its bioactivation *via* embryonic prostaglandin synthase and/or maternal cytochromes P450. This study examined whether DPH bioactivation and teratogenicity could be reduced by dietary n-3 fatty acids. Female CD-1 mice were fed diets containing 2 wt% safflower oil and 10 wt% of either hydrogenated coconut oil, safflower oil, or a cod liver oil/linseed oil mixture (CLO/LO) for three weeks prior to impregnation and throughout gestation. DPH (55 or 65 mg/kg) was administered *via* intraperitoneal injections to pregnant mice at 0900 on gestational days 12 and 13, and on day 19 fetuses were given teratologic assessments. A similar dietary study evaluated *in vivo* covalent binding of radiolabeled DPH administered on day 12, and dams were killed 24 h later. A reduction in DPH-induced cleft palates and a decrease in DPH covalent binding to embryonic protein was observed in the CLO/LO group. Feeding CLO/LO enhanced incorporation of n-3 fatty acids into embryos and inhibited embryonic prostaglandin synthase activity. No differences in maternal hepatic cytochromes P450 activities were observed among dietary treatments. These data indicate that dietary n-3 fatty acids could reduce DPH teratogenicity *via* inhibition of embryonic prostaglandin synthase bioactivation of DPH.
***Lipids* 27, 721–728 (1992).**

Phenytoin (5,5-diphenylhydantoin, Dilantin, DPH) is one of the most efficacious and widely used anticonvulsants in North America (1). DPH is also a known teratogen in humans (2–4), mice (5,6) and rats (7). In humans, DPH-associated malformations are collectively known as the fetal hydantoin syndrome and characterized by a number of dysmorphic features including cleft lip and palate, malformation of heart and urogenital systems, central nervous system dysfunction and a distinct craniofacial pattern (2,3). Between 10% and 40% of offspring of mothers using the drug during pregnancy have been indicated to have some features of the fetal hydantoin syndrome (2,3).

Although the relationship between DPH metabolism and its teratogenicity remains controversial, there is considerable evidence supporting the involvement of a reactive intermediate in the teratogenicity of DPH. DPH has been shown to bind covalently to embryonic, placental and hepatic tissues indicating bioactivation to a reactive intermediate has occurred (6,8), and significantly higher levels of fetal DPH covalent binding has been observed in fetuses with cleft palate (6). *In vivo* and *in vitro* evidence from a number of human and animal studies have suggested that the teratogenic activity of DPH could result from both cytochromes P450-mediated bioactivation of DPH to an arene oxide intermediate (4,6) and prostaglandin synthase-catalyzed bioactivation of DPH to a reactive free radical (9,10). For instance, covalent binding of a reactive intermediate of DPH to proteins has been shown to be catalyzed by NADPH-dependent cytochromes P450 activity in rodent liver microsomes (8,9). In addition, incubations containing purified prostaglandin synthase or murine hepatic microsomes incubated with arachidonic acid have also stimulated *in vitro* covalent binding of DPH to proteins (9). Potentially important enzymatic pathways of detoxification that have been demonstrated in DPH teratogenicity include hydration of the arene oxide by epoxide hydrolase (4,8) and interactions involving glutathione (11). Some paradoxical observations, however, have suggested difficulties with the arene oxide hypothesis (5,10). For example, pretreatment with phenobarbital, an inducer of cytochromes P450, inhibited DPH teratogenicity in pregnant mice, whereas SKF 525A, an inhibitor of cytochromes P450, increased DPH teratogenicity (5). On the other hand, pretreatment of mice with aspirin, an irreversible inhibitor of the cyclooxygenase component of prostaglandin synthase, markedly inhibited the *in vivo* teratogenic effects of DPH (10). DPH-induced embryopathy and covalent binding of DPH have been observed in murine embryo cultures in the absence of maternal bioactivating enzymes indicating a role for embryonic bioactivation of DPH to a teratogenic reactive intermediate (12). Prostaglandin synthase bioactivation of DPH could be an important teratogenic mechanism that takes place at the embryonic level since at early stages of development embryonic prostaglandin synthase activity is high (13), while embryonic cytochromes P450 have been shown to be low or negligible (14).

The potential of dietary n-3 fatty acids to reduce DPH teratogenicity *via* inhibition of embryonic prostaglandin synthase bioactivation of DPH was evaluated in the present study. Although it has been well demonstrated that feeding a diet rich in n-3 fatty acids reduces the prostaglandin synthesizing capacity of a variety of tissues (15–17), little is known concerning the effect of these diets on embryonic prostaglandin synthase activity. The effect of n-3 fatty acid diets on maternal liver cytochromes P450 content and activities was also studied since diet-induced alterations in these enzyme activities could modulate DPH metabolism and teratogenicity.

MATERIALS AND METHODS

Animals, dietary treatments and animal breeding. Virgin female CD-1 mice (Charles River Canada, Inc., St. Constant, Quebec, Canada), with body weights 20–25 g, were

Abbreviations: CLO/LO, cod liver oil/linseed oil; DPH, phenytoin; FAME, fatty acid methyl esters; HCO, hydrogenated coconut oil; $PGA_{2\alpha}$, prostaglandin $A_{2\alpha}$; $PGE_{2\alpha}$, prostaglandin $E_{2\alpha}$; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$; PUFA, polyunsaturated fatty acids; SAFF, safflower oil.

housed in plastic cages with ground cob bedding (Beta Chips, Northeastern Products Corp., Warrensburg, NY). Animals were kept in a temperature-controlled room with a 12-h light-dark cycle automatically maintained (light cycle 0700 to 1900). After 3 d of feeding a nonpurified diet (Purina Mouse Chow, Ren's Feed and Supply, Oakville, Ontario, Canada), mice were weighed and randomly assigned into one of three dietary regimens of purified diets. Each group of mice was fed a modified AIN-76A diet with the following dry ingredients (g/100 g): casein (vitamin-free), 18.0; methionine, 0.03; glucose, 56.1; α-cellulose, 5.0; AIN-76 mineral mix, 6.0; AIN-76 vitamin mix, 2.2; and choline chloride, 0.4. Added to these dry ingredients was either hydrogenated coconut oil (HCO), safflower oil (SAFF) or a mixture (1:1) of cod liver oil and linseed oil (CLO/LO) such that the diets contained 10% fat by weight. All diets were supplemented with 2 g/100 g safflower oil to provide essential fatty acids in the diets, such that final diets contained 12% fat by weight. In addition, *dl*-α-tocopheryl acetate was added at 7.4 mg/g oil. All dietary components were supplied by ICN Nutritional Biochemicals (Cleveland, OH). The fatty acid profile of the diets is shown in Table 1. Autoxidation of the oils was prevented by the addition of synthetic antioxidant (0.01% butylated hydroxytoluene, Sigma Chemical Co., St. Louis, MO) to the oils. Fresh diet was provided every other day, and uneaten food was discarded. Food intake was recorded every third day throughout the experiment. Mice were fed the diets for at least three weeks prior to mating and were maintained on the diets throughout gestation. Three females were housed with one male mouse of the same strain overnight between 1500 and 0900. Pregnancy was ascertained the next morning by the presence of a vaginal plug, and this time was designated as gestational day 1. Food and water was provided *ad libitum* throughout the experiment. Fresh diets were stored in sealed containers, flushed with nitrogen and stored at 4°C until used. Lipid peroxidation of diets either stored at −20°C or kept at room temperature for 48 h did not increase as measured by the thiobarbituric acid assay (18).

To obtain data on phospholipid fatty acid profiles, and on P450 and prostaglandin synthase activities, mice receiving dietary treatments alone were killed by cervical dislocation on gestational day 12. All embryos were surgically removed from the dams, dissected free from their investing membranes in 9 g/L saline, weighed, immediately frozen in liquid nitrogen and stored at −80°C until assayed. Maternal livers and placenta were also removed immediately, washed in isotonic saline, blotted on paper to remove excess fluid, weighed, frozen in liquid nitrogen and stored at −80°C until analysis.

Drug treatments. DPH was dissolved in normal saline containing 2 mM sodium hydroxide (Fisher Scientific Co., Toronto, Ontario, Canada) at a final pH of 10.5. Teratogenic doses of DPH of either 55 or 65 mg/kg, were administered *via* intraperitoneal injection to 15 to 20 dams in each HCO, SAFF and CLO/LO treatment group as a two-dose regimen at 1100 on gestational days 12 and 13. Saline controls received intraperitoneal injections of sterile physiological saline instead of DPH. Dams were killed for toxicological assessment by cervical dislocation on gestational day 19, one day before spontaneous delivery. In a second study, in order to examine dietary fat effects on covalent binding of DPH *in vivo*, tritiated DPH (5,5-[*phenyl*-4-^{3}H(*N*)] diphenylhydantoin, 51.5 Ci/mmol; New England Nuclear, Lachine, Quebec, Canada) was mixed with unlabeled DPH and administered, 1 μCi/g body weight, on gestational day 12 to four dams in each of the dietary treatment groups. All solutions were prepared immediately prior to administration and were constituted to maintain a standard injection volume of 10 mL/kg body weight.

TABLE 1

Fatty Acid Composition of Dietary Fats

Fatty acid[b]	Diet[a] HCO	SAFF	CLO/LO[c]
14:0	29.3	0.9	3.1
16:0	17.1	7.2	10.7

Unsaturated index[g]	63	168	211

[a]HCO, hydrogenated coconut oil; SAFF, safflower oil; CLO/LO, cod liver oil/linseed oil.
[b]Fatty acids are identified by the number of carbon atoms and the number of double bonds, followed by the position of the first double bond from the methyl end of the fatty acid.
[c]Mixture of 1 part cod liver oil to 1 part linseed oil.
[d]Trace (<0.5%).
[e]Not detectable.
[f]Polyunsaturated to saturated fatty acid ratio.
[g]Unsaturation index is the sum of percentages of individual fatty acids multiplied by the number of double bonds.

Teratological assessment. Following laparotomy on day 19 of gestation, the uterus was exteriorized, and the number and location of resorptions and each fetus were noted and fetuses were sexed and weighed. After being fixed for at least two days in Carnoy's solution, a transverse incision was made between the upper and lower jaw of each fetus and the palatal shelves were examined with the unaided eye for the presence or absence of a cleft.

Covalent binding studies. Radiolabeled DPH was administered with unlabeled DPH at 1100 on gestational day 12. Dams were killed at 1100 on gestational day 13, and the amount of radiolabeled DPH covalently bound to protein in maternal and embryonic tissues was determined. For the determination of covalent binding of tritiated DPH, all placenta and embryos from each litter were pooled separately whereas livers from all dams were assayed individually. The determination of covalent binding of tritiated DPH involved a validated modification of an exhaustive washing method to permit more accurate determinations to microgram quantities of embryonic tissue (9). Tissue samples from maternal liver, placenta and embryos were homogenized in ice-cold KCl 1.15 g/L for 20 s with a probe homogenizer (Ultra-Turrax, Janke and Kundel GmbH, Staufen, Germany). As previously

described (9), proteins were precipitated, washed and digested for counting of covalently bound radiolabeled DPH. The amount of protein in each sample was assayed by a modified method of Lowry (19), and the level of covalently bound radiolabeled DPH was standardized per mg protein.

Extraction of lipids and tissue fatty acid analysis. For fatty acid analysis, maternal livers, placenta and embryos were thawed and homogenized in chloroform/methanol (2:1, vol/vol) containing 0.005 g/L (wt/vol) butylated hydroxytoluene following the procedures by Folch *et al.* (20). Tissue phospholipids were separated by adsorption chromatography on silica cartridges 25 mm × 10 mm i.d. (Sep-pack, Supelco, Oakville, Ontario, Canada) by the method described by Juaneda and Rocquelin (21). Fatty acid methyl esters (FAME) of total phospholipids were prepared with boron trifluoride methanol reagent according to Morrison and Smith (22). FAME were separated and quantified by gas-liquid chromatography (Varian 3700 gas chromatograph fitted with dual FID detectors—Varian, Palo Alto, CA) with 1.82 m × 6.3 mm packed glass column packed with 10% Silar 10 CP on 100/120 chromosorb Supelcoport (Supelco, Oakville, Ontario, Canada) and a Shimadzu C-R6A Chromatopac integrator (Kyoto, Japan). Identification of the fatty acid methyl esters was by comparison of retention times with those of authentic standards (Nu-Chek Prep, Elysian, MN).

Prostaglandin $PGF_{2\alpha}$ determinations. Production of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) by embryonic homogenates was determined according to a modification of the method of Klein *et al.* (23). Frozen embryos were placed into a polypropylene test tube and quickly homogenized in the semi-frozen state by vortexing for 20 s. Homogenates were incubated at 37°C for 1 h in a shaking water bath. Following incubation, 4 mL of absolute ethanol was placed into each tube and incubated in an ice bath for 30 min. The samples were centrifuged for 20 min at 1600 × *g* and the supernatant was collected. The supernatant was dried under nitrogen and reconstituted in absolute ethanol. The pellets were saved to determine their protein content (19) and to measure the DNA content using a fluorometric assay (24). Levels of $PGF_{2\alpha}$ of the supernatant were determined by a double antibody (Method 2) radioimmunoassay kit using rabbit antiprostaglandin $PGF_{2\alpha}$ serum (Incstar Corporation, Stillwater, MN) according to the manufacturer's instructions. This antiserum is reported by the manufacturer to have minimal cross-reactivity (less than 2%) with prostaglandin $A_{2\alpha}$ ($PGA_{2\alpha}$), prostaglandin $E_{2\alpha}$ ($PGE_{2\alpha}$) and $PGF_{2\alpha}$ metabolite. The levels of $PGF_{2\alpha}$ assayed are expressed as ng of $PGF_{2\alpha}$ synthesized per gram of embryonic protein.

Cytochromes P450 content and activities. After dams were killed, their livers were removed and stored at −80°C until analysis. Liver microsomes were prepared by differential centrifugation as previously described (9). Concentration of cytochromes P450 was determined in microsomes diluted to 2.0 g protein/L with 0.1 mol/L phosphate buffer using the Beckman DU-40 spectrophotometer (Beckman, Fullerton, CA) according to the method of Omura and Sato (25). P450 isozyme activities were assayed using a Sequoia-Turner (Mountain View, CA) single beam fluorescence spectrophotometer, with the excitation wavelength set at 530 nm, the emission wavelength set at 585 nm, and the entrance and exit slits set at 10 nm. 7-Pentoxyresorufin *O*-dealkylase activity was assayed at 11.2 μmol/L 7-pentoxyresorufin (final concentration) according to Lubet *et al.* (26). The activity of 7-ethoxyresorufin *O*-deethylase was determined using a final concentration of 0.9 μmol/L 7-ethoxyresorufin (27). Linear increases were measured for several minutes and compared to resorufin used as a standard.

Statistical analyses. Statistical analyses were performed on both an individual fetus and a litter basis. The incidence of cleft palates was calculated as the number of fetuses with cleft palates divided by the number of fetuses and the resorption incidence as the number of resorptions divided by the number of implantation sites (fetuses plus resorptions). Incidence data (*i.e.*, cleft palates and resorptions) were analyzed by Chi-square. Statistical comparisons of differences between groups were analyzed by one-way ANOVA using the Statistical Analysis System for personal computers (SAS Institute, Cary, NC). As fatty acid and covalent binding determinations were conducted on the pooled embryos and placenta from a litter, the litter represents the unit of analysis for these measures. The embryo was used as the unit of analysis for prostaglandins, protein and DNA content. When significant differences occurred, the treatment mean differences were identified by Tukey's test. A probability of $P < 0.05$ was accepted as the minimal level of significance.

RESULTS

Teratology. Figure 1 shows the teratogenic responses to doses of DPH (55 and 65 mg/kg/day) given on days 12 and 13 of gestation to mice fed the SAFF, HCO, and CLO/LO diets. Mice given the SAFF and HCO diets had approximately 19% and 21% incidences of cleft palate after the 55 mg/kg DPH dose treatment. Mice fed the CLO/LO diet, however, showed approximately a 72% lowered incidence of cleft palate as compared to the other dietary groups. Fetal weight and the resorption frequency were not affected by the source of dietary fats in DPH-treated mice (Fig. 1). After the 65 mg/kg dose treatment of DPH, mice fed the SAFF and HCO diets had cleft palate incidences of 42% and 41%, respectively. In contrast, the response of cleft palates to the higher dose of DPH was inhibited in mice fed the CLO/LO diet which showed an incidence of 28% cleft palate (Fig. 1). The resorption frequency was not affected by any of the dietary treatments; however, fetal weight showed a slight decrease (6%) in the DPH-treated dams receiving the CLO/LO diet (Fig. 1). The vehicular solution for DPH which was composed of NaOH (2 mM/L) in normal saline did not cause cleft palates in any of the dietary treatment groups, and the saline-treated mice showed a low incidence of resorptions (4.2%). The mean fetal weight of the saline controls was 1.29 ± 0.01 g (mean ± SEM).

Covalent binding. The covalent binding of radiolabeled DPH to maternal and embryonic tissues measured on gestational day 13 is shown in Figure 2. The CLO/LO dietary treatment resulted in a 33% decrease in covalent binding of radiolabeled DPH to embryonic protein ($P < 0.05$) relative to the other dietary treatments, with no effect on binding to the associated placentas. Conversely, the CLO/LO diet increased covalent binding of DPH in maternal liver relative to the SAFF dietary group ($P < 0.05$).

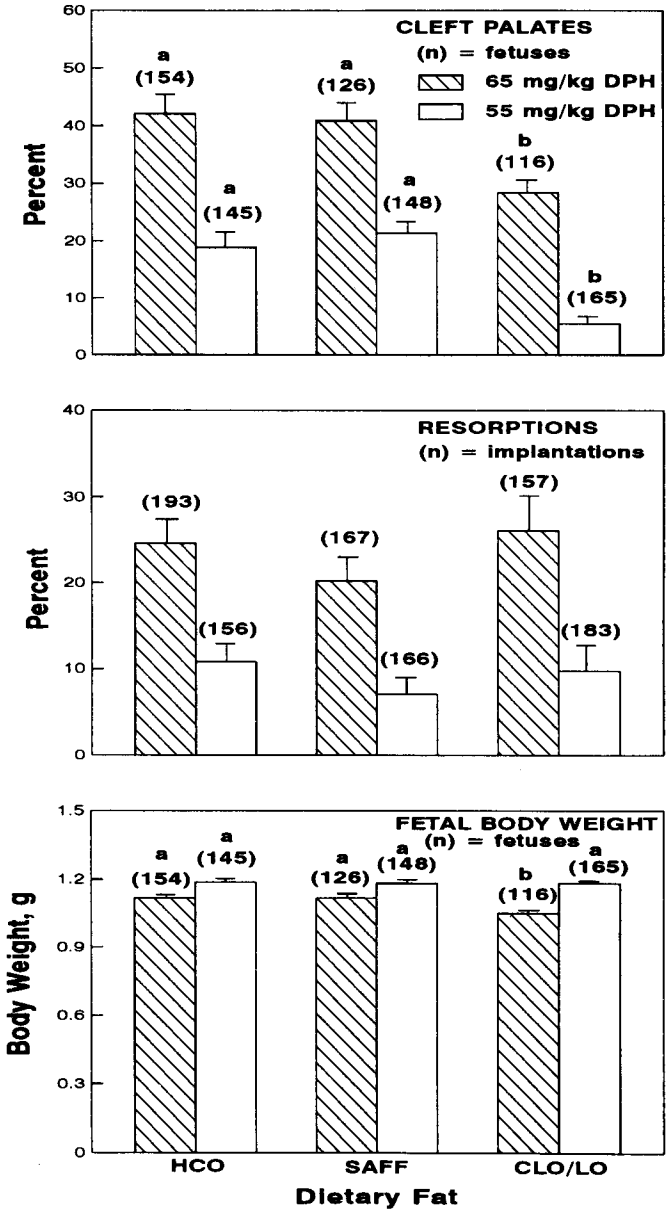

FIG. 1. The effect of modifications in dietary fats on DPH embryopathy. Groups of 15 to 20 CD-1 mice were fed diets containing 2 wt% safflower oil (SAFF) and 10 wt% of either hydrogenated coconut oil (HCO), SAFF, or a cod liver oil/linseed oil mixture (CLO/LO) for three weeks prior to impregnation and throughout gestation. At 0900 on gestational days 12 and 13 mice were administered 55 or 65 mg/kg DPH i.p. Each bar represents the mean plus the standard error for the number of embryos given in parentheses. Values for a dietary treatment with a particular drug dose with different letters are significantly different ($P < 0.05$) as determined by ANOVA with means separated by Tukey's test.

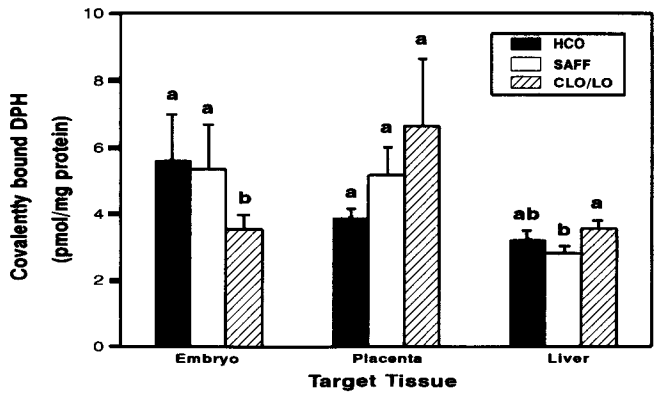

FIG. 2. Effect of modifications in dietary fats on the covalent binding of DPH to embryonic, placental and maternal liver tissues. Groups of five CD-1 mice were fed diets containing 2 wt% safflower oil (SAFF) and 10 wt% of either hydrogenated coconut oil (HCO), SAFF, or a cod liver oil/linseed oil mixture (CLO/LO) for three weeks prior to impregnation and throughout gestation. Pregnant mice were administered DPH, 65 mg/kg i.p., at 1100 on gestational day 12. The dose of radiolabeled DPH was 1 μCi/g body weight. Dams were killed 24 h later. Each bar represents the mean plus the standard error; n = 4. Values for a particular dietary treatment with different letters are significantly different ($P < 0.05$) as determined by ANOVA with means separated by Tukey's test.

Effects of diet on gestational indices, food intake, protein and DNA content. All diets were well accepted by the female mice, and no differences were observed in terms of food intake between the dietary treatments (6 g/d per mouse). Maternal consumption of a diet containing CLO/LO resulted in gestational day 12 embryo weights (0.089 ± 0.003 g) (mean ± SEM) that were significantly ($P < 0.05$) lower than those of mouse pups fed a diet containing either SAFF (0.100 ± 0.003 g) or HCO (0.096 ± 0.005 g) as fat sources. The mean DNA content per embryo was significantly lower in the CLO/LO embryos on gestational day 12, although the ratio of protein to DNA was increased in CLO/LO embryos relative to the other dietary treatments (Table 2). The growth retardation was not likely the consequence of lower maternal weight gain as no significant differences were also observed between the HCO and CLO/LO diet groups in terms of mean body weight of the dams on gestational day 12 (data not shown). The total number of implantation sites per dam, the number of embryos per litter, placental weights and resorptions per litter did not differ between dietary treatments (data not shown).

Fatty acid composition of total phospholipids in maternal livers, placenta and day 12 embryos. The polyunsaturated fatty acid (PUFA) composition of the maternal hepatic, placental and embryonic phospholipids was highly dependent upon the composition of dietary lipid (Table 3). A comparison of the three dietary groups reveals that CLO/LO resulted in a significant increase in embryonic, placental and maternal liver phospholipid content of C_{20}n-3 and C_{22}n-3 fatty acids. The concentrations of 20:5n-3, 22:5n-3 were detectable only in embryos of CLO/LO-fed animals, and embryonic concentrations of 22:6n-3 increased approximately four-fold in comparison to the HCO and SAFF treatments. The incorporation of n-3 fatty acids in all the tissues was associated with a decrease in 20:4n-6 relative to that found in the HCO- and SAFF-fed groups (Table 3). The concentration of 20:4n-6 was similar in both HCO- and SAFF-fed groups. Levels of 18:2n-6 in liver phospholipids reflected dietary availability of this fatty acid, with SAFF mice accumulating greater amounts relative to the other dietary groups. The levels of 18:2n-6, however, did not vary in embryonic and placental phospholipids between SAFF and CLO/LO dietary treatments although the dietary HCO group showed depressed levels as compared to the other dietary

TABLE 2

DNA and Protein Contents of Day 12 Embryos from Mice Fed Three Different Sources of Fat

	Dietary fat		
	HCO[a]	SAFF	CLO/LO
Total DNA, μg	30.28 ± 1.33[b]	30.83 ± 0.98[b]	22.55 ± 2.90[c]
Total protein, mg	2.84 ± 0.26[b]	3.56 ± 0.14[b,c]	3.81 ± 0.23[c]
Total protein/total DNA	4.87 ± 0.39[b]	5.80 ± 0.24[c]	7.97 ± 0.88[d]

[a]Pregnant mice were fed diets containing 2 wt% safflower oil (SAFF) and 10 wt% of hydrogenated coconut oil (HCO), SAFF, or a cod liver oil/linseed oil (CLO/LO) mixture for three weeks prior to impregnation and until gestational day 12.

[b–d]Mean ± SEM, n = 10; different letters denote statistical significance (ANOVA; $P < 0.05$). When significant differences occurred ($P < 0.05$), treatment mean differences were identified by Tukey's test.

groups (Table 3). The feeding of the CLO/LO and SAFF diets was also accompanied by lowered levels of 16:1n-7 and 18:1n-9 when compared with animals fed diets containing HCO. The phospholipid content of embryos, placenta and livers of the CLO/LO group was found to have markedly higher n-3 concentrations and n-3/n-6 ratios and lower n-6 concentrations as compared to the other diet groups. Dietary treatment had no effect on the ratio of PUFA to saturated fatty acids or the unsaturation index in embryo phospholipids, despite large differences in these indices in the diet. Conversely, the CLO/LO diet induced significant increases in the PUFA content, polyunsaturated to saturated ratio and unsaturation index in membrane phospholipids of placental and hepatic tissues (Table 3).

Prostaglandin measurements. Embryo tissue synthesis of prostaglandin $F_{2\alpha}$ from the three diet groups are depicted in Figure 3. Consistent with the lower levels of 20:4n-6 and higher concentrations of 20:5n-3 in the total phospholipids of CLO/LO embryos, CLO/LO embryo homogenates synthesized markedly lower levels of prostaglandin $F_{2\alpha}$ than did embryo homogenates from the other diet groups after 1 h of incubation at 37°C. No significant differences in prostaglandin $F_{2\alpha}$ levels were observed between SAFF and HCO embryos.

Effects of diet on microsomal enzymes. The effects of dietary treatments on cytochromes P450 content and activities in maternal livers are shown in Table 4. There was no significant dietary effect on cytochromes P450 content. The constitutive levels of the activities of microsomal *O*-dealkylation of 7-pentoxyresorufin and *O*-deethylation of 7-ethoxyresorufin were low, and no significant differences were observed among dietary groups (Table 4).

DISCUSSION

The inhibition of DPH-induced cleft palate together with the decreased covalent binding of radiolabeled DPH to embryonic protein in mice fed the CLO/LO diet suggests that the teratologic inhibition was due to decreased embryonic exposure to the reactive intermediate of DPH. The decrease in cleft palate incidence in the CLO/LO group occurred without any change in the incidence of resorptions. This is noteworthy since detection of cleft palates would have been precluded by a high resorption incidence in the CLO/LO group which could have led to artifactually lowered estimates of teratogenicity.

The present study demonstrated that tissue phospholipids of embryos, placenta and liver reflected high maternal intakes of n-3 fatty acids following consumption of the CLO/LO mixture for approximately five weeks. This was anticipated since previous studies have demonstrated significant increases in 20:5n-3 and 22:6n-3 content and a reduction in 20:4n-6 in lung phospholipids of newborn offspring of rats fed high n-3 PUFA diets for three weeks (16,17). The relationship of a high n-3 fatty acid content in membrane phospholipids of day 12 murine embryos with decreased embryonic prostaglandin synthase activity is a new observation although prostaglandin synthesis has been detected in day 11 rat embryo homogenates (23) and reduced prostaglandin synthase activity has been demonstrated in lung tissue of newborns of n-3 fatty acid-fed dams (17).

The reduction of embryonic prostaglandin synthase activity in the CLO/LO diet group provides support for the concept that a mechanism by which CLO/LO embryos were protected against DPH teratogenicity involved inhibition of embryonic prostaglandin synthase bioactivation of DPH. Increased tissue n-3 fatty acid content can inhibit prostaglandin synthase activity *via* several mechanisms including: (i) reduced levels of 20:4n-6 availability (28); (ii) an elevation of n-3 fatty acids, particularly eicosapentaenoic acid (20:5n-3), which directly competes with 20:4n-6 as a substrate for cyclooxygenase (28,29); and (iii) a direct inhibition in cyclooxygenase activity by n-3 fatty acids *via* decreased peroxide tone (30). The comparable prostaglandin synthesizing activities observed between HCO and SAFF embryos are consistent with the equivalent concentrations of the 20:4n-6 precursor present in the embryonic membrane phospholipids. The mice fed the HCO and SAFF diets elongated and desaturated 18:2n-6 to a similar degree as reflected by the equivalent amounts of 20:4n-6 in embryonic, placental and liver tissue phospholipids of HCO- and SAFF-fed mice. These findings support and extend the idea that desaturation and chain elongation of 18:2n-6 is regulated such that increasing dietary intake of 18:2n-6 above a threshold value of approximately between 1 and 2% of energy does not lead to any further increase in 20:4n-6 levels (31). Similar findings have been reported by other investigators who demonstrated unchanged prostaglandin synthesis in renal homogenates despite twenty-fold increases in dietary linoleic acid above 0.4 wt% (31).

The present dietary studies support previous work by

TABLE 3

Fatty Acid Composition of Embryo, Placenta and Liver Total Phospholipids Isolated from Mice Fed Diets Containing 10 wt% of Either Hydrogenated Coconut Oil (HCO), Safflower Oil (SAFF), or a Cod Liver Oil/Linseed Oil Mixture (CLO/LO)[a]

Fatty acid	Tissue	Dietary fat

[a]Pregnant mice were fed diets containing 2 wt% safflower oil (SAFF) and 10 wt% of either hydrogenated coconut oil (HCO), SAFF, or a cod liver oil/linseed oil mixture (CLO/LO) for three weeks prior to impregnation and until day 12 of gestation. The values are expressed as means ± SEM of five litters of pooled embryos or pooled placenta and nine maternal livers in each group; values in a row for a particular tissue with different superscript letters (b,c) are significantly different ($P < 0.05$) as determined by ANOVA and Tukey's test comparisons; n.d. = not detectable.

[b]Polyunsaturated to saturated fatty acid ratio.

[c]Unsaturation index is the sum of percentages of individual fatty acids multiplied by the number of double bonds.

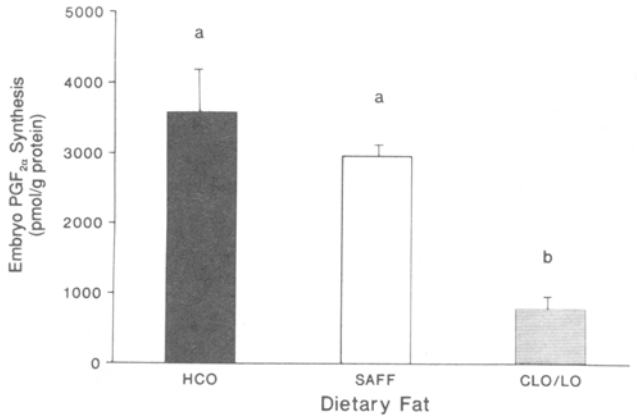

FIG. 3. $PGF_{2\alpha}$ production by homogenates of day 12 embryos removed from mice fed three different sources of fat. Pregnant mice were fed diets containing 2 wt% safflower oil (SAFF) and 10 wt% of either hydrogenated coconut oil (HCO), SAFF, or a cod liver oil/linseed oil mixture (CLO/LO) for three weeks prior to impregnation and until day 12 of gestation. Values are expressed as means ± SEM; n = 10. Values for a particular dietary fat with different letters are significantly different ($P < 0.05$) as determined by ANOVA with means separated by Tukey's test comparisons.

Wells *et al.* (10) showing a marked reduction in DPH-induced cleft palates and covalent binding in CD-1 mice following pretreatment by acetylsalicylic acid, a potent inhibitor of prostaglandin synthase activity. Correspondingly, acetylsalicylic acid pretreatment did not protect against DPH-induced resorptions and reductions in fetal body weight, further suggesting that a similar protective mechanism was involved in both studies. As prostaglandin synthase activity is high in embryonic (13) and certain extrahepatic tissues (9), this pathway may contribute substantially to DPH bioactivation in these tissues.

The lack of protective effects of the CLO/LO diet against DPH-induced fetal resorptions and weight loss suggests that other mechanisms could be involved in these toxicities. In fact, a small (6%) but statistically significant decrease in mean fetal weight was observed in the CLO/LO dietary group following administration of 65 mg/kg DPH. This result may be biologically significant since a decreased embryo weight was observed in the untreated CLO/LO dietary group on gestational day 12. Embryonic DNA concentrations on gestational day 12 were also lowered in the CLO/LO embryos indicating that cell proliferation was delayed and that gestational delay in organ development in CLO/LO embryos may have taken place. This finding suggests the possibility that delayed organ growth of CLO/LO embryos may have been in part responsible for the decreased cleft palate incidence by delaying the critical period of susceptibility to DPH-induced cleft palate. Fetal growth retardation has been previously observed following feeding n-6 fatty acid deficient HCO diets or diets with a high ratio of n-3 to n-6 fatty acids (16). The cause of growth retardation in developing embryos which are accompanied by high n-3 to n-6 fatty acid ratios is unclear. One possible mechanism by which n-3 rich diets may exert growth-suppressing effects may be mediated *via* a depression in the growth stimulating action of prostanoids since PGE_2 has been found to stimulate DNA synthesis and growth of cultured cells (32).

The present observations contradict a recent proposal (33) that DPH disrupts craniofacial development by inhibiting arachidonic acid release from membrane phospholipids for cyclooxygenase-mediated conversion into prostaglandins. This hypothesis was tested by Kay *et al.* (33) by incubation of exogenous arachidonic acid in embryo cultures treated with DPH. Although a marked reduction in gross morphological defects was noted in cultures containing arachidonic acid, the capability of exogenous arachidonic acid to stimulate cyclooxygenase activity in the embryos was not assessed. In contrast, the present study indicates that a decreased incorporation of arachidonic acid into embryonic tissue phospholipids and a reduction in embryonic prostaglandin synthesizing capacity was associated with an abatement of DPH-induced cleft palate. Moreover, recent embryo culture experiments from our laboratory have indicated that mouse embryos from CLO/LO dams demonstrated decreased morphological defects following incubation with DPH in comparison with SAFF embryos which were treated with DPH at the same embryological age (High, K. and Kubow, S., unpublished data).

The content and activities of liver microsomal cytochromes P450 were investigated since the activities of this system are known to be influenced by the fatty acid composition of phospholipids of microsomal membranes (34,35) and as altered cytochromes P450 activities could alter DPH metabolism and teratogenicity. As CLO/LO dietary treatment did not alter either total cytochromes

TABLE 4

Influence of Different Sources of Dietary Fats on Total P450 and the Activities of Microsomal Enzymes in Livers of Pregnant Mice[a]

	Dietary fat		
	HCO	SAFF	CLO/LO
Total P450 content, nmol/mg protein	0.47 ± 0.05	0.44 ± 0.05	0.35 ± 0.02
Ethoxyresorufin deethylase, pmol/(min•mg protein)	50 ± 5	43 ± 5	47 ± 3
7-Pentoxyresorufin *O*-dealkylase, pmol/(min•mg protein)	83 ± 13	64 ± 9	78 ± 11

[a]Pregnant mice were fed diets containing 2 wt% safflower oil (SAFF) and 10 wt% of either hydrogenated coconut oil (HCO), SAFF, or a cod liver oil/linseed oil mixture (CLO/LO) for three weeks prior to impregnation and until day 12 of gestation. Values are expressed as means ± SEM of ten mice in each group.

P450 content nor the activities of cytochromes P450 isozymes known to bioactivate DPH, it is unlikely that differences in maternal cytochromes P450 metabolism of DPH could account for the observed protective effects of the CLO/LO diet. The similarity of liver cytochromes P450 content and activities between the CLO/LO and SAFF diets is in agreement with other studies demonstrating that dietary 18:3n-3, 20:5n-3 and 22:6n-3 are similarly effective to dietary 18:2n-6 and 20:4n-6 in increasing the content and activity of the liver microsomal cytochromes P450 mixed function oxidase system (35). Somewhat surprising was the lack of differences observed between the HCO diet and the dietary PUFA treatments as previous work has indicated that an elevation of PUFA intake increases cytochromes P450 activities (34,35). However, as a result of variables such as hormonal changes during pregnancy, inducibilities of cytochromes P450 between the pregnant and non-pregnant state may be altered (36).

In summary, the results reported herein provide support for the hypothesis of the involvement of embryonic prostaglandin synthase in the bioactivation of DPH as a mechanism of DPH teratogenicity. Additionally, the role of gestational delay in palatal development in decreasing DPH-induced cleft palate incidence in n-3 fatty acid fed mice is suggested and requires further study. These observations do not discount a contribution from maternal enzymatic pathways of phenytoin metabolism for the decreased sensitivity of n-3 fatty acid-fed mice to DPH-induced cleft palate. Further research is needed to investigate the possibility that differences in distribution, conjugation and/or excretion pathways of DPH induced by n-3 diets may alter the plasma half-life and embryonic exposure to the drug. Since the final teratological endpoints of DPH toxicity depend on a balance among pathways involving bioactivation, detoxification and fetal cell repair, the protective effects of dietary n-3 fatty acids may result from a combination of effects exerted at a number of these metabolic steps.

Plasma Lipids and Fatty Acids in Urbanized Bushmen, Hereros and Kavangos of Southern Africa (Namibia)

H.Y. Tichelaar[a,*], A.J.S. Benadé[a], S.J.D. O'Keefe[b], P.L. Jooste[a], S.A. Swanevelder[c] and E. Van Staden[a]

[a]National Research Programme for Nutritional Intervention, Tygerberg, 7505, Republic of South Africa, [b]Department of Gastroenterology and Internal Medicine, Mayo Clinic, Rochester, Minnesota 55905 and [c]Institute for Biostatistics of the Medical Research Council, Tygerberg, 7505, Republic of South Africa

Thirty-nine urbanized ethnic Namibian people comprising 21 Bushmen (semi-urbanized), 7 Hereros and 11 Kavangos were assessed for plasma lipids and fatty acid (FA) composition. Total cholesterol and triacylglycerol concentrations were measured by enzymatic methods, and neutral lipid FA composition by gas-liquid chromatography. The results demonstrated that while total cholesterol concentrations were not significantly different, significant differences in triacylglycerol concentrations ($P < 0.05$) were seen between Bushmen and Kavangos. By comparing Bushmen with Hereros and Kavangos, significant differences between Bushmen and Kavangos were also observed in plasma triacylglycerol FA compositions, particularly 16:0 (32.73% *vs.* 25.05%), 16:1n-7 (7.00% *vs.* 5.06%), 18:2n-6 (9.30% *vs.* 22.25%) and 20:3n-6 (0.12% *vs.* 0.48%), while Kavangos had higher 20:4n-6 levels than Hereros (1.44% *vs.* 2.00%). In plasma cholesteryl esters, Bushmen were significantly different from Kavangos in 16:1n-7 (8.85% *vs.* 4.93%), 18:1n-9 (32.06% *vs.* 23.07%) and 20:4n-6 (6.91% *vs.* 10.00%). Significant differences were also observed between Bushmen and Hereros in 18:0 (1.08% *vs.* 1.29%) and 18:2n-6 (35.68% *vs.* 45.50%). The FA of Namibian groups were also compared with South African reference groups comprising urbanized whites and Xhosas and rural Vendas. The differences in blood lipid values can be explained primarily by excessive alcohol consumption. These results suggest that semi-urbanized Bushmen have changed their diets under urbanized conditions which may increase their risk of coronary heart disease.

***Lipids* 27, 729–732 (1992).**

Very little information is available on the plasma lipids and fatty acids (FA) in the different ethnic groups of Namibia, especially on Bushmen (1,2). Various studies have demonstrated that the plasma FA compositions, especially those of plasma cholesteryl esters (CE), reflect the dietary FA intake (3–6). Urbanization increases the risk of all groups to develop coronary heart disease (CHD), presumably due to changes in their dietary food intake (5–8), *e.g.*, increased alcohol consumption and a decreased dietary intake of vegetable fat. An increased mortality rate from CHD may endanger the existence of Bushmen in modern society (1).

We performed this study to examine the lipids and FA in semi-urbanized Bushmen *per se*, with comparison to Hereros and Kavangos of the same area, and white, Xhosa and Venda South African reference groups in order to investigate the extent of these dietary changes. White South Africans with a high incidence of CHD followed a typical Western diet with a high fat, low polyunsaturated to saturated fatty acids (P/S) ratio and low carbohydrate intake. The urbanized Xhosas are rapidly adopting a Western lifestyle which increases the risk of developing CHD. Rural Vendas consume a traditional diet of maize meal supplemented with mopanie worms.

Abbreviations: AA, arachidonic acid; CE, cholesteryl esters; CHD, coronary heart disease; DGLA, dihomo-gammalinolenic acid; EPA, eicosapentaenoic acid; FA, fatty acids; GLC, gas-liquid chromatography; LA, linoleic acid; OA, oleic acid; P/S, polyunsaturated to saturated fatty acid ratio; TAG, triacylglycerol; TC, total cholesterol; TLC, thin-layer chromatography.

MATERIALS AND METHODS

A total of 39 urbanized ethnic Namibian people, in the Ojinene district of east Hereroland, comprising 21 Bushmen, 7 Hereros and 11 Kavangos with average ages of 29, 33 and 41, respectively, were assessed for plasma lipids and FA compositions. The Bushmen studied were no longer purely nomadic; most of them live for variable times in association with Herero villages, but tend to migrate from one place to another depending upon work and food availability. They are accordingly very much "in transition." Anthropometric measurements and dietary intake on the same study individuals have been reported previously by O'Keefe and Lavender (9). Approval to conduct a study on these ethnic groups was originally obtained from the local administrator or village headman. After an interview, informed consent was obtained from the subjects before blood samples were taken with the assistance of local district nurses. All participants were adults older than 18 years.

All blood samples were taken in the early morning, in either fasting or semi-fasting (light maize meal and water) conditions. Blood samples were taken in heparinized containers, and separated plasma samples were deep-frozen until analysis could be carried out, which was always within two weeks. Total cholesterol (TC) and triacylglycerol (TAG) concentrations were determined enzymatically (Boehringer Mannheim GmbH Diagnostica, Mannheim, Germany; CHOD-PAP and GPO-PAP kits, respectively). Neutral lipids were separated by thin-layer chromatography (TLC) and analyzed by gas-liquid chromatography (GLC) as described previously (10). The significance of these results was evaluated using the nonparametric Kruskal-Wallis test to compare group means statistically at the 5% level. Although mean values were used, median values may be a better estimate of the true location of the mean. Robust standard deviations (SD) were used as an improvement on the usual SD calculated for the subgroup specifically, due to the small sample size of the Herero and Kavango groups. FA results are compared with urbanized whites and blacks (Xhosas), and rural blacks (Vendas) in South Africa (unpublished data).

RESULTS

The findings of the trial are summarized in Tables 1, 2 and 3. It should be noted that Table 1 includes data for only 13 Bushmen, 4 Hereros and 10 Kavangos, compared with the data of 21 Bushmen, 7 Hereros and 11 Kevangos in Tables 2 and 3. This was due to insufficient sample size

to analyze the lipids of all the 39 participants, as priority was given to fatty acid analyses.

Statistically significant differences were found for TAG ($P < 0.05$) between Bushmen and Kavangos. Interestingly, Bushmen had the same TAG levels as the South African reference whites (Table 1). In neutral lipids the most important differences can be seen in plasma TAG percentage (TAG%) linoleic acid levels (LA; 18:2n-6), which were significantly higher in Kavangos compared to Bushmen and Hereros ($P < 0.05$) with a concomitant reduction of stearic acid (18:0). Bushmen had significantly higher ($P < 0.05$) palmitic acid (16:0) and palmitoleic acid (16:1n-7) and lower dihomo-gammalinolenic acid (DGLA; 20:3n-6) levels than Kavangos, while Kavangos also had significantly higher arachidonic acid (AA; 20:4n-6) levels than Hereros. Compared to the South African reference groups comprising urbanized whites and blacks (Xhosas) and rural blacks (Vendas), Vendas appear to have plasma TAG% palmitic acid levels similar to those of Bushmen and Hereros, while urban Xhosas and Kavangos have similar TAG% FA levels. Whites, however, have the highest LA levels of all the groups, with the Namibian groups all having higher oleic acid (OA; 18:1n-9) levels than any seen in the reference groups. Only Vendas have AA levels which are less than those of the Kavangos. In contrast, the reference groups have much higher eicosapentaenoic acid (EPA) levels than seen in the Namibian groups (Table 2).

Bushmen had significantly higher ($P < 0.05$) palmitoleic acid and OA levels and lower AA levels than Kavangos in plasma percentage cholesteryl esters (CE%), where individual FA were expressed as percentages of the total area of all FA peaks. Bushmen also had significantly lower ($P < 0.05$) stearic acid and LA levels than Hereros. Compared to the South African reference groups, Xhosas and Vendas have CE% composition palmitic acid levels which are similar to that of the Hereros, while whites seem to have the lowest levels of all groups. Palmitoleic acids are even lower in whites and Xhosas when compared with the levels of Hereros and Kavangos. Xhosas also have the highest stearic acid levels while Vendas have the lowest of all groups. Whites have the lowest OA levels of all groups, while Xhosas and Vendas have OA levels comparable to those of the Kavangos and Hereros, respectively. Both whites and Xhosas have higher LA levels than seen in all the Namibian groups, with whites having the highest. Although whites and Bushmen have similar AA levels, whites and Xhosas seem to have generally higher AA levels than seen in the other Namibian groups (Table 3). It should be noted that the reference whites also have the highest eicosapentaenoic acid (EPA; 20:5n-3)/AA ratio (0.29), compared to Xhosas (0.14), Bushmen (0.09), Hereros (0.07) and Kavangos (0.03). Bushmen also have a lower P/S ratio in their CE% FA than whites, 5.57 *vs.* 7.23, respectively (Table 3). Unfortunately, no phospholipid levels were measured to support the CE% FA; this could have provided a more specific interpretation of the habitual dietary intake of each group.

DISCUSSION

Bushmen, the original inhabitants of southern Africa, are scattered over large areas of northeast Namibia. Their diet varies dramatically and depends primarily on availability, with the only consistent component being maize meal. Home brewed beer consumption (2–4 liters per day) provides a daily energy intake from alcohol of 740–1480 kcal and contributes 156–312 grams of carbohydrate. Little or no vegetables and fruit are eaten. The Kavangos live in the far north and rely mainly on agriculture. Their staple diet consists of "African millet" (*mahongo*), a whole grain product, supplemented by fish from the river. Their diet is well balanced and reasonably constant. Hereros, the major black group, occupy the central areas of the territory. They mainly consume meat and dairy products with a staple diet of refined maize meal, 2–3 times daily. Hereros tend to consume more vegetables, fruits and fresh milk during the short rainy season.

An interesting observation was made when comparing the data in Table 1. Bushmen had substantially higher mean TAG concentrations than Kavangos. While TAG concentrations for Kavangos and Hereros were similar to previous observations in rural groups (1,2), the values for Bushmen were nearly doubled. This could be ascribed, possibly, to excessive alcohol consumption which causes TAG accumulation in the liver (11). Whilst total caloric and animal protein intake is low (1,9), animal fat (lard) is used when available mainly for flavoring by mixing with maize meal. TC concentrations were similar in all groups, but the general tendency was lower than in the rural population (1) and lower compared to other groups (12–13).

This communication compares for the first time the neutral lipid FA compositions in these southern African groups. Groups were not separated according to sex, because no sex difference could be detected in studies by Holman *et al.* (14) and Manku *et al.* (15). The effect of age should have little influence on the CE% FA composition (16); accordingly, population CE% FA differences are most likely to be due to dietary differences (6). The high LA content in the plasma CE of Hereros and Kavangos, and concomitant decreases in palmitoleic acid in these groups compared to Bushmen, suggests that these groups consume relatively less animal products than do the Bushmen, because plasma CE FA are known to have highly significant associations with dietary fat consumption due to the preference to plasma CE as indicators of dietary fat compositions (4–6). These findings are in accordance with a study of Melchert *et al.* (17). The lower LA content in Bushmen may also indicate a reduced polyunsaturated fat intake by this group (18) and a relatively high saturated fat intake, because vegetable and fruit consumption is little to none at all, which could be expected to increase the risk for CHD or atherosclerosis (6–7,19). Only few of the rural Bushmen, living from hunting and gathering, survive today. They had high LA TAG% FA values of 25.9% compared with the 9.3% as measured in the participating group (2,9). Because the plasma CE% FA of Bushmen are similar to those of normal Italian subjects, this may be indicative of a similar dietary P/S ratio (3). The FA of the Kavangos and Hereros are similar to values for groups reported by other investigators (19–21). However, South African whites and Xhosas have higher LA levels (unpublished data).

Bushmen do, however, have the highest OA levels in their plasma CE. Compared to the other groups, this could protect Bushmen because OA tends to resist oxidative modifications of FA while it simultaneously reduces the concentration of low density lipoprotein cholesterol. The net effect could be a reduction in the progression of

atherosclerosis, which may explain in part the low incidence of CHD in Bushmen (22). The white control group had the lowest OA levels of all groups, which may be a contributory factor to the high incidence of CHD in this group (13). The white group also had higher CE P/S ratios than the Bushmen. Greenland Eskimos, well documented as having a reduced incidence of CHD (23), are characterized by having high OA levels and corresponding low CE P/S ratios (4,17). Lipid and FA comparisons of the different groups may oversimplify the risk elements of CHD and exclude the potential importance of genetic factors. However, very little information exists on the risk factors of the Namibian groups.

The high palmitoleic acid and OA levels in the CE% FA of Bushmen with concomitant low LA levels have typical FA patterns of chronic alcoholics after acute alcohol abuse (24), and may indicate excessive alcohol consumption. Both palmitoleic acid and OA are known to correlate positively with alcohol consumption, while LA correlates negatively with these variables. Alcohol is known to alter lipid metabolism (8), probably by stimulating hepatic FA biosynthesis or inhibition of Δ6 desaturase activity in these individuals (25).

Bushmen also had the lowest AA levels and the highest EPA/AA ratio of the Namibian groups. However, this is still considerably less than the EPA/AA ratio of the reference whites, who are known to be at risk of CHD (12). Although low ratios may increase the risk of developing CHD, the group of Bushmen studied had no clinical signs of CHD. This could perhaps become a problem with economic improvements resulting in increased total caloric intake. The change from their traditional lifestyle has resulted in a high incidence of malnutrition (9), especially reduced fat and protein stores (70% and 75%, respectively). The severe malnutrition is primarily responsible for the predominance of infectious disease in Bushmen, especially tuberculosis (9). One fact that was extremely clear was the high incidence of alcoholism. Urbanization of Bushmen may thus have dire consequences for their continued survival as an independent ethnic group in modern society (9,26).

ARTICLE

Comparison of the Effect of the Amount and Degree of Unsaturation of Dietary Fat on Plasma Low Density Lipoproteins in Vervet Monkeys

M. Kruger[a,*], C.M. Smuts[a], A.J.S. Benadé[a], J.E. Fincham[a], C.J. Lombard[a], E.A. Albertse[b] and K.J. van der Merwe[c]

[a]SA Medical Research Council, Tygerberg, 7505, [b]Nutrition Unit, Faculty of Medicine, University of Stellenbosch, Tygerberg, 7505 and [c]Department of Biochemistry, University of Stellenbosch, Stellenbosch, 7600, South Africa

The effects of the degree of unsaturation and of the amount of dietary fat on low density lipoprotein (LDL) concentration and composition were determined in vervet monkeys. Diets with fat contents of 41, 31 and 18% energy, each with a low and a high polyunsaturated to saturated fatty acid ratio (P/S; 0.27–0.38 and 1.13–1.47) were fed to six female vervet monkeys for two months. Another six females were given a low fat, high P/S diet for the same period of time, to serve as a reference. The cholesterol contents of the diets were low (21–33 mg per day) and relatively constant. LDL cholesterol concentrations decreased significantly ($P \leq 0.01$) when the dietary fat content decreased from 31 to 18% of energy. The dietary P/S ratio only affected LDL cholesterol concentrations during moderate (31% of energy) fat intake, where LDL cholesterol increased ($P \leq 0.01$) with a decrease in dietary P/S. Substantial individual variations were observed in LDL cholesterol concentration responses to dietary fat changes. The changes in LDL cholesterol concentrations were the result of changes in the concentration of LDL particles, as the molecular composition did not differ significantly between dietary periods. The high density lipoprotein cholesterol and the plasma triacylglycerol concentrations were not influenced by the dietary fat changes. During the high P/S diets, the percentage of 18:2 (linoleic acid) increased ($P \leq 0.01$) and that of 18:1 (oleic acid) decreased ($P \leq 0.01$) in LDL esterified cholesterol, as compared to the low P/S diets. In adipose tissue triacylglycerol the percentage of 18:2 was three times higher ($P \leq 0.01$) during the high P/S diets than during the low P/S diets. A decrease in the amount of dietary fat (from 31 to 18% of energy) was associated with an increase in the percentage of 18:1 in LDL esterified cholesterol.

Lipids 27, 733–739 (1992)

Increased plasma (and especially low density lipoprotein) cholesterol concentration is a major risk factor for atherosclerosis (1). The cholesterol lowering effect of increasing the ratio of polyunsaturated to saturated fatty acids (P/S) in the diet have been demonstrated both in humans (2–7) and in non-human primates (8–11). Increasing the dietary P/S also is associated with increased percentages of 18:2 (linoleic acid) in adipose tissue and plasma lipids, which are negatively correlated with atherosclerosis (12–15). Dietary P/S used in these studies were often unrealistically high (P/S $\geq$ 2) (2,3,5,7,8,11).

Several human populations with low fat diets have low plasma cholesterol concentrations and risks for atherosclerosis (16–18). Usually these diets also have low saturated fat and cholesterol contents (17,19). In some experiments reductions in the amount of dietary fat were associated with decreases in plasma and low density lipoprotein (LDL) cholesterol concentrations (5,20,21), but not in others (4,6,22). Decreased high density lipoprotein (HDL) cholesterol (4,5, 19,21,22) and increased plasma triacylglycerol (TAG) concentrations (4–6,20), as well as decreased percentage of 18:2 in adipose tissue (23) (which have been reported during low fat diets), may increase the risk for atherosclerosis (1,14).

Alterations in the composition of LDL have been implicated in the etiology of atherosclerosis (15,24–26). Enlarged LDL particles with an increased esterified cholesterol content are associated with diet-induced hypercholesterolemia and atherosclerosis in non-human primates (15,27). The degree of unsaturation and the quantity of fat in the diet appear to be major factors in promoting these compositional changes in primates (2).

Only a few studies have compared the effects of increasing the P/S ratio and decreasing the amount of fat in the diet on lipoprotein metabolism (4–6,10,28,29). However, none of these studies determined the effect of a change in the degree of unsaturation of dietary fat during a moderate or low fat intake. Lipoprotein composition was not determined in any of these studies.

The aim of the present study was to determine both the combined and the independent effects of quantity and composition of dietary fat on plasma lipid and lipoprotein concentrations in female vervet (African green) monkeys. LDL molecular composition, as well as fatty acid composition of adipose tissue and LDL lipids, was selected for detailed investigation because of its documented association with atherosclerosis in this species (15,30).

MATERIALS AND METHODS

The study was approved by the Ethical Committee of the South African Medical Research Council.

The study group was comprised of 12 female vervet monkeys *(Ceropithecus aethiops)* between 1.5 and 4.5 years of age. The group was stratified for age and cholesterolemic response to a high fat (41% of energy), low polyunsaturated to saturated fatty acid ratio (P/S; 0.29) diet. The animals were then randomized into two groups of six animals each. The vervets were individually caged and kept in a controlled environment (31).

All 12 vervets were stabilized on a low fat (18% of

energy), high P/S (1.47) diet (LF-HP diet) for two months before the start of the experiment. The experimental group was fed a series of six diets which differed in the amount and/or type of dietary fat. The diets fed in consecutive periods were: high fat, low P/S diet (HF-LP diet); high fat, high P/S diet (HF-HP diet); moderate fat, high P/S diet (MF-HP diet); moderate fat, low P/S diet (MF-LP diet); low fat, low P/S diet (LF-LP diet) and the LF-HP diet. From the HF-LP to the LF-HP diet only one dietary variable changed after each dietary period. Each diet was fed for two months. Dietary studies on vervets showed that this period was sufficient for plasma cholesterol concentrations to stabilize after a dietary change (Smuts, C.M., and Kruger, M., unpublished data). The second group served as a reference group and was maintained on the LF-HP diet for the duration of the experiment.

The diets fed in the six sequential dietary periods consisted of food components common to human diets and were formulated from information contained in the NRIND Food Composition Tables (32). Food was provided in the form of baked patties. The major fat sources of the low P/S diets were beef, chicken (not in the low fat diet), butter and brick margarine; and in the high P/S diets they were beef, chicken, soft margarine (not in the high fat diet), brick margarine (only in the high fat diet) and sunflower oil. The other ingredients of the baked patties were skimmed milk powder, hake (white fish), egg, dried beans, rice, wheat bread meal (white or brown), sugar, syrup, potatoes, cabbage, carrots and bananas. Vitamin C (40 mg per vervet daily) was added after baking.

The diets were calculated to have the same energy, protein, fiber and cholesterol contents. The calculated fat content of the high, moderate and low fat diets was 40, 30 and 18% of energy, respectively, with a P/S of 0.25 for the low P/S diets and 1.50 for the high P/S diets, and a cholesterol content of 35 mg per monkey per day. The energy provided by carbohydrates compensated for changes in the energy provided by fat in the various diets. Total fat and cholesterol content and fatty acid composition of the diets were determined as described previously (30).

At the end of each dietary period, blood and adipose tissue samples were taken under ketamine anaesthesia (10 mg/kg body mass, intramuscular) with atropine premedication (0.05 mg/kg body mass, intramuscular). Blood samples were taken after a fasting period of at least 12 h. Blood was collected from the vervets into tubes containing ethylenediaminetetraacetic acid (EDTA; 1 mg/mL blood) and immediately centrifuged at 4°C to separate the plasma. Lipoprotein fractions were isolated by sequential ultracentrifugation. Very low density lipoprotein (VLDL) was isolated at a density of <1.006 g/mL, intermediate density lipoprotein (IDL) between 1.006 and 1.019 g/mL and LDL between 1.019 and 1.063 g/mL in a 40.3 Beckman (Palo Alto, CA) rotor at 40,000 rpm for 20 h at 10°C. The HDL fraction was isolated from the plasma by precipitating apolipoprotein B (apo B) containing lipoproteins with heparin-manganese chloride (33).

Total plasma and HDL cholesterol were measured using enzymatic methods (Boehringer Mannheim, Mannheim, Germany; CHOD-PAP method). Total and free cholesterol (FC) of the lipoprotein fractions isolated by ultracentrifugation were determined by an enzymatic iodide method (34,35). The enzymes used were cholesterol oxidase and esterase (Boehringer Mannheim). The esterified cholesterol concentration was obtained by subtraction. Plasma TAG concentration was determined enzymatically (Boehringer Mannheim). Apo B in LDL was assayed by endpoint laser nephelometry using a monospecific antibody to human apo B prepared in sheep (Boehringer Mannheim). All procedures were according to prescribed methods (36). The use of human anti-apo B antiserum against non-human apo B was validated as described (30).

Lipids in LDL and adipose tissue were extracted with chloroform/methanol (2:1, vol/vol) (37,38). Butylated hydroxytoluene was used as an antioxidant. Esterified cholesterol (EC), TAG and phospholipids were separated by thin-layer chromatography (30). The fatty acids of EC and TAG were transmethylated and analyzed by gas chromatography as described previously (30). Total phospholipids (TPL) were quantified by microchemical assays (39). The number of molecules of EC, FC TAG and TPL per LDL particle and LDL particle mass were calculated (30). Molecular weights (in g/mol) used in these calculations are 651 for EC, 387 for FC, 885.4 and 879.4 for TAG (for low and high P/S diets, respectively), 787 for TPL and 512,000 for apo B.

For the statistical analysis, the changes (delta values) within each individual vervet between consecutive dietary periods were calculated by taking differences. This was done for each vervet in both groups. By calculating these individual changes, each vervet is used as its own control. The two-sample Wilcoxon test was used to compare the delta values of the experimental and reference groups. The reference group values provided a measure of the non-dietary effect against which the changes in the experimental group could be assessed.

For comparison of the high and low P/S ratio diets, the mean of the values during the high and during the low P/S ratio diets, respectively, were calculated for each vervet in the experimental group. The differences (delta values) between these means were taken. These calculations also were done on the values of the corresponding periods in the reference group. The delta values of the two groups were compared by the two-sample Wilcoxon test. The effect of the amount of dietary fat was tested in the same way. Medians and range (minimum to maximum) were used for descriptive statistics. The median is a robust statistic for estimating the central location of a sample.

RESULTS

The content and composition of dietary fat in the six diets as determined by biochemical analyses are shown in Table 1. These results confirmed the calculated fat content of the diets. The analyzed P/S of the diets was higher (0.27–0.38) for the low P/S diets, and lower (1.13–1.47) for the high P/S diets than calculated from the food composition tables (0.25 and 1.50, respectively). The analyzed cholesterol contents of the diets were 61–92% of the estimated amount.

The baseline median body masses of the experimental (3.01 kg) and reference (2.65 kg) groups increased gradually over the experimental period by 0.35 kg and 0.45 kg, respectively. The lipid profiles of the two groups during the different dietary periods are shown in Table 2. Figure 1 shows the individual and median changes in plasma total and LDL cholesterol between consecutive dietary

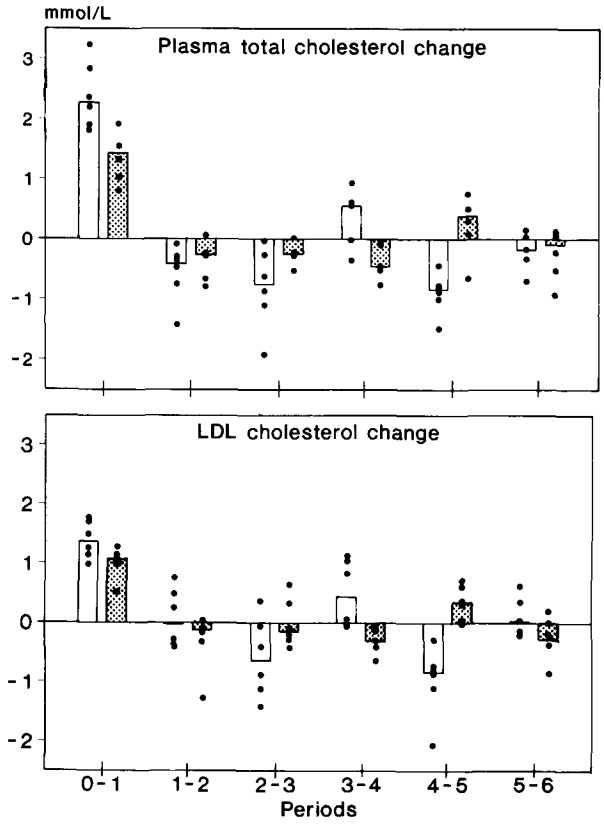

FIG. 1. Changes in individual (dot) and median (bar) plasma total and LDL cholesterol concentrations in experimental (open bar) and reference (dotted bar) groups between consecutive dietary periods. Dietary changes in the experimental group associated with the different periods were: 0–1, low fat, high P/S to high fat, low P/S; 1–2, high fat, low P/S to high P/S; 2–3, high fat, high P/S to moderate fat, high P/S; 3–4, moderate fat, high P/S to low P/S; 4–5, moderate fat, low P/S to low fat, low P/S; and 5–6, low fat, low P/S to high P/S.

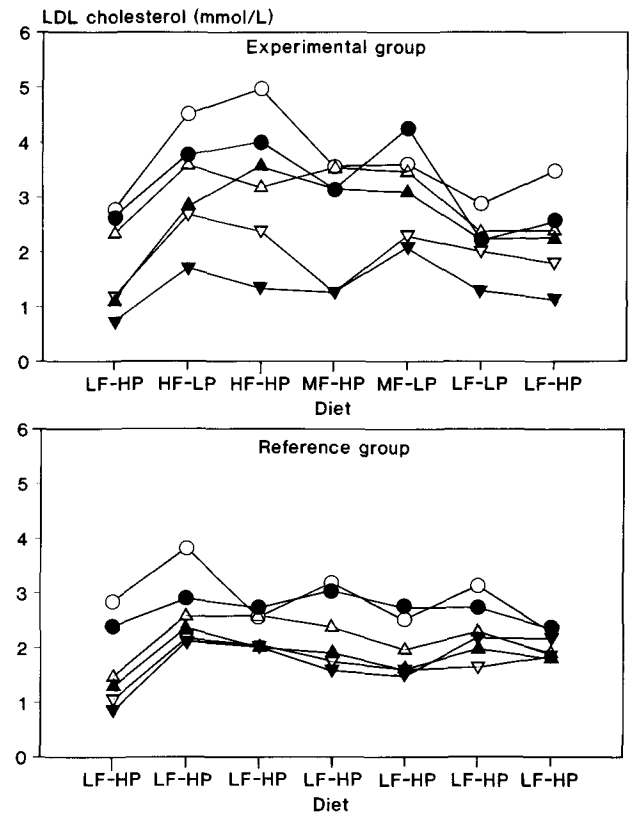

FIG. 2. Comparison of LDL cholesterol concentrations of individuals in experimental and reference groups. Diets: LF-HP, low fat, high P/S; HF-LP, high fat, low P/S; HF-HP, high fat, high P/S; MF-HP, moderate fat, high P/S; MF-LP, moderate fat, low P/S; and LF-LP, low fat, low P/S.

periods for the experimental and reference group. The median plasma total cholesterol concentrations of the experimental group decreased when the intake of fat with a low P/S was decreased from a moderate (31% of energy) intake to a low (18% of energy) intake ($P \leq 0.01$; Fig. 1, periods 4 to 5). The mean plasma total cholesterol concentrations were also lower during the low fat than during the moderate and high (41% of energy) fat dietary periods, when P/S was not taken into account ($P \leq 0.01$). The change in dietary P/S from 1.26 to 0.27 during the moderate fat intake was associated with a significant increase in the median plasma cholesterol concentration relative to the changes in the reference group (Fig. 1, periods 3 to 4). During the high and low fat diets the P/S did not have a significant effect on plasma total cholesterol (Fig. 1, periods 1 to 2 and 5 to 6, respectively). Plasma TAG and HDL cholesterol concentrations of the experimental group did not change significantly between dietary periods as compared to the reference group.

The individual and median values for LDL cholesterol concentrations of the experimental and reference groups are given in Figure 2 and Table 2, respectively. In the experimental group, changes in the LDL cholesterol concentrations were similar to those in plasma total cholesterol (Fig. 1). A decrease in the fat content of the diet from 31 to 18% of energy during the low dietary P/S was associated with decreases in the LDL cholesterol concentrations of all six vervets ($P \leq 0.01$; Fig. 2). Increasing the dietary P/S during the moderate fat intake resulted in lower LDL cholesterol concentrations in three of the vervets ($P \leq 0.01$; Fig. 2). The molecular composition (number of EC, FC, TAG and TPL molecules per molecule apo B) of LDL was not significantly affected by the amount or degree of unsaturation of fat in the diet (values not shown). This was also true for the calculated particle mass of LDL.

The percentages of 18:2 (linoleic acid) and 18:1 (oleic acid) in adipose tissue and LDL lipids are shown in Table 3, as well as changes in these parameters between consecutive dietary periods in Figure 3. An increased percentage of 18:2 in the dietary fat (high P/S diets, irrespective of the amount of dietary fat) was associated with increases in the percentages of 18:2 in adipose tissue and LDL lipids ($P \leq 0.01$; Tables 1 and 3). The percentage of 18:2 in adipose tissue TAG was about three times higher ($P \leq 0.01$) during the high P/S (P/S 1.13–1.47) than during the low P/S diets (P/S 0.27–0.38). In LDL-EC the percentage of 18:2 increased ($P \leq 0.01$), while that of 18:1 decreased ($P \leq 0.01$) during the high P/S diets. This situation was

[c]Significant difference between high (-HP) and low P/S (-LP) diets ($P \leq 0.01$).
[d]and [e]Differed significantly ($P \leq 0.01$), when the changes in the experimental group were compared with the changes between corresponding periods in the reference group.

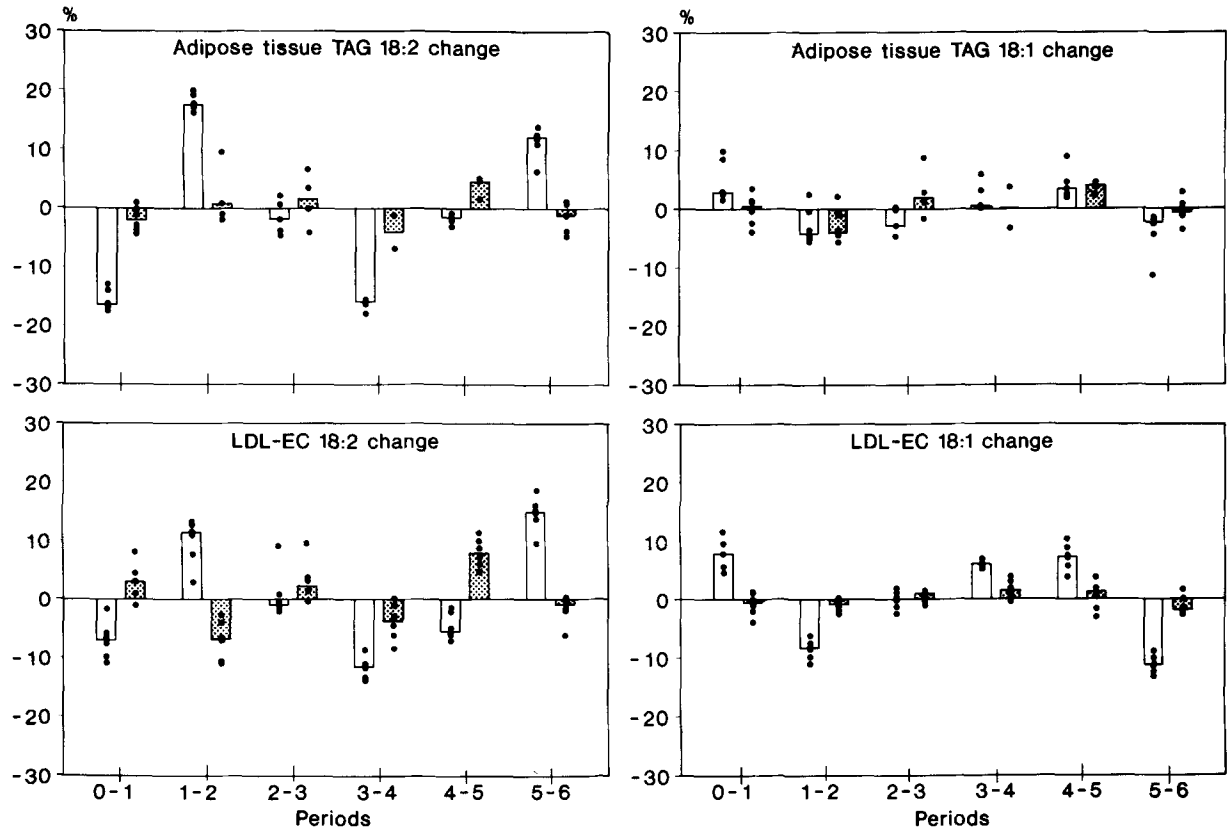

FIG. 3. Changes in individual (dot) and median (bar) percentages of 18:2 and 18:1 in adipose tissue triacylglycerol (TAG) and LDL esterified cholesterol (LDL-EC) in experimental (open bar) and reference (dotted bar) groups between consecutive dietary periods. Dietary changes in the experimental group associated with the different periods were: 0-1, low fat, high P/S to high fat, low P/S; 1-2, high fat, low P/S to high P/S; 2-3, high fat, high P/S to moderate fat, high P/S; 3-4, moderate fat, high P/S to low P/S; 4-5, moderate fat, low P/S to low fat, low P/S; and 5-6, low fat, low P/S to high P/S.

reversed with a change to a low P/S diet. The change in dietary fat content from 31 to 18% of energy was associated with an increase in the percentage of 18:1 in LDL-EC during a low dietary P/S ($P \leq 0.01$; Fig. 3, periods 4 to 5). The percentage of 18:2 in adipose tissue and LDL lipids tended to decrease when dietary fat contents were decreased, although not significantly. Neither changes in the degree of unsaturation nor the amount of dietary fat influenced the percentage of 18:1 in adipose tissue TAG or the percentage of 16:0 in adipose tissue TAG or LDL-EC (values not shown).

DISCUSSION

This study provides evidence that the amount of dietary fat had a greater influence on plasma cholesterol concentration than a moderate change in dietary P/S in vervets. Plasma cholesterol concentration tended to decrease with the reduction in dietary fat from 41 to 31%, while a greater, significant decrease ($P \leq 0.01$) was observed with the reduction from 31 to 18% of energy. The effects of dietary fat on plasma cholesterol were mainly through changes in LDL cholesterol concentrations. This agrees with reports for non-human primates where dietary fat contents were decreased from at least 27% to less than 7% of energy (10,28). In some studies on humans a reduction in dietary fat (from 40 to 27% of energy) was associated with decreases in plasma and LDL cholesterol concentrations in a five-week period (20,21). As in this study, Weisweiler *et al.* (6) found that a smaller change in greater quantities of dietary fat (from 42 to 32% of energy) did not significantly effect plasma cholesterol concentrations in humans. The lack of an effect of fat reduction in other studies (4,22) may be attributed to shorter dietary periods (≤3 weeks).

The significant increase in LDL cholesterol concentration with the decrease in P/S (from 1.26 to 0.27) during the moderate fat intake was smaller in effect than the decrease with the reduction in fat intake from 31 to 18%. The small increase (4%) in the median LDL cholesterol concentration with an increase in dietary P/S in the present study may be partly due to the fact that only female vervets were used. This is supported by the finding of Lewis and Taylor (41) that the decreases in the plasma cholesterol concentrations with an increase in dietary P/S were smaller in female African green monkeys as compared to the males.

The lack of an effect of dietary P/S changes during the high fat intake is in contrast to findings of other studies on African green monkeys (9,11). In these studies, however, changes in dietary P/S were greater (5- to 25-fold, compared to 4-fold), and cholesterol contents higher (0.4–0.8 mg/kcal, compared to 0.2 mg/kcal) than in the present study. The finding that an increase in dietary P/S does not further decrease plasma and LDL cholesterol concentrations during low fat intake is supported by the observations of Kuusi *et al.* (42) in humans during a fat intake of 23% of energy. However, during a fat intake of 25% of energy, Judd *et al.* (43) found that plasma total and LDL cholesterol concentrations decreased with a P/S increase of 0.3 to 1.0.

This study was not designed to compensate for any possible carryover effects. However, at the end of the experimental period the median plasma total cholesterol concentration of the experimental group was 8.4% higher than the baseline value. For the reference group the corresponding increase was 15.1%. This indicates that the effects of the different diets fed to the experimental group were not carried over to the last dietary period. The increases in plasma total and LDL cholesterol concentrations in the reference group in the first dietary period were probably due to non-dietary influences, *e.g.*, stress associated with the experimental procedure.

The vervets showed marked individual differences in LDL cholesterol concentration response to both the amount and the degree of unsaturation of fat in the diet. Individual reactions to a reduction in dietary fat (in humans, see refs. 29,44) and to changes in the dietary P/S (in non-human [9,45] and human primates [23,29,46–48]) have been reported previously. Genetic factors probably play a major role in the determination of an individual's sensitivity to changes in dietary factors (49). "Normal" fluctuations in an individual's plasma cholesterol concentration over time may obscure or minimize the response to dietary changes (50). In females, this fluctuation is partly the effect of periodic changes in the levels of their sex hormones (51). The influences of hormonal changes can be reduced by analyzing blood drawn at corresponding points during menstrual cycles. This would mean that experiments have to last longer.

The low fat diets were not associated with increased plasma TAG concentrations or decreased HDL cholesterol concentrations, as reported in studies on non-human (10) and human primates (4,5,22,42,52). A longer-term study on humans (53) has failed to produce an increase in plasma TAG concentration, indicating that this may be a transient effect of dietary fat reduction.

The strong effect of the P/S of the diet on the fatty acid composition of lipoprotein and adipose tissue lipids agrees with previously reported results in rhesus monkeys (8) and humans (3,54). This is especially true for 18:2 (linoleic acid) and 18:1 (oleic acid). In this study the percentage of 18:2 in the diet was reflected in LDL-EC and adipose tissue TAG levels within two months; in humans, however, it can take as long as three years before adipose tissue fatty acids reflect dietary fatty acids (23,55,56). The fast rate of these changes in vervets, which have a much lower percentage of body fat and a higher metabolic rate than humans, is probably due to a faster turnover of adipose tissue fatty acids (55). The observation that the median percentage of 18:1 in the adipose tissue TAG of the vervets was higher than in the dietary fat is indicative of a high rate of synthesis of 18:1 in this tissue. Fatty acid synthesis also has been reported to be more rapid in rat and in swine adipose tissue than in humans (57,58). The increased percentage of 18:1 in LDL-EC in periods of relatively low 18:2 intake was described previously in vervets (30) and in humans (3). This phenomenon may possibly be a compensatory mechanism to maintain fluidity in the LDL lipids. A significant positive correlation was found between atherosclerosis in non-human primates and the percentage of 18:1 in adipose tissue and LDL-EC (30), and the ratio of 18:1 to 18:2 in plasma EC (15). In this study decreasing the quantity of fat during a constant P/S was not associated with significant decreases in 18:2 in LDL or adipose tissue lipids, as was reported previously (23).

In theory an increased percentage of 18:2 in the core lipids of LDL particles can result in a reduction in the number of EC molecules per particle (2,3). The results of

the present study indicate that the EC content of LDL particles remained relatively unchanged during the six different dietary periods. LDL particle mass was also not influenced significantly by dietary fat changes, which supports previous findings both in vervets (30) and in humans (7,25,59). The loading of LDL with EC and FC, and increased LDL particle mass reported in these studies in non-human primates fed an atherogenic diet probably resulted from excessive cholesterol intake (24,26,27,60). The changes in the plasma and LDL cholesterol concentrations observed in the present study during dietary fat changes were therefore likely to be due to changes in the number of circulating LDL particles of relatively constant composition.

ACKNOWLEDGMENTS

The skillful technical assistance of Martelle P. Marais, Gert P. Engelbrecht and Jurgen V. Seier is gratefully acknowledged. We thank Sonja M. de Lange and Piet W. de Lange for the preparation of the diets, and Michael A. Roberts for feeding and caring for the vervets. We also thank Ria A. Laubscher for help with statistical analysis and Alma E. Nel for typing. The butter, margarines and oil used in the experimental diets were generously provided by Van den Bergh & Jurgens (Pty) Ltd.

Diets rich in linoleic acid (CO) from corn oil, or in linoleic acid and either α-linolenic acid (LO) based on linseed oil or n-3 fatty acids (MO) from menhaden oil were fed to male and female Cynomolgus monkeys for 15 wk. In the liver a 40% reduction of α-tocopherol occurred in the MO group relative to the CO and LO groups followed by increased formation of lipofuscin *in vivo*. A four-fold increase of α-tocopherol in the MO diet (MO + E) brought the level in the liver to that found with CO and LO. The increased peroxidation in the MO group in the liver phospholipids was associated with the replacement of 60% of the n-6 fatty acids by n-3 fatty acids from menhaden oil. Similar fatty acid profiles were found in groups fed MO and MO + E, respectively. Compared to the CO fed group, feeding α-linolenic acid only resulted in a slight incorporation of n-3 fatty acids in the liver membranes mainly due to a direct incorporation of α-linolenic acid. However, in monkeys fed menhaden oil more than 30% of the total fatty acids in the liver phospholipids were n-3 fatty acids. The various diets did not influence the activity of liver catalase (EC 1.11.1.6) nor superoxide dismutase (EC 1.15.1.1), but glutathione-peroxidase activity (EC 1.11.1.9) was higher in monkeys fed the MO diet. The catalase activity in females was 20% higher than in males. In an *in vitro* assay, liver microsomes from monkeys fed the MO diet or the MO diet supplemented with tocopherol produced similar amounts of thiobarbituric acid reactive substances and at a much higher rate than microsomes from the CO and LO groups. It appeared that α-tocopherol did not protect long-chain n-3 C_{20} and C_{22} fatty acids as well as n-6 fatty acids against peroxidation. The present data showed that monkeys were not fully able to compensate for increased peroxidative stress but a four-fold supplement of vitamin E to the diets reduced the oxidation.

Lipids 27, 740–745 (1992).

Diets rich in n-3 fatty acids have been shown to increase unsaturation in the membrane phospholipids of rat heart, liver and kidney (1,2) and of erythrocytes of cynomonkeys (3). Yet, little is known how the cells respond to the resulting increase in peroxidative stress. There is also only little information on the effects of dietary, highly unsaturated fatty acids on tissue lipid composition in primates in general.

The present study was undertaken to examine the effects of highly unsaturated dietary fats such as linseed oil and menhaden oil on the fatty acid profiles of liver phospholipids in monkeys. We further examined whether the monkey compensates for the increased oxidative stress by an induction of the three enzymes: catalase, superoxide dismutase (SOD) and glutathione-peroxidase (GSH-Px), which are known to remove the oxygen species believed to initiate lipid peroxidation (4). Furthermore, the ability of α-tocopherol to inhibit lipid peroxidation was examined.

MATERIALS AND METHODS

Four groups of Cynomolgus monkeys *(Macaca fascicularis)*, five males and five females in each group, were fed diets containing 15% (w/w) fat for 15 wk as previously described (3). The diets were: Diet 1, fat consisting of corn oil (Mazola Oil, Ottawa, Canada) and lard (Canada Packers, Toronto, Canada) designated corn oil (CO) diet; Diet 2, fat consisting of lard and linseed oil (Maple Leaf Monarch, Toronto, Canada) designated linseed oil (LO) diet; Diet 3, fat consisting of corn oil, lard and menhaden oil (Zapata Haynie Corp., Reedville, VA) designated menhaden oil (MO) diet; Diet 4, same as MO diet, supplemented with *all-rac* α-tocopheryl acetate and designated MO + E diet (Table 1). According to the manufacturer the menhaden oil contained 50 ppm free α-tocopherol and only 0.20% free fatty acids. In order to reduce the autoxidation to a minimum, all dietary oils were stored at −18°C under nitrogen, and the diets were freshly prepared every week and kept at 4°C as a gel. The monkeys were 6.5 ± 0.3 years old at the start of the feeding experiment.

After being fed the experimental diets for 15 wk, the monkeys were fasted for 18 h and anaesthetized with ketamin·HCl (Rogarsetic, Bristol Laboratories, Syracuse, NY). Blood was quickly drained from the *vena cava* by syringe. Liquid containing 10% (wt/vol) sodium citrate and 0.9% (wt/vol) NaCl was perfused through the body from a syringe in the left ventricle. The still-pumping heart caused an efficient perfusion of the whole body in a few minutes after which the liver was quickly removed. Portions of approximately 4 g were immediately frozen in liquid nitrogen and stored at −78°C for subsequent assays. Liver tissue (7 g) was immediately cooled in ice-cold 0.25 M sucrose, homogenized by a Potter-Elvehjem glass/Teflon homogenizer and adjusted with 0.25 M sucrose to a 10% (wt/vol) crude homogenate. Whole cells and cell debris were removed by centrifugation at 600 × *g* for 10 min. The supernatant (named liver homogenate) was kept on ice and enzyme, lipofuscin and protein assays were performed the day the animals were killed.

For the tocopherol analysis, 2 g of frozen liver was homogenized for 10 s in 4 mL of 0.25 M sucrose with a Polytron homogenizer (Kinematika AG, Littau, Switzerland) and adjusted to a 25% (wt/vol) homogenate. Following extraction, α- and γ-tocopherol was assayed by the high-performance liquid chromatography (HPLC) method of Thompson and Hatina (5) as described by Behrens and Madère (6).

Abbreviations: CO, corn oil diet; GLC, gas-liquid chromatography; GSH-Px, glutathione peroxidase; HPLC, high-performance liquid chromatography; LO, linseed oil diet; MO, menhaden oil diet; MO + E, menhaden oil diet supplemented with *all-rac* α-tocopheryl acetate; SOD, superoxide dismutase; TBARS, thiobarbituric acid reactive substances; TLC, thin-layer chromatography.

TABLE 1

Fatty Acid Compositions of Dietary Fats and Content of α- and γ-Tocopherol[a]

Fatty acids	Dietary group			
	CO	LO	MO	MO + E
	(area percent)			
Saturated	39.7	39.7	43.9	43.1
Monoenoic	35.2	35.5	32.8	35.5
18:2n-6	24.7	11.8	10.6	10.8
18:3n-3	0.4	13.0	0.9	0.9
18:4n-3	—	—	1.8	1.9
20:5n-3	—	—	4.7	4.6
22:6n-3	—	—	2.8	2.4
Σ (n-6)	24.8	11.8	10.8	11.2
Σ (n-3)	0.4	13.0	10.9	10.2
	(μg/g diet)			
α-tocopherol	70.2	59.3	61.6	270.2
γ-tocopherol	59.0	9.4	8.5	6.5

[a]The dietary fats were the following: CO diet (36% corn oil and 64% lard); LO diet (34% linseed oil and 66% lard); MO diet (68% menhaden oil, 16% lard, and 16% corn oil); MO + E diet (68% menhaden oil, 16% lard, and 16% corn oil + an additional four-fold supplement of *all-rac* α-tocopheryl acetate). Fatty acid composition was determined by GLC after extraction and transmethylation of the lipids from the diets, and the tocopherols in the diets were measured by HPLC after saponification using external standards.

Lipofuscin was extracted from the liver homogenate and measured by fluorescence spectroscopy as described by Koster and Slee (7), and protein was assayed by the method of Lowry *et al.* (8).

The activity of the selenium containing GSH-Px (EC 1.11.1.9) was determined by the method of Flohé and Günzler (9). The activity of Cu,Zn-SOD (EC 1.15.1.1) was determined in the liver homogenate, diluted 10 times with 1% Tween-80 in 50 mM phosphate buffer, pH 7.0, using the procedure given by Prohaska (10). The assay for catalase (EC 1.11.1.6) was performed as previously described (11).

The lipids were extracted from the liver by the method of Bligh and Dyer (12), and the phospholipids were separated from the neutral lipids by thin-layer chromatography (TLC) (13), saponified, and methylated (14). The relative contents of the methyl esters were determined by gas-liquid chromatography (GLC) (15).

Microsomes for measurement of nonenzymatic peroxidation were prepared from a 25% (wt/vol) liver homogenate in 0.25 M sucrose by centrifugation at 20,000 × *g* for 15 min, followed by ultracentrifugation of the supernatant at 105,000 × *g* for 1 h. The pellet was resuspended in 50 mM Tris/HCl, 140 mM NaCl buffer pH 7.5 and kept on ice.

The microsomes were incubated with $FeCl_3$ and ascorbate to induce lipid peroxidation by the modified method of Hill and Burk (16). The final concentrations during the incubations were as follows: 12 μM $FeCl_3$, 2 mM ADP, 0.5 mM ascorbic acid, 50 mM Tris/HCl (pH 7.5), 140 mM NaCl, and microsomes corresponding to 0.5 mg protein/mL; the total volume was 1.5 mL. The mixture was incubated for 50 min at 37°C with vigorous shaking. After the incubation, aliquots were taken for tocopherol and TBA assays (17). For basal levels, Tris/HCl buffer replaced the ascorbic acid. Three incubations were carried out for each animal. Data were statistically analyzed by Student's *t*-test.

RESULTS

α- and γ-Tocopherol in monkey liver. Three of the diets contained similar levels of α-tocopherol; no differences in α-tocopherol contents were found in livers from monkeys fed either a diet rich in 18:2n-6 (CO diet) or rich in both 18:3n-3 and 18:2n-6 (LO diet), whereas feeding menhaden oil as a source of n-3 fatty acids (MO diet) reduced the level of α-tocopherol in the liver by 40% (Table 2). A four-fold higher dietary supplement of α-tocopherol given in the MO + E diet resulted in a liver content similar to the level found in the CO and LO groups.

The diets contained various amounts of γ-tocopherol of which corn oil, in particular, is a rich source (18). The level of γ-tocopherol in the liver reflected the level in the diets, the content in the CO group being approximately five times higher than in the three other groups. The levels of γ-tocopherol in the liver were in general lower in the MO and MO + E groups than in the LO group although these three groups received comparable dietary levels. No significant difference in either α- or γ-tocopherol between males and females given the same diets was observed. The presence of significant amounts of γ-tocopherol in the liver indicated that sufficient antioxidative capacity was present in the diets considering the superior antioxidant activity of γ-tocopherol compared to α-tocopherol in an oil (19). In addition the menhaden oil had a natural content of free α-tocopherol of 50 μg/g.

Lipofuscin. The content of extractable lipofuscin in liver homogenate was used as an indicator of *in vivo* lipid peroxidation. The level in the male MO group was three-fold higher than in the CO and LO groups (Table 3), whereas the level in monkeys fed the fish oil diet enriched in vitamin E, MO + E group, was neither significantly different from the MO nor the CO and LO groups. The same tendencies were found in the corresponding female groups, but the differences were not significant. No sex-related difference was observed in monkeys fed the same diets.

Catalase, superoxide dismutase and GSH-peroxidase activity in liver homogenate. The activities of catalase, SOD and GSH-Px were measured in a liver homogenate. The female monkeys had a 20% higher catalase activity than the males (significant only for CO and MO groups). The catalase activity was influenced neither by the dietary fat nor the vitamin E levels used in this experiment (Table 4).

The SOD activity seemed to be independent of the diets fed to the monkeys; no sex-related differences were observed.

The activity of the Se-containing GSH-Px was slightly increased in the groups fed the fish oil diets (MO and MO + E groups) but the increase was only significant in the female MO and MO + E groups, when compared with the CO group. The activity with LO fell between that obtained with CO and MO, without being significantly different from either of them. The activity found in the monkeys was of the same order of magnitude as found in human liver (36–62 nmol NADPH/min/mg protein (20)).

Fatty acid composition of phospholipids from liver. The fatty acid composition of liver phospholipids generally

TABLE 2

The α- and γ-Tocopherol Contents of Monkey Liver After Fifteen Weeks on the Experimental Diets[a]

	Dietary group			
	CO	LO	MO	MO + E
α-Tocopherol (μg/g liver)				
Males	21.0 ± 1.5[b]	20.0 ± 1.9[b]	12.4 ± 2.5[c]	26.7 ± 3.7[b]
Females	20.2 ± 1.7[b]	20.9 ± 3.9[b,c]	11.7 ± 1.0[c]	23.7 ± 2.9[b]
γ-Tocopherol (μg/g liver)				
Males	9.1 ± 0.7[b]	1.9 ± 0.3[c]	1.2 ± 0.3[c,d]	0.8 ± 0.1[d]
Females	8.4 ± 1.1[b]	2.1 ± 0.4[c]	0.9 ± 0.1[d]	0.8 ± 0.2[d]

[a]Contents of α- and γ-tocopherol determined in a 25% liver homogenate as measured by HPLC relative to external standards. Values represent mean ± SEM (n = 5). Values within each row not sharing a common superscript letter (b,c,d) are statistically different at $P < 0.05$. The dietary fats are as in Table 1.

TABLE 3

Content of Extractable Lipofuscin in Monkey Liver Homogenate[a]

	Dietary group			
	CO	LO	MO	MO + E
	(% T per mg protein)			
Males	7.7 ± 1.3[b]	7.4 ± 1.9[b]	23.4 ± 6.3[c]	13.5 ± 3.3[b,c]
Females	5.4 ± 0.4	10.0 ± 5.0	16.9 ± 5.0	8.0 ± 2.3

[a]Lipofuscin was measured by fluorescence spectroscopy; 50 mM sulfuric acid and 84.4 nM quinine hydrobromide was used for calibration at 0% and 100% transmittance, respectively. Excitation maximum: 344 nm; emission maximum: 540 nm. Values represent mean ± SEM (n = 5). Means in the same row not sharing a common superscript (b,c) are significantly different at $P < 0.05$. Dietary fats are as in Table 1.

TABLE 4

Activity of Catalase, Cu, Zn-Superoxide Dismutase (SOD) and Se-GSH-Peroxidase (GSH-Px) in Monkey Liver[a]

		Dietary group			
Enzyme	Sex	CO	LO	MO	MO + E
Catalase	M	32.5 ± 1.4[b]	33.4 ± 2.6	32.6 ± 2.1[b]	28.6 ± 2.7
	F	39.5 ± 2.1	39.6 ± 2.2	38.2 ± 0.9	34.9 ± 1.6
SOD	M	113 ± 6	115 ± 8	115 ± 6	104 ± 9
	F	118 ± 9[b,c]	132 ± 4[b]	120 ± 5[b,c]	112 ± 6[c]
GSH-Px	M	74 ± 8	78 ± 3	96 ± 8	89 ± 11
	F	71 ± 7[b]	92 ± 7[b,c]	99 ± 7[c]	89 ± 3[c]

[a]The activities were determined in a 10% liver homogenate after removal of cell debris by centrifugation at 600 × *g*. The units are: SOD (U/mg protein); GSH-Px (nmol NADPH/min/mg protein); catalase ($\Delta OD_{240\ nm}$/min/mg protein). The values represent mean ± SEM (n = 5). Means in a row not sharing a common superscript letter (b,c) are statistically different at $P < 0.05$. Dietary fats are as in Table 1.

[b]The activity in males (M) is significantly different ($P < 0.05$) from the activity in females (F) belonging to the same dietary group.

reflected the dietary fatty acids, the LO group being a noteworthy exception, as can be seen from Figure 1. The LO group fed the diet rich in both 18:3n-3 and 18:2n-6 differed only little in fatty acid composition from the CO group fed the high 18:2n-6 diet. The relative content of n-3 fatty acids was doubled in the LO group, but quantitatively the changes were small. The increase was mainly caused by incorporation of 18:3n-3, whereas the levels of some of its desaturation products, 20:5n-3, and 22:5n-3, were only slightly increased when compared to the CO group. No changes, however, were seen in the relative content of 22:6n-3.

The increase in n-3 fatty acids in the LO group was counterbalanced by a general decrease in the content of all the n-6 fatty acids. As a result the percentage of polyunsaturated fatty acids was similar in the CO and LO groups.

Feeding a diet rich in both 18:2n-6 and n-3 fatty acids

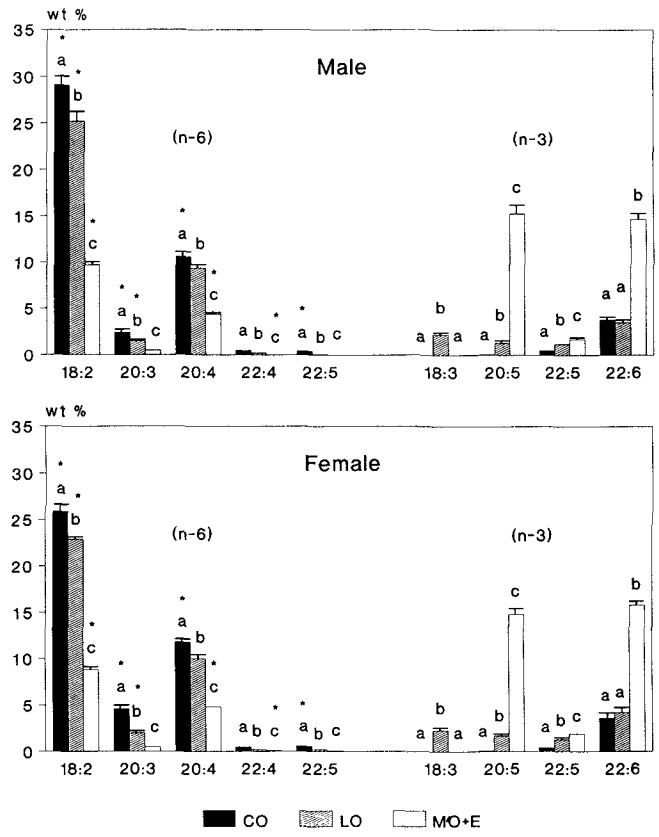

FIG. 1. Distribution of the major polyunsaturated fatty acids in liver phospholipids from monkeys fed the CO, LO and MO + E diets (area percentages determined by GLC). Each bar represents the mean ± SEM (n = 5), and bars for one fatty acid not sharing the same label are significantly different ($P < 0.05$); *, indicates a sex-related difference ($P < 0.05$).

from menhaden oil led to much more pronounced changes in the composition of the polyunsaturated fatty acids in the liver phospholipids. Compared to the CO group, the relative content of all the n-6 fatty acids was reduced by more than 60%, and was replaced particularly by 20:5n-3 and 22:6n-3. These highly unsaturated n-3 fatty acids were the most abundant polyunsaturated fatty acids in the liver phospholipids of monkeys fed the MO and MO + E diets. The addition of four times more α-tocopherol to the MO diet did not influence the fatty acid composition; therefore only the fatty acid composition for the CO, LO and MO + E groups are shown in Figure 1.

In general, similar tendencies were found in males and females, but a comparison between sexes fed the same diets showed that the females were lower in 18:2n-6 and higher in its desaturation products, 20:3n-6 and 20:4n-6. This sex-related difference was observed in all the dietary groups.

In vitro *lipid peroxidation in liver microsomes.* The microsomal contents of α-tocopherol in the CO, LO and MO + E groups were similar, whereas the content in the MO group was 10 times lower (Table 5).

After 50 min of incubation, all tocopherol levels decreased, with the CO group having a higher amount of α-tocopherol than the MO group; the levels in the LO and MO + E groups were not significantly different from the levels found in the CO or the MO groups. γ-Tocopherol levels in the microsomes were below the detection limit.

The basal TBARS level of the MO group was four times higher than that of the CO and LO groups, and twice as high as the MO + E group (difference not significant in the female MO + E group). Microsomes prepared from the MO + E group contained twice as much TBARS as the CO and LO groups (Table 5).

The monkeys fed the diets containing fish oil (MO and

TABLE 5

α-Tocopherol and TBARS in Monkey Liver Microsomes Before and After Fifty Minutes of Incubation with Fe^{3+} and Ascorbic Acid[a]

		Dietary group			
		CO	LO	MO	MO + E
α-Tocopherol (ng/mg protein)					
t_0	M	109 ± 15^{c}	89 ± 12^{c}	8 ± 2^{d}	120 ± 37^{c}
	F	130 ± 24^{c}	105 ± 24^{c}	13 ± 5^{d}	123 ± 29^{c}
t_{50}	M	56 ± 20^{c}	54 ± 26^{c,d}	4 ± 2^{d}	17 ± 15^{c,d}
	F	96 ± 18^{c}	35 ± 24^{c,d}	4 ± 3^{d}	54 ± 48^{c,d}
TBARS (nmol MDA/mg protein)[b]					
t_0	M	1.2 ± 0.2^{c}	1.0 ± 0.2^{c}	4.8 ± 0.8^{d}	2.6 ± 0.6^{e}
	F	1.2 ± 0.2^{c}	1.4 ± 0.2^{c}	5.2 ± 0.8^{d}	3.4 ± 0.6^{d}
t_{50}	M	22 ± 9^{c}	24 ± 10^{c}	106 ± 5^{d}	92 ± 9^{d}
	F	13 ± 7^{c}	39 ± 10^{d}	98 ± 4^{e}	72 ± 17^{d,e}

[a]The final incubation mixture contained 12 μM $FeCl_3$, 2 mM ADP, 0.5 mM ascorbic acid, 50 mM Tris/HCl (pH 7.5), 140 mM NaCl, and microsomes corresponding to 0.5 mg protein/mL. α-Tocopherol was determined by HPLC, and TBARS were measured in a TBA-assay; t_0 indicates the basal level in the microsomes, t_{50} indicates the level after 50 min incubation. Values represent mean ± SEM (n = 5). Means in a row not sharing a common superscript (c,d,e) are significantly different at $P < 0.05$. M, males, F, females. Dietary fats as in Table 1.

[b]TBARS relate to a MDA standard.

MO + E) produced more TBARS than the CO group (males four-fold higher and females eight-fold). TBARS production in the microsomes in the female LO group was significantly higher than in the CO group (three-fold) and lower than in the MO group (two-fold), although the CO, LO and MO diets contained the same amount of α-tocopherol. Compared to the MO + E group, the microsomes from the LO group produced 2-3 times less TBARS; however, the difference was only significant in the male groups.

It should be noted that the intra group variation for lipofuscin, α-tocopherol and TBARS contents was very large even though the experimental error was less than 5%. This reflected uniformly scattered data caused by biological variations between individuals.

DISCUSSION

Superoxide dismutase, catalase and GSH-Px participate in the cellular protection against lipid peroxidation *in vivo* by removing the potential initiators of the peroxidative processes, $O_2^{\cdot -}$, H_2O_2 and possibly other peroxides as well (4,21,22). In the present experiment only selenium containing GSH-Px seemed to be induced in the liver by the higher peroxidative stress associated with the intake of menhaden oil. However, the increase in activity could not fully compensate for the decrease in vitamin E in preventing the high accumulation of lipofuscin when fish oil was fed.

The very long-chain fatty acids, 20:1 and 22:1, are metabolized in the peroxisomes and induce higher peroxisomal β-oxidation and catalase activity in liver when fed to rats (23,24). Similarly, it was shown in a short term study that 20:5n-3 increased the peroxisomal β-oxidation in rat liver (25) and together with 22:6n-3 appears to be metabolized mainly by the peroxisomes (26). However, menhaden oil, rich in 20:5n-3 and 22:6n-3, did not seem to induce increased peroxisomal activity in the monkey liver when catalase activity was used as an indicator for the peroxisomal β-oxidation, even though the two n-3 fatty acids are likely to be better substrates for peroxisomal β-oxidation than 20:4n-6 as was shown in rats (27).

The higher catalase activity in females may indicate increased β-oxidation activity in the peroxisomes in females compared to males. A similar effect was observed in rats fed partially hydrogenated marine oil, where the increased peroxisomal β-oxidation in the female rats was accompanied by a lower accumulation of triglycerides in the heart compared to male rats fed the same diet (24). The increase in the content of 20:3n-6 and 20:4n-6 relative to 18:2n-6 seen in females did not affect the peroxidative status. Alternatively, the higher catalase activity prevented increased peroxidation.

The amount of α-tocopherol fed to the monkeys is considered to be adequate to fulfill the nutritional needs for vitamin E under normal conditions (28). In monkeys fed a diet similar to a typical Western European diet (the CO diet), the liver contents corresponded well to those observed in humans: 18.3 μg/g tissue and 9.2 μg/g tissue for α- and γ-tocopherol, respectively (29).

From the γ- to α-tocopherol ratio, it seemed that the absorption or retention of γ-tocopherol in the liver was less efficient than of α-tocopherol. It was the actual content of γ-tocopherol in the diet that influenced the γ-tocopherol content in the liver rather than the ratio of the two tocopherols. These results are in good accordance with the findings of Bieri and Evarts (30) and Peake and Bieri (31), who found that α- and γ-tocopherol were similarly absorbed but that γ-tocopherol was excreted more rapidly. Behrens and Madère (32), however, observed that a high amount of α-tocopherol affected the amount of γ-tocopherol absorbed, transported and taken up by tissues. The present data obtained on primates did not support the idea that additional dietary α-tocopherol affected the level of γ-tocopherol *in vivo*.

The levels of both antioxidants in the liver were reduced equally by the intake of the highly unsaturated menhaden oil as compared to monkeys fed diets rich in 18:3n-3. This suggests that although the biological antioxidant activity of γ-tocopherol is only about 30% of the activity of α-tocopherol (33,34), both tocopherols may play an important role as antioxidants *in vivo*. The reduced levels of tocopherols observed when menhaden oil was fed without vitamin E supplementation (MO group) were associated with increased lipid peroxidation, as indicated by the increased levels of lipofuscin and TBARS. This is in accordance with Mouri *et al.* (35), who demonstrated an increase in liver TBARS and a decrease in liver α-tocopherol when rats were fed increased amounts of cod liver oil. A four-fold increase in dietary α-tocopherol normalized the liver level when menhaden oil was fed, which is in good agreement with the findings of Meydani *et al.* (36) in mice. This, however, did not fully restore the antioxidative capacity of the liver *in vivo* (when lipofuscin is used as an indicator for peroxidation) and *in vitro* as measured by TBARS formation.

Feeding 18:3n-3 to the monkeys did not affect the peroxidative status of the liver *in vivo* compared with monkeys fed 18:2n-6. This can be explained by the moderate influence of the dietary 18:3n-3 on the fatty acid composition in liver phospholipids. Replacing the 18:3n-3 in the diets with the more unsaturated n-3 fatty acids of marine origin led to an extensive replacement of the less unsaturated n-6 fatty acids with the more unsaturated n-3 fatty acids, 20:5n-3 and 22:6n-3, followed by increased lipid peroxidation. This peroxidation could not be fully compensated for by a four-fold increase in dietary α-tocopherol. The liver phospholipid fatty acid pattern of monkeys fed menhaden oil with normal or high vitamin E content was similar, despite the increased level of one of the fatty acid peroxidation products, lipofuscin, found in the MO group. This could indicate that the damaged fatty acids were rapidly replaced by fatty acids from the diets or that the actual amount of polyunsaturated fatty acids lost due to lipid peroxidation is low compared to the total amount present in the membranes. However, it should be pointed out that the implication of lipofuscin formation is not clear.

In the *in vitro* experiment, even a small increase in the relative content of n-3 fatty acids after feeding linseed oil resulted in a higher risk of peroxidation under stressed conditions. Risk of peroxidation was further increased when the linseed oil was replaced by menhaden oil and a ten-fold increase of microsomal α-tocopherol could not reduce the peroxidation rate. It thus seems that α-tocopherol cannot protect membranes rich in n-3 fatty acids, especially with five or six double bonds, as efficient-

ly as membranes rich in n-6 fatty acids. This has also been observed in rat tissues (37-40).

The results from the Fe(III)/ascorbate incubation assay were in accordance with the results for lipofuscin formation; only the differences between the groups were much more pronounced in the *in vitro* assay. The non-enzymatic *in vitro* peroxidation in microsomes could as such be used as a measure of the peroxidation *in vivo* due to the dietary treatment.

Previous experiments have established that a four-fold supplement of α-tocopherol normalized the lipofuscin in rats fed marine oil (41). The present study indicated that such an additional supplement of α-tocopherol to primates did not fully prevent the peroxidative changes when menhaden oil was fed. This is probably caused by a higher level of polyunsaturated n-3 fatty acids incorporated in the liver from primates (32%) compared to rats (21%) after intake of marine oil, mainly due to a high incorporation of 20:5n-3 in the monkeys. This indicates that in primates a supplement of α-tocopherol beyond the levels used in this study is necessary in order to prevent peroxidation *in vivo*.

ACKNOWLEDGMENTS

This study was supported by grants from Direktør Ib Henriksens Fond, Frants Allings Legat and the National Council for Technical and Scientific Research. Members of the Animal Resource Division, Ottawa, cared for the animals, and Lis Christensen and Grete Peitersen provided excellent assistance in the analysis of the fatty acids.

Modulation of Cyclic Nucleotide Phosphodiesterase by Dietary Fats in Rat Heart

Madeleine Dubois, Martine Croset, Georges Némoz, Michel Lagarde and **Annie-France Prigent***
INSERM U 352, Laboratoire de Chimie Biologique de l'Institut National des Sciences Appliquées de Lyon, 69621 Villeurbanne, France

Feeding oils of different fatty acid composition modifies the fatty acid composition of cardiac membrane phospholipids, thereby inducing changes in cardiac contractility and altering response of adenylate cyclase to catecholamines. In the present study, the effect of such dietary manipulations on cyclic nucleotide phosphodiesterase, which is involved in the control of cyclic nucleotide intracellular levels and in the control of cardiac contractility, was investigated. Rats were fed either a saturated fatty acid-enriched diet (8 weight percent [%] coconut oil + 2% sunflower oil), an n-6 fatty acid-enriched diet (10% sunflower oil) or an n-3 fatty acid-enriched diet (8% fish oil + 2% sunflower oil). The fatty acid composition of cardiac phospholipids, as well as the nonesterified fatty acid content of heart were markedly altered by the diets. The 18:2n-6 and 20:4n-6 content of cardiac phospholipids was markedly (−49%) depressed by fish oil as compared with sunflower oil feeding, but the nonesterified fatty acid level of heart membrane was lowest in coconut oil-fed rats. In addition, fish oil feeding more drastically depressed the n-6/n-3 fatty acid ratio in the nonesterified fatty acid pool than in cardiac phospholipids. Cyclic AMP phosphodiesterase activity was the lowest in both the particulate and soluble fractions of heart from rats fed sunflower oil, whereas cyclic GMP phosphodiesterase activity was not altered by the diets. Cyclic AMP phosphodiesterase activity was decreased by 18 and 12% in heart membranes of the sunflower oil group as compared to that of the coconut oil and fish oil groups, respectively. In heart cytosol, the activity decreased by 30% when compared with the activity of the coconut oil group. Additional *in vitro* experiments showed that polyunsaturated fatty acids were more potent inhibitors of cyclic AMP phosphodiesterase than saturated fatty acids. These results suggest that polyunsaturated fatty acid-enriched diets might decrease heart cyclic AMP phosphodiesterase activity by increasing non-esterified polyunsaturated fatty acids, especially those of the n-6 series, but more complex and indirect mechanisms are very likely to be involved.
Lipids 27, 746–754 (1992).

Several studies support the hypothesis that alterations in dietary lipids, particularly saturated *vs.* unsaturated fatty acids, can affect cardiac functions such as left ventricular work and coronary flow (1). Feeding sunflower oil as compared to saturated or standard diets has been shown to decrease the maximal response of adult rat atria to catecholamines (2) or the positive inotropic response of papillary muscles to calcium (3). Diets rich in polyunsaturated fatty acids (PUFA) not only decrease the occurrence of spontaneous tacchyarrythmias (3), but also reverse the high vulnerability to cardiac arrythmias previously induced in rats by feeding long-term a diet supplemented with saturated fatty acids (4). Dietary n-3 PUFA seem to offer greater protection than dietary n-6 fatty acids in several experimental models of myocardial ischemia (5,6). Diets supplemented with n-3 PUFA have been reported to reduce both the incidence and the severity of ventricular tacchycardia induced by myocardial ischemia and reperfusion (7), while those supplemented with n-6 PUFA have been shown to increase the sensitivity of rat myocardium to catecholamine-induced damage (8). Dietary fats can influence the lipid composition of plasma membranes in several tissues, including heart (9–11). These diet-induced alterations of the acyl constituents of membrane phospholipids can, in turn, induce functional changes in several ways. First, the acyl changes can alter the arachidonic acid content of membrane phospholipids and thus influence the production of bioactive eicosanoids. Second, as fatty acids are the major components of the hydrophobic core of the membrane bilayer, they can interact with and directly influence the functioning of some crucial membrane proteins involved in cellular communication and homeostatic processes such as receptors, ion channels and enzymes (12). Adenylate cyclase which controls cyclic nucleotide intracellular levels is one of the major enzymes involved in transmembrane signalling and, as such, is a key regulator of cell function, especially in the heart where cyclic nucleotides play a crucial role in regulating contractility (13). The β-adrenergic/adenylate cyclase system of cardiac membranes has been extensively studied. Alam *et al.* (14) have shown that both basal and stimulated adenylate cyclase activities were significantly increased in rats fed diets rich in n-3 PUFA. Although these results suggest that increasing cardiac PUFA content is associated with increased responsiveness of adenylate cyclase to adrenergic stimulation, not all investigators have come to this conclusion. Thus, Laustiola *et al.* (15) have reported that atria from rats fed n-3 PUFA-enriched diets had low basal and isoproterenol-stimulated accumulation of cyclic AMP, and Reibel *et al.* (16) have reported that dietary fish oil was associated with reduced inotropic responsiveness to α-, but not β-adrenoceptor stimulation when compared to n-6 fatty acids. However, the α_1-adrenoceptor-mediated phosphatidylinositol turnover rate does not seem to be affected by changes in the PUFA composition of membrane phospholipids in neonatal rat ventricular myocytes (17).

Intracellular cyclic nucleotide levels result from an equilibrium between their synthesis by the cyclases and their degradation by cyclic nucleotide phosphodiesterases (PDE, E.C. 3.1.4.17.). This enzyme system may play a crucial role in the control of cardiac functioning because

Abbreviations: ANOVA, analysis of variance; BHT, butylated hydroxytoluene; CO, coconut oil; DMA, dimethylacetal; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; EFA, essential fatty acid; FO, fish oil; IC_{50}, concentration of a drug which inhibited 50% of the enzymatic activity; PDE, cyclic nucleotide phosphodiesterase (E.C. 3.1.4.17); PMSF, phenylmethylsulfonylfluoride; PUFA, polyunsaturated fatty acid; SO, sunflower oil; TLC, thin-layer chromatography; Tris, trishydroxymethylaminomethane.

inhibitors of PDE are able to stimulate cardiac contractility and are used as potential therapeutic agents in the treatment of heart failure (18,19). Among the growing isoenzyme families of PDE, some of them, such as the calcium and calmodulin-stimulated isoform, can be activated by certain fatty acids and phospholipids (20) whereas others, such as the cyclic GMP-stimulated isoform, are rather inhibited, especially by unsaturated fatty acids (21). Until now, relatively few studies have addressed the question of the influence of dietary fats on PDE activity (22).

Therefore, the aim of the present study was to examine the influence of diets enriched with different fatty acids (saturated, n-6 and n-3) on PDE activity of rat heart. Diets were supplemented with a mixture of 8% coconut oil + 2% sunflower oil (relatively rich in saturated fatty acids and sufficient in essential fatty acids; EFA), 10% sunflower oil (relatively rich in n-6 fatty acids) or a mixture of 8% fish oil + 2% sunflower oil (relatively rich in n-3 fatty acids and sufficient in EFA) to induce changes in both the nonesterified fatty acid content of hearts and in the fatty acid composition of cardiac membrane phospholipids. The consequence of these changes on the enzyme activity was further examined.

MATERIALS AND METHODS

Animals and diets. O.F.A. rats (Iffa Credo, L'Arbresle, France) weighing 130–150 g were housed individually at 22 ± 1°C, given a commercial nonpurified diet and water *ad libitum*, and kept under a 12 h dark/light cycle for one week to acclimate the animals to laboratory conditions. Rats were then weighed and randomly divided into three groups of nine rats each so that the average weight per group was the same. They were fed semi-purified diets (differing only in the type of oils added) for a period of three weeks. The composition of the base semi-purified diet (Unité Rationnelle d'Alimentation, Villemaison, France), before the addition of 10 weight percent (%) oils, is summarized in Table 1. The coconut oil (CO) group was fed the base diet supplemented with 8% CO (source of saturated fat) mixed with 2% sunflower oil (SO) to prevent EFA deficiency. The SO group was fed the base diet supplemented with 10% SO as a source of n-6 fatty acid. The fish oil (FO) group was fed the base diet supplemented with 8% of purified concentrate of FO as a source of n-3 fatty acid, mixed with 2% SO. Commercial edible coconut and sunflower oils were obtained locally. Refined fish oil (Feniko) was purchased from Fournier Laboratories (Dijon, France). The fatty acid compositions of the diets are shown in Table 2. Fresh diets were prepared every four days by thoroughly mixing after the addition of oils. Daily amounts were stored in capped plastic tubes, under nitrogen, at −20°C, in the dark. Uneaten food was discarded and replaced with fresh diets stored as indicated above, daily. The absence of thiobarbituric acid reactive materials indicated that there was no oxidation of dietary fats.

Blood sampling. At the end of the feeding period, rats were killed by decapitation. Sacrifices were spread out over a period of three days (between 8–11 a.m.). Blood (4 mL) was collected immediately into plastic tubes that had been rinsed with heparin. Samples were then transferred to polypropylene tubes containing heparin (50 U/mL blood), gently mixed by inversion and centrifuged at 2,000 × *g* for 15 min. Plasma was removed and butylated hydroxytoluene (BHT) (5×10^{-5} M) was added before freezing at −80°C until further analyses.

Preparation of heart particulate and cytosolic fractions. Hearts were removed, perfused through aortic cannulae with physiological saline to remove blood, chopped into small pieces with scissors and homogenized in a glass-glass Potter-Elvejhem homogenizer with 5 vol (vol/wt) of 10 mM Tris-HCl buffer (pH 7.5) containing 0.32 M sucrose, 1 mM ethylenediaminetetraacetic acid (EDTA), 5 mM dithiothreitol (DTT) and 0.1 mM phenylmethylsulfonylfluoride (PMSF). The homogenate was centrifuged at 1,000 × *g* for 10 min. The supernatant was then

TABLE 1

Composition of the Diets (g/100 g)[a]

	Coconut oil group	Sunflower oil group	Fish oil group
Delipidated casein[b]	20.25	20.25	20.25
Cornstarch + glucose	57.0	57.0	57.0
Cellulose	5.50	5.50	5.50
Mineral mix[c]	6.25	6.25	6.25
Vitamin mix[d]	1.0	1.0	1.0
Sunflower oil	2	10	2
Coconut oil	8	0	0
Fish oil	0	0	8

[a]Diets were isoenergetic and provided 14.6 Mcal/kg diet.

[b]Supplied in amino acids (mg/g diet): arginine, 8.5; cystine, 3; lysine, 17.4; methionine, 7.1; tryptophane, 5.0; and glycine, 1.0.

[c]Provided (g/kg diet): $CaHPO_4x2H_2O$, 30; KCl, 7; MgO, 3; $MgSO_4x7H_2O$, 3.5; Fe_2O_3, 0.2; $FeSO_4x7H_2O$, 0.35; $MnSO_4xH_2O$, 0.17; $CuSO_4x5H_2O$, 0.03; $ZnSO_4x7H_2O$, 0.14; $CoSO_4x7H_2O$, 0.0003; and stabilized KI, 0.0006.

[d]Provided (mg/kg diet): retinyl acetate, 6.93; cholecalciferol, 0.0025; thiamine HCl, 20; riboflavin, 15; dl-calcium pantothenate, 70; pyridoxine HCl, 10; meso-inositol, 150; cyanocobalamin, 0.05; dl-α-tocopheryl acetate, 170; menadione sodium bisulfite, 40; nicotinic acid, 100; choline, 1360; folic acid, 5; *p*-aminobenzoic acid, 50; and biotin, 0.3.

22:6n-3			17.10

[a]Values are reported as mol % of total fatty acids and represent an average of two determinations.

centrifuged at 105,000 × *g* for 1 h. The resultant pellet was resuspended in the above buffer without sucrose and centrifuged at 105,000 × *g* for 1 h. The first 105,000 × *g* of supernatant and the second 105,000 × *g* of pellet were used as cytosolic and membrane fractions and stored at −80°C until further analysis for both lipid composition and phosphodiesterase activity.

Enzyme assays. PDE activity of heart cytosolic and membrane fractions from rats fed the various diets was assayed by a two-step radioisotopic procedure modified according to Prigent *et al.* (23), with the following substrate conditions: 0.25 μM cyclic AMP, which reflects mainly the activity of the cyclic AMP-specific PDE isoforms; 0.25 μM cyclic GMP in the presence of either 1 mM EGTA or 100 U calmodulin plus 1 mM $CaCl_2$, which reflects the activity of the calmodulin-stimulated isoform. The cyclic GMP-stimulated PDE activity was measured with 5 μM cyclic AMP as substrate in the presence or absence of 5 μM cyclic GMP as the allosteric effector. Phosphodiesterase activities were expressed as pmol cyclic nucleotides hydrolyzed per min per mg protein. The inhibitory potency of several fatty acids was examined on the cytosolic cardiac enzyme prepared from rats fed a standard diet. The IC_{50} (concentration of a drug which inhibited 50% of the enzymatic activity) of fatty acids was calculated by plotting the percentage of enzymatic activity determined at 0.25 μM substrate concentration *vs.* the logarithmic concentration of the fatty acid. Fatty acids were dissolved in ethanol. Controls with vehicle were performed in each case. The 95% confidence limits for the IC_{50} values were determined by linear regression analysis according to Hubert (24).

Lipid extraction. Plasma and cytosolic, as well as particulate fractions from rat heart were extracted according to Bligh and Dyer (25). Heptadecanoic acid and diheptadecanoyl phosphatidylcholine were added to samples as internal standards. Briefly, 3 mL chloroform/methanol (1:2, vol/vol) containing 0.001% BHT were added to 1 mL samples and left at 4°C under N_2 for 10 min. Samples were then partitioned after addition of 1 mL saline and 1 mL chloroform. The lower phase was removed after centrifugation and the medium re-extracted with 2 mL chloroform. The combined organic phases were dried under N_2 stream.

Fatty acid analysis. For fatty acid analysis of total phospholipids and for nonesterified fatty acid determination, lipid samples were chromatographed on thin-layer chromatographic plates, developed with hexane/diethyl ether/acetic acid (70:30:1, vol/vol/vol). Areas corresponding to phospholipids (at the origin) and free fatty acids (R_f 0.36) were scraped from the plate. Free fatty acid samples were methylated with diazomethane and phospholipid samples were directly transmethylated with boron trifluoride/methanol as described by Morrison and Smith (26). Fatty acid methyl esters and dimethylacetals (DMA) were quantified by gas-liquid chromatography (Girdel 3000, Lyon, France) using a 0.25 mm × 60 m SP 2380 capillary column (Supelco, Bellefonte, PA) and helium as a carrier gas. The oven temperature was held at 150°C for 3 min, and then programmed from 150 to 210°C at 1°C per min. Fatty acids were identified by comparison of retention times with those of known standards (27).

Protein assay. Proteins were measured by the dye-binding method of Bradford (28) using bovine serum albumin as a standard.

Statistical analysis. Results presented in the tables and the figures are means ± SEM. Statistical significance of mean differences between dietary groups was investigated by analysis of variance (ANOVA) with the Sheffé multiple comparison method at $P \leq 0.05$ for lipid analyses and with the Fisher PLSD comparison method for phosphodiesterase activity, using the Statviews Program MacIntosh.

RESULTS

There was no significant difference in the body weight gains of rats fed the various diets over the three-week feeding period. Heart weights were not significantly different in rats fed sunflower oil or fish oil (in g, 1.36 ± 0.02 and 1.33 ± 0.06, respectively) but were found slightly but significantly increased ($P < 0.04$, 1.52 ± 0.06) in the coconut oil group. Also, there was no difference in the cytosolic to membrane protein ratios among the three dietary groups.

Feeding a diet supplemented with saturated, n-6 or n-3 fatty acids for a short-term period induced drastic changes in the fatty acid composition of both plasma (Table 3) and cardiac (Table 4) total phospholipids. Supplementing the diet with n-6 fatty acid rich sunflower oil increased the PUFA content of plasma phospholipids at the expense of monounsaturated fatty acids, although this diet contained the highest amount of oleic acid. The main fatty acid of the sunflower oil diet, 18:2n-6, was the highest in plasma phospholipid of this group. Supplementing the diet with n-3 rich fish oil significantly decreased the contents of 18:2n-6 and 20:4n-6 of plasma phospholipids and, in parallel, increased the contents of 20:5n-3, 22:5n-3 and 22:6n-3, resulting in a drastic fall in the n-6/n-3 fatty acid ratio as compared to those of the two other dietary groups. In addition, the total saturated fatty acid content of plasma phospholipids was significantly higher in the fish oil group than in the two other groups. The content of 18:2n-6 decreased only slightly in plasma phospholipids from rats fed coconut oil, despite the low amount of this fatty acid in the diet, while the 20:4n-6 concentration remained unchanged as compared with the n-6-enriched dietary group. Among the saturated fatty acids, 14:0 increased in the coconut oil group compared to the sunflower oil group while 16:0 and 18:0 were unaltered. The content of 16:0 was the highest in the fish oil group, and that of 18:0 was the lowest.

The total amount of fatty acids esterified into cardiac phospholipids was the same regardless of the diet (Table 4). Cardiac membranes maintained constant amounts of phospholipid saturated fatty acids, even in the sunflower oil group, which had the lowest level of these fatty acids in their plasma phospholipids. However, the PUFA distribution reflected the changes in the plasma fatty acid composition observed in each group. Thus, the n-6/n-3 fatty acid ratio was much lower in fish oil-fed rats than in sunflower oil and coconut oil fed rats. In the fish oil group, the content of 22:6n-3 in cardiac phospholipids was about sixfold higher than that of 20:5n-3, although 20:5n-3 was the main fatty acid of plasma phospholipids. The 22:5n-3 content of cardiac phospholipids was similar to that of 20:5n-3, whereas it was sixfold lower than the level of 20:5n-3 in plasma phospholipids. These data suggest that 20:5n-3 was either efficiently elongated or less

n-6/n-3	13.30 ± 1.63[b]		1.10 ± 0.02[c]		9.14 ± 0.64[d]	

[a]Values are reported as μg fatty acid/mg protein and are means ± SEM (n = 6). Values in parentheses are % weight of total fatty acids. Values not bearing the same superscript letters are different at $P < 0.05$; DMA, dimethylacetal; n.d., not determined.

rapidly incorporated by cardiac membranes than other n-3 fatty acids. As previously observed in plasma phospholipids, the contents of 18:2n-6 and 20:4n-6 in cardiac phospholipids were markedly (−49%) depressed by fish oil feeding as compared to sunflower oil feeding. The level of 14:0, a fatty acid not detected in cardiac phospholipids of FO and SO groups, was increased in these phospholipids by coconut oil feeding. The 16:0 level was 20–30% higher in this group than in the two others, although the fatty acid was more abundant in plasma phospholipids from fish oil fed rats. Despite the low amount of available 18:2n-6 in the coconut oil-enriched diet, cardiac membrane efficiently incorporated this fatty acid into their phospholipids. The 18:2n-6 level was only slightly decreased (−17%) in the coconut oil group as compared to that of the sunflower oil group, whereas the 20:4n-6 level was not significantly different between both groups.

Variations observed in the nonesterified fatty acid content of rat heart membranes (Table 5) as a function of the different diets resembled those observed in the fatty acid content of cardiac phospholipids, but differences were found. Although the total fatty acid content of cardiac phospholipids was not affected by the diets, the nonesterified fatty acid content of heart membranes was 1.34- and 1.18-fold higher in the sunflower oil group and the fish oil group, respectively, than in the coconut oil group. The nonesterified PUFA content was the lowest in the coconut oil group, whereas cardiac phospholipid PUFA were most depressed in the fish oil group. This low amount of nonesterified PUFA in membrane fractions from coconut oil-fed rats as compared to sunflower oil-fed rats reflected the 51 and 27% decrease in the contents of 18:2n-6 and 20:4n-6, respectively, whereas only minor modifications of these two PUFA were observed in the cardiac phospholipid pool. In addition, fish oil feeding more drastically depressed the n-6/n-3 fatty acid ratio in the nonesterified fatty acid pool (71.5-fold SO *vs.* FO and 40-fold CO *vs.* FO) than in the cardiac phospholipid pool (12-fold SO *vs.* FO and 8.3-fold CO *vs.* FO).

The nonesterified fatty acid content of cytosolic heart fractions (Table 6) was far less affected by the diets than that of heart membrane. No difference was observed either in the total PUFA or in the total saturated fatty acid content of all groups. As previously observed in cardiac phospholipids, the nonesterified 18:2n-6 content was only slightly decreased (−29%), while the 20:4n-6 level did not change in the coconut oil group as compared to those of the sunflower oil group. Although less important than in the nonesterified fatty acid membrane pool, variations in the n-6/n-3 fatty acid ratios between the three dietary groups were markedly higher in the cytosolic compartment (31.3-fold SO *vs.* FO and 20.1-fold-CO *vs.* FO) than in cardiac phospholipids (12-fold SO *vs.* FO and 8.3-fold CO *vs.* FO).

The specific activity of cyclic nucleotide phosphodiesterase in the cytosolic and membrane fractions of rats fed the three diets is shown in Figure 1, A and B. Cyclic AMP phosphodiesterase specific activity was the lowest in both the soluble and particulate fractions of hearts from rats fed sunflower oil and the highest in the coconut oil group. In the cytosolic fraction, cyclic AMP phosphodiesterase activity of the CO group was 30% higher than that of the SO group ($P \leq 0.01$) and 15% higher than that of the FO group ($P \leq 0.05$). The difference observed between the SO and the FO groups was not significant. In the particulate fraction, the activity of the CO group was significantly higher (+18%, $P \leq 0.05$) than that of the SO group, but was not different from that of the FO group. In marked contrast, neither the basal level of cyclic GMP phosphodiesterase activity assayed in the presence of

ethyleneglyco-*bis*-(β-aminoethyl ether)*N,N,N′,N′*-tetraacetic acid (Fig. 1, A and B) nor the calmodulin-stimulated level was altered by the diets. In the membrane fraction from rat hearts where the cyclic GMP-stimulated isoform of phosphodiesterase is more preponderant, coconut oil feeding significantly increased (+20%, $P \leq 0.05$) the basal level of cyclic AMP phosphodiesterase activity as compared to the sunflower oil group while the cyclic GMP stimulated activity was not modified (Fig. 2). As a consequence, the stimulating effect of cyclic GMP upon cyclic AMP hydrolysis was significantly higher ($P \leq 0.01$) in the SO group (+272%) than in the CO group (+216%).

The *in vitro* influence of the main fatty acids of each diet upon the cytosolic PDE activity of hearts from rats fed a standard diet was also investigated. As shown in Table 7, polyunsaturated fatty acids proved to be more potent inhibitors than saturated fatty acids. Furthermore, the fatty acids affected cyclic AMP and cyclic GMP phosphodiesterase activities similarly.

DISCUSSION

The present results indicate that feeding rats an n-6 PUFA enriched diet for three weeks decreases cyclic AMP phosphodiesterase activity in both the cytosolic and membrane compartments. Feeding of n-3 PUFA does not significantly alter phosphodiesterase activity when compared with saturated fatty acid feeding. The fact that cyclic GMP hydrolysis remains unaffected by the various diets suggests that the calmodulin activated isoforms which hydrolyze the main part of cyclic GMP in heart cytosol are not very sensitive to dietary manipulations of the fatty acid composition of heart lipids.

None of the various diets used in the present study induced any significant difference in body weight of the animals at the end of the experiment, in accordance with previous results (4,10,14). However, Ruiz-Gutierrez *et al.* (29) reported that rats fed diets containing fish oil exhibited lower body weights than those fed corn, olive or soybean oil.

Marked changes in plasma phospholipid fatty acid composition were induced by feeding saturated, n-6 or n-3 fatty acids. Animals given diets enriched with saturated or n-3 fatty acids and supplemented with 2% of 18:2n-6-rich sunflower oil maintained a very low (undectable) level of 20:3n-9 (not shown). This indicated that the rats were not EFA deficient. The coconut oil-enriched diet, which contained 62% of fats as saturated fatty acids, did not increase the uptake of saturated fatty acids in plasma phospholipids. The saturated fatty acid level was higher in fish oil-fed animals which incorporated 16:0 more efficiently than rats from the two other groups. The monoenoic fatty acid proportion was significantly depressed in plasma phospholipids from rats fed the sunflower oil diet which contained the highest concentration of 18:1n-9, suggesting a competitive acylation between 18:1n-9 and 18:2n-6. In coconut oil-fed rats, the content of 18:2n-6 was significantly decreased compared to that of the SO group, while 20:4n-6 levels were similar in both groups. This result suggests that in the CO group the Δ6 desaturation/elongation process is efficient enough to maintain a 20:4n-6 concentration similar to that observed in sunflower oil-fed rats. In contrast, both 18:2n-6 and 20:4n-6 were replaced by n-3 fatty acids in the fish oil group, in accordance with previous reports (30).

The cardiac fatty acid composition markedly differed from that observed in plasma phospholipids. Although the total amount of fatty acids tended to be higher in the phospholipids of rats fed sunflower oil, this increase was only significant in the membrane pool of nonesterified fatty acids. No significant variations in the total saturated fatty acid levels were induced by the diet, whatever the considered cellular compartment. However, feeding a

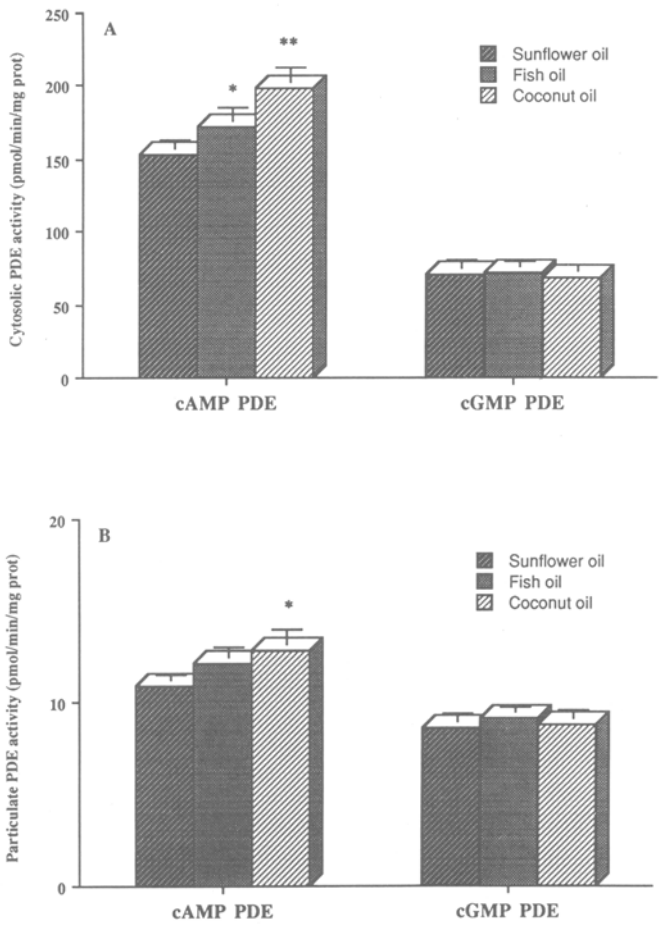

FIG. 1. Cardiac cyclic nucleotide phosphodiesterase activity from rats fed diets supplemented with sunflower oil, fish oil or coconut oil diets. Cytosolic (A) and particulate (B) fractions were prepared as described in Materials and Methods. Cyclic nucleotide phosphodiesterase activity was assayed with either 0.25 μM cyclic AMP or 0.25 μM cyclic GMP in the presence of 1 mM EGTA. * and **, Significantly different from the sunflower oil group at $P < 0.05$ and 0.01, respectively.

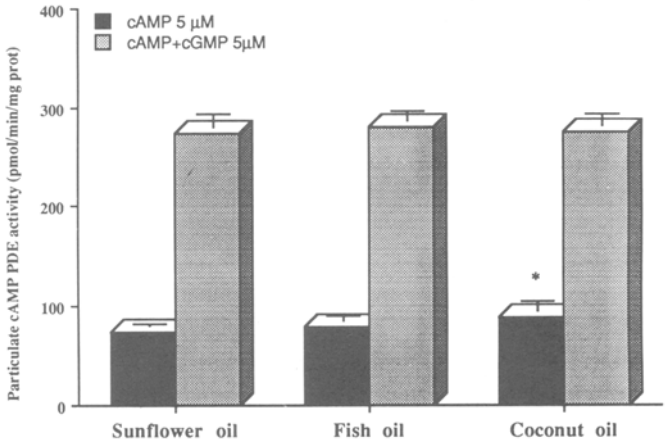

FIG. 2. Cyclic GMP-stimulated cyclic AMP hydrolysis in cardiac particulate fractions from rats fed diets supplemented with sunflower oil, fish oil or coconut oil diets. Cyclic AMP phosphodiesterase activity was assayed with 5 μM cyclic AMP, with or without 5 μM cyclic GMP. *, Significantly different from the sunflower oil group at $P < 0.05$. Percent stimulation of cyclic AMP hydrolysis by cyclic GMP was 272 ± 11, 255 ± 14 and 216 ± 13 for sunflower oil-, fish oil- and coconut oil-fed rats, respectively. Percent stimulation values of the coconut oil group were significantly different from values of the sunflower oil group at $P < 0.01$.

saturated fatty acid-enriched diet enhanced the level of monoenoic fatty acids in cardiac phospholipids, as previously reported by Awad and Chattopadhyay (9). The high saturated fatty acid content of the diet may stimulate Δ9 desaturase, hence increasing monoenoic fatty acid formation. Coconut oil feeding significantly decreased the total PUFA content only in the membrane nonesterified fatty acid pool, whereas normal levels of 18:2n-6 and 20:4n-6 were maintained in phospholipids, despite the low supply of 18:2n-6 in the diet. By contrast, the fish oil diet which provided the same amount of 18:2n-6 significantly decreased the n-6 fatty acid content of cardiac phospholipids when compared with the two other diets. This

22:6n-3	115 (105-125)	58 (31-109)

[a] Fatty acids were dissolved in ethanol and appropriately diluted with the enzyme assay buffer so that ethanol concentration did not exceed 1% vol/vol in the final assay medium. They were preincubated with the enzyme for 30 min at 37°C before the initiation of assay by substrate addition. Values are representative of two experiments performed in triplicate.

[b] Values in parentheses represent 95% confidence limits.

apparently results from a lower incorporation of 18:2n-6 due to the competitive replacement of n-6 by n-3 fatty acids. Furthermore, the low content of n-6 long chain fatty acids (22:4n-6 and 22:5n-6) in fish oil-fed animals may also result from the inhibition of Δ6 desaturase and elongase systems by n-3 PUFA (31,32).

Hearts from rats fed an n-3 fatty acid-rich diet selectively incorporated high amounts of n-3 PUFA, in agreement with results of others (10,14,15,33); high proportions of n-3 fatty acids were found in phospholipids as well as in the cytosolic and membrane nonesterified fatty acid pools. Specific acyltransferases selective toward some n-3 PUFA have been reported in heart tissue (34). Recently, Bouroudian *et al.* (35) have discovered the presence of an acyl-CoA synthetase with peculiar kinetic properties toward 22:6n-3, responsible for the inhibition of arachidonic acid incorporation into heart phospholipids. Whereas 20:5n-3 was the main n-3 fatty acid of plasma phospholipids, the concentration of 22:6n-3 was about fivefold higher than that of 20:5n-3 in heart phospholipids. Interestingly, Hagve and Sprecher (36) have shown that 20:5n-3 is taken up at a slower rate than other n-3 and n-6 fatty acids by isolated rat cardiac myocytes.

Several mechanisms might be involved in the lowering of cardiac cyclic AMP phosphodiesterase activity by sunflower oil feeding. Since n-6 polyunsaturated fatty acids are more potent inhibitors than saturated fatty acids (Table 7), the decrease in cyclic AMP phosphodiesterase activity observed after a three-week feeding period might result from a direct inhibitory effect by n-6 PUFA which accumulate more in the sunflower oil group than in the two other groups, especially in the membrane nonesterified fatty acid pool. However, *in vitro* addition of n-6 PUFA inhibited similarly cyclic AMP and cyclic GMP phosphodiesterase activities, whereas only cyclic AMP phosphodiesterase activity was affected by dietary manipulations. Thus, a direct interaction between nonesterified fatty acids and the phosphodiesterase isoenzymes may only partly explain the results obtained *in vivo* after a three-week feeding period.

Changes in the fatty acid composition of heart lipids also may influence phosphodiesterase activity through indirect and more complex mechanisms. The increase in nonesterified arachidonic acid content of the membrane pool caused by sunflower oil feeding may, in turn, increase prostanoid formation. However, no clear-cut relationship has yet been established between cellular eicosanoid content and phosphodiesterase activity. Several prostaglandins, as well as thromboxane B_2, were reported to have no direct effect on the activity of purified cyclic GMP-stimulated phosphodiesterase from calf liver *in vitro* (21). In platelets, prostaglandins are known to stimulate, through cyclic AMP-dependent phosphorylation, the activity of a cyclic AMP specific, cyclic GMP-inhibited isoform (37) which is found only in minor amount in rat heart tissue (38). Similarly, no direct influence of hydroperoxy fatty acids upon phosphodiesterase activity seems to exist in rat heart. An increased level of lipid peroxidation has been suggested to occur in fish oil-fed animals (39). However, PDE activity was not altered in the fish oil-fed group as compared with the coconut oil-fed group, suggesting that lipid peroxide levels do not directly influence cardiac phosphodiesterase activity, although some reports have indicated deleterious effect of hydroperoxides, such as H_2O_2 on platelet phosphodiesterase (40).

We have previously shown that compounds generated through phospholipid breakdown modulate cytosolic (41) as well as particulate (42) phosphodiesterase activities of rat heart. Synthetic diacylglycerols and phosphatidic acids were shown to stimulate cyclic AMP hydrolysis *in vitro*, dipalmitoyl phosphatidic acid being more efficient than egg yolk phosphatidate (42). Since the palmitic acid content of heart phospholipids was higher in the coconut oil-fed group than in the two other groups, coconut oil feeding may generate phosphatidate species containing higher levels of palmitic acid than PUFA feeding, thus increasing cyclic AMP phosphodiesterase activity.

Results of the present work showing that n-6 PUFA feeding and saturated fatty acid feeding are associated with decreased and increased cardiac cyclic AMP phosphodiesterase activity, respectively, might be physiologically relevant. Cyclic AMP phosphodiesterase inhibition is associated with increased intracellular cyclic AMP levels and increased cardiac contractility (18,19). Thus our results are in accordance with reports showing an increased sensitivity to catecholamines upon n-6 PUFA feeding (8) and with works reporting an impairment of cardiac functions associated with a relative n-6 fatty acid deficiency such as that induced by n-3 fatty acid feeding (15).

[Received June 21, 1991, and in revised form March 6, 1992; Revision accepted July 4, 1992]

The Effect of a Histidine-Excess Diet on Cholesterol Synthesis and Degradation in Rats

Eri Hitomi-Ohmura, Nobuyuki Amano, Yoritaka Aoyama* and **Akira Yoshida**
Laboratory of Nutritional Biochemistry, Department of Agricultural Chemistry, School of Agriculture, Nagoya University, Nagoya 464-01 Japan

Feeding a diet high in excess histidine (5% L-histidine) resulted in hypercholesterolemia and enlargement of the liver in rats. To clarify the mechanism of the hypercholesterolemia, cholesterol synthesis and degradation were followed. We found that hepatic 3-hydroxy-3-methylglutaryl-coenzyme A reductase activity in histidine-excess diet rats was significantly higher than in rats fed a basal diet. Incorporation of [^{3}H]water into cholesterol of liver slices from rats fed the histidine-excess diet was higher than incorporation into liver slices from rats fed the basal diet (expressed per liver per 100 g body weight). *In vivo* incorporation of [^{3}H]water into hepatic cholesterol was also higher, but the incorporation into cholesterol of the small intestine was lower in histidine-fed rats than in rats fed the basal diet (expressed per liver per 100 g body weight). Hepatic cholesterol 7α-hydroxylase activity was similar in both groups. The data suggest that the hypercholesterolemia caused by histidine-excess diet appears to be due to the stimulation of cholesterol synthesis in the liver. *Lipids 27*, 755–760 (1992).

In previous studies, growth retardation has been observed in rats fed diets enriched with a single amino acid (1). Several amino aicds were shown to affect cholesterol metabolism as well as growth. Dietary excess lysine (2,3), cystine (4,5) and histidine (2,6-11) can cause hypercholesterolemia in experimental animals. Solomon and Geison (6), Harvey *et al.* (7), Aoyama *et al.* (8-10) and Ohmura *et al.* (11) reported that dietary supplementation with excess-histidine leads to growth depression, hepatomegaly and increased plasma cholesterol levels in rats. Although histidine-fed rats did not ingest cholesterol, serum cholesterol significantly increased (6-11). Thus, the hypercholesterolemia induced by excess-histidine was not due to exogenous cholesterol. The distribution of serum high density, low density and very low density lipoprotein cholesterol in rats fed the histidine-excess diet was similar to that of rats fed the basal diet (11).

The mechanism of the increase in serum cholesterol has been investigated. Qureshi *et al.* (12) reported that the incorporation of [^{14}C]acetate or [^{14}C]mevalonate into cholesterol was significantly higher in the 5,000 × *g* liver supernatant fraction of histidine-supplemented chow-fed rats compared to controls. Solomon and Geison (13) also reported that a histidine-excess diet caused a 100% increase in the incorporation of [^{14}C]acetate or [^{14}C]octanoate into cholesterol of liver slices from weanling rats. These results suggested that cholesterol synthesis was stimulated by dietary excess histidine in the *in vitro* system. Cholesterol degradation has not been studied previously under histidine-excess dietary conditions.

Abbreviations: EDTA, ethylenediaminetetraacetic acid; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A.

Because measurement of cholesterol synthesis with ^{14}C-labelled precursors may underestimate the actual rate of cholesterol formation (14-16), we used in the present study [^{3}H]water under *in vivo* and *in vitro* conditions to assess cholesterogenesis in animals fed the histidine-excess diet. It is well established that 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase [EC.1.1.88] is the rate-limiting enzyme of cholesterogenesis (17-19) and that cholesterol 7α-hydroxylase [EC.1.14.13.7], the initial step in the conversion of cholesterol to bile acids, is the rate-limiting step in cholesterol degradation (20). We therefore examined liver HMG-CoA reductase and cholesterol 7α-hydroxylase activities to shed light on the regulation of cholesterol synthesis and degradation in rats fed a histidine-excess diet.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (Japan SLC, Inc., Hamamatsu, Japan) were used. Rats were housed individually in screen-bottomed cages in an air-conditioned room kept at 22 ± 2°C on a 12-h light (0800-2000 h) dark (2000-0800 h) cycle. The rats were fed a basal diet (Table 1) for 3 to 5 days, allowing them to adapt to the shifted feeding pattern described below, and then were offered the experimental diets. The histidine-excess diet consisted of the basal diet with addition of 5% L-histidine (Ajinomoto Co., Inc., Tokyo, Japan) (Table 1). The addition of L-histidine was compensated for by adjusting the amount of carbohydrates. No dietary fibers were added to the experimental diets.

Changes in serum cholesterol (Experiment 1). Rats were fed the experimental diets for 0, 7 or 14 days. Diets were

offered from 1800 to 1000 h, and rats were sacrificed at 1000–1030 h by heart puncture.

HMG-CoA reductase activity (Experiment 2). Because food intake of rats fed the histidine-excess diet was significantly lower than that of rats fed the basal diet, a pair-fed basal group was used. Pair-fed rats were offered the same amount of a basal diet as consumed by the rats fed the histidine-excess diet. Diets were offered from 1800 to 1000 h, and the rats were sacrificed at 2300–2330 h by decapitation (21).

(i) Preparation of liver microsome. Aliquots of liver (1.5 g) were weighed and homogenized with 4 vol of cold buffer containing 0.3 M sucrose, 10 mM 2-mercaptoethanol, 10 mM sodium ethylenediaminetetraacetic acid (EDTA; pH 7.4) and 50 mM sodium fluoride using Potter-Elvehjem Teflon homogenizer (22). The resulting homogenate was centrifuged for 15 min at 12,000 × *g* at 4°C and the postmitochondrial supernatant was then centrifuged for 60 min at 105,000 × *g* at 4°C to sediment microsomes. The pellets were immediately stored at −80°C. Pellets could be stored for 10 days without loss of enzyme activity. Pellets were resuspended in 1 mL of preincubation medium before use.

(ii) Assay of microsomal HMG-CoA reductase activity. To assay the total activity of HMG-CoA reductase, the microsomes were preincubated at 37°C for 60 min with a preincubation mixture containing the following components in a volume of 45 μL: 20 mM imidazole chloride (pH 7.4), 5 mM dithiothreitol, 1.0–1.5 mg of microsomal protein and 10 units of alkaline phosphatase (*E. coli*) to convert "inactive" to "active" HMG-CoA reducase. For assay of native "active" HMG-CoA reductase activity, no alkaline phosphatase was added.

A solution (45 μL) containing 0.2 M potassium phosphate (pH 7.4), 20 mM NADPH, 20 mM sodium EDTA and 10 mM dithiothreitol was added to the preincubation mixture. The HMG-CoA reductase assay was then initiated by addition of DL[3-^{14}C]HMG-CoA (2,500 dpm/nmole)(52 mCi/mmol or 1.92 GBq/mmol)(Amersham Japan, Ltd., Tokyo, Japan) to a final concentration of 470 μM (final assay volume, 100 μL). After incubation for 30 min at 37°C, the [^{14}C]mevalonate formed was converted into lactone, isolated by thin-layer chromatography, using benzene/acetone (1:1, vol/vol) as the developing solvent, and counted using an internal standard of [^{3}H]mevalonate to correct for recovery. HMG-CoA reductase activity was expressed in nmoles of [^{14}C]mevalonate formed per hour per milligram of microsomal protein, nmoles per hour per gram of liver and nmoles per hour per liver per 100 gram of body weight.

In vivo *incorporation of [^{3}H]water into cholesterol (Experiment 3).* Rats were fed either a basal or a histidine-excess diet for 10 days. Diets were offered from 1000 to 1800 h. The rats were injected intraperitoneally with 250 μL of [^{3}H]water (1 mCi) (37 MBq) (Amersham Japan Ltd.). At 1 h after injection, the rats were sacrificed by heart puncture between 1400 and 1500 h. The liver and small intestine (0.5 cm below pylorus and 0.5 cm above cecum) were quickly removed. Intestinal contents were removed by rinsing with ice-cold saline. Both liver and small intestine were frozen in liquid nitrogen and stored at −20°C. An aliquot of the stored liver, small intestine and serum was saponified in 15% ethanolic potassium hydroxide for 60 min at 75°C. The hydrolysate was then extracted 4 times with petroleum hydrocarbon (b.p. 30–60°C). An aliquot of the petroleum hydrocarbon fraction was counted for radioactivity in the unsaponifiable fraction. Sterols in another of the petroleum hydrocarbon fraction were purified as digitonin-precipitable sterols by the method of Kelley and Tsai (23). The rate of synthesis was estimated by the formula of Turley *et al.* (24) based on serum ^{3}H-content. The rate of synthesis was expressed as nmoles of [^{3}H]water incorporated into digitonin-precipitable sterols per gram of tissue per h or nmoles per tissue per hour per 100 g body weight.

In vitro *incorporation of* [^{3}H]*water into hepatic cholesterol (Experiment 4).* The rats were fed either a basal or a histidine-excess diet for 10 days. Diets were offered from 1000 to 1800 h and rats were sacrificed between 1400 and 1500 h to prepare liver slices (0.5 mm thick) by hand. The liver slices weighing about 500 mg were incubated in 1.5 mL of Krebs Ringer bicarbonate buffer (pH 7.4) gassed with 95% O_2/5% CO_2 and containing 3.3 μCi (122 KBq) of [^{3}H]water (Amersham Japan Ltd.) and 16 μmoles of sodium acetate (25). At the end of the 2-h incubation with shaking at 37°C in an atmosphere of 95% O_2/5% CO_2, 2 mL of 15% ethanolic potassium hydroxide solution was added to the flask. The flasks' contents were saponified, extracted and purified as already described. The radioactivity of the nonsaponifiable fraction or digitonin-precipitable sterols was counted and expressed as μmoles of [^{3}H]water incorporated per gram of liver per hour or μmoles of ^{3}H per hour per liver per 100 gram body weight.

Assay of cholesterol 7α-hydroxylase (Experiment 5). Rats were fed the basal or the histidine-excess diet for 10 days. Pair-fed rats were offered the same amount of a basal diet as consumed by the rats fed the histidine-excess diet. Diets were offered from 1800 to 1000 h, and the rats were sacrificed between 2300 and 2330 h by decapitation.

(i) Preparation of liver microsome. Aliquots of liver (1.0 g) were weighted and then homogenized with a Potter-Elvehjem homogenizer with a Teflon pestle in 4 vol of ice-cold potassium chloride isotonic solution. The homogenate was centrifuged for 15 min at 12,000 × *g* at 4°C and the supernatant was then centrifuged for 60 min at 105,000 × *g* (4°C). The pellets were finally resuspended in 0.1 M potassium phosphate buffer (pH 7.4) (26,27).

(ii) Assay of microsomal cholesterol 7α-hydroxylase. The final incubation mixture (1 mL) contained 100 mM potassium phosphate buffer (pH 7.4), 20 mM cysteamine, 4 mM magnesium chloride, 5 mM NADPH and 1.0–1.5 mg of microsomal protein (26,27). The substrate [7(n)-^{3}H]cholesterol (5 μCi, 185 KBq) (7.45 Ci/mmol, 276 GBq/mmol) (Amersham Japan Ltd.) and 300 μM cholesterol were introduced into the incubation medium using a minimal volume of a concentrated solution in Tween-80 (26). Samples were incubated for 30 min in a shaking bath at 37°C. The enzymatic reaction was stopped by adding 3 vol of 20% (wt/vol) trichloroacetic acid solution. The tubes were centrifuged for 5 min at 3,000 × *g*. Then aliquots of the supernatants were transferred into appropriate tubes containing chloroform, and the content was extracted twice to remove unmetabolized [7(n)-^{3}H]cholesterol. The final water layer was counted for radioactivity.

Assay of serum and liver components. Lipids of the liver were extracted and purified according to the procedure of Folch *et al.* (28). Liver, serum and microsomal choles-

terol were measured enzymatically (29). Microsomal protein was measured by the method of Lowry *et al.* (30).

Statistical analysis. Data were analyzed by Student's *t*-test (31).

RESULTS

Changes in serum and liver cholesterol in rats fed either a basal or a histidine-excess diet. Food intake, body weight gain, serum cholesterol, liver weight and liver cholesterol of rats fed either a basal or a histidine-excess diet for 7 and 14 days are summarized in Table 2. Food intake and body weight gain were suppressed by the histidine-excess diet. Serum cholesterol and liver weight in rats fed the histidine-excess diet were significantly higher than those of rats fed the basal diet. Liver cholesterol content in rats fed the histidine-excess diet was lower when expressed as mg per gram liver, but higher when expressed as milligram per livers per 100 gram body weight than that in rats fed the basal diet.

Liver HMG-CoA reductase activity. Food intake, body weight gain, serum cholesterol, microsomal cholesterol and HMG-CoA reductase activity of rats fed a basal or a histidine-excess diet are summarized in Table 3. Food intake and body weight gain of rats fed a histidine-excess diet were lower than those of rats fed the basal diet *ad libitum* or those of pair-fed rats. Since pair-fed rats were fed the same amount of food eaten by rats fed the histidine-excess diet, body weight gain of pair-fed rats was similar to those of rats fed the histidine-excess diet. Serum cholesterol levels in pair-fed rats were higher than those in rats fed the basal diet *ad libitum*. Serum cholesterol levels in rats fed the histidine-excess diet were significantly higher than those in rats fed the basal diet *ad libitum* or those in pair-fed rats. Microsomal cholesterol levels were not affected by the histidine-excess diet. Total and "active" liver HMG-CoA reductase activities at midnight in rats fed the histidine-excess diet were higher than those in rats fed the basal diet *ad libitum* or those in pair-fed rats when expressed as milligram protein, gram liver or liver per 100 gram body weight. HMG-CoA reductase activity in pair-fed rats was similar to that in rats fed the basal diet *ad libitum*. The percentages of "active" activity in total activity were as follows: basal *ad libitum*, 25 ± 2; basal pair-fed, 26 ± 2; and histidine-excess *ad libitum*, 29 ± 2 (Experiment 2).

In vivo *and* in vitro *incorporation of [^{3}H]water into sterols.* The effects of dietary excess histidine on *in vivo* incorporation of [^{3}H]water into sterols are summarized in Table 4. *In vivo* incorporation of [^{3}H]water into liver digitonin-precipitable sterols, expressed as μmoles per hour per gram, in rats fed the histidine-excess diet was not significantly different from the incorporation in rats fed the basal diet. However, when expressed as μmoles per hour per liver per 100 gram body weight, the *in vivo* incorporation of [^{3}H]water into digitonin precipitable sterols was higher in rats fed the histidine-excess diet. Small intestine [^{3}H]digitonin-precipitable sterols, expressed as μmoles per hour per gram in rats fed the histidine-excess diet were similar to those in rats fed the basal diet. When expressed as μmoles per hour per tissue per 100 gram body weight, [^{3}H]digitonin-precipitable sterols in rats fed the histidine-excess diet was lower than that in rats fed the basal diet. There were no significant changes in serum [^{3}H]digitonin-precipitable sterols and serum ^{3}H-content between rats fed the basal and the histidine-excess diets.

In *in vitro* experiments (Table 5), ^{3}H-incorporation into the nonsaponifiable fraction was higher than that into the digitonin-precipitable sterols. ^{3}H-Incorporation into the nonsaponifiable fraction and digitonin-precipitable sterols in rats fed the histidine-excess diet was not significantly different from that in rats fed the basal diet when expressed as μmoles per hour per gram. When expressed as μmoles per hour per liver per 100 gram body weight, ^{3}H-incorporation into either fraction was signficantly higher in rats fed the histidine-excess diet than in rats fed the basal diet.

Cholesterol 7α-hydroxylase. Cholesterol 7α-hydroxylase activity of rats fed the histidine-excess diet (*ad libitum*) was similar to that of rats fed the basal diet (*ad libitum*). 7α-Hydroxylase activity of rats fed the histidine-excess diet was significantly higher than that of rats fed the basal diet (pair-fed) when expressed as nmoles per hour per liver per 100 kg body weight (Table 6).

DISCUSSION

Our observation that feeding a histidine-excess diet causes growth retardation, hepatomegaly and hypercholestrolemia is consistent with previous reports by Solomon and Geison (6), Aoyama *et al.* (8–10) and Ohmura *et al.* (11).

In the present study, 5% dietary L-histidine levels were used following the method of Solomon and Geison (6).

In a preliminary study we had found that histidine levels higher than 3.5% in the diet induced hypercholesterolemia (Ohmura, E., Aoyama, Y. and Yoshida, A., unpublished data). The histidine levels used here should be considered pharmacological and/or toxicological and would not occur in a normal human diet. Thus, hypercholesterolemia caused by excess histidine should be seen as a model for endogenously induced hypercholesterolemia.

Dietschy and McGarry (14), and Stange and Dietschy (15) have demonstrated that ^{14}C-labeled substrates such as acetate or octanoate can be used for the estimation of sterols synthesis. Using ^{14}C-labeled substrate, the ability of the substrate to penetrate cell membranes, as well as intracellular dilution may have profound effects (16). Thus, methods based on ^{14}C-labeled substrates can underestimate (or sometimes overestimate) the true rate of cholesterol synthesis. Therefore, the use of [^{3}H]water seemed preferable for measuring the rates of cholesterogenesis. Rates of cholesterogenesis measured *in vivo* and *in vitro* (Tables 4 and 5) mostly reflect the activity of hepatic HMG-CoA reductase. Indeed, the activity of hepatic HMG-CoA reductase was higher in a histidine-

excess group than in a basal group even though diets were offered from 1000 to 1800 h or 1800 to 1000 h (data not shown).

Food intake of rats fed the histidine-excess diet was lower than intake of rats fed the basal diet (Tables 2–6). To exclude the effect of reduced food intake due to excess histidine, pair-fed controls were used for following HMG-CoA reductase activity. Although food intake of pair-fed rats was restricted to 70% of that of rats that consumed the basal diet *ad libitum*, HMG-CoA reductase activity of pair-fed rats was not affected when compared with that of rats fed the basal diet *ad libitum* (Table 3). These results suggested that lower food intake in rats fed the histidine-excess diet had no effect on the activity of the enzyme. Thus, increased HMG-CoA activity in rats fed the histidine-excess diet appears to be due to excess histidine intake.

It is well known that HMG-CoA reductase activity is modulated by short-term and by long-term mechanisms (32–35). *In vivo*, short-term changes in enzyme activity can depend on the modulation of the enzyme by phosphorylation and dephosphorylation (32, 33), while long-term changes in the activity of the enzyme can depend on protein synthesis and/or degradation. In our study, long-term regulation of cholesterol synthesis may play a role in histidine-induced hypercholesterolemia because serum cholesterol in rats fed a histidine-excess diet was also increased by daytime feeding. Our results showed that the percentage of "active" activity in total activity was constant whether excess histidine was present or not (Table 3) suggesting long-term regulation rather than short-term regulation in the rats fed the histidine-excess diet. The total activity (active + inactive form) of HMG-CoA reductase is thought to reflect the protein level of HMG-CoA reductase in the liver (35). Our results (Table 3) showed that total HMG-CoA activity in rats fed the histidine-excess diet was significantly higher than that in rats fed the basal diet, suggesting that the content of HMG-CoA reductase protein may be higher in rats fed the histidine-excess diet as compared to that in rats fed the basal diet.

HMG-CoA reductase has a short half-life of about 2 h (36); so its level can easily be changed by dietary conditions (35) or circadian rhythm (37). Although the serum cholesterol level was high in rats fed the histidine-excess diet, the feedback system from serum cholesterol to hepatic HMG-CoA reductase might not be active.

We also examined that the possibility that histidine *per se* may be an *in vitro* activator of HMG-CoA reductase. L-Histidine was added to the assay mixture of HMG-CoA reductase. Microsomes obtained from rats fed the basal diet were used for the assay. The HMG-CoA reductase activities (nmoles per hour per milligram protein) were 1.35 for 0 mM histidine, 1.33 for 10 mM histidine and 1.66 for 50 mM histidine, suggesting that *in vitro* activation of HMG-CoA reductase by excess histidine may not be a factor. The possibility that histidine by itself is an activator of the enzyme can thus be excluded.

The activity of cholesterol 7α-hydroxylase, the regulatory enzyme of cholic acid synthesis, was unchanged by excess dietary histidine (Table 6). Thus, from both the increase in the activity of hepatic HMG-CoA reductase and the lack of an effect on cholesterol 7α-hydroxylase, the mechanism by which excess dietary histidine produces an increase in serum cholesterol appears to be the stimulation of cholesterol synthesis.

Total liver HMG-CoA reductase activity measured in rats fed during the light period and killed at midday was similar to results from rats fed during the dark period and killed at midnight. In rats fed during the light period and killed at midday, total liver HMG-CoA reductase activity in rats fed the histidine-excess diet was significantly higher than that in rats fed the basal diet when expressed as milligram protein or liver per 100 g body weight (not shown). Therefore, *in vivo* and *in vitro* incorporation of tritiated water was measured using rats fed during the light period and killed at midday (Experiments 3 and 4). Data obtained in the *in vivo* study (Table 4) suggest that cholesterol synthesis in the small intestine of rats fed a histidine-excess diet does not contribute to an increase in serum cholesterol.

[^{3}H]Digitonin-precipitable sterols in serum were measured to determine the export of newly synthesized cholesterol from tissues (Table 4). There was no difference in serum [^{3}H]digitonin-precipitable sterols between rats fed the basal diet or the histidine-excess diet. Work of Turley *et al.* (24) had indicated that nearly all [^{3}H]digitonin-precipitable sterols present in blood were derived from hepatic sources and that the high level of the liver [^{3}H]digitonin-precipitable sterols in rats fed the histidine-excess diet may not be due to decreased export of [^{3}H]digitonin-precipitable sterols from liver to serum. According to their results, the [^{3}H]digitonin-precipitable sterols in serum of rats fed the histidine-excess diet should be higher than that in rats fed the basal diet. However, this discrepancy may be due to the low amount of serum [^{3}H]digitonine-precipitable sterols exported within 60 min. More detailed investigations will be needed to shed light on the transport system for newly synthesized cholesterol.

trans Fatty Acids. 5. Fatty Acid Composition of Lipids of the Brain and Other Organs in Suckling Piglets

Jan Pettersen and **Johannes Opstvedt***
Norwegian Herring Oil and Meal Industry Research Institute, N-5033 Fyllingsdalen, Bergen, Norway

The effects of dietary *trans* fatty acids on the fatty acid composition of the brain in comparison with other organs were studied in 3-wk-old suckling piglets. In Experiment (Expt.) 1 the piglets were delivered from sows fed partially hydrogenated fish oil (PHFO) (28% *trans*), partially hydrogenated soybean oil (PHSBO) (36% *trans*) or lard (0% *trans*). In Expt. 2 the piglets were delivered from sows fed PHFO, hydrogenated fish oil (HFO) (19% *trans*) or coconut fat (CF) (0% *trans*) with two levels of dietary linoleic acid (1 and 2.7%) according to factorial design. In both experiments the mother's milk was the piglets' only food. The level of incorporation of *trans* fatty acids in the organs was dependent on the levels in the diets and independent of fat source (*i.e.*, PHSBO, PHFO or HFO). Incorporation of *trans* fatty acids into brain PE (phosphatidylethanolamine) was non-detectable in Expt. 1. In Expt. 2, small amounts (less than 0.5%) of 18:1 *trans* isomers were found in the brain, the level being slightly more on the lower level of dietary linoleic acid compared to the higher. In the other organs the percentage of 18:1 *trans* increased in the following order: heart PE, liver mitochondria PE, plasma lipids and subcutaneous adipose tissue. Small amounts of 20:1 *trans* were found in adipose tissue and plasma lipids. Other very long-chain fatty acids from PHFO or HFO (*i.e.*, 20:1 *cis* and 22:1 *cis* + *trans*) were found in all organ lipids except for brain PE. Dietary *trans* fatty acids increased the percentage of 22:5n-6 in brain PE. Except for the brain and the heart, dietary *trans* fatty acids reduced the percentage of saturated fatty acids and increased the percentage of monoenoic acids (including *trans*). The overall conclusion was that dietary *trans* fatty acids had no noticeable effect on the brain PE composition but slight to moderate effects on the fatty acid profile of other organs of suckling piglets.
Lipids 27, 761–769 (1992).

Human diets in Western society contain about 0.6-2 percent *trans* fatty acids (1,2) that mostly come from industrially processed fat with only small amounts being consumed in fats from ruminant animals. The fact that most of the *trans* fatty acids are of industrial rather than natural origin has been of concern and has led to a number of studies. *In vitro* studies have shown that *trans* fatty acids may inhibit the synthesis of longer chain essential n-6 and n-3 fatty acids from their lower homologues (3,4). These findings have led to speculation that *trans* fatty acids may interfere with the formation of eicosanoids (1,2,5,6) and may affect the biological properties of membranes (7).

*To whom correspondence should be addressed.

Abbreviations: CF, coconut fat; GLC, gas-liquid chromatography; HFO, hydrogenated fish oil; HPLC, high-performance liquid chromatography; LC, long-chain; PE, phosphatidylethanolamine; PHFO, partially hydrogenated fish oil; PHSBO, partially hydrogenated soybean oil; PUFA, polyunsaturated fatty acids; SFO, sunflower seed oil.

Because it has been shown that long-chain polyunsaturated fatty acids (LC-PUFA) are essential for nerve function (8,9), it is particularly important to ascertain whether consumption of *trans* fatty acids causes incorporation of *trans* fatty acids or alters the LC-PUFA profile in nerve tissue. In humans, brain growth occurs during late *prenatal* and early *postnatal* life (10), *i.e.*, the structural lipids of nerve tissues are formed in a relatively early stage. In a series of experiments comprising *prenatal* life (11) and the growth period to maturation (12), we have studied the effect of *trans* fatty acids with emphasis on nerve tissues. The observations include histology and functionality of nerve tissues (13) in addition to examining the content of *trans* fatty acids and fatty acid composition in general in the brain and several other organs (11,12). This final study concerned the effect of dietary *trans* fatty acids consumed from the mothers' milk during early *postnatal* life. The transfer of *trans* fatty acids from the mothers' diet to the milk has been reported (14). We have used pigs as models because of their physiological resemblance to humans (15,16), particularly with regard to brain growth (10) and accretion of LC-PUFA in nervous tissue (17). Further, we decided to focus on the very long-chain (*i.e.*, 20 and 22 carbon atoms) *trans* fatty acids found in partially hydrogenated fish oil (18); previous studies have mainly used partially hydrogenated vegetable oils that do not contain very long-chain *trans* fatty acids.

The present study consisted of two experiments. The first experiment compared diets with *trans* fatty acids from partially hydrogenated soybean oil and partially hydrogenated fish oil. The second experiment compared two fish oils differing in *trans* fatty acid contents when fed with two levels of dietary linoleic acid. Our analytical capacity did not allow us to analyze more than one phospholipid class. Since phosphatidylethanolamine (PE) has a high content of long-chain PUFA (19), which are assumed to be of particular importance for membrane structure and function, PE was chosen as the target lipid class. Lipid samples were obtained from the offspring after three weeks of suckling as the only nutrient supply. The brain was the principal organ of this investigation, but in order to compare the results from this study with those from previous ones, other tissues were analyzed as well.

EXPERIMENTAL PROCEDURES

General procedures. From 1 to 4 (depending on litter size) male and female piglets from each Norwegian Landrace sow were allowed to suckle and had no access to other feeds until they were three weeks old, when they were sacrificed by electrocution. Samples of 3 g each from heart, liver and adipose tissues, and 2.5 g from brain plus 1 mL of blood (right ventricle) plasma were immediately obtained for chemical analysis. Samples from individual piglets of each sex were pooled to two composite samples per sow (litter), *i.e.*, 8 (2 × 4) composite samples per diet. In Expt. 1 the piglets were bred from sows that from three weeks of age were fed diets based on cereals, solvent

extracted soybean meal, and 4 wt percent SFO (sunflower seed oil, 65% linoleic acid). To the respective diets were added 14 wt percent lard (control, diet 1), PHFO (partially hydrogenated capelin oil, m.p. 30–32°C, diet 2) or PHSBO (partially hydrogenated soybean oil, m.p. 40°C, diet 3). In Expt. 2, the piglets were bred from sows that through gestation were fed diets based on cereal grains and solvent extracted soybean meal to which was added 14 wt percent CF (coconut fat, diet 1.1 and 2.1), PHFO (diet 1.2 and 2.2) or HFO (hydrogenated fish oil, m.p. 50–52°C, diet 1.3 and 2.3) either without (diet 1.1, 1.2 and 1.3) or with (diet 2.1, 2.2 and 2.3) the addition of 3 wt percent SFO according to a 3 × 2 factorial design. Both experiments used four sows (litters). Details of the sows' diets and management have been presented earlier (13). The design of the experiments and the fatty acid composition of the sows' diets are shown in Table 1.

Chemical methods. Total lipids were extracted from the different organs by the method described by Folch *et al.* (20) except in the case of the brain, for which a slight modification of the Folch procedure was used (21). Membrane lipids of liver mitochondria were isolated as described by Høy and Hølmer (22). All lipids were stored at −25°C pending further analysis. Phosphatidylethanolamine (PE) of the liver mitochondria, heart and brain was isolated by high-performance liquid chromatography (HPLC). PE plasmalogen was not separated from PE since both coeluted in HPLC. The fatty acid composition reported for PE is therefore the combined composition of PE and PE plasmalogen. The fatty acid composition was analyzed by gas-liquid chromatography (GLC) using a capillary (CP Sil 88) column as described earlier (12). The contents of 16:1 *trans* fatty acids were determined only for the dietary fats used in Expt. 2 (Table 1). The 16:1 *trans* isomers of organ lipids could not be identified due to interference by other components on the chromatograms. Some organ lipids apparently contained 22:1 *trans*, but due to the low content, the *trans* and *cis* isomers could not be separated quantitatively.

Statistical methods. The basic principle of the statistical methods used was estimation of maximum likelihood. The program package used was BMDP, program P2V (23).

RESULTS

Brain. The fatty acid composition of brain PE is shown in Table 2. Although the percentages of some of the fatty acids in the offspring were significantly influenced by the dietary fats fed to the sows, the differences between diets were small. No *trans* fatty acids were incorporated into

[a] From mothers fed these diets from 3 wk of age through pregnancy (Expt. 1) and from gestation through pregnancy (Expt. 2). All abbreviations as in Table 1.

[b] Significance means ($P < 0.05$): A, Interactions of experimental fats and SFO-level; B, effect of SFO-level; C, effect of experimental fats. Average of eight replicates. Pooled std. dev., pooled standard deviation, (error mean square)$^{1/2}$.

[c] n.d., Not detectable.

brain PE in Expt. 1. In Expt. 2 low, but significant, amounts of *trans* 18:1 were detected when the sows were fed PHFO. The percentage of 18:1 *trans* was higher when PHFO was fed in combination with the lower level of linoleic acid compared with the higher level. In neither of the experiments was 20:1 *trans* found in the offspring. Percent 20:1 *cis* was slightly, but significantly, increased in offspring from sows fed PHFO in Expt. 1. This effect was not found in PHFO or in HFO in Expt. 2. Neither in Expt. 1 nor in Expt. 2 could 22:1 *cis* and *trans* be detected.

In Expt. 2, feeding hydrogenated fats to the sows increased the percentage of 20:3n-9 in their offspring. This effect was independent of the dietary level of linoleic acid. However, an increase in percent 20:3n-9 was also found as a consequence of low dietary levels of linoleic acid, independently of the content of hydrogenated fats in the diets.

In Expt. 1 the content of linoleic acid increased and the content of arachidonic acid decreased in the offspring when hydrogenated fats were fed to the sows. This was not observed in Expt. 2. In Expt. 2 hydrogenated fat increased the content of 22:5n-6. This was observed in Expt. 2 only when hydrogenated fat was fed in combination with the higher level of linoleic acid.

In Expt. 1, feeding PHFO and PHSBO to the sows reduced the content of 22:6n-3 in the offspring. In Expt. 2, PHFO and HFO increased 22:6n-3 in sows fed the higher level of EFA and had variable effects on sows on diets with restricted amounts of EFA.

Total content of PUFA was about 10% higher in Expt. 1 compared with Expt. 2. The fat sources fed to the sows had only minor effects on the total contents of saturated, monoenoic and polyunsaturated fatty acids in the offspring, but the higher dietary level of linoleic acid increased the contents of all n-6 fatty acids, except linoleic acid, and decreased the content of n-3 fatty acids.

Heart. The fatty acid composition of PE from the heart is shown in Table 3. In both experiments, feeding partially hydrogenated fat to the sows led to elevated levels of 18:1 *trans* in the offspring. However, lower but detectable levels of 18:1 *trans* were also found in offspring from the sows fed the control diets without partially hydrogenated fat. The content of 18:1 *trans* in the offspring was not influenced by the levels of linoleic acid in the diets of the sows in Expt. 2.

Feeding hydrogenated fats in combination with the lower level of linoleic acid to the sows in Expt. 2 increased the content of 20:3n-9 in the offspring. This effect of hydrogenated fats was not seen when fed together with the higher level of linoleic acid. Feeding partially hydrogenated fat to the sows in both experiments increased the content of linoleic acid and linolenic acid, and, except for the HFO in Expt. 2, decreased the content of arachidonic acid in the offspring. In both experiments, PHFO increased the content of 20:3n-6. PHFO and HFO in Expt. 2 increased the content of 20:5n-3.

The content of monoenoic fatty acids in the offspring reflected that of the fats fed to the sows in both

[a]From mothers fed these diets from 3 wk of age through pregnancy (Expt. 1) and from gestation through pregnancy (Expt. 2). All abbreviations as in Table 1.

[b]Significance means ($P < 0.05$): A, Interactions of experimental fats and SFO-level; B, effect of SFO-level; C, effect of experimental fats. Average of eight replicates. Pooled std. dev., pooled standard deviation, (error mean square)$^{1/2}$.

[c]n.d., Not detectable.

experiments. However, only low levels of 22:1 *cis* plus *trans* were found and 20:1 *trans* was not detected.

In Expt. 1, feeding partially hydrogenated fat to the sows decreased the content of saturated fatty acids, increased the content of monoenoic acids but was without effect on the PUFA in the offspring. Similar effects were found for PHFO in Expt. 2, while HFO increased the content of PUFA but had only minor effects on the monoenoic acids. Increasing the level of linoleic acid in the sows' diets in Expt. 2 increased the content of the n-6 fatty acids and reduced the content of 20:3n-9 and n-3 fatty acids in the offspring.

Liver. The fatty acid composition of liver mitochondria PE from the piglets is shown in Table 4. In both experiments, feeding all types of partially hydrogenated fats to the sows increased the content of 18:1 *trans* in the offspring. Contrary to what was found for brain and heart, feeding of PHFO also led to incorporation of 20:1 *trans*. The level of linoleic acid in the sows' diets had no effect on the level of *trans* fatty acids in the offspring (Expt. 2).

The fatty acid profiles of the fats fed to the sows influenced the fatty acid composition of liver PE of the offspring.

In Expt. 1, PHSBO caused a marked increase in the percentage of 18:1 *cis* and a marked reduction in the percentage of 20:4n-6, 22:5n-3 and 22:6n-3. It is worth noting that despite a relatively high content of 20:1 *cis* and 20:1 *trans* and of 22:1 *cis* + *trans* in the diets of the sows fed PHFO and HFO, only very low to non-detectable levels of these fatty acids were found in the offspring. In total, feeding PHFO to the sows in both experiments increased the percentage of monoenoic acids and reduced the percentage of saturated acids. In Expt. 1, feeding PHFO increased and PHSBO decreased the percentage of PUFA in the offspring.

Increased levels of linoleic acid in the sows' diets in Expt. 2 reduced the percentage of 20:3n-9 and 20:5n-3 and increased the percentage of 18:2n-6, 20:4n-6 and 22:4n-6 in the offspring. Further, linoleic acid additions increased the percentage of PUFA n-6 and total PUFA and reduced the percentage of monounsaturated acids.

Blood. The fatty acid composition of total plasma lipids of venous blood is shown in Table 5. In both experiments, the percentage of 18:1 *trans* in the offspring increased significantly when the lactating sows were fed hydrogenated fats, but were not influenced by the dietary level of linoleic acid in Expt. 2. Feeding PHFO, and to a lesser degree HFO, to the sows gave appreciable levels of 20:1 *trans* in the offspring. In contrast to what was found for 18:1 *trans*, 20:1 *trans* was higher in piglets from sows fed the diet with the lower level of linoleic acid compared with the higher level. The percentages of 20:1 *cis*, 22:1 *cis* +

[a] From mothers fed these diets from 3 wk of age through pregnancy (Expt. 1) and from gestation through pregnancy (Expt. 2). All abbreviations as in Table 1.

[b] Significance means ($P < 0.05$): A, Interactions of experimental fats and SFO-level; B, effect of SFO-level; C, effect of experimental fats. Average of eight replicates. Pooled std. dev., pooled standard deviation, (error mean square)$^{1/2}$.

[c] n.d., Not detectable.

trans and 20:0 in the offspring increased when PHFO or HFO was fed to the sows in Expt. 2.

In Expt. 1 the percentage of linoleic acid increased, and in both experiments the percentage of arachidonic acid decreased in the offspring when hydrogenated fat was fed to the sows. Feeding CF led to a significant increase in the percentage of 12:0 and 14:0 in the offspring, especially when the sows were fed the diets with the lower level of linoleic acid.

The overall effect of feeding hydrogenated fat to the sows on the fatty acid composition in the offspring was a reduction in the percentage of saturated acids which was compensated for by an increase in the percentage of monounsaturated acids. Furthermore, the percentage of total n-6 PUFA was increased and the percentage of n-3 PUFA decreased when the sows were fed the diet with the higher level of linoleic acid compared with the lower level.

Adipose tissues. The fatty acid composition of the total lipids of subcutaneous adipose tissue of the piglets is shown in Table 6. In both experiments the percentage of 18:1 *trans* increased in the offspring when hydrogenated fats were fed to the sows. Furthermore, the percentage of 20:1 *trans* increased as a consequence of PHFO or HFO feeding, the percentage of 20:1 *trans* being higher when PHFO was fed together with the lower level of linoleic acid compared with the higher dietary level.

The percentage of 20:0, 20:1 *cis* and 22:1 *cis* + *trans* increased when PHFO or HFO was fed. Feeding hydrogenated fats to the sows had variable and inconsistent effects on the percentage of linoleic acid in the offspring. Thus, in Expt. 1, the percentage of linoleic acid increased when PHFO was fed, while the opposite occurred upon PHSBO-feeding. In Expt. 2 feeding PHFO and HFO increased the percentage of linoleic acid in the offspring when fed together with the higher dietary level of linoleic acid, while PHFO and HFO reduced the percentage of linoleic acid when fed together with the lower level of linoleic acid.

The percentage of arachidonic acid decreased in the offspring when PHFO or HFO was fed together with the lower dietary level of linoleic acid in Expt. 2 but not when fed together with the higher level. Feeding CF increased the percentage of 12:0 and 14:0.

As shown for the other organ lipids, feeding hydrogenated fats to the sows decreased the percentage of saturated fatty acids in the offspring and this was partly compensated by an increase in the percentage of monoenoic acids, *i.e.*, *cis* plus *trans* isomers.

[c]n.d., Not detectable.

Further additions of linoleic acid to the sows' diets increased the percentage of n-6 PUFA but had little effect on the percentage of n-3 PUFA in the offspring.

DISCUSSION

Nervous tissue contains large quantities of long-chain polyunsaturated, essential n-6 and n-3 fatty acids (LC-PUFA) which play important roles in nerve structure and function (24). It is therefore anticipated that nutritional deficiencies and imbalances and metabolic disorders that affect fatty acid metabolism may have a particularly detrimental effect on nervous tissue. Accretion of nervous tissue occurs over a relatively brief period of time during late gestation and early *postnatal* life (10,25). Since *in vitro* (3,4,26) and *in vivo* (27–29) studies have indicated that *trans* fatty acids may interfere with the metabolism of essential fatty acids, the content of *trans* fatty acids in the maternal diet during pregnancy and nursing is of concern for the development of nervous tissue in the offspring. Our previous studies showed no effect of *trans* fatty acids in the maternal diet on nervous tissue histology and function in 3-wk-old suckling piglets (13). However, we did find that *trans* fatty acids in the diets of the sows were transferred into the milk but had only marginal effects on the overall fatty acid composition of the milk (14).

The present study focused on the effect of the content of *trans* fatty acids in the maternal diet (and consequently in the milk) on the fatty acid composition of the offspring after nursing for three weeks after birth. In addition, comparisons were made in Expt. 1 between a hydrogenated fat of vegetable origin (PHSBO) containing *trans* fatty acids with 16 and 18 carbons and a hydrogenated fat of fish origin (PHFO) which in addition to C_{16} and C_{18} *trans* fatty acids also contained *trans* fatty acids with 20 and 22 carbons. Since dietary levels of linoleic acid have been claimed to influence the effect of *trans* fatty acids (1,30), different levels of *trans* fatty acids in hydrogenated fish oils were studied at two levels of dietary linoleic acid in Expt. 2.

The general outcome of the study is consistent with the results of our previous investigations and with mature pigs being fed diets with *trans* fatty acids for a six-month period (12). Thus, *trans* fatty acids present in the milk were absorbed by the young piglets and deposited in various tissues. These results are also consistent with previous findings in suckling rats (31). In agreement with our earlier results with new born (11) and mature (12) pigs, the deposition of *trans* fatty acids varied greatly between different organs, being highest in adipose tissue and lowest in brain. Thus, despite the fact that appreciable levels of *trans* fatty acids were present in the milk (14),

[c]n.d., Not detectable.

trans fatty acids were not detected in the brains of the offspring in Expt. 1, and only low levels of 18:1 *trans* and no 20:1 *trans* were found in Expt. 2. These results are in entire agreement with our previous results from mature and newborn pigs (11,12). In experiments with rats, Cook (32) found that small amounts (0.2%) of elaidic acid (18:1 *trans*) injected into the stomach of young rats were recovered in the brain. It therefore appears that although *trans* fatty acids may pass the blood-brain barrier in suckling animals, the amount actually being deposited in the brain is indeed very limited.

Table 7 shows the discrimination factors (*i.e.*, the relation of the percentage of *trans* isomers of the total monoene contents of the organ lipids to that of the respective dietary lipids) in the different organs of the 3-wk-old piglets compared to those of mature (12) and *neonatal* (11) pigs. In order to relate the findings in the 3-wk-old piglets to maternal nutrition, the calculation is based both on the milk and on the sows' diets. The relative values between the different organs were similar in 3-wk-old and mature pigs, but relatively more *trans* fatty acids from the diet (*i.e.*, milk) were incorporated into the organs of the 3-wk-old pigs compared to the mature pigs.

Indeed, the percentage of the *trans* fatty acids in the mothers' diet incorporated into the suckling piglets was similar to that found in the mothers themselves (12). It is possible that the relatively high incorporation of *trans* fatty acids in the 3-wk-old pigs was due to a low *de novo* fatty acid synthesis in these animals consuming milk in which a very high portion of the total energy came from fat. Except for liver mitochondria in which relatively more *trans* fatty acids were incorporated from the PHFO than from PHSBO, the discrimination factors were similar for the two fat sources in common with that found for mature pigs. With the exception of the brain, in which the incorporation of 18:1 *trans* was significantly increased on the lower dietary levels of linoleic acid compared with the higher levels, dietary levels of linoleic acid did not affect the incorporation of *trans* fatty acids. This result is contradictory to those of Hill *et al.* (33) who found a significant effect from dietary levels of linoleic acid on *trans* fatty acid incorporation. The reason for this discrepancy is not immediately evident.

To what extent the levels of *trans* fatty acids in the organs continue to increase over a life span is an intriguing question. The newborn and 3-wk-old pigs were offspring of the mature pigs used in this study (*i.e.*, Expt. 1), and all pigs were subjected to the same dietary regimen. The data therefore lend themselves to showing age effects on the levels of *trans* fatty acids in various organs. Figure 1 shows the percentage of *trans* fatty acids in PE of heart, liver mitochondria and adipose tissue of newborn, 3-wk-old and mature pigs when fed PHFO and PHSBO in Expt. 1. The figure shows that in these organs there was a sharp

[a]Fed the diets from 3 wk of age through gestation. For the suckling piglets (*i.e., postnatal*) discrimination factors based on the respective milk lipids (14) also were calculated. All abbreviations as in Table 1.

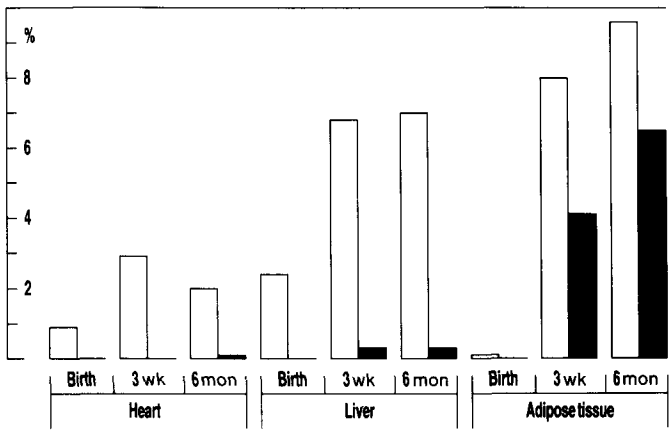

FIG. 1. Average percentage of 18:1 *trans* (white bars; animals fed PHFO and PHSBO) and 20:1 *trans* (black bars; animal fed PHFO) in organs of newborn, 3-wk-old, and mature pigs.

increase in the percentage of *trans* fatty acids during the first three weeks of life and that no consistent changes occurred thereafter. It thus appears that the content of *trans* fatty acids reaches a steady level early in life and is dependent on the dietary level of *trans* fatty acids.

Previous *in vitro* studies have shown that *trans* fatty acids may interfere with the metabolism of the essential n-6 and n-3 fatty acids through inhibition of the Δ5 (4,26) and Δ6 (3,4,26,30) desaturases. If such effects were of significant magnitude, they could influence fatty acid composition of the brain and consequently brain function. In the present study the effects of *trans* fatty acids on brain fatty acid composition were negligible although a slight increase in 18:2n-6 and 22:5n-6, and a small and inconsistent decrease in 20:4n-6 and 22:6n-3 were seen. These findings are in agreement with our previous results on newborn (11) and mature (12) pigs and with those of Lawson *et al.* (27) on rats being fed *trans* fatty acid for two generations. They are also in agreement with the findings of Sanders *et al.* (34) who found a reduction in brain 22:6n-3 and an increase in brain 22:5n-6 when fed *trans* fatty acid containing margarine to rats.

The effect of *trans* fatty acids on the fatty acid composition (*i.e.,* the levels of n-6 and n-3 fatty acids) in the other organs was similar in nature but of somewhat greater magnitude than that found in the brain, and this is in agreement with our previous results with newborn (11) and mature pigs (12).

This paper concludes a series of experiments with the aim of studying the effects of dietary *trans* fatty acids, with emphasis on nervous tissue. Since knowledge of the effect of long-chain *trans* fatty acids is meager, comparisons were made between partially hydrogenated soybean oil and partially hydrogenated fish oil. Pigs were used as model animals due to their resemblance to humans with regard to lipid metabolism and nerve tissue accretion (10,17). The study comprised the intrauterine period, early *postnatal* life (suckling period) and the growth period through the first pregnancy.

The pigs were fed diets that resembled human diets in Western society with regard to content of fat (about 40 cal%) and linoleic acid (2 to 9 cal%) and had a P/S (polyunsaturated fatty acids/saturated fatty acids) ratio from about 0.1 to 0.8, but contained 2 to 4 times more *trans* fatty acids (*i.e.,* 6 to 12 cal% *vs.* 3–4 cal%) (1). The combined results allow us to draw the following conclusions. *trans* Fatty acids were absorbed and deposited in the body of juvenile and mature pigs, but the level of depositoin varied between different organs. Since *trans* fatty acids were absent or only present at very low levels in brain PE of pigs of all ages, the transfer of *trans* fatty acids through the blood-brain barrier must have been very limited. Moreover, no effects of *trans* fatty acids on nerve histology and function were found. PE of heart and liver mitochondria, and of lipids in adipose tissues and in plasma contained *trans* fatty acids at levels that reflected the dietary content, the level being somewhat lower in the former than in the two latter tissues.

The levels of *trans* fatty acids were generally lower in the tissues compared to that in the corresponding diets. The reason for this finding may be that the *trans* fatty acids were catabolized rather than deposited, but may also be due to the *trans* fatty acids, being diluted in the tissues with *de novo* synthesized *cis* monoenoic fatty acids. Since *trans* fatty acids were found in the tissues of the newborn pigs, transfer of *trans* fatty acids through the placenta must have occurred. *trans* Fatty acids were secreted into the milk with little discrimination and absorbed and deposited in the body of the suckling pig. Newborn pigs

from mothers fed *trans* fatty acids had markedly lower levels of *trans* fatty acids in their bodies than their mothers. The levels of *trans* fatty acids rose quickly during the first weeks of suckling and had reached the levels of the mature animals three weeks after birth. The depositions of 18:1 *trans* were similar in PHSBO and PHFO. The deposition of 20:1 *trans*, only present in PHFO, was markedly lower than that of 18:1 *trans* in PE, while the two isomers were deposited to a similar degree in adipose tissues.

The dietary content of linoleic acid had no consistent effect on the deposition of *trans* fatty acids. Dietary *trans* fatty acids had minor but consistent effects on the profile of essential fatty acids (*i.e.*, n-6 fatty acids) in the organs, causing a minor increase in the content of the lower homologs and a minor decrease in the content of the chain-elongated and desaturated higher homologs. All together, consumption of *trans* fatty acids from PHSBO and PHFO at levels of three times that consumed by humans in Western society showed no effects in the pigs that could be considered detrimental.

Influence of Dietary Fatty Acids on the Glycerophospholipid Composition in Organs of Cod (*Gadus morhua*)

Øyvind Lie*, Gro-Ingunn Hemre and **Georg Lambertsen**
Institute of Nutrition, Directorate of Fisheries, N-5024 Bergen, Norway

Cod (mean start weight of 26 g) were fed three diets for 15 months, each based on a dry pellet coated at a level of 9 g/100 g with soybean oil, capelin oil or sardine oil. The fatty acid compositions of neutral lipids and four glycerophospholipids of white muscle, liver, gills and heart were determined. The fatty acid composition of dietary lipids influenced the composition of neutral lipids in all organs. Linoleic acid (18:2n-6) from soybean oil was selectively incorporated into phosphatidylcholine of the four tissues. Similar levels of 20:5n-3 and 22:6n-3 in phosphatidylcholine and phosphatidylethanolamine were found in all organs from cod fed capelin oil and sardine oil in spite of highly differentiated feed fatty acid levels. The polyunsaturated fatty acid (PUFA) composition of phosphatidylinositol was least influenced by dietary lipids. The preferred monoenoic fatty acid in phospholipids of cod was 18:1n-9, independent of dietary intake, whereas the longer chain monoenoic acids seemed to be preferentially catabolized. The results suggest that 20:4n-6 as well as 20:5n-3 and 22:6n-3 fatty acids are essential for cod.
***Lipids 27,* 770–775 (1992).**

While it is known that the fatty acid composition of fish lipids generally reflects the dietary intake, the influence of dietary lipids differs between triacylglycerols and phospholipids, as has been shown for cod (1). However, detailed studies documenting the effect of the fatty acid composition of dietary lipids on the fatty acid composition of phospholipids in cod tissues have not been undertaken.

Polyunsaturated fatty acids (PUFA) in organs and tissues of marine fish are mainly of the n-3 series, whereas the n-6 PUFA are prominent in terrestrial animals. In the major phospholipids of marine animals, 20:5n-3 and 22:6n-3 are most prominent; however, phosphatidylinositol also contains high levels of 20:4n-6 (2–6).

The factors that govern the specific incorporation of the n-3 and n-6 fatty acids into membrane phospholipids, and the role of PUFA in the membranes, are not fully understood. The extent to which n-3 fatty acids can substitute for n-6 fatty acids in the biomembranes of mammals is of considerable interest. Many studies on blood platelets and tissue lipids confirm that long-chain n-3 fatty acids from diets are incorporated into membrane lipids (7). Variations in the composition of polyunsaturated fatty acids in the diet effectively modulate eicosanoid biosynthesis, which generally depends on the composition of the fatty acid precursor pool (8,9).

In the present study, we examined the influence of dietary fatty acids on the composition of individual glycerophospholipid classes in tissues of cod and the ability of cod to modify the fatty acids taken up from the diet.

MATERIALS AND METHODS

Fish and diets. Cod, average weight 26 ± 2 g, hatched and reared at the Institute of Marine Research, Austevoll Aquaculture Research Station (N-5392 Storebø, Norway) were placed in 3 sea cages (380 fish in each) in November 1988. The fish were fed *ad libitum* once daily pellets of dry feed (produced by T. Skretting, Stavanger, Norway) which contained per 100 g: 36 g fishmeal ("Norseamink" and "LT-meal"; Norsildmel, Bergen, Norway), 32 g concentrated soybean meal (Danpro A, Aarhus Oliefabrik A/S, Århus, Denmark), 16 g wheat flour and 6 g mineral and vitamin premixes. The dry pellets were coated with 9 g/100 g of soybean oil (diet A), capelin oil (diet B) or sardine oil (diet C). The oils were supplemented with vitamin E (α-tocopheryl acetate) and L-ascorbic acid (suspended in the oil to avoid loss in processing) to give final feed concentrations of 300 mg/kg vitamin E and 500 mg/kg ascorbic acid, respectively. The mean analyzed lipid content of the three feeds was 10.5%. Feed batches of 15 kg were prepared several times during the feeding period. The fish were studied from a start weight of 26 g to maturity, a period of 15 mon, and had then reached an average weight of 980 g ± 200 g. Five fish from each group were collected in March 1990, anaesthetized with benzocaine and killed by a sharp blow on the head. Pooled samples of white muscle, liver, gill and heart were collected. The samples were immediately frozen on dry ice (−80°C), and kept at this temperature until analyses were carried out.

Analytical methods. The organs were homogenized and extracted. The neutral lipids and the glycerophospholipids, phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI) and phosphatidylserine (PS) were separated according to Lie and Lambertsen (10). High-performance liquid chromatography (HPLC) was done using a Constametric II pump, a steel column (25 × 0.46 cm) equipped with a Rheodyne (7125) sample injection valve with a 20-μL loop, and a variable wavelength spectrophotometer (LDC Spectromonitor III). Stepwise elution was achieved by means of a Rheodyne six-position rotary valve. The column was packed with silica gel (LiChrosorb 5 μm, Merck, Darmstadt, Germany) using a Maximator pump (MSE 72, Schmidt, Kranz & Co. GmbH, Zorge/Südharz, Germany). All solvents were of HPLC grade (Rathburn Chemicals Ltd., Walkerburn, Scotland). The flow rate was maintained at 1 mL/min and elution was monitored at 205 nm.

The identity and purity of the phospholipids isolated were verified by thin-layer chromatography (TLC; Merck, Kieselgel 60) by comparison with standard phospholipids. PC, PE, PI and PS were from Sigma (St. Louis, MO); lysophosphatidylcholine (LysoPC) was from Serdary Research Laboratories (London, Canada). The solvent system was ethyl acetate/*n*-propanol/chloroform/methanol/0.25% aqueous KCl (15:25:25:10:4.5, by vol).

The fractions were evaporated in a block heater with a stream of N_2; 19:0 fatty acid was added as an internal standard. The fatty acids were trans esterified in 12% BF_3 in methanol. The methyl esters were separated on a Carlo Erba 2900 gas chromatograph using on column injection with a 50-m, 0.3 mm i.d., CP-sil 88 fused silica capillary column (Chrompack, Middelburg, The Netherlands). The fatty acid composition was calculated using a Maxima 820 (Chromatography Workstation, installed in an IBM-AT), connected to the gas chromatograph. Peaks were identified by reference to standard mixtures of methyl esters (Nu-Chek, Elysian, MN).

RESULTS

Weight gains, feed intakes, liver weights and hepatosomatic indices were not significantly different among the dietary treatments. The fatty acid compositions of the experimental diets are given in Table 1, which show that the n-3 fatty acids accounted for 15, 20 and 30% of the sum, in feeds A, B and C, respectively. In the liver, the fatty acid composition of the neutral lipids was similar to that of the feed lipids, except for lower levels of 20:1n-9 and 22:1n-11, and higher levels of 18:1n-9 (Table 2). The n-3 fatty acid levels in the neutral lipids in the liver and the feed were similar, but the level of 22:6n-3 was higher in the liver in groups B and C than in the feed. Linoleic acid (18:2n-6) accumulated in all phospholipids in the liver from group A, while the levels of n-3 fatty acids were lower in this group than in the PC fractions from the two other groups. The high levels of 22:1n-11 and 20:1n-9 in feed B (30%) were incorporated into the liver glycerophospholipids only to the extent of 8% and the major monoenoic acid in group B was 18:1n-9, as it was in groups A and C. In all groups, 22:6n-3 was the major n-3 fatty acid in the phospholipids.

Table 3 details the fatty acid composition of the neutral lipids and of the four glycerophospholipids in the muscle tissue from the three groups. The linoleic acid from diet A was heavily incorporated into all muscle lipids. The levels of n-3 fatty acids and n-3/n-6 ratios in neutral lipids corresponded to those of the lipids in the diets. The glycerophospholipids of group A had the lowest n-3 levels, and the n-3 level of the glycerophospholipids of group B and C were at the same high levels, *i.e.*, 40–60%. The content of 18:3n-3 in the dietary lipid of group A was reflected in the composition of the neutral lipids, of PC and of PE. The level of 18:4n-3 in the diet B lipids was reflected in the neutral lipids of this group. All lipids of group C showed elevated levels of 20:4n-6.

The fatty acid composition of neutral lipids and individual phospholipids in the heart is shown in Table 4. The fatty acid composition of the neutral lipids was to some extent altered by the dietary lipids, as exemplified by the n-3/n-6 ratio. The levels of 20:5n-3 and 22:6n-3 were high in all lipids from the three groups and seemed little affected by the dietary lipid composition. The levels of arachidonic acid in heart PI were 12.3% in group A, 15.3% in group B, and 20.5% in group C.

Table 5 details the fatty acid composition of neutral lipids and individual phospholipid classes from the gills. As for the other tissues, linoleic acid was heavily incorporated into all lipid classes of group A, particularly into neutral lipids and PC. The values for 20:4n-6, 20:5n-3 and 22:6n-3 were quite similar in gill phospholipids from all three groups regardless of the dietary lipid composition. High levels of 20:2n-6 (1.4–2.6%) were found in the neutral lipids as well as in the individual phospholipids of the gills of cod fed diet A.

DISCUSSION

Several reviews discuss the requirement of essential fatty acids (EFA) for fish (11–14). In the present study the fish behaved normally and no apparent signs of nutritional imbalance or pathology were observed during the feeding period, indicating that the dietary level of EFA was adequate to allow normal growth in all groups.

Cod stores triacylglycerols (TAG) exclusively in the liver, which may reach a fat content of 60–70%; the relative weight of this organ may increase from 5 to 15% as a result of excessive feeding or of a high fat diet (1,15). The fatty acid composition of the dietary lipids has been shown to have a pronounced effect on the composition of liver triacylglycerols, and also to affect the composition of polar lipid fatty acids in liver and muscle (1). The fatty acid composition of the neutral lipids in the liver, consisting mainly of triacylglycerols, confirms that cod stores the feed lipids with only minor modifications, such as preferring 22:6n-3 over 20:5n-3, and some discrimination against 20:1 and 22:1 isomers.

The fatty acid composition of the individual phospholipids in liver, fillet, heart and gills from cod was generally

TABLE 2

The Fatty Acid Composition of Neutral Lipid (N), Phosphatidylcholine (PC), Phosphatidylethanolamine (PE), Phosphatidylinositol (PI) and Phosphatidylserine (PS) in Liver of Cod Fed Diets Containing Soybean Oil, Capelin Oil or Sardine Oil

in good agreement with previous findings (2,4,10,16). The fatty acid composition of the phospholipids is important for the function of biomembranes. The balance between saturated, monounsaturated and polyunsaturated fatty acids maintains the so-called fluidity of the biomembranes, and the requirement of n-3 PUFA in fish is directly related to their role as components of membrane phospholipids (17). The incorporation of 18:2n-6 into PC of fillet, heart and gill in cod fed diet A was only partly balanced by a corresponding reduction in 20:5n-3 and 22:6n-3. Hence, 18:2n-6 may be incorporated into PC as an alternative to monoenoic or saturated fatty acids, and may be less "essential" for cod phospholipids. In spite of a 50% higher intake of 20:5n-3 and 22:6n-3 in feed C compared to feed B, cod fed these diets had similar levels of the two fatty acids in PC and PE, suggesting that an optimum level of n-3 was achieved in cod fed diet B.

Interestingly, PI (but to some extent also PS) PUFA composition in cod tissues were least influenced by dietary intake, which warrants special attention. The fatty acid composition of fish PI, having a high content of the molecular species 18:0/20:4n-6, resembles that of terrestrial animals, where PI has been shown to play a critical role in the transduction of hormone signals and in the provision of precursors for eicosanoid synthesis (18,19). PI in cod fed the highest level of 20:5n-3 (and of 20:4n-6) had the lowest 20:5n-3/20:4n-6 ratio in all tissues, and particular attention should therefore be given to the ratio 20:5n-3/20:4n-6 when studying fish eicosanoid synthesis. The ratio of 20:5n-3/20:4n-6 in phospholipids of mammals has been used as an index of the availability of precursors for platelets proaggregatory compounds (20,21). Henderson *et al.* (22) reported a higher rate of prostaglandin synthesis in gills than in liver. The capacity of gill tissue of aquatic species to form prostaglandins indicates a potential role for these compounds in controlling osmoregulation and perhaps respiratory processes. The regulated PI composition in the cod gills in this experiment points to the importance of the fatty acid composition for the function of the gills.

All feed lipids contained substantial amounts of 20:1 and 22:1, due to the fish meal lipids. In particular, diet B had very high levels of the two fatty acids (13.2% and 16.5%, respectively) from capelin oil in the feed. Lie and Lambertsen (23) reported considerably lower levels compared to the contents in the diets of these acids and higher levels of 18:1n-9 in the intestinal wall as well as in chylomicra, and pointed to the role of intestinal cells in the catabolism of 22:1n-11 and possibly of 20:1n-9. The presence of only minor amounts of n-11 monoene isomers of shorter chain length (17,19,21) indicates that a peroxisomal chain shortening, as shown for rat tissues, is not a major pathway for disposing of ingested 22:1n-11. Cod tissues may have specific enzymes for the catabolism of 22:1n-11 to respiratory products or acetyl CoA, the latter being used for *de novo* synthesis of 16:0 and 18:1n-9. Neither 22:1n-11 nor 20:1n-9 are prominent in the glycerophospholipids of cod, with the exception of the levels found in PS in the erythrocytes (5). The preferred monoenoic fatty acid in phospholipids of cod evidently is 18:1n-9, independent of the dietary intake.

Fish are capable of modifying dietary as well as endogenous fatty acids by desaturation and elongation. The ability of fish to modify dietary n-6 and n-3 fatty acids has been demonstrated for some species, particularly for salmonids (24,25; Lie, Waagbø and Sandnes, unpublished observation). In fish as in mammals, the substrate preference for Δ6 fatty acids desaturase decreases in the order 18:3n-3 > 18:2n-6 ⩾ 18:1n-9 (26,27). Cod fed diet A contained more 18:3n-3 than did the other groups in all tissues and in the individual phospholipids examined, suggesting that little or no 18:3n-3 was desaturated and elongated to C_{20} and C_{22} PUFA. This was also true for 18:4n-3 in cod fed diet B. As already discussed, 18:2n-6 was incorporated into all phospholipids analyzed, and high levels were observed in all tissues of cod fed diet A and only trace levels of 18:3n-6, 20:2n-6 and 20:3n-6 were found. Diet C, however, contained the highest concentration of 20:4n-6 (although only 0.8%), and with the exception of gill PI, the tissue phospholipids of the cod fed this diet had the highest levels of arachidonic acid.

The present feeding experiments thus indicate that very limited enzyme activity exists in cod to modify C_{18} PUFA, n-6 as well as n-3, except perhaps for the gills, when adequate amounts of n-3 PUFA are fed. Leger *et al.* (28), concluded that the longer chain n-3 PUFA as 22:6 inhibit Δ6 desaturase in rainbow trout, preventing desaturation of both 18:2n-6 and 18:3n-3. Cod seems to convert 20:5 to 22:6 in all tissues, as generally higher levels of 22:6 were found. This was also seen in group C which was fed a diet having a higher level of 20:5 than of 22:6.

The present results suggest that 20:4n-6, 20:5n-3 and 22:6n-3 are essential for normal growth in cod and also further the preferential catabolism of the longer chain monoenoic acids (20:1n-9 and 22:1n-11).

ACKNOWLEDGMENTS

The work was supported by a grant from the Norwegian Fisheries Research Council; the feeds were given by BP-Nutrition ARC. The skilled technical assistance of Leikny Fjeldstad is gratefully acknowledged.

Two Unsaturated 9*R*-Hydroxy Fatty Acids from the Cyanobacterium *Anabaena flos-aquae f. flos-aquae*

Nobutoshi Murakami, Hideaki Shirahashi, Akito Nagatsu and **Jinsaku Sakakibara***
Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467, Japan

(9*R*-10*E*,12*Z*,15*Z*)-9-Hydroxyoctadecatrienoic acid and (9*R*,10*E*,12*Z*)-9-hydroxyoctadecadienoic acid were isolated from the nitrogen fixing cyanobacterium *Anabaena flos-aquae f. flos-aquae* and characterized as the corresponding methyl esters. This is the first report of the natural occurrence of 9*R*-oxygenated fatty acids.
Lipids 27, 776–778 (1992).

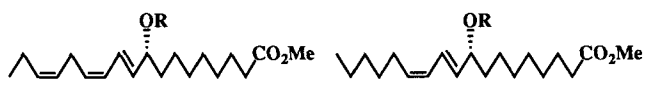
Our previous work had shown that cyanobacteria contain glyceroglycolipids in high amounts and that their fatty acid distribution is different from that of higher plants (1,2). Furthermore, we characterized the novel galactolipid, 1,6′-*O*-diacyl-3-*O*-β-D-galactopyranosyl-*sn*-glycerol, from the cyanobacterium *Anabaena flos-aquae f. flos-aquae* (3). As a continuation of our investigation of lipophilic constituents in *A. flos-aquae f. flos-aquae,* we have now isolated two 9*R*-hydroxy unsaturated fatty acids and characterized them as their methyl esters.

EXPERIMENTAL PROCEDURES

General. ^{1}H nuclear magnetic resonance (NMR) spectra were recorded on a JEOL (Akishima, Japan) EX-270 (270 MHz) or GSX-400 (400 MHz) spectrometer using tetramethylsilane (TMS) as internal standard. Infrared (IR) spectra were obtained with a Perkin-Elmer (Norwalk, CT) 1650QS Fourier transform IR (FTIR) spectrometer. Ultraviolet (UV) spectra were recorded with a Shimadzu (Kyoto, Japan) UV-2100 spectrometer. Optical rotations were measured on a JASCO (Tokyo, Japan) DIP-140 digital polarimeter. Circular dichroism (CD) spectra were obtained with a JASCO J-600 spectrometer. High-performance liquid chromatography (HPLC) was carried out using a JASCO 880-PU pump equipped with a Shodex RI (Tokyo, Japan), SE-11 differential refractometer. For gas chromatography/mass spectrometry (GC/MS), a JEOL D-300 mass spectrometer interfaced to a Hewlett-Packard (Palo Alto, CA) 5710A gas chromatograph with a JEOL JMA 2000 data processing system was used. Thin-layer chromatography was done on Merck (Darmstadt, Germany) precoated Kieselgel 60F_{254} plates and fractions were detected by illumination with an ultraviolet lamp, or by spraying the plate with either 5% vanillin/conc.H_2SO_4 or 1% $Ce(SO_4)_2$/10% H_2SO_4 followed by heating. Column chromatography was carried out on silica gel BW-200 or BW-300 (Fuji Davison Chemicals Co., Ltd., Kasugai, Japan).

Culture conditions. The strain of *Anabaena flos-aquae f. flos-aquae* (NIES-74) used for the present study was provided by the National Institute for Environment Studies. *A. flos-aquae f. flos-aquae* was cultured in eight 5-L Erlenmeyer flasks containing CB medium. Cultures were illuminated continuously at 1500 lux with cool-white fluorescent lamps and vigorously aerated with sterilized air passed through a 0.2 μm membrane filter at a rate of 0.5 L/min. After three weeks, the alga was harvested by centrifugation at 20,000 × *g* from the combined 40-L culture and lyophilized.

Extraction and isolation. Lyophilized alga (8.02 g) was homogenized in $CHCl_3$/MeOH (1:1, vol/vol) and extracted at room temperature three times for 12 h. The resulting extract (1.16 g) was successively subjected to silica gel column chromatography ($CHCl_3$/MeOH, 20:1→10:1, vol/vol) to afford a fraction containing the free acids of 1 and 2.



1: R=H
1a: R=Bz
1b: R=(+)-MTPA

2: R=H
2a: R=Bz
2b: R=(+)-MTPA

The fraction was treated with etheral diazomethane to prepare the corresponding methyl esters, which were purified by silica gel column chromatography (*n*-hexane/EtOAc, 5:1, vol/vol) followed by HPLC (Nucleosil 50-5; Gasukuro Kogyo Inc., Tokyo, Japan; *n*-hexane/EtOAc, 88:12, vol/vol) to furnish 1 (7.9 mg) and 2 (1.5 mg).

1: A colorless oil. $[\alpha]_D^{23}$ −10.8° (c = 0.39, EtOH). UV λ_{max}^{MeOH}nm (ε): 235 (28100). Positional determination of the hydroxyl groups in 1 and 2. A solution of **1** (1.0 mg) or **2** (1.0 mg) in ethyl acetate (1.0 mL) was treated with 5% palladium on carbon under a stream of hydrogen gas for 16 h. Filtration of the reaction mixtures and concentration of the filtrates gave crude hydrogenated compounds. The hydrogenated products were treated with *N,O-bis*(trimethylsilyl)acetamide (0.1 mL) at room temperature for 5 min. The reaction mixtures were analyzed by GC/MS. The conditions for GC/MS measurements were as follows: Gas chromatography: column, Silicone DB1 (0.25 mm i.d. × 30 m) (J&W Scientific, Folsom, CA); injection temperature, 250°C; column temperature, 160–300°C, 3°C/min; carrier gas, He, 0.9 mL/min. Mass spectrometry: EI mode: ionization voltage, 70 eV; ionization current, 100 μA; ion source temperature, 240°C; CI mode: reactant gas, ammonia; ionization voltage, 180 eV. GC/MS spectrum of the TMS ether of the hexahydro derivative of **1**: R_t 23.2 min; CI mode: 404 ($M^+ + NH_4$, 15), 387 ($M^+ + H$, 41), 297 (100); EI mode: 259 ($M^+ - C_9H_{19}$, 100), 229 ($M^+ - C_9H_{17}O_2$, 94).

GC/MS spectrum of the TMS ether of the tetrahydro derivative of **2**: R_t 23.1 min; CI mode: 404 ($M^+ + NH_4$, 26), 387 ($M^+ + H$, 58), 297 (100); EI mode: 259 ($M^+ - C_9H_{19}$, 100), 229 ($M^+ - C_9H_{17}O_2$, 90).

Benzoylation of 1 and 2. A solution of **1** (1.0 mg) in dry pyridine (0.1 mL) was treated with benzoyl chloride (11.9 μL). The reaction mixture was stirred at room temperature for 20 min. The reaction mixture was poured into H_2O and extracted with EtOAc. The EtOAc extract was successively washed with 5% HCl, saturated aqueous $NaHCO_3$, and brine, and then dried over $MgSO_4$. Removal of the solvent under reduced pressure gave a product which was purified by HPLC (YMC, Kyoto, Japan; A-024; *n*-hexane/EtOAc, 97:3, vol/vol) to furnish **1a** (1.3 mg, 95%). Similarly, **2a** (1.4 mg, 92%) was prepared from **2** (1.1 mg).

1a: A colorless oil. $[\alpha]_D^{25}$ −37.0° (c = 0.16, $CHCl_3$). UV λ_{max}^{EtOH}nm (ε): 237 (16400). IR ν_{max}^{film} cm^{-1}: 1741, 1717, 1270, 1110, 985. ^1H NMR ($CDCl_3$, 270 MHz, δ): 0.97 (3H, *t*, *J* = 7.5 Hz, 18-H_3), 2.00–2.20 (2H, *m*, 17-H_2), 2.29 (2H, *t*, *J* = 7.5 Hz, 2-H_2), 2.91 (1H, *dd*, *J* = 6.9, 6.9 Hz, 14-H_2), 3.66 (3H, *s*, CO_2CH_3), 5.24–5.62 (4H, *m*, 9-H, 13-H, 15-H, 16-H), 5.71 (1H, *dd*, *J* = 7.3, 15.0 Hz, 10-H), 5.98 (1H, *dd*, *J* = 11.0, 11.0 Hz, 12-H), 6.62 (1H, *dd*, *J* = 11.0, 15.0 Hz, 11-H), 7.40–7.65 (3H, *m*), 8.02–8.18 (2H, *m*). MS *m/z* (%): 290 ($M^+ - PhCO_2H$, 33), 161 (5), 146 (16), 133 (20), 122 (33), 105 (100), 91 (38), 89 (32). Preparation of 1b and 2b. (+)-α-Methoxy-α-trifluoromethylphenylacetyl chloride was added to a solution of **1** (1.0 mg), triethylamine (4.0 μL), and dimethylaminopyridine (7.6 mg) in dry CH_2Cl_2 (1.0 mL) at room temperature. The reaction mixture was stirred for 30 min, poured into water, and extracted with EtOAc. The organic layer was successively washed with 5% HCl, saturated aqueous $NaHCO_3$, and brine, and then dried over $MgSO_4$. Removal of the solvent under reduced pressure and column chromatography (*n*-hexane/EtOAc, 15:1, vol/vol) furnished **1b** (1.6 mg, 95%). In a similar manner, **2b** (1.8 mg, 96%) was prepared from **2** (1.1 mg).

1b: A colorless oil. $[\alpha]_D^{25}$ +10.2° (c = 0.11, $CHCl_3$). UV λ_{max}^{EtOH}nm (ε): 237 (20400). RESULTS AND DISCUSSION

The $CHCl_3$/MeOH (1:1, vol/vol) extract was subjected to silica gel column chromatography which yielded a fraction containing the oxygenated fatty acids. Since the fraction was too complex to allow separation of the two fatty acids, they were isolated and characterized after being derivatized to their methyl esters. Final separation of the methyl esters was achieved by silica gel column chromatography followed by normal phase HPLC. Compound **1**, $[\alpha]_D^{23}$ −10.8°, was found to possess the molecular formula $C_{19}H_{32}O_3$ based on electron impact mass spectrometry (EI-MS) and high resolution electron impact mass spectrometry (HR-EIMS). The IR spectrum of **1** showed absorption bands due to a hydroxyl and an ester carbonyl group, while the UV spectrum exhibited an absorption maximum at 235 nm indicative of the presence of a conjugated diene. The ^1H NMR spectrum showed the signals due to a methine proton adjacent to both a hydroxyl group and an olefinic carbon along with a terminal methyl and six olefinic proton signals. Homonuclear decoupling experiments revealed the presence of the 1-hydroxy-2*E*,4*Z*-diene moiety (9-hydroxy-10*E*,12*Z*-diene in **1**) (see Experimental Procedures). They also showed that the other two olefinic protons were coupled to each other with a *J* value of 10.6 Hz indicating the presence of a *Z*-geometric olefin. The coupling pattern (15-H in **1**) of the olefinic proton signal also changed from *dtt* into *dt*

(J = 1.5, 10.6 Hz) upon irradiation of the methylene proton linked to the 1-hydroxy-2*E*,4*Z*-diene moiety. The partial structure of a 1-hydroxy-2*E*,4*Z*,7*Z*-triene was thus established. The hydroxyl group was localized by GC/MS upon hydrogenation and trimethylsilylation: GC/MS showed a fragmentation ion at *m/z* 229 and at 259 indicative of a trimethylsilyloxy group at C-9 of a C_{18} fatty acid (4). Based on these data the structure of **1** was identified as (10*E*,12*Z*,15*Z*)-9-hydroxyoctadecatrienoate. The absolute configuration at C-9 was determined by measuring the CD spectrum of the benzoate (**1a**). The CD spectrum displayed a negative Cotton curve; thus the R-configuration was assigned to C-9 (5,6). The optical purity of **1** was confirmed by the ^{1}H NMR spectrum of the corresponding (+)-α-methoxy-α-trifluoromethylphenylacetyl ester (**1b**). The ^{1}H NMR spectrum showed no signals due to its diastereomer (7). Consequently, compound **1** was concluded to be methyl (9*R*,10*E*,12*Z*,15*Z*)-9-hydroxyoctadecatrienoate.

Compound **2** $[\alpha]_D^{23}$ −5.8°, $C_{19}H_{34}O_3$, had almost the same physicochemical properties as **1** except for the molecular ion peak in MS and the number of olefinic protons in ^{1}H NMR. This suggested that **2** was a dihydro analogue of **1**. The chemical structure of **2** was determined to be methyl (9*R*,10*E*,12*Z*)-9-hydroxyoctadecadienoate.

Most lipoxygenases from various organisms have been shown to give predominantly 13*S*- or 9*S*-hydroxy acids from unsaturated C_{18} fatty acids (8). Therefore, the occurrence of 9*R*-hydroxy acids in the cyanobacterium may suggest that this organism contains an unusual type of lipoxygenase which favors 9*R*-hydroxy fatty acid formation (9). Alternatively, the oxygenated acids could be generated in the course of a biogenetic pathway involving other enzymes.

ACKNOWLEDGMENTS

We thank S. Kato and T. Nakano for ^{1}H NMR measurements. This work was supported by a Grand-in-Aid from the Ishida Foundation and the Nakano Foundation, and by a Grant for Scientific Research from the Ministry of Education, Science and Culture of Japan.

The fatty acid composition of phospholipids from the Senegalese sponge *Cinachyrella alloclada* was examined. Two new fatty acids not hitherto found in nature, namely 10,13-octadecadienoic acid and 16-tricosenoic acid, were identified. 8-Hexadecenoic, 13-nonadecenoic and 5,9,13-trimethyltetradecanoic fatty acids were also found for the first time in sponges. The latter compound (1.4% of the total fatty acid mixture), an isoprenoid fatty acid, accompanies the major fatty acid, 4,8,12-trimethyltridecanoic acid (19.7%). The monomethyl branched fatty acids (22%) identified include 23-methylpentacosanoic acid (anteiso-26:0), not previously observed in sponges. The major long-chain fatty acids encountered were the known 17-tetracosenoic, 19-hexacosenoic, 25-methyl-5,9-hexacosadienoic, 26-methyl-5,9-heptacosadienoic and 5,9,23-tricontatrienoic acids. Some sixty fatty acids were identified as methyl esters and *N*-acyl pyrrolidides by gas chromatography and gas chromatography/mass spectrometry.
***Lipids* 27, 779–784 (1992).**

Marine sponges are a source of many unusual phospholipid fatty acids (1–4). A number of sponges from different locations and orders have been investigated. Unusual structural patterns of unsaturation, methyl branching and 2-oxo-substitution have been found. The Senegalese demosponge *Higginsia tethyoïdes* (subclass *Tetractinomorpha*, order *Axinellida*, family *Desmoxydae*) has been shown to contain a series of closely related 2-methoxy fatty acids (5).

The present work is devoted to the demosponge *Cinachyrella alloclada*, formerly named *Cinachyra alloclada* before the recent taxonomic reevaluation (6) of the family *Tetillidae* (subclass *Tetractinomorpha*, order *Spirophorida*). This sponge is abundant in the same area that *H. tethyoïdes* is found, and only a few chemical studies have been published so far on *Tetillidae* sponges (7). Antimicrobial and other biological activies of *Cinachyra alloclada* have been reported (8,9). Chemotaxonomic investigations have been carried out to compare fatty acid compositions of sponges including *Cinachyra* n.sp. (10). In this latter work, fatty acids from total lipids were analyzed and classified according to chain length, degree of unsaturation and methyl branching. However no precise molecular structures were presented.

In this paper we would like to report the phospholipid fatty acid composition of the sponge *C. alloclada* collected at the Senegalese coast. Saturated, monounsaturated and polyunsaturated fatty acids, respectively, accounted for 70, 18 and 12% of the total fatty acids. Sponge specimens have been shown to contain two hitherto not described fatty acids, namely 10,13-octadecadienoic acid and 16-tricosenoic acid. Four of the sixty-one fatty acids have not previously been reported in any marine sponge, namely 8-hexadecenoic acid, 5,9,13-trimethyltetradecanoic acid, 13-nonadecenoic acid and 23-methyl-pentacosanoic acid (*anteiso*-26:0).

EXPERIMENTAL PROCEDURES

Specimens of *Cinachyrella alloclada* Uliczka (11) (Demosponge, *Tetractinomorpha, Spirophorida, Tetillidae*) were collected near Joal (~100 km south of Dakar, Senegal) at the seashore at low tide, in November 1989. These sponges, 3–8 cm in diameter, are yellow and globular. Their surface is rough, and the inhalant openings are located in aquiferous pits (porocalices). The principal skeleton is radial and composed of siliceous spicules, principally oxeas, protriaenes and spinispires. There is no differentiation of a cortical skeleton.

The sponges were washed in seawater, carefully cleaned, cut into small pieces, ground in a Waring blender with chloroform/methanol (1:1, vol/vol) and steeped twice in this solvent for 24 h (room temperature). The combined extracts yielded the crude total lipids. Phospholipids were separated from other lipids by column chromatography on silica gel (70–230 mesh) with hexane, chloroform, acetone and methanol (phospholipids) as successive eluents. For example, 170 mg of phospholipids were recovered from 220 g of sponge (dry weight).

The phospholipid fatty acids were converted to methyl esters by reaction (30 min under reflux) with methanolic hydrogen chloride, dissolved in hexane (12) and purified by column chromatography (silica gel, hexane/diethyl ether, 10:1, vol/vol). The resulting methyl esters were analyzed by gas-liquid chromatography (GLC) using a Carlo-Erba 4130 chromatograph (Milano, Italy) and a nonpolar OV-1 silica capillary column (25 m × 0.32 mm i.d. 0.40 μ); the carrier gas was hydrogen (0.5 bar, split 5/100). Thin-layer chromatography (TLC) was performed on 200 μ precoated layers of silica gel and fractions were made visible by exposure to iodine or by clearing after spraying with sulfuric acid (50%). The phospholipid composition was determined by TLC (chloroform/methanol/water, 65:25:4, vol/vol/vol). Standard phospholipid samples, and normal odd- and even-numbered fatty acid (from C_{20} to C_{31}) and monoenoic (C_{16}, C_{18}, C_{20}) fatty acid methyl esters were purchased from Sigma Chemical Co. (St. Louis, MO). *N*-Acyl pyrrolidides were prepared by direct treatment of methyl esters with pyrrolidine/acetic acid (10:1, vol/vol) under reflux (2 h) and purified by TLC on 0.5-mm layers of silica gel with hexane/diethyl ether (1:2, vol/vol) as developing solvent. Fatty acid methyl esters were hydro-

Abbreviations: ECL, equivalent chain length; FAME, fatty acid methyl ester; GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; IR, infrared; LCFA, long-chain fatty acid; MS, mass spectrum; TLC, thin-layer chromatography; 4,8,12-TMTD, 4,8,12-trimethyltridecanoic acid; 5,9,13-TMTD, 5,9,13-trimethyltetradecanoic acid.

genated by stirring (4 h), at ambient pressure and temperature, in methanol with catalytic amounts of platinum (IV) oxide (Adam's catalyst). Infrared (IR) spectra were recorded on a Perkin-Elmer model 257 spectrophotometer on liquid films (0.025 mm) between KBr plates.

In capillary gas chromatography, the temperature was programmed at 3°C/min, from 180 to 300°C for the methyl esters and from 230 to 310°C for the pyrrolidides. An initial isothermal step at 195°C for separation of short-chain fatty acids was followed by a 5°C/min gradient up to 300°C. Combined gas chromatography/mass spectrometry (GC/MS) was done on a Girdel 30 gas chromatograph linked to a Ribermag R-10-10B mass spectrometer and coupled with a Sidar computer. The GC column was a 0.32 mm × 25 m fused silica capillary column coated with OVI (0.15 μ phase thickness). The column temperature was programmed from 170 to 300°C at 3°C/min for fatty acid methyl esters and from 200 to 310°C at 3°C/min for pyrrolidides (carrier gas, helium; ion source, 220°C; ionizing voltage, 70 eV).

RESULTS

The major phospholipid classes were shown to be phosphatidylethanolamine, phosphatidylserine, phosphatidylcholine and phosphatidylinositol. The phospholipid fatty acid composition of *C. alloclada* is shown in Table 1. As can be seen, approximately 70% of the fatty acids were saturated, of which 50% were branched ranging from 12 to 20 carbons in length. The two main phospholipid fatty acids were the isoprenoic 4,8,12-trimethyltridecanoic acid (19.7%) and palmitic acid (16:0, 8.9%); all other fatty acids were found at levels of less than 5%.

Many of the fatty acids compiled in Table 1 have been identified by comparing their equivalent chain lengths (ECL) (as methyl esters) with those of known standards, and by co-injection with standards including the LCFA methyl esters 24:0, 26:0, 28:0 and 30:0. Capillary GC analysis of a hydrogenated aliquot also provided useful information for identification of unsaturated fatty acids. For many of the components GC/MS data for the pyrrolidide derivatives were obtained to confirm the structures and to determine double bond positions. The IR spectrum of the phospholipid fatty acid methyl ester fraction displayed no prominent absorption 968–980 cm^{-1}, indicating the absence of (*E*)-unsaturation. Mass spectral data of key fatty acids are as follows:

8-Hexadecenoic acid pyrrolidide. MS *m/z* (rel. intensity), 307 (M^+, 7.8), 278(1.8), 264(2.1), 250(3), 236(5.7), 223(1.4), 222(2.0), 210(1.5), 208(2.2), 196(2.0), 194(3.2), 183(2.0), 182(9.2), 180(2.0), 168(4.0), 166(2.0), 154(3.0), 140(9.0), 127(12), 126(60.2), 113 (100), 98(33.5), 85(14), 82(7), 72(36.3), 71(20), 70(45.8), 67(13.8), 55(88).

16-Tricosenoic acid pyrrolidide. MS *m/z* (rel. intensity), 405 (M^+, 1.4), 376(1.9), 363(4.9), 362(3.0), 348(1.2), 335 (1.6), 334(2.2), 321(2.2), 320(2.9), 306(2.7), 294(2.6), 282(2.0), 281(3.7), 280(4.0), 279(2.0), 266(2.5), 252(2.4), 238(2.2), 225(2.4), 224(2.9), 210(2.5), 196(2.4), 183(2.8), 182(3.3), 168(4.1), 155(37), 154(7.0), 141(55.3), 126(29.1), 113(94.4), 98(28.3), 97(33), 95(35.6), 85(23.6), 83(36.4), 82(18), 81(47), 79(15.5), 75(10.8), 71(100), 67(47.4), 57(58.3), 55(93).

Saturated fatty acids. The total monomethyl branched fatty acids accounted for about 22% of the total fatty acids. *Anteiso*-26:0 (1.1%) and *anteiso*-27:0 (0.6%) were identified as fatty acid methyl esters (FAME) by their ECL values of 25.74 and 26.73, respectively, and by their fractional chain lengths of 0.72–0.74 (13). The two acids remained unchanged upon catalytic hydrogenation. *Anteiso*-26:0 fatty acid has, to our knowledge, not yet been found in sponges, but is well known as a hydrogenation product of the corresponding 5,9-diunsaturated fatty acids (13,14). The *anteiso*-27:0 acid was discovered very recently in the sponge *Petrosia pellasarca* (4).

Of particular interest was the presence of a rare isoprenoic acid, not previously found in any sponge, namely 5,9,13-trimethyltetradecanoic acid (5,9,13-TMTD), which occurs together with the well known 4,8,12-trimethyltridecanoic acid (4,8,12-TMTD) (1.4% and 19.7%, respectively). The latter (4,8,12-TMTD) was readily identified by coupled capillary GC/MS of its methyl ester (5) and pyrrolidide (14) and by comparison with an authentic sample. The former (5,9,13-TMTD) showed a very low ECL value of 15.40 (as FAME) with a molecular peak at *m/z* 284 corresponding to a 17-carbon acid. The compound remained unchanged upon catalytic hydrogenation, which indicated that no unsaturation was present. These results clearly point towards methyl branching as observed previously (16). The mass spectrum (MS) of the methyl ester (base peak *m/z* 74) showed key fragments at *m/z* 101 (17%) and 129 (23%) indicative of methyl branching at the C-5 position (3% for the fragment *m/z* 115). Methyl branching at the C-9 position was indicated by significant peaks at *m/z* 171 (6%) and *m/z* 199 (4%) and by the absence of an ion peak at *m/z* 185. A very prominent peak at *m/z* 241 (16%) indicated the presence of a third methyl group at the C-13 position. The structure of 5,9,13-TMTD was confirmed by the MS of the pyrrolidide. The partial MS (Fig. 1) shows a diminished peak at *m/z* 154 flanked by elevated peaks at *m/z* 140 and *m/z* 168, clearly pointing towards the methyl group at C-5; the lack of peaks at *m/z* 224 and 294 confirmed the methyl branchings at the C-9 and C-13 positions. This isoprenoic fatty acid has not been reported in marine sponges but was recently isolated from certain fish oils (16).

Monoenoic fatty acids. Three monoenoic fatty acids were identified in *C. alloclada*. The first (1.1% of the total fatty acids) showed as FAME an ECL value of 15.75 and a molecular ion at *m/z* 268, suggesting an hexadecenoic structure. The MS of the pyrrolidide (Fig. 2) showed a molecular ion at *m/z* 307 (16:1) and key fragments at *m/z* 182 and *m/z* 194 clearly indicating unsaturation between C-8 and C-9 (Δ8 unsaturation); it also provided evidence for a lack of chain branching. The rare acid Δ8-16:1 had been detected previously (17), but no mass spectrum has been published to date.

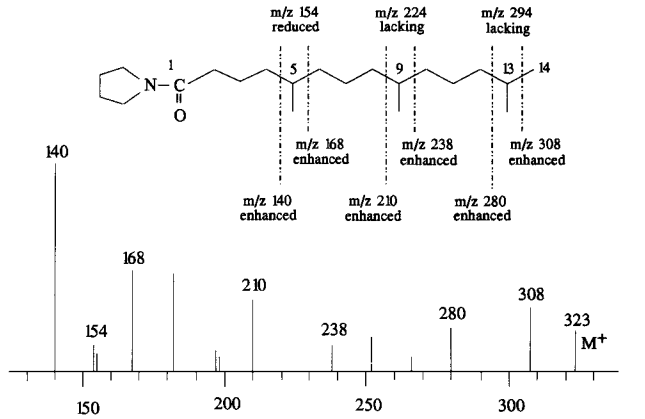

FIG. 1. Partial mass spectrum (× 10 expanded) of 5-methyl, 9-methyl, and 13-methyl-tetradecanoic acid pyrrolidide.

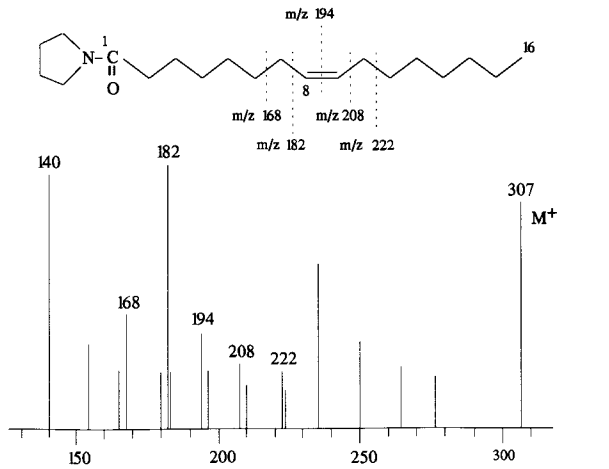

FIG. 2. Partial mass spectrum (× 10 expanded) of 8-hexadecenoic acid pyrrolidide.

The second monoenoic fatty acid (2.6%) showed as FAME an ECL value of 18.84 and a molecular ion peak at *m/z* 310 indicative of the nonadecenoic (19:1) structure. Upon catalytic hydrogenation the compound was converted to the methyl ester of nonadecanoic acid (19:0) confirming the absence of any branching. The MS of the pyrrolidide was used to locate the double bond. The spectrum (Fig. 3) showed a molecular ion peak at *m/z* 349 consistent with the nonadecenoic acid structure. A difference of 12 amu between the fragments *m/z* 252 (C-12) and *m/z* 264 (C-13) indicated Δ13 unsaturation. The data are consistent with a 13-nonadecenoic acid structure. This rather unusual fatty acid was previously found in cultures of *Thiobacillus* (18), but not in any marine sponge.

The third monoenoic fatty acid (1.1%) had an ECL value (as FAME) of 22.80 and a molecular weight of 366 amu, suggesting a 23:1 structure. Upon catalytic hydrogenation, this compound was converted to the methyl ester of tricosanoic acid (23:0), thus excluding any branching. The MS of the pyrrolidide (Fig. 4) showed a molecular ion peak at *m/z* 405 confirming the tricosenoic acid structure. A difference of 12 amu between the fragments *m/z* 294 and *m/z* 306 (C-15 and C-16) indicated Δ16 unsaturation. Therefore, we identified the acid as 16-tricosenoic acid, an n-7, odd-numbered, monoenoic, long-chain fatty acid.

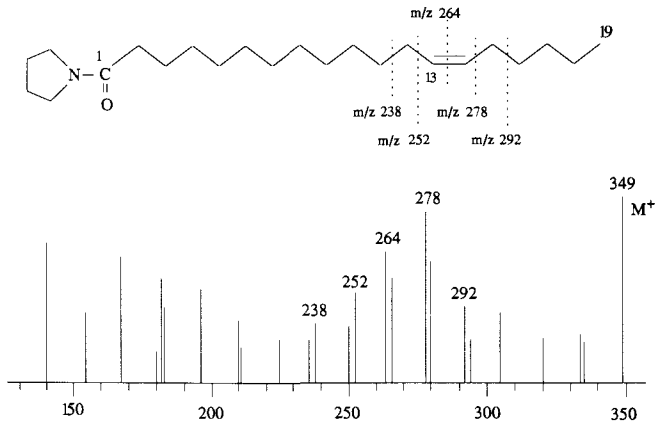

FIG. 3. Partial mass spectrum (× 10 expanded) of 13-nonadecenoic acid pyrrolidide.

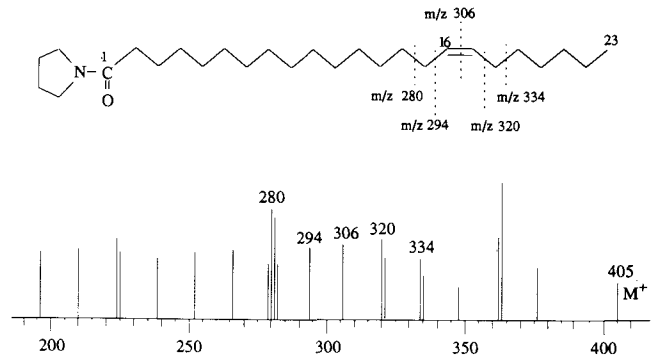

FIG. 4. Partial mass spectrum (× 10 expanded) of 16-tricosenoic acid pyrrolidide.

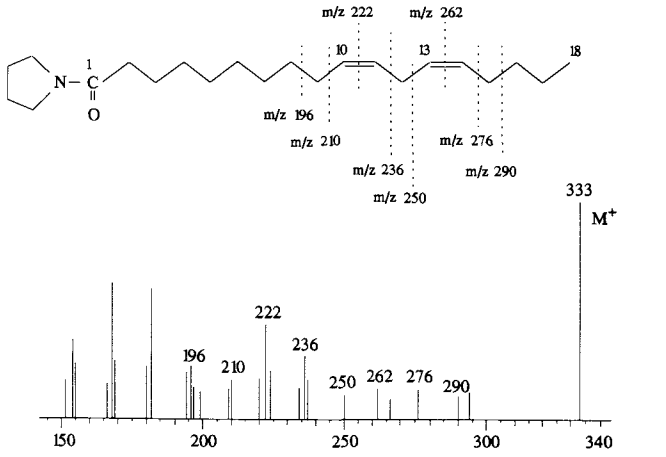

FIG. 5. Partial mass spectrum (× 10 expanded) of 10,13-octadecadienoic acid pyrrolidide.

Two other monoenoic LCFA previously found in several sponges were also identified in this study, namely 17-tetracosenoic (Δ17-24:1, 3.6%) and 19-hexacosenoic (Δ19-26:1, 2.4%) acids, which were readily characterized by their ECL values and by the MS data obtained on their pyrrolidides. The first pyrrolidide produced a molecular ion at *m/z* 419 (24:1) and showed a difference of 12 amu between the fragments *m/z* 308 (C-16) and *m/z* 320 (C-17) indicating Δ17 unsaturation. The second pyrrolidide showed a molecular ion at *m/z* 447 (26:1) and a difference of 12 amu between the fragments *m/z* 336 (C-18) and *m/z* 348 (C-19) indicating Δ19 unsaturation.

Several minor monoenoic acids were also detected and tentatively identified as 22:1, 25:1 and 28:1 acids based on their ECL values and by conversion into 22:0, 25:0 and 28:0 acids upon hydrogenation. However, the position of the double bonds could not be determined *via* the pyrrolidide derivatives due to the small amounts of material available.

Dienoic fatty acids. An interesting dienoic acid (0.9% of total fatty acids) was also detected in the phospholipid fatty acids of *C. alloclada.* Its methyl ester had an ECL value of 17.52 and a molecular ion peak at *m/z* 294 indicative of an 18:2 structure. Upon catalytic hydrogenation, the acid was converted into octadecanoic acid (18:0), excluding the possibility of any branching. The MS of the pyrrolidide (Fig. 5) showed a molecular peak at *m/z* 333 consistent with the 18:2 structure. The two double bonds were located by the 12-amu differences between the peaks at *m/z* 210 (C-9) and *m/z* 222 (C-10), indicating Δ10 unsaturation and between the peaks *m/z* 250 (C-12) and *m/z* 262 (C-13) indicating Δ13 unsaturation. The chromatographic behavior and the MS of the methyl ester have already been described (19).

Δ5,9 LCFA. Six demospongic acids possessing 5,9-unsaturation were characterized by GC (Table 1) and GC/MS (11.1% of the total fatty acids). The MS of the pyrrolidides showed the corresponding molecular peak and the key peak at *m/z* 180 (>80%) resulting from allylic cleavage (20). The third double bond of the triacontatrienoic acid could readily be located by the 12-amu difference between the peaks at *m/z* 388 (C-22) and *m/z* 400 (C-23) indicating Δ23 unsaturation. To confirm the structures, the compounds were hydrogenated and identified by coinjection with authentic straight-chain samples. The acids were 5,9-26:1; 5,9-27:2; 5,9-28:2; *iso*-5,9,-27:2; *iso*-5,9,-28:2; and the well-known 5,9,23-30:3.

DISCUSSION

Two saturated isoprenoic fatty acids, 4,8,12-trimethyltridecanoic and 5,9,13-trimethyltetradecanoic acids, were found together for the first time in a sponge. To our knowledge only the three saturated isoprenoic fatty acids have been previously isolated from sponge phospholipids: 4,8,12-TMTD, 3,7,11,15-tetramethylhexadecanoic (phytanic), and 3,7,11-trimethyldodecanoic acids (21). The monoenoic isoprenoic fatty acid 2,6,10-trimethyl-Δ5-14:1 was previously identified in *Aplysina fistularis* (20).

Our finding of a fourth saturated isoprenoic fatty acid completes a series of three homologous acids which have been encountered in sponge phospholipids to date: 3,7,11-trimethyl-12:0, 4,8,12-trimethyl-13:0 and 5,9,13-trimethyl-14:0 acids. These three acids can be derived from the phytyl side chain of chlorophyll contained in cyanobacterial symbionts (22). As suggested by Ratnayake *et al.* (16) for fish oils, a biosynthetic chain elongation of 3,7,11-trimethyl-12:0 to 5,9,13-trimethyl-14:0 may occur in sponges. 4,8,12-TMTD was identified in ten marine sponges including *Higginsia tethyoïdes* (5) and *Spheciospongia vesparium* (15) at levels of 8.1% and 23% of the

total fatty acids, respectively. This acid forms about 20% of the total fatty acids of *C. alloclada*, and samples studied at different times of the year and at different depths have all shown similar values (Barnathan, G., unpublished data). Carballeira *et al.* (23) suggested recently that 4,8,12-TMTD may be useful for taxonomic purposes in the order Hadromerida. A number of sponges do not possess this acid in their phospholipids, and we believe that this interesting suggestion should be extended to the order Spirophorida and reserved for further studies to instances in which the 4,8,12-TMTD would be found in very large amounts. However, there is little doubt that in such cases 4,8,12-TMTD is part of sponge cellular membranes as was demonstrated recently by Lawson *et al.* (24).

Ratnayake *et al.* (16) have recently identified 5,9,13-TMTD in certain fish oils, particularly in the non-urea complexing fraction. This acid, among several other isoprenoic fatty acids, has also been detected as a trace component in human milk (25) and in some shales from ancient sediments (26,27). Oxidation of 2,6,10-trimethyltetradecane by *Mycobacterium fortuitum* gave 5,9,13-TMTD as the major product (28). The association between sponges and bacteria is now well established (22,29,30) and a number of symbiotic bacteria frequently occur in massive sponges (29,31). Certain medium-chain fatty acids typically arising from bacteria have been found in sponge phospholipids (20,22), especially a number of monomethyl-branched fatty acids (*e.g.*, 10-methyl-hexadecanoic, Table 1). Significant amounts of this less common fatty acid were found in two marine sponges (14,20). The fatty acid also occurs in several bacteria, especially anaerobic sulfate-reducing bacteria, which have been observed in *Aplysina fistularis* (32).

The occurence in *C. alloclada* of the very rare monounsaturated 8-hexadecenoic acid is intriguing. It is the second case of Δ8 unsaturation found in sponge fatty acids after the case of the Caribbean sponge *Desmapsama anchorata* (Ceractinomorpha, Poecilosclerida, Myxillidae) (33). 8-Hexadecenoic acid has been described in the green alga *Chlorella kesleri* (17) but only in autotrophically grown culture. In a study (34) reported recently by Ackman (35), the body oil of menhaden fish was shown to contain 9-hexadecenoic and 8-hexadecenoic acids in a ratio of 6:1, *C. alloclada* also contains a mixture of both acids, the 8-hexadecenoic acid being predominant. The latter acid could be of dietary or symbiotic origin.

Significant amounts of 13-nonadecenoic acid were found in specimens of *C. alloclada* collected along the coast in shallow waters (Barnathan, G., unpublished results). This unusual fatty acid has been found in trace amounts in polar lipids of *Thiobacillus acidophilus* and *T. thiooxidans* (18). The Thiobacilli form a group of acid-producing aerobic microorganisms which need reduced sulfur as characteristic substrates. These marine bacteria occur primarily in shallow waters (36,37). The area of collection of *C. alloclada* is known to be rich in red algae belonging to the genus *Hypnea* (38) which contains high levels of sulfated polysaccharides (kappa-carageenan). The fermentation of thick accumulations of such algae provides reduced sulfur, and 13-nonadecenoic acid in the sponges is likely derived from a sulfur-oxidizing symbiont.

The 16-tricosenoic acid, hitherto not found in nature, completes the series of n-7 monounsaturated fatty acids found in *C. alloclada*, (Δ9-16:1, Δ10-17:1, Δ17-24:1, and Δ19-26:1 acids), all of which have been found in sponges (5,14,15,22). The monoenoic long-chain fatty acid (LCFA) can be readily explained by chain elongation from short precursors such as *cis*-vaccenic acid. The presence in *C. alloclada* of two odd-numbered n-7 monounsaturated fatty acids suggests the existence of a possible biosynthetic pathway in the odd-numbered series from 10-heptadecenoic acid, as proposed by Ayanoglu *et al.* (5). *H. tethyoides* contains several odd- and even-numbered monounsaturated LCFA which always contain the 2-methoxy group. These authors described the 2-MeO-Δ16-23:1 as a minor compound. Another interesting finding was the isolation from a Caribbean *Cinachyra alloclada* of a free long-chain glycerol monoether (17-*Z*-tetracosenyl-1-glycerol ether (7)), which could be correlated with our report of the 17-tetracosenoic acid as the major long-chain fatty acid (3.6% of the total fatty acids) in the Senegalese specimen. Work is in progress to identify other monounsaturated fatty acids found as minor components, particularly pentacosenoic and octacosenoic acids.

To the best of our knowledge, 10,13-octadecadienoic acid which we have identified here in *C. alloclada*, has not previously been found in nature. This methylene-interrupted dienoic acid has long been known as a synthetic compound (19,40). Only two methylene-interrupted octadecadienoic acids were known in sponges, Δ5,8-18:2 acid in *Microciona prolifera* (39) and the common Δ9,12-18:2 acid in *Pseudaxynissa* sp. (2). The complete series of methylene-interrupted 18:2 acids has been synthesized (19,40,41) to study the effects of double-bond position in biological systems (42), and to elucidate the structure essential to express the biological activity of linoleic acid (43,44). The Δ10,13-18:2 acid was shown to exhibit a weak specific activity for microsomal chain elongation by malonyl-CoA (45).

[Received May 30, 1991, and in revised form April 14, 1992; Revision accepted July 23, 1992]

Lipids and Lipophilic Pollutants in Three Species of Migratory Shorebirds and Their Food in Shepody Bay (Bay of Fundy, New Brunswick)

Guillermo E. Napolitano[a,b,1], Robert G. Ackman[a,*] and Christopher C. Parrish[a,2]
[a]Canadian Institute of Fisheries Technology, Technical University of Nova Scotia, Halifax, Nova Scotia, Canada B3J 2X4 and [b]Department of Oceanography, Dalhousie University, Halifax, Nova Scotia, Canada B3J 4J1

To study food web transfers of lipids in the intertidal zone, three specimens of each of the semipalmated sandpiper (*Calidris pusilla* [L.]), the semipalmated plover (*Charadrius semipalmatus* Bonaparte) and the short-billed dowitcher (*Limnodromus griseus* [Gmelin]) were examined after capture during the summer of 1989. They were feeding intensively, prior to migration, on the amphipod, *Corophium volutator*, on the mudflats of Dorchester Cape, New Brunswick, Canada. The ragworm, *Nereis diversicolor*, and samples of sea foam were also collected from the mudflats at the same location in 1989 and 1990. Total body lipids of semipalmated sandpipers and short-billed dowitchers were about 20% of the wet weights, while those of the semipalmated plovers ranged from 35 to 40%. Adipose tissue fatty acids showed a trend from marine fatty acids (20:5n-3, 22:6n-3) at 10% of *C. pusilla* acids through 5% in *C. semipalmatus* to 1% in *L. griseus*. These proportions confirm differences in feeding habits proposed from analyses of gut contents. Short-billed dowitcher adipose fat included the lowest values of polychlorinated biphenyls (0.078 to 0.266 ppm). The other two species of shore-birds showed levels as high as 1.64 ppm. Concentrations of 1,1-*bis*(4-chlorophenyl)-2,2,2-trichloroethane and 2,2-*bis*(4-chlorophenyl)-1,1-dichloroethylene were also variable, but with three exceptions were ≤ 0.1 ppm of adipose fat. Sea foam collected in the tidal channels and at the edge of the water during the rising tides was found to include diverse lipophilic materials, capable of transfer to higher trophic levels. Triacylglycerols, phospholipids, sterols, hydrocarbons and pigments were typically present at a concentration of 65 × 10^3 μg/L. The long-chain isoprenoid squalene, of endogenous origin and apparently derived from feather-wax, was the only hydrocarbon present in the depot fats of the three species of birds analyzed. This indicates that the birds basically inhabited a pristine environment free of hydrocarbon pollutants. The hydrocarbon present in the sea foam consisted of a series of normal alkanes, from C_{20} to C_{39}, with no odd/even chain-length preference (carbon preference index = 1.008). These hydrocarbons probably originated in detritus from decaying vascular plants but could possibly reflect a very low level of petroleum contamination. The lack of local pollution appears to favor continued success of the migratory pattern of these birds.
***Lipids* 27, 785–790 (1992).**

The semipalmated plover, the semipalmated sandpiper, the short-billed dowitcher and other shorebirds feed heavily on the benthic invertebrates of the mudflats around the head of the Bay of Fundy before migrating to the southern hemisphere for the winter (1–3). In building up large fat reserves, these migratory birds create a potential repository for lipophilic pollutants. If this process concentrated such materials, present at low levels in the food chain, a useful environmental marker could be created. Although the amphipod, *Corophium volutator*, is the major component of the diet of these shorebirds, its actual contribution to the diet is very different in each species. For example, *C. volutator* is, on average, 86.3% of the food of semipalmated sandpipers, but only 70% and 47.6% of the food of short-billed dowitchers and semipalmated plovers, respectively (4). The polychaetes *Nereis* sp. and *Glycera* sp., the bivalve *Macoma balthica*, and the gastropod *Hydrobia totteni* were reported (4) to be much more important in the diet of semipalmated plovers than in the diet of semipalmated sandpipers.

As a continuation of earlier studies on *C. volutator* lipids (5), we hypothesized that these dietary differences were responsible for the different organochlorine levels reported in plovers and short-billed dowitchers from the general area (6). This paper reports the lipid, hydrocarbon and organochlorine pollutant [various polychlorinated biphenyls (PCB), 1,1-*bis*(4-chlorophenyl)-2,2,2-trichloroethane (DDT) and 2,2-*bis*(4-chlorophenyl)-1,1-dichloroethylene (DDE)] contents of body fats in three shorebirds, the semipalmated plover, the semipalmated sandpiper and the short-billed dowitcher. In addition, pollutants were measured in the whole bodies of the polychaete *Nereis diversicolor*, an important constituent of the diet of shorebirds, and lipids were measured in sea foam which in turn may be an important component of the diet of benthic invertebrates.

MATERIALS AND METHODS

Semipalmated sandpipers, *Calidris pusilla* (L.), semipalmated plovers, *Charadrius semipalmatus* Bonaparte, and short-billed dowitchers, *Limnodromus griseus* (Gmelin), were captured at Dorchester Cape on the Bay of Fundy by staff of the Canadian Wildlife Service of Fredericton, New Brunswick (Table 1), and kindly supplied by Dr. P.A. Pearce. In the laboratory, adipose tissue (*ca.* 5 g) was separated from the carcasses of all birds, and the lipids of both were extracted. Ragworms, *Nereis diversicolor* O.F. Muller, were collected on November 9, 1989, at Porter Point (Minas Basin), Nova Scotia, and on May 29, 1990, at medium and upper intertidal levels near Dorchester Cape (Shepody Bay), New Brunswick. Foam samples for lipid analyses were collected at the edge of the

water during the rising tide and placed in clean glass jars, previously rinsed with clean local seawater. Foam samples were extracted with chloroform under mechanical agitation.

Total body lipids, including adipose tissue from the birds and whole ragworms, were extracted following the method described by Bligh and Dyer (7). The total body lipid content was determined gravimetrically after exhaustive removal of the solvent. A hydrocarbon-rich fraction was obtained from adipose tissue by both column chromatography using Florisil (Floridin Co., Pittsburgh, PA) (8), and by multiple thin-layer chromatography (TLC) of lipids as described elsewhere (5,9). An Iatroscan Mark III analyzer (Iatron Laboratories, Tokyo, Japan) was used for the quantitative analysis of lipid classes after separation on silica gel coated Chromarods-SII (Iatron Laboratories) (10). Squalene in the bird adipose tissue and carcasses was quantified by gas-liquid chromatography (GLC) using squalane as an internal standard. Hydrocarbon analyses were performed with a Perkin-Elmer 990 (Norwalk, CT) gas-liquid chromatograph equipped with flame ionization detection (FID), and a fused-silica wall-coated open-tubular DB-1 (J & W Scientific, Folsom, CA) column (methyl silicone; 60 m long and 0.25 mm i.d.). The preparation of fatty acid methyl esters (FAME) from other lipids and the GLC conditions are described elsewhere (11).

To examine the lipids for organochlorine contaminants, 500 mg of adipose tissue extract from birds or lipids of ragworms was digested with concentrated H_2SO_4 following the method described by Waliszewski and Szymczynski (12). Organochlorine analyses were performed on a Perkin-Elmer Sigma 4 gas chromatograph fitted with a ^{63}Ni electron capture detector and a fused silica capillary column SPB-5 (Supelco, Inc., Bellefonte, PA), 15 m in length and 0.53 mm i.d. Operating conditions were: column temperature, 240°C, carrier gas argon/methane (95:5) at a flow rate of 10.5 mL/min. PCB was quantified by comparing the detector response to four major congeners of an Aroclor 1260 standard (Supelco). For PCB analysis of *N. diversicolor* and bird tissues, extracts were cleaned up using Florisil (12). Unfortunately it was not possible to analyze foam samples for organochlorines because of insufficient sample.

RESULTS AND DISCUSSION

Hydrocarbons and biogenic lipids in shorebirds. Levels of total lipid and hydrocarbons in the three species of shorebirds collected at Dorchester Cape (New Brunswick) are given in Table 1. The total lipid contents of semipalmated sandpipers and short-billed dowitchers were 19.6% and 18.2% of wet weight, respectively. These values are similar to the lowest levels of lipid contents measured previously in five semipalmated sandpipers in this laboratory (11). The relatively low lipid contents indicate a recent arrival at the feeding grounds of Shepody Bay, where the feeding period is normally six to eight weeks (4). Lipid contents of semipalmated plovers were higher (37.7%) than in the other two species, and comparable to semipalmated sandpipers captured in the same area during the late summer of 1986 (11).

The detailed analysis of hydrocarbons present in the adipose tissue of the three species of birds showed the presence of the isoprenoid alkene squalene (2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene) as a single component (Table 1). Squalene was present at 22.5 and 25.1 μg/g of adipose tissue in semipalmated sandpipers and short-billed dowitchers, respectively. Semipalmated plovers had a higher mean value, 47.0 μg/g of this lipid.

The presence of squalene as a single or dominant hydrocarbon in birds has been previously reported in the preen

(uropygial) gland and in stomach oils of several species of marine birds (13,14). Squalene is a widespread hydrocarbon among marine animals. Some species of cartilaginous fish accumulate large quantities of this hydrocarbon in their livers (14), possibly for adjusting buoyancy. Much lower levels of squalene are ubiquitous in both marine and terrestrial animals and presumably reflect the role of squalene as an intermediate metabolite for the *de novo* synthesis of cholesterol taking place mainly in the liver. The anatomical distribution of squalene and its high concentration in the feathers (11) indicate that it originated in the uropygial gland and is included in feather wax (14). Enhanced hydrophobicity of feathers is likely to be an asset in birds with this feeding pattern. The fact that no other hydrocarbon could be detected in the animals analyzed suggests that the bird population is not polluted by hydrocarbons.

Animal triacylglycerol energy reserves normally reflect the sources of food through fatty acid input. Thus, in order to obtain additional information regarding the food web structure of the mudflats of the Bay of Fundy, we analyzed the fatty acid compositions of the depot fat in the three species of shorebirds (Table 2). The proportions of polyunsaturated fatty acids typically of marine origin were distributed differently among the three shorebirds studied. Semipalmated sandpipers showed the highest level of the four n-3 polyunsaturated fatty acids (PUFA) readily available from marine invertebrates (*i.e.*, 18:4n-3, 20:5n-3, 22:5n-3 and 22:6n-3). Short-billed dowitchers had the lowest proportions of marine n-3 fatty acids, and semipalmated plovers had in all cases intermediate levels between the other two bird species. The level of presumably exogenous eicosapentaenoic acid (EPA, 20:5n-3) in the bird depot fats shows perfectly this gradation from a relatively marine to a more terrestrial pattern of fatty acid composition. The EPA content in fatty acids of semipalmated sandpipers was 8.41% of the total, whereas in semipalmated plovers and short-billed dowitchers it was 4.03% and 0.87%, respectively. These fatty acid profiles are in agreement with the feeding habits of these shorebirds as described by Hicklin and Smith (4) and *C. volutator* fatty acids as reported earlier (5).

Chlorinated pollutants in shorebirds. The levels of PCB and two selected chlorinated pesticides were measured in the adipose tissue of three specimens of each species of shorebirds (Table 1). Mean values of PCB in depot fats of semipalmated sandpipers, short-billed dowitchers and semipalmated plovers were 0.85, 0.14 and 0.77 ppm of lipids, respectively. Two of these values, when converted to a wet weight basis, are very similar to those previously reported for semipalmated sandpipers and semipalmated plovers by Baril *et al.* (6). PCB levels reported here for short-billed dowitchers are, however, lower than Baril *et al.* (6) reported. Comparing the overall levels of PCB in other birds and environments (15,16), these three species of shorebirds have relatively low values.

DDT and DDE contents in sandpipers, plovers and short-billed dowitchers are shown in Table 1. Low levels of these contaminants were found in all of the shorebirds except for two semipalmated plovers, specimens No. 89161

and 89164. Mean values of DDT and DDE in semipalmated sandpipers were 0.028 and 0.074 ppm of body depot fats. Short-billed dowitchers had higher levels of DDT (0.041 ppm) and DDE residues (0.14 ppm). Pesticide residues in semipalmated plovers showed quite inconsistent results. Although the DDT levels in this shorebird were intermediate between those of the other two species, levels of DDE were low in two specimens (0.09 and 0.03), and high in a third animal (0.10 ppm). One bird (89164) was a juvenile but it did not differ as markedly in DDT burden as did one of the adults.

Chlorinated pollutants in N. diversicolor. In an attempt to investigate the possible different sources of hydrocarbons and chlorinated contaminants in this shorebird population, we measured the PCB level in the marine polychaete *N. diversicolor.* This invertebrate is an important food source for these birds while feeding on the mudflats of the Bay of Fundy. Although the amphipod *C. volutator* is the dominant component of the diet of most of the shorebirds of the area, *N. diversicolor* is also present in their diet (4).

Hydrocarbon levels in these ragworms were below detectable levels. The content of PCB in this sample of polychaetes was 0.0165 ± 0.0074 ppm of lipids. The level of chlorinated pesticides in this invertebrate in the area of study was below detectable limits. The level of PCB found in this marine polychaete is within the expected range of values considering both its environment and trophic position, and is about one order of magnitude lower than in lipids of birds, and about half of that reported in the same species inhabiting more polluted coastal areas of the North Sea (17).

Lipids in foam. In a search for lipophilic material in the Bay of Fundy, we examined lipids, fatty acids and hydrocarbons in the foam produced in the tidal channels and at the edge of the water on the mudflats of Shepody Bay at Dorchester Cape. Due to the pronounced tidal action in the Bay of Fundy, we expected a close interaction between surface water (involved in the formation of the foam) and the organic matter in the sediments. Thus the foam is considered to be a place for the concentration of organic matter present in the seawater (18,19), which would be a source of food for both filter and deposit-feeding invertebrates (20).

The lipid fraction of the foam collected in Shepody Bay was composed of an unidentified acetone-mobile component band on TLC/FID Chromarods [probably composed of algal pigments and refractory material; compare "AMPL band" described by Parrish (10) for seawater and pigments discussed by Scribe *et al.* (21)], phospholipids, sterols, triacylglycerols and hydrocarbons. The total level of lipids in the foam was 65×10^3 μg/L of foam, about 5 times that found in foam below Niagara Falls (22), suggesting that foam could be an important feature of the food web and lutant dynamics in the Bay of Fundy. The total level of hydrocarbons was, however, 750 μg/L of foam which, while very high compared to coastal bulk water concentrations (23), is just half of those found in foam below Niagara Falls (22).

An interesting feature of this lipid-rich fraction of seawater in the Bay of Fundy was the hydrocarbon composition. It consisted of a complete series of normal saturated alkanes, from C_{20} to C_{39} (and trace levels of longer chain homologous hydrocarbons), with no dominance of odd or even chain components in the overall range (carbon preference index [CPI] = 1.008) (Fig. 1). This hydrocarbon pattern is likely to reflect the input of terrestrial material or possibly low level petroleum contamination.

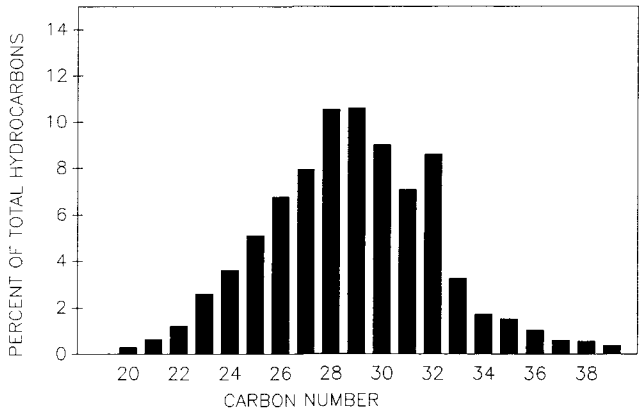

FIG. 1. Normal alkane hydrocarbon distribution in foam collected on the mudflats of the Bay of Fundy.

Information regarding composition of lipophilic material, and *n*-alkane distributions of sea water or other samples with high particle loads must be interpreted with caution (21). Both the sea water from the head of the Bay of Fundy and the foam formed from it are very turbid due to a high particle load (24). It has been reported that liquid-liquid extraction of lipids of particle-rich waters gives a low yield of high molecular weight *n*-alkanes (25). In spite of this consideration, it is interesting to point out that a very similar hydrocarbon profile was determined in the amphipod *C. volutator* in Minas Basin (5).

In order to obtain additional information regarding the origin of the organic matter present in the coastal surface seawater in Shepody Bay, we analyzed the fatty acid composition of the total lipids present in the foam (Table 3). Fatty acids in foam contained a rather low proportion of saturated fatty acids, mainly 16:0 (17.0%) and 18:0 (7.0%), since these would be expected to remain if unsaturated fatty acids were destroyed by oxidation, absorption on particles, bacterial action or other means. They were also low by comparison with the fatty acids of the shorebirds (Table 2) and seawater sampled from Nova Scotia inlets (23). The proportions of the monounsaturated fatty acids were more similar to those observed in the shorebirds, but 18:1n-9 was more than twice as abundant in foam (Table 3) than in coastal bulk water (23). Polyunsaturated fatty acids accounted for 25% of the total in foam, with almost equal proportions of fatty acids of the n-6 series (mainly 18:2n-6) and of the long-chain n-3 series. The proportions of these acids were high compared with bird adipose tissue and marine dissolved and particulate matter (23). The 18:2n-6 possibly indicates a direct terrestrial plant input, but 18:2n-6 can be common in algae as well (26).

The fatty acid profile in the foam thus indicates a heterogeneous but mostly marine origin for the organic matter input to the coastal waters in the mudflats of the Bay of Fundy. The high proportions of the labile but typical marine fatty acids, such as the C_{18}, C_{20} and C_{22} polyunsaturated fatty acids, which can be rapidly oxidized after being released into seawater, suggest a large contribution

TABLE 3

Fatty Acid Composition (wt %) of Foam Collected from Seawater at Dorchester Cape (New Brunswick)

Fatty acid	%	Fatty acid	%

		Σ n-6	12.3

of fresh biogenic material to foam. The excess of 20:5n-3 over 22:6n-3 could indicate an origin from benthic and planktonic diatoms (26), in accordance with fatty acids of total lipids in *C. volutator* (5).

Regional environmental aspects. The values of PCB and chlorinated pesticides in the three species of shorebirds reported here were reproducible in most semipalmated sandpipers and short-billed dowitchers. Semipalmated plovers, however, showed higher and more variable levels. This is not surprising, since a recent literature review of heavy metal and chlorinated hydrocarbon concentrations in the marine environment (27) showed that variation of contamination in the same or very closely related organisms at one location can be large, often up to three orders of magnitude.

Comparable results for organochlorine pollutants have been found by Baril and co-workers (6) in semipalmated sandpipers and semipalmated plovers. The undetectable level of hydrocarbon pollution in the bird's adipose tissue is consistent with the generally uncontaminated condition of the population which migrates from presumably uncontaminated Arctic feeding grounds.

Mean concentrations of PCB in body adipose tissues in all birds were below 1 ppm. However, levels of these chlorinated pollutants varied considerably among the different species, and among individuals within species. The overall levels of chlorinated pollutants in the shorebirds analyzed and in two important local food resources (*C. volutator* and *N. diversicolor*) are confirmed as comparatively low. Although the level of PCB contamination in ragworms in the Bay of Fundy is very low compared to other areas of the world (17), PCB levels in *N. diversicolor* are higher than in *C. volutator* from the same region (5). Mean levels of DDT and DDE, and maximum individual PCB levels, in adipose tissue of semipalmated plovers, were higher than in the other two species examined. Each of the three species of shorebird has slightly different feeding habits. Semipalmated plovers, for example, include more *N. diversicolor*, and especially insects, in their diet (4). Thus, these two food items may be responsible in part for the higher levels of PCBs and pesticides found in some specimens of semipalmated plovers.

Interestingly, similar profiles of normal alkane hydrocarbons were found in both foam (Fig. 1) and in *C. volutator* (5). The source of these hydrocarbons is likely to be salt marsh plant detritus, but low-level petroleum oil contamination cannot be ruled out. While the level of PCB- and DDT-derived pollutants seems to be gradually declining in the northern hemisphere after their use was banned more than a decade ago (27), the level of petroleum contamination is likely to be rising. Therefore, any monitoring program of pollution in this region should carefully look at any possible trend in levels of hydrocarbon pollution. The information presented in this report should be useful as a reference for baseline levels.

The importance of the input of organic matter and food of terrestrial origin into the mudflats system was illustrated by the hydrocarbon composition of foam and the fatty acid composition of adipose tissue in shorebirds. In this situation we cannot exclude the possibility that chlorinated pesticides, largely used in the past on the agricultural and forest lands bordering the Bay of Fundy, are still present in the soils of certain areas, and are being very gradually released and introduced into the marine environment. Shorebirds, as far as we know, arrive with pristine fat deposits from feeding in the high Arctic. Their annual visits and systematic deposition of large reserves of fat from feeding in a small area provide natural accumulators for monitoring highly localized concentrations of such pollutants.

Lipids in Cancer: An Introduction[1]

Leonard A. Cohen*
Division of Nutrition and Endocrinology, American Health Foundation, Valhalla, New York 10595

It is generally believed that cancers which occur in epithelial tissues result from the interaction between host factors and the environment and that only a small percentage of these cancers can be attributed to genetic factors alone. Two of the major environmental risk factors which are under voluntary control are cigarette smoking and diet. Hence, modification of smoking and eating patterns, on a broad societal scale, offers a hopeful, feasible means of significantly reducing the incidence of an estimated 60-90% of human cancers. Among the dietary factors associated with cancer, with the possible exception of vitamin A and/or β-carotene, dietary fat has received the lion's share of attention. Although the role of dietary lipids in carcinogenesis has been known for over half a century, consideration of this topic actually began in earnest in the 1960s with the work of E. L. Wynder and of K. K. Carroll. Since then, a rapidly expanding literature, including both epidemiological, laboratory animal model and clinical studies, has appeared linking high fat intake with cancer of the breast, colon, pancreas and prostate. A look at the time trends of this phenomenon (Fig. 1) indicates an almost logarithmic increase in the number of publications over the period 1966 to 1989. It is instructive to note that the greatest attention has been paid to cancer of the breast and least to prostatic cancer. The reasons for this discrepancy are not entirely clear but appear to be related to the paucity of animal models with which to study prostate cancer and the fact that prostate cancer is more a disease of old age than breast, colon or pancreatic cancer.

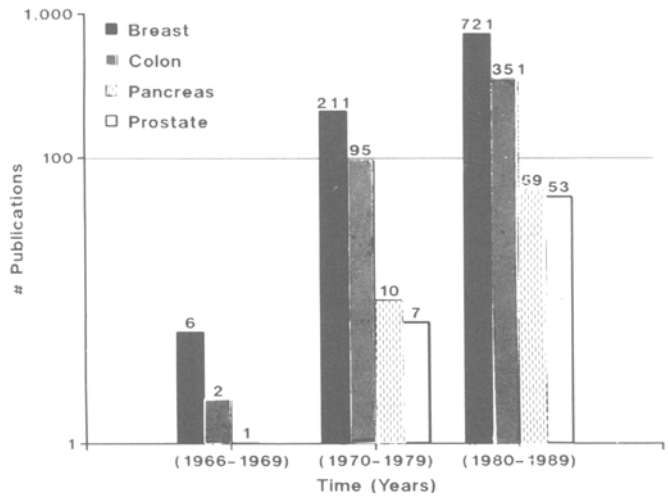

FIG. 1. Publication trends: dietary fat and cancer. Data are from Medline (National Library of Medicine) Washington, D.C.

[1]Based on a paper presented at the Symposium on Lipids in Cancer held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

Abbreviations: EGF, epidermal growth factor; P/S, polyunsaturated/saturated fatty acid ratio; TGF_a, transforming growth factor x.

(Over 80% of clinically diagnosed prostate cancer occurs in men over age of 65.) The impact of these four epithelial cancers on the nation's health can be seen in Table 1. Taken together, they represent 40% of all cancers (incidence) and almost 30% of all cancer deaths.

The purpose of this symposium was to review critically the epidemiological, animal model, clinical and anthropological evidence for a role of lipids in each of these four cancers, to provide insight into possible mechanisms, and to discuss current thinking concerning dietary recommendations to the public for cancer prevention. Each of the contributors provided an overview of the subject at hand, ranging from the diet of paleolithic man (B. Eaton) to the current status of dietary intervention trials (N. Boyd).

The role of the type and amount of fat in breast and colon cancer was reviewed by K. K. Carroll and B. S. Reddy, respectively. By using chemically-induced mammary and colon tumor model systems, it has been shown that the effects of dietary fat are exerted primarily on the promotional phase of carcinogenesis. K. K. Carroll reviewed the evidence associating dietary fat with breast cancer, pointing out the shortcomings of retrospective case-control studies, and the need for a prospective trial involving dietary intervention. In addition, the role of different types of fat (n-3 *vs.* n-6) was addressed as was the fat-calorie controversy which, put briefly, pits the view that fat acts *via* its high caloric density *vs.* the view that fat acts independently of its caloric content.

B. S. Reddy reviewed the extensive body of experimental data linking colon cancer with high fat intake. As with breast cancer, the type as well as quantity of fat influences the development of colon tumors. High fat diets rich in triglycerides containing medium-chain (coconut oil), monounsaturated (olive oil) or n-3 polyunsaturated fatty acids (fish oil) apparently lack colon tumor promoting effects compared to oils rich in n-6 polyunsaturated fatty acids (safflower, sunflower).

The biological mechanisms underlying the fat effect in breast and colon cancer are poorly understood. Regarding breast cancer, available evidence suggests that high fat intake alters endocrine balance, eicosanoid production and/or immune functions. With regard to colon cancer, a current hypothesis holds that an increase in bile acid production, under high fat conditions, is associated with an

TABLE 1

Estimated Cancer Incidence and Mortality for Four Organ Sites: USA, 1991[a]

	Incidence	Mortality
Breast	175,000	44,500

accelerated conversion by gut bacteria of primary to secondary bile acids. Secondary bile acids in turn exert colon tumor promoting activity *via* induction of polyamine synthesis and/or membrane-bound signal transduction systems.

D. P. Rose's talk provided an excellent example of the use of *in vitro* methods to unravel the effects of dietary fat at the cellular and molecular levels. After the somewhat inconsistent epidemiological evidence that dietary fat influences prostate cancer etiology was reviewed, the effect of specific types of fatty acids on the growth of human prostate cancer cells *in vitro* was described. The mechanisms underlying the stimulatory effects of n-6 and the inhibitory effects of n-3 polyunsaturated fatty acids containing fats appear to involve alterations in eicosanoid pathways. Evidence was presented suggesting that the stimulation of prostate cancer cells by n-6 polyunsaturated fats is associated with autocrine regulation by epidermal growth factor (EGF) and transforming growth factor α (TGF_α) and their respective cellular receptors. These studies, in neoplastic cells, may provide insights into the link between dietary lipids and cellular growth factors, and may provide new treatment modalities for prostate cancer patients.

Pancreatic cancer is unique in that the five year survival is only 3–4% of the cases. Hence, it is, by far, the most lethal of the lipid-responsive cancers. Like prostate cancer, studies of pancreatic cancer have lagged behind those of breast and colon largely because of the paucity of good animal models. B. Roebuck, a major contributor to this field, described the epidemiology of the disease and critically reviewed his, and other, studies which indicate that both the type and amount of fat modulate the development of chemically-induced pancreatic foci in a manner remarkably similar to that described for mammary and colon cancer. There is a need for further studies on possible mechanisms for the enhancing effect of dietary lipids on pancreatic carcinogenesis, both as a means to gain insight into etiology and to provide a rational basis for dietary intervention.

A relatively new discipline, nutritional anthropology has shown that the past weighs heavily on the present both in terms of health and disease. Based on the analysis of the dietary practices of over 20 hunter-gatherer tribes which have persisted from the late Stone Age to the present, B. Eaton and colleagues developed the intriguing hypothesis that 20th century *Homo sapiens* is maladapted to our contemporary diet. According to Eaton, contemporary man's digestive system and metabolism is structurally and functionally designed for a diet typical of the late Stone Age: high fiber (over 50 g/d), low fat (20–25% total calories) with a polyunsaturated/saturated (P/S) fatty acid ratio of substantially over 1.0. Consequently, "diseases of civilization" have resulted, at least in part, from the inability of our Stone Age metabolism to cope with diets containing 12–15 g fiber/day and 38–40% of total fat calories with a P/S ratio of approximately 0.44.

In the last analysis, however, neither animal model, nor epidemiological studies nor studies of the diets of our distant ancestors can provide proof, in themselves, that an individual's risk of cancer can be reduced by decreasing fat intake; at best, they can provide insights and clues to etiology to prove the lipid hypothesis will require a long-term prospective dietary intervention trial. Despite the weight of evidence being in favor of such a trial, all attempts at launching one in the United States have been stymied by logistic, financial and ethical considerations (2). In Canada, however, a low-fat intervention trial is underway and its progress was reviewed by N. Boyd. One of the criticisms of low-fat intervention trials has been the problem of compliance. However, both in the Canadian study and in two feasibility studies in the United States. (The Women's Health Trial [WHT] and the ongoing Women's Intervention Nutrition Study [WINS]), it has been demonstrated that free-living women can comply with a 20–25% fat diet down from 37–39% fat as calories, for months at a time. Several key issues regarding the design of such trials remain, such as the optimal balance of polyunsaturated, monounsaturated and saturated fat (the general consensus being 1:1:1), the proportion of n-6 and n-3 PUFA, and the possible interactive role of dietary fat, fiber and energy expenditure.

In conclusion, while the lipid hypothesis remains to be unambiguously proven, the overwhelming weight of evidence suggests that interim guidelines such as lowering fat intake to below 30% of total calories would serve to decrease the risk of these four cancers with few, if any, detrimental side effects. Such guidelines have the advantage that they can be amended or revised to reflect new information as it becomes available.

REVIEW

Dietary Fat and Breast Cancer[1]

Kenneth K. Carroll[2]
Human Nutrition Centre, Department of Biochemistry, University of Western Ontario, London, Ontario N6A 5C1 Canada

High-fat diets are thought to increase the risk of breast cancer because animals develop mammary cancer more readily when they are fed high-fat compared to low-fat diets, and breast cancer incidence and mortality are higher in countries with high-fat as compared to those with low-fat diets. Prospective cohort studies and case-control studies have failed to provide much support for this theory, but such studies are less capable of showing the relationship because of smaller differences in dietary fat intakes of the study populations; difficulties in assessing the diets of individuals over a period of time; and possible differences in genetic susceptibility of cases and controls to breast cancer. Studies on migrants have shown that breast cancer incidence and mortality increase in populations who move from countries with low-fat to those with high-fat diets, indicating that observed geographical differences in breast cancer are due to environmental rather than genetic factors. This is supported by time-trend studies showing that breast cancer increases in countries as the level of fat in the diet rises. Controlled, long-term dietary trials are needed to determine whether the converse is true: namely, that reduction of dietary fat can reduce the risk of breast cancer. Large groups are required to achieve statistical significance, but smaller numbers may be adequate for studies on high-risk individuals. Preliminary experiments already have demonstrated the feasibility of carrying out such dietary trials.
Lipids 27, 793-797 (1992).

The idea that dietary fat has an important influence on breast cancer incidence and mortality is based primarily on the results of studies on experimental animal models and on on inter-country correlations derived from epidemiological data.

Studies on the effects of dietary fat on mammary cancer in animals began with the work of Tannenbaum (1) and were continued in a number of laboratories over a period of about 15 years (2). The experiments consistently showed that mice and rats developed mammary tumors more readily when they were fed high-fat as compared to low-fat diets, but these observations attracted relatively little attention until they were correlated with epidemiological data from different countries showing that breast cancer mortality increases with increasing levels of dietary fat (3-5).

This evidence for breast cancer and similar findings for cancer at other sites, such as the colon, led the National Research Council (NRC) Committee on Diet, Nutrition, and Cancer (6) to conclude ". . . that of all the dietary components it studied, the combined epidemiological and experimental evidence is most suggestive for a causal relationship between fat intake and the occurrence of cancer."

In contrast to the data from experimental studies and inter-country correlations, the results of case-control and prospective cohort studies have not provided strong evidence for an association between dietary fat and breast cancer (7-11). There also have been suggestions that energy balance has a more important influence on breast cancer than dietary fat (11,12).

Meanwhile, the observations implicating dietary fat in breast cancer have stimulated dietary trials which have demonstrated the feasibility of reducing the level of fat to about 20% of total calories in the diets of North American women (13,14). It is not possible to draw conclusions regarding the effect of dietary fat reduction on breast cancer based on the results to date, but other benefits have been reported, including a reduction in plasma or serum cholesterol (14,15) and relief from symptoms of cyclical mastopathy (16).

The aim of this paper is to discuss the evidence in more detail and to present ideas designed to stimulate more experimentation and discussion on the role of dietary fat in breast cancer.

DEVELOPMENTAL ASPECTS OF BREAST CANCER

In countries where breast cancer is prevalent, the incidence is much higher after menopause than before (17). However, there is substantial evidence to suggest that initiation occurs at a much younger age. Thus, early menarche increases the risk of breast cancer while an early first pregnancy decreases the risk (8,18). Such observations point to an early onset and suggest that hormonal factors play an important part in development of the disease (19,20).

Epidemiological data on migrants from countries such as Japan, China, Poland and Italy to the United States or Australia have shown that the incidence of breast cancer increases rather slowly (21). Similarly, in post-war Japan, breast cancer mortality has increased more slowly than that of colon cancer (8). These observations also suggest a relatively long latent period for breast cancer.

Experiments on animals have provided evidence that initiation of mammary cancer is more likely to occur at a young age. Carcinogens such as 7,12-dimethylbenz(a)anthracene (DMBA) and *N*-methylurea (NMU) are much more effective in young compared to older animals (22,23). Studies in our laboratory showed that using a low dose of DMBA for initiation greatly extended the latent period while still producing a high incidence of mammary cancer (24,25). This may be similar to the pattern of development of breast cancer in humans, since humans are more likely to be exposed to low rather than high doses of carcinogenic agents.

Russo *et al.* (26) have done extensive histological studies comparing the development of mammary tumors in rats and in humans. They have shown that the incidence of mammary tumors induced in rats by DMBA is directly proportional to the density of highly proliferating terminal end buds, which is highest in young animals and declines sharply after 55 days of age (27). In humans, cell replication in terminal ducts of the mammary gland reaches a peak in early adulthood and decreases considerably with age (26).

[1]Based on a paper presented at the Symposium on Lipids in Cancer held at the AOCS Annual Meeting, Baltimore, MD, April 1990.
[2]Career Investigator of the Medical Research Council of Canada.
Abbreviations: DMBA, 7,12-dimethylbenz(a)anthracene; NMU, *N*-methylurea.

These observations are compatible with the idea that initiation of breast cancer is more likely to occur in young women when the breasts are developing and the epithelial cells are dividing at a more rapid rate. The differentiation of cells associated with pregnancy and lactation appears, however, to render them less susceptible to transformation, although pregnancy ensuing after initiation can accelerate the carcinogenic process (28).

As suggested above, hormonal factors evidently play an important role in the initiation of breast cancer. This idea is reinforced by observations that the ability of carcinogens, such as DMBA and NMU, to induce mammary cancer in rats varies with the stage of the estrous cycle at which they are administered (29,30). The hormonal environment also appears to be an important factor in later stages of breast cancer development, since ovariectomized women and women who experience early menopause appear to be at lower risk (8). Environmental factors, such as diet, also may have a significant effect on breast cancer by modulating its rate of development (4,5).

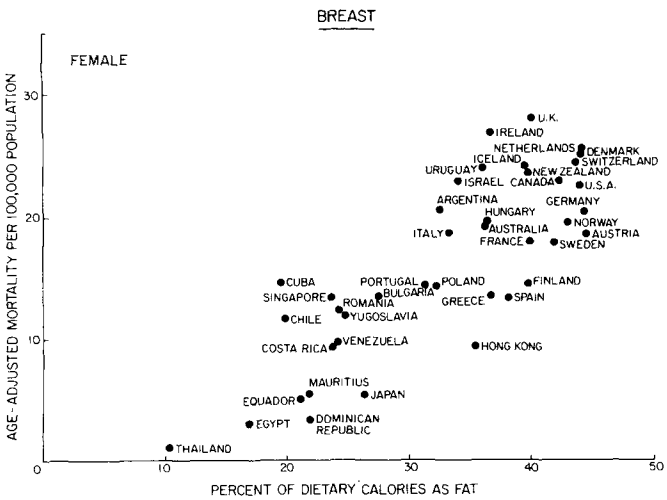

FIG. 1. Correlation between percentage of dietary calories as fat and age-adjusted mortality from breast cancer in different countries (reproduced from Carroll; ref. 38).

DIETARY FAT AND BREAST CANCER

In studies on diet in relation to breast cancer, much of the emphasis has been focused on dietary fat (6,7). This is based on epidemiological evidence showing a strong positive correlation between dietary fat and breast cancer incidence and mortality in different countries (3,31); and on laboratory experiments showing that animals fed high-fat diets develop mammary cancer more readily than those fed low-fat diets (3,5). This has been observed consistently in animals fed *ad libitum*, both with spontaneous tumors and with tumors induced by various means (32).

Studies on migrating populations have provided evidence that geographical differences in breast cancer incidence and mortality are related to environmental rather than genetic factors (21). This is supported by time trends showing marked increases in age-adjusted death rates from breast cancer in a number of countries in recent years (33,34).

In contrast to the strong positive correlation between dietary fat and breast cancer incidence and mortality observed in inter-country comparisons, case-control and prospective cohort studies have shown little evidence of such a relationship (6–8). There are, however, a number of possible reasons for this apparent discrepancy (35–37).

Case-control and prospective studies usually involve smaller and more homogeneous populations than those on which inter-country comparisons are based, and the range of dietary fat intake may not be sufficient to show marked differences in breast cancer. For example, inter-country comparisons show little correlation between breast cancer mortality and dietary fat among countries where dietary fat contributes more than 30% of total calories, but in most of those countries breast cancer mortality is higher than in countries where fat accounts for less than 30% of calories (Fig. 1). Overall, the data plotted in Figure 1 suggest the possibility of a straight-line relationship between breast cancer mortality and percent of dietary calories as fat. Breast cancer clearly causes less mortality in countries where a smaller proportion of dietary calories comes from fat, but the scatter in the data, which may be due to a variety of factors, makes it difficult to distinguish effects of small increments of dietary fat.

Another problem with case-control and prospective cohort studies is the difficulty of measuring the fat intake of individuals (35,36). Even if it can be measured with reasonable accuracy at a given point in time, the dietary habits of individuals change with time, and it is nearly impossible to assess their intake over periods of years, particularly when it involves dietary recall.

A more fundamental problem with case-control studies relates to the influence of genetic or other non-dietary factors that influence breast cancer incidence and mortality. Even in countries where breast cancer is more prevalent, only about 10% of women develop the disease, so those who do not are presumably less susceptible to environmental risk factors. Thus, the failure of control subjects to develop breast cancer on a high-fat diet may be related to this lack of susceptibility, whereas the more susceptible cases may develop the disease even when their fat intake is lower than that of the controls. In comparing relatively small numbers of cases and controls, the differing characteristics of individuals increase the difficulty of detecting effects of diet or other environmental factors. Even so, a recent analysis of a number of case-control studies indicated that cases had significantly higher fat intake than did controls (10).

Studies on migrants suggest that the range of genetic susceptibility to breast cancer is similar in the populations of different countries, because with time, the incidence in migrants approaches that of their country of adoption. In comparing large populations with similar distribution of susceptibility to breast cancer, a large proportion of each population will not develop cancer under the environmental conditions existing in either country. However, a certain proportion of the more susceptible individuals may develop it under the conditions of one country (Environment B) but not under those of the other (Environment A) (Fig. 2). It is thus possible to observe the effects on breast cancer of environmental variables, such as dietary fat, by comparing incidence or mortality in two populations having roughly similar proportions of individuals with comparable susceptibility to the disease. The hypothetical variation in genetic susceptibility to

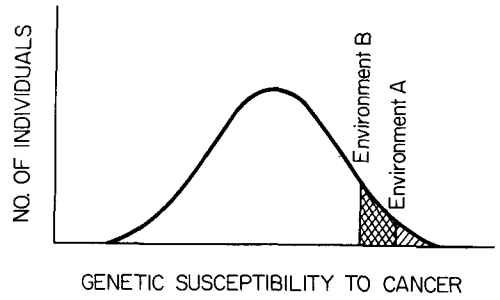

FIG. 2. Hypothetical variation in genetic susceptibility to breast cancer in a large population of women. Because of lower genetic susceptibility, most women will not develop breast cancer, even under environmental conditions that promote the disease (represented by the open area under the curve). Highly susceptible individuals will develop breast cancer under almost any set of conditions (represented by the shaded area to the right of Environment A). Individuals with a relatively high susceptibility, who may be protected from breast cancer under one set of environmental conditions, but not under another, are represented by the cross-hatched area between Environments A and B (Reproduced from ref. 39).

breast cancer shown in Figure 2 may be due partly to differences in the genomes of different individuals, and partly to variations in exposure to carcinogenic stimuli during their lifetime.

EFFECTS OF DIFFERENT TYPES OF DIETARY FAT

Experiments in animals have provided evidence that promotion of mammary cancer is influenced by both the amount and type of dietary fat (40). In particular, there is a requirement for a certain amount of polyunsaturated fat, up to a level of 4–5% of total calories (41–43). When this requirement is met, the incidence and yield of mammary tumors induced by DMBA increases in proportion to the total amount of fat in the diet (42,43). Dietary fish oil has an inhibitory effect on mammary carcinogenesis when fed at higher levels in the diet (44,45), but a relatively high proportion of fish oil to polyunsaturated vegetable oil is required to produce the effect (46).

In contrast to results obtained with experimental animals, the polyunsaturated fat content of the diet shows little correlation with breast cancer mortality in humans (47). This is probably because the polyunsaturated fat content of most human diets is above the threshold required for maximum effect on cancer promotion. Thus, the observed positive correlation between dietary fat and breast cancer mortality in humans is more likely to be related to total fat intake than type of fat.

Saturated and monounsaturated fatty acids predominate in the higher fat diets consumed in Western industrialized countries, and both tend to increase as total fat increases. This is not true for polyunsaturated fatty acids, which vary over a much narrower range and do not show a correlation with total dietary fat (48). As a result, both saturated and monounsaturated fatty acids are positively correlated with breast cancer mortality in human populations, whereas polyunsaturated fatty acids are not (47).

DIETARY FAT *VS.* CALORIC INTAKE

Because fat is a much more concentrated source of energy than either carbohydrate or protein, high-fat diets have a high energy density as compared to low-fat diets. Dietary protein varies over a narrower range than either fat or carbohydrate (49), so high-fat diets are generally low in carbohydrate and *vice versa*. The higher energy density of high-fat diets tends to encourage a higher caloric intake and, thus, there is a strong positive correlation between dietary fat and calories (5).

Many experiments have shown that carcinogenesis can be inhibited in experimental animals by dietary restriction (2,4,50), and this has been observed with high-fat as well as with low-fat diets (51). Such observations have led to the conclusion that dietary fat exerts a promoting effect on mammary carcinogenesis only under *ad libitum* feeding conditions (12,52). Although it is difficult to dissociate effects of dietary fat from those of caloric intake, Freedman *et al.* (53) recently concluded on the basis of a survey of a large number of animal experiments that higher caloric intake and higher fat intake independently increase mammary tumor incidence in rats and mice. Animals given the opportunity to exercise voluntarily were observed to have a lower incidence of mammary cancer than their sedentary counterparts (54), so energy utilization also appears to be an important factor in mammary carcinogenesis.

It seems rather impractical to suggest that people reduce their caloric intake in the presence of an abundance of food, even if it were to reduce their risk of developing cancer. They can, however, be persuaded to reduce their fat intake by eating a diet containing larger amounts of complex carbohydrates, and feasibility trials have shown that women will adhere to lower fat diets for prolonged periods of time (14,55). If the objective is to decrease the risk of breast cancer and if it can be achieved by reducing dietary fat intake, this appears to be a more practical approach than trying to restrict food intake.

RATIONALE FOR CLINICAL TRIALS ON DIETARY FAT AND BREAST CANCER

The positive correlation between breast cancer incidence and mortality and dietary fat in different countries does not necessarily indicate a causative relationship. Increasing the level of dietary fat in diets fed to experimental animals clearly increases their susceptibility to mammary cancer, but this finding cannot be extrapolated to humans with certainty. The studies on migrants and the changing trends in cancer mortality with time provide strong evidence that observed differences in breast cancer mortality are due to environmental rather than genetic factors. The populations involved in these studies have typically increased their dietary fat intake and have experienced an increase in breast cancer incidence and mortality.

It is very desirable to know whether the converse is true (*i.e.*, that reducing the level of dietary fat would lead to a decrease in breast cancer), and it appears that the only way to establish this is by conducting controlled dietary trials. The original Women's Health Trial did not proceed beyond the feasibility stage for a variety of reasons, including the expense involved. However, there is now re-

newed interest in this type of trial, which can be designed to investigate effects on other health problems, such as cardiovascular disease, and thus provide more useful information with little added expense (56).

Trials on healthy women or women with moderately increased risk of breast cancer require relatively large numbers of subjects, who need to be followed for lengthy periods of time. In the case of women with benign breast disease, who have a substantially higher risk of developing breast cancer (55,57,58), the number of subjects required to assess the effect of dietary fat is likely to be smaller. There is, however, the possibility that the response of these subjects may not be typical of that for the population as a whole.

Another study population consists of women who have already developed breast cancer. In this case, the primary aim is to determine whether reducing the level of dietary fat will decrease the risk of recurrence of cancer (59). There is already some evidence that recurrence occurs less frequently in populations on low-fat compared to those on high-fat diets (60).

CONCLUSIONS

Most dietary guidelines that have been issued in recent years have advocated a reduction in dietary fat as a means of preventing obesity and reducing the risk of a number of chronic diseases, including cancer. These guidelines are based on a substantial amount of scientific data, but definitive proof of their validity is still lacking. It therefore seems appropriate to recommend strongly that the potential benefits of low-fat diets be tested by controlled dietary trials. The cost of such trials is miniscule compared to the current economic and social burden of diet-related chronic diseases.

Dietary Fat, Fatty Acids and Prostate Cancer[1]

David P. Rose* and **Jeanne M. Connolly**
Division of Nutrition and Endocrinology, American Health Foundation, Valhalla, New York 10595

International comparisons suggest a relationship between prostate cancer incidence and dietary fat, an inference supported by migration studies, the changing incidence rates and levels of animal fat consumption in Japan and the results from some case-control studies. Overall, however, epidemiological studies have been inconclusive, and although prostate cancer is one of the hormone-dependent tumors, evidence of interactions between dietary fats and male endocrine function is incomplete. Laboratory experimentation has shown that n-6 fatty acids stimulate and n-3 fatty acids inhibit human prostate cancer cells in culture; also, feeding diets rich in marine oils suppresses growth of these cells as solid tumors in athymic nude mice. These growth effects of polyunsaturated fatty acids appear to involve both prostaglandins and leukotrienes and to interconnect with autocrine regulation by epidermal growth factor-related polypeptides.
Lipids 27, 798–803 (1992).

Prostate cancer is now the second leading cause of cancer deaths in males, and the most frequently diagnosed cancer among men in the United States (1). Moreover, because of the changing age distribution, there will inevitably be further increases in cases and prostate cancer-related deaths as time goes on.

In general, the populations with a high incidence of prostate cancer are those of northern Europe, or of northern European origin, although African-Americans, even after adjustment has been made for disparity in socioeconomic status, constitute an important exception to this general rule (2). Intermediate in rank are the southern European countries and those of Latin America, while the Far East shows the lowest mortality rates. Yet, despite the pronounced differences in clinically manifest prostate cancer, and consequently in the mortality rates, cancers which are restricted to the prostate gland and have remained undiagnosed in life ("latent" or "histological" prostate cancer) are found at autopsy with about the same frequency in Japanese men as in white males in the United States, Canada, England and Austria (2). This observation was refined by Akazaki and Stemmerman (3) who, having noted that the prostate cancer mortality rate for Japanese in Hawaii is closer to that of the American white population than to the rate for native Japanese, performed a histological study of latent carcinoma of the prostate. They found no difference in the actual prevalance rates between the two groups, but larger lesions suggestive of rapid growth rates were more common among the migrants to Hawaii.

Jackson *et al.* (4) made a pathological comparison of prostate cancers in high-risk African-Americans and low-risk black Africans. Included was autopsy material from 249 males in Ibadan, Nigeria, and 243 in Washington, D.C.; none had had clinically manifested prostate cancer. Small ("microscopic") carcinomas of the prostate were detected with approximately equal frequency in the two groups, whereas invasive cancer was more common among the African-Americans.

Another internationally based autopsy study compared the frequency and histopathological characteristics of latent prostate cancers in seven geographical areas (5). Small, so-called "focal," latent carcinomas occurred with approximately the same incidence in Hong Kong, Singapore, Israel, Jamaica, Uganda, Germany and Sweden. However, although larger, diffuse infiltrating carcinomas within the prostate gland were common in the two European and in the Jamaican black populations, they were seen much less frequently in the two Chinese and the Jewish population. From these results, it appears that diffuse latent carcinomas are very likely on their way to becoming clinically manifest, whereas focal latent prostate cancers are usually either extremely slow in their progression, or are truly in a state of growth arrest and potential regression.

Carter *et al.* (6) have proposed that while phenotypic changes have occurred in the cells that constitute what is commonly designated a "focal latent carcinoma," a term which they avoid, additional events are necessary for the emergence of invasive clinical disease. While the biological mechanisms which determine the step-wise progression of a few transformed prostatic epithelial cells to a life-threatening, clinically overt, cancer remain to be elucidated, one possibility is that dietary fat, or specific fatty acids, are involved in this process.

DIETARY FAT, OBESITY AND PROSTATE CANCER

The putative involvement of dietary fat in breast cancer etiology is discussed elsewhere in this issue. Figure 1 shows that, overall, there is a fairly strong positive correlation between the mortality rates for breast and prostate cancer in different countries. Particularly noteworthy is the low risk for both of these forms of cancer in Japan, an oriental country which shares many of the environmental hazards of the western industrialized countries. Wynder *et al.* (2) pointed out that when Japanese males migrate to the United States their risk of dying of prostate cancer increases and suggested that adopting the typical American diet, relatively high in fat, might be a contributing factor. Similar arguments do, of course, apply to breast cancer.

Armstrong and Doll (7) showed that prostate cancer mortality rates for different countries were highly correlated with estimates of total fat consumption. Using nutritional data published by the Food and Agriculture Organization of the United Nations and international cancer mortality statistics prepared by Kurihara *et al.* (8) we have confirmed and extended their observations. Figure 2 confirms that there is a strong correlation ($r = 0.704$) between available fat from animal sources for 28 countries,

expressed as percent of total calories *per capita* per day, and the corresponding age-adjusted prostate cancer mortality rates. However, a relationship is completely absent when only fats from vegetable sources are examined (Fig. 3). When we sought correlations between the estimated consumption of various food groups in 30 different countries and prostate cancer mortality rates, we found a strong positive correlation with milk, a much weaker one with meats, and a strong negative relationship to the consumption of cereal products (9).

In general, there is a strong correlation between fat consumption and energy intake. However, when we examined the data for 28 countries, we found only a weak association between prostate cancer mortality rates and estimates of daily caloric intake (9). Next, the sources of energy were considered, and the results followed those observed for dietary fat; a strong positive correlation was seen when only calories of animal origin were included (r = 0.68), whereas for vegetable-derived calories the relationship was a negative one (r = −0.44).

A number of case-control studies have been performed to examine the relationships between prostate cancer and dietary fat intake. Table 1 summarizes eight of these, all but one of which provide some support for the association. Particularly convincing are the results from studies (12,13,16) which showed a positive relationship between increasing estimates of fat intake and risk. The exception is a study from Japan, which found no relationship between prostate cancer risk and the consumption of meat and milk (17). Likewise, a prospective investigation of

TABLE 1

Dietary Fat and Prostate Cancer Risk: Case-Control Studies

Study: First author (ref)	Study design	Outcome
Rotkin (10)	111 matched-pairs, hospital controls.	Association with animal fats: excess intake of pork, dairy products, eggs.
Schuman *et al.* (11)	Case control study.	Higher intake of margarine and other high-fat foods.
Graham *et al.* (12)	262 cases and 259 hospital controls, excluding those with digestive diseases. All white.	Association with animal fats: increasing intake of meats and fish. Statistically significant, and with a clear dose-response only for those ≥70 yr, similar trends for those <70 yr.
Kolonel *et al.* (13)	243 cases and 321 population controls; all 5 ethnic groups in Hawaii included.	≤60 Years, no association; ≥70 years, positive dose-response gradient for total fat; gradient for total fat.
Heshmat *et al.* (14)	Age and race-matched case-control study, 181 pairs, all black patients. Food frequency questionnaire for when aged 30–49 and ≥50 years.	Total and saturated fats higher at age 30–49 years, but not statistically significant at $P < 0.05$.
Talamini *et al.* (15)	Italian study of 166 cases and 202 hospital controls.	Significant positive relation with milk, cheese and meat consumption.
Ross *et al.* (16)	142 matched-pairs; population controls. White- and African-Americans.	Higher (animal) fat intakes associated with increasing risk: positive dose-response.
Mishina *et al.* (17)	Japanese study of 100 cases and population controls.	No association.

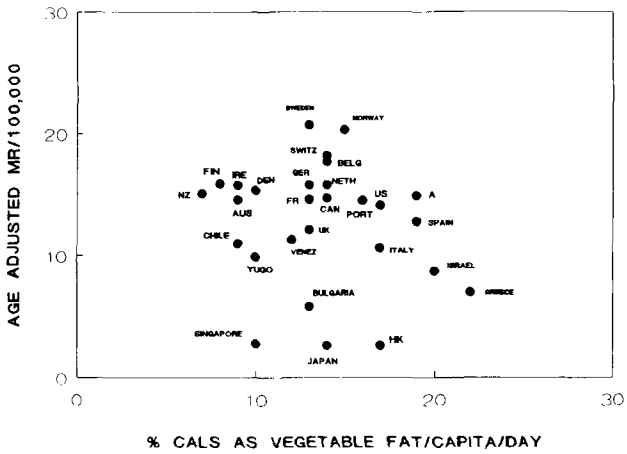

FIG. 3. The lack of correlation between age-adjusted prostate cancer mortality rates and estimates of daily vegetable fat consumption for 28 countries.

122,261 Japanese males failed to detect any association between these two fat sources and risk (18).

Despite these negative results, which could conceivably be due to the inaccuracy of dietary recall data when obtained from a low-risk, homogeneous population, most of whom are consuming low levels of the foods in question, an examination of time-trends in Japan does provide some indirect support for a relationship between dietary fat and prostate cancer risk. Wynder *et al.* (19) reevaluated this aspect of cancer epidemiology and pointed out that there has been a fourfold increase in fat consumption, notably from animal sources, in Japan since the early 1950s. While these dietary changes have occurred, prostate and breast cancer incidence rates have increased steadily since the late 1960s. But, on the other hand, when Severson *et al.* (20) studied 7,999 men of Japanese ancestry born and living in Hawaii, whose prostate cancer risk has been calculated to be 10 times that in Japan (21), dietary fat, estimated from 24-h recall data, was not found to be associated with prostate cancer.

A large prospective study of 6,763 white American Seventh-Day Adventists was performed by Snowdon *et al.* (22). They observed a significant positive association with milk consumption, and suggestive but weaker ones for dairy products and meat consumption and risk of death from prostate cancer.

Obesity has been associated with breast cancer risk in most, but not all, studies of postmenopausal women (23,24), and the same relationship has been sought in studies of prostate cancer. The results of seven reports, three of which were positive, are summarized in Table 2. Overall, it seems prudent to conclude on present evidence that obesity is unlikely to be a strong risk factor for prostate cancer, and that any positive association may be due to a third element which is common to both high body weight and prostate cancer risk.

HORMONES AND PROSTATE CANCER: RELATION TO DIETARY FAT

Both prostate and breast tissues are targets for endocrine action, and cancers arising from both of these sites possess steroid receptors and are hormone-dependent at some stage in their development. Suppression of estrogen activity is standard therapy for breast cancer, as is elimination of androgen stimulation in the case of prostate cancer.

Many studies have been performed in an attempt to demonstrate abnormal hormone levels in blood from prostate cancer patients, and, specifically, elevations in the serum androgens. No consistent differences compared with the serum levels of healthy men of similar age have been detected, perhaps because these operate in early life and are no longer evident at the time of diagnois (27).

The results of a study performed by Ross *et al.* (28) provide support for this interpretation. They compared the total and nonprotein-bound (biologically available) serum testosterone levels in college-aged African-American and white-American males. The black men, who possess the highest risk of developing prostate cancer in later life of all population groups worldwide, had significantly higher total and unbound testosterone levels. The authors considered the possibility that dietary fat intakes were involved in this difference in circulating androgens, but concluded that this explanation was unlikely because nutritional surveys in the United States have demonstrated no real differences in dietary fat intakes between blacks and

TABLE 2

Obesity and Prostate Cancer Risk

Study: First author (ref)	Study design	Outcome
Wynder *et al.* (2)	Case-control; 300 cases and 400 hospital controls.	No association.
Greenwald *et al.* (25)	Retrospective case-control; 268 fatal cases and 536 population controls.	No association between college age body weight and later risk.
Garfinkel (26)	Prospective; 336,442 American males.	Positive: mortality ratio 1.33 for those 130–139% above average weight.
Graham *et al.* (12)	Case-control; (Table 1).	No association.
Snowdon *et al.* (22)	Prospective; 6,763 Seventh-Day Adventists.	Positive: compared with 90–109% ideal body weight, relative risk of 2.5 for those 130–249%.
Talamini *et al.* (15)	Italian case-control (Table 1).	Compared with <65 kg, risk estimates 2.3 for 85–94 kg, and 3.0 for ≥95 kg.
Ross *et al.* (16)	Case-control (Table 1).	No association.

whites when matched, as was done in their study, for socioeconomic status.

Jackson *et al.* (4) included serum hormone assays in their comparative study of blacks in the United States and Nigeria, and did find that the testosterone and estradiol concentrations were lower in African black prostate cancer patients compared with the corresponding controls. Moreover, among the controls there were trends for the testosterone, but not estradiol, levels to be higher among the African-Americans. Dietary data were not included in this investigation.

There is, however, evidence that diet can influence blood hormone levels in men. Obesity is accompanied by *reduced* plasma testosterone concentrations (29,30); the percentage that is nonprotein-bound shows little or no change (30), but because the plasma sex hormone-binding globulin concentration in middle-aged men is negatively correlated with body weight (31), the absolute level of biologically active testosterone is not necessarily reflected in the percent distribution of binding. In any event, these observations do not provide a basis for concluding that obesity and increased androgen biological activity are related risk factors for prostate cancer.

The Seventh-Day Adventist Church recommends that its members abstain from meat, consume eggs and cheese sparingly and use milk as a protein source. In the United States, male Seventh-Day Adventists have been found to have a considerably lower prostate cancer mortality rate than the general population (32). Howie and Shultz (33) used 3-d food records to assess the dietary intake of lacto-vegetarian and non-vegetarian Seventh-Day Adventists, and non-Seventh-Day Adventist omnivorous males, all aged 49–62 years. The three groups did not differ in their consumption of fat, but the vegetarians consumed more crude and dietary fiber. Their plasma testosterone and estradiol levels were both significantly lower than those of the other two groups of men and were inversely correlated with the estimates of dietary fiber. We have discussed elsewhere the relationships between dietary fiber and fat, and circulating hormone levels in the context of breast cancer (34).

One study has been published in which men at risk of fatal heart disease were placed on low-fat, low-cholesterol and high-complex carbohydrate diets (35). After 26 d, their serum estradiol concentrations were reduced by an average of approximately 50%; perhaps unexpectedly, there were no changes in the testosterone levels.

ANIMAL MODELS

Attempts to develop animal models for human prostate cancer have met with only limited success and have not really provided a stimulus for experimental studies of dietary factors and prostatic carcinogenesis on a par with those seen in breast cancer research (36–41). Pollard and Luckert (37) observed the spontaneous development of prostate cancers in a genetically susceptible strain of Wistar rats and obtained some indication for a promotional effect of a diet supplemented with linoleic acid (LA)-rich corn oil so as to bring its total fat content to 20% (w/w). When the chemical carcinogen *N*-nitrosomethylurea (NMU) was administered, the prostatic tumor yield was increased, an effect which was enhanced by testosterone administration, and also by a high-fat diet (38,39). However, in another NMU-induced prostate cancer model developed by Bosland *et al.* (40), different levels or types of dietary fat had no promotional effects on tumorigenesis (41).

FATTY ACIDS, GROWTH FACTORS AND PROSTATE CANCER CELL GROWTH

Recent studies in our laboratory have indicated that the fatty acid composition of the diet, as well as the absolute amounts of fat consumed, may influence prostate cancer risk. Our interest in this possibility was stimulated by a combination of epidemiological observations and the results which we had obtained from related investigations into dietary fatty acids and human breast cancer cell growth (42,43).

Prostate and breast cancer incidence rates have both been increasing in the United States, as well as in Japan. We postulated (44), as did others (45,46), that there might be a relationship between the rising breast cancer risk in these countries and an increase in the consumption of vegetable oils rich in LA. Although obviously highly speculative, these arguments may be applied also to carcinoma of the prostate.

As a first approach to the issue, we have performed a series of experiments *in vitro* to examine the effects of both LA, an n-6 polyunsaturated fatty acid (PUFA) and docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), two n-3 fatty acids, on the growth of human prostate cancer cells (47). The PC-3 prostate cancer cell line was responsive to LA, its growth being stimulated in a concentration-dependent manner over a 5–750 ng/mL range when the fatty acid was incorporated into serum-free, bovine serum albumin (BSA) supplemented culture medium. In contrast, the n-3 fatty acids inhibited PC-3 cell growth, an effect which was also dose-dependent and due to an arrest of proliferation rather than nonspecific toxicity. This inhibition *in vitro* was particularly interesting because we had shown previously that the growth of human prostate cancer cells as solid tumors in athymic mice is suppressed by feeding a diet containing (n-3)-rich Menhaden fish oil (48).

There is some epidemiological support for a protective influence of n-3 fatty acids against both prostate and breast cancer. In a study from Japan, where fish traditionally provides the major source of animal protein, Mishina *et al.* (17) reported that a low consumption of seafood was associated with increased prostate cancer risk. Alaskan Eskimo men who eat large quantities of fish are at low risk for prostate cancer, as are Eskimo women for breast cancer (49). To examine this issue further in the context to breast cancer, Kaizer *et al.* (50) made international comparisons and showed an inverse association between percent of calories from fish and disease rates *after* adjustment for dietary fat intake; on the basis of Figures 1 and 2, it is to be expected that this relationship would also apply to prostate cancer.

The n-3 fatty acids compete with LA and its metabolic product arachidomic acid (AA) for enzymes which regulate eicosanoid biosynthesis (Fig. 4). We used pharmacological inhibitors of prostaglandin (PG) and leukotriene (LT) synthesis to demonstrate a requirement for both families of eicosanoids for normal human prostate cancer cell growth *in vitro*, and its stimulation by LA (47). Particularly

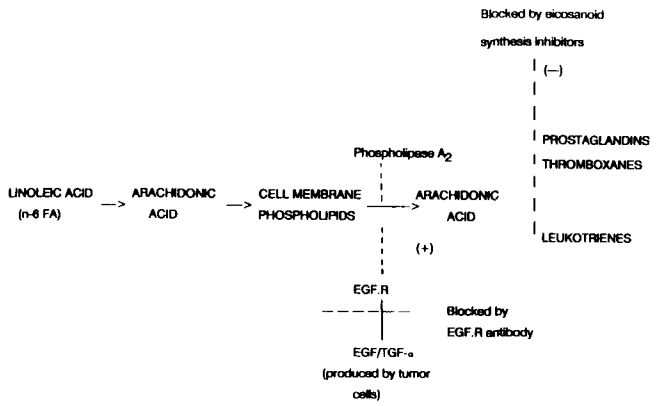

FIG. 4. Interaction of n-6 fatty acids and epidermal growth factor in eicosanoid biosynthesis: sites of metabolic inhibition.

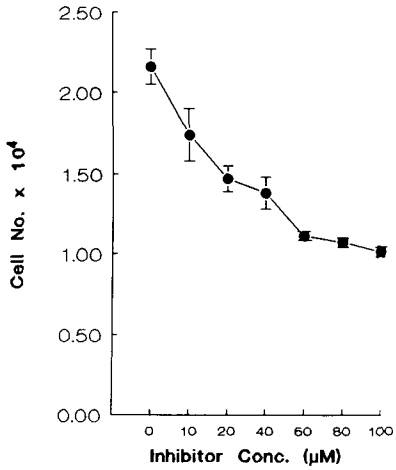

FIG. 5. Suppression of PC-3 human prostate cancer cell growth by caffeic acid, an inhibitor of leukotriene biosynthesis.

significant was the suppressive effect of esculetin (6,7-dihydroxycoumarin) on PC-3 cell growth, because this compound inhibits the lipoxygenase enzymes, and hence LT synthesis, but actually enhances production of the PG (51). As shown in Figure 5, caffeic acid, which has similar effects on LT and PG biosynthesis (52), is also an effective inhibitor of prostate cancer cell growth *in vitro*.

Like PC-3 cells, the DU145 human prostate cancer cell line does not require the presence of androgens for its growth; it grows readily in the absence of serum and synthesizes both epidermal growth factor (EGF) and the related polypeptide transforming growth factor α (TGF-α). These two growth factors, which share the same cell membrane receptors, are secreted into the culture medium by the tumor cells (53). Both PC-3 and DU145 cells possess EGF/TFG-α receptors, and we suggested that an auto-crine loop exists for the regulation of prostate cancer cell growth (47,53). More recently, we obtained direct evidence for such autocrine control by showing that DU145 prostate cancer cell growth is suppressed if the EGF binding sites are rendered inaccessible to the ligands by exposing them to a receptor protein-blocking antibody (54).

After prolonged passage *in vitro*, a subline of DU145 prostate cancer cells was obtained which, like PC-3 cells, is stimulated to grow by LA. Using this subline, we ex-

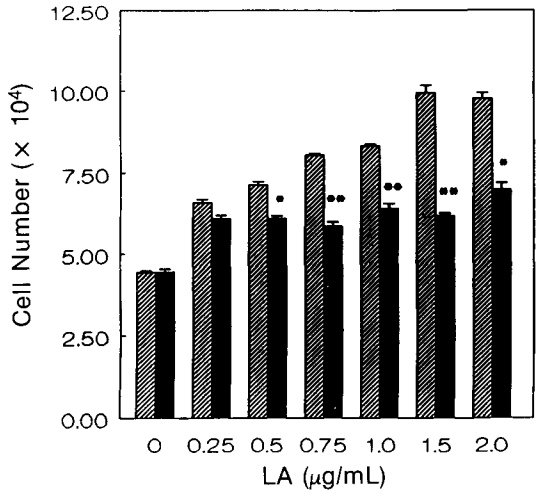

FIG. 6. The stimulation of growth of a DU145 human prostate cancer subline by linoleic acid (cross-hatched blocks), and its inhibition by an antibody (1×10^{-9}M) to the cell membrane epidermel growth factor (EGF) receptors (solid blocks)., The cells were grown in RPMI-1650 plus 1% fetal bovine serum for 3 d. Significant differences between cell number in the presence and absence of the antibody: $^{**}P \oplus 0.001$; $^{*}P \oplus 0.01$).

amined the possibility that a relationship exists between EGF-like polypeptide secretion by the cancer cells and this (n-6)-induced growth response (Fig. 4). When AA is formed from LA, it is largely incorporated into the cell membrane phospholipids where it provides a reserve of substrate for eicosanoid biosynthesis. Mobilization of AA involves phospholipase A_2, an enzyme which has been shown to be stimulated by EGF in BALB/c 3T3 fibroblasts (55,56). Figure 6 shows the concentration-related growth stimulation of the DU145 subline when it was cultured in the presence of LA, and the suppression of this growth response when EGF/TGF-α binding sites were blocked with receptor antibody. Additional experiments will be required to demonstrate that this inhibition is associated with a reduction in eicosanoid biosynthesis and is reversible by high concentrations of exogenous EGF.

COMMENTARY

The epidemiological evidence that dietary fat is involved in determining prostate cancer risk is conflicting, and is of an inferential character. International comparisons show an association between prostate cancer mortality rates and estimates of the consumption of fats of animal, but not vegetable, origin. This distinction holds also for breast cancer (9), but in both cases the association could be a spurious one. More persuasive are the trends in prostate cancer incidence and dietary fat consumption in Japan and the consequences of migration to areas of high prostate (and breast) cancer risk.

There is a need for investigations of dietary composition and prostate cancer risk which are analyzed to distinguish between the effects of fat and energy intakes. This is an important issue and could be examined by appropriately located case-control studies which provide an adequate range of dietary patterns. One such study was performed in northwestern Italy by Toniolo *et al.* (57), and demonstrated a significant association between breast

cancer risk and saturated fat consumption after adjusting for caloric intake.

We have discussed the geographical variation in the prevalence and histological characteristics of prostate cancer pathology at some length because comparative investigations of dietary composition in relation to latent carcinoma of the prostate would be extremely valuable.

Another target for future studies should surely be the large difference in prostate cancer risk for African-Americans and white Americans. A dietary-hormonal hypothesis of prostate cancer etiology is obviously strengthened if it provides a mechanistic explanation for this discrepancy. There is an urgent need for carefully regulated experimental dietary studies into the effects of fat and fiber on male plasma hormone levels. These should include both young men, as a follow-up to the reported differences in serum testosterone levels (28), and middle-aged and older males, many of whom will have preexisting latent carcinomas of the prostate.

Attention should also be focussed on the influence of different types of fatty acids on the biology of human prostate cancer cells. For this work, growth studies *in vitro* should be combined with experiments *in vivo* using athymic nude mice.

It may be considered premature to attempt dietary intervention trials aimed at reducing prostate cancer risk. However, progress is being made in the development of similar trials in breast cancer (58,59), and these will offer the opportunity to include male members of the family in pilot studies and biochemical investigations.

Dietary Fat and the Development of Pancreatic Cancer[1]

B.D. Roebuck
Department of Pharmacology and Toxicology, Dartmouth Medical School, Hanover, New Hampshire 03756

Pancreatic cancer is the fifth most common cause of death due to cancer. Except for an association with cigarette smoking, its etiology is poorly understood. Because of the dearth of epidemiological clues as to causation, studies with experimental animal models assume greater importance. Rodent models of pancreatic cancer indicate that while dietary fat *per se* does not cause pancreatic cancer, it does enhance or promote tumor development. Subsequent to treatment with a pancreatic carcinogen, high intakes of dietary unsaturated fats of the n-6 series, but not saturated fats, enhance or promote tumor development. A requisite level of linoleic acid is needed for this promotion. Fats of the n-3 series (*e.g.*, certain fish oils) are inhibitory to tumor growth. Promotion by dietary fats appears only partly related to the high caloric content of fat. Mechanistically, certain dietary unsaturated fats appear to selectively enhance the growth rate of carcinogen-induced, pre-cancerous lesions. Irrespective of precise understanding of mechanisms of promotion, it appears possible to intervene in the process of cancer development and reduce the burden of cancer. Experimentally, this may be accomplished by decreasing total fat intake, decreasing caloric intake, increasing exercise or increasing the intake of n-3 fatty acids.
Lipids 27, 804–806 (1992).

In the United States, pancreatic cancer ranks eighth with respect to incidence of cancer yet it is the fifth most common cause of death due to cancer with about 24,000 deaths per year (1). Total mortality is approximately equal by sexes and the age-adjusted cancer death rates for both sexes have been essentially unchanged over the last 20 years. Pancreatic cancer is usually diagnosed late in the course of the disease thus precluding effective treatment. The median survival following diagnosis is only a few months and the 5-yr survival is now only 3 to 4% of all cases of pancreatic cancer. The last 20 yr have seen an increase in the 5-yr survival from only 1% to the present levels (1). These survival rates are among the lowest of all forms of cancer. With the exception of an association with the smoking of cigarettes, the etiology of pancreatic cancer is largely unknown (2).

There have been hints that dietary factors are associated with pancreatic cancer. Carroll and Khor (3) identified correlation coefficients between *per capita* consumption of dietary fat in various countries of the world and age-adjusted mortality in those countries from pancreatic cancer to be +0.67 for males and +0.50 for females. While a correlation exists, it is very weak compared to similar observations for breast cancer (+0.94) and colon cancer (+0.93 for males and +0.91 for females). In an independent study using a similar approach, Wynder (4) reached the same conclusion. With correlations possible among many factors including other dietary practices and other nutrients, especially protein intake, this form of epidemiological evidence is not strong. More recent epidemiologic data using the more direct and powerful case-control approach find only a moderate association of pancreatic cancer with the intake of fat or fat-containing foods (5–7).

Because of the dearth of clues as to causation of pancreatic cancer in humans, experimental studies with animal models of this disease assume great importance. For example, results from rodent models indicate that dietary fats are indeed causally related to pancreatic carcinogenesis (8–10) thus adding strength to the relatively weak associations shown from human epidemiological data.

Experimental animal models of human cancers obviously have limitations and such is the case for rodent models of pancreatic carcinogenesis. The two best characterized and most extensively used models of pancreatic cancer are (i) the Wistar or Lewis rat treated with azaserine to produce adenocarcinomas composed predominantly of acinar cells (11) and (ii) the Syrian golden hamster treated with one of several nitrosoamines to yield adenocarcinomas that are predominantly duct-like (12). For two reasons, we have primarily used the rat model of pancreatic cancer. First, the database from other rat models involving both cancer at various sites and nutrition is extremely large and useful. Second, the rat model is quantifiable and suitable to experiments as short as a 4-mon duration.

The rat model is characterized by the early appearance of atypical acinar cell foci and nodules with the subsequent development of adenocarcinomas that predominantly have acinar cell characteristics (11). All evidence indicates that the lesions are of acinar cell origin. Within one month following a single dose of azaserine, foci of atypical acinar cells are commonly observed. Two phenotypically different populations of foci have been identified. Foci of the basophilic phenotype appear to have a low growth potential and are relatively resistant to pancreatic growth stimuli; whereas the acidophilic foci grow throughout the life of the rat and are responsive to various growth stimuli (13). Neither phenotypic population of foci shows signs of regression. Subsequent to a single dose of azaserine (30 mg/kg) to 7-wk-old Lewis rats, carcinomas *in situ* are observed as early as 9 mon, and the incidence of rats with adenocarcinomas increases progressively from 12 to 18 mon (14). Several studies have shown the utility of quantitatively measuring the number and size of the early putative preneoplastic lesions as a predictive index of the ultimate incidence of neoplasms. This quantitative short-term model has been described in detail elsewhere (9,15,16).

Using the rodent model of pancreatic cancer described above, the effects of dietary fats in general, fish oils in particular, and calories and exercise will be discussed.

DIETARY FATS

The first experiments studying dietary fats and pancreatic carcinogenesis in the rat utilized multiple doses of azaserine during an initiation phase of several weeks' duration (17,18). Though multiple doses of an initiating carcinogen are considered less than ideal, multiple

[1]Based on a paper presented at the Symposium on Lipids in Cancer held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

injections of azaserine appear equally as effective as a single dose of the same total quantity of azaserine when individual doses are below the cytotoxic level (19). Weekly doses of azaserine for 5 wks concurrent with feeding diets high in unsaturated fat (20% by weight corn oil) and saturated fat (18% hydrogenated coconut oil and 2% corn oil) resulted in no statistically significant difference between the two high fat diets in either the incidence, multiplicity or severity of pancreatic neoplasms (18). Furthermore, the two groups which were fed high levels of dietary fat did not differ statistically from the control diet group (5% unsaturated fat). Taken together these data indicate that saturated and unsaturated fats fed at a high level have no effect upon the initiation phase of carcinogenesis by azaserine in the rat. Similar conclusions have been drawn for the hamster model of pancreatic cancer (20).

The rat has been extensively used in chronic toxicity and carcinogenicity studies of upwards to two years' duration. Microscopic proliferative lesions of the pancreas, that is, foci of the acidophilic phenotype, have been observed in old rats and the incidence of these lesions were increased significantly when the rats were gavaged with corn oil (21). The quantity of corn oil delivered to these vehicle-control rats in chronic cancer studies increases their fat intake from about 5% to approximately 15% fat by weight in the diet. These foci are observed in pancreases of several rodent species and strains of rats (22) and we have observed increased numbers of these acidophilic foci as rats age (14,19). Though not the only possibility, an attractive explanation of these observations is that dietary unsaturated fat increases the development of "spontaneously" occurring lesions of the pancreas.

The post-initiational enhancement of pancreatic neoplasia by high levels (20% by weight of corn or safflower oil) of dietary unsaturated fats as compared to similar high levels of saturated fats or low (2 to 5%) levels of unsaturated fats in rats was first reported in 1981 (17,18). As discussed above, this phenomenon occurs after chemical carcinogen exposure and is operationally defined as a post-initiational or promotional event (18). Observations from short-term studies with the rat/azaserine model and using the size and number of acidophilic foci as an end point provide many clues regarding the role of dietary fat in pancreatic carcinogenesis. Experiments have shown that from 4% to 8% essential fatty acid (linoleic acid) in diets totaling 20% fat is an approximate threshold for essential fatty acid above which both the number and size of the acidophilic foci grow (23). At essential fatty acid levels below this threshold, the foci do not grow irrespective of the presence of large quantities of dietary fat. Other studies have shown that the [^{3}H]thymidine labeling index, a measure of cell growth, is increased in the acidophilic foci of rats fed unsaturated fat and this increased growth rate is not seen in foci of rats fed either a high dietary level of saturated fat or a low level of dietary unsaturated fat (15). The basophilic foci showed a low labeling index indicative of their low growth potential and presumed general unimportance in the ultimate development of cancers in the rat model.

Again in experiments with the short, 4-mon post-initiation or promotion model, growth of the foci can be modulated upward by feeding a high level (20%) of unsaturated fat to rats which were previously fed a low fat diet and *vice versa* (24). These experiments are similar in concept to the intervention trials by epidemiologists. Basically, halfway through the 4-mon post-initiation phase, the diet is switched from low fat to high fat or *vice versa*. In this latter experiment as well as in previous experiments, these dietary unsaturated fats do not increase the size of the pancreas of non-carcinogen treated controls, thus promotion appears to be relatively specific for the carcinogen-induced foci (25), and spontaneously occurring foci (26).

FISH OILS

A number of studies have indicated that the consumption of n-3 fatty acids may inhibit carcinogenesis. With regard to pancreatic carcinogenesis, only experiments in the rat model have addressed this phenomenon and these experiments have used the 4-mon, short-term foci model. When 20% by weight of the diet was menhaden oil (approximately 7% of the diet being n-3 fatty acids), the number of foci was significantly reduced and no neoplasms were observed (27). Rats fed a similar level of total fat, but of n-6 fatty acids, had a high focal burden and a small but definite incidence of pancreatic neoplasms (27). When all diets were formulated to contain 20% fat, but with various ratios of corn oil to menhaden oil, a threshold in the azaserine-induced focal burden of the pancreas was apparent between 3 and 6% linoleic acid in the diet (28). This is similar to the threshold noted in earlier experiments with this model (23) and in experiments using a model of mammary carcinogenesis (29). While the mechanism by which menhaden oil inhibits pancreatic carcinogenesis is not clear, one observation was that the effect was primarily upon the number of foci observed and not upon the growth of the foci. This implies that the effect occurs early in the post-initiation or promotion phase. Using the intervention concept described above, we have shown that substituting 20% menhaden oil for 20% corn oil in the rat diet for the last 2 mon of the 4-mon experiment significantly suppressed pancreatic foci development. The opposite occurred if rats were switched from menhaden oil to corn oil (28).

CALORIES AND EXERCISE

There is considerable debate over the relative importance of dietary fat intake *per se vs.* the total caloric intake as modulators of carcinogenesis. Numerous investigations have shown that mammary carcinogenesis is enhanced by intakes of high levels of fat especially during the post-initiation phase of carcinogenesis and that there is a minimum level of linoleic acid required for enhancement (29). Since fat is the most calorie dense ingredient in the diet, high fat diets are also calorie-rich. Thus, it has been very difficult to separate the potential effects of fat from calories. Studies by Kirtchevsky *et al.* (30,31) and Boissonneault *et al.* (32) have drawn attention to the importance of calories in the enhancing or promotional effects of dietary fat. It is hypothesized that fat may exert its promotional effects by being more efficiently utilized as an energy source as compared to either protein or carbohydrate. As with many rodent models of cancer, we have shown that restriction of food intake to approximately 90% of the amount consumed by the *ad libitum* fed rats suppressed pancreatic carcinogenesis (17,18).

Recent reports have rekindled an interest in energy utilization as a way of controlling the promotional effects of dietary fats. Cohen *et al.* (33) showed that both caloric restriction and energy utilization (exercise) inhibited the development of *N*-nitrosomethylurea-induced mammary tumors. The exercise group had free access to running wheels and averaged 2.9 km (1.8 miles) per day over the 20-wk experiment. Interestingly, of the rats in the exercise group, the ones which ran the least attained the greatest benefit with respect to protection against mammary tumorigenesis. It is unknown *via* what mechanism voluntary exercise modulates mammary carcinogenesis. Reddy *et al.* (34) observed that for male rats voluntary exercise on running wheels inhibited azoxymethane-induced colon cancer. Similar results in different organ cancer models imply that the mechanism of inhibition of carcinogenesis is not organ specific and must be fairly general in nature. We have observed that voluntary exercise virtually identical to that used by Cohen *et al.* (33) and Reddy *et al.* (34) suppressed pancreatic foci development in our azaserine model (35). The growth of the acidophilic foci are suppressed in the pancreases of the exercise group of rats (35). Thompson *et al.* (36) found that rats initiated with 7,12-dimethylbenz[a]anthracene and exercised on a treadmill actually had enhanced mammary tumor development as compared to the sedentary group. The treadmill activity consisted of running 20 m/min for 15 min/d (0.3 km/d) at a 1% incline for 5 d of the week. Additional studies by Thompson *et al.* (37) indicated the reproducibility of the effect on mammary tumor enhancement and that enhancement occurred with both high (24.6% by weight) and low (5.0%) levels of unsaturated fat, but not when the diet was composed of high levels of primarily saturated fats. Clearly, there are likely to be considerable differences between voluntary and treadmill exercise with regard to the anaerobic and aerobic exercise and the possible stress of exercise. Caution is important, especially when attempting to extrapolate to the human situation.

CONCLUSION

Pancreatic cancer is a serious disease in humans and its causation is not understood. Prevention may be possible even if we do not know the primary cause. Using a rat model of pancreatic cancer, we have shown that diet can retard the development of putative precancerous lesions (acidophilic foci) and adenocarcinomas. A decrease in the total amount of fat, a decrease in calories, an increase in exercise, and a substitution of n-3 fatty acids for n-6 fatty acids will all suppress pancreatic carcinogenesis in the rat. Intervention trials in this rodent model indicate that such dietary alterations can be instituted during the post-initiation phase and need not be "in place" for the entire life of the animal.

ACKNOWLEDGMENTS

The author thanks Karen Baumgartner for many helpful suggestions in the writing of this manuscript. This work has been supported in part by the American Institute for Cancer Research, Washington, D.C.

Dietary Fat and Colon Cancer: Animal Model Studies[1]

Bandaru S. Reddy*
Division of Nutritional Carcinogenesis, American Health Foundation, Valhalla, New York 10595

Since it was first suggested that high dietary fat is a risk factor in colon cancer, there have been several studies to test this hypothesis. Epidemiologic studies suggested a positive association between dietary fat and colon cancer. Laboratory animal model studies demonstrated that not only the amount of fat, but also types of fat differing in fatty acid composition are important determining factors in colon tumor development. Chemically-induced colon tumor incidence was increased in rats fed the semipurified diets containing 23% corn oil, safflower oil, lard or beef tallow (high-fat) as compared to those fed 5% corn oil, safflower oil, lard or beef tallow diets (low-fat). Diets containing 23% coconut oil, olive oil or fish oil, or high-fat diets containing varying levels of *trans* fat, had no colon tumor-enhancing effect compared to their respective low fat diets. The stage at which the effect of dietary fat is exerted appears to be mostly during the post-initiation phase of colon carcinogenesis. Lack of a colon tumor enhancing effect of dietary fish oil is observed both during the initiation and postinitiation phases. The mechanisms by which various dietary fats increase colon carcinogenesis are not fully understood. In most instances, however, the high-fat diet appears to enhance tumorigenesis through elevation of agents, such as secondary bile acids, that act as promoters of tumor development. Lack of colon tumor promotion by dietary fish oil and *trans* fat appears to be mediated through their effect on mucosal ornithine decarboxylase activity, colonic secondary bile acids and/or prostaglandin synthesis.
***Lipids 27,* 807–813 (1992).**

Cancer of the colon is one of the most common cancers in the western countries, including North America, exhibiting more than a tenfold excess when compared to rural populations in Asia, Africa and certain parts of South America. Studies of cancer incidence in high risk areas such as the United States, and low risk countries, such as Japan and Finland, indicate that rates are increasing faster in low than in high incidence areas of the world. It is the second leading cause of cancer deaths in the United States, with estimated 157,500 new cases and about 60,500 deaths in 1991 (1).

Since Wynder *et al.* (2) and Burkitt (3) first suggested that dietary factors in general, and specifically dietary fat and fiber, might play a role in the etiology of colon cancer, a substantial amount of progress has been made in understanding the relationship between nutritional factors and the development of colon cancer in humans. Continuing population studies revealed that the diets particularly high in total fat and low in certain dietary fibers are generally associated with an increased risk of developing colon cancer (4). In addition, dietary fat may be a risk factor in the absence of factors that are protective, such as use of high dietary fiber and fibrous foods (4). Several case-control studies suggest a positive association between dietary fats, especially saturated fat (5,6). A recent prospective study provided evidence that a high intake of animal fat, but not vegetable fat, increases the risk of colon cancer (7). Animal model studies performed in our laboratory and elsewhere have consistently supported human epidemiologic studies and further provided evidence that the colon tumor-promoting effect of dietary fat depends on the type of fat (8). These studies also suggested that the main effect of dietary fat in colon carcinogenesis is during the postinitiation phase of carcinogenesis. Unquestionably, there are areas where more research is necessary and, of course, no single dietary factor and mechanism can account for all colon cancer.

Since several reviews have already appeared on the relationship between dietary fat and colon carcinogenesis, this report will provide a brief overview of current knowledge as to the relationship between the types of dietary fat and colon carcinogenesis in laboratory animal models with emphasis on ω3 fatty acids (fish oil). The basis for the latter point is that epidemiologic studies have found that people who traditionally consume (either regularly or frequently) diets containing fish and marine animals have a lower incidence of several chronic diseases, including cancer, than those who do not or rarely consume such foods (9–11).

AMOUNT OF DIETARY FAT AND COLON CANCER

A variety of compounds, namely 1,2-dimethylhydrazine (DMH), azoxymethane (AOM), methylazoxymethanol (MAM) acetate, 3,2′-dimethyl-4-aminobiphenyl (DMAB) and methylnitrosourea (MNU), that are carcinogenic for the colon have been used in a number of laboratory animal models to investigate the effect of dietary fat on tumorigenesis at this site (12). Although our early experiments (12–14) and those of others (15–18) did not distinguish between the effect of fat on the initiation and postinitiation phases of carcinogenesis, these studies nonetheless indicated a strong relationship between the amount of dietary fat and colon cancer in animal models.

Nigro *et al.* (15) studied the effect of diets containing 5 and 35% beef fat on AOM-induced intestinal tumors in Sprague-Dawley rats. Animals fed the high beef-fat diet developed more intestinal tumors and more metastases in the abdominal cavity, lungs and liver than did the animals fed the low-fat diet. Howarth and Pihl (17) demonstrated that DMH-induced colon tumors were increased in male D/A rats fed a high-fat diet compared with those fed a low-fat diet. Studies conducted in our laboratory indicate that animals fed 20% lard or corn oil diets were more susceptible to DMH-induced colon tumors compared with those fed 5% lard or corn oil diets. The type of fat
